increase in the overlap population between these atoms.[2]

Although it has been a common practice to associate a decrease in the bond length with an increase in the covalent bond order (overlap population), an interpretation in terms of ionic bond order may sometimes be more suitable. A particular example is the carbon–phosphorus bond length of a phosphonium ylide. There has been much discussion (16) concerning the relative importance of the ylide (**1**) and ylene (**2**) representations of these species. The ylene formulation, which usually invokes $(p \rightarrow d)_\pi$ conjugation, has been favored by some workers because of the 0.09–0.17 Å shortening of the C—P bond that accompanies the deprotonation of a phosphonium salt (**3**) (see ref. 17 for a discussion of this point). However, n.m.r. and e.s.r. studies (18) seem more compatible with the ylide structure.

$\overset{+}{R_3P}—\overset{-}{C}HR$ (**1**) $\quad R_3P{=}CHR$ (**2**) $\quad \overset{+}{R_3P}—CH_2R\ X^-$ (**3**)

Absar and Van Wazer (19) have performed *ab initio* computations on $H_3\overset{+}{P}—CH_2^-$ and $H_2P—CH_3$ using fixed C—P bond lengths in each case. Inspection of their wave functions (Table 2) reveals that, in the ylide, which has the shorter bond length, both the ionic bond order and the overlap population of the C—P bond are greater, whether d-type functions are present on phosphorus or not. In addition, π-like interactions are present in the C—P bonds, even when d character is not allowed (19). Therefore, it seems unnecessary to rationalize the shorter C—P bond of the ylide in terms of $(p \rightarrow d)_\pi$ conjugation. One should, rather, emphasize the correlation with the ionic bond order. We believe that the significance of the present work is to demonstrate that, since the length of a chemical bond is the result of both ionic and covalent effects, the ionic interaction should not be ignored in the explanation of bond length variations of charged and zwitterionic systems.

[2]Because the Mulliken population employed in the present work is not basis set invariant (15), conclusions based upon this analysis are subject to the usual criticisms of the Mulliken population analysis. However, it should be noted that our arguments are based upon trends observed from computations with the same quality basis set for each series of closely related compounds. For a modified population analysis see ref. 15*c*.

We thank the National Research Council of Canada for financial support of this work, and Prof. S. Fliszár and a second, anonymous, referee for their constructive criticism of the manuscript.

Reaction of Xenon Difluoride. Part II. Oxidative-fluorination of Phosphorus and Iodine Compounds and Cleavage of Silicon–Sulfur and Silicon–Nitrogen Bonds[1]

JAMES ANDREW GIBSON, RONALD KIRK MARAT, AND ALEXANDER F. JANZEN

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received March 10, 1975

JAMES ANDREW GIBSON, RONALD KIRK MARAT, and ALEXANDER F. JANZEN. Can. J. Chem. **53**, 3044 (1975).

Reaction of alkyl(aryl)phosphines with xenon difluoride gives alkyl(aryl)hydridofluorophosphoranes which were characterized by proton and fluorine n.m.r. spectroscopy. With phenylchlorophosphines, substitution of chlorine by fluorine accompanied oxidative-fluorination to give phenylfluorophosphoranes, $(C_6H_5)_nPF_{5-n}$. With *tert*-butylchlorophosphines, chlorination of the *tert*-butyl group accompanied oxidative-fluorination, and a mixture of products was obtained. Reaction of xenon difluoride with methyl iodide gives methyliodine(III) difluoride, characterized by proton and fluorine n.m.r. spectroscopy.

Silicon–sulfur and silicon–nitrogen bonds are cleaved by xenon difluoride and an intermediate containing a xenon–nitrogen bond is postulated.

Reaction of xenon difluoride with hexafluoroacetone, perfluoropinacol, or disodium perfluoropinacolate failed to give stable xenon esters.

JAMES ANDREW GIBSON, RONALD KIRK MARAT et ALEXANDER F. JANZEN. Can. J. Chem. **53**, 3044 (1975).

La réaction des alkyl(aryl)phosphines avec le difluorure de xénon conduit aux alkyl(aryl)-hydridofluorophosphoranes que l'on a caractérisé par spectroscopie r.m.n. du proton et du fluor. Avec les phénylchlorophosphines, une substitution du chlore par du fluor accompagne la fluoration oxydative pour fournir des phénylfluorophosphoranes, $(C_6H_5)_nPF_{5-n}$. Avec les *tert*-butylchlorophosphines, une chloration du groupement *tert*-butyle accompagne la fluoration oxydative et on obtient un mélange de produits. La réaction du difluorure de xénon avec l'iodure de méthyle fournit le méthyl difluorure d'iode(III) que l'on a caractérisé par spectroscopie r.m.n. du fluor et du proton.

Les liens Si—S et Si—N sont coupés par le difluorure de xénon et on fait l'hypothèse qu'il y a formation d'un intermédiaire contenant un lien Xe—N.

La réaction du difluorure de xénon avec l'hexafluoroacétone, le perfluoropinacol ou le perfluoropinacolate de sodium ne donne pas d'esters stables du xenon.

[Traduit par le journal]

The reactions of xenon difluoride with a variety of main group compounds were investigated with the aim of comparing the reactivity and fluorinating ability of XeF_2 to the more common fluorinating agents of groups VA to VIIA. Previously we described some reactions of XeF_2 with organosilicon compounds (1) and with $(C_6H_5)_2PC(OH)(CF_3)_2$ (2), while other workers have reported the reactions with organic compounds, including aromatics (3), olefins (4), acetylenes (5), and acids (6). XeF_2 is known to react with chlorides of various metals (7), and the oxidation of zinc tetraphenylporphyrin has been reported (8). Adducts of XeF_2 with metal fluorides have been studied in some detail and recent review articles are available (9).

Results and Discussion

XeF_2 and Phosphines

The previous finding that XeF_2 did not attack silicon–hydrogen bonds (1) suggested that oxidative-fluorination of phosphines might occur without destruction of the P—H bond. This was confirmed for reactions of XeF_2 with dialkyl(aryl)phosphines and monoalkylphosphines (eqs. 1 and 2).

TABLE 1. Proton and fluorine n.m.r. chemical shifts and coupling constants of some alkyl(aryl)hydridofluorophosphoranes

Compound	Chemical shifts (p.p.m.)*		Coupling constants, J (Hz)				
	H_e	F_a	H_eP	H_ePF_a	H_ePCH	F_aP	F_aPCH
1*a* $(C_6H_5)_2PHF_2$	−6.45	+51.7	773.4	110	—	612	—
1*b* $(NCCH_2CH_2)_2PHF_2$	−6.92	+61.2	757.7	100.5	3.5	595	6.5
2*a* $NCCH_2CH_2PH_2F_2$	−6.94	+60.5	743.0	89	3.8	556	6.0
2*b* $C_6H_{11}PH_2F_2$	−6.75	+65.2	714	92	br	567	br

*Proton and fluorine chemical shifts relative to internal TMS and external $CFCl_3$. Compounds were dissolved in 1:2 (v/v) mixture of $CDCl_3$ and CD_3CN and spectra recorded at ambient probe temperatures.

[2] $RPH_2 + XeF_2 \longrightarrow R{-}P(F)(H)(H)(F) + Xe$ (**2**)

a R = CH_2CH_2CN
b R = C_6H_{11}

Reactions were carried out in acetonitrile solution in standard n.m.r. tubes under anhydrous conditions at −35 to −15 °C and the products were formed in yields of at least 90%. Xenon gas was removed and identified by mass spectrometry and the products were characterized by proton and fluorine n.m.r. The n.m.r. data are consistent with trigonal bipyramidal geometry in which fluorines occupy axial positions and alkyl(aryl) and hydrogen substituents occupy equatorial positions.

The chemical shifts and coupling constants of products **1** and **2** are summarized in Table 1 and typical proton n.m.r. spectra of **1***b* and **2***a* are shown in Figs. 1 and 2. The n.m.r. spectra are well resolved at room temperature thus indicating that intermolecular fluorine or hydrogen exchange is extremely slow on the n.m.r. time scale. Only the cyclohexyldihydridofluorophosphorane **2***b* showed somewhat broadened lines in the n.m.r. spectrum, hence J_{F_aPCH} and J_{H_ePCH} could not be estimated, but this broadening could be due to conformational equilibrium of the cyclohexyl ring.

The n.m.r. spectra were recorded in acetonitrile solution and, since it is known that acetonitrile forms a 1:1 complex with phosphorus pentafluoride (10), it is possible that products **1** and **2** interact with solvent CH_3CN in a typical Lewis acid–base manner (eq. 3) involving five and six

[3] $RPH_2F_2 + CH_3CN \rightleftharpoons RPH_2F_2{:}NCCH_3$

coordinate structures. In order to examine this possibility the preparation of $NCCH_2CH_2PH_2F_2$ **2***a* was carried out in CH_2Cl_2 solution. The

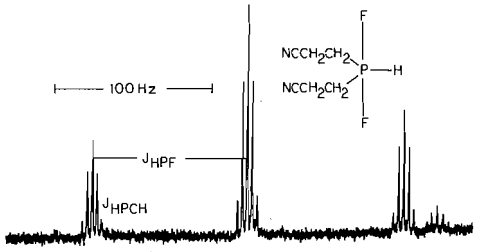

FIG. 1. Proton n.m.r. spectrum of $(NCCH_2CH_2)_2PHF_2$ showing low field half of symmetrical doublet (P—H coupling). Chemical shifts and coupling constants are found in Table 1.

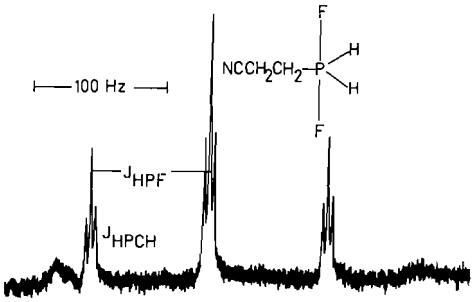

FIG. 2. Proton n.m.r. spectrum of $NCCH_2CH_2PH_2F_2$ showing low field half of symmetrical doublet (P—H coupling). Chemical shifts and coupling constants are found in Table 1.

n.m.r. spectrum in CH_2Cl_2 gave a chemical shift of F_a = 58.7 p.p.m. and $J_{H_ePF_a}$ = 89 Hz, J_{H_ePCH} = 3.8 Hz, and J_{F_aP} = 566 Hz. These values are reasonably close to those observed in acetonitrile solution and therefore the equilibrium of [3], if it is rapid, must be essentially to the left and the data of Table 1 refer to five coordinate molecules.

Rapid intramolecular Lewis acid–base reaction is also possible, but the equilibrium of [4] must lie essentially to the left, since the chemical shifts and coupling constants of **1***a* and **2***b*, where no cyano substituent is present, are very similar to those of **1***b* and **2***a*.

[4] 
The reaction of XeF_2 with phosphines represents a convenient synthesis of mono- and dihydridofluorophosphoranes, although other synthetic routes are known, such as addition of alcohols, thiols, or amines to fluorophosphines (11), reaction of fluorophosphoranes with trimethylstannane or trimethylsilane (12), and reaction of KHF_2 with chlorophosphines or HF with alkylphosphines and phosphorous acids (13).

Reaction of chlorophosphines with XeF_2 was studied since it was of interest to establish whether oxidative-fluorination would occur without affecting the P—Cl bond. In the case of organosilicon chlorides, XeF_2 invariably converted Si—Cl to Si—F bonds (1).

The reaction of chlorophenylphosphines with XeF_2 gave fluorophenylphosphoranes, as well

[5] $$C_6H_5PCl_2 \xrightarrow{XeF_2} C_6H_5PF_4$$

[6] $$(C_6H_5)_2PCl \xrightarrow{XeF_2} (C_6H_5)_2PF_3$$

as Xe and Cl_2. Intermediate chlorofluorophenylphosphoranes were not identified and the relative ease of oxidative-fluorination *vs.* chlorine substitution could not be studied. Since one of the end products of reactions 5 and 6 is Cl_2, there is the further possibility that fluorophenylphosphoranes are formed as a result of oxidative-chlorination followed by fluorination. The reaction with triphenylphosphine was therefore carried out, as Cl_2 is not produced in this re-

[7] $$(C_6H_5)_3P \xrightarrow{XeF_2} (C_6H_5)_3PF_2$$

action, and oxidative-fluorination occurred under conditions very similar to those of $C_6H_5PCl_2$ and $(C_6H_5)_2PCl$; hence it is reasonable to assume that XeF_2 is the effective oxidizing reagent in reactions 5–7.

When the reaction was extended to *tert*-butylchlorophosphines, oxidative-fluorination was again observed but, at the same time, extensive chlorination of the *tert*-butyl group occurred and the products were not characterized. Chlorination of alkyl groups was observed previously during reactions of $(CH_3)_2SiCl_2$ and $C_6H_5(CH_3)_2SiCl$ where $CH_3(CH_2Cl)SiF_2$ and $C_6H_5(CH_3)(CH_2Cl)SiF$ were formed in about 25% yield (1).

XeF_2 and Iodine Compounds[2]

The syntheses of perfluoroalkyliodine(III and V) fluorides involve the use of powerful fluorinating agents such as F_2, BrF_3, and ClF_3 (14–19) and these would not be applicable to the syntheses of alkyliodine fluorides owing to destructive fluorination of alkyl groups. Since XeF_2 oxidizes phosphorus(III) compounds without attacking alkyl or aryl groups (unless a P—Cl bond is present), it seemed reasonable that oxidation of iodine compounds might also be accomplished under mild conditions.

The reaction of XeF_2 with an excess of methyl iodide proceeded smoothly for 20 min, in the absence of solvent at room temperature, in essentially quantitative yield; no reaction was observed below −40 °C.

$$XeF_2 + CH_3I \rightarrow CH_3IF_2 + Xe$$

The proton and fluorine n.m.r. spectra of CH_3IF_2, dissolved in excess methyl iodide, gave a triplet at −4.23 p.p.m. (external TMS) and a quartet at +176.4 p.p.m. (external $CFCl_3$) with J_{HCIF} = 7 Hz (Fig. 3). The fluorine chemical shift is close to that of CF_3IF_2 (+172.7 p.p.m. (15)) and other iodine(III) fluorides, such as CF_3IF_2·pyridine (+174.6 (17), $SF_5(CF_2)_2IF_2$ (+175.6 (16)), and IF_3 (+165 (18)).

CH_3IF_2 was found to be surprisingly stable in solution, 50% remaining after 4 h at 20 °C, suggesting that the product is at least as stable as CF_3IF_2 (14, 15). Excess of methyl iodide may be removed *in vacuo* from the involatile product. The product reacts slowly with glass and rapidly with mercury, while decomposition at room temperature gives iodine and oily material.

The reaction of XeF_2 with isopropyl iodide was also carried out; however, the reaction was extremely rapid at 0 °C and iodine was one of the end products. Fluorine n.m.r. confirmed the disappearance of XeF_2 but failed to detect the desired isopropyliodine(III) difluoride.

Reaction of XeF_2 with excess phenyl iodide proceeded at 0 °C to give a product with a fluorine chemical shift of +170.4 p.p.m. (half-height width 4 Hz). The chemical shift is characteristic of iodine(III) fluorides and is assigned to $C_6H_5IF_2$. The product is fairly stable, 80% remaining after standing at 5 °C for 12 h. During this time another peak appeared at +173.8 p.p.m., half-height width 18 Hz, which may be

[2]The synthesis of methyliodine(III) difluoride has been reported in a preliminary account (40).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

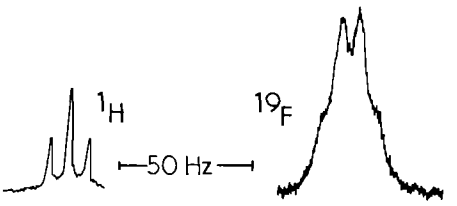

FIG. 3. Proton and fluorine n.m.r. spectra of CH_3IF_2. See text for chemical shifts and coupling constants.

assigned to partially fluorinated phenyliodide(III) difluoride, $C_6H_xF_yIF_2$, since the chemical shift is that of an iodine(III) fluoride while the half-height width is consistent with coupling to *ortho* fluorines (J_{FICF} = 26 Hz for $C_6F_5IF_4$ (19)).

The stability of $C_6H_5IF_2$ may be compared with $C_6F_5IF_2$ which decomposes rapidly above −5 °C (20). It is interesting that both CH_3IF_2 and $C_6H_5IF_2$ are found to be at least as stable as their perfluoro analogs, however, this 'stability' probably reflects the influence of impurities, since any synthesis involving XeF_2 probably introduces fewer impurities than reagents such as F_2 or ClF_3 and catalyzed decompositions are less likely.

Reaction of XeF_2 with I_2 in acetonitrile solution occurred very slowly and the iodine color was discharged over a period of 24 h at 20 °C. This slow reaction is probably due to the introduction of HF, as a result of decomposition of XeF_2/CH_3CN solution (1, 39), since it has been shown that I_2 is rapidly oxidized by XeF_2 in CH_3CN if an acid such as HF is introduced (21). It was also observed that reaction with I_2 could be speeded up by adding $(CH_3)_3SiF$ to the solution, and the iodine color was now discharged within 5 min. In separate experiments it was shown that $(CH_3)_3SiF$ does not react with XeF_2 or with I_2, therefore, $(CH_3)_3SiF$ must be a sufficiently strong Lewis acid to catalyze oxidation of I_2 in the manner of HF, BrF_3, and SO_2 (21, 22).

XeF_2 and Organosilicon Compounds

Reactions of Si—S, Si—N, and Si—O compounds with, for example, fluorides of phosphorus (23), sulfur (24), or iodine (25) have been widely used to prepare substituted derivatives of these elements. We therefore studied the reactions of Si—S and Si—N compounds (Si—O bonds are unreactive towards XeF_2 (1)) with the aim of preparing Xe—S or Xe—N compounds or, failing that, to gain evidence of their formation as intermediates.

The reaction of XeF_2 with *tert*-butylthiotrimethylsilane in acetonitrile solution proceeded smoothly to give di-*tert*-butyldisulfide in high

$$XeF_2 + (CH_3)_3SiSC(CH_3)_3 \rightarrow (CH_3)_3CSSC(CH_3)_3 + (CH_3)_3SiF + Xe$$

yield, along with minor amounts of $(CH_3)_3CSSSC(CH_3)_3$ and $(CH_3)_3CSH$. Xenon and $(CH_3)_3SiF$ were recovered quantitatively.

In the absence of solvent, the reaction was more complex, most probably due to the rapidity of the reaction and inadequate cooling, and the products were S_8, $(CH_3)_3CS_nC(CH_3)_3$ where n = 2–7, and $(CH_3)_3CF$, as well as the expected Xe and $(CH_3)_3SiF$.

The reactions of XeF_2 with silicon–nitrogen compounds such as $[(CH_3)_3Si]_2NH$ and $(CH_3)_3SiNR_2$ where R = CH_3, C_2H_5, $(CH_3)_2CH$ were studied extensively but few firm conclusions can be made at this time, partly because of the hazardous nature of these reactions (see Experimental section).

Despite difficulties, it was possible to show that reaction

$$XeF_2 + 2(CH_3)_3SiNR_2 \rightarrow 2(CH_3)_3SiF + Xe + R_2N(?)$$

gave quantitative yield of xenon and always more than 90% $(CH_3)_3SiF$. The fate of the dialkylamino fragment was investigated as described in greater detail in the Experimental section. All reactions produced dialkylamines with yields in the order $(CH_3)_2NH < (C_2H_5)_2NH < [(CH_3)_2CH]_2NH$. Presumably, $R_2N\cdot$ radicals are formed in solution, followed by hydrogen abstraction from solvent acetonitrile or reagents. Nitrogen-containing radicals are known to react with CH_3CN (26) and a g.c./m.s. study of products from reaction of $(CH_3)_3SiN(CH_3)_2$ showed a g.c. peak with ions *m/e* 84, 83, 58, 44, 42 assigned to $(CH_3)_2NCH_2CN$.

Oily, polymeric material was formed in all reactions with Si—N compounds, in some cases molecular weights greater than 750 were confirmed by mass spectrometry. Polymerization via dialkylamino, *e.g.*

$$(CH_3)_2N\cdot \rightarrow CH_3N{=}CH_2 \rightarrow \text{polymer}$$

radicals has been suggested in the literature (27).

The original goal of preparing Xe—N or Xe—S compounds was not realized, however, the production of $R_2N\cdot$ and $RS\cdot$ radicals is consistent with homolytic bond fission of intermediates such as F—Xe—NR_2 or F—Xe—SR. The

For personal use only.

reaction of $(CH_3)_3SiN(CH_3)_2$ with XeF_2 gave further evidence of an intermediate, since it was observed that reaction at -25 to -30 °C produced a white solid, before the onset of violent reaction, and it is tentatively suggested that the solid is $FXeN(CH_3)_2$. LeBlond and DesMarteau have reported very recently the synthesis of a stable Xe—N compound $FXeN(SO_2F)_2$ which decomposes at 70 °C to give $[N(SO_2F)_2]_2$, Xe, and XeF_2 (28).

Attempts to prepare xenon–nitrogen compounds[3] by reaction of XeF_2 and $(CH_3)_3SiN{=}C(CF_3)_2$ gave only Xe, $(CH_3)_3SiF$, and $(CF_3)_2C{=}NH$, while reaction with $(CF_3)_2C{=}NLi$ gave Xe, $(CF_3)_2C{=}NH$, and LiF.

Impurities and Fluorine Exchange

Previously we showed that H_2O and HF impurities are invariably present in solutions containing reactive fluorides and that n.m.r. spectroscopy may conveniently monitor the presence of these impurities (29). In the case of the less reactive $(CH_3)_3SiF$, hydrolysis and fluorine exchange are catalyzed by dialkylamines (30).

The elimination of trace amounts of impurities was also one of the recurring experimental problems encountered in this work. Since reactions were carried out with XeF_2/CH_3CN solutions, which decompose at room temperature in Pyrex glassware (1, 39), it appears likely that HF and H_2O, along with other impurities, were present in reaction mixtures. Decomposition of hydridofluorophosphoranes and methyliodine(III) difluoride was catalyzed by impurities and it is not known to what extent the isolation of new xenon derivatives may have been prevented by impurities.

In some reactions, n.m.r. spectroscopy confirmed the presence of H_2O and HF impurities. For example, $(CH_3)_3SiF$ and dialkylamines were produced in reactions of XeF_2 and silicon–nitrogen compounds (*vide supra*) and the proton n.m.r. spectrum of $(CH_3)_3SiF$ in some samples showed a single peak rather than the expected doublet. This collapse of the doublet is due to the dialkylamine catalyzed hydrolysis of $(CH_3)_3SiF$

$$(CH_3)_3SiF + H_2O \rightleftharpoons (CH_3)_3SiOH + HF$$

as reported previously (30). No evidence was found of fluorine exchange between XeF_2 and $(CH_3)_3SiF$, as the chemical shift and coupling constant of unreacted XeF_2 showed no change in these solutions.

XeF_2 and Hexafluoroacetone, Perfluoropinacol, and Disodium Perfluoropinacolate

No reaction was detected between hexafluoroacetone and XeF_2, either in acetonitrile as solvent, without solvent, or in the presence of CsF. Some $(CF_3)_2CFOH$ was produced slowly when reaction was carried out in acetonitrile, but this may be explained as the product of HF addition to $(CF_3)_2CO$. Perfluoropinacol was also resistant to attack by XeF_2.

Reaction of XeF_2 with $OC(CF_3)_2C(CF_3)_2O^{2-}2Na^+$ failed to give a stable xenon heterocyclic derivative, the products being NaF, Xe, $(CF_3)_2CO$, and $HOC(CF_3)_2C(CF_3)_2OH$. Perhaps the desired intermediate was formed, which then oxidized to $(CF_3)_2CO$ or reacted with trace amounts of HF or H_2O to liberate perfluoropinacol, but this could not be established.

Experimental

CAUTION: Reaction of XeF_2 with silicon–nitrogen compounds may lead to explosions. Furthermore, the production of Cl_2 or Cl from reaction of XeF_2 with chlorides of P, Si, Ge, etc., may lead to potentially hazardous chlorinations. All reactions involving XeF_2 were carried out behind $\frac{3}{8}$ in. acrylic plastic safety shields within a fume cupboard.

General

XeF_2 was prepared photochemically (31) or obtained commercially (PCR, Gainesville) and dissolved in dried (P_2O_5) and distilled CH_3CN to give approximately 0.5 *M* solutions. These solutions were standardized by reacting aliquots with mercury and weighing xenon gas produced. $(CH_3)_3SiN(CH_3)_2$ was prepared by treating $(CH_3)_3SiCl$ with a 2:1 excess of dimethylamine in xylene (32) and distilling the product. $(CH_3)_3SiN[CH(CH_3)_2]_2$ was prepared in a similar manner. $(CH_3)_3SiN(C_2H_5)_2$ (PCR) and methyl iodide (Eastman) were redistilled prior to use. $(CH_3)_3SiSC(CH_3)_3$ was kindly supplied by O. C. Vaidya and checked to be free of *tert*-butylthiol. Hexamethyldisilazane (Alfa), organochlorosilanes (PCR), $(CH_3)_3GeBr$ (Alfa), organophosphines (Aldrich), chloro-*tert*-butylphosphines (Strem), and di-*tert*-butyldisulfide (PCR) were used without further purification.

Fluorine and proton nuclear magnetic resonance spectra were recorded on Varian A-56/60A and HA100D spectrometers. Chemical shifts are relative to TMS and $CFCl_3$, positive shifts indicating high field shifts. Mass spectra were obtained on a Finnigan 1015 quadrupole mass spectrometer coupled to a Varian 1700 gas chromatograph. Electron spin resonance experiments were carried out on a Varian E-3 e.p.r. instrument. Elemental analyses were performed by Alfred Bernhardt, West Germany.

XeF_2 and Triphenylphosphine

$(C_6H_5)_3P$ (0.052 g, 0.20 mmol) in CH_3CN (0.3 ml) was added to XeF_2 (0.12 mmol) in CH_3CN (0.3 ml) at −10 °C. Reaction occurred on warming to room temperature, complete within 4 min, to give $(C_6H_5)_3PF_2$ (94%), identified by fluorine n.m.r. (33).

XeF_2 and Diphenylphosphine

$(C_6H_5)_2PH$ (0.14 g, 0.75 mmol) was syringed onto XeF_2 (0.64 mmol) in CH_3CN (0.2 ml) at −196 °C. Reaction occurred at −25 °C to give $(C_6H_5)_2PHF_2$, identified by proton and fluorine n.m.r. (Table 1).

A violent reaction occurred when a chloroform solution of $(C_6H_5)_2PH$ was added to solid XeF_2 at room temperature.

XeF_2 and Bis(2-cyanoethyl)phosphine

$(NCCH_2CH_2)_2PH$ (0.12 g, 0.85 mmol) in CD_3CN was syringed onto XeF_2 (0.82 mmol) in CD_3CN (0.4 ml) at −196 °C. All operations were carried out in a dry box. Reaction occurred at −20 °C and was complete within 5 min to give $(NCCH_2CH_2)_2PHF_2$, identified by proton and fluorine n.m.r. (Table 1 and Fig. 1). The clear solution turned yellow and a solid formed after several days at room temperature.

XeF_2 and (2-Cyanoethyl)phosphine

$NCCH_2CH_2PH_2$ (0.1 g, 1.2 mmol) was syringed onto XeF_2 (0.87 mmol) in CD_3CN (0.4 ml) at −196 °C. All operations were carried out in a dry box. Reaction occurred at −35 °C and was complete within 5 min to give $NCCH_2CH_2PH_2F_2$, identified by proton and fluorine n.m.r. (Table 1 and Fig. 2). The clear solution turned yellow and a solid formed after several days at room temperature.

The reaction was repeated on the same scale in CH_2Cl_2 solvent. Reaction occurred at −15 °C and required 30 min for completion to give $NCCH_2CH_2PH_2F_2$. Decomposition to a white solid occurred within 1 day.

XeF_2 and Cyclohexylphosphine

$C_6H_{11}PH_2$ (0.10 g, 0.86 mmol) was syringed onto XeF_2 (0.83 mmol) in CD_3CN (0.4 ml) at −196 °C in a dry box. Reaction occurred at −20 °C to give $C_6H_{11}PH_2F_2$, identified by proton and fluorine n.m.r. (Table 1). The product decomposed after several days at room temperature to give a yellow solid.

XeF_2 and Diphenylchlorophosphine

$(C_6H_5)_2PCl$ (0.022 g, 0.10 mmol) was added to XeF_2 (0.15 mmol) in CH_3CN (0.3 ml) at −10 °C. Reaction occurred on warming to room temperature, complete within 4 min, to give $(C_6H_5)_2PF_3$, identified by fluorine n.m.r. (33).

XeF_2 and Phenyldichlorophosphine

$C_6H_5PCl_2$ (0.012 g, 0.07 mmol) was condensed into a solution of XeF_2 (0.15 mmol) in CH_3CN (0.3 ml) at −196 °C. On warming to 0 °C, a vigorous reaction occurred, complete within 1 min, to give $C_6H_5PF_4$, identified by fluorine n.m.r. (33).

XeF_2 and Di-tert-butylchlorophosphine and tert-Butyldichlorophosphine

$[(CH_3)_3C]_2PCl$ (0.11 g, 0.61 mmol) was added in aliquots of 10 μl to XeF_2 (0.59 mmol) in CH_3CN (0.2 ml) at −20 °C. Reaction occurred immediately on addition of $[(CH_3)_3C]_2PCl$ to give a pale yellow–green solution and a mixture of products which were not fully characterized but assumed to be partially chlorinated alkylfluorophosphoranes, since the mass spectrum revealed fragments containing three chlorine atoms (isotopic ratio) and the proton n.m.r. showed complex peaks in the *tert*-butyl region, while the fluorine n.m.r. showed a sharp doublet (J_{FP} = 726 Hz) at +71.6 p.p.m. (external $CFCl_3$) and a broad doublet (J_{FP} = 1030 Hz) at +56.8 p.p.m.

When the reaction was repeated in cyclohexene solution, the products again showed complex peaks in the *tert*-butyl region, but a fluorine signal was not observed.

Similar results were obtained for the reaction of XeF_2 with $(CH_3)_3CPCl_2$.

XeF_2 and Methyl Iodide

Solid XeF_2 (0.6 mmol) was added to excess methyl iodide (1.5 g) at −196 °C and the solution slowly warmed to room temperature. No reaction was observed below −40 °C; however, at room temperature the reaction proceeds smoothly for 20 min to give an essentially quantitative yield of CH_3IF_2, as monitored by fluorine n.m.r. Excess of methyl iodide may be removed *in vacuo* from the involatile product; however, attempts to purify the product were unsuccessful.

CH_3IF_2 could also be prepared by reaction of XeF_2 (0.20 mmol) in CH_3CN (0.4 ml) with excess methyl iodide at +20 °C. The reaction was slower, requiring 100 min for 75% reaction, while decomposition appeared to be faster and was complete after several hours.

XeF_2 and Phenyl Iodide and Isopropyl Iodide

Reaction of XeF_2 (0.1 g, 0.6 mmol) with excess phenyl iodide (1.9 g) was carried out at 0 °C. The fluorine n.m.r. spectrum of the product showed a single peak (half-height width 4 Hz) at +170.4 p.p.m. assigned to $C_6H_5IF_2$. After 12 h at 5 °C a second peak appeared at +173.8 p.p.m. (half-height width 18 Hz) of relative intensity 18%, which may be assigned to *ortho*-fluorinated $C_6H_4FIF_2$ or $C_6H_3F_2IF_2$.

The reaction of XeF_2 with excess isopropyl iodide at 0 °C was extremely rapid and appeared to give iodine as the major product. Fluorine n.m.r. examination failed to detect any iodine(III) difluoride product.

XeF_2 and Iodine

A few crystals of iodine were dissolved in a solution of XeF_2 (0.12 mmol) in CH_3CN (0.4 ml). The color of the iodine was discharged slowly over a period of 24 h at 20 °C.

In a similar experiment, a few crystals of iodine were dissolved in a solution of XeF_2 (0.11 mmol) in CH_3CN (0.4 ml) but this time dried $(CH_3)_3SiF$ was slowly bubbled into the solution. The iodine color was now replaced by a milky brown coloration which in turn faded to give a colorless solution. The reaction took 3–5 min for completion.

Reaction of XeF_2 with tert-Butylthiotrimethylsilane

In Solvent Acetonitrile

$(CH_3)_3SiSC(CH_3)_3$ (0.28 g, 1.73 mmol) was added to XeF_2 (0.83 mmol) in CH_3CN (0.3 ml) at −196 °C. The reaction mixture was allowed to warm to −7 °C in an ice–salt bath and reaction was complete within 7–9 min, resulting in a pale solution. Products were separated by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

trap-to-trap distillation and identified by n.m.r. and mass spectrometry by comparison with authentic samples. Products (and yields) were Xe (100%), $(CH_3)_3SiF$ (100%), $(CH_3)_3CSSC(CH_3)_3$ (85%), $(CH_3)_3CSSSC(CH_3)_3$ (7%), and $(CH_3)_3CSH$ (7%).

Without Solvent

XeF_2 (0.83 mmol) was weighed into a U-tube, cooled to −196 °C, and $(CH_3)_3SiSC(CH_3)_3$ (0.25 g, 1.54 mmol) was added. On warming to about −30 °C, a rapid exothermic reaction occurred, complete within 1 min, and the final temperature of the mixture was +60 °C. Volatile products were removed and identified as Xe (100%), $(CH_3)_3SiF$ (86%), and $(CH_3)_3CF$ (12%). The residue consisted of a solid identified as S_8 (0.12 g), and a yellow oil which was soluble in $CHCl_3$. The oil showed no fluorine peaks in the n.m.r. but the proton n.m.r. showed at least six singlet peaks in the *tert*-butyl region. By comparison with authentic samples, it was possible to identify $(CH_3)_3CSSC(CH_3)_3$ (12%) and $(CH_3)_3CSSSC(CH_3)_3$ (3%). The remaining *tert*-butyl peaks in the n.m.r. spectrum are assigned to $(CH_3)_3CS_nC(CH_3)_3$ where $n = 4$–7, since mass spectral examination of the oil confirmed the presence of compounds with $n = 2$–7. After three weeks at room temperature, S_8 precipitated from the oil and the yield of $(CH_3)_3CSSC(CH_3)_3$ and $(CH_3)_3CSSSC(CH_3)_3$ increased.

Reaction of XeF_2 with Dimethylaminotrimethylsilane

Without Solvent

Reactions of XeF_2 and $(CH_3)_3SiN(CH_3)_2$ in the absence of solvent were found to be explosive and the following behavior was typical: a mixture of XeF_2 and $(CH_3)_3SiN(CH_3)_2$ appeared stable from −196 to −35 °C. No reaction was apparent on standing at −35 °C for 10 h. At −30 to −25 °C, XeF_2 was observed to react and a white solid formed, followed shortly by a loud detonation which completely destroyed the glass reaction tube. Explosions occurred on two other occasions. When the reaction was attempted in $CFCl_3$, in which XeF_2 is insoluble, a detonation occurred on warming the mixture to approximately −15 °C, shortly after the formation of a white solid had been observed. A similar detonation occurred when a saturated solution of XeF_2 in CH_3CN was used.

Using adequate safety precautions, $(CH_3)_3SiN(CH_3)_2$ (0.35 g, 3.0 mmol) was condensed onto solid XeF_2 (1.65 mmol) at −196 °C and the reaction monitored by changes in pressure. By alternately warming the reaction mixture to −22 °C to initiate reaction, and rapidly cooling to −196 °C, the reaction could be moderated. When pressure build-up ceased, the reaction was assumed complete and all volatile products were removed and identified as Xe (100%), $(CH_3)_3SiF$ (86%), and $(CH_3)_2NH$ (17%). A liquid residue showed a variety of peaks in the dimethylamino region. One of these peaks, at −2.21 p.p.m., is tentatively assigned to $(CH_3)_2NN(CH_3)_2$ (20%) on the basis of the n.m.r. of an authentic sample (kindly supplied by H. D. Gesser) and the m.p. of its methyl iodide derivative 207–211 °C (lit. (34) 222–223 °C). Removal of liquid products under reduced pressure left behind an oil (0.04 g) which analyzed as C, 33.07%; H, 9.17%; N, 19.17%; F, 38.91%. The high fluorine content of the oil and the carbon to nitrogen to hydrogen ratio of 2.01:1.00:6.65 suggests that the oil consists of a mixture of ionic $(CH_3)_2NH_2F$, $(CH_3)_2NH_2HF_2$, and polymeric $(C_2H_6N)_n$.

In Solvent Acetonitrile

Reactions in CH_3CN solution were carried out many times. Typically, $(CH_3)_3SiN(CH_3)_2$ (0.049 g, 0.42 mmol) was condensed onto a solution of XeF_2 (0.20 mmol) in CH_3CN (0.3 ml) at −196 °C. As reactants warmed to above −20 °C a brisk exothermic reaction occurred, complete within 1–2 min. The color of the resulting solution depended on the effectiveness of the cooling of the mixture during reaction. Pale brown solutions could be obtained by maintaining the temperature between −20 and −15 °C, while over-heating resulted in very dark solutions and larger quantities of oily, intractable material. Separation of volatile products gave Xe and $(CH_3)_3SiF$ in quantitative yield and $(CH_3)_2NH$ in 20–30% yield.

Attempts to identify products remaining in CH_3CN solution were unsuccessful, partly because the reactions were carried out on a small scale for safety reasons. Nuclear magnetic resonance showed at least 12 singlet peaks in the dimethylamino region −1.25 to −3.25 p.p.m., their relative intensities varying from reaction to reaction and some products appeared unstable with time. Combined gas chromatography – mass spectrometry using columns Chromasorb 103 and 8% FFAP on Chromasorb 45 showed at least 20 compounds, most of their fragmentation patterns suggesting products containing some or more of the groupings $(CH_3)_2N$, CH_2CN, and CH_3NCH_2. One g.c. peak showed ions *m/e* 84, 83, 58, 44, 42 which may be assigned to $(CH_3)_2NCH_2CN$ and its fragments. Other products could not be assigned with certainty.

Removal of all volatile components from reaction mixture left behind an oily material.

An electron spin resonance study was undertaken to see if free radicals could be detected. $(CH_3)_3SiN(CH_3)_2$ (0.025 g, 0.21 mmol) was allowed to react with XeF_2 (0.10 mmol) in CH_3CN (0.3 ml) at −10 °C in a silica tube. At the onset of a vigorous reaction, the solution was rapidly cooled to −196 °C and the e.s.r. spectrum recorded. A very poorly resolved but nevertheless reproducible spectrum was obtained, with splitting of 28 G, in agreement with that reported for the $(CH_3)_2N$ radical (35). If the reaction was allowed to go to completion, no e.s.r. signal was observed. Starting materials were checked to be free of e.s.r. signals.

Reaction of XeF_2 with Diethylaminotrimethylsilane

In a typical reaction, $(CH_3)_3SiN(C_2H_5)_2$ (0.049 g, 0.34 mmol) was added to a solution of XeF_2 (0.16 mmol) in CH_3CN (0.5 ml) at −10 °C. A brisk reaction occurred, complete within 1–2 min, to give a brown solution. Products were Xe (100%), $(CH_3)_3SiF$ (90%), diethylamine, and an oily residue. The yield of diethylamine was variable, but generally accounted for 70–80% of available diethylamino groups. In an e.s.r. experiment similar to that above, no free radicals could be detected.

The reaction was repeated many times in baked out glassware, silylated glassware, Teflon tubes, monel reactor, and polypropylene container, all giving essentially similar results.

Reaction of XeF_2 with Diisopropylaminotrimethylsilane

In a typical reaction, $(CH_3)_3SiN[CH(CH_3)_2]_2$ (0.074 g,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

0.42 mmol) was added to XeF_2 (0.20 mmol) in CH_3CN (0.4 ml) at −10 °C. On warming to room temperature the solution turned brown and reaction was complete within 5 min to give Xe (100%), $(CH_3)_3SiF$ (90%), $[(CH_3)_2CH]_2NH$ (80–90%), and an oily residue.

Electron spin resonance experiments proved misleading, since a well resolved signal was observed at room temperature, but this signal was also observed in a sample of unreacted $(CH_3)_3SiN[CH(CH_3)_2]_2$ and may be attributed to a trace of $[(CH_3)_2CH]_2NO$ (36), present in the starting material.

Reaction of XeF_2 with Hexamethyldisilazane

$[(CH_3)_3Si]_2NH$ (0.52 g, 3.3 mmol) was condensed onto XeF_2 (3.2 mmol) in CH_3CN (8 ml) at −196 °C and reaction monitored by changes in pressure. Reaction occurred slowly at room temperature and was complete after 30 min to give Xe (100%), $(CH_3)_3SiF$ (95%), a small amount of noncondensable gas (at −196 °C) assumed to be nitrogen, and an oily residue.

The oil contained organic polymeric material since the mass spectrum showed peaks up to *m/e* 750, with a complex fragmentation pattern dominated by loss of 14 mass units (loss of CH_2 or N). Washing the oily residue with CH_3CN and drying under vacuum gave a pale brown solid (0.03 g) which analyzed as C, 7.55%, H, 5.55%; N, 22.56%; F, 30.30%. The ratio H:N:F of 3.42:1.00:0.99 suggests the solid is mainly NH_4F. Its i.r. spectrum showed broad N—H bands and the solid was soluble in water and partly soluble in acetone.

Monitoring the Reaction of XeF_2 with Organosilicon Chlorides

The production of Cl_2 from reaction of XeF_2 with organosilicon chlorides (1) was confirmed in this study as follows: a u.v. cell with two chambers, each of 4.375 mm path length, was stoppered with a drilled (to permit escape of Xe) Teflon stopper. One chamber contained XeF_2 (0.33 mmol) in CH_3CN, the other $(CH_3)_3SiCl$ (0.074 g, 0.68 mmol) in CH_3CN. The cell was cooled to 0 °C and reaction initiated by quickly inverting cells. The u.v. spectrum was scanned every 20–30 s and an increase in absorption at 315–320 nm (37) confirmed the production of Cl_2. Repeating the experiment with a 20:1 molar ratio of $(CH_3)_3SiCl$ to XeF_2 suppressed the build-up of Cl_2. Evidently, chlorination of excess $(CH_3)_3SiCl$ gave $(CH_2Cl)(CH_3)_2SiCl$. Chloromethyl derivatives gave characteristic downfield shifts of the CH_2Cl protons, −3.06 p.p.m. for $CH_2Cl(CH_3)_2SiCl$ and −2.98 p.p.m. for $CH_2Cl(CH_3)_2SiF$.

To verify the n.m.r. spectra of chloromethyl derivatives, $CH_2Cl(CH_3)SiF_2$ was prepared from a commercial sample of $(CH_3)_2SiF_2$ (1.97 g, 20.5 mmol) and Cl_2 (1.12 g, 15.8 mmol) in a sealed Pyrex tube exposed to sunlight for 3 days. Fluorine n.m.r. of the product gave a quartet of triplets at +138.2 p.p.m. $J_{F-CH_3} = 6$ Hz, $J_{F-CH_2Cl} = 4$ Hz. Proton n.m.r. showed a triplet (CH_3) at −0.56 p.p.m. and a triplet (CH_2Cl) at −2.91 p.p.m., with intensity ratio 3:2, consistent with the product $CH_2Cl(CH_3)SiF_2$.

Reaction of organochlorosilanes could also be monitored by fluorine n.m.r., for example reaction of XeF_2 with $(CH_3)_3SiCl$ in CH_3CN occurred at a moderate rate at 0 °C, and the decrease of XeF_2 and increase of $(CH_3)_3SiF$ concentration could be followed conveniently. However, accurate rate studies were not carried out.

Reaction of XeF_2 and Trimethylgermanium Bromide

$(CH_3)_3GeBr$ (0.079 g, 0.40 mmol) was added to XeF_2 (0.25 mmol) in CH_3CN (0.4 ml). Reaction occurred at 25 °C and was complete within 10 min to give Xe and $(CH_3)_3GeF$ in quantitative yield, and bromine. The color of the solution was reddish brown and the presence of Br_2 was confirmed by adding olefins which discharged the color. $(CH_3)_3GeF$ was identified by mass spectrometry and fluorine n.m.r., dectet at +186.5 p.p.m., $J_{FH} = 7$ Hz, and proton n.m.r., doublet at −0.6 p.p.m.

XeF_2 and Hexafluoroacetone

Hexafluoroacetone (0.10 g, 0.60 mmol) was condensed onto XeF_2 (0.15 mmol) in CH_3CN (0.3 ml) at −196 °C and contents sealed in an n.m.r. tube. Fluorine n.m.r. showed no initial reaction, however, after 3 weeks at room temperature, all XeF_2 was consumed and the solution now contained $(CF_3)_2CFOH$, identified by fluorine n.m.r., doublet ($J_{FF} = 2$ Hz) at +82.8 p.p.m. and septet at +125.8 p.p.m.

In attempts to prepare a fluoroxy derivative, $(CF_3)_2CFOF$, hexafluoroacetone and XeF_2 without solvent were kept at room temperature for 5 days; in another experiment CsF was added as a catalyst, but no evidence of the desired product was found.

XeF_2 and Disodium Perfluoropinacolate

Disodium perfluoropinacolate, $OC(CF_3)_2C(CF_3)_2O^{2-}$ $2Na^+$ was prepared in THF (38). In separate experiments it was found that solutions of XeF_2 in THF were unstable, hence it was necessary to replace THF by CH_3CN by removing THF under vacuum and adding CH_3CN and repeating procedure several times.

In a typical experiment XeF_2 (0.35 mmol) was added to a solution of $OC(CF_3)_2C(CF_3)_2O^{2-}$ $2Na^+$ (0.32 mmol) in CH_3CN (0.5 ml), prepared as described above, at −196 °C and the reaction monitored by pressure changes. At −20 °C, the original pale brown solution turned yellow to greenish-yellow and finally colorless, and a white solid formed. Volatile products were identified as $(CF_3)_2CO$ and $HOC(CF_3)_2C(CF_3)_2OH$. The solid was identified as sodium fluoride by X-ray powder pattern; very faint lines indicated that the powder contained some Na_2SiF_6.

Perfluoropinacol was found to be resistant to attack by XeF_2.

The financial assistance of the National Research Council of Canada and the Petroleum Research Fund, administered by the American Chemical Society, is gratefully acknowledged. We also thank NRCC for a postgraduate scholarship (to J.A.G.).

Reagents for High Temperature Aqueous Chemistry: Trifluoromethanesulfonic Acid and its Salts

LEONARD FABES AND THOMAS WILSON SWADDLE[1]

Department of Chemistry, The University of Calgary, Calgary, Alberta T2N 1N4

Received June 13, 1975

LEONARD FABES and THOMAS WILSON SWADDLE. Can. J. Chem. **53**, 3053 (1975).

The rate of decomposition of trifluoromethanesulfonic acid (HTFMS) in water is first order with respect to each of H^+ and $TFMS^-$. The bimolecular rate coefficient k_H can be represented by

$$k_H = 1.7 \times 10^{14} \exp(2.15 \times 10^5/8.314T) \text{ kg mol}^{-1} \text{ s}^{-1}$$

at ionic strength 1.0 mol kg^{-1} over the temperature range $571 < T < 593$ K, although the decomposition occurs by two pathways of comparable importance, one leading to C(II) and S(VI) and the other to C(IV) and S(IV). In alkaline solution, the rate of decomposition of $TFMS^-$ is first order in each of $TFMS^-$ and OH^-, and the bimolecular rate coefficients k_{OH} at ionic strength 2.3 are given by

$$k_{OH} = 4.1 \times 10^8 \exp(1.46 \times 10^5/8.314T) \text{ kg mol}^{-1} \text{ s}^{-1}$$

This represents a single reaction pathway leading initially to C(II) and S(VI) and ultimately to CO_3^{2-}, SO_4^{2-}, F^-, and H_2, since C(II) (as formate) reduces aqueous alkali to H_2 under the reaction conditions. No decomposition of NaTFMS could be detected after 24 h at 620 K in neutral aqueous solution. HTFMS reduces certain aqueous species at significant rates at moderate temperatures (*e.g.*, Fe(III) to Fe(II) at 470 K), and metals which depend on oxide films for their corrosion resistance are attacked by HTFMS even at 294 K (*e.g.*, Ti dissolves giving $Ti(H_2O)_6^{3+}$). Otherwise, HTFMS and its salts have good potentialities as inert electrolytes for aqueous studies at high temperatures.

LEONARD FABES et THOMAS WILSON SWADDLE. Can. J. Chem. **53**, 3053 (1975).

La vitesse de décomposition de l'acide trifluorométhane sulfonique (HTFMS) dans l'eau est du premier ordre par rapport à H^+ et par rapport à $TFMS^-$. Le coefficient de vitesse bimoléculaire, k_H, peut être représenté par l'équation

$$k_H = 1.7 \times 10^{14} \exp(2.15 \times 10^5/8.314T) \text{ kg mol}^{-1} \text{ s}^{-1}$$

à une force ionique de 1.0 mol kg^{-1}, à des températures allant de 571 à 593 K même si la décomposition se produit suivant deux voies d'égale importance, une conduisant à C(II) et S(VI) et l'autre à C(IV) et S(IV). En solution alcaline, la vitesse de décomposition du $TFMS^-$ est du premier ordre en $TFMS^-$ et du premier ordre en OH^- et le coefficient de vitesse bimoléculaire, k_{OH}, à force ionique 2.3, est donné par l'équation

$$k_{OH} = 4.1 \times 10^8 \exp(1.46 \times 10^5/8.314T) \text{ kg mol}^{-1} \text{ s}^{-1}$$

Ceci represente une seule voie pour la réaction qui conduit originalement à C(II) et S(VI) et ultérieurement à CO_3^{2-}, SO_4^{2-}, F^- et H_2 puisque C(II) (sous forme de formate) réduit, dans les conditions de la réaction, une solution aqueuse d'alkali en H_2. A 620 K, en solution aqueuse neutre, on ne peut pas noter de décomposition du NaTFMS après 24 h. A des températures modérées, l'acide HTFMS réduit à des vitesses significatives certaines espèces en solutions aqueuses (par exemple Fe(III) en Fe(II) à 470 K); les métaux qui dépendent sur la formation de films d'oxyde pour devenir résistants à la corrosion sont aussi attaqués par l'acide HTFMS même à 294 K (par exemple le Ti se dissout pour donner du $Ti(H_2O)_6^{3+}$). Autrement il semble que l'acide HTFMS et ses sels présentent de bonnes potentialités comme électrolytes inertes pour des études aqueuses à hautes températures.

[Traduit par le journal]

Introduction

Measurements of the parameters (acid dissociation constants, stability constants, rate coefficients, etc.) which govern the chemistry of aqueous electrolytes can, in principle, be made on pressurized solutions far above the normal boiling point of water, much as at room temperature, if a thermally stable, strongly ionized,

poorly complexing, 'inert' electrolyte is available. The traditional electrolyte, perchloric acid, is remarkably stable kinetically towards spontaneous thermal decomposition in dilute aqueous solution, largely as a result of a high activation energy combined with a high reaction order (1), but recent work by T. C. T. Wong in our laboratories has shown that this decomposition can be catalyzed by aqueous metal ions. Thus, aqueous $HClO_4$ (1.0 *m*, *i.e.* 1.0 mol kg^{-1}) containing 0.01 *m* Fe(III) yields 0.01 *m* chloride ion after 28 h at 473 K in Teflon lined autoclaves, whereas in the absence of Fe(III) the acid would decompose only to the extent of 3×10^{-8} *m* (1). Furthermore, perchloric acid solutions can oxidize many species of interest directly as one goes toward high temperatures and kinetic barriers are removed (2, 3).

A nonoxidizing alternative to perchloric acid is trifluoromethanesulfonic acid, HTFMS ('trimsylate' (4) or 'triflic acid'). The discoverers of this acid (5) recognized its remarkable resistance to thermal decomposition and hydrolysis, and also that it is one of the strongest protonic acids known, as has subsequently been amply verified (6–13). No universal series of relative acid strength exists, since the protonating powers of various acidic solutes vary from solvent to solvent (13), but it seems safe to conclude that HTFMS will be at least as fully ionized in water at high temperatures as is $HClO_4$, which cannot be more than slightly associated in water up to 600 K (1). The $TFMS^-$ ion is also a very weak complexing agent, being only slightly more effective in complexing aqueous Cr(III) than is perchlorate ion (14), although $TFMS^-$ complexes with UO_2^{2+} (15) and Mo_2^{4+} (16) have been isolated. Thus, $TFMS^-$ offers an excellent alternative to ClO_4^-, BF_4^-, PF_6^-, etc., especially when reagents which are potential oxidants or are solvolytically unstable must be avoided (17–19).

The aqueous $TFMS^-$ ion has been reported to be stable in acidic solution up to at least 550 K (20) and in neutral or alkaline solution up to 620 K (21). This stability, however, is kinetic rather than thermodynamic, and we have therefore sought to define it in terms of the appropriate rate equations and parameters for the various hydrolysis pathways as functions of p*H* and temperature, thereby permitting upper limits to be set to the extent of spontaneous decomposition of the reagent in typical experimental situations, as well as gaining information on the reaction mechanisms.

Experimental

Anhydrous HTFMS, as purchased from the 3M Company, was black, presumably with organic char (20), but a simple distillation under anhydrous conditions at reduced pressure was sufficient to give a product which analyzed correctly for H^+, contained no detectable HF, and gave the same kinetic results from batch to batch. A further careful fractional distillation of this colorless liquid led to no detectable change.

Kinetic Measurements

The pressure vessels, previously described (1), were of titanium – 0.2% palladium alloy or (with basic samples only) of Type 316 stainless steel, and were protected from corrosion by the samples with silica liners (acidic solutions only) or Teflon liners; the silica liners were slightly attacked, presumably by the HF produced in the decomposition of HTFMS, but the Teflon vessels appeared to be completely inert to both acidic and alkaline solutions. The free volume in the autoclaves was 47 cm^3. The $TFMS^-$ solutions were made up on a volume basis, but concentrations were expressed on the molal (mol/kg) scale using the measured densities and corrected for the evaporative loss entailed in generating the saturated vapor pressure of the solution (taken to be that for pure water) at the reaction temperatures. The derived kinetic results were the same whether a 10 or a 25 cm^3 aliquot of the $TFMS^-$ solution was placed in the autoclave.

The solution samples were sealed into the autoclaves under an air or a nitrogen atmosphere at 0.1 MPa (the results were shown to be independent of the presence or absence of oxygen) and brought to the desired temperature in a preheated Blue M Conwate CW-160HF-1 forced-convection oven (constancy ± 0.3 K during a run). It was established, by extrapolating reactant concentrations back to their original values as functions of time, that the effective zero time of the reactions was the same at which the oven temperature (measured as described previously (1)) was seen to be stabilized, which was 40 min after placing the vessels in the oven. In general, conditions were chosen to give slow reaction rates, so as to minimize any errors associated with sample warm-up. Autoclaves were removed as required and quenched rapidly to room temperature with water.

The $TFMS^-$ content of the solutions could not easily be determined directly with good precision, but it was found that an Orion 92-81 perchlorate ion selective electrode, used in conjunction with an Orion 801 p*H* meter and 90-02 double-junction reference electrode, gave a linear response to $TFMS^-$ when the p*H* was adjusted to about 5 with sodium acetate, and could be used to measure $[TFMS^-]$ in the range 0.002–0.05 *m* without significant interference from the decomposition products F^-, HCO_3^-, HSO_3^-, or SO_4^{2-}. The Gran method (22) enabled $TFMS^-$ concentrations to be measured with a standard deviation of 7%, which, though poor, was acceptable for measurement of the rate of disappearance of $TFMS^-$ in acidic solutions, since the usual alternative of following the formation of the reaction products was not feasible; the S and C products were distributed amongst various oxidation states, while the F product,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

present as volatile HF, was partially depleted by reaction with the autoclave walls or possibly by vapor loss on opening the pressure vessels.

The fluoride contents of the solutions were measured with about 1% precision using an Orion 94-09 ion selective electrode, as previously described (23). This method was effective in measuring the rate of hydrolysis of $TFMS^-$ in alkaline solution.

Reaction Products

Dissolved fluoride was measured with the Orion 94-09 electrode. Sulfate was measured gravimetrically as $BaSO_4$. Sulfite was estimated by redox titration. Carbonate was measured by a p*H* titration procedure, which also gave rough indications of the F^- and SO_3^{2-} contents through inflexions in the titration curves at lower p*H* than for CO_3^{2-}.

The gaseous decomposition products of aqueous HTFMS were determined by mass spectroscopy, the samples of the aqueous acid having been sealed into quartz ampoules which were heated in autoclaves, partially filled with water to pressurize the tubes externally. This procedure was not followed with alkaline $TFMS^-$ solutions, as these would have attacked any available material other than Teflon, which would have been too soft to form a gastight ampoule at high temperatures. Nevertheless, when NaTFMS was decomposed in 9 *m* NaOH for 19 h in a Teflon lined autoclave at 572 K, a sample drawn from the gas space of the cooled autoclave immediately on opening was found by mass spectrometry to contain much hydrogen gas; in the same way, sodium formate was shown to yield H_2 under these conditions.

Results

Reaction Products

The gaseous products of the partial thermal decomposition of aqueous HTFMS were primarily CO_2, CO, and SO_2, with traces of H_2S, F_2CO, CS_2, and some trivial components with unassignable mass numbers. The recorded 44:28 (CO_2:CO) mass ratio rose from 1.6 for samples decomposed at 563 K to 2.9 for 593 K, as compared with 5.7 for pure CO_2 (CO_2^+ undergoes partial fragmentation to CO^+); these data indicate that two parallel paths of comparable importance were operating in the decomposition of HTFMS in acidic solution, one of relatively low activation energy E_a leading to CO and one of higher E_a leading to CO_2. Some elemental sulfur was recovered, especially at the higher temperatures, so that this product may be associated with the CO_2 producing reaction. The aqueous phase contained HF, HCO_3^-, SO_4^{2-}, and HSO_3^-. It was shown in separate experiments that S(IV) disproportionates to S(0) and S(VI) in aqueous acid at high temperatures (*e.g.*, in 3 *m* HCl or H_2SO_4 at 584 K over 19 h), thus accounting for the presence of elemental sulfur in the decomposition products of HTFMS. The disproportionation of S(IV) is thermodynamically possible in aqueous systems at all p*H* values even at 298 K (24), but mechanistic limitations evidently prevent its occurrence except at high temperatures (~570 K) and high acidities, on the usual experimental time scale. The disproportionation reaction was insufficient to account for all the S(VI) produced in the acidic decomposition of HTFMS, and in any event the decomposition path leading to C(II) (carbon monoxide) must produce S(VI) directly. The main reactions in the decomposition of $TFMS^-$ in acidic solutions are therefore 1, 2*a*, and 2*b*.

[1] $CF_3SO_3^- + 2H_2O = 3HF + HSO_4^- + CO$

[2*a*] $CF_3SO_3^- + 2H_2O + H^+ = 3HF + H_2SO_3 + CO_2$

[2*b*] $3H_2SO_3 = 2HSO_4^- + S + H_2O + 2H^+$

In alkaline solutions at about 570 K, $TFMS^-$ was hydrolyzed *quantitatively* to $3F^-$, SO_4^{2-}, and CO_3^{2-}, and it was shown qualitatively that H_2 was a major product. It was also established that SO_3^{2-} quantitatively survives heating at about 580 K in 1 *m* NaOH for several days, so that no pathway analogous to reaction 2 could have been operative in the alkaline decomposition of $TFMS^-$. In alkaline solution, a S(VI) producing reaction analogous to reaction 1 would yield formate rather than CO (ref. 24, p. 278), and formate ion is thermodynamically capable of reducing alkaline water to H_2 even at 298 K (25):

[3] $HCO_2^- + OH^- = H_2 + CO_3^{2-}$ $\Delta G^0 = -35$ kJ mol^{-1}

Thus, the final products of an alkaline hydrolysis of $TFMS^-$ producing initially S(VI) and C(II) should be F^-, SO_4^{2-}, CO_3^{2-}, and H_2, if reaction 3 is sufficiently rapid at the reaction temperature, and this is indeed what is observed.

[4] $CF_3SO_3^- + 6OH^- = 3F^- + SO_4^{2-} + CO_3^{2-} + H_2 + 2H_2O$

Exploratory measurements showed that the rate of decomposition of formate ion in 1.9 *m* NaOH at 586 K, as followed by $KMnO_4$ titration, was very close to that calculated by Arrhenius extrapolation (see below) for the disappearance of $TFMS^-$ under the same conditions, so that a substantial buildup of formate ion during the alkaline hydrolysis of $TFMS^-$ was neither expected nor observed.

Kinetics

Because the formal reaction 2*a* (at least) consumes H^+ whereas reaction 1 does not, the time dependence of the HTFMS concentration could not be expected to follow a simple integrated rate expression over a substantial fraction of the decomposition reaction. Instead, the concentration of $TFMS^-$ was monitored over the first 20% of the reaction in acidic solution, and the slope of the crudely linear plot of $[TFMS^-]$ against time t was taken to be $-d[TFMS^-]/dt$ at the mean $[TFMS^-]$. These data are collected in Table 1. The reproducibility of these rates was as poor as $\pm 14\%$, but this is as good as could be expected in view of the 7% uncertainty in the $[TFMS^-]$ analyses and the difficulty of presetting the nominal reaction temperatures accurately.

Log–log plots of the rate data of Table 1 at a given nominal reaction temperature against stoichiometric [HTFMS] when $[H^+] = [TFMS^-]$ were linear, within the experimental uncertainty, with a slope of about 1.8, which suggests a second-order reaction with a retarding ionic strength effect (*cf.* the decomposition of aqueous $HClO_4$, which is actually 4th order with an apparent reaction order of 3.5). A plot of log(rate) *vs.* log $[H^+]$ for 583 K and nearly constant ionic strength (2.6–2.7 *m*) had slope ~0.9, showing the reaction to be essentially first order with respect to each of H^+ and $TFMS^-$, and accordingly bimolecular rate coefficients k_H are given in Table 1. At the nominal temperatures 582.6 and 592.9 K, k_H values generally decreased as the ionic strength I increased, and can be represented to within the rather large experimental error by equations 5 and 6.

$$[5] \quad k_H^{582.6} = (10.3 - 1.8I) \times 10^{-6}\ m^{-1}\ s^{-1}$$

$$[6] \quad k_H^{592.9} = (2.6 - 0.5I) \times 10^{-5}\ m^{-1}\ s^{-1}$$

For $I = 1.0\ m$, we have $k_H \sim 4.3 \times 10^{-6}$, 8.5×10^{-6}, and $2.1 \times 10^{-5}\ m^{-1}\ s^{-1}$ at 571.6, 582.6, and 592.9 K respectively. These data give a somewhat curved Arrhenius plot (concave upwards, as expected for two parallel reactions having the same rate law) but can be reproduced satisfactorily by an activation energy of 215 kJ mol^{-1} and a preexponential factor of 1.7×10^{14} $m^{-1}\ s^{-1}$, the uncertainty in these parameters being about 20%.

The rate of disappearance of $TFMS^-$ in alkaline solution is much more readily measured as one-third of the rate of formation of F^-, low concentrations of which were determined with 1% precision. This permitted rate measurements to be made with OH^- in large excess over $TFMS^-$, and the initial rates of $TFMS^-$ collected in Table 2 were reproducible to 5%, most of this margin representing the difficulty of reproducing the reaction temperature from one run to another. Examination of the data of Table 2 shows that the reaction is accurately first order in each of OH^- and $TFMS^-$ at a given ionic strength, and the corresponding bimolecular rate coefficients k_{OH} listed for 552 K, $I = 2.2 \pm 0.1\ m$ are obviously constant within 5% standard deviation. The data for $I = 2.28\ m$ as a function of temperature gave a good Arrhenius plot with $E_a = 146$ kJ mol^{-1} and a preexponential factor of $4.1 \times 10^8\ m^{-1}\ s^{-1}$. The alkaline hydrolysis rate is evidently accelerated by increasing the ionic strength; this is opposite to the ionic strength effect on the acidic hydrolysis reaction, as expected for reactions of opposite charge types.

Neutral solutions of NaTFMS (1 *m*) underwent no detectable decomposition, even at 620 K over 24 h.

Reaction of HTFMS with Metals and Metal Ions

At 294 K, type 316 stainless steel tubing was visibly etched within one day by deaerated HTFMS (1.0 *m*), and commercial titanium dissolved in it to give a purple solution of $Ti(H_2O)_6^{3+}$ over a few hours; Ti – 0.2% Pd alloy was more resistant, but nevertheless gave an appreciably yellow-orange solution over 24 h. By contrast, these metals were not detectably attacked by 1 *m* $HClO_4$ or H_2SO_4 over several days.

The divalent metal ions Mn, Fe, Co, Ni, and Cu were unchanged after 24 h in 1.0 *m* HTFMS at 570–580 K. Further studies in our laboratories by T. C. T. Wong, however, have shown that HTFMS reduces aqueous iron(III) to iron(II) under relatively mild conditions (*e.g.*, 0.05 *m* Fe(III) in 1.5 *m* HTFMS is reduced to the extent of at least 7% in 24 h at 473 K, with the concomitant formation of HF).

Discussion

The rate determining step in the alkaline hydrolysis of $TFMS^-$ evidently involves nucleophilic attack of OH^- on the S atom of $TFMS^-$

$$[7] \quad HO^- + SO_3CF_3^- \rightarrow HOSO_3^- + CF_3^-$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The actual initial products of this step may be SO_4^{2-} and HCF_3, or SO_4^{2-}, CF_2, and F^-, but in any event the fluorocarbon moiety will hydrolyze to HCO_2^- in alkali (26). We have demonstrated that formate ion is oxidized to carbonate with H_2 evolution at a rate sufficiently rapid at the temperatures involved here to to account for the observed reaction products, sulfate, carbonate, fluoride, and hydrogen.

In acidic solution, the reactions 1 and 2*a* occur simultaneously, with reaction 1 accounting for some 33% of the decomposition rate at 563 K and about 16% at 593 K, on the basis of the mass spectroscopic yields of CO and CO_2, corrected for the difference in the ionization cross-sections of these molecules (27). Both acidic decomposition pathways are evidently first order in each of $TFMS^-$ and H^+, if ionic strength effects are allowed for, and accordingly, neutral solutions of $TFMS^-$ were found not to hydrolyze significantly even at temperatures approaching the critical point of water. The decomposition mechanisms presumably involve the undissociated HTFMS molecule (in which case HTFMS must still be a fairly strong acid in water at 600 K, in order to give the observed reaction orders).

[8] $$H^+ + CF_3SO_3^- \rightleftharpoons CF_3SO_3H$$

Assuming, for argument's sake, a bimolecular mechanism for the hydrolysis of HTFMS, nucleophilic attack of water on the S atom of HTFMS will be seen to give S(VI) and C(II), much as in equation 7, whereas attack of the water molecule on the C atom will yield C(IV) and S(IV),

[9] $$H_2O + CF_3SO_3H \rightarrow HOCF_3 + H_2SO_3$$

the postulated trifluoromethanol intermediate hydrolyzing rapidly to carbonic acid and HF.

Whether the decomposition of $TFMS^-$ proceeds via reaction 1, 2*a*, or 4, the potential reducing power of this anion is clearly seen, since a familiar reducing agent (CO, SO_2, H_2) is produced in each case. This reducing power can be exercised directly at relatively low temperatures. Thus, Fe(III) is reduced to Fe(II) in acidic aqueous solution around 470 K, and metals (*e.g.*, titanium) or alloys (*e.g.*, stainless steels) which are corrosion resistant by virtue of having a tenacious oxide film are attacked quite rapidly by aqueous HTFMS even at 290 K, presumably because of reduction of the oxide coat. The latter property has been utilized to activate passive metals prior to chromium plating (28). These considerations limit the usefulness of HTFMS as a high-temperature aqueous reagent, but nevertheless it can be of great value in situations where a strong electrolyte of good thermal stability is required and reducing conditions can be tolerated.

Finally, this study serves to illustrate the fact that much familiar 'room temperature chemistry' exists only by virtue of high kinetic barriers to the realization of thermodynamic exigency. The resistance of $TFMS^-$ to hydrolysis is due in part to the high activation energies of the various hydrolysis pathways, and in part to the need to involve either H^+ or OH^- in the decomposition mechanisms. Similarly, SO_2 should disproportionate in water, and formate ion (*i.e.*, CO) should reduce aqueous alkali to hydrogen, at 298 K; these reactions do occur on a relatively short time-scale at 500–600 K, where many kinetic barriers are overcome.

We thank J. W. Cobble for first drawing our attention to the potential uses of HTFMS, and Atomic Energy of Canada, Ltd., for financial support of this work.

The Electroreduction of some *N*-Haloamides[1]

DENIS BÉRUBÉ, JEAN CAZA, FRANK M. KIMMERLE, AND JEAN LESSARD
Département de chimie, Université de Sherbrooke, Sherbrooke, Québec J1K 2R1

Received January 9, 1975

DENIS BÉRUBÉ, JEAN CAZA, FRANK M. KIMMERLE, and JEAN LESSARD. Can. J. Chem. **53**, 3060 (1975).

The electroreduction of nine *N*-haloamides (ZCONRX) at a dropping mercury electrode has been investigated in protic and aprotic media. Preparative electrolysis indicated the possibility of capturing the intermediate amide radical by intermolecular addition to olefins or by intramolecular hydrogen abstraction.

DENIS BÉRUBÉ, JEAN CAZA, FRANK M. KIMMERLE et JEAN LESSARD. Can. J. Chem. **53**, 3060 (1975).

On a étudié la réduction électrochimique de neuf *N*-haloamides (ZCONRX) à l'électrode à goutte de mercure tombante en milieu protique et aprotique. Les électrolyses préparatives laissent croire que le radical amide intermédiaire peut être capté par addition intermoléculaire à des oléfines et par abstraction intramoléculaire d'hydrogène.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Our interest in *N*-haloamides and amide radicals (1–4), and in particular in the chromous chloride promoted addition of *N*-haloamides to olefins (1, 2), led us to study the electrochemical reduction of some *N*-haloamides. It is obvious that if by an electrochemical route the reduction of the nitrogen–halogen bond leads to an amide radical Z—CO—$\dot{N}$—R then a facile means of the production of a promising synthetic intermediate has been attained. Furthermore, it was hoped that the study of the electron transfer at a solid electrode would give additional insight regarding the mechanism of the transition metal catalyzed reaction. As a first step in this direction we have investigated the reduction of the nine compounds in Table 1 by classical d.c. polarography, cyclic voltammetry and preparative electrolysis.

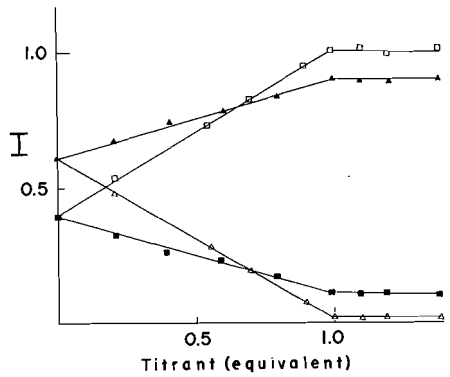

FIG. 1. Amperometric titration of NCU (**1**) (20 m*M*) in 0.2 *M* methanolic solution of $LiClO_4$. (*a*) Titrant is acetic acid: □ I_1, △ ($I_2 - I_1$). (*b*) Titrant is sodium methoxyde: ■ I_1, ▲ ($I_2 - I_1$). I_1 (at −1.0 V *vs.* s.c.e.) and I_2 (at −1.6 V *vs.* s.c.e.) are given in arbitrary units.

Polarographic Studies

In methanolic solutions *N*-chlorourethane (NCU) (**1**), and *N*-chloroacetamide (NCA) (**2**), show two diffusion controlled reduction waves. NCU: $(E_{1/2})_1 = -0.60$ V, $(E_{1/2})_2 = -0.96$ V *vs.* a saturated calomel electrode (s.c.e.); NCA: $(E_{1/2})_1 = -0.43$ V, $(E_{1/2})_2 = -1.12$ V *vs.* s.c.e. $(E_{1/2})_1$ is p*H* independent, $(E_{1/2})_2$ is displaced cathodically only at operational p*H* values in excess of p*H* 11, but the respective currents I_1 and I_2 are p*H* dependent. The dependence is so exact that it can serve as the basis of an amperometric titration analysis illustrated in Fig. 1 for NCU (**1**).

Indeed, the waves correspond to highly irreversible two electron reduction steps involving the neutral molecule (acid) and the anion (base) respectively:

[1] $SH^+ + ZCONHCl + 2e^- \rightarrow ZCONH_2 + Cl^- + S$

and

[2] $2SH^+ + ZCO\bar{N}Cl + 2e^- \rightarrow ZCONH_2 + Cl^- + 2S$

where SH^+ is a proton donor (*e.g.* ZCONHCl or CH_3OH). The overall reactions are in perfect accord with the results of mass electrolysis (100 ± 2% coulombic efficiency) and chemical

[a]Of isolated products.
[b]Not determined.
[c]By v.p.c. The electrolysis in the presence of an equivalent of acetic acid gave a quantitative yield of urethane.
[d]The exact yield was not determined because of the high solubility of the amides in water.
[e]No preparative electrolysis was carried out.

analysis of the products (see Preparative Electrolyses).

For electroanalytical purposes it may be noted that the polarographic diffusion currents are linear functions of the concentration from 10^{-4} to 5×10^{-3} *M* and vary with the square root of the mercury column height for all compounds listed in Table 1. The half wave potentials do not vary with concentration although for compounds **3** to **6** they are somewhat ill defined (±0.05 V) due to incipient polarographic maxima.

In an aprotic medium such as acetonitrile, NCU (**1**), NCA (**2**), and *N*-bromoacetamide (NBA) (**6**) show the two reduction waves due to the neutral molecule [1] and the anion [2] respectively (Table 1). Indeed the corresponding lithium salts show the second wave only; upon addition of acetic acid, the first wave appears and when two or more equivalents of acid are added, only the first wave can be seen. The polarographic reduction of NCU (**1**) and NCA (**2**) remains truly irreversible (αn values of the order of 0.3 and 0.4 for the first wave) and the reduction products (urethane, acetamide) are not reoxidized even at a platinum anode before the anodic decomposition of the electrolyte. The polarographic reduction of the *N*-chloro-α-chloroacetamides **3** to **5** is also irreversible ($\alpha n \sim 0.9$, $n = 2$). At potentials more cathodic than −0.8 V *vs.* s.c.e., two or more waves appear, one being most probably due to the reduction of the N—Cl bond of the anions, and the other(s) to the reduction of the C—Cl bonds; this region was not further investigated.

Since the mechanism proposed by Lessard *et al.*[2] for the chromous chloride promoted addition of *N*-haloamides to olefins implied an amide radical species, we had hoped to be able to discern two consecutive one electron transfer steps (*e.g.* [3] and [4]) constituting [1] or [2]:

$$[3] \qquad ZCONHCl + e^- \rightarrow ZC\dot{O}NH$$

$$[4] \qquad ZC\dot{O}NH + e^- + SH^+ \rightarrow ZCONH_2 + S$$

In retrospect it may not be surprising that the insertion of the second electron [4] should be faster than or as fast as the insertion of the

first and hence indiscernable by normal electroanalytical techniques. We also searched for chemical evidences of the formation of the amide radical [3], by coupling, trapping by hydrogen abstraction from methanol, and by addition to olefins, in preparative electrolyses at a mercury and a platinum cathode but without any success.[3] However addition products have been isolated when preparative electrolyses of NCU (**1**) were carried out at a graphite electrode in the presence of an olefin under special conditions.

Although standard electrode potentials could not be established (anodic region inaccessible), the $E_{1/2}$ values show useful trends with the chemical structures of the depolarizers (Table 1). Since we can assume that the same functional group (—C(=O)—NH—X) is involved, we expect the $E_{1/2}$ values to reflect the activation energy of the first electron transfer step and also the stability of the intermediate species (7).

The two possible mechanisms for the addition of the first electron are: (*1*) addition to the N—X bond whose fission leads to the amide radical and the halide anion [5];

$$[5] \quad ZCONHX + e^- \rightarrow [ZCONH \cdots X]^{\cdot -} \rightarrow ZCO\dot{N}H + X^-$$

(*2*) addition to the π system with the subsequent cleavage of the N–X bond (which might be concerted with the electron transfer) leading to the amide radical and the halide anion [6].[4]

$$[6] \quad ZCONHX + e^- \rightarrow [Z\overset{O^{\cdot}}{\overset{|}{C}}-NH-X]^- \rightarrow ZCO\dot{N}H + X^-$$

For both mechanisms, one would expect that an electron withdrawing group Z should facilitate electron acceptance and render the reduction potential more anodic, but probably more so for the second mechanism. For the reduction of the *N*-chlorocarboxamides, $E_{1/2}$ becomes more anodic in the sequence **2** ($Z = CH_3$) < **3** ($Z = CH_2Cl$) < **4** ($Z = CHCl_2$) < **5** ($Z = CCl_3$), the effect being the largest for the introduction of the first chlorine. The reduction potential of NCU (**1**, $Z = OC_2H_5$) is more anodic than that of NCA (**2**, $Z = CH_3$) but more cathodic than that of *N*-chloro-α-chloroacetamide (**3**, $Z = CH_2Cl$). Although an ethoxy group should have a stronger inductive effect than a chloromethyl group, this effect should be partly compensated in the former by its ability to share its electrons with the carbonyl group of the amide. The more anodic reduction potential of *N*-chlorosuccinimide (**7**) as compared to that of *N*-chloroacetamide (**2**) can be accounted for also by either mechanism. *N*-chloro-*N*-ethylacetamide (**8**) and *N*-chloro-*N*-tertiobutylpentanamide (**9**) are more easily reduced than *N*-chloroacetamide (**2**) in agreement with the stabilizing influence of an alkyl group, as compared to an hydrogen atom, in the intermediate amide radical. Finally NBA (**6**) is more readily reduced than NCA (**2**) as expected on the basis of bond strength, polarizabilities and ease of reduction of organic (alkyl, aryl, vinyl) halides (10).

Preparative Electrolyses

In methanol, using $LiClO_4$ electrolyte, the reduction of NCU (**1**) at a mercury electrode in

[3]The experimental results for the reduction at a mercury electrode do not allow us to distinguish between the direct reduction of the amide radical [4] and the reduction of an intermediate species resulting from the trapping of the amide radical by mercury. Mann *et al.* (5) suggested an analogous interaction of the organo radical with mercury in the reduction of a cyclopropyl bromide.

Two reduction waves have been observed for the alkylmercuric halides (6). In order to eliminate the possibility of the two reduction waves of NCU (**1**), NCA (**2**), and NBA (**6**) being due to the rapid formation of organomercuric halides upon contact with mercury, the reaction of NCU (**1**) and NBA (**6**) with mercury was investigated. The original polarographic waves disappeared slowly, a new wave appeared, and a grey precipitate, consisting primarily of colloïdal mercury and calomel, was formed. These reactions could be prevented by imposing a slightly cathodic potential on the mercury metal and were not investigated extensively (see Experimental).

[4]For the electroreduction of the vinyl halides, Miller and Riekena (8) have suggested that the first electron may add to the π system to give an anion radical which loses a halide anion to form the vinyl radical. For the reductive hydrogenolysis of *p*-carbomethoxy- and *p*-cyano-substituted benzyl methyl ether, benzyl acetate and benzylidyne trifluoride in protic medium, electron transfer to the substituent followed by the cleavage of the C—O and C—F bonds has been proposed as the first step (9).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the presence of an equimolar amount of acetic acid (reduction of the neutral molecule)[5] yielded 92% (isolated) urethane. The reduction carried out in the presence of an equimolar quantity of sodium methoxyde (reduction of the anion)[5] gave a quantitative yield (by v.p.c.) of urethane. In either reduction, no *N*,*N*′-dicarboethoxyhydrazine (coupling of two urethane radicals) could be detected by vapor phase chromatography (v.p.c.). Also attempts to detect formaldehyde prove inconclusive.[6]

In acetonitrile ($LiClO_4$ electrolyte), the reduction of NCU (**1**) and the *N*-chloroacetamides **2** to **5** at the mercury electrode gave the corresponding amides in the yields indicated in Table 1. No traces of dimerization products (coupling of amide radicals) could be detected. The results were identical for the reduction of NCU (**1**) at a platinum electrode.

Electroreduction of NCU (**1**) in the presence of electron-poor olefins such as acrylonitrile (**10**, Y = CN) and methyl acrylate (**10**, Y = $COOCH_3$) in a methanol–chloroform (2:3) mixture readily led to the addition product $C_2H_5OCONHCH_2CH_2Y$ (**11**). The mechanism does not involve radicals but involves the addition of anions. The product may be formed directly from the urethane anion, the path followed being similar to that proposed by Baizer and Chruma (11) in their study of the reduction of organic *gem*-halides in the presence of electrophilic double bonds:

$$[7]\quad C_2H_5OCO\bar{N}H + \underset{\mathbf{10}}{CH_2{=}CHY} \rightarrow C_2H_5OCONHCH_2\bar{C}HY \xrightarrow{SH^+} \underset{\mathbf{11}}{C_2H_5OCONHCH_2CH_2Y}$$

where SH^+ is a proton donor, predominantly $C_2H_5OCONHCl$ (**1**). A ready source of protons will favor the formation of urethane (reaction 1, Z = OC_2H_5) while extremely low concentrations of SH^+ would favor polymerization reactions (11). Alternatively, the product may be formed indirectly from the NCU anion:

$$[8]\quad C_2H_5OCO\bar{N}Cl + \underset{\mathbf{10}}{CH_2{=}CHY} \rightarrow C_2H_5OCONCH_2\bar{C}HY \xrightarrow{SH^+} \underset{\mathbf{12}}{C_2H_5OCONCH_2CH_2Y}$$

(Cl on the N of the first product and on the CH of the second)

followed by:

$$[9]\quad \underset{\mathbf{12}}{C_2H_5OCONCH_2CH_2Y} + 2e^- \xrightarrow{SH^+} \underset{\mathbf{11}}{C_2H_5OCONHCH_2CH_2Y} + Cl^-$$

It was shown that the homogeneous reaction 8 followed by bisulfite reduction yielded **11** (*e.g.* 46% yield for Y = CN). As has been demonstrated above, the *N*-chloro-*N*-alkyl carboxamides are more readily reduced than the ZCONHCl species itself so that [9] competes favorably with [1]. In mass electrolysis **12** is thus readily reduced and **11** constitutes the major product (50% yield for Y = CN, 61% yield for Y = $COOCH_3$).[7] No trace of α-chlorinated products ($C_2H_5OCONHCH_2\underset{Cl}{C}HY$) expected from a radical chain mechanism could be detected.

Reduction of NCU (**1**) at a mercury cathode in acetonitrile in the presence of norbornene (10 fold excess) gave urethane only according to v.p.c. analysis. No traces of addition products could be detected. Thus, if a radical is indeed formed upon addition of the first electron [3], it would seem that in the competition between the insertion of a second electron and the chemical reaction, the former usually wins out. This is in direct contrast to the chromous chloride catalysed addition of *N*-chlorourethane to olefins where each Cr(II) ion can contribute but one electron. There, the competition depends on the chance encounter with a second chromous ion or the olefin. In that case addition was favored by maintaining the concentration of the discrete electron source, the Cr(II)

[5]NCU (**1**) is a weaker acid than acetic acid (ΔpK_a = 3.3 in methanol–water 1:1) but much stronger than methanol.

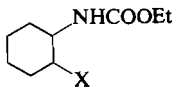
[6]Formaldehyde was formed in the chromous chloride reduction of NCU (**1**) in methanol as the result of hydrogen abstraction from methanol by the urethane radical (see footnote 2).

[7]No attempt was made to identify the nature of the remaining products.

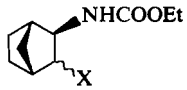
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

species, as low as practical. At the electrode however, a virtually unlimited supply of electrons is available and it becomes necessary to enhance the chances of chemical reaction.

In order to increase the concentration of olefin near the electrode we employed a cathode consisting of a graphite paste constituted by mixing NCU (**1**) with a five fold excess of cyclohexene or norbornene. After electrolysis for nine hours at room temperature the *cis* and *trans* addition products were obtained, analyzed, and isolated. With cyclohexene, a 18% yield of 1,2-adducts **13** and **14** (*cis–trans* 0.5:1) was obtained, and with norbornene the yield was 14% of **16** and **17** (*cis–trans* 1:1). Urethane still constituted the major product. In a control experiment in which the graphite paste (NCU (**1**) and cyclohexene) was kept at room temperature for ten hours, there was an 8% loss of active chlorine (iodometric titration) and formation of *ca.* 0.9% (by v.p.c.) of 1,2-adducts **13** and **14** (*cis–trans* 0.5:1).

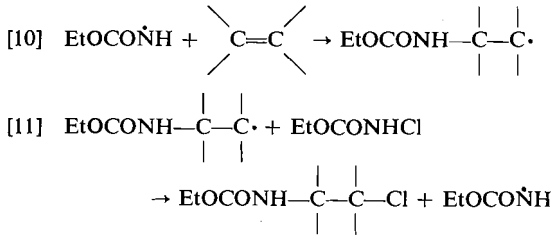


13 X = Cl (*cis*)
14 X = Cl (*trans*)
15 X = H



16 X = Cl (*exo*)
17 X = Cl (*endo*)
18 X = H

Thus it seems probable that, in the above electrolyses, most of the addition products were formed via the electrochemically generated urethane radical [3] by a chain mechanism:

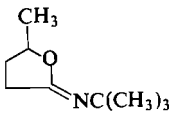


Chain termination by a second electron transfer step to the radical according to [4] is in fair accord with the number of coulombs passed and p*H* changes. No traces of the reduced products, *N*-cyclohexylurethane (**15**) or *N*-(2-*exo*-norbornyl)urethane (**18**), could be detected. Compound **18** is the major product (54%) in the chromous ion reduction of NCU in the presence of norbornene (1).

The addition products **13** to **18** were shown to be much more difficult to reduce than NCU and thus, once formed, unlikely to disappear during electrolysis. We therefore conclude that the reduction of the intermediate β-amidoalkyl radical must be slower than its reaction with NCU [11].

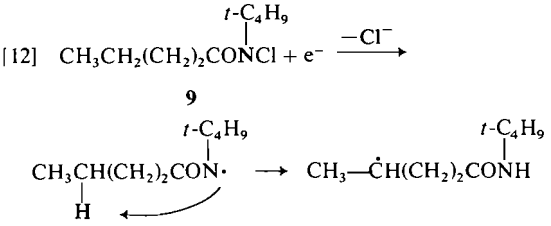
In order to confirm the intervention of an amide radical in the electrolytic reduction of the *N*-chloro-*N*-alkyl carboxamides we employed another approach since the addition of *N*-alkylamido radicals to olefins is more difficult than the addition of the corresponding *N*-hydroamido radicals (3, 4). Neale *et al.* (12) have shown that aliphatic (C_4 to C_6) *N*-chloro-*N*-alkyl carboxamides can be rearranged photolytically to the 4-chloro derivative, the preferred *N*-substituent being the *t*-butyl group. For instance, photolysis of *N*-chloro-*N*-*t*-butyl pentanamide (**9**) in benzene gave the 4-chloro derivative **19** and *N*-*t*-butyl pentanamide (**20**) in a 43% and 42% yield respectively (12). The radical chain reaction involved include a selective intramolecular hydrogen abstraction at C_4 by the amide radical through a six atom transition state.

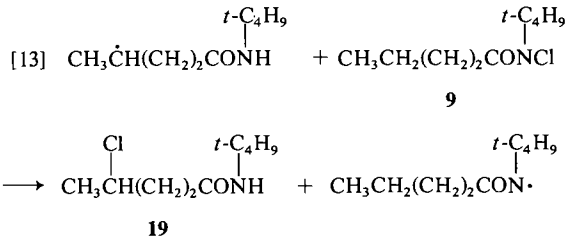
Electrolysis of *N*-chloro-*N*-*t*-butyl pentanamide (**9**) at the mercury cathode yielded 37% of the 4-chloro derivative **19** and 55% of the carboxamide **20** for a total product yield of 92% (the proportion of **19** and **20** was calculated from the n.m.r. spectrum of the crude product. The chemical proof of the presence of **19** was obtained by the synthesis of the iminolactone **21**).



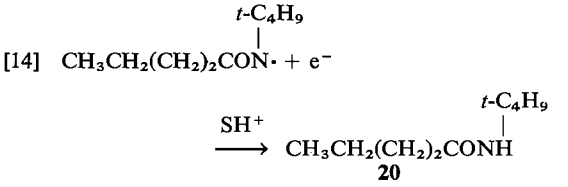
21

Here the product yield is competitive with the photolysis results. The coulombic efficiency was close to 200%, clearly indicating a radical-chain mechanism:





The main chain termination step most likely involves the reaction 14 giving rise to **20**:



Under conditions identical to those of the electrolysis but without applying any potential, the *N*-chloroamide **9** reacted with mercury (31% loss of active chlorine) with the formation of a black precipitate. No 4-chloro-*N*-*t*-butyl-pentanamide (**19**) could be detected, the sole organic product formed being the pentanamide **20**. Therefore the formation of the 4-chloro derivative **19** during the electrolysis most probably involves the electrochemically generated amide radical [12].

Conclusions

The electroreduction of *N*-halocarboxamides and *N*-chlorourethane (**1**) in aprotic and protic media proceeds at the mercury electrode at $E_{1/2}$ potentials depending on the chemical nature of the depolarizer, the p*H* and to a lesser degree the nature of the solvent. The reduction involves two consecutive one electron steps. The very irreversible first electron transfer and formation of a radical species is followed by a considerably faster uptake of the second electron to form the anion. We believe that the intermediate radical in the reduction of NCU (**1**) has been trapped under special conditions by intermolecular addition to olefins. In the case of *N*-chloro-*N*-*t*-butyl pentamide (**9**) the radical has been captured by intramolecular hydrogen abstraction to a degree offering possible applications in synthesis. The addition of NCU (**1**) to acrylonitrile and methylacrylate has been shown to proceed readily and to involve the addition of anions.

Experimental

Solvents and Electrolyte

Acetonitrile (Fischer ACS reagent) was purified by distillation from phosphorous pentoxide. Chloroform (anhydrous reagent, Fischer) was used without further purification and absolute methanol was obtained by standard procedure. Lithium perchlorate (anhydrous reagent, Alfa Inorganics Co.) was used after drying in a vacuum oven for 24 h at 100 °C.

Electrochemical Instrumentation

A three electrode potentiostat (Tacussel type ASA 100) with an automatic drop dislodger (Tacussel type MPO3) or a rotating platinum electrode (Tacussel type Controvit) was used to record respectively the polarograms and voltammograms. Potentials were measured with respect to an aqueous saturated calomel electrode with a KCl saturated agar salt bridge separated from the electrolysis vessel by a compartment containing supporting electrolyte between two fritted glass discs in order to prevent water contamination.

A glass cell of concentric construction containing the anode in a central compartment separated by a fritted glass disc from the exterior catholyte compartment (50 or 200 ml volume) was employed for mass electrolysis. A three electrode system controlled by a Tacussel type ASA 100 potentiostat was employed for all but the electrolysis involving a graphite paste electrode. In the latter case the high resistance of the porcelaine cup (see below) rendered potentiostatic control impossible unless the reference electrode was buried in the carbon paste, but the conditions employed (both electrolysis at fixed current and constant applied potential) correspond to about 1/5 of the limiting current and entail little danger of provoking alternate reactions. For coulometric determination the progress of the electrolysis was followed by recording polarograms after a fixed number of coulombs had passed and by iodometric titration of the remaining halogen derivatives. The charge passed was obtained by graphically integrating the current time curves and by using an electrochemical coulometer.

All voltammetric analyses as well as mass electrolyses were carried out in a nitrogen atmosphere. For the polarographic reduction of *N*-bromoacetamide (**6**), Nujol was added at the bottom of the cell to isolate the solution from mercury and the cell was cooled in an ice bath. In mass electrolyses, a slight negative potential was applied at the mercury electrode before adding the *N*-haloamide in order to prevent the formation of a precipitate (see reaction of *N*-haloamides with mercury).

Analysis of Products and Starting Materials

Melting points were determined on a Büchi apparatus and are uncorrected. The i.r. spectra were determined on a Perkin-Elmer 257 spectrometer. The n.m.r. spectra were recorded on a Varian A-60 instrument and chemical shifts are reported in δ. The mass spectra were taken on a Hitachi RMU-6E spectrometer. The v.p.c. analyses were performed on a Hewlett Packard chromatograph model 5750 equipped with both thermal conductivity and flame-ionization detectors. A 6 ft × 0.25 in. OS-138 on Chromosorb W column was used. Merck silica gel GF_{254} was used for thin and preparative layer chromatography. Organic phases from extractions were dried over anhydrous sodium sulfate.

N-Haloamides

N-Chlorourethane (**1**) (88% active chlorine), *N*-chloro-2-chloroacetamide (**3**) and *N*-chloro-2,2-dichloroacetamide (**4**) (100% active chlorine) were prepared from the corresponding amides by the sodium hypohalite method (13). *N*-Chloroacetamide (**2**) was prepared according to the method described by Orton and Bradfield (14), m.p. 109–110 °C (100% active chlorine). *N*-Chloro-2,2,2-trichloroacetamide (**5**) was prepared according to the method of Park *et al.* (15), m.p. 124–125 °C (100% active chlorine). *N*-Chloro-*N*-ethylacetamide (**8**) was prepared by treatment of an aqueous solution of the corresponding amide containing sodium bicarbonate with chlorine followed by extraction with methylene chloride and distillation under reduced pressure; b.p. 46–47 °C (15 Torr) (96% active chlorine, 75% yield). *N*-Chloro-*N*-tertiobutylpentanamide (**9**) was prepared by the method described by Neale *et al.* (12) in a 65% yield (85% active chlorine). The *N*-bromoacetamide (**6**) and *N*-chlorosuccinimide (**7**) were obtained commercially (Aldrich Chemical Co.) and were recrystallized from methylene chloride (> 99% active chlorine).

The lithium salts of NCU (**1**) and NBA (**6**) were obtained as a foam by treating the *N*-haloamide with an equimolar amount of lithium methoxyde in anhydrous methanol and evaporating to dryness under vacuum.

Reaction of N-Haloamides with Mercury

N-Chlorourethane (1)

A solution of 626 mg (99% active chlorine, 5.07 mmol) of NCU (**1**) in 10 ml of a 0.2 *M* $LiClO_4$ solution in acetonitrile was stirred at room temperature with 11 g of mercury under a nitrogen atmosphere. A grey precipitate began to appear after a few minutes. The reaction was followed by polarography. A new wave appeared at +0.10 V *vs.* s.c.e., the waves due to NCU and its anion disappearing gradually. The current of the new wave reached a maximum after 5.5 h corresponding to 48% of $I_1 + I_2$ of the starting solution and then decreased slightly. After 20 h the reaction mixture was filtered and the precipitate washed with acetonitrile then methylene chloride. The resulting solution was concentrated under reduced pressure (~ 10 ml) and water (40 ml) was added. There was no NCU left according to iodometric assay. Continuous extraction with methylene chloride afforded 253 mg of urethane (56% yield). The grey precipitate (3.9 g) was treated with dilute nitric acid and the resulting solution continuously extracted with methylene chloride to yield an additional 82 mg of urethane (total yield of 74%).

The reaction was repeated and the precipitate was isolated after 3 h, dried, and analyzed for mercury and chloride ion: Hg, 92.6 ± 1.1%; Cl^-, 4.1 ± 0.4%; the remaining 3% was probably organic in nature.

The reaction was carried out in CD_3CN and followed by n.m.r., each aliquot being carefully freed from the solid suspension. After a few hours, the spectrum showed only unresolved broad absorptions for possibly NH protons and protons of an ethoxycarbonyl group. After 24 h, the spectrum was well resolved and identical to that of urethane.

N-Bromoacetamide (6)

The reaction was carried out on 0.98 mmol of NBA in the polarographic cell. A white precipitate was formed immediately upon the addition of mercury and became grey after a few minutes. The wave at *ca.* −0.1 V *vs.* s.c.e. disappeared while a new wave at −0.29 V was appearing. After 4 h the polarogram showed only this new wave. No attempt was made to isolate and characterize the products.

N-Chloro-N-tertiobutylpentanamide (9)

A solution of 1.13 g (85% active chlorine, 4.95 mmol) of *N*-chloro-*N*-tertiobutylpentanamide (**9**) in 10 ml of a 0.2 *M* $LiClO_4$ solution in acetonitrile was stirred at room temperature with 4 g mercury under a nitrogen atmosphere. A black precipitate began to appear almost as soon as mercury was added. After 24 h, the reaction mixture was filtered, worked up in the usual way, analyzed for active chlorine (3.40 mmol, 69% of unreacted **9**), then treated with a saturated solution of sodium bisulfite until the reduction of active chlorine was completed. Extraction with methylene chloride gave 0.825 g of *N*-tertiobutylpentanamide (**20**), m.p. 44–47 °C (89% by taking into account the 15% present in the starting material). The presence of the 4-chloro-derivative **19** could not be detected in the n.m.r. spectrum. The precipitate (2.24 g) was analyzed for mercury and chloride ion: Hg, 97.2 ± 0.3%; Cl^- (as Hg_2Cl_2), 2.6 ± 0.1% (total of 99.8 ± 0.3%). An X-ray powder diffraction analysis confirmed the presence of the crystalline Hg_2Cl_2 phase.

An identical solution of the *N*-chloroamide **9** kept at room temperature for 24 h but without adding mercury gave the following results: 4.75 mmol (92%) of unreacted **9**; 0.850 g of *N*-tertiobutylpentanamide (**20**), m.p. 43–47 °C (91%) after reduction with sodium bisulfite.

Electrolyses

Some typical electrolyses are summarized below.

Electroreduction of N-Chlorourethane (1)

In Methanol—A solution of 1.22 g (88% active chlorine, 10 mmol) of *N*-chlorourethane (**1**) and 0.6 g (10 mmol) of acetic acid in 50 ml of a 0.2 *M* methanolic solution of $LiClO_4$ was electrolyzed at a cathode potential of −0.7 V. The anode compartment (auxiliary electrode, Mg) contained 5 to 7 ml of the 0.2 *M* electrolyte solution. The electrolysis was discontinued when no more active chlorine was present (negative potassium iodide – starch paper test). The catholyte was poured into water (*ca.* 50 ml) then extracted with methylene chloride (3 × 100 ml). The organic layers were washed with water then combined and dried. The solution was concentrated to a volume of *ca.* 50 ml by distilling the solvent and then analyzed by v.p.c. (170 °C). Urethane was the main component. No traces of the dimer *N,N'*-dicarboethoxyhydrazine could be detected. Small amounts of products with lower retention times than that of urethane were present and were not investigated. Removal of the solvent in the rotatory evaporator left 0.81 g (92%) of urethane, m.p. 43–45 °C, identified further by comparison of the i.r. and n.m.r. spectra with those of an authentic sample (Aldrich Chemical Co.).

The electrolysis carried out in the presence of an equimolar (10 mmol) amount of sodium methoxyde (instead of acetic acid) and at a cathode potential of −1.2 V, the other conditions being exactly the same as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

above, gave urethane only according to the v.p.c. analysis (100% yield).

In Acetonitrile—The electrolysis was carried out on 10 mmol as described above except that acetonitrile was used as solvent and no base or acid was added. The cathode potential was −0.3 V (auxiliary electrode, Mg). The usual work-up gave, after complete evaporation of the solvent, 0.84 g (94%) of urethane, m.p. 44–45 °C. The dimer *N,N'*-dicarboethoxyhydrazine could not be detected by v.p.c. analysis.

The electrolysis was repeated in the presence of an excess of norbornene (100 mmol). Urethane was the only product formed according to the v.p.c. analysis. No traces of the adducts **16**, **17** or **18** could be detected.

Electrochemical Reduction of N-Chloro-2,2,2-trichloroacetamide (5)

A solution of 315 mg (1.50 mmol) of *N*-chloro-2,2,2-trichloroacetamide (**5**) in 50 ml of a 0.2 *M* solution of $LiClO_4$ in acetonitrile was electrolyzed at a cathode potential of −1.0 V (auxiliary electrode, Mg) until the test for active chlorine was negative. The usual work-up followed by evaporation of the solvent left 155 mg of a crystalline residue. The v.p.c. analysis showed that it consisted of trichloroacetamide and dichloroacetamide in a 9:1 ratio (authentic samples were used as standards). Crystallization from methylene chloride gave practically pure trichloroacetamide, m.p. 138–140 °C. Continuous extraction with methylene chloride for several days gave an additional 16 mg of 2,2-dichloroacetamide. Thus the yield of trichloroacetamide was 70% and that of dichloroacetamide 19%. Both amides were further identified by the comparison of their i.r. spectra with those of authentic samples.

Electroreduction of N-Chlorourethane (1) in the Presence of Methyl Acrylate and Acrylonitrile

Methyl Acrylate—The cathode compartment was filled with 50 ml of a 0.2 *M* $LiClO_4$ solution in a 2:3 mixture of absolute methanol and chloroform and 42 ml (40 g, 465 mmol) of methylacrylate were added. The anode compartment (auxiliary electrode, Pt) contained 10 to 15 ml of the electrolyte solution. A potential of −0.3 V was applied and 8 ml of a 2.25 *M* *N*-chlorourethane (**1**) solution (18 mmol) in methanol–chloroform 2:3 were added dropwise in order to maintain a current of 50 mA. The addition took 3 h and, after the current had reached 10 mA, 20 ml of a saturated $NaHSO_3$ solution were added to reduce the active chlorine left. The mixture was extracted with methylene chloride (3 × 100 ml). The organic layers were combined and dried. The resulting solution was concentrated in the rotatory evaporator then transferred into a 50 ml volumetric flask with methylene chloride. Analysis by v.p.c. (180 °C) showed that methyl 3-carboethoxyaminopropionate (**11**, Y = $COOCH_3$) was formed in a 61% yield. An authentic sample prepared from β-alanine[8] was used as standard. Evaporation of the solvent followed by distillation of the residue under reduced pressure gave 1.51 g (48%) of adduct **11** (Y = $COOCH_3$), b.p. 134 °C (5 Torr), identified with the authentic material by comparison of the i.r. and n.m.r. spectra.

Acrylonitrile—The reduction was carried out exactly as described above except that methylacrylate was replaced by acrylonitrile (500 mmol). Microdistillation of the residue at 115 °C (1 Torr) afforded 0.53 g of a mixture of urethane and compound **11** (Y = CN). Separation of an aliquot by preparative v.p.c. (OS-138, 175 °C, 6 ft × 3/8 in. column) gave the pure 3-carboethoxyaminopropionitrile (**11**, Y = CN) but with low recovery due to decomposition on the column; υ_{max} ($CHCl_3$) 3420 (>NH), 2240 (—C≡N), 1720 (amide I), 1515 (amide II), 1250 and 1200 cm^{-1} (—CO—O—Et); δ ($CHCl_3$), 1.25 (t, J = 7 Hz, CH_3—CH_2—O—), 2.62 (t, J = 7 Hz, —CH_2—CH_2—CN), 3.50 (q, J = 7 Hz, —NH—CH_2—CH_2—), 4.20 (q, J = 7 Hz, CH_3—CH_2—O—), and 5.22 (m, —NH—); *m/e* 142 (M^+).

The reaction was repeated and the yield of **11** (Y = CN) was determined by v.p.c. using the pure sample obtained above as standard: 50%.

Addition of the Lithium salt of N-Chlorourethane (1) to Acrylonitrile

The solution of 18 mmol of *N*-chlorourethane in 150 ml of a 2:3 mixture of absolute methanol and chloroform was treated with an equimolar amount of lithium methoxyde (prepared from lithium metal and absolute methanol). Excess acrylonitrile (33 ml) was added and the mixture was kept at room temperature overnight under a nitrogen atmosphere. Sodium bisulfite (20 ml of a saturated aqueous solution) was added to reduce the active chlorine and the mixture was extracted with methylene chloride (3 × 100 ml). The organic layers were combined and dried, and the solvent was removed at the rotatory evaporator. Analysis by v.p.c. (175 °C) showed that 3-carboethyoxyaminopropionitrile (**11**, Y = CN) was formed in a 46% yield using the authentic sample obtained above as standard.

Electroreduction of N-Chlorourethane (1) at Graphite Cathode in the Presence of Olefins

In the Presence of Cyclohexene—In a cylindrical (20 × 175 mm) porous porcelain crucible were placed 6 g of graphite powder, 3.50 g (88% active chlorine, 25 mmol) of *N*-chlorourethane (**1**) and 10 ml (8.1 g, 99 mmol) of cyclohexene. The mixture was stirred with a glass rod until an homogeneous paste was obtained. The electrical contact was ensured by a graphite rod immersed in the paste. A cylindrical platinum anode surrounded the cathode compartment and the anolyte consisted of 50 ml of a 0.2 *M* solution of $LiClO_4$ in acetonitrile. A potential of −10 V was applied between the two electrodes and the electrolysis was discontinued when the active chlorine test (potassium iodide – starch paper) was negative; 2789 coulombs (29×10^{-3} F) were passed in 9 h. The anolyte was extracted with methylene chloride in the usual manner after the addition of water (*ca.* 20 ml). The two solutions were combined, concentrated, then transferred into a 50 ml volumetric flask. The v.p.c. analysis gave the following results: urethane, 66%; ethyl *cis*-*N*-(2-chlorocyclohexyl)carbamate (**13**), 6%; and ethyl *trans*-*N*-(2-chlorocyclohexyl)carbamate (**14**), 12%. Authentic samples of **13** and **14** (1) were used as standards. No trace of *N*-cyclohexylurethane (**15**) could be detected. The isolation of compounds **13** and **14** for complete identification is described below.

The solution above was further concentrated and ether was added. A crystalline product was collected

[8]H. Driguez, Ph.D. Thesis, Université de Sherbrooke, 1971.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(580 mg, m.p. 134–135 °C) and was identified as *trans-N*-(2-chlorocyclohexyl)acetamide by comparison of the i.r. and n.m.r. spectra with those of an authentic sample.[8] The formation of this product can be explained by the diffusion of cyclohexene from the catholyte to the anolyte since Faita *et al.* (16) have shown that the oxidation of chloride ions in the presence of cyclohexene in acetonitrile gave *trans-N*-(2-chlorocyclohexyl)acetamide, the chloride ions being provided in the present case by the reduction of *N*-chlorourethane (**1**).

Separation of the mother liquors by preparative layer chromatography on silica gel afforded 1.22 g of urethane (48% taking into account the presence of 12% in the starting material), 0.27 g (5%) of the *cis* adduct **13** m.p. 53–56 °C, and 0.59 g (12%) of the *trans* adduct **14** m.p. 90–92 °C. Both adducts were fully identified by comparison of their i.r. and n.m.r. spectra with those of authentic samples (1).

In a control experiment the graphite paste was kept at room temperature for 10 h under a nitrogen atmosphere without applying any potential. After work up as above, the solution was analyzed for active chlorine: 4.6 mmol, 92% of unreacted NCU (**1**). The active chlorine was reduced with a saturated sodium bisulfite solution. The organic phase was washed with water then dried. The v.p.c. analysis gave the following results: urethane, 96%; *cis* 1,2-adduct **13**, ~0.3%; *trans* 1,2-adduct **14**, ~0.6%.

In the Presence of Norbornene—The reaction was carried out as described above for cyclohexene with 9.0 g (95 mmol of norbornene and 3.20 g (88% active chlorine, 22.8 mmol) of *N*-chlorourethane (**1**). No active chlorine was present after 962 coulombs (9.96×10^{-3} F) were passed. The methylene chloride washings of the catholyte and the methylene chloride phases from the extraction of the anolyte were combined and the solvent removed in the rotatory evaporator. The residue was separated by preparative layer chromatography on silica gel to yield 0.80 g (35%, taking into account the presence of 12% in the starting material) of urethane, 0.36 g (7%) of ethyl *N*-[2-*exo*-(3-*exo*-chloronorbornyl)]-carbamate (**16**), m.p. 45–58 °C, and 0.33 g (7%) of ethyl *N*-[2-*exo*-(3-*endo*-chloronorbornyl)]carbamate (**17**), m.p. 85–88 °C. Both 1,2-adducts **16** and **17** were fully identified by comparison of their i.r. and n.m.r. spectra with those of authentic samples (1). The v.p.c. analysis of the other fractions showed no trace of *N-exo*-norbornylurethane (**18**), and they were not examined further.

Electroreduction of N-Chloro-N-tertiobutylpentamide (9)

A solution of 4.18 g (85% active chlorine, 18.5 mmol) of *N*-chloro-*N*-tertiobutylpentanamide (**9**) in 25 ml of 0.2 *M* $LiClO_4$ in acetonitrile was electrolyzed at a cathode potential of −0.3 V. The anode compartment (Pt auxiliary electrode) contained 10 ml of the 0.2 *M* electrolyte solution. The electrolysis was discontinued when no more active chlorine was present (23 h at a current of *ca.* 10 mA). The usual working-up (addition of water, methylene chloride extractions, etc.,) gave 2.93 g of crude product. The n.m.r. spectrum was compared with that of the crude product obtained from the photolysis of the same *N*-chlorocarboxamide **9** carried out as described by Neale *et al.* (12). The weight ratio of *N*-tertiobutylpentanamide (**20**) to *N*-tertiobutyl-4-chloropentanamide (**19**) was calculated to be approximately 1:2 from the relative integration of the protons of the terminal methyl group which appears at 0.9 δ (ill-defined triplet) in the carboxamide **20** and at 1.51 δ (d, J = 6 Hz) in the 4-chloroderivative **19**. Thus assuming that the carboxamide **20** and the 4-chloro derivative **19** were the sole components of the crude product (in fact some impurities were present in small amount, <5% according to the n.m.r. spectra), the yield of the 4-chlorocarboxamide **19** is 37% and that of the carboxamide **20**, 55%.

A chemical proof of the presence of the 4-chlorocarboxamide **19** in the crude product was obtained in the following manner. An aliquot of 1.46 g of the crude product from the electroreduction was treated with an excess of silver perchlorate (10 mmol) in 50 ml of 50% aqueous acetonitrile at 60 °C for 1 h. The mixture was poured onto crushed ice, treated with 5% NaOH, then extracted with ether (3 × 50 ml). The ether layers were combined and dried. Removal of the ether by distillation was followed by microdistillation of the residue at 69 °C (10 Torr) to give 0.26 g of the iminolactone **21**. The i.r. and n.m.r. spectra were identical to those of the sample obtained by the same procedure from the photolysis crude product. The hydrochloride had m.p. 120–121 °C (lit. (12), m.p. 123 °C).

Support for this work by the Ministère de l'Education, Québec, and the National Research Council of Canada is gratefully acknowledged.

The Importance of Anharmonicity of the Vibrational Excited States in Chemical Kinetics

JAN BRON

Department of Chemistry, University of Natal, Durban, South Africa

Received March 26, 1975

JAN BRON. Can. J. Chem. **53**, 3069 (1975).

The corrections to rate constants for anharmonicity of vibrational excited states have been evaluated over the temperature range of 200–1100 K. The reaction $O_2 + X$, where X is H or D, has been chosen as the model system. Only the influence of vibrational anharmonicity of the triatomic transition state has been determined. Two geometric shapes for the transition state, bent and isosceles configurations, have been investigated in detail by the bond order method.

It is found that the correction can be large, depending upon the geometry and force field of the transition state and the temperature. The magnitude of the correction for anharmonicity of the vibrational excited states depends mainly, at a particular temperature, on the strength of the O—X bond in the transition state. In the case of a large correction, anharmonicity may lead to a nonlinear Arrhenius plot.

Because of cancellation effects, the correction for anharmonicity of the excited vibrational states in kinetic isotope effects can be ignored in the lower temperature region. It has also been found that anharmonicity of the vibrational *ground state* can explain unexpected large isotope effects.

JAN BRON. Can. J. Chem. **53**, 3069 (1975).

On a évalué, pour des températures allant de 200 à 1100 K, les corrections qu'il faut apporter aux constantes de vitesse à cause de l'anharmonicité des états vibrationnels excités. On a choisi la réaction $O_2 + X$, où X = H ou D, comme système modèle. On a déterminé uniquement l'influence de l'anharmonicité de l'état de transition triatomique. On a étudié en détail, par la méthode des ordres de liaison, deux formes goémétriques de l'état de transition soit les configurations isocèle et penchée.

On a trouvé que suivant la température, la géométrie et le champ de force de l'état de transition, la correction peut être grande. L'amplitute de la correction pour l'anharmonicité des états excités vibrationnels dépend principalement, à une température donnée, de la force de la liaison O—X dans l'état de transition. Dans le cas d'une correction importante, l'anharmonicité peut conduire à une relation d'Arrhénius qui ne soit pas linéaire.

Dû à des effets d'annulation, on peut omettre, à basse température, la correction pour l'anharmonicité des états vibrationnels excités dans les effets isotopiques cinétiques. On a aussi trouvé que l'anharmonicité de l'état vibrationnel *fondamental* peut expliquer des effets isotopiques plus grands que prévus autrement.

[Traduit par le journal]

Introduction

Rate constants of chemical reactions are usually calculated by making the simplifying assumption that the molecule vibrates harmonically (1–4). The correction for anharmonicity of the vibrational ground state for kinetic isotope effects has been discussed recently (5, 6). Anharmonicity of the vibrational excited states was ignored since it was argued that, at reasonably low temperatures, excited states were not sufficiently important and hence could be ignored.

Rate constant calculations involve, within the framework of the transition state theory, the evaluation of the partition functions of reactants and transition state (1). In order to calculate the partition function of any molecular species, the complete potential energy surface should be known. For only a few small stable molecules, the potential energy surface has been evaluated by spectroscopic methods. The potential energy surfaces of transition states can only be evaluated by theoretical means which, at the moment, are inferior to the experimental methods used for stable molecules.

In stable molecules, anharmonicity is usually a small perturbation and perturbation theory can be used to evaluate the expressions for the anharmonicity constants. It can be argued that anharmonicity in transition states is much more important than in stable molecules (2) and, since anharmonicity may then be a large pertur-

bation, the usual perturbation methods cannot be applied. No quantitative evidence supplied by detailed calculations have been given so far as to the importance of anharmonicity in transition states. However, judging solely by the success of the harmonic approximation, in rate constant and rate constant ratio (kinetic isotope effect) calculations, in explaining the detailed behavior of chemical reactions, anharmonicity *may be*, at least for normal modes with real frequencies, of similar magnitude in both transition states and stable molecules.

The purpose of the present investigation is to determine the validity of the assumption that anharmonicity of the excited states can be ignored in rate constant and kinetic isotope effect calculations and to determine under which conditions this assumption becomes invalid. As before (5, 6), it will be postulated that the reaction coordinate, which corresponds to the normal mode with the zero or imaginary frequency, is completely separate from the other normal modes with real frequencies of vibration.

General Considerations

The reactions that serve as a model system are

[1] $$H + O_2 \rightleftharpoons HO_2^* \rightarrow OH + O \ (k_H)$$
$$D + O_2 \rightleftharpoons DO_2^* \rightarrow OD + O \ (k_D)$$

The molecules HO_2^* and DO_2^* are the transition states. The rate constants, which have been measured in the temperature region of 800 to 1000 K by Kurzius and Boudart (7), may be written for present purposes as

[2] $$k_X = k_X' \cdot \alpha(X) \cdot \beta(X) \quad (X = H, D)$$

The quantities $\alpha(X)$ and $\beta(X)$ are the corrections for anharmonicity of the vibrational ground and excited states respectively and apply only to the transition states XO_2^*. The rate constant k_X' is a calculated quantity in which the assumption that the transition state vibrates harmonically is the only approximation.

No attempt will be made to reproduce the magnitude of the experimental rate constants for the $O_2 + X$ reaction theoretically, since this has already been done (7) by Kurzius and Boudard (K.B.). Strictly speaking, the experimental value for k_X should put constraints on the range of transition state parameters that determine $\alpha(X)$ and $\beta(X)$. However, since the theoretical quantity k_X' involves in itself many adjustable parameters, any change in the parameters that determine $\alpha(X)$ and $\beta(X)$ can be compensated for by a corresponding adjustment of the parameters that determine k_X'. These adjustments should, of course, be reasonable.

As mentioned above, transition state parameters cannot be evaluated by experimental means directly. Transition state parameters are usually assigned values by analogy to stable, real molecules. However, some quantities are typical for transition states, such as a zero or imaginary frequency of vibration. K.B. assumed the complex to be "entirely loose with the reactants of masses m_1 and m_2 preserving their identity", which is, again, only possible for a transition state. The "looseness" of the bonds between the fragments or atoms making up the transition state can be defined in terms of bond order.

The bond order approach will be used in the present study; a low bond order will mean a loose bond. Bond order and transition state parameters, such as bond distances and force constants, will be related by equations to be given in the next section. These relationships have been postulated to be valid also for transition states, since they hold approximately for stable molecules. However, no direct theoretical evidence exists that these relationships are valid for transition states. Therefore, the implications of deviations from these relationships for $\alpha(X)$ and $\beta(X)$ will be investigated. It will be implied that some of the conclusions drawn below can be extrapolated to other reactions involving the isotopes of hydrogen. Larger transition states cannot be investigated in the same detail, since the addition of one extra atom to the transition state increases the computer time required for the calculation of $\alpha(X)$ and $\beta(X)$ by a factor of about 50.

The correction for anharmonicity of the ground vibrational state of the transition state, XO_2^*, has the form (5, 6)

[3] $$\alpha(X) = \exp\left[\left(\tfrac{1}{2}\textstyle\sum\omega_i - \mathrm{ZPE}\right)hc/kT\right]$$

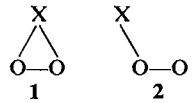
The quantity ZPE, for which the explicit expression has been given before (8), is the ground state vibrational energy. The quantity $\frac{1}{2}\sum\omega_i$ is the harmonic zero-point energy and ω_i is the harmonic frequency of vibration. The correction to a partition function due to anharmonicity of the excited states in the absence of vibrational degeneracy has been given by Pennington and Kobe (9)

$$[4]\quad \beta(X) = \prod_i \left(\frac{1 - \exp(-u_i)}{1 - \exp(-u_1')}\right) \times \left(1 - \sum_{i \leqslant j} \sum f_{ij}\right)$$

Here $u_i = \omega_i hc/kT$ and ω_i is the harmonic frequency; $u_i' = \nu_i hc/kT$ and ν_i is the fundamental frequency; $\nu_i = \omega_i + 2x_{ii} + \frac{1}{2}\sum_{k \neq i} x_{ik}$; $f_{ij} = x_{ij}(hc/kT)[\exp(u_i') - 1]^{-1}[\exp(u_j') - 1]^{-1}$; $f_{ii} = 2x_{ii}(hc/kT)[\exp(u_i') - 1]^{-2}$, and x_{ij} is the anharmonicity constant.

Geometry, Internal Coordinates, and Force Field for XO_2* Species

The isosceles **1** and bent **2** shapes of the XO_2* activated complex will be investigated.



1 **2**

The bond lengths and force constants follow the relationships given by Johnston (1) and Pauling (10): $R = R^{(s)} - 0.26 \ln(n)$ and $F(r) = F(r)^{(s)}n$. The maximum values of the bond order for the O—H and O—O bonds in the activated complexes are unity. The force constants and bond lengths of the O—H and O—O bonds in the HO_2* species are based on those of the O_2 and OH molecules. From the frequencies of vibration of the diatomic molecules given by Herzberg (11), it follows that $F(r)_{OH}^{(s)} = 8.6697$ mdyn/Å and $F(r)_{O_2}^{(s)} = 11.7676$ mdyn/Å. The bond distances $R_{OH}^{(s)} = 0.9706$ Å and $R_{O_2}^{(s)} = 1.2074$ Å are also given in the same reference.

Only diagonal cubic and quartic stretching force constants have been considered (5, 6). They follow the relationships which are approximately followed by stable molecules (5), $F_{rrr} = -12F_{rr}$ and $F_{rrrr} = 48F_{rr}$. The bending quadratic force constants are 0.1 of the arithmetic mean of the two O—H and O—O diagonal quadratic force constants, which in turn are calculated from the bond order relationships. The bent species has the two bond stretches (S_1, S_2) and valence angle bending (S_3) as internal coordinates. For the triangular species (isosceles) the three bond stretches (S_1, S_2, and S_3) have been chosen as coordinates. The harmonic frequencies of vibration of the transition state have been calculated by means of the **FG** matrix method. The above relationships only reflect the magnitudes of the cubic and quartic force constants, whose units are (mdyn/Å^2) and (mdyn/Å^3) respectively. The input parameters for [4] have been calculated by methods used previously (5) and by making use of standard definitions (11).

In the bent transition state a zero frequency has been obtained by taking the geometric mean of the two diagonal quadratic stretching force constants as the interaction force constant, *i.e.* $F_{12} = (F_{11}F_{22})^{1/2}$. Similarly, in the triangular species the interaction force constant between the two diagonal quadratic force constants, that correspond to the two OH stretches, has been taken as the geometric mean of these two force constants. As before (5, 6), once the reaction coordinate has been identified by its zero frequency, *all* spectroscopic quantities related to this frequency and the normal coordinate were either set equal to zero or left out in the calculation of the anharmonicity correction.

Results and Discussion

The expression for $\beta(X)$, [4], shows that part of the correction for anharmonicity of the excited states for the partition function of XO_2* consists of replacing the harmonic by the fundamental frequency. The second part of the correction, which involves $\sum\sum f_{ij}$, is usually smaller (12). The temperature dependence of $\beta(X)$ is complex and a plot of $\ln \beta(X)$ *vs.* T^{-1} may not be linear if $\beta(X)$ varies considerably over a certain temperature range.

In order to determine the value of the correction for anharmonicity of the excited states of the transition state, $\beta(X)$, the bent species has been studied first. The bond orders n_1(O—O bond) and n_2 (O—H bond) have been varied from 0.1 to 0.9, while keeping their sum equal to unity. In all these cases $\beta(H)$ and $\beta(D)$ varied at the most from 1.001 at 200 K to 1.05 at 1100 K, values which for most purposes are negligible. The correction factor $\alpha(X)$ is, especially at lower temperatures, always larger than $\beta(X)$. For example, if the bond order of the O—H bond is equal to 0.9, $\alpha(H)$ and $\beta(H)$ are 3.08 and 1.00 respectively at 200 K. The correction terms $\alpha(D)$ and $\beta(D)$ are, under these circumstances, 1.80 and unity respectively. The latter result is not unexpected since anharmonicity is less important for heavier particles.

The corrections $\alpha(X)$ and $\beta(X)$ are largest when the bond order of the O—X bond is almost unity. The bond orders of the bonds determine,

via the relationships stated above, the quadratic, cubic, and quartic force constants. It has been found that anharmonicity is due mainly to the anharmonicity of the O—X stretching vibration. Figure 1 shows the dependency of β(X) on F_{11}, which is the quadratic stretching force constant of the O—X bond ($n_2 = 0.9$), at 1100 K. All other parameters of the XO_2* species are unchanged. It can be seen that β(H) is quite insensitive towards changes in F_{11} up to the point $F_{11} = 5.0$, after which it increases sharply. The quantity β(D) seems to be quite insensitive over the whole range.

Figure 2 shows the variation of β(H) with F_{111} ($n_2 = 0.9$, O—H bond) and is compared with α(H). The results are similar to the one shown in Fig. 1. Again the temperature is 1100 K and all other transition state parameters have been kept constant. The decrease of F_{111} and F_{11} have the effect, if the other force constants are kept the same, of increasing the anharmonicity (6). The exact shapes of the curves of β(X) in Figs. 1 and 2 are difficult to explain, since β(X) is at a given temperature a complex function of the harmonic and fundamental frequencies and the anharmonicity constants.

The isosceles transition state XO_2* has also been investigated by varying the bond orders of the O—O and O—H bonds. In this species the bond orders n_1 and n_2 of the two O—X bonds are always equal. The O—O bond has been assigned a bond order of n_3. The sum of n_1, n_2, and n_3 is kept equal to unity. This triangular transition state is similar to the one used previously (6) to investigate the effect of anharmonicity of the vibrational ground state on the kinetic isotope effect in a 1,2-hydride shift. The bond order n_3 has been varied from 0.9 to 0.1. Between these limits β(X) increased from a few percent to a factor of two ($n_3 = 0.1$) at 1100 K. It seems that anharmonicity of the excited states is much more important for the isosceles transition state. As before, β(X) is largest at high temperatures and maximum O—H bond order. The results for the variation of α(H) and β(H), with n_3 (O—O bond) equal to 0.1, with temperature can be found in Fig. 3. It should be noted that, from the bond order of the O—O bond (0.1) and the above definitions, all parameters for the transition state can be deduced.

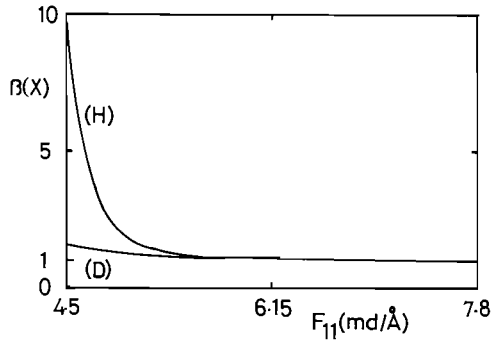

FIG. 1. The correction for anharmonicity of the excited states, β(X), as a function of the *quadratic* stretching force constant F_{11} (bent species); bond order of the O—X bond determines all transition state parameters via the relationships given in text, except F_{11} (and F_{12}, to obtain a zero frequency), which has been varied.

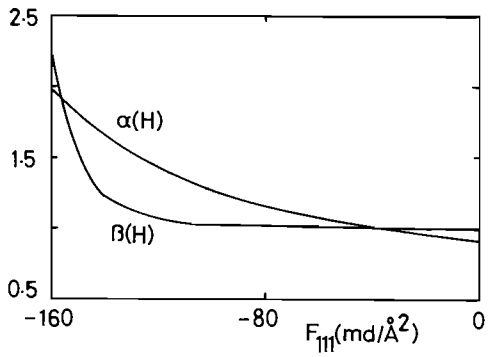

FIG. 2. The correction for anharmonicity of the excited states, β(H), as a function of the *cubic* stretching force constant F_{111} (bent species; bond order of the O—X bond is 0.9, 1100 K). The bond order of the O—X bond determines all transition state parameters, via the relationships given in text, except F_{111}, which has been varied. β(H) is compared with α(H).

Also plotted in Fig. 3 is the function EXC(H). This quantity can be defined by the equation:

$$[5] \quad \mathrm{EXC(H)} = \left[\frac{(1 - e^{-u})_{O_2}}{(1 - e^{-u_1^*})(1 - e^{-u_2^*})}\right]$$

The quantities u_1* and u_2* refer to the two real nonzero harmonic frequencies of vibration of the transition state, while $u(O_2)$ is determined by the frequency of vibration of the O_2 (reactant) molecule. EXC(H) is the excitation term in k_H'. It takes into account the contribution of the vibrational (harmonic) excited states to the partition functions of reactant molecules and transition state.

The shapes of the curves in Fig. 3 deserve some comments. It follows from the definition, [3], that the relationship between ln α(H) and T^{-1} is linear. It can be seen in Fig. 3 that the

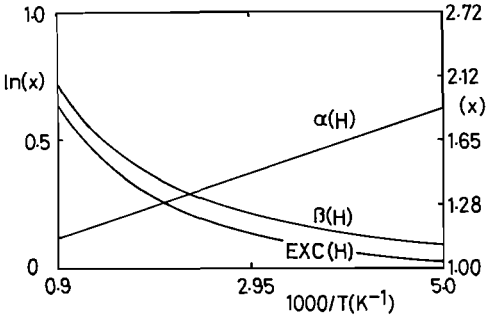

FIG. 3. Arrhenius type of plot of α(H), β(H), and EXC(H) for isosceles transition state HO_2^*. The bond order of the O—O bond is 0.1 and all other transition state parameters can be deduced from the relationships given in text.

plots of ln β(H) and ln EXC(H) *vs.* T^{-1} show considerable curvature, which is not unexpected considering the forms of [4] and [5]. Furthermore, the magnitudes of EXC(H) and β(H) are similar. The curvature of ln EXC(H) is mainly caused by the smallest harmonic frequency of vibration (489 cm^{-1}) of the transition state. The curvature of ln β(H) mainly arises from differences between the two harmonic frequencies of vibration (489 and 3418 cm^{-1}) and the fundamental frequencies (320 and 3180 cm^{-1}) of the transition state. Hence the sources of curvature in plots of ln EXC(H) and ln β(H) *vs.* T^{-1} are basically different.

Curvature in Arrhenius plots of reactions involving H or D can also be associated with tunnelling through the energy barrier (13). Tunnelling is usually important at lower temperatures. However, β(X) and EXC(X) assume considerable values only at higher temperatures. For intermediate temperatures curvature may then be caused by tunnelling, anharmonicity of vibration, and EXC(X). Tunnelling is most important for reactions involving protons, which is similar to the behavior of α(X) and β(X). It follows that, under certain conditions, it may be ambiguous to explain curvature of an Arrhenius plot in terms of tunnelling only. The results as summarized in Fig. 3 were obtained for a force field for which the frequency associated with the reaction coordinate is zero, and hence, the tunnelling correction as given by (14)

$$[6] \qquad \tau = \tfrac{1}{2}|u^*|/\sin(\tfrac{1}{2}|u^*|)$$

is unity. Curvature in Arrhenius plots due to quantum-mechanical tunnelling has been discussed recently by Stern and Weston (15).

From the above results it appears that the correction β(X) may be considerable, depending upon the temperature, geometry, and force field. At temperatures around 300 K β(X) is usually close to unity and may be ignored. However, at high temperatures β(X) is not necessarily negligible and it is worthwhile to take it into account. The importance of anharmonicity decreases as the atomic weight of X increases, so α(H) > α(D) and β(H) > β(D). The anharmonicity corrections are determined mainly by the anharmonicity of vibration of the O—X bond which contains the light atom.

The kinetic isotope effect, k_H/k_D, can be written by means of [1] as (1)

$$[7] \qquad \frac{k_H}{k_D} = \frac{q(D)}{q(H)} \cdot \frac{q(HO_2^*)}{q(DO_2^*)} = 2.8250 \frac{q(HO_2^*)}{q(DO_2^*)}$$

The quantities q in [7] are the partition functions of the species indicated in parentheses. For k_H/k_D the corrections β(X) largely cancel. Therefore, the present calculations seem to indicate that the assumption that anharmonicity of the excited states is not important for kinetic isotope effects is a reasonable one, especially at lower temperatures.

In addition to explaining curvature of an Arrhenius plot, quantum-mechanical tunnelling is also used to rationalize unexpected high isotope effects (16). An upper limit for kinetic isotope effects is calculated by means of the harmonic approximation (16). Considerable deviations from this upper limit, especially for hydrogen isotope effects, are then explained in terms of tunnelling. However, the correction for anharmonicity of the vibrational–rotational ground state, which, like the tunnelling correction, increases with decreasing temperature (*cf.* [3]), can also explain deviations from the estimated upper limit for k_H/k_D, since for a given geometry and force field of the initial and transition states in a particular reaction, a correction factor of two at 200 K can be obtained readily. It is interesting to note that α(H)/α(D) = 2 at 200 K gives a correction factor of 1.0×10^6 at 10 K and 1.6 at 300 K.

Similarly to tunnelling, the anharmonicity corrections α and β are largest for reactions involving the isotopes of hydrogen. At low temperatures the correction for anharmonicity of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

excited states, β, can be safely taken as unity. The correction factor α may be considerable however, but, as mentioned above, the temperature dependence of α does not account for curvature in an Arrhenius plot. As has been reported earlier (6), the correction α can also be smaller than unity for kinetic isotope effects and, therefore, α can also account for smaller effects than expected. From the above discussion a situation can be created in which the tunnelling correction is large (always greater than unity for k_H/k_D), but results in a "normal" isotope effect because of anharmonicity.

As mentioned earlier, the study of reactions involving a larger transition state (more than three atoms) is prohibitive because of computation time. However, it is anticipated that the anharmonicity corrections, α(X) and β(X), will increase if the number of bonds which vibrate anharmonically is increased. This is especially important for bonds containing light isotopes. Therefore, the estimates for α(X) and β(X) for the triatomic transition states may be *lower* limits. In these calculations anharmonicity of vibration in the initial state (O_2) has been ignored. This is reasonable since the anharmonicity correction for molecules containing only heavy atoms is small (5).

In fact, it is more general to allow the correction factors α and β to include anharmonicity for both reactants and transition state. If anharmonicity is important in both reactants and transition state, the correction factors α and β may still be small because of cancellation. Hence, α and β for the model reaction chosen, [1], for this discussion may be greater than the corresponding correction factors for other systems.

The anharmonicity correction α for a system for which the anharmonic force field of the transition state is closely related to that of a stable molecule, has been discussed recently (6). In transition states, atomic movements are much greater than in stable molecules and anharmonicity effects may be larger for these unstable species. Hence, the postulate, that anharmonic force fields of transition states are closely related to the force fields of stable molecules, may be an oversimplification, but this final point can be settled by a detailed theoretical study.

Geminate Recombination of Ion Pairs in the Radiolysis of Dense Hydrocarbon Gases[1]

MASARU NISHIKAWA

Department of Pure and Applied Sciences, University of Tokyo, 3-8-1 Komaba, Meguro-ku, Tokyo, Japan 153

Received March 17, 1975

MASARU NISHIKAWA. Can. J. Chem. **53**, 3075 (1975).

The distribution functions of ion–electron pair separation distances in irradiated hydrocarbon gases are transformed into those of neutralization times by means of the r^3 rule of time–distance obtained under the approximation that Coulomb field predominates in their mutual diffusion. In this approximation lifetime distribution is a function of $(3Dr_c)^{1/3}/b$, where D is the total diffusion constant, $D_+ + D_e$, r_c is the Onsager distance, and b is the characteristic distance of the respective spatial distribution function. Using the values of parameters previously estimated for supercritical hydrocarbons, it was found that for butanes the lifetime in the gas phase at density $\simeq$0.4 g/ml is shorter than that in the liquid phase at room temperature.

MASARU NISHIKAWA. Can. J. Chem. **53**, 3075 (1975).

On transforme les fonctions de distribution des distances de séparation ion–paire d'électron dans des hydrocarbures gaseux irradiés en fonction de temps de neutralisation à l'aide de la règle en r^3 du temps *vs.* distance lorsque l'on fait l'approximation que le champ de Coulomb prédomine lors de leur diffusion mutuelle. Dans cette approximation, la distribution des durées de vie est une fonction de $(3Dr_c)^{1/3}/b$ où D est la constante totale de diffusion, $D_+ + D_e$, r_c est la distance de Onsager et b la distance caractéristique des fonctions respectives de distribution spaciale. Utilisant les valeurs de paramètres obtenues antérieurement pour des hydrocarbures supercritiques, on a trouvé pour les butanes que la durée de vie en phase gaseuse à densité d'environ 0.4 g/ml est plus courte que celle en phase liquide à température de la pièce.

[Traduit par le journal]

The lifetime distribution of the electron produced in a medium by irradiation with respect to neutralization has been the subject of numerous theoretical studies, in which several different approaches have been used (1–6, 12). In one approach the evolution of neutralization is described by the Smoluchowski equation, which is then solved either under 'the prescribed diffusion' approximation (1), numerically (2), with analog computer (3), or by Laplace transform method (4). In another approach the motion of electrons is approximated by their drift motion in the Coulomb field of ions (forced diffusion approximation), where the distribution of neutralization times is generated by the distribution of ion–electron separation distances (5, 6). The results obtained along with these and other approaches give rise to different forms of the distribution, but the experimental data to compare with them are rather limited at the present time. However, the comparison of both approximations made by Dodelet and Freeman (5), and a recent success of the latter approximation in describing the observed neutralization in liquid propane (6) seem to indicate the usefulness of the forced diffusion approximation.

The objective of the present calculation is to find out semiquantitatively how the lifetime of electrons is related to the density of gases, utilizing the fact that a spatial distribution function can easily be transformed into that of lifetime under the forced diffusion approximation.

Lifetime Distribution Functions

Under the assumption that the process of geminate neutralization is dominated by the ion–electron Coulomb force, Williams obtained a simple time–distance relationship

$$[1] \qquad t = \varepsilon kTr^3/(3De^2) = r^3/(3Dr_c)$$

$$r_c = e^2/(\varepsilon kT)$$

where t is the return time for neutralization starting from the separation distance r, D is the mutual diffusion coefficient, and ε is the di-

electric constant of the medium (7). Admittedly this approximation is an oversimplification which tends to underestimate the neutralization time (1, 8), but in view of the usefulness of this approach it should be sufficient for the present purpose.

Using this relationship in a spatial distribution, $f(r)$, one obtains the corresponding distribution function $f(t)$. $f(t)\mathrm{d}t$ represents the fraction that undergoes neutralization between t and $t + \mathrm{d}t$. The fraction of ion pairs, $F(t)$, which exists at any time t after an instantaneous pulse irradiation can be determined simply by integrating $f(t)$ over all values greater than t

$$[2] \qquad F(t) = \int_t^\infty f(t)\,\mathrm{d}t$$

Although hitherto numerous forms of $f(r)$ have been compared and tested against experimentally observed behaviors of electrons in liquid hydrocarbons (5, 9, 10, 17), no single form has yet been established as the universally satisfactory $f(r)$ (10). Since no such test has been performed in dense gases, we choose a single parameter Gaussian, [3], and a simple exponential function, [6], in the calculation mainly on grounds of their simple forms and of the fact that both forms have been shown to give an adequate description of experimental results under some restriction in the range of applicability (9, 10), which appears to fit the present case (11).

For a Gaussian spatial distribution function [3], $f(t)$ and $F(t)$ are

$$[3] \quad f(r) = (4r^2/\pi^{1/2}b^3)\exp(-r^2/b^2)$$

$$[4] \quad f(t) = (4a^2t^{2/3}/\pi^{1/2}b)\exp(-a^2t^{2/3})$$

$$a = (3Dr_c)^{1/3}/b$$

$$[5] \quad F(t) = (2at^{1/3}/\pi^{1/2})\exp(-a^2t^{2/3}) + \mathrm{erfc}(at^{1/3})$$

$$\mathrm{erfc}\,x = \frac{2}{\sqrt{\pi}}\int_x^\infty \mathrm{e}^{-s^2}\,\mathrm{d}s$$

For a simple exponential distribution function [6], they are,

$$[6] \qquad f(r) = (1/b)\exp(-r/b)$$

$$[7] \qquad f(t) = (1/b)\exp(-at^{1/3})$$

$$[8] \qquad F(t) = \exp(-at^{1/3})$$

Lifetime Distribution in Dense Gases

The values of b and D for dense gases have been estimated previously (11).[2] *n*-Butane and isobutane are chosen, both in liquid and gaseous states, as the model for the calculation of lifetime distribution. The values of parameters to be used in the calculation are summarized in Table 1. $F(t)$ calculated by [5] are shown in Fig. 1. For liquid *n*-butane, $F(t)$ by [8] together with the one obtained by Rzad *et al.* ([9]) on the basis of an empirical dependence of electron scavenging on scavenger concentration (12) are included in Fig. 1 for comparison.

$$[9] \qquad F(t) = \exp(\lambda t)\,\mathrm{erfc}\,(\lambda t)^{1/2}$$

where $\lambda = 3Dr_c/b^3$ (13).

All the curves start at unity and decrease to the respective fractions of free ion. It is interesting to note that the lifetime distributions according to [8] and [9] are quite similar to each other and they are both characterized by a faster initial decay and a longer tail. A much shorter tail for [5] is simply a reflection of the Gaussian form of spatial distribution pointed out previously (9, 14). The general trend in the lifetimes that in a medium with faster decay the free ion fraction is larger is in agreement with the result obtained under the prescribed diffusion approximation (1).

In the density range from 0.36 to about 0.6 g/cm^3 (in the liquids), lifetimes are seen to decrease with the decrease in the density. It is more clearly demonstrated by the magnitude of $t_{1/2}^{gn}$, time required for the fraction not neutralized to reach $1.0 - 0.5F_{gn}$ where F_{gn} is the fraction of electrons that undergo geminate neutralization (Table 1). Evidently the lifetimes are much longer in dilute gases at an ordinary irradiation dose rate where ions and electrons recombine homogeneously (15). Thus, the present calculation suggests that in the intermediate regions where neutralization is still largely geminate, electrons may be more short-lived than in the liquid phase. The behavior is common to all three equations of $F(t)$, [5], [8], and [9], which are expressed by the same set of parameters, D, r_c, and b.

[2]Extrapolation of recently determined electron mobilities in dense ethane gas (18) to higher densities indicates that the estimated values (11) are in the right order of magnitude.

†Calculated from $D = \mu_e kT/e$ from μ_e given in ref. 19.

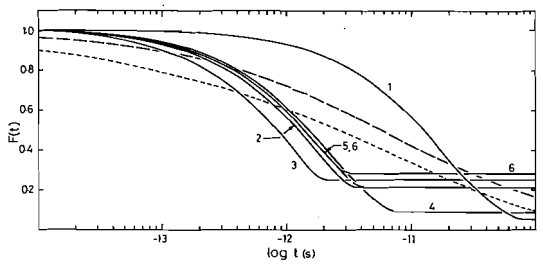

FIG. 1. Ion–electron neutralization time distributions calculated according to [5] for *n*-butane and isobutane. *n*-Butane: *1*, liquid; $d = 0.583$ g/ml, 293 K; *2*, $d = 0.41$ g/ml, 443 K; *3*, $d = 0.36$ g/ml, 443 K. Isobutane: *4*, liquid, $d = 0.552$ g/ml, 294 K; *5*, $d = 0.42$ g/ml, 443 K; *6*, $d = 0.36$ g/ml, 443 K. The --- and – – – curves were calculated for liquid *n*-butane (293 K) using [8] with a properly chosen set of parameter values for the exponential distribution and [9] with those for the Gaussian distribution, respectively.

Obviously, this density dependence is determined by a rather rapid increase in the estimated values of D with the decrease in density. Lifetime curves relatively insensitive to density change for isobutane are due to a more gradual change in D with density compared to that in *n*-butane, which is further moderated by the increase in b upon determining the magnitude of a. A similar tendency has been experimentally observed for the electron mobilities in butanes at the phase change from liquid to gas (16). It is highly desirable to establish the values of electron mobilities and other parameters directly in dense gases, as the conclusion of this calculation is strongly dependent on their reliability.

The author appreciates valuable discussions with Dr. Kenji Fueki of Nagoya University.

Stereospecific Synthesis and Acetolysis of *anti*-Tricyclo[4.4.1.1^{2,5}]dodecan-11-yl and Related Derivatives

J. HAYWOOD-FARMER,[1] B. T. FRIEDLANDER, A. CRAWFORD, L. M. THOMPSON, AND W. WETZER

Department of Chemistry, Bishop's University, Lennoxville, Quebec J1M IZ7

Received April 25, 1975

J. HAYWOOD-FARMER, B. T. FRIEDLANDER, A. CRAWFORD, L. M. THOMPSON, and W. WETZER. Can. J. Chem. **53**, 3078 (1975).

Stereospecific conversion of tricyclo[4.4.1.1^{2,5}]dodecan-11-one and of several related unsaturated and cyclopropanated ketones into *syn* or *anti* alcohols is described. Acetolysis of *anti*-tricyclo[4.4.1.1^{2,5}]dodecan-11-yl *p*-bromobenzenesulfonate, *anti*-tricyclo[4.4.1.1^{2,5}]dodec-3-en-11-yl *p*-bromobenzenesulfonate, and *anti*-tetracyclo[5.4.1.1^{2,6}.0^{3,5}]tridecan-12-yl *p*-bromobenzenesulfonate each proceeds at about the same rate as other equatorial cyclohexyl *p*-bromobenzenesulfonates to give complex mixtures of rearranged acetates and hydrocarbons. No evidence for neighboring group participation by the remote double bond or cyclopropane ring in these esters was found. The stereochemically interesting ketone reductions, the unambiguous structural proofs of the reduction products, and possible explanations of the solvolysis rates are discussed.

J. HAYWOOD-FARMER, B. T. FRIEDLANDER, A. CRAWFORD, L. M. THOMPSON et W. WETZER. Can. J. Chem. **53**, 3078 (1975).

On décrit la conversion stéréospécifique de la tricyclo[4.4.1.1^{2,5}]dodécanone-11 et de plusieurs cétones non-saturées et cyclopropaniques apparentées en alcools *syn* ou *anti*. Les vitesses d'acétolyse des *p*-bromobenzènesulfonates des tricyclo[4.4.1.1^{2,5}]dodécanol-11 *anti*, tricyclo[4.4.1.1^{2,5}]dodécène-3 ol-11 et tétracyclo[5.4.1.1^{2,6}.0^{3,5}]tridécanol-12 sont toutes semblables et d'un ordre de grandeur similaire à d'autres *p*-bromobenzènesulfonates de cyclohexanols équatoriaux et les produits sont toujours formés d'un mélange complexe d'hydrocarbures et d'acétates réarrangés. Les résultats n'indiquent pas qu'il y a participation de la double liaison ou du noyau cyclopropanique dans ces réactions. On discute des réductions stéréochimiquement intéressantes des cétones, des preuves non ambigues des structures des produits de réduction et des explications plausibles des vitesses de solvolyse.

[Traduit par le journal]

Introduction

The use of rigid polycyclic molecules with reasonably well-known geometries has been instrumental to a better understanding of many aspects of organic chemistry including the study of neighboring group participation in carbonium ion and related reactions (1, 2). In an attempt to define better the geometrical requirements for interactions of double bonds and cyclopropane rings with remote electron deficient centers we have undertaken the synthesis and solvolytic study of several rigid polycyclic derivatives. It is our hope that the relative importance of the several geometrical factors of importance to neighboring group participation (2) can be understood once the behavior of a number of molecules with different geometries is known.

Towards this end we have developed stereospecific syntheses of alcohols with the tricyclo[4.4.1.1^{2,5}]dodecan-11-yl skeleton and have studied the acetolysis of suitable derivatives which we would like to report at this time.

Results and Discussion

It has been known for some time that reduction of trienone **1** with $LiAlH_4$ in ether gives only **2**-OH (3, 4), the structure of which was based on the very small value observed for $J_{1,11}$ and on the acetolysis behavior of **2**-OTs. We expected that a similar steric course would be followed in the reduction of closely related ketones and were surprised, therefore, when **5** (5) was reduced under the same conditions to yield predominantly **6**-OH (Table 1) with C-11 inverted with respect to **2**-OH.[2] This stereochem-

[1]To whom correspondence should be addressed.

[2]This reduction has been reported in preliminary form by other workers (6) with no comment regarding its stereochemistry and, although different physical constants for **5** and **6**-OH were reported than those obtained by us, Dr. Itô has kindly informed us that the i.r. spectra of the independently prepared samples are virtually identical.

5	12	n.m.r., g.l.c.
11	0	n.m.r., g.l.c.

[a]Values considered accurate to ±4%; the remaining fraction is *anti* epimer.

ical assignment was tentatively made on the basis of the larger observed value (*ca.* 5 Hz) for $J_{1,11}$ compared to that for **2**-OH but we felt that this conclusion was ambiguous. Although the unsaturated C-7–C-10 bridge of **2**-OH is rigid giving relatively fixed dihedral angles at C-11 of *ca.* 85 and 35°,[3] the saturated bridge of **6**-OH is flexible with at least three different conformations. In the two eclipsed conformers, **12** and **13**, both dihedral angles at C-11 are *ca.* 60° but in the staggered conformer, **14**, angles of *ca.* 85 and 35° are found once more. Because we could not unequivocally determine which conformer is preferred or, whether or not **6**-OH is conformationally mobile at the temperature and time scale of our n.m.r. instrument, we were uncertain of the C-11 configuration of **6**-OH. Because it was obviously crucial for our solvolytic studies to correctly assign this structure, we sought a more rigorous structural proof.

Addition of small amounts of the n.m.r. shift reagent Eu(fod)$_3$ to a solution of **2**-OH in $CDCl_3$ caused a marked downfield shift of the H-3 (H-4) signal and a much smaller downfield shift for H-7–H-10 (Fig. 1). Similar treatment of **6**-OH did not shift the olefinic proton appreciably although the behavior of H-11 was similar to that in **2**-OH (Fig. 1). These differences are in full accord with the assigned structures of **2**-OH and **6**-OH.

Catalytic hydrogenation of **2**-OH and **6**-OH gave the two saturated alcohols **3**-OH and **7**-OH, respectively, which were shown to be epimeric by their oxidation to the single known ketone **4** (5, 7). These two compounds have almost identical melting points which are not depressed on mutual mixing and, in our hands proved to be inseparable by g.l.c., but they had distinctly different i.r. and n.m.r. spectra. In particular, the H-11 signal is a relatively sharp singlet in

[3]These are the dihedral angles between H-1 (H-6) and the *syn* and *anti* positions at C-11, respectively, as measured from Dreiding models.

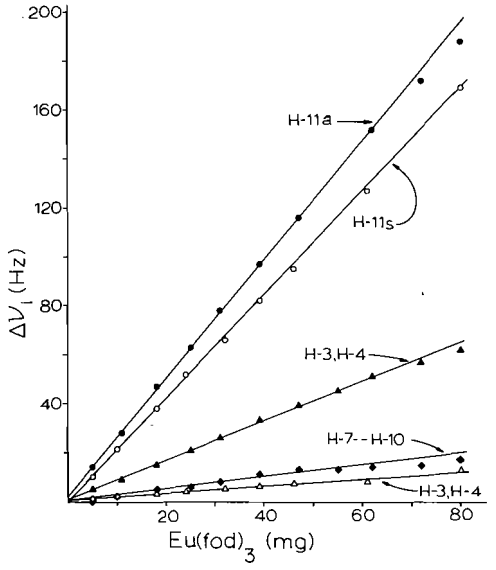

FIG. 1. A plot of chemical shift induced by shift reagent, $\Delta\nu_i$, *vs.* amount of added shift reagent for some protons of **2**-OH (solid points) and **6**-OH (open points).

3-OH ($w_{1/2}$ = 3.5 Hz) at slightly higher field (0.2 p.p.m.) than the broad singlet ($w_{1/2}$ = 11 Hz) of **7**-OH. These data are in accord with a predominance of conformer **14** for the tricyclo-[4.4.1.1^{2,5}]dodecane ring system. Unlike the distinct triplets observed for H-11 of the unsaturated **6**-OH and cyclopropanated **10**-OH (*vide infra*), no fine structure was observed in the broad peak of **7**-OH. The reason for this behavior is unclear.

Prolonged reduction of **1** with $LiAlH_4$ in refluxing tetrahydrofuran gave the dienol **8**-OH whose u.v. spectrum is typical of the conjugated diene chromophore (5). This reaction is similar to the well-known stereospecific reduction of the *syn* double bond of 7-oxygenated norbornadienes (8) and provides interesting support for the structure of **2**-OH. Oxidation gave the known ketone **9** (7); the sequence of reduction of **1** followed by oxidation to **9** provides an alternative route to the previously reported (7) selective hydrogenation of the isolated double bond of **1**.

The spectroscopic and chemical evidence outlined above provides overwhelming proof of the structures of **2**-OH and **6**-OH and for the other alcohols prepared in this study.

Treatment of either **6**-OH or **5** with CH_2N_2 in the presence of Cu_2Cl_2 (9) led cleanly to **10**-OH and **11** respectively. The cyclopropane

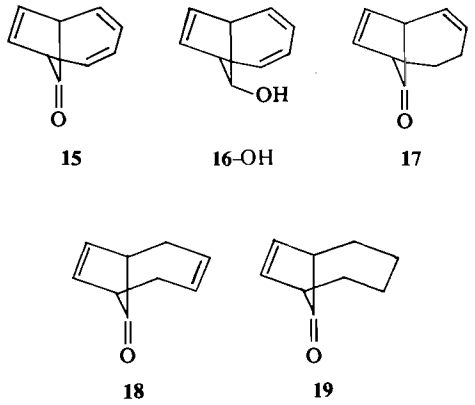
ring was assigned the *exo* structure found in the related epoxide (5). The n.m.r. spectrum showed H-3 and H-5 to be coupled only very weakly to H-2 and H-6 as anticipated (5). H-4_{exo} is found at relatively high field (*ca.* τ 9.8); this value is typical of *exo*-tricyclo[3.2.1.$0^{2,4}$]octanes (10) and demonstrates the previously noted (5) similarity of the tricyclo[4.4.1.$1^{2,5}$]dodecanyl and norbornyl ring systems.

The stereochemistry of reduction of **1**, **4**, **5**, **9**, and **11** has proven to be most interesting. Both **1** and **9**, in which the C-7–C-10 diene unit is present, reduce to give *syn* alcohols **2**-OH and **8**-OH exclusively (Table 1). In **4**, **5**, and **11**, however, the steric preference is reversed, *anti* alcohols **7**-OH, **6**-OH, and **10**-OH now being the predominant products. We are unaware of another example in which partial or total hydrogenation of remote unsaturation so dramatically changes the preferred direction of approach of reducing agents to a carbonyl group. In a related study (11) **15** was shown to reduce to only the *syn* alcohol **16**-OH. Partial or complete saturation of the diene unit (*i.e.* **17**, **18**, and **19**) resulted in an increase in attack from the *syn* side but the predominant products still had the *syn* stereochemistry. Despite a recent explanation of the stereochemistry of cyclohexanone reductions based on the induction of anisotropy in the electron density of the carbonyl group by the σ bonds in the six-membered ring (12), and other possible electronic explanations, we prefer to interpret our results in simple steric terms. Examination of a Dreiding model of **1** and calculations of congestion (13) based on this model[4] reveal that the *anti* side of the molecule is much more open to attack than is the *syn* side. In **9** attack from the *syn* side is even more hindered. These two ketones thus give exclusively *syn* alcohol. In **4**, **5**, and **11** the situation is reversed. The two most likely conformers, **12** and **14**, have severe congestion on the *anti* side of the carbonyl group making the *syn* side much more



15 **16**-OH **17**

18 **19**

open to attack by nucleophiles and explaining the observed steric preference. The third conformer, **13**, does not have the *anti* side congestion of **12** and **14** but is probably not a major component because of a severe interaction between H-12*a* and the C-8—C-9 bond. We are not yet able to explain why reduction of **11** is more stereospecific than that of **4** or **5**.

The acetolysis of each ester (**6**-OBs, **7**-OBs, and **10**-OBs) is a clean first order process (Table 2) with no evidence in either the kinetic or product studies to indicate ion pair return. The three brosylates acetolyze at about the same rates as suitable model compounds (Table 3). Particularly striking is the similarity to molecules which also incorporate an equatorially substituted cyclohexane chair despite the improbability (Bredt's rule (*cf.* 14)) of direct hydrogen elimination leading to olefinic products. This is a major pathway in the acetolysis of cyclohexyl sulfonates (*cf.* 15). We conclude that neighboring group participation is a relatively inefficient process in the acetolysis of **6**-OBs and **10**-OBs. This conclusion is in accord with the assumed geometrical similarity of ketones **4**, **5**, and **11**, in ν_{CO} (**4**: 1707; **5**: 1710; **11**: 1706; cyclohexanone: 1716 (16)) and in λ_{max} n $\rightarrow \pi^*$ (**4**: 297 (ε 22); **5**: 294 (ε 35); **11**: 294 (ε 31); cyclohexanone: 283 (ε 17)) both of which have been correlated with anchimeric assistance in other systems (16–18). Recent ^{13}C n.m.r. data (19), however, do indicate a possible interaction between the double bond and carbonyl group of **5**.

The acetolyses of **6**-OBs, **7**-OBs, and **10**-OBs all result in the formation of very complex mixtures of as yet unidentified products (Table 2) which are >95% rearranged. The principal products in all cases are those of elimination. The

[4]Although we believe that these calculations are qualitatively meaningful, the angles in the C-7–C-10 bridge of the model are somewhat larger than 120° so that the six atoms C-1, C-6–C-10 may be incorporated in a coplanar arrangement. In the molecule itself it is possible that the conjugated diene unit is puckered to relieve the strain of angle distortion. The present lack of accurate structural data on **1** or any other member of this ring system makes quantitative discussion impossible. Such a puckering would alter the magnitude of the congestion factors but probably not their relative order. Models of **4**, **5**, and **11** appear to be relatively unstrained.

presence of major peaks at $\tau > 9.5$ in the n.m.r. spectrum of the crude product from **10**-OBs indicates retention of the cyclopropane ring. The complex nature of the product mixtures, although not unprecedented in systems exhibiting large anchimeric assistance (20), is corroborative evidence for the absence of neighboring group participation.

Our failure to observe even a portion of the tremendous anchimeric acceleration found in other systems, notably in those related to 7-norbornyl (1*a*, 2), is at first surprising in view of the apparent similarity in geometry between **6**-OBs, **10**-OBs, and the more reactive molecules. Closer examination reveals a number of rationalizations based on geometrical and electronic factors that could be advanced to explain the apparent discrepancy; we are not yet in a position to choose between them. The distance between the potential neighboring group and the reaction center in **6**-OBs and **10**-OBs is 2.6–2.8 Å (Dreiding models), somewhat longer than that in *anti*-7-norbornenyl and related esters (2.3–2.4 Å). This distance was cited previously (21) to explain the absence of participation by the double bond in the acetolysis of *exo*-bicyclo[3.2.1]oct-6-en-3-yl tosylate. Molecular models also predict that the developing p orbitals of **6**-OBs and **10**-OBs lie almost parallel to, but displaced from, the planes of the potential neighboring groups. The effective overlap predicted (18*b*, 22) for the transition states for the ionization of *anti*-7-norbornenyl and related esters is therefore much less likely for the ionization of **6**-OBs and **10**-OBs. Also

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

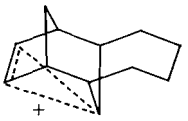
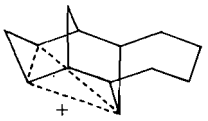
pertinent is the expectation that a molecular distortion analogous to that predicted (18*b*) to increase overlap, and hence stability, in the delocalized 7-norbornenyl cation, should decrease overlap in **20** and **21**. The differences in *I* strain (*cf.* 23) between the tricyclo[4.4.1.$1^{2,5}$]dodecan-11-yl and 7-norbornyl systems might also be used to explain our kinetic results.

Finally, it has been predicted recently by Goldman (24) that the homoaromatic stabilization expected for ions such as **20** and **21** (*cf.* 25) should be overcome by the antisymmetric alignment of the flanking σ bonds, *i.e.* C-1—C-2 and C-5—C-6, possibly resulting in a rate retardation by the potential neighboring group. Experimental verification of this proposal is not yet available in compounds without geometrical ambiguities so that its applicability to the present study is uncertain.



20



21

We are continuing our efforts to analyze the complex products from **6**-OBs, **7**-OBs, and **10**-OBs and also to synthesize and study the ionization of other geometrically interesting molecules.

Experimental

Melting points were determined on a Thomas–Hoover apparatus and are uncorrected. The n.m.r. spectra were obtained on a Varian A60 A spectrometer in $CDCl_3$ solution. Peak positions are given in units of τ relative to internal tetramethylsilane at τ 10.00 or $CHCl_3$ at τ 2.75; in all cases the relative peak areas are consistent with the assigned structure. Infrared spectra were recorded on Nujol mulls, neat liquids, and solutions in CCl_4 using a Unicam SP 200, a Beckman IR 10, or a Perkin-Elmer 710 spectrophotometer; the peak positions are given in wave numbers. Ultraviolet spectra were recorded in 95% ethanol solution on a Unicam SP 800 recording spectrophotometer; peak positions are given in nm. Gas–liquid chromatographic analyses were carried out on Varian Aerograph A90 P3 or an F and M 700 chromatograph employing copper or stainless steel columns packed with Carbowax 20M unless otherwise stated. Combustion microanalyses were obtained from Galbraith Laboratories, Inc., Knoxville, Tenn. 37921.

General Procedure for $LiAlH_4$ Reductions

About 50 mg of pure ketone was added to a stirred slurry of *ca.* 100 mg of $LiAlH_4$ in 15 ml $(C_2H_5)_2O$ at room temperature under an atmosphere of N_2. The mixture was refluxed for *ca.* 0.5 h, cooled to 0 °C and the excess $LiAlH_4$ destroyed by the cautious addition of H_2O. The precipitated aluminum salts were dissolved by adding 10% aqueous H_2SO_4 and the aqueous solution extracted with 3 × 50 ml $(C_2H_5)_2O$. The ether was washed with 10% aqueous Na_2CO_3 solution and dried ($MgSO_4$), and the solvent removed to give crude product which was analyzed directly by g.l.c. or n.m.r.

syn-Tricyclo[4.4.1.$1^{2,5}$]dodeca-3,7,9-trien-11-ol, 2-OH

Treatment of **1** as described above gave a yellow oil which crystallized on standing. A pure sample of **2**-OH was prepared by g.l.c., m.p. 29.5–31.5 °C (lit. (3) m.p. 32.5–34.5 °C); n.m.r.: 3.62 (singlet, H-3, H-4), 4.03 (multiplet, H-1, H-2, H-5, H-6, OH), 7.73 (doublet, J = 10.5 Hz, H-12*a*), 8.3–8.8 (multiplet, H-12*s*); n.m.r. and g.l.c. revealed that only one alcohol was present.

syn-Tricyclo[4.4.1.$1^{2,5}$]dodecan-11-ol, 3-OH

Crude **2**-OH (50 mg) was dissolved in 5 ml of 95% C_2H_5OH and stirred under H_2 at *ca.* 1.1 atm at room temperature in the presence of 35 mg of 10% Pd-on-charcoal. After the H_2 uptake had ceased, the mixture was filtered and the solvent removed to give 50 mg (95% yield overall from **1**) of white crystals of **3**-OH which could be purified by g.l.c. or by vacuum sublimation (105 °C, 15 Torr), m.p. 75–76.5 °C. A mixed sample with **7**-OH had m.p. 74–76 °C; i.r.: 3375, 1075, 1040, 1035, 1025; n.m.r.: 6.12 (singlet, $w_{1/2}$ = 3 Hz, H-11*a*), 7.8–9.2 (multiplet, all other protons).

Anal. Calcd. for $C_{12}H_{20}O$: C, 79.94; H, 11.18. Found: C, 80.02; H, 11.29.

Oxidation of 3-OH

The oxidation was carried out according to the published procedure (26). A solution of 30 mg **3**-OH in *ca.* 110 μl of $(C_2H_5)_2O$ was treated at 0 °C for 10 min with 220 μl of a solution containing 100 g $Na_2Cr_2O_7$ and 136 g 97% H_2SO_4 and diluted with H_2O to a total volume of 500 ml. The reaction mixture was diluted with *ca.* 50 ml $(C_2H_5)_2O$ and 20 ml H_2O, the layers separated, and the aqueous one extracted with 50 ml $(C_2H_5)_2O$. The combined $(C_2H_5)_2O$ solutions were washed with 10% aqueous Na_2CO_3 solution, dried ($MgSO_4$), filtered, and the solvent evaporated to give 19 mg (64%) of a colorless oil; g.l.c. showed that only one component was present; i.r. showed it to be identical to a previously prepared sample of **4** (5); i.r.: 1707; u.v.: λ_{max} 297, ε 22.

anti-Tricyclo[4.4.1.$1^{2,5}$]dodec-3-en-11-ol, 6-OH

Treatment of 60 mg of the previously prepared **5** (5) (i.r.: 1710; u.v.: λ_{max} 294, ε 35) with $LiAlH_4$ as described in the general procedure above gave 60 mg (99%) of yellowish crystals. The g.l.c. and n.m.r. analyses of the crude product showed the presence of two alcohols in the ratio of 88:12. The major component was identified as **6**-OH, the minor one was assumed to be its C-11 epimer on the basis of the shape of the H-11 n.m.r. signal (see text) but this product was not further characterized. A sample of **6**-OH was purified by g.l.c., m.p. 82–83.5 °C (lit. (6) volatile liquid[2]); i.r.: 3400, 3075, 1580; n.m.r.: 3.78 (singlet, H-3, H-4), 5.69 (triplet, J = 5.5 Hz, H-11*a*), 7.2–9.2 (complex multiplet, all other protons).

Nuclear Magnetic Resonance Shift Experiments

Solutions of **2**-OH and **6**-OH of *ca.* 1.2 *M* were prepared in a total volume of *ca.* 450 μl $CDCl_3$ and a total

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of 80 mg of the shift reagent europium(III)-tris-1,1,-1,2,2,3,3-heptafluoro-7,7-dimethyl-4,5-octanedione (Eu-(fod)$_3$) (Norell Chemical Co., Landisville, New Jersey 08326) added to each sample in increments of *ca.* 8 mg. The n.m.r. spectrum was recorded after each addition, the chemical shift change of each peak measured (assuming no change in internal tetramethylsilane) and the results plotted. Each peak in the spectrum of **2**-OH could be analyzed but only the olefinic peaks and H-11*s* could be analyzed for **6**-OH because of unresolved peak overlap. The plots for the most pertinent signals are shown in Fig. 1 and clearly show that the assigned configurations of **2**-OH and **6**-OH are correct.

anti-Tricyclo[4.4.1.1^{2,5}]dodecan-11-ol, 7-OH

A 50 mg sample of purified **6**-OH was dissolved in 5 ml of 95% C_2H_5OH, 40 mg of 10% Pd-on-charcoal added and the mixture stirred under H_2 at *ca.* 1.1 atm at room temperature. After the gas uptake had ceased, the mixture was filtered and the solvent evaporated to give 48 mg (95%) of white crystalline **7**-OH, a sample of which was purified by g.l.c., m.p. 72–73.5 °C. A mixed sample with **3**-OH had m.p. 74–76 °C; i.r.: 3350, 1070, 1020; n.m.r.: 5.93 (broad singlet, $w_{1/2}$ = 11 Hz, H-11*s*), 7.7–9.3 (complex multiplet, all other protons).

Anal. Calcd. for $C_{12}H_{20}O$: C, 79.94; H, 11.18. Found: C, 79.76; H, 11.00.

Similar hydrogenation of a crude sample of **6**-OH gave a solid whose n.m.r. spectrum clearly showed the presence of both **7**-OH and **3**-OH in the ratio of 88:12.

Oxidation of 7-OH

A sample of **7**-OH (35 mg) was oxidized as described above for **3**-OH to give 32 mg (92%) of a single ketone shown by i.r. to be **4** (5).

Reduction of 4

A freshly prepared sample of **4** (from hydrogenation of **1** (5)) was reduced with $LiAlH_4$ according to the general procedure described above giving a quantitative yield of crystalline alcohol. The n.m.r. analysis showed that it contained **7**-OH and **3**-OH in the ratio 92:8. These two alcohols proved to be unseparable by g.l.c. on columns of Carbowax 20M, LAC 728, SE 30, UCW 98, Apiezon L, and TCEP.[5]

syn-Tricyclo[4.4.1.1^{2,5}]dodeca-7,9-dien-11-ol, 8-OH

Solid **1** (310 mg) was added to a stirred slurry of *ca.* 1 g $LiAlH_4$ in 35 ml of freshly distilled tetrahydrofuran and the mixture refluxed for 50 h. The solution was cooled to 0 °C and H_2O slowly added to destroy the excess $LiAlH_4$. The precipitated aluminum salts were dissolved by adding 10% aqueous H_2SO_4 and the solution extracted with 3 × 100 ml of $(C_2H_5)_2O$. The combined $(C_2H_5)_2O$ layers were washed with 100 ml H_2O, 10% aqueous Na_2CO_3 solution, dried ($MgSO_4$), and filtered. Evaporation of the solvent gave 285 mg of a yellowish oil which was shown by g.l.c. to contain at least five components. The major one (*ca.* 70%) was purified by g.l.c. and vacuum sublimation (115 °C, 12 Torr) and shown to be **8**-OH, m.p. 75–76 °C; i.r.: 3320, 3020, 1595; u.v.: λ_{max} 275, ε 2990; 264, ε 5400; 254, ε 5240; 249, sh; 245, sh; n.m.r.: 4.41 (multiplet, H-7–H-10), 5.62 (singlet, $w_{1/2}$ = 4 Hz, H-11*a*), 7.1–9.2 (complex multiplet, all other protons).

Anal. Calcd. for $C_{12}H_{16}O$: C, 81.77; H, 9.15. Found: C, 81.47; H, 9.22.

Tricyclo[4.4.1.1^{2,5}]dodeca-7,9-dien-11-one, 9

Crude **8**-OH (155 mg) was oxidized as described above for **3**-OH to give 110 mg of a yellowish oil from which 40 mg of pure **9**, m.p. 96.5–98.5 °C (lit. (7) m.p. 92 °C) was obtained by g.l.c.; n.m.r.: 3.8–4.5 (complex multiplet H-1, H-6), 7.1–9.2 (complex multiplet, all other protons).

Reduction of 9

A sample of **9** was treated with $LiAlH_4$ according to the general procedure described above. Both n.m.r. and g.l.c. analyses of the crude product showed the presence of only one alcohol confirmed by i.r. to be **8**-OH. Other unidentified products were formed in this reaction but they contained neither carbonyl nor hydroxyl groups.

anti-Tetracyclo[5.4.1.1^{2,6}.0^{3,5}]tridecan-12-ol, 10-OH

Diazomethane was prepared by treatment of *N*-methyl-*N*-nitrosourea with 50% aqueous KOH solution and carried in a stream of N_2 into a stirred solution of 917 mg **6**-OH in 25 ml anhydrous $(C_2H_5)_2O$ containing 500 mg suspended Cu_2Cl_2 according to the convenient procedure of Pincock and Wells (9). The cyclopropanation was monitored by g.l.c. After several hours when the reaction was near completion it was terminated, the solution filtered, and the solvent removed to give 1.04 g of a green oil which was eluted with $(C_2H_5)_2O$ through a short column of alumina to remove the residual copper compounds. A small sample of the resulting colorless crystals (1.0 g, 100%) was purified by g.l.c., m.p. 67–68 °C; i.r.: 3380, 3070, 3010; n.m.r.: 5.38 (triplet, J = 5.5 Hz, H-12*s*), 7.2–8.9 (complex multiplet, H-1, H-2, H-6–H-11, H-13, OH), 9.08 (doublet of doublets, J = 3.6, 8 Hz, H-3, H-5), 9.34–9.95 (multiplet, H-4).

Anal. Calcd. for $C_{13}H_{20}0$: C, 81.20; H, 10.48. Found: C, 81.01; H, 10.54.

Tetracyclo[5.4.1.1^{2,6}.0^{3,5}]tridecan-12-one, 11

A 50 mg sample of **10**-OH was treated as described above for the oxidation of **3**-OH to give 32 mg (65%) of liquid **11** which was purified by g.l.c.; i.r.: 3100, 3050, 1706; u.v.: λ_{max} 294, ε 31; n.m.r.: 7.35 (multiplet, H-1, H-7), 7.78–8.67 (complex multiplet, H-2, H-6, H-8–H-13), 8.92 (doublet of doublets, H-3, H-5), 9.3–9.85 (multiplet, H-4).

Anal. Calcd. for $C_{13}H_{18}O$: C, 82.06; H, 9.53. Found: C, 81.83; H, 9.48.

This ketone could also be formed by direct cyclopropanation of **5** as described for the synthesis of **10**-OH in which attack by diazomethane at the carbonyl group with subsequent ring expansion did not effectively compete.

Reduction of 11

Treatment of 50 mg of **11** with $LiAlH_4$ by the general procedure described above gave 50 mg (99%) of an alcohol which was shown by g.l.c. and n.m.r. to be sterically homogeneous and by i.r. to be **10**-OH.

General Procedure for the Preparation of p-Bromobenzenesulfonates (Brosylates)

Equimolar amounts of alcohol and *p*-bromobenzene-

[5]The analyses on the TCEP capillary column were carried out by D. C. Wigfield, Carleton University, Ottawa, Canada to whom we express our thanks.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

sulfonyl chloride were dissolved in dry pyridine (*ca.* 2 ml per g acid chloride) and the solution allowed to stand in a refrigerator at 0 °C until the deposition of pyridine hydrochloride appeared to be complete. This usually took several days. Water was then added to the mixture and the resulting crystalline mass of crude brosylate collected by filtration. The crystals were washed well with H_2O and 10% aqueous Na_2CO_3, dried, and recrystallized from hexane.

anti-Tricyclo[4.4.1.1^{2,5}]dodecan-11-yl p-Bromobenzenesulfonate, 7-OBs

The brosylate isolated in 60% yield by the above procedure had m.p. 79.5–80 °C (dec.); n.m.r.: 2.33 (multiplet, aromatic ring protons); 5.13 (broad singlet, $w_{1/2}$ = 11 Hz, H-11*s*), 7.4–9.3 (multiplet, all other protons).

Anal. Calcd. for $C_{18}H_{23}SO_3Br$: C, 54.14; H, 5.80; S, 8.03; Br, 20.01. Found: C, 54.35; H, 5.76; S, 9.13; Br, 20.21.

anti-Tricyclo[4.4.1.1^{2,5}]dodec-3-en-11-yl p-Bromobenzenesulfonate, 6-OBs

The brosylate isolated in 60% yield by the above procedure had m.p. 87–88 °C (dec.); n.m.r.: 2.33 (multiplet, aromatic protons), 4.05 (singlet, $w_{1/2}$ = 4 Hz, H-3, H-4), 5.05 (triplet, J = 5.5 Hz H-11*s*), 7.4–9.0 (multiplet, all other protons).

Anal. Calcd. for $C_{18}H_{21}SO_3Br$: C, 54.41; H, 5.33; S, 8.07; Br, 20.11. Found: C, 54.54; H, 5.40; S, 8.15; Br, 20.27.

anti-Tetracyclo[5.4.1.1^{2,6}.0^{3,5}]tridecan-12-yl p-Bromobenzenesulfonate, 10-OBs

The brosylate isolated in 65% yield by the above procedure had m.p. 120.5–121 °C (dec.); n.m.r.: 2.25 (multiplet, aromatic protons), 4.53 (triplet, J = 6.2 Hz, H-12*s*), 7.5–8.8 (multiplet, H-1, H-2, H-6–H-11, H-13), 9.04 (doublet of doublets, J = 3.6, 8 Hz, H-3, H-5), 9.3–9.9 (multiplet, H-4).

Anal. Calcd. for $C_{19}H_{23}SO_3Br$: C, 55.48; H, 5.63; S, 7.79; Br, 19.43. Found: C, 55.60; H, 5.70; S, 7.77; Br, 19.44.

Kinetic Studies

Acetolysis rates of the three brosylates **7**-OBs, **6**-OBs, and **10**-OBs were measured by the usual procedure (*cf.* 27). Solutions *ca.* 0.01 *M* in brosylate were prepared in glacial acetic acid buffered with *ca.* 0.025 *M* NaOAc and divided equally among 12 sample tubes which were then sealed. The tubes were placed simultaneously in an oil bath at the appropriate temperature. After a short thermal equilibration period (*ca.* 10 min), the zero sample was removed and cooled quickly to room temperature. Other samples were similarly removed at appropriate times. After all samples had been taken, 1-ml aliquots of each were added to 5 ml of *ca.* 0.005 *M* $HClO_4$ in glacial acetic acid and the excess $HClO_4$ titrated with *ca.* 0.005 *M* NaOAc in glacial acetic acid to the bromophenol blue end point. Each run was followed for at least 2.5 half-lives, infinity samples being taken after at least 8 half-lives. No color developed in runs on **7**-OBs and **10**-OBs but **6**-OBs samples turned yellow particularly at long reaction times. All runs gave good first-order plots. One run on each compound was carried out at a concentration of *ca.* 0.005 *M* in brosylate. This did not affect the obtained rate constants. The data are given in Table 2.

Product Studies

Samples of the brosylates, *ca.* 0.01 *M*, were prepared in glacial acetic acid containing 0.02 *M* NaOAc and heated at an appropriate temperature for more than 10 half-lives. The solutions were cooled to room temperature, diluted with pentane, and the pentane solution extracted with H_2O. The H_2O washes were back-extracted with pentane and the combined pentane solutions washed with H_2O and 10% aqueous $NaHCO_3$ and dried ($MgSO_4$). The mixture was filtered and the solvent removed to leave an oily product which was analyzed spectroscopically and by g.l.c. on several columns. The mixtures were reduced with $LiAlH_4$ and hydrogenated over Pd-on-charcoal by the general procedures described above. None of the large number of products was identified. Our preliminary data is collected in Table 2 and discussed briefly in the text.

Des esters chromiques dérivés d'alcools tertiaires ont été synthétisés et caractérisés par spectroscopie infrarouge, ultraviolette et résonance magnétique nucléaire.

JEAN-CLAUDE RICHER and JEAN-MARIE HACHEY. Can. J. Chem. 53, 3087 (1975).
Chromic acid esters derived from tertiary alcohols have been synthesized and characterized via infrared, ultraviolet, and proton magnetic resonance spectroscopy.

Introduction

Les esters chromiques dérivés d'alcools tertiaires ont été décrits sommairement par un grand nombre de chercheurs; dans un article de revue, Treibs (1) rappelle les principaux travaux publiés dans ce domaine depuis les origines jusqu'à 1967. Des esters chromiques dérivés d'amines (2–4), des esters di- et trichromiques dérivés du tertiobutanol (5), des esters chromiques polymérisés dérivés de diols (6, 7) de même que des esters chromiques dérivés de thiols (8) sont décrits dans la littérature. En 1956, Zeiss et Matthews (9) proposent un mécanisme pour la formation des esters chromiques dérivés d'alcools tertiaires. Plus récemment, des chercheurs ont élucidé la structure d'esters chromiques dérivés d'alcools tertiaires à l'aide du spectre de diffraction des rayons-X (10).

Dans ce travail, nous décrivons des méthodes de synthèse et caractérisons des esters chromiques dérivés d'alcools tertiaires par i.r., u.v. et r.m.n. Plusieurs de ces esters chromiques ont été utilisés comme agents oxydants (11).

Résultats et discussion

Synthèse d'esters chromiques dérivés d'alcools tertiaires

Des descriptions typiques de la synthèse d'esters chromiques solides ou liquides sont données dans la partie expérimentale.

Les remarques suivantes pourraient être faites concernant la synthèse des esters chromiques décrites ici: (*a*) Les rendements sont pratiquement quantitatifs (90% et plus en général). (*b*) Lorsqu'ils ne sont pas en solution dans un solvant neutre, les esters chromiques liquides se décomposent assez rapidement au contact de l'air, de la lumière, de la chaleur pour donner un résidu visqueux brun-noir. (*c*) Une autre méthode de synthèse décrite par Zeiss et Pease (12) consistant à utiliser le chlorure de chromyle en solution dans le CCl_4 présente au départ certains inconvénients à cause de la grande réactivité du CrO_2Cl_2. Après l'essai infructueux des divers procédés expérimentaux décrits dans la littérature (7, 13) pour la synthèse d'esters chromiques polymérisés, la synthèse faisant intervenir CrO_2Cl_2 fut tentée pour les diols suivants: le bicyclo[2.2.2]octanediol-1,4 et le benzopinacol. Ces réactions donnèrent après évaporation du solvant un résidu gommeux brun-noir qui ne fut pas étudié davantage. (*d*) Lorsqu'ils ne sont plus en solution dans un solvant neutre (benzène, CCl_4, pentane. . .) les esters chromiques liquides sont relativement instables. La détermination de leurs propriétés physiques (n_D, analyse du chrome, i.r., u.v., r.m.n.) s'est donc avérée particulièrement délicate. (*e*) Les résultats obtenus ont permis de constater que l'utilisation de solution aqueuse de CrO_3 donnait des rendements inférieurs ou nuls en esters chromiques.

Propriétés d'esters chromiques dérivés d'alcools tertiaires

Analyse du chrome

Dans le cas des esters chromiques liquides, la teneur en chrome est déterminée par une méthode volumétrique (14): il s'agit de trans-

former tout le chrome sous forme de bichromate puis de réduire le bichromate en Cr(III) au moyen du sulfate ferreux ammoniacal. Les esters chromiques solides sont analysés selon une méthode gravimétrique (9), la combustion d'un ester chromique laissant un résidu de Cr_2O_3. Les résultats des analyses du chrome sont donnés au tableau 1.

Spectre infrarouge

Les bandes d'absorption en infrarouge pour quelques esters chromiques ont été rapportées dans la littérature (1, 5, 9). Les esters chromiques synthétisés au cours de ce travail présentent des bandes d'absorption Cr—O dans l'infrarouge entre 785 et 993 cm^{-1}. Des bandes i.r. caractéristiques sont résumées au tableau 1.

Spectre ultraviolet

Les esters chromiques examinés dans ce travail présentent deux bandes d'absorption dans l'ultraviolet (solvant: *n*-pentane), une première

se situant entre 280 et 298 nm et une seconde entre 368 et 395 nm. Il est à noter que Wiberg et Schafer (15) indique un log ε 3.47 et 3.46 pour le chromate de ditertiobutyle alors que dans ce travail, des valeurs de 3.4 et 3.5 sont rapportées. Le détail des spectres u.v. se trouve au tableau 1.

Spectre résonance magnétique nucléaire

Une comparaison entre les spectres r.m.n. des alcools tertiaires étudiés et de leurs esters chromiques permet de souligner les caractéristiques suivantes pour ces esters. (*i*) Disparition complète du groupement hydroxyle (confirmée également par i.r.). (*ii*) Selon la structure de la molécule, l'effet de déblindage du groupement chromate varie de ~12 à ~20 Hz pour les protons aliphatiques liés à des carbones directement fixés sur le carbone carbinolique et s'atténue progressivement avec l'éloignement. (*iii*) De façon générale et, compte tenu des limites de précision de l'appareil (±0.5 Hz), la valeur de la constante de couplage J de l'alcool n'est pas sensiblement affectée dans l'ester chromique correspondant. Toutefois, le spectre r.m.n. du chromate de diadamantyl-1 laisse voir une coalescence de signaux; dans ce cas, deux singulets larges sont observés. Le signal à 1.37 p.p.m. et celui à 1.93 p.p.m. sont attribués respectivement aux six protons en position δ d'une part et aux neuf protons en position β et γ d'autre part. Ces attributions sont basées sur la remarque faite au paragraphe précédent. Ainsi, un déblindage de 19.8 Hz est observé pour les protons en β dans l'ester chromique dérivé de l'adamantanol-1.

Les caractéristiques des spectres r.m.n. de quelques alcools tertiaires et de leurs esters chromiques sont résumées au tableau 2.

Partie expérimentale

Les points de fusion sont déterminés sur un microscope chauffant de la compagnie Reichert (Autriche) à l'aide d'un thermomètre calibré. Les spectres i.r. sont pris sur un spectrophotomètre modèle IR-8 de la compagnie Beckman. Les produits liquides sont examinés sans solvant et sous forme de film; les solides sont mis en suspension sous forme d'émulsion dans le Nujol. Les indices de réfraction sont mesurés sur un réfractomètre de type Abbe de la compagnie Karl Zeiss. Les analyses par chromatographie en phase gazeuse sont effectuées de la façon suivante. Alcools tertiaires: Appareil de la compagnie F & M à détection par ionisation de flamme; colonne en cuivre (14 pied × ¼ po) contenant 10% d'Hyprose sur Chromosorb P 60/80; gaz vecteur: 60 ml He/min^{-1}; température de la colonne: 140 °C. Alcools secondaires: Appareil de la compagnie Microtek à détection par conductivité thermique; colonne en cuivre (12 pied × ¼ po) contenant 10% de silicone SE-30 sur Chromoport XXX; gaz vecteur: 60 ml He/min; température de la colonne: 180–200 °C.

Les spectres u.v. sont déterminés sur un spectrophotomètre de la compagnie Bausch & Lomb, modèle Spectronic 505, solvant: pentane.

Les spectres r.m.n. sont déterminés sur un spectrophotomètre Varian, modèle A-60 et Hitachi-Perkin-Elmer, modèle R-24, solvant: CCl_4. Les déplacements chimiques se réfèrent au TMS utilisé d'une façon interne.

Propriétés des alcools tertiaires

Les alcools tertiaires utilisés dans la synthèse des esters chromiques provenaient de la compagnie Aldrich. Ils ont d'abord été soumis à une distillation (ou à une recristallisation dans le pentane) puis à une détermination du point d'ébullition (ou du point de fusion).

La chromatographie en phase gazeuse sur une colonne d'Hyprose 10% à 140 °C telle que décrite au début de la partie expérimentale révéla la présence d'un seul pic dans chaque cas. Le spectre i.r. confirma également la pureté de ces alcools. Les propriétés physiques (points d'ébullition ou points de fusion et indices de réfraction) des alcools tertiaires purifiés se comparent bien à celles décrites dans la littérature (16–24).

Synthèse et propriétés d'esters chromiques dérivés d'alcools tertiaires

L'expérience a permis de constater que deux modes de synthèse peuvent être employés pour l'obtention d'esters chromiques dérivés d'alcools tertiaires suivant que l'alcool soit solide et peu soluble dans les solvants peu polaires ou apolaires (pentane, benzène, CCl_4, . . .) ou liquides. De plus, il a été observé que les alcools liquides étudiés donnaient des esters chromiques liquides et que les alcools solides donnaient des esters chromiques solides.

Préparation d'un ester chromique dérivé d'un alcool tertiaire solide insoluble dans les solvants peu polaires

Selon la méthode générale de Wienhaus (25) en utilisant AcOH glacial au lieu du pentane

La réaction se fait à la température ambiante. Il suffit de dissoudre le CrO_3 solide dans une solution d'acide acétique[3] contenant déjà une quantité équimolaire d'alcool. Le mélange réactionnel se colore immédiatement rouge-orange. La recristallisation de l'ester chromique est réalisée dans l'acide acétique[3] après avoir chassé l'excès de solvant s'il y a lieu *i.e.* si la recristallisation de l'ester n'est pas amorcée après *ca.* 30 min.

Selon la méthode décrite par Fieser et Ourisson (7)

Dans cette méthode, $Na_2Cr_2O_7{\cdot}2H_2O$ est utilisé au lieu du CrO_3 solide. Le solvant pour la réaction et la recristallisation est l'acide acétique glacial purifié par reflux et distillation sur CrO_3. Les proportions de réactifs sont toutefois de 1 mol de $Na_2Cr_2O_7{\cdot}2H_2O$ pour 2 mol d'alcool.

Préparation d'un ester chromique dérivé d'un alcool tertiaire liquide

La méthode suivante qui constitue une adaptation de la méthode générale décrite par Wienhaus (25) s'est avérée la plus efficace (sauf pour le *tert*-BuOH où on doit faire réagir le CrO_3 et l'alcool selon le rapport molaire 1.1 et 2 respectivement).

L'alcool tertiaire (0.3–1 g) à estérifier est dissous dans 25 ml de pentane pur contenu dans un ballon de 50 ml; la réaction se fait à la température de la pièce. Tout en maintenant l'agitation (au moyen d'un agitateur magnétique) une quantité équimoléculaire de CrO_3 anhydre (conservé dans un dessicateur) est ajoutée. Il y a coloration immédiate de la solution en rouge-orange et apparition de gouttelettes d'eau au fond du ballon. L'agitation est poursuivie durant 3–5 min à la température ambiante. Le mélange réactionnel est ensuite décanté, transféré dans une fiole conique puis séché sur du Na_2SO_4 anhydre. L'ester chromique anhydre ainsi obtenu est finalement débarrassé de son solvant par évaporation sous pression réduite à la température de la pièce. Il est préférable de toujours protéger le mélange réactionnel de l'action de la lumière durant toute la durée de la synthèse. Un produit liquide plus ou moins visqueux, rouge foncé est ainsi obtenu.

La procédure expérimentale suivante fut adoptée pour la détermination des caractéristiques physiques et spectroscopiques: sur l'échantillon d'ester chromique fraîchement préparé (0.3–0.5 g) la pureté était d'abord contrôlée par i.r. (disparition totale de la bande —OH et apparition de bandes Cr—O). Une propriété était alors déterminée. La synthèse était répétée jusqu'à ce que l'on obtienne au moins deux ou trois valeurs subséquentes identiques.

Détermination de la teneur en chrome des esters chromiques préparés

Détermination volumétrique (14)

C'est une réaction d'oxydo-réduction. La méthode consiste à transformer tout le chrome sous forme de bichromate par l'intermédiaire du nitrate d'argent et du persulfate d'ammonium puis à réduire le bichromate sous forme de Cr(III) au moyen du sulfate ferreux ammoniacal; la diphényl amine fut utilisée comme indicateur.

Détermination gravimétrique (9)

Elle repose sur le fait que la combustion d'un ester chromique laisse un résidu solide vert (Cr_2O_3). Quelques 100–300 mg de l'ester chromique à analyser sont placés

[3]AcOH purifié par reflux et distillation sur CrO_3.

dans un creuset en porcelaine recouvert partiellement d'un couvercle. L'intensité du chauffage est accrue lentement afin d'éviter toute projection. Après quelques minutes, le chauffage est poussé au maximum avec un brûleur Fisher durant 20–30 min. Le creuset est ensuite refroidi à l'air libre pendant quelques minutes puis transféré dans un dessicateur. Le résidu vert de Cr_2O_3 est finalement pesé. Cette méthode est apparue difficilement applicable dans le cas des esters chromiques liquides (à cause des projections difficiles à éviter) mais elle s'est avérée très efficace pour les esters chromiques solides.

Les auteurs remercient vivement le Conseil national de recherches du Canada, la compagnie C.I.L. et le Conseil de recherches pour la défense pour leur aide financière.

Oxilorphan and Butorphanol.[1] Potent Narcotic Antagonists and Nonaddicting Analgesics in the 3,14-Dihydroxymorphinan Series. Part V[2]

IVO MONKOVIĆ,[3] HENRY WONG, ANTHONY W. PIRCIO,[4] YVON G. PERRON, IRWIN J. PACHTER,[4] AND BERNARD BELLEAU

Bristol Laboratories of Canada, Candiac, Quebec J5R 1J1

Received May 26, 1975

IVO MONKOVIĆ, HENRY WONG, ANTHONY W. PIRCIO, YVON G. PERRON, IRWIN J. PACHTER, and BERNARD BELLEAU. Can. J. Chem. **53**, 3094 (1975).

A series of 3,14-dihydroxymorphinans **8** was synthesized via a method of (*a*) acylation of 3-methoxy-$\Delta^{8,14}$-morphinan **4***a* (*b*) stereospecific epoxidation of the resultant amides to β-epoxides **5** (*c*) simultaneous reduction of amide and epoxide functions and (*d*) demethylation of the resultant 3-methoxy-14-hydroxymorphinans **7**. Alternatively deblocking of the amine function in **5***b* by hydrolysis followed by reduction of the resultant amino epoxide **5***e* afforded 14-hydroxy-3-methoxymorphinan **7***e*, which is readily alklyated and demethylated to give various **8**. On a basis of interesting pharmacological profiles compounds *l*-**8***c* (oxilorphan) and *l*-**8***d* (butorphanol) were selected for clinical studies.

IVO MONKOVIĆ, HENRY WONG, ANTHONY J. PIRCIO, YVON J. PERRON, IRWIN J. PACHTER et BERNARD BELLEAU. Can. J. Chem. **53**, 3094 (1975).

On a synthétisé une série de dihydroxy-3,14 morphinanes **8** par l'intermédiaire des réactions suivantes: (*a*) acylation du méthoxy-3 $\Delta^{8,14}$ morphinane **4***a*, (*b*) époxydation stéréospécifique en β des amides obtenues, (*c*) réduction simultanée des fonctions amide et époxyde et (*d*) déméthylation du méthoxy-3 hydroxy-14 morphinane **7** qui en résulte. On peut aussi (*a*) débloquer la fonction amine de **5***b* par hydrolyse et (*b*) réduire l'amino époxyde **5***e* qui en découle pour obtenir l'hydroxy-14 méthoxy-3 morphinane, **7***e*, qui peut être alkylé facilement puis déméthylé pour fournir une variété de composés **8**. En se basant sur des profils pharmacologiques intéressants, on a choisi les *l*-**8***c* (oxilorphane) et *l*-**8***d* (butorphanol) pour des études cliniques.

[Traduit par le journal]

Introduction

The rapid increase in drug abuse in recent years has stimulated the renewal of research efforts in order that this serious medical and socioeconomic problem may be effectively controlled. To this end we have reported earlier as part of our efforts to synthesize potent, long acting, orally effective, pure narcotic antagonists and non-abusable analgesics via the versatile intermediate 4a-(2-aminoethyl)-1,2,3,4,4a,9-hexahydro-6-methoxyphenanthrene **1** (Chart 1) (1, 2). The experimental work which led to butorphanol, oxilorphan and their congeners, as well as preliminary and more advanced pharmacological studies, form the subject of this communication.

Results and Discussion

Two different routes led to 3-methoxy-$\Delta^{8,14}$-morphinan **4***a*, a crucial intermediate in the synthesis of 3,14-dihydroxymorphinans. The first involves the dehydration of the 17-carboethoxy-14-hydroxyisomorphinan (**3**) to **4***b* followed by hydrolysis to **4***a* (1). A shorter and more practical route involves the bromocyclization of unsaturated amine **1** to bromohasubanan **2** followed by rearrangement to **4***a* (2).[5]

Further transformations of the unsaturated system of **4** to the 14-hydroxymorphinan system **7** appears straight forward provided that the double bond can yield the corresponding β-epoxide stereoselectively. Our initial studies on the epoxidation of **4***b* by treatment with *m*-chloroperbenzoic acid indicated the formation of a 1:1 mixture of epoxides **5***a* and **6**, which was difficult to separate. The desired 14-hydroxymorphinan **7***b* was prepared in low yield by

[1]Approved generic names for *l*-17-cyclopropylmethyl-3,14-dihydroxymorphinan and *l*-17-cyclobutylmethyl-3,14-dihydroxymorphinan.

treatment of this mixture with sodium borohydride followed by isolation of **7***a* (column chromatography), and reduction with lithium aluminum hydride. Fortunately, amides **4***c*, **4***d*, and **4***e*, which were prepared by standard procedures from **4***a*, underwent stereoselective epoxidation to give predominantly β-epoxides **5***c*, **5***d*, and **5***e*. The corresponding α-isomers were detected by t.l.c. and these minor constituents were removed as such (**5***b* and **5***e*), or after the next step (**5***d*) simply by recrystallization.

Evidently, the ratio of α- to β-epoxides is affected by the nature of the substituent on the nitrogen. The directional effect could be rationalized in terms of an amide–percid complex (or lack of it) prior to the epoxidation step. A similar *cis*-directing effect in the epoxidation of an allylic amide in cyclohexene series has been observed previously by Goodman, Winstein, and Boschan (4).

The amide and epoxide functions in **5***c* and **5***d* were reduced simultaneously by treatment with lithium aluminum hydride. As expected, reduction of the epoxide ring led exclusively to the formation of the tertiary rather than secondary alcohols.

Alternatively hydrolysis of epoxyamide **5***b* followed by reduction of the resultant epoxyamine **5***e* with lithium aluminum hydride afforded the versatile intermediate 14-hydroxy-3-methoxymorphinan **7***e* which could be easily converted to various *N*-substituted derivatives either via direct alkylation (**7***h–k*) or via acylation followed by reduction (**7***f*, *g*).

Resolution of **7***e* with *d*- and *l*-tartaric acids gave the optical isomers (*l*-**7***e* and *d*-**7***e*). Reductive *N*-methylation of *l*-**7***e* (formaldehyde, Raney Ni/H_2) afforded *l*-14-hydroxy-3-methoxy-17-methylmorphinan (*l*-**7***b*), which was identical in every respect with an authentic specimen derived from thebaine (3).

Demethylation of the methyl ethers **7** was effected in most cases (**7***b*, *c*, *g–j*) with boron tribromide in dichloromethane (5). Alternatively **7***e* was demethylated with pyridine hydrochloride, and **7***k* with sodium ethylthiolate (6). Demethylation of **7***i* with boron tribromide led to partial hydration of the double bond, and in addition to the expected unsaturated base **8***h*, we also obtained some triol **8***i*.

Resolution of the biologically most interesting products **8***c* and **8***d* was effected by recrystallization of the respective *d*- and *l*-tartaric acid salts. Methoxy methylation of the resultant *l*-isomers (*l*-**8***c* and *l*-**8***d*) to **9***a* and **9***b* was accomplished by treatment with sodium hydride and chloromethyl methyl ether in benzene.

Biological Results

The methods of biological evaluation are outlined in the experimental part. Compounds **8**, **9** and several previously reported 3,14-dihydroxyisomorphinans **10** (1) were screened for narcotic antagonist and analgesic activities and the results are shown in Table 1. It is evident that the *l*-3,14-dihydroxymorphinans **8** are the most active compounds of the series, while the corresponding *d*-isomers are inactive and isomorphinans **10** are only moderately active. The most interesting compounds *l*-**8***c*, a strong narcotic antagonist with weak analgesic activity and *l*-**8***d*, a powerful analgesic with moderate antagonist activity, were further biologically evaluated, and

comparative data with reference agents are given in Table 2. In these studies, *l*-**8***c* was four times more potent than *dl*-cyclazocine as an antagonist; *l*-**8***d* was 30 times more potent than *dl*-pentazocine both as an antagonist and as an analgesic. Furthermore, acute and chronic toxicity and addiction potential evaluations in laboratory animals, including monkeys, showed that these drugs possess high therapeutic ratios with low abuse potential. Consequently, these agents were selected for clinical investigations. In initial studies with non-dependent humans, the duration of the agonist action of *l*-**8***c* was equivalent to that of *dl*-cyclazocine (7). However, the side effect potential of *l*-**8***c* was estimated to be only one quarter of *dl*-cyclazocine. These findings indicate, therefore, that the duration of antagonist activity of *l*-**8***c* should be comparable to that of *dl*-cyclazocine.

In the course of initial studies in man, *l*-**8***c* was also found to increase urinary output (8). The potential clinical significance of this effect is under study.

In postoperative patients, double blind studies showed that *l*-**8***d* is a potent analgesic surpassing morphine and *dl*-pentazocine, in potency by factors of 10 and 30 respectively (9). Thus the effective parenteral dose appears to be in the range of 1 to 2 mg, a level at which the drug is well tolerated.

In addition, *l*-**8***d* was found to be a powerful antitussive agent in animals. By the subcutaneous route of administration, it was up to 140 times as active as codeine (10), which is a surprising novel feature of a narcotic antagonist.

Because of current shortages of opium-derived products and the need for their replacement with safer, nonabusable synthetic drugs *l*-**8***d* may find a number of useful clinical applications.

Experimental

The melting points were determined on a Gallenkamp apparatus, and are uncorrected. The infrared (i.r.) spectra were recorded on a Unicam Sp-200G grating i.r. spectrometer. The n.m.r. spectra were recorded on a Varian A-60A spectrometer using deuteriochloroform. The chemical shifts are expressed in δ values using tetramethylsilane as internal reference. Microanalyses were performed by Micro-Tech Laboratories Inc., Skokie, Ill.

Assays for Analgesic and Antagonist Activities

The method used for evaluation of analgesic activity was essentially that described by Siegmund *et al.* (11). Compounds were administered subcutaneously (15 min) before the intraperitoneal injection of phenylquinone (2 mg/kg). Beginning 5 min after the phenylquinone injection, the animals were observed for writhing and the number of writhes was counted over a period of 10 min. The dose which produced a 50% reduction in the number of writhes, as compared to the control group, was called the ED_{50}.

The antagonist assays were as follows: Mice were injected with oxymorphone (2 mg/kg s.c.), and the potential antagonist was administered subcutaneously 10 min after oxymorphone. The antagonist ED_{50} was defined as the dose which antagonized the Straub tail response (elevation greater than 45°) in 50% of the mice.

The ability to reverse oxymorphone narcosis in the rat was used as a measure of narcotic antagonist activity (12). The antagonist ED_{50} was defined as the dose which reversed the loss of righting reflex in 50% of the rats.

The percent antagonism and the ED_{50} of morphine induced analgesia were calculated as described by Harris and Pierson (13).

Racemic 3-Methoxy-17-trifluoroacetyl-$\Delta^{8,14}$-morphinan, **4***c*

To a cooled (ice), stirred solution of **4***a* (71.4 g) and triethylamine (31.3 g) in dichloromethane (300 ml) was added dropwise a solution of trifluoroacetic anhydride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

(65.1 g) in dichloromethane (150 ml). After addition, the mixture was stirred for 15 min, and then washed with ice-cold water (500 ml), followed by dilute hydrochloric acid and again with water. The organic layer was dried (Na_2SO_4), filtered over charcoal and evaporated *in vacuo* to give 98 g (theoretical yield) of amide **4***c* as a thick oil; i.r. neat 1700 cm^{-1}; n.m.r. δ 6.6–7.2 (3H, m), 5.85 (1H, t, J = 4 Hz), 4.2–5.4 (2H, m), 3.82 (3H, s), 2.5–4.1 (3H, m), 1.2–2.3 (8H, m). The oil crystallized from ether to give white solid, m.p. 94–96 °C.

Anal. Calcd. for $C_{19}H_{20}NO_2$: C, 64.95; H, 5.74; N, 3.99. Found: C, 65.34; H, 5.75; N, 4.03.

Racemic 3-Methoxy-17-cyclopropylcarbonyl-$\Delta^{8,14}$-morphinan, 4d

The amide **4***d* was similarly prepared in 95% yield by treatment of **4***a* with cyclopropane carboxylic acid chloride. A sample recrystallized from ether showed m.p. 133–135 °C; i.r. (Nujol) 1645 cm^{-1}; n.m.r. δ 6.6–7.1 (3H, m), 5.78 (1H, t, J = 4 Hz), 3.8–5.5 (2H, m), 3.8 (3H, s), 0.5–3.5 (16H, m).

Anal. Calcd. for $C_{21}H_{25}NO_2$: C, 77.98; H, 7.79; N, 4.33. Found: C, 77.86; H, 7.87; N, 4.30.

Racemic 3-Methoxy-17-cyclobutylcarbonyl-$\Delta^{8,14}$-morphinan, 4e

The amide **4***e* was similarly prepared in 88.5% yield by treatment of **4***a* with cyclobutanecarboxylic acid chloride. Recrystallization from cyclohexane gave an analytical sample, m.p. 95–97 °C; i.r. (Nujol), 1650 cm^{-1}; n.m.r. δ 6.7–7.2 (3H, m), 5.8 (1H, d, J = 4 Hz), 4.2–5.6 (2H, m), 3.83 (3H, m), 1.2–3.6 (18H, m).

Anal. Calcd. for $C_{22}H_{27}NO_2$: C, 78.30; H, 8.06; N, 4.15. Found: C, 78.35; H, 8.15; N, 4.24.

Racemic 17-Ethoxycarbonyl-8,14-epoxy-3-methoxymorphinan, 5a and Corresponding Isomorphinan, 6

To a cooled (ice), stirred solution of urethane **1***b* (7.0 g) in dichloromethane (25 ml) was added in small portions *m*-chloroperbenzoic acid (5.63 g, 85% purity) and the mixture was left at room temperature for 6 h. Then the solid was removed by filtration, and the filtrate washed with aqueous sodium sulfite followed by 5% aqueous sodium bicarbonate and finally with water. Drying, filtration over celite-charcoal mixture, and concentration *in vacuo* gave 5.64 g of a mixture of **5***a* and **6**; i.r. (neat) 1700 cm^{-1}; n.m.r. δ 6.6–7.2 (3H, m), 4.16 (2H, q, J = 7 Hz), 3.8 (3H, s), 1.25 (3H, t, J = 7 Hz), 1.0–4.5 (14H, m). A sample for analysis distilled at 145 °C/0.05 Torr.

Anal. Calcd. for $C_{20}H_{25}NO_4$: C, 69.25; H, 7.34; N, 4.08. Found: C, 69.39; H, 7.35; N, 4.05.

Racemic 8,14-Epoxy-3-methoxy-17-trifluoroacetylmorphinan, 5b

The epoxide **5***b* was obtained as a white solid in 83% yield by oxidation of **4***c* with *m*-chloroperbenzoic acid by the procedure given for the preparation of **5***a*; m.p. 102–105 °C from ether; i.r. (Nujol) 1705 cm^{-1}; n.m.r. δ 6.7–7.3 (3H, m), 4.2–4.6 (1H, m), 3.85 (3H, s), 0.8–4.2 (14H, m).

Anal. Calcd. for $C_{19}H_{20}F_3NO_3$: C, 62.12; H, 5.49; N, 3.82. Found: C, 62.07; H, 5.38; N, 3.73.

Racemic 17-Cyclopropylcarbonyl-8,14-epoxy-3-methoxymorphinan, 5c

The epoxide **5***c* was obtained in 71% yield as a white solid by oxidation of **4***d* by the above given procedure; m.p. 140–142 °C from ether; i.r. (Nujol), 1650 cm^{-1}; n.m.r. δ 6.7–7.2 (3H, m), 3.9–4.6 (2H, m), 3.83 (3H, s), 0.6–3.4 (17H, m).

Anal. Calcd. for $C_{21}H_{25}NO_3$: C, 74.31; H, 7.42; N, 4.13. Found: C, 74.13; H, 7.39; N, 4.13.

Racemic 17-Cyclobutylcarbonyl-8,14-epoxy-3-methoxymorphinan, 5d

The epoxide **5***d*, an oil, containing some α-epoxide, was obtained in quantitative yield by oxidation of **4***e* as described above; i.r. (neat) 1650 cm^{-1}; n.m.r. δ 6.6–7.2 (3H, m), 3.8–4.7 (2H, m), 3.85 (3H, s), 1.1–3.7 (19H, m). Mol. Wt. Calcd. for $C_{31}H_{48}O_3$: 353. Found (mass spectrum): 353. In the course of the preparation of this manuscript, an ether solution of **5***d* was crystallized to give a white solid, m.p. 110–111 °C.

Racemic 8,14-epoxy-3-methoxymorphinan, 5e

A mixture of the epoxide **5***b* (18.35 g) and sodium borohydride (1.9 g) in dry ethanol (100 ml) was heated under reflux for 5 min. After cooling, the reaction mixture was acidified with dilute hydrochloric acid and extracted with ether. The ether extract was discarded and the aqueous layer was made basic with ammonium hydroxide and extracted with dichloromethane. The resulting extract was dried (Na_2SO_4) and concentrated *in vacuo* to yield 12.9 g of epoxide **5***e* as an oil; i.r. (neat) 3300 cm^{-1}; n.m.r. δ 6.6–7.3 (3H, m), 3.8 (3H, s), 0.8–3.7 (14H, m). Mol. Wt. Calcd. for $C_{17}H_{21}NO_2$: 271. Found (mass spectrum): 271.

Racemic 17-Ethoxycarbonyl-14-hydroxy-3-methoxymorphinan, 7a

To a mixture of epoxides **5***a* and **6** (2.5 g) in dry ethanol (100 ml) was added sodium borohydride (0.76 g), and the resultant mixture was heated under reflux for 3 h, after which time additional portions of sodium borohydride (0.38 g) were added every hour during 7 h. Then the mixture was cooled, acidified with dilute hydrochloric acid, and extracted with dichloromethane. The extract was dried and concentrated *in vacuo* and the residual oil was chromatographed over alumina. Elution with chloroform gave at first some 14-hydroxyisomorphinan analog, which was described earlier (1) followed by 1.27 g of **7***a*, as a white solid from ether-petroleum ether; m.p. 139–140 °C; i.r. (Nujol) 1690, 3434 cm^{-1}; n.m.r. δ 6.4–7.1 (3H, m), 4.1 (2H, q, J = 7 Hz), 3.8–4.3 (2H, m), 3.7 (3H, s), 1.2. (3H, t, J = 7 Hz), 0.9–3.4 (13H, m).

Anal. Calcd. for $C_{20}H_{27}NO_4$: C, 69.54; H, 7.88; N, 4.05. Found: C, 69.09; H, 7.99; N, 4.02.

Racemic 14-Hydroxy-3-methoxy-17-methylmorphinan, 7b

To a stirred solution of lithium aluminum hydride (0.17 g) in anhydrous tetrahydrofuran (10 ml) was added, under nitrogen, a solution of urethane **7***a* (0.518 g) in tetrahydrofuran (10 ml) and the mixture heated under reflux for 18 h. After cooling and the usual isolation procedure, the product, an oil, crystallized from petroleum ether to give 280 mg of **7***b*. Recrystallization from methanol gave an analytical sample: m.p. 113–115 °C; i.r. (Nujol) 3360 cm^{-1}; n.m.r. 6.5–7.2 (3H, m), 3.8 (3H, s), 2.38 (3H, s), 1.1–3.7 (14H, m), 1.0 (1H, dt, J_1 = 7 Hz, $J_2 \simeq$ 1.5 Hz).

Anal. Calcd. for $C_{18}H_{25}NO_2$: C, 75.23; H, 8.77; N, 4.87. Found: C, 75.26; H, 8.76; N, 4.68.

For personal use only.

Racemic 17-Cyclopropylmethyl-14-hydroxy-3-methoxymorphinan, 7c

A solution of epoxide **5c** (60 g) in anhydrous tetrahydrofuran (100 ml) was added dropwise during 30 min to a stirred suspension of lithium aluminum hydride (18 g) in tetrahydrofuran (500 ml) and the mixture heated under reflux for 1 h. After cooling and the usual work-up, the product, an oil, was dissolved in acetone and treated with dry hydrogen chloride followed by an addition of a few ml of ether. The deposited crystals were collected by filtration to give after drying 61.5 g of **7c** hydrochloride; m.p. 223–225 °C. An analytical sample crystallized with $\frac{1}{2}H_2O$ from methanol–ether; m.p. 259–260 °C. Free base, i.r. (neat) 3420 cm^{-1}; n.m.r. δ 6.6–7.2 (3H, m), 3.8 (3H, s), 1.08 (1H, d, J = 9 Hz), 0.0–3.3 (21H, m).

Anal. Calcd. for $C_{21}H_{29}NO_2 \cdot HCl \cdot \frac{1}{2}H_2O$: C, 67.67; H, 8.37; N, 3.76. Found: C, 67.70; H, 8.02; N, 3.72.

Racemic 17-Cyclobutylmethyl-14-hydroxy-3-methoxymorphinan, 7d

The hydroxymorphinan **7d** was obtained in 69% yield by reduction of epoxide **5d** as described for the preparation of **4c**; i.r. (neat) 3440 cm^{-1}; n.m.r. δ 66.72 (3H, m), 3.8 (3H, s), 1.2–3.3 (23H, m), 1.0 (1H, d, J = 9 Hz). The hydrochloride salt was recrystallized from methanol; m.p. 248–250 °C.

Anal. Calcd. for $C_{22}H_{31}NO_2 \cdot HCl \cdot \frac{1}{2}H_2O$: C, 68.28; H, 8.60; N, 3.62. Found: C, 68.25; H, 8.40; N, 3.75.

From mother liquors it was possible to isolate by fractional crystallization or chromatography on alumina 10–15% of the corresponding isomorphinan (1).

Racemic 14-Hydroxy-3-methoxymorphinan, 7e

A solution of amino-epoxide **5e** (8 g) in tetrahydrofuran (50 ml) was added dropwise to a solution of lithium aluminum hydride (5 g) in tetrahydrofuran (50 ml) and the mixture was heated under reflux for 15 min. After cooling and the usual work-up, the product, an oil, was dissolved in ether, filtered over a celite–charcoal mixture and the filtrate treated with a solution of hydrogen chloride in ether to give 7.2 g of **7e** as its hydrochloride salt. A sample recrystallized from methanol contained $\frac{1}{2}$ mol of methanol of crystallization; m.p. 243–244 °C; free base: i.r. (neat), 3340, 3440 cm^{-1}; n.m.r. δ 6.7–7.2 (3H, m), 3.8 (3H, s), 1.2–3.6 (15H, m), 0.97 (1H, d, t, J = 13 Hz, J_2 = 2 Hz).

Anal. Calcd. for $C_{17}H_{23}NO_2 \cdot HCl \cdot \frac{1}{2}CH_3OH$: C, 64.50; H, 8.04; N, 4.30. Found: C, 64.18; H, 7.81; N, 4.25.

Resolution of 14-Hydroxy-3-methoxymorphinan, 7e

To a hot solution of racemic amino-alcohol **7e** (27.3 g) in methanol (60 ml) was carefully added a hot solution of *l*-tartaric acid (15. 0 g) in methanol (40 ml), and the mixture left at room temperature for five days. The separated solid (32.0 g) was removed by filtration and recrystallized from methanol (1.1 l) to give after drying at 80 °C/0.05 Torr, 12 g of acidic *l*-**7e** *l*-tartrate; m.p. 214–217; $[\alpha]_D^{25}$ −32.5° (*c* 0.1, CH_3OH).

Anal. Calcd. for $C_{17}H_{23}NO_2 \cdot C_4H_4O_6$: C, 59.56; H, 6.90; N, 3.31. Found: C, 59.90; H, 7.04; N, 3.26.

The free base showed m.p. 106–108 °C and $[\alpha]_D^{25}$ −44.97° (*c* 0.53, $CHCl_3$).

Anal. Calcd. for $C_{17}H_{23}NO_2$: C, 74.69; H, 8.48; N, 5.12. Found: C, 74.56; H, 8.46; N, 5.08.

The mother liquors were combined, evaporated to dryness and the residue partitioned between aqueous ammonium hydroxide and chloroform to afford after drying and evaporation of chloroform 18.0 g of the free base **7e**, which was similarly treated with *d*-tartaric acid to give 6.6 g of *d*-**7e** *d*-tartarate; m.p. 215–217 °C; $[\alpha]_D^{25}$ +33.4° (*c*, 0.39, CH_3OH).

Anal. Calcd. for $C_{17}H_{23}NO_2 \cdot C_4H_4O_6$: C, 59.56; H, 6.90; N, 3.31. Found: C, 60.00; H, 6.97; N, 3.31.

The free base had m.p. 107–109 °C and $[\alpha]_D^{25}$ +45.0° (*c* 1.2, $CHCl_3$).

l-14-Hydroxy-3-methoxy-17-methylmorphinan, 7b

The *l*-amino alcohol **7e** (2.70 g) in methanol (5 ml) was added to a suspension of Raney nickel catalyst in methanol (100 ml) and formaldehyde (1 ml of 36% aqueous solution), and the mixture was hydrogenated for 30 min at 40 p.s.i. The catalyst was removed by filtration and filtrate was concentrated to dryness to afford 2.7 g of *l*-**7b** as a white solid. A sample for analysis was recrystallized from methanol; $[\alpha]_D^{25}$ −77° (*c* 0.1, $CHCl_3$); m.p. 142–144 °C; lit. (3) $[\alpha]_D$ −76.6°; m.p. 143–144.5 °C

Anal. Calcd. for $C_{18}H_{25}NO_2$: C, 75.23; H, 8.77; N, 4.87. Found: C, 75.20; H, 8.89; N, 4.68.

d-14-Hydroxy-3-methoxy-17-methylmorphinan, 7b

The *d*-hydroxymorphinan **7b** was similarly prepared from the corresponding *d*-amino alcohol **7e**; $[\alpha]_D$ +77.1° (*c* 0.35, $CHCl_3$); m.p. 142–144 °C.

Anal. Calcd. for $C_{18}H_{25}NO_2$: C, 75.23; H, 8.77; N, 4.87. Found: C, 75.38; H, 8.72; N, 4.85.

Racemic 14-Hydroxy-3-methoxy-17-propionylmorphinan, 7h

To a cooled (ice) stirred solution of racemic amino alcohol **7e** (1.14 g) and triethylamine (0.50 g) in dichloromethane (15 ml) was added dropwise a solution of propionylchloride (0.42 g) in dichloromethane (5 ml). After the usual work-up, there was obtained 1.13 g of **7f** as a white solid; m.p. 149–150 °C from methanol; i.r. (Nujol) 3320, 1620 cm^{-1}; n.m.r. δ 6.7–7.3 (3H, m), 4.2–5.0 (2H, m), 3.9 (3H, s), 1.18 (3H, t, J = 7 Hz), 0.8–3.7 (17H, m).

Anal. Calcd. for $C_{20}H_{27}NO_3$: C, 72.92; H, 8.26; N, 4.25. Found: C, 72.98; H, 8.39; N, 4.08.

Racemic 14-Hydroxy-3-methoxy-17-propylmorphinan, 7g

The reduction of amide **7f** to the amine **7g** was accomplished by a procedure similar to the one given above for the reduction of amido epoxides. The product was obtained in 92% yield as an oil. Infrared (neat) 3340 cm^{-1}; n.m.r. δ 6.6–7.2 (3H, m), 3.8 (3H, s), 0.8–3.2 (19H, m), 0.92 (3H, t, J = 7 Hz). The hydrochloride salt was recrystallized from ethanol–ether; m.p. 259–261 °C.

Anal. Calcd. for $C_{20}H_{29}NO_2 \cdot HCl$: C, 68.26; H, 8.59; N, 3.98. Found: C, 68.06; H, 8.60; N, 3.88.

Racemic 17-Allyl-14-hydroxy-3-methoxymorphinan, 7h

Allylbromide (6.05 g) was added to a solution of racemic amino alcohol **7e** (0.90 g) and triethylamine (1.7 g) in absolute ethanol (12 ml), and the mixture was heated under reflux under nitrogen for 18 h. Then it was evaporated to dryness, and the residue partitioned between ether and 20% aqueous sodium carbonate. The ether layer was washed with water, dried and filtered through a celite–charcoal mixture. The filtrate was evaporated to dryness to give 620 mg of **7h** as an oil; i.r. (neat) 3430 cm^{-1}; n.m.r. δ 6.6–7.2 (3H, m), 5.0–6.2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(3H, m), 3.78 (3H, s), 1.1–3.5 (16H, m), 1.0 (1H, d, $J = 8$ Hz). Mol. Wt. Calcd. for $C_{20}H_{27}NO_2$: 313. Found (mass spectrum): 313.

The hydrochloride salt was recrystallized from methanol–ether; m.p. 244–246 °C.

Anal. Calcd. for $C_{20}H_{27}NO_2 \cdot HCl$: C, 68.65; H, 8.07; N, 4.00. Found: C, 68.01; H, 7.97; N, 3.90.

l-17-(3,3-Dimethylallyl)-14-hydroxy-3-methoxymorphinan, 7i

A mixture of *l-7e* (1.85 g), triethylamine (3.33 g) and dimethylallyl bromide (1.49 g) in dry ethanol (25 ml) was heated under reflux for 3 days. Work-up as above afforded an oil which was chromatographed on alumina (elution with chloroform) to yield 1.50 g of *l-7i* as an oil; i.r. (neat) 3430 cm^{-1}; n.m.r. δ 6.5–7.0 (3H, m), 5.09 (1H, t, $J = 7$ Hz), 3.7 (3H, s), 1.7 (3H, s), 1.63 (3H, s), 1.1–3.2 (16H, m), 1.0 (1H, d, $J = 8$ Hz). The hydrochloride salt was recrystallized from methanol–ether; m.p. 224–226 °C.

Anal. Calcd. for $C_{22}H_{31}NO_2 \cdot HCl$: C, 69.91; H, 8.53; N, 3.71. Found: C, 69.88; H, 8.42; N, 3.54.

l-14-Hydroxy-3-methoxy-17-propargylmorphinan, 7j

To a cooled mixture of *l-7e* (1.65 g) and triethylamine (0.61 g) in dichloromethane (10 ml) was added a solution of propargyl bromide (0.72 g) in dichloromethane (5 ml) and the mixture stirred at room temperature for 3 days. Then it was evaporated *in vacuo*, and the residual oil partitioned between aqueous sodium carbonate and ether. Drying and evaporation of solvent gave an oil which was chromatographed on an alumina column. Elution with chloroform yielded 0.50 g of solid *l-7j* which was recrystallized from methanol; m.p. 132–134 °C; $[\alpha]_D$ −62.02° (*c* 0.466, $CHCl_3$); i.r. ($CHCl_3$) 3450 cm^{-1}; n.m.r. δ 6.4–7.0 (3H, m), 3.68 (3H, s), 3.25 (2H, d, $J = 2$ Hz, CH_2—C≡CH), 2.17 (1H, t, $J = 2$ Hz, —C≡CH), 0.8–3.1 (15H, m).

Anal. Calcd. for $C_{20}H_{25}NO_2$: C, 77.14; H, 8.09; N, 4.52. Found: C, 77.05; H, 8.22; N, 4.28.

Racemic 17-(3-Butenyl)-14-hydroxy-3-methoxymorphinan, 7k

The *N*-homoallyl-morphinan **7***k*, an oil, was prepared by the procedure given for the preparation of **7***h*; i.r. (neat) 3430 cm^{-1}; n.m.r. δ 6.7–7.2 (3H, m), 4.8–6.1 (3H, m), 3.78 (3H, s), 1.1–3.1 (18H, m), 1.0 (1H, d, $J = 9$ Hz; outer signal split into t, $J = 3$ Hz). The hydrochloride salt was recrystallized from methanol–ether; m.p. 223–225 °C.

Anal. Calcd. for $C_{21}H_{29}NO_2 \cdot HCl$: C, 69.31; H, 8.31; N, 3.85. Found: C, 69.36; H, 8.19; N, 3.78.

Racemic 3,14-Dihydroxymorphinan, 8a

A mixture of amino alcohol **7***e* (2.0 g) and pyridine hydrochloride (8.0 g) was heated at 185–200 °C under nitrogen for 1 h. After cooling, the mixture was treated with concentrated aqueous ammonium hydroxide (4 ml) and water (4 ml) and extracted with a mixture of chloroform–ethanol (9:1). The extract was dried and evaporated *in vacuo* to give 1.5 g of a solid **8***a*. A sample for analysis was recrystallized from 90% ethanol; m.p. 259–261 °C; i.r. (Nujol), 3360, 3440 cm^{-1}; n.m.r. (DMSO-d_6) δ 6.6–7.2 (3H, m), 3.1–3.3 (2H, m), 2.5–3.0 (3H, m), 1.8–2.3 (4H, m), 1.3–1.8 (5H, m), 1.0 (1H, dt, $J_1 = 11$ Hz, $J_2 \simeq 1.5$ Hz).

Anal. Calcd. for $C_{16}H_{21}NO_2$: C, 74.10; H, 8.16; N, 5.40. Found: C, 73.84; H, 8.35; N, 5.33.

l-3,14-Dihydroxymorphinan, 8a

The *l*-isomer was similarly prepared from *l-7e*; $[\alpha]_D$ −30.0° (*c* 0.14, CH_3OH); m.p. 242–244 °C.

3,14-Dihydroxymorphinans, 8b–8g

The phenolic compounds **8***b*–**8***g* were prepared by demethylation of the corresponding methyl ethers by the method of McOmie *et al.* (5).

To a stirred solution of boron tribromide (3.53 g, 0.14 mol) in dichloromethane (50 ml) under nitrogen was added dropwise during 1 h a solution of the methyl ether (80 mmol) in dichloromethane (100 ml). The stirring was continued for 3 h and then the mixture was carefully treated with water (50 ml) and concentrated aqueous ammonia (*ca.* 50 ml) and extracted with dichloromethane.

Drying and concentration yielded dihydroxymorphinans **8***b*–**8***g* which were purified as free bases or as hydrochloride salts. In the latter case, most salts crystallized with ½ mol of solvent of crystallization.

Racemic 3,14-Dihydroxy-17-methylmorphinan, 8b

The yield of **8***b* was 94%; m.p. 206–208 °C from methanol; i.r. (Nujol) 3300 cm^{-1}; n.m.r. δ 6.6–7.2 (3H, m), 3.37 (3H, s), 1.2–3.36 (14H, m), 1.05 (1H, d, $J = 8$ Hz).

Anal. Calcd. for $C_{17}H_{23}NO_2$: C, 74.69; H, 8.48; N, 5.12. Found: C, 74.82; H, 8.58; N, 4.97.

l-3,14-Dihydroxy-17-methylmorphinan, 8b

The yield of *l-8b* was 93%; m.p. 244–246 °C from methanol; $[\alpha]_D$ −79.2° (*c* 1.048, $CHCl_3$); lit. (3) m.p. 246–248 °C, $[\alpha]_D$ −80.3° (*c* 1.048, $CHCl_3$).

Anal. Calcd. for $C_{17}H_{23}NO_2$: C, 74.69; H, 8.48; N, 5.12. Found: C, 74.82; H, 8.57; N, 5.00.

Racemic 17-Cyclopropylmethyl-3,14-dihydroxymorphinan, 8c

The yield of **8***c* was 87%; m.p. 157–159 °C from methanol; i.r. (Nujol) 3250 cm^{-1}; n.m.r. δ 6.6–7.2 (3H, m), 0.0–3.0 (21H, m), 1.03 (1H, d, $J = 9$ Hz). The hydrochloride salt was recrystallized from methanol; m.p. 179–181 °C.

Anal. Calcd. for $C_{20}H_{27}NO_2 \cdot HCl \cdot \frac{1}{2}CH_3OH$: C, 67.32; H, 8.37; N, 3.83. Found: C, 67.56; H, 8.20; N, 3.90.

Racemic Cyclobutylmethyl-3,14-dihydroxymorphinan, 8d

The yield of **8***d* was 86%; m.p. 186–188 °C from benzene; i.r. (Nujol) 3240 cm^{-1}; n.m.r. 6.6–7.1 (3H, m), 1.2–3.1 (23H, m), 1.0 (1H, d, $J = 10$ Hz).

Anal. Calcd. for $C_{21}H_{29}NO_2$: C, 67.96; H, 8.49; N, 3.69. Found: C, 67.59; H, 8.26; N, 3.71.

Racemic 3,14-Dihydroxy-17-propylmorphinan, 8e

The yield of amine **8***e* (white solid) was 92%; i.r. (Nujol) 3240 cm^{-1}; n.m.r. δ 6.6–7.1 (3H, m), 0.95 (3H, m), 0.95 (3H, t, $J = 7$ Hz), 0.8–3.1 (19H, m). The hydrochloride salt was recrystallized from ethanol–ether; m.p. 170–172 °C.

Anal. Calcd. for $C_{19}H_{27}NO_2 \cdot HCl \cdot \frac{1}{2}C_2H_5OH$: C, 66.56; H, 8.66; N, 3.88. Found: C, 66.42; H, 8.34; N, 4.07.

For personal use only.

Racemic 17-Allyl-3,14-dihydroxymorphinan, 8f

The yield of **8***f* was 47%, isolated as its hydrochloride salt, after crude product was chromatographed on alumina column (grade IV, eluent:chloroform). It was recrystallized from methanol–acetone; m.p. 190–192 °C. Free base: i.r. (Nujol) 3250 cm^{-1}; n.m.r. δ 6.6–7.1 (3H, m), 5.0–6.3 (3H, m), 3.1 (2H, d, J = 6 Hz), 1.1–3.0 (14H, m), 1.0 (1H, d, J = 10 Hz).

Anal. Calcd. for $C_{10}H_{25}NO_2 \cdot HCl \cdot \frac{1}{2}CH_3OH$: C, 66.56; H, 8.02; N, 3.98. Found: C, 66.65; H, 7.76; N, 3.88.

l-3,14-Dihydroxy-17-propargylmorphinan, 8g

The yield of **8***g* was 88%; m.p. 173–175 °C from methanol; $[\alpha]_D$ −67.2° (*c* 0.44, $CHCl_3$); i.r. (Nujol) 3240 cm^{-1}; n.m.r. δ 6.4–7.1 (3H, m), 3.28 (2H, d, J = 2 Hz, $CH_2C{\equiv}CH$), 1.7–3.1 (5H, m), 0.8–1.7 (10H, m).

Anal. Calcd. for $C_{19}H_{23}NO_2$: C, 76.73; H, 7.80; N, 4.71. Found: C, 76.63; H, 7.86; N, 4.52.

l-3,14-Dihydroxy-17-(2,2-dimethylallyl)-morphinan, 8h and l-3,14-Dihydroxy-17-(3-hydroxy-3-methylbutyl)-morphinan, 8i

The dimethylallyl intermediate **7***i* (3.012 g) was treated with borontribromide as above to yield 2.4 g of an oil. This was stirred with 1 *N* hydrochloric acid in methanol (20 ml) for 1 h and then partitioned between water and ether. The water layer was made alkaline with ammonium hydroxide and extracted with dichloromethane. The extract was dried and evaporated *in vacuo* to give 1.8 g of a mixture of **8***h* and **8***i*. This was chromatographed over alumina to afford at first (elution with chloroform containing 2% methanol) **8***h* as an oil, which was recrystallized as its hydrochloride salt from methanol–ether to give 450 mg of solid; m.p. 243–245 °C; $[\alpha]_D^{22}$ −69.1° (*c* 0.36, CH_3OH). Free base, i.r. (neat) 3300 cm^{-1}; n.m.r. δ 6.4–7.0 (3H, m), 4.7 (1H, t, J = 7 Hz), 2.4–3.1 (7H, m), 1.76 (6H, s) 1.1–2.4 (9H, m), 1.02 (1H, d, J = 9 Hz).

Anal. Calcd. for $C_{21}H_{29}NO_2 \cdot HCl \cdot \frac{1}{2}CH_3OH$: C, 67.96; H, 8.49; N, 3.69. Found: C, 67.57; H, 8.51; N, 3.81.

Further elution of the column with chloroform–methanol yielded an oil, which was purified as its hydrochloride salt by recrystallization from methanol–ether–acetone to give 600 mg of **8***i*; m.p. 188–190 °C, $[\alpha]_D^{22}$ −42.8° (*c* 0.37, CH_3OH); n.m.r. (free base) δ 6.5–7.0 (3H, m), 2.4–3.0 (7H, m), 1.27 (6H, s), 1.2–2.3 (12H, m), 1.0 (1H, d, J = 9 Hz).

Anal. Calcd. for $C_{21}H_{31}NO_3 \cdot HCl \cdot \frac{1}{2}CH_3OH$: C, 64.89; H, 8.61; N, 3.52. Found: C, 65.04; H, 8.42; N, 3.26.

Racemic 17-(3-Butenyl)-3,14-dihydroxymorphinan, 8j

To a stirred suspension of sodium hydride (1.3 g of 56%, washed with hexane) in DMF (10 ml) under nitrogen was added a solution of ethanethiol (1.86 g) in DMF (15 ml). This was stirred for 30 min and then to it was added a solution of methoxymorphinan **7***k* (1.1 g) in DMF (20 ml) and the mixture heated under gentle reflux for 18 h. After cooling, it was partitioned between water and benzene–ether mixture. Drying and evaporation of the organic layer gave 0.60 g of crude **8***j* as an oil. It was purified as its hydrochloride salt by recrystallization from methanol–ether; m.p. 244–246 °C; n.m.r. (free base) δ 6.6–7.1 (3H, m), 4.9–5.8 (3H, m), 1.2–3.2 (18H, m), 1.0 (1H, d, J = 9 Hz).

Anal. Calcd. for $C_{20}H_{27}NO_2 \cdot HCl$: C, 68.65; H, 8.07; N, 4.00. Found: C, 68.36; H, 8.34; N, 3.90.

l-17-Ethyl-3,14-dihydroxymorphinan, 8k

A solution of *l*-**8***a* (300 mg), acetic anhydride (2 ml) and triethylamine (2 ml) in benzene (5 ml) was heated under reflux for 30 min. Then, to it was added methanol (3 ml) and heating continued for another 5 min. After cooling, the mixture was partitioned between water and benzene, and the organic layer was dried and evaporated *in vacuo*. The residual oil (360 mg) was dissolved in THF (5 ml) and this solution was added to a boiling solution of lithium aluminum hydride (300 mg) in THF (10 ml). After heating under reflux for 4 h and usual work-up procedure, there was obtained 180 mg of a crude **8***k* as a thick oil. It was dissolved in acetone, and the solution filtered to remove solid impurities. The filtrate was treated with a solution of equimolar amount of *d*-tartaric acid in acetone. A solid precipitate was recrystallized from methanol–acetone to give 220 mg of acidic *l*-**8***k* *d*-tartarate; m.p. 207–209 °C; $[\alpha]_D^{22}$ −33.0° (*c* 0.10, CH_3OH); n.m.r. (free base), δ 6.5–7.1 (3H, m), 1.07 (3H, t, J = 7 Hz), 1.0–3.1 (17H, m).

Anal. Calcd. for $C_{18}H_{25}NO_2 \cdot C_4H_6O_6$: C, 60.39; H, 7.14; N, 3.20. Found: C, 60.01; H, 7.23; N, 3.18.

Resolution of 17-Cyclopropylmethyl-3,14-dihydroxymorphinan, 8c

To a solution of the racemic **8***c* (52.0 g) in hot methanol (100 ml) was added a solution of *d*-tartaric acid (25.9 g) in methanol (50 ml), followed by acetone (300 ml) and the mixture let stand at 5 °C for 3 days. The deposited solid was removed by filtration and recrystallized twice from methanol–acetone (2:1) to give 18.0 g of the salt. This was dissolved in minimum amount of hot water (8 ml) and left at room temperature for 24 h, to give 13.5 g of optically pure *d*-**8***c* as its *d*-tartarate with $\frac{1}{2}H_2O$ of crystallization; m.p. 184–187 °C; $[\alpha]_D^{22}$ +86.4° (*c* 0.103, H_2O).

Anal. Calcd. for $C_{20}H_{27}NO_2 \cdot \frac{1}{2}C_4H_6O_6 \cdot \frac{1}{2}H_2O$: C, 66.48; H, 7.86; N, 3.52. Found: C, 66.76; H, 7.87; N, 3.46.

The mother liquors were combined and concentrated. The residual oil was dissolved in hot water, and this solution was made basic with ammonium hydroxide. After cooling, the solid was collected by filtration and dried in the air to afford 40 g of the free base. This was dissolved in hot methanol (80 ml) and treated with a solution of *l*-tartaric acid (19.2 g) in methanol (40 ml) followed by acetone (240 ml). The above procedure was then followed to afford 22.0 g of a salt which was recrystallized from water (10 ml) to yield 16.5 g of optically pure *l*-**8***c* as its acidic *l*-tartarate with $\frac{1}{2}H_2O$ of crystallization; m.p. 184–187 °C, $[\alpha]_D^{22}$ −86.1° (*c* 0.1, H_2O).

Anal. Calcd. for $C_{20}H_{27}NO_2 \cdot \frac{1}{2}C_4H_6O_6 \cdot \frac{1}{2}H_2O$: C, 66.48; H, 7.86; N, 3.52. Found: C, 66.62; H, 7.78; N, 3.56.

The free base showed m.p. 173–175 °C (methanol), and $[\alpha]_D$ −102.5° (*c* 0.44, $CHCl_3$).

Resolution of 17-Cyclobutylmethyl-3,14-dihydroxymorphinan, 8d

To a hot suspension of racemic **8***d* (262 g) in methanol

(1 l) was added carefully a hot solution of *l*-tartaric acid (120 g) in methanol (250 ml). The solution was filtered to remove insoluble material, and let stand at room temperature for 5 days to give 126 g of solid. This was dissolved in hot water – methanol (9:1 1.1 l) mixture. After standing at room temperature for 5 days, the solid was removed by filtration and dried for 2 days under high vacuum in a dessicator. There was obtained 108 g of *l*-**8***d* as its *l*-tartaric acid salt; m.p. 217–219 °C;, $[\alpha]_D^{22}$ −64.0° (*c* 0.4; MeOH).

Anal. Calcd. for $C_{21}H_{29}NO_2 \cdot C_4H_6O_6$: C, 62.87; H, 7.39; N, 2.93. Found: C, 62.55; H, 7.40; N, 2.92.

The free base showed m.p. 215–217 °C (methanol), and $[\alpha]_D$ −70.0° (*c* 0.1, CH_3OH).

The mother liquors were combined and concentrated to a small volume. This was made basic with ammonium hydroxide and the solid removed by filtration to afford 200 g of the free base **8***d* enriched in the *d*-isomer. This was treated with *d*-tartaric acid by the procedure given above to give 136 g of *d*-**8***d* as its acidic *d*-tartarate; m.p. 217–219 °C; $[\alpha]_D$ +63.0° (*c* 0,4. MeOH).

Anal. Calcd. for $C_{21}H_{29}NO_2 \cdot C_4H_6O_6$: C, 62.87; H 7.39; N, 2.93. Found: C, 62.56; H, 7.46; N, 3.00.

The mother liquors were kept for isolation of additional amounts of the *l*-**8***d*.

l-17-Cyclopropylmethyl-14-hydroxy-3-methoxymethyl-morphinan, 9a and Corresponding d-Isomer

A solution of *l*-dihydroxymorphinan **8***c* (3.14 g) in dry benzene (60 ml) was added dropwise to a suspension of sodium hydride (870 mg of 55%, washed with hexene) in benzene (10 ml) and the mixture stirred for 1 h. Then, to it was added a solution of chloromethylmethyl ether (1.61 g) in benzene (10 ml) and the mixture stirred for 18 h. Work-up afforded 3.6 g of crude product, which was chromatographed on alumina. Elution with chloroform gave 2.6 g of *l*-**9***a* as an oil. A sample for analysis was distilled at 170 °C/0.02 Torr; $[\alpha]_D$ −82.5° (*c* 0.412, $CHCl_3$); i.r. (neat) 3420 cm^{-1}; n.m.r. δ 6.7–7.1 (3H, m), 5.15 (2H, s), 3.5 (3H, s), 0.0–3.1 (21H, m), 1.02 (1H, d, J = 9 Hz).

Anal. Calcd. for $C_{22}H_{31}NO_3$: C, 73.91; H, 8.74; N, 3.91. Found: C, 73.51; ,H 8.50; N, 3.65.

Similarly prepared was *d*-**9***a*; $[\alpha]_D$ +82.0° (*c* 0.410, $CHCl_3$).

l-17-Cyclobutylmethyl-14-hydroxy-3-methoxymethyl-morphinan, 9b

The *l*-methoxymethyl ether **9***b*, an oil, was similarly prepared. The analytical sample was obtained by drying at 80 °C/0.05 Torr; $[\alpha]_D^{22}$ −70.87° (*c* 0.388, $CHCl_3$); i.r. (neat) 3420 cm^{-1}; n.m.r. δ 6.8–7.2 (3H, m), 5.18 (2H, s), 3.52 (3H, s), 1.2–3.1 (23H, m), 1.0 (1H, d, J = 4 Hz).

Anal. Calcd. for $C_{23}H_{33}NO_3$: C, 74.36; H, 8.95; N, 3.77. Found: C, 74.14; H, 9.08; N, 3.47.

The Selective Lithiation and *In Situ* Trimethylsilylation of Benzyldiphenylchlorosilane and its Methoxy Analog. Compounds Which Could Conceivably Lead to Stable Si=C Species on Pyrolysis

K. G. RUTHERFORD[1] AND R. J. SEIDEWAND[2]

Department of Chemistry, University of Windsor, Windsor, Ontario N9B 3P4

Received April 8, 1975

K. G. RUTHERFORD and R. J. SEIDEWAND. Can. J. Chem. **53**, 3103 (1975).

The selective lithiation and *in situ* trimethylsilylation of benzyldiphenylchlorosilane and its methoxy analog to give (α-trimethylsilylbenzyl)diphenylchlorosilane and (α-trimethylsilylbenzyl)diphenylmethoxysilane in excellent yields is reported. These compounds exhibit much greater stability on pyrolysis than β-halocarbosilanes. A stable Si=C species was not obtained on pyrolysis of the compounds synthesized.

K. G. RUTHERFORD et R. J. SEIDEWAND. Can. J. Chem. **53**, 3103 (1975).

On rapporte la lithiation sélective et la triméthylsilylation *in situ* du benzyldiphénylchlorosilane et de son analogue méthoxylé; ces réactions qui se produisent avec d'excellents rendements conduisent au (α-triméthylsilylbenzyl)diphénylchlorosilane et au (α-triméthylsilylbenzyl)diphénylméthoxysilane. Ces composés, comparés aux β-halocarbosilanes, sont beaucoup plus stables vis-à-vis de la pyrolyse. On n'a pu obtenir d'espèces Si=C par pyrolyse des composés synthétisés.

[Traduit par le journal]

Introduction

The exceptional thermal instability of β-haloalkylsilanes (1, 2) has been known for some time. A few representative compounds shown in Fig. 1 decomposed (3, 4) upon attempted distillation to produce a silyl halide and an olefin.

$$Et_3SiCH_2CH_2Cl \xrightarrow{80\,^\circ C} Et_3SiCl + CH_2{=}CH_2$$

$$Me_3SiCH_2CHBrCH_3 \xrightarrow{40\,^\circ C} Me_3SiBr + CH_2{=}CHCH_3$$

$$Me_3SiCH_2CHClCH_3 \xrightarrow{90\,^\circ C} Me_3SiCl + CH_2{=}CHCH_3$$

FIG. 1. Thermal cleavage of β-haloalkylsilanes.

These elimination reactions have been postulated to proceed through a four-centered activated complex (Fig. 2), promoted by overlap of the lone pair of electrons on the β-heteroatom with the vacant d orbitals of silicon (2).

In addition to halogen substituents, the cleavage reaction also occurs when there is a β-oxygen atom capable of being transferred, presumably in a *cis*-like manner, to silicon via a similar four-centered transition state.

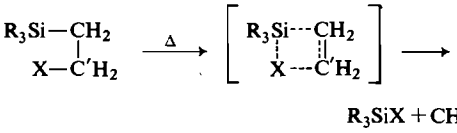

FIG. 2. Proposed mechanism for β-haloalkylsilane cleavage.

The intriguing ramifications of this mechanism involve the carbon atom C′. If C′ were to be replaced by a silicon atom and if appropriate groups were to be attached to the Si and C atoms which could allow for resonance and/or steric stabilization, the possibility of generating a stable silico-olefin may be realized on pyrolysis. Incorporation of a sufficient molecular weight may also add to the stability of the resultant Si=C species. The transient existence of molecules containing (p–p)π bonded silicon and germanium has been well documented in the literature over the past few years (5), however, stable systems have not as yet been synthesized. Model compounds[3] aimed at providing stable systems were thus synthesized for pyrolytic studies.

Results and Discussion

Benzyldiphenylchlorosilane (**1**) was readily

obtained from the reaction of benzylmagnesium chloride and diphenyldichlorosilane. Benzyldiphenylmethoxysilane (**2**) was obtained from the methanolysis of **1**.

In 1971, West (7) reported that the methyl group of trimethylsilyl derivatives can be metalated by the strongly hindered base, *tert*-butyllithium. Trimethylchlorosilane (**3**), for example, can be metalated and then trapped by excess chlorosilane. We found that the addition of *tert*-butyllithium to a *mixture* of **1** and **3** proved to be an excellent procedure for the synthesis of (α-trimethylsilylbenzyl)diphenylchlorosilane (**4**). An analogous selective lithiation reaction with a mixture of **2** and **3** conveniently afforded (α-trimethylsilylbenzyl)diphenylmethoxysilane (**5**). The above reactions (crude yields ≥75%) are summarized in Fig. 3. Both compounds **4** and **5** now provided us with the desired 1,4-juxtaposition of silicon and a heteroatom substituent (Fig. 2).

Attempted pyrolytic elimination (6) of **3** from **4** at temperatures up to 470 °C resulted essentially only in recovery of starting material. The pyrolysis of **5** in the temperature range 300–470 °C did result in decomposition but led to a complex mixture, as shown by i.r. and n.m.r. analysis, as well as furnishing trimethylmethoxysilane **6**, $(CH_3)_3SiOCH_3$, in a 50% yield. None of the desired Si=C compound was obtained.

The nature of the route leading to **6** can only be speculated, but if it does involve the formation of $Ph_2Si{=}CHPh$, the high temperatures employed probably favor intermolecular processes leading to a complex high molecular weight residue.

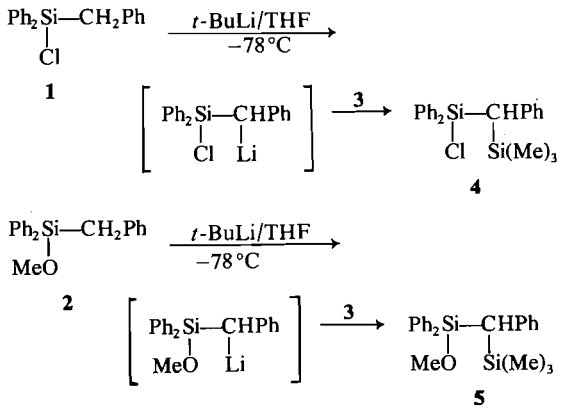

FIG. 3. Selective lithiation by *tert*-butyllithium and *in situ* trapping by trimethylchlorosilane.

The reason for the stability of **4**, when under the same conditions **5** completely decomposes, remains rather obscure at this point.

Experimental

Infrared spectra were recorded on a Beckman IR-12 spectrometer in chloroform. Nuclear magnetic resonance spectra were obtained with a Jeolco C-60 HL spectrometer in deuteriochloroform with methylene chloride as an internal standard (τ 4.70). Gas–liquid chromatography (g.l.c.) was performed on Hewlett Packard 720 and 5750 instruments. Columns utilized were as follows: 6 ft × ¼ in. 10% SE 30 on 60–80 Chromosorb W, 8 ft × ¼ in. 20% SE 30 on 60–80 Chromosorb W and 6 ft × ¼ in. 10% Dexsil 300 on 60-80 Chromosorb W. All reactions were run in dried apparatus under an atmosphere of nitrogen and the silyl chlorides were purified prior to use. Microanalyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, N.Y.

Benzyldiphenylchlorosilane (1)

Benzylmagnesium chloride (200 mmol) in 150 ml of ether and diphenyldichlorosilane (53.2 g, 210 mmol) in 125 ml of ether were stirred for 15 min at 0 °C and then refluxed 2 h. Upon cooling, the solution was filtered through Super Cel under an atmosphere of N_2 with the aid of an additional 150 ml of ether and the filtrate was concentrated. Methylene chloride (50 ml) was added and the solution was refiltered and concentrated to a pale yellow liquid. Short path distillation gave 40.9 g (66%) of **1**: b.p. 147–150 °C (0.003 Torr); m.p. 52–57 °C; n_D^{25} 1.6085; i.r. 7.0, 8.97, and 19.0 (SiCl) μ; n.m.r. τ 2.7 (m, 15) and 7.2 (s, 2).

Anal. Calcd. for $C_{19}H_{17}ClSi$: C, 73.87; H, 5.54;, Cl, 11.47. Found: C, 73.76; H, 5.58; Cl, 11.38.

(α-Trimethylsilylbenzyl)diphenylchlorosilane (4)

To 4 g (13 mmol) of **1** and 1.65 ml (13 mmol) of **3** in 25 ml of THF at −78 °C was added dropwise 6.2 ml (14 mmol) of 2.26 *M* *tert*-butyllithium in pentane in 25 ml of pentane. The resulting clear orange solution was stirred at −78 °C for 2 h. After addition of 0.3 ml (2 mmol) of **3** the solution was allowed to warm to room temperature and then stirred for an additional 2 h. Lithium chloride was removed by filtration under nitrogen using Super Cel and the colorless filtrate was concentrated. Methylene chloride (20 ml) was added and the solution was refiltered, concentrated, and distilled (short path) to give 3.0 g of a colorless viscous oil: b.p. 154–155.5 °C (0.003 Torr); n_D^{25} 1.5877. Gas–liquid chromatography and subsequent i.r. and n.m.r. analyses revealed **4** (94%), **1** plus a lower retention component (1%), and an unidentified high retention time component (5%). Preparative g.l.c. afforded pure **4**: i.r. 7.0, 9.03, 11.7, and 19.4 μ; n.m.r. τ 2.6 (m, 15), 7.52 (s, 1, CH), and 10.1 (CH_3Si).

Anal. Calcd. for $C_{22}H_{25}ClSi_2$: C, 69.34; H, 6.61; Cl, 9.30. Found: C, 69.23; H, 6.89; Cl, 9.35.

Benzyldiphenylmethoxysilane (2)

Benzyldiphenylchlorosilane (**1**) (5.17 g) was converted by the method of Sauer (9) into **2** (3.9 g, 76%); b.p. 142–144 °C (0.005 Torr); n_D^{25} 1.5923; i.r. 3.52, 7.0, 8.93, and 9.17 μ; n.m.r. τ 2.7 (m, 15), 6.42 (s, 3), and 7.24 (s, 2).

Anal. Calcd. for $C_{20}H_{20}OSi$: C, 78.89; H, 6.62; Si, 9.22. Found: C, 78.55; H, 6.78; Si, 8.90.

(α-Trimethylsilylbenzyl)diphenylmethoxysilane (5)

To 3.96 g (13 mmol) of **2** and 1.65 ml (13 mmol) of **3** in 25 ml of THF at −78 °C was added dropwise 6.2 ml (14 mmol) of 2.26 *M tert*-butyllithium in pentane in 20 ml of pentane. The resulting yellow solution was stirred at −78 °C for 2 h. After addition of 0.3 ml (2 mmol) of **3** the solution was allowed to warm to room temperature and then stirred for an additional 2 h. Lithium chloride was removed by filtration under nitrogen using Super Cel and the colorless filtrate was concentrated. Methylene chloride (20 ml) was added and the solution was refiltered, concentrated, and distilled (short path) to give 3.8 g of a colorless viscous oil; b.p. 151–153 °C (0.005 Torr); n_D^{25} 1.5757. Gas–liquid chromatography and subsequent i.r. and n.m.r. analysis revealed **5** (88%) and an unresolved peak (12%) at the same retention time as **2**. Preparative g.l.c. gave pure **5**: i.r. 3.53, 7.0, 8.98, 9.18, 11.7, and 19.2 μ; n.m.r. τ 2.6 (m, 15), 6.45 (s, 3, OCH_3), 7.75 (s, 1, CH), and 10.05 (s, 9, CH_3Si).

Anal. Calcd. for $C_{23}H_{28}OSi_2$: C, 73.34; H, 7.49; Si, 14.91. Found: C, 73.39; H, 7.51; Si, 14.61.

Studies in Solvolysis. Part VII. The Neutral Hydrolysis of Methyl Perchlorate

ROSS ELMORE ROBERTSON AND ADRIANNA ANNESA
Chemistry Department, University of Calgary, Calgary, Alberta
AND
JOHN MARSHALL WILLIAM SCOTT
Chemistry Department, Memorial University of Newfoundland, St. John's, Newfoundland A1C 5S7

Received January 20, 1975

ROSS ELMORE ROBERTSON, ADRIANNA ANNESA, and JOHN MARSHALL WILLIAM SCOTT. Can. J. Chem. **53**, 3106 (1975).

The temperature dependence of the rate of hydrolysis of methyl perchlorate has been measured and the entropy ($\Delta S^{\neq}$), enthalpy ($\Delta H^{\neq}$), and heat capacity ($\Delta C_p^{\neq}$) of activation calculated. The measurements confirm that the perchlorate ion is superior to all other leaving groups in water. The isotope effect related to the hydrolysis of methyl-d_3 perchlorate has been measured at three temperatures and shown to be inverse. The thermodynamic parameters and the isotope effect were examined with respect to the mechanism of substitution at a primary carbon atom.

ROSS ELMORE ROBERTSON, ADRIANNA ANNESA et JOHN MARSHALL WILLIAM SCOTT. Can. J. Chem. **53**, 3106 (1975).

On a mesuré l'influence de la température sur les vitesses d'hydrolyse de perchlorate de méthyle et on a calculé l'entropie ($\Delta S^{\neq}$), l'enthalpie ($\Delta H^{\neq}$) et la capacité calorifique ($\Delta C_p^{\neq}$) d'activation. Ces mesures confirment que, dans l'eau, l'ion perchlorate est le meilleur nucléofuge. On a mesuré, à trois températures, l'effet isotopique relié à l'hydrolyse du perchlorate de méthyle-d_3 et on a montré qu'il est inverse. On a examiné les paramètres thermodynamique et l'effet isotopique en fonction du mécanisme de substitution au niveau d'un carbone primaire.
[Traduit par le journal]

Introduction

On the basis of a series of kinetic studies Koskikallio (1–3) has suggested that the reaction between methyl perchlorate and water

[1] $CH_3ClO_4 + 2H_2O \rightarrow CH_3OH + H_3O^+ + ClO_4^-$

takes place via an S_N1 mechanism. This conclusion follows from the fact that the entropy of activation for reaction 1 is positive[1] (0.92 e.u.) in contrast to negative values found for the hydrolyses of methyl chloride (−4.77 e.u.), methyl bromide (−2.97 e.u.), methyl nitrate (−1.88 e.u.), and methyl benzenesulfonate (−9.27 e.u.). On the other hand, the mechanism for the methanolysis of methyl perchlorate was considered to be S_N2 because of a much lower enthalpy of activation [$\delta_M\Delta H^{\neq}(H_2O \rightarrow MeOH) = -7$ kcal/mol] and a negative entropy of activation in the alcoholic solvent ($\Delta S^{\neq} = -20.9$ cal mol^{-1} deg^{-1}). The solvent change from water to acetone–water was also considered to alter the mechanism in the S_N2 direction.

Entropies of activation are often useful in detecting mechanistic changes but only in cases where $\delta_R\Delta S^{\neq}$ is large (5, 6) can mechanistic distinctions be drawn with confidence.[2] Thus the change in mechanism $B_{Ac}2 \rightarrow S_N1$ for simple alkyl trifluoroacetates is characterized by a very large change in the entropy of activation ($\delta_R\Delta S^{\neq} \simeq 50$ e.u.), whereas the difference between $\Delta S^{\neq}$ for methyl chloride and methyl perchlorate is relatively small ($\delta_X\Delta S^{\neq} \simeq 6$ e.u.). There are, however, other ways of explaining the

[1]The original value reported (5.62 e.u. (2)) is not in agreement with the value reported in the more extensive study reported here, but both studies concur in that $\Delta S^{\neq}$ is positive at 25 °C (see Table 2 in this paper). The entropy values are compared at 25 °C and were calculated from the reported B and C coefficients (4) of the temperature dependence equation

[2] $$\log k = A/T + B \log T + C$$

from which the expression

[3] $$\Delta S^{\neq}(25\,^{\circ}C) = 13.3098(B-1) + 4.57573C - 47.2128$$

can be derived via the absolute rate theory at $T = 25$ °C. A comparison between our value and that reported by Koskikallio is best made at 12.5 °C (see Table 2).

[2]δ_R and δ_X are chemical operators denoting changes in the structure of the alkyl group (R) and leaving group (X), respectively.

small positive shift between the chloride and perchlorate without invoking mechanistic differences.

The acceleration of a given displacement at a saturated carbon atom by added lyate ion (OH^-) is one of the classical tests for an S_N2 process (7) and acceleration of the rate of displacement by this reagent signals the importance of nucleophilic driving forces. Koskikallio (2) observed such an acceleration for methyl perchlorate reacting with hydroxide ion, but the mechanistic conclusions related to this observation were ignored. Since the solvolytic rate in water for methyl perchlorate, when divided by the molar concentration of water is correlated by the Swain–Scott (8) linear free energy relationship (l.f.e.r.) the bimolecular nature of the rate-determining step appears well established. Finally, the displacement rates of methyl perchlorate in water and methanol give a value of the Grunwald–Winstein "m" parameter (9) for methyl perchlorate ($m = 0.13$) which is a "typical S_N2" value. Clearly, the evidence presented by Koskikallio conflicts with his own mechanistic proposals since the experimental data are all consistent with a simple S_N2 interpretation.[3]

In the present paper we report a study of the temperature dependence of the enthalpy of activation ($\Delta C_p^{\ddagger}$) for methyl perchlorate as well as the secondary isotope effect involving methyl-d_3 perchlorate. These results combined with other data provide a useful basis for certain theoretical considerations.

Experimental

Methyl perchlorate was synthesized by the reaction of dry silver perchlorate (12) with methyl iodide in carbon tetrachloride at room temperature. The resulting ester was purified by distillation, b.p. 50 °C/670 mm Hg.[4] The deuterated ester was prepared in the same way using methyl-d_3 iodide which was nominally 99% deuterium content (Merck, Sharp and Dohme; lot E 223). Mass spectra showed that both isotopic samples of the perchlorate ester contained trace amounts of carbon tetrachloride and the appropriate methyl iodide. In both cases the contaminants were considered to be kinetically insignificant ($t_{1/2}$ at 25 °C for methyl iodide is estimated from available data (13) to be *ca.* 104 days). A second sample of methyl-d_3 perchlorate gave an isotope effect identical to that observed for the first specimen.

Rate Measurements

The rates of hydrolysis of the normal and deuterated esters were determined conductimetrically, and the details of the method have been described elsewhere (14). Rate constants measured at various temperatures are reported in Table 1. Assuming all the significant errors to be in the rate rather than in the temperature, a least squares treatment of the temperature dependence of the nonaveraged rates for methyl perchlorate gives

$$[4] \quad \log k = 92.3541 - 27.1347 \log T - 8340.40/T$$

Rate constants calculated from [4] at 0, 15, and 25 °C are respectively, 5.12×10^{-5}, 4.66×10^{-4}, and 1.74×10^{-3} s^{-1}. Koskikallio (2) reports 5.04×10^{-5}, 4.66×10^{-4}, and 1.79×10^{-3} s^{-1} at the same temperatures.

[3]The S_N1 description has also been rejected by Kevill and Shen (10) on the basis of $k(MeX)/k(EtX)$ ratios.

[4]NOTE: Methyl perchlorate is usually considered to be a very dangerous substance (11).

TABLE 2. Derived pseudothermodynamic parameters for the hydrolysis of methyl perchlorate in water

T(°C)	$\Delta H^{\ddagger}$ (kcal mol^{-1})	$\Delta S^{\ddagger}$ (cal mol^{-1} deg^{-1})
5	22.59	4.82
15	22.30	2.84
25	21.49	0.93
35	20.91	−0.91
50	20.70	−3.56
75	18.67	−7.73
100	17.27	−11.61
12.5	22.17	3.32
12.5[a]	22.53	5.62

[a]Taken from ref. 2.

The agreement between the two sets of data is generally satisfactory, but the differences show a slight trend. The pseudothermodynamic parameters reported in Table 2 were obtained by invoking the usual premises of the absolute rate theory along with the further assumption that the experimental errors do not justify any further terms in T to adequately reproduce the experimental rates. Since our rates differ from those of Koskikallio the observation that values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ calculated from our data differ from the same parameters derived from the earlier work is not surprising. A comparison of the two sets is best made at 12.5 °C, the midpoint of the temperature range employed in the previous study (see Table 2).

The rate data for the two samples of methyl-d_3 perchlorate are reported in Table 2 and the isotope effect is inverse and similar in magnitude (0.931) to that observed for the Menschutkin reaction involving the perchlorate and *N,N*-dimethylaniline (15).

Discussion

Relative Rates, Free Energies of Activation

In Table 3 we have collected rate data for a series of primary halides and esters. The range of reactivity of the substances listed in Table 3 exceeds six powers of ten, methyl perchlorate being the most reactive compound.

There is an unjustified but general tendency in chemical literature to regard "fast" S_N displacements as tending towards the S_N1 type (21). This may partly explain Koskikallio's predilection for the S_N1 description for the solvolysis of methyl perchlorate. However, knowledge of the relative rates of a single nucleophile attacking a series of methyl compounds (see Table 3) does not establish the mechanism of displacement for any particular methyl compound in the series. Since all the methyl compounds in Table 3 react with hydroxide ion faster than they react with water the mechanisms are anticipated to be uniformly S_N2 or "S_N2-like" with both water and hydroxide. This proposal is further supported by the observation that several of these methyl compounds when reacting with a series of nucleophiles yield second order rate constants which are adequately correlated by the Swain–Scott (8) l.f.e.r. (see however (22)). Thus, the high reactivity of methyl perchlorate with water is not a compelling reason for invoking an S_N1 mechanism.

The Entropy of Activation

Although substances which are considered to react by S_N1 displacement often have positive entropies of activation in water,[5] the sign of the entropy of activation for any particular substance is not a reliable mechanistic criterion. Indeed, as a consequence of the large heat capacity of activation associated with displacement, the entropy of activation for methyl perchlorate changes sign at *ca.* 30 °C. This observation further emphasizes the inadequacy of using isolated thermodynamic quantities as a basis for mechanistic diagnosis. On the other hand the entropy of the transition state $S^{\ddagger}$ appears to be a useful quantity in assessing the significance of the entropies of activation from a series of closely related reactions (23). The quantity $S^{\ddagger}$ is calculated from

$$[5] \qquad S^{\ddagger} = S_g^0 + \delta_s S + \Delta S^{\ddagger}$$

where the quantities on the right hand side are in the order given; the gas phase entropy of the substrate, the entropy of solution of the substrate, and the entropy of activation. The approach adopted is to compare the quantity $S^{\ddagger}$ with the entropies of thermodynamically stable species which might reasonably be expected to resemble the transition state. For a series of methyl compounds, CH_3X, the following linear relationsip was proposed (23)

$$[6] \qquad S^{\ddagger}(CH_3X) = \alpha S(X^-) + \text{constant}$$

where $S(X^-)$ is the standard entropy of the aqueous ionic leaving group. In cases where experimental values of S_g^0 and $\delta_s S$ are not available, satisfactory estimates of these quantities can be calculated from

$$[7] \qquad S_g^0(CH_3X) = S_g^0(HX) + 11.3$$

and

[5]See for instance Table VIB in ref. 4.

$$[8]\quad \delta_s S(CH_3X) = (-0.19 \pm 0.04)V(CH_3X) - (8.58 \pm 1.88)$$

where the quantity $V(CH_3X)$ is the "molecular volume" of the methyl compound. The quantity $V(CH_3X)$ can be readily calculated from data reported by Edward (24) and ourselves (23). The meanings of the other symbols in [7] and [8] require no further comment.

The general background to these calculations together with a collection of related data are given in ref. 23 and the numerical quantities relevant to the present study are reported in Table 4. For X = —F, —Cl, —Br, —I, —NO_3, and —ClO_4 the correlation between $S^{\ddagger}(CH_3X)$ and $S(X^-)$ is

$$[9]\quad S^{\ddagger}(CH_3X) = (0.64 \pm 0.06)S(X^-) + (21.71 \pm 1.50)$$

and a graphical representation of the relationship is given in Fig. 1. The correlation is considered satisfactory since the errors in $S^{\ddagger}(CH_3X)$ may be *ca.* ±3 e.u. These arise in part because the calculation of the entropies of activation for methyl fluoride and methyl nitrate require extrapolations remote from the temperature range of the experimental measurements (see ref. 4 and references therein). The slope of the correlation between $S^{\ddagger}$(MeX) and $S(X^-)$ may be related reasonably to the charge development ($Z^{\ddagger}$) in the transition state (23). If $S(X^-)$ is proportional to Z^2 then $Z^{\ddagger} = 0.80$,

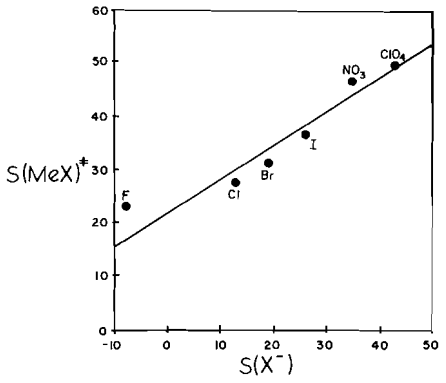

FIG. 1. A correlation between the entropy of the transition state with the entropy of the related anion.

or if $S(X^-)$ varies directly as Z then $Z^{\ddagger} = 0.64$. Further aspects of the interpretation of the slope of the $S^{\ddagger}(MeX)$ *vs.* $S(X^-)$ correlation have been discussed elsewhere (23, 28). Irrespective of how $S(X^-)$ depends on Z, the slope of the correlation will give a lower limit to $Z^{\ddagger}$. This is a consequence of the fact that the structure $CH_3^+(nH_2O)$ is associated with the anion in the transition state. Such a structure will exert a "ponderal effect" (29) on the entropy of the transition state. The ponderal increase to $S^{\ddagger}$-(MeX) will be most significant for the least massive anion. This may account in part for the positive deviation in the case of the fluoride ion – methyl fluoride point in Fig. 1, but the other reasons mentioned above are probably of equal importance. The previous conclusions with respect to $Z^{\ddagger}$ are now modified only to the extent that the range of $Z^{\ddagger}$ is either $0.64 < Z^{\ddagger} < 1$ or $0.80 < Z^{\ddagger} < 1$. Hence the entropies of activation lend support to an ion-pair mechanism for displacement reactions of the methyl halides, previously advanced (16) by one of us. For such a mechanism the quantity $S^{\ddagger}(CH_3X)$ will refer to the second transition state of the scheme.

$$[10] \qquad CH_3X \underset{k_2}{\overset{k_1}{\rightleftharpoons}} CH_3^+ X^- \xrightarrow{k_{2n}} \text{products}$$

Since the second step is relatively rapid (see ref. 16) the transition state for this step will, according to the Hammond postulate (30), resemble the intermediate. The Hammond postulate requires both the intermediate and the second transition state to have ionic character if the above interpretation of the relationship between $S^{\ddagger}(CH_3X)$ and $S(X^-)$ is acceptable.

The Heat Capacity of Activation

Since methyl perchlorate is the first perchlorate ester for which the heat capacity of activation has been measured, comparison is not possible. However, the value of the heat capacity of activation of methyl perchlorate derived from the temperature dependence of the rates is similar to that found for methyl iodide (13).

The perchlorate ion combines large size with the presence of oxygen atoms, and, like the nitrate ion, when fully charged, should be a "structure breaker". On the basis of arguments advanced by Robertson (4) this might lead to a more negative heat capacity of activation for perchlorate in comparison with iodide. That a more negative heat capacity of activation is not found might be interpreted as a reflection of less charge development in the case of the perchlorate. Such a notion would be consistent with the Hammond postulate (30) in the sense that methyl perchlorate, being the most reactive of the methyl esters, should have a transition state which most resembles the reactant molecule. However, the correlation between $S^{\ddagger}(CH_3X)$ and $S(X^-)$ discussed above strongly suggests activation leads to fairly uniform charge development[6] in the methyl compounds and the charge on the anion and cationic moieties in the transition state are close to unity.

Isotope Effects

Secondary hydrogen–deuterium isotope effects related to methyl and methyl-d_3 esters and halides have been reported frequently for both solvolytic (32) and definite bimolecular displacements (33–37). According to Shiner (38) these effects are related to the net change between initial and transition states of the force constants between the α C—H (or C—D) bond and the incoming and leaving groups. These effects can be usefully grouped in two ways. Firstly there are those effects in which the nucleophile (N) is fixed and the leaving group (X) is altered and secondly there are effects for which the nucleophile is varied in relation to a constant leaving

[6]Streitwieser (31) states that the Hammond postulate refers primarily to geometry, not charge distribution, and argues that for a given geometrical change a delocalized system will have a correspondingly greater charge separation. This may be true but the logic of the proposal is not obvious. Delocalization will be absent in the case of the halogens but may be important in the nitrate and perchlorate ions.

[a]Rate constants are all second order constants in the usual units. (See ref. 16.) $\Delta G_{0n}^{\ddagger}$, $\Delta G_{2n}^{\ddagger}$ are in kcal mol^{-1} and $\delta_1\Delta G^{\ddagger}$ is in cal mol^{-1}.
[b]Isotope effects in 50% v/v ethanol–water are more inverse by *ca.* 6% on the basis of a comparison of reaction 12 in water and the mixed aqueous solvent.

group. A collection of all the available data relevant to the present discussion is assembled in Table 5. The isotope effects are reported in terms of the quantity $\delta_1\Delta G^{\ddagger}$ which is related to the observed rate ratio $k(H)/k(D)$ and the temperature (T) by

$$[11] \quad \delta_1\Delta G^{\ddagger} = -\{2.3026\, RT/n\} \log \{k(H)/k(D)\}$$

The quantity n is the number of α-deuterium atoms in the deuterated substrate, three in the case of the methyl compounds and two in the case of the ethyl compounds. The range of reactivity displayed by the methyl compounds in Table 5 precludes the preferred situation in which all the isotope effects are measured and compared at a common temperature. Hopefully, the use of [11] to quantify the isotope effects will normalize any differences which are a consequence of temperature. The secondary isotope effects when combined with the correlation between $S^{\ddagger}$(MeX) and $S(X^-)$ and the kinetic solvent isotope effect (k.s.i.e.), $k(H_2O)/k(D_2O)$, provide considerable insight into the structure of the transition state for the displacement process.

The Hammond postulate[7] is a useful tool for relating the magnitude of the isotope effect to the structural characteristics of the transition state. Prior to the application of the Hammond postulate the statistical treatment used by Shiner must be translated into less formal chemical language. This necessity is accomplished readily by relating the isotope effect to the extent of bond making and bond breaking in the transition state.

When the nucleophile (N) is varied and the leaving group (X) is fixed the Hammond postulate requires that the extent of bond making will be the greatest for the weakest nucleophile (H_2O). Since the isotope effect for the attack of thiosulfate ion on methyl and methyl-d_3 iodide is inverse, and since thiosulfate ion is the most reactive nucleophile known towards the methyl halides (see Table 3), then nucleophiles weaker than thiosulfate are anticipated to give isotope effects which are more inverse than that observed for thiosulfate. The experimental results are in almost complete accordance with this simple prediction. Indeed, there is a smooth relationship (Fig. 2) between $\delta_1\Delta G^{\ddagger}$ and $\Delta G^{\ddagger}$ for methyl iodide and methyl-d_3 iodide reacting with water, azide, cyanide, acetate, and thiosulfate. However the symmetrical displacement

$$[12] \quad CL_3I + I^{*-} \rightarrow CL_3I^* + I^-$$

where L = H or D gives an isotope effect which is poorly correlated with the free energy of activation for the L = H process. The reasons for the deviant behavior of [12] are not clear. Since Seltzer and Zavitsas's (34) rate for the reaction (L = H, $T = 20$ °C) does not agree

[7]For a pithy version of the Hammond postulate see Schowen (ref. 42, p. 307).

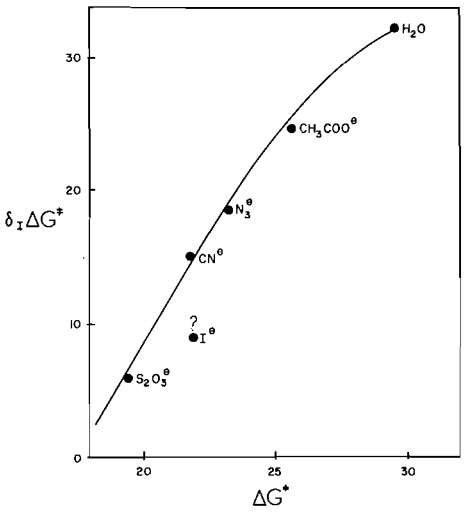

FIG. 2. A correlation of $\delta_I\Delta G^\ddagger$ *vs.* $\Delta G^\ddagger$ for a fixed leaving group.

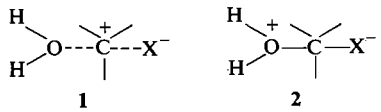
with that calculated from the older measurements reported by Swart and le Roux (40) the more recent measurements may be in error. Combining Seltzer's rate for L = D with the L = H rate constant calculated from the Arrhenius parameters reported by Swart and le Roux gives an inverse effect, whereas Seltzer's own measurements give a normal effect which deviates from the correlation in Fig. 2 so much that it cannot be represented on the graph. Without new experimentation further discussion of the deviant behavior of [12] is unwarranted.

Whilst the relative degree of bond making in the reaction of a series of nucleophiles with a fixed methyl compound can be deduced from the Hammond postulate the extent of bond making for any particular nucleophile remains obscure. This question is usefully considered via the entropy correlation presented above. Displacement reactions at primary carbon centers are standard examples of S_N2 reactions. Such a reaction takes place by the Heitler–London mechanism with a parallelism (7) between the bond-making and bond-breaking processes, *i.e.*, bond making and bond breaking are concerted. The correlation between $S^\ddagger$(MeX) and $S(X^-)$, when water is the nucleophile, signifies substantial bond breaking for the weakest nucleophile which is presumably accompanied by considerable bond making, *i.e.*, the reaction of the methyl compounds with water is characterized by a product-like transition state.

The k.s.i.e., when examined for the substrates for which the solvolytic displacement rates and secondary isotope effects are known, suggest that the product-like description is inadequate when water is the nucleophile. Schowen (42), in a recent review of the $k(H_2O)/k(D_2O)$ ratios (43) considers the k.s.i.e. is consistent with S_N2 transition states which are only 20–30% "towards products". The conclusions from the k.s.i.e. are evidently in conflict with the entropy correlation. This disagreement can be resolved if the water molecule is postulated to attack a highly reactive ionic intermediate which can be described as a tight or intimate or contact ion pair. Since the intermediate is reactive the transition state related to its destruction will resemble the intermediate. This suggests that the transition state has little oxonium ion character, *i.e.*, resembles **1** rather than **2**



1 **2**

We now turn our attention once more to the secondary rather than the solvent isotope effects. For such the pre-equilibrium mechanism [10],

$$[13] \qquad \log k_0 = \log K_e + \log k_{2n}$$

If δ_I is an operator which denotes changes in the isotopic content of the substrate then

$$[14] \qquad \delta_I \log k_0 = \delta_I \log K_e + \delta_I \log k_{2n}$$

The variation of the isotope effect with the nature of the nucleophile N is established using the operator δ_N

$$[15] \qquad \delta_N\delta_I \log k_0 = \delta_N\delta_I \log K_e + \delta_N\delta_I \log k_{2n}$$

Since $\delta_N\delta_I \log K_e = 0$ then changes in the magnitude of the isotope effect for the fixed substrate variable N case are dominated by changes in the k_{2n} step. Thus, the ion-pair mechanism requires minor modification of our previous discussion of the fixed X variable N case in terms of a classical S_N2 displacement. The main difference between the descriptions is related to the bond-making step which now involves an ion pair rather than a neutral substrate.

In cases where the nucleophile is fixed and the substrate is altered the ion-pair mechanism provides a more convincing analysis of the

For personal use only.

secondary isotope effect than the S_N2 unitary mechanism. For the fixed N variable X case the Hammond postulate becomes less reliable. This statement is particularly true for methyl perchlorate. According to the Hammond postulate methyl perchlorate involves the least amount of nucleophilic assistance since it is the most reactive methyl ester.[8] However only the halides have isotope effects which are more inverse, and, if Shiner's normalized isotope effects for methyl substrates are correct (38) then methyl perchlorate has the most inverse effect of all the methyl compounds so far investigated. The failure of the Hammond postulate in the case of methyl perchlorate provides an important mechanistic clue which can be understood in terms of the ion-pair mechanism.

When the leaving group is fixed and the nucleophile is altered the overall reactivity change depends only on the k_{2n} step since for a fixed substrate the quantity K_e is independent of the attacking nucleophile. However, alteration of the leaving group gives rise to simultaneous alteration of K_e and k_{2n}, and the overall rate consequently reflects both of these quantities, not just the k_{2n} step. If the k_{2n} step is the paramount factor in determining the isotope effect then a relationship between $\delta_I\Delta G^{\ddagger}$ and $\Delta G_{2n}{}^{\ddagger}$ is anticipated with the isotope effect becoming more inverse as the height of the k_{2n} barrier increases. The calculation of k_{2n} proceeds via the calculation of K_e using the expression

$$[16]\quad \log K_e = \frac{\rho_{nw}}{\rho_{nw} - \rho_{nI}} \log k_{0w} - \frac{\rho_{nI}}{\rho_{nw} - \rho_{nI}} \log k_{0I} + C$$

The quantities k_{0w} and k_{0I} are respectively the second order rate constants of the substrate with water and hydroxide ion, and C is a constant. The selectivity of the hydroxide ion ρ_{nI} is taken as unity and the best numerical value[9] for ρ_{nw} is $\rho_{nw} = (1.285 \pm 0.058)\rho_{nI}$.[10] These values differ from those reported previously. Because the newer values are based on a more extensive series of measurements,[11] they are to be preferred to those reported earlier (16). A more extensive discussion of the new quantities associated with [16] will appear elsewhere. The alteration of the numerical values appropriate to [16] requires no major revision with respect to the conclusions in an earlier presentation (13) although the k_{2n} values reported in that paper are increased and the K_e values decreased. The quantities required for these calculations are assembled in Table 3.

In Fig. 3 we present a correlation between $\delta_I\Delta G^{\ddagger}$ and $\Delta G_{2n}{}^{\ddagger}$ for all the primary centers for which data are available. The correlation is satisfactory and in the sense anticipated. The scatter observed may arise as a consequence of the diversity of temperatures at which the isotope effects were established. In contrast, the correlation (Fig. 4) between $\delta_I\Delta G^{\ddagger}$ and $\Delta G^{\ddagger}$, the free energy of activation for the overall rate of the hydrogen compound, is random apart from the series considered specifically in Fig. 2.

Kinetic isotope effects for a particular series of chemical reactions are manifestations of the degree of curvature of potential energy hypersurfaces in regions of the surface which define the reactants and transition states. In the present context, the Hammond postulate represents a very restrictive condition requiring that changes in the curvature between the appropriate turning points parallel the differences in free energies between the two equilibrium states defined by the turning points. Such intricate requirements suggest the correlation in Fig. 3 to be remarkable rather than merely satisfactory.

The above considerations also cast some light on a correlation between $k_0(H_2O)/k_0(OH^-)$ for a series of CH_3X compounds and the related isotope effect $k(CH_3X)/k(CD_3X)$ measured in water originally established by Hartman and Robertson (18). Although this correlation differs from that presented in Fig. 3 in several respects the differences are less important than the similarities. When water is the nucleophile [13] gives

[8]There are indications in the literature that methyl trifluoromethanesulfonate may be more reactive than methyl perchlorate but the appropriate measurements in water have not yet been reported.

[9]The former empirical relationship was (16)

$$[17]\quad \log k_{nw} = (1.51 \pm 0.13) \log k_{nI} - 5.97 \pm 0.22$$

whereas more extensive data (41) give

$$[18]\quad \log k_{nw} = (1.285 \pm 0.058) \log k_{nI} - 5.545 \pm 0.09$$

[10]Equation 16 is derived from [18] by eliminating k_{nw} and k_{nI} using the relationship between log K_e and k_{0w} and k_{0I} which is specified in [13] for n = l and n = w.

[11]J. M. W. Scott, unpublished results.

$$\log k_{0w} = \log K_e + \log k_{2nw}$$

or

[19] $$\log k_{2nw} = \log k_{0w} - \log K_e$$

Eliminating $\log K_e$ between [19] and [16] gives

[20] $$\log k_{2nw} = -\frac{\rho_{nw}}{\rho_{nl} - \rho_{nw}} \log \frac{k_{0l}}{k_{0w}} + C$$

Hence the rates of destruction of the ion-pairs in water (k_{2nw}) are related to the k_{0l}/k_{0w} rates and thus the correlation between the isotope effect and k_{0l}/k_{0w} is formally equivalent to the correlation in Fig. 3. The fact that log (k_{0l}/k_{0w}) = log k_{2nl}/k_{2nw} is obvious enough but the relationship represented by [20] is less so.

The above discussion indicates that α deuterium isotope effects associated with attack at primary centers are mainly influenced by the endothermicity of the k_{2n} step and in harmony with the Hammond postulate, become more inverse as the endothermicity of this step increases. Since the observed isotope effect contains $\delta_I \log K_e$ term, the empirical observations presented suggest that $\delta_X \delta_I \log K_e \simeq 0$, *i.e.*, the isotope effect on K_e is relatively insensitive to the nature of the leaving group. This conclusion appears to be in agreement with some theoretical calculations reported by Stern and Wolfsberg (44, 45) in which the $K_e(H)/K_e(D)$ ratio for the stretching of the C—X bond in CD_3X and CH_3X to what might be termed a contact ion pair, seems relatively insensitive to the nature of X and also gives a normal effect. In contrast, the extension of the theoretical calculations to S_N2-like transition states gives inverse effects which are much larger (more inverse) than those observed experimentally. Stern and Wolfsberg (44, 45) point out that adjustments of the force constants can be made to accommodate the model to experiment. If the ion-pair description for these reactions is valid and if the isotope on the ratio $K_e(H)/K_e(D)$ is the same as the theoretical value then the small (less inverse) $k_{2n}(H)/k_{2n}(D)$ must relate to the force constants of the second transition state of the ion-pair displacement mechanism (eq. 13). If binding between the nucleophile and the leaving group is weak the transition state will be "looser" with respect to the methyl out-of-plane bending vibration. This will produce an isotope effect which is either less inverse or possibly normal.

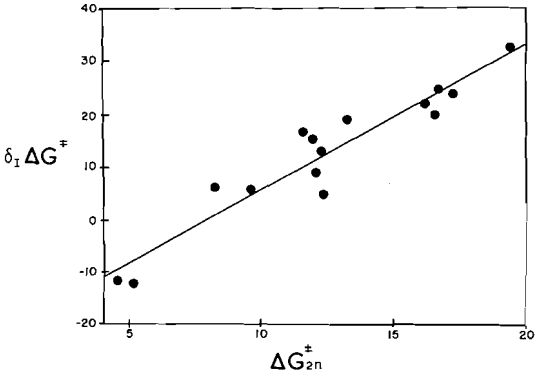

FIG. 3. A correlation of $\delta_I \Delta G^{\neq}$ and $\Delta G_{2n}{}^{\neq}$ for a series of displacement reactions.

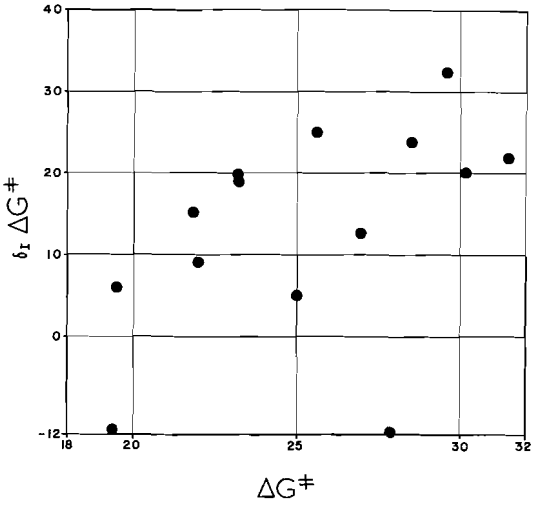

FIG. 4. An attempted correlation between $\delta_I \Delta G^{\neq}$ and $\Delta G^{\neq}$ for a series of substitution reactions.

The contact ion-pair mechanism thus offers a satisfactory account of the entropy correlation, the k.s.i.e. and the secondary isotope effects whereas the classical S_N2 description provides fewer insights. The above evidence also repudiates some recent criticisms by Abraham (46, 47) which are based on a crude thermochemical calculation and which make no attempt to explain the complexities of these reactions (see ref. 16). We believe that the results presented in this paper cannot be understood in terms of a unitary S_N2 displacement.

The authors wish to thank the National Research Council of Canada for partly defraying the cost of this work.

Formation Cross Sections of Iodine and Tellurium Isomers Produced in the Fission of ^{238}U by Protons of Energies 30–85 MeV[1,2]

M. DIKŠIĆ AND L. YAFFE

Department of Chemistry, McGill University, Montreal, Quebec H3C 3G1

Received February 26, 1975

M. DIKŠIĆ and L. YAFFE. Can. J. Chem. **53**, 3116 (1975).

Formation cross sections of isomers of ^{130}I, ^{132}I, ^{134}I, ^{131}Te, and ^{133}Te have been obtained from the fission of natural uranium by protons of energies 30–85 MeV. The high-spin isomer is favored in the production and increase in bombarding energy favors the production of the high-spin isomer. From the isomer ratios values of $(\overline{J^2})^{1/2}$, the root-mean-square angular momentum, were obtained. These increase with increasing bombarding energy.

M. DIKŠIĆ et L. YAFFE. Can. J. Chem. **53**, 3116 (1975).

On a obtenu la section efficace de formation des isomères de ^{130}I, ^{132}I, ^{134}I, ^{131}Te et ^{133}Te à partir de la fission de l'uranium naturel par des protons d'énergie 30–85 MeV. L'isomère à spin élevé est favorisé lors de la production et une augmentation de l'énergie de bombardement favorise la formation de l'isomère de haut spin. On a obtenu les moments angulaires quadratiques moyens $(\overline{J^2})^{1/2}$ à partir des rapports des valeurs. Ceux-ci augmentent lorsque l'on augmente l'énergie de bombardement.

[Traduit par le journal]

Introduction

A knowledge of formation cross sections of isomers and their ratios is intrinsically important. In addition, however, light may be cast upon the mechanism of the fission process itself by using the ratios to obtain information about the distribution of the angular momentum of the fragments after scission. At this point in the fission process the nucleus is greatly deformed and finally divides into the two fragments. A knowledge of the dynamics of these nascent fragments is very important, particularly since recent theoretical calculations (1) have used such data to derive information about the fission process using a two-dimensional deformed harmonic oscillator for the description of the nuclear fission process. Several theoretical studies (2, 3) do attempt to predict the angular momentum of the fragments but, unfortunately at the present time, insufficient experimental data have been derived in order to test the validity of the models. Theoretical attempts to derive ratios of production cross sections of the metastable and ground state isomers, σ_m and σ_g respectively, suffer from too many adjustable parameters.

Some experimental isomer ratios for various nuclei and various fissioning systems have been measured (4–6) in our laboratory, and an energy-dependent calculation was developed for the calculation of isomer ratios formed in fission in the proton bombarding-energy range of 30–85 MeV. The calculation was based on the formalism of Huizenga and Vandenbosch (7). A calculation based on the same formalism has been made for ^{115}Cd and ^{134}Cs isomers in several fissioning systems by Loveland and Shum (8). In all of these calculations the root-mean-square angular momentum, $(\overline{J^2})^{1/2}$, was adjusted until the calculated ratio agreed with that determined experimentally.

In this paper are reported isomer ratios for ^{130}I, ^{132}I, and ^{134}I, as well as the independent cross sections for both isomers in the fission of ^{238}U with protons in the energy range 30–85 MeV. Isomeric ratios for ^{131}Te and ^{133}Te isomers are reported, based on earlier data by Dikšić *et al.* (9).

Experimental

Experimental procedures have been reported in detail elsewhere (9, 10) and only a very brief description is given here.

Uranium metal foil or uranyl nitrate was irradiated for periods ranging from 1–5 min in the internal circulating beam of the McGill proton synchrocyclotron. Different energies of irradiation were obtained by placing the targets at various radii.

[1]This paper is dedicated to Professor C. A. Winkler of McGill University on the occasion of his sixty-fifth birthday by one of his colleagues (L.Y.).

The fission-produced iodine was chemically separated and converted to silver iodide for the activity measurements. These were done with a 30 cc Ge(Li) detector coupled to a 4096-channel pulse-height analyzer. The resolution of the system was 2.8 keV at 1.33 MeV. The net peak areas were computed using a computer code which subtracted a straight-line background. The resultant decay curves were resolved into their various components by use of the CLSQ least squares computer program (11).

The isomer ratios, σ_m/σ_g, were calculated by using the count rates under several full-energy peaks, except for ^{134}I where the independent cross-section for ^{134m}I was calculated. In addition, values of $\sigma_m + \sigma_g$ were obtained, thus enabling one to obtain values of σ_m and σ_g.

Errors in isomeric ratios for the iodine isomers then arise only from small uncertainties in the measured activities. No errors due to uncertainties in the half-lives were included in the case of the iodine isotopes. These would be of the order of 2–3%. Total errors, however, in the determination of the Te isomers are reported.

Results

In Table 1 are given the cross sections for the metastable and ground states. From these the isomeric ratios, σ_H/σ_T, have been calculated where H refers to the high-spin isomer and T the total. Because of the repeated determinations and the relatively high production yields at these bombarding energies it was possible to determine the half-lives very accurately: ^{130m}I = 8.9 ± 0.2 min, ^{132m}I = 83.6 ± 0.1 min, ^{134m}I = 3.8 ± 0.1 min.

Values for ^{130m}I and ^{134m}I agree well with presently-accepted values of 9.2 min (12) and 3.56 min (13) respectively, while as yet there has only been published (10) the above value for ^{132m}I.

Treatment of Results

The theoretical cross section ratios were calculated using the Huizenga–Vandenbosch formalism (7) adapted for fission by Saha and Yaffe (4).

In the present calculations it was assumed that each fragment has an initial spin distribution of form (14)

$$[1] \quad N(J_i) = (2J_i + 1) \exp [-J_i(J_i + 1)/2b^2]$$

where $(\overline{J^2})^{1/2}$, the root-mean-square angular momentum of the primary fragment, is given by

$$[2] \quad (\overline{J^2})^{1/2} = 2^{1/2}b$$

The parameter b is adjustable and was varied until the best fit, between experimental and theoretical results, was obtained. The energy of the emitted neutrons was taken as $2T$ (4), where T is the nuclear temperature of the residual nucleus. The average excitation energy removed by each emitted neutron is $B_n + 2T + \delta$, where B_n is the neutron binding energy (21) and δ is the pairing energy (15). The relationship (16) between nuclear temperature and excitation energy, U, is given by

$$[3] \quad E = aT^2 - 4T$$

where a is the level-density parameter, taken (17) equal to $A/10$ MeV^{-1}, A being the fragment mass number.

The excitation of a nucleus undergoing fission was calculated as previously described (9) using the VEGAS calculation (18, 19) and a Monte Carlo evaporation code (20). The excitation energy of the two primary fragments was estimated using eq. 5 in the Saha–Yaffe calculation (4). Mass excesses and the average total kinetic energy of the complementary primary fragments have been taken from refs. 21 and 22 respectively. The simple assumption was made that the excitation energy of the fissioning nucleus would divide itself in proportion to the masses of the complementary primary fragments (4).

The average γ energy (16), $\bar{E}_\gamma$, and the number of γ-rays (23), N_γ, emitted in the last stage of de-excitation were estimated by

$$[4] \quad \bar{E}_\gamma = 4[(E/a) - (5/a^2)] \text{ MeV}$$

and

$$[5] \quad N_\gamma = (aE)^{1/2}/(L + 1)$$

where E is the excitation energy and L is the multipolarity of the γ-rays. All γ-rays were assumed to be dipolar (7). The transmission coefficients, $T_l(E_n)$, for neutrons used in this calculation were computed for a diffuse-edge, surface-absorption potential according to Bjorklund and Fernback (24), using Auerbach's ABACUS-2 code (25).

The formalism of Huizenga and Vandenbosch (7) and code of Hafner *et al.* (26) were used to calculate the spin distribution after the emission of neutrons and γ-rays. New values of the spin cut-off parameters, σ_n and σ_γ, were entered into the calculation after the emission of each neutron and γ-ray, from the relationships (26, 27) $\sigma_n^2 = I_R t/\hbar^2$ and $\sigma_\gamma^2 = I_{eff} t/\hbar^2$, where I_R and I_{eff} are the rigid body and effective moments of inertia, respectively, and t is the thermodynamic

temperature (27), related to the excitation energy E, by $E = at^2 - t$. Dudey and Sugihara (28) have pointed out that, for $E < 10$ MeV, $I_{eff} < I_R$. Ericson (27) and Lang (33) have shown that the moment of inertia increases with increasing excitation energy and approaches the rigid body value as an upper limit. Since neutron emission takes place in the high excitation region, $E > 10$ MeV, we used the above relation for the determination of σ_n. The rigid body moment of inertia of the fragment was computed from $I_R = \frac{2}{5}(MAR^2)$, where M is the nuclear mass, and the nuclear radius $R = r_0A^{1/3}$ where r_0, the radius parameter, was taken to be 1.2×10^{-13} cm. The ratio (for excitation energies less than 10 MeV) of I_{eff}/I_R used was 0.6 to calculate σ_γ. This was not varied, since b was used as an adjustable parameter.

The assumptions were made that the final fragment spin distribution was divided between the isomeric states, and that the transition to any state involves the lowest spin change. In the event of a transition which involved equal spin change to either state, equal population of both states has been assumed. Values of $(\overline{J^2})^{1/2}$ are given in Table 2.

Discussion

It is very difficult to investigate the effects of the various parameters on the final cross-section ratios, since these represent averages resulting from many different primary fragments, which depend on the excitation energy and its division between the fragments, the kinetic energies of the fragments, the nature of the fissioning system, etc.

Various investigators have analyzed isomer ratios in different fissioning systems to obtain values of $(\overline{J^2})^{1/2}$ and some examples are given below. Sarantites *et al.* (29), for thermal fission of ^{235}U obtained a value of 6 $\hbar$ for isomers of ^{131}Te and ^{133}Te. Saha and Yaffe (4) reported values of 11–16 $\hbar$ for ^{134}Cs isomers in the fission of ^{239}Pu with protons of energies 30–85 MeV. Hoffman (30) calculated an average angular momentum of the fragments for thermal neutron fission of ^{233}U, ^{235}U, and ^{239}Pu, using a torque on uniformly charged bodies to simulate fragments in the latter stages of the fission process and obtained values of 5–6 $\hbar$ for each fragment. Using γ-ray anisotropies as an indicator for quadrupole transitions he found an average angular momentum of $7 \pm 2\hbar$. The fragment angular momentum deduced from γ-ray angular momentum correlation measurements is an average over all fragment masses. He proposed, as did Strutinski (31) earlier, that angular momentum is generated in the fission process.

Loveland and Shum (8) who, as discussed earlier, had investigated fission fragment angular momenta for ^{134}Cs and ^{115}Cd from several fissioning systems had concluded that the fragment angular momentum did not correlate with the compound nucleus angular momentum. They suggested that an increase of fragment angular momentum occurred with decreasing values of Z and A of the fissioning system.

An increase of fragment angular momentum with increasing bombarding energy has been found by several workers (4–6, 8, 32).

From Table 1 in this paper it is clear that, with the possible exception of ^{134}I, the isomers with high spin are favored, and the fraction of total cross section appearing in the high-spin portion increases with increasing bombarding energy. Isomers of ^{134}I may be being influenced by neighboring shells. Theoretical values for $(\overline{J^2})^{1/2}$ vary from 10–11 $\hbar$ at 30 MeV to 16–17 $\hbar$ at 85 MeV, except for ^{131}Te and ^{134}I which do not show as great an increase with increasing bombarding energy. In general these values agree with those found previously (4–6) in the same energy range for fission of ^{233}U and ^{239}Pu, using the same assumptions. However, it should once again be emphasized that the absolute values of the angular momenta of the fragments are still uncertain because of the lack of detailed knowledge about the de-excitation cascade, energy division between fragments, etc.

Nevertheless, it can be concluded that the fragment angular momenta in medium-energy

TABLE 2. Values of root-mean-square angular momentum

Fragment*	$(\overline{J^2})^{1/2}$† (units of $\hbar$)
^{130}I(5^-,2^+)	10–16
^{132}I(5^+,8^-)	11–17
^{134}I(5^+,8^-)	11–13
^{131}Te($3/2^+$,$11/2^-$)	10–11
^{133}Te($3/2^+$,$11/2^-$)	8.5–17

*The numbers in parentheses are the spins used for theoretical calculation of the isomeric cross-section ratios.

†The initial primary-fragment angular momentum which gave agreement between the theoretical and experimental results in the proton energy region 30–85 MeV; the first gave the best fit at 30 and the second one at 85 MeV protons.

fission are higher than those observed in low-energy fission. As the bombarding energy increases, the higher-spin isomer is preferentially populated. On the basis of the ^{134}Cs data, no difference can be seen if one compares these data with the fission of ^{233}U (6), ^{235}U (6), and ^{239}Pu (4), showing very little influence of these fissioning systems on the fragment angular momenta.

The authors acknowledge with thanks the ready co-operation of Dr. S. K. T. Mark, Director of the Foster Radiation Laboratory, with regard to the irradiations performed in connection with this work.

Ligand Field Photochemistry of Cobalt(III) Phenanthroline and Bipyridyl Complexes

CAROL P. J. VUIK, NOEL A. P. KANE-MAGUIRE, AND COOPER H. LANGFORD[1]

Chemistry Department, Carleton University, Ottawa, Canada K1S 5B6

Received April 3, 1975

CAROL P. J. VUIK, NOEL A. P. KANE-MAGUIRE, and COOPER H. LANGFORD. Can. J. Chem. **53**, 3121 (1975).

The ligand field photochemistry of $Cophen_2C_2O_4^+$, $Cobipy_2C_2O_4^+$, and of $Cophen_3^{3+}$ in the presence of added oxalate has been investigated. In all cases reduction to cobalt(II) complexes occurs with moderate quantum yields (>0.01). The nature of the reactive excited states is discussed, as is the mechanism of the $Cophen_3^{3+}$–oxalate photoreaction.

CAROL P. J. VUIK, NOEL A. P. KANE-MAGUIRE et COOPER H. LANGFORD. Can. J. Chem. **53**, 3121 (1975).

On a examiné la photochimie de ligand de champ des $Cophen_2C_2O_4^+$, $Cobipy_2C_2O_4^+$ et $Cophen_3^{3+}$ en présence d'oxalate additionné. Dans tous les cas, il y a une réduction aux complexes du Co(II) qui se produit avec des rendements quantiques modérés (>0.01). On discute de la nature des états excités réactifs de même que du mécanisme de la photoréaction entre du $Cophen_3^{3+}$ et l'oxalate.

[Traduit par le journal]

Introduction

The ligand field (l.f.) photochemistry of cobalt(III) complexes, so far as it is known, exhibits two major types of behavior. The very strong field $Co(CN)_6^{3-}$ and $Co(CN)_5OH_2^{2-}$ complexes undergo cyanide aquation with high quantum yields (1) while the weaker field amine complexes undergo photosubstitution with very low quantum yields (2). (A puzzling exception to this generalization is the report (3) that on irradiation at 520 nm $Co(NH_3)_5N_3^{2+}$ loses ammonia with a quantum yield of 0.2.) The low quantum yields found for simple amines have been ascribed by several authors (4) to high rates of relaxation to the $^1A_{1g}$ ground state from the $^1T_{1g}$ or $^3T_{1g}$ excited states considered responsible for photoreaction. However, there is some evidence against this hypothesis. In the presence of $Fe(CN)_6^{4-}$, l.f. irradiation of $Coen_3^{3+}$ gives a red product, apparently via intermediate formation of $Coen_3^{2+}$ and $Fe(CN)_6^{3-}$; the quantum yield for this reaction is 0.2 (5). This suggests that not only can the primary quantum yield for a cobalt(III) complex be relatively high, but also that if a suitable reducing agent is present, the predominant photoreaction following this Co(III) l.f. excitation is reduction, not substitution.

It has been reported (6) that on irradiation with sunlight, neutral solutions of both $Cophen_2C_2O_4^+$ and $Cobipy_2C_2O_4^+$ (phen = 1,10-phenanthroline and bipy = 2,2′-dipyridyl) deposit pink–orange, paramagnetic materials, presumably containing Co(II). The possibility of observing photoreduction on irradiation of l.f. bands, without adding an external reducing agent, prompted an investigation of these complexes using precisely defined wavelengths from laser sources to populate l.f. states.

Experimental

Synthesis of Complexes and Spectra

$[Cophen_3](ClO_4)_3.3H_2O$ was prepared by the method of Gorton and co-workers (7) and characterized by elemental analysis.

Anal. Calcd. for $C_{36}H_{30}N_6O_{15}Cl_3Co$: C, 45.42; H, 3.18; N, 8.83. Found: C, 45.74; H, 3.31; N, 8.91.

$[Co(bipy)_2C_2O_4]I.H_2O$ and $Cophen_2C_2O_4I.H_2O$ were prepared by the method of Broomhead and Kane-Maguire (6), and converted to solutions of the chloride salts by metathesis with silver chloride. $[Cophen_2C_2O_4]Cl.4H_2O$ was isolated from such a solution by adding saturated sodium chloride and keeping at 0 °C for 24 h. It was characterized by elemental analysis.

Anal. Calcd. for $C_{26}H_{24}N_4O_8ClCo$: C, 50.79; H, 3.93; N, 9.11. Found: C, 50.58; H, 4.23; N, 9.27.

An attempt to isolate the chloride salt of $Cobipy_2C_2O_4^+$ in the same way failed due to the greater solubility of this salt. All experiments involving this complex were accordingly carried out using the $Cobipy_2C_2O_4^+$ solution which contained excess sodium chloride.

The pink precipitate formed on photolyzing $Cophen_2C_2O_4^+$ in neutral solution was identified as the stoichiometric composition $[CophenC_2O_4]^0$.

Anal. Calcd. for $C_{14}H_8N_2O_4Co$: C, 51.4; H, 2.45; N, 8.56; Co, 17.9. Found: C, 51.75; H, 2.40; N, 8.53; Co (as Co(II)), 15.30.

Spectra of the phenanthroline and bipyridyl complexes used in this study were either recorded on a Cary 14 spectrophotometer, or plotted manually using a Gilford 240 spectrophotometer. Resolution of the visible spectra into Gaussian components was performed with a DuPont curve analyzer on spectra of absorbance plotted against frequency.

Photochemistry

The stoichiometry of the photolysis of $Cophen_2C_2O_4^+$ was determined by photolyzing a degassed aliquot of $Cophen_2C_2O_4^+$ solution with a 150 W tungsten reflector spot lamp. The carbon dioxide produced was determined manometrically using an apparatus which had been calibrated using carbon dioxide produced by photolyzing $Fe(C_2O_4)_3^{3-}$. For neutral solutions, the pink precipitate which formed was filtered off, washed with water, and dissolved in 7 *M* sulfuric acid (1 ml). The resulting solution was analyzed for Co(II) by the method of Kitson (8). An aliquot of the filtrate was similarly acidified and analyzed for Co(II). (Throughout this study solutions containing phenanthroline or dipyridyl complexes were acidified before being analyzed for Co(II), to prevent interferences by Co(II) complexes of these ligands.)

Quantum yields were determined using monochromatic light from a Coherent Radiation 1 W argon ion laser (457.9, 488, and 514.5 nm) or a Rayonet photoreactor (350 nm). In the experiments using the laser, the beam was passed through an appropriate interference filter, a lens to defocus the beam, and into a thermostatted 10 cm quartz cell containing the photolyte. Except for the experiments at 457.9 nm, where only *ca.* 90% of the incident light was absorbed by the solution, photolyte concentrations were such that > 99% of the incident light was absorbed. Light intensities at 457.9, 488, and 514.5 nm were measured by Reinecke's salt actinometry (9), absorbance-matched solutions being used at 457.9 nm. Light intensities at 350 nm were measured by ferrioxalate actinometry (10). Cobalt(II) was measured as outlined above, and photolyses were carried out to less than 10% conversion. Although neutral or basic solutions of $Cophen_3^{3+}$ containing oxalate ion initially remain clear on photolysis, on standing they slowly deposit yellow crystals which give a strong positive test for Co(II). Immediately after photolysis, the clear photolyte (*ca.* 30 ml) was therefore quantitatively diluted to 50 ml with concentrated sulfuric acid, which prevented the precipitation of the Co(II) product. The solution was then analyzed for Co(II) in the usual manner. Analyses for NH_3 were carried out using the indophenol method (11).

For interpretation purposes, it was important to resolve visible spectra into components corresponding to l.f. and c.t. bands. For analysis of spectra of the phenanthroline and bipyridyl complexes it was not possible to exactly reproduce the spectra with Gaussian components. Since knowledge of the maximum amount of reaction occurring by direct irradiation of c.t. bands is crucial to the interpretation of the l.f. bands, the component curves in the visible region were chosen to *maximize* the contribution of the higher frequency (c.t.) component. For the discussion, this is a worst case choice.

Results

The stoichiometries of the l.f. irradiation of $Cophen_2C_2O_4^+$ in acid and neutral solutions are given in Table 1. Under neutral conditions a yellow solution is produced as well as the pink precipitate noted by Broomhead *et al.* (6). If a neutral solution is irradiated for a short period of time (< 10 min), the pink precipitate does not appear immediately, but only on standing. It analyzes for the formula $CophenC_2O_4$. The pink material can also be slowly precipitated by mixing Co^{2+} and phenanthroline (1:2) with $Cophen_2C_2O_4^+$; Co^{2+} in the absence of phenanthroline has no detectable effect on $Cophen_2C_2O_4^+$. The yellow solution produced on photolysis initially gave a negative test for Co(II); on prolonged heating a positive test is obtained. Thus at room temperature and in neutral solution the overall reaction is

$$[1]\quad 4Cophen_2C_2O_4^+ \xrightarrow{h\nu} 2[CophenC_2O_4]^0(s) + 2Co(III) + 6phen + C_2O_4^{2-} + 2CO_2$$

The exact disposition of the phenanthroline ligands in the yellow solution is undetermined, but speculatively we suggest $Cophen_3^{3+}$. The spectrum is consistent with this assignment and the neutral solution gives a negative test for free phenanthroline after passage through cation exchange paper.

In view of the complicated nature of the reactions in neutral solution, all further experiments

were carried out in acidified solutions where the simpler stoichiometry of [2] obtains

$$[2]\quad 2Cophen_2C_2O_4^+ \xrightarrow{h\nu} 2Co^{2+} + 4phen + C_2O_4^{2-} + 2CO_2$$

By analogy with [2] the photolyses of $Cobipy_2C_2O_4^+$ in acid solution and of the $Cophen_3^{3+}/C_2O_4^{2-}$ mixtures were assumed to obey [3] and [4] respectively.

$$[3]\quad 2Cobipy_2C_2O_4^+ \xrightarrow{h\nu} 2Co^{2+} + 4bipy + C_2O_4^{2-} + 2CO_2$$

$$[4]\quad 2Cophen_3^{3+} + C_2O_4^{2-} \xrightarrow{h\nu} 2Co^{2+} + 6phen + 2CO_2$$

Quantum yields for photolysis at 25 °C of $Cophen_2C_2O_4^+$, $Cobipy_2C_2O_4^+$, and of $Cophen_3^{3+}$ and $Coen_3^{3+}$ in the presence of oxalate are given in Table 2. Table 2 also gives the temperature-dependence of $\phi_{Co(II)}$ for the irradiation of $Cophen_2C_2O_4^+$ at 514.5 nm; from these values the apparent activation energy over the temperature range 25–45 °C can be calculated to be 1000–1400 cm^{-1}. Table 2 also gives the result of an experiment to determine the effect on the quantum yield, ϕ_{NH_3}, for loss of ammonia from $Co(NH_3)_5Cl^{2+}$ of adding isopropanol as a chlorine radical scavenger. The reason for this experiment will be mentioned below.

Discussion

Analysis of the Spectra and the Nature of the Electronic States Populated by the Incident Radiation

In the case of $Cophen_2C_2O_4^+$, laser lines were available for irradiation on both the high and low energy sides of the maximum in the l.f. band of the spectrum. This allowed for irradiation at points where the intensity of any tail from the u.v. band (of either metal to ligand charge transfer or intraligand character) would vary considerably. The invariance of quantum yield between the two wavelengths shows that reaction originates *from population of the l.f. state* not from the weak tail of the u.v. band. This is, *a priori*, the most reasonable assignment because (*a*) the c.t. tail must be weak and (*b*) the c.t. state being metal to ligand is not of the sort associated with metal reduction. We assume that this conclusion can be extended to the $Cobipy_2C_2O_4^+$ and $Cophen_3^{3+}$ reactions, but the assumption can be supported by reasonable approximate arguments.

Gaussian curve analysis of the spectra of $Cophen_2C_2O_4^+$ and $Cobipy_2C_2O_4^+$ indicated that irradiation of either complex at 514.5 nm initially populates only the $^1T_{1g}$ l.f. state centered at 507 and 495 nm respectively. Similarly, less than 1% of the radiation absorbed by $Cophen_2C_2O_4^+$ at 457.9 nm populates the c.t. state centered at *ca.* 350 nm; the rest of the light at this wavelength populates the $^1T_{1g}$ l.f. state. These figures differ somewhat from those given in an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

earlier publication (12), which were calculated by a less rigorous method, but the conclusions are invariant under the change of approximation. There may be slight reaction at 457.9 nm via direct population of the c.t. state, but if so, reaction via this pathway is not much more efficient than reaction via the l.f. state.

Analysis of the $Cophen_3^{3+}$ spectrum is more difficult, and the results are less clear-cut. The tail of the intense c.t. transition centered at *ca.* 290 nm is not well separated from the peak of the weak l.f. band at *ca.* 465 nm. However, even allowing a maximum contribution from the c.t. state, the Gaussian curve analysis showed that at 488 nm less than 5% of the light absorbed could be ascribed to the c.t. component, the other 95% corresponding to the $^1A_{1g} \rightarrow {}^1T_{1g}$ l.f. transition. At 350 nm, however, 100% of the light absorbed populates a c.t. state.[2] These figures disagree somewhat with those calculated using Gorton and co-workers' analysis (7) of the spectrum of $Cophen_3^{3+}$. However, the method of Gorton and co-workers (13) was used only to define the position of the l.f. maximum; it was not intended to measure the relative importances of l.f. and c.t. transitions in the region where the latter decrease very rapidly. Furthermore, an attempt was made to analyze the spectrum by assuming Gorton's values of ε_{max} and λ_{max} for the l.f. band and a Gaussian shape for the c.t. band, but it was not possible to reproduce the observed spectrum with these conditions. The Gaussian analysis of the spectrum given above, and the values of $\phi_{Co(II)}$ found in 0.2 *M* oxalate indicate that both the l.f. and c.t. states are photoactive, but to a different degree. Assuming a maximum of 5% c.t. character at 488 nm, the wavelength dependence of $\phi_{Co(II)}$ for $Cophen_3^{3+}$ in 0.2 *M* oxalate gives $\phi_{Co(II)}$ for the c.t. state as 0.056 and for the l.f. state as $\geqslant 0.026$ and $\leqslant 0.028$ under the conditions obtaining.

Stoichiometry and Nature of the Reactive State in the $Cophen_2C_2O_4^+$ and $Cobipy_2C_2O_4^+$ Irradiations

The stoichiometry of the photoreactions of $CoL_2C_2O_4^+$ (L = phen, bipy) in acidic solutions can be explained by the mechanism

$$[5] \quad CoL_2C_2O_4^+ \xrightarrow{h\nu} [CoL_2C_2O_4^+]^*$$

$$[6] \quad [CoL_2C_2O_4^+]^* \rightarrow [Co^{II}L_2(C_2O_4^-)]^+$$

$$[7] \quad [Co^{II}L_2(C_2O_4^-)]^+ \rightarrow CoL_2^{2+} + C_2O_4^-$$

$$[8] \quad CoL_2C_2O_4^+ + C_2O_4^- \rightarrow CoL_2C_2O_4^0 + 2CO_2$$

Without a flash photolysis experiment, no information can be deduced as to the exact nature of the radical intermediates in [6] to [8]; as written, these equations are in accord with recent results (14, 15) on the flash photolysis of $Co(C_2O_4)_3^{3-}$. But regardless of the nature of the oxalato-radicals, at some stage the reactive state (not necessarily $^1T_{1g}$) must relax onto the potential surface corresponding to a Co(II) complex and an organic radical ([6]). In addition, the observed quantum yield is that for the sum of processes 5 to 8, so that the values of $\phi_{Co(II)}$ given in Table 2 are twice the quantum yield for the primary photochemical act ([5] to [7]), as the Co(II):CO_2 ratio requires.

The complicated stoichiometry seen in neutral solutions is due to subsequent thermal reactions of the Co(II) complexes produced in steps 7 and 8, *viz*:

$$[9] \quad CoL_2C_2O_4^0 \rightleftharpoons CoL_2^{2+} + C_2O_4^{2-}$$

$$[10] \quad CoL_2C_2O_4^+ + CoL_2^{2+} \rightarrow [CoLC_2O_4]^0(s) + CoL_3^{3+}$$

In acidic solutions the equilibrium

$$[11] \quad CoL_2^{2+} + 2H^+ \rightleftharpoons Co^{2+} + 2LH^+$$

lies far to the right; since Co^{2+} itself does not react with $Cophen_2C_2O_4^+$ (*vide supra*) [9] and [10] do not occur.

Both the mode of reaction and the relatively high quantum yields found for $Cophen_2C_2O_4^+$ and $Cobipy_2C_2O_4^+$ are unusual in the photochemistry of cobalt(III) amine complexes. Thus the presence of heterocyclic aromatic amines confers special physical or chemical properties on the complexes. Balzani *et al.* (16) suggested that the observation of wavelength-dependent photoreduction on irradiating l.f. bands of $Co(NH_3)_5NO_2^{2+}$ could be explained by assuming reaction occurred via a c.t. state which is substantially distorted from the ground state geometry. Its potential minimum thus lies lower than that of the l.f. state, even though Franck–Condon restrictions means the absorption $^1A_{1g} \rightarrow$ c.t. appears at higher energies than the $^1A_{1g} \rightarrow {}^1T_{1g}$ l.f. tran-

[2]Although there are inherent limitations to Gaussian analysis, we remind the reader that c.t. contribution was maximized (see experimental) so that we present our conclusions for the conditions least favorable to our argument. This should compensate for deviation from Gaussian behavior.

For personal use only.

sition. A similar situation is possible for the $Cophen_2C_2O_4^+$ and $Cobipy_2C_2O_4^+$ complexes where even in vertical excitation the absorptions corresponding to c.t. transitions lie fairly close ($\sim$370 nm for $Cophen_2C_2O_4^+$ and $\sim$350 nm for $Cobipy_2C_2O_4^+$) to those for the octahedral $^1A_{1g} \rightarrow {}^1T_{1g}$ transition. Since the lowest c.t. bands in $Coen_2C_2O_4^+$ occur at $\sim$225 nm, the low-lying bands in $Cophen_2C_2O_4^+$ and $Cobipy_2C_2O_4^+$ no doubt involve Co–phen and Co–bipy charge transfer, quite probably in the metal to ligand direction. If this is so, it is hard to see why populating these states leads to oxidation of oxalate, even though a few cases of 'wrong ligand' oxidation have been documented (17). It is noteworthy that the low apparent activation energy for the $Cophen_2C_2O_4^+$ irradiation at 514.5 nm is normal for transition metal complexes (4*b*, p. 12); it is also low enough to exclude reaction via a reactive c.t. state for which the potential minimum is much more than 1 kK above that of the $^1T_{1g}$ state.

It is more interesting to consider the possibility that reaction occurs from one of the ligand field states. Either the $^1T_{1g}$ state directly populated on irradiation or the $^3T_{1g}$ state which can be reached by intersystem crossing could be the reactive state. Both these states have the electronic configuration $t_{2g}^5 e_g^1$ and one-electron transfer from the oxalate ligand to the t_{2g} shell would produce an unstable low-spin Co(II) phenanthroline or bipyridyl complex. Rapid reaction of this species to the corresponding high-spin complex would provide a pathway for relaxation to the observed products. The high ligand field strengths of phenanthroline and bipyridyl should stabilize the low-spin Co(II) species, where a lower field ligand like ethylenediamine would not. This could explain why $Cophen_2C_2O_4^+$ and $Cobipy_2C_2O_4^+$ are photoactive but simple amine oxalato-complexes are not. Alternatively, Kane-Maguire and Langford (5) have suggested that provided a suitable reducing agent is available, photoreduction is a normal consequence of ligand field irradiation, and that the reaction might occur via the $^5T_{2g}$ state. The Tanabe–Sugano diagram for Co(III) shows that at the average ligand field strength for amino-oxalato-complexes the lowest-lying l.f. state is $^3T_{1g}$. But if the excited states are distorted from the ground state geometry, the average ligand field experienced by the Co(III) will decrease, and the lowest l.f. state may become $^5T_{2g}$. The electronic configuration of this state is $t_{2g}^4 e_g^2$. Therefore it only requires a one-electron transfer from the oxalate ion to the t_{2g} shell to give the stable high-spin Co(II) product.

Although the nature of the reactive excited state is in doubt among three candidates, a phenomenological explanation of the unusual reactivity of the phenanthroline and bipyridyl complexes is possible. It appears that the thermodynamic ease of reduction of the substrate to the stable, high-spin Co(II) product is a major factor in determining photosensitivity. The $E_{1/2}{}^0$ values are not available for $Cophen_2C_2O_4^+$ and $Cobipy_2C_2O_4^+$, but Ohashi (18) has demonstrated a linear correlation between $E_{1/2}{}^0$ for the process

[12] $$CoL_2C_2O_4^{n+} + e^- \rightarrow CoL_2C_2O_4^{(n-1)+}$$

and the second order rate constant for the reaction

[13] $$CoL_2C_2O_4^{n+} + Fe^{2+} \rightarrow CoL_2C_2O_4^{(n-1)+} + Fe^{3+}$$

Extrapolation of this correlation gives $E_{1/2}{}^0$ as 0.095 for $Cophen_2C_2O_4^+$ and 0.060 for $Cobipy_2C_2O_4^+$. Not only are these values substantially more favorable than that for reduction of $Coen_2C_2O_4^+$, but their ratio is within experimental error equal to the ratio of quantum yields for the two complexes. It is possible to explain this behavior qualitatively by remembering that the excited state must relax onto the potential surface corresponding to a Co(II) complex and the oxalate radical. The smaller the energy gap between the excited state and product surfaces, the more efficient this relaxation will be. For simple amineoxalates like $Coen_2C_2O_4^+$ the Co(II) product is relatively unstable and the energy gap is too large for photoreduction to occur. A similar explanation rationalizes photoreduction by oxalate of $Cophen_3^{3+}$ and not $Coen_3^{3+}$, and also the insensitivity of ϕ_{NH_3} for $Co(NH_3)_5Cl^{2+}$ to the presence of isopropanol (see Table 2). For $Co(NH_3)_5Cl^{2+}$ and similar complexes it is possible to consider the reaction mechanism

[14] $$Co(NH_3)_5Cl^{2+} \xrightarrow{h\nu} [Co(NH_3)_5Cl^{2+}]^*$$

[15] $$[Co(NH_3)_5Cl^{2+}]^* \rightarrow Co^{II}(NH_3)_5(Cl^{\cdot})^{2+}$$

[16] $$Co^{II}(NH_3)_5(Cl^{\cdot})^{2+} + H_2O \rightarrow Co^{II}(NH_3)_4(H_2O)(Cl^{\cdot})^{2+} + NH_3$$

[17] $$Co^{II}(NH_3)_4(H_2O)(Cl^{\cdot})^{2+} \rightarrow Co^{III}(NH_3)_4(H_2O)(Cl^-)^{2+}$$

Although isopropanol would scavenge any $Cl^{\cdot}$ radicals that were formed (19), the potential sur-

face for $Co(NH_3)_5^{2+}$ and the chlorine radical lies too far above that of the excited state for the redox reaction to occur.

The Photoreduction of Cophen$_3^{3+}$ by Oxalate

In line with [5] to [8], the overall reaction occurring on irradiation of $Cophen_3^{3+}$ in the presence of oxalate is assigned as

$$[18]\quad Cophen_3^{3+} + C_2O_4^{2-} \xrightarrow{h\nu} Cophen_3^{2+} + C_2O_4^{-}$$

$$[19]\quad Cophen_3^{3+} + C_2O_4^{-} \rightarrow Cophen_3^{2+} + 2CO_2$$

Again the observed quantum yields given in Table 2 are twice the quantum yields for the primary photochemical act ([18]).

The dependence of the quantum yields on the concentration of oxalate is shown in Fig. 1. A weighted least squares fit to the function

$$[20]\qquad \phi_{Co(II)} = \frac{a[C_2O_4^{2-}]}{1 + b[C_2O_4^{2-}]}$$

assuming that there is a constant percentage error in $\phi_{Co(II)}$ gives $a = 0.44 \pm 0.04$, $b = 11.4 \pm 1.4$ M^{-1}, and the percentage error in $\phi_{Co(II)}$ as 5%. The observed dependence on $[C_2O_4^{2-}]$ can be explained by considering two simple schemes (although some more complex ones might also work).

In the first scheme, two absorbers with similar extinction coefficients at 488 nm are postulated, namely $Cophen_3^{3+}$ and *its ion pair with oxalate*. Only the ion pair is considered to be reactive. In this model, the parameter b is the ion pairing equilibrium constant. The success of the model turns on the reasonableness of a value of 11.4 ± 1.4 M^{-1} for this ion pairing constant. No convenient approach for an independent experimental determination of the constant in these media is available. However, many studies of thermal kinetics in similar media show that the Fuoss–Eigen equation is a successful method of approximating such ion association constants. Extrapolating the value of 11.4 M^{-1} at ionic strength 0.3 (our lowest experimental ionic strength) to zero ionic strength with the Davies equation (20) gives a value of 320 M^{-1}. A calculation following Fuoss (21), assuming a distance of closest approach of 7.5 Å, gives 270 M^{-1}. The model must be regarded as satisfactory in qualitatively accounting for the results.

In the second simple scheme, the reaction is assumed to proceed via a *dynamic competition* between deactivation of the reactive excited state and its reaction with oxalate. This will lead to an equation of the form of [20] if the rate constant for deactivation is much less than the product of the rate constant for diffusional encounter between $Cophen_3^{3+}$ and oxalate multiplied by the oxalate concentration. In particular, the value of b requires that the deactivation rate constant is smaller than the diffusion rate constant by a factor of at least 11.4. This is also qualitatively reasonable although it requires a longer lifetime for a Co(III) excited state than earlier workers have preferred (4).

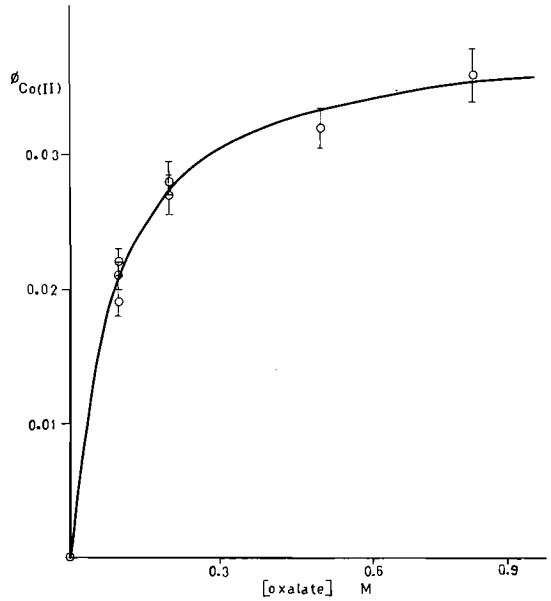

FIG. 1. The quantum yield for reduction of $Cophen_3^{3+}$ as a function of oxalate concentration.

As to the intimate mechanism of the outer sphere reduction, electron transfer from the oxalate ion into the t_{2g} shell would generate a low spin $Cophen_3^{2+}$ complex, which would be relatively stabilized by the phen ligands. Hoffman and Simic (22) showed low spin $Cobipy_3^{2+}$ was not generated during the thermal reaction of $Cobipy_3^{3+}$ with a solvated electron, but this process requires electron transfer to the high energy e_g level, so it does not *a priori* exclude low spin $Cophen_3^{2+}$ as an intermediate in reactions of a $^3T_{1g}$ or $^1T_{1g}$ excited state with a vacancy in the t_{2g} shell. Consequently, the present results taken in conjunction with those of Hoffman and Simic cannot be used to favor reaction from a ^5T excited state, however reasonable such a mechanism may seem.

Direct Observation of the Radicals Formed in the Radiolysis of Liquid Benzyl Alcohol. An Electron Spin Resonance and Spin Trapping Method[1]

FREDERICK PETER SARGENT AND EDWARD MICHAEL GARDY

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba R0E 1L0

Received June 5, 1975

FREDERICK PETER SARGENT and EDWARD MICHAEL GARDY. Can. J. Chem. **53**, 3128 (1975).

Intermediates formed during radioylsis of benzyl alcohol have been identified by an e.s.r. and spin trapping method. Solutions of *tert*-BuNO in benzyl alcohol were irradiated *in situ* with 3 MeV electrons and the e.s.r. spectra of the resulting nitroxides directly recorded.

$$\textit{tert}\text{-BuNO} + R\cdot \rightarrow \textit{tert}\text{-BuN}(O\cdot)\text{—}R$$

These demonstrated that benzyl, $PhCH_2\cdot$, and hydroxybenzyl, $Ph\dot{C}HOH$, radicals are formed in the radiolysis. By an examination of the effects of the addition of electron scavengers, it was shown that the benzyl radicals are probably directly formed from the reaction of electrons with benzyl alcohol. Since these scavengers had no effect on the yield of $Ph\dot{C}HOH$ trapped, this radical is not derived from the reactions of electrons. It is suggested that it is partly produced by reaction of the alkoxy radical, $PhCH_2O\cdot$, with the solvent benzyl alcohol.

$$PhCH_2O\cdot + PhCH_2OH \rightarrow Ph\dot{C}HOH + PhCH_2OH$$

FREDERICK PETER SARGENT et EDWARD MICHAEL GARDY. Can. J. Chem. **53**, 3128 (1975).

On a identifié, par r.p.e. et par la méthode de piégeage de spin, les intermédiaires qui se forment au cours de la radiolyse de l'alcool benzylique. On a irradié, *in situ* avec des électrons à 3 MeV, des solutions de *tert*-BuNO dans l'alcool benzylique et on a enregistré directement les spectres r.p.e. des nitroxydes qui se forment.

$$\textit{tert}\text{-BuNO} + R\cdot \rightarrow \textit{tert}\text{-BuN}(O\cdot)\text{—}R$$

Ces spectres ont permis de démontrer que des radicaux benzyles, $PhCH_2\cdot$, et hydroxybenzyles, $Ph\dot{C}HOH$, se forment lors de la radiolyse. En examinant les effets produits par addition de pièges à électrons, on a pu montrer que les radicaux benzyles se forment probablement directement par réaction des électrons avec l'alcool benzylique. Puisque l'addition de ces pièges n'a aucune influence sur le rendement en radicaux $Ph\dot{C}HOH$ on peut en déduire que ce radical n'est pas formé par réactions des électrons. On croit qu'il se forme, en partie, par réaction du radical alkoxy, $PhCH_2O\cdot$, avec l'alcool benzylique.

$$PhCH_2O\cdot + PhCH_2OH \rightarrow Ph\dot{C}HOH + PhCH_2OH$$

[Traduit par le journal]

Introduction

We have recently used the technique of spin trapping (1) to detect the intermediates formed in the radiolysis of simple alcohols (2, 3). In this paper we describe its application to a study of the radiation chemistry of benzyl alcohol. The method involves conversion of the reactive intermediates, R·, formed in the radiolysis, and which have lifetimes in the range of micro- to milliseconds, to comparatively stable nitroxides. This is achieved by their addition to a nitrone or a nitroso compound as in [1] and [2].

[1] $$\textit{tert}\text{-BuNO} + R\cdot \rightarrow \textit{tert}\text{-BuN}(O\cdot)\text{—}R$$

[2] $$PhCH{=}NO\text{—}\textit{tert}\text{-Bu} + R\cdot \rightarrow PhCH(R)\text{—}N(O\cdot)\text{—}\textit{tert}\text{-Bu}$$

The resulting nitroxide has an e.s.r. spectrum characteristic of R·. The most commonly used trapping agents are nitroso-*tert*-butane, *tert*-BuNO, and phenyl-*tert*-butyl nitrone. Although

each has its merits, we prefer to use *tert*-BuNO because the resulting nitroxide spectra are distinctive and vary considerably with R·. However, one of the disadvantages of this compound is that although the nitroxides are much longer lived than their precursors, R·, they are not completely stable and some of them decay in a few seconds (2). We have overcome this problem by coupling the e.s.r. spectrometer to a high energy electron accelerator, which permits the direct observation of e.s.r. spectra while the sample is being irradiated.

The transient optical absorption detected in pulse irradiated neat benzyl alcohol (4) and its solution in cyclohexane (5) has been assigned to benzyl radicals. It was suggested that these were formed by the dissociative electron capture reaction

[3] $$PhCH_2OH + e \rightarrow PhCH_2\cdot + OH^-$$

Our spin trapping results support this but also show the presence of another radical not detected in the pulse radiolysis studies. The e.s.r. coupling constants show this to be the PhĊHOH radical.

Experimental

The e.s.r. spectrometer was coupled to a nominally 4 MeV electron accelerator by extending the flight tube axially into the magnet. The pole caps were fitted with a field compensating device to give a field homogeneity of 5 μT (50 mG) over the sample volume. The conventional T102 rectangular microwave cavity was modified to permit irradiation of the samples.

Solutions to be irradiated were deoxygenated by bubbling with 99.999% argon and continuously flowed through the e.s.r. sample cavity where they were irradiated with 3 MeV electrons at beam currents in the range of 1 to 7 μA at temperatures a few degrees above ambient. The sample tubes were made of cerium doped glass which does not give an appreciable e.s.r. signal on irradiation (6, 7). The magnetic field sweep ranges were calibrated with an n.m.r. magnetometer and were found to be reproducible to at least 1%.

Nitroso-*tert*-butane, *tert*-BuNO, was prepared by oxidation of *tert*-butylamine using the method of Stowell (8), recrystallized from *n*-pentane and stored in a refrigerator. Benzyl alcohol was Fisher Certified grade which contains less than 0.20% chloride. Reagent grade methyl iodide and carbon tetrachloride were used as received.

Results and Discussion

The e.s.r. spectrum observed during the radiolysis of benzyl alcohol containing 10 mol/m^3 (0.01 *M*) *tert*-BuNO is shown in Fig. 1. This is a composite of the spectra from three different nitroxides, referred to as **1**, **2**, and **3**, which are formed by the trapping of three different intermediates. The spectrum is interpreted in terms of nitroxide **1** with a nitrogen coupling of 1.4 mT (14.0 G) and a proton coupling of 1.27 mT (12.7 G), nitroxide **2** with a nitrogen coupling of 1.52 mT (15.2 G) and a proton coupling of 0.3 mT (3.0 G), and nitroxide **3** with a nitrogen coupling of 1.60 mT (16.0 G) and a pair of protons with a coupling of 0.84 mT (8.4 G). The simulated composite spectrum shown in Fig. 1*b* was computed with these values and the ratios of concentrations were adjusted to give close agreement with the observed spectrum. Nitroxide **1** is identified as *tert*-BuNHO·, and the coupling constants are in close agreement with those previously observed in other alcohols (2, 3) and water (9). Nitroxide **3** is formed by the trapping of benzyl radicals, [4],

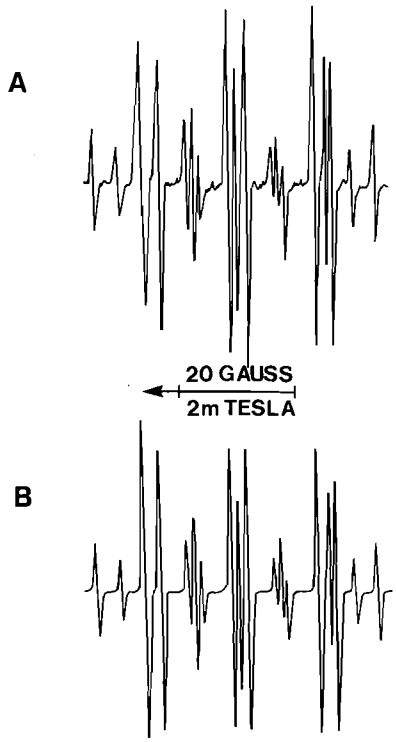

FIG. 1. (*a*) Electron spin resonance spectrum observed during irradiation of benzyl alcohol containing 10 mol/m^3 (0.01 *M*) *tert*-BuNO. (*b*) Computer simulated spectrum.

[4] $$PhCH_2\cdot + \textit{tert}\text{-BuNO} \rightarrow \textit{tert}\text{-BuN}(O\cdot)\text{—}CH_2\text{—Ph}$$

and the coupling constants are in reasonable agreement with those reported (10) after allowing for the well known solvent effect. Nitroxide **2**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

comes from the trapping of a radical with only one α-proton. This, together with the magnitude of the coupling constants, strongly suggests PhĊHOH, as in [5]

[5] $$PhĊHOH + \textit{tert}\text{-BuNO} \rightarrow \textit{tert}\text{-Bu}\underset{\displaystyle O\cdot}{\overset{\displaystyle H}{N-C}}\text{—Ph}\quad (OH)$$

Saturating the solution with nitrous oxide prior to radiolysis had no effect on the observed e.s.r. spectrum suggesting that [6] does not occur to any appreciable extent.

[6] $$e + N_2O \rightarrow N_2 + O^-$$

This could mean that solvated electrons are not formed in benzyl alcohol; certainly, none were detected in the pulse radiolysis study (4). However, since the solubility of nitrous oxide in benzyl alcohol is unknown, we decided to examine the effects of high concentrations of other electron scavengers such as methyl iodide, carbon tetrachloride, and benzophenone. These had a most marked effect on the relative intensity of nitroxide **3**. This is best illustrated by the addition of benzophenone as in Fig. 2 where the solution contained 10 mol/m^3 (0.01 *M*) *tert*-BuNO and 50 mol/m^3 (0.05 *M*) benzophenone. This had little effect on nitroxides **1** and **2** but **3** was considerably diminished, indicating a lower yield of benzyl radicals. When methyl iodide was used, not only was **3** decreased but methyl radicals were also trapped due to [7] and [8].

[7] $$e + CH_3I \rightarrow CH_3\cdot + I^-$$

[8] $$CH_3\cdot + \textit{tert}\text{-BuNO} \rightarrow \textit{tert}\text{-Bu}\underset{\displaystyle O\cdot}{N}\text{—}CH_3$$

These results show that the benzyl radicals are indeed derived from electrons and provide supporting evidence for [3].

Since electron scavengers had very little effect on the yield of *tert*-BuNHO· it is clearly not derived from electrons. We propose that it originates from the reaction of PhĊHOH with *tert*-BuNO as in [9].

[9] $$\textit{tert}\text{-BuNO} + PhĊHOH \rightarrow \textit{tert}\text{-BuNHO}\cdot + PhCHO$$

This reaction, which is in competition with [5], might involve electron or hydrogen atom transfer. Analogous reactions of the α radicals of simple alcohols, such as $\cdot CH_2OH$ or $(CH_3)_2\cdot COH$, are well established (11). It has also been shown

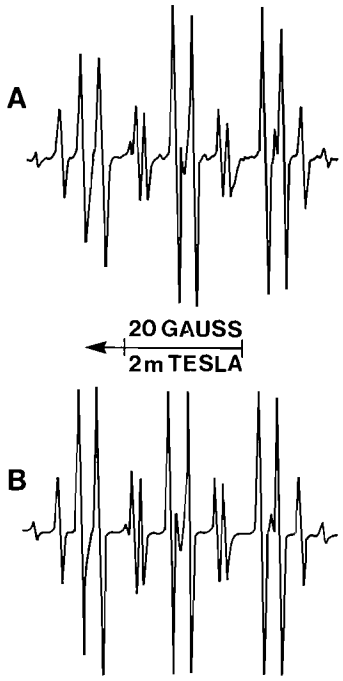

FIG. 2. (*a*) Electron spin resonance spectrum observed during irradiation of benzyl alcohol containing 10 mol/m^3 (0.01 *M*) *tert*-BuNO and 50 mol/m^3 (0.05 *M*) benzophenone. (*b*) Computer simulated spectrum.

that the rate of such reactions is much higher in alkaline solutions where the donor would be the radical anion (12). Therefore, we examined the effects of base on the spectra from solutions of *tert*-BuNO in benzyl alcohol. The e.s.r. spectrum in Fig. 3 was taken during radiolysis of a solution of *tert*-BuNO containing 10 mol/m^3 (0.01 *M*) potassium hydroxide. This shows the presence of **1** and **3** but **2** is absent and in addition the yield of **1** is considerably enhanced.[2] This means that all the α-radicals, PhĊHOH, have reacted by the electron transfer reaction 10 and none have been trapped. If benzophenone is also added to suppress the formation and trapping of benzyl radicals, the spectra (see Fig. 4), consists principally of *tert*-BuNHO from [10] and [11].

[10] $$PhĊHOH + OH^- \rightarrow PhCHO^- + H_2O$$

[2]The *tert*-BuNHO· is not converted to *tert*-BuNO$^-$ by the KOH in benzyl alcohol. This seems to be generally true for alcohols since *tert*-BuNHO· is observed in alkaline methanol and ethanol (F. P. Sargent and E. M. Gardy, unpublished results). This is in marked contrast to aqueous solutions where the transition to *tert*-BuNO$^-$ occurs in quite weakly alkaline solutions at p*H* 7–9 (16).

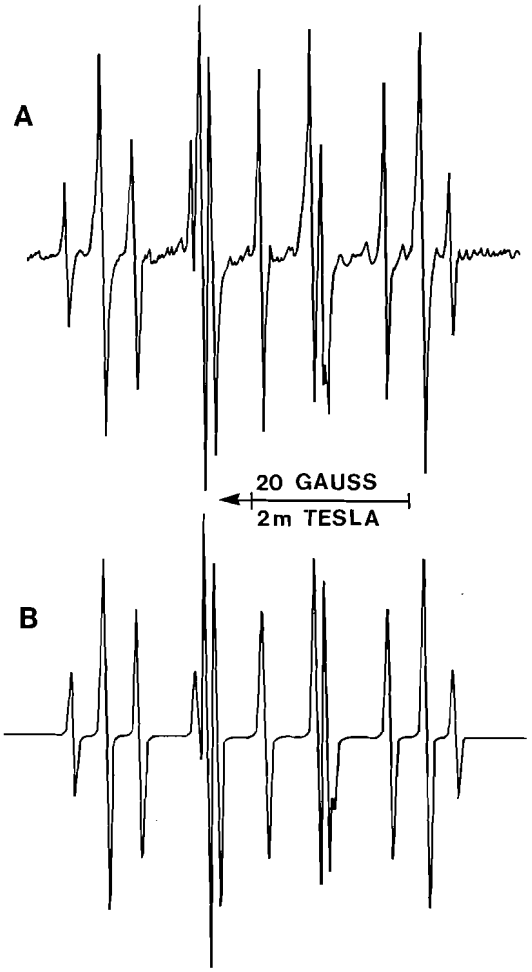

FIG. 3. (*a*) Electron spin resonance spectrum observed during irradiation of benzyl alcohol containing 10 mol/m^3 (0.01 *M*) *tert*-BuNO and 10 mol/m^3 (0.01 *M* potassium hydroxide. (*b*) Computer simulated spectrum.

[11] $PhCHO^- + \textit{tert}\text{-BuNO} + PhCH_2OH \rightarrow$
$\textit{tert}\text{-BuNHO}\cdot + PhCHO + PhCH_2O^-$

These results show that the radiolysis of benzyl alcohol does indeed produce benzyl radicals and that these are derived from electrons. They do not provide concrete proof for [3] since there are other reactions of the electrons which might conceivably produce benzyl radicals but [3] is the most probable.

Using the spin trapping technique, we have been able to show the presence of PhĊHOH radicals which were not detected by pulse radiolysis (4). However, we were unable to detect any nitroxides which would show the presence of the alkoxy radical $PhCH_2O\cdot$. This failure could be due to several factors. The *tert*-BuNO might not be a very efficient trapper of these radicals. It is certainly known that the nitroxides formed by the trapping of simple alkoxy radicals are unstable. In addition, Perkins and Roberts (13) have recently shown that the trapping efficiency for *tert*-butoxy radicals decreases with increasing temperatures because the reverse reaction becomes more dominant. These factors together with the possibility of [12], which undoubtedly is very rapid, make it most unlikely that $PhCH_2O\cdot$ would be trapped. Therefore failure to detect this radical cannot be taken as evidence that it is not formed in the radiolysis.

[12] $PhCH_2O\cdot + PhCH_2OH \rightarrow$
$PhĊHOH + PhCH_2OH$

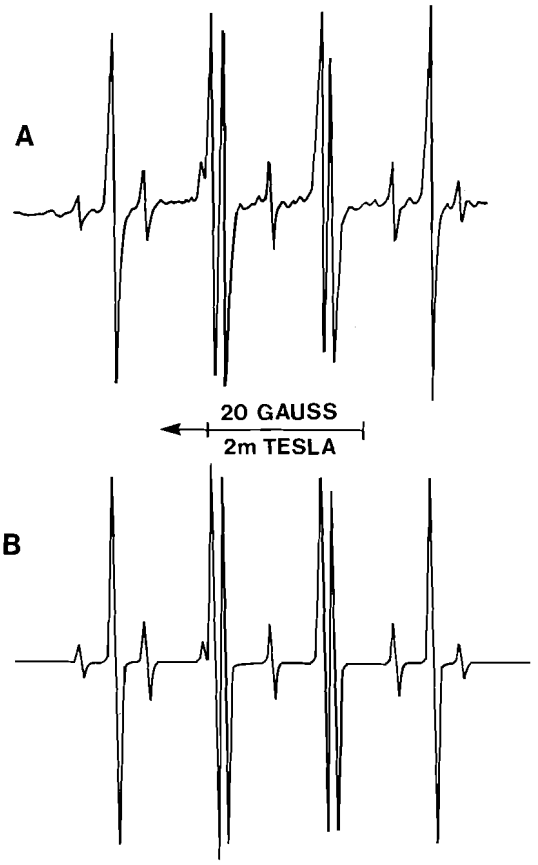

FIG. 4. (*a*) Electron spin resonance spectrum observed during irradiation of benzyl alcohol containing 10 mol/m^3 (0.01 *M*) *tert*-BuNO, 50 mol/m^3 (0.05 *M*) benzophenone, and 10 mol/m^3 (0.01 *M*) potassium hydroxide. (*b*) Computer simulated spectrum.

In view of this uncertainty, we cannot establish whether PhĊHOH is a primary product of the radiolysis or whether it all comes from [12]. However, by analogy with the known radiation chemical yields in simple alcohols such as methanol and ethanol (14, 15), it is probable that the primary yields of $PhCH_2O\cdot$ and PhĊHOH are of the same order of magnitude.

The Water-activity of Supersaturated Aqueous Solutions of NaCl, KCl, and K_2SO_4 at 25 °C

FABIO LENZI, TUONG-TU TRAN, AND TJOON-TOW TENG

Département de Génie Chimique, Ecole Polytechnique, Campus de l'Université de Montréal, Case Postale 6079, Succursale "A", Montréal, Québec H3C 3A7

Received May 23, 1975

FABIO LENZI, TUONG-TU TRAN, TJOON-TOW TENG. Can. J. Chem. **53**, 3133 (1975).

Reverse application of the Reilly–Wood–Robinson and Zdanovskii–Stokes–Robinson equations to the water-activity data of various ternary aqueous systems containing NaCl, KCl, K_2SO_4 as one of the components yields self-consistent estimates of the water-activity of binary aqueous supersaturated solutions of the individual salts; these can be further extended by curvilinear extrapolation to give: $a_{w(NaCl)} = 1 + \Sigma_1^{10} A_i m^i$ with $A_1 = -3.28806 \times 10^{-2}$, $A_2 = 1.12512 \times 10^{-4}$, $A_3 = -4.30034 \times 10^{-4}$, $A_4 = 2.70506 \times 10^{-5}$, $A_5 = 1.43435 \times 10^{-6}$, $A_6 = 1.30209 \times 10^{-7}$, $A_7 = -1.51941 \times 10^{-8}$, $A_8 = 1.00520 \times 10^{-9}$, $A_9 = -4.21593 \times 10^{-10}$, $A_{10} = 2.62532 \times 10^{-11}$, valid to $a_{w(NaCl)} = 0.5422$, $m_{NaCl} = 11.0 \approx 1.8 \times m^{sat}_{NaCl}$; $a_{w(KCl)} = 1 + \Sigma_1^7 B_i m^i$ with $B_1 = -3.21884 \times 10^{-2}$, $B_2 = 9.77773 \times 10^{-4}$, $B_3 = -6.05349 \times 10^{-4}$, $B_4 = 1.18422 \times 10^{-4}$, $B_5 = -7.91572 \times 10^{-6}$, $B_6 = -3.88125 \times 10^{-8}$, $B_7 = 1.55125 \times 10^{-8}$, valid to $a_{w(KCl)} = 0.7115$, $m_{KCl} = 9.00 \approx 2.0 \times m^{sat}_{KCl}$; $a_{w(K_2SO_4)} = 1 + \Sigma_1^4 C_i m^i$ with $C_1 = -4.16810 \times 10^{-2}$, $C_2 = 1.16033 \times 10^{-2}$, $C_3 = -4.80543 \times 10^{-3}$, $C_4 = 7.15536 \times 10^{-4}$, valid to $a_{w(K_2SO_4)} = 0.9301$, $m_{K_2SO_4} = 2.20 \approx 3.0 \times m^{sat}_{K_2SO_4}$.

L'application à rebours des équations de Reilly–Wood–Robinson et de Zdanovskii–Stokes–Robinson aux données de l'activité de l'eau de plusieurs systèmes ternaires contenant du NaCl ou du KCl ou du K_2SO_4 a été effectuée. Des valeurs de l'activité de l'eau de solutions aqueuses binaires sursaturées de chacun de ces sels ont été obtenues avec, dans chaque cas, bonne concordance. Les plages d'estimation ont été prolongées par extrapolation curvilineaire.

Introduction

A knowledge of the water-activity, a_w, is important in the correlation and prediction of both equilibria and kinetics in moderate to concentrated mixed aqueous solutions of electrolytes and nonelectrolytes. Areas of application include, for example, crystallization and reverse osmosis. In particular a knowledge of the a_w of mixed aqueous solutions near, at, or beyond saturation is required for the prediction of ternary solubility diagrams from binary data.

It has been noted (1, 2) that supersaturated binary data are often necessary for the computation of a_w of mixed concentrated ternary or more complex solutions from binary data. In the case of electrolytes the computation of the ternary a_w from binary data can, in principle, be made accurately via the full Reilly–Wood–Robinson (3), RWR, equation; this requires binary and extensive ternary common-ion a_w values at the ionic strength of the mixed concentrated solution. In the absence of such ternary data, coarser but still useful estimates can be made using only binary a_w data and either the first approximation to the RWR equation or its other approximate forms (4). In either situation it is necessary to estimate the a_w or φ (osmotic coefficient) values of binary aqueous solutions at the ionic strength of the mixed solution. This latter value may itself be higher than that of the binary at saturation, thus leading to a need for binary supersaturated a_w values.

The prediction of the a_w of mixed concentrated aqueous solutions containing nonelectrolytes or electrolytes and nonelectrolytes can be done in general by the Zdanovskii–Stokes–Robinson (5), ZSR, equation. In this case it is necessary to know the molality m of a binary aqueous solution at the a_w of the mixed solution, which is often less than the a_w of the binary at saturation. Again this calls for binary supersaturated a_w values.

Empirical and semiempirical methods of estimating supersaturated binary a_w values have been recently reviewed (2); the authors concluded that

For personal use only.

the safest way of obtaining such values was to use the ZSR equation in reverse on ternary data. In this paper we shall show that reverse RWR is equally applicable, and we shall use both methods on various ternary data to obtain self-consistent estimates of supersaturated a_w values for binary aqueous solutions of NaCl, KCl, and K_2SO_4 up to twice their molality at saturation.

Reverse Application of the Reilly–Wood–Robinson Equation to Ternary Data

This will be illustrated by the calculation of supersaturated a_w values for aqueous NaCl by the reverse application of the RWR[1] equation to the ternary data for $LaCl_3$–NaCl in water (6).

Consider the three aqueous solutions shown in Fig. 1. Then, in the RWR nomenclature (3), for the common-ion mixture:

$$1 - \varphi_{mix} = -\frac{1}{mE}\left[\frac{(Z_{Na}m_{Na})(-Z_{Cl}m_{Cl})(Z_{Na} - Z_{Cl})(1 - \varphi^0_{NaCl})}{Z_{Na}Z_{Cl}} + \frac{(Z_{La}m_{La})(-Z_{Cl}m_{Cl})(Z_{La} - Z_{Cl})(1 - \varphi^0_{LaCl_3})}{Z_{La}Z_{Cl}}\right]$$

where $$E = \sum_{\text{cations}} (Zm) = Z_{Na}m_{Na} + Z_{La}m_{La} = m_{Na} + 3m_{La}$$

and $$m = \sum_{\text{anions+cations}} m_i = m_{Cl} + m_{Na} + m_{La}$$

thus

[1] $$1 - \varphi_{mix} = \frac{1}{m(m_{Na} + 3m_{La})}[2m_{Na}m_{Cl}(1 - \varphi^0_{NaCl}) + 4m_{La}m_{Cl}(1 - \varphi^0_{LaCl_3})]$$

and

$$1 - \varphi^0_{NaCl} = \frac{1}{2m_{Na}m_{Cl}}[m(m_{Na} + 3m_{La})(1 - \varphi_{mix}) - 4m_{La}m_{Cl}(1 - \varphi^0_{LaCl_3})]$$

but

$$m_{Na} = m_1, \quad m_{La} = m_2, \quad m_{Cl} = m_1 + 3m_2, \quad \text{and} \quad m = 2m_1 + 4m_2$$

also

$$\varphi^0_{NaCl} = -\frac{\ln a^0_{w(NaCl)}}{2(m_{NaCl})_I \times 0.018}$$

$$\varphi^0_{LaCl_3} = -\frac{\ln a^0_{w(LaCl_3)}}{4(m_{LaCl_3})_I \times 0.018}$$

$$\varphi_{mix} = -\frac{\ln a_{w(mix)}}{(2m_1 + 4m_2) \times 0.018}$$

If $$A \equiv \frac{1}{2m_1(m_1 + 3m_2)}\left[m(m_1 + 3m_2)\left\{1 + \frac{\ln a_{w(mix)}}{0.018(2m_1 + 4m_2)}\right\} - 4m_2(m_1 + 3m_2)\left\{1 + \frac{\ln a^0_{w(LaCl_3)}}{4(m_{LaCl_3})_I 0.018}\right\}\right]$$

then

[2] $$a^0_{w(NaCl)} = e^{\{(A-1)2(m_{NaCl})_I 0.018\}}$$

which constitutes the reverse RWR equation.

[1]The relation used here is the first approximation (3) to the full RWR expression; it is not possible to use the full expression to compute a_w or φ for a common-ion system unless a full set of ternary data is available. In this case the following aqueous ternary systems: NaCl–LaX_3 or NaX–$LaCl_3$, NaCl–NaX, NaX–LaX_3, $LaCl_3$–LaX_3 (where X is a suitable anion), as well as all the individual binary aqueous data, would be necessary to compute NaCl–$LaCl_3$.

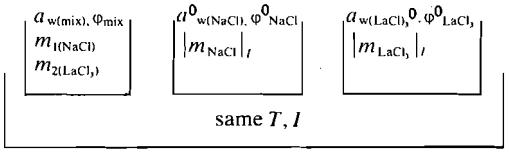

FIG. 1. Binary solutions of aqueous NaCl and $LaCl_3$ at the same temperature and ionic strength as a ternary aqueous system containing both NaCl and $LaCl_3$.

At 25 °C the saturation molality of aqueous NaCl is 6.0 m = ionic strength, I; the ternary data of Kirgintsev and Luk'yanov (6) at $I < 6.0$ for aqueous NaCl–$LaCl_3$ are shown in Table 1 together with values calculated by the RWR first approximation, [1]. Comparison of the a_w values in Table 1 shows that the RWR first approximation gives very good predictive results in this case, and that there is consequently no need to make an empirical correction analogous to the Kirgintsev–Luk'yanov (7) b for ZSR deviations. Indeed $LaCl_3$–NaCl (aqueous) is a type 'A' system (5) with a very small value of b.

It would thus appear reasonable to assume that there is no sudden departure in applicability of [1], and hence of [2], as the ionic strength passes from below to above 6 m, the saturation value for aqueous NaCl. (Tran and Lenzi (2) have shown that there is no essential change in character of the a_w *vs.* molality plots as saturation is reached and passed.) The ternary data (6) at $I > 6$ have been collected in Table 2, together with binary supersaturated values of $a_{w(NaCl)}$ calculated by [2]. These values are plotted in Fig. 2. It can be observed that all the values of $a^{obs}_{w(mix)}$ lie above the value of $a^{sat}_{w(NaCl)} = 0.76$, thus making the reverse application of ZSR impossible in this case.

Other Ternary Data Involving NaCl

For aqueous NaCl at 25 °C, $a^{sat}_{w(NaCl)} = 0.76$, $m^{sat}_{(NaCl)} = 6.0$; thus reverse RWR will only apply to ternary data whose $I_{mix} > 6.0$ m, while

TABLE 1. Ternary data for aqueous NaCl–$LaCl_3$ (6) at 25 °C for $I_{mix} < 6.0$ m

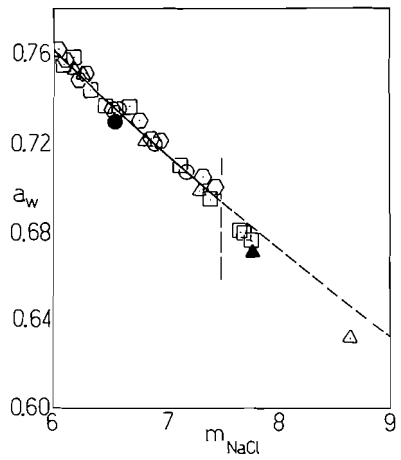

FIG. 2. Supersaturated binary aqueous values of a_w for NaCl: △, data from $LaCl_3$/NaCl; ○, data from LiCl/NaCl; ●, data from Na_2SO_4/NaCl; ▲, data from $MgSO_4$/NaCl; □, data from $MgCl_2$/NaCl; ◇, data from $MnCl_2$/NaCl; —, polynomial from [4]; ---, curvilinear extrapolation ([4*a*]).

reverse ZSR will only be of interest when $a_{w(mix)} < 0.76$. In each case the procedure followed is similar to that shown above for NaCl–$LaCl_3$ for reverse RWR or to that already given (1) for reverse ZSR. Ternary data below $I_{mix} = 6.0$ m or above $a_{w(mix)} = 0.76$ are examined and compared with a_w values calculated either by the RWR first approximation or the uncorrected form of the ZSR equation. Should there be good agreement, as is shown in Table 1 in the case of NaCl–$LaCl_3$, then the uncorrected RWR first approximation (or the uncorrected ZSR equation) is used to compute supersaturated a_w values. Otherwise an empirical correction term of the 'b' (7) type is fitted to the unsaturated $a_{w(mix)}$ data either as a constant 'b' independent of a_w, or, if necessary, as a simple function of a_w, such as $b = b_0 + b_1 a_w$, as previously suggested (1).

In case of appreciable deviations of the ternary data from the RWR first approximation at $I_{mix} < I^{sat}$ of the solute of interest, it has been found[2] that at roughly constant ionic fraction of one solute, the departures from the RWR first approximation can be expressed by

$$[3] \quad \frac{1}{0.018 \sum_j \nu_j m_j} \ln \frac{a_w^{obs}}{a_w^{cal}} = c_0 + c_1 a_w^{obs}$$

*ZSR corrections obtained by using a Kirgintsev–Luk'yanov b correction of the form (1) $b = b_0 + b_1 a_w$ while RWR corrections obtained via [3].

where a_w^{cal} = water-activity calculated by the RWR first approximation. Provided suitable $I_{mix} < I^{sat}$ ternary data are available to determine c_0 and c_1, the values of $a_w^{supersat}$ can be obtained by the use of [2] and [3]. Examples of the results of such a procedure are given in Table 3 for NaCl (as well as in Tables 4 and 5 for KCl and K_2SO_4).

The supersaturated points for $a_{w(NaCl)}$ from Tables 2 and 3 are plotted in Fig. 2. In general the results for six different ternaries using both reverse methods show fair agreement. The agreement is satisfactory up to 7.5 m, beyond which there is some spread in the results. A polynomial (8) to give a minimum standard deviation has been fitted to the unsaturated a_w–molality data (9, 10) and the 26 supersaturated points obtained

here to 7.5 m:

$$[4] \qquad a_{w(NaCl)} = 1 + \sum_1^5 A_i' m^i$$

with $A_1' = -3.13449 \times 10^{-2}$, $A_2' = -2.22625 \times 10^{-3}$, $A_3' = 6.28750 \times 10^{-4}$, $A_4' = -1.52868 \times 10^{-4}$, $A_5' = 1.16207 \times 10^{-5}$, and $\sigma = 0.00134$ where σ is the standard deviation of the fit. The range for supersaturated values can be further extended by means of the curvilinear extrapolation (2) recently proposed to $m = 11.0$ $m \approx 1.5 \times 7.5$ m. The final polynomial thus obtained to $a_w = 0.5422$, $m_{NaCl} = 11.0$ is given by

$$[4a] \qquad a_{w(NaCl)} = 1 + \sum_1^{10} A_i m^i$$

with $A_1 = -3.28806 \times 10^{-2}$, $A_2 = 1.12512 \times 10^{-4}$, $A_3 = -4.30034 \times 10^{-4}$, $A_4 = 2.70506 \times 10^{-5}$, $A_5 = 1.43435 \times 10^{-6}$, $A_6 = 1.30209 \times 10^{-7}$, $A_7 = -1.51941 \times 10^{-8}$, $A_8 = 1.00520 \times 10^{-9}$, $A_9 = -4.21593 \times 10^{-10}$, $A_{10} = 2.62532 \times 10^{-11}$, $\sigma = 0.00012$, and is shown in Fig. 2.

Ternary Data Involving KCl

For aqueous KCl at 25 °C, $a_{w(KCl)}^{sat} = 0.8426$, $m_{KCl}^{sat} = 4.8$. Table 4 lists the ternary systems used to obtain supersaturated data by both reverse methods. It was found[3] that differences between the ZSR equation and the observed (11) NaCl–KCl data were corrected better by a Kirgintsev–Luk'yanov (7) correction $b' = b_0' + b_1' I$ rather than by the more usual (1) $b = b_0 + b_1 a_w$ correction term. The supersaturated a_w values for KCl from Table 4, together with directly-obtained (12) supersaturated values are plotted in Fig. 3. Except for two of the four RWR $NaNO_3$–KCl points and the two NaCl–KCl points, there is good overall agreement between the nineteen calculated and the two experimental supersaturated values. The $NaKCl_2$ complex formation noted by Stearn (13) may account for the $NaNO_3$–KCl and NaCl–KCl deviations.

A polynomial (8) has been fitted to the unsaturated a_w–molality data and to the 19 corroborated points to $m_{KCl} = 6.0$ m:

$$[5] \qquad a_{w(KCl)} = 1 + \sum_1^4 B_i' m^i$$

with $B_1' = -3.22956 \times 10^{-2}$, $B_2' = 8.25683 \times 10^{-4}$, $B_3' = -3.67164 \times 10^{-4}$, $B_4' = 3.83407 \times$

1.80	0.9421*
2.00	0.9361*
2.20	0.9031*

*Calculated from [6*a*].

The results for all three salts are summarized in Tables 6 and 7 which list supersaturated a_w values at rounded values of the molality for the three salts calculated via [4], [4*a*], [5], [5*a*], and [6], [6*a*].

The generally good agreement obtained for different ternaries by both reverse methods confirms the validity of the approach. The errant points obtained for KCl from $NaNO_3$–KCl and NaCl–KCl show the need for using as many different ternary systems as possible.

The Bioorganic Chemistry of *N*-Allyl and *N*-Propargyl Substituents in Drug Interactions with Flavin-linked Oxidases

J.-L. KRAUS[1] AND B. BELLEAU

Department of Chemistry, McGill University, Montreal, Quebec H3C 3G1

Received May 12, 1975

J.-L. KRAUS and B. BELLEAU. Can. J. Chem. **53**, 3141 (1975).

Attention is focused on recent mechanistic proposals concerning the unique inhibitory properties of *N*-propargyl substituents toward flavin-linked oxidases. Model studies with sarcosine oxidase have revealed that the enzyme displays absolute substrate specificity. Unexpectedly however, substitution of the *N*-methyl group of the substrate by the *N*-allyl or *N*-propargyl functions led to a time-dependent irreversible inactivation of the enzyme. The rate of inactivation by these substrate analogs was markedly retarded by deuterium substitution in the methylene group of the allyl and propargyl functions. It is concluded, mainly on that basis, that *N*-allyl and *N*-propargyl glycine are inhibitory substrates for the enzyme, alkylating species being generated at the active site level of the enzyme. The implications of these findings in the mechanism of action of medicinally important drugs are briefly mentioned.

J.-L. KRAUS et B. BELLEAU. Can. J. Chem. **53**, 3141 (1975).

Le mécanisme de l'action inhibitrice unique du substituent *N*-propargyle au niveau des oxydases du type flavine est soumis à l'étude. A l'aide du système modèle sarcosine oxydase, il a été établie que l'enzyme possède une spécificité absolue pour son substrat. Cependant, la substitution du *N*-méthyle de la glycine par un *N*-allyle ou *N*-propargyle conduit à une inhibition irreversible qui apparait graduellement. La vitesse d'inactivation par ces deux analogues est fortement retardée par la substitution des hydrogènes du groupement méthylène de l'allyle et du propargyle par le deutérium. Ceci conduit à la conclusion que ces deux analogues du substrat se comportent comme des substrats 'inhibiteurs' de l'enzyme, des intermédiaires à propriétés alkylantes étant générés au niveau du centre actif. Les implications de ces résultats dans le mécanisme d'action de drogues d'une importance thérapeutique sont brièvement discutées.

Recently much interest has been focused on the rational chemical development of specific active site-directed irreversible inhibitors of enzymes using as a basis the latter's potential ability to generate catalytically from suitable substrate analogs highly reactive intermediate species capable of covalent bond formation with an active site nucleophile (1, 2). Of fundamental relevance to medicinal chemistry is the recent discovery that various drugs incorporating a favorably disposed acetylenic function can behave as specific 'irreversible inhibiting substrates' (or k_{cat} inhibitors (2)) for certain flavin-linked oxidases such as monoamine-oxidase (MAO) (2) and bacterial lactate oxidase and dehydrogenase (3). Other interesting examples of inhibitory substrates for pyridoxal and nicotinamide adenine dinucleotide-linked enzymes have been reviewed and discussed by Rando (2). For the medicinally important case of acetylenic amines of the Parglyine class of drugs, the enzymatically catalyzed formation of a reactive allene intermediate is thought to be involved in the inactivation reaction of the MAO active site (2). However, no evidence is available for this mechanism. Very recently, bioorganic model studies with 3-methyl lumiflavin led to the elucidation of the structure of an adduct with 3-dimethylamino-1-propyne. It was shown that covalent bond formation between N-5 of the cofactor and C-1 of the inhibitor (4) is involved. The relevance of these observations to MAO inactivation by Pargyline remains to be determined. The fact that oxidative *N*-dealkylations and especially *N*-demethylations play an important role in drug activation and inactivation *in vivo* led us to ask the following questions. (*a*) Is the concept of inhibitory sub-

[1]Holder of a France–Quebec Exchange Programme Fellowship. Present address: Department of Chemistry, Université de Bretagne Occidentale, Brest, France.

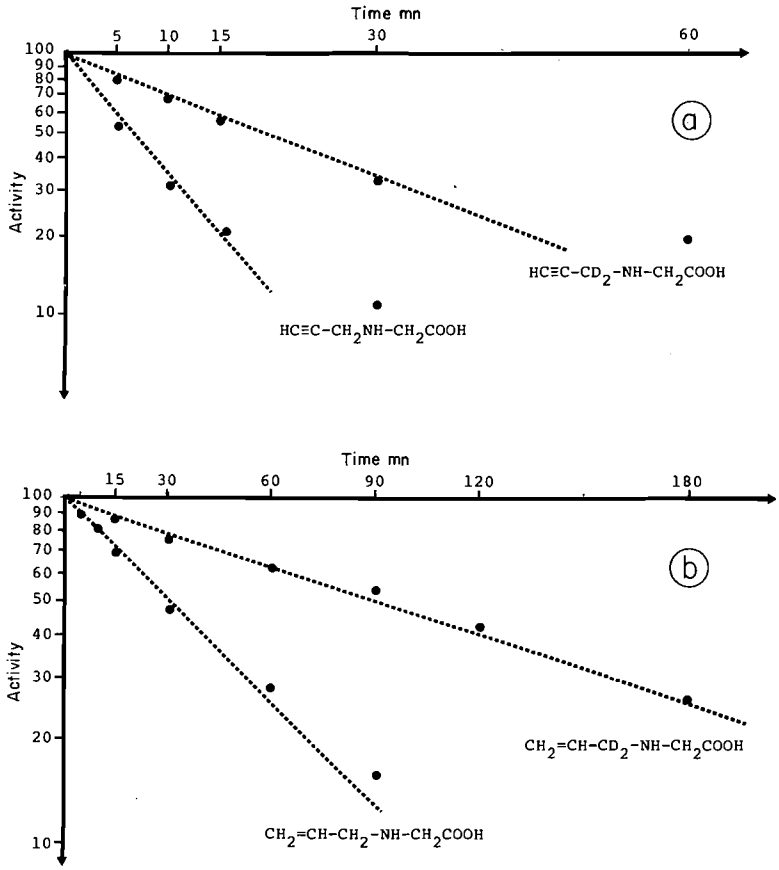

FIG. 1. Percentage inhibition of rat liver sarcosine oxidase *vs.* pre-incubation time with 10 μmoles of irreversible inhibitors in a total volume of 2.4 ml of suspension containing mitochondria from 0.5 g of rat liver (5, 6) in 0.075 *M* phosphate buffer (0.1 m*M* in Mg^{+2}), p*H* 7.8 at 37 °C. Residual enzyme activity was evaluated by measuring formaldehyde production from sarcosine according to the literature (5, 6). (*a*) Pseudo first-order kinetics of inhibition by the *N*-propargyl glycines ($r = 0.998$ and 0.973); rate ratio $k_H/k_D = 2.0$. (*b*) Pseudo first-order kinetics of inhibitors by the *N*-allyl glycines ($r = 0.985$ and 0.998); rate ratio $k_H/k_D = 2.3$. The fall-off in rates after 80–90% inhibition by the propargyl glycines (Fig. 1*a*) indicates that secondary reactions may occur in the late stages. This is not the case with the *N*-allyl analogs.

strates applicable to other flavin-linked oxidases including substrate specific *N*-demethylases? (*b*) Is the proposed mechanism of enzyme inactivation by acetylenic amines generally correct and of predictive value in drug design? The present communication is to offer preliminary answers to these questions. For our purposes, we selected the well-known flavin-linked enzyme sarcosine oxidase which demethylates the specific substrate sarcosine to glycine (5, 6) and submitted it to the action of candidate inhibitory substrates.

Rat liver sarcosine oxidase was isolated and assayed as described in the literature (5, 6). Using conventional literature methods (7), the following *N*-substituted glycines were prepared: ethyl (8), m.p. 175 °C; *n*-propyl (9), m.p. 195 °C; *n*-butyl (10), m.p. 192 °C; allyl (11, 12), m.p. 121 °C; propargyl, m.p. 162 °C; cyclopropylmethyl, m.p. 185 °C; benzyl, m.p. 182 °C. The synthesis of *N*-(α,α-dideuterioallyl)glycine and *N*-(α,α-dideuteriopropargyl)glycine (**1** and **2** respectively) was accomplished by the same

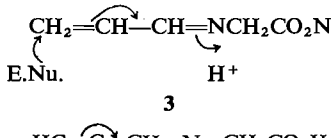
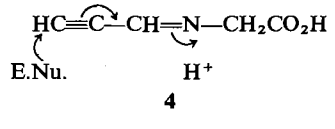
amines which in turn were prepared as follows: the anthracene adduct with acrylonitrile (13) was reduced to the amine with excess $LiAlD_4$ followed by retro-Diels–Alder to α,α-dideuterioallyl amine (14) (>98% labelled). Reduction of propiolonitrile (15) with $LiAlD_4$ in the presence of magnesium bromide (16) gave α,α-dideuteriopropargyl amine (>98% labelled) in 20–25% yield. The rate of enzyme inactivation was followed by assaying for residual sarcosine oxidase activity as a function of time. All incubations were carried out at 37 °C at p*H* 7.8 in phosphate buffer as previously described (5, 6). The results were as follows: none of the simple alkyl analogs of sarcosine acted as substrates or inhibitors (up to 10^{-2} *M*) of the enzyme. However, both the *N*-allyl and *N*-propargyl analogs at 10^{-4} to 10^{-3} *M* caused gradual irreversible inhibition of the enzyme (no activity recovered after dialysis at 0 °C for 24 h against 0.075 *M* phosphate buffer, p*H* 7.8). The time-course of these inhibitory reactions is shown in Figs. 1*a* and *b* where it can be seen that α,α-dideuteration of the allyl and propargyl group decreased the rate of inhibition by factors of 2.3 and 2.0 respectively. Clearly then, a rate-limiting abstraction of an α-hydrogen from the allyl or propargyl group conditions the appearance of irreversible inhibition, thus establishing that the enzyme generates reactive alkylating species leading to covalent bond formation with the active site. An attractive mechanism for these reactions is illustrated in **3** and **4**. Alternatively, intermediates **3** and **4** may generate acrolein and propargyl-



3



4

aldehyde at the active site followed by alkylation of a proximal nucleophile. Experiments are under way which should allow a choice between these two possibilities. The mechanistic significance of similar primary deuterium isotope effects on the rates of inhibition was discussed previously (17, 18). As expected, the competitive inhibitor methoxyacetate (6) was markedly effective in retarding the inactivation reaction. On that basis, we conclude that *N*-allyl and *N*-propargyl glycine behave as inhibitory substrates for the substrate binding site of sarcosine oxidase. While the results are not inconsistent with the formation of an intermediate allene in the inhibitory action of the *N*-propargyl derivative (2), the fact that the *N-allyl analog can hardly give rise to such an intermediate* strongly favors the alternative mechanism illustrated in **3** and **4**. Interestingly, the *N*-cyclopropylmethyl glycine analog behaved only as a weak reversible inhibitor ($K_1 \simeq 10^{-2}$ *M*) of the enzyme. One may recall that this *N*-substituent confers highly effective antagonistic properties to a variety of opiate-like structures (19). These observations bring to light a previously unsuspected specific equivalence of a substrate *N*-methyl group and *N*-allyl or *N*-propargyl functions as regards *productive* binding on a flavin-linked enzyme. The implications of these findings in medicinal chemistry and especially drug design deserve further investigation.[2]

We are grateful to the National Research Council of Canada for the financial support of this work.

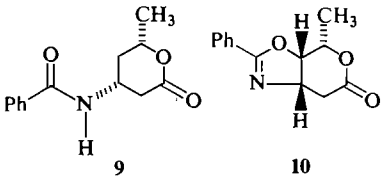
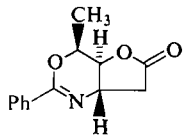
m); *m/e* 226 (M^+)) was obtained by cyanide displacement in a sealed tube employing liquid hydrogen cyanide as a cosolvent (KCN:HCN–Et_2O, 75 °C, 36 h). Reaction of **6** with hydrogen chloride-saturated methanol gave the methyl ester **7** (ν_{CO} 1740 and 1680 cm^{-1}; δ 2.57 (3H, s) 3.75 (3H, s), 4.5 (2H, s), 7.3–7.6 (3H, m), and 7.9–8.2 (2H, m); *m/e* 259 (M^+)) which was hydrolyzed to the carboxylic acid **8** (m.p. 194 °C dec.; ν_{CO} 1725 and 1683 cm^{-1}) by HCl in aqueous HOAc at ambient temperature. This acid underwent decarboxylation readily on heating to regenerate the oxazole **4**, therefore it must be handled with care. Treatment of **8** with thionyl chloride in anhydrous chloroform afforded the desired oxazolo-α-pyrone (m.p. 185–187 °C dec.; ν 1740 and 1690 cm^{-1}; δ 2.517 (3H, d, J = 0.8 Hz) and 6.158 (1H, q, J = 0.8 Hz); *m/e* 227 (M^+)).

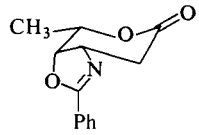


9 **10**

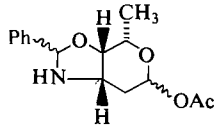


11

Attempts at hydrogenating **3** using Adams catalyst in ethyl acetate resulted in the generation of the benzamide **9** (ν_{CO} 1730 and 1670 cm^{-1}) and its hexahydro derivative. Hydrogenolysis could be avoided when the reduction was carried out with 5% Rh/Al_2O_3 as catalyst. The product retained a C=N bond and its structure **10** was supported by spectral data, especially its mass spectrum. It was thermodynamically unstable, and was converted upon heating into a γ-lactone **11** (ν_{CO} 1760 cm^{-1}). This facile transformation suggested that **10** indeed possesses an all *cis* stereochemistry whose preferred conformation is **10***a* with the oxygen atom of the oxazoline ring assuming an axial orientation, whereas both the nitrogen and the methyl group are equatorial. In view of the occurrence of this rearrangement,



10*a*



12

the lactone carbonyl was reduced by sodium di(2-methoxyethoxy) aluminum hydride to the lactol and then acetylated [Ac_2O-pyr]. Further hydrogenation (5% Rh/Al_2O_3 in EtOAc) of this lactol acetate gave compound **12**. The benzylidene group was removed by acid treatment and the crude product was reacetylated to yield the triacetyl derivatives. Preparative t.l.c. on silica gel permitted the isolation of triacetyldaunosamine. Identification of this final product was by spectral comparison (i.r., m.s.) with a sample derived from natural sources.

Borohydride reduction of the ketoester **8** afforded lactone **13** which could be a useful synthetic intermediate of ristosamine **14** (7). All new compounds gave satisfactory analysis or exact mass molecular ions.

The Radical Ion $S_3N_2^+$. Preparation, Electron Spin Resonance Spectrum, and Crystal Structure of Thiodithiazyl Hexafluoroarsenate $S_3N_2^+AsF_6^-$

R. J. GILLESPIE, P. R. IRELAND, AND J. E. VEKRIS

Department of Chemistry, McMaster University, Hamilton, Ontario, L8S 4M1

Received April 29, 1975

R. J. GILLESPIE, P. R. IRELAND, and J. E. VEKRIS. Can. J. Chem. **53**, 3147 (1975).

The compound $S_3N_2^+AsF_6^-$ has been prepared by the reaction of S_4N_4 with AsF_5. The crystal structure has been determined from three-dimensional X-ray counter data. Crystals are monoclinic, space group $P2_1/c$ with $a = 8.499(4)$, $b = 8.298(4)$, $c = 11.069(8)$, $\beta = 94.59(5)$, $V = 778.1$ Å^3, $Z = 4$, and $D_c = 2.67$ g cm^{-3}. The structure was solved by Patterson methods and refined to a conventional R factor of 0.028 for 798 independent reflections with $I \geqslant 3\sigma(I)$. The structure consists of discrete AsF_6^- ions and planar cyclic $S_3N_2^+$ ions. Solutions of $S_3N_2^+AsF_6^-$ in methylene chloride gave a five-line electron spin resonance spectrum with an intensity ratio of 1:2:3:2:1 showing that the unpaired electron in $S_3N_2^+$ is coupled to two equivalent nitrogen atoms in full accord with the results of the crystal structure determination.

R. J. GILLESPIE, P. R. IRELAND et J. E. VEKRIS. Can. J. Chem. **53**, 3147 (1975).

Le composé $S_3N_2^+AsF_6^-$ a été préparé par la réaction de S_4N_4 avec AsF_5. La structure du cristal de ce composé a été déterminée par un compteur de données de rayons-X à trois dimensions. Les cristaux sont monocliniques, groupe d'espace $P2_1/c$ avec $a = 8.499(4)$, $b = 8.298(4)$, $c = 11.069(8)$, $\beta = 94.59(5)$, $V = 778.1$ Å^3, $Z = 4$ et $D_c = 2.67$ g cm^{-3}. La structure a été résolue par la méthode de Patterson et raffinée jusqu'à un facteur conventionnel final R de 0.028 pour 798 réflexions indépendantes avec $I \geqslant 3\sigma(I)$. La structure consiste en cations planaires cycliques $S_3N_2^+$ et en anions AsF_6^- discrets. Des solutions dans du chlorure de méthylène ont donné un spectre de résonance paramagnétique électronique montrant cinq bandes avec un rapport d'intensités de 1:2:3:2:1 ce qui indique que l'électron apparié de $S_3N_2^+$ est couplé avec deux atomes d'azote qui sont équivalents comme le montrent les résultats de la détermination de la structure cristalline.

[Traduit par le journal]

Introduction

Although tetrasulfur tetranitride was first prepared in 1835 (1) many aspects of its chemistry are still far from well understood. Several investigators have reported the formation of a sulfur–nitrogen radical in freshly prepared solutions of S_4N_4 in concentrated sulfuric acid but this radical has never been identified with certainty. Chapman and Massey (2) observed a five-line e.s.r. spectrum from a solution of S_4N_4 in concentrated sulfuric acid which they attributed to a radical containing two equivalent nitrogen atoms and which they supposed to be SN_2^+. Later Symons and his co-workers (3) observed the same e.s.r. spectrum from solutions of S_4N_4 in both SbF_5 and sulfuric acid and on the basis of spin density calculations concluded that the radical could not be SN_2^+ but was more probably $S_2N_2^+$ with a square planar structure analogous to that of the neutral molecule S_2N_2 (4). Further studies of the e.s.r. spectrum of solutions of S_4N_4 in 100% H_2SO_4 were made by Jolly and co-workers (5) who found in agreement with the earlier workers that the radical had $g =$

For personal use only.

2.011 and a hyperfine coupling constant of 3.21 G. In order to establish the number of sulfur atoms in the radical they also made measurements using S_4N_4 enriched in ^{33}S. They found that they could simulate the complicated spectrum that they obtained by assuming that the radical contained two equivalent sulfur atoms, but they could not exclude the possibility that the radical might also contain other nonequivalent sulfur atoms or even oxygen.

We have shown recently (6) that elemental sulfur is oxidized by various oxidizing agents including sulfuric acid, oleum, AsF_5, and SbF_5 to the polyatomic cations S_{16}^{2+}, S_8^{2+}, and S_4^{2+} and it seemed reasonable to suppose that the oxidation of S_4N_4 by sulfuric acid or by SbF_5 might be a similar process and that we might be able to establish the nature of the products by the same methods as we had used previously. We have also found that similar cationic species can be made from selenium and tellurium (6) and that a useful general reaction for the preparation of such species is reaction of the neutral molecule with a solution of AsF_5 in SO_2. We show in this paper that the reaction of AsF_5 with S_4N_4 in solution in SO_2 leads to the formation of $S_3N_2^+AsF_6^-$ and we describe the determination of the structure by X-ray crystallography and also some e.s.r. studies.

Experimental Section

Preparation of $S_3N_2^+AsF_6^-$

In a typical preparation AsF_5 (3.62 mmol) was condensed onto a frozen solution of S_4N_4 (1.206 mmol) in sulfur dioxide at −196 °C. The mixture was allowed to warm slowly to room temperature and stirred for 24 h. A clear red solution was obtained as the reaction mixture warmed up to room temperature and no further changes were observed during the next 24 h. On slow evaporation of the volatile materials, *i.e.*, the solvent sulfur dioxide, excess arsenic pentafluoride and arsenic trifluoride produced in the reaction, deep red-brown, almost black, crystals were obtained together with a light brown microcrystalline powder, which was not identified. Suitable crystals for X-ray crystallographic work were selected in a dry box equipped with a microscope and were then sealed in thin-walled quartz capillaries.

Crystal Data

$S_3N_2^+AsF_6^-$ f.w. = 313.10

Monoclinic, $a = 8.499(4)$, $b = 8.298(4)$, $c = 11.069(8)$ Å, $\beta = 94.59(5)°$, $V = 778.1$ Å^3, $Z = 4$, $D_c = 2.67$ g cm^{-3}. No experimental density was obtained because of the sensitivity of the compound to moisture. Single crystal precession photographs revealed the systematic absences: $h0l$, $l = 2n + 1$; $0k0$, $k = 2n + 1$. These unambiguously indicated the space group $P2_1/c$, No. 14 in the *International Tables for X-ray Crystallography* (7).

X-Ray Measurements

A small, poorly formed, but approximately spherical crystal (radius 0.1 mm) was mounted on a Syntex P$\bar{1}$ diffractometer. Intensities were measured with graphite monochromated MoK_α radiation ($\lambda = 0.71069$ Å). Accurate cell parameters were obtained from a least squares refinement using 12 high angle reflections in the region $20 < 2\theta < 30°$. Intensity data were collected at room temperature (20 °C) by the θ–2θ scan technique, with scan rates varying from 2.0 to 24.0 deg min^{-1} (in 2θ) so that the weaker reflections were examined more slowly to minimize counting errors. Stationary background counts with a time equal to half the scan time for each reflection were made at each end of the scan range. The scan width varied from 2° at low 2θ to 2.5° for the higher angle data. Two standards were regularly checked to monitor the stability of the crystal and its alignment, but no significant time dependent trends were observed. Reflections with a unique quadrant with $2\theta < 55°$ were measured resulting in 798 reflections with intensities greater than three times their standard deviation based on counting statistics. The linear absorption coefficient for the material is 54.4 cm^{-1} for the MoK_α radiation used, with $\mu R = 0.5$. Absorption effects were therefore negligible, and no absorption corrections were applied. Lorentz and polarization corrections were applied to the observed data.

Solution and Refinement of the Structure

The positions of the heavy As atoms were readily located from inspection of the three dimensional Patterson function. Least squares refinement of positional and isotropic temperature parameters for this atom gave a conventional agreement index R_1, ($R_1 = \Sigma\Delta/\Sigma|F_o|$ where $\Delta = ||F_o| - |F_c||$), of 0.39. A difference Fourier synthesis revealed the positions of the 11 remaining atoms. Full matrix refinement of positional and anisotropic temperature factors for all atoms converged at $R_1 = 0.028$, while the weighted agreement index R_2, ($R_2 = (\Sigma w\Delta^2/\Sigma wF_o)^{1/2}$) was 0.031 with unit weights. An examination of the data showed that $\Sigma w\Delta^2$ was approximately independent of $|F_o|$ and $(\sin\theta)/\lambda$ with unit weights, so no weighting scheme was considered necessary. The largest shift of any parameter divided by its estimated standard deviation was 0.2 in the final refinement cycle. The top three peaks in a final difference Fourier, (0.3–0.5 e/Å^3) were all within 1.0 Å of the AsF_6^- ion which had been refined with highly anisotropic thermal parameters. No systematic trends indicating the need for an extinction correction were evident in the data.

Atomic scattering factors for arsenic, sulfur, fluorine, and nitrogen atoms with anomalous dispersion corrections for the arsenic atom were taken from ref. 8. All calculations were performed on a CDC 6400 computer using the series programs in the X-ray 71 system (9) and our own programs. The final atomic positional coordinates and temperature factors are presented in Table 1. A tabulation of observed and calculated structure factors is available.[1]

Electron Spin Resonance Measurements

Spectra were obtained with a JEOLCO Model JES

*x, y, and z are atomic coordinates expressed as fractions of the cell edges. The form of the anisotropic thermal ellipsoid is: $[\exp -2\pi^2(h^2a^{*2}U_{11} + \ldots + 2hka^*b^*U_{12} + \ldots)]$. Least-squares-estimated standard errors in the least significant digits are given in parentheses.

3B5-X spectrometer and g values were obtained by comparison with the third and fourth lines of the spectrum of a trace manganous ion contained in solid SrO.

Materials

A sample of tetrasulfur tetranitride[2] had been prepared and purified by the method described by Becke-Goehring (10). Arsenic pentafluoride (Ozark-Mahoning) was used without purification, its purity having been checked by gas-phase infrared spectroscopy. Sulfur dioxide (Matheson) and methylene chloride (Fisher) were repeatedly distilled from, and kept over, phosphoric oxide before they were used.

Discussion

Figure 1 shows the atom labelling, thermal ellipsoids, and the important bond lengths in the $S_3N_2^+$ cation, while Table 2 gives a more complete list of intermolecular and intramolecular distances and angles. The packing of the ions in the unit cell is shown in Fig. 2. It is clear that the compound $S_3N_2^+AsF_6^+$ consists of discrete $S_3N_2^+$ and AsF_6^- ions, the former being a planar five-membered ring and the AsF_6^- ion being octahedral. The average As—F distance in AsF_6^- is 1.69 Å. The $S_3N_2^+$ cation is unusual in that it is a stable radical ion and is the only known sulfur–nitrogen radical that has been obtained as a stable crystalline salt. It is the second example of a five-membered S–N ring, the other being the closely related $S_3N_2Cl^+$ ion (11).

The average S—N bond length in the $S_3N_2^+$ ion is 1.58 Å. This is comparable to the average S—N distance in other S–N ring compounds, *e.g.*, $S_4N_3^+$ 1.55 Å (12), $S_3N_2Cl^+$ 1.59 Å (11), $S_3N_3Cl_3$ 1.61 Å (13), and S_4N_4 1.62 Å (14) and is much shorter than the value of 1.74 Å calculated for an S—N single bond from Paulings covalent radii. Two compounds in which the S—N bonds seem very likely to be single bonds are $S_4N_4H_4$ (15) and $NH_3SO_3^-$ (16) where the bond distances are respectively 1.67 and 1.73 Å. Thus it may be concluded that the S—N bonds in $S_3N_2^+$ have considerable double-bond character. The S—S bond has a length of 2.15 Å which is very similar to that found for the unique S—S bond in $S_3N_2Cl^+$ (2.14 Å) (11) and slightly longer than that in $S_4N_3^+$ (2.06 Å) (12) and in the S_8 molecule (2.04 Å) (16). It seems reasonable to suppose, therefore, that the S—S bond in $S_3N_2^+$ may be regarded as a single bond. As an isolated $S_3N_2^+$ ion would be expected to have C_{2v} symmetry the different lengths of the S(3)N(2) and S(2)N(1) and of the S(1)N(2) and S(1)N(1) bonds may be due to experimental error or to distortion of the ion in the crystal. However, the average S(1)N(1), S(1)N(2) and S(2)N(1), S(3)-N(2) bond lengths of 1.56 and 1.60 Å respectively would appear to be significantly different. Indeed this difference can be predicted on the basis of simple valence-bond structures. If it is assumed that structures in which there is more than one charged atom and/or an S—S double bond are relatively unimportant and may be ignored, there is a total of nine possible structures, *a* to *e* in Fig. 3 where *a*, *b*, *c*, and *d* each represent two structures as a consequence of the presumed C_2 axis. Assuming that each of these structures has equal weight leads to a bond order of 1.66 for the S(1)N(1) bond and of 1.44 for the S(2)N(1) bond. These bond orders are consistent with our

conclusion that the S(1)N(1) bonds are shorter than the S(2)N(1) bonds.

It is interesting to compare the geometry of $S_3N_2^+$ with that of $S_3N_2Cl^+$. The latter is slightly puckered but nevertheless the bond angles in the two rings are very similar as are the bond distances. Using the same criteria as above only three reasonable valence-bond structures can be written for $S_3N_2Cl^+$ (*f*, *g*, and *h*, Fig. 3). These simple structures predict bond orders of 1.66 for the S(3)N(2) and S(1)N(1) bonds and 1.33 for the S(1)N(2) and S(2)N(1) bonds. As may be seen from Table 3 these bond orders are quite consistent with the observed bond lengths for $S_3N_2Cl^+$ and they are also consistent with the bond orders and bond lengths for $S_3N_2^+$ and with a bond order of 1.5 for $S_3N_3Cl_3$ which has six equal S—N bond lengths (13).

A solution of $S_3N_2^+AsF_6^-$ in methylene chloride gave a five-line e.s.r. spectrum with intensity ratios of 1:2:3:2:1, $g = 2.01$, and a hyperfine coupling constant of 3.15 G. This is clearly the same spectrum obtained by Jolly and co-workers (5) and other workers (2, 3) from

TABLE 3. Bond lengths and bond orders for some SN bonds*

Bond	Order	Length (Å)
$\overset{+}{N}H_3SO_3^-$	1.0	1.73
$S_4N_4H_4$	1.0	1.67
$S_3N_2Cl^+$	1.33	1.62
$S_3N_2^+$	1.44	1.61
$S_3N_3Cl_3$	1.5	1.605
$S_3N_2Cl^+$	1.66	1.56†
$S_3N_2^+$	1.66	1.56‡
SN	2.5	1.49§
NSF	3.0	1.45‖
NSF_3	3.0	1.42¶

*The bond orders quoted here have been obtained as indicated in the text. SN is assumed to have a bond order of 2.5 and N≡S—F and N≡SF_3 are assumed to have bond orders of 3.0. These bond order values are somewhat lower than those given recently by Nyburg (18), as he takes the bond order in SN^+ (1.25 Å) to be 3.0. In the present authors' opinion this bond length is anomalously short; perhaps because of the positive charge and we believe that the bond lengths in NSF and NSF_3 correspond more closely to a bond order of 3.0.

†Mean of the observed distances of 1.54 and 1.58 Å.

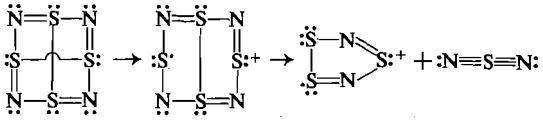
solutions of S_4N_4 in sulfuric acid and by Symons and co-workers (3) from a solution of S_4N_4 in SbF_5. It would appear that $S_3N_2^+$ is an important initial product of the reaction of S_4N_4 with sulfuric acid but it is unstable in this medium and appears to undergo oxidation to other as yet unidentified species.

The five-line e.s.r. spectrum is due to coupling of the odd electron with the two equivalent nitrogen atoms and this is consistent with the structures in Fig. 3, particularly with the two structures *c* in which the unpaired electron is on the two equivalent nitrogen atoms. These structures predict spin densities of 0.33 on each of the equivalent sulfur atoms, of 0.11 on each of the nitrogen atoms, and of 0.11 on the nonequivalent sulfur atom.

The mechanism of the reaction by which S_4N_4 is oxidized to $S_3N_2^+$ by AsF_5 is not entirely clear at the present time as the other products of the reaction were not identified. However, as S_8 is oxidized initially by AsF_5 to S_8^+ (6) it seems reasonable to suppose that the first step of the oxidation is the loss of one electron to give $S_4N_4^+$ with the consequent rupturing of one of the weak S—S bonds followed by fission of the molecule, as follows



NOTE ADDED IN PROOF:

Since submitting this paper for publication we have become aware of a recent determination of the crystal structure of the closely related compound $S_6N_4^{2+}(S_2O_6Cl^-)_2$ (22). The cation consists of two symmetry related planar S_3N_2 rings held together by two long SS bonds (3.027 Å). The dimensions of the rings S(1)N(1) 1.57 Å, S(2)N(1) 1.60 Å, ∠NSS 97°, ∠SNS 119°, ∠NSN 108°, are almost identical with those listed in Table 2.

The Formation and Reactions of Disulfide Radical Anions in Aqueous Solution

TZU-LIN TUNG[1] AND JOHN A. STONE
Chemistry Department, Queen's University, Kingston, Ontario K7L 3N6
Received May 28, 1975

TZU-LIN TUNG and JOHN A. STONE. Can. J. Chem. **53**, 3153 (1975).

Transient disulfide radical anions have been produced by flash photolysis. Cyclic anions decay only by second order reaction as opposed to the first order decay found for linear ones at low concentration. Linear disulfides, except oxidized penicillamine, increase the rate of decay of the cystine radical anion. The p*H* dependence of the reaction with cystine suggests that the disulfide radical anion is an electrophile.

TZU-LIN TUNG et JOHN A. STONE. Can. J. Chem. **53**, 3153 (1975).

Faisant appel à la photolyse flash, on a produit, à l'état transitoire, les radicaux anions du disulfure. Les anions cycliques ne se décomposent que par une réaction du deuxième ordre alors que les anions linéaires se décomposent, à basse concentration, par une réaction du premier ordre. Les disulfures linéaires, à l'exception de la penicillamine oxydée, augmentent le taux de décomposition du radical anion de la cystine. Le fait que la réaction avec la cystine dépend du p*H* indique que le radical anion du disulfure est un électrophile.

Introduction

The lifetimes of disulfide radical anions ($RSSR^-$) are increased in the presence of sulfhydryl compounds (1, 2). By studying the flash photolysis and pulse radiolysis of aqueous solutions of cysteine we showed that this increased lifetime was due to a complex mode of decay (3). Our postulated reaction scheme is shown by [1] to [6] in which CyS· represents the cysteinyl group and Cy· the alanyl radical.

[1] $$CyS^- + h\nu \rightarrow CyS\cdot + e_{aq}^-$$

[2] $$e_{aq}^- + CySH \rightarrow Cy\cdot + SH^-$$

[3] $$Cy\cdot + CySH \rightarrow CyH + CyS\cdot$$

[4] $$CyS\cdot + CyS^- \rightleftharpoons CySSCy^-$$

[5] $$CyS\cdot + CySSCy^- \rightarrow \text{Products}$$

[6] $$H_2O + CySSCy^- \rightarrow CyH + CySS\cdot + OH^-$$

In the presence of excess cysteine the equilibrium 4 supercedes the usual fast, first order decay observed following electron capture by a disulfide (2).

[7] $$CySSCy^- \rightarrow CyS\cdot + CyS^-$$

The mode of decay then depends on concentration. At disulfide radical anion concentrations greater than $\sim 10^{-6}$ *M* a second order p*H* dependent decay occurs (reaction 5) while at concentrations less than 6×10^{-7} *M* there is a p*H* independent, first order decay (reaction 6). Similar first order decays have also been observed in the pulse radiolysis of penicillamine (4) and in the flash photolysis of 2-mercaptoethanol and benzenethiol (5).

Since the participation of disulfides in reactions leading to radiation protection of biological materials has been suggested (6) a knowledge of the properties of these radical anions is required. We here report studies of their decay in the presence and absence of disulfides of differing structure and also studies of the decay of cyclic disulfide radical anions which may be representative of bridge disulfide linkages which are important in biological systems.

Experimental

The flash photolysis and pulse radiolysis procedures have been described (3). The optical absorptions due to disulfide radical anions were usually followed at 410 nm. All solutions were deoxygenated by bubbling with oxygen free nitrogen.

Results and Discussion

The Decay of Cyclic Disulfide Radical Anions

Flash photolysis of aqueous solutions of lipoic acid ($\overline{CH_2CH_2S—SCH(CH_2)_4COOH}$) or of any of the other disulfides studied did not yield observable transients in the region 370–500 nm. A

[1]Present address: University of California, Berkeley, California 94720.

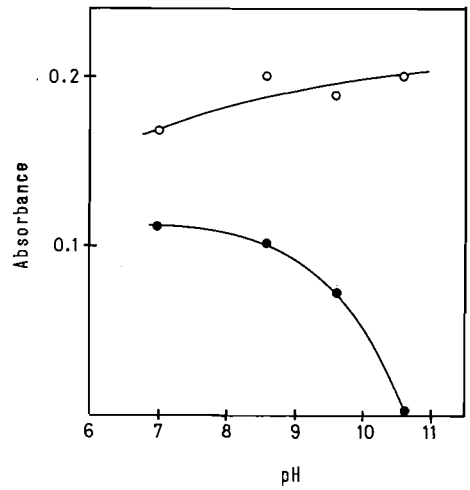

FIG. 1. Initial absorbance at 410 nm for a solution 1.0×10^{-3} *M* in cysteine; ●, no lipoic acid; ○, 5×10^{-4} *M* lipoic acid.

transient absorption was observed for solutions 5×10^{-4} *M* in lipoic acid and 1×10^{-3} *M* in cysteine at p*H* values in the range 7–10.6. At p*H* 7 the decay of the absorbance at 410 nm showed two components (*a*) at times below 1 ms an approximately first order decay ($k \sim 1.6 \times 10^3$ s^{-1}) attributable to the decay of $CySSCy^-$ while above 1 ms the decay became second order ($k \sim 2 \times 10^8$ M^{-1} s^{-1}) which is consistent with the second order decay of the disulfide radical anion formed from lipoic acid ($k = 1.4 \times 10^8$ M^{-1} s^{-1} (2)). With increasing p*H* the first order decay became less marked, consistent with the reported decreasing yield of $CySSCy^-$ (3). At p*H* 10.6 an almost pure second order decay was observed ($k = 2.5 \times 10^8$ M^{-1} s^{-1}). Figure 1 shows the initial yield of the transient at 410 nm together with the absorbance at this same wavelength obtained for the same flash intensity but in the absence of lipoic acid. This result is consistent with flash photolysis producing solvated electrons from CyS^- (reaction 1) which are then scavenged by lipoic acid. Electron transfer from $CySSCy^-$ to lipoic acid might also account for these results. However production of $CySSCy^-$ by pulse radiolysis of an N_2O saturated solution 1×10^{-3} *M* in cysteine and 1×10^{-5} *M* in lipoic acid at p*H* 9.6 when $CySSCy^-$ alone is formed initially showed only the first order decay of $CySSCy^-$ with no evidence of a longer lived transient that could have been formed by electron transfer from $CySSCy^-$ to lipoic acid.

In summary the above results show that the disulfide radical anion formed at low concentration from lipoic acid does not exhibit the slow first order decay found for linear disulfide radical anions and electron transfer from $CySSCy^-$ to lipoic acid does not occur to any measurable extent ($k < 10^7$ M^{-1} s^{-1}).

The absorption spectrum of the cyclic transient obtained by flash photolysis of dithiothreitol ($HSCH_2CH(OH)CH(OH)CH_2SH$) at p*H* 7 is identical in the region above 350 nm with that obtained by pulse radiolysis (7). The transient decays by a pure second order process independent of dithiothreitol concentration with a rate constant of $2k = 4.1 \times 10^8$ and 3×10^8 M^{-1} s^{-1} at p*H* 8.7 and 10 respectively (literature values 6.0×10^8 M^{-1} s^{-1} at p*H* 7 (7) and $\sim 1.7 \times 10^8$ M^{-1} s^{-1} at p*H* 7–10 (8)). There is no evidence for a change to first order decay at radical ion concentrations as low as 8×10^{-8} *M*.

Small cyclic disulfide radical anions are therefore different in their decay behavior than the linear ones. The reaction equivalent to [5] is not readily available to these species since the close proximity of the RS· and RS^- groups ensures an extremely low concentration of RS· radicals. The nonoccurrence of the first order reaction, thought to involve the solvent (reaction 6), must be due to steric limitations imposed by the small size ring. Such effects may also play a part in the radiation chemistry of biological molecules containing disulfide bridges especially those shielded from the aqueous environment. If neither the second order nor the first order decay is open to the relatively immobile disulfide radical anion formed by the addition of an electron then they will be very long lived. Klassen *et al.* (9) have observed a very slow first order decay ($k \sim 600$ s^{-1}) of the disulfide radical anions formed in the pulse radiolysis of the large ring disulfides oxytocin and lysine vasopressin. These may be examples of behavior intermediate between those of linear and small ring disulfide radical anions.

The Reaction of the Cystine Radical Anion with Disulfides

Flash photolysis of aqueous cysteine solutions in the presence of cystine under conditions where only the first order decay of the radical anion occurs produced $CySSCy^-$ in exactly the same yield as in the absence of disulfide. This is as expected since the electron formed in reaction 1 can also be scavenged by cystine ($k \sim 10^{10}$ M^{-1}

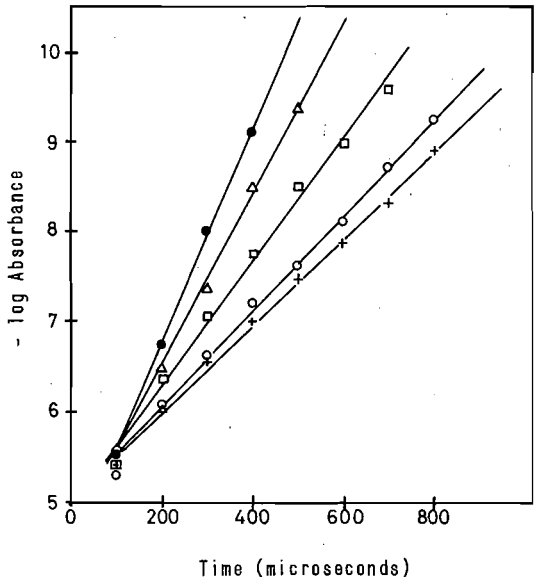

FIG. 2. The decay of $CySSCy^-$ in the presence of cystine at pH 7. Cystine concentrations: +, 0; ○, 2×10^{-4} M; □, 4×10^{-4} M; △, 6×10^{-4} M; ●, 10×10^{-4} M. Cysteine 1.0×10^{-3} M.

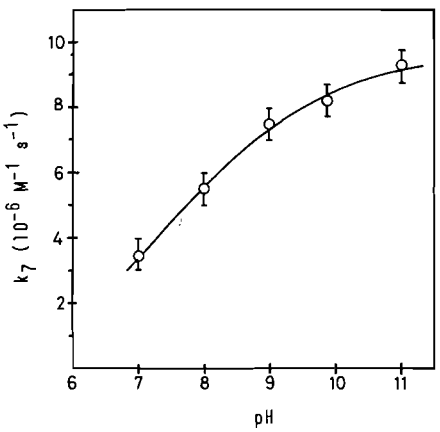

FIG. 3. The rate constant for the reaction of $CySSCy^-$ and cystine as a function of pH.

s^{-1} (2)). The fast first order decay of the resulting $CySSCy^-$ ($k \sim 3 \times 10^5$ M^{-1} s^{-1} (2)) will bring $CySSCy^-$, CyS·, and CyS^- into equilibrium within the time of first measurement (~50 μs from the commencement of the 30 μs flash). Afterwards the decay of $CySSCy^-$ still remains first order but the rate constant k_{obs} now depends on the cystine concentration

$$k_{obs} = k_7[CySSCy] + k_6$$

where k_6, the rate constant for reaction 6, is practically independent of pH (3). The value for k_{obs} obtained from the first order plots shown in Fig. 2 yields $k_7 = 3.4 \times 10^6$ M^{-1} s^{-1} at pH 7. The pH dependence of k_7 is shown in Fig. 3. Direct involvement of $CySSCy^-$ and not the CyS· radical is indicated since an increase in cysteine concentration from 1 to 3×10^{-3} M has no effect on k_7 whereas if the radical were a reactant k_7 would be proportional to $1/[CyS^-]$. Electron transfer from disulfide radical anion to disulfide cannot be a factor since such a reaction would leave the system unchanged.

Since the observed reaction apparently does not involve electron transfer from the anion the increase in k_7 with pH (Fig. 3) can be associated with the increasing ionization of cystine (pK_a = 7.85 (10)). The disulfide radical anion shows behavior similar to other radical anions *e.g.* $(CNS)_2^-$, Br_2^-, Cl_2^-, and I_2^- which are electrophilic, reacting at a greater rate as the degree of ionization of the added solute increases (11). By analogy a suggested mechanism for the reaction is electron transfer from the disulfide to the radical anion followed by hydrolysis of the resulting disulfide cation.

[8] $CySSCy^- + RSSR \rightarrow 2CyS^- + RSSR^+$

[9] $RSSR^+ + H_2O \rightarrow$ Products

An attempt was made to study the effects of other disulfides on the decay of $CySSCy^-$. Solutions containing 1.0×10^{-3} M cysteine together with one of the disulfides oxidized glutathione, oxidized penicillamine, dithiodipropionic acid, and cystamine were flash photolyzed. In all cases there was a decrease in the yield of the transient absorbing at 410 nm which was roughly linear with disulfide concentration. The decrease was greatest for dithiodipropionic acid and least for cystamine as shown in Fig. 4. It was ascertained that there was no decrease in total thiol concentration in these systems. The time between initial mixing of thiol and disulfide in the aqueous solution and photolysis was at least 15 min and in this time there will probably have been almost complete randomization of RS groups between thiol and disulfide (12, 13). The maximum absorbance of the transient remained at or near 410 nm in all cases as might be expected even for mixed disulfide radical anions since the absorbances of most disulfide radical anions maximize close to this wavelength (2). The decreases

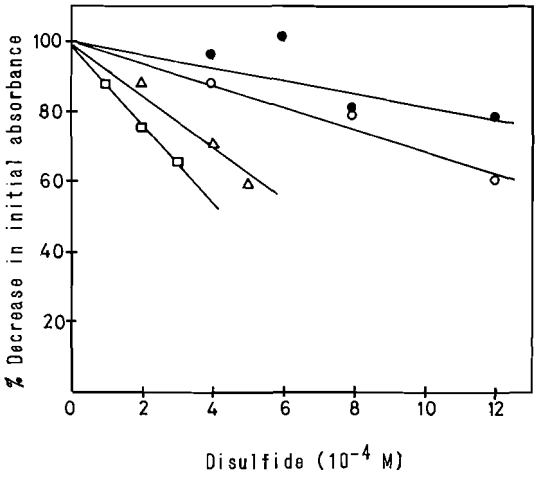

FIG. 4. The decreases in the initial absorbances at 410 nm for 1.0×10^{-3} *M* cysteine solutions containing: ●, cystamine; ○, oxidized penicillamine; △, 3,3′-dithiodipropionic acid; □, oxidized glutathione.

in yields of transients can be attributed to one or both of two factors: (*a*) A difference in the number of thiyl radicals formed by the flash. For example at p*H* 8.7 there is more cysteine in the form of the anion CyS^- than there is glutathione in the form of the anion GS^- (14). (*b*) The equilibrium analogous to 4 for the mixture will probably be different than that for cysteine alone. For example the equilibrium constant for penicillamine (4) is an order of magnitude less than that for cysteine (2).

Just as with the cysteine/cystine system the decay rate of the 410 nm transient is increased with increasing disulfide concentration (Table 1). Because of exchange the form of the disulfides is not known but at low concentrations of added disulfide the mixed disulfide or cystine should predominate. The increased decay rate bears no relation to the decrease in maximum absorbance at 410 nm and the enhanced decay must be attributed to a reaction of disulfide radical anion with disulfide. The only linear disulfide for which enhanced decay is not observed is penicillamine which is consistent with the suggested electron transfer reaction (8) since the methyl groups of penicillamine in either the disulfide or the disulfide radical anion would sterically hinder electron transfer.

TABLE 1. Rate constants (k_7) for the reactions of disulfides with $CySSCy^-$

Disulfide	p*H*	k_7 (M^{-1} s^{-1})
Oxidized glutathione	7	4.3×10^6
	8.7	13.4×10^6
Cystamine	8.7	5.7×10^5
3,3′-Dithiodipropionic acid	8.7	3.1×10^6
Oxidized penicillamine	8.7	$< 10^5$
Cystine	7	3.4×10^6
	8.7	7.5×10^6

Flash Photolysis in the Presence of Alcohols

It has been shown on numerous occasions that sulfhydryl compounds are able to 'repair' the radicals formed by H abstraction from alcohols by OH radicals (4, 14). For example with methanol the following sequence is suggested to occur

$$OH\cdot + CH_3OH \rightarrow H_2O + \cdot CH_2OH$$

$$\cdot CH_2OH + RSH \rightarrow CH_3OH + RS\cdot$$

Dixon and Grant (15) studied the photolysis of aqueous alcoholic solutions of cystine in quartz cells and attributed the increasing yields of cysteine with increasing alcohol concentration to scavenging of CyS· radicals by the alcohol which would "otherwise undergo pair wise combination in the solvent cage". If such scavenging can occur then flash photolysis of alcoholic cysteine solutions should lead to no increase in the absorbance of the transient at 410 nm but might indeed lead to a decrease together with an increased rate of decay. For 1 *M* isopropanol there is actually an increase of ~10% in transient yield. We suggest that the explanation is that flash photolysis of alcoholic solutions of thiols and disulfides produces radicals in addition to thiyl radicals, in particular H atoms (16, 17) which will lead to cysteine production when scavenged by cystine.

In alcoholic solution the first order decay rate of the $CySSCy^-$ transient decreases, being 1.5×10^3 and 1.3×10^3 s^{-1} in 1 and 9 *M* *tert*-butyl alcohol respectively compared with 2.0×10^3 in nonalcoholic solution. The decay is not pure first order above a concentration of 3×10^{-7} *M*, *i.e.* about one-half that in aqueous solution. Both these observations are in line with decay via reactions 4 and 6.

Réactivité de la combinaison anthracène–lithium vis-à-vis des nitriles[1]

JEAN-PAUL MAZALEYRAT

Groupe de Recherche n° 12, C.N.R.S., 2 à 8 rue Henri Dunant, 94320 Thiais, France

Reçu le 28 février 1975

JEAN-PAUL MAZALEYRAT. Can. J. Chem. **53**, 3158 (1975).

L'anthracène–lithium en solution éthérée se comporte comme un réactif basique vis à vis des nitriles possédant un hydrogène acide. Mais dans le cas des nitriles à C_α tertiaire, deux réactions compétitives peuvent avoir lieu: l'addition nucléophile et le transfert d'électron. L'addition nucléophile est la réaction la plus rapide, mais à cause de sa réversibilité, le mélange réactionnel évolue par le processus de transfert d'électron, suivi de la coupure irréversible de la liaison C—CN, vers la formation d'un alcoyl-9 dihydro-9,10 anthracène.

JEAN-PAUL MAZALEYRAT. Can. J. Chem. **53**, 3158 (1975).

Lithium anthracenylide in ethereal solution behaves as a basic reagent towards nitriles with acidic hydrogens. However, in the case of nitriles with a tertiary α-carbon atom, two competitive reactions may occur: nucleophilic attack and electron transfer. The nucleophilic addition is faster, but because of its reversibility, the reaction proceeds, through the electron transfer process which is followed by the irreversible breaking of the C—CN bond, towards the formation of 9-alkyl-9,10-dihydroanthracene.

Introduction

Il est connu que la coupure C—CN des nitriles peut être réalisée par les métaux alcalins au sein de différents solvants. C'est le cas, par exemple, pour le sodium dans l'éthanol, qui donne deux réactions compétitives; la réduction du groupement CN, conduisant à une amine, et l'élimination réductrice du CN, conduisant à un hydrocarbure (1).

$$\text{R—CN} \xrightarrow[\text{(éthanol)}]{\text{Na}} \begin{matrix}\text{RH + NaCN}\\ \text{RCH}_2\text{NH}_2\end{matrix}$$

L'utilisation de l'hexamethylphosphorotriamide (HMPT) comme solvant, a permis récemment d'orienter ces réductions vers la formation sélective de l'hydrocarbure RH (2).

La liaison C—CN des nitriles (3, 4), de même que celle des α-aminonitriles (5, 6), est également coupée par les métaux dissous dans l'ammoniac liquide. Dans les deux cas, un mécanisme en plusieurs étapes impliquant un transfert d'électron, a été proposé (3, 6) (schéma 1).

$$[1]\quad \text{R—CN} + \text{NH}_3\,\dot{}\,\text{M}^+ \rightarrow \text{R—CN}\,\dot{}\,\text{M}^+ + \text{NH}_3$$

$$[2]\quad \text{R—CN}\,\dot{}\,\text{M}^+ \rightarrow \text{R}\cdot + \text{CN}^-\text{M}^+$$

$$[3]\quad \text{R}\cdot + \text{NH}_3\,\dot{}\,\text{M}^+ \rightarrow \text{R}^-\text{M}^+ + \text{NH}_3$$

$$[4]\quad \text{R}^-\text{M}^+ + \text{NH}_3 \rightarrow \text{RH} + \text{NH}_2^-\text{M}^+$$

[1]Ce travail fait partie de la Thèse de Doctorat d'Etat de J. P. Mazaleyrat, enregistrée au C.N.R.S. sous le N° AO 7747.

a R = —C(|)— *b* R = —C(|)—N(/ \)

SCHÉMA 1

Lorsque les électrons sont fournis, non plus par un métal alcalin, mais par voie électrochimique, les nitriles subissent également la coupure C—CN (7).

Ainsi, dans deux types de réactions où le milieu est susceptible de fournir des électrons solvatés, le groupement CN se comporte comme un pseudo-halogène, et les nitriles subissent une hydrogenolyse de la même façon que les halogénures.

Or, il est connu que les combinaisons métaux alcalins – hydrocarbures aromatiques constituent également une source d'électrons, et en particulier, qu'elles sont susceptibles de substituer l'halogène des halogénures d'alcoyle, par un mécanisme tout à fait comparable au précédent (8) (schéma 2*a*).

$$[5]\quad \text{A}\,\dot{}\,\text{M}^+ + \text{RX} \rightarrow \text{R}\cdot + \text{MX} + \text{A}$$

$$[6]\quad \text{R}\cdot + \text{A}\,\dot{}\,\text{M}^+ \rightarrow \text{AR}^-\text{M}^+$$

$$[7]\quad \text{AR}^-\text{M}^+ \xrightarrow{\text{SH}} \text{ARH} + \text{MS (ou MOH)}\ \text{(ou } \text{H}_2\text{O)}$$

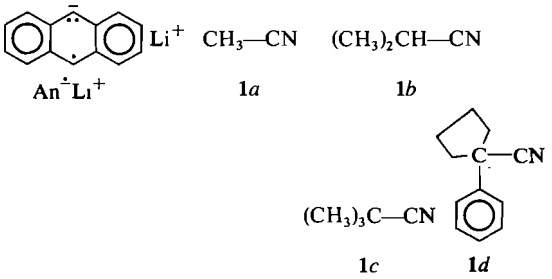

FIG. 1. Les composés **1***a*, **1***b*, **1***c* et **1***d*.

Par conséquent, puisque le groupement nitrile peut, au même titre qu'un halogène, être éliminé par coupure hydrogénolytique au moyen des métaux alcalins ou par voie électrochimique, il y a lieu de supposer qu'il puisse l'être également par les combinaisons métaux alcalins – hydrocarbures aromatiques.

Dans le cas des α-aminonitriles, il se produit effectivement une réaction d'aminoalcoylation de l'hydrocarbure aromatique (9), dont le mécanisme est comparable à celui qui a lieu avec les halogénures[2] (schéma 2*b*). Mais on peut penser toutefois que les α-aminonitriles constituent un cas particulier dans lequel la possibilité de coupure C—CN peut être due à la stabilité du radical aminoalcoyle $-\dot{C}-N\diagup\diagdown$ formé au cours de l'étape 5.

Pour savoir ce qu'il en était dans le cas des nitriles ordinaires, nous avons recherché les produits formés dans la réaction de la combinaison anthracène–lithium $An^{\cdot-}Li^+$, avec les composés **1***a*, **1***b*, **1***c* et **1***d* (fig. 1).

Résultats

Les réactions ont été effectuées en additionnant les différents nitriles à une solution de radicaux anions anthracène–lithium préparée dans l'éther par action directe du lithium sur l'anthracène. Les rendements en chacun des composés obtenus après hydrolyse, ont été déterminés soit directement par pesée, soit par chromatographie en phase gazeuse, au moyen d'étalons internes.

[2]Une différence entre le cas des halogénures et celui des α-aminonitriles est que pour ces derniers, il y a formation intermédiaire d'un radical anion aminonitrile $RCN^{\cdot-}M^+$ (9), qui se coupe dans une étape ultérieure, alors que pour les halogénures, le radical anion $RX^{\cdot-}M^+$ n'étant certainement pas suffisamment stable pour constituer un intermédiaire (10), le transfert d'électron doit être accompagné de la coupure R—X.

Les résultats montrent que lorsque le nitrile est énolisable (composés **1***a* et **1***b*), il se produit seulement une réaction d'arrachement de l'hydrogène acide (conduisant à la formation ultérieure de dihydro-9,10 anthracène), ce qui n'est pas étonnant car il est connu que les combinaisons métaux alcalins – hydrocarbures aromatiques sont des entités basiques qui réagissent sur l'eau (11), mais qui sont également susceptibles d'arracher tout proton suffisamment mobile situé en α d'un groupement attracteur CO (12) ou CN (13).

Avec le pivalonitrile **1***c* (tableau 1), nous obtenons, au bout de 20 h d'agitation, et après hydrolyse acide prolongée, le *tert*-butyl-9 dihydro-9,10 anthracène **2***c* résultant de la coupure, avec un très faible rendement, l'essentiel du nitrile de départ étant récupéré. A côté de cet hydrocarbure, nous obtenons une cétone **4***c* qui provient de l'imine **3***c*. La proportion hydrocarbure **2***c* – cétone **4***c* est d'environ 1:2 (14).

Avec le phényl-1 cyclopentane nitrile **1***d*, nous constatons qu'après un temps de réaction voisin, le rendement en hydrocarbure **2** est très nettement supérieur à celui obtenu avec le pivalonitrile et qu'il ne se forme pas d'imine **3***d*. Par contre, si nous hydrolysons le mélange réactionnel dès la fin de l'addition du nitrile, les proportions sont complètement changées: l'imine **3***d* est obtenue avec un bon rendement, tandis que l'hydrocarbure **2***d* n'est présent qu'à l'état de traces. Une étude approximative par c.p.g. de l'évolution des produits confirme que l'imine **3***d*, formée quasi immédiatement, voit sa concentration diminuer au cours du temps, tandis que la concentration en **2***d* augmente parallèlement.

Enfin, lorsque l'imine **3***d* est mise dans les conditions réactionnelles, en présence d'un gros excès de combinaison anthracène–lithium, elle disparait totalement après 17 h d'agitation, pour donner naissance à l'hydrocarbure **2***d*, accompagné d'une faible proportion de nitrile **1***d*.

Identification. Données de résonance magnétique nucléaire

Les structures des composés ont été établies de la manière habituelle (voir Partie Expérimentale), et, dans ce qui suit, nous discuterons seulement le spectre de r.m.n. du composé **2***d*, lequel est très différent des spectres habituels des dihydro-9,10 anthracènes monosubstitués en position 9. En effet, ces derniers présentent généralement aux alentours de δ 4 p.p.m., un

FIG. 2. La conformation proposée pour le composé **2***d*.

TABLEAU 2. Déplacements chimiques (en p.p.m. par rapport au TMS) des protons H_A, H_B et H_M (fig. 2)

Composés	δ H_M	δ H_A	δ H_B	J_{AB} (Hz)
4*c*	5.47	4.74	3.74	18
3*d*	4.82	4.35	3.68	18
2*c*	3.55	4.15	3.58	19
2*d*	4.08	1.85	3.12	19

quadruplet caractéristique du système AB constitué par les deux protons en position 10, dont la constante de couplage se situe toujours aux environs de 18–20 Hz (15), et dont les signaux relatifs au proton le plus déblindé sont élargis (16). En outre, le groupement substituant R adoptant préférentiellement la position quasi-axiale ou *perp* (fig. 2), il est connu que le doublet 'élargi' apparaissant au champ le plus faible, correspond au proton H_A *perp*, et que le doublet 'fin' apparaissant au champ le plus fort, correspond au proton H_B *lin* (15, 16).

Les valeurs de déplacement chimique relatives aux protons H_A et H_B, des composés **4***c*, **3***d*, et **2***c* (tableau 2), reflètent bien la situation attendue. Cependant, dans le cas du composé **2***d*, nous constatons que l'un des deux doublets relatifs aux hydrogènes en position 10 apparait à un champ très élevé tout à fait inhabituel (1.85 p.p.m.), à tel point qu'il se trouve noyé dans le massif correspondant aux protons du groupement cyclopentyle. Le second doublet apparait également à un champ relativement élevé (3.12 p.p.m.).

Ce résultat peut s'interpréter en envisageant, pour le composé **2***d*, l'existence d'une conformation privilégiée dans laquelle le groupement phényle est axé vers l'intérieur du cycle central dihydroanthracénique (fig. 2). Dans cette géométrie en effet, nous constatons que les protons H_A et H_B se trouvent tous deux dans la partie blindante du cône d'anisotropie du phényle, ce qui explique que leurs signaux soient déplacés vers les champs forts. Cependant, le proton H_A *perp* se trouvant très proche du phényle, doit subir un effet de blindage beaucoup plus intense que le proton H_B *lin*: nous pensons donc que le doublet à 3.12 p.p.m. correspond au proton H_B, la règle générale "proton *perp* à champ plus faible que proton *lin*" se trouvant ici mise en

SCHÉMA 3

défaut pour la première fois à notre connaissance.[3]

Discussion

Il est connu que les combinaisons métaux alcalins – hydrocarbures aromatiques peuvent se comporter de différentes manières: ce sont comme nous l'avons vu des réactifs basiques, mais aussi à la fois des agents de transfert d'électron et des agents nucléophiles (8, 17). Les produits obtenus lors de l'action du radical anion anthracène–lithium sur les nitriles représentent une illustration de ces trois modes de réactivité; il se forme en effet trois types de composés: le dihydro-9,10 anthracène, un hydrocarbure **2** et une imine **3** (ou la cétone correspondante).

Mécanisme de formation de l'hydrocarbure 2

La formation de l'hydrocarbure **2** implique une rupture de liaison C—CN. Par analogie avec le cas des halogénures (8), ou des α-aminonitriles (9), il est permis de penser que cette rupture ne devient possible qu'après apport préalable d'un électron, fourni par le radical anion anthracène–lithium $An^{\cdot-}Li^+$, et conduisant à un radical anion nitrile. Ce dernier peut alors conduire, par

[3]Ainsi que le suggère l'un des rapporteurs, que nous remercions, l'effet Overhauser observé lors de l'irradiation des protons des noyaux phényle du groupement dihydro-9,10-anthryle, doit être plus important pour le signal relatif au proton H_B que pour le signal relatif au proton H_A (15). Cependant, cette étude comparative n'est possible que si les signaux en question sont bien isolés dans le spectre, et ce n'est malheureusement pas le cas pour le doublet attribué au proton H_A, qui se trouve noyé dans un massif. Pour le moment donc, notre attribution du signal à champ fort pour le proton H_A, et du signal à champ faible pour le proton H_B, résulte d'une interprétation qui nous parait raisonnable, mais souffre de l'absence de preuve ferme.

départ de LiCN, à un radical R$^{\bullet}$, lequel se recombine avec un second radical anion $An^{\dot{-}}Li^{+}$, pour donner un organométallique **B** précurseur de l'hydrocarbure **2** (schéma 3; voie *b*).

Ainsi que nous l'avons souligné précédemment, ce mécanisme est tout à fait comparable au mécanisme de la réduction de ces mêmes nitriles par les métaux dissous ou par électrolyse, le radical anion $An^{\dot{-}}Li^{+}$ jouant le rôle d'une cathode. La seule différence est que, après formation du radical R$^{\bullet}$, la réaction évolue vers un organométallique **B**, au lieu d'évoluer vers un anion R^{-} comme dans le cas de la réduction (schéma 1). Cela est certainement dû au fait que l'hydrocarbure aromatique utilisé est l'anthracène, lequel possède une grande affinité électronique (10), ce qui explique que le radical anion $An^{\dot{-}}Li^{+}$ préfère capter le radical R$^{\cdot}$ et son électron, plutôt que de lui céder un deuxième électron.

Mécanisme de formation de l'imine 3

La formation de l'imine **3** est une illustration du comportement nucléophile du radical anion anthracène–lithium, lequel s'additionne sur le carbone électrophile du groupement —C≡N de la même façon qu'il s'additionne sur les cétones (18) ou sur le CO_2 (19). Le mécanisme généralement admis de ces réactions d'addition nucléophile (17, 20), implique la formation d'un dianion **D** qui se protonne lors de l'hydrolyse du mélange réactionnel pour conduire au composé **3** (schéma 3; voie *a*).

Signification des résultats

La nature des produits formés dans les différents cas étudiés permet d'avoir une idée de la façon dont le radical anion anthracène–lithium fait son choix parmi les possibilités de réaction énumérées précédemment.

Dans le cas d'un nitrile tertiaire, où la réaction d'énolisation (schéma 3; voie *c*) ne peut avoir lieu, les résultats montrent qu'il n'y a pas réellement compétition entre la réaction de coupure conduisant, par l'intermédiaire d'un radical R$^{\bullet}$, à l'organométallique **B** (schéma 3; voie *b*), et la réaction d'addition nucléophile conduisant au dianion **D** (voie *a*).

Cette dernière est en effet beaucoup plus rapide puisque lorsque nous hydrolysons le mélange réactionnel seulement 3 min après l'addition du nitrile **1***d*, nous obtenons l'imine **3***d* avec un bon rendement (66%), alors que l'hydrocarbure **2***d* n'est présent qu'à l'état de traces (3%). La formation ultérieure de l'hydrocarbure, au détriment de l'imine, ne peut alors s'expliquer que par une réversibilité de la voie *a*, alimentant le milieu en radicaux anions $An^{\dot{-}}Li^{+}$ et en nitrile, et permettant ainsi à la réaction irréversible de coupure C—CN (voie *b*) de se produire. Cette réversibilité de la voie *a* peut être attribuée à la formation d'un intermédiaire dianionique **D**, dont l'énergie doit être relativement élevée.

Quant à la vitesse de formation, de l'hydrocarbure **2**, elle dépend de la vitesse de coupure C—CN, laquelle est liée à la stabilité du radical R$^{\bullet}$. Lorsque R$^{\bullet}$ est un radical *tert*-butyle, le composé **2***c* est formé en 20 h avec un rendement de 5%, alors que dans le cas du nitrile **1***d*, où le radical R$^{\bullet}$ doit être particulièrement stable, l'électron célibataire se trouvant en α d'un groupement phényle et sur un cyclopentane (9), le composé **2***d* est formé en 17 h avec un rendement de 78%.

Le fait que l'imine **3***d* placée dans un excès de combinaison anthracène–lithium, conduise à la formation de **2***d*, peut constituer une preuve de la réversibilité de la voie *a*, bien qu'il soit possible d'envisager aussi la formation intermédiaire d'un organométallique **E** (au lieu du dianion **D**), suivie d'un départ de nitrile R—CN (schéma 4).

Par conséquent, l'ensemble des résultats relatifs à l'action du radical anion $An^{\dot{-}}Li^{+}$ sur le nitrile **1***d* ou sur l'imine **3***d*, permet de conclure à l'existence d'une réaction d'addition nucléophile rapide du radical anion sur le groupement nitrile, la formation lente de l'hydrocarbure **2** n'ayant lieu que grâce à la réversibilité de cette réaction d'addition.

Il reste encore à comprendre pourquoi le rendement global (**2** + **3**) est si différent pour les nitriles **1***c* (15%) et **1***d* (78%), ou en d'autres termes, pourquoi la fraction de nitrile **1** qui ne s'est pas transformée en hydrocarbure **2** en fin de réaction, n'est-elle pas toujours récupérée totalement sous forme d'imine **3** après hydrolyse. Les deux explications possibles tiennent compte des vitesses de protonation du radical anion $An^{\dot{-}}Li^{+}$ et du dianion **D**, entités en équilibre dans le milieu au moment de l'hydrolyse (schéma 5).

Si l'interconversion entre le radical anion $An^{\dot{-}}Li^{+}$ et le dianion **D** est lente par rapport à

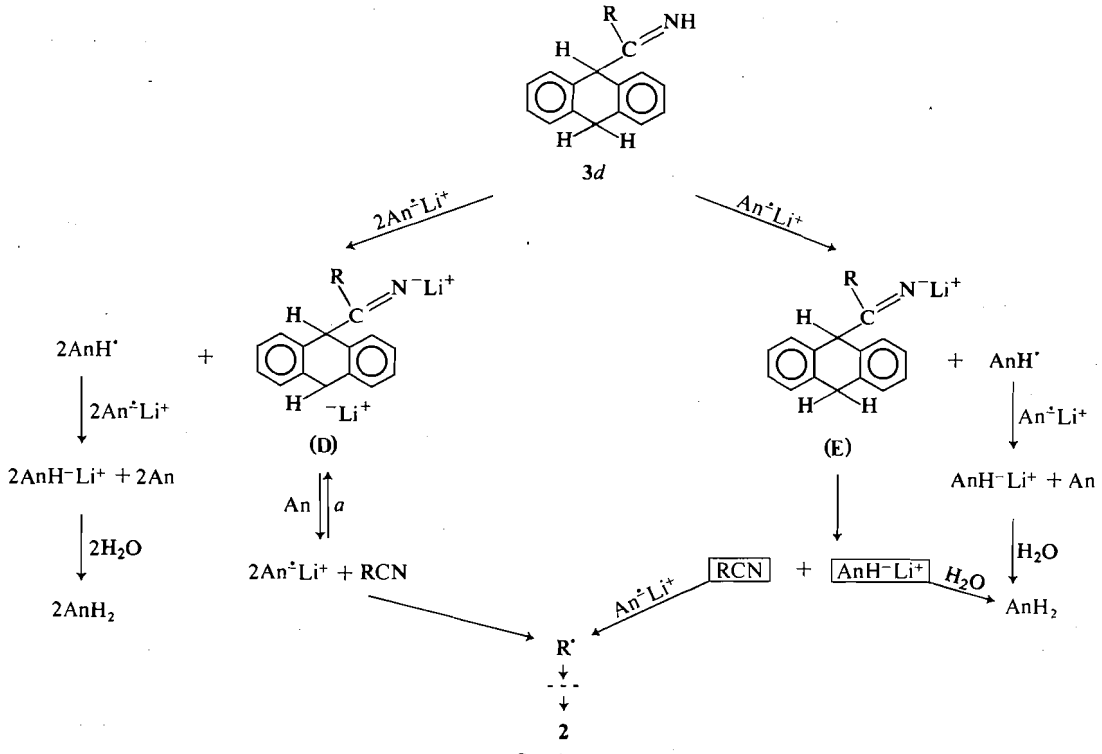

SCHÉMA 4

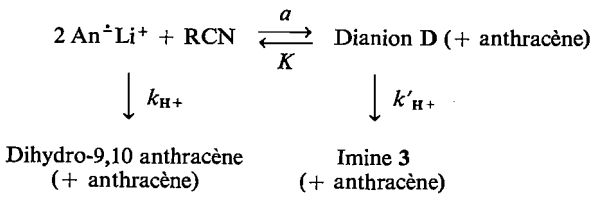

SCHÉMA 5

leurs vitesses de protonation par l'eau, k_{H^+} et k'_{H^+}, la composition du mélange obtenu après hydrolyse doit refléter uniquement la proportion de ces deux espèces. Dans cette optique, si l'equilibre est très déplacé vers le dianion **D**, nous devons obtenir une majorité d'imine **3** (ce serait le cas pour le nitrile **1***d*), et si l'équilibre est très déplacé vers le radical anion $An^{\cdot-}Li^+$, nous devons obtenir très peu d'imine et une majorité de dihydro-9,10 anthracène (ce serait le cas pour le nitrile **1***c*).

Si l'interconversion entre $An^{\cdot-}Li^+$ et **D** est rapide par rapport aux vitesses de protonation par l'eau k_{H^+} et k'_{H^+} de ces deux espèces, la composition du mélange doit refléter surtout le rapport k_{H^+}/k'_{H^+}. Dans cette optique, étant donné que k_{H^+} doit être constant quelle que soit la nature du nitrile, les résultats obtenus signifieraient que k'_{H^+} (**1***c*) est inférieur à k'_{H^+} (**1***d*).

Le même raisonnement peut être tenu dans le cas des nitriles énolisables **1***a* et **1***b*. En effet, comme il est connu que les radicaux anions métaux alcalins–anthracène ne sont que des entités faiblement basiques (11), il peut sembler étonnant de ne pas obtenir d'imine en fin de réaction, mais seulement du dihydro-9,10 anthracène. Ce résultat peut signifier que la vitesse d'établissement de l'équilibre *a* est lente devant la vitesse k_{H^+} de protonation du radical anion $An^{\cdot-}Li^+$ par un hydrogène énolisable du nitrile

(c'est à dire que la basicité de l'anthracène–lithium l'emporte sur sa nucléophilie); cependant même si la vitesse d'interconversion entre $An^{\cdot-}$-Li^+ et **D** est grande par rapport à k_{H^+}, il est possible d'obtenir uniquement du dihydro-9,10 anthracène si k'_{H^+} est beaucoup plus petit que k_{H^+}.

Conclusions

En résumé, malgré la complexité liée à la réactivité des radicaux anions anthracène–lithium, qui peuvent se comporter soit comme agents de transfert d'électron, soit comme réactifs basiques, soit comme réactifs nucléophiles, les présents résultats permettent d'apporter les précisions suivantes concernant le mécanisme et la généralité de leur action sur les nitriles: (*i*) Lorsque le nitrile est énolisable, l'anthracène–lithium en solution éthérée se comporte uniquement comme un agent basique; (*ii*) dans la compétition entre l'addition nucléophile sur le nitrile, conduisant à une imine, et le mécanisme de rupture de la liaison C—CN, conduisant à un hydrocarbure, c'est l'addition nucléophile qui est la réaction la plus rapide; (*iii*) cette addition nucléophile est réversible, ce qui est sans doute dû à l'instabilité de l'intermédiaire dianionique formé; (*iv*) l'existence d'une telle réversibilité rend possible la réaction de coupure de la liaison C—CN, plus lente, mais irréversible; (*v*) par analogie avec les réactions de réduction des nitriles, effectuées au moyen des métaux dissous, ou par électrolyse, il est permis de penser que cette coupure se produit après transfert préalable d'un électron fourni par le radical anion anthracène–lithium, ce qui augmente le niveau d'énergie de la molécule de nitrile et active ainsi le départ de l'ion cyanure, habituellement mauvais groupe partant dans les réactions hétérolytiques.

Partie expérimentale

Les points de fusion ont été déterminés sur un appareil Tottoli. Les analyses élémentaires ont été effectuées par le Centre de Microanalyse de Thiais. Les spectres infrarouge ont été enregistrés sur un spectromètre Infracord Perkin-Elmer et sur un appareil EPI G 2 Hitachi. Les spectres de r.m.n. ont été enregistrés sur des spectromètres Varian A 60 et T 60, le tétraméthylsilane étant pris comme référence interne. La chromatographie en phase gazeuse analytique a été effectuée sur un appareil Girdel 75 FS à ionisation de flamme.

Les nitriles **1***a*, **1***b*; **1***c* et **1***d* sont commerciaux. La combinaison anthracène–lithium est préparée dans l'éther, par action du lithium sur l'anthracène. Le lithium est préalablement décapé dans l'alcool absolu, séché, et découpé en fins morceaux. La solution de coloration violette est agitée pendant 4 h à température ambiante, sous atmosphère d'argon sec. On y additionne alors un défaut de nitrile. Après un temps d'agitation variable, le mélange réactionnel est hydrolysé.

*Action des nitriles **1a** et **1b***

Réactifs: anthracène, 0.04 mol; lithium, 0.04 mol; éther, 200 cm^3; **1***a* ou **1***b*, 0.02 mol. Après hydrolyse, la phase éthérée est lavée à l'eau et séchée. Dans les deux cas, le spectre de r.m.n. du produit brut, ainsi que la c.p.g. analytique, indiquent l'absence de composés de substitution du type **2** et d'addition du type **3**. Les seuls produits 'lourds' présents dans le mélange sont l'anthracène et le dihydro-9,10-anthracène.

*Action du pivalonitrile (**1c**)*

Réactifs: anthracène, 3.9 g (0.022 mol); lithium, 0.25 g (0.035 mol); éther, 150 cm^3; **1***c* 0.83 g (0.01 mol). Après hydrolyse au bout de 20 h d'agitation, la phase éthérée est agitée pendant 3 h en présence d'une solution aqueuse de HCl 20%. La phase aqueuse acide est ensuite lavée à l'éther, puis alcalinisée par la soude; l'extraction à l'éther ne fournit aucun produit. La phase éthérée acide est reprise, lavée à l'eau, et séchée; l'éther est chassé. Cette partie neutre est constituée d'un mélange des composés suivants: dihydro-9,10 anthracène et anthracène; nitrile de départ **1***c* (rendement, 77%); composés **2***c* (rendement, 5%) et **4***c* (rendement, 10%).

Le dihydro-9,10 anthracène en excès, et l'anthracène, sont partiellement éliminés par cristallisation dans l'éthanol. Les composés **2***c* et **4***c* sont ensuite séparés par c.p.g. préparative (appareil Aerograph 700; colonne SE 52 5%, *T* 200 °C; débit d'hydrogène, 250 cm^3/min).

*tert-Butyl-9 dihydro-9,10 anthracène (**2c**)*—p.f. (EtOH) 123 °C (litt. (15) p.f. 125–126 °C); spectre r.m.n. (CS_2) identique à celui décrit dans la littérature (15).

Anal. calc. pour $C_{18}H_{20}$: C, 91.47; H, 8.53. Trouvé: C, 91.35; H, 8.56.

*Pivaloyl-9 dihydro-9,10 anthracene (**4c**)*—p.f. (éther de pétrole) 129–132 °C; spectre i.r.: bande C=O à 1700 cm^{-1}; spectre r.m.n. ($CDCl_3$): massif à 7.16 p.p.m., correspondant à 8 protons aromatiques; singulet à 5.47 p.p.m., correspondant au proton H_M; quadruplet AB (J = 18 Hz), correspondant aux protons H_A et H_B, constitué d'un doublet 'élargi' centré à 4.74 p.p.m. pour le proton H_A, et d'un doublet 'fin' centré à 3.74 p.p.m. pour le proton H_B; singulet à 1.23 p.p.m., correspondant à 9 protons du groupement *tert*-butyle.

Anal. calc. pour $C_{19}H_{20}O$: C, 86.32; H, 7.63; O, 6.05. Trouvé: C, 86.45; H, 7.71; O, 6.07.

*Action du phenyl-1 cyclopentane nitrile (**1d**)*

1ère expérience

Réactifs: anthracène, 1.78 g (0.01 mol); lithium, 0.07 g (0.01 mol); éther, 100 cm^3; **1***d*, 0.428 g (0.0025 mol). Dès le début de l'addition du nitrile à la solution violette d'anthracène–lithium, la coloration vire au marron-rouge. Après 17 h d'agitation, la solution est de couleur marron-noir. L'hydrolyse est alors effectuée et la phase éthérée est lavée à l'eau. Une extraction acide-base fournit deux parties: (*a*) partie basique: 0.008 g; (*b*) partie neutre: 2.033 g, constituée du mélange suivant: dihydro-9,10 anthracène et anthracène; nitrile de départ **1***d* (rendement, 9%); composé **2***d* (rendement, 78%).

3 h	48.6
4 h	38.6
5 h	31.2
19 h	15.7
21 h	15.0

2ème expérience

Réactifs: anthracène, 7.12 g (0.04 mol); lithium 0.28 g (0.04 mol); éther, 350 cm^3; **1***d*, 1.76 g (0.0103 mol). Le nitrile **1***d* est ajouté rapidement à la solution violette d'anthracène–lithium. L'hydrolyse est effectuée après 3 min d'agitation, alors que la coloration de la solution est marron-rouge. Une extraction acide-base fournit deux parties: (*a*) partie basique: 2.382 g d'imine **3***d*, soit rendement, 66%; (*b*) partie neutre, constituée du mélange suivant: dihydro-9,10 anthracène et anthracène; nitrile de départ **1***d* (rendement, 21%); composé **2***d* (rendement 3%).

3ème expérience

Les proportions des réactifs sont identiques aux précédentes. Des prélèvements du mélange réactionnel sont effectués au cours du temps, à l'aide d'une seringue. Après hydrolyse de chaque prélèvement, le produit brut est piqué en c.p.g. (colonne SE 52 5%; 0.50 mètre; T = 190 °C; t_R **2***d*, 1 min 36 s; t_R **3***d*, 4 min 48 s). On détermine le rapport des surfaces des pics correspondant aux composés **2***d* et **3***d* (tableau 3).

(Phényl-1′ cyclopentyl)-9 dihydro-9,10 anthracène (2d)

Le dihydro-9,10 anthracène et l'anthracène sont éliminés partiellement de la partie neutre de la **1**ère expérience par cristallisation dans l'éthanol. L'hydrocarbure **2***d* est ensuite séparé par chromatographie sur plaques (Kieselgel 60 F 254 PSC Fertigplatten–Merck; éluant, pentane): p.f. (pentane), 109–110 °C; spectre r.m.n. ($CDCl_3$): massif entre 6.3 et 7.7 p.p.m., correspondant à 13 protons aromatiques; singulet à 4.08 p.p.m. correspondant au proton H_M; doublet 'fin' centré à 3.12 p.p.m. (J = 19 Hz), correspondant au proton H_B; doublet centré à 1.85 p.p.m. (J = 19 Hz), correspondant au proton H_A; massif entre 1.3 et 2.7 p.p.m. correspondant à 8 protons du cycle cyclopentanique.

Anal. calc. pour $C_{25}H_{24}$: C, 92.54; H, 7.46. Trouvé: C, 92.51; H, 7.29.

L'irradiation du proton H_A à 1.85 p.p.m. a pour conséquence la disparition du couplage et l'apparition d'un pic à 3.12 p.p.m., au centre du doublet correspondant au proton H_B.

De même, l'irradiation du proton H_B à 3.12 p.p.m. a pour conséquence l'apparition d'un pic à 1.85 p.p.m., au centre du doublet correspondant au proton H_A. Spectre de masse: pic moléculaire à *m/e* 324; pic (M − 2) à *m/e* 322, correspondant à une aromatisation par départ de H_2.

(Dihydro-9,10 anthryl)-9 (phényl-1′ cyclopentyl) cétimine (3d)

L'imine **3***d* obtenue à l'état brut (partie basique de la 2ème expérience), est cristallisée dans l'éthanol. On obtient des cristaux blancs: p.f. 139–140 °C; spectre i.r.: bande C═NH à 1620 cm^{-1}; spectre r.m.n. ($CDCl_3$): massif entre 6.3 et 7.5 p.p.m., correspondant à 13 protons aromatiques; singulet à 4.82 p.p.m., correspondant au proton H_M; quadruplet AB (J = 18 Hz), correspondant aux protons H_A et H_B, constitué d'un doublet 'élargi' centré à 4.35 p.p.m. pour le proton H_A, et d'un doublet 'fin' centré à 3.68 p.p.m. pour le proton H_B; massif entre 1.5 et 2.5 p.p.m., correspondant à 8 protons du cycle cyclopentanique.

Anal. calc. pour $C_{26}H_{25}N$: C, 88.84; H, 7.17; N, 3.98. Trouvé: C, 88.91; H, 7.13; N, 3.97.

Action de l'imine 3d

Réactifs: anthracène, 0.9 g (0.005 mol); lithium, 0.035 g (0.005 mol); éther, 160 cm^3; **3***d*, 0.350 g (0.001 mol). Après addition de l'imine à la solution violette d'anthracène–lithium, la coloration vire au marron rouge (comme lors de l'addition du nitrile correspondant **1***d*). Au bout de 17 h d'agitation, la solution possède une coloration marron-noir. Après hydrolyse et extraction acide–base, nous constatons l'absence de partie basique. La partie neutre est constituée d'un mélange des composés suivants: dihydro-9,10 anthracène et anthracène; nitrile **1***d* (rendement, 6%); composé **2***d* (rendement, 67%).

Etude Magnétique des sels alcalins de quelques amino acides

MAURICE A. BERNARD, NICOLE BOIS ET MICHELLE DAIREAUX
Laboratoire de Chimie Minérale B – Groupe de Cristallographie et Chimie du Solide, E.R.A. 305 – U.E.R. de Sciences – Université de Caen – 14032 Caen Cedex – France

Reçu le 9 juin 1975

MAURICE A. BERNARD, NICOLE BOIS et MICHELLE DAIREAUX. Can. J. Chem. **53**, 3167 (1975).

Nous avons déterminé par la méthode de Faraday les susceptibilités magnétiques molaires des sels alcalins M(NH_2—R—COO) de quelques amino acides. (R = —CH_2—, >CH—CH_3, >CH—CH(—CH_3)(—CH_3), >CH—$(CH_2)_2$—CH_3, >CH—CH(—CH_3)—CH_2—CH_3, >CH—$(CH_2)_3$—CH_3).

Nous en déduisons par la méthode de Veiel les susceptibilités magnétiques des anions (NH_2—R—COO^-).

MAURICE A. BERNARD, NICOLE BOIS, and MICHELLE DAIREAUX. Can. J. Chem. **53**, 3167 (1975).

Using the Faraday method molar magnetic susceptibilities of the alkali metal salts M(NH_2—R—COO) of several amino acids (R = —CH_2—, >CH—CH_3, >CH—CH(—CH_3)(—CH_3), >CH—$(CH_2)_2$—CH_3, >CH—CH(—CH_3)—CH_2—CH_3, >CH—$(CH_2)_3$—CH_3) have been determined.

Using the Veiel method, the magnetic susceptibilities of the anions (NH_2—R—COO^-) were deduced.

Introduction

Dans le cadre d'une étude générale sur les glycinates métalliques, nous avions déterminé les susceptibilités magnétiques des glycinates alcalins (1). Nous avons étendu ce travail aux sels alcalins des amino acides suivants:

les α-alaninates (amino-2 propanoates) M(NH_2—CH(—COO)—CH_3); les valinates (amino-2 méthyl-3 butanoates) M(NH_2—CH(—COO)—CH(—CH_3)—CH_3); les norvalinates (amino-2 pentanoates) M(NH_2—CH(—COO)—CH_2—CH_2—CH_3); les isoleucinates (amino-2 méthyl-3 pentanoates) M(NH_2—CH(—COO)—CH(—CH_3)—CH_2—CH_3); les norleucinates (amino-2 hexanoates) M(NH_2—CH(—COO)—CH_2—CH_2—CH_2—CH_3); M = Li, Na et K.

Nous nous sommes limités aux amino acides de commercialisation courante (c'est pourquoi nous n'avons pas envisagé l'étude de sels d'amino acides dont la chaîne carbonée serait formée de quatre carbones) et nous avons essayé de regrouper un amino acide simple avec ses homologues supérieurs. Par exemple, l'α-alanine, la norvaline et la norleucine, sont les homologues supérieurs de la glycine.

Partie expérimentale

Préparation des produits

L'action de la glycine sur les nitrates alcalins dissous dans l'ammoniac liquide permet d'isoler les glycinates alcalins (2). Ce mode opératoire n'est pas généralisable aux sels alcalins des autres amino acides.

Nous les avons isolé par la réaction de Voss et Guttman (3), c'est à dire par action de l'amino acide sur une solution diluée du métal dans l'ammoniac. Ces réactions sont particulièrement violentes, la coloration caractéristique du métal dans l'ammoniac liquide disparaît rapidement et un précipité très fin, blanc, difficile à filtrer, apparaît progressivement.

Nous avons ainsi préparé les sels de lithium, sodium et potassium de l'α-alanine, la valine, la norvaline, l'isoleucine et la norleucine. Ces produits blancs, pulvérulents et très hygroscopiques, n'ont pas été, à notre connais-

	−84.9	−88.9	+4.0
	−86.7	−88.9	+2.2

sance, signalés dans la littérature, à l'exception de l'α-alaninate de sodium mentionné sans précision sur sa préparation (3). Les pourcentages expérimentaux en carbone, hydrogène, azote et métal des composés préparés sont en bon accord avec les pourcentages théoriques correspondants.

Dispositif expérimental

Les susceptibilités magnétiques de ces composés ont été déterminées par la méthode de Faraday avec une balance de Cahn. Les mesures ont été effectuées avec un champ de 3000 G sur un échantillon de poudre. La référence utilisée a été le mercurithiocyanate de cobalt dont la susceptibilité magnétique est de $+16.23 \times 10^{-6}$ (en c.g.s.) à 298 K par gramme de substance.

Résultats et discussion

Détermination des susceptibilités magnétiques molaires des amino acides étudiés

Nous n'avons trouvé dans la littérature que les susceptibilités magnétiques molaires de l'α-alanine, de l'isoleucine et de la valine (4). Pour combler cette lacune, nous avons déterminé les susceptibilités magnétiques molaires de la norvaline et de la norleucine. Tous ces composés sont diamagnétiques.

Nous avons ensuite essayé de calculer théoriquement ces susceptibilités magnétiques. En effet, pour les composés d'après Pascal *et al.* (5):

$$\chi_M = \Sigma n_A \chi_A + \lambda$$

n_A = nombre d'atomes de susceptibilité χ_A dans la molécule; λ est un terme correctif dépendant de la nature des liaisons. Les susceptibilités magnétiques des éléments ont été empruntées à la systématique de Pascal *et al.* (6, 7). L'increment de structure λ a été calculé pour les amino acides considérés.

Nous avons rassemblé dans le tableau 1 les valeurs des susceptibilités magnétiques molaires, les calculs théoriques de $\Sigma n_A \chi_A$ et les valeurs de λ. Dans le cas de la glycine, les résultats sont empruntés à un travail antérieur (8). Une étude critique des résultats nous permet d'estimer que l'erreur commise sur les valeurs déterminées est toujours inférieure à 1%.

Détermination des susceptibilités magnétiques molaires des sels alcalins

Nous avons déterminé à 298 K les susceptibilités magnétiques molaires des sels alcalins des amino acides étudiés. Tous ces sels sont diamagnétiques.

Les valeurs des susceptibilités magnétiques molaires sont données dans le tableau 2. Elles résultent chacune de la moyenne d'au moins 10 mesures. Ces valeurs sont d'ailleurs en assez bon accord avec les valeurs théoriques que nous avons pu calculer en adoptant les increments déterminés précédemment.

TABLEAU 2. Susceptibilités magnétiques molaires des sels alcalins des amino acides

R	M	$\chi_M \times 10^6$ (en c.g.s.) Expérimentales	Théoriques
$-CH_2-$	Li	−41.4	−42.5
	Na	−46.3	−47.5
	K	−53.5	−56.8
	Rb	−66.8	−65.5
$>CH-CH_3$	Li	−50.3	−51.8
	Na	−56.8	−56.8
	K	−63.6	−66.1
$>CH-CH<^{CH_3}_{CH_3}$	Li	−73.7	−75.6
	Na	−80.7	−80.6
	K	−87.6	−89.9
$>CH-(CH_2)_2-CH_3$	Li	−75.4	−76.9
	Na	−82.5	−81.9
	K	−88.7	−91.2
$>CH-\underset{CH_3}{CH}-CH_2-CH_3$	Li	−85.4	−86.2
	Na	−90.6	−91.2
	K	−97.8	−100.5
$>CH-(CH_2)_3-CH_3$	Li	−87.4	−88.0
	Na	−92.4	−93.0
	K	−99.6	−102.3

La principale cause d'erreur est due au fait que les sels alcalins avec lesquels nous opérons sont particulièrement hygroscopiques. Nous devons effectuer rapidement les pesées pour limiter au maximum l'incertitude sur nos mesures qui ont été effectuées sous une atmosphère inerte. Dans ces conditions opératoires, nous estimons la précision à 1% environ.

Détermination des susceptibilités magnétiques des anions (NH_2—R—COO^-)

Afin de déterminer la susceptibilité magnétique de l'anion (NH_2—R—COO^-), nous avons employé la méthode de Veiel (9). D'après Veiel, en effet lorsque la susceptibilité molaire est portée sur un graphique en fonction du numéro atomique du métal pour un groupe d'éléments donné du tableau périodique, on obtient une droite. Nous avons constaté en portant les valeurs trouvées pour les sels de lithium, sodium et potassium des amino acides que celles-ci étaient pratiquement alignées. Dans le cas de la glycine, nous avons également le sel de rubidium qui est le seul sel de rubidium que nous avons pu isoler (8). L'ordonnée à l'origine pour chacune des droites donne la valeur de la susceptibilité de l'anion (NH_2—R—COO^-). Les résultats obtenus sont consignés dans le tableau 3.

TABLEAU 3. Susceptibilités magnétiques des anions (NH_2—R—COO^-)

R	$\chi_M \times 10^6$ (NH_2—R—COO^-) (en c.g.s.)
$-CH_2-$	−38.4
$>CH-CH_3$	−48.5
$>CH-CH<^{CH_3}_{CH_3}$	−72.2
$>CH-(CH_2)_2-CH_3$	−73.6
$>CH-\underset{CH_3}{CH}-CH_2-CH_3$	−82.5
$>CH-(CH_2)_3-CH_3$	−84.4

De plus, nous constatons que ces droites sont parallèles elles ont une pente de −0.77. Nous pouvons établir une relation permettant d'estimer

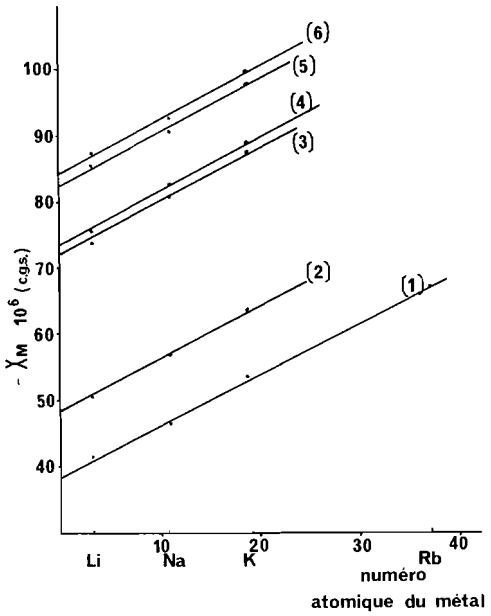

FIG. 1. Susceptibilités magnétiques molaires des sels alcalins des amino acides en fonction du numéro atomique du métal correspondant:

(1) $-CH_2-$; *(2)* $>CH-CH_3$;

(3) $>CH-CH<^{CH_3}_{CH_3}$; *(4)* $>CH-(CH_2)_2-CH_3$;

(5) $>CH-\underset{CH_3}{CH}-CH_2-CH_3$; *(6)* $>CH-(CH_2)_3-CH_3$

les susceptibilités magnétiques molaires des sels alcalins des amino acides (NH_2—R—COOH).

$$\chi_{M(NH_2RCOO)} = \chi_{(NH_2RCOO^-)} - 0.77Z$$

Z = numéro atomique du métal.

Nous avons de cette façon déterminé les susceptibilités magnétiques molaires des sels de rubidium et de césium. En effet, ces composés, très difficiles à isoler sont tellement hygroscopiques qu'ils ne peuvent donner lieu à des mesures magnétiques. Les valeurs sont rassemblées dans le tableau 4. Notons que cette méthode pourrait également permettre d'estimer les susceptibilités magnétiques molaires d'autres amino acides (par exemple des amino acides dont la chaîne carbonée serait formée de quatre carbones).

TABLEAU 4. Estimation des susceptibilités magnétiques molaires des sels de rubidium et de césium des amino acides étudiés

Sterically Hindered Aromatic Compounds. VI. A Remote ε-Deuterium Kinetic Isotope Effect in the Solvolysis of Perdeutero-2,4,6-tri-*tert*-butylbenzyl Chloride

L. Ross C. Barclay, John R. Mercer, and Peter J. MacAulay

Department of Chemistry, Mount Allison University, Sackville, New Brunswick E0A 3C0

Received May 21, 1975

L. Ross C. Barclay, John R. Mercer, and Peter J. MacAulay. Can. J. Chem. **53**, 3171 (1975).

2,4,6-Tri-*tert*-butylbenzyl chloride deuterated at the three *tert*-butyl groups was synthesized. Conductimetric solvolysis studies of the normal and perdeutero-2,4,6-tri-*tert*-butylbenzyl chloride at 30.06 °C in 80% ethanol–water provides evidence for an inverse remote ε-deuterium isotope effect, $k_H/k_D = 0.873$–0.874. Under the same conditions the α-deuterium isotope effect was $k_H/k_{\alpha D} = 1.166$ per deuterium, indicative of limiting solvolytic behavior. The remote ε-deuterium isotope effect for the perdeutero compound is discussed in terms of the inductive effect of deuterium and steric effects on the transition state conformation.

L. Ross C. Barclay, John R. Mercer et Peter J. MacAulay. Can. J. Chem. **53**, 3171 (1975).

On a synthétisé du chlorure de tri-*tert*-butyl-2,4,6 benzyle deutéré dans les trois groupements *tert*-butyles. Des études de solvolyse conductimétriques effectuées sur des chlorures de tri-*tert*-butyl-2,4,6 benzyles normal et perdeutéré, à 30.06 °C et dans un mélange à 80% d'éthanol–eau, indiquent qu'il existe un effet isotopique inverse dû au deutérium-ε éloigné, $k_H/k_D = 0.873$–0.874. Dans les mêmes conditions, l'effet isotopique du deutérium α est $k_H/k_{\alpha D} = 1.166$ par deutérium indiquant un comportement solvolytique liminant. On discute de l'effet isotopique du deutérium-ε éloigné en termes d'effet inductif du deutérium et d'effets stériques sur la conformation de l'état de transition.

[Traduit par le journal]

Introduction

There has been a continuing interest in the role of steric contributions to secondary deuterium isotope effects since Bartell (1) estimated that a major part of such α and β effects could be attributed to differences in nonbonded repulsions between hydrogen and deuterium. The expectation for a steric contribution to isotope effects is based on the fact that the amplitudes of vibration of hydrogen atoms are greater than those of deuterium atoms. In effect this means that deuterium occupies less space than hydrogen. In a recent review of steric isotope effects, Carter and Melander (2) suggested certain specific requirements for experimental tests of such effects; namely, (*1*) the reaction should cause a minimum of change in the reaction medium; (*2*) it is desirable that steric effects play as important a role in the reaction as possible; (*3*) a transition state of well-known conformation is a necessary prerequisite for the quantitative application of the theory. These requirements are met during configurational inversion of suitably substituted biaryls and considerable experimental results on steric deuterium isotope effects have been observed for isotopically substituted biaryl derivatives (2). Recently Boekelheide and coworkers (3) reported an interesting large ($k_D/k_H = 1.20 \pm 0.04$) isotope effect for conformational flipping of a monodeuterated (2,2)-metaparacyclophane.

As Carter and Melander pointed out (2), solvolytic reactions do not generally fulfill the 'requirements' for experimental tests of steric isotope effects. Such reactions involve changes in structure of both the medium and the substrate; the role of the steric effect is not necessarily dominant, and the transition state geometry is difficult to define precisely.

For this investigation we selected perdeutero-2,4,6-tri-*tert*-butylbenzyl chloride (**1**) as a model to probe the relative importance of steric effects in remote deuterium isotope effects.

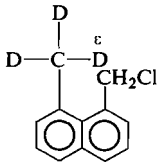
There are certain properties of this system which make it useful in this study of the question of steric deuterium isotope effects in solvolysis. (*1*) There is ample evidence for severe steric interactions between the functional group and the *o-tert*-butyl groups from both chemical and physical properties (4, 5). (*2*) The mechanism of solvolysis of 2,4,6-tri-*tert*-butylbenzyl chloride has been established to be limiting by previous studies (4, 5). The deuterium isotope effects from the *o-tert*-butyls would be expected to be magnified 18 times and any effects would be readily detected by the available precision conductimetric method. (*3*) Electronic effects from the ε-C—D(H) bonds are expected to be slight at the reaction site and the controversial question of hyperconjugation effects should not concern us. (*4*) Finally solvolysis of **1** might give further insight into the unusual high reactivity of 2,4,6-tri-*tert*-butylbenzyl chloride.

Karabatsos and coworkers (6) earlier studied remote (ε) deuterium isotope effects in such systems as **2** as a test of the relative importance of hyperconjugation and nonbonded interactions to secondary isotope effects.



2

However the overall isotope effect here was relatively slight (k_H/k_D = 1.013). Furthermore the pronounced steric effects present in 2,4,6-tri-*tert*-butylbenzyl chloride are not so evident in **2**, for neither kinetic acceleration nor n.m.r. compression shifts (7).

Experimental[1]

Syntheses of Deuterium Labelled Compounds

Perdeutero-1,3,5-tri-tert-butylbenzene (1)

It was desirable to modify the procedure involving direct alkylation of benzene with a large excess of *tert*-butyl chloride (8) because of the prohibitive expense involved with the labelled chloride. Benzene (0.391 g, 5 mmol) and *tert*-butyl-d_9 chloride (Merck Sharp & Dohme, minimum isotopic purity 99 atom % D, 3.08 ml, 25 mmol) were added to a small three-necked flask and the system purged with dry nitrogen. The mixture was cooled below −40 °C and anhydrous aluminum chloride (0.335 g) was added over 15 min to the mixture which was maintained at −40 °C for 35 min. The temperature was slowly raised to −13 °C in 30 min; between −30 and −20 °C reaction was rapid with copious evolution of hydrogen chloride. The progress of the reaction was followed by g.l.c. analysis on small aliquots using an 8 ft. × ¼ in. 20% carbowax column at 165 °C and 60 ml/min flow rate of helium. Under these conditions the 1,3,5-tri-*tert*-butylbenzene has a shorter retention time than 1,4-di-*tert*-butylbenzene.

The results were as follows:

Reaction time (h)	1,3,5-$(C_4D_9)_3C_6H_3$ (%)	1,4-$(C_4D_9)_2C_6H_4$ (%)
2	88	12
3	92	8
4	90	3.4

The reaction mixture was terminated after four hours by which time it contained 90% 1,3,5-tri-*tert*-butylbenzene and approximately equal amounts (3%) of *tert*-butylbenzene, 1,3-di-*tert*-butylbenzene and 1,4-di-*tert*-butylbenzene. The 1,3,5-*tert*-$(C_4D_9)_3C_6H_3$ was identified by separation and analysis on a Varian MAT 111 GC-MS. It showed the expected parent mass at 273.

An estimate of the deuterium content of the 1,3,5-*tert*-$(C_4D_9)_3C_6H_3$ was made by n.m.r. integrations of the small peak in the region for ordinary *tert*-C_4H_9- in this hydrocarbon (1.34 δ) relative to the resonance for the aryl-H^s (7.37 δ). The *tert*-butyl groups contained slightly more than 99% deuterium.

Perdeutero-2,4,6-tri-tert-butylbromobenzene, 2,4,6-tert-$(C_4D_9)_3C_6H_2Br$

The crude perdeutero-1,3,5-tri-*tert*-butylbenzene was brominated using the 'neutral' conditions of Myhre and coworkers (9). The required bromo compound (79% of the crude product) was separated by a g.l.c. method on a Wilkens Autoprep using repeated injections of a benzene solution on an 8 ft × ¼ in. 20% Carbowax column at 215 °C and 60 ml/min He. Recrystallization of the collected material from methanol yielded colorless crystals, m.p. 171.5–172.5 °C (lit. (10) m.p. 177–177.5 °C).

The mass spectrum[2] of this perdeutero compound was compared with that of ordinary 2,4,6-tri-*tert*-butylbromobenzene. The latter showed molecular ions at *m/e* 324 and 326 of equal intensity corresponding to the bromine isotopes in $C_{18}H_{29}Br$. The base peaks were at *m/e* 309 and 311 for $M^+ - CH_3$. Peaks for $M^+ - C_4H_9$ at *m/e* 267 and 269 were approximately 3% of the base peaks. The perdeutero compound showed the expected mass spectral pattern with the molecular ions at *m/e* 351 and 353 of equal intensity corresponding to $C_{18}D_{27}H_2Br$. The base peaks now were at *m/e* 333 and 335 corresponding to $M^+ - CD_3$. Peaks for $M^+ - C_4D_9$ appeared at 285 and 287 as expected.

Perdeutero-2,4,6-tri-tert-butylbenzyl Chloride (1), 2,4,6-tert-$(C_4D_9)_3C_6H_2CH_2Cl$

The required substituted benzyl chloride (**1**) was synthesized by reaction of the aryl lithium derivative with

[1]The general procedures were as outlined previously (4).

[2]The comparative mass spectra reported herein were obtained on a Dupont 21-110B instrument.

TABLE 1. Solvolysis of 2,4,6-tri-*tert*-butylbenzyl chloride and -α-d_2 chloride in 80% ethanol–water at 30.06 °C

Compound	Rate constants ($k_1 \times 10^4$ s^{-1})	Average	% deviation
2,4,6-Tri-*tert*-butylbenzyl chloride	4.128 4.128 4.103 4.163	4.130	0.60
2,4,6-Tri-*tert*-butylbenzyl-α-d_2 chloride	3.046 3.037 3.022 3.034	3.034	0.32
		$k_H/k_D = \frac{4.130}{3.034} = 1.361$	
		k_H/k_D per D = 1.166	

TABLE 2. Solvolysis of perdeutero-2,4,6-tri-*tert*-butylbenzyl chloride in 80% ethanol–water at 30.06 °C

Run*	Rates ($k_1 \times 10^4$ s^{-1})	Average	% deviation	k_H/k_D
1	4.742 4.711 4.712 4.726	4.723	0.31	$\frac{4.130}{4.723} = 0.874$
2	4.761 4.716 4.709 4.733	4.729	0.49	$\frac{4.130}{4.729} = 0.873$

*The two runs were carried out by different investigators, J. R. Mercer and P. J. MacAulay.

chloromethyl methyl ether, followed by low temperature cleavage of the resulting substituted methyl benzyl ether with boron trichloride according to the reaction sequences used earlier (11). The chloride (**1**) obtained was purified by fractional vacuum sublimation to give colorless crystals, m.p. 141–142 °C (lit. (11) m.p. 141–144 °C).

The mass spectrum of this deuterated chloride (**1**) was compared with that of ordinary 2,4,6-tri-*tert*-butylbenzyl chloride. The latter showed the molecular ion as expected at *m/e* 294. The base peak was at *m/e* 259 for $M^+ - Cl$. A peak at *m/e* 279 for $M^+ - CH_3$ was 50% of the base peak. The perdeutero chloride (**1**) showed the expected mass spectral pattern with the molecular ion at *m/e* 321 corresponding to $(C_4D_9)_3C_6H_2CH_2Cl$. The base peak was at *m/e* 286 corresponding to $M^+ - Cl$. The peak at *m/e* 303 for $M^+ - CD_3$ was 50% of the base peak.

Kinetic Measurements

Kinetic measurements were made using the solvent 80% ethanol–water in stirred cells by the precision conductance method. Four determinations of each rate constant were made. Details on the procedure and the treatment of the data were published earlier (4, 5). The results are outlined in Tables 1 and 2 (Results and Discussion).

Results and Discussion

The α-Deuterium Isotope Effect

It was desirable to first determine the α-deuterium isotope effect for the system chosen and under the conditions used in this investigation (80% ethanol–water, 30.06 °C). The results of this study are given in Table 1.

The high value (approximately 1.17 per D) for the α-deuterium isotope effect confirms the limiting nature of the solvolysis under these conditions and is consistent with our earlier results (5).

The Remote ε-Deuterium Isotope Effect

Results for the solvolysis of perdeutero-2,4,6-tri-*tert*-butylbenzyl chloride are summarized in Table 2.

A significant *inverse* overall kinetic isotope effect was observed (k_H/k_D = 0.873–0.874) for the perdeutero compound with very good reproducibility of the results. A qualitative evaluation of these results is in order in terms of the main contributing electronic and steric effects that might be expected and the anticipated effect that these remote ε-deuteriums should have at least in the direction, *acceleration* or *retardation*, on the solvolysis rate.

Inductive Effect of Deuterium

It has long been recognized that deuterium is electron releasing relative to hydrogen (12) and the inductive contribution on secondary deuterium isotope effects is inverse and relatively slight. For example the δ-nonadeuterated derivative of dimethylneopentylcarbinyl chloride $(CD_3)_3CCH_2C(CH_3)_2Cl$ showed $k_H/k_D = 0.983$ in 80% ethanol–water and the result was attributed to the inductive effect of deuterium (13). The inductive isotope effect of an alkyl, such as a *meta*-trideuteromethyl (14), on the limiting solvolysis reaction of a substituted benzylic chloride is similarly small and inverse. It is very probable that the multiple inductive isotope effect of the *three* nonadeutero *tert*-butyl groups accounts for a significant portion (at least a half) of the observed inverse isotope effect in **1**.

Steric Acceleration Effects

If a reaction proceeds with relief of strain from a sterically congested initial state (*e.g.* steric acceleration) involving congestion of hydrogen atoms, the hydrogen derivative is expected to be more strained than the deuterium derivative in the initial state and the former would react at a faster rate. This kind of argument has been used before (1, 12, 15) but there is relatively meager convincing evidence of this 'normal' isotope effect, at least in systems where the possibility of hyperconjugation effects do not obscure this steric factor. It has been estimated (6) that, in ordinary systems where hyperconjugation is possible, only a small portion (2–5%) of the observed effect is due to nonbonded interactions. Despite the severe crowding in 2,4,6-tri-*tert*-butylbenzyl chloride, we find little (if any) evidence for this kind of steric contribution to the isotope effect although other effects could mask such effects (see below).

The Question of Long Range Vertical Stabilization of the Cation

It was suggested earlier (4) that the solvolytic reactivity of 2,4,6-tri-*tert*-butylbenzyl chloride might be accounted for by through space vertical stabilization of the cation by interaction (σ–π) between the cationic center and the C—H bonds of the *o-tert*-butyls which are very close in space. Such an effect would weaken these C—H bonds in the transition state and therefore result in a significant 'normal' isotope effect ($k_H/k_D > 1$) for the perdeutero chloride (**1**). This is obviously not at all the case so we now discount this as a possible explanation for the high reactivity of this chloride.

Steric Effect on the Transition State Conformation

Steric inhibition of coplanarity could affect the geometry of the 2,4,6-tri-*tert*-butylbenzyl cation by twisting the carbonium ion away from the plane of the benzene ring (4).

The resulting steric inhibition of resonance could be somewhat less when all hydrogens of the *o-tert*-butyls are replaced by deuterium. The result would be a somewhat more stable cation for the perdeutero compound and a more favorable transition state leading to it. This isotope effect would tend to accelerate the rate but we have no way as yet to estimate the magnitude of this effect.

We conclude that the inductive effect of deuterium combined with a possible steric effect on the transition state geometry account for the inverse kinetic isotope effect observed in the solvolysis of **1**. On the other hand, relief of steric strain does not appear to be a significant factor in such remote deuterium isotope effects.

Financial support of this research provided by the National Research Council of Canada is gratefully acknowledged. We thank Dr. W. D. Jamieson of the National Research Council, Atlantic Regional Laboratory for the mass spectral analyses.

Mass Spectrometry of *N*-Benzoyl-2-hydroxyalkylamines. Role of the Hydroxylic Hydrogen in the Fragmentation Pattern

DON C. DEJONGH,[1] DENIS C. K. LIN, PIERRE LECLAIR-LANTEIGNE, AND DENIS GRAVEL[1]

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal, Québec H3C 3V1

Received May 2, 1975

DON C. DEJONGH, DENIS C. K. LIN, PIERRE LECLAIR-LANTEIGNE, and DENIS GRAVEL. Can. J. Chem. **53**, 3175 (1975).

An interesting rearrangement has been observed in the mass spectra of a series of *N*-benzoyl-2-hydroxyalkylamines. The hydrogen atom of the hydroxyl group is transferred to the *N*-benzoyl portion of the molecular ion and the bond between positions 1 and 2 in the *N*-alkyl group is cleaved. A rearrangement ion, observed at *m/e* 135, is formed along with a neutral aldehyde or ketone. When the hydroxylic hydrogen is replaced by a trimethylsilyl substituent, the latter group is transferred with comparable efficiency. Differences in the relative importance of this rearrangement in the mass spectra of a series of related compounds with decreasing substitution at position 2, have been explained by differences in the stabilities of the neutral molecules formed along with *m/e* 135 and by the occurrence of a double hydrogen rearrangement which competes if hydrogen atoms are present in a relationship *gamma* and *delta* to the carbonyl group.

DON C. DEJONGH, DENIS C. K. LIN, PIERRE LECLAIR-LANTEIGNE et DENIS GRAVEL. Can. J. Chem. **53**, 3175 (1975).

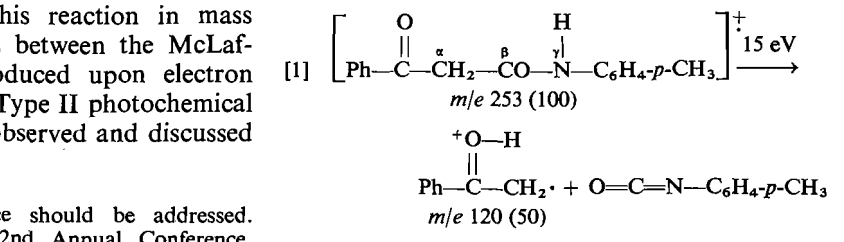
Un réarrangement intéressant a été observé dans les spectres de masse d'une série de *N*-benzoyl hydroxy-2-alkylamines. Dans ce réarrangement, l'atome d'hydrogène du groupe hydroxyle est transposé à la partie *N*-benzoyle de l'ion moléculaire et le lien entre les positions 1 et 2 dans le groupe *N*-alkyle est scindé. Ceci donne lieu à la formation d'un ion, observé à *m/e* 135, ainsi qu'à un fragment neutre aldéhyde ou cétone. Lorsque l'hydrogène hydroxylique est remplacé par un groupe triméthylsilyle, ce dernier est aussi transposé avec une facilité comparable. Les différences observées dans l'importance relative de ce réarrangement dans les spectres de masse d'une série de composés reliés ont été expliquées par des différences dans les stabilités relatives des molécules neutres produites à côté de l'ion *m/e* 135 ainsi que par l'apparition d'un réarrangement à deux hydrogènes qui entre en compétition avec le processus décrit plus haut, lorsque la molécule possède des hydrogènes en position *gamma* et *delta* par rapport au carbonyle.

Introduction

Much attention has been focused on intramolecular hydrogen rearrangements observed upon electron impact. A recent review has covered those undergone by aliphatic hydrocarbons and aromatic compounds (1), whereas another has treated exclusively the so-called McLafferty rearrangement (2). The fact that the latter review contains 651 references attests to the importance of this reaction in mass spectrometry. Similarities between the McLafferty rearrangement, produced upon electron impact, and the Norrish Type II photochemical reaction also have been observed and discussed (3–6).

[1]To whom correspondence should be addressed. Presented in part at the 22nd Annual Conference, American Society for Mass Spectrometry, Philadelphia, May 1974.

The McLafferty rearrangement is defined as the transfer of a hydrogen in a relationship *gamma* to a double-bonded atom through a six-membered transition state, with *beta* bond cleavage (2). For example, an abundant ion is found in the mass spectrum of *N*-*p*-tolyl-3-phenyl-3-oxopropionamide, corresponding to the McLafferty rearrangement, Eq. 1 (4). At 15 eV, the molecular ion is the base peak in the



mass spectrum, and the relative intensity of the rearrangement ion at *m/e* 120 is 50%. Upon

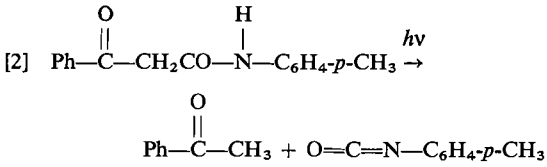
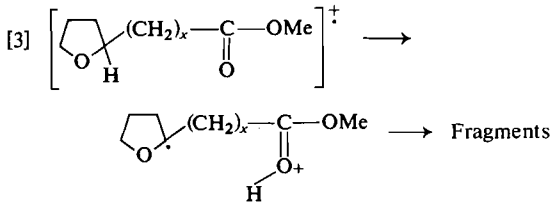
photolysis, the same compound decomposes to acetophenone and *p*-tolylisocyanate, via the Norrish Type II reaction, Eq. 2.

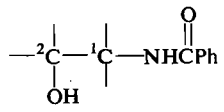


The McLafferty rearrangement has been observed in all classes of carbonyl compounds and also in noncarbonyl systems, such as unsaturated systems, sulfur-containing systems, nitrogen-containing systems, etc. If a hydrogen *gamma* to the double-bonded atom is not available or if the normal process is less favorable for structural or energetic reasons, an alternative or competing process may be preferred. For example, in the mass spectra of some esters containing the tetrahydrofuranyl system, a hydrogen remote from the carbonyl group is abstracted, Eq. 3 (7).



x = 2, 4, 7, and 13

In conjunction with a study of the photochemistry of *N*-substituted unsaturated amides, we have observed a rearrangement in the mass spectra of a series of *N*-benzoyl-2-hydroxyalkylamines of general structure **1**. During the course of the rearrangement, the hydrogen atom of the hydroxyl group is transferred to the *N*-benzoyl



1

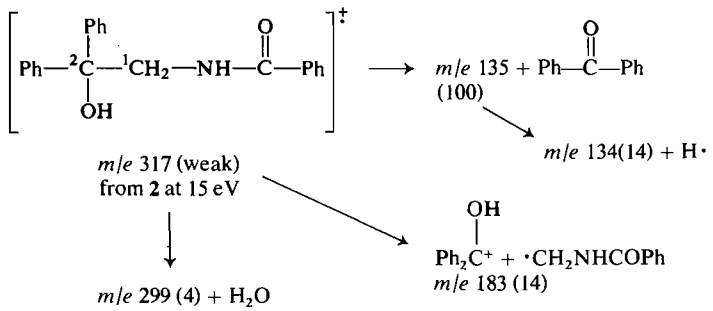
portion of the molecular ion and the single bond between carbons 1 and 2 cleaves.

Mass spectra of amides have been previously reported (8–10). If a γ-hydrogen atom is present in the acyl group of an amide, the McLafferty rearrangement predominates in its mass spectrum. McLafferty rearrangements can also occur between the carbonyl oxygen and a hydrogen in the *N*-alkyl group of the amide. Furthermore, the cleavage of the bond between positions 1 and 2 in the *N*-alkyl group is characteristic of the fragmentation of secondary amides.

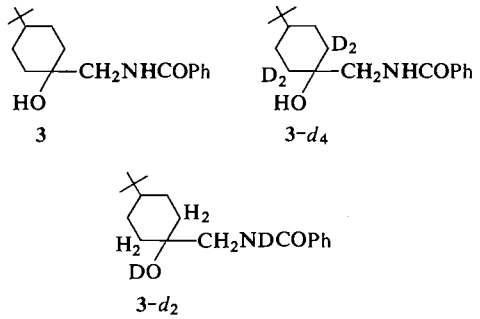
In this article, we will present the mass spectra of a series of compounds of general structure **1** in order to define the rearrangement. Then, we will show the effects of substitution in the 2-position of the *N*-alkyl group and compare the hydrogen-donating aptitudes of various groups. Mass-spectral data are presented in Schemes; however, structures given in the Schemes for ions are speculative. Relative intensities are also given in the Schemes, in parentheses.

Results

In the 15 eV mass spectrum of *N*-benzoyl-2-hydroxy-2,2-diphenylethylamine (**2**), the molecular ion is weak and the base peak is found at *m/e* 135, Scheme 1. Minor peaks are present corresponding to fragmentations expected from alcohols: cleavage adjacent to the hydroxyl group (*m/e* 183) and elimination of H_2O (*m/e* 299). In the present case, we will focus our



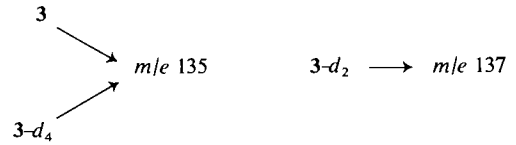
SCHEME 1



attention on the formation of the ion found at *m/e* 135.

In the low-voltage mass spectrum of *N*-benzoyl-1-aminomethyl-4-*tert*-butylcyclohexanol (**3**), essentially the only peak present is the one at *m/e* 135. At 70 eV, there are weak peaks corresponding to the molecular ion and loss of $CH_3\cdot$, H_2O, and $CH_3\cdot + H_2O$, and intense peaks at *m/e* 135, 134 ($135 \xrightarrow{m^*} 134 + H\cdot$), 105 (PhCO), and 77 ($C_6H_5$).

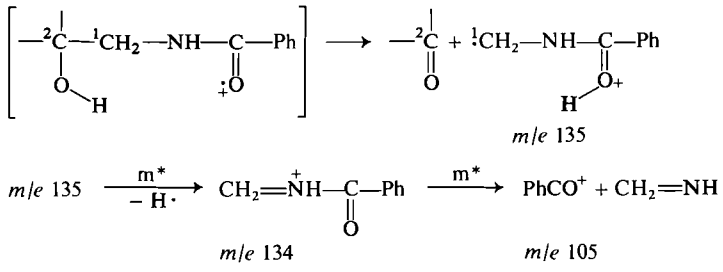
Two deuterated analogs of **3**, **3**-d_4, and **3**-d_2, were also studied and provide some insight into the formation of this ion found at *m/e* 135. In the 15 eV mass spectrum of **3**-d_4, the rearrangement ion remains exclusively at *m/e* 135; however, in the 15 eV mass spectrum of **3**-d_2, the ion is found at *m/e* 137:



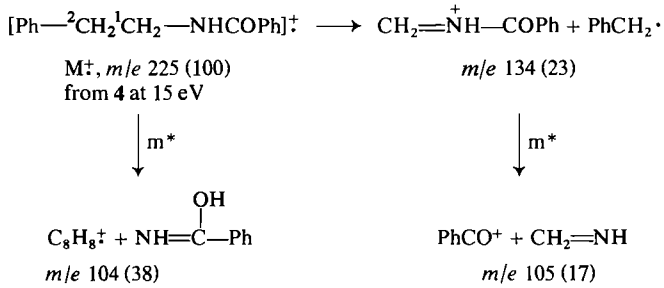
After correcting for the percentage of monodeuteration (there was ~16.5% d_1), the ratio of *m/e* 136 to *m/e* 137 was found to be 6:94 in the mass spectrum of **3**-d_2. Thus, there is no less than 94% transfer of deuterium from —OD and no more than 6% of transfer of hydrogen from C—H.

In terms of mass spectra taken at various voltages, deuterium labeling, exact-mass measurements, and metastable peaks, the rearrangement and subsequent fragmentations are consistent with the pathway presented in Scheme 2. The hydroxyl hydrogen is transferred to the *N*-benzoyl group and the bond between carbons 1 and 2 in the *N*-alkyl group cleaves, resulting in the elimination of a stable molecule containing a carbonyl group. We have placed the transferred hydrogen on the carbonyl group of the amide in Scheme 2, in analogy with the McLafferty rearrangement, although we have no information on the exact structures of the ions.

In order to have a point of reference, we have compared the mass spectra of **2** and **3** with the fragmentations observed in the 15 eV mass



SCHEME 2



SCHEME 3[2]

[2]The structures and formulas are in agreement with the results of exact-mass measurements.

spectrum of *N*-benzoyl-2-phenylethylamine (**4**), Scheme 3. Compound **4** lacks a hydrogen in the *N*-alkyl group which could be involved in a transfer analogous to the one shown in Scheme 2. However, it does contain hydrogens *gamma* to the carbonyl, making the McLafferty rearrangement possible in the *N*-2-phenylethyl group. Two major fragmentation pathways are observed: (*1*) the cleavage of the benzylic bond, yielding the ion at *m/e* 134, and (*2*) a McLafferty rearrangement, with the charge remaining on the C_8H_8 portion. These are precisely the fragmentations expected from secondary amides (8–10).

In order to examine the effect of substitution on the carbon atom bearing the hydroxyl group in **1**, we have studied a series of *N*-benzoyl-2-hydroxyalkylamines, **5–7**. Compound **5** is similar to compounds **2** and **3** in the sense

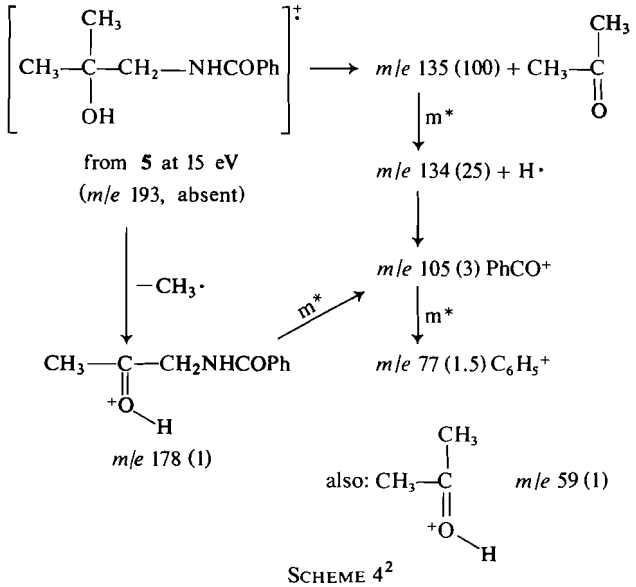
	R_1	R_2
5	CH_3	CH_3
6	CH_3	H
7	H	H

that it contains no hydrogen atoms *gamma* to the carbonyl group, thus the McLafferty rearrangement is blocked. However, compounds **6** and **7** do have hydrogen atoms *gamma* to the carbonyl group, as does **4**, as well as the hydrogen atom on the hydroxyl group, making possible a competition between the two rearrangements.

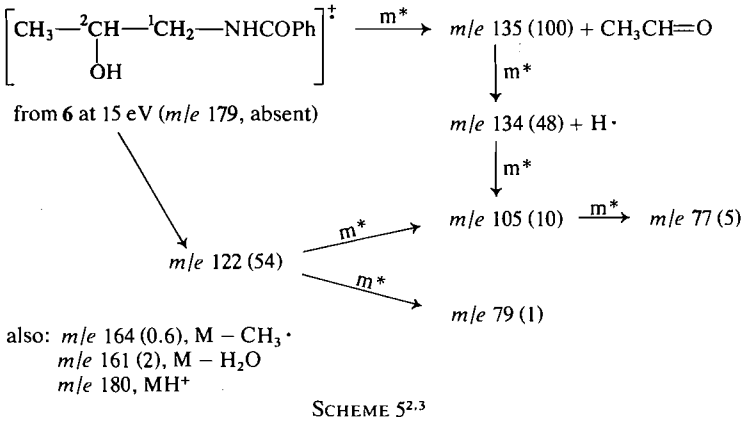
The 70 eV mass spectra of **5–7** are given in Table 1. Even though no molecular ions are observed in the spectra of **5** and **6**, peaks are found for MH^+ and $MH^+ - H_2O$ at high sample pressures, from a small amount of chemical ionization. Peaks are present for a fragmentation giving an ion corresponding to $M^{\cdot+} - CH_3\cdot$. All three compounds eliminate H_2O for which a metastable peak is present in the mass spectrum of **7**. From the consistent behavior of these compounds in different mass spectrometers at different ion-source temperatures, we feel confident that the elimination of H_2O from **5** and **6**, also, is induced by electron impact rather than by thermal excitation.

In the 15 eV mass spectrum of **5**, Scheme 4 (70 eV mass spectrum is given in Table 1), there is only one prominent fragmentation pathway, the elimination of acetone. This is essentially the same result observed in the mass spectra of compounds **2** and **3**. No peak is found for the molecular ion; however, peaks are present for MH^+, arising from a small amount of chemical ionization, and for the loss of a methyl group.

In the mass spectra of **6** (15 eV, Scheme 5; 70 eV, Table 1), there are indeed two competing hydrogen rearrangements. However, the McLafferty rearrangement, Eq. 4, is not observed.

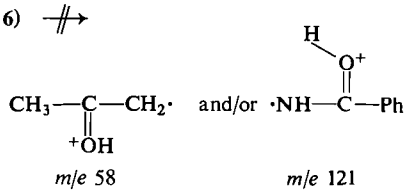


SCHEME 4[2]



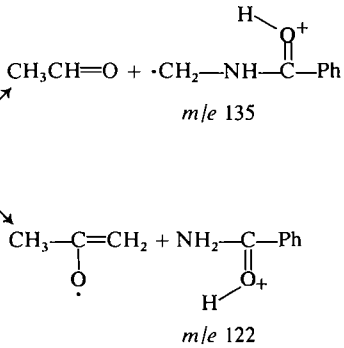
SCHEME 5[2,3]

[4] M^{+}(from **6**) ⇢



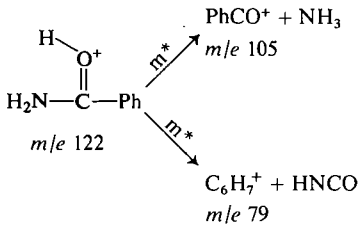
The rearrangements observed are those leading to the fragment at *m/e* 135, already observed in the spectra of **2**, **3**, and **5**, and a double hydrogen rearrangement leading to the ion found at *m/e* 122, Eq. 5. The double hydrogen transfer is a reaction typical of esters (11).

[5] M^{+} (from **6**)



The presence of metastable peaks indicates that there are at least two further fragmentations of the ion found at *m/e* 122, Eq. 6. It is possible that the structure of the ion at *m/e* 122 is better represented by protonation on nitrogen, or by a mixture of protonated, tautomeric forms.[4] We have obtained the chemical ionization (isobutane) mass spectrum of benzamide. The MH^{+} ion at *m/e* 122 is the base peak. The only important fragmentation is the elimination of NH_3

[6]



giving *m/e* 105, along with a metastable peak for the process.

In the mass spectrum of **7** (15 eV, Scheme 6; 70 eV, Table 1), the situation has shifted largely in favor of the double hydrogen transfer: the base peak is the ion at *m/e* 122. The molecular ion is relatively abundant, as is the loss of H_2O. Thus, as substitution decreases on the 2-carbon atom (in **1**), the relative importance of cleavage of the bond between positions 1 and 2 decreases and the intensity of the molecular ion increases. Also, the double hydrogen transfer becomes more abundant with increasing hydrogen atom availability on the 2-carbon.

In contrast to what is observed in the spectra of previous compounds, *m/e* 134 is more intense than *m/e* 135, in the spectrum of **7**. This can be rationalized by a competing formation of *m/e* 134 by cleavage of the 1,2-bond, as was observed in the mass spectrum of **4**, Scheme 3, and as is observed in the mass spectra of secondary amides in general (8–10).

It now becomes important to look more closely at the competition between hydrogen

[3]Also see Eqs. 5 and 6.

[4]The u.v. spectra of benzamide in concentrated sulfuric acid show a tautomeric change from the *N*-protonated form in 60% sulfuric acid to the *O*-protonated form in 100% sulfuric acid (12).

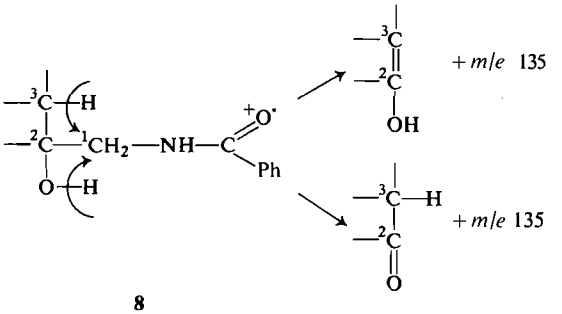
transfers from OH and from CH, giving ketonic *vs.* enolic neutral products (see structure **8**). We have already shown (*vide supra*) that the ion at *m/e* 135 in the mass spectrum of **3** shifts overwhelmingly to *m/e* 137 in the mass spectrum of **3**-d_2. This preference is all the more impressive in light of the statistical factor of 4 in favor of C—H transfer over O—D transfer, and the

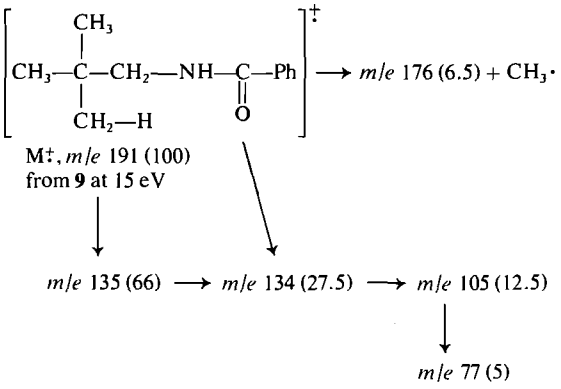
[5]The abundance of *m/e* 135 has been corrected for the isotopic contribution of *m/e* 134.



8

isotope effect which would run in favor of transfer of H over D.

We were also interested in observing the course which fragmentation would take if there were no 2-hydroxyl group and if the McLafferty and double hydrogen rearrangements were rendered impossible. To that effect, the *N*-benzoyl derivative (**9**) of 2,2-dimethylpropylamine was prepared, and its mass spectrum (Scheme 7) was compared with that of 2-



SCHEME 7[2,5]

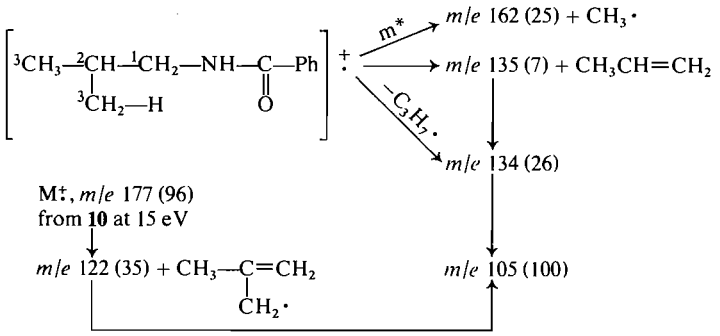
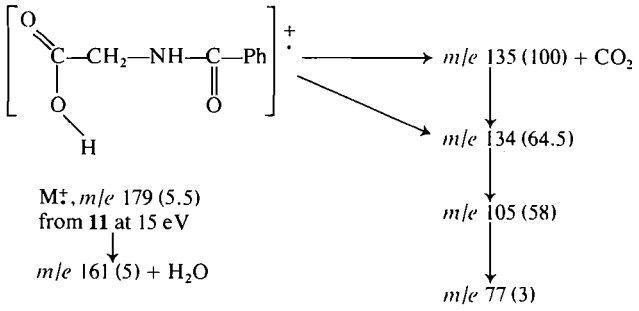


SCHEME 8[2,5]



SCHEME 9[2]

hydroxy-2-methylpropylamine (**5**, Scheme 4). The fragmentations are essentially the same. However, the molecular ion from **5** is absent, whereas the molecular ion from **9** is the base peak; the rearrangement ion found at *m/e* 135 is the base peak in the mass spectrum of **5**. The presence of the rearrangement ion at *m/e* 135 in the mass spectrum of **9** shows that hydrogen is transferred from carbon if the other rearrangements are blocked by lack of appropriate hydrogens to transfer. However, transfer of hydrogen from a methyl group on the 2-position is obviously much less favorable than transfer of hydrogen from a hydroxyl group on the 2-position.

Likewise, **6** was compared with its counterpart having a methyl group in place of hydroxyl. In the 15 eV mass spectrum (Scheme 8) of the *N*-benzoyl derivative of isobutylamine (**10**), the double hydrogen rearrangement, giving *m/e* 122, is more prominent than the formation of *m/e* 135. Once again, hydrogen transfer from OH is shown to be more favorable than transfer from CH_3.

In order to test the generality of the observed rearrangement of hydroxylic hydrogen atoms, we have taken the mass spectrum of the *N*-benzoyl derivative of glycine (**11**; 15 eV spectrum, Scheme 9). Now there is only one abundant fragmentation path, the formation of *m/e* 135. In the mass spectrum of the ethyl ester of **11**, on the other hand, the formation of ion 135 is blocked. The base peak corresponds to the molecular ion, and there are two fragmentation pathways: (*1*) loss of EtOH, and (*2*) loss of EtO· followed by CO, or of EtOCO·, giving *m/e* 134.

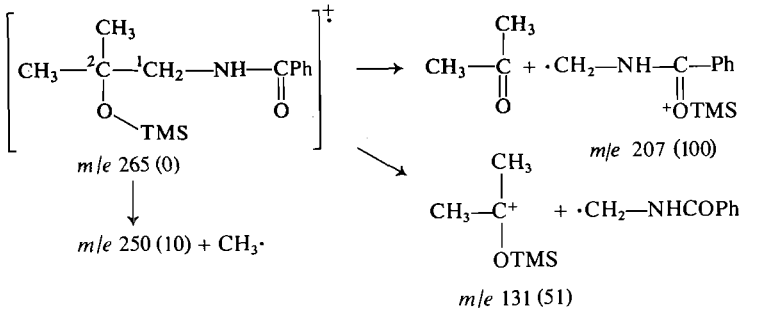
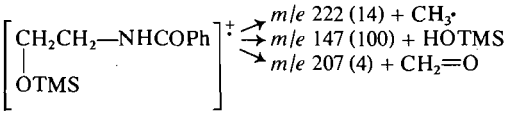
[8]



The result obtained from the ethyl ester shows that, even though the hydrogen transfer is highly favored, transfer of an alkyl group does not occur. However, trimethylsilyl (TMS) groups have been found to be transferred in the mass spectra of *N*-trifluoroacetyl α-amino acid trimethylsilyl esters, Eq. 7 (13). For this reason, we prepared the TMS esters of compounds **5** and **7**. The base peak in the mass spectrum of the *O*-TMS derivative of **5** is found at *m/e* 207, Eq. 8. The only other abundant ion present in the 15 eV spectrum of this derivative is found at *m/e* 131, due to cleavage of the bond between positions 1 and 2.

In contrast, the 15 eV mass spectrum of the *O*-TMS derivative of **7** is dominated by the elimination of HOTMS, Eq. 9, and the intensity of *m/e* 207 is only 4%. These are fragmentations characteristic of the mass spectra of *O*-TMS derivatives of alcohols (14).

[9]

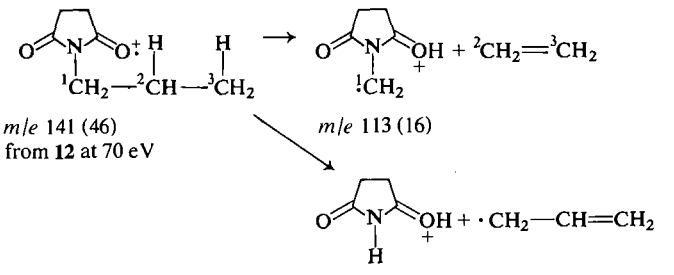


m/e 237 (4)

Discussion

It is interesting to compare our results with those obtained from *N*-*n*-propylsuccinimide (**12**) (15). Even though the McLafferty rearrangement is not important in the mass spectrum of **12**, a competition between single hydrogen transfer and double hydrogen transfer occurs, Scheme 10. The authors were not willing to decide upon a most-favored structure for the ion at *m/e* 113; however, deuterium labeling showed that the two hydrogens on the 1-carbon were retained and that 90% of the hydrogen transferred originated from the 3-carbon atom of the alkyl chain. The base peak occurs at *m/e* 100; in this case the source of the transferred hydrogens was principally the 2- and 3-carbon atoms of the *N*-alkyl chain.

In the case of the compounds of general structure **1**, the one hydrogen transfer is, for all practical purposes, the only fragmentation if there are no hydrogens on the 2-carbon atom of the *N*-alkyl chain. Hydrogen from a hydroxyl group on C-2 is much more readily transferred than hydrogen from a methyl group on C-2. If hydrogen is present on the 2-position, two transfers compete, just as they do in the mass spectrum of **12** (compare Schemes 10 and 11).



SCHEME 10

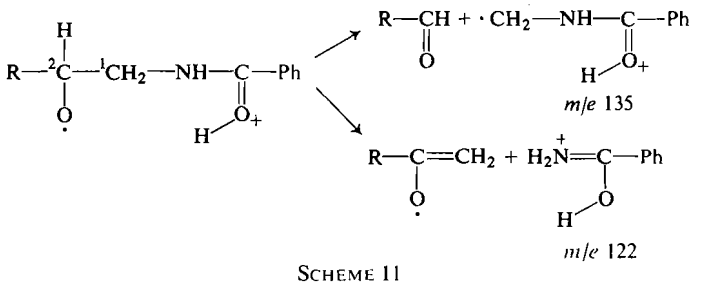

SCHEME 11

In fact, we can use the deuterium-labeling studies (Scheme 10) reported earlier (15) to support our suggestion in Scheme 11 that the peak at *m/e* 122 forms via transfer of hydrogens from the 2-carbon atom and from the hydroxyl group. We have shown the rearrangements in two steps rather than concerted. This is in agreement with evidence, recently reviewed (2), that indicates that the McLafferty rearrangement proceeds via a stepwise pathway: initial hydrogen transfer followed by carbon–carbon bond cleavage.

It is interesting to note that the base peak in the mass spectrum of *N*-*n*-propyl-2-pyrrolidone is *m/e* 98, resulting from α-cleavage of the alkyl chain (15). The abundance of the ion due to double hydrogen rearrangement (*m/e* 86) is only 7% and that due to single hydrogen rearrangement (*m/e* 99, similar to formation of *m/e* 113 in Scheme 10) is 6.5%. The authors speculated that the difference in the modes of fragmentation of the molecular ions of the *N*-alkylsuccinimides and the *N*-alkyl-2-pyrrolidones studied might be attributed to the larger number of atoms involved in resonance forms of the molecular ions in the former compounds. In regard to our compounds, the ions formed from these two rearrangements are always *m/e* 122 and *m/e* 135, so we must attribute differences in fragmentation to differences in the *N*-alkyl groups and the neutral species formed.

It has been generally observed that a large proportion of skeletal rearrangements induced by electron impact are accompanied by expulsion of neutral entities which have favorably negative heats of formation (16). This is also true of the neutral molecules ejected from the *N*-benzoyl-2-hydroxyalkylamines (**5–7**) and from the *N*-benzoyl derivative (**11**) of glycine upon formation of *m/e* 135, as shown in Table 2. The percentage of the total ion current carried by *m/e* 135 is included in Table 2 for comparison.

TABLE 2. Heats of formation (17) of neutral molecules accompanying the formation of *m/e* 135

From compound	Neutral molecule	(g kcal/mol at 25 °C) ΔH_f	*m/e* 135[a]
5	$(CH_3)_2C{=}O$	−51.8	76

11	CO_2	−94.1	42

[a]Percent of total ion current.

It can be seen from Table 2 that the importance of *m/e* 135 decreases in the series **5–7** and **9–10**. This can be rationalized by two factors: (*1*) the stabilities of the neutral molecules formed decrease,[6] and (*2*) as the substitution decreases on position 2, competing rearrangements occur. The differences in the stabilities of the neutral molecules formed can also be involved to explain the greater importance of *m/e* 135 in the mass spectra of **5** compared to **9** and of **6** compared to **10**.

The relative intensities of the molecular ions and of the rearrangement ions *m/e* 135 and 122 are compared in Table 3. Two main observations can be made from these data. First, the presence

[6]The assumption implied here is that the compounds compared are sufficiently similar to allow the following approximations: since compound A: AP (*m/e* 135) = ΔH_f (*m/e* 135) + ΔH_f (neutral fragment) − ΔH_f (compound A) + E_A, and compound B: AP (*m/e* 135) = ΔH_f (*m/e* 135) + ΔH_f (neutral fragment) − ΔH_f (compound B) + E_B. Then, ΔAP (*m/e* 135) = $\Delta\Delta H_f$ (neutral fragments) − $\Delta\Delta H_f$ (compounds), where (*1*) $\Delta\Delta H_f$ (neutral fragments) > $\Delta\Delta H_f$ (compounds), (*2*) $E_A \cong E_B$, and (*3*) the ion at *m/e* 135 is the same from compounds A and B.

TABLE 3. Relative intensities of M^+, *m/e* 135, and *m/e* 122

Compound	M^+	*m/e* 135	*m/e* 122	Preferred fragment expelled
	**2**	~0	100	—	
	**11**	5.5	100	—	CO_2
	**3**	0	100	—		**5**	0	100	—		**9**	100	66	—		**6**	0	100	54		**10**	~100	7	35		**7**	24	12	100	
of a hydroxyl group at position 2 of the *N*-alkyl group renders the molecular ions very labile. It can be seen from Eqs. 8 and 9 that this is also true of the presence of an *O*-TMS group. This is related to the fact that the transfer of hydrogen from a hydroxyl group on C-2 is preferred over the transfer of hydrogen from a methyl group at C-2, as was shown in the spectra of **3** and its deuterated analogs. This conclusion is supported by the fact that the molecular ions are the base peaks in the spectra of **9** and **10** which contain no hydroxyl groups. This behavior is in agreement with the weaker bond strength of the O—H bond with respect to the C—H bond and also in agreement with the greater stability of keto forms over corresponding enol forms (18).

The second main observation drawn from Table 3 is that the formation of *m/e* 122, the ion formed by double hydrogen rearrangement competes increasingly successfully with formation of *m/e* 135 as substitution decreases at position 2 and in the absence of a hydroxyl group at position 2. From the comparison of the spectra of **6** and **10**, it can be seen that the hydroxylic hydrogen still plays a predominant role in giving fragmentation patterns which should reflect to a certain extent the relative stabilities of the neutral fragments formed. However, a more rigorous analysis cannot be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

made at this stage due to the large number of variables at play.

Experimental

Mass spectra were obtained from AEI MS902 and Hitachi Perkin-Elmer RMU6D mass spectrometers, via the direct-probe introduction system. The low-voltage data reported are values read directly from the dials. In each case, spectra were taken at various dial readings, and small variations of the voltage did not change the results qualitatively. Exact-mass data were obtained from the MS 902, in conjunction with a PDP-8 computer.

The i.r. spectra were recorded in $CHCl_3$ solution, unless otherwise stated, on a Beckman model IR-8 double beam spectrometer. The n.m.r. spectra were recorded in $CDCl_3$ solution, unless otherwise specified, using a Varian A-60 spectrometer; peak positions are recorded in δ units and the internal standard used was TMS. Melting points were taken on a Büchi apparatus and are uncorrected.

N-Benzoyl-1-aminomethyl-4-tert-butylcyclohexanol-cis (3)

Product **3** is prepared under Schotten–Baumann conditions (19) by adding over a period of 3 h a solution of 3.44 g (24 mmol) of benzoyl chloride in 200 ml of benzene to a dispersion of 4.51 g (24 mmol) of 1-aminomethyl-4-*tert*-butylcyclohexanol (20), 3.26 g (24 mmol) of potassium carbonate, 50 ml of ether, and 50 ml of water. The mixture is left standing overnight and after the usual work-up and crystallization from chloroform–hexane yields 5.65 g (80%) of the pure *N*-benzoyl derivative (**3**); m.p. 192–193 °C; i.r. (Nujol) 3330, 1640, and 1545 cm^{-1}; n.m.r. (CF_3COOH) 0.95 (9H, s), 1.70 (10H, m), 4.00 (2H, d, J = 6 Hz), 7.80 (5H, m), and 9.10 p.p.m. (1H, t, J = 6 Hz).

N-Benzoyl-1-aminomethyl-4-tert-butyl-2,2,6,6-tetradeuterocyclohexanol-cis (3-d_4)

The tetradeuterated analog of **3** is prepared in the same manner as described above with the exception that 4-*tert*-butyl-2,2,6,6-tetradeuterocyclohexanone instead of the undeuterated ketone is used as starting material. The deuteration is carried out according to the procedure of Cope and Gale (21), *i.e.* by heating to reflux a mixture of 4-*tert*-butylcyclohexanone and heavy water. Yield 88%; mass spectrum *m/e* 158, 157, and 156 in respective ratios of 93%, 6%, and 1% which indicates 98% deuteration; i.r. (Nujol) 3350, 1640, and 1545 cm^{-1}; n.m.r. 0.95 (9H, s), 1.42 (5H, m), 2.45 (1H, m), 3.43 (1H, d, J = 6 Hz), 3.60 (1H, d, J = 6 Hz), 6.80 (1H, m), and 7.70 p.p.m. (5H, m).

N-Deutero-O-deutero-N-benzoyl-1-aminomethyl-4-tert-butylcyclohexanol-cis (3-d_2)

The dideutero analog **3**-d_2 is prepared by stirring 0.110 g (0.4 mmol) of the *N*-benzoyl derivative **3** in 1 ml of methanol O—D (purity 99%). After exchange is complete, aliquots of the solution are introduced into the mass spectrometer by means of a direct probe. Methanol O—D was introduced simultaneously via a reservoir inlet system.

N-Benzoyl-β-phenethylamine (4)

The title compound is prepared by treating 6.05 g (50 mmol) of β-phenethylamine with benzoyl chloride under Schotten–Baumann conditions (*vide supra*). Yield 10.46 g (93%); m.p. (chloroform–hexane) 116–117 °C; i.r. 3470, 1655, and 1515 cm^{-1}; n.m.r. 2.85 (2H, t, J = 7.2 Hz), 3.63 (2H, m), 6.64 (1H, broad), and 7.41 p.p.m. (10H, complex system).

N-Benzoyl-2-hydroxyisobutylamine (5)

2-Hydroxyisobutylamine

The title compound is prepared according to the procedure of Nace and Smith (22) by adding 13.60 g (150 mmol) of acetone cyanohydrin (23), dissolved in 200 ml of anhydrous ether, to a stirred suspension of 6.1 g (160 mmol) of lithium aluminum hydride in 300 ml of anhydrous ether. The mixture is heated to reflux for 3 h and the intermediate salts hydrolyzed with 7 ml of water and 7 ml of 5% aqueous potassium carbonate. The mixture is decanted and the residue triturated and digested with 200 ml of ether. The mixture is cooled and decanted after which both ethereal fractions are joined, dried, and evaporated to yield 4.81 g (34%) of the amino alcohol which is purified by distillation; b.p. 49 °C/2.5 Torr (lit. (24) 81 °C/20 Torr).

N-Benzoyl-2-hydroxyisobutylamine (5)

The title compound is prepared by treating 7.53 g (60 mmol) of 2-hydroxyisobutylamine hydrochloride with benzoyl chloride under Schotten–Baumann conditions (*vide supra*). Yield 11.03 g (95%); m.p. (chloroform–hexane) 104–105 °C; i.r. 3500–3300, 1650, and 1525 cm^{-1}; n.m.r. 1.25 (6H, s), 3.43 (2H, d, J = 6 Hz), 4.18 (1H, s), and 7.72 p.p.m. (6H, m).

N-Benzoyl-2-hydroxy-n-propylamine (6)

The title compound is prepared by treating 7.50 g (100 mmol) of 2-hydroxy-*n*-propylamine with benzoyl chloride under Schotten–Baumann conditions (*vide supra*). Yield 17.23 g (96%); m.p. (chloroform–hexane) 93–94 °C; i.r. 3500–3300, 1645, and 1525 cm^{-1}; n.m.r. 1.15 (3H, d, J = 6 Hz), 3.30 (2H, m), 3.80 (1H, m), 3.90 (1H, s), and 7.50 p.p.m. (6H, m).

N-Benzoyl-2-hydroxyethylamine (7)

The title compound is prepared by treating 4.88 g (80 mmol) of ethanolamine with benzoyl chloride under Schotten–Baumann conditions (*vide supra*). Yield 11.52 g (87%); m.p. (chloroform–hexane) 64–65 °C; i.r. (Nujol) 3500–3300, 1630, and 1550 cm^{-1}; n.m.r. 3.57 (4H, m), 4.77 (1H, s), and 7.48 p.p.m. (6H, m).

N-Benzoylneopentylamine (9)

Pivalaldoxime

The title compound is prepared (25) by adding 60 ml of an aqueous solution of sodium carbonate (10.6 g, 100 mmol) to a stirred suspension of 12.92 g (150 mmol) of pivalaldehyde in a solution of 14.02 g (200 mmol) of hydroxylamine hydrochloride in 25 ml of cold water. The mixture is stirred for one additional hour and extracted three times with 15 ml of chloroform. The organic layer is then washed with a saturated solution of sodium chloride, dried, and evaporated *in vacuo*. The residue is recrystallized from hexane to yield 10.45 g (69%) of pivalaldoxime, m.p. 38–39 °C (lit. (26) 41 °C).

Neopentylamine Hydrochloride

Pivalaldoxime is reduced according to the procedure of Cristol and Stermitz (27) by adding a solution of 10.10 g (100 mmol) of the oxime in 200 ml of anhydrous ether to a stirred suspension of 7.6 g (200 mmol) of lithium aluminium hydride in 100 ml of anhydrous ether, at such a rate as to cause a slight reflux. The mixture is then heated to reflux for 18 h and the intermediate hydrolyzed, first with humid ether, then with 5–10 ml of water. The ethereal layer is decanted and the white residual mass digested with 200 ml of chloroform for 1 h. The chloroformic phase is decanted, combined with the ethereal fraction, dried, and evaporated *in vacuo*. The residue is dissolved in 100 ml of anhydrous ether and treated with gaseous hydrogen chloride to yield 6.34 g (52%) of neopentylamine hydrochloride; m.p. (absolute ethanol – ether) 266–267 °C (lit. (28*a*) 274 °C; lit. (28*b*) 275 °C; lit. (28*c*): 273 °C).

N-Benzoylneopentylamine (9)

The title compound is prepared by treating 6.20 g (44 mmol) of neopentylamine hydrochloride under Schotten–Baumann conditions (*vide supra*). Yield 8.03 g (84%); m.p. (chloroform–hexane) 112–113 °C; i.r. 3480, 1660, and 1520 cm^{-1}; n.m.r. 0.98 (9H, s), 3.24 (2H, d, $J = 6.8$ Hz), 6.27 (1H, broad), and 7.59 p.p.m. (5H, complex system).

N-Benzoylisobutylamine (10)

The title compound is prepared by treating 7.3 g (100 mmol) of isobutylamine with benzoyl chloride under Schotten–Baumann conditions (*vide supra*). Yield 16.65 g (94%); m.p. (chloroform–hexane) 57–58 °C; i.r. 3480, 3380, 1660, and 1520 cm^{-1}; n.m.r. 0.93 (6H, d, $J = 6.6$ Hz), 1.85 (1H, n, $J = 6.6$ Hz), 3.17 (2H, t, $J = 6.6$ Hz), and 7.50 p.p.m. (6H, complex system).

Ethyl-N-benzoylglycinate

The title compound is obtained by treating 27.92 g (200 mmol) of ethylglycinate hydrochloride with benzoyl chloride under Schotten–Baumann conditions (*vide supra*). Yield 33.48 g (80%); m.p. (chloroform–hexane) 59–60 °C; i.r. 3450, 3370, 1740, 1660, and 1520 cm^{-1}; n.m.r. 1.23 (3H, t, $J = 6.8$ Hz), 4.05 (2H, d, $J = 5.3$ Hz), 4.09 (2H, quad., $J = 6.8$ Hz), and 7.53 p.p.m. (6H, complex system).

N-Benzoylglycine (11)

A solution of 8.90 g (43 mmol) of ethyl-*N*-benzoylglycinate in 50 ml of methanol is treated with 50 ml of a 10% aqueous solution of potassium hydroxide and the mixture heated to reflux for 6 h. The methanol is evaporated *in vacuo* and the remaining aqueous solution is washed with chloroform, acidified with dilute hydrochloric acid, and cooled in the refrigerator to complete crystallization, filtered *in vacuo*, and dried. Yield 6.36 g (83%); m.p. (chloroform–hexane) 186–187 °C (lit. (29) 186–187 °C); i.r. (Nujol) 3355, 3500–2500, 1740, 1600, and 1550 cm^{-1}; n.m.r. 4.05 (2H, d, $J = 5.7$ Hz), 6.70 (5H, complex system), 8.87 (1H, t, $J = 5.7$ Hz), and 11.68 p.p.m. (1H, broad).

N-Benzoyl-2-hydroxy-2,2-diphenylethylamine (2)

A solution of 20.70 g (100 mmol) of ethyl-*N*-benzoylglycinate in 50 ml of ether is added dropwise to a solution of phenylmagnesium bromide in ether at such a rate as to cause a slight reflux. The Grignard reagent is prepared by adding slowly, at room temperature, a solution of 31.4 g (200 mmol) of phenyl bromide in 400 ml of ether to 5.28 g (220 mmol) of magnesium turnings covered with a little ether. The reaction mixture is stirred at room temperature for an additional 15 min. The resulting magnesium salt is hydrolyzed with an ice-cold saturated solution of ammonium chloride in water until two layers are formed. The layers are decanted and the aqueous solution extracted with chloroform. The ethereal and chloroformic fractions are joined and the resulting mixture dried and evaporated *in vacuo*. Yield 25.42 g (82%); m.p. (absolute ethanol) 181–182 °C; i.r. (Nujol) 3435, 3360, 1630, and 1530 cm^{-1}; n.m.r. (DMSO-d_6) 4.12 (2H, d, $J = 5.3$ Hz), 6.25 (1H, s), 7.43 (15H, complex system), and 8.00 p.p.m. (1H, t, $J = 5.3$ Hz).

We wish to acknowledge financial support from the National Research Council of Canada. The exact-mass data were obtained by Dr. A. S. Blair.

Rate Constants for the Reaction of Fluorine Atoms with Nitric Oxide in the Presence of Various Third Bodies[1,2]

EDWARD G. SKOLNIK, STEPHEN W. VEYSEY, MAHMOODA G. AHMED, AND WILLIAM E. JONES

Department of Chemistry, Dalhousie University, Halifax, Nova Scotia B3H 4J3

Received October 1, 1974[3]

EDWARD G. SKOLNIK, STEPHEN W. VEYSEY, MAHMOODA G. AHMED, and WILLIAM E. JONES. Can. J. Chem. **53**, 3188 (1975).

Absolute rate constants are reported for the reaction of fluorine atoms with nitric oxide in the presence of the third bodies Ar, He, Ne, N_2, NO, CO_2, CF_4, SF_6, and C_2F_6. The values determined in the present study are compared to those found for reactions of Cl, H, and O with NO.

EDWARD G. SKOLNIK, STEPHEN W. VEYSEY, MAHMOODA G. AHMED et WILLIAM E. JONES. Can. J. Chem. **53**, 3188 (1975).

On rapporte les constantes absolues des vitesses de réaction des atomes de fluor avec l'oxyde d'azote en présence de Ar, He, Ne, N_2, NO, CO_2, CF_4, SF_6 et C_2F_6. On compare les valeurs obtenues au cours de ce travail avec celles rapportées pour les réactions du Cl, H et O avec NO.

[Traduit par le journal]

Introduction

Until recent years, very few studies of the reaction kinetics of fluorine atoms were attempted. This was mainly due to the difficulty of producing fluorine atoms while at the same time minimizing competitive reactions involving fluorine molecules. Recently, fluorine atoms have been produced from a radio-frequency discharge through F_2 (1), by reaction of active nitrogen with NF_2 (2), by photolysis of heavy metal fluorides (3–5), and by microwave discharge through F_2 (6) or CF_4 (7).

In this paper we describe measurements of the kinetics of the reaction of fluorine atoms with nitric oxide in the presence of various third bodies. In the present study, fluorine atoms have been produced by microwave decomposition of CF_4. Kolb and Kaufman (7) found that microwave decomposition of CF_4 produced fluorine atoms essentially free of contamination by molecular fluorine.

Johnston and co-workers (8, 9) found that the reaction of fluorine atoms with nitric oxide produced a continuous visible emission between 640 and 510 nm, with a maximum intensity at 609.5 ± 1 nm. The reaction of fluorine atoms with nitric oxide in the presence of a third body produces nitrosyl fluoride in both ground and excited electronic states. The electronically excited FNO* molecules decay to ground state FNO by both radiative and nonradiative processes. In addition to reaction with NO, fluorine atoms may be lost by a wall reaction. The process may be represented as follows:

$$\text{[1]} \qquad \mathrm{F + NO + M} \xrightarrow{k_{1a}} \mathrm{FNO + M}$$

$$\mathrm{F + NO + M} \xrightarrow{k_{1b}} \mathrm{FNO^* + M}$$

$$\text{[2]} \qquad \mathrm{FNO^*} \xrightarrow{k_2} \mathrm{FNO} + h\nu$$

$$\text{[3]} \qquad \mathrm{FNO^* + M} \xrightarrow{k_3} \mathrm{FNO + M}$$

$$\text{[4]} \qquad \mathrm{F + (wall)} \xrightarrow{k_w} \text{Products}$$

The intensity of the observed emission is directly proportional to the concentration of FNO*. By assuming steady state conditions for [FNO*], it may be shown that for any given concentration of nitric oxide and third body M, the intensity is directly proportional to the concentration of fluorine atoms

$$\text{[5]} \qquad I \propto \frac{k_{1b}k_2[\mathrm{NO}][\mathrm{M}]}{k_2 + k_3[\mathrm{M}]}[\mathrm{F}]$$

By measuring the emission I at various reaction times, the variation in fluorine atom concentration with time may be determined and the absolute rate of the reaction of fluorine atoms with nitric oxide, $k_1 = k_{1a} + k_{1b}$, may be calculated.

Experimental

The fast flow apparatus (Fig. 1) consisted of a rectangular Pyrex reaction cell, 35 cm in length and 2.8 cm on a side. CF_4 (flow rate 0.2 μmol s^{-1}) and either Ar or He were passed through a 2450 MHz microwave discharge produced by a Burdick MW/200 Microwave Diathermy unit. The fluorine atoms produced were introduced through a 0.5 mm nozzle fitted concentrically into the reaction cell by means of a Soveril screw joint. Nitric oxide and various third bodies entered the reaction cell through a 10 mm tube 3 cm upstream from the nozzle. The fluorine atoms and carrier gas thus entered an atmosphere of nitric oxide and third body. Flow rates were calibrated and controlled by standard methods. The pressure in the reaction cell was monitored by a manometer filled with Dow Corning #702 Silicone Oil. The Welch Vacuum Pump Model 1397 had a pumping speed of 500 l min^{-1}. Flow rates varied from 50–700 μmol s^{-1} depending upon the nature of the third body and object of the experiment.

The emission was monitored by a photomultiplier tube (EMI 9592 B) operating at e.h.t. 1050 V, equipped with an Oriel interference filter allowing transmission from 615 to 625 nm. The photomultiplier was mounted on a movable base which allowed tracking along the length of the reaction cell. The photomultiplier output was recorded on a Texas Instrument Recorder. By moving the photomultiplier along the reaction zone at a constant speed, a reaction profile (emission intensity *vs.* time) was obtained.

Argon and helium were obtained from Linde, and were passed through a trap containing 80–100 mesh molecular sieve #5A at −196 °C (He) or −78 °C (Ar). Nitric oxide (Matheson) was degassed and purified by passing it through ascarite. Neon, carbon tetrafluoride, sulfur hexafluoride, and perfluoroethane (Matheson) were degassed and used without further purification. Nitrogen (Linde) was passed through a silica gel trap immersed in Dry Ice and then through a liquid nitrogen trap. Carbon dioxide (Liquid Carbonic) was stated to have a purity of 99.99% and was used after degassing without further purification.

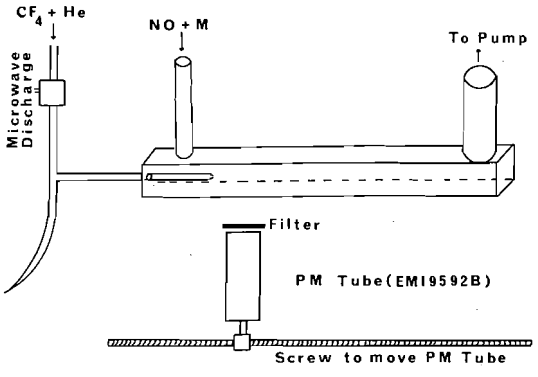

FIG. 1. Schematic of reaction vessel.

Results

Any of the substances present in the reaction zone may act as third bodies. For the very simplest case this means that at least NO and the inert carrier gas will act in this way. Additional third bodies are present during other experiments. For the general case, the steps resulting in the removal of fluorine atoms are:

$$[1NO] \quad F + NO + NO \xrightarrow{k_{1NO}} FNO + NO$$

$$[1M] \quad F + NO + M \xrightarrow{k_{1M}} FNO + M$$

$$[1M'] \quad F + NO + M' \xrightarrow{k_{1M'}} FNO + M$$

and other third bodies as necessary.

$$[4] \quad F\,(+\text{ wall}) \xrightarrow{k_w} \text{Products}$$

The disappearance of fluorine atoms may be expressed as

$$[6] \quad -\frac{d[F]}{dt} = k_{1NO}[F][NO]^2 + k_{1M}[F][NO][M] + k_{1M'}[F][NO][M'] + \ldots + k_w[F]$$

Under pseudo-first order conditions ([F] ≪ [NO] and [M]),

$$[7] \quad -\frac{d[F]}{dt} = k'[F]$$

where $k' = k_{1NO}[NO]^2 + k_{1M}[NO][M] + k_{1M'}[NO][M'] + \ldots + k_w$

Since [F] ∝ I, a plot of ln I *vs.* time, gives a slope k'. Sample plots showing this pseudo-first order behavior are presented in Fig. 2, where fluorine atoms are allowed to react with excess NO in the presence of He.

A series of values of k' were determined by the above method at various concentrations of helium while maintaining a constant concentration of nitric oxide. A plot of k'/[NO] *vs.* [He] as shown in Fig. 3 gives a straight line, the slope of which is $k_{1He} = (4.2 \pm 0.1) \times 10^{16}$ cm^6 mol^{-1} s^{-1}.

In order to calculate a value for k_{1NO}, values of k' were determined for various concentrations of NO, at a constant concentration of car-

For personal use only.

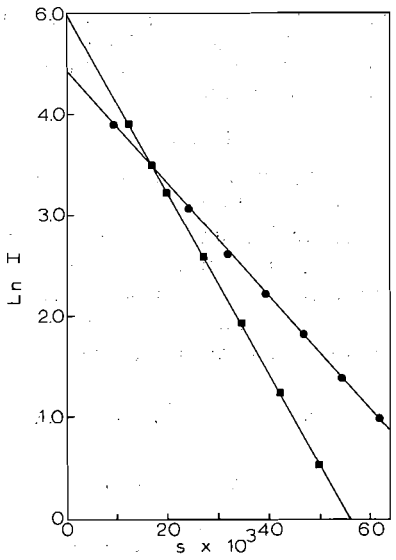

FIG. 2. Sample plots showing pseudo-first order behavior for reaction of nitric oxide with fluorine atoms in helium. [He] = 80.2×10^{-9} mol cm^{-3}; ■, [NO] = 22.1×10^{-9} mol cm^{-3}; ●, [NO] = 12.8×10^{-9} mol cm^{-3}.

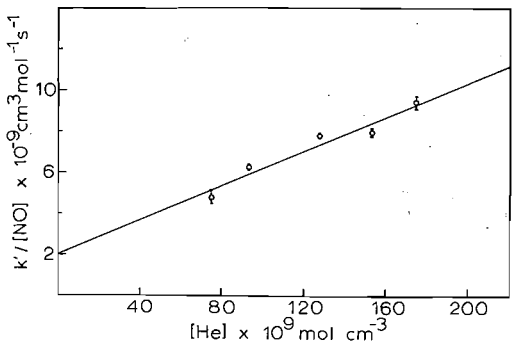

FIG. 3. Dependence of k'/[NO] on the concentration of helium for the reaction of fluorine atoms with nitric oxide in the presence of helium. [NO] = 8.0×10^{-9} mol cm^{-3}.

rier gas (He). The set of equations $k' = k_{1NO}[NO]^2 + k_{1He}[He][NO] + k_w$ was solved using linear regression techniques to give the best values of k_{1NO}, k_{1He}, and k_w. The value determined for k_w was 12 ± 19 s^{-1}, in reasonable agreement with Pollock and Jones (10). k_{1NO} was found to be $(4.8 \pm 6.4) \times 10^{16}$ cm^6 mol^{-2} s^{-1}, which may be compared with a value of 11×10^{16} cm^6 mol^{-2} s^{-1} obtained by MacLean and co-workers from e.s.r. studies (11), and k_{1He} was calculated to be $(3.2 \pm 2.8) \times$

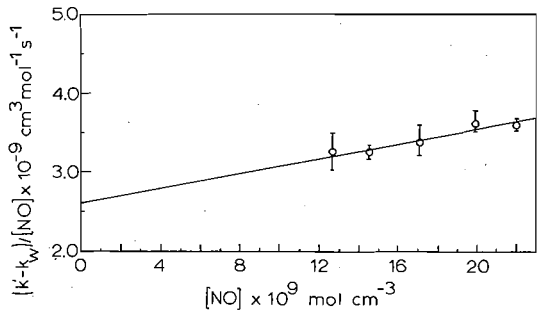

FIG. 4. Dependence of $(k' - k_w)$/[NO] on the concentration of nitric oxide for the reaction of fluorine atoms with nitric oxide in the presence of helium. [He] = 80.2×10^{-9} mol cm^{-3}.

10^{16} cm^6 mol^{-2} s^{-1}, which compares favorably with the value of $4.2 \pm 0.4 \times 10^{16}$ cm^6 mol^{-2} s^{-1} determined by variation of [He]. This value may also be compared to the value of 2.8×10^{16} cm^6 mol^{-2} s^{-1} found by MacLean and co-workers (11). In order to give an indication of the variation of the data in these calculations a plot of $(k' - k_w)$/[NO] *vs.* [NO] is given in Fig. 4. As is subsequently shown in the discussion, the effect of CF_4 as a third body may be ignored in these calculations.

The values of k_{1M} were determined for M = Ar, Ne, N_2, CO_2, CF_4, SF_6, and C_2F_6, from plots of k'/[NO] *vs.* [M] as shown in Figs. 5 and 6. In each case at least six determinations of k' were made from plots of ln I *vs.* time at each concentration of M. All values determined for k' have been collected in several tables and placed in the Depository of Unpublished Data.[4]

For M = Ar, two different sets of measurements were made. The first in which argon was used both as the gas to support the microwave discharge with additional argon mixed with the nitric oxide, and the second in which helium was used as the carrier gas and argon was added only to the nitric oxide stream. A plot of k'/[NO] *vs.* [Ar] for each set of measurements is given in Fig. 5. The values of k_{1Ar} obtained in the absence and presence of helium are $(3.2 \pm 0.3) \times 10^{16}$ and $(2.5 \pm 0.1) \times 10^{16}$ cm^6 mol^{-2} s^{-1}. These values may be compared with the

[4]Complete set of tables is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2, or directly from Dr. W. E. Jones, Department of Chemistry, Dalhousie University, Halifax, Nova Scotia B3H 4J3.

*This value is an average of that obtained in the presence and absence of helium.

able, values from other determinations are included for comparison purposes.

Discussion

In the calculations of all the rate constants, an assumption is made that the concentration of CF_4 used as the source of fluorine atoms is too small to be an effective third body. The rate constant k_{1CF_4} is 1.6×10^{17} cm^6 mol^{-1} s^{-1}. The CF_4 concentration in those experiments where CF_4 is used only as a fluorine atom source is of the order of 0.1×10^{-9} mol cm^{-3}. The NO concentration is of the order of 12×10^{-9} mol cm^{-3}. The importance of CF_4 as a third body is represented by the term $k_{1CF_4}[CF_4][NO]$ in the expression for k'. Under the above conditions the value of this term is about 0.2 s^{-1} which is insignificant when compared with the overall value of k'.

In Table 2 we have compared the rate constants obtained for the reaction of F + NO in the presence of various third bodies with the atom – diatomic molecule reactions Cl + NO, H + NO, O + NO, and O + O_2.

The only previous measurement for the rate constant of the reaction of F + NO + M is also included in Table 2. The results by MacLean and co-workers were presented in two different reports (11, 12). Although there is some disagreement among their values as presented in the two reports (see Table 1), especially for M = NO, the value for M = Ar agrees favorably with the value found in the present work. The values presented in ref. 11 for M = Ar, He, and NO, show a similar trend to those found in the present study when the ratios k_{1M}/k_{1Ar} are compared.

When the reactions of F + NO are compared with other combination reactions of an atom with a diatomic molecule, very similar results are observed for the rate constant ratios k_{1He}/k_{1Ar}, k_{1Ne}/k_{1Ar}, and k_{1N_2}/k_{1Ar}. However, minor variations are observed when the ratios for larger third bodies are compared.

We thank Dr. J. A. Coxon of the Department of Chemistry, Dalhousie University, for helpful comments.

CNDO/2 Studies on Ion Solvation by Methanol

MARK SALOMON
335 Fair Haven Road, Fair Haven, New Jersey 07701
Received April 3, 1975

MARK SALOMON. Can. J. Chem. **53**, 3194 (1975).

CNDO/2 calculations are presented for the solvation of the ions H^+, Li^+, Na^+, F^-, and Cl^- by methanol. The results are compared with previous calculations for solvation by water and with the experimental data of Kebarle. Predicted stabilization energies are grossly overestimated but differences in stabilization energies agree well with the experimental data.

MARK SALOMON. Can. J. Chem. **53**, 3194 (1975).

On présente des calculs CNDO/2 pour la solvatation des ions H^+, Li^+, Na^+, F^- et Cl^- dans le méthanol. On compare les résultats avec des calculs antérieures de solvatation par l'eau et aussi avec des données expérimentales de Kebarle. Les énergies de stabilisation prédites sont de beaucoup surestimées mais les différences entre les énergies de stabilisation s'accordent bien avec les données expérimentales.

Introduction

Semiempirical and *ab initio* SCF–MO calculations have been reported for a variety of hydrogen bonded systems (1). These calculations have led to several important structural features concerning the hydrogen bond. In pure water (2) and methanol (2*a*, 2*b*, 3) the trend is of increasing H-bond energies as the size of the solvent cluster increases. CNDO studies on $(H_2O)_n$ polymers indicate that chain structures are favored for small values of n ($n = 2, 3$) (2*a*, 2*b*) and cyclic structures are favored for large values of n ($n \geq 4$) (3*a*). *Ab initio* studies on $(H_2O)_n$ favor cyclic over chain structures for $n \geq 3$ (2*c*). For methanol polymers, $(MeOH)_n$, CNDO studies show that open chain structures are more stable than cyclic ones for values of n from 2–6 (2*a*, 2*b*, 3*b*). CNDO and *ab initio* studies on protonated water (4), $H^+(H_2O)_n$, show similar behavior; the former calculations (4*a*) weakly favor open chain structures whereas the latter ones (4*b*) favor cyclic structures for $n > 4$. Both methods show that protons serve as a bridge for charge delocalization and that charge transfer along the chain is significant. The present paper is mainly concerned with the analogous system $H^+(MeOH)_n$.

Alkali metal and halide ion solvation by water have been studied by the CNDO (5–8) and *ab initio* (7, 9) methods and CNDO calculations are presented below for the solvation of these ions by methanol. The reactions studied are

[1] $$n\text{MeOH} + M^+ = M^+(\text{MeOH})_n$$

and

[2] $$\text{MeOH} + X^- = X^-(\text{MeOH})$$

where M = H, Li, and Na, and X = F and Cl. For proton solvation, clusters of up to five molecules are considered and for all other cases, only the monomer ($n = 1$) is considered.

Calculations and Results

The CNDO/2 method of Pople *et al.* (10) was used in its original form. Complete evaluation of the potential energy surfaces was not attempted. Carbon was assumed always to be tetrahedral and the C—O and C—H bond distances were fixed at 1.43 and 1.09 Å, respectively. The C—O—H and H. . .O—H angles and O—H and O. . .O distances were optimized.

$MeOH_2^+$ Monomer

Figure 1 shows the geometrical model of $CH_3OH_2^+$. Both β and θ were optimized starting with a planar configuration where $\beta = 120°$ and $\theta = 0°$. Selected results for total energies, E_t, stabilization energies, ΔE_s, and the stabilization energy per O. . .H interaction, $\Delta E_s/n$, are given

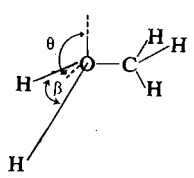

FIG. 1. $CH_3OH_2^+$ monomer geometry.

TABLE 1. CNDO results for selected protonated methanol species

Structure type	Species	$-E_t$ (a.u.)	$-\Delta E_s$ (kcal)	$-\Delta E_s/n$
Planar chains (Fig. 2*c*)	$H^+(MeOH)$	28.9788	265.0	265.0
proton between	$H^+(MeOH)_2$	57.6022	318.2	159.1
molecules 1 and 2	$H^+(MeOH)_3$	86.2206	345.8	115.3
	$H^+(MeOH)_4$	114.8054	363.5	90.9
	$H^+(MeOH)_5$	143.3862	378.7	75.7
proton between	$H^+(MeOH)_4$	114.8182	371.5	92.9
molecules 2 and 3	$H^+(MeOH)_5$	143.4008	387.9	77.6
Eigen	$H^+(MeOH)_3$	86.2308	340.3	113.4
	$H^+(MeOH)_4$	114.8076	349.1	87.3

in Table 1.[1] The stabilization energy is defined by

$$[3]\quad \Delta E_s = E_t\{H^+(MeOH)_n\} - nE_t(MeOH)$$

For the methanol monomer, E_t(MeOH) values were obtained from previous work (3*b*). For planar $H^+(MeOH)_n$, E_t(MeOH) for the staggered configuration and a C—O—H angle of 120° equals −28.5565 a.u. For the optimized $H^+(MeOH)_n$ structures, E_t(MeOH) is −28.5628 a.u. (staggered structure where the C—O—H angle is 109.5°). Although the planar structure is not the most stable one, it is of interest since X-ray data indicate its predominance in liquid MeOH (see discussion, ref. 3*b*). The rotational energy, ΔE_R, for planar $MeOH_2^+$ is negligible (0.02 kcal/mol). The calculation of ΔE_R for the optimized $MeOH_2^+$ was not performed.

$H^+(MeOH)_n$ Polymers

In Fig. 2, models of planar $(MeOH)_n$ and $H^+(MeOH)_n$ are shown. Calculations for cyclic structures were not carried out. Several chain type structures were considered. Figure 2*b* is the structure where $MeOH_2^+$ exists as a separate entity in the chain. The most stable configuration turned out to be that for a symmetrically located proton as shown in Fig. 2*c*. In Fig. 2*c*, the proton is shown between MeOH molecules 1 and 2 and moving the proton between molecules 2 and 3 resulted in an increase in stability (see Table 1).

The geometric quantities optimized for the planar chains were the O—H and O. . .H distances. The O—H distance in O—H. . .O is 1.05 Å compared to 1.03 Å for a free hydroxyl group. For these planar structures, both the C—O—H and H—O. . .H angles were fixed at 120° and the O. . .H—O angles at 180°. Optimization of these bond angles was carried out and resulted in C—O—H, H—O. . .H, and O. . .H—O angles of 109.5, 109.5, and 180°, respectively. These optimized structures are referred to as bent chains.[1]

Several other $H^+(MeOH)_n$ structures were investigated. Figure 3 shows an Eigen type structure for $H^+(MeOH)_4$ which is modeled after the structures for $H_9O_4^+$ and $H_{11}O_5$ (11). Removing the MeOH molecule marked with an asterisk in Fig. 3 results in an Eigen type structure for $H^+(MeOH)_3$ which differs from the bent chain structure in that $MeOH_2^+$ exists as a separate entity whereas in the latter, the proton is symmetrically located between molecules 1 and 2 of Fig. 2*c*. Another structure was considered in which a proton is coordinated to the oxygens of MeOH for n values of 3 and 4. For these central proton models, both planar and trigonal pyramidal configurations (O. . .H. . .O angle = 109.5°) were investigated for $n = 3$, and a tetrahedral configuration for $n = 4$.[1]

Alkali Metal and Halide Monosolvates

The geometric models for monomer solvates are shown in Figs. 4 and 5 for cations and anions, respectively. Also shown in these figures are the models for the water solvates. The results for the monomer solvates are given in Table 2. The stabilization energies in Table 2 were calculated from [4].

$$[4]\quad \Delta E_s = E_t\{\text{ion} - (MeOH)_n\} - (n-1)E_t(MeOH) - E_t(MeOH + \text{ion})$$

The last term in this equation, E_t(MeOH +

ion), refers to the reactants at infinite separation, r_∞. For calculation purposes, r_∞ was taken as 15–20 Å. Included in Table 2 are the aqueous CNDO/2 results which were obtained from refs. 4–8.

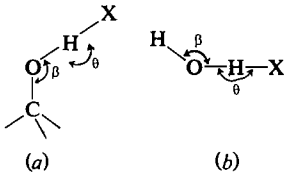

FIG. 5. Models for anion solvation by (*a*) methanol and (*b*) water.

Discussion

$H^+(MeOH)_n$ Systems

In calculating ΔE_s from [3], the important structures appear to be the open chain planar and bent models. The Eigen type and central proton structures are not considered to contribute significantly to the structure of $H^+(MeOH)_n$ clusters. The stabilization energies for the reactions

[1] $$H^+ + n\text{MeOH} = H^+(MeOH)_n$$

are grossly overestimated, *e.g.* the experimental proton affinity of methanol is −182 kcal/mol

(12) whereas the CNDO result is −265 kcal/mol. Similarly, the proton affinity of water is, experimentally, −165 kcal/mol (13) and the CNDO result (4*a*) is −250 kcal/mol. The overestimation of stabilization energies is a recognized weakness of the CNDO method (10, 14, 15), but trends in stabilities and geometries do appear to be well reproduced (14, 15). ΔE_s for [1] is, correctly, given by [4]. Taking $r_\infty = 20$ Å for the MeOH. . .H^+ separation, $E_t(\text{MeOH} + H^+) = -27.0393$ a.u.[2] Using this value for the last term in [4] leads to abnormally large ($\simeq 10^3$ kcal) values for ΔE_s. If one considers the reactions

[5] $\quad H^+(\text{MeOH})_{n-1} + \text{MeOH} = H^+(\text{MeOH})_n$

where $n \geq 2$, for which

[6] $\quad \Delta E_5 = E_t\{H^+(\text{MeOH})_n\} - E_t\{H^+(\text{MeOH})_{n-1}\} - E_t(\text{MeOH})$

it is found that considerable accuracy in the CNDO results is achieved. Table 3 compares the calculated ΔE_5 values with the experimental (12) enthalpies, ΔH_5, for the gas phase reactions. It should be noted that E_t values neglect kinetic, zero-point, and correlation energies, but a considerable portion of these factors probably cancel when differences in E_t values are considered.

The addition of a proton to MeOH results in a large delocalization of the positive charge to every atom except carbon.[1] Successive solvation of $MeOH_2^+$ results in progressive delocaliza-

[2]The closed shell CNDO calculation for this state is actually that for $MeOH^{2+} + H^-$ and is not therefore the state of interest. A proper occupation of orbitals would permit [4] to be used. (The author is grateful to one of the reviewers for pointing out this fact.)

tion of positive charge over the chain. For $n \geq 3$, a significant donation of electrons to the chain oxygens occurs mainly from the methyl hydrogens. Similar results were reported for $H^+(H_2O)_n$ chains (4). This is due to the shielding of the oxygens in the chain due to the increasing positive charges on the H-bonded hydrogens. The stabilization energy per O. . .H interaction, $\Delta E_s/n$ (Table 1) is seen to decrease as n increases. This result suggests that the O. . .H. . .O bonds weaken as the chain length increases. In $(MeOH)_n$ clusters, charge transfer was observed to increase to the terminal molecules of the chain and the stabilization energy per O. . .H interaction thereby increased (3).

The nature of proton solvation by methanol thus appears to be similar to that by water with the exception that Eigen type and, probably, cyclic type clusters do not contribute significantly to the overall properties. If the planar and bent structures can be identified with the condensed and gas phases respectively, then the average strength of a hydrogen bond appears to be greater in the condensed system. In Frank and Wen's flickering cluster model of solvent structure (16), the increase or decrease in chain length (see also discussion in refs. 3 and 4) can be thought of as being followed by rapid charge delocalization amongst the hydroxyl hydrogens thus affording the anomalous Grothuss type conductivity properties. In water–methanol mixtures containing 15–20 mol% methanol, the protonic conductivity reaches a minimum value which is attributed to classical transport of H_3O^+ and/or $MeOH_2^+$ (17). It would be of interest to extend the CNDO calculations to mixed H_2O–MeOH clusters.

Alkali Metal and Halide Monosolvates

Experimental data for ion solvation by methanol are scarce. For the solvation of Cl^- by MeOH, the enthalpy for the gas phase reaction 2 is 14.1 kcal/mol (18). For the gas phase reactions with water

$$[7] \qquad H_2O + Y = Y(H_2O)$$

the following enthalpies were measured: for Y = F^- and Cl^-, $\Delta H_7^0 = 23.3$ and 13.1 kcal/mol, respectively (18); for Y = Li^+ and Na^+, $\Delta H_7^0 = 34.0$ and 24.0 kcal/mol, respectively (19). *Ab initio* results (9) for [7] give the following: for Y = Li^+ and Na^+, $\Delta H_7^0 = 34.1$ and 23.3 kcal/mol, respectively. There is no doubt that the CNDO results overestimate the stabilization energies to an extent which cannot be corrected for by the kinetic, zero-point, and correlation energies which amount, at most, to ~3 kcal/mol (9). A similar effect was seen above to exist for the $H^+(MeOH)_n$ systems and which is typical of the CNDO method. However differences in stabilization energies were seen to give acceptable results. For the alkali metal cations and halide anions, stabilization energy differences (ΔE_8) for the gaseous reactions are defined for

$$[8] \qquad MeOH + Y(H_2O) = H_2O + Y(MeOH)$$

where Y is Li^+, Na^+, F^-, or Cl^-. Table 4 compares the CNDO/2 values of ΔE_8 with the experimental (12, 18) enthalpies, ΔH_8. For the two cases where experimental data exist, the agreement is quite good despite the neglect of kinetic, zero-point, and correlation energies from ΔE_8. The fact that ΔE_8 for Li^+ and Na^+ are 2–4 times larger than that for H^+ is similar to the behavior of these ions in solution (20).

TABLE 4. CNDO/2 and experimental energies for reaction 8

Ion	ΔE_8 (kcal/mol)	ΔH_8*
H^+	−15.3	−15.2
Li^+	−56.6	
Na^+	−36.5

Received May 22, 1975

F. PATRICIA MULLINS and COLUMBA CURRAN. Can. J. Chem. **53**, 3200 (1975).

Mössbauer, infrared, and electric dipole moment data are reported for several complexes of the type (*i*) $R_2Sn(NCS)_2L_2$ and (*ii*) R_2SnX_2B (where R = C_4H_9, C_2H_3, C_6H_5; X = Cl, NCS; L = monodentate ligands with O, S donor atoms; B = bidentate ligands with O, P, As donor atoms). Quadrupole splittings indicate *trans* C—Sn—C bonds in octahedral complexes of divinyl- and diphenyltin diisothiocyanate with bidentate oxygen-donor ligands, in contrast to a *cis* configuration for complexes with bidentate nitrogen-donor ligands. Data indicate that the 1:2 complex of 2,2-bipyridyl-*N*,*N*′-dioxide with $Bu_2Sn(NCS)_2$ is polymeric, with octahedral monomer units having one bridging and one terminal NCS group, a bridging $bipyO_2$ ligand and *trans* butyl groups. $[Ph_2Sn(NCS)_2]_2 \cdot bipyO_2$ appears to be a dimer with a bridging $bipyO_2$ ligand and five-coordinate tin atoms. Mössbauer parameters for $R_2SnX_2L_2$ and R_2SnX_2B complexes having oxygen donors are similar.

F. PATRICIA MULLINS et COLUMBA CURRAN. Can. J. Chem. **53**, 3200 (1975).

On rapporte, pour plusieurs complexes de type (*i*) $R_2Sn(NCS)_2L_2$ et de type (*ii*) R_2SnX_2B (où R = C_4H_9, C_2H_3, C_6H_5; X = Cl, NCS; L = ligands monodentates avec des atomes d'oxygène et de soufre comme donneurs; B = ligands bidentates avec des atomes d'oxygène, de phosphore et d'arsenic comme donneurs), des données de Mössbauer, d'infrarouge et de moment dipolaire. Les couplages quadripolaires indiquent que les liens C—Sn—C sont *trans* dans les complexes octaédriques des diisothiocyanates de divinyl- et diphényl étain avec des ligands bidentates contenant des atomes d'oxygène comme donneurs alors qu'ils ont une configuration *cis* pour les complexes avec des ligands bidentates contenant des atomes d'azote comme donneurs. Les données indiquent que le complexe 1:2 du bipyridyl-2,2 *N*,*N*′-dioxyde avec le $Bu_2Sn(NCS)_2$ existe à l'état de polymère avec des unités octaédriques possédant un groupe NCS terminal et un autre servant de pont, un ligand $bipyO_2$ agissant comme pont et des groupements butyles en position *trans*. Il semble que le $[Ph_2Sn(NCS)]_2 \cdot bipyO_2$ existe sous forme de dimère avec un ligand $bipyO_2$ agissant comme pont et des atomes d'étain pentacoordonnés. Les paramètres de Mössbauer pour les complexes $R_2SnX_2L_2$ et R_2SnX_2B possédant des oxygènes comme donneurs sont semblables.

[Traduit par le journal]

Introduction

Previous studies of Mössbauer spectra and electric dipole moments of complexes of $R_2Sn(NCS)_2$ with *o*-phenanthroline and with 2,2-dipyridyl reveal a change from *trans* C—Sn—C bonds in dibutyl compounds to *cis* C—Sn—C bonds in divinyl and diphenyl compounds; the corresponding R_2SnCl_2 complexes are all *trans* (1–3). $R_2Sn(tropolonate)_2$ compounds also have *trans* butyl and *cis* vinyl and phenyl groups (3, 4). It is of interest to determine the configuration of complexes of $R_2Sn(NCS)_2$ with neutral bidentate ligands having oxygen donor atoms. The work of Bancroft *et al.* (5) on complexes of R_2SnCl_2 with the dioxides of 1,2-bis(diphenylphosphino)ethane, bis(diphenylarsino)methane, and 2,2′-bipyridyl suggested the complexing of these oxygen-donor ligands, along with 1,2-bis(diphenylarsino)ethane dioxide, with $R_2Sn(NCS)_2$. Attempts to prepare complexes of the diisothiocyanates with bidentate ligands having P, As, and S as donor atoms were unsuccessful.

Complexes with R_3PO and R_3AsO afford a comparison with those of the above bidentate ligands. Holloway *et al.* (6) report only 1:1 complexes of these monodentate ligands with $Ph_2Sn(NCS)_2$; only 2:1 complexes were isolated in the present investigation.

Previous studies have shown an excellent correlation between configurations of octahedral diorganotin(IV) complexes as revealed by Mössbauer spectra of solids and electric dipole moments in solution (1–3, 7). In the present study only the Bu_3PO and Ph_3AsO complexes of $R_2Sn(NCS)_2$ were sufficiently soluble and undissociated in benzene for meaningful dielectric constant measurements.

Experimental

Preparation of Compounds

Hexamethylphosphoric triamide (HMPA) was a Baker Analyzed reagent, and tetramethylthiourea (TMTU) was purchased from Aldrich Chemical Co. Inc. 1,2-Bis(diphenylphosphino)ethane, 1,2-bis(diphenylarsino)ethane, bis(diphenylarsino)methane, and *o*-phenylenebis(dimethylarsine) (DIARS) were obtained from Strem Chemicals Inc. Absolute ethanol was purchased from Consolidated Alcohols Ltd; all other solvents were Baker or Fisher Scientific Analyzed Reagents. The sources of other reagents have been indicated previously (3, 7). Thiophene-free benzene was refluxed over phosphorus pentoxide for several hours before being distilled.

Di-*n*-butyl-, diphenyl-, and divinyltin diisothiocyanate were prepared as described previously (2, 3). Complexes of these compounds with monodentate ligands were formed by mixing their absolute ethanol solutions with the ligands in diethyl ether and/or benzene solutions in a 1:2 ratio; diphenyltin diisothiocyanate was also mixed with these ligands in a 1:1 ratio. In all cases chemical analyses showed that 1:2 complexes were formed with the monodentate ligands. The complexes of Ph_3PO, Ph_3AsO, and HMPA formed as white precipitates on mixing; that of $Ph_2Sn(NCS)_2$ with TMTU precipitated as a cream–yellow powder. The complexes of Bu_3PO were obtained on evaporation of ethanol–benzene–ether solutions as cream (dibutyl) and peach (diphenyl) colored crystals.

The dioxides of the bidentate ligands, 2,2′-bipyridyl, 1,2-bis(diphenylphosphino)ethane, 1,2-bis(diphenylarsino)ethane, and bis(diphenylarsino)methane (hereafter referred to as $bipyO_2$, B(DPO)E, B(DAO)E, and B(DAO)M respectively) were prepared by their oxidation with 30% hydrogen peroxide as described previously (8–12). They were obtained as white powders: $bipyO_2$, decomposed above 270 °C (lit. (8) 297 °C, (9) 310 °C (dec.)); B(DPO)E, m.p. 262–264 °C (lit. (10) 256–258 °C, (11) 275–276 °C, (12) 266 °C); B(DAO)E, 160 °C (dec.) (lit. (10) 178–179 °C); B(DAO)M, 130 °C (dec.). Complexes of these ligands were obtained as white or pale cream precipitates on mixing absolute ethanol solutions of R_2SnX_2 with the ligands in ethanol and/or benzene solutions. Data for complexes of $bipyO_2$ with $R_2Sn(NCS)_2$ indicated bridging, but the other complexes were obtained as 1:1 monomers. R_2SnX_2 complexes with B(DP)E and DIARS were obtained as white and cream powders upon evaporation or cooling of their ethanol–benzene–ether solutions.

All precipitates were filtered under vacuum, washed with the solvent used and light petroleum ether (b.p. 30–60 °C) and all complexes were dried under vacuum for several hours.

Attempts to isolate complexes of dimethylsulfoxide, 8-aminoquinoline, triphenylphosphine, triphenylarsine, tetramethylenediamine, tetramethylurea, dimethoxyethane, triphenylphosphine sulfide, tripiperidinephosphine sulfide, tripyrrolidinophosphine sulfide with $R_2Sn(NCS)_2$ were not successful. Attempts to purify $R_2Sn(NCS)_2$ complexes of B(DP)E, B(DA)E, and DIARS resulted in dissociation.

Analytical data and melting points for the complexes are given in Table 1.

Mössbauer and Infrared Spectra

The instrumentation and data processing were described previously (1, 3, 7), except that an LTV LING AITEC LTD (England) Type 106 constant acceleration transducer was used instead of an Austin Science Associates Mössbauer Spectrometer Drive Model S3 Model K3 constant acceleration linear motor. In measurements with the AM-1 spectrometer, dibutyltin(kojate)$_2$ was used as a secondary standard (δ = 1.38 mm s^{-1}, ΔE_Q = 3.70 mm s^{-1} (5)). Isomer shifts, δ, relative to barium stannate and quadrupole splittings, ΔE_Q, listed in Table 3 are considered to be accurate to $\pm$0.05 mm s^{-1} with a relative precision of $\pm$0.03 mm s^{-1}. Γ_1 and Γ_2 are absorption half-widths. The spectrum of $Ph_2Sn(NCS)_2(TMTU)_2$ is illustrated in Fig. 1. Asymmetries are present in the doublet spectra for compounds **5**, **6**, **7**, **18**, **20**, and **22**.

Infrared spectra in potassium bromide disks were obtained with Perkin-Elmer 521 and 457 and Beckman IR-33 spectrometers.

Dielectric Constants of Benzene Solutions

These were obtained as in previous investigations (13) using an oscillator similar to that described by Estok (14). The $\Delta\varepsilon/wf_2$ ratios listed in Table 2 are extrapolated values, except for $Ph_2Sn(NCS)_2(Ph_3AsO)_2$ where an average value was used. Electric moments were calculated from the Higasi equation, using a value of 0.8481 for B (15–17).

Discussion of Results

Complexes with Monodentate Ligands

The quadrupole splittings obtained for compounds **1–9** indicate that they have octahedral configurations with the R groups *trans* in the solid state. As in *trans* complexes investigated previously (2, 3), the isomer shifts are smaller and the quadrupole splittings larger for the diisothiocyanates than for the corresponding dichlorides, consistent with a greater polarity for the Sn—NCS than for the Sn—Cl bond.

Ph_3AsO has a greater dipole moment than Ph_3PO (18) and is expected to effect a slightly greater electron release to tin on complex formation. In line with this expectation, the quadrupole splittings for the Ph_3AsO complexes, **1**, **5**, are smaller than for the corresponding Ph_3PO complexes, **3**, **7**. The electric dipole moments of R_3PO and R_3AsO complexes, Table 2, are complicated by rotation about the O—Sn bond.

TABLE 1. Analysis and melting points of $R_2SnX_2L_2$ and R_2SnX_2B complexes

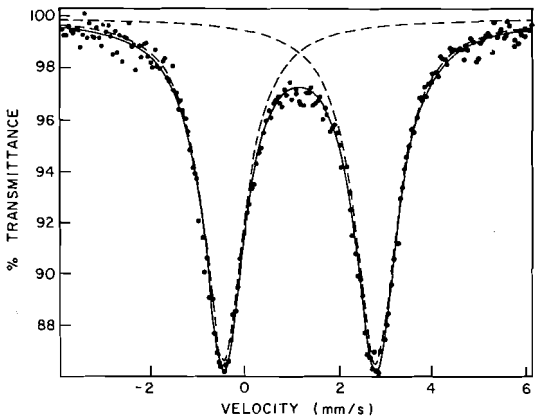

FIG. 1. ^{119m}Sn Mössbauer spectrum of $Ph_2Sn(NCS)_2(TMTU)_2$ *vs.* a $Ba^{119m}SnO_3$ source.

Values calculated for an all-*trans* configuration are 5 and 6 D, respectively, for the Bu_3PO and Ph_3AsO complexes (7), and for a *cis* arrangement of oxide ligands, 13.5 and 15 D (7, 2). The experimental values indicate a *trans* arrangement of all ligands. The values of $\Delta\varepsilon/wf_2$ for the dibutyltin(IV) complexes increase with decreasing solute concentration; the values listed in Table 2 are extrapolated. For complete dissociation of the complexes, the calculated values of $\Delta\varepsilon/wf_2$ are 10.6 and 10.5. The data suggest a partial dissociation of these all-*trans* complexes, increasing with decreasing concentration.

TABLE 2. Electric moment data in benzene solutions at 25 °C

Compound	$1000wf_2$	$\Delta\varepsilon/wf_2$	μ_H (D)
$Bu_2Sn(NCS)_2(Ph_3AsO)_2$	1.1–18.4	5.9	7.4
$Bu_2Sn(NCS)_2(Bu_3PO)_2$	14.7–38.3	7.6	7.4
$Ph_2Sn(NCS)_2(Ph_3AsO)_2$	5.4–10.1	3.5	5.8
$Ph_2Sn(NCS)_2(Bu_3PO)_2$	13.6–44.4	4.8	6.0

A comparison of the quadrupole splittings for $Ph_2Sn(NCS)_2(HMPA)_2$, 3.73 mm s^{-1}, and $Vin_2Sn(NCS)_2(HMPA)_2$, 4.20 mm s^{-1} (3), indicates a significant deviation from 180° for the C—Sn—C bond angle in the former compound. The Mössbauer parameters for both

						860sh
24 $Ph_2SnCl_2 \cdot B(DAO)M$	1.20	3.63	1.13	1.12		870
						855sh
25 $Ph_2SnCl_2 \cdot DIARS$	1.30	3.07	1.24	1.17		
26 $Ph_2SnCl_2 \cdot B(DP)E$	1.31	3.27	1.07	1.11		

$Ph_2SnCl_2 \cdot TMTU$, **10**, and $Vin_2SnCl_2 \cdot TMTU$ (3) are expected values for five-coordinate tin complexes. The relatively small quadrupole splitting for $Ph_2Sn(NCS)_2(TMTU)_2$, **9**, is a reflection of the greater electron release by sulfur than by oxygen on complex formation. The larger isomer shift for this compound than for compounds **5** to **8** indicates that the tin s character of the Sn—S bond is more important than the shielding effect of the electrons of the Sn—S bond in determining the relative isomer shift.

A single infrared absorption associated with the O → Sn stretching vibration is expected for compounds **1** to **8** in an all-*trans* configuration. The complexity of the spectra makes it difficult to assign a definite absorption to this or to the N—Sn vibration. However, in the majority of spectra, a single peak, not assigned to the ligands, is present in each of the 407–367 and in the 336–288 cm^{-1} regions, lending support to an all-*trans* configuration. The absorptions assigned to ν_{P-O} in Table 3 represent the expected decreases in frequency on complex formation. The absorption associated with the N—C—N antisymmetric stretching vibration at 1504 cm^{-1} in tetramethylthiourea (19) is shifted to 1555 and 1578 cm^{-1} in the spectra of **9** and **10** respectively; these frequencies compare with 1550 and 1579 cm^{-1} for the corresponding divinyl compounds (3).

Complexes with Bidentate Ligands

The large quadrupole splittings obtained for the 1:1 complexes of diphenyl- and divinyltin diisothiocyanate with B(DPO)E and B(DAO)E reveal *trans* C—Sn—C bonds in these complexes, in contrast to *cis* C—Sn—C bonds in complexes with *o*-phenanthroline and 2,2-bipyridyl (2, 3). These two sets of complexes differ not only in the nature of the donor atoms, but in having seven-membered and five-membered chelate rings, respectively. It is of interest to study complexes of $R_2Sn(NCS)_2$ with bidentate ligands having one oxygen and one nitrogen donor atom; attempts at synthesis of such complexes are underway in these laboratories. The absorptions associated with the PO stretching vibrations in the B(DPO)E complexes listed in Table 3 compare with 1185 cm^{-1} for pure B(DPO)E (12).

The similarity in the Mössbauer parameters of compounds **19** and **23**, and of **21** and **24**, indicate a negligible difference between the effects of the seven-membered ring in the B(DAO)E complexes and the six-membered ring in the B(DAO)M complexes. The relative quadrupole splittings for **14** and **19**, and for **18** and **22**, indicate a greater electron release by the AsO than by the PO donor groups, as in the complexes of the monodentate ligands.

The relative values of the quadrupole splittings for Ph_2SnCl_2·DIARS, 3.07 cm^{-1} and Ph_2SnCl_2·B(DP)E, 3.27 cm^{-1}, indicate the expected greater electron release by the arsenic than by the phosphorus donor atoms, and signficantly greater electron release than by the AsO and PO groups. The similar isomer shifts for the DIARS and B(DP)E complexes may indicate a greater tin s-character for the Sn—As bond, resulting in a decreased tin s-character for the Sn—C bond in the DIARS complex.

$BipyO_2$ forms a 1:2 complex with $Bu_2Sn(NCS)_2$, **13**. The shift in the absorptions associated with the NO stretching vibrations from 1262 and 1255 cm^{-1} in $bipyO_2$ (20) to 1218 and 1200 cm^{-1} in the spectrum of the complex indicates the formation of O → Sn dative bonds. The composition requires a bridging $bipyO_2$ ligand. The presence of two approximately equal absorptions in the antisymmetric NCS stretching region, at 2070 and 2040 cm^{-1}, indicate that half the NCS groups are bridging and half terminal. This implies polymerization with six-coordination for each tin atom. The 2070 cm^{-1} absorption compares to about 2100 cm^{-1} for Sn—NCS—Sn bridging in solid $R_2Sn(NCS)_2$ compounds and suggests a weaker S—Sn bond in **13**, likely associated with steric effects. The large quadrupole splitting, 4.02 cm^{-1} (which compares with 4.07 for $Me_2Sn(NCS)_2$·$bipyO_2$ (5)), indicates *trans* C—Sn—C bonds. The values of δ and ΔE_Q for **13** are intermediate between those for bridged $Bu_2Sn(NCS)_2$ and unbridged $Bu_2Sn(NCS)_2$·bipy (2). We have obtained a 1:1 complex of $Vin_2Sn(NCS)_2$ with $bipyO_2$ for which the infrared spectrum in the C—Sn stretching region (3) indicates *trans* C—Sn—C bonds. The composition, the NO frequencies at 1205 and 1220 cm^{-1}, and the single NCS absorption at 2040 cm^{-1} indicate a bridged dimer for $[Ph_2Sn(NCS)_2]_2$·$bipyO_2$, **12**, with five-coordination for each tin atom.

The financial assistance of the National Research Council of Canada and the generous cooperation of Dr. M. Falk of the Atlantic Regional Laboratory in Halifax are gratefully acknowledged. Special thanks are due to Dr. W. Lieper and his research assistants of the Physics Department, to Dr. O. Knop of the Chemistry Department of Dalhousie for the use of their Mössbauer facilities and computer programs, and to E. Nelson of Mount St. Vincent University for technical assistance with the monodentate ligand work. We are also grateful to the Radiation Laboratory for the use of their Mössbauer and computer facilities for the bidentate ligand portion of the study. The Radiation Laboratory is operated by the University of Notre Dame under contract with the U.S. Energy Research and Development Administration; this is ERDA Document No. C00-38-1003.

Apparent Molal Volumes and Heat Capacities of Tetrabutylammonium Bromide in Aqueous Electrolyte Solutions

NICOLE DESROSIERS AND JACQUES E. DESNOYERS[1]

Department of Chemistry, Université de Sherbrooke, Sherbrooke, Quebec J1K 2R1

Received April 30, 1975

NICOLE DESROSIERS and JACQUES E. DESNOYERS. Can. J. Chem. **53**, 3206 (1975).

The apparent molal volumes and heat capacities of Bu_4NBr were measured in aqueous solutions of NaF, NaCl, NaBr, KBr, NaAc, and NH_4Ac at 25 °C with a flow densimeter and a flow microcalorimeter. The derived transfer functions of Bu_4NBr from water to the electrolyte solutions, after correction for the long-range coulombic forces, are all negative. This suggests that the noncoulombic interactions between hydrophobic and hydrophilic ions result in negative contributions to volumes and heat capacities.

NICOLE DESROSIERS et JACQUES E. DESNOYERS. Can. J. Chem. **53**, 3206 (1975).

Les capacités calorifiques et les volumes apparents molaires de Bu_4NBr ont été mesurés dans les solutions aqueuses de NaF, NaCl, NaBr, KBr, NaAc et NH_4Ac à 25 °C au moyen d'un microcalorimètre et d'un densimètre digital à écoulement continu. Les capacités calorifiques et les volumes de transfert de Bu_4NBr de l'eau aux solutions électrolytiques, dérivés à partir de ces données et corrigés pour les forces coulombiennes à longue portée, sont tous négatifs. Ceci suggère que les interactions non-coulombiennes entre un ion hydrophobe et un ion hydrophile contribuent négativement aux volumes et aux capacités calorifiques.

Introduction

The studies of aqueous mixed electrolyte solutions are usually aimed at a better understanding of the specific ion interactions in solutions (1). As seen from the recent review of Anderson and Wood (2), most of the thermodynamic functions of mixing of the electrolytes were measured on common ion mixtures at constant ionic strength. Using Friedman's nomenclature (3), the maximum free energy of mixing of the electrolytes MX and NX is characterized by the parameter

$$[1]\quad g_0 = (B_{MN} - B_{MM} - B_{NN}) + I(B_{MNX} - B_{MMX} - B_{NNX})$$

where the B's are the cluster integrals representing the various pair and triplet interactions between ions and I is the ionic strength. Similar equations can be written for the other thermodynamic functions of mixing.

The mixing functions involving tetraalkylammonium halides are of particular interest since the larger members of this family of electrolytes are hydrophobic. The free energies (4), enthalpies (5), and volumes (6) of mixing are vastly different in magnitude and sign from the mixing of inorganic electrolytes. For example, Wood and Anderson (5) find that the heats of mixing of two structure breakers are usually endothermic while those of structure breakers with hydrophobic electrolytes are large and exothermic. These functions of mixing are reflecting primarily the decrease in the hydrophobic–hydrophobic interactions due to a dilution effect and do not give us much information on the interactions between hydrophobic and hydrophilic ions. To overcome this difficulty, it is often preferable to measure the standard functions of transfer of hydrophobic electrolytes from water to aqueous electrolyte solutions. Keeping the hydrophobic electrolyte near infinite dilution and varying the concentration of the hydrophilic electrolyte, it should be possible to see the importance of increasing hydrophobic–hydrophilic interactions. Such measurements were made by Cassel and Wen (7) for the transfer free energies, enthalpies, and entropies of tetraalkylammonium bromides from water to aqueous urea solutions and by Ahluwalia and co-workers for the enthalpies of transfer of the larger tetraalkylammonium bromides from water to aqueous electrolyte solutions (8). From the temperature dependence of these enthalpies of transfer it is possible to derive the corresponding heat capacities of transfer (8), but this method is not always sufficiently precise to determine unambiguously the dependence of the heat capacities of transfer on the electrolyte concen-

tration and its specificity with various electrolytes.

We therefore felt it would be useful to measure the heat capacities and volumes of transfer of Bu_4NBr from water to aqueous electrolyte solutions from specific heat and density data.

Experimental

The origin of and the purification procedure for alkali halides (9) and Bu_4NBr (10) have been given elsewhere. The ammonium and sodium acetates (NH_4Ac and NaAc) (Fisher Certified) were dried under vacuum for about 36 h at 50 °C. The NH_4Ac solutions were prepared under nitrogen atmosphere, and the densities of the solutions were found to be identical, within experimental uncertainty, to those obtained with solutions prepared from the freeze-dried salt (11). All solutions were prepared by weight with deionized distilled water (Continental Deionized Water System) and the concentrations expressed in molalities, *i.e.*, number of moles of solute per kg of solvent (or mixed solvent). The general technique and instrumentation used for density (12) and heat capacity (13) measurements have been described elsewhere.

Results

The apparent molal volumes ϕ_V and heat capacities ϕ_C of Bu_4NBr in the electrolyte solutions were calculated in the usual manner (14) from the experimental densities and volumetric specific heats considering the mixture (water + electrolyte) as the solvent. Combining these results (15) with the corresponding ones in pure water (16, 17), the standard functions Y of transfer from water (W) to an electrolyte solution (W + E) can be derived:

$$[2]\quad \Delta\overline{Y}^0_{Bu_4NBr}(W \rightarrow W + E) = \overline{Y}^0(W + E) - \overline{Y}^0(W)$$

These standard partial molal functions would normally be obtained by extrapolation of the ϕ_Y data to infinite dilution. However, we have found that even the transfer functions of Bu_4NBr from water to 11.4 m ammonium acetate were the same, within experimental uncertainty, for Bu_4NBr concentrations of 0.05 and 0.1 m. Therefore all measurements were made at 0.1 m Bu_4NBr, and the transfer functions were assumed to be equal to those at infinite dilution.

Contrary to the mixing functions at constant ionic strength, the transfer functions are influenced by the long-range coulombic forces; Bu_4NBr is dilute but not the added electrolyte. Since we are primarily interested in the more specific noncoulombic interactions, it would be preferable, if possible, to correct the data for the long-range coulombic forces. This can be achieved by subtracting from each ϕ_V or ϕ_C the contribution from the limiting Debye–Hückel law at 25 °C; for ϕ_V in $cm^3\ mol^{-1}$ and ϕ_C in $J\ K^{-1}\ mol^{-1}$ these terms are respectively 1.868 $(d_0I)^{1/2}$ (18) and 28.99 $(d_0I)^{1/2}$ (16) where d_0 is the density of the pure solvent. These corrections are of course exact only at very low concentrations, but they are still useful in showing the correct initial trends in the transfer functions.

The corrected standard transfer volumes $\Delta\overline{V}^*_{Bu_4NBr}(W \rightarrow W + E)$ and heat capacities $\Delta\overline{C}^*_{Bu_4NBr}(W \rightarrow W + E)$ are shown in Figs. 1 and 2 for the systems where the cosolvents are NaF, NaCl, NaBr, KBr, NaAc, and NH_4Ac. The corresponding apparent molal quantities of the binary system can be represented as a function of the molality by

$$[3]\quad \phi_Y = \phi_Y^0 + A_Y(d_0m)^{1/2} + B_Ym + \ldots$$

where A_Y is the slope of the limiting Debye–Hückel theory. The functions $\phi_Y - \phi_Y^0 - A_Y(d_0m)^{1/2}$ are plotted against m in Fig. 3. At low concentrations, these results agree well with those previously published for alkali halides (9, 19), sodium and ammonium acetates (11).

In order to distinguish between pair and triplet interactions in the ternary systems, the complementary transfer functions $\Delta \bar{Y}^*_{NaAc}$(W → W + Bu_4NBr) were also measured and are shown in Figs. 1 and 2.

Discussion

The observed $\Delta \bar{Y}^*_{Bu_4NBr}$(W → W + E), corrected for the Debye–Hückel interactions, are all negative at low concentrations. There have been two main approaches to the interpretation of the transfer functions of electrolytes from water to binary systems: the binary system may be considered a uniform medium less structured or more structured than water or the ternary system can be interpreted in terms of solute–solute interactions.

The first approach can be exemplified with urea as a cosolvent. The transfer functions to urea solutions, $\Delta \bar{Y}^0_{Bu_4NBr}$(W → W + urea) all tend to level off at high concentration and their signs are opposite those we would expect for the hydration function of Bu_4NBr (20). If most of the hydration of Bu_4NBr is assumed to be structural in origin, *i.e.* if it depends on the long-range structure of water, then we can interpret the data in terms of the urea–water mixture being a less-structured medium than pure water (21, 22).

The uniform solvent approach fails if the cosolvent is hydrophobic or if it is an hydrophilic electrolyte. The enthalpy of transfer $\Delta \bar{H}^0_{Bu_4NBr}$(W → W + *tert*-butyl alcohol) is positive (23), while a negative value is predicted if a *tert*-butyl alcohol solution is assumed to be more structured than pure water at low concentration. Also $\Delta \bar{V}^0_{Bu_4NBr}$(W → W + alkali halide) are negative in contradiction with $\Delta \bar{V}_{Bu_4NBr}$(W → W + urea) (22) if both alkali halides and urea are assumed structure breakers. Finally, the lack of correlation between the ternary (Figs. 1 and 2) and binary systems (Fig. 3) seems to exclude this model as being generally applicable.

The solute–solute approach seems more promising. The present transfer functions can be interpreted in a way similar to the ternary system electrolyte–nonelectrolyte–water (24, 25). The cosolvent concentration dependence of the general transfer functions, corrected for the long-range coulombic forces, is given by

$$[4]\quad \frac{d}{dm_E}\{\Delta \bar{Y}^*_{Bu_4NBr}(W \rightarrow W + E)\} = \sum B_{ij} + m_E \sum B_{ijj} + \ldots$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where the B's are interaction parameters between pairs, triplets, etc. At low cosolvent concentrations where only pair interactions are important $\sum B_{ij}$ should be equal to $\sum B_{ji}$ (24). It therefore follows that if the reference electrolyte is at infinite dilution

$$[5]\quad \frac{d}{dm_E}\{\Delta \bar{Y}^*_{Bu_4NBr}(W \rightarrow W + E)\} = \frac{d}{dm_{Bu_4NBr}}\{\Delta \bar{Y}_E^*(W \rightarrow W + Bu_4NBr)\}$$

This is in fact observed in the case of NaAc; it therefore seems that the transfer functions of electrolytes at 0.1 m are not too different from the standard values.

Neglecting the self interactions of Bu_4NBr in comparison with the mixed interactions, there is a total of four pair interactions responsible for the observed initial slopes: Bu_4N^+–X^-, Bu_4N^+–M^+, Br^-–M^+, and Br^-–X^-. The magnitude of the interactions between hydrophilic ions can be predicted from the excess functions of alkali halides (9, 19). Up to 1 m, ϕ_V and ϕ_C can be represented by [3] where B_Y is a measure of all the interactions in excess to the Debye–Hückel ones. With alkali halides, these B_Y parameters are in general an order of magnitude smaller than $\sum B_{ij}$ of the ternary system. Therefore, the pair interactions Br^-–M^+ and Br^-–X^- cannot be too important in comparison with the ones involving Bu_4N^+. An examination of Fig. 1 also shows that, in general, changing the anion of the electrolyte MX has a larger effect than changing the cation. This is expected from the Brønsted principle (1, 26), which states that specific interactions between like charged particles are less probable than between unlike charged ones. Therefore, it seems that the observed transfer functions of Bu_4NBr from water to an electrolyte solution are primarily reflecting interactions between hydrophobic and hydrophilic ions of opposite signs, and these interactions are negative for both volumes and heat capacities.

The signs of the specific hydrophobic–hydrophilic pair interactions between ions are the same as those observed between nonelectrolytes and hydrophilic ions. Ben-Naïm and Egel-Thal (27) and Tiepel and Gubbins (28) have measured the transfer functions of argon from water to aqueous electrolyte solutions and their results suggest that the hydrophobic–hydrophilic parameters are positive for free energies, enthalpies, and entropies and negative for volumes. Desnoyers *et al.* (24) also measured similar transfer enthalpies, volumes, and heat capacities of *tert*-butyl alcohol from water to electrolyte solutions and found endothermic interactions for enthalpies and negative volumes and heat capacities for the transfer to hydrophilic electrolyte solutions. They have also measured transfer volumes of *tert*-butyl alcohol from water to water + Bu_4NBr mixtures. They have observed a minimum, the values being initially negative and becoming positive around 2 m Bu_4NBr. Tiepel and Gubbins (28) have measured a positive transfer volume of argon from water to an aqueous solution of Bu_4NBr at approximately 2 m. As they do not have results at lower concentrations, it is impossible to know if the transfer of argon also shows a minimum at low concentration of Bu_4NBr. It is important to note that while hydrophobic–hydrophilic and hydrophobic–hydrophobic interactions seem to have the same sign for volumes and enthalpies, they seem to have opposite ones for heat capacities; the interactions between two strongly hydrophobic solutes lead to a positive contribution to the concentration dependence of the heat capacity (14, 20, 24). While the signs of these interactions are now fairly well established, there is not, to our knowledge, any simple model that can account for all these trends.

The volumes of transfer seem to be much more specific to the nature of the anion than the heat capacities of transfer. In some cases the origin of the specificity is obvious. For example, in the transfer functions $\Delta\bar{Y}^*_{NaAc}(W \rightarrow W + Bu_4NBr)$, the deviations from linearity are in the direction of hydrophobic bonding. In the vicinity of hydrophobic ions, Bu_4N^+ will have a stronger tendency to associate, and this association results in an increase in volume and decrease in heat capacity (14). No such association is possible with NaAc and the transfer functions $\Delta\bar{Y}^*_{Bu_4NBr}$ $(W \rightarrow W + NaAc)$ are linear to much higher concentrations.

At very high concentration, $\Delta\bar{Y}^*_{Bu_4NBr}(W \rightarrow W + E)$ must be tending to $\Delta\bar{Y}^*_{Bu_4NBr}(W \rightarrow E)$, where E represents the hypothetical molten electrolyte at 25 °C. It therefore seems that in a molten salt ϕ_C^0 of Bu_4NBr would be much less positive than in pure water. This is not unexpected if we consider that the three-dimensional structure of water, which is responsible for the high heat capacity of Bu_4NBr, is no longer present. The sign of $\Delta\bar{V}^*_{Bu_4NBr}(W \rightarrow E)$ is less

obvious since this function is also sensitive to geometrical factors and coulombic interactions in addition to structural effects. It does not seem possible at present to draw any unambigous relation between the order of the transfer functions at high cosolvent concentration and the properties of the cosolvent electrolyte.

We are grateful to the Defence Research Board of Canada for financial assistance. N.D. would also like to thank the National Research Council of Canada for the award of a scholarship.

Reaction of Hydrazonyl Halides with Derivatives of Thiourea and Thiosemicarbazide; A New Source of *C*-Amino- and *C*-Hydrazino-1,2,4-triazoles

PEDER WOLKOFF

Department of General and Organic Chemistry, University of Copenhagen, H. C. Ørsted Institute, Universitetsparken 5, DK-2100 Copenhagen, Denmark[1]

AND

STEVEN T. NEMETH AND MARTIN S. GIBSON[2]

Department of Chemistry, Brock University, St. Catharines, Ontario L2S 3A1

Received April 23, 1975

PEDER WOLKOFF, STEVEN T. NEMETH, and MARTIN S. GIBSON. Can. J. Chem. **53**, 3211 (1975).

Reaction of hydrazonyl halides with (substituted) thioureas and thiosemicarbazides gives mainly 1,3,4-thiadiazolines, the stronger base being preferentially eliminated in the process. Similar reactions in presence of triethylamine give *C*-amino- and *C*-hydrazino-1,2,4-triazoles, respectively, together with the hydrazonyl sulfide.

Potassium cyanide cleavage of a hydrazonyl disulfide gives the corresponding 1,3,4-thiadiazoline and thiohydrazide.

PEDER WOLKOFF, STEVEN T. NEMETH et MARTIN S. GIBSON. Can. J. Chem. **53**, 3211 (1975).

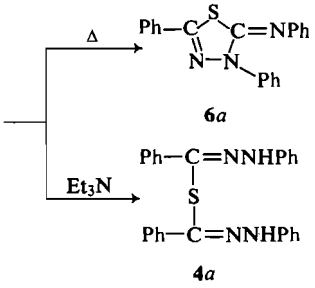
La réaction des halogénures d'hydrazonyle avec des thiourées et des thiosemicarbazides (substituées) conduit principalement au thiadiazolines-1,3,4; au cours de ce processus, la base la plus forte est éliminée. Des réactions semblables effectuées en présence de triéthylamine donnent respectivement des *C*-amino et des *C*-hydrazinotriazoles-1,2,4 aux côtés de sulfure d'hydrazonyle.

La rupture d'un disulfure d'hydrazonyle par le cyanure de potassium conduit à la thiohydrazide et à la thiadiazoline-1,3,4 correspondante.

[Traduit par le journal]

Reaction of hydrazonyl halide **1***a* with phenylthiourea in ethanol in presence of excess triethylamine (molar ratio 2:1:4) was found to give the hydrazonyl sulfide **4***a* in high (88%) yield, contrasting markedly with the formation of 5-phenylimino-2,4-diphenyl-1,3,4-thiadiazoline (**6***a*), when **1***a* and phenylthiourea (molar ratio 1:1) were refluxed together in ethanol (1); see eq. 1. The significant difference in reaction course led us to reexamine and extend the previous work by Fusco on the reaction of hydrazonyl halides (**1**) with various derivatives of thiourea and thiosemicarbazide (1, 2).

[1] $PhCCl{=}NNHPh + PhNHCSNH_2$



The two hydrazonyl halides **1***a* and *b* used in this study together with products isolated are depicted in Scheme 1 and the results of the reactions examined are summarized in Table 1.

The reactions performed in refluxing ethanol reveal two general trends: (*i*) the products isolated are all 1,3,4-thiadiazolines, (*ii*) the least basic part of the sulfur nucleophile (Base–C(S)–Base′) remains in the cyclic product (*cf.* Table 1). These results may be rationalized in terms of a sulfur attack at the α carbon atom in **1** with displacement of the halogen, exemplified in eq. 2 with **1***a* and 4-phenyl-3-thiosemicarbazide, to give a hydrazonylated adduct, which undergoes ring closure; elimination of hydrazine, followed by deprotonation then affords **6***a*. The base elimination step follows principally the sequence $NH_3 > NH_2NH_2 > PhNHNH_2 > PhNH_2$ according to the decreasing order of base strength; in reaction 2, hydrazine is preferred over aniline as the leaving base. Normally the eliminated base

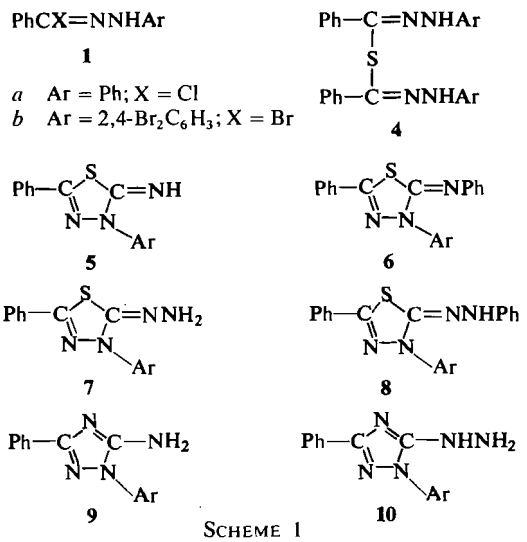
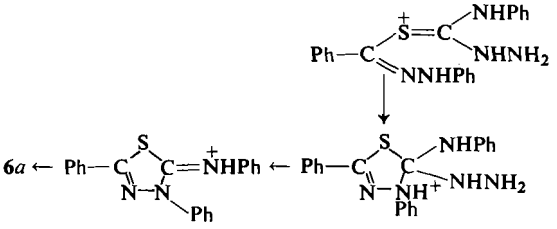


SCHEME 1

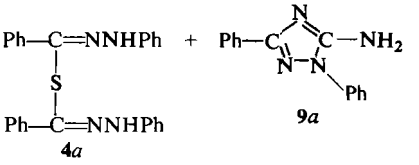
[2] $PhCCl{=}NNHPh + PhNHCSNHNH_2 \xrightarrow{-Cl^-}$ (1a)



functions as the deprotonating agent but in the reaction of **1***a* with 1,4-diphenylthiosemicarbazide, the eliminated phenylhydrazine is apparently not sufficiently strong for this purpose as **6***a* was isolated as the hydrochloride from this reaction.

Similar experiments (see Table 1) were conducted in the presence of excess triethylamine (4 equiv.) and the general products were found to be the hydrazonyl sulfide (**4**) and a 1,2,4-triazole (**9** and **10**). Thus reacting **1***a* with thiourea in ethanol in presence of triethylamine (molar ratio 2:1:4) gave **4***a* (21%) and 5-amino-1,3-diphenyl-1,2,4-triazole (**9***a*) (59%); see eq. 3. These results

[3] $PhCCl{=}NNHPh + NH_2CSNH_2 \xrightarrow{Et_3N}$ (1a)



may be interpreted in terms of two competitive reactions, one leading to **4** and one to **9** (or **10**, in the case of thiosemicarbazide), via a common intermediate. Hydrogen sulfide abstraction from thiourea by the reactive nitrilimine (**2***a*), formed *in situ* by dehydrochlorination of **1***a* with triethylamine (3), produces a thiohydrazide (**3***a*) and cyanamide (eqs. 4 and 5); **3***a* then becomes the source of **4***a* (eqs. 6–9) by processes already discussed (4).

9*a*

A cycloaddition reaction between **2***a* and the cyanamide formed may give **9***a* (eq. 10) in a similar way to the nitrilimine–nitrile reaction to give 1,2,4-triazoles (5). The initial formation of thiohydrazides and cyanamides is supported in some experiments by examination of reaction mother liquors (t.l.c. and mass spectrum); in the reaction between **1***a*, phenylthiourea, and triethylamine, phenylcyanamide was actually recovered after benzoylation as the benzoyl derivative Ph(PhCO)NC≡N.

The competition between these reactions is very favorable to triazole formation with thiourea, but less so with thiosemicarbazide, and so unfavorable with phenylthiourea that no triazole was obtained in the cases examined. In the last cases, hydrazonyl sulfides are the major products and a new process becomes evident which leads (by loss of aniline) to a 1,3,4-thiadiazoline (**5***b*). The former reactions constitute reasonable sources of the triazole derivatives.

Finally the reactions of **1** with KSCN and the hydrazonyl disulfide **11** with KCN were examined. The reaction with KSCN afforded **5**, independently of reaction conditions and with no detection of a hydrazonyl thiocyanate (**1**; X = SCN) (i.r.).[3] Indirect evidence for an intermediate hydrazonyl thiocyanate was found when **4***b* was isolated as a by-product from treatment of **11** with KCN at room temperature in chloroform, the major products being **5***b* and **3***b*. The isolation of **4***b* may be rationalized in terms of heterolytic cleavage of the hydrazonyl S—S bond by action of the cyanide ion, in a similar way to that known for ordinary disulfides (6), to give the thiohydrazide anion and **1** (X = SCN); see eq. 11. Nucleophilic displacement of thiocyanate ion from **1** (X = SCN), before cyclization to **5***b*, by the thiohydrazide anion would then give the sulfide **4***b*. Compound **11** is very easily cleaved by KCN in refluxing acetonitrile to give approximately equal amounts of **3***b* and **5***b*.

[11] Ph—C(S—S—C(Ph)=NNH-2,4-$Br_2C_6H_3$)=NNH-2,4-$Br_2C_6H_3$ + CN^- ⟶ PhC(S⁻)=NNH-2,4-$Br_2C_6H_3$

PhC(SCN)=NNH-2,4-$Br_2C_6H_3$ ⟶ **5***b*

11

This work provides a convenient alternative method for the preparation of *C*-amino- and *C*-hydrazino-1,2,4-triazoles (7).

Experimental

Melting points were determined using a Reichert microscope. Ethanol (EtOH) used was absolute grade. All experiments performed under basic conditions were stirred at least 2 h before the addition of triethylamine (Et_3N).

Reactions with Thiourea

Et_3N (5 ml) was added to a stirred solution of **1***a* (8, 9) (2.30 g, 10.0 mmol) and thiourea (0.38 g, 5.0 mmol) in EtOH (250 ml). After 7 h the solution was concentrated *in vacuo* to *ca.* 50 ml, filtered, and the solid washed carefully with water to give **4***a* (0.41 g, 21%), m.p. 161–162 °C (lit. (4) 158–160 °C) (0.24 g after crystallization from benzene; identified by i.r. spectrum (4)). The ethanolic filtrate was evaporated and the residue was dissolved in benzene (20 ml). Addition of aqueous HCl (20 ml; 4 *M*) afforded a precipitate which was collected and washed with ether to give a white solid (1.32 g). This was stirred in concentrated ammonia (15 ml) for 30 min, filtered, and dried. Crystallization from benzene–hexane (1:1) gave **9***a* (0.70 g, 59%), m.p. 149–151 °C (after recrystallization, m.p. 149–151 °C); mass spectrum *m/e* 236 (M^+).

Anal. Calcd. for $C_{14}H_{12}N_4$: C, 71.17; H, 5.12; N, 23.71. Found: C, 70.93; H, 5.05; N, 24.15.

[3]Recently the synthesis of 5-imino-2-benzoyl-4-aryl-1,3,4-thiadiazolines by reacting aroylhydrazonyl halides with KSCN has been reported (13).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The benzene – aqueous HCl filtrate was separated and the benzene layer washed with water, dried, and evaporated; t.l.c. showed one main spot corresponding to **3***a* (4).

Compound **1***b* (10) (4.33 g, 10.0 mmol) and thiourea (1.52 g, 20.0 mmol) were refluxed together in EtOH (25 ml) for 1 h. The solution was filtered and evaporated; dissolution in $CHCl_3$, washing (aqueous NaOH, water), drying and evaporation gave an oil. A mass spectrum showed *m/e* 413, 411, 409 consistent with the formation of **5***b*. The oil was treated with benzoyl chloride (2 ml) in pyridine (20 ml) for 30 min and the mixture was then poured into EtOH (50 ml), stirred, and filtered to give 5-(*N*-benzoylimino)-2-phenyl-4-(2,4-dibromophenyl)-1,3-4-thiadiazoline (3.58 g, 70%), m.p. 201–202 °C (lit. (2) 198 °C).

Compound **1***b* (10.0 mmol), thiourea (0.38 g, 5.0 mmol), and Et_3N (5 ml) were stirred together in EtOH (300 ml) for 3 days. Filtration afforded **4***b* (0.27 g, 7%), m.p. 193–196 °C. Addition of water precipitated a further quantity (0.14 g) of **4***b* contaminated with **9***b* (mass spectrum). The ethanol–water filtrate was extracted with $CHCl_3$ and the chloroform phase was worked-up. Crystallization from benzene afforded **9***b* (1.26 g, 64%), m.p. 221–222 °C; mass spectrum *m/e* 396, 394, 392 (M^+).

Anal. Calcd. for $C_{14}H_{10}Br_2N_4$: C, 42.67; H, 2.56; N, 14.21. Found: C, 42.82; H, 2.73; N, 13.76.

Reactions with Phenylthiourea

Compound **1***a* (1.15 g, 5.0 mmol) and phenylthiourea (0.76 g, 5.0 mmol) were refluxed together in EtOH (25 ml) for 1 h. The solution was chilled overnight (refrigerator) and filtered. Two crystallizations from ether gave **6***a* (0.40 g, 24%), m.p. 113–116 °C (lit. (1) 122 °C); mass spectrum *m/e* 329 (M^+).

Compound **1***a* (4.60 g, 20.0 mmol), phenylthiourea (1.52 g, 10.0 mmol), and Et_3N (10 ml) were stirred together in EtOH (200 ml) for 6 h. Filtration and careful washing with water gave **4***a* (3.70 g, 88%), m.p. 162–164 °C (after crystallization from benzene 3.13 g (75%), m.p. 162–164 °C (corr.); identified by i.r. spectrum). The ethanolic filtrate was evaporated, the residue was dissolved in benzene, and the solution washed with water, dried (Na_2SO_4), and evaporated. The residual oil was treated with benzoyl chloride (1 ml) in pyridine (10 ml) for 30 min and the mixture was poured into water whereupon an oil deposited. The aqueous phase discarded. Addition of EtOH afforded a white solid which crystallized from EtOH to give *N*-benzoyl-*N*-phenylcyanamide (0.40 g, 18%), m.p. 122–125 °C; ν_{max} 2240 (C≡N) and 1730 cm^{-1} (C=O); mass spectrum *m/e* 222 (M^+).

Anal. Calcd. for $C_{14}H_{10}N_2O$: C, 75.65; H, 4.54; N, 12.61. Found: C, 75.68; H, 4.06; N, 12.44.

Compound **1***b* (2.16 g, 5.0 mmol) and phenylthiourea (0.76 g, 5.0 mmol) were refluxed together in EtOH (25 ml) for 1 h. An oil separated on cooling; the ethanol phase was discarded and the oil dissolved in ether, filtered, and left at room temperature for evaporation. Crystallization from ethanol–chloroform (2:1) afforded **6***b* (1.12 g, 46%), m.p. 111–117 °C (lit. (1) 116 °C); mass spectrum *m/e* 487, 485, 483 (M^+).

Compound **1***b* (4.32 g, 10.0 mmol), phenylthiourea (0.76 g, 5.0 mmol) and Et_3N (5 ml) were stirred together in EtOH (300 ml) for 20 h. Filtration give **4***b* (2.41 g, 66%), m.p. 193–195° C (after crystallization from benzene, 2.15 g (58%); m.p. 202–204° C; identified by i.r. spectrum (4)). The ethanolic filtrate was evaporated, the residue was dissolved in benzene, and the solution washed with aqueous acetic acid and water, dried, and evaporated. The residual oil was treated with benzoyl chloride (1 ml) in pyridine (10 ml) for 30 min. Addition of EtOH (25 ml), stirring (30 min), and filtration gave 5-(*N*-benzoylimino)-2-phenyl-4-(2,4-dibromophenyl)-1,3,4-thiadiazoline (0.54 g, 21%), m.p. 198–201 °C; mass spectrum *m/e* 517, 515, 513 (M^+).

Reactions with Thiosemicarbazide

Compound **1***a* (2.30 g, 10.0 mmol), thiosemicarbazide (0.46 g, 5.0 mmol), and Et_3N (5 ml) were stirred together in EtOH (100 ml) for 4 h. Filtration followed by careful washing with water gave **4***a* (0.93 g, 44%), m.p. 166–167 °C (after crystallization from benzene, 0.67 g (32%), m.p. 162–164 °C; identified by i.r. spectrum). The ethanolic filtrate was evaporated. The residue, which appeared to consist of **10***a* contaminated with **7***a* and possibly **3***a* and **5***a* (mass spectrum), was suspended in $CHCl_3$ (20 ml) and filtered. Crystallization from acetonitrile gave the hydrochloride of **10***a* (0.51 g, 36%), m.p. 251–253 °C (dec.) (second crystallization).

Anal. Calcd. for $C_{14}H_{13}N_5 \cdot HCl$: C, 58.43; H, 4.90; N, 24.34. Found: C, 58.45; H, 4.91; N, 24.28.

Compound **1***b* (2.16 g, 5.0 mmol) and thiosemicarbazide (0.46 g, 5.0 mmol) were refluxed together in EtOH (50 ml) for 1 h. Thin-layer chromatography of the reaction mixture showed six spots, one corresponding to thiohydrazide **3***b* (4). The solution was left for one week at room temperature and filtered. Crystallization of the crude product (0.65 g) from benzene–ethanol (4:1) gave a solid (0.10 g), m.p. 286–289 °C (lit. (1) 285–286 °C). Attempts to isolate **7***b* were not pursued, but it was confirmed that **1***b* and acetone thiosemicarbazone gave the acetone derivative of **7***b* (1).

Compound **1***b* (10.0 mmol), thiosemicarbazide (0.46 g, 5.0 mmol), and Et_3N (5 ml) were stirred together in EtOH (300 ml) for 4 h. Filtration gave **4***b* (0.51 g, 14%), m.p. 195–197 °C (after crystallization, m.p. 202–204 °C; identified by i.r. spectrum). From the ethanolic filtrate was isolated the hydrobromide of **10***b* (0.77 g, 31%) (after crystallization from acetonitrile), m.p. 252–254 °C (dec.).

Anal. Calcd. for $C_{14}H_{11}Br_2N_5 \cdot HBr$: C, 34.31; H, 2.47; N, 14.29. Found: C, 34.20; H, 2.54; N, 14.46.

Reactions with Substituted Thiosemicarbazides

Compound **1***a* (1.15 g, 5.0 mmol) and 1-phenyl-3-thiosemicarbazide (0.84 g, 5.0 mmol) were refluxed together in EtOH (25 ml) for 2 h. Thin-layer chromatography of the dark green reaction mixture showed one main spot together with four minor ones, one of these corresponding to the thiohydrazide **3***a* (4). The solution was cooled for 5 h and filtered. Crystallization of the crude product (1.12 g) from ethanol–water (5:1) gave **8***a* (0.53 g, 31%) as brown prisms, m.p. 121–125 °C; ν_{max} 3280 cm^{-1} (N—H); mass spectrum *m/e* 344 (M^+).

Anal. Calcd. for $C_{20}H_{16}N_4S$: C, 69.74; H, 4.68; N, 16.27; S, 9.31. Found: C, 69.60; H, 4.88; N, 16.29; S, 9.32.

Compound **1***a* (1.15 g, 5.0 mmol) and 4-phenyl-3-thiosemicarbazide (0.84 g, 5.0 mmol) were refluxed together in EtOH (25 ml) for 45 min. The solution was chilled overnight (refrigerator) and filtered. The crude product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was **6***a* apparently contaminated with **7***a* (mass spectrum). Crystallization from EtOH gave **6***a* (0.37 g, 22%), m.p. 111–113 °C; identified by i.r. and mass spectrum.

Compound **1***a* (2.30 g, 10.0 mmol) and 1,4-diphenylthiosemicarbazide (2.44 g, 10.0 mmol) were refluxed together in EtOH (25 ml) for 90 min. The solution was evaporated to dryness and the residue suspended in benzene. Water was added and the solid was filtered off and washed with water. Crystallization of the crude product (2.08 g) from acetonitrile gave the hydrochloride of **6***a*, m.p. *ca.* 260 °C (dec.); ν_{max} 2730 (broad) (N^+—H) and 1575 cm^{-1} (strong) (C=N) (lit. (11) 1575 cm^{-1}).

Anal. Calcd. for $C_{20}H_{15}N_3S \cdot HCl$: C, 65.65; H, 4.41; N, 11.49; Cl, 9.69. Found: C, 65.50; H, 4.00; N, 11.70; Cl, 9.58.

Reactions with KSCN

Compound **1***a* (1.15 g, 5.0 mmol) and KSCN (0.50 g, 5.0 mmol) were refluxed together in EtOH (25 ml) for 30 min and filtered. Evaporation and treatment of the residue with benzene followed by filtration and evaporation afforded an oil with properties consistent with **5***a* (1.25 g, 99%); mass spectrum *m/e* 253 (M^+). Benzoyl chloride (1 ml) in pyridine (5 ml) for 1 h in the normal way afforded 5-(*N*-benzoylimino)-2,4-diphenyl-1,3,4-thiadiazoline (0.85 g, 48%), m.p. 164–165 °C (lit (2) 166 °C).

Compound **1***a* (1.15 g, 5.0 mmol) KSCN (0.50 g, 5.0 mmol), and Et_3N (2.5 ml) in EtOH (150 ml) gave **5***a* (1.23 g, 98%); mass spectrum *m/e* 253 (M^+). Treatment with benzoyl chloride gave 5-(*N*-benzoylimino)-2,4-diphenyl-1,3,4-thiadiazoline (1.17 g, 66%), m.p. 163–164 °C; mass spectrum *m/e* 357 (M^+).

Compound **1***b* (2.16 g, 5.0 mmol) and KSCN (1.00 g, 10.0 mmol) gave a semicrystalline mass (2.15 g). The mass spectrum was consistent with formation of **5***b* (*m/e* 413, 411, 409 (M^+)); i.r. spectrum showed no SC≡N. Benzoylation afforded 5-(*N*-benzoylimino)-2-phenyl-4-(2,4-dibromophenyl)-1,3,4-thiadiazoline (98%), m.p. 202–203 °C.

Compound **1***b* (2.16 g, 5.0 mmol), KSCN (0.50 g, 5.0 mmol), and Et_3N (2.5 ml) gave after benzoylation 5-(*N*-benzoylimino)-2-phenyl-4-(2,4-dibromophenyl)-1,3,4-thiadiazoline (1.70 g, 66%), m.p. 200–201 °C (after crystallization from ethyl acetate); mass spectrum *m/e* 517, 515, 513 (M^+); i.r. spectrum showed no SC≡N.

Cleavage of Hydrazonyl Disulfide ***11***

(*i*) Compound **11** (12) (3.08 g, 4.0 mmol) and KCN (0.52 g, 8.0 mmol) were stirred together in $CHCl_3$ (50 ml) for 2 days. The solution was filtered and the solvent removed *in vacuo*; the residue was suspended in EtOH (25 ml) and filtered. Crystallization from benzene gave **4***b* (0.15 g, 5%), m.p. 198–201 °C; identified by i.r. spectrum. The ethanolic filtrate was evaporated and the residue was dissolved in benzene and extracted twice with aqueous NaOH. The benzene layer was washed with water, dried, evaporated, and benzoylated (in pyridine) to give 5-(*N*-benzoylimino)-2-phenyl-4-(2,4-dibromophenyl)-1,3,4-thiadiazoline (1.62 g, 79%), m.p. 201–203 °C; identified by i.r. spectrum. The aqueous NaOH phase was neutralized and extracted with benzene; the benzene phase was washed with water, dried, and evaporated. Crystallization of the crude product (1.60 g) from benzene–hexane (1:1) gave **3***b* as small pale yellow needles (0.70 g, 46%), m.p. 107–109° C (lower melting polymorph); identified by i.r. spectrum ($CHCl_3$) (4); mass spectrum *m/e* 388, 386, 384 (M^+).

Anal. Calcd. for $C_{13}H_{10}Br_2N_2S$: C, 40.44; H, 2.61; N, 7.26. Found: C, 40.55; H, 2.76; N, 7.34.

(*ii*) Compound **11** (1.54 g, 2.0 mmol) and KCN (0.52 g, 8.0 mmol) were refluxed together in CH_3CN for 30 min. The i.r. spectrum of the filtered and evaporated reaction mixture showed no presence of SC≡N. Work-up (as above) gave 5-(*N*-benzoylimino)-2-phenyl-4-(2,4-dibromophenyl)-1,3,4-thiadiazoline (0.75 g, 73%), m.p. 202–204° C and **3***b* (0.71 g, 92%); crystallization from benzene–hexane (1:1) gave **3***b* (45%), m.p. 106–108 °C.

We thank the National Research Council of Canada and the Danish Statens naturvidenskabelige Forskningsraad (to P. W.) for financial support.

Isotope Effects in Nucleophilic Substitution Reactions. I. The Mechanism of the Reaction of Phenylbenzyldimethylammonium Ion with Thiophenoxide Ion

KENNETH CHARLES WESTAWAY AND RAYMOND ALCIDE POIRIER

Department of Chemistry, Laurentian University, Sudbury, Ontario P3E 2C6

Received March 3, 1975

KENNETH CHARLES WESTAWAY and RAYMOND ALCIDE POIRIER. Can. J. Chem. **53**, 3216 (1975).

A kinetic study of the nucleophilic substitution reactions of a series of *para*-substituted phenylbenzyldimethylammonium nitrates with sodium thiophenoxide at 0 °C in *N,N*-dimethylformamide containing a large excess of sodium nitrate, has shown the reaction to be a second-order process which is first-order in both the substrate and the nucleophile. A Hammett ρ value of +2.04 for different *para*-substitutents on the *N*-phenyl group of the quaternary ammonium salt and a large nitrogen kinetic isotope effect of 1.0200 ± 0.0007 have excluded any mechanism involving a carbonium ion intermediate but are in accord with an S_N2 mechanism with a substantial amount of carbon–nitrogen bond rupture in the transition state.

KENNETH CHARLES WESTAWAY et RAYMOND ALCIDE POIRIER. Can. J. Chem. **53**, 3216 (1975).

Une étude cinétique des réactions de substitution nucléophile d'une série de nitrates de *p*-X-phénylbenzyldiméthylammonium par le thiophénolate de sodium, à 0 °C dans la *N,N*-diméthylformamide contenant un grand excès de nitrate de sodium, a permis de démontrer que la réaction est du deuxième ordre soit du premier ordre dans chacun des réactifs. Sur la base (*a*) d'une valeur ρ de Hammett de +2.04 pour différents substituants en *para* du groupement phényle du sel d'ammonium quaternaire et (*b*) d'un grand (1.0200 ± 0.0007) effet isotopique cinétique de l'azote, on peut exclure tout mécanisme impliquant un intermédiaire carbocationique; toutefois les résultats sont en accord avec un mécanisme S_N2 impliquant une portion importante de rupture du lien carbone–azote dans l'état de transition.

[Traduit par le journal]

Introduction

Several authors (1–7) have studied the nucleophilic substitution reactions of quaternary ammonium ions

[1] $$Nu^- + R'\overset{+}{N}R_3 \rightarrow NuR' + \ddot{N}R_3$$

Nu^- = Nucleophile

and the reverse of this reaction (the Menschutkin reaction) in both protic (1–4) and dipolar aprotic solvents (4–7). The earliest reports, based on extensive kinetic studies using alcohols or water as a solvent, indicated that these reactions proceed by a simple S_N2 mechanism, eq. 2.

[2] $$Nu^- + R'\overset{+}{N}R_3 \rightarrow [\overset{\delta-}{Nu}\text{---}R'\text{---}\overset{\delta+}{N}R_3] \rightarrow NuR' + \ddot{N}R_3$$

More recently, Leffek and co-workers (5–7) have studied these reactions in the dipolar aprotic solvents chloroform and acetone and have concluded on the basis of an extensive kinetic study (5) and large alpha secondary hydrogen–deuterium isotope effects (1.20 in acetone and 1.25 in chloroform (6)) that these reactions proceed by an "ionic internal nucleophilic substitution mechanism" (6, 7) involving triple ions of the type $[(R'\overset{+}{N}R_3)_2Nu^-]^+$.[1] The rate-determining step of the reaction involves ionization of the carbon–nitrogen bond to give a carbonium ion intermediate (R'^+) which reacts in a fast step with the nucleophile in the triple ion complex to give the products, eq. 3.

[3] $$3\ R'\overset{+}{N}R_3\overset{-}{X} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [(R'\overset{+}{N}R_3)_2\overset{-}{X}]^+ + [R'\overset{+}{N}R_3\overset{-}{X}_2]^-$$

$$[(R'\overset{+}{N}R_3)_2\overset{-}{X}]^+ \xrightarrow{\text{slow}} [R'\ddot{N}R_3\ R'\overset{+}{N}R_3\ \overset{-}{X}]^+ \xrightarrow{\text{fast}} R'X + \ddot{N}R_3 + R'\overset{+}{N}R_3$$

Leffek's work which suggested that quaternary ammonium salts reacted by an S_N1 mechanism fits very nicely with a proposal by Sneen and Larsen (8, 9) which suggested that all nucleophilic substitution reactions proceed by the ionizing or carbonium ion mechanism illustrated in eq. 4. A quaternary ammonium ion has been

[1] K. T. Leffek, private communication.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

used to illustrate how Sneen's proposal would apply to the reactions under investigation.

$$\overset{+}{R'}\ddot{N}R_3 \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} R'^{+} + \ddot{N}R_3 \qquad [4]$$

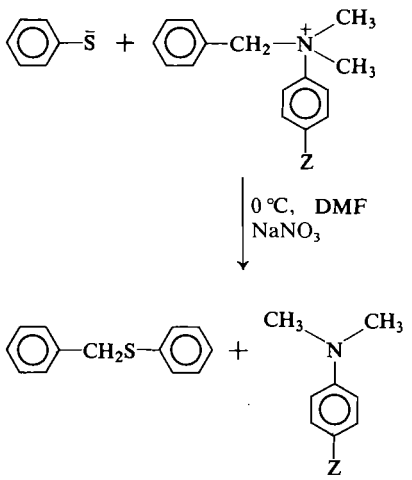
$$R'^{+} + Nu^- \xrightarrow{k_2} R'—Nu$$

If the k_1 step in eq. 4 is rate determining ($k_2 \gg k_{-1}$ [$\ddot{N}R_3$]) then first-order kinetics would be observed. This corresponds to the normal S_N1 mechanism. If, on the other hand, the k_2 step is rate-determining (k_{-1} [$\ddot{N}R_3$] $\gg$ k_2) then there is a pre-equilibrium followed by a slow bimolecular reaction and second-order kinetics would be observed. This mechanism, which has been referred to as an 'ion-pair S_N2' (10) or an S_N2C^+ (11) mechanism, often cannot be distinguished from the normal S_N2 mechanism even by a detailed kinetic analysis (10). Thus both Sneen's proposal which suggests that reactions involving a carbonium ion intermediate can be kinetically identical to normal S_N2 reactions, and Leffek's work imply that quaternary ammonium ions react only by a carbonium ion mechanism rather than by the S_N2 mechanism proposed by earlier workers. This investigation, which was started with the object of establishing whether the nucleophilic substitution reactions of quaternary ammonium ions occur by an S_N1–S_N2C^+ or by an S_N2 mechanism, was undertaken because it was not obvious why a reaction thought to proceed by an S_N2 mechanism in protic solvents should react by an S_N1 mechanism in dipolar aprotic solvents and because several workers (12) had cast doubt on Sneen's proposal that all nucleophilic substitution reactions proceed by a carbonium ion mechanism.

Results

Product Analysis

The reactions of several *para*-substituted phenylbenzyldimethylammonium nitrates with sodium thiophenoxide were studied at 0 °C in *N*,*N*-dimethylformamide containing a large excess of an inert salt (sodium nitrate) to eliminate the salt effects which were observed at lower ionic strengths. The products of the reaction were identified from their spectra and from a comparison of their gas chromatographic retention times with those of authentic samples. A quantitative gas chromatographic analysis using



[5]

the internal standard technique (13), showed that the benzylphenyl sulfide was formed quantitatively. This result was confirmed when it was found that a theoretical yield of *N*,*N*-dimethylaniline could be recovered from a reaction taken to completion. This analysis was done using the micro-kjeldahl method (14) on the *N*,*N*-dimethylaniline recovered from a reaction taken to completion. Finally, the only possible side products (methylphenyl sulfide and benzylmethylphenyl amine produced by attack at an *N*-methyl carbon) were found in a gas chromatographic analysis to account for only 0.4% of the product. Thus there is, in essence, only one reaction occurring and the isotope effects and other constants are clearly those associated with the reaction shown in eq. 5.

Kinetics and Hammett ρ Value

The reactions of the different *para*-substituted phenylbenzyldimethylammonium salts were monitored by titrating the unreacted thiophenoxide ion with mercury(II) ion (15). The individual rate constants were obtained when the data was treated using the usual method for a second-order reaction that is first-order in each reactant. Good straight line plots (correlation coefficients of > 0.99) up to more than 90% of completion were obtained for each run. The rate constants given in Table 1 are the average of the values obtained from at least three separate kinetic runs where the concentration of the quaternary ammonium salt was approximately 0.025 *M* and where the concentration of the thiophenoxide ion ranged from 0.025 to 0.080 *M*.

The rate constants in Table 1 were used to

TABLE 1. Rate constants for the nucleophilic substitution reaction of *para*-substituted phenylbenzyldimethylammonium nitrates with thiophenoxide ions at 0 °C

Substituent (Z) on the *N*-phenyl group	$k \times 10^2$ (l mol^{-1} s^{-1})
—Cl	5.55
—H	1.73
—CH_3	0.917
—OCH_3	0.493

construct the Hammett plot shown in Fig. 1. The ρ value for substitution in the leaving group was found to be +2.04 with a correlation coefficient of 0.998. This ρ value indicates that there is a substantial reduction of the positive charge on the nitrogen atom bonded to the phenyl group in the transition state of the rate-determining step of the reaction.

Nitrogen Kinetic Isotope Effect

The nitrogen kinetic isotope effect for the reaction of phenylbenzyldimethylammonium nitrate and sodium thiophenoxide at 0 °C was calculated using eq. 6 (16).

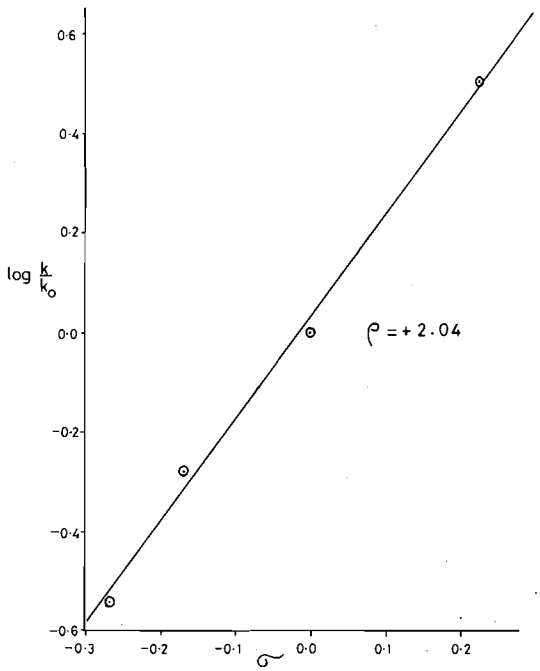

FIG. 1. Correlation of log k/k_0 and the Hammett ρ constants for the reaction of a series of *para*-substituted phenylbenzyldimethylammonium nitrates with sodium thiophenoxide in DMF.

$$[6] \qquad k^{14}/k^{15} = \frac{\ln (1 - f)}{\ln \left(1 - \left(\frac{R_0}{R_f}\right) f\right)}$$

where f is the mole fraction of quaternary ammonium salt that has reacted, R_0 is the ratio of the $^{14}N/^{15}N$ in the ammonium nitrogen of the starting material and R_f is the ratio of the $^{14}N/^{15}N$ in the nitrogen of the *N,N*-dimethylaniline produced when the reaction was taken to small extents of completion. Since there were two nitrogen atoms in the starting material, the $^{14}N/^{15}N$ ratio of the ammonium nitrogen atom had to be determined by analyzing the nitrogen gas obtained from the degradation of the *N,N*-dimethylaniline (17) that was produced in a reaction taken 100% to completion. The $^{14}N/^{15}N$ ratio in the product was obtained by analyzing the nitrogen gas from the *N,N*-dimethylaniline produced when the reaction was taken to various extents of reaction between 17 and 38% of completion. The results of these experiments are given in Table 2. The large nitrogen kinetic isotope effect, $k^{14}/k^{15} = 1.0200$ indicates that there is substantial carbon–nitrogen bond rupture in the transition state of the rate-determining step of this reaction.

Discussion

Product Analysis and Kinetic Studies

The product analysis study has shown that the nucleophilic substitution reaction of each of the *para*-substituted phenylbenzyldimethylammonium ions with thiophenoxide ion occurs only at the benzyl carbon to give a quantitative yield of benzylphenyl sulfide and the corresponding *para*-substituted *N,N*-dimethylaniline. This ensures that all the parameters reported in this paper are those for the nucleophilic substitution reaction shown in eq. 5.

This reaction can occur by way of either an S_N2 mechanism, eq. 7, or by one of the several possible variations of the carbonium ion mechanism shown in Scheme 1.

The kinetic study showed that each of these reactions were second-order processes which were first-order in both the nucleophile and the substrate. While these results do not establish the mechanism they can be used to eliminate some of the mechanisms depicted in eq. 7 and Scheme 1.

Second-order kinetics are obviously consistent with the simple, one-step S_N2 mechanism.

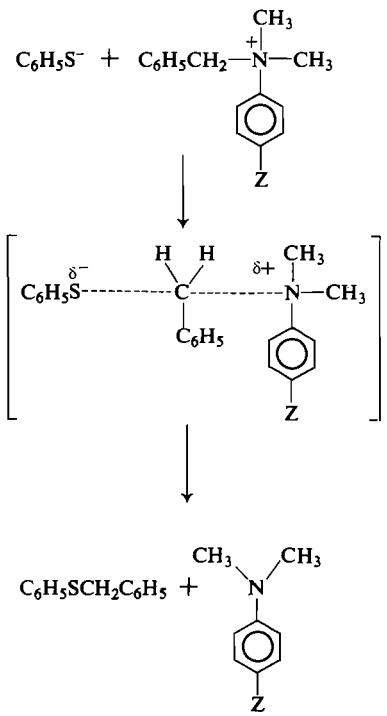
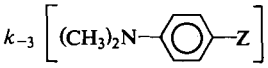
[7]



They are not, however, consistent with several of the mechanisms described in Scheme 1. If the slow or rate-determining step of the reaction is any of the k_1, the k_2 or the k_3 steps of Scheme 1, the rate will only depend on the concentration of the quaternary ammonium ion and first-order kinetics will be observed. The rate expressions for these three possible mechanisms are shown as No. 2, 3 and 4 of Table 3. It is perhaps worth noting that this conclusion holds true no matter how the products are formed *i.e.* by reaction 4, 5 or 6 or even by some combination of these three reactions. These mechanisms are examples of the S_N1 mechanism.

The second group of mechanisms that are described in Scheme 1 are the S_N2C^+ mechanisms where the reaction between one of the carbonium ion intermediates and the thiophenoxide ion is the slow or rate-determining step of the reaction. Two possibilities exist within this framework. The first mechanism involves the formation of a free carbonium ion ($C_6H_5CH_2^+$) which reacts in the slow k_6 step with the thiophenoxide ion. Since the k_6 step is slow and since the $C_6H_5CH_2^+$ does not accumulate during the reaction, the free carbonium ion is formed reversibly and

This requires the rate expression to have a term



in the denominator (mechanism 5, Table 3) and means that the observed rate constant should decrease during the reaction in the same way, and for the same reason that the mass law effect is observed.

Since the second-order rate constants do not decrease during the reaction even though the concentration of the *para*-substituted *N,N*-dimethylaniline increases markedly, the nucleophilic substitution reaction cannot proceed to any substantial degree by way of the free carbonium ion.

†The rate expression does not imply that the reactants are ion pairs.
‡Assumes that no product is formed via the k_4 step.
§Assumes that no products are formed by either the k_4 or k_5 steps.

The second set of mechanisms where the final step is rate-determining involve the formation of either the intimate or solvent separated carbonium ion complexes in pre-equilibrium steps which are followed by a slow reaction (k_4 for the intimate ion complex and k_5 for the solvent separated complex respectively) with the thiophenoxide ion. Both these mechanisms would lead to second-order kinetics (No. 6 and 7, Table 3) and are, therefore, consistent with the observed results. This would also be true for a process where both the intimate and solvent

5		90% acetone 10% water	−3.30	19*b*

separated ion complexes exist and react with the nucleophile in a slow step (mechanism 8, Table 3).

Thus, the kinetic investigation has eliminated several mechanisms and has indicated that these reactions are either S_N2 or S_N2C^+ processes involving an intimate and/or a solvent separated carbonium ion complex.

Hammett ρ Value

The Hammett plot shown in Fig. 1 indicated that the ρ value found by changing the *para*-substituent on the phenyl ring of the leaving group (eq. 5) was +2.04. The sign of the ρ value indicates that the positive charge on the quaternary ammonium nitrogen has decreased in the transition state of this reaction (18). An estimate of the extent to which the positive charge has been reduced and thus the amount of carbon–nitrogen bond rupture that has occurred in the transition state, can be obtained by comparing the observed ρ value with those found in similar reactions of other quaternary ammonium salts. Some relevant reactions and their ρ values are given in Table 4.

Burns and Leffek (18) found a ρ value of +1.4 for the reactions of *para*-substituted phenylbenzyldimethylammonium ions with iodide ion in chloroform and suggested that there was only a small degree of carbon–nitrogen bond rupture in the transition state. Other workers (19, 20) who have studied equilibrium reactions where the positive charge is completely destroyed (mechanisms 2–4, Table 4) have found large ρ values ranging from +3.4 – +4.2.[2] Since the observed ρ value of +2.04 is approximately half way between the value reported by Burns and Leffek and the extreme values observed for the equilibrium reactions, it would seem that there is quite a substantial reduction in the positive charge on nitrogen and thus considerable (but not nearly complete) carbon–nitrogen bond rupture in the transition state of this reaction.

The magnitude of the ρ value can also be used to give some indication of the mechanism of the reaction. The S_N2C^+ mechanism requires that the carbon–nitrogen bond is broken in a rapid pre-equilibrium step and that the product is formed in a rate-determining reaction between one of the carbonium ion complexes and the nucleophile. If the reaction proceeds by this mechanism then the ρ value should be that observed for an equilibrium reaction of the type shown in Table 4 *i.e.* a ρ value of greater than +3.4.[2] The much smaller value of +2.04 is obviously not consistent with the S_N2C^+ mechanism.

The smaller ρ value is however, in the range

[2]The ρ value should be at least as large for an equilibrium involving quaternary ammonium salts since hydrogens on the ammonium nitrogen hydrogen bond to solvent and lower the ρ value. Equilibrium ρ values range from +2.8 – +3.5 for anilinium ions (19, 20) and from +3.4 – +4.2 for *N,N*-dimethylanilinium ions where hydrogen bonding to solvent is greatly reduced (20).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

expected for an S_N2 mechanism. The ρ value for the formation of a quaternary ammonium salt from methyl iodide and *para*-substituted *N,N*-dimethylanilines (reaction 5, Table 4) is large and negative ($\rho = -3.30$) indicating that the nitrogen atom has attained almost a full positive charge and that the carbon–nitrogen bond formation is almost complete in the transition state of this S_N2 reaction. The principle of microscopic reversibility requires that the transition state for the reverse reaction, the decomposition of the quaternary ammonium salt in an S_N2 reaction, have an early transition state with a fairly small amount of carbon–nitrogen bond rupture. As a result, a reasonably small positive ρ value should be observed. The observed ρ value of +2.04 is obviously consistent with an S_N2 mechanism.

Thus the ρ value suggests that the nucleophilic substitution reactions of *para*-substituted phenylbenzyldimethylammonium ions with thiophenoxide ion proceed by way of an S_N2 mechanism with considerable, but not nearly complete carbon–nitrogen bond rupture in the transition state.

Nitrogen Kinetic Isotope Effect

The above conclusions have been confirmed by the large nitrogen kinetic isotope effect ($k^{14}/k^{15} = 1.0200 \pm 0.0007$) observed for this reaction. In an S_N2C^+ reaction the carbon–nitrogen bond is broken in a pre-equilibrium step and the nitrogen isotope effect should be very small, probably only a few tenths of one percent.[3] For an S_N2 process on the other hand, the carbon–nitrogen bond is broken in the transition state of the rate-determining step and a normal nitrogen kinetic isotope effect of 1–3% ($k^{14}/k^{15} = 1.01$–1.03) should be observed.

The nitrogen kinetic isotope effect of 1.0200 observed for this reaction is approximately half of the theoretical maximum nitrogen isotope effect of 1.03–1.04 at 0 °C (21) and clearly illustrates that the carbon–nitrogen bond is broken in the rate-determining step of the reaction. Since the kinetics have established that the carbon–sulfur bond is formed in the rate-determining step, both the bond changes must occur in the same step and thus the nucleophilic substitution reactions of quaternary ammonium ions in dipolar aprotic solvents do, indeed, proceed by way of an S_N2 mechanism.

It is worth noting that a test for an S_N2C^+ mechanism, based on the leaving group isotope effect (22), fails in this case. Graczyk and Taylor have shown that the value of a leaving group heavy atom isotope effect will vary in an S_N2C^+ process when the concentration of the attacking nucleophile is changed. This occurs because the ionization (k_1) step (eq. 4) becomes more rate-determining as the concentration of the attacking nucleophile is increased and k_2 [Nu^-] becomes greater than k_{-1} [$\dot{N}R_3$]. This shift in the rate-determining step requires that the observed heavy atom isotope effect (significant only when the carbon-leaving group bond is broken in the rate-determining step) increase with increasing concentration of the attacking nucleophile.[4] This trend is not even suggested by the individual results shown in Table 2, even though the relative concentrations of thiophenoxide ion (attacking nucleophile) have been varied over a larger range than those of Graczyk and Taylor, *i.e.* from very small values (reaction 2 where $[C_6H_5S^-]/R_4\overset{+}{N}NO_3^-] = 1.18$) to large values (reaction 3 where $[C_6H_5S^-]/[R_4\overset{+}{N}NO_3^-] = 3.15$).

The magnitude of the nitrogen kinetic isotope effect has been used to give an accurate measure of the relative amount of carbon–nitrogen bond rupture in the transition states of a series of closely related compounds (23). This comparison cannot be made with any certainty in this case because the isotope effect measured in this study is the first value that has been determined for a nucleophilic substitution reaction of a quaternary ammonium salt. Some estimate of the degree of carbon–nitrogen bond rupture can be obtained however, from a comparison with the nitrogen isotope effects for concerted 1,2-elimination reactions of quaternary ammonium salts where a C—N^+ bond is broken in the transition state. Typical values for these reactions range from $k^{14}/k^{15} = 1.009$–1.0186 at 60 °C (23) and the reactions with an isotope effect of $\gtrsim 1.014$ are thought to have substantial carbon–nitrogen bond rupture in the transition state.

[3]A simple calculation (19c) of the isotope effect expected for a pre-equilibrium C—N bond rupture has shown that the isotope effect, based on the observed frequencies of the stretching vibrations of the quaternary ammonium salt and the *N,N*-dimethylaniline, is very small or inverse. The bending modes do not appear to modify the value of the isotope effect to any significant degree.

[4]This effect would be observed only if k_{-1} [$\dot{N}R_3$] and k_{-2} [Nu^-] are the same order of magnitude.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The nitrogen isotope effect in the substitution reaction under investigation would be roughly equivalent to an isotope effect of 1.016–1.017 at 60 °C (14). Since this value is near the largest values observed for elimination reactions and in fact, is approximately half of the theoretical maximum isotope effect, it would appear that there must be substantial weakening of the carbon–nitrogen bond in the transition state of this reaction. Finally, it is worth noting that the magnitude of the Hammett ρ value and the nitrogen isotope effect both indicate that this reaction is one where there is substantial carbon–nitrogen bond rupture in the transition state.

Selectivity of the Reaction

The mechanism of these reactions has been confirmed in yet another way. The benzhydryldimethylphenylammonium ion was prepared and treated under the normal reaction conditions. If a carbonium ion intermediate were produced during the reaction, then this compound would form a very stable carbonium ion and react very much faster than the benzyl compounds reported in this paper. In fact, the benzhydryl compound did not react and it is safe to conclude that the benzhydryl carbonium ion did not form. It is then obvious that the less stable benzyl carbonium ion would not form and one must again conclude that the phenylbenzyldimethylammonium ions react by an S_N2 mechanism. The benzhydryl compound probably fails to react because the benzhydryl carbon is too sterically crowded to allow the nucleophile to attack in an S_N2 reaction.

Finally, one unusual feature of the reactions of the phenylbenzyldimethylammonium ions is the high selectivity, *i.e.* the benzyl carbon is approximately 500 times more reactive than the methyl carbon. This difference in reactivity, which is more characteristic of carbonium ion processes (benzyl:methyl greater than 400:1) than of S_N2 reactions (benzyl:methyl $\simeq$ 4:1) (24), is thought to be caused by the poor leaving groups in these reactions. This large difference in reactivity has been observed in reactions of other quaternary ammonium salts (1–3, 25) and thus would seem to be normal for S_N2 reactions with poor leaving groups. This suggests that a large selectivity cannot be used as an indication of a carbonium ion mechanism.

In conclusion, these results clearly illustrate (*1*) that Sneen's proposals concerning nucleophilic substitution reactions are incorrect and that while many reactions do proceed by the S_N1–S_N2C^+ mechanism (22, 26) that some reactions do, indeed, react by way of an S_N2 mechanism, and (*2*) that the nucleophilic substitution reactions of quaternary ammonium salts in dipolar aprotic solvents and probably also in protic solvents as the early results indicated (1–3), react by an S_N2 mechanism. Finally the reasonably large Hammett ρ value and nitrogen kinetic isotope effect both suggest there is substantial carbon–nitrogen bond rupture in the transition state of these reactions.

Experimental

Materials

The quaternary ammonium bromides were prepared by stirring benzyl bromide with a 10% excess of the appropriate *para*-substituted *N,N*-dimethylaniline in benzene at room temperature for 24 h. The solid bromides were recovered by filtration, dissolved in water, and treated with silver oxide for 3 h (14). The solution was filtered and the filtrate neutralized with nitric acid (1). The water was then removed under reduced pressure to give the quaternary ammonium nitrates which were purified by recrystallization. All the products except the *p*-methoxyphenylbenzyldimethylammonium nitrate which was recrystallized from acetone and ether, were recrystallized from isopropanol–ether mixtures. The yields of the purified products based on the benzyl bromide and the melting points of each product are: *p*-methoxyphenylbenzyldimethylammonium nitrate (40%, 95.5–96.0 °C), *p*-methylphenylbenzyldimethylammonium nitrate (59%, 138–139 °C), *p*-chlorophenylbenzyldimethylammonium nitrate (55%, 127–128 °C), and phenylbenzyldimethylammonium nitrate (70%, 157–158 °C). All of the reactants with the exception of the *p*-methoxy- and *p*-chloro-*N,N*-dimethylanilines were commercially available.

The *p*-methoxy-*N,N*-dimethylaniline was prepared from *p*-anisidine using the method described by Leffek (18). The *p*-chloro-*N,N*-dimethylaniline was prepared from *p*-chloroaniline using the method described by Chambers (27). Freshly distilled *p*-chloroaniline (63 g, 0.49 mol) were mixed with 230 g (0.68 mol) of polyphosphoric acid and 48 g (1.5 mol) of methanol at room temperature. After the mixture had been heated at 190–200 °C for 24 h, it was cooled and made basic by adding a 40% NaOH solution. The product was then extracted with ether. The remaining alkaline solution was mixed with 128 g NaOH and steam distilled. The additional product in the distillate was extracted with ether. The combined ether layers were dried, the ether removed under reduced pressure, and the product distilled under reduced pressure to give 48 g (63%) of *p*-chloro-*N,N*-dimethylaniline. The melting point of the product was 33–34 °C; lit. (18) m.p. 32–33 °C.

The benzhydryldimethylphenylammonium bromide was prepared by refluxing 9.45 g (0.038 mol) of benzhydryl bromide with 6.90 g (0.057 mol) of *N,N*-dimethylaniline in 20 ml of anhydrous benzene for 24 h. The benzene was removed under reduced pressure and the solid

recrystallized from acetone and water to give 5.5 g (39%) of benzhydryldimethylphenylammonium bromide of m.p. 134.5–135.0 °C. The benzhydryl bromide required for this synthesis was obtained by bubbling HBr through a solution of 10.0 g (0.054 mol) of benzhydrol in 25 ml of anhydrous benzene for 2 h, removing the benzene under reduced pressure, and recrystallizing the solid from ligroin (b.p. 30–60 °C) (28). The yield of benzhydryl bromide was 9.45 g (71%) and the m.p. was 39–39.5 °C; lit. (28) m.p. 42–44 °C.

The solvent, Fisher reagent grade *N,N*-dimethylformamide, was further purified before use. After the solvent had been dried for at least 24 h over solid NaOH, several grams of sodium thiophenoxide were added and the solvent was distilled at a reduced pressure under a nitrogen atmosphere.

The sodium thiophenoxide was prepared by mixing a 10% excess of freshly distilled benzene thiol with a sodium ethoxide solution prepared from anhydrous ethanol. The ethanol was removed under reduced pressure and the solid was quickly transferred to a glove bag filled with nitrogen. The product was washed several times with ether and then transferred to a vacuum desiccator where it was stored under vacuum until it was required.

Product Identification and Analysis

All the *para*-substituted *N,N*-dimethylanilines were available or had been prepared during the synthesis of the quaternary ammonium salts. The other products were prepared as follows. The benzylphenyl sulfide was formed when 9.3 g (0.05 mol) of benzyl bromide were refluxed for 2 h with a sodium thiophenoxide solution prepared from 5.7 g (0.04 mol) of benzene thiol and 30 ml of a 2.25 *N* solution of sodium ethoxide in ethanol (29). The product was recovered by filtration of the solid that formed when the reaction mixture was poured into a large excess of water. Recrystallization from ethanol gave 6.2 g (72%) of benzylphenyl sulfide, m.p. 42 °C; lit. (29) m.p. 40–41 °C. Methylphenyl sulfide was produced in the same way by refluxing 30 g (0.21 mol) of methyl iodide with 100 ml of a 2.25 *N* solution of sodium thiophenoxide in ethanol. The product, a liquid, was separated from the aqueous layer, dried and distilled under reduced pressure (b.p. 60–62 °C at 8 Torr; lit. (30) b.p. 58–60 °C at 6 Torr). The yield was 22.5 g (86%).

The amine impurity, benzylmethylphenyl amine was prepared using the procedure described by Grillot and co-workers (31, 32). Equimolar amounts (0.1 mol) of benzene thiol (10 g) *N*-methylaniline (10.7 g) and a 35–40% solution of formaldehyde (8 ml) were dissolved in 20 ml ethanol and refluxed for 9 h. After the mixture had cooled, the bottom layer was removed and extracted with ether. The combined ether layers were dried and then the ether was removed under reduced pressure and the product distilled (b.p. 159 °C at 1 Torr, lit. (31) m.p. 36–38 °C) to give 32 g (70%) of *N*-methyl-*N*-phenylaminomethyl sulfide. This product was mixed with THF and added slowly to the Grignard reagent prepared by reacting 25.2 g (0.16 mol) bromobenzene with 4 g (0.17 mol) magnesium in THF. The mixture was refluxed for 1 h after the addition was complete, and then poured onto a mixture of 350 g crushed ice, 20 g NH_4Cl and 200 ml of water. The product was extracted with ether. The ether layers were washed with a 10% solution of NaOH and then the amine was extracted with 2 *N* HCl.

The aqueous extracts were made basic and the amine was extracted into ether. After drying over KOH the ether was removed under reduced pressure and the product distilled to give 27.6 g (70%) of benzylmethylaniline with a b.p. 120 °C at 1 Torr, lit. (32) b.p. 162–3 °C at 8 Torr.

The products of the reaction were recovered quantitatively from reaction mixtures in the following manner. The reaction mixture was poured into 1400 ml of p*H* 12 water (the p*H* was adjusted using NaOH) and the products were extracted with 100, 75, 70 and 70 ml of ether. The last traces of DMF were removed by extracting the combined ether layers three times with 50 ml of p*H* 12 water.

The products were identified in two ways. One method involved concentrating the ether layer to a volume of a few ml on a rotary evaporator and examining the concentrate by gas chromatography. The analysis was done using a flow rate of 50 ml/min and a 15 ft, ¼ in. column of 10% Carbowax 20 M on Chromosorb P at 168 °C until the dimethylaniline and methylphenyl sulfide had been eluted, and then at 235 °C where the benzylphenyl sulfide and benzylmethylphenyl amine were eluted. The products had retention times identical to those of authentic samples. An analysis based on the area under each peak indicated that at least 99.6% of the product was formed by reaction at the benzyl carbon.

The major products were also identified by comparing their infrared and n.m.r. spectra with those of authentic samples. The products were first separated by extracting the ether solution once with 70 ml and three times with 40 ml of 2.5% H_2SO_4. Evaporation of the ether gave the sulfide product which was dissolved in a few ml of spectrograde CCl_4. The acid layers were combined, made basic by adding solid NaOH and extracted with three 50 ml portions of ether. Evaporation of the ether gave the amine product which was dissolved in a few ml of spectrograde CCl_4. These solutions were examined by n.m.r. and i.r. spectroscopy. The spectra were identical to those of authentic samples of benzylphenyl sulfide and the *para*-substituted *N,N*-dimethylanilines.

The extent of reaction and yield of each product were obtained from the quantitative analysis of both the benzylphenyl sulfide and the *N,N*-dimethylaniline. The analyses were carried out on the ether solution containing the sulfide and the sulfuric acid solution containing the dimethylaniline. The analysis of the benzylphenyl sulfide involved concentrating the ether solution to approximately 5 ml on the rotary evaporator and adding it to approximately 45 mg (accurately weighed) of the internal standard, diphenyl ether. The solution was diluted to 10 ml and analyzed using the internal standard technique (13) on a 15 ft, ¼ in. column of 10% SE-30 on Chromosorb P at 150 °C and a flow rate of 110 ml/min.

The first step in the analysis of the *N,N*-dimethylaniline was removing the water in the sulfuric acid solution under reduced pressure. The concentrate was then mixed with 100 mg of red mercuric oxide, 2.5 g of potassium sulfate and 2 ml of concentrated H_2SO_4 and heated for approximately 6 h (2 h after the solution had become clear and colorless) in a kjeldahl digestion apparatus.

The ammonium sulfate solution from the kjeldahl

For personal use only.

digestion was placed in a kjeldahl-type distillation apparatus, made basic with an excess of 40% aqueous sodium hydroxide solution, and the ammonia distilled into 50 ml of 0.01 *N* sulphuric acid. Back titration with 0.01 *N* NaOH gave the amount of ammonia and thus the amount of the *N,N*-dimethylaniline that had been produced in the reaction.

Quantitative yields of benzylphenyl sulfide and the *N,N*-dimethylanilines were obtained for reactions taken 100% to completion. The extent of reaction in runs stopped part way to completion was obtained by averaging the results of the benzylphenyl sulfide and the *N,N*-dimethylaniline analyses.

Kinetic Measurements

The rates of the reactions were measured at 0 °C in an ice-distilled water bath. The following preparations for a kinetic run were performed in a glove bag under a nitrogen atmosphere. Thirty ml of DMF cooled to 0 °C, were pipetted into a 50 ml volumetric flask containing 2.40 g of $NaNO_3$ and sufficient quaternary ammonium salt to prepare 50 ml of a 0.025 *M* solution of the quaternary ammonium salt. An amount of sodium thiophenoxide such that 20 ml of the solution would contain sufficient thiophenoxide ion to prepare 50 ml of a solution between 0.030 and 0.075 *M* in thiophenoxide ion, was weighed into a tared 25 ml volumetric flask. Finally, approximately 30 ml of cold DMF were placed in a ground-glass stoppered flask.

After all the containers had been temperature equilibrated, 25 ml of DMF were added under a stream of nitrogen, to the 25 ml volumetric containing the sodium thiophenoxide. When the salt had dissolved, 20 ml of this solution was poured under a stream of nitrogen into the 50 ml volumetric flask containing the quaternary ammonium salt. This flask was fitted with a serum cap and the reaction was followed by titrating the unreacted thiophenoxide ion contained in a 2.5 ml sample with a standard solution of Hg^{2+} ion (15).

Nitrogen Kinetic Isotope Effect

The nitrogen isotope effect was determined by comparing the $^{14}N/^{15}N$ ratios of the nitrogen in the *N,N*-dimethylaniline formed after small extents of reaction, between 17 and 38% of completion, with this ratio in the ammonium nitrogen in the starting material. The latter was obtained by measuring this ratio of the nitrogen in the *N,N*-dimethylaniline from a reaction taken to completion (16).

The *N,N*-dimethylaniline was recovered from the reaction mixture and decomposed in a kjeldahl digestion to ammonium sulfate using the procedure described in the section titled product identification and analysis. Finally, the ammonium ions were oxidized to nitrogen gas for mass spectrometric analysis (17). The magnitudes of the isotope effects shown in Table 2 do not vary either directly or indirectly with the extent of reaction. This indicates that the samples are not contaminated with traces of nitrogen containing impurities since impurities of this type would contaminate the samples of varying $^{14}N/^{15}N$ ratio with some nitrogen of constant isotopic ratio and thus would alter the observed effect in a way that would be related to the extent of reaction.

The authors are greatly indebted to President E. J. Monahan of Laurentian University for the financial support required to complete this study. We also wish to acknowledge the contribution of Mr. G. Alexiuk who helped to work out many of the techniques required in this investigation.

Aziridines saturées et insaturées. Synthèses par réduction de cyclohexénones oximes et études spectroscopiques

LOUIS FERRERO,[1] SERGE GERIBALDI, MICHEL ROUILLARD ET MARCEL AZZARO

Laboratoire de Chimie Physique Organique, Université de Nice, Campus Valrose, 06034 Nice Cédex, France

Reçu le 24 janvier 1975

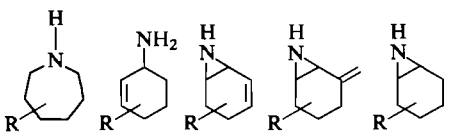
LOUIS FERRERO, SERGE GERIBALDI, MICHEL ROUILLARD et MARCEL AZZARO. Can. J. Chem. **53**, 3227 (1975).

Les réductions de plusieurs oximes de cyclohexénones par $LiAlH_4$ et $NaAlH_2(OCH_2CH_2OCH_3)_2$ (Red-Al) conduisent à des aziridines saturées et insaturées du type aza-7 bicyclo[4.1.0]-heptane, ainsi qu'à des cyclohexène-2 amines. L'utilisation d'oximes de configuration *E* ou (et) *Z* permet de mettre en évidence la régiosélectivité des réductions et de proposer les schémas réactionnels d'obtention des différents types de produits.

LOUIS FERRERO, SERGE GERIBALDI, MICHEL ROUILLARD, and MARCEL AZZARO. Can. J. Chem. **53**, 3227 (1975).

The reduction of several cyclohexenone oximes using lithium aluminum hydride and sodium dihydrobis-(2-methoxyethoxy)aluminate yields saturated and unsaturated aziridines with a 7-azabicyclo[4.1.0]heptane skeleton and cyclohex-2-ene amines. The use of oximes of *E* and/or *Z* configuration demonstrates the regioselectivity of the reduction and allows us to propose reaction schemes explaining the formation of the different types of products.

Si les réductions d'oximes saturées linéaires et cycliques ont fait l'objet d'un nombre considérable de travaux, il n'en est pas de même en série éthylénique. Récemment, divers auteurs se sont intéressés aux oximes α,β-éthyléniques cycliques (1–4); cependant, leurs travaux ne concernent qu'un nombre restreint d'oximes, réduites avec un seul réducteur, $LiAlH_4$. L'utilisation de cyclohexène-2 one oximes diversement substituées et de deux réducteurs aluminiques, $LiAlH_4$ et $NaAlH_2(OCH_2CH_2OCH_3)_2$ (Red-Al) nous permet d'accéder à des séries d'aziridines saturées et insaturées de structures inédites, ainsi qu'à des amines primaires éthyléniques et secondaires transposées (schéma 1).



R = alkyle

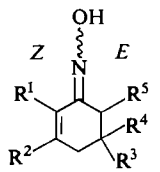
SCHÉMA 1

Le phénomène de régiosélectivité des réductions, depuis longtemps démontré en série saturée et observé en série insaturée (5), peut être généralisé pour les oximes α,β-éthyléniques. Les études en résonance magnétique nucléaire du proton et en infrarouge permettent de préciser les structures des composés azotés synthétisés. Par ailleurs, les configurations des aziridines substituées sont confirmées par hydrogénation catalytique en amine primaire (6). Les études spectroscopiques font l'objet de la seconde partie de ce mémoire.

[1]Ce travail fait partie de la thèse de 3ème cycle de L. Ferrero présentée à Nice, le 15 octobre 1974.

Resultats et discussion

Toutes les réductions ont été menées sur trois types de cyclohexénone oximes choisies d'après un critère configurationnel (schéma 2) : (*i*) isomérie *E* et *Z* possibles sur le même type d'oxime: isophorone oxime **1** et méthyl-3 cyclohexène-2 one-1 oxime **2**; (*ii*) isomérie *E* seule possible: carvone oxime **3** et méthyl-2 cyclohexène-2 one-1 oxime **4**; (*iii*) isomérie *Z* seule possible: pipéritone oxime **5**.



1: $R^1 = R^5 = H$ $R^2 = R^3 = R^4 = CH_3$
2: $R^1 = R^3 = R^4 = R^5 = H$ $R^2 = CH_3$
3: $R^1 = CH_3$ $R^2 = R^4 = R^5 = H$ $R^3 = C(=CH_2)(CH_3)$
4: $R^1 = CH_3$ $R^2 = R^3 = R^4 = R^5 = H$
5: $R^1 = R^3 = R^4 = H$ $R^2 = CH_3$ $R^5 = CH(CH_3)_2$

Réduction par $LiAlH_4$ dans l'éther diéthylique

Si la réduction des oximes saturées par $LiAlH_4$ dans l'éther ne peut conduire qu'à des amines primaires et secondaires, il n'en est pas de même en série insaturée où des aziridines peuvent être obtenues (1–4). En effet, les processus généraux d'obtention d'aziridines par réduction d'oxime s'effectuent, soit par arrachement d'un proton

mobile (cas des oximes saturées), soit par addition d'un ion hydrure (cas des oximes éthyléniques) (schéma 3).

Dans le premier cas, l'utilisation du tétrahydrofurane facilite le départ du proton; dans le second cas, un tel solvant n'est plus nécessaire. Ainsi, dans l'éther diéthylique, l'addition d'un ion hydrure est nettement favorisée par rapport à l'arrachement d'un proton aliphatique; le cours de la réaction est donc simplifié, ce qui nous a permis de mettre en évidence un phénomène de régiosélectivité. Toutes les réductions ont été opérées en respectant les conditions suivantes : (*i*) $LiAlH_4$ en excès : de 4 à 5 moles de réducteur par mole d'oxime; (*ii*) solvant : éther diéthylique; concentration en oxime : 10^{-1} *M*; (*iii*) température : au reflux du solvant; (*iv*) temps de réaction : jusqu'à disparition totale de l'oxime, soit de 24 à 72 h.

Les différentes réductions peuvent être schématisées comme suit (schéma 4). Les pourcentages en produits de réaction, obtenus à partir des données de la c.p.v. analytique, sont notés dans le tableau 1.

Trois conclusions principales se déduisent de ces résultats:

1. Avant le début de nos travaux, la formation d'aziridines dans l'éther n'avait été observée qu'à partir d'oximes éthyléniques substituées par des noyaux phényles. Nous constatons donc que l'obtention de tels composés est possible même en l'absence d'une telle substitution. Ces résultats sont en accord avec les observations de C. Glacet et ses collaborateurs (2).

2. Parmi les autres produits, nous trouvons des amines β,γ-éthyléniques et secondaires. Il est à noter que ces structures n'avaient été que très rarement observées dans des réductions analogues (1, 2).

3. Nous constatons que quelle que soit la substitution des oximes de départ, l'isomère *Z* (*syn*) conduit toujours préférentiellement à la formation d'aziridines, alors que l'isomère *E* (*anti*) favorise l'obtention des amines.

Ce dernier résultat nous permet donc de conclure que le phénomène de régiosélectivité déjà observé en série saturée (7) peut être étendu aux oximes α,β-éthyléniques (5). L'interprétation de ce phénomène peut être faite sur la base des études mécanistiques menées par Kotera et ses collaborateurs (7) et par Dimmock et al. (1). Le processus de formation des aziridines à partir des isomères *Z* peut se concevoir à partir du chemin réactionnel suivant (schéma 5):

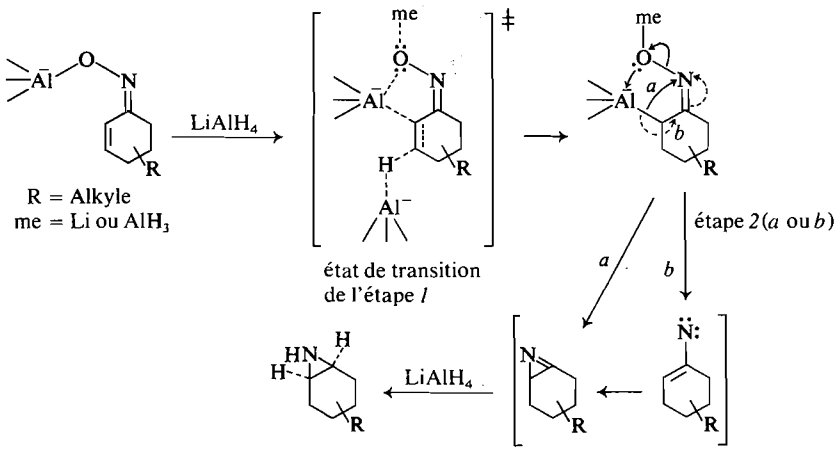

SCHÉMA 5

La régiosélectivité est commandée à la fois par les étapes *1* et *2*. La délocalisation électronique du complexe d'isomérie *Z* favorise l'addition de la seconde molécule d'hydrure métallique. La seconde étape est la *cis*-élimination intramoléculaire avec participation d'un doublet libre de l'oxygène.

Il est à remarquer que l'état de transition proposé pour mener à l'organo-métallique intermédiaire possède déjà la structure nécessaire au processus de *cis*-élimination. Les étapes *1* et *2* peuvent donc être confondues, ce qui expliquerait le fait que nous n'ayons jamais pu isoler d'oxime saturée résiduelle.

TABLEAU 1. Réductions par $LiAlH_4$ dans Et_2O

Oximes	Rapport Z:E	Amines				Aziridines			
		Primaires	Secondaires		Ethylénique				
			6		**7**	**8**			**9**
1	1:1		6%		40%	24%			30%
	1:2		6%		54%	18%			22%
			10		**11**	**12**			**13**
2	1:0	8%	4%		12%	42%			34%
	1:2	13%	16%		31%	21%			19%
			14	**15**	**16**		**17**		
3	0:1	13%	8%	42%	13%		24%		
			18		**19**		**20**		
4	0:1	0%	42%		34%		24%		
						21	**22**	**23**	**24**
5	1:0	0%	0%		0%	34%	20%		46%

L'étude détaillée de cette régiosélectivité a fait l'objet d'une récente étude (8).

Réduction par $LiAlH_4$ dans le tétrahydrofurane

Comme nous l'avons déjà fait remarquer précédemment, l'utilisation du THF favorisant l'élimination des protons mobiles, du fait de l'augmentation de la température de réaction et de l'accroissement de la polarité du solvant (9), la cyclisation en aziridines peut suivre les deux voies distinctes (*a*) et (*b*) (schéma 6) : (*a*) addition

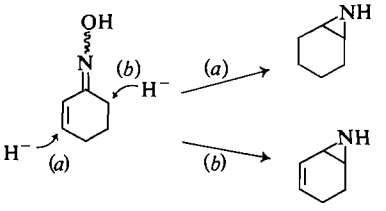

SCHÉMA 6

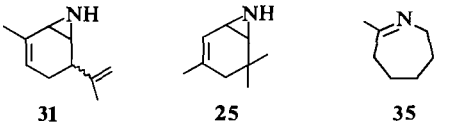
de l'ion hydrure sur le carbone éthylénique C_3 comme dans l'éther diéthylique; (*b*) élimination d'un proton mobile aliphatique en α de la fonction oximino comme dans le cas des oximes saturées (7).

Les conditions de réductions sont semblables à celles menées dans l'éther. Les temps de réactions varient de 3 à 6 h; les oximes *E* réagissant plus lentement que les isomères *Z*. Les composés obtenus à partir des cinq oximes de cyclohexénones sont identiques à ceux précédemment décrits, sauf en ce qui concerne l'isophorone oxime **1** et la carvone oxime **3** qui conduisent en plus aux aziridines éthyléniques **25** et **31**, et l'oxime **4** qui donne l'imine **35** (schéma 7).



31 **25** **35**

SCHÉMA 7

Comme précédemment, les proportions en produits azotés varient principalement en fonction de la configuration des oximes de départ. Toutefois, pour des oximes de même configuration, l'influence de la substitution sur le carbone 5 n'est pas à négliger. Les résultats sont résumés dans le tableau 2.

La réduction des oximes α,β-éthyléniques par $LiAlH_4$ est fortement influencée par l'emploi du THF à 66 °C. Comme l'a déjà fait observer G. Ricart (9), cette influence peut avoir deux origines, d'une part, l'augmentation de la polarité du solvant et d'autre part, un accroissement de la température de réaction. Il est toutefois difficile d'évaluer l'apport de ces deux effets puisque les réductions menées dans le THF à 35 °C sont beaucoup plus lentes qu'à 66 °C et que le rendement global est nettement plus faible (9). Ces effets de solvant et de température sont fortement marqués dans le cas de l'isophorone oxime **1** et se traduisent par l'apparition d'un composé nouveau, l'aza-7 triméthyl-3,5,5 bicyclo[4.1.0]heptène-2, **25**. Cependant, cette constatation ne peut être généralisée aux autres cyclohexénones oximes où l'emploi du THF à 66 °C provoque principalement une diminution des temps de réaction et une augmentation sensible des proportions en aziridines saturées. Remarquons que la formation de **25** est prépondérante lorsque

l'oxime **1** est de configuration *E*, ce qui est conforme au phénomène de régiosélectivité observé sur les oximes saturées, déjà interprété par Kotera et ses collaborateurs (7).

Réduction par le Red-Al '$NaAlH_2(OCH_2CH_2OCH_3)_2$' dans le tétrahydrofurane

Avant nos travaux, ce réactif avait été employé avec succès dans la réduction de deux oximes : une aldoxime aromatique et la cyclohexanone oxime (10); cependant, seule la formation d'amines primaires avait été observée. L'utilisation de ce réducteur avec l'isophorone oxime **1** a montré que des aziridines éthyléniques pouvaient être obtenues (11). Ceci nous a incité à généraliser ce type de réduction à une série d'oximes de cyclohexénones.

Les conditions de réactions sont identiques à celles précédemment décrites. Les temps de réaction varient de 1 à 3 h. La complexité des bilans réactionnels est résumée dans le schéma 8. Les proportions en composés azotés obtenues

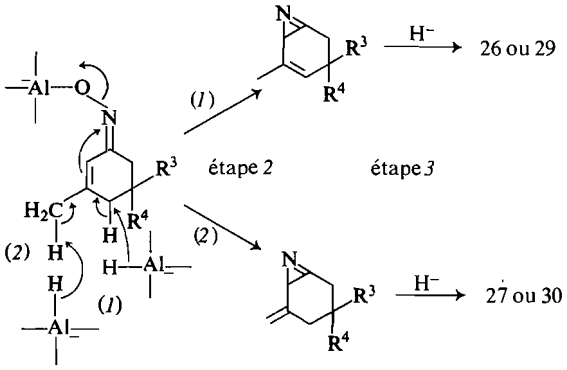
par c.p.v. analytique sont données dans le tableau 3.

Ces résultats confirment bien la spécificité de ce nouveau réducteur. En effet, toutes les cyclohexénone oximes traitées par le Red-Al donnent des taux importants d'aziridines α,β-éthyléniques, alors que $LiAlH_4$ n'a jamais permis l'obtention de ces produits (sauf cas de **1** dans le THF) de façon prépondérante. Nous observons à nouveau la régiosélectivité de la réaction qui est parfaitement démontrée dans le cas des oximes **1** et **2**, où les aziridines éthyléniques **25** et **28** ne sont formées qu'à partir d'oximes de configuration *E* par cyclisation sur le carbone aliphatique (7), alors que les aziridines insaturées **26**, **27** et **29**, **30** dérivent essentiellement des oximes de configuration *Z* suivant le processus réactionnel suivant (schéma 9).



1: $R^3 = R^4 = CH_3$

2: $R^3 = R^4 = H$

SCHÉMA 9

Le Red-Al diffère donc de $LiAlH_4$ par son aptitude à favoriser les réactions procédant par élimination d'un proton mobile en α d'une insaturation. Cette propriété peut être expliquée par la conjugaison des deux facteurs suivants: (*i*) le facteur stérique inhérent à la taille du groupement méthoxy-2 éthoxy qui s'oppose à une approche suffisante de l'oxime par la molécule de Red-Al chargée d'additionner l'ion hydrure sur la liaison éthylénique (12); (*ii*) la basicité ou dureté du réducteur, c'est-à-dire l'aptitude du Red-Al à éliminer les protons aliphatiques mobiles.

Par ailleurs, il est important de noter que la réactivité du Red-Al se manifeste de façon analogue dans l'éther diéthylique et le tétrahydrofurane. Ceci peut être vérifié, par exemple, sur l'oxime **1**, dont les résultats comparatifs sont rapportés dans le tableau 4. Il semble donc que l'influence de ce réducteur est telle qu'elle masque pratiquement les effets du solvant et de la température qui ne sont, dans ce cas, que minimes.

Conclusion

Les réductions de cyclohexénone oximes de configuration *E* ou (et) *Z* par $LiAlH_4$ et $NaAlH_2(OCH_2CH_2OCH_3)_2$ ont permis de synthétiser un grand nombre d'aziridines et, en particulier, avec le dernier réactif, d'accèder à une nouvelle série de composés inédits qui sont des aziridines α,β-éthyléniques du type aza-7 bicyclo[4.1.0] heptane. Parmi les nombreux facteurs qui déterminent les voies de réduction suivies, notre étude en fait ressortir les quatre plus importants, à savoir, l'influence du solvant, de la température de réaction, la nature de l'agent réducteur et l'effet de la configuration de l'oxime. Nos travaux ont été axés plus particulièrement sur ce dernier facteur; en effet, le phénomène de régiosélectivité déjà connu sur les oximes saturées a pu être étendu en série α,β-éthylénique.

Il nous paraîtrait donc intéressant d'essayer d'appliquer, dès à présent, ce type de réduction par le Red-Al à la synthèse d'aziridines α,β-éthyléniques. Nos travaux actuels ont pour but de rechercher les conditions réactionnelles optimales afin d'orienter le cours des réductions essentiellement vers la formation de telles aziridines, en particulier par l'emploi d'autres hydrures complexes, ainsi qu'une méthode de séparation efficace permettant d'isoler ces composés avec de meilleurs rendements.

Etudes spectroscopiques r.m.n. et i.r.

Les structures des composés azotés nouveaux dont la synthèse a été décrite précédemment, ont été établies, d'une part, par transformations chimiques (hydrogénolyse des aziridines en amines primaires (6)), et d'autre part, par analyse spectroscopique, en particulier par résonance magnétique nucléaire du proton et par infra-rouge. Nous ne donnerons ici que les signaux caractéristiques nécessaires à l'identification des structures. Les déplacements chimiques et constantes de couplages relatifs à chaque produit sont donnés dans la partie expérimentale.

Les aziridines bicycliques α,β-insaturées étant les plus riches en information de par la présence des protons éthyléniques, seront étudiées en premier lieu.

TABLEAU 4. Comparaison entre les réductions dans l'éther et le THF (pour l'isophorone avec le Red-Al)

Solvant	Rapport Z:E	Amines			Aziridines

	1:2	2%		9%	4%	5%	58%	7%	15%

Etudes des aziridines α,β-éthyléniques

Les spectres r.m.n. des aziridines éthyléniques présentent plusieurs types de signaux caractéristiques : (*i*) entre 4 et 6 p.p.m., les protons éthyléniques ; (*ii*) entre 1.8 et 2.5 p.p.m., les protons des carbones tête de pont en position 1 et 6 ; ces signaux, plus ou moins séparés, permettent de confirmer la position *cis* de ces deux protons (constante de couplage classique $J_{1,6}$ = 6 Hz) (13) ; leurs déplacements chimiques et les autres constantes de couplage sont caractéristiques de la structure de la molécule ; (*iii*) entre 0.5 et 0.8 p.p.m., le proton de la fonction aziridine; (*iv*) les signaux des autres protons du cycle ne sont que très rarement exploitables.[2]

Les aziridines éthyléniques à double liaison exocyclique sont de plus, caractérisées par le système vinylique, observable en infra-rouge (3080, 1650 et 880 cm^{-1}). L'ensemble des signaux caractérisant les aziridines insaturées étudiées et leurs évolutions pour les différents isomères sont résumés dans le schéma 10.

Nous noterons en particulier : (*i*) les protons éthyléniques résonnant pour chaque type de structure à des champs bien différenciés (5.60, 5.20, 4.94 et 4.80 p.p.m.); (*ii*) les protons en tête de pont et en particulier, le proton en C_1 faiblement sensible aux effets de substitution.

Etudes des aziridines bicycliques saturées

Du fait de l'absence de liaison éthylénique, les protons résonnent à des champs très voisins, ce qui rend les spectres r.m.n. de composés

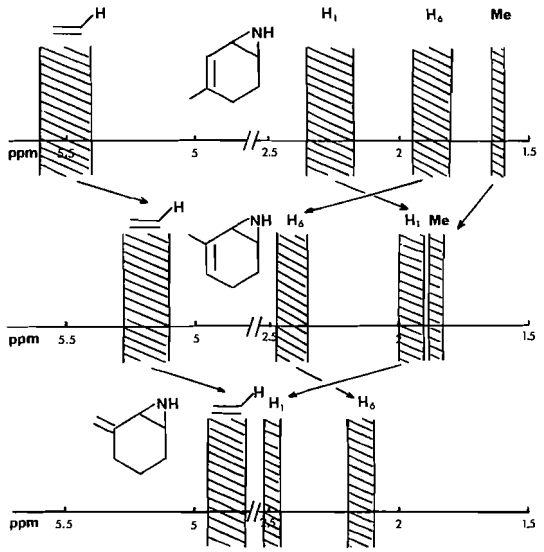

SCHÉMA 10

beaucoup plus complexes que ceux précédemment décrits. De plus, un nouveau problème apparaît : la position *cis* ou *trans* des différents substituants par rapport au cycle aziridinique. Ce problème d'isomérie ayant été résolu par hydrogénolyse (6) (voir partie expérimentale); il nous a donc été possible de relever les principales caractéristiques r.m.n. des différentes aziridines saturées.

Les cyclohexénimines méthylées en tête de pont présentent peu de signaux exploitables, le méthyle tête de pont blindant le proton voisin en C_6. Seul, le déblindage de ce méthyle (1.20 p.p.m.) est notable.

Les isomères *cis* et *trans* des différentes cyclohexénimines méthylées en position 2 présentent des spectres r.m.n. voisins; cependant, nous pouvons dégager des valeurs observées un certain nombre de résultats caractéristiques. La substitution en C_2 ou C_5 entraîne un blindage

[2]Il a cependant été possible, pour certains composés, en particulier pour les dérivés de l'isophorone oxime **1**, d'attribuer un grand nombre de signaux et dans certains cas, de mettre en évidence l'existence de conformations privilégiées. Nous ne développerons pas ici ce problème conformationnel, bien que le simple spectre r.m.n. (Varian A 60A, température ambiante, sans découplage) permette sa mise en évidence; ces différents problèmes seront exposés dans un prochain mémoire.

SCHÉMA 11

des protons en tête de pont lorsqu'elle s'effectue en *trans* du petit cycle, tandis que la substitution en *cis* provoque des effets négligeables. Les couplages vicinaux des protons en C_1 et C_6 sont un critère valable (s'ils sont mesurables). Nous noterons en particulier le couplage $J_{1,2}$ nul, caractéristique des composés **9** et **13**, tous deux *trans* méthylés.

Etudes des amines éthyléniques

Dans cette série, trois types de signaux sont exploitables : (*i*) à champ faible, le proton éthylénique centré vers 5.35 p.p.m.; (*ii*) vers 3.2 p.p.m., le proton en α du NH_2 fonctionnel; (*iii*) vers 1.65 p.p.m., le méthyle éthylénique.

Il est, de plus, possible de différencier les amines méthylées, soit en C_2, soit en C_3; en effet, le signal des protons du méthyle est légérement déblindé lorsque ce dernier est en C_2 (1.70 p.p.m. au lieu de 1.63 p.p.m. en position C_3). Inversement, le proton éthylénique en C_2 (5.25 p.p.m.) est blindé par rapport à un proton en C_3 (5.33 p.p.m.). Cependant, la largeur à mi-hauteur du signal de ce proton éthylénique reste le critère le plus significatif : elle est d'environ 6 Hz pour le proton en C_2 (un seul couplage vicinal $J_{1,2}$) et d'environ 10 Hz pour le proton en C_3 (deux couplages vicinaux).

Etudes des amines secondaires transposées et de l'imine 35

Les spectres r.m.n. des amines secondaires transposées sont assez peu explicites, la plupart des signaux étant superposés. La seule partie intéressante du spectre (entre 2.40 et 3.0 p.p.m.) concerne les protons portés par les carbones C_2 et C_7 en α de la fonction amine. L'intégration des signaux de cette région du spectre est liée au nombre de ces protons; trois protons pour les composés **14** et **18**, méthylés en C_2; quatre protons pour le composé **10**, confirmant l'absence de substitution en α de l'azote.

Pour le composé **35**, la présence d'une double liaison, l'absence de proton éthylénique et de proton fonctionnel lié à l'azote sont en bon accord avec la structure proposée pour ce composé basique. Ce produit disparaît du mélange réactionnel (avec l'amine β,γ-éthylénique) par simple lavage avec une solution de chlorure d'ammonium, ce qui n'est pas le cas pour les aziridines moins basiques et plus stables. Bien que l'hydrogénolyse en amine **18** n'ait pu être réalisée, les données i.r., r.m.n., masse et les travaux de C. Glacet et ses collaborateurs (2) confirment la structure proposée.

Cette étude r.m.n. nous a permis de confirmer les structures de tous les composés azotés synthétisés ainsi que d'envisager un dosage des mélanges réactionnels : les composés insaturés présentent tous, à champ faible, des signaux qui caractérisent leur appartenance à une série de composés bien déterminée, de plus, dans une même série, ces déplacements permettent de déduire directement la substitution. Une telle spécificité des déplacements chimiques et surtout l'absence de toute superposition de signaux, permet, pour chaque oxime réduite, un dosage du mélange réactionnel par intégration des signaux des protons éthyléniques (schéma 11), confirmant ainsi les résultats des chromatographies en phase gazeuse.

Partie expérimentale

Conditions générales

Les spectres i.r. ont été enregistrés sur un appareil Perkin-Elmer 457. Les masses des composés ont été mesurées à l'aide d'un spectromètre Varian MAT 111 (14).

Les caractéristiques r.m.n. ont été obtenues sur appareil Varian A 60A en utilisant le tétrachlorure de carbone et le chloroforme deutérié comme solvants et le tétraméthylsilane comme référence interne.

La pureté des oximes a été vérifiée par c.p.v. sur appareil Perkin-Elmer F 11, équipé d'une colonne analytique de 1.60 m (diamètre $\frac{1}{8}$ po) imprégnée d'une

phase Carbowax 20 M à 10% sur support Chromosorb WDMCS, température 130 °C, vecteur azote.

La chromatographie gazeuse des aziridines a été effectuée sur deux colonnes différentes : (*1*) colonne analytique A : 3 m (diamètre $\frac{1}{8}$ po), Chromosorb P80/100 imprégné de 2% de potasse et 12.5% d'Hyprose; vecteur azote 3 cm/s; température de 100 à 120 °C; (*2*) colonne analytique B : 3 m (diamètre $\frac{1}{8}$ po), Chromosorb WDMCS 80/100 imprégné de 5% de potasse et de 10% de Carbowax 20M; vecteur azote 3 m/s; température de 95 à 125 °C.

La séparation des amines et des aziridines a été faite par chromatographie préparative en phase gazeuse sur un appareil Carlo Erba Fractovap 2400V : (*1*) colonne A préparative : 2 m (diamètre $\frac{3}{8}$ po), Chromosorb P80/100 imprégné de 2% de potasse et de 12% d'Hyprose; vecteur azote 4 cm/s; température de 110 à 130 °C; (*2*) colonne B préparative : 4 m (diamètre $\frac{3}{8}$ po), Chromosorb P80/100 imprégné de 5% de potasse et de 12.5% de Carbowax 20M; vecteur azote 4 cm/s; température 140 °C.

Les séparations de certains composés étant améliorées sur Carbowax ou sur hyprose, l'emploi de deux types de colonne nous a paru préférable.

Procédés généraux de préparation des oximes

Les méthodes de synthèses d'oximes α,β-éthyléniques, décrites par Sato et al. (15) ont toujours été employées. Cependant, si trois cyclohexénones ne peuvent conduire qu'à des oximes d'un seul type de configuration *E* ou *Z*, à cause de la substitution en α de la fonction carbonyle (cas des oximes **3**, **4** et **5**), il n'en est pas de même pour l'isophorone et la méthyl-3 cyclohexéne-2 one-1 dont les oximes peuvent être *Z* et *E* et où il est important d'obtenir des proportions variables d'isomères. En fait, le p*H* du milieu réactionnel oriente la synthèse vers la formation préférentielle d'un des isomères *syn* ou *anti* de l'oxime. Ainsi:

(*a*) Synthèse à p*H* basique : suivant (15), on obtient pour **1** un mélange d'isomères *Z* et *E* en proportion 1:2. Ce mélange peut être réduit tel quel ou être préalablement cristallisé dans un mélange éthanol–eau (90:10) de manière à isoler l'isomère *E* majoritaire (p.f. 98 °C). De même, les isomères *Z* et *E* de l'oxime **2** sont obtenus en proportion 1:2 avec un rendement de 75%.

(*b*) Synthèse à p*H* acide : on obtient le chlorhydrate des oximes. Celles-ci sont régénérées par lavage de leur chlorhydrate avec une solution aqueuse de soude. L'oxime **1** est présente sous la forme des deux isomères *Z* et *E* en proportions égales (1:1) tandis que l'oxime **2** n'est isolée que sous la forme *Z*.

Le tableau 5 résume les résultats des différentes oximations.

Les études r.m.n. des oximes de cyclohexénones ayant été déjà décrites pour la plupart (15, 16, 17), l'identification des oximes **3** et **4** d'isomérie *E* et de l'oxime **5** d'isomérie *Z*, n'offre aucune difficulté. Cependant, les spectres r.m.n. des oximes **1** et **2** existant sous les formes *Z* et *E* permettent d'établir les proportions exactes d'isomères grâce aux déplacements chimiques du proton éthylénique qui est fortement influencé par la position du groupement hydroxyle (tableau 6).

Par ailleurs, les spectres i.r. (KBr) de ces oximes présentent toutes les bandes caractéristiques du groupement oximino: 3290–3180 cm^{-1} (ν —OH), 1640 cm^{-1} (ν C=N), 930–970 cm^{-1} (ν N—O).

Procédés généraux de réduction

Réduction par $LiAlH_4$ dans l'éther diéthylique

Les réductions sont menées dans un ballon bicol de 250 cm^3 équipé d'un réfrigérant, surmonté d'un tube desséchant et d'une agitation magnétique. A une suspension de 1.90 g (50 mmol) de $LiAlH_4$ dans 80 cm^3 d'éther anhydre, refroidie à 0 °C, on ajoute sous agitation, une solution de 10 mmol d'oxime dans 20 cm^3 de ce solvant. A la fin de l'addition, la solution est portée au reflux. La fin de la réaction est indiquée par la disparition de l'oxime en c.p.v. et c.c.m. (hexane, benzène, éther, 5:3:2). Le mélange réactionnel est alors hydrolysé à 0 °C par addition d'eau. Les produits de la réaction sont alors extraits au pentane ou à l'éther, puis séchés sur carbonate de sodium. Le solvant est évaporé sous pression réduite et le mélange réactionnel est soumis aux différentes analyses.

Réduction par $LiAlH_4$ dans le tétrahydrofurane

Les conditions opératoires sont identiques aux précédentes, à l'exception de l'étape finale. Lorsque l'oxime a entièrement réagi, le THF est évaporé sous pression réduite entre 45 et 50 °C. Le résidu est repris par un volume égale d'éther diéthylique et hydrolysé dans ce solvant par addition d'eau à 0 °C. Cette technique a pour but d'éviter que des produits de réduction volatils soient

perdus lors de l'élimination du solvant de la réaction.

Réduction par le Red-Al dans le tétrahydrofurane

Les réductions sont effectuées dans un ballon bicol de 250 cm^3 équipé d'un réfrigérant surmonté d'un tube desséchant et d'une agitation magnétique. La quantité appropriée de Red-Al (solution commerciale à 70% dans le benzène), soit 14.4 g pour 50 mmol est d'abord concentrée sous vide à 50 °C afin d'éliminer le benzène. Le réactif est ensuite dilué dans 80 cm^3 de THF anhydre; 10 mmol d'oxime dissoutes dans 20 cm^3 de ce solvant sont alors additionnées lentement à cette solution refroidie à 0 °C et agitée magnétiquement. A la fin de l'addition, le mélange réactionnel est porté au reflux. La réduction de l'oxime est suivie par c.p.v. et c.c.m. La phase finale de la manipulation est identique à celle déjà décrite pour $LiAlH_4$: le THF est remplacé par de l'éther sulfurique anhydre avant l'hydrolyse. Celle-ci est effectuée par une solution aqueuse de soude 5 *N* à 0 °C. Les produits de la réaction sont extraits au pentane ou à l'éther. La phase organique est lavée plusieurs fois à l'eau afin d'éliminer le glyme (produit d'hydrolyse du Red-Al). Elle est ensuite séchée sur carbonate de sodium. Enfin, le solvant est évaporé sous vide et le mélange réactionnel est soumis aux différentes analyses.

Analyses et identifications des produits de réduction

Dans tous les cas, les rendements des réductions en produits azotés varient de 60 à 70%. Ceux-ci ont été calculés approximativement à partir du poids du résidu réactionnel sur la base des masses moléculaires des composés obtenus, de leurs proportions chromatographiques et à l'aide de la technique des références internes.

Les études spectroscopiques, et en particulier, la résonance magnétique nucléaire du proton, nous ont permis d'identifier sans ambiguité les structures de tous les composés isolés. Ces études détaillées font l'objet de la seconde partie de ce mémoire.

Cependant, afin de préciser avec une certitude absolue la configuration de chaque aziridine isomère, nous avons été conduits à pratiquer une analyse chimique pour chaque diastéréoisomère. Les méthodes d'analyses chimiques appropriées à l'étude structurale des aziridines sont basées sur l'ouverture de l'hétérocycle azoté; l'ouverture par hydrogénolyse catalytique est la plus commode (6) : l'aziridine ne peut donner que deux amines primaires, isomères de position qui ont même configuration que l'aziridine de départ.

L'hydrogénolyse sur nickel de Raney des différentes aziridines isolées, suivant la méthode de Takano et ses collaborateurs (6) conduisent à des amines primaires connues (17). Ainsi, les caractéristiques r.m.n. des amines obtenues, comparées à celles décrites dans la littérature, nous ont permis d'assigner toutes les configurations.

Absorption r.m.n. et i.r.

Nous utilisons les dénominations suivantes : s, singulet; d, doublet; t, triplet; q, quadruplet; m, multiplet.

Aziridines α,β-éthyléniques à double liaison intracyclique

Composé **25** : r.m.n. δ (p.p.m.) 5.56 (H en C_2, d de d déquadruplé, $J_{1,2} = 4.5$ Hz, $J_{2,4a} = 3$ Hz, $J_{2,CH_3} = 1.5$ Hz), 2.16 (H en C_1, d de d, $J_{1,2} = 4.5$ Hz, $J_{1,6} = 6$ Hz), 1.90 (H axial en C_4, d, $J_{4,4} = 17$ Hz), 1.86 (H en C_6, d de d, $J_{1,6} = 6$ Hz, $J_{6,4e} = 1.6$ Hz), 1.62 (CH_3 en C_3, d, $J_{2,CH_3} = 1.5$ Hz), 1.35 (H équatorial en C_4, d de d, $J_{4,4} = 17$ Hz, $J_{4e,6} = 1.6$ Hz), 1.10 et 0.85 ($2CH_3$ équatorial et axial en C_5, 2s), 0.58 (H fonctionnel); i.r. (cm^{-1}) 3230 (ν NH), 3030 et 835 (CH éthylénique), 1665 (ν C=C) 1370 et 1360 (*gem*-diméthyle).

Composé **26** : r.m.n. δ (p.p.m.) 5.13 (H en C_3, m, $J_{3,CH_3} = 1.2$ Hz), 2.40 (H en C_6, m, $J_{1,6} = 6$ Hz, $J_{5a,6} \simeq J_{5e,6} \simeq 3$ Hz), 2.03 (H en C_1, d, $J_{1,6} = 6$ Hz), 1.84 (CH_3 en C_2, d, $J_{3,CH_3} = 1.2$ Hz), 1.01 et 0.96 ($2CH_3$ en C_4, 2s), 0.50 (H fonctionnel); i.r. (cm^{-1}) 3250 (ν NH), 3010 et 800 (CH éthylénique), 1650 (ν C=C), 1380 et 1360 (*gem*-diméthyle).

Composé **28** : r.m.n. δ (p.p.m.) 5.64 (H en C_2, m. $J_{1,2} = 4.5$ Hz, $J_{2,CH_3} = 1$ Hz), 2.25 (H en C_1, $J_{1,2} = 4.5$ Hz, $J_{1,6} = 6$ Hz), 1.90 (H en C_6, m, $J_{1,6} = 6$ Hz), 1.63 (CH_3 en C_3, d, $J_{2,CH_3} = 1$ Hz), 0.72 (H fonctionnel); i.r. (cm^{-1}) 3250 (ν NH), 3075 et 830 (CH éthylénique), 1643 (ν C=C).

Composé **29** ≡ **32**: r.m.n. δ (p.p.m.) 5.25 (H en C_3, m, $J_{1,3} = 1$ Hz), 2.38 (H en C_6, m, $J_{1,6} = 6$ Hz), 1.96 (H en C_1, m, $J_{1,3} = 1$ Hz, $J_{1,6} = 6$ Hz), 1.84 (CH_3 en C_2), 0.72 (H fonctionnel); i.r. (cm^{-1}) 3350, 3250 (ν NH), 3010 et 815 (CH éthylénique), 1665 (ν C=C).

Composé **31** (2 isomères): r.m.n. δ (p.p.m.) 5.24 (H en C_3), 4.83 et 4.73 (CH_2 isopropényle), 2.66 (H en C_5), 2.40 (H en C_6), 1.90, 1.83 et 1.71 (CH_3 en C_2 et CH_3 isopropényle), 0.73 (H fonctionnel); i.r. (cm^{-1}) 3240 (ν NH), 3085, 3075 (ν C=CH_2), 1650 (ν C=C), 885 et 820 (CH éthyléniques), 3040 (γ C=C—H).

Composé **33** (2 isomères): r.m.n. δ (p.p.m.) 5.24 (H en

C_3, m, $J_{1,3} = 0.5$ Hz), 2.28 (H en C_6, m, $J_{1,6} = 6$ Hz, $J_{5,6} = 6$ Hz), 1.95 (H en C_1, m, $J_{1,6} = 6$ Hz, $J_{1,3} = 0.5$ Hz), 1.84 (CH_3 en C_2), 0.99 et 0.90 ($2CH_3$ isopropyle, 2s, $J_{\text{isopropyle H,CH}_3} = 6$ Hz), 0.80 (H fonctionnel); i.r. (cm^{-1}) 3240 (ν NH), 3010–818 (CH éthylénique), 1650 (ν C=C), 1385–1370 (*gem*-diméthyle).

Aziridines α,β-éthyléniques à double liaison exocyclique

Composé **27**: r.m.n. δ (p.p.m.) 4.90 et 4.77 (2H éthyléniques, d de d, $J_{7,7} = 1.7$ Hz, $J_{7\alpha,3a} \simeq J_{7\beta,3a} = 1.5$ Hz), 2.51 (H en C_1, d, $J_{1,6} = 6$ Hz), 2.22 (H en C_6, d de t, $J_{1,6} = 6$ Hz, $J_{5e,6} = 6$ Hz, $J_{5a,6} = 3$ Hz), 2.10 (H axial en C_5, d de d, $J_{5,5} = 13$ Hz, $J_{5a,6} = 3$ Hz), 1.60 (H équatorial en C_5 et 2H en C_3), 0.88 et 0.77 ($2CH_3$ en C_4, s), 0.50 (H fonctionnel); i.r. (cm^{-1}) 3250 (ν NH), 3080 et 880 (CH_2 vinylique), 1650 (ν C=C) 1390 et 1367 (*gem*-diméthyle).

Composé **30**: r.m.n. δ (p.p.m.) 4.94 et 4.84 (2H éthyléniques), 2.49 (H en C_1, $J_{1,6} = 6$ Hz), 2.30 (H en C_6, m, $J_{1,6} = 6$ Hz, $J_{5,6\ \text{moyen}} = 3$ Hz), 0.73 (H fonctionnel); i.r. (cm^{-1}) 3240 (ν NH), 3085, 880 (CH_2 vinylique), 1655 (ν C=C).

Composé **34** (2 isomères) : r.m.n. δ (p.p.m.) 4.90 et 4.77 (2H éthyléniques), 2.49 (H en C_1, m, $J_{1,6} = 6$ Hz), 2.10 (H en C_6, m, $J_{1,6} = 6$ Hz, $J_{5,6\ \text{moyen}} = 3$ Hz), 1.01 et 0.85 ($2CH_3$ isopropyle, 2d, $J_{\text{H-CH}_3} = 7$ Hz), 0.50 (H fonctionnel); i.r. (cm^{-1}) 3230 (ν NH), 3075–880 (CH_2 vinylique), 1645 (ν C=C), 1385–1370 (*gem*-diméthyle).

Cyclohexénimines méthylées en tête de pont

Composé **17** (2 isomères): r.m.n. δ (p.p.m.) 4.60 (CH_2 isopropényle), 1.80 (H en C_6), 1.65 (CH_3 isopropényle), 1.22 (CH_3 en tête de pont C_1), 0.90 (H fonctionnel); i.r. (cm^{-1}) 3282–3275 (ν NH), 3080 et 870 (CH_2 éthylénique), 1645 (ν C=C).

Composé **20**: r.m.n. δ (p.p.m.) 1.80 (H en C_6), 1.20 (CH_3 en tête de pont C_1), 0.18 (H fonctionnel); i.r. (cm^{-1}) 3250 (ν NH).

Cyclohexénimines trans méthylées en position 2

Composé **9** *trans*: r.m.n. δ (p.p.m.) 2.12 (H en C_6, m, $J_{1,6} = 6$ Hz, $J_{6,5a} = 4$ Hz, $J_{6,5e} = 1.5$ Hz), 1.75 (H en C_1, d, $J_{1,2} = 0$ Hz, $J_{1,6} = 6$ Hz), 1.05 (CH_3 en C_2, d, $J_{2,\text{CH}_3} = 7$ Hz), 0.92 et 0.86 ($2CH_3$ en C_4, 2s), 0.50 (H fonctionnel); i.r. (cm^{-1}) 3250 (ν NH), 1390–1370 (*gem*-diméthyle).

Composé **13** *trans*: r.m.n. δ (p.p.m.) 2.09 (H en C_6, $J_{1,6} = 6$ Hz), 1.73 (H en C_1, d, $J_{1,2} = 0$ Hz, $J_{1,6} = 6$ Hz), 1.05 (CH_3 en C_2, d, $J_{2,\text{CH}_3} = 7$ Hz), 0.30 (H fonctionnel); i.r. (cm^{-1}) 3250 (ν NH).

Composé **24** *trans-trans*: r.m.n. δ (p.p.m.) 1.87 (2H en C_1 et C_6), 1.03 (CH_3 en C_2, d, $J_{2,\text{CH}_3} = 7$ Hz), 0.98 et 0.95 ($2CH_3$ isopropyle, 2d, $J_{\text{H,CH}_3} = 6.5$ Hz), 0.61 (H fonctionnel); i.r. (cm^{-1}) 3250 (ν NH), 1387–1370 (*gem*-diméthyle).

Cyclohexénimines cis méthylées en position 2

Composé **8** *cis*: r.m.n. δ (p.p.m.): 2.00 (2H en C_1 et C_6), 0.99 (CH_3 en C_2, d, $J_{2,\text{CH}_3} = 7$ Hz), 0.83 et 0.80 (2 CH_3 en C_4), 0.57 (H fonctionnel); i.r. (cm^{-1}) 3280 (ν NH), 1385–1360 (*gem*-diméthyle).

Composé **12** *cis*: r.m.n. δ (p.p.m.) 2.00 (2H en C_1 et C_6), 0.99 (CH_3 en C_2, d, $J_{2,\text{CH}_3} = 7$ Hz), 0.70 (H fonctionnel); i.r. (cm^{-1}) 3260 (ν NH).

Composé **21** *cis-cis*: r.m.n. δ (p.p.m.) 2.10 (2H en C_1 et C_6), 0.98 (CH_3 en C_2, d, $J_{2,\text{CH}_3} = 7$ Hz), 1.00 et 0.95 (2 CH_3 isopropyle, 2d, $J_{\text{H,CH}_3} = 6.5$ Hz), 0.30 (H fonctionnel); i.r. (cm^{-1}) 3245 (ν NH), 1385–1367 (*gem*-diméthyle).

Amines éthyléniques

Composé **7**: r.m.n. δ (p.p.m.) 5.23 (H en C_2), 3.20 (H en C_1), 1.62 (CH_3 en C_3), 1.23 (2H fonctionnels), 0.95 et 0.85 (2 CH_3 en C_5); i.r. (cm^{-1}) 3370–3300 (ν NH_2), 3030–815 (CH éthylénique), 1590 (ν C=C), 1380–1360 (*gem*-diméthyle).

Composé **11**: r.m.n. δ (p.p.m.) 5.28 (H en C_2), 3.20 (H en C_1), 1.63 (CH_3 en C_3), 0.91 (2H fonctionnels); i.r. (cm^{-1}) 3360–3300 (ν NH_2), 3025–810 (CH éthylénique), 1610 (ν C=C).

Composé **15** *cis*: r.m.n. δ (p.p.m.) 5.39 (H en C_3), 4.70 (CH_2 isopropényle), 3.25 (H axial en C_1), 1.70 (CH_3 en C_2 et CH_3 isopropényle), 1.00 (2H fonctionnels); i.r. (cm^{-1}) 3370–3300 (ν NH_2), 3085–3077 (ν C=CH_2), 3010 (ν C=CH), 1648–1600 (ν C=C), 885–800 (CH éthylénique).

Composé **16** *trans*: r.m.n. δ (p.p.m.) 5.34 (H en C_3), 4.64 (CH_2 isopropényle), 3.12 (H en C_1, t, $J_{1,6a} = J_{1,6e} = 4$ Hz), 1.70 (CH_3 en C_2 et CH_3 isopropényle), 1.70 (2H fonctionnels); i.r. (cm^{-1}) 3370–3290 (ν NH_2), 3080–3075 (ν C=CH_2), 3010 (ν C=CH), 1648–1610 (ν C=C), 885–805 (CH éthylénique).

Composé **19**: r.m.n. δ (p.p.m.) 5.33 (H en C_3), 3.02 (H en C_1), 1.70 (CH_3 en C_2), 0.95 (2H fonctionnels); i.r. (cm^{-1}) 3360–3290 (ν NH_2), 3020–795 (CH éthylénique), 1600 (ν C=C).

Amines secondaires transposées. Imine 35

Composé **10**: r.m.n. δ (p.p.m.) 2.95 (H équatorial en C_2, $J_{2,2} = 13$ Hz, $J_{2e,3} = 4$ Hz), 2.46 (H axial en C_2, d de d, $J_{2,2} = 13$ Hz, $J_{2a,3} = 9$ Hz), 2.30 (H fonctionnel), 0.92 (CH_3 en C_3, d, $J_{3,\text{CH}_3} = 7$ Hz); i.r. (cm^{-1}) 3320 (ν NH).

Composé **14** (2 isomères): r.m.n. δ (p.p.m.) 4.60 (CH_2 isopropényle), 3.00 (H fonctionnel), 3.05 (H équatorial en C_7, $J_{7,7} = 13$ Hz, $J_{7e,6a} = J_{7e,6e} = 4$ Hz), 2.57 (H axial en C_7, $J_{7,7} = 13$ Hz, $J_{7a,6a} = 13$ Hz, $J_{7a,6e} = 4$ Hz), 1.66 (CH_3 isopropényle), 1.02 (CH_3 en C_2, d, $J_{2,\text{CH}_3} = 7$ Hz); i.r. (cm^{-1}) 3360 (ν NH), 3090–885 (CH_2 éthylénique), 1630 (ν C=C).

Composé **18**: r.m.n. δ (p.p.m.) 1.90 (H fonctionnel), 1.04 (CH_3 en C_2, d, $J_{2,\text{CH}_3} = 7$ Hz); i.r. (cm^{-1}) 3350 (ν NH).

Composé **35** (imine): r.m.n. δ (p.p.m.) 3.40 (2H en C_7), 2.28 (2H en C_3), 1.92 (CH_3 en C_2); i.r. (cm^{-1}) 1662 (ν C=N).

Procédé général d'hydrogénolyse des aziridines

L'hydrogénolyse des aziridines se fait sous atmosphère d'hydrogène dans un hydrogénateur de Brown. A une suspension de 0.9 g de nickel de Raney dans 10 cm^3 de méthanol anhydre sont ajoutées 2 mmol d'aziridine. Après introduction de l'hydrogène dans le réacteur, le mélange est agité magnétiquement. La réaction est terminée lorsqu'il n'y a plus absorption d'hydrogène. Les produits formés sont analysés par c.p.v. sur colonne analytique B. Une première identification des amines formées est effectuée par comparaison des temps de rétention avec des échantillons purs. La solution méthanolique est ensuite filtrée; 2 mmol d'acide acétique sont ajoutées à froid afin de former les acétates des produits de réduction. Le méthanol est alors évaporé sous vide. Les acétates sont dissouts dans 2 cm^3 d'eau et basicifiés par une solution de soude 5 *N*. Les amines sont extraites au pentane et séchées sur carbonate de sodium. Le mélange réactionnel obtenu par évaporation du solvant

est analysé par r.m.n. Les spectres obtenus, comparés à ceux de Feltkamp et al. (18), ont permis de préciser toutes les configurations. Notons qu'il est parfois possible d'isoler l'une des deux amines formées par cristallisation sélective de son acétate dans l'éther anhydre. Le rendement des réactions, mesuré après passage à l'acétate, basification et extraction au pentane, est de l'ordre de 90%. L'analyse par c.p.v. montre que toute l'aziridine de départ est réduite au bout d'un jour de réaction, environ.

Les auteurs remercient Monsieur J. Cassan pour l'enregistrement des spectres de masse et Mademoiselle Y. Girault qui leur a fourni la plupart des échantillons d'amines primaires authentiques.

On the Mechanism of Oxetan Formation in the Photocycloaddition of *p*-Benzoquinone to Alkenes[1]

NIGEL J. BUNCE AND MARY HADLEY

Guelph-Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ontario N1G 2W1

Received May 26, 1975

NIGEL J. BUNCE and MARY HADLEY. Can. J. Chem. **53**, 3240 (1975).

Photochemical oxetan formation from *p*-benzoquinone and simple alkenes takes place from the lowest $^3n,\pi^*$ state of the quinone. It is suggested that an exciplex is formed between the alkene and the excited quinone, but that a biradical is nevertheless the immediate precursor of the oxetan.

NIGEL J. BUNCE et MARY HADLEY. Can. J. Chem. **53**, 3240 (1975).

La formation photochimique d'oxétannes à partir de *p*-benzoquinone et d'alcènes simples se produit à partir de l'état $^3n,\pi^*$ le plus bas de la quinone. On suggère qu'un exciplex est formé entre l'alcène et la quinone excitée mais on croit toutefois qu'un biradical est le précurseur immédiat de l'oxétanne.

[Traduit par le journal]

In common with other saturated and unsaturated carbonyl compounds, *p*-quinones afford cycloaddition products upon irradiation with alkenes (1). With *p*-benzoquinone, addition to the carbonyl group is the only mode of cyclization that has so far been observed (Eq. 1), although reaction at the olefinic linkage to give a cyclobutane might have been possible, and indeed is found with other *p*-quinones.

[1] 
The resulting spirooxetan adducts are often formed in high yield, and the scope and preparative value of this reaction have been examined in some detail (2). To date, however, little is known about its mechanism; Bryce-Smith and his colleagues noted that oxetan production was more efficient upon irradiation into the $^1n,\pi^*$ band of the quinone rather than into either of the accessible $^1\pi,\pi^*$ bands, and that the yield of oxetan was reduced in the presence of oxygen. They suggested that a $^3n,\pi^*$ state might be the reactive intermediate, but the following observations may vitiate the basis for this interpretation. Short wavelength radiation destroys the product oxetan, optimal yields being obtained when wavelengths shorter than 400 nm are excluded. Additionally, recent findings by Wilson and his co-workers suggest that oxygen may participate chemically in the reaction rather than act as a triplet quencher; illumination of *p*-benzoquinone with alkenes under oxygen using an argon ion laser source affords trioxan adducts in addition to oxetans (3). The ratio of trioxan to oxetan is increased upon raising the oxygen pressure (4), suggesting that both adducts are formed competitively from a common precursor (Eq. 2). On these grounds,

[2] 
we considered the mechanism of oxetan formation to be incompletely established, and in this paper we report our findings on the mechanism of the reaction under anaerobic conditions.

Assignment of the Excited State

Participation of a triplet excited state of *p*-benzoquinone in the cycloaddition was demonstrated by various sensitization and quenching studies. In this respect, the quinone behaves like most other carbonyl compounds, but due to the equivocal nature of some of the results, the experiments are discussed in a little detail.

In solutions containing benzophenone (E_T = 69 kcal/mol) where the ketone absorbed >90% of the incident light, the disappearance of *p*-benzoquinone (E_T = 50 kcal/mol) in the presence of cyclooctene was as fast as in solutions containing no sensitizer. Correspondingly, in the presence of 9,10-dibromoanthracene (E_T = 47 kcal/mol) under conditions where no light was absorbed by the quencher, the rate of reaction was markedly reduced. This result is not unambiguous because the quinone and the quencher form a charge transfer complex, a process known to decrease triplet lifetimes (5). This would have the same effect as quenching by energy transfer; in addition, the range of possible quencher concentrations is limited because at high dibromoanthracene concentrations, it is the complex rather than the free quinone that absorbs. In our experiments at least 85% of the light was absorbed by the free quinone. Consequently, it was not possible to quench oxetan formation completely, so that while we believe that the reaction is mainly triplet in character, a competing singlet pathway cannot be excluded, especially since dibromoanthracene may also be able to quench singlet states directly. Attempts to find other quenchers were limited by the low triplet energy of *p*-benzoquinone itself and by charge transfer complexation (*e.g.* pyrene, E_T = 49 kcal/mol, could not be used).

Recently, 2,2,3,3,-tetramethylazetine-*N*,*N*-dioxide has been suggested as a low energy quencher ($E_T \sim 40$ kcal/mol) that is capable of quenching triplet but not singlet states (6). This compound failed to quench oxetan formation from *p*-benzoquinone and cyclooctene, which seems to suggest a singlet state pathway to oxetan, since we were able to rule out a specific and preferential reaction of the quencher with the quinone. Alternatively, quenching may be ineffective due to the extremely short lifetime of *p*-benzoquinone in solution (7). In view of the high quantum yield for oxetan formation (2), we believe a wholly singlet pathway to be unlikely since intersystem crossing yields for carbonyl compounds are usually so high. Unfortunately, it is difficult to measure the intersystem crossing yield for *p*-benzoquinone experimentally, because its low triplet energy and oxetan formation preclude measurements based on photoisomerization of alkenes (*cf.* ref. 8). Certainly a triplet state pathway is possible in view of the photosensitization results, and since the direct and photosensitized reactions occur at equal rates, it would be coincidental if both singlet and triplet reactions proceeded with equal quantum yield. Consequently, we are inclined to favor a triplet state pathway for oxetan formation.

Phosphorescence measurements (in 3-methylpentane, 77 K) supported the triplet state assignment. *p*-Benzoquinone quenched the phosphorescence spectrum of benzophenone, and although the quinone itself did not phosphoresce at the concentrations used, illumination of the quinone in the presence of dibromoanthracene caused emission from the quencher.

Having implicated a triplet state for at least the major reaction pathway, we reasoned that the state was $^3n,\pi^*$ as follows. The phosphorescence spectrum of *p*-benzoquinone shows fine structure and has been attributed (9) to emission from a lowest $^3n,\pi^*$ state, although its lifetime is unusually short (7). We have found that oxetan formation from cyclooctene and either *p*-benzoquinone or its d_4 analog proceed at almost equal rates; Brus and McDonald (10) found that these two quinones have very similar triplet lifetimes. This seems to be typical of $^3n,\pi^*$ lifetimes of carbonyl compounds (11), whereas deuteration usually increases $^3\pi,\pi^*$ lifetimes appreciably (12); in that case an increase in the quantum yield for oxetan formation would have been expected upon deuteration.

A $^3n,\pi^*$ reactive state implies an electron deficient oxygen atom; if, as is believed to be the case for ketones (13), oxetan production is initiated by bond formation between oxygen and the alkene, electron withdrawing substituents in the alkene should disfavor this initial attack by oxygen. This was demonstrated for a series of chloro-substituted ethylenes which reacted in the order: cyclooctene $\gg$ $CH_2{=}CHCl$ > $CCl_2{=}CHCl$ > $CH_2{=}CCl_2$ > $CHCl{=}CHCl$ > $CCl_2{=}CCl_2$, although this reactivity order cannot be interpreted only in terms of progressive electron withdrawal by chlorine.[2]

[2]Whether this reactivity order would also be observed for addition of alkoxy radicals to these olefins is unknown. The obvious model radical, *tert*-butoxy, does not add to alkenes (14); recently, the perfluoro-*tert*-butoxy radical has been shown to add to alkenes (15) but no comparative data are yet available. Copolymerization studies (16) indicate that carbon based radicals add to these alkenes at rates that depend mainly upon the number of chlorine substituents present.

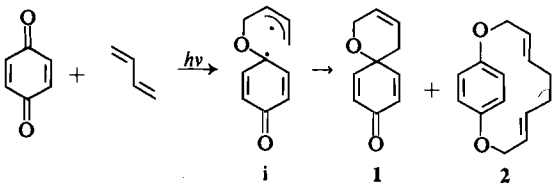
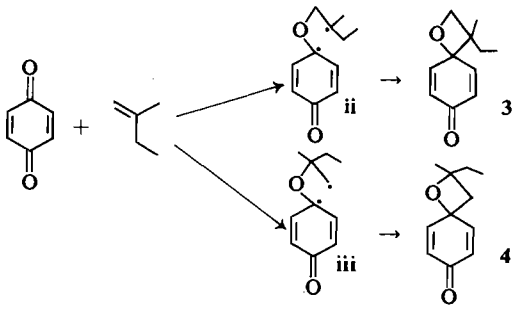
Possibility of Exciplex Intermediates

At this point our efforts were directed towards the establishment of a simple biradical mechanism, such as has been outlined for the photoaddition of several ketones with alkenes (13). The participation of a triplet excited state makes it improbable that the reaction is concerted, since a triplet excited state of the spirooxetan would then be produced. This is unlikely, especially considering the instability of the spirooxetan towards photolysis and by analogy with the arguments of Salem (17) on the course of ketone/alkene cycloadditions. The work of Barltrop and Hesp (18) provides some support for the intermediacy of a biradical which must close with spin-inversion before the product is obtained; illumination of benzoquinone with butadiene gave the spiropyran **1** and a macrocyclic ether **2**. The latter compound may be imagined as arising by attack of the allylic biradical **i** upon another molecule of diene rather than ring closure.[3]



Support for the intermediacy of a biradical was obtained by photolyses of *p*-benzoquinone with *cis*- and *trans*-2-butene. Both geometric isomers afforded the same mixture of spirooxetans, suggesting that the biradical intermediate is sufficiently long lived that its stereochemical integrity is lost. Control experiments showed that negligible isomerization of the isomeric alkenes occurred during the photolyses. The trapping experiments of Wilson and Wunderly (4) provide strong additional evidence for the intermediacy of 1,4-biradicals in *p*-benzoquinone/olefin photoreactions.

Reactions proceeding by way of biradicals commonly afford predominantly the product derived from the more stable biradical when there is more than one possible orientation. An example is the reaction of benzophenone with 2-methylpropene (19). It was therefore anticipated that the irradiation of *p*-benzoquinone with 2-methyl-1-butene would afford **3** (derived from the tertiary biradical **ii**) as the major product with **4** in only small amounts. Unexpectedly, in both direct and benzophenone-sensitized photolyses, almost equal quantities of oxetans **3** and **4** were formed.



Possible explanations for this behavior are: (*i*) attack upon the alkene is indiscriminate, *i.e.*, radicals **ii** and **iii** are not formed under thermodynamic control; (*ii*) the alkene and the quinone are randomly (or possibly, symmetrically, *cf.* ref. 20) aligned before the first bond is formed; (*iii*) radical **ii** is formed in greater amount, but because of greater steric hindrance towards closure, it reverts to starting material more often than **iii**. The equivalent yields of **3** and **4** are thus fortuitous.

We believe explanation (*iii*) to be a likely possibility since we have demonstrated that oxetan formation proceeds with low quantum efficiency with this olefin. However, it may be more than coincidental that Bryce-Smith and his associates also observed an exactly 1:1 formation of isomeric oxetans in the photocycloaddition of 1-octene to benzoquinone (2), just as we did with 2-methyl-1-butene. This could support an exciplex intermediate if the exciplex had the geometry proposed by Caldwell *et al.* (20) for the benzophenone/2-butene cycloaddition, and collapse of the exciplex to biradical led to bond formation at either end of the alkene linkage with equal probability. This would imply that the relative stabilities of the resultant biradicals were unimportant at the transition state for bond formation.

Tenuous support for the participation of exciplex intermediates in oxetan formation comes from photo-CIDNP studies;[4] these were

[3]Actually, **1** and **2** may not be formed competitively from **i**, since it has been shown that allylic radicals maintain their geometry (14). Possibly the *s-cis* form of **i** closes to **1** while the *s-trans* is unable to do so, and consequently affords **2**.

[4]These experiments were carried out in collaboration with Drs. M. Cocivera and H. Chen, to whom we express our thanks.

For personal use only.

undertaken in the hope of observing nuclear polarization in the oxetan and hence of providing evidence for polarization in 1,4-biradicals. Previously, the phenomenon has been observed only in 1,5 and longer biradicals (21). Nuclear magnetic resonance spectra run during the photolysis of *p*-benzoquinone with a variety of alkenes in benzene-d_6 showed polarization in only two cases. With cyclooctene and with trichloroethylene, the benzoquinone resonance was seen in emission, but polarization of neither the alkene nor the oxetan was observed. Polarization was not found when either reactant was photolyzed separately in benzene-d_6, nor when the benzoquinone–cyclooctene adduct was irradiated to destruction.

Observation of the CIDNP phenomenon definitely establishes the presence of radical pairs (or biradicals) in the photolyzing solution, but identification of the species causing the polarization is more difficult. The results do not support a simple biradical mechanism with polarization occurring at the biradical, for that would have also caused polarization of the adduct. One possibility is the involvement of a polarization-inducing intermediate that can either revert to reactants, or be transformed to the biradical, where the polarization is lost and hence not observed in the final product. An exciplex would be an attractive candidate for the polarization-inducing intermediate. There is however the possibility, since CIDNP is such a sensitive technique, that the source of the polarization is a reversible side reaction altogether unconnected with the main pathway leading to oxetan.

The following evidence points to an exciplex intermediate much more strongly. Solvation of the components of the exciplex should be much more efficient in a polar solvent, allowing them to separate. Separation should therefore reduce the likelihood of oxetan production and, consistent with this suggestion, oxetan formation was found to proceed much more slowly in acetonitrile than in benzene. Yomosa (22) has suggested that exciplexes have a large polar contribution to the total wave function (unlike Mulliken's (23) view of ground state charge transfer complexes in their ground states) and hence have a strong tendency to dissociate in polar solvents. In addition, we obtained traces of methoxycyclooctane from irradiations of *p*-benzoquinone and cyclooctene in methanol or acetonitrile/methanol. This product represents entrapment of a cyclooctene radical cation by methanol, and is analogous to the alcohol/alkene adducts obtained by Neunteufel and Arnold (24) in reactions sensitized by methyl benzoates. In our studies, however, the quantity of the methanol adduct was always very small. As to the multiplicity of the proposed exciplex, we believe it to be of the triplet configuration since the benzoquinone/2-methyl-1-butene photolyses gave the same 1:1 mixture of products whether or not the reaction was photosensitized. Had a singlet exciplex been involved, it would have been bypassed in the benzophenone assisted reaction.

In conclusion, our experiments suggest that oxetan formation from *p*-benzoquinone and simple alkenes involves the lowest $^3n,\pi^*$ excited state. The details of the subsequent chemical events are complex, but some features are clear. First, a biradical intermediate is likely the immediate precursor of the oxetan, as shown by the similarity of the products from *cis*- and *trans*-2-butene. Second, an excited state species with considerable polar character is present on the evidence of the methanol trapping experiment, the effect of acetonitrile as solvent on the reaction rate and possibly, by the CIDNP results. What is not clear is the relationship between these two species; several possibilities exist, and our data permit no distinction to be drawn between them.

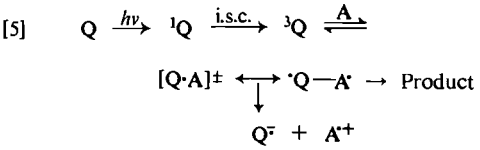
(*i*) The exciplex is not on the reaction path to oxetan (Eq. 3). Here Q, A, $[Q^{\cdot}A]^{\pm}$, and $^{\cdot}Q—A^{\cdot}$ represent respectively quinone, alkene, exciplex, and biradical and it is to be inferred that all excited intermediates may also revert to ground state reactants.

$$[3]\quad Q \xrightarrow{h\nu} {}^1Q \xrightarrow{\text{i.s.c.}} {}^3Q \begin{cases} \xrightarrow{A} {}^3[Q—A]^{\pm} \rightleftharpoons Q^{-} + A^{\cdot+} \\ \xrightarrow{A} {}^{\cdot}Q—A^{\cdot} \rightarrow \text{Product} \end{cases}$$

(*ii*) The exciplex is on the main reaction pathway (Eq. 4), and has a stereochemical structure different from that of the biradical. Caldwell's proposed structure is one such possibility.

$$[4]\quad Q \xrightarrow{h\nu} {}^1Q \xrightarrow{\text{i.s.c.}} {}^3Q \xrightarrow{A} \begin{cases} \rightleftharpoons Q^{-} + A^{\cdot+} \\ [Q^{\cdot}A]^{\pm} \\ \rightarrow {}^{\cdot}Q—A^{\cdot} \rightarrow \text{Product} \end{cases}$$

(*iii*) An extreme form of proposal (*ii*) would arise if the geometry of the exciplex and the biradical were the same (Eq. 5). Under these circumstances there would be two exciplexes when the alkene was unsymmetrical, and the exciplex and biradical could then be viewed as different valence-bond descriptions of the same species.



Experimental

Solvents were of reagent or spectroscopic grade, used as supplied except for benzene (dried over sodium). Chromatographic separations on columns employed silica gel (Davison Grade 12, 28–200 mesh) or alumina (Fisher, Brockman Activity I, 80–280 mesh). Reaction mixtures and chromatographic separations were analyzed qualitatively by t.l.c. using alumina (J. T. Baker, type 9F) or silica gel (E. Merck PF_{254} #7747) both of which contained a fluorescer to aid in locating the spots.

Compounds were identified using the usual spectroscopic methods; instruments used included Beckman IR5A and IR12 infrared, Unicam SP 800 and Beckman DB u.v.–visible, Varian Associates A60-A n.m.r., and Varian-MAT model CH7 mass spectrometer operated at 70 eV ionizing voltage. Microanalyses on purified samples were carried out by Mr. H. S. McKinnon of this department.

Preparative Irradiations

Benzoquinone (BDH) was sublimed before use and stored protected from the light. Cyclooctene (Matheson Coleman and Bell) was dried over molecular sieves, type 3A; 2-methyl-1-butene (Baker), and *cis*- and *trans*-2-butene (Matheson) were used as supplied. Reactions were carried out in the absence of oxygen, either in an immersion well apparatus of 300 ml capacity equipped with a nitrogen flush, or in Pyrex glass ampoules of various capacities which were degassed at $< 10^{-3}$ Torr by three freeze–pump–thaw cycles. The Hanovia model 679A 450W mercury arc source was cooled by the cooling jacket of the immersion well apparatus in the latter case, the distance from the source to the ampoules being about 2–3 in. Unless specified the radiation used was filtered through Pyrex glass ($\lambda > 300$ nm); when light input was to be restricted to $\lambda > 400$ nm an additional filter was used, either a nitrite–biphthalate filter solution (25), filter A, or a 3 in. × 6 in. Corning glass filter CS3-73 #3389, filter B.

Benzoquinone with Cyclooctene

In Benzene—The method was similar to that of Bryce-Smith *et al.* (2) except that after washing the crude photolysate with aqueous NaOH, the product was purified by chromatography over neutral alumina rather than by vacuum distillation. Infrared (cyclohexane) ν_{max} 1700 (s), 1665 (s), 1630 (s), 1605 (m), 1495 (m), 975 (m); n.m.r. identical to that reported (2); M^+ 218.

In Methanol—Benzoquinone (1 g) and methanol were irradiated through filter B in the presence of cyclooctene. After removal of methanol, the residue was examined by v.p.c. on columns of SE30, Carbowax 20M, and DEGS (diethylene glycol succinate). In each case a small peak was observed with a retention time identical to that of an authentic sample of methoxycyclooctane, prepared by the Williamson synthesis from cyclooctanol. Similar results were obtained when an equal volume mixture of methanol and acetonitrile was used as the solvent.

Benzoquinone with 2-Methyl-1-butene

(*i*) Freshly sublimed benzoquinone (2 g), 2-methyl-1-butene (20 ml), and benzene (40 ml) were irradiated under a nitrogen flush through the filter glass B for 220 h. After extraction with 0.1 *M* NaOH solution, the dried organic phase was evaporated and the residue chromatographed over basic alumina, when the mixture of oxetans **3** and **4** was obtained as a yellow oil: λ_{max} (cyclohexane) 233 (ε 14 000), 359 nm (ε 800); i.r. (cyclohexane) ν_{max} 1695 (s), 1640 (s); n.m.r. (CCl_4) δ 0.46, 0.68 (2 triplets, $J = 7$ Hz, $2CH_3$ groups), 1.0, 1.2 (2 singlets, ratio 1:1, $2CH_3$ groups), 1.4, 1.5 (2 overlapping quartets, $J = 7$ Hz, $2CH_2$ groups), 2.1–2.4, 3.9–4.1 (multiplets, ratio 1:1, $2CH_2$ groups), 5.7–5.8, 6.7–7.1 (ring protons); M^+ 178. Attempts to separate the isomers by t.l.c. or by gas chromatography were unsuccessful.

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.12; H, 7.93. Found: C, 73.72; H, 7.91.

(*ii*) The reaction was repeated using benzoquinone (1 g), the alkene (12 ml), benzophenone (2.3 g), and benzene (170 ml) in the immersion well apparatus. After irradiation for 45 min, the mixture was evaporated and the n.m.r. spectrum run on the crude residue. In the region δ 0–6 not obscured by benzophenone, the spectrum was essentially unaltered from that previously observed.

Benzoquinone with cis- and with trans-2-Butene

The procedure is exemplified for the *cis* isomer. On to *p*-benzoquinone (1 g) in a Pyrex ampoule was condensed *cis*-2-butene (1.2 ml), and benzene (50 ml) was added. The ampoule was evacuated and sealed and irradiated through filter B for 24 h. The cooled ampoule was opened, and after reservation of a sample for v.p.c. analysis, the reaction mixture was washed with 0.5 *M* NaOH, dried, and evaporated. After obtaining an n.m.r. spectrum of the crude material, the residue was dried in a drying pistol. The n.m.r. spectrum of the purified material was indicative of two oxetans in the approximate ratio of 1:9.[5] Major isomer: δ 0.82 (doublet, $J = 7$ Hz, CH_3), 1.30 (doublet, $J = 7$ Hz, CH_3), 2.1–2.6 (quartet, each line further split once, CH), 4.2–4.6 (quartet, each line further split once, CH), 5.9–6.3 (multiplet, 2 ring CH), 6.7–7.2 (multiplet, 2 ring CH); minor isomer: same except that oxetan CH resonances appear at δ 2.5–3.0 and 4.5–5.1; i.r. ($CHCl_3$) ν_{max} 1680 (s), 1640 (s), 1610 (m); M^+ 164.

[5]By analogy with the benzophenone/2-butene photocycloaddition and from steric considerations, we presume the *trans* isomer predominates (see ref. 20).

TABLE 1. Photochemical reactivity of *p*-benzoquinone under various conditions

Reagents and conditions	Filter	Relative rates
PBQ + C_8H_{14}, benzene: no Ph_2CO *vs.* Ph_2CO	Pyrex	1:1.06 ± 0.13
PBQ + C_8H_{14}, benzene: no DBA *vs.* DBA	A	1:0.43 ± 0.02
PBQ + C_8H_{14}, benzene: no TMD *vs.* TMD	A	1:1.00 ± 0.03
C_8H_{14}, benzene: PBQ-d_0 *vs.* PBQ-d_4	Pyrex	1:0.94 ± 0.15
PBQ, benzene: C_8H_{14} *vs.* 2-methyl-1-butene	A	1:0.24 ± 0.05[a]
PBQ + C_8H_{14}: in benzene *vs.* CH_3CN	Pyrex	1:0.63 ± 0.10

[a]Since ϕ_r for cyclooctene ($\lambda > 400$ nm) is 0.55 ± 0.05 (2), this gives ϕ_r as 0.13 ± 0.05 in the case of 2-methyl-1-butene.

Anal. Calcd. for $C_{10}H_{12}O_2$: C, 73.11; H, 7.37. Found: C, 73.09; H, 7.50.

A mixture with identical spectroscopic properties was obtained from a similar irradiation using *trans*-2-butene.

Sensitization, Quenching, and Relative Rate Experiments

In these experiments, several reaction mixtures were irradiated simultaneously with the 450 W source using a rotating 'merry-go-round' apparatus to ensure equal illumination. These studies were all monitored by following the disappearance of the n,π^* absorption band of *p*-benzoquinone. The solutions were contained in Pyrex ampoules 1 × 1 × 5.5 cm of square cross-section, joined to 8 mm tubing for attachment to the vacuum line to permit degassing and sealing. The ampoules fitted directly into the sample chamber of the Beckman DB spectrophotometer. Before use, the ampoules were cleaned in chromic acid, rinsed several times (H_2O, NH_4OH, H_2O) and dried at 110 °C overnight. The results of the studies are given in Table 1. In each case the values quoted are the average of several runs at slightly different concentrations. Typical ranges of concentration were quinone (PBQ), 4–8 × 10^{-2} *M*; quenchers, dibromoanthracene (DBA) or 3,3,4,4-tetramethyl-1,2-diazetine-1,2-dioxide (TMD),[6] 10^{-3} *M*; alkene 0.9 *M*.

In the case of relative reactivities of chloroethylenes, the results were irreproducible from run to run and the average values are not quoted. Part of the problem seems to be polymerization of the alkene (purified by distillation). Various phenols were added to the reaction mixtures as radical traps, but because of charge transfer complexation between phenol and quinone, only modest success was achieved.

For the isotopic study, benzoquinone-d_4 was prepared from hydroquinone as follows. Hydroquinone-d_6 was obtained by exchange using D_2O/H_2SO_4 then D_2O/D_2SO_4 giving > 95% deuterium incorporation. Oxidation to the quinone was effected using silver carbonate on Celite (26) without loss of deuterium.

Phosphorescence Studies

The phosphorimeter was based on the Farrand Mark I fluorometer, modified with the manufacturer's accessories for phosphorescence. As supplied, the sample chamber did not permit degassing of samples, so it was redesigned to accommodate quartz ampoules of 8 mm o.d. 3-Methylpentane (Matheson, Coleman and Bell) was used as the glass medium; it was purified by treatments with oleum, water, and distillation under nitrogen after the method of Parker (27), then stored under nitrogen at −40 °C.

As a check on the effectiveness of the design of the new sample chamber, the phosphorescence spectrum of benzophenone was obtained: λ 419, 450, 486, 531, 570 nm as reported (28). The lifetime of the phosphorescence (Tektronix 2B67 oscilloscope) was 5.0 ms (lit. (28) 5.2 ms).

Benzoquinone samples for phosphorescence were triply sublimed; the samples were degassed and sealed after three freeze–pump–thaw cycles at 10^{-4} Torr. All samples were stored at −40 °C until the phosphorescence spectrum was run, and were carefully protected from the light throughout.

Photo-CIDNP Studies

The experimental arrangement was that described by Tomkiewicz *et al.* (29) employing a Varian Associates HA100 spectrometer, and a 1000W Hanovia high pressure mercury–xenon arc which was focussed onto the samples while the spectrum was recorded. Both degassed and aerated samples were examined. Benzene-d_6 solutions of benzoquinone (0.05 *M*) were studied with the following alkenes (~0.1 *M*): cyclooctene, trichloroethylene, vinyl chloride, 1,1- and 1,2-dichloroethylene, tetrachloroethylene, vinyl acetate, methyl vinyl ether, acrylonitrile, and fumaronitrile. Negative results were obtained with all but the first two olefins mentioned.

We acknowledge gratefully the help of Drs. M. Cocivera and H. Chen for running the photo-CIDNP spectra. We also thank Drs. P. de Mayo and D. R. Arnold for helpful discussions, and the National Research Council of Canada for financial support.

[6]The absence of a specific reaction between the quinone and TMD was demonstrated in experiments where the two components, each 2 × 10^{-2} *M* were photolyzed in benzene. The rate of disappearance of quinone was very slow, and was no faster than in control experiments where the TMD was omitted.

The Isolation and Synthesis of *E*-24-Ethylidene-5α-lanost-8-en-3β-yl Acetate

S. SAFE AND L. M. SAFE

Department of Chemistry, University of Guelph, Guelph, Ontario N1G 2W1

Received June 9, 1975

S. SAFE and L. M. SAFE. Can. J. Chem. **53**, 3247 (1975).

Extraction of the fungus *Mucor rouxii* gave small amounts of a 32 carbon triterpene (M^+ 454). Spectroscopic studies suggested a lanosterol ring skeleton with a 24-ethylidene group introduced into the side chain. The structure was confirmed by synthesis and shown to be *E*-24-ethylidene-5α-lanost-8-en-3β-yl acetate.

S. SAFE et L. M. SAFE. Can. J. Chem. **53**, 3247 (1975).

L'extraction du mycite *Mucor rouxii* permet d'isoler des petites quantités d'un triterpène de masse 454 possédant 32 atomes de carbone. Des études spectroscopiques ont suggéré que la structure de ce dérivé comporte un squelette de lanosterol auquel un groupe éthylidène a été attaché en position 24. On a confirmé la structure par synthèse et démontré ainsi qu'il s'agit de l'acétate du *E* éthylidène-24 (5α) lanostène-8 yl-3β.

[Traduit par le journal]

Mucor rouxii is a fungus capable of growth under a wide variety of environmental conditions; aerobic cultivation of the fungus gave filamentous mycelium whereas under oxygen-limiting conditions or in the presence of phenethyl alcohol, spherical budding yeast-like cells are produced (1, 2). The morphological changes in the cells are also accompanied by both quantitative and qualitative variations in the lipid levels with respect to fatty acids, sterols and triterpenes (3, 4). Examination of the triterpene fractions obtained from the yeast-like and filamentous cells indicated that lanosterol was the major component and this was accompanied by lower levels of 24-methylene-5α-lanost-8-en-3β-ol (3, 4). The triterpene fraction also contained trace quantities of a third component whose mass spectrum exhibited a molecular ion at *m/e* 454 and this paper describes the isolation, structure proof, and synthesis of this compound.

Results and Discussion

The mycelia of *Mucor rouxii* (5) obtained from 500 l of media were extracted with chloroform–methanol and the triterpene fraction was isolated by thin layer chromatographic (t.l.c.) procedures. Acetylation of the triterpene fraction and subsequent purification by argentation t.l.c. gave 3 bands. The least polar band gave material which was identified as lanosteryl acetate whereas the most polar band contained 24-methylene-5α-lanost-8-en-3β-yl acetate (3, 4). The band of intermediate polarity (5.5 mg) gave a single peak on gas-liquid chromatography (g.l.c., R_c = 7.65 retention time relative to the internal standard 5α-cholestane) and exhibited a molecular ion at *m/e* 496. Hydrolysis of the unknown acetate gave an alcohol for which high resolution mass measurement of the molecular ion indicated a molecular formula of $C_{32}H_{54}O$.

The mass spectrum of the acetate gave major fragment ions at *m/e* 481 ($M^+ - CH_3$) and 421 ($M^+ - CH_3 - HOAc$). The mass spectra of both lanosteryl acetate and 24-methylene-5α-lanost-8-en-3β-yl acetate also exhibited the corresponding ions for the losses of CH_3 and (CH_3 + HOAc) from the molecular ion. In addition the ion abundance data below *m/e* 340 for the three triterpene acetates were remarkably similar, suggesting a common lanostane ring skeleton.

The 220 MHz nuclear magnetic resonance (n.m.r.) spectrum of the 32 carbon triterpene acetate integrated for 56 protons using the proton at 5.19 p.p.m. as a 1H standard. The spectrum exhibited several signals between 0.5–1.6 p.p.m. which could be assigned to the 5 CH_3 groups on the ABCD rings of the lanostane skeleton as well as the C_{21}, C_{26}, and C_{27} methyl groups on the side chain (see Table 1). A three proton doublet was observed at 1.58 p.p.m. (J = 6 Hz) and this indicated a methyl group adjacent to an olefinic double bond and coupled to the olefinic proton. The low field quartet observed at 5.19 p.p.m. supported this assignment and since this olefinic proton was coupled only to the methyl group this was evidence for a trisubstituted double bond (*e.g.* CH_3—CH=C). Fucosterol and isofucosterol

C_{28}—H	5.19	5.19	5.13

*Major product (R_c 7.65) from Grignard reaction.
†Major product (R_c 7.95) from Wittig reaction.

both contain 24-ethylidene moieties and the chemical shift and coupling constants for the ethylidene protons in the respective sterols were similar to the triterpene data (6–8). Since the n.m.r. and mass spectral data suggested a conventional lanostane ring skeleton a possible site for the trisubstituted double bond in the side chain would be at C_{24} since this position is biogenetically favored for side chain alkylation.

The structure of the 32 carbon triterpene acetate was confirmed by synthesis of 24-ethylidene-5α-lanost-8-en-3β-yl acetate from 24-keto-5α-lanost-8-en-3β-yl acetate using both the Grignard (9) and Wittig (10) condensation reactions. Both synthetic schemes gave two major reaction products as indicated by g.l.c. analysis (R_c 7.65 and 7.95) with the R_c 7.65 compound having the same retention time as the natural 32 carbon acetate. This material was the major component in the Grignard reaction and repeated argentation t.l.c. gave >98% pure fraction of this compound whose mass and n.m.r. spectra (see Table 1) were identical to the spectra of the natural product.

Previous studies on the n.m.r. spectra of 24-ethylidenecholest-5-en-3β-ol have shown that the orientation of the substituents about the C_{24}—C_{28} olefinic bond influences the chemical shift of the C_{25} proton (6–8). The signal for this proton appears as a heptet at 2.80 p.p.m. for the *Z* configuration (*i.e.* isofucosterol) whereas the resonance shifts upfield to 2.20 p.p.m. for the *E* configuration (*i.e.* fucosterol). These differences in chemical shift were also observed in the n.m.r. spectra of the geometrical isomers of 24-ethylidene-5α-lanost-8-en-3β-ol. The n.m.r. spectra of the natural product and the major component of the Grignard reaction (R_c = 7.65) exhibited the heptet at 2.19 p.p.m. whereas the corresponding signal appeared at 2.85 p.p.m. in the n.m.r. spectrum of the major product of the Wittig reaction (R_c = 7.95). These data thus indicate that the structure of the 32 carbon triterpene acetate from *M. rouxii* is *E*-24-ethylidene-5α-lanost-8-en-3β-yl acetate which is presumably formed by two successive alkylations of lanosterol at C_{24} in the side chain (9).

Experimental

Spectroscopic and Chromatographic Procedures

Mass spectra were obtained with a Dupont CEC 21-110B double-focussing high resolution mass spectrometer at 70 eV. Nuclear magnetic resonance spectra were recorded on a Varian HR220 instrument and the samples were dissolved in deuteriochloroform.

Gas chromatographic analyses of the triterpene acetates were carried out with a Hewlett Packard 700 gas chromatograph on a ⅛ in. × 6 ft glass column packed with 2% OV-17 (100–120 mesh) at 260 °C.

Isolation of the 32 Carbon Triterpene Acetate

Cultivation and growth of *M. rouxii* (Calmette) Wehmer (HLX 1093) from sheep rumen contents have been described (5). The mycelia from 500 l of aerobically grown *M. rouxii* were freeze-dried, macerated with chloroform–methanol (2:1) in a Waring blender and the triterpene fraction isolated by t.l.c. as described. The crude triterpene acetates were prepared and the three components were separated by argentation t.l.c. (3, 4). The isolation of lanosteryl acetate and 24-methylene-5α-lanost-8-en-3β-yl acetate have been described (3, 4). In this large scale extraction a third triterpene acetate (5.5 mg) was also isolated and gave: n.m.r. spectrum ($CDCl_3$), (see Table 1); *m/e* 496, 481, 421; m.p. 135–138 °C; R_c 7.65 (relative to 5α-cholestane). Hydrolysis of the acetate gave the sterol:

high resolution mass measurement; calculated for $C_{32}H_{54}O$, 454.4174; found, 454.4169; n.m.r. ($CDCl_3$) 0.60 (3H, s, C_{18}—CH_3), 0.81 and 0.87 (6H, s, $C_{4\alpha,4\beta}$—CH_3), 0.96–1.02 (15H, m, C_{19}, C_{14}, C_{21}, C_{26}, and C_{27}—CH_3), 1.57 (3H, d, J = 6 Hz, C_{29}—CH_3), 2.29 (1H, heptet, J = 6 Hz, C_{25}—H), 3.24 (1H, q, J = 5 Hz, 3α-H), 5.29 (1H, q, J = 6 Hz, C_{28}—H).

Syntheses of Z- and E-24-Ethylidene-5α-lanost-8-en-3β-yl Acetate

Grignard Reaction—The condensation reaction of 24-keto-5α-lanost-8-en-3β-yl acetate (100 mg) and vinyl magnesium bromide was carried out as described by Sucrow and Raduchel (10) to give the crude condensation product. This compound was converted into the 29-bromo derivative by treatment with phosphorus tribromide (9); the reaction of the crude bromide with lithium aluminum hydride followed by reacetylation gave a mixture of *E*- and *Z*-24-ethylidene-5α-lanost-8-en-3β-yl acetate (18 mg). Gas-liquid chromatographic analysis indicated a 3:1 mixture of the *E* and *Z* isomers respectively (R_c 7.65 and 7.95). Argentation t.l.c. gave a fraction enriched in the *E* isomer, m.p. 135–138 °C, n.m.r. as given in Table 1.

Wittig Reaction—The condensation of 24-keto-5α-lanost-8-en-3β-yl acetate (40 mg) and the phosphonium salt of ethyl bromide was carried out as described by Fryberg *et al.* (11) except that ethyl lithium was used instead of butyl lithium. Gas-liquid chromatographic analysis of the crude *Z*- and *E*-24-ethylidene-5α-lanost-8-en-3β-yl acetate (12 mg) gave two peaks (R_c 7.65 and 7.95) in a ratio of 4:1 *Z*:*E*. Argentation t.l.c. gave an enriched fraction (>95% pure) of the *Z*-isomer, m.p. 131–134 °C; n.m.r. as given in Table 1.

Formation et stabilité de lyato-complexes de l'argent(I) en solution hydro-méthanolique[1]

JEAN PIUZE[2] ET A. OTTO GÜBELI

Département de Chimie, Université Laval, Québec, Québec G1K 7P4

Reçu le 10 fevrier 1975

JEAN PIUZE et A. OTTO GÜBELI. Can. J. Chem. **53**, 3250 (1975).

La solubilité totale de l'oxyde d'argent en fonction du pH^* non-aqueux dans un mélange contenant 52.1% de méthanol en poids dans l'eau a été déterminée pour une force ionique constante décimolaire ($NaNO_3$) à 25 °C et à pression atmosphérique. La prise en considération des divers équilibres en jeu dans le milieu hydro-méthanolique a conduit à un traitement mathématique permettant d'identifier les complexes formés par solvolyse avec les ions lyate, c'est-à-dire OH^- et CH_3O^-, et de calculer les constantes de stabilité molaires pertinentes. La corrélation entre ces résultats et ceux de travaux antérieurs sur la solubilité de $Ag_2O(s)$ en milieu aqueux a été examinée.

JEAN PIUZE and A. OTTO GÜBELI. Can. J. Chem. **53**, 3250 (1975).

The total solubility of silver oxide as a function of the nonaqueous pH^* in a mixture containing 52.1 wt.% methanol in water was measured for a constant decimolar ionic strength ($NaNO_3$) at 25 °C and at atmospheric pressure. After examination of the different equilibria involved in the hydro-methanolic medium, mathematical expressions were derived, leading to the identification of the complex species formed through solvolysis phenomena with the lyate ions, *i.e.* OH^- and CH_3O^-, and to the calculation of the relevant molar stability constants. The correlation between these results and those from previous publications on the aqueous solubility of $Ag_2O(s)$ was investigated.

Introduction

La littérature chimique compte bon nombre de travaux sur la stabilité de complexes de cations de métaux avec une multitude de ligands inorganiques et organiques dans des mélanges hydro-méthanoliques de divers pourcentages (1, 2). Toutefois, à notre connaissance, aucun auteur[3] ne traite de la solvolyse de ces ions métalliques pour donner des hydroxo- ou des méthoxo-complexes, chacun s'attachant uniquement à examiner les espèces formées avec un ligand, autre que OH^- ou CH_3O^-, ajouté à la solution. Aussi, afin d'examiner cette possibilité inexplorée de formation de complexes par solvolyse non-aqueuse, avons-nous entrepris l'étude de la solubilité de $Ag_2O(s)$ dans un mélange eau–méthanol.

Cependant, la plupart des méthodes de détermination de constantes de stabilité, y compris la méthode de solubilité, ne permettent pas de distinguer un complexe d'une paire d'ions (5). C'est pourquoi, lorsqu'on désire considérer uniquement la formation de complexes, il faut toujours s'assurer que la constante diélectrique (permittivité relative, ε_r) du solvant est supérieure à 40, car on peut alors supposer le comportement d'électrolyte fort et négliger la formation de paires d'ions, tout au moins en solution suffisamment diluée (6). Dans le cas du mélange à 52.1% de méthanol en poids dans l'eau choisi, une interpolation des données de ε_r pour le système binaire H_2O–CH_3OH à 25 °C (7) fournit une valeur de 55.4, indiquant donc que l'association d'ions devrait pouvoir y être négligée, étant donné la force ionique relativement faible de 0.1 (M) maintenue.

Considérations théoriques

La méthode adoptée pour le traitement des données de solubilité a été élaborée par Ste-Marie (8) à la suite de travaux comme ceux de Schwarzenbach et Widmer (9). L'applicabilité de cette méthode graphique, dite "des pentes", à l'identification de complexes prédominants en milieu hydro-méthanolique requiert toutefois la prise en considération de certains éléments nouveaux.

Dans un solvant mixte constitué d'eau et de méthanol, si l'on ne tient pas compte des divers modes de solvatation des ions, on trouve qu'il y a six espèces chimiques à considérer: H_2O, CH_3OH, H_3O^+, $CH_3OH_2^+$, OH^- et CH_3O^- (10). L'acti-

vité des molécules du solvant étant invariante en solution diluée, il est possible de relier ces différentes particules en définissant des constantes apparentes, valables pour un mélange donné:

$$[1] \qquad k_1 = \{H_3O^+\}\{OH^-\}$$

$$[2] \qquad k_2 = \{CH_3OH_2^+\}\{CH_3O^-\}$$

$$[3] \qquad k_3 = \frac{\{H_3O^+\}}{\{CH_3OH_2^+\}}$$

$$[4] \qquad k_4 = \frac{\{OH^-\}}{\{CH_3O^-\}}$$

où les accolades dénotent une activité molaire. On pose ensuite le produit ionique du solvant,

$$[5] \quad K_a = \{H_3O^+\}(\{OH^-\} + \{CH_3O^-\})$$

où le terme $\{CH_3OH_2^+\}$ ne figure plus puisque les ions méthoxonium sont négligeables dans les mélanges contenant plus de 10% d'eau (10). Le pH^* dans ce solvant mixte est donc égal au cologarithme de $\{H_3O^+\}$.

Afin d'exprimer le produit de solubilité de l'oxyde d'argent en milieu aqueux, on peut supposer qu'une réaction d'hydrolyse à la surface de Ag_2O(s) amène d'abord la formation d'un film d'hydroxyde, AgOH(s) (11). Parallèlement, une réaction de solvolyse en surface du solide dans le solvant mixte devrait mener soit à AgOH(s), soit à $AgOCH_3$(s); mais Bradley (12) mentionne que les alcoxydes de métaux sont tous très facilement hydrolysés, même par des traces d'eau. Par conséquent, il semble fort plausible que la solubilisation de Ag_2O(s) dans le mélange eau–méthanol se fasse également par l'intermédiaire de AgOH(s) dont le produit de solubilité s'écrit

$$[6] \qquad K_{s0} = [Ag^+]\{OH^-\}$$

où les crochets dénotent une concentration molaire.

Hydroxo-méthoxo complexes

Lorsqu'on choisit des conditions telles qu'on puisse négliger les espèces polynucléaires, la formation de complexes de l'argent(I) en solution hydro-méthanolique peut être représentée par un équilibre menant à la définition de la constante cumulative de formation,

$$[7] \qquad \beta_{xy} = \frac{[Ag(OH)_x(OCH_3)_y{}^{1-x-y}]}{[Ag^+]\{OH^-\}^x\{CH_3O^-\}^y}$$

Après l'introduction des éqs 4, 5 et 6 dans l'éq. 7, on peut écrire la relation exprimant la concentration totale d'argent en solution en équilibre avec l'oxyde précipité:

$$[8] \quad [\Sigma Ag] = \sum_{x=0}^{n} \sum_{y=0}^{n-x} \beta_{xy} K_{s0} K_a{}^{x+y-1} k_4{}^{x-1} \times (1 + k_4)^{1-x-y}\{H_3O^+\}^{1-x-y}$$

où n représente l'indice de coordination usuel du métal en solution.

Si l'on pose qu'un seul complexe existe en concentration prédominante dans un intervalle de pH^* assez restreint, les deux symboles de sommation de l'éq. 8 disparaissent et $[\Sigma Ag]$ correspond à la concentration du seul complexe important dans cette région. La dérivation subséquente par rapport au pH^* de la forme cologarithmique de l'éq. 8 réduite à un seul terme nous révèle que la pente $(1 - x - y)$ d'une courbe de solubilité de $p[\Sigma Ag]$ en fonction du pH^* sera caractéristique d'une espèce prédominante de charge $(1 - x - y)$, comme on peut le constater au tableau 1. Il ressort clairement de ce tableau qu'une pente de (-1), par exemple, sur la courbe de solubilité permettra de conclure qu'on se trouve en présence d'un complexe contenant un total de deux ligands parmi OH^- et CH_3O^-, sans qu'on puisse distinguer entre $Ag(OH)_2^-$, $Ag(OH)(OCH_3)^-$ et $Ag(OCH_3)_2^-$. D'ailleurs, comment pourrait-il en être autrement lorsqu'on ne détermine expérimentalement qu'une seule variable, soit $\{H_3O^+\}$? Il est en effet bien évident, à la lumière des éqs 4 et 5, que la courbe de solubilité en fonction du pH^* ne pourra livrer des renseignements que sur la somme des ligands OH^- et CH_3O^-, non sur chacun d'eux.

Hydroxo-complexes simples

Cependant, si l'on pouvait démontrer l'absence de méthoxo-complexes prédominants dans le mélange eau–méthanol, c'est-à-dire ($y = 0$), l'éq. 8 résultante serait alors l'expression de la somme des concentrations de Ag^+ et des seuls hydroxo-complexes en solution.

Le fait que les alcoxydes solides soient immédiatement hydrolysés par des traces d'eau (12) suggère que les méthoxo-complexes pourraient peut-être eux aussi être transformés en hydroxo-complexes dans le solvant mixte. Ainsi, Jørgensen (13) rapporte que, dans une solution de Fe^{3+} dans du méthanol rendue alcaline à l'aide de KOH, il est difficile de savoir si $Fe(OCH_3)_6^{3-}$ ou $Fe(OH)_6^{3-}$ ou encore un complexe mixte se

TABLEAU 1. Espèces pouvant théoriquement résulter de la solvolyse de Ag^+ en solution hydro-méthanolique

Pente $dp[\Sigma Ag]/dpH^*$ $(1-x-y)$	$x+y$	x	y	Espèce $Ag(OH)_x(OCH_3)_y^{1-x-y}$
1	0	0	0	Ag^+
0	1	1	0	$Ag(OH)$
0	1	0	1	$Ag(OCH_3)$
−1	2	2	0	$Ag(OH)_2^-$
−1	2	1	1	$Ag(OH)(OCH_3)^-$
−1	2	0	2	$Ag(OCH_3)_2^-$

forme, mais qu'on peut faire cristalliser de cette solution un produit jaune ne contenant pas de carbone, peut-être $K_3Fe(OH)_6$. A plus forte raison, lorsqu'il y a une quantité d'eau importante dans le solvant, la formation d'hydroxo-complexes pourrait-elle être favorisée. Toutefois, il importe de remarquer que la connaissance des espèces précipitées ne permet pas de tirer des conclusions sur la nature des espèces effectivement présentes en solution.

Du point de vue de la solvatation, dans les mélanges contenant jusqu'à 80% de méthanol, c'est l'eau qui de loin joue le rôle prépondérant (14 à 16). De plus, Jørgensen (13) mentionne que les ions des éléments de transition préfèrent l'eau aux alcools dans leur première sphère de coordination. Il apparaît donc vraisemblable que solvatation soit synonyme d'hydratation dans le mélange contenant 52.1% de méthanol en poids. Par conséquent, si l'on postule que la solvatation des cations métalliques constitue une étape du mécanisme de formation des complexes en solution par solvolyse, on peut s'attendre à ce que la solvatation préférentielle de Ag^+ par l'eau favorise la formation d'hydroxo-complexes simples.

Finalement, si l'on savait le lien Ag—OH beaucoup plus fort que la liaison Ag—OCH_3, ou vice-versa, on pourrait en tirer des conclusions quant à la nature des complexes existant en solution. Toutefois, il y a peu d'information disponible à ce sujet, si ce n'est que le lien métal–alcool est plus faible que le lien métal–eau dans les ions métalliques solvatés (17) mais que la différence d'énergie entre ces deux liaisons est petite (18).

Il semble donc que la formation d'hydroxo-complexes simples soit favorisée par rapport à celle de méthoxo-complexes, mais aucun des arguments invoqués n'en constitue une preuve expérimentale formelle.

Lyato-complexes

Il ressort de ce qui précède que, même si la formation d'hydroxo-complexes simples prédominants semble plus probable, la présence de méthoxo-complexes n'en demeure pas moins possible. C'est pourquoi nous avons choisi d'interpréter nos résultats en termes plus généraux qui incluent toutes les possibilités. Pour ce faire, nous utilisons une nomenclature où l'acide conjugué d'une molécule du solvant est appelé ion lyonium et la base conjuguée, ion lyate (19). Dans notre milieu hydro-méthanolique, ion lyonium est synonyme de H_3O^+ tandis que l'ion lyate, symbolisé par OL^-, désigne à la fois OH^- et CH_3O^-. La constante d'autoprotolyse du solvant peut donc s'écrire

$$[9] \qquad K_a = \{H_3O^+\}\{OL^-\}$$

La formation de lyato-complexes dans ce milieu peut alors être représentée par un équilibre général dont la constante cumulative de formation s'écrit

$$[10] \qquad \beta_r = \frac{[Ag(OL)_r^{1-r}]}{[Ag^+]\{OL^-\}^r}$$

La combinaison des éqs 4 et 5 fournit une expression pour $\{OH^-\}$:

$$[11] \qquad \{OH^-\} = \frac{K_a k_4}{(1+k_4)\{H_3O^+\}}$$

Et si l'on introduit tour à tour les éqs 6, 9 et 11 dans l'éq. 10, on obtient comme expression de la solubilité totale de l'oxyde d'argent en solution hydro-méthanolique:

$$[12] \quad [\Sigma Ag] = \sum_{r=0}^{n} \beta_r K_{s0} K_a^{r-1} k_4^{-1} \times (1+k_4)\{H_3O^+\}^{1-r}$$

Selon un raisonnement identique à celui qui faisait suite à l'éq. 8, l'examen du tableau 1, où

$(x + y)$ est égal à r, révèle que la pente $(1 - r)$ de la courbe de solubilité en fonction du pH^* indique quelle espèce $Ag(OL)_r^{1-r}$ prédomine dans une région donnée.

Méthode expérimentale

Le solvant mixte a toujours été préparé par pesée d'eau bidistillée et de méthanol pur (Fisher A-412) et tous les réactifs chimiques utilisés étaient de pureté garantie. Dans des fioles de 100 ml, nous avons introduit quelques millilitres d'une solution mère de $AgNO_3$ contenant une petite quantité du traceur radioactif ^{110}Ag. Le pH^* a ensuite été ajusté à l'aide de NaOH et HNO_3 de telle sorte qu'il y avait toujours un précipité en équilibre avec la solution. Enfin, les solutions ont été complétées avec les quantités de $NaNO_3$ nécessaires dans le solvant pour maintenir une force ionique décimolaire. Puis elles ont été placées à l'abri de la lumière à 25 °C et agitées régulièrement au cours des premiers jours. Au bout d'un mois, après avoir vérifié par échantillonnage périodique que l'équilibre était atteint, nous avons procédé aux analyses.

Le solide précipité a été identifié par diffraction des rayons X à l'aide d'une caméra Guinier: dans tous les cas, il s'agissait de Ag_2O, quoique la présence d'un peu d'argent métallique ait aussi été observée. En outre, la formation d'un miroir d'argent très mince sur la paroi intérieure des fioles a été notée dans la plupart des cas. Toutefois, le métal déposé n'affectait pas l'équilibre puisqu'il restait toujours un grand excès d'oxyde d'argent précipité.

La concentration totale d'argent en solution a été mesurée par radiométrie γ à l'aide d'un compteur à scintillations de marque Philips. Un couple d'électrodes argent–calomel (saturée dans l'eau), dont la jonction était assurée par un pont d'agar–agar dans $NaNO_3$ 0.1 M, a été utilisé pour déterminer la concentration d'argent cationique.

Nous ne mentionnerons ici que les grandes lignes de notre façon d'aborder la mesure du pH^* en milieu non-aqueux (20), tant du point de vue théorique que pratique, puisque tout cela a été décrit en détail ailleurs (21). Nous avons obtenu le pH^* de chaque solution au moyen du couple d'électrodes mentionné plus haut, dans lequel une électrode de verre (Metrohm UX) avait été substituée à l'électrode d'argent, puis étalonnée à l'aide des tampons précis mis au point par Bates et ses collaborateurs (22) pour les pH^* jusqu'à 11.5 environ dans ce solvant. Pour les quelques valeurs supérieures à 11.5, l'étalonnage des électrodes a été réalisé à l'aide de solutions de NaOH dans le solvant non-aqueux pour lesquelles on était arrivé à une assez bonne valeur de pH^* en soustrayant un terme constant δ de la lecture de pH obtenue après avoir utilisée des solutions-tampons aqueuses pour étalonner la chaîne de mesure (20 à 22). Il est primordial de remarquer que l'échelle de pH^* définie pour un mélange hydro-méthanolique n'est pas reliée à celle du pH dans l'eau (22, 23). On ne peut en effet utiliser, pour tous les mélanges eau–méthanol, une seule échelle universelle d'activité protomique se référant à l'eau, à moins d'être en mesure d'évaluer l'effet de milieu (24) avec précision, ce qui n'a pas encore été réalisé de façon pratique (20).

Résultats

La courbe de solubilité de l'oxyde d'argent dans le mélange eau–méthanol apparaît à la fig. 1, tandis que la variation de la concentration de Ag^+ en fonction du pH^* est présentée à la fig. 2. L'examen de la courbe de $p[\sum Ag]$ en fonction du pH^* révèle une pente $(dp[\sum Ag]/dpH^*)$ de l'ordre de $(+1)$ dans la région de pH^* comprise entre 6.5 et 9.5, suivie d'un plateau (pente 0) entre pH^* = 11 et 12.5, puis d'un début de remontée qui semble s'amorcer selon une pente voisine de (-1). En consultant le tableau 1, on

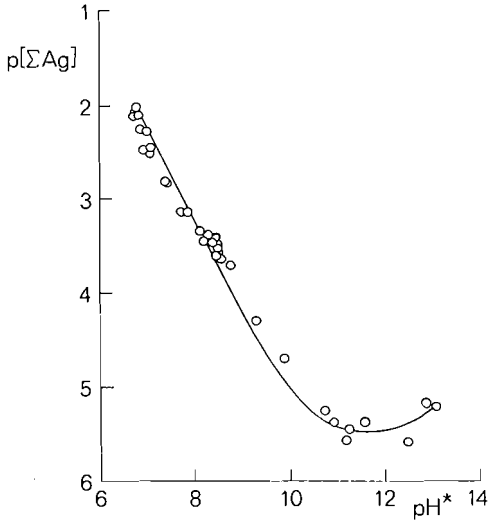

FIG. 1. Solubilité totale de $Ag_2O(s)$ en fonction du pH^* dans le solvant hydro-méthanolique.

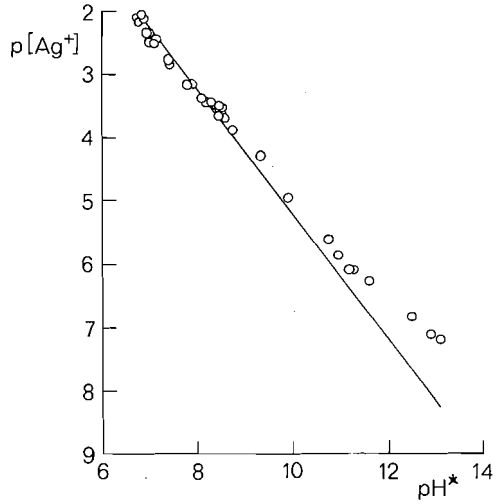

FIG. 2. Solubilité cationique de l'oxyde d'argent en fonction du pH^* dans le mélange eau–méthanol.

conclut donc que l'allure de la courbe de solubilité s'explique par la prédominance successive des espèces Ag^+, $Ag(OL)$ et $Ag(OL)_2^-$.

L'introduction des valeurs expérimentales de $[\sum Ag]$ et de $\{H_3O^+\}$ dans l'éq. 12 permettrait de résoudre des systèmes de trois équations à trois inconnues (K_{s0}, β_1 et β_2), à condition de connaître K_a et k_4. Cependant, il est important de pouvoir d'abord caractériser les équilibres en solution étudiés par des constantes de solubilité précises ne faisant appel ni à l'évaluation approximative de k_4, ni même à K_a. Pour ce faire, on peut considérer le processus global suivant de formation de lyato-complexes à partir de la phase intermédiaire solide AgOH:

$$[13]\quad AgOH(s) + H_3O^+ + rOL^- \rightleftharpoons Ag(OL)_r^{1-r} + 2H_2O$$

équilibre pour lequel la constante s'écrit

$$[14]\qquad {}^*K_{sr} = \frac{[Ag(OL)_r^{1-r}]}{\{H_3O^+\}^{1-r}}$$

après qu'on y ait exprimé $\{OL^-\}$ en termes de $\{H_3O^+\}$ en utilisant l'éq. 9.

Comme la solubilité totale de l'argent est égale à la somme des trois espèces chimiques identifiées, on peut écrire

$$[15]\quad [\sum Ag] = {}^*K_{s0}\{H_3O^+\} + {}^*K_{s1} + {}^*K_{s2}\{H_3O^+\}^{-1}$$

Les constantes ${}^*K_{sr}$ suivantes et leur écart type (σ) ont été calculés et raffinés en langage APL:

$$\log {}^*K_{s0} = 4.8 \quad (\sigma = \pm 0.2)$$

$$\log {}^*K_{s1} = -5.5 \quad (\sigma = \pm 0.1)$$

$$\log {}^*K_{s2} = -18.6 \quad (\sigma = \pm 0.2)$$

pour une force ionique de 0.1 ($NaNO_3$) à 25 °C. L'introduction de ces constantes dans l'éq. 15 permet alors de calculer la courbe tracée à la fig. 1.

De plus, les résultats de $p[Ag^+]$ assurent un contrôle de la valeur obtenue plus haut pour ${}^*K_{s0}$. En effet, partant de l'éq. 14, on peut écrire

$$[16]\qquad \log {}^*K_{s0} = pH^* - p[Ag^+]$$

Si l'on se reporte à la fig. 2, on constate que seuls les points de pH^* inférieur à 11 peuvent vérifier l'équation de cette droite de pente unitaire positive en fonction du pH^*. Insérés dans l'éq. 16, ils fournissent la valeur moyenne suivante:

$$\log {}^*K_{s0} = 4.77 \ (\sigma_m = \pm 0.04)$$

σ_m étant l'écart moyen. Cette dernière constante introduite dans l'éq. 16 permet de calculer la droite tracée à la fig. 2.

De la comparaison des éqs 12 et 14 découle la relation

$$[17]\quad {}^*K_{sr} = \beta_r K_{s0} K_a^{r-1} k_4^{-1}(1 + k_4)$$

Sachant que β_0 est égal à l'unité, il est possible de calculer K_{s0} à l'aide de l'éq. 17 si l'on connaît les valeurs de K_a et de k_4. On pourra ensuite utiliser K_{s0} calculé pour obtenir β_1 et β_2. La valeur de pK_a pour le solvant hydro-méthanolique (14.19 à 25 °C sur l'échelle molaire) peut être interpolée à partir des données expérimentales de Koskikallio (25). Ce dernier auteur a également obtenu la valeur d'une constante k_4' reliée à k_4 de l'éq. 4 par

$$[18]\qquad k_4 = k_4' \frac{\{H_2O\}}{\{CH_3OH\}}$$

Du point de vue thermodynamique, une des meilleures approximations du rapport des activités des composants du solvant mixte consiste à remplacer, tout comme l'a fait Oiwa (26), $\{H_2O\}$ par (p_1/p_1^0) et $\{CH_3OH\}$ par (p_2/p_2^0) où p_1 et p_2, les tensions de vapeur partielles respectives de l'eau et du méthanol au-dessus du mélange de solvants, sont calculés par interpolation des données de Butler et collaborateurs (27) et où les tensions de vapeur p_1^0 et p_2^0 de chacun des solvants à l'état pur sont respectivement égales à 23.76 Torr (26) et 126.6 Torr (27). La valeur de k_4 calculée par l'éq. 18 est alors 0.19. L'introduction des valeurs appropriées des diverses constantes dans une forme logarithmique de l'éq. 17 conduit ensuite aux résultats suivants: $pK_{s0} = 10.2$, $\log \beta_1 = 3.9$, $\log \beta_2 = 5.0$.

Discussion

La précision de la constante ${}^*K_{s0}$ paraît certainement satisfaisante lorsque l'on considère que deux méthodes d'analyse différentes, l'une radiométrique et l'autre potentiométrique, en ont fourni la même valeur logarithmique, soit 4.8. Notons ici qu'on peut expliquer, à la suite de Côté (11), la déviation positive des résultats potentiométriques en milieu alcalin, observée à la fig. 2, par le fait que la formation d'une couche d'oxyde d'argent à la surface de l'électrode d'argent en solution basique (28) peut causer un abaissement du pH^* local de la portion de solution en contact direct avec l'électrode.

D'après la définition physique même de la constante diélectrique, on sait que, si l'on peut

assimiler les ions en solution à des sphères chargées dans un milieu fluide continu (29), la stabilité d'espèces ioniques solubles sera d'autant plus grande que ε_r sera élevé. Il est donc possible de prévoir à peu près l'effet d'un changement de solvant sur une réaction chimique équilibrée en considérant la charge z de toutes les particules y prenant part afin d'appliquer la règle de Δz^2 (29):

$$[19] \quad \Delta z^2 = \sum z^2 \text{ (produits)} - \sum z^2 \text{(réactifs)}$$

Il ressort de ce qui précède que la diminution de la constante diélectrique macroscopique, lorsqu'on passe de l'eau ($\varepsilon_r = 78.5$ (7)) au mélange eau–méthanol utilisé ($\varepsilon_r = 55.4$), devrait faire augmenter ou diminuer la constante d'équilibre d'une réaction selon que Δz^2 est négatif ou positif. Lorsqu'on applique cette règle aux trois réactions dont les constantes d'équilibre sont K_{s0}, β_1 et β_2 (voir les éqs 6 et 10), on trouve des valeurs respectives de (+2), (−2) et (−2) pour Δz^2. Ceci signifie que la valeur de K_{s0} devrait décroître et que celles de β_1 et β_2 devraient s'accroître dans le solvant mixte par rapport au milieu aqueux, ce qui est effectivement le cas pour les données comparatives du tableau 2. C'est pourquoi on peut parler de solubilité plus faible de l'oxyde d'argent et de stabilité accrue des lyato-complexes de Ag(I) dans le solvant hydro-méthanolique. Il est à noter que le raisonnement qui précède ne tient pas compte des effets non électrostatiques, plus difficiles à évaluer, qui peuvent résulter des changements dans les interactions soluté–solvant (24).

A la fig. 3, la courbe de solubilité de $Ag_2O(s)$ pour le mélange de solvants est mise en parallèle avec les tracés pour le milieu aqueux calculés à l'aide des constantes qui apparaissent au tableau 2. Il est essentiel de mentionner que si l'ordonnée est la même dans le cas des trois courbes de la fig. 3, il n'en va pas de même de l'abscisse qui correspond au pH ($pK_a = 14.00$ (1, 2)) pour le milieu aqueux et au pH^* ($pK_a = 14.19$) pour le

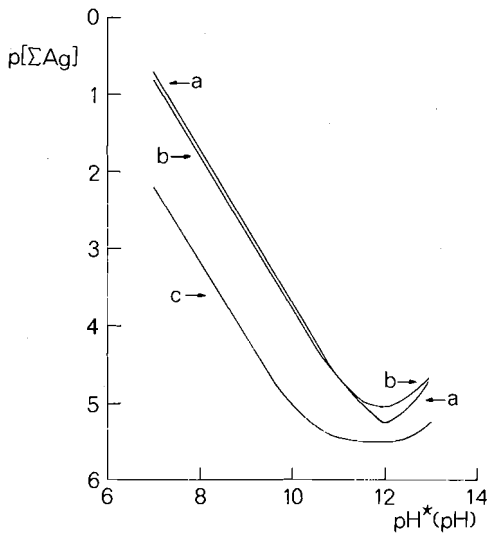

FIG. 3. Solubilité totale calculée pour l'oxyde d'argent: (*a*) en milieu aqueux d'après les constantes de Biedermann et Sillén (30), et (*b*) d'après celles de Côté (11); (*c*) en milieu hydro-méthanolique, d'après le présent travail.

milieu non-aqueux. Deux conséquences logiques de la diminution de la constante diélectrique ressortent ici: dans le mélange eau–méthanol, la solubilité complexe de $Ag_2O(s)$ est plus faible et l'intervalle de prédominance de l'espèce neutre Ag(OL), plus grand.

L'utilisation de l'éq. 15 pour exprimer la concentration totale d'argent en solution n'est justifiable que dans la mesure où la formation de nitrato-complexes de Ag(I) peut être négligée. Or il semble que $Ag(NO_3)$ soit la seule espèce soluble susceptible de se former de façon importante (1, 2). Fritz et Waki (31) ont obtenu des valeurs de 0.27 et 0.53 pour la constante de stabilité à 25 °C de $Ag(NO_3)$ respectivement dans l'eau et dans le 2-propanol à 40% en poids dans l'eau ($\varepsilon_r = 49.7$ (32)). Il est donc plausible de supposer que, dans le mélange eau–méthanol ($\varepsilon_r = 55.4$), la constante

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

de stabilité est de l'ordre de grandeur de 0.5. On peut alors écrire

$$[20]^{\ddagger} \qquad \frac{[AgNO_3]}{[Ag^+]} \cong 0.5[NO_3^-]$$

Dans le présent travail, le fait que la concentration totale maximum de nitrate soit égale à 0.1 signifie que $[AgNO_3]$ sera inférieur à 5% de $[Ag^+]$ et que ce nitrato-complexe pourra être négligé, même aux pH* auxquels Ag^+ prédomine.

En outre, l'utilisation de l'éq. 15 exige que les espèces polynucléaires en solution soient négligeables. D'une part, comme ces dernières peuvent être négligées lors de l'étude de la solubilité de $Ag_2O(s)$ dans l'eau (30), il est légitime de penser qu'elles peuvent également l'être dans le solvant mixte où la concentration totale d'argent est encore plus faible. D'autre part, il n'y a pas lieu de croire que le processus de formation d'espèces polynucléaires doive être nettement favorisé par la constante diélectrique inférieure du milieu hydrométhanolique, puisque l'on constate, d'après les pentes observées à la fig. 1, que les seuls complexes polynucléaires prédominants possibles devraient posséder la même charge que les espèces mononucléaires identifiées précédemment.

Les auteurs désirent remercier le Conseil national de recherches du Canada de son aide financière qui a permis la réalisation de ce travail.

Hydrogen–Water Deuterium Exchange Over Metal Oxide Promoted Nickel Catalysts[1,2]

NORMAN H. SAGERT, PAUL E. SHAW-WOOD, AND RITA M. L. POUTEAU

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba R0E 1L0

Received April 11, 1975

NORMAN H. SAGERT, PAUL E. SHAW-WOOD, and RITA M. L. POUTEAU. Can. J. Chem. **53**, 3257 (1975).

Specific rates have been measured for hydrogen–water deuterium isotope exchange over unsupported nickel promoted with about 20% of various metal oxides. The oxides used were Cr_2O_3, MoO_2, MnO, WO_2–WO_3, and UO_2. Nickel surface areas, which are required to measure the specific rates, were determined by hydrogen chemisorption. Specific rates were measured as a function of temperature in the range 353 to 573 K and as a function of the partial pressure of hydrogen and water over a 10-fold range of partial pressure.

The molybdenum and tungsten oxides gave the highest specific rates, and manganese and uranium oxides the lowest. Chromium oxide was intermediate, although it gave the highest rate per gram of catalyst. The orders with respect to hydrogen and water over molybdenum oxide and tungsten oxide promoted nickel were consistent with a mechanism in which nickel oxide is formed from the reaction of water with the catalyst, and then is reduced by hydrogen. Over manganese and uranium oxide promoted catalysts, these orders are consistent with a mechanism in which adsorbed water exchanges with chemisorbed hydrogen atoms on the nickel surface. Chromium oxide is intermediate. It was noted that those oxides which favored the nickel oxide route had electronic work functions closest to those of metallic nickel and nickel oxide.

NORMAN H. SAGERT, PAUL E. SHAW-WOOD et RITA M. L. POUTEAU. Can. J. Chem. **53**, 3257 (1975).

On a mesuré les vitesses spécifiques d'échange isotopique H/D entre de l'hydrogène et de l'eau sur du nickel sans support mais activé par environ 20% de divers oxydes de métaux. On a utilisé les oxydes suivants: Cr_2O_3, MoO_2, MnO, WO_2–WO_3 et UO_2. On a déterminé, par chemisorbtion de l'hydrogène, les surfaces disponibles du nickel nécessaires pour mesurer les vitesses spécifiques. On a mesuré les vitesses spécifiques en fonction de la température entre 353 et 573 K et aussi en fonction des pressions partielles d'hydrogène et d'eau alors que l'on a fait varier les pressions partielles par un facteur de 10.

Les oxydes de molybdène et de tungstène donnent les vitesses spécifiques les plus élevées alors que les oxydes de manganèse et d'uranium donnent les plus basses. L'oxyde de chrome est intermédiaire mais il donne la plus haute vitesse par gramme de catalyseur. Les ordres des réactions par rapport à l'hydrogène et à l'eau pour les réactions sur du nickel activé par MO_2 et WO_2–WO_3 sont en accord avec un mécanisme dans lequel de l'oxyde de nickel, formé par réaction de l'eau avec le catalyseur, est ensuite réduit par l'hydrogène. Sur des catalyseurs activés par des oxydes de manganèse et d'uranium, les ordres sont en accord avec un mécanisme dans lequel il y aurait échange des molécules d'eau adsorbées à la surface du nickel avec des atomes d'hydrogène qui y seraient attachés par chemisorbtion. L'oxyde de chrome est intermédiaire. On a noté que les oxydes qui favorisent la route impliquant l'oxyde de nickel ont des fonctions électroniques de travail les plus rapprochées de celles du nickel soit métallique et soit sous forme d'oxyde.

[Traduit par le journal]

Introduction

Nickel, promoted with chromia, is known to be a good catalyst for hydrogen–water deuterium exchange (1–3). The chromia has two functions. It protects the metallic nickel particles against sintering during reduction and use, so that the nickel surface area is much higher than it would be in the absence of chromia (2). This may be called structural promotion. At the same time, the rate per unit surface area of exposed nickel, the so-called specific rate, is much higher than it would be in the absence of chromia (2). This promotion may be called chemical, or electronic, promotion.

Although it is generally conceded that a chemical, or electronic, interaction between the

For personal use only.

oxide and the metal is responsible for chemical promotion (4–6), the way in which electronic promotion occurs has not been clearly established. We, therefore, examined the kinetics of hydrogen–water deuterium exchange using nickel catalysts promoted with various oxides, and have looked for correlations of specific rates with oxide properties.

Although one mechanism for this exchange over nickel–chromia catalysts, involving the formation and reduction of nickel oxide on the catalyst surface, is generally favored (3, 7), this mechanism is not universally accepted (8, 9). We measured kinetic parameters over all the catalysts used in an attempt to establish the mechanism over these catalysts.

Experimental

Rates were measured in a flow system at a total pressure of 110 ± 10 kPa as previously described (10, 11). Purified argon was used as a diluent to reduce the partial pressure of hydrogen, and the partial pressure of water was controlled by varying the saturator temperature (10, 11). Catalysts as mixed carbonates were evacuated for 2 h at 423 K. They were then reduced *in situ* in flowing hydrogen for 18 h at 530 K and cooled to room temperature in flowing hydrogen. Their activity became constant after about 30 min conditioning in a hydrogen–water stream and remained constant (±5%) indefinitely, provided that they were kept in flowing hydrogen at ~400 K when runs were not being performed.

Metal surface areas were measured by hydrogen chemisorption at room temperature as previously described (12). Total surface areas were measured by nitrogen adsorption at 77 K using a Perkin-Elmer Sorptometer. Catalysts were evacuated and reduced in the same way as those used for rate measurements, and were evacuated at 550 K for 16 h to at least 1.5×10^{-4} Pa before adsorption isotherms were measured. X-Ray diffraction patterns were measured as described previously (12) and thermograms were done in hydrogen using a Perkin-Elmer thermobalance.

The sources and means of purifying water, deuterium oxide, hydrogen, and argon have been described (12). Catalysts were prepared by coprecipitation. For most preparations, a solution containing 2 mol/kg $Ni(NO_3)_2$ plus the promoter as the nitrate was slowly added to an equal volume of solute containing 3.5 mol/kg of ammonium carbonate. The precipitate of mixed carbonates was aged overnight, filtered, washed, and dried. It was then lightly crushed and sieved, retaining the 40–80 mesh size. The manganese promoted catalyst was prepared from $MnCl_2 \cdot 4H_2O$ using a similar procedure. The tungsten promoted catalyst was made using $Na_2WO_4 \cdot 2H_2O$. In this case the tungstate was present in the ammonium carbonate solution. The molybdenum promoted catalyst was prepared using separate $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ and $NiCl_2$ solutions which were added simultaneously to the ammonium carbonate solution.

TABLE 1. Surface area of the catalysts

Catalyst	Total surface area (10^3 m^2/kg)	Nickel surface area (10^3 m^2/kg)
20/80 Cr/Ni	104	34.7
20/80 W/Ni	57	0.62
20/80 Mo/Ni	79	0.07
20/80 Mn/Ni	62	11.5
20/80 U/Ni	18	10.5
Ni	—	1.54

Results

Total surface areas and nickel surface areas are shown in Table 1. Total surface areas were calculated using the standard BET equation, taking the area of a nitrogen molecule to be 1.58×10^{-19} m^2. Metal surface areas were calculated by extrapolating the volume of hydrogen adsorbed at pressures between 1 and 5 kPa to zero pressure and using this volume as a measure of chemisorbed hydrogen. Nickel surface areas were then calculated, assuming that one hydrogen atom covers one nickel atom, and taking the area of an exposed nickel atom[3] as 6.76×10^{-20} m^2. The technique of extrapolating the volume of hydrogen to zero pressure should eliminate physically adsorbed hydrogen on the support. Nevertheless, the possibility remains that some chemisorption takes place on the oxides, although this has been shown not to be significant with nickel–chromia catalysts (2). Thus the metal surface areas are maximum areas, and the specific rates (see below) are minimum specific rates.

All rates and surface areas are quoted on the basis of the weight of mixed carbonate loaded into the reactor or surface area cell. This procedure was adopted for convenience. For nickel–chromia catalysts, the weight loss as the catalysts were heated in hydrogen corresponded within 5% to conversion to nickel metal plus Cr_2O_3.

We calculated the stable form of the oxide in hydrogen at 523 K using known free energies and entropies at 298 K and a three coefficient expression for heat capacities as a function of temperature (13). Thermochemically, the stable oxides are MoO_2, WO_2 in equilibrium with WO_3, UO_2, MnO, and Cr_2O_3. Nickel would be present as the metal. Recently Cr_2O_3 has been identified as the oxide present when chromium is the promoter (14) and nickel is present as the

[3]J. H. Rolston, private communication.

For personal use only.

metal. X-Ray analysis showed the metallic nickel was present and that nickel particle sizes were in the range 5 to 30 nm. No distinct lines were seen for the oxide. Either the oxide is amorphous or the oxide particles are so small that the lines are too broad to be apparent.

The reaction rate coefficient, k, in mol of HD per kg of catalyst per s, can be calculated from [1] provided that deuterium concentrations are less than 5% (2, 12)

$$[1] \qquad k = \frac{F}{(\alpha + 1/\beta)W} \ln\left(\frac{n_e - n_0}{n_e - n}\right)$$

In this equation, F is the flow rate of hydrogen in mol/s, α is the reciprocal of the equilibrium constant for [2], β is the ratio of water to hydrogen partial pressures, W is the catalyst weight in kg, and the n's are HD concentrations in the incoming hydrogen (n_0), at the reactor exit (n), and at equilibrium (n_e)

$$[2] \qquad HDO + H_2 = H_2O + HD$$

Specific rates were calculated by dividing the rate coefficient, k, by the nickel surface area per kg of catalyst. To avoid confusion, it should be emphasized that the specific rates are reported in terms of the nickel surface area rather than the total surface area. The specific rates are shown in Fig. 1 as a function of reciprocal temperature in the Arrhenius fashion. The rates were all calculated from measurements made at several flow rates by taking initial slopes to plots of $\ln (n_e - n_0)/(n_e - n)$ against W/F. This procedure should eliminate the effects of external diffusion. Previously, it was shown (15) that with Graphon supported platinum catalysts, external diffusion was eliminated if the catalyst particles were smaller than 0.35 mm. The rates over the most active nickel catalyst were of the same order as those over the Graphon supported platinum, although the surface areas of the nickel catalysts were higher by a factor of 2. Thus external diffusion should not be important. The specific rates shown in Fig. 1 were all measured at a hydrogen pressure of 78 kPa and a water pressure of 24 kPa. Apparent activation energies, taken from the slopes of the lines in Fig. 1 are shown in Table 2. Unfortunately, the low rate over unpromoted nickel meant that rates could only be measured at the higher temperatures and even then with low precision. Thus kinetic parameters are not quoted for unpromoted nickel.

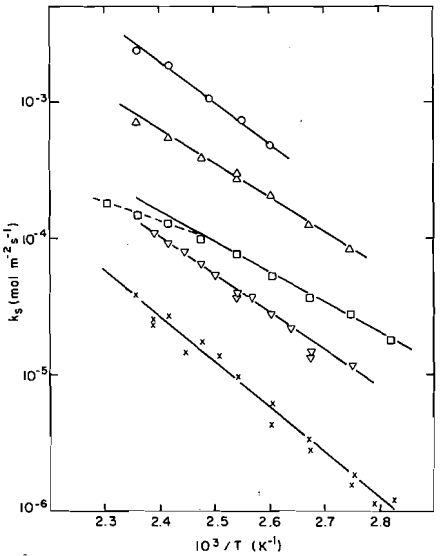

FIG. 1. Arrhenius plots of specific rates, measured with P_{H_2} = 78 kPa and P_{H_2} = 24 kPa, ○, MoO_2/Ni; △, WO_3/Ni; □, Cr_2O_3/Ni; ▽, UO_2/Ni; ×, MnO/Ni.

Rates were studied as a function of hydrogen and water pressure. Double logarithmic plots of the rate against hydrogen pressure were linear and the slopes, *i.e.* the orders with respect to hydrogen, are shown in Table 2. Double logarithmic plots of rate against water pressure are shown in Fig. 2 for all the catalysts except the uranium oxide promoted one. The order with respect to water was 0.1 for the uranium oxide promoted catalyst, but for the other catalysts, curved lines were obtained.

Discussion

The results will be discussed initially in terms of the mechanism proposed by Temkin and co-workers (7, 16, 17) for hydrogen–water exchange over nickel–chromia catalysts. This mechanism assumes that exchange takes place

TABLE 2. Kinetic parameters for H_2–HDO exchange over promoted nickel catalysts

Catalyst	E_{app} (kJ/mol)	Order in hydrogen (±0.1)	Specific rate at 393 K (10^{-5} mol HD m^{-2} s^{-1})
20/80 Cr/Ni	43.5	0.3	7.61
20/80 W/Ni	53.1	0.4	26.6
20/80 Mo/Ni	52.3	0.45	130
20/80 Mn/Ni	67.0	0.0	1.1
20/80 U/Ni	55.6	0.0	4.19
Ni	—	—	0.002

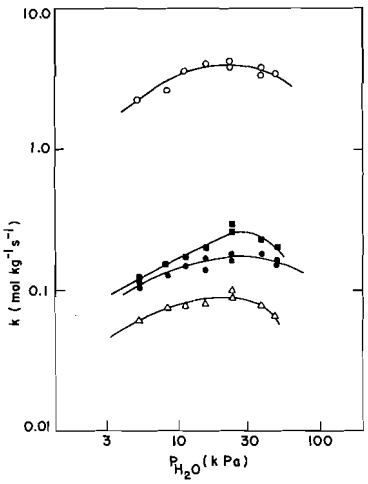

FIG. 2. Variation of the rate with water pressure measured with P_{H_2} = 78 kPa and at 393 K except for 20% Mn/Ni which was measured at 418 K. ○, Cr_2O_3; ■, MnO; ●, WO_3; △, MoO_3.

by the formation and subsequent reduction of an oxide film on the nickel surface (reactions 3 and 4).

[3] $$HDO + S = SO + HD$$

[4] $$H_2 + SO = H_2O + S$$

where S is a vacant surface site. The rate expression has been derived in detail by Temkin (16) but the steps in this derivation will be described here for convenience.

The virtual, or effective partial pressure of oxygen, P_{O_2}*, in equilibrium with the oxide film is given by [5].

[5] $$2P_{H_2O} = 2P_{H_2} + P_{O_2}^*$$

If the oxygen adsorption is described by a Freundlich isotherm, then

[6] $$\theta_0 = (a_0 P_{O_2}^*)^{m/2}$$

where a_0 is a constant and m equals RT/q, q being the heat of adsorption. Thus

[7] $$\theta_0 = \left(\frac{a_0}{K_5}\right)^{m/2}\left(\frac{P_{H_2O}}{P_{H_2}}\right)^m = a\left(\frac{P_{H_2O}}{P_{H_2}}\right)^m$$

where $(a_0/K_5)^{m/2} = a$. At equilibrium

[8] $$k_3 P_{HDO} f(O) = k_{-3} a P_{HD}\left(\frac{P_{H_2O}}{P_{H_2}}\right)^m$$

where $f(O)$ is a function giving the variation of the oxygen coverage with the partial pressures of hydrogen and water. Also from [4] at equilibrium

[9] $$ak_4 P_{H_2}\left(\frac{P_{H_2O}}{P_{H_2}}\right)^m = k_{-4} P_{H_2O} f(O)$$

Thus, recalling that $1/\alpha = K_3K_4$, where α is the reciprocal of K_2, and taking the net rate of reaction v as the forward rate minus the backward rate

[10] $$v = ak_3k_4 P_{HDO}\left(\frac{P_{H_2}}{P_{H_2O}}\right)^{1-m} - ak_3k_4\alpha P_{HD}\left(\frac{P_{H_2O}}{P_{H_2}}\right)^m$$

Furthermore, the derivation of [1] (3, 9) makes it clear that also

[11] $$v = k(N - \alpha n)$$

where N and n are the mole fractions of HDO and HD in the H_2O and H_2 respectively.

Comparing [10] and [11] it follows that

[12] $$k = ak_3k_4 P_{H_2O}\left(\frac{P_{H_2}}{P_{H_2O}}\right)^{1-m} = k_0 P_{H_2O}\left(\frac{P_{H_2}}{P_{H_2O}}\right)^{1-m}$$

where $k_0 = ak_3k_4$.

For this mechanism to be valid, a double logarithmic plot of k/P_{H_2O} against P_{H_2}/P_{H_2O}, *i.e.* k/P_{H_2O} against $1/\beta$, should be linear with a slope of $(1 - m)$. This should be so regardless of whether the hydrogen or the water pressure is varied.

The results over tungsten oxide and uranium oxide promoted nickel are shown as a double logarithmic plot of k/P_{H_2O} against $1/\beta$ in Figs. 3 and 4 respectively. For convenience, $k(P_T/P_{H_2O})$

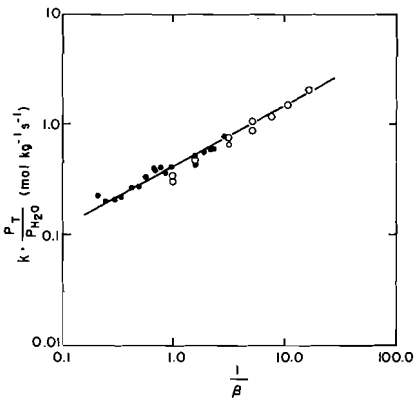

FIG. 3. Test for validity of Temkin mechanism with the 20% W/Ni catalyst, measured at 393 K. A single line indicates that Temkin kinetics are possible. ●, Hydrogen pressure varied; ○, water pressure varied.

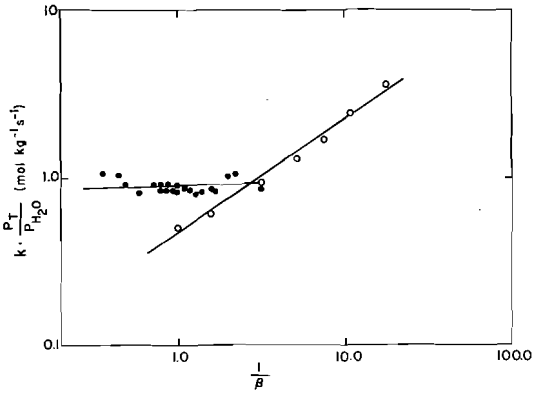

FIG. 4. Test for validity of Temkin mechanism with the 20% U/Ni catalyst, measured at 378 K. The points fall on two lines, so Temkin kinetics are not followed. ●, Hydrogen pressure varied; ○, water pressure varied.

is plotted as the ordinate where P_T is the total pressure which was always in the range 110 ± 10 kPa. A distinction is made between those runs where 1/β was changed by varying P_{H_2O} (from 5 to 41 kPa with hydrogen making up the difference), and those where 1/β was changed by varying the H_2 pressure by lowering the hydrogen pressure using argon as the diluent, and keeping P_{H_2O} constant at 27.3 kPa. For the tungsten oxide promoted catalyst, the data can be described by a single line, although if the best straight line is drawn through the two sets of points, slightly different slopes are obtained. For the uranium oxide promoted catalyst, the data points clearly fall on separate lines. Thus the Temkin mechanism may apply over the tungsten oxide promoted catalyst, but it clearly does not apply over the uranium oxide promoted catalyst.

Figure 5 shows ($m_{H_2} - m_{H_2O}$) plotted against

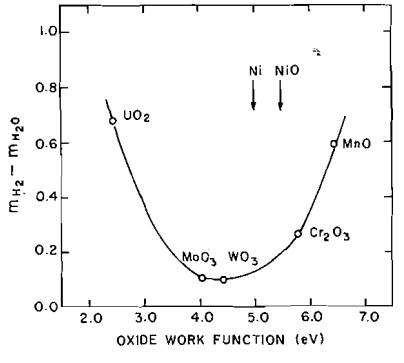

FIG. 5. Difference in Temkin m parameters for P_{H_2} variation and P_{H_2O} variation, plotted as a function of oxide work function. If the Temkin mechanism were obeyed m_{H_2} would equal m_{H_2O}.

the oxide work functions. The values for the work functions of Ni, NiO, MnO, and Cr_2O_3 were obtained from Krylov's monograph (18), that for UO_2 was taken from the work of Riviere (19), and that for MoO_2 was taken to be the same as that of MoO_3. The values of m_{H_2O} and m_{H_2}, in Fig. 5, were determined by varying the water and hydrogen pressures respectively as described. If the Temkin mechanism were followed exactly, this difference should be zero. Figure 5 shows that for the molybdenum oxide and tungsten oxide promoted catalysts, the difference is close to zero, so the Temkin mechanism may apply. For the uranium oxide and manganese oxide promoted catalysts, we can definitely say that the Temkin mechanism does not apply. For the 20% Cr_2O_3 catalyst shown in Fig. 5, the difference of 0.26 is somewhat greater than the assumed experimental error of ±0.2 if m can be determined to ±0.1. Therefore this case is unresolved.

The Temkin mechanism involves one adsorbed species, the oxygen atom, whose coverage is controlled by the ratio of hydrogen to water pressures. Thus the effects of changing hydrogen and water pressures are coupled. For the catalysts which do not follow the Temkin mechanism, the effects of changing the hydrogen and water pressures are not coupled. It seems likely that the mechanism in the cases involves exchange between adsorbed hydrogen atoms and adsorbed water (or OH groups) as has been previously proposed for supported noble metal catalysts (9, 11). If the adsorption–desorption steps are in equilibrium and the exchange is controlled by [13]

$$[13] \qquad H_{ads} + HDO_{ads} \rightarrow H_2O_{ads} + D_{ads}$$

then the rate expression is given by

$$[14] \qquad k_4 = k_{13}\theta_{H_2O}\theta_H$$

Assuming a Freundich isotherm for adsorption of hydrogen and water leads to

$$[15] \qquad k = k^1 P_{H_2O}{}^a P_{H_2}{}^b$$

The relationship is obeyed for the uranium oxide promoted catalyst and it is obeyed at all except the highest water pressures for the manganese oxide promoted catalysts. For these catalysts a and b are independent of each other.

Thus we have case A where an exchange type mechanism dominates with promotors such as manganese and uranium oxides and case B

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where either the exchange type or the Temkin mechanism may dominate with promotors such as tungsten and molybdenum. Furthermore, the specific rate is higher (see Table 2) in case B.

The specific rates, shown in Table 2, vary considerably. This means that there are large chemical promotion effects, and it is natural to look for the source of these effects in the electronic interaction of the nickel and the promotor. This has already been attempted in Fig. 5, where $m_{H_2} - m_{H_2O}$, a parameter which indicates the relative importance of the oxidation–reduction mechanism and the exchange mechanism, is plotted as a function of the promotor oxide electronic work function. It is evident that the oxide film reduction mechanism predominates where the promotor oxide work function is close to the work function of nickel and nickel oxide. If the work function of the oxide is much higher than that of nickel, the Fermi level in the nickel will be lowered by donation of electrons to the oxide. Since oxygen adsorption adds electrons to the nickel, it is likely that the oxide film formed by water adsorption will be too strongly held to be reduced easily by hydrogen. Conversely, if the work function of the oxide is much lower than that of nickel, an oxide film will not be formed.

The exchange mechanism, as opposed to the oxide reduction mechanism, occurs with equal facility on both sides of the maximum. Thus, at first glance, it does not seem to be affected by variations in the nickel Fermi level. Nevertheless, the specific rates obtained over catalysts where the exchange mechanism is clearly dominant are still much higher than those over bulk nickel (Table 2). Clearly, the promoting oxide must have some chemical effect on the exchange mechanism. For the small particles of nickel present in these catalysts (20) adsorption of hydrogen and water could result in very large changes in the Fermi level. One suggestion is that the promotor acts as a sink and source for electrons to keep the Fermi level of the nickel from changing too much.

We had originally hoped that kinetic parameters such as true surface activation energies and frequency factors could be obtained and compared. However, as at least two mechanisms are involved, and for some catalysts these may occur simultaneously, it seems premature to attempt such analyses at the present time.

We thank A. M. Soulodre for measuring the BET surface areas, and R. E. Von Massow for the use of programs to calculate oxide stabilities. Useful discussions with G. G. Strathdee and H. C. Chen are also gratefully acknowledged.

Volumes and Heat Capacities of Dimethylsulfoxide, Acetone, and Acetamide in Water and of some Electrolytes in these Mixed Aqueous Solvents

OSAMU KIYOHARA, GÉRALD PERRON, AND JACQUES E. DESNOYERS[1]

Department of Chemistry, Université de Sherbrooke, Sherbrooke, Quebec J1K 2R1

Received May 15, 1975

OSAMU KIYOHARA, GÉRALD PERRON, and JACQUES E. DESNOYERS. Can. J. Chem. **53**, 3263 (1975).

The densities and volumetric specific heats of binary mixtures of dimethylsulfoxide (DMSO), acetone (ACT), and acetamide (ACM) in water were measured at 25 °C with a flow densimeter and a flow microcalorimeter. The same properties were also determined for ternary mixtures of 0.1 *m* LiCl, NaCl, Me_4NBr, and Bu_4NBr in ACT–water and DMSO–water mixtures, and volumes for 0.1 *m* Bu_4NBr in ACM–water and urea–water mixtures. The derived apparent molal volumes and heat capacities of nonelectrolytes in water and the transfer functions of the electrolytes from water to the mixed solvents suggest that, contrary to urea, the present nonelectrolytes are slightly hydrophobic but, with the possible exception of ACT, their overall influence on water structure has practically no influence on the various solute–solute interactions.

OSAMU KIYOHARA, GÉRALD PERRON et JACQUES E. DESNOYERS. Can. J. Chem. **53**, 3263 (1975).

Les masses volumiques et capacités calorifiques du diméthylsulfoxyde (DMSO), de l'acétone (ACT) et de l'acétamide (ACM) ont été mesurées dans l'eau à 25 °C avec un densimètre et un microcalorimètre à écoulement continu. Les mêmes propriétés ont été obtenues pour LiCl, NaCl, Me_4NBr et Bu_4NBr à 0.1 *m* dans les mélanges eau–ACT et eau–DMSO et les volumes pour Bu_4NBr (0.1 *m*) dans les mélanges eau–ACM et eau–urée. Les capacités calorifiques et volumes apparents molaires des nonélectrolytes dans l'eau et les fonctions de transfert des électrolytes de l'eau aux mélanges de solvants suggèrent que ACM, ACT et DMSO sont, par opposition à l'urée, légèrement hydrophobes dans l'eau mais que l'effet structural global n'a practiquement pas d'influence sur les interactions soluté–soluté, sauf peut-être dans le cas de l'ACT.

Introduction

The aqueous solutions of dimethylsulfoxide (DMSO), are amongst the best-known mixed solvents and reaction media. However, despite the extensive studies of their properties, the nature of the interactions between DMSO and water is still far from being fully understood (1–4). On the other hand, acetone (ACT), which has a molecular structure similar to DMSO, is usually considered to be hydrophobic in water (5, 6). Urea (U), which also has a similar geometry, is usually assumed to be a structure breaker. We therefore felt that a comparative study of acetamide (ACM), ACT, and DMSO in water, combined with data previously obtained with U (7–9), might give us a better understanding of the interactions between DMSO and water.

Another approach which has been found useful in the study of mixed aqueous solvents is to study the transfer functions of well-characterized electrolytes from water to the mixed solvent (9–11). As in previous work (11), the four electrolytes chosen are LiCl, NaCl, Me_4NBr, and Bu_4NBr so as to cover typical hydrophilic and hydrophobic electrolytes.

The properties chosen for these investigations are the volumes and heat capacities, since they are readily measurable and have proven sensitive to changes in the structure of the mixed solvents (7–11).

Experimental

The instruments and techniques used for density (12) and specific heat (13) measurements have been described previously. The difference between the density of the solution and that of the solvent $d - d_0$ can be determined to $\pm 3 \times 10^{-6}$ g cm^{-3}, and the change in volumetric specific heat $\sigma - \sigma_0$ to $\pm 7 \times 10^{-5}$ J K^{-1} cm^{-3} for a temperature increment of 1.8 K and a flow rate of 0.7 cm^3 min^{-1}.

The origin and purification of the electrolytes (LiCl, NaCl, Me_4NBr, and Bu_4NBr) have been given elsewhere (14, 15). The nonelectrolytes were purified as follows: ACT and DMSO (Certified A.C.S., Fisher Scientific Co.) were dried with a molecular sieve (Davidson Chemical, grade 564, 8–12 mesh beads), ACM (Baker Analytical

Reagent) was recrystallized from absolute methanol and dried under vacuum.

All solutions were prepared by weight with deionized (Continental Deionized Water System) distilled water. All measurements were made at a mean temperature of 25.00 ± 0.01 °C.

Results

The apparent molal volumes ϕ_V and heat capacities ϕ_C of the nonelectrolytes in water and of the electrolytes in the mixed solvent were calculated in the usual way from the densities and volumetric specific heats (10). The results[2] for ACM, ACT, and DMSO are plotted in Figs. 1 and 2 against the molality and compared with the literature values (4, 16–20). In general, the present ϕ_V are in excellent agreement with the literature values but show less scatter, especially at low concentration. The good agreement in the case of ϕ_V and the proven reliability of the flow technique for differential specific heat measurements gives us confidence that the ϕ_C data are probably also reliable within an experimental uncertainty of ± 1 J K^{-1} mol^{-1}. The only heat capacity data reported in the literature for ACT and DMSO are those of Arnaud *et al.* (21); these data show a much larger scatter than the present ones and have not been included in Fig. 2.

The ϕ_V and ϕ_C data were fitted with a polynomial equation in molality

$$[1] \qquad \phi_Y = \phi_Y^0 + A_Y m + B_Y m^2 + \ldots$$

where Y stands for V or C_p. The parameters of [1] are listed in Table 1. The values for U which have been published elsewhere (8, 13) are also included for comparison.

The standard functions of transfer of an electrolyte E from water (W) to a mixed solvent (W + N) are given by

$$[2] \quad \Delta Y_E(W \rightarrow W + N) = \bar{Y}_E^0(W + N) - \bar{Y}_E^0(W)$$

where $\bar{Y}_E^0$ are the standard partial molal quantities. It has been shown previously (10) that the transfer functions obtained from the apparent molal quantities for electrolytes at 0.1 m were very close to the infinite dilution values. The functions ϕ_V and ϕ_C were therefore measured at 0.1 m electrolyte concentration[2]

[2]Complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

in ACT–water and DMSO–water mixtures, and the corresponding data in pure water at 25 °C were taken from the literature (14, 22–24): at 0.1 *m*, ϕ_V of the electrolytes LiCl, NaCl, Me_4NBr, and Bu_4NBr are respectively 17.46, 17.21, 114.80, and 300.00 $cm^3\ mol^{-1}$ and the corresponding ϕ_C are −53.3, −70.4, 129.2, and 1213 $J\ K^{-1}\ mol^{-1}$ respectively. The ϕ_V of Bu_4NBr was also measured in ACM–water and urea–water mixtures.[2]

The transfer functions of the four electrolytes from W to W + ACT and from W to W + DMSO are plotted in Figs. 3 and 4 against the cosolvent molality. The volumes of transfer of Bu_4NBr from water to aqueous solutions of U, ACM, and ACT at low cosolvent concentration are also shown in Fig. 5. Macdonald and Hyne (25) have measured $\overline{V}^0$ of tetraalkylammonium chlorides in aqueous ACT and DMSO solutions and their results agree qualitatively with the present results of Me_4NBr and Bu_4NBr. Mohanty *et al.* (26) have derived $\Delta C_{Bu_4NBr}{}^0(W \rightarrow W + ACT)$ from the temperature dependence of heats of solutions and found a maximum at about 0.04 mole fraction

($\sim$2.3 *m*) of ACT. The present results do not show such a concentration dependence.

Discussion

Group Additivity

Group additivity can often be used as a means of verifying the self-consistency of data and of predicting data of more complicated molecules. For the binary systems, the differences $\bar{V}_{ACM}^0 - \bar{V}_U^0$ and $\bar{V}_{ACT}^0 - \bar{V}_{ACM}^0$ are respectively 11.37 and 11.31 $cm^3\ mol^{-1}$ for $\bar{V}^0$ and 76.3 and 77.5 $J\ K^{-1}\ mol^{-1}$ for $\bar{C}_p^0$. This additivity being comparable with the expected uncertainties ($\pm 0.05\ cm^3\ mol^{-1}$ and $\pm 1\ J\ K^{-1}\ mol^{-1}$), it seems that the degree of substitution has little effect on the hydration of each group with these simple molecules in water. If the CH_3— group contribution to $\bar{V}^0$ and $\bar{C}_p^0$ is taken as 26.6 and 178 (27), then the —NH_2 contribution is 15.3 $cm^3\ mol^{-1}$ and 101 $J\ K^{-1}\ mol^{-1}$ for aliphatic molecules in water at 25 °C.

Binary Systems

An examination of Table 1 shows that $\bar{V}^0$ and $\bar{C}_p^0$ increase in the order U → ACM → ACT; DMSO has the largest $\bar{V}^0$ but its $\bar{C}_p^0$ is only slightly larger than ACM. The difference between $\bar{C}_p^0$ and the intrinsic heat capacity is often used as a criterion for the overall effect of a solute on water (23, 28). The intrinsic heat capacities can be taken as approximately equal to those of the pure substances: 93 (29) for U, 125 (30) for ACT, and 153 (31) for DMSO. Since there are little data in the literature for pure ACM at 25 °C, its densities and specific heats were measured in a polar organic solvent; 1-propanol was found to be convenient for this purpose. Up to approximately 3 *m*, ϕ_V (56.3 $cm^3\ mol^{-1}$) and ϕ_C (165 $J\ K^{-1}\ mol^{-1}$) are essentially independent of concentration. It therefore seems that $\bar{C}_p^0$ in water is significantly larger than the intrinsic heat capacity with ACT, slightly larger with DMSO, approximately equal with ACM, and slightly smaller with U. The concentration dependence of ϕ_C of the nonelectrolytes in water (Fig. 2) also shows that ϕ_C is rapidly decreasing to the intrinsic value with ACT, DMSO, and ACM while with U, ϕ_C increases with concentration (13). Again this change is significant with ACT but very small with ACM. On the other hand, even with ACT, there is little evidence of any structural hydrophobic–hydrophobic interactions; with strongly hydrophobic solutes, these hydrophobic interactions produce a positive contribution to the excess heat capacity which opposes the decrease of ϕ_C towards the intrinsic values, the net effect being a maximum or a positive hump in ϕ_C (10). No such behavior is apparent with these solutes. These nonelectrolytes are therefore affecting water in a way similar to dioxane, morpholine, and piperazine (11); whatever is causing the high heat capacity at infinite dilution is disappearing at higher concentration.

The increase in $\bar{V}^0$ when going from U to DMSO is reflecting primarily the increasing intrinsic volume and cannot give us much information on the overall structural hydration. On the other hand, ϕ_V of ACT and DMSO show a minimum typical of hydrophobic solutes. Presumably a minimum would also be observed with ACM if data were available at higher concentrations. These minima occur at rather high concentrations, especially with DMSO (and probably ACM) suggesting again that the hydrophobic character is rather small.

An examination of the binary system data therefore suggests that ACM, DMSO, and ACT are slightly hydrophobic in water in contrast with U, but the overall structural change is certainly not large, especially with ACM. The increasing hydrophobic character from U to ACT comes from the substitution of an hydrophilic —NH_2 by the hydrophobic —CH_3 and the much smaller hydrophobic character of DMSO compared with ACT comes from the higher dipole moment (3.96 compared with 2.88 D).

Ternary Systems

The transfer functions $\Delta Y_E^0(W \rightarrow W + N)$ are not simple to interpret since, at high cosolvent concentration, they must tend to $\Delta Y_E^0(W \rightarrow N)$, where N represents the pure liquid cosolvent. Since the ions are solvated differently in water and in the pure cosolvent, $\Delta Y_E^0(W \rightarrow W + N)$ will change gradually from one state to another. If in addition to a mean solvation there are new interactions which occur in the ternary system, this will result in some anomalies in the shape of the concentration dependence of $\Delta Y_E^0(W \rightarrow W + N)$, usually in the water-rich region.

The transfer functions $\Delta Y_E^0(W \rightarrow W +$ DMSO) in Fig. 4 are all changing in a regular

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

way with DMSO concentration, suggesting that at any concentration $\Delta Y_E^0(W \rightarrow W + N)$ is reflecting primarily some mean solvation of the ions. As seen from Fig. 5, $\Delta V_{Bu_4NBr}^0(W \rightarrow W +$ ACM) is also fairly regular. On the other hand, if we compare $\Delta Y_E^0(W \rightarrow W +$ ACT) in Fig. 3 with $\Delta Y_E^0(W \rightarrow W +$ *tert*-butyl alcohol) (10) or $\Delta Y_E^0(W \rightarrow W +$ piperidine) (11), the slight hump in the concentration dependence of $\Delta C_{Bu_4NBr}^0(W \rightarrow W +$ ACT), minimum with $\Delta V_{Bu_4NBr}^0(W \rightarrow W +$ ACT), and the slight minima with $\Delta Y_{NaCl}^0(W \rightarrow W +$ ACT) suggest that with ACT there are some specific structural interactions which are in the direction we would expect if ACT was slightly hydrophobic. The value of $\bar{C}_p^0$ of ACT in water was larger than its intrinsic heat capacity but the concentration dependence of ϕ_C did not show any maximum or hump characteristic of hydrophobic–hydrophobic interactions. It therefore seems that the hydrophobic–hydrophobic interaction between Bu_4N^+ and ACT and hydrophilic–hydrophobic ones between NaCl and ACT are somewhat larger than the structural interactions between two ACT molecules.

Little can be said on the transfer functions of Me_4NBr and LiCl. Even in ACT the transfer functions are all fairly regular. The overall structural hydration of these electrolytes is probably too weak to cause any significant change in structural electrolyte–nonelectrolyte interactions.

Conclusion

The present volume and heat capacity data suggest that the hydrophobic character of the nonelectrolytes decreases in the order ACT, DMSO, ACM but only in the case of ACT is there any evidence of some structural solute–solute structural interaction between a reference ion and the cosolvent. Like dioxane (11), DMSO is therefore an ideal cosolvent for water in the study of the influence of macroscopic properties such as dielectric constant and viscosity on various equilibria or reaction rates in aqueous medium.

C. RULLIÈRE, E. C. COLSON, and P. C. ROBERGE. Can. J. Chem. **53**, 3269 (1975).

The triplet–triplet (T–T) absorption spectrum of 1,3,6,8-tetraphenylpyrene (TPP) was measured from 400 to 620 nm. The data obtained are compared with theoretical calculations using the Ruedenberg–Scherr FEMO model. A planar triplet state is evidenced by fine vibrational structure. The T–T quenching rate constant measured ($1.3 \pm 0.1 \times 10^9\ M^{-1}\ s^{-1}$) is 20% of the expected diffusion-controlled value.

C. RULLIÈRE, E. C. COLSON et P. C. ROBERGE. Can. J. Chem. **53**, 3269 (1975).

Le spectre d'absorption triplet–triplet (T–T) du tétraphényl-1,3,6,8 pyrene (TPP) a été obtenu dans le domaine de 400 à 620 nm. Le calcul des énergies de transition T–T utilisant le modèle de Ruedenberg et Scherr permet de vérifier l'interprétation suggérée des résultats expérimentaux. Une structure plane du premier état triplet permet d'expliquer la structure vibrationnelle observée. La valeur de la constante d'annihilation T–T mesurée ($1.3 \pm 0.1 \times 10^9\ M^{-1}\ s^{-1}$) est cinq fois plus faible que la valeur prévisible pour une réaction limitée par diffusion.

Introduction

There are very few experimental data available on the effect of substituents on T–T absorption spectra of aromatic molecules (1). In the framework of a general study of the phenyl substituent effect on T–T absorption spectra, we report here results on 1,3,6,8-tetraphenylpyrene (TPP). Unsubstituted pyrene has been extensively studied: $S_n \leftarrow S_0$ and $T_n \leftarrow T_1$ absorption spectra are available (2–5).

Berlman (2) has measured the $S_n \leftarrow S_0$ absorption and fluorescence spectra of both pyrene and TPP. Whereas pyrene spectra show fine vibrational structure, TPP spectra are very diffuse. This finding can be attributed to a nonplanar ground state of TPP (6). In pyrene, fluorescence originates from the ^1L_b state. The transition $^1B_{1u}^- \leftarrow {}^1A_g^-$, oriented along the short axis of the molecule, is parity forbidden and the ^1L_b state is longlived (300 ns) (7). TPP fluorescence lifetime is however much shorter (2.68 ns) (2) and TPP fluorescence must originate from the ^1L_a state. Introduction of the phenyl substituents in the 1,3,6 and 8 positions red shifts the $^1B_{2u}^+ \leftarrow {}^1A_{1g}^-$ transition by 4000 cm^{-1}, causing at the same time an hyperchromic effect on the corresponding absorption band. The small overall fluorescence red shift ($\sim$900 cm^{-1}) indicates that the ^1L_b state is not much affected by the substitution. This interpretation of Berlman's results implies that phenyl substitution in the 1,3,6, and 8 positions affects mainly the long-axis oriented transitions of pyrene. This conclusion, which can easily be reached on geometrical grounds, will be very important for the interpretation of the T–T absorption spectrum of TPP. Of course, the possibility of having, upon phenyl substitution, new transitions of TPP as a whole must not be overlooked.

Experimental

Flash Apparatus

A flash of 15 μs duration ($t_{1/e}$) is obtained by discharging a set of capacitors (max. 3.0 kJ) through two oxygen-filled linear flash lamps of the type B described by Claesson and Lindqvist (8). The condenser bank consists of ten 1-μF high voltage, low inductance Hivotronic capacitors; the connections are such that three units of 2, 5, and 10 μF respectively can be formed. These units can be charged at variable voltages from 13 to 25 kV. The discharge is initiated by applying a 30 kV pulse at a spark gap in nitrogen. The lamps are placed along a jacketted, cylindrical silica cell with end windows (length

20 cm, i.d. 1.3 cm). A $CuSO_4$ solution was circulated through the cell jacket. Transient changes in light transmission of the solution contained in the cell were measured at selected wavelengths. Either a quartz–iodine lamp (FCR 100W-12V) or a d.c. xenon discharge lamp (Osram XB0 150 W/1) can be used as analytical light source; appropriate glass filters reduce photochemical effects of the measuring light. The light transmitted by the cell passes through a monochromator (Jarrell-Ash 82-410, 150 μm slit width, 0.6 nm resolution) and is measured using a photomultiplier (RCA 931 A or RCA 4832). The anode current of the photomultiplier is amplified either by a differential probe (Tektronix P6046) or by a cathode follower built according to Lindqvist (9). With both types of amplifiers, the signal resulting from exposure of the detector to light of constant intensity can be adjusted to zero with the aid of a calibrated d.c. offset (Hewlett-Packard 1803A plug-in) thus allowing a high amplification of small changes in signal. The amplified signal is fed either to a storage oscilloscope (Hewlett-Packard 181-A equipped with 1822A and 1083A plug-ins) or to a transient recorder (Biomation 610B). The sweep triggering pulse for the oscilloscope or the transient recorder is obtained from a photocell exposed to the flash lamps through a pinhole.

The data reported here have been obtained using the RCA 931A photomultiplier, the Tektronix differential probe, and the storage oscilloscope. Transmission changes of 0.4% were detectable over most of the wavelength range studied (400–620 nm). The rise time of the total detection system was 0.1 μs.

Preparation of Solutions

1,3,6,8-Tetraphenylpyrene (K & K) was purified by chromatography on alumina and absorption and emission spectra compared with Berlman's spectra (2). Cyclohexane (Fisher spectroanalyzed) was used without further purification. The solutions were outgassed by six cycles of freezing, pumping, thawing, and saturation with oxygen-free argon (Linde) after which the cell was sealed under vacuum (10^{-5} mm Hg). The use of the $CuSO_4$ filter restricted the excitation to the first absorption band of TPP and in these conditions there was no photodecomposition of the solution. All experiments were done at room temperature (21 ± 2 °C).

Results and Discussion

Flash excitation of solutions of TPP in cyclohexane produced a transient decrease of ground state TPP absorption and the appearance of a structured absorption lasting a few milliseconds (*ca.* 3–7 ms). This transient absorption is attributed to the triplet state of TPP. It is shown in Fig. 1, that the transient triplet absorption reaches a limit at electrical discharge energies higher than *ca.* 2 kJ for low TPP concentration. Since triplet absorption lasted much longer than the flash, this light saturation effect indicates that all TPP was converted to the triplet state at the higher flash energies, thus making possible the determination of triplet extinction coefficient.

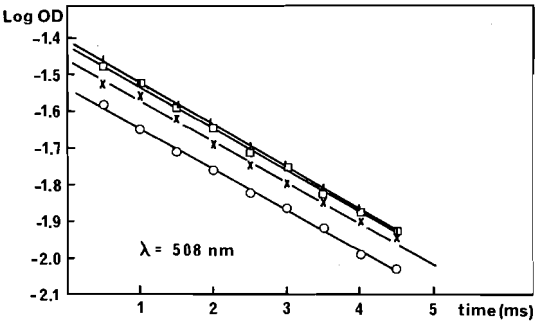

FIG. 1. Decay of the transient absorbance observed at 508 nm through a 20 cm cell containing a solution 1.08×10^{-7} *M* TPP in cyclohexane (21 ± 2 °C) exposed to flashes of varying discharge energy. ○, 1300 J; ×, 1600 J; □, 1800 J; |, 2000 J (saturation).

Before we discuss the T–T absorption spectrum of TPP, let us review the information available on T–T absorption of pyrene. In the region from 350 to 600 nm, there are two main absorption bands (3–5). The first progression at 19 200, 20 600, and 22 000 cm^{-1} ($f = 0.14$) is polarized along the short axis of pyrene and has been attributed to a ${}^3B_{3g}^- \leftarrow {}^3B_{2u}^+$ transition (3, 4). The second and more intense progression with peaks at 24 200, 25 500, and 27 000 cm^{-1} ($f = 0.31$) shows long-axis polarization and has been assigned to a ${}^3A_g^- \leftarrow {}^3B_{2u}^+$ transition (3, 4). The assignment is in agreement with Orloff's theoretical calculations (10). However, the polarization measurements indicate the presence of a hidden short-axis polarized absorption around 24 000 cm^{-1} which would correlate with the weak ${}^3B_{3g}^- \leftarrow {}^3B_{2u}^+$ transition calculated by Orloff at 27 000 cm^{-1}.

The T–T absorption spectrum of TPP is shown in Fig. 2; the absorption maxima are gathered in Table 1. This spectrum is the result of more than 400 flashes. Peaks have been numbered in Fig. 2 in order to facilitate the discussion. At first sight, the location of the two absorption bands is very similar to the pyrene case. However there is an inversion of the intensity of the two absorption bands in going from pyrene to TPP. The system of axes chosen is given in Fig. 2.

Assignment of the Spectrum

As already noticed, phenyl substitution in the 1,3,6 and 8 positions of pyrene should produce an important bathochromic shift of the long-axis polarized transitions, the short-axis oriented transitions being virtually unaffected by such a

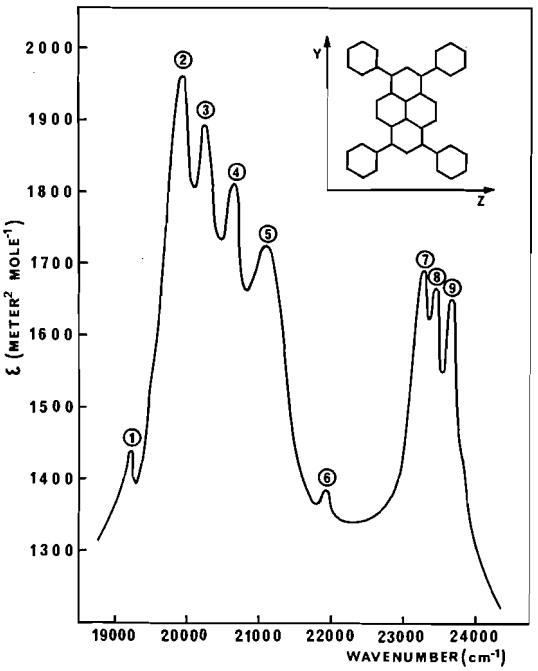

FIG. 2. Absorption spectrum of triplet TPP in cyclohexane.

substitution. Therefore, peaks 1 and 6 at 19 030 and 21 740 cm^{-1} are attributed to the first and third member of the progression corresponding to the short-axis polarized $^3B_{3g}^- \leftarrow {}^3B_{2u}^+$ transition, the second member of this progression being hidden under the absorption starting at $\sim$19 400 cm^{-1}. These two peaks are only very slightly red shifted ($\sim$200 cm^{-1}) when compared with the equivalent absorption maxima of the first T–T band of pyrene (3). This red shift is not significant and could be a trivial solvent effect. The progression involves the same 1400 cm^{-1} vibrational mode in both pyrene and TPP.

Peaks 2, 3, 4, and 5 are attributed to the long-axis polarized $^3A_g^- \leftarrow {}^3B_{2u}^+$ transition. This assignment implies a 4300 cm^{-1} red shift of the $^3A_g^- \leftarrow {}^3B_{2u}^+$ pyrene transition upon phenyl substitution, which is consistent with the expected phenyl substituent effect. Polarization measurements would allow this assignment to be checked. The progression involves a 450 cm^{-1} vibrational mode. The red shift of the $^3A_g^- \leftarrow {}^3B_{2u}^+$ transition clears the absorption region above 23 000 cm^{-1}. The three peaks at 23 095, 23 280, and 23 475 cm^{-1} could therefore correspond to the second $^3B_{3g}^- \leftarrow {}^3B_{2u}^+$ transition ($I^-(z)$) calculated by Orloff at 27 000 cm^{-1}. This attribution fits nicely with the suggestion of a weak hidden z-polarized transition around 24 000 cm^{-1} in pyrene (3). The vibrational progression in this third transition is $\sim$200 cm^{-1}.

Another weak band at 16 300 cm^{-1} was observed. However, as the lifetime of the species giving rise to this absorption was much shorter than the triplet lifetime, this band is not included in Fig. 2 and Table 1.

Vibrational Structure

In contrast to the $S_n \leftarrow S_0$ spectrum, the $T_n \leftarrow T_1$ spectrum of TPP shows very fine vibrational structure. This suggests a planar or quasi-planar $^3B_{2u}^+$ state. Orloff has shown that using an aromatic resonance integral (β) for the ring–ring bond in the first triplet state of 1-phenylnaphthalene gives the best fit to experimental data for zero-field splitting and triplet energy (11). Steric hindrance of the phenyl substituents in 1,3,6,8-tetraphenylpyrene is identical to the steric hindrance of the phenyl group in 1-phenylnaphthalene and it is expected that TPP lowest triplet state is also planar.

Assuming that TPP has the same symmetry (D_{2h}) in the equilibrium positions of higher and lowest triplet states, only excitations of totally symmetric vibrations should occur accompanying the $T_n \leftarrow T_1$ allowed electronic transitions (6). The appearance of fine vibrational structure ($\sim$450 cm^{-1}) in T–T absorption upon phenyl substitution seems to be a current phenomenon; it does show up in phenyl oxadiazoles,[3] as well as in 9,10-diphenylanthracene (12). The sole A_g vibration in substituted benzenes in the right energy range is the c type vibration (13–15). This substituent-sensitive vibration is mode 18a of benzene which involves appreciable coupling with the ring–ring C—C stretching frequency in phenyl substituted aromatic compounds. The displacement of the frequency of this vibration, from the value of 512 cm^{-1} in toluene, has already been suggested as an indication of the importance of the coupling between phenyl rings in biphenyl (315 cm^{-1}) and polyphenyl methanes (14). The c type vibration could therefore be responsible for the vibrational progressions of 450 cm^{-1} and 200 cm^{-1} in the $^3A_g^- \leftarrow {}^3B_{2u}^+$ and second $^3B_{3g}^- \leftarrow {}^3B_{2u}^+$ transitions, respectively.

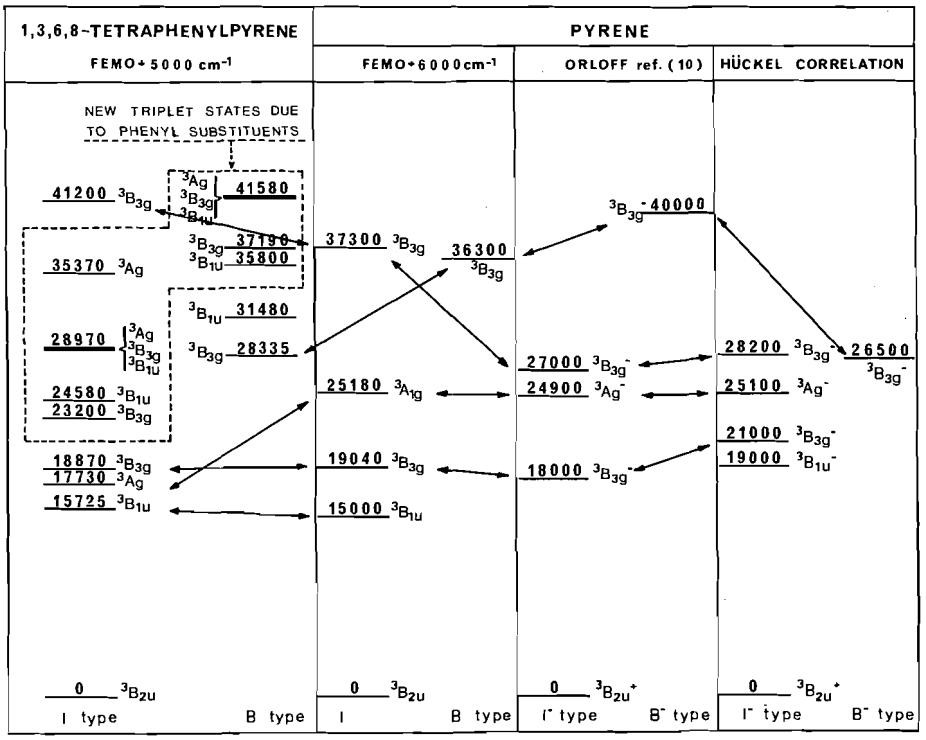

FIG. 3. Correlation of the calculated triplet energies (referred to the lowest ${}^3B_{2u}{}^+$) for pyrene and TPP.

However, if the T_n states are not planar and have lower symmetry than the lowest triplet, excitation of the torsional mode can occur accompanying the electronic transitions. If this is so, excitation of the torsional frequency does not blur the fine structure of the T–T spectrum as it does in the $S_n \leftarrow S_0$ spectrum. The 450 and 200 cm^{-1} vibrational modes could therefore be the torsional frequencies in the corresponding higher triplet states. Due to the aromatic character of the ring–ring bond, these frequencies would be of much higher energy than in the ground state ($\sim$110 cm^{-1} in biphenyl (14, 15)).

FEMO Calculated Transition Energies

FEMO calculations using the Ruedenberg–Scherr model (16) have been done to evaluate the T–T transition energies in TPP. This model is very simple and should be quite convenient for planar, phenyl substituted aromatic molecules, especially if, as suggested here for TPP in the triplet state, the ring–ring bonds are nearly aromatic. As the singlet–triplet splits are neglected in this model, the barycenter of the singlet–triplet energy is obtained for each state. However, except for the lowest triplet, the triplet states of interest (mainly I^- states according to Hoÿtink's notation (17)) are degenerate or nearly degenerate with the corresponding singlet states (18). Therefore, after a correction has been applied for the energy of the lowest triplet state (${}^3B_{2u}{}^+$), the Ruedenberg–Scherr model should give good approximations to the T–T transition energies. As a check, a calculation on pyrene has been undertaken. The results are presented in Fig. 3. A scaling factor of 6000 cm^{-1} has been added to the calculated energies in order to fit the first ${}^3B_{3g}{}^- \leftarrow {}^3B_{2u}{}^+$ transition energy with experiment. This scaling factor is very close to the energy difference (4500 cm^{-1}) between the ${}^3B_{2u}{}^+$ experimental energy and the calculated barycenter of the ${}^3B_{2u}{}^+$ and ${}^1B_{2u}{}^+$ energies. The FEMO predictions are compared in Fig. 3 with Orloff's calculations as well as with predictions using a semiempirical Hückel correlation (19, 20). Except for the second ${}^3B_{3g}{}^- \leftarrow {}^3B_{2u}{}^+$ transitions ($I_4{}^-(z)$), there is a good agreement between the different calculations. FEMO calculations also give remarkable agreement with experiment for triplet energies of *trans*-stilbene and 1,4-diphenyl-1,3-butadiene (21).

The FEMO calculated triplet energies for TPP

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and a correlation with pyrene are given in Fig. 3, the scaling factor here being 5000 cm^{-1}. The calculation evidences the important bathochromic shift of the $^3A_{1g}^- \leftarrow {}^3B_{2u}^+$ transition and supports the assignment given previously. However, in the region above 23 000 cm^{-1}, new transitions due to phenyl substitution are predicted. The absorption band experimentally observed at 23 095 cm^{-1} was previously assigned to the $I_4^-(z)$ transition calculated by Orloff at 27 000 cm^{-1} in pyrene (FEMO calculation gives 41 200 cm^{-1} for this transition in TPP). This band could very well be attributed either to the $B_1^-(z)$ transition calculated at 28 335 cm^{-1} (40 000 cm^{-1} by Orloff) or to a new $I_\phi^-(z)$ transition appearing upon phenyl substitution and calculated at 23 200 cm^{-1}. As all three transitions are short-axis polarized, polarization studies would not help clarify this point.

Triplet Decay Kinetics

The triplet decay kinetics were measured over the whole range of wavelengths and over a wide range of concentrations and flash energies. The results are satisfactorily accounted for by the following scheme:

$$[1] \qquad T \xrightarrow{k_1} S_0$$

$$[2] \qquad T + Q \xrightarrow{k_2} S_0 + Q$$

$$[3] \qquad T + T \xrightarrow{k_3} \begin{cases} T + S_0 \\ S_1 + S_0 \\ 2S_0 \\ D^* \end{cases}$$

where T designates the lowest triplet state, S_0 and S_1 respectively the ground state and the first excited state of TPP, D* the excimer, and Q any impurity quencher. The decay of triplet absorption was found to be pseudo first-order at low triplet concentrations. The corresponding triplet lifetime (~2–7 ms) is probably limited by oxygen quenching ($Q = O_2$). Process 3 occurred at higher TPP concentrations and high flash energies. Under these conditions the triplet decay curves deviate from the first-order decay mode observed at lower energies, as shown on Fig. 4. The decay law can be written:

$$[4] \qquad -\frac{d[T]}{dt} = (k_1 + k_2[Q])[T] + k_3[T]^2$$

At high enough flash energies and at short times after excitation, the decay is controlled by

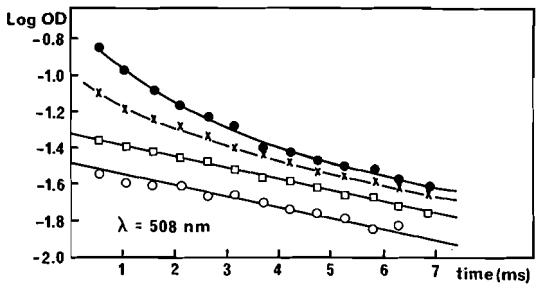

FIG. 4. Decay of the transient absorbance observed at 508 nm through a 20 cm cell containing a solution 5.4×10^{-7} *M* TPP in cyclohexane (21 ± 2 °C) exposed to flashes of varying discharge energy. ○, 1000 J; □, 1300 J; ×, 1500 J; ●, 2200 J.

T–T quenching (process 3). Integration of [4] under these conditions gives:

$$[5] \qquad [[T](t)]^{-1} = [[T](0)]^{-1} + k_3 t$$

or

$$[6] \qquad [OD_\lambda(t)]^{-1} = [OD_\lambda(0)]^{-1} + k_3/\varepsilon_\lambda l t$$

where OD_λ is the absorbance at wavelength λ, ε_λ is the triplet extinction coefficient at this wavelength, and l is the length of the cell. A representative curve obtained at 508 nm is given in Fig. 5. The mean determined value of k_3 is $1.3 \pm 0.1 \times 10^9\ M^{-1}\ s^{-1}$. This value is 20% of the diffusion controlled rate constant for pyrene in cyclohexane (7×10^9 at 22 °C (22)).

Conclusion

On experimental and theoretical grounds, we assigned the first observed T–T absorption band of TPP (peaks 1–6 in Fig. 1) to a superposition of the $I_2^-(z)$ and $I_3^-(y)$ transitions. This last transition is red shifted by as much as 4300 cm^{-1} when compared to pyrene. The second band (peaks 7–9 in Fig. 1) is due to a $^3B_{3g}^- \leftarrow {}^3B_{2u}^+$ transition, but it might correspond to $I_4^-(z)$, $B_1^-(z)$, or $I_\phi^-(z)$. This second T–T band seriously overlaps with the fluorescence of TPP. If it were not for this second band appearing upon phenyl substitution, pyrene could be considered as a perfect case of the $A_2{}^1a$ constellation, according to Pavlopoulos and Hammond's notation for laser dyes (23). As a matter of fact, laser action was easily obtained with TPP in cyclohexane (21, 24). Laser action was even obtained using the window of the cell as sole cavity mirrors, indicating a high gain in this system. However, the effect of T–T absorption on the laser action was clearly evidenced (21). It surely limits the

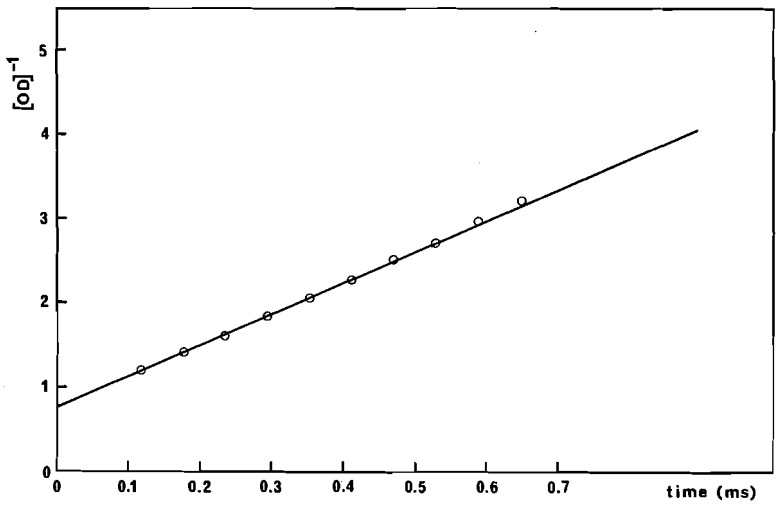

FIG. 5. Second order decay of the transient absorption observed at 508 nm through a 20 cm cell containing a solution of 2.7×10^{-6} *M* TPP in cyclohexane (21 ± 2 °C) exposed to a flash of 2400 J discharge energy ($k_3 = 1.3 \times 10^9$ $M^{-1}s^{-1}$).

efficiency of TPP laser and prevents any flash-lamp pumping of this system.

If the second T–T absorption band corresponded to the $I_\phi^-(z)$ transition, pyrene would be a member of the $A_2{}^1a$ constellation. Replacement of the phenyl substituents in TPP by auxochromic groups (*e.g.* $N(C_2H_5)_2$) should allow good improvement of the laser efficiency. On the other hand, if that band corresponds to $I_4^-(z)$ or $B_1^-(z)$, there is not much hope that changing the substituent will improve the laser efficiency.

We wish to thank the National Research Council of Canada and the Ministère de l'Education de la Province de Québec (FCAC) for financial support.

The synthesis of 5-allyl-2′-methoxy-9-oxo-6,7-benzomorphan (**5***b*) is described. The 10-hydroxy-2-methyl-1,11-propano-9*H*-indeno-1,2,10,11-tetrahydro[2,1-*c*]pyridine (**7***a*) and the corresponding 6-methoxy derivative (**7***b*) are unexpected products of pyrolysis of 5-allyl-2-methyl-9-oxobenzomorphan methobromide (**4***a*) and 5-allyl-2′-methoxy-2-methyl-9-oxobenzomorphan methobromide (**4***b*) respectively. The molecular structure of **7***a* ($C_{16}H_{19}NO$) has been determined from spectral and microanalytical data, and confirmed by X-ray single crystal analysis on its hydrobromide salt using the heavy atom technique. The crystals of $[C_{16}H_{20}NO]^+Br^-$ are monoclinic, $P2_1/a$, with $a = 13.724(2)$, $b = 14.022(3)$, $c = 7.495(2)$ Å, $\beta = 97.33(5)°$, and $Z = 4$. The crystal structure has been refined by block-diagonal least-squares calculations to R and $R_w = 0.036$ for the 2197 observed reflections. The N atom has planar trigonal coordination, and forms one double and two single C—N bonds of lengths 1.273(4), 1.465(4), and 1.474(4) Å, respectively. The Br is hydrogen-bonded to O. The N and O atoms are *trans*.

On décrit la synthèse de l'allyl-5 méthoxy-2′ oxo-9 benzo-6,7 morphane (**5***b*). L'hydroxy-10 méthyl-2 propano-1,11 9*H*-indènotétrahydro-1,2,10,11[2,1-*c*]pyridine (**7***a*) et le dérivé méthoxy-6 correspondant (**7***b*) sont des produits inattendus des pyrolyses respectives des méthobromures de l'allyl-5 méthyl-2 oxo-9 benzomorphane (**4***a*) et de l'allyl-5 méthoxy-2′ méthyl-2 oxo-9 benzomorphane (**4***b*). On a déterminé la structure moléculaire de **7***a* ($C_{16}H_{19}NO$) à partir de données spectroscopiques et microanalytiques et on l'a confirmée par rayons-X sur un cristal unique de bromhydrate utilisant la technique des atomes lourds. Les cristaux de $[C_{16}H_{20}NO]^+Br^-$ sont monocliniques, $P2_1/a$, avec $a = 13.724(2)$, $b = 14.022(3)$, $c = 7.495(2)$ Å, $\beta = 97.33(5)°$ et $Z = 4$. On a affiné la structure cristalline par la méthode des moindres carrés blocs diagonaux jusqu'à des valeurs de R et R_w de 0.036 pour 2197 réflexions observées. L'atome d'azote a une coordination trigonale planaire et forme un lien double et deux liens C—N simples avec des longueurs respectives de 1.273(4), 1.465(4) et 1.474(4) Å. Le brome est lié à l'oxygène par un pont hydrogène. Les atomes d'azote et d'oxygène sont *trans*.

[Traduit par le journal]

Introduction

A research project designed to study the synthesis and pharmacological properties of various 5,9-disubstituted-2′,9-dihydroxybenzomorphans required 5-allyl-2′-methoxy-2-methyl-9-oxobenzomorphan **5***b* (Scheme 1) as starting material. In part one of this series, we have reported the synthesis of benzomorphanone **5***a* starting with 2-tetralone (1). We now report the synthesis of **5***b* via the same reaction sequence (**1***b*–**4***b*) starting with 7-methoxy-2-tetralone. We should also like to report on the isolation and structure determination of certain unexpected products (**7***a*, **7***b*) of pyrolytic dequaternization of methobromides **4***a* and **4***b* respectively.

Results and Discussion

Chromatographic separation of the reaction mixture obtained by thermal dequaternization of **4***a* has been described earlier (1). In addition to the expected products due to the *N*-demethylation (**5***a*) and Hofmann elimination (**6***a*) there was obtained in 11% yield another unknown basic constituent (**7***a*). The pure base crystallized

from aqueous methanol as a white solid (slightly orange colored), m.p. 96–97 °C. The molecular formula of $C_{16}H_{19}NO$ (same as that of **5***a*) was obtained by microanalytical data and confirmed by mass spectrometry. However, its spectral properties were strikingly different from either **5***a* or **6***a* indicating a deep seated structural change with multiple bond breaking and bond formation. The least affected part of the molecule appeared to be the aromatic ring as seen in the n.m.r. spectrum (Table 1). An AX system (2H, doublets centered at 5.84 and 3.45 δ) whose upfield proton is labile and exchanges on shaking with D_2O with concomitant collapse of the downfield doublet (5.84 δ) to a singlet, is characteristic of an enamine function (2), which is attached to a quaternary carbon atom (C^t indicates a quaternary carbon atom). An AB quartet (doublets centered at 3.28 and 2.44 δ) is indicative of an isolated pair of benzylic protons bonded to a quaternary carbon atom. The singlet at 3.4 δ is characteristic of an N—CH_3 group and it signifies loss of one of the original *N*-methyl groups. The most conspicuous n.m.r. spectral feature is the disappearance of the signals due to allylic double bond, and the absence of a terminal methyl group, suggesting that a terminal bonding to the allylic double

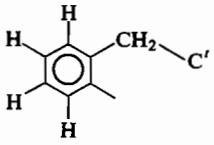
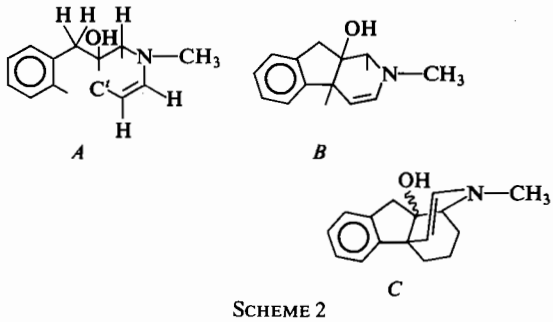
bond must have taken place. Such bonding would be expected to give rise to a propylene envelope in the n.m.r. spectrum and indeed it is present at 1.4–2.4 δ mixed with an exchangeable proton, presumably due to OH. Another significant spectral feature is the lack of a carbonyl absorption and presence of an hydroxyl absorption (3570 cm^{-1}) in the i.r. spectrum, which was assumed to be due to a tertiary OH (C′—OH); a secondary or primary OH would have deshielded the adjacent proton(s) in the n.m.r. spectrum. Thus based on the above spectral evidence, the following molecular fragments emerged:



$CH_3N—CH=CH—C'$,

$—CH_2CH_2CH_2—$, C′—OH

accounting possibly for all, or all but one carbon, and one hydrogen atom. The absorption in the n.m.r. spectrum due to the missing proton appears at 3.08 δ as an unresolved multiplet (almost a singlet), and it is characteristic of either an isolated benzylic proton or a methine proton adjacent to nitrogen (>CH—N<). Its correct assignment was made possible by analysis of the lanthanide induced shifts (l.i.s.) in the n.m.r. spectrum. The utility of lanthanide shift reagents in the analysis of n.m.r. spectra of bifunctional compounds is well established (3). The recorded l.i.s. in Table 1 suggest that the primary site of coordination of the europium complex is the hydroxyl rather than the enamine function since there are a number of protons which are more deshielded than the ones attached to carbons adjacent to the nitrogen. Furthermore, the greater l.i.s. for the isolated methine proton ($\Delta\delta = 4.95$) than for any other one in the spectrum indicates that it is surrounded by a highly complexed environment. Such an environment would exist in a molecular fragment *A* (Scheme 2) in which coordination on the nitrogen as well as on the oxygen would influence its l.i.s. The atomic arrangement in *A* also accounts for the observed n.m.r. pattern, chemical shifts and l.i.s. due to the isolated pair of benzylic protons. At this point, out of two possible bonding combinations for the two out of three unattached bonds on the quaternary carbon atom in *A* (C′—) the only likely one appeared to be that represented by *B*. Finally, insertion of the propylene group



SCHEME 2

gave the complete structure for **7***a* as that shown by *C*.

Additional support for the proposed structure was obtained by chemical transformation and mass spectral evidence. Treatment of **7***a* with sodium borohydride in ethanol afforded a saturated base $C_{16}H_{21}NO$, whose n.m.r. and i.r. spectra were consistent with the structure **8***a*. The mass spectra of both **7***a* and **8***a* have peaks at $M - 17$, $M - 42$, and $M - 59$ formed by elimination of the OH and/or propylene bridge (Table 2). In addition, **8***a* has a peak at $M - 25$ formed by elimination of the ethylene bridge.

The remaining questions to be solved were the stereochemistry of the hydroxyl function and the reaction mechanism which could account for this remarkable transformation of **4***a* to **7***a*. We suggest that **7***a* is formed by the sequence shown in Scheme 3. The quaternary base undergoes homolytic $C_1—C_8$ fission to give diradical *i* followed by an intramolecular attack of this diradical on the carbonyl and allyl groups to give another diradical, *ii*, in which a new molecular skeleton is already formed. Next, one inter-

SCHEME 3

molecular and one intramolecular (1–5) hydrogen transfer give the immoniun radical *iii*, and the sequence is completed by demethylation and abstraction of a proton by the solvent. Radical mechanisms have been demonstrated in nitrogen (4) and sulfur (5) ylide rearrangements,[5] although we are unaware of any example in the literature of the next step postulated in Scheme 3, *i.e.* radical attack on the carbonyl carbon. The reverse reaction *i.e.* radical oxidation of a secondary alcohol to give a ketone is well documented (6). The alternative ionic mechanism is considered less likely to be operative, since it would have to involve an unlikely electrophilic attack by a benzylic carbo-cation on the carbonyl carbon.

If the reaction sequence shown in Scheme 3 was indeed to take place, then the stereochemistry of the hydroxyl group should be α or *trans* in relation to the nitrogen atom. This, as well as the overall structure has been verified by an X-ray crystallographic study of the hydrobromide salt of **7***a* (*vide infra*).

The synthesis of benzomorphanon **5***b*, an important intermediate for the investigations in the field of analgesics and narcotic antagonists was accomplished analogously to that of **5***a* (1). Pyrolysis of **4***b* again gave a mixture of **5***b*, **6***b*, and **7***b*, which was similarly separated by column chromatography. Reduction of **7***b* with lithium aluminum hydride yielded saturated base **8***b*, which was further transformed to the phenolic base **8***c* by treatment with boron tribromide.

Crystal Structure

The molecular structure, as viewed along the normal to the benzene ring, is presented in Fig. 1. The same conformation was also deduced from the spectroscopic data. The bond lengths and valency angles (uncorrected for thermal vibration) for the non-hydrogen atoms are listed in Table 3. The C—H lengths are in the range 0.88–1.04(3) Å, mean = 0.96 Å, and O—H = 0.87(4) Å. All the bond lengths are in the range of their expected values.

The conformation of the rings, described in terms of the torsion angles of the bonds and the deviations of the atoms from some selected mean planes, is presented in Fig. 2. The benzene ring is planar, the five-membered ring is near envelope, the six-membered ring containing the N atom is an approximate sofa, and the remaining six-membered ring is a slightly distorted chair. The three C—N bonds are coplanar, and form C—N—C angles of 121.8(7), 121.5(8), and 116.7(2)°, where the smallest angle is opposite the double bond.

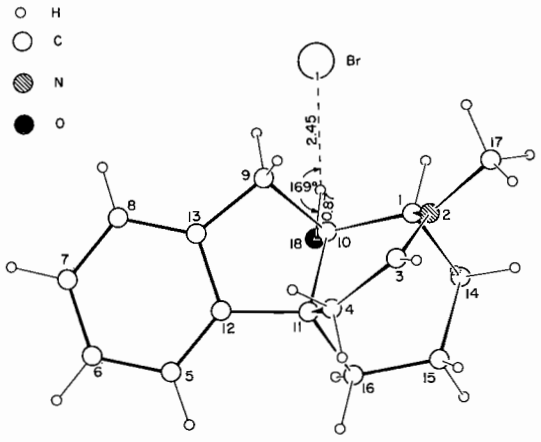

FIG. 1. A view of $C_{16}H_{19}NO{\cdot}HBr$ normal to the benzene ring, showing the conformation and the Br...H—O hydrogen bond. The interatomic distances are in Å.

flotation in toluene and carbon tetrachloride solution at 25 °C). Radiation: CuKα and Ni filter, $\lambda(K\alpha_1) = 1.54050$, $\lambda(K\alpha_2) = 1.54434$ Å, $\mu(Cu) = 42.34$ cm^{-1}. Crystal shape: slightly oblique prism of length 0.53 mm, and a hexagonal cross section of sides 0.23, 0.23, and 0.33 mm.

Intensities

The intensities were measured on an automatic diffractometer by the θ–2θ scan method, up to a limit of 125° in 2θ. Of the 2280 reflections scanned, 2197 (96%) were observed above threshold, thus giving 8.7 observations per parameter. The measured net intensities were corrected for L*p*, absorption (7), and extinction based on the linear plot of (I_o/I_c) against I_o.

Structure Determination

The position of Br was derived from a sharpened Patterson map, then the other non-hydrogen atoms were located from a vector superposition map. After some preliminary refinement of the atomic parameters by block-diagonal least-squares calculations, the *R* index was reduced to 0.07. The H atoms were then identified from a difference map and the refinement was continued until the parameter shifts were reduced to an average of 0.2σ and a maximum of 1.0σ. For the final parameters listed in Table 4, both *R* and R_w were 0.036 for the 2197 observed reflections,[6] and all the unobserved reflections were calculated less than 1.8 times their threshold amplitudes. The residual electron density in the final difference map was −0.7 to 0.4 e $Å^{-3}$ near Br and within ±0.3 e $Å^{-3}$ elsewhere.

The quantity minimized in the least-squares refinement was $\Sigma w(|F_o| - |F_c|)^2$, where $w = 1/\{1 + [(|F_o| - 35)/30]^4\}$ and $1.5 \leq |F_o| \leq 176.3$. The scattering factor curves were those of refs. 8 and 9 except that the curves for N and Br were modified to allow for the state of ionization (N^+ and Br^-) and to include the $\Delta f'$(Br) anomalous contribution. All calculations were carried out with the NRCC set of crystallographic programs (10).

Synthetic Procedures

The melting points were determined on a Gallenkamp apparatus, and are uncorrected. The infrared (i.r.) spectra were recorded on a Unicam Sp-200G grating i.r. spectrometer. The n.m.r. spectra were recorded on a Varian A-60A spectrometer. In addition, spectra of **7***a* were recorded on a 100 Mc spectrometer (Table 1). The chemical shifts are expressed in δ values using tetramethylsilane as internal reference. Microanalyses were performed by Micro-Tech Laboratories Inc., Skokie, Illinois.

10-Hydroxy-2-methyl-1,11-propano-9H-indeno-1,2,10,11-tetrahydro[2,1-c]pyridine, 7a

The chromatographic separation of a mixture of **5***a* and **6***a*, obtained by thermal decomposition of methiodide **4***a* was described earlier (1). The first fraction (255 mg, 11% based on **4***a*) which is now shown to be enamine **7***a* was purified by recrystallization from aqueous methanol to give a slightly orange solid; m.p. 96–97 °C; i.r. (CCl_4) 3570 (strong), 3515 (weak), 3430 (broad), 1632 cm^{-1}; n.m.r. (CCl_4) δ 7.2–7.5 (4H, m), 6.1 (1H, d, $J = 8$ Hz), 3.83 (1H, d, $J = 8$ Hz, exchanges with D_2O with collapse of a d at δ 3.45 to a s), 3.42 (1H, d, $J = 15$ Hz), 3.24 (1H, unresolved m), 2.88 (3H, s), 2.58 (1H, d, $J = 15$ Hz), 1.5–2.3 (7H, m).

Anal. Calcd. for $C_{16}H_{19}NO$: C, 79.63; H, 7.93; N, 5.80. Found: C, 79.72; H, 8.08, N, 5.62.

The hydrobromide salt was recrystallized from methanol acetone; m.p. 246–248 °C.

Anal. Calcd. for $C_{16}H_{19}NO{\cdot}HBr$: C, 59.63; H, 6.25; N, 4.35. Found: C, 59.33; H, 6.21; N, 4.27.

10-Hydroxy-2-methyl-1,11-propano-9H-indeno-1,2,3,4,10,11-hexahydro[2,1-c]pyridine, 8a

A mixture of enamine **7***a* (100 mg) ethanol (10 ml, 99%) and sodium borohydride (10 mg) was heated under reflux for 30 min. After cooling, it was treated with dilute hydrochloric acid, made alkaline with sodium bicarbonate, and extracted with ether to give after drying and evaporation of solvent 90 mg of crude solid **8***a*. An analytical sample was prepared by recrystallization from aqueous methanol; m.p. 99–100 °C; i.r. ($CHCl_3$) 3545 (sharp), 3430 (broad); n.m.r. ($CDCl_3$) δ 7.0–7.4 (4H, m), 3.83 (1H, d, $J = 16$ Hz), 2.58 (1H, d, $J = 16$ Hz), 2.55–3.0 (3H, m), 2.45 (3H, s), 1.5–2.4 (7H, m).

Anal. Calcd. for $C_{16}H_{21}NO$: C, 78.97; H, 8.69; N, 5.75. Found: C, 78.81; H, 8.59; N, 5.69.

3,4-Dihydro-7-methoxy-1-allyl-2(1H)-naphthalenone, 1b

To a stirred solution of 7-methoxy-2-tetralone (50 g, 0.284 mol) in dry benzene (200 ml) was added during 5 min under nitrogen a solution of pyrrolidine (40.5 g, 0.5 mol) in benzene (50 ml). The mixture was heated under reflux for 1 h (5 ml of water was collected in a Dean–Stark apparatus) and after cooling, it was added cautiously under nitrogen to a solution of allyl bromide (60.5 g, 0.5 mol) in benzene (300 ml). The resulting mixture was heated under reflux for 3 h. Then water (200 ml) was added and heating resumed for another 30 min. After cooling, the benzene layer was separated, washed with water, followed by water saturated with sodium chloride, dried, and evaporated to dryness. The residue was distilled to give **1***b* (52.2 g, 85% yield); b.p. 106–112 °C/0.05 Torr; i.r. (neat) 1715 cm^{-1}; n.m.r. (CCl_4) δ 6.6–7.4 (3H, m), 4.8–6.2 (3H, m), 3.8 (3H, s), 3.3–3.6 (1H, m), 2.4–3.21 (6H, m).

Anal. Calcd. for $C_{14}H_{16}O_2$: C, 77.74; H, 7.45. Found: C, 77.47; H, 7.50.

3,4-Dihydro-1-allyl-1-(2-dimethylaminoethyl)-7-methoxy-2(1H)-naphthalenone Hydrobromide, 2b

A mixture of dry benzene (400 ml), *tert*-pentyl alcohol and sodium hydride (10.62 g of a 55% suspension in mineral oil, 0.25 mol) was heated under reflux under nitrogen until all the hydride was consumed (*ca.* 30 min). Then a solution of allyltetralone **1***b* (47.2 g, 0.22 mol) in benzene (100 ml) was added slowly while distilling off the excess of *tert*-pentanol. Another 100 ml of benzene was added and distilled off followed by dropwise addition of a solution of 2-chloro-*N*,*N*-dimethylethylamine (28 g, 0.3 mol) in benzene (100 ml). The reaction mixture was heated under reflux for 20 h, and after cooling, washed twice with water, diluted with ether, and extracted with 1 *N* hydrochloric acid. The acidic extract was warmed to 60 °C for 1 h, cooled and extracted with ether to recover after drying and evaporation of ether 15 g of allyl tetralone **1***b*. The acidic extract was cooled, made alkaline with ammonium

For personal use only.

hydroxide, and extracted with ether. The extract was dried and filtered with charcoal, followed by treatment with dry hydrogen bromide to give **2***b* (33.8 g, 61.5%) as a white solid. A sample recrystallized from methanol–ether melts at 139–140 °C; i.r. (free base neat) 1710 cm^{-1}; n.m.r. (free base, CCl_4) δ 6.65–7.2 (3H, m), 4.7–5.8 (3H, m), 3.82 (3H, s), 2.0 (6H, s), 1.5–3.2 (10H, m).

Anal. Calcd. for $C_{18}H_{25}NO_2 \cdot HBr$: C, 58.69; H, 7.11; N, 3.80. Found: C, 58.63; H, 7.16; N, 3.59.

3-Bromo-3,4-dihydro-1-allyl-1-(2-dimethylaminoethyl)-7-methoxy-2(1H)-naphthalenone Hydrobromide, 3b

To a stirred solution of aminotetralone **2***b* (15 g, 41 mmol) in dichloromethane (100 ml) and THF (300 ml) was added dropwise in the dark over a period of 4 h a solution of pyrrolidone hydrotribromide (20.58 g, 41.5 mmol) in THF (300 ml). After the addition, the reaction mixture was allowed to stand overnight at room temperature, and then it was concentrated *in vacuo* and the solid residue recrystallized from 2-propanol (700 ml) to give 17.7 g (68.5%) of bromotetralone hydrobromide **3***b*; m.p. 149–150 °C; i.r. (Nujol) 1725 cm^{-1}.

Anal. Calcd. for $C_{18}H_{24}BrNO_2 \cdot HBr$: C, 48.34; H, 5.63; N, 3.13. Found: C, 48.64; H, 5.70; N, 3.14.

5-Allyl-2′-methoxy-2-methyl-9-oxo-6,7-benzomorphan Methobromide, 4b

The hydrobromide salt **3***b* (12.6 g, 28 mmol) was dissolved in ice cold water, made alkaline with ammonium hydroxide, and extracted with ether. The layers were separated as rapidly as possible, and the organic layer was concentrated *in vacuo*. The residual oil was dissolved in acetone and the solution was allowed to stand overnight. The deposited solid was collected by filtration to give 6.55 g (64%) of **4***b* containing ½ mol of water of crystallization. An analytical sample was prepared by recrystallization from 2-propanol; m.p. 175–177 °C; i.r. (Nujol) 1735 cm^{-1}; n.m.r. ($CDCl_3$–DMSO) δ 6.8–7.4 (3H, m), 5.0–6.0 (3H, m), 4.62 (1H, d, J = 4 Hz), 3.83 (3H, s), 3.77 (3H, s), 3.48 (3H, s), 1.9–4.3 (8H, m).

Anal. Calcd. for $C_{17}H_{21}NO_2 \cdot CH_3Br \cdot \frac{1}{2}H_2O$: C, 57.60; H, 6.71; N, 3.73. Found: C, 57.44; H, 6.78; N, 3.58.

5-Allyl-2′-methoxy-2-methyl-9-oxo-6,7-benzomorphan, 5b and 10-Hydroxy-6-methoxy-2-methyl-1,11-propano-9H-indeno-1,2,10,11-tetrahydro[2,1-c]-pyridine, 7b

The procedure for thermal dequaternization of **4***b* (2 g) was similar to that of **4***a* (1). The product, an oil (1.23 g) was chromatographed on a silica gel column (100 g). Elution with ether gave at first **7***b* as an oil, which was treated with dry hydrogen chloride in ether to afford 415 mg (16%) of the salt. It was purified by recrystallization from methanol–acetone; m.p. 241–243 °C; free base, m.p. 105–107 °C (from CH_2Cl_2); i.r. ($CHCl_3$) 3555, 1632 cm^{-1}; n.m.r. (CCl_4) δ 6.4–7.2 (3H, m), 5.85 (1H, d, J = 7 Hz), 3.7 (3H, s), 3.64 (1H, d, J = 7 Hz,) 3.2 (1H, d, J = 15 Hz), 3.0 (1H, unresolved m), 2.75 (3H, s), 2.31 (2H, d, J = 15 Hz), 1.3–2.3 (7H, m).

Anal. Calcd. for $C_{17}H_{21}NO_2 \cdot HCl$: C, 66.32; H, 7.20; N, 4.55. Found: C, 65.96; H, 7.27; N, 4.38.

A second product to emerge from the column was benzomorphanone **5***b* (735 mg, 50%) as an oil; i.r. (neat) 1730 cm^{-1}; n.m.r. (CCl_4) δ 6.55–7.2 (3H, m), 4.8–6.2 (3H, m), 3.75 (3H, s), 2.98–3.7 (3H, m), 2.37 (3H, s), 1.8–2.9 (3H, m), 1.56 (1H, unresolved d, J = 12 Hz). The oil was treated with an aqueous solution of oxalic acid to yield monohydrate oxalate salt, m.p. 115–120 °C with solidification and subsequent melting at 160–161 °C.

Anal. Calcd. for $C_{17}H_{24}NO_2 \cdot C_2H_2O_4 \cdot H_2O$: C, 60.15; H, 6.64; N, 3.69. Found: C, 60.52; H, 6.72; N, 3.70.

Continued elution of the column with a mixture of ether and methanol gave a small amount of the Hofmann elimination product **6***b* as judged by its n.m.r. spectrum, which was similar to that of **6***a*.

10-Hydroxy-6-methoxy-2-methyl-1,11-propano-9H-indeno-1,2,3,4,10,11-hexahydro[2,1-c]pyridine, 8b

To a solution of lithium aluminum hydride (100 mg) in dry ether, was added in small portions enamine **7***b* (450 mg) and the mixture was stirred and heated under reflux for 1 h. After work up in the usual manner, there was obtained 410 mg of **8***b* as an oil; i.r. (CCl_4) 3545, 3430 cm^{-1}; n.m.r. (CCl_4) δ 6.5–7.2 (3H, m), 3.65 (3H, s), 3.62 (1H, d, J = 15 Hz), 2.44 (3H, s), 2.33 (1H, d, J = 15 Hz), 1.5–3.1 (11H, m). A sample for analysis was purified as the hydrochloride salt by recrystallization from aqueous ethanol (80%); m.p. 270–272 °C.

Anal. Calcd. for $C_{17}H_{23}NO_2 \cdot HCl$: C, 65.90; H, 7.81; N, 4.52. Found: C, 66.04; H, 7.94; N. 4.38.

6,10-Dihydroxy-2-methyl-1,11-propano-9H-indeno-1,2,3,4,10,11-hexahydro[2,1-c]pyridine, 8c

A solution of **8***b* (546 mg, 2 mmol) in dry dichloromethane (10 ml) was added dropwise to a cooled (ice) and stirred solution of boron tribromide (1.8 g, 7.1 mmol) in dichloromethane (4 ml). The mixture was stirred at room temperature for 1 h, and then worked up in the usual manner (12) to give 420 mg (82% yield) of crude solid **8***c*; m.p. 198–204 °C. An analytical sample was prepared by recrystallization from methanol; m.p. 208–211 °C; i.r. (Nujol) 3250, 3180 cm^{-1}; n.m.r. ($CDCl_3$–DMSO) δ 6.4–7.2 (3H, m), 3.63 (1H, d, J = 15 Hz), 2.5 (1H, d, J = 15 Hz), 2.42 (3H, s), 1.5–3.0 (11H, m).

Anal. Calcd. for $C_{16}H_{21}NO_2$: C, 74.10; H, 8.16; N, 5.40. Found: C, 74.33; H, 8.11; N, 5.60.

The authors are grateful to Mrs. M. E. Pippy of NRCC for valuable assistance with the computations, and to Dr. D. N. McGregor and Dr. H. Brown of Bristol Laboratories, Syracuse, N.Y. for 100 MHz n.m.r. spectra and mass spectra respectively.

Four New Sesquiterpene Analogs of Common Monoterpenes

STUART J. TERHUNE, JAMES W. HOGG, A. CHRISTINE BROMSTEIN, AND BRIAN M. LAWRENCE

Stange Canada Ltd., 3340 Orlando Drive, Mississauga, Ontario L4V 1C7

Received September 11, 1974[1]

STUART J. TERHUNE, JAMES W. HOGG, A. CHRISTINE BROMSTEIN, and BRIAN M. LAWRENCE. Can. J. Chem. **53**, 3285 (1975).

Four new sesquiterpenes: sesquithujene, *cis*-sesquisabinene hydrate, and 2-methyl-6-(*trans*-4′-methyl-4′-hydroxycyclohex-2′-enyl)-hept-2-ene (zingiberenol) from *Zingiber officinale* and sesquisabinene from *Piper nigrum* are reported. Similarities in the i.r. and n.m.r. spectra between monoterpenes and their sesquiterpene analogs are used to assist in the structural elucidation.

STUART J. TERHUNE, JAMES W. HOGG, A. CHRISTINE BROMSTEIN et BRIAN M. LAWRENCE. Can. J. Chem. **53**, 3285 (1975).

On a isolé quatre nouveaux sesquiterpènes: le sesquithujène, l'hydrate du sesquisabinène *cis* et le méthyl-2 (méthyl-4′ hydroxy-4′ cyclohexène-2′ yl *trans*)-6 heptène-2 (zingibérénol) à partir du *Zingiber officinale* et le sesquisabinène à partir du *Piper nigrum*. On a utilisé les similarités qui existent entre les spectres i.r. et r.m.n. des monoterpènes et des sesquiterpènes correspondants pour élucider les structures de ces derniers.

[Traduit par le journal]

Introduction

During the analysis of the essential oils of *Zingiber officinale* Rosc. and *Piper nigrum* L., four previously uncharacterized sesquiterpenes were isolated. It was during the analysis of the structure yielding information of these compounds that we noticed strong similarities between the i.r. and n.m.r. spectra of a given monoterpene and its corresponding sesquiterpene analog, which is obtained by the addition of an isopentylidene (3-methyl-2-butenyl) group to one of the monoterpene's geminal methyls. We will describe the nature of these similarities and show how they were used to assist in the identification of sesquisabinene, sesquithujene, *cis*-sesquisabinene hydrate, and zingiberenol.

Experimental

Dried *Zingiber officinale* rhizomes (6.7 kg) from Kerala, India were ground (60–180 mesh) and immediately steam distilled for 12 h. The resulting essential oil (130 g) was subsequently vacuum distilled through a 35 theoretical plate, spinning band column until the head and pot temperatures reached 65 and 128 °C, respectively, under a maximum vacuum of 150 μ. The distillation residue was then column chromatographed over neutral alumina (Brockman Activity II) using 30–60 petroleum ether, diethyl ether, and methanol as solvents. The sesquiterpenes, which were eluted with petroleum ether, were rechromatographed using the same three solvents, over neutral alumina which had been coated with silver nitrate (5:1 w/w). Each fraction from the silver nitrate alumina column was then analyzed by temperature programmed (60–180 °C at 4 °C/min) preparative g.l.c. using a 6 ft × ¼ in. Carbowax 20M column (19% on 80/100 Chromasorb W). If the compound collected was still impure, a 10 ft × ¼ in. SF96 column (12% on 80/100 Chromosorb W) was then used to purify it. The sesquiterpene alcohols were eluted from the alumina column with ether–methanol and rechromatographed using a silver nitrate–alumina column if further purification was necessary before preparative g.l.c. *Piper nigrum* fruits (14.6 kg) obtained from the same source were also distilled and analyzed using the above procedure.

Analytical g.l.c. was used throughout to monitor the isolation and purification of each component. This system consists of two 150 ft × 0.01 in. stainless steel capillary columns, one coated with Carbowax 6000 and the other with SF96. Temperature programming (4 °C/min 60–170 °C) and flow programming (2 p.s.i./min 15–65 p.s.i.) were used throughout.

As a precaution against unknown rearrangements occurring during steam distillation, a carbon disulphide extract of each plant was prepared at room temperature. The analytical chromatograms of these extracts were then compared with those of the steam distilled oil. During these tests, the injector and detector temperatures were lowered from 195 to 150 °C and the rate of flow programming was increased to test for possible thermal rearrangements during analytical g.l.c. Furthermore, each fractionation step was checked for possible artifacts by taking aliquots of each resulting subfraction, recombining them, and comparing the resulting chromatogram with that of the initial mixture.

The n.m.r. spectra were done at the Canadian 220 n.m.r. Centre, Ontario Research Foundation, Sheridan Park, Ontario. The solvents were either deuterated chloroform or carbon tetrachloride using TMS as an

*Long range couplings present made accurate measurement impossible.

internal standard. The mass spectra were done with a Varian Aerograph EM-600 using an internal standard of *n*-alkyl benzenes. The infrared spectra were obtained using a Beckman IR 8 and/or a Perkin Elmer 237B on neat liquids between sodium chloride plates. Spacer thickness was varied between 0.013 and 0.05 mm in order to obtain a spectrum of reasonable definition in the fingerprint region. Polystyrene was used to calibrate the instruments. Published i.r. spectra were used as standards for the following monoterpenes: α-thujene and sabinene (1), *cis*- and *trans*-*p*-menth-2-en-1-ol (2), and *cis*- and *trans*-sabinene hydrate (3).[2]

The sesquiterpene alcohols were dehydrated using thionyl chloride in pyridine at 0 °C (4). Dehydration was also accomplished using a 6 ft × ¼ in. Carbowax 20M column isothermally at 200 °C with an injector temperature of 230 °C. All reaction products were isolated by preparative g.l.c. and were identified by their g.l.c. retention times and their i.r. spectra. For further information on the techniques used, refer to a detailed description previously published (5).

Results and Discussion

Sesquithujene (1)

When silver nitrate – alumina column chromatography was performed on the sesquiterpenes from *Zingiber officinale*, an unknown sesquiterpene hydrocarbon, **1**, (M^+ 204, $C_{15}H_{24}$) was found in the same fraction as *trans*-α-bergamotene. Since compounds with the same number and type of double bonds tend to elute together from this type of column, **1** can be suspected of having two internal double bonds.

A comparison of the n.m.r. spectra of **1** and α-thujene is given in Table 1. The addition of an isopentylidene group to one of the geminal methyls of α-thujene can be seen quite clearly: one tertiary methyl absorption in the spectrum of α-thujene (δ 0.950) is replaced with an ethano group (δ 1.1) in the spectrum of **1**. Similarly, the *gem*-dimethyl proton (δ 1.41) changes from a septet to a multiplet (δ 1.4). The isopentylidene group contributes one ethano group α to a double bond (δ 2.04), one vinyl proton (δ 5.12), and two tertiary vinyl methyls (δ 1.61 and 1.68). The remaining protons common to both structures show very similar chemical shifts and multiplicity.

After the n.m.r. spectrum was completed, the solution of **1** and deuterated chloroform –

[2]All monoterpenes named according to 'Nomenclature for Terpene Hydrocarbons' American Chemical Society, 1955.

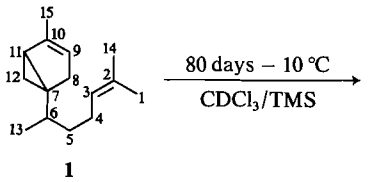
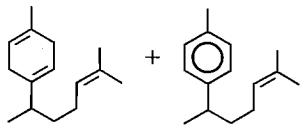
TMS was stored in a sealed glass tube for 80 days at −10 °C. On re-examination, it was found to contain **1** (60%), β-curcumene (**2**) (37%), and aromatic curcumene (**3**) (10%). The formation of these two compounds is in agreement with the proposed structure.



1



2 **3**

As with the n.m.r. spectra, the i.r. spectra of sesquithujene and α-thujene (Fig. 1) show only small and for the most part, interpretable, differences. The *gem*-dimethyl split (6) in α-thujene's i.r. spectrum (7.26 and 7.35 μ) is replaced with a single absorption at 7.25 μ in sesquithujene's spectrum. This spectrum also has two additional absorptions at 8.96 and 12.04 μ due to the isopentylidene group. The latter absorption is due to the out of plane deformation of the vinyl hydrogen (7). Based on the above information, it is proposed that sesquithujene has structure **1**.

cis-Sesquisabinene Hydrate (4)

Also isolated from the essential oil of *Zingiber officinale* was a sesquiterpene alcohol **4** (M^+ 222, $C_{15}H_{26}O$). It was found in the same alumina column fraction as α-cadinol and was purified

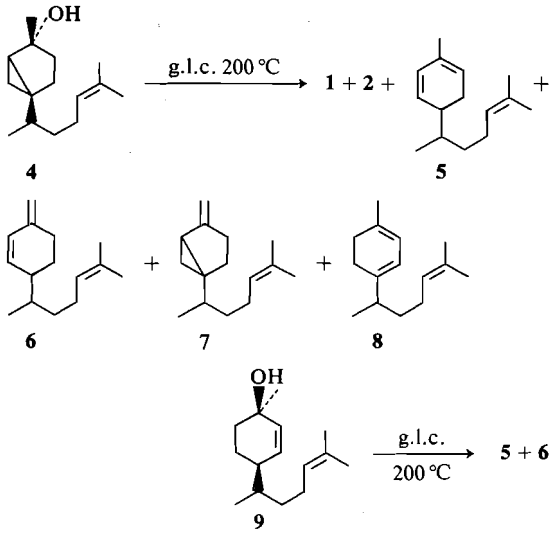
by g.l.c. using both the Carbowax and SF96 columns at reduced temperatures (160 °C) and increased flow (115 ml/min) to decrease the possibility of thermal dehydration.

A comparison of the n.m.r. data of **4** and *cis*-sabinene hydrate is given in Table 2. Again, the similarity in chemical shifts of common protons can be seen as well as the effect of the isopentylidene group; the loss of one geminal methyl absorption (δ 0.882), the addition of two vinyl methyl groups (δ 1.60, 1.68), one ethano group α to a double bond (δ 2.00), and a single vinyl proton (δ 5.09) are all consistent with the addition of an isopentylidene group to *cis*-sabinene hydrate. Due to absorption overlap, no definite conclusions about the *gem*-dimethyl proton or the C_5 ethano group can be drawn.

Dehydration of **4** using thionyl chloride produced **2** (45%) and **1** (40%). Thermal dehydration yielded **1** (2.8%), **2** (8.7%), zingiberene (**5**) (11%), β-sesquiphellandrene (**6**) (14%), sesquisabinene (**7**) (11%), γ-curcumene (**8**) (9.1%), and unreacted **4** (43%). The gross structure of this alcohol can thus be proposed as being the sesquiterpene analog of sabinene hydrate. The n.m.r. comparison suggests that the sesquiterpene has, in fact, *cis* stereochemistry. Further evidence in favor of this proposal can be found



in the comparison of the i.r. spectrum of **4** with those of *cis*- and *trans*-sabinene hydrate (Fig. 2). The i.r. spectrum of **4** is virtually identical to that of *cis*-sabinene hydrate (with additional absorptions at 9.1 and 12.06 μ due to the isopentylidene group) and is considerably different from the i.r. spectrum of *trans*-sabinene hydrate. The i.r. spectrum of the sesquiterpene also shows no evidence of a *gem*-dimethyl split

(7.3 μ). Not shown in Fig. 2 is the typical —OH stretching absorption (3.0 μ) present in all three alcohols. The above evidence suggests that **4** has *cis* stereochemistry and is, in fact, *cis*-sesquisabinene hydrate.

Sesquisabinene (7)

Another sesquiterpene hydrocarbon **7**, (M^+ 204, $C_{15}H_{24}$) was isolated from the essential oil of *Piper nigrum* in the same silver nitrate – alumina column fraction as β-sesquiphellandrene, indicating the presence of one exocyclic and one endocyclic double bond. An examination of the n.m.r. data comparison between **7** and sabinene (Table 3) suggests that **7** is the sesquiterpene analog of sabinene. The presence of the isopentylidene group in **7** is indicated by two vinyl methyl groups (δ 1.58, 1.66) and one vinyl hydrogen at δ 5.01. Of the two additional ethano groups, the one α to the double bond is a poorly resolved multiplet at δ 2.0 and the other's location is uncertain. The remainder of the protons, common to both structures have, again, very similar chemical shifts. The i.r. comparison in Fig. 3 shows that the spectrum of **7** is similar to that of sabinene. The loss of the *gem*-dimethyl split and the two additional absorptions due to the isopentylidene group at 8.99 and 12.08 μ can be seen in the spectrum of **7**. Further structural evidence for **7** is the previously mentioned dehydration of **4**.

Zingiberenol (2-Methyl-6-(trans-4'-methyl-4'-hydroxy-cyclohex-2'-enyl)-hept-2-ene) (9)

During the analysis of the essential oil of *Zingiber officinale*, another sesquiterpene alcohol, **9** (M^+ 222, $C_{15}H_{26}O$) was found in a slightly later alumina column fraction than *cis*-sesquisabinene hydrate. As the fraction in which **9** was found was quite complex, silver nitrate – alumina column chromatography followed by preparative g.l.c. was needed to purify it. The n.m.r. data (Table 4) indicates that **9** could be the sesquiterpene analog of *cis*- or *trans-p*-menth-2-en-1-ol. The two vinyl methyls at δ 1.60 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

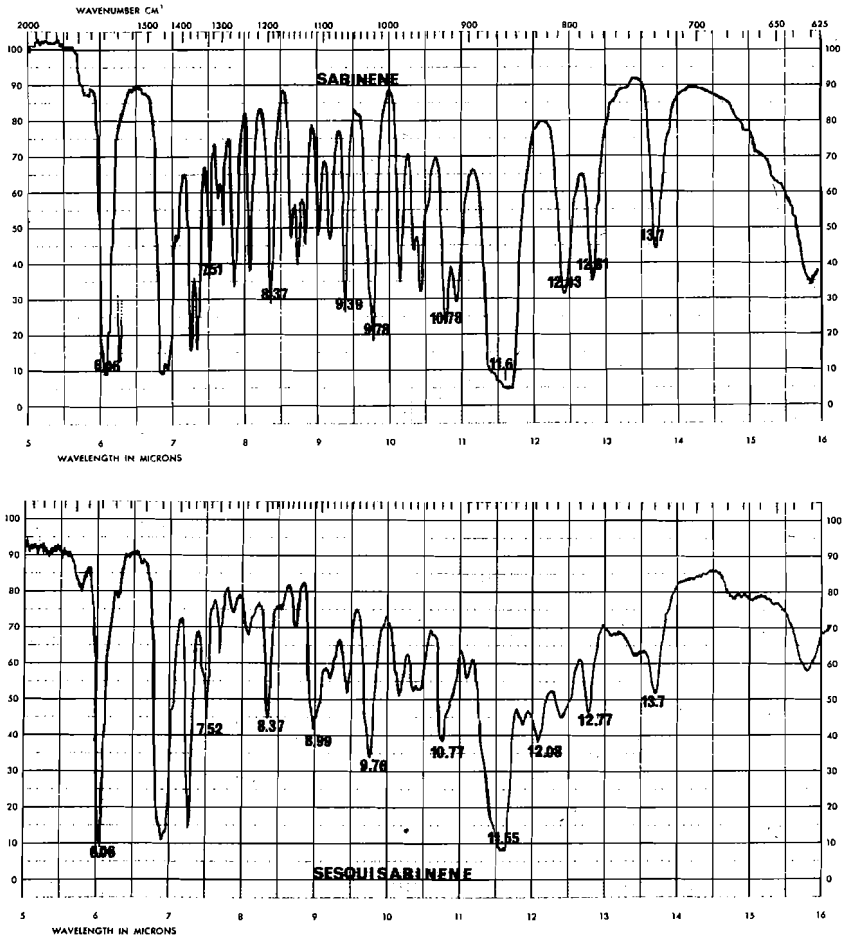

FIG. 3. The infrared spectra of sabinene and sesquisabinene.

1.68 and the vinyl hydrogen triplet at δ 5.1 are, once again, indicative of an isopentylidene group. Unfortunately, no suitable n.m.r. data for either *cis*- or *trans*-*p*-menth-2-en-1-ol could be obtained but the remaining absorptions in Table 4 are approximately what one would predict. Additional evidence for the gross structure of **9** was obtained by dehydration on g.l.c. which produced **5** (16%), **6** (20%), and unreacted **9** (60%).

To determine if **9** has *cis* or *trans* stereochemistry, a comparison of its i.r. spectrum to those of *cis*- and *trans*-*p*-menth-2-en-1-ol was made (Fig. 4). It can be seen that the i.r. spectrum of **9** is very similar to that of *trans*-*p*-menth-2-en-1-ol and it was on this evidence that the *trans* stereochemistry was assigned to **9**. Again, the loss of the *gem*-dimethyl split (7.3 μ)

and the presence of the isopentylidene group (12.05 μ) can be seen in the spectrum of **9**. The additional peak at 9 μ in the spectrum of the sesquiterpene cannot be observed due to the C—O stretching absorption.

Conclusion

The effect of the isopentylidene group on the i.r. or n.m.r. spectra, when comparing analogous monoterpenes and sesquiterpenes, is usually either predictable or negligible. The i.r. spectrum of the sesquiterpene consistently contains two additional peaks of weak to moderate intensity at 9.12 ± 0.17 μ and 12.05 ± 0.1 μ. The 10–16 μ region is otherwise very similar to that of the monoterpene in both peak intensity and position. The fingerprint region, 7.5–10 μ, as expected, shows less similarity but there is generally some correlation between the two spectra. The 'geminal dimethyl split', very often present in the monoterpene spectrum, is not present in that of the sesquiterpene as no geminal dimethyl group exists. The n.m.r. spectrum of the sesquiterpene will contain easily identifiable additional absorptions due to the two vinyl methyl groups (about δ 1.6) and an extra vinyl proton which appears as a triplet (about δ 5.1). The loss of one secondary methyl absorption (monoterpene to sesquiterpene) as well as the addition of two ethano groups can also be observed.

It is generally recognized that the use of n.m.r. and particularly i.r. spectra to assign structures and even stereochemistry to unknown compounds can by no means be regarded as an absolute proof of those structures. The authors have, however, examined 29 sets of i.r. spectra of monoterpenes and their sesquiterpene analogs and have found that they all support the proposed theory. It must be emphasized that the spectra, particularly the i.r. spectra, must have absorptions of reasonable intensity and definition before any comparisons can be made.

The one remaining commonly occurring monoterpene for which the analogous sesquiterpene has not been found is car-3-ene. There are, however, many monoterpene alcohols, ketones, etc. for which analogous sesquiterpenes have not been found. It is hoped that the techniques described in this paper may aid in the identification of some of these.

Synthèse et propriétés des pentaméthyl-2,3,3,5,5 et tétraméthyl-3,3,5,5 *N*-pipéridinométhyl-2 cyclohexanones et de leurs dérivés

JEAN-CLAUDE RICHER ET RAPHAEL ARLOTTO[1]

Département de Chimie, Université de Montréal, B.P. 6210, Montréal, Québec H3C 3V1

Reçu le 25 novembre 1974[2]

JEAN-CLAUDE RICHER et RAPHAEL ARLOTTO. Can. J. Chem. **53**, 3294 (1975).

On rapporte la préparation des méthylène-2 et butylthiométhylène-2 tétraméthyl-3,3,5,5 cyclohexanones et leur transformation en pentaméthyl-2,3,3,5,5 cyclohexanone. On rapporte aussi la synthèse de la *N*-pipéridinométhyl-2 tétraméthyl-3,3,5,5 cyclohexanone. Les propriétés des cétones ainsi que la stéréochimie de leur réduction par les hydrures complexes sont examinées.

JEAN-CLAUDE RICHER and RAPHAEL ARLOTTO. Can. J. Chem. **53**, 3294 (1975).

The preparation is reported of 2-methylene- and of 2-butylthiomethylene-3,3,5,5-tetramethylcyclohexanone as is their transformation into 2,3,3,5,5-pentamethylcyclohexanone. The synthesis of 2-*N*-piperidinomethyl-3,3,5,5-tetramethylcyclohexanone is described. The properties of the ketones as well as the stereochemistry of their reduction by complex hydrides was examined.

[Journal translation]

Introduction

Dans le cadre de nos travaux sur la réduction, par les hydrures complexes, de méthylène-2 cycloalkanones substituées (1) et sur la stéréochimie des additions sur les cétones cycliques (2), nous avons été amenés (*a*) à préparer, à titre de produits de référence, des tétraméthyl-3,3,5,5 méthylène-2 cyclohexanones (**1**) de même que quelques-uns de leurs produits de réduction comme le tétraméthyl-3,3,5,5 méthylène-2 cyclohexanol (**2***a*) et les cétones saturées (**3**) et (*b*) à examiner la stéréochimie de la réduction, par les hydrures complexes, des cétones saturées (**5**). Ce sont les résultats obtenus au cours de ces études qui font l'objet de la présente note.

(*e*) Y = OH

Résultats et discussion

On a préparé l'hydroxyméthylène-2 tétraméthyl-3,3,5,5 cyclohexanone (**1***e*) à l'aide de réactions connues (3) appliquées à la cétone saturée **4**. Le produit ainsi obtenu présente les caractéristiques qui lui ont été attribuées par Vonderwahl et Schinz (4). Le spectre r.m.n. de **1***e* ne présente à bas champ qu'un pic à 8.93 p.p.m. (J = 3 Hz) et un autre à 15.16 p.p.m. (J = 3 Hz) qui deviennent tous les deux des singulets par addition de D_2O et c'est sur la base de ces données que la forme hydroxyméthylénique est proposée; Garbisch (5) a déjà noté que des systèmes tendus favorisent ces formes. Plus récemment Barker et Bartley (6) ont suggéré que la constante de couplage *H*—O—C—*H* dépend de l'angle dièdre formé par ces protons; la constante de 3 Hz observée dans le cas présent suggèrerait que cet angle est d'environ 120°.

On peut transformer **1***e* en **1***a* en appliquant la technique de Manson et Wood (7); comme il a pu être démontré antérieurement (8) pour d'autres systèmes, **1***e* se dimérise pour donner **4**. Par ailleurs on a obtenu **1***b*, **1***c* et **1***d* en soumettant **1***e* à des réactions bien connues (9, 10); les spectres r.m.n. de ces dérivés ne montrent la présence que d'un seul proton éthylénique pour

2 4 5

(*a*) R = H
(*b*) R = CO—$C_6H_4NO_2$-*p*

les composés **1***b* et **1***c* et de deux types de protons éthyléniques (rapport 0.65:0.35) pour le composé **1***d*. En se basant sur la règle d'additivité (11)

$$\delta = 5.25 + \delta\ gem + \delta\ cis + \delta\ trans$$

on a construit le tableau 1 grâce auquel on a déduit que le groupe OBu est *trans* par rapport au carbonyle et que le groupe $-NC_5H_{10}$ est *cis* par rapport au groupement carbonyle. Dans le cas du thioéther énolique, 65% du SBu serait *cis* et 35% du SBu serait *trans* par rapport au carbonyle. Le tableau 2 met en relief l'influence stérique des substituants en α de la double liaison sur la position de l'équilibre *cis–trans* autour de la double liaison de thioéthers énoliques préparés au cours des dernières années dans notre laboratoire (12–14).

TABLEAU 1. Déplacements chimiques des protons vinyliques des cétones **1**

Produits	Isomères	Calculé	Observé	Pourcentage
1*c*	*cis*	7.09	—	—
	trans	7.31	7.33	100
1*d*	*cis*	6.98	6.90	65
	trans	7.20	7.53	35
1*b*	*cis*	6.67	6.30	100
	trans	6.92	—	—

Cette observation suggère que les variations notées dans le tableau 1 relativement à la position de l'équilibre *cis–trans* autour de la double liaison sont probablement dues à des effets stériques; par exemple, la présence dans **1***d* par rapport à **1***c*, d'une grande proportion d'isomère *cis* pourrait provenir du fait que le lien C—S est plus long que le lien C—O et que le groupe SBu, par opposition au groupe OBu, peut s'accommoder plus facilement, au point de vue stérique, avec la présence de l'oxygène voisin.

Le spectre u.v. du dérivé **1***b*, déterminé dans l'éthanol 95%, montre deux bandes d'absorption: l'une à 288 nm avec log ε = 3.84 et l'autre à 356 nm avec log ε = 3.24. Si le solvant contient une trace d'acide chlorhydrique, une seule bande est observée à 288 nm avec un log ε = 3.87; cette absorption serait due à la transition $\pi \rightarrow \pi^*$ des électrons π du carbonyle et de la double liaison conjuguée. L'autre absorption qui disparait en présence d'acide serait due aux électrons du système conjugué: carbonyle, double liaison et doublet libre sur l'atome d'azote.

La réduction de la cétone **1***a*, selon la méthode de Meerwein–Pondorff–Verley (15), conduit au tétraméthyl-3,3,5,5 méthylène-2 cyclohexanol (**2***a*) qui par traitement en milieu acide chlorhydrique (10) fournit la pentaméthyl-2,3,3,5,5 cyclohexanone (**3***a*). On peut obtenir la même cétone **3***a* plus aisément par désulfurisation du thioéther énolique **1***d* en présence de nickel de Raney (10). Par ailleurs, l'hydrogénation catalytique des méthylènecétones **1***b* et **1***c* en présence de palladium à 5% sur charbon fournit les cétones saturées correspondantes **3***b* et **3***c*.

La réduction, par $LiAlH_4$, des cétones saturées **3***a* et **3***b* conduit dans le premier cas à 94% d'alcool *cis* (**6***a*) et dans le deuxième cas à 80%

TABLEAU 2. Pourcentage d'isomères *cis* et *trans*[a] présents dans diverses butylthiométhylène-2 cyclohexanones

	Isomères *trans*		Isomères *cis*	
Produits	Observé	Pourcentage	Observé	Pourcentage
Diméthyl-4,4 (réf. 14)	7.60	100	—	—
Diméthyl-5,5 (réf. 13)	7.50	100	—	—
Triméthyl-3,5,5 (réf. 12)	7.45	78.8	6.85	21.2
Tétraméthyl-3,3,5,5	7.53	35	6.90	65

[a]La notation *trans* ou *cis* se réfère à la position du groupe butylthio- par rapport au groupement carbonyle.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

d'alcool *cis* (**6***b*); ces résultats impliquent que, dans chaque cas, le facteur principal influençant la stéréochimie de la réduction est la présence de méthyles axiaux en position β du centre réactionnel (16). La différence notable entre les résultats stéréochimiques obtenus, lors de la réduction de **3***a* et de **3***b*, pourrait être attribuée à la présence du groupe méthylpipéridine attaché au carbone en position 2; dans la conformation énergétiquement privilégiée, le groupe pipéridine vient masquer la face équatoriale du groupement carbonyle et force la réduction à se produire en partie par la face axiale. Ces résultats pourraient être utilisés pour déduire qu'il n'y a pas de complexation entre le réducteur et l'amine; en effet si tel était le cas, la conformation privilégiée de la chaîne latérale favoriserait une entrée encore plus grande de l'hydrure par la face équatoriale de la cétone **3***b*.

Partie expérimentale

Les techniques expérimentales générales ont déjà été rapportées (17). Les analyses par chromatographie en phase gazeuse (c.p.g.) ont été effectuées avec des chromatographes F et M, modèles 700 et 810; les conditions utilisées sont les suivantes: colonne de diglycérol à 14% avec 2% d'eau sur Chromosorb W 60–80 mesh, de 7 pieds × ¼ po; colonne de Zonyl E-7 à 10% sur Chromosorb W 60–80 mesh, lavé à l'acide et traité au diméthyldichlorosilane de 7 pieds × ¼ po; colonne de succinate de butanediol-1,4 à 10% sur Chromosorb P 60–80 mesh de 7 pieds × ¼ po; colonne d'hyprose à 15% sur Chromosorb P 30–60 mesh de 7 pieds × ¼ po; colonne de Carbowax 4000 à 10% sur Chromosorb W 60–80 lavé à l'acide et traité audi méthyldichlorosilane de 7 pieds × ¼ po; colonne de UCW-98 à 10% sur Chromosorb W 80–100 de 6 pieds × ⅛ po; le gaz vecteur utilisé est l'azote.

Méthylène-2 tétraméthyl-3,3,5,5 cyclohexanones substituées (1)

Hydroxyméthylène-2 tétraméthyl-3,3,5,5 cyclohexanone (1e)

Obtenu avec 95% de rendement, en suivant les indications de Johnson et Posvic (3), **1***e* présente les caractéristiques suivantes: p.é. 120–121 °C/24 Torr (litt.(3) p.é. 104 °C/11 Torr); n_D^{24} 1.4905 (litt.(4) n_D^{20} 1.4940); i.r. bande large entre 1640 et 1570 cm^{-1} due au carbonyle conjugué; u.v. (EtOH 95%) λ_{max} à 293 nm, log ε de 3.80; r.m.n. (CCl_4), signaux à 1.00 (singulet, deux méthyles), 1.26 (singulet, 2 méthyles), 1.43 singulet, —CH_2— en position 4), 2.11 (—CH_2— en position 6), 8.93 (doublet, J = 3 Hz., proton vinylique qui devient singulet dans D_2O) et 15.16 p.p.m. (doublet, J = 3 Hz, proton hydroxylique qui disparait dans D_2O); spectre de masse, ion moléculaire à *m/e* de 182.

Méthylène-2 tétraméthyl-3,3,5,5 cyclohexanone (1a)

Suivant la technique décrite par Manson et Wood (7), 4 g (22 mmol) de **1***e*, 16 g de carbonate de potassium et 16 ml de formaldéhyde à 37% sont agités à la température ambiante durant 30 min. L'extraction à la manière habituelle conduit, avec un rendement de 85%, à **1***a* qui présente les caractéristiques suivantes: p.é. 48 °C/0.05 Torr; n_D^{26} 1.4670; i.r. bandes à 1690 (carbonyle conjugué), 1610–1580 (double liaison) et 930 cm^{-1} (méthylène exocyclique); u.v. (EtOH 95%) λ_{max} à 230 nm et log ε = 3.69; r.m.n. (CCl_4) signaux à 1.01 (singulet, deux méthyles), 1.22 (singulet, deux méthyles), 1.60 (singulet, —CH_2— en position 4), 2.26 (singulet, —CH_2— en position 6), 5.22 (doublet, J = 1.5 Hz, proton vinylique *trans* par rapport au carbonyle) et 5.90 p.p.m. (doublet, J = 1.5 Hz, proton vinylique *cis* par rapport au groupe carbonyle); spectre de masse, ion moléculaire à *m/e* de 166.

La tétraméthyl-3,3,5,5 méthylène-2 cyclohexanone (**1***a*) ainsi obtenue, conservée quelques jours à la température ambiante, se transforme, avec un rendement quantitatif, en un solide blanc (**5**) qui, recristallisé de l'éther de pétrole, possède les caractéristiques suivantes: p.f. 53–54 °C; p.é. 80–85 °C/0.3 Torr; i.r. bandes à 1720 (carbonyle saturé), 1680 (double liaison), 1290, 1225, 1150 et 1070 cm^{-1} (C—O); r.m.n. (CCl_4) signaux de 0.9–1.05 (8 groupes méthyles), 1.30 (singulet, deux méthylènes entre les *gem*-diméthyles), 1.4–2.0 (massif de 6 protons des trois groupes méthylènes) et 2.40 p.p.m. (quadruplet, J = 11.25 et J = 36 Hz pour le méthylène en α du carbonyle); spectre de masse, ion moléculaire à *m/e* de 332.

Butoxyméthylène-2 tétraméthyl-3,3,5,5 cyclohexanone (1c)

La réaction de 5 g de l'énol **1***e* avec 9 ml de butanol en présence d'une quantité catalytique d'acide *p*-toluènesulfonique dans 20 ml de benzène, en suivant les indications de Seifert et Schinz (9), conduit à 6.4 g (98% du rendement théorique) de l'éther **1***c* qui présente les caractéristiques suivantes: p.é. 120 °C/0.7 Torr: n_D^{27} 1.4798; i.r. bandes à 1670 (carbonyle conjugué) et 1577 cm^{-1} (double liaison); u.v. (EtOH 95%) λ_{max} à 278 nm et log ε = 4.19; r.m.n. (CCl_4) signaux à 1.00 (singulet, trois méthyles), 1.26 (deux méthyles), 1.50 (singulet, —CH_2— en position 4), 2.04 (singulet, —CH_2— en position 6) et 7.33 p.p.m. (singulet, proton vinylique); spectre de masse, ion moléculaire à *m/e* de 238.

Butylthiométhylène-2 tétraméthyl-3,3,5,5 cyclohexanone (1d)

Ce dérivé est préparé avec un rendement de 93% en suivant la méthode décrite par Ireland et Marshall (10); il se présente sous forme de liquide de p.é. 130 °C/0.4 Torr; n_D^{27} 1.5245; i.r. bandes à 1665 (carbonyle conjugué) et 1520 cm^{-1} (double liaison); u.v. (EtOH 95%) λ_{max} à 320 nm et log ε = 4.33; r.m.n. (CCl_4) signaux à 1.07 (singulet, trois méthyles), 1.23 (singulet, deux méthyles), 2.10 et 2.19 (singulets d'intensités relatives 0.35:0.65 dus aux —CH_2— *syn* et *anti* en position 6) et 6.90 et 7.53 p.p.m. (singulets d'intensités relatives de 0.65 et 0.35, dus aux protons vinyliques des isomères *cis* et *trans* autour de la double liaison); spectre de masse, ion moléculaire à *m/e* de 254.

N-Pipéridinométhylène-2 tétraméthyl-3,3,5,5 cyclohexanone (1b)

Préparé avec un rendement de 75% par action de la pipéridine sur l'énol **1***e* en présence d'acide *p*-toluènesulfonique et de benzène, ce dérivé se présente sous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

forme de solide de p.f. 73–74 °C; p.é. 135 °C/0.5 Torr; i.r. bandes à 1620 (carbonyle conjugué) et 1515 cm^{-1} (double liaison); u.v. (EtOH 95%) λ_{max} à 288 (log ε de 3.84) et 356 nm (log ε de 3.24) et dans EtOH 95% contenant des traces d'acide chlorhydrique, λ_{max} à 286 nm avec log ε de 3.87; r.m.n. (CCl_4) signaux à 0.97 (singulet, deux méthyles), 1.17 (singulet, deux méthyles), 1.47 (singulet, —CH_2— en position 4), 1.99 (singulet, —CH_2— en position 6) et 6.30 p.p.m. (singulet, proton vinylique); spectre de masse, ion moléculaire à *m/e* de 249.

Méthylène-2 tétraméthyl-3,3,5,5 cyclohexanol (2a)

La réduction de 3 g (18 mmol) de la cétone **1***a*, par 6 g d'isopropylate d'aluminium en présence de 100 ml d'alcool isopropylique selon la méthode de Meerwein–Pondorff–Verley (15), conduit, après extractions habituelles, à 2.35 g (84% rendement) d'alcool purifié par l'intermédiaire de son *p*-nitrobenzoate (**2***b*) de p.f. 108 °C; i.r. bandes à 1725 (carbonyle de l'ester), 1640 (double liaison), 1608 et 1520 (noyau aromatique) et 880 cm^{-1} (double liaison exocyclique); r.m.n. (CCl_4), signaux à 1.02 (singulet, groupe méthyle), 1.18 (singulet, groupe méthyle), 1.27 (singulet, deux groupes méthyles), 1.40 (singulet, —CH_2— en position 4), 1.57 et 1.87 (hydrogènes en position 6), 4.91 (massif, =CH_2), 5.86 (quadruplet, J = 12 et 4.8 Hz, C*H*O—) et 8.25 p.p.m. (singulet, 4 protons aromatiques); spectre de masse, ion moléculaire à *m/e* de 317. La saponification de ce dérivé conduit à l'alcool **2***a* pur (par c.p.g. sur colonne de butanediol-1,4 succinate) de p.é. 126 °C/38 Torr; n_D^{26} 1.4758; i.r. bandes à 3350 (hydroxyle), 1640 (double liaison), 1050 (C—O) et 900 cm^{-1} (double liaison exocyclique); r.m.n. (benzène) signaux à 0.82 (singulet, groupe méthyle), 1.00 (singulet, méthyle), 1.08 (singulet, deux groupes méthyles), 1.10–2.00 (massif, méthylènes en position 4 et 6 et proton hydroxylique), 4.10–4.60 (massif, C*H*OH), 4.94 et 5.32 p.p.m. (protons vinyliques); spectre de masse, ion moléculaire à *m/e* de 168.

Pentaméthyl-2,3,3,5,5 cyclohexanones (5)

Pentaméthyl-2,3,3,5,5 cyclohexanone (5a)

Par désulfurisation de la butylthiométhylène-2 tétraméthyl-3,3,5,5 cyclohexanone (1d)—La désulfurisation de 4.4 g (17 mmol) de l'éther **1***d* par 22 g de nickel de Raney en présence de 80 ml d'éthanol en suivant les indications de Ireland et Marshall (10), conduit, après extractions habituelles, à 2.25 g (78% rendement) de la cétone désirée **5***a* de p.é. 92 °C/15 Torr; n_D^{28} 1.4538; i.r. bandes à 1705 (carbonyle) et 1375 cm^{-1} (*gem*-diméthyles); r.m.n. (100 MHz, CCl_4) signaux à 0.81 (singulet, groupe méthyle), 0.89 (doublet, J = 6.5 Hz, méthyle en position 2), 0.98 (singulet, groupe méthyle), 1.04 (singulet, deux groupes méthyles), 1.48 (quadruplet, J = 14 et 1.25 Hz, proton équatorial en position 4), 1.70 (doublet, J = 14 Hz, proton axial en position 4), 2.03 (quadruplet, J = 12.5 et 1.25 Hz, proton équatorial en position 6), 2.18 (doublet, J = 12.5 Hz, proton axial en position 6) et 2.19 p.p.m. (quadruplet, J = 6.5 Hz, proton axial en position 2); spectre de masse, ion moléculaire à *m/e* de 168. La semicarbazone de cette cétone se présente sous forme de solide de p.f. 186–188 °C; spectre de masse, ion moléculaire à *m/e* de 225. La dinitro-2,4 phénylhydrazone dérivée de **5***a* se présente sous forme de solide de p.f. 157–158 °C, r.m.n. ($CDCl_3$) signaux à 0.83 (singulet, méthyle), 0.95 (singulet, méthyle), 1.17 (singulet et doublet, trois méthyles), 1.50 (singulet, méthylène en position 4), 1.9–2.7 (multiplet, trois protons du méthylène en position 6 et du proton en position 2), 7.88 (doublet, J = 10 Hz, proton aromatique en position 6), 8.68 (quadruplet, J = 10 et 2.5 Hz, proton aromatique en position 5), 9.83 (doublet, J = 2.5 Hz, proton aromatique en position 3) et 11.10 p.p.m. (singulet du —N*H*—); spectre de masse, ion moléculaire à *m/e* de 348.

Par transposition en milieu acide du tétraméthyl-3,3,5,5 méthylène-2 cyclohexanol (2)—On chauffe à reflux, durant 70 h, une solution éthanolique de HCl à 10% et 0.5 g d'un mélange (74:26) de cétone **5***a* et d'alcool **2***a*. On obtient alors 0.45 g (90% du rendement) de cétone **5***a* chromatographiquement pure qui possède les mêmes constantes physiques et données spectrales que la cétone **5***a* obtenue dans la section précédente.

Tétraméthyl-3,3,5,5 N-pipéridinométhyl-2 cyclohexanone (5b)

L'hydrogénation de 0.5 g de cétone **1***b*, en solution dans 10 ml d'éthanol absolu en présence de 60 mg de Pd/C à 5%, conduit à 0.45 g (90% rendement) de la cétone **5***b* présentant les caractéristiques suivantes: p.f. 86.5 °C; i.r. bandes de Bohlmann à 2793, 2750 et 2705 et C=O à 1705 cm^{-1}; r.m.n. (C_6H_6) signaux à 0.71 (singulet, CH_3), 0.81 (singulet, CH_3), 0.86 (singulet, CH_3), 0.98 (singulet, CH_3), 1.27 (singulet, CH_2 en position 4), 1.20–1.70 (massif, 6 protons, —CH_2—CH_2—CH_2), 1.70–2.50 (massif, 7 protons soit CH_2—N—CH_2, CH_2—C—CH), 2.83 et 2.93 p.p.m. (N—CH_2 sous forme

ABX avec J_{AB} = 21, J_{AX} = 10 et J_{BX} = 11.2 Hz); spectre de masse, ion moléculaire à *m/e* de 251.

Butoxyméthyl-2 tétraméthyl-3,3,5,5 cyclohexanone (5c)

L'hydrogénation de 900 mg d'éther **1***c*, en solution dans 5 ml d'éthanol absolu et en présence de 60 mg de Pd/C à 5%, conduit à l'absorption d'une mole d'hydrogène et fournit 750 mg (83% rendement) de cétone **5***c* présentant les caractéristiques suivantes: p.é. 138 °C/10 Torr; n_D^{26} 1.4587; i.r. bandes à 1710 (C=O); r.m.n. (C_6H_6) signaux à 1.88 (doublet, J = 12 Hz, proton C), 2.10 (doublet, J = 12 Hz, proton D), 2.34 (quadruplet, J_{AX} = 3.91 et J_{BX} = 8.09 Hz, proton X), 2.30 (triplet, J = 6.4 Hz des hydrogènes), 3.35 (quadruplet, J_{AX} = 3.91 et J_{AB} = 9.23 Hz, proton A) et 3.83 p.p.m. (quadruplet, J_{BX} = 8.09 et J_{AB} = 9.23 Hz, proton B). Le spectre a pu être reproduit par un ordinateur à partir des données suivantes: J_{AB} = 9.23, J_{BX} = 8.09 et J_{AX} = 3.91 Hz, et δ_X = 140.75, δ_A = 201.2 et δ_B = 230.3 Hz; spectre de masse, ion moléculaire *m/e* à 240 trop peu intense pour être mesuré.

Cyclohexanols 6 et 7

Pentaméthyl-2,3,3,5,5 cyclohexanols (6a et 7a)

Réduction de la cétone 5a par $LiAlH_4$—La réduction de 0.7 g (4 mmol) de cétone **5***a* par 0.02 g (5 mmol) de $LiAlH_4$ dans 10 ml d'éther anhydre, conduit à 0.68 g (96% rendement) d'alcools correspondants qui peuvent être analysés en c.p.g. sur une colonne de Zonyl à 110 °C ou de diglycérol à 105 °C; la quantité d'alcool *cis* **6***a* est de 95 ± 1% et cet alcool est purifié par l'intermédiaire de

son *p*-nitrobenzoate qui, recristallisé dans le méthanol, présente les caractéristiques suivantes: p.f. 92 °C; i.r. bandes à 1740 (C=O) et 1285 cm^{-1} (C—O); r.m.n. (CCl_4) 0.9–1.15 (massif, cinq méthyles), 1.15–2 (massif, 5 protons), 5.40 (proton carbinolique) et 8.18 p.p.m. (massif, 4 protons aromatiques); spectre de masse, pas d'ion moléculaire; poids moléculaire (osmométrie, dans $CHCl_3$), trouvé 313 et calculé 319.

L'hydrolyse de ce dérivé conduit, avec un rendement de 90%, au pentaméthyl-2,3,3,5,5 cyclohexanol *cis* (**6***a*) pur qui, après recristallisation dans l'éther de pétrole, se présente sous forme d'aiguilles fines ayant les caractéristiques suivantes: p.f. 72 °C; p.é. 110 °C/17 Torr; i.r. bandes à 3290 (OH), 1070 et 1022 cm^{-1} (C—O); r.m.n. (100 MHz, CCl_4) signaux à 0.93–1.1 (massif, 15 protons de 5 groupes méthyles), 1.22–1.40 (massif, 5 protons), 2.90 (singulet du OH, échange avec D_2O) et 4.03 p.p.m. (octuplet, J = 4.25, 5.5 et 8.5 Hz, proton carbinolique); spectre de masse, l'ion moléculaire n'est pas observé.

Réduction de la cétone **5***a par le sodium et l'éthanol*—La cétone **5***a* (1 g 6 mmol), réduite par du sodium (1 g, 44 mmol) et 25 ml d'éthanol, conduit à 0.9 g (90% rendement) d'un mélange d'alcools dans lequel **6***a* et **7***a* sont présents dans le rapport 22:78. La chromatographie sur alumine permet d'enrichir le mélange en produit *trans* (**7***a*) qui est ensuite purifié par l'intermédiaire de son dérivé *p*-nitrobenzoate présentant les caractéristiques suivantes: p.f. 102.5–103.5 °C; i.r. bandes à 1705 (C=O) et 1205 cm^{-1} (C—O); r.m.n. (CCl_4) 0.87–1.01 (massif, 4 méthyles), 1.15 (singulet, méthyle), 1.3–2.1 (massif, 5 protons), 5.07 (proton carbinolique) et 8.22 p.p.m. (massif, 4 protons aromatiques); spectre de masse, pas d'ion moléculaire; poids moléculaire (osmométrie avec $CHCl_3$), trouvé 318 et calculé 319.

L'hydrolyse de ce dérivé conduit au pentaméthyl-2,3,3,-5,5 cyclohexanol *trans* (**7***a*) pur présentant les caractéristiques suivantes: p.f. 46 °C; p.é. 110 °C/20 Torr; i.r. bandes à 3300 (OH) et 1025 cm^{-1} (C—O); r.m.n. (100 MHz, CCl_4) pics à 0.85–1.00 (massif, 4 méthyles), 1.01 (singulet, méthyle), 1.05–1.54 (massif, 4 protons), 2.09 (singulet, OH échange avec D_2O) et 3.39 p.p.m. (proton carbinolique); spectre de masse, ion moléculaire à *m/e* de 170.

Tétraméthyl-3,3,5,5 N-pipéridinométhyl cyclohexanols **6***b et* **7***b*

Réduction de la cétone **5***b par* $LiAlH_4$—La réduction de 200 mg (0.8 mmol) de cétone **5***b*, par 120 mg (3 mmol) de $LiAlH_4$, conduit, avec un rendement quantitatif, à un mélange d'amino-alcools qui peut être analysé par c.p.g. à l'aide d'une colonne U.C.W. 98 à 170 °C; les alcools **6***b* et **7***b* sont présents dans le rapport 80:20. Deux recristallisations, dans l'éther de pétrole 30–60, permettent d'isoler l'alcool **6***b* pur présentant les caractéristiques suivantes: p.f. 62–63 °C; p.é. 160 °C/7 Torr; i.r. bandes à 3200 (OH), 2800 et 2600 (bandes de Bohlmann), 1110 et 1055 cm^{-1} (C—O); r.m.n. signal à 4.00 p.p.m. (massif du proton carbinolique); spectre de masse, ion moléculaire à *m/e* de 253.

Réduction de la cétone **5***b par le sodium dans l'éthanol*—La réduction de 2 g de cétone **5***b*, par 0.6 g de sodium en présence de 100 ml d'éthanol, fournit 2 g d'un mélange d'amino-alcools dans lequel les alcools **6***b* et **7***b* sont présents dans le rapport 14:86. On peut déduire des propriétés de ce mélange que le proton carbinolique de l'alcool *trans* **7***b* apparaît à 3.5 p.p.m.

Vapor Pressures of Triethylamine + Chloroform and of Diethyl Ether + Chloroform at 298.15 K

YASH PAUL HANDA AND DAVID EDWARD JONES[1]

Department of Chemistry, University of Otago, Dunedin, New Zealand

Received April 2, 1975

YASH PAUL HANDA and DAVID EDWARD JONES. Can. J. Chem. 53, 3299 (1975).

Vapor pressures of triethylamine + chloroform and of diethyl ether + chloroform were measured at 298.15 K with a calibrated quartz spiral. The ideal associated solution model has been used to determine the equilibrium constants and standard enthalpies of formation of the complexes from the thermodynamic properties derived from the vapor pressure measurements and from earlier calorimetric measurements. These complex formation constants are compared with values obtained by calorimetric and spectroscopic methods.

YASH PAUL HANDA et DAVID EDWARD JONES. Can. J. Chem. 53, 3299 (1975).

On a mesuré, à 298.15 K et à l'aide d'une spirale en quartz calibrée, les tensions de vapeur de mélange de triéthylamine + chloroforme et d'éther éthylique + chloroforme. On a utilisé le modèle de la solution associée idéale pour déterminer les constantes d'équilibre et les enthalpies standards de formation des complexes à partir des propriétés thermodynamiques obtenues à l'aide des mesures de tension de vapeur et aussi en faisant appel à des mesures calorimétriques antérieures. On compare ces constantes de formation de complexes avec celles obtenues par des méthodes calorimétriques et spectroscopiques.

[Traduit par le journal]

Introduction

The experimental investigation of liquid mixtures which form complexes has in the past been largely the domain of spectroscopic and other nonthermodynamic measurements. Often there is evidence for complex formation in the system of interest from solid–liquid phase equilibrium studies. Recently, thermodynamic measurements (1, 2) have been used with considerable success both to supplement the results obtained independently and to improve their precision.

In particular triethylamine (A) + chloroform (B) has been studied extensively and there is considerable spectroscopic and thermodynamic evidence for the chemical reaction

$$[1] \qquad A + B = AB$$

The molar excess enthalpies (3), partial molar enthalpies of solution (4) at 298 K, and the vapor pressures (2) at 283.15 K of this system have been used in conjunction with the ideal associated solution model to determine the equilibrium constant and standard enthalpy of formation of the complex AB. The same model has been used to explain the sign of the temperature coefficient of the molar excess volume for this system and other systems containing chloroform (5).

Complete application of the theory of the ideal associated solution model to triethylamine + chloroform has not been entirely satisfactory since the vapor pressures were measured with a mercury manometer (2) and restricted in the temperature range studied. We report here the vapor pressures of triethylamine + chloroform at 298.15 K measured with an apparatus which uses a calibrated quartz spiral as the pressure sensor.

Thermodynamic and spectroscopic evidence suggests that diethyl ether (A) + chloroform (B) mixtures consist of A, B, and the complex AB. Molar excess enthalpies of ethers + chloroform at 298 K (6) have been used with the ideal associated solution model to determine the complex formation constants (7). Constant pressure liquid–vapor equilibrium results for diethyl ether + chloroform at higher temperatures were analyzed using the ideal associated solution model (7). The equilibrium constant at 298 K (obtained by extrapolation) was in good agreement with that obtained from calorimetric and spectroscopic measurements but the scatter in the experimental results precluded determination of the standard enthalpy of formation of

the complex AB. We report measurements of the vapor pressures of diethyl ether + chloroform at 298.15 K.

Experimental

Materials

Chloroform and triethylamine were purified as reported previously (2).

Diethyl ether (Baker, anhydrous A.R. grade) was shaken with one-tenth its volume of a 10% (by mass) $NaHSO_3$ solution intermittently for a period of 1 h. The aqueous phase was withdrawn and the ether washed with a saturated NaCl solution containing 0.5% (by mass) NaOH. Diethyl ether was then washed initially with a saturated NaCl solution containing a small amount of H_2SO_4, and subsequently with two portions of saturated NaCl solution. Storage of diethyl ether overnight over lithium aluminum hydride was followed by refluxing for 2 h in the presence of lithium aluminum hydride and then by fractional distillation in a column of 15 theoretical plates at a reflux ratio of 20. Dry and oxygen free nitrogen was bubbled through during the treatment with lithium aluminum hydride and the distillation. The distillation apparatus was wrapped in black cloth to exclude light.

All materials were thoroughly degassed by vacuum sublimation (8) and then by successive freezing (using a Dry Ice – acetone mixture), pumping, and distillation cycles. The degassed liquids were distilled under vacuum and the middle fractions collected in preweighed ampoules. The ampoules were sealed under vacuum and stored in the dark.

Constant values of the vapor pressure of a given liquid sample resulted when successive amounts of material were distilled from it and this is good evidence for the purity of each of the liquids used.

Vapor Pressure Measurements

Vapor pressures of mixtures of known total composition and volume were measured in a vacuum system similar to one used previously (9). A quartz spiral mounted in a pressure gauge (Texas Instruments Model 145) was used as the pressure sensor. The quartz spiral was calibrated with a precision Hg manometer over the pressure range covered by each system studied. The equilibrium cell was thermostatted to 298.15 K with a probe and temperature controller (Tronac Model 40).

Material was added to the equilibrium cell from ampoules on a line external to the thermostat bath. For each system two sets of measurements were done in order to cover the entire mole fraction range with some overlap about the midregion of the mole fraction scale.

Table 1 gives a comparison of the measured and literature values of the vapor pressures of triethylamine, chloroform, and diethyl ether at 298.15 K.

TABLE 1. Vapor pressures p of pure materials at 298.15 K

mole fractions are less than ±0.004 and those in the vapor pressures arising both from random and systematic errors in the cathetometer and from fluctuations in the thermostat are ±0.015 kPa or less.

The liquid and vapor compositions and the calculated vapor pressures in Table 2 were determined from a set of equilibrium pressures, known total amounts of each component, and known total volume of the equilibrium cell line by using a modified form of Barker's analysis (15). The properties of the pure components listed in Tables 1 and 3 were used in the analysis.

The molar excess Gibbs free energy, G_m^E of a binary mixture of mole fractions x_k (liquid) and y_k (vapor) is given by

$$[2]\quad G_m^E = \sum_k x_k[RT \ln (y_k p/x_k p_k^0) + (B_{kk} - V_k^0)(p - p_k^0) + \delta(1 - y_k)^2 p]$$

where k = A, B, and p_k^0 and V_k^0 are respectively the saturated vapor pressure and the molar volume of liquid k at temperature T. The term δ is given by $2B_{AB} - B_{AA} - B_{BB}$, where B_{kj} is a second virial coefficient.

An iterative technique (9) was used to determine the liquid and vapor compositions and the coefficients in the series

$$[3]\quad G_m^E/\text{kJ mol}^{-1} = x_A x_B \sum_{i=1}^{m} g_i(1 - 2x_B)^{i-1}$$

with x_B the mole fraction of chloroform, were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

adjusted to minimize the difference in the observed and calculated pressures. Use of reasonable estimates (18) for B_{AB}, the cross virial coefficient of the mixture, had no significant effect on the calculated values for G_m^E, hence the results given in Table 2 are obtained by setting δ equal to zero.

The results for both systems were fitted satisfactorily using $m = 3$ in [3] and the coefficients g_i and their respective standard deviations are listed in Table 4. Included in Table 4 are the values of $\sigma(p)$ the standard deviation in the vapor pressure given by

$$[4] \qquad \sigma(p) = \{\sum(\Delta p)^2/(N - m)\}^{1/2}$$

where Δp is the deviation of the calculated from the observed vapor pressure and N is the number of experimental points. The calculated liquid and vapor compositions and vapor pressures listed in Table 2 were determined using the values of g_i given in Table 4.

The values of G_m^E obtained from our vapor pressure measurements at 298.15 K were combined with published values of the molar excess enthalpy, H_m^E at 298 K (3, 6) to give TS_m^E at 298 K, where S_m^E is the molar excess entropy. Table 5 lists the excess thermodynamic properties of triethylamine + chloroform and of diethyl ether + chloroform at 298 K.

Discussion

With the notation given in Table 6 the equilibrium constant K for [1] can be expressed as

$$[5] \qquad K = r(1 - r)/(x_A x_B - r + r^2)$$

where $r = n/(N_A + N_B)$.

Previously, McGlashan and Rastogi have shown (19) that K can be related to the activities a_A and a_B by

$$[6] \qquad K = (1 - a_A - a_B)/a_A a_B$$

which is a contracted form of the more general expression

$$[7] \qquad K_1 + K_2 a_B = (1 - a_A - a_B)/a_A a_B$$

derived for systems in which there was an additional equilibrium resulting in the formation of complex AB_2.

Expressions for molar excess thermodynamic properties X_m^E of mixtures which form complexes have been derived (1, 2) using the ideal associated solution model with the following thermodynamic cycle (p^θ = 101.325 kPa)

$$[8] \qquad \begin{array}{ccc} A(1)\,[N_A,T,p^\theta] + B(1)\,[N_B,T,p^\theta] & \xrightarrow{(N_A + N_B)\Delta X_m} & \text{Mixture}(1)\,[N_A + N_B,T,p^\theta] \\ \downarrow n\Delta X^\theta & & \uparrow \Delta X^* \\ A(1)\,[N_A - n,T,p^\theta] + B(1)\,[N_B - n,T,p^\theta] + AB(1)\,[n,T,p^\theta] & & \end{array}$$

where X is any extensive thermodynamic property. The notation used is summarized in Table 6.

The molar X of mixing, ΔX_m is related to the standard X of complex formation ΔX^θ by

$$[9] \qquad (N_A + N_B)\Delta X_m = n\Delta X^\theta + \Delta X^*$$

Use of the ideal associated solution model allows representation of ΔX^* by the appropriate ideal solution expression.

The equation for H_m^E has been derived previously (3) and applied to various systems (1) and will not be discussed here. The following expressions were obtained for G_m^E and S_m^E (2)

$$[10] \qquad G_m^E = RT[x_A \ln(1 - r/x_A) + x_B \ln(1 - r/x_B) - \ln(1 - r)]$$

$$[11] \qquad S_m^E = r\Delta H^\theta/T - R[x_A \ln(1 - r/x_A) + x_B \ln(1 - r/x_B) - \ln(1 - r)]$$

The equation for V_m^E, the molar excess volume

$$[12] \qquad V_m^E = r\Delta V^\theta$$

has been applied and discussed elsewhere (5).

The methods used to calculate K and ΔH^θ have been described (2) and can be summarized as follows: (*i*) the term $(1 - a_A - a_B)/a_A a_B$ calculated from the smoothed activities, which were in turn derived from the vapor pressure results, was plotted against a_B as indicated by [7], (*ii*) [10] was solved for r and the value of r obtained was substituted in [5] to obtain K, (*iii*) values of S_m^E derived from Table 5 were used in [11] and

[b]Reference 4.

r values were adjusted to give the most constant value of ΔH^θ over the entire mole fraction range.

The values of K and ΔH^θ (where determined) at 298 K for triethylamine + chloroform are given in Table 7. These values are compared with values previously reported and obtained by calorimetric or spectroscopic methods. With the exception of those values of K derived directly from the vapor pressure measurements there is satisfactory agreement. The low values of K which result from the use of [7] and [10] may be attributed to failings in the ideal associated solution model. A reasonable estimate of the 'physical' contribution to G_m^E would increase the value of K.

Bertrand (20) has discussed the effect of an estimation of the physical contribution on the results obtained for triethylamine + chloroform.[2] The values of K and ΔH^θ derived by application of this extension of the ideal associated solution model to the calorimetric results (3, 4) are respectively 2.0 ± 0.5 and -20.4 ± 2 kJ mol^{-1}. These values are claimed to be in better agreement with those derived from spectroscopic studies (Table 7). Use of the same values for the weighting and interaction parameters introduced by Bertrand gives a physical contribution to G_m^E of approximately 200 J mol^{-1} and $K/K_{id} = 1.4$ where K_{id} is given by [5]. The approximations involved in using (*i*) the solubility parameters to estimate the interaction parameter and (*ii*) the same weighting and interaction parameters as used for the calorimetric results indicate the qualitative nature of these calculations. The range of K values and their respective uncertainties in Table 7 includes the possible variation in K from an estimate of the physical contribution to X_m^E.

The values of K (and ΔH^θ where determined) at 298 K for diethyl ether + chloroform are summarized in Table 8. For comparison values previously obtained by spectroscopy, calorimetry, and liquid–vapor equilibrium are also listed.

Application of Bertrand's procedure (20) for estimation of the physical contribution to G_m^E

[2]We are indebted to one of the referees for bringing this paper to our attention.

Equation 10	1.9 ± 0.3	
Equation 11	2.0 ± 0.5	12.6 ± 0.3

[a]Reference 7, K values of 1.46 and 3.76 based on n.m.r. measurements in CCl_4 and c-C_6H_{12} solutions respectively.

(using the solubility parameters to estimate the interaction parameter) gives qualitatively the same results as obtained for triethylamine + chloroform. In view of the magnitude of G_m^E and the effect of an estimation of the physical contribution on the value of K, the values of K obtained directly from the vapor pressure results using [7] and [10] are unexpectedly large and in direct contrast with the corresponding results for triethylamine + chloroform.

Furthermore, the values of $(\partial V_m^E/\partial T)_p$ are of opposite sign for diethyl ether + chloroform (21) and for triethylamine + chloroform (5). In the former system $(\partial V_m^E/\partial T)_p$ is positive, as expected for a system in which there is complex formation. The term involving the variation in extent of complex formation with temperature is necessarily positive and for diethyl ether + chloroform is larger in magnitude than that which includes the temperature dependence of ΔV^0, the molar volume of complex formation.

NOTE ADDED IN PROOF: Becker *et al.* (22) reported vapor pressure measurements for diethyl ether and chloroform at 298.15 K and found K = 1.742 from application of the ideal associated solution model to their results.

Mechanism of Electron Capture and Hydrogen Formation by HBr Irradiated in Mixtures with C_2F_6, CO_2, and Xe

SURJIT S. NAGRA AND DAVID A. ARMSTRONG
Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received April 16, 1975

SURJIT S. NAGRA and DAVID A. ARMSTRONG. Can. J. Chem. **53**, 3305 (1975).

The gas phase ^{60}Co γ-radiolysis of HBr in mixtures with C_2F_6 and CO_2 has been studied at room temperature, using doserates determined from ionization chamber measurements. A new value of $W_{C_2F_6} = 32.7$ eV is reported, but W_{CO_2} was in agreement with earlier work. Ionization yields and hydrogen yields in the mixtures followed a linear energy partitioning equation.

The increase in the fraction of scavengable electrons with increasing pressure of buffer gas can be satisfactorily explained by enhanced moderation of the energies of subexcitation electrons. A study of the competition for thermal electrons between SF_6 and HBr indicates that the rate of electron capture by HBr maintains a second order dependence on HBr pressure over the 50 to 600 Torr range both in the presence and absence of buffer gas. There was no evidence for the collisional stabilization of HBr^{-*} by the buffer gases and it is pointed out that thermal electron capture may involve $(HBr)_2$ dimers.

SURJIT S. NAGRA et DAVID A. ARMSTRONG. Can. J. Chem. **53**, 3305 (1975).

On a étudié, à la température de la pièce, la radiolyse-γ (^{60}Co) en phase gazeuse du HBr en mélange avec C_2F_6 et du CO_2; pour ces études on a utilisé des vitesses de dose déterminés à partir de mesures de chambre à ionisation. Une nouvelle valeur de $W_{C_2F_6} = 32.7$ eV est obtenue mais la valeur de W_{CO_2} est en accord avec cette détermination lors de travaux antérieurs. Des rendements en ionisation et des rendements en hydrogène dans les mélanges suivent une équation de partitionnement d'énergie qui est linéaire.

Une augmentation dans la fraction d'électrons piégeables avec une augmentation de la pression du gaz tampon peut être expliquée facilement par une modération accrue des énergies des électrons sous-excités. Une étude de la compétition pour les électrons thermiques entre SF_6 et HBr indique que la vitesse de capture des électrons par HBr maintient une dépendance du second ordre sur la pression de HBr entre 50 et 600 Torr en présence et en absence de gaz tampon. Il n'y a pas d'indication pour une stabilisation provenant de collision de HBr^{-*} avec les gaz tampons et on indique que la capture d'électron thermique peut impliquer des dimères de $(HBr)_2$.

[Traduit par le journal]

Introduction

Electron capture reactions in HBr have previously been studied by both physical and chemical techniques. Low pressure beam experiments (ref. 1, chapt. 6) have established the existence of a resonance capture reaction

$$[1] \qquad e + HBr \rightarrow H + Br^- \qquad \text{(1)}$$

having a peak cross section of 2.7×10^{-16} cm^2 molecule^{-1} at 0.3 eV. Chemical studies of the competition for thermal electrons between HBr and CCl_4 (2) and HBr and SF_6 (3) have demonstrated that there is a second reaction occurring at thermal or near thermal electron energies and with a rate which is second order in HBr. As in the case of related experiments with HCl (4, 5) these studies are consistent with the formation of one molecule of hydrogen per electron captured. The purpose of the present work was to extend the competition-kinetic studies to systems containing large amounts of buffer gases so that measurable electron yields could be obtained at lower HBr pressures and the effects of stabilizing 'third bodies' on the rate of capture examined. Sulfur hexafluoride was used as the electron scavenger since it does not react with hydrogen atoms (5) and the kinetics of its electron capture reactions have been extensively studied (1). Also its electron capture cross section peaks sharply near zero, making it highly selective for low energy electrons.

Hexafluoroethane, carbon dioxide, and xenon were chosen as buffer gases since they are chemically inert to thermal electrons (see refs. 1, 6–8) and cannot themselves produce hydrogen. Furthermore the radiolyses of C_2F_6 (9, 10) and

CO_2 (11, 12) have been studied and the yields and reactions of primary free radicals and ions are reasonably well understood.

The electrons were produced by irradiating the HBr – buffer gas mixture with ^{60}Co γ rays. Since the radiation ionizes and excites both the HBr and the buffer gas molecules, the product yields can also be used to obtain information concerning the partition of energy in the mixtures. For the HBr–C_2F_6 and HBr–CO_2 systems the energy partitioning was relatively straightforward and it is discussed here. For the HBr–Xe system there was concrete evidence for complex interactions between the excited species of the two components. The results dealing with this will be presented and discussed in detail elsewhere. Only the competition for thermal electrons in the HBr–Xe system is considered here.

Experimental

Materials

Hydrogen bromide (99.8% minimum purity), carbon dioxide (99.6% minimum purity), SF_6 (99.99% pure), and hexafluoroethane (99.6% pure) were all obtained from the Matheson company. The hydrogen bromide was purified by irradiation with X-rays and distillation through Cu turnings and a trap at 170 K before being stored at liquid nitrogen temperature. All other gases were condensed in liquid nitrogen and thoroughly degassed before distillation through the trap at 170 K. Middle fractions were stored in bulbs attached to the mercury free preparation line.

Apparatus and Procedure

Samples for product yield determinations were irradiated in 10 cm diameter cylindrical Pyrex cells of volume 354 cm^3 at a dose rate of $\sim 2.6 \times 10^{18}$ eV g^{-1} h^{-1} to total doses of 1 to 6×10^{18} eV g^{-1}. The cells were sealed during irradiation by Hoke high vacuum metal valves with Teflon seats. Prior to this they were filled with the required quantities of each gas measured in standard bulbs with a Wallace-Tiernan precision dial manometer.

After ^{60}Co radiolysis with an AECL γ cell 220 the condensible gases were condensed in a small liquid nitrogen trap attached to the radiation cell. Noncondensible gases were pumped into a calibrated volume and the hydrogen content established by the fall in pressure on diffusion through a heated palladium thimble as previously described (3).

Samples for ionization yield determinations were prepared on the same vacuum line and transferred to cylindrical Pyrex cells fitted with coaxial electrodes (3) and having the same 10 cm diameter as those used for product yield determinations. However, these cells had a volume of 230 ml and were irradiated at a somewhat lower dose rate of about 5.2×10^{16} eV g^{-1} h^{-1} to facilitate complete ion collection. Saturation ionization currents were obtained with a Keithly model 621 electrometer connected to the center electrode and a 0–6000 V high voltage power supply attached to the outer one. Good current–voltage plateaus, which were independent of polarity, were obtained in all cases.

Dose Rate Determinations

As in previous work with CO_2, C_2F_6, and several other gases (13, 14), plots of saturation ionization current, I^s, *vs.* pressure were linear over the range 50 to 700 Torr, see Fig. 1. The dose rate, D_m, in eV per h for each mixture in the ionization chamber was calculated from the sum of the dose rates of the two components, each taken as $(3600 I^s W/e)$, where I^s is the saturation ionization current read from Fig. 1 for the required partial pressure of the component, e is the electron charge, and W the energy required to create an ion pair in the pure component (13–15, ref. 1, Table 2.1).

The dose rates used in the determination of product yields were obtained in the following way. The total dose expected for a mixture of the same composition in the ionization chamber was calculated as described above and then multiplied by a constant factor to correct for the increased γ ray intensity. The hydrogen yield from pure HBr irradiated at the higher intensity and the known value of $G(H_2)_{HBr} = 9.8 \pm 0.1$ (5) molecules per 100 eV were used to calculate the dose rate in HBr. The intensity factor was obtained by comparing this to the dose rate in HBr in the ionization chamber calculated from the saturation ionization currents and W_{HBr}.

Results

W Values and Ionization Yields

The Bragg–Gray cavity ionization principle has been shown to hold for low atomic number gases ($Z \gtrsim 20$) in Pyrex cells irradiated by ^{60}Co γ rays under the conditions which applied in our cells (14, 15). Therefore for two such gases, with properties denoted by the subscripts 1 and 2, the W values and ionization currents per unit pressure or J values should be accurately related by the expression $W_2 = W_1 \times \overline{\rho_1^2} \times J_1/J_2$. The symbol $\overline{\rho_1^2}$ is the weighted mean stopping power ratio for the spectrum of energies of the electrons

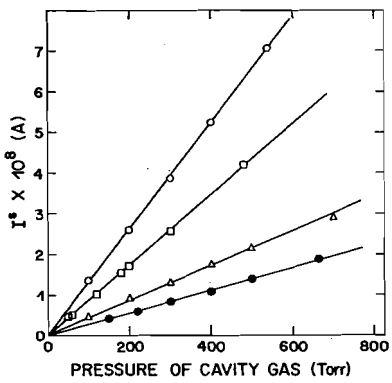

FIG. 1. Dependence of saturation ionization current (I^s) on pressure of cavity gas: ●, air; △, CO_2; □, HBr; ○, C_2F_6.

traversing the Pyrex chamber. It is equal to $S_A(BG)_1/S_A(BG)_2$ in Huyton and Woodward's notation and was obtained from their tables (14). Using air as a standard gas with $W = 33.8$ eV (ref. 1, Table 2.1) the ratios of J values in our ionization chamber gave $W_{CO_2} = 33.3$ eV and $W_{C_2F_6} = 32.7$ eV. The former value agrees within 1.5% with 32.8 recommended by Christophorou (ref. 1, Table 2.1), while $W_{C_2F_6} = 32.7$ is 9% less than 35.7 eV reported by Cooper and Mooring (13). Our value of $W_{C_2F_6}$ was used throughout the present work, both for self consistency and also because the stopping power ratios employed in the present calculation of $\overline{\rho_1{}^2}$ are averaged over the electron energy spectrum while Cooper and Mooring's were for 0.7 MeV electrons. W_{CO_2} and W_{HBr} were taken as 32.8 eV (ref. 1, Table 2.1) and 24.4 eV (15) respectively.

Using the dose rates, D_m, calculated for the mixtures and the observed saturation ionization currents, $I_m{}^s$, the values of the ionization yields in ion pairs per 100 eV in the mixtures were calculated from the relationship $G_m{}^i = 3600 I_m{}^s/eD_m$. They are plotted in Fig. 2 *a* and *c* as a function of Z, the stopping power fraction of HBr in the mixture. The value of Z is given by the relation $Z = (1 + \overline{\rho_{HBr}{}^2}P_2/P_{HBr})^{-1}$, where $\overline{\rho_{HBr}{}^2}$ is the ratio of the weighted mean stopping powers taken from ref. 14 and P_2 and P_{HBr} are the pressures of the added gas and HBr respectively.

Product Yields

Figure 2 *b* and *d* show values of the total hydrogen yields, G_m(total H_2), for mixtures of HBr with C_2F_6 and CO_2 plotted as a function of Z. The points on the lowest lines are values of (G_m(total H_2) $- G_m{}^i$) and are expected to represent the hydrogen yield from excited HBr molecules (see below).

The effects of the electron scavenger SF_6 on the hydrogen yields for C_2F_6 and CO_2 mixtures with HBr are shown in Figs. 3*a* and 4*a*. The reductions in hydrogen yield are due to the scavenging of thermal (or near thermal) electrons in [2]

$$[2] \qquad e + SF_6 \rightarrow SF_6{}^- \qquad \text{(rate of e capture by HBr)}/k_2[SF_6][e]\}/G_m{}^s.$$

The competition may be described in terms of the expression $\Delta G(H_2) = G_m{}^s\{1 +$ (rate of e capture by HBr)/(rate of e capture by SF_6)$\}^{-1}$, where $G_m{}^s$ is the yield of scavengable electrons. This can be rearranged to $(\Delta G(H_2))^{-1} = \{1 +$ Plots of $(\Delta G(H_2))^{-1}$ against $[SF_6]^{-1}$ were made for the data in Figs. 3*a* and 4*a* and the (rate of e capture by HBr)/[e] was calculated for each mixture by multiplying the ratio of the slopes to the intercepts by 2×10^{-7} cm^3 molecule^{-1} s^{-1}, which is the mean value observed for k_2 in a great variety of gases (16). The results from additional experiments with pure HBr at 360 Torr and from a mixture of 200 Torr of xenon and 50 Torr of HBr were treated similarly. The

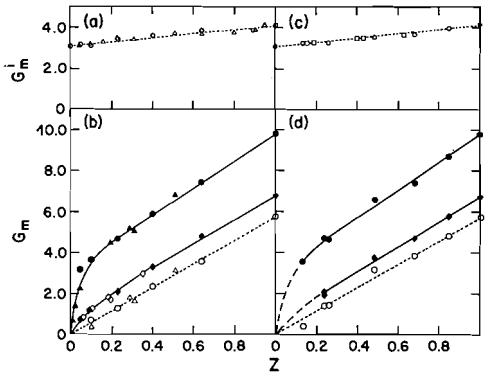

FIG. 2. Ionization yields, $G_m{}^i$, and hydrogen yields, G_m, in C_2F_6–HBr mixtures (*a* and *b*) and CO_2–HBr mixtures (*c* and *d*) plotted as a function of stopping power fraction, Z. Total pressures were: ○, ●, ◆, 600 Torr; △, ▲, ◇, 200 Torr; □, a constant pressure of 120 Torr HBr with varying pressure of buffer gas up to 900 Torr. In *b* and *d*: ●, ▲, total hydrogen yields; ◇, ◆, hydrogen yields observed in the presence of 3 mol% SF_6; ○, △, total hydrogen yields less $G_m{}^i$.

Effect of SF_6 on hydrogen yields from C_2F_6–HBr mixtures (*a*) $G(H_2)$ *vs.* [SF_6]/[HBr]; (*b*) $1/\Delta G(H_2)$ *vs.* [HBr]/[SF_6]; △, 540 Torr C_2F_6 and 120 Torr HBr, dose rate = 2.89×10^{18} eV g^{-1} h^{-1}; ○, 540 Torr C_2F_6 and 60 Torr HBr, dose rate = 2.92×10^{18} eV g^{-1} h^{-1}.

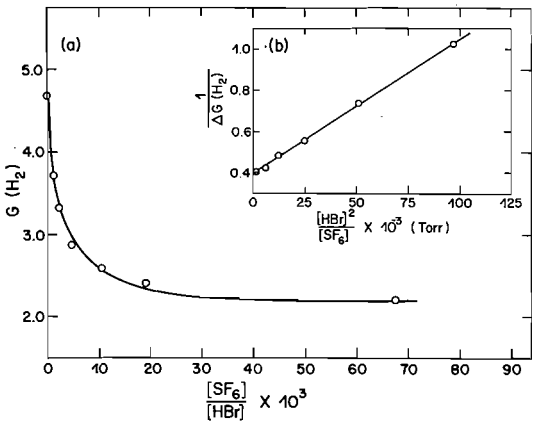

FIG. 4. Effect of SF_6 on hydrogen yields for a CO_2–HBr mixture: (*a*) $G(H_2)$ *vs.* $[SF_6]/[HBr]$; (*b*) $1/\Delta G(H_2)$ *vs.* $[HBr]^2/[SF_6]$; 540 Torr CO_2 and 120 Torr HBr, dose rate = 2.54×10^{18} eV g^{-1} h^{-1}.

data for the xenon HBr mixture are shown in Fig. 5.

Figure 6 shows a log–log plot of the rate of electron capture by HBr against the pressure of HBr. The line passing through the points for the present study was drawn with a slope of two. The earlier results of Chen and Armstrong (3) lie above it by 20% which is well within the combined uncertainties of the two measurements. It is evident from the overall behavior in Fig. 6 that the electron capture rate maintains a second order dependence on HBr pressure over the 50 to 600 Torr range, both in the presence and absence of diluent gases. The term $k_s[e][HBr]^2$

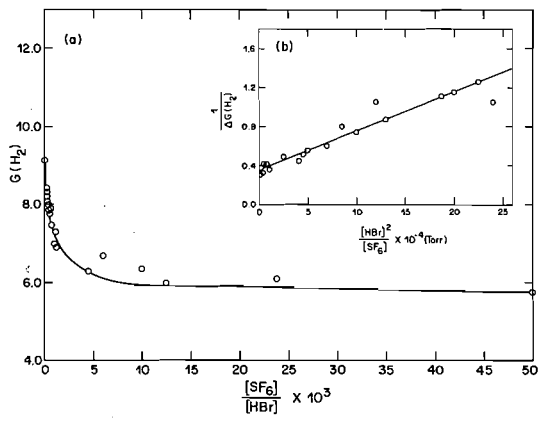

FIG. 5. Effect of SF_6 on hydrogen yields for a Xe–HBr mixture: (*a*) $G(H_2)$ *vs.* $[SF_6]/[HBr]$; (*b*) $1/\Delta G(H_2)$ *vs.* $[HBr]^2/[SF_6]$; 200-Torr Xe and 50 Torr HBr, dose rate = 2.4×10^{18} eV g^{-1} h^{-1}.

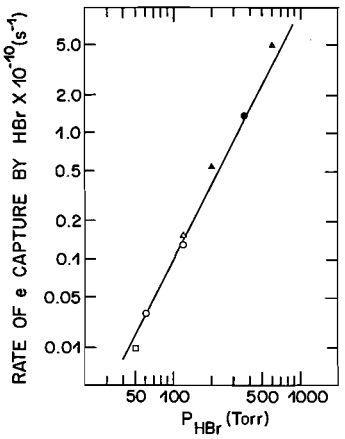

FIG. 6. Log–log plot of the rate of electron capture by HBr as a function of HBr pressure at 298 K. ▲, Data of ref. 3 for pure HBr in the 200 to 600 Torr pressure region; present data: — pure HBr; ●, HBr with buffer gases; ○, CO_2 at 540 Torr; △, C_2F_6 at 540 Torr; □, xenon at 200 Torr.

TABLE 1. Competition kinetic data for scavengable electrons

Mixture composition		$(k_s/k_2) \times 10^{22}$ (cm^3 $molecule^{-1}$) (uncertainty = ±1)
P_{HBr} (Torr)	P_2 (Torr)	
360	0	5.12
120	540(C_2F_6)	4.53
60	540(C_2F_6)	4.87
120	540(CO_2)	5.03
50	200(Xe)	3.74

was therefore substituted for (rate of e capture by HBr) to give:

$$[3] \quad (\Delta G(H_2))^{-1} = \{1 + k_s[HBr]^2/k_2[SF_6]\}/G_m^s$$

The values k_s/k_2 shown in Table 1 were then obtained from the ratios of slopes to intercepts of plots according to [3] as shown in Figs. 3*b*, 4*b*, and 5*b* for the C_2F_6, CO_2, and Xe mixtures respectively.

The diamonds in Fig. 2 *b* and *d* are hydrogen yields observed in mixtures containing 3 mol% SF_6. Except for those systems with more than 100 Torr of HBr this SF_6 concentration was sufficient to completely suppress the yield of hydrogen from thermal electrons. Corrections were made on the basis of $k_s/k_2 = 5 \times 10^{-22}$ cm^3 $molecule^{-1}$ from Table 1 where it was not. Subtraction of these yields from G_m(total H_2) therefore gives the yields of electrons scavengable by SF_6. The magnitudes of G_m^s obtained in

this way for several compositions are given in Table 2, where they are also expressed as fractions of G_m^i.

Discussion

The ionization yield in a mixture of two gases can be related to the yields in the pure components, G_1 and G_2 by the expression $G_m^i = G_1(1 + aP_2/P_1)^{-1} + G_2(1 + P_1/aP_2)^{-1}$ (17). The symbol a is an energy partition parameter and P_1 and P_2 the pressures of the two components. The mixture is said to behave ideally when a is equal to the ratio of the stopping powers, $\overline{\rho_1^2}$. This is seen to be the case within our precision of $\pm 3\%$ in Fig. 2 *a* and *c*, where the experimental points may be compared with the dashed line calculated for $a = \overline{\rho_{HBr}^2}$.

The occurrence of a linear energy partitioning in the ionization yields as in Fig. 2 *a* and *c* indicates the absence of any 'Jesse effect' and of interactions which prevent ionization of preionizing states of either component. It is also a strong indication that the electron energy degradation spectra in the mixtures are similar to those in the pure components (18), and under these circumstances one expects that the yields of products produced from excited molecules of each component should obey a linear energy partitioning expression with a similar a value. For the hydrogen yield G(ex. H_2) from excited HBr molecules the relationship would be: $G_m(\text{ex. } H_2) = G_{HBr}(\text{ex. } H_2)\{1 + \overline{\rho_{HBr}^2}P_2/P_{HBr}\}^{-1}$.

Previous studies of hydrogen formation from pure HBr at 23 °C (3) are consistent with a yield of one hydrogen molecule per electron and there is no evidence for hydrogen production in ion recombination (5). Taking the total electron yield as being equal to G^i, then G(ex. H_2) should be given by $G(\text{total } H_2) - G^i$. The bottom lines in Fig. 2 *b* and *d* are the values of G_m(ex. H_2) calculated from the relationship $G_m(\text{ex. } H_2) = \{G_m(\text{total } H_2) - G_m^i\} = \{G_{HBr}(\text{total } H_2) - G_{HBr}^i\}(1 + \overline{\rho_{HBr}^2}P_2/P_{HBr})^{-1}$, where the G terms with subscripts m and HBr refer respectively to yields in the mixtures and in pure HBr. The experimental values of $\{G_m(\text{total } H_2) - G_m^i\}$ are seen to conform to this expression.

Yields of the noncondensible products CO and O_2 from CO_2 were not separately identified and are not reported in detail. However, it may be noted that in the CO_2–HBr mixtures the total yields of noncondensible gas other than hydrogen were observed to follow a linear relationship of the form: $G_m(\text{noncondensible}) = (5.1 \pm 0.5)\{1 + P_{HBr}/\overline{\rho_{HBr}^{CO_2}}P_{CO_2}\}^{-1}$. The intercept of 5.1 ± 0.5 for pure CO_2 is consistent with values of G(CO) in the range 4.5 to 5.2 observed at low dose rates or in the presence of electron scavengers (12). Oxygen formation from atom combinations

[4] $$O(^3P) + O(^3P) \rightarrow O_2 + M$$

is probably suppressed by reactions 5 and 6:

[5] $$O(^3P) + HBr \rightarrow OH + Br$$

[6] $$OH + HBr \rightarrow H_2O + Br$$

which have rate constants of 4.4×10^{-14} and 5.1×10^{-12} cm^3 molecule^{-1} s^{-1} at 23 °C respectively (19). Radicals produced from C_2F_6 would also abstract hydrogen atoms from HBr (9). However, at low doses the products of these reactions are not expected to interfere with hydrogen formation, and no dose dependence was observed over the range employed in this work.

Reference to Fig. 2*b* shows that G_m(total H_2) rises very rapidly below $Z = 0.1$ and above $Z = 0.2$ becomes a linear function in Z, which extrapolates to G_{HBr}(total H_2) at $Z = 1.0$. This suggests that for Z between 0.2 and 1.0 all electrons form H_2. Although the data are less extensive it is evident that a similar behavior occurs with CO_2.

The fact that G^s in HBr (see Table 2) is only $\sim 73\%$ of G^i has been attributed to the occurrence of reaction 1 since the average initial

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

energy of subexcitation electrons in HBr (~2.5 eV (5)) far exceeds the peak energy of the reaction (~0.3 eV (1)) and also the SF_6 capture cannot compete with HBr at this energy. According to Magee and Burton (20), in pure HBr the fraction of electrons escaping capture in reaction 1 (*i.e.* (G^s/G_i)) is given by

$$[7] \qquad -\ln (G^s/G^i) = \int_{E_s}^{E_i} \frac{\sigma_c(E) \cdot dE}{\frac{\sigma_{HBr}(E) \cdot E}{\eta_{HBr}(E)}}$$

where E_i and E_s are the initial and final energies of the electrons, $\eta_{HBr}(E)$ is the mean energy lost per collision of the electron at energy E and $\sigma_c(E)$ and $\sigma_{HBr}(E)$ are the capture and total collision cross sections respectively. Since the resonance capture processes in CO_2 (1, 8) and C_2F_6 (21) occur at much higher energies than in HBr and have relatively low cross sections, the only effect of these gases on G^s/G^i should be through an increase in the number of moderating collisions giving for mixtures

$$[8] \qquad -\ln \left\{\frac{G_m{}^s}{G_m{}^i}\right\} = \int_{E_s}^{E_i} \frac{f_{HBr} \frac{\sigma_c(E)}{\sigma_{HBr}(E)} \frac{dE}{E}}{f_{HBr}\eta_{HBr}(E) + f_2\eta_2(E)}$$

Here the f refer to collision fractions, for example

$$f_{HBr} = \frac{\sigma_{HBr}(E)[HBr]}{\sigma_{HBr}(E)[HBr] + \sigma_2(E)[2]}$$

with [2] signifying the concentration of the added moderating gas. In the absence of detailed information concerning $\eta_{HBr}(E)$ and $\sigma_{HBr}(E)$ we make the assumption that they are energy independent from 0.15 to 0.7 eV where $\sigma_c(E)$ is significant. Simplifying and rearranging the above expression one then has[1]

$$[9] \qquad \frac{1}{-\ln \left\{\frac{G_m{}^s}{G_m{}^i}\right\}} = \frac{\sigma_{HBr}\eta_{HBr}}{I} + \frac{\sigma_2\eta_2}{I} \times \frac{[2]}{[HBr]}$$

in which

$$[10] \qquad I = \int_{E_s}^{E_i} \frac{\sigma_c(E)\, dE}{E}$$

A linear plot of $1/-\ln\{G_m{}^s/G_m{}^i\}$ *vs.* $[CO_2]/[HBr]$ was made from the data in Table 2. It exhibited a slope of 0.45 and an intercept of 3.2. The ratio of these leads to $\sigma_{CO_2}\eta_{CO_2}/\sigma_{HBr}\eta_{HBr} = 0.14$. From Figs. 4.37 and 4.4 of ref. 1 one can obtain $\eta_{CO_2} = 0.05$ and $\sigma_{CO_2} = 2 \times 10^{-15}$ cm^2 molecule^{-1} respectively at 0.35 eV. Therefore $\sigma_{HBr}\eta_{HBr} \sim 0.05 \times 2 \times 10^{-15}/0.14 \sim 7 \times 10^{-16}$ cm^2 molecule^{-1}, which is similar to 3×10^{-16} cm^2 molecule^{-1} for HCl calculated from earlier data (5).

Since $\sigma_{HBr}\eta_{HBr}/I = 3.2$ we find $I \sim 7 \times 10^{-16}/3.2 = 2.2 \times 10^{-16}$ cm^2 molecule^{-1}. One may evaluate I using an energy dependent cross section fitted to the data in Fig. 6.15 of ref. 1. Taking $\sigma_1 = 2 \times 10^{-16}$ for 0.15 to 0.3 eV and $2.75 \times 10^{-17}(E - 0.2)^{-1}$ for 0.3 to 0.7 eV,[2] I was calculated to be 2.4×10^{-16} cm^2 molecule^{-1} in good agreement with 2.2×10^{-16} cm^2 molecule^{-1} from the experimental data. Thus the differences between G^s and G^i and the increase in $G_m{}^s/G_m{}^i$ for increasing $[CO_2]/[HBr]$ in Table 2 can be satisfactorily explained by the occurrence of reaction 1 and by the enhanced moderation of the energies of subexcitation electrons by CO_2 molecules. A similar explanation should hold for C_2F_6, but there are at present no data on η or σ to facilitate quantitative comparisons for this molecule.

It may also be noted here that application of [9] and [10] to the capture of 'hot' electrons by SF_6 shows that fewer than 3% would be captured above 0.15 eV for $[SF_6]/[HBr] \leq 0.01$. This calculation was based on $\sigma_{HBr}\eta_{HBr} = 7 \times 10^{-16}$ cm^2 molecule^{-1} and $\sigma_2 = 3.24 \times 10^{-16} E^{-2.37}$ for the 0.15 to 0.4 eV electron energy range and $1.03 \times 10^{-16}E^{-3.6}$ for the 0.4 to 0.8 eV range. These values were obtained by trial fits to the results in Fig. 4*a* of ref. 23. Since the values of $[SF_6]/[HBr]$ used in finding k_s/k_2 in the present mixtures were normally less than 0.01 errors introduced by SF_6 competing with [1] are negligible. The values of $G_m{}^s$ obtained from hydrogen yields in mixtures with 3% SF_6 will be slightly high (~2%), but the errors are close to experimental uncertainties and also tend to compensate for the slight increase in $G_m{}^i$ caused by the addition of SF_6. Thus no corrections for them were made.

Returning to the reactions of scavengable electrons we note that the magnitudes of k_s/k_2 in Table 1 are within experimental error the same in pure HBr and in all the buffer gases except xenon. This is of interest, since the mech-

[1]This is analogous to Wolfgang's treatment of the reaction and moderation of kinetically hot atoms (see for example ref. 22).

[2]The accuracy of the fit to the overall shape of σ_1 ($= \sigma_c$) was checked by evaluating $\int_0^\infty \sigma_c(E)dE$. The result was 7.4×10^{-17} cm^2 eV, in agreement with the value in ref. 24.

For personal use only.

anism of the overall reaction 2 is considered to be (1)

[11] $$e + SF_6 \leftrightarrows SF_6^{-*}$$

[12] $$SF_6^{-*} + M \rightarrow SF_6 + M + e$$

Thus k_2 is equal to $k_{11}k_{12}(k_{-11} + k_{12})^{-1}$, and with k_{11} being dependent on the -0.62 power of the electron kinetic energy in the thermal energy range (1), buffer gases may modify k_2 by either failing to moderate the electrons to thermal energy or by virtue of different rate constants (*i.e.*, k_{12}) for stabilizing the vibrationally excited SF_6^{-*} ion initially produced. The lower value of k_s/k_2 for the xenon–HBr mixture in Table 1 cannot be due to a smaller value of k_{12}. It may be due to incomplete thermalization of the electrons, since the inert gases are very poor moderators for electrons (25). However, if this effect is important then the capture reaction for HBr must have a stronger inverse dependence on electron energy than [11], since k_s/k_2 is *smaller* in xenon than in the other gaseous mixtures.

Actually there is reason to believe that the scavengable electrons are reacting at thermal energies for most if not all of the conditions of the present study. From a recent analysis of electron thermalization in gases Warman and Sauer (25) give a thermalization rate coefficient, K_u, of 6×10^{-9} cm^3 s^{-1} for CO_2. Thus based on the CO_2 alone the thermalization rate (*i.e.* d(electron excess kinetic energy)/dt) for the CO_2–HBr mixture in Table 1 would have been 3×10^{10} s^{-1} which is 20 times the rate of electron capture calculated from the competition with SF_6 using $k_2 = 2 \times 10^{-7}$ cm^3 molecule^{-1} s^{-1}. Measured values of K_u are not available for C_2F_6 or for HBr itself. However, for the latter one expects a somewhat higher value than for CO_2 due to (*a*) its larger dipole moment (25) and (*b*) vibrational and/or rotational excitation due to temporary negative ion formation and auto detachment (1, 26). Taking K_u for HBr = 6×10^{-9} cm^3 molecule^{-1} s^{-1} one finds minimum thermalization rates which exceed the capture rates for the mixtures in Table 1 by a factor of four or more. Only for pure HBr at 360 and 600 Torr do the calculated minimum thermalization rates approach the capture rates. The absence of marked differences in k_s/k_2 for these conditions and for the mixtures suggests that thermalization is essentially complete under all conditions, K_u for HBr being somewhat larger than for CO_2. This indeed was suggested by the preceding analysis which lead to $\sigma_{HBr}\eta_{HBr} \sim 6\sigma_{CO_2}\eta_{CO_2}$ for the 0.15 to 0.7 eV region of electron energies.

The present investigation has shown that the second order dependence on HBr of the electron capture rate persists in the presence of a five- to tenfold excess of buffer gas, and k_s/k_2 is $5 \pm 1 \times 10^{-22}$ cm^3 molecule^{-1} for all our conditions. Taking $k_2 = 2 \times 10^{-7}$ we find $k_s = 1 \times 10^{-28}$ cm^6 molecule^{-2} s^{-1}. There are two mechanisms which must be considered in attempting to explain this. One involves a transitory HBr^{-*} species:

[13] $$e + HBr \underset{k_{-13}}{\overset{k_{13}}{\rightleftarrows}} HBr^{-*}$$

[14′] $$HBr^{-*} + M \overset{k_{14}'}{\rightarrow} HBr^- + M$$

[15′] $$HBr^{-*} + M \overset{k_{15}'}{\rightarrow} HBr + M + e$$

[14] $$HBr^{-*} + HBr \overset{k_{14}}{\rightarrow} HBr^- + HBr$$

[15] $$HBr^{-*} + HBr \overset{k_{15}}{\rightarrow} 2HBr + e$$

[16] $$HBr^{-*} + HBr \overset{k_{16}}{\rightarrow} H_2 + Br_2^- \text{ or } H + Br{-}H{-}Br^-$$

[17] $$HBr^- + HBr \overset{k_{17}}{\rightarrow} H_2 + Br_2^- \text{ or } H + Br{-}H{-}Br^-$$

Since [18] is fast (5) each HBr^{-*} undergoing [16]

[18] $$H + HBr \rightarrow H_2 + Br$$

and each HBr^- consumed in [17] will eventually produce a hydrogen molecule. Hence, the rate of hydrogen formation

$$\left(\frac{d[H_2]}{dt}\right)_s$$

from scavengable electrons is given by:

$$\left(\frac{d[H_2]}{dt}\right)_s = -\frac{d[e]}{dt} = k_s[e][HBr]^2$$

$$= \frac{k_{13}\{k_{14} + k_{16} + k_{14}'[M]/[HBr]\}}{k_{-13} + (k_{14} + k_{15} + k_{16})[HBr] + (k_{14}' + k_{15}')[M]}[e][HBr]^2$$

The second order dependence on [HBr] in the absence of M requires k_{-13} to be very large, and on simplifying one obtains

$$k_s = \frac{k_{13}\{k_{14} + k_{16} + k_{14}'[M]/[HBr]\}}{k_{-13}}$$

Taking $k_{13} \simeq 10^{-7}$ cm^3 molecule^{-1} s^{-1}, $k_{14} + k_{16}$ = a typical ion–molecule rate constant of 10^{-9} cm^3 molecule^{-1} s^{-1} and $k_{-13} = 10^{12}$ s^{-1} as for O_2^{-*} (27), the value of $k_{13}(k_{14} + k_{16})/k_{-13} = 10^{-28}$ cm^6 molecule^{-2} s^{-1} in pure HBr can be rationalized. However the fact that any contribution from $k_{14}'[M]$ constituted less than the 20% uncertainty in k_s shows that k_{14}' for CO_2 is $\leq (k_{14} + k_{16})/25$ and k_{14}' for C_2F_6 is $\leq (k_{14} + k_{16})/40$. Although they do not completely vitiate it, the small magnitudes of these rate constant ratios cast considerable doubt on the possible importance of the foregoing mechanism and lead to the consideration of an alternative involving dissociative electron capture by an HBr dimer:

[19] $$HBr + HBr + M \leftrightarrows (HBr)_2 + M$$

[20] $$e + (HBr)_2 \rightarrow H + Br—H—Br^- \text{ or } H_2 + Br_2^-$$

For this mechanism $k_s = k_{20}K_{19}$ and the capture rate has no dependence on buffer gas concentration. Also the value of $k_s = 1 \times 10^{-28}$ cm^6 molecule^{-1} s^{-1} can be satisfactorily accounted for if $K_{19} = 3 \times 10^{-22}$ cm^3 molecule^{-1} as calculated from the PVT data (28, 29) for HBr, and $k_{20} \simeq 3 \times 10^{-7}$ cm^3 molecule^{-1} s^{-1}, which is comparable to k_2 and the electron capture rate constant for CCl_4 (6).

Further work will be required to establish the precise mechanism for the thermal electron capture by HBr and the application of physical techniques is clearly of great importance. However, since many physical techniques employ relatively low reagent concentrations it is important that the second order dependence of the capture rate be taken into account. For example to observe an electron half-life of 10^{-3} s one would require an HBr concentration of 3×10^{15} molecules cm^{-3} as opposed to about 3×10^9 for SF_6. Furthermore the apparent two body capture rate coefficient would be about 2×10^{-13} cm^3 molecule^{-1} s^{-1}. This is much smaller than rate coefficients previously reported for swarm and e.c.r. experiments at about this concentration (see refs. 30 and 31 and comment about them in ref. 6). It is therefore doubtful that the same capture reaction was being observed in those experiments.

A Differential Spectroscopic Technique for Obtaining the Spectra of Chemisorbed Molecules

M. MOSKOVITS, C. J. HOPE, and B. JANTZI

Lash Miller Laboratories and Erindale College, University of Toronto, Toronto, Ontario M5S 1A1

Received July 25, 1975

M. MOSKOVITS, C. J. HOPE, and B. JANTZI. Can. J. Chem. 53, 3313 (1975).

A technique for recording the first derivative with respect to wavelength of the infrared spectrum of a substance is described. Its use allows one to detect with enhanced sensitivity a weak spectrum superimposed upon a strong, featureless background such as is encountered in the specular reflectance spectra of monolayers adsorbed on metal surfaces. The method is illustrated by the infrared spectrum of CO adsorbed on deposited copper.

M. MOSKOVITS, C. J. HOPE et B. JANTZI. Can. J. Chem. 53, 3313 (1975).

On décrit une technique pour l'enregistrement de la première dérivée, par rapport à la longueur d'onde, du spectre infrarouge d'une substance. Son utilisation permet de détecter, avec une sensibilité accrue, un spectre faible superposé à un fond fort et sans caractéristique tel qu'on le rencontre dans les spectres de réflexion spéculaire de couches monoléculaires adsorbées sur des surfaces métalliques. On illustre la méthode par le spectre infrarouge du CO adsorbé sur du cuivre déposé.

[Traduit par le journal]

Introduction

The use of infrared spectroscopy in observing vibrations due to molecules adsorbed on metals and oxides is now well established. By far the largest part of the literature in this field has been devoted to the observation of CO, hydrogen, and olefins chemisorbed on metal particles suspended in a support material such as silica or alumina. These systems approximate, more or less, commercial catalysts and are therefore of considerable interest. The spectra obtained in these systems are, however, characteristic of the heterogeneous nature of the metal surface as a result of the distribution of surface sites on particles of various sizes. This gives rise to many bands usually coalescing into broad envelopes. The spectra are, moreover, sensitive to the nature of the support. These facts have led workers such as Pritchard and Sims (1), Tompkins and Greenler (2), and Dignam *et al.* (3) to measure the specular reflectance spectra (or as Greenler refers to them, the reflectance absorption spectra) of molecules adsorbed on metal surfaces using multiple external reflection to enhance the signal. Recently Pritchard and co-workers (4) have reported spectra of CO adsorbed on several single-crystal faces of copper obtained with one single reflection only. The study of adsorption onto single-crystal faces demands the use of single reflection spectroscopy.

Pritchard has also recently published preliminary data for CO absorbed on Cu using wavelength modulation infrared spectroscopy (5).

Infrared reflectance spectra of monolayers adsorbed on metal substrates are characterized by a large, almost featureless background on which is superimposed a weak (<2% absorbance) absorption due to the adsorbate. In order to improve the sensitivity with which one observes the adsorbate absorption one must reject the large background reflection. In this paper we describe a technique for doing this by taking the derivative of the infrared reflectance spectrum. The derivative of the slowly varying background is, of course, small compared with that of the relatively sharp absorption peaks making it easier to amplify and observe the latter. We illustrate the method with a single-reflection spectrum of CO adsorbed on polycrystalline copper.

Experimental

The apparatus is described in detail elsewhere (6). Briefly, it consists of an ion-pumped ultrahigh vacuum

system fitted with CaF_2 windows. Copper is deposited from a tantalum filament onto a Pyrex slide. The spectrometer consists of a Nernst glower source, and mirrors which focus the source radiation onto the sample; another mirror focuses the reflected light (the angle of incidence is approximately 80°) onto the slit of a Spex Minimate grating monochromator. The derivative spectrum is obtained by vibrating a sodium chloride disc about an axis parallel to the exit slit using a vibrating galvanometer in front of the exit slit of the monochromator. The dispersed bean is thereby periodically swept across the slit and the outgoing radiation is detected by means of a cooled indium antimonide detector whose output is amplified and measured on a lock-in amplifier. A synchronous reference signal from the galvanometer amplifier is provided to the lock-in amplifier.

Theory

The theory of derivative spectroscopy has been previously discussed by others (7–9). We shall therefore give only a brief account of it.

Assume the combined spectrum resulting from the source radiation, optics and detector response function in the system described is given by $S(\lambda)$. The intensity of the radiation specularly reflected from the sample at wavelength λ is therefore

$$[1] \qquad I_0(\lambda) = S(\lambda)R_0(\lambda)$$

when the sample surface is bare and

$$[2] \qquad I(\lambda) = S(\lambda)[R_0(\lambda) + \Delta R(\lambda)]$$

when the sample surface is covered with a layer of adsorbate.

If the beam falling on the exit slit of the monochromator is deflected by a small amount $\delta\lambda$ the measured intensity is then given by

$$[3] \quad I(\lambda + \delta\lambda) \simeq I(\lambda) + \delta\lambda\frac{dI}{d\lambda} + \tfrac{1}{2}(\delta\lambda)^2\frac{d^2I}{d\lambda^2} + \ldots$$

If $\delta\lambda$ varies sinusoidally with time so that

$$[4] \qquad \delta\lambda = \delta\lambda_{max} \sin \omega t$$

then the Fourier component of $I(\lambda)$ having frequency ω has an amplitude proportional to $dI/d\lambda$ as given by [3]. From [2]

$$[5] \quad \frac{dI}{d\lambda} = \frac{d[S(\lambda)R_0(\lambda)]}{d\lambda} + S(\lambda)\frac{d\Delta R}{d\lambda} + \Delta R\frac{dS(\lambda)}{d\lambda}$$

The first term of [5] is small if $S(\lambda)R_0(\lambda)$ is a slowly varying function of λ while the last term is small for small values of ΔR. Equation 5 is therefore dominated by the term $S(\lambda)(d\Delta R/d\lambda)$ which is proportional to the first derivative of the absorption due to the presence of the adsorbate, as required. The first term in [5] can also be subtracted out by first recording the first derivative spectrum of the bare substrate. Thus

$$[6] \qquad S(\lambda)\frac{d\Delta R}{d\lambda} = \frac{dI}{d\lambda} - \frac{dI_0}{d\lambda}$$

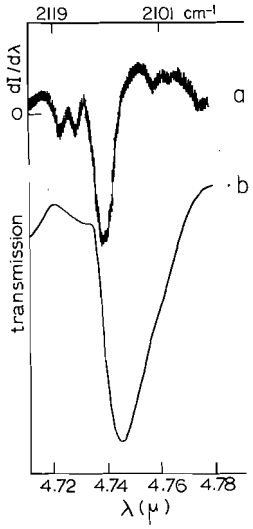

FIG. 1. (*a*) The difference between the first derivative single-reflection spectrum of CO adsorbed on polycrystalline copper and that of the bare substrate. (*b*) The integral of the above.

Results

Using this technique we have succeeded in recording the single-reflection reflectance spectrum of CO on copper. The CO pressure was approximately 0.5 μ.

Figure 1*a* shows the difference in derivative spectra with CO covered and bare copper surfaces as stated by [6]. Figure 1*b* is a digitally integrated spectrum of the data displayed in Fig. 1*a*, giving a conventional transmission spectrum except that the large reflection background has been suppressed. The observed spectrum has a maximum absorbance at 2107 cm^{-1} with a shoulder at lower wavenumbers as reported by Pritchard and Sims (1). The absorbance of the feature at its maximum is approximately 0.5% and it was not observable by direct reflectance.

Librations Around the C(S)—Phenyl Bond in *N*-Thiobenzoylmorpholines Observed by 220 MHz Proton Magnetic Resonance Spectroscopy

ADRIAN O. FULEA[1] AND PETER J. KRUEGER

Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received April 18, 1975

ADRIAN O. FULEA and PETER J. KRUEGER. Can. J. Chem. **53**, 3315 (1975).

The 220 MHz p.m.r. spectra of 4-(4′-nitrothiobenzoyl)-2,6-dimethylmorpholine (**1**) provide evidence for the progressive freezing of the librations of the thioamide group around the C(S)—Ph bond as the temperature is lowered. This is supported by spectral data on related compounds in which the aromatic and hetero-ring substituents are altered.

ADRIAN O. FULEA and PETER J. KRUEGER. Can. J. Chem. **53**, 3315 (1975).

Le spectre r.m.p. à 220 MHz du (nitro-4′ thiobenzoyl)-4 diméthyl-2,6 morpholine (**1**) fournit une preuve qu'il y a un arrêt progressif de la libration du groupe thioamide autour du lien C(S)—Ph au fur et à mesure que la température est abaissée. Cette conclusion est supportée par des données spectrales sur des composés connexes dans lesquels les substituants du cycle aromatique et de l'hétérocycle sont changés.

[Traduit par le journal]

Previously we have shown (1) that the librations around the C—N bond, *i.e.* oscillations about the local potential energy minimum for intramolecular rotation, in 1-(2′-hydroxythiobenzoyl)-piperidine and 4-(2′-hydroxythiobenzoyl)-morpholine can be investigated by p.m.r. spectroscopy, using the magnetically nonequivalent NCH_2 protons as sensors in a system where an intramolecular OH···S hydrogen bond locks the internal motions of the thiobenzoyl group. It has also been demonstrated that torsional librations can decouple spin systems, and sharpen or broaden p.m.r. signals (2).

[1]Izaak Walton Killam Scholar.

The 220 MHz p.m.r. signal patterns for the 2′ and 6′ protons of **1** at different temperatures in CS_2, acetone-d_6, and $CDCl_3$ solution are shown in Fig. 1.[2] At or below −30 °C all rotations around the C(S)—Ph bond in **1** are frozen on the 220 MHz scale (Fig. 1*b* and 1*c*); we believe this to be the first case where freezing of the rotation around this bond has been observed in thiobenzamides which are not *o*-substituted (3).

Two rotational energy barriers can be envisaged for rotation about the C(S)—Ph bond:

[2]We thank Mrs. C. Fulea for the synthesis of this compound. Proton magnetic resonance spectra were obtained at the Canadian 220 MHz n.m.r. Centre, Sheridan Park, Ontario, under the direction of Dr. A. E. Grey.

This demonstrates the usefulness of the described technique.

We thank the National Research Council of Canada for financial support and the Connaught Fund for a grant.

Librations Around the C(S)—Phenyl Bond in *N*-Thiobenzoylmorpholines Observed by 220 MHz Proton Magnetic Resonance Spectroscopy

ADRIAN O. FULEA[1] AND PETER J. KRUEGER

Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received April 18, 1975

ADRIAN O. FULEA and PETER J. KRUEGER. Can. J. Chem. **53**, 3315 (1975).

The 220 MHz p.m.r. spectra of 4-(4′-nitrothiobenzoyl)-2,6-dimethylmorpholine (**1**) provide evidence for the progressive freezing of the librations of the thioamide group around the C(S)—Ph bond as the temperature is lowered. This is supported by spectral data on related compounds in which the aromatic and hetero-ring substituents are altered.

ADRIAN O. FULEA and PETER J. KRUEGER. Can. J. Chem. **53**, 3315 (1975).

Le spectre r.m.p. à 220 MHz du (nitro-4′ thiobenzoyl)-4 diméthyl-2,6 morpholine (**1**) fournit une preuve qu'il y a un arrêt progressif de la libration du groupe thioamide autour du lien C(S)—Ph au fur et à mesure que la température est abaissée. Cette conclusion est supportée par des données spectrales sur des composés connexes dans lesquels les substituants du cycle aromatique et de l'hétérocycle sont changés.

[Traduit par le journal]

Previously we have shown (1) that the librations around the C—N bond, *i.e.* oscillations about the local potential energy minimum for intramolecular rotation, in 1-(2′-hydroxythiobenzoyl)-piperidine and 4-(2′-hydroxythiobenzoyl)-morpholine can be investigated by p.m.r. spectroscopy, using the magnetically nonequivalent NCH_2 protons as sensors in a system where an intramolecular OH···S hydrogen bond locks the internal motions of the thiobenzoyl group. It has also been demonstrated that torsional librations can decouple spin systems, and sharpen or broaden p.m.r. signals (2).

[1]Izaak Walton Killam Scholar.

The 220 MHz p.m.r. signal patterns for the 2′ and 6′ protons of **1** at different temperatures in CS_2, acetone-d_6, and $CDCl_3$ solution are shown in Fig. 1.[2] At or below −30 °C all rotations around the C(S)—Ph bond in **1** are frozen on the 220 MHz scale (Fig. 1*b* and 1*c*); we believe this to be the first case where freezing of the rotation around this bond has been observed in thiobenzamides which are not *o*-substituted (3).

Two rotational energy barriers can be envisaged for rotation about the C(S)—Ph bond:

[2]We thank Mrs. C. Fulea for the synthesis of this compound. Proton magnetic resonance spectra were obtained at the Canadian 220 MHz n.m.r. Centre, Sheridan Park, Ontario, under the direction of Dr. A. E. Grey.

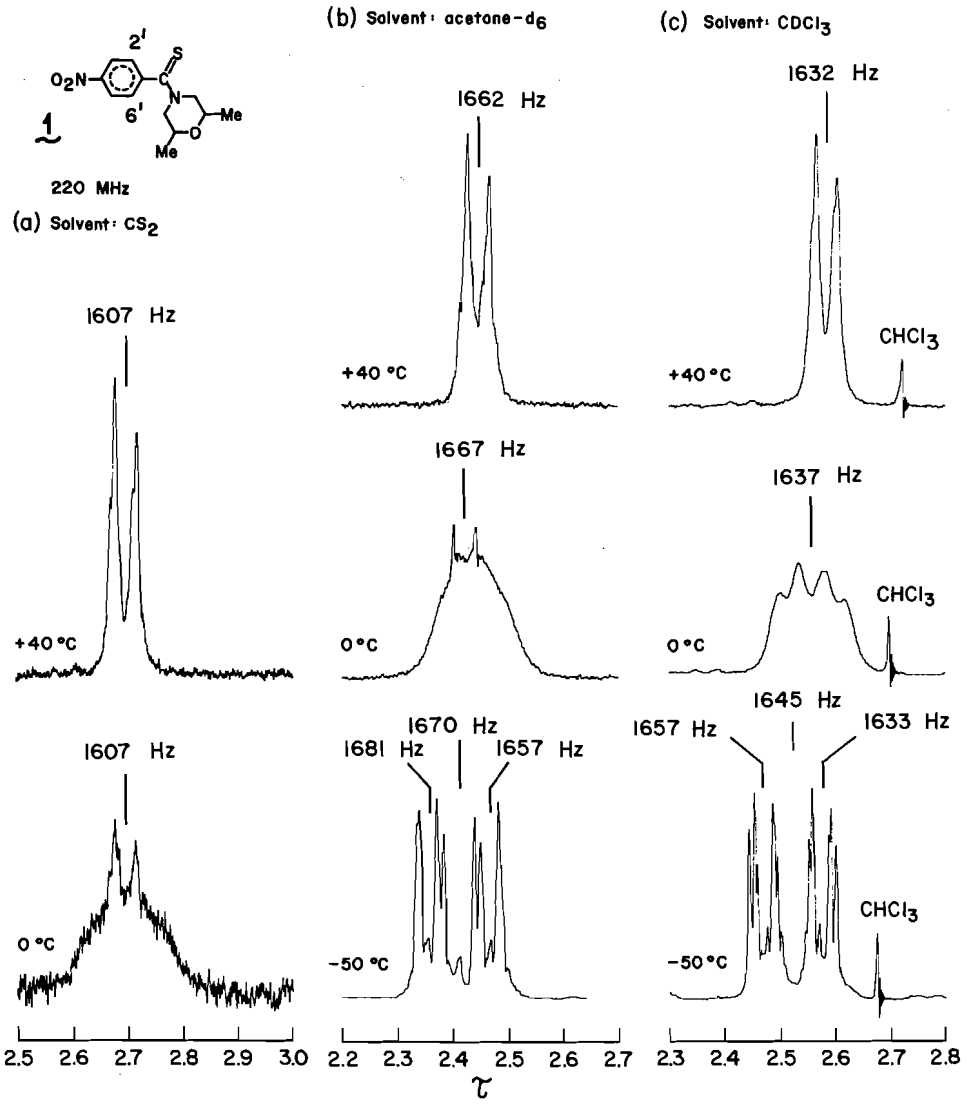

FIG. 1. 220 MHz p.m.r. spectra of **1** in (*a*) CS_2, (*b*) acetone-d_6, and (*c*) $CDCl_3$ solutions. Internal TMS reference.

E_{steric} for the process by which *o*-protons would pass through the thioamide plane, and E_π for the process by which the phenyl ring passes through a plane perpendicular to the thioamide plane (the barrier in this case arising from the breaking of conjugation); the relative magnitudes would be $E_{steric} > E_\pi$. The spectral features observed cannot be explained by the freezing of the rotation due to the E_{steric} barrier, since the chemical shift of the *syn* and *anti* *o*-protons will still be equalized by passage over the E_π barrier, *i.e.* a given *o*-proton oscillates between *syn* and *anti* positions on the same side of the thioamide plane.[3] Rotation over the E_{steric} barrier (and rotation around the CN bond) is frozen for these compounds throughout the temperature range under consideration. Nevertheless, as can be seen from Fig. 1*a*, part of the *o*-proton signal is unchanged when the temperature drops from 40 to 0 °C, whereas the

[3]The *o*-protons would both have the same chemical shift:

$$\tau = \tfrac{1}{2}(\tau_{anti} + \tau_{syn})$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

other part broadens, but with good approximation still has the same chemical shift of 1607 Hz on the 220 MHz scale.[4]

We presume that the rotation over the E_π barrier in **1** freezes above 0 °C on the n.m.r. scale, based on the chemical shift difference between *syn* and *anti* *o*-protons at −30 °C in both CS_2 and acetone-d_6 solution. The chemical shift of the *syn* and *anti* *o*-protons in CS_2 is unchanged relative to their chemical shift when this rotation is rapid, because relatively high amplitude librations move the *syn* and *anti* protons in regions with the same chemical shift. The broadening of *half* of the signal is attributed to the freezing of the higher energy liberations of the thioamide group around the C(S)—Ph bond.[5] The two parts of the molecule will oscillate in opposite directions around this bond, with different amplitudes, the part with the lower moment of inertia around the axis of rotation (*i.e.* the aromatic ring) having the higher amplitude. On decreasing the temperature the librations with high amplitude begin to freeze and the average angle between the aromatic ring and the C(S)—N plane (when both are in their equilibrium position, *i.e.* most of the time) decreases.[6] The sharp peaks in CS_2 and acetone-d_6 solution at 0 °C are due to the *o*-proton *anti* to the C=S bond. The broadened peaks are due to the *o*-proton *syn* to the C=S bond, where the gradient of deshielding is higher. To explain this broadening by librational transitions, which usually are between levels differing little in energy, we envisage that the degree of steric interaction between the 5 and 6′ protons in **1** depends on the torsional amplitude (torsional state with angular amplitude θ, measured from the equilibrium position in the torsional ground state). Some θ states will be highly unfavorable energetically because of steric hindrance, and hence will be unpopulated, increasing the difference between populated levels, which correspond to amplitudes accompanied by a 'cogwheel' configuration of the three hydrogen atoms (5). For these states the energy difference may be approximately equal to the difference in the resonance energies that correspond to the two dihedral angles, respectively. On the n.m.r. scale, the signal averaging will thus take place over a smaller number of states, but which have a larger energy separation between them. The chemical shift of the *syn* aromatic *o*-protons will be different in two populated 'cogwheel' torsional states, and this leads to the broadening of their signal.

A change in the chemical shift of *o*-protons due to librational movement has been observed previously in biphenyls (6).

In $CDCl_3$ solution the rotation around the C(S)—Ph bond involving the E_π barrier is also frozen, but here the librations of the phenyl part of the molecule cannot equalize the chemical shift of the *o*-protons at 0 °C, presumably due to the higher bond order of the C(S)—Ph bond in this solvent as a result of intermolecular CD···S hydrogen bond formation.

In $CDCl_3$ and acetone-d_6 solutions the chemical shift of the *o*-protons in **1** moves downfield with decreasing temperature, *e.g.* in $CDCl_3$ (Fig. 1*c*) from 1632 Hz at 40 °C to 1645 Hz at −50 °C, due to the progressive freezing of higher energy (and amplitude) librations around the C(S)—Ph bond as the temperature is lowered, since the angle between the phenyl ring and thioamide planes decreases.

In marked contrast, the 220 MHz spectrum of 4-(4′-nitrothiobenzoyl)-morpholine, **2**, exhibits no change in the aromatic *o*-proton signal from +40 to −50 °C. Following the usual interpretation a rotational barrier of about 14 kcal/mol might be implied for **1**, and a barrier of less than 11 kcal/mol for **2**. This is extremely unlikely, since the basic structural features of **1** and **2** are the same, dictating virtually identical barriers to rotation for the process which would equalize *syn* and *anti* protons,[7] and the

[4]We thank one of the referees for helpful comments regarding line-widths.

[5]Strictly speaking, this liberation will take place around an intramolecular axis through the center of mass, and not coincident with the C(S)—Ph bond.

[6]Due to steric hindrance the aromatic ring and the C(S)—N group cannot be coplanar if the conjugation in the thioamide group is maximized. A phenyl ring twist angle of about 50° is estimated from Dreiding models. Twisting in thiobenzamides has recently been discussed in the literature (4). The high rotational barrier E_π for **2** can be explained by a smaller phenyl ring twist angle out of the thioamide plane in the ground state than is envisaged from a Dreiding model, with steric interactions accommodated to some extent by distortion of bond angles.

[7]The barrier E_{steric} for rotation around the C(S)—Ph bond differs in **1** and **2** due to the 'cogwheeling' effect in the latter, but this barrier cannot be determined by observation of the *o*-proton signal.

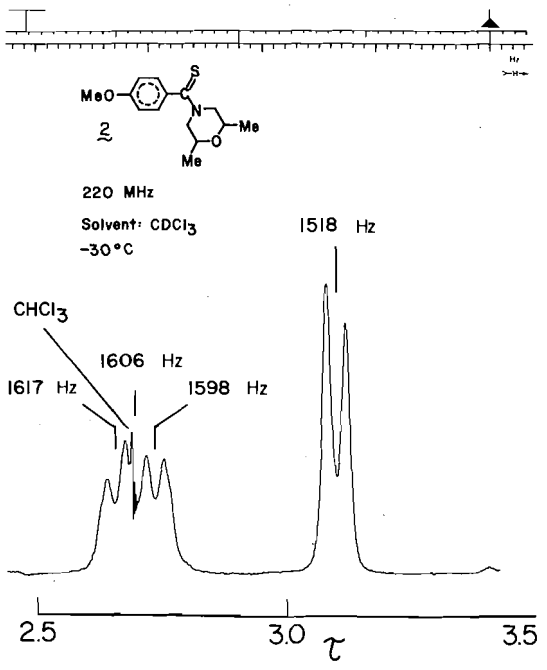

FIG. 2. 220 MHz p.m.r. spectrum of **2** in $CDCl_3$.

same chemical shift for the *o*-proton in the ground state. The much lower moment of inertia of the thioamide group about the internal axis in **2** is the principal feature which differentiates **2** from **1**. Thus the librations of the thioamide group in **2** have a much higher amplitude than in **1**, equalizing the *syn* and *anti* *o*-protons down to -50 °C. Even for **1** the coalescence point cannot be determined precisely,[8] and thus the E_π barrier cannot be determined accurately.

Similar observations have been made for other selected *N*-benzoyl morpholines, piperidines, and piperazines. Compound **1** is an excellent choice for this study because the *o*-protons are well separated in the p.m.r. spectrum, the two methyl groups on the morpholine ring increase the moment of inertia of the thioamide group, and the strongly electron-withdrawing *p*-NO_2 substituent enhances the C—N bond order because the N atom is more responsive to this effect than the S atom (7). This makes the thioamide frame stiffer and precludes interference from torsional oscillations about the C—N bond. In 4-(4′-methoxythiobenzoyl)-2,6-dimethylmorpholine, **3**, where the thioamide frame is not as stiff as in **1** (*i.e.* lower CN bond order) the *o*-proton signal is a sharp doublet in $CDCl_3$ at 0 °C, and only by -30 °C (Fig. 2) does the observed pattern resemble that seen for **1** at 0 °C.

The hitherto puzzling finding that sometimes one of the magnetically nonequivalent geminal protons in sterically crowded molecules exhibits a broad p.m.r. signal pattern whereas that of the other proton is sharp (8) can now be explained in the light of this study and our earlier work (1). The broadening of the signal from only one geminal proton can be due to the freezing of a libration in which this proton moves in a very high gradient of deshielding.

Kinetics and Mechanism of the Oxidation of Thiocyanate by Tris(1,10-phenanthroline)iron(III) and its Derivatives

FLORA T. T. NG AND PATRICK M. HENRY

Guelph-Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ontario N1G 2W1

Received May 8, 1975

FLORA T. T. NG and PATRICK M. HENRY. Can. J. Chem. **53**, 3319 (1975).

Oxidation of thiocyanate by tris(1,10-phenanthroline)Fe(III) to give cyanide and sulfate ions was studied at 25 °C in both H_2SO_4 and $HClO_4$ media. The rate of oxidation showed a first order dependence on the Fe(III) complex and a second order dependence on potassium thiocyanate at $\geq 4.0 \times 10^{-4}$ *M* potassium thiocyanate. The value of k_{obs} decreased with increasing $[H^+]$. This acid inhibition is consistent with the protonation of SCN^- to give an inactive HSCN species. A mechanism consistent with the data involved an initial equilibrium formation of $[Fephen_3SCN]^{2+}$ which subsequently undergoes an outer-sphere electron transfer with SCN^- to eventually give Fe(II)$phen_3$, CN^-, and SO_4^{2-}. Similar kinetic behavior was found with the substituted tris(1,10-phenanthroline)Fe(III) complexes. The value of the third order rate constant was found to increase with the increase in the reduction potential of the complexes. This result indicates a direct dependence of the standard free energy of the reaction and the free energy of activation.

FLORA T. T. NG et PATRICK M. HENRY. Can. J. Chem. **53**, 3319 (1975).

On a étudié, à 25 °C, dans des milieux H_2SO_4 et $HClO_4$, l'oxydation du thiocyanate par le tris(phénanthroline-1,10)Fe(III) conduisant aux ions cyanure et sulfate. A des concentrations $\geq 4.0 \times 10^{-4}$ *M* en thiocyanate de potassium, la vitesse d'oxydation est du premier ordre en complexe ferrique et du deuxième en thiocyanate de potassium. La valeur de k_{obs} diminue avec une augmentation de $[H^+]$. Cette inhibition par les acides est en accord avec une protonation du SCN^- conduisant à une espèce HSCN inactive. Un mécanisme en accord avec les données implique une formation initiale en équilibre de $[Fephen\ SCN]^{2+}$ qui subit d'une façon subséquente un transfert d'électron avec SCN^- dans la sphère extérieure puis finalement donne du Fe(II) $phen_3$, du CN^- et SO_4^{2-}. On a trouvé des comportements cinétiques semblables pour des complexes de tris(phénanthroline-1,10)Fe(III) substitués. On a trouvé que la constante de vitesse du troisième ordre augmente avec une augmentation des potentiels de réduction de ces complexes. Ce résultat indique qu'il existe une relation directe entre l'énergie libre standard de la réaction et l'énergie libre d'activation.

[Traduit par le journal]

Introduction

There have been recent reports of thiocyanate assisted outer-sphere electron transfer reactions between inorganic complexes (1, 2). Similarly, thiocyanate has been found to catalyze electron transfer in cytochrome C and porphyrin complexes (3–5). We are interested in the effect of anions on the rate of oxidation of organics by tris(1,10-phenanthroline)Fe(III).[1] In the absence of organic, tris(1,10-phenanthroline)Fe(III) was reduced by SCN^- at an appreciable rate. We studied the reaction in the absence of any organics in some detail since this might elucidate the mechanism of the SCN^- assisted outer-sphere electron transfer reactions.

We have chosen the latter standard ($\varepsilon = 1.03 \times 10^4$) as reference for calculating the concentration of Fe(II)phen$_3$.

Results

Stoichiometry and Products

Reduction of tris(1,10-phenanthroline)Fe(III), commonly known as ferriin, Fe(III)phen$_3$, by KSCN in acid yielded tris(1,10-phenanthroline)Fe(II), also known as ferroin, Fe(II)phen$_3$. Fe(II)phen$_3$(ClO_4)$_2$ was identified by microanalysis and comparison of its infrared and visible spectrum with an authentic sample of Fe(II)phen$_3$(ClO_4)$_2$. Cyanide was identified as the oxidation product via precipitation as AgCN and comparison of its —C≡N stretch with an authentic sample of AgCN. The presence of SO_4^{2-} was indicated by immediate formation of a white precipitate of $BaSO_4$ on addition of $BaCl_2$ to a reaction mixture in which the ferriin has been completely reduced. The weight of the precipitate of $BaSO_4$ was approximately that expected from the initial concentration of ferriin.

Stoichiometry of the reaction was determined in the presence of excess Fe(III)phen$_3$. The formation of Fe(II)phen$_3$ was followed at 510 nm as shown in Table 1. For every mole of KSCN present in the reaction mixture, an average of 5.8 ± 0.2 mol of Fe(II)phen$_3$ was produced at the end of the reaction. Thus, the stoichiometry of the reaction is as follows

[1] $6Fe(III)phen_3 + SCN^- + 4H_2O \rightarrow 6Fe(II)phen_3 + CN^- + SO_4^{2-} + 8H^+$

Kinetics of the Oxidation of Thiocyanate by Ferriin in $HClO_4$

In the presence of excess KSCN, good pseudo first order kinetics was observed over at least two half lives. The pseudo first order rate constant, k_{obs}, was found to be second order in total thiocyanate concentration, [SCN]$_T$, at $\geq 4.0 \times 10^{-4}$ M KSCN in 1 M $HClO_4$ (Fig. 1). The value of k_3'', $k_{obs}/[SCN]_T^2$, was $(5.5 \pm 0.6) \times 10^3$ M^{-2} s^{-1} at 25 °C.

Wilmarth and co-workers (7) reported a rate law of the form

[2] $k_{obs} = k_1[SCN^-] + k_2[SCN^-]^2$

in the oxidation of SCN^- by tris(2,2′-bipyridyl)Fe(III) at 0.1 M ionic strength and 25 °C where $k_1 = 11\ M^{-1}\ s^{-1}$ and $k_2 = 1.5 \times 10^4\ M^{-2} s^{-1}$. Oxidation of thiocyanate at low [SCN]$_T$ was carried out under our reaction conditions to determine if the k_1 term existed. In the absence of thiocyanate, a freshly prepared 5.0×10^{-4} M stock solution of ferriin in concentrated $HClO_4$ when diluted with H_2O to 1 M [H^+] was reduced to ferroin with a k_0 value comparable to the k_{obs} value at low [SCN]$_T$ (Table 2). The origin of the k_0 term was not clear and appeared to be dependent on the 'age' of the stock solution. Results in Table 2 represent data obtained from a same stock solution of ferriin. When k_0 was subtracted from k_{obs} to give k_{obs}', the experimental value of

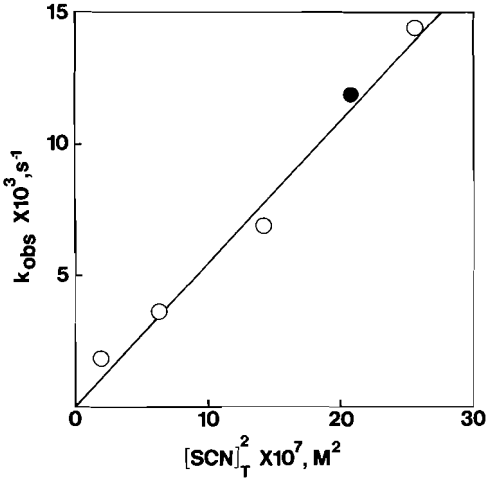

FIG. 1. Variation of k_{obs} with $[SCN]_T^2$ at 25 °C and 1 M $HClO_4$. ○, [Ferriin] = 1.00×10^{-4} M; ● [Ferriin] = 1.12×10^{-4} M.

$k_{obs}'/[SCN]_T$ compared well with the calculated value of $k_{obs}/[SCN]_T$, assuming the presence of only a second order term in $[SCN]_T$. When $k_{obs}'/[SCN]_T$ was plotted against $[SCN]_T$, a straight line with an intercept of 0 ± 0.3 M^{-1} s^{-1} was found. Such a k_1 value is considerably lower than the k_1 value of 11 M^{-1} s^{-1} reported by Wilmarth and co-workers. Although the first order term in $[SCN]_T$ cannot be ruled out completely, this term is of negligible significance under most of our reaction conditions.

k_{obs} appears to have a complicated $[H^+]$ dependence. At 1 M ionic strength, k_{obs} was practically independent of $[H^+]$ at $[H^+] \leq 0.06$ M and then decreased with increasing $[H^+]$. At 2 M ionic strength, k_{obs} was practically independent of $[H^+]$ up to $[H^+] \leq 1$ M and then decreased with increasing $[H^+]$. At 4 M ionic strength, the value of k_{obs} decreased with increasing $[H^+]$ (Table 3).

Oxidation of Thiocyanate by Ferriin in H_2SO_4

The reaction was found to be first order in $Fe(III)phen_3$ and second order in $[SCN]_T$ where $[SCN]_T$ was varied from 7.2×10^{-4} to 1.44×10^{-3} M. The value of k_3'' was $(2.8 \pm 0.5) \times 10^4$ M^{-2} s^{-1} in 1 M H_2SO_4 at 25 °C. At ≤ 0.2 M $[H^+]$ and ionic strength of 2 M, k_{obs} was found to increase with increasing $[SO_4^{2-}]$ (Table 4).

Oxidation of Thiocyanate by 5-Methylferriin in H_2SO_4

Oxidation of thiocyanate by 5-methylferriin, $Fe(III)(Mephen)_3$, was carried out in H_2SO_4 medium because $Fe(II)(Mephen)_3$ is only slightly soluble in $HClO_4$ and precipitation occurred during the reaction. The value of k_{obs} showed a second order dependence on $[SCN]_T$ (Table 5) and the value of k_3'' was found to be $(1.4 \pm 0.4) \times 10^4$ M^{-2} s^{-1} at 25 °C. Air did not affect the reaction (Table 5).

Variation of k_{obs} with $[H^+]$ was studied in HBF_4 medium. k_{obs} decreased slightly as $[H^+]$ was increased from 0.25 to 1.0 M (Table 6).

Variation of k_3'' with the Reduction Potential, E^0, for the Substituted Ferriin Complexes

Oxidation of thiocyanate by a number of other substituted ferriin complexes was studied in 1 M H_2SO_4 since the methyl substituted ferriin com-

plexes are not very soluble in 1 M $HClO_4$. In addition, the reduction potentials (ref. 6, p. 113) of these complexes were reported in H_2SO_4 medium. The value of k_3'' increased as the E^0 value of the complexes increased (Table 7, Fig. 2).

Discussion

Identification of $Fe(II)phen_3$ at the end of the reaction suggested an outer-sphere electron transfer mechanism. If dissociation of phenanthroline occurred during the reaction, substitution of SCN^- into the first coordination sphere of the Fe(III) complex might be expected to occur to give $Fe(III)phen_2(SCN)_3$ which was reported to be a dark red solid (8). Although oxidation of SCN^- by Fe(III) in acetonitrile produced $(SCN)_2$ (9), we are not surprised that CN^- and SO_4^{2-} are the oxidation products since $(SCN)_2$ is known to decompose readily in aqueous medium (10). Oxidation of SCN^- by $Fe(H_2O)_6^{3+}$ (11) and H_2O_2 (12) in acidic medium was reported to produce CN^- and SO_4^{2-}.

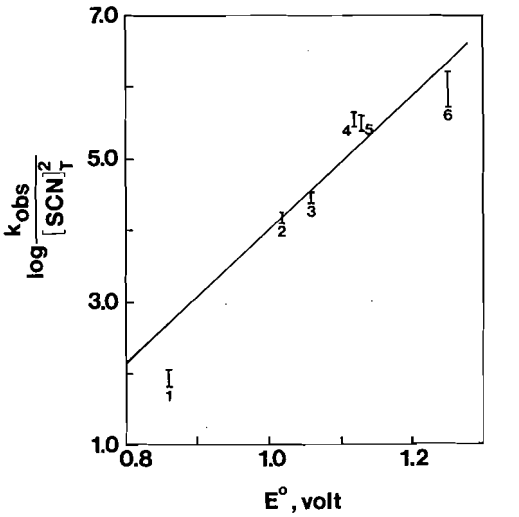

FIG. 2. Plot of log ($k_{obs}/[SCN]_T^2$) *vs.* E^0 for the substituted ferriin complexes at 25 °C and 1 M H_2SO_4: *1*, 4,7-dimethylferriin; *2*, 5-methylferriin; *3*, ferriin; *4*, 5-chloroferriin; *5*, 5-bromoferriin; *6*, 5-nitroferriin.

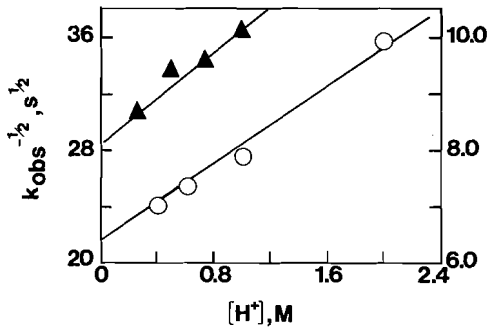

FIG. 3. Plot of $k_{obs}^{-1/2}$ *vs.* $[H^+]$, [Fe(III)] = 1.00 × 10^{-4} *M*, [KSCN] = 8.00 × 10^{-4} *M*, 25 °C. ○, Ferriin in $HClO_4$ at 4 *M* ionic strength (left hand scale); △, 5-methylferriin in HBF_4 at 1 *M* ionic strength (right hand scale).

Our data indicated that under our reaction conditions, 1 *M* $[H^+]$ and ionic strength of 1 *M*, the important term in the oxidation is given by the second order term. Thus, the rate law at constant $[H^+]$ is shown in [3].

$$[3] \quad \frac{d[Fe(II)phen_3]}{dt} = k_3''[SCN]_T^2[Fe(III)phen_3]$$

Inverse dependence on $[H^+]$ suggests that SCN^- is the reactive species which was protonated at higher acidity. Since k_{obs} showed a second order dependence on $[SCN]_T$ and an inverse dependence on $[H^+]$, the dependence of k_{obs} on $[H^+]$ is as follows:

$$[4] \quad k_{obs} = \frac{k_3'[SCN]_T^2}{\left(1 + \frac{[H^+]}{K_a}\right)^2}$$

Equation 4 can be rearranged to

$$[5] \quad k_{obs}^{-1/2} = \frac{1}{k_3'^{1/2}[SCN]_T} + \frac{[H^+]}{K_a k_3'^{1/2}[SCN]_T}$$

Thus, a plot of $k_{obs}^{-1/2}$ *vs.* $[H^+]$ should give a straight line at constant $[SCN]_T$ and from the ratio of intercept/slope, the value of K_a could be obtained and compared with literature data.

The data for $[H^+]$ dependence in $HClO_4$ for ferriin was analyzed according to [5] where $k_{obs}^{-1/2}$ was plotted against $[H^+]$. A reasonable straight line was obtained at 4 *M* ionic strength (Fig. 3) and K_a was evaluated as 3.3 ± 0.4 *M*. There was considerable scatter for the data at 1 and 2 *M* ionic strength, however, reasonable values of K_a, 3.5 ± 0.8 and 3.4 ± 2.0 *M* at 2 and 1 *M* ionic strength were obtained respectively. From the intercept of graphs plotted as in [5], values of k_3' at 1, 2, and 4 *M* ionic strength were 1.44 ± 0.5 × 10^4, 7.7 ± 1.2 × 10^3, and 3.3 ± 0.2 × 10^3 M^{-2} s^{-1} respectively. A plot of log k_3' *vs.* $\sqrt{I}$ gave a straight line with a slope of −0.66 (Fig. 4).

The $[H^+]$ dependence data for 5-methylferriin were also analyzed according to [5] (Fig. 3). The value of K_a was found to be 3.3 ± 0.4 *M*.

Literature values of K_a varied from 0.1 to 100 (13). However, a K_a value of 5 *M* is believed to be the best value (14). Thus, values of K_a obtained from analysis of our data appeared to be in fair agreement with literature data. Apparently K_a does not vary much with ionic strength, which was a little surprising.

A mechanism consistent with the kinetic data is as follows:

$$[6] \quad Fe(III)phen_3 + SCN^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [Fephen_3SCN]^{2+} \quad \mathbf{1}$$

$$[7] \quad [Fephen_3SCN]^{2+} + SCN^- \xrightarrow{k_3} Fe(II)phen_3 + (SCN)_2^{\cdot-}$$

$$[8] \quad SCN^- + H^+ \overset{K_a^{-1}}{\rightleftharpoons} HSCN$$

The initial step of the reaction involves formation of a reactive intermediate **1**. **1** then reacts with another molecule of SCN^- to give Fe(II)-$phen_3$ and $(SCN)_2^{\cdot-}$ radical. Subsequent fast reaction of $(SCN)_2^{\cdot-}$ with $Fe(III)phen_3$ or H_2O produces $Fe(II)phen_3$, CN^-, and SO_4^{2-}.

Applying steady state approximation for the formation of the intermediate **1**, the following rate expression was obtained.

$$[9] \quad \frac{d[Fe(II)phen_3]}{dt} = \frac{k_1k_3[SCN^-]^2[Fe(III)phen_3]}{k_{-1} + k_3[SCN^-]}$$

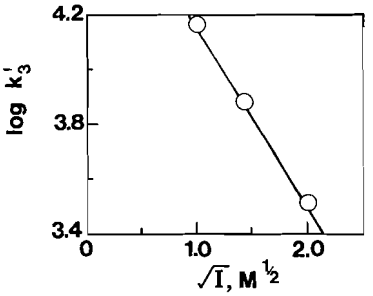

FIG. 4. Plot of log k_3' *vs.* $\sqrt{I}$ at 25 °C.

Fairly good second order dependence on $[SCN]_T$ was observed over a wide range of thiocyanate concentration, hence under the reaction conditions, $k_{-1} \gg k_3[SCN^-]$ and [9] reduces to

$$[10] \quad \frac{d[Fe(II)phen_3]}{dt} = \frac{k_1 k_3 [Fe(III)phen_3][SCN^-]^2}{k_{-1}} = k_3'[Fe(III)phen_3][SCN^-]^2$$

The concentration of free SCN^- may be expressed in terms of total thiocyanate such that

$$[11] \quad [SCN^-]_T = [SCN^-] + [HSCN] = [SCN^-]\left(1 + \frac{[H^+]}{K_a}\right)$$

Therefore

$$[12] \quad \frac{d[Fe(II)phen_3]}{dt} = \frac{k_3'[Fe(III)phen_3][SCN^-]_T^2}{\left(1 + \frac{[H^+]}{K_a}\right)^2}$$

where

$$[13] \quad k_3' = \frac{k_1 k_3}{k_{-1}}$$

Thus, the derived rate expression 12 is consistent with our kinetic data.

Possible mechanisms for the formation of the intermediate $(Fephen_3SCN)^{2+}$ are discussed below.

The initial complex formation could simply be an ion-pairing formation to give $(Fephen_3^{3+}, SCN^-)$ whereby the SCN^- molecule acts as a bridge for intramolecular electron transfer from another SCN^- to the ion pair and subsequently produces $Fe(II)phen_3$ and $(SCN)_2^{\cdot-}$. Existence of the radical anion has been documented (15) and was proposed to be an intermediate in the oxidation of SCN^- by $Fe(H_2O)_6^{3+}$ (11). Alternatively, the 'soft' sulfur atom in the SCN^- molecule in the ion pair may be polarized to give $Fe(III)phen_3...^{\delta-}SCN^{\delta+}$. The polarized $^{\delta-}SCN^{\delta+}$ molecule may induce electron transfer from another SCN^- molecule to give $(SCN)_2^{\cdot-}$. A third possibility is the formation of a radical cation intermediate, $(Fe(II)phen_3SCN^{\cdot}) \equiv (Fephen_3SCN)^{2+}$, via the interaction of filled π orbitals of the sulfur atom with the π^* orbitals of the phenanthroline or by nucleophilic attack of the sulfur on the carbon bearing a partial positive charge. The latter mode of attack is less likely because substituents on the phenanthroline ring which block positions for nucleophilic attack have little effect on the rate. The radical cation intermediate will readily oxidize a SCN^- molecule to give $Fe(II)phen_3$ and $(SCN)_2^{\cdot-}$. Relatively stable precursor complexes have been postulated to exist for $Co(phen)_3^{2+,3+}$, and $Fe(phen)_3^{3+,2+}$ reactions involving thiocyanate (1, 2). The preferred mechanism for their formation involved interaction of the π orbitals on the thiocyanate with the π^* orbitals of the phenanthroline ring. On the basis of the present data, it is not possible to distinguish whether the initial complex formation is an ion-pair formation, ion pair formation prior to radical cation formation, or radical cation formation. However, we found that in the presence of acetone, a limiting value of k_{obs} was found at $\sim 2\ M$ [acetone] and k_1 was estimated to be $\sim 55\ M^{-1}\ s^{-1}$.[1] In the absence of SCN^-, acetone did not appear to be oxidized.[1] The rate constant for ion-pairing is documented to approach the diffusion limit, 10^9–$10^{10}\ M^{-1}\ s^{-1}$ (16). Thus, radical cation intermediate formation is favored. However, ion-pairing prior to radical cation formation could not be ruled out. Formation of an intermediate, $[Fephen_3HSO_3]^{2+}$ between HSO_3^- and $Fe(III)phen_3$ prior to electron transfer from S(IV) to Fe(III) has been proposed (17), but the question exists whether it is only an ion pair or if a more specific interaction exists.

It is interesting to note that simple electron transfer from SCN^- to $Fe(III)phen_3$ to give a $SCN^{\cdot}$ radical is not favored thermodynamically. The E^0 value for $Fe(III)phen_3 \rightarrow Fe(II)phen_3$ is 1.06 V (ref. 6, p. 113), while that for $SCN^- \rightarrow SCN^{\cdot}$ is 1.8 V (18). The initial complexation as represented in [6] probably serves to lower the potential energy for subsequent electron transfer. The first order term reported by Wilmarth and co-workers (7) could result from decomposition of **1** to give $Fe(II)phen_3$ and $SCN^{\cdot}$. In the present study this pathway was found to be unimportant compared to the path second order in thiocyanate. The reason that **1** does not prefer to decompose to thiocyanate radical directly is probably related to the fact that $SCN^{\cdot}$ is a very high energy species.

An estimate of the equilibrium constant K_2 for production of free $SCN^{\bullet}$ *i.e.*

$$[14] \quad Fe(III)phen_3 + SCN^- \underset{}{\overset{K_2}{\rightleftarrows}} Fe(II)phen_3 + SCN^{\bullet}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

is of the order of 10^{-12}. The equilibrium value, K_1, for the initial complex formation to give radical cation intermediate must be greater than 10^{-12} since there is extra stabilization energy due to π complex formation. The experimental value for K_1k_3 is $\sim 10^4\ M^{-2}\ s^{-1}$ for ferriin (Table 6). Since k_3 cannot exceed the diffusion controlled limit of $10^{10}\ M^{-1}\ s^{-1}$, K_1 is $\sim \geq 10^{-6}$ which is greater than 10^{-12}. Unfavorable energy requirements are suggested to account for the complicated mechanism in the oxidation of I^- and CN^- by $Fe(H_2O)_6^{3+}$ (19) and $Fe(CN)_6^{3-}$ (20) and radical anions such as $I_2^{\cdot-}$ (21) and $(CN)_2^{\cdot-}$ (21) were thought to be involved.

The plot of $\log k_3'$ *vs.* E^0 (Fig. 2) does not give a good straight line through all the points. However, if points **1** or **6** are eliminated, reasonably good straight lines can be drawn through the other five points. If **6** is eliminated a line with a slope higher than the theoretical slope predicted by the Marcus theory (22) is obtained. If **1** is eliminated a line with a theoretical slope of 0.5 can be drawn. This line is shown in Fig. 2. If in fact, the Marcus relationship does hold and **1** is off the line the reason could arise from the fact that this complex has 4,7-substituents while the others have 5-substituent. The 4,7-substituents could provide steric hindrance to positions at which the thiocyanate prefers to approach to form intermediate **1** or it could be these positions are the preferred points for electron transfer through the phenanthroline ring. Electron density has been calculated to be different at the different carbons of the phenanthroline ring (23). In any case, the present results do not justify a further discussion of this plot.

Since the rate determining step is preceded by equilibrium two potential surfaces are involved. If the equilibrium constant represented by [6] does not change markedly between each complex, the value of k_3'' will be proportional to k_3 and hence we might expect to get a linear free energy dependence. It is not unreasonable that rates of reaction would increase as ΔG^0 becomes more positive, regardless of mechanism. The fact that ΔG^0 does enter into the rate equation has been interpreted physically in that where there is an overall decrease in free energy, the requirement for any atomic rearrangement prior to electron transfer is reduced since the product can be formed in a vibrationally excited state (24).

Oxidation of $S_2O_8^{2-}$ by substituted ferriin complexes have been found to show a direct dependence of $\log k$ *vs.* E^0 and the expected slope for the Marcus correlation (25). Oxidation of thiourea and *N*-substituted derivatives by cerium(IV) (26) has been reported to have a linear free energy plot with a slope of -0.14 ± 0.2 in the opposite sense to that of $+0.5$ predicted by theory. The deviation from Marcus theory was attributed to the strong interactions between the reactants involved in the formation of radicals, change in formal reduction potentials of the reacting species or that an inner-sphere mechanism occurs. However, there are instances of inner-sphere electron transfer found to give a linear free energy plot (27).

The specific catalytic effect of SO_4^{2-} on the value of k_{obs} (Table 4) in the ferriin case is not clear. Ion pairing is expected to occur (28) but the ion pair, $Fe(III)phen_3,SO_4^{2-}$, may be expected to be less reactive than $Fe(III)phen_3$ towards interaction with SCN^- on electrostatic grounds. Almost identical values of k_3'', $1.44 \times 10^4\ M^{-2}\ s^{-1}$ in 1 *M* H_2SO_4 and $1.42 \times 10^4\ M^{-2}\ s^{-1}$ in 1 *M* HBF_4, were observed for the 5-methylferriin complex. BF_4^- is less effective for ion-pairing compared with SO_4^{2-}, partly because of its univalent positive charge. It is not clear what specific roles the anions, ClO_4^-, SO_4^{2-}, BF_4^- are playing in the oxidation. Specific salt effect (29) is expected to be of importance since high ionic strengths were used in these studies.

The slope of the ionic strength dependence plot (Fig. 4) has the right sign ($-$ve) for reaction between two oppositely charged species. The absolute value of the slope is immaterial since the Debye–Hückel relationship only holds for dilute solutions (<0.01 *M*).

Experimental

1,10-Phenanthroline and the substituted 1,10-phenanthroline derivatives were purchased from G. Frederick Smith Chemical Company. Potassium thiocyanate was AnalaR grade purchased from BDH chemicals and was recrystallized from H_2O before use. Perchloric acid was purchased from G. Frederick Smith Chemical Company. H_2SO_4 was obtained from Matheson, Coleman and Bell Manufacturing Company.

Tris(1,10-phenanthroline)Fe(II), ferroin, and the substituted ferroin complexes were prepared by a published procedure (30) which consists of adding an equivalent amount of appropriate ligand to a solution of $FeSO_4 \cdot 7H_2O$ in a 3:1 molar ratio. The Fe(III) complexes were obtained by oxidation of the Fe(II) complexes with PbO_2 in $\sim 1\ M$ H_2SO_4. The Fe(III) complexes were precipitated as perchlorate salts. Stock solutions of the Fe(III) complexes were made up in concentrated H_2SO_4

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

or $HClO_4$ medium. Such solutions were diluted with water to the desired acid strength immediately before each kinetic run.

Kinetic Studies

The Fe(II) complexes have extinction coefficients of the order of 10^4 in the region of 510 nm while the corresponding Fe(III) complexes are practically transparent at this wavelength. Thus, the rate of oxidation of SCN^- was conveniently monitored by following the increase in optical density at ~510 nm with time.

Kinetic studies for the oxidation were carried out on a Durrum stopped-flow spectrophotometer, Unicam SP 800, Unicam SP 1700, and Cary 118 spectrophotometers. The reaction was carried out under pseudo first order conditions with excess KSCN and reasonably good pseudo first order kinetics were obtained. The pseudo first order rate constants were obtained by plotting log $(O.D._\infty - O.D._t)$ against time.

The concentration of the stock KSCN solution was determined by titration with standard $AgNO_3$ using ferric ammonium sulfate as indicator. Stock solutions of KSCN kept in deionized water were stable for several months. However, acidic solutions of KSCN were not stable for a long period of time due to the production of H_2S (11).

Product Analysis

$Fe(II)phen_3(ClO_4)_2$ is less soluble than $Fe(III)phen_3(ClO_4)_3$. In experiments designed for product analysis, a high concentration of $Fe(III)phen_3(ClO_4)_3$, 10^{-2} *M*, was used and during the reduction, an orange red precipitate was observed. The orange red precipitate was washed with water and collected. The infrared spectrum was identical to a standard $Fe(II)phen_3(ClO_4)_2$ sample. Satisfactory microanalysis for C, H, N were also found.

Anal. Calcd. for $Fe(II)phen_3(ClO_4)_2$: N, 10.95; C, 54.53; H, 2.87. Found N, 10.6; C, 54.5; H, 3.02.

The visible spectrum of the orange red precipitate also resembled that of $Fe(II)phen_3(ClO_4)_2$.

CN^- was determined by precipitation as AgCN. A solution containing 4.56×10^{-3} mol of $Fe(III)phen_3$ and 7.6×10^{-4} mol of KSCN in 3 *M* H_2SO_4 was stirred in a closed system. Argon was passed slowly into the solution to purge any HCN produced into a $AgNO_3$ solution. After a period of 2 d, there was sufficient white precipitate for a spectrum. The solid was collected from the $AgNO_3$ solution and the infrared spectrum of the white solid was recorded using a Beckman IR12 spectrophotometer. The spectrum showed an intense absorption at 2168 cm^{-1} which is characteristic of the —C≡N stretch of AgCN. The characteristic —C≡N absorption for AgSCN is at 2152 cm^{-1}.

A solution containing 4×10^{-4} mol of ferriin was suspended in 10 ml 6 *M* $HClO_4$ and 2.4×10^{-4} mol of KSCN were added. The solution was stirred for a day and the red precipitate of $Fe(II)phen_3$ was filtered. The solution was made basic with NaOH and the dissociated phenanthroline was precipitated and filtered. The resulting solution was acidified with $HClO_4$ and a white precipitate of $BaSO_4$ was obtained on adding a solution of $BaCl_2$.

Consumption of Cetyl Trimethyl Ammonium Bromide (CTAB) during Electrodeposition of Lead Dioxide

KAPISTHALAM CHETLUR NARASIMHAM, SRINIVASARAGHAVAN VASUNDARA, AND HANDADY VENKATAKRISHNA UDUPA

Central Electrochemical Research Institute, Karaikudi 623 006, India

Received February 3, 1975

KAPISTHALAM CHETLUR NARASIMHAM, SRINIVASARAGHAVAN VASUNDARA, and HANDADY VENKATAKRISHNA UDUPA. Can. J. Chem. **53**, 3327 (1975).

The beneficial effect of the addition of CTAB during electrodeposition of lead dioxide led to the investigations on the necessity to control the concentration of the addition agent for obtaining a smooth and adherent deposit of the same on a stationary graphite anode. To achieve this, it is important to know the consumption pattern of the addition agent. It has been observed that the CTAB is consumed not only for cathodic reaction but also for anodic reaction. Increasing temperature lowers the consumption of CTAB.

KAPISTHALAM CHETLUR NARASIMHAM, SRINIVASARAGHAVAN VASUNDARA et HANDADY VENKATAKRISHNA UDUPA. Can. J. Chem. **53**, 3327 (1975).

L'effet advantageux qu'on obtient par l'addition de CTAB pendant le dépôt electrolytique de dioxyde de plomb conduit à examiner la necessité d'asservir le concentration avec le but d'obtenir un dépôt uniforme et adhérent de dioxyde de plomb sur un anode stationnaire de graphite. Pour cela, c'est important de savoir la maquette de consommation de l'agent actif. Il a été observé que la consommation de CTAB est non seulement lors de la réaction cathodique mais aussi lors de la réaction anodique. L'accroissement de la temperature abaisse la consommation de CTAB.

Introduction

In the course of the study on the measurement of internal stress in electrodeposited lead dioxide from lead nitrate – copper nitrate bath, Gnanasekaran *et al.* (1) found that the addition of CTAB not only lowered the stress but also helped in getting a deposit free from pinholes under stationary condition. The beneficial effect of addition of CTAB and other alkyl trimethyl ammonium bromide during electrodeposition of lead dioxide has been studied in detail and found to give a smooth and adherent deposit of lead dioxide on a stationary graphite anode (2, 3). In order to obtain a desirable deposit of lead dioxide it is necessary to control the concentration of addition agent. To achieve this, it is important to know the consumption pattern of the addition agent. A suitable analytical procedure for the determination of alkyl trimethyl ammonium bromide in the presence of lead and copper nitrates has earlier been reported by Narasimham *et al.* (4) and using this method the consumption of CTAB during deposition has been estimated and the results are presented in this paper.

Experimental

Cell Assembly

A 1 l Pyrex beaker fitted with a PVC cover containing suitable holes to introduce anode, cathode, and thermometer, acted as cell container. Two rectangular stainless steel plates (14 × 3 × 0.1 cm each) placed on either side of the anode acted as cathode. A graphite rod (1 cm diameter × 15 cm long) with the lower end rounded off served as anode. Before electrolysis the anode was given the usual pretreatment (5).

The electrolyte was an aqueous solution of lead nitrate (350 ± 10 g/l) and copper nitrate (25 ± 2 g/l) containing CTAB. For determining CTAB consumption during copper deposition from copper nitrate solution alone, copper nitrate of 25 ± 2 g/l concentration was used. To determine the consumption of CTAB in pure lead nitrate solution (350 ± 10 g/l) a porous pot was introduced in which 5% (v/v) nitric acid was taken as catholyte to prevent the deposition of lead at the cathode. CTAB (1.2 g/l) was added in all the cases.

Electrolysis

The p*H* of the electrolyte before starting the deposition was adjusted to 4 and 850 ml of this solution was then taken for the experiment. Both anode and cathode were kept stationary during electrolysis. Direct current was supplied from a selenium rectifier (0–12 V and 50 A). The deposition of lead dioxide or copper or both was carried out for different durations and the amount of CTAB consumed was determined. Similarly, the consumption of CTAB was determined at different tempera-

†Fresh anode was used every two hours of electrolysis.

tures. Experiments were conducted in duplicate and the results varied within 1%.

Internal Stress

The internal stress of the electrodeposited lead dioxide obtained from lead nitrate – copper nitrate bath containing various concentrations of CTAB (due to consumption for different durations) was measured employing a Hoar and Arrowsmith balance (6, 7) and using the procedure described by Gnanasekaran *et al.* (1) earlier.

Analysis

Lead and copper concentrations in the electrolyte were estimated by EDTA method (8) and iodometric (9) method respectively. The single-phase titration of CTAB in presence of lead and copper nitrates, with sodium tetraphenyl boron at pH 3 using methyl yellow as indicator, as reported by Narasimham *et al.* (4), was the method adopted for the determination of the consumption of CTAB in the electrolyte.

Results and Discussion

Table 1 shows the results of experiment. It is seen that CTAB is being consumed both for anodic and cathodic reactions, the consumption for the latter being greater. Since CTAB is a cationic surfactant, its consumption for cathodic reaction can very well be expected. However, the consumption of CTAB for the anodic reaction cannot normally be expected, but the results obtained are similar to the observations made by Lorking (10) in the experiments on anodic polishing of copper. The consumption of CTAB can be attributed to depletion arising out of adsorption and/or oxidation of the organic molecule itself. The consumption of CTAB in lead nitrate – copper nitrate mixture almost corresponds to the total consumption of the surfactant in lead nitrate and copper nitrate present separately.

The consumption of CTAB in the mixture of lead nitrate – copper nitrate decreases with increase in temperature as can be seen from Fig. 1. Thus at higher temperature not only is the consumption of CTAB less but there is also the practical advantage that the deposit obtained is adherent, smooth, and free from pinholes. However this observation is not in conformity with the usual expectation of increased consumption of organic molecule with increased temperature. Aspects relating to the mechanism of consumption and the anomalous temperature effect on the consumption of CTAB are not studied in detail in this paper, since the primary

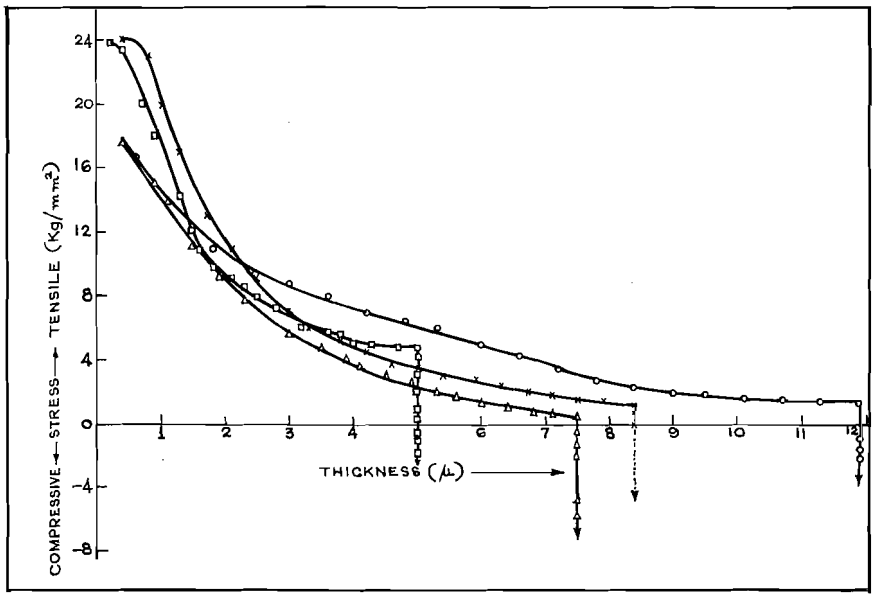

FIG. 2. Variation of internal stress due to consumption of CTAB. ○, at start; ×, after 2 h; △, after 4 h; □, after 6 h.

aim of this investigation is to ascertain the consumption pattern of the surfactant during the deposition.

From Fig. 2, it can be seen that the peak stress of fresh bath is lower. The mean stress remains tensile even with the electrolyte used for 6 h of electrolysis without replenishing CTAB. The compressive aftereffect is seen in all the solutions as observed earlier (1). The lead dioxide deposits obtained were shiny, smooth, adherent, and free from pinholes.

Conclusion

The beneficial effect of a cathodic surface active agent like CTAB, which is a typical example of quaternary ammonium surfactants, on the anodic deposition of lead dioxide offers an interesting study. It is now well established that the cationic surfactant is also consumed, perhaps by adsorption/oxidation at the anode during the deposition of lead dioxide, and these results are similar to the observations of Lorking (10). The lower consumption of CTAB in the electrolyte coupled with the obtaining of the desired deposit at higher temperature during the deposition of lead dioxide make the process interesting and attractive from a practical point of view.

A Kinetic Determination of the Dissociation Energy of the C—O Bond in Anisole

S. PAUL AND M. H. BACK

Chemistry Department, University of Ottawa, Ottawa, Canada K1N 6N5

Received June 12, 1975

S. PAUL and M. H. BACK. Can. J. Chem. **53**, 3330 (1975).

The rate of dissociation of anisole into phenoxy and methyl radicals has been measured using a toluene scavenging technique. The rate was measured by the production of methane over the range of temperature 720–795 K and was shown to be first order in anisole concentration and homogeneous. The rate constant, expressed in the Arrhenius form, was

$$\log k\,(s^{-1}) = 13.7 \pm 0.3 - \frac{58000 \pm 2000}{2.3RT}$$

The dissociation energy, $D_{298}(C_6H_5O—CH_3)$, therefore equals 57 ± 2 kcal/mol, giving $\Delta H_f(C_6H_5O) = 5$ kcal/mol. The stabilization energy of the phenoxy radical is discussed.

S. PAUL et M. H. BACK. Can. J. Chem. **53**, 3330 (1975).

On a mesuré le taux de dissociation de l'anisole en radicaux phénoxy et méthyle en utilisant la technique de piégeage au toluène. On a mesuré la vitesse par la production de méthane à des températures allant de 720 à 795 K et on a montré que cette vitesse est du premier ordre en concentration d'anisole et qu'elle est homogène. La constante de vitesse, exprimée sous une forme d'Arrhénius, est

$$\log k\,(s^{-1}) = 13.7 \pm 0.3 - \frac{58000 \pm 2000}{2.3RT}$$

L'énergie de dissociation $D_{298}(C_6H_5O—CH_3)$ est donc égale à 57 ± 2 kcal/mol donnant un $\Delta H_f(C_6H_5O) = 5$ kcal/mol. On discute de l'énergie de stabilisation du radical phénoxy.

[Traduit par le journal]

Introduction

There is an abundance of evidence that the thermal decomposition of dialkyl, diaryl, and alkyl aryl ethers occurs by an initial dissociation into radicals, followed by radical chain processes (1, 2). Some cyclic ethers, such as dioxalane (3) and tetrahydrofuran (4) also decompose in this way. Nevertheless there are no direct measurements of the dissociation energy of the C—O bond in ethers.[1] These values are available only through the heats of formation of the alkoxy radicals, and few of these are known with confidence (6). In order to provide a direct measurement of the dissociation energy of an ether linkage, the present study of the thermal decomposition of anisole was undertaken.

Anisole was the ether chosen for study because it was expected that the $C_6H_5O—CH_3$ bond would be considerably weakened due to the stabilization of the phenoxy radical. Toluene would therefore provide a suitable scavenger so that the rate of the initial dissociation could be measured. The technique involved the pyrolysis of mixtures of anisole and toluene in a static system. The following reactions would be expected to occur.

[1] $$C_6H_5OCH_3 \rightarrow C_6H_5O + CH_3$$

[2] $$CH_3 + C_6H_5CH_3 \rightarrow CH_4 + C_6H_5CH_2$$

[3] $$C_6H_5O + C_6H_5CH_3 \rightarrow C_6H_5OH + C_6H_5CH_2$$

[4] $$2C_6H_5CH_2 \rightarrow (C_6H_5CH_2)_2$$

From the measurement of the rate of formation of methane or phenol, the rate of bond fission in anisole may be obtained. With certain assumptions, the temperature-dependence of this rate may be equated to the bond dissociation energy.

Experimental

The experiments were performed in a conventional glass vacuum apparatus which included a 3-l mixing vessel, a 342-cc quartz reaction vessel, and a series of traps for fractionation of the products of the reaction. The mixing vessel and storage flasks were enclosed in an oven maintained at 110 °C, to ensure sufficient pressure

[1] In a concurrent study by Pacey (5) a value for $D(CH_3—OCH_3)$ has been determined.

of the reactants. The pressure in the mixing vessel was measured with a glass diaphragm gauge operated as a null measurement. A second reaction vessel, packed with glass tubes to give a S/V ratio of 9 cm^{-1} was used for several series of experiments to test for a heterogeneous reaction. The reaction vessel was enclosed in an electrically heated iron cylinder and the temperature was controlled within $\pm 0.5°$. Mixtures of reactants were allowed to equilibrate for at least 18 h and were admitted to the reaction vessel through heated capillary tubing. The final pressure in the mixing vessel was the initial pressure of the reactants in the reaction vessel. Several series of experiments were done for a fixed reaction time with the same mixture in the mixing vessel, but with a continuously decreasing pressure in the reaction vessel, corresponding to the ratio of volumes of the reaction vessel and the mixing vessel.

Toluene was research grade (99.9%) obtained from Phillips Petroleum Co. Anisole was reagent grade from Fisher Scientific Co. Analysis by gas chromatography showed that the most probable impurities, benzene, toluene, methyl anisole, and phenetole, if present, were less than 0.1% of the anisole. Hydrogen, methane, carbon monoxide, and ethane, used for calibrations, were research grade from Phillips Petroleum Co. Other compounds used for calibration were research grade from various suppliers.

At the end of an experiment, the products and reactants were fractionated through traps at −78 and −196 °C. The noncondensable gases were collected and the total amount measured in the gas burette. These products, which consisted of hydrogen, carbon monoxide, and methane, were analyzed by gas chromatography using a silica gel column (9 ft × 1/4 in.) at −35 °C. The carrier gas was He and a thermal conductivity detector was used. Under these conditions the sensitivity for detection of hydrogen is not great and in some experiments, where the amount of hydrogen was small, the yield of hydrogen was calculated as the difference between the yields of methane and carbon monoxide and the total yield of noncondensable products. The fraction collected at −196 °C was analyzed on the same silica gel column maintained at 30 °C. The fraction collected at −78 °C was weighed and the volume calculated by assuming a density equal to that of toluene. Aliquot samples were taken for analysis by gas chromatography. The column used was 4% silicone grease SE 30 on chromosorb G (9 ft × 1/4 in.) maintained initially at 100 °C. After the major products, phenol and xylenes, together with the reactants anisole and toluene, were eluted, the temperature was quickly raised to 170 °C and, after stabilization, dibenzyl and other dimers were eluted. Calibrations of the liquid products were made from solutions in toluene. The reproducibility was about ±4%.

Results

The reaction was studied over the temperature range 720–795 K and at pressures of anisole from 16 to 4 Torr. The major products were methane, phenol, dibenzyl, and hydrogen. Carbon monoxide, ethylbenzene, xylenes, and benzyl phenyl ether were minor products.

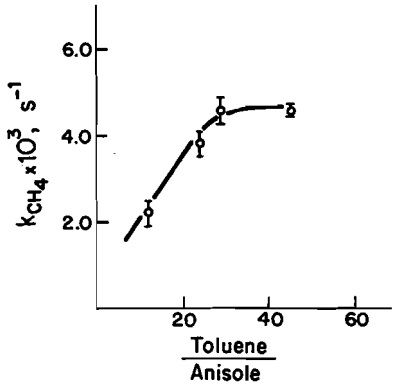

FIG. 1. Variation of the rate constant for the formation of methane as a function of the ratio toluene/anisole at 795 K. Range of anisole pressure, 4–13 Torr.

Ethane, benzaldehyde, and cresols were shown to be absent. Identification was made by coincidence of retention time with pure samples on two different columns. A small amount of product was tentatively identified as $C_6H_5CH_2$-OC_6H_5, the cross-combination product, because its retention time was intermediate between that of diphenyl ether and dibenzyl ether. The yield of xylenes and ethyl benzene was always less than 5% of the yield of methane or phenol. The yield of methane and hydrogen from the decomposition of toluene itself was shown to be negligible in the temperature range studied.

The rate of formation of methane from the decomposition of anisole was first studied as a function of the ratio of toluene to anisole, in order to determine the pressure of toluene necessary to scavenge all the radicals formed in the initial dissociation. The rate constant for the formation of methane is shown as a function of the ratio of toluene/anisole in Fig. 1. For this calculation, the rate of formation of methane was assumed to be first order with respect to anisole; evidence to support this will be presented later. Complete scavenging of the methyl radicals occurs at a ratio of toluene/anisole above 30. In most of the subsequent series of experiments, the ratio of toluene/anisole was kept at 30. In a few series, the ratio was increased to 45 and no change in the rate constant was observed.

The Primary Products, Methane, Phenol, and Dibenzyl

The yields of methane, phenol, and dibenzyl are shown as a function of initial pressure of anisole for a given time of reaction in Fig. 2.

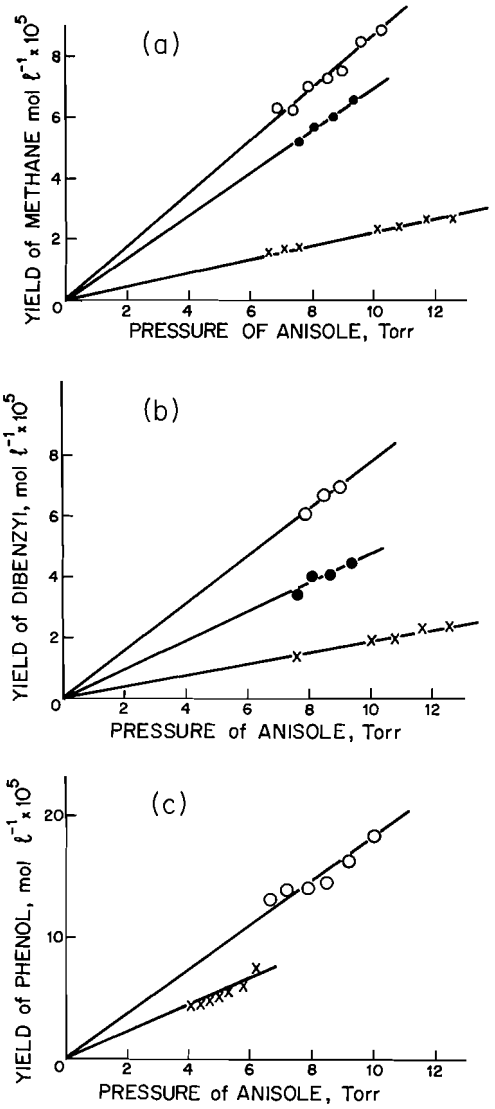

FIG. 2. Yields of the major primary products as a function of initial pressure of anisole. (*a*) Methane, 762 K; (*b*) dibenzyl, 762 K; (*c*) phenol, 795 K. ○, 500 s; ●, 400 s; ×, 100 s.

The linearity of these plots, extrapolating to the origin, shows that the rates of formation of these products are first order with respect to anisole. Yield–time plots for each of these products were obtained by interpolation for a particular pressure of anisole from series of experiments such as given in Fig. 2. An example is shown in Fig. 3. The integrated first order rate equation for methane at 762 and 795 K is shown in Fig. 4. Thus, both the concentration dependence and the time dependence show that

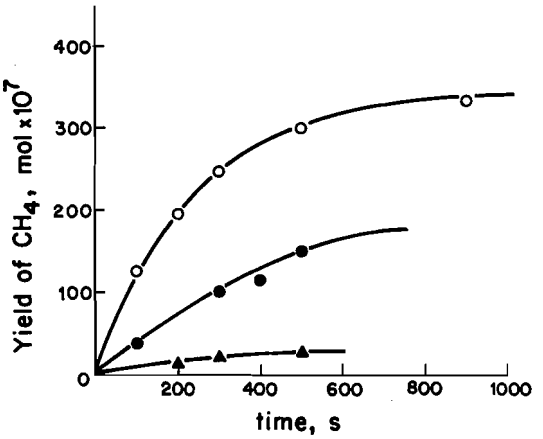

FIG. 3. Yield of methane as a function of time. Anisole pressure = 5 Torr. ○, 795 K; ●, 762 K; ▲, 740 K.

the rate of formation of methane is first order with respect to anisole.

In previous studies of dissociation reactions using the toluene-carrier technique, one of the most serious errors was caused by the fact that under the conditions of high temperature and low pressure, the dissociation was often in its pressure-dependent region (6). In the flow system used for these studies, a suitable test for order could not always be achieved. In the present technique, using toluene as a scavenger in a static system, this error is not important. At the lower temperatures, the measured rate constants are 100–1000 times less than typical values measured by the toluene-carrier technique. This, combined with the higher pressures of the static system, ensures that the rate constants for dissociation are truly first order.

According to the simple mechanism given by [1]–[4], the yields of phenol and methane should be equal and the yield of methane or of phenol should equal the yield of dibenzyl. Some of the results, showing the stoichiometry, are given in Table 1. The ratio of phenol/methane is close to one under most conditions and is independent of time, further evidence that phenol is a primary product. The ratio dibenzyl/methane is close to one at the lowest temperature, 720 K, but becomes less than one as the temperature is increased. Dibenzyl is relatively unstable at these temperatures and might be expected to undergo secondary decomposition. That this is the case is shown by the decrease in the ratio of dibenzyl/methane with time, illustrated in Fig. 5. Complementing the loss of dibenzyl with time is the appearance of hydrogen as a product. Ratios of hydrogen/methane as a function of time are shown in Fig. 6, which clearly indicates that hydrogen is a secondary product.

It seems reasonable to suggest that secondary decomposition of dibenzyl yields hydrogen. Two possible mechanisms for this decomposition may be suggested: (*a*) molecular decomposition to give hydrogen and stilbene; (*b*) dissociation by C—H bond rupture followed by hydrogen-

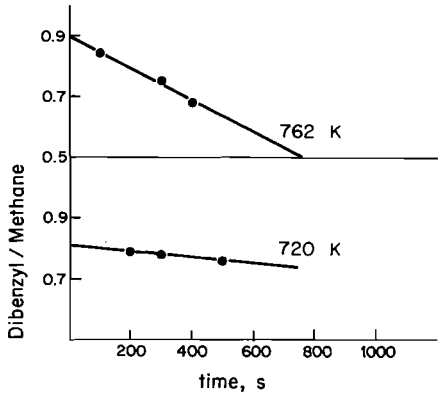

FIG. 5. The ratio of dibenzyl/methane as a function of time. Range of total pressure = 180 − 300 Torr.

atom abstraction. An early study of the thermal decomposition of dibenzyl (7) in the region of 1000 K at low pressure showed that, in the absence of a scavenger, hydrogen was a minor product. Blades *et al.* (8), however, found that when dibenzyl was pyrolyzed in the presence of toluene, hydrogen was an important product. It appears reasonable to conclude that in the present study, secondary decomposition of dibenzyl yields hydrogen as a main product.

The extrapolation of the ratio dibenzyl/methane to zero time was always less than one and usually varied between 0.9 and 0.8. The complete collection of dibenzyl was difficult because of its low volatility and it may be assumed that some loss occurred in this way. Because of the temperature-programming required for the analysis of dibenzyl, the error in its calibration, ±5%, was larger than that of

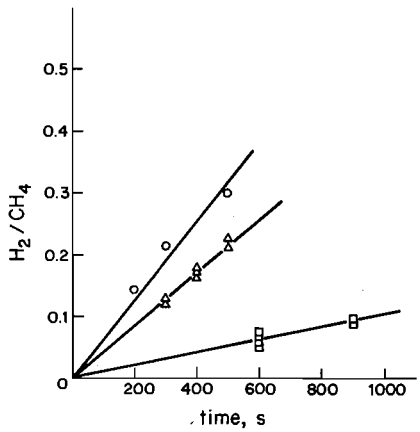

FIG. 6. The ratio of hydrogen/methane as a function of time. Range of total pressure 200–300 Torr. ○, 795 K; △, 762 K; □, 720 K.

TABLE 2. Rate constants

the other major products. The low ratio of dibenzyl/methane observed in the present study may be attributed to experimental error, compounded by the loss by secondary decomposition, and not to any serious complication to the simple series of reactions 1 to 4. That complete scavenging of the methyl and phenoxy radicals occurred seems a reasonable conclusion in view of the fact that combination products of the methyl radical, such as ethyl benzene and xylenes were never more than 5% of the methane.

Calculation of Rate Constants

The rate constants were calculated from the yield of methane, using the integrated first order rate equation, since the measurement of this product was judged to be the most accurate. An average rate constant was obtained from each series of experiments, usually comprising six or seven measurements, such as illustrated in Fig. 2. Each of these rate constants were again averaged to obtain a final value for each temperature. A summary of the rate constants obtained in the packed and unpacked vessels, with the number of series used to obtain the average, is given in Table 2. The Arrhenius plot of the rate constants is shown in Fig. 7. From these results, the activation energy of the reaction is 58 ± 2 kcal/mol and log A (s^{-1}) is 13.7 ± 0.3.

Minor Products

The minor products, which amounted to about 5% of the yield of methane, were xylenes, ethylbenzene, and carbon monoxide. The formation of xylenes suggests that in the reaction of radicals with toluene, there was some interaction with the ring, either as abstraction or as addition.

[5] $CH_3 + C_6H_5CH_3 \rightarrow CH_4 + C_6H_4CH_3$

$C_6H_4CH_3 + CH_3 \rightarrow$ xylenes

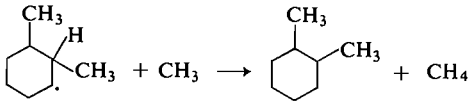
[6] $CH_3 + C_6H_5CH_3 \rightarrow$ 



and other isomers

Similarly, ethylbenzene may be formed by the combination of benzyl and methyl radicals. The formation of these products represents a loss of methane and dibenzyl. A correction was therefore applied to the yield of methane equivalent to the sum of the yields of xylenes and ethylbenzene. The maximum correction at the highest temperature was not more than 5% of the yield of methane and was negligible at the other temperatures.

A small amount of carbon monoxide, about 2% of the yield of phenol, was detected at the highest temperature. The rate of formation of carbon monoxide was first order in anisole and the most likely reaction leading to its formation is the decomposition of the phenoxy radical

This reaction was suggested as the source of carbon monoxide formation in the pyrolysis of anisole at 1223 K, where it was a major product (9). In the present experiments the ratio toluene/anisole was constant for the determination of the order.

Discussion

The identification of the activation energy for the rate of formation of methane with the bond dissociation energy $D(C_6H_5O—CH_3)$ in anisole is substantiated by the following results: (*1*) The rate of formation of methane is first order with respect to anisole. (*2*) The ratio of dibenzyl/methane is close to one. (*3*) Other products formed from methyl radicals, for example, xylenes and ethylbenzene, are a small fraction of the methane and a correction for loss of methyl radical may be made with reasonable accuracy. (*4*) The formation of methane is a homogeneous reaction. (*5*) The frequency factor is in the range expected for this type of dissociation reaction.

Thus, we may conclude that the rate of formation of methane may be equated to the rate of the homogeneous unimolecular dissociation of anisole into phenoxy and methyl radicals and, with the assumption that the combination of phenoxy and methyl radicals requires no activation energy, the activation energy of the rate may be equated to the dissociation energy of the bond broken.

The uncertainty in the measurement of k is largely the result of errors in recovery and analysis of the products and in the temperature control. The largest average deviation of the rate constant was $\pm 5\%$ at the highest temperature. A reasonable estimate for the random error in the activation energy is therefore ± 2 kcal/mol.

The measured value of the frequency factor for [1] may be combined with the entropy change of the reaction to obtain a value for the frequency factor for the reverse reaction, which, if no activation energy is involved, is the rate constant for combination of the phenoxy and methyl radicals. Although entropy data are not available for the phenoxy radical, the entropy change of the reaction may be assumed to be similar to that for the dissociation of *N*-methylaniline, $C_6H_5NHCH_3$, for which $\Delta S^0 = 36.5$ cal deg^{-1} mol^{-1} (10). A value for k_{-1} of 6×10^7 l mol^{-1} s^{-1} is thus obtained.

The measured values for the combination rate constants for small radicals in the gas phase lie between 10^9 and 10^{10} l mol^{-1} s^{-1}, while the estimated values for resonance-stabilized radicals appear lower, in the range 10^8 to 10^9 l mol^{-1} s^{-1} (10). Although no direct measurement has been made in the gas phase, measurements of the

rate constant for dimerization of phenoxy radicals in solution (11) indicate a value of 8×10^8 l mol^{-1} s^{-1} and for the combination of phenoxy and alkyl peroxy radicals (12), a similar value. On the other hand, a recent measurement of the rate of disappearance of phenoxy radicals in aqueous solution (13) gave a value for the rate constant of about 10^7–10^8 l mol^{-1} s^{-1}. Although the value of k_{-1} calculated from the present results appears low, it may be concluded, in view of the lack of direct measurements of combination rate constants for large radicals and the uncertainties in comparing rate constants measured in liquid and gas phase, that the value lies within an acceptable range. It should be pointed out that some of the errors associated with the toluene carrier technique, for example, pressure-dependence of the rate constant or chain propagation by benzyl radicals, have in the past sometimes led to low values of the activation energy and frequency factor for bond fission reactions (10). These errors should have been eliminated under the conditions of lower temperature and higher pressure used in the present experiments. In the following tables, therefore, the activation energy measured in the present experiments will be the value given for the dissociation energy of the C—O bond in anisole.

Taking ΔC_p for [1] as approximately equal to RT, the present result gives the dissociation energy of the C—O bond, $D_{298}(C_6H_5O—CH_3) = 57 \pm 2$ kcal/mol. Using this value, the heat of formation of the phenoxy radical may be calculated from the equation

$$\Delta H_f(C_6H_5OCH_3) + D_{298}(C_6H_5O—CH_3) = \Delta H_f(C_6H_5O) + H_f(CH_3)$$

This value and related bond dissociation energies are given in Table 3.

The Stabilization Energy of the Phenoxy Radical

In a qualitative sense the phenoxy radical has long been recognized as being particularly stable. The kinetics and thermodynamics of its reactions in solution (14), its inhibitory effect on the oxidation of hydrocarbons (12), and the energetics of its oxidation–reduction system (15), combined with the fact that aromatic peroxides are not stable at room temperature (16), all indicate a large resonance stabilization. Nevertheless, an unambiguous value for its heat of formation has been difficult to obtain.

From measurements of the critical potentials of oxidation–reduction systems, Hush (15) estimated a value for $D(C_6H_5O—H)$ of 84 kcal/mol, which leads to a value of +9 kcal/mol for $\Delta H_f(C_6H_5O)$. In a study of the kinetics and thermodynamics of reactions of substituted phenoxy radicals with their parent phenol molecule, Mahoney and DaRooge (14) obtained values for the difference in heats of formation between the radicals and parent molecules. The heats of formation of the substituted phenoxy radicals obtained in this way were grouped around the value of +9 kcal/mol for phenoxy estimated by Hush. From the measurement of the ionization potential of the phenoxy radical, Fisher *et al.* (17) calculated a value for $\Delta H_f(C_6H_5O) < 20$ kcal/mol, but suggested that this was probably high by about 10 kcal/mol. Natalis and Franklin (18) reached a similar conclusion from a study of the appearance potential of the $C_6H_5CO^+$ ion from several different sources. Their value of $\Delta H_f(C_6H_5CO^+)$ when combined with relevant thermochemical

and appearance potential data, gave $\Delta H_f(C_6H_5O) = 9$ kcal/mol. These estimates are about 4–5 kcal/mol higher than the present measurement, but scarcely outside the combined errors of each technique.

The heat of formation of a radical in itself is not a quantitative measure of its stability. Bond dissociation energies involving the radical, however, provide a direct means of estimating its stabilization energy (19). The difference in dissociation energies of two bonds, one of which, on dissociation, gives a stabilized radical while the other gives an unstabilized radical, may be taken as the stabilization energy. If the present measurement of $D(C_6H_5O—CH_3)$ (57 kcal/mol) is compared to the dissociation energy of the C—O bond in dimethyl ether (77 kcal/mol) (5), a stabilization energy of 20 kcal/mol for the phenoxy radical is indicated. A similar value was suggested by Thomas (12) from a study of the inhibition of the oxidation of hydrocarbons by phenol. He concluded that the phenoxy radical was only slightly less stabilized than the alkyl peroxide radical, RO_2, which was estimated to be stabilized by as much as 25 kcal/mol.

To compare the stabilization of the phenoxy radical with the isoelectronic benzyl and anilino radicals, a group of C—H, N—H, and O—H bond dissociation energies are compared in Table 4. The group of three values is shown in order to minimize the effect of uncertainties in individual values. The total decrease through the series is largest for the O—H bonds and smallest for the C—H bonds. In each case, the energy decrease observed when the phenyl group replaces the methyl group is larger than the decrease observed when a methyl group replaces a hydrogen atom. With the N—H bonds, the difference is not large, but these values should be accepted with caution since dissociation energies of bonds containing nitrogen are not, except for a few cases, well established.

Calculations of the spin density distribution and measurements of the e.p.r. hyperfine splittings have been interpreted to indicate a trend toward a more symmetric ring in going from benzyl to phenoxy (20). This is in accord with the suggestion that the ionic form of the phenoxy radical makes a substantial contribution to the total structure. In a kinetic study of reactions involving the phenoxy and the benzyl radicals (21) the results indicated a greater tendency of the phenoxy radical to undergo reaction at a ring site. These interpretations suggest that the stabilization energy should increase in going from benzyl to phenoxy and the present results bear out these expectations.

Stereochemistry of the Bucherer–Bergs and Strecker Reactions of 4-*tert*-Butylcyclohexanone

JOHN T. EDWARD AND CHOTE JITRANGSRI

Department of Chemistry, McGill University, P.O. Box 6070, Station A, Montreal, Quebec H3C 3G1

Received May 16, 1975

JOHN T. EDWARD and CHOTE JITRANGSRI. Can. J. Chem. **53**, 3339 (1975).

The spirohydantoin (α-isomer) obtained from 4-*tert*-butylcyclohexanone by the Bucherer–Bergs reaction has been shown by n.m.r., u.v., and considerations of steric hindrance to have the *tert*-butyl group and 1′-nitrogen atom *cis*; the β isomer obtained via the Strecker reaction, or via modified Bucherer–Bergs reactions employing carbon disulfide or carbon oxysulfide, has these groups *trans*. The differing stereochemical courses of the various reactions can be explained by a detailed consideration of their mechanisms.

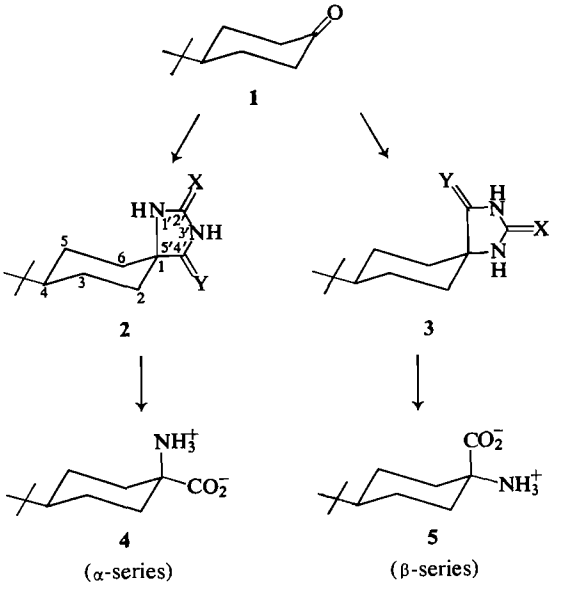
JOHN T. EDWARD et CHOTE JITRANGSRI. Can. J. Chem. **53**, 3339 (1975).

On montre par des études r.m.n., u.v., et chimiques que dans la spirohydantoïne (α) fournie par la *tert*-butyl-4 cyclohexanone dans la réaction de Bucherer–Bergs il y a une relation *cis* entre le groupement *tert*-butyle et le 1′-N de l'anneau hydantoïne. Les composés *spiro* fournis par la réaction de Strecker, ou par les réactions modifiées de Bucherer–Bergs utilisant le disulfide de carbone ou l'oxysulfide de carbone, montrent une relation *trans* entre ces groupements. Par une considération en détail des mécanismes de ces réactions, on peut expliquer les résultats stéréochimiques différents.

Introduction

One of the most convenient routes to α-amino acids involves the reaction of aldehydes or ketones with ammonium carbonate and sodium cyanide to form hydantoins (the Bucherer–Bergs reaction), followed by hydrolysis of the latter to amino acids. The alternative route from ketones via amino nitriles (the Strecker reaction) generally gives the same products, but in poorer yields. However, with some ketones the two routes lead to different products. Thus Munday (1) found that the Bucherer–Bergs reaction of 4-*tert*-butylcyclohexanone (**1**) gave preponderantly one isomeric hydantoin (designated α (2)), accompanied by only a trace of a second (β) isomer. These must have the structures **2** and **3** (X = Y = O). Hydrolysis of the hydantoins furnishes two isomeric amino acids (**4** and **5**). While the amino acid of the α series is the major product by this route, only the amino acid of the β series could be obtained from the amino nitrile furnished by the Strecker reaction (1).

Carrington and co-workers discovered two modifications of the Bucherer–Bergs reaction: one in which the ammonium carbonate of the usual reaction is replaced by ammonium chloride and carbon disulfide (3); a second in which it is replaced by ammonium chloride and carbon oxysulfide (4). These reactions give a 2,4-dithiohydantoin and a 4-thiohydantoin, respectively.



SCHEME 1

We have now found that 4-*tert*-butylcyclohexanone (like many other substituted cyclohexanones studied by Carrington (3)) furnishes exclusively spiro compounds of the β series by these reactions. This was proved by treating the major (α) hydantoin from the normal Bucherer–Bergs reaction with phosphorus pentasulfide (5) and converting it into a 2,4-dithiohydantoin

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

which turned out to differ from the product afforded by Carrington's procedure. On the other hand, 2,4-dithiohydantoin produced by treating with phosphorus pentasulfide the spiro-4-hydantoin afforded by his second modified procedure using carbon oxysulfide, was identical to the compound produced by using carbon disulfide.

The configurations of the α- and β-isomeric compounds obtained from 4-*tert*-butylcyclohexanone have up until now remained unsettled. On the basis of various physical and chemical properties, Munday (1) assigned the structure **2** (X = Y = O) to the α-hydantoin and **3** (X = Y = O) to the β-hydantoin. On the basis of other properties, Cremlyn and Chisholm (6) reversed this assignment. More recently, Maki and Masugi (7) obtained two isomeric 4-benzoyloxycyclohexane-1-spiro-5′-hydantoins (**2** and **3**; X = Y = O; PhCOO in place of *tert*-Bu) from 4-benzoyloxycyclohexanone (**1**; PhCOO in place of *tert*-Bu) by the Bucherer–Bergs reaction, and established by unequivocal chemical evidence that the minor (β) isomer had the structure **3** (X = Y = O; PhCOO in place of *tert*-Bu). This supports, by analogy, Munday's assignment.

In the present paper we offer more direct evidence for this assignment, which is the one shown in Scheme 1. Furthermore, our preliminary studies of the mechanism of the Bucherer–Bergs reaction in its various modifications enable us to explain the curious dependence of the stereochemistry of the product on whether carbon dioxide (in the form of ammonium carbonate), carbon oxysulfide, or carbon disulfide are used.

Experimental

All melting points are in degrees Centigrade and are uncorrected. The proton n.m.r. spectra were determined in the specified solvents with tetramethylsilane as internal standard on a Varian T-60 spectrometer. The carbon-13 n.m.r. spectra were determined on a Bruker 22.63 MHz spectrometer. The infrared spectra were measured on a Perkin-Elmer 257 spectrophotometer. The ultraviolet spectra were obtained with a Unicam SP800 spectrophotometer. Analyses were done by Dr. C. Daessle of Montreal.

*1-Amino-4-tert-butylcyclohexanecarboxynitrile (**14**)*

A solution of 4-*tert*-butylcyclohexanone (30 g), potassium cyanide (13 g), ammonium chloride (11 g) in methanol (150 ml) and water (100 ml), on standing at room temperature for 6 d, deposited a white solid (27.2 g, 77%); ν_{max} (KBr): 3330, 3140 (ν_{N-H}), 2225 (ν_{CN}), and 1615 cm^{-1} (δ_{NH}); δ ($CDCl_3$) 0.91 (s, 9H, *t*-Bu), 1.0–2.2 (m, 9H, cyclohexane), 2.2 (s, 2H, NH_2).

A small amount of this crude aminonitrile was suspended in water, the solution was acidified with hydrochloric acid and the mixture was extracted with ether. The aqueous layer was neutralized with sodium hydroxide and precipitated a white solid having an infrared spectrum identical with that of the crude product. The small amount of neutral compound obtained by evaporating the ether layer showed infrared absorption bands (KBr) at 3400 (ν_{O-H}) and 2225 cm^{-1} (ν_{CN}), but no band at about 1620 cm^{-1} (N—H deformation), and was probably the cyanohydrin **9**.

*4-tert-Butylcyclohexane-1-spiro-5′-hydantoin (α-Isomer, **2**, X = Y = O)*

(a) Normal Bucherer–Bergs Hydantoin Synthesis Using Ammonium Carbonate

A solution of 4-*tert*-butylcyclohexanone (15 g), potassium cyanide (6.8 g), and ammonium carbonate (42 g) in ethanol (220 ml) and water (220 ml) was heated under reflux at 50–55 °C for 5 h, then diluted with water and cooled. The precipitated solid was filtered off, washed with water, and recrystallized from absolute ethanol, giving the α-hydantoin as shiny white crystals; m.p. 315–318 °C (lit. (1) 322 °C; (2) 330 °C) (14.7 g, 68%); ν_{max} (KBr) 3265, 3180 (ν_{N-H}), 1773 ($\nu_{C=O}$), and 1730 cm^{-1} ($\nu_{C=O}$); δ (DMSO-d_6) 0.85 (s, 9H, *t*-Bu), 1.0–2.0 (m, 9H, cyclohexane), 8.62 (s, 1H, 1′), and 10.65 (s, 1H, 3′).

Anal. Calcd. for $C_{12}H_{20}N_2O_2$: C, 64.2; H, 9.0; N, 12.5. Found: C, 64.0; H, 8.9; N, 12.4.

(b) Using Carbon Dioxide

The mixture of 4-*tert*-butylcyclohexanone (5 g), potassium cyanide (2.5 g), and ammonium chloride (2.2 g) in methanol (140 ml) and water (100 ml) was heated to 50–55 °C with stirring. Carbon dioxide was passed into the solution over 4 h. The mixture was diluted with water and cooled. The crude product (5.34 g) was recrystallized from ethanol, and yielded the α-form of the hydantoin, identified by its infrared spectrum.

(c) From 1-Amino-4-tert-butylcyclohexanecarboxynitrile and Ammonium Carbonate

A solution of aminonitrile **18** (1.0 g) and ammonium carbonate (0.52 g) in ethanol–water 20:3 (v/v) (46 ml) was heated to 50–55 °C for 10 h. The crude product (0.32 g) was recrystallized from ethanol, giving the pure α-hydantoin, identified by its infrared spectrum.

(d) From 1-Amino-4-tert-butylcyclohexanecarboxynitrile and Carbon Dioxide

Carbon dioxide was passed into an aqueous ethanol solution of the aminonitrile at 50–55 °C for 4 h. The mixture was treated as above, and yielded a product containing only the α-hydantoin, identified by infrared spectrum.

*4-tert-Butylcyclohexane-1-spiro-5′-hydantoin (β-Isomer, **3** X = Y = O)*

A solution of 1-amino-4-*tert*-butylcyclohexanecarboxynitrile (14) hydrochloride (8 g) and potassium cyanate (14 g) in acetic acid (120 ml) and water (60 ml) was heated at 100 °C under reflux for 1 h. The mixture was cooled and diluted with water, and a white solid filtered off. This was heated with concentrated hydrochloric acid (60 ml) for 30 min. The reaction mixture was diluted with water, cooled, and the crude product was filtered off and was recrystallized from absolute methanol: shiny colorless crystals; m.p. 335–338 °C (dec.); lit. (6) 346–350 °C (3.8

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

g, 46%); ν_{max}(KBr) 3200 (ν_{N-H}), 1772 ($\nu_{C=O}$), and 1720 cm^{-1} ($\nu_{C=O}$); δ (DMSO-d_6) 0.87 (s, 9H, *t*-Bu), 1.1–2.1 (m, 9H, cyclohexane) 7.8 (s, 1H, 1′), and 10.55 (s, 1H, 3′).

Anal. Calcd. for $C_{12}H_{20}N_2O_2$: C, 64.2; H, 9.0; N, 12.5. Found: C, 64.2; H, 9.3; N, 12.4.

4-tert-Butylcyclohexane-1-spiro-5′-(2′,4′-dithiohydantoin) (α-Isomer, 2, X = Y = S)

A mixture of 4-*tert*-butylcyclohexane-1-spiro-5′-hydantoin (α-form, m.p. 315–318 °C) (4 g), phosphorus pentasulfide (4 g), and tetralin (150 ml) was heated under reflux for 2 h. The hot solution was decanted from some tar and was allowed to cool. The crude product was removed by filtration and washed with a small amount of cold benzene. It crystallized from methanol as colorless crystals; m.p. 305–306 °C (1.9 g, 42%); ν_{max}(KBr) 3165, 3095 (ν_{N-H}), 1525 cm^{-1} (—N—C=S I band); δ (DMSO-d_6) 0.89 (s, 9H, *t*-Bu), 1.1–2.1 (m, 9H, cyclohexane), 11.5 (s, 1H, 1′), and 13.5 (s, 1H, 3′).

Anal. Calcd. for $C_{12}H_{20}N_2S_2$: C, 56.2; H, 7.8; N, 10.9; S, 25.0. Found: C, 56.4; H, 7.9; N, 10.9; S, 24.7.

4-tert-Butylcyclohexane-1-spiro-5′-(2′,4′-dithiohydantoin) (β-Isomer, 3, X = Y = S)

(a) Carbon Disulfide Modification of the Bucherer–Bergs Hydantoin Synthesis

A solution of 4-*tert*-butylcyclohexanone (4 g), sodium cyanide (2 g), ammonium chloride (2.1 g), and carbon disulfide (2.6 ml) in ethanol (25 ml) and water (10 ml) was heated under reflux to 50–55 °C for 24 h. The mixture was cooled and the crude product was recrystallized from aqueous ethanol, yielding the β-form of the dithiohydantoin as bright yellow crystals; m.p. 277–279 °C (dec.) (3.8 g, 57%); ν_{max}(KBr) 3125 (ν_{N-H}), and 1555 cm^{-1} (—N—C=S I band); δ (DMSO-d_6) 0.90 (s, 9H, *t*-Bu), 1.1–2.4 (m, 9H, cyclohexane), 10.70 (s, 1H, 1′), and 13.28 (s, 1H, 3′).

Anal. Calcd. for $C_{12}H_{20}N_2S_2$: C, 56.2; H, 7.8; N, 10.9; S, 25.0. Found: C, 56.1; H, 7.8; N, 10.7; S, 24.8.

(b) From the Aminonitrile and Carbon Disulfide in Ethanol

A solution of 1-amino-4-*tert*-butylcyclohexanecarboxynitrile (β-isomer) (1 g), and carbon disulfide (1.5 ml) in ethanol (15 ml) was heated under reflux at 50–55 °C for 14 h. The solution was cooled and the bright yellow crystals were removed by filtration and recrystallized from aqueous ethanol, giving the pure β-dithiohydantoin (0.6 g, 42%), i.r. spectrum identical with that of the product from method (*a*).

(c) Replacement of Oxygen in 4-tert-Butylcyclohexane-1-spiro-5′-(4′-thiohydantoin) (β-Isomer, 3, X = O, Y = S) by Sulfur

4-*tert*-Butylcyclohexanespiro-5′-(4′-thiohydantoin) (β-form, m.p. 339–341 °C) (see below) was heated with phosphorus pentasulfide in tetralin for 2 h. The dithiohydantoin thus obtained was identical (i.r.) with the product from method (*a*).

4-tert-Butylcyclohexane-1-spiro-5′-(2′-thiohydantoin) (α-Isomer, 2, X = S, Y = O)

4-*tert*-Butylcyclohexane-1-spiro-5′-(2′,4′-dithiohydantoin) (α-form, m.p. 305–306 °C) (0.6 g), 2-aminoethanol (2 ml), and water (4 ml) were heated under reflux for 1 h. The 4′-β′-hydroxyethylimino derivative was removed by filtration of the cooled solution and was heated with concentrated hydrochloric acid (25 ml) and water (20 ml) under reflux for 45 min. After cooling, the crude product was removed and recrystallized from absolute ethanol: colorless crystals; m.p. 358 °C (sublimes) (0.2 g, 36%); ν_{max}(KBr) 3175 (ν_{N-H}), 1735 ($\nu_{C=O}$), and 1517 cm^{-1} (—N—C=S I band); δ (DMSO-d_6) 0.87 (s, 9H, *t*-Bu) 1.0–2.0 (m, 9H, cyclohexane), 10.85 (s, 1H, 1′), and 11.85 (s, 1H, 3′); λ_{max} (EtOH) 265 nm (ε 18 400), 225 nm (ε 7460).

Anal. Calcd. for $C_{12}H_{20}N_2OS$: C, 59.9; H, 8.4; N, 11.6; S, 13.3. Found: C, 60.3; H, 8.3; N, 11.6; S, 13.6.

4-tert-Butylcyclohexane-1-spiro-5′-(2′-thiohydantoin) (β-Isomer, 3, X = S, Y = O)

4-*tert*-Butylcyclohexane-1-spiro-5′-(2′,4′-dithiohydantoin) (β-form, m.p. 277–279 °C) (1.5 g), 2-aminoethanol (2 ml), and water (2 ml) were heated under reflux for 1 h. The crude product was removed and heated with concentrated hydrochloric acid (20 ml) and water (10 ml) for 45 min. The solution was allowed to cool and a pale yellow solid crystallized out. It was washed with water and recrystallized from aqueous ethanol, giving colorless crystals; m.p. 310–313 °C (dec.) (0.6 g, 43%); ν_{max} (KBr) 3235, 3125 (ν_{N-H}), 1760 ($\nu_{C=O}$), and 1564 cm^{-1} (—N—C=S I band); δ (DMSO-d_6) 0.87 (s, 9H, *t*-Bu), 1.2–2.3 (m, 9H, cyclohexane), 10.13 (s, 1H, 1′), and 11.71 (s, 1H, 3′); λ_{max} (EtOH) 267 nm (ε 19 800), 227 nm (ε 7340).

4-tert-Butylcyclohexane-1-spiro-5′-(4′-thiohydantoin) (β-isomer, 3, X = O, Y = S)

(a) Carbon Oxysulfide Modification of the Bucherer–Bergs Hydantoin Synthesis

A solution of 4-*tert*-butylcyclohexanone (2.5 g), potassium cyanide (2.1 g), and ammonium chloride (1.8 g) in ethanol (50 ml) and water (15 ml) was heated to 50–55 °C under reflux. Carbon oxysulfide was passed into the solution for 3 h while stirring. The solution was cooled and a pale yellow solid removed and recrystallized from absolute ethanol: pale yellow needles; m.p. 339–341 °C (2.1 g, 54%); ν_{max} (KBr) 3200, 3075 (ν_{N-H}), 1740 cm^{-1} ($\nu_{C=O}$); δ (DMSO-d_6) 0.90 (s, 9H, *t*-Bu) 1.1–2.4 (m, 9H, cyclohexane), 8.5 (s, 1H, 1′), and 12.4 (s, 1H, 3′).

Anal. Calcd. for $C_{12}H_{20}N_2OS$: C, 59.9; H, 8.4; N, 11.6; S, 13.3. Found: C, 60.1; H, 8.5; N, 11.8; S, 13.5.

(b) From the Aminonitrile 14 and Carbon Oxysulfide

Carbon oxysulfide was passed into a stirred solution of 1-amino-4-*tert*-butylcyclohexanecarboxynitrile (5 g) in ethanol (100 ml) at 50–55 °C for 4 h. The mixture was cooled and the solid product was recrystallized from absolute ethanol; pale yellow needles (1.8 g, 27%). These had an i.r. spectrum identical with that of the 4′-thiohydantoin obtained above by method (*a*).

4-tert-Butylcyclohexane-1-spiro-5′-(3′-methyl-2′,4′-dithiohydantoin) (α-Isomer)

4-*tert*-Butylcyclohexane-1-spiro-5′-(2′,4′-dithiohydantoin) (**2**, X = Y = S) (0.92 g) was dissolved in ether (50 ml) and cooled in an ice-bath. The solution was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

treated with a cooled ethereal solution containing about 0.15 g of diazomethane, and the clear yellow solution was left overnight at room temperature.

The ether was evaporated and the residue was recrystallized from aqueous methanol, giving pale yellow needles; m.p. 258 °C (dec.) (0.31 g, 31.9%); ν_{max} (KBr) 3200 (ν_{N-H}), 1520 cm^{-1} (—N—C=S); δ ($CDCl_3$) 0.90 (s, 9H, *t*-Bu), 1.0–2.3 (m, 9H, cyclohexane), 3.60 (s, 3H, 3′-CH_3), 8.5 (broad, 1H, 1′).

Anal. Calcd. for $C_{13}H_{22}N_2S_2$: C, 57.7; H, 8.2. Found: C, 57.6; H, 8.3.

4-tert-Butylcyclohexane-1-spiro-5′-(3′-methyl-2′,4′-dithiohydantoin) (β-Isomer)

4-*tert*-Butylcyclohexane-1-spiro-5′-(2′,4′-dithiohydantoin) (**3**, X = Y = S) (0.58 g) in ether (60 ml) was treated with an ethereal solution containing about 0.15 g of diazomethane, and worked up by the same procedure as above: yellow crystals; m.p. 215–217 °C (0.2 g, 32.7%); ν_{max} (KBr) 3200 (ν_{N-H}), 1539 cm^{-1} (—N—C=S I band); δ ($CDCl_3$) 0.96 (s, 9H, *t*-Bu), 1.2–2.3 (m, 9H, cyclohexane), 3.60 (s, 3H, 3′-CH_3), 7.9 (broad, 1H, 1′).

Anal. Calcd. for $C_{13}H_{22}N_2S_2$: C, 57.7; H, 8.2. Found: C, 57.6; H, 8.4.

Dissociation Constants of α- and β-isomers of 4-tert-Butylcyclohexane-1-spiro-5′-(3′-methyl-2′,4′-dithiohydantoin)

The ultraviolet absorption spectra of the α- and β-isomers were obtained in 50% (v/v) aqueous ethanol, in 0.1 *N* aqueous sodium hydroxide, and in phosphate buffer of p*H* 11.0 in 50% (v/v) aqueous ethanol, and analyzed by conventional methods (8) to give the following pK_a values: α-isomer, 10.8 ± 0.1; β-isomer, 10.85 ± 0.15.

4-tert-Butylcyclohexane-1-spiro-5′-(1′,3′-dimethyl-2′,4′-dithiohydantoin) (α-Isomer)

4-*tert*-Butylcyclohexane-1-spiro-5′-(2′,4′-dithiohydantoin) (α-form, m.p. 305–306 °C) (0.45 g), dissolved in ether (50 ml), was treated with an excess of ethereal diazomethane and left overnight at room temperature. The solvent was removed, the residue was washed with sodium hydroxide solution and was taken up in ether. The ether was evaporated and the oily yellow residue was recrystallized from aqueous ethanol: colorless needles; m.p. 101–105 °C (0.25 g, 51%); ν_{max} (KBr) 1580 cm^{-1} (—N—C=S I band); δ ($CDCl_3$) 0.91 (s, 9H, *t*-Bu), 1.1–2.2 (m, 9H, cyclohexane), 2.63 (s, 3H, 1′-CH_3), and 3.40 (s, 3H, 3′-CH_3).

4-tert-Butylcyclohexane-1-spiro-5′-(3′-acetylhydantoin) (α-Isomer)

A solution of 4-*tert*-butylcyclohexane-1-spiro-5′-hydantoin (**2**; X = Y = O) (m.p. 320 °C) (1.05 g) in acetic anhydride (100 ml) was heated under reflux for 42 h. The solvent was evaporated off under reduced pressure and the residue was recrystallized from aqueous ethanol, giving pale-cream crystals; m.p. 180–184 °C (0.85 g, 74%); ν_{max} (KBr) 3220 (ν_{N-H}), 1787 ($\nu_{C=O}$), 1770 ($\nu_{C=O}$), and 1720 cm^{-1} ($\nu_{C=O}$); δ ($CDCl_3$) 0.91 (s, 9H, *t*-Bu), 1.4–2.4 (m, 9H, cyclohexane), 2.63 (s, 3H, acetyl), and 9.2 δ (s, 1H, 1′).

Anal. Calcd. for $C_{14}H_{22}N_2O_3$: C, 63.1; H, 8.3; N, 10.5. Found: C, 63.5; H, 8.5; N, 10.8.

The 3′-acetyl compound (0.27 g) was boiled with 10 ml of 0.1 *N* NaOH for 30 min. The mixture was cooled, filtered and the white residue was washed with water. The crude solid was shown by i.r. to be the α-form of 4-*tert*-butylcyclohexane-1-spiro-5′-hydantoin (**2**; X = Y = O).

4-tert-Butylcyclohexane-1-spiro-5′-(1′,3′-diacetylhydantoin) (β-Isomer)

A solution of 4-*tert*-butylcyclohexane-1-spiro-5′-hydantoin (β-form) (1.34 g) in acetic anhydride (100 ml) was heated under reflux for 12 h. After the solvent was removed by evaporation under reduced pressure, the residue was crystallized from absolute ethanol, giving pale-cream needles; m.p. 155–160 °C (0.87 g, 51%); ν_{max} (KBr) 1811 ($\nu_{C=O}$), 1764 ($\nu_{C=O}$), and 1704 cm^{-1} ($\nu_{C=O}$); δ ($CDCl_3$) 0.95 (s, 9H, *t*-Bu), 1.2–2.1 (m, 9H, cyclohexane), and 2.65 δ (d, 6H, two acetyls).

Anal. Calcd. for $C_{16}H_{24}N_2O_4$: C, 62.3; H, 7.8; N, 9.1. Found: C, 62.6; H, 8.1; N, 9.1.

4-tert-Butylcyclohexane-1-spiro-5′-(1′-acetylhydantoin) (β-Isomer)

4-*tert*-Butylcyclohexane-1-spiro-5′-(1′,3′-diacetylhydantoin) (0.31 g) was boiled with 10 ml 0.1 *N* NaOH for 30 min. The mixture was cooled and filtered, and the residue was washed with water and recrystallized from aqueous ethanol, giving colorless needles of 4-*tert*-butylcyclohexane-1-spiro-5′-(1′-acetylhydantoin); m.p. 252–255 °C (0.25 g, 93%); ν_{max} (KBr) 3220 (ν_{N-H}), 1790, 1745, ($\nu_{C=O}$), 1615 cm^{-1}; δ ($CDCl_3$) 0.90 (s, 9H, *t*-Bu), 1.5–2.1 (m, 9H, cyclohexane), 2.6 (s, 3H, acetyl), 8.4 (broad, 1H, 3′).

1-Amino-trans-4-tert-butylcyclohexane Carboxylic Acid (4)

The amino acid was prepared by the method described by Munday (1). 4-*tert*-Butylcyclohexane-1-spiro-5′-hydantoin (**2**; X = Y = O) (2.4 g) was heated with 70% sulfuric acid (20 ml) at 150 °C for 24 h. The mixture was diluted with water and cooled. The precipitated solid was dissolved in ammonium hydroxide and was decolorized by boiling with animal charcoal. The ammonium hydroxide was evaporated off, and the residue was recrystallized from aqueous acetic acid: m.p. 354–356 °C (sublimes) (lit. (1) 300–304 °C, (6) 360 °C (sublimes)) (1.0 g, 46%); ν_{max} (KBr) 3300 (ν_{N-H}), 1664 (asym. $\delta_{NH_3^+}$), 1585 (asym. ν_{C-O}), and 1530 cm^{-1} (sym. $\delta_{NH_3^+}$).

Results and Discussion

Configurations of α and β-Isomers

The evidence for assigning structure **2** to hydantoins and thiohydantoins of the α series, and structure **3** to compounds of the β series, comes from the following lines of evidence:

(a) ^{13}C *n.m.r.*

Compounds **2** and **3** (X = Y = S) differ in having the 4′-carbon atom equatorial and axial, respectively, so that in **2** this atom will be *gauche* with respect to all four hydrogen atoms at C-2 and C-6, but in **3** it will be *anti* with respect to two of them. Recent work (9) indicates that the vicinal coupling constants, $^3J_{(^{13}C-^1H)}$, should be greater in the latter case, so that one should expect a wider ^{13}C peak for the axial carbon of **3** than the equatorial carbon of **2**.

In order to apply these ideas, it is necessary to identify the different peaks in the spectra. These are listed in Table 1 and their assignments shown. The resonance of the thiocarbonyl carbon of thioacetamide is at 207.2 p.p.m. (10*a*) (relative to tetramethylsilane), and so the peaks at lowest field in **2** and **3** (X = Y = S) can be assigned to the 4′-carbon atom. The next lowest peaks will be due to the thiourea 2′-carbon atoms (*cf.* δ 182.8 for thiocarbonyl carbon of Et-NHCSNHEt (10*a*)). The peaks at higher field come from the cyclohexane (11) and *tert*-butyl carbon atoms and can be assigned by noting the splitting patterns caused by the hydrogen atoms attached to them.

The C-4′ peak of the β-compound shows a half-width of 18.0 Hz, while the corresponding peak of the α-compound shows a half-width of 9.5 Hz (Table 2). Consequently, we can assign the structure **3** (X = Y = S) to the β compound and **2** (X = Y = S) to the α compound.

The hydantoins **2** and **3** (X = Y = O) would be expected to have 2′ and 4′ peaks at higher fields (*cf.* CH_3CONH_2 carbonyl: 172.7 (10*b*) urea, 161.2 p.p.m. (10*c*)). However, both α- and β-forms proved insoluble in the usual n.m.r. solvents and so the spectra were obtained using deuterated sulfuric acid (95%) as solvent. In acid of this strength it is likely that both carbonyl oxygen atoms are deuterated (12) so that, for example, **3** (X = Y = O) exists as **6** with both C-2′ and C-4′ shifted downfield, but with their relative chemical shifts unaltered. In fact, it can be seen from Table 1 that any downfield shift must be modest. Again the 4′-carbon atom of the β-compound shows the greatest half-width, indicating the structure **3** (X = Y = O) for it.

Finally, the n.m.r. spectra of trifluoroacetic acid solutions of the α- and β-forms of the amino acids (**4** and **5**) were obtained (Tables 1 and 2), and the half-widths of the carboxyl carbon peaks indicated the α-compound to be **4** and the β-compound to be **5**.

The other n.m.r. evidence, summarized in Table 1, also supports (albeit less decisively) the structural relations indicated in Scheme 1. The distance between the 1′-hydrogen atom of the hydantoin ring and the 3,5-axial hydrogen atoms of the cyclohexane ring in **2** can be calculated by trigonometry to be 2.10 Å, assuming tetrahedral angles for the cyclohexane ring (*cf.* cyclohexylamine hydrochloride (13*a*)) and the ring angles of creatinine (13*b*) for the hydantoin ring. This compares with a distance of 2.40 Å when the van der Waals surfaces of the atoms are in contact (14), or a compression of 0.30 Å if the cyclohexane ring remained undistorted from its normal shape. Similar calculations for **3** (X = Y = O) show a more serious compression (0.54 Å) between the 3,5-axial hydrogens and the 4′-oxygen atom, which becomes further aggravated (compression 1.01 Å) in **3** (X = Y = S). This compression of the axial hydrogen atoms should lead to shifts in electron density, causing C-3 and C-5 of **3** (X = Y = O or X = Y = S) to resonate at higher field than these atoms in **2** (X = Y = O or X = Y = S); again, this supports the identification of the compounds of the β-series with **3** (see Table 1). On the other hand, for the amino acids **4** and **5** the reverse should be true: now the axial hydrogens of **4** are subjected to greater compression, when account is taken

of the relative conformational free energies of the axial ammonium and carboxyl groups (15). Again, the experimental results (Table 1) support the assignments shown in Scheme 1.

In summary, n.m.r. evidence from a variety of compounds points unequivocally to the structures indicated in Scheme 1.

(b) Ultraviolet Absorption Spectra

The ultraviolet absorption characteristics of some mono- and dithiohydantoins in ethanol solution are given in Table 3, the absorption bands being classified according to Janssen (16). The band of low intensity and at longest wavelength (Band I) is due to an n → π* transition of the 4-thiocarbonyl group in 4-thiohydantoins or 2,4-dithiohydantoins (8). Such transitions are sensitive to solvent, the band undergoing a red shift when the solvent is changed from ethanol (which stabilizes the ground state by hydrogen bonding) to hydrocarbon (16). Hence we can expect Band I of **3** (X = Y = S) in ethanolic solution to be at longer wavelength than Band I of **2** (X = Y = S), because of the greater accessibility of the 4-thiocarbonyl sulfur to solvent in the latter compound. The relative positions of Band I (Table 3) again indicate the α-isomer to be **2** (X = Y = S) and the β-isomer to be **3** (X = Y = S).

Cyclohexane-spiro-5′-(2′,4′-dithiohydantoin) (**7**, X = S) lacks the anchoring *tert*-butyl group, and hence can exist in the two conformations **7**α and **7**β (X = S). The latter would be expected to be extremely disfavored because of the much greater steric compression between the 3,5-axial hydrogen atoms and the 4′-sulfur atom of **7**β than between the 3,5-axial hydrogen atoms and the 1′-hydrogen atom of **7**α, as discussed above. This is confirmed by the position of Band I (Table 3), which is closer to that of **2** (X = Y =

S), the α isomer. For similar reasons, **7**α would be expected to be the favored conformation of cyclohexanespiro-5′-(4′-thiohydantoin) (**7**, X = O), and again this is supported by the spectral evidence (Table 3).

(c) Acetylation of α- *and* β-*Hydantoins*

Acetylation of hydantoin at both 1- and 3-positions is reported to take place readily (17). Consequently it would be expected that acetylation at both the 1′- and 3′-positions of **3** (X = Y = O) would also take place readily, but that **2** (X = Y = O) would be acetylated only at the 3′-position, because of the extreme steric pressures for an acetyl group at the 1′-position. In fact, the β-compound was diacetylated by treatment for 12 h in refluxing acetic anhydride,[1] while the α-compound was only monoacetylated after 42 h under these conditions. The diacetyl derivative of the β compound readily lost one acetyl group by mild alkaline hydrolysis: this was probably from the more labile 3′-position (17).

From a similar consideration of steric effects, it might be expected that **3** (X = Y = S) would react with diazomethane to form the 1′,3′-dimethyl derivative, but that **2** (X = Y = S) would form only the 3′-monomethyl derivative. In fact, with an excess of diazomethane both α- and β-compounds formed a dimethyl derivative, and with one mole of diazomethane both formed a monomethyl derivative which could be expected to be the 3′-derivative (19); this was confirmed by the pK_a values of the compounds (8). The α- and β-isomers proved to be essentially identical in acid strength although one has its ionizing group in an axial position and the other in an equatorial position (*cf.* refs. 20, 21). However, apart from the steric complexities of these compounds, it is becoming apparent (22) that relations between axial or equatorial configuration and acid or base strength are not straightforward.

The 2-thiohydantoins **2** and **3** (X = S, Y = O) were prepared from the 2,4-dithiohydantoins **2** and **3** (X = Y = S) by reaction with ethanolamine to form the 2-hydroxyethylimino derivatives **2** and **3** (X = S, Y = $HOCH_2CH_2N$) followed by hydrolysis of the latter with concentrated hydrochloric acid (23). Again, it was expected that **3** (X = Y = S) would react much more slowly than **2** (X = Y = S), because of the strain to be expected in the tetrahedral intermediates issuing from the former, but the yields from the two compounds were similar. Possibly if milder reaction conditions were investigated, pronounced differences in reactivity of the two isomers **2** and **3** (X = Y = S) might become apparent.

In summary, the different lines of physical and chemical evidence outlined above cohere in supporting the configurational assignments shown in Scheme 1, originally advanced on other grounds by Munday (1). Some of the counter-arguments advanced by Cremlyn (6) seem very plausible: in particular, that based on the effect to be expected from changing solvent composition on the pK_a of axial and equatorial groups (24). We are currently reexamining this effect.

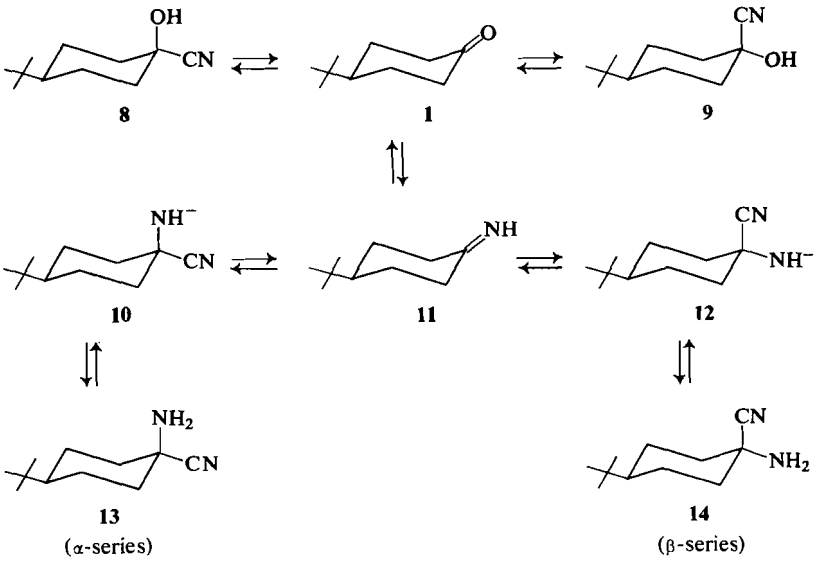
Mechanistic Considerations: the Strecker Reaction

The sole amino acid obtained from the Strecker reaction of 4-*tert*-butylcyclohexane (**1**) was the β-compound **5**. Examination of the infrared spectrum of the hydrolysis product of the amino nitrile showed no trace of a peak at 675 cm^{-1}, characteristic of the α-isomer **4**.[2]

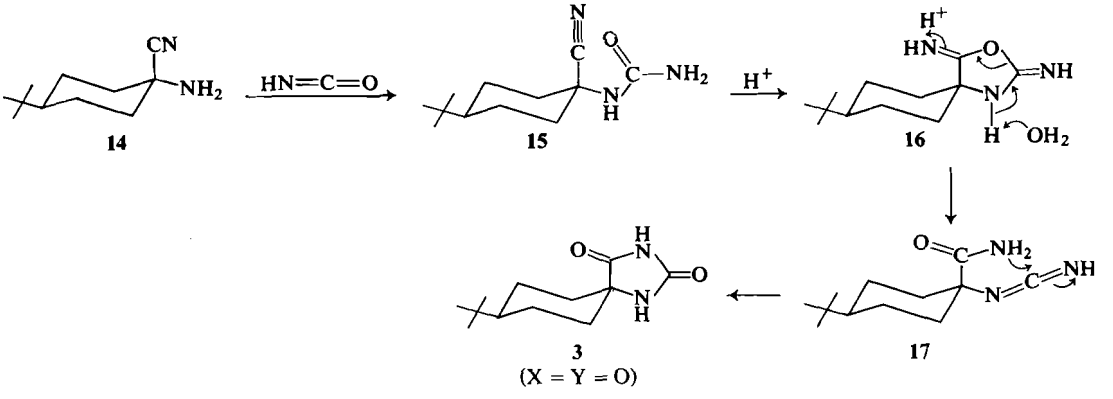
If equilibrium is established between the various compounds of Scheme 2, it would be expected, on the basis of the ΔG^0 values of axial amino and nitrile groups (15), that the crude amino nitrile would be made up of 7% of **13** (of the α-series) and 93% of **14** (β). Our cursory examination of the crude amino nitrile indicates the presence also of a small amount of cyanohydrin, presumably **9** (25) and some **8**. The amino nitrile and its hydrochloride are quite unstable to recrystallization, and the various equilibria of Scheme 2 merit further investigation. On mechanistic grounds it seems reasonable that the various equilibria of Scheme 2 are established rapidly in alkaline solution (through the intermediacy of **10** and **12**) but not in acid solution. This assumption, which is crucial to our further discussions of mechanism, receives some support from observations of Tager and Christen-

[1]These conditions are considerably more drastic than those reported in the literature for hydantoin (17), possibly because the acetic anhydride of 70 years ago contained acidic impurities which catalyzed the reaction: *cf.* W. J. Chute *et al.* (18) for a parallel case.

[2]The total recovery of amino acid was only 60% of theoretical, so that the α-isomer expected as a minor product in this reaction was probably lost in the isolation process.



SCHEME 2



SCHEME 3

sen (22); we hope to study the effect of p*H* on the equilibria of Scheme 2 in the future. The evidence discussed below indicates that even in the weakly alkaline solution produced by dissolving the crude amino nitrile (**14** and some **13**; $pK_a \sim 7$ (26)) in aqueous ethanol the rates for the interconversion **13** ⇌ **14** are very fast.

Mechanistic Considerations: the Bucherer–Bergs Reaction

With these assumptions it now becomes possible to explain how the same amino nitrile can yield either the α- or the β-hydantoin, according to reaction conditions. Thus Cremlyn and Chisholm (6) found, and we have confirmed, that the amino nitrile (mostly **14**) reacts with cyanic acid in acetic acid to form a urea (**15**) which can then by cyclized to the β-hydantoin **3** (X = Y = O). A possible reaction sequence is given in Scheme 3, although variations of this sequence can be envisaged. The important fact is that the reaction is conducted under acidic conditions, so that the interconversion **13** ⇌ **14** does not take place, and hence the β-isomer **3** (X = Y = O) is the main product of the reaction.

On the other hand, the same amino nitrile treated with carbon dioxide in aqueous ethanol gives the α-hydantoin **2** (X = Y = O). Under

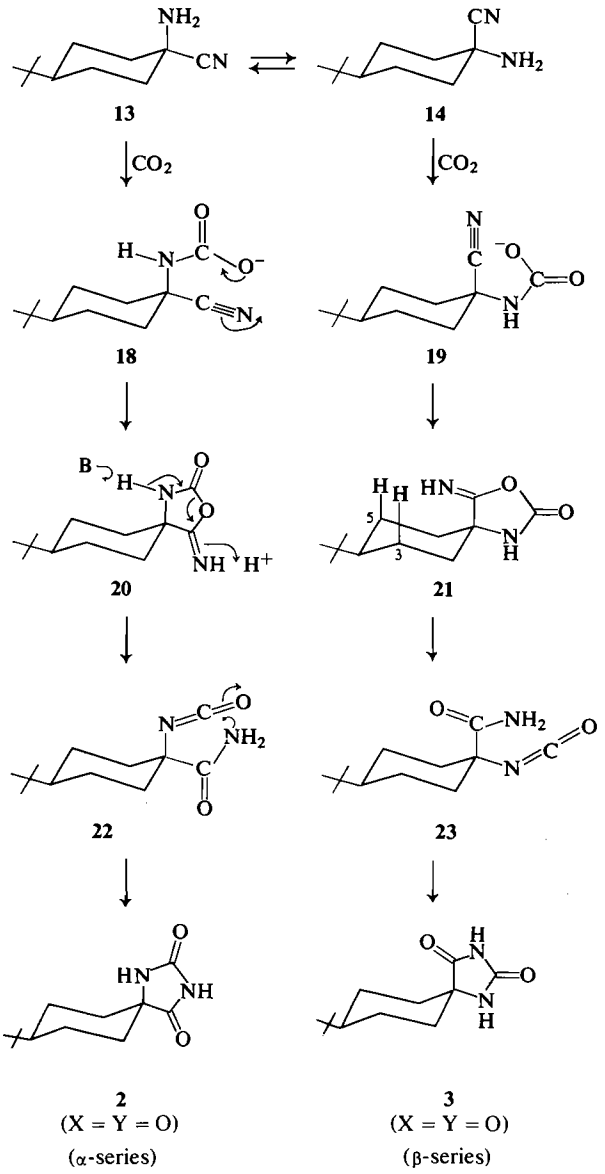
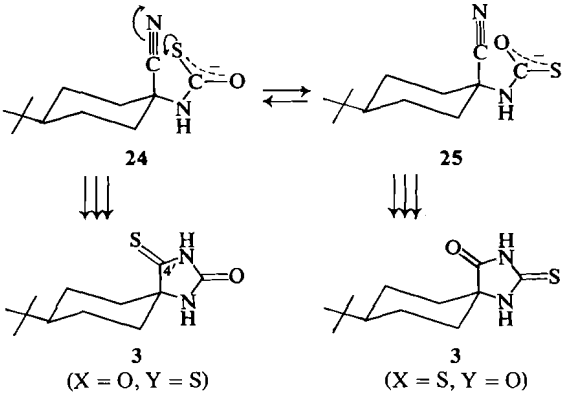


SCHEME 4

these conditions we assume the interconversion **13** ⇌ **14** to be rapid. The mechanism for this reaction shown in Scheme 4 is an elaboration of that of Bucherer and Steiner (27). The fact that the α-hydantoin is formed in preference to the β-hydantoin indicates that the former route involves a lower overall energy barrier in going from reactants to the rate-determining step than does the latter. It seems likely that the rate-determining step on the path to **3** (X = Y = O) is **19** → **21**. If this is endothermic, the transition state will resemble **21** (Hammond principle (28)), and hence be subject to severe steric hindrance because of the compression between the developing C═NH group and the 3,5-axial hydrogen atoms. (In **21** the van der Waals surfaces are compressed by 0.65 Å). Consequently, this path is a highly disfavored one. The other path (**14** → **13** → **18** → **20** → **22** → **2** (X = Y = O)) leading to the α-compound should be less favored in its

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



SCHEME 5

earlier, pre-equilibrium steps: for steric reasons, **13** → **18** should be less favored than **14** → **19**; but by the Hammett–Curtin principle, the relative rates by the α- and β-paths depend upon the *overall* barrier between **14** and the intermediate after the rate-determining step, and this should, for steric reasons, be larger on the β-path.

Why should the replacement of carbon dioxide by carbon disulfide cause the reaction now to take the β-path? If the sulfur atom is very much more nucleophilic than the oxygen atom, the reaction **19** → **21** (S in place of O) should be exothermic and should have a transition state resembling **19** rather than **21** (S in place of O). In that case, the bending of the nitrogen atom towards the 3,5-axial hydrogen atoms should have progressed by only a small amount when the transition state is reached. Consequently, the steric barrier impeding the β-path to the hydantoin is missing on the β-path to the 2,4-dithiohydantoin, whereas the various steric factors disfavoring the α-path, and mentioned above, are still present.

A similar rationale can be offered for the formation of the β- rather than the α-4′-thiohydantoin when carbon dioxide is replaced by carbon oxysulfide. It may be remarked that the fact that this reaction affords the 4′-thiohydantoin (**3**, X = O, Y = S) rather than the 2′-thiohydantoin (**3**, X = S, Y = O) shows that the thiocarbamic acid intermediate cyclizes when in the conformation **24** and not **25** (Scheme 5): a further example of the superior reactivity of the sulfur over the oxygen atom in attacking the nitrile group.

Conclusion

These mechanisms, which explain for the first time the differing stereochemical courses of the Strecker and Bucherer–Bergs reactions (2), require a pre-equilibrium **13** ⇌ **14** which is susceptible to experimental proof or disproof. Further, they can serve to predict the stereochemical outcome for the reaction of various ketones, such as norbornanone (22), *cis*- and *trans*-(1- and 2-)decalone (6), and 5α-cholestan-3-one (29), which have been submitted to some but not all of the various reactions discussed here. In particular, it can be expected that one of the two possible epimeric amino acids may be accessible by a modified Bucherer reaction when it is not accessible by a Strecker reaction (6).

We hope to explore some of these possibilities in future work.

We are most grateful to Professor A. S. Perlin for suggesting the ^{13}C n.m.r. studies, and for much help in interpreting spectra, to Dr. N. Cyr for the ^{13}C n.m.r. measurements, to Dr. P. G. Farrell for advice and assistance, to the Canadian government for a C.I.D.A. Scholarship (to C. Jitrangsri), and to the National Research Council of Canada for financial support.

The Structures of some Stress Metabolites from *Solanum melongena*[1,2]

A. STOESSL, J. B. STOTHERS, AND E. W. B. WARD

Agriculture Canada Research Institute and the Chemistry Department, University of Western Ontario, London, Ontario N6A 3K7

Received May 28, 1975

A. STOESSL, J. B. STOTHERS, and E. W. B. WARD. Can. J. Chem. **53**, 3351 (1975).

The structures of the acyclic sesquiterpenes **1–5** and the bicyclic sesquiterpenes **6** and **7**, all isolated from eggplant fruit inoculated with fungi, were elucidated with the aid of ^1H and ^{13}C n.m.r. studies. Trienone **1** was found to be identical to 9-oxonerolidol from camphor leaf oil while **2** and **3** are isomeric alcohols derived from **1**. Compounds **4** and **5** are probably artifacts. The hydroxyaldehyde **6** is identical with the potato phytoalexin lubimin, originally represented by a structure shown here to be incorrect. Enone **7** is a novel eudesmane. The stereochemistries of these compounds are discussed.

A. STOESSL, J. B. STOTHERS et E. W. B. WARD. Can. J. Chem. **53**, 3351 (1975).

Utilisant des études de r.m.n. du ^1H et du ^{13}C, on a étudié les structures des sesquiterpènes acycliques **1–5** et des sesquiterpènes bicycliques **6** et **7**, tous isolés d'aubergines inoculées avec des champignons. On a trouvé que la triènone **1** est identique à l'oxo-9 nérolidol obtenu à partir de l'huile de la feuille du camphrier alors que **2** et **3** sont des alcools isomères dérivés de **1**. Les composés **4** et **5** sont probablement des 'artefacts'. L'hydroxyaldéhyde **6** est identique avec la phytoalexine lubimin de la pomme de terre qui avait été représentée antérieurement par une structure qui s'avère fausse. L'énone **7** est un nouvel eudesmane. On discute de la stéréochimie de ces composés.

[Traduit par le journal]

Incubation of fruit of the eggplant (*Solanum melongena*) with spore suspensions of *Monilinia fructicola* or other fungi results in the production of a complex mixture of compounds which are not found in fruit incubated with water alone (1). Seven, essentially pure, compounds were isolated from this mixture but, of these, two are probably artifacts. The other five substances, however, are stress metabolites and may function as agents, 'phytoalexins', in the natural defense of the plant against disease (1). Details of the isolation and biological significance of these materials have been reported (1) while structures and biogenetic relationships for the five stress metabolites have been presented in preliminary form (2). In this paper we wish to present the full spectroscopic and experimental data which led to structural assignments for compounds **1–7** and to discuss the stereochemistry of these substances briefly.

Compound **1** was formulated as 9-oxonerolidol on the basis of its i.r., u.v. and ^1H n.m.r. spectra. While our work was in progress the same structure was assigned to a compound isolated from the nonvolatile terpenoids in the leaf oil of the camphor tree (3). In a direct comparison,[3] the two substances were indistinguishable in all essential aspects (see Experimental). A slight difference between the optical activities of our preparation ($[\alpha]_D^{23}$ +24; *c*, 1.0, CCl_4) and that of Hiroi ($[\alpha]_D^{23}$ +19), as determined in these laboratories, is attributable to the presence of small amounts of different impurities in the two specimens (~6% in each, by g.l.c.). Thus, the two substances have identical configurations. The stereochemistry, as depicted in **1**, has been assigned by Hiroi on the basis of the ^1H n.m.r. and o.r.d. data (4). The *trans* geometry of the central double bond (Δ^6) is supported by the ap-

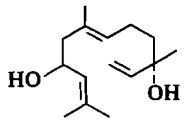
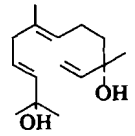
pearance of a methyl signal at 16.4 p.p.m. in the ^{13}C spectrum of **1**; a similar signal was found in the spectra of **2** and **3** (see Table 1). Its assignment to C-14 in this series followed from a comparison with the data for geraniol (**8***a*), nerol (**8***b*), citral *a* (**8***c*), and citral *b* (**8***d*) (5, 6). For these pairs of isomers the geometry about the 6–7 double bond is clearly revealed by the C-10 methyl carbon shielding difference of ~7 p.p.m. In **8***a* and **8***c*, the *cis* relation between this methyl and the terminal group shifts the methyl signal to 16–17 p.p.m. while in the *trans* cases, **8***b* and **8***d*, this methyl carbon absorbs near 24 p.p.m. This is a general tendency in olefinic systems (6) and has been exploited for stereochemical assignments in a variety of systems (7), for example, in a distinction between *cis*- and *trans*-phytoene isomers (8) which also serves as a model for the present case.



2



3

The quaternary methyl signal near 28 p.p.m. in **1–3** was assigned by comparison with the corresponding absorption for linalool and dihydrolinalool (9). The remaining methyl signals, therefore, arise for C-12 and C-15 with the more shielded of the two, in **1** and **2** assigned to the methyl *cis* to C-9, for the reasons given above; it may be noted that the geminal methyl shieldings differ by 7 p.p.m. in each case, in good agreement with expectations. For similar reasons, the methylene signal near 23 p.p.m. was assigned to C-5. Each compound gave rise to a methylene signal near 42 p.p.m. which was readily assigned to C-4, since structural changes at C-9 and beyond would not be expected to affect this carbon significantly. The carbonyl carbon, at 198.9 p.p.m., was easily assigned and its shielding clearly indicates its conjugated nature (10). Of the two signals from fully substituted olefinic carbons, that at 155.4 p.p.m. arises from C-11 since it is β to the carbonyl group. The consistent appearance of a signal at 145 p.p.m. in the spectra of **1–3** for an olefinic carbon with one directly bonded proton led to its assignment as the C-2 signal, while the remaining assignments for **1** appear to be the most probable on the basis of comparison with model systems (9, 10).

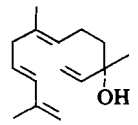
Eggplant metabolite **2** was characterized as 9-hydroxynerolidol by its spectroscopic properties and by oxidation with manganese dioxide in benzene to **1**. Also, a sample of 9-oxonerolidol (**1**) obtained by Hiroi[3] gave a diol upon reduction with sodium borohydride which was identical by i.r., t.l.c. and g.l.c. with eggplant metabolite **2**, except for the presence of an unidentified impurity (3.5% by g.l.c.) in the reduction product. The o.r.d. curves of the two substances showed virtually no optical activity between 350 and 700 nm. As noted by Hiroi and Takaoka (3), the reduction product was expected to be a mixture of diastereoisomers and the proton spectrum suggested this to be the case, although no separation was achieved by t.l.c. A comparison of the ^{13}C spectra of natural **2**, and **2** obtained by reduction of **1**, however, revealed slight differences (0.05–0.2 p.p.m.) in the shieldings of seven of the carbons. In the ^{13}C spectrum of the reduction product, these seven carbons each gave rise to a pair of signals of essentially equal intensity while the ^{13}C spectrum of natural **2** contained a predominant set for one diastereomer with a second set of weaker signals indicating the presence of ~20% of the second stereoisomer. The fact that the natural metabolite is a mixture (~4:1) of diastereomers suggests that **2** and **3** may be interconverted in the plant or during the isolation. The assignment of the ^{13}C signals for the diastereomeric pair followed from considerations analogous to those outlined above for **1**. The observed doubling of the signal near 132 p.p.m. for a fully substituted olefinic carbon was taken to distinguish C-11 from C-7, but this is not unequivocal. Similar reasoning led to the assignments for C-6 and C-10. The small but measurable, shielding differences for C-1, -2, -3, -5, -11, -12, and -13 indicate that the two diastereomers favor significantly different conformations since it seems most probable that the C-3 configuration is the same in each, but the observed shielding changes cannot be interpreted in any further detail. Since Hiroi's specimen of **1** was used for the reduction, this experiment further confirmed the identity of the eggplant and camphor tree metabolites.

Compound **3** showed neither carbonyl absorption in its infrared spectrum nor u.v. absorption above 220 nm. The ^{1}H spectrum, however, was particularly revealing containing the absorptions for six olefinic protons, four methyl

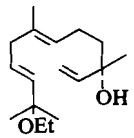
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

groups, and a methylene group as the readily assigned features. The ABX pattern characteristic of the vinyl group in **1** and **2** was evident together with a triplet of sextets ($J \sim 7$ and 2 Hz, respectively) centered at 5.16 p.p.m. Simultaneous irradiation of the olefinic methyl doublet at 1.63 changed this pattern to a triplet of triplets while irradiation of the broadened doublet at 2.65 p.p.m., arising from two protons of a methylene group, changed it to a triplet of quartets. The latter experiment also collapsed the absorption of the two remaining olefinic protons to a singlet, presumably the central lines of an AB system produced by the decoupling. The results indicated the pattern at 5.16 p.p.m. to arise from H-6 having long range coupling to the olefinic methyl on C-7 and the C-8 methylene protons (2.65 p.p.m.). Simultaneous irradiation at 1.63 and 2.65 p.p.m. indeed reduced the pattern at 5.16 p.p.m. to a triplet which was then collapsed to a singlet by irradiation at 2.04 p.p.m. The remaining olefinic absorption was that of H-9 and H-10, which are nearly equivalent. To simplify the spectrum and to confirm the above analysis, a spectrum of **3** in $CDCl_3$ containing $Eu(fod)_3$ was recorded. Upon irradiation of the methylene doublet, which was shifted to 3.06 p.p.m., H-9 and H-10 gave rise to a well-defined AB pattern with $J_{AB} = 16$ Hz. These results led directly to structure **3**, an allylic isomer of **2**, and the ^{13}C data are entirely consistent with this formulation. Although the signals for C-6 and C-9 cannot be unequivocally assigned, their similarity indicates that both double bonds are *trans*. The presence of a moderately strong band at 978 cm^{-1} in the i.r. spectrum of **3** but absent in those of **1** and **2** also suggested that the C-9–C-10 double bond is *trans* (11). The proton–proton coupling constant, however, proved the point.

It must be pointed out that while **3** was always detected in appreciable amounts in freshly prepared extracts from *S. melongena* diffusates, it could, nevertheless, have been formed by a nonenzymatic allylic rearrangement of **2**, either during incubation of the diffusates or during extraction, despite the mildness of the conditions employed (1). Some evidence to support this possibility comes from the fact that **2** from eggplants, was partially racemized at C-9, as discussed above. There can be little doubt that compounds **4** and **5** are such artifacts, generated during work-up, since neither could be detected in freshly prepared ether extracts. Although only small amounts of these materials (1.5 and 2 mg respectively) were available for n.m.r. analysis their structures were readily deduced from spectral data.

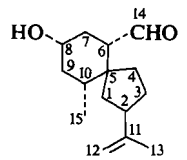


4

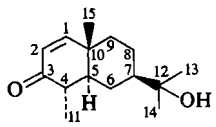


5

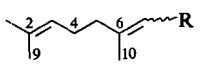
Both compounds exhibited in their ^1H n.m.r. spectra the bands attributable to the C-1 to C-8 moiety, as found in **1–3**. In addition **4** clearly contained a diene system, incorporating a new terminal methylene and an olefinic methyl group, from the proton spectrum and the u.v. absorption, λ_{max} 230 nm (ε 19 600). Apparently dehydration of **2** during work-up is responsible for the formation of **4**. The proton spectrum of **5** was remarkably similar to that of **3** with the significant addition of the characteristic absorption of an ethoxyl group. Like **2** and **3**, **5** is transparent in the near ultraviolet. Presumably **5** arises by an allylic rearrangement of **2** in ethanol-containing solvents.



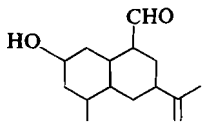
6



7



8*a* R = *E*—CH_2OH
b R = *Z*—CH_2OH
c R = *E*—CHO
d R = *Z*—CHO



9

Compound **6** accounted for much of the antifungal activity of the diffusate extract from which it was isolated as a major constituent (1). Our results from infrared, proton and mass spectra virtually coincided with those published for lubimin, a phytoalexin from potatoes, which has been described by Metlitskii and co-workers in a series of studies (12). To confirm the identity of the eggplant metabolite **6**, we isolated lubimin from potatoes essentially as described by the Russian

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

workers. The two compounds were found to be identical in every respect. However, their ^{13}C spectra showed clearly that structure **9**, originally proposed for lubimin, was untenable. The key feature was an absorption for a quaternary sp^3 carbon which is incompatible with **9**. The ^{13}C spectrum also contained signals for two methyl, five methylene and three methine carbons in addition to those for an aldehydic carbonyl, one carbinyl and two olefinic carbons; these shieldings are listed in Table 1. This array of signals suggested the spiro structure **8** having the vetispirane skeleton. The shieldings of the carbinyl and secondary methyl carbons indicated that the hydroxyl and methyl groups were equatorial and this was confirmed by the ^1H spectrum, which was also utilized to establish the orientation of the formyl group. Irradiation of the formyl proton doublet (J = 3.5 Hz) at 9.79 p.p.m. collapsed a doublet of triplets at 2.26 p.p.m. to a doublet of doublets (J = 8 and 3.5 Hz) while irradiation at 1.60 p.p.m. eliminated the larger coupling of 8 Hz in the 2.26 p.p.m. pattern. In the latter experiment, the carbinyl absorption was also narrowed by ~8 Hz. This indicated that the proton vicinal to the formyl group is axial and is coupled to an axial proton near 1.60 p.p.m. which, in turn, is coupled to the axial carbinyl proton. A second large coupling in the carbinyl absorption was eliminated by irradiation at 1.40 p.p.m. Spin decoupling also revealed that the secondary methyl protons (0.94 p.p.m.) were coupled to a proton at 1.55 p.p.m. Spin decoupling at 1.55 and 2.26 p.p.m. did not affect the carbinyl absorption. Thus, these results indicated the presence of the fragment $-CH_2-CH(OH)-CH_2-CH(CHO)-C<$. A precise mass determination gave the formula $C_{15}H_{24}O_2$ showing the compound to be bicyclic. While these results can be accommodated by a number of structures only **6** incorporates a known sesquiterpenoid skeleton and is plausible on biogenetic grounds. Subsequent to our preliminary communication (2), the same conclusion was reached independently by other workers (13).

Compound **7** has the formula $C_{15}H_{24}O_2$, as shown by a precise mass determination and contains a six- or higher-membered cyclic enone with λ_{max} 227 nm (ε 8650) and ν_{max} 1667 cm^{-1}, as well as a *tert*-hydroxyl group (ν_{max} 3455 cm^{-1}). The ^1H n.m.r. pattern for the olefinic protons was a simple AB system (J_{AB} = 10 Hz, δ_A = 5.86, δ_B = 6.78) showing that the adjacent carbon is fully substituted. These data for the enone moiety are remarkably similar to those reported for the enone fragment in tuberiferine (**10**): λ_{max} 224 nm (ε 11 200), ν_{max} 1680 cm^{-1}, J_{AB} = 9.9 Hz, δ 5.90 and 6.75 (14). In addition, the proton spectrum contained a singlet (6H, δ 1.40) a secondary methyl doublet (δ 1.13, J = 8.5 Hz), and a singlet (3H, δ 1.16). In C_6D_6 solution these methyl signals were shifted to 1.02, 1.01, and 0.83 p.p.m., respectively, which indicated that the secondary methyl is α to the carbonyl and equatorial while the lone *tert*-methyl is γ to the carbonyl (15). The two equivalent methyl groups could be assigned to an oxyisopropyl group. In addition the proton spectrum contained a well-defined doublet of quartets centered at 2.45 p.p.m. ($CDCl_3$). Upon irradiation at 1.13 p.p.m. this pattern collapsed to a doublet (J ~6 Hz) from which it was clear that this absorption arose from the proton vicinally coupled to the secondary methyl protons and to one other proton. The ^{13}C spectrum of **7** contained fifteen signals comprised of four methyl, three methylene, three methine, two quaternary (one of which was carbinyl at 72.6 p.p.m.), two monoprotonated olefinic, and a carbonyl carbon (see Table 1). Selective decoupling using a C_6D_6 solution of **7**, identified the individual signals for the angular and secondary methyl carbons and the latter's shielding (13.4 p.p.m.) is as expected for methyl α to carbonyl (16) while the value for the angular methyl seemed to be in good agreement with that expected for C-15 in structure **7** on the basis of the available data for angular methyl carbons in related *trans*-decalones (17). However, it seemed worthwhile to determine the methyl shielding in a better model system and to this end we prepared olefin **11** as described in the accompanying paper (18). Its methyl carbon absorbed at 18.9 p.p.m. or 2 p.p.m. upfield from the corresponding signal for **7**. This difference agreed very nicely with that predicted from the results for **12** and **13** (17). The angular methyl shieldings for the latter pair differ by 3 p.p.m. with **12** at higher field. Since it is known that the equatorial hydroxyl in **12** deshields the angular methyl by 1 p.p.m. in the *trans*-decalin system (19), the effect of the 3-carbonyl group on the angular methyl shielding is *ca.* 2 p.p.m., as was observed for **7** *vs.* **11**. Equatorial alkyl substituents on the

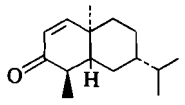
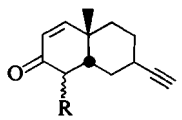
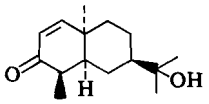
13 X = O; Y = H



14



15*a* R = α-CH_3
b R = β-CH_3



16

trans-decalin ring system are not expected to influence the angular methyl shielding appreciably. Thus, the n.m.r. results led to **7** as the formulation best representing the eggplant metabolite. It may be noted that, on biogenetic grounds, this structure fits in very nicely with the other bicyclic sesquiterpenoidal stress compounds of the *Solanaceae* (2).

Enone **14**, which has been synthesized (20), differs from **7** only by the absence of the C-12 hydroxyl and the spectral properties of **7** and **14** are closely similar, confirming our structural deductions. The absolute configuration of **14** is known and its o.r.d. curve, exhibits a complex positive Cotton effect and bears an essentially mirror image relation to that of **7** apart from constant amplitude differences, presumably due to the low optical purity reported (20). A complex positive Cotton effect has been reported for **15***a* while **15***b* exhibits a negative effect (21). These results were readily interpreted in terms of the different conformational preferences produced by the changes in orientation of the α-methyl group. It should also be noted that the olefinic β proton (H-1) was spin coupled to H-5 in **15***a* but not in **15***b*. In the former H-1 and H-5 are in a nearly planar W orientation which is ideal for long range coupling between protons separated by four bonds. As an additional model compound for comparison with **7**, we have recorded the n.m.r. spectra for **16**,[4] an intermediate in the synthesis of occidentalol described by Deslongchamps and co-workers (22). The ^{13}C data are listed in Table 1 and the main feature is the markedly lower shielding observed for the angular methyl carbon (C-15) relative to that for **7**, a difference of 6.3 p.p.m. which is entirely consistent with the change in geometry at the ring junction (7). In the proton spectrum the β olefinic proton showed long range coupling (2 Hz) with H-5, analogous to that noted above for **15***a*, since protons 1 and 5 are in a nearly planar W arrangement. If the ring junction in **7** was *cis*, *i.e.* the 5β-form with 3α-methyl substitution, the same long range coupling should occur and the vicinal coupling (H_4–H_5) would be expected to be smaller than 6 Hz as observed. All of this evidence strongly supports structure **7** for the eggplant metabolite.

The biogenetic interrelationships between **6**, **7**, and other bicyclic sesquiterpenes of the *Solanaceae* have been outlined (2) and we are currently exploring these in further detail.

[4]We are grateful to Professor Deslongchamps and Mrs. M. Sergent-Guay for specially preparing a sample of **16** for our examination, and to Dr. J. S. Roberts for drawing our attention to this compound.

Experimental

General

Melting points were determined on a Kofler hot-stage. Infrared spectra were recorded for liquid films with a Unicam SP 1000 instrument; ultraviolet spectra were obtained in 96% ethanol using either a Beckman DK or a Pye-Unicam SP 8000 spectrophotometer. Optical rotatory dispersion curves were obtained with a Jasco ORD-UV5 spectropolarimeter using a 0.1 dm path length. For optical activity measurements at 589 nm only, a Schmidt-Haensch polarimeter was used with a 1 dm path length. Proton n.m.r. spectra were obtained with Varian A60A and HA100 instruments, using $CDCl_3$ as solvent and TMS as the internal reference. The ^{13}C n.m.r. spectra were recorded with a Varian XL-100-15 system operating in the Fourier transform mode. Mass spectra were determined on a Varian M-66 spectrometer at 70 eV. Camag DF5 silica gel, activated at 110 °C, was used for thin layer (300 μ) chromatography. Gas chromatography was done with a Hewlett-Packard 5750 instrument, equipped with a digital integrator, using a 6 ft glass column, 0.25 in. diameter, packed with 3% SE-30 on Gas-Chrom Q (80–120 mesh) at 160 °C with a nitrogen flow of 40 ml/min. Low boiling petroleum ether (30–60 °C) was used and all solvents were redistilled before use.

All compounds **1**–**7** were obtained as essentially colorless syrups. Their isolation and purification, by repeated preparative t.l.c., have been described in detail (1).

9-Oxonerolidol (1)

Both the eggplant metabolite and Hiroi's sample had λ_{max}^{EtOH} 238 nm (ε 12 000), ν_{max} 3490, 3140, 1690, 1625, and 923 cm^{-1}. Infrared and mass spectra of the samples differed only in a few minor bands which apparently arose from small amounts of different impurities as revealed by g.l.c. analyses. The retention times in minutes (and rela-

tive peak areas, %) were: eggplant specimen; 1.1(0.14), 3.9(0.21), 4.3(0.10), 4.8(5.1), 6.1(94.4), and 7.5(0.08). Hiroi's specimen: 4.0(0.16), 5.2(6.1), 6.1(93.6), and 8.2-(0.11). The proton spectra were essentially identical and have been described (3).

9-Oxynerolidol (2)

This diol had ν_{max} 3420, 3130, and 922 cm^{-1}; *m/e* 239(M + 1), 238(M), 236, 221, 220, 85, and was transparent in the near u.v. It was identical by i.r., ^1H n.m.r., t.l.c. (methanol–chloroform, 5:95; *sec*-butanol – ethyl acetate, 5:95) and g.l.c. (retention time 6.3 min (98%)) with the product obtained from Hiroi's sample of **1** upon reduction with $NaBH_4$ in methanol (3) except that the reduction product, despite purification by preparative t.l.c., contained 3.5% of an impurity (retention time, 5.5 min). The o.r.d. curves of the two substances (5 mg/ml in EtOH) showed virtually no optical activity between 350 and 700 nm. The two samples exhibited slightly different ^{13}C n.m.r. spectra in that seven carbons each gave rise to two closely spaced signals (see Table 1) which were of approximately the same intensity in the spectrum of the reduction product but in a ratio of ~4:1 for the natural product.

Diol **2** (7 mg, eggplant specimen) was shaken with a large excess of manganese dioxide in benzene at room temperature for 48 h (23). The main product (40% yield), isolated by preparative t.l.c. (MeOH–Et_2O, 1:9) was identical with **1** by t.l.c. and g.l.c. as well as i.r. and u.v. spectra.

Triendiol 3 (3,11-Dihydroxy-3,7,11-trimethyldodeca-1,6,9-triene)

This compound had $[\alpha]_D^{23}$ +14 (*c*; 1.0, CCl_4), ν_{max} 3420, 3120, 978, 926, and 692 cm^{-1} and *m/e* 239(M + 1), 238(M), 221, 220, 205, 202, 193, 187, and 138 (base). The proton spectrum ($CDCl_3$) contained an ABX pattern, δ_A 5.190, δ_B 5.051, J_{AB} = 1.5 Hz (H-1), δ_X 5.936 (H-2), J_{AX} = 17.4, J_{BX} = 10.6 Hz, an ABX_2 pattern δ_A 5.625 (H-10), δ_B 5.605 (H-9), J_{AB} = 16 Hz, δ_X 2.65 (H-8), J_{BX} = 4.5 Hz and an olefinic proton at 5.16 p.p.m. (H-6), $J_{5,6}$ = 7 Hz, $J_{6,8}$ = 1.5 Hz. Methyl absorption occurred at δ 1.30 (3-Me), 1.33 (11-Me's), and 1.62 (7-Me, J ~ 1.5 Hz).

Tetraenol 4 (3-Hydroxy-3,7,11-trimethyldodeca-1,6,9,10-tetraene)

This unsaturated alcohol exhibited λ_{max}^{EtOH} 230 nm (ε 19 600) and ν_{max} 3450, 3095, 1610, 970, 927, and 889 cm^{-1}. The proton spectrum contained an ABX pattern; δ_A 5.195, δ_B 5.055, J_{AB} = 1.5 (H-1), δ_X 5.93 (H-2), J_{AX} = 10.5, J_{BX} = 17.5 Hz; an ABX_2 pattern δ_A 6.146, (H-10), δ_B 5.610 (H-9), J_{AB} = 15.5 Hz, J_{BX} = 7.5 Hz, δ_X 2.80 (H-8); a triplet (J ~7 Hz) of closely spaced multiplets δ 5.16 (H-6) and a multiplet at δ 4.85 (2H, H-12). Methyl absorption appeared at δ 1.30 (3-Me), 1.63 (7-Me), and 1.86 (11-Me).

Hydroxyether 5 (11-Ethoxy-3-hydroxy-3,7,11-trimethyldodeca-1,6,9-triene)

This compound was transparent in the ultraviolet spectrum and exhibited ν_{max} 3450, 3100, 985, 828, and 695 cm^{-1}. The proton spectrum had an ABX pattern δ_A 5.30, δ_B 5.14, J_{AB} = 1.5 (H-1), δ_X 6.08 (H-2), J_{AX} = 18, J_{BX} = 10 Hz; δ 5.26 (t, J ~7) for H-6 and the AB part (δ_A 5.60, δ_B 5.58, H-10 and H-9, respectively) of an ABX_2, δ_X 2.72 (H-8). Methyl absorption occurred at δ 1.28 (3-Me), 1.26 (6H, 11-Me's), 1.60 (6-Me), and the triplet, δ 1.14, for the methyl of the ethoxyl group (—CH_2—O, δ 3.40).

Lubimin (6)

From Eggplants

The isolation of **6** has been described (1). An o.r.d. curve was recorded at 32 °C in ethanol: $[\phi]_{589}$ +92, $[\phi]_{450}$ +203, $[\phi]_{350}$ +762, $[\phi]_{322}$ +1680, $[\phi]_{299}$ 0, and $[\phi]_{280}$ −920. Mol. Wt. Calcd. for $C_{15}H_{24}O_2$: 236.1775. Found: 236.1762.

The proton spectrum contained formyl proton absorption δ 9.79, J = 3.5 Hz coupled to a doublet (J ~8) of triplets (J ~3.5) at δ 2.26 and carbinyl absorption as a triplet (J ~10.5) of triplets (J ~4.5) at δ 3.69. Double irradiation at 1.60 p.p.m. removed one large coupling in each of the patterns at 2.26 and 3.69 p.p.m. while triple irradiation at 1.40 and 1.60 p.p.m. reduced the carbinyl pattern to a triplet (J ~4.5 Hz). Methyl absorption appeared at δ 1.70 (olefinic methyl) and δ 0.93 (d, J ~7 Hz); the doublet was collapsed to a singlet upon irradiation at 1.55 p.p.m.

From Potatoes

Potato tubers (*ca.* 130 lb) were cleaned and cut into slices ~2 cm thick under sterile conditions. Circular wells (2 cm diameter, 1 cm deep) were scooped out from one side of each slice and filled with spore suspensions of *Monilinia fructicola* (Wint.) Honey (5 × 10^5 spores/ml). After incubation in covered trays at room temperature for 48 h, the liquid was collected from the wells (*ca.* 5 l) and extracted with petroleum ether (3 × 2.5 l). The residue (150 mg) obtained by evaporation of the washed and dried extracts was chromatographed over a column of silica gel (100 g, unactivated Camag DF 5) packed in MeOH–$CHCl_3$ (5:95). Elution with the same solvent in 5 ml fractions gave an oil (44 mg, fractions 16–21) which had the spectral properties reported for lubimin (i.r., ^1H n.m.r., mass spectra); $[\alpha]_D^{32}$ 46 (lit. (12) $[\alpha]_D^{20}$ 27).

This product was identical with the material isolated from eggplant as judged by i.r., ^1H and ^{13}C n.m.r., o.r.d. and mass spectra as well as by t.l.c. (in 3 systems), g.l.c., m.p. and mixture m.p. (137–141 °C) of the 2,4-dinitrophenylhydrazones (lit. (12) m.p. 124–127 °C).

Reduction of the substance (34 mg) with sodium borohydride (6 mg) in methanol (3 ml) at 10 °C gave a diol (33 mg, m.p. 127–128 °C) which has since been described (lit. (13) m.p. 128–130 °C).

Enone 7

A small amount of the enone, whose isolation has been described (1), was sublimed *in vacuo* at 70 °C and was found to crystallize slowly when kept at −10 °C, m.p. 65–68 °C; λ_{max} 227 nm (ε 8650) with a weak shoulder at 310 nm (ε 54); ν_{max} 3455, 2990, 2955, 2890, 1667, 920, 827, and 756 cm^{-1}; *m/e*, 236(M), 221, 203, 178, 163, and 59 (base). Mol. Wt. Calcd. for $C_{15}H_{24}O_2$: 236.1775. Found: 236.1772.

An o.r.d. curve was recorded at 32 °C in ethanol: $[\phi]_{589}$ 0, $[\phi]_{500}$ 0, $[\phi]_{450}$ −94, $[\phi]_{400}$ −470, $[\phi]_{370}$ −1605, $[\phi]_{365}$ −1790, $[\phi]_{359}$ −1628, $[\phi]_{345}$ 0, $[\phi]_{312}$ +3900, $[\phi]_{285}$ +3350, and $[\phi]_{270}$ +3870.

We wish to thank D. Hairsine, R. Lazier, G. L. Rock, H. Schroeder, I. Grikis, and Dr. M. B. Rampersad for

technical assistance. We are grateful to Profs. Hiroi and Deslongchamps for so kindly providing generous samples of **1** and **16**, respectively, for comparisons with our materials.

We acknowledge with thanks, the financial support of the National Research Council of Canada.

On the Alkaline Degradation of 2-Furfurylidene-10-methyl-*trans*-1-decalone[1]

A. STOESSL AND J. B. STOTHERS

Agriculture Canada Research Institute and the Chemistry Department, University of Western Ontario, London, Ontario N6A 3K7

Received May 28, 1975

A. STOESSL and J. B. STOTHERS. Can. J. Chem. **53**, 3359 (1975).

The reaction of 2-furfurylidene-10-methyl-*trans*-1-decalone with base (NaOH – aqueous $HOCH_2CH_2OH$) has been reinvestigated and found to give nine products. Elucidation of the structures of eight of these products, which accounted for *ca.* 80% of the process, was accomplished from their spectroscopic data and confirmed by chemical interconversions. The product mixture obtained shows that the reaction involves competition between the retroaldol process and various hydride reductions with some allylic isomerization.

A. STOESSL et J. B. STOTHERS. Can. J. Chem. **53**, 3359 (1975).

On a réétudié la réaction de la furfurylidène-2 méthyl-10 décalone-1 *trans* avec les bases (NaOH – $HOCH_2CH_2OH$ aqueux) et on a trouvé qu'il y a formation de neuf produits. On a élucidé la structure de huit de ces composés (représentant environ 80% de la réaction) à l'aide de données spectroscopiques et on les a confirmés par des interconversions chimiques. Le mélange de composés obtenus montre que la réaction implique une compétition entre la réaction rétroaldolique et diverses réductions par des hydrures avec un peu d'isomérisation allylique.

[Traduit par le journal]

As a model compound for the structural elucidation of some stress metabolites reported elsewhere in this issue (1) we required 10-methyl-Δ^1-*trans*-decalin (**1**). Since a quantity of 2-furfurylidene-10-methyl-*trans*-1-decalone (**2**) was on hand from an earlier study (2), we elected to prepare 10-methyl-*trans*-decal-1-ol (**3**) as a precursor for **1** from **2** as described in the literature (3). In our hands, the latter procedure gave in addition to **3**, seven compounds (**4**–**10**) which have been characterized. In our attempts to prepare **1**, recently described for the first time by Heathcock *et al.* (4) we found that **4**, the 1α epimer of **3**, is a much better precursor for **1**.

In the original description of the preparation of **3** from **2** (3), the product was isolated by distillation of the steam volatile fraction. However, since thin layer chromatography (t.l.c.) of the latter material showed the presence of nine distinct components, we chromatographed it preparatively on silica gel to obtain eight major fractions. Rechromatography of some of these fractions led to the isolation of eight compounds, **3**–**10**. One additional component, observable on analytical t.l.c., apparently decomposed during preparative chromatography. The isolated products accounted for 80% of the reaction, with **3** and **4** obtained in 33% and 17% yields, respectively, which may be compared with the 31% yield originally reported for the alcohol product of unspecified stereochemistry. The remaining six components included two ketones (**5** and **8**) and four alcohols, as shown by their i.r. and ^{13}C n.m.r. spectra; further, each was found to contain a furan moiety from the u.v. and n.m.r. spectra. The latter data also showed that **10** retained the furfurylidene

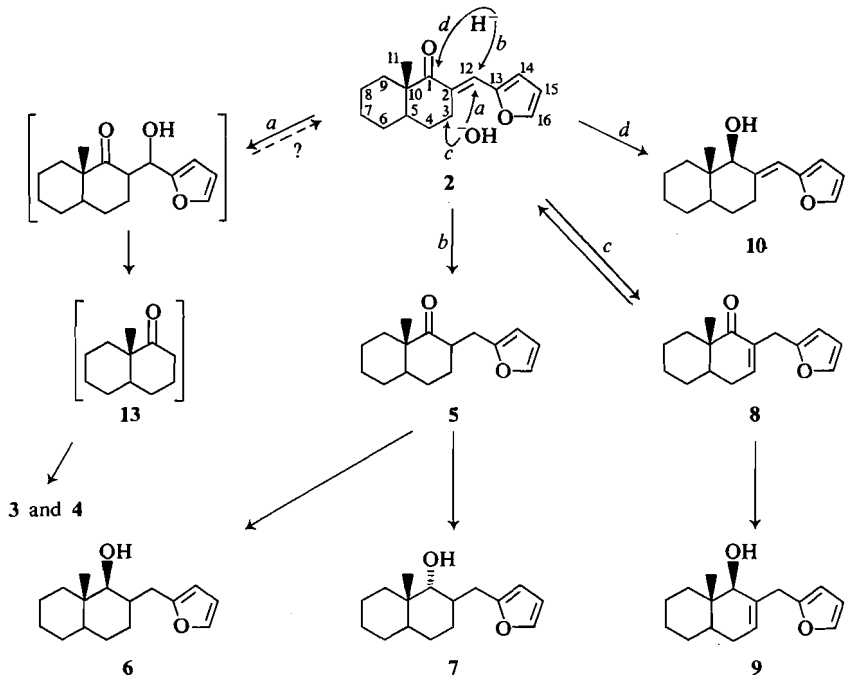
*In p.p.m. from TMS for $CDCl_3$ solutions.



SCHEME I

group while **8** and **9** contained a trisubstituted double bond which in **8** was conjugated with the carbonyl group, thereby placing it at C-2,3 in the decalin skeleton. Conversion of **8** → **9** and **2** → **10** was readily accomplished by $NaBH_4$ reduction. A similar reduction of **5** gave a mixture of **6** and **7** with **6** as the major component. An examination of the ^1H and ^{13}C n.m.r. spectral data for the series led to the assigned structures; the ^{13}C data are collected in Table 1, including the results for models **11** and **12**.

A comparison of the noise decoupled and off-resonance decoupled ^{13}C spectra readily distinguished the signals for the methyl, methylene, methine and fully substituted carbons from which it was apparent that the decalin and furan moieties were intact in all cases. The methyl and carbonyl shieldings for **5** were identical to those for 10-methyl-*trans*-1-decalone (5), thus indicating its structure since an equatorial α alkyl substituent is not expected to affect these shieldings appreciably (6). Firm support for the location of the carbonyl group was provided by the spectra of the epimeric alcohols **6** and **7** formed from **5**. The carbinyl protons in each gave rise to a doublet, $J = 10.3$ and 2.0 Hz, respectively, while the carbinyl carbons absorbed at 83.1 and 77.3 p.p.m. with the corresponding methyl signals at 10.6 and 15.9 p.p.m.; these ^{13}C data are comparable to those for **3** and **4** (2). These results established **6** as the β-epimer while **7** has an α-hydroxyl group. The methyl shieldings of **9** and **10** at 10.3 and 10.2 p.p.m., respectively, similarly indicated the presence of a β-hydroxyl group in each of these alcohols. The remaining assignments of the carbon resonances as set out in Table 1 are entirely in agreement with the proposed structures with the noteworthy consistency of the shifts for the furan ring and C-6–C-9 of the decalin skeleton.

The major course of the overall process is the crossed Cannizzaro reaction with **13** as the presumed intermediate formed by a retro aldol reaction after hydroxide attack at C-12 of **2** (route *a* in Scheme 1). The presence of ketone **5** shows that hydride ion attack at C-12 is a competitive process (route *b* in Scheme 1). Presumably proton abstraction by hydroxide ion at C-3 in **2** leads to its conversion to **8** (route *c*) while hydride ion attack directly at the carbonyl group of **5**, **8**, and **2** led to the formation of **6**, **7**, **9**, and **10**. The ratios of the products obtained under the original conditions indicated that route *a* constituted ~67% of the overall process,

b ~18%, *c* ~9%, and *d* ~6%. However, under slightly less severe conditions, the product composition differed somewhat having a higher proportion of **8** and smaller amounts of **3** and **4**, indicating a reversible allylic isomerization, **2** ⇄ **8**. This was confirmed by the formation of **3**–**10** from **8** upon treatment of the latter under the milder conditions.

A second point of interest in this study is that olefin **1** is much more readily accessible from **4** than **3** presumably because **4** has an axial hydroxyl function. Heathcock *et al.* (4) obtained **1** in 43% yield by heating the tosylate of **3** in lithium chloride – dimethylacetamide to 100 °C, and these authors found that several other reagents gave zero yields. We found, similarly, that the treatment of **3** with (*a*) phosphorus oxychloride in pyridine, (*b*) thionyl chloride in pyridine, (*c*) aluminum oxide – pyridine (7), and (*d*) heating the mesylate of **3** in pyridine or in quinoline at 210–222 °C, gave products essentially devoid of the desired olefin. We obtained **1** in only moderate yields as a component of a complex mixture by pyrolysis of the acetate of **3** as well as in the solvolysis of the tosylate of **3** (4). In contrast **1** was prepared very conveniently and in 80% purity by the treatment of **4** with phosphorus oxychloride in pyridine at 0 °C. Presumably the dehydration of **4** proceeds more readily to **1** than with **3** because one of the vicinal hydrogens is axial and periplanar to the axial hydroxyl as required for facile elimination.

Experimental

General experimental procedures and the instrumentation employed were as described in the accompanying paper (1), except that infrared spectra were recorded for solutions (2% in CCl_4) with a Beckman IR 20 spectrophotometer. Unless otherwise noted, both column and thin layer chromatography employed Camag DF5 silica gel as adsorbent with methylene chloride as irrigant, but the adsorbent was activated (by heating to 110 °C) only for t.l.c.

Reaction of 2-Furfurylidene-10-methyl-trans-1-decalone (2) with Base

Ketone **2** (2.62 g) was added to a solution of NaOH (30 g) in freshly distilled ethylene glycol (150 ml) and water (15 ml) at 110 °C. The temperature of the mixture was raised to approximately 150 °C during 2 h, maintained near 150 °C for the next 7 h, and then raised to 175 °C for another 2 h. The product was allowed to cool to room temperature, diluted with water, and distilled in steam until the distillate was no longer cloudy (3.6 l). After saturation with sodium chloride, the distillate was extracted with ether (2 × 750, 1 × 200 ml); the combined extracts were dried over sodium sulfate, filtered, and evaporated to dryness, the remaining traces of moisture being removed by re-evaporation from absolute ethanol. The product (1.84 g) was eluted from a column of silica gel (500 g) in 25 ml fractions (see Table 2). A compound just slower than **3** was observed on analytical t.l.c. but apparently decomposed during preparative chromatography. Fractions 84–101 were further separated into crude **9** (52 mg) and **6** (36 mg) by preparative t.l.c.; fractions 102–119 afforded **9** (2 mg), **6** (87 mg), and **4** (50 mg) on rechromatography over a column of silica (100 g).

Compound **5**, after repeated recrystallization from petroleum ether (30–60 °C) at −10 °C, had m.p. 73 °C, λ_{max} 217 nm (log ε 3.94), and ν_{max} 1711 cm^{-1}.

Anal. Calcd. for $C_{16}H_{22}O_2$ (mol. wt. 246.1619): C, 78.01; H, 9.00. Found (246.1628): C, 77.82; H, 9.03.

The ketone **5** (86 mg) in ethanol (8.6 ml) was treated

with $NaBH_4$ for 10 min at 25 °C. The product was poured onto ice, extracted into chloroform, washed, dried, and chromatographed over silica (100 g). Elution with methylene chloride (5 ml fractions) gave **7** (14 mg; fractions 17–21) and **6** (53 mg; fractions 22–27), both identified by ^1H n.m.r., i.r., and t.l.c.

Compound **8** was a syrup, λ_{max} 220, λ_{sh} 236 nm (log ε 4.05, 3.83), ν_{max} 1676 cm^{-1}. Calcd. for $C_{16}H_{20}O_2$: 244.1462; found *m/e*: 244.1446. The ketone accrued in much greater yield (approx. 250 mg from 2.75 g of **1**) under slightly less vigorous conditions (termination after 7.5 h and the temperature not exceeding 155 °C). The alcohols **3** and **4** obtained in this run, together amounted to only 760 mg compared to the 900 mg yield for the first run.

Enone **8** (34 mg) was heated at 156 °C in ethylene glycol (1.5 ml) containing water (0.15 ml) and sodium hydroxide (0.3 g) for 7.5 h. The product (14 mg), isolated by steam distillation and having the odor characteristic of alcohol **3**, was found by t.l.c. to contain compounds **3**–**10** in proportions similar to those in the product obtained by the alkaline degradation of **2**.

Compound **10** (119 mg) crystallized on cooling a concentrated solution of fractions 64–83 in petroleum ether (30–60 °C) to −10 °C. Repeated recrystallizations gave material melting at 88–95 °C, invariably contaminated with decomposition products formed during the process. A pure sample, m.p. 99–101.5 °C, for a precise mass determination was obtained by sublimation *in vacuo* at 65–70 °C. Larger amounts of material, sufficiently pure for n.m.r. and i.r. spectroscopy, were obtained by extracting crystalline material at room temperature with a moderate excess of petroleum ether (30–60 °C), filtration from the insoluble decomposition products, and rapid removal of the solvent *in vacuo*, immediately before use. The compound was stable in dilute solution in deuteriochloroform at room temperature for several days, and also when purified by sublimation, but was unstable if concentrated or when kept in inadequately purified form, even at −10 °C. Essentially pure material exhibited λ_{max} 265, 271, and 283 nm (log ε 4.37, 4.41, and 4.23) and ν_{max} 3640 cm^{-1}. Calcd. for $C_{16}H_{22}O_2$: 246.1619; found *m/e*: 246.1618.

Ketone **2** (59 mg) in ethanol (6 ml) was treated with sodium borohydride (16 mg + 6 mg after 60 min) at room temperature for 70 min. The product was taken up in ice water (50 ml), acidified with a few drops of acetic acid and exhaustively extracted with chloroform (9 × 20 ml). Evaporation of the washed and dried extracts gave a quantitative yield of crystalline **10** identified by m.p., mixture m.p., t.l.c., and ^1H n.m.r. and i.r. spectra. The material, though obtained pure originally, commenced to decompose during recovery from spectroscopic solutions, at a rate which appeared to accelerate during subsequent recrystallization.

Compound **7** (45 mg) was isolated as a syrup (ν_{max} 3640 cm^{-1}) by rechromatography over silica gel (100 g) of the mother liquors from which **10** had crystallized. Except for the presence of a little of the latter, it was identical (^1H n.m.r., i.r., t.l.c.) with the minor reduction product from compound **5**. The mass spectrum was almost indistinguishable from that of compound **6**.

Compound **9**, λ_{max} 218 nm (log ε 3.96), ν_{max} 3620 and 3598 cm^{-1}, was obtained as a syrup by preparative t.l.c. of the crude substance on aluminum oxide (Camag DSF 5) with carbon tetrachloride as irrigant.

The same compound (^1H n.m.r., i.r., t.l.c.) was obtained as the main product (28 mg) of the reduction of compound **8** (70 mg) in ethanol (7 ml) with sodium borohydride (124 mg, added in portions during 60 min) by chromatography of the crude product over silica (50 g).

Compound **6** was a syrup, λ_{max} 218 nm (log ε 3.96), ν_{max} 3640 and 3620 cm^{-1}, identical by ^1H n.m.r., i.r., and t.l.c. with the major borohydride reduction product from compound **5**. Calcd. for $C_{16}H_{24}O_2$: 248.1775; found *m/e*: 248.1737.

Compound **4**, purified by recrystallization from petroleum ether (30–60 °C) at −10 °C or by sublimation at 30–40 Torr at *ca.* 55 °C, had m.p. 61–62.5 °C and ν_{max} 3630 and 3490 cm^{-1}. The pure material was almost odorless.

Anal. Calcd. for $C_{11}H_{20}O$: C, 78.51; H, 11.98. Found: C, 78.14; H, 12.29.

Compound **3**, recrystallized from petroleum ether (30–60 °C) at −10 °C, had m.p. 53–54 °C (lit. (4) m.p. 52–56 °C), ν_{max} 3620 and 3490 cm^{-1}, and a strong odor of peppermint. The derived tosylate, filtered from carbon tetrachloride insoluble impurities and recrystallized from petroleum ether (30–60 °C), had m.p. 93–95 °C (lit. (4) m.p. 95–102 °C). The ^1H n.m.r. data for **3** and its tosylate were in close accord with those published (2).

*Oxidation of **3** and **4** to 10-Methyl-trans-decalone (**13**)*

Fractions 142–157 (Table 2) (105 mg), containing compounds **3** and **4** in the ratio 70:30 (g.l.c. on a Carbowax column (10%) at 130 °C), in acetic acid (1 ml) were treated dropwise during 5 min with a solution of $Na_2Cr_2O_7 \cdot 2H_2O$ (*ca.* 65 mg) in acetic acid (2 ml). After stirring at room temperature for another 30 min, the mixture was poured on ice, neutralized with solid sodium carbonate, and the product extracted into chloroform. Apart from unreacted **3** (16 mg), the extract (69 mg) contained only a single product (44 mg), which was eluted from silica gel (5 g) by methylene chloride–petroleum ether (30–60 °C) (3:7) and proved identical with **13** by ^1H n.m.r. and t.l.c.

*2-Furfurylidene-trans-1-decalol (**12**)*

A solution of **11** (3) (60 mg) in ethanol (6 ml) was treated with $NaBH_4$ (18 mg + 9 mg after 10 min) to give the pure decalol, m.p. 155–156 °C, λ_{max} 263, 270, and 281 nm (log ε 4.34, 4.38, and 4.20), ν_{max} 3630, ν_{sh} 3595 cm^{-1}, and M^+ 232. The compound was as unstable as **10** to recrystallization from petroleum ether (30–60 °C). An analytical sample was prepared by sublimation.

Anal. Calcd. for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68. Found: C, 77.20; H, 8.66.

*Dehydration of Compound **3** to Olefin **1***

(*a*) Treatment of **3** with phosphorus oxychloride or with thionyl chloride in pyridine at 0 °C; or heating the derived mesylate (methanesulfonylchloride–pyridine at room temperature) in pyridine (no reaction) or in quinoline at 210–222 °C during 2 h, gave products which

did not show the singlet absorption at δ 5.47 which is characteristic of olefin **1** (4). Treatment with aluminum oxide – pyridine (7) at 175 or at 230 °C gave a product, also free of the desired olefin, whose main components were starting material and ketone **13** (^{1}H n.m.r., t.l.c., borohydride reduction to starting material).

(*b*) Pyrolysis of the derived acetate at 500 °C for 0.5 h, in a sealed pyrex tube filled with nitrogen, gave a complex product which contained a small proportion (20–30%) of olefin **1** (^{1}H n.m.r.).

(*c*) Treatment of the tosyl derivative with lithium chloride in dimethylacetamide as in the literature (4) gave a mixture containing a similarly small proportion of the olefin.

*Dehydration of **4** to Olefin **1***

Alcohol **4** (208 mg) in pyridine (2 ml) at 0 °C was treated dropwise with phosphorus oxychloride (0.5 ml) in pyridine (2 ml) during about 2 min. After 4 days at 5 °C, the mixture was poured onto ice (20 g), and extracted with several portions of ice-cold ether. The extracts were washed in turn with water, 2 *N* sulfuric acid, water, 5% sodium hydrogen carbonate solution, and water, all at 0 °C. The ether layers were combined, dried over sodium sulfate at 5 °C, filtered, and evaporated *in vacuo*. The product (92 mg), comprising olefin **1** (*ca.* 80%) and two unidentified compounds (*ca.* 10% each by g.l.c. on a Carbowax column (10%) at 130 °C) was suitable for n.m.r. spectroscopy without purification.

We thank G. L. Rock for experimental assistance, H. Schroeder for the determination of 100 MHz proton spectra, and R. Lazier and D. Hairsine for the mass spectra. We are grateful to the National Research Council of Canada for financial support.

SAUL WOLFE, H. BERNHARD SCHLEGEL, IMRE G. CSIZMADIA, and FERNANDO BERNARDI. Can. J. Chem. **53**, 3365 (1975).

Non-empirical SCF–MO computations have been performed on $[CH_2CHO]^-$, the simplest enolate anion. Following a preliminary search of the conformational hypersurface using an STO-3G basis set to determine the C—C and C—O bond lengths as a function of rotation about the C—C bond, the rotation–inversion surface has been generated with an STO-4G basis set. The energy minimum of this surface is the all-planar anion whose C—C and C—O bond lengths are entirely compatible with the usual description $^-CH_2CHO \leftrightarrow CH_2{=}CHO^-$. The planar structure results from extensive conjugative stabilization amounting to over 30 kcal/mol (based on the C—C rotational barrier). When the CH_2 plane is perpendicular to the CHO plane, the conjugative interaction is symmetry forbidden and the electron-withdrawing inductive effect of the formyl substituent leads to a pyramidal carbanion. Experimental implications of these results are discussed.

SAUL WOLFE, H. BERNHARD SCHLEGEL, IMRE G. CSIZMADIA et FERNANDO BERNARDI. Can. J. Chem. **53**, 3365 (1975).

On a effectué des calculs SCF–MO non-empiriques sur $[CH_2CHO]^-$, l'anion énolate le plus simple. On a effectué une étude préliminaire de l'hypersurface conformationnelle utilisant une base STO-3G afin de déterminer les longueurs des liaisons C—C et C—O en fonction de la rotation du lien C—C; on a ensuite généré la surface de rotation–inversion utilisant une base STO-4G. Le minimum d'énergie de cette surface correspond à l'anion complètement plan pour lequel les longueurs des liaisons des liens C—C et C—O sont compatibles avec la description usuelle $^-CH_2CHO \leftrightarrow CH{=}CHO^-$. La structure planaire est le résultat d'une stabilisation importante provenant de la conjugaison et correspondant à plus de 30 kcal/mol (en se basant sur la barrière à la rotation C—C). Quand le plan du CH_2 est perpendiculaire au plan CHO, l'interaction de conjugaison n'est pas permise par la symétrie et l'effet inductif d'attraction des électrons par le groupe formyle conduit à un carbanion pyramidal. On discute des implications expérimentales de ces résultats.

[Traduit par le journal]

Introduction

"The generally-accepted mechanism of racemization, hydrogen isotope exchange, and halogenation of carbonyl compounds is rate-determining enolization followed by fast reaction of the enol or enolate ion" (1) (Eq. 1). The classic experiments upon which this mechanism rests (2, 3) were designed to demonstrate that "if the carbon atom bearing mobile hydrogen is an asymmetric center of optical activity, and is the only one present in the molecule, then optical activity must be lost in the mesomeric anion" (4).

[1] 
The purpose of the present investigation is to examine theoretically the circumstances under which an enolate anion will have trigonal planar geometry at carbon and will, therefore, be achiral. The work was initiated because of the implications that may be drawn from three types of study: (*i*) the extensive literature on the symmetry properties of tricoordinated species (5) indicates that attachment of a carbonyl group to a carbanionic center will cause a lowering of the barrier to pyramidal inversion at

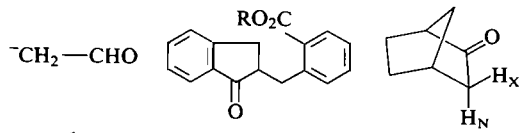
carbon if the conjugative effect of the carbonyl group dominates; however, the electron-withdrawing *inductive* effect of the carbonyl group operates in the opposite direction and will tend to increase the inversion barrier. Depending upon the balance between conjugative and inductive effects in this system, the barrier to pyramidal inversion at carbon in the anion of acetaldehyde (**1**) might be higher, lower, or equal to that in methylcarbanion. (*ii*) Although several claims that conjugated asymmetric carbanions had been generated (6) could not be confirmed (7), Marquet and co-workers (8) have succeeded in repeating and extending the observations of Leuchs (9). Thus the ketone **2** undergoes chlorination and bromination with retention of configuration at the asymmetric center, the degree of asymmetric induction depending upon the nature of the halogenating agent and the solvent. (*iii*) A number of examples now exist (10) of large differences in the rates of appearance of deuterium at the *exo* and *endo* methylene positions of certain bicyclic ketones (*e.g.* **3**), when these compounds are subjected to base catalyzed hydrogen–deuterium exchange.



1 **2** **3**

These latter observations have been interpreted in terms of a kinetic model which assumes a difference in the rates of protonation (deuteration) of an achiral intermediate (the enol or enolate anion) from *exo* and *endo* faces. However, there is an alternative interpretation of such observations if it is supposed that the asymmetry resides in the anionic intermediate itself, and not in the capture of this intermediate. In this event, the experimental observations would be consistent with either a greater rate of *abstraction* of the *exo* proton, or with exchange of the *exo* proton with retention of configuration and exchange of the *endo* proton with *inversion* of configuration (11). Analysis of experimental data in terms of such a mechanism would require a more complex kinetic model (12).

To assess the validity of these views, and the possible role of conformational effects in creating and maintaining asymmetry (*i.e.*, non-planar geometry at carbon) in an enolate anion, we have carried out a theoretical study of a portion of the conformational hypersurface of **1** corresponding to rotation about the carbon–carbon bond and pyramidal inversion at the carbanionic center. We were aware of the fact that formamide, H_2NCHO, which is isoelectronic with **1**, may have a non-planar configuration at nitrogen (13).

Method

The Hartree–Fock–Roothaan equations were solved using the Gaussian 70 program system (14). A preliminary search of the energy hypersurface was performed with an STO-3G basis set (15) and detailed investigation of the rotation–inversion surface was then carried out with the STO-4G basis set.[2] As a result of convergence problems, the computations could not be extended to the 4-31G level (16).

All computations were performed on a CDC 6600 computer at the University of Bologna.

Calculations

Because of the low (*ca.* 1 kcal/mol) inversion barrier in formamide (13), it was recognized that a crude optimization of the out-of-plane angle of **1** could well overlook a non-planar anion. In addition, the degree of non-planarity was expected to depend strongly upon both the C—C and C—O bond lengths. For example, shorter C—C and longer C—O bonds should enhance the conjugative effect and diminish any tendency towards a non-planar anion. The computations were, therefore, carried out in three stages.

In the first stage, the C—C and C—O bond lengths were varied with the carbanionic center non-planar (C—H = 1.09 Å; $\angle$CCO = $\angle$OCH = 120°; $\angle$HCH = $\angle$HCC = 115°; HCCO dihedral angle = 20° and both methylene hydrogens on the same side of the CCHO plane). These results are summarized in Table 1, together with a similar optimization with the carbanionic center planar. The second stage consisted of a complete optimization beginning with a slightly non-planar structure. Starting from $\angle$HCH = $\angle$HCC = 119°, all bond lengths and angles were optimized, with the inversion coordinate varied last. This led to a fully planar structure for the energy minimum. In the third stage of the work, this optimized structure represented the starting point for the STO-4G calcu-

[2]Minimal basis sets tend to overestimate barriers to pyramidal inversion. Therefore, energy differences in this paper which deal with changes in the inversion coordinate should be regarded as upper limits of these values.

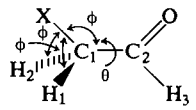
lations of the rotation–inversion surface. The coordinates are defined as shown in **4**; in this structure, the point X is included to facilitate the definition of the inversion coordinate.



4

Thus $\phi = 90$, $\theta = 0$ defines the all-planar conformation.

At each of three dihedral angles ($\theta = 0$, 45, and 90°), the C—C and C—O bond lengths and the HC_1C_2 valence angles were reoptimized with ϕ maintained at 90°. Then the inversion cross-sections were scanned by permitting ϕ to vary. The relationship between the HC_1C_2 angles and

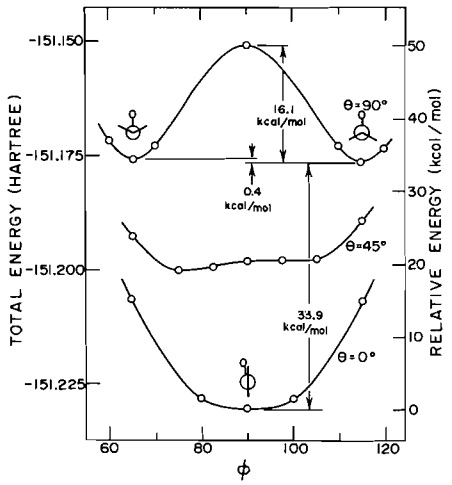


FIG. 1. Cross-sections of the rotation–inversion surface of **1** corresponding to $\theta = 0°$ (the all-planar conformation), $\theta = 45°$, and $\theta = 90°$.

ϕ is given in Eq. 2, and corresponds to the assumption that the projected HC_1C_2 angle about the C_1X axis remains constant.

$$[2]\quad \cos(\angle HC_1C_2)_\phi = \cos^2\phi + \cos(\angle HC_1C_2)_{90}\sin^2\phi$$

These latter cross-sections are displayed in Fig. 1 and summarized in Table 2.

An analytical expression having the form shown in Eq. 3 was then fitted to the data of Table 2. The coefficients of Eq. 3 are given in Table 3. With the aid of this equation, a perspective view of the final rotation–inversion surface was generated, and is presented in Fig. 2.[3]

$$[3]\quad \begin{aligned} E = {} & C_0 + C_1(\phi - 90)^2 + C_2\exp[-1.05(\phi - 90)^2] \\ & + C_3\sin\theta\cdot(\phi - 90) + C_4\sin\theta\cdot(\phi - 90)^3 \\ & + C_5\sin^2\theta + C_6\sin^2\theta\cdot(\phi - 90)^2 \\ & + C_7\sin\theta\cdot\exp[-1.05(\phi - 90)^2] + C_8\sin^3\theta\cdot(\phi - 90) \\ & + C_9\sin^3\theta\cdot(\phi - 90)^3 + C_{10}\sin^4\theta \\ & + C_{11}\sin^4\theta\cdot(\phi - 90)^2 + C_{12}\sin^4\theta\cdot\exp[-1.05(\phi - 90)^2] \end{aligned}$$

Discussion

The all-planar structure is the minimum point on the rotation–inversion surface because of the overriding effect of the conjugative stabilization that is present in this conformation. The magnitude of this conjugative effect may be gauged from the 33.9 kcal/mol barrier to rotation about the C_1—C_2 bond and the decrease in this bond length from 1.472 Å at $\theta = 90°$ to 1.379 Å at

[3]This surface is generated by a series of computer programmes SURFPLOT, which may be obtained from the authors.

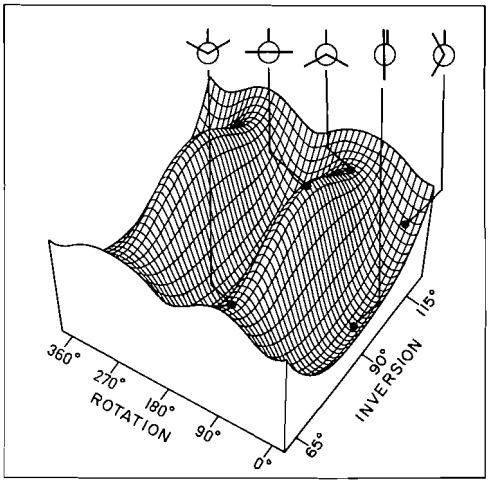

FIG. 2. The rotation–inversion surface of **1**.

θ = 0°, accompanied by a lengthening of the C_2—O bond from 1.233 to 1.270 Å. Inspection of the π-type molecular orbitals (Fig. 3) reveals that conjugation is achieved by a four-electron three-orbital interaction between the carbon lone pair and the π and π* C_2—O orbitals. Even when the methylene group is rotated 45° out of the plane of the formyl group, substantial conjugation remains, as indicated by the short C_1—C_2 bond (1.404 Å). However, at θ = 90°, this conjugative interaction is now symmetry forbidden and the methylene group behaves normally, *i.e.*, it is pyramidal. The inversion barrier is 16.1 kcal/mol, which may be compared to the 21.7 kcal/mol barrier computed for CH_3^- with the same basis set.

Our expectation that the electron-withdrawing formyl substituent might bring about some stabilization of the pyramidal configuration at the methylene group is thus not confirmed, either at θ = 0° (the all-planar structure) or at θ = 90°. The reason for this can be seen upon considera-

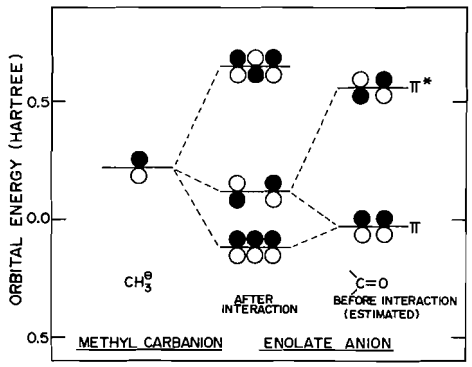

FIG. 3. Interaction of the π-type molecular orbitals in the energy minimum of **1**.

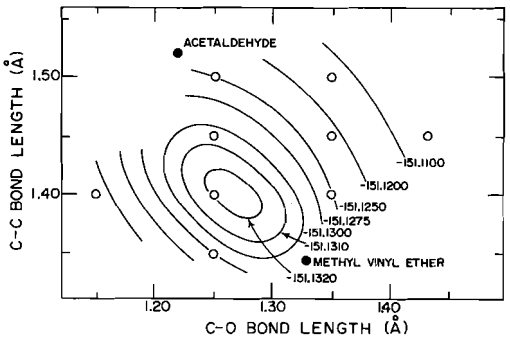

FIG. 4. The relationship between the computed (STO-3G) C—C and C—O bond lengths of **1**. Experimental data for methyl vinyl ether and acetaldehyde are indicated by ●.

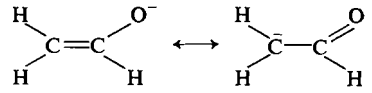
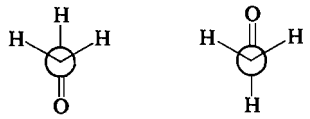
tion of the nature of the charge transfer between the methylene and formyl groups. Within the framework of the Mulliken population analysis, there is, in the all-planar structure, a π charge transfer of 0.47 electron from CH_2^- to CHO, and a σ charge transfer of only 0.04, illustrative of the dominating influence of the conjugative interaction. In the θ = 90° conformation, the σ charge transfer is 0.27 electron from CH_2^- to CHO, but some π charge transfer, amounting to 0.05 electron in the same direction, or 18% of the σ charge transfer, remains. This is caused by a hyperconjugative interaction between the methylene group and the formyl group. This hyperconjugative interaction works against the inductive (*i.e.* σ) effect of the formyl group, and it leads to a net destabilization of the pyramidal configuration, as compared to CH_3^-.

The C—C and C—O bond lengths are strongly coupled to each other (*cf.* Table 1). The contour plot of Fig. 4 shows this coupling for the STO-3G calculations. For comparison, the experimental bond lengths of acetaldehyde (C—C and C=O) and methyl vinyl ether (C=C and C—O) are included in this figure. It is clear that the structure of acetaldehyde enolate anion is very well represented by the usual resonance description



The C—C and C—O bond lengths are also coupled to the out-of-plane bending of the methylene group. In the 0° rotational structure, for instance, the out-of-plane bending allows the orbitals of H_1 and H_2 to mix with the π orbitals and withdraw charge from them. In doing so, the π conjugation is reduced and the net effect is to lengthen both the C—C bond and the C—O bond as the geometry at C_1 is made non-planar. However, the stabilization gained by this out-of-plane bending is unable to overcome the concomitant destabilization of the π system.

The rotation–inversion surface shows in some detail the dependence of the energy on the rotation and inversion coordinates. It is noteworthy that the more stable of the two pyramidal structures has the Y conformation **5**. Such behavior has been found previously in $^-CH_2OH$ (17), whose C—O bond length is similar to the C_1—C_2 bond length of the enolate anion. The Y conformation is favored when the structure is dominated by the nuclear component of the total energy. However, in the θ = 45° cross-section, the structure is dominated by the electronic component of the total energy (*i.e.*, the conjugative effect), and the more crowded W conformation (**6**) is favored.



5 **6**

Conclusions

The suggestion that the simplest enolate anion might have non-planar geometry at carbon has not been supported. Although the electron-withdrawing effect of the carbonyl group can be shown to exist, in the absence of conformational constraint it does not overcome the conjugative interaction leading to a planar carbanion. The

For personal use only.

required conformational constraint is found in the ketone **7** (18). The observation that the bridgehead protons of this compound undergo base-catalyzed exchange demonstrates that, as computed for the $\theta = 90°$ structure, a pyramidal enolate anion has some stability. However, since the pyramidal conformation is much higher in energy than the all-planar conformation, the exchange is extremely slow.

In each of the bicyclic ketones (*e.g.*, **3**, **8–12**) for which stereoselective hydrogen exchange has been reported (10) a planar enolate anion is possible. Consequently it is valid to analyze stereoselective exchange in such compounds in terms of a kinetic model which assumes asymmetric capture of an inherently symmetrical intermediate. For stereoselective exchange of methylene protons adjacent to a carbonyl group to proceed via an asymmetric intermediate it will be necessary to employ a substrate containing diastereotopic methylene protons which cannot achieve a planar conformation in the enolate anion. Inspection of molecular models suggests that the ketone **13** may be suitable for such a study.

Results and Discussion

Several attempts have been made to estimate the ^{119}Sn Mössbauer isomer shift that a bare stannous ion ($5s^2$ configuration) would have. These estimates range from 4.76 mm/s (1) to 7.7 mm/s (2) and while the approach used for the former estimate has been shown to be incorrect (3, 4), isomer shift values for compounds containing Sn(II) are all lower than 4.76 mm/s. This either means that none of the compounds so far examined contain a bare $5s^2$ or that Lees and Flinn's approach (1) fortuitously gives the correct estimate. Very large shift values accompanied by zero quadrupole splitting have been taken to indicate that the $5s^2$ electrons are not involved in the metal–ligand bonds (5) and this is supported by crystallographic evidence for the $[SbX_6]^{3-}$ system (6). The analogous Sn(II) compound $[SnCl_6]^{4-}$ has not yet been prepared but such an ion might have a stereochemically inactive 5s electron pair and give a large positive isomer shift.

The only compound of Sn(II) known to exist in a cubic environment is SnTe (7). Its isomer shift (3.28 mm/s) is more positive than one might have expected from the electronegativity of Te and furthermore has no resolvable quadrupole splitting (2). However, SnTe cannot be considered to contain a bare Sn(II) ion since this is only likely to be achieved with the most electronegative ligands. Fluorine, being the most electronegative element, might have been expected to have the desired effect on a tin atom and produce a compound with a very high isomer shift. Invariably, however, tin(II) fluorides have distorted tin environments (8–11) and this is reflected in their Mössbauer parameters (Table 1) (12). $Sn(SbF_6)_2$ does have a very large positive isomer shift with no resolvable quadrupole splitting (Table 1) and might be considered an example of a compound containing a bare stannous ion, but other spectroscopic evidence suggests (13) that there is interaction between the Sn^{2+} and the SbF_6^- ions. Crystallographic data is not available on this compound to clarify this point.

TABLE 1. Mössbauer data for some tin(II) compounds

Compound	Isomer shift δ (mm/s)	Quadrupole splitting Δ (mm/s)
$Sn(SbF_6)_2$*	4.40	—

†Reference 18.

Stannous chloride has a large positive isomer shift (14, 15) but it is polymeric in the solid state (16) and cannot be considered an ionic compound. We have repeated Mössbauer measurements on this compound and while our isomer shift agrees with the literature value we find that the spectrum could only be satisfactorily analyzed in terms of a quadrupole split doublet rather than a single line. Figure 1 shows these fits with χ^2 values of 334 and 192 for the one and two line fits respectively. A quadrupole split absorption is more consistent with the distorted octahedral environment about the tin (16).

The tin(II)–oxygen systems appear to offer the best chance of obtaining the stannous ion in a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

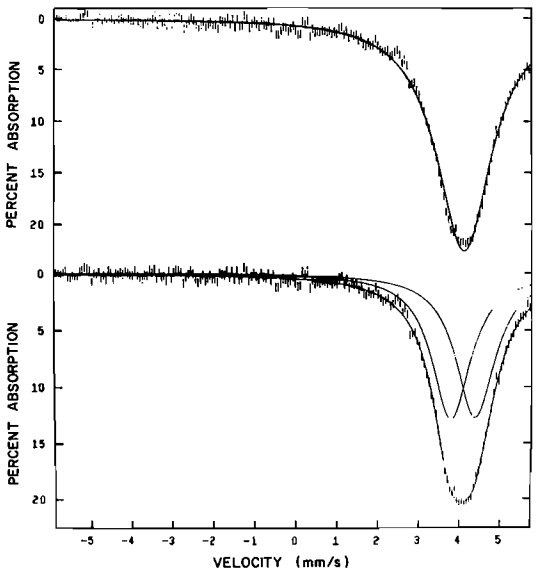

FIG. 1. ^{119}Sn Mössbauer spectra of $SnCl_2$ using one and two line fits.

regular octahedral environment with the oxygen ligand being sufficiently electronegative to leave the tin with a bare $5s^2$ configuration. We report in Table 1 data for α- and β-$SnWO_4$ and $Sn(SO_3X)_2$ which, when we began this work, we thought might contain Sn(II) in regular octahedral environments. If this had been the case very high isomer shifts with zero quadrupole splitting would have been observed. Both of the tungstates are now known to have distorted tin environments with the 5s electron pair clearly stereochemically active (17, 18). The bonding participation of the 5s electrons is reflected in the Mössbauer parameters where the isomer shift is lower than expected with a clearly resolved quadrupole splitting. The isomer shifts for these two compounds are not very different but are in the order one would expect from a comparison of their average Sn—O bond lengths. If one considers that the average of the Sn—O bond lengths is a measure of s electron withdrawal, and/or p–d electron donation, and that both have six significantly bonded oxygens, then α-$SnWO_4$ having Sn—O(average) = 2.47 Å should have a lower isomer shift then β-$SnWO_4$ (Sn—O(average) = 2.51 Å), as is observed. $SnSO_4$ has Sn—O(average) > 2.64 Å, longer than either of the tungstates, and it has a more positive isomer shift. Examination of the crystallographic data for these tungstates shows that the immediate tin environment in α-$SnWO_4$ is more distorted than in the β form, yet the quadrupole splitting is largest for the β form. It must be remembered however that the splitting is made up of a lattice as well as a valence contribution and the smaller value for α-$SnWO_4$ may be the result of a larger lattice contribution, which is likely to be of opposite sign to the valence contribution (19).

The Sn(II) halosulfonates are somewhat closer to the Sn^{2+} ideal, having very positive isomer shifts but still significant quadrupole splittings (Fig. 2). This again suggests participation of the 5s electron pair in the bonding, probably to about the same extent as in $SnCl_2$. The structures of these halosulfonates are almost certainly similar to that of $SnCl_2$ with the Sn atoms being linked by halosulfonate bridges to form polymeric chains. The bridging would, by analogy to $(CH_3)_2Sn(SO_3F)_2$ (20), be through the SO_3X^- oxygens rather than the halogen and the immediate tin environment would have one short and two longer Sn—O bonds on one side of the tin with the distorted octahedron probably being completed by two oxygens and a halogen on the lone pair side. Based upon a comparison of the isomer shift data for the Sn—O compounds of known structure one would anticipate that the

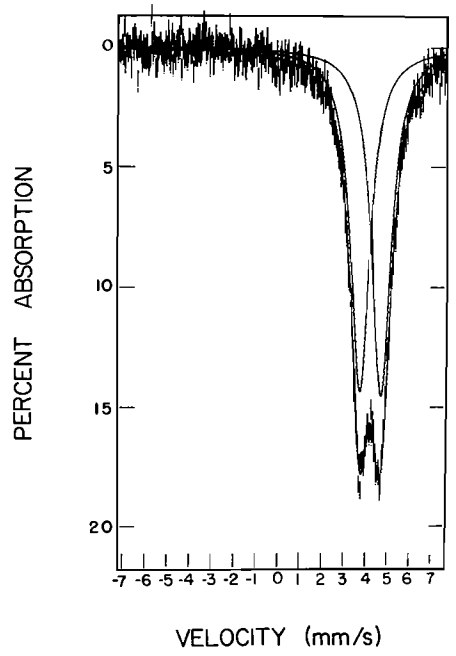

FIG. 2. ^{119}Sn Mössbauer spectra of $Sn(SO_3Cl)_2$ at 77 K.

Sn—O bonds would be longer than in $SnSO_4$ by ~0.1 Å. We are currently attempting crystallographic analyses of these $Sn(SO_3X)_2$ compounds.

Experimental

The Mössbauer spectra were recorded and computer fitted by procedures already described (21). Samples contained ~10 mg Sn/cm^2 and were cooled to 77 K. Isomer shifts are reported relative to $BaSnO_3$ at room temperature and are accurate to ±0.05 mm/s. Raman spectra were recorded on a Spex Industries Model 1400 Spectrometer with Ar^+ excitation (5145 or 4880 Å) from a Spectra Physics 164 Laser. α- and β-$SnWO_4$ were kindly supplied by Dr. A. W. Sleight, E.I. duPont de Nemours Co. Ltd., Wilmington, Delaware and have been fully characterized (17, 18).

Preparation of $Sn(SO_3X)_2$

$Sn(SO_3Cl)_2$

Pure dry SO_2 was condensed onto a pure sample of $SnCl_2$ at −63.5 °C in a glass apparatus which has been described (13). Liquid SO_3 in excess was added and the tube sealed. On removing the tube from the cold bath and warming to room temperature a vigorous reaction occurred. All of the stannous chloride went into solution and after a time a white precipitate formed, which was filtered, and washed with liquid SO_2 and then dried under vacuum.

Anal. Calcd. for $Sn(SO_3Cl)_2$: Sn, 33.94. Found: Sn, 33.88, 33.12.

$Sn(SO_3F)_2$

An excess of freshly distilled HSO_3F was condensed onto pure dry $SnCl_2$ in the apparatus described (13). Hydrogen chloride was evolved and a white precipitate formed. SO_2 was condensed in and the reaction mixture was for some time. The precipitate was filtered, washed with SO_2, and dried under vacuum.

Anal. Calcd. for $Sn(SO_3F)_2$: Sn, 37.48. Found: 37.46, 37.76.

The Raman spectrum showed that this compound was identical with that prepared from SnF_2 though the Mössbauer isomer shift is slightly smaller than reported previously (13).

Rates of OH Radical Reactions. I. Reactions with H_2, CH_4, C_2H_6, and C_3H_8 at 295 K[1]

R. P. OVEREND, G. PARASKEVOPOULOS, AND R. J. CVETANOVIĆ

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received June 20, 1975

R. P. OVEREND, G. PARASKEVOPOULOS, and R. J. CVETANOVIĆ. Can. J. Chem. **53**, 3374 (1975).

A fast flash photolysis kinetic spectrophotometer capable of measuring rates of up to 10^5 s^{-1} is described. The rates of hydrogen abstraction from H_2, CH_4, C_2H_6, and C_3H_8 by OH radicals at 295 ± 2 K, have been measured in the gas phase by hydroxyl resonance absorption spectrophotometry. The influence of secondary reactions on the measured rates and the derivation of the absolute rate constants is discussed in detail.

The absolute rate constants in units of cm^3 mol^{-1} s^{-1} were found to be: $k_{H_2} = 3.49 \pm 0.16 \times 10^9$, $k_{CH_4} = 3.92 \pm 0.16 \times 10^9$, $k_{C_2H_6} = 1.59 \pm 0.10 \times 10^{11}$, and $k_{C_3H_8} = 12.17 \pm 0.63 \times 10^{11}$.

R. P. OVEREND, G. PARASKEVOPOULOS et R. J. CVETANOVIĆ. Can. J. Chem. **53**, 3374 (1975).

Nous décrivons un spectrophotomètre à photolyse-éclair et à cinétique rapide capable de mesurer des vitesses de réaction de l'ordre de 10^5 s^{-1}. Les vitesses d'abstraction des atomes d'hydrogène de H_2, CH_4, C_2H_6 et C_3H_8 par des radicaux OH, à 295 ± 2 K ont été mesurées en phase gazeuse par spectrophotométrie d'absorption de résonance du radical hydroxyle. L'influence de réactions secondaires sur les vitesses mesurées et l'obtention des constantes de vitesse absolues sont discutées en détail.

Nous avons trouvé que les constantes de vitesse absolues en unités de cm^3 mol^{-1} s^{-1} sont: $k_{H_2} = 3.49 \pm 0.16 \times 10^9$, $k_{CH_4} = 3.92 \pm 0.16 \times 10^9$, $k_{C_2H_6} = 1.59 \pm 0.10 \times 10^{11}$ et $k_{C_3H_8} = 12.17 \pm 0.63 \times 10^{11}$.

Introduction

Hydroxyl radicals have long been recognized as being a chain carrier in the oxidative combustion of hydrogen and hydrocarbons; they also play an important role in the chemistry of the upper and lower atmosphere where they act as an oxidant. There is, therefore, a need for accurate values of the rate parameters of the reactions of OH with hydrogen, hydrocarbons, and atmospheric gases for use in numerical modelling of the above processes. Such reactions have been widely studied by various experimental techniques. However, data from earlier studies using flame, shock tube, and flow system experiments showed large discrepancies in the reported values of the kinetic parameters. More recently direct techniques have been developed, using spectroscopic, e.s.r., and resonance fluorescence detection of OH, which have improved the accuracy and precision of the data, so that at present the rate constants of some of the reactions (*e.g.*, H_2, CH_4) are established within a 20% range. The data for OH reactions have been reviewed by Drysdale and Lloyd (1) and Wilson (2), and it appears that further work is necessary, in particular using direct determinations.

In the present paper we describe a fast flash photolysis apparatus coupled with time resolved resonance absorption detection of OH. Signal averaging is employed to improve the signal-to-noise ratio. The apparatus is capable of measuring first order rates of up to 10^5 s^{-1}, thus enabling a more complete range of experimental conditions to be examined than hitherto.

We have in progress an extensive program of study on both abstraction and addition reactions of OH radicals in the gas phase. In this paper, the first of a series, we describe in detail the method used and report the rate constants of abstraction of hydrogen from H_2, CH_4, C_2H_6, and C_3H_8 at room temperature. The reaction of OH + H_2 is much studied and serves as a standard against which we compare our technique. We have also examined the effect of secondary radical reactions on the rate measurements by numerical simulation, and established the conditions for which such an effect is negligible.

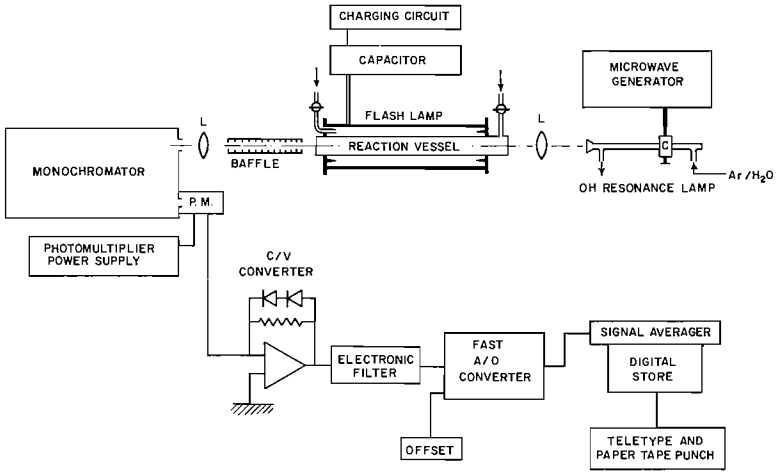

FIG. 1. Block diagram of the apparatus. L, lenses; P.M., photomultiplier; C/V converter, current-to-voltage converter; A/D converter, analog-to-digital converter.

Experimental

The apparatus consists of a fast flash photolysis system coupled with a spectrophotometric detection system. The block diagram of the experimental arrangement is given in Fig. 1. The flash lamp and reaction vessel are a low inductance coaxial assembly based in part on the design concepts of Furumoto and Ceccon (3). The 30 cm length flash discharge is in an annulus 1 mm deep around the 25 mm diameter reaction vessel. The electrodes are polished stainless-steel knife-edged rings. The flash lamp is discharged by lowering the pressure of dry air within the annulus. A range of energies from 100–600 J is obtained by charging either a 1.5 μF or a 5.1 μF capacitor to the appropriate voltage (10–16 kV). With the smaller capacitor the flash peaks at 650 ns and has a decay ($1/e$) time of 850 ns.

Two 50 cm long, 25 mm diameter reaction vessels were used, both made of Suprasil quartz. The first vessel was a simple tube; the second was a double wall tube in which the reaction mixture occupied the 10 mm diameter inner tube and could be surrounded by a suitable optical shield placed in the outer tube.

The OH concentration in the vessel is monitored by following the time resolved attenuation of the OH resonance radiation ($A^2\Sigma^+ \rightarrow X^2\Pi$) produced by a 2.45 GHz microwave discharge in a low pressure (~1 Torr) Ar/H_2O mixture (~5% H_2O). The resonance lamp is similar to that described by Carrington and Broida (4). After each flash attenuation of either the Q_1^3 or Q_1^4 rotational lines of the (0,0) band is followed by means of a 1 m Czerny-Turner spectrophotometer (Jarrell-Ash) and a S-5 photo cathode photomultiplier. The spectrometer has a resolution of 0.87 nm/mm and is operated at a band pass of 0.05–0.2 nm.

The photomultiplier voltage divider is wired for fast pulse response and high peak-current capability. The dynode voltage supply is a well regulated high current supply. Together these ensure fast recovery (≃5–10 μs) after the flash. To further protect the electronics after the photomultiplier from the flash pulse, two high speed signal diodes were wired across the load resistor in the current-to-voltage converter.

The signal is then passed to a variable low pass electronic filter which has a 4 pole Bessel response. The cutoff frequency of the filter was set at >2 × rate to be measured in the experiment; this provides adequate filtering of high frequency noise with a tolerable distortion of the rise to maximum OH absorption. The filtered signal is then accumulated by the fast analog-to-digital (A/D) converter and signal averager combination. Signal averaging techniques are required on account of the low intensity of the resonance lamp and the large electronic instrument bandwidth required to measure rates of 10^5 s^{-1}. The signal-to-noise (S/N) ratio of the system is 10 at 1 MHz and 30 at 100 kHz. With signal averaging the S/N ratio improves to 100 with less than 64 flashes.

The main source of OH radicals was the photolysis of water vapor mixed with the reactant and, in a few experiments with H_2 and CH_4, the photolysis of N_2O followed by the reactions:

$$N_2O + h\nu \rightarrow N_2 + O(^1D)$$

$$O(^1D) + H_2 \rightarrow H + OH$$

$$O(^1D) + CH_4 \rightarrow CH_3 + OH$$

The results with both sources of OH radicals were the same within the experimental error.

The gases were handled in a conventional mercury-free vacuum line provided with a Cellows gauge and an oil manometer. The experimental procedure was to prepare an accurately measured mixture made up from the hydroxyl source, the reactant, and the diluent gas (He). The mixture was mixed with a magnetic stirrer before transfer to the reaction vessel, where it was flashed the required number of times to achieve a satisfactory S/N ratio.

The materials were of the highest available purity and in all cases except H_2 and He were subjected to degassing and bulb-to-bulb distillation *in vacuo* before use.

Results

Experiments with varying low water vapor pressures and a constant flash energy showed the expected logarithmic dependence of the maximum OH absorption on the pressure of water, *i.e.*, $\ln I_0/I = KP_{H_2O}$, for absorptions of up to ~40%. The absorption decreased by about 40% when the total pressure in the vessel increased from 100 to 760 Torr; this was attributed to pressure broadening of the rotational line. Trainor and von Rosenberg (5) have discussed in detail the effect of pressure on absorption. In our experiments, in which we measure relative absorption with time, there should be no effect of pressure broadening on the measured rates. In the majority of our experiments the pressure of H_2O was such that the maximum absorption of OH was less than 10%. Using the formula of Kaufman and co-workers (6) and their suggested value of 8×10^{-4} for the oscillator strength of the hydroxyl $A^2\Sigma \rightarrow X^2\Pi$ transition we calculate that 25% absorption in 30 cm path length corresponds to a concentration of $[OH] \approx 1.3 \times 10^{-10}$ mol cm^{-3}. In our experiments the average initial absorption of OH was ~7–12% corresponding to an average concentration of ~3.3–5.8 $\times 10^{-11}$ mol cm^{-3}.

At the wavelengths used >160 nm the OH($X^2\Pi$) is formed without vibrational or rotational excitation (such excited OH, if present, might relax thereby producing an apparent decrease in the measured rates). The absence of OH with vibrational and rotational excitation has been shown experimentally by Welge and Stuhl (7) who found that throughout the 186–140 nm continuum the energy of the photons, in excess of that required to break the H—OH bond appears mainly as translational energy of the H and OH fragments, *i.e.* they found that the intensity of the $v'' = 1$ bands was only a few percent of the (0,0) band, and that the rotational distribution of OH($X^2\Pi$) was practically the room temperature equilibrium distribution.

The alternative source of hydroxyl radicals (*i.e.*, $N_2O + h\nu \rightarrow O(^1D) + N_2$, $O(^1D) + H_2 \rightarrow OH^* + H$) produced results in agreement with those from the photolysis of water. Thus, although the $O(^1D) + H_2$ reaction has been shown to produce vibrationally excited OH^* (8), the excited species have evidently relaxed by the time our measurements commence.

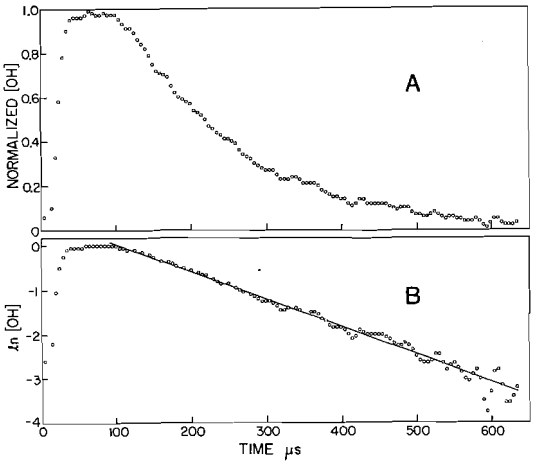

FIG. 2. Example of computer plots of (*A*) normalized [OH], and (*B*) ln [OH] against time for OH + H_2. The conditions of the experiment were: H_2 = 21.36 Torr, H_2O = 2.68 Torr, He = 499.3 Torr, time = 5 μs per channel.

In our experiments the concentration of the second reactant was always made much greater than the initial OH concentration. Under these conditions the reaction is pseudo-first order.

The digital data recorded on the paper tape consist of values of $\Delta I = I_0 - I$ at various time intervals and were processed on an off-line IBM 360 computer. The data were smoothed using a nine-point quadratic approximation suggested by Savitzky and Golay (9). The OH concentration, $[OH] = \ln (I_0/I)$, expressed in normalized

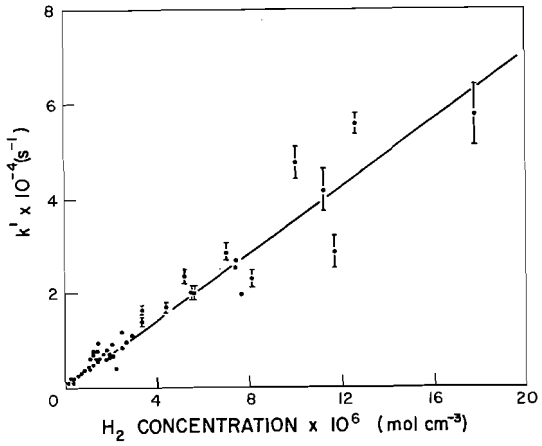

FIG. 3. Plot of pseudo-first order rate constant, k' against the H_2 concentration for the reaction OH + $H_2 \rightarrow H_2O$ + H.

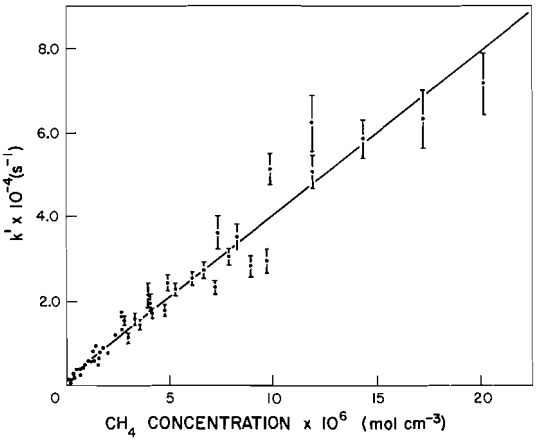

FIG. 4. Plot of pseudo-first order rate constant, k', against the CH_4 concentration for the reaction OH + $CH_4 \rightarrow H_2O + CH_3$.

units (*i.e.* as fraction of the concentration at maximum absorption), as well as ln [OH] = ln (ln (I_0/I)) were plotted against time. Such plots are shown in Fig. 2. The latter plots (pseudo-first order plots) were linear over 2–5 half-lives depending on the conditions.

The pseudo-first order rate constant for the OH decay k', was obtained from the slopes of the linear plots. The data had sometimes superimposed on them a sporadic spike noise which occurred in only one direction, as will be illustrated in the next section. The effect was easily filtered out by eye and the slope drawn by hand.

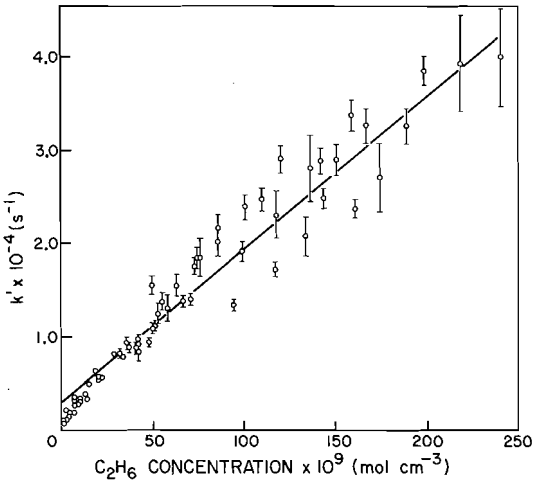

FIG. 5. Plot of pseudo-first order rate constant, k', against the C_2H_6 concentration for the reaction OH + $C_2H_6 \rightarrow H_2O + C_2H_5$.

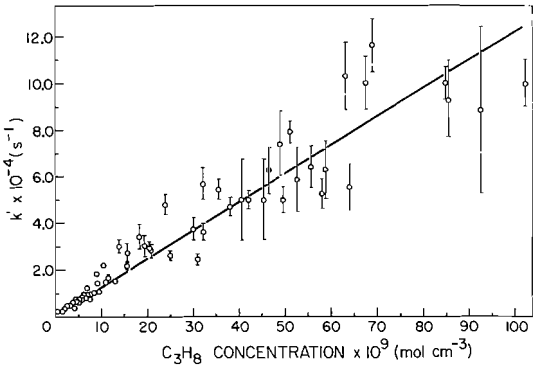

FIG. 6. Plot of pseudo-first order rate constant, k', against the C_3H_8 concentration for the reaction OH + $C_3H_8 \rightarrow H_2O + C_3H_7$.

The pseudo-first order rate constant k' obtained over a range of reactant [RH] concentrations is related to the bimolecular rate constant k by the equation $k' = \alpha + k[RH]$. Plots of k' against [RH] are shown in Figs. 3–6, for RH = H_2, CH_4, C_2H_6, and C_3H_8, respectively. The bimolecular rate constants, k, were evaluated from the slope of these plots. The slopes were obtained from least square fits of the equation $k' = \alpha + k[RH]$ to the points with weights of $1/\sigma^2$ where σ is the error in k' evaluated separately as described below. The least square values of the bimolecular rate constants and the standard deviation of the fit are listed in Table 1.

The total pressure in the experiments with all four reactants was varied between 40 and 760 Torr. The measured rate constants were found to be independent of the total pressure.

The effect of accumulation of reaction products (*e.g.* C_2H_6 in the reaction $CH_4 + OH \rightarrow CH_3 + H_2O$) on the measured rates was considered. The reaction mixture in a representative experiment was irradiated repeatedly and the data collected in consecutive batches of four flashes. Comparison of the signal for the first 4 and last 4 in 32 flashes showed no significant difference. A simple calculation shows that in the

TABLE 1. Bimolecular rate constants of the reaction OH + RH → H_2O + R at 295 ± 2 K

Reactant RH	k ($cm^3\ mol^{-1}\ s^{-1}$)	Number of experiments
H_2	$3.4_9 \pm 0.1_6 \times 10^9$	72
CH_4	$3.9_2 \pm 0.1_6 \times 10^9$	60
C_2H_6	$1.5_9 \pm 0.1_0 \times 10^{11}$	42
C_3H_8	$12.1_7 \pm 0.6_3 \times 10^{11}$	59

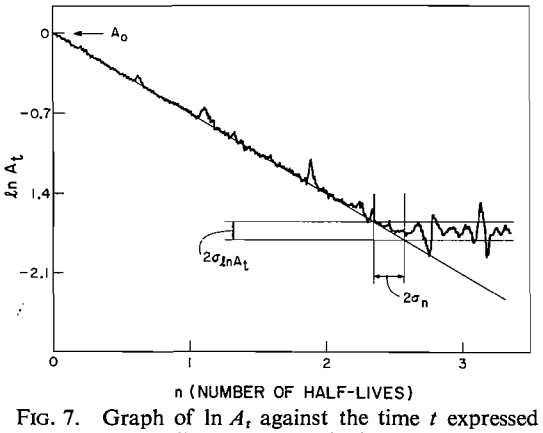

FIG. 7. Graph of ln A_t against the time t expressed as number of half-lives. (The graph shows the unidirectional noise and the error $\sigma_{\ln A_t}$ expressed as uncertainty in the number of half-lives $n \pm \sigma_n$.)

case of CH_4 the effect of accumulation of C_2H_6 from recombination of CH_3 radicals will not perturb the measurements. (It is calculated that after 32 flashes the ratio of the rate of OH with the accumulated C_2H_6 and with CH_4 is about 5×10^{-3}.) In the case of propane the calculation shows that the accumulation of products could possibly affect the measurements. The test described above was carried out more frequently with propane and the total number of flashes was kept at a minimum.

Evaluation of Error

The method of estimation of the error, σ, of the individual values of pseudo-first order rate constant, k', has been described in detail in Appendix I of ref. 10, and will be outlined only briefly here. As mentioned above the slope $\Delta \ln [OH]/\Delta t$ of the graph of the decay curve of ln [OH] against time expressed as number of half-lives and shown in Fig. 7 was drawn by hand. Figure 7 shows also the previously mentioned sporadic unidirectional noise. The error in the slope can be determined from the two extremes of the line

$$k' = \Delta(\ln [OH])/\Delta t = \ln (A_0/A_t)/\Delta t$$

where A_0 = absorbance at $t = 0$, A_t = absorbance at $t = t$, and $\Delta t = t - t_0$ or

$$R_f = \Delta t \times k' = \ln (A_0/A_t)$$

where R_f is defined as rate function. By determining or assessing the experimental precisions at each stage of the measurement of the quantities on the graph of ln A_t against t and using the propagation of error equation we obtain (10)

$$\sigma_{A_t}^2 = \exp(-1.4n)[\sigma_{A_0}^2 + (0.693 A_0 \sigma_n)^2]$$

where n = the number of half-lives over which the straight line in Fig. 7 fits the experimental line; σ_n was estimated from the experimental plots. Graphs of fractional error σ_{R_f}/R_f at constant n's against A_0 are shown in Fig. 8. It may be seen from the graphs that the fractional error, *i.e.*, precision of the pseudo-first order rate constant, k', is $\sim 3\%$ for high A_0 and good straight lines of several half-lives. On the other hand a low A_0 and low n combine to give very poor precision. The errors in k' are shown as error bars of length 1σ in Figs. 3–6.

The time base of the ADC/signal averager was calibrated with an accurate frequency standard. The accuracy is about 1 part in 10^4. The measurement of pressures and concentrations was considered to be both accurate and precise to about 1%. Under these conditions the contribution of these sources to the overall error in the bimolecular rate constant k (evaluated from the slope of the plot of k' against concentration, [RH]) is negligible in comparison to that of spectrophotometry. The overall precisions of the bimolecular rate constants in Table 1 are 10–15% at one standard deviation. The accuracy

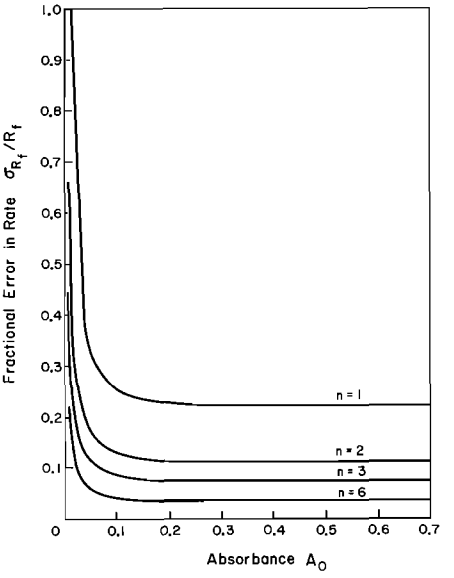

FIG. 8. Graphs of fractional error σ_{R_f}/R_f at constant n against initial absorbance, A_0, for various values of n. (The graphs illustrate the variation of the fractional error with A_0 and with the number of half-lives n.)

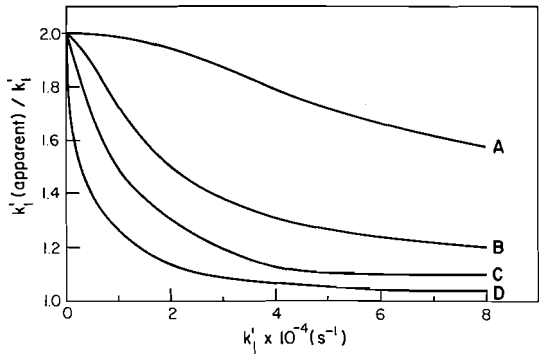

FIG. 9. Effect of the initial OH concentration on the dependence of the k_1'(apparent)/k_1' ratio on k_1' (*i.e.* on the RH concentration) at constant k_2. (The curves were calculated for $k_2 = Z$ (collision frequency) and initial [OH] in mol cm^{-3}: (*A*), 5×10^{-10}; (*B*), 10^{-10}; (*C*), 5×10^{-11}; and (*D*), 2×10^{-11}.)

was estimated to be in the region $\pm 5\%$; this value was estimated from the influence of the flash period, electronic bandwidth, system linearity, and A/D converter resolution on the measured rates.

Discussion

The following reactions were considered for the discussion and interpretation of our experimental results

$$H_2O + h\nu \rightarrow OH + H$$

[1] $$OH + RH \rightarrow H_2O + R$$

[2] $$OH + R \rightarrow \text{Products}$$

[3] $$OH + OH + M \rightarrow H_2O_2 + M$$

[4] $$OH + H + M \rightarrow H_2O + M$$

[5] $$OH + OH \rightarrow H_2O + O$$

where RH = H_2, CH_4, C_2H_6, and C_3H_8. We will examine first if (and to what extent) side reactions of OH affect our results and then we will compare them with other results in the literature.

Effect of Radical–Radical Reactions of OH

The effect of the radical–radical reactions of OH, reactions 2, 3, 4, and 5, was tested by a numerical simulation model in which the differential equations describing the system were integrated numerically for the following initial conditions: (*1*) Since [RH] is present in large excess over OH, reaction 1 was taken as a first order reaction of the form $-d[OH]/dt = k_1'[OH]$ where $k_1' = k_1[RH]$, and k_1' was varied in the model over a range 10^3 to 10^5 s^{-1}. (*2*) The rate of reaction 2 was taken initially to be the collisional rate. (*3*) Other rate constants were taken from the reviews of Drysdale and Lloyd (1) and Wilson (2). (*4*) The initial concentration of OH radicals was taken to be that estimated earlier using the value of 0.8×10^{-3} for the oscillator strength of OH.

The simulation results showed for measured pseudo-first order rate constants larger than 5×10^3 s^{-1} a negligible influence of radical–radical reactions other than reaction 2, *i.e.* the influence of reactions 3, 4, and 5 was negligible. The plots of ln [OH] against t were curved only in the time region below 5×10^3 s^{-1} showing a second order contribution from reactions 3 and 4. Similarly plots of k_1' against concentration in this time region (very low reactant pressures) were not entirely linear for H_2, and the effect became more pronounced for the C_1–C_3 hydrocarbons. In view of this result and in order to speed the numerical calculations a simplified scheme consisting only of reactions 1 and 2 was modelled over the experimental range. In this model a series of values of k_1 and k_2 were used as input to calculate concentrations of OH at various time intervals. It was found that the scheme nearly always produced linear plots of the ln [OH] against time. From these plots apparent pseudo-first order rate constants, k_1'(apparent), were obtained. The simple model results plotted as a ratio, k_1'(apparent)/k_1', against k_1', (*i.e.* against the RH concentration), are shown in Figs. 9 and 10. Figure 9 shows the influence on the ratio of the initial concentration of OH at constant $k_2 = Z$ (Z = collision frequency) and Fig. 10 shows the influence of k_2

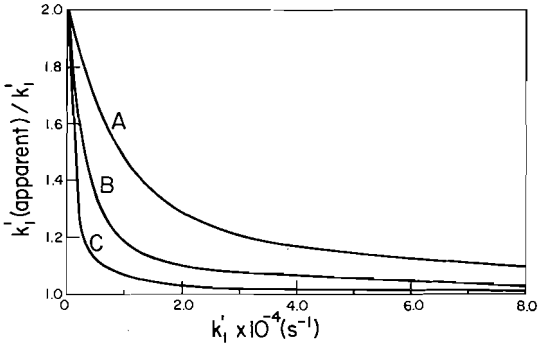

FIG. 10. Effect of the value of k_2 on the dependence of the k_1'(apparent)/k_1' ratio on k_1' (*i.e.* on the RH concentration) at constant initial OH concentration of 5×10^{-11} mol cm^{-3}. (The curves were calculated for k_2 expressed as fraction of the collision frequency Z, (*A*), $k_2 = Z$; (*B*), $k_2 = Z/3$; (*C*), $k_2 = Z/10$.)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

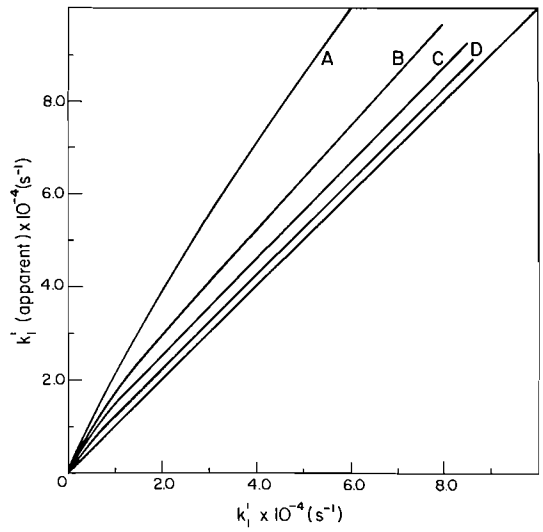

FIG. 11. Dependence of k_1'(apparent) on k_1' (*i.e.* on the RH concentration) at different initial OH concentrations and constant $k_2 = Z$. (The lines were calculated for $k_2 = Z$ and initial OH concentration in mol cm^{-3}; (*A*), 5×10^{-10}; (*B*), 10^{-10}; (*C*), 5×10^{-11}; (*D*), 2×10^{-11}.)

on the ratio at a constant initial concentration of [OH] = 5×10^{-11} mol cm^{-3}. Thus, the simple model indicates that at high measured rates and low initial concentrations of OH the ratio is close to unity, *i.e.* the measured rates will not be appreciably affected by reaction 2. On the other hand at low overall rates and high initial OH concentrations the model predicts an apparent rate increase by almost a factor of two, *i.e.* the plot of the pseudo-first order rate *vs.* concentration is still linear but the slope is almost twice the true bimolecular rate, since the radical R can be considered to be in a steady state. This is illustrated in Fig. 11, where k_1'(apparent) is plotted against k_1', for $k_2 = Z$ and at various values of the initial OH concentration. It may be seen in Fig. 11 that for OH concentrations of 2–5 $\times$ 10^{-11} mol cm^{-3} and rates larger than 5–10 $\times$ 10^3 s^{-1} the lines are almost parallel to the 45° line, *i.e.*, for these conditions the measured slopes are not affected. Subsequent experiments with propane verified this behavior. The general behavior of the series H_2 to C_3H_8 suggests that the rate of reaction of the smaller radicals with OH, *i.e.*, k_2 may be appreciably smaller than that of the propyl radical. The combination of low measured rates and high initial OH concentration, is probably the reason that the rates of OH with CH_4 and C_2H_6 obtained by Horne and Norrish (11) are almost a factor of two larger than the currently accepted values.

Similar considerations apply to the measurement of OH rate constants by the resonance fluorescence technique, where the bimolecular rate constant is obtained from plots of k_1' *vs.* the concentration of RH. A single simulation was made using typical experimental conditions of this technique (12, 13) (*i.e.* initial [OH] = 5×10^{-13} mol cm^{-3} and k_1' = 25–300 s^{-1}). The simulation indicated that k_1'(apparent)/k_1' assumes values close to 2 for low k_1', but decreases with increasing k_1' and approaches 1 at high k_1'.

In the OH concentration range of the present work, the points corresponding to small concentrations of RH on the plots of the first order rate constant *vs.* RH concentration will indicate twice the true bimolecular rate constant, but as the RH concentration increases will gradually assume the true value. Plots of bimolecular rate constants against the RH concentration served to indicate the concentration region in which the points have a large dependence on RH concentration, and these points were not used in the evaluation of the slope so that the measured slopes correspond closely to the true value of the bimolecular rate constant. As a result the small intercepts in Figs. 3–6 cannot be ascribed to a single predominant cause. In the two limiting cases the intercept should be zero, *i.e.* when re-

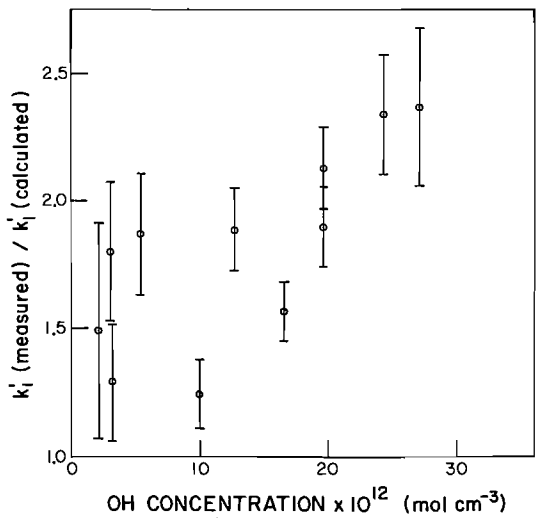

FIG. 12. Variation of k_1'(measured)/k_1'(calculated) with the OH concentration, for k_1'(calculated) of 1.53 $\times$ 10^3 s^{-1} (*i.e.* k_1 = 12.17 $\times$ 10^{11} and [C_3H_8] = 1.26 $\times$ 10^{-9} mol cm^{-3}.)

TABLE 2. Comparison of the room temperature rate constants for the reaction RH + OH → H_2O + R determined by different techniques

Reactant	k (cm^3 mol^{-1} s^{-1}) This work	Literature values	Reference
H_2	$3.49 \pm 0.16 \times 10^9$	$3.96 \pm 1.2 \times 10^9$	2
		$3.92 \pm 0.78 \times 10^9$	17
		$4.28 \pm 0.64 \times 10^9$	12
		$4.60 \pm 0.46 \times 10^9$	18
		$4.28 \pm 0.60 \times 10^9$	19
		$4.20 \pm 0.42 \times 10^9$	20
CH_4	$3.92 \pm 0.16 \times 10^9$	$6.85 \pm 4.80 \times 10^9$	2
		$4.51 \pm 0.06 \times 10^9$	13
C_2H_6	$1.59 \pm 0.10 \times 10^{11}$	1.61×10^{11}	2
		$1.79 \pm 0.17 \times 10^{11}$*	16
C_3H_8	$12.17 \pm 0.63 \times 10^{11}$	$6.81 \pm 0.67 \times 10^{11}$*	16
		$5.10 \pm 1.0 \times 10^{11}$	21
		$13.25 \pm 3.6 \times 10^{11}$	22

*These values are our estimates of the weighted means of the corrected rate constants, at room temperature, given in Table II of ref. 16; the weights w were taken to be equal to $1/\sigma^2$ where σ is the reported error of each rate constant.

action 2 causes no interference, and when the concentration of the radical R is in steady state.

Examination of Fig. 9 shows that at a low true rate k_1', for example a rate of 2–3 × 10^3 s^{-1}, the dependence of k_1'(apparent)/k_1' on the concentration of [OH] will be very marked. Figure 12 shows results for propane in this region. The trend in increasing relative rate with OH concentration is evident. The large error bars reflect the difficulty of the measurements at low OH concentrations (*i.e.* poor *S/N* ratios). The apparent trend of the ratio k_1'(measured)/k_1'(calculated) to a value larger than 2 may well be correct, as the simple model discussed above may have shortcomings in this concentration/rate region.

The values of 2–2.5 for the measured to calculated ratio of k_1' led us to consider that photolysis of propane was producing an excessive initial concentration of radicals. In the case illustrated in Fig. 12 where the concentration of propane is 1.26×10^{-9} mol cm^{-3} and that of OH is 25–30 × 10^{-12} mol cm^{-3}, the reported absorption coefficients of propane (14) and water (15) and the path length suggest that the extent of propane photolysis and thus the concentration of radicals formed will be less than 0.001% of the total OH produced (*i.e.* less than 3 × 10^{-16} mol cm^{-3}). This would make a negligible contribution to the rate in the presence of 1.26×10^{-9} mol cm^{-3} of propane.

Comparison of Rate Constant Values

As mentioned in the introduction the reactions of OH with hydrogen and hydrocarbons have been studied widely by a variety of indirect and direct techniques. Prominent among the direct studies is the pioneering work of Greiner (ref. 16 and references therein) who used the flash photolysis kinetic spectroscopy technique. The rate constant of the H_2 reaction, in particular, is more reliably known and is used to test our technique. On the other hand there are few direct determinations of rate constants for the C_2H_6 and C_3H_8 reactions. The rate constants determined in this work together with literature values are given in Table 2. The first entry for H_2, CH_4, and C_2H_6 is the recommended value from the review of Wilson (2), the second entry for H_2 is from the review of Baulch *et al.* (17). Both reviews have summarized work up to 1972; the other entries are values reported after that date.

Our values for H_2 and CH_4 although somewhat lower are, within experimental error, in reasonable agreement with those in the literature. The value for C_2H_6 agrees well with both the recommended value and the value of Greiner (16). The reported values for C_3H_8 (16, 21, 22) differ by over a factor of 2. Our value agrees well with the higher value of Gorse and Volman (22), determined indirectly, relative to the rate constant of the reaction OH + CO.

Crystal and Molecular Structure of Dithiocyanato(triphenylarsine)mercury(II)

JOSEPH HUBERT, ANDRÉ L. BEAUCHAMP, AND ROLAND RIVEST

Département de Chimie, Université de Montréal, C.P. 6210, Montréal, Québec H3C 3V1

Received May 29, 1975

JOSEPH HUBERT, ANDRÉ L. BEAUCHAMP, and ROLAND RIVEST. Can. J. Chem. **53**, 3383 (1975).

The crystal and molecular structure of dithiocyanato(triphenylarsine)mercury(II) has been determined from X-ray diffraction data. The crystals are monoclinic, space group $P2_1/c$, with $a = 10.290(7)$, $b = 21.199(23)$, $c = 10.719(7)$ Å, $\beta = 112.00(2)°$, and $Z = 4$. The structure has been solved by the heavy-atom method and refined by block-diagonal least-squares calculations. The agreement factor R obtained for 2607 'observed' reflections is 0.030. The crystal consists of single molecules. The 'characteristic' coordination number of mercury is three, with two sulfur and one arsenic atoms at the apexes of a triangle. The nitrogen atoms of the thiocyanate groups are at 2.67 and 2.74 Å from the adjoining mercury atoms and therefore link the dif ferent molecules together.

JOSEPH HUBERT, ANDRÉ L. BEAUCHAMP et ROLAND RIVEST. Can. J. Chem. **53**, 3383 (1975).

Les structures cristalline et moléculaire du dithiocyanato(triphénylarsine)mercure(II) ont été déterminées par diffraction de rayons X. Les cristaux sont monocliniques, de groupe d'espace $P2_1/c$ et de paramètres de maille: $a = 10.290(7)$, $b = 21.199(23)$, $c = 10.719(7)$ Å, $\beta = 112.00(2)°$ et $Z = 4$. La structure a été résolue par la méthode de l'atome lourd et affinée par moindres carrés (matrice à blocs diagonaux). Le facteur d'accord R obtenu pour les 2607 réflexions 'observées' est de 0.030. Le cristal est constitué de molécules monomères. Le nombre de coordination 'caractéristique' du mercure est de trois, et la coordination est assurée par deux atomes de soufre des thiocyanates et l'atome d'arsenic. Les atomes d'azote des groupements thiocyanates se trouvent à des distances de 2.67 et 2.74 Å d'atomes de mercure voisins et relient les diverses molécules entre elles.

Introduction

Reactions of mercuric halides with monodentate ligands often lead to dimeric halide-bridged 1:1 complexes in which mercury has a tetrahedral coordination. Several examples of similar thiocyanate complexes are also known. On the basis of preliminary X-ray results (1), we recently reported that mercury is three-coordinated in $Hg(SCN)_2 \cdot As(C_6H_5)_3$. The complete crystal structure analysis on that compound is described in the present paper.

Experimental Section

Crystal data

$C_{20}H_{15}AsHgN_2S_2$ f.w. = 622.99

Monoclinic, $P2_1/c$, $a = 10.290(7)$, $b = 21.199(23)$, $c = 10.719(7)$ Å, $\beta = 112.00(2)°$, $V = 2168$ Å^3, $\rho_o = 1.90(1)$, $Z = 4$, $\rho_c = 1.909$ g cm^{-3}, $\mu = 90.72$ cm^{-1} (23 °C; $MoK_{\bar{\alpha}}$, $\lambda = 0.71069$ Å).

The complex was prepared by reaction of 1.9 mmol of $Hg(SCN)_2$ and 2.1 mmol of $As(C_6H_5)_3$ in 125 ml of ethanol. By slow evaporation of the solution, well-shaped crystals were obtained.

The set of data used to solve the structure (1) was collected with CuK_α radiation on a relatively large crystal of complicated geometry. Refined values of some temperature factors were high, presumably because of the high absorption coefficient for copper radiation and problems in describing the crystal faces. For those reasons, another crystal of simpler geometry was selected and a new set of data was collected with MoK_α radiation. This crystal had dimensions $0.35 \times 0.12 \times 0.20$ mm perpendicular to [011], [010], and [110] respectively. The crystal was mounted on a Picker FACS-1 automatic four-circle diffractometer equipped with a graphite monochromator. The lattice parameters were calculated by least-squares refinement (2) on the setting angles of 12 MoK_α reflections ($12 < 2\theta \leqslant 30°$).

A total of 3046 MoK_α reflections (hkl and $hk\bar{l}$) were measured up to a 2θ value of 48°. The intensities were collected by the $\theta/2\theta$ scan technique at a constant speed of 1° per min. The scan range was 1.75° symmetrically disposed with respect to the calculated peak center and backgrounds were counted for 20 s on each side of the scanning range. During data collection, three standard reflections were measured every 50 reflections as a test on crystal and instrument stability. No systematic changes were observed and the intensity fluctuations were within ±5%.

Integrated intensities $I = N - (B_1 + B_2) \times T/2t$ were calculated and standard deviations $\sigma(I)$ were estimated according to the formula

$$\sigma^2(I) = N + 0.25 \times (T/t)^2 \times (B_1 + B_2) + (cI)^2$$

where N is the total counts from scanning for T s, B_1 and B_2 are the background counts measured during t s each, and c, the instability factor, is 0.05.

A set of 2607 reflections for which $I \geqslant 2.5\sigma(I)$ were considered as observed and later used in least-squares refinement.

[a]The expression for the anisotropic temperature factor is $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + U_{12}hka^*b^* + U_{13}hla^*c^* + U_{23}klb^*c^*]$.

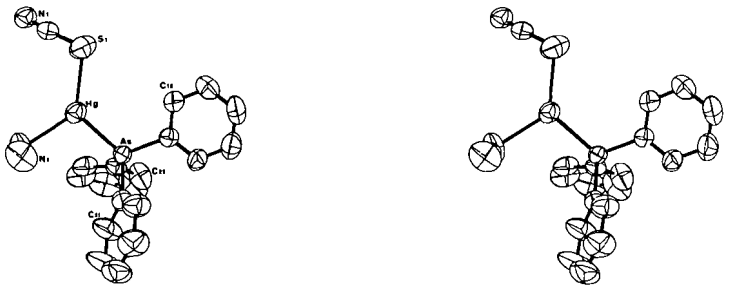

FIG. 1. The molecular structure of $Hg(SCN)_2 \cdot As(C_6H_5)_3$.

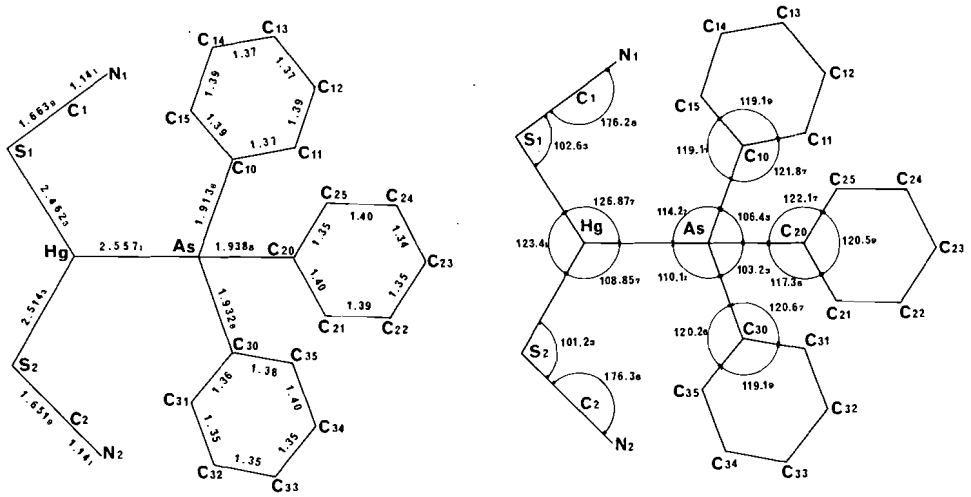

FIG. 2. Bond lengths and angles in $Hg(SCN)_2 \cdot As(C_6H_5)_3$. The values for Hg—As—C(20) and C(10)—As—C(30) are 115.7(2) and 106.3(3)° respectively. Standard deviations are given as subscripts.

An absorption correction based on the crystal faces was applied.[1] The calculated transmission factor ranged from 0.16 to 0.37. The usual corrections for polarization and Lorentz effects were finally applied. During the absorption correction the coefficient $dA^*/d\mu$ was evaluated for secondary extinction correction (3).

Mercury was located from an origin-removed sharpened Patterson map. After two cycles of least-squares refinement, a difference Fourier map revealed all nonhydrogen atoms. Block-diagonal least-squares refinement with unit weights, of the scale factor, the positional and individual isotropic temperature factors led to $R = (\Sigma||F_o| - |F_c||)/\Sigma|F_o| = 0.089$. The R factor reduced to 0.033 by introducing and refining anisotropic temperature factors and a secondary extinction coefficient (4). At this stage, the phenyl hydrogen atoms were placed at the calculated position (C—H = 0.95 Å) and were included in structure factor calculations with fixed isotropic factors ($B = 7$ Å^2). The function minimized in least-squares refinements was $\Sigma w(|F_o| - |F_c|)^2$, where $w = 1/\sigma^2$ and $\sigma = a + bF_o + cF_o^2$ (5). After three additional least-squares cycles the final R and $Rw = [\Sigma w(F_o - F_c)^2/\Sigma wF_o^2]^{1/2}$ were respectively 0.030 and 0.040. The values of a, b, and c were adjusted in order to minimize the variations of the $\Sigma w\Delta F^2$ function *vs.* F_o (final values $a = 5.38$, $b = -0.08$, and $c = 0.0006$). The standard deviation of an observation of unit weight was 1.65. In the final least-squares cycle the highest and the average shifts were respectively 0.6σ and 0.4σ.

On the final difference Fourier map, the highest peaks had an intensity of $+0.6$ e/Å^3 and were located at less than 1 Å from the mercury atom.

The scattering factors used for the nonhydrogen atoms were taken from Cromer and Waber (6), the scattering curve of hydrogen was from Stewart *et al.* (7), and the anomalous dispersion coefficients for the heavy atoms (Hg, As, S) from Cromer (8).

The final positional and thermal parameters are given in Table 1. The carbon atoms belonging to phenyl rings are identified with labels of the type $C(ij)$, where i is the

ring number and j corresponds to sequential numbering of the ring vertices with $j = 0$ for the atom bound to arsenic. The structure factor table is available.[2]

Results and Discussion

The crystal consists of single molecules as shown in Fig. 1. Intramolecular bond lengths and angles are given in Fig. 2.

Molecular Structure

Mercury forms strong bonds to one arsenic and two sulfur atoms and its so-called 'characteristic' coordination number (9) is three. The Hg—S bonds are significantly different (2.514(3) and 2.462(3) Å) but still in the range observed for $[(C_6H_5)_4P][Hg(SCN)_3]$, another (12) three-coordinate mercury complex. Mercury is shifted toward N(1) of another molecule and is only 0.14 Å above the plane defined by As, S(1), and S(2). Intramolecular nonbonded interactions with the phenyl rings of triphenylarsine could be partly responsible for the angular distortions around the mercury atom. S(1) lies close to the plane of ring (1) and increasing the S(1)—Hg—As angle to 126.9° probably helps to minimize S(1)... H(15) (3.3 Å) repulsions. Ring (3) which is closest to S(2), is approximately perpendicular to the coordination plane and S(2)—Hg—As can reduce to 108.9° before appreciable S(2)... C(31) (3.04 Å) repulsions are experienced. The S(1)—Hg—S(2) angle is normal at 123.4°.

As commonly observed in mercury–thiocyanate compounds, the SCN groups are linear, the Hg—S—C angles are close to 100°, and the S—C and C—N bond lengths are 1.65–1.66 and 1.14 Å respectively.

The three As—C bonds (1.91–1.93 Å) in triphenylarsine are equal within experimental errors and the expected tetrahedral geometry is observed with some distortions. The phenyl rings are planar within 1σ. Their C—C distances and bond angles range from 1.34 to 1.40 Å (average = 1.37(1) Å) and 118.5 to 121.5° (average = 120(1)°) respectively.

Molecular Packing

The molecules are linked in infinite zigzag chains along the *c* direction by weakly bridging SCN groups (Fig. 3).

The Hg–N distances (2.67 and 2.74 Å, Table 2), although shorter than the sum of the van der Waals radii (3.0 Å), correspond to the weak intermolecular contacts found in $Hg(SCN)_2$ (10) and $Hg(CN)_2$ (11). The type of bridging reported for $[Hg(SCN)_3]^-$ ions (12), though geometrically similar, involves much greater participation of the terminal nitrogens, with Hg–N distances of 2.40 Å.

When the two Hg–N contacts are taken into account, the effective coordination of mercury corresponds to a very distorted trigonal bipyramid (Table 2).

The chains are held together by normal van der Waals contacts.

We wish to thank the National Research Council of Canada for a research grant.

Synthesis and Spectral Properties of $[Cr(en)_2NH_3X]^{n+}$ Compounds

CARL F. C. WONG AND A. D. KIRK

Department of Chemistry, University of Victoria, Victoria, British Columbia V8W 2Y2

Received June 5, 1975

CARL F. C. WONG and A. D. KIRK. Can. J. Chem. **53**, 3388 (1975).

Preparation of the compounds *cis*- and *trans*-$[Cr(en)_2NH_3F](ClO_4)_2$, $[Cr(en)_2NH_3NO_2]BrClO_4$, *cis*- and *trans*-$[Cr(en)_2NH_3Cl](ClO_4)_2$, *cis*-$[Cr(en)_2NH_3Br](ClO_4)_2$, *trans*-$[Cr(en)_2NH_3H_2O]Br_3$, *trans*-$[Cr(en)_2NH_3H_2O]Cl_3 \cdot xH_2O$, and *trans*-$[Cl(en)_2CrOHCr(en)_2Cl](ClO_4)_3$ is described. The compounds have been characterized by analysis and u.v.–visible and i.r. spectral data. Spectral criteria for establishing *cis* and *trans* configuration are discussed.

CARL F. C. WONG et A. D. KIRK. Can. J. Chem. **53**, 3388 (1975).

On décrit la préparation des composés suivants: $[Cr(en)_2NH_3F](ClO_4)_2$-*cis* et *trans*, $[Cr(en)_2NH_3NO_2]BrClO_4$, $[Cr(en)_2NH_3Cl](ClO_4)_2$-*cis* et *trans*, $[Cr(en)_2NH_3Br](ClO_4)_2$-*cis*, $[Cr(en)_2NH_3H_2O]Br_3$-*trans*, $[Cr(en)_2NH_3H_2O]Cl_3 \cdot xH_2O$-*trans* et $[Cl(en)_2CrOHCr(en)_2Cl](ClO_4)_3$-*trans*. On les a caractérisés par analyse et par spectroscopie u.v.–visible et i.r. On discute des critères spectraux utilisés pour attribuer les configurations *cis* et *trans*.

Although an extensive series of mixed amine complexes of Co(III) has been known for a considerable time (1), few analogous Cr(III) complexes have been reported (2). In particular, cobalt complexes of the type $[Co(en)_2NH_3X]^{2+}$, where en is ethylenediamine and X is an acido ligand, were prepared by Werner, and others, and have been studied kinetically in attempts to establish the stereochemistry of Co(III) solvation reactions (3–6).

Despite the superficial similarities between the chemistries of Co(III) and Cr(III) complexes no reports of any of the Cr(III) analogs appeared until recently when the synthesis of *cis*- and *trans*-$[Cr(en)_2NH_3NCS](NCS)_2$ was reported (7). Because of their great potential to yield detailed stereochemical information about Cr(III) photo-solvations, we have continued to attempt to find synthetic methods for other complexes of this type.

Results and Discussion

Synthetic Methods

In order to develop a fairly general synthetic method several approaches were tried. By analogy with synthetic methods for the cobalt compounds the first attempts involved oxidation of the *N*-bonded thiocyanate ligand with Cl_2 or H_2O_2 to convert the ligand to NH_3. The method has the advantage, in principle, of conserving the stereochemistry around the Cr(III) center. Attempts to oxidize, for example, *trans*-$[Cr(en)_2NCSCl]^{2+}$ to *trans*-$[Cr(en)_2NH_3Cl]^{2+}$ failed completely. Invariably complete loss of thiocyanate occurred, leading to aquo or acido complexes depending on conditions. This was presumably a reflection of the greater lability of Cr(III) complexes and the affinity of Cr(III) for oxygen-bonding ligands.

The only reasonably general approach found was reaction of *cis*- or *trans*-$[Cr(en)_2XY]^+$ with liquid ammonia, where, of the X and Y acido ligands, Y is the more readily substituted by ammonia. This procedure enabled the successful preparation of *cis*- and *trans*-$[Cr(en)_2NH_3NCS](NCS)_2$ (7), *cis*- and *trans*-$[Cr(en)_2NH_3F](ClO_4)_2$ and *cis*- and *trans*-$[Cr(en)_2NH_3NO_2]BrClO_4$, although in the last case the lability of the product mixture prevented isolation of the separate isomers.

The method failed to be completely general, however, owing to a number of problems, not the least of which was the preparation of the required starting materials. Also, while *cis* starting materials gave *cis* products, the *trans* compounds reacted to produce *cis*/*trans* product mixtures in unpredictable proportions, it proved difficult to isolate the *trans* isomer from some of these mixtures. Some compounds, *e.g.* *trans*-$[Cr(en)_2ClBr]^+$, gave rise to both chloride and bromide substitution, and once one halide had been replaced the second was more readily substituted. Thus the reaction yielded a mixture of *cis* and *trans* isomers of $[Cr(en)_2NH_3Cl]^{2+}$, $[Cr(en)_2$-

For personal use only.

$NH_3Br]^{2+}$, and $[Cr(en)_2(NH_3)_2]^{3+}$ together with unreacted starting material. It proved to be impossible to obtain pure samples of the desired complexes from such a mixture.

Attempts were made to overcome the problem of substitution of both acido ligands by carrying out the ammonolysis in nonaqueous solvents such as acetonitrile, but these failed as the desired product was more soluble than the starting material (as perchlorates or halide salts) and therefore again reacted all the way to the $[Cr(en)_2(NH_3)_2]^{3+}$ compounds. This gave a cleaner synthesis of these compounds but left the problem of preparing $[Cr(en)_2NH_3X]^{2+}$ for X = Cl, Br.

Consequently the possibility of preparing these from compounds already prepared was considered. Reaction of *cis*-$[Cr(en)_2NH_3F]^{2+}$ with concentrated HCl or HBr was found to give a clean substitution of the fluoride, but this reaction failed to go for the desired *trans* isomer. As a second approach *trans*-$[Cr(en)_2NH_3NCS]^{2+}$ was treated in aqueous solution with mercuric chloride, but no reaction occurred. Crude $[Cr(en)_2NH_3NO_2]BrClO_4$ was reacted with HCl and HBr; depending on conditions mainly *trans*-$[Cr(en)_2NH_3H_2O]^{3+}$ and *cis*-$[Cr(en)_2NH_3Br]^{2+}$ or *cis*-$[Cr(en)_2NH_3Cl]^{2+}$ would be isolated; either no anation of *trans*-$[Cr(en)_2NH_3H_2O]^{3+}$ occurred, or the *trans* products, once formed, decomposed too readily.

A successful approach to these elusive *trans* compounds was finally found through preparation of *trans*-$[Cr(en)_2NH_3H_2O]^{3+}$ and its subsequent anation. First attempts to prepare this compound by reaction of *trans*-$[Cr(en)_2ClH_2O]^{2+}$ with ammonia failed (probably the ammonolysis is base catalyzed and was vanishingly slow in the strongly acid solution of the complex). The compound *trans*-$[Cl(en)_2CrOHCr(en)_2Cl](ClO_4)_3$ was therefore prepared and reacted with liquid ammonia in the presence of a small amount of lithium amide. Acidification of the product (with HBr) yielded *trans*-$[Cr(en)_2NH_3H_2O]Br_3$ in good yield. Since it was found that *trans*-$[Cr(en)_2NH_3H_2O]^{3+}$ was not anated by concentrated HBr in aqueous solutions, and solubility difficulties were anticipated for anation in nonaqueous solvents, the haloammines were prepared by heating of the solid halide salt even though this led to some isomerization, and some loss of NH_3 rather than H_2O. This enabled us to prepare *trans*-$[Cr(en)_2NH_3Cl](ClO_4)_2$; the pure bromo analog has not yet been obtained by this technique. It is likely that this same procedure could be used to prepare other $[Cr(en)_2NH_3X]^{2+}$ compounds.

Characterization of Compounds

The compounds were characterized by analysis and their u.v.–visible and i.r. spectra. In the main the characterization was straightforward and the only difficulties were with establishing the geometric configuration of the compounds and their isomeric purity.

Hughes and McWhinnie (8) considered the problem of distinguishing *cis* and *trans* isomers of Cr(III) bisethylenediamine compounds by infrared spectra and concluded that the best criterion lay in the band pattern between 550 and 395 cm^{-1}. They used compounds having a variety of anions, and found that *cis* compounds always had a pattern of four bands: one strongly split, at 545–535 cm^{-1}, two other strong bands at approximately 480 and 430 cm^{-1} and one much weaker band at about 405 cm^{-1}. *Trans* complexes showed three strong bands in this region, at about 540 (sometimes split), 490, and 440 cm^{-1}. These criteria were found to be met by the spectra of *cis*- and *trans*-$[Cr(en)_2NH_3NCS](NCS)_2$ (7). However, the data shown in Table 1 for the complexes of this work lead to some doubt about the absolute reliability of these criteria for these compounds. All the *cis* compounds show the expected band pattern, but the *trans* complexes in three cases show a band at *ca.* 400 cm^{-1}, depending on the nature of the anion. The observed influence of the anion suggests that the criterion of the band at 400 cm^{-1} should be used with caution. Other than this the band patterns are as suggested by the above authors and the band positions support the geometric assignments made in drawing up Table 1.

Table 2 compares the wavelength maxima and minima and molar absorptivities for the compounds. Our earlier work (7) showed that, like the cobalt analogs, the *cis* and *trans* isomers of $[Cr(en)_2NH_3NCS]^{2+}$ had the same λ_{max} value but the molar absorptivity of the *cis* isomer was 50% higher than the *trans*, due to the lower symmetry of the former. The data in Table 2 show that this criterion is valid for these new compounds. It is clear that, particularly for the low energy ligand field band, the *trans* isomer has roughly the same molar absorptivity as the pentammine, while that of the *cis* isomer is on

†The values in parentheses are the corresponding molar absorptivities (l mol^{-1} cm^{-1}). All wavelengths are in nm.
‡Estimated from spectral curve in ref. 14.

average about 40% higher. The λ_{max} for both *cis* and *trans* are more or less the same and shifted to slightly higher energy than the pentammine. Taken together with chemical analysis and ion-exchange determination of isomer purity we believe the u.v.–visible data to be the best available criterion of geometric configuration and, by means of repeated fractional crystallization and measurement of molar absorptivity, a good criterion of isomer purity. Figures 1 through 3 give the spectra of the compounds for easy reference.

In addition to the above checks, where the isomer purity was questionable, as in the case of *trans*-$[Cr(en)_2NH_3Cl](ClO_4)_2$ which was isolated from a mixture containing at least six complexes, ion-exchange chromatography was carried out. For the case cited, the complex was found to be virtually 100% pure (no *cis* isomer or 1+ ions were present, small amounts of 3+ ions would have remained on the column undetected).

Experimental

Starting Materials

trans-$[Cr(en)_2FBr]ClO_4$ was prepared by the method of Wirth *et al.* (9) except that the anation of *trans*-$[Cr(en)_2(H_2O)F]^{2+}$ with NH_4Br in methanol was found to be very much accelerated by refluxing at 70 °C. A reaction time of 45 min was found to give optimum yields (*ca.* 40% after crystallization as the perchlorate). Too long a reaction time caused production of a rather insoluble pinkish solid in addition to the desired product.

trans-$[Cr(en)_2(NO_2)Br]ClO_4$ and *trans*-$[Cr(en)_2(H_2O)Cl]Br_2$ were prepared as described by Fee *et al.* (10).

trans-[Cl(en)$_2$CrOHCr(en)$_2$Cl](ClO$_4$)$_3$

trans-$[Cr(en)_2H_2OCl]Br_2$ (10 g) was dissolved in 10 ml of water. Saturated $NaClO_4$ (10 ml) was added to the filtered solution, and, after cooling to 0 °C, 10 ml of 1.0 *M* NaOH were added dropwise over a 10-min period to the continuously stirred solution. The red crystals

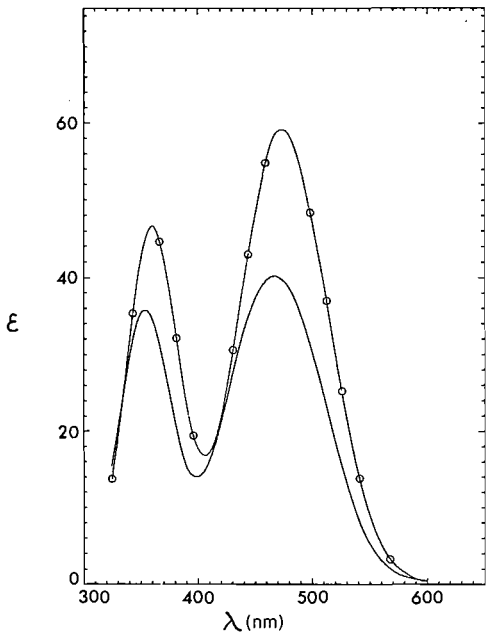

FIG. 1. Ultraviolet–visible spectra of *trans*(—) and *cis*-$[Cr(en)_2NH_3H_2O]^{3+}$ (○—○—○). The circles in the figure (as in the other figures) are not experimental points, but are added to distinguish the spectra.

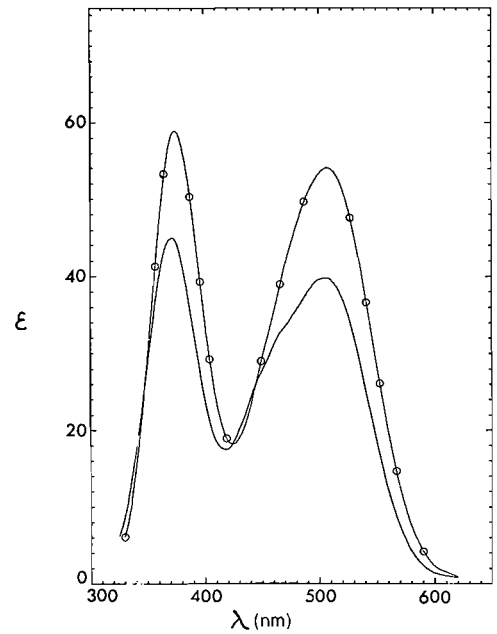

FIG. 2. Ultraviolet–visible spectra of *trans*(—) and *cis*-$[Cr(en)_2NH_3Cl]^{2+}$ (○—○—○).

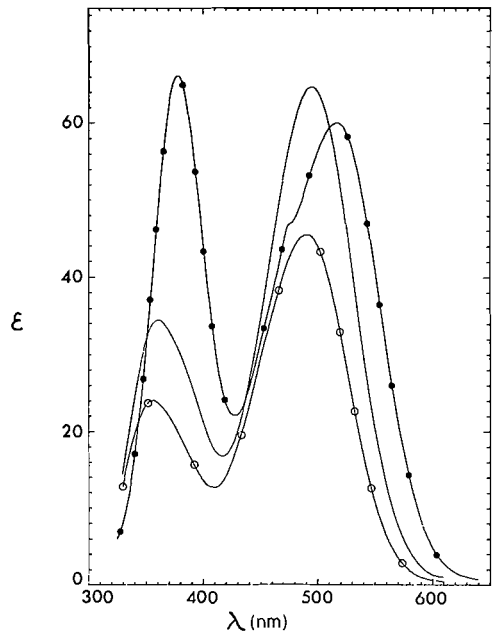

FIG. 3. Ultraviolet–visible spectra of *cis*(—) and *trans*-$[Cr(en)_2NH_3F]^{2+}$ (○—○—○) and *cis*-$[Cr(en)_2NH_3Br]^{2+}$ (●—●—●).

(with a slight purple tint) were filtered and washed with methanol and acetone (yield 7–8 g, 81–93%).

The method used was an attempt to make *trans*-$[Cr(en)_2OHCl]ClO_4$. That the product was a binuclear species was indicated by its u.v.–visible spectrum in 1 *M* HCl. The spectrum in acid medium is identical to that of *trans*-$[Cr(en)_2H_2OCl]^{2+}$ but the absorbances at its λ_{max} values (as compared with the ε_{max} values of Quinn and Garner (11)) were consistent with a chromium content for the solid product of 13.8 ± 0.1%. This differs significantly from that for $[Cr(en)_2OHCl]ClO_4$ (16.04%), but agrees reasonably with that for the hydroxyl bridged binuclear compound (14.23%). A third possibility, $[Cl(en)_2CrOCr(en)_2Cl](ClO_4)_2$, should also be considered, but the chromium content for this compound, 16.54%, is too high. It should be noted that the analytical C, H, and N values are also somewhat low, but as this compound was to be used only as an intermediate, no further attempts were made to identify any impurities.

Anal. Calcd. for $[Cl(en)_2CrOHCr(en)_2Cl](ClO_4)_3$: C, 13.16; N, 15.34; H, 4.55. Found: C, 12.7; N, 14.8; H, 4.3.

Preparation of $[Cr(en)_2NH_3X]^{2+}$ Compounds

Crude $[Cr(en)_2NH_3F]BrClO_4$

An 8-g sample of dried *trans*-$[Cr(en)_2FBr]ClO_4$ with about 1 mg of NH_4ClO_4 was reacted with about 20 ml of distilled, potassium-dried ammonia for 2 h at 0 °C in a sealed 200 ml Carius tube (7). The crude product was an approximately 60%/40% mixture of *cis*/*trans*-$[Cr(en)_2NH_3F]BrClO_4$ as evidenced by the u.v.–visible and i.r. spectra.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Separation of cis- and trans-[Cr(en)$_2$NH$_3$F](ClO$_4$)$_2$

An 8-g sample of crude [Cr(en)$_2$NH$_3$F]BrClO$_4$ was dissolved in 8 ml of 0.1 *M* HCl at room temperature. On cooling to 0 °C, large orange prisms of *trans*-[Cr(en)$_2$NH$_3$F](ClO$_4$)$_2$ precipitated and were filtered, washed with methanol, and dried. A second fraction was obtained by adding 2 ml of 60% HClO$_4$ to the filtrate, and cooling to 0 °C. The total yield of pure *trans*-[Cr(en)$_2$NH$_3$F](ClO$_4$)$_2$ was 3 g. Third and fourth fractions were similarly obtained by stepwise 2-ml additions of HClO$_4$ (4.0 and 0.5 g, respectively). Fraction 3 was a mixture of *cis* and *trans* material, but fraction 4 was practically pure *cis*-[Cr(en)$_2$NH$_3$F](ClO$_4$)$_2$. Further purification of both the *trans* and *cis* products was carried out by repeated fractional recrystallizations.

Anal. Calcd. for [Cr(en)$_2$(NH$_3$)F](ClO$_4$)$_2$: C, 11.80; N, 17.2; H, 4.70. Found for the *trans* product: C, 11.9; N, 17.0; H, 4.75. Found for the *cis* product: C, 11.9; N, 17.0; H, 4.65.

Crude [Cr(en)$_2$NH$_3$NO$_2$]BrClO$_4$

A 10-g sample of dried *trans*-[Cr(en)$_2$(NO$_2$)Br]ClO$_4$, *ca.* 1 mg of NH$_4$ClO$_4$, and dried liquid ammonia (*ca.* 10 ml) were reacted for 20 min at 0 °C in a sealed Carius tube. The dried product is very heat sensitive and inflames violently on heating with a hot glass rod. The crude product appears to be about 60% *cis* isomer. No attempt was made to separate the isomers due to the lability of the complex in aqueous solution.

cis-[Cr(en)$_2$NH$_3$Cl]Br$_2$

A 2-g sample of crude [Cr(en)$_2$(NH$_3$)NO$_2$]BrClO$_4$ was slurried with 10 ml of concentrated HCl. After evolution of NO$_2$ had stopped, 2 ml of water were added to completely dissolve the aquo-product(s). The solution was filtered, left to anate for 2 h, cooled to precipitate the small amount of unreacted aquo-product(s), and filtered off. Concentrated HBr (3 ml), 2 volumes of isopropanol, and excess ether were added to the filtrate to yield a red oil. After decanting the pale orange supernatant, the oil was taken up with 2 ml of 5 *M* HBr. Upon dropwise addition of isopropanol to cloudiness and overnight cooling at 0 °C, a pink–red precipitate was filtered off. The crude product was recrystallized by dissolving in a minimum of HBr-acidified water, adding isopropanol until just cloudy, and cooling in ice. The orange–red crystals were filtered, washed with isopropanol and acetone, and dried under vacuum. This procedure yielded only the *cis*-product (yield, about 20%).

Anal. Calcd. for [Cr(en)$_2$(NH$_3$)Cl]Br$_2$: C, 12.50; N, 18.22; H, 4.98. Found: C, 12.6; N, 18.2; H, 5.1.

cis-[Cr(en)$_2$NH$_3$Br]Br$_2$ was prepared from crude [Cr(en)$_2$(NH$_3$)NO$_2$]BrClO$_4$ as for the chloro-complex except that HBr was used instead of HCl for the anation. Only the *cis* product was obtained.

Anal. Calcd. for [Cr(en)$_2$NH$_3$Br]Br$_2$: C, 11.20; N, 16.32; H, 4.46. Found: C, 11.1; N, 15.8; H, 4.4.

trans-[Cr(en)$_2$(NH$_3$)H$_2$O]Br$_3$

trans-[Cl(en)$_2$CrOHCr(en)$_2$Cl](ClO$_4$)$_3$ (10 g) was reacted with about 20 ml of liquid NH$_3$ containing a trace of LiNH$_2$ for 1 h at 20 °C in a sealed Carius tube. (The reaction appears to be 100% stereoretentive as determined by the molar absorptivity of the crude product.) After removal of the unreacted NH$_3$, first by evaporation and then by pumping, the purple product was taken up with 5 ml of 1 *M* HBr and reprecipitated with 10–15 ml 48% HBr. During the acidification, the hydroxyl bridge is presumably cleaved and both the solution and any solid product becomes yellow–orange in color. The crude product was filtered and washed with 10 ml of methanol and acetone. A second crop could be obtained by adding isopropanol to the filtrate (total yield, about 9 g (74%)).

The crude bromide salt was recrystallized by dissolving 1.0 g in 2 ml of water and adding, dropwise, 3 ml 48% HBr and 3 ml isopropanol to the filtered solution while it was continuously stirred and cooled in ice (yield, 95%).

Anal. Calcd.: C, 10.75; N, 15.67; H, 4.74. Found: C, 10.5; N, 15.1; H, 4.7.

trans-[Cr(en)$_2$NH$_3$H$_2$O]Br$_2$ClO$_4$

Crude *trans*-[Cr(en)$_2$NH$_3$H$_2$O]Br$_3$ was dissolved in a minimum amount of water, 60% HClO$_4$ was added dropwise until cloudy and the solution cooled to 0 °C. The product was filtered and washed with methanol and acetone.

The method used was an attempt to make the triperchlorate salt. That the salt obtained is the one indicated was suggested by the λ_{max} absorbances of its u.v.–visible spectrum and by its i.r. spectrum. The u.v.–visible spectrum indicated the salt to have a formula weight of 464 ± 3, agreeing well with that of 466.5 for the Br$_2$(ClO$_4$) salt. That the sample is not a mixture of the tribromide and triperchlorate salts is suggested by a slight difference between its infrared spectrum and that of the tribromide; no band at ~400 cm^{-1} is observed in the former (see Table 1).

trans-[Cr(en)$_2$(NH$_3$)H$_2$O]Cl$_3$·xH$_2$O

A 2.0 g sample of *trans*-[Cr(en)$_2$(NH$_3$)H$_2$O]Br$_3$ was dissolved in 3 ml of water at 30–35 °C and quickly filtered. Concentrated HCl (6 ml) was then added dropwise to the stirred solution. After cooling, the yellow crystals (pale orange tint) were filtered and washed with 2–3 ml of methanol and acetone. The product was recrystallized by dissolving the crude chloride in 2 ml of water, adding 4 ml of concentrated HCl to the stirred solution, and cooling in ice (yield, 1.1 g, 80%). The filtrate may be treated with HBr and isopropanol to recover most of the complex still in solution.

trans-[Cr(en)$_2$NH$_3$Cl]Br$_2$

Gently ground solid *trans*-[Cr(en)$_2$NH$_3$H$_2$O]Cl$_3$ was heated for 1 h with periodic mixing at 95–100 °C. The crude product was examined by ion-exchange chromatography and found to contain about 65–70% *trans*-[Cr(en)$_2$NH$_3$Cl]$^{2+}$, 25–30% *cis*-[Cr(en)$_2$NH$_3$Cl]$^{2+}$, and traces of *cis*- and *trans*-[Cr(en)$_2$H$_2$OCl]$^{2+}$ and *cis*- and *trans*-[Cr(en)$_2$Cl$_2$]$^+$. For crystallization, a 2.0 g sample of the crude product was dissolved in 4 ml of water and 1 ml of 40% HBr was added. Acetone (50 ml) was then added dropwise to the rapidly-stirred solution at room temperature. It should be noted that acetone must be added very slowly (~ one drop every second) after precipitation begins or a gum may result. The orange-red crystals were filtered off and washed with acetone (yield, 2.0 g (55%)). The product may be recrystallized by dissolving in water, adding about a one-half volume of 48% HBr, and adding acetone.

trans-[Cr(en)$_2$NH$_3$Cl](ClO$_4$)$_2$

trans-$[Cr(en)_2NH_3Cl]Br_2$ (2.0 g) was dissolved in 3 ml of water at ~30 °C, 1 ml of 60% $HClO_4$ was added to the filtered solution and then left for a few minutes in an ice-bath. The orange–red crystals were filtered off, washed with 2 ml of methanol and ether (yield, 1.2 g (55%)). The filtrate was treated with HBr and acetone to recover most of the complex still in solution. Repeated recrystallizations are necessary to obtain a bromide-free sample.

Anal. Calcd.: C, 11.34; N, 16.53; H, 4.52. Found: C, 11.6; N, 16.6; H, 4.6.

cis-[Cr(en)$_2$NH$_3$H$_2$O]$^{3+}$

Although this complex is present in the aquo-product obtained in the nitrito destruction of the crude $[Cr(en)_2NH_3NO_2]BrClO_4$ product; isolation was not attempted. For the purpose of u.v.–visible spectral characterization, this ion was produced in solution by aquating *cis*-$[Cr(en)_2NH_3Br]^{2+}$ in 0.1 *N* $HClO_4$ for about 3 h at 40 °C (such reactions are known to be stereoretentive). The reaction was followed spectrally and the sharp isobestic points observed at 359, 422, and 492 nm suggest that secondary aquation of *cis*-$[Cr(en)_2NH_3H_2O]^{3+}$ occurs at a rate slow enough that a satisfactory spectrum of the desired ion is obtainable by this method.

Spectral Measurements

All u.v.–visible spectra were obtained using a Cary 17 spectrophotometer and infrared spectra using a Beckman IR-20 spectrometer.

Ion Exchange Chromatography

Ion-exchange chromatography was carried out using Baker analyzed CGC-241 cation exchange resin (200–400 mesh) and solutions of $(NH_4)_2SO_4$ as eluent. For a typical run involving separation of *cis* and *trans* isomers of 2+ charge, a 10-cm column was used, at 20 °C, and eluent, 0.5 → 1.0 *M* $(NH_4)_2SO_4$, was pumped through at 100 ml per h. Eluted complexes were detected, after oxidation with basic peroxide, as chromate ion.

Received June 26, 1975

IAN A. OXTON, OSVALD KNOP, and MICHAEL FALK. Can. J. Chem. **53**, 3394 (1975).

Infrared spectra of polycrystalline $(NH_4)_2GeF_6$, β-$(NH_4)_2SiF_6$, and $(NH_4)_2Pb(SO_4)_2$ have been recorded at room and liquid-nitrogen temperatures. The N—D stretching and bending fundamentals of the isotopically dilute NH_3D^+ ion in these compounds have been studied with particular attention. The occurrence of N—D stretching doublets and bending triplets, of approximate intensity ratios 1:3 and 2:3:3 respectively, confirms the C_{3v} symmetry of the ammonium ion and suggests that the isotopic dilution technique will prove useful as a diagnostic tool for ascertaining site symmetries of the ammonium ion. The spectra are consistent with non-rotating ammonium ions. The frequencies of dilute NH_3D^+ ions suggest that for the ammonium ion in $(NH_4)_2Pb(SO_4)_2$ a trifurcated hydrogen bond is stronger than a normal hydrogen bond.

IAN A. OXTON, OSVALD KNOP et MICHAEL FALK. Can. J. Chem. **53**, 3394 (1975).

On a enregistré les spectres infrarouge des $(NH_4)_2GeF_6$, β-$(NH_4)_2SiF_6$ et $(NH_4)_2Pb(SO_4)_2$ polycristallins à températures de la pièce et de l'azote liquide. Dans ces composés on a étudié avec une attention particulière les vibrations fondamentales de valence et de déformation de l'ion NH_3D^+ isotopiquement dilué. La présence de *deux* bandes N—D de valence, dans des proportions relatives 1:3, et de *trois* bandes de déformation, dans des proportions relatives 2:3:3, dans les spectres confirme que l'ion ammonium existe dans la symétrie C_{3v}. Cette charactéristique laisse prévoir l'utilisation de la dilution isotopique comme moyen diagnostique pour déterminer la symétrie de site de l'ion ammonium. Les spectres sont en accord avec l'absence de rotation libre dans l'ion NH_4^+. Les fréquences de l'ion NH_3D^+ dilué suggèrent que pour l'ion ammonium dans le $(NH_4)_2Pb(SO_4)_2$ une liaison hydrogène trifurquée est plus forte qu'une liaison hydrogène normale.

In the first paper of this series (1) we described the i.r. spectra of the partially deuterated ammonium ion species in $(NH_4)_2PtCl_6$ and $(NH_4)_2TeCl_6$, at sites of tetrahedral symmetry. The present paper is concerned with the spectroscopic behavior of the ammonium ion in trigonal surroundings, more precisely at sites of C_{3v} symmetry, and with the manifestations of hydrogen bonding in the spectra of the isotopically isolated NH_3D^+ ion in such situations.

The first systematic criterion for the presence of hydrogen bonding in ammonium salts was advanced by Waddington (2), who suggested that the appearance of the combination band $\nu_4 + \nu_6$ in the i.r. spectrum, where ν_6 is a librational mode, indicated the presence of hydrogen bonding. Waddington also considered that the existence of K or Rb isomorphs of a particular ammonium salt was indicative of the absence of hydrogen bonding in that salt. The validity of this latter criterion has been questioned (3). For example, cubic $(NH_4)_2SiF_6$ has K, Rb, and even Cs isomorphs (4), yet it has been reported to contain hydrogen bonds (5). Mathieu and Poulet (6) have discussed the problem of hydrogen bonding in ammonium salts in terms of the lowering of the N—H stretching frequencies from their hypothetical "free ion" values but introduced no new criteria. In a study of the vibrational spectra of a series of complex ammonium halides Dunsmuir and Lane (3) re-examined Waddington's criteria and recommended the detection of hydrogen bonding in such compounds by (*i*) the observation of *both* $\nu_4 + \nu_6$ and $\nu_2 + \nu_6$ in the i.r. spectrum; (*ii*)

the broadening of lattice-mode absorptions; and (*iii*) the frequency of ν_4. They also suggested that the converse of Waddington's second rule might be true, *viz.* where the NH_4 salt is *not* isomorphous with the K and Rb analogs, the dissimilarity of the crystal structure of the ammonium salt is likely to be the result of hydrogen bonding.

In the present study we have examined examples of trigonally coordinated ammonium ions with reference to some of the criteria of hydrogen bonding. The term hydrogen bonding, as applied in the following to the ammonium ion, shall include all factors which restrict rotation of the ion to torsional oscillations.

Infrared spectra of undeuterated, or fully deuterated, ammonium salts have proved intractable for such purposes as the diagnosis of site symmetries of the ammonium ion (for discussion, see ref. 1). The i.r. spectra of isotopically dilute NH_3D^+, on the other hand, have been found to yield considerable information even for high site symmetry (T_d, ref. 1), and it was hoped that this would also prove to be the case in environments of lower symmetry. We have also attempted to correlate the i.r. spectra of isotopically dilute NH_3D^+ ions with the known structural features of the compounds studied.

Consider the simplest case of a trigonally distorted NH_4^+ ion, *i.e.* an ion of symmetry C_{3v} held in a fixed orientation by hydrogen bonds to four acceptor atoms. Suppose one of the H atoms is exchanged for a D atom. The four equally probable orientations of the NH_3D^+ ion will produce two distinguishable configurations, with an abundance ratio of 1:3. We will refer to these as *axial* (*a*-NH_3D^+, of symmetry C_{3v}) and *non-axial* (*n*-NH_3D^+, of symmetry C_s). Consequently, at low deuteration, two $\nu_1(NH_3D^+)$ bands should appear. The separation of this doublet should be a measure of the difference in the hydrogen bonding of the on-axis and off-axis H atoms. If this difference is small, the doublet would be expected to exhibit integrated intensities in the approximate ratio 1:3. Prediction of the expected absorptions in the bending region of NH_3D^+ follows a similar argument. Absorptions arising from *a*-NH_3D^+ will be qualitatively similar to those of a NH_3D^+ ion at a site of tetrahedral symmetry (1), whilst those arising from *n*-NH_3D^+ will be as expected from Table 1. Thus for a bending mode such as

TABLE 1. Correlation of vibrational modes for axial and non-axial NH_3D^+ ions at sites of C_{3v} symmetry*

Mode of "free" NH_3D^+	Axial (*a*) NH_3D^+	Non-axial (*n*) NH_3D^+
$\nu_1(a_1)$	$\nu_1(a_1)$	$\nu_1(a')$
$\nu_2(e)$	$\nu_2(e)$	$\nu_{2a}(a') + \nu_{2b}(a'')$
$\nu_{3a}(a_1)$	$\nu_{3a}(a_1)$	$\nu_{3a}(a')$
$\nu_{3bc}(e)$	$\nu_{3bc}(e)$	$\nu_{3b}(a') + \nu_{3c}(a'')$
$\nu_{4a}(a_1)$	$\nu_{4a}(a_1)$	$\nu_{4a}(a')$
$\nu_{4bc}(e)$	$\nu_{4bc}(e)$	$\nu_{4b}(a') + \nu_{4c}(a'')$

*Designation of fundamental modes as in Herzberg (7) and ref. 1.

$\nu_{4bc}(NH_3D^+)$ we may expect three bands in the approximate intensity ratio of 2:3:3.

In contrast, the spectrum of a *freely rotating* NH_3D^+ ion should be qualitatively similar to that of an NH_3D^+ ion at a site of full tetrahedral symmetry (1). Absorption arising from $\nu_1(NH_3D^+)$ should then consist of a single band, probably broadened by unresolved rotational fine structure.

In the intermediate case of an NH_3D^+ ion which undergoes frequent reorientation but does not rotate freely, the spectrum would be qualitatively similar to that of the non-rotating ion. At high rates of reorientation the absorption bands would be broadened by the short lifetime of the upper vibrational state.

Choice of Test Compounds

Our first choice was β-$(NH_4)_2SiF_6$. This is an example *par excellence* of a compound containing trigonally coordinated ammonium ions: all ammonium ions in the structure are equivalent and located at sites of C_{3v} symmetry (Table 2). However, we did not succeed in obtaining spectra completely free from bands of the cubic α-$(NH_4)_2SiF_6$ (see Results).[3] Even though these parasitic bands were uniquely identifiable by comparison with the spectra of the pure α form, we decided to use as our main example $(NH_4)_2GeF_6$, which is isostructural with β-$(NH_4)_2SiF_6$ (Table 2) and gives clean i.r. spectra.

In β-$(NH_4)_2SiF_6$ and $(NH_4)_2GeF_6$, an ammonium ion has 12 nearest F neighbors arranged in four triangles: three isosceles, related by the threefold axis containing the N atom, and one equilateral, with the threefold axis as its own symmetry axis (Fig. 1). If the NH_4^+ ion were

[3]Both forms of $(NH_4)_2SiF_6$ occur in nature, α as the mineral *cryptohalite*, β as the mineral *bararite*.

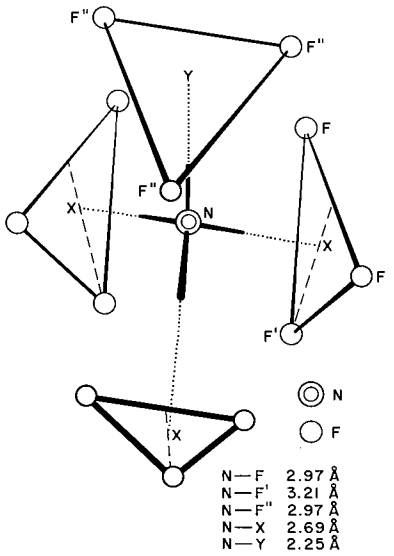

FIG. 1. The fluorine environment of an ammonium ion in β-$(NH_4)_2SiF_6$ and $(NH_4)_2GeF_6$. The nitrogen atom and point Y lie on a threefold axis. The interatomic distances shown are for the silicate (*cf.* footnote 4).

rigid and at rest, the *on-axis* N—H vector would most likely point to the center of the equilateral triangle, Y. If in addition the ion preserved the *internal* T_d symmetry, the three *off-axis* N—H vectors would most likely point to positions X on the symmetry axes of the isosceles triangles, somewhat below the center of gravity of the triangles. In the silicate the N—X distance is 2.69 Å and the N—Y distance is 2.25 Å. The uncertainties in the corresponding distances in the germanate, as calculated from the data of refs. 9 and 11, are so large that no distinction can be made in this respect between the β form of the silicate and the germanate at present. With the N—H vectors pointing towards X and Y all four H atoms may be considered as forming trifurcated hydrogen bonds. The fluorine environment of an NH_4^+ ion in β-$(NH_4)_2SiF_6$ and in $(NH_4)_2GeF_6$ is topologically equivalent to that in the cubic α-$(NH_4)_2SiF_6$, in which the ion is at a site of symmetry T_d; Fig. 1 of ref. 1 shows the analogous Cl environment in $(NH_4)_2PtCl_6$, which is isostructural with α-$(NH_4)_2SiF_6$.

In the third compound chosen, $(NH_4)_2Pb(SO_4)_2$, the ammonium ions again are all equivalent and in sites of symmetry C_{3v} (Table 2). However, out of the ten nearest oxygen neighbors of an ammonium ion, nine, O(2), are arranged in three isosceles triangles related by the threefold axis containing the N atoms, and the tenth, O(1), is on the threefold axis (Fig. 2). The N—O(1) distance would thus correspond to a "normal", *i.e.* straight, hydrogen bond, while the three N—X distances, along the N—H vectors of the rigid tetrahedral NH_4^+ ion, would correspond to trifurcated hydrogen bonds.

Experimental

The low-deuterium samples of $(NH_4)_2GeF_6$ were obtained from commercial material (Alfa Chemicals) by

TABLE 3. Infrared frequencies of isotopically dilute NH_3D^+ in $(NH_4)_2GeF_6$, β-$(NH_4)_2SiF_6$, and $(NH_4)_2Pb(SO_4)_2$ at liquid-nitrogen temperature

†The spectrum of β-$(NH_4)_2SiF_6$(1% D) contained two bands, at 2437 and 1262.1 cm^{-1}, arising from an α-$(NH_4)_2SiF_6$ impurity (see text). In the spectrum of pure α-$(NH_4)_2SiF_6$ these bands appear at 2437 and 1261.3 cm^{-1} respectively (13).

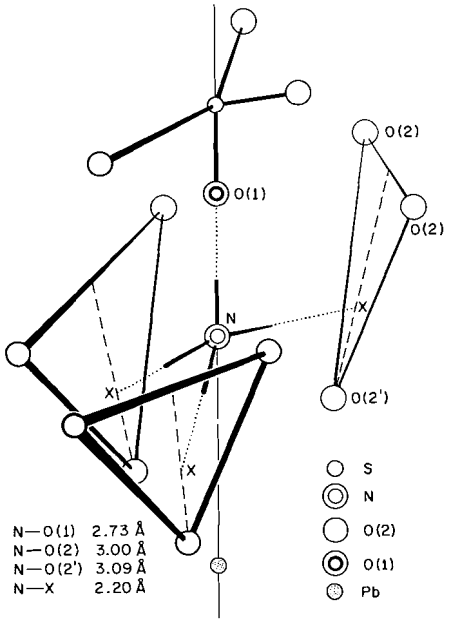

FIG. 2. The oxygen environment of an ammonium ion in $(NH_4)_2Pb(SO_4)_2$. The threefold axis which passes through the nitrogen atom is indicated as a thin solid line.

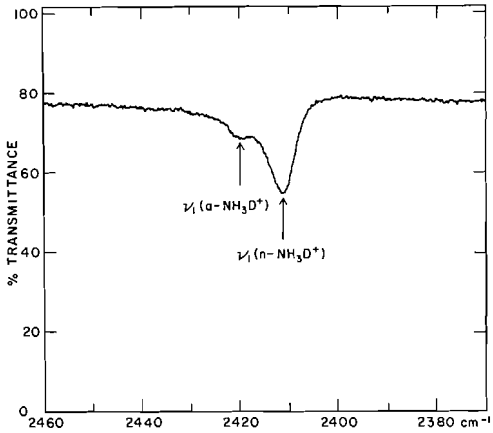

FIG. 3. The N—D stretching region of the i.r. spectrum of $(NH_4)_2GeF_6$(1% D) measured at liquid-nitrogen temperature.

recrystallization from dilute HF containing 1% D. Samples of the trigonal β-$(NH_4)_2SiF_6$ were prepared by recrystallizing cubic α-$(NH_4)_2SiF_6$ at 3 °C from water containing 1% D. $(NH_4)_2Pb(SO_4)_2$ was prepared as in ref. 10, as was the sample of low D content.

Spectra were recorded at room temperature and liquid-nitrogen temperature as Nujol mulls on a Perkin–Elmer model 180 spectrophotometer thoroughly purged with dry air. Frequencies are believed to be accurate to ± 0.5 cm^{-1}.

Results

The observed vibrational frequencies of the NH_3D^+ ion isotopically isolated in $(NH_4)_2GeF_6$, β-$(NH_4)_2SiF_6$, and $(NH_4)_2Pb(SO_4)_2$, at liquid-nitrogen temperature, are shown in Table 3. The corresponding room-temperature frequencies could not be determined with any accuracy, as has previously been found to be the case with $(NH_4)_2PtCl_6$ (1).

Two sharp bands are present in the N—D stretching region of the i.r. spectrum of isotopically dilute NH_3D^+ in $(NH_4)_2GeF_6$ (Fig. 3). Unfortunately their frequency separation, 8 cm^{-1}, is small compared to their half-widths and an accurate estimate of their relative intensities is not possible. The more intense band is assigned to $\nu_1(n\text{-}NH_3D^+)$ and the weaker band, to $\nu_1(a\text{-}NH_3D^+)$. The 1300 to 1220 cm^{-1} region of the spectrum (Fig. 4), in which we expect to observe bands due to $\nu_{4bc}(NH_3D^+)$ (1, 12), contains three bands. The highest- and lowest-fre-

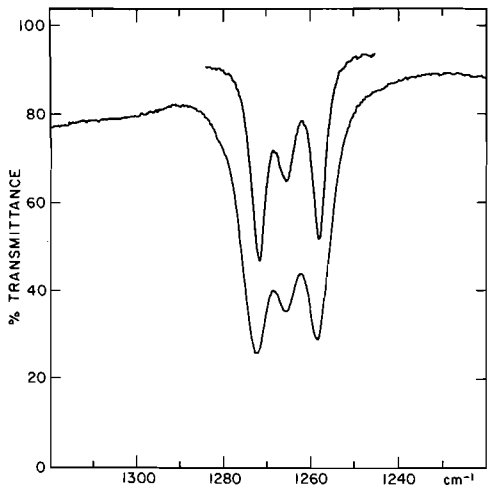

FIG. 4. The N—D bending region of the i.r. spectrum of $(NH_4)_2GeF_6$(1% D) measured at liquid-nitrogen temperature.

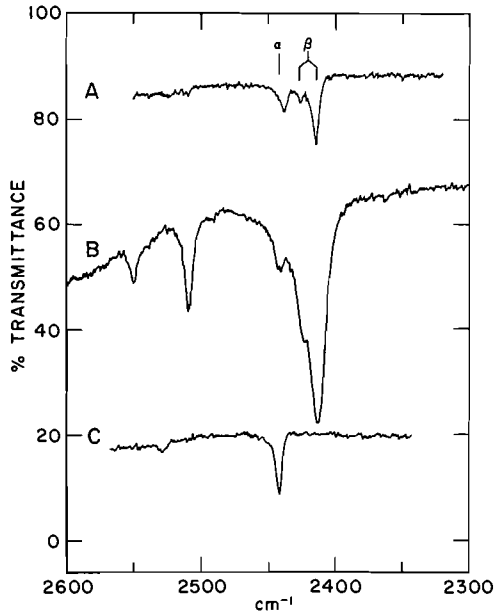

FIG. 5. The N—D stretching region of the i.r. spectrum of $(NH_4)_2SiF_6$(1% D) measured at liquid-nitrogen temperature. Spectra *A* and *B* refer to the β-form contaminated with different concentrations of the α-form. Spectrum *C* is that of the pure α-form.

quency bands are of approximately equal intensity, whilst the central band is of lower intensity. We thus assign the central band to $\nu_{4bc}(a\text{-}NH_3D^+)$.

The corresponding regions of the spectrum of β-$(NH_4)_2SiF_6$(1% D) are found to be similar, with the addition of a weak band in each region. It was, however, noted that the frequencies of the extra bands were very close to those of the corresponding modes in α-$(NH_4)_2SiF_6$(1% D) (13). The relative intensities of the extra bands varied with the amount of grinding during mull preparation, and it was concluded that grinding induced the β-to-α phase change in a small quantity of the material. Subsequently it was found that even the gentlest grinding introduced a small amount of the cubic impurity and that complete elimination of the extraneous bands could not be effected. The N—D stretching regions of the i.r. spectra of cubic and trigonal $(NH_4)_2SiF_6$(1% D) are shown in Fig. 5.

The bands arising from $\nu_1(NH_3D^+)$ of $a\text{-}NH_3D^+$ and $n\text{-}NH_3D^+$ in $(NH_4)_2Pb(SO_4)_2$-(1% D) were the best-resolved of the examples chosen, with a separation of 21.0 cm^{-1}, and the relative intensities of these bands were in the ratio (2.9 ± 0.2):1 (Fig. 6). Three bands were present in the 1300 to 1220 cm^{-1} region. They were assigned by analogy with those of the hexafluorogermanate.

In order to apply to these salts the criterion

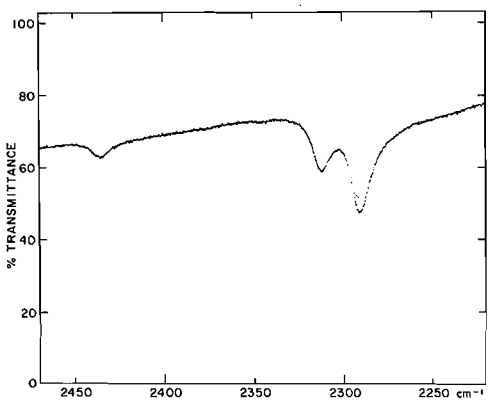

FIG. 6. The N—D stretching region of the i.r. spectrum of $(NH_4)_2Pb(SO_4)_2$(1% D) measured at liquid-nitrogen temperature.

of Waddington (2, 3), the i.r. spectra of the undeuterated salts were examined for the presence of bands attributable to combination modes involving the librational mode ν_6. The vibrational frequencies of these bands, where observed, are listed in Table 4. The observed frequencies were practically independent of temperature.

*$2\nu_3$ of the sulfate ion also occurs in this region.

Discussion

The i.r. spectra of the NH_3D^+ ion in the trigonal environments investigated in this work are in good agreement with the spectrum predicted, in the introduction, for the hypothetic H-bonded ion of C_{3v} symmetry. We shall now consider the possible rotational motions of the ammonium ion in the three compounds.

The i.r. spectra of isolated NH_3D^+ ions are not consistent with a freely rotating ammonium ion in any of the three cases: a *freely* rotating ion would yield a single ν_1 frequency, the four H atoms being equivalent. The presence of two distinct $\nu_1(NH_3D^+)$ bands in the low-temperature spectra does not rule out the possibility of free rotation about one hydrogen bond, of the type suggested to occur in the high-temperature form (phase *I*, CsCl type) of ammonium iodide (14–16).[4] However, the frequency differences $\nu_1(a\text{-}NH_3D^+) - \nu_1(n\text{-}NH_3D^+)$ for $(NH_4)_2GeF_6$, β-$(NH_4)_2SiF_6$, and $(NH_4)_2Pb(SO_4)_2$ are 8.0, 11.5, and 21.0 cm^{-1}, respectively (Table 3) and thus only a small fraction of the total range, 135 cm^{-1}, of isolated N—D stretching frequencies encountered in these compounds. It thus appears that the environments of the axial and non-axial H atoms *within* each compound are sufficiently similar to preclude the possibility of free rotation about a preferred single axis. The comparable half-widths of the $\nu_1(a)$ and $\nu_1(n)$ bands in each compound rule out the possibility of rapid reorientation about the threefold axis.

The existence of *two* $\nu_1(NH_3D^+)$ frequencies and the occurrence of i.r. bands arising from combination modes involving ν_6 are evidence that in the three cases considered the ammonium ions are fixed in position at their lattice sites and that, *at least during the life-time of a vibrationally excited state*, the only rotational motions are librational.

The structural features (Fig. 1) suggest that the orientation of the NH_4^+ ion in $(NH_4)_2GeF_6$ and β-$(NH_4)_2SiF_6$ is maintained by four trifurcated hydrogen bonds, three of which are equivalent and the fourth involving a distance N—*Y* shorter than N—*X*. If N—*X* and N—*Y* measure the length of a trifurcated hydrogen bond, and if it is assumed that this "effective" length is the dominant factor affecting the $\nu_1(NH_3D^+)$ frequency, $\nu_1(a\text{-}NH_3D^+)$ would be expected to occur at a lower frequency than $\nu_1(n\text{-}NH_3D^+)$. Although two bands arising from $\nu_1(NH_3D^+)$ are observed for each compound, in approximately the expected intensity ratio, the order of frequency is the reverse of the expectation. This indicates that other factors exist which influence the strength of the N—H...F bond, at least as important as the "effective" length. We intend to discuss the apparent anomalies found for these two compounds more fully when we have accumulated ampler experimental evidence from other ammonium compounds.

In $(NH_4)_2Pb(SO_4)_2$ the oxygen closest to the nitrogen is the O(1) on the threefold axis (Fig. 2). From the $\nu_1(NH_3D^+)$ frequencies for the sulfate, however, it is apparent that the stronger hydrogen bonds are formed by the off-axis H atoms, hence a trifurcated hydrogen bond is stronger than a normal bond when the acceptor atoms are situated at comparable distances from the nitrogen.

The importance of this conclusion to the structural role of the ammonium ion in crystals is illustrated by Khan and Baur's (18) observation that out of thirty ammonium oxo-salts they reviewed only six contained the ion in approximately tetrahedral, fourfold coordination, *i.e.* capable of forming nearly straight N—H...O contacts. With the exception of the cubic phases of the ammonium halides, the straight H bond, as found in the structure of $(NH_4)_2Pb(SO_4)_2$, appears to be something of a rarity. It would seem that any meaningful correlation of N—H stretching frequency (or isolated $\nu_1(NH_3D^+)$ frequency in the approach adopted here) and N—H...*X* distance would require the separate

[4]Recent re-interpretation of Levy and Peterson's (14) neutron-diffraction intensities of phase *I* of ND_4Br by Press (17) supports the existence of a librational motion of the ND_4^+ ion rather than free rotation about a single axis.

consideration of each type of H bond, *i.e.* separate correlations for normal, bifurcated etc. H bonds.

We may now apply the criteria suggested at the beginning of this paper to the three examples studied.

$(NH_4)_2GeF_6$ is isomorphous with the corresponding K and Rb salts (19). This observation would suggest, on Waddington's idea (2), that no H bonding exists in its structure. A band corresponding to $\nu_4 + \nu_6$ is, however, observed in the i.r. spectrum of the hexafluorogermanate. Previous authors (2, 3) are in agreement that the appearance of this combination band confirms the presence of H bonding. The spectral data from isolated NH_3D^+ in $(NH_4)_2GeF_6$ support that conclusion.

K and Rb analogs of β-$(NH_4)_2SiF_6$ have not been reported and may not exist under normal circumstances. A band arising from the combination mode $\nu_4 + \nu_6$ is found in the i.r. spectrum of the ammonium compound at room temperature. This example thus appears to bear out Dunsmuir and Lane's (3) suggestion that any departure by the ammonium salt from the structure of the K and Rb analogs might be attributed to the presence of H bonding in the ammonium salt. This conclusion is supported by the isotopically dilute NH_3D^+ spectra of β-$(NH_4)_2SiF_6$.

The double sulfates $M_2Pb(SO_4)_2$ (M = K, Rb, NH_4) form an isomorphous series (4), which would suggest, on Waddington's criterion, the absence of H bonding. Infrared bands are, however, found corresponding to the combination modes $\nu_4 + \nu_6$ *and* $\nu_2 + \nu_6$ in the room-temperature spectrum of the ammonium compound. This provides evidence in favor of a H-bonded ammonium ion. The isolated $\nu_1(NH_3D^+)$ results presented above confirm the existence of H bonding; in addition, they lead to indications of the relative strengths of the H bonds present in the sulfate structure.

Summary

The i.r. spectra of isotopically dilute NH_3D^+ ions at crystal sites of C_{3v} symmetry in $(NH_4)_2GeF_6$, β-$(NH_4)_2SiF_6$, and $(NH_4)_2Pb(SO_4)_2$ at liquid-nitrogen temperature, have been shown to be consistent with non-rotating ammonium ions. This conclusion is in agreement with the observation of at least one band, in the i.r. spectrum of each compound, which may be assigned to a combination mode involving the libration ν_6.

The results of this study demonstrate the usefulness of isotopically dilute NH_3D^+ ions as a diagnostic tool for the spectroscopic recognition of trigonal site symmetry of ammonium ions in crystal structures. For the site symmetries C_{3v} and C_3 the orientation of the ammonium ion is uniquely determined, while for the other trigonal site symmetries (D_{3h}, D_{3d}, D_3, C_{3h}, C_{3i}) orientational disorder may occur. The spectra of isolated NH_3D^+ provide for a ready investigation of the rotational behavior of ammonium ions in crystals and for a more reliable detection of H bonding in ammonium salts than has been proposed previously.

This investigation was supported by the National Research Council of Canada through a grant-in-aid of research to one of us (O.K.).

Group VI Metal Carbonyl Derivatives of *cis*-$(CH_3)_2AsC(CF_3)=C(CF_3)As(CH_3)_2$

WILLIAM R. CULLEN AND LYNN MIHICHUK

Chemistry Department, University of British Columbia, Vancouver, British Columbia V6T 1W5

Received June 16, 1975

WILLIAM R. CULLEN and LYNN MIHICHUK. Can. J. Chem. **53**, 3401 (1975).

The carbonyls $M(CO)_6$ (M = Cr, Mo, W) react with *cis*-$(CH_3)_2AsC(CF_3)=C(CF_3)As(CH_3)_2$ (L—L) to give the chelate derivatives (L—L)$M(CO)_4$. These react with excess (L—L) on ultraviolet irradiation affording *cis*-(L—L)$_2M(CO)_2$ and *trans*-(L—L)$_2M(CO)_2$ and two isomers of *fac*-(L—L)$_2M(CO)_3$ where one (L—L) is acting as a monodentate ligand, and is either the *cis* ligand or its *trans* isomer.

WILLIAM R. CULLEN et LYNN MIHICHUK. Can. J. Chem. **53**, 3401 (1975).

Les carbonyles $M(CO)_6$ (M = Cr, Mo, W) réagissent avec le $(CH_3)_2AsC(CF_3)=C(CF_3)As(CH_3)_2$-*cis* (L—L) pour conduire aux chélates (L—L)$M(CO)_4$. Par irradiation u.v., ces derniers réagissent avec un excès de L—L pour fournir (L—L)$_2M(CO)_2$-*cis* et (L—L)$_2M(CO)_2$-*trans* et deux isomères du (L—L)$_2M(CO)_3$-*fac* où un (L—L) agit comme ligand monodentate; il est soit le ligand-*cis* ou son isomère-*trans*.

[Traduit par le journal]

Although chelate derivatives of the Group VI hexacarbonyls of formula (bidentate)$M(CO)_4$ are well known (M = Cr, Mo, W; bidentate is a ligand such as diphos, $(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2$ which contains two Group V donor atoms), there is a surprising lack of knowledge about derivatives of the type (bidentate)$_2M(CO)_2$ and (bidentate)$_2M(CO)_3$ (1–3). In the latter case one ligand is coordinated by only one of the two potential donor atoms.

The ligand *cis*-$(CH_3)_2AsC(CF_3)=C(CF_3)As(CH_3)_2$ (L—L) is readily available from the reaction of tetramethyldiarsine with hexafluoro-2-butyne (4) and is closely related to the versatile $f_4$fars, $(CH_3)_2AsC=CAs(CH_3)_2CF_2CF_2$ (5). The 'bite' of (L—L) is expected to be less than that of $f_4$fars and so the former should tend to form chelate complexes rather than the bridged derivatives such as $f_4farsFe_3(CO)_{10}$ (6–8) characteristic of the fluoroalicylic-bridged ligand.

The present paper is concerned with a study of the reactions of L—L with the Group VI hexacarbonyls.

Experimental

Air-sensitive starting materials were handled in a nitrogen atmosphere. A standard vacuum system was used for the manipulation of volatile reactants. Infrared spectra were recorded on a Perkin-Elmer 457 double beam spectrophotometer and calibrated using polystyrene and cyclohexane. Nuclear magnetic resonance (n.m.r.) spectra were run on Varian T-60 and HA-100 spectrometers with chemical shifts given in p.p.m. downfield from internal TMS for ^1H spectra and upfield from internal $CFCl_3$ for ^{19}F spectra. Melting points were determined in open capillaries using a Gallenkamp melting point apparatus and are uncorrected.

Ultraviolet irradiations were performed using a 200 W Hanovia 654A-36 lamp situated 20 cm from the sealed reaction tube. The tube was continuously shaken and cooled by an air stream. In some cases irradiations were performed using a 450 W Hanovia lamp placed in a water cooled quartz jacket. This was inserted into a larger glass jacket containing the solution to be irradiated. Nitrogen was bubbled through the solution during the course of the reactions.

Microanalyses were performed by P. Borda of this department.

The Group VI metal hexacarbonyls were purchased from Strem Chemical Company and were used without further purification. The ligand *cis*-2,3-bis(dimethylarsino)-1,1,1,4,4,4-hexafluorobut-2-ene (L—L) has been previously described (4, 8).

Preparation of (L—L)M(CO)$_4$ Complexes

The following general method was used for the preparation of all new (L—L)M(CO)$_4$ complexes from the reaction of (L—L) with the Group VI hexacarbonyls.

A benzene solution (15–20 ml) containing a 1:1 mole ratio of ligand to hexacarbonyl was heated at 150 °C in an evacuated Carius tube for 19–42 h. At the end of the reaction period the solution (initially pale yellow) was dark yellow (except for (L—L)Cr(CO)$_4$ which was amber). The solvent was removed under reduced pressure and the resulting solid residue chromatographed on Florisil. Petroleum ether (b.p. 30–60 °C) eluted a yellow band which upon recrystallization from a methylene chloride – hexane mixture afforded the (L—L)M(CO)$_4$ complexes.

Analytical, preparative, and spectroscopic data for the new complexes are listed in Tables 1, 2, and 3.

Reactions of (L—L)M(CO)$_4$ and M(CO)$_6$ with Excess (L—L)

A number of reactions between M(CO)$_6$ and the (L—L)M(CO)$_4$ complexes with (L—L) are given in tabular form in Table 2. All pyrolysis reactions were performed in sealed evacuated Carius tubes; ultraviolet irradiations (200 W) were performed in evacuated quartz tubes. In all cases the crude reaction mixture was evaporated to dryness and the residue was chromatographed on Florisil using nitrogen saturated solvents as indicated in Table 2. All complexes were recrystallized from a degassed methylene chloride – hexane mixture at −20 °C.

Analytical and spectroscopic data for the new complexes are listed in Tables 1 and 3.

Results and Discussion

(L—L)M(CO)$_4$ Complexes

Reaction of the Group VI metal hexacarbonyls with an equimolar amount of (L—L) for 1–2 d in a sealed evacuated Carius tube, yields in the usual manner (1–3) the disubstituted chelate complexes (L—L)M(CO)$_4$. The complexes are yellow (except for the chromium derivative which is amber), air-stable, crystalline solids moderately soluble in nonpolar organic solvents and very soluble in polar organic solvents.

The infrared spectra are as expected for chelate derivatives and the ^1H and ^{19}F n.m.r. spectra show one arsenic methyl singlet and one trifluoromethyl singlet. This data indicates that either the five-membered ring (determined by the metal, two arsenic, and two carbon atoms of the ligand) is planar in solution (*i.e.* a symmetric structure), or the ring is involved in a rapid conformational equilibrium between two envelope forms.

fac-(L—L)^b(L—L)$^m{}_{cis}$M(CO)$_3$ and fac-(L—L)^b(L—L)$^m{}_{trans}$M(CO)$_3$[1]

These tricarbonyl complexes are best prepared by photolyzing a benzene solution of the parent hexacarbonyl or tetracarbonyl derivative and excess (L—L). Pyrolysis at temperatures of 150–200 °C does not yield the tricarbonyl derivative.

Hitherto no tricarbonyl complex containing two bidentate ligands has been reported from the reaction of a Group VI metal hexacarbonyl with an excess amount of a potentially bidentate ligand. However, the literature relating to complexes of the type (L$_2$)(L)M(CO)$_3$ (M = Cr, Mo, W; L$_2$ is a bidentate ligand; L is a monodentate ligand) has been well documented (9, 10).

Two isomeric tricarbonyl derivatives are obtained from the 450 W photochemical reaction. Analytical data suggest the formula (L—L)$_2$-M(CO)$_3$.

The i.r. spectra of the two isomers are identical in the carbonyl region; hence, the configuration of the carbonyl groups is probably the same in both isomers. The band intensities suggest both isomers are *fac* isomers (9, 10).

The basic difference in the n.m.r. spectra of the two isomeric *fac* complexes is the magnitude

[1] b and m denote bidentate and monodentate.

of the ^{19}F–^{19}F coupling constants of the resonances assigned to the monodentate ligand. This indicates that the two isomers differ in the configuration of the monodentate ligand since the bidentate ligand in each isomer *must* possess a *cis* configuration to form a chelate complex.

The structural assignments indicated in the tables are based on the well established result

$$\begin{matrix} & X & Y \\ & | & | \\ cis\text{-}CF_3— & C= & C—CF_3 \end{matrix}$$

(11) that $^5J_{FF}$ for *cis*-CF_3—C=C—CF_3 is ~12 Hz whereas for the *trans* geometry it is ~2 Hz. The ^1H n.m.r. spectrum of each complex is in agreement with this interpretation. Independent experiments show that the source of the *trans* ligand in these $M(CO)_3$ derivatives is an isomerization of (L—L) that occurs in the 450 W photochemical reaction such that the *cis* and *trans* forms of the ligand are in equilibrium, with the ratio of *cis* to *trans* being 9:1 as shown by ^{19}F n.m.r. spectroscopy.

The tricarbonyl complexes are unstable in nondegassed solvents but indefinitely stable in the solid state. The monodentate ligand in the two isomeric tricarbonyl derivatives is easily displaced by carbon monoxide, resulting in the formation of the tetracarbonyl complexes $(L—L)M(CO)_4$.

cis$(L—L)_2M(CO)_2$ *(M = Cr, Mo, W) and* *trans*-$(L—L)_2M(CO)_2$ *Complexes (M = Cr, Mo)*

The *cis* dicarbonyl complexes are best prepared by irradiating (450 W) a benzene solution of the tetracarbonyl complex and excess ligand (L—L). Heating the reactants at 175 °C yields the molybdenum dicarbonyl complex. Trace amounts of the chromium and tungsten derivatives are obtained at higher temperatures (190–210 °C) after prolonged heating and occasional removal of the accumulated carbon monoxide.

Further irradiation of *cis*-$(L—L)_2M(CO)_2$ (M = Cr, Mo) gives the isomeric *trans*-$(L—L)_2M(CO)_2$ derivatives.

The *cis* dicarbonyl complexes show the expected two bands (at considerably lower frequencies than the $(L—L)M(CO)_4$ complexes) in the ν(CO) region consistent with other characterized Group VI *cis* dicarbonyl complexes (12–15). Their ^1H n.m.r. spectra show four arsenic methyl singlets of equal area in accordance with the *cis* dicarbonyl structure. However the ^{19}F n.m.r. spectra consist of singlets rather than the anticipated doublet of quartets. Presumably the trifluoromethyl groups are insensitive to the different methyl environments about each arsenic atom. This has been noted in cobalt carbonyl complexes of $f_4$fars and related ligands (16, 17).

The i.r. spectra of the *trans* derivatives show the expected one carbonyl band and have the appropriate n.m.r. spectra.

The *cis* complexes are thermodynamically more stable than the isomeric *trans* complexes. Complete *trans* to *cis* isomerization occurs for the molybdenum derivative upon refluxing in benzene for 44 h and the chromium derivative upon refluxing for 1.5 h.

Trans to *cis* isomerization is also found when the molybdenum and chromium derivatives are chromatographed on Florisil and the *trans* chromium complex even isomerizes in the solid state.

Bond and co-workers (15, 18) have recently reported on an electrochemical investigation of the complexes $[M(CO)_2(bidentate)_2]^{0,+1,+2}$ (bidentate = $(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2$ and $(C_6H_5)_2PCH_2P(C_6H_5)_2$). They find that for the neutral complexes, where both *cis* and *trans* isomers can be identified, the *cis* isomer is the more stable. However, oxidation results in increased stability of the *trans* species.

The authors are grateful to the National Research Council of Canada for financial support of this work in the form of operating grants to W.R.C. and scholarships to L.M.

Kinetic Study of the Reaction between Substituted Triphenylmethyl Perchlorates with Pyridines in Nitromethane and 1,2-Dichloroethane Solvents[1]

CHANG B. KIM[2] AND KENNETH T. LEFFEK

Chemistry Department, Dalhousie University, Halifax, Nova Scotia B3H 4H6

Received April 28, 1975

CHANG B. KIM and KENNETH T. LEFFEK. Can. J. Chem. 53, 3408 (1975).

Second-order rate constants at 25 °C have been measured for the reaction of triphenylmethyl carbonium ion with pyridine and substituted pyridines in nitromethane and 1,2-dichloroethane solvent. The activation parameters are in the range 1 to 3 kcal mol^{-1} for the enthalpies of activation and -20 to -45 cal mol^{-1} deg^{-1} for the entropies of activation. The results are compared to the analogous measurements for Menschutkin reactions and it is concluded that the enthalpy of activation of a Menschutkin reaction results mainly from the bond breaking process and solvation changes associated with it, since the carbon–nitrogen bond making process seems to be entropy controlled.

Rate measurements have also been made for 2-methylpyridine reacting with a series of *para*-substituted triphenylmethyl carbonium ion substrates in 1,2-dichloroethane solvent. A plot of $\log k_2$ *vs.* $\Sigma\sigma^+$ is non-linear and the curvature is interpreted as a saturation effect.

CHANG B. KIM et KENNETH T. LEFFEK. Can. J. Chem. 53, 3408 (1975).

On a mesuré les contantes de vitesse du deuxième ordre à 25 °C pour la réaction du carbocation triphénylméthyle avec la pyridine et des pyridines substituées; le nitrométhane et le dichloro-1,2 éthane ont été utilisés comme solvant. Les paramètres d'activations sont de l'ordre de 1 à 3 kcal mol^{-1} pour les enthalpies d'activation et de -20 à -45 cal mol^{-1} deg^{-1} pour les entropies d'activation. On compare ces résultats avec des mesures analogues pour des réactions de Menschutkin et on en conclut que l'enthalpie d'activation d'une réaction de Menschutkin provient principalement du processus de bris de lien et de changements de solvatation qui lui sont associés; cette conclusion est basée sur le fait que le processus de formation du lien C—N semble être contrôlé par l'entropie.

On a aussi mesuré, dans le dichloro-1,2 éthane, des vitesses de réaction de la méthyl-2 pyridine avec une série de carbocations triphénylméthyles substitués en *para*. La relation $\log k_2$ *vs.* $\Sigma\sigma^+$ n'est pas linéaire et on interprète la courbature en fonction d'un effet de saturation.

[Traduit par le journal]

Introduction

It has been known for a long time (1) that the triphenylmethyl (trityl) carbonium ion in dipolar aprotic solvents very rapidly loses its characteristic yellow color upon addition of reagents with lone pair electrons such as ethers and tertiary amines. The strength of the bond between the electron deficient carbon atom and the electron rich basic atom should depend upon the pK_a of the base and be stronger for tertiary amines than for ethers (2). Gelles, Hughes, and Ingold (3) observed an immediate discharge of the yellow color of trityl chloride in nitromethane upon the addition of pyridine which they described as the formation of a complex between the pyridine and the trityl chloride carbonium ion-pairs. They represented this complex as the tritylpyridinium ion, $(C_6H_5)_3C\overset{+}{N}C_5H_5$. Streitwieser (4) also favored the formation of triphenylmethylpyridinium chloride as the explanation of this reaction, despite the fact that there had been several unsuccessful attempts to synthesize this compound (5–11). However, in 1970, the preparation of the compound was reported by Okamoto and Shimakawa (12) using a pressure of 4000–5000 atm at 60–70 °C. In contrast, these workers prepared tritylpyridinium perchlorate and tetrafluoroborate in acetonitrile solvent at room pressure and temperature in 10 min.

Some experiments have been reported on the equilibrium constants for the reaction of trityl carbonium ion with diethyl ether in nitromethane and in acetic anhydride (13), which gave

an equilibrium constant of 0.8×10^{-4} l mol^{-1} in nitromethane, and of trityl bromide carbonium ion-pairs with pyridine in 1,1,2,2-tetrachloroethane (14), which gave $K = 3 \times 10^5$ l mol^{-1}. These values reflect the different basicities of ether and pyridine. However, due to the high velocity of the reactions, no kinetic measurements have been made. The kinetics of the reaction of carbonium ions with tertiary amines are of interest because this type of reaction is analogous to a Menschutkin reaction in which there is no carbon–halogen bond breaking component. Therefore, the rates and activation parameters for such a reaction should allow a more meaningful interpretation of analogous parameters in Menschutkin reactions.

In the present study, the perchlorates were selected as the substrate molecules since triphenylmethyl perchlorate is an ionic compound in the solid state (2, 15) and in solution (16), and is known to react readily with pyridine to give the quaternary ammonium salt (12). Pyridine, 2-picoline, and 2,6-lutidine were used as the nucleophilic reagents with unsubstituted triphenylmethyl perchlorate in order to make a comparison of the steric effect of the methyl group substituents in the amines in this reaction with that effect in the Menschutkin reaction. A second series of experiments was made with substituted triphenylmethyl perchlorates with the base 2-picoline.

Results and Discussion

Reaction of Triphenylmethyl Perchlorate with Substituted Pyridines

Pseudo first-order rate constants for the disappearance of the yellow color due to the trityl carbonium ion by reaction with an excess of tertiary amine were just slow enough to be determined using a stopped-flow spectrophotometer. These rate constants, measured at 25 °C, are shown in Table 1 for the two solvents nitromethane and 1,2-dichloroethane.

Similar measurements to those in Table 1 were made at several other temperatures in an attempt to measure the activation parameters. The second-order rate constants derived from these measurements, calculated by a least squares computation from the reaction $k_1 = k_2$[Amine], are shown in Table 2. It can be seen that the second-order rate constants have large standard deviations compared to the range of k_2 values for the 25 °C temperature spread. Nevertheless,

the activation parameters obtained from plots of $\ln (k_2/T)$ *vs.* $1/T$, given in Table 3, show that the enthalpies of activation for triphenylmethyl perchlorate reacting with all three amines are in the range of 1 to 3 kcal mol^{-1} in both solvents and that the entropies of activation are in the order of -20 to -45 cal mol^{-1} deg^{-1}. The enthalpies of activation are probably reliable to within 1 kcal mol^{-1}, with corresponding uncertainty in the entropies of activation.

In each solvent, the free energy of activation increases from pyridine to 2,6-lutidine, as has been observed for Menschutkin reactions. The

reactions with pyridine and with 2,6-lutidine are about 3 times faster in 1,2-dichloroethane than they are in nitromethane, but for 2-picoline the reaction is about 10 times slower in 1,2-dichloroethane than in nitromethane. We have no explanation for this irregular behavior.

Since the reaction involves more delocalization of the positive charge in the transition state relative to the initial state, it would be expected to proceed faster in the less polar solvent (17), that is, faster in 1,2-dichloroethane than in nitromethane.

The rate changes with *ortho*-methyl substitution of pyridine which we have observed are large (*ca.* 1000) compared to similar changes observed in Menschutkin reactions (generally less than 10) in similar solvents (18, 19). In the latter reactions, changes in ΔH^* are less than 1 kcal and changes in ΔS^* are 1 to 2 cal mol^{-1} deg^{-1}. Although we may have ΔH^* changes of 1 kcal, the major change in k_2 in Table 2 results from ΔS^* changing by about 20 cal mol^{-1} deg^{-1}.

It is concluded, therefore, that most of the enthalpy of activation of a Menschutkin reaction is due to the bond breaking process and solvation changes associated with it. The carbon–nitrogen bond making process, judged from

the present measurements, is entropy controlled, requiring only the reorientation of the reacting and solvent molecules with very little energy input.

Reaction of 2-Methylpyridine with Substituted Triphenylmethyl Perchlorates

The reaction of 2-methylpyridine with a series of *para*-substituted triphenylmethyl perchlorates was studied in 1,2-dichloroethane by measuring pseudo first-order rate constants with the nucleophile in large excess. Second-order rate constants were calculated as before. The results are given in Tables 4 and 5.

A plot of $\log k_2$ *vs.* $\sum\sigma^+$ shown in Fig. 1 is seen to be non-linear. The values of σ^+ used are those calculated by Deno and Evans (20) for triarylmethyl cation equilibria. The slope of the graph indicates a positive ρ value as expected for a reaction in which negative charge is accumulated adjacent to the benzene ring and ρ becomes smaller as the electron releasing power of the substituent increases. The value of ρ drops from about 5.5 to about 0.7 indicating a decreasing sensitivity to negative charge accumulation. This has been described as a saturation effect (2, 21, 22): the more the positive charge on the carbonium ion is delocalized in the initial state, the smaller the extra delocalization is obtained from an additional *para*-methyl substituent. The delocalization of positive charge in the initial state parallels the decrease in reactivity. 4,4′-Dimethylaminotriphenylmethyl carbonium ion does not react at all with pyridine in methanol solution (23).

The kinetic Hammett plot is not unique. The plot of $\Delta F_{R+}{}^0$, the thermodynamic stability of carbonium ions derived from alcohols, against $\sum\sigma^+$ which is given by Freedman (24) shows very similar behavior for the same compounds when plotted on the same scale, although the ρ value is negative in this case. However, the curvature is less pronounced and over a $\sum\sigma^+$ range of more than 5 the plot is almost linear. Thus, although the saturation effect is smaller for the thermodynamic stability case, qualitatively the same phenomenon is seen. If the curvature of the plot is ignored a least squares treatment yields $\rho = 2.9 \pm 0.6$ somewhat less than the value of 4.0 ± 0.15 found for substituted triphenylmethyl carbonium ions reacting with water at 25 °C (25).

Experimental

Materials

Triphenylmethyl perchlorate was prepared from the carbinol and 70% perchloric acid in acetic anhydride solvent as described by Dauben *et al.* (26). The yellow crys-

TABLE 5. Second-order rate constants for the reaction of 2-methylpyridine with *para*-substituted triphenylmethyl perchlorates in 1,2-dichloroethane at 25 °C

Substrate	k_2 (l mol^{-1} s^{-1})
Triphenylmethyl perchlorate	4200 ± 300
p-Tolyldiphenylmethyl perchlorate	195 ± 40
Di-*p*-tolylphenylmethyl perchlorate	40 ± 2
Tri-*p*-tolylmethyl perchlorate	33 ± 3
p-Anisyldiphenylmethyl perchlorate	28 ± 2
p-Chlorophenyldiphenylmethyl perchlorate	ca.10^6

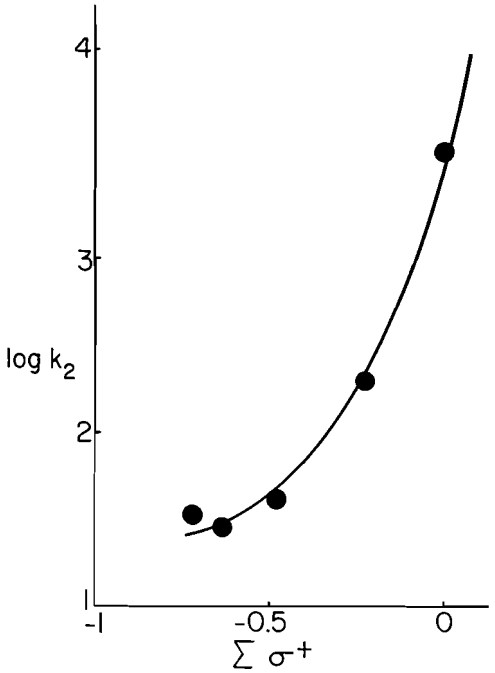

FIG. 1. Plot of the logarithm of the second-order rate constant *vs.* $\Sigma\sigma^+$ for the reaction of *para*-substituted triphenylmethyl perchlorate with 2-methylpyridine in 1,2-dichloroethane at 25 °C

tals, after vacuum drying for 5 h, had m.p. 143 °C in a sealed tube (lit. (26, 27) 143–144 °C). *p*-Tolyldiphenylmethyl carbinol was prepared by a Grignard reaction of *p*-tolylmagnesium bromide and benzophenone. After 4 h under reflux, 0.1 *M* H_2SO_4 was used to generate the alcohol which was recovered as an oil. The middle cut of a vacuum distillation gave a viscous oil, which crystallized after several hours. Recrystallization from petroleum ether (30–60 °C) gave crystals m.p. 75 °C (lit. (28) 73–74 °C). Di-*p*-tolylphenylmethyl carbinol was prepared by a Grignard reaction of *p*-tolylmagnesium bromide and methyl benzoate. The product was vacuum distilled and recrystallized from petroleum ether, m.p. 74 °C (lit. (29) 76.5–77.5 °C).

Tri-*p*-tolylmethyl carbinol was prepared by a Grignard reaction of *p*-tolylmagnesium bromide and ethyl *p*-toluate. The product was vacuum distilled and the middle cut was esterified with glacial acetic acid. The ester crystallized at low temperature and was recrystallized from petroleum ether. The carbinol was obtained by treatment with NaOH and recrystallized from petroleum ether, m.p. 97 °C (lit. 96.5 °C (30), 93 °C (31)).

p-Methoxyphenyldiphenylmethyl carbinol was prepared by a Grignard reaction of *p*-methoxyphenylmagnesium bromide and benzophenone. The high boiling fraction of a vacuum distillation was recrystallized with some difficulty from petroleum ether, m.p. 57 °C, (lit. (32) 58–61 °C).

p-Chlorophenyldiphenylmethyl carbinol was prepared by a Grignard reaction of *p*-chlorophenylmagnesium bromide and benzophenone. The product was recrystallized from petroleum ether, m.p. 85 °C (lit. (33, 34) 84.8–85.5 °C).

Each of the substituted triphenylmethyl carbinols was converted to the perchlorate by treating a solution of the alcohol in glacial acetic acid with concentrated $HClO_4$. After removal of solvent under vacuum, the product was recrystallized from glacial acetic acid.

Reagent grade pyridine and 2-picoline were fractionally distilled over NaOH pellets and 2,6-lutidine was distilled from zinc dust.

Reagent grade nitromethane was purified by the procedure of Thompson *et al.* (35), which consists of successive washings with sodium bicarbonate, sodium bisulfite, and sulfuric acid solutions, followed by drying with P_2O_5 and distillation at reduced pressure. We added the additional step of passing the solvent through a column of molecular sieve Linde Type 4A before the distillation.

Reagent grade 1,2-dichloroethane was washed with KOH solution and water, dried over Driente, passed through a molecular sieve column and fractionally distilled at atmospheric pressure. Only material boiling at 83.5 °C was collected since the azeotropic mixture with water boils at 81–83 °C.

Kinetic Measurements

The reaction rates were measured using a Durrum stopped-flow spectrophotometer using an optical cell with a 2 mm pathlength according to the standard procedure described previously (36, 37). The increase in transmittance was observed over the 90–100% range at 430 nm wavelength. Several individual runs were superimposed on the oscilloscope screen and first order rate constants were calculated from the composite trace.

It is well known that very small amounts of impurity in nitromethane react rapidly with triphenylmethyl car-

bonium ion (38, 39). However, in carefully purified nitromethane, the carbonium ion is stable for 24 h (13, 40). We verified the latter statement and used in our kinetic experiments only nitromethane in which the carbonium ion was stable for at least 7 h.

Effect of Pressure on the Alkaline Hydrolysis of Ethyl Acetate in Acetone–Water Solutions. Parameters of Activation at Constant Volume[1]

M. L. TONNET[2] AND E. WHALLEY

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received October 28, 1974[3]

M. L. TONNET and E. WHALLEY. Can. J. Chem. **53**, 3414 (1975).

The effect of pressures up to 3 kbar on the rate of the base-catalyzed hydrolysis of ethyl acetate in acetone–water mixtures has been measured. From these measurements and the enthalpy and entropy of activation at constant pressure measured by others, the internal energy and entropy of activation at constant volume have been obtained as a function of solvent composition. The constant-volume parameters of activation vary with composition in a simpler way than the constant-pressure parameters. It seems likely that theoretical discussions of the solvent effect are easier if they are based on the constant-volume parameters. At low acetone concentrations, the addition of acetone reduces the rate constant at low pressure, but increases it at 3 kbar.

M. L. TONNET et E. WHALLEY. Can. J. Chem. **53**, 3414 (1975).

On a mesuré l'effet de pressions allant jusqu'à 3 kbar sur la vitesse d'hydrolyse basique de l'acétate d'éthyle dans des mélanges d'eau-acétone. A partir de ces mesures et aussi utilisant l'enthalpie et l'entropie d'activation à pression constante mesurées par d'autres, on a pu obtenir l'énergie interne et l'entropie d'activation à volume constant en fonction de la composition du solvant. Les paramètres d'activation à volume constant varient en fonction de la composition d'une façon beaucoup plus simple que les paramètres à pression constante. Il semble probable que les discussions théoriques de l'effet de solvant sont plus simples si elles sont basées sur des paramètres à volume constant. A des concentrations d'acétone basses, l'addition d'acétone réduit la constante de vitesse à basse pression; toutefois à 3 kbar, elle l'augmente.

Introduction

Many reactions in aqueous organic solvents have minima in the constant-pressure enthalpy $\Delta H_p^{\ddagger}$ and entropy $\Delta S_p^{\ddagger}$ of activation as a function of solvent composition. This minimum is frequently interpreted as indicating changes in the structure of the solvent at the location of the minimum (1).

But there are two major causes of extrema in physical properties; those due to causes inherent in a single phenomenon, such as the maximum in the light absorption due to an energy transition, and those due to the opposing effects of several independent or partially independent causes. For example, a particular measurement a may be considered as the result of two more fundamental processes a_1 and a_2

$$a = a_1 + a_2$$

and a maximum in a as a function of a parameter x will occur where

$$\partial a_1/\partial x = -\partial a_2/\partial x$$

In this case, the reasons for the location of the maximum must be sought in the reasons for the values of the parameters controlling $a_1(x)$ and $a_2(x)$. The simplest example of this phenomenon occurs when $a_1 = b_1x$, $a_2 = b_2x^2$, and an extremum in a occurs at $x = -b_1/2b_2$.

As was mentioned, minima in $\Delta H_p^{\ddagger}$ and $\Delta S_p^{\ddagger}$ as a function of solvent composition have often been used to infer specific changes in the solvent at this composition. But the minima may be due to two or more opposing effects as outlined above. An examination of the same results in another coordinate system, (a change of coordinate system is a well-known scientific technique for denying or confirming inferences) might help to decide whether the minima are due to specific changes in the structure of the solvent at the composition of the minimum, or are due to opposing effects which do not imply such specific changes in the structure.

When the temperature is changed to measure an activation energy, the way in which the pressure and volume change must be specified, because the pressure, volume, and temperature of a

homogenous system are related by an equation of state, and two of them must be specified to specify the state.

Because we live in a nearly constant-pressure world, it is usual to keep the pressure constant when reactions in solution are studied and the enthalpy and entropy of activation at constant pressure are determined. An alternative possibility is to keep the volume constant, and then the energy and entropy of activation at constant volume are determined. The relation between the constant-volume and constant-pressure parameters is (2)

$$\Delta U_v^{\ddagger} = \Delta H_p^{\ddagger} - T\alpha\Delta V^{\ddagger}/\kappa$$

$$T\Delta S_v^{\ddagger} = T\Delta S_p^{\ddagger} - T\alpha\Delta V^{\ddagger}/\kappa$$

It does not appear to be possible to argue *a priori* whether constant-pressure or constant-volume conditions are to be preferred for a theoretical interpretation (3).

In a number of papers from this laboratory, the effect of solvent composition in aqueous organic solvents on the enthalpy and entropy of activation for the neutral hydrolysis of benzyl (4*a*, 5, 6) and *tert*-butyl (4*b*) chlorides, the acid-catalyzed enolization of acetone and acetophenone (7), the acid-catalyzed hydrolysis of methyl acetate and ethylene oxide (8), and the base-catalyzed decomposition of diacetone alcohol (9, 10), have been found to appear simpler after the coordinate transformation from constant-pressure conditions to constant-volume conditions. In particular, the minima that occur in the constant-pressure parameters are much smaller or are nonexistent in the constant-volume parameters. The main reason for the difference, with the commoner aqueous organic solvents, is that the thermal expansivity α changes greatly with solvent composition because the thermal expansivity of water at ordinary temperatures is much smaller than that of the organic solvents. When a solvent system for which the thermal expansivity changes only slightly is used, such as aqueous glycerol, both the constant-pressure and constant-volume parameters vary in a relatively simple way (5, 6).

It would appear from these results that there is no need to invoke specific structural changes at the location of the minimum in $\Delta H_p^{\ddagger}$ and $\Delta S_p^{\ddagger}$, because it disappears if the coordinate system is changed. It was concluded that the minimum could be interpreted as a relatively simple behavior of $\Delta U_v^{\ddagger}$ (a curve with a small slope at low concentrations of organic solvent and a concave upward curvature, which would occur if transition states solvated wholly by water carried the reaction in dilute organic solutions) and a strong effect of composition on the thermal expansivity and to a lesser extent on the activation volume.

The purpose of the present work is to inquire whether a base-catalyzed ester hydrolysis behaves in the same way, and the hydrolysis of ethyl acetate in acetone–water mixtures was chosen.

Experimental Methods and Results

Reagent grade ethyl acetate was used after drying over potassium carbonate and distilling under reduced pressure. It contained no detectable acid.

The reaction solutions were made by adding 25, 37.5, and 50 cm^3 of acetone to suitable solutions of ethyl acetate and sodium hydroxide and making up to 100 cm^3 to produce solutions that were 5 mM in both ethyl acetate and sodium hydroxide. The acetone concentrations in the three solutions were 24.0, 32.0, and 42.4% by weight.

The reaction was followed conductimetrically using a General Radio 1680-A automatic capacitance–conductance bridge and digital readout. About 10 conductances were measured during each run, and during a run the concentrations of sodium hydroxide and ethyl acetate dropped from about 2.5 to about 0.2 mM. The pressure equipment and conductance cells were similar to those used earlier (6, 11). They had a capacity of about 15 cm^3, and two were placed in the vessel at the same time. The thermostat temperature was controlled to 20 mK by a mercury contact regulator and was measured with a platinum resistance thermometer.

The first conductance readings were taken after allowing an hour for the system to reach thermal equilibrium, by which time about half the reaction had gone. The reactions were then followed for periods of 5–6 h.

The rate constants were calculated from the integrated form of the second-order rate equation with equal concentrations. Because of the time required for thermal equilibrium after pressurizing the sample, an arbitrary starting time t_0 at which some reaction has already occurred must be used. The ionic concentration remains constant at 5 mM during the run, although hydroxide ions are replaced by acetate ions. A linear relation between conductance and extent of reaction is therefore

valid to a good accuracy. The integrated form of the rate equation is then

$$[1] \qquad G_t = \left(\frac{1}{kc_{t_0}}\right)\frac{G_{t_0} - G_t}{t - t_0} + G_\infty$$

where G_{t_0}, G_t, and G_∞ are the conductances at times t_0, t, and ∞, and c_{t_0} is the concentration of hydroxide ion and of ethyl acetate at time t_0.

The value c_{t_0} was obtained from the conductance G_{t_0} by comparing it with the conductance of various mixtures of sodium hydroxide and sodium acetate of total concentration 5 mM at various pressures. In the kinetic runs, c_{t_0} was 2.5 mM or less. No allowance was made for the reaction of acetone and sodium hydroxide as it is negligible under the experimental conditions. The measured conductances were fitted to Eq. 1 by least squares, minimizing the sum of squares of $G_{t_0} - G_t$. The standard deviation was about 0.5%.

The rate constants are summarized in Table 1 and are plotted against pressure at constant composition and against composition at constant pressure in Figs. 1 and 2. The concentration units are those at 1 bar because in the expression for the volume of activation $(\partial \ln k/\partial p)_T = -\Delta V^{\ddagger}/RT$, the rate constants must be expressed in suitable pressure-independent units.

The rate constants at 1 bar are lower than those

TABLE 3. Thermal expansivity and compressibility of acetone–water mixtures at 10.02 °C

Acetone in water (% w/w)	α/MK^{-1}	κ/Mbar^{-1}
0	91.9	47.9
20.4	495	44.7
31.0	745	46.8
42.8	967	48.0

previously reported (12, 13) probably because of the strong effect of the ionic strength (14, 15) on the rate constant.

The volume of activation was determined graphically by plotting $(\log k_i/k_j)/(p_i - p_j)$ against $\frac{1}{2}(p_i + p_j)$, where p_i and p_j are pressures corresponding to the rate constants k_i and k_j (8). The results are summarized in Table 2.

The volume of activation in water agrees well with the value −8.8 cm^3 mol^{-1} at 25 °C reported by Laidler and Chen (13) but less well with the values of $-4.5 \pm \sim 1$ cm^3 mol^{-1} calculated (2) from Cohen and Kaiser's (16) data at 2.4 °C and −5.6 and −6.4 cm^3 mol^{-1} reported by Andersen *et al.* (17) at 20 and 30 °C. The rate measurements of Andersen *et al.* were made at 0, 5, and 8 kbar only. Because of the curvature of the plot of log k *vs.* p in Fig. 1, these pressure intervals are quite inadequate (2, 18) and will yield a value numerically too low.

The energy and entropy of activation at constant volume, $\Delta U_v^{\ddagger}$ and $\Delta S_v^{\ddagger}$, were calculated from the enthalpy and entropy of activation at constant pressure, $\Delta H_p^{\ddagger}$ and $\Delta S_p^{\ddagger}$, by the relations

$$\Delta U_v^{\ddagger} = \Delta H_p^{\ddagger} - T\alpha\Delta V^{\ddagger}/\kappa$$

$$T\Delta S_v^{\ddagger} = T\Delta S_p^{\ddagger} - T\alpha\Delta V^{\ddagger}/\kappa$$

where T is the temperature and α and κ the thermal expansivity and compressibility of the solution. The compressibility and thermal expansivity

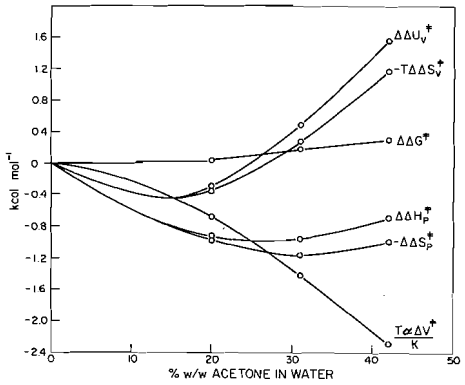

FIG. 3. Graph of the change, from the values in pure water, of the parameters of activation at constant pressure and at constant volume for the alkaline hydrolysis of ethyl acetate in acetone–water mixtures. The data are from Table 2.

were determined from literature values, (19–23) with interpolation and extrapolation as required. The errors of the values should cause no significant error for our purpose. The values of α and κ are listed in Table 3 and the constant-volume parameters are listed in Table 2. The constant-pressure and constant-volume parameters are plotted against solvent composition in Fig. 3.

Discussion

Energy and Entropy of Activation at Constant Volume

Both $\Delta H_p^{\ddagger}$ and $-T\Delta S_p^{\ddagger}$ have a minimum at about 25% w/w acetone in water, as shown in Fig. 3, as do many other reactions in this and related solvents. The depth of the minimum is reduced to about one third by the coordinate transformation to the constant-volume parameters. The addition of a small amount of acetone to the reaction mixture should change the energy of activation for the reaction only slightly, because

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

reactant molecules solvated by water will react faster than those solvated partly by acetone. But the low reactivity of some of the molecules increases the entropy of activation. At higher concentrations of acetone, molecules solvated partly by acetone begin to carry an appreciable part of the reaction, and the activation energy increases and at the same time the activation entropy starts to decrease. It appears, therefore, that constant-volume parameters vary with acetone concentration in a way more as expected on simple grounds than the constant-pressure parameters do. This is true of several other reactions also, which are reviewed in the Introduction.

When phenomena look simpler after a coordinate transformation, it is usual to think that the theoretical interpretation of the simpler-looking phenomena is simpler, unless there is strong reason to think otherwise. It is concluded therefore, until there is evidence to the contrary, that the constant-volume parameters are the simpler to understand.

The difference between the constant-pressure and constant-volume parameters is, of course $T\alpha\Delta V^{+}/\kappa$. The quantity that varies the most in our solvent range is the thermal expansivity, which as Table 3 shows, changes by a factor of about ten. The volume of activation changes by a factor of about 1.8, and the compressibility hardly changes at all. The minimum in the constant-pressure parameters can be ascribed largely to a relatively simple variation of the constant-volume parameters complicated by the large variation in the thermal expansivity.

If this is so, then in solvent mixtures that have only a small variation of the thermal expansivity with composition, even the constant-pressure parameters should be relatively simple. This prediction has been verified for the spontaneous hydrolysis by benzyl chloride in water-glycerol mixtures (5, 6).

We are greatly indebted to A. Lavergne for help with the high-pressure equipment.

^{13}C Fourier Transform Nuclear Magnetic Resonance. XI. Pyridine *N*-Oxide Derivatives

ROBERT J. CUSHLEY, DAVID NAUGLER, AND CARLOS ORTIZ
Department of Chemistry, Simon Fraser University, Burnaby, British Columbia V5A 1S6

Received October 8, 1974[1]

ROBERT J. CUSHLEY, DAVID NAUGLER, and CARLOS ORTIZ. Can. J. Chem. **53**, 3419 (1975).

Formation of the *N*-oxide for several pyridine derivatives results in a large upfield shift of the 2-, 4-, and 6-carbons and a significant downfield shift of the 3- and 5-carbons. The chemical shifts ($\Delta\delta$) are consistent with a resonance and electric field mechanism. Molecular orbital calculations using CNDO/2 show a qualitative correlation between excess charge density and $\Delta\delta$.

ROBERT J. CUSHLEY, DAVID NAUGLER et CARLOS ORTIZ. Can. J. Chem. **53**, 3419 (1975).

La transformation de plusieurs dérivés de la pyridine en *N*-oxyde conduit à de grands déplacements vers les hauts champs pour les carbones 2, 4 et 6 et à des déplacements importants vers les bas champs pour les carbones 3 et 5. Les déplacements chimiques ($\Delta\delta$) sont en accord avec un mécanisme de résonance et de champ électrique. Des calculs d'orbitale moléculaire CNDO/2 montrent qu'il y a une corrélation qualitative entre l'excès de la densité de charge et le $\Delta\delta$.

[Traduit par le journal]

Introduction

The *N*-oxide group has become increasingly more important as a biological functionality. Aliphatic *N*-oxides were recognized as early as 1945, when it was discovered that trimethylamine was oxidized to trimethylamine *N*-oxide in hog liver microsomes (1). Aromatic *N*-oxides were found to be biologically active when Neuberg (2) conducted his classic studies with pyridine *N*-oxide. Chemically, the $N \rightarrow O$ group s analogous to OH^+, hence, protonated *N*-oxides represent possible electrophilic reagents. Much more important however, is their role as a biological oxygenating agent. *N*-oxides have been depicted as the main moiety responsible for biological demethylation of *N*-methyl derivatives (3, 4). Nicotinamide *N*-oxide has been shown to be an intermediate in uric acid formation, being first converted to xanthine with xanthine oxidase (5). Many *N*-oxides have been found in nature. For instance, substituted quinoline *N*-oxides and quinoxalin *N*,*N*-dioxides have been found to be antiviral agents (6) and a large number of *N*-oxides have been shown to have antibacterial activity including the antibiotics aspergillic acid, emimycin, iodinin, and myxin. The latter compounds are all formally related to diketopiperazines.

Finally, several pyrrolizidine alkaloids such as senecionine *N*-oxide have been demonstrated to be the tumor inhibitory principals of plant extracts (7). It must be added, however that purine *N*-oxides have proven to be potent oncogenic[2] agents.

In order to gather insight into the structures and electronic configurations of this class of biologically important compounds, we have determined the ^{13}C chemical shift parameters of a series of pyridines and their *N*-oxides. ^{13}C chemical shifts have been shown to be an effective means for calculation of electron densities and *vice versa*. The sensitivity of the method derives from the fact that in the ^{13}C shielding constant tensor (8)

$$[1] \qquad \sigma = \sigma_d + \sigma_p + \sigma'$$

the paramagnetic term, σ_p, dominates, hence, the large dispersion of ^{13}C shifts results.

Pugmire and Grant (9) have reported that carbons α to the nitrogen in various five-membered nitrogen heterocycles are strongly shielded on protonation of the nitrogen, by about 9.0 p.p.m. Explanations of this phenomenon differ; Grant has proposed a change in the N—C bond order, while Adam *et al.* (10) have considered changes in the average excitation energy. This protona-

tion of a heterocycle has been envisioned as primarily a σ-bond change (10*a*). However, ^{13}C chemical shifts must be correlated with total (σ and π) electron density distributions (11, 12).

Results and Discussion

We have studied pyridine (**1**), α-, β-, and γ-picolines (2-, 3-, and 4-methylpyridines, **3**, **5**, **7**) and their *N*-oxides (**2**, **4**, **6**, **8**). The model compounds 4-cyanopyridine (**9**) and 2,5-dimethylpyridine (**10**) were also studied. The complete ^{13}C chemical shift assignments for compounds **1–10** are contained in Fig. 1 and Table 1 contains the chemical shifts for the pyridine – pyridine *N*-oxide pairs **1–8**. The ^{13}C assignments were made on the basis of previous literature values (13–15), model studies, and single resonance spectra. In

order to obtain the single resonance spectra we utilized gated proton decoupling. Our needs were the usual, to observe small ^{13}C–^{1}H splittings while cutting down scanning time by utilizing Overhauser enhanced signals due to pulsed double resonance effects (16). To this end we have had cause to construct a Digital Gate Width Control unit for pulsed double resonance studies (see Experimental).

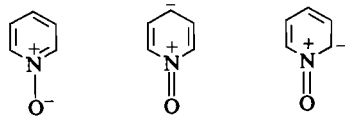
The first pulsed double resonance ^{13}C–Fourier transform (FT) spectrum, shown in Fig. 2*A*, is that of 4-picoline (4-methylpyridine, **7**). In Fig. 2*A* the spectrometer resolution is 1.25 Hz. The C_2,C_6 peaks on either side of the C_4 sextet show a *unique* coupling pattern. The same pattern is seen in the splitting pattern for 4-cyanopyridine, **9**, Fig. 2*C*. The FT resolution of **7** was increased as shown in Fig. 2*B* for the region 65–78 p.p.m. downfield from the solvent peak, $CHCl_3$. The resolution was increased to 0.31 Hz (8K data set; 2.5 kHz digitizing rate) and clearly shows the outermost lines as pentets while the innermost lines remain doublets. The C_3,C_5 peaks, not shown, resolve into 15 line doublets indicating a 4-bond coupling to the methyl protons. As well, the methyl resonance consists of broadened quartets of triplets, indicating a small (<0.3 Hz) 4-bond coupling between the side-chain methyl carbon and the 2,6-protons.

The single resonance ^{13}C spectrum of the 4-cyano compound **9** shows an altered C_3,C_5 region, illustrated in the following 0.31 Hz resolution segment, Fig. 2*D*. The expected eight line multiplet for each peak of the doublet is shown and reinforces the assignment for 4-picoline, **7**. The ^{13}C resonance for the cyano group, although broadened by the quadrupolar nitrogen, does show a triplet of triplets indicating side chain carbon to ring hydrogen coupling of 4-bonds.

Although several examples of long range cross-ring coupling have appeared in the literature there is a paucity of information on ring to side-chain coupling. Thus, while cross-ring coupling has been reported for pyrrole and 2,5-dimethylpyrrole by Weigert and Roberts (17), no data was reported for side-chain to ring ^{13}C–^{1}H coupling.

We have previously reported on ring to side-chain long range couplings in pyrroles (18) and the present single resonance work provides further evidence for such interactions.

Figure 1 lists the chemical shift behavior of the pyridines upon *N*-oxide formation as well as their assignments. In all cases, upon *N*-oxide formation, the *ortho* and *para* positions undergo an upfield ^{13}C shift of up to 10 p.p.m. (225 Hz), while the *meta* positions undergo a smaller but still substantial downfield shift. The significant changes in ^{13}C shifts represent a substantial change in the electronic configuration of *N*-oxides as compared to the unoxidized parent compound. The results agree qualitatively with the canonical forms by which pyridine *N*-oxide may be represented, *viz.*



Increased electron density at the C_2,C_6 and C_4 carbons due to the oxygen function cause a paramagnetic shift. The lesser downfield shift of C_3,C_5 may be explained by a resonance polar effect (19) wherein the increased electron density at C_2,C_6 or C_4 causes a decrease in electron density at C_3,C_5, hence, the 3- and 5-carbons shift downfield. Such an effect is a π (resonance) effect or an electric field effect. Support both for and against resonance quinoid forms for the *N*-oxides has been suggested by a very recent molecular structure determination of **2** (20) which shows a shortened C=N bond distance, and the X-ray data of Ulku *et al.* (21) who suggest N—O and C_2—C_3 bond distances disfavor quinoid forms.

To shed further light on the situation we have calculated the electron densities of our series of *N*-oxides *vs.* unoxidized substrates by means of CNDO/2 calculations using the Dobosh modification of the CNDO/MO computer program (22). Calculations were performed on an IBM 370-155 computer. The charge densities are given in Table 2.

The shielding tensor for ^{13}C can be represented by

$$\sigma = \sigma_d + \sigma_p$$

where σ_d is given by the formula

$$\sigma_d = (e^2/3mc^2) \sum_i \langle r_i^{-1} \rangle$$

where $\langle r_i^{-1} \rangle$ is the mean inverse distance of the ith electron from the nucleus (23).

$$\sigma_p^A = (2e^2h^2/3m^2c^2)(\Delta E)\langle r^{-3} \rangle_{2p}(P_1 - P_2 - P_3)$$

$$P_1 = (P_{xx} + P_{yy} + P_{zz})_{AA}$$

TABLE 2. Charge densities calculated by CNDO/2

Compound	Position 2	3	4	5	6	Me
1	3.8450	4.0278	3.9304	4.0278	3.8450	—

7	3.8420	4.0403	3.9215	4.0406	3.8420	3.9594
8	3.9949	3.9648	3.9834	3.9645	3.9944	3.9450

$$P_2 = (P_{xx}P_{yy} + P_{yy}P_{zz} + P_{zz}P_{xx})_{AA}/2$$

$$P_3 = \sum_{B \neq A} (P_{xx}P_{yy} + P_{yy}P_{zz} + P_{zz}P_{xx})_{AB}/2$$

where

$$(P_{xx})_{AB} = 2\sum_{i}^{occ} C_{xA}{}^{i}C_{xB}{}^{i}$$

and $C_{xA}{}^{i}$ is the coefficient of the $2P_x$ atomic orbital of carbon A in the ith MO. Here the principal simplifications are neglect of two center integrals and substitution of the average excitation energy, ΔE, for the electronic excitation energies (23). Thus, this semiempirical calculation is dependent on the choice of ΔE (10*b*), however, a recent study by Strong *et al.* (24) has shown that the use of ΔE (=10 eV) is a good approximation of the sum over all energy states, $\sum_{n \neq 0}(E_n - E_0)$, for a variety of compounds. The above treatment predicts a proportionality between the ^{13}C chemical shifts, $\Delta\sigma$, and the excess charge density, ΔQ_{2p}, calculated by CNDO/2 if $\Delta\delta$ is due to a total electron density change. A plot of $\Delta\delta$ *vs.* ΔQ_{2p} is shown in Fig. 3 for the compound pairs **1–8** based on the chemical shifts contained in Table 1 and the charge densities contained in Table 2.

In the cases of picolines and picoline *N*-oxides, the minimum interaction between the methyl group and heteroaromatic ring has been calculated before evaluating MO's. This was performed using the perturbation treatment of configuration interaction, PCILO (25). Thus, molecular geometries from X-ray, microwave, or

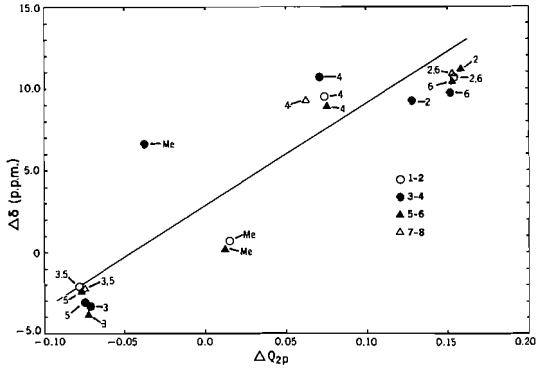

FIG. 3. Plot of ^{13}C chemical shifts between pyridines and their *N*-oxides *vs.* excess charge density. The solid line is represented by $\Delta\delta = \beta\Delta Q_{2p} + \alpha$ where $\beta = 58.85$ ($\sigma = 6.11$) and $\alpha = 2.539$ ($\sigma = 0.612$).

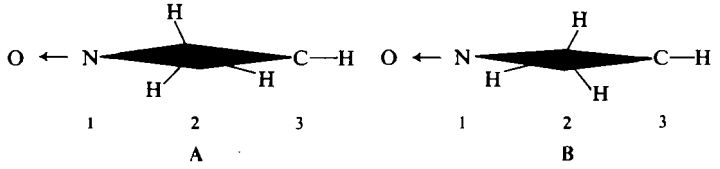
standard geometries are treated by PCILO. The output includes a new set of atomic coordinates corresponding to the minimum energy conformation which are used directly as the input data for the CNDO calculation.

Minimum energy calculations for compounds **3–8** predict essentially free rotation of the methyl substituent on the heteroaromatic ring except in the case of 2-picoline *N*-oxide (**3**). In the case of **3** a nonbonded interaction between N–O and C_2–CH_3 leads to a preferred conformation **A** where a methyl C—H eclipses the C_3—H bond. Conformation **A** is more stable by 3.2 kcal than conformation **B** where the methyl C—H would eclipse the N → O, and 1.2 kcal more stable than the staggered form (CH_3 rotated 90°).



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Evidence of a steric interaction between the methyl group and oxygen probably accounts for the failure of the C_2 methyl group to conform to the plot in Fig. 3. A nonbonded interaction of this sort might result in bond length or bond angle changes not accounted for in the CNDO calculations but reflected in the lower $^{13}CH_3$ chemical shift in compound **3** (Fig. 1 and Table 1).

Experimental

Compounds **1–10** were obtained commercially (K and K Chemicals, ICN, Eastman, and MCB), and used without further purification.

Spectra were obtained using a Computer Controlled Fourier Transform system described previously (26) and samples composed of 20% w/v solutions in $CHCl_3$ containing 20% C_6F_6 for field frequency locking and with TMS as internal standard. For the proton noise decoupled spectra FT system settings were: data set = 8192; pulse width = 50 μs; receiver skip = 100 μs; digitizing rate = 10 kHz. For pulsed double resonance spectra FT system settings were: data set = 8192; pulse width = 50 μs; receiver skip = 100 μs; IRRAD[3] = 1.0 s; program delay = 1.0 s; digitizing rate = 2.5 kHz.

The chemical shift values in Table 1 were obtained using a Varian XL-100 spectrometer fitted with a 20K TT100 Fourier transform accessory. Samples were 20% w/v in $CDCl_3$ (deuterium internal lock) using internal TMS as a standard. Settings were: data set = 16K; pulse width 22 μs; receiver skip = 100 μs; digitizing rate = 10 kHz.

[3]The pulse for gating the proton noise-decoupling frequency (IRRAD) is created when the leading edge of the receiver gating pulse (26) triggers a Gate Width Control Unit whose pulse length is selected by thumb wheels. The IRRAD pulse is delayed for a period just greater than required to accumulate 8192 data points at rates (in the present instance) as low as 2.5 kHz. Concomitant with the IRRAD pulse, the next r.f. pulse is delayed by a time greater than the IRRAD pulse length, using the program delay inherent in the routine NIN10 (26).

Diprotonation of 5-Acyl-1,2,3,4,5-pentamethylcyclopentadienes

RONALD F. CHILDS AND MAUNG ZEYA
Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

Received June 17, 1975

RONALD F. CHILDS and MAUNG ZEYA. Can. J. Chem. **53**, 3425 (1975).

5-Acyl-1,2,3,4,5-pentamethylcyclopentadienes could potentially be protonated on either or both of two sites, the diene moiety in the five-membered ring or the carbonyl oxygen. The protonation of a series of 5-acylpentamethylcyclopentadienes has been examined and evidence is presented which shows that the former site is essentially completely protonated in FSO_3H and that the carbonyl oxygen is also partially protonated. The extent of diprotonation is shown to be dependent both on the nature of the acyl groups and also the acidity of the medium. At temperatures above 40 °C these protonated species undergo a clean fragmentation to give protonated pentamethylcyclopentadiene from which pentamethylcyclopentadiene can be recovered in good yield on quenching the acid solution.

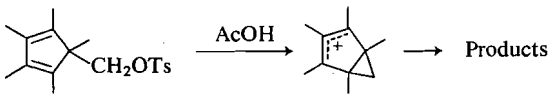
RONALD F. CHILDS et MAUNG ZEYA. Can J. Chem. **53**, 3425 (1975).

En théorie, les acyl-5 pentaméthyl-1,2,3,4,5 cyclopentadiènes peuvent se protoner sur l'un ou l'autre ou sur deux sites soit la portion diénique du cycle à cinq chainons ou l'oxygène du carbonyle. On a étudié la protonation d'une série d'acyl-5 pentaméthylcyclopentadiènes et on présente des données qui démontrent que le premier site est pratiquement complètement protoné dans le FSO_3H et que l'oxygène du carbonyle est aussi partiellement protoné. On montre que la quantité de diprotonation dépend à la fois de la nature des groupes acyles et aussi de l'acidité du milieu. A des températures supérieures à 40 °C, les espèces protonées subissent une fragmentation propre pour conduire au pentaméthylcyclopentadiène protoné à partir duquel on peut recupérer du pentaméthylcyclopentadiène avec de bons rendements en diluant la solution acide dans de l'eau.

[Traduit par le journal]

Introduction

In order to extend our studies on the bicyclo-[3.1.0]hexenyl cations and to explore the importance of the related cyclopentadienylcarbinyl cations in their five-fold degenerate rearrangement (1), it became necessary to prepare examples of these cations with an oxygen substituent at C_6. As it has been previously shown that ionization of the cyclopentadienyl ester **1** takes place with anchimeric assistance to give the bicyclohexenyl cations **2** (2), one obvious synthetic route to these cations would be the reaction of the carbonyl oxygen of a 5-acylcyclopentadiene with a suitable electrophile. When Lewis acids are used as the electrophile this approach works well (3), however the situation is much more complex when a proton is employed. We describe here the results of a study of the protonation of several 5-acylpentamethylcyclopentadienes in FSO_3H and show that protonation of the diene moiety occurs in addition to protonation of the carbonyl oxygen.



1 **2**

Results and Discussion

5-Acetylpentamethylcyclopentadiene, **3**, was protonated by extraction from CH_2Cl_2 into FSO_3H at −78 °C. From the complexity of the low temperature n.m.r. spectrum of the resulting solution, Fig. 1, it was quite clear that protonation was not simply occurring on the carbonyl oxygen. So as to ensure that the n.m.r. spectrum obtained derived simply from products of protonation of **3** and not subsequent rearrangements or fragmentations, the acid solution was quenched in an ether–HCO_3^- suspension to yield **3** in greater than 90% recovery.

In order to identify the resonance attributable to the C_6 methyl group, the related ketones **4**, **5**, and **6** were protonated with FSO_3H. Examination of the n.m.r. spectra of the solutions so obtained, showed that in each case a similar product to that obtained from **3** was formed. It was apparent that the resonance at 3.07 δ in the

spectrum of protonated **3** was due to the C_6 methyl group and that the rest of the signals must be due to the methyl groups on the five-membered ring.

The high field doublets present in the n.m.r. spectra of these protonated ketones suggested that protonation on the five-membered ring had occurred. Consistent with this is presence of a broad resonance 3.7–4.0 δ, which is in a similar position to that found for a methine proton adjacent to an allylic cation in a five-membered ring (4). Confirmation of this ring protonation was obtained by solution of **6** in FSO_3D when the n.m.r. spectrum so obtained differed from that of **6** in FSO_3H in that the two high field doublets at 1.68 δ and 1.45 δ were now singlets and the resonance at 4.10 δ was absent.

There are two possible structural isomers that could result from protonation of the diene moiety; the proton could be situated either *cis* or *trans* with respect to the acyl group. A similar situation has been found for the protonation of pentamethylcyclopentadiene **7** (5), which gives both **8** and **9** upon solution in super acids. The cations **8** and **9** indeed serve as good models for what would be expected for the positions of the ring methyl resonances of the ketones if protonation of the diene were occurring. Thus while the cations derived from **3**, **4**, **5**, and **6** lack the inherent symmetry of **8** and **9**, it can be seen from Table 1 that the n.m.r. spectra of these two sets of cations are very similar. It would appear clear that protonation of these ketones is taking place on the five-membered ring and that the products can be at least partially represented as being made up of a mixture of **10** and **11**.

While it has not been possible to distinguish between **10** and **11** on the basis of their spectra, it is apparent that they are not produced in

10 11

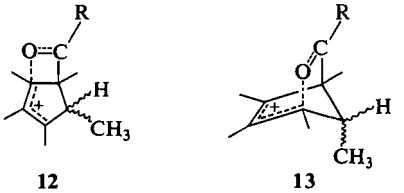
R = Acyl R = Acyl or protonated acyl

equal amounts on protonation of **3** at low temperatures. As is shown in Fig. 1*A*, the two isomers were initially present in a ratio of 80:20. At higher temperatures **10** and **11** interconverted and a thermodynamic product distribution was eventually reached in which the ratio was 15:85, Fig. 1*B*, which was the inverse of the initial kinetic distribution of products. This interconversion of the two isomers was rapid at 0 °C (pseudo first-order rate constant *ca.* 10^{-2} s^{-1}). When **3** was protonated in FSO_3H–SbF_5 (4:1), the same 80:20 kinetic distribution of products was observed, however in this stronger acid medium (6) no interconversion of the isomers **10** and **11** could be detected up to 40 °C, when other rearrangements and a general decomposition occurred. Comparable kinetic and thermodynamic product distributions have been reported with the cations **8** and **9** derived by protonation of **7** (5).

It is not unexpected that protonation of the diene moiety of these ketones is occurring in FSO_3H. 3-Methylene-1,4,4,5,5-pentamethylcyclopent-1-ene is sufficiently basic to be 50% protonated in 33% H_2SO_4 ($pK_a = -1.8$) (7) and other similarly alkylated cyclopentenyl cations are formed in acid of about the same strength. The carbonyl function, however, would be expected to be much less basic than the diene. Pinacolone, which is a reasonable model for **3**, is half protonated in 81% H_2SO_4 ($pK_a = -7.1$) (8). Even the aryl substituted carbonyl groups of **5** and **6**, are expected to be less basic than the diene. Acetophenone is half protonated in 74% H_2SO_4 ($pK_a = -6.15$) and *p*-methoxyacetophenone in 63% H_2SO_4 ($pK_a = -4.71$) (9). Fluorosulfuric acid is a much stronger acid than any of these aqueous sulfuric acid solutions (6) and it is sufficiently acidic to essentially completely protonate either of the two possible sites, the diene or the carbonyl oxygen. From the results presented above it is apparent that protonation of the diene to give a cyclopentenyl cation has taken place. The question arises, however, as to whether the carbonyl oxygen is also protonated in FSO_3H, either in competition with, or in addition to that of the diene.

In the unprotonated ketone **3**, the resonance attributable to the C_6 methyl group occurs at 1.50 δ. When dissolved in FSO_3H, the signal due to this methyl is shifted very considerably further downfield and appears at 3.07 δ. Typically the resonance of a methyl group adjacent to a protonated carbonyl group of an aliphatic ketone occurs at *ca.* 3.0 δ (10), for example, those of acetone and pinacolone occurring at 2.97 δ and 2.90 δ respectively.[1] The large downfield shift of the C_6 methyl group of **3** and the close similarity in its position to other protonated ketones is suggestive that the carbonyl oxygen of **3** is at least partially protonated in FSO_3H. Additional support for this suggestion can be found by examining the changes that occur in the aryl regions of the n.m.r. spectra of **5** and **6** on protonation and comparing them with those observed on protonation of acetophenone and *p*-methoxyacetophenone (11), Table 2.

It is conceivable that instead of protonation on oxygen some interaction of the carbonyl oxygen with the cyclopentenyl cation such as is shown with **12** or **13**, could account for the observed deshielding of the C_6 groups. However, the magnitude of this deshielding and the similarity of the resonance positions of the C_6 substituents with model protonated ketones would render this suggestion unlikely.



12 13

Further, definitive evidence for the protonation of the carbonyl group comes from the observation of an OH resonance in the n.m.r. spectrum of protonated **6**. The spectrum of **6**

[1]Care has to be taken in simply taking published literature values for the chemical shifts of cations as different standards are used as references. The values quoted in this paper are all based upon internal CH_2Cl_2 taken as 5.30 δ.

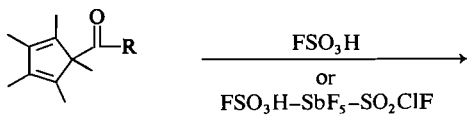
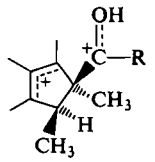
*In p.p.m., measured from internal CH_2Cl_2 taken as 5.30 δ for protonated species.

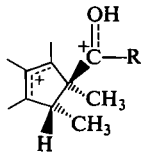
when protonated in a FSO_3H–SbF_5–SO_2ClF (4:1:4) medium was identical to that observed in FSO_3H with the exception that at low temperatures (−70 °C) an additional singlet at 12.70 δ was found. On warming the solution, this peak moved upfield and appeared to average with the solvent peak. The position of this low field resonance is just that expected for the OH signal of a protonated *p*-methoxyphenyl substituted ketone (11, 12). Thus, protonation of **6** would seem to be occurring both on the five-membered ring and also on the carbonyl oxygen. Either this could be taking place at the same time, resulting in the formation of two dications, or there could be an equilibrium between C and O protonated monocations. The latter possibility can be ruled out on several counts. Firstly, as has been previously pointed out, the resonance positions of both the ring methyls and also C_6 substituents are not consistent with a mixture of monoprotonated species being present. More importantly, in FSO_3H–SbF_5–SO_2ClF, observation of both hydroxy proton and methine proton resonances of protonated **6** at the same time shows that if two separate cations were responsible for these resonances, then their rate of interconversion must be slow on the n.m.r. time scale. However as the rest of the spectrum is not compatible with a slow equilibration between O and C monoprotonated cations, it can only be concluded that the hydroxy and methine proton resonances originate from the same species, dications **14** and **15**.[2]



6 R = *p*-$MeOC_6H_4$—



14 R = *p*-$MeOC_6H_4$—



15 R = *p*-$MeOC_6H_4$—

As was pointed out earlier, the n.m.r. spectra of the cations derived by solution of **3** in FSO_3H cannot be simply accounted for on the sole basis of protonation of the five-membered ring. It was not possible however, to detect any —O*H* proton resonance in the low temperature n.m.r. spectra of **3** in FSO_3H–SbF_5 media, although the addition of SbF_5 to the acid did produce an effect on the positions of the methyl resonances. In particular, it will be noted in Table 1 that the resonance attributed to the C_6 methyl moved downfield by 0.24 p.p.m. in going from FSO_3H to a FSO_3H–SbF_5 mixture. This would imply that diprotonation of **3** is not complete in FSO_3H, and that the system exists as a fast equilibrating mixture of mono- and diprotonated species, Scheme 1. As the acidity of the medium is enhanced by the addition of SbF_5, the equilibrium position would be expected to be displaced further in favor of the diprotonated forms, resulting in a downfield shift of the C_6-methyl group.

Thermal Fragmentation

While FSO_3H solutions of ketones **3–6** were stable for long periods of time when kept below

[2]While the two dications **14** and **15** should give rise to two *OH* resonances, only one such signal could be detected. The second *OH* resonance would be expected to be only some 20–25% of the one observed and could be either lost in baseline noise or coincident with the peak at 12.70 δ.

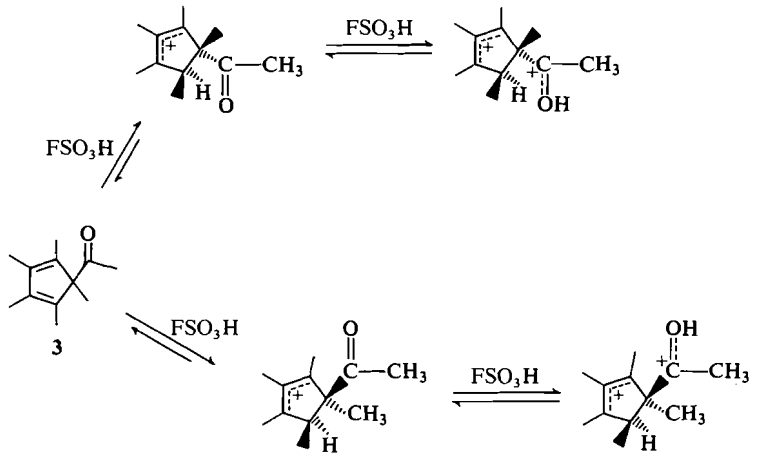

SCHEME 1

room temperature, at higher temperatures they underwent a thermal fragmentation to give protonated pentamethylcyclopentadiene. Thus **3** in FSO_3H reacted at 44 °C (half life 45 min) to give a mixture of **8** and **9**, Fig. 1*C*. Reaction of this acid solution with ether–HCO_3^- at −78 °C gave pentamethylcyclopentadiene **7** in high recovery.

$$\mathbf{3} \xrightarrow[\substack{44\,^\circ C \\ t_{1/2}\ 45\ min}]{FSO_3H} \mathbf{8} + \mathbf{9} \xrightarrow[\substack{ether \\ -78\,^\circ C}]{NaHCO_3} \mathbf{7}$$

The n.m.r. spectrum, Fig. 1*C*, of the products of this fragmentation reaction differed from that of authentic protonated pentamethylcyclopentadiene by the presence of an additional methyl resonance at 2.80 δ. Acyl cations are known to be stable in super acid media such as FSO_3H–SbF_5, and in the case of the fragmentation of protonated **3**, a methyl resonance attributable to the methyloxocarbonium ion at *ca.* 4 δ would be expected (13). The fragmentation of protonated **3** did not take place cleanly in FSO_3H–SbF_5, however the addition of SbF_5 to a FSO_3H solution after fragmentation caused a resonance corresponding to three protons, formally at 2.80 δ, to be shifted to 3.91 δ. It would appear that the acylium cation formed on fragmentation of **3** in FSO_3H must react with a nucleophile present in the acid medium to form a protonated acetic acid derivative, a reaction which is reversed upon the addition of SbF_5.

As pentamethylcyclopentadiene is not a readily available material (14) and acetylpentamethylcyclopentadiene can be obtained in one step from the commercially available hexamethylbicyclo[2.2.0]hex-2,5-diene (15, 16) the scale up of this fragmentation reaction in FSO_3H seemed attractive. However, whereas we have been able to carry out this reaction with up to 200 mg of material at a time, the yields drop as the reaction size is increased and these reactions do not as yet provide a viable alternate synthetic route to **7**.

Experimental

Nuclear magnetic resonance spectra were obtained on Varian HA-100 and A-60 spectrometers fitted with variable temperature probes. Probe temperature was measured with a copper–constantan thermocouple and Leeds and Northrup 8692 temperature potentiometer. The thermocouple was mounted at the appropriate depth in a nonrotating sample tube. Chemical shifts are referred to TMS or in the case of the cations, internal CH_2Cl_2 taken as 5.30 δ. Vapor phase chromatographic analyses were performed on an Aerograph 204B instrument, using 8 ft × $\frac{1}{8}$ in. columns packed with 15% SE-30 on 60–80 Chromosorb W and 20% Carbowax on 60–80 Chromosorb W.

Materials

Pentamethylcyclopentadiene was prepared by the method of de Vries (14). 5-Acylpentamethylcyclopentadienes were obtained by reaction of lithium pentamethylcyclopentadienide (15) with the appropriate acid halide (17). FSO_3H was distilled from a small quantity of NaF and stored in sealed glass ampoules until used. SbF_5 was doubly distilled and stored under nitrogen in a dry box. FSO_3H–SbF_5 solutions were prepared under nitrogen.

Preparation of Cations

Protonations in FSO_3H and FSO_3H–SbF_5 were carried out by slowly adding a CH_2Cl_2 solution (0.2 ml)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of the appropriate compound (20 mg) down the side of an n.m.r. tube which contained FSO_3H at −78 °C. After 15 s the two phases were mixed with a glass rod.

Preparation of Pentamethylcyclopentadiene, 7, from 5-Acetylpentamethylcyclopentadiene, 3

5-Acetyl-1,2,3,4,5-pentamethylcyclopentadiene, **3**, (178 mg) in methylene chloride (1 ml) was extracted into $HFSO_3$ (2 ml) kept at −78 °C. The sample was gradually warmed to 40 °C and kept for 3–4 h, complete reaction being checked for by n.m.r.

A suspension of sodium bicarbonate (5 g) in ether (25 ml) was stirred at −78 °C while the acid solution was added dropwise. The resulting mixture was warmed to 0 °C. Ice-water was added to the mixture and the stirring was continued for 15 min. The resulting solution was filtered *in vacuo* and the filtrate extracted with ether (3 × 25 ml). The extract was dried (Na_2CO_3) and evaporation of ether *in vacuo* yielded 148 mg of organic material.

The product was characterized as pentamethylcyclopentadiene by the comparison of its n.m.r. spectrum with that of an authentic sample. No other signal was observed in the n.m.r. spectrum of the product. Only two peaks were observed on the chromatogram when the product was subjected to v.p.c. analysis. The ratio of the amount of the major product to that of the minor was 19:1. The major product was collected and identified as pentamethylcyclopentadiene by the comparison of the n.m.r. spectra with an authentic sample.

Hindered Internal Rotation About Aryl C—N Bonds in Aryl Substituted Heterocyclic Compounds: 3-Aryl-2-benzyl-4(3*H*)-quinazolinones

LAWRENCE D. COLEBROOK AND H. GWYNNE GILES
Department of Chemistry, Sir George Williams Campus, Concordia University, Montreal, Quebec H3G 1M8

Received November 13, 1974[1]

LAWRENCE D. COLEBROOK and H. GWYNNE GILES. Can. J. Chem. **53**, 3431 (1975).

The proton magnetic resonance spectra of a number of 3-aryl substituted 2-benzyl-4(3*H*)-quinazolinones indicate that internal rotation about the aryl C—N bond is highly hindered. Substantial free energy barriers (18.9–19.8 kcal/mol) have been measured even when the aryl groups lack bulky *ortho* substituents.

LAWRENCE D. COLEBROOK et H. GWYNNE GILES. Can. J. Chem. **53**, 3431 (1975).

Les spectres r.m.n. d'un certain nombre d'aryl (substitués)-3 benzyl-2 (3*H*)-quinazolinones-4 indiquent que la rotation interne autour du lien C(aryl)—N est très empêchée. On a mesuré des barrières importantes (18.9–19.8 kcal/mol) d'énergie libre même lorsque les groupes aryles ne portent pas de substituants *ortho* volumineux.

[Traduit par le journal]

As part of a study of restricted internal rotation about aryl C—N bonds in aryl substituted heterocyclic compounds (1–5)[2], we have prepared a series of 3-aryl substituted 2-benzyl-4(3*H*)-quinazolinones and have investigated their proton magnetic resonance spectra. Of particular interest are the barriers to internal rotation of the 3-aryl groups and their dependence on the nature of the 3-aryl group substituents. The steric barriers to aryl group rotation in these compounds are expected to be high, since, in the transition states for rotation there should be severe crowding between the *ortho* substituents on the 3-aryl group and the heterocyclic ring substituents adjacent to the 3-position, *i.e.* the benzyl group in the 2-position, and the oxygen atom of the carbonyl group. Large dihedral angles between the 3-aryl and the heterocyclic moieties are expected in the conformational ground states (4), which are enantiomeric in the compounds studied.

The 3-aryl-2-benzyl-4(3*H*)-quinazolinones are stereochemically analogous to biphenyls, and undergo similar interconversion processes between enantiomeric rotational isomers. Other examples of compounds in which the biphenyl-like restriction to rotation about C—N bonds linking two cyclic moieties is predominantly steric in origin have been reported: 2-aryl-1,4-dihydro-3(2*H*)-isoquinolinones (6), 3-aryl-3,4-dihydro-2*H*-1,3-benzoxazines (7), 2-methyl- and 2,2-dimethyl-1-aryl-1,2-dihydro-4,6-diamino-*s*-triazines (1, 2), 3-arylhydantoins and 3-aryl-2-thiohydantoins (1–5), and 1-arylhydantoins (3, 5). The stereochemistry, based on the biphenyl model, of the process of torsion about the C—N pivot bonds of such compounds has been discussed in detail by Shvo *et al.* (6).

In addition to acting as a steric blocking group to rotation of the 3-aryl group, the 2-benzyl substituent functions as a 'probe' to enable the restricted rotational process to be detected in the proton magnetic resonance spectrum. Provided that the substitution pattern on the 3-aryl group is unsymmetric, the benzylic methylene protons in these compounds are diastereotopic, and may be expected to give rise to an AB quartet if rotation of the 3-aryl group is slow on the n.m.r. time scale. If aryl group rotation is fast on the n.m.r. time scale, the AB quartet should collapse to a singlet. Rate constants should be obtainable by complete line shape analysis of the partially collapsed methylene group signals at intermediate rates of rotation (8), providing that the chemical shift difference is sufficiently large. Rotation of the 3-aryl group is the only conformational exchange process in these compounds which can result in exchange of the environments of the benzylic methylene protons, causing collapse of the AB quartets.

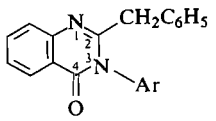
Results and Discussion

With a suitable choice of solvent, all eight compounds prepared for this investigation exhibited AB quartets, arising from the benzylic methylene protons, in their 100 MHz n.m.r. spectra at normal probe temperatures (about 26 °C), indicating that rotation of the 3-aryl group about the aryl C—N bond was slow on the n.m.r. time scale. The chemical shifts between the benzylic methylene protons showed a strong solvent dependence, which is not easily predictable. Thus, the 3-(2-tolyl), **4**, and the 3-(2-fluorophenyl), **5**, compounds exhibited



1 Ar = 2-chloro-6-methylphenyl
2 Ar = 2-bromophenyl
3 Ar = 2-chlorophenyl
4 Ar = 2-tolyl
5 Ar = 2-fluorophenyl
6 Ar = β-naphthyl
7 Ar = 3-bromophenyl
8 Ar = 3-acetylphenyl

no chemical shift difference between the benzylic methylene protons in nitrobenzene solution. The chemical shift differences for the remaining six compounds ranged from 0.088–0.295 p.p.m. These two compounds showed chemical shift differences of 0.057 and 0.143 p.p.m., respectively, in bromoform solution. In view of the high rotational barriers exhibited in nitrobenzene solution by all the other compounds (**1–3**) with *ortho*-substituted 3-aryl groups, and the behavior of these two compounds in bromoform solution, the observation of a singlet for the benzylic methylene protons cannot be attributed to the effects of fast rotation of the 3-aryl group.

Compounds with ortho-Substituted 3-Aryl Groups

Attempts to measure the rate of rotation of the 3-aryl groups by line shape analysis of the AB quartets at elevated temperatures failed for all those compounds (**1–5**) with *ortho*-substituted 3-aryl groups. No indications of collapse of the AB quartets through time averaging were detectable at the highest temperatures employed (150–187 °C), even for compounds with small blocking substituents, such as fluoro, in an *ortho* position.

Minimal possible values for the free energies of activation (Table 1) were estimated from rate constants (9) calculated from the chemical shifts and coupling constants (10) on the assumption that the spectra had collapsed to the coalescence points at the highest temperatures employed. Since no signs of incipient temperature dependence were observed at these sample temperatures, it may safely be assumed that the true free energies of activation for 3-aryl group rotation in these compounds are considerably higher than those shown in Table 1. These figures suggest that compounds of this type should be resolvable and have substantial optical stability at normal temperatures.

Compounds with meta-Substituted 3-Aryl Groups

In view of the high barriers to internal rotation in those compounds with blocking substituents in the ortho positions of the 3-aryl groups, three compounds (**6–8**) were prepared in which the only blocking substituents present in the *ortho*-positions are hydrogen atoms (2). Barriers to internal rotation in these compounds would be expected to be much lower than in the other series. The steric requirements of one of the *ortho* hydrogen atoms may be increased by buttressing with the adjacent substituent. This situation is unavoidable since an unsymmetrical substitution pattern on the 3-aryl group is necessary to render the benzylic methylene protons diastereotopic.

These compounds showed well resolved AB quartets arising from the benzylic methylene protons, with chemical shift differences of 0.088–0.132 p.p.m. (nitrobenzene solutions). When the samples were warmed the AB quartets collapsed to singlets, with coalescence temperatures in the range 94–116 °C (Table 1), indicating fast internal rotation about the aryl C—N bonds on the n.m.r. time scale. The original spectra reappeared when the samples were cooled.

Although, in principle, a complete set of activation parameters should be obtainable by complete line shape analysis of the partially collapsed AB quartets over a range of temperatures, this was not considered practicable in the present case. The chemical shifts between the diastereotopic methylene protons are small, and the nuclei tightly coupled (Table 1), limiting the temperature range over which the spectra show sufficient temperature dependence for accurate line shape analysis. In such cases only

free energies of activation are likely to be accurate. Values of $\Delta G^{\ddagger}$ at the coalescence temperatures, calculated from rate constants (9) obtained by computer simulation of the line shapes (11) in the coalescence region, are reported in Table 1.

Compensation for the poor blocking ability of the *ortho* hydrogen atoms in these compounds is provided by the high steric requirements of the 2-benzyl group and the oxygen atom of the carbonyl group in the 4-position, resulting in severe steric interaction between the two moieties in the transition states for aryl group rotation. A large contribution to the steric barrier to rotation appears to result from the geometry at the 2-position of the hetero ring. Coplanarity between the bond joining the benzylic carbon and C-2 with the hetero ring maximizes steric interaction between the benzyl group and the ortho substituents on the 3-aryl group in the transition states for rotation (assumed to be approximately planar). In closely related compounds with the N-1—C-2 bond reduced, so that the hydridization at C-2 is formally sp^3, the barriers to rotation are considerably lower (12).

Experimental

Preparation of Materials

The 2-benzyl-3-aryl-4(3*H*)-quinazolinones were prepared by an adaptation of the method of Klosa (13). *N*-(Phenylacetyl)anthranilic acid (prepared by the method of de Diesbach *et al.* (14)) was employed as the precursor in all cases. Reaction of this compound with the appropriate aryl amine was carried out in the presence of polyphosphoric acid. Normally, two recrystallizations from methanol yielded analytically pure products. However, **8** required chromatography before the pure material was obtained.

Experimental details of two representative syntheses are given. No attempts were made to maximize yields. Analytical data are shown in Table 2. The structures were confirmed by n.m.r. and i.r. spectra. Elemental analyses were performed either by Galbraith Laboratories, Knoxville, Tennessee, U.S.A., or by Alfred Bernhardt, Mikroanalytisches Laboratorium, West Ger-

many. Infrared spectra were taken (KBr discs) on a Perkin-Elmer 457 spectrophotometer, and melting points on a Mettler FP1 apparatus.

2-Benzyl-3-(2-naphthyl)-4-(3H)-quinazolinone, **6**

N-(Phenylacetyl)anthranilic acid (10.0 g, 0.0392 mol), 2-naphthylamine (Eastman) (3.26 g, 0.0228 mol) and polyphosphoric acid (40 g) were heated to 180 °C with stirring, and kept at that temperature for 30 min. After cooling, the solution was poured into a concentrated sodium carbonate solution. When neutralization was complete, the product was extracted with chloroform (100 ml). When the resulting solution was washed with hydrochloric acid (6 *N*, 50 ml) a white precipitate (probably the amine salt) formed in the organic layer. This precipitate was removed by filtration. The process of washing with hydrochloric acid was repeated until no more precipitate formed. The chloroform layer was then neutralized with sodium carbonate solution, washed, and dried over molecular sieves (British Drug Houses, type 4A). The chloroform was removed under vacuum to yield an oil that solidified after standing for 30 min. The crude product was recrystallized three times from methanol to give pale needles that were then dried under vacuum.

2-Benzyl-3-(3-acetylphenyl)-4(3H)-quinazolinone, **8**

N-(Phenylacetyl)anthranilic acid (10.0 g, 0.0392 mol), *m*-aminoacetophenone (K and K) (5.29 g, 0.0392 mol), and polyphosphoric acid (44 g) were heated to 180 °C with stirring and kept at that temperature for 25 min. After cooling, the solution was poured into a concentrated sodium carbonate solution. When neutralization was complete the product was extracted with chloroform (100 ml) and the resulting solution was washed with hydrochloric acid (6 *N*, 50 ml) to remove any unreacted amine, and was then washed with sodium bicarbonate solution. The organic layer was separated and the chloroform solvent was removed under vacuum, yielding a brown oil. The oil was dissolved in an ether–ethanol (50:50) mixture and was chromatographed on silica gel (100 g, 60–120 mesh, British Drug Houses). The column was first eluted with ether (fraction 1, 120 ml, orange; fraction 2, 80 ml, black; fraction 3, 130 ml, orange), then ethanol (fraction 4, 60 ml, yellow; fraction 5, 120 ml, orange), and finally chloroform (fraction 6, 500 ml, yellow). The solvent was evaporated from fraction 2 to yield a red oil. The oil was dissolved in acetone and the solution was poured into water, yielding a yellow suspension. After 2 days a yellow solid which had formed was filtered off and dried under vacuum, then recrystallized from methanol.

Magnetic Resonance Measurements

Proton magnetic resonance spectra were taken using a Varian HA-100 spectrometer operating in the field sweep mode and employing the standard variable temperature equipment. The AB quartets arising from the benzylic methylene protons of the substituent in the 2-position were recorded at maximum convenient scale expansion. Temperatures, believed to be accurate to ± 2°C, were determined immediately after each spectrum was taken by measuring the peak separation of a standard Varian ethylene glycol sample.

Because of the high barriers to internal rotation in this series of compounds and the consequent high temperatures at which spectral measurements must be made, it is necessary to use high boiling solvents. The choice of solvent is important, since the chemical shift differences resulting from anisotropic shielding by the aryl groups may be small and solvent dependent. For example, the room temperature spectrum of the 3-(3-bromophenyl) compound, **7**, in bromoform solution shows a singlet rather than an AB quartet in the methylene region at $\delta 3.85$, although quartets appear when nitrobenzene or deuterochloroform solutions are used. In the case of the 3-(2-fluorophenyl) compound, **5**, AB quartets were exhibited by deuterochloroform and bromoform solutions, and singlets by nitrobenzene, DMSO-d_6, and 2-chloropyridine solutions. Nitrobenzene was found to be a useful high boiling solvent for this series, but, as noted, it could not be used in all cases.

This work was supported by grants from the National Research Council of Canada.

A Novel Base-promoted Rearrangement of Penicillin G

SAUL WOLFE, JEAN-BERNARD DUCEP, AND JOHN DWAYNE GREENHORN
Department of Chemistry, Queen's University, Kingston, Ontario K7L 3N6

Received June 30, 1975

SAUL WOLFE, JEAN-BERNARD DUCEP, and JOHN DWAYNE GREENHORN. Can. J. Chem. **53**, 3435 (1975).

The cleavage of methyl benzoate by alkyl-oxygen fission is just as efficient with lithium isopropyl and *tert*-butylmercaptide as with lithium *n*-propylmercaptide when hexamethylphosphoric triamide is employed as the solvent. The reaction of methyl benzylpenicillinate with lithium *tert*-butylmercaptide does not lead to cleavage of the ester but, rather, to a dehydration product having a thiazole structure.

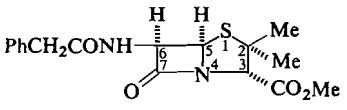
SAUL WOLFE, JEAN-BERNARD DUCEP et JOHN DWAYNE GREENHORN. Can. J. Chem. **53**, 3435 (1975).

Lorsque le HMPT est utilisé comme solvant, la fission alkyl-oxygène du benzoate de méthyle est aussi efficace avec les isopropylthiolate et *tert*-butylthiolate de lithium qu'avec le *n*-propylthiolate de lithium. La réaction de benzylpenicillinate de méthyle avec le *tert*-butylthiolate de lithium ne conduit pas à la coupure de l'ester mais plutôt à un produit de déshydratation possédant la structure d'un thiazole.

[Traduit par le journal]

A number of base-catalyzed reactions of penicillin derivatives have been reported recently. These include epimerization at C6 (1), and rearrangement to anhydropenicillins (2), to 1,3-thiazines (3), to 1,4-thiazines (4), and to 1,4-thiazepines (5).

We report here a novel rearrangement of **1**, the methyl ester of Penicillin G. The rearrangement was encountered in the course of an unsuccessful attempt to effect hydrolysis of the



1

ester by a modification of the method of Bartlett and Johnson (6). These workers found that lithium *n*-propylmercaptide (**2**), in hexamethylphosphoric triamide (HMPT), effects efficient nucleophilic displacement of carboxylate anions from methyl esters at room temperature. Because the β-lactam carbonyl group of a penicillin ester seemed likely to offer a ready alternative site for attack by a nucleophilic reagent, it was considered that a bulkier nucleophile than *n*-propylmercaptide would be required.

To check that cleavage of a methyl ester is not impaired by such a modification, the cleavage of methyl benzoate was examined using **2**, lithium isopropylmercaptide (**3**), and lithium *tert*-butylmercaptide (**4**). All reactions were performed, as described by Bartlett and Johnson, in dry oxygen-free HMPT, with the additional modification that *n*-butyllithium was employed in place of lithium hydride to generate the reagent. This procedure permitted the filtration step to be avoided and, in each case, afforded a clear, pale yellow solution which was stable in the cold for at least one month and from which aliquots could be withdrawn for reaction as required.

After 1 h at room temperature, the yields of benzoic acid from methyl benzoate were 89%, 98%, and 99%, using **2**, **3**, and **4**, respectively. No ester cleavage was observed when the HMPT solvent was replaced by tetrahydrofuran.

The ester **1** was recovered unchanged following exposure to excess *tert*-butylmercaptan in HMPT for 2 days. However, it reacted rapidly with the lithium salt of the mercaptan. One equivalent of **4** was added dropwise to **1** during 2.5 h. As the addition proceeded, a transient orange color appeared, which slowly faded to a pale yellow. Only traces of unidentified, biologically inactive, acidic material were obtained, most of the product remaining in the neutral phase. From this phase was obtained, in 80% yield, an optically inactive crystalline compound,

m.p. 128–129 °C, which analyzed as $C_{17}H_{18}N_2O_3S$, *i.e.*, **1** *minus* H_2O.

The nuclear magnetic resonance (n.m.r.) spectrum showed a broad one proton singlet at δ 8.58, and sharp singlets at 7.98 (1H), 7.30 (5H), 4.32 (2H), 3.74 (3H), 2.20 (3H), and 1.92 (3H). The compound thus retains the benzyl and methoxycarbonyl groups, and the C2 methyl groups have become vinylic.

The infrared (i.r.) spectrum displayed a sharp N—H peak at 2.97 μm, ester absorption at 5.80 μm, and, in addition, strong peaks at 5.95, 6.50, and 6.71 μm, the latter being assigned to the isopropylidene group. The peaks at 5.95 and 6.50 are characteristic of α, β-unsaturated γ-thiolactones (2*a*) and strained thiazolines, respectively.[1] They also correspond to the 'I' and 'II' peaks of thiazoles (7). The one proton singlet at 7.98 in the n.m.r. is reminiscent of peaks in the same region in the thiazepines **5** (H7) (8) and **6** (H5) (5); the H5 proton of thiazoles is also found in this region (9).

The spectral data are consistent with structures **7** and **8** as the rearrangement products. The formation of **7** can be rationalized using various precedents in the literature. Thus, thiazepines of type **6** are known products of base-promoted rearrangement of the penicillin nucleus (5), and both **5** and **6** (3, 5, 10) undergo ready β-elimination (**5** → **9**; **6** → **10**). In the case of the ester **1**, these two reactions lead to an intermediate **11**, which can cyclize in the manner indicated to the thiazolone **7**.

The formation of **8** can be rationalized in terms of the chemistry of mercaptoazetidinones (**12**) (11) and related (12) compounds. In this case, the rearrangement would be initiated by the β-elimination **1** → **12**(R = $PhCH_2$) → **13** ⇄ **14** and the thiazole would be produced following cyclization of this latter intermediate. 16

tively, **12** might cyclize to the thiazoline **15**. Such thiazolines are known (13) to undergo prototropic rearrangement to thiazoles of type **8**.

A distinction between the two proposed structures **7** and **8** could be obtained on the basis of the mass spectrum, which showed prominent peaks at 330 (M^+), 202, 175, and 128. The peaks at 202 and 128 are compatible with either structure, by the fragmentations indicated, but the peak at 175 corresponds to a fragment **16** (calcd. 175.0456; found 175.0456), which must originate from the thiazole **8**.

To check this assignment, methyl 2-benzylthiazole-4-carboxylate (**17**) was prepared by the Hantzsch synthesis shown in Scheme 1. Its mass spectrum contained a prominent peak at 175. Attempts to convert **17** to **8**, or to isolate **17** following ethanolysis of the unknown compound were unsuccessful. The thiazole **8** was, therefore, synthesized from **1** by the route shown in Scheme 2, which is the method employed by Cooper and

José (13) to prepare the analogous thiazole derivative of Penicillin V. The compound obtained from the thiazoline **15** was identical in all respects with the lithium *tert*-butylmercaptide rearrangement product. The intriguing possibility that **8** is formed via **15** in this latter rearrangement remains to be established.

Experimental

Hexamethylphosphoric triamide was distilled from lithium aluminum hydride or lithium hydride at 116–117 °C/19–20 Torr and, after degassing, was stored under nitrogen over 4A molecular sieves in a flask fitted with a rubber septum. *n*-Butyllithium in hexane, obtained from Ventron Inc., was determined by acid–base titration to be 2.28 *M*. Commercial isopropylmercaptan was distilled before use; *n*-propyl (15) and *tert*-butyl mercaptan (16) were prepared by the literature methods. All reactions with organometallic reagents were performed under an atmosphere of dry nitrogen.

The i.r. spectra were recorded on a Beckmann 5A spectrometer; n.m.r. spectra were obtained on Varian A60 or T60 spectrometers, in $CDCl_3$, with internal TMS. The mass spectra were obtained on a JEOL-JMS-O1SC instrument.

Reaction of Methyl Benzoate with Lithium n-Propylmercaptide

To HMPT (10 ml) were added successively, at room temperature, *n*-propylmercaptan (0.8 ml, 8.9 mmol) and *n*-butyllithium (3.5 ml, 8 mmol). To the resulting pale yellow solution was added methyl benzoate (300 mg, 2.2 mmol). There was no significant color change. The reaction mixture was stirred for 1 h, then poured into cold *N* HCl (150 ml) and extracted with ether. The crystalline residue obtained following evaporation of the dried ether solution was shaken with a mixture of ether and 2 *N* sodium hydroxide. Acidification of the aqueous phase then afforded 238 mg (89%) of benzoic acid, m.p. 121–122 °C, identified by i.r., n.m.r. and a mixture melting point with authentic material.

Repetition of this experiment, using isopropyl and *tert*-butylmercaptan in place of *n*-propylmercaptan, led to benzoic acid in 98% and 99% yields, respectively.

Reaction of 1 with Lithium tert-Butylmercaptide

The methyl ester of penicillin G (215 mg, 0.62 mmol), in HMPT (1.5 ml), was treated dropwise during 2.5 h with 1.4 ml (0.66 mol) of a 0.47 *M* solution of lithium *tert*-butylmercaptide in HMPT. An orange color was produced with each drop of the reagent, and this color faded slowly to a pale yellow. The final yellow solution was allowed to stand for 2 h and then diluted with ice-cold water, acidified to p*H* 2.5, and extracted with ether. The ether extract was washed with bicarbonate, dried, and evaporated to yield a solid residue. Recrystallization from ethyl acetate – hexane afforded 170 mg (80%) of **8**, m.p. 128–129 °C.

Anal. Calcd. for $C_{17}H_{18}N_2O_3S$: C, 61.79; H, 5.49; N, 8.48; S, 9.66. Found: C, 62.02; H, 5.42; N, 8.52; S, 9.77.

Synthesis of Methyl 2-Benzylthiazole-4-carboxylate

Phenylacetic acid (35 g) and urea (15 g) were ground together and the mixture was heated at 160 °C for 2 h. It was then cooled, triturated with water, and filtered. The resulting solid was washed successively with *N*/10 NaOH and water, and dried overnight *in vacuo* at 70 °C. The resulting material was then recrystallized from hot ethanol to give 14.8 g (42%) of phenylacetamide, m.p. 154–157 °C. To this 14.8 g (0.11 mol) of material, in 120 ml of refluxing dry xylene, was added P_4S_{10} (7.5 g) during a 20 min period, and the refluxing was continued for an additional 1.5 h. The mixture was then allowed to stand for 24 h, and the supernatant material was decanted from the precipitated polymer and washed with 2 *N* NaOH and water, dried, and evaporated. The phenylthioacetamide was used directly in the next step.

To ethyl bromopyruvate (9.75 g, 0.05 mol), cooled in an ice bath, was added phenylthioacetamide (7.55 g, 0.05 mol). When the addition was complete, the mixture was heated cautiously to 100 °C and maintained at this temperature for 1 h. The sticky brown residue was triturated with hot chloroform, filtered to remove some insoluble material, and the chloroform solution was evaporated to dryness. The residue, in the minimum amount of methylene chloride, was filtered through a column of 200 g of silica gel. Elution with methylene chloride and evaporation of the eluate afforded a crystalline residue. Recrystallization from hot ethyl ether gave 2.24 g of long white fluffy needles, m.p. 68.0–69.5 °C. Nuclear magnetic resonance: 8.03 (1H, s), 7.28 (5H, s), 5.27 (2H, s), 4.42 (2H, q), 4.37 (3H, s), and 1,37 (3H, t).

Anal. Calcd. for $C_{13}H_{13}NO_2S$: C, 63.13; H, 5.30. Found: C, 63.20; H, 5.26.

Conversion of 1 to 8 via the Sulfoxide

The methyl ester of Penicillin G (1.23 g, 3.54 mmol), in methylene chloride (36 ml), was treated, dropwise with stirring during 1.5 h, with a cooled (0 °C) solution of 85% *m*-chloroperbenzoic acid (0.72 g, 3.54 mmol) in methylene chloride (28 ml). The solution was then warmed to room temperature and stirred overnight. It was then washed with saturated bicarbonate (2 × 15 ml), 5% bisulfite (2 × 15 ml), bicarbonate again (2 × 10 ml), dried, and evaporated to give a pale yellow solid (1.08 g, 84%). A portion (0.62 g) was recrystallized from ethyl acetate – petroleum ether to give fine white plates (0.44 g, 52% overall yield), m.p. 122–123 °C.

The sulfoxide (0.33 g, 0.916 mmol) and trimethylphosphite (0.12 ml, 0.124 g, 1.0 mmol) were refluxed in 12 ml of dry benzene. The reaction was followed by thin layer chromatography until the sulfoxide had disappeared (42 h). The solution was then evaporated to give a white amorphous solid in quantitative yield. A portion (0.082 g) was recrystallized from ethyl acetate – petroleum ether to give fine elongate prisms (0.060 g, 73%), m.p. 98–99 °C. Nuclear magnetic resonance 7.23 (5H, s), 5.90 (2H, s), 4.92 (3H, m), 3.85 (2H, s), 3.72 (3H, s), and 1.68 (3H, s). This β,γ-olefin (0.23 g, 0.76 mmol) and triethylamine (0.08 g, 0.79 mmol) were stirred in absolute methanol (15 ml) for 25 min, and the solution was then evaporated to give the thiazoline **15** (R = $PhCH_2$) as a sticky solid. The n.m.r. spectrum suggested sufficient purity to proceed to the next step: 7.17 (5H, s), 5.98 (1H, d, J = 4 Hz), 5.80 (1H, d, J = 4 Hz), 3.88 (2H, s), 3.72 (3H, s), 2.18 (3H, s), and 1.62 (3H, s).

The oily thiazoline **15** (0.23 g, 0.70 mmol) was refluxed with trifluoroacetic acid (6 ml) in chloroform (15 ml) for 2 h, at which time the n.m.r. spectrum showed the presence of **8** and **15** in an approximately 1:1 ratio. Further refluxing did not increase the proportion of **8**. The solvent was, therefore, removed and a portion of the residue (0.19 g) was subjected to preparative layer chromatography (Merck silica gel 60 F-254, 2 mm) using benzene – ethyl acetate (3:1) as eluant. The fraction containing the thiazole **8** weighed 0.0625 g (27%). Recrystallization from ethyl acetate – hexane gave fine white needles, m.p. 129–130 °C. The i.r. and n.m.r. spectra were identical to those of material prepared in the lithium *tert*-butylmercaptide rearrangement.

We thank the National Research Council of Canada for financial support of this research, and Dr. R. D. G. Cooper for suggesting the synthesis shown in Scheme 2.

A Photoelectron Investigation of the Peroxide Bond

R. S. BROWN

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2E1

Received March 14, 1975

R. S. BROWN. Can. J. Chem. **53**, 3439 (1975).

The photoelectron spectra of several peroxides and their interpretation is presented. The effects of substituents is separated from vicinal orbital interactions using as a guideline the effect of similar substitution on the ether analogues. It is found that by comparison of Raman spectroscopic frequencies of the peroxide ground state, and vibrational frequencies for the ion (via pes), that the HOMO of peroxides is antibonding with respect to the O—O linkage. Additionally, the dependence of the splitting of the two highest occupied molecular orbitals on dihedral angle is verified by the pe spectra of several well-defined cyclic peroxides. Finally, the pe spectrum of tetramethyl-1,2-dioxacyclobutane (tetramethyl dioxetane) is presented indicating that it is not unlike other cyclic peroxides.

R. S. BROWN. Can. J. Chem. **53**, 3439 (1975).

On présente les spectres photoélectroniques de plusieurs péroxydes ainsi que leur interprétation. On sépare les effets des substituants des interactions orbitalaires vicinales en faisant appel comme référence les effets de substitutions semblables sur des éthers similaires. On a trouvé par comparaison des fréquences de vibration spectroscopique de l'état fondamental du peroxyde en Raman et les fréquences de vibration de l'ion (par l'intermédiaire de spe) que l'HOMO des peroxydes est antiliante par rapport au lien O—O. De plus on a vérifié, à l'aide de spectres pe de plusieurs peroxydes cycliques bien définis, la relation qui existe entre le dédoublement des deux HOMO et l'angle dièdre. Finalement on présente le spectre pe du tétraméthyldioxa-1,2 cyclobutane (tétraméthyl dioxétanne); il n'est pas dissimilaire de ceux d'autres peroxydes cycliques.

[Traduit par le journal]

Recently photoelectron (pe) spectroscopic studies have been conducted on lone pair – lone pair interactions occurring in such molecules as hydrazines (1) and disulfides (2). The situation for hydrazines has proved interesting and a clearer understanding for the n–n interactions as a function of dihedral angle has emerged.

Very recently, initial work of Batich and Adam (3) on some alkyl peroxides, and Osafune and Kimura (4) on hydrogen peroxide has provided some information about the n–n interactions within peroxides. Unlike the hydrazines in which there is only one 'non-bonded' pair of electrons per nitrogen yielding an n^+ and n^- combination which are easily identified, the peroxides present a rather more complex situation in that each oxygen formally possesses two n_0 pairs of electrons. Additionally, the greater electronegativity of oxygen places the n^+ combination(s) at relatively high ionization potentials (ip) making their accurate location difficult.

While peroxides represent an important class of compounds, little of the wide variety of information available on such molecules (5) relates to their electronic structure. The following study was undertaken to investigate electronic interactions within peroxides.

In particular, two areas were investigated concerning the distinction of substituent effects from n-orbital interactions, and the relationship of ionization potential and dihedral angle.

The first section of the following deals with the changes in ip of an isolated oxygen 2p orbital when the substitution on that oxygen atom changes from two hydrogens to two *tert*-butyl groups. With this guideline in hand we will then turn our attentions to an investigation of the additional perturbations in effect when two oxygens are linked together and symmetrically substituted.

Experimental

Photoelectron spectra were recorded using a MacPherson Model 36 ESCA spectrometer equipped with a He(I) ionization source. All spectra were run using argon as an internal calibrating gas. While under optimum conditions the resolution of the $Ar_{3/2}$–$Ar_{1/2}$ doublet was 17 meV at 60 000 Hz, a resolution of 24 to 28 meV was noticed during actual recording of spectra.

Raman spectra were determined on neat samples using a SPEX 1401 Laser Raman Spectrometer. Repeated runs showed no laser decomposition of the samples.

TABLE 1. Ionization potentials for water,[a] dimethyl ether,[b] and and di-*tert*-butyl ether[c]

Compound	Assignment	Ionization potential (eV) Vertical	Adiabatic
H_2O	$b_1(n_0)$	12.62	12.61
	$a_1(O_{2p_z})$	14.73	13.7
	$b_2(O_{2p_x})$	18.55	17.22
CH_3OCH_3	$b_1(n_0)$	10.04	
	$a_1(O_{2p_z})$	11.91	
	$b_2(O_{2p_x})$	13.43	
$((CH_3)_3C)_2O$	$b_1(n_0)$	9.16	8.81
	$a_1(O_{2p_z})$	10.24	9.76
	$b_2(O_{2p_x})$	10.95	

[a]Reference 10.
[b]Reference 13.
[c]This work. An adiabatic ionization potential for di-*tert*-butyl ether of 8.94 eV was previously reported (14).

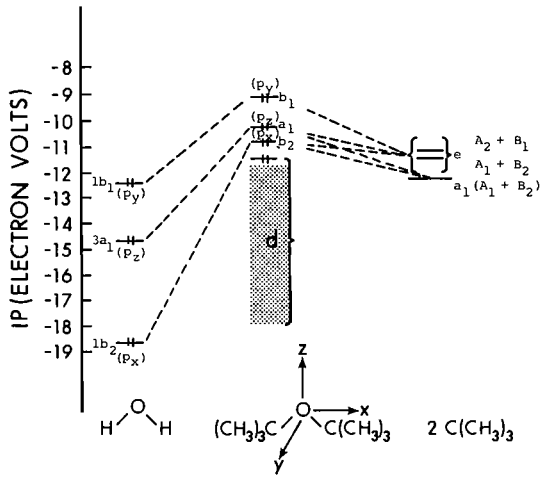

FIG. 1. Energy level diagram for H_2O and di-*tert*-butyl ether (I) utilizing vertical ip's determined by pe spectra. The two *tert*-butyl groups of local C_{3v} symmetry each contain an *e* orbital and an a_1 orbital. Utilizing Koopmans' theorem (11) one can assign the energy level of the *e* orbital as being roughly equal to the average value for the Jahn–Teller splitting of the $3t_2$ orbital in $C(CH_3)_4$ of 11.2 eV (12). The a_1 orbital is *assumed* to be at somewhat higher binding energy. If one treats each of the two components of the *e* orbital on both *tert*-butyl groups as a pseudo orbital, the p_y pseudo orbitals transform as $A_2 + B_1$ under the C_{2v} point group while the p_x pseudo orbitals transform as $A_1 + B_2$. The a_1 orbital of the *tert*-butyl groups transforms as $A_1 + B_2$ under the C_{2v} point group. The shaded area represents an unresolvable series of ionizations presumably arising from σ bonds.

Hydrogen peroxide was commercially obtained from the Food Machinery and Chemical Corporation in 98% purity. Initial determination of the pe spectrum of 98% H_2O_2 indicated a large proportion of water in the vapor state; however, after 10 to 12 h of periodically monitoring the spectra, only small peaks which may be attributed to water remained. The reported spectrum below was obtained after no further diminution of the assumed H_2O peak at 12.61 eV.

Di-*tert*-butyl ether (I) was prepared by the method of West, Powell, Lee, and Whatley (6).

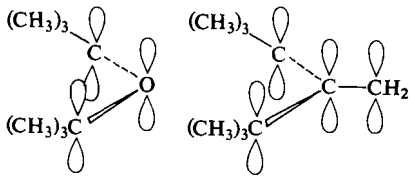
Ascaridole (IV) was obtained from the Fluka A.G. Chemische Fabrik (Switzerland) and was purified by low temperature recrystallization from isopentane at −78 °C to a constant melting point of 3 °C (lit. m.p. 3.3 °C (7)). Dihydroascaridole (V) was prepared via the procedure of Paget (8) and recrystallized from pentane to a constant melting point of 19 °C (lit. m.p. (8) 19.5 °C).

3,3,5,5-Tetramethyl-1,2-dioxacyclopentane (VIII) and 3,3,6,6-tetramethyl-1,2-dioxacyclohexane (IX) were prepared according to literature procedures (9).

Results and Discussion

Before discussing the actual peroxides, it would be of benefit to distinguish those perturbations caused by the presence of the alkyl substituents, from n-orbital interactions by examining systems in which the latter complications are absent. A comparison of H_2O and di-*tert*-butyl ether (I) ought to provide an estimate of the substituent effect of two *tert*-alkyl groups on the oxygen orbitals. The energy level diagram for H_2O and I is shown in Fig. 1, while the corresponding data are provided in Table 1.

Substitution of two *tert*-butyl groups lowers the first ip ($1b_1$ orbital (n_0)) from 12.62 eV in H_2O (10) to 9.16 eV in I. Decreasing ip of the $1b_1$ orbital with increasing substitution is well known (13–15) and results from the greater electron releasing ability of these alkyl groups relative to hydrogen. The difference of 3.46 eV in passing from H_2O to I is observed to be some-



I II

what greater than the analogous substitution on carbon as indicated by values of 10.52 and 8.80 eV for ethylene and 1,1-di-*tert*-butylethylene (**II**), respectively (15). We assume that there must be significant buttressing between the two *tert*-butyl groups in both **I** and **II**, based upon inspection of molecular models. We can perhaps observe this distortion by observing changes in the $1b_1$ orbital and highest occupied a_1 orbital in passing from H_2O, to dimethyl ether, to di-*tert*-butyl ether. Figure 2 shows the orbitals in terms of their dominant oxygen atomic component.

From water (R = H) to dimethyl ether (R = CH_3) the change in the vertical ip of the $1b_1$ and a_1 orbitals is 2.58 and 2.82 eV, respectively. The corresponding change in these orbitals from water to di-*tert*-butyl ether (R = $C(CH_3)_3$) is 3.46 and 4.97 eV, respectively, indicating that the a_1 orbital is more sensitive to *tert*-butyl substitution than the $1b_1$ orbital. Were any of the above molecules linear, the $1b_1$ and highest occupied a_1 orbital would be degenerate. In part then, the splitting of these two orbitals reflects the non-linearity of the molecule which causes a_1 to become more bonding and hence of lower energy than $1b_1$. The $1b_1$–a_1 splitting for **I** is 1.08 eV, while that for water and dimethyl ether is 2.1 and 1.87 eV, respectively, and using the above argument, one predicts that di-*tert*-butyl ether is "more linear" than either H_2O or dimethyl ether.

The important point for this discussion, is that dialkyl substitution lowers the first ip of the oxygen non-bonding orbital by 3.46 eV in changing from H_2O to **I**. Such substitution also lowers the ip of other occupied orbitals but of a magnitude dependent upon steric interactions of the alkyl groups.

Vicinal n-orbital interactions independent of substituent effects can be illustrated by investigating the simplest peroxide. The pe spectrum of H_2O_2 was determined and is presented in Fig. 3 while the corresponding data are displayed in Table 2. While the gross spectrum is similar to that presented by Osafune and Kimura (4) the

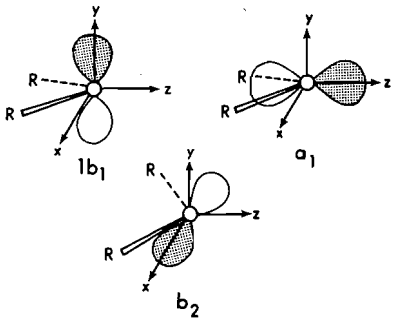


FIG. 2. The three highest occupied molecular orbitals of R_2O illustrating oxygen 2p components (ref. 10).

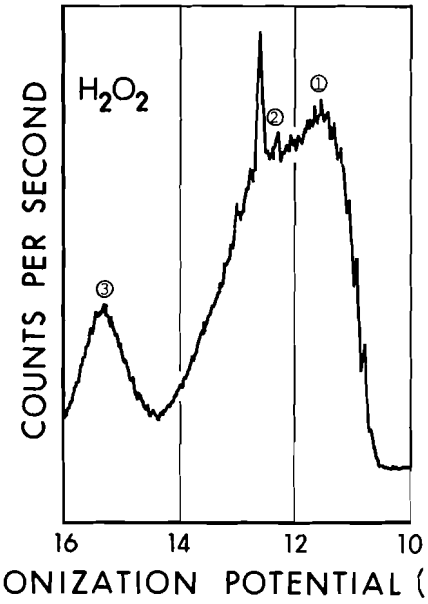

FIG. 3. Photoelectron spectrum of H_2O_2 between 16 and 10 eV. Peak at 12.61 eV is H_2O impurity.

resolution here is superior and allows us to draw some conclusions about the HOMO.

Ab initio calculations for H_2O_2 (16) have predicted that the HOMO is an antisymmetric combination of the n_0 orbitals (n^-), illustrated for visualization in Fig. 4. While this assignment has been made before (4), the spectrum provided here gives additional confirming vibrational evidence. Raman investigations of H_2O_2 have placed the O—O stretch at 880 cm^{-1} (17) which, in conjunction with our value of 1080 ± 50 cm^{-1} for the O—O stretch of $H_2O_2^+$, indicate that the orbital from which the first electron comes must be antibonding (18) with respect to the O—O linkage.

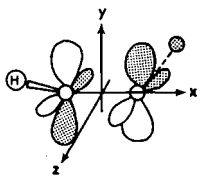
TABLE 2. Experimentally determined ionization potential for H_2O_2

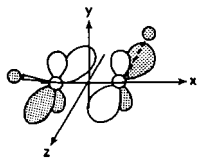
Ionization potential (eV)				
	This work		Vibrational spacing	
Literature[a]	Vertical	Adiabatic	(cm^{-1})	Assignment
11.69	11.51	10.54	1080 ± 50	$4b(n^-)$
12.69	12.56			$5a$
15.33	15.26			$4a$
17.40	17.35			$3a$, $3b$

[a]Reference 4. Note that these values differ slightly from those in ref. 4, probably due to difficulties arising in assignment of the maxima of such broad bands. Electron impact studies place the first ip of H_2O_2 at 10.92 ± 0.05 eV (26).



$4b(n^-)$

$-0.23(P_zO_1 + P_zO_2) + 0.66(P_yO_1 - P_yO_2)$



$5a$

$+ 0.55(P_zO_1 - P_zO_2) - 0.22(P_yO_1 + P_yO_2)$

FIG. 4. Two highest occupied molecular orbitals of H_2O_2 showing their dominant components. Data are from ref. 16*d*. Calculations above refer to equilibrium dihedral angle of 111°30′.

Band *2*, according to calculations (16), arises from an orbital containing predominant antisymmetric combinations of the OH σ-bonds as shown in Fig. 4. This band is obscured by bands from slight impurities which from their regular progression can certainly be assigned to water and oxygen. Even after repeated experiments with 98% H_2O_2 we were unable to eliminate these impurities which suggest that a metathesis reaction of H_2O_2 was occurring within the spectrometer.

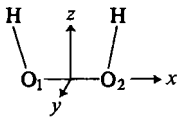
If H_2O_2 were linear then the top two orbitals (*4b* and *5a*) would be degenerate, however, the non-linearity of H_2O_2 with a dihedral angle of $\theta = 111°30'$ (19) effectively removes the degeneracy, making *5a* more bonding than *4b*.

The important feature of the above is that while the assignments for the HOMO of peroxides had been given (3, 4) this spectrum, to our knowledge, provides the first confirmatory pe data for the antibonding nature of the HOMO.

The effect of introducing the second oxygen atom to produce H_2O_2 from water apparently lowers the HOMO by 1.1 eV. It is difficult to compare these two orbitals however, since the $1b_1$ orbital (HOMO) in H_2O is non-bonding, while that in H_2O_2 is antibonding with respect to the O—O bond.

Alkyl Peroxides

As a guide in assigning the spectra of some dialkyl peroxides, we have extensively used the *ab initio* calculations of Fink and Allen (16*c*) and Kaldor and Shavitt (16*d*) concerning H_2O_2. While it is recognized that this extrapolation may be simplistic with regard to the additional perturbations introduced by the alkyl groups which may alter or even invert some of the molecular orbitals, less sophisticated computations (3) per-



III

cis-H_2O_2; dihedral angle $\theta = 0°$

LUMO $5a_1 = 0.46(O_12S + O_22S) + 0.57(O_12P_z + O_22P_z) - 0.71(H_1 + H_2)$

HOMO $1a_2 = 0.73(O_12P_y - O_22P_y)$

$4a_1 = -0.22(O_12S + O_22S) + 0.62(O_1P_x - O_2P_x) + 0.17(O_1P_z + O_2P_z)$

$3b_2 = 0.38(O_12S - O_22S) - 0.51(O_1P_z - O_2P_z) - 0.44(H_1S - H_2S)$

FIG. 5. The three highest and lowest unoccupied molecular orbitals of *cis*-H_2O_2.

TABLE 3. Ionization potentials for ascaridole (IV) and dihydroascaridole (V)

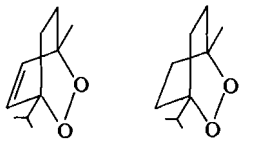
Compound	Assignment	Ionization potential (eV) Vertical	Adiabatic
IV	n^- (band *1*)	8.42[a]	8.07
	π(C—C)	9.70	9.35
	σ^-(C—O) (band *2*)	10.71	10.26
V	n^- (band *1*)	8.50	8.09
	σ^-(C—O) (band *2*)	10.36	9.83

[a]Band *1* of IV exhibits a vibrational progression of 1008 ± 50 cm^{-1}.

formed on dimethyl peroxide show similar trends to those found for H_2O_2. At least this extrapolation can serve to assign the HOMO, and offer a tentative suggestion about the second highest molecular orbital.

If we are allowed to use these computations (16) then the *cis*-dialkyl peroxides may be analyzed in terms of the corresponding orbitals calculated for *cis*-H_2O_2 (**III**, C_{2v} symmetry). The three highest, and lowest unoccupied molecular orbitals are presented in Fig. 5.

Ascaridole (**IV**) is a *cis*-dialkyl peroxide with a dihedral angle of 0°.[1]



IV $\theta = 0° \pm 5°$ **V** $\theta = 15° \pm 5°$

Ionization potentials for **IV** and **V** are presented in Table 3, while the spectra from which the data were obtained are presented in Fig. 6.

Band *1* in both **IV** and **V** is assigned to the removal of an electron from an antisymmetric π^* combination (n^-). That this band in effect corresponds to ionization of an antibonding electron is evidenced by the vibrational spacing of 1008 ± 50 cm^{-1} appearing on band *1* of **IV**. Raman studies of **IV** and **V** indicate an O—O stretching frequency of 730 ± 2 cm^{-1} in both species. An appreciable interaction of this orbital with the double bond can be ruled out on symmetry grounds and by noting that band *1* appears at roughly the same position in both **IV** and **V**.

The second peak in the pe spectrum of **IV** can be assigned to ionization of the C—C π-bond. A

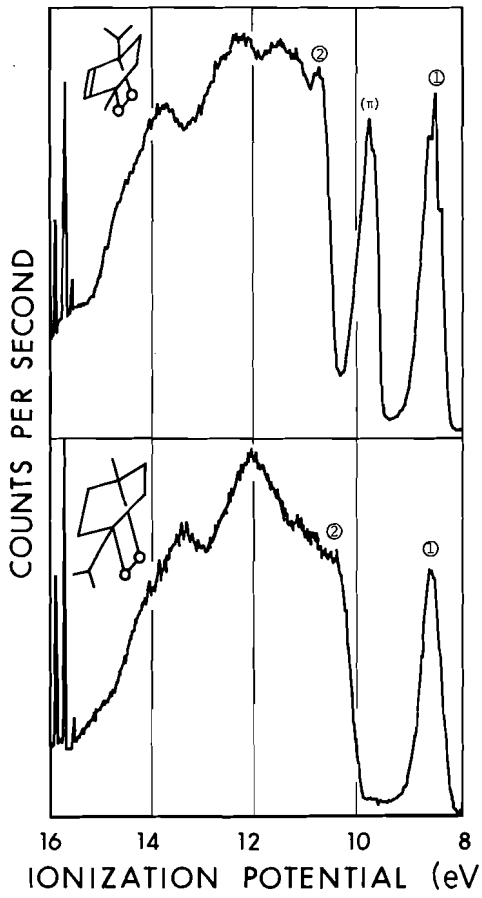


FIG. 6. Photoelectron spectra of ascaridole (**IV**) and dihydroascaridole (**V**) using argon as a calibrating gas.

[1]Dreiding models suggest **IV** possesses a dihedral angle of 0°. While these models are unable to assess the contribution of tortional effects on the dihedral angle, **IV** is sufficiently rigid so that little distortion from 0° is expected. Dihydroascaridole (**V**) exhibits slightly more flexibility and thus an angle of 15° ± 5° is assumed based upon the models.

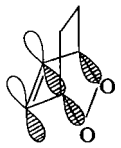
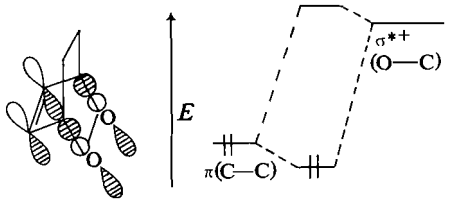
comparison of the ip of 9.70 eV with that of bicyclooctene (9.05 eV (20)) indicates a significant stabilizing perturbation in the former. While we cannot exclude the possibility of an interaction of the π-bond with the *bonding* σ-framework as shown in **VI**, such an interaction would be expected to raise the π-level rather than lower it.



VI

Of the effects which could be contributing to the stabilization of the π-bond in **IV**, perhaps the simplest to visualize is an inductive withdrawal of electron density from the π-bond by the electronegative oxygens. Alternatively, if we are allowed to extrapolate the calculated orbitals for *cis*-H_2O_2 (16*d*) to the peroxide linkage in **IV**, a through-bond type of stabilization can be envisioned. The only orbital of appropriate symmetry localized on the peroxide portion of **IV** which can interact with the π-bond is the LUMO (*cf.* **III**), which is predominantly a symmetric combination of antibonding σ-orbitals. Hence one could envision an interaction between the π-bond and σ^{*+} as shown in **VII**, which effectively transfers electron density from the π-bond to the unoccupied C—O orbitals, exerting a net stabilizing influence on the double bond. The present study offers no solution to the mechanism of stabilization, and further work will be required to provide an answer.

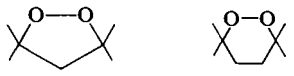


VII

Band *2* in both **IV** and **V** can be assigned on the basis of calculations (16) of *cis*-H_2O_2 to ionization occurring from either an orbital consisting of an antisymmetric combination of C—O σ-bonds (σ^-) or an O—O σ-bond. The calculations indicate that these two orbitals are very close in energy, and certainly the pe data cannot clearly distinguish the two ionizations.

As has been noted before (4) the separation of the two highest occupied molecular orbitals of peroxides should have maximum (but not necessarily equal) values at θ = 0° and 180°, and become degenerate at θ = 90° where the two orbitals cross each other (3, 4, 16*c*, 16*d*).

While alkyl substitution undoubtedly affects this dependence, qualitatively one expects to observe a decrease in the separation of the first two peroxide bands as the dihedral angle progresses from 0° to 90°. An extension of the plot of Δip *vs.* dihedral angle (3) for compounds **IV**, **V**, **VIII**, and **IX** is presented in Fig. 6. While it is not certain what the exact dependence should be, it can be seen that there appears to be a steady decrease from ascaridole (**IV**, θ = 0° ± 5°), Δip = 2.29 eV to 3,3,6,6-tetramethyl-1,2-dioxacyclohexane (**IX**, θ = 75° ± 5°), Δip = 0.41 eV.



VIII $\theta = 30° \pm 5°$[2] **IX** $\theta = 75° \pm 5°$[2,3]

Vertical ip { 9.26 eV (n^-), 10.47 eV (σ^-) } 9.56 eV { 9.35 eV (n^-), 9.76 eV (σ^-) }

Computations (3, 4, 16*c*, 16*d*) suggest a similar dependence upon dihedral angle from 180° to 90°, although there is no experimental evidence that the 90° to 180° section should mirror that from 0° to 90°. In fact, while electric-dipole measurements in solution indicate that di-*tert*-butyl peroxide possesses a dihedral angle of 123° (21), the splitting observed as 1.75 eV corresponds more to a gas phase angle of 160° to 180° if Fig. 6 is mirrored from 90° to 180°.

In view of the recent interest in dioxetanes (22) the pe spectrum of tetramethyl-1,2-dioxacyclobutane **X** was obtained. Initial attempts to obtain this spectrum gave only that of the decomposition product acetone, however, suitable modification of the spectrometer inlet system allowed the recording of the spectrum listed in

[2]In a fashion similar to that used for **IV** and **V**[1], Dreiding models suggest to us angles for **VIII** and **IX** of 30° ± 5° and 75° ± 5°, respectively, slightly different than those assumed in ref. 3.

[3]Curve resolution of the broad intense peak at 9.56 eV indicates two peaks of equal dimensions centered at 9.35 and 9.76 eV. It is felt that the breadth and intensity of this peak relative to the σ-framework indicates the presence of two overlapping bands.

TABLE 4. Ionization potentials for tetramethyl-1,2-dioxacyclobutane (X)

Band	Vertical ip (eV)	Assignment[b]	Major orbital components
1	8.98[a]	$2a_2(\pi^*_y)$	$-(\pi^*_yO + \pi^*_yC)$
2	10.94	$3b_1$	$-(\pi^*_zC + \pi^*_zO)$
3	11.41	$5a_1$	$-(\sigma_xO + \sigma_xC)$
4	12.09	$1a_2$	$\pi^*_yO - \pi^*_yC$

[a]Onset potential for band *1* is 8.53 eV. FWHM = 0.53 eV.

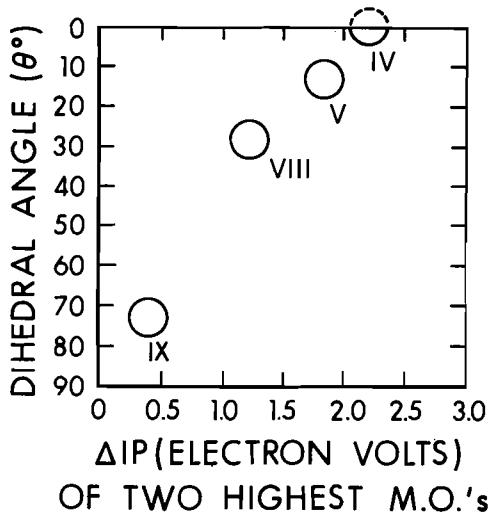

FIG. 7. A graphical presentation of the Δip for the two highest bands in dialkyl peroxides as a function of dihedral angle θ. Refer to footnotes 1 and 2.

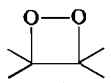
Fig. 7. Table 4 lists the corresponding ip's and assignments for **X**.

Molecular models indicate that dioxetane **X**, like ascaridole (**IV**), should possess a dihedral



X
$\theta = 0° \pm 5°$

angle of 0°.[1] Although **X** contains a peroxide linkage it is possible that the extra strain in the four-membered ring (estimated at 26 kcal/mol (22*c*)) alters the orbitals such that **X** is an abnormal peroxide in terms of its electronic structure. Inspection of Fig. 7 shows that the pe spectrum of **X** is similar to that of other cyclic peroxides, particularly the appearance of the first band.

Assignment of the orbitals giving rise to the pe spectrum is based largely upon the CNDO/2 calculations of Barnett for the parent compound 1,2-dioxacyclobutane (23). Band *1* (vip 8.98 eV) is assigned to removal of an electron from an antisymmetric π^*_y orbital. While there is little well-resolved vibrational structure on this band, it is expected that the orbital giving rise to it is similar in character to the HOMO of ascaridole (**IV**) or dihydroascaridole (**V**). Band *2* is suggested (23) to arise from an antisymmetric combination of C—O σ*-orbitals, while band *3* corresponds to a symmetric combination of O—O and C—C σ-bonds. Calculations (23) predict *2* and *3* to be very close in energy, in good agreement with our observation. Additionally, the computed splitting between the two highest occupied molecular orbitals ($3b_1$–$2a_2$) is 2.17 eV while the experimental value determined for **X** is 1.96 eV. Interestingly, if one naively places the latter value on the plot shown in Fig. 6 it falls gratifyingly close to that expected for a peroxide with a 0° dihedral angle.[4]

Based upon this experimental data and the application of Koopman's theorem (11), one can draw a correlation diagram for the construction of **X** from O_2 and tetramethylethylene under C_{2v} point group symmetry as shown in Fig. 8.

We have been careful to include in our study of alkyl peroxides only tertiary dialkyl peroxides. While one could have chosen to study the hydroperoxides, the lack of symmetry in these molecules precludes group theoretical analysis. The dialkyl peroxides at least preserve the local C_2 symmetry about the peroxide portion. Additionally, since each peroxide contains di-*tert*-

[4]The second highest occupied molecular orbital of **X** ($3b_1$) is described (23) as an antisymmetric combination of σ* orbitals, while the analogous orbital of *cis*-H_2O_2 ($3b_2$) is suggested to be an antisymmetric combination of the O—H σ-bonds. Since these two orbitals are unlike in their overall character, it leads to some question about the comparison of **X** with other peroxides in terms of Fig. 6. However, the Δip of bands *1* and *2* in **X** is still an experimental observation regardless of the nature of the orbital giving rise to band *2*.

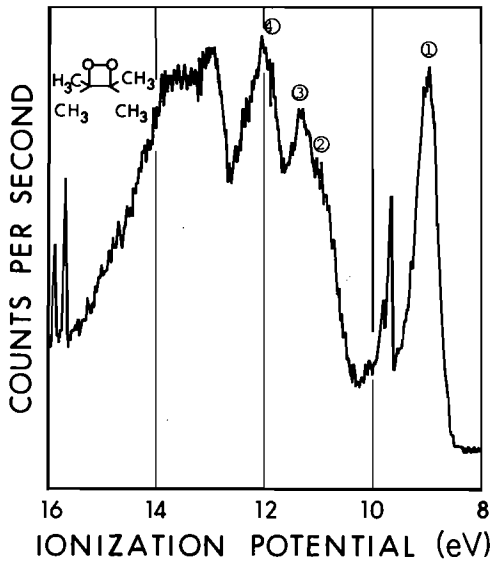

FIG. 8. Photoelectron spectrum of tetramethyl-1,2-dioxacyclobutane (**X**) using argon as an internal calibrating gas. Band centered at 9.70 eV is attributable to acetone formed from the decomposition of **X**.

alkyl substitution, to a first approximation the substituent effects on the HOMO might be expected to be similar.[5] The difference between a methyl group and an isopropyl group is not expected to markedly alter the substituent effect.

Since di-*tert*-butyl ether (**I**) has the ip of its HOMO ($1b_1$) 3.46 eV lower in energy than H_2O, one might expect to find such a lowering in the peroxides as well. Indeed, substitution of two *tert*-alkyl groups for H lowers the ip of the HOMO in all the dialkyl peroxides studied as can be seen from Table 5.

Table 5 indicates that the ip of the HOMO of these dialkyl peroxides is not constant. As expected from the calculations (3, 4, 16) those peroxides in which the dihedral angle tends toward 0° (or 180°) are the ones which exhibit the lowest ip, presumably due to increasing the antisymmetric vicinal orbital interactions. Rotation about the O—O bond apparently lessens these repulsive interactions and hence allows the HOMO to reach higher binding energy as evidenced by the ip of **IX** (9.35 eV). Assuming **IX**

[5]Substituent effects of the alkyl groups may be due to a hyperconjugative interaction of the appropriate symmetry orbitals located on the alkyl residue with the adjacent oxygen orbitals, and/or a difference in the group electronegativity relative to H, which alters its electron-releasing ability. We cannot distinguish between these two possibilities in this study.

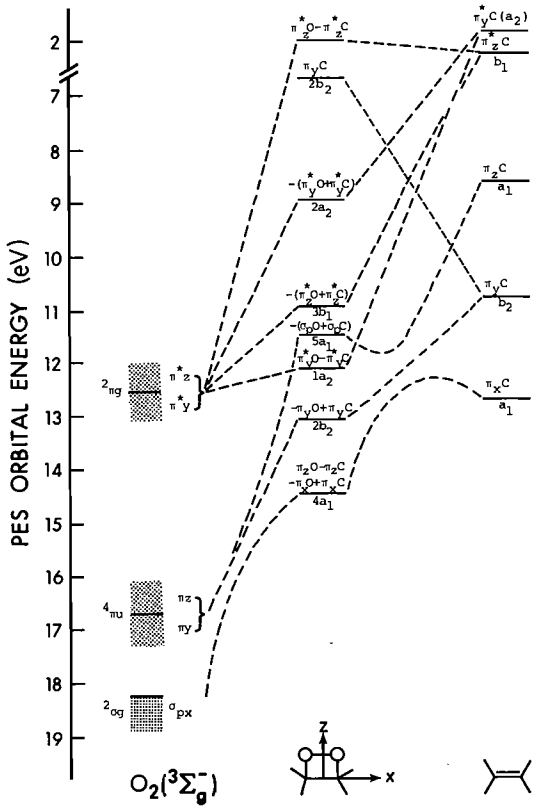

FIG. 9. Partial correlation diagram for tetramethyl-1,2-dioxacyclobutane from O_2 and tetramethylethylene under the C_{2v} point group. C_{2v} symmetry. Assignments for orbitals of the tetramethyl dioxetane based upon those given in ref. 23. O_2 assumed to be in $^3\Sigma_g^-$ state (27). π^*_zC calculated from the $\pi \rightarrow \pi^*$ absorption energy for tetramethylethylene as found in ref. 28.

to be our best *experimental* case for the minimization of vicinal orbital effects ($\theta = 75° \pm 5°$) it appears that in the absence of other effects, substitution of two *tert*-alkyl groups for hydrogens raises the HOMO of the peroxide linkage by at least 2 eV relative to H_2O_2.

Assuming this substitution effect to be constant at roughly 2 eV, the rotational dependence between 90° and 0° of this orbital is seen to be roughly 1 eV. While this is undoubtedly oversimplified (particularly since the gas phase geometry of H_2O_2 is *not* 90° but 111°30′ (19), and the ip of the HOMO of H_2O_2 is suspected to show rotational dependence), it does serve to demonstrate that the substituent caused lowering of the HOMO in the peroxides studied is less than that experienced in passing from H_2O to **I**.

One will notice that dioxetane **X** does not fit this expectation well. It is expected that if **X**

TABLE 5. A comparison of the ip of the HOMO in several dialkyl peroxides

Peroxide	ip of HOMO (eV)	$\Delta(ip_{H_2O_2} - ip_{peroxide})$ (eV)
H_2O_2	11.51	0.0
Ascaridole (**IV**)	8.42	3.09
Dihydroascaridole (**V**)	8.50	3.02
Tetramethyl-1,2-dioxacyclobutane (**X**)	8.98	2.54
3,3,5,5-Tetramethyl-1,2-dioxacyclopentane (**VIII**)	9.26	2.26
3,3,6,6-Tetramethyl-1,2-dioxacyclohexane (**IX**)	9.35	2.17
Di-*tert*-butyl ether peroxide	8.79	2.73

were a "normal" peroxide with a dihedral angle of 0°, it ought to have a first vip of ~8.5 eV. That the observed ip is somewhat greater (8.98 eV) can perhaps be best related to the internal strain of the molecule. By analogy, decreasing the endocyclic angles in the cyclic ethers causes a marked increase in ip. Hence the vip of tetrahydrofuran (**XI**) is 8.89 eV (18) while that of the four-membered oxetane (**XII**) is 9.67 eV (24) and that of ethylene oxide (**XIII**) is 10.57 eV (25).

Conductance Study of Ion Pairing of Alkali Metal Tetrafluoroborates and Hexafluorophosphates in Acetonitrile

H. L. YEAGER

Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

AND

B. KRATOCHVIL

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2E1

Received June 25, 1975

H. L. YEAGER and B. KRATOCHVIL. Can. J. Chem. **53**, 3448 (1975).

High precision conductance measurements are reported for sodium, potassium, and rubidium tetrafluoroborate and hexafluorophosphate in acetonitrile at 25 °C. The results are analyzed using the expanded form of the Fuoss–Hsia conductance equation. The ion size parameter, *d*, was systematically varied to obtain the value which gave best fit of the data to the equation. All salts were found to be associated, and the trends in association are discussed in terms of the ability of acetonitrile to solvate cations and anions.

H. L. YEAGER et B. KRATOCHVIL. Can. J. Chem. **53**, 3448 (1975).

On rapporte des mesures de conductivité de haute précision qui ont été effectuées à 25 °C, sur des solutions, dans l'acétonitrile, de tétrafluoroborates et d'hexafluorophosphates de sodium, de potassium et de rubidium. On analyse les résultats en faisant appel à une forme étendue de l'équation de Fuoss–Hsia pour la conductivité. On a fait varier d'une façon systématique le paramètre, *d*, ayant trait à la grosseur de l'ion; on a ainsi obtenu la valeur qui permet d'arriver à la meilleur corrélation entre nos données et l'équation. On a trouvé que tous les sels sont associés et on discute des tendances dans l'association en termes de l'habilité de l'acétonitrile à solvater les cations et les anions.

[Traduit par le journal]

Introduction

Acetonitrile has served for a number of studies of nonaqueous electrolyte solutions. It is a dipolar aprotic solvent of moderate cation solvating ability and rather weaker anion solvating ability (1, 2). Results of several conductance investigations (3, 4) indicate that many 1:1 univalent salts are at most only slightly associated in acetonitrile, in accordance with this solvent's dielectric constant of 35.95 (5). In recent years increasing interest has developed in obtaining information on solvation, ion-pairing, and complexation of alkali metals, especially sodium and potassium. Part of this interest is a result of the synthesis of new ligands that form complexes of appreciable stability with these ions, and part is due to studies of the role of these ions in biological systems and of the mechanisms by which they are transported through cell membranes, especially as complexes with macrotetrolide antibiotics (see for example, ref. 6, which contains four review articles on complexation of alkali and alkaline earth cations).

Techniques used to gain the needed information include ^{23}Na and ^{7}Li n.m.r. spectroscopy in a range of solvents (7), infrared spectroscopy (8), and electrical conductance (9). By a combination of conductance and n.m.r. spectroscopic measurements it is often possible to identify contact and solvent-separated ion pairs, and to calculate the fraction of metal ion present in each form. Since many interesting ligands are not water soluble, the use of other solvents such as acetonitrile is often necessary. To provide adequate solubility and minimal interaction, anions of large radius and low charge density are often employed. We report here high precision conductance measurements for several alkali metal tetrafluoroborates and hexafluorophosphates in acetonitrile. These two anions are spherically symmetrical and noncoordinating, and therefore ion pair association constant trends for their salts may be considered in

terms of anion size and simple ion–dipole interaction. These results are compared with previously reported conductance data for alkali metal perchlorates and tetraphenylborides (10) to demonstrate ion pairing trends with increasing cation and anion size.

Experimental Section

Sodium tetrafluoroborate (Ventron) was recrystallized from an 80:20 ethanol–water mixture and dried under vacuum at 120 °C for 15 h. Sodium hexafluorophosphate (Ventron) was recrystallized from absolute ethanol and dried under vacuum at 25 °C for 8 h. Potassium tetrafluoroborate (Ventron) was recrystallized from a 50:50 water–ethanol mixture and dried under vacuum at 25 °C for 8 h and then at 120 °C for 8 h. Potassium hexafluorophosphate (Matheson, Coleman, Bell) was recrystallized four times from water and dried under vacuum at 25 °C for 10 h before the first conductance run. As a check on the purity of the salt and reproducibility of the conductance measurements, the salt was recrystallized from water a fifth time, redried another 10 h, and a second conductance run made. Rubidium bromide was prepared by combining a slight excess of hydrobromic acid (Baker Analyzed Reagent) with rubidium carbonate (A. D. Mackay Inc.). This product was dissolved in water and slowly mixed with an aqueous solution of sodium tetrafluoroborate to produce rubidium tetrafluoroborate. The precipitate was recrystallized twice from a 50:50 water–methanol mixture and dried under vacuum at 25 °C for 4 h and then at 105 °C for 6 h. Rubidium hexafluorophosphate was prepared in similar fashion, except that sodium hexafluorophosphate was used in the second step. The product was recrystallized two times from water and dried under vacuum at 50 °C for 12 h before the first conductance run. As a check on the purity, the material was recrystallized a third time from water, redried at 55 °C for 11 h under vacuum, and a second conductance run made. Accurate analysis of these salts is difficult, but an estimate of purity can be obtained from the limiting equivalent conductances, which should equal the sum of the limiting ionic conductivities (4). On this basis, the purities of the salts in percent are: $NaBF_4$, 99.4; KBF_4, 100.1; $RbBF_4$, 99.6; $NaPF_6$, 98.6; KPF_6, 99.9; and $RbPF_6$, 99.5. In two instances (potassium and rubidium hexafluorophosphate), an additional recrystallization was performed prior to a second conductance run; the change in the limiting equivalent conductance was slight in each case. Excessive drying temperatures cause decomposition of many of these salts, as does prolonged storage.

The method of acetonitrile purification, the apparatus, and the experimental procedure are described in ref. 11. Values used for the physical properties of acetonitrile were: density, 0.7767 g/ml (11); viscosity, 0.003412 P (11); and dielectric constant, 35.95 (5).

Results and Discussion

The measured equivalent conductances and corresponding electrolyte concentrations have been placed in the Depository of Unpublished Data.[1] The data were analyzed using the expanded form of the Fuoss–Hsia equation (12, 13)

$$\Lambda = \Lambda_0 - S(C\gamma)^{1/2} + EC\gamma \log C\gamma + J_1 C\gamma - J_2(C\gamma)^{3/2} - K_A C\gamma f_\pm^2 \Lambda$$

where all symbols have their usual meaning. This equation and the comparable expanded Pitts equation (13*a*, 14) have been shown to be superior to the earlier Fuoss–Onsager equation (15) in fitting conductance data (13*b*, 16, 17). In order to evaluate the limiting equivalent conductance and ion pair association constant for a set of conductance data the third parameter in the equation, distance of closest approach of the ions, d, must also be evaluated. The d parameter appears in the J_1, J_2, and $f_\pm$ terms, and several approaches have been taken to optimize its value in the equation. These include assigning a value of the Bjerrum distance (18, 19) or some other value to d in the J_1 and $f_\pm$ terms and performing a three-parameter fit for Λ_0, K_A, and J_2, or assigning a value of d in J_1, J_2, and $f_\pm$ and performing a two-parameter fit (20). Perhaps a more reasonable approach is to perform several two-parameter analyses of the data using a series of values for d (16, 21). The distance parameter which yields a minimum standard deviation of fit, $\sigma\Lambda$, to the conductance data along with the corresponding Λ_0 and K_A values is chosen as the optimized parameter. We have employed the latter approach in this work.

A computer program which provided a two-parameter least-squares fit of conductance data was employed. Values of d were varied from 2.0 to 20.0 Å in 0.2 Å steps, and the least-squares fit was performed several times for each salt. Two types of behavior were observed in the results. Either a broad minimum in $\sigma\Lambda$ was observed over a range in d values, or two minima were found. In the latter case one d value would be in the range of 2–4 Å, and for salts with slight association would yield a corresponding K_A value which was negative. Similar results

Rb^+	60(52)	31(31)	25(20)	7(5)
Cs^+	—	34(34)	—	19(17)

*Averaged values from Table 1. Values in parentheses are those obtained using d = 7.8 Å.
†Reanalysis of data from ref. 10.

have been found by other workers using this method of data treatment in different solvents (16, 17, 21). Table 1 lists the results of the least-squares fitting. When two minima were observed, the results for the larger d are given. The optimized Λ_0 and K_A values are included, along with standard deviations of fit and the d value used.

Kohlrausch differences calculated for the tetrafluoroborate and hexafluorophosphate salts of sodium, potassium, and rubidium are 5.73, 4.77, and 4.55. These values can be compared to the difference for the corresponding purified silver salts of 4.50 (11). The high value for the sodium salts can be attributed to quality of the hexafluorophosphate, which decomposes readily upon drying.

In Table 2 are listed association constants from Table 1 along with values for the alkali metal perchlorates and tetraphenylborides obtained by reanalysis of the data from ref. 10 by the method described here. Again, several sets of data for these salts showed two minima in $\sigma\Lambda$ with changing d. As before, the K_A value at the larger d is reported in each instance.

Although the limiting equivalent conductances from our reanalyses are virtually identical to those obtained by Kay *et al.* (10), the K_A values are systematically larger. The original treatment used the Fuoss–Onsager conductance equation (15), and similar trends in limiting equivalent conductance and K_A values upon reanalysis have been observed and discussed (16, 17). Association trends are not affected by the equation used however. Kay *et al.* found that the only tetraphenylboride salt which indicated association was the cesium salt. Reanalysis by the improved conductance equation confirms that only this salt has significant association behavior.

The association trends in Table 2 may be explained by assuming that the alkali metal ions are solvated by acetonitrile, while the larger anions are not. This assumption is reasonable not only on a size basis but also in terms of the ability of acetonitrile to function as a better Lewis base than Lewis acid. Therefore association increases with increasing crystallographic radii of the alkali metal ions due to decreasing cation solvation. Alternately, association decreases in the order $BF_4^- > ClO_4^- > PF_6^- > BPh_4^-$ due to the increase in size of the relatively unsolvated anion. The results in Table 2 illustrate a smooth trend in association with anion size for these spherically symmetrical noncoordinating anions.

To test whether the data analysis procedure affects the trends shown in Table 2, association constants are also listed for each salt when the ion size parameter is fixed at 7.8 Å, the Bjerrum distance in acetonitrile. With the possible exception of $RbBF_4$, the association constants do not change substantially.

Apparent Molal Volumes and Heat Capacities of Some Tetraalkylammonium Bromides, Alkyltrimethylammonium Bromides, and Alkali Halides in Aqueous Glycerol Solutions

GIUSEPPA DIPAOLA[1] AND BERNARD BELLEAU

Department of Chemistry, McGill University, Montreal, Quebec H3C 3G1

Received July 24, 1975

GIUSEPPA DIPAOLA and BERNARD BELLEAU. Can. J. Chem. **53**, 3452 (1975).

The densities and volumetric specific heats of some tetraalkylammonium bromides, alkyltrimethylammonium bromides, and some alkali halides (0.02 to 0.5 aquamolal) were measured in 0 to 30 wt.% glycerol in water with a flow densimeter connected in series with a flow microcalorimeter at 24 and 25 °C respectively. The derived volumes and heat capacities of transfer of the electrolytes from water to glycerol–water mixtures are consistent with the corresponding transfer functions from water to D_2O and from water to urea–water mixtures, and suggest that structural interactions are reduced in aqueous glycerol solutions. The volumes and heat capacities of micellization of *n*-nonyltrimethylammonium bromide were determined in water, glycerol–water mixtures, urea–water mixtures, and in D_2O. Both the transfer and the micellization study indicate that glycerol behaves in an analogous manner to urea. An effect other than a simple alteration of the water structure must be invoked to account for their different effects on protein stability.

GIUSEPPA DIPAOLA et BERNARD BELLEAU. Can. J. Chem. **53**, 3452 (1975).

Les densités et les chaleurs spécifiques volumiques des bromures de tetra-alkylammonium, alkyl-trimethylammonium et des halogénures d'alkalis (0.02–0.5 aquamolal) ont été mesurées dans des mélanges eau–glycérol (0–30 wt.%) à 24 et 25 °C respectivement au moyen d'un densimètre et d'un microcalorimètre dynamique. Les volumes et capacités calorifiques de transfert de l'eau aux mélanges eau–glycérol sont en accord avec les fonctions de transfert correspondantes de l'eau à D_2O et de l'eau aux mélanges eau–urée, et suggèrent que les effets structuraux d'hydration sont moins prononcés dans les mélanges eau–glycérol que dans l'eau. On a mesuré les volumes et capacités calorifiques de micellisation du bromure de *n*-nonyl-trimethylammonium dans des mélanges eau–glycerol, eau–urée et dans D_2O. L'étude des fonctions de transfert et l'étude de micellisation indiquent que le glycérol agit comme l'urée. Pour expliquer la différence entre l'urée et le glycérol sur la stabilité des protéines, il faut invoquer d'autres effets que la modification de la structure de l'eau.

Introduction

The ability of glycerol and other polyhydroxy compounds to stabilize highly organized biological substances is a widely recognized phenomenon (1–8). However, postulated mechanisms on the nature of these effects belong to the realm of speculation. Glycerol is one of the more effective of the polyhydroxy compounds in the protection of enzymes against the denaturing effects of cooling (2, 3) and urea (3), and against heat inactivation (4, 5). The minimum concentration of glycerol required is usually 20% (v/v). It has been suggested (1, 3, 6, 7) that a possible reason for glycerol's mechanism of action is its effect on water structure. However, no definitive conclusions could yet be reached.

Many physicochemical properties of glycerol and its aqueous solutions are now known, such as dielectric constants (9, 14), densities (10, 14), heats of dilution (11, 12, 14), and specific heats (13, 14).

We are presently in the process of studying the calorimetric and volumetric behavior of aqueous solutions of a homologous series of polyhydric alcohols. It is hoped that such a study might give some insight into the problem at hand. This paper reports the volumes and heat capacities of binary and ternary systems containing glycerol.

Experimental

Heat capacities were measured with a flow microcalorimeter described by Picker *et al.* (15). The instrument used can detect differences between the volumetric specific heat of a solution (σ) and that of a reference solvent (σ_0) to $\pm 3 \times 10^{-5}$ J K^{-1} cm^{-3}, during a temperature rise of 2 °C and a liquid flow rate of 0.80 cm^3

min^{-1}. The overall precision on $\Delta\sigma/\sigma_0$ is 0.3% (16). Densities were determined with a flow digital densimeter (17) sensitive to $\pm 3 \times 10^{-6}$ g cm^{-3}, connected in series with the microcalorimeter. Thermostatic control of the instrument was achieved with a closed-loop bath (18) whose stability was better than 0.001 °C.

Apparent molal volumes (ϕ_v) and heat capacities (ϕ_c) were derived from

$$[1] \qquad \phi_v = M/d - W_{55.51}(d - d_0)/dd_0m$$

and

$$[2] \qquad \phi_c = MC_p + W_{55.51}(C_p - C_{p0})/m$$

where all symbols have their usual meaning (19). The weight specific heats (C_p and C_{p0}) are calculated from the volumetric specific heats (σ and σ_0); thus

$$[3] \qquad C_p/C_{p0} = (\sigma/\sigma_0)(d_0/d)$$

All heat capacity measurements were made at 25.00 °C. Because of the experimental setup, density measurements were obtained at 24.00 °C. The values for C_{p0} and d_0 of pure water were taken as 4.1793 J K^{-1} g^{-1} (20) and 0.997299 g cm^{-3} (21). The error introduced by taking the ratio of densities at 24 °C rather than at 25 °C is negligible.

Transfer functions are defined as follows:

$$\Delta\phi_x = \phi_{x(\text{soln})} - \phi_{x(H_2O)}$$

where ϕ_x represents the appropriate molal quantity at a specific concentration.

The tetraalkylammonium bromide salts (Eastman Kodak Reagents) were purified as described in the literature (22). The alkyltrimethylammonium bromide salts used were reported previously (23). Urea (Schwarz/Mann Ultra Pure Reagents) was dried under vacuum at 60 °C for several hours. The following were used without further purification: NaF, NaBr (Anachemia Reagents); NaCl, NaI, KBr (Fisher Certified Reagents); glycerol (Fisher Certified Spectranalyzed); glycerol-d_3 and D_2O (99.7%) (Merck, Sharp and Dohme); and D_2O (99.7%) (Aldrich).

All solutions were prepared by weight with double-distilled, deionized water and used the same day. To facilitate comparison in different solvents, all salt concentrations are expressed in aquamolalities (m).

Results

Densities and heat capacities were determined for the following systems:[2] (*1*) glycerol–water and glycerol-d_3–D_2O from 0 to 30 wt.%, (*2*) Me_4NBr, NaCl, NaF in the concentration range of 0.02 to 0.5 m at a fixed glycerol concentration (0 and 20 wt.%), (*3*) Me_4NBr, n-Bu_4NBr, NaCl, NaF at a fixed aquamolality of 0.05 m in a variable glycerol concentration (0 to 30 wt.%), (*4*) homologous series of n-alkyltrimethylammonium bromide salts, NaBr, NaI, KBr at a fixed aquamolality (0.05 m) and a fixed glycerol concentration (20 wt.%), and (*5*) n-nonyltrimethylammonium bromide salt (0.02 to 0.6 m) in water, 10 and 20 wt.% glycerol–water, 1 and 3 m urea, D_2O and in a solution containing molar ratios of glycerol:urea:water of 1:1:50.

All experimental measurements of σ/σ_o were determined in duplicate or more. Since the densities are known to better than 1 part in 10^5, the uncertainty in ϕ_c depends mainly on the error in the difference (or ratio of) in volumetric specific heats, which is of the order of 0.3% under the best conditions. The values of ϕ_c are thus reliable to 1 to 5 J K^{-1} mol^{-1} at low aquamolalities, and better than 1 J K^{-1} mol^{-1} above 0.1 m (24).

The concentration dependence of ϕ_c and ϕ_v for glycerol in water and for glycerol-d_3 in D_2O is similar (Table 1). There is a slight but significant[3] decrease in ϕ_c accompanied by an increase in ϕ_v. The infinite dilution water to D_2O transfer functions are found by graphical extrapolation of a ϕ_c or ϕ_v *vs.* m plot (not shown) to be $\Delta\phi_{ctr}^0 = 5 \pm 2$ J K^{-1} mol^{-1} and $\Delta\phi_{vtr}^0 = -0.15 \pm 0.1$ cm^3 mol^{-1}. In this case, no significance can be attached to the transfer functions due to the given uncertainties.

Apparent molal heat capacities and volumes at infinite dilution were obtained for Me_4NBr, n-Bu_4NBr, NaCl, and NaF in water by graphical extrapolation of a plot of the apparent molal quantity (corrected for the Debye–Hückel limiting law contribution) *vs.* aquamolality to $m = 0$ (not shown). Results for ϕ_c^0 at 25 °C are 123, 1221, −81, and −77 J K^{-1} mol^{-1} respectively. There is good agreement with corresponding literature values of 109, 1209 (25), and −81 and −73 J K^{-1} mol^{-1} (16) at 25 °C. Results for ϕ_v^0 at 24 °C are 114.35, 300.30, 16.75, and −2.50 cm^3 mol^{-1} which are in reasonable agreement with literature values 114.26 (26), 300.59 (27), 16.62 and −2.48 cm^3 mol^{-1} (28). Only recent literature data of comparable precision have been included.

The concentration dependence of the salts studied in 20 wt.% glycerol–water follows a similar behavior pattern to that observed in water. The Debye–Hückel limiting law coefficients for ϕ_v and ϕ_c are not known for electrolytes

[2]Complete set of tabular data for d_0/d, σ/σ_0, ϕ_v, and ϕ_c is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

[3]Uncertainty on ϕ_c for a 0.1, 1, 2 m solution is 1–2, 0.1–0.2, and 0.05–0.1 J K^{-1} mol^{-1} respectively.

*To eliminate rounding-off errors, at least one extra digit is included.
†Value of d_0 is taken as 0.997299 g cm^{-3} in H_2O (20).
‡Values calculated using C_{p0} = 4.1793 J K^{-1} g^{-1} (19).
§Measured values for D_2O (Merck, Sharp and Dohme): C_{p0}(25 °C) = 4.2094 J K^{-1} g^{-1}; d_0(24 °C) = 1.10404 g cm^{-3}.

in glycerol–water mixtures. Since the dielectric properties of glycerol–water mixtures (14) are close to those of water, one can assume that as a first approximation, the limiting Debye–Hückel slopes are about equal. Since we are interested in trends rather than in absolute values, any systematic differences that would be encountered by treating the data in a more quantitative manner will be ignored.

The heat capacities of transfer of 0.05 *m* tetraalkylammonium bromides from water to glycerol–water mixtures up to 30 wt.% are shown in Fig. 1 (the volumes of transfer are not shown). The transfer functions of *n*-Bu_4NBr are linear functions of the glycerol concentration, and are negative. No definitive conclusion could be reached regarding the sign of the transfer functions for Me_4NBr especially $\Delta\phi_{vtr}$, due to the proximity of the values to zero.

The transfer functions of 0.05 *m* alkyltrimethylammonium salts from water to 20 wt.% glycerol–water are negative. The heat capacities of transfer are linear functions of the alkyl chain length, *i.e.*, the absolute magnitude increases as the hydrophobicity of the molecule increases (Fig. 2). A regularity is observed in the variation of ϕ_c with increasing chain length of the alkyl group of the trimethylammonium salts (0.05 *m*) in water (Fig. 3), and in 20 wt.% glycerol–water. Both ϕ_c and ϕ_v increase linearly with the number of carbon atoms in the chain. The average incremental group contribution of each $-CH_2$ group in water was found to be 88 ± 6 J K^{-1}

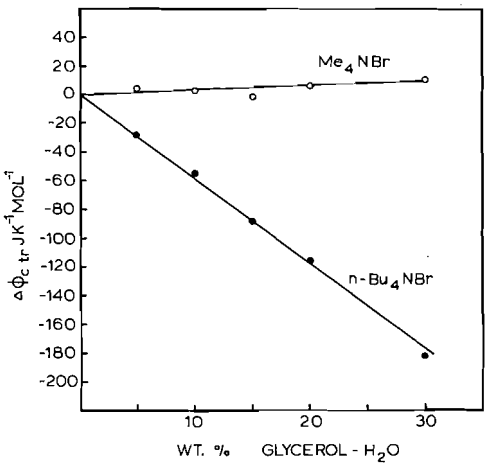

FIG. 1. Apparent molal heat capacities of transfer of 0.05 *m* tetraalkylammonium bromides from water to glycerol–water mixtures at 25 °C.

For personal use only.

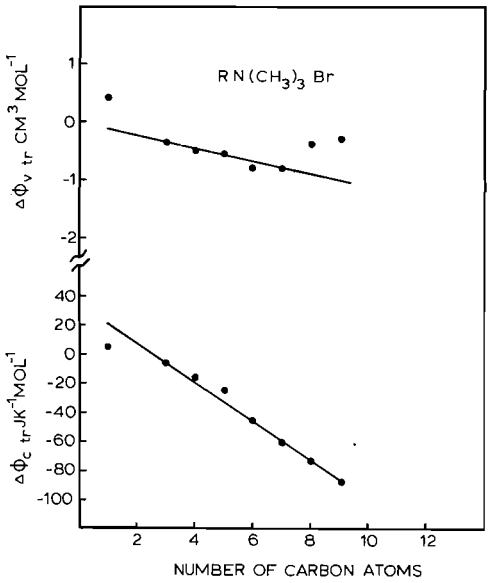

FIG. 2. Apparent molal volumes and heat capacities of 0.05 *m* alkyltrimethylammonium bromides from water to 20 wt.% glycerol–water at 24 and 25 °C respectively.

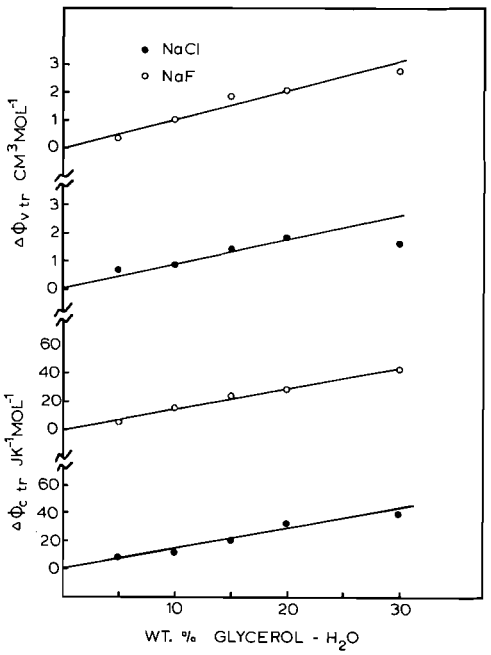

FIG. 4. Apparent molal volumes and heat capacities of transfer 0.05 *m* NaF and NaCl from water to glycerol–water mixtures at 24 and 25 °C respectively.

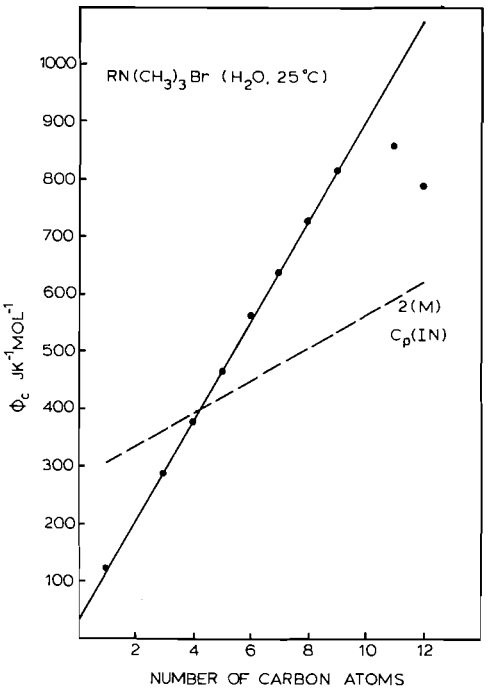

FIG. 3. Apparent molal heat capacities of 0.05 *m* alkyltrimethylammonium bromides in water at 25 °C. (Deviations for $C_{11}H_{23}N(CH_3)_3Br$ and $C_{12}H_{25}N(CH_3)_3$-Br are due to micellization.)

mol^{-1} (Fig. 3) and 15.8 ± 0.2 cm^3 mol^{-1} at 25 and 24 °C respectively. This agrees with the corresponding values that have been obtained for other homologous series in H_2O at 25 °C, such as the *n*-alkylamine hydrobromides (ref. 29 and references cited therein, 30).

The volumes and heat capacities of transfer of 0.05 *m* NaCl and NaF are positive (Fig. 4) and are linear functions of the glycerol concentration. A mirror-image relationship is observed on comparing the slopes for the transfer from water to glycerol–water, and urea–water (31) systems to transfer to the D_2O system (28).

The apparent molal volumes and heat capacities of *n*-nonyltrimethylammonium bromide were determined as a function of salt concentration in different glycerol–water mixtures (Fig. 5). For comparative purposes, the study was extended to include 1 and 3 *m* urea and D_2O. For each system studied, there is a sharp increase in ϕ_v and decrease in ϕ_c at the critical micelle concentration (c.m.c.) of the surfactant. If the c.m.c. is associated with the beginning of micellization, the c.m.c. of *n*-nonyltrimethylammonium bromide in water is approximately 0.12 *m* (Fig. 6) which is in very good agreement

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

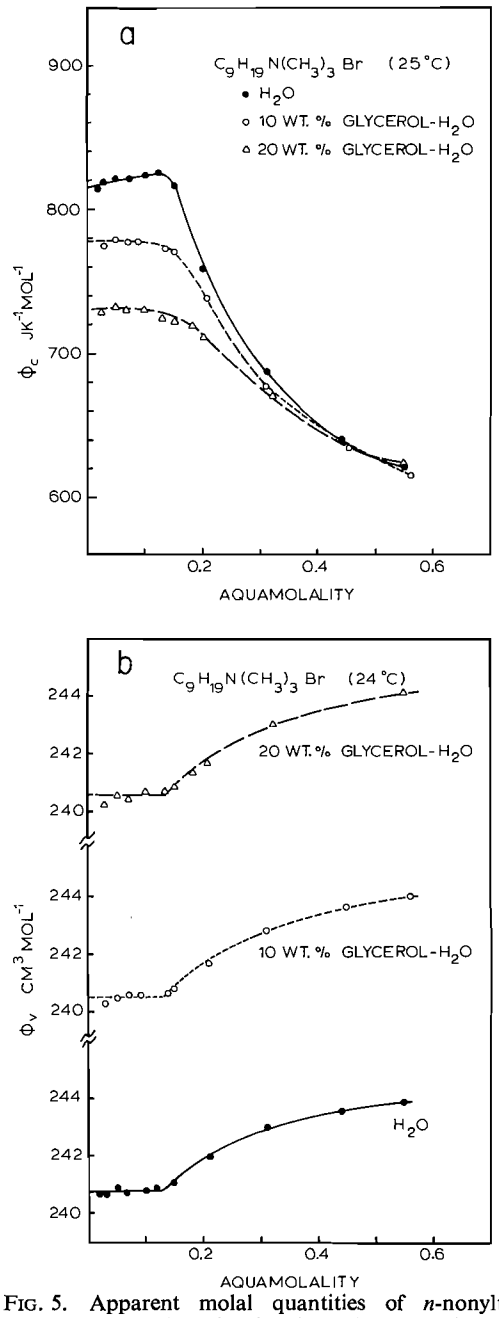

FIG. 5. Apparent molal quantities of *n*-nonyltrimethylammonium bromide in glycerol–water mixtures: (*a*) apparent molal heat capacities at 25 °C; (*b*) apparent molal volumes at 24 °C.

with the value of 0.13 *M* found by Musbally *et al.* at 25 °C (32). The c.m.c. in 10 and 20 wt.% glycerol–water is slightly decreased to 0.10 *m*. The c.m.c. in 1 and 3 *m* urea is approximately

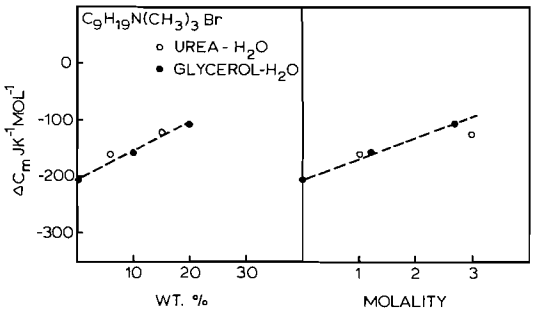

FIG. 6. The concentration dependence of the heat capacity of micellization of *n*-nonyltrimethylammonium bromide in glycerol–water and urea–water mixtures at 25 °C.

0.15 and 0.20 *m* respectively; that in D_2O is 0.10 *m*. The changes in volume (ΔV_m) and heat capacities (ΔC_m) on micellization were determined. These thermodynamic functions are not easily evaluated since the micellization region is not very sharp. They were approximated from the differences in the functions at 0.6 *m* and the corresponding values just below the c.m.c. The estimated uncertainties on ΔC_m and ΔV_m are ± 10 J K^{-1} mol^{-1} and ± 0.5 cm^3 mol^{-1} respectively (Table 4).

Discussion

Much of the recent work on aqueous solutions seems to indicate the presence of structural interactions in all solutions, which affect both the solute–solvent and solute–solute interactions. Since the apparent molal heat capacity is related to the second derivative of the chemical potential with respect to temperature, it is particularly sensitive to structural effects (16). Because of various contributions to ϕ_v this quantity is not easily explained (30, 33, 34). Studies of apparent molal quantities in dilute solution and of their concentration dependence have been shown to be useful tools in the study of solute–solvent and solute–solute interactions (25, 29, 35).

The predominance of structural interactions can best be illustrated through a study of transfer functions. The dielectric properties of water (36) and those of low concentrations of glycerol in water (14) are similar. The dipole moments of water and glycerol are respectively 1.83 (36) and 2.68 D (37). As a first approximation, all electrostatic ion–solvent interactions will be equal in both water and aqueous glycerol. Although the electrostatic contribution will be larger for simple ions as compared to larger hydrophobic ions, it

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

will be negligible for both when the transfer quantities are considered. The contribution due to the intrinsic quantities C_p(in) and $\overline{V}$(in) disappears when these functions are considered. Therefore, the transfer functions (as a first approximation) primarily reflect structural changes.

No marked concentration dependence is seen in the apparent molal volumes and heat capacities of glycerol in water (0 to 30 wt.%). This indicates that solute–solute interactions play a minor (and negligible) role in the glycerol–water system and that no long-range effects should therefore be expected. Similar suggestions have been made by Franks *et al.* (38). The difference between ϕ_c^0 of glycerol in water and the heat capacity of pure glycerol in the liquid state should reflect the structural influence of glycerol on water (35, 38). The specific heat capacity of pure glycerol at 25 °C is approximately 220 J K^{-1} mol^{-1} (14); ϕ_c^0 is 240 J K^{-1} mol^{-1}. The similar values suggest only a small structural effect on water. Similar conclusions have been reached by other workers (39, 40). The solvent isotope effect (as shown by $\Delta\phi_{vtr}^0$ and $\Delta\phi_{ctr}^0$ from water to D_2O) shows only negligible differences. An attempt at interpretation would be unjustified since any exchange (D–H) would contribute to masking possible differences between the two systems. The slight trends in the concentration dependence of ϕ_v and ϕ_c observed for the glycerol–water system are repeated for the glycerol-d_3–D_2O system.

An abnormally large ϕ_c in comparison with C_p(in) is usually associated with structure making and a small ϕ_c with structure breaking. The intrinsic heat capacity (C_p(in)) is not known for these solutes (Fig. 3). Since most organic liquids have specific heats of the order of 2 J K^{-1} g^{-1}, C_p(in) can be estimated as 2 × mol. wt. (29).[4] A comparison of the estimated C_p(in) values with the experimental ϕ_c values for the trimethylammonium bromide salts in water (Fig. 3) shows that there is a negative hydration contribution with the lower homologs and a positive hydration contribution (extra heat capacity) with the higher homologs. A crossover point is obtained at *n*-butyl-$N(CH_3)_3Br$. Leduc *et al.* (29) also obtained a crossover point at *n*-butyl-NH_3Br for a similar study in water. The apolar portion of the molecule again apparently dominates the heat capacity behavior in aqueous solution. An intuitive expectation is a group contribution dependent on the distance from the $N^+(CH_3)_3$ and the CH_3 groups. No such dependence is noted here. The constancy of the incremental group contribution (—CH_2) suggests an additive effect on water structure *i.e.* the environment of each —CH_2 group is similar and independent of effects from the previous group. The average incremental group contribution in 20 wt.% glycerol–water is 76 ± 6 J K^{-1} mol^{-1}, approximately 12 J K^{-1} mol^{-1} lower than the value in water. This suggests a reduction in structural hydration effects as compared to those in water.

The negative apparent molal heat capacities of transfer of *n*-Bu_4NBr, and *n*-propyl- to *n*-nonyl-$N(CH_3)_3Br$ from water to aqueous glycerol (Table 2 and Figs. 1 and 2) suggest that the structure-making propensity possessed by these hydrophobic salts in pure water is reduced in glycerol–water mixtures, and decreases regularly as the concentration of glycerol increases (0–30 wt.%). This effect on structural interactions also increases in absolute magnitude with increasing hydrophobic character of the molecules.

Based on these results, the volumes of transfer are expected to be positive if the cavity effect predominates as has been suggested in the literature (30, 33, 34). However, negative values are observed for the transfer of the hydrophobic salts. This apparent anomaly can be accounted for as follows. Warner (41) has pointed out that the glycerol molecule can adopt a conformation in which the oxygen atoms are spaced at a distance of 4.8 Å. The oxygen spacings are thus compatible with the second nearest neighbor distance of the oxygens in liquid water. Because of this structural compatibility, the dimensions of icelike aggregates formed would be similar, and the cavity-filling effect might be about the same in both water and dilute aqueous glycerol solutions. The negative value of $\Delta\phi_{vtr}$ of the large hydrophobic salts therefore reflects primarily the change in icelikeness of the hydrophobic hydration cosphere.[5] A similar proposal was put

[4] A list of other references can be found in ref. 29.

[5] The structural contribution is negative in the presence of structure breakers and positive with structure makers. The cavity effect for hydrophobic hydration is negative. If $\Delta\phi_{vtr}$ primarily reflects the structural contribution then ϕ_v in the less-ordered (glycerol–water) would be less than ϕ_v in a more ordered, more icelike environment (water). Therefore, $\Delta\phi_{vtr}$ for the hydrophobic probes is negative.

forward by Philip and Desnoyers (25) to explain the apparent anomaly in $\Delta\phi_{vtr}^0$ of *n*-Bu_4NBr from water to D_2O.

The thermodynamic parameters of transfer for the alkali halides (electrostrictive structure breakers) are also consistent with a decrease in structural interactions in aqueous glycerol. The small dependence of the transfer functions on ionic size are in the same direction and of the same order of magnitude as that observed in the urea–water system (31).

A comparison of our present results for the transfer of several ionic probes from water to glycerol–water mixtures and literature data for transfer to D_2O and 3 *m* urea systems is summarized in Tables 2 and 3. The transfer behavior is qualitatively and quantitatively similar to transfers to 3 *m* urea, and opposite in sign from those to the D_2O system. This comparison suggests that there is less structural order in glycerol–water than in pure water. Of the available models describing the thermodynamic behavior of aqueous solutions of hydrophilic solutes, the specific site hydration model proposed by Tait *et al.* (42) seems to be the most appropriate in describing the behavior of the glycerol–water system.

Micellization Study

Micelle formation can serve as a model system for hydrophobic bonding and for understanding more complex solution phenomena. It is usually considered to be an entropy-driven process in which hydrocarbon chains associate to minimize the overall hydrophobic hydration. Determination of heat capacities (29, 43–46) and volumes (29, 30, 47–49) for micelle formation are rather scarce. In all cases, ΔC_m has been found to be negative and ΔV_m found to be positive. The signs of these thermodynamic functions are consistent with a decrease in hydrophobic hydration during association. The positive structural heat capacity

molar ratios 1:1:50	754	−124	241.0	4.1

*Values obtained by linear extrapolation (Fig. 5); they are uncorrected for Debye–Hückel limiting law contribution. ϕ_c^0 values are at 25 °C, and ϕ_v^0 values at 24 °C.
†Estimated uncertainty is ±10 J K^{-1} mol^{-1}.
‡Estimated uncertainty is ±0.5 cm^3 mol^{-1}.

contribution to ϕ_c^0 of the hydrophobic monomer is lost, and the reappearance of free space around the solute causes a positive contribution to the volume. Addition of cosolvents (glycerol, urea) to water, or replacement of water by D_2O affects the monomeric state (pre-c.m.c.) rather than the micellular state (post-c.m.c.) (Fig. 6). Quantitative differences exist between effects of various additives. However, post-c.m.c. values tend toward a common value which is of the same order of magnitude as the molar heat capacity for the pure organic liquid (estimated C_p(in) of *n*-nonyl-N$(CH_3)_3$Br is 532 J K^{-1} mol^{-1}). This suggests that the interior of the micelle resembles the organic liquid. The ΔC_m values observed are negative and the ΔV_m values are positive. The heat capacity of micellization is much more sensitive to solvent effects than the volume of micellization. Examination of the data reveals that ΔC_m is much more positive in the glycerol–water and urea–water mixtures than in water alone. The values of ΔC_m decrease in absolute magnitude with increasing cosolvent concentration. In the glycerol–water system the ΔC_m is a linear function of the glycerol concentration (Fig. 6). The largest ΔC_m occurs in D_2O. It is possible that the relative magnitudes of ΔC_m can be used to differentiate between so-called 'structured' and 'unstructured' solvents. The ΔV_m values are constant in H_2O, D_2O, and aqueous glycerol. Lower values are ΔV_m are observed in urea, suggesting that less icelike water of hydration is released upon micellization in this solvent mixture.

It would be unjustifiable to emphasize the small effects on the c.m.c. observed in D_2O and in glycerol–water. Complications arising from solvent penetration of the micelle by glycerol are not expected. Emerson and Holtzer (50) have pointed out that the numerical value of the c.m.c. should not be taken as a single criterion for hydrophobic bond strength in micelles. Micelles may contain different number of monomers for different additives. There is a 67% increase in the c.m.c. on addition of 3 *m* urea. This large effect points to a decrease in the hydrophobic bond strength and destabilization of the micelle.

The results for micellization for a system containing 1:1:50 molar ratio of glycerol:urea:water are found in Table 4. The effects of glycerol and urea on the heat capacity of micellization are additive. The molalities of glycerol and urea in the solvent are approximately 1 *m* each. The result for ΔC_m can be predicted from Fig. 6 by considering the value of ΔC_m to be analogous to either a 2 *m* glycerol–water or a 2 *m* urea–water solvent system. They are apparently affecting the water structure independently of one another and leaving their respective 'structure-altering' properties unchanged. The value of ΔV_m resembles that in glycerol–water. The c.m.c. is identical to value in 1 *m* urea.

Conclusion

The transfer studies have shown that there is little difference between the effect of urea and that of glycerol on water structure. Structural interactions are reduced in both systems. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

micellization study also shows that urea and glycerol behave in very much the same way. The model system used shows no specific correlations.

Glycerol and urea, however, have very different effects on protein conformation. Glycerol protects proteins against urea inactivation. There have been several attempts in the past to correlate the denaturing ability of a compound and its effect on water structure (51–55). These have met with little success. Our results lead us to believe that an effect other than a simple alteration of the water structure must be postulated to explain the stabilizing influence of glycerol. Unpublished model evidence from our laboratories indicates that glycerol and related polyols may directly interact with centers of nucleation for protein unfolding and thus stabilize the native conformation through an enhancement of the freezing effect of water (56) on the rotation of strategic peptide linkages.

Some Reactions of *trans*-Hydridochlorobis(tricyclohexylphosphine)nickel(II), *trans*-Ni(Cl)(H)[P(C_6H_{11})$_3$]$_2$[1]

HOWARD C. CLARK AND ALAN SHAVER[2]

Department of Chemistry, University of Western Ontario, London, Ontario N6A 5B7

Received June 10, 1975

HOWARD C. CLARK and ALAN SHAVER. Can. J. Chem. **53**, 3462 (1975).

Some reactions of the title compound with several ligands, including olefins and acetylenes have been conducted and the new complexes *trans*-[NiH{P(C_6H_{11})$_3$}$_2$L]BF_4, L = methylpyridine or acetonitrile have been isolated. Although the bulky phosphine apparently hinders reaction sterically, with hexafluoro-2-butyne a product is obtained which is tentatively characterized as Ni($CF_3C{\equiv}CCF_3$)$_3$P(C_6H_{11})$_3$. This compound is thought to contain the seven-membered ring nickelahexakis(trifluoromethane)cyclohepta-*cis,cis,cis*-triene. Pyrolysis of this compound yields hexakis(trifluoromethyl)benzene. A reaction of the nickel hydride also occurs with carbon monoxide in the presence of $TlBF_4$ to give Ni(CO)$_3$P(C_6H_{11})$_3$ and [P(H)(C_6H_{11})$_3$]BF_4. This reaction can be considered to result from the reductive elimination of [P(H)(C_6H_{11})$_3$]Cl.

HOWARD C. CLARK et ALAN SHAVER. Can. J. Chem. **53**, 3462 (1975).

On a effectué quelques réactions du composé mentionné dans le titre avec plusieurs ligands y compris des alcènes et des alcynes et on a isolé les nouveaux complexes [NiH{P(C_6H_{11})$_3$}$_2$L]BF_4-*trans*, où L = méthylpyridine ou acétonitrile. Quoique la volumineuse phosphine semble empêcher la réaction pour des raisons stériques, on a obtenu, avec l'hexafluorobutyne-2, un produit auquel on attribue provisoirement la structure Ni($CF_3C{\equiv}CCF_3$)$_3$P(C_6H_{11})$_3$. On croit que ce composé contient le cycle à sept chaînons nickelahexakis(trifluorométhane)-cycloheptatriène-*cis,cis,cis*. La pyrolyse de ce composé fournit l'hexakis(trifluorométhyl) benzène. Une réaction de l'hydrure de nickel se produit aussi avec le monoxyde de carbone en présence de $TlBF_4$; il y a alors formation de Ni(CO)$_3$P(C_6H_{11})$_3$ et de [P(H)(C_6H_{11})$_3$]BF_4. On peut considérer que cette réaction provient d'une élimination réductive de [P(H)(C_6H_{11})$_3$]Cl.

[Traduit par le journal]

As part of a general interest in metal hydrides, we have been particularly concerned with the chemistry of neutral and cationic platinum hydrides (1, 2). The previously reported (3, 4) compound *trans*-Ni(Cl)(H)(Cy_3P)$_2$, where Cy_3P = P(C_6H_{11})$_3$, was chosen for study in an attempt to supply some comparisons to these platinum systems.

We hoped that the presence of the bulky phosphine ligands would help to stabilize reaction products, since σ-bonded hydride and carbon derivatives of nickel are often air sensitive and unstable at room temperature (3, 5).

Experimental

Inert atmosphere techniques were used. Solvents were generally dried over molecular sieves and purged with dry nitrogen before use; tetrahydrafuran and toluene were distilled from sodium–benzophenone under dry nitrogen just before use. *trans*-Ni(Cl)(H)(Cy_3P)$_2$ was prepared as previously reported (3).

Hydrido-4-methylpyridinebis(tricyclohexylphosphine)-nickel Tetrafluoroborate

trans-Ni(Cl)(H)(Cy_3P)$_2$, 0.378 g (0.50 mmol), was dissolved in 40 ml THF. 4-Methylpyridine, 0.6 ml (6.3 mmol) was added and a slight color change from yellow–brown to yellow occurred. $TlBF_4$, 0.146 g (0.50 mmol) was added in one portion and a white precipitate of TlCl formed immediately. The yellow reaction mixture was stirred at room temperature for 1 h, then filtered and stripped to a yellow oil which gave crystals upon pumping. These were extracted with 10 ml acetone and the solution filtered. Addition of ether and cooling to −78 °C caused the product to crystallize. It was collected on a fritte and washed with ether. Yield = 0.266 g (66.5%); decomposes at 165 °C *in vacuo*; i.r. ν(Ni—H) 1995 cm^{-1} (Nujol mull); n.m.r. (acetone) τ(Ni—H) 33.4 (triplet, J(P–H) = 139 Hz), τ(CH_2) 8.48 (multiplet), τ(CH_3) 7.50 (singlet), τ($NC_5H_4CH_3$) 2.48 and 1.16 (doublets, J = 6 Hz).

Anal. Calcd. for $C_{42}H_{72}NP_2NiBF_4$: C, 63.0; H, 9.25. Found: C, 63.2; H, 9.31.

Hydridoacetonitrilebis(tricyclohexylphosphine)nickel Tetrafluoroborate

This compound was prepared in an analogous manner. It was noted that if the $TlBF_4$ was added to the nickel

complex in the absence of acetonitrile there was no reaction. However, addition of acetonitrile caused a rapid formation of TlCl. The product, isolated as above, decomposes above 150 °C; i.r. ν(Ni—H) 1992 cm^{-1} (Nujol mull); n.m.r. (acetone) τ(Ni—H) 31.6 (triplet, J(P–H) = 153 Hz), τ(CH_2) 8.42 (multiplet), τ(CH_3) 7.49 (singlet).

Anal. Calcd. for $C_{38}H_{70}NP_2NiBF_4$: C, 61.0; H, 9.37. Found: C, 61.0; H, 9.49.

Tricyclohexylphosphinetricarbonylnickel and Tricyclohexylphosphonium Tetrafluoroborate

trans-Ni(Cl)(H)(Cy_3P)$_2$ (0.5 mmol) was dissolved in 20 ml THF. $TlBF_4$ (0.50 mmol) was added and carbon monoxide was bubbled into the yellow–brown slurry. There was an immediate precipitation of TlCl. The color changed first to lemon green, then after ½ h treatment with CO, to pale blue. The reaction mixture was filtered and concentrated to about 2 ml. Addition of ether caused precipitation of a white product identified as P(H)-$(C_6H_{11})_3 \cdot BF_4$ (yield = 0.14 g, 76%). It was recrystallized from THF–ether, m.p. = 163 °C.

Anal. Calcd. for $C_{18}H_{34}PBF_4$: C, 58.7; H, 9.24. Found: C, 58.8; H, 9.26.

The THF–ether mother liquors from the reaction solution were stripped to dryness and recrystallized from a minimum of ether at −70 °C to give $Ni(CO)_3P(C_6H_{11})_3$, (yield > 60%, decomposes at 96 °C), which was identified by its infrared spectrum (6) and analysis.

Anal. Calcd. for $C_{21}H_{33}NiPO_3$: C, 59.6; H, 7.80. Found: C, 59.9; H, 8.00.

Reaction with Hexafluoro-2-butyne

trans-Ni(Cl)(H)(Cy_3P)$_2$, 0.514 g (0.68 mmol) was dissolved in 20 ml toluene. The yellow–brown solution was frozen, the flask evacuated, isolated from the vacuum line, and allowed to warm at room temperature. Then $CF_3C{\equiv}CCF_3$ was admitted and the pressure adjusted to about 0.9 atm. The uptake of acetylene was monitored by means of a manometer and the pressure was readjusted to 0.9 atm by the admission of more acetylene as the reaction progressed. After stirring for about 1 h, an orange precipitate formed. After 3 h the reaction was complete and uptake of acetylene had ceased. The reaction mixture was filtered and the orange precipitate collected. The red mother liquors were concentrated to about 5 ml and cooled to −20 °C overnight to give 0.25 g of white crystals. These were readily sublimed at room temperature (10^{-2} Torr) (m.p. 206 °C (sealed capillary)) and were identified as hexakis(trifluoromethyl)benzene by means of the mass spectrum, infrared, and ^{19}F n.m.r. spectra (7) (yield = 76% based on Ni).

The orange precipitate was extracted with 10 ml CH_2Cl_2 and the solution filtered. Hexane (*ca.* 15 ml) was added and the solution cooled at −20 °C overnight and then to −40 °C for a further 4 h. Well-formed orange crystals were isolated by removing the mother liquors with a syringe and washing the crystals with cold hexane; yield = 0.28 g (50% assuming the formula $NiP(C_6H_{11})_3(C_4F_6)_3$). The compound melts with decomposition at 128 °C. When a sample was heated to this temperature in an evacuated flask white crystals collected on a sublimation probe and were identified as hexakis(trifluoromethyl)benzene. Despite several attempts, reproducible analytical results for the complex could not be obtained. Analyses were conducted by Chemalytics, Tempe, Arizona; Spang Microanalytical Laboratory, Ann Arbor, Michigan; Midwest Microlab Indianapolis, Indiana, and Alfred Bernhardt, Elbach uber Engelskirchen, West Germany. The complex showed: i.r. (Nujol mull) 1675(w), 1645(m), 1616(w), 1330(s), 1300(s), 1262(vs), 1233(vs), 1195(vs), 1150(vs), 1100(s), 1005(w), 941(w), 730(m), 684(m), 663(m), 638(m); ^{19}F n.m.r. (CH_2Cl_2): peak A 50.1 p.p.m. (multiplet), peak B 54.9 p.p.m. (quartet, J = 8.8 Hz), peak C 59.6 p.p.m. (multiplet); A:B:C = 1:1:1. Double irradiation of C reduced A and B to singlets. Double irradiation of A reduced C to a quartet J = 8.8 Hz.

Results and Discussion

The first reactions were attempts to remove the chloride ligand from *trans*-Ni(Cl)(H)(Cy_3P)$_2$ and generate a solvated cationic metal hydride. In platinum systems this type of complex is quite reactive (1, 2, 8–10). Extensive decomposition occurred with $AgPF_6$ so $TlBF_4$ was used. However in contrast to the analogous platinum complex (9), the chloride could not be removed in THF or acetone solution. Instead the presence of a small, highly coordinating ligand was necessary to cause precipitation of TlCl and formation of complexes of the type *trans*-[Ni(H)(L)(Cy_3P)$_2$]BF_4, where L = acetonitrile or 4-methylpyridine.

A color change from yellow–brown to yellow

was observed when 4-methylpyridine was added to a solution of *trans*-Ni(Cl)(H)(Cy_3P)$_2$. Also there was no precipitation of TlCl from a slurry of $TlBF_4$ and *trans*-Ni(Cl)(H)(Cy_3P)$_2$ until one or two drops of acetonitrile were added. These two facts seem to imply coordination of the incoming ligand before the chloride is displaced. This is surprising since we felt that the large cone angle (11) of Cy_3P (180°) might inhibit the formation of a five-coordinate intermediate. This is apparently not the case, at least for small or narrow bases. Several other ligands were tested but all failed to displace the chloride under similar reaction conditions. These included trialkyl and aryl phosphines and some acetylenes. Attempts to displace the coordinated acetonitrile with some acetylenes were also unsuccessful.

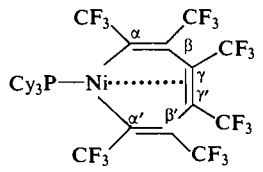
The reaction with carbon monoxide probably proceeds initially in the same way as the acetonitrile reaction. The first step is displacement of chloride and formation of *trans*-[Ni(H)(CO)(Cy_3P)$_2$]BF_4. In the presence of excess CO a reductive elimination occurs to give Ni(CO)$_3$(Cy_3P) and [PCy_3(H)]BF_4.

Since a labile cationic nickel hydride complex could not be produced by abstraction of chloride from *trans*-Ni(Cl)(H)(Cy_3P)$_2$ a number of reactions of the complex itself with olefins and acetylenes were conducted. Again the complex proved somewhat unreactive; in most cases it was recovered unchanged. Although dimethylcarboxylate acetylene seemed to polymerize readily in the presence of the complex, no nickel–acetylene complex formation could be detected and starting material was recovered. However, hexafluoro-2-butyne reacts readily with the complex to give a mixture of products.

The mechanics of the reaction with C_4F_6 are important. In one experiment an excess of the acetylene was condensed onto the frozen toluene solution of the nickel complex and the mixture allowed to warm. As it became soft the acetylene layer was polymerized into a white perforated disk. The reaction was continued as usual and the normal products were obtained (see Experimental). The disk was removed from the flask with tweezers and found to be quite resistant to tearing. It was also insoluble in an assortment of common solvents. In another experiment the toluene was not allowed to warm sufficiently and C_4F_6 condensed in the liquid. The rapid stirring dispersed the liquid acetylene into fine droplets which polymerized to form tough white beads. After this polymerization, reaction continued normally.

In the usual reaction, the complex was dissolved in toluene at room temperature and exposed to 0.9 atm of C_4F_6. There was a smooth uptake of acetylene that gradually stopped over a period of 3 h. Much of this acetylene was converted to hexakis(trifluoromethyl)benzene (0.75 mol per mol of nickel). The gradual slowing of acetylene uptake was accompanied by the production of the orange nickel complex (50% yield).

Although we have experienced difficulty in obtaining reproducible analyses, the characterization of this complex has been aided by the report of a nickel complex (12) containing a nickelahexakis(trifluoromethyl)cyclohepta-*cis,trans,cis*-triene ring, whose stereochemistry was proven by X-ray analysis. The close similarity of the ^{19}F n.m.r. spectra of the two compounds leads us to propose a similar seven-membered ring for our complex. The exact stereochemistry must be decided by a crystal structure determination. However, since our orange complex yields hexakis(trifluoromethyl)benzene at 130 °C it seems reasonable to propose a *cis,cis,cis* structure as shown in **1**. A possible interaction (12)



1

between nickel and the olefin across the ring is indicated with a dotted line. The quartet in the ^{19}F n.m.r. is assigned to the CF_3 in the α position while peaks C and A are assigned to the β and γ positions respectively.

The fact that hexakistrifluorobenzene (HTFB) and **1** are produced in 125% yield from starting nickel hydride is notable. **1** does not polymerize C_4F_6 when treated with the acetylene in freshly made THF or CH_2Cl_2 solutions. It is probable that a different nickel species acts as a cyclotrimerization catalyst and is also a precursor to **1**. As **1** is produced the concentration of the proposed catalyst decreases until all the nickel is converted to unreactive species. We have been

unable to isolate compounds other than **1** and HFTB from the reaction mixture.

The demonstration that **1** is an intermediate in the production of HFTB is significant since similar structures are often proposed in the mechanism of cyclotrimerization of acetylenes by transition metals.

The Preparation of Some Hydridotricyclohexylphosphine Platinum(II) Complexes

THOMAS G. ATTIG[1] AND HOWARD C. CLARK

Department of Chemistry, University of Western Ontario, London, Ontario N6A 5B7

Received June 10, 1975

THOMAS G. ATTIG and HOWARD C. CLARK. Can. J. Chem. **53**, 3466 (1975).

The reaction of the platinum(II) hydride containing bulky tricyclohexylphosphine ligands, *trans*-$PtHCl(PCy_3)_2$, PCy_3 = tricyclohexylphosphine, with $AgPF_6$ in methanol affords the air-stable cationic hydrido complex [*trans*-$PtH(CH_3OH)(PCy_3)_2]^+PF_6^-$, **1**, The reaction of **1** with a number of neutral molecules, L, leads to simple substitution of the coordinated methanol molecule by L. The reaction of **1** with terminal acetylenes in methanol affords hydrido–methoxycarbene complexes rather than vinylic derivatives. The role of the bulky tricyclohexylphosphine ligand in these reactions is discussed. The reactions of **1** are compared to those of cationic platinum(II) hydrides containing other phosphines.

THOMAS G. ATTIG et HOWARD C. CLARK. Can. J. Chem. **53**, 3466 (1975).

La réaction de $AgPF_6$ dans le méthanol avec l'hydrure de platine(II) contenant le ligand volumineux tricyclohexylphosphine, *trans*-$PtHCl(PCy_3)_2$ dans lequel PCy_3 = tricyclohexylphosphine, conduit au complexe hydrido cationique stable en présence d'air [*trans*-$PtH(CH_3OH)(PCy_3)_2]^+PF_6^-$, **1**. La réaction de **1** avec une variété de molécules neutres, L, conduit à une substitution simple de la molécule de méthanol par L. La réaction de **1** en solution dans le méthanol avec des acétylènes vrais fournit des complexes hydrido–méthoxy carbènes plutôt que des dérivés vinyliques. On discute du rôle du ligand volumineux tricyclohexylphosphine dans ces réactions. On compare la réactivité de **1** avec celles d'hydrures cationiques de platine(II) contenant d'autres phosphines.

[Traduit par le journal]

Introduction

Our interest in the reactivity of platinum(II) hydrides has prompted us to examine the reactions of those containing very bulky phosphines (*e.g.*, tricyclohexylphosphine) with acetylenes, olefins, and a number of other neutral molecules.

While frequent use is made of steric constraints to rationalize unusual chemical behavior or unexpected spectroscopic parameters, a more precise understanding of the steric requirements of different types of ligands has yet to be developed. Tertiary phosphines and phosphites comprise a large and important class of closely related ligands for which the concept of 'cone angle' is frequently cited as a description of their steric requirements. This concept, developed by Tolman *et al.* (1, 2), provides a quantitative measure of steric effects in phosphorus – transition metal complexes, based on measurements on atomic models. With some allowance for ligand flexibility, these cone angles were estimated to be in the range of 87 ± 2° (for PH_3) to 194 ± 6° (for $P(o\text{-}C_6H_4CH_3)_3$). As Tolman pointed out, to the extent that these phosphorus ligands approach cylindrical symmetry about the M—P bond, coordination of six, four, three, or two such ligands should not be possible for cone angles larger than 90, 109.5, 120, or 180°, respectively, although this takes no account of any possible 'meshing' of the ligands. The large cone angle of 179 ± 10° for tricyclohexylphosphine suggests that square planar platinum(II) complexes containing two *cis* PCy_3 ligands would not exist. On the other hand, the existence of low coordination complexes of Pt(0) and Pd(0) (*e.g.*, $Pt(PCy_3)_2$ (3) and $Pd(PCy_3)_2$ (4) has been attributed to the bulk of the PCy_3 ligand.

We felt that the use of PCy_3 as a ligand might allow the isolation of different types of products from the reactions of platinum(II) hydrides with a variety of substrates. For example, we hoped to isolate hydrido–acetylene complexes by the following sequence

[1] *trans*-$PtHCl(PCy_3)_2 + RC{\equiv}CR + AgPF_6 \rightarrow$ [*trans*-$PtH(RC{\equiv}CR)(PCy_3)_2]^+PF_6^- + AgCl$

analogous to the isolation of [*trans*-$PtCH_3(RC{\equiv}CR)L_2]^+PF_6^-$ from the reaction of *trans*-$PtCH_3ClL_2$ with acetylenes in the presence of $AgPF_6$ (5). It was our feeling that the bulkiness of the two PCy_3 ligands would prevent the insertion of the acetylene into the Pt—H bond, since the Pt—H bond and the acetylene could not easily come into close proximity.

Herein we describe the reaction of [*trans*-$PtH(CH_3OH)(PCy_3)_2]^+PF_6^-$ with terminal acetylenes as well as with a number of other neutral molecules.

Results and Discussion

It has been shown that the hydridoplatinum cations [*trans*-$PtH(solvent)L_2]^+$, where solvent = acetone or methanol, are useful as synthetic intermediates in the reactions of olefins and acetylenes with platinum(II) hydrides (6–9). The complex *trans*-$PtHCl(PCy_3)_2$ readily reacts with $AgPF_6$ in methanol to give, after removal of the precipitated AgCl, colorless solutions of [*trans*-$PtH(CH_3OH)(PCy_3)_2]^+PF_6^-$, **1**. Methanolic solutions of **1** are particularly stable for long periods of time (greater than one month without yellowing). Solutions of [*trans*-$PtH(solvent)L_2]^+PF_6^-$ where $L \neq PCy_3$, on the other hand, are only stable for several hours (9). White, air-stable crystals of **1** were obtained upon cooling a concentrated methanolic solution of **1**. However, good analytical characterization was not possible, presumably due to the difficulty of obtaining exact stoichiometric content of methanol. By comparison, the corresponding hydridonickel(II) complex [*trans*-$NiH(solvent)(PCy_3)_2]^+PF_6^-$ cannot be prepared from the reaction of *trans*-$NiHCl(PCy_3)_2$ and $AgPF_6$ (10).

The methanol molecule in **1** exhibits a weak *trans influence* as is evidenced by the high values for ν(Pt—H), τ(Pt—H), and *J*(Pt—H) (11). It is readily displaced by neutral molecules such as CO, γ-picoline, and triethylphosphine to afford the complexes [*trans*-$PtH(PCy_3)_2L]^+PF_6^-$, **2**, according to [2].

[2] [*trans*-$PtH(CH_3OH)(PCy_3)_2]^+PF_6^-$ + L → [*trans*-$PtH(PCy_3)_2L]^+PF_6^-$ + CH_3OH

where L = CO, γ-pic, PEt_3.

While the isolation of **2** where L = CO and γ-picoline was expected, the isolation of **2** where L = PEt_3 was not. The recently determined crystal structure of *trans*-$PtI_2(PCy_3)_2$ shows it to be a highly crowded molecule (12). From cone angle values of 179 ± 10° and 134 ± 2° for PCy_3 and PEt_3, respectively, it would seem unlikely that a large ligand such as PEt_3 could be easily accommodated between the two *trans* PCy_3 ligands of **2**. Our results suggest that there must be considerable meshing of the three phosphines and that the absolute value for the cone angle of 179 ± 10° does not accurately describe the steric bulk of the PCy_3 ligand.

The reaction of **1** with terminal acetylenes such as $CH{\equiv}CCH_3$ and $CH{\equiv}CC_6H_5$ in methanol leads to the formation of the hydrido–alkoxycarbene complexes [*trans*-$PtH[C(OCH_3)(CH_2R)](PCy_3)_2]^+PF_6^-$, **3** according to [3], rather than the vinylic insertion products which might have been expected according to [4].

[3] [*trans*-$PtH(CH_3OH)(PCy_3)_2]^+PF_6^-$ + $CH{\equiv}CR$

$$\xrightarrow{R'OH} \left[H{-}Pt(PCy_3)_2{-}C(OR')(CH_2R) \right]^+ PF_6^-$$

The reaction of **1** with $CH{\equiv}CCH_2CH_2OH$ in dichloromethane afforded the cyclic carbene complex [*trans*-$PtH(:\overline{COCH_2CH_2CH_2})(PCy_3)_2]^+PF_6^-$.

[4] [*trans*-$PtH(CH_3OH)(PCy_3)_2]^+PF_6^-$ + $RC{\equiv}CR'$ → [*trans*-$Pt(CR{=}CHR')(CH_3OH)(PCy_3)_2]^+PF_6^-$

The reactions in [3] are analogous to those reported for *trans*-$PtCH_3ClL_2$ with terminal acetylenes in methanol or ethanol in the presence of $AgPF_6$ (13).

[5] *trans*-$PtCH_3ClL$ + $CH{\equiv}CR$ + $AgPF_6$

$$\xrightarrow{R'OH} \left[CH_3{-}Pt(L)_2{-}C(OR')(CH_2R) \right]^+ PF_6^- + AgCl$$

The formation of the alkoxycarbene complexes according to [5] is believed to proceed via the formation of the 'metal-induced carbonium' ion, $CH_3{-}Pt{-}C^+{=}CHR$, which is subsequently attacked by methanol or ethanol to afford the alkoxycarbene ligand (14).

The formation of vinylic complexes from insertion of the acetylene into the Pt—H bond according to [4], was not observed. Thus, the rate of carbene formation is very much greater

For personal use only.

than the rate of insertion; the rate difference perhaps being influenced by the bulkiness of the PCy_3 ligands which prevents the coordinated acetylene and Pt—H bond from coming into close proximity, thus preventing insertion. Such a difference between the rate of carbene formation and the rate of insertion may be quite general. For example, the acetylene $CH{\equiv}CC_6H_5$ inserts into the Pt—H bond of [*trans*-$PtH(CH_3OH)(PEt_3)_2]^+PF_6^-$ but only in low yields (~20%).[2] It is likely that in such systems most of the hydride is consumed in carbene formation, the latter products being undetected due to the reaction conditions employed.

The infrared and proton n.m.r. spectra of some hydridotricyclohexylphosphine platinum(II) complexes are tabulated in Tables 1 and 2 respectively. The Pt—H proton, except when L = PEt_3, appears as a 1:2:1 triplet accompanied by ^{195}Pt satellites, indicating the *trans* geometry of the PCy_3 ligands. When L = PEt_3 a doublet of triplets with ^{195}Pt satellites was observed. Although the geometry of **2** when L = PEt_3 cannot be unequivocally determined from the proton n.m.r. spectrum, it has been assigned a *trans* geometry based on the *trans* geometries of the other compounds prepared in this and in other studies (15).

The value of ν(Pt—H) and J(Pt—H) for the hydrido proton reflects the relative *trans influence* of the ligand L (11). The carbene ligand in **3** exhibits the lowest values for ν(Pt—H) and J(Pt—H) as reflective of the large *trans influence* of this ligand. The large *trans influence* of carbene ligands has been previously reported for the complexes [*trans*-$PtCH_3$(carbene)$L_2]^+$ (13), as well as [*trans*-$PtH[C\overline{N(CH_3)CH_2CH_2}N(CH_3)]PEt_3)_2]^+BF_4^-$ (16). The high values for ν(Pt—H) and J(Pt—H) where L = CH_3OH, conversely, indicate the relative low *trans influence* of methanol.

The reactions and products described above reveal several characteristics of tricyclohexylphosphine as a ligand. Comparison of these results with those of analogous complexes containing other tertiary phosphine ligands reveals that:

(*a*) PCy_3 increases stability (including thermal stability). The ability of PCy_3 to stabilize the low-coordination complex $Pt(PCy_3)_2$ (3) has been described previously. The high thermal stability is exemplified by the high melting points of many products, *e.g.*, *trans*-$PtHCl(PCy_3)_2$ melts reversibly at 240 °C while *trans*-$PtHCl(PEt_3)_2$ melts reversibly at 82 °C (18). Similarly, the general stability of the salt containing the methanol cation, [*trans*-$PtH(CH_3OH)(PCy_3)_2]^+PF_6^-$, compared to those containing other [*trans*-PtH(solvent)$L_2]^+$ cations reflects the increased stability due to the PCy_3 ligand. The cyclic carbene complex [*trans*-$PtH(:\overline{COCH_2CH_2CH_2})L_2]^+PF_6^-$ where L = PCy_3 is an air-stable white compound, while the analogous complex when L = PEt_3 is found to decompose slowly to a black tar.[3]

(*b*) The cone angle of a tertiary phosphine is only a crude measure of steric requirements and, since it makes no allowance for meshing of

organic substituents, it cannot be used in any predictive sense.

(*c*) The steric bulk of the PCy_3 ligands may be the dominant factor in determining product distributions when more than one reaction pathway is available for a reaction intermediate. For example, in the reaction of **1** with terminal acetylenes the initial intermediate is probably [*trans*-PtH(CH≡CR)(PCy_3)$_2$]$^+PF_6^-$ obtained by the displacement of the coordinated methanol by the acetylene (5). This intermediate can lead to (*1*) vinylic products via insertion of the coordinated acetylene into the Pt—H bond, or (*2*) carbene products via a 'metal-induced carbonium' ion. If one of the steps necessary for insertion is a *trans* to *cis* isomerization (18) of the two PCy_3 ligands, the rate will be slow relative to carbene formation, since the PCy_3 ligands cannot readily reside in a *cis* geometry because of their bulkiness. Not unexpectedly then, the only products isolated from these reactions are carbene complexes in high yields.

The reactions of **1** with *non*terminal activated acetylenes such as $CH_3CO_2C{\equiv}CCO_2CH_3$ are found to afford vinylic products; however, these reactions were shown to proceed via a mechanism other than insertion.[4]

Experimental

The following chemicals were obtained commercially and were used without further purification: $AgPF_6$ from Cationics, Inc., $PCy_3 \cdot CS_2$ from Strem Chemicals, Inc., PEt_3 and $CH{\equiv}CCH_2CH_2OH$ from Aldrich Chemical Co., $CH{\equiv}CCH_3$ from Matheson, $CH{\equiv}CC_6H_5$ from BDH Chemicals, and γ-picoline from Eastman. Tricyclohexylphosphine was prepared by decomposing $PCy_3 \cdot CS_2$ in boiling ethanol under a nitrogen atmosphere. The complexes *trans*-PtHCl(PEt_3)$_2$ (17) and *trans*-PtHCl(PCy_3)$_2$ (19) were prepared according to the literature. We have also prepared *trans*-PtHCl(PCy_3)$_2$ from the $NaBH_4$ reduction of *cis*-$PtCl_2(Et_2S)PCy_3$ in the presence of 1 mol at PCy_3. With a large excess of $NaBH_4$, the dihydride *trans*-$PtH_2(PCy_3)_2$ was also isolated.

Infrared spectra were recorded on a Perkin-Elmer 621 spectrophotometer as Nujol mulls or in dichloromethane solution and were calibrated with a polystyrene film. Proton n.m.r. spectra were obtained on a Varian T-60 or Varian HA-100 spectrometer with TMS as an internal standard. Elemental analyses were performed by Midwest Microlab, Ltd., Indianapolis, Indiana.

Preparation of [trans-PtH(CH$_3$OH)(PCy$_3$)$_2$]$^+PF_6^-$, 1

The methanol cation, **1**, was prepared by the slow addition of a methanolic solution of 1 equiv. of $AgPF_6$ to a rapidly stirred CH_2Cl_2 solution of *trans*-PtHCl(PCy_3)$_2$. After removal of the AgCl by centrifugation, the resulting clear solution was concentrated and upon cooling the white crystals of **1** precipitated and were subsequently recrystallized from dichloromethane–hexane. Generally **1** was not isolated, but was used *in situ*.

Reaction of 1 with Neutral Ligand L

L = CO

Carbon monoxide was bubbled through a dichloromethane solution of **1**, for 15 min. The solvent was evaporated to dryness and the residue was recrystallized from dichloromethane–hexane to give the white crystals of [*trans*-PtH(CO)(PCy_3)$_2$]$^+PF_6^-$ (82%).

L = γ-picoline

To a dichloromethane solution of **1** was added 1 equiv. of γ-picoline and the solution stirred for 15 min. The

solvent was evaporated and the residue was chromatographed on Florisil with dichloromethane. The eluent was concentrated and upon addition of hexane the white crystals of [*trans*-PtH(γ-pic)$(PCy_3)_2]^+PF_6^-$ (80%) were obtained.

$L = PEt_3$

The complex [*trans*-$PtH(PEt_3)(PCy_3)_2]^+PF_6^-$ was similarly prepared. Recrystallization from dichloromethane–ether afforded the white crystals of the product in 61% yield.

Reaction of ***1*** *with Terminal Acetylenes*

Preparation of [trans-$PtH\{:C(OCH_3)(C_2H_5)\}(PCy_3)_2]^+PF_6^-$

Propyne was bubbled through a 1:1 dichloromethane–methanol solution of **1** for 10 min. The solution was concentrated and product precipitated. Recrystallization from dichloromethane–methanol gave the white crystals of [*trans*-$PtH\{:C(OCH_3)(C_2H_2)\}(PCy_3)_2]^+PF_6^-$ (85%).

Preparation of [trans-$PtH\{:C(OCH_3)(CH_2C_6H_5)\}(PCy_3)_2]^+PF_6^-$

To a 1:1 dichloromethane–methanol solution of **1** was added 1 equiv. of phenylacetylene. The reaction was stirred for 30 min. The solvent was evaporated and the residue was recrystallized from dichloromethane–hexane to give the white crystals of [*trans*-$PtH\{:C(OCH_3)(CH_2C_6H_5)\}(PCy_3)_2]^+PF_6^-$ (74%).

Preparation of [trans-$PtH(:\overline{COCH_2CH_2CH_2})(PCy_3)_2]^+PF_6^-$

To a dichloromethane solution of **1** was added 1 equiv. of $CH{\equiv}CCH_2CH_2OH$. The solution was concentrated and upon addition of methanol the white crystals of [*trans*-$PtH(:\overline{COCH_2CH_2CH_2})(PCy_3)_2]^+PF_6^-$ (75%) were obtained.

Thermal Decomposition of EDTA, NTA, and Nitrilotrimethylenephosphonic Acid in Aqueous Solution[1]

A. E. MARTELL,[2] R. J. MOTEKAITIS, A. R. FRIED, J. S. WILSON, AND D. T. MACMILLAN

Department of Chemistry, Texas A & M University, College Station, Texas 77843

Received December 23, 1974[3]

A. E. MARTELL, R. J. MOTEKAITIS, A. R. FRIED, J. S. WILSON, and D. T. MACMILLAN. Can. J. Chem. **53**, 3471 (1975).

The decomposition of ethylenediaminetetraacetic acid (EDTA) in water solution at 200 and 260 °C, nitrilotriacetic acid (NTA) at 260 and 293 °C, and of nitrilotrimethylenephosphonic acid (NTPO) at 260 °C was studied by n.m.r. as a function of time at p*H* 9.5 and decomposition rates and products were determined. The primary (fast) decomposition reaction of EDTA involves the hydrolytic cleavage of the ethylenic C—N bond to produce the relatively stable pair: *N*-(2-hydroxyethyl)iminodiacetic acid and iminodiacetic acid. NTA does not cleave below 260 °C but decomposes at about 290 °C and above through a stepwise decarboxylation reaction. NTPO cleaves hydrolytically at 260 °C at two C—N bonds to produce aminomethylenephosphonic acid and 2 mol of hydroxymethylenephosphonic acid. The further breakdown of the primary products of EDTA at higher temperatures occurs by the loss of carbon dioxide producing the corresponding methylamines, concomitantly with the hydrolytic cleavage of the remaining CH_2CH_2—N bond giving ethylene glycol. The pseudo first order rate constant k_{obs} for NTA decarboxylation at 293 °C and p*H* 9.3 is 0.19 ± 0.01 h^{-1}. The value of k_{obs} for EDTA hydrolysis at 200 °C is 1.4 ± 0.2 h^{-1}.

A. E. MARTELL, R. J. MOTEKAITIS, A. R. FRIED, J. S. WILSON et D. T. MACMILLAN. Can. J. Chem. **53**, 3471 (1975).

On a étudié, par r.m.n. en fonction du temps à un p*H* de 9.5, la décomposition de l'acide éthylènediaminetétraacétique (EDTA) dans des solutions aqueuses à 200 et 260 °C de l'acide nitrilotriacétique (NTA) à 260 et 293 °C et de l'acide nitrilotrimethylenephosphonique (NTPO) à 260 °C et on a déterminé les vitesses de décompositions et la nature des produits formés. La réaction de décomposition initiale (rapide) de l'EDTA implique un clivage hydrolytique du lien C—N éthylénique pour conduire à la paire relativement stable: acide *N*-(hydroxy-2 éthyliminodiacétique) et acide iminodiacétique. Le NTA ne se coupe pas en-dessous de 260 °C mais se décompose à environ 290 °C et plus haut par l'intermédiaire d'une série de réaction successive de décarboxylation. Le NTPO se coupe d'une façon hydrolytique à 260 °C à deux des liens C—N; il y a formation d'acide aminométhylènephosphonique et de deux moles d'acide hydroxyméthylènephosphonique. Des coupures ultérieures des produits initiaux de l'EDTA à des températures plus élevées se produisent par perte de CO_2 conduisant aux méthylamines correspondants; il y a un clivage hydrolytique concomitant du lien CH_2CH_2—N risiduel conduisant à l'éthylène glycol. La constante de vitesse du pseudo premier ordre (k_{obs}) pour la décarboxylation de NTA, à 293 °C et un p*H* de 9.3, est de 0.19 ± 0.01 h^{-1}. La valeur de k_{obs} pour l'hydrolyse de EDTA à 200 °C est 1.4 ± 0.2 h^{-1}.

[Traduit par le journal]

Introduction

Among the many differing applications of the two organic chelating agents ethylenediaminetetraacetic acid (EDTA) and nitrilotriacetic acid (NTA) are their use in aqueous solution at high temperatures for metal oxide solubilization (*i.e.*, scale removal) (1). To understand the chemical processes that occur in such applications, it is essential to know the hydrolytic stabilities of these ligands, and to determine if the ligands present at the time of reaction are actually those introduced into the solution. Thus the determination of the breakdown of these ligands at high temperatures in aqueous solution is of considerable practical value, as well as being essential to a basic understanding of complexation reactions occurring at high temperatures. Indeed, it turns out that EDTA and NTA are not in fact stable in aqueous solution at high temperatures.

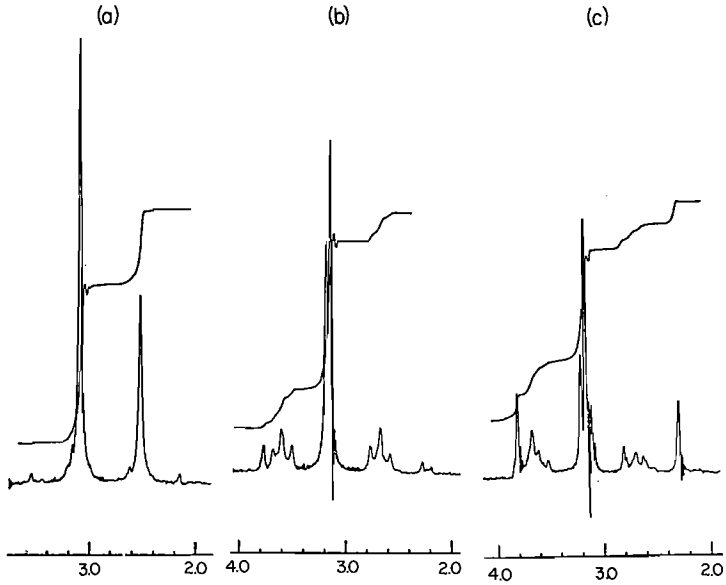

FIG. 1. Nuclear magnetic resonance spectra of EDTA samples heated at 260 °C at (*a*) $t = 0$, (*b*) $t = 0.5$ h, (*c*) $t = 7.5$ h. Solvent = 5% $NaOD/D_2O$.

This work results from a program of synthesis and testing (2, 3) of organic chelating ligands of potential use for the removal of scale deposits on heat transfer surfaces of high pressure boilers.

It had been proposed (4, 5) that at 200 °C, $EDTA^{4-}$ decomposes stepwise through the sequential loss of acetate groups. Likewise, it was concluded (6, 7) that both Na_3NTA and Na_2HNTA are exceptionally stable for at least 100 h at 200 °C. Later, the EDTA decomposition route was reinterpreted (8) to proceed through the hydrolysis of the ethylenic C—N link in agreement (2) with earlier findings in these laboratories.

This paper describes the sequential chemical reactions occurring in the aqueous decomposition of EDTA, NTA, and NTPO (nitrilotrimethylenephosphonic acid), and identifies the various decomposition products formed in each case. The p*H* of ~9.5 for this study represents a realistic working p*H* where the ligands would be efficient as scale removers yet at the same time the hydrolytic and boiler wall reactions would be kept reasonably low.

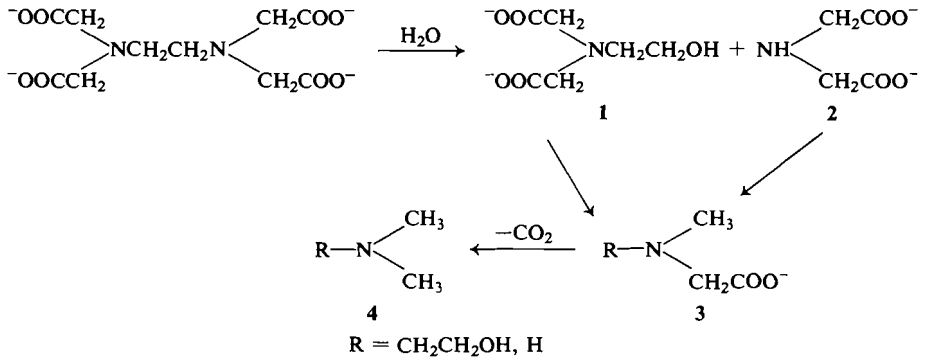
Experimental

A 2-l titanium Parr stirred autoclave was charged with 1.00 l of 0.015 *M* deoxygenated (< 1 p.p.m. O_2) solutions of EDTA, NTA, and NTPO adjusted to p*H* ~ 9.5 with NaOH and was heated rapidly with stirring to 200, 260, or 293 °C. Aliquots (10 ml) were withdrawn at periodic intervals and were evaporated to dryness under vacuum. The solvent was replaced by D_2O several times, followed by evaporation, and finally the solution was made up to 0.50 ml with 5% NaOD in D_2O. Precision n.m.r. tubes were employed and calibrated by integration of a standard EDTA solution. The n.m.r. spectra relative to TMS (trimethylsilylpropanesulfonic acid, sodium salt) were recorded and analyzed with a Varian T-60 n.m.r. spectrometer. The Varian HA-100 n.m.r. spectrometer was also used in earlier experiments on EDTA to identify and confirm the closely spaced peaks, but for routine measurements the T-60 resolution was found to be adequate.

Results and Discussion

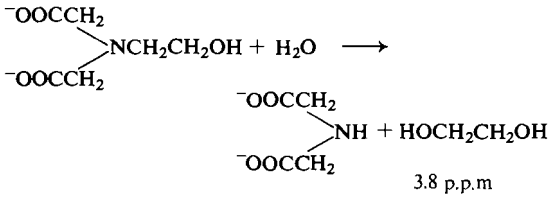
Figure 1 shows that at 260 °C EDTA decomposes after about 30 min to its primary degradation products, *N*-(2-hydroxyethyl)iminodiacetic acid, **1**, and iminodiacetic acid, **2**. The two singlets in 2:1 ratio corresponding to the acetate methylenes and ethylene bridge protons of EDTA (Fig. 1*a*) have disappeared and were replaced by two closely spaced singlets at 3.1–3.2 p.p.m., and two triplets at 2.7 and 3.6 p.p.m. relative to TMS. At 200 °C, the $t_{1/2}$ for this transformation at p*H* 11.4, 0.15 *M* Na_4EDTA has been stated to be 15 h (6). Our calculations (Fig. 4) show that the half-life of EDTA at 200 °C under our conditions is ~0.5 h. The two singlets (Fig. 1*b*) are assigned to the acetate methylene protons of the cleaved

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



species **1** and **2**; their similar chemical shifts are caused by the difference in —H and —CH_2-CH_2OH substitution on the nitrogens. The two triplets represent the latter group with the absorption at 3.6 p.p.m. assigned to the methylene adjacent to the hydroxyl group. These assignments were confirmed by a direct comparison with the n.m.r. spectra of authentic samples of **1** and **2**.

After some time at 260 °C (Fig. 1*c*), the primary decay products of EDTA decarboxylate to the various substituted methylamines. This conclusion is reached both from the work on NTA and from an appreciation of the chemical shifts shown in Fig. 1*c*. The peak at approximately 2.3 p.p.m. is a methyl bound to nitrogen such as shown in **3** or **4**. The singlet that grows in at approximately 3.8 p.p.m. is indicative of further hydrolysis of *N*-(2-hydroxyethyl)iminodiacetic acid to ethylene glycol and iminodiacetic acid.



NTA apparently does not undergo hydrolytic cleavage, but does decompose at 293 °C via decarboxylation to *N*-methyliminodiacetic acid, **5**, methylsarcosine, **6**, and trimethylamine, **7**. Figure 2 shows the decay of NTA in 4 h, indicating a mixture of these products. The half-life of 4.0 h is appreciably longer than that associated with the initial decay of EDTA, but at this temperature is comparable to the decomposition rate of the primary decomposition products formed from EDTA. Indeed it has been estimated that at the lower temperature of 200 °C, the half-lives of NTA^{3-} and $HNTA^{2-}$ are both > 1000 h (7).

	4.0	0.46	0.19
	6.0	0.37	0.17
		Average	0.19

Mean of averages: $k_{obs} = 0.19 \pm 0.01 \ h^{-1}$

*Discarded point.

The broadness of the 2.2 p.p.m. resonance (Fig. 2*b*) and the growth of closely spaced peaks at 3.0 p.p.m. support the composition of the mixture indicated in the equation above. Clearly, the 2.2 p.p.m. resonance represents three types of N—CH_3 groups (**5**–**7**), and the 3.0 p.p.m. peak shows the presence of three types of acetate methylenes (NTA, **5**, **6**).

Since the NTA decay rate at 293 °C was considerably slower that that of EDTA at the lower temperature investigated, a kinetic analysis for the initial NTA decomposition reaction was also undertaken in addition to the product analysis described above. Reaction kinetics was also obtained for EDTA hydrolysis within the limitation that a significant fraction of the starting substrate decomposes during heat-up time.

Table 1 summarizes the reaction conditions at four initial concentrations of NTA. It is seen that the observed rate constant does not vary with initial concentration. Thus the reaction rate at 293 °C and p*H* 9.3 for the decarboxylation of NTA follows pseudo first order kinetics with $k_{obs} = 0.19 \ h^{-1}$.

TABLE 2. Kinetic analysis of EDTA decomposition at 200 °C

EDTA initial concentration (*M*)	Time (h)	*F* Fraction remaining	$-\ln F$	k_{obs} (h^{-1})
0.0112	0.5	0.59	0.53	
	1.0	0.20	1.61	1.27
	2.0	0.08	2.53	
0.0056	0.5	0.40	0.92	
	1.0	0.18	1.71	1.37
	2.0	0.05	3.00	
0.0028	0.5	0.20	1.61	
	1.0	0.05	3.00	1.65
	2.0	0.015	4.20	
			Average	1.43 ± 0.20

Similarly, over a fourfold initial concentration range (Table 2) the pseudo first order rate constant for EDTA hydrolysis is found to be rather invariant within $\sigma = 0.2 \ h^{-1}$ with a value of $k_{obs} = 1.4 \ h^{-1}$.

The n.m.r. spectra of NTPO at 260 °C show the complete disappearance of the parent doublet ($J_{PCH} = 12$ Hz) after 0.25 h, replaced by two doublets with the same coupling constant and an intensity ratio of 2:1, both at lower field strength (Fig. 3*a*). The smaller doublet was determined to be aminomethylphosphonic acid (AMP) by the addition of an authentic sample

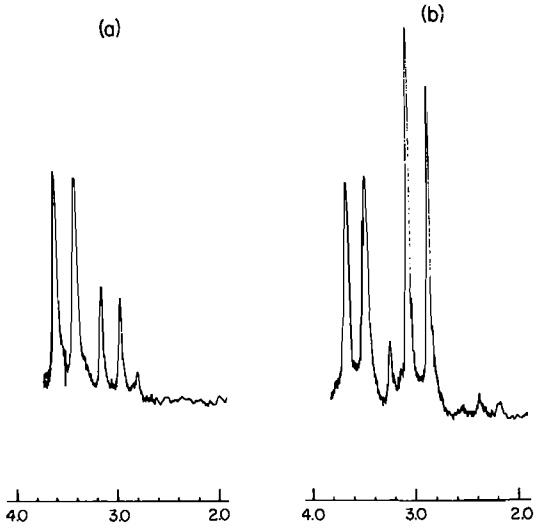

FIG. 3. Nuclear magnetic resonance spectra of NTPO sample at (*a*) $t = 0.25$, (*b*) $t = 0.25$ h, with aminomethylenephosphonic acid added. $T = 260$ °C, solvent = 5% $NaOD/D_2O$.

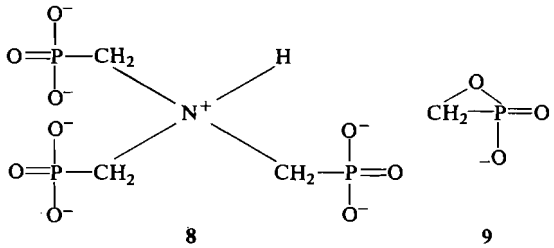
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of AMP to the n.m.r. tube (Fig. 3*b*). The larger doublet is therefore hydroxymethylphosphonic acid. Thus the fast hydrolytic reaction may be concluded to proceed as

$$N(CH_2PO_3^{2-})_3 \xrightarrow{H_2O} H_2NCH_2PO_3^{2-} + 2HOCH_2PO_3^{2-}$$

This behavior is quite different from that found with NTA, which does not undergo carbon–nitrogen bond fission even at much higher temperatures. Since the presence of high negative charge resulting from the phosphonate groups would seem to repel hydroxide ions and thus decrease base-catalyzed carbon–nitrogen hydrolytic fission relative to what is observed in NTA, the question arises as to the special nature of the NTPO anion that would tend to promote hydrolytic splitting. In this connection, it should be noted that the basicity of the tertiary amino group in NTPO is at least two orders of magnitude greater than NTA (9). Hence, even at the high temperatures involved in these studies, a considerable proportion of the ligand must be in the *N*-protonated form, **8**.

The positive charge on the nitrogen would be expected to assist carbon–nitrogen bond fission by transfer of the bonding electron pair to nitrogen.



8

9

There is also the possibility that hydrolytic fission of **8** may be assisted by the formation of an intermediate **9** which would be rapidly converted by hydroxide ion attack to hydroxymethylenephosphonic acid, which has been demonstrated to be one of the reaction products.

Figure 4 shows the relatively fast decomposition rate for EDTA, when compared to NTA. This, taken together with the above discussion, explains that the coordinating activity of aqueous solutions of EDTA at high temperatures (*i.e.*, above 200 °C) is due not to EDTA itself, but is primarily due to the complexing ability of the more thermally stable primary breakdown products **1** and **2**. By virtue of its

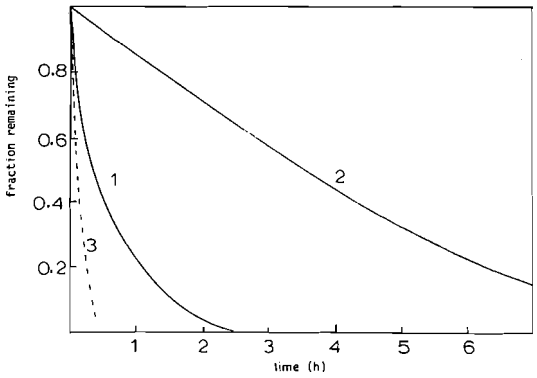


FIG. 4. Thermal decay plots of (*1*) EDTA at 200 °C, (*2*) NTA at 293 °C, (*3*) NTPO at 260 °C The decay in (*3*) is so rapid as to be difficult to measure. The decay of (*1*) was measured at $[EDTA]_0$ of 0.0112, 0.0056, and 0.0028 *M*; it showed no concentration dependence within the large experimental error induced by relatively long heat-up time compared to the rate of breakdown.

hydroxyethyl moiety **1** should be particularly suited for Fe^{3+} complexation, as is amply demonstrated in the literature and probably is the more active ingredient in such solutions. Both **1** and iminodiacetic acid, **2**, would be effective toward divalent transition metal ions. Thus from an economic point of view, as well as for the purpose of maintaining maximum chemical effectiveness, it would probably be reasonable to use *N*-hydroxyethyliminodiacetic acid as a sequestering agent for transition metals at elevated temperature (~200 °C and above) in place of more rapidly-hydrolyzed substances such as EDTA. At the present time NTA is the least expensive organic sequestering agent available. Since its slower breakdown leads to *N*-methyliminodiacetic acid which still retains considerable effectiveness, and since NTA is itself an order of magnitude more stable than EDTA, it may very well be the chelating agent of choice at the present time.

The above argument is based on the relative stabilities of the ligands themselves, rather than the metal chelates. While this is logical from the point of view of maintaining an effective concentration of ligands for the purposes of scale removal, the abilities of the metal chelates to resist hydrolytic breakdown is also important to prevent redeposition of metal hydroxides in aqueous solution at elevated temperatures.

A New Mode of Photorearrangement in the Azoxybenzene Series

NIGEL J. BUNCE

Guelph-Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ontario N1G 2W1

Received May 26, 1975

NIGEL J. BUNCE. Can. J. Chem. **53**, 3477 (1975).

Both isomers of 4-methoxyazoxybenzene photorearrange to the same *o*-hydroxyazo compound. In the case of β-4-methoxyazoxybenzene, prior photoisomerization to the α-isomer is involved.

NIGEL J. BUNCE. Can. J. Chem. **53**, 3477 (1975).

Les deux isomères du méthoxy-4 azoxybenzène se réarrangent photochimiquement pour conduire au même composé *o*-hydroxyazo. Dans le cas du β-méthoxy-4 azoxybenzène il y a photoisomérisation préalable en isomère α.

[Traduit par le journal]

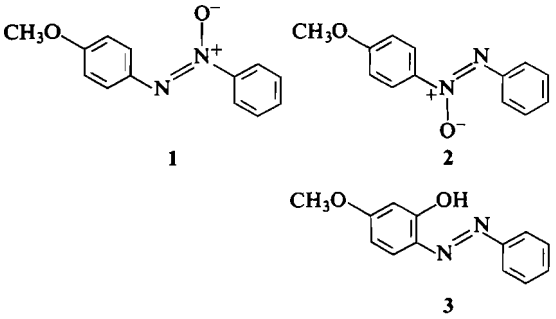
Photolysis of aromatic azoxy compounds causes them to isomerize into *o*-hydroxyazo compounds (1). The usual mode of rearrangement involves oxygen migration to the distant aromatic ring [1]. This was shown by analysis of the products of irradiation of unsymmetrically substituted azoxy compounds (2), and later confirmed by isotopic tracer experiments (3).

[1] 
Concurrently with photorearrangement, *cis–trans* isomerization at the azoxy linkage may also be observed (4). In this paper is reported an instance in which both isomers of a monosubstituted azoxybenzene photorearrange to the same *o*-hydroxyazo compound.

Illumination of ethanolic solutions of either **1** or **2** through Pyrex glass afforded the same rearrangement product **3**. The identity of the samples was established by mixture m.p., u.v. and n.m.r. spectra, and also by mass spectrometry. Aromatic azo compounds are well known to fragment predominantly to the ions represented in [2] (5), so that the observation of major fragment ions at *m/e* 77, 105, 123, and 151 corresponding to $C_6H_5^+$, $C_6H_5N_2^+$, $CH_3OC_6H_3OH^+$, and $CH_3OC_6H_3(OH)N_2^+$ (and the absence of the alternative *m/e* 93, 107, 121, and 135) locates the hydroxy and methoxy substituents in the same ring.



1 **2** **3**

[2] $Ar—N{=}N—Ar' \xrightarrow{e.i.} Ar^+, ArN_2^+, Ar'^+, Ar'N_2^+$

Formation of **3** on a photolysis of **2** appears to violate the generality of the photorearrangement pathway of [1], established by Badger and Buttery (2). That this is probably not so was revealed by examination of the azoxy compound remaining after photolysis; from the irradiation of **2**, its isomer **1** was recovered. Thus the 'abnormal' rearrangement product is unlikely to be formed directly from **2**, but rather results from prior isomerization of **2** to **1**. Consistent with this proposal, **3** was found to be produced more slowly from **2** than from **1**.

Although it has not proved possible to isolate or detect any intermediates in the transformation **2** → **1**, analogy with the work of Greene and Hecht (6) suggests **4** as a likely intermediate. Interestingly, when **2** is photolyzed in quartz equipment, the expected rearrangement product **5** is produced along with **3**, perhaps indicating

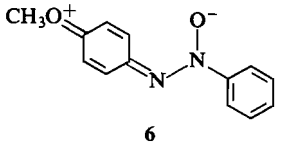
4 **5**

that **4** and **5** may be formed from different excited states of **2**.

A significant question is why position isomerization occurs for **2**, but not for **1** nor apparently for the unsymmetrical compounds studied by Badger and Buttery (2). Zero-order HMO calculations of the electron distributions in the π molecular orbitals of **1**, **2**, and unsubstituted azoxybenzene give no suggestion that the electron densities or free valence indices in the low lying excited states of **2** are significantly different from those in **1** or in unsubstituted azoxybenzene. Data for the n,π* states have been included since recent work suggests that this may be the reactive state for the azoxybenzene photorearrangement, rather than the π,π* as is usually assumed.[1] Table 1 notes these parameters for the nitrogen and oxygen atoms that would be involved if cyclization to **4** occurred. Another possibility might be the greater stability of **1** as compared with **2** arising from contributions from resonance structures such as **6**; this could



6

act as a driving force for the interconversion since no comparable structures can be drawn for **2**. Again, however, Table 1 suggests that this effect is small, judging by the very modest reduction in charge on the central nitrogen that results from interaction with the methoxy group.

At this point, we are unable to offer an explanation for the ability of **2** to photoisomerize in this new manner. However, position isomerization now joins photorearrangement and *cis–trans* photoisomerization as a possible and observed mode of photoreaction in the azoxybenzene series. It remains to be seen whether the new reaction occurs in other unsymmetrical aromatic azoxy compounds, though previous

TABLE 2. Relative rates of appearance of hydroxyazo compound **3** from azoxy compounds **1** and **2**

Concentration (*M*)	Rate (**2**)/rate (**1**)
5.5×10^{-5}	0.52
2.8×10^{-4}	0.50
5.5×10^{-4}	0.50

work (2, 3) indicates that it must usually be extremely inefficient.

Experimental

Solvents were reagent grade materials except ligroin for use in chromatography and preparative t.l.c., which was commercial hexane (fraction from petroleum). All were used without purification. Instrumentation included a Pye–Unicam SP 800 u.v.–visible spectrophotometer, a Varian Associates A-60A n.m.r. spectrometer, and a Varian-MAT CH7 mass spectrometer operated at 70 eV ionizing voltage. Melting points are uncorrected.

Isomeric 4-Methoxyazoxybenzenes

p-Hydroxyazobenzene (5 g) was methylated with dimethyl sulphate in aqueous alkaline solution, affording, after purification of the crude product by chromatography over alumina, *p*-methoxyazobenzene, m.p. 53–54 °C (lit. (7) 54 °C). The product (3 g) was oxidized in acetic acid solution with 30% H_2O_2 (5 ml) on a steam bath for 5 h. The crude product was purified by chromatography over alumina, eluting with ligroin, to give the isomeric *p*-methoxyphenylazoxybenzenes (2.23 g) as a pale yellow solid. Repeated fractional crystallization from methanol gave the pure isomers; the purest fractions were: 4-methoxyphenyl-*NNO*-azoxybenzene, **1**, m.p. 73–74 °C (lit. (8) 67 °C), and 4-methoxyphenyl-*ONN*-azoxybenzene, **2**, m.p. 39–40 °C (lit. (8) 42 °C).[2] Ultraviolet absorption maxima (EtOH) were respectively 348 and 337 nm (lit. (9) 350 and 338 nm).

Preparative Irradiations

These were carried out in ethanol solution in the presence of atmospheric amounts of oxygen, using a 450 W Hanovia medium pressure mercury arc and an immersion well apparatus. The outer jacket of the apparatus, which had a capacity of 325 ml with the immersion well in place, had a flat base to permit agitation of the solution using a magnetic stirrer. After photolysis, the solvent was removed and the residue resolved by preparative t.l.c. on silica gel PF_{254} (E. Merck #7747). The bands were scraped off and the compounds extracted into chloroform (Soxhlet extractor), which was filtered prior to evaporation and recrystallization of the residue from ethanol.

*Irradiation of **1**, Pyrex Filter*

The reactant (0.30 g) had m.p. 65–68 °C. The products were recovered **1**, (0.22 g), m.p. 70–72 °C, and 5-methoxy-2-phenylazophenol, **3**, (0.06 g), matted orange needles from ethanol, m.p. 111–112 °C (lit. (10) 115 °C). Ultraviolet λ_{max} (EtOH) 374 nm (ε 19 100) and 255 (6500); λ_{max} (EtOH–0.5 *M* KOH) 454 nm (ε 12 200), and 335 (11 000); n.m.r. (CCl_4) δ 13.4 (s, OH), 6.2–7.9 (m, ArH), and 3.85 (s, OCH_3); mass spectrum (70 eV): *m/e* 228 (M^+, 100%), 151 (61), 123 (83), 105 (23), and 77 (33).

*Irradiation of **2**, Pyrex Filter*

The reactant was **2**, (0.40 g), m.p. 37–41 °C. The products obtained were the azoxy compound **1**, (0.23 g), m.p. 61–65 °C, λ_{max} (EtOH) 346 nm, and the azo compound **3** (0.05 g), red needles from ethanol, m.p. 112–113.5 °C, not depressed by admixture with the product of irradiation of **1**. Mass spectrum *m/e* 228 (M^+, 100%), 151 (52), 123 (60), 105 (16), and 77 (36); u.v. and n.m.r. spectra identical to those reported above.

*Irradiation of **2**, Quartz Equipment*

The reactant was **2**, (0.35 g), m.p. 39–40 °C. After irradiation the products were the azoxy compound **1**, (7 mg), λ_{max} 345 nm, and two red substances. The more mobile on silica gel was 2-hydroxy-4′-methoxyazobenzene,[3] **5**, (36 mg), red needles from ethanol, m.p. 72–74 °C. Ultraviolet λ_{max} (EtOH) 380 nm (ε 19 000), 348 (20 500), and 248 (12 700); λ_{max} (EtOH–0.5 *M* KOH) 460 nm (ε 9700) and 317 (15 300); n.m.r. (CCl_4) δ 3.85 (s, OCH_3), 7.1–8.0 (m, ArH), and 15.9 (s, OH); mass spectrum *m/e* 228 (M^+, 63%), 135 (38), 121 (12), 107 (100), 93 (37), and 91 (35).

Anal. Calcd. for $C_{13}H_{12}N_2O_2$: C, 68.41; H, 5.30; N, 12.27. Found: C, 68.13; H, 5.55; N, 12.23.

The other red substance was the hydroxyazo compound **3**, (51 mg); red needles from ethanol, m.p. 113–114 °C. Nuclear magnetic resonance and mass spectra were identical to those reported above.

Anal. Calcd. for $C_{13}H_{12}N_2O_2$: C, 68.41; H, 5.30; N, 12.27. Found: C, 68.30; H, 5.51; N, 12.20.

Relative Rate Experiments

The 450 W mercury arc, cooled by the Pyrex immersion well, was surrounded by a filter solution (1 cm of 2×10^{-3} *M* K_2CrO_4 in 1% K_2CO_3) to restrict light absorption to 300–330 nm, where the reactants absorbed strongly. This assembly was placed in a constant temperature bath at 30 ± 0.2 °C. Corked Pyrex ampoules containing 4 ml aliquots of the azoxy compounds dissolved[4] in ethanol–0.5 *M* KOH were irradiated simultaneously using a 'Merry-go-round' to ensure equal illumination of samples. Samples were irradiated for specified times and then examined spectrophotometrically for the appearance of the anion of **3** (λ = 454 nm). The results are given in Table 2.

The author thanks the National Research Council of Canada for financial support.

[2]Compounds **1** and **2** are respectively the α and β isomers in the older system of nomenclature.

[3]The possible structure 4-hydroxy-4′-methoxyazobenzene is ruled out by the higher m.p., 142 °C (11), of the latter.

[4]The alkaline solution was used so that the hydroxyazo compound produced could be monitored as its anion. Experiments with azoxybenzene have shown that neither the rate nor the identity of the product is affected by using this solvent rather than pure ethanol.

The Mechanism for the Thermal Decomposition of *E*-Aldoxime Carbonates[1]

J. M. PROKIPCAK AND P. A. FORTE

Department of Chemistry, University of Guelph, Guelph, Ontario N1G 2W1

Received May 22, 1975

J. M. PROKIPCAK and P. A. FORTE. Can. J. Chem. **53**, 3481 (1975).

Pyrolysis of aldoxime carbonates at relatively low temperatures (100–120 °C) produced nitriles in excellent yields. These decompositions followed first-order kinetics and the decomposition rates showed little dependence on inductive effects or solvent polarity. Low entropy values along with the fact that the *E* and *Z*-isomers behaved quite differently led to the proposal of a cyclic transition state for the decompositions.

J. M. PROKIPCAK et P. A. FORTE. Can. J. Chem. **53**, 3481 (1975).

La pyrolyse des carbonates d'aldoxime à des températures relativement basses (100–120 °C) conduit aux nitriles avec d'excellents rendements. Ces décompositions se produisent suivant une cinétique du premier ordre et les vitesses de décomposition ne sont que peu affectées par les effets inductifs ou la polarité du solvant. En se basant sur le fait que les entropies sont basses et que les isomères *E* et *Z* se comportent très différemment, on suggère un état de transition cyclique pour ces décompositions.

Introduction

It was shown in an earlier publication (1) that the thermal decomposition of *E*-benzaldoxime carbonates was a useful synthetic route in the preparation of nitriles. This route was particularly valuable since the conversion of the *E*-aldoxime carbonates to the corresponding nitriles required no acidic or basic reagents.

Other recent articles have appeared in the literature which describe the conversion of aldehydes to nitriles under mild conditions (2–4). These conversions are suggested to be fragmentation reactions but no real attempts were made to determine the mechanisms involved. A continuing study of the thermal fragmentation of aldoxime carbonates was carried out in an effort to allow some conclusions to be made with regard to the mechanism involved. It was felt that two possible modes for the decomposition were possible (Scheme 1) and that the investigation of inductive effects and solvent effects would allow a more conclusive picture to be made regarding the actual transition state involved in the decomposition. All the benzaldoximes used in this study were readily prepared from the respective aldehydes using standard methods. The benzaldoximes were treated with phenyl chloroformate (or a *p*-substituted phenyl chloroformate) in the presence of an equimolar amount of pyridine. The aldoxime carbonates were then heated to 100–120 °C giving the corresponding nitriles, phenols, and CO_2. The variation in the decomposition rate due to structural changes in the benzaldoxime and phenyl chloroformate portion of the molecule were examined. Also the effect of solvent polarity and nature of the oxime (*i.e.* whether the aldoxime was the *E*- or *Z*-form) was investigated. This report gives the results of these studies and a mechanism for the thermal decomposition is proposed.

Experimental

Synthesis of Chloroformates

Phenyl chloroformate, 4-methoxyphenyl chloroformate, and 4-nitrophenyl chloroformate were obtained commercially and used without further purification. The 4-methylphenyl and 4-chlorophenyl chloroformates were prepared by the reaction of the properly substituted phenol with phosgene according to the method of Zabik and Schuetz (5).

Synthesis of Benzaldoxime Carbonates

The general synthesis procedure used for the preparation of these compounds can be found in previous work (1). The complete list of *E*-benzaldoxime carbonates prepared and used in this study along with physical constants and elemental analyses is given in Table 1.

In addition to the *Z*-isomers, the *E*-isomer of benz-

aldoxime was prepared (6). However, attempts to prepare the carbonate from the *E*-benzaldoxime failed and the reaction gave the nitrile directly.

Kinetics of the Decompositions

Since all the starting carbonates had a carbonyl group which gave a strong absorption band in the infrared over the region 1900–1700 cm^{-1} and since this absorption was not close to any other major absorptions, the base-line method was used to analyze each spectrum. Furthermore, earlier experiments with standard solutions of the carbonates in various solvents employed showed that the intensity of the carbonyl band did indeed obey Beer's Law and that a plot of $\log P_0/P$ (P = absorptions) *vs.* concentration resulted in a straight line. Thus all the decompositions carried out in this study were followed by means of i.r. using the following general method.

A solution of the carbonate (3–4 g) dissolved in a solvent (5–8 ml) such as diphenyl ether, benzonitrile, or dimethyl sulfoxide was made. Then using a syringe (1 ± 0.01 ml), equal aliquots (0.50 ml) of this solution were put into a series of reaction tubes which were placed simultaneously into a constant temperature oil bath which was maintained at a desired temperature (100–120 ± 0.05 °C). At spaced intervals of time, each tube was removed quickly from the oil bath and immediately quenched in an acetone – Dry Ice mixture. After all the reaction tubes had been quenched and allowed to return to room temperature, 0.7 ml of spectral grade chloroform was added to each tube to dilute the reaction mixture. The absorption of the carbonyl peak was measured on the IR-5A and the absorbance was obtained by the base-line method (7). The average absorbance was then multiplied by the slope of the Beer's

Law plot to give the concentration of the sample. A plot of log concentration *vs.* time was made and the rate constant obtained.

Results and Discussion

Using the aforementioned method, the decompositions were found to exhibit good first-order kinetics and Table 2 summarizes the results of the various kinetic runs. The method of least squares was used to determine the slopes of the lines and in all cases, regression coefficients of at least 0.990 were obtained.

The first-order kinetics could be applied to three basic modes of decomposition; homolytic type, ionic heterolytic type, or concerted heterolytic type. Even though the latter two (heterolytic types) are the most probable reaction pathways for the reaction (Scheme 1), the possibility of a homolytic cleavage (or radical mechanism) could not be overlooked. This possibility was examined by means of a procedure called chemically induced dynamic nuclear polarization (CIDNP) (8, 9) which makes use of the fact that the presence of any radicals in the reaction flask would give rise to significant changes in the absorption intensities of a n.m.r. spectrum. When the progress of the decomposition of *E*-benzaldoxime phenyl carbonate was followed in a n.m.r. tube using DMSO as a solvent, the n.m.r. spectra showed no enhanced or unexplainable absorption or emmission lines. Even though this does not completely disprove the existence of nonpaired radicals, one can with reasonable confidence conclude that a dissociative radical mechanism is most likely not operative in this reaction whether the *E*- or *Z*-isomer is involved.

In heterolytic processes, transition states or intermediates often develop charge character and appropriate substituents at or near the reaction center may affect their formation. Also induced electron withdrawal or supply may influence the bond heterolysis taking place in the process. In order to examine the charge characteristics of the transition state or intermediate, the dependence of the decomposition rates on the inductive effect of substituents both on the benzaldoxime portion and chloroformate portion of the compounds was investigated. Figure 1 shows the results when Hammett plots were made for each series. The resultant plot of $\log k/k_0$ versus σ (10) for the *E*-4-substituted benzaldoxime carbonates gave a straight line with a ρ value of -0.249. This low negative ρ value indicates only small inductive

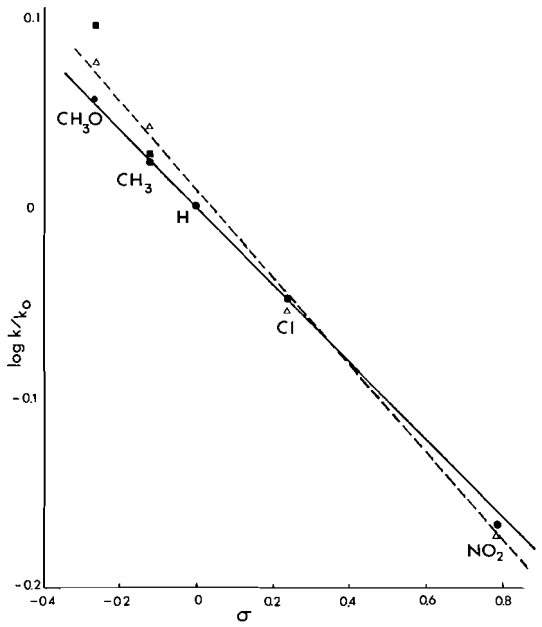

FIG. 1. Plot of $\log k/k_0$ for aldoxime carbonates *vs.* Hammett σ values: (*a*) —△—△—△— 4-substituted benzaldoxime phenyl carbonates in DMSO ($\rho = -0.249$); (*b*) —●—●—●— benzaldoxime 4-substituted phenyl carbonates in DPE ($\rho = -0.213$); (*c*) ■ values for benzaldoxime 4-substituted phenyl carbonates in DMSO. Note, for benzaldoxime 4-chlorophenyl carbonate $\log k/k_0 = 0.782$, and for benzaldoxime 4-nitrophenyl carbonate $\log k/k_0 = 0.578$.

effects operating and also that the transition state has a greater demand for electrons than the ground state. These results would be indicative of a small positive charge build-up on the nitrogen as the N—O bond begins to break.

The effect of substituents on the phenoxide portion of the molecule were next examined by measuring the rates of decomposition of *E*-benzaldoxime 4-substituted phenyl carbonates in DMSO. However, when the $\log k/k_0$ versus σ plot was made for this series, no orderly progression of electronic effects was found (Fig. 1). These substituents would be expected to appreciably affect the electron density around the phenoxide oxygen which should in turn affect the strength of the phenoxide–carbonyl bond and ultimately the stability of the phenoxide ion if it were formed. Electron-releasing groups such as CH_3O— and CH_3— had little effect on the decomposition rates; on the other hand, electron-withdrawing groups such as Cl and NO_2 did enhance the decompositions but to a much greater extent than was originally expected. It is possible that the electron-withdrawing groups affected the strength of the bonds around the carbonyl grouping thereby causing the appearance of a secondary mechanism which is more ionic in nature. Furthermore, the nitro and chloro groups could enhance breakdown of any intermediate to products and CO_2 by stabilizing the phenoxide once it has formed. This coupled with the ability of the solvent (DMSO) to support an ionic mechanism could explain the increased decomposition rate.

In order to substantiate the possible existence of a secondary ionic mechanism, the same *E*-benzaldoxime 4-substituted phenyl carbonates were pyrolyzed in diphenyl ether rather than DMSO and the substituent effects were observed. A Hammett plot in this case (Fig. 1, solid line) gave a straight line of slope −0.213 which indicates that a solvent which does not favor an ionic process returns the decomposition to an orderly dependence on electronic effects. Again the small negative slope indicates that electrons are needed in the transition state but only to a very small extent. A possible explanation for this dependence is that the electrons on the phenolic oxygen are required in the transition state or intermediate; electron-donating groups such as CH_3O— and CH_3— increase this electron density whereas electron-withdrawing groups such as Cl and NO_2 decrease it.

If a highly ionic intermediate or even an appreciable charge build-up were involved in the process, the decomposition rates should show a dependence on solvent polarity. When the decomposition of *E*-benzaldoxime phenyl carbonate was carried out in diphenyl ether, benzonitrile, and dimethyl sulfoxide, *i.e.* solvents of different polarity, the first-order rate constants were 1.81×10^{-4}, 1.5×10^{-4}, and $2.00 \times 10^{-4}\ s^{-1}$ respectively. These extremely close values indicate a very small or almost non-existent solvent effect and would not support the existence of a very charged intermediate. Indeed this lack of solvent effect is analogous to that reported for the Claisen rearrangement (11) of allylic ethers which has been shown to undergo rearrangement via a cyclic, concerted process.

The 4-substituted phenyl carbonates of *E*-benzaldoxime gave similar results when the decompositions were carried out in different solvents. The only variation occurred with the *E*-benzaldoxime-4-chlorophenyl and -4-nitro-

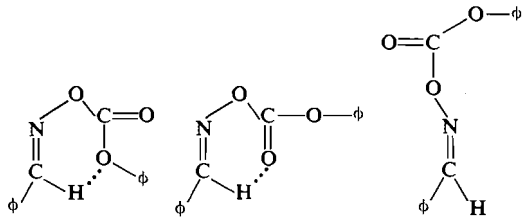
phenyl carbonates which decomposed approximately six times faster in dimethyl sulfoxide than in diphenyl ether. This difference in behavior, as already mentioned, could be a result of a change towards a more ionic mechanism and which is supported by the Eyring plots which indicated the appearance of a secondary mechanism in the case of the NO_2 substituted system.

The activation parameters for both the *p*-substituted-*E*-benzaldoxime and *p*-substituted phenyl series were calculated (Table 2) in an attempt to shed some light on the nature of the intermediate in the decomposition. In all cases (except the one given above), the Eyring plots gave straight lines which were used to calculate enthalpies of activation ($\Delta H^{\ddagger}$) and entropies of activation ($\Delta S^{\ddagger}$). The $\Delta H^{\ddagger}$ were approximately 28.4 kcal mol^{-1} for all the systems studied while the $\Delta S^{\ddagger}$ were all very small and mainly positive. The $\Delta S^{\ddagger}$ values were somewhat surprising at first since normally large positive values would be expected for an ionic process and negative values would be expected (11) for a concerted process where a certain amount of orientation is needed in the transition state. The small value for $\Delta S^{\ddagger}$ would seem to indicate that the orientation in the reactant or ground state is very close to that required in the transition state for the process to occur. Thus it would seem that little change in geometry of the molecule was required and the entropy did not change appreciably even when solvents of different polarity were used. This inherent desired orientation can probably be attributed to the imino double bond.

The presence of the imino double bond did present two questions that had to be considered. The first raised the possibility that isomerization was occurring between the *E*- and *Z*-isomers of the carbonates. However, work by Curtin *et al.* (12) on 4-chlorobenzophenone ketoxime methyl ether and by Philips (13) on benzaldoximes would indicate that this type of isomerization is very unlikely under the reaction conditions. The second involved seeing whether the *E*- and *Z*-isomers did actually behave differently *i.e.* was the geometry of the starting aldoxime important in the process. Investigation of this aspect gave some interesting results. When attempts were made to carry out the aldoxime to aldoxime carbonate to nitrile sequence on the *Z*-benzaldoxime, no intermediate carbonate could be isolated. Rather the *Z*-isomer was converted directly to the nitrile, CO_2 and phenol. Thus the *E*- and *Z*-isomers both gave the same final results but the *Z*-isomer required much milder conditions. Apparently two different decomposition paths are involved and a possible explanation for this difference can be found if one considers the various interactions that can occur which are a result of the stereochemistry around the imino double bond. The *E*-form of the benzaldoxime carbonate permits the intramolecular interaction of the phenolic oxygen **1** or carbonyl oxygen **2** with the imino



1 **2** **3**

hydrogen which can result in a cyclic transition state and eventually to decomposition. The *Z*-form **3** on the other hand offers no locations for similar major intramolecular overlap or interaction. Thus the imino hydrogen of the *Z*-form could be prone to attack from external reagents such as pyridine to give a simple base-catalyzed *trans* elimination. Banthrope (14) used this argument to explain the much greater ease with which base-promoted formation of nitriles occurred with *Z*-aldoxime acetates than with the *E*-isomers.

Conclusions

From the data obtained in this study, there is little support for the ionic mechanism given in Scheme 1, Path 1*A* or *B*. The low ρ values would not be expected if indeed there were an appreciable charge build-up in the transition state. Furthermore the general lack of dependence of decomposition rate on solvent polarity would not support the presence of an ionic intermediate. The low entropy values indicate the orientation in the ground state is very close to that in the transition state. This along with the difference in behavior between the *E*- and *Z*-isomers would indicate that the *E*-benzaldoxime carbonates undergo decomposition via a cyclic process as indicated in Scheme 1, Path 2.

Received June 2, 1975

J. G. CONTRERAS and D. G. TUCK. Can. J. Chem. **53**, 3487 (1975).

The Raman spectra of the solids *n*-$Pr_4N[CdX_3]$, where X is Cl, Br, or I, show that trihalogenocadmate anions possess C_{2v} symmetry in the solid state. Force constants have been calculated using the Urey–Bradley approximation and are correlated with the values reported for other tricoordinate species.

Introduction

Like other d^{10} cations, cadmium(II) forms an interesting range of anionic complexes with halide ligands. The salt K_4CdCl_6 contains octahedral $CdCl_6^{4-}$ anions; (*1*), $CdCl_5^{2-}$ has D_{3h} symmetry; (*2*), and the CdX_4^{2-} complexes (X = Cl, Br, I) must clearly be tetrahedral. The information with respect to the solids $MCdX_3$ is more complicated. Vibrational spectra and X-ray diffraction studies (3, 4) have shown that salts of the type $MCdCl_3$, where M = K, Rb, NH_4, have structures containing anionic chains $(CdCl_3^-)_\infty$ of C_{2h} line group symmetry. On the other hand, the Raman spectra of aqueous and non-aqueous solutions of various $Cd^{2+}:X^-$ ratios (X = Cl, Br, or I) have been studied by Davies and Long (5), who identified CdX_3^- species. In each case, a medium-to-strong polarized Raman band was assigned to the symmetric cadmium–halogen stretching mode. Two depolarized emissions were assigned to the antisymmetric stretching and bending modes of the planar CdX_3^- anion, of D_{3h} symmetry. Sanyal and Singh (6) have calculated Urey–Bradley force constants, using the results reported by Davies and Long, and assuming D_{3h} symmetry.

In contrast, Macklin and Plane (7) studied the stepwise formation of cadmium/bromide complexes in aqueous solutions, and found three bands (173, 73, and 44 cm^{-1}), which they assigned to $CdBr_3^-$ species of C_{3v} symmetry. The failure to observe the other vibrations required for C_{3v} was attributed to the extensive overlap of various other bands. Clarke *et al.* (8) recently reported a Raman emission at 264 cm^{-1} in solutions of $Cd(NO_3)_2$ + KCl in molten sodium nitrate – potassium nitrate mixtures. This vibration was assigned to the $CdCl_3^-$ anion; no corresponding bands from the $CdBr_3^-$ species were detected, in keeping with the fact that $CdBr_4^{2-}$ is the predominant complex ion in solution in the cadmium/bromide melt system.

Some further study of these CdX_3^- systems seems called for, and we have accordingly prepared crystalline salts of these anions with the large tetrapropylammonium cation, and recorded their Raman spectra. Force constant calculations support the assignment of C_{2v} symmetry for the anions in these solids. The results lead to some interesting comparisons with those for the analogous complexes of other d^{10} ions.

Experimental

General

The Raman spectra were recorded on a Laser He/Ne Carry 81 spectrometer. Cadmium analyses were by atomic absorption spectroscopy; halide was analyzed gravimetrically.

Preparative

A general preparative method was used throughout this work. Cadmium dihalides were either dissolved or suspended in anhydrous methanol, the stoichiometric amount of the appropriate tetrapropylammonium salt added, and the solution left with stirring for 3–4 h. Solvent was then pumped off and the resulting solid dissolved in a 1:1 mixture of either acetone/acetonitrile or methanol/acetonitrile. Slow evaporation yielded colorless crystals which were recrystallized twice from the same solvent mixtures. Analyses and molar conductivities in acetonitrile (approximate m*M* concentration) are given below.

Anal. Calcd. for $(C_3H_7)_4N{\cdot}CdCl_3$: C, 35.6; H, 6.9; N, 3.5; Cd, 27.8; Cl, 26.3. Found: C, 35.4; H, 7.0; N, 3.4; Cd, 27.7; Cl, 26.3.

$\Lambda_M^{25} = 128\ ohm^{-1}\ cm^{-2}$; m.p. 190 °C.

Anal. Calcd. for $(C_3H_7)_4N{\cdot}CdBr_3$: C, 26.8; H, 5.2; N, 2.6; Cd, 20.9; Br, 44.5. Found: C, 26.9; H, 5.3; N, 2.6; Cd, 20.9; Br, 44.3.

$\Lambda_M^{25} = 131\ ohm^{-1}\ cm^{-2}$; m.p. 193 °C.

Anal. Calcd. for $(C_3H_7)_4N{\cdot}CdI_3$: C, 21.2; H, 4.1; N, 2.1; Cd, 16.6; I, 56.1. Found: C, 21.5; H, 4.1; N, 2.0; Cd, 16.6; I, 56.0.

$\Lambda_M^{25} = 124\ ohm^{-1}\ cm^{-2}$; m.p. = 234 °C.

Calculations

Since no molecular structure parameters are available for these anions, bond distances were taken from the literature (9); the values used were 2.62 and 2.40 Å for Cd—Br and 2.35 and 2.30 Å for the Cd—Cl bond distances. The X—Cd—X angles were all assumed to be 120°.

The normal coordinate analysis utilized the program described by Overend and Scherer (10), with local modifications. The program was set up in cartesian coordinates. Computations were carried out on the IBM 1620 computer of the Universidad de Concepciòn.

The calculations gave values for the five in-plane normal modes; the out-of-plane deformation mode was not calculated.

Results and Discussion

There are pronounced differences between the Raman spectra of $Pr_4N{\cdot}CdCl_3$ and those reported for the solids $MCdCl_3$, where M = K, Rb, NH_4, or Me_4N (3). Since the latter group of compounds involve halogen-bridged structures (3, 5), it is reasonable to assume that the anions are effectively individual units in the tetrapropylammonium salt, due to the effect of the large cation. In view of the agreement between our spectra and those reported for CdX_3^- species in solution (7, 8), we believe that we are observing the Raman emission from discrete CdX_3^- anions.

Table 1 shows the observed spectra, with assignments based on C_{2v} symmetry for the anions, following the work of Davies and Long (5). The splitting of the E' vibrational modes was ascribed to the effect of the site symmetry, which brings about a non-equivalence in one of the halide ligands, possibly through a long contact with another molecule in the unit cell. The molecular symmetry therefore cannot be D_{3h} (or D_3); although vibrational spectroscopy does not allow a differentiation between C_{2v} and C_s symmetries, the former was assumed for all three CdX_3^- species in the present work.

The correlation between the D_{3h} and C_{2v} irreducible representations of the fundamentals can be written as

ν_4 } B_2	314	312	97(2)+3(5)
ν_5 } B_2	76	77	1(2)−5(3)+104(5)

[a]Force constant number given in parentheses refers to list in Table 2.

The Raman bands of the solids were assigned by comparison with those reported for the same species in solution (7, 8). Table 1 shows the spectral bands for the solids $[(C_3H_7)_4N][CdX_3]$ (X = Cl, Br, or I) used in our calculations, and their assignments. The spectral results for solutions of CdX_3^- species are also given (5). Force constant calculations using the Urey–Bradley approximation for these species on a C_{2v} model support the conclusion that they possess such a symmetry in the solid state.

In each case we observed one very weak emission, located at 184, 143, and 105 cm^{-1} for the chloro, bromo, and iodo complexes, respectively. This band has been assigned to the $\nu_6(B_1)$ out-of-plane vibrational mode which was not included in the calculations. Since there are six unknown force constants to be calculated from the five vibrational modes, we have used the value of the repulsive force constant, $F_I(X_{II}...X_{II})$ of the corresponding D_{3h} species in solution as calculated by Sanyal and Singh (6). As usual F' was assumed to be equal to $-0.1F$. The set of force constants calculated on this basis are given in Table 2, and the potential energy distribution amongst the force constants is shown in Tables 3 to 5.

The calculated eigenvectors, and the potential energy distribution amongst the force constants, show that ν_4 and $\nu_5(B_2)$ are essentially pure antisymmetric Cd—X_{II} and X_I—Cd—X_{II} stretching and bending modes, respectively. For ν_1, however, there is a significant contribution of K_{II}, varying from 29% for CdI_3^- through 9% for $CdBr_3^-$ to 4% for $CdCl_3^-$, so that the coupling of the Cd—X_I and Cd—X_{II} stretching modes changes appreciably through this series. Similarly, the difference in the corresponding stretching force constants $K_I - K_{II}$ has the values 0.43, 0.24, and 0.20 for X = Cl, Br, and I, respectively; for D_{3h} symmetry, there is one such stretching force constant, so that the difference $K_I - K_{II}$ reflects the extent of the deviation from D_{3h} symmetry. Finally, the splitting of ν_3 mode of the D_{3h} CdX_3^- species into $\nu_2 + \nu_4$ (see Table 1) amounts to 20, 14, and 9 cm^{-1} for $CdCl_3^-$, $CdBr_3^-$, and CdI_3^-. Each of these three tests shows that the $CdCl_3^-$ anion is most strongly distorted from D_{3h} symmetry in the compounds studied, and CdI_3^- the least.[1] Both K_I and K_{II} show a smooth decrease from $CdCl_3^-$ to CdI_3^-,

[1]We are grateful to a referee for suggesting this argument.

as was found in calculations of the primary stretching force constants of the tetrahedral InX_4^- anions (X = Cl, Br, I) (11), where the values change from 0.760 for $InCl_4^-$ to 0.625 × 10^5 dyn cm^{-1} for InI_4^-. We have discussed previously (11) the dependence of these force constants upon the electronegativity difference $\Delta\chi$ ($= \chi_{halogen} - \chi_{metal}$); in the present work, K_1 and K_{11} clearly change monotonically with $\Delta\chi$. As in the earlier study, the inference that the cadium halide bond is ionic in character is more important than any discussion as to the exact nature of the relationship between K_1 (or K_{11}) and $\Delta\chi$. We also note, in this context, that the stretching force constants for the tetrahedral CdX_4^{2-} species (X = Cl, Br, I) also decrease with decreasing ligand electronegativity (f_r = 1.41, 1.19, and 0.98 × 10^5 dyn cm^{-1} for X = Cl, Br, and I, respectively (5)). These values are smaller than those for the isoelectronic InX_4^- species (11), in keeping with an ionic bonding model.

In our previous work (11), we showed that a linear relationship exists between the logarithim of the stretching force constant and the oxidation state of the metal in the tricoordinate isoelectronic InX_3^{2-}, SnX_3^-, and SbX_3 species. We have tested this relationship against our present results, and find that despite the difference in the symmetry and electronic configuration of the central atom, the values for CdX_3^- fit remarkably well onto the earlier curve. The conclusion is then that for the CdX_3^- and SnX_3^- anions, the difference in stereochemistry has little effect on the stretching force constants, a

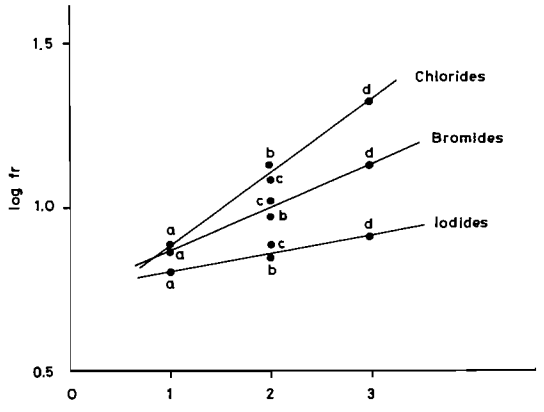

FIG. 1. The dependence of the stretching force constant upon oxidation state for some MX_3 species. *a*, indium; *b*, cadmium; *c*, tin; *d*, antimony.

conclusion which further supports the ionic character of the bonding in these species (Fig. 1).

In summary, the calculated stretching force constants for the CdX_3^- complexes depend on the electronegativity of the ligand in a manner which is very similar to that observed for other related species (11, 12), and which supports the concept of a significantly ionic type of bonding.

Coordination Compounds of Indium. Part XXX. Pyrrole Complexes of Indium(III) and Dimethylindium(III)

HENRY L. CHUNG AND DENNIS G. TUCK

Department of Chemistry, University of Windsor, Windsor, Ontario N9B 3P4

Received June 18, 1975

H. L. CHUNG and D. G. TUCK. Can. J. Chem. **53**, 3492 (1975).

Preparative and spectroscopic studies show that the interaction of 2-formylpyrrole, $C_4H_4N{\cdot}CHO$, and 2-acetylpyrrole, $C_4H_4N{\cdot}COCH_3$ (=HL), with In(III) may involve the organic base as either a bidentate organic anion ligand to give InL_3 complexes, (L = 2-acetylpyrrolate only) or as a neutral monodentate species to form $InCl_3{\cdot}3HL$. The spectroscopic and kinetic properties of the organometallic derivatives Me_2InL are also discussed. The polarographic reduction of InL_3 (L = 2-acetylpyrrole anion) involves three one-electron reduction steps.

H. L. CHUNG et D. G. TUCK. Can. J. Chem. **53**, 3492 (1975).

Des études de préparation et de spectroscopie permettent de montrer que l'interaction du formyl-2 pyrrole, C_4H_4NCHO, et de l'acétyl-2 pyrrole, $C_4H_4N{\cdot}COCH_3$ (=HL), avec In(III) peut impliquer la base organique soit sous forme de ligand organique anionique bidentate conduisant à des complexes InL_3, (L = seulement l'acétyl-2 pyrrolate) ou sous forme d'espèces monodentates neutres amenant la formation de $InCl_3{\cdot}3HL$. On discute aussi des propriétés spectroscopiques et cinétiques des dérivés organométalliques Me_2InL. La réduction polarographique de InL_3 (L = anion acétyl-2 pyrrole) implique trois transferts d'un électron.

[Traduit par le journal]

Introduction

One of the interesting features of complexes of indium(III) with bidentate ligands is that polarographic reduction in nonaqueous solvents may take place via three one-electron steps, in contrast to the single three-electron reduction observed for simple In(III) species in aqueous solution. The details of such reduction processes for In(III)–dithiolate and In(III)–diketonate species have been discussed elsewhere (1–3). The original aim of the present work was to prepare complexes of indium(III) with 2-formylpyrrole (**1**; R = H) and related compounds in order to investigate the effect of the group R on the reduction to the formally In(II) and In(I) states, but this was not in fact achieved because the synthesis of the InL_3 complexes proved much more difficult than expected. The preparative and spectroscopic work did, however, reveal that pyrrole derivatives may coordinate as either neutral or anionic ligands. We have also prepared the corresponding Me_2InL complexes, examples of an increasing number of dimethylindium(III) derivatives of bidentate organic bases.

Previous work with pyrrole compounds as ligands has been entirely concerned with transition metals. Emmert *et al.* (4) reported the preparation of the copper(II) complex of 2-formylpyrrole; this compound, the cobalt(III) analog, and related compounds with R = CH_3, were studied spectroscopically by Perry and Weber (5). Davies and Gogan (6) obtained CrL_3 compounds of various pyrrole ligands, starting with $Cr(CO)_6$, and showed that in these compounds the ligand is bidentate and formally anionic, chelating through basic oxygen and nitrogen atoms. Later work by these authors (7), and others (8), established that pyrroles can also function as π-donors, in which the ligand donates electrons from the C_4H_4N ring. To these two modes of ligation can now be added a third, in which the basic oxygen bonds to the metal ion, with retention of the nitrogen acidic proton, which is involved in intramolecular hydrogen-bonding to a halide ligand also coordinated to the metal ion.

Experimental

General, Materials

Spectroscopic and analytical methods were as described in previous work (1–3). Operations involving organoindium compounds were carried out in a dry oxygen-free glove box.

2-Formylpyrrole was prepared according to the method described by Silverstein *et al.* (9). 2-Acetylpyrrole was obtained by a modification of this method; *N,N*-dimethylacetamide (48 g) was treated with phosphorus oxychloride (85 g); after about 15 min, ethylene dichloride (125 ml) was added to the reaction mixture, followed by 34 g of freshly distilled pyrrole in ethylene dichloride (125 ml). This mixture was refluxed for 20 min, cooled to 25 °C, and aqueous sodium acetate (375 g in 500 ml) added. After refluxing for a further 20 min the organic phase was worked up to give a white crystalline material (m.p. 90 °C) which was sublimed *in vacuo*.

Trimethylindium was prepared by the reaction of indium(III) chloride and methyl lithium.

Preparation of Dimethylindium(III) Derivatives

When equimolar quantities of trimethylindium and 2-formylpyrrole were stirred together in dry ether at room temperature, a white precipitate formed after about 5 min. After 30 min, during which time the solution changed from colorless to yellow, the final precipitate was collected and dried *in vacuo*. The compound (dimethylindium(III)-2-formylpyrrolate) is soluble in acetone, methanol, ethanol, dimethylsulfoxide, chloroform, and hot benzene, but insoluble in ether, petroleum ether, carbon tetrachloride, carbon disulfide, and cyclohexane. The solid material darkened on standing over some weeks in a sealed tube. Analytical results for this and other compounds are given in Table 1. The preparation and properties of dimethylindium(III)-2-acetylpyrrolate were similar to those of the formyl compound.

An adduct of dimethylindium(III)-2-formylpyrrolate was prepared by mixing solutions of this compound and 2,2′-bipyridyl in acetone; addition of cyclohexane produced a yellow solid. We were unable to obtain this material in a form suitable for elemental analysis since attempted crystallization gave only gummy solids, but integration of the n.m.r. spectrum of the dissolved material showed that the bipy:pyrrole:CH_3 proton ratio was 8:4:6, as required for a $Me_2In(pyr{\cdot}CHO)(bipy)$ compound.

Attempted Preparations of $In(pyr{\cdot}CHO)_3$

Via Indium(III) Carbonate

Following the work of Emmert *et al.* (4), a suspension of indium(III) carbonate (prepared from the reaction of indium(III) chloride and sodium carbonate) was refluxed with 2-formylpyrrole in xylene. After about 15 min orange crystals were visible, but these proved to be merely contaminated indium carbonate. After longer refluxing (~10 h), the solution phase was evaporated to yield a purple solid which appeared to be polymer contaminated with pyrrole.

Via Solvent Extraction

Indium(III) chloride was dissolved in water and the p*H* adjusted to 6; this solution was then refluxed with a chloroform solution of 2-formylpyrrole. Although this method works successfully for $In(acac)_3$ (10), refluxing over periods from 2 h to 3 days yielded only unchanged pyrrole in the organic phase of the present experiments.

Via Lithium 2-Formylpyrrolate

The lithium derivative of 2-formylpyrrole, prepared by the reaction of the parent compound and methyl lithium suspended in chloroform, was treated with indium chloride in the same solvent. The color of the suspension changed from white through orange to red, but the solution phase did not yield the desired InL_3 compound.

Via $InCl_3(Hpyr{\cdot}CHO)_3$

This complex (see below) was treated with triethylamine in the hope of forming $Et_3NH{\cdot}Cl$ and $In(pyr{\cdot}CHO)_3$. Reaction of these materials in acetone produced an immediate white precipitate, insoluble in water, and containing 18.1% Cl (calculated for Et_3NHCl, 25.8% Cl); the n.m.r. spectrum showed the presence of ethyl groups in the solid. The filtrate from this reaction yielded 2-formylpyrrole as the only significant solid.

Via $Me_2In(pyr{\cdot}CHO)$

Dimethylindium(III)-2-formylpyrrolate and excess of 2-formylpyrrole in toluene were heated in a sealed tube at 110 °C for 10 min, after which the tube was opened and gaseous products removed by pumping. This cycle was repeated six times. The final solution produced brownish crystals on cooling, or on reduction in volume, but this material again proved to be 2-formylpyrrole, and contained no indium.

Preparation of $In(pyr{\cdot}COCH_3)_3$

Dimethylindium(III)-2-acetylpyrrolate and 2-acetylpyrrole (1:3 mole ratio) were heated in benzene in a

sealed tube for 10 min, after which the mixture was degassed *in vacuo*. After repeating this cycle six times, the solution was held at 110 °C for 3 days. The solvent was then pumped off, leaving a yellow residue of $In(pyr{\cdot}COCH_3)_3$. The mass spectrum of this solid had strong peaks at *m/e* 115 (In^+), 223 (InL^+), 331 (InL_3^+), and 439 (InL_3^+).

Preparation of $InCl_3(Hpyr{\cdot}CHO)_3$ and $InCl_3(Hpyr{\cdot}COCH_3)_3$

When ether solutions of $InCl_3{\cdot}3H_2O$ and 2-formylpyrrole (1:3 mole ratio) were mixed and stirred at room temperature, a white precipitate began to form after 5 min. After 30 min the solid material was collected, washed, and dried *in vacuo*. This material, $InCl_3(Hpyr{\cdot}CHO)_3$, m.p. 143 °C, is soluble in acetone, ethanol, and dimethylsulfoxide, but insoluble in carbon tetrachloride, benzene, ethylenedichloride, petroleum ether, and carbon disulfide.

The corresponding derivative of 2-acetylpyrrole was prepared by a similar reaction, but the resultant white crystalline solid decomposed very readily on removal of solvent at or below room temperature, so that only indium and chloride analyses were possible, and no spectroscopic results were obtained for this compound. This decomposition, which is not photodependent, involves the loss of a gas identified as hydrogen chloride. In a subsequent experiment, we collected the materials evaporating from the reaction mixture during the final removal of the solvent. No significant material was detected in the first (70 ml) or second (8 ml) fractions, but the final 2 ml contained both H^+ and Cl^-. We return to this point below.

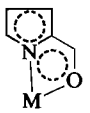
Results and Discussion

Preparative Studies

The present work apparently represents the first attempt to prepare derivatives of pyrrole compounds with main group elements. It is clear that the indium(III) tris(2-formylpyrrolate) complex was not obtained by any of the five methods investigated, despite the fact that the corresponding 2-acetylpyrrole compound is reasonably stable. The reason for the differing behavior of the two compounds is not immediately obvious.

The difficulty in stabilizing indium(III), relative to transition metal species, may reflect extra stabilization in the latter due to delocalization in the metal–ligand ring system. The ready formation of dimethylindium(III) derivatives of both pyrrole anions shows that there can be no steric barrier to the chelation of these ligands to indium(III).

The delocalization has been discussed by Gogan and Davies (6, 7) in terms of the structure and to the extent that this structure depends upon the metal d_π-orbitals, the low stability of the indium(III) compounds may be due to charge being confined to the pyrrole ring.



In addition to the difficulties experienced in the preparation of neutral InL_3 species with these pyrroles, we have the formation of unusual adducts in which the pyrrole is a protonated monodentate ligand. The spectroscopic evidence on the structure of these compounds is reviewed below.

Nuclear Magnetic Resonance Spectroscopy

The n.m.r. (^1H) spectra of 2-formyl- and 2-acetylpyrrole are given in Table 2; that for the 2-formylpyrrole is in good agreement with published material (11).

The spectrum of 2-formylpyrrole shows little dependence on solvent apart from a slight shift in the broad and readily identifiable N—H proton signal (e). Similarly, substitution of —CHO by $—COCH_3$ at the 2-position causes a small downfield shift of ~0.40 p.p.m. in the ring proton resonances. The formation of the dimethylindium complexes $Me_2In(pyr{\cdot}CHO)$ and $Me_2In(pyr{\cdot}COCH_3)$ produces a shift of ~0.1 p.p.m. in protons a, b, and c, corresponding to a deshielding associated with electron donation from the chelating oxygen atoms to the Me_2In group. Changes of similar magnitude were observed in the formation of γ-pyrone complexes of indium(III) (2).

It was necessary to obtain the spectrum of $In(pyr{\cdot}COCH_3)_3$ in benzene-d_6 and in consequence a direct comparison with that of $Me_2In(pyr{\cdot}COCH_3)$ in acetone-d_6 is not possible. The ring protons appear to be significantly more deshielded in the former (shifts ~0.3 p.p.m.), relative to the parent ligand. The compound formed by the direct addition of 2-formylpyrrole to indium(III) chloride shows virtually no shift in the resonance of any of the protons.

As part of the n.m.r. studies, we find that a solution of a mixture of $Me_2In(pyr{\cdot}CHO)$ and 2-formylpyrrole in acetone-d_6 at 0 °C shows two resonances in the 9.3 p.p.m. region (−CHO). These resonances coalesce at 35 °C, and from this, and the measured frequency difference of 22.2 Hz between ligand and complex at 0 °C, we calculate that the free energy of ligand exchange in this system is 14.8 kcal mol^{-1}. This value is in the same order as that reported previously for

ligand exchange involving dimethylindium complexes of β-diketonates (12).

We note finally that solutions of dimethylindium pyrrole species are rather unstable, depositing white solids after some hours at room temperature. The spectra reported are for freshly prepared solutions.

Vibrational Spectra

The vibrational spectrum of 2-formylpyrrole has been analyzed and assigned by Lord and Miller (13). The most important features relevant to the present work are ν(N—H) at 3400 cm^{-1} (br) and ν(C=O) at 1650 cm^{-1}. From our work, the corresponding values in 2-acetylpyrrole are ν(N—H) 3275 and ν(C=O) 1649 cm^{-1}.

The infrared spectra of the two dimethylindium(III) derivatives show an absence of ν(N—H), and a lowering of approximately 50 cm^{-1} in ν(C=O). A band at 725 cm^{-1} in Me_2In(pyr·$COCH_3$), and a shoulder at 720 cm^{-1} in Me_2In(pyr·CHO), are assigned to δ(In—CH_3) by analogy with a number of other dimethylindium(III) derivatives. Both compounds have vibrations which can be assigned to ν(In—CH_3): Me_2In(pyr·CHO), 545s + 480m (i.r.); 546m + 482m (R); Me_2In(pyr·$COCH_3$), 541m + 489mw (i.r.); 544m + 490s (R). Again, these values are in keeping with previous work.

The only interesting features of the infrared spectrum of the complex In(pyr·$COCH_3$)$_3$ are the absence of ν(N—H) and the shift in ν(C=O) to 1640vs cm^{-1}. The latter is, on the face of it, surprisingly small, but mixing of vibrations is believed to hinder the analysis of vibrations in other bis- and tris-chelate systems (e.g. β-diketonates (14)) and the same phenomenon may well be important in the present case. Finally, in $InCl_3$(Hpyr·CHO)$_3$, ν(C=O) is at 1645vs cm^{-1}; ν(N—H) of the free ligand is absent, and a very broad absorption centered at about 2800 cm^{-1} may be the stretching mode of the N—H---Cl system (see below).

Structural Discussion

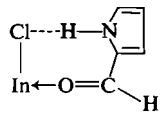
The spectroscopic and kinetic properties of Me_2In(pyr·CHO) and Me_2In(pyr·$COCH_3$) are in keeping with those of other dimethylindium(III) complexes with bidentate chelate ligands, and require no special comment. It is probable that the solid phase involves polymerization via intermolecular bonding as in Me_2In(OAc) (15). By analogy with the behavior of the latter, the adduct Me_2In(pyr·CHO) (bipy) should be one member of a series of adducts with neutral donors. The failure of the attempts to prepare In(pyr·CHO)$_3$ is puzzling and no specific reason is obvious. The compound In(pyr·$COCH_3$)$_3$ has the properties to be expected of a six-coordinate InO_3N_3 chelate complex.

Finally, we turn to the unusual compounds $InCl_3$(HL)$_3$ (HL = 2-formyl or 2-acetylpyrrole). The n.m.r. spectroscopic evidence (Table 2) shows unambiguously that there are five proton resonances per pyrrole in $InCl_3$(Hpyr·CHO)$_3$, in keeping with the presence of three chloride ligands in the molecule. The simplest assumption then is that intramolecular hydrogen bonding stabilizes the N—H proton. Hydrogen-bonding by pyrrole itself has been the subject of a number of studies. Infrared spectroscopy (16, 17) has been used to show that pyrrole interacts in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solution with various organic bases, and similar conclusions have been reached from dielectric polarization studies (18–20). Proton n.m.r. results in such systems have been discussed by Reeves (21), Freymann and Freymann (22), and Happe (23). None of these studies, unfortunately, refers to interactions in the solid state, or to pyrroles with substituted basic groups.

The structure



is proposed to explain the bonding in the solid state. Molecular models, based on reasonable interatomic distances, show that the overall molecular structure easily accommodates three such interactions, with three *cis* chlorides. The model appears free of significant strain. The intramolecular stabilization of acidic hydrogen atoms is not unusual; a relevant example is the molecule $[(Meen)_2Cu(CF_3{\cdot}CO{\cdot}CH{\cdot}CO{\cdot}CF_3)_2]$ (Meen = $(CH_3)_2N{\cdot}C_2H_4{\cdot}NH_2$) in which there are two monodentate β-diketonate ligands whose noncoordinated oxygens are each hydrogen-bonded to an NH_2 group of the diamine (24). The n.m.r. results (Table 2) are incompatible with the existence of the above structure in acetone solution, since the spectrum of a freshly prepared solution is almost identical with that of free Hpyr·CHO. This could imply that the solution decomposition process is

$$[1] \qquad InCl_3{\cdot}3HL \rightleftharpoons InCl_3 + 3HL$$

The broad resonance at +11.2 is clearly that of a hydrogen-bonded system, but unfortunately the resonance frequency is an unreliable structural guide in such cases.

An alternative decomposition could be

$$[2] \qquad InCl_3{\cdot}3HL \rightleftharpoons InL_3 + 3HCl$$

and the reality of this process for the 2-acetylpyrrole adduct of $InCl_3$ is illustrated by the loss of HCl in the final stages of the preparative procedure (see Experimental). In this latter system, the existence of a stable InL_3 compound serves to move the equilibrium completely to the right. A solution of $InCl_3(Hpyr{\cdot}CHO)_3$ in acetone turns red–brown on standing at room temperature, again suggesting decomposition by reaction 2. Thus we conclude that the failure to obtain a pure crystalline sample of $InCl_3(Hpyr{\cdot}COCH_3)_3$ is a consequence of the stability of $In(pyr{\cdot}COCH_3)_3$; equally the isolation of $InCl_3(Hpyr{\cdot}CHO)_3$ may in part reflect the instability of $In(pyr{\cdot}CHO)_3$.

The question of why substitution of H by CH_3 in the sidechain at the 2-position of pyrrole has such a pronounced effect on the ligating properties of these compounds must remain unanswered at the present time.

Polarographic Reduction

An initial aim of this work was to investigate polarographic reduction of In(III) pyrrole complexes; in the event we were only able to study $In(pyr{\cdot}COCH_3)_3$. In acetone solution containing the complex and 0.1 *M* $Et_4N{\cdot}ClO_4$, with Ag/AgCl and dropping mercury electrodes, we observed three one-electron reduction steps, with $E_{1/2}{}^{I}$ 0.37 V, $E_{1/2}{}^{II}$ −1.30 V, and $E_{1/2}{}^{III}$ −1.98 V. All three steps are polarographically irreversible (α^{I} 0.14, α^{II} 0.24, α^{III} 0.48). The reduction of 2-acetylpyrrole under the same conditions showed only one polarographic wave, $E_{1/2}$ = −1.60 V (α = 0.31), so that at least the first two reduction steps in InL_3 must be associated with reduction of the complex. In this respect then, $In(pyr{\cdot}COCH_3)_3$ behaves similarly to other neutral indium(III) complexes with bidentate chelating ligands.

This work was supported in part by Operating Grants from the National Research Council of Canada. Dr. J. J. Habeeb is thanked for carrying out the preparative work on $InCl_3(Hpyr{\cdot}COCH_3)_3$.

Acid-catalyzed Reactions of 3β-Acetoxy-9α-hydroxy-11-keto-5α-lanostane: 19(10→9β)*abeo*-lanostenes[1]

OLIVER E. EDWARDS AND ZDSISLAW PARYZEK[2]

Division of Biological Sciences, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received September 9, 1975

OLIVER E. EDWARDS and ZDSISLAW PARYZEK. Can. J. Chem. **53**, 3498 (1975).

Acid-catalyzed dehydration of 3β-acetoxy-9-hydroxy-11-keto-5α-lanostane gave under varying conditions 3β-acetoxy-11-keto-14(13 → 12)*abeo*-lanost-12-ene, or the two cucurbitanes 3β-acetoxy-11-keto-19(10 → 9β)*abeo*-lanost-1(10)-ene and the corresponding 5(10)-ene.

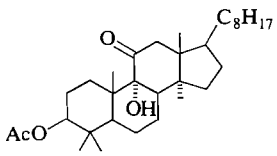
OLIVER E. EDWARDS et ZDSISLAW PARYZEK. Can. J. Chem. **53**, 3498 (1975).

La déshydratation, en milieu acide, de l'acétoxy-3β hydroxy-9 oxo-11 5α-lanostane conduit, suivant les conditions, à l'acétoxy-3β oxo-11 14(13 → 12) *abéo*-lanostène-12 ou aux deux cucurbitanes acétoxy-3β oxo-11 19(10 → 9β) *abéo*-lanostène-1(10) et l'alcène correspondant avec une double liaison en 5,10.

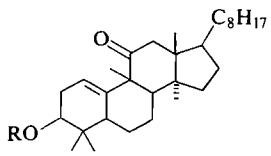
[Traduit par le journal]

Attempts have been made without success in several laboratories to convert lanostane derivatives, by processes involving cationic carbon, into cucurbitanes (1–3).[3] We now report the first such transformation.

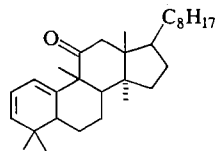
The ketol **1**, m.p. 183 °C, $[\alpha]_D$ 63° (*c*, 1.3 in chloroform), ν_{max} ($CHCl_3$) 1712, and 1691 cm^{-1}, was prepared from 3β-acetoxylanost-9(11)-ene(4) via the 9α,11α-diol, m.p. 164 °C. Its structure was confirmed by thionyl chloride – pyridine dehydration to 3β-acetoxy-11-keto-5α-lanost-8-ene. Under Westphalen dehydration conditions (sulfuric acid in acetic acid – acetic anhydride mixture at room temperature), **1** gave two olefinic products A and B in 19 and 15% yields respectively.



1



2



3

Compound A was a trisubstituted olefin, m.p. 84 °C, with ν_{max} ($CHCl_3$) 1725, and 1685 cm^{-1}. The following evidence established its structure as **2** (R = Ac). It gave ^1H n.m.r. signals at δ 5.14 (br s, 1H), 4.84 (dd, 1H), a pair of doublets (2H, Δδ 23 Hz, J = 15 Hz) centered at δ 2.59, and a 3H singlet at δ 2.06. It could be hydrolyzed to an alcohol (**2**, R = H) with c.d.$_{max}$ 300 nm, Δε 4.65 which gave ^{13}C n.m.r. signals at 214, 139, and 119.6 p.p.m. The action of pyridine on the tosylate of this alcohol produced a homo-annular diene **3**, m.p. 115 °C, ν_{max} ($CHCl_3$) 1695 cm^{-1}, M^+ 424, λ_{max} 270 nm, ε 6450. Its ^1H n.m.r. spectrum had a complex group of signals (3H) between δ 5.2 and 5.8.

Oxidation of **2** (R = H) with Jones' reagent gave an amorphous diketone with ν_{max} ($CHCl_3$) 1710 and 1690 cm^{-1}. This gave ^1H n.m.r. signals at δ 5.26 (m, 1H), 2.82 (m, 2H), and 2.62 (pair of doublets, 2H, Δδ 27 Hz, J = 14 Hz). Double irradiation showed that the olefinic proton was coupled with the methylene resonating at δ 2.82. The action of selenium dioxide in hot

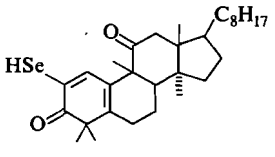
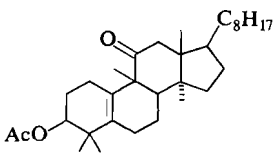
[3]The multifunctional cucurbitacins are derivatives of 19(10 → 9β)*abeo*-lanostane. We suggest that this skeleton be named cucurbitane.



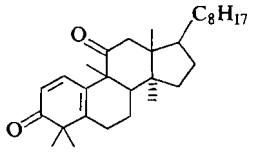
4



5

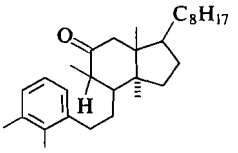
wet dioxane on the diketone produced pale yellow needles of a compound with possible structure **4**, m.p. 205 °C, λ_{max} 370 nm, ε 2340, ν_{max} 1690, 1646, and 1623 cm^{-1}, ^1H n.m.r. signals at δ 7.18 (1H) and 2.6 (2H).

Compound B was a tetrasubstituted olefin, m.p. 149 °C whose structure proved to be **5**. It had ν_{max} 1725 and 1690 cm^{-1}, ^1H n.m.r. signals at δ 4.65 (1H), 2.55 (2H), and 2.05 (3H), ^{13}C n.m.r. signals at 216, 180, 134, and 128 p.p.m. and c.d.$_{max}$ 300 nm, Δε 7.5. On hydrolysis this gave an amorphous keto alcohol (Δε 8.0 at 300 nm) which could be oxidized to an amorphous diketone with ν_{max} 1712 and 1693 cm^{-1}. This diketone was oxidized by selenium dioxide in hot wet dioxane to a mixture of a homoannular dienone **6** (36%) (λ_{max} 325 nm, ε 4750, ν_{max} 1690, 1660, and 1625 cm^{-1}) and a 16% yield of **4** thus relating it to A.

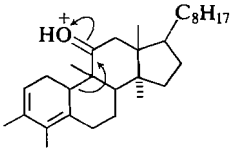


6

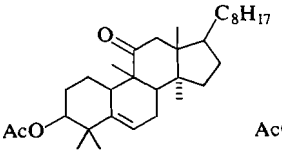
The action of anhydrous *p*-toluenesulfonic acid in hot benzene on B gave among other products a 20% yield of an amorphous aromatic compound with ν_{max} ($CHCl_3$), 1690 cm^{-1}; λ_{max} 271 nm (ε 178), 263 nm (ε 220) with intense end absorption. It had ^1H n.m.r. signals at δ 7.08 (s, 3H), 2.7 (t, 2H), 2.53 (s, 2H), 2.30 (s, 3H), and 2.23 (s, 3H). Its mass spectrum had M^+ 424 and intense peaks at *m/e* 317, 304, and 291 corresponding to loss of the aromatic ring and one or two extra carbons respectively. The use of $Eu(dpm)_3$ shift reagent caused rapid movement of both the signal from a methylene group which was originally at δ 2.5 (finally transforming it into a pair of doublets with Δδ 42 Hz and J = 16 Hz (—CH_2CO—)) and a broad signal for a third hydrogen (CHCO). A 3H doublet (CH_3-CHCO) moved with moderate speed as the shift reagent concentration increased. This evidence is consistent with structure **7**, formed in a mechanistically plausible way from a protonated species such as **8**.



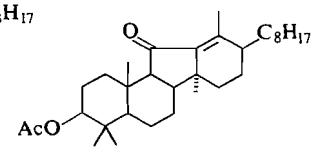
7



8



9



10

24-Deoxybryogenin acetate **9** was prepared from bryogenin. It had m.p. 140 °C, c.d.$_{max}$ 298 nm, Δε 6.6. When treated with *p*-toluenesulfonic acid in benzene as for B it gave a 60% yield of **7** thus interrelating A and B with an authentic cucurbitacin.

As far as we are aware, A and B are the first 19(10 → 9β)*abeo*-lanostane derivatives to be obtained by partial or total synthesis.

The action of *p*-toluenesulfonic acid hydrate in hot benzene on **1**, followed by alkaline hydrolysis, gave among other products the *C*-nor-*D*-homo derivative **10** (3β-hydroxy-11-keto-14(13 → 12)*abeo*-lanost-12-ene). It had m.p. 159 °C, ν_{max} (CH_2Cl_2) 1620 and 1695 cm^{-1}, and λ_{max} 255 nm (ε 15 000) and 356 nm (ε 100). Its ^1H n.m.r. spectrum contained a 3H singlet at δ 2.1. This appears to be the first report of a *C*-nor-*D*-homo lanostane derivative.

We thank Mr. R. Kolt for valuable technical assistance, Dr. R. E. Williams for the circular dichroism measurements, and Dr. I. C. P. Smith and co-workers for the ^{13}C n.m.r. spectra.

Polymerization *in situ* Accompanying Field Desorption Mass Spectrometry

GORDON WALTER WOOD AND DONNA LEE WADE
Department of Chemistry, University of Windsor, Windsor, Ontario N9B 3P4

Received August 11, 1975

GORDON WALTER WOOD and DONNA LEE WADE. Can. J. Chem. **53**, 3500 (1975).

Field desorption mass spectrometry of hydroxycarboxylic acids results in ions corresponding to condensation polymerization with water loss. The phenomenon is particularly marked with 3-hydroxypropanoic acid where at high anode temperatures the base peak corresponds to $6M - 5H_2O$ and ions up to $13M - 12H_2O$ are observed.

GORDON WALTER WOOD et DONNA LEE WADE. Can. J. Chem. **53**, 3500 (1975).

La spectrométrie de masse avec une source à désorption de champ, d'acides hydroxycarboxyliques provoque la formation d'ions correspondants à une polymérisation par condensation avec perte d'eau. Le phénomène est particulièrement marqué avec l'acide hydroxy-3 propanoïque, où à des températures élevées de l'anode, le pic de base correspond à $6M - 5H_2O$ et où on observe des ions jusqu'à $13M - 12H_2O$.

[Traduit par le journal]

We wish to report the first observation of a process in field desorption mass spectrometry (f.d.m.s.) which has the characteristics of thermal polymerization of a hydroxyacid to form polyester chains.

Field desorption mass spectrometry has undergone very rapid growth since its development in 1969, particularly in the 2 years since commercial instrumentation became available (1, 2). The initial emphasis on this technique for determining molecular weights of organic compounds not amenable to electron impact mass spectral study is still evident (3), but the scope of the method has been expanded to include a wide variety of compounds including salts, phospholipids, sugars, amino acids and oligopeptides, metal complexes, and DNA pyrolysis products. During this work it has been discovered that variation of anode heating current produces important changes in spectra. In particular, many compounds give structurally significant fragments at higher temperatures. On the other hand, hydrogen rearrangements and exchange processes frequently make difficult the assignment of structures to *m/e* peaks.

Further difficulty arises from the presence of cluster ions frequently involving several molecules and/or ions. The results to be reported here represent another process with potential for complicating the interpretation of f.d. spectra.

In connection with an extensive survey of the behavior of carboxylic acids and salts on f.d.m.s., we have determined the spectra of a number of hydroxyacids. The compounds tested thus far all show some evidence of condensation accompanied by water loss prior to ionization. For example, lactic, glycolic, and gluconic acids all show ions corresponding to $2M - H_2O$. Lactic acid shows oligomer peaks up to $5M - 4H_2O$, while the other two show 'lactide peaks' at $2M - 2H_2O$. The amino acids threonine and homoserine did not show appreciable evidence of this behavior. The only peak of any significance found was $2M - H_2O$ (3%) in homoserine (4).

Intensities of polymerization peaks are particularly high for 3-hydroxypropanoic acid as shown in Table 1. The base peak of this spectrum is *m/e* 235 which corresponds to $(3M - 2H_2O) + H$. The M + H ion (*m/e* 91) has a relative intensity of 8% and the only true cleavage peak occurs at *m/e* 59 (CH_2COOH). An extensive series of peaks corresponding to $[xM - (x - 1)H_2O] + H$ consists of ions for every value of x from 2 to 9 (*m/e* 163, 235, 307, 379, 451, 523, 595, 667). Of the remaining ions, six may be attributed to $[xM - (x - 2)H_2O] + H$ (*m/e* 470, 541, 613, 685, 756, 829), and another eight appear to be decarboxylation products of the above. About 13 ions are still unassigned; further work will be necessary to discover their origin and to confirm the tentative assignments already made.

An indication of the dependence of the degree of polymerization on anode temperature may be obtained from Table 2. It is apparent that spectra may be recorded over a wide temperature range (approximately 50–200°) with a fairly reg-

ular progression of base peak and highest polymer detected as temperature is increased.[1]

[1]Following a referee's suggestion, we determined the effect on molecular weight distribution of heating the sample-coated anode before applying high voltage. Heating the sample to 15 mA prior to field desorption at 9 mA resulted in an increased degree of polymerization ($x = 4$ became base peak and other intensities were shifted accordingly), indicating that at least part of the observed effect of anode heating arises from thermal polymerization rather than a field effect.

It will be some time before the significance of these results is established, but it is apparent that care must be taken in interpretation of f.d.m.s. whenever molecules containing 2 or more functional groups capable of reaction are involved. Some support for the view that the conditioned field anode should be regarded as a micro-reactor is also provided. The focussing requirements for the polymer ions observed here suggest that ionization may occur outside the

condensed phase region. However, more detailed study will be required before a mechanism for this process can be proposed.

Secondary β-Hydrogen Isotope Effects in Ketal Formation Equilibria[1]

VALERIE A. STOUTE AND MITCHELL A. WINNIK[2]

Erindale College and Lash Miller Laboratories, Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received June 5, 1975

VALERIE A. STOUTE and MITCHELL A. WINNIK. Can. J. Chem. **53**, 3503 (1975).

An n.m.r. technique was used to measure K_H/K_D of ketal formation in methylene chloride solution for acetone and phenylacetone. For acetone, $K_H/K_D = 0.95$ per D for methyl ketal formation. Phenylacetone-1,1-d_2, -3,3,3-d_3, and -1,1,1,3,3-d_5 were examined for both dimethyl and ethylene ketal formation. For both ketals, $K_H/K_D = 0.91$ per D, for each ketone. Liquid scintillation counting was used to examine K_H/K_T for ketal formation in methylene chloride. An extraordinarily large isotope effect was found for ethylene ketal formation in 1,3-diphenylacetone. Here $K_H/K_T = 0.67$ for one tritium atom. This isotope effect is too large to arise from hyperconjugative effects alone. It must have a substantial steric component.

VALERIE A. STOUTE et MITCHELL A. WINNIK. Can. J. Chem. **53**, 3503 (1975).

On a utilisé une technique de r.m.n. pour mesurer le K_H/K_D de la formation de cétals de l'acétone et de acétophénone en solution dans le chlorure de méthylène. Pour l'acétone, $K_H/K_D = 0.95$ par D pour la formation du cétal de méthyl. On a étudié les formations des diméthyl et éthylène cétals des phénylacétones -1,1-d_2, -3,3,3-d_3 et -1,1,1,3,3-d_5. Pour les deux cétals on a trouvé un $K_H/K_D = 0.91$ par D pour chaque cétone. On a utilisé le comptage par scintillation liquide pour étudier le K_H/K_T de la formation des cétals en solution dans le chlorure de méthylene. On a trouvé qu'il y a un effet isotopique très grand pour la formation de l'éthylène cétal de la diphényl-1,3 acétone. Dans ce cas, le $K_H/K_T = 0.67$ pour un atome de tritium. Cet effet isotopique est trop grand pour dériver uniquement d'effets d'hyperconjuguaison; il doit y avoir en plus une composante stérique.

[Traduit par le journal]

The wealth of secondary deuterium isotope data on the kinetics of nucleophilic addition to carbonyl compounds, (1) and hydrolysis of ketone adducts, (2) has not been accompanied by a similar effort to determine isotope effects on corresponding carbonyl addition equilibria (3). Equilibrium isotope effects serve as an important point of reference for kinetic isotope effects studies (3*c*). The latter are easier to carry out. Results can be obtained with greater precision, and, for the most part, that has been where the attention has been focused.

In the course of our studies of isotope effects in the Baeyer–Villiger reaction, (4) it became necessary to model the isotope effect on the pre-equilibrium step. This meant determining an equilibrium isotope effect for an appropriate reaction involving nucleophilic addition to a ketone. Since we were concerned with an oxygen nucleophile, hemiketal or ketal formation seemed appropriate. In our original communication (4) we reported application of the method of Jones and Bender (3*a*) to obtain the isotope effect for hemiketal formation in phenyl-2-pro-

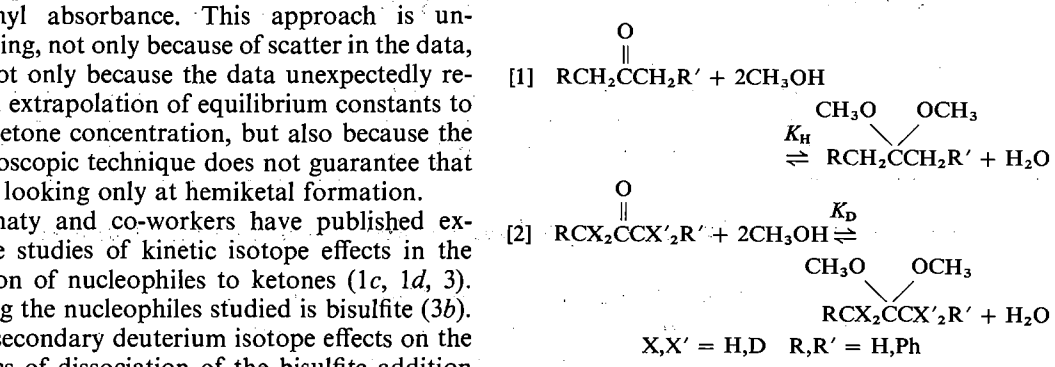
panone (phenylacetone). In this approach, the ketone, in methanol–dioxane, is treated with an acid catalyst and the equilibrium concentrations of all species are inferred from the decrease in carbonyl absorbance. This approach is unsatisfying, not only because of scatter in the data, and not only because the data unexpectedly required extrapolation of equilibrium constants to zero ketone concentration, but also because the spectroscopic technique does not guarantee that one is looking only at hemiketal formation.

Lamaty and co-workers have published extensive studies of kinetic isotope effects in the addition of nucleophiles to ketones (1*c*, 1*d*, 3). Among the nucleophiles studied is bisulfite (3*b*). Here secondary deuterium isotope effects on the kinetics of dissociation of the bisulfite addition complex were measured. K_H/K_D has been measured in this system and k_H/k_D for formation of the complex calculated from these data.

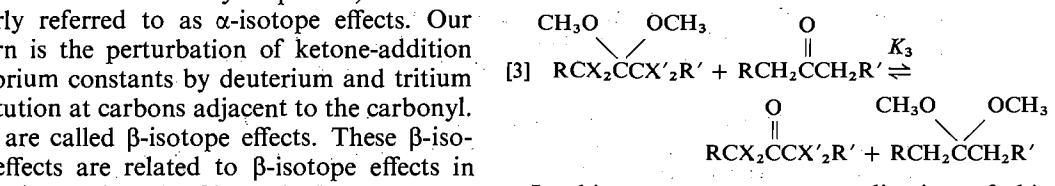
Isotope effects on equilibria of addition to aldehydes have recently been reported (3*c*). These isotope effects derive from substitution of deuterium for the aldehyde proton, and are properly referred to as α-isotope effects. Our concern is the perturbation of ketone-addition equilibrium constants by deuterium and tritium substitution at carbons adjacent to the carbonyl. These are called β-isotope effects. These β-isotope effects are related to β-isotope effects in solvolysis reactions (5, Chapt. 2, 6).

From the work of Lamaty and co-workers (3*b*) and of Bender and co-worker (3*a*) it is clear that nucleophilic addition to carbonyls gives rise to inverse β-deuterium isotope effects, $K_H/K_D < 1$. The magnitude of these isotope effects (*i.e.* the degree to which K_H/K_D differs from 1.0) is significantly greater than kinetic isotope effects for addition to carbonyls (1, 3*c*). Much more is known about the variation of k_H/k_D with changes in ketone and nucleophile structure than about K_H/K_D. To understand kinetic isotope effects sufficiently to use them for inferring the position of the transition state along the reaction coordinate, corresponding values for k_H/k_D and K_H/K_D must be obtained. Lamaty has accomplished this for bisulfite additions to ketones (3*b*).

We have turned to an n.m.r. method to determine isotope effects in ketone–ketal equilibria in an unambiguous manner. What we wished to obtain was the ratio of equilibrium constants for reactions 1 and 2 under conditions in which hemiketal formation would be unimportant and the concentrations of all species at equilibrium could be monitored.



We recognized (5, p. 97) that the equilibrium constant for reaction 3 was equal to the isotope effect on reactions 1 and 2, $K_3 = K_H/K_D$. The isotope effect could be obtained by mixing solutions of the deuterated ketone and undeuterated ketal, effecting equilibrium by addition of an acid catalyst, and observing all species by n.m.r.



In this paper we report application of this method to determine K_H/K_D for acetone dimethyl ketal formation, and for formation of both dimethyl and ethylene glycol ketals of three specifically-deuterated phenylacetones. A modified approach allowed us to measure K_H/K_T, by scintillation counting, for formation of the ethylene glycol ketal of tritiated dibenzyl ketone.

Results

Most reactions were carried out in dry methylene chloride solution. Reactions of acetone were also examined in 1,1,2,2-tetrachloroethane (*sym*-TCE). $BF_3 \cdot Et_2O$ was used as the acid catalyst. For the reactions discussed here, equilibrium was achieved in 2–10 h at room temperature (22 ± 1 °C), although reactions in some cases were examined up to 48 h after adding catalyst. The catalyst could be quenched by removing solvent and catalyst at reduced pressure. Monitoring the n.m.r. intermittently after several hours gave identical results. For tritiated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

dibenzyl ketone, the approach to equilibrium could not be followed by n.m.r. Instead, the reaction was examined at successive reaction times until K_H/K_D became constant.

Proton–deuterium and proton–tritium exchange was a constant source of concern. The methylene position in phenyl acetone and dibenzyl ketone exchanges readily in base, more slowly in acid. Strict controls were run in which deuterated, partially deuterated, and tritiated ketones were exposed to the reaction conditions and then examined by n.m.r. and mass spectrometry. No exchange was detectable under these reaction conditions. In addition, all ketals were unchanged when exposed to the reaction conditions.

One technique was used to measure the isotope effects in the phenylacetone and acetone systems. In these series of experiments, the equilibrium isotope effect is given by Eq. 4.

$$[4]\quad \frac{K_H}{K_D} = K_3 = \frac{[\text{ketone} - d_x]_{eq}[\text{ketal} - d_0]_{eq}}{[\text{ketone} - d_0]_{eq}[\text{ketal} - d_x]_{eq}}$$

(*i*) For phenylacetone, values of K_H/K_D were determined both for dimethyl ketal formation and for ethylene ketal formation. These were obtained for each of the three deuterated species $PhCD_2COCH_3(d_2)$, $PhCH_2COCD_3(d_3)$, and $PhCD_2COCD_3(d_5)$. Mixtures of the deuterated ketones and undeuterated ketals were dissolved in dry methylene chloride. $BF_3 \cdot Et_2O$ in dry methylene chloride was added as a catalyst. The reaction was monitored by n.m.r. Once equilibrium was established, the solvent and catalyst were distilled off at room temperature. The relative concentrations of the deuterated and nondeuterated species were calculated from the n.m.r. spectrum and substituted into Eq. 4 to yield K_H/K_D.

$$[5]\quad PhCH_2^{a}COCH_3^{b} + PhCX_2CCX'_3 \overset{K_5}{\rightleftharpoons} PhCH_2^{c}CCH_3^{d} + PhCX_2COCX'_3$$

(CH_3O, OCH_3^{e} on the ketal carbon)

$$[6]\quad PhCH_2^{a}COCH_3^{b} + PhCX_2CCX'_3 \overset{K_6}{\rightleftharpoons} PhCH_2^{f}CCH_3^{g} + PhCX_2COCX'_3$$

(O—O ketal, ^{h})

For the equilibrium mixtures in Eqs. 5 and 6 the equilibrium constants could be obtained by direct manipulation of the various n.m.r. intensities. The protons labelled by *a*, *b*, *c*, *d*, *e* and the phenyl hydrogens *p* in Eq. 5 all show discrete and resolved signals (see Table 1). The integrals for each signal were normalized by dividing the integral by the number of hydrogens contributing to the signal. These normalized values I_x were taken to be representative of the concentration of the species x in the mixture (Eqs. 7–14). Eq. 16 gives the equilibrium isotope effect for both d_3 and for d_5, while Eq. 17 allows K_H/K_D to be obtained for d_2 and d_5.

$$[7]\quad \text{Total } [\text{ketal}]_{eq} \propto I_e$$

$$[8]\quad [\text{ketal} - d_0]_{eq} \propto I_c \text{ or } I_d$$

$$[9]\quad [\text{ketal} - d_x]_{eq} \propto (I_e - I_c) \text{ or } (I_e - I_d)$$

$$[10]\quad \frac{[\text{ketal} - d_0]_{eq}}{[\text{ketal} - d_x]_{eq}} = \frac{I_c}{I_e - I_c} \text{ or } \frac{I_d}{I_e - I_d}$$

$$[11]\quad \text{Total } ([\text{ketal}]_{eq} + [\text{ketone}]_{eq}) \propto I_p$$

$$[12]\quad \text{Total } [\text{ketone}]_{eq} \propto (I_p - I_e)$$

$$[13]\quad [\text{ketone} - d_0]_{eq} \propto (I_a \text{ or } I_b)$$

$$[14]\quad [\text{ketone} - d_x]_{eq} \propto I_p - (I_e + I_a) \text{ or } I_p - (I_e + I_b)$$

TABLE 1. Nuclear magnetic resonance shifts for the compounds in the ketal–ketone equilibrium mixtures

[15] $$\frac{[\text{ketone} - d_x]_{eq}}{[\text{ketone} - d_0]_{eq}} = \frac{I_p - (I_e + I_a)}{I_a}$$

or $$\frac{I_p - (I_e + I_b)}{I_b}$$

[16] $$\left(\frac{K_H}{K_D}\right) = \left(\frac{I_p - (I_e + I_b)}{I_b}\right)\left(\frac{I_d}{I_e - I_d}\right)$$

for d_3 and d_5

[17] $$\left(\frac{K_H}{K_D}\right) = \left(\frac{I_p - (I_e + I_a)}{I_a}\right)\left(\frac{I_c}{I_e - I_c}\right)$$

for d_2 and d_5

For the ethylene ketals in reaction 6, the methylene signals *a* overlapped part of the ketal signals *h*. We were able to correct for the appropriate intensity of *h* and obtain I_a by difference. The equilibrium constants for reaction 6 are described by equations identical to 16 and 17 with I_h substituted for I_e, and I_f and I_g substituted respectively for I_c and I_d.

(*ii*) A small modification of this method was necessary for calculation of K_H/K_D for equilibria involving acetone. There is no way of obtaining, from the n.m.r. spectrum of the equilibrium mixture, the relative concentrations of the deuterated and non-deuterated acetone present. If the system is depicted by Eq. 18, K_H/K_D is given by Eq. 19.

[18]

	$CD_3COCD_3 + CH_3^{(j)}CCH_3^{(k)}$	$\rightleftharpoons$	$CD_3CCD_3 + CH_3^{(l)}COCH_3$
Initially:	$[a]$ $[b]$		0 $[c]$
At equilibrium:	$[a - x]$ $[b - x]$		$[x]$ $[c + x]$

[19] $$\frac{K_H}{K_D} = \frac{[a - x][b - x]}{[c + x][x]}$$

The relative ketal concentrations can be calculated (Eqs. 20–23) from the n.m.r. spectrum as before. Equation 23 can be solved for *x* and this value, along with the known concentrations [*a*], [*b*], [*c*], can be substituted into Eq. 19. The concentration [*c*] derives from a small and unavoidable amount of acetone in the freshly distilled 2,2-dimethoxypropane.

[20] Total $[\text{ketal}]_{eq} \propto I_k$

[21] $[\text{ketal} - d_0]_{eq} \propto I_j$

[22] $[\text{ketal} - d_x]_{eq} \propto (I_k - I_j)$

[23] $$\frac{[\text{ketal} - d_0]}{[\text{ketal} - d_x]} = \frac{[b - x]}{[x]} = \frac{I_j}{I_k - I_j}$$

(*iii*) The equilibrium with dibenzyl ketone could not be monitored by n.m.r. Furthermore, once equilibrium was achieved and the catalyst removed under vacuum, problems arose in attempts to separate and purify ketone and ketal. The most serious problem was that chromatography of the ketone on Florisil, alumina, or silica gel resulted in loss of radiolabel. Control experiments indicated that dibenzyl ketone could be reduced to 1,3-diphenyl-2-propanol with lithium aluminum hydride in ether at −78 °C, without loss of molar activity, ***M***.

[24] $PhCH_2{}^*CCH_2Ph + PhCH_2CCH_2Ph \rightleftharpoons$

$PhCH_2{}^*CCH_2Ph + PhCH_2CCH_2Ph$

[25] $$\frac{K_H}{K_T} = \frac{M_{ketone}}{M_{ketal}}$$

The equilibrium mixture of ketone and ketal in ether was treated with lithium aluminum hydride at −78 °C. The product diphenylpropanol and unreacted ketal were chromatographed on activity II alumina using methanol–hexane as the eluting solvents. Radioactivities of the purified compounds were measured by scintillation counting. Absolute molar activities were not calculated. The a.e.s. (automatic external standardization) ratios of the ketal, ketone, and alcohol were found to be identical. Relative molar activities were obtained; $M_{alcohol}$ was substituted for M_{ketone}; and K_H/K_T was obtained from Eq. 25.

[e]K_H/K_T, calculated from scintillation counting experiments.
[f]In *sym*-tetrachloroethane solvent using $BF_3{\cdot}Et_2O$ as a catalyst.

The extraordinary magnitude of the isotope effect in reaction 24 suggested special care in examining the validity of our experimental method. Since K_H/K_T is inverse, we were concerned that the number we obtained might be artificially too small. Two factors convince us that this is not the case. First, lithium aluminum hydride reduction of the ketone, followed by chromatography of the alcohol and distillation, gave diphenylpropanol with the same molar activity as that of the starting ketone. Second, the molar activity of the ketal plus that of the diphenylpropanol equalled that of the starting ketone. These controls demand that artifacts in K_H/K_T be less than one percent.

Discussion

Calculated equilibrium isotope effects are presented in Table 2. In each case, the isotope effects are strongly inverse, $K_H/K_D < 1.0$. Inverse β-deuterium isotope effects in carbonyl addition reactions are associated with decrease in the positive charge on the carbonyl carbon in rehybridization from sp^2 to sp^3 (3, 5, 6). The relationship between the magnitude of the β-deuterium isotope effect and the amount of positive charge at the adjacent carbon is well demonstrated by three examples taken from the literature. Protonation of acetophenone (7), (Eq. 26), occurs with a large isotope effect. Solvolysis of acetyl chloride (1*e*), (Eq. 27), in 10% and 20% aqueous acetone has a kinetic β-isotope effect in the opposite direction to that of the base catalysed hydrolysis of acetate esters (1*e*). The β-isotope effect is a useful probe of charge development at an adjacent center. This makes it particularly useful for studies of solvolysis reactions (8). Other factors, however, are involved.

$k_H/k_D = 0.90$

Isotope effects arise from changes in zero-point energies for C—H and C—D vibrational modes in going from reactants to the transition state (k_H/k_D) or products (K_H/K_D). These changes derive from changes in force constants for the respective modes, which in turn are determined by the shapes of the potential energy wells associated with the C—H bonds at which attention is focused (ref. 5, Chapt. 4 and p. 138). Steeper wells give rise to larger force constants, with greater separation of C—H and C—D zero-point energies.

Isotopic substitution does not affect the shape of the electronic energy surface. The origin of secondary hydrogen isotope effects is purely vibrational. An explanation of the magnitude of isotope effects observed in an experiment must be couched in terms of the effect (steric, electronic) of the rest of the molecule on the C—H and C—D vibrations (ref. 5, Chapt. 4 and p. 138, and ref. 9).

V. J. Shiner has pointed out (ref. 5, p. 97) that there are two major contributors to β-isotope effects; the extent of nuclear attachment at the reactive carbon and the internal electronic distribution. The latter factor is sensitive to the dihedral angle between the β C—H or C—D bond and a p orbital at the electron deficient carbon. The charge induces a dipole into those adjacent C—H bonds with proper overlap. The C—H potential energy well is broadened, giving rise to weaker force constants, larger vibrational amplitudes, and decreased separation of C—H and C—D zero-point energies (ref. 5 Chapt. 4 and p. 138).

While the word 'hyperconjugation' is properly used to describe these dipole-induced dipole interactions, explanations which cite the greater polarizability of C—H bonds adjacent to a charge as the source of the β-isotope effect, focus on the wrong part of the potential energy surface. Hyperconjugation is a word commonly used. Keeping in mind its proper focus, we have found both the concept and the word convenient.

In these terms, the major contributor to the inverse isotope effects presented in Table 2 is the loss of hyperconjugative delocalization when the ketones react to form ketals. The most compelling evidence for this point of view is the nearly identical isotope effects observed for both dimethyl ketal and ethylene glycol ketal formation from the three different deuterated phenyl-2-propanones. Small changes in ketal structure apparently do not perturb the equilibrium isotope effects.

In the phenyl-2-propanones, the β-isotope effects are cumulative. For ethylene glycol ketal formation K_H/K_D for $d_2 = 0.82$, K_H/K_D for $d_3 = 0.75$, and their product $(0.75)(0.82) = 0.615$. This value compares favorably with the value 0.60 ± 0.02 measured for d_5. Cumulative kinetic isotope effects were observed for these three ketones in their Baeyer–Villiger oxidation (4). Both results imply that $PhCD_2$— and CD_3— make the same contribution to the isotope effect in d_5 and in d_2 and d_3, respectively.

From the tritium isotope effect K_H/K_T for dibenzyl ketone, one can calculate from the Swain–Schaad equation, [29], (10) the corresponding isotope effect associated with a single deuterium. For dibenzyl ketone we calculate $K_H/K_D = 0.76$

$$[29] \qquad \frac{K_H}{K_D} = \left[\frac{K_H}{K_T}\right]^{0.693}$$

The isotope effect for dimethyl ketal formation in acetone is significantly smaller than that for phenylacetone. On a per-deuterium basis, these differences become even more striking (see below).

In Table 3, our experimental results are presented in terms of the secondary β-isotope effect per deuterium. It is customary to present these results as $\Delta\Delta G/n$ values, where $\Delta\Delta G^0$ and $\Delta\Delta G^{\ddagger}$ are, respectively the change in standard free energy or activation free energy, in cal/mol, for substituting n hydrogens with deuteriums. Before commenting on the implications of the data, we ask the reader to note that small changes in K_H/K_D per D lead to large changes in $\Delta\Delta G/n$, and that the K_H/K_D values from which the $\Delta\Delta G^0/n$ values are calculated, for all examples in Table 3, are known only to about ± 0.01.

One obvious and important conclusion from the data in Table 3 is that deuterium substitution at CH_2 and CH_3 in phenylacetone contributes equally to the observed isotope effect.

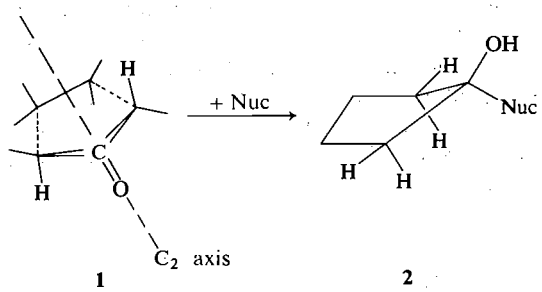
This result is somewhat surprising (3*b*). It is often found that β-isotope effects, per deuterium, are larger for methylene than for methyl (11). Note as an example the $\Delta\Delta G^0/n$ values for acetone and cyclopentanone hemiketal formation in Table 3, taken from experiments by Jones and Bender (3*a*). This empirical generalization does not yet have a sound theoretical basis. The observations probably reflect the effects of structural modification on either the C—H vibrational force constants or the preferred conformations of the molecule. The number of hydrogens adjacent to the reaction center, *per se*, may not be important.

A more difficult challenge is to understand how structural changes give rise to changes in $\Delta\Delta G^0/n$. For example $\Delta\Delta G^0/n$ nearly doubles for methyl ketal formation from 32 cal/mol in acetone to 55 cal/mol in phenylacetone. The same trend is seen in methyl hemiketal formation, with cyclopentanone having as large an effect as phenylacetone. Bisulfite addition is rather peculiar in that $\Delta\Delta G^0/n$ follows hemiketal formation for acetone and cyclopentanone, but is significantly smaller than for those reactions of phenylacetone (3*b*).

A complete normal coordinate analysis for proto- and deuteroketones, ketals, and bisulfite addition products is central to a complete understanding of these isotope effects. In its absence we can only speculate on the source of the isotope effects.

The larger isotope effect in cyclopentanone than acetone is probably related to the ketone conformations in solution. The most favorable



1 2

conformation of cyclopentanone is the half-chair form, which minimizes hydrogen eclipsing interactions (12). The pseudoaxial protons adjacent to the carbonyl overlap well with the ketone C=O p-orbital. Not only is this hyperconjugation lost on formation of a tetrahedral product, but there is significant increase in hydrogen-eclipsing interactions. If these interactions narrow the energy well in those cross-sections of the potential energy surface describing the C—H bonds on the β carbon, the isotope effect will increase over that in acetone, *almost irrespective of the reacting nucleophile*.

In tetrahedral phenylacetone addition prod-

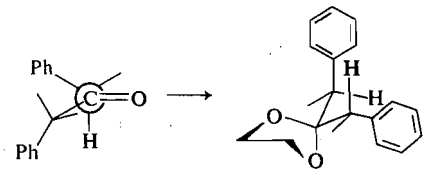
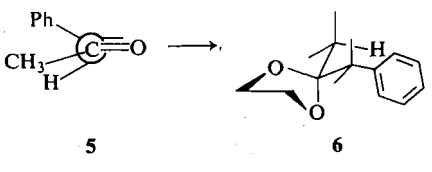
ucts, coupling of the carbon–nucleophile vibrational modes with the β C—H modes must be important. The bisulfite adduct, with its relatively long C—S bond, contributes less to the isotope effect than does the shorter C—O bond in the ketal and hemiketal. Similar trends appear in kinetic isotope effects determined by Lamaty (*3b*) (*cf.* Table 3). A significantly smaller kinetic isotope effect is observed in the addition of bisulfite to phenylacetone when compared to hydroxylamine. These differences are not apparent for the addition of those nucleophiles to acetone and cyclopentanone. Comparison of the kinetic and equilibrium isotope effects give some indication of what fraction of the carbonyl character is lost in the transition state for nucleophilic addition.

The β-isotope effect of extraordinary magnitude is that for ketal formation in dibenzyl ketone. It is our belief that such a large isotope effect must reflect a preferred conformation in the ketone giving rise to a strong hyperconjugative interaction between the ketone and the β-hydrogens. In addition, steric crowding in the tetrahedral product must seriously perturb its C—H bending or stretching modes.[3] A comparison of phenylacetone and dibenzyl ketone is shown. Differences in ketone conformations and the energetics of ketal formation result primarily from phenyl–phenyl interactions in the latter. Space-filling molecular models suggest that the preferred conformation of dibenzyl ketone has a C—H bond parallel to the C=O π-bond. Phenylacetone has a slightly different geometry of lowest energy.



3 4



5 6

[3]We do not wish to imply that **4** is extraordinarily strained; **4** is more strained than any tetrahedral adduct for which equilibrium isotope effects have been measured.

In phenylacetone, as in most α-CH_2 ketones, the preferred geometry has a CH bond eclipsing C=O. This allows a staggered geometry between α-substituents of the ketone. Phenyl–phenyl repulsion is rather severe in dibenzyl ketone. Increasing the dihedral angle between these staggered substituents increases the overlap between one C—H bond and the C=O π-bond. In no way does it appear possible for two C—H bonds simultaneously to achieve such overlap.

In the corresponding ketals, 1–3 steric interactions appear to dominate conformational preferences. These are difficult to assess. In conformation **4** there are obvious destabilizing steric interactions involving the hydrogens at which the isotope effect is probed. There is no doubt, however, that the ketal derived from dibenzyl ketone is significantly more crowded than that derived from phenylacetone. With the increase in isotope effects paralleling the increasing difficulty (primarily steric) in forming tetrahedral addition products from ketones, (13), it is likely that these steric factors are in part responsible for the size of the β-deuterium isotope effect.

Experimental

Acetone-d_6 was purchased from Merck, Sharp, and Dohme. Specifically deuterated phenyl-2-propanones were prepared and purified by methods we reported previously (14). Methylene chloride was distilled fresh from phosphorus pentoxide. *Sym*-tetrachloroethane was washed with concentrated sulfuric acid, followed by aqueous sodium carbonate. $BF_3 \cdot Et_2O$ was freshly distilled. Nuclear magnetic resonance spectra were run on a Varian T-60 spectrometer. Peak areas were determined by repetitive integration. The details of the n.m.r. method and typical correlation coefficients have been reported (15). Scintillation counting in toluene-Omnifluor was carried out in a Packard-Tri-Carb liquid scintillation spectrometer, model 3375. Counting data were recorded by teletype. Sample counts per minute normally had standard deviations of 0.1%. Those with deviations greater than 0.2 were discarded. An automatic external standardization (a.e.s.) feature allowed a.e.s. ratios to be measured. These give an indication of the counting efficiency of each sample.

1,3-Diphenyl-2-propanone-1-t

A solution of 32.5 g (0.15 mol) of 1,3-diphenyl-2-propanone (J. T. Baker, recrystallized from petroleum ether 30–60 °C) in 50 ml of pyridine was prepared. To this was added a mixture of 1.5 ml tritiated water (New England Nuclear Co., 1 mCi/ml) and 15 ml distilled deionized water. The reaction mixture was refluxed for 10 h. The pyridine and water were distilled off, and the ketone was twice recrystallized from petroleum ether, m.p. 33–34 °C. The sample activity was 2.1×10^9 c.p.m./mol.

For personal use only.

2,2-Dibenzyl-1,3-dioxolan (Dibenzyl Ketone Ethylene Ketal)

Dibenzyl ketone (10.5 g, 0.050 mol) was refluxed with ethylene glycol (0.049 mol) in toluene using 0.5 g *p*-toluenesulfonic acid as a catalyst. Water was removed via a Dean–Stark trap. After 5 h, the catalyst was quenched with powdered anhydrous potassium carbonate. After filtering, the solution was concentrated and then chromatographed on a column of activity II alumina. Hexane was used as the eluting solvent. Concentration of the hexane gave white crystals, m.p. 36–37 °C free of detectable traces of ketone. The overall yield was 88%.

2-Phenyl-2-methyl-1,3-dioxolan (Phenylacetone Ethylene Ketal)

An identical procedure gave the ketal as a liquid, which was distilled at 90 °C (pot temperature)/0.2 Torr through a 10 in. Vigreux column. The yield of product was 75%; however, it contained 5.5% phenylacetone by n.m.r. as the sole impurity. Further purification was unnecessary, as our analytical technique allowed us to monitor concentrations of all species at equilibrium.

1-Phenyl-2,2-dimethoxypropane (Phenylacetone Dimethyl Ketal)

Phenylacetone (2.08 g, 15.5 mmol) in 60 ml anhydrous methanol (distilled from magnesium) was treated with 10 ml 2,2-dimethoxypropane and 80 mg bis(*p*-nitrophenyl)phosphoric acid (Aldrich). After 15 min reflux, the acid was quenched with 10% aqueous sodium hydroxide. The solution was concentrated, taken up in hexane, washed with aqueous bicarbonate, dried with magnesium sulfate, and chromatographed on a 45 cm × 1 cm Florisil column. Benzene (10%) in hexane was used as the eluant. The dimethyl ketal was collected as a colorless oil, rechromatographed on Florisil and distilled at 60 °C (pot)/0.4 Torr. It was stored in a desiccator. The overall yield, 0.3 g, was poor, 11%, but the n.m.r. showed it to be free of ketone.

2,2-Dimethoxypropane (Aldrich) was fractionally distilled (82–83 °C) through a 10 in. Vigreux column. The compound decomposed in the g.l.c. on both DEGS and Carbowax columns. An n.m.r. analysis of the fraction used indicated that it contained 7.2% acetone. There was no detectable trace of methanol or other impurities in the n.m.r. spectrum. A suitable correction for this acetone impurity was applied to the calculation of isotope effects (see text).

Ketone–Ketal Equilibria

In general, the catalytic solution of $BF_3 \cdot Et_2O$ (freshly distilled) in dry methylene chloride or *sym*-tetrachloroethane was prepared and a 0–5 ml aliquot of this was added to a pre-weighed mixture of the labelled ketone and unlabelled ketal.

(*i*) *Acetone*—Acetone-d_6 (150 mg, 2.58 mmol) and 2,2-dimethoxypropane (210 mg, 2.0 mmol) were mixed together in 0.5 ml of solvent containing $BF_3 \cdot Et_2O$ (0.05 mmol). In separate experiments methylene chloride or *sym*-tetrachloroethane was used as the solvent. The reaction was monitored by n.m.r. and spectra, recorded between 2–15 h after the addition of catalyst, were used to calculate values for K_H/K_D.

(*ii*) *Phenylacetone*—Mixtures of the ketone (0.75 mmol) and the ketal (0.60 mmol) were stirred together in methylene chloride using $BF_3 \cdot Et_2O$ (0.05 mmol). The three deuterated species $PhCD_2COCD_3$, $PhCD_2COCH_3$, and $PhCH_2COCD_3$ were all examined in this way Mixtures of the d_5 and of the d_2 compounds with 2,2-dimethoxy phenylpropane and with phenylacetone ethylene ketal were studied. The d_3 species was equilibrated only with phenylacetone ethylene ketal. The solutions were concentrated at reduced pressure to remove solvent and catalyst. The n.m.r. spectra of these mixtures, recorded between 10–48 h after contact with the catalyst, were used to calculate values for K_H/K_D.

(*iii*) *Dibenzyl Ketone*—Tritium labelled dibenzyl ketone (0.75 mmol) and unlabelled dibenzyl ketone ethylene glycol ketal were dissolved in 0.5 ml dry methylene chloride, containing 0.010 mmol $BF_3 \cdot Et_2O$. The reaction mixture was stirred for 16 h. The methylene chloride and $BF_3 \cdot Et_2O$ were removed at room temperature under reduced pressure. The solid residue was dissolved in 5 ml of dry ether and added dropwise to three molar equiv. of lithium aluminum hydride in 10 ml ether at −78 °C. The reactants were stirred ten minutes at −78 °C. The stirring was continued for 1 h as the contents of the reaction flask warmed to room temperature.

The reaction was quenched by slowly adding a saturated aqueous solution of sodium sulfate until a white powdery precipitate formed. After filtering, the ether solution was washed with 5 ml water followed by an equal volume of saturated sodium chloride solution. The concentrate was applied to a small (3 in. × ½ in.) column of activity II alumina. The ketal came off the column in hexane, whereas addition of methanol to the hexane was necessary to recover the 1,3-diphenyl-2-propanol. The ketal was crystallized, and the alcohol was molecularly distilled at 110 °C (pot)/0.2 Torr. Radioactivities of each were measured by scintillation counting.

The authors wish to thank the National Research Council of Canada for its financial support, and Professor A. Guha for the use of the scintillation counter.

Isotope Effect Studies on Elimination Reactions. XI. The Nature of the Transition State for the E2 Reaction of 2-Phenylethyldimethylanilinium Salts Containing Substituents in the Aniline Ring with Sodium Ethoxide in Ethanol[1]

PETER SCHMID AND ARTHUR NEWCOMBE BOURNS

Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

Received May 21, 1975

PETER SCHMID and ARTHUR NEWCOMBE BOURNS. Can. J. Chem. **53**, 3513 (1975).

Kinetic isotope effects have been determined for the E2 reactions of a series of 2-phenylethyldimethylanilinium salts containing substituents in the aniline ring with sodium ethoxide in ethanol at 40 °C. The nitrogen isotope effect, $(k^{14}/k^{15} - 1)100$, is not very sensitive to substituent changes but appears to increase slightly with increasing electron-withdrawing ability of the substituents, *i.e.*, 1.19 ± 0.07, 1.13 ± 0.06, 1.12 ± 0.08, 1.30 ± 0.07, and 1.32 ± 0.06 for *p*-OCH_3, *p*-CH_3, *p*-H, *p*-Cl, and, *m*-CF_3, respectively. The hydrogen–deuterium isotope effects pass through a minimum in the region of the unsubstituted compound and increase both with increasing electron-donating as well as with electron-withdrawing power of the substituents, *i.e.* k^H/k^D = 4.70 ± 0.06, 4.61 ± 0.04, 4.51 ± 0.04, 4.53 ± 0.09, 5.00 ± 0.07, and 5.39 ± 0.07 for *p*-OCH_3, *p*-CH_3, *p*-H, *p*-Cl, *m*-CF_3, and *p*-CF_3, respectively. The results are discussed in terms of recent theoretical treatments of the effect of structural variations in the reactants on the nature of the transition state of E2 elimination reactions. The conclusion is reached that the transition states in the present reaction series can be characterized as 'central with slight carbanion character' and that the effect of a change in the ability of the leaving group on the structure of the transition state manifests itself mainly in the direction perpendicular to the reaction coordinate. A simple novel hypothesis is formulated which emphasizes the importance of the location of the transition state in a More O'Ferrall-type potential energy diagram in determining its sensitivity to structural changes in the reactants.

PETER SCHMID et ARTHUR NEWCOMBE BOURNS. Can. J. Chem. **53**, 3513 (1975).

On a déterminé les effets isotopiques cinétique de réactions E2 d'une série de sels de phényl-2 éthyl diméthylanilinium (substitués sur le noyau de l'aniline) avec l'éthylate de sodium dans l'éthanol à 40 °C. L'effet isotopique de l'azote $(k^{14}/k^{15} - 1)100$ n'est pas très sensible aux changements de substituant mais il semble qu'il augmente légèrement avec la facilité qu'ont les substituants d'attirer les électrons soit respectivement 1.19 ± 0.07, 1.13 ± 0.06, 1.12 ± 0.08, 1.30 ± 0.07 et 1.32 ± 0.06 pour *p*-OCH_3, *p*-CH_3, *p*-H, *p*-Cl et *m*-CF_3. Les effets isotopiques de l'hydrogène passent par un minimum dans la région du composé non-substitué et augmentent avec une augmentation des effets électroaffinitaires et électrodonneurs des substituants soit respectivement k^H/k^D = 4.70 ± 0.06, 4.61 ± 0.04, 4.51 ± 0.04, 4.53 ± 0.09, 5.00 ± 0.07 et 5.39 ± 0.07 pour *p*-OCH_3, *p*-CH_3, *p*-H, *p*-Cl, *m*-CF_3 et *p*-CF_3. On discute de ces résultats en termes de traitements théoriques récents de l'effet de variations structuralles dans les réactifs sur la nature de l'état de transition des réactions d'élimination E2. On arrive à la conclusion que les états de transition de la série de réactions actuelles peuvent être caractérisés comme étant 'centrés avec un faible caractère carbanionique' et que l'effet d'un changement dans la capacité du nucléofuge sur la structure de l'état de transition se manifeste principalement dans la direction perpendiculaire des coordonnées de la réaction. On formule une nouvelle hypothèse simple qui met en relief l'importance de la position de l'état de transition dans un diagramme d'énergie potentielle du type More O'Ferrall pour déterminer sa sensibilité vis-à-vis des changements structuraux dans les réactifs.

[Traduit par le journal]

Introduction

A large body of evidence suggests that the nature of the transition state in an E2 elimination reaction is variable, *i.e.* that the reacting bonds can be broken or formed in varying degrees (for recent reviews see refs. 3 and 4). A number of sometimes conflicting theories concerning the effect of structural changes in the reactants on the nature (*i.e.* the structure and energy) of the transition state have been put forward (5–9).

Bunnett's theory (4, 5), which was developed mainly on an intuitive basis, suggests that a structural change which makes the cleavage of the C_β—H bond easier will lead to more exten-

sive breaking of this bond in the transition state while the C_α—X bond (where X is the leaving group) will be correspondingly less broken. In Thornton's treatment (6) substituent effects are considered as linear perturbations of the vibrational potentials for the normal coordinate motions both parallel to and perpendicular to the reaction coordinate. The effects on the parallel motion are expected to dominate in many, but not all, cases. This leads to the prediction that a structural change which makes the breaking of the C_β—H bond easier will cause this bond to be broken less in the transition state. The other bond (in our example the C_α—X bond) will then follow along in the direction of the coordinate motion set by the former one, and be shorter as well. Recently Thornton and co-worker (7) have expanded the theory to explain more recent data which indicate that in some cases the influence of a substituent change on the perpendicular motion outweighs the effect on the parallel one. A system where this is the case would appear to behave according to Bunnett's theory. A third approach has been developed by More O'Ferrall (8). In his model, reactants, products, and transition state are represented on a common potential energy surface, along with carbonium ion and carbanion intermediates of stepwise reaction paths.[2] He concludes that structural changes which mainly influence the stability of products and/or reactants are transmitted along the reaction coordinate, resulting in a more or less product-like or reactant-like transition state. This is in agreement with Thornton's theory (6) and the Hammond postulate (11). Structural changes affecting mainly the stability of the carbonium ion and/or the carbanion, however, are expected to exert their effect in the direction perpendicular to the reaction coordinate. Their effect, then, would correspond to what is expected on the basis of Bunnett's theory (4, 5). Jencks (12), in a recent paper, has arrived at essentially the same predictions for structure–reactivity relationships. A somewhat related model has been presented by Critchlow (9). It allows the prediction of the configuration and energy of the transition state of a concerted reaction from the energies required to form the intermediates of the hypothetical stepwise processes. Substitution in the attacking or leaving portion of a concerted reaction system should manifest itself only in changes in the more remote bond. Interestingly, this model suggests that the energetically less demanding part of the overall process has made greater progress at the transition state. This is in accordance with the principles stated in Bunnett's theory (4, 5), but contrary to the Hammond postulate (11).

In a recent report from this laboratory (2) it was suggested that the apparent contradiction between the theories of Bunnett (4, 5) and Thornton (6) might have its origin in a different sensitivity of the transition state to structural changes, depending on its position in More O'Ferrall's potential energy diagram (8). It was pointed out that in the studies of Bartsch and Bunnett (13) and Bartsch (14) which lend support to Bunnett's theory, the leaving group is always a 'good' one, namely a halogen. In systems which behave according to Thornton's theory, on the other hand, the leaving group is always a 'poor' one, *e.g.* trimethylamine. We may assume as a working hypothesis that compounds with relatively good leaving groups undergo elimination with strong bases by way of a central transition state in which the extent of C_β—H and C_α—X bond breaking is approximately equal. For elimination reactions with most quaternary ammonium salt substrates studied so far the transition states appear quite clearly to be strongly carbanion-like (considerably more C_β—H than C_α—X bond rupture). Reference to More O'Ferrall's potential energy diagram (Fig. 2) shows that a structural change influencing mainly the energy of the carbanion will exert its effect essentially through the perpendicular vibrational mode for a central transition state. For a transition state with considerable carbanion character, however, a similar effect may manifest itself to a greater extent in a direction along the reaction coordinate than perpendicular to it. In the latter case the curvature of the potential energy surface may well be considerably greater in the perpendicular than in the parallel direction whereas in the case of a central transition state the opposite may be true.

Even though there is no question that the leaving group is a very important factor in determining the structure of the transition state in an E2 reaction (ref. 15, p. 499; ref. 4, pp. 72, 73) there have been few systematic studies carried out in this area. In this paper we wish to report the results of such an investigation. We have

studied the reactions of a series of 2-phenylethyldimethylanilinium salts containing substituents in the aniline ring with ethoxide ion in ethanol. These substrates were chosen for a number of reasons. They are closely related to 2-phenylethylammonium ions which have been studied earlier in these laboratories (2, 16, 17). On the other hand, they contain a much better leaving group and may therefore allow us to test our hypothesis concerning the apparent discrepancies between the theories of Bunnett and Thornton. Furthermore, they contain substituents in the aromatic ring of the leaving group. This feature makes the compounds suitable for a systematic study of the influence of the leaving group by a method combining isotope and substituent effects.[3]

Results

Hydrogen–Deuterium Isotope Effects

Rate constants have been determined for the elimination reactions of a series of 2-phenylethyldimethylanilinium bromides containing substituents in the aniline ring and their 2,2-dideuterated analogs with sodium ethoxide in ethanol at 40 °C. All the reactions studied were found to be of second order overall, first order with respect to each reactant. The spectrophotometric procedure used to determine the kinetics is described in the experimental section. The measured rate constants are shown in Table 1.

The Hammett plots of log k/k_0 *vs.* σ^- which were obtained for the undeuterated and the deuterated series are reasonably linear. However, a small but apparently systematic deviation from linearity is noticeable in both plots. The slope, ρ, for the undeuterated series is $+1.07 \pm 0.08$, with a correlation coefficient, r, of 0.988. For the 2,2-dideuterated series ρ is $+1.01 \pm 0.08$, with a correlation coefficient of 0.985. The errors given are standard deviations.

The primary hydrogen–deuterium kinetic isotope effects calculated from the rate data and the σ^- substituent constants are also presented in Table 1.

It is interesting to note that the rates of the elimination reactions are subject to a strong salt effect while the kinetic isotope effects are independent of the ionic strength, at least in the narrow range studied.

Nitrogen Isotope Effects

The results of the nitrogen isotope effect study of the reaction of 2-phenylethyldimethylanilinium bromides with sodium ethoxide in ethanol at 40 °C are shown in Table 2. The nitrogen isotope effects were determined by comparing the $^{14}N/^{15}N$ ratio of the starting material of natural isotopic abundance with that of the dimethylaniline formed in the reaction carried to some

known extent of completion. The experimental procedure is outlined in the experimental section.

Discussion

Inspection of the isotope effect data in Tables 1 and 2 shows that the reactions of 2-phenylethyldimethylanilinium salts with ethoxide ion in ethanol exhibit β-hydrogen and leaving group isotope effects of significant magnitude. The conclusion seems warranted that both effects are primary ones, *i.e.* that both bonds are being broken in the rate determining step of the reaction (ref. 21, p. 215). This then implies that the reactions occur by a genuine synchronous E2 mechanism, in analogy with the corresponding reactions of 2-phenylethyltrimethylammonium salts (2, 16, 17).

Interestingly, the variation in the nitrogen isotope effect is rather small, while the hydrogen isotope effect changes over a comparably larger range. Clearly, a substituent change in the leaving group has a considerable influence on the breaking of the more distant C_β—H bond. This indicates that there must be rather extensive coupling between the C_α—X and C_β—H bond breaking processes, an observation which has also been made by Willi (22) in his investigation of elimination reactions in 2,2-diphenylethylarenesulfonate systems. Intuitively, one might have expected the substituent change to manifest itself more strongly in the closer bond (ref. 6, p. 2919).

Of special interest is the striking similarity in the shape of the plots of the two isotope effects *vs.* the σ^- constants (Fig. 1). Both are clearly not linear but rather seem to level out in the direction of stronger electron-donating substituents, *i.e.* upon going to more basic ('poorer') leaving groups. The hydrogen isotope effect even appears to pass through a minimum. The slight increase

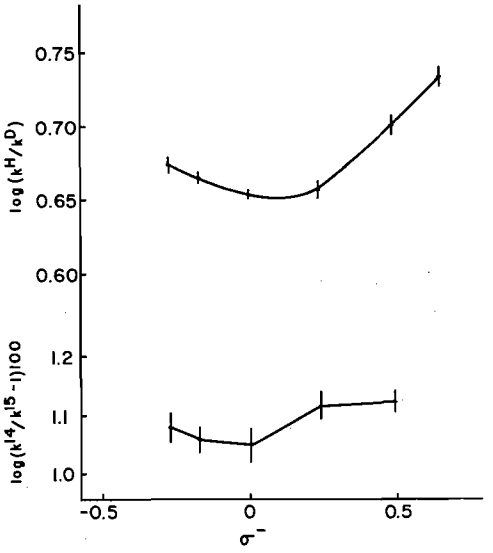

FIG. 1. Plot of log (k^H/k^D) and log ($k^{14}/k^{15} - 1$)100 *vs.* σ^- for the reaction of 2-phenylethyldimethylanilinium salts containing substituents in the aniline ring with sodium ethoxide in ethanol at 40 °C.

in the direction of decreasing σ^- values seems to be just outside the experimental error limits. The possible significance of this point will be discussed below.

Leaving Group Isotope Effects

Since the magnitude of the nitrogen isotope effect depends on the extent to which the composite force constant of the C_α—N^+ bond is decreased in going from the initial to the transition state, the effect will increase regularly in a reaction series with the extent of bond weakening in the transition state. The experimental results, therefore, indicate that the extent of carbon–nitrogen bond rupture in the transition state is greater the more electron-withdrawing the substituent, *i.e.* the 'better' the leaving group.

The numerical values of the nitrogen isotope effects are substantial, amounting to between 25 and 40% of the theoretical maximum value.[4] This implies that there is a fairly sizeable amount of C_α—N^+ bond stretching in the transition state of, perhaps, 25–50%. We shall not attempt to specify more accurately the extent of bond weakening at this point. Theoretical calculations by Saunders and co-workers (refs. 24 and 3*a*, pp. 76, 77) demonstrate that a general relationship between the value of the leaving group isotope effect and the absolute extent of bond stretching in the transition state is hardly a straightforward matter and depends greatly on the models on which the calculations are based. Further complications can occur when there is extensive coupling between the various atomic motions in the transition state, as seems to be the case in our system. In addition, the present treatment of isotope effects does not take into account solvation effects which, in the case of charged substrates, might be of considerable importance. In spite of these complications we feel that within our reaction series the qualitative interpretation of isotope effects in terms of bond rupture is justified, since the structural changes made in the reactants are only relatively minor and the solvent is the same in all cases.

β-*Hydrogen Isotope Effects*

The correlation of the magnitude of the hydrogen isotope effect with the degree of bond stretching in the transition state is somewhat more complicated because the reacting hydrogen is involved in a three-center reaction. In this situation the value of k^H/k^D is expected to reach a maximum when the force constants of the bonds being formed and broken are equal, *i.e.* the proton is half transferred, as has been pointed out by Melander (25), Westheimer (26) and others (27–29). The unambiguous interpretation of a measured isotope effect, which is smaller than the theoretical maximum, therefore, requires a knowledge of whether the proton is more or less than half transferred in the transition state. This can be obtained from the calculations and experimental results of Steffa and Thornton (30) on the secondary isotope effect k^{OD^-}/k^{OH^-}, for proton abstraction by OD^- in D_2O and OH^- in H_2O. The theoretical value of this isotope effect for a reaction with complete proton transfer at the transition state is 1.88 at 80 °C. For half transfer the effect is the square root of this maximum value, namely 1.37.

The results of Steffa and Thornton's study are presented in Table 3, along with primary hydrogen isotope effect data. One notes that all the secondary isotope effects are greater than 1.37 and, furthermore, that the decrease in k^{OD^-}/k^{OH^-} as one proceeds down the table is paralleled by an increase in primary isotope effect. The combination of these two findings establishes rather convincingly that the proton must be more than half transferred in all the cases listed (compare refs. 2 and 21, p. 272).

After taking into account the possibility of a fairly substantial solvent isotope effect Steffa and Thornton conclude that the reaction of the sulfonium ion represents a case where the proton is approximately half transferred in the transition state. The large value of the primary isotope effect is consistent with this view. Since the isotope effects for the dimethylanilinium salt are rather similar it is reasonable to conclude that in this case the proton is slightly more than half transferred in the transition state.

The Hammett ρ values listed in Table 4 lend further support to this conclusion. The ρ value for the dimethylanilinium leaving group is similar to that for chlorine and dimethylsulfonium leaving group.

On the basis of these findings it is possible to indicate the position of the transition state of the reaction of unsubstituted 2-phenylethyldimethylanilinium ion with ethoxide ion in ethanol in More O'Ferrall's potential energy diagram (Fig. 2). It appears to be located in the quadrant adjoining the carbanion intermediate, close to the center of the diagram. In other words, the transition state is a very central one with slight carbanion character. This is in contrast to what has been found for reactions of 2-phenylethyltrimethylammonium ions where the leaving group is much worse and the transition state is strongly carbanion-like in character (*i.e.* the C_β—H bond is much more stretched than the C_α—X bond) (2).

Furthermore, we can relate the trend in the magnitudes of k^H/k^D and k^{14}/k^{15} with relative amounts of bond rupture. On the side of positive σ^- values (*i.e.* upon going to better leaving groups) both k^H/k^D and k^{14}/k^{15} increase. This

[4]Biegeleisen and Wolfsberg (23) have calculated a theoretical maximum for the kinetic nitrogen isotope effect of 1.032. Saunders and Cockerill (ref. 3*a*, p. 89) mention a value of 1.040–1.045.

means that an increase in C_α—X bond length is coupled with a decrease in C_β—H bond length and indicates that the main effect of changing a substituent in the leaving group is felt in the direction perpendicular to the reaction coordinate. This finding is in contrast with what has been usually found in reactions with quaternary ammonium salts (2, 36, 37). Only recently one case has been found,[5] namely the E2 reaction of 9-(4-substituted-benzyl)-fluorene-9-trimethylammonium ions with ethoxide in ethanol, where substituents show their effect primarily in the direction perpendicular to the reaction coordinate, rather than parallel to it.

On the side of negative σ^- values (*i.e.* on going to 'poorer' leaving groups) there is relatively little change in the isotope effects and thus the bond lengths. The nitrogen isotope effect levels out (within experimental error), whereas k^H/k^D increases very slightly, indicating a decrease in C_β—H bond length.

A few cases reported in the literature represent interesting parallels to this situation: Banger *et al.* (15) investigated the reaction of substituted 2-phenylethylarenesulfonates with potassium-*tert*-butoxide in *tert*-butyl alcohol and found that substitution in the 2-phenyl ring has an effect on the Hammett ρ constant and thus the structure of the transition state which is uniform and linear over the entire range studied. This is in complete analogy with observations in 2-phenylethyl systems with trimethylammonium (2) and dimethylanilinium[6] leaving groups. The effect of substitution in the leaving group, on the other hand, only becomes notable for the stronger electron-withdrawing substituents (*i.e.* the better leaving groups), as is the case in our system. This is taken as an indication of a shift to transition states with less carbanion character. Similarly, Willi (22) observed in his study of elimination reactions of 2,2-diphenylethylarenesulfonates that a *para*-nitro substituent in the arenesulfonate leaving group gave rise to an unexpectedly large increase in the β-hydrogen isotope effect. Winey and Thornton (7), finally, also found in their study of secondary isotope effects in reactions of 2-(*p*-trimethylammoniophenyl)-ethyl derivatives with lyoxide ions in water and deuterium oxide, respectively, that the isotope effects become an increasingly more sensitive function of the leaving group as the leaving group ability increases. They, too, conclude that the transition state of the reaction becomes less carbanion-like (or more central) the 'better' the leaving group.

The results of our study, then, can be summarized as follows: (*i*) the transition state of the reaction of unsubstituted 2-phenylethyldimethylanilinium ion with ethoxide ion in ethanol is a fairly 'central' one; (*ii*) a substituent change in the leaving group manifests itself mainly in a direction perpendicular to the reaction coordinate; (*iii*) going to stronger electron-donating substituents, *i.e.* 'poorer' leaving groups, shifts the structure of the transition state towards the $E1_{cb}$-like extreme; (*iv*) with increasing $E1_{cb}$ character the transition state geometry becomes less sensitive to further changes in the leaving group.

A Comment on Theoretical Predictions of the Effect of Structural Variations on Transition State Geometry

Table 5 summarizes the effects of structural variations in the reactants on the geometry of the transition state as predicted by the several theories to which reference was made in the Introduction. The following discussion will be limited to the effect of changes in the leaving group.

Interestingly, all the theories agree in their predictions of the influence of a change in the leaving group on the (more distant) C_β—H bond. The better the leaving group, the less stretched is the C_β—H bond in the transition state, *i.e.* the less carbanion character is developed. A large body of evidence, including the kinetic isotope effects and the Hammett reaction constants listed in Table 4 and our own data, lends support to this view. Thornton's updated theory (7) suggests in addition that the C_β—H bond is less sensitive to changes in the leaving group in carbanion-like transition states than in central ones. This is precisely the behavior displayed by our reaction system as well as the ones studied by Banger *et al.* (15), Willi (22), and Winey and Thornton (7).

There is no agreement between the predictions of the various theories for the effect of a change in the leaving group on the C_α—X bond. Bunnett (4) and Thornton (6) come to exactly opposite conclusions. Clearly, Bunnett's and Thornton's views represent two extremes, one considering the effect on the perpendicular, the other one on the parallel motion only. If both effects are taken into account (as in More O'Ferrall's (8) and Critchlow's (9) models and in Thornton's updated theory (7)) an unambiguous prediction is no longer possible. The result of the present as well as various other studies (*e.g.* Bartsch and Bunnett (13), Bartsch (14), Banger *et al.* (15)) suggest that in general the effect on the perpendicular motion may be more important. However, the present data also indicate that the sensitivity of the C_α—X bond to further changes in the leaving group may be smaller when the leaving group is already a poor one and the transition state shows an appreciable degree of carbanion character.

One point emerges more and more clearly. The hope to find a unique general correlation between the effect of a substituent change on the C—H and C—X bonds in the transition state of an E2 reaction (such as 'any increase in C—H bond length is necessarily coupled with an increase in C—X bond length') is no longer realistic. A theory relating the effect of structural

changes with transition state geometry must take into account both parallel and perpendicular effects if it is to explain all the experimental data available. The single most important factor determining whether the parallel or perpendicular effect will dominate in a particular case appears to be the position of the transition state in the potential energy diagram. However, Thornton's updated theory (7) is the only one which incorporates to some extent the concept of differential sensitivity of the transition state geometry towards structural changes, depending on the character of the transition state. We would therefore like to propose a simple new working hypothesis which, while relying essentially on Thornton's original ideas (6), emphasizes the importance of the location of the transition state in a potential energy diagram as it was developed by More O'Ferrall (8) for elimination reactions (see Fig. 2). It may be stated as follows.

1. The closer the transition state of a concerted reaction is located to a corner of the potential energy diagram, the larger will be the slope of the potential energy surface in the direction to the corner. This will be true as long as there is a considerable energy difference between the corner itself and the transition state. A larger slope very likely corresponds to a large curvature of the energy surface along the line defined by the transition state and the adjacent corner.

2. If the transition state is very reactant- or product-like, the curvature of the energy surface in the parallel direction, *i.e.* along the reaction coordinate, will be large. If, on the other hand, it is very carbanion- or carbonium ion-like the curvature will be large in the perpendicular direction. Implicit in these statements is the assumption that the curvature in the corresponding other direction will be smaller.

3. In accordance with Thornton's theory (6) a perturbation caused by a substituent change will produce a greater shift in bond lengths, the smaller the curvature of the unperturbed curve. For a reactant- or product-like transition state the effect of a structural change should therefore manifest itself more strongly in the perpendicular than in the parallel direction. Conversely, for a carbanion- or carbonium ion-like transition state the effect in the parallel direction should dominate.

4. For very central transition states it is not possible to predict *a priori* which of the two effects will outweigh the other.

Support for this hypothesis comes mainly from the studies of Smith and Bourns (1) and Smith (38)[5] in which the effect of structural variations on the C—H and C—N^+ bond was simultaneously studied. The transition state of the E2 reaction of 2-arylethyltrimethylammonium ions with ethoxide in ethanol has considerable El_{cb} character (2). In this system any structural change which causes one bond (C—H) to be weakened more in the transition state has a corresponding effect on the other bond (C—N^+). This is the result expected when the effect on the parallel motion dominates. The transition state of the E2 reaction of 9-(4-substituted-benzyl)-fluorene-9-trimethylammonium ions with ethoxide in ethanol appears to be reactant-like (38). In this case a trend towards more C—H bond rup-

ture is associated with a trend towards less C—N^+ bond rupture.[5] This combination is consistent with the assumption that the perpendicular motion is more important.[7] The reaction of 2-phenylethyldimethylanilinium ions with ethoxide in ethanol (this work) occurs via a fairly central transition state; the same probably holds true for reactions of 2-phenylethylarenesulfonates with potassium *tert*-butoxide in *tert*-butyl alcohol (15). In both these systems the perpendicular effect is predominant. However, as structural changes shift the transition state structure towards the $E1_{cb}$ extreme, the transition state geometry becomes less sensitive to or almost independent of further structural variations. It appears that in this region parallel and perpendicular effects more or less balance. Presumably the curvature of the potential energy surface in the two directions is of comparable magnitude. It is not unreasonable to assume that in this area we may encounter small changes in bond lengths which are not *a priori* predictable but reflect subtleties of the energy surface. The small increase in C—H bond weakening upon going from a dimethylanilinium to a dimethyl-*p*-anisidinium leaving group, which we observed in this work, may be interpreted on this basis.

Since our working hypothesis has been derived on purely geometrical grounds, which are not peculiar to carbon elimination reactions, the respective conclusions should be equally valid for any reaction which can be represented in a three-dimensional More O'Ferrall-type potential energy diagram.

Experimental

Materials

2-Phenylethyldimethylanilinium Bromide

A threefold excess of methyl bromide (15 g, 0.15 mol), cooled in an acetone – Dry Ice bath, was added to a similarly cooled solution of 11.1 g (0.05 mol) *N,N*-2-phenylethylmethylaniline in 50 ml of acetonitrile. The flask was sealed and the solution was allowed to stand for 60 h in the dark at room temperature. The quaternary salt was precipitated by addition of ether and recrystallized four times from ethanol–ether; yield 14.9 g (92%); m.p. 169–170 °C lit. (30) 169–170 °C).

N,N-2-Phenylethylmethylaniline

This compound was prepared using the method of Oki and Mutai (39): 27.75 g. 2-Bromoethylbenzene (0.15 mol) (Eastman) and 16.05 g (0.15 mol) *N*-methylaniline (Eastman) were treated with 45 ml of 20% aqueous sodium hydroxide for 30 min. Most of the unreacted halide and amine were removed by steam distillation. The residue was extracted with ether. The ethereal solution was dried over potassium carbonate. Removal of the solvent and distillation produced 11.1 g (35%) of the pure product; b.p. 98 °C/0.04 Torr (lit. (40) 124–128 °C/0.3 Torr, (41) 131–134 °C/0.75 Torr). Recrystallization from ethanol yielded a white solid, m.p. 42–43 °C (lit. (41) 42–43 °C, (42) 44 °C).

2-Phenylethyldimethyl-p-anisidinium Bromide

This compound was prepared from *N,N*-2-phenylethylmethyl-*p*-anisidine and methyl bromide by the same procedure as the unsubstituted compound; m.p. 181–182 °C.

Anal. Calcd. for $C_{17}H_{22}NOBr$: C, 60.72; H, 6.59; N, 4.17. Found: C, 60.74; H, 6.60; N, 3.98.[8]

N,N-2-Phenylethylmethyl-p-anisidine

This compound was prepared by means of the Eschweiler–Clarke (43) procedure. To 17 g (0.075 mol) of *N*-2-phenylethyl-*p*-anisidine were added 10 g (0.195 mol) of 90% formic acid and 7.5 g (0.085 mol) of 35% formaldehyde and the mixture heated on the steam bath for 10 h. After cooling and addition of 40 ml 4 *N* hydrochloric acid, the excess of formaldehyde and formic acid was removed by distillation under reduced pressure. The residue was rendered alkaline with 40% aqueous sodium hydroxide and extracted with ether. After drying over potassium carbonate and removal of the solvent 17.4 g (100%) of the crude product were recovered. Vacuum distillation produced 10 g (59%) of the pure wax-like yellowish white product; b.p. 118 °C/0.03 Torr.

N-2-Phenylethyl-p-anisidine

This compound was prepared by the same method as *N,N*-2-phenylethylmethylaniline. From 18.5 g (0.1 mol) 2-bromoethylbenzene and 12.3 g (0.1 mol) *p*-anisidine, 11 g (48%) of pure product were obtained; b.p. 140–142 °C/0.5 Torr.

2-Phenylethyldimethyl-p-toluidinium Bromide

This material was prepared from *N,N*-2-phenylethylmethyl-*p*-toluidine and methyl bromide by the procedure described for the unsubstituted compound; m.p. 177 °C.

Anal. Calcd. for $C_{17}H_{22}NBr$: C, 63.75; H, 6.92; N, 4.37. Found: C, 63.76; H, 6.75; N, 4.27.[8]

N,N-2-Phenylethylmethyl-p-toluidine

N-2-Phenylethyl-*p*-anisidine (12.3 g, 0.058 mol) was converted into 10.3 g (80%) of this compound by means of the Eschweiler–Clarke procedure described for the corresponding *p*-anisidine derivative. The material was quaternized without further purification.

N-2-Phenylethyl-p-toluidine

4′-Methyl-phenylacetanilide (12.3 g, 0.054 mol) was

[7]Smith's data (38)[5] represent a problem, however, and cannot be considered as final proof of the present hypothesis. Although they seem to indicate that a trend towards the shortening of one bond is associated with a trend towards the lengthening of the other one, they do not appear to represent an effect on the perpendicular motion as interpreted in Thornton's (6, 7) theory, since the sense of the variation is exactly opposite to the one predicted on the basis of this theory. We are currently trying to establish the causes and implications of Smith's results.

[8]Elemental analyses were performed by Galbraith Laboratories Inc., Knoxville, Tennessee.

For personal use only.

placed in the thimble of a Soxleth extraction apparatus, the flask of which contained 5.2 g (0.135 mol) lithium aluminum hydride (BDH Chemicals) and 350 ml ether. The extraction and reduction was allowed to proceed for 24 h. After cooling, water was carefully added dropwise until the reaction mixture appeared white. The precipitated aluminum hydroxide was then filtered and washed with ether. Removal of the solvent yielded 11.5 g (100%) of the product, a white, wax-like solid. It was used for the next step without further purification.

4′-Methyl-phenylacetanilide

A solution of 27 g (0.25 mol) *p*-toluidine (Eastman) and 50 g triethylamine in 50 ml benzene was added slowly whilst stirring to a solution of 38.7 g (0.25 mol) of phenylacetylchloride in 100 ml benzene. After allowing the reaction mixture to stand for 1 h the triethylamine hydrochloride formed was removed by filtration. The benzene solution was concentrated on the rotary evaporator. The precipitated anilide was filtered and thrice recrystallized from ethanol; yield 12.3 g (22%), m.p. 130 °C. Additional crude product was obtained on concentration of the mother liquors.

2-Phenylethyldimethyl-4-chloroanilinium Bromide

This material was prepared from *N,N*-2-phenylethylmethyl-4-chloroaniline and methyl bromide by the procedure described for the unsubstituted compound; m.p. 170–171 °C.

Anal. Calcd. for $C_{16}H_{19}NClBr$: C, 56.40; H, 5.62; N, 4.11. Found: C, 56.22; H, 5.66; N, 4.04.[8]

N,N-2-Phenylethylmethyl-4-chloroaniline

N-2-Phenylethyl-4-chloroaniline was methylated by the Eschweiler–Clarke procedure described for the corresponding *p*-anisidine derivative with nearly quantitative yield. The product was purified by dissolving it in petroleum ether and filtering through aluminum oxide, followed by recrystallization from ethanol; m.p. 61–62 °C.

N-2-Phenylethyl-4-chloroaniline

This compound was prepared by reduction of 4′-chloro-phenylacetanilide with lithium aluminum hydride as described for the corresponding *p*-toluidine derivative. It was purified by vacuum distillation; b.p. 126–128 °C/0.15 Torr.

4′-Chloro-phenylacetanilide

This compound was prepared by the procedure described for 4′-methyl-phenylacetanilide; m.p. 163 °C (lit. (44) 163–164 °C).

2-Phenylethyldimethyl-3-trifluoromethylanilinium Bromide

This compound was prepared by quaternization of *N,N*-2-phenylethylmethyl-4-trifluoromethylaniline with methyl bromide, as described for the unsubstituted compound; m.p. 160–161 °C.

Anal. Calcd. for $C_{17}H_{19}NF_3Br$: C, 54.55; H, 5.12; N, 3.74. Found: C, 54.35; H, 5.10; N, 3.66.[8]

N,N-2-Phenylethylmethyl-4-trifluoromethylaniline

N-2-Phenylethyl-4-trifluoromethylaniline was methylated by the Eschweiler–Clarke procedure described for the corresponding *p*-anisidine derivative. The product was quaternized without further purification.

N-2-Phenylethyl-4-trifluoromethylaniline

This compound was prepared by heating 16.1 g (0.1 mol) 4-trifluoromethylaniline with 13 g (0.13 mol) triethylamine and 18.5 g (0.1 mol) 2-bromoethylbenzene in a sealed flask for 48 h. After addition of 100 ml water, the mixture was extracted with ether. After drying over potassium carbonate, removal of the solvent and distillation, 2.7 g (11%) of the pure product were obtained; b.p. 114 °C/0.03 Torr.

2-Phenylethyldimethylanilinium-2,2-d_2 Bromide

This material was prepared from *N,N*-2-phenylethylmethylaniline-2,2-d_2 and methyl bromide as described for the undeuterated compound and purified by recrystallization from isopropanol–ether; m.p. 168 °C.

Anal. Calcd. for $C_{16}H_{18}D_2NBr$: C, 62.34; H + D, 7.19; N, 4.54. Found: C, 62.30; H + D, 7.01; N, 4.60.[8] Deuterium content: 1.96 atoms D per molecule.[9]

N,N-2-Phenylethylmethylaniline-2,2-d_2

2-Bromoethylbenzene-1,1-d_2 (4.6 g, 0.025 mol) and 5.4 g (0.05 mol) *N*-methylaniline were heated in a sealed flask for 24 h on the steambath. The reaction product was extracted with ether. After drying of the ethereal solution over potassium carbonate, removal of the solvent and vacuum distillation 2.6 g (50%) of the pure product were obtained; b.p. 102 °C/0.02 Torr.

2-Bromoethylbenzene-1,1-d_2

2-Phenylethanol-2,2-d_2 (6.2 g, 0.05 mol) and 31 g (0.18 mol) 48% hydrobromic acid were heated to reflux for two hours. Extraction of the cool solution with ether, drying of the organic phase over sodium sulfate and removal of the solvent yielded 8.3 g (88%) of the desired bromide.

2-Phenylethanol-2,2-d_2

Phenylacetic acid-α,α-d_2 (8.2 g, 0.061 mol) dissolved in 50 ml ether was added dropwise to a solution of 2.64 g (0.07 mol) lithium aluminum hydride in 75 ml ether. After heating the resulting solution to reflux for 2 h, just enough water was added to transform all the lithium aluminum hydride into aluminum hydroxide, which was then filtered off and washed with anhydrous ether. After removal of the solvent 6.6 g (87%) of product were obtained.

Phenylacetic Acid-α,α-d_2

A solution of 93 g (0.39 mol) diethylphenylmalonate (Eastman) in 390 ml dry petroleum ether (30–60 °C) was filtered through a column of alumina (80–200 mesh, Brockman activity 1) and then added to a well-stirred mixture of 170 ml petroleum ether and 18.6 g (0.39 mol) of a 50% dispersion of sodium hydride in mineral oil (Metal Hydrides Inc).

The resulting white solid was removed by filtration and washed repeatedly with petroleum ether. The solvent was removed from the solid by pumping overnight in a vacuum desiccator. The dried sodium salt, 66 g (0.26 mol), was added to 70 ml deuterium oxide. The resulting solution was heated to reflux for 8 h in a dry nitrogen atmosphere. After cooling, the solution was acidified by adding thionyl chloride and heated again to reflux for 2 h to bring about decarboxylation. After extraction with ether, drying over sodium sulfate and removal of the solvent, 31 g of the crude product were obtained. Recrystallization from petroleum ether yielded 22 g (41%) of pure phenylacetic acid-α,α-d_2.

[9]Deuterium analyses were performed by Mr. J. Nemeth, 303 W. Washington Street, Urbana, Illinois.

2-Phenylethyldimethyl-p-anisidinium-2,2-d_2 Bromide

This salt was prepared from *N,N*-2-phenylethylmethyl-*p*-anisidine-2,2-d_2 and methyl bromide as described for the corresponding undeuterated unsubstituted material; m.p. 180 °C.

Anal. Calcd. for $C_{17}H_{20}D_2NOBr$: C, 60.36; H + D, 7.15; N, 4.14. Found: C, 60.28; H + D, 6.93; N, 4.13.[8] Deuterium content: 1.96 atoms D per molecule.[9]

N-2-Phenylethylmethyl-p-anisidine-2,2-d_2

N-2-Phenylethyl-*p*-anisidine-2,2-d_2 (1.65 g, 0.0073 mol) was transformed into 1.5 g (85%) of the corresponding *N*-methyl compound by the Eschweiler–Clarke procedure described for the undeuterated compound. The product was quaternized without further purification.

N-2-Phenylethyl-p-anisidine-2,2-d_2

4′-Methoxy-phenylacetanilide-α,α-d_2 (2.5 g, 0.024 mol) was reduced with lithium aluminum hydride to yield 2.1 g (89%) of the desired amine, using the procedure described for the corresponding undeuterated *p*-toluidine derivative.

4′-Methoxy-phenylacetanilide-2,2-d_2

A solution of 5 g (0.033 mol) phenylacetylchloride-α,α-d_2 in 10 ml dry benzene was added dropwise to a stirred solution of 4 g (0.033 mol) *p*-anisidine (Eastman) and 3.4 g (0.033 mol) triethylamine in 50 ml benzene. The mixture was allowed to stand for 1 h, after which time the white product was removed by filtration, washed with deuterium oxide and recrystallized from benzene; yield 4.5 g (57%); m.p. 122 °C.

Phenylacetyl Chloride-α,α-d_2

A mixture of 11 g (0.079 mol) phenylacetic acid-α,α-d_2 and 9.4 g (0.079 mol) thionyl chloride (BDH) was provided with a few boiling chips and allowed to stand at room temperature for 24 h. The reaction was quantitative and the product was used without further purification.

2-Phenylethyldimethyl-p-toluidinium-2,2-d_2 Bromide

This material was available from an earlier study.[10] It was recrystallized four times from ethanol–ether; m.p. 178 °C.

Anal. Calcd. for $C_{17}H_{20}D_2NBr$: C, 63.35; H + D, 7.50; N, 4.35. Found: C, 63.31; H + D, 7.06; N, 4.34.[8] Deuterium content: 1.94 atoms D per molecule.[9]

2-Phenylethyldimethyl-4-chloroanilinium-2,2-d_2 Bromide

This compound was prepared from *N,N*-2-phenylethylmethyl-4-chloroaniline-2,2-d_2 and methyl bromide as described for the unsubstituted, undeuterated material; m.p. 170 °C.

Anal. Calcd. for $C_{16}H_{17}D_2NClBr$: C, 56.07; H + D, 6.17; N, 4.09. Found: C, 56.15; H + D, 5.95; N, 3.95.[8] Deuterium content: 1.89 atoms D per molecule.[9]

N,N-2-Phenylethylmethyl-4-chloroaniline-2,2-d_2

N-2-Phenylethyl-4-chloroaniline-2,2-d_2 (2.6 g, 0.0113 mol) was transformed into the corresponding *N*-methylaniline by the Eschweiler–Clarke procedure described for the corresponding undeuterated *p*-methoxy compound; yield 2.46 g (88%). The product was quaternized without further purification.

N-2-Phenylethyl-4-chloroaniline-2,2-d_2

Phenylacetyl-4-chloroanilide-α,α-d_2 (3.7 g, 0.0151 mol) was reduced with lithium aluminum hydride to the desired amine, as described for the corresponding undeuterated *p*-toluidine derivative.

Phenylacetyl-4-chloroanilide-α,α-d_2

A solution of 5 g (0.033 mol) phenylacetylchloride-α,α-d_2 in 10 ml dry benzene was added dropwise to a stirred solution of 4.15 g (0.033 mol) 4-chloroaniline-*N,N*-d_2 and 3.4 g (0.033 mol) triethylamine (Eastman) in 50 ml benzene. The mixture was allowed to stand for 1 h, after which time the white product was removed by filtration, washed with deuterium oxide, and recrystallized from chloroform–ether; yield 3.8 g (47%); m.p. 163 °C.

4-Chloroaniline-N,N-d_2

A mixture of 10 g (0.079 mol) 4-chloroaniline (Eastman), 20 ml deuterium oxide and enough pyridine to bring all the aniline into solution was allowed to stand overnight at room temperature. Most of the solvent was then removed on the rotation evaporator. This treatment was repeated once. The product was then recrystallized from petroleum ether; m.p. 70 °C. Nuclear magnetic resonance analysis indicated a deuterium content of 1.92 atoms D per molecule.

2-Phenylethyldimethyl-3-trifluoromethylanilinium Bromide-2,2-d_2

This compound was available from an earlier study.[10] It was recrystallized three times from ethanol–ether; m.p. 125 °C.

Anal. Calcd. for $C_{17}H_{17}D_2NF_3Br$: C, 54.26; H + D, 5.62; N, 3.72. Found: C, 54.18; H + D, 5.52; N, 3.66.[8] Deuterium content: 1.89 atoms D per molecule.[9]

2-Phenylethyldimethyl-4-trifluoromethylanilinium Bromide-2,2-d_2

This material was available from an earlier investigation.[10] It was recrystallized twice from ethanol–ether; m.p. 159 °C. Nuclear magnetic resonance analysis indicated more than 90% deuteration in the benzyl position.

Absolute Ethanol

This solvent was dried by the method of Lund and Bjerrum (45) and stored under anhydrous conditions.

Sodium Ethoxide

Stock solutions of this base were prepared by dissolving clean sodium metal in ethanol under strictly anhydrous conditions in a nitrogen atmosphere.

Product Analyses

The appropriate undeuterated quaternary ammonium salt (300 to 500 mg) was dissolved in 25 ml of a 1.48 *N* solution of sodium ethoxide in ethanol and the solution allowed to stand for 18–24 h in a thermostatted bath at 40 °C. The solution was then diluted with 25 ml water and extracted three times with 50 ml portions of petroleum ether. After removal of the solvent under reduced pressure the mixture was analyzed by g.l.c., using a column packed with 15% silicon rubber SE30 on Chromosorb W. This procedure was applied to the *p*-Me, *p*-H, *p*-Cl, and *m*-CF_3 substrates. In all cases three peaks could be distinguished. The two large ones corresponded to the two products of the elimination reaction (styrene and a substituted *N,N*-dimethylaniline) the third very small one corresponded to the product of a competing substitution reaction, namely a substituted *N,N*-2-phenylethylmethylaniline. The various peaks were identified by comparing them with the peaks corresponding to authentic samples. A rough comparison of the peak areas indicated the

[10]A. N. Bourns and B. Wang, unpublished work.

following maximal amounts of substitution products: *p*-Me, 0.18%; *p*-H, 0.16%; *p*-Cl, 0.23%; *m*-CF_3, 0.85%. It appears that the percentage of substitution reaction is larger for stronger electron-withdrawing substituents in the leaving group, a trend which has also been observed by Willi (22).

A visual comparison of the u.v. spectra of the actual reaction solutions at infinite time gave no indication of any appreciable amounts of competing substitution reaction. Deuterated and undeuterated starting materials produced solutions with virtually identical spectra. Furthermore, the spectra of the reaction solutions at infinite time appeared identical to the spectra of solutions prepared from authentic samples. This, together with the fact that the infinity value of the optical density in the kinetic runs was within $\pm 1\%$ of the expected value, was taken as evidence that competition by substitution reactions was not important under the experimental conditions chosen.

Kinetic Measurements

The rate of reaction of undeuterated and deuterated 2-phenylethyldimethylanilinium salts with sodium ethoxide in ethanol was determined by spectrophotometrically monitoring the increase in the amount of reaction product (*i.e.* styrene and *N,N*-dimethylaniline) as a function of time. All the reactions were carried out directly in the spectrophotometer cell and followed to a minimum of 75% completion. Standard wavelength for all the measurements was 248 mm, the wavelength of the absorption maxima of styrene and unsubstituted dimethylaniline. At this wavelength absorption caused by the reactants was negligible. A compilation of the absorption maxima and molar extinction coefficients of the various reaction products as measured under the reaction conditions is given in Table 6.

A Hitachi–Perkin-Elmer model 139 spectrophotometer fitted with a thermostatted cell compartment was used throughout for the kinetic measurements. The temperature in the cell compartment was kept constant at 40 ± 0.05 °C. Ultraviolet–visible spectra were recorded on a Cary 14 spectrophotometer.

The reaction solutions were prepared by mixing appropriate amounts of thermostatted stock solutions of the quaternary anilinium salts and the base in 50 ml volumetric flasks. All reactions were measured under pseudo first-order conditions with the base in large excess (*ca.* 400 fold) over the quaternary salt. The same sodium ethoxide solution was used for a complete set of experiments. This ensured a constant ionic strength. The substrate concentration was chosen such that a convenient value of the optical density of the reaction solutions at infinite time would be obtained, *i.e.* $3\text{–}4 \times 10^{-5}$ mol/l. Reactions with undeuterated and deuterated substrates were always carried out simultaneously. Excellent first-order plots were obtained in all cases.

Solutions of the quaternary anilinium salts were entirely stable. Elimination was caused only by ethoxide ion, not by ethanol. No deuterium exchange was detected in solutions of the deuterated salts.

The pseudo first-order rate constants, k', were calculated as -2.3 times the slope of the first-order plots (46). This slope was determined either by visually drawing a straight line or by least-squares treatment, both methods giving the same result. The second-order rate constants, k_E, were then obtained by division of k' by the ethoxide ion concentration, *i.e.* $k_E = k'/[EtO^-]$. The rate constants given in Table 1 represent the average of 3 to 6 kinetic runs.

Nitrogen Isotope Effects

The nitrogen isotope effects were determined by comparing the nitrogen isotopic abundance of the dimethylaniline formed in reactions carried out to some known fractional extent (partial reactions) with the isotopic abundance in the starting material or in the product after complete reaction.

The desired extent of reaction was achieved by adding the appropriate amount of base to the quaternary salt solution and allowing the reaction to proceed for more than ten half lives. Runs were set up so that 0.2 mmol of dimethylaniline would be formed, a convenient quantity for the subsequent mass spectrometric analysis. The faster reactions were carried out in 50 ml volumetric flasks, the slower ones in evacuated ampoules. The concentrations were small enough to ensure that practically no reaction occurred during mixing of the reactants. The reaction vessels were kept in a thermostatted bath at 40 ± 0.02 °C.

After the reaction had proceeded for ten or more half lives, water (twice the amount of the alcoholic reaction solution) was added to the reaction mixture. The aqueous solution was extracted three times with 50 ml portions of petroleum ether (30–60); 2.5 ml of concentrated sulfuric acid were then added to the organic phase and the solvent removed on the rotary evaporator. The acid residue was washed with water into a Kjeldahl flask. After the water had been removed by gentle heating, 2 g potassium sulfate and 0.10 g mercuric oxide were added. This mixture was digested in the usual manner for 2.5–3 h. Ammonia was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

then liberated by addition of sodium hydroxide and transferred into excess standard sulfuric acid by steam distillation. The overall yield was always over 90%, usually between 95 and 100%.

This extraction technique was used for partial and complete reactions. For the preparation of nitrogen samples from the quaternary salts it was necessary to remove the halogen by oxidation with hydrogen peroxide prior to digestion, as described by Ayrey *et al.* (47).

The ammonium sulfate solution resulting from the Kjeldahl digestion was concentrated and oxidized with sodium hypobromite to nitrogen gas, which was purified and then analyzed by mass spectrometry. Details of the procedure are given by Ayrey *et al.* (47).

The kinetic isotope effects were calculated as described previously (47).

Financial support for this work was provided by the National Research Council of Canada and McMaster University. We wish to thank Professors E. R. Thornton and W. H. Saunders, Jr. for discussions.

The Direct Formation of 3-Vinylthiophenes Using Butadienylphosphonium Salts[1]

JOHN M. MCINTOSH[2] AND FREDERICK P. SEGUIN
Department of Chemistry, University of Windsor, Windsor, Ontario N9B 3P4

Received June 9, 1975

JOHN M. MCINTOSH and FREDERICK P. SEGUIN. Can. J. Chem. **53**, 3526 (1975).

The reaction of α-mercaptoaldehydes and ketones with 1,3-butadien-1-yltriphenylphosphonium salts (**4**) unexpectedly leads to 3-vinylthiophenes and triphenylphosphine. This result is attributed to the retardation of the usual Wittig cyclization reaction which allows the competing reaction to occur.

JOHN M. MCINTOSH et FREDERICK P. SEGUIN. Can. J. Chem. **53**, 3526 (1975).

La réaction des α-mercaptoaldéhydes et cétones avec les sels du butadiène-1,3 yl-1 triphénylphosphonium (**4**) conduit d'une façon inattendue aux vinyl-3 thiophènes et à la triphénylphosphine. On attribue ce résultat à un retardement de la réaction de cyclisation de Wittig habituelle qui permet à la réaction compétitive de se produire.

[Traduit par le journal]

The concept of 'umpolung' (1) or reversed polarity synthons in organic synthesis has become a center of intense investigation since the principle was first enunciated by Corey (2). By far the most concentrated attention has been on the generation of the nucleophilic equivalent of a carbonyl carbon atom and several successful variations of this have been achieved (for an excellent review of methods, see ref. 3). In recent years, several groups have been concerned with the reaction of another type of compound which fits into this type of classification, *viz.* vinylphosphonium salts (**1**) (ref. 4 and previous papers in the series) which can be visualized as the equivalent of a reversed-polarity enolate ion (**2**). Our

1 **2**

particular interest has been in the use of **1** and α-mercaptoaldehydes and ketones as convenient routes to conjugated dienes (5) and thiophenes (6) via the intermediacy of 2,5-dihydrothiophenes (**3**) [1]. As part of our program to enlarge the scope of these reactions we decided to prepare and investigate the use of some functionalized phosphonium salts. One of the simplest, yet most interesting of these is 1,3-butadien-1-yltriphenylphosphonium chloride (**4**) which is readily available from either the bis-salt **5**[3] or the monophosphonium salt **6** (7) by the appropriate elimination reaction. It is evident that salt **4** is related to the enolate of crotonaldehyde in the same way that **1** is related to **2**. Although **4** is a well-known entity (8), until recently, little work on its chemistry has been reported. More results using the closely related diethyl 1,3-butadien-1-ylphosphonate (**7**) are available (9). Unlike the alkylations of extended enolate ions which occur at the β-carbon atom

[3]The extreme ease of formation of **5** from triphenyl phosphine and 1,4-dichloro-2-butene contrasts sharply with the reported difficulty of forming the same salt from the dibromide (7).

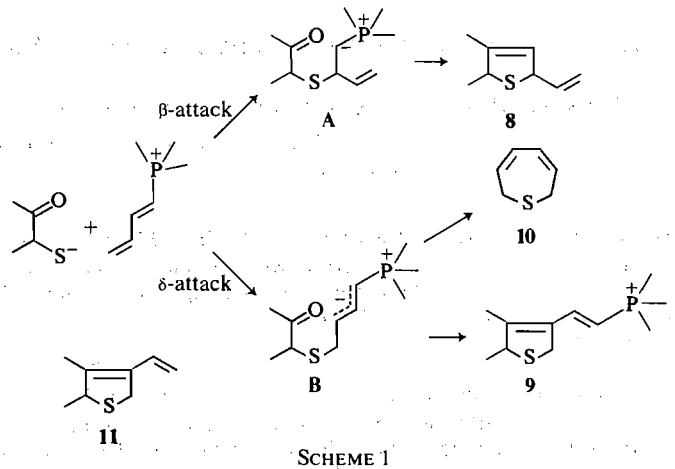


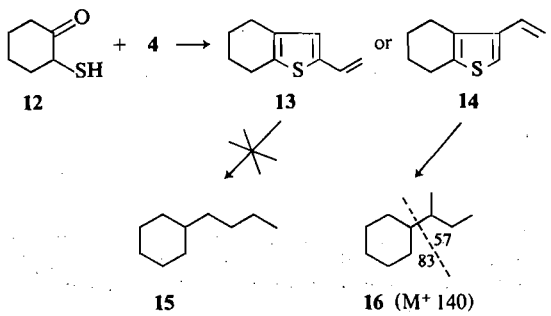
SCHEME 1

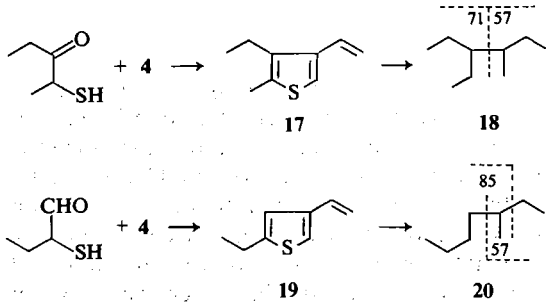
(10), all reports on the reactions of **4** and **7** implicate attack at the δ-position.

Depending on the site of initial attack on **4**, several products (**8–10**) can be envisioned as arising from its reaction with α-mercaptocarbonyl compounds (Scheme 1). A notable absence from this scheme is **11** which cannot arise by any simple loss of triphenylphosphine oxide from either of intermediates **A** or **B**.

Results and Discussion

When salt **4** was prepared *in situ* from **5** and reacted with 2-mercaptocyclohexanone (**12**) in pyridine solution, a single nonpolar compound was isolated in moderate yield after removal of triphenylphosphine. This was achieved by converting it into the sulfide using elemental sulfur (10) followed by chromatography. The n.m.r. spectrum of the remaining material clearly indicated the product was not of the expected type. The presence of a terminal vinyl group attached to an *aromatic* ring and one other low-field proton was clearly evident. The mass spectrum showed a molecular ion at *m/e* 164. All the data





were in accord with either 2- or 3-vinyl-4,5,6,7-tetrahydrobenzo[*b*]thiophene (**13** or **14**). Attempts to reduce the product to the 2- or 3-ethyl compound using homogeneous catalysis (11) were unsuccessful. However, reductive desulfurization using Raney nickel (12) afforded a single saturated hydrocarbon, the mass spectrum of which coincided with that of **16**, but not its isomer **15** which established the structure of the product to be **14**. Similar results were obtained in the other two cases tried. In each instance, the 3-vinylthiophene (**17** and **19**) derivative was obtained. The yields of thiophene product were in the 30–40% range when pyridine was used as solvent. However, substitution of 2-picoline as solvent raised these to the 50–70% range.

These reactions of salt **4** produce a product in a higher formal oxidation state than those reactions of salts **1** previously investigated (5). The possibility of disproportionation of **3** to thiophene was eliminated by the absence of the corresponding tetrahydrothiophene from the reaction mixture and since all reactions were performed under a nitrogen atmosphere, aerial

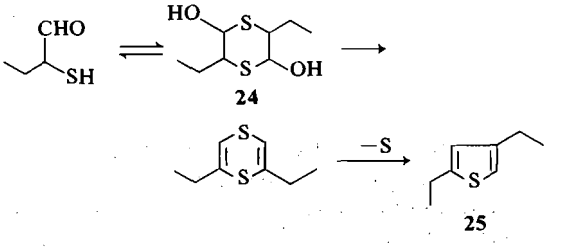
22

SCHEME 2

oxidation seems unlikely. The formation of large amounts of triphenylphosphine whether salt **5** or **6** was used as the starting material, and the total absence of triphenylphosphine oxide in the reaction mixture suggested an alternate mechanism might be operating (Scheme 2).[4] Acid catalysis of the cyclization–dehydration step, if necessary, could be provided by the amine hydrochloride present in the mixture. An analogous mechanism has recently been proposed (13) for the isomerization of a thiochromene to a benzothiophene. The *Z*-configuration of **21** required for proton transfer should be easily accessible.

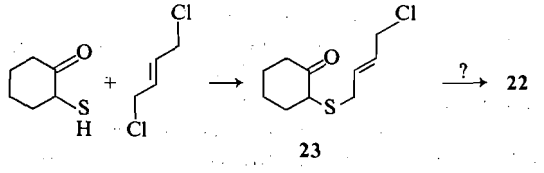
In an attempt to verify this hypothesis, sulfide **23** was prepared and subjected to a variety of reaction conditions. In no case was any thiophene detected although **23** was consumed. The reactions uniformly turned black and decomposition of **23** leading to products other than **22** may account for this negative result.

In the reaction of 2-mercaptobutyraldehyde with **4**, a second product was isolated and identified as 2,4-diethylthiophene, **25**. This product appears to be formed from a decomposition product of the aldehyde dimer **24** since its formation depends on the purity of **24**. Attempted distillation or recrystallization of **24** leads to partial dehydration and the amount of **25** subsequently formed increases dramatically. Such extrusion reactions have previously been reported (14) for a variety of types of organic materials and the mechanisms suggested in those cases are clearly applicable here.



24

25



23

Why thiophenes and not dihydrothiophenes should be formed when salt **4** is used is not intuitively obvious. However, our experience has been that such factors as α-substitution of the vinyl salts which retard the rate of betaine formation generally increase the amount of thiophene in a mixture. It appears possible therefore, that the proton migration step is a competing side reaction in all cases, but only successfully competes with the intramolecular Wittig reaction when the latter is slow. Clearly the delocalized character of intermediate **B** (Scheme 1) and the unfavorable entropy term associated with the formation of **10** would be expected to result in a slower Wittig reaction and increased amounts of thiophene as is observed.

Experimental

Nuclear magnetic resonance spectra were run on Varian EM360 or JEOLCO C 60HL instruments and are reported in p.p.m. downfield from TMS as internal standard. Infrared spectra were recorded on a Beckmann IR 12 and mass spectra on a Varian MATCH-5DF spectrometer. Gas–liquid chromatographic analyses were carried out on

[4]A referee has suggested an alternative route from **21** involving proton transfer, cyclization, and dehydration to give **i**, followed by elimination of triphenylphosphine as shown.

a Hewlett-Packard Model 5750 instrument using helium carrier gas at a flow rate of 1 ml/s. Unless otherwise noted, the drying agent was anhydrous magnesium sulfate and column chromatography was performed using Fisher acidic alumina, activity grade I. Pyridine was dried over solid sodium hydroxide and was decanted prior to use. Microanalyses were performed by A.B. Gygli, Microanalysis Laboratory, Toronto, Ontario.

2-Butenyl-1,4-bistriphenylphosphonium Dichloride (5)

A mixture of 12.4 g (0.1 mol) of 1,4-dichloro-2-butene and 52.4 g (0.2 mol) of triphenylphosphine in 400 ml acetonitrite was heated at reflux for 15 h. The cooled solution was filtered and the residue was washed well with ether and dried under vacuum at 85 °C. The yield was 64.5 g (98%), m.p. 255–258 °C.

When an attempt was made to prepare the mono-salt either in benzene or acetonitrite solvent, only the bis-salt **5** could be obtained.

3-Vinyl-4,5,6,7-tetrahydrobenzo[b]thiophene (14)

A solution of salt **5** in 150 ml dry pyridine and 10 ml of triethylamine was stirred at room temperature for 30 min. Mercaptoketone **12** (15) (4.2 g, 0.032 mol) was added all at once, the system was purged with nitrogen, and the solution was refluxed for 72 h. The cooled solution was diluted with 700 ml of water and extracted with ether (2 × 100 ml) and pentane (2 × 100 ml). The combined organic extracts were washed with 10% hydrochloric acid until the washings were acidic and then with water. Removal of the solvent from the dried solution gave a semisolid material which was dissolved in 300 ml of benzene containing excess sulfur flowers and the mixture was refluxed for 3.5 h. The benzene was removed, ice-cold pentane was added and the precipitated solids were removed by filtration. The filtrate was chromatographed on alumina using 10% ether in pentane as eluant. Thiophene **14** eluted rapidly and was pure to g.l.c. analysis; (20% SE 30, 160 °C); yield 2.51 g (51%); i.r. (CCl_4) 3090, 2930, 2850, 2840, 1630, 1440, 1420, 990, and 905 cm^{-1}; n.m.r. (CCl_4) 6.85 (1H, s), 6.46 (1H, dd, J = 17, 11 Hz), 5.36 (1H, dd, J = 17, 2 Hz), 501 (1H, dd, J = 11, 2 Hz), 2.6 (4H, m), and 1.82 (4H, m).

Anal. Calcd. for $C_{10}H_{12}S$: C, 73.12; H, 7.36. Found: C, 72.92; H, 7.01.

Increasing the reaction time did not raise the yield, but using 2-picoline as solvent increased the yield to 62%. The same product was obtained when phosphonium salt **6** was substituted for **5**.

2-Methyl-3-ethyl-4-vinylthiophene (17)

Working on a 0.03 mol scale and using pyridine as solvent the thiophene **17** was obtained in 31% yield; i.r. (CCl_4) 3090, 2970, 2930, 2870, 1625, 1450, 1420, 1375, 1190, 1065, 990, 950, 910, and 870 cm^{-1}; n.m.r. ($CDCl_3$) 7.03 (1H, s), 6.62 (1H, dd, J = 17, 10 Hz), 5.50 (1H, dd, J = 17, 1.5 Hz), 5.14 (1H, dd, J = 10, 1.5 Hz), 2.57 (2H, q, J = 7 Hz), 2.35 (3H, s), and 1.10 (3H, t, J = 7 Hz); λ_{max}(cyclohexane) 258 (6450), 231 (12 880), and 225 (14 650) nm.

Anal. Calcd. for $C_9H_{12}S$: C, 71.00; H, 7.94. Found: C 70.86; H, 8.03.

2-Ethyl-4-vinylthiophene (19) and 2,4-Diethylthiophene (25)

When 2-mercaptobutyraldehyde (16) was employed in pyridine solution, two compounds were isolated from the alumina chromatography. The g.l.c. analysis (20%, Carbowax 20M, 130 °C) separated these and gave **19** (35%); i.r. (CCl_4) 3095, 2970, 2930, 2870, 1630, 1460, 1210, 990, 900, 860, and 840 cm^{-1}; n.m.r. (CCl_4) 6.82 (2H, s), 6.53 (1H, dd, J = 16, 11 Hz), 5.43 (1H, dd, J = 16, 2 Hz), 5.08 (1H, dd, J = 11, 2 Hz), 2.82 (2H, q, J = 7.5 Hz), and 1.07 (3H, t, J = 7.5 Hz).

Anal. Calcd. for $C_8H_{10}S$: C, 68.55; H, 7.30. Found: C, 68.70; H, 7.24.

Also isolated was **25**; i.r. (CCl_4) 2960, 2930, 2870, 1455, and 790 cm^{-1}; n.m.r. (CCl_4) 6.55 (2H, s), 2.70 (4H, m), and 1.24 (6H, m).

Anal. Calcd. for $C_8H_{12}S$: C, 68.55; H, 8.63. Found: C 68.77; H, 8.63.

The ratio of **19** and **25** varied from experiment to experiment and the variation was traced to the use of different preparations of the aldehyde.

Desulfurization Experiments

The thiophene (0.5–2 g) was dissolved in 300 ml ethyl acetate (THF in the case of **19**) and 6–10 g W-2 Raney nickel (17) was added. The solution was stirred 1 h, and then refluxed for 1 h. The solution was filtered and the solvent removed by distillation at 1 atm through a 20 cm Vigreaux column. The residue was analyzed by g.l.c. (20% TCEP, 90 °C) and in each case consisted of a major product and two minor ones. The major products gave mass spectra identical to those recorded for **16** (18) **18** (19), and **20** (ref. 19, p. 419). The minor product in each case has a molecular weight (mass spectral) two units lower than the major fraction and fragmentation patterns consistent with unsaturated derivatives.

2-(4-Chloro-2-butenylthio)cyclohexanone (23)

A solution of 5 g of **12** in 50 ml of dimethyl formamide was added all at once to 4.4 g (1 equiv,) of potassium *tert*-butoxide in 50 ml of the same solvent. The reaction was stirred for 5 min at ambient temperature and then 5 ml of 1,4-dichloro-2-butene was added. The yellow color was immediately quenched. After stirring for 1 h at ambient temperature, the solution was poured into 300 ml of water and extracted with ether. The extracts were washed with water, dried, and evaporated to give a quantitative yield of a pale yellow oil. This oil could not be effectively purified, but the spectral characteristics of the crude material indicated it to be at least 90% pure **23**; n.m.r. ($CDCl_3$) 6.02–5.35 (2H, m), 4.03 (2H, m), 3.45–3.00 (3H, m), and 2.51–1.40 (8H, m).

Treatment of this material with pyridine and triethylamine with and without added triphenyl phosphine, or DBU in methylene chloride resulted in destruction of the starting material, but no identifiable products could be obtained.

Determination of the Rate Constant of the $O + H_2 \rightarrow OH + H$ Reaction using Atomic Oxygen Resonance Fluorescence and the Air Afterglow Techniques

RICHARD N. DUBINSKY AND DONALD J. MCKENNEY[1]

Department of Chemistry, University of Windsor, Windsor, Ontario N9B 3P4

Received May 12, 1975

RICHARD N. DUBINSKY and DONALD J. MCKENNEY. Can. J. Chem. **53**, 3531 (1975).

Measurements of the rate of the reaction

[1] $$O(^3P) + H_2(^1\Sigma_g^+) \rightarrow OH(^2\Pi) + H(^2S_{1/2})$$

were made over the temperature range of 347 to 832 K and a pressure range of 140 to 739 N m^{-2}. Experiments were carried out using a discharge fast-flow system with a fixed observation port. O atoms, generated by the $N + NO \rightarrow N_2 + O$ reaction, were reacted with H_2 added downstream under pseudo first-order conditions ($[H_2] \gg [O]$). Relative O atom concentrations were determined using two independent methods: atomic resonance fluorescence at 130.6 nm and the air afterglow technique. The rate coefficients derived from our data can be expressed as $k_1 = (8.3 \pm 3.8) \times 10^{-12} \exp\{-36.0 \pm 2.0 \text{ kJ mol}^{-1}/RT\}$ cm^3 $molecule^{-1}$ s^{-1} (by resonance fluorescence), and $k_1 = (8.8 \pm 5.0) \times 10^{-12} \exp\{-34.9 \pm 2.0 \text{ kJ mol}^{-1}/RT\}$ cm^3 $molecule^{-1}$ s^{-1} (by air afterglow method). Comparisons are made with selected published results.

The Arrhenius plot of our data shows no evidence of curvature at low temperature.

RICHARD N. DUBINSKY et DONALD J. MCKENNEY. Can. J. Chem. **53**, 3531 (1975).

On a mesuré la vitesse de la réaction

[1] $$O(^3P) + H_2(^1\Sigma_g^+) \rightarrow OH(^2\Pi) + H(^2S_{1/2})$$

à des températures allant de 347 à 832 K et à des pressions de 140 à 739 N m^{-2}. On a effectué des expériences impliquant un système de décharge à flux rapide avec un point d'observation fixe. On a fait réagir les atomes d'oxygène, générés par la réaction $N + NO \rightarrow N_2 + O$, avec de l'hydrogène additionné en aval sous des conditions de réaction de pseudo premier ordre $[H_2] \gg [O]$. On a déterminé les concentrations relatives d'atomes d'oxygène en faisant appel à deux méthodes indépendantes: la fluorescence de résonance atomique à 130.6 nm et la technique de la lueur de l'air.

Les coefficients de vitesse dérives de nos données peuvent etre exprimés sous la forme $k_1 = (8.3 \pm 3.8) \times 10^{-12} \exp\{-36.0 \pm 2.0 \text{ kJ mol}^{-1}/RT\}$ cm^3 $molécule^{-1}$ s^{-1} (par fluorescence de résonance) et $k_1 = (8.8 \pm 5.0) \times 10^{-12} \exp\{-34.9 \pm 2.0 \text{ kJ mol}^{-1}/RT\}$ cm^3 $molécule^{-1}$ s^{-1} (par la méthode de la lueur d'air). On fait des comparaisons avec des valeurs publiées choisies.

Le diagramme d'Arrhénius de nos données ne montre pas de courbature à basse température.

[Traduit par le journal]

Many studies (1*a*) of the rate of the $O + H_2 \rightarrow OH + H$ reaction have been made. Data obtained in discharge flow systems at temperatures of 400–900 K now appear to be fairly consistent. The low temperature end, however, is less well defined with very few data for temperatures below 400 K. Westenberg and de Haas (2) using e.s.r. detection of O atoms obtained curvature of their Arrhenius plot at temperatures from about 420 to 357 K. They attributed this behavior to quantum mechanical tunnelling.

In this paper we wish to report a series of experiments designed to measure the rate of the title reaction over a wide temperature range extending to temperatures as low as possible in our apparatus (832–347 K) and over a very wide range of O/H_2 ratio. Two methods of atom detection were employed: resonance fluorescence of atomic oxygen at 130.6 nm (3) and the well-known air afterglow technique (4). Results are compared with published work and an Arrhenius expression for k_1 is recommended for temperatures up to ~830 K. Published results obtained at high temperature ($T > 900$ K) from separate shock tube, ignition limit studies, etc. (1*a*) are much less consistent, but rate constants are generally higher than that predicted by extrapolation of the linear Arrhenius plot obtained at

low temperature. It has been suggested (5) that the O + H_2 reaction is therefore another example of a simple elementary process for which the rate coefficients at high temperature would be better represented on a curved Arrhenius plot. This point is discussed briefly.

Experimental

Flow System

A fast-flow discharge system was used for the production of $O(^3P)$ ground state atoms for reaction with ground state molecular hydrogen. Figure 1 shows a schematic diagram of the flow reactor and detection system. The $O(^3P)$ atoms were generated by the rapid reaction N + NO $\rightarrow$ N_2 + O, $k \simeq 3 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} (1*b*). The N atoms were formed by partial dissociation of molecular N_2 by passage through a 2.45 GHz microwave discharge (Microton 200) operated at 25–100 W power output. A discharge bypass arrangement as described by Clyne and Cruse (6) was used to obtain low [N]. Purified NO was added at known flows through a jet some 15 cm downstream of the discharge. The reactor flow tube was a 2.5 cm i.d. quartz tube provided with nine inlet jets spaced over a distance of 30 cm. Purified H_2 could be added through any of the jets or bypassed through an additional jet downstream of the observation ports.

For measurements at elevated temperatures a furnace was constructed around the reaction zone. The column was heated using Chromel heating element wire wound around the column in three sections, each of which was controlled by a variac auto transformer. Ceramic fiber held in place by asbestos board and covered with aluminum foil provided sufficient insulation. The temperature was measured at any point along the flow tube using two moveable chromel–alumel thermocouples located adjacent to the walls and on opposite sides of the flow tube. Simple adjustment of the variacs allowed temperature control to within ± 5 °C over the length of the reaction zone. A small water jacket surrounded the flow tube between the furnace and the observation port. The observation cell with its LiF windows was thus maintained at room temperature and protected from thermal shock.

The flow tube wall was coated with a mixture of CH_3SiCl_3 and $(CH_3)_2SiCl_2$ and baked at $\sim$400 K for several hours. This coating has been reported to inhibit atom removal on the wall (7).

Total pressure was measured at both ends of the flow tube, using a silicone oil manometer.

The downstream end of the flow tube led through a large bore (2.0 cm) stopcock to a liquid nitrogen-cooled high conductance trap to a Welch 500 l/min (model 1397) rotary pump.

Lamps and Detection Systems

The observation cell (Fig. 1*b*) was equipped with three polished LiF windows (Harshaw Manufacturing Co.). A fourth window of polished quartz which was positioned opposite Lamp B, (Fig. 1*b*), served to reduce scattered light entering the monochromator slit by multiple reflection. Lamps A and B were identical to each other and similar to that used by Bemand and Clyne (3). Cylinder argon dried by passage at low pressure through a liquid nitrogen-cooled trap packed with glass wool flowed through either lamp for excitation by means of a 2.45 GHz discharge operated at $\sim$25 W. Total pressure in the lamp was maintained at 1–2 $\times$ 10^2 N m^{-2} for a typical flow rate of $\sim$1 μmol s^{-1}. The conditions used were chosen to maximize the signal-to-noise ratio.

For those experiments in which relative [O] was measured from air afterglow intensities, the detector was an RCA 1P28 photomultiplier tube fitted with a Wratten No. 61 gelatin filter which transmits between 490.0–600.0 nm (maximum at 520.0 nm). The photomultiplier was fixed adjacent to the flow tube just below the observation cell. Signal currents were measured using a Keithley model 417 high speed picoammeter.

The detector system for the resonance fluorescence studies consisted of a McPherson monochromator (0.3 m, model 218) joined to the flow reactor by a simple tube collimator which directs emitted radiation to the entrance slit. The monochromator incorporated a 1200 line mm^{-1} MgF_2 coated diffraction grating (blazed at 500 nm). De-

tection was accomplished using a Bendix Channeltron electron multiplier operated at 2800 V d.c. (the power supply, Fluke, model 408B, specified line regulation of 0.001%). Signal pulses were amplified with a home-made preamplifier and Ortec timing filter amplifier (model 454). Counting rates were obtained after discrimination (Ortec integral discriminator, model 421) by either a rate meter (Ortec model 441) recorder system or a digital counter (Ortec model 775), coupled to a variable timer (Ortec model 719).

A pressure of $\sim 6.5 \times 10^{-5}$ N m^{-2} was maintained in the monochromator detector system by separate pumping (Fig. 1).

Reagents

Nitrogen (Liquid Carbonic) 99.996% stated purity was further purified by passage at ~ 101.3 kN m^{-2} pressure over divided copper (673 K), copper oxide powder (673 K), followed by a cold trap at 195 K. On the low pressure side of the flow-meter was another trap maintained at 77 K which contained silica gel on glass wool. Argon (Liquid Carbonic) was dried by passage at low pressure through a glass-wool packed cold trap (77 K). Hydrogen (Liquid Carbonic) was passed through a catalytic purifier (Deoxo-Engelhard Mfg.) and a silica gel glass wool trap (77 K). Nitric oxide (Matheson) was distilled repeatedly at 77–195 K under vacuum.

Procedure

The reaction was followed by monitoring the decay of relative [O] by either atomic resonance fluorescence or by the air afterglow method. In the former method resonance radiation emitted by the microwave-powered lamp, served to excite atomic resonance fluorescence of O(^{3}P) in the flow tube reactor. Measurements of the photon fluxes were made at λ 130.6 nm, corresponding to the transition O, 3s,$^3S_1$–2p^4,$^3P_0$. The air afterglow method involved the addition of a slight excess of NO beyond the nitrogen afterglow extinction point so that the greenish yellow emission from excited NO_2 could be readily measured. The emission intensity under the conditions employed in this work is directly proportional to [O] (4).

Kinetic Analysis

The removal of O atoms is considered with reference to the following processes:

[1] $$O + H_2 \rightarrow OH + H$$

[2] $$O + OH \rightarrow O_2 + H$$

[3] $$OH + H_2 \rightarrow H_2O + H$$

Assuming a steady-state concentration of OH the rate expression for O-atom consumption is

$$\frac{-d[O]}{dt} = k_1[O][H_2]\left(1 + \frac{1}{1 + \frac{k_3[H_2]}{k_2[O]}}\right)$$

$$= \alpha k_1[O][H_2]$$

where α corresponds to the term in parentheses. α, which must have values between 1 and 2, can be calculated for each run provided the ratio $[H_2]/[O]$ is known since k_2 and k_3 are both reasonably well established (8): $k_2 = (4.2 \pm 1.7) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} ($E = 0$), $k_3 = 3.8 \times 10^{-11}$ exp $\{-21.6$ kJ mol$^{-1}/RT\}$ cm^3 molecule^{-1} s^{-1}.

Most studies carried out in discharge flow systems have been studied under conditions such that only reactions 1 and 2 need be considered. In this work, however, the ratio $[H_2]_0/[O]_0$ was varied over a very wide range ($\sim$2000 to 40) partly because the resonance fluorescence work necessitated limiting [O] to values less than 2×10^{13} cm^{-3}. With very large $[H_2]_0/[O]_0$ ratios reaction 3 can be quite important relative to [2] for OH removal. Therefore, the contribution of reaction 3 was calculated for each run and the rate constant k_1 determined from plots of the equation

$$\log \{[O]_0/[O]\} = \frac{\alpha k_1}{2.303}[H_2]_0 t$$

A small correction ($\sim$5% maximum) was made for any pressure gradient along the length of the flow tube. Corrections for radial axial and back diffusion were found to be negligible.

Results

Heterogeneous Removal of H, OH, and O

A series of runs were carried out with the intention of obtaining k_1 by measuring the rate of production of H atoms. In this case Lyman-α resonance fluorescence at λ 121.6 nm was used to monitor relative [H] as a function of time. The data, which tended to show rather large scatter, indicated rapid loss at the wall. The H-atom fluorescence signal generally passed through a maximum with increasing reaction distance. Unfortunately, a quantitative comparison of H production to O loss was not possible. However, loss of H by heterogeneous processes is not expected to affect the kinetics of O decay (9).

If first-order OH removal on the wall was rapid enough, the apparent calculated value of k_1 may be too low by as much as a factor of two. This requires k_w^{OH} (rate coefficient for wall removal of OH) to be of the same magnitude or larger than $k_2[O]$. Thus, for $[O] = 10^{11}$–10^{13} cm^{-3}, k_w^{OH} would have to be greater than 10^2–10^3 s^{-1}. Recent estimates (10) of k_w^{OH} in similar systems have produced values of $\sim$10–100 s^{-1}. Although surface activity is often not compar-

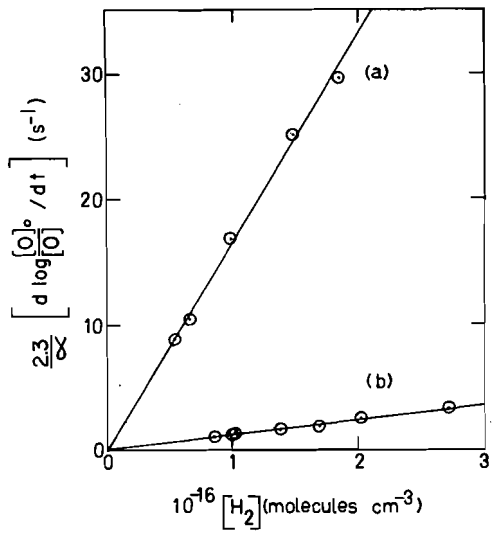

FIG. 2. Plot of $(2.3/\alpha)$[d log $\{[O]_0/[O]\}/dt$] *vs.* hydrogen concentration. (*a*) 508 K; by the resonance fluorescence technique. (*b*) 375 K; by the air afterglow method.

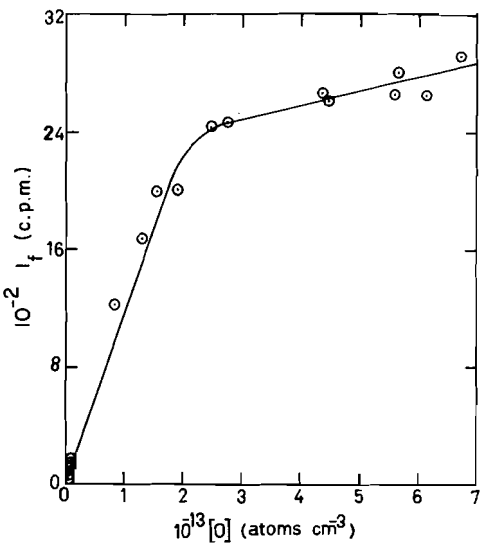

FIG. 3. Plot of fluorescence intensity (corrected for background) *vs.* oxygen atom concentration at λ 130.6 nm (unresolved) showing approximate linearity up to $\sim 2 \times 10^{13}$ cm^{-3}. (See ref. 3.)

able from one apparatus to another, the close agreement of our kinetic data (below) with those obtained by others suggests that heterogeneous removal of OH was not a serious problem in this work. Variation of $[O]_0$ over the range 10^{11}–10^{13} cm^{-3} produced no significant change in the value of k_1 calculated on the basis of negligible OH removal by heterogeneous processes.

Wall removal of O atoms does not interfere with the kinetic analysis provided that the removal is first-order and wall activity is not a function of added hydrogen (9). This assumption was verified by plots of [d log $[O]_0/[O]$)]/$dt \times (2.3/\alpha)$ *vs.* $[H_2]$ (Fig. 2). Within experimental scatter, these were straight lines with zero intercept, confirming that [1] is strictly first order with respect to $[H_2]$.

k_1 by Resonance Fluorescence

Pseudo first-order conditions were used throughout with H_2 in great excess ($[H_2]_0/[O]_0$ ~2000–40) (see Table 1*a*). The oxygen triplet emission from the source was readily resolved and showed considerable self-reversal typical of such lamps (3). Peak ratios were 1:2:2 which is to be compared with the theoretical ratios of 1:3:5 for the O $^3S_1$–$^3P_0$ (λ 130.6 nm), O $^3S_1$–$^3P_1$ (λ 130.5 nm), and O $^3S_1$–$^3P_2$ (λ 130.2 nm) respectively. In the fluorescence mode, however, loss of radiation necessitated the use of large slit widths (typically 100 μm) on the monochromator preventing full resolution under most conditions. Nevertheless, a few calibration runs showed that the intensity of the peak centered at λ 130.6 nm was approximately a linear function of [O] up to $\sim 2 \times 10^{13}$ cm^{-3} (Fig. 3). This result is consistent with the very extensive work of Bemand and Clyne (3) who obtained data for each line of the O $^3S_1$–^3P_J multiplet. Initial O atom concentrations[2] were kept below 2×10^{13} cm^{-3} to ensure linearity of fluorescence signal with [O].

Figure 4*a* shows a typical plot of log $[O]_0/[O]$ *vs.* time obtained by this technique. Table 1*a* summarizes all data obtained from resonance fluorescence measurements corrected for background levels of scattered light (typically ~50 Hz). The relatively low concentrations of O atoms required by this technique and the slow reaction rate restricted our measurements to temperatures above 495 K. Figure 5 shows an Arrhenius plot of all the data and the results are summarized in Table 2 in the form of Arrhenius parameters derived from a weighted least mean

[2] $[O]_0$ for the three runs done at 832 K (Table 1*a*) were slightly greater than 2×10^{13} cm^{-3}. At this temperature however, calculation shows that the concentration of O is reduced to $< 2 \times 10^{13}$ cm^{-3} in $< 7 \times 10^{-3}$ s (corresponding to < 10 cm). Thus, the relative changes in [O] for the jets within 10 cm of the observation cell were in error and were therefore ignored in determining the slope.

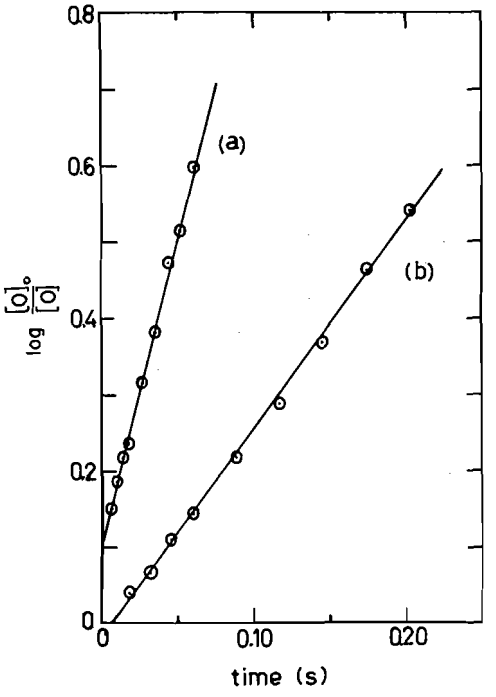

FIG. 4. Decay plots of relative [O]: (*a*) 508 K; resonance fluorescence technique, P_{tot} = 320 N m^{-2}, $[H_2]_0$ = 1.13 × 10^{16} molecules cm^{-3}, $[O]_0$ = 8.4 × 10^{12} atoms cm^{-3}; (*b*) 375 K; air afterglow technique. P_{tot} = 522 N m^{-2}, $[H_2]_0$ = 2.72 × 10^{16} molecules cm^{-3}, $[O]_0$ = 1.93 × 10^{14} atoms cm^{-3}. Zero of time scale differs from reaction time = 0.

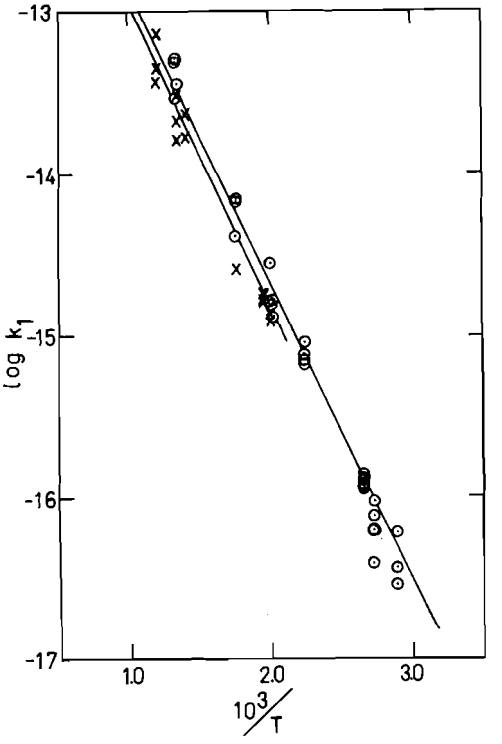

FIG. 5. Arrhenius plot of all data obtained in this work. ×, resonance fluorescence data; ○, air afterglow data.

squares analysis (see Appendix). Error limits quoted are 2σ (σ is the standard deviation). The statistical treatment applied to our resonance fluorescence data yields a 'best' line which is ~25% lower than that derived from our air afterglow results over the range 495–832 K. However, within the rather large uncertainty limits cited, the Arrhenius frequency factor and activation energy determined by both techniques are in reasonable agreement. Results also agree with those of Clyne and Thrush (11) but are significantly lower than those determined using the e.s.r. technique by other workers (12–14).

k_1 by the Air Afterglow Method

Measurements by this technique were carried out over the temperature range of 347–742 K which well overlaps the range studied by resonance fluorescence. The minimum ratio $[H_2]/[O]$ was approximately 40. At the lowest temperature $[H_2]/[O] \sim 1000$ with $[H_2] \sim 4 \times 10^{16}$ cm^{-3} (corresponding to a mole fraction $\chi_{H_2} \sim 0.2$).

Figure 4*b* shows a typical decay plot obtained by the air afterglow technique and results are listed in Table 1*b*. No significant contribution to the total emission photocurrent by HNO was expected using the Wratten No. 61 filter. Results are plotted, along with results from the resonance fluorescence experiments on Fig. 5. It can be seen that all the results are fairly consistent within experimental scatter. The derived Arrhenius parameters are shown in Table 2.

For comparison Table 2 and Fig. 6 also show results from other studies. Over approximately the same temperature range, all rate coefficients are generally in good agreement, but the Arrhenius parameters obtained from the data of Balakhnin *et al.* (14) are considerably higher than all others.

Discussion

The existing data on the O + H_2 reaction have been reviewed several times in recent years (1*a*).

[a]Low temperature values were derived from averages at each temperature from this work and from refs. 11–14. A weighted least mean squares analysis of the Arrhenius plot yielded parameters cited (Appendix). Error limits are 2σ.

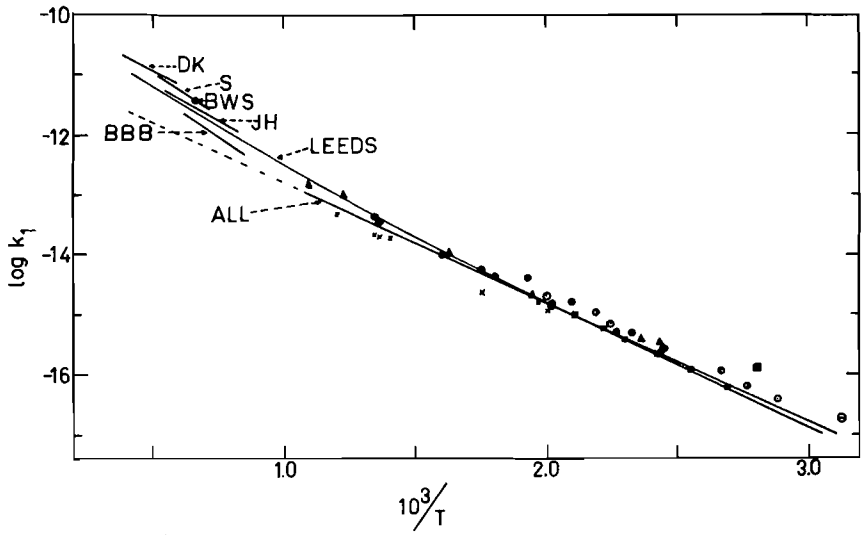

FIG. 6. Summary Arrhenius plot showing derived values of k_1, over the temperature range 320–~2600 K. DK, ref. 19; S, ref. 5; BWS, ref. 16; JH, ref. 17; BBB, ref. 18; LEEDS, ref. 1*a*; ALL, all low temperature data; △, ref. 12; ×, resonance fluorescence, this work; ○, air afterglow, this work; ◑, ref. 14; ●, ref. 11; ■, ref. 2; □, ref. 13; ⊖, ref. 15.

To our knowledge no new work at low temperature (<900 K) has appeared since the work of Balakhnin *et al.* in 1970 (14). Except for the few exceptions discussed in (1*a*) which for various reasons are not very reliable, the data reported is in fairly good agreement. In view of the variety of experimental techniques employed, considerable confidence can be placed in the results for the temperature range ~340–830 K.

Our data show no evidence of quantum mechanical tunnelling. We obtain a reasonably linear Arrhenius plot (Figs. 5 and 6) which (using the air afterglow technique) extrapolates to within ~11% of Campbell and Thrush's (15) value at 320 K. This linearity, however, is at variance with Westenberg and de Haas' results (2) which showed pronounced curvature at low temperature on their Arrhenius plot. The Westenberg and de Haas value at 357 K is approximately a factor of two higher than ours.

The last entry in Table 2 gives parameters derived from all low temperature data. It should be emphasized however that these values are not necessarily 'best' values. This is because a proper weighting of the data must take into account random and systematic errors in all data and this was not possible. On the other hand, data from all sources were statistically analyzed in the same way (Appendix). Therefore, the parameters derived from all low temperature data are probably the most reliable estimates which can be made at the present time. All the

low temperature (<900 K) results shown on Fig. 6, were selected as the most comprehensive and reliable, and nearly all values fall within about 50% of the 'all data' plot over the range 340–900 K. The discrepancy between our results and those of Westenberg and de Haas at low temperature is not readily explained. The excellent agreement of all workers over most of the temperature ranges studied probably rules out very serious systematic errors in flow calibrations etc. Assuming no large errors of this type, high values of k_1 would require enhancement of O decay, perhaps by heterogeneous processes involving H or OH.

Extrapolation of our results to the high temperature region (1000–2000 K) shows that a linear Arrhenius plot does not adequately describe the temperature dependence of this reaction over the extended temperature range. Figure 6 shows some of the more recent (post-1969) results acquired at high temperature in various shock tube and flame studies. The plot recommended by the Leeds group (Baulch *et al.* (1*a*) from an evaluation of selected low and high temperature results is also shown. The more recent data of Schott *et al.* would seem to indicate that the Baulch expression

$$k_1 = 3.0 \times 10^{-14} T \exp\{-37.2\ \text{kJ mol}^{-1}/RT\}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$$

does not show quite enough curvature. Our low temperature results tend to bear out this conclusion.

There have been several other examples (20) of nonlinear Arrhenius behavior recently reported. Two different interpretations are usually made for this behavior. One, which has been applied in several cases (20), invokes transition state theory (t.s.t.). This was the approach taken by Schott *et al.* (5) to fit the low temperature results of Westenberg and de Haas (12) to their own high temperature data. In it the semiempirical bond-energy–bond-order (b.e.b.o.) method (21) which had earlier been applied to [1] by Mayer and Schieler (22) was combined with t.s.t. The computed values of k_1 fall along a smooth curve as expected, the curvature caused mainly by the changing contribution of a T^n term within the t.s.t. Gardiner *et al.* (23) have questioned the value of t.s.t. in this connection because of the large number of adjustable parameters required by the theory. Gardiner therefore prefers a second interpretation which in principle can be experimentally tested. This view suggests increasing participation of excited vibrational states of reactants with increasing temperature. The $O + H_2$ reaction presents an interesting test case. Because the energy separation between the first two vibrational levels in H_2 is very large (49.4 kJ (24)), the fraction of thermally produced vibrationally excited molecules ($H_2^{\ddagger}$) even at relatively high temperatures is quite small (*i.e.* $\sim 10^{-2}$ at 1500 K). Thus for reaction

[4] $$O + H_2^{\ddagger} \rightarrow OH + H$$

to contribute significantly to removal of O, an extremely large rate constant (at least equal to collision frequency) would be required if the high temperature results of Schott *et al.* (5) are to fit the low temperature data. We are now in the process of measuring k_4 in a newly designed apparatus by Lyman-α resonance fluorescence of H at λ 121.6 nm. Knowing k_1 the $O + H_2$ reaction can be used as a reliable calibration source for [H] (25) below 800 K.

We wish to thank the National Research Council of Canada for financial assistance in the form of an operating grant. We also wish to thank Dr. J. L. Hencher of this department for helpful discussions.

Appendix

Evaluation of Arrhenius parameters from the familiar logarithmic form of the Arrhenius equation is usually done using an unweighted least mean squares treatment. However it has recently been pointed out (26)[3] that because the treatment involves a change in variable form k to $\ln k$ the low temperature data are in fact more heavily weighted. In order to compensate for this a weighted least squares treatment (26) is required where the weighting factor, $w_i' = w_i k_i^2$, is k^2/σ_k^2. (w_i are the statistical weights of the points.) In the case of the O + H_2 reaction, the k^2 term clearly dominates; *e.g.* $(k_{832}/k_{347})^2 \sim 10^6$. Thus the high temperature points are very heavily weighted. The standard deviation, σ_k, which is a measure of the precision of each k determination can be estimated from a complete assessment of the propagation of random errors. We have carried out this procedure for several experimental situations (below). Expected random errors generally fell in the range 9–28% using reasonable limits on each variable. This is to be compared with the observed scatter of 3–45% (σ) in the resonance fluorescence results and 6–40% (σ) in the air afterglow results. Such large scatter may indicate other sources of random error *e.g.* fluctuations in discharges, etc., which cannot easily be taken into account. We therefore used σ values from experimentally observed deviations for the weighting factors to derive the parameters cited in Table 2. (In cases where insufficient data were available estimates roughly equal to average σ's were made.) In two cases (refs. 13 and 14) rate constants were extracted from Arrhenius plots in order to apply the weighted least squares treatment, and in these cases the standard deviation for each point was arbitrarily (and optimistically) taken as 10%. Reference 11 gives average k's and corresponding deviations at each temperature. They were used 'as is'.

It is instructive to examine the consequences of the weighting procedure in detail on a set of apparently consistent data. Consider the most recent results of Westenberg and de Haas (12). They report the Arrhenius expression $k_1 = 5.3 \times 10^{11} \exp\{-42.7 \text{ kJ mol}^{-1}/RT\} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ for the range 500–900 K. Including their point at 423 K we obtain $k_1 = 3.2 \times 10^{-11} \exp\{-40.2 \text{ kJ mol}^{-1}/RT\} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$. Both of these expressions were obtained using the unweighted least squares analysis. Using the weighted treatment with a weighting factor of $w_i' = k^2$ (which assumes all w_i are equal) we obtain the result, $k_1 = 8 \pm 4 \times 10^{-12} \exp\{-30.0 \pm 3.8 \text{ kJ mol}^{-1}/RT\} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$! In this case the low temperature (and incidentally more precise) points are virtually ignored by the weighting treatment. Now taking $w_i' = k^2/\sigma^2$ and using standard deviations calculated from their data for each temperature we obtain $k_1 = 3.5 \pm 2.0 \times 10^{-11} \exp\{-41.1 \pm 2.8 \text{ kJ mol}^{-1}/RT\} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ which is the value cited in Table 2. While this is probably the best expression that can be derived from these data, it is clearly obvious that if accurate

[3]We thank one of the referees for drawing our attention to ref. 26 and for helpful suggestions.

Arrhenius parameters are to be obtained normal statistical distributions of data over a wide range of temperature must be available.

Propagation of Errors

Following Cvetanović *et al.* (26), estimates of random errors were made using the propagation of errors equation,

$$\sigma_Q = \left\{\sum_i \left(\frac{\partial F}{\partial M_i}\sigma_i\right)^2\right\}^{1/2}$$

where Q is the quantity being determined in the experiment from measurements, M_i. Q is a function F of M_i, $Q = F(M_i)$. σ_i are the standard deviations of the uncorrelated separate measurements M_i.

In this work k_1 was determined from

$$k_1 = \frac{2.303 \log ([O]_0/[O])}{\alpha[H_2]_0 t} = \frac{2.303(\text{slope})}{\alpha[H_2]_0}$$

The ratio $[O]_0/[O]$ is equal to the ratio of emission intensities measured, in the case of resonance fluorescence, as the number of photons less background counted over a 1 min period. In the air afterglow case it is measured as a current on a picoammeter. The rated time base accuracy is $< \pm 0.1\%$ for the Ortec (Model 719) timer. Statistical error in count rate amounts to $(\text{c.p.m.})^{1/2}$ which usually was $\sim \pm 2\%$. Rated error in current measurement is ± 2–3%. Nonlinearity of the resonance fluorescence signal *vs.* [O] at high [O] would contribute to the overall error. However, this is not expected to be a very serious problem since [O] is decreased quite rapidly in moderate reaction times.[2] At $[O] < 1 \times 10^{13}$ atom cm^{-3} linearity has been demonstrated for the λ 130.6 nm line (3).

Rapid deterioration of the LiF windows and consequent reduction of detection sensitivity was a serious practical problem since replacement of windows was not easily accomplished. For low signals the statistical error and spurious noise levels are relatively greater, possibly as large as 3%. Error in slope includes the random errors mentioned and also the error in t (s). The time, t, is calculated from $t = xAp/\sum F\,RT$ where x is the distance which defines the reaction zone, and A is the cross-sectional area of the flow tube, p is the total pressure, $\sum F$ is the total flow rate, R is the gas constant, and T is temperature. The errors in x and A are negligible and systematic. The error in T amounts to $\sim$1–1.5% (± 5 K). Pressures can generally be measured to at least ± 0.1 cm. For total pressures of 133–1000 N m^{-2} ($\sim$1–10 cm oil) the error amounts to 10–1%. The largest error in $\sum F$ probably arises from random fluctuations in flow rates but the error in flow meter readings can be significant for small Δp. We conclude that the combined error in t is of the order of $\pm$5–15% which generates a combined error of $\sim \pm$5–20% in the slope.

$$[H_2]_0 = \frac{f_{H_2}}{\sum F}\frac{p}{RT}$$

and therefore is considered precise to same limits as t ($\pm$5–15%). The error in $[O]_0$ can be quite large and contributes to the error in α. $[O]_0$ is equal to [NO] at the end point of the N + NO titration. This was usually determined visually. In addition the relatively low flows of NO are difficult to determine. Since $[NO] = f_{NO}p/(\sum F)RT$, errors in p, $\sum F$, and T also contribute. Limits of $\pm 30\%$ are therefore assumed. This, however, is not a large contributor to the overall error in k, because α is not very sensitive to small changes in $[O]_0$.

Substitution of all these limits into the propagation of errors equation leads to error values of $\pm$9–28% in k.

The Molecular Structure of Tetramethylgermane Determined by Gas Phase Electron Diffraction

J. LAWRENCE HENCHER AND FRANK J. MUSTOE

Department of Chemistry, University of Windsor, Windsor, Ontario N9B 3P4

Received May 8, 1975

J. LAWRENCE HENCHER and FRANCIS S. MUSTOE. Can. J. Chem. **53**, 3542 (1975).

The molecular structure of tetramethylgermane has been determined by vapor phase electron diffraction. The structural parameters, based on r_g interatomic distances are r(GeC) = 1.945 ± 0.003 Å, r(CH) = 1.12 ± 0.02 Å, and ∠(GeCH) = 108 ± 2°. Tetrahedral symmetry of the GeC_4 skeleton was preserved in the analysis by including a shrinkage correction for the C...C interatomic distance. The quoted uncertainties were estimated to include both systematic and random errors.

J. LAWRENCE HENCHER et FRANCIS S. MUSTOE. Can. J. Chem. **53**, 3542 (1975).

On a déterminé la structure moléculaire du tétraméthylgermane par diffraction électronique en phase vapeur. Les paramètres structuraux, basés sur des distances interatomiques r_g, sont r(GeC) = 1.945 ± 0.003 Å, r(CH) = 1.12 ± 0.02 Å et ∠(GeCH) = 108 ± 2°. La symétrie tétraédrique du squelette du GeC_4 est maintenue dans l'analyse en faisant intervenir une correction pour le raccourcissement de la distance interatomique C...C. On a estimé les incertitudes rapportées en incluant à la fois les erreurs systématiques et les erreurs dus au hasard.

[Traduit par le journal]

Introduction

The molecular structure of tetramethylgermane was first reported by Brockway and Jenkins (1). They reported a GeC bond length of 1.98 ± 0.03 Å which is longer than that observed in more recent structure determinat ons of CH_3GeH_3 (2), $(CH_3)GeH_2$ (3), and $(CH_3)_3GeH$ (4).

In view of the uncertainty in the GeC bond length, the structure of tetramethylgermane was redetermined as a necessary prelude to studies of the $(CH_3)_nGeX_{4-n}$ (X = F, Cl, Br, I) series.

Experimental

The sample of $(CH_3)_4Ge$ was obtained from Alfa Inorganics, Inc. and was used without further purification after checks of the gas phase infrared spectrum and the n.m.r. spectrum revealed no absorption peaks attributable to impurities.

Sectored electron diffraction patterns were recorded on the University of Windsor camera (5) on 4 × 5 in. Kodak Electron Image Plates for two nozzle-to-plate distances. The sample was maintained as vapor at 10 Torr in a 5 l flask. CS_2 patterns were recorded concurrently at each distance in order to calibrate the s scale ($s = (4\pi/\lambda)\sin(\theta/2)$ where λ is the electron wavelength and $\theta = \tan^{-1}$ (radius/camera length)). The parameters used for CS_2 in the calibration were those reported by Kuchitsu (6). The typical experimental conditions are given in Table 1.

The optical densities, $D(r)$, of the plates were samples at 0.1095 mm radial intervals, r, from the pattern center, on a specially constructed microdensitometer (5). Relative intensities were obtained by the emulsion linearity correction (7), $I(r) = D(r)[1 + 0.1D(r)]$. The experimental total intensity, obtained as $I_t(r) = I(r)/\Phi(r)$ where $\Phi(r)$ is the sector function,[1] was interpolated at $\pi/10$ Å^{-1} intervals in s by the Lagrange method (six point interpolation for long camera, three point for short camera), and converted to the levelled form $I_0(s) = s^4 I_t(s)$.

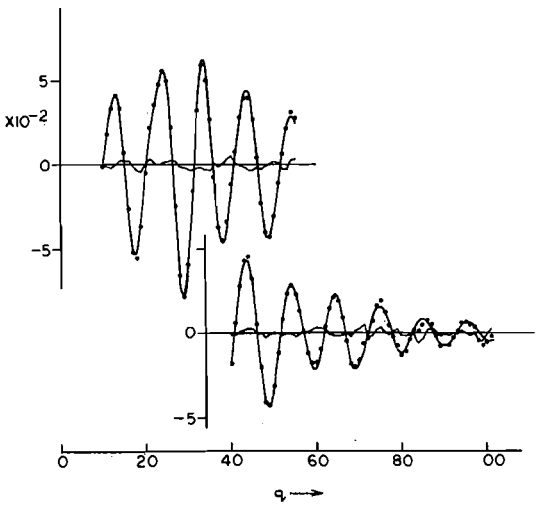

FIG. 1. The molecular intensity, $sI_m(s)$ of $(CH_3)_4Ge$. Experimental (dots), theoretical (solid curve), and difference curves from long camera and short camera diffraction patterns.

[1]The sector function, $\Phi(r)$, was calibrated to give a smooth $I(r)/\Phi(r)$ curve for experimental argon scattering.

R[f]		0.084			

[a]Distances in Å. Angles in degrees. Standard deviations estimated to include systematic and random errors.
[b]Dependent parameters.
[c]Parameter value fixed in the least squares analysis.
[d]The r.m.s. amplitude, l_{ij}, and perpendicular correction, K_{ij} calculated from normal coordinates for 298 K.
[e]Shrinkage correction, $-\delta(\text{C...C}) = K(\text{C...C}) - \frac{2}{3}\sqrt{6}\,K(\text{GeC})$ used in the analysis.
[f]$R = \{\sum_s [sI_m(s)_{exp} - sI_m(s)_{th}]^2 / \sum_s [sI_m(s)_{th}]^2\}^{1/2}$ is a measure of goodness of fit.

The molecular intensity, $I_m(s)$ was extracted by dividing $I_0(s)$ by its background (5, 7). The theoretical expression for $I_m(s)$ employed complex elastic scattering factors (8) and a correction for inelastic scattering (9).

The interatomic distances, r_g, were calculated from the independent parameters (10), r(CH), r(GeC), and ∠(GeCH). Tetrahedral symmetry was preserved by adding a shrinkage correction (11) to the C...C distance. This correction was calculated as $-\delta(\text{C...C}) \approx K(\text{C...C}) - \frac{2}{3}\sqrt{6}K(\text{GeC})$ from the perpendicular corrections, K_{ij}, which were obtained from the molecular force field by the method of Stölevik *et al.* (12). The force constants ($K_{CH} = 4.83$, $H_{HCH}/r_{CH}^2 = 0.44$, $H_{GeCH}/(r_{CH}r_{GeC}) = 0.22$, $K_{GeC} = 2.8$, and $H_{CGeC}/r_{GeC}^2 = 0.11$ mdyn Å^{-1}) were obtained from the frequency assignments of Lippincott and Tobin (13). Anharmonicity corrections of 2 Å^{-3} were assumed for the GeC and CH distances (14).

In the least squares analysis a diagonal (zeroth order)

weight matrix was assumed. The standard deviations in the refined parameters were estimated as three times the least squares values (15) in order to provide for systematic errors and the effect of the nonoptimum weighting on the random errors. The observed and calculated molecular intensity curves are presented in Fig. 1.[2] The correlation matrix for the refined parameters is given in Table 2. The principal interatomic distances, r_g, and the angles are presented in Table 3.

Results and Discussion

The GeC bond length determined here, 1.945 $\pm$ 0.003 Å, is substantially shorter than the earlier reported value of 1.98 $\pm$ 0.03 Å. The difference is probably a reflection of 40 years of development of the electron diffraction technique. The shorter bond length makes the $(CH_3)_4Ge$ structure consistent with CH_3GeH_3 (1.9453 $\pm$ 0.0005 Å) (2), $(CH_3)_2GeH_2$ (1.950 $\pm$ 0.003 Å) (3), and $(CH_3)_3GeH$ (1.947 $\pm$ 0.006 Å) (4). The shortness of the GeC bond compared to the sum of the covalent radii ($\frac{1}{2}(H_3Ge—GeH_3)$ + $\frac{1}{2}(H_3C—CH_3)$ = 1.97 Å (16)) is probably due to bond polarity.

Although the variation in angles through the above series is barely discernible, it appears that $\angle$(CGeC) is larger in dimethyl than in trimethyl germane as was observed for $(CH_3)_2GeF_2$ and $(CH_3)_3GeF$ (17).

This work was supported in part by an Operating Grant from the National Research Council of Canada.

Thiobinupharidines Epimeric at C-1 and C-1′

ROBERT THOMAS LALONDE AND CHUNFOOK WONG

Department of Chemistry, State University of New York, College of Environmental Science and Forestry, Syracuse, New York 13210

Received June 16, 1975

ROBERT THOMAS LALONDE and CHUNFOOK WONG. Can. J. Chem. **53**, 3545 (1975).

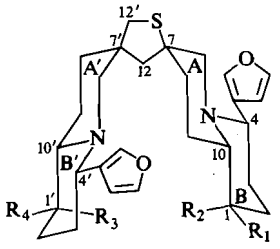
Thiobinupharidine epimers possessing axial methyl groups at C-1 and C-1′ have been isolated from extracts of *Nuphar luteum*. ^{13}C chemical shift data for the methyl and ring carbons demonstrate that both methyl groups are axial in 1-*epi*-1′-*epi*-thiobinupharidine and that one of two methyls is axial in 1-*epi*- and in 1′-*epi*-thiobinupharidine.

ROBERT THOMAS LALONDE et CHUNFOOK WONG. Can. J. Chem. **53**, 3545 (1975).

On a isolé à partir d'extraits du *Nuphar luteum* des épimères du thiobinupharidine possédant des groupes méthyles axiaux en C-1 et en C-1′. Les données de la résonance magnétique nucléaire du ^{13}C pour les groupes méthyles et les carbones du cycle démontrent que chacun des groupes méthyles est axial dans l'*épi*-1 *épi*-1′ thiobinupharidine et qu'un des deux méthyles est axial dans l'*épi*-1 et l'*épi*-1′ thiobinupharidine.

[Traduit par le journal]

In the course of a search for hemiaminal derivatives of neothiobinupharidine (1) we reduced a chromatographic fraction with sodium borodeuteride for the purpose of ascertaining the position of the hemiaminal hydroxyl group. Comparative thin layer chromatography of the product mixture indicated the presence of thiobinupharidine, **1**, neothiobinupharidine, and a component believed to be deoxynupharidine, but since determination of the position of the deuterium label was desired, the components were separated and their mass spectra were determined. Surprisingly, the component possessing the thin layer chromatographic behavior of deoxynupharidine (molecular weight 231) gave a mass spectrum showing a parent ion at *m/e* 495, a mass number consistent with a singly labelled thiaspirane Nuphar alkaloid. These observations led us to reexamine fractions of earlier separations containing the 'deoxynupharidine spot'. The reexamination has led to the isolation of 1-*epi*-1′-*epi*-thiobinupharidine, **2**, and a mixture of 1-*epi*-, **3**, and 1′-*epi*-thiobinupharidine, **4**. This paper discloses the details of isolation and the evidence for the structures, the latter relying heavily on ^{13}C n.m.r. and previous ^{13}C studies of quinolizidine compounds (2, 3).



1 $R_1 = CH_3$(C-11); $R_4 = CH_3$(C-11′); $R_2 = R_3 = H$
2 $R_1 = R_4 = H$; $R_2 = CH_3$(C-11); $R_3 = CH_3$(C-11′)
3 $R_1 = R_3 = H$; $R_2 = CH_3$(C-11); $R_4 = CH_3$(C-11′)
4 $R_1 = CH_3$(C-11); $R_3 = CH_3$(C-11′); $R_2 = R_4 = H$

The mass spectra of **2** was typical of the C_{30} thiaspirane Nuphar alkaloids (4) and thus indicated the general skeletal characteristics. However, the presence of some of the separate structural features was clearly evident from other spectral characteristics. The i.r. absorption at 877 cm^{-1} and the ^{13}C n.m.r. signals in the 109–143 p.p.m. region (see Experimental) demonstrated the incorporation of two 3-furyl groups (3). The doublets at 1.11 and 1.14 p.p.m. in the ^1H n.m.r. and the separate lines at 13.6 and 13.7 p.p.m. in the ^{13}C n.m.r. indicated the presence of two methyls, involved as $HCCH_3$, the stereochemistry of which is discussed below. The AB quartet at 2.34 p.p.m. and the broad singlet found at 1.90 p.p.m. in the ^1H spectra were characteristic of methylenes in the thiolane ring (5). The ^1H n.m.r. absorption in the region 2.7–3.1 was typical of C-6 equatorial and C-4 axial protons in *trans*-fused quinolizidines that are substituted at C-4 by a 3-furyl group.

The stereochemical features of the ring systems were ascertained as follows. The i.r. Bohlmann bands, whose intensities were equivalent to those exhibited by thiobinupharidine, showed that *trans* quinolizidines were involved. The 2.34 p.p.m. AB quartet, attributed to the thiomethyl-

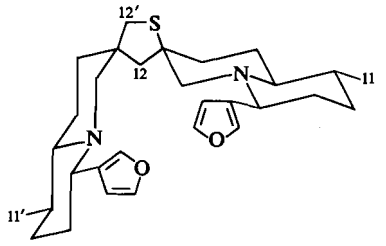
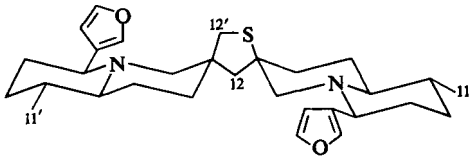
ene group, indicated that the new alkaloid belonged to either the thiobinupharidine or thionuphlutine B (**5**) families of thiaspiranes but not



5



6

the neothiobinupharidine (**6**), nor a fourth as yet undiscovered stereochemical type, since neothiobinupharidine possesses an axial thiomethylene attached to the A′B′ quinolizidine moiety and this thiomethylene appears at 2.72 p.p.m. The thiomethylene in the fourth stereochemical possibility would also be axial and would be expected to appear in the 2.7 p.p.m. region but not the 2.3 p.p.m. region. However, the positions of the C-12 and C-12′ ^{13}C resonances, 44.4 and 42.6 p.p.m. respectively, are uniquely consistent with the thiobinupharidine lines appearing at 45.3 and 42.7 p.p m. (Fig. 1). The line positions of the C-12 and C-12′ methylenes are related to the number of axial and equatorial attachments in which these methylenes are involved (3). Thus the C-12′ thiomethylene carbon in neothiobinupharidine is axial with respect to the A′B′ quinolizidine ring and appears upfield at 39.1 p.p.m. The C-12 methylene in thiobinupharidine is axial to both the AB and A′B′ quinolizidines and is found further upfield than the corresponding signals of thionuphlutine B (50.6 p.p.m.) or neothiobinupharidine (54.5 p.p.m.) in which the C-12 methylenes are respectively equatorial to one or both quinolizidine systems. Therefore, the evidence from ^{1}H and ^{13}C n.m.r. establishes that the new alkaloid **2** belongs to the thiobinupharidine stereochemical family of thiaspirane Nuphar alkaloids.
