Energy calculations were carried out on models of molecular-level structures likely to be present in solutions of alkali halides in dimethyl sulfoxide (DMSO). Classical electrostatic interactions were assumed, and polarization of a DMSO molecule was assumed due to the fields of the ions only. The validity of this assumption was tested. DMSO molecules were represented by increasingly detailed models, with most calculations carried out with each molecule represented by 10 point charges and 9 polarizable bonds. A program including up to 14 such molecules and two ions was used for energy and distance calculations, and is made available. Polarization effects are as important as interactions between permanent charges for energy calculations. The configurations of minimum energy determined by classical electrostatics often do not involve overlap of the "hard-sphere radii" of neighboring species, so that the neglect of quantum mechanical repulsive forces seems justified. Energy cycles using the calculated energies for ion–solvent complexes predicted experimental cation enthalpies with some success. The form of the potential for vibration of a cation in a solvent shell was investigated and found in cases not to have an energy minimum at the shell center. Calculations including next-nearest solvating DMSO's indicate a rather loose structure. An energy profile for an anion moving from a solvent-separated ion pair position to a contact-ion pair position is presented.

MERRILL S. GOLDENBERG, PEETER KRUUS et STEPHEN K. F. LUK. Can. J. Chem. **53**, 1007 (1975).

On a effectué des calculs d'énergie sur des modèles de structures moléculaires susceptibles d'être présentes dans des solutions d'halogénures d'alkalis dans le diméthyl sulfoxyde (DMSO). On a fait l'hypothèse que des interactions électrostatiques classiques existent et que la polarisation de la molécule DMSO est due uniquement au champ des ions. On a évalué la validité de cette hypothèse. On a représenté les molécules de DMSO par des modèles de plus en plus détaillés; la plupart des calculs ont été effectués avec chaque molécule représentée par 10 charges ponctuelles et 9 liens polarisables. Pour les calculs d'énergie et de distance, on a utilisé un programme incluant jusqu'à 14 molécules de ce genre et deux ions; ce programme est disponible. Pour lés calculs d'énergie, les effets de polarisation sont aussi importants que les interactions entre les charges permanentes. Souvent les configurations d'énergie minimum déterminées par les théories électrostatiques et classiques n'impliquent pas d'interaction "rayon de sphère dure" avec les espèces environnantes et l'on peut en déduire qu'il est justifié de négliger les forces répulsives de la mécanique quantique. Les cycles d'énergie utilisant les énergies calculées pour les complexes ion–solvant ont prédit avec quelques succès les enthalpies expérimentales des cations. La forme du potentiel pour la vibration d'un cation dans une cellule de solvant a été examinée et on a trouvé dans certains cas qu'il n'y avait pas d'énergie minimum au centre de la cellule. Des calculs impliquant les molécules de DMSO plus loin que les molécules les plus près indiquent que la présence d'une structure lache. On présente un profil d'énergie pour un anion se déplaçant d'une position de paire d'ions séparés par le solvant vers une position de paire d'ions de contact. [Traduit par le journal]

Introduction

Although ultrasonic studies on ion pairing in solutions have been carried out since 1953 (1), there is still difficulty in obtaining a definitive mechanism for 2–2 electrolytes in water (2, 3). Ultrasonic absorption studies were therefore carried out on solutions of alkali halides in dimethyl sulfoxide (DMSO) (4). This provided data on systems which could possibly be described by relatively simple, yet realistic models; the ions are univalent and spherical, and the anions are essentially unsolvated (5).

These studies (4) indicated that there was an

excess absorption with a relaxation frequency between 3 and 8 MHz in solutions of several alkali halides in DMSO. The relaxation was assigned to the final step in the formation of a contact ion pair, with the relaxation frequency controlled by the rate of movement of a solvent molecule rather than an ion.

This paper describes attempts to investigate the energies of models of various molecular-level structures which could be present in solutions of alkali halides in DMSO. The results of such calculations, when related to experimental results (4), could eventually lead to a quite definitive picture of molecular level structures in such solutions.

The calculations involved electrostatic interaction calculations, with each DMSO molecule described by 10 point charges. Polarization of the DMSO was also included by considering each bond to have a longitudinal and transverse polarizability, so that induced dipoles are set up in the DMSO by the field set up by the ions. Some simpler models were also tested.

Such calculations have been carried out previously for aqueous systems (*e.g.* refs. 6 to 9). These have usually only involved tetrahedral and octahedral hydration for the purpose of predicting heats, entropies, and free energies of solvation. In this case, the calculations are extended to include bond polarizabilities and the presence of a second ion.

Theoretical approaches used to describe interactions in electrolyte solutions can be considered from the point of view of two limiting cases. In the one case, the solvent is considered as a continuum; in the other, a quantum mechanical interaction between ion and solvent molecules is attempted. The first approach (10–12) has the advantage of including many interactions, also those taking place at long ranges, but has the disadvantage of neglecting the detail of the ion–molecule interaction in the first solvation shells where the fields are strong. The other approach (13–17) describes such interaction in detail, but is limited to consideration of only a few molecules.

The molecular level, classical electrostatic approach used here sacrifices some of the accuracy in description of ion–molecule interaction, but with use of high-speed computers makes the inclusion of a substantial number of molecules possible. This approach would seem most suitable for this case. Interactions beyond the first solvation shells would seem to be relatively unimportant when the results are considered relative to different alkali halide salts. Direct quantum mechanical effects would seem to be of secondary importance in the case of alkali halides, and not worth pursuing at the expense of exclusion of molecules from the model.

The calculations described here include up to 2 ions and 14 solvent molecules, each molecule represented by 10 point charges and 9 polarizable bonds. The computer program used for the calculations is set up generally enough so that few changes are needed to alter it for calculations on other systems, or for inclusion of more molecules. Copies of the program are available on request from the authors (P.K.).

Results and Discussion

(I) Structure and Charge Distribution in DMSO

To calculate the structure and the charge distribution for DMSO from first principles is a monumental task. An attempt has been made at a calculation for methyl sulfoxide, but the results (18) show the dipole in a direction opposite to the experimentally determined one. Experimental data on DMSO was therefore used whenever available.

Bond distances and angles were taken from X-ray data on solid DMSO at 5 °C (19). The structure of DMSO in the liquid seems likely to resemble the solid structure rather than the gaseous structure, and structure determinations in the gas phase through electron diffraction (20) and rotational spectroscopy (21) are less precise. Table 1 gives the data used.

A semiclassical model (22, 23) of the charge distribution was used. The model consists of touching, conducting spheres centered on the atoms, with each sphere having a radius equal to the covalent bond radius of that atom. To obtain the 10 charges representing the DMSO molecule, the following data and assumptions were used. The data is summarized in Table 2.

TABLE 1. Bond distances and angles for DMSO

Bond	Distance (Å)	Bonds	Angle (deg)
S—O	1.531	O—S—C	106.7
S—C	1.798	S—C—C	97.4
C—H	1.08	S—C—H	109.5
		H—C—H	109.5

O—S	29.0*	14.7*	0.55‡	1.04

*Reference 26.
†Reference 27.
‡Reference 24.

(*i*) Pauling's single-bond covalent radii (24) were used for all atoms except oxygen. The triple bond radius (0.55 Å as compared to 0.66 Å for the single-bond) was used for O in order to make it consistent with the S—O bond length.

(*ii*) Each bond polarizability tensor was assumed to have one longitudinal component α_l and two equal transverse components α_t (25).

(*iii*) Slater's screening rules were used to estimate the effective nuclear charge felt by the valence shell electrons in the molecule.

(*iv*) The bond moment arising from the internal field for a bond was represented as a dipole with equal and opposite point charges at the nuclei.

(*v*) The experimentally determined dipole moment (3.96 ± 0.04 D (21)) was used in the simultaneous equation solved.

(*vi*) Data for methane (26) and dimethylsulfide (27) were used to obtain bond parameters for the C—H and the C—S bonds. These parameters are very sensitive to the values of the screening constants and bond radii and the use of experimental data seems advisable.

Combining this data into equations analagous to those used by Smith and co-worker (22) gave six equations with five unknowns. Two of the equations referred to the experimental dipole moment, one to total charge neutrality, and three to net charges in the H, C, and O atoms. Four of the unknowns were the magnitudes of the charges centered on the 4 different types of atoms. The fifth was a parameter for the O—S bond.

Using only one of the dipole equations gave the following solution for the charges: C, 1.66; H, −0.202; O, −1.63; S, −0.474 ($\times 10^{-10}$ e.s.u.). These values differ somewhat from those of Jullien *et al.* (23) who used different values for the DMSO structural parameters and the dipole moment. When the values obtained are substituted into the second dipole equation, the resultant dipole component in the plane bisecting the C—S—C angle is 0.245 D. This gives a resultant dipole of 3.99 D at an angle 4° off the experimentally determined angle.

The polarizability matrices of the 9 bonds can be resolved along a common set of axes and combined to give a polarizability matrix for the whole molecule. With the axes set as shown in Fig. 1 the components α_{xx}, α_{yy}, and α_{zz} are 91.7, 87.7, and 100.3 × 10^{-25} cm^3 respectively. The averaged scalar polarizability calculated on this model is thus 93.2 × 10^{-25} cm^3. This is somewhat higher than the value of 83.72 × 10^{-25} cm^3 calculated for DMSO in ref. 28. It should be noted that only electron polarization is assumed in the model. Atomic polarization, *i.e.* distortion of the interatomic distances and bonds, is neglected. Furthermore, electrons in the various bonds are assumed independent in using bond polarizabilities. This seems to be a reasonable assumption in the case of molecules with no resonance contributions (25). Hyperpolarizability effects are also ignored (29).

Such a description of a DMSO molecule has several uncertainties. The 10 point charge description of the electronic structure in DMSO is more realistic than a multipole expression, especially for calculations where there is substantial interaction. However, a more precise description may be desirable, especially one incorporating descriptions of the electronic distributions about the O and the S atoms.

This most detailed model (A) was simplified to three different models for some calculations to test the sensitivity of the energy calculations

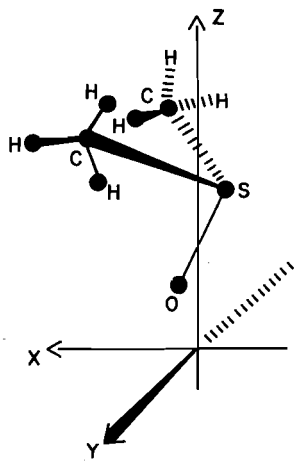

FIG. 1. Positioning of DMSO in a coordinate axis.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

to the detail of the DMSO model. Model B pictured the DMSO as 4 point charges (O, S, and 2 methyls) and 3 polarizable bonds, model C as 4 point charges and a single scalar polarizability, and model D simply as a point dipole and a scalar polarizability. Most calculations were performed using model A, however, as interatomic distances could be obtained with this model.

(II) Contributions to the Interaction Energy of Ion–Solvent Structures

Regular geometric arrangements of DMSO molecules were assumed around the cation for making energy calculations. For an ion with 4 DMSO's around it, the DMSO's were set in a tetrahedron, 5 in a trigonal bipyramid, 6 in an octahedron, and 8 in a square antiprism. The permanent dipoles of the DMSO's were set pointing at the cation (Fig. 1).

Such a structure is unrealistic in that the solvent molecules would in reality not have such regular arrangements at all times. They would also be in continuous thermal motion and would be exchanging with each other. The effect of such thermal motion is difficult to evaluate and is neglected here. There has been evidence, however, that averaged over time, the cation in DMSO is in a solvent cage (30) with the oxygen atom in direct proximity to the metal and the dipole oriented towards it (31).

To construct this model in the computer, a DMSO molecule was first placed on the z-axis as shown in Fig. 1. The coordinates for the other DMSO's can then be obtained simply by rotation of the coordinates of the atoms in the first DMSO by specific amounts. Details of this procedure for the 4, 5, 6, and 8-coordinated cases considered can be found in copies of the computer programs used.

According to ref. 19, the methyl groups are eclipsed, and an activation energy of 11 kJ mol^{-1} is present for the barrier of methyl group rotation about the C—S bond (32). A calculation in which the methyl groups were rotated showed two hydrogens to be at 2.1 Å, within the van der Waals distance of 2.4 Å. It was thus assumed that the methyl groups did not rotate, and the conformation of methyl groups as depicted in ref. 19 was used throughout.

The change in the electrostatic energy due to intermolecular interaction of the permanent charges describing the molecules which took place on rotation of a DMSO molecule about its dipole was found to be negligibly small: less than 0.2% for 6 coordination of a cation with an ion–oxygen distance of 2.4 Å and less than 2% for 5 coordination of an anion with ion–oxygen distance 5.6 Å. Thus the configuration of the DMSO's about the dipole axis was left in the position in which they fell on rotation of the coordinates about the main coordinate axis.

The energy calculations were done taking account of 9 terms: (*i*) E_{AP}, the interaction energy due to permanent charges on the anion and the DMSO molecules, (*ii*) E_{AI}, that due to the permanent anion charge and induced dipoles in the DMSO's, (*iii*) E_{CP} and (*iv*) E_{CI}, the corresponding cation–molecule interaction energies, (*v*) E_{PP}, the interaction energy due to permanent charges on the DMSO, (*vi*) E_{PI}, that due to permanent charges and induced dipoles in the DMSO's, (*vii*) E_{II}, that due to induced dipoles in DMSO's, (*viii*) E_{AC}, that due to permanent charges on the anion and cation, and (*ix*) E_{ACI}, that due to induced dipoles in the ions.

In all the calculations, it was assumed that the induced dipoles were due only to the fields of the ions. This assumption is good in the case of ions, as the DMSO's around the ions were placed with sufficient symmetry so that the fields at the ion due to charge distributions in the DMSO's essentially cancel each other. The degree of validity of this assumption in the case of molecules can be illustrated by considering the three particle problem illustrated in Fig. 2, composed of an ion (I) and two molecules (II, III) modelled as polarizable dipoles pointing towards I.

Before proceeding with this, the mathematical relations for the interactions will be illustrated with the aid of Fig. 2. The relationships are set

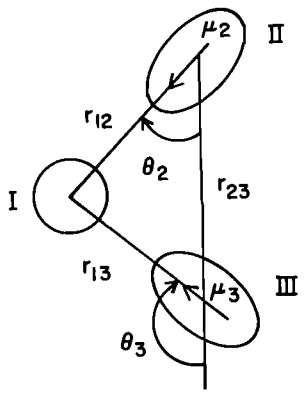

FIG. 2. Schematic illustration of 3-body interaction.

For personal use only.

up for use of the more familiar c.g.s. e.s.u. units. The conversion of the final energy values to SI units is simple. Thus the field F at a distance r from an ion is

$$[1] \qquad F = (qr/r^3)$$

The interaction energy of an ion (I) and a permanent point-dipole μ (II) is then

$$[2] \qquad E_{q\mu} = -\mu \cdot F = -q\mu_2 \cos\theta/r_{12}^2$$

Here θ is the angle between μ and r (taken as zero in Fig. 2). The field due to a permanent dipole is

$$[3] \qquad F = \frac{-\mu}{r^3} + \frac{3r(\mu \cdot r)}{r^5} = \frac{-\mu_2}{r_{23}^2} + 3r_{23}\frac{\mu_2 \cos\theta_2}{r_{23}^4}$$

if the field at III due to II is considered. The interaction energy between two permanent point-dipoles is thus

$$[4] \qquad E_{\mu\mu} = -\mu_3 \cdot F = \frac{-\mu_2\mu_3}{r_{23}^3} \times (2\cos\theta_2 \cos\theta_3 - \sin\theta_2 \sin\theta_3)$$

A 2-dimensional model is assumed here, with μ_2 and μ_3 lying in the same plane.

The interaction energy due to polarization is given in the case of a scalar polarizability α as

$$[5] \qquad E = -\tfrac{1}{2}\alpha F^2$$

A polarizable entity in the field of an ion has energy

$$[6] \qquad E_{qi} = -q_1^2\alpha_2/(2r_{12}^4)$$

while in the field of a point-dipole it has

$$[7] \qquad E_{\mu i} = -\mu_2^2\alpha_3 (3\cos^2\theta_2 + 1)/(2r_{23}^6)$$

Finally, the energy of interaction between two induced dipoles α_2F_{12} and α_3F_{13} due to fields F_{12} and F_{13} at II and III respectively due to I is from [1] and [4]

$$[8] \qquad E_{ii} = -q^2\alpha_2\alpha_3 (2\cos\theta_2 \cos\theta_3 - \sin\theta_2 \sin\theta_3)/r_{12}^2 r_{13}^2 r_{23}^3$$

These relationships were used in the computer energy calculations and the calculations on the model in Fig. 2.

To illustrate the validity in the method of calculating energies, consider the field at II to be made up of 3 components

$$[9] \qquad F_2 = F_{12} + F_{32} + F_{32}^1$$

Here F_{12} is the field at II due to I ([1]), F_{32} the field at II due to the permanent dipole at III ([3]), and F_{32}^1 the field at II due to the dipole induced at III, $\mu_3^1 = \alpha_3F_3$. The field F_{32}^1 will be of the same form as F_{32}, with μ_3 replaced by α_3F_3. Thus $F_{32}^1 = \beta F_3$. The field F_3 can be expressed in a form analogous to [9].

By appropriate substitution, F_2 can be solved to be

$$[10] \qquad F_2 = (F_{12} + F_{32} + \beta F_{13} + \beta F_{23})/(1 - \beta^2)$$

Thus the total energy of II in this field

$$[11] \qquad E_2 = -\mu_2 \cdot F_2 - \tfrac{1}{2}\alpha_2 F_2^2$$

results in 14 terms. Of these, only 6 are considered in the calculations. These correspond to E_{CP}, E_{CI}, E_{PP}, E_{PI}, (twice), E_{II}. Note that E_{AP}, E_{AI}, E_{AC}, and E_{ACI} are nonexistent as the model in Fig. 2 has no anion. The neglected terms are all of an order β smaller than these 6. Taking the simplest model (D) with $q_1 = 4.80 \times 10^{-10}$ e.s.u., $\mu_2 = \mu_3 = 3.96 \times 10^{-18}$ e.s.u. cm, $\alpha_2 = \alpha_3 = 83.7 \times 10^{-25}$ cm^3, $\theta_2 = 45°$, and $r_{12} = r_{13} = 3.8 \times 10^{-8}$ cm, then $\beta = 0.12$. This corresponds to an oxygen–ion distance of 2.4 Å, the distance of closest approach of a DMSO to an Na^+. Thus errors of up to 15% at most can be expected through neglect of the 8 terms as the accuracy of the approximation improves as r increases. The terms E_{II} and E_{PI} contain β in the numerator, but the large values of the other factors (F_{12}, F_{13}) at small r makes them appreciably large (Fig. 5).

Ion–solvent interactions have been described in a similar way in (33), including also quadrupole, dispersion, and repulsion effects. In the actual calculations carried out here, however, it is not necessary to consider permanent dipole (or quadrupole) effects as molecules are described in greater detail by 10 point charges. Dispersion effects are assumed negligible as compared to classical electrostatic effects, and the ions and atoms in DMSO were assumed to behave as hard spheres at distances less than their crystal or covalent radii. Thus the energy is assumed to become infinitely positive if atoms in different molecules or the ion approach the sum of their radii.

For the ions, the most recently available crystal radii (34) were chosen as listed in Table 3 together with polarizabilities (35). There would be a small difference in the effective size of the

I^-	2.01	65.4

*Reference 34.
†Reference 35.

ion radius in the crystal and the solution (36), and the uncertainty in the measured radii are 0.05 Å. The van der Waals radius used for S was 1.85 Å and for H, 1.2 Å (22). In the solid form of DMSO, the smallest H—H distance observed was 2.51 Å, but a short H—O contact of 2.40 ± 0.3 Å was observed (19). Thus the effective radius for O in DMSO was taken to be 1.20 Å. A considerable error can arise from the uncertainty in the van der Waal's radius for oxygen, as this determines the closest distance to which the DMSO's can approach the ion. However, often electrostatic repulsion rather than "hard sphere" contact determined interatomic distances.

(III) Solvation of Alkali Metal and Halide Ions in DMSO

Solvent–ion interaction studies were initially done by setting 4, 5, or 6 DMSO around the ion as described in (*II*). For cations the DMSO dipoles were set pointing towards the ion as in Fig. 1, while for anions the orientations of the DMSO's were reversed. The DMSO molecules were initially placed far from the ion and then brought simultaneously toward the ion.

Figure 3 shows the results for cations and Fig. 4 for anions. Distances of ion–oxygen hard-sphere contact are indicated for the various ions, and DMSO–DMSO hard-sphere contact distances are also noted. It is interesting to note that the classical electrostatic calculations performed here predict in some cases a configuration of minimum energy which corresponds closely to the hard-sphere contact configuration. The source of the repulsion at low ion–DMSO distances is illustrated in Fig. 5. At $r_{C-O} < 1.9$ Å the effective induced dipole in DMSO is greater than the permanent one, and induced interactions become predominant. The magnitude and

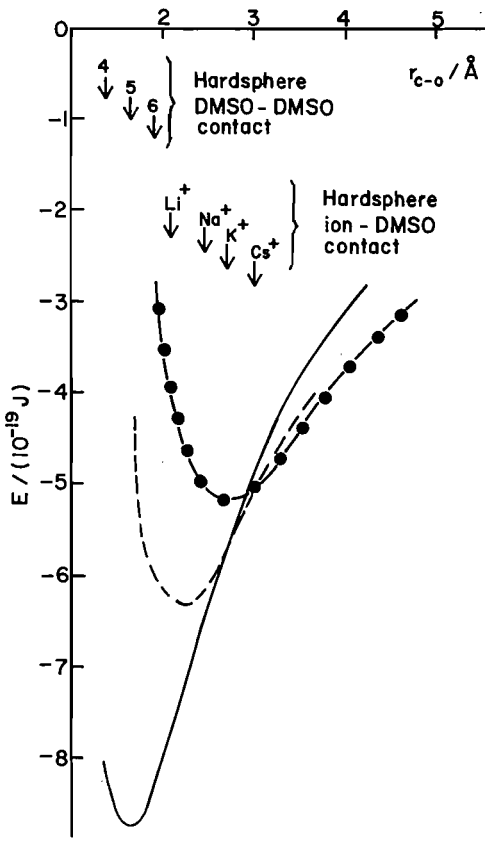

FIG. 3. Energy of cation–solvent complex with 4, 5, and 6 DMSO. —, 4; ---, 5; ●—●, 6 coordination.

positioning of the polarizability in the DMSO becomes thus of extreme importance for realistic calculations.

Figure 6 illustrates the sensitivity of the *E vs. r* curve at small *r* to the DMSO model. Model B is shown to give a smaller energy minimum at larger distances, as the polarizability is effectively closer to the cation than in Model A, thus giving larger E_{II} and E_{PI} repulsion terms. In Model C, the minimum is larger and closer in, as the polarizability is effectively further from the cation, the polarizability of the O—S bond now being located near the S atom. The simplest model (D) gives reasonable agreement with the most detailed, but the positioning of the point dipole and polarizability were adjusted to be 1.08 Å from the O atom to give agreement at large values of *r*.

A number of further calculations of cation solvation were made with solvent shells assumed to be composed of 6 DMSO's with a cation–

oxygen distance of 2.4 Å. This corresponds to hard-sphere Na^+–oxygen contact.

A physical model of such a system using wax models of the DMSO molecules showed considerable free space remaining in the form of a square antiprism. The number of DMSO's was thus increased in some runs to 14, 6 nearest neighbors and 8 next-nearest neighbors. With the 6 nearest neighbors set at $r_{co} = 2.4$ Å, the 8 next-nearest neighbors were simultaneously brought towards the cation. When the dipoles of the 8 were pointing towards the cation, an energy minimum -5.8×10^{-19} J was obtained at r_{co} (for the 8) of 9.3 Å, considerably larger than the r_{co} distance of 4.2 Å where DMSO–DMSO hard-sphere contact occurs. With the directions of the dipoles of the 8 next-nearest molecules reversed, the energy again decreased when r_{co} distances were greater than the hard-sphere contact distance (9.0 Å). Thus classical electrostatics predicts a rather loose structuring of solvent about a cation. A lower-energy, less structured, and more tightly packed configuration may possibly be found by a Monte-Carlo type calculation, however.

Values of ΔH^0 for solvation of ions in DMSO (more correctly ΔU^0) can be estimated on the basis of the data in Figs. 3 and 4. Such calcula-

tions are presented for Li^+, Na^+, K^+ and Cl^-. It will be assumed following Fig. 3 that Li^+ is 4 coordinated with an energy for the ion–solvent complex (at $r_{co} = 2.1$ Å) of -7.5×10^{-19} J; Na^+ to be 4 coordinated with an energy (at $r_{co} = 2.41$ Å) of -6.5×10^{-19} J; K^+ to be 5 coordinated with an energy (at $r_{co} = 2.7$ Å) of -5.7×10^{-19} J. From Fig. 4, Cl^- is likely to be 5 coordinated with an energy -3.5×10^{-19} J. For the cations, the coordination numbers might be larger than those listed above for cations if a higher value, *e.g.* 1.4 Å rather than 1.2 Å were used as the hard-sphere radius for O. Lower coordination numbers would be favored in liquid solutions, however, as addition of extra DMSO's into the coordination shell must lower the energy by about 50 kJ mol^{-1} (see Table 4) if the step DMSO(1) → DMSO (coordination shell) is to be exothermic.

Table 4 gives the contributions to the ΔH^0 of solvation calculated on the speculative constant energy cycle described below. The rows in Table 4 correspond to the steps:

(*1*) A hole the size of a DMSO is formed to hold the cation. This requires an energy equal to the internal latent heat of vaporization (37), $\Delta H_v - RT = 50.3$ kJ mol^{-1} at 25 °C when the figure 52.8 kJ mol^{-1} is used for the latent heat of vaporization, ΔH_v (38).

(*2*) The second step involves the simultaneous orientation of the sterically least hindered DMSO's into the appropriate coordinating positions, and nearby DMSO's into the next coordination shell. This energy is difficult, if not impossible, to calculate. An estimate was made on the basis of calculations comparing interaction energies between two DMSO's in a variety of positions in the first solvation shell. An energy of 50 kJ mol^{-1} was estimated for this step based on the difference in energy between unfavorable and favorable dipole energies, and the energy to force out interfering DMSO's (estimated as 8 kJ mol^{-1}). In an analogous problem with methanol (39), interfering molecules were not considered. The energy for the first steps was estimated as 35 ± 20 kJ mol^{-1}.

(*3*) These are simply the energies as calculated, noting that 10^{-19} J ion^{-1} equals 60.23 kJ mol^{-1}.

(*4*) The interactions between the coordinating DMSO's must be subtracted here, as they are already included in the structure in step (*2*). These terms can be computed with the general program, setting the charge on the ion equal to zero.

(*5*) Finally, the interaction between the ion and the outer coordination shells must be considered. The outer shells are considered as structureless, homogeneous, and incompressible (no electrostriction) with the macroscopic dielectric constant. The first coordination shell was considered irrotationally bound to the ion as part of a charged sphere representing the ion–DMSO complex. The radii of these spheres were determined from the furthest H-distances and were 6.8 Å for Li^+, 7.1 Å for Na^+, and 7.4 Å for K^+ and Cl^-. An expression for the ΔH was obtained from the Born equation (40), with values of the dielectric constants obtained from refs. 41–43. Use of the Born equation should be quite appropriate as the next-nearest neighbors are likely to be located at distances such that their centers are over 10 Å from the cation.

(*6*) This row gives the single ion solvation enthalpies as calculated by the above cycle.

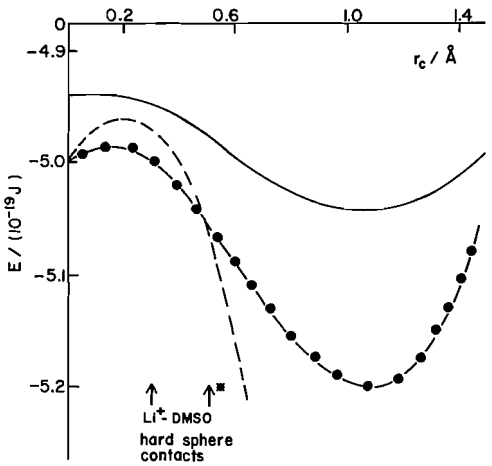

FIG. 7. Energy as a function of cation distance from the shell center with 6 coordinating DMSO: —, O atoms 3.0 Å from shell center, movement in 1,1,1 direction; ---, O atoms at 2.4 Å, movement along z axis; ●—●, O atoms at 2.4 Å, movement in 1,1,1 direction.

The values should be compared with those in row (*9*). The agreement is good, considering the crude assumptions made in (*1*), (*2*), and (*4*). It is significant that both the right order of magnitude and the correct trend are predicted.

The experimental values in row (*9*) were determined from single ion enthalpies of hydration (44) and the energy of transfer from water to DMSO (45). The difference between ΔH^0 solvation in row (*9*) between Li^+ and K^+ is 183 kJ mol^{-1} in agreement with the figure obtained from ref. 36 assuming the Li^+ value shown. The calculated ΔH^0 solvation for LiCl (−819 kJ mol^{-1}) is smaller than the experimental one (−874 kJ mol^{-1} (36)) by nearly 10%. The small changes of ΔH^0 solvation in going from Cl^- to Br^- to I^- are also predicted from the curves in Fig. 4.

For a more definitive test of the validity of the calculations on ion–solvent energies carried out, a comparison to gas phase solvation experiments such as those in ref. 46 would be desirable. No systems are yet available for which both experimental results and calculation from the general model described here exist.

(IV) Vibration of Cations in Solvent Shells

The infrared spectra of alkali metal salts in DMSO have been interpreted as due to alkali metal ions vibrating in cages under the influence of electrostatic forces (30). The frequencies for Li and Na salts are 425 and 200 cm^{-1}, irrespective of anion. It was decided to look at the energy as a function of the position of the cation in solvent shells of varying sizes. The results are shown in Fig. 7 for three types of vibrations.

In all three cases, the cation was assumed 6 coordinated. When the cation is moved along the *z* axis, then the energy is a maximum near the center and falls steeply as the cation approaches the O of the DMSO on the *z* axis. The hard-sphere contact distances with O atoms 2.4 Å from the center of the cage is shown for Li^+. The second distance (*) is for the negative side of the graph where the curve is not shown. The curves are not exactly symmetrical about r_c (distance of cation from center of cage), as the O atoms are not exactly on the coordinate axes (see Fig. 1). When the cation is taken to vibrate along the 1,1,1 direction, a minimum in the energy occurs away from the center of the cage, with a repulsion predicted from electrostatics.

The force constants for vibrations in the 1,1,1 direction are (*i*) for the O's 2.4 Å from the center, 1.3×10^{-9} N $Å^{-1}$ and (*ii*) for 3.0 Å, 6.5×10^{-10} N $Å^{-1}$. The force constants for Li^+ and Na^+ in DMSO calculated in ref. 30 are 7.7×10^{-9} N $Å^{-1}$ and 6.2×10^{-9} N $Å^{-1}$. The results are qualitatively correct, in that the force constant increases as the size of the ion cage decreases. The results calculated here are lower by nearly an order of magnitude, however. A low value would be expected, as the addition of a nonclassical exponential repulsion term would increase the curvature. As indicated in Fig. 7, vibrations in directions other than the 1,1,1 direction are also likely to have larger force constants, but to obtain a value for them it is necessary to introduce repulsion potentials smoother than the hard-sphere potential. Thus classical electrostatic considerations are not sufficient to explain the vibration phenomenon quantitatively.

The results described in this section suggest that the high-symmetry configurations used for the calculations may not necessarily be the lowest energy ones. To find lower energy, less symmetrical configurations, it would seem necessary to do Monte-Carlo type calculations. It is also likely that the solvent cages are on the average considerably larger than those predicted on the basis of O-ion hard-sphere contact in Fig. 3. Both of these effects add to the imprecision of the calculations summarized in Table 4.

TABLE 5. Energies of various configurations

System	Energy of configuration (10^{-19} J)	Energy difference (10^{-19} J)
1 Tetrahedral 4-coordinated cation, no anion	−6.5	−5.4
2 As in 1 but with anion at Na^+–Cl^- hard-sphere distance	−11.9	
3 4-coordinated cation (trigonal bipyramid less one DMSO)	−6.2	
4 As in 3 but with anion	−12.0	−5.8
5 5-coordinated cation (octahedral less one DMSO)	−5.8	
6 As in 5 but with anion	−11.0	−5.2
7 6-coordinated cation (octahedral)	−5.8	
8 As in 7 but with anion	−10.6	−5.6
9 14 DMSO's about cation 6 octahedral, 8 square antiprism	−5.8	
10 As in 9 with anion, direction of 1 DMSO reversed, ions touching	−10.5	−4.7
11 As in 9 with anion one DMSO removed from cation.	−9.3	−1.2

(V) Ion Pairs in Dimethyl Sulfoxide

Energy calculations were made on a number of configurations including both an anion and a cation. It was hoped to be able to follow the energy of configurations for the reaction: solvent-separated ion pair going to contact ion pair. The energy of the transition state could in such a case be obtained and comparison made to the kinetic data for the systems (4). This goal has not been fully reached in this study, however.

A number of calculations were made with only the first coordination shell DMSO's considered. The results are summarized in Table 5. All systems assumed a cation–oxygen distance of 2.4 Å. Results for the inclusion of 14 DMSO's are also included. All the systems assumed the cation to be Na^+ and the anion Cl^-.

The first 5 pairs of systems (*i.e.* 1 and 2, 3 and 4 etc.) each give the ΔE for a reaction. Solvated cation + free anion → solvated ion pair. Only in the case of the last set is the solvation of the anion reasonably complete. The first 4 pairs give approximately the same ΔE for this reaction -5.6×10^{-19} J configuration^{-1}, or −330 kJ mol^{-1}. In all cases E decreased monotonically as the anion approached the cation.

The value −330 kJ mol^{-1} is meaningful only for the ΔU^0 of the formation of such an ion pair in the gas phase. The ΔE is rather insensitive to the number and the configuration of the DMSO's present. If no DMSO's are present then the ΔE for the formation of the ion pair is -8.7×10^{-19} J. This assumes hard-sphere interaction occurs at an ion–ion distance 2.86 Å. The experimental value, and that calculated with an ion–ion distance of 2.51 Å and an r^{12} repulsion is -9.1×10^{-19} J (47).

When the anion in the model is somewhat solvated (system 9), then the ΔE is somewhat smaller. The ΔE for going from systems 11 to 10 is considerably smaller. The configurations for these two systems are shown in Fig. 8, with only two of the 8 next-nearest solvation molecules shown. This is a more realistic ΔU^0 for the solvent separated ion pair – contact ion pair postulated to be the cause for the excess absorption in ref. 4. The value would be even smaller if the anion in system 11 would be solvated by a third shell of DMSO's.

It is noteworthy as shown in Fig. 8 using wax models, that even with octahedral 6 coordination, there is room enough for the anion to approach nearly all the way in to the hard-sphere distance without touching the DMSO's.

Table 6 gives the energies for a number of configurations intermediate between systems 10 and 11 in Table 5. These configurations could be transition states for the contact ion pair – solvent separated ion pair reaction. In all cases the cation is in the center, the 6 nearest neighbor DMSO are at $r_{co} = 2.4$ Å and the 8 next-nearest neighbors are at $r_{co} = 9.3$ Å. Several configurations intermediate to systems 4 and 5 in Table 6 were examined, but in each case there was a hard-sphere interaction. Thus some relaxation of the DMSO's from the symmetrical positions

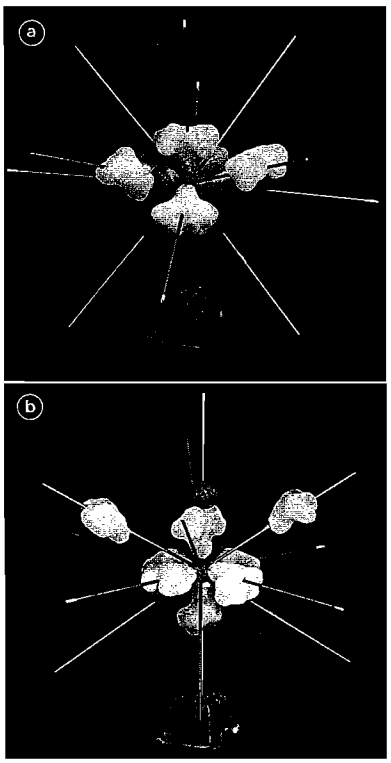

FIG. 8. Models of systems 10 and 11 of Table 5 with 6 nearest and 2 next-nearest DMSO's shown: (*a*) contact ion pair (system 10); (*b*) solvent separated ion pair (system 11).

TABLE 6. Energies of configurations intermediate to contact and solvent-separated ion pairs

	Coordinates of anion (Å)			Energy
	x	*y*	*z*	(10^{-19} J)
1.	System 10, Table 5			−10.5
2.	1.65	0.165	1.65, as (1) but one DMSO reversed	−10.3
3.	1.8	1.8	1.8	−10.2
4.	2.0	2.0	2.0	−10.2
5.	1.0	1.0	7.6	−9.07
6.	0	0	7.6	−9.29
	System 11, Table 5			

used here seems necessary for the process to proceed.

The energy difference between systems 5 and 6 suggests that an activation energy of about 0.22×10^{-19} J (13 kJ mol^{-1}) may be present in the process, but this may not be the lowest energy reaction coordinate. On the other hand, higher-energy transition states may be present which were not detected in the calculations. The energy can be lowered by about 12 kJ mol^{-1} by reversing the orientation of the next-nearest neighbor DMSO closest to the anion. This makes the activation energy for the reverse process of the order of 80 kJ mol^{-1}. The results in ref. 4 indicate a low activation energy for the process responsible for the excess ultrasonic absorption.

In order to get more meaningful results, calculations on far more configurations must be done. These should ideally be done by a Monte-Carlo type approach, allowing configurations to "relax" to their positions of lowest energy.

Conclusions

The classical electrostatic models used in the calculations presented here seem to be a good compromise between the quantum mechanical and the continuum models used for description of microscopic structures in liquids and solutions. The description of the DMSO molecule need not be as detailed as that used here for molecules farther from ions. However, specifying the coordinates of all the atoms makes it easy to extend the calculation to include repulsive forces. Thus in addition to the coulomb interactions due to the charge centered on atoms, a repulsive term of a form $C_1 \exp[-C_2(r-C_3)]$ or $C_1(C_2/r)^{C_3}$ can be added to the calculations.

For an adequate description of the solvent-separated ion pair, it seems necessary to add a third shell of solvent molecules. Most likely, about 10 molecules forming a third shell in the positive *z* half of the coordinate system seems sufficient. This would bring the number of molecules up to 24.

It would seem desirable to also include in the calculation of the electric field causing polarization the contributions from the neighboring molecules. Close to the ion, the ion field is predominant, but fields due to neighboring molecules may be significant when outer shell molecules are considered. It may however be adequate to describe the polarization through a single judiciously placed scalar polarizability rather than 9 polarizable bonds.

The most realistic configurations of the lowest energy for contact and solvent separated ion pairs as well as intermediate states can be best obtained through Monte-Carlo type calcula-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

tions. The system can be allowed to find the configuration of lowest energy with one or both of the ion coordinates fixed. A promising initial configuration can be chosen on the basis of geometrical models such as shown in Fig. 8.

Incorporation of these features into the calculations are quite feasible in principle, but require more computational resources than those used for the calculations presented here. Such calculations can be set up quite generally so that other solvent systems can be studied. Because of the neglect of dispersion forces and quantum mechanical effects, the calculations are most realistic for systems involving polar molecules and/or relatively simple univalent ions.

The authors wish to thank Dr. D. R. Dickson for assistance in programming parts of the calculations, and Dr. W. J. Meath, Dr. P. M. Laughton, and Dr. J. M. Holmes for useful discussions. The project was supported financially by the National Research Council of Canada.

Reactions of Alkyl Azidoformates with Norbornylene[1]

OLIVER E. EDWARDS, JOHN W. ELDER,[2] MAURICE LESAGE, AND ROBERT W. RETALLACK[3]

Biochemistry Laboratory, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received November 5, 1974

OLIVER E. EDWARDS, JOHN W. ELDER, MAURICE LESAGE, and ROBERT W. RETALLACK. Can. J. Chem. **53**, 1019 (1975).

Evidence is presented that the reactions of alkyl azidoformates with norbornylene induced by direct irradiation do not involve intermediate triazolines. The products of this, and acetophenone-photosenzitized reaction of the mixtures in cyclohexane, are described and contrasted with those from the direct photolysis of the corresponding *N*-alkoxycarbonyl triazolines. The action of aqueous dioxane at 170° converted 2,3-iminonorbornane (3-azatricylo[3.2.1.$0^{2,4}$]octane) into 3-aminonortricyclene and *syn*-7-amino-2-*exo*-hydroxynorbornane. Three preparations of derivatives of 2-*exo*-aminonorbornan-3-one are described. The trimethylsilyl ether of the enol of norbornan-2-one (2-trimethylsilyloxynorborn-2-ene) was prepared.

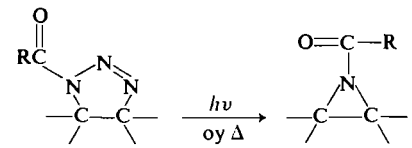
OLIVER E. EDWARDS, JOHN W. ELDER, MAURICE LESAGE et ROBERT W. RETALLACK. Can. J. Chem, **53**, 1019 (1975).

On présente des données indiquant que les réactions induites par irradiation directe, entre les azidoformates d'alkyles et le norbornylène, n'impliquent pas de triazolines comme intermédiaires. On donne une description des produits de ces réactions, de même que de ceux qui ont été obtenus de ces mêmes mélanges, par irradiation photosensibilisée par l'acétophénone, dans le cyclohexane. La comparaison de ces produits, montre des différences marquées par rapport à ceux qui se forment durant la photolyse directe des triazolines *N*-alkoxycarbonylées correspondantes. Sous l'action du dioxanne aqueux, à 170°, l'imino-2,3 norbornane (aza-3 tricyclo-[3.2.1.$0^{2,4}$]octane) se transforme en amino-3 nortricyclène et en *syn*-amino-7 *exo*-hydroxy-2 norbornane. On décrit trois préparations des dérivés de l'*exo*-amino-2 norbornanone-3. On a préparé l'éther triméthylsilylé de l'énol de la norbornanone-2 (triméthylsilyloxy-2 norbornène-2).

Introduction

The photolysis of azidoformates in the presence of compounds with isolated carbon double bonds (1), enol acetates (2), and of dihydropyran (3) has been shown to give aziridines. The internal photochemical addition of acyl azides to olefinic double bonds has also been described (4, 5). In the case of unreactive double bonds, comparison of the products of photochemical reaction and the reaction of the olefin with chemically generated singlet nitrenes suggested that the former also were singlet nitrene reactions (1). However, this is not necessarily true for polarized or strained olefins. These could react with electronically excited azide to give vibrationally excited triazoline. This could lose nitrogen directly or require electronic excitation by another photon before giving aziridine (eq. 1).

[1] $RCON_3^* + \text{>C=C<} \longrightarrow$



It seemed to us that comparison of photolysis of a triazoline with the photolysis of the azide–olefin mixture might throw light on this problem.

When this work was initiated (summer 1964) the acyl triazoline **1** had been described (6) as product of reaction of ethyl azidoformate with *N*-(1-cyclohexenyl)morpholine and it had been concluded that **2** was the product of reaction of benzoyl azide with norbornylene (7). Our attempts to intercept acyl triazolines in thermal reactions of ethyl azidoformate with 1-methoxycyclohexene (8) or with dihydropyran (3) were unsuccessful. However it was found that reaction of methyl and ethyl azidoformates with the reactive double bond of norbornylene was much

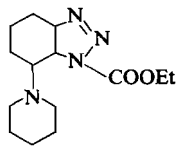
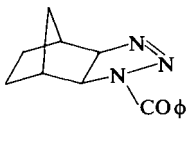
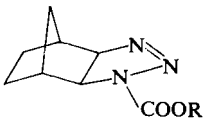
more rapid than the loss of nitrogen from the adduct, which was presumed to be the triazoline **3**. The adduct rapidly lost nitrogen when heated



1

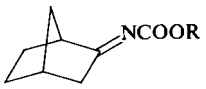


2

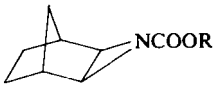


3

at 135°, when treated with acids, or when irradiated with u.v. light. The major products were the imine **4** and a tricyclic urethane A, which appeared to be a derivative of either the aziridine **5** or azetidine **6**. The n.m.r. spectrum



4



5

6

of A was more easily reconciled with structure **5** since the two protons on carbon carrying nitrogen gave a singlet at δ 2.63 ($w_{1/2}$ 2.2 Hz). However, when the alkoxycarbonyl group of A was removed by mild alkaline hydrolysis, then the resulting amine **7** heated in aqueous dioxane at 170°, the main products were nortricyclylamine (**8**) (8%), *anti*-7-amino-2-*exo*-hydroxynorbornane **28** (8%), and *syn*-7-amino-2-*exo*-hydroxynorbornane **9** (81%) (structure proof below). This suggested that "A" was actually the *N*-alkoxycarbonyl azetidine **6** and thus cast doubt on the structure of the proposed triazoline.

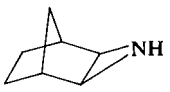
While this work was in progress the preparation and reaction of a number of *N*-acyl triazolines derived from norbornylene was reported (9–11) and the thermal decomposition of the apparent triazolines from azidotropones and norbornylene described (12). Evidence was also presented for triazoline formation from *t*-butyl azidoformate and birdcage hydrocarbon (13). Of more direct relevance, Scheiner reported the preparation of triazoline **3** and claimed that its photolysis gave essentially pure **5** (14). Zalkow and Oehlschlager and their co-workers (15) described the preparation, thermolysis and photolysis of **3**. Tanida *et al.* (16) showed that **3** rapidly lost nitrogen at room temperature in alcohols giving the same major product as thermolysis (presumably **5**). In all these cases the structure of **5** was deduced from n.m.r. evidence (14–16) and a band at 1190 cm^{-1} attributed to the aziridine ring (14). The only chemical evidence bearing on its structure was the ambiguous acid-catalyzed ring opening to a 2,7-disubstituted norbornane (16).

In order to decisively settle the question of structure an X-ray analysis of the *N*-*p*-bromobenzoyl derivative **10** prepared from A was carried out by Dr. Gopalakrishna (17). This determined that A actually had the aziridine structure **5** and hence that the original adduct was the triazoline **3**. Hence rearrangement took place even on ring opening of **5** in basic medium. For similar observations with the norbornylene – benzenesulfonyl azide adduct see refs. 18 and 19.

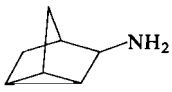
Structure Proof

The imine **4** was never obtained pure since it hydrated with great ease to **11**. This decomposed on heating or when injected onto g.l.c. columns into urethane and norbornanone. However this imine has been described as a product of thermolysis of **3** (15*b*) and its n.m.r. spectrum reported.

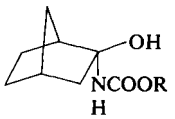
The amino alcohol **9** obtained by hydrolytic opening of the aziridine **7**, derived from **5**, was



7



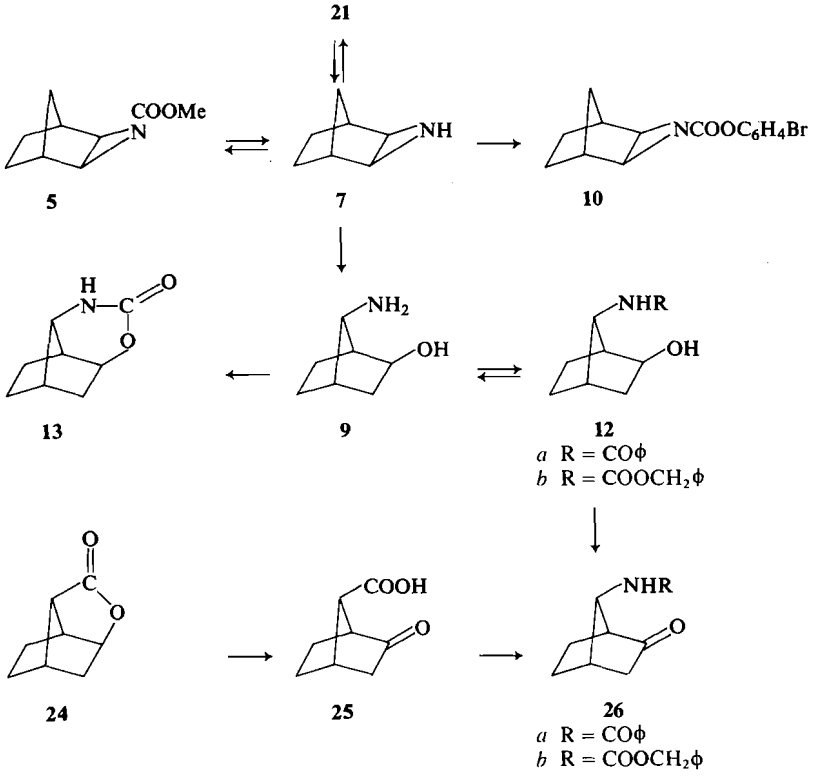
8



11

characterized as its *N*-benzoyl- (**12***a*) and *N*-benzyloxycarbonyl (**12***b*) derivatives (Scheme 1). The fact that it could be converted into a cyclic carbamate **13** indicated that it was either *syn*-7-amino-2-*exo*-hydroxynorbornane (**9**) or 2-*exo*-amino-3-*exo*-hydroxynorbornane (**16**). In order to establish which structure was correct we undertook independent syntheses of both.

Derivatives of 2-*exo*-amino-3-*exo*-hydroxynorbornane were prepared in three ways (Scheme 2).



SCHEME 1

(*a*) Following Schechter *et al.* (20), a mixture of 2-*exo*-nitronorbornan-3-ols **14** was prepared by N_2O_4 addition to norbornylene. This was reduced to a mixture of the amino alcohols **15** and **16** which were converted to the *N*-benzyloxycarbonyl derivative **17** and the cyclic carbamate **18**, respectively. Oxidation of **17** gave 3-*exo*-benzyloxycarboxamidonorbornan-2-one (**20***b*).

(*b*) The enol ether of norbornanone **19** was prepared by the action of triphenylmethyl anion on the ketone in the presence of trimethylsilyl chloride. Using the method of Lessard *et al.* (21), chromous chloride catalyzed addition of *N*-chlorobenzylcarbamate to the enol ether was carried out. After mild hydrolysis of the product the *N*-benzoylcarbonyl derivative **20***b* was again obtained in low yield.

(*c*) Huisgen *et al.* (9) had claimed on the basis of n.m.r. evidence that addition of benzoyl azide to norbornylene led with loss of nitrogen to the *N*-benzoylaziridine **21**. On heating, this was reported to give the dihydrooxazoline **22**. We were unable to repeat the reported base-catalyzed hydrolysis of **22**. However acid hydrolysis gave a benzamido alcohol **23**. This could be oxidized to a benzamido ketone **20***a* which was related to the benzyloxycarbamido ketone from routes *a* and *b*. Thus the structural conclusions of Huisgen *et al.* were correct and the *exo*-nitro geometry of **14** was substantiated. Both the cyclic carbamate **18** and the derivatives **20***a* and **20***b* were distinct from the corresponding compounds obtained from **7**, hence the 2,7 disubstituted derivatives were synthesized.

The known lactone (22) of 2-*exo*-hydroxynorbornan-7-*syn*-carboxylic acid **24** was converted via the keto acid **25** into the *N*-benzoyl- (**26***a*) and *N*-benzyloxycarbonyl (**26***b*) derivatives of *syn*-7-aminonorbornan-2-one. These proved identical with the products derived from **7** hence the hydrolytic opening at 170° gives the rearranged amino alcohol **9**. The cyclic carbamate from **9** hence has structure **13**.

A significant product (8%) in the hydrolytic opening of quite pure **7** was characterized as its benzamido derivative. On oxidation this gave a benzamido ketone distinct from either **20***a* or **26***a*. The relatively sharp n.m.r. signal for the

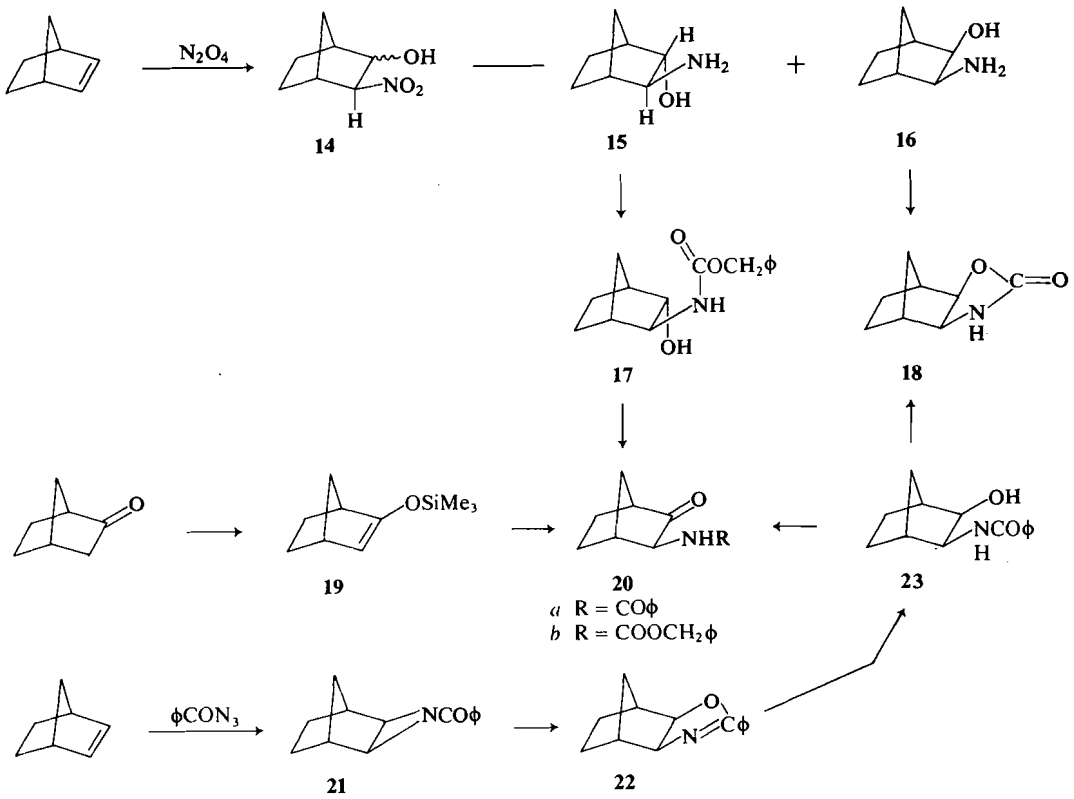
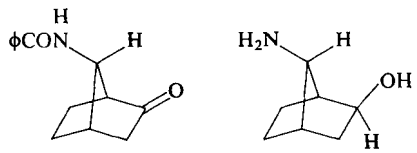


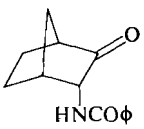
SCHEME 2

proton on the carbon carrying the benzamido group (after D_2O exchange) was consistent with a 7-benzamido function. Therefore the benzamido ketone was apparently **27** and the minor amino alcohol was most probably 7-*anti*-amino-2-*exo*-hydroxynorbornane **28**. This probably arose from small amounts of 2,3-*endo*-aziridine produced in the alcohol-catalyzed decomposition of **3**. (For its formation in thermolysis of **3** see ref. 15*b*.)



27

28



29

A very minor product (1%) encountered in the hydrolytic opening of **7** was characterized as the benzamido alcohol and ketone. It appeared that the ketone had structure **29** (2-*endo*-benzamidonorbornan-3-one) since the 2-hydrogen after exchange of the amide hydrogen using acidic deuterium oxide gave a doublet with J = 5 Hz. This was confirmed by comparison with a sample prepared from 2-*endo*-aminonorbornan-3-one (23). Hence the amino alcohol was 2-*endo*-amino-3-*exo*-hydroxynorbornane derived by hydrolytic opening without rearrangement of the 2,3-*endo*-aziridine.

Photolytic Studies

The direct irradiations were done with lamps with peak emission at 254 nm. The rate of nitrogen evolution from irradiated mixtures of ethyl azidoformate and norbornylene in cyclohexane did not change as the ratio of these changed from 1:1.7 to 1:10. However the amount of attack on solvent giving *N*-cyclohexylurethane decreased sharply with the higher

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

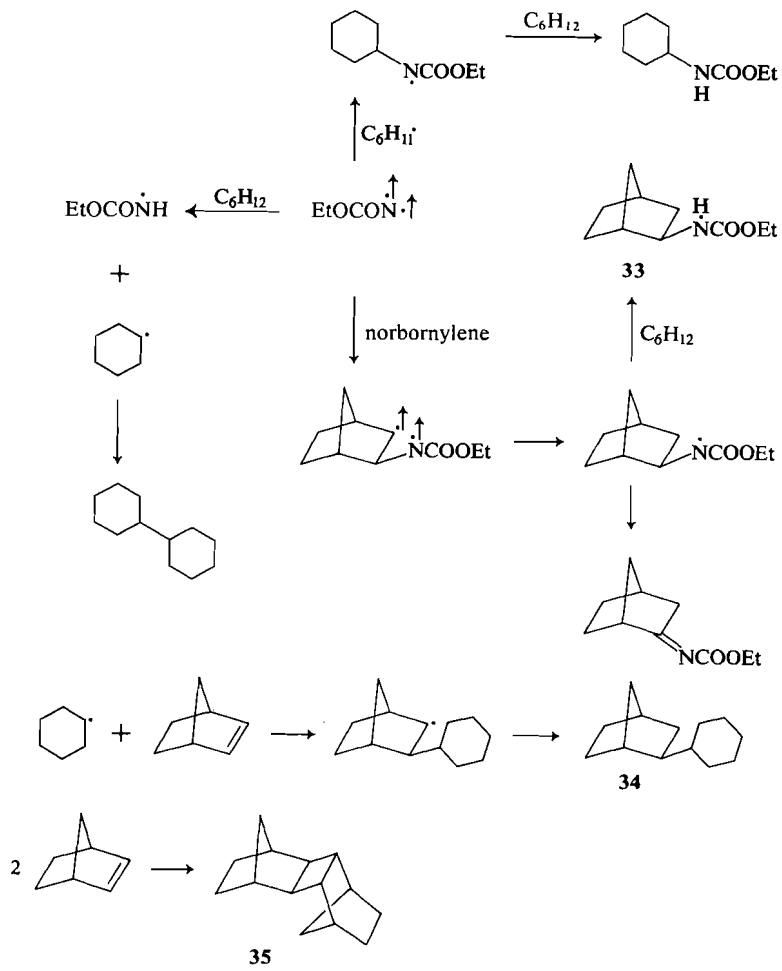

SCHEME 3

olefin concentration. Although cyclohexylurethane certainly arises by singlet nitrene insertion into CH bonds (24), this observation is not inconsistent with a competition between decomposition of excited azide and its addition to the olefin. The major product at higher olefin to azide ratios was the aziridine **5**. Most significantly, no imine **4** was produced. However when the triazolines **3** were irradiated the major products were the aziridine **5** (60–65%) and the imine **4** (20–25%).

None of the characteristic i.r. bands of the triazoline could be detected when a mixture of methyl azidoformate and norbornylene were irradiated. However under comparable conditions the triazoline photolyzed at a similar rate, hence a low steady state concentration could have escaped detection.

Acetophenone-photosensitized decomposition of ethyl azidoformate in the presence of norbornylene, with cyclohexane as solvent, gave an array of products. The ones characterized are shown in Scheme 3. Attempts to obtain photosensitized reaction of the triazoline **3** using energy transfer from acetophenone or benzophenone resulted in very slow reaction, hence where abandoned. This contrasts with the observation of Scheiner with aryl triazolines (11). The products of thermolysis and irradiation experiments are summarized in Table 1.

Discussion

The absence of products of skeletal rearrangement in the thermal or alcohol-catalyzed decomposition of the triazoline **3** means that if the zwitterion **30** is an intermediate it has a very

30 **31** **32**

short lifetime. However both the effect of dielectric constant on the rate (15) and the dramatic effect of protic solvents (16) on the decomposition indicate charge development in the transition state (see also ref. 12).

The formation of imine in the triazoline photodecomposition and its absence in the products from irradiation of the azide–olefin mixture excludes the intervention of the triazoline in the latter case (see eq. 1). Hence we conclude that the photoaddition of acyl azides to olefins involves singlet nitrene addition (see also ref. 4), again with a very short lifetime for any zwitterionic intermediate such as **30**.

The photosensitized reaction of azidoformates raises interesting questions. The products in the presence of norbornylene with cyclohexane as solvent clearly derive from nitrogen-centered and carbon-centered radicals. It is tempting to interpret these as arising from the triplet nitrene as illustrated in Scheme 3 (see also ref. 25). However McConaghy and Lwowski (1) have argued that 30% of the alkoxycarbonyl nitrenes produced in direct irradiation of the azidoformates are in the triplet state. If this is correct, we would expect the products shown in Scheme 3 to accompany the products derived from singlet nitrene. However in our direct irradiation studies we were unable to observe these. Thus, either their conclusion is wrong or the photosensitized reaction does not produce triplet nitrene. Indeed, McConaghy and Lwowski have suggested that either triplet excited azide or an excited acetophenone–azide complex is the initial hydrogen-abstracting species (1). If either of these species could abstract one hydrogen and lose nitrogen to give the urethanyl radical EtOCONH, all the products in Scheme 3 could be accounted for. We are unable to settle this question.

Scheiner (11*a*) has suggested that irradiation of triazolines gives C,N-diradicals with antiparallel spins (*e.g.* **31**). If this were so, one might expect to see some radical-type products. However in our direct irradiation of **3** in cyclohexane no dicyclohexyl or 2-alkoxycarboxamidonorbornane were found. Hence if such a diradical is formed it has such a short lifetime that the process is difficult to distinguish from bond reorganization synchronous with nitrogen expulsion.

The products of hydrolytic opening of the 2,3-*exo*-aziridine **7** are interesting. The aziridine was inert in dry dioxane at 170°, hence the water was playing an important role. Since no 2-*exo*-amino-3-*endo*-hydroxynorbornane was produced, the water was not assisting ionization of a C—N bond by back-side displacement. Hence it must accelerate reaction by its dielectric properties. This accords with the production of the rearranged product **9** and the nortricyclylamine. The formation of the latter has parallels in the homoenolate formation from norbornanone (26) and tricyclanone formation on deamination of 2-*exo*-aminonorbornan-3-one (27). We conclude that the aziridine **7** in aqueous dioxane at 170° opens to a zwitterion which before interception by water has the character of the delocalized ion **32**.

Experimental

Infrared spectra were taken in chloroform unless otherwise stated, and n.m.r. spectra are of deuteriochloroform solutions with tetramethylsilane as internal reference. Thin-layer chromatography was done using silica gel with G_{254} fluorescent indicator. Analytic gas liquid chromatography involved a thermal conductivity detector and an OS-138 column (20% polyphenyl ether on dimethylsilylated chromosorb W) with o.d. 0.25 in. and

length 6 ft. Preparative separations were done on a similar column 10 ft in length.

Photolyses were conducted in a Rayonet Photochemical Reactor with a cylindrical reflecting chamber and 16 lamps around the periphery.

*3-Ethoxycarbonyl-3,4,5-triazotricyclo[5.2.1.0^{2,6}]dec-4-ene (**3**, R = C_2H_5)*

A mixture of 1.23 g (12 mmol) of ethyl azidoformate and 1.95 g (21 mmol) of norbornylene in 10 ml of cyclohexane was heated in the dark at 75° for 24 h, when the azide had all reacted. The solvent and excess norbornylene were removed under reduced pressure. Since attempts at short-path distillation had resulted in some loss of nitrogen, the product was simply left under 0.1 mm pressure while agitated until the nitrogen analysis remained constant.

Anal. Calcd. for $C_{10}H_{15}N_3O_2$: N, 20.08. Found: N, 20.0.

The n.m.r. spectrum of **3** (R = C_2H_5) contained a triplet at δ 1.4, a broad 2H doublet centered at δ 2.72 (J = 9 Hz), a 1H doublet centered at δ 3.72 (J = 8.5 Hz), 2H quartet centered at 4.41 and a 1H doublet centered at 4.63 (J = 8.5 Hz). It had ν_{max} (cyclohexane) 1765 (med str), 1725 (str), 1527 (med), 1420, 1388, 1353 (str), 1150 cm^{-1} (str).

*3-Methoxycarbonyl-3,4,5-triazotricyclo[5.2.1.0^{2,6}]dec-4-ene (**3**, R = CH_3)*

Using the same molar ratios and concentration as for the ethoxy analog, reaction was much faster. The azide had completely reacted in 5 days at room temperature. After removal of unreacted solvent and norbornylene under reduced pressure the product crystallized. After recrystallization from hexane it had m.p. 35.5–37° (lit. (15*b*) m.p. 35.5°).

Anal. Calcd. for $C_9H_{13}N_3O_2$: C, 55.37; H, 6.71; N, 21.53. Found: C, 55.48; H, 6.88; N, 21.19.

Its n.m.r. spectrum contained a broad 2H doublet centered at δ 2.7 (J = 8.5 Hz), a 1H doublet centered at 3.75 (J = 8.5 Hz), a 3H singlet at 3.96, and a 1H doublet centered at 4.69 (J = 8.5 Hz).

Compound **3** (R = CH_3) had ν_{max} (cyclohexane) 1755 (str sh), 1720 (str), 1520 (med), 1380 (str), 1355 (str sh), 1147 cm^{-1} (str).

*Thermal Decomposition of **3***

When **3** (R = CH_3) was maintained at 85° for 18 h nitrogen evolution was complete. Gas–liquid chromatographic analysis on an OS-138 column showed the presence of aziridine **5** (70%), imine **4** (19%), and two minor peaks totalling 11% of peak areas.

When **3** (R = CH_3) was injected into a gas chromatograph (OS-138 column, injector block at 280°, column at 200°) the ratios of areas of peaks were: **5**, 33%, **4**, 32%, two minor products, 15%.

*Photolysis of **3** (R = CH_3)*

A solution of 375 mg of **3** (R = CH_3) in 10 ml of cyclopentane was irradiated in a Rayonet photoreactor using lamps with peak emission at 254 nm and a Vycor cell. Cooling was by water at 0° and the reaction mixture was protected from i.r. radiation by a water-filled quartz jacket. The theoretical amount of nitrogen was evolved in 3 h. Gas–liquid chromatographic analysis on an OS-138 column showed the major products to be aziridine **5** (60–65%) and imine **4** (20–25%). At least three very minor components were also evident. However no ethyl urethane, *N*-methoxycarbonyl norbornylamine or dicyclohexyl were detected.

*N-Alkoxycarbonyl 3-Azatricylo[3.2.1.1^{2,4}]octane (**5***a* *and b)*

The ethoxycarbonyl derivative (**5***a*) was an oil. Its n.m.r. gave a 1H doublet centered at δ 0.78 (J = 10 Hz), a triplet (—CH_2—CH_3) centered at 1.25, a broad 2H singlet at 2.52, a sharp 2H singlet at 2.59, and a quartet (–CH_2—CH_3) centered at 4.14.

The methoxycarbonyl derivative (**5***b*) was also an oil with ν_{max} (cyclohexane) 1710 (str), 1440 (str), 1380 (med), 1325 (med sh), 1305 (str), 1272 (str), 998 cm^{-1} (med).

*3-Azatricyclo[3.2.1.0^{2,4}]octane **7***

The *N*-alkoxycarbonyl derivative **5** could be hydrolyzed by 5 h refluxing with potassium hydroxide in methanol. The bulk of the methanol was removed under reduced pressure, the residue diluted with water and the base extracted into ether. The oily base gave n.m.r. signals at δ 0.57 (1H singlet), 0.75 (1H singlet), 1.93 (2H singlet), and a broad 2H singlet at 2.30. It was characterized and stored as its picrate, m.p. 123°.

Anal. Calcd. for $C_{13}H_{14}N_4O_7$: C, 46.16; H, 4.17; N, 16.56. Found: C, 45.98; H, 4.33; N, 16.39.

The aziridine was unchanged by heating at 172° for 16 h in dioxane under nitrogen. The base could be reconverted to **5***b* by methyl chloroformate in ether containing triethylamine at −10°. Compound **7** gave an oily *N*-benzoyl derivative **21** when treated with benzoyl chloride in ether containing trimethylamine at −10°. This gave n.m.r. signal between δ 0.7 and 1.9 (6H), a broad 2H peak at 2.58, and a sharp 2H singlet at 2.73 ($w_{1/2}$ 2.3 Hz). Benzyloxycarbonyl chloride in ether the containing triethylamine at 0° converted it to the oily *N*-benzyloxycarbonyl derivative. This gave n.m.r. signals at δ 2.45 (broad, 2H), a 2H peak at 2.59 a sharp 3H singlet at 5.15, and a 5H signal at 7.4.

Anal. Calcd. for $C_{15}H_{17}NO_2$: C, 74.05; H, 7.04; N, 5.76. Found: C, 73.90; H, 6.87; N, 6.01.

The *N-p*-bromobenzoyl derivative **10** was prepared as for the benzoyl derivative. It had m.p. 119–121° after recrystallization from methanol and gave n.m.r. signals at δ 7.83 (quartet-4H), sharp (2H) singlet at 2.80, broad (2H) singlet at 2.63, a series of broad peaks (6H) between 1.85 and 1.1, and a broad 1H doublet centered at 0.90 (J = 10 Hz).

Anal. Calcd. for $C_{14}H_{14}BrNO$: C, 57.54; H, 4.83; Br, 27.39; N, 4.98. Found: C, 57.65; H, 4.93; Br, 27.16; N, 4.98.

This derivative was used for X-ray analysis (17).

*Imine **4***

This compound was isolated by preparative g.l.c. of the reaction mixture from the decomposition of triazoline. Upon reinjection of **4** on g.l.c., it partly decomposed into norcamphor and urethane. From its i.r. spectrum it was obvious that **4** was hydrating very easily to **11** in the presence of moisture. Hence the fraction collected by g.l.c. (31 mg) was dissolved in methylene chloride (5 ml) and shaken with 0.1 *N* HCl (3 ml) for 3 h. The organic phase was separated and to it 2,4-dinitrophenylhydrazine hydrochloride (75 mg) in methanol was added. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

methylene chloride was evaporated and the methanolic solution left at room temperature to crystallize. The crystals obtained had m.p. 130–132° giving no depression on admixture with the corresponding derivative of norbornanone.

Photosensitized Decomposition of Triazoline 3

A solution of 1.03 g of the methoxycarbonyl triazoline **3** and 2 g of benzophenone in 75 ml of cyclopentane was placed in a Vycor cell. This was surrounded by a Pyrex sleeve and cooled by a cold finger with circulating ice water. The mixture was irradiated while stirred magnetically in the Rayonet apparatus using lamps with peak emission at 350 nm. In this, and a comparable experiment using the ethoxycarbonyl triazoline (2 g) and acetophenone (1.5 g) less than 30% of the theoretical amount of nitrogen was liberated in 3 days. Hence these experiments were abandoned.

Photoaddition of Ethyl Azidoformate to Norbornylene

A mixture of norbornylene (10 g, 0.106 mol) and 1.12 g (10 mmol) of ethyl azidoformate in 50 ml of cyclohexane in a Vycor apparatus with water-cooled central finger was irradiated in a Rayonet photoreactor using lamps with peak emission at 254 nm. After 4 h irradiation at approximately 20 °C the theoretical amount of nitrogen had evolved. The solvent was removed on a rotating evaporator and the residue analyzed by g.l.c. on a OS-138 column. The two main products were cyclohexyl urethane (20%) and aziridine **5** (59%). Ethyl urethane (11%) and seven other minor components were detected. However, no *N*-ethoxycarbonyl norbornylamine (**33**) or dicyclohexyl were detected.

The photolysis was repeated with the same ethyl azidoformate concentration but only 1.7 mmol of norbornylene. The rate of nitrogen evolution was unchanged but the ratio of peak areas of aziridine **5** to cyclohexyl urethane was now 1:1.

Acetophenone-photosensitized Decomposition of Ethyl Azidoformate

A mixture of 1 g (1 mmol) of ethyl azidoformate, 7.1 g (1.2 mmol) of norbornylene and 1.82 g (1.5 mmol) of acetophenone in 80 ml of cyclohexane was irradiated in a Pyrex vessel using a Rayonet photoreactor with lamps with peak emission at 350 nm. In 48 h gas evolution had stopped after 92% of the theoretical amount of nitrogen had been collected. Neither direct irradiation nor heating of the product resulted in evolution of more nitrogen. After removal of the solvent the residue was partially separated on a column of alumina (25-fold, activity II). Pentane eluted a mixture of dicyclohexyl, 2-cyclohexylnorbornane (**34**), norbornylene dimer (**35**), and acetophenone. Ether eluted a mixture of ethyl urethane, norbornanone, and acetophenone, followed by *N*-ethoxycarbonyl cyclohexylamine, then *N*-ethoxycarbonyl norbornylamine **33**. The pentane eluate was further separated by chromatography on a 25-fold ratio of alumina, activity I. The early eluates contained the hydrocarbon products almost free of acetophenone.

N-Ethoxycarbonyl-2-exo-norbornylamine 33

This was an oil with ν_{max} 3445 and 1705 cm^{-1}. Its ^1H n.m.r. spectrum had a triplet centered at δ 1.23 (CH_2CH_3), a broad 2H singlet centered at 2.22 (bridgehead hydrogens), a 6-line multiplet centered at 3.50 which collapsed to a 4-line signal on D_2O – *p*-toluenesulfonic acid exchange, a quartet centered at 4.12 (CH_2CH_3), and a broad singlet (NH) at 4.5. Its mass spectrum had peaks at *m/e* 79, 82, 90, 93, 94, 95, 102, 110, 115, 128, 154, 168, and 183 (M^+).

Anal. Calcd. for $C_{10}H_{17}NO_2$: C, 65.54; H, 9.35; N, 7.64. Found: C, 65.71; H, 9.27; N, 7.56.

It proved identical (i.r., ^1H n.m.r.) to an authentic specimen prepared from 2-*exo*-norbornylamine.

2-Cyclohexylnorbornane 34

This had ν_{max} 1453 cm^{-1} and its n.m.r. spectrum contained a broad peak (2H) centered at δ 2.18. Its mass spectrum at 10 eV had peaks at *m/e* 67, 81, 82, 95, 96, 109, 121, 122, 135, 149, and 178 (M^+).

Anal. Calcd. for $C_{13}H_{22}$: C, 87.56; H, 12.44. Found: C, 87.45; H, 12.30.

Norbornylene Dimer 35

This hydrocarbon from the photosensitized reaction had ν_{max} 1482, 1458, 1270, and 1190 cm^{-1}. Its n.m.r. spectrum contained a broad (2H) peak centered at δ 2.22, and its mass spectrum had peaks at *m/e* 79, 80, 81, 105, 159, and 188 (M^+).

Hydrolysis of 7

The aziridine 7 (2.5 g) in dioxane–water (60 ml) (1:2, v/v) was sealed under N_2 in a pressure tube and heated at 180° for 16 h. The tube was cooled, opened, the reaction mixture adjusted to p*H* 6, and evaporated to near dryness. The residue was suspended in water and made basic with potassium carbonate (12 g). The reaction was then kept at 0° while a solution of benzoyl chloride (10 g) in 15 ml of dioxane was added dropwise. After vigorous stirring for 16 h the mixture was diluted with water, the volume reduced by half to eliminate the dioxane, then the basic aqueous solution extracted with ether. The ether contained 4.6 g of viscous benzoate and dibenzoate mixture.

This mixture was separated by chromatography on activity I neutral alumina (32×). The readily eluted products (ether) were partially hydrolyzed to give a mixture of the hydroxybenzamide **12***a* and *N*-benzoyl nortricyclylamine. This mixture was separated on activity II neutral alumina (30×).

The more strongly adsorbed products from the first chromatogram proved to be a mixture of **12***a* and two minor components, which also analyzed for monobenzoates, in yields of 8 and 1%. The components could be separated by very careful rechromatography on a 40-fold ratio of alumina activity II. It was found more convenient to partially separate the components on alumina, then separate each main fraction using high pressure liquid chromatography (Waters Associates) on a Porasil A column, length 4 ft diameter 0.375 in. and elution with 2% MeOH–$CHCl_3$ (4 ml/min). In this way very pure samples of the three hydroxybenzamides were obtained.

The total yield of 7-*syn*-benzamido-3-*exo*-hydroxynorbornane was 81% and of *N*-benzoyl nortricyclylamine was 8%.

7-syn-Benzamido-2-exo-benzoyloxynorbornane

When recrystallized from benzene this had m.p. 151–152 °C and ν_{max} 3460 (med), 1720 (str), 1660 (str), 1607 (wk), 1583 (wk), and 1520 cm^{-1} (str). Its n.m.r. spectrum contained a complex set of signals (6H) between δ 1.0

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

and 2.3, a broad 2H singlet at 2.64, a broad 1H doublet at 4.35, a broad 1H multiplet at 5.26, and a series of peaks (10H) between 7.1 and 8.4.

Anal. Calcd. for $C_{21}H_{21}NO_3$: C, 75.20; H, 6.31; N, 4.18. Found: C, 75.25; H, 6.45; N, 3.83.

7-syn-Benzamido-2-exo-hydroxynorbornane ***12a***

This was recrystallized from acetone–hexane, m.p. 144–145°, yield, 81%. It had ν_{max} 3590 (wk), 3380 (med), 1640 (str), 1580 (med), 1530 (str), 1490 (med), 1183 (med), 1145 (wk), 1110 (wk), 970 cm^{-1} (wk). Its n.m.r. spectrum had two fairly sharp singlets at δ 0.967 and 1.10, a broad 1H singlet at 2.19, a broad 1H singlet at 2.42, a broad 2H multiplet centered at 4.12, a broad 1H (—O*H*) singlet at 4.82, a set of signals between 7.2 and 8.1 (5H), and a broad 1H (—N*H*) doublet centered at 8.45.

Anal. Calcd. for $C_{14}H_{17}NO_2$; C, 72.70; H, 7.41; N, 6.06. Found: C, 72.43; H, 7.29; N, 5.95.

7-syn-Benzamidonorbornane-2-one ***26a***

When recrystallized from methanol this melted at 200°. It had ν_{max} 3360 (med), 3420 (med), 1740 (str), 1660 (str), 1300 (wk), 1275 cm^{-1} (wk). Its n.m.r. spectrum had a series of peaks (6H) between δ 1.3 and 2.5, three broad 1H singlets at 2.74, 3.02, and 4.25, a broad (1H, —N*H*) multiplet at 6.75, and a series of peaks (5H) between 7.25 and 8.15.

Anal. Calcd. for $C_{14}H_{15}NO_2$: C, 73.34; H, 6.59; N, 6.11. Found: C, 73.07; H, 6.69; N, 6.37.

Cyclic Carbamate ***13***

A solution of 7-*syn*-amino-2-*exo*-hydroxynorbornane **9** (270 mg) in benzene (5 ml) and triethylamine (300 mg) was prepared. The solution was cooled to 0° and ethyl chloroformate (900 mg) was added slowly while stirring. The reaction was then left overnight at room temperature. The precipitate was filtered and the filtrate reduced to a syrup (392 mg). This was dissolved in ethanol and stirred vigorously with potassium carbonate (1 g) for 5 h at room temperature to hydrolyze the 2-ethoxycarbonyl function. The mixture was then diluted with water, evaporated to remove the alcohol, the aqueous solution extracted with methylene chloride, dried, and evaporated to dryness. The resulting hydroxy carbamate (340 mg) was dissolved in dioxane (15 ml), sodium hydride (300 mg) was added, and the mixture was refluxed overnight. The mixture was then evaporated to dryness and the solid residue (190 mg) carefully washed with benzene. When recrystallized from ethyl acetate – methanol the product had m.p. 165–166°; mol wt. 158 (osmometry). It had ν_{max} 3450 (wk), 3250 (wk), 3120 (wk), 1710 (str), 1363 (wk), 1133 (med), 1095 (med), 1040 (wk), 1024 (med), 1004 (wk), 985 (wk), 970 (wk) 952 cm^{-1} (wk). Its n.m.r. spectrum had a series of peaks (8H) between δ 0.8 and 3.2, a broad 1H singlet at 3.37, a broad 1H doublet (J = 5 Hz) at 4.34, and a broad (1H, –N*H*) singlet at 7.04.

Anal. Calcd. for $C_8H_{11}NO_2$: C, 62.72; H, 7.24; N, 9.14. Found: C, 62.66; H, 7.25; N, 9.14.

The cyclic carbamate could be reconverted to the original hydroxybenzamide.

7-anti-Benzamido-2-exo-hydroxynorbornane

This was sublimed at 120°/10^{-2} mm, m.p. 158–159°, yield 8%. It had ν_{max} 3500 (wk), 3410 (wk), 1675 (str), 1578 (med), 1515 (wk), 1485 (wk), 1445 (wk), 1372 cm^{-1} (med str). Its n.m.r. spectrum had a 2H singlet at δ 2.40 and a 1H singlet at 2.46 which exchanged with D_2O, a broad 1H multiplet at 3.86, a broad 1H doublet collapsing to a broad singlet on D_2O exchange and becoming a sharp singlet at 4.33 when exchanged with D_2O–H^+, and a series of peaks (5H) between 7.1 and δ 7.9.

Anal. Calcd. for $C_{14}H_{17}NO_2$: C, 72.70; H, 7.41; N, 6.06. Found: C, 72.81; H, 7.53; N, 6.10.

2-exo-Acetoxy-7-anti-benzamidonorbornane

This derivative was recrystallized from methanol–pentane, m.p. 113–115°. It had ν_{max} 3440 (wk), 1720 (str), 1655 (str), 1580 (wk), 1450 (med), 1420 (str), 1250 (str), 1070 (med), 1015 cm^{-1} (wk). Its n.m.r. had a series of peaks (6H) between δ 1.0 and 1.9, a sharp 3H singlet (O—CH_3) at 1.96, a broad 2H singlet at 2.35, a broad 1H doublet at 4.21 collapsing to a singlet on D_2O acid exchange, a broad 1H multiplet at 4.57, a broad 1H doublet (—N*H*) at 6.14, and a series of peaks (5H) between 7.1 and 7.9.

7-anti-Benzamidonorbornane-2-one ***27***

This compound was sublimed at 110°/10^{-2} mm, m.p. 150–152°. It had ν_{max} 3440 (wk), 3330 (wk), 1745 (str), 1660 (str), 1602 (wk), 1580 (wk), 1510 (str), 1485 (str), 1300 (med), 1270 (med str), 1165 (med str), 1070 cm^{-1} (med). Its n.m.r. spectrum had a broad singlet (2H) at δ 2.77, a broad doublet (1H) at 4.22, collapsing to a sharp singlet after exchange with D_2O–H^+, a broad 1H doublet (—N*H*) at 6.55, and a series of peaks (5H) between 7.1 and 7.9.

Anal. Calcd. for $C_{14}H_{15}NO_2$: C, 73.34; H, 6.59; N, 6.11. Found: C, 73.35; H, 6.74; N, 6.16.

2-endo-Benzamido-3-hydroxynorbornane

After sublimation at ~130°/10^{-2} mm this had m.p. 184–185°. It had ν_{max} 3600 (v wk), 3520 (wk sh), 3450 (med), 1650 (str), 1605 (wk), 1580 (med str), 1510 (str), 1485 (str), 1310 (wk), 1290 (med), 1012 cm^{-1} (med).

Anal. Calcd. for $C_{14}H_{17}NO_2$: C, 72.70; H, 7.41; N, 6.06. Found: C, 72.54; H, 7.37; N, 6.01.

2-endo-Benzamidonorbornane-3-one ***29***

After sublimation at 110–112°/10^{-2} mm this had m.p. 170–171°. It had ν_{max} 3420 (wk), 1750 (str), 1645 (str), 1605 (wk), 1585 (wk), 1525 (str), 1475 (str), 1340 (v wk), 1320 (v wk), 1305 (wk), 1298 (wk), 1275 (wk), 1160 (v wk), 1140 (v wk), 1080 cm^{-1} (med). Its n.m.r. spectrum had a broad 1H singlet at δ 2.72, a broad 1H singlet at 3.14, a 1H triplet centered at 4.24 which collapses to a doublet (J = 5 Hz) on exchange with D_2O–H^+, a broad 1H singlet (—N*H*) at 6.51, and a series of peaks (5H) between 7.1 and 8.0.

Anal. Calcd. for $C_{14}H_{15}NO_2$: C, 73.34; H, 6.59; N, 6.11. Found: C, 73.51; H, 6.67; N, 6.13.

Compound **29** proved identical (mixed m.p., mass spectrum, and i.r. spectrum) with a sample prepared in low yield by benzoylation of authentic 2-*endo*-amino-norbornan-3-one (21).

Nortricyclylamine Derivatives

The *O*-methyl oxime of nortricyclanone (4 g) was dissolved in dioxane (50 ml) and while cooling and stirring, $LiAlH_4$ (2 g) was added in small portions. After the addition was completed, the mixture was left at room temperature for 15 min and then refluxed for 1 h. After

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

that time, it was cooled, methanol was added carefully followed by a saturated Na_2SO_4 solution. The precipitate was filtered, the filtrate acidified to congo red using perchloric acid, then evaporated to dryness. The residue crystallized from MeOH, m.p. 204–206°.

Anal. Calcd. for $C_7H_{12}ClNO_4$: C, 40.02; H, 5.77; N, 6.69. Found: C, 39.74; H, 5.86; N, 6.72.

The *N*-benzoyl derivative was prepared. This crystallized from methanol – ethyl acetate, m.p. 150–151°. Its n.m.r. had a sharp 3H singlet at δ 1.25, a broad 1H singlet at 2.20, a broad (1H–C_3) doublet centered at 4.07 which collapses to a singlet upon exchange of the —NH (δ 6.32) with D_2O–acid, and aromatic protons (5H) centered at 7.75. It has ν_{max} 3445 (wk), 1655 (str), 1510 (str), 1485 cm^{-1} (str).

Anal. Calcd. for $C_{14}H_{15}NO$: C, 78.84; H, 7.09; N, 6.57. Found: C, 78.98; H, 7.06; N, 6.66.

Stability of Nortricyclylamine

The amine was treated under the same conditions as for the aziridine ring opening. The recovered base was benzoylated giving a quantitative recovery of *N*-benzoyl amine.

*2-exo-Amino-3-hydroxynorbornanes **15** and **16***

Addition of dinitrogen tetroxide in ether at −5° to norbornene following Shechter *et al.* (20), followed by overnight hydrolysis by stirring with aqueous sodium bicarbonate gave a mixture of dinitro compound and nitro alcohols. The water solution of the nitro alcohols was extracted with ether in a continuous extractor. A mixture of the nitro alcohols (6.2 g) was reduced in acetic acid by hydrogen over platinum (from 180 mg PtO_2) during 36 h. Work-up gave 5.9 g of a crystalline mixture of amino alcohols **15** and **16**.

*2-exo-Benzyloxycarboxamido-3-endo-hydroxynorbornane **17***

A mixture of the amino alcohols **15** and **16** (5.9 g) in 40 ml of 1:1 dioxane–water containing 5 g of sodium hydroxide was stirred vigorously overnight with 3 ml of benzyl chloroformate. The product was extracted into ether, then the ether washed with water, dried, and distilled. Chromatography on a 25-fold ratio of alumina (activity III) and elution with progressively increasing percentages of benzene in hexane gave benzyl alcohol, the hydroxyurethane **17** as an oil, followed by the cyclic carbamate **18**. The hydroxyurethane was distilled at a bath temperature of 105–125°/0.03 mm.

Anal. Calcd. for $C_{15}H_{19}NO_3$: C, 68.94; H, 7.33; N, 5.36. Found: C, 69.12; H, 7.49; N, 5.46.

*2-exo-Benzyloxycarboxamidonorbornan-3-one **20b***

Jones' reagent (28) (2.5 ml) was added slowly to a solution of 2-*exo*-benzyloxycarbonamido-3-*endo*-hydroxynorbornane **17** in 50 ml of acetone at 0°. After 30 min stirring at 0° the excess oxidizing agent was reduced with methanol. The bulk of the acetone was removed under reduced pressure, water added, and the product extracted into ether. The 760 mg of crystalline product was sublimed *in vacuo* then recrystallized from hexane. It was dimorphic, m.p. 104–107° (blades) and 110–112° (needles). It had ν_{max} 3430 (—NH) (med), 1758 (str), 1725 (str), 1505 (str), 1250 (str), 1060 cm^{-1} (med), and its n.m.r. spectrum had a series of signals (6H) between δ 2.10 and 1.25, a broad 2H multiplet at 2.6 (bridgehead hydrogens), a broad 1H quartet at 3.55 collapsing to a doublet (J = 2.8 Hz) after exchange with D_2O–HCl, a sharp (2H, —O—CH_2—φ) singlet at 5.08, a broad (1H, N—*H*) doublet at 5.32 collapsing to a broad singlet upon exchange with D_2O–HCl, and a sharp (5H, C_6H_5) singlet at 7.29.

Anal. Calcd. for $C_{15}H_{17}NO_3$: C, 69.48; H, 6.61; N, 5.40. Found: C, 69.47; H, 6.67; N, 5.50.

*Cyclic Carbamate **18***

2-Benzamido-3-hydroxynorbornane **23** (512 mg) and 0.5 g of potassium hydroxide were dissolved in 10 ml of methanol. The solution was refluxed under nitrogen for 16 h, cooled, acidified using hydrochloric acid, then evaporated to small volume. The residue was diluted with water and extracted with methylene chloride to remove unchanged amide. The aqueous layer was made alkaline with a large excess of potassium carbonate, then benzyloxycarbonyl chloride (1 g) added dropwise with vigorous stirring. Stirring was continued for 2 h, then the product extracted into methylene chloride, and recrystallized from *n*-hexane–$CHCl_3$ to give m.p. 136–137°. It had ν_{max} ($CHCl_3$) 3465 (med), 3260 (wk), 1745 (str), 1140 (wk), 1050 cm^{-1} (med). Its n.m.r. spectrum had a series of peaks (6H) between δ 0.9 and 2.0, a broad 1H singlet at 2.25, a broad 1H singlet at 2.46, a pair of 1H doublets (J = 7 Hz) at 3.68 (C-3) and 4.50 (C-2), and a broad (1H, N*H*) singlet at 6.88.

Anal. Calcd. for $C_8H_{11}O_2N$: C, 62.72; H, 7.24; N, 9.14. Found: C, 62.62; H, 7.19; N, 9.04.

This proved identical to the readily eluted product from the carbobenzoxylation of the mixture of **15** and **16**.

*1-Trimethylsilyloxynorbornene **19***

A solution of 2.5 g of norbornan-2-one in ether at 0° was added slowly with stirring under nitrogen to a suspension of potassium triphenylmethide in ether until the red color disappeared. Fresh salt and ketone were added until the norbornanone had been converted to enolate. Then 5.5 ml of trimethylsilyl chloride was added dropwise during 10 min at 0°. After 30 min of stirring the mixture was filtered under nitrogen pressure, the ether distilled then the product distilled in a chain of bulbs at 80°/0.3 mm, giving 4.13 g (77%) of the trimethylsilyl ether. Its n.m.r. spectrum contained a sharp 9H singlet at δ 0.11, a broad 1H singlet at 2.45, a broad 1H singlet at 2.67, and 1H doublet (J = 3.2 Hz) centered at 4.55.

Anal. Calcd. for $C_{10}H_{18}OSi$: C, 65.88; H, 9.93. Found: C, 66.03; H, 9.86.

*Conversion of **19** into **20b***

A solution of 365 mg (2 mmol) of **19** and 742 mg (4 mmol) of *N*-chlorobenzylcarbamate in 5 ml of chloroform was cooled to −78° in a carbon dioxide atmosphere. A methanol solution of 8 mmol of chromous chloride, which had been stirred with powdered calcium carbonate, was added to this under carbon dioxide during 1 h at −78°. The reaction mixture was stirred for an additional 10 min in the cold, allowed to warm to room temperature, then diluted with water. The products were extracted into methylene chloride, then separated on preparative thin-layer plates developing with 1:2 ether–hexane mixture. The 58 mg of crude **20b** after recrystallization had m.p. 108–110° and proved identical by mixture m.p. and comparison of n.m.r. spectra with the product of oxidation of **17**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

7-Benzyloxycarboxamidonorbornan-2-one 26b

Following Beckmann and Geiger (22) the lactone **24** was converted to the keto acid **25** m.p. 121–122°. This (427 mg) was converted to its sodium salt which was carefully dried, suspended in 10 ml of hexane, and converted to the acid chloride by cautious addition of 0.5 ml oxalyl chloride in hexane. The solvent and excess oxalyl chloride were removed under reduced pressure then the acid chloride distilled over a short path at 110°/10 mm. It gave a single sharp peak on g.l.c. analysis on an SE-30 column.

The acid chloride (178 mg) was dissolved in dry acetone, then added with vigorous stirring to an ice-cold solution of 1 g of sodium azide in 5 ml of water. After 2 h stirring at 0° sodium carbonate was added and the product extracted into pentane. After evaporation of the pentane below room temperature, 80 mg of acyl azide remained. This was dissolved in 2 ml of benzyl alcohol and heated at 100° for 1 h. After removal of the benzyl alcohol *in vacuo* the 7-benzyloxycarbonyl derivative **26b** had n.m.r. and i.r. spectra identical to those of the benzyloxycarboxamido ketone prepared from **9** via **12b**.

2-exo-Benzamido-3-exo-hydroxynorbornane 23

Following Huisgen *et al.* (9), the *N*-benzoyl aziridine **21** was prepared from norbornylene and benzoyl azide. This rearranged in 20 min at 240° under nitrogen into the previously described Δ^2-oxazoline **22**. Alkaline hydrolysis (KOH in refluxing methanol; see however ref. 9) failed to open this. The Δ^2-oxazoline (14.6 g) in 50 ml of 2 *N* sulfuric acid was refluxed for 4 h. The solution was diluted with 100 ml of water and extracted with methylene chloride, giving 3.7 g of starting material. The aqueous solution was basified using potassium hydroxide then extracted with chloroform. The benzamido alcohol **23** recovered from this (11 g) after recrystallization from ethyl acetate had m.p. 114–115° (lit. (9) m.p. 114.5°). It had ν_{max} 3600, 3410, and 1640 cm^{-1} and gave n.m.r. signals at δ 2.32 (broad 2H doublet) and a 2H triplet (?) centered at 3.9.

2-exo-Benzamidonorbornan-3-one 20a

An acetone solution (10 ml) of 1.3 g of the benzamido alcohol **23** was cooled to 0°. Jones' reagent (28) was added dropwise with stirring at 0° until excess oxidant persisted for 15 min. The reaction mixture was evaporated under reduced pressure, the residue taken up in water, and the solid product collected by filtration. The 1.02 g of solid, m.p. 180° was recrystallized from methanol–chloroform mixtures to give 453 mg, m.p. 209–211°. It had ν_{max} 3280, 1755, and 1635 cm^{-1}.

Anal. Calcd. for $C_{14}H_{15}NO_2$: C, 73.34; H, 6.59; N, 6.11. Found: C, 73.20; H, 6.71; N, 5.97.

2-exo-Amino-3-exo-hydroxynorbornane 16

This was prepared by hydrolysis of hydroxybenzamide **23** with sodium hydroxide in aqueous methanol at 160°. The free base had m.p. 93.5–94° after sublimation *in vacuo*.

Anal. Calcd. for $C_7H_{13}NO$: C, 66.10; H, 10.30; N, 11.01. Found: C, 65.99; H, 10.48; N, 10.89.

Its hydrochloride after recrystallization from methanol – ethyl acetate had m.p. 242°.

Anal. Calcd. for $C_7H_{14}ClNO$: C, 51.37; H, 8.56; N, 8.63. Found: C, 51.54; H, 8.49; N, 8.63.

Received September 16, 1974

PIERRE COLSON, KEITH N. SLESSOR, H. J. JENNINGS, and IAN C. P. SMITH. Can. J. Chem. **53**, 1030 (1975).

Complete assignments of the carbon-13 n.m.r. spectra of the following compounds in aqueous solution are presented: 6-chloro-6-deoxy-D-glucose, 6-*O*-methyl-D-glucose, ribitol, glucitol, 4-*O*-methyl-glucitol, maltose, maltitol, 6,6′-dichloro-6,6′-dideoxymaltose, 6′-chloro-6′-deoxymaltose, isomaltose, isomaltitol, and 6′-chloro-6′-deoxyisomaltose. Some earlier assignments for maltose are reversed. Chlorination on the exocyclic carbon of the glucopyranose ring usually results in a substantial decrease in the chemical shift of the substituted carbon (−17 p.p.m.) and the next-nearest carbon (−1.2 p.p.m.); methylation leads to an increased chemical shift for the contiguous carbon (+10 p.p.m.) and only small changes for other carbons in the molecule. The response to 4-*O*-methylation in glucitol is opposite for C-3 (+0.7 p.p.m.) and C-5 (−0.8 p.p.m.) demonstrating that response of a particular carbon to substitution at a neighboring carbon depends upon the configuration of the particular carbon. Dissolution of these compounds in pyridine results in a bunching together of resonances which makes unambiguous assignments very difficult. The data for this series of compounds are useful in assigning the more complex spectra of microbial polysaccharides.

PIERRE COLSON, KEITH N. SLESSOR, H. J. JENNINGS et IAN C. P. SMITH. Can. J. Chem. **53**, 1030 (1975).

Nous présentons l'attribution complète des spectres de résonance magnétique nucléaire en carbone-13 des composés suivants étudiés en solution aqueuse: 6-chloro-6-désoxy-D-glucose, 6-*O*-methyl-D-glucose, ribitol, glucitol, maltose, maltitol, 6,6′-dichloro-6,6′-didésoxymaltose, 6′-chloro-6′-désoxymaltose, isomaltose, isomaltitol et 6′-chloro-6′-désoxyisomaltose. Certaines attributions antérieures du maltose sont inversées. La chloruration du carbone exocyclique de l'anneau glucopyranose conduit généralement à une diminution importante du déplacement chimique du carbone substitué (−17 p.p.m.) et de son voisin le plus proche (−1.2 p.p.m.); par contre, la méthylation provoque une augmentation importante du déplacement chimique du carbone substitué (+10 p.p.m.) sans influencer de façon notoire les autres carbones de la molécule. La méthylation en position 4 du glucitol est différemment ressentie par les carbones adjacents (C-3, +0.7 p.p.m.; C-5, −0.8 p.p.m.). Ceci démontre que la stéréochimie des carbones adjacents à un carbone substitué peut différencier leur comportement lors d'une substitution. La mise en solution de ces composés dans la pyridine conduit à un resserrement des résonances et l'attribution de certaines d'entre elles reste ambiguë. Les données de cette série de composés sont utiles pour attribuer les spectres plus complexes de polysaccharides microbiens.

Introduction

Simple carbohydrates have been studied extensively by ^{13}C n.m.r. (1). Numerous investigations have been devoted to glucose and related compounds (2–14) and to complex carbohydrates containing these residues (15–20). Nearly all the resonances of glucose have been resolved and assigned, particularly by the study of the influence of *O*-methylation (5–7, 10–12), *O*-acetylation (6, 10), and deuterium incorporation (2, 12, 13). Cyclic and acylic polyol spectra have also been assigned (14, 21–22). Recently, the influence of methylation on the ^{13}C chemical shifts of galactose derivatives and galactitols has been reported (23–24).

We describe here the usefulness of chlorinated and polyol derivatives of glucose and related disaccharides in the assignment process. The correlations deduced here can be used to resolve difficult assignments and related problems of other carbohydrates, such as sialic acid, which is composed of a cyclic sugar and an acyclic

polyol (20) and polymers containing glycerol side chains.

Experimental

Nuclear magnetic resonance spectra were obtained on a Varian XL-100-15 (sample tubes of outside diameter 12-mm, 32°) or a Varian CFT-20 (10-mm tubes, 30°) spectrometer with complete proton decoupling. Chemical shifts were measured relative to tetramethylsilane in a sealed concentric tube of outside diameter 5 mm and are expressed as increasingly positive with increasing frequency (decreasing field) from the resonance of Me_4Si. Differences in susceptibility correction between the 12- and 10-mm tubes were less than the experimental accuracy of 0.1 p.p.m. and were neglected. Carbohydrate samples were 100 mg/ml in neutral deuterium oxide.

Paper chromatographic analysis was carried out on Whatman No. 1 filter paper using the following solvent system: butan-1-ol, pyridine, water (6:4:3, v/v) and the mobilities of the components are given relative to that of D-glucose (R_{Glc} 1.0).

4-*O*-Methyl-D-glucose was prepared by the method of Kenner and Richards (25) and 6-*O*-methyl-D-glucose by the hydrolysis of 6-*O*-methyl-α-D-glucopyranoside (26). 4-*O*-Methyl-D-glucitol was prepared by the sodium borohydride reduction of 4-*O*-methyl-D-glucose.

Maltose and isomaltose were commercial samples used without further purification and maltitol and isomaltitol were obtained by the sodium borohydride reduction of the respective reducing disaccharides using standard procedures.

6,6′-Dichloro-6,6′-dideoxy maltose was prepared in the following way. Maltose (5 g) was treated with sulfuryl chloride and pyridine by a procedure previously described for the synthesis of fully chlorosulfated pentapyranosyl chlorides (27). In the case of maltose due to the presence of exocyclic primary hydroxyl groups specific chloro substitution of these groups occurred to yield syrupy 6′,6-dichloro-6′,6-dideoxymaltosyl chloride 2′,2,3′,3,4′-pentachlorosulfate (10.2 g, 80%). Additional 4′-chloro substitution, which normally occurs when the product of this reaction is isolated at ambient temperature (28), was avoided by the low-temperature isolation (−10 to 0°) of the product. The syrupy pentachlorosulfate (5 g) was treated with sodium iodide in aqueous acetone (29) and the resultant solution was deionized and concentrated to yield a syrup (1.5 g; 69.4%) which was shown to be homogeneous by paper chromatographic analysis (R_{Glc} 2.6) and had $[\alpha]_D$ +99.6° (*c*, 2.0 in water). Hydrolysis of the syrupy product (*N* sulfuric acid at 100° for 16 h) gave only 6-chloro-6-deoxy-D-glucose (R_{Glc} 2.5), which was characterized as its known crystalline peracetate derivative (30).

6′-Chloro-6′-deoxyisomaltose was prepared by an identical procedure to that described above. From isomaltose (0.5 g), syrupy 6′-chloro-6′-deoxyisomaltose was obtained in an overall yield of 58% (0.29 g). The product was homogeneous by paper chromatographic analysis (R_{Glc} 1.1) and hydrolysis (*N* sulfuric acid at 100° for 16 h) yielded both glucose and 6-chloro-6-deoxyglucose (paper chromatographic analysis). Recently, 6-chloro-6-deoxy-D-glucose has also been synthesized by this procedure and this preparation will be reported in detail in a subsequent communication (31).

6′-Chloro-6′-deoxymaltose was prepared according to the method of Melton and Slessor (32).

Results and Discussion

Glucose and Related Derivatives

In order to study derivatives of maltose and isomaltose chlorinated at C-6, it was first necessary to assign the resonances of the analogous monomer, 6-chloro-6-deoxy-D-glucose. In Table 1, its resonances are compared to those of glucose and 6-*O*-methyl-D-glucose. We are in agreement with the published assignments for these compounds (4, 10, 11). However, we could resolve two resonances due to C-6 in each of D-glucose and 6-chloro-6-deoxy-D-glucose and assign them to the α- and β-anomer species by taking into account the relative populations of the two anomers, as manifest in the C-1 resonances. We also distinguished between the C-2 and C-5 resonances in 6-*O*-methyl-β-D-glucose because no chemical shift effect is expected on C-2 due to methylation of C-6. Thus, the peaks at 75.9 and 75.5 p.p.m. are assigned to C-5 and C-2, respectively. The chlorination effect on the contiguous carbon occurs in the sense opposite to that of methylation and is considerably larger (*ca.* −17 and +10 p.p.m. displacements for chlorination and methylation, respectively). Qualitatively, these effects can be foreseen taking into account that the replacement of a substituent by a more polar group causes an upfield shift of the carbon bearing this substituent (33). In fact, we substitute an —OH group by an $—OCH_3$ or —Cl group and the order of polarity is —Cl > —OH > $—OCH_3$. If we refer to the ^{13}C chemical shifts observed in the alkanes (34), a −17 p.p.m. displacement is expected when a chlorine is substituted for a hydroxyl group. This comparison with alkanes is reasonable as the substitution is done on the exocyclic carbon. Chlorination at C-6 of glucose results in better resolution of the resonances due to this carbon in the two anomers (0.1 and 0.5 p.p.m. in D-glucose and 6-chloro-6-deoxy-D-glucose, respectively). The effect on the nearest neighbor carbon, a so-called β-effect, of the two substituents is nearly equivalent, −1.2 p.p.m., in the two anomers. As previously observed (4, 5), methylation usually produces negligible effects beyond the nearest neighbor carbon. However, a chemical shift change of +0.6 p.p.m. is observed on C-4 of the two anomers.

†Uncertainty concerning relative assignments.
‡Differentiation based on the more important influence of 4-*O*-methylation on the resonance of C-3 than on that of C-2.
§Resonance of methyl group at C-4.

equivocal distinction between the C-2″ and C-4″ resonances can be made at present because they differ in chemical shift by so little (0.2 p.p.m.). However, regardless of the assignment, comparison of the chemical shifts of C-2″ of glucitol (72.2 or 72.4 p.p.m.) with that of ribitol (73.4 p.p.m.) demonstrates a *ca.* 1 p.p.m. influence of reversing the configuration of a neighboring carbon atom in a polyol. The peak at 63.7 p.p.m. can be attributed to C-6″ of glucitol, the conformational environment of which is more similar to those of C-1″ and C-5″ of ribitol than to that of C-1″ of glucitol (64.0 p.p.m.). Of the two possible assignments for C-3″ and C-5″ of glucitol (70.9 and 74.1 p.p.m.), that in Table 2 is chosen because it minimizes the difference in chemical shift between C-5″ of glucitol and C-2″ of ribitol which it closely resembles. In 4-*O*-methyl-D-glucitol, the methylation effect is greatest on C-4″, +10.4 p.p.m. It is of considerable interest to note that the effects of methylation at C-4″ are approximatly equal in magnitude but opposite in sign for C-3″ (+0.7 p.p.m.) and C-5″ (−0.8 p.p.m.) due to the different relative positions of the hydroxyl groups of C-3″ and C-5″ with respect to the substituent on C-4″. As no significant geminal effect, a so-called γ-effect, is foreseen, the resonance at 72.4 p.p.m. for 4-*O*-methyl-D-glucitol must be due to C-2″, whereas those at 63.9 and 63.5 p.p.m. are unambiguously attributable to C-1″ and C-6″ carbons, respectively. The resonance at 61.0 p.p.m. is assigned to the *O*-methyl group by reference to the derivatives of glucose methylated on the ring (5, 11, 19).

Glucobioses and Related Compounds

Maltose (O-α-D-Glucopyranosyl-(1 → 4)-O-α-D-glucopyranose)

Assignment of the ^{13}C n.m.r. spectrum of maltose (Fig. 2) has been previously attempted (9–11). Numerous uncertainties remain in the data of Voelter *et al.* (9) and a significant difference in chemical shift is present for all the resonances with respect to those given by other authors, due to the choice of an indirect chemical

For personal use only.

shift reference. The assignments of C-3α and C-3β made by Dorman and Roberts (10) have to be interchanged with those of C-5α and C-5β to be consistent with the assignment of 4-*O*-methyl-D-glucose and methyl 4-*O*-methyl-α-D-glucopyranoside previously given (11, 19). As seen in Table 2, our assignment of the maltose resonances agrees very well with those of Usui *et al.* (11). In some cases, we were able to obtain better resolution for some resonances. Taking into account the relative intensities of these resonances, the peaks at 78.3 and 78.1 p.p.m. can be assigned to C-4α and C-4β, respectively, and the C-6 peaks at 62.0, 61.8, and 61.7 p.p.m. to C-6α, C-6β, and C-6′, respectively. Finally, the two peaks at 74.4 and 74.1 p.p.m. are due to C-3α and C-3′, respectively.

The maltitol assignment (Fig. 2) can be facilitated by considering that the reducing glucose unit of maltose is replaced by 4-*O*-methyl-D-glucitol. This direct comparison shows that only C-1′ differs by more than 0.5 p.p.m. with respect to the additive spectra of the constituents. This change of chemical shift by +0.8 p.p.m. demonstrates the relative effects of substitution of a glucopyranose ring by a polyol aliphatic chain or by another glucose residue. Turning to the glucitol moiety, C-4″ is displaced by +0.4 p.p.m. more on substitution with a glucosyl residue than with a methyl group. A corresponding difference of 0.3 p.p.m. exists for C-2″ and C-5″, whereas the influences of methyl and glycosyl substitution on C-3″ are equal. This underlines again the observation that the response on neighboring carbon chemical shifts to substitution depends on the orientation of their substituents relative to those of the carbon being substituted. All other resonances in the comparison correspond. Thus, the C-6′ resonance situated at 61.6 p.p.m. confirms our previous assignment of this carbon in maltose.

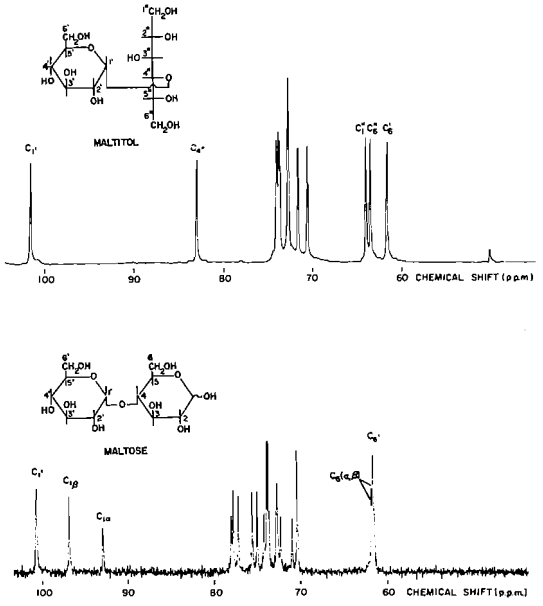

FIG. 2. ^{13}C n.m.r. spectra of maltitol and maltose, 100 mg/ml in D_2O, 32°, p*D* 7.0, spectral width 2.5 KHz, 6K data points, cycle time 1.2 s, pulse angle 45°, 21 900 and 7700 transients for maltitol and maltose, respectively.

Chlorination of C-6′ of the nonreducing unit of maltose is not expected to produce changes in the chemical shifts of reducing unit carbons, as seen in Table 2. This substitution could be expected to produce displacements of the chemical shifts of C-4′, C-5′, and C-6′, by comparison of 6-chloro-6-deoxy-α-D-glucose with α-D-glucose. However, account must be taken that the nonreducing unit is actually a glycoside. The increased shielding of C-6′ by 16.3 p.p.m. on chlorination is comparable to that observed in glucose (α, −16.1 p.p.m.; β, −16.7 p.p.m.) but a corresponding effect on C-5′ is not found. The glycosidic link at C-1′ must be responsible for this decreased sensitivity. The small displacements of C-2′ and C-3′ by −0.4 and −0.5 p.p.m., respectively, are mainly due to the chlorination effect, as well as the +0.7 p.p.m. change in chemical shift of C-4′ (Table 2).

In the dichlorinated derivative, we expect effects in the nonreducing moiety similar to those found for 6′-chloro-6′-deoxymaltose. This is generally true, including the absence of an effect of chlorination on the chemical shift of C-5′ and the decreased shielding of C-4′ (Table 2). The reducing end is comparable to glucose with the complication of a linkage at C-4. The changes in chemical shift of C-6 (α, −15.9 p.p.m.; β, −16.2 p.p.m.) are comparable to those found for 6-chloro-6-deoxy-D-glucose (Table 1). Similarly, an increased shielding is found for C-5 (α, −1.5 p.p.m.; β, −1.7 p.p.m.), in contrast to the anomalous behavior of the nonreducing end. This predicted behavior for the C-5 resonances confirms our proposed alteration of the assignments of Dorman and Roberts (10). The distinction between the C-6 resonances of the α- and β-anomers of the reducing end is enhanced relative to maltose as was found for glucose.

Isomaltose (O-α-D-Glucopyranosyl-(1 → 6)-α-D-glucopyranose)

We agree with the assignments of Usui *et al.* (11) for isomaltose itself, except that we were able to resolve more resonances, including those of C-2β and C-5β (75.3 and 75.5 p.p.m., respectively). However, the resonance region between 74.3 and 70.8 p.p.m. has to be discussed. Of the two signals at 70.8 and 71.3 p.p.m. (relative intensities 149 to 42, respectively), C-4′ must be assigned to the former, as this is the only signal of sufficient intensity to accommodate a complete carbon signal (based on an average relative intensity of 90 per carbon signal in the spectrum). The resonances of C-4α and C-4β must also be located at or in close proximity to the C-4′ signal as it has been demonstrated that C-4 of glucose derivatives exhibits little sensitivity to either anomeric change or C-6 substitution (Table 1). In addition the C-5α resonance must also be located in this region as model compounds indicate almost identical chemical shifts for C-4α, C-4β, and C-5α (Table 1). The resonance at 71.3 p.p.m. is too intense to accommodate C-5α alone which should have an approximate relative intensity of 30 based on the intensity of C-5β and the known ratio of the two anomers. Therefore two interpretations are consistent with the intensity data for the C-4α, C-4β, and C-5α signals. The signal at 71.3 p.p.m. can be assigned either to both C-4α and C-5α or to C-4β. This leaves the signal at 70.8 p.p.m. assignable to C-4β or to both C-4α and C-5α, respectively. Finally, by comparison with maltose, the C-3′ and C-3α resonances are positioned at 74.3 p.p.m. and the C-2α resonance at 73.0 p.p.m. The peaks at 73.25 and 72.7 p.p.m. are assigned to C-2′ and C-5′. As reported earlier (16, 19), the passage from the (α-1 → 4) to the (α-1 → 6) linkage has induced a change of −1.5 p.p.m. in the position of the C-1′ resonance, of −7 p.p.m. for the two C-4 resonances of the reducing moiety, and of +5 p.p.m. for the two resonances of the linked C-6 of the reducing moiety. This information is all necessary for the assignment of isomaltitol.

The assignment of isomaltitol is achieved by comparison of its spectrum with that of maltitol and by taking into account the different kind of linkage in isomaltitol (α-1 → 6). Thus, in the cyclic unit, the C-1′ and C-2′ resonances must be displaced relative to their values in maltitol. They undergo displacements of −2.1 and −0.5 p.p.m., respectively (similar to the corresponding differences between maltose and isomaltose). In the polyol chain, the substitution at C-6″ of the glucitol entity results in displacement of C-6″ and C-5″ by +6.2 and −1.0 p.p.m., respectively, whereas the other resonances are essentially unchanged from the values in glucitol. These effects are responsible for the chemical shift differences between C-3″, C-5″, and especially C-4″ in isomaltitol and maltitol, and aid in confirming the assignments between 74.2 and 70.7 p.p.m. in Table 3. Finally, the C-6″ resonance of the polyol chain is logically positioned at 69.9 p.p.m. Indeed, a carbon resonance is less shielded if linked to a methyl group or to an aliphatic chain than if linked to another ring (19). Replacement of the glucose ring by an aliphatic chain modifies the C-1′ resonance less in the (α-1 → 6) than in the (α-1 → 4) linkage (0.2 and 0.8 p.p.m., respectively). This is suggestive of the conformational influence on chemical shifts detected when comparing the relatively rigid cyclodextrins with linear (α-1 → 4) homopolymers or oligomers of glucose (19), and is due mainly to the extra degree of freedom in the linked C-6 moiety of a disaccharide relative to a linked C-4, C-3, or C-2.

In 6-′chloro-6′-deoxyisomaltose, the positions of the C-1, C-6, C-2β, C-3β, and C-5β resonances are well defined. As expected, the C-6′ resonance is the only one to undergo a drastic change in chemical shift on chlorination, −16.3 p.p.m. with respect to isomaltose. The region between 74.3 and 70.6 p.p.m. must again be discussed in greater detail. By comparison with isomaltose and isomaltitol, the C-3α and C-3′ resonances are located at 74.3 and 74.0 p.p.m., respectively, taking into account their relative intensities, whereas the C-2′ and C-2α resonances must be at 72.6 p.p.m. because they are not expected to change on chlorination of C-6′. On the other hand, the resonance at 71.9 p.p.m. can be assigned to C-5′, which undergoes an expected high-field shift. The four resonances between 71.4 and 70.6 p.p.m. (C-4α, C-4β, C-4′, C-5α) are assigned according to their relative intensities: 71.4 p.p.m. to the nonreducing end, 71.1 and 70.7 p.p.m. to the α-carbons, and 70.6 p.p.m. to a β-carbon of the reducing end. An uncertainty remains in the relative assignments of 71.1 and 70.7 p.p.m. for C-4α and C-5α.

The Influence of Dissolution in Pyridine

*Uncertainty concerning relative assignments.

studied in pyridine solution. Pyridine was chosen because some chlorinated carbohydrates are only sparsely soluble in water. In pyridine the resonances cluster closely together and unambiguous assignments cannot be made without parallel studies of specifically-deuterated compounds. Therefore the data are not reported in detail but are available upon request.

Variable Temperature Nuclear Magnetic Resonance Studies of Some Five-Membered Ring Chelate Complexes

WILLIAM R. CULLEN, LAURANCE D. HALL, AND JOHN E. H. WARD[1]

Department of Chemistry, University of British Columbia, Vancouver, British Columbia V6T 1W5

Received September 16, 1974

WILLIAM R. CULLEN, LAURANCE D. HALL, and JOHN E. H. WARD. Can. J. Chem. **53**, 1038 (1975).

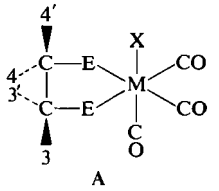
The temperature dependence of the n.m.r. spectra of nine ditertiary arsine chelate complexes of formula $(CH_3)_2AsC(3)(3')C(4)$ $(4')As(CH_3)_2M(CO)_3X$ has been studied (M = Mo, Cr; X = CO; M = Mn; X = halogen; (3), (3'), (4), (4') = H, F, $Si(CH_3)_3$, CN; but not all combinations). Significant variation in coupling constants, indicating a shift in the conformer populations, was found only for the $CHFCF_2$ bridged $Mn(CO)_3Cl$ complex, the CH_2CF_2 bridged $Mn(CO)_3Cl$ complex, and the CHFCHF bridged $Mo(CO)_4$ complex. In the last case the $^3J_{HH}$ coupling constants were used to estimate $\Delta H \sim 1$ kcal/mol and $\Delta S \sim 3$ e.u for the conformational equilibrium.

WILLIAM R. CULLEN, LAURANCE D. HALL et JOHN E. H. WARD. Can. J. Chem. **53**, 1038 (1975).

On a étudié, en fonction de la température les spectres r.m.n. de neuf complexes contenant une arsine ditertiaire comme chelate et possédant la formule $(CH_3)_2AsC(3)(3')C(4)$ $(4')As(CH_3)_2M(CO)_3X$ dans lesquels (M = Mo, Cr; X = CO; M = Mn; X = halogène, (3), (3'), (4), (4') = H, F, $Si(CH_3)_3$, CN; toutes les combinaisons n'ont toutefois pas été étudiées). D'une façon générale les constantes de couplage étaient semblables; toutefois on trouve des changements importants, indiquant une variation dans les populations de conformères, pour le complexe du $CHFCF_2$ ponté au $Mn(CO)_3Cl$, pour le complexe de CH_2CF_2 ponté au $Mn(CO)_3Cl$ et pour le complexe de CHFCHF ponté au $Mo(CO)_4$. Dans le dernier cas les constantes de couplage $^3J_{HH}$ ont été utilisées pour établir la valeur de $\Delta H \sim 1$ kcal/mol et $\Delta S \sim 3$ e.u pour l'équilibre conformationnel. [Traduit par le journal]

Introduction

We have completed several investigations (1–4) of the conformational preferences of five-membered chelate rings in octahedral transition metal complexes of the general type **A**, where M = Cr, Mo, W, or Mn; E = $As(CH_3)_2$ or $P(CH_3)_2$; X = Cl, Br, or I (for M = Mn)



A

or CO (for M = Cr, Mo, W); and 3, 3', 4, and 4' are substituents such as: H, F, Cl, CN, and $Si(CH_3)_3$. It was shown that a "bulky" substituent such as a trimethylsilyl group prefers the "equatorial" orientation on the puckered five-membered chelate ring, whereas a fluorine substituent frequently prefers the "axial" orientation (1–4). On the other hand, certain substituents such as a chloro or cyano group do not seem to strongly favor a particular orientation. In ideal cases, the changes in the puckering of the chelate rings arising from variations in the transition metal and *cis* (axial) substituents could be roughly predicted (3, 4).

In an attempt to derive further conformational information for these systems we have carried out variable temperature n.m.r. experiments on nine selected chelate complexes. The present paper is concerned with the results of these studies.

Experimental

All the chelate complexes used in this study were prepared by methods which we have already described (1–4).

The n.m.r. spectra were obtained using an extensively modified Varian HA-100 spectrometer and were recorded in the frequency sweep mode on carefully calibrated charts, using TMS as the internal reference. Computer analyses of the n.m.r. spectra were obtained

with an IBM 360-67 computer and a modified version of the LAOCOON III program.[2]

Table 1 lists the chelate complexes **1–9** examined in this work.

Results and Discussion

The chemical shifts and coupling constants obtained by iterative computer analysis of the n.m.r. spectra of **1–9** are summarized in Tables 2 and 3, respectively. Specific details of the spectral analysis of these derivatives have been presented elsewhere (1–4).

Theory

A number of results (6–8) indicate that the energy differences between conformers of five-membered chelate rings are small. It has been shown (9) that the energy barriers to conformational inversion of these rings are also small. Thus, all conformations determined by the n.m.r. method should be subject to some degree of time averaging. Thus a single specific conformation cannot be assigned, although it may be that in some instances one section of the pseudo-rotational cycle is extensively populated (6, 7, 10, 11). Because of the experimental techniques we are using, we can discuss only those conformers which involve rotation about the carbon–carbon bond of the ethane bridge.

It is sometimes assumed for compounds undergoing dynamic intramolecular processes in solution that the n.m.r. parameters of the protons or fluorines in the individual isomers are temperature invariant (12). Usually, this assumption leads to no serious errors on the calculation of exchange rates and thermodynamic data, provided that the protons or fluorines change equally. However, it has been demonstrated (13) for rigid molecules such as the difluorethylenes that the proton chemical shifts, ^1H–^{19}F, and ^{19}F–^{19}F coupling constants may exhibit a substantial temperature dependence, while the geminal and vicinal ^1H–^1H coupling constants are essentially temperature invariant. Thus caution should be used in interpreting the data obtained from variable temperature n.m.r. studies of dynamic systems and an attempt should be made to separate the changes arising from inherent temperature dependences from those arising from alterations in the dynamic equilibrium (14).

Chelate Ring Conformational Preferences

Complexes of the Ligands $(CH_3)_2AsCH_2$-$CHXAs(CH_3)_2$ (X = $Si(CH_3)_3$, CN, F)

We have shown previously (1) that the vicinal ^1H–^1H coupling constants of the trimethylsilyl derivative **1** indicate that the bulky trimethylsilyl group adopts the equatorial orientation on the ethane bridge as in **B**, rather than the axial position as in **C** at 34°.

[a]The vicinal ^1H–^1H coupling constants obtained at 90° differ by < 0.2 Hz from those obtained at 34°.
[b]The vicinal ^1H–^1H coupling constants obtained at 100° differ by < 0.2 Hz from those obtained at 34°.
[c]The vicinal ^1H–^1H coupling constants obtained at 120° differ by < 0.5 Hz from those obtained at 34°.
[d]Signals arising from the CH_2 and CF_2 groups are triplets, Σ^3J_{HF} = 72 Hz. Negligible changes in the triplet spacings (^1H n.m.r. spectrum, in $CDCl_3$) were observed on cooling the sample to −50°.
[e]^{19}F n.m.r. spectrum not recorded.
[f]The vicinal ^1H–^1H coupling constant obtained at −20° differs by < 0.5 Hz from that obtained at 80°.
[g]The vicinal ^1H–^{19}F coupling constants obtained at 95° differ by < 0.5 Hz from those obtained at 34°.

We now find that the n.m.r. spectrum of **1** at 90° shows that although the chemical shifts of the three vicinal protons change from those obtained at 34° the vicinal ^1H–^1H coupling constants do not vary appreciably. This result indicates a strong preference for conformer **B** and we conclude that the ground state energy of that conformer is substantially lower than that of **C**. Calculations on the related 1,2-propanediamine chelate ring reveal that the conformer with the methyl group in the axial orientation is 0–3 kcal/mol higher in energy than the conformer with the methyl group in an equatorial orientation (6). A more recent report indicates that this difference is *ca.* 2.5 kcal/mol (8).

The cyano derivative **2** probably undergoes some degree of conformational inversion between **D** and **E** (1, 3). While the vicinal ^1H–^1H coupling constants indicate that form **D** is preferred, the relative proportions of **D** and **E** can apparently be changed by solvent variations (3). The present variable temperature n.m.r. studies reveal only small changes between the $^3J_{HH}$ values obtained at 34 and 100°. Thus, it appears that conformer **D** is highly populated at least in nitrobenzene solution.

In contrast, the vicinal ^1H–^1H and ^1H–^{19}F coupling constants of the monofluoro complex **3** unexpectedly revealed a strong preference for the fluoro substituent to adopt the axial orientation on the five-membered chelate ring (1) as in **F**.

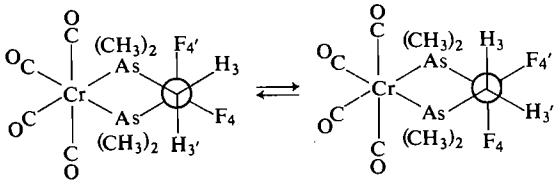
The ^1H n.m.r. spectrum at 120° shows that the vicinal ^1H–^{19}F coupling constants do not vary appreciably from those obtained at 34°. Thus the fluoro substituent strongly prefers the axial orientation on the five-membered chelate ring as in **F**.

Complexes of $(CH_3)_2AsCH_2CF_2As(CH_3)_2$

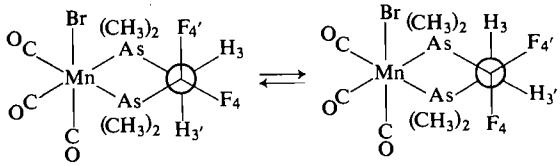
The appearance of the ^1H n.m.r. spectrum of the methylene region of the geminal-difluoro chromium complex **4** as a triplet suggested that inversion between two conformers is occurring rapidly on the n.m.r. time scale as in **H**. If the



H

rate of the equilibrium reaction could be slowed down on the n.m.r. time scale, an ABXY spectrum would arise from the individually "locked" conformers. However, when the sample was cooled to −50°, only very small changes in the ^1H n.m.r. spectrum of **4** were observed and we thus conclude that the equilibrium reaction **H** is occurring quite rapidly on the n.m.r. time scale, which is not unexpected.

For the geminal-difluoro bromo manganese complex **5**, two distinct conformers **I** and **J**

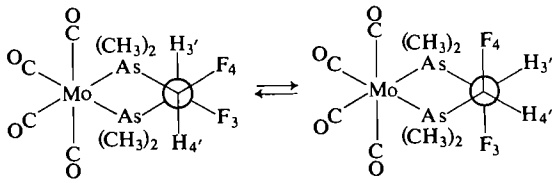


I **J**

are possible. We have previously found that the vicinal ^1H–^{19}F coupling constants of **5** are markedly solvent dependent (4) indicating that the equilibrium between **I** and **J** is being shifted by changes in the solvent. To check this conclusion, we obtained the ^1H n.m.r. spectrum of **5** at 80°. This reveals substantial changes in the $^3J_{HF}$ values. For example J_{34} decreases by *ca.* 3 Hz from 42.0 to 39.4 Hz, while $J_{3'4}$ increases by *ca.* 1 Hz, from 14.9 to 16.2 Hz. Thus, it seems that, (*i*) there is indeed an equilibrium between **I** and **J**, (*ii*) the changes in the vicinal ^1H–^{19}F coupling constants due to solvent variations are *not* due to the inherent solvent dependences of those coupling constants, and (*iii*) the equilibrium is shifted by varying the temperature or the solvent. Unfortunately, since the $^3J_{HF}$ values of the individual locked conformers **I** and **J** should be approximately the same, we cannot deduce which conformer is favored with the increase in temperature.

Complexes of $(CH_3)_2AsCHFCHFAs(CH_3)_2$

The vicinal ^1H–^1H and ^1H–^{19}F coupling constants of the vicinal-difluoro molybdenum complex **6** exhibit a marked sensitivity to temperature changes. We have already interpreted the ^3J values obtained at ambient probe temperature for this complex in terms of a dynamic equilibrium between conformers **K** and **L** (3).



K **L**

Since the vicinal ^1H–^1H coupling constants increase with decreasing temperature, we conclude that **K** is the low energy form of **6** since that conformer contains the two protons in a mutually *trans* orientation. Because all the vicinal coupling constants obtained at 69° are equal, within the experimental error (±0.1 Hz), to these obtained at 89°, it appears that the high temperature limit has been attained at 69°. Thus at that and higher temperatures, the equilibrium consists of equal proportions of **K** and **L**.

If it is assumed that (*i*) the inherent temperature dependence of the vicinal ^1H–^1H coupling constants is negligible (13), (*ii*) conformers **K** and **L** have the same dihedral angles, and (*iii*) simple Karplus relationships (15, 16) apply to both **K** and **L**, *i.e.* they have the same Karplus coefficients, we can derive an estimate of the enthalpy difference between **K** and **L** as follows.

$$[1] \qquad {}^3J_{HH} = A\cos^2\phi \qquad 0 \le \phi \le 90°$$

$$[2] \qquad = B\cos^2\phi \qquad 90 \le \phi \le 180°$$

If ϕ is the dihedral angle and θ the in-plane projection of the "tetrahedral" angles (assumed to be 120° (15, 17)) about the ring carbon atoms as in **M**, we can derive expressions for the

TABLE 4. Thermodynamic data for the equilibrium **K** = **L**

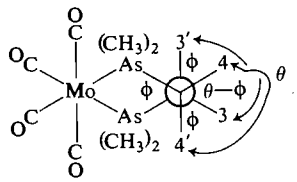
vicinal ^1H–^1H coupling constants of the individual conformers **K** and **L**.



M

[3] $$^3J_{HH}(trans, \mathbf{K}) = B\cos^2(\theta + \phi)$$

[4] $$^3J_{HH}(gauche, \mathbf{L}) = A\cos^2\phi$$

Expressing the observed vicinal ^1H–^1H coupling constants, $^3J_{obs}$, as a sum of the contributions from the conformers **K** and **L**

[5] $$^3J_{obs} = X\,^3J_{HH}(trans, \mathbf{K}) + (1 - X)\,^3J_{HH}(gauche, \mathbf{L})$$

where X is the fractional population of **K**, and solving for X we find

[6] $$X = \frac{^3J_{obs} - {}^3J_{HH}(gauche, \mathbf{L})}{^3J_{HH}(trans, \mathbf{K}) - {}^3J_{HH}(gauche, \mathbf{L})}$$

The equilibrium constant K for **K** = **L** is $(1 - X)/X$, and thus

[7] $$K = \frac{^3J_{HH}(trans, \mathbf{K}) - {}^3J_{obs}}{^3J_{obs} - {}^3J_{HH}(gauche, \mathbf{L})}$$

Substituting eqs. 3 and 4 into eq. 7 yields:

[8] $$K = \frac{B\cos^2(\theta + \phi) - {}^3J_{obs}}{^3J_{obs} - A\cos^2\phi}$$

If we now assume that $A = 0.9B$ (3, 18) and $\phi = 55°$, as was revealed by X-ray determinations of a variety of related derivatives (19) and calculations based on the vicinal coupling constants of analogous complexes (3, 4), the equilibrium constant can be expressed as

[9] $$K = \frac{B\cos^2(175°) - {}^3J_{obs}}{^3J_{obs} - 0.9B\cos^2(55°)}$$

In order to obtain an estimate for B, we can solve eq. 9 for the high temperature limit (69°), where $^3J_{obs} = 8.1$ Hz and $K = 1$. This calculation yields a value of 12.6 Hz for B which is similar to those of carbocyclic systems (20, 21). Thus it seems that the electron donating properties of the two dimethylarsino groups are apparently almost equally offset by the electron withdrawing properties of the fluorine atoms.

We can now use this value of B in eq. 9 to determine the equilibrium constants K for the process **K** = **L**. These values are assembled in Table 4, together with the calculated values of ΔG and X. A plot of ΔG *vs.* T is shown in Fig. 1. Linear regression analysis of the data for this plot yields eq. 10.

[10] $$\Delta G = -2.94T + 997$$

where

$$r = 0.998$$

Thus, ΔH for the equilibrium is *ca.* 1 kcal/mol, while ΔS is *ca.* +3 e.u. The small value of ΔH is entirely consistent with our expectations that the energy barriers to conformational inversion in five-membered chelate rings are very small.

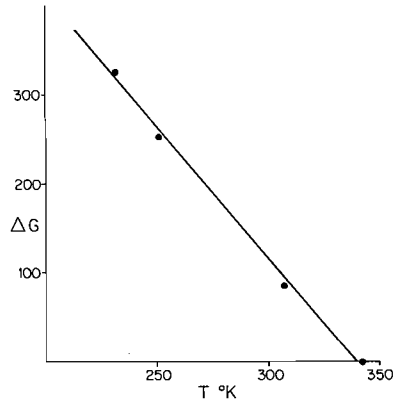


FIG. 1. Plot of ΔG *vs.* T for the variable temperature ^1H n.m.r. study of $(CH_3)_2AsCHFCHFAs(CH_3)_2$-$Mo(CO)_4$ **6**.

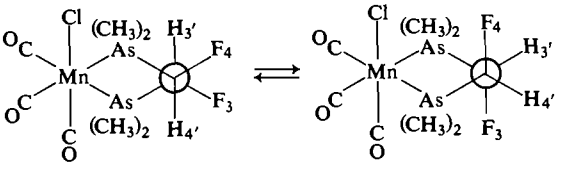
The slight deviation of the points from the line described by eq. 10 may arise from the failure of the Karplus coefficients for **K** and **L** to remain the same. Recent evidence (22–25) indicates that the assumption that they are the same may not be valid.

In the case of the analogous chloro manganese derivative **7** the vicinal ^1H–^1H coupling constants do not vary appreciably when the ^1H n.m.r. spectrum of the sample was taken at 80°. Thus, we conclude that the conformer with the two protons *trans* to one another, as in **N**, is highly favored relative to **O**, the conformer with a *gauche* proton–proton orientation.

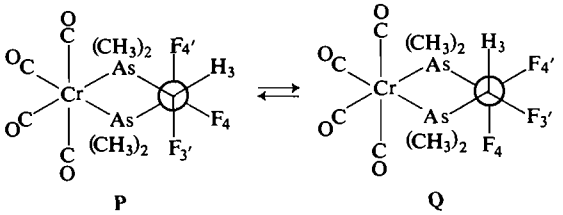


N **O**

Thus, for both **6** and **7** the low energy conformation is the form with mutually *trans* protons. Apparently the dipolar and/or steric interactions of the *cis*-chloro and single carbonyl ligand with the five-membered ring in **7** differ significantly from those interactions of the two *cis*-carbonyls with the chelate ring in **6**.

Complexes of $(CH_3)_2AsCHFCF_2As(CH_3)_2$

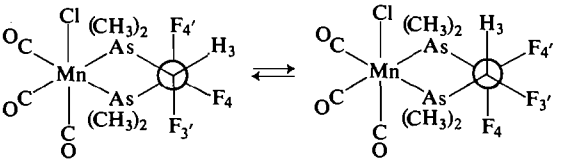
The ^1H and ^{19}F n.m.r. parameters obtained at 34° for the trifluoro chromium complex **8** (3) indicate a major preference for two of the fluorine atoms to have the axial orientation as in **P**. The vicinal ^1H–^{19}F coupling constants



P **Q**

obtained from the ^1H n.m.r. spectrum at 95° do not appear appreciably different so the preference for **P**, which has two axial fluorine atoms, seems quite marked.

In contrast with the chromium trifluoro derivative **8** (4), the conformer of the trifluoro manganese complex **9** with the hydrogen in the axial position in **S**, has an appreciable population in equilibrium with **R** at 34°. This conclusion is based on the observations (3, 4) that one of the *gauche* ^1H–^{19}F coupling constants (*ca.* 26 Hz) in **9** is substantially higher (*ca.* 15 Hz) than that in **8**. This is probably conformationally significant since Karplus coefficients of the ethane bridge are not particularly sensitive to changes in the transition metal or its *cis*-axial ligands (3, 4). However, since the dihedral angles in the chelate rings may differ in **8** and **9** such an interpretation is not unequivocal. Our variable temperature n.m.r. studies show that the two vicinal ^1H–^{19}F coupling constants in **9** are indeed temperature sensitive: J_{34} increases from 25.3 to 27.0 Hz when the temperature is lowered from 145 to −12°, while $J_{34'}$ decreases from 7.4 to 6.7 Hz. Since the temperature dependences of these vicinal ^1H–^{19}F coupling constants are opposite, it appears that the changes observed are not due to the inherent temperature dependence of the $^3J_{HF}$ values for the individual conformers **R** and **S**. Thus, we may interpret these coupling constant changes in terms of a dynamic equilibrium between **R** and **S**. It is tempting to carry a discussion of this dynamic process further by estimating the thermodynamic parameters for this equilibrium; however, since we are unable to unambiguously assign the vicinal constants to particular nuclei, such calculations would necessarily have a restricted value. Nevertheless, since the changes observed are relatively small for a wide temperature range, we infer that the energies of conformers **R** and **S** are quite similar.



R **S**

Thus, it seems that the steric and/or dipolar interactions of the trifluoro chelate rings in **9** differ significantly from those in the chromium analog **8**. We have already noted a similar difference between the vicinal difluoro analogs **6** and **7**.

It is a pleasure to thank the National Research Council of Canada for its generous financial support of this work in the form of operating grants to L.D.H. and W.R.C., and the Alfred P. Sloan Foundation for a research fellowship to L.D.H.

The Crystal Structure of Dimedone

ISHWAR SINGH
Department of Chemical Technology, Mohawk College, Hamilton, Ontario L9C 1G1
AND
CRISPIN CALVO
Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

Received June 12, 1974

ISHWAR SINGH and CRISPIN CALVO. Can. J. Chem. **53**, 1046 (1975).

Dimedone, $C_8H_{12}O_2$, crystallizes with monoclinic symmetry, $a = 10.079(7)$, $b = 6.835(3)$, $c = 12.438(4)$ Å, $\beta = 110.24(5)°$, space group $P2_1/n$ and $Z = 4$. The structure of this compound was solved by direct methods and refined by full-matrix least-squares techniques using 1205 unique reflections to a final R of 0.047. In the solid state it exists in the enolic form and these molecules pack in the crystal in systems of infinite chains linked together by hydrogen bonds in the y direction. These results are virtually the same as recently reported by Semmingsen.

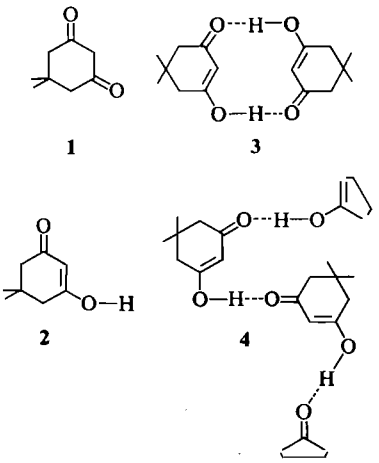
ISHWAR SINGH et CRISPIN CALVO. Can. J. Chem. **53**, 1046 (1975).

Le dimédon, $C_8H_{12}O_2$, cristallise avec une symétrie monoclinique $a = 10.079(7)$, $b = 6.835(3)$, $c = 12.438(4)$ Å, $\beta = 110.24(5)°$, groupe d'espace $P2_1/n$ et $Z = 4$. On a résolu la structure de ce composé par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) utilisant 1205 réflections uniques jusqu'à une valeur finale de R de 0.047. A l'état solide, le dimédon existe sous forme énolique et les molécules s'arrangent dans le cristal dans un système de chaines infinies liées entre elles par des ponts hydrogène dans la direction y. Ces résultats sont pratiquement les mêmes que ceux rapportés récemment par Semmingsen.

[Traduit par le journal]

Introduction

Dimedone, also known as 5,5-dimethylcyclohexane-1,3-dione, methone, or 5,5-dimethyldihydroresorcinol, can exist in the form of keto (**1**), enol (**2**), dimeric enol (**3**), and polymeric enol (**4**) structure as shown below.



Studies in solution by infrared spectroscopy (1, 2) and C^{13} n.m.r. spectrometry (3) show the presence of both the keto and enol forms in different concentrations and under different conditions. But in the solid state dimedone can exist either in the dimeric or polymeric enol form. The dimeric enol form does not seem very probable from the geometric considerations. This study was undertaken to determine the structure in the solid state by single crystal X-ray diffraction method. While this report was in the hands of the referees a report of the structure of dimedone appeared (4). Since both results appear to be of comparable quality a detailed comparison seemed advisable.

Experimental

A crystal of dimedone having approximate dimensions $0.05 \times 0.03 \times 0.03$ cm^3 was used for all the X-ray measurements. The space group was uniquely determined as $P2_1/n$ from systematic absences (conditions limiting possible reflections: $h00$, $h = 2n$; $0k0$; $k = 2n$; $00l$, $l = 2n$; $h0l$, $h + l = 2n$). Crystal data are as follows:

$C_8H_{12}O_2$ f.w. = 140

Monoclinic, $a = 10.079(7)$, $b = 6.835(3)$, $c = 12.438(4)$ Å, $\beta = 110.24(5)°$, $V = 803.94$ Å^3 at $T = 25$ °C. $Z = 4$, $D_x = 1.15 \pm 0.05$ g/cm^3 (20 °C), $\lambda(MoK_{\bar{\alpha}}) = 0.71069$.

The dimensions of the unit cell were obtained from a least squares refinement of 13 values of 2θ measured with $MoK_{\bar{\alpha}}$ radiation using a P$\bar{1}$ Syntex automatic diffrac-

tometer. A total of 1205 unique reflections lying in the range $0 < 2\theta \leq 55°$ were measured on this diffractometer using graphite monochromatized $MoK_{\bar{\alpha}}$ radiation. Reflections were scanned in the θ–2θ mode at a rate between 2 and 24° per minute depending on the peak intensity. Backgrounds were recorded on either side of the peak and used to determine the integrated intensity together with an estimated standard deviation based upon counting statistics. Those reflections whose intensity were less than 3σ, 473 in number, were regarded as unobserved. The data were corrected for Lorentz and polarization effects but not absorption. The XRAY-71 package of programs for X-ray crystallography published by the University of Maryland as adopted for use with the CDC 6400 by H. D. Grundy were used for all computations.

The positions of 8 carbon atoms and two oxygen atoms were determined from the E map after the phases of reflections were determined by the direct method (5). These initial positions were refined with their individual isotropic temperature factors and a scale factor. This yielded a minimum R of 0.13. The atomic scattering curves were obtained from the International tables for X-ray crystallography (6). A difference electron density map at this stage revealed the positions of all the 12 hydrogen atoms of the dimedone molecule. Further refinements were carried out, using anisotropic temperature factors for the nonhydrogen atoms and isotropic temperature factors for the hydrogen atoms. Weights were given by $\omega = [0.6520 - 0.1420F_o + 0.0110F_o^2]^{-1}$. These weights were chosen so that $\omega|F_o - F_o|^2$ would locally be independent of F_o, the observed structure factor. The unobserved reflections were weighted as the observed and were also included in the refinement. The final refinement resulted in a minimum R of 0.047 and $R\omega = [\Sigma\omega|F_o - F_c|^2/\Sigma\omega|F_o|^2]^{1/2}$ equal to 0.045. The average shift/error in the final cycle of refinement and the standard deviations of an observation, $[\Sigma\omega|F_o - F_c|^2/(m - n)]^{1/2}$, were 0.097 and 0.49 respectively. A final difference Fourier map contained no more electron density variations than ± 0.34 e/Å^3. The final atomic parameters are listed in Table 1 and the observed and calculated structure factors are in Table 2.[1] A list of the bond lengths and angles with standard deviations calculated from the standard errors derived from the least-squares matrix is given in Table 3.

Description of the Structure

A view of the molecule is seen in Fig. 1. It is found that the structure of dimedone is of enol form in the solid state. In the enolic form atoms O1, C1, C2, C3, and O2 are coplanar with H6 −0.14 Å and C5 0.53 Å out of this plane. The negative deviation for H1 indicates that it is on the opposite side of the plane from C5. A plane defined by H6, O1, and C1 makes an acute angle of 7° with the plane defined by atoms O1, C1, C2, C3, and O2. This allows for increased distance between atoms H6 and H1, thereby decreasing the interaction between them. This is further supported by the fact that angle C1—C2—H1 (Table 3) is 131.4° instead of 120.00° as expected. This may arise from the repulsion between the atoms H6 and H1. Thus it seems that the presence of H6 on the side of C2, as found in this structure, rather than on the side of C6 is not really the preferred orientation but is perhaps necessary for the packing of the dimedone molecule in the solid state. The conformation of the molecule can be best described as an envelope with C5 0.62 Å out of the plane defined by O1, O2, C1, C2, C3, C4, and C6. The plane defined by C4, C5, and C6 makes an angle of 136.14° with the last plane. Deviations from this plane, (*b*) in Table 4, are positive for C1, C2, C3, and C6 and are on the same side as C5 whereas for O1, O2, and C4 they are negative.

The molecules of dimedone attains the polymeric enol structure in the solid state as evidenced by a hydrogen bond of length 1.71(4) Å between the atoms H6 of the asymmetric unit and O2 of the molecule generated by the equivalent positions $-x + \frac{1}{2}$, $y - \frac{1}{2}$, $-z + \frac{1}{2}$ and similarly O2 of the asymmetric unit is bonded through a hydrogen bond to H6 of another molecule related by the equivalent positions $-x + \frac{1}{2}$, $y + \frac{1}{2}$, $-z + \frac{1}{2}$. These chains extend in the y direction thereby allowing the dimedone molecules to pack closely. The bond angle O1—H6....O2 is 167(3)°. However, this nonlinearity is not an exception to the various hydrogen bond angles found in many other compounds (7). The other hydrogen bond lengths and angles are given in Table 5. The intermolecular H6...H1 contact distance is 2.485 Å close to corresponding intramolecular distance of 2.483 Å.

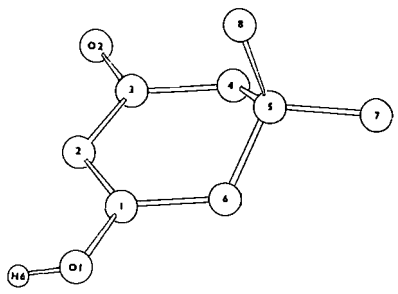

FIG. 1. Molecular structure of dimedone.

*U and U_{ij} have been multiplied by 100. The thermal factor is: $\exp -2\pi^2(U_{11}h^2b_1^2 + \ldots + 2U_{12}hkb_1b_2 + \ldots)$ where b_i are reciprocal vectors.
†These are the corresponding parameters from ref. 4.

Comparisons of Two Structures

The structure of dimedone reported by Semmingsen (4) is in $P2_1/c$ space group, with cell dimensions $a = 10.040(1)$, $b = 6.823(1)$, $c = 12.984(2)$ Å, $\beta = 116.20(1)°$ which on transformation to space group $P2_1/n$ does not change a and b but $c = 12.421(2)$ and $\beta = 110.20(1)°$ at 18 °C. These lattice parameters values differ from those in the present report because of the difference in temperature. We have determined the cell dimensions at different temperatures to find that the a, b, and c axes increase by 0.0012,

0.001, and 0.001 Å respectively per °C rise in temperature. This difference might be reflected in different thermal parameters between the refinements. Hamilton's (8) χ square test and Abraham and Keve's (9) half-normal probability plot can be used to compare the sets of results. This is accomplished by calculating δp_i using the following relationship

$$\delta p_i = ||p(1)_i| - |p(2)_i||/\{\sigma^2 p(1)_i + \sigma^2 p(2)_i\}^{1/2}$$

and then examining the hypothesis that δp_i are drawn from a normal population with unit variance and zero mean by testing $\delta^2 p$, which is equal to $\sum_{i-1}^{N} \delta^2 p_i$, against χ^2 with N degrees of freedom. If the calculated value of $\delta^2 p$ exceeds the tabulated value of $\chi_{N,\alpha}{}^2$, the hypothesis may be rejected with $100\alpha\%$ probability of falsely rejecting a true hypothesis. For half-normal probability plot δp_i values are plotted against the expected values, tabulated by Hamilton and Abrahams (10) for samples of size <41, and for no differences in two sets of data the plot should be a straight line of unit slope and zero intercept. Using this procedure a $\delta^2 p$ value of 49.87 for the 30 nonhydrogen positional parameters was calculated. This value falls in between the two tabulated values of $\chi^2_{30,0.05} = 43.77$ and $\chi^2_{30,0.01} = 50.89$. This does not show very significant differences between these sets of parameters. This is further shown by the half-normal probability plot for these positional parameters in Fig. 2. If it is assumed that the line passes through the origin, then a slope of 0.95 is obtained. However, the analysis of variance shows a better line determined by least squares methods with a slope of 0.72 and intercept 0.35. This slight systematic effect is perhaps due to small standard deviations obtained in Semmingsen's results, which in turn is due to 343 more reflections beyond 2θ of 55° collected by him. Similarly hydrogen positional parameters gave a value of $\delta^2 p$ of 141.4 while tabulated value for $\chi^2_{36,0.05}$ is about 51. This significant difference in the two sets can perhaps be ex-

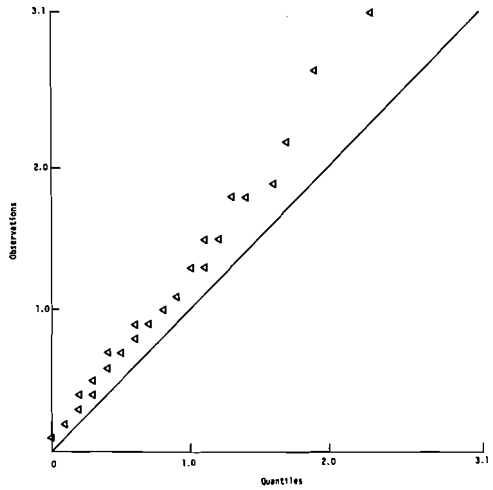

FIG. 2. δp half-normal probability plot.

plained due to different sets of scattering curves used in these two investigations and also in part due to more high angle data collected in the other investigation. As indicated in Table 1 the thermal parameters for the methyl hydrogens in dimedone were not refined by Semmingsen.

The thermal parameters U_{11}, U_{22}, and U_{33} when analyzed for any systematic differences gave 467.7 as the value of $\delta^2 p$ compared to $\chi^2_{30,0.05} = 43.77$. This significant difference probably arises from the different temperatures at which the two data sets were collected and other reasons mentioned above. It is interesting to note that in the earlier investigation of dimedone U_{12} and U_{23} gave values smaller than the present investigation.

Bond lengths and angles from two investigations are given in Table 3. A $\delta^2 p$ value of 12.62 compared to $\chi^2_{10,0105} = 18.31$ for bond lengths of nonhydrogen atoms show no differences at all. A similar analysis for bond angles of these atoms does not show any difference. The only difference of significance is the hydrogen bond angle O1—H6...O2 as noted in Table 5. However, the conformation of the molecule is exactly the same in the two investigations and the structures are of comparable accuracy.

Studies in Solvolysis. Part VI. An Examination of the Heat Capacity of Activation for the Hydrolysis of 4-Methoxybenzyl Trifluoroacetate

JUNE GERTRUDE WINTER, JOHN PATRICK BARRON, AND JOHN MARSHALL WILLIAM SCOTT

Chemistry Department, Memorial University, St. John's, Newfoundland A1C 5S7

Received October 8, 1974

JUNE GERTRUDE WINTER, JOHN PATRICK BARRON, and JOHN MARSHALL WILLIAM SCOTT. Can. J. Chem. **53**, 1051 (1975).

The heat capacity of activation for the hydrolysis of 4-methoxybenzyl trifluoroacetate in water containing 9.05×10^{-2} mol fraction of acetone has been measured and shown to be positive. This unusual result is consistent with the notion that the ester reacts by two distinct routes: one involving acyl–oxygen fission, the other, alkyl–oxygen fission. The relative importance of the two paths for the 4-methoxy ester has been established quantitatively via a Hammett σ–ρ correlation for a series of 4-substituted-benzyl trifluoroacetates. Such an assessment allows the observed heat capacity, entropy, and enthalpy of activation to be factored into parts appropriate to each of the two reaction paths.

JUNE GERTRUDE WINTER, JOHN PATRICK BARRON et JOHN MARSHALL WILLIAM SCOTT. Can. J. Chem. **53**, 1051 (1975).

On a mesuré la capacité calorifique d'activation de l'hydrolyse du trifluoroacétate de méthoxy-4 benzyle dans l'eau contenant 9.05×10^{-2} mol d'acétone; on a trouvé que cette valeur est positive. Ce résultat inattendu est en accord avec le fait que l'ester peut réagir par deux routes distinctes: une impliquant une fission acyle–oxygène et l'autre une fission alkyle–oxygène. En faisant appel à une corrélation σ–ρ de Hammett pour une série de trifluoroacétates de benzyles substitués en position 4, on a pu établir d'une façon quantitative, pour l'ester étudié, l'importance relative des deux chemins. Une telle détermination permet d'attribuer à chacune des deux routes de la réaction les capacités calorifiques, les entropies et les enthalpies d'activation appropriées. [Traduit par le journal]

Introduction

The temperature dependence of the enthalpy of activation ($\Delta C_{p_o}^{\ddagger}$) has been measured frequently for S_N1/S_N2 solvolytic displacements (1, 2). The studies reported by Robertson's group (1) have been largely concerned with displacement reactions in pure water, whereas Kohnstam's group (2) have examined the heat capacity parameter in mixed aqueous solvents. Heat capacities of activation have also been measured for the hydrolyses of carboxylic esters and anhydrides (3–5) which usually react by an acyl–oxygen fission mechanism ($B_{Ac}2$). Both the $B_{Ac}2$ and S_N processes[1] give rise to negative heat capacities of activation. The negative sign appears to be diagnostic of reactions which include the kinetic or equilibrium production of ions from originally neutral reactants. Extensive discussions are available for such kinetic phenomena (1, 2, 6).

[1]The designations 1 and 2 have been purposefully omitted since the present paper attempts no mechanistic distinctions of this sort.

Recently we have examined the rate of hydrolysis of a series of 4-substituted-benzyl trifluoroacetates (7) and we were able to show that the 4-methoxy ester reacts by a mechanism in which alkyl–oxygen fission (S_N) and acyl–oxygen fission ($B_{Ac}2$) contribute almost equally to the observed rate.

Thus for the scheme represented by

[1] Ester $\xrightarrow{k_b}$ Product ($B_{Ac}2$ route); Ester $\xrightarrow{k_s}$ Product (S_N route)

the observed rate constant k_o is related to the $B_{Ac}2$ and S_N rate constants by

$$[2] \qquad k_o = k_b + k_s$$

where the quantity γ is defined by

$$[3] \qquad \gamma = k_s/k_b$$

The observed heat capacity of activation for a reaction proceeding according to the scheme summarized by reaction 1 is given by the readily derived expression

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$[4]\quad \Delta C_{po}^{\ddagger} = \frac{1}{1+\gamma}\Delta C_{pb}^{\ddagger} + \frac{\gamma}{1+\gamma}\Delta C_{ps}^{\ddagger} + \frac{\gamma}{(1+\gamma)^2}\frac{(\Delta H_b^{\ddagger} - \Delta H_s^{\ddagger})^2}{RT^2}$$

where $\Delta C_{pb}^{\ddagger}$ and $\Delta C_{ps}^{\ddagger}$ are respectively the heat capacities of activation for paths B and S, and $\Delta H_b^{\ddagger}$ and $\Delta H_s^{\ddagger}$ are the enthalpies of activation appropriate to the same routes. The other symbols in eq. 4 have their usual significance and the quantity γ is defined in eq. 3.

When γ is close to unity and the quantity $|\Delta H_b^{\ddagger} - \Delta H_s^{\ddagger}|$ is large (the value is *ca.* 15 kcal mol^{-1} in water, see ref. 3) the third term on the r.h.s. of eq. 4 might conceivably outweigh the normally negative values of $\Delta C_{pb}^{\ddagger}$ and $\Delta C_{ps}^{\ddagger}$ to yield a net value of $\Delta C_{po}^{\ddagger}$ which is positive.

The purpose of the present paper is to relate the above analysis of $\Delta C_{po}^{\ddagger}$ for a bifurcated mechanism to the temperature dependence of the enthalpy of activation of 4-methoxybenzyl trifluoroacetate for which the quantity γ has already been shown to approximate unity at 5.05 °C in water containing 1.2×10^{-2} mol fraction of acetone. Clearly the ubiquity of negative heat capacities of activation lends considerable interest to one which is positive in sign. Moreover, such a positive heat capacity of activation would provide further evidence for the bifurcated $S_N/B_{Ac}2$ mechanism proposed for 4-methoxybenzyl trifluoroacetate on the basis of other observations.

Experimental

The 4-substituted-benzyl trifluoroacetates were prepared and their purity established as previously described (7). Acetone was treated with potassium permanganate, dried with anhydrous potassium carbonate, and distilled (b.p. 57.5 °C). Distilled deionized water was used to prepare all solutions.

Kinetics

Rates were measured by conductance in an acetone–water mixture containing 9.05×10^{-2} mol fraction of the nonaqueous component which was added to reduce supersaturation of the substrates. Frequent density measurements were made to monitor and then maintain the composition of the solvent during preparation and use. At twelve of the eighteen temperatures for which rates are recorded for the 4-methoxy ester the density of the solvent (T = 25 °C) was 0.96284 ± 0.00004 g ml^{-1}. The remaining six density measurements averaged at 0.96249 ± 0.00023 g ml^{-1}. The variation of the rate constants arising from changes in solvent composition corresponding to the above range of densities is less than the spread of rate constants at any particular temperature. Hence errors arising from variations in the solvent composition during the course of the work are negligible. A small quantity of trifluoroacetic acid was added to the solvent to reduce the resistance of the solvent to a convenient value. Otherwise the general technique of measuring the rates was similar in most respects to that described in ref. 3. A more detailed description of the apparatus is given elsewhere (8, 9). The rate constants measured for the five esters studied are quoted in Table 1.

The temperature dependence of the rates of hydrolysis for benzyl trifluoroacetate is expressed by

$$[5]\quad \log(k/T) = -1862.7/T + 0.9781$$

in which the coefficient of $1/T$ and the constant term are least squares values. The conversion of

these numerical constants to the pseudothermodynamic quantities, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, was accomplished in the usual way (3). The more extensive study of the 4-methoxy ester gave rates whose temperature dependence could be represented by[2]

$$[6] \quad \log k = 2431.4/T + 45.73537 \log T - 123.7229$$

The numerical coefficients in eq. 6 were determined using a least squares program which is based on some considerations reported by Clarke and Glew (10). The individual rates (not the meaned rates reported in Table 1) were used in the least squares computation. In the present study all but two of the 84 rates measured were accepted by the program. The two rejected rate constants deviated by more than 2.6% from the value calculated from eq. 6. The conversion of the numerical coefficients of eq. 6 to give values of $\Delta H_0^{\ddagger}$ and $\Delta S_0^{\ddagger}$ at any selected temperature and a value of $\Delta C_{p_0}^{\ddagger}$ follows usual practice (1). The value for $\Delta C_{p_0}^{\ddagger}$ was found to be 89 ± 17 cal mol^{-1} deg^{-1}. The relatively large error in the heat capacity of activation from the coefficient of log T in eq. 6 is probably a consequence of supersaturation, a problem which proved to be a significant factor in the hydrolysis of *t*-butyl trifluoroacetate (11). The various thermodynamic quantities derived from the kinetic data are reported in Table 2.

TABLE 2. Thermodynamic parameters for the hydrolysis of 4-methoxybenzyl trifluoroacetate at various temperatures*

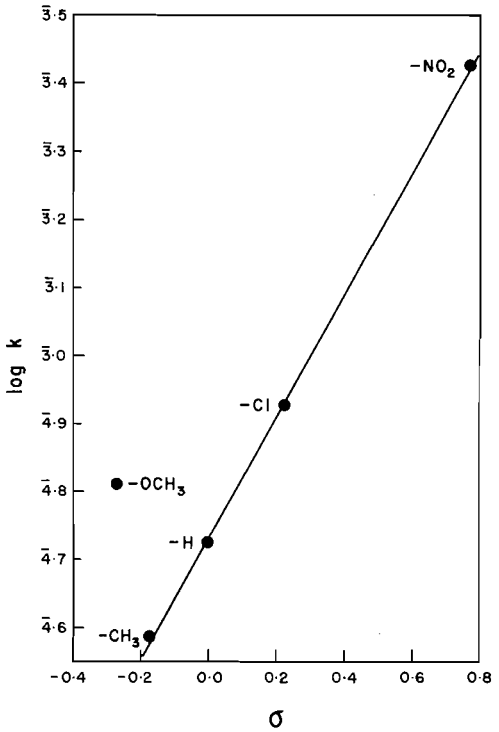

FIG. 1. Correlation of the rates of hydrolysis at 5 °C of a series of 4-substituted-benzyl trifluoroacetates with the Hammett σ parameter.

Discussion

Relative Rates, Free Energies of Activation

The general behavior of the five 4-substituted benzyl trifluoroacetates (4-X—$C_6H_4CH_2OCOCF_3$ where X = —OCH_3, —CH_3, —H, —Cl, and —NO_2) is very similar to that observed in our previous study (7) for an acetone–water mixture richer in water (1.02×10^{-2} mol fraction of acetone). The Hammett plot is also similar and the positive deviation of the 4-methoxy ester from the $B_{Ac}2$ line (see Fig. 1), as interpreted previously (see ref. 3), gives $k_s = 3.34 \times 10^{-4}$ s^{-1} and $k_b = 3.09 \times 10^{-4}$ s^{-1}, *i.e.*, the S_N and $B_{Ac}2$ routes are again of roughly equal importance in the new solvent system ($\gamma = 1.081$).

Enthalpies and Entropies of Activation

The $\Delta H_0^{\ddagger}$ and $\Delta S_0^{\ddagger}$ values for the unsubstituted ester calculated from the numerical coefficients in eq. 5 correspond to $T = 9.9$ °C

[2]Equation 6 assumes that $\Delta C_{p_0}^{\ddagger}$ is independent of temperature which is at variance with eq. 4. The $\Delta C_{p_0}^{\ddagger}$ obtained from eq. 6 is an averaged value over the range of temperatures studied. The rates measured in the present study are not considered to be sufficiently accurate to establish the temperature dependence of $\Delta C_{p_0}^{\ddagger}$ but the "large error" in $\Delta C_{p_0}^{\ddagger}$ may possibly be associated with factors implicit in eq. 4. However, the large error can be accounted for in other ways, *e.g.* the small temperature range over which the reaction rates were studied.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

which is the midpoint of the experimental range over which the rates were determined. The values of $\Delta H_o^{\ddagger}$ and $\Delta S_o^{\ddagger}$ at 9.9 °C for the 4-methoxy ester both show a positive shift from the related quantities observed for the unsubstituted ester. This shift is consistent with a contribution from the S_N reaction to k_o for this ester, since the S_N reaction is characterized with a positive shift in both $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ (see part I (3) of the present series).

The expressions relating the observed $\Delta H_o^{\ddagger}$ and $\Delta S_o^{\ddagger}$ values for the 4-methoxy ester to parameters characterizing the separate mechanisms are

$$[7] \quad \Delta H_o^{\ddagger} = \frac{1}{1+\gamma}\Delta H_b^{\ddagger} + \frac{\gamma}{1+\gamma}\Delta H_s^{\ddagger}$$

and

$$[8] \quad \Delta S_o^{\ddagger} = \frac{1}{1+\gamma}\Delta S_b^{\ddagger} + \frac{\gamma}{1+\gamma}\Delta S_s^{\ddagger} - 2.3026R \times \{\log k_b + \gamma \log k_s - (1+\gamma)\log k_0\}$$

Using eqs. 7 and 8 in conjunction with the experimental data the enthalpies, entropies, and heat capacities characterizing the $B_{Ac}2$ and S_N reactions for 4-methoxybenzyl trifluoroacetate may be estimated.

From the value of k_b, (quoted above) the free energy of activation for the $B_{Ac}2$ mechanism, $\Delta G_b^{\ddagger}$, may be calculated as 20.71 kcal mol^{-1} (for $T = 5$ °C). Since the enthalpy of activation associated with the $B_{Ac}2$ mechanism ($\Delta H_b^{\ddagger}$) is not particularly sensitive to structure (3), the unsubstituted benzyl ester provides a model for estimating $\Delta H_b^{\ddagger}$ for the 4-methoxy ester. The value of $\Delta H_b^{\ddagger}$ for the unsubstituted ester is 8.54 kcal mol^{-1} and in the case of the 4-methoxy ester we raise this value to 9.0 kcal mol^{-1} on two counts. Firstly, the negative $\Delta C_{pb}^{\ddagger}$ anticipated for the $B_{Ac}2$ mechanism will raise $\Delta H_b^{\ddagger}$ (T changes from 9.9 → 5 °C) and secondly, the 4-methoxy ester is the least reactive ester with respect to the complete series of benzyl esters reacting by the $B_{Ac}2$ path. Combining $\Delta H_b^{\ddagger}$ and $\Delta G_b^{\ddagger}$ for the 4-methoxy ester gives $\Delta S_b^{\ddagger}$ ($T = 5$ °C) = −42.1 cal mol^{-1} deg^{-1}. For the same temperature $\Delta H_o^{\ddagger} = 13.6$ kcal mol^{-1} and $\gamma = 1.081$ which from eq. 7 gives $\Delta H_s^{\ddagger} = 17.86$ kcal mol^{-1}. From similar considerations involving eq. 8 with $\Delta S_o^{\ddagger}$ ($T = 5$ °C) = −24.1 cal mol^{-1} deg^{-1} yields $\Delta S_s^{\ddagger} = -10.1$ e.u. Combining $\Delta H_s^{\ddagger}$ and $\Delta S_s^{\ddagger}$ in the usual way yields a value of $\Delta G_s^{\ddagger}$ which is consistent with the value of k_s obtained via the Hammett plot (3.34×10^{-4} s^{-1}). The $\Delta H_s^{\ddagger}$ and $\Delta S_s^{\ddagger}$ values are in the "general region" for an S_N process in acetone–water mixtures. Moffat and Hunt (12) report $\Delta S_s^{\ddagger} = -5.8$ cal mol^{-1} deg^{-1} and $\Delta H_s^{\ddagger} = 23.0$ kcal mol^{-1} for *t*-butyl trifluoroacetate in 70% acetone–water. Since the reaction of the latter compound involves the attack at a tertiary center and the solvent systems are not identical, the S_N character of the calculated $\Delta S_s^{\ddagger}$ and $\Delta H_s^{\ddagger}$ for the 4-methoxybenzyl trifluoroacetate is adequately established by comparison.

The Heat Capacity of Activation

With $\Delta H_b^{\ddagger} = 9.00$ kcal mol^{-1} and $\Delta H_s^{\ddagger} = 17.86$ kcal mol^{-1} the final spurious heat capacity term (11) in eq. 4 can be calculated as 127.5 cal mol^{-1} deg^{-1}. This value combined with $\Delta C_{po}^{\ddagger} = 89$ then gives

$$[9] \quad 0.418\Delta C_{pb}^{\ddagger} + 0.519\Delta C_{ps}^{\ddagger} = -38.5$$

For many S_N reactions in acetone–water mixtures (2) $\Delta C_p^{\ddagger}/\Delta S^{\ddagger} = 3$ which gives $\Delta C_{ps}^{\ddagger} = -30$. Substituting this value into eq. 9 gives $\Delta C_{pb}^{\ddagger} = -55$ which is reasonable (*cf.* ref. 3) for such a process.

General Comments

The mechanistic bifurcation postulated in the case of 4-methoxybenzyl trifluoroacetate was originally devised to account for the deviation from a Hammett plot as well as an unusual value for the solvent isotope effect $k(H_2O)/k(D_2O)$ observed for this ester (7). The same hypothesis is capable of explaining the unique positive heat capacity of activation for this process. The present study further vindicates the notion that careful temperature dependence studies are of considerable mechanistic utility (1, 2) in spite of forceful statements presenting an opposite point of view (13).

The authors wish to thank the National Research Council of Canada for partly helping with the cost of this work. We also wish to express our gratitude to the technical services unit at Memorial University for their continued assistance and Dr. Peter Golding for some useful criticisms. We also thank Dr. R. E. Robertson of the University of Calgary for providing the least squares computer program.

The Observable Thirtyfold Degenerate Camphenehydro Cation. A Stereospecific *exo*-3,2-Methyl Shift and *endo*-6,2(*exo* 6,1)-Hydride Shift

R. HASELTINE, E. HUANG, K. RANGANAYAKULU, AND T. S. SORENSEN

Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received June 25, 1974

R. HASELTINE, E. HUANG, K. RANGANAYAKULU, and T. S. SORENSEN. Can. J. Chem. **53**, 1056 (1975).

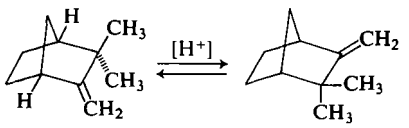
The observable camphenehydro cation **2** has been prepared and is shown to undergo two degenerate rearrangements, both well known in an indirect sense from many studies on the racemization of camphene. The results from both methods are compared and some advantages of the direct method are given; in particular it is shown that the 3,2-methyl shift is highly stereospecific. An eventual irreversible rearrangement of **2** is observed and the ion products characterized. A computer is used to systematically investigate the shortest paths from reactant to product ions.

R. HASELTINE, E. HUANG, K. RANGANAYAKULU et T. S. SORENSEN. Can. J. Chem. **53**, 1056 (1975).

On a préparé et observé le cation hydrocamphène **2**; on démontre qu'il subit deux réarrangements dégénérés qui sont chacun bien connus d'une façon indirecte à partir de plusieurs études sur la racémisation du camphène. On compare les résultats obtenus à partir des deux méthodes et on indique quelques avantages de la méthode directe; en particulier, on montre que le réarrangement du groupe méthyle de la position 3 vers la position 2 est hautement stéréospécifique. On observe un réarrangement irréversible éventuel de **2** et on caractérise les produits ioniques. On utilise un ordinateur pour étudier d'une façon systématique les chemins les plus courts entre les réactifs et les produits ioniques. [Traduit par le journal]

Introduction

The racemization of camphene, **1***a* ⇌ **1***b*, by acid catalysts is a well-known reaction dating



1*a* **1***b*

back over 40 years (1). Although a 3,2-methyl shift (the Nametkin rearrangement) in the intermediate camphenehydro cation **2**[1] (Scheme 1, path *A*) served to explain the racemization, it later became apparent (3) that another sequence of reactions could also explain the result (Scheme 1, path *B*), a sequence involving a Wagner–Meerwein shift in **2**, a 6,2-hydride shift[2] (6,1 if the original numbering is used), and then the reverse Wagner–Meerwein shift (abbreviated in this paper WM-6,2-WM rearrangement). In classic experiments using a ^{14}C label, Roberts and Yancey (4) and Vaughan and Perry (5) showed that both processes occur, *i.e.* there is a redundancy in the racemization mechanism. In fact, there are probably three mechanisms operative since it seems probable that a minor pathway involves tricyclene **3** as an intermediate (6, 7) (Scheme 2).

The overall nature of the 3,2-methyl shift in **2** is still controversial. Vaughan *et al.* (7), in a continuation of their earlier work, have recently suggested that, while the *exo*-3,2 shift is dominant, a measurable amount of *endo*-3,2 shift also occurs. Collins and Lietzke have, however, reanalyzed the same data (8) and conclude that the fit is equally good assuming an exclusive *exo*-3,2-methyl shift. There is, of course, a substantial body of literature (9, 10) showing preferential *exo*-3,2 shifts but *endo* shifts have been reported (11, 12).

The present study, *i.e.* the preparation of the long-lived camphenehydro cation, was undertaken in the hope that one could directly observe the ion-to-ion rearrangements shown in Scheme 1. There are certain advantages inherent in this: (*i*) It can be shown (see Results) that tricyclene most definitely cannot be an intermediate under

[1]Not until the pioneering paper of Meerwein and van Emster (2) in 1922 were carbonium ions actually postulated as intermediates in organic reactions.

[2]Cation structures in Scheme 1, for visual clarity, are not intended to distinguish between classical or nonclassical types.

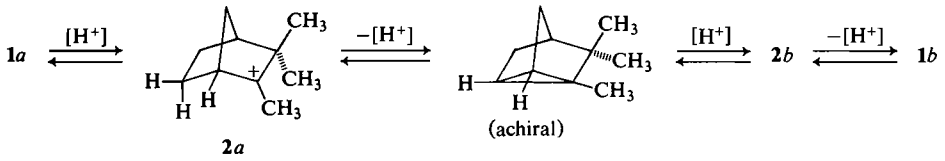

SCHEME 2

these conditions and that hopefully one needs only to consider two mechanisms. (*ii*) The n.m.r. line broadening method can be considered as a superior labelling experiment where *all* of the groups are specifically labelled. One anticipates therefore that *all* stereospecific processes may be detected.

Results

The long-lived camphenehydro cation can be prepared[3] by the addition of camphene, tricyclene, or isoborneol (but not borneol, see later) to FSO_3H or mixtures of this acid diluted with SO_2ClF at −80 to −120 °C. The ion can also be prepared in FSO_3D and in this case, there is no incorporation (other than in the initial preparation) of deuterium into the cation. No neutral intermediates are involved therefore in the degenerate rearrangements observed in this work since these would automatically incorporate deuterium in going back to the cation. The proton n.m.r. spectrum of the ion at −120 °C is shown in Fig. 1 (lower right) and the corresponding ^{13}C spectrum in Fig. 2 (bottom). Both represent 'frozen out' spectra in that all separate peaks are observable and no appreciable line broadening is apparent. The assignment of the proton peaks is based partly on the line broadening observed at higher temperatures and by comparison with chemical shifts observed for other norbornyl cations (13, 14). The assignments and measurable coupling constants are listed in Table 1. The ^{13}C chemical shift assignments (Table 1) were made from off-resonance studies, ^{13}C line-broadening studies and by comparison with ^{13}C chemical shifts observed for the 2-methyl-2-norbornyl cation.

Above −120 °C, line broadening is observed in both ^1H and ^{13}C spectra. The original spectrum is observed on recooling the sample so that the processes responsible for the line broadening are degenerate. In Fig. 1, some representative ^1H n.m.r. spectra are shown covering the temperature range −120 to −53 °C and in Fig. 2, ^{13}C spectra for −100 and −70 °C are shown. Above about −40 °C, an irreversible rearrangement becomes rapid so that line broadening cannot be studied above this temperature. This irreversible rearrangement is discussed later.

[3]Partly described in an earlier communication (13).

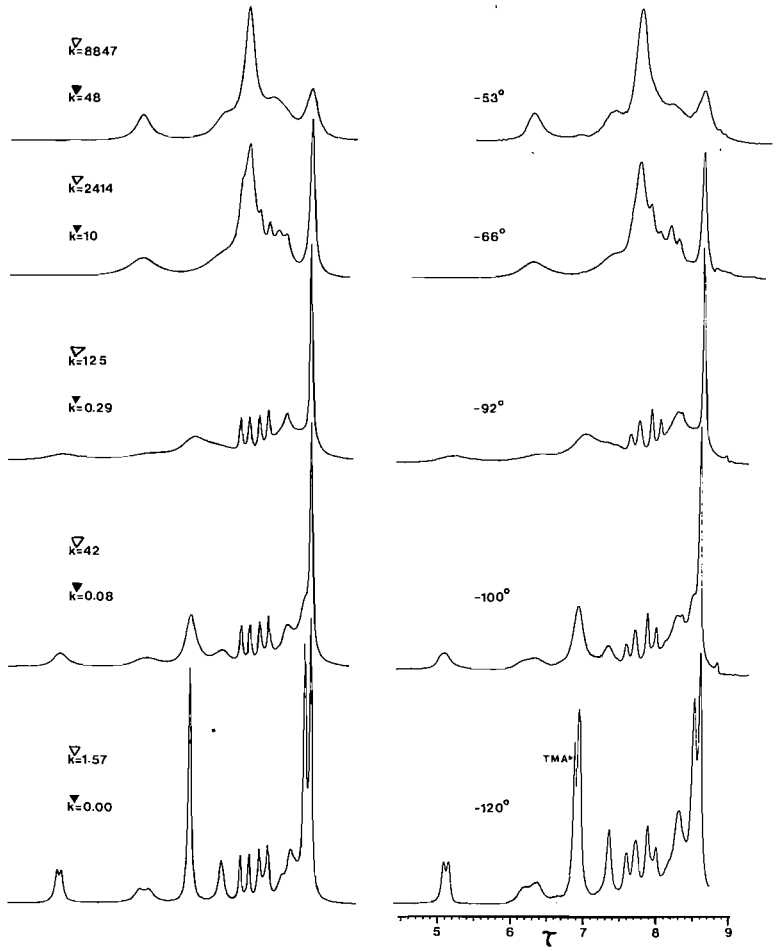

FIG. 1. Right, experimental ^{1}H n.m.r. spectra of the camphenehydro cation at various temperatures. Left, calculated ^{1}H n.m.r. spectra, $k^{\nabla} \equiv$ the *exo*-3,2-methyl shift rate in s^{-1}, $k^{\blacktriangledown} \equiv$ the WM-6,2-WM rearrangement rate in s^{-1}.

The most noticeable feature of the proton spectra obtained in the temperature range -120 to -70 °C is that all peaks broaden except for one methyl group and a four line portion (Fig. 1, temperatures -100 and -92 °C). This line-broadening pattern can be unequivocally attributed to a *stereospecific* 3,2-methyl shift. The groups becoming equivalent are shown in **I**.

[b]Doublet, J = 6.5 Hz.
[c]When averaged by the 3,2-methyl shift, the peak for the H_6 *endo* and H_5 *endo* protons is a doublet at 8.21, J = 11 Hz. Since there is a recognizeable peak at 8.3–8.4 in the frozen-out spectrum, this is assigned to H_5 *endo* and H_5 *exo*. H_6 *endo* is then assigned by interpolation.
[d]Both are AB doublets, J = 11.8 Hz. The assignment made on the assumption that H_7 *syn* will be at the higher field position.
[e]In some spectra, these peaks are resolved but no definite assignment is possible.

Although one cannot unequivocally assign the 3-*endo* and 3-*exo* methyl peaks in Fig. 1, and hence decide which migrates, the previous work on ^{14}C labelled camphene and work described in a following publication (15) makes it quite clear that this must be the 3-*exo* methyl. This fact has been assumed in **I** and will be tacitly incorporated in the subsequent discussion. The groups not undergoing exchange, therefore, are the 3-*exo*-methyl group and the C-7-*syn* and -*anti* protons, the latter giving rise to the four lines and analyzing as an AB quartet. The ^{13}C line-broadening

spectra are completely in accord with the proton assignments. All ^{13}C peaks broaden except for one methyl carbon and a CH_2 carbon (Fig. 2, -100 °C).

Starting at about -70 °C, and well before there is complete coalescence of exchanging peaks from the *exo*-3,2-methyl shift, the remaining sharp methyl peak starts to broaden (Fig. 1, -66 and -53 °C). The nature of this second, slower degenerate process is much more difficult to ascertain since most other peaks are still rather broad from the effects of the 3,2-methyl shift and because of an irreversible rearrangement, one cannot obtain spectra much above -40 °C, a temperature still below the coalescence temperature for the process. However, the two obvious choices for a second degenerate rearrangement involving the remaining methyl group are: (*i*) an *endo*-3,2-methyl shift or (*ii*) a WM-6,2-WM rearrangement (see Scheme 1).

Although both predict a broadening of the remaining methyl group, there are other crucial differences. An *endo*-3,2-methyl shift does not further average (beyond that shown in **I**) any of the other protons, while a WM-6,2-WM process will result in further broadening (assuming the peaks were not already broad). The protons becoming equivalent as a result of this process are shown in **II**.

symmetry plane

A *stereospecific* migration of the original C-6-*exo* proton to C-1 has been assumed (this is the 6,2-shift, if the intermediate in **II** is renumbered in the proper manner). Once again, there is solvolysis-type evidence for this stereospecificity (16, 17) but in a study of the observable 2-methyl-2-norbornyl cation (13), we have shown the process to be indeed an extremely stereospecific migration. In fact, even in the camphene hydrocation, as will be shown, there is evidence that the process, within the crude limits of the experimental measurements, must be stereospecific.

In order to differentiate between the 3,2-*endo* methyl shift and the WM-6,2-WM process, the following techniques were used.

(*i*) The double irradiation spin-saturation transfer (DISST) method of Forsén and Hoffman (18) was employed. The DISST method consists of saturating a given proton or protons while observing the position into which it is suspected they are exchanging. It is possible to analyze the results quantitatively and to measure the rate of the exchange process but in the present case, major complications arise because of the prior b , adening of peaks from the 3,2-methyl shift and we have obtained only an order of magnitude value (see later). The method is, however, equally valuable from a qualitative point of view and tells one not only that exchange is occurring but also what the mutual exchange processes are. The results of this experiment are shown in Fig. 3. The plot is an INDOR type where the variable f_2 frequency is the saturating external oscillator frequency, the observing frequency f_1 scans the averaged (from the 3,2-methyl shift) C-1–C-4 proton peak (the lowest field peak in Fig. 1, -53 °C). The other axis is the arbitrary height of this peak. This decreases when the f_2 saturating frequency begins to overlap the rather broad C-1–C-4 peak because direct saturation occurs, as expected. The dashed line in Fig. 3 represents the expected peak height behavior caused by direct saturation on the high field side of the peak, *assuming no exchange processes occurred.* That exchange between C-1–C-4 and other protons is occurring is very evident and to show the specific mutual exchanges, the graph shows the location (from Fig. 1) of the averaged C-5-*endo*–

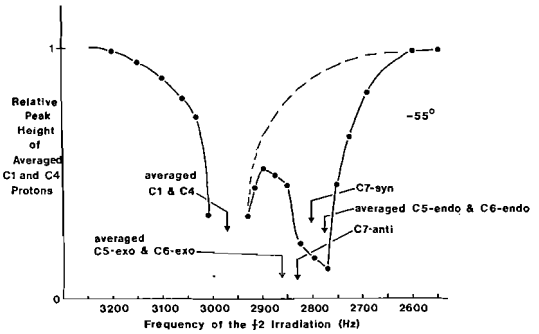

FIG. 3. Application of the n.m.r. DISST technique in detecting specific proton exchanges in the camphenehydro cation.

C-6-*endo* protons, the averaged C-5-*exo*–C-6-*exo* protons, and the separate C-7-*syn* and C-7-*anti* protons. It is apparent that the C-1–C-4 protons do exchange with the C-5-*endo*–C-6-*endo* protons and also probably with the C-7-*syn* proton since the slight asymmetry shown in Fig. 3 is quite reproducible at other temperatures and with different external oscillator power. Nothing very definite can be deduced concerning the C-7-*anti* proton since the 'resolution' of the method is poor; however, it appears very probable that the C-6-*exo*–C-5-*exo* protons are *not* exchanging within the crude limits of the experiment with the C-1–C-4 protons. It is worth emphasizing that an *endo*-3,2 shift would not have caused any of these observations and that the equivalences shown in **I** and **II** predict that the C-1–C-4 protons *should* further exchange with C-5-*endo*–C-6-*endo* and C-7-*syn* but *not* with C-7-*anti* or C-5-*exo*–C-6-*exo* (see subsequent discussion).

(*ii*) From the above discussion, it can be seen that the averaged C-1–C-4 proton peak should further broaden in the WM-6,2-WM mechanism but that no further exchanges are introduced by a 3-*endo* methyl shift process. Accurate rate constants can be calculated for both the two-methyl and three-methyl broadening processes, using the methyl peak line shapes (see next section), the latter calculated broadening pattern being identical for either of the two mechanisms being considered here. Using the derived rate constants for the three-methyl broadening, one can calculate the hypothetical behavior of the averaged C-1–C-4 proton peak and compare this with experiment (Fig. 4) (the small peak to the right is one of the growing irreversible rearrangement product peaks). The line shapes at the three

lowest temperatures are still governed by the fast *exo*-3,2-methyl shift process but starting at about −60 °C, the observed peak appears to 'mark time' before finally broadening again, starting at about −45 °C. This behavior is exactly as predicted for the WM-6,2-WM mechanism (top calculations) but totally at variance with an *endo*-3,2-methyl shift (bottom calculations).

(*iii*) The rate of the WM-6,2-WM rearrangement has been accurately measured in two related carbocations where this is the only low temperature rearrangement process. The agreement with the rate calculated from the three-methyl broadening in this work is excellent.

The above observations leave no doubt that the observed second slower degenerate rearrangement is the WM-6,2-WM rearrangement, although one must concede that a small amount of *endo*-3,2-methyl shift would be undetectable (however, see ref. 15).

Quantitative Rate Comparison of the Two Steps

One of the objects of this work concerns the comparison of rate processes observed in long-lived carbocations with those generated as intermediates under 'solvolysis-type' conditions. It is of interest therefore to calculate accurately $k_{exo\text{-}3,2\text{-methyl shift}}$ and $k_{\text{WM-6,2-WM}}$ (and hence the ratio). In addition, activation energies for both processes will be required (for temperature–rate extrapolations) since the camphene racemizations have been carried out from 100 to 180 °C, compared to the −120 to −40 °C range in the observable carbocations.

In the preliminary communication (13), the comparison of calculated and observed n.m.r. line broadening curves was done using only the methyl peaks. Matching the peaks becomes somewhat difficult however because of the distortion caused by the underlying absorptions of some of the eight other protons in the molecule. The calculations have been repeated therefore using all of these protons. The actual system consists of 17 more-or-less closely coupled protons and it is impossible to attempt an exact solution. The approximations used consist of treating the methyl groups separately, treating the C-5-*exo*, C-6-*exo*, and C-7-*anti* protons as another group and the remaining protons as a third group. Small coupling constants are mimicked by using the appropriate T_2 value while separate peaks are included for large couplings but these are all approximated as first-order couplings and a restricted number of spin states are used. In practice, most of these approximations will not seriously affect the intermediate exchange rate spectra (19) where the methyl peak matchings are made.

The rate processes for both steps are not separated enough to treat separately and the kinetic matrix used included both. In addition to changing the absolute values of $k_{exo\text{-}3,2\text{-methyl shift}}$ and $k_{\text{WM-6,2-WM}}$, it was necessary to adjust the ratio of the two in order to finally fit the observed spectra. Several of the calculated and observed spectra are shown in Fig. 1. From this comparison, the following data were obtained in the usual way: for the *exo*-3,2-methyl shift, $\Delta H^{\ddagger} = 8.4$ kcal/mol, $\sigma = 0.2$, $\Delta G^{\ddagger}_{-104\,^{\circ}\text{C}} = 8.3$ kcal/mol, $\Delta S^{\ddagger} = 0.5 \pm 1$ e.u., a typical k being 29.5 s^{-1} at −101.9 °C; for the WM-6,2-WM process, $\Delta H^{\ddagger} = 10.1$ kcal/mol, $\sigma = 0.2$, $\Delta G^{\ddagger}_{-64\,^{\circ}\text{C}} = 10.7$ kcal/mol, $\Delta S^{\ddagger} = -3 \pm 1$ e.u., a typical k being 21 s^{-1} at −59.5 °C. The calculated ^{13}C line shapes shown in Fig. 2 were made using the above activation parameters and show good agreement with the observed spectra. This provides a useful check on the validity of these.

The DISST n.m.r. method provides a further order-of-magnitude value for $k_{\text{WM-6,2-WM}}$. A value of *ca.* 10 s^{-1} at −56 °C was obtained by measuring the equilibrium C-1–C-4 peak height while irradiating the C-5-*endo*–C-6-*endo* protons and assuming a T_1 value of *ca.* 1 s.[4] The extrapolated value from the line broadening is 30.9 s^{-1} at this temperature.

A detailed discussion of both the 3,2-methyl shift and the WM-6,2-WM rearrangement is deferred at this time since it is possible to devise systems where 3,2-methyl shifts occur in the absence of the WM-6,2-WM rearrangement and vice versa (15).

Comparison with Camphene Racemization Results

The original data obtained by Roberts and Yancey have been corrected slightly by Vaughan *et al.* (20). Using a hydrated titanium dioxide catalyst at 160°, the ratio $k_{3,2\text{-shift}}/k_{\text{WM-6,2-WM}}$ was about 0.5; using aniline hydrochloride in

[4]Normally both T_1 and k can be obtained by measuring the time dependence of the peak decrease. This works at temperatures where $T_1 \sim 1/k$, a situation not realizable in this case because the C-1–C-4 proton peak is very broad from the effects of the 3,2-methyl shift (see Fig. 4), −67 °C spectrum as an example.

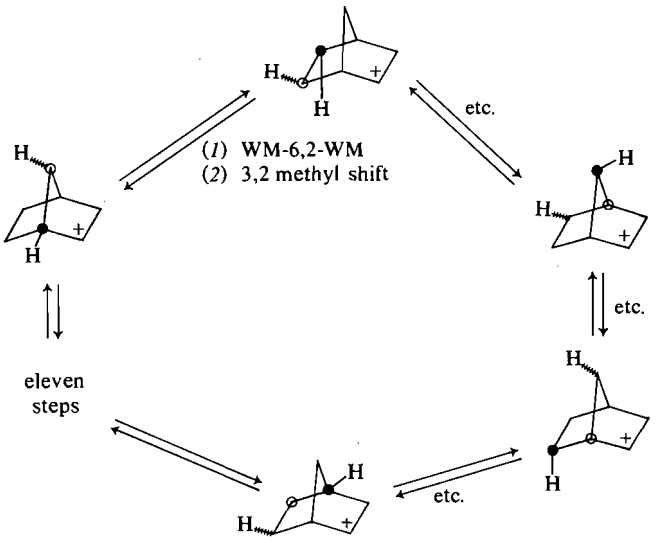

FIG. 5. Fifteenfold degenerate rearrangement cycle for the *R*-camphenehydro cation. For simplicity only two carbons and two protons are shown.

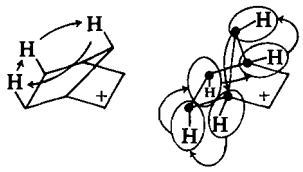
aniline at 180 °C, 0.33 and using pyruvic acid – acetonitrile at 156 °C, 4.0. In their most recent work, Vaughan and co-workers (7) have used freshly distilled pyruvic acid in acetonitrile at 137–138 °C and find the ratio 1.3. The ratios obtained in this work are 596 at −104 °C, 233 at −64 °C, 39.5 at 100 °C, 32.2 at 137 °C, and 26.7 at 180 °C. The best isothermal comparison is 1.3 for pyruvic acid – acetonitrile *vs.* 32.2 for the fluorosulfonic acid – sulfuryl chlorofluoride system (there is no evidence in fact that changes in the strong acid media affect the rates in any significant manner (13)). In extrapolating the two rates over large temperature ranges one has potentially large errors introduced. This made it necessary that we did the most careful line shape analysis possible in determining E_a. An error propagation analysis has also been carried out. At the 90% confidence level, the minimum value for this ratio in our work is 7.4 (140 as a maximum), still well above the 1.3 ratio for the acid-catalysis work. It is quite apparent that the camphene results vary significantly with the medium used so that it is not too surprising to find the above variance in the comparison to the strong acid results. We feel however that the strong acid results should serve as an 'intrinsic' ratio to which one might compare the specific changes brought about by other solvent systems.

The Thirty-fold Degeneracy of the Camphenehydro Cation

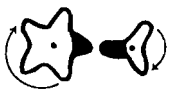
Previous labelling work on camphene has concerned only the methyl and exocyclic methylene groups but labelling the other protons (as in n.m.r. line broadening or in isotopic substitution) is equally of interest. Using alternating *exo*-3,2-methyl shifts and *endo*-6,2(*exo*-6,1)-hydride shifts one can show readily that the camphenehydro cation is 30-fold degenerate. A part of the 30-step cycle is shown in Fig. 5. The 30 structures can be divided into 15 of each enantiomer and since the two series are otherwise identical, only one needs to be considered. In completing a rearrangement cycle to give all the degenerate structures, the overall topology in this process is such that the three protons on the 'outside' of the molecule, C-6-*exo*, C-5-*exo*, and C-7-*anti* circulate, keeping their same relative order (**III**). The five protons, C-1, C-6-*endo*, C-5-*endo*, C-4, and C-7-*syn*, which lie in an equatorial belt, also circulate (**IV**), while the methyl groups occupy each of the three nonequivalent sites in turn. The five-proton group remains attached always to the same carbon so that both 'partners' are moving in the process. The three-proton group changes carbon 'partners' in a regular pattern. For each rearrangement step (within the same enantiomer group), the three-proton group

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



III IV

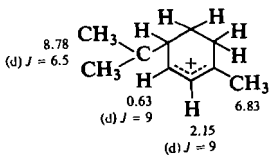
circles one position while the five protons circle two positions in the same direction (or three in reverse). This 'square dance' analogy clearly shows (V) that a double label, one in the three-proton group and one in the five-proton group, completely removes the degeneracy. The two dark lobes in V might represent for example the initial orientation of two deuterium atoms. It can be easily verified that 15 (5 × 3) steps are needed to regain the original positions.



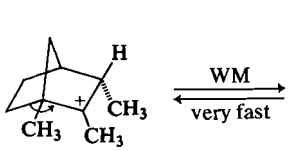
V

The Irreversible Rearrangement

The camphenehydrocation **2** rapidly rearranges at −30 °C, $k_{disappearance} = 9.8 \times 10^{-4}\ s^{-1}$. The products are a cyclohexenyl cation **4** (38%) and another 2-norbornyl cation system **5** (62%). The latter proved to be identical to a cation obtained by protonating 1,2,3-trimethyl-2-norbornene (ε-fenchene) (14) and was thus easily identified. The cyclohexenyl cation **4** was characterized from the observed n.m.r. spectrum (see structure **4**) and by comparison with the authentic specimen. This same cation is produced from a wide range of terpenes in fluorosulfonic acid, *e.g.* α-terpineol, β-pinene, sabinene, etc.



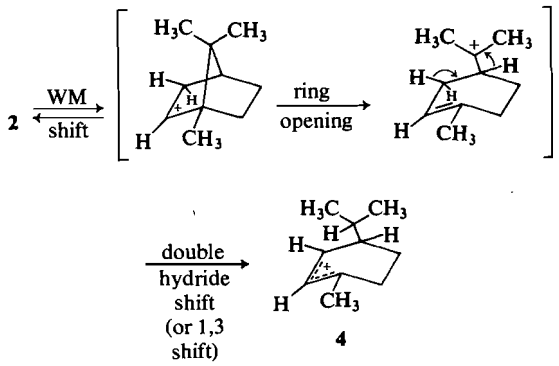
4



5

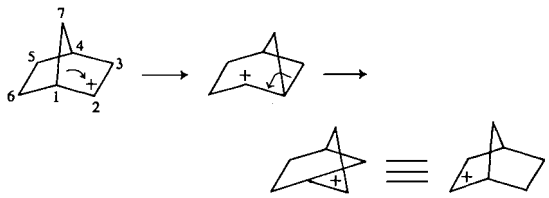
(+ 3-*exo* methyl and 7-*syn* methyl pair)

The cyclohexenyl cation formation is readily explained by an opening of the bicyclic ring, a reaction type first observed by Deno and Houser (21) (Scheme 3).



SCHEME 3

There are a great many ways by which the camphenehydro cation **2** could have formed **5**. This can be seen in the graph theory treatment of Johnson and Collins (22) as applied to trimethyl-2-norbornyl cations. For the rearrangement of **2** to **5** we have not constructed a complete graph but have simply calculated (by computer) all pathways of 10 steps or less (for four different rearrangement processes). All processes containing loops or regenerating starting material were discarded. The rearrangement processes were given the following symbols: Wagner–Meerwein 6,1–6,2 shift≡1; *exo*-3,2-shift≡2; *endo*-6,2-hydride shift≡3; double Wagner–Meerwein 7,1–7,2 shift (really two steps)≡4.



SCHEME 4

For further characterization, the *exo*-3,2-shift was broken down into 3,2-hydride shifts, 2H, and 3,2-methyl shifts, 2M. Furthermore, the substitution on C-2, *i.e.* H≡S (secondary), CH_3≡T (tertiary) was determined before and after the rearrangement, *i.e.* 2MTT refers to an *exo*-3,2-methyl shift starting with a tertiary C^+ center and ending up with another tertiary C^+ center. For rearrangement *4*, the processes 4TT-TT and

4SS-SS are equivalent to 1SS and 1TT and the former were dropped. The symbol 4TT implies a secondary bicyclo[3.1.1]heptyl cation intermediate, etc.

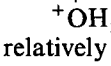
Although rearrangement *4* is known to occur in some cases (22), there is a question concerning the activation energy for this step, *i.e.* it may be quite high. We have therefore carried out two series; in the first series, all four processes were employed. Restricting the path length to 10 steps yields 15 sequences all requiring a *4* step. In a second series, the rearrangement *4* was excluded and a path length of up to 13 steps considered. This yields five sequences, the shortest being 11 steps. In Table 2, we list the sequences for both series.

We prefer the shortest path, seven steps, involving a single *4* step. This initially converts the camphenehydro cation into the α-fenchyl cation and we have previously shown that the α-fenchyl cation gives **5** rapidly at −90 °C (14). Also, both products **4** and **5** would then arise from the initial weakening of the C-7—C-1 bond, *i.e.* it either shifts or opens up.

We are hopeful that activation energies can eventually be assigned to each of the subdivided steps, thus enabling one to predict the most probable route on a rational basis.

The Protonation of Borneol and Isoborneol in Fluorosulfonic Acid

Although not part of the investigation, an interesting sidelight to this work was the observation of an enormous difference in the rate at which protonated borneol and isoborneol were converted to the camphenehydro cation. Protonated borneol (methyl peaks at τ 8.52, 8.60, and 8.64, C—H at 4.36, broad doublet, J = 10) is



relatively stable, the heterolysis of the C—$^+OH_2$ bond does not take place readily until about −30 °C. At this temperature, only the camphenehydro cation rearrangement products **4** and **5** are formed. Protonated isoborneol, on the other hand, is very difficult to obtain. By conducting the addition at −120 °C in FSO_3H–SO_2ClF (1:4), it has been possible to obtain a spectrum which, although rather broad and featureless, is probably the 'onium' cation contaminated with some of the camphenehydro cation (methyls at τ 8.84 and 8.90, C—H, broad, at 5.08), These

peaks disappear quite rapidly at −105 °C to yield the camphenehydro cation. Large rate differences in the solvolysis of *exo*- and *endo*-2-norbornyl derivatives are very well known (23);

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

however the reactions in FSO_3H are somewhat unique in that the solvent (FSO_3H) or nucleophile (FSO_3^-) assistance in the actual C—$^+OH_2$ bond breaking step is probably minimal.

Experimental

Camphene and tricyclene were a gift of the Hercules Powder Co. The ion preparation followed standard techniques previously described (24). The n.m.r. spectra were measured using a Varian Assoc. HA-100 spectrometer equipped with a variable temperature probe. Temperatures were measured by directly inserting a thermocouple into the n.m.r. tube, the reading being taken as the pen passed over the spectra region being used for the line-broadening comparison.

In the DISST technique, the audio power was varied and measurements were made on both spinning and non-spinning samples, the results being substantially the same in both cases. The external oscillator power was always allowed to load the RF circuit, the actual irradiation being accomplished by a sudden switch from a noninterfering frequency to that desired. The f_1 observing power was also kept very low to minimize any direct saturation effects.

^{13}C n.m.r. spectra were recorded on a Bruker HFX-90 Fourier transform spectrometer. Between 1K and 2K scans were collected for each temperature. The heteronuclear fluorine lock material, trifluoromethyltrichloroethene, was contained with TMS in a 5 mm capillary.

Line-broadening Calculations

In all computer calculations, the kinetic matrix used included both mutual exchange processes. The Arrhenius plot for each mutual exchange process was used to extrapolate the rates, *i.e.* the values quoted in Fig. 1 for the slower step, in the region where line-broadening effects are due to the faster process and also in the values quoted for the faster process in the temperature region where the line-broadening effects are principally due to the slower step. ^{13}C spectra were calculated using Lorenzian line shapes and using the rate constants derived from the proton comparisons.

The authors thank the National Research Council of Canada for generous financial support. We wish to thank Professor R. K. Brown for his aid in obtaining the ^{13}C n.m.r. spectra and Drs. C. Johnson and C. Collins for preprints of their work on the application of graph theory to norbornyl cation rearrangements.

A Comparison of the Stereospecificity of Carbocation to Rearranged Carbocation Reactions under Observable Ion and Steady-state Intermediate Conditions

ROLLIN P. HASELTINE AND TED S. SORENSEN

Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received June 25, 1974

ROLLIN P. HASELTINE and TED SORENSEN. Can. J. Chem. **53**, 1067 (1975).

From observable ion studies on a series of polymethyl tertiary 2-norbornyl cations, a huge difference in the migratory aptitudes (stereospecificity) of 3-*exo* and 3-*endo* methyl groups was observed. The same trend was observed under typical acid catalysis conditions where the *same* rearrangements are involved but where the cation is in this case a fleeting intermediate. In related work, a comparison was made of the absolute rate of an *exo*-3,2-hydride and an *exo*-3,2-methyl shift and a direct measurement of the H–D isotope effect in a 3,2-hydride shift was made.

ROLLIN P. HASELTINE et TED SORENSEN. Can. J. Chem. **53**, 1067 (1975).

En se basant sur des études des ions qui peuvent être observés dans une série de cations tertiaires dérivés de polyméthyl-norbornyl-2, on a observé de grandes différences dans les aptitudes à la migration (stéréospécificité) des groupes méthyles *exo*-3 et *endo*-3. On a observé la même tendance dans des conditions de catalyse acide typique dans lesquelles les mêmes réarrangements sont observés mais où le cation n'est dans ces cas qu'un intermédiaire éphémère. Dans des travaux parallèles, on a pu faire une comparaison des vitesses absolues des transferts d'hydrures *exo*-3 vers 2 et des transferts de méthyles de *exo*-3 vers 2 et on a aussi fait une mesure directe de l'effet isotopique H–D lors du transfert d'hydrure de la position 3 vers la position 2. [Traduit par le journal]

Introduction

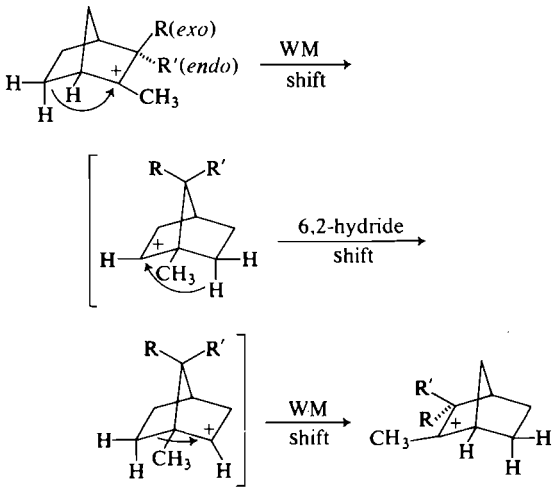
A study of the directly observable camphenehydro cation (1) shows that an *exo*-3,2-methyl shift in this system is preferred over a possible *endo* shift by a rate factor of at least 250 at −64 °C. However two important questions remain unanswered:

(*i*) What *is* the actual absolute rate of an *endo*-3,2-methyl shift in an observable 2-norbornyl cation? In the camphenhydro cation, a second rearrangement process which interconverts the 3-*exo* and 3-*endo* substituents (Scheme 1) makes this question impossible to answer in this case.

(*ii*) To what extent are rate comparisons derived from observable ion rearrangements applicable to solvolysis or acid-catalysis type conditions where the carbocations exist as temporal intermediates? Indications from the camphene racemization problem and the directly observable camphenehydro cation rearrangements (1) indicate some differences.

The Overall Plan

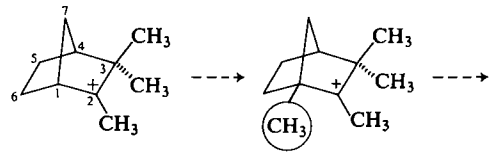
In order to allow equal statistical choice between a degenerate migration of an *exo* or *endo* methyl substituent one requires the basic three



SCHEME 1

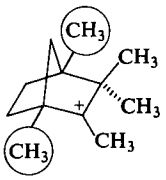
methyl groups of the camphenehydro cation **1**. In deciding first of all on systems which do not allow for interconversion of the 3-position substituents by the Scheme 1 reactions, one can consider cations with an extra methyl substituent at C-1, *i.e.* **2**. However, in order to make the rearrangement degenerate (as in the camphene-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



1
basic skeleton wanted

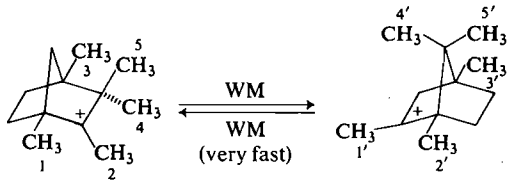
2



3

hydro cation) one requires a further methyl substituent at the C-4 position, giving **3**. The reason that **3** does not interconvert the 3-position methyl groups by the sequence of reactions shown in Scheme 1 can best be shown if one attempts to carry these out on **3** (Scheme 2). No symmetry plane exists in this series of reactions, *i.e.* both C-3 methyl substituents retain their separate identity. Even if **5** is kinetically accessible, as long as **5** is thermodynamically less stable than **3** it will not interfere in any way with the planned experiments.

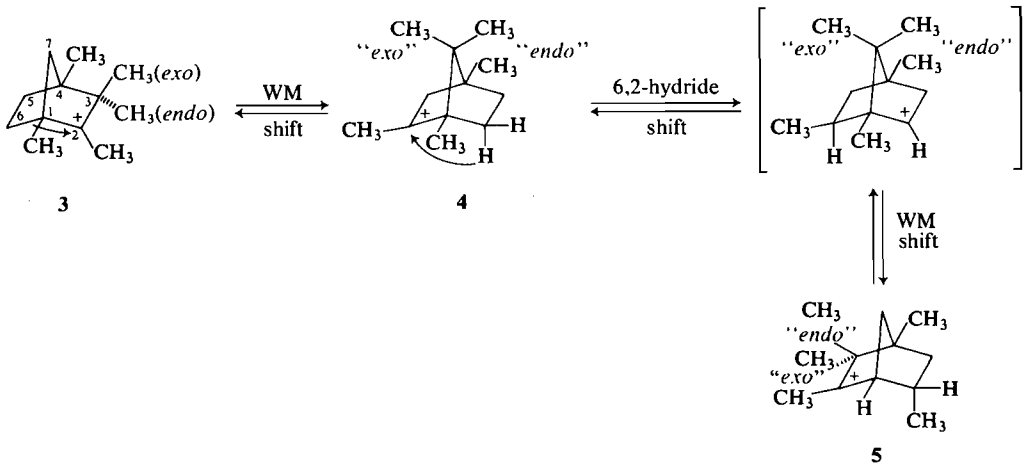
One finds experimentally that the first Wagner–Meerwein (WM) shift process shown in Scheme 2 is extremely fast. It is so fast in fact that at all temperatures one only sees averaged n.m.r. peaks for the two cations **3** and **4**. As in another pair of this type which we have recently studied (2), the equilibrium constant **3**/**4** is not one, and so the averaged peaks are naturally more representative of the major isomer of the pair. In the structures **3***a* and **4***a*, the groups which average are given the symbols 1 and 1′, etc. It turns out,



3*a* **4***a*

in this case, that one isomer, **4**, is structurally incapable of *any* low-energy degenerate rearrangements so that only **3** needs to be considered. However, for quantitative purposes, in order to compare with the camphenehydro cation results, one should know the equilibrium concentration of **3**, and there are ways to obtain this.

As it turns out, ion **3** (accompanied by **4**) is useful for studying the *exo*-3,2-methyl shift but an irreversible rearrangement which becomes very rapid by about −20 °C effectively limits the search for an *endo* shift to temperatures below this. This has led to the investigation of other systems containing the same basic five methyl groups of **3**, but with an additional methyl group in the C-7-*anti* position, structures **6** and **7**. This pair is stable (observable) up to nearly room temperature before, again, an irreversible rearrangement becomes rapid. As will be shown, besides the degenerate *exo*-3,2-methyl shift in **6**, a degenerate 3,2-hydride shift occurs in **7** and a useful direct comparison between an *exo*-3,2-hydride and *exo*-3,2-methyl shift is possible. The



3 **4** **5**

SCHEME 2

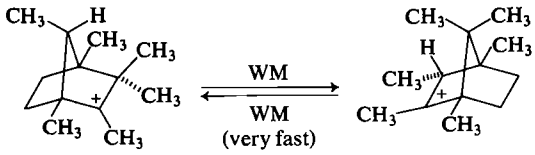
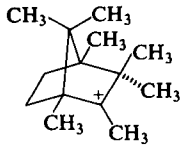
For personal use only.



6 7

application of both degenerate rearrangements together with the WM shift leads to an overall 20-fold degenerate rearrangement process whereby five of the six methyl groups become equivalent on the n.m.r. time scale, the remaining methyl *not* becoming equivalent *unless* an *endo*-3,2-methyl shift is allowed. The extended temperature range over which **6** (and **7**) exist proves very useful in allowing one finally to obtain evidence for an *endo* shift in **6**.

Finally, a heptamethyl cation **8** was investi-

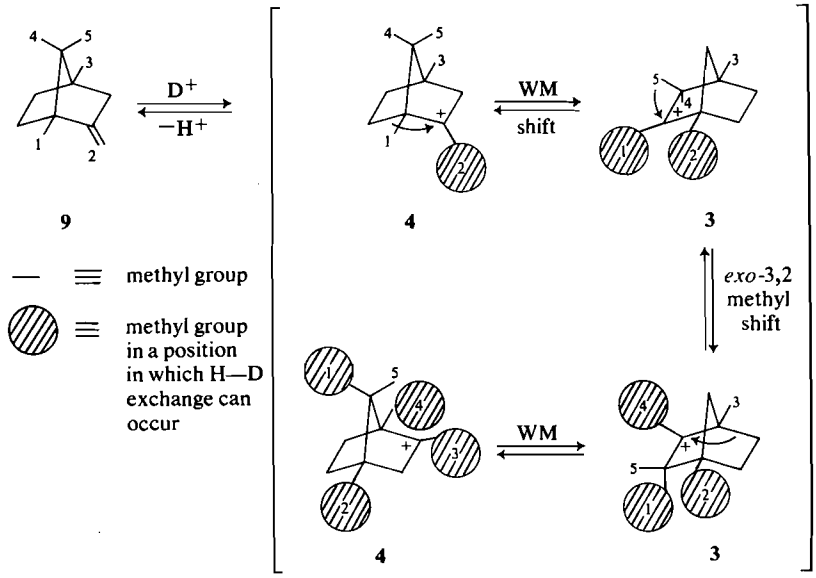


8

gated in order to test the stereospecificity and the absolute rate of the 3,2-methyl shift when a C-7-*syn* methyl substituent was present. This substituent was expected to decrease substantially the rate of an *exo*-3,2 shift but to have no effect on the *endo* shift.

It turns out that all three systems are very amenable to study involving acid-catalysis conditions, the second objective of this work. The particular acid-catalysis reaction studied was the hydrogen–deuterium substitution of the corresponding alkenes in deuterio acetic acid containing a small amount of deuterio sulfuric acid (fairly typical acid-catalysis conditions). As an illustrative example of what is being attempted, one can take the alkene **9**, a precursor of the pentamethyl cation system **3**–**4**, and show how the exchange occurs (Scheme 3). In order to exchange with solvent D, a CH_3 group must be located adjacent to a cationic center. If no rearrangement whatever occurred, only the *exo*-methylene group 2 would be exchanged. If only the WM shift were allowed, only the C-1 methyl and $=CH_2$ in **9** would eventually be exchanged. If both WM shift and an *exo*-3,2-methyl shift were allowed, three of the four methyl groups (only the one labelled 5 in structure **9** remains unexchanged) and $=CH_2$ can be exchanged (Scheme 3). If a WM shift and both *exo*- and *endo*-methyl shifts are allowed, *all* methyls in **9** will exchange (not shown in Scheme 3). There is thus a clear-cut experimental distinction to test the stereospecificity of the 3,2-methyl shift in **3**, under acid-catalysis type conditions where **3** has only a fleeting existence.

In the hexamethyl **6** and **7**, and heptamethyl **8** cation systems similar distinctions are possible.



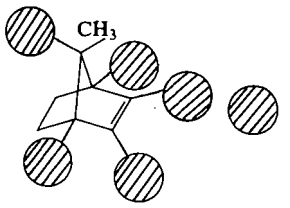
9 4 3 4 3

SCHEME 3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

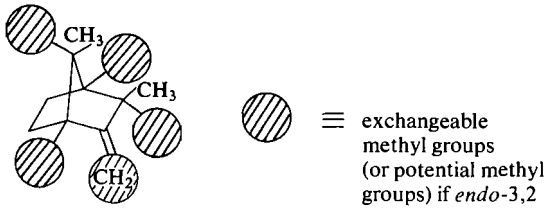
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In the former case, allowing only an *exo*-3,2-methyl shift as well as the WM shift and 3,2-hydride shift, the precursor alkene **10** will exchange five of the six methyl groups (see structure **10**). All six will exchange if, in addition, an *endo*-3,2-methyl shift occurs.



10

In the heptamethyl cation case, four of the six methyl groups in the precursor alkene **11** will exchange if only the WM shift and the *exo*-3,2-methyl shift are allowed, while all six will exchange if, in addition, an *endo*-methyl shift occurs.

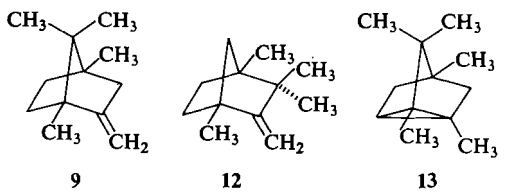


11

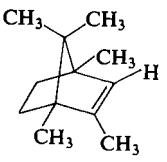
Since each system is somewhat different, the pentamethyl, hexamethyl, and heptamethyl cation series will be treated in order, asking in each case the following questions: (*i*) What are the relative propensities in the observable ions for *exo*- and *endo*-3,2-methyl shifts? and (*ii*) how does this ratio compare with that determined in the acid-catalyzed H–D exchange where the ions are fleeting intermediates?

Pentamethyl Cation Series 3–4

The starting material for this study was the hydrocarbon **9**. This $C_{12}H_{20}$ isomer is by far the most thermodynamically stable of the four hydrocarbons **9**, **12**, **13**, and **14** related to cations **3**–**4**. The equilibrium percentages of **9**, **12**, **13**, and **14** are 78, 14, 6.5, and 1.5%, respectively, at 25 °C in 0.5% H_2SO_4–CH_3COOH. The synthesis of these hydrocarbons will be reported separately. There is no particular advantage in using **9** to prepare the cations (other than the ready availability of the alkene) but in the H–D exchange study, where complete equilibration of the four hydrocarbons accompanies exchange, starting with **9** means that this remains the major component of the mixture.

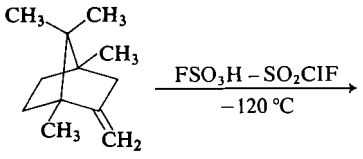


9 **12** **13**

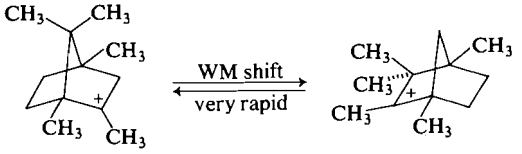


14

Addition of **9** to FSO_3H–SO_2ClF (1:4) at −120 °C gives a light yellow solution showing a very clean ^1H n.m.r. spectrum. At −120 °C, there are five separate methyl peaks in the spectrum, corresponding to the methyls numbered 1, 2, 3, 4, and 5 in the previously shown structures **3***a* and **4***a*. These averaged peaks, as well as those for the remaining protons, are reported in Table 1. The two lowest field methyl peaks are found at



9



4 **3**

equilibrium mixture of these

τ 7.36 and 8.01 at −90 °C and the separation δ (65 Hz) is temperature dependent, reflecting the changing equilibrium constant, K = **3**/**4**, with temperature changes. This temperature dependence can be analyzed by a procedure pre-

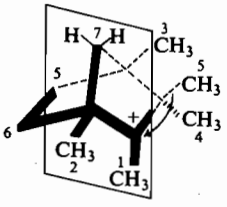
[a] In τ p.p.m. from internal tetramethylammonium cation = 6.90.
[b] The assumption that **4** is more stable than **3** is based on analogy to several other systems (2, 3, 5, 12), temperature −90 °C.
[c] These assignments follow from the assigned positions for 1–1′ and 2–2′ and the positions of the coalesced peaks after exchange with 3–3′ and 4–4′.
[d] In the dominant isomer **4**, this peak is expected to be shielded more than peak 4′ because it is closer to the maximum shielding region of the cation π system.
[e] Assigned because these peaks are not line broadened by the methyl shift.
[f] Located knowing 1–1′ and 2–2′ (at −119 °C) and the averaged 1–1′, 7–7′, and 2–2′, 3–3′ at higher temperatures.
[g] Reasoning analogous to *d*.
[h] These values obtained at −30 °C and are averages, *i.e.* 8–8′ = 10–10′ *etc.* The two sets form an A_2B_2 pattern.
[i] Triplet, J = 5.5 Hz.

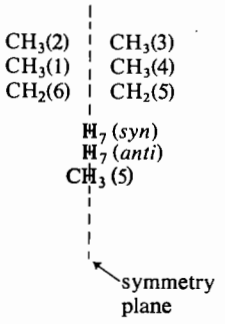
viously reported (2) and yields an equilibrium constant value of 0.3 at −90 °C.

As the temperature of the solution of **3**–**4** is raised above −120 °C, four of the five methyl peaks begin to broaden. This is due to a stereospecific 3,2-methyl shift in **3**, which can be categorized further as an *exo*-3,2 shift if the assignment made in Table 1 is correct, *i.e.* that the highest field peak is due to the methyl 5–5′ in structures **3***a*–**4***a* (see notes to Table 1).

The *exo*-3,2 shift results in the following averaging:



3*a*



The migrating methyl 5 does not change environment (except for *R*–*S* interconversion) and remains unbroadened. The numbered peaks are already averages of **3** and **4** but the above broadening only occurs via ion **3**. The absolute rate of this shift in **3** can be related to the overall observed broadening in **3**–**4** by the relationship:

$$4 \underset{}{\overset{K}{\rightleftarrows}} 3 \xrightarrow{k_{exo\ \text{shift}}} 3'$$

The rate for the *exo*-3,2-methyl shift was obtained directly by comparing the observed spectra with spectra calculated for various values of $k_{exo\ \text{shift}}$, assuming the WM shift to be very fast and allowing K to change with temperature (an extrapolation of the observed changes at low temperature into the temperature region of line broadening). The matching spectra are not shown but are similar in principle to those of the more complex hexamethyl cation series shown in Fig. 2. A typical rate constant is 14 s^{-1} at −94 °C, $\Delta G^{\ddagger}$ = 9.4 kcal/mol. An Arrhenius plot gives $\Delta H^{\ddagger}$ = 10 ± 2 kcal/mol. The *exo*-3,2-methyl shift rate in **3** is quite similar to the value found for the camphenehydro cation, K = 14 s^{-1} *vs.* 92 s^{-1}, both at −94 °C. This indicates that the added methyl groups in **3** have only a small effect on this reaction.

Since the main point of using the **3**–**4** system is to look for an *endo*-3,2-shift, one looks for the

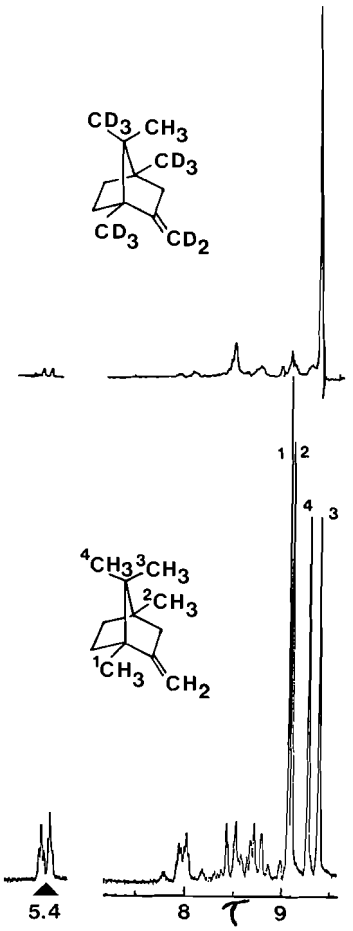

FIG. 1. Lower, n.m.r. spectrum of pure **9**. Upper, n.m.r. spectrum of pure **9** isolated after H–D exchange of $=CH_2$ and three of the four methyl groups.

remaining sharp methyl peak to broaden and eventually average with 2 and 4 (structure **3***a*). However, up to -20 °C, the highest temperature at which it was possible to still observe this peak because of a very rapid irreversible rearrangement, it still remained sharp. On analysis of this, the maximum possible rate constant for an *endo* shift must be less than 10 s^{-1} at -20 °C. Extrapolating the *exo* shift rate to -20 °C yields a minimum $k_{exo\ shift}/k_{endo\ shift}$ ratio of *ca.* 6×10^3 at -20 °C.

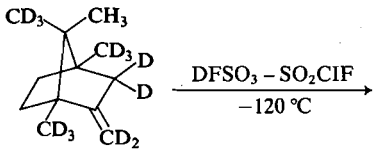
Turning next to the H–D exchange results, when the alkene **9** is dissolved in 0.9% D_2SO_4–CD_3COOD at 25 °C, one notices a rapid (in the n.m.r. spectrum) decrease in the size of the *exo* methylene $=CH_2$ group and the C-1 methyl peak. The C-4 and C-7-*anti* methyl peaks decrease somewhat slower. The half-life for the exchange of the protons in the latter is *ca.* 2 h at 25 °C. Within 1 day, there is virtually only one methyl peak of **9** left showing in the spectrum, the one assigned to the C-7-*syn* methyl. There are, as well, equilibrium amounts[1] of the three other hydrocarbons **12**, **13**, and **14**, each showing as well only a single methyl peak, C-3-*exo* in **12** and **13**, and C-7-*syn* in **14**. After several days in the deuterated acid, the hydrocarbons **9**, **12**, and **13** were isolated and purified. In Fig. 1, a spectrum of **9**, thus isolated, is compared to the original **9**. Comparisons of **12** and **13** are similar.

When the original solution is left at 25 °C for an extended period, it requires *ca.* 150 days for half of the remaining C-7-*syn* methyl signal in **9** to be lost. This loss may in small part be due to decomposition of **9** since there are no non-exchangeable positions to serve as a reference. However, if one assumes the total loss is due to H–D substitution brought about by an *endo*-3,2-methyl shift, the minimum rate difference for $k_{exo\ shift}/k_{endo\ shift}$ is 150 days/0.08 days $= 2 \times 10^3$.[2]

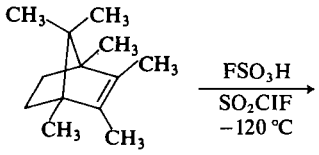
The isolation of the specifically labelled alkene **9***b* allows one to obtain the corresponding observable carbocation **3***b*–**4***b* when this is added to $DFSO_3$–SO_2ClF (1:4) at -120 °C. The n.m.r. spectrum of the resulting solution consists basically of one peak as expected, the same peak as in the all-proton ions **3**–**4** which occurred at highest field and which did not broaden (exchange). If any proof is needed, these results

[1]The relative amounts of the hydrocarbons **9**, **12**, **13**, and **14** show interesting variations with time. Very soon after dissolution of **9** in the deuterated acid the concentration of **12** increases to several times the proton equilibrium value (see previous values for these) and then slowly decreases again over a period of days to the same equilibrium value as found in the protonated case. Much more slowly, the tricyclene **13** also builds up over the proton equilibrium value and then likewise decreases. These results can be attributed to a kinetic isotope effect which favors the loss of H over D in the intermediate ions **3**–**4**.

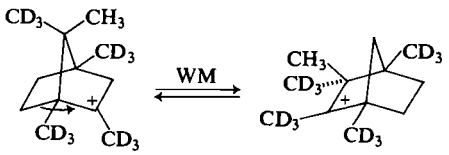
[2]The actual relationship between the rate of loss of the proton signal and the rate of the *exo* or *endo* shift is complex. The simplest case would be one where the exchange of the C-1 methyl and $=CH_2$ positions in **9** is much faster than the 3,2-methyl shifts. This is certainly not true in the present case as far as the *exo*-3,2-shift is concerned. In this circumstance, the rate of the *exo*-3,2-methyl shift will be *faster* than that observed for the loss of protons in the C-4 and C-7-*anti* methyl groups. On two counts, therefore, the *exo* shift/*endo* shift ratio must be regarded as a minimum figure.



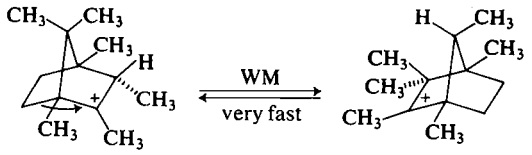
9b



10



4b 3b



7 6

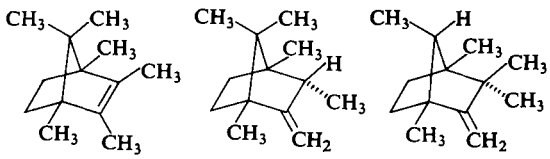
prove that the observable ion rearrangement and that occurring in the acid catalysis are the same.

However, one can now look for exchange of the CD_3 groups and the CH_3 group in the cations **3***b*–**4***b* *on a conventional kinetic basis* as opposed to the rapid rates needed to give line broadening and which we have discussed in the earlier results. Up to the temperature where the cations **3***b*–**4***b* are decomposing irreversibly at a rapid rate (and hence decreasing the size of the CH_3 signal), there is only a very slight indication of proton area 'growing' into the CD_3 peak positions. The maximum possible rate constant for the *endo*-3,2-methyl shift is *ca.* 1×10^{-3} s^{-1} at -40 °C. The minimum ratio for $k_{exo\ shift}/k_{endo\ shift}$ is now extended to *ca.* $10^4/10^{-3} = 10^7$ at -40 °C. The above results also make it obvious why no line broadening was observed for the remaining sharp methyl group in the spectrum of **3**–**4**.

Although the carbocation system **3**–**4** allows one to show a huge difference between *exo* and *endo* shifts, it has still not been possible to obtain a satisfactory measure of the actual rate of an *endo*-3,2-methyl shift. For this reason, another series was investigated.

Hexamethyl Cation Series 6–7

For reasons discussed in the Overall Plan, the five methyl groups of **3** constitute the basic requirement. In considering other systems, it was found experimentally that adding yet another methyl group to the C-7-*anti* position of **3** gave a system which was stable to much higher temperatures than was **3**. This results again in a pair of cations **6**–**7**, like **3**–**4**, averaged on the n.m.r. time scale by a very rapid WM shift. The starting material for these cations was the alkene **10**, chosen like **9**, because it is the most thermodynamically stable of the $C_{13}H_{22}$ hydrocarbons **10**, **15**, and **16** related to the ions **6**–**7**. The equilibrium concentrations of these are, 87, 8, and 4%, respectively, for **10**:**15**:**16** in 0.5% H_2SO_4–CH_3COOH at 25 °C. The synthesis and characterization of these will be reported in a separate publication.



10 15 16

Addition of **10** to FSO_3H–SO_2ClF (1:4) at -120 °C results in a pale yellow carbocation solution whose n.m.r. spectrum can be satisfactorily analyzed in terms of a very rapidly equilibrating mixture of **6**–**7**. Some of the observed n.m.r. spectra are shown in Fig. 2, as a function of temperature. At the very lowest temperatures (-130 °C), six separate methyl peaks are implied (although not all resolved in the viscous solution). The chemical shifts of these and the other protons in **6**–**7** are listed in Table 1 (see notes to this table for a description of how the assignments were made). The proton at C-3 in **7** is assigned an *exo* geometry to account for the very rapid rate observed for the *exo*-3,2-hydride shift in **7**, a rate similar to that observed in a related cation (3). In addition, protonation is normally found to occur from the *exo* side in norbornyl systems (4), although the C-7-*syn* methyl substituent might possibly have been expected to have changed this. In any case, all of the results are consistent with this assigned geometry.

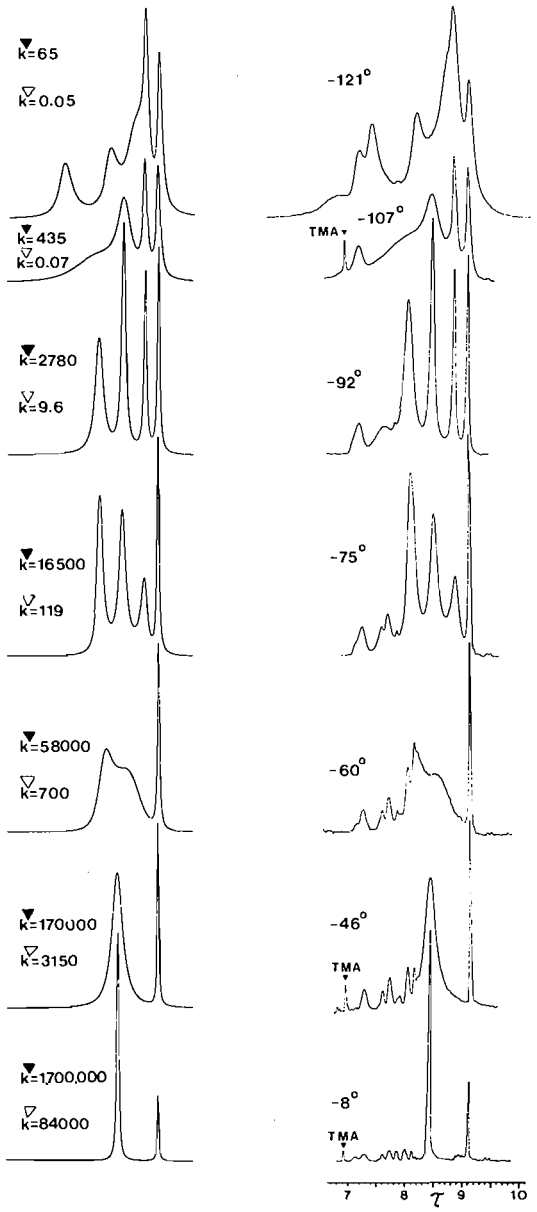

FIG. 2. Right, representative experimental ^1H spectra of the cations **6**–**7** measured at various temperatures. TMA is the reference, the tetramethylammonium cation. Left, calculated spectra for the methyl groups in **6**–**7**, $k^{\blacktriangledown}$ = rate of *exo*-3,2-hydride shift in **7** and $k^{\triangledown}$ = rate of *exo*-3,2-methyl shift in **6**.

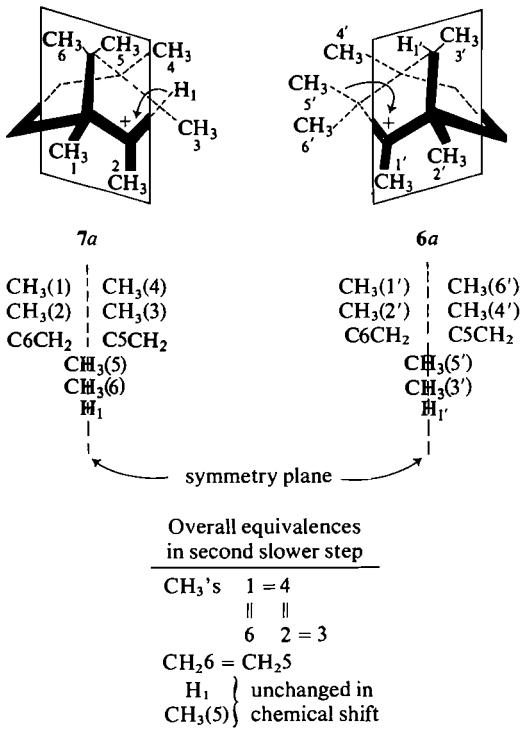
At the temperature where six separate methyl peaks occur, one is dealing with a very similar situation to that described for the pentamethyl cation case. An analogous analysis of the temperature dependence of the separation (δ) of the two lowest field methyl peaks gives K = **6**/**7** = 0.21 at −121 °C. However, whereas in the pentamethyl ion only one line-broadening process occurs, *i.e.* that due to the *exo*-3,2-methyl shift in **3**, there are two separate line-broadening processes in **6**–**7**. As the solution is warmed above −130 °C, four (the lowest field four) of the six methyl peaks broaden and eventually coalesce so that by −92 °C (Fig. 2), one has four peaks in an area ratio 6:6:3:3. Further warming results in the two 6H peaks and the lower field of the 3H peaks broadening and eventually coalescing into a single peak so that at high temperatures (−8 °C), one has two sharp peaks of relative area 15:3 (Fig. 2).

The actual form of the broadening indicates conclusively that the lower temperature broadening is due to an *exo*-3,2-hydride shift in **7** and the higher temperature broadening to an *exo*-3,2-methyl shift in **6**. The actual equivalences are shown below:



Thus, if the lowest temperature broadening had involved the *exo*-3,2-methyl shift in ***6a***, one of the two remaining unchanged methyls should have been a doublet (3–3′ in ***7a***–***6a***). From Fig. 2, −92 °C spectrum, this clearly is not the case. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

exo-3,2-hydride shift requires methyls 5 and 6 to remain unchanged and these are clearly singlets.

The calculated spectra (representative examples are shown in Fig. 2) were obtained using three different rate constants and a temperature-dependent equilibrium constant in the kinetic matrix. The rate constant for the WM process was made very large in all cases. Numerical values for $k_{3,2\text{-hydride}}$ and $k_{exo\text{-}3,2\text{-methyl}}$ can be obtained with relative ease using spectra obtained at very low temperatures (−130 to −100 °C) for the former and at the higher range (−75 to 0 °C) for the latter, avoiding in the first instance those temperatures where both rate processes contribute to line broadening (*ca.* −75 to −100 °C). Having derived rates and activation energies for the two processes, one can then check the spectra in this region for consistency, that shown in Fig. 2 at −92 °C is illustrative of the close fit of the experimental and calculated curves. A typical rate constant for the 3,2-hydride shift is 375 s^{-1} at −110 °C, $\Delta G^{\ddagger}$ = 7.4 kcal/mol. From the Arrhenius plot, $\Delta H^{\ddagger} = 7 \pm 1$ kcal/mol. For the *exo*-3,2-methyl shift, a typical rate constant is 400 s^{-1} at −67 °C, $\Delta G^{\ddagger}$ = 9.4 kcal/mol. The Arrhenius plot in this case is shown in Fig. 3 and yields $\Delta H^{\ddagger} = 9.8 \pm 1$ kcal/mol. Although the analysis needed to obtain these rate constants is admittedly complex, this should not be allowed to distract from the simple answers obtained, *i.e.* the rate for the 3,2-hydride shift in **7** and the rate for the *exo*-3,2-methyl shift in **6**. The *exo*-3,2-methyl shift rate in **6** is quite close to that observed for **3**, the extrapolated rate constant from Fig. 3 for **6** at −94 °C is 7.4 s^{-1} *vs.* 14 s^{-1} for **3**, again indicating that the additional methyl in **6** does not affect the *exo*-3,2-methyl shift rate appreciably.

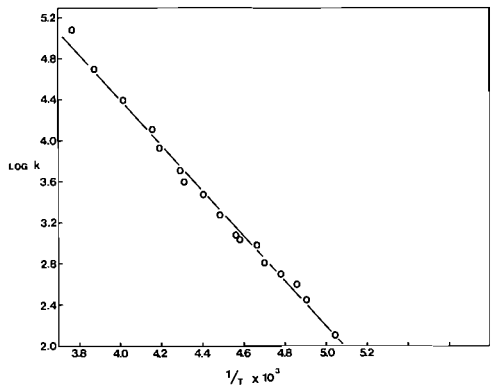


FIG. 3. Plot of log k for the *exo*-3,2-methyl shift in **6** *vs.* $1/T$.

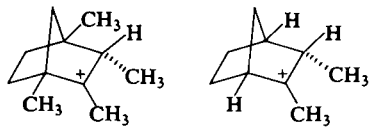
Surprisingly, the rate of the *exo*-3,2-hydride shift in **7** is not greatly affected by the presence of the C-7-*anti* methyl substituent if one compares this with the corresponding rate in the cation **17**, $k_{exo\text{-}3,2\text{-hydride}}$ = *ca.* 270 s^{-1} at −115 °C for **17** *vs.* 125 s^{-1} for **7** at −115 °C. In the 2,3-*endo*-dimethyl-2-norbornyl cation **18**, the rate is only about 25 times as fast (5).



17 **18**

The sharp high-field methyl peak shown for the −8 °C spectrum in Fig. 2 can still be observed as a sharp peak at +30 °C, although an irreversible rearrangement of **6**–**7** is taking place very rapidly at this temperature. One can assign a maximum rate constant of 10 s^{-1} at +30 °C for the *endo*-3,2-methyl shift required to broaden this line (see Overall Plan). The extrapolated rate constant for the *exo*-3,2-methyl shift from Fig. 3 is 9.3×10^5 s^{-1} at 30 °C, giving the minimum ratio $k_{exo\text{-methyl shift}}/k_{endo\text{-methyl shift}} = 9.3 \times 10^4$.

The increased temperature stability of **6**–**7** relative to **3**–**4** is of interest and may be due to a statistical entropy stabilization in the former case. If one carries out a sequence 3,2-hydride shift, WM shift, *exo*-3,2 methyl shift, WM shift, 3,2-hydride shift, *etc.* on **6** and **7**, it requires 20 steps in one direction before one again reaches an identity with all of the unique methyl groups back in their original positions. This is shown in Fig. 4. There are 10 degenerate structures in **7** and 10 in **6**. The 10 structures in each correspond to a permutation of the 5 unique exchanging positions, C-1, 2, 3-*endo*, 4 and 7-*anti*, and the five unique substituents 1, 2, 3, 4, and 6 at each of these positions, the substituents maintaining an unique order with respect to one another. There are series involving both the 1*R* and 1*S* forms of the assymmetric 2-norbornyl cation (but never involving enantiomers), to give the total of 10 of each. If one follows the reaction scheme of Fig. 4 in a clockwise direction, the fixed relationship of the substituents involves a clockwise rotation in **6** and **7** to an observer facing the

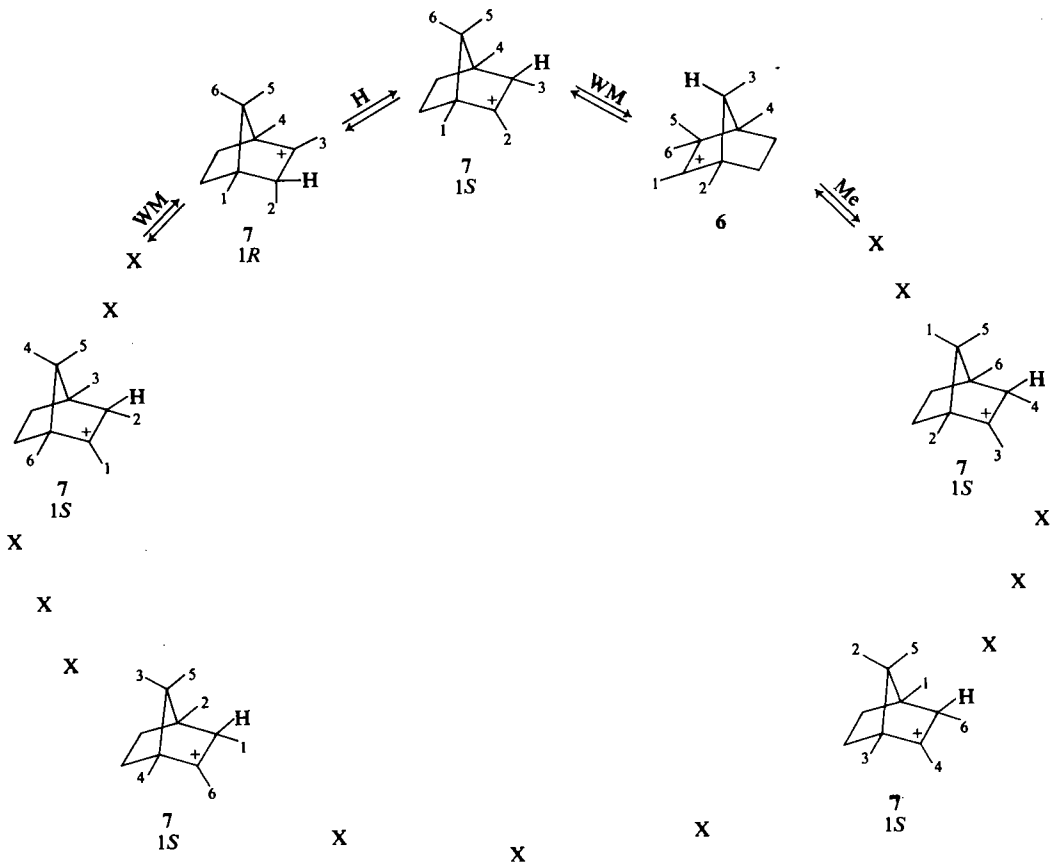


FIG. 4. Degenerate rearrangement cycle for the cations **6**, **7**. There are 10 structures for **6** and 10 for **7**. One-half in each case are 1*S* enantiomers and one-half 1*R*.

structures as written below. The C-3 proton in **7**, C-7 *syn* in **6**, resides with each of five methyl substituents 1, 2, 3, 4, and 6 in turn, and in order to get complete averaging of the coupling would require a complete sequence of steps. Experimentally the line widths in **6**–**7** are too broad (see for example the 15H peak at −8 °C in Fig. 2) to show the subtle changes expected as the coupling becomes averaged, although one can show the effects in calculations by using artificially narrow line widths.

6 and **7** series

The degeneracy present in **6**–**7** will result in a stabilization of these cations relative to other hexamethyl cations in which this degeneracy is not present by at least 1 kcal/mol. Thus, when the only doubly degenerate pentamethyl cations **3**–**4** irreversibly rearrange, they are apparently forming other more stable pentamethyl-2-norbornyl cations. When the (each) 10-fold degenerate **6**–**7** rearrange, they are directly forming a cyclopentenyl cation.

In the H–D exchange part of this work, the alkene **10** was dissolved in 0.55% D_2SO_4–CD_3COOD. The solution was then heated to 50 °C and the sequence of events shown in Fig. 5 was observed. The two largest peaks in the initial spectrum (*E*) of **10** are assigned to the C-1–C-4 and C-2–C-3 methyls, the former the higher field. The highest field of the 'single' methyl peaks is assigned to the 7-*syn* methyl, the other to the 7-*anti* methyl. Both 6H peaks decrease relatively fast, $t_{1/2}$ *ca.* 10 min for the C-2–C-3 methyls and *ca.* 40 min for the C-1–C-4 methyls. The C-7-*anti*

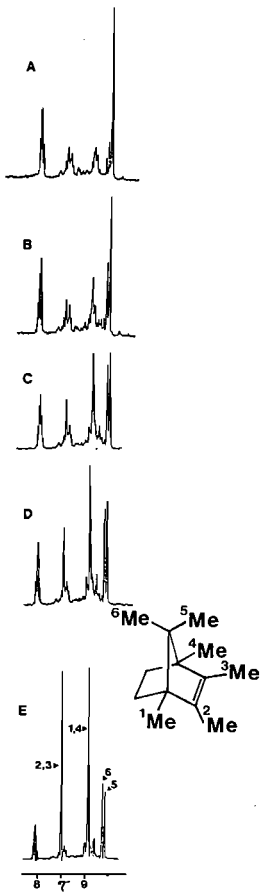

FIG. 5. The H–D exchange with time of protons in the alkene **10**, measured in 0.55% D_2SO_4–CD_3COOD at 50 °C. *E*, initial; *D*, 30 min; *C*, 45 min; *B*, 100 min; *A*, 27 h. The peak to the left is the peak height reference signal, CHD_2COOD.

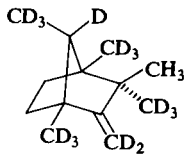
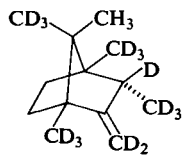
methyl decreases more slowly, $t_{1/2}$ *ca.* 90 min. After 2 days, only one methyl signal remains, spectrum *A* in the Fig. 5 sequence. The two small peaks to the lower field side of the large peak in *A* are due to single CH_3 peaks in the two alkenes **16***a* and **15***a*, the proportions *ca.* 1:2.



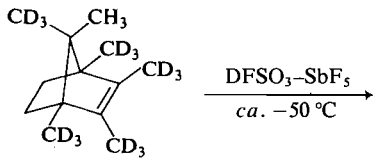
16*a*



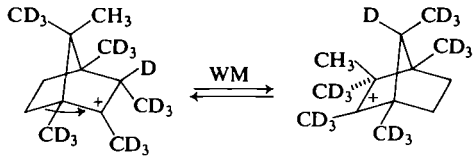
15*a*

The above solution was then kept at 25 °C for *ca.* 120 days before one-half of the remaining CH_3 peak had disappeared. The rate of this decrease is very similar to that observed in the pentamethyl alkene **9** for the related methyl group. Although the rate of H–D exchange due to the *exo*-3,2-methyl shift, *i.e.* as measured by the loss of the C-7-*anti* methyl, is slower in **10** compared to **9**, this is quite probably caused by an intrinsically slower H–D exchange rate in **10**. This occurs because the dominant deprotonation process of the cations **6–7** is loss of the C-3 proton, which does not lead of course to exchange in the methyl groups, whereas in **3–4**, the dominant loss is from a methyl group. It seems probable to us that the actual rate of the *exo*-3,2-methyl shift is similar in both the H–D exchanges in **9** and **10** so that the ratio quoted for the pentamethyl series, 2×10^3, is roughly applicable to **10**.

When a solution of **10** was kept at 50 °C for 2 days in the deuterated acid and then worked up, the pure alkene **10***a* could be isolated. Adding this to 1:1 (by weight) $DFSO_3$–SbF_5 at *ca.* −50 °C yields a solution of the carbocations **6***a*–**7***a*.



10*a*



6*a* **7***a*

An n.m.r. spectrum of **6***a*–**7***a* at −30 °C is shown in Fig. 6*A*. In addition to the sharp single methyl peak of **6***a*–**7***a*, there is a small, broad peak for the residual CHD_2 protons of the five coalesced methyl peaks in **6***a*–**7***a* and some residual protons in the C-5–C-6 region which were not exchanged out in **10***a*. This spectrum can be contrasted to that shown in Fig. 2 for the all-proton analog.

When the solution of **6***a*–**7***a* was warmed to −10 °C, exchange of the remaining methyl group with the other five was finally observed. The intact CH_3 group in **6***a*–**7***a* is finding its way into the five-methyl rearrangement manifold and

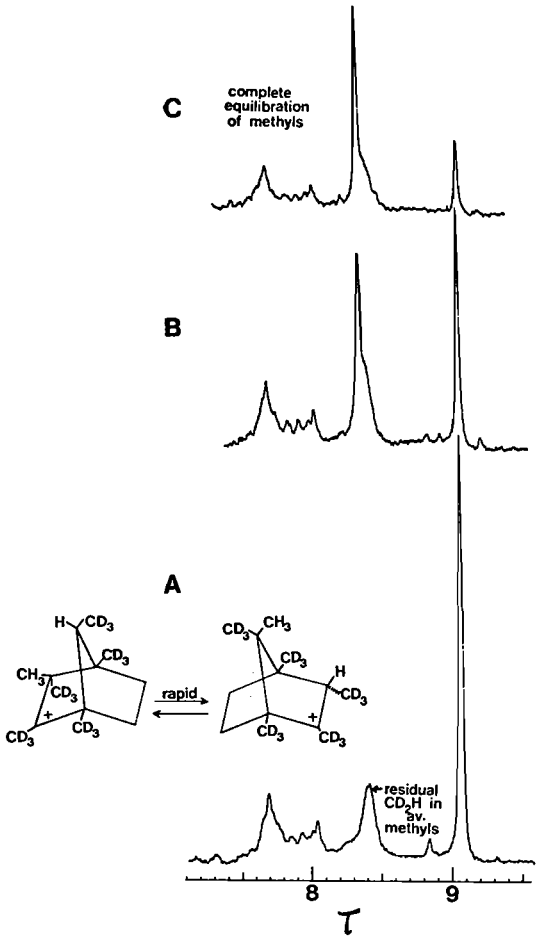

FIG. 6. The ions **6**, **7** prepared from the partially deuterated alkene **10***a*. *A*, −30°C; *B*, after 30 min at −10 °C; *C*, after complete equilibration at 0 °C.

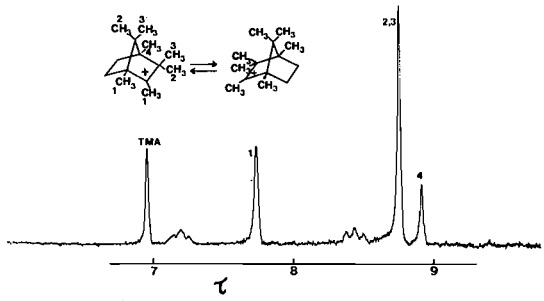

FIG. 7. Nuclear magnetic resonance spectrum at −70 °C of the carbocation **8**.

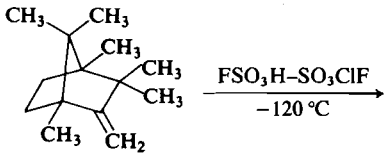
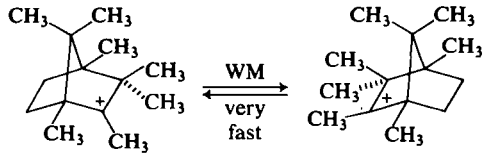
is appearing as a sharp peak[3] superimposed on the residual CD_2H protons already there. The rate constant for this process was *ca.* 4×10^{-4} s^{-1} at −10 °C. If this overall exchange is the result of an *endo*-3,2-methyl shift in cation **6***a*, then the rate constant for this shift is *ca.* 1×10^{-4} s^{-1} (taking the unfavorable equilibrium concentration of **6***a* into consideration). An actual value for $k_{exo\text{-}3,2\text{-methyl shift}}/k_{endo\text{-}3,2\text{-methyl shift}} = 7 \times 10^4/1 \times 10^{-4} = 7 \times 10^8$ at −10 °C can finally be arrived at.

Heptamethyl Cation Series **8**

Addition of the alkene **11** to FSO_3H–SO_2ClF (1:4) at −120 °C generates the carbocation **8** whose n.m.r. spectrum is shown in Fig. 7. As in



11



8

the other ions, the WM shift, which is degenerate in this case, is very rapid on an n.m.r. time scale. The chemical shifts for the WM averaged structure are listed in Table 1, the chemical shifts of the 3-*endo*–7-*anti* and 3-*exo*–7-*syn* methyl 'pairs' being accidentally equivalent. Up to the temperature (−50 °C) where an irreversible rearrangement becomes rapid, there is no sign of line broadening in the n.m.r. spectrum of **8**. Using the double irradiation spin-saturation transfer technique of Forsén and Hoffman (6), it was possible to observe a decrease in the size of the C-1–C-2 methyl groups on irradiation of the C-4 methyl at −50 °C. Very approximately (assuming $T_1 = 1$ s), this yields the rate constant for the exchange, $k = 1$ s^{-1}. The actual exchange

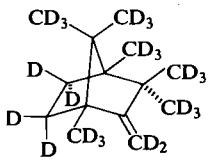
[3]The use of the much stronger acid $DFSO_3$–SbF_5 was necessary because in $DFSO_3$–SO_2ClF (1:4), there is direct exchange of solvent deuterium with carbocation protons at −10 °C, *i.e.* as soon as the CH_3 group exchanges into the five-methyl manifold it becomes exchanged out.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

may be due to an *endo*- or *exo*- (or both) 3,2-methyl shift. Assuming that the rate were for an *exo*-3,2-methyl shift, the minimum factor by which the C-7-*syn* methyl slows down the *exo*-3,2-methyl shift would be $1/(2 \times 10^3)$ (from **6**–**7** data) $= 5 \times 10^{-4}$. This can be contrasted with the minimal effect of a C-7 *syn* methyl on the 3,2-hydride shift, *cf.* ions **7** and **17**. The difference is not unexpected in view of the differing steric requirements for H and CH_3 but this study puts a quantitative value on it.

In the H–D exchange studies, the hydrocarbon **11** was dissolved in 0.85% D_2SO_4–CD_3COOD and heated to 58 °C. Within 10 min at this temperature there is virtually no signal left for the C-1 methyl group or the *exo*-methylene protons of **11**. This is shown in Fig. 8*D*, the peak *1* corresponding to the residual C-1 methyl signal. After 20 h at this temperature (spectrum *C*), there is a noticeable decrease in the C-4–C-6 methyl peak relative to the others. The bath temperature was then raised to 80 °C and after 5 h at this temperature, spectrum *B* was obtained. The final spectrum *A* was obtained after a total of 9 h at 80 °C. The results obtained indicate that both *exo*- and *endo*-3,2-methyl shifts are occurring, the decrease in peaks *2* and *6* indicative of the *exo* shift and the decrease in *3* and *5* indicative of the *endo* shift. The results suggest that the *exo*-3,2-methyl shift is marginally faster.

A comparison of the *exo* and *endo* shifts in **11** with alkenes **9** and **10** is difficult because of the different temperatures involved. When exchange in **9** was carried out at 58 °C, the half-life for exchange of the C-4 and C-7-*anti* methyl groups (indicative of the *exo*-3,2-methyl shift) was *ca.* 5 min. One can estimate the half-life for the corresponding H–D exchange in **11** as perhaps 60 h



11*a*

at 58 °C, giving an approximate ratio of 1.5×10^{-3} for the decreased rate of the *exo*-3,2-methyl shift in **11**. This is of the same order of magnitude as that found in the observable ion comparisons. The rate of the *endo*-3,2-methyl shift in **11** may be somewhat faster than in **9** and **10** but there is certainly no dramatic difference.

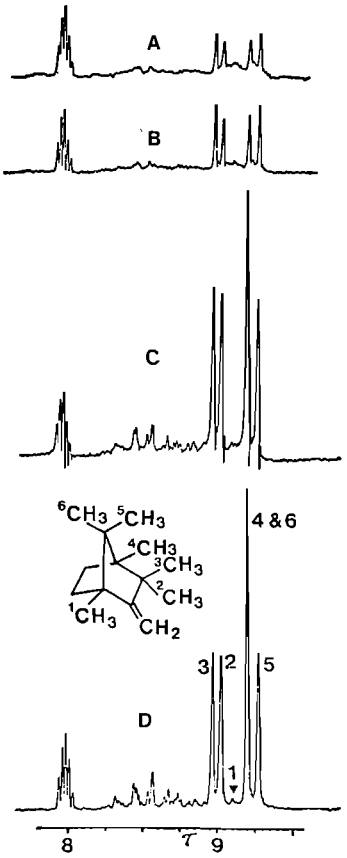


FIG. 8. The H–D exchange with time of the protons in alkene **11**, measured in 0.85% D_2SO_4–CD_3COOD. *A*, less than 10 min at 58 °C; *B*, after 20 h at 58 °C; *C*, after a further 5 h at 80 °C; *D*, after 9 h at 80 °C. The peak to the left is CHD_2COOD, which was used as a constant peak height reference.

When the deuterated acid solution of **11** is heated at 80 °C, a deep violet color develops and in order to ascertain whether the peak decrease shown in Fig. 8 is simply due to decomposition, the hydrocarbon (expected to be partly **11***a*) was reisolated. The mass spectrum of this recovered **11** (parent ions) indicated the following species and percentages: d_{11}, <1%; d_{12}, 1%; d_{13}, 2%; d_{14}, 4%; d_{15}, 6%; d_{16}, 9%; d_{17}, 12%; d_{18}, 14%; d_{19}, 15%; d_{20}, 14%; d_{21}, 11%; d_{22}, 7%; d_{23}, 3%; and d_{24} (perdeuterioalkene **11***a*), 1%. Since one is exchanging out 24 protons, there is considerable equilibrium proton content in **11**. Clearly, the results are consistent with both *exo* and *endo* shifts since a maximum d_{18} species would be produced if only one of the 3,2-methyl shifts were involved. The loss of the C-5 and C-6

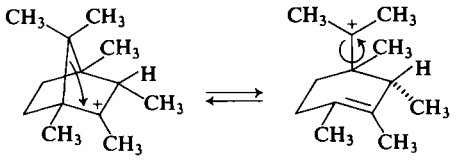
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

methylene protons can occur via the corresponding tricyclene which appears to be a minor equilibrium constituent along with **11**.

Alternatives to an endo-3,2-Methyl Shift

The *exo*-3,2-methyl shift in the observable cations is unambiguously established because the n.m.r. line-broadening method essentially labels each unique group. Likewise, because one knows the absolute rate of this shift to be fast, it is very reasonable to interpret the H–D exchanges in the ion intermediates in terms of this. The proposed *endo*-3,2-methyl shift is so slow and the evidence is based on a much less unique labelling scheme so that alternative explanations should at least be considered.

We have been unable to formulate *any* reasonable process in the observable ions which would involve a symmetry plane developing in the 2-norbornyl cation structure and which would equate the C-3-*exo* methyl group with either the C-3-*endo* methyl or the C-2 methyl. The only processes which appear remotely possible are ones involving ring opening, rotation and reclosure, for example, as in Scheme 4. A similar



SCHEME 4

process could occur with breaking of the C-6–C-1 bond of an intermediate norbornyl cation. All things considered, the most reasonable rationalization of the CH_3 scrambling observed in Fig. 6 is to formulate the *endo* methyl shift.

In the H–D exchange work, all that is required for a methyl to exchange is that it be located next to the positive center of a carbocation intermediate. One can imagine equilibrium processes, Scheme 5, which accomplish this but do not ever equate the methyls concerned with any other (in contrast, the observable ion studies require this). The actual alkene produced from **19** would have to be thermodynamically much less stable than **10** since one can account for all of the observed g.l.c. peaks in terms of alkenes related to the ions **6**–**7** (see hexamethyl cation results). Large stability differences between these alkenes seem somewhat unlikely; however, an even stronger case for an actual *endo*-3,2-methyl shift comes from a careful analysis of the H–D substitution pattern in the alkene **11** (shown in Fig. 8 and analyzed in Scheme 6).

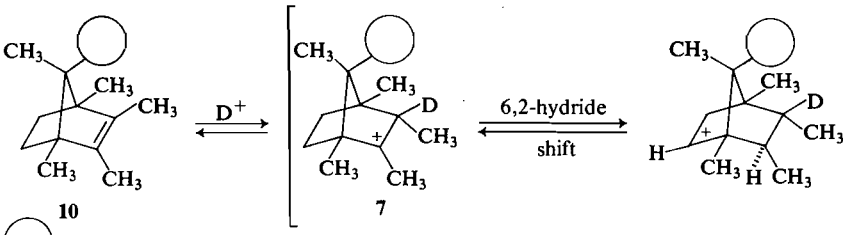
Experimentally, methyl 1 is very quickly exchanged. A migration of any of the four methyls 2, 3, 5, 6 allows for subsequent substitution of the 4-methyl group (which is unfortunately overlapped by 6). The actual substitution pattern for this group is consistent with this picture, *i.e.* by the time the other groups have decreased by a factor of two, the 4-methyl should have decreased by a factor of eight (the *exo* and *endo* processes occur at nearly the same rate). Hence, in Fig. 8*B*, where the decrease in peaks 2, 3, 5, and 6 is somewhat more than a factor of two, the 4-methyl has been, within experimental error, fully exchanged. This particular pattern would not likely have occurred if the exchange had taken place by some other mechanism (as in Scheme 5) and all things considered, the H–D exchange rates appear to us to reflect the *exo*- and *endo*-3,2-methyl shifts.

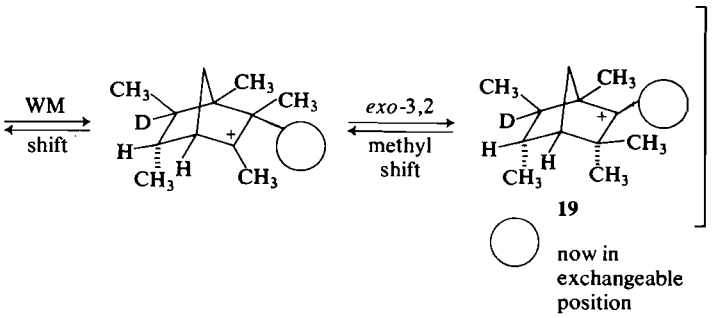
Direct Measurement of the H–D Kinetic Isotope Effect for a 3,2-Hydride Shift

When the alkene **10** was added to $DFSO_3$–SO_2ClF (1:4), the cations **6**–**7** which were produced had, surprisingly, a considerable C-3 proton content (Scheme 7). We have no explanation for this but in any case, when the cation solution is carefully warmed, there is preferential exchange of solvent deuterium with this position before any appreciable exchange occurs in other positions. When the line broadening due to the 3,2-D shift is analyzed, the rate is found to be about eight times slower than for the corresponding proton shift, giving $k_H/k_D = 8$ at -110 °C. This experiment is included in this paper because vicinal hydride shifts in observable cations are usually too fast to measure. The fact that the hydride shift in **6**–**7** is measurable and amenable to a rather accurate kinetic treatment made it worthwhile to show the potential for the direct measurement of isotope effects in cation rearrangements. Further studies are in progress.

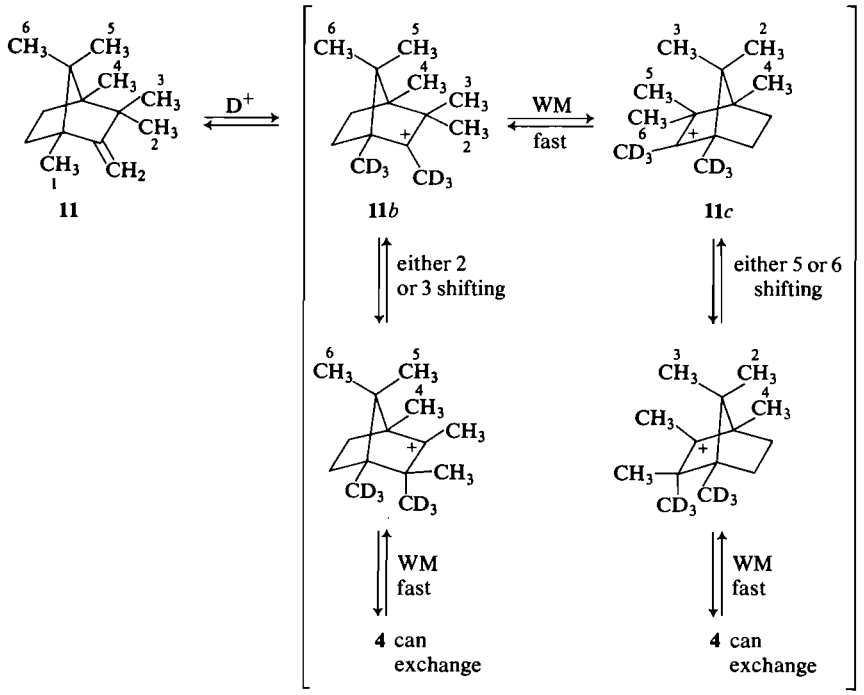
Discussion

This work shows that *exo*-3,2-methyl shifts in tertiary 2-norbornyl cations are overwhelmingly preferred to *endo* shifts. Thus the recently reported (7) occurrence of an *endo*-3,2-methyl shift must be seriously questioned, as indeed Collins





SCHEME 5



SCHEME 6

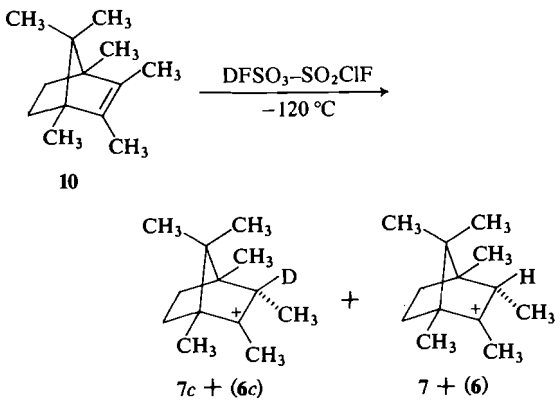
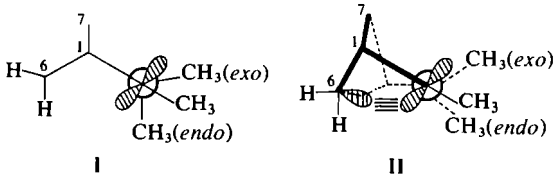


SCHEME 7

and Lietzke (8) have also done but on other grounds.

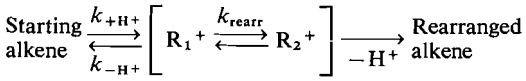
Nevertheless, the stereospecificity of the 3,2-shift is much higher in the observable ions, *cf.* for the **6**–**7** system, 7×10^8 *vs.* 2×10^3 for acid catalysis, although in part this occurs because reactions are more selective at low temperatures. Some stereospecificity for *exo*-3,2-shifts in solvolytically generated 2-norbornyl cations is a well established phenomenon (9, 10) and in the report by Vaughan and co-workers (7) concerning an *endo*-3,2-methyl shift, the *exo* shift is still reported as being dominant. The uncertainty we hope to have answered in this paper is one of quantity. This stereospecificity in 2-norbornyl cations has generally been attributed to a nonclassical structure for the ions (9, 10) or to tortional effects (9). In the present ions, the existence of the two WM-shift isomers **3**–**4** is firmly established and a nonclassical structure definitely ruled out. If one makes a normal model of the 2-norbornyl cation, the geometry looking down the C-2–C-3 bond is approximately as shown in **I**, as noted previously by Schleyer (9). There is evi-



I II

dence in observable tertiary norbornyl cations for some overlap of the empty $2p_z$ orbital with a back lobe on C-6 (11) and this can be visualized as a twisting of the $2p_z$ orbital (**II**). This makes the *exo* substituent more colinear and the *endo* substituent less so and is an obvious way to rationalize the experimental facts. In more nucleophilic solvents, such as are used in acid catalysis or solvolysis work, there may be less need for internal stabilization via C-2–C-6 bonding and hence a geometry in which the stereospecificity is somewhat diminished. One might also predict that a phenyl substituent at C-2 would act in much the same way as a nucleophilic solvent, *i.e.* that it would delocalize charge from C-2 without the need for internal stabilization and that the stereospecificity would also be diminished in this case.

In determining absolute rearrangement rates for carbocations, one should in principle be able, *if* these rates are applicable to the more nucleophilic solvents, to calculate overall rates in conventional acid catalysis rearrangement reactions. Such a reaction is outlined in Scheme 8. If



SCHEME 8

$k_{-H^+} > k_{rearr}$, then the overall rate constant is given by $k_{overall} = Kk_{rearr}$. If one could assign an accurate pK_a value to the carbocation and if the p*H* or acidity function of the solvent system were known, one could calculate $k_{overall}$. Unfortunately, k_{-H^+} seems to be competitive with k_{rearr} in the examples in this work except for the heptamethyl case or for the *endo*-3,2-methyl shifts. An ideal situation for this kind of study would in fact be a k_{rearr} rate constant somewhere between the *exo*- and *endo*-shift value, *i.e.* easily measurable as a degenerate process in observable cations and fast enough so that dilute acid solutions of well-defined p*H* and moderate temperatures could be used for the acid catalyzed rearrangement. The other possibility would be to increase k_{-H^+} in the present examples by using a more basic solvent system.

Conclusions

(*i*) From observable ion studies, there is a huge difference in the migratory aptitudes of 3-*exo* and 3-*endo* methyl groups in 2-norbornyl cations.

(*ii*) The same trend is readily apparent in acid-catalyzed rearrangements but to a lesser extent.

(*iii*) A C-7-*syn* methyl substituent has a very large effect on an *exo*-3,2-methyl shift but almost none on an *exo*-3,2-hydride shift.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(*iv*) An *exo*-3,2-hydride shift is very much faster than an *exo*-3,2-methyl shift (a factor of 1.6×10^3 at -80 °C).

Experimental

All n.m.r. measurements were made using a Varian HA-100 spectrometer equipped with a variable temperature probe. Temperatures were measured using a thermocouple inserted directly into the n.m.r. tube. For the spin-saturation transfer experiments, the precautions outlined in the preceding paper (1) were followed. The preparation of the carbocations and the quenching procedures were similar to those previously described (3).

H–D Exchange Studies

The pure alkene (2% by weight of the final solution) was added to the D_2SO_4–CD_3COOD mixture and a small sample removed for the n.m.r. study. The rates of the H–D exchanges were based on peak heights, the unchanging CHD_2 peak of the deuterated acetic acid being used as an internal standard. When the n.m.r. study had determined the time and temperature necessary for the complete exchange (specific), the same conditions were applied to the bulk solution. For the recovery of the alkenes, the acid solution was added dropwise to an ice-cold stirred solution of excess Na_2CO_3 in D_2O and the alkene extracted 3 x with ether. After drying over anhydrous K_2CO_3, the ether was removed to yield the crude alkene mixture, which could be separated by preparative g.l.c. using a 12 ft × 3/8 in. column of Carbowax 20 M at 165 °C.

Nuclear Magnetic Resonance Line-Broadening Calculations

The calculated spectra were obtained by solving the Bloch equations. The major problem in both the pentamethyl and hexamethyl series comes in the variation of the equilibrium constant with temperature. Once this relationship has been established, it is necessary to match the experimental spectra at each temperature with spectra calculated specifically for this temperature (running through a series of rate constants in order to determine the best fit). Since the calculated spectra involve only the methyl groups, the calculations need take into account only first-order coupling effects.

The authors wish to thank the National Research Council of Canada for generous financial support.

The Activity of AgCl in AgCl–LiCl–KCl Melts

ANTHONY C. GRUNER[1] AND WILLIAM T. THOMPSON

Department of Mining and Metallurgical Engineering, McConnell Engineering Building, McGill University, Montreal, Quebec H3C 3G1

Received September 12, 1974

ANTHONY C. GRUNER and WILLIAM T. THOMPSON. Can. J. Chem. **53**, 1084 (1975).

Thermodynamic properties of silver chloride in molten silver chloride – lithium chloride – potassium chloride melts were studied using a silver chloride formation cell employing a chlorine electrode of novel design which facilitated measurements in ternary melts. The data were treated by analytical methods resulting in the generation of activity and the partial molar excess free energy at 500 °C.

The measured properties were interpreted with the aid of a model which presupposed the existence of free silver ions as well as those "bonded" to adjacent chloride ions. With three adjustable parameters it was possible to account for the thermodynamic behavior of silver chloride.

ANTHONY C. GRUNER et WILLIAM T. THOMPSON. Can. J. Chem. **53**, 1084 (1975).

On a étudié les propriétés thermodynamiques du chlorure d'argent dans des masses fondues contenant du chlorure d'argent, du chlorure de lithium et du chlorure de potassium; ces études ont été effectuées en faisant appel à une cellule à formation de chlorure d'argent munie d'une électrode à chlore redessinée pour faciliter les mesures dans des masses fondues ternaires. On a traité les données par des méthodes analytiques de façon à en déterminer la génération d'activité et les énergies libres molaires partielles à 500 °C.

On a interprété les propriétés mesurées à l'aide d'un modèle qui présuppose l'existence d'argent sous forme d'ions libres de même que d'autres "liés" à des ions chlorures adjacents. En faisant intervenir trois paramètres ajustables, il est possible d'expliquer le comportement thermodynamique du chlorure d'argent. [Traduit par le journal]

Introduction

In view of the importance of fused salt electrowinning processes to extractive metallurgy, numerous studies of molten salts and solutions thereof have been conducted by metallurgists in the past two or three decades. Of basic importance is a knowledge of the thermodynamic properties. These are useful in understanding melt structure.

Thermodynamic studies have generally been restricted to binary systems in spite of the importance of ternary solutions in many practical electrolyte systems. In recent years, however, there have been systematic investigations of silver chloride – alkali chloride ternary systems; these include the systems silver chloride – sodium chloride – potassium chloride (1) and silver chloride – sodium chloride – cesium chloride (1) and most recently, silver chloride – sodium chloride – rubidium chloride (2). The properties of these three systems are much the same because of the chemical similarity of the alkali metals from sodium to cesium. It is expected that there would be much different behavior for a ternary system of silver chloride containing lithium chloride because of the small ionic radius of lithium.

This report is concerned with the measurement and interpretation of the properties of the molten silver chloride – lithium chloride – potassium chloride system. This system is slightly more difficult to study than those cited previously because of the tendency of lithium chloride to react with atmospheric water vapor to form lithium hydroxide and hydrogen chloride. However, in other respects this system is amenable to precise study especially because of the low temperature eutectic in the lithium chloride – potassium chloride binary system. This permits useful data to be gathered on the melt without the necessity of measurements at temperatures in excess of 535 °C.

Experimental Procedure

Thermodynamic properties of molten silver chloride – lithium chloride – potassium chloride electrolytes were

[1]This work was submitted by A. C. Gruner in partial fulfilment of the requirements for the M. Eng. degree at McGill University.

determined by measuring the Gibbs free energy change for the reaction

$$Ag_{(s)} + \tfrac{1}{2}Cl_{2(g)} \rightarrow AgCl_{(l)}$$

in electrolytes of different silver chloride concentration over the approximate temperature range of 370 to 535 °C. The proven electrochemical technique which makes use of the cell

$$-Ag/AgCl\text{–}LiCl\text{–}KCl/Cl_2, C+$$

was employed exclusively in this work (3).

The cell is shown in Fig. 1; construction details of this mainly Pyrex apparatus are largely self-explanatory.

Prior to cell assembly the crucible was filled with a chloride solution. This solution was purified *in situ* by passing anhydrous hydrogen chloride vapor over the salts (4) and then filtering the melt through Pyrex wool. The solution was then purged of dissolved hydrogen chloride by bubbling argon through the melt for 2 h.

The silver electrode was a fine-silver wire 3 mm in diameter immersed about 2 cm into the melt.

The chlorine electrode basically consisted of a graphite rod in contact with the melt and a chlorine atmosphere. A detailed drawing appears in Fig. 2. The graphite rods were 6 mm in diameter and made of spectroscopic grade material. The graphite was nevertheless pretreated by baking in vacuum at 900 °C for 12 h and then in a chlorine atmosphere for 48 h. The use of the movable tapered glass joint at the bottom of the electrode assembly made it possible to achieve a cell resistance of 500 to 3000 ohm. With such a resistance chlorine diffusion to the silver electrode is effectively eliminated. It has been found that it is only when chlorine diffusion is reduced to very low values that reproducible and thermodynamically meaningful e.m.f. measurements can be made (3).

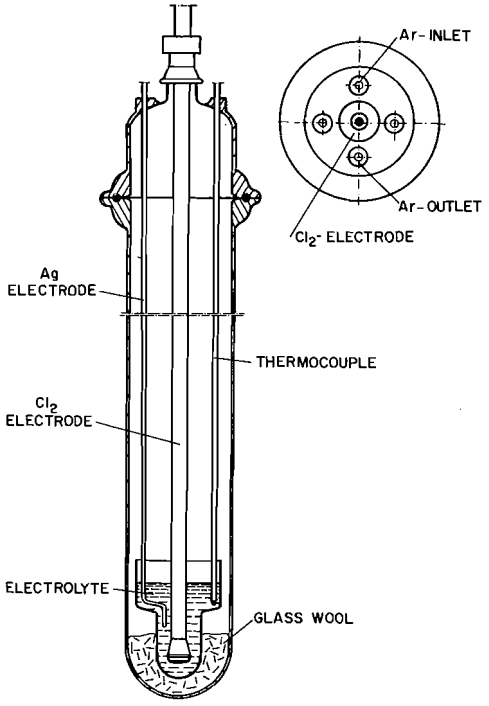

FIG. 1. Overall view of electrochemical cell.

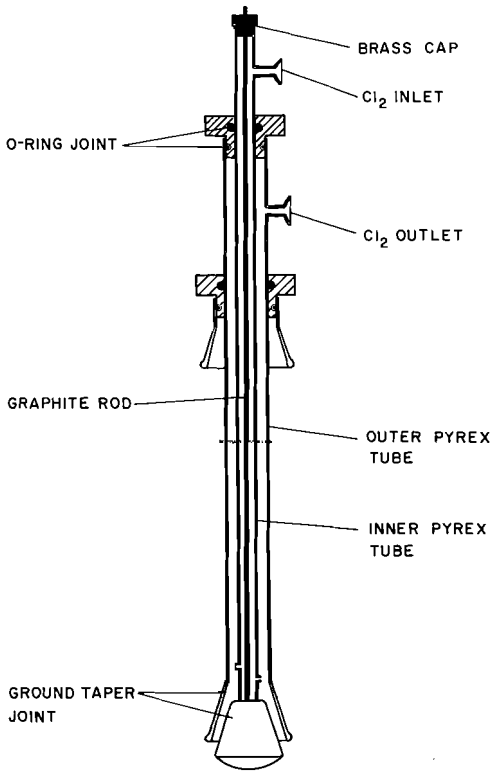

FIG. 2. Detail of chlorine electrode.

Measurements were conducted on pure silver chloride and 13 ternary solutions. Compositional changes along paths of constant lithium chloride to potassium chloride ratio were made by adding silver chloride directly to the melt. After each addition, anhydrous hydrogen chloride was bubbled through the melt followed by argon purging. The tapered glass joint at the bottom of the chlorine electrode was found to be particularly useful for such composition changes. In particular it was easy to ensure that the melt composition was uniform throughout the entire cell by simply opening the tapered joint and moving the electrode up and down a few times in the melt.

After each change in composition, it took several hours to reach a stable e.m.f. This is attributed to the time required for chlorine to saturate the electrolyte. The chlorine pressure was measured with a manometer and typically was about 10–12 Torr above atmospheric pressure.

Measurements of e.m.f. were stable to within 0.2 mV for a period of 1 h and responded immediately to changes in temperature. The values were reproducible on increasing and decreasing the temperature.

The temperature was measured with a calibrated chromel–alumel thermocouple. With it the temperature gradient within the melt was determined to be about

0.4° (C) cm^{-1}. Since the overall depth of the melt was 10 cm, the uncertainty in temperature is about $\pm 2°$ (C).

When the e.m.f. measurements of a particular composition were completed, two samples of the melt were taken for silver chloride and potassium chloride analysis. The analysis was carried out by dissolving the frozen salt mixture in ammonium hydroxide and distilled water. The silver chloride was precipitated from the solution after expelling the ammonium hydroxide (5). The precipitate was collected, dried, and weighed. The filtrate was saved and then analyzed gravimetrically for potassium chloride by using the perchlorate method (6). The lithium chloride concentration was determined by subtracting the combined weights of potassium chloride and silver chloride from the total sample weight.

During sampling partial freezing of the electrolyte may have resulted in some sample bias due to segregation. This and other systematic errors accumulate so that the mole fractions of the components were regarded as not more accurate than 1 mol%

Experimental Results

The electromotive force, E, is related to the activity of silver chloride, a_{AgCl}, the pressure of chlorine in atm, P_{Cl_2}, the absolute temperature T, and the standard formation potential E^0, by the Nernst equation.

$$[1] \quad E = \frac{RT}{2F} \ln P_{Cl_2} = E^0 - \frac{RT}{F} \ln a_{AgCl}$$

where F is the Faraday. The measured e.m.f., however, does not give E directly because of the thermoelectric effect associated with dissimilar electrodes. The silver and carbon electrodes effectively constitute a thermocouple in series with the electrochemical cell, but the small correction for this effect can be made without difficulty (7). The left hand side of eq. 1, which will be referred to as E^*, is the potential of the cell with respect to the standard chlorine electrode; that is to say, one in which the chlorine pressure is 1 standard atmosphere.

Standard Formation Potential of Silver Chloride

In order to determine the thermodynamic properties associated with AgCl in the melt, for example a_{AgCl}, the standard formation potential of pure AgCl, E^0, must be known as a function of temperature; that is, E^* must be determined for the case when the electrolyte is pure silver chloride.

Although several investigations have reported values for E^0 (3, 8–13) a redetermination was undertaken in order to test the operation of the cell. These measurements are depicted in Fig. 3.

In order to achieve a satisfactory interpolation

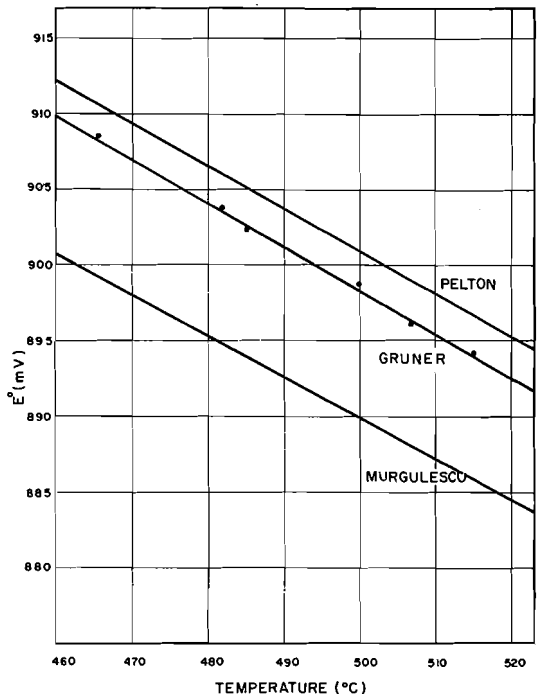

FIG. 3. Standard formation potential of silver chloride bracketed by highest and lowest reported measurements.

of the measurements, a regression analysis was performed recognizing the known difference in heat capacity between silver chloride, silver, and chlorine gas (14, 15).

$$[2] \quad (C_p)_{AgCl(l)} - (C_p)_{Ag(s)} - \tfrac{1}{2}(C_p)_{Cl_2(g)} = 4.195 - 2.07 \times 10^{-3}T - 0.02 \times 10^{5}T^{-2} \text{ cal mol}^{-1}\text{ K}^{-1}$$

It follows that

$$[3] \quad \Delta H^0 = A + 4.195T - 1.035 \times 10^{-3}T^2 + 0.02 \times 10^{5}T^{-1}$$

$$[4] \quad \Delta S^0 = B + 4.195 \ln T - 2.07 \times 10^{-3}T + 0.01 \times 10^{5}T^{-2}$$

where A and B are integration constants and ΔH^0 and ΔS^0 are the standard molar enthalpy and entropy changes for the formation of AgCl. Since

$$[5] \quad \Delta G_T^0 = -FE^0 = \Delta H^0 - T\Delta S^0$$

where ΔG^0 is the standard free energy change at temperature T, it follows that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[6] $\Sigma = -FE^0 - 4.195T + 4.195T \ln T - 0.01 \times 10^5 T^{-1} - 1.035 \times 10^3 T^2 = A - BT$

A linear regression of Σ *vs.* T gives values of $-28\,449$ cal mol^{-1} for A and -32.899 cal K^{-1} mol^{-1} for B.

The variation of E^0 with respect to temperature as determined by the regression is displayed in Fig. 3. The highest reported measurements (3) and the lowest reported measurement (11) bracket the present work and within a few mV the various determinations of E^0 concur; for all subsequent calculations discussed the following equation based upon the Σ function calculation on the present measurements was employed

[7] $E^0 = 1233.6 - 1.609T + 0.182T \ln T - 43.4T^{-1} - 4.48 \times 10^{-5} T^2$

Thus at 500 °C, $E^0 = 898.4$ mV.

Relative Partial Molar Free Energy

Thirteen different compositions in the AgCl–LiCl–KCl ternary system were studied. The compositions are depicted on the Gibbs triangle shown in Fig. 4. Points on the silver chloride – potassium chloride binary are those of Pelton and Flengas (3). Points on the silver chloride – lithium chloride binary are those of Panish *et al.* (9). The compositions studied in this investigation were limited to the central region of this system because of the Pyrex construction of the apparatus which limited the upper temperature of this investigation to 535 °C.

The e.m.f. as measured between a standard chlorine electrode and a silver electrode, E^*, is plotted *vs.* temperature in Figs. 5 and 6.

The general scatter of points is comparable with that of Panish *et al.* for the AgCl–LiCl binary system and Pelton and Flengas for the AgCl–KCl binary system shown in Figs. 7 and 8 respectively. In this respect it should be realized that the e.m.f. and temperature scales are more expanded for the present measurements owing to the limited temperature range. The lines in Figs. 5–8 represent traces of a regression analysis performed on all the data at once. Details of this analysis follows.

The difference between the electromotive force of a cell in which silver chloride is dissolved in a lithium chloride and potassium chloride melt, E^*, and that of a cell involving pure silver chloride, E^0, gives the free energy of mixing for the following process

$$(AgCl)_{(l)} + n\{(Ag,Li,K)Cl\}_{(l)} \rightarrow (n+1)\{(Ag,Li,K)Cl\}_{(l)}$$

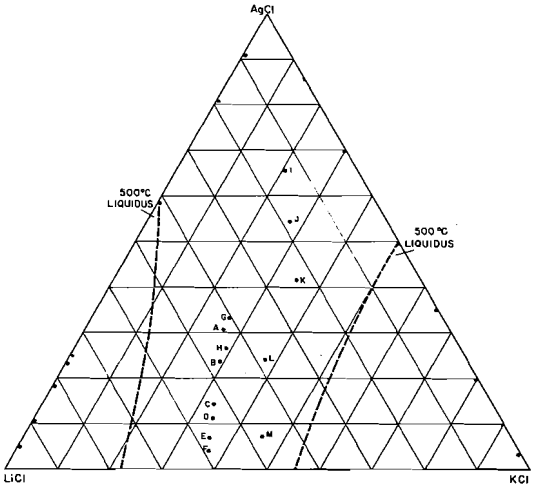

FIG. 4. Compositional points studied in the AgCl–LiCl–KCl system. Melts studied in the present investigation are given a code letter. Points on the AgCl–LiCl edge are from Panish *et al.* (9) Points on the AgCl–KCl edge are from Pelton and Flengas (3).

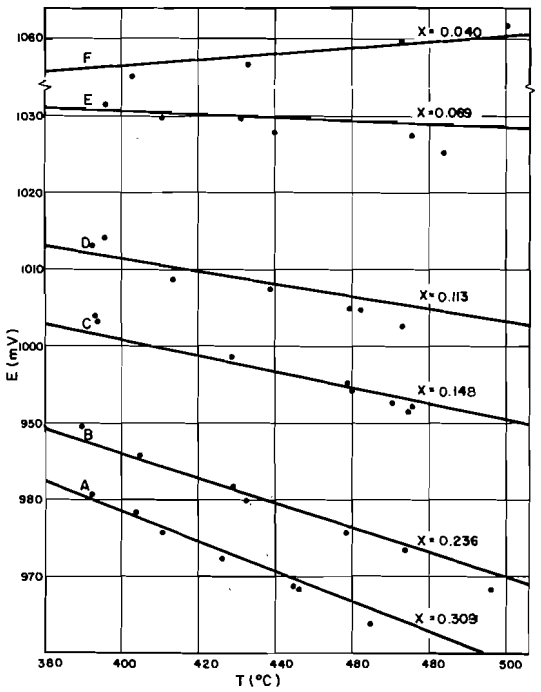

FIG. 5. Experimental measurements relative to a standard (1 atm) chlorine electrode. The mole fraction of AgCl, X, is indicated. The lines represent traces obtained by a multiple regression analysis.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

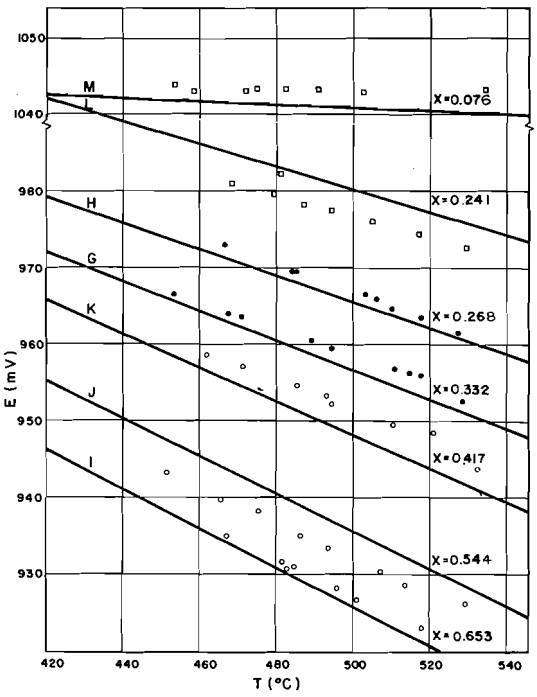

FIG. 6. Experimental measurements relative to a standard (1 atm) chlorine electrode. The mole fraction of AgCl, X, is indicated. The lines represent traces obtained by a multiple regression analysis.

where $n \gg 1$. That is to say, the relative partial molar free energy of silver chloride $\Delta\bar{G}_{AgCl}$, is

$$[8]\quad (\Delta\bar{G})_{AgCl} = \Delta\bar{H}_{AgCl} - T\Delta\bar{S}_{AgCl} = -F(E^* - E^0)$$

The relative partial molar free energy is related as indicated to the partial molar enthalpy and entropy, $\Delta\bar{H}_{AgCl}$ and $\Delta\bar{S}_{AgCl}$; these properties vary insignificantly with pressure and temperature but do vary with respect to composition. The following empirical series (16) may be employed to express these variations:

$$[9]\quad \Delta\bar{H}_{AgCl} = \sum_{j=2}\sum_{k=0} a_{jk}(\Lambda^j)(\Psi^k)$$

$$[10]\quad \Delta\bar{S}_{AgCl} = \sum_{j=2}\sum_{k=0} b_{jk}(\Lambda^j)(\Psi^k) - R \ln X_{AgCl}$$

where X_{AgCl} is the mole fraction of AgCl, $\Lambda = (1 - X_{AgCl})$, and $\Psi = X_{KCl}/(X_{LiCl} + X_{KCl})$.

The lower limits of summation guarantee Raoultian behavior of silver chloride in concentrated solutions. Combining eqs. 8–10 yields

$$[11]\quad E^* + \frac{RT}{F}\ln X_{AgCl} - E^0 = -\frac{1}{F}\sum_{j=2}\sum_{k=0}(a_{jk} - Tb_{jk})(\Lambda^j)(\Psi^k)$$

The coefficients a_{jk} and b_{jk} in the right hand side of eq. 11 were determined by a multiple linear regression analysis based upon 198 points (103 of which were determined in this investigation). An arbitrary truncation of the series is required; the following twelve coefficient series was found to express the variation E^* well.

$$\begin{aligned}[12]\quad E^* = -\frac{1}{F}\{&-3895.7\Lambda^2 + 5.8202T\Lambda^2 \\ &+ 3320.4\Lambda^2\Psi - 7.2596T\Lambda^2\Psi \\ &- 881.3\Lambda^2\Psi^2 + 0.2054T\Lambda^2\Psi^2 \\ &+ 7114.6\Lambda^3 - 6.7819T\Lambda^3 \\ &- 3246.2\Lambda^3\Psi + 4.4283T\Lambda^3\Psi \\ &- 3884.0\Lambda^3\Psi^2 + 3.5212T\Lambda^3\Psi^2\} \\ &- \frac{RT}{F}\ln(1-\Lambda) + E^0\end{aligned}$$

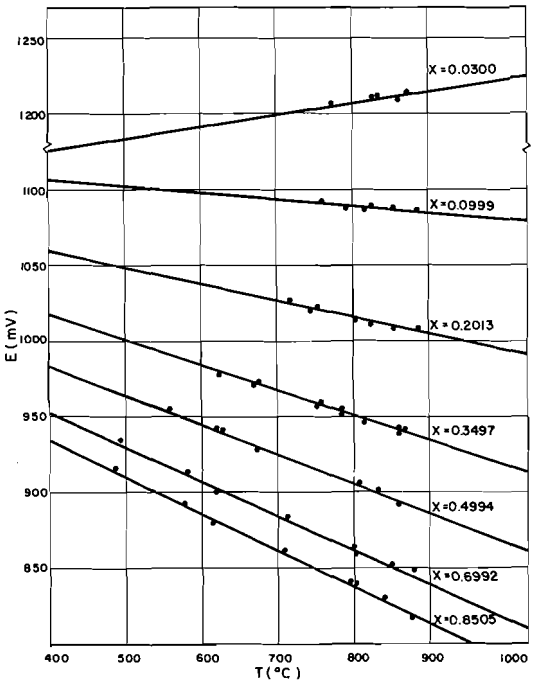

FIG. 8. Measurement of Pelton and Flengas (3) for AgCl–KCl melts relative to a standard (1 atm) chlorine electrode. The mole fraction of AgCl, X, is indicated. The lines represent traces obtained by a multiple regression analysis.

The standard deviation for the regression analysis was 2.5 mV; the mean absolute deviation was 1.8 mV. Equation 13 expresses within about 15 mV seventeen measurements made by Yang and Hudson (17) on five solutions of AgCl dissolved in LiCl–KCl eutectic ($\Psi = 0.42$).

As mentioned previously the lines which appear in Figs. 5–8 represent the behavior of eq. 12 at particular values of Λ and Ψ. The notable feature is that several of the lines are systematically above or below the experimental E^* values. This is regarded as being due mainly to an error associated with the determination of composition. For example, a variation in the AgCl mole fraction of 0.01, say, from 0.40 to 0.41, consistent with the analytical accuracy discussed previously causes a change in E^* at 500 °C of 1.6 mV. This together with temperature gradients in the cell combine to account for the slight systematic deviation most apparent in Fig. 6.

Another approach to fitting the experimental measurements would have involved the independent regression of each E^* *vs.* T line and the subsequent smoothing of the calculated relative partial molar properties. However, in view of the short temperature range covered in the present study it was felt that a single data analysis in which all measurements pertinent to this system were smoothed at once would provide a more representative empirical equation.

It may be shown that the term in braces in eq. 12 is the partial molar excess Gibbs free energy of AgCl, $\bar{G}_{AgCl}^{E}$. This property of the melt is plotted on the Gibbs triangle in Fig. 9 for a temperature of 500 °C. The lines of constant $\bar{G}_{AgCl}^{E}$ are shown extrapolated beyond the 500 °C liquidus lines.

Figure 10 illustrates the behavior of the silver chloride activity at 500 °C calculated from the excess free energy using

$$[13] \qquad a_{AgCl} = X_{AgCl} \exp\left(\frac{\bar{G}_{AgCl}^{E}}{RT}\right)$$

The form of the isotherm is similar to that empirically predicted by Moser (18).

Equation 12 in principle permits the determination of the relative partial enthalpy and entropy of AgCl. In view of the short temperature range studied and the errors associated with the measurement of E^*, these calculations would not be very reliable. Accordingly, they are not reported here.

Discussion

In recent years there has been considerable success in interpreting the thermodynamic behavior of molten salt solutions with ionic

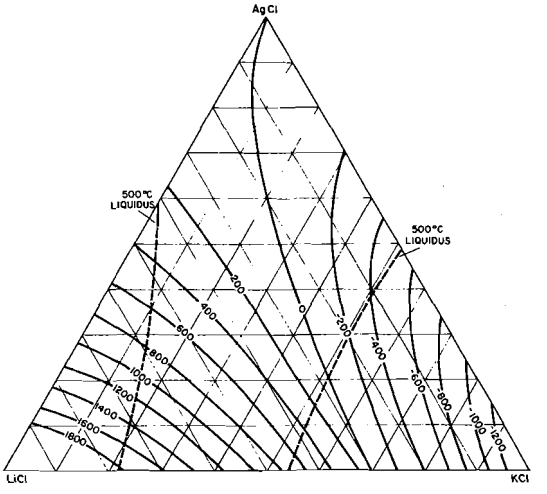

FIG. 9. Partial molar excess free energy of AgCl, $\bar{G}_{AgCl}^{E}$, at 500 °C based upon experimental measurements. The units are cal mol^{-1}.

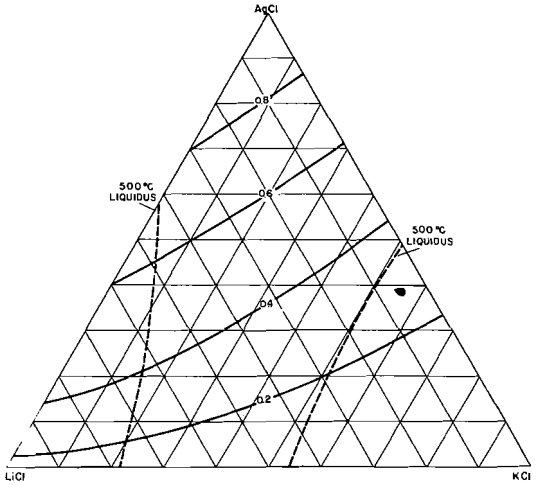

FIG. 10. Activity of AgCl (relative to liquid AgCl) at 500 °C based upon experimental measurements.

models that make reference to the existence of complex ions (19–23). It is postulated that certain cations are bound to adjacent anions; these units are treated as independent entities in the melt.

For the case of silver chloride – alkali chloride binary solutions Pelton and Flengas have proposed a dual-bonding model (3). This treatment recognizes the distinction between free silver ions and other silver ions considered to be "bonded" to adjacent anions. The model does not require postulates about the stoichiometry of this arrangement, *i.e.* it is immaterial whether the "bonded" silver exists as $AgCl_2^-$, $AgCl_3^{2-}$, etc., or silver chloride "molecules". This treatment has had success in interpreting precisely measured thermochemical properties for the silver chloride – alkali chloride binary melts from sodium chloride through to cesium chloride. This is remarkable because of the few adjustable parameters involved in the theory, one per salt.

An extension of this treatment to the ternary melts can be made as follows. Consider the isothermal formation of a mole of molten ternary solution by combining silver chloride with a lithium chloride – potassium chloride melt of fixed composition. This process may be represented as follows

$$[14]\quad X_1AgCl_{(l)} + (1 - X_1)(Li,K)Cl_{(l)} \rightarrow (Ag,Li,K)Cl_{(l)}$$

For the purpose of subsequent discussion AgCl, LiCl, and KCl will be referred to as components 1, 2, and 3 respectively.

The configurational entropy of the ternary solution is determined by the number of distinguishable ways Li^+, K^+, Ag^+, and Ag* ("bonded" silver) can be arranged over the available cationic sites. Let this multiplicity be Ω. Regarding the number of sites for a mole of solution as simply Avogadro's number, N, and α as the fraction of the total silver that exists as Ag* in the molten solution, the multiplicity is given by the following expression

$$[15]\quad \Omega = \Omega_1\Omega_2\Omega_3$$

where Ω_2 is the number of distinguishable ways of arranging X_2N lithium ions over N positions. Assuming random mixing

$$[16]\quad \Omega_2 = \frac{N!}{(N - X_2N)!(X_2N)!}$$

Ω_3 is the number of distinguishable ways of arranging X_3N potassium ions over the remaining $(N - X_2N)$ available positions.

$$[17]\quad \Omega_3 = \frac{(N - X_2N)!}{(N - X_2N - X_3N)!(X_3N)!}$$

and Ω_1 is the number of distinguishable ways of arranging the αX_1N "bonded" silver ion over the remaining $(N - X_2N - X_3N)$ available positions.

$$[18]\quad \Omega_1 = \frac{(N - X_2N - X_3N)!}{(N - X_2N - X_3N - \alpha X_1N)!(\alpha X_1N)!}$$

There is no freedom with regard to the distribution of the free silver ions or the chloride ions. Simplifying eqs. 15–18 yields for 1 mol of solution

$$[19]\quad \Omega = \frac{N!}{(X_2N)!([1 - \alpha]X_1N)!(\alpha X_1N)!(X_3N)!}$$

The total configurational entropy of the ternary solution (Ag, Li, K)Cl is determined by applying Boltzmann's equation

$$[20]\quad S_{(Ag,Li,K)Cl} = \frac{R}{N}\ln\Omega = -R[X_2 \ln X_2 + X_3 \ln X_3 + \alpha X_1 \ln \alpha X_1 + (1 - \alpha)X_1 \ln (1 - \alpha)X_1]$$

The configurational entropy for a mole of pure silver chloride is, by similar reasoning

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$$[21]\quad S_{AgCl}{}^{0} = -R[\alpha^0 \ln \alpha^0 + (1-\alpha^0)\ln(1-\alpha^0)]$$

where α^0 is a fraction of silver that exists as Ag* in pure molten silver chloride. If the configurational entropy of a mole of the lithium chloride and potassium chloride melt in reaction 14 is simply given by

$$[22]\quad S_{(Li,K)Cl} = -R\left(\frac{X_2}{X_2+X_3}\ln\frac{X_2}{X_2+X_3} + \frac{X_3}{X_2+X_3}\ln\frac{X_3}{X_2+X_3}\right)$$

wherein it is assumed that the lithium and potassium ions are randomly mixed, then it is possible to evaluate the configurational entropy change for the mixing process given by reaction 14.

$$[23]\quad \Delta S = S_{(Ag,Li,K)Cl} - X_1 S^0{}_{AgCl} - (1-X_1)S_{(Li,K)Cl}$$

This will be regarded as the total entropy change for the process; that is, vibrational entropy changes will be neglected. Therefore, $\Delta S = S(\alpha, \alpha^0)$.

The enthalpy change for the reaction expressed by [14] is assumed to be mainly the result of an increase or decrease in the fraction of silver that is "bonded". A change in this fraction is expected as the character of the melt is altered by changes in the relative population of alkali cations.

Let ε_1, ε_2, ε_3 refer to the energy per mole associated with the process $Ag^+ \rightarrow Ag^*$ in pure silver chloride, "pure" lithium chloride, and "pure" potassium chloride respectively. Further, suppose that in the ternary solution, as a first approximation, the energy for this process is given by

$$[24]\quad \varepsilon = X_1\varepsilon_1 + X_2\varepsilon_2 + X_3\varepsilon_3$$

Regarding the energy liberated during the formation of the solution as being entirely due to the energy associated with a change in α, and neglecting the formal distinction between enthalpy and internal energy because the volume change on mixing is small, the enthalpy change per mole of solution for reaction 14 is given by

$$[25]\quad \Delta H = \alpha X_1(X_1\varepsilon_1 + X_2\varepsilon_2 + X_3\varepsilon_3) - \alpha^0 X_1\varepsilon_1$$

The value of α at any composition is that which results in the minimum free energy of the solution

$$[26]\quad \frac{\partial G}{\partial \alpha} = \frac{\partial H}{\partial \alpha} - T\frac{\partial S}{\partial \alpha} = 0$$

$$[27]\quad \frac{\partial H}{\partial \alpha} = X_1{}^2\varepsilon_1 + X_1X_2\varepsilon_2 + X_1X_3\varepsilon_3$$

$$[28]\quad \frac{\partial S}{\partial \alpha} = -RX_1 \ln\frac{\alpha}{1-\alpha}$$

Accordingly

$$[29]\quad X_1\varepsilon_1 + X_2\varepsilon_2 + X_3\varepsilon_3 + RT\ln\frac{\alpha}{1-\alpha} = 0$$

Rearranging

$$[30]\quad \alpha = \frac{\prod_{i=1}^{3}\left(\exp\left(\frac{-X_i\varepsilon_i}{RT}\right)\right)}{1+\prod_{i=1}^{3}\left(\exp\left(\frac{-X_i\varepsilon_i}{RT}\right)\right)}$$

by similar reasoning α^0 may be found

$$[31]\quad \alpha^0 = \frac{\exp\left(\frac{-\varepsilon_1}{RT}\right)}{1+\exp\left(\frac{-\varepsilon_1}{RT}\right)}$$

Thus ΔS, ΔH, ΔG for reaction 14 are determined entirely by the values assigned to ε_1, ε_2, ε_3. These parameters are, of course, adjustable for the purposes of fitting the experimentally observed behavior of the system. However, to be consistent with the previous work of Pelton, ε_1 and ε_3 must have the values -3500 and -5500 cal mol^{-1} respectively. Thus ε_2 was treated as the only adjustable number in fitting the experimental data reported in the previous section. That experiment however did not yield direct measurements of ΔG for reaction 14; rather, relative partial molar free energies of silver chloride were measured. These are related to the properties of reaction 14 as follows. It may be shown (16) that along a composition path of a constant Ψ that

$$[32]\quad \Delta\bar{G}_{AgCl} = -\Lambda\frac{d\Delta G_{mix}}{d\Lambda} + \Delta G_{mix}$$

where ΔG_{mix} is the integral free energy of mixing for the ternary solution. But this is equivalent to

$$[33]\quad \Delta\bar{G}_{AgCl} = -\Lambda\frac{d[\Delta G_{mix} - \Lambda(\Delta G_{mix}{}^*)]}{d\Lambda} + (\Delta G_{mix} - \Lambda\Delta G_{mix}{}^*)$$

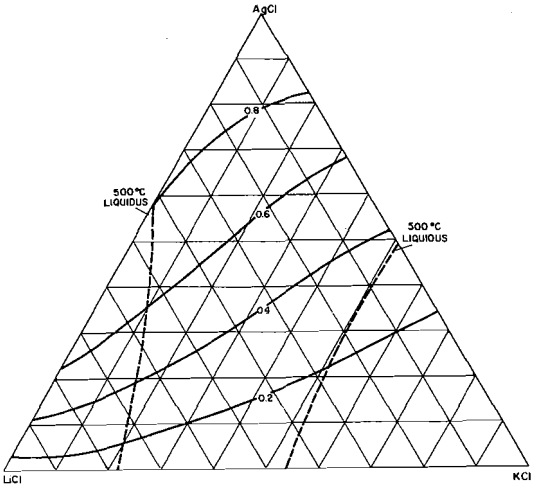

FIG. 11. Activity of AgCl (relative to liquid AgCl) at 500 °C based upon calculations using the dual-bonding model (3). Compare with Fig. 10.

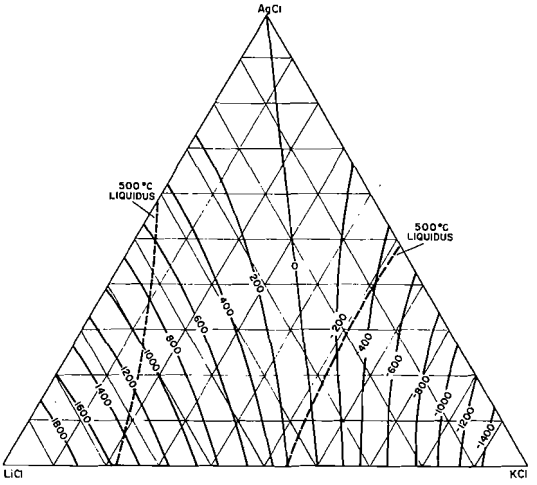

FIG. 12. Partial molar excess free energy of AgCl, $\bar{G}_{AgCl}{}^{E}$, at 500 °C based upon calculations using the dual-bonding model (3). The units are cal mol^{-1}. Compare with Fig. 9.

where the constant, $\Delta G_{mix}{}^{*}$, is the molar integral free energy of mixing of the binary lithium chloride – potassium chloride melt with the composition falling on the composition path, Ψ. The term $(\Delta G_{mix} - \Lambda\Delta G_{mix}{}^{*})$ may be recognized as the ΔG referred to previously in connection with reaction 14.

This means that by the application of eq. 33 it is possible to establish $\Delta\bar{G}_{AgCl}$ from ΔG for reaction 14.

With a value of -500 cal mol^{-1} for ε_2, $\Delta\bar{G}_{AgCl}$ was calculated and the activity at 500 °C was determined. The calculated activity isotherm appears in Fig. 11. This compares well with the measured property, Fig. 10. To further the comparison between the theoretical and measured properties, the $\bar{G}_{AgCl}{}^{E}$ isotherm was calculated using the model. This appears in Fig. 12 for a temperature of 500 °C. This may be compared with Fig. 9.

The major drawback of this treatment probably relates to eq. 22, which assumes random mixing of lithium and potassium ions. In view of the relatively large difference in ionic radius this assumption may not be entirely correct. Nevertheless, the dual-bonding model appears to be a reasonable way of interpreting the thermodynamic behavior of silver chloride – lithium chloride – potassium chloride melts.

Oligoribonucleotide Synthesis. VIII.[1] Insertion of Terminal 5′-Phosphate Groupings

THOMAS NEILSON, K. V. DEUGAU, T. E. ENGLAND, AND E. S. WERSTIUK
Department of Biochemistry, McMaster University, Hamilton, Ontario L8S 4J9

Received September 6, 1974

THOMAS NEILSON, K. V. DEUGAU, T. E. ENGLAND, and E. S. WERSTIUK. Can. J. Chem. **53**, 1093 (1975).

General oligoribonucleotide synthesis using phosphotriester protection has been extended to allow insertion of terminal 5′-phosphates. Selective removal of 5′-triphenylmethoxyacetyl groups allow phosphorylation by TPS-activated mono-2,2,2-trichloroethylphosphate on protected oligomers.

THOMAS NEILSON, K. V. DEUGAU, T. E. ENGLAND et E. S. WERSTIUK. Can. J. Chem. **53**, 1093 (1975).

On a étendu la synthèse générale des oligoribonucléotides utilisant la protection par les phosphotriesters pour permettre l'introduction de phosphates-5′ terminaux. L'enlèvement sélectif de groupe triphénylméthoxyacétyl-5′ permet la phosphorylation par des monotrichloro-2,2,2 éthylphosphates activés par le TPS sur des oligomères protégés. [Traduit par le journal]

All known native transfer ribonucleic acids (tRNAs) possess a 5′-terminal phosphate. Since the stem regions of tRNA's are possible partial aminoacyl-tRNA synthetase recognition sites (2), an attractive proposition to study the elements of recognition requires short duplices of known sequence, one strand having a 5′-terminal phosphate (3). Anticodon–codon studies have shown that short oligoribonucleotide sequences bind more securely to tRNA when they possess a phosphate moiety at their 5′-terminal (4). Existing syntheses of oligonucleotides carrying a 5′-phosphate start with appropriate protection of the 5′-phosphate of mononucleotide derivatives. Various chemical functional groups have been used in this capacity (5, 6). Protected oligonucleotides are then assembled stepwise from these nucleotide units and, after deblocking, a free oligonucleotide-5′-phosphate is obtained (5).

Consequently, in our continuing efforts to synthesize discrete portions of tRNAs (1), it was necessary to develop a convenient insertion of 5′-phosphate groupings during synthesis of oligoribonucleotides using phosphotriester protection. Our method for the synthesis of oligoribonucleotide-5′-phosphates is an extension of our general method for the synthesis of oligoribonucleotides which proceeds stepwise (7) or in blocks (1, 8) from the 5′- to the 3′-terminus. The nucleoside residue, destined to become the bearer of the 5′-phosphate of the completed oligonucleotide is initially protected with a 5′-trityloxyacetyl (Trac) group which allows ready detection of the protected oligomer at all stages of its synthesis. Selective removal of the Trac group provides an unprotected oligomer with a free 5′-hydroxyl group allowing 5′-specific phosphorylation.

In this communication we describe the conversion of a trinucleoside diphosphate to 5′-trinucleotide using protected, pApUpA, as an experimental illustration. To show that phosphorylation also occurs at the 5′-position when G and C are the 5′-terminal bases in protected oligomers, data on the syntheses of pCpU and pGpG are also included. A synthetic outline is shown in Scheme 1[2] and a summary of experimental data is given in Table 1.

5′-Triphenylmethoxyacetate (**2**) of the low R_F diastereoisomer of *N*-benzoyl-2′-*O*-tetrahydropyranylnucleoside (**1**) (10) was converted to protected dinucleoside phosphate (**4**) from the high R_F diastereoisomer of *N*-benzoyl-2′-*O*-tetrahydropyranylnucleoside (**3**) (10) and mono-

[1]For part VII, see ref. 1.

[2]The abbreviations used are those suggested by IUPAC–IUB (9): Trac is triphenylmethoxyacetyl; t is 2′-*O*-tetrahydropyranyl; $\overset{*}{X}$, $\overset{*}{Y}$, and $\overset{*}{Z}$ = $\overset{b_2}{A}$, $\overset{b_2}{C}$, $\overset{b_2}{G}$, or U (*N*-benzoylnucleosides); X, Y, and Z = A, C, G, or U; p- between two characters, *e.g.* $\overset{*}{x}$tp-$\overset{*}{y}$t, indicates a 2,2,2-trichloroethyl phosphotriester internucleotide linkage.

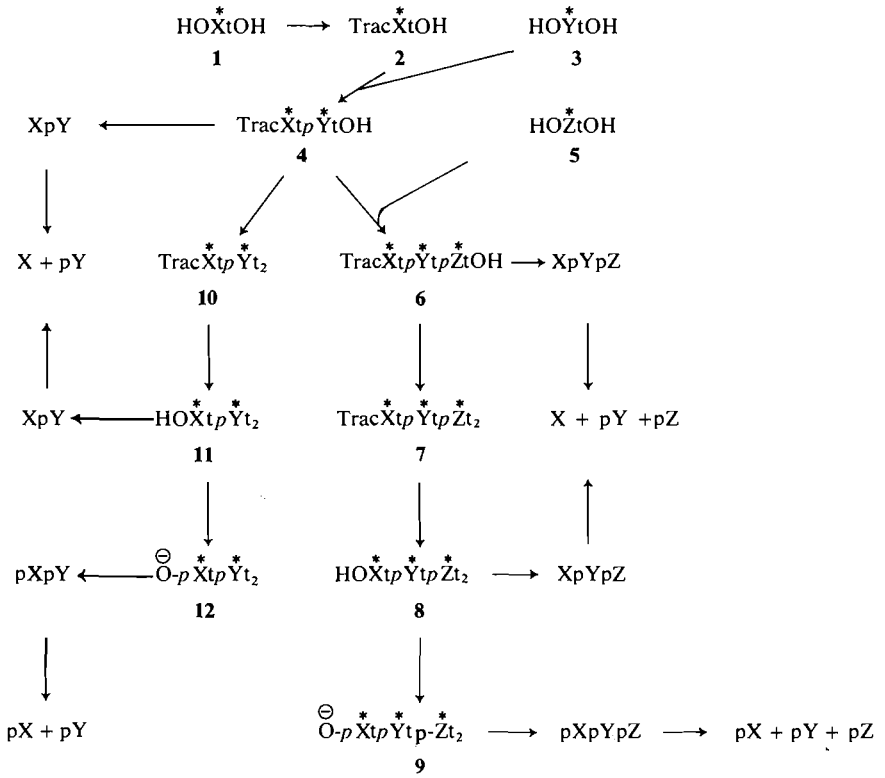
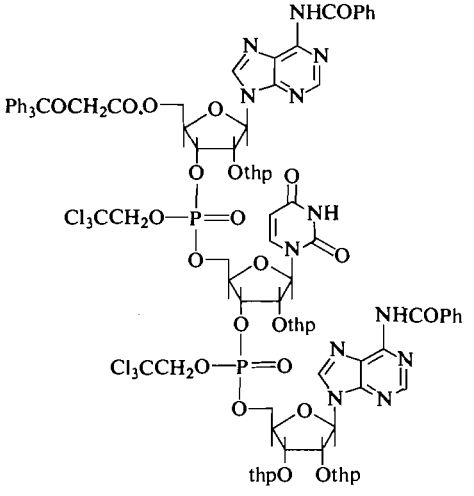


SCHEME 1

2,2,2-trichloroethylphosphate (11) using the previously described two-step coupling procedure (7). In a similar coupling, **4** and **5** were converted to a protected trinucleoside diphosphate (**6**). Each of these products was completely deblocked using the published three-step procedure (7) and the products subjected to snake venom diesterase digestion analysis.



Trac XtpYtpZt2 (7: X = Z = A; Y = U)

Since specific 5′-phosphorylation is required, the 3′-hydroxyl groups of **4** and **6** must be blocked using protection which will survive the mild basic conditions used for selective removal of a 5′-trityloxyacetyl grouping. If at any time, 3′,5′-diphosphorylation was required, the 3′-hydroxyl would be left unprotected. An acid-labile blocking group seemed an appropriate choice and smooth reaction of **4** and **6** with dihydropyran in anhydrous acid medium gave the corresponding 3′-*O*-tetrahydropyranyl ethers **10** and **7**, respectively. Subsequent removal of the 5′-trityloxyacetyl from **10** and **7** to give **11** and **8**, respectively, was carried out using dilute methanolic ammonia (8).

Phosphorylation at the free 5′-hydroxyl groups of **11** and **8** using the pyridinium salt of mono-2,2,2-trichloroethylphosphate and triisopropylbenzenesulfonyl chloride (TPS) gave the pyridinium salts of **12** and **9**, respectively, which were immediately deblocked in the usual manner to give the corresponding ammonium salts of pXpY and pXpYpZ, respectively. Satisfactory

enzymic analyses were found using snake venom diesterase, with and without pretreatment with alkaline phosphatase.

Some aspects of this synthesis are worthy of note. Actual phosphorylation is accomplished after assembly of nucleotide units and, in fact, is the last step before deblocking. Thus syntheses of *any* oligoribonucleotide and its corresponding 5′-phosphate derivative are possible from the *same* starting materials and by the *same* route with only minor divergence near the end of the overall synthesis.

Methanolic ammonia cleavage behavior of various TracXt-YtOH (**4**) and their 3′-phosphate derivatives, has been discussed previously (12). The nature and sequence of the bases and the nature of the group at 3′, control the type of reaction, and its kinetics. Since the 3′-position in **10** was protected by a tetrahydropyranyl ether which should have little or no inter- or intramolecular catalytic effect, the opportunity arose to compare alkaline cleavage behavior between examples of **4** and **10**. Data in Table 2 show that substitution of the 3′-hydroxyl with a tetrahydropyranyl group causes an approximate fourfold retardation in the hydrolysis of the trityloxyacetyl group. This result is in agreement that the nature of the 3′-grouping controls the rate of cleavage.

Experimental

The p.m.r. spectra were recorded on a Varian T60 or Varian HA-100 spectrometer in 10–15% (w/v) DMSO-d_6–D_2O solutions and line positions are reported in p.p.m. from the reference (TMS).

Silica gel (Baker Analyzed Reagent) was used for column chromatography; and Analtech prescored silica gel plates were employed for t.l.c. The plates were usually developed in 5 or 10% methanol in methylene chloride mixtures. The t.l.c. detection was carried out using a ceric sulfate spray (1 g $H_4Ce(SO_4)_4$ in 10% aqueous sulfuric acid solution) and followed by heating the plates at 300–400 °C. Compounds containing a trityl group develop as yellow spots, while others appear as brown colorations.

Paper chromatography was performed using the descending technique on Whatman No. 1 or 3 MM paper. Analtech precoated cellulose plates (Avicel F) were used for t.l.c. of deblocked nucleotides. The solvent systems employed for p.c. on Whatman No. 1 and t.l.c. on cellulose were (*A*) ethanol – 1 *M* ammonium acetate, p*H* 7.5 (7:3, v/v) and (*B*) 1-PrOH – concentrated NH_4OH – H_2O (55:10:35, v/v), respectively. Paper electrophoresis was performed at 1400 V/66 cm using Whatman 3 MM paper and (*C*) 0.05 *M* triethylammonium bicarbonate, p*H* 8. A short wave u.v. lamp was used for detection.

It was essential that moisture be excluded form all coupling reactions. After evaporation *in vacuo* of the pyridine solution, normal pressure was restored with dry nitrogen and *not* atmospheric air. All such evaporations were carried out in the temperature range of 30–40 °C. Emulsion, frequently obtained during methylene chloride extractions of aqueous pyridine solutions, was broken by the addition of a few milliliters of saturated sodium chloride solution.

*N^6-Benzoyl-2′-O-tetrahydropyranyl-5′-O-triphenylmethoxyacetyladenosine (**2**: X = A)*

Sodium triphenylmethoxyacetate (3.64 g, 0.011 mol) (8) was evaporated *in vacuo* from anhydrous pyridine (2 × 40 ml) and finally its volume reduced to *ca.* 25 ml. The solution was sealed under nitrogen, TPS (2.00 g, 0.066 mol) added, and the reaction set aside at room temperature for 2 h. The low R_F diastereoisomer of N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**1**: X = A) (10*b*) (2.30 g, 0.005 mol; R_F 0.48 in 10% CH_3OH–CH_2Cl_2) was evaporated *in vacuo* from anhydrous pyridine (2 × 40 ml) and finally its volume reduced to *ca.* 15 ml. This solution was then added to the trityloxyacetic acid – TPS complex (prepared above) and reaction mixture stored at room temperature for 2–3 days in the dark. A further portion of TPS (0.5 g) was added after 1 day to ensure complete esterification; t.l.c. indicated *ca.* 90% conversion into a product of R_F 0.80 in 10% CH_3OH–CH_2Cl_2. Ice (30 g) was then added to the mixture and stirring continued for a further hour. The mixture was poured into ice water (100 ml) and repeatedly extracted with methylene chloride (6 × 40 ml). The combined organic extracts were washed and evaporated to dryness *in vacuo*. The light brown glass was purified by chromatography on silica gel (80 g) in methylene chloride. Elution with methylene chloride (1000 ml) removed some impurities. Elution with 0.5% CH_3OH–CH_2Cl_2 gave some diester (R_F 0.8 in 10% CH_3OH–CH_2Cl_2). Pure N^6-benzoyl-2′-*O*-tetrahydropyranyl-5′-*O*-trityloxyacetyladenosine (2.8 g, 73%) (R_F 0.75 in 10% CH_3OH–CH_2Cl_2) was obtained on elution with 1% CH_3OH–CH_2Cl_2 (1000 ml). The p.m.r. spectrum showed signals (δ TMS) at 11.41 (1H-multiplet; N^6 amide proton), 8.66 (2H-singlet; 2- and 8-protons of A), 8.02 (2H-multiplet; *o*-benzoate protons), 7.32 (18H-multiplet; other aromatic protons), 6.20 (1 H-doublet; J = 6 Hz; 1′-anomer proton); 4.79 (1 H-singlet; thp acetal proton), 3.80 (2 H-singlet; OCH_2CO), 3.20 (2 H-multiplet; OCH_2 of thp), 1.55 p.p.m. (6 H-broad multiplet; C—CH_2 of thp).

Anal. Calcd. for $C_{43}H_{41}N_5O_8 \cdot H_2O$ (mol. wt. 773.8):

C, 66.74; H, 5.60; N, 9.05. Found: C, 66.64; H, 5.42; N, 8.81.

*N^6-Benzoyl-2′-O-tetrahydropyranyl-5′-O-triphenylmethoxyacetyladenylyl[3′-(2,2,2-trichloroethyl)-5′]2′-O-tetrahydropyranyluridine (**4**: X = A; Y = U)*

Biscyclohexylammonium mono-2,2,2-trichloroethyl phosphate (11) (1.31 g, 2.92 mmol) was dissolved in anhydrous pyridine (20 ml) with warming and converted to its pyridinium salt by repeated evaporation *in vacuo* and solution in pyridine (5 × 40 ml). TPS (1.77 g, 5.84 mmol) was then added to the pyridine salt in pyridine (10 ml). After 1 h a pyridine solution (10 ml) of N^6-benzoyl-2′-O-tetrahydropyranyl-5′-O-triphenylmethoxyacetyladenosine (**2**: X = A) (1.10 g, 1.46 mmol; R_F 0.75 in 10% CH_3OH–CH_2Cl_2) was added to the yellow solution and the reaction mixture sealed under dry nitrogen and stored at room temperature in the dark. After 2 days t.l.c. indicated complete conversion into products of R_F 0.0–0.20 in 10% CH_3OH–CH_2Cl_2. Ice (5 g) was added and the quenched reaction left for 30 min, poured into ice water (150 ml), and repeatedly extracted with methylene chloride (4 × 40 ml). The combined organic phases were washed with water (4 × 40 ml) and methylene chloride removed by evaporation *in vacuo* and replaced by anhydrous pyridine (10 ml) by repeated evaporation *in vacuo* and solution in pyridine (3 × 20 ml). TPS (443 mg, 1.46 mmol) was added to the blocked adenylate derivative and activation allowed to proceed for 30 min at room temperature. The high R_F diastereoisomer of 2′-O-tetrahydropyranyluridine (**3**: Y = U) (10*a*)(705 mg, 2.19 mmol; R_F 0.45 in CH_3OH–CH_2Cl_2) dissolved in anhydrous pyridine (10 ml) was added and the reaction mixture sealed under dry nitrogen and stored at room temperature in the dark. On the second day, a further portion of TPS (100 mg) was added to ensure complete coupling. After 3 days t.l.c. indicated complete conversion to a product of R_F 0.70 in 10% CH_3OH–CH_2Cl_2. Ice (10 g) was added to the mixture and stirring continued for a further 30 min. The reaction mixture was poured into ice water (150 ml) and repeatedly extracted with methylene chloride (6 × 50 ml). The combined organic extracts were washed with water (5 × 40 ml) and evaporated to dryness *in vacuo*, the last traces of pyridine being removed by co-distillation with toluene (3 × 20 ml). The light brown residue was dissolved in methylene chloride (50 ml) and the bulk of triisopropylbenzenesulfonic acid separated and was filtered off. The filtrate was subjected to chromatography on silica gel (50 g) in methylene chloride. Elution with 2% CH_3OH–CH_2Cl_2 gave the desired product (**4**: X = A; Y = U) (1.4 g, 75%; R_F 0.66 in 10% CH_3OH–CH_2Cl_2) on removal of solvent. The p.m.r. spectrum showed signals (δ TMS) at 12.4 (1 H-broad multiplet; N^6-proton of A), 8.65 (2 H-overlapping singlets; 2- and 8-protons of A), 8.1 (2 H-multiplet; *o*-benzoate protons), 7.4 (19 H-broad multiplet; other aromatic protons and 6-proton of U), 6.28 (1 H-doublet; J = 5 Hz; 1′-proton of A), 5.9 (1 H-doublet; J = 5 Hz; 1′-proton of U), 3.85 (2 H-singlet; OCH_2CO), 1.6 p.p.m. (12 H-broad multiplet; C—CH_2 protons of thp). Since **4** occurs as a diastereoisomeric pair (P atom is chiral center), its spectrum is not as sharp as that of **2**.

*N^6-Benzoyl-2′-O-tetrahydropyranyl-5′-O-triphenylmethoxyacetyladenylyl[3′-(2,2,2-trichloroethyl)-5′]2′-O-tetrahydropyranyluridylyl[3′-(2,2,2-trichloroethyl)-5′] N^6-benzoyl-2′-O-tetrahydropyranyladenosine (**6**: X = Z = A; Y = U)*

Similar phosphorylation (as described above for **2**; X = A) of blocked ApU (**4**; X = A; Y = U) (720 mg, 0.564 mmol; R_F 0.66 in 10% CH_3OH–CH_2Cl_2) and subsequent coupling with N^6-benzoyl-2′-O-tetrahydropyranyladenosine (**5**; Z = A) (385 mg, 0.846 mmol; R_F 0.48 in 10% CH_3OH–CH_2Cl_2) gave the desired product as a solid foam (730 mg; R_F 0.64 in 10% CH_3OH–CH_2Cl_2) in 66% yield. Complete deblocking (7) gave ApUpA in 86%; R_{Up} 0.59 (0.60 (13)) in solvent *A*. ApUpA was completely digested by snake venom diesterase to give A, pU, and pA in the ratio of 1:1:1 and by pancreatic RNase and subsequent alkaline phosphatase treatment to give ApU and A.

*N^6-Benzoyl-2′-O-tetrahydropyranyl-5′-O-triphenylmethoxyacetyladenylyl[3′-(2,2,2-trichloroethyl)--5′]2′-O-tetrahydropyranyluridylyl[3′-(2,2,2-trichloroethyl)-5′] N^6-benzoyl-2′,3′-O-ditetrahydropyranyladenosine (**7**: X = Z = A; Y = U)*

A solution of *p*-toluenesulfonic acid monohydrate (24 mg, 0.013 mmol) in dry dioxan (2 ml) containing molecular sieves (10 mg) was cooled in ice till solidified. Dihydropyran (184 mg, 0.22 mmol) was then added dropwise with stirring, followed by a dioxan solution (1 ml) of blocked ApUpA (**6**: X = Z = A; Y = U) (300 mg, 0.156 mmol; R_F 0.38 in 5% CH_3OH–CH_2Cl_2). The reaction mixture was allowed to warm up to room temperature after 30 min and stirring was continued a further 4 h. Thin-layer chromatography indicated complete conversion into a product R_F 0.50 in 5% CH_3OH–CH_2Cl_2 and the reaction mixture was neutralized with 0.15 *N* methanolic ammonia. Evaporation *in vacuo* of the solution gave a yellow oil which was purified by chromatography on silica gel (15 g) in methylene chloride. Elution with 2.5% CH_3OH–CH_2Cl_2 gave the desired product as a light brown foam (261 mg, R_F 0.50 in 5% CH_3OH–CH_2Cl_2 and 0.73 in 10% CH_3OH–CH_2Cl_2).

*N^6-Benzoyl-2′-O-tetrahydropyranyladenylyl[3′-(2,2,2-trichloroethyl)-5′]2′-O-tetrahydropyranyluridylyl-[3′-(2,2,2-trichloroethyl)-5′]N^6-benzoyl-2′,3′-O-ditetrahydropyranyladenosine (**8**: X = Z = A; Y = U)*

Blocked ApUpA (**7**: X = Z = A; Y = U) (261 mg, R_F 0.73 in 10% CH_3OH–CH_2Cl_2) was dissolved in 0.15 *N* methanolic ammonia (35 ml) and stirred for 2.5 h. Thin-layer chromatography indicated almost complete cleavage of the Trac group, R_F 0.73 (yellow) → 0.62 (black), and the reaction was quenched by evaporation *in vacuo*. The residue was subjected to chromatography on silica gel (15 g) in methylene chloride. Elution with 4% CH_3OH–CH_2Cl_2 gave the desired product (131 mg, R_F 0.62 in 10% CH_3OH–CH_2Cl_2) in 59% yield. Complete deblocking (7) gave ApUpA in 93% yield.

*N^6-Benzoyl-2′-O-tetrahydropyranyl-5′-(2,2,2-trichloroethylphosphoryl)adenylyl[3′-(2,2,2-trichloroethyl)-5′]2′-O-tetrahydropyranyluridylyl[3′-(2,2,2-trichloroethyl)-5′]N^6-benzoyl-2′,3′-O-ditetrahydropyranyladenosine (**9**: X = Z = A; Y = U)*

Biscyclohexylammonium mono-2,2,2-trichloroethyl-

phosphate (59 mg, 0.14 mmol) (11) was converted to its corresponding pyridinium salt as described earlier. TPS (85 mg, 0.28 mmol) was added to the anhydrous pyridine solution (2 ml) and activation allowed to proceed for 2 h under dry nitrogen. Blocked ApUpA (**8**: X = Z = A; Y = U) (131 mg, 0.077 mmol, R_F 0.62 in 10% CH_3OH–CH_2Cl_2) was dissolved in anhydrous pyridine (1 ml) and added to the TPS complex. The volume of the reaction mixture was reduced to 1 ml by gentle evaporation *in vacuo*. Thin-layer chromatography indicated phosphorylation was complete in 2 h, R_F 0,62 → 0.2–0.3 in 10% CH_3OH–CH_2Cl_2. Ice (0.5 g) was added and the quenched reaction left for 30 min, poured into ice water (20 ml), and repeatedly extracted with methylene chloride (6 × 5 ml). The combined organic phases were washed with water (2 × 25 ml) and evaporated to dryness *in vacuo*, the last traces of pyridine being removed by codistillation with toluene (2 × 10 ml). The residue was purified by column chromatography on silica gel (8 g) in methylene chloride. Elution with 4% CH_3OH–CH_2Cl_2 gave the desired product as a glass (98 mg, 70%; R_F 0.2 in 10% CH_3OH–CH_2Cl_2).

5′-Phosphoryladenylyl(3′-5′)uridylyl(3′-5′)adenosine (pApUpA)

Crude blocked pApUpA (**9**: X = Z = A; Y = U) (10 mg, 0.005 mmol) was dissolved in DMF (0.8 ml) and Cu/Zu couple (*ca.* 10 mg) was added and the mixture stirred overnight. Thin-layer chromatography indicated loss of all 2,2,2-trichloroethyl groups (R_F 0.2 → 0.0 in 10% CH_3OH–CH_2Cl_2). Concentrated ammonia (half diluted with methanol) (1 ml) was added and stirring continued a further day. Loss of N^6-benzoyl groups was indicated by conversion to a major species (R_F 0.7 → 0.4, cellulose plates in solvent *A*). Dowex-50 (NH_4^+ form) (*ca.* 1 g) was added and gentle stirring continued for 30 min. The resin was removed by filtration. The filtrate was reduced to *ca.* 5 ml by evaporation *in vacuo* and its p*H* adjusted to 2 with 2 *N* hydrochloric acid. Overnight stirring removed the tetrahydropyranyl groups as indicated by t.l.c. (R_F 0.4 → 0.0, cellulose plates in solvent *A*). The p*H* was adjusted to 7 with *N* ammonium hydroxide and the solution reduced to *ca.* 2 ml by evaporation *in vacuo*. pApUpA was purified by paper chromatography on Whatman 3 MM developed for 18 h in solvent *B*. The most intense band (R_F 0.2) was eluted with distilled water and the eluate stored as a frozen solution; yield 128 $o.d._{260}$ units, 66%. Alkaline phosphatase digestion gave a single product ApUpA, R_{Up} 0.59, in solvent *A*. Snake venom diesterase digestion gave pA and pU in the expected ratio of 2:1.

General Method for the Preparation of Protected Dinucleotides

Procedures similar to that described earlier for blocked ApUpA, were followed. Complete deblocking of dinucleotides **4**, **11**, and **12** gave XpY, XpY, and pXpY, respectively, in good yields (see Table 1 for details). Enzymic digestion analysis was satisfactory in all cases.

*Selective 5′-De-O-triphenylmethoxyacetylation of Protected Dinucleotides **4** and **10***

Substrates were dissolved in 0.15 *N* methanolic ammonia (12). Solutions were sealed and stored at room temperature and reaction progress monitored by t.l.c. in 10% CH_3OH–CH_2Cl_2. Half-lives of the starting materials were determined.

On the Mechanism of Base-catalyzed Hydrogen Isotope Exchange in Cyclic Ketones

SUJIT BANERJEE AND NICK H. WERSTIUK[1]

Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

Received December 31, 1974

SUJIT BANERJEE and NICK H. WERSTIUK. Can. J. Chem. **53**, 1099 (1975).

The kinetics of H → D exchange in norcamphor (**1**) and of D → H exchange in norcamphor-*3,3-d*$_2$ (**6**) have been determined. The rate ratio k_{exo}/k_{endo} drops from 661 in H → D exchange to 72 for D → H exchange. These data imply the presence of a dual mechanism for *endo* exchange and emphasize the importance of isotope effects in dictating exchange selectivity.

SUJIT BANERJEE et NICK H. WERSTIUK. Can. J. Chem. **53**, 1099 (1975).

On a déterminé la cinétique de l'échange de H → D dans le norcamphre (**1**) et pour l'échange de D→ H dans le dideutéro-*3,3-d*$_2$ norcamphre (**6**). Le rapport des vitesses k_{exo}/k_{endo} tombe de 661 dans l'échange H → D à 72 pour l'échange D → H. Ces données impliquent la présence d'un mécanisme double pour l'échange *endo* et mettent en évidence l'importance des effets isotopiques dans la direction de la sélectivité de l'échange. [Traduit par le journal]

Stereoselectivity in the base-catalyzed deuteration at the 3-position of norcamphor (**1**) has been noted by several workers (1–3). Kinetic measurements have shown that in dioxane-D_2O $k_{exo}^{H\rightarrow D}/k_{endo}^{H\rightarrow D}$ is approximately 650 (2, 3).[2] As a part of our studies on the isotope exchange of bicyclic mono- and diketones (3), we have measured the dedeuteration of norcamphor-*3,3-d*$_2$ (**6**) in protic media, and have found $k_{exo}^{D\rightarrow H}/k_{endo}^{D\rightarrow H}$ to be 72.[3] In this communication we present our findings and show that the difference between H → D and D → H exchange rates provides information on the mechanism of exchange.

Rates of H → D exchange in **1** and D → H exchange in **6** were measured in 60% dioxane–H_2O (D_2O) at 30.0 °C by monitoring the decrease in substrate by mass spectrometry (2, 3). The observed rate data are listed in Table 1, and second-order rate constants derived from these are collected in Table 2. Since *exo* exchange is faster than *endo* exchange, the deuteration of **1** proceeds with predominant retention (5) to give **3** (2). If secondary isotope effects are neglected, the difference between $k_{exo}^{H\rightarrow D}$ and $k_{exo}^{D\rightarrow H}$ is then the product of the *exo* primary isotope effect and the solvent isotope effect.

For *endo* exchange, the general mechanisms outlined in Schemes 1 and 2 are expected to apply. Now, if in Scheme 1, **2**, **4**, and **5** are steady-state intermediates then

$$k_{endo}^{H\rightarrow D} = k_6 + k_1 - \frac{k_1k_2(k_4 + k_5)}{(k_2 + k_3)(k_4 + k_5) - k_3k_4}$$

Further, since

$$(k_2 + k_3)(k_4 + k_5) \gg k_3k_4$$

[1] $$k_{endo}^{H\rightarrow D} = k_6 + k_1a$$

where

$$a = \left(1 - \frac{k_2}{k_2 + k_3}\right)$$

and

[2] $$k_{endo}^{D\rightarrow H} = k_6' + k_1'a'$$

where

$$a' = \left(1 - \frac{k_2'}{k_2' + k_3'}\right)$$

If k_6 and k_6' were the major contributors to $k_{endo}^{H\rightarrow D}$ and $k_{endo}^{D\rightarrow H}$, respectively, then $k_{endo}^{H\rightarrow D}$ would exceed $k_{endo}^{D\rightarrow H}$ on account of primary and solvent isotope effects. On the other hand, although a in

[1]To whom enquiries should be addressed.

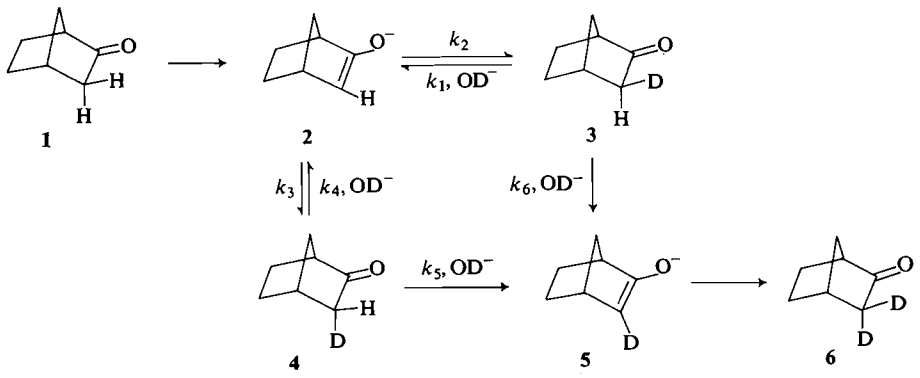
[2]$k_{exo}^{H\rightarrow D}$ and $k_{endo}^{H\rightarrow D}$ refer to the rates of protium → deuterium exchange of the *exo* and *endo* proton, respectively.

[3]A similar effect has been observed in camphor, where $k_{exo}^{H\rightarrow D}/k_{endo}^{H\rightarrow D}$ is 18 and $k_{exo}^{D\rightarrow H}/k_{endo}^{D\rightarrow H}$ is 2 (4).

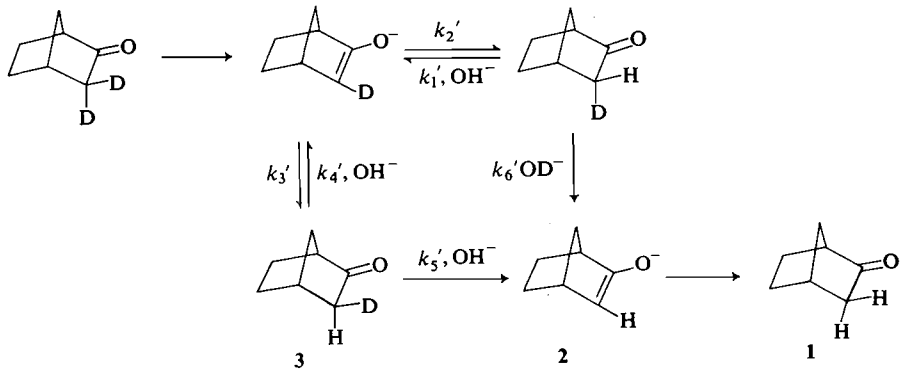
TABLE 1. Variation of rates of H → D and D → H exchange in norcamphor (**1**) and norcamphor-*3,3-d*$_2$ (**6**) with base concentration*

Substrate	[NaOH(D)](M)	$k_{exo} \times 10^3$ (s^{-1})	$k_{endo} \times 10^5$ (s^{-1})
6	0.008	0.0568	
6	0.020	0.143	0.158
6	0.040	0.265	0.289
6	0.100	0.688	0.672
6	0.140		0.958
6	0.200	1.195	1.70
1	0.045	2.65	0.403†

*Single determinations unless otherwise specified.
†Average of two determinations (average deviation; 1.4%).



SCHEME 1. H → D exchange in norcamphor (**1**).[4]



SCHEME 2. D → H exchange in norcamphor-*3,3-d*$_2$ (**6**).

[1] is small, since $k_1 \gg k_6$, $k_1 a$ is by no means negligible as compared to k_6. For $k_{endo}^{H \to D}$ (Scheme 1) a primary isotope effect operates in k_1, whereas for $k_{endo}^{D \to H}$ (Scheme 2) $k_{6'}$ is decreased relative to k_6 due to a primary isotope effect. Clearly, the influence of an isotope effect on k_1 in [1] is compensated for by a similar effect on $k_{6'}$ in [2], so that $k_{endo}^{H \to D} \approx k_{endo}^{D \to H}$.

This establishes that H → D exchange in ketones and likely sulfoxides containing two chemically different C—H bonds α to the carbonyl (sulfoxyl) groups must be described by Scheme 1 regardless of the exchange selectivity.

[4]Although the intermediates **2** and **5** are illustrated as enolates they are kinetically indistinguishable from the corresponding enols.

TABLE 2. Rate constants for H → D and D → H exchange in norcamphor (**1**) and norcamphor-*3,3-d*$_2$ (**6**)

Parameter	H → D	D → H
k_{exo} (M^{-1} s^{-1})	5.89×10^{-2}*	5.96×10^{-3}†
k_{endo} (M^{-1} s^{-1})	9.07×10^{-5}*	8.26×10^{-5}†
k_{exo}/k_{endo}	661	72

*Obtained by dividing the observed rate constant by base concentration.
†Obtained from plots of k_{obs} *vs.* [NaOH].

Since exchange of the less reactive proton must involve two pathways, the previous relative rate values determined in these systems by the exchange method (2–5) must be to some extent reexamined. We have derived more complete expressions, (which contain the isotope effects and the intrinsic selectivity), relating the various rates in water and in D_2O, and are presently continuing studies on H → D and D → H exchanges in 3-substituted norcamphors.

Preparation and Thermolysis of some 1,2-Dioxetanes[1,2]

KARL R. KOPECKY, JOHN E. FILBY,[3] CEDRIC MUMFORD, PETER A. LOCKWOOD,[4] AND JAN-YIH DING

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2E1

Received October 10, 1974

KARL R. KOPECKY, JOHN E. FILBY, CEDRIC MUMFORD, PETER A. LOCKWOOD, and JAN-YIH DING. Can. J. Chem. **53**, 1103 (1975).

Treatment of the bromohydroperoxides of 2-methyl-2-butene and ethylidenecyclohexane with cold methanolic base produces trimethyl- and 4-methyl-3,3-pentamethylene-1,2-dioxetane, **3** and **8**. Under these conditions the bromo- and iodohydroperoxides of 2,3-dimethyl-2-butene A, 1,2-dimethylcyclohexene B, and $\Delta^{9,10}$-octalin C are converted rapidly to the corresponding allylic hydroperoxides. The reaction in methylene chloride between silver ion and the bromo- and iodohydroperoxides of A and the iodohydroperoxides of B and C produces the corresponding dioxetanes in 20–30% yield: tetramethyl-1,2-dioxetane **11**, 3,4-dimethyl-3,4-butano-1,2-dioxetane **15**, and 3,4:3,4-dibutano-1,2-dioxetane **23**. About 50% of the corresponding allylic hydroperoxides also are formed as are pinacolone, ~15%, 1-acetyl-1-methylcyclopentane, ~20%, and $\Delta^{9,10}$-octalin, ~1%, from the appropriate halohydroperoxides.

All the dioxetanes are yellow, thermolyze to give only carbonyl cleavage products, and are luminescent. Reduction of **3** with bisulfite ion produced trimethyloxacyclopropane and with iodide ion 2-methyl-2,3-butanediol. Reduction of **8**, **11**, **15**, and **23** with lithium aluminum hydride at −78° gave good yields of the corresponding diols. Treatment with triphenylphosphine of **11** gave tetramethyloxacyclopropane, of **15**, a 1:3 ratio of 2-methylene-1-methylcyclohexanol and 2,3-dimethylcyclohexen-3-ol, and of **23**, 10-hydroxy-$\Delta^{1,9}$-octalin.

Activation parameters for thermolysis of the dioxetanes are (dioxetane, E_a, kcal/mol, ΔS^*, e.u.) **3**, 23.5 ± 0.5, −5 ± 2; **11**, 25.8 ± 0.5, −2 ± 2; **15**, 25.7 ± 0.7, 2 ± 2; **23**, 22.7 ± 0.9, −3 ± 3.

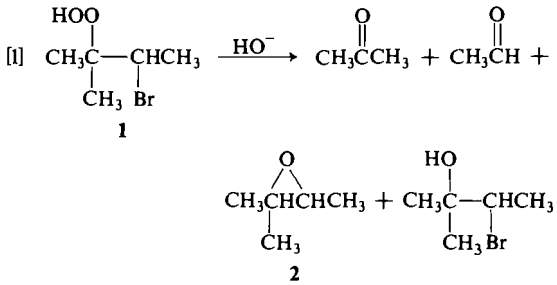
20–30%: tétraméthyldioxétanne-1,2, **11**, diméthyl-3,4 butano-3,4 dioxétanne-1,2, **15**, et dibutano-3,4:3,4 dioxétanne-1,2, **23**. Dans ces réactions, il se forme environ 50% des hydroperoxydes allyliques correspondants et suivant les hydroperoxydes utilisés de la pinacolone, 15% (approx), de l'acétyl-1 méthyl-1 cyclopentane, 20% (approx), et de la $\Delta^{9,10}$-octaline, 1% (approx).

Tous les dioxétannes sont des composés jaunes et luminescents, dont la thermolyse ne donne que les produits de fission carbonylique. La réduction de **3** avec le bisulphite donne le triméthyloxacyclopropane alors que les ions iodures conduisent au méthyl-2 butanediol-2,3. La réduction de **8**, **11**, **15** et **23** avec l'hydrure de lithium et aluminium à $-78°$ donne des bons rendements des diols correspondants. Le traitement de **11** avec de la triphénylphosphine transforme **11** en tétraméthyloxacyclopropane; **15** en méthylène-2 méthyl-1 cyclohexanol et en diméthyl-2,3 cyclohexèn-3-ol dans le rapport 1:3; et **23** en hydroxy-10 $\Delta^{1,9}$-octaline.

Les paramètres d'activation pour la thermolyse des dioxétannes sont (dioxétanne, E_a, kcal mol^{-1}, ΔS^* cal deg^{-1} mol^{-1}); **3**, 23.5 ± 0.5, −5 ± 2; **11**, 25.8 ± 0.5, −2 ± 2; **15**, 25.7 ± 0.7, 2 ± 2; **23**, 22.7 ± 0.9, −3 ± 3.

Introduction

In an attempt to devise a general non-photochemical reaction sequence for the conversion of alkenes to allylic hydroperoxides it was found that β-halohydroperoxides of di- and trisubstituted ethylenes gave cleavage products when treated with base (1). For example, 3-bromo-2-methyl-2-butyl hydroperoxide **1** appeared to be converted mainly to acetone and acetaldehyde. Some trimethyloxacyclopropane **2** and 3-bromo-2-methyl-2-butanol were also formed, reaction 1.



Similar behavior was exhibited by 2-bromo-1-phenylethyl hydroperoxide. Examples of such cleavage reactions had been noted already with some other suitably substituted hydroperoxides (2), where it was suggested that the cleavage products resulted from the decomposition of transient 1,2-dioxetanes.

In contrast to the reactions just described the reaction between base and β-halohydroperoxides of tetrasubstituted ethylenes apparently leads to the exclusive formation of allylic hydroperoxides (1). We thought originally that these transformations also proceeded by way of transient 1,2-dioxetanes which reacted rapidly with base to give allylic hydroperoxides more rapidly than they cleaved to give carbonyl products. A more careful study of the reactions of β-halohydroperoxides has shown that this is not so and has resulted in the isolation of the several 1,2-dioxetanes reported here. The 1,2-dioxetanes derived from 2-methyl-2-butene and from ethylidenecyclohexane are formed by treating the corresponding bromohydroperoxides with base, while the 1,2-dioxetanes of 2,3-dimethyl-2-butene, 1,2-dimethylcyclohexene, and $\Delta^{9,10}$-octalin can be prepared by treatment of the corresponding bromo- or iodohydroperoxides with silver ion. The characterization and rates of thermolysis of these 1,2-dioxetanes are described in this paper also.

Since the first reports of the preparation and thermal decomposition of trimethyl-1,2-dioxetane **3** appeared (3) a number of other members of this class of compound has been isolated from the reaction between alkenes and singlet oxygen (4) or triphenyl phosphite ozonide (5), from β-bromohydroperoxides (6), and from α-hydroperoxy acids (7).

Results

Trimethyl-1,2-dioxetane, 3

The initial indication that **3** might be stable enough to be isolated was obtained by comparing the rate of appearance of bromide ion with the rate of disappearance of peroxide content of basic methanolic solutions of the bromohydroperoxide **1** at 0°. Bromide ion was formed rapidly with a rate that appeared to be nicely first order with respect to both base and **1**. The peroxide content of the solution disappeared much more slowly. In fact, most of the peroxide content was still left when nearly all of the inorganic bromide had been released. It is clear that a rather stable bromine-free peroxidic product was formed. Evidence for the formation of a relatively

For personal use only.

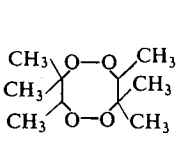
stable new compound also was obtained by n.m.r. spectroscopy. At 0° a 90:10 methanol: water solution initially 1.0 *M* in **1** and 1.1 *N* in sodium hydroxide slowly developed a yellow color. The n.m.r. spectrum of the yellow carbon tetrachloride extract, obtained after 45 min reaction, showed a new quartet centered at τ 4.80 approximately equal in area to that of the quartet at τ 5.50 due to remaining **1**. Four new signals in the methyl region of the spectrum were also present. Thus, about 50% of the starting material had been consumed. However, only about 5% acetone and acetaldehyde had been formed at this time as judged by the intensity of a singlet at τ 7.98.

The product is volatile with carbon tetrachloride and low pressure distillation of the extract at 0° gave a solution of **3** free of starting material. Carbon tetrachloride or benzene solutions of relatively pure (80 to 90%) **3** at concentrations up to 1 *M* have been made in this way in ~30% overall yield. Longer contact time with base before workup results in the formation of by-products (see below). Pure **3** was obtained as yellow crystals, m.p. 5–7°, from an isopentane extract of the reaction mixture by removing solvent at low temperature followed by low pressure distillation of the residue and crystallization of the distillate from isopentane. The i.r. spectrum showed no absorption for a hydroxyl group and very weak absorption in the carbonyl region. The n.m.r. spectrum showed signals for the methine and methyl protons with relative areas of 1.0 to 9.0. The properties of **3** found in the present work agree well with those reported (6*d*).

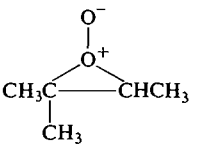
In solution this dioxetane may be stored at −10°) for several months with little decomposition. At higher temperatures **3** decomposes to give acetone and acetaldehyde as the only detectable products. This decomposition is accompanied by luminescence as has been reported already (3*b*, 6*d*). At 60° in aerated solutions in benzene and in carbon tetrachloride **3** has a half-life of ~25 min. It decomposes much more slowly in dilute solution than when pure or in concentrated solutions. Although we have had no explosions yet while handling **3** it certainly must be regarded as being potentially explosive in view of our experience with the tetramethyl analog (see below). This appears to have been the first example of the isolation of a 1,2-dioxetane.

Final characterization of **3** involved its reduction by iodide ion in acetic acid to 2-methyl-2,3-butanediol **4** in 50% yield. Attempted catalytic reduction of **3** over palladium on charcoal resulted in rapid cleavage of the molecule to acetone and acetaldehyde.[5] Bisulfite ion reduces **3** to the epoxide **2**, presumably by way of the intermediate **5** which would result from attack of the bisulfite ion on an oxygen atom of **3**. The reactions described so far are outlined in Scheme 1 and serve to confirm the structure **3** for the bromine-free peroxidic product of the reaction between base and **1**.

A compound with a structure such as **6** might also undergo the reactions described to give the observed products but it is not compatible with the observed molecular weight (6*d*).



6

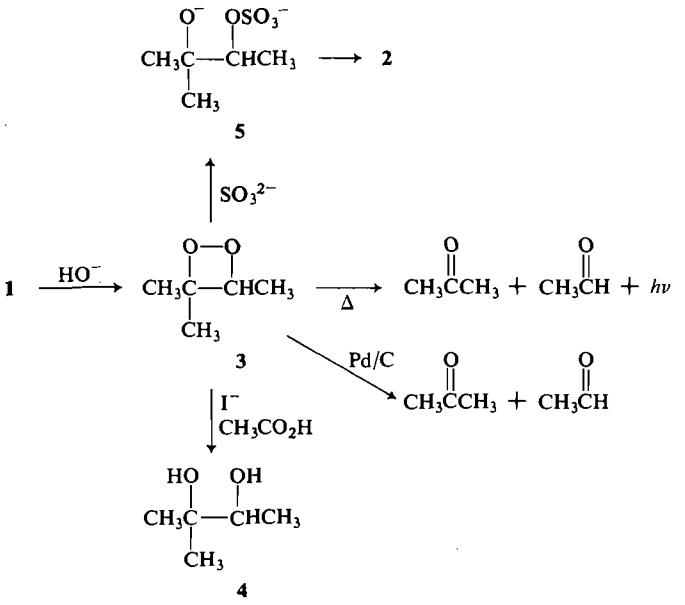


7

Another possible structure for the material in hand might be the perepoxide **7**. It might be visualized that **7** would rearrange thermally to **3** which would then very rapidly cleave to the carbonyl compounds. However, **7** probably would not be reduced to the diol **4** by iodide ion. Also, perepoxides are believed to be intermediates in the reaction between base and β-halohydroperoxides of tetrasubstituted ethylenes which produces allylic hydroperoxides exclusively and not 1,2-dioxetanes (9). Sulfoxide and amine oxide analogs of perepoxides do not rearrange to four-membered ring compounds but do undergo ring opening elimination (10). Thus, it is quite unlikely that we are dealing here with a compound of structure **7**.

When the reaction between base and **1** is allowed to proceed for too long other products in addition to **3** are formed and solutions of **3** obtained by the extraction–distillation method are quite contaminated. The other products include those of reaction 1, the diol **4**, and some unidentified materials. The routes by which these

[5]It appears that transition metals and their salts, in general, may cause rapid decomposition of 1,2-dioxetanes; inadvertent contact of solutions of **3** with cupric and ferric salts caused vigorous reaction to occur. The products were not determined. Similar behavior has been noted with tetramethyl-1,2-dioxetane (8).



SCHEME 1

products are formed have not been identified but it has been shown that base reacts with **3** to form a variety of products among which acetaldehyde, acetone, and **4** predominate. In spite of a careful search no evidence was obtained for the formation of any allylic hydroperoxide. Control experiments showed that both possible allylic hydroperoxides (11) would have survived the reaction conditions. Diol and epoxide have been observed also during a careful study of the reaction between base and 1-chloro-2-methyl-2-propyl hydroperoxide (6*a*). The mechanisms suggested for the formation of these reduction products quite likely apply to the present system as well.

4-Methyl-3,3-pentamethylene-1,2-dioxetane **8**[6]

This compound was prepared as a result of reports of its formation on ozonolysis of ethylidenecyclohexane in pinacolone solvent (12). We have shown already that, contrary to these reports, **8** is not present among the products of ozonolysis (13) and report here the details of the reactions used for its preparation and characterization, Scheme 2.

The structure of 1-(1-bromoethyl)cyclohexyl hydroperoxide **9** follows from its n.m.r. spectrum, the methyl group protons absorb at $\tau(CCl_4)$ 8.32 which is where the analogous methyl group protons of **1** absorb (1), and by analogy with results of recent studies of bromohydrin formation from cyclohexane derivatives with exocyclic double bonds (14). These studies showed, in contrast to an earlier report (15), that the bromine atom becomes attached to the exocyclic carbon atom.

It was necessary to precipitate **9** as the 1,4-diazabicyclo[2.2.2]octane complex (16) in order to obtain pure material. We have found that this is the best method for freeing from impurities β-halohydroperoxides which are difficult to crystallize.

It appears that **8** is more sensitive to base than is **3** for the reaction between **9** and base must be interrupted quickly in comparison to the reaction between base and **1** in order to obtain pure **8** on workup. The pure dioxetane **8** is isolated by low pressure distillation at 20°. It is an unstable yellow oil, m.p. $\sim -11°$, and it is necessary to carry out all operations during its isolation and for its characterization as quickly as possible or it will be contaminated by decomposition products.

Pure **8** (97.8% active oxygen) is monomeric, mol. wt. found (cryoscopic, benzene) 155, and decomposes in benzene-d_6 at 50° with a half-life of ~15 min to acetaldehyde and cyclohexanone in 90 and 95% yield, respectively.

[6]The Chemical Abstracts will index this compound as 3-methyl-1,2-dioxaspiro[3.5]nonane.

*1,3-dibromo-5,5-dimethylhydantoin

SCHEME 2

The rate of thermal decomposition of **8** appears to be about three to four times that of **3**. The decomposition is accompanied by luminescence whose intensity is greatly enhanced by the addition of 9,10-dibromoanthracene (DBA) (17). Reduction of **8** using lithium aluminum hydride at −40° gave 1-(1-hydroxyethyl)cyclohexanol **10** in 87% yield. The spectral properties of **8** are also consistent with the proposed structure.

Tetramethyl-1,2-dioxetane, 11

The reaction between base and 3-bromo-2,3-dimethyl-2-butyl hydroperoxide **12***a* produces 3-hydroperoxy-2,3-dimethyl-1-butene **13** in >98% yield (1, 9) even at −40°. After it was found that solutions of **3** emitted light when warmed to 50° an attempt was made to detect the presence of **11** by addition of a solution of **12***a* to a boiling solution of base and DBA in methanol. Luminescence could be observed clearly, suggesting that at least some **11** was formed under these conditions. However, no evidence for **11** and only trace amounts of acetone were ever detected by conventional means when the reaction between base and **12***a* was conducted under a wide variety of conditions.

When it became clear that **11** could not be isolated from **12***a* under basic conditions attempts were made to effect cyclization using silver salts. These attempts proved to be successful. In preliminary experiments only acetone and **13** appeared to be formed when **12***a* was treated with the silver salts of several strong acids. This had been observed already (2*b*). The use of silver acetate or silver benzoate does lead to the formation of reasonable amounts of **11**. A mixture of **11**, **13**, and pinacolone is formed in ratios that vary from about 1:4:1 to about 3:3:1, depending upon the solvent and temperature used, when solutions of **12***a* are shaken with suspensions of silver acetate or silver benzoate in nonpolar aprotic solvents, Scheme 3. Formation of pinacolone and **13** on treatment of **12***a* with silver tetrafluoroborate was noted recently but **11** apparently was not detected (18). Solutions of the dioxetane in solvents boiling below ~80° can be evaporated under reduced pressure at 0° to a yellow oil from which pure dioxetane may be isolated by distillation at 0.01 mm followed by crystallization of the residue from isopentane. The yellow crystals of pure **11** melt at 77–78° to a yellow liquid which emits a faint, deep blue luminescence. Optimum yields of pure dioxetane appear to be ~35%. Essentially the same distribution of products is obtained from the iodohydroperoxide **12***b* as from **12***a*.[7]

We have experienced numerous explosions with sublimed samples of **11** kept in sealed, evacuated tubes. However, samples of **11** have been kept at −20° for many months under air with little or no decomposition. Solutions up to 2 *M* in **11** do not appear to be explosive.

The proof of structure of **11** is similar to that described for **3** and **8**. It is monomeric, also mol. wt. found (cryoscopic, benzene) 112, and it was reduced to pinacol by lithium aluminum hydride in 98% yield. Acetone, 98% yield, is the

[7]The iodohydroperoxide was prepared after it was found that the iodohydroperoxide of $\Delta^{9,10}$-octalin readily formed the dioxetane on treatment with silver ion whereas the bromohydroperoxide did not, see below.

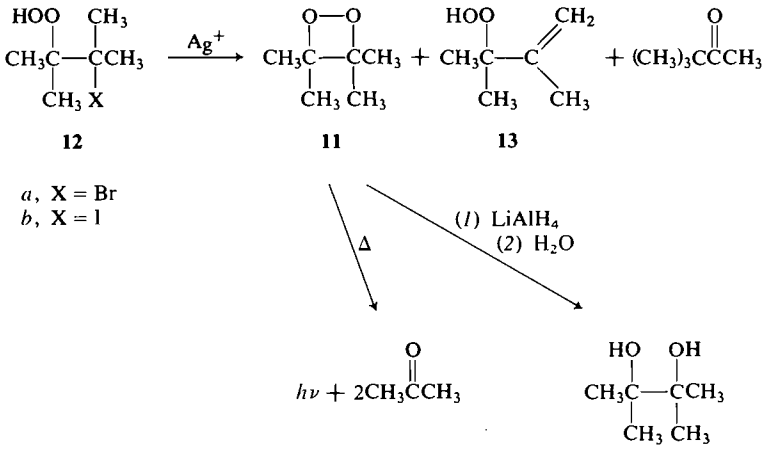
For personal use only.

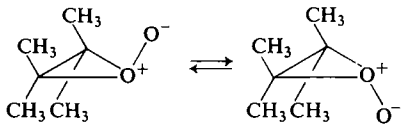


SCHEME 3

only product detectable on thermolysis of **11** in benzene or in carbon tetrachloride.

Attempts to determine the molecular weight of **11** by mass spectrometry were inconclusive. Using electron impact a very weak peak at *m/e* 116 was observed only occasionally, and its relative intensity (~0.1%) was variable from run to run when it was observed. The spectrum was very similar to that of acetone. The dioxetane appears to fragment to acetone and the acetone radical ion exclusively on electron impact. The peak seen occasionally at *m/e* 116 could result from association of an acetone molecule with the radical ion at high pressure of dioxetane. Chemical ionization using ammonium ion also resulted in cleavage of the dioxetane. Peaks due to clusters of ammonium ion with acetone molecules were observed at *m/e* 86, 134, 192, and 250. The relative intensities of the peaks varied from run to run with the peaks at higher *m/e* increasing in intensity as the probe temperature increased.

The n.m.r. spectrum of **11** consists of a sharp singlet at $\tau(CCl_4)$ 8.58. No broadening of the signal was observed even at −90° ($CFCl_3$). This may be taken as evidence against a perepoxide structure **14** in which the two pairs of vicinal methyl groups should become nonequivalent at low temperature (*4b*).[8]



14

It was found that **11** is quite insensitive to acid and to base at 25° or below in methanol. After 48 h at 0° three methanol solutions initially 0.1 *M* in **11** of which one was neutral, one was 0.3 *N* in sodium hydroxide, and one was 0.3 *M* in trifluoroacetic acid had all lost 25 to 30% of the original dioxetane content. Acetone was the only product formed. No trace of the allylic hydroperoxide **13** could be detected in any of the reaction mixtures by n.m.r. spectroscopy. The half-life of **11** can be calculated to be ~90 h under these conditions. The rate of decomposition of **11** in methanol at 0° is then ~100 times that calculated in benzene or carbon tetrachloride (see below). At 50° in benzene the rate of decomposition of **11** is only 50% greater in the presence of 1.0 *M* trifluoroacetic acid than it is in pure benzene. Acetone was the only product detected.

Greatly enhanced rates of decomposition of **11** in methanol relative to those in benzene have been reported already (19) and shown to be due to a rapid dark reaction caused by trace amounts of impurities (8). This rapid dark reaction may mask smaller effects of acid or base on the rate of decomposition of **11** in methanol. Nevertheless, there certainly is no

[8]The barrier for the pyramidal inversion of the perepoxide of ethylene has been calculated to be 18 ± 1 kcal/mol (33).

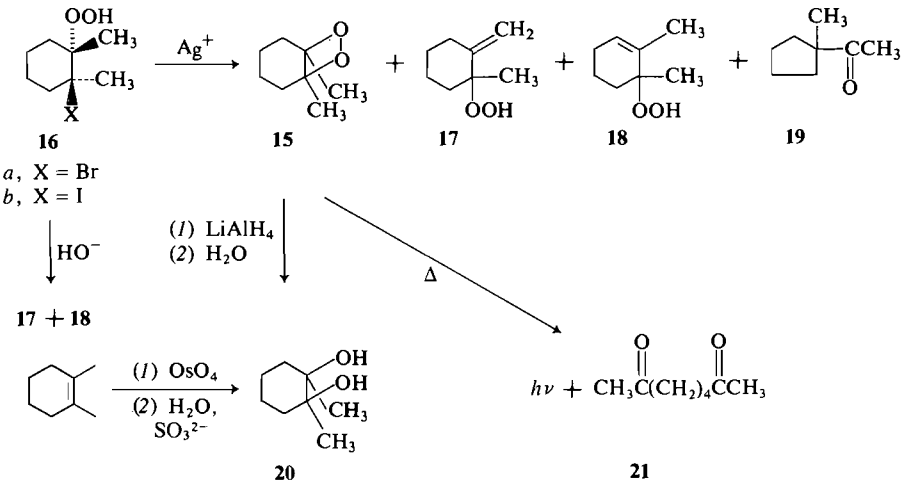


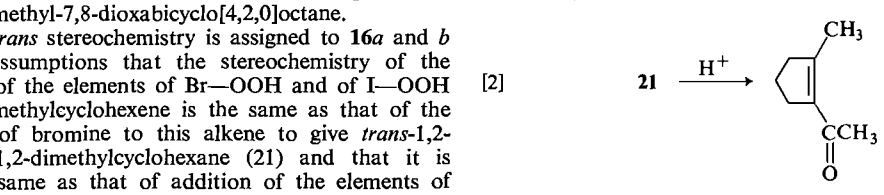
SCHEME 4

very fast acid or base catalyzed reaction of **11** in this solvent.

cis-3,4-Dimethyl-3,4-butano-1,2-dioxetane, ***15***[9]

This material was prepared, Scheme 4, in order to determine whether the route used to prepare **11** might be a general one for the synthesis of tetrasubstituted 1,2-dioxetanes. Treatment of *trans*-2-iodo-1,2-dimethylcyclohexyl hydroperoxide **16***b*[10] with a suspension of silver acetate in methylene chloride at 20° rapidly produces a mixture of four products: **15**, 1-methyl-2-methylenecyclohexyl hydroperoxide **17** (1), 2,3-dimethylcyclohexen-3-yl hydroperoxide **18** (1), and 1-acetyl-1-methylcyclopentane **19**. The ratio of **17**:**18** is about 1:4 which is quite different from the ratio, ~95:5, that is obtained on treatment of **16***a* or *b* with base. Pure **15**, 98.5% active oxygen, can be isolated in 15 to 25% yield as yellow crystals, m.p. 48–50°, by distilling it from the oily mixture of products under high vacuum at ~20° and crystallizing the distillate from pentane. This product is monomeric, mol. wt. found 142, and was reduced with lithium aluminum hydride to *cis*-1,2-dimethylcyclohexane-1,2-diol in 93% yield. Consistently higher yields of **15** were obtained from the iodohydroperoxide[7] **16***b* than from the bromohydroperoxide **16***a* which was much less reactive.

Solutions containing **15** also emit light when heated. At 100° in cyclohexane **15**, ~1 *M*, decomposed to give 2,7-octanedione **21** in 100% yield. Thermolysis of **15** in carbon tetrachloride at 100° resulted in the formation of darkened solutions whose color deepened and which slowly deposited oily droplets, presumably water, on standing at ~22°. Again the major product was **21** but some 1-acetyl-2-methylcyclopentene **22** was also formed as were smaller amounts of several other unidentified products. The amount of **22** formed was ~2% immediately after decomposition but increased slowly when the solutions were allowed to stand. It appears that **22** might be formed by an acid catalyzed cyclization of **21**. A small amount of acid could be formed as a result of some chlorine atom abstraction from solvent by the excited **21** formed from **15**. A sample of authentic **22** was prepared by heating **21** with acid (20), reaction 2.



[9]Chemical Abstracts will index this compound as *cis*-1,6-dimethyl-7,8-dioxabicyclo[4,2,0]octane.

[10]The *trans* stereochemistry is assigned to **16***a* and *b* on the assumptions that the stereochemistry of the addition of the elements of Br—OOH and of I—OOH to 1,2-dimethylcyclohexene is the same as that of the addition of bromine to this alkene to give *trans*-1,2-dibromo-1,2-dimethylcyclohexane (21) and that it is also the same as that of addition of the elements of Br—OOH to $\Delta^{9,10}$-octalin, see below.

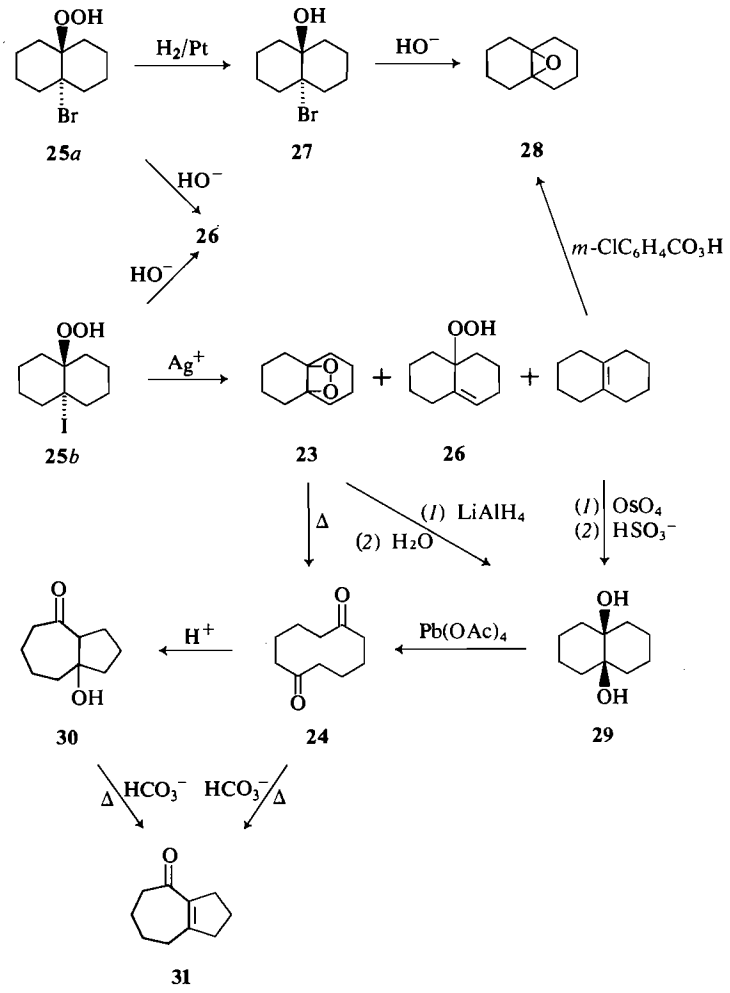

SCHEME 5

3,4:3,4-Dibutano-1,2-dioxetane, 23[11]

This material was prepared in order to assess the effect of strain in the product of thermolysis, 1,6-decanedione, **24**, on the stability and luminescence of the dioxetane. Recent calculations indicate that **24** possesses 8.2 kcal/mol of strain energy (21).

The reaction between 10-bromo-*trans*-9-decalyl hydroperoxide **25***a* and silver ion could not be used to prepare **23**. No reaction occurred at 25°. A slow reaction took place at 60° in benzene. The main product appeared to be 10-hydroperoxy-$\Delta^{1,9}$-octalin **26**. Some of the dione **24** was formed but no evidence could be found for the presence of **23** in the reaction mixture. The *trans* configuration was assigned to **25***a* because the bromohydrin **27** derived from it was converted to the epoxide **28** by base, Scheme 5. The *cis*-bromohydrin presumably would be converted to 10-hydroxy-$\Delta^{1,9}$-octalin by base (see the reaction between **23** and triphenylphosphine below).

The iodohydroperoxide **25***b* was then prepared and found to react rapidly with silver ion, Scheme 5, to produce a mixture of the dioxetane **23**, the allylic hydroperoxide **26**, and $\Delta^{9,10}$-octalin. Product yields were ~35, ~5, and ~1%, respectively. The pure dioxetane can be isolated as yellow crystals, m.p. 34–36°, by chromatography of the concentrated reaction mixture on silica gel at −50° followed by crystallization from the eluent isopentane at −78°.

[11]Chemical Abstracts will index this compound as octahydro-4a,8a-epidioxynaphthalene.

Thermolysis of **23** either in solution or neat produces a quantitative yield of pure diketone, **24**. The reaction is accompanied by emission of a faint, deep blue light which can be seen in a dark room. Reduction of **23** with lithium aluminum hydride produces 9,10-dihydroxy-*cis*-decalin **29** in 98% yield. The molecular weight of **23** was not determined, but its spectral and chemical properties are consistent with its formulation as a 1,2-dioxetane.

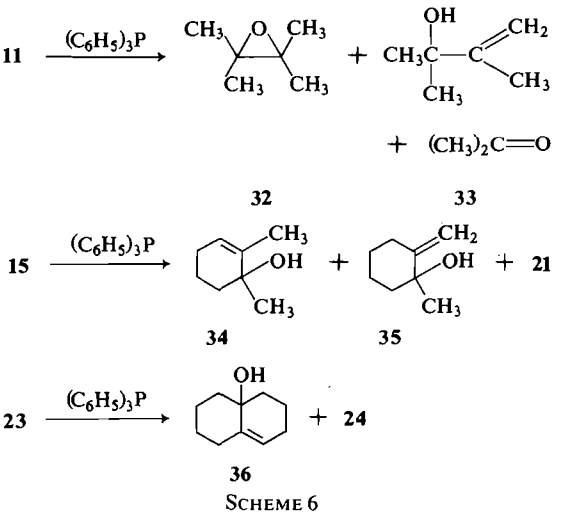
The reaction between **25***a* or *b* and silver ion produces no rearranged ketone product corresponding to pinacolone from **12** or to **19** from **16**. The elimination of the elements of I—OOH from **25***b* to form $\Delta^{9,10}$-octalin is a reaction which was not noticed in the other halohydroperoxide reactions although no especial effort was made to detect it.

Considerable amounts, up to 30% yields, of 9-hydroxy-4-ketodecahydroazulene **30** were isolated sometimes from initial reactions between **25***b* and silver acetate. These runs were carried out by using about equivalent amounts of reagents and, after removal of the silver salts, allowing the reaction mixtures to stand at 5° or −20° for up to 48 h. Apparently, some strong acid was generated under these reaction conditions. This catalyzed the cyclization of the diketone **24**, which was formed by decomposition of the dioxetane (subsequently discovered to be quite unstable, half-life = 16 h at 10°), to the hydroxyketone **30**. No **30** was ever found when an excess of silver acetate was used. Treatment of a solution of the diketone **24** with some trifluoroacetic acid did in fact produce **30**. The structure **30** was assigned from its spectral properties and its ready dehydration with mild base to 4-keto-$\Delta^{9,10}$-octahydroazulene **31**, which was identical with an authentic (22) sample, Scheme 5.

In common with the behavior of other halohydroperoxides from tetrasubstituted ethylenes **25***a* and *b* on treatment with base are converted to the allylic hydroperoxide **26**, exclusively.

Reduction of 1,2-Dioxetanes with Triphenylphosphine

In order to obtain some indication of the chemical reactivity of the peroxide bond in 1,2-dioxetanes some of these compounds were treated with triphenylphosphine. Triphenylphosphine reacted rapidly at 0° in carbon tetrachloride with **11**, **15**, and **23**. The yellow color of the dioxetane was discharged immediately. The nature of the reduction products depends upon the structure of the dioxetane, Scheme 6. Tetramethyloxacyclopropane **32**, 2,3-dimethyl-1-buten-3-ol **33**, and acetone were formed from the monocyclic dioxetane **11** in about 85, 10, and 5% yields, respectively. Only allylic alcohols were formed as reduction products from the bicyclic and tricyclic dioxetanes **15** and **23**. From **15** there were formed 2,3-dimethylcyclohexen-3-ol **34**, 1-methyl-2-methylenecyclohexanol **35**, and **21** in about 70, 20, and 10% yields, respectively. The only detectable products that were formed from **23** were 10-hydroxy-$\Delta^{1,9}$-octalin **36**, isolated in 31% yield, and some **24**.



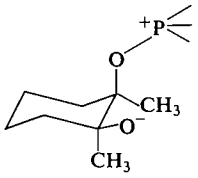
SCHEME 6

A more careful study of the reaction between **11** and triphenylphosphine has been reported already (23). The pentavalent phosphorane product of insertion into the O—O bond was isolated in nearly quantitative yield when the reaction was conducted in benzene. The phosphorane was shown to decompose rapidly to triphenylphosphine oxide and the epoxide **32** only in several solvents including carbon tetrachloride. Thus, the allylic alcohol **33**, found to be a minor product of the reaction between **11** and triphenylphosphine, probably is not formed by way of the phosphorane so that the phosphorane does not appear to be the exclusive initial product of reaction in carbon tetrachloride as it is in benzene.

The reduction products of the reaction between triphenylphosphine and the dioxetane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

are consistent with the formation and subsequent decomposition of zwitterionic intermediates (24), such as **37**, formed directly or



37

from pentacovalent phosphoranes. If such a zwitterion were part of an open chain system it could form an epoxide. If it were part of a cyclic system, as in **37**, in which the two oxygen functions are constrained to be *cis* the backside intramolecular displacement of triphenylphosphine oxide is impossible. Elimination occurs instead to give allylic alcohol.

It is not clear how the ketonic cleavage products are formed. The dioxetanes are stable thermally at 0°. Amines have been observed to catalyze the decomposition of *cis*-3,4-diethoxy-1,2-dioxetane to ethyl formate (25). Perhaps amines and phosphines can catalyze the cleavage of dioxetanes in similar ways.

Ultraviolet and Infrared Spectra of 1,2-Dioxetanes

All the 1,2-dioxetanes reported here are yellow as a result of a weak absorption tail which extends to ~450 nm from a low intensity maximum at ~280 nm[12], Fig. 1. The yellow color of these 1,2-dioxetanes is neither a universal nor a unique characteristic of this class of peroxide. At least some 1,2-dioxetanes are reported to be white (4*a*, 4*f*) and the endoperoxides, 2,3-dioxabicyclo[2.2.2]oct-5-ene (26) and 2,3-dioxabicyclo[2.2.2]hept-5-ene (27), are yellow. The spectrum of *cis*-3,4-diethoxy-1,2-dioxetane does not show a maximum (28) as exhibited in Fig. 1, and simple alkyl peroxides show only weak, nearly structureless absorption below 400 nm. The spectra exhibited by peroxides is thus quite dependent on their structure.

Peroxides are reported to absorb in the range 890 to 830 cm^{-1} in the i.r. (29). The dioxetanes **3**, **11**, and **15** have weak to medium intensity

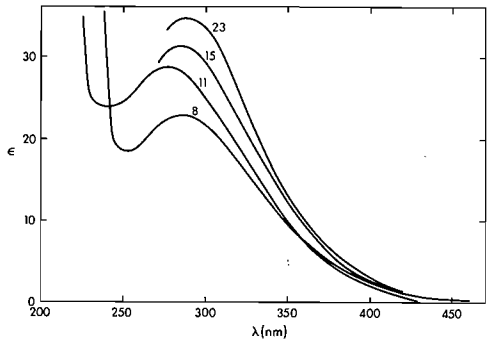


FIG. 1. Ultraviolet–visible spectra of 10^{-2} *M* dioxetanes. Solvents: **8** in heptane, **11** in carbon tetrachloride, **15** and **23** in cyclohexane.

absorptions at 886, 868, and 882 and 870 cm^{-1}, respectively.[13]

Rates of Thermolysis

The rates of thermolysis of the 1,2-dioxetanes in carbon tetrachloride or benzene were determined by a variety of methods, Table 1. Relative rates of thermolysis are included in Table 2. Rates obtained by n.m.r. analysis and by fluorescence decay measurements in the presence of DBA agree reasonably well with those obtained by iodometric analysis in those cases where comparisons were made. This is consistent with other work (6*b*, 6*c*, 28). The rate of fluorescence decay of a degassed solution of **11** containing DBA was twice that of a similar aerated solution. It was observed qualitatively that **15** and **23** also decomposed more rapidly in degassed than in aerated solutions. This phenomenon already has been studied carefully and explained (28); oxygen in aerated solutions quenches the excited state ketone or fluorescer formed on thermolysis of the dioxetane. This prevents energy from being transferred to the dioxetane which would result in its decomposition.

There appeared to be no effect of concentration on the rate of decomposition of the dioxetanes in aerated solution in the concentration range 1 to 0.01 *M*. Dioxetanes appear to be quite stable to strong acid, at least in nonpolar solvents. The rate of disappearance of **11** at 50° in benzene containing 1 *M* trifluoroacetic

[12]Solutions of dioxetane lost less than 5% of their peroxide content during the time that the spectra were recorded.

[13]NOTE ADDED IN PROOF: However the Raman spectrum of **11** has been obtained recently and shows strong absorption at 672 cm^{-1}. The i.r. bands at 868 and 882 cm^{-1} are not Raman active and thus are not O—O stretching bands.

TABLE 1. Rates of thermolysis of 1,2-dioxetanes

Dioxetane	Solvent	Concentration (M)	Temperature (°C)	Method[a]	$k \times 10^4$ (s^{-1})[b]

TABLE 2. Relative rates and activation parameters for thermolysis of 1,2-dioxetanes

Dioxetane	Relative rate at 40°	E_a (kcal/mol) Found	E_a (kcal/mol) Calculated	$\Delta S^{\ddagger}$ (e.u.) Found (at 40°)	$\Delta S^{\ddagger}$ (e.u.) Calculated
3	6.4	23.5±0.5[a]	[b]	−5±2	−4[c]
8	~15	—	—	—	—
11	1	25.8±0.5	24.7[c]	−2±2	−5[c]
15	1.2	25.7±0.7	22.2[d]	2±2	−2[d]
23	88	22.7±0.9	22.2[d]	−3±3	−2[d]

[a]This value differs slightly from that reported (31*a*), 23.7. More kinetic runs have been made since then.
[b]E_a for thermolysis of 3 was used as a basis for the thermochemical calculations (31).
[c]Reference 31.
[d]Calculated using the method described (31).

acid was only twice that in acid-free carbon tetrachloride.

Activation parameters for the thermolysis of the dioxetanes, Table 2, were calculated from rates obtained from runs made using aerated solutions. Only rates determined by the same method at each of the different temperatures involved were used for the calculations for each compound. Under these conditions all available points of plots of log k *vs.* 1000/T fell on a straight line for each dioxetane except **11**. For this compound the point at 70° lay above the line defined by the points at 40, 50, and 60°. The rate of decomposition of **11** at 70° was reproducibly faster than expected by a factor of ~1.4 and was not affected by degassing the solution. Perhaps the concentration of oxygen in carbon tetrachloride and benzene at this temperature is too small to prevent some induced decomposition (28, 30) of **11** by the electronically excited acetone molecules which are formed by thermolysis.

The energy of activation for thermolysis of **11** is in good agreement with reported values (8, 19). The activation parameters for thermolysis of **11** and **23** agree well with those calculated on the basis of a two step biradical mechanism for the thermolysis (31). However, those for **15** do not agree with calculated values. Both **15** and **23** are calculated to have the same activation parameters for thermolysis, but **15** is clearly seen to be much more stable than **23** even on a qualitative basis in the laboratory. Indeed, **23** is the least stable tetrasubstituted 1,2-dioxetane so far prepared.[14]

Discussion

Compounds which have been assigned a 1,2-dioxetane structure have been reported numerous times (32) prior to the present work, but for most of these compounds such structures have been suggested to be improbable (ref. 31*a*, footnote 3) or are known to be incorrect on the basis of other evidence (34). It is unlikely that the stable peroxidic material isolated from autooxidation of methyl oleate (32*f*) can be a dioxetane since known disubstituted dioxetanes are too unstable thermally (6*a–c*, 31*a*) to survive the reaction conditions used.

General interest in dioxetanes was first aroused after it was proposed that these may be the critical intermediates which decompose to give the electronically excited products that emit light in some chemiluminescent and bioluminescent reactions (35). The fact that all the stable dioxetanes isolated to date are luminescent (at least in the presence of added fluorescers) lends strong support to this suggestion.[15] Since the first report of the isolation and luminescence of a stable dioxetane numerous members of this class of compound have been prepared (4–7) and many energy transfer experiments have been performed with **3** (6*d*, 37) and **11**. A review article has already been written about experiments carried out with **11** (38) and dioxetanes have been suggested as being sources of energy for some dark biological reactions (36*f*, 39). The thermochemistry and the possible mechanisms of the thermolysis of dioxetanes have been discussed elsewhere as well (28, 31, 38, 40, 41).

The isolation of stable dioxetanes also has a bearing on the mechanism of the formation of allylic hydroperoxides in the reaction between singlet oxygen and alkenes. Dioxetanes are not converted to allylic hydroperoxides either thermally or by acid or base. This shows that, in general, dioxetanes cannot be intermediates in such singlet oxygen oxidations, contrary to what has been suggested (42). It appears that in singlet oxygen reactions where both dioxetanes (or their fragmentation products) and allylic hydroperoxides are produced (4*g*, 4*j*, 42, 43) these materials are formed by parallel, not consecutive reactions.

Finally, some comments about the reported preparation of several 1,2-dioxetanes will be made. A number of alkenes are reported to have been converted to dioxetanes by the reaction with ozone in pinacolone solvent (12). Specifically, **8** reportedly was formed in high yield from ethylidenecyclohexane. However, no **8** could be detected among the products when the reaction was repeated (13, 44). Also, the reported synthesis, using this reaction, of the dioxetane of bifluorenylidene (45) could not be repeated in two laboratories (36*f*, 46). Dioxetane structures have been assigned to some products isolated, directly or after some treatment, from the reaction between singlet oxygen and phenyl substituted ethylenes (4*e*, 47). These materials appear to be exceptionally stable for dioxetanes of the structures given and the possibility remains that they are actually 1,2-dioxane derivatives formed by a 1,4-addition of singlet oxygen, reaction 3.

[3] 
These products could rearrange to dioxetanes on heating to give cleavage products and might form products seemingly derived from dioxetanes on chemical characterization. There is ample precedent for 1,4-addition of singlet oxygen to aryl substituted ethylenes (48) and such 1,2-dioxanes have been suggested to rearrange easily to dioxetanes (47*a*, 48*a*). The endoperoxide of 1,4-dimethoxy-9,10-diphenyl-

[14]A referee has suggested that there may be compensating errors in E_a and $\Delta S^{\ddagger}$ for thermolysis of **15**, and that if $\Delta S^{\ddagger}$ were -5 e.u., E_a would become 23.2 kcal/mol.

[15]Several reviews of chemiluminescence and bioluminescence have appeared recently (36).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

anthracene also rearranges readily to a dioxetane (49). A trisubstituted dioxetane structure was assigned to a product isolated from the reaction between olivetol and citral in refluxing pyridine (50). There is not enough information to decide whether the product is a dioxetane, but such a dioxetane could not have survived the reaction conditions and it is difficult to see how it could have been formed during the reported workup.

The results of some energy transfer experiments and the determination of yields of excited states formed on thermolysis of the dioxetanes **3**, **11**, **15**, and **23** will be reported later (51).

Experimental

CAUTION! All preparations and reactions of hydroperoxides and dioxetanes were carried out behind shields. Numerous small explosions and vigorous decompositions occurred throughout this research.

Melting points and boiling points are uncorrected. Ultraviolet spectra were recorded with Cary 15 and Bausch and Lomb Spectronic 600 recording spectrophotometers. Nuclear magnetic resonance spectra were recorded with Varian analytical spectrometers models HA-100, A-60, and A-56/60 (^{1}H spectra) using tetramethylsilane internal standard and with a Brucker HFX 10 spectrometer (^{13}C spectra). The latter were obtained on 0.2 to 1 *M* solutions using Fourier transform and 1000 to 4000 pulses were collected. Gas–liquid chromatography analyses were carried out on Aerograph 202 and A-90-P3 gas chromatographs. Infrared spectra were recorded on Perkin–Elmer Model 421 and Model 337 spectrophotometers. Mass spectra were obtained with A.E.I. MS-2 and MS-12 mass spectrometers. Refractive indices were measured with a Bausch and Lomb Abbe-3L refractometer.

Anhydrous magnesium sulfate was used as drying agent unless otherwise noted. Solvents were removed with a rotary evaporator unless stated otherwise. Iodometric analyses were carried out using the method of Organic synthesis (52).

Alkenes

Commercial samples of 2-methyl-2-butene, 2,3-dimethyl-2-butene, and ethylidenecyclohexane were used. The synthesis (53) of $\Delta^{9,10}$-octalin was modified to use tetralin as the starting material which doubled the amount of product formed without increasing the scale of the reaction. Use of crude material containing ~30% of the $\Delta^{1,9}$-isomer gave almost as good yields of the halohydroperoxides **25***a* and *b* as did use of the purified product. It was necessary to use isomerically pure 1,2-dimethylcyclohexene (54) and to store it under nitrogen or in evacuated ampoules in order to obtain crystalline halohydroperoxides **16***a* and *b*.

Preparation of β-Halohydroperoxides

These materials were prepared by the reaction in ether between the appropriate alkene, 98% hydrogen peroxide, and 1,3-dibromo- or 1,3-diiodo-5,5-dimethylhydantoin (Arapahoe Chemicals) using the general method described previously (1) with the following exceptions. For the preparation of the iodohydroperoxides the ether solutions, after having been extracted repeatedly with water, were shaken with cold aqueous bisulfite solution until the ether layer lost the iodine color. It was necessary to keep the temperature of the reaction mixture at −40° for at least 4 h during the preparations of **9**. Otherwise the product was contaminated by significant amounts of a material, perhaps the dibromide of ethylidenecyclohexane, which had a methyl group doublet (J = 7 Hz) absorption at τ 7.9.

Compound **12***a* has been characterized already (1, 2*c*). Compounds **1** and **16***a* were obtained previously as oils (1) but have now been prepared in pure crystalline form. All the compounds but **1** and **9** could be purified by crystallization (sometimes at −78°) of the crude product from pentane, isopentane, or hexane solvents. It was necessary to free from impurities compounds **1** and **9** by precipitating them as the 1,4-diazabicyclo[2.2.2]octane (DABCO) complexes (16), as described below for **1**, before they could be crystallized.

Properties of the β-halohydroperoxides are given in Table 3.

Preparation of 3-Bromo-2-methyl-2-butyl Hydroperoxide, 1

A 7.0 g (0.1 mol) sample of 2-methyl-2-butene was converted to the bromohydroperoxide in the usual way (1). After the repeated extraction with water the ether layer was dried and then 5.6 g (0.05 mol) of DABCO was added. The resulting solution was cooled with swirling to −78° over 20 min, during which time a precipitate was formed, and kept at −78° for 3 h. The crystals were filtered on a precooled Buchner funnel, washed twice with cold ether, and then shaken with a mixture of ether and ice water. The ether layer was shaken twice with water, dried, and concentrated to give 10.1 g of an oil. Crystallization of the oil from isopentane at −78° gave 9.0 g (50%) of **1**.

Trimethyl-1,2-dioxetane, 3

A solution of 0.4 g (0.01 mol) sodium hydroxide in 1 ml water and 3 ml methanol was added dropwise to a stirred solution of 1.9 g (0.01 mol) of pure **1** in 6 ml methanol at 0°. After 100 m the mixture was extracted with 3 × 25 ml isopentane. The combined extracts were dried and concentrated at 0° under reduced pressure. The residual yellow oil was distilled at room temperature under ~0.1 mm pressure into a cold trap. A colorless forerun was discarded. The main fraction, a yellow solid, was recrystallized twice from isopentane at −78° to give 0.1 g (10%) of yellow crystals, m.p. 5–7°, 97.2, 99.7% active oxygen; n.m.r. (CCl_4) τ 4.80 (q, J = 6.5 Hz, 1H), 8.51 (s, 3H), 8.56 (s, 3H), 8.68 (d, J = 6.5 Hz, 3H); i.r. (CCl_4): 1370, 1360, 1202, 1156, 886 cm^{-1}. This material has a very pungent odor.

Benzene or carbon tetrachloride solutions up to 1 *M* in **3** containing less than 10% of impurities can be made using crude **1**, by extracting the reaction mixture with the appropriate amounts of these solvents and, after drying, distilling the yellow extract at low temperature until the residue is pale yellow. The dioxetane, obtained in ~30% yield in this way is slightly less volatile than these solvents. Late fractions of the distillate are richer in dioxetane than are early fractions.

TABLE 3. Properties of β-halohydroperoxides

Compound	Yield (%)	Melting point (°C)	Active oxygen (%)	Nuclear magnetic resonance absorptions, $\tau(CDCl_3)$[a]
1	50[b]	−7 to −5[c]	99.2	1.4 (s, OOH), 5.56 (q, J = 7 Hz, CH), 8.32 (d, J = 7 Hz, CH_3), 8.63 and 8.72 (s, *gem.* —CH_3's)[d]
9	41[b]	44.0–45.5	99.6	2.29 (s, OOH), 5.60 (q, J = 7 Hz, CH), 8.32 (d, J = 7 Hz, CH_3), 7.9–8.8 (broad, CH_2's)
12*b*	~80	32–35 (dec.)[e]		1.48 (s, OOH), 7.95 (s, β-CH_3's), 8.50 (s, α-CH_3's)[d]

[a]See ref. 71 for discussion of assignments of CH_3 absorptions.
[b]Yield of crystalline material. Crude material, 95% active oxygen, obtained in 90% yield is sufficiently pure for the preparation of the dioxetane.
[c]*p*-Nitrobenzoyl derivative, m.p. 86–88°. Anal. Calcd. for $C_{12}H_{14}BrNO_5$: C, 43.38; H, 4.24; Br, 24.08; N, 4.22. Found: C, 42.76, 43.16; H, 4.25, 4.36; Br, 23.92, 24.49; N, 4.35, 4.63.
[d]In CCl_4.
[e]Crystalline material free of solvent explodes within 5 min at room temperature. No attempt was made to determine the active oxygen content.
[f]For crude oily product.
[g]In spite of many attempts no satisfactory analysis was obtained on any of several samples of otherwise apparently pure (n.m.r., t.l.c.) crystalline material.

Lower yields of less pure **3** were obtained if the reaction between **1** and base was allowed to continue for much beyond 100 min. The n.m.r. spectrum of a reaction mixture after 20 h indicated the presence of about 30% acetone in addition to several other materials. Evaporation of the mixture left an oily residue which was evaporated several times with carbon tetrachloride and then taken up in their solvent. The n.m.r. spectrum of the solution was identical to that of an authentic sample of 2-methyl-2,3-butanediol **4**.

4-Methyl-3,3-pentamethylene-1,2-dioxetane, ***8***[8]

A solution of 2.3 g (0.01 mol) **9** in 6 ml cold methanol was added dropwise to a solution of 0.4 g (0.01 mol) of sodium hydroxide in 1 ml water and 3 ml methanol at 0°. The mixture was stirred for 25 min after which 10 ml water and 10 ml carbon tetrachloride were added. The yellow organic layer was shaken with 2 × 20 ml ice water, dried, and then concentrated under reduced pressure to a yellow oil. These operations were all carried out as quickly as possible at 0°. The oil was quickly distilled at 20° under 0.01 mm pressure into a cold trap. A colorless forerun was discarded. The main fraction, a yellow solid, was redistilled twice more in this way to give 180 mg (12.5%) of a yellow solid, m.p. −11°, 98.0% active oxygen, n.m.r. (CCl_4) τ 4.91 (q, J = 6.5 Hz, 1H) and 8.66 (d, J = 6.5 Hz) superimposed on broad absorption from 7.7 to 8.9 (total 13H), mol. wt. found (cryoscopic, C_6H_6): 155.

This compound appears to be considerably less stable than **3** and all operations involving it must be carried out as quickly as possible. The luminescence of **8** appeared to be considerably more intense than that of **3** in solutions of similar concentrations at similar temperatures.

Tetramethyl-1,2-dioxetane, ***11***

A solution of 4.0 g (0.02 mol) of **12***a* in 20 ml methylene chloride was added quickly to a rapidly stirred slurry of 12 g (0.07 mol) silver acetate[16] in 80 ml methylene chloride. The resulting mixture was stirred 15 min at 25° and then filtered through Celite. The pale yellow filtrate was washed with 30 ml water and with 30 ml 10% sodium carbonate, dried, and concentrated at 0° to a yellow oil. The oil was distilled at 20° under 0.01 mm pressure into a cold trap. The distillate was crystallized from isopentane at −78° to give 0.7 g (30%) yellow crystals, m.p. (sealed tube) 73–76°. This was easily sublimed to give a solid that was still yellow, m.p. (sealed tube, m.p. block preheated to 70°) 76–77° (the melt emitted a faint blue glow), 98.7% active oxygen, mol. wt. found (cryoscopic, C_6H_6): 112; ^1H n.m.r. (CCl_4) τ 8.49 (s), ^{13}C n.m.r. (acetone-d_6) 89.33 and 23.55 p.p.m. downfield from internal TMS; i.r. (CCl_4): 1380, 1370, 1202, 1168, and 868 cm^{-1}.

The residue remaining from the distillation of the crude reaction mixture was almost pure allylic hydroperoxide **13**, 1.2 g (55%), as judged from the n.m.r. spectrum. The filtrate from the crystallization of **11** was concentrated at 0° to an oil which showed strong absorption at τ 7.95 (s) and 8.9 (s), area ratio 1:3, in the n.m.r. spectrum. Pinacolone 2,4-dinitrophenylhydrazone was isolated in 15% yield from this oil.

[16]Consistently better yields of dioxetanes were obtained when silver acetate powder produced by J.T. Baker Chemical Co. was used as supplied than when other commercially available samples of silver acetate were used. Silver acetate or benzoate prepared under a variety of conditions in our laboratories were less effective, also.

Use of the iodohydroperoxide **12***b* for this preparation resulted in essentially the same product distribution as was obtained from **12***a*.

cis-3,4-Dimethyl-3,4-butano-1,2-dioxetane, ***15***[9]

A solution of 3 g (0.011 mol) **16***b* in 20 ml methylene chloride was added quickly in portions to a rapidly stirred mixture of 6 g (0.036 mol) silver acetate in 80 ml methylene chloride at 25°. At each addition the mixture turned red, then yellow. Reaction appeared to occur almost instantaneously. Five minutes after the addition was complete the mixture was filtered through Celite. The filtrate was dried and concentrated to a yellow oil, 1.3 g, which was distilled under 0.01 mm at 20°. The volatile material was crystallized from isopentane at −78°. Two recrystallizations gave 0.35 g (25%) of pale yellow crystals, m.p. 48–50°, 99.2% active oxygen, mol. wt. found (osmometric, CH_2Br_2): 134; ^1H n.m.r. ($CDCl_3$) τ 8.6 (s) superimposed on broad absorption from τ 7.9 to 8.7, ^{13}C n.m.r. (acetone-d_6) 19.61, 22.91, 34.41, and 88.34 p.p.m. downfield from internal TMS; i.r. (CS_2): 2900, 2850, 1380, 1205, 1180, 1050, 910, 882, 877 cm^{-1}. The mass spectrum (70 eV) was identical to that of 2,7-octanedione **21** (55) except that the weak $M^+ + 1$ peak in the mass spectrum of **21** was absent in that of **15**.

The mother liquor from the crystallization of **15** was concentrated to an oil which was converted to the semicarbazone derivative. This product, 0.4 g (20%), was recrystallized from aqueous methanol, m.p. 138–141°, mixed m.p. with the semicarbazone of authentic (56) 1-acetyl-1-methylcyclopentane **19** 138–141°. The authentic semicarbazone had m.p. 138–141° (lit. (57) m.p. 140.5–141°).

The residue remaining upon the distillation of **15** and **19** from the crude reaction mixture appeared to consist mainly of the allylic hydroperoxides **17** and **18** (~50% yield) in a ratio of ~1:4 as judged from the n.m.r. spectrum.

Treatment of the bromohydroperoxide **16***a* with silver acetate resulted in the formation of the same products that were formed from **16***b* but the yield of **15** was always rather low and the reaction quite slow.

3,4:3,4-Dibutano-1,2-dioxetane, ***23***[11]

A solution of 2.0 g (0.007 mol) of **25***b*, freshly recrystallized from heptane, in 20 ml methylene chloride was added quickly to a rapidly stirred suspension of 5.0 g (0.03 mol) of silver acetate in 80 ml methylene chloride at 20°. The resulting suspension was stirred for 5 min and then filtered through Celite. The filtrate was washed with cold 10% sodium bicarbonate and with ice water, then dried at 0° and concentrated at 0° to give 1.2 g yellow oil. This oil was taken up in a little pentane and the solution transferred to a jacketed chromatography column containing 12 g silica gel at −50°. All the above operations were carried out as quickly as possible. The yellow band due to the dioxetane was eluted with 0.5% ether in pentane. The fractions containing **23** (yellow) were kept at −78° until the solvent became colorless. Solvent was decanted from the yellow crystals which formed. These were taken up in a little isopentane. This solution was quickly transferred to a glass ampoule and cooled to −78° until crystallization was complete. Solvent was removed under 0.01 mm pressure at −78° leaving 0.14 g (12%) of yellow crystals which melted at 34–36° to a melt which emitted a faint deep blue glow. The melt resolidified on further heating at 3°/min at ~80° to a white solid, m.p. 98–99° (lit. (58) m.p. 99–99.5° for 1,6-cyclodecanedione). Pure **23** had 100.4% active oxygen, ^1H n.m.r. (CCl_4) τ 7.8–8.8 (broad), ^{13}C n.m.r. (acetone-d_6) 21.20, 35.12, and 87.99 p.p.m. downfield from internal TMS.

Iodometric titration of the combined dioxetane containing fractions from the chromatography indicated that the actual yield of **23** formed in each of several runs was 30 to 37%.

Further elution of the column with 0.5% ether in pentane removed the allylic hydroperoxide **26** which was formed in ~50% yield. Finally, the dione **24**, ~5% was eluted.

Concentration of the fractions which eluted before those containing **23** gave ~1% of an oil which was identified as $\Delta^{9,10}$-octalin on the basis of its n.m.r. spectrum and behavior on t.l.c.

Carbonyl Compounds from Thermal Decomposition of 1,2-Dioxetanes

Trimethyl-1,2-dioxetane, ***3***

A 0.1 *M* solution of **3** in carbon tetrachloride, containing some benzene as internal standard, was heated at 60° for 12 h in a sealed n.m.r. tube. Only signals for acetone and acetaldehyde were observed in the n.m.r. spectrum of the solution which showed that these materials were formed in 93% yield. Only product peaks due to acetone and acetaldehyde could be detected on g.l.c. analysis of the solution.

Tetramethyl-1,2-dioxetane, ***11***

A 0.1 *M* solution of **11** in carbon tetrachloride, containing some anisole as internal standard, was heated at 70° for 10 h in a sealed n.m.r. tube. The n.m.r. spectrum of the solution indicated that acetone was the only product formed in 96% yield. Only acetone could be detected on g.l.c. analysis of the solution.

4-Methyl-3,3-pentamethylene-1,2-dioxetane, ***8***

A solution of 38 mg **8** in 0.5 ml benzene-d_6, containing some benzene as internal standard, was heated at 50° for 6 h in a sealed n.m.r. tube. The only products detected were acetaldehyde in 90% yield (by n.m.r.) and cyclohexanone in 95% yield, isolated as the 2,4-dinitrophenylhydrazone after driving off the acetaldehyde by boiling the solution briefly. The half-life of **8** was ~15 min under these conditions.

Thermolysis of **8** in carbon tetrachloride at 50° gave a dark solution and some unidentified products other than acetaldehyde and cyclohexanone were detected by n.m.r. spectroscopy.

cis-3,4-Dimethyl-3,4-butano-1,2-dioxetane, ***15***

A solution of 0.1 g **15** in 10 ml pentane was allowed to stand at 25° until the yellow color had faded completely (5 d), then cooled to −10° overnight. White crystals formed, 0.1 g (100%), m.p. 43–45°, mixed m.p. with authentic (59) 2,7-octanedione **21** 43–45°.

Gas–liquid chromatography analysis of the decomposition at temperatures up to 100° of 0.1 *M* in degassed hydrocarbon solvents indicated that > 99% of the product was the dione **21**. Less than 0.03%, if any, of acetone was formed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Thermolysis of 0.08 g **15** in 1 ml carbon tetrachloride at 100° for 15 min resulted in the formation of a dark solution. This solution darkened further when allowed to stand at −10° for 8 h and deposited droplets of a second phase. The reaction mixture was applied to a thick layer plate of silica gel which was developed with 1:10 ether:Skelly B. The major fraction was extracted from the silica gel and found to be 1-acetyl-2-methylcyclopentene **22** on the basis of its n.m.r. spectrum and semicarbazone, m.p. 221°, mixed m.p. with the semicarbazone of authentic **22** 218–220°.

Authentic **22** was prepared by the acid catalyzed cyclization (60) of 2,7-octanedione (59) and purified by column chromatography on silica gel using 1:10 ether:Skelly B as eluent, semicarbazone m.p. 218–220° (lit. (60) m.p. 221°).

3,4:3,4-Dibutano-1,2-dioxetane, 23

As was reported under the preparation of **23**, heating of **23** above its melting point produced pure 1,6-cyclodecanedione. Therefore, the yield of product is 100%.

Reduction of 1,2-Dioxetanes by Triphenylphosphine

Dioxetanes **11** and **15** were each reduced by adding 0.04 g of dioxetane in 1 ml carbon tetrachloride dropwise to 25 ml carbon tetrachloride containing 1.1 equivalents of triphenylphosphine at 0°. The yellow color of the dioxetane was discharged immediately. The relative yields of products were determined by integration of the n.m.r. spectra taken immediately after reaction. Only acetone, 5%, **33**, 10%, and **32**, 85%, could be detected as products from **11** by n.m.r. spectroscopy or by g.l.c. on an FFAP column at 30 or 66°. From **15** only **21**, 10%, **35**, 20%, and **34**, 70%, could be detected by n.m.r. spectroscopy or by t.l.c. using several solvent systems.

A solution of 0.25 g (15 mmol) of **23** in 5 ml carbon tetrachloride was slowly added to 0.430 g (16 mmol) of triphenylphosphine in 30 ml carbon tetrachloride at −10°. The resulting solution was allowed to stand for a short time. Thin-layer chromatography analysis indicated the presence of mainly **36** and a little **24** as products. Solvent was removed and the residue stirred well with 5 ml benzene. The resulting mixture was filtered and the filtrate was applied to a column of 100 g of basic alumina. Elution with 5% ether in benzene gave 0.070 g (31%) **36**, m.p. 85–87°, mixed m.p. with authentic **36** 84–87°.

Reduction of 1,2-Dioxetanes with Lithium Aluminum Hydride

The same procedure was used for reduction of all 4 dioxetanes below.

Reduction of Tetramethyl-1,2-dioxetane, 11

A solution of 0.12 g freshly sublimed **11** in 10 ml ether was added slowly to a stirred mixture of 0.2 g lithium aluminum hydride in 10 ml ether at −78°. The resulting mixture was stirred at −78° for 20 min and then allowed to warm to 20°. A solution of 10% aqueous potassium hydroxide was added slowly until a clear solution had formed. The precipitate was filtered and washed several times with ether. The combined washings and filtrate were concentrated to give 0.14 g white crystals of pinacol, m.p. 42–44°, containing 1.5 mol water of crystallization, as judged from the n.m.r. spectrum. Thus, the yield of pinacol was 100%. Recrystallization of the product from benzene gave pure pinacol, m.p. 39–41°, which had i.r. and n.m.r. spectra identical to those of authentic material.

Reduction of cis-3,4-Dimethyl-3,4-butano-1,2-dioxetane, 15

Reduction of 0.11 g of **15** and removal of the ether after workup and drying gave an oily solid which was recrystallized twice from isopentane to give 0.049 g (44%) of *cis*-1,2-dimethylcyclohexane-1,2-diol **20**, m.p. 48–50° (lit. (61) m.p. 49.5–50°), mixed m.p. with authentic **20** 46–48°. Osmium tetroxide oxidation (62) of 1,2-dimethylcyclohexene gave authentic **20**, m.p. 46–48°.

Reduction of 3,4:3,4-Dibutano-1,2-dioxetane, 23

A 20 ml fraction of the dioxetane containing eluent from the chromatographic purification of **23** was found to contain 45 mg **23** by iodometric titration. This fraction was treated with lithium aluminum hydride as described above. The crude product was repetitively evaporated with benzene and taken up in 25 ml benzene. Analysis of an aliquot of the solution for diol content using lead tetracetate (63) indicated a yield of 98%. Crystalline 9,10-dihydroxy-*cis*-decalin **29**, 15 mg (30%), m.p. 89–90°, mixed m.p. with authentic **29** 89–90°, was isolated on concentration of the remaining solution.

Oxidation of 0.55 g $\Delta^{9,10}$-octalin with osmium tetroxide (58) gave 0.60 g (88%) of the authentic *cis*-diol 29, m.p. 88–89° (lit. (58) m.p. 90°).

Reduction of 4-Methyl-3,3-pentamethylene-1,2-dioxetane, 8

Reduction of 45 mg of **8**, gave after drying and evaporation of the ether solution to a thin film, 44 mg (96%) of a colorless oil whose i.r. and n.m.r. spectra were the same (except for the OH absorptions) as those of authentic diol **10** (64). Thin-layer chromatography analysis showed no impurities.

Reduction of Trimethyl-1,2-dioxetane, 3

Sulfite Ion

Three millilitres of carbon tetrachloride containing 0.33 *M* **3** was added to a stirred solution of 0.126 g sodium sulfite in 3 ml water at 0°. The p*H* of the solution was kept between 7 and 9 by periodic addition of 10% hydrochloric acid. When all the peroxide had been consumed (KI test) the mixture was separated. The n.m.r. and i.r. spectra of the dried organic layer were identical with those of authentic (65) trimethyloxacyclopropane **2**. The aqueous layer was acidified with 10% hydrochloric acid and then treated with barium chloride solution. The precipitate was filtered, washed, and dried to give 0.162 g (70%) of barium sulfate.

Iodide Ion

A mixture of 5 ml carbon tetrachloride containing 0.1 *M* **3**, 5 ml glacial acetic acid, and 1 ml saturated aqueous potassium iodide was allowed to stand at 26° for 15 min in the dark. Sufficient 0.2 *M* aqueous sodium thiosulfate was then added to just decolorize the solution. Solid sodium carbonate was added in portions until the evolution of gas ceased. The resulting slurry was shaken for 1 h with each of 4 × 25 ml aliquots of ether. The combined ether layers were dried and concentrated to a thin film whose n.m.r. spectrum in carbon tetrachloride containing toluene as an internal standard was identical to that of authentic 2-methyl-2,3-butanediol **4**, except for the absorptions due to toluene, and indicated that the yield of **4** was 50%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

2-Methyl-2,3-butanediol, 4

Authentic **4** was prepared by shaking a mixture of 3.7 g trimethyloxacyclopropane **2** (65) and 12 ml water containing two drops of concentrated sulfuric acid at 10° until the sharp odor of **2** had faded. The homogeneous solution was neutralized with 10% aqueous sodium carbonate. Water was removed under reduced pressure and the residue was washed repeatedly with ether. The ether washings were combined, dried, and concentrated. The residual oil was distilled to give 2.35 g (53%) of **4**, b.p. 63–64° (4 mm), n_D^{28} 1.4361 (lit. (66) b.p. 75–76° (14 mm), n_D^{25} 1.4375).

Stability of Tetramethyl-1,2-dioxetane, 11, to Acid and Base

Three methanolic solutions ~0.1 *M* in **11** of which one was neutral, one was 0.3 *N* in sodium hydroxide, and one was 0.3 *M* in trifluoroacetic acid were allowed to stand at 0°. The solutions, which also contained some benzene as internal standard, were analyzed periodically by n.m.r. spectroscopy. After 48 h the neutral solution had 69%, the basic solution 75%, and the acidic solution 72% of the original amount of **11**. No product other than acetone could be detected by g.l.c. using several columns from any of the solutions at this time or after they had been allowed to stand at 22° for another 72 h when most of the dioxetane had disappeared.

7-Hydroxybicyclo[5.3.0]decan-2-one, 30

Method A

Powdered silver acetate, 9.0 g (0.054 mol), was added over a period of 30 min to a solution of 15 g (0.051 mol) of **25***b* in 100 ml methylene chloride at 0 to −10°. The mixture was stirred for 4 h at 0 to −10° and then filtered through Celite. The filtrate was washed with 3 × 50 ml 100% sodium bicarbonate solution, dried, and concentrated to give 2 g (24%) white crystals which were recrystallized twice from heptane, m.p. 96–97°, n.m.r. (CCl_4) τ 8.75 (broad, t, 1H) 7.5 (broad, 2H) and 8.6 (s, exchangeable with D_2O) superimposed on broad absorption from 7.5–8.5 (total 13H); i.r. (CCl_4): 3600 (sharp), 3480 (broad), 1700 cm^{-1}. On dilution the intensity of the 3600 cm^{-1} band increased relative to that of the 3480 cm^{-1} band.

Anal. Calcd. for $C_{10}H_{16}O$: C, 71.34; H, 9.59. Found: C, 71.09; H, 9.52.

Method B

A solution of 0.1 g of the dione **24** and 10 mg trifluoroacetic acid in 5 ml methylene chloride was allowed to stand at ~22° for 24 h and then shaken with 20 ml water. The organic layer was concentrated to an oil which was applied to a 1.5 × 9 cm column of silica gel. Elution with 1 to 5% ether in hexane removed little material. Elution with 10% ether in hexane gave 0.031 g (30%) of white crystals, m.p. 96–97.5°, mixed m.p. with product from Method A 95–97°.

Dehydration of 30 to Bicyclo[5.3.0]dec-1(7)-ene-2-one, 31

The hydroxyketone **30**, 0.2 g, was heated under reflux with 20 ml saturated sodium bicarbonate solution for 1 h. The reaction mixture was cooled and extracted with 2 × 10 ml methylene chloride. The organic layer was dried and concentrated to an oil which was purified by chromatography on silica gel. The n.m.r. spectrum of the product was identical to that of authentic (67) **31** which had n_D^{25} 1.5251 (lit. (22) n_D^{25} 1.5260). The semicarbazone had m.p. 188–190° (lit. (67) m.p. 195–200°), mixed m.p. with the semicarbazone of authentic (67) **31** 188–190°.

9-Bromo-10-hydroxy-trans-decalin, 27

Method A

A solution of 0.578 g (23 mmol) of 9-bromo-10-hydroperoxy-*trans*-decalin **25***a* in 25 ml ether was added to a solution of 0.657 g (24 mmol) of triphenylphosphine in 10 ml ether at 20–30°. The resulting solution was allowed to stand a few minutes, then cooled to −10°, and a few drops of 98% hydrogen peroxide added. The precipitate was filtered, the filtrate concentrated to an oil, and the oil adsorbed on a column of silica gel. The product was eluted with 20% ether–pentane. Repeated crystallization from isopentane gave two sharp melting fractions. One, 0.080 g, m.p. 64–66° (dec.) showed absorption due to both aromatic and aliphatic protons in the n.m.r. spectrum, no OH absorption in the i.r. spectrum, and was not further identified. The other, 0.062 g (11%), m.p. 40–41°, showed sharp absorption at 3620 cm^{-1}.

Anal. Calcd. for $C_{10}H_{17}BrO$: C, 51.52; H, 7.34; Br, 34.27. Found: C, 51.79, H, 7.27; Br, 34.23.

Method B

A mixture of 0.79 g of **25***a* and 10 mg platinum oxide in 25 ml ethanol was hydrogenated until one equivalent of hydrogen had been absorbed. The catalyst was removed, the organic layer poured into 100 ml water, and this mixture was extracted with 3 × 25 ml pentane. The combined pentane layers were washed twice with water, dried, and concentrated to a small volume. The product was crystallized at −78° and recrystallized twice from isopentane to give 0.390 g (56%) white needles, m.p. 39–41°, mixed m.p. with **27** from A 39–41°.

$\Delta^{9,10}$-Octalin Epoxide, 28

Addition of 0.78 g of **27** to 15 ml methanol containing 0.5 g potassium hydroxide produced a white precipitate almost immediately. The mixture was stirred for 1 h and poured into 20 ml water. The resulting mixture was shaken with 3 × 5 ml pentane. The combined pentane layers were shaken twice with water dried and concentrated. Distillation of the residue through a short-path still at 20 mm gave 0.34 (67%) of a colorless oil, n_D^{20} 1.4816 (lit. (68) n_D^{19} 1.4851), whose n.m.r. and i.r. spectra were identical with those of an authentic sample of **28** prepared by oxidation of $\Delta^{9,10}$-octalin with *m*-chloroperbenzoic acid and which had n_D^{20} 1.4808.

Reaction of 3-Iodo-2,3-dimethyl-2-butyl Hydroperoxide, 12b, with Base

A solution of 0.25 g freshly recrystallized **12***b* in 2 ml methanol was added to a solution of 0.05 g sodium hydroxide in 5 ml methanol. The mixture was stirred at 0° for 10 min and then diluted with water. The resulting mixture was extracted with 3 × 10 ml methylene chloride. The combined extracts were dried and concentrated to give a 0.10 g (90%) of an oil whose n.m.r. spectrum was identical to that of an authentic (1) sample of **13**.

2-Methylene-1-methylcyclohexyl Hydroperoxide, 17

Treatment of the iodohydroperoxide **16***b* with methanolic base and subsequent work-up of the reaction

mixture was carried out as described for **12***b* above. The n.m.r. spectrum of the product indicated that it consisted of **17** together with a trace of the isomeric 2,3-dimethyl-3-cyclohexenyl hydroperoxide **18**. Distillation of this material under 0.01 mm pressure at 40° gave pure (by n.m.r.) **17**, n_D^{25} 1.4840.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.93. Found: C, 67.37; H, 9.95.

10-Hydroperoxy-$\Delta^{1,9}$*-octalin, 26*

Treatment of 1.25 g of the bromohydroperoxide **25***a* with methanolic base and workup of the reaction mixture as described above for **12***b* produced an oily residue. Crystallization from Skelly B gave 0.8 g (89%) white crystals, m.p. 58–59° (lit. (69) m.p. 60°).

A 95% yield of **26** was obtained when the iodohydroperoxide **25***b* was treated in this way.

10-Hydroxy-$\Delta^{1,9}$*-octalin, 36*

A 0.58 g (34 mmol) sample of the allylic hydroperoxide **26** was added to a solution of 0.1 g (21 mmol) sodium borohydride in 10 ml methanol at −10°. The solution was allowed to warm to 20°, heated on the steam bath for 5 min, and then poured into 20 ml ice water. The precipitate was filtered, washed with water, and air dried to give 0.38 g (81%) of a white solid, m.p. 83–85° (lit. (70) m.p. 87–88°).

Kinetic Studies

(A) Iodometric Method

Solutions of the dioxetanes in benzene or carbon tetrachloride in a round-bottomed flask fitted with a reflux condenser were immersed in a Colora constant temperature bath. Aliquots of the solutions were withdrawn at suitable intervals after temperature equilibrium had been reached, cooled to 0°, and titrated for peroxide content (52). Measurements on degassed solutions were made on samples in ampoules which had been degassed to 10^{-3} mm by three freeze–thaw cycles.

(B) Chemiluminescence Decay

A Turner Model 430 spectrofluorometer with the xenon lamp source turned off was used with the 60 nm emission monochromator bandwidth. Solutions of the dioxetanes containing $\sim 10^{-2}$ *M* DBA were placed in a 10 cm jacketed polarimeter type cell with one end silvered. The cell was placed in a specially made compartment with the unsilvered end centered about 2 cm from the entrance slit. Water from a constant temperature bath was circulated through the jacket and the internal temperature of the solution was measured.

(C) Nuclear Magnetic Resonance Method

A carbon tetrachloride solution of **15** in an n.m.r. tube was placed in the heated probe of the 100 MHz spectrometer. The concentration of **15** was monitored by comparing the area of the signal due to the methyl protons of **15** with total area of the signals.

The results of the kinetic runs are given in Table 1.

We wish to thank Professor W. H. Richardson for helpful comments and Dr. K. L. Loening for information about nomenclature.

Kinetic, Electron Spin Resonance, and Product Studies of the Reaction Between 2,2-Diphenyl-1-picrylhydrazyl and 2,4,6-Tri-*t*-butylbenzenethiol

JAMES FLOOD AND KENNETH E. RUSSELL

Department of Chemistry, Queen's University, Kingston, Ontario K7L 3N6

Received October 16, 1974

JAMES FLOOD and KENNETH E. RUSSELL. Can. J. Chem. **53**, 1123 (1975).

The reaction of 2,2-diphenyl-1-picrylhydrazyl (DPPH) with 2,4,6-tri-*t*-butylbenzenethiol (TBBT) in benzene solution has been studied. The two major products, 2,2-diphenyl-1-picrylhydrazine (DPPH-H) and di-(2,4,6-tri-*t*-butylphenyl) disulfide, are those anticipated for a reaction in which DPPH abstracts hydrogen from the thiol yielding thiyl radicals which undergo coupling to produce the disulfide. About 30% of the DPPH is converted into a derivative in which a nitro group has been displaced by a 2,4,6-tri-*t*-butylphenylthiyl group. Displacement of NO_2 from DPPH by the tri-*t*-butylphenylthiyl radical is thought to constitute an important secondary reaction.

In the presence of excess thiol, the rate constant for disappearance of DPPH, determined spectrophotometrically, is $1.23 \pm 0.04\ M^{-1}\ s^{-1}$ at 25 °C, and the activation energy is 5.8 ± 0.5 kcal mol^{-1}. The rate of reaction is halved when the thiol is deuterated at the SH group, confirming that the primary step involves hydrogen transfer. Addition of DPPH-H retards the overall reaction indicating that this primary step is reversible.

An e.s.r. study of the reacting solutions shows that the concentration of thiyl radical is relatively low until most of the DPPH disappears; it also shows the slow buildup of the 2,4,6-tri-*t*-butylphenylthiyl derivative of DPPH. The e.s.r. spectrum of the latter derivative has been analyzed and shown to be consistent with nitrogen coupling constants $A_1 = 10.4 \pm 0.2$ G and $A_2 = 6.45 \pm 0.2$ G.

JAMES FLOOD et KENNETH E. RUSSELL. Can. J. Chem. **53**, 1123 (1975).

On a étudié la réaction du radical diphényl-2,2 picryl-1 hydrazyle (DPPH) avec le tri-*t*-butyl-2,4,6 benzène thiol (TBBT) en solution benzénique. Les deux produits majeurs, la diphényl-2,2 picryl-1 hydrazine (DPPH-H) et le disulfure de di(tri-*t*-butyl-2,4,6 phényl) sont ceux attendus pour une réaction dans laquelle le DPPH enlève des atomes d'hydrogène du thiol amenant la formation de radicaux thiyles qui subissent alors une réaction de couplage pour fournir le disulfure. Environ 30% du DPPH est transformé en un dérivé dans lequel le groupe nitro a été remplacé par un groupe tri-*t*-butyl-2,4,6 phénylthiyle. On croit que le remplacement du NO_2 du DPPH par un radical tri-*t*-butylphénylthiyle est une réaction secondaire importante.

En présence d'un excès de thiol la constante de vitesse pour la disparition du DPPH, tel que déterminé spectrophotométriquement, est de $1.23 \pm 0.04\ M^{-1}\ s^{-1}$ à 25 °C et l'énergie d'activation est de 5.8 ± 0.5 kcal mol^{-1}. La vitesse de la réaction est réduite de moitié quand le thiol est deutéré dans le groupe SH; ceci confirme que l'étape primaire de la réaction implique un transfert d'hydrogène. L'addition du DPPH-H retarde la réaction globale et ceci indique que l'étape primaire est réversible.

Une étude r.p.e. des solutions réagissantes montre que la concentration de radical thiyle est relativement basse jusqu'à ce que pratiquement tout le DPPH soit disparu; il montre aussi qu'il y a une accumulation lente du dérivé tri-*t*-butyl-2,4,6 phénylthiyle du DPPH. On a analysé le spectre r.p.e. de ce dernier dérivé et montré qu'il est en accord avec des constantes de couplage de l'azote $A_1 = 10.4 \pm 0.2$ G et $A_2 = 6.45 \pm 0.2$ G.

[Traduit par le journal]

Introduction

The early studies of Goldschmidt and Renn (1) demonstrated that DPPH can react with the hydrogen donor, hydroquinone, to give DPPH-H and benzoquinone. More recently it has been shown that DPPH can abstract hydrogen from aliphatic thiols (2), aromatic amines (3), and phenols (4, 5). The rate constants for the overall disappearance of DPPH vary markedly with the type of X—H bond and, in the case of phenols, with the substituents in the ring. The results have been discussed in terms of polar and steric influences on the primary hydrogen abstraction step.

DPPH-H is isolated from the various reaction mixtures in high yield. The donor molecules yield free radicals in the primary step and these may react with themselves or with a second molecule

of DPPH. Products derived from the donor are however more difficult to isolate and the importance of the various secondary reactions is not generally known. The reactions are frequently retarded by DPPH-H, suggesting that the primary hydrogen abstraction step is reversible.

One of the few reactions of DPPH to be thoroughly investigated is the reaction with 2,4,6-tri-*t*-butylphenol (6). Abstraction of the phenolic hydrogen by DPPH yields DPPH-H and the 2,4,6-tri-*t*-butylphenoxy radical; in the absence of air, the phenoxy radical does not enter into secondary reactions. Spectrophotometric and e.s.r. studies yield rate and equilibrium constants for the known primary reaction. DPPH has a relatively wide line e.s.r. spectrum and 2,4,6-tri-*t*-butylphenoxyl a narrow line spectrum and their concentrations in reaction mixtures can be readily determined. The present study of the reaction between DPPH and 2,4,6-tri-*t*-butylbenzenethiol was performed with the hope that it would lead to a corresponding understanding of the reaction between DPPH and an aromatic thiol. Comparison of the results for the hindered thiol and phenol should provide information on factors influencing reactivities of these hydrogen donors.

Experimental

Materials

2,4,6-Tri-*t*-butylbenzenethiol (TBBT) was prepared from benzene. Alkylation of benzene with *t*-butyl chloride in the presence of aluminum chloride was conducted at −40 °C (7); after two recrystallizations the 1,3,5-tri-*t*-butylbenzene was obtained in 62% yield, m.p. 71–73 °C (lit. (7) m.p. 72–73 °C, (8) m.p. 73–73.5 °C). Bromination of the tri-*t*-butylbenzene was performed according to the procedure of Betts and Barclay (9). The 2,4,6-tri-*t*-butylbromobenzene, after five recrystallizations, was obtained as white plates, yield 20%, m.p. 176–177 °C (lit. (9) m.p. 177–177.5 °C). Conversion of the 2,4,6-tri-*t*-butylbromobenzene to the corresponding thiol was effected by preparing the magnesium Grignard reagent of the bromobenzene in dry tetrahydrofuran, allowing it to react with sulfur, and reducing the product with lithium aluminum hydride (*cf.* Rundel (10)). After removal of THF by steam distillation, the TBBT was extracted from the residue by shaking with ether; the ether extracts were concentrated to give 5 ml solution and the TBBT separated by chromatography on neutral alumina. After three recrystallizations from acetone, the 2,4,6-tri-*t*-butylbenzenethiol was obtained as white needles, yield 25%, m.p. 179–181 °C (lit. (10) m.p. 180–181 °C).

DPPH (Eastman Organic Chemicals) was heated to 80 °C *in vacuo* in order to remove any complexed solvent (11). DPPH-H was used as supplied. Benzene (Fisher Scientific) was of 99 mol% grade.

Spectroscopic Studies

Benzene solutions of DPPH and TBBT were separately degassed in an apparatus similar to that used in earlier studies (6, 12). The apparatus was immersed in a thermostat for 20 min, the solutions were mixed, and the mixture transferred to an optical cell of 1 cm pathlength. The decrease in absorbance at 640 nm was observed by means of a Unicam SP600 spectrophotometer fitted with a special thermostat bath and cell holder (12). For studies with deuterated TBBT, benzene solutions of thiol were shaken with heavy water and the kinetic measurements performed using solutions saturated with heavy water. The conversion of SH to SD was estimated to be >99%. In separate studies it was shown that rates of disappearance of DPPH are the same in dry benzene as in water-saturated benzene.

Reaction mixtures for e.s.r. study were similarly prepared except that the mixed solutions were transferred to a quartz tube of 9 mm internal diameter. The e.s.r. spectra were determined by means of a Varian V4502 X-band spectrometer with 100 kHz modulation.

Reaction Products

Solutions of DPPH (2.3×10^{-3} *M*; 0.113 g) and TBBT (4.6×10^{-3} *M*; 0.160 g) in benzene were separately degassed and mixed and allowed to react for 15 h in the dark. The reaction mixture was concentrated by evaporation under reduced pressure and chromatographed on silica gel or neutral alumina, using petroleum ether and benzene as eluents.

The first pale yellow band (0.13 g) consisted of a mixture of unreacted TBBT and the corresponding disulfide as shown by n.m.r. spectra of the mixture and of authentic samples. The n.m.r. spectrum of TBBT showed bands at τ 8.65 (s, 9H; *p*-*t*-butyl), 8.36 (s, 18H; *o*-*t*-butyl), 6.40 (s, 1H; S—H), 2.57 (s, 2H; *m*-protons) and the n.m.r. spectrum of the disulfide showed bands at τ 8.71 (s, 9H; *p*-*t*-butyl), 8.66 (d, 18H; *o*-*t*-butyl), 2.78 (d, 2H; *m*-protons). The integrated absorptions of the S—H proton and of the total aromatic protons of the mixture showed that the mixture contained approximately 0.055 g TBBT and 0.080 g disulfide.

A purple band yielded 0.043 g reddish-brown material which after recrystallization and drying *in vacuo* at 60 °C gave crystals m.p. 159 °C. Identification of this material is described in the section on Results.

A brown band yielded 0.065 g brown solid; m.p. 171–173 °C (lit. (1) DPPH-H m.p. 172–173 °C), mixed m.p. with DPPH-H 171–173 °C. The mass spectra of the brown solid and DPPH-H were identical. Three other bands were observed but the yields of these were low and the materials were not identified.

Results

The major products of the reaction of DPPH with TBBT in dilute solution are DPPH-H and bis(2,4,6-tri-*t*-butylphenyl) disulfide. In addition, a reddish-brown compound (**1**) was isolated which on oxidation with lead dioxide in benzene gave a stable radical whose e.s.r. spectrum is typical of a substituted hydrazyl. Analytical data for **1** are in agreement with the values calculated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

for a derivative of DPPH-H in which a nitro-group has been replaced by a 2,4,6-tri-*t*-butylphenylthio group.

Anal. Calcd. for $C_{36}H_{42}N_4O_4S$: C, 68.98; H, 6.75; N, 8.94; O, 10.21; S, 5.11. Found: C, 68.65; H, 6.65; N, 8.87; O, 10.44; S, 5.43.

The mass spectral results are shown in Fig. 1. High resolution studies yielded the following results: *m/e* 626.3 (M^+), 168.078 (Ph_2N^+), 169.086 (Ph_2NH^+), and 459.215 ($H_2NC_6H_2(NO_2)_2(SC_6H_2Bu_3^t)^+$). The cracking pattern of **1** is similar to that of DPPH-H. We thus conclude (13) that displacement of a nitro-group from DPPH by the 2,4,6-tri-*t*-butylthio radical is an important secondary process in the reaction of DPPH with TBBT. The absorption spectrum of **1** in the 250–600 nm range resembles that of 2,2-diphenyl-1-(2,6-dinitrophenyl) hydrazine rather than that of the corresponding 2,4-dinitrophenyl derivative (14) suggesting that the nitro-group has been displaced from the *para-* rather than the *ortho-* position of the picryl ring. A similar conclusion is reached on examination of the absorption spectra of solutions of the corresponding hydrazyls.

The yields of the above products from a reaction mixture initially 1.15×10^{-3} *M* in DPPH and 2.3×10^{-3} *M* in TBBT indicate that at least 60% of the DPPH is converted to DPPH-H and a further 25–30% to the thiyl derivative of DPPH. At the same time over 75% of the reacting TBBT is converted to disulfide. The stoichiometry of the reaction depends however on the concentrations of reactants. Colorimetric estimation of excess DPPH in reaction mixtures containing initially 10^{-4} *M* DPPH and 0.25×10^{-4}, 0.5×10^{-4}, 0.75×10^{-4} *M* TBBT indicated that the ratios of DPPH to TBBT reacting after 20 h at 50 °C were respectively 1.7, 1.3, and 1.1. A variation of molar ratios with concentration of reactant was

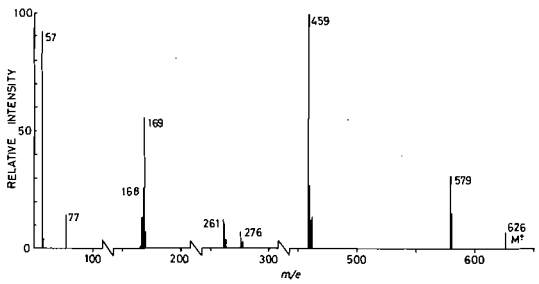

FIG. 1. Mass spectrum of hydrazine **1**.

observed in earlier studies by Brook *et al.* (15) of the reaction of DPPH with thiophenol.

The rates of disappearance of DPPH in benzene solutions were obtained for reaction mixtures containing initially 10^{-4} *M* DPPH and 5×10^{-4}, 7.5×10^{-4}, and 10×10^{-4} *M* TBBT. Plots of log [DPPH] *vs.* time are linear for the first 25% of the reaction and the apparent first order rate constants at 25 °C ($6.14 \pm 0.18 \times 10^{-4}$, $9.6 \pm 0.2 \times 10^{-4}$, and $11.8 \pm 0.5 \times 10^{-4}$ s^{-1}) indicate that the reaction is of first order with respect to TBBT. The second order rate constant at 25 °C is 1.23 ± 0.04 M^{-1} s^{-1}. Rate constants at 37.5 and 50 °C are respectively 1.57 $\pm$ 0.1 and 2.22 $\pm$ 0.1 M^{-1} s^{-1} and the overall activation energy for the disappearance of DPPH under the above reaction conditions is 5.8 ± 0.5 kcal mol^{-1}. The rate constant for the reaction of DPPH with the deuterated thiol is 0.62 ± 0.02 M^{-1} s^{-1} at 25 °C so that the apparent kinetic isotope effect is 2.0 ± 0.1. Addition of 5×10^{-4} *M* DPPH-H to a reaction mixture of 10×10^{-4} *M* DPPH and 5×10^{-4} *M* TBBT causes the rate to be halved.

Electron spin resonance spectra of a reaction mixture are shown in Fig. 2; the solution initially contained 5×10^{-4} *M* DPPH and 2×10^{-3} *M* TBBT and the spectra correspond to times of 8, 14, 21, 57, 148, and 191 min. The arrow in each spectrum marks the center of the DPPH spectrum. After 8 min the concentration of DPPH dropped to about one-half of its initial value but DPPH was the only radical observable at this stage. After 24 min the central region of the spectrum has changed significantly, suggesting that the solution contains one or more DPPH derivatives (16) in addition to DPPH itself. After 148 min the spectrum suggests the presence of a nonhydrazylic radical. The three lines of the triplet have equal intensity and the hyperfine coupling and *g* factor are 8.2 ± 0.2 G and 2.008 ± 0.001 respectively. The *g* factor is appreciably higher than those of typical nitrogen-centered free radicals such as DPPH ($g = 2.0036$) and is closer to the *g* factors of nitroxides ($g = 2.005$–2.006) (17) and of the *o*-nitrophenylsulfenylimine radical ($g = 2.0076$) (18) in which there is some unpaired spin density on sulfur. A nitrogen radical in which the nitrogen atom is adjacent to a sulfur atom would satisfy the *g* factor requirements and structures **2** and **3** are possible. The observation of Balaban *et al.* (19) that picryl-3,4-dimethoxylphenyl

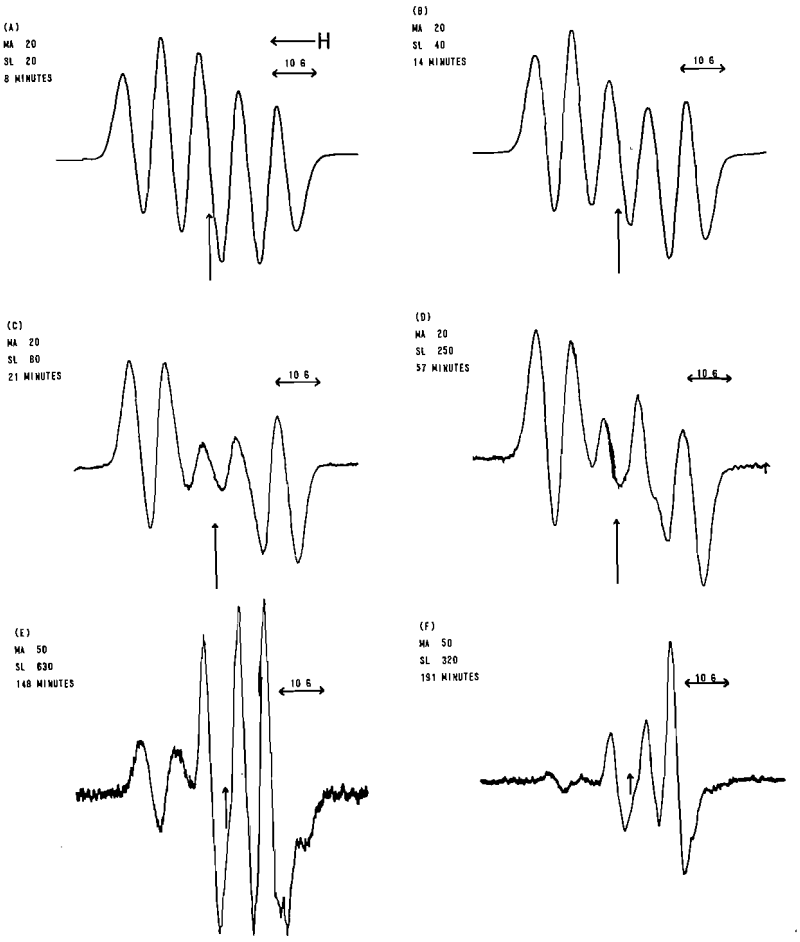

FIG. 2. Electron spin resonance spectra of a reaction mixture of DPPH and TBBT. (*A*) 8 min, (*B*) 14 min, (*C*) 21 min, (*D*) 57 min, (*E*) 148 min, (*F*) 191 min.

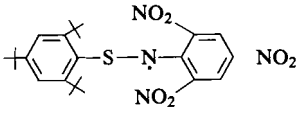
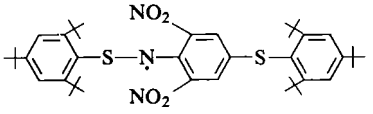


2



3

nitrogen gives a triplet spectrum with $a_N = 8.0$ G and $g = 2.0036$ is taken as supporting evidence for these suggested assignments.

After 191 min, the hydrazyl has almost disappeared and a singlet is superimposed on the low field line of the triplet. The g factor of the singlet is 2.010 ± 0.001 and the linewidth is close to 2 G; it appears to arise from the 2,4,6-tri-*t*-butylbenzenethiyl radical observed by Rundel (20) on u.v. photolysis or lead dioxide oxidation of TBBT in benzene or carbon tetrachloride solution. This sulfur radical is only observed at the end of the DPPH–TBBT reaction and its concentration is relatively low during the main course of the reaction, in contrast to the high concentration of 2,4,6-tri-*t*-butylphenoxyl which is observed in the corresponding reaction of DPPH with 2,4,6-tri-*t*-butylphenol (6).

Oxidation of the reddish-brown hydrazine **1** with lead dioxide in benzene solution gives a radical whose e.s.r. spectrum is shown in Fig. 3*A*. The spectrum is comparable to that of DPPH derivatives (16) and is thus attributed to the hydrazyl corresponding to the hydrazine **1**.

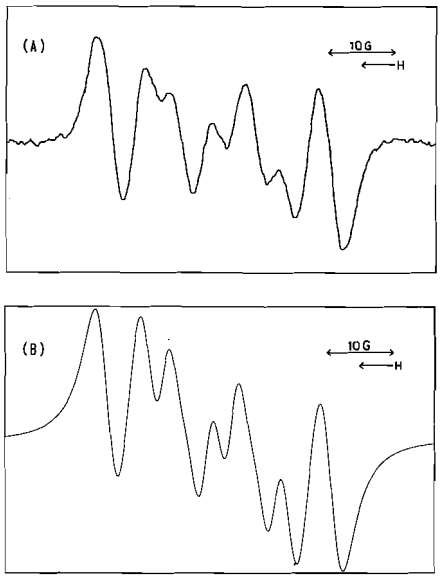


FIG. 3. (*A*) Electron spin resonance spectrum of radical obtained by lead dioxide oxidation of hydrazine **1**. (*B*) Computer simulated spectrum.

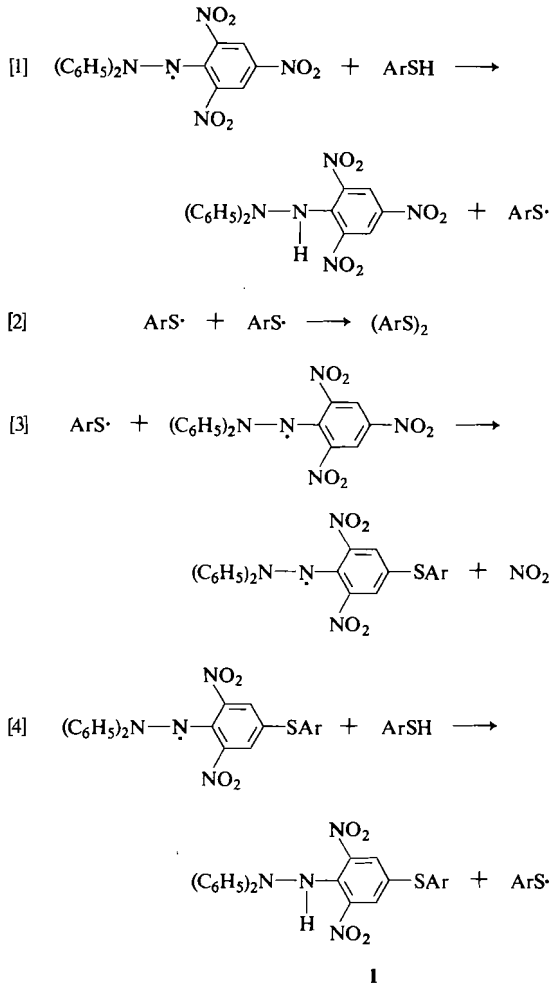
The spectrum shown was obtained in the absence of air and with a hydrazyl concentration approximately 10^{-4} *M*. Figure 3*B* shows a computer simulation of the spectrum with nitrogen coupling constants A_1 and A_2 equal to 10.4 and 6.45 G. A change in either of the coupling constants by ± 0.20 G gives simulated spectra which are discernibly different from the experimental spectrum. In spectra of various hydrazyls labelled with N^{15} at N(1) (the nitrogen atom adjacent to the picryl group), it is found that the larger coupling constant is normally associated with N(1) (16), and it is assumed that the same conclusion applies here. According to a theory developed by Walter (21), substitution of the hydrogen in the 4-position of the 2,6-dinitrophenyl group in 2,2-diphenyl-1-(2,6-dinitrophenyl-) hydrazyl by an electron donating group should lead to a decrease in the ratio A_2/A_1. The ratio is found to decrease from 0.70 (22) to 0.62 for the hydrazyl derived from **1** indicating that the 2,4,6-tri-*t*-butylphenylthio group acts as an electron donor.

Discussion

Product analysis of the reaction of DPPH with TBBT in benzene solution is most simply interpreted in terms of the following reactions:



1

Reactions 1 and 2 account for the large yields of DPPH-H and the disulfide. Reactions 3 and 4 account for the formation of the hydrazine **1**. The e.s.r. spectrum of a reacting solution after 57 min is very similar to the spectrum of the hydrazyl derived from **1** and the hydrazyl is thus an intermediate as suggested in the above mechanism. Our work gives no information on the fate of the NO_2 produced in reaction 3 but studies by Weil *et al.* (16) and Kopecky and coworker (23) show that it probably attacks the *para*-position of a phenyl group of DPPH.

It has frequently been noted that hydrogen abstraction reactions involving DPPH lead both to the major product DPPH-H and to unidentified derivatives of DPPH-H (see *e.g.* (2, 3, 15)). In the reaction of DPPH with TBBT the main DPPH-H derivative is the hydrazine **1** formed almost certainly via the displacement reaction 3.

Studies of the decomposition of certain azoalkanes in the presence of DPPH (23) show that alkyl radicals can also react with DPPH at the 4-position of the picryl group. Displacement reactions of this type thus compete with dimerization of alkyl and of thiyl radicals and they may well occur to a significant extent in many other reactions of DPPH with hydrogen donors. If **2** or **3** is present in the reaction with TBBT, DPPH and its derivatives may take part to a limited extent in further displacement reactions. These assignments require additional evidence, but alternatives of the type Pic—N—Ar appear

to be much less likely since they involve rearrangement and are also susceptible to steric strain.

The observation of secondary reactions and the variation of stoichiometry with concentrations of reactants show that the rate of the hydrogen abstraction [1] cannot be identified with the rate of disappearance of DPPH. The kinetic results are based on spectrophotometric studies of the initial stages of the reaction and under these conditions the rate constants for reaction 1 may be as much as 30% lower than the quoted values for disappearance of DPPH. The reaction is subject to a deuterium isotope effect of 2.0, showing that the hydrogen abstraction reaction 1 is a rate controlling process. The retardation observed on addition of DPPH-H affords evidence that reaction 1 is reversible (5, 6). Retardation by the product DPPH-H in normal reaction mixtures is small provided that observations are limited to the initial stages of the reaction.

The observed rate constant for loss of DPPH, 1.23 M^{-1} s^{-1} at 25 °C, compares with a value of 0.14 M^{-1} s^{-1} for the corresponding reaction of DPPH with 2,4,6-tri-*t*-butylphenol. The activation energy for the reaction with TBBT, 5.8 ± 0.5 kcal/mol, is significantly lower than the activation energy for the reaction with the hindered phenol, 6.9 ± 0.2 kcal/mol (12). Thus the A factors for the two reactions are both about 2×10^4 M^{-1} s^{-1}; they could differ by a factor of 3 or so because of the uncertainties in the activation energies. The low A factor for the reaction with the phenol has been in part ascribed to steric hindrance to the hydrogen abstraction reaction (4, 5) and it had been anticipated that the A factor for the reaction with the thiol would be significantly greater than 2×10^4 M^{-1} s^{-1}. Steric hindrance is thought to be significant in the reaction of DPPH with 2-methyl-2-propanethiol (2) but further studies are required before any conclusion can be reached with regard to aromatic thiols.

We thank Professor L. R. C. Barclay for helpful discussion of the preparation of intermediates. This research was supported by a grant from the National Research Council of Canada.

Effet de substituant et de solvant sur l'enthalpie de dimérisation de diméthyl-2,6 phénols. Etude par résonance magnétique nucléaire

D. BARON, M. TANGUY ET N. LUMBROSO-BADER

Université de Paris VI, Laboratoire de Chimie Physique du C.N.R.S., 2, rue Henri Dunant, 94320, Thiais, France

Reçu le 2 août 1974

D. BARON, M. TANGUY et N. LUMBROSO-BADER. Can. J. Chem. **53**, 1129 (1975).

Des valeurs précises d'enthalpie de dimérisation de phénols encombrés ont été déterminées par r.m.n.: chloro-4 diméthyl-2,6 phénol dans CCl_4 (−2.5 kcal/mol); triméthyl-2,4,6 phénol dans CCl_4 (−3.8 kcal/mol); diméthyl-2,6 phénol dans C_6H_{12} (−4.8 kcal/mol) et dans C_6H_6 (−2.3 kcal/mol).

L'étude des diméthyl-2,6 phénols parasubstitués permet, par comparaison avec des résultats antérieurs obtenus notamment sur des phénols non encombrés (1, 2), de confirmer, pour ces derniers, la prédominance des structures cycliques des dimères; les variations de ΔH_2 sont donc essentiellement dues à la répercussion de l'effet de substituant sur les propriétés acido-basiques du groupement hydroxyle (augmentation de ΔH_2 avec le pK).

De plus, les différences entre les valeurs de ΔH_2 obtenues dans CCl_4 et dans C_6H_{12} suggèrent que l'hydrogène acide n'est sans doute pas le site prépondérant de la solvatation dans CCl_4 et que la variation de ΔH_2 avec le substituant est alors certainement due à la variation de la charge électronique de l'oxygène phénolique.

D. BARON, M. TANGUY, and N. LUMBROSO-BADER. Can. J. Chem. **53**, 1129 (1975).

Some precise values for the enthalpy of dimerization of substituted phenols were determined by n.m.r.: 4-chloro-2,6-dimethylphenol in CCl_4 (−2.5 kcal/mol); 2,4,6-trimethylphenol in CCl_4 (−3.8 kcal/mol); 2,6-dimethylphenol in C_6H_{12} (−4.8 kcal/mol) and in C_6H_6 (−2.3 kcal/mol).

By comparison with earlier (1, 2) results obtained, especially on nonsterically hindered phenols, the study of the *p*-substituted 2,6-dimethylphenols confirms the predominance of cyclic structures for the dimers of the latter. The variations of ΔH_2 are thus due essentially to the influence of the substituent effect on the acid–base properties of the hydroxyl group (increase of ΔH_2 with pK).

In addition, the differences between the values of ΔH_2 obtained in CCl_4 and in C_6H_{12} suggest that the acidic hydrogen is doubtlessly not the chief site of solvation in CCl_4, and that the variation of ΔH_2 with the substituent is thus certainly due to the variation of electronic charge on the phenolic oxygen. [Journal translation]

Introduction

La structure des dimères de phénols a été très controversée (2–8). L'étude de ce problème est difficile en raison de la présence, même aux faibles concentrations, d'agrégats d'ordre supérieur (ouverts ou fermés), ce qui peut fausser très sensiblement les résultats thermodynamiques ou spectroscopiques. Il faut donc se limiter aux très grandes dilutions ou mieux aux données à dilution infinie. Profitant de la grande sensibilité aux interactions moléculaires du déplacement chimique du OH phénolique, nous avons mis au point une méthode précise de détermination des pentes à l'origine des courbes de dilution $\delta_{OH} = f(x_A{}^0)$, $x_A{}^0$ fraction molaire de phénol (1, 2). L'enthalpie de dimérisation est obtenue à partir de la variation de ces pentes avec la température.

Nos premiers travaux portaient notamment sur la détermination des enthalpies de dimérisation dans CCl_4 d'alcoyl-4 phénols non encombrés (dont le *p*-crésol, $\Delta H_2 = -6.7$ kcal/mol) ainsi que du phénol (−5.7 kcal/mol), du *p*-chlorophénol (−4.3 kcal/mol) et enfin du diméthyl-2,6 phénol (−3.2 kcal/mol). Ces résultats avaient permis de conclure à une structure ouverte des dimères, dans le cas du diméthyl-2,6 phénol, et cyclique, dans celui des alcoylphénols non encombrés. Par contre, les valeurs plus faibles obtenues avec les phénols plus acides pouvaient s'expliquer soit par une proportion importante de structures ouvertes, soit par une valeur notamment différente de la force des liaisons hydrogène due, par exemple, à une moindre basicité de l'oxygène phénolique ou à un phénomène de solvatation.

Il était donc intéressant, pour élucider ce problème, de mesurer l'effet de substituant en *para* (Cl ou Me) sur la force d'une liaison hydrogène; nous avons pour cela déterminé les enthal-

pies de dimérisation dans CCl_4 de diméthyl-2,6 phénols *para* substitués que l'empêchement stérique contraint à la formation d'une seule liaison hydrogène dans le dimère. Par ailleurs, pour préciser le rôle de CCl_4, nous avons également étudié le diméthyl-2,6 phénol dans d'autres solvants "inertes" (C_6H_{12}) ou légèrement complexant (C_6H_6).

Partie expérimentale et résultats

Les phénols sont d'origine commerciale (diméthyl-2,6: Eastmann Kodak; chloro-4-diméthyl-2,6: Aldricht; triméthyl-2,4,6: K et K). Ils ont été sublimés avant utilisation. Les solvants (Eastmann Kodak Spectrograde) ont été desséchés sur tamis moléculaire Linde 4 Å. Tous les produits ont été conservés à l'abri de l'humidité.

Les déplacements chimiques ont été mesurés à 60 MHz avec un spectromètre Jeol C-60-H. Pour minimiser les effets dus à l'anistropie du milieu, seul le déplacement chimique intramoléculaire $\delta = \delta_{OH} - \delta_{CH_3}$ a été pris en considération.[1]

Le domaine de concentration permettant d'assimiler à une droite le diagramme $\delta = f(x_A^0)$, x_A^0 fraction molaire du phénol, est limité à environ $x_A^0 = 1.5\%$ dans le cas des diméthyl-2,6 phénols dans CCl_4. La concentration maximale est abaissée dans C_6H_{12} et augmentée dans le

[1]On peut rendre compte de la validité de la référence intramoléculaire $\delta_{OH} - \delta_{CH_3}$ dans le cas du diméthyl-2,6 phénol par la mesure des déplacements chimiques (en Hz) du monomère, à 30 °C, dans CCl_4 (125.1), C_6H_6 (122.8) et C_6H_{12} (121.8). Ces déplacements chimiques sont peu différent.

†$\delta_M = (\delta_{OH} - \delta_{CH_3})_{x_A{}^0=0}$ en Hz (60 MHz).
‡$\beta = (d\delta/dx_A{}^0)_{x_A{}^0=0}$ en Hz/10^{-2} f.m.

benzène (*cf.* tableau 1). Huit solutions, au minimum, ont été étudiées à plusieurs températures, t, entre 5 et 75 °C environ. Des courbes $\delta_{x_A{}^0=cte} = f(t)$ on déduit les valeurs $\delta_{x_A{}^0,t}$ à sept températures: 10, 20, . . . , 70 °C.

Pour chaque température, on a la relation linéaire

$$\delta = \delta_M + \beta x_A{}^0$$

δ_M et β peuvent donc être calculés par une méthode de moindres carrés. Mais nous avons montré que généralement δ_M varie linéairement avec T (1, 2). En utilisant cette hypothèse on peut calculer δ_M et β à chaque température à partir de l'ensemble des données expérimentales d'un système.[2] Si l'hypothèse est vérifiée, la déviation standard σ, relative aux déplacements chimiques, doit être plus faible que dans le cas d'une détermination indépendante à chaque température.

Le tableau 2 rassemble les résultats obtenus. Seules les données relatives au système diméthyl-2,6 phénol – C_6H_6 ont nécessité une analyse indépendante à chaque température, une légère courbure apparaissant dans le diagramme $\delta_M = f(t)$; dans ce cas, le gradient $d\delta_M/dT$ n'est qu'une valeur moyenne. σ est toujours inférieur à 0.2 Hz (0.17 avec C_6H_6; 0.13 pour les autres systèmes).

Moyennant deux hypothèses que nous avons justifiées (1), (possibilité de négliger l'effet de milieu anisotrope et la variation, avec la température, du déplacement chimique moyen du OH dans le dimère), les pentes des diagrammes log $K_2 = f(1/T)$ et log $\beta = f(1/T)$ sont identiques. Les bonnes corrélations linéaires généralement obtenues (fig. 1) se traduisent, sauf dans le cas de C_6H_6, par une déviation standard sur ΔH_2 de l'ordre de 0.1 kcal.

[2]Pour la méthode de calcul, *cf.* réf. 1.

Discussion

Effet de substituant en para et structure des dimères de phénols

L'introduction dans un phénol de deux groupements méthyles en *ortho* a notamment pour conséquences: (*a*) d'empêcher la formation de dimères cycliques; (*b*) d'augmenter la basicité de l'oxygène (pK_a: phénol 9.95; diméthyl-2,6 phénol 10.65; *p*-crésol 10.26; triméthyl-2,4,6 phénol 10.89); (*c*) d'augmenter par effet stérique la distance O . . . O dans le dimère ouvert, comme cela a été mis en évidence dans le cas assez voisin des complexes phénol–acétone (9).

Dans l'hypothèse d'une structure cyclique des dimères de phénols non encombrés, on ne s'attend donc pas, pour le rapport $(\Delta H_2)_{X\text{-}4}/(\Delta H_2)_{X\text{-}4(CH_3)_2\text{-}2,6}$, à une valeur rigoureusement égale à 2. On obtient en fait 1.7 à 1.8 (*cf.* tableau 3). Ceci peut s'interpréter par l'absence de différences fondamentales dans la structure des dimères du *p*-chlorophénol, du phénol et du *p*-crésol. Or nous avons montré que pour ce dernier les dimères cycliques devraient être nettement prépondérants. Il en sera donc de même pour le *p*-chlorophénol et le phénol. Par ailleurs, ces rapports, inférieurs à 2, indiquent que la force de la liaison hydrogène dans les diméthyl-2,6 phénols est plus sensible à l'augmentation de basicité de l'oxygène phénolique qu'à un allongement de la liaison hydrogène dû à un effet stérique.

De plus, on peut comparer, dans les deux séries de composés substitués en *para* (phénols non encombrés et diméthyl-2,6 phénols) l'incrément de ΔH_2 lié au changement du substituant.

Le rapport

$$(\Delta H_2)_{X\text{-}4} - (\Delta H_2)_{Y\text{-}4}/(\Delta H_2)_{X\text{-}4(CH_3)_2\text{-}2,6} - (\Delta H_2)_{Y\text{-}4(CH_3)_2\text{-}2,6}$$

est voisin de 2 pour X = Cl, Y = H et de 1.7 pour X = H, Y = CH_3.

Compte tenu de la précision obtenue sur ces rapports, on peut en conclure que les incréments liés au changement de substituant en *para* sont sensiblement deux fois plus grands dans les phénols non encombrés que dans les diméthyl-2,6 phénols. Ceci confirme encore la structure cyclique prépondérante des dimères de tous les phénols non encombrés.[3]

Effet de substituant en para et valeurs de ΔH_2

L'ensemble des résultats met en évidence, lorsque l'acidité du phénol diminue, une augmentation de la valeur absolue de l'enthalpie de dimérisation par liaison hydrogène, mesurée dans CCl_4. Avant de conclure quant à l'influence du substituant en *para* sur les valeurs de ΔH_2, il fallait examiner si cette variation pouvait provenir d'une interaction phénol–CCl_4 (11).

Pour résoudre ce problème, on a étudié le diméthyl-2,6 phénol dans d'autres solvants: C_6H_{12}, considéré comme suffisamment inerte, et C_6H_6 où une interaction est généralement admise. Par comparaison des résultats obtenus sur les deux systèmes, on peut dégager quatre critères d'interaction: (*a*) une variation non linéaire de δ_M avec la température (l'écart maximum à la linéarité est de 0.2 Hz dans le domaine étudié); (*b*) une augmentation du gradient moyen $d\delta_M/dT$; (*c*) une courbure négative dans le diagramme $\log \beta = f(1/T)$ (*cf.* fig. 1); (*d*) une diminution de $|\Delta H_2|$.

En fait, dans le cas des systèmes phénol–CCl_4

[3]Il a été proposé (10) qu'un abaissement de l'enthalpie d'autoassociation qui serait d'environ 25% par méthyle en *ortho* puisse expliquer les différences entre phénols encombrés ou non, sans faire intervenir de dimères cycliques dans le cas de phénols non encombrés. Rappelons (2) que cette hypothèse ne rend alors pas compte du fait que les ΔH_2, surtout dans le cas des alcoylphénols non encombrés, soient nettement plus grands que les ΔH des complexes phénol–acétone (4.5 à 5 kcal/mol environ) (9) bien que la basicité de l'acétone soit plus grande que celle d'un oxygène phénolique.

TABLEAU 3. Comparaison des valeurs de ΔH_2* des phénols dans CCl_4 en fonction de l'encombrement et de la substitution en *para*

Substituants		ΔH_2 pour X = Cl	H	CH_3	Différences Cl/H	H/CH_3
X-4	(A)	−4.35±0.19	−5.72±0.11	−6.67±0.21	1.37±0.30	0.95±0.32
X-4 $(CH_3)_2$-2,6	(B)	−2.54±0.08	−3.23±0.07	−3.78±0.12	0.69±0.15	0.55±0.19
Rapport (A)/(B)		1.71±0.12	1.77±0.07	1.76±0.10	2.0±0.7	1.7±0.8

*ΔH_2 en kcal/mol.

TABLEAU 4. Comparaison des valeurs des enthalpies de dimérisation par liaison hydrogène dans CCl_4 et C_6H_{12} en fonction du pK_a des phénols

Phénols	pK_a	$\Delta H_2(C_6H_{12})$	$\Delta H_2(CCl_4) - \Delta H_2(C_6H_{12})$* n
p-Chloro phénol	9.4	−5.82±0.13	0.73±0.16
p-Crésol	10.25	−9.07±0.10	1.20±0.15
Diméthyl-2,6 phénol	10.65	−4.84±0.04	1.61±0.11

*ΔH_2 en kcal/mol. Pour ΔH_2 dans CCl_4, voir tableau 3; $n = 2$ pour les phénols non encombrés; $n = 1$ pour le diméthyl-2,6 phénol.

(1, 2), on a toujours obtenu des variations linéaires de δ_M avec la température.[4] Par contre, on a effectivement observé que, pour un phénol donné, le gradient $d\delta_M/dT$ était plus élevé qu'avec C_6H_{12} mais ces variations de gradient avec le solvant ne semblent pas liées à l'acidité du phénol (2). Enfin, la très légère courbure négative qui existe dans les diagrammes log $\beta = f(1/T)$ des phénols non encombrés n'étant pas mesurable avec précision, les trois premiers critères ne permettent pas de préciser le mode d'interaction entre le phénol et CCl_4.

Par contre, on note que la différence d'enthalpie par liaison hydrogène, lorsque l'on passe de CCl_4 à C_6H_{12}, augmente avec le pK_a du phénol (*cf.* tableau 4). Ceci serait donc en faveur d'une interaction phénol–CCl_4 de type  $ClCCl_3$ plutôt que φ OH . . . $ClCCl_3$.[5] En tous cas l'augmentation, avec le pK_a du phénol, de la valeur absolue de l'enthalpie de dimérisation, mesurée dans CCl_4, ne peut pas s'expliquer par l'existence d'interactions phénol–CCl_4. On peut en conclure que la variation importante des valeurs de ΔH_2 est donc essentiellement due à la répercussion, sur la force des liaisons hydrogène, des modifications de basicité de l'oxygène liées à la nature du substituant en *para*.

[4]Sauf dans le cas du *p*-chlorophénol où une variation non linéaire de δ_M avec T est observée, tant dans CCl_4(1) que dans C_6H_{12}(2).

[5]Ceci est à rapprocher des mesures de polarisation diélectrique de Gomel *et coll.* (12) qui mettent en évidence des interactions spécifiques entre solutés basiques (tels que tétrahydrofurane) et solvants chlorés.

Received November 13, 1974

GÉRALD PERRON, JACQUES E. DESNOYERS, and FRANK J. MILLERO. Can. J. Chem. **53**, 1134 (1975).

The densities and volumetric specific heats of Na_2SO_4, K_2SO_4, $MgSO_4$, Na_2CO_3, $NaHCO_3$, and NaOH were measured up to an ionic strength of 1 in water at 25 °C with a flow densimeter and a flow microcalorimeter. From these data, the heat capacity for the formation of the ion pair $MgSO_4^0$ was evaluated as 84.9 J K^{-1} mol^{-1}. There is an anomalous increase in the apparent molal heat capacities of Na_2CO_3 at low concentration but the apparent molal volumes are normal. This anomaly can be suppressed with NaOH. Attempts to account quantitatively for this behavior by an hydrolysis correction were not successful.

GÉRALD PERRON, JACQUES E. DESNOYERS et FRANK J. MILLERO. Can. J. Chem. **53**, 1134 (1975).

Les masses volumiques et les chaleurs spécifiques volumiques de Na_2SO_4, K_2SO_4, $MgSO_4$, Na_2CO_3, $NaHCO_3$ et NaOH ont été mesurées dans l'eau à 25 °C au moyen d'un densimètre et d'un microcalorimètre dynamiques jusqu'à une force ionique unité. A partir de ces données le changement de capacité calorifique pour la formation de la paire d'ions $MgSO_4^0$ a été évalué à 84.9 J K^{-1} mol^{-1}. Il y a une augmentation anormale dans la capacité calorifique apparente molaire de Na_2CO_3 aux faibles concentrations mais aucune anomalie avec les volumes apparents molaires. Cette anomalie peut être supprimée par l'addition d'une faible quantité de NaOH mais les tentatives de corriger les données originales en supposant l'hydrolyse de Na_2CO_3 ont échouées.

Introduction

The thermodynamic properties of aqueous sulfate and carbonate salts are of much interest since they are normal components of sea water and other natural waters. While activity and volume data are fairly well known for most of the naturally occurring sulfates and carbonates (1), their thermochemical data are scarcer and often of doubtful accuracy. In particular, the precise heat capacities are lacking for many of these systems; these values are useful to calculate the temperature dependence of activity data (2) and to convert adiabatic compressibilities into isothermal ones (3). We therefore felt it would be useful to measure or remeasure the heat capacities of the naturally occurring carbonates and sulfates in water using a precise flow microcalorimeter (4).

The systems investigated were Na_2SO_4, K_2SO_4, $MgSO_4$, Na_2CO_3, and $NaHCO_3$. The heat capacities of NaOH were also determined to calculate the correction for the hydrolysis of Na_2CO_3. Since precise densities are required for the calculation of apparent molal heat capacities from volumetric specific heats (4), the densities of the present electrolytes were also measured with a flow densimeter (5). These volume data, when compared with literature values, can at least be used as a check of the purity of the salts and of the accuracy of the concentrations.

Experimental

The volumetric specific heats σ were measured relative to that of the solvent σ_0 with a flow microcalorimeter (4) having a precision of 0.3% (6) on $\Delta\sigma/\sigma_0$ up to the limit of the sensitivity on $\Delta\sigma$ which is 7×10^{-5} J K^{-1} cm^{-3} for a temperature rise of 1.6 K and a liquid flow rate of 0.5 cm^3 min^{-1}. The densities were determined with a flow densimeter (5) capable of evaluating differences in densities $d - d_0$ to 2 p.p.m.

All salts (Fisher Certified) were used as such after drying in a vacuum oven. The solutions were prepared by weight with deionized distilled water (Continental Deionizer). The NaOH was Fisher Certified 1 *N* stock solution. Other solutions were prepared by weight dilution with deionized water. Whenever necessary, the molarities c were calculated from the molalities m using the measured densities of the solutions. All measurements were made at 25.00 ± 0.02 °C.

Results and Discussion

The apparent molal volumes ϕ_V and heat capacities ϕ_C were calculated in the usual manner from the densities and volumetric specific heats (6).

The differences in densities $d - d_0$ and relative differences in volumetric specific heats $(\sigma - \sigma_0)/\sigma_0$ are given elsewhere[2] along with the derived ϕ_V and ϕ_C. The density d_0 and volumetric specific heat σ_0 of pure water were taken as 0.997047 g cm^{-3} (7) and 4.1670 J K^{-1} cm^{-1} (8).

The apparent molal quantities are usually fitted to a Redlich type (9) equation in terms of c or m (6, 10).

$$[1] \quad \phi_V = \phi_V^0 + k_V\omega^{3/2}c^{1/2} + B_V'c + \ldots$$

$$[2] \quad \phi_V = \phi_V^0 + k_V\omega^{3/2}(d_0m)^{1/2} + B_Vm + \ldots$$

$$[3] \quad \phi_C = \phi_C^0 + k_C\omega^{3/2}c^{1/2} + B_C'c + \ldots$$

$$[4] \quad \phi_C = \phi_C^0 + k_C\omega^{3/2}(d_0m)^{1/2} + B_Cm + \ldots$$

where k_V and k_C are given by the limiting Debye–Hückel law as 1.868 and 28.95 in water at 25 °C for ϕ_V and ϕ_C expressed respectively in cm^3 mol^{-1} and J K^{-1} mol^{-1}. The valence factor ω is given by

$$[5] \quad \omega = 0.5 \sum_i \nu_i Z_i^2$$

There is no real advantage in expressing ϕ_V and ϕ_C in c or m. It is preferable to express them in c if we wish to back calculate d or σ. On the other hand, parameters related to m are required to calculate the pressure or temperature dependence of activity data (2). It is therefore simpler to calculate both sets of parameters. Also with multivalent electrolytes it is often preferable to express concentrations in ionic strengths. Equations 1 to 4 may be readily converted to this scale by replacing m by I_m/ω and c by I_c/ω.

Plots of $\phi_V - \omega k_V I_C^{1/2}$ and $\phi_C - \omega k_C(d_0 I_m)^{1/2}$ against I_c or I_m are shown in Figs. 1 and 2. In all cases where these functions were linear, the parameters ϕ_V^0, B_V, B_V', ϕ_C^0, B_C, B_C' were determined from a weighted least squares analysis and are summarized in Table 1.

The present volume data are in excellent agreement with those of Dunn (11), Wirth (12), Millero *et al.* (13), and Hepler *et al.* (14) with the exception of Na_2SO_4 where the present data are more positive than those of Dunn by about 0.15 cm^3 mol^{-1}. The present ϕ_V of $MgSO_4$ are also systematically 0.3 cm^3 mol^{-1} more positive than the literature values averaged by Millero

TABLE 1. Parameters of eqs. 1 to 4 for some carbonates and sulfates in water at 25 °C for ϕ_V and ϕ_C given respectively in $cm^3\ mol^{-1}$ and $J\ K^{-1}\ mol^{-1}$

Electrolyte	ϕ_V^0	B_V	B_V'	ϕ_C^0	B_C	B_C'
Na_2SO_4	11.76	2.70	2.75	−187.0	126.1	128.2
K_2SO_4	32.00			−246.9	54.7	57.4
$NaHCO_3$	23.45	1.32	1.38	−5.1	(34.0)	35.3
Na_2CO_3*	−6.13	1.77	1.79	−176.3	100.9	63.7
NaOH	−5.20	1.12	1.11	−93.2	26.5	26.4

*To extend the data up to 1 *m* an extra parameter in $c^{3/2}$ (−44.4) or $m^{3/2}$ (−11.2) is required for ϕ_C.

and co-worker (15). We have no reasons to believe that the present measurements are less reliable than the others. At any rate, the agreement is still sufficiently good that we would not expect an error much larger than 1 $J\ k^{-1}\ mol^{-1}$ in ϕ_C resulting from errors in densities and concentrations.

The agreement of the present heat capacity data with those of the literature is less satisfactory. With the exception of NaOH, where the agreement is excellent, differences of 5 to 10 $J\ K^{-1}\ mol^{-1}$ are observed with the ϕ_C of Randall and Rossini (16), Gucker and Schminke (17), and Gardner *et al.* (18). The generally good agreement between the present result and literature in the case of volumes and the proven reliability of the flow technique for heat capacity measurements (6) gives us confidence that the present data are the more accurate.

The $MgSO_4$ shows a strong departure from linearity at low concentration with both the ϕ_V and ϕ_C data. The infinite dilution ϕ_V^0 and ϕ_C^0 can be calculated from the data for $MgCl_2$ (19) and Na_2SO_4, using the additivity rule. The predicted ϕ_V^0 and ϕ_C^0 are thus $-7.46\ cm^3\ mol^{-1}$ and $-286.4\ J\ K^{-1}\ mol^{-1}$ suggesting significant association of this electrolyte in water. Since the association constant of this electrolyte is known (20), it is possible to apply to heat capacities the same treatment that was used by Millero and Masterton (15) to calculate the volume and by Leung and Millero (21) to calculate the enthalpy of an ion pair. The observed ϕ_C can be related to those of the ion pair $MgSO_4^0$ and of the free ions (Mg^{2+}, SO_4^{2-}) by the relation

$$[6]\quad \phi_C(\text{obs}) = (1-\alpha)\phi_C(MgSO_4^0) + \alpha\phi_C(Mg^{2+},SO_4^{2-})$$

where α is the fraction of free ions. The degree of association $1-\alpha$ is given by

$$[7]\quad 1-\alpha = K_a(\gamma\pm)^2 m$$

where K_a is the association constant and $\gamma\pm$ the mean activity coefficient of the electrolyte, and has been calculated by Millero and Masterton (15) for $MgSO_4$ in water at 25 °C.

The values of $\phi_C(Mg^{2+}, SO_4^{2-})$ can be calculated assuming additivity of ϕ_C at all concentrations. This is of course only an approximation since the concentration dependence of ϕ_C depends on *all* ion–ion interactions, but it becomes exact as the concentration tends to zero. From

$$[8]\quad \phi_C(Mg^{2+},SO_4^{2-}) = \phi_C(MgCl_2) + \phi_C(Na_2SO_4) - 2\phi_C(NaCl)$$

where each ϕ_C is assumed to be given by eq. 4, an approximate expression for the concentration dependence of $\phi_C(Mg^{2+},SO_4^{2-})$ can be predicted

$$[9]\quad \phi_C(Mg^{2+},SO_4^{2-}) = -286.4 + 243.2m^{1/2} - 68.2m$$

The value of $\phi_C(Mg^{2+},SO_4^{2-})$ cannot be calculated from the potassium salts since K_2SO_4 also shows signs of association.

The method developed by Leung and Millero (21) can be used to evaluate $\Delta\bar{C}_p^0(MgSO_4^0)$, the standard change in heat capacity for the formation of an ion pair. By using the relative apparent molal heat capacity, $\phi_J = \phi_C - \phi_C^0$, eq. 6 can be rearranged to

$$[10]\quad \phi_J(\text{obs}) = \alpha\phi_J(Mg^{2+},SO_4^{2-}) + (1-\alpha) \times [\phi_J(MgSO_4^0) + \phi_C^0(MgSO_4^0) - \phi_C^0(Mg^{2+},SO_4^{2-})]$$

and since

$$[11]\quad \Delta\bar{C}_p^0(MgSO_4^0) = \Delta\phi_C^0(MgSO_4^0) = \phi_C^0(MgSO_4^0) - \phi_C^0(Mg^{2+},SO_4^{2-})$$

eq. 10 becomes

$$[12]\quad \phi_J(\text{obs}) = \alpha\phi_J(Mg^{2+},SO_4^{2-}) + (1-\alpha) \times [\phi_J(MgSO_4^0) + \Delta\bar{C}_p^0(MgSO_4^0)]$$

By assuming ϕ_J for $MgSO_4^0$ is a linear function of the concentration of the ion pair $(1 - \alpha)m_T$, this equation upon rearrangement can be simplified to

$$[13] \quad [\phi_J(\text{obs}) - \alpha\phi_J(Mg^{2+},SO_4^{2-})]/(1 - \alpha) = \Delta\bar{C}_p^0(MgSO_4^0) + k(1 - \alpha)m_T$$

A plot of the left-hand side of eq. 13 against $(1 - \alpha)m$ is shown in Fig. 3. As is quite apparent from Fig. 3 ϕ_J of $MgSO_4^0$ is not linear. By using a second degree fit, a value of $\Delta\bar{C}_p^0 = 84.9$ J K^{-1} mol^{-1} is obtained for the formation of $MgSO_4^0$.

Not too much importance should be placed on the shape of $\phi_J(MgSO_4^0)$ because of the approximations made in estimating $\phi_J(Mg^{2+}, SO_4^{2-})$. The order of magnitude of the $\bar{C}_p^0(MgSO_4^0)$ (-200 J K^{-1} mol^{-1}) when compared with the heat capacity of solid $MgSO_4$ (96 J K^{-1} mol^{-1}) (22) and $\bar{C}_p^0(Mg^{2+},SO_4^{2-})$ (-286.4 J K^{-1} mol^{-1}) indicates that the ion pair still has about 80% of its hydration contribution remaining. This would suggest that these ion pairs still strongly interact with water, in agreement with volume and compressibility measurements (15, 23).

The large increase in ϕ_C of Na_2CO_3 in pure water was intriguing since no such behavior was observed with ϕ_V. The measurements were therefore repeated in 0.005 *m* NaOH instead of pure water. The ϕ_C data at low concentrations were substantially lowered while the ϕ_V data were unaffected (see Figs. 1 and 2). A few measurements in 0.01 *m* NaOH suppressed the anomally completely. This therefore suggests that the anomalously high values for ϕ_C of Na_2CO_3 were due to hydrolysis and that an estimate of the true ϕ_C^0 could be obtained by extrapolating the high concentration data (Table 1).

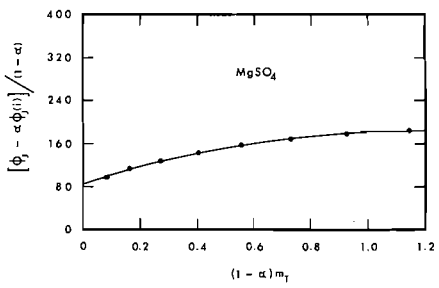

FIG. 3. Heat capacity of the formation of the ion pair $MgSO_4^0$ in water at 25 °C.

A correction can in principle be made to the data since the hydrolysis constant of Na_2CO_3 is known. If the treatment of Monk (24) is applied to ϕ_V and ϕ_C neglecting the influence of CO_2 in water, then

$$[14] \quad m\phi_C(\text{obs}) = (m - x)\phi_C(NaCO_3) + x\{\phi_C(NaOH) + \phi_C(NaHCO_3)\}$$

$$[15] \quad m\phi_V(\text{obs}) = (m - x)\phi_V(NaCO_3) + x\{\phi_V(NaOH) + \phi_V(NaHCO_3)\}$$

where x, the concentration of the carbonate that has hydrolyzed, has been estimated by Monk. Such a treatment indicates that hydrolysis should have only a small effect on ϕ_C but a large one on ϕ_V, which is the opposite of what we have observed.

The effect of CO_2 on the density and specific heat of water was investigated. The density of a saturated solution of CO_2 hardly changes from that of pure water while a significant change in specific heat is observed ($\sigma - \sigma_0 \simeq 0.0012$ J K^{-1} cm^{-3}). If σ of water saturated with CO_2 was used instead of that of pure water to calculate ϕ_C of Na_2CO_3, then most of the anomalies which we attributed to hydrolysis tended to disappear. However, deionized water was used as a reference and not water equilibrated with CO_2 in the actual experiments. This CO_2 might come from the neutralization of some of the CO_3^{2-} ions by the slight acidity of the water used (p*H* 5 to 6) (25). In a basic solution no such equilibrium would be possible which would explain the suppression of the anomaly with NaOH.

The Crystal Structure of the [Pt(diethylenetriamine)Br]Br Complex

ROBERT MELANSON, JOSEPH HUBERT, AND F. D. ROCHON

Département de chimie, Université du Québec à Montréal, C.P. 8888, Montréal, Québec H3C 3P8

Received November 11, 1974

ROBERT MELANSON, JOSEPH HUBERT, and F. D. ROCHON. Can. J. Chem. **53**, 1139 (1975).

The molecular and crystal structure of the [Pt(dien)Br]Br complex (dien = diethylenetriamine) has been studied by X-ray diffraction. The compound belongs to the orthorhombic $Pca2_1$ space group and the cell parameters are: $a = 14.211$, $b = 4.940$, $c = 13.450$ Å, and $Z = 4$. The refinement of the positional and anisotropic thermal parameters, carried out by full matrix least squares calculations, converged to $R = 0.039$ and $R_w = 0.036$.

The coordination around the platinum atom is planar. The crystal consists of alternate layers of $[Pt(dien)Br]^+$ cations and Br^- ions parallel to the *ac* plane.

ROBERT MELANSON, JOSEPH HUBERT et F. D. ROCHON. Can. J. Chem. **53**, 1139 (1975).

La structure moléculaire et cristalline du complexe [Pt(dien)Br]Br (dien = diéthylènetriamine) a été étudiée par diffraction des rayons-X. Le composé cristallise dans le système orthorhombique et le groupe spatial $Pca2_1$. Ses paramètres de maille sont: $a = 14.211$, $b = 4.940$, $c = 13.450$ Å et $Z = 4$. Les coordonnées et les facteurs thermiques anisotropes ont été affinés par la méthode des moindres carrés à matrice entière jusqu'à $R = 0.039$ et $R_w = 0.036$.

La coordination autour de l'atome de platine est plane. Le cristal est formé de couches de cations $[Pt(dien)Br]^+$ et d'anions Br^- alternées, parallèles au plan *ac*.

Introduction

Kinetic studies by Basolo, Gray, and Pearson (1) on the replacement of a ligand X in complexes of the type $[Pt(diethylenetriamine)X]^+$ and $[Pt(tripyridine)X]^+$ by pyridine in aqueous solution, have shown that the $[Pt(tripy)X]^+$ complexes (tripy = tripyridine) react 1000 to 10 000 times faster than the corresponding $[Pt(dien)X]^+$ complexes (dien = diethylenetriamine). This result was somewhat surprising since $[Pt(bipy)Cl_2]$ (bipy = bipyridine) and $[Pt(en)Cl_2]$ (en = ethylenediamine) do not differ appreciably in their reactivity. The authors explained the results of their kinetic studies by the fact that the two types of complexes $[Pt(dien)X]^+$ and $[Pt(tripy)X]^+$ would have square planar structures, but the latter would be very strained. This strain would cause the complexes $[Pt(tripy)X]^+$ to be unstable and explain their high reactivity.

The crystal structures of several complexes of the types $[M(dien)X_3]$ (2, 3) and $[M(dien)_2]^{2+ \text{ or } 3+}$ (4–7) have been determined. All the complexes possess distorted octahedral geometry. The two terminal nitrogen atoms in the diethylenetriamine ligand are coordinated either *cis* or *trans* to each other. Therefore the tridentate ligand can have a planar or a bent conformation.

The crystal structure of a compound from each type of complexes [Pt(dien)X]X and [Pt(tripy)X]X was studied in our laboratory. In this paper, we report our results on the crystal structure of [Pt(dien)Br]Br.

Experimental Section

Crystal Data

$PtBr_2C_4H_{13}N_3$ f.w. = 458.08

Orthorhombic $Pca2_1$, $a = 14.211(7)$, $b = 4.940(3)$, $c = 13.450(8)$ Å, $Z = 4$, $V = 944.3(1.35)$ Å^3, $\rho_o = 3.17(5)$ g/cm^3 (flotation), $\rho_c = 3.221$ g/cm^3, λMoKα = 0.71069 Å, μMoKα = 240.57 cm^{-1}, $T = 22$ °C.

The compound [Pt(dien)Br]Br was prepared as previously described (8) and recrystallized as plates from water. The pale yellow crystals are stable to air and to X-rays. A set of precession photographs indicated that the $h0l$, $h = 2n + 1$ and $0kl$, $l = 2n + 1$ reflections are systematic absences. These extinctions are found for space groups $Pca2_1$ (no. 29) and *Pacm* (no. 57) (non-standard setting for *Pbcm*). The cell parameters were calculated by least squares refinement from the setting angles of 15 automatically centered reflections (MoKα radiation) on a Syntex P$\bar{1}$ diffractometer equipped with a graphite monochromator.

Collection and Reduction of Intensity Data

The intensity data were collected from a crystal of dimensions 0.646 × 0.093 × 0.268 mm. A total of 1647 independent reflections were measured in the region of $2\theta < 60°$ by the $2\theta/\theta$ scan technique using MoKα radiation. The data collection was done at a variable speed (24° to 1°/min) depending on the intensity of the reflection (Syntex $2\theta/\theta$ autocollection program). The

majority of the reflections were measured at a speed of 1°/min. A 2θ scan range of 1.2° below $K\alpha_1$ and 1.2° over $K\alpha_1$ was selected. The background time to scan time ratio was 0.40. During the data collection, two standard reflections (4,2,−1 and 2,1,−2) were measured after every 25 reflections. Their variations were less than 2% from their respective means. The 1647 independent measurements reduced to a set of 1435 independent reflections after taking out the systematically absent reflections. The 307 reflections for which the intensity was less than 2.5 $\sigma(I)$ were considered as unobserved. The standard deviation $\sigma(I)$ was calculated in the following manner:

$$\sigma^2(I) = \frac{1}{\tau}\left\{\left(T + \frac{B}{(\mathrm{BSR})^2}\right) *\mathrm{SCRT}^2 + (p*N)^2\right\}$$

where τ = transmission coefficient, T = total count, B = total background count, N = net count, BSR = background to scan time ratio, SCRT = scan rate, $p = 0.04$ long term instability constant. Finally, 1128 independent observed reflections remained. An absorption correction based on the equations of the crystal faces was then applied. The transmission factors varied from 0.0205 to 0.1321. The data were finally corrected for the Lorentz and polarization effects.

The scattering factors for platinum, bromine, carbon, and nitrogen were those of Cromer and Waber (9) and those of Stewart, Davidson, and Simpson were used for hydrogen (10). The anomalous dispersion terms of platinum ($\Delta f' = -2.05$, $\Delta f'' = 8.43$) and bromine ($\Delta f' = -0.21$, $\Delta f'' = 2.68$) (11) were included in the calculation.

Structure Determination

The $N(Z)$ test and the distribution of the normalized structure factors $|E|$ values suggested the space group $Pca2_1$ (12). The platinum atom was easily located from the three-dimensional Patterson map. The positions of all other atoms except the hydrogen atoms, were obtained by structure factor and Fourier map calculations. The refinement of the parameters was carried out by full matrix least squares calculations. In the early stages of refinement, unit weight was assigned to all observed reflections. Individual weights w according to the equation $1/w = a + bF_o + cF_o^2$ were calculated. a, b, and c were adjusted to make the distribution of $w|\Delta F|^2$ constant with respect to $|F_o|$ and $\sin\theta/\lambda$ ($a = 263$, $b = -2$, and $c = 0.005$). An isotropic secondary extinction correction (13) was also introduced. The hydrogen atoms of the methylene groups were fixed at the calculated positions, while those on the nitrogen atoms were neglected. The refinement of the scale factor, the coordinates and anisotropic temperature factors of all nonhydrogen atoms converged to $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$ of 0.039 and a weighted residual $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ of 0.036. The standard deviation of an observation of unit weight is 1.147. The final difference Fourier map using all observed reflections did not show peaks higher than ± 1 e/Å^3.[1] The refined parameters are given in Table 1.

[1]The structure factor table is available, for a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

The calculations were performed with a CDC 6400 computer. The following programs were used: NRC crystallographic programs (14), NUCLS a modified version of ORFLS, and Zalkin (FORDAP).

Results and Discussion

The structure consists of an arrangement of the complex cation $[Pt(dien)Br]^+$ and of Br^-. The atoms were labelled according to Fig. 1.

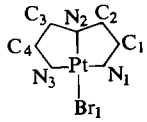

FIG. 1. Atom identification in complex cation $[Pt(dien)Br]^+$.

Structure of the Cation

A stereoscopic view of the $[Pt(dien)Br]^+$ is shown in Fig. 2. The most important bond distances and angles are listed in Table 2. Three nitrogen and one bromine atoms form the square planar coordination expected for Pt(II) complexes. The weighted best plane was calculated through the platinum, the bromine, and the three nitrogen atoms. The deviations from this plane are: Pt, 0.0000; Br_1, 0.002; N_1, −0.112; N_2, 0.120; and N_3, −0.119 Å. The angles around platinum are close to the expected 90 and 180° but there seems to be some slight deviations. The N_1—Pt—N_2 and N_2—Pt—N_3 angles (87.3, 83.4°) are smaller than the N_1—Pt—Br_1 and N_3—Pt—Br_1 angles (95.3, 94.5°). A slight strain caused by the tridentate ligand might be responsible for this deviation from the ideal square planar coordination. The Pt—Br_1 bond (2.434 Å) is of normal length (15). The Pt—N bond lengths are normal (16–19) and one Pt—N_3 bond (2.12 Å) appears significantly longer than the two other Pt—N bonds (1.98 and 1.96 Å). Values of 1.95 to 2.31 Å have been reported for Pt—N bonds.

The complex cation $[Pt(dien)Br]^+$ approxi-

mates a C_s point group symmetry with a mirror plane through N_2, Pt, and Br_1 atoms.

Packing in the Crystal

Figure 3 illustrates the packing in the [Pr(dien)Br]Br crystal. The latter consists of alternate layers of $[Pt(dien)Br]^+$ cations and Br^- ions parallel to the *ac* plane.

The environment of the bromine atoms was examined to locate possible hydrogen bonding to the nitrogen atoms. Only the ionic bromide ion seems to be involved in the hydrogen bonding. Br–N distances within a range of 3.3 to 3.6 Å have been suggested for hydrogen bonding of this type (20). Five nitrogen atoms at distances smaller than 3.6 Å from the bromide

ion form a distorted pyramid. A sixth nitrogen atom N_2 located at 4.29 Å completes a trigonal antiprism geometry around Br_2 (Fig. 3). These Br_2–N contacts and the related angles are shown in Table 3. No nitrogen atoms are in the close environment (< 3.6 Å) of the bonded bromine atom (Br_1) except the two terminal atoms of the ligand (3.26 and 3.53 Å). The unfavorable angles C_1–N_1–Br_1 (152.4°) and C_4–N_3–Br_1 (151.8°) do not suggest any intramolecular hydrogen bonding of this type.

Grateful acknowledgment is made to the National Research Council of Canada for financial support and to Dr. Pi-Chang Kong for the synthesis of the analyzed compound.

FERNANDO BERNARDI, IMRE G. CSIZMADIA, H. BERNHARD SCHLEGEL, and SAUL WOLFE. Can. J. Chem. **53**, 1144 (1975).

Nonempirical SCF-MO computations have been performed on CH_2O, CH_2S, and their protonated derivatives $\overset{+}{C}H_2OH$ and $\overset{+}{C}H_2SH$. The methylene group of CH_2O is strongly positive and that of CH_2S is slightly negative, because oxygen in CH_2O behaves towards carbon as a π-donor and σ-acceptor, but sulfur in CH_2S behaves as both a π- and σ-donor. The total π-overlap in CH_2O is greater than that in CH_2S.

The stable conformations of $\overset{+}{C}H_2OH$ and $\overset{+}{C}H_2SH$ correspond in each case to a structure in which all atoms lie in the same plane. In this conformation, both the C—O and C—S bond lengths are substantially shorter than those of methanol and methanethiol, indicative of conjugative interaction between the cationic center and the adjacent heteroatom. From the results of a Mulliken-type population analysis it is found that, relative to hydrogen, OH and SH behave towards an adjacent $\overset{+}{C}H_2$ group as electron-withdrawing and electron-releasing ligands, respectively. When $\overset{+}{C}H_2OH$ is considered to form from $\overset{+}{C}H_2$ and OH fragments, π-donation from O to C amounts to 0.38 electron, but σ-donation in the opposite direction amounts to 0.35 electron; the π-overlap population is 0.1496. A similar analysis of $\overset{+}{C}H_2SH$ reveals π- *and* σ-donation from S to C of 0.53 and 0.15 electron, respectively, and a π-overlap population of 0.1734, so that *sulfur forms a stronger π-bond to the adjacent cationic center.*

Geometrical isomerization of $\overset{+}{C}H_2OH$ proceeds by linear inversion at oxygen, with a barrier of 13.98 kcal/mol; but that of $\overset{+}{C}H_2SH$ proceeds by rotation about the C—S bond, with a barrier of 36.47 kcal/mol. This latter value is substantially higher than that (23 kcal/mol) computed for $\overset{+}{C}H_2OH$ with a rigid rotor model, and reflects the greater strength of the π-bond between sulfur and the adjacent cationic center.

FERNANDO BERNARDI, IMRE G. CSIZMADIA, H. BERNHARD SCHLEGEL et SAUL WOLFE. Can. J. Chem. **53**, 1144 (1975).

On a effectué des calculs non-empiriques SCF-MO sur le CH_2O, le CH_2S et leurs dérivés protonés $\overset{+}{C}H_2OH$ et $\overset{+}{C}H_2SH$. Le groupe méthylène du CH_2O est fortement positif et celui du CH_2S est faiblement négatif; ces résultats proviennent du fait que l'oxygène dans le CH_2O agit vis-à-vis le carbone comme un donneur d'électrons π et un accepteur d'électrons σ mais que le soufre du CH_2S agit comme donneur d'électrons π et d'électrons σ. Le recouvrement total d'orbitales π dans le CH_2O est plus grand que dans le CH_2S.

Les conformations stables de $\overset{+}{C}H_2OH$ et $\overset{+}{C}H_2SH$ correspondent dans chaque cas à une structure dans laquelle tous les atomes sont dans le même plan. Dans cette conformation, les longueurs de liaison C—O et C—S sont passablement plus courtes que les liaisons correspondantes du méthanol et du méthanethiol indiquant une interaction conjugative entre le centre cationique et l'hétéroatome adjacent. On trouve, à partir des résultats d'une analyse de population du type Mulliken, que par rapport à l'hydrogène, les groupes OH et SH agissent respectivement vis-à-vis un groupe $\overset{+}{C}H_2$ adjacent comme des groupes électro-affinitaires et électro-répulsifs. Lorsque l'on

considère que $\overset{+}{C}H_2OH$ se forme à partir de fragments $\overset{+}{C}H_2$ et OH, on calcule qu'il y a eu don d'électrons π de l'oxygène au carbone de 0.38 électrons mais un don d'électrons σ dans la direction opposée correspondant à 0.35 électrons; la population de recouvrement d'électrons π est de 0.1496. Une analyse similaire de $\overset{+}{C}H_2SH$ révèle qu'il y a des dons d'électrons π et σ du S vers le carbone qui équivalent respectivement à 0.53 et 0.15 électrons et que la population de recouvrement d'électrons π est de 0.1734 *ce qui implique que le soufre forme un lien π plus fort avec le centre cationique adjacent.*

L'isomérisation géométrique de $\overset{+}{C}H_2OH$ se produit par une inversion linéaire à l'oxygène avec une barrière de 13.98 kcal/mol; celle de $\overset{+}{C}H_2SH$ se produit toutefois par une rotation autour du lien C—S avec une barrière de 36.47 kcal/mol. Cette dernière valeur est considérablement plus élevée que celle (23 kcal/mol) calculée pour $\overset{+}{C}H_2OH$ avec un modèle de rotor rigide et implique une plus grande force du lien π entre le soufre et le centre cationique adjacent.

[Traduit par le journal]

Introduction

There is an extensive literature concerning the relative effects of oxygen and sulfur upon the properties of adjacent cationic, radical, and anionic centers (*e.g.* ref. 1). It seems that, in solution, it is easier to generate a carbanion (*e.g.* ref. 2) or radical (*e.g.* ref. 3) adjacent to sulfur than to oxygen, but the reverse is observed in the case of carbonium ions (ref. 4 and references cited therein). These various trends have usually been rationalized (2–4) in terms of appropriate conjugative interactions: $(p \rightarrow d)_\pi$ conjugation in the case of anions and radicals, with the ability of the heteroatom to enter into such conjugation being possible only for the second row atom (sulfur); p_π–p_π conjugation in the case of cations, with the magnitude of this interaction inversely proportional to the internuclear separation and, thus, favored for the system having the shorter bond length (oxygen).

It is noteworthy that, in all such rationalizations, it is the π-type interactions which are emphasized; the possible role of σ-interactions and steric effects is ignored. In addition, these rationalizations have tended to assume that the observed effects are caused by differences in the interactions between the carbon center and the adjacent heteroatom, and not by differential solvation effects. However, it now seems well established that solvation effects cannot be ignored, at least in some cases (2, 5). In the gas phase, where solvation effects are not present, the dissociation energies of CH bonds adjacent to oxygen and to sulfur are identical (6), indicating no difference in the ease of formation of a radical center adjacent to oxygen and to sulfur; and, on the basis of appearance potential measurements (6, 7), there also seems to be no significant difference in the ease of formation of *cationic* centers adjacent to oxygen and to sulfur.

It is inappropriate to conclude from such observations that one heteroatom "stabilizes" an adjacent reactive center better than or as well as the other, because in one case what is being observed is the breaking of a CH bond adjacent to *sulfur* to form a reactive center adjacent to *sulfur*; and in the other case, a CH bond adjacent to *oxygen* is broken to form a reactive site adjacent to *oxygen.*

There is no simple theoretical solution to this problem because, in addition to the point just raised, a theoretical treatment introduces two additional difficulties. Consider, for example, the heterolytic bond breaking or bond making process shown in reaction 1, in which the electron

[1] 
pairing scheme is formally unchanged, so that both the initial and final states have closed electron shells. The first problem is that, if we were to define stabilization energy (s.e.) in terms of the double energy difference shown in eq. 2,

$$[2] \qquad \text{s.e.} \equiv \Delta\Delta E = \Delta E(\text{S}) - \Delta E(\text{O})$$

it would be necessary to compute four different energy values. Even in the ideal situation of a reaction such as [1], only computations performed very close to the Hartree–Fock limit would allow us to hope for a minimum of two significant figure accuracy in $\Delta\Delta E$. The second problem is that, even if $\Delta\Delta E$ were considered to be reliable, it is not clear what are the relative contributions to this quantity of π-conjugative effects, σ-effects, steric effects, etc. However, what the theoretical analysis allows is a determination of the changes in bonding which take place between the heteroatom and the adjacent

carbon as a result of the chemical reaction 1 and, therefore, of the nature of the effects exerted by the heteroatoms in each case.

In previous work, we have found that a variety of the static, dynamic, and chemical properties of carbanions (8) and radicals (9) adjacent to oxygen and to sulfur are reproduced faithfully by nonempirical quantum chemical calculations, but that 3d-orbital conjugation in the case of sulfur (*i.e.*, a π-type effect) is not responsible for differences between the two systems. Rather, it is the differences in the sizes of the two heteroatoms and, therefore, differences in their electronegativities, polarizabilities, and energies of the atomic lone pair orbitals that cause these conformational and chemical differences.

The subject of the present work is a comparative quantum chemical investigation of the reaction represented by reaction 3 in which X = oxygen and sulfur. Protonated aliphatic

[3] 
3 **4**

aldehydes, including formaldehyde (reaction 3, X = O), and protonated aliphatic ketones have been observed experimentally by Olah *et al.* (10) to display geometrical isomerism about the carbon–oxygen bond. However, the barrier to interconversion of geometrical isomers was not determined by these workers, and experimental data concerning the protonation of thioaldehydes and thioketones (reaction 3, X = S) have not yet been reported.

If the magnitude of the barrier to *rotation* about the C—X bond of **4** were to constitute a rough measure of the *π-conjugative* stabilization afforded by X, then current chemical intuition would suggest that hydroxymethylcarbonium ion should have the higher rotational barrier. Therefore, a prime objective of the present work was the computation of the energetics and mechanisms of geometrical isomerization of the cations **4** (for previous investigations of $\overset{+}{C}H_2OH$ see ref. 11), and the changes in bonding that occur in the formation of these species from **3**. In disagreement with expectation, we find $\overset{+}{C}H_2SH$ to have the higher rotational barrier, *i.e.*, that the π-conjugative effects *are greater for the second row atom* than for the first row atom. In agreement with this conclusion is the finding that the computed amount of π-charge transfer from the heteroatom to the CH_2^+ center and the π-overlap populations are greater for sulfur than for oxygen.

Method

The method employed was the single-determinant LCAO-MO-SCF procedure, in which each molecular orbital ψ_i is expressed as a linear combination of a set of contracted Gaussian type functions (eq. 4).

$$[4] \qquad \psi_i = \sum_j C_{ij}\phi_j$$

A split valence shell basis set (4-31G) has been used throughout the work (12*a*, *b*). In this basis set each inner shell is represented by a four term Gaussian expansion, and the valence shell is split into three- and one-term expansions of the inner and outer parts, respectively. The molecular orbitals were determined by solution of the Roothaan–Hartree–Fock equations using the Gaussian 70 program system (12*c*) with full optimization of the geometries of each of the four species **3** (X = O, S) and **4** (X = O, S). All computations were performed on a CDC 6600 computer at the University of Bologna.

Results and Discussion

Geometry Optimization of CH_2O and CH_2S

Table 1 lists the computed optimized geometries of formaldehyde (12*a*) and thioformaldehyde, together with the experimentally determined (13) geometries of these molecules. Formaldehyde has been investigated previously by a number of workers (11*a*, 11*c*, 14, 15), but with the exception of ref. 12*a*, the objectives were different from those of the present work, and full geometry optimization was not performed. It is evident that the optimized geometries of **3** agree well with the experimental values in both cases; this provides some confidence that the basis set employed in the work can also provide accurate geometries of the species **4**, for which experimental data are not available.

Geometry Optimization of $\overset{+}{C}H_2OH$ and $\overset{+}{C}H_2SH$

The most stable conformation in each case is the fully planar structure **5**. In each case, the energy was optimized with respect to all geometrical parameters except the C—H bond length of $\overset{+}{C}H_2OH$, kept constant at the value 1.0835 Å previously computed at the minimal basis set level (16). The optimized value of the C—H bond length for $\overset{+}{C}H_2SH$ is 1.0677 Å, and this value was kept constant in all subsequent computations

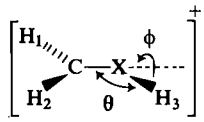
reported here for this species. The computed geometrical parameters of structure **5** in the two cases are summarized in Table 2. In both protonated systems



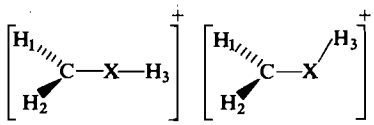
5

the C—X bonds are longer than those of the parent molecules **3** (0.04 and 0.02 Å for X = O and X = S, respectively). However, these bond lengths are substantially shorter than those of CH_3OH and CH_3SH (1.428 and 1.819 Å, respectively (17)), so that significant double bond character remains following protonation.

The H_2CX and CXH_3 bond angles (see Table 2) are of some interest, and have important consequences for the mechanisms of geometrical isomerization of the two species. Compared to CH_3OH, whose COH angle is 105.9° (17), $\overset{+}{C}H_2OH$ has a COH angle of 124.76°. In contrast, the CSH angle of $\overset{+}{C}H_2SH$ is only 4.4° larger than that of CH_3SH (17). We suggest that the origin of this large COH bond angle is the small (2.07 Å) internuclear separation that would otherwise have been present between H_2 and H_3. The movement of these nuclei away from each other leads to an opening not only of the COH angle but also of the H_2CO angle which is now greater than 120°. The H_2CS angle in $\overset{+}{C}H_2SH$ is less than 120°.

Geometrical Isomerization of $\overset{+}{C}H_2OH$ and $\overset{+}{C}H_2SH$ SCF Computations

As pointed out by others (11*a*, *b*), two mechanisms are possible for the geometrical isomerization of a species such as **4**. In the first, the transition state has the structure **6**, and the process may be termed "linear inversion" (18). In the second, the transition state has the structure **7**, and the process is one of torsion along the C—X bond.



6 **7**

Linear inversion in $\overset{+}{C}H_2OH$ was studied by computation of the total energy as a function of θ = ∠COH; at θ = 124.76° (the energy minimum) and θ = 180° (the transition state) the geometry was optimized with respect to the CO

and OH bond lengths and the HCH angle. The results of these calculations are found in the first and fifth columns of Table 2, and they give a value of the barrier to linear inversion of 13.98 kcal/mol. Linear inversion in $\overset{+}{C}H_2SH$ was studied in the same way, and the results for $\theta = 100.9°$ (the energy minimum) and $\theta = 180°$ (the transition state) are collected in the second and sixth columns of Table 2. The barrier to linear inversion in this case is 66.95 kcal/mol. It will be noted that, in both cations, the optimized CX bond length in the transition state for linear inversion is slightly shorter than that of CH_2X.

The barriers to linear inversion in H_2O and H_2S are 26.4 and 37.0 kcal/mol, respectively (19). The simplest interpretation of this difference is that the bond angle of H_2O changes from 105 to 180° but that of H_2S changes from 96.4 to 180°. On this basis, the substantial decrease in the barrier to linear inversion at oxygen on going from H_2O to $\overset{+}{C}H_2OH$ is a direct consequence of the geometry relaxation in the ground state of the latter species, already discussed.

We were unable to compute an accurate value for the rotational barrier of $\overset{+}{C}H_2OH$. Optimization of the molecular geometry as a function of the dihedral angle ϕ between the HCH and COH planes led to a COH angle of 180° for $\phi = 90°$. This means that the rotation is disfavored with respect to linear inversion. An approximate value of the rotational barrier of 23 kcal/mol was obtained (*cf.* Table 2, columns one and three) by maintaining the COH angle at 124.76°, the same value as in the planar conformation. Our results parallel those of Ros (11*a*), in whose study of $\overset{+}{C}H_2OH$ rotation was found to be disfavored with respect to linear inversion with a rigid rotor model, and those of Lehn *et al.* (11*b*), who found linear inversion to be the favored process in $CH_2{=}NH$ and $CH_2{=}CH^-$.

In contrast, rotation is the favored process in $\overset{+}{C}H_2SH$. Table 2, column 4 lists the optimized geometry and energy of the transition state (7) for this process, from which the barrier is computed to be 36.47 kcal/mol. Two features of the geometry of this transition state are of interest: the C—S bond length is now 1.81 Å indicating that conjugation between carbon and sulfur has been completely destroyed; and the angle between the HCH plane and the CS bond is not zero, so that attachment of a nonconjugating SH ligand to the carbonium ion makes this center

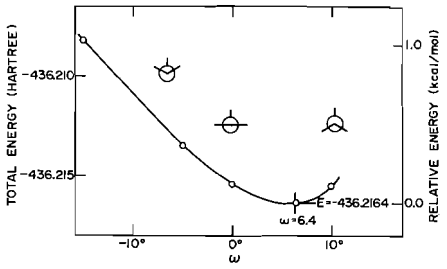

FIG. 1. The total energy of **7** (X = S) as a function of ω, the angle between the HCH plane and the C—S bond.

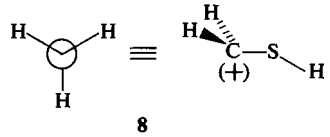
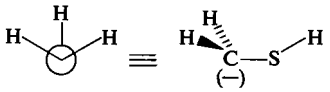
nonplanar. Figure 1 displays the total energy of **7** (X = S) as a function of the angle ω between the HCH plane and the CS bond, from which it is evident that, in this rotational conformation, the cation adopts the Y conformation **8**, in contrast to the corresponding anion, which adopts the W conformation **9** (8).



8



9

For the analysis of effects such as the relative stabilities of Y and W conformations, it is useful to consider the relative contributions to the total energy of nuclear and electronic effects (8, 20–22). When electronic effects dominate, the more crowded conformation (W in this case) is the more stable. On this basis, the greater stability of the W conformation in the case of the anion **9** is the result of the increased electronic interactions associated with the additional electron pair.

A Configuration Interaction Study

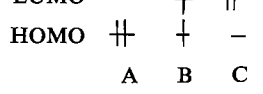
Closed shell restricted Hartree–Fock theory is sometimes unable to provide accurate results because of the overrestrictive nature of the wavefunction. Thus, in the computation of rotational barriers about a bond containing a significant amount of double bond character, a single determinantal approach may not be sufficient (23*a*). For example, in the computation of the rotational barrier of ethylene, unacceptably high values are obtained from a single determinantal

TABLE 3. Total energies (a.u.) computed with a single determinantal (SCF) approach and with a CI procedure for $\overset{+}{C}H_2SH$ in conformation 7 at different C—S bond lengths

Bond length (Å)	E_{SCF}	E_{CI}	CI eigenvectors
1.70	−436.21147	−436.21150	0.9999 0.86×10^{-18} -0.7476×10^{2}
1.75	−436.21499	−436.21501	0.9999 0.85×10^{-18} 0.6124×10^{-2}
1.8136	−436.21639	−436.21640	0.9999 0.81×10^{-18} -0.4755×10^{-2}

approach, but the inclusion of one additional configuration is sufficient to afford much improved results (23*b*).

Since the results just described, of rotation in $\overset{+}{C}H_2SH$, are highly significant if correct, it seemed desirable to check the role of configuration interaction. The rotational barrier was, therefore, recomputed using a limited CI procedure.[2] The configurations taken into account are the three illustrated in the following Scheme 1, where HOMO refers to the highest occupied molecular orbital, and LUMO to the lowest unoccupied molecular orbital obtained in the single determinant SCF calculation.



SCHEME 1

The CI energy of **7** (X = S) was computed by solving a 3 × 3 secular determinant at three C—S bond lengths: 1.6, 1.7, and 1.8136 Å, the latter corresponding to the optimized value afforded by the single determinantal approach. The results of this study are shown in Table 3. They reveal that the CI procedure does not change the energy of **7** significantly as compared to the value computed by the single determinantal approach. In addition, the eigenvectors show that the ground electronic configuration predominates. This suggests that a single configuration SCF wavefunction can be used with confidence to study rotation along a polarized bond such as C—O and C—S, even when this bond has appreciable double bond character.

[2]We thank Professor W. J. Hehre for providing us with the program.

The higher rotational barrier in $\overset{+}{C}H_2SH$ therefore seems to be real. Since as noted above, π-conjugation between carbon and sulfur is completely destroyed during rotation, we must conclude that *π-conjugation in $\overset{+}{C}H_2SH$ is greater than in $\overset{+}{C}H_2OH$*. Quantitative support for this interpretation is provided by the Mulliken-type population analysis, discussed later.

The Rotation – Linear Inversion Surfaces of $\overset{+}{C}H_2OH$ and $\overset{+}{C}H_2SH$

The dynamic properties of the two cations can be represented conveniently in the form of rotation–inversion surfaces. Equations for such surfaces were obtained by "least squares" fittings of the expression.

$$[5]\quad E = E_0 + C_1\phi^2 + C_2\phi^4 + C_3\phi^2\cos 2\theta + C_4\phi^4\cos 2\theta$$

to the SCF computed energies of a number of conformations. The inversion coordinate φ and the rotation coordinate θ are as defined previously. The energies of the conformations used in the fitting procedure are summarized in Table 4. Each of the entries in Table 4 has been fully optimized with respect to geometrical parameters other than rotation and inversion. The constants for eq. 5 are given in Table 5.

Plots of the surfaces are shown in Figs. 2 and 3. In both cations, the inversion process is energetically allowed, as indicated by paths *A* in the figures, and proceeds via the linear transition state. However, in the sulfur cation, an alternate isomerization mechanism is favored. Path *B* of Fig. 3 shows that rotation is the lower energy process. As indicated by the broken path in Fig. 2, a similar rotation in protonated formaldehyde is energetically not allowed, because any attempt to rotate H_3 about the C═O axis

C_4	—	0.008962

results in a path proceeding through the linear transition state, as shown by path *B* of Fig. 2. Since the endpoints of paths *A* and *B* are identical (H_3 *anti* to H_1), these paths are indistinguishable experimentally. Hence, inversion is the only energetically allowed mechanism of geometrical isomerization in protonated formaldehyde, whereas both rotation and inversion are allowed in protonated thioformaldehyde, with rotation being the favored process.

Proton Affinities of CH_2O and CH_2S

In the quantum mechanical convention, proton affinity is defined as the difference between the energies of the protonated (MH^+) and deprotonated (M) species (eq. 6), since the energy of the proton is zero, by definition. This value is also a measure of the gas phase

$$[6] \qquad \text{p.a.(M)} = E(MH^+) - E(M)$$

basicity of the species M and the gas phase acidity of the species MH^+. The proton affinity values computed for formaldehyde and thioformaldehyde are shown in Table 6. The two values are of the same order of magnitude, with that of formaldehyde slightly greater.

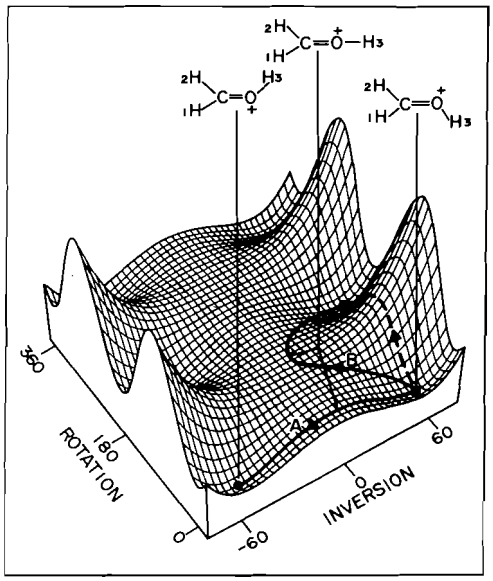

FIG. 2. The rotation – linear inversion surface of $\overset{+}{C}H_2OH$.

Mulliken Population Analyses of 3 and 4

Table 7 summarizes the net atomic charges and gross orbital populations of the valence orbitals of CH_2O and CH_2S. Table 8 lists the same data for $\overset{+}{C}H_2OH$ and $\overset{+}{C}H_2SH$.

The two parent molecules have opposite charge distributions. In formaldehyde the methylene group has a net charge of +0.51 electron, and in thioformaldehyde the net charge of this group is −0.08 electron. Alternatively, we may state that oxygen is strongly negative in formaldehyde, but sulfur is slightly positive in thioformaldehyde. Inspection of the data of

TABLE 7. Net atomic charges (q) and gross orbital populations of the valence atomic orbitals for CH_2O and CH_2S*

	CH_2O			CH_2S		
	H	C	O	H	C	S
q	+0.16	+0.17	−0.49	+0.22	−0.52	+0.08
s	0.84	1.22	1.96	0.78	1.42	1.89
p_x	—	1.10	1.90	—	1.19	1.97
p_y	—	0.73	1.27	—	0.83	1.20
p_z	—	0.79	1.36	—	1.08	0.93

*The coordinate system is  C = X → Z.

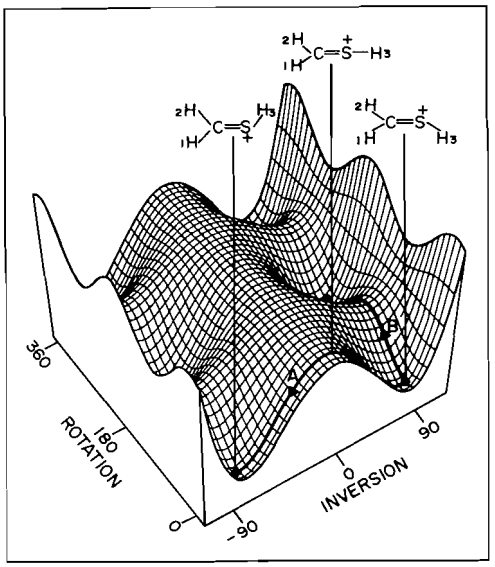

FIG. 3. The rotation – linear inversion surface of CH_2SH.

Table 7 reveals that oxygen in formaldehyde behaves as a π and a σ acceptor towards carbon, but in thioformaldehyde sulfur behaves as a π acceptor and a σ *donor*.

Both molecules belong to the C_{2v} symmetry point group. If we define two reference planes, one of which is the plane of the molecule and the other is perpendicular and bisects the HCH angle, then two types of π molecular orbitals can be distinguished, as shown below.

Structure	Orbital symmetry type	Orbital energy X = O	Orbital energy X = S
	b_1	−0.4421	−0.3461
	b_2	−0.5283	−0.4062
	b_1	−0.7064	−0.6466

In terms of this representation, the total π-overlap population in formaldehyde is 0.2357 (0.2149 from b_1 and 0.0208 from b_2); and in thioformaldehyde it is 0.2257 (0.2119 from b_1 and 0.0138 from b_2), so that π-bonding between carbon and oxygen is slightly stronger than π-bonding between carbon and sulfur.

The situation is different in the protonated species. Scheme 2 displays the charge on the methylene group in $\overset{+}{C}H_3$, $\overset{+}{C}H_2OH$, and $\overset{+}{C}H_2SH$.

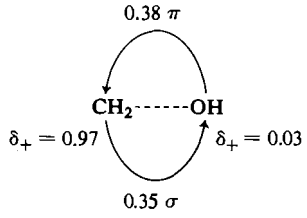
SCHEME 2

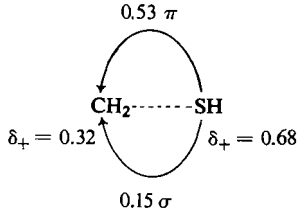
With respect to hydrogen we see that OH behaves towards $\overset{+}{C}H_2$ as an electron-withdrawing ligand by 0.31 electron, but SH behaves as an electron-releasing ligand by 0.34 electron.

Perhaps the most informative way to discuss the population analyses of these protonated species is to consider the interaction of the two fragments $\overset{+}{C}H_2$ and XH. Reference to the p_x and p_z overlap populations listed in Table 6 shows that, if $\overset{+}{C}H_2OH$ is considered to be formed by the combination of the fragments $\overset{+}{C}H_2$ and OH, π-donation from oxygen amounts to 0.38 electron. This corresponds to a charge transfer from the $2p_x$ oxygen lone pair to the vacant π orbital of $\overset{+}{C}H_2$, with the consequent formation of a relatively strong π bond between C and O. The π-overlap population is now 0.1496, less than that in $\overset{+}{C}H_2O$, so that the C—O bond in $\overset{+}{C}H_2OH$ is longer than that in CH_2O. As shown in **10**, the π-donation of 0.38 electron from O to C must be counterbalanced by a σ-donation from C to O of 0.35 in order to account for the total charge distribution δ_+.

In $\overset{+}{C}H_2SH$, a similar analysis reveals that π-donation from S to C amounts to 0.53 electron and that σ-donation from *S to C* amounts to an additional 0.15 electron. These are shown schematically in **11**. The important finding is that the π-donation from S to C (0.53 electron) is greater than that from O to C (0.38 electron).



10



11

The π-overlap population in $\overset{+}{C}H_2SH$ is, therefore, also larger (0.1734), indicating a stronger π-bond between C and S than between C and O.

These analyses are thus in agreement with the interpretations given earlier of the rotational barriers. We must conclude that, in contrast to the current view of the nature of the interactions between first row and second row heteroatoms and an adjacent carbonium ion center, π-conjugative effects are greater for the second row atom. This result can be rationalized in terms of the interaction between the $2p_x$ heteroatom lone pair and the vacant carbon $2p_x$ orbital. The charge transfer associated with such an interaction is inversely proportional to the energy difference between the interacting orbitals so that greater stabilization is afforded by a sulfur lone pair than by an oxygen lone pair, because

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the ionization potential of a second row atom is always less than that of the corresponding first row atom (*e.g.* ref. 24: H_2O, 12.61 eV; H_2S, 10.48 eV). A detailed account of this rationalization is presented elsewhere (25).

We thank NATO, the Italian CNR, and the donors of the Petroleum Research Fund, administered by the American Chemical Society, for financial support of this work.

Substituent Effects in Electron Transfer Reactions: The Preparation and Chromium(II) Reduction of 3-Formylpentane-2,4-dionatobis(ethylenediamine)cobalt(III). Preparation of the Linkage Isomer 2-Acetylbutane-1,3-dionatobis(ethylenediamine)cobalt(III)

ROBERT J. BALAHURA[1] AND N. A. LEWIS

Department of Chemistry, University of Guelph, Guelph, Ontario N1G 2W1

Received October 30, 1974

ROBERT J. BALAHURA and N. A. LEWIS. Can. J. Chem. **53**, 1154 (1975).

The preparation of the linkage isomers, 3-formylpentane-2,4-dionatobis(ethylenediamine)-cobalt(III), (**1**), and 2-acetylbutane-1,3-dionatobis(ethylenediamine)cobalt(III), (**2**), are described. The kinetics of the reaction of $Cr(OH_2)_6^{2+}$ with **1** and the parent complex, 2,4-pentanedionatobis(ethylenediamine)cobalt(III), (**3**), have been studied spectrophotometrically in acidic solution. For **1**, the reduction is described by the rate law $-$ d ln [Co(III)complex]/dt = $k[Cr^{2+}]$, and $k = 0.0863\ M^{-1}\ s^{-1}$ at 25 °C, $\mu = 1.0\ M$ ($LiClO_4$). The activation parameters for this reaction were found to be $\Delta H^{\ddagger} = 9.9 \pm 0.5$ kcal mol^{-1} and $\Delta S^{\ddagger} = -30 \pm 3$ e.u. The reaction proceeded by an inner-sphere mechanism and the product of this reaction was isolated and characterized as 2-acetylbutane-1,3-dionatotetraaquochromium(III). The linkage isomer of this complex was also prepared. The parent complex (**3**) was not reduced by $Cr(OH_2)_6^{2+}$ at an observable rate and an upper limit for the rate constant of this reaction was assigned a value of 10^{-4}–$10^{-6}\ M^{-1}\ s^{-1}$ at 25 °C. The ability of the formyl group to enhance the rate of electron transfer is discussed, and the chromium(II) reduction studies of related chelated systems are compared with the results obtained in this investigation.

ROBERT J. BALAHURA et N. A. LEWIS. Can. J. Chem. **53**, 1154 (1975).

On décrit la préparation des isomères de liaisons, formyl-3 pentanedionato-2,4 bis(éthylènediamine) cobalt(III) (**1**) et acétyl-2 butanedionato-1,3 bis(éthylènediamine) cobalt(III) (**2**). On a étudié spectrophotométriquement en solution acide la cinétique de la réaction du $Cr(OH_2)_6^{2+}$ avec **1** et avec le complexe parent pentanedionato-2,4 bis(éthylènediamine) cobalt(III) (**3**). Pour **1** la réduction est décrite par la loi de vitesse $-$ d ln [Co(III) complexe]/dt = $k[Cr^{2+}]$ et $k = 0.0863\ M^{-1}\ s^{-1}$ à 25 °C, $\mu = 1.0\ M$ ($LiClO_4$). On a trouvé que les paramètres d'activation pour cette réaction sont $\Delta H^{\ddagger} = 9.9 \pm 0.5$ kcal mol^{-1} et $\Delta S^{\ddagger} = -30 \pm 3$ e.u. La réaction se produit par un mécanisme de sphère intérieure et le produit de 'a réaction peut être isolé et caractérisé comme étant l'acétyl-2 butanedionato-1,3 tétraaquochrome(III). On a aussi préparé les isomères de liaisons de ce complexe. Le complexe parent (**3**) n'est pas réduit par $Cr(OH_2)_6^{2+}$ à une vitesse mesurable et on a attribué une limite supérieure pour la constante de vitesse de cette réaction de 10^{-4} à $10^{-6}\ M^{-1}\ s^{-1}$ à 25 °C. On discute de l'habilité du groupe formyle d'augmenter la vitesse de transfert d'électron; on compare les résultats obtenus au cours de cette étude avec ceux d'études sur la réduction par du chrome(II) de systèmes chelates apparentés. [Traduit par le journal]

Introduction

Linkage isomerism involving metal chelates is exceedingly rare (1). Generally, synthesis of separate isomers has been effected by changing reaction conditions such as solvent (2), temperature (3), counterion (4), or bulkiness of other ligands (5). In this study we wish to report on the synthesis and characterization of the linkage isomers of 3-formylpentane-2,4-dione with bis(ethylenediamine)cobalt(III), **1** and **2**.

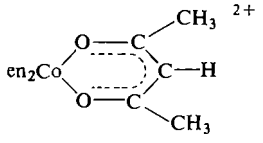
These isomers were prepared using two different preparative procedures since both **1** and **2** were found to be stable, with respect to isomerization, upon changing reaction conditions.

Our original aim in preparing these compounds was to investigate their redox properties. There are few studies of mechanistic behavior involving chelated bridging ligands in oxidation–reduction reactions. A recent report (6) of the chromium(II) reduction of cobalt(III)-mercaptoacetate, $[Co(en)_2(OOCCH_2S)]^+$, and alkoxide, $[Co(en)_2(OOCCH_2O)]^+$ complexes has indicated that the reaction occurs via an inner-sphere process by attack of the reductant at the coordinated sulfur and alkoxide oxygen respectively. In complexes of the above type there are three potential sites for attack of the reductant and it is difficult to determine unambiguously the site of attack. The large rate difference found for reaction of the mercaptide complex with respect to the alkoxide complex has also been the source of much speculation.

A potentially simpler system involves the pseudoaromatic chelate formed with 2,4-pentanedione. It was anticipated that the complex



3

would react by an outer-sphere mechanism rather than one which involved attack of reductant at one of the coordinated oxygens. We hoped then to substitute the methylene hydrogen with other groups capable of acting as inner-sphere bridges towards chromium(II). The synthesis of **1** has allowed us to investigate the electron-transfer-inducing ability of the formyl group. Furthermore, reduction of **2**, where small structural changes in the chelate ring have been made, may indicate some of the factors influencing electron transfer involving chelate complexes.

It has been shown that electronic effects can be transmitted from one chelate group to another in the same complex (*7a*, *b*). Thus, a systematic variation of substituents on the chelate ring as well as a variation in the number and type of chelate groups may help to indicate the importance of electronic delocalization in electron transfer reactions. Also, it appears that the electron transfer process involves activation of the entire chelate ring and not just the bridging atom (8). This effect may be observed when comparing complexes **1** and **2**.

In inner-sphere reactions of this type, the chelates are initially bonded to chromium(III) as monodentate ligands but usually the final products involve a chelated complex. In these systems this would allow us to investigate the ring closure reactions as well as being helpful in indicating the initial position of attack of the reductant.

Experimental

Reagents

All reagent solutions were prepared in water redistilled from alkaline permanganate in an all glass apparatus. Lithium perchlorate solutions were prepared and standardized as described previously (9).

Chromium(II) perchlorate solutions were prepared by reduction of chromium(III) perchlorate using zinc–mercury amalgam. These solutions were stored and handled in an atmosphere of high-purity argon.

Kinetic Measurements

The rate of reduction of 3-formylpentane-2,4-dionatobis(ethylenediamine)cobalt(III) was followed by observing the change in absorbance of the longest wavelength maximum of the cobalt(III) complex. The kinetic runs were performed on a Beckman Acta CIII spectrophotometer with the temperature controls described previously (10). All reactions were carried out in cylindrical cells sealed with rubber serum caps in the absence of oxygen. The reactions were run under pseudo first-order conditions (reductant in a 10–50 fold excess over oxidant).

Physical Measurements

The proton magnetic resonance spectra were obtained on a Varian A60 spectrometer. The ultraviolet and visible spectra were measured on a Beckman Acta CIII spectrophotometer. The infrared spectra were recorded on a Beckman IR 12 spectrophotometer.

Preparation of Complexes[2]

$[en_2Co(ptdn)](PF_6)_2$

The compound was prepared as reported in the literature (11). It was dissolved in water and purified by ion-exchange chromatography on Rexyn 102(H) weak acid cation exchange resin (Fisher Scientific Co.) converted to the sodium ion form. Elution with 0.1 *M* NaCl separated the product from the principal impurity $[en_3Co]^{3+}$. The resin containing the desired complex was

[2]The abbreviation, acac, commonly used to denote 2,4-pentanedione (acetylacetone) was not employed in this work since a corresponding abbreviation could not be found for 1,3-butanedione. We have elected to use instead the abbreviations ptdn = 2,4-pentanedione and btdn = 1,3-butanedione based on IUPAC names.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

separated physically and washed with distilled water, which was filtered off under suction. Enough distilled water was then added to the resin to make a thick slurry and concentrated HCl was added dropwise to the rapidly stirred slurry until the complex was removed from the resin, complete removal being signified by the presence of free hydrogen ions. The complex was precipitated with NH_4PF_6, filtered, washed with ether, and air-dried.

Anal. Calcd. for $[Co(C_2N_2H_8)_2(C_5O_2H_7)](PF_6)_2$: C, 19.05; H, 4.05; N, 9.86. Found: C, 19.05; H, 4.27; N, 9.84.

$[en_2Co(3\text{-formyl-ptdn})](PF_6)_2$

A mixture of dry dimethylformamide (100 ml), Davidson Molecular Sieves (15 g, 8–12 mesh, 4 Å effective pore size), and $[en_2Co(ptdn)]I_2$ (11) (5 g) recrystallized from KI was allowed to stir for 1 h to ensure dryness. Then $POCl_3$ (8 ml) was added over a 10 min interval. The reaction was slightly exothermic but there was no need to cool the reaction mixture. Stirring was continued for 2 h at room temperature.

The solution was filtered and added slowly to ether (500 ml). The mixture was stirred to extract a yellow organic material in the ethereal layer which was then decanted off. The red layer containing the desired product was gradually stirred into acetone (800 ml). A pink precipitate formed immediately and was filtered off, dissolved in water (1000 ml), and ion-exchanged as described above. The unreacted $[en_2Co(ptdn)]^{2+}$ separated from the formyl product as a red band upon elution with 0.1 *M* NaCl. The $[en_2Co(3\text{-formyl-ptdn})]^{2+}$ moved down the column as an orange band. The bands were separated physically and the complexes removed from the resin, as described in the above preparation. The formyl complex was precipitated with NH_4PF_6, washed with ether, and air-dried. Yield 1.6 g, 30.5%.

Anal. Calcd. for $[Co(N_2C_2H_8)_2(C_6H_7O_3)](PF_6)_2$: C, 20.15; N, 9.39; H, 3.86. Found: C, 19.99; N, 9.37; H, 4.01.

3-Formylpentane-2,4-dione

The free ligand, 3-formylpentane-2,4-dione was prepared following Beilstein (12) and purified by the method of Akehurst and Bartels-Keith (13). The compound was found to be unstable if stored at room temperature in a P_2O_5 dessicator under vacuum but it could be stored for several weeks at 5 °C.

$[en_2Co(2\text{-acetyl-btdn})](PF_6)_2$

The complex $[en_2Co(CO_3)]^{2+}$ (14) (2.2 g) was treated with 8 ml of 2 *M* HCl. The ligand 3-formylpentane-2,4-dione (2.1 g) was dissolved in 12 ml of 1 *M* NaOH. The ligand solution was added to the stirring metal complex solution. The reaction mixture was allowed to sit at room temperature for a week, after which time the mixture was diluted to 700 ml with distilled water and ion-exchanged as described above. Elution with 0.1 *M* NaCl separated a red and an orange band, the first being identified as $[en_2Co(ptdn)]^{2+}$ and the latter as the desired complex. Other bands of higher charge remained at the top of the column and were not identified. The orange band was eluted off the column with 0.1 *M* NaCl and was taken to dryness on a rotovap. The chloride salt obtained in this manner was converted to the PF_6^- salt using NH_4PF_6.

Anal. Calcd. for $[Co(N_2C_2H_8)_2(C_6H_7O_3)](PF_6)_2$: C, 20.15; N, 9.39; H, 3.86. Found: C, 20.12; N, 9.25; H, 4.12.

$[(OH_2)_4Cr(ptdn)]^{2+}$

A solution of 10 ml of 2,4-pentanedione and 20 ml of 0.5 *M* $[Cr(OH_2)_6]^{3+}$ in 0.2 *M* $HClO_4$ was allowed to stir in a covered flask for 48 h. A 3 ml portion of the reaction mixture was then subjected to ion-exchange on Dowex 50W-X8 cation exchange resin at 5 °C. The first band moved as a 1+ ion and was the disubstituted product, $[(OH_2)_2Cr(ptdn)_2]^+$; the second band moved as a 2+ and was the monosubstituted product $[(OH_2)_4Cr(ptdn)]^{2+}$, and the third band was unreacted $[(OH_2)_6Cr]^{3+}$. Extinction coefficients were based on the chromium concentration which was determined spectrophotometrically as chromate.

$[(OH_2)_4Cr(2\text{-acetyl-btdn})]^{2+}$

Chromatographic separation of reaction mixtures at different acidities and at a 1:1 ratio of Cr^{2+} to $[en_2Co(3\text{-formyl-ptdn})]^{2+}$ afforded this complex as the only product. Separations were obtained on Dowex 50W-X8. Elution and analysis were performed as described previously (9).

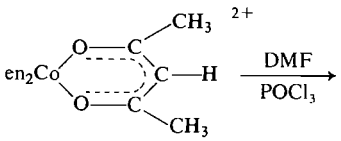
$[(OH_2)_4Cr(3\text{-formyl-ptdn})]^{2+}$

The free ligand, 3-formylpentane-2,4-dione (2 g) was added to 10 ml of 0.5 *M* $[Cr(OH_2)_6]^{3+}$ in 0.2 *M* $HClO_4$. The ligand was not immediately soluble in this solution but dissolved over a 2 h period to give a purple solution. Ion-exchange of portions of the reaction mixture was accomplished on Dowex 50W-X8 after 2 to 8 h of reaction time. Three bands were obtained, corresponding to $[(OH_2)_2Cr(3\text{-formyl-ptdn})_2]^+$, $[(OH_2)_4Cr(3\text{-formyl-ptdn})]^{2+}$, and $[(OH_2)_6Cr]^{3+}$. Increasing amounts of the disubstituted product were obtained as the reaction time was increased.

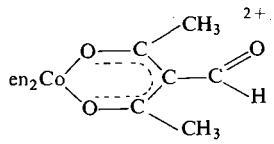
Results and Discussion

Preparation and Characterization of Complexes

The substitution of the methylene proton was accomplished by reaction of the unsubstituted complex with $POCl_3$ in dimethylformamide (DMF)



3



1

in a procedure similar to that of Collman *et al.* (15). The mixture of $POCl_3$ and DMF is a potent formylating agent (16), the active

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

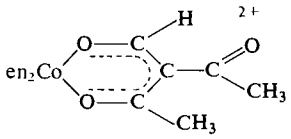
species probably composed of an addition compound of $POCl_3$ and DMF (17):

$$[(CH_3)_2N{-}\overset{+}{C}H{-}Cl \leftrightarrow (CH_3)_2\overset{+}{N}{=}CH{-}Cl]\bar{O}POCl_2$$

The complex was purified by cation-exchange chromatography and eluted as the expected 2+ ion.

The linkage isomer of **1** was prepared from reaction of the free ligand, 3-formylpentane-2,4-dione with $[Co(en)_2(OH_2)_2]^{3+}$

$[Co(en)_2(H_2O)_2]^{3+}$ + 3-formyl-ptdn →



2

Purification via ion-exchange indicated that **2** is formed selectively since no trace of **1** was observed. Attempts to prepare **2** by heating **1** at elevated temperatures in a variety of solvents proved unsuccessful.

Infrared Spectra

The infrared spectra of β-diketone complexes have been well documented (18, 19). The bands that appear in the region $1515 \pm 10\ cm^{-1}$ (B band) and $1575 \pm 30\ cm^{-1}$ (A band) have been assigned to the C=O and C=C stretching modes, respectively (20). However, labelling experiments suggest that the A band corresponds to a pure C=O stretch whereas the B band is a pure C=C stretch (21, 22). Later, Mikami *et al.* showed that the two modes are coupled slightly to each other (23). The presence of these bands provides excellent proof of chelate formation. The A and B bands in the parent compound, $[Co(en)_2(ptdn)]^{2+}$, appear at 1582 and 1523 cm^{-1} (24).[3]

Previously (25), Dryden and Winston had shown that substitution of the methylene hydrogen at the 3-position results in only one band in the 1500–1600 cm^{-1} region. However, the nitro chelates prepared by Collman *et al.* (15) exhibited two bands in this region, the band at 1520 cm^{-1} being assigned to an asymmetric nitro stretching frequency. It has been found that when the group substituted for hydrogen is a double-bonded species such as acetyl, a doublet persists in the 1500–1600 cm^{-1} region. In the formyl derivative **1**, $[Co(en)_2(3\text{-formyl-ptdn})][PF_6]_2$, a spectrum as a Nujol mull also shows a doublet in this region (at 1589 and 1565 cm^{-1}). When the infrared spectrum is run as a KBr disk only one peak at 1578 cm^{-1} is observed. The free carbonyl stretching frequency of the formyl group appears at 1695 cm^{-1} in a Nujol mull and as a doublet at 1670 and 1675 cm^{-1} in a KBr disk. The carbonyl stretching frequency of the formyl group appears at 1660 cm^{-1} in the complex (3-formyl-2,4-pentanedionato)bis(2,4-pentanedionato)cobalt(III) (2). The infrared spectrum of the free ligand 3-formylpentane-2,4-dione shows a ν(C=O) at 1674 cm^{-1}.

The infrared spectrum of the linkage isomer **2** in Nujol shows intense bands at 1572 and 1587 (1610 sh) cm^{-1}. The latter band is probably due to the ν(C=O) of the coordinated aldehydo and keto oxygens of the ring. In a KBr disk only one band is observed for the coordinated keto and aldehydo ν(C=O) at 1586 cm^{-1}. The free acetyl carbonyl stretching frequency is observed at 1665 cm^{-1} in both Nujol and a KBr disk.

It is apparent that the number and type of bands obtained in the 1500 cm^{-1} region for these complexes are dependent upon the particular medium chosen in obtaining the spectrum. Thus we feel that caution should be exercised in applying Dryden's rule (25). Also, other physical studies are necessary for an unambiguous structural interpretation.

Proton Magnetic Resonance Spectra

The proton magnetic resonance spectra provide perhaps the best structural characterization of the linkage isomers. The spectra of complexes **1**, **2**, and **3** in DMSO-d_6 and D_2O are shown in Fig. 1. A tabulation of chemical shifts appears in Table 1. In D_2O the NH_2 protons on the ethylenediamine rings exchange with the solvent and are not visible. As shown in Fig. 1*a* the NH_2 protons appear as two broad peaks in the 4–6 δ region. Each peak integrates for four protons. The CH_2 protons of the ethylenediamine rings appear near or superimposed upon the solvent peak at about 2.50 δ. The shapes and positions of these peaks depend upon the solvent and nature of the

[3]Boucher and Bailar report 1565 and 1523 cm^{-1} for the iodide salt. The spectra reported in our study are for the hexafluorophosphate salts.

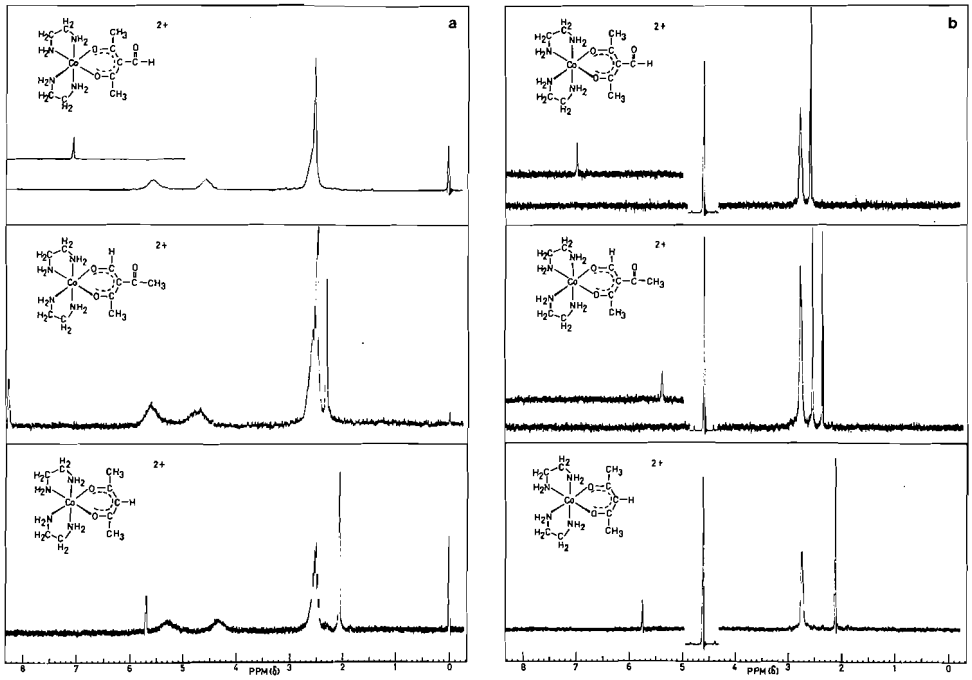


FIG. 1. (*a*) Proton magnetic resonance spectra of cobalt(III) complexes in DMSO-d_6 (offsets are 200 Hz). (*b*) Proton magnetic resonance spectra of cobalt(III) complexes in D_2O (offsets are 200 Hz).

*Peak occurs with solvent peak for DMSO-d_6.
†Amine protons exchange with solvent in D_2O and are not observed.
‡Chemical shifts in DMSO-d_6 are relative to TMS. Chemical shifts in D_2O are relative to HDO peak at 4.61 δ. All spectra in DMSO-d_6 originally contained a peak due to a water impurity which was shifted downfield with trifluoroacetic acid.

group in the 3-position of the 2,4-pentanedione ring.

The methylene proton in the unsubstituted complex, **3**, appears at ~5.78 δ in both DMSO-d_6 and D_2O. This is in good agreement with the position of this peak in other 2,4-pentanedione complexes (5.4–6.0 δ) (*7b*, 15). The disappearance of this peak is an excellent confirmation of substitution at the 3-position.

For complex **1** the lack of a peak in the 5–6 δ region and the appearance of a peak due to one proton at ~10 δ is expected for substitution of a formyl group in the 3-position. The fact that only a singlet is observed for the CH_3 protons of the 2,4-pentanedione ring (integration in D_2O gives 6 protons) implies that rotation about the C_3—C_{formyl} bond is fast and that there is little conjugation between the formyl group and

*All spectra were run in aqueous solution.

the pseudo aromatic chelate ring. This is consistent with the spectrum observed (2) for (3-formylpentane-2,4-dionato)bis(2,4-pentanedionato)cobalt(III) where only one methyl resonance was observed for the substituted chelate at 2.7 δ. In this complex the formyl proton was observed at 10.20 δ.

The proton magnetic resonance spectrum of the linkage isomer **2** is more complex than that of **1**. Again, substitution is indicated by the absence of the C_3 proton peak and the presence of a resonance due to one proton at 8.38 δ. This latter resonance is assigned to the proton on the coordinated formyl group. Two resonances are expected for the two inequivalent CH_3 groups and these are observed in D_2O at 2.30 and 2.48 δ. These results are similar to those observed (2) for the complex (2-acetylbutane-1,3-dionato)bis(2,4-pentanedionato)-cobalt(III) where the methyl groups are observed at 2.35 and 2.68 δ.

Thus the proton magnetic resonance spectra allow a clear distinction to be made between the linkage isomers.

Electronic Spectra

The positions of the absorption bands in the visible and ultraviolet regions of the spectrum for **1**, **2**, and **3** are given in Table 2. The lowest energy band in the visible region of the spectrum can be assigned to the d–d transition $^1A_{1g} \rightarrow {}^1T_{1g}$. The position of this band for the complexes reported here as well as similar complexes (24, 26) with different β-diketones does not vary appreciably. This indicates that the ligand field around the central cobalt metal remains essentially constant and is determined by the two ethylenediamine rings and the two oxygen atoms of the β-diketone. The expected $^1A_{1g} \rightarrow {}^1T_{2g}$ transition is observed as a shoulder at 376 nm in $[Co(en)_2(ptdn)]^{2+}$ but is obscured by ligand transitions in complexes **1** and **2**.

The remaining bands in the ultraviolet are due to ligand and charge-transfer transitions. In analogy to assignments made by Boucher and Bailar (24) the peaks at about 300 nm correspond to a $d\varepsilon \rightarrow \pi^*$ metal–ligand charge-transfer transition. The remaining ultraviolet bands, especially those at approximately 250 nm, can be assigned to π–π^* transitions.

It has been pointed out previously (7*b*, 27) that the methyl groups in 2,4-pentanedione complexes prevent coplanarity of acetyl and nitro groups with the chelate ring. However, halogen, sulfur, and formyl substituents can remain conjugated with the chelate ring. Thus a comparison of the ultraviolet spectra of substituted 2,4-pentanedione complexes can indicate the extent of steric inhibition of resonance of the substituents with the chelate ring. The data for complexes **1** and **2** imply that the formyl and acetyl groups are not sterically hindered from attaining coplanarity with the ring. This will be important in considering the electron transfer data.

Kinetic Studies

The kinetics of reduction of $[Co(en)_2(3\text{-formyl-ptdn})]^{2+}$ by chromium(II) follows the rate law

$$-\frac{d \ln [Co(III)complex]}{dt} = k[Cr^{2+}] = k_{obsvd}$$

A summary of the kinetic data is given in Table 3. The progress of the reaction was also followed by scanning the range from 300–700 nm with varying ratios of $[Cr^{2+}]$ and $[Co^{3+}]$ and with different hydrogen ion concentrations. A typical scan is given in Fig. 2. Good isosbestic behavior was observed in all cases with isosbestic points at 402, 430, 548, and 651 nm. The final spectrum obtained indicates that the final product of the reaction is not $Cr(OH_2)_6^{3+}$ and therefore an inner-sphere

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

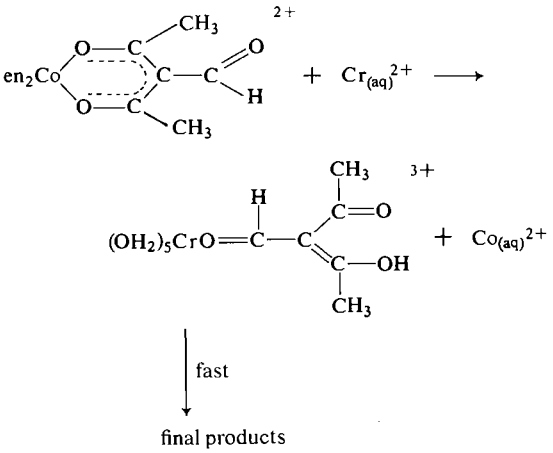
reaction is indicated. The peak maxima obtained for the chromium(III) product were at approximately 558 and 412 nm whereas for $Cr(OH_2)_6^{3+}$ the maxima occur at 574 and 408 nm (28).

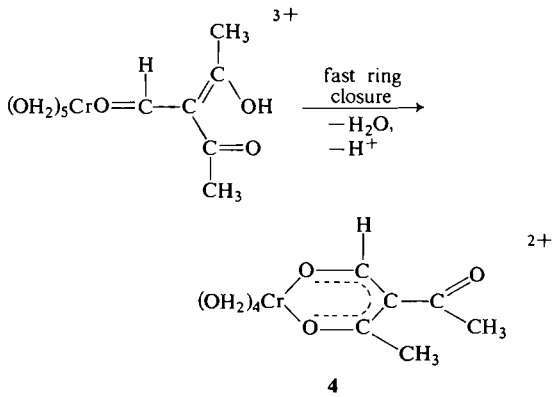
An attempt was made to study the reduction of $[Co(en)_2(ptdn)]^{2+}$ by chromium(II) but no reaction was observed under a variety of conditions. In one particular study no reaction was detected after 13 h at 55 °C for $[Cr^{2+}] = 1.87 \times 10^{-1}\ M$, $[Co^{3+}] = 7.70 \times 10^{-4}\ M$, and $[H^+] = 0.10\ M$. For comparative purposes it is probably reasonable to assume that this reaction is at least 10^4 to 10^6 times slower than the reduction of the 3-formyl derivative just described.

These results, as well as those previously described, are consistent with an inner-sphere mechanism for reduction of $[Co(en)_2(3\text{-formyl-ptdn})]^{2+}$ as outlined below



Since a monodentate complex of a substituted 2,4-pentanedione ligand was not anticipated the products of the reduction were isolated by cation exchange chromatography of reaction mixtures. Reaction mixtures with approximately 1 to 1 molar ratios of $[Cr^{2+}]$ to $[Co^{3+}]$ and varying acidity were subjected to cation exchange chromatography on Dowex 50W-X8. In all cases only one product was obtained. The average percent ligand transfer is 71% as determined by three such separations. It should be mentioned that the complex was difficult to remove from the column and based on the isosbestic behavior observed we feel that the transfer of ligand is nearly quantitative.

This product had elution characteristics of a 2+ ion. The visible–ultraviolet spectrum shows peak maxima (extinction coefficient) at 547(35.0), shoulder at 408(48.3), 309(5200), 246(13 150), and 238 nm(12 750 M^{-1} cm^{-1}). The spectrum is identical in both 1.0 M $HClO_4$ and 0.01 M $HClO_4$. Based on the extinction coefficients reported here and those of known monodentate and chelate complexes of chromium(III) (29, 30) we assign a chelate structure, **4**, to the final product obtained from the reduction. This product can be formed from the initial product of the reduction as shown below:



4

This reaction is expected to be extremely fast since it is known that Cr(III)–keto bonds are very labile (31, ref. 14 of (31)). In fact aquation of keto-coordinated ligands is generally characterized by half-times in the region of 20–30 ms (32, 33).[4] If ring closure were not fast, significant amounts of $Cr(OH_2)_6^{3+}$ would be expected. This would have been detected in the scan runs and isosbestic behavior would not have been observed.

Chelation between the reductant and one of the coordinated oxygens and the free formyl oxygen in the transition state could lead directly to a chelated product. Examination of molecular models, however, shows that the oxygens appear too far away in the complex to make this

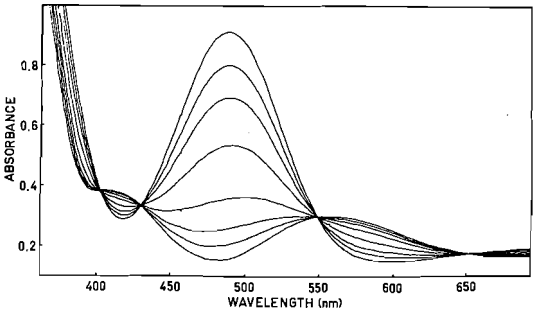

FIG. 2. Changes in the visible spectrum during reduction of (3-formyl-ptdn)bis(ethylenediamine)cobalt(III) (3.16×10^{-3} M) by Cr^{2+} (1.54×10^{-2} M); [H$^+$] = 2.86×10^{-2} M; path length = 2.0 cm; 25 °C. The spectral scans were started at 0.5, 4.0, 8.0, 16.0, 30.0, 45.0, 60.0, 130.0, and 215.0 min after mixing. The last two show no change.

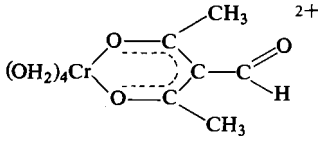
mechanism attractive. In addition, reactions where chelation has been definitely shown to occur (34) are usually much faster than that observed here. If this type of mechanism were operative one might expect attack at a coordinated oxygen in the parent compound as well, resulting in an observable rate for reduction.

Synthesis of Chromium(III) Complexes

An attempt was made to prepare the chelated product obtained from electron transfer independently by reaction of the ligand, 3-formylpentane-2,4-dione with $Cr(OH_2)_6^{3+}$. Chromatography of the reaction mixture gave three complexes. Band I eluted as a 1+ ion and was formulated as $Cr(OH_2)_2$(3-formyl-ptdn)$_2^+$. Band II had elution characteristics of a 2+ band and was formulated as $Cr(OH_2)_4$(3-formyl-ptdn)$^{2+}$. Band III was identified as unreacted $Cr(OH_2)_6^{3+}$. Band II had peak maxima (extinction coefficient) in the electronic spectrum at 557(30.4), 315(4640), 244(11 600), and 231 nm (14 100 M^{-1} cm^{-1}). This product is different from that obtained from the reduction of complex **1** and is formulated as the linkage isomer of **4** as below



5

Substitution of the free ligand on $Cr(OH_2)_6^{3+}$ was unusually facile. Reaction mixtures containing a five-fold excess of ligand turned from blue to violet in 2 h at room temperature. The ligand was initially insoluble in water but dissolved as the reaction proceeded. If the reaction were allowed to proceed for 10 h or more, the

spectrum of the 2+ band obtained from cation exchange chromatography was erratic and quite different from that obtained if the reaction proceeds from 2–9 h. In particular the extinction coefficient at the 315 nm peak was altered by up to 50% depending upon the particular run.

Both $[Cr(OH_2)_4(3\text{-formyl-ptdn})]^{2+}$ (from the free ligand) and $[Cr(OH_2)_4(2\text{-acetyl-btdn})]^{2+}$ (from the reduction) appear to be very stable (no decomposition occurs in 2 d at room temperature). This indicated that the free ligand decomposed to 2,4-pentanedione after 9 h in solution and the contaminant was $[Cr(OH_2)_4(ptdn)]^{2+}$. This hypothesis was strengthened by the observation that in the preparation of the cobalt complex **2** some $[Co(en)_2(ptdn)]^{2+}$ was also obtained even though **2** does not decompose to the 2,4-pentanedione complex once formed. To establish that the spectrum reported for $[Cr(OH_2)_4(3\text{-formyl-ptdn})]^{2+}$ was due only to this complex with no contamination by the 2,4-pentanedione complex, a series of product analyses were carried out over reaction times of from 2 to 8 h. Identical spectra were obtained indicating that 3-formylpentane-2,4-dione remained intact for this time period.

To verify the assignments made for **4** and **5** the complex $[Cr(OH_2)_4(ptdn)]^{2+}$ was prepared by reacting 2,4-pentanedione and $Cr(OH_2)_6^{3+}$ in acidic solution. Cation exchange chromatog-

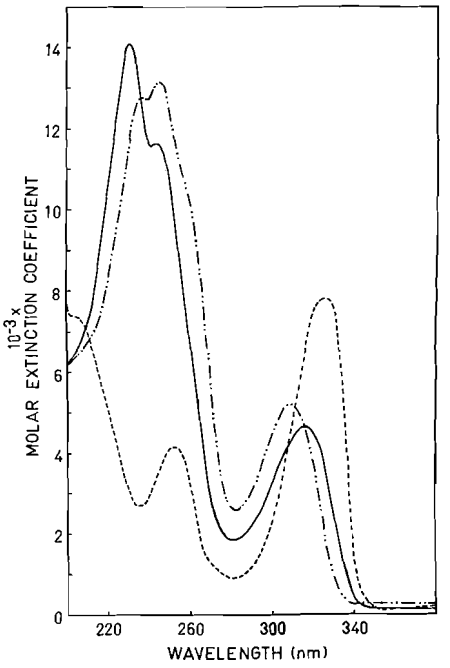

FIG. 3. Ultraviolet spectra of chromium(III) products: —, $Cr(OH_2)_4$(3-formyl-ptdn)$^{2+}$; ---, $Cr(OH_2)_4$(ptdn)$^{2+}$; ·····, $Cr(OH_2)_4$(2-acetyl-btdn)$^{2+}$.

raphy again gave three bands which eluted as 1+, 2+, and 3+ ions. The 2+ ion was formulated as $(OH_2)_4Cr(ptdn)^{2+}$ and had peak maxima (extinction coefficient) in the visible–ultraviolet at 553(27.0), 326(7880), 253(4140), and 204 nm (7380 M^{-1} cm^{-1}). This is sufficiently different from the spectra of **4** and **5** to support the previous formulations. The spectra of $[Cr(OH_2)_4$(3-formyl-ptdn)$]^{2+}$, $[Cr(OH_2)_4$(2-acetyl-btdn)$]^{2+}$, and $[Cr(OH_2)_4(ptdn)]^{2+}$ are given in Fig. 3 for comparative purposes.

Comparison of Kinetic Data With Related Systems

The kinetic parameters for reduction of $[Co(en_2)$(3-formyl-ptdn)$]^{2+}$ and related complexes by chromium(II) are collected in Table 4. Comparison of the rate of reduction of $[en_2Co(ptdn)]^{2+}$ to $[en_2Co$(3-formyl-ptdn)$]^{2+}$ and of $(NH_3)_5CoN{\equiv}C\langle\bigcirc\rangle^{3+}$ (35) to $(NH_3)_5CoN{\equiv}C\langle\bigcirc\rangle CHO^{3+}$ (36) indicates that the formyl group enhances electron transfer by a factor of approximately 10^7 M^{-1} s^{-1}. In both cases the unsubstituted complexes are probably reduced by an outer-sphere process while the substituted complexes react via inner-sphere mechanisms. For the reduction of complex **1** it appears that the chelate ring exhibits its aromatic behavior in a similar fashion to benzene in the 4-formylbenzonitrile ligand which is more reducible than the substituted chelate. Therefore, electron transfer occurs much more readily in the former complex. Also in the case of the chelate, two O—Co bonds must be stretched in the activation process prior to electron transfer whereas for the 4-formylbenzonitrile complex only stretching of the nitrogen–cobalt bond of the ligand need occur. A "remote attack" (32) mechanism has been demonstrated by product analysis in the case of the substituted chelate investigated in this work and by spectroscopic observation of the labile Cr(III) aldehyde-coordinated complex involving 4-formylbenzonitrile. In both cases the formyl group can attain planarity with the rest of the ligand and thus facilitate orbital overlap and electron transfer.

Our initial studies on reduction of the linkage isomer **2** indicate that electron transfer proceeds by a different mechanism. Changes in absorbance which occurred during electron transfer indicate that reactive intermediates are formed prior to reduction of Co(III). These changes depend upon the chromium(II) and cobalt(III) concentrations in an undetermined manner. When compared to the results obtained for reduction of **1** these differences may imply attack at the coordinated aldehyde group.[5] Studies on the reduction of **2** are in progress but are hampered by the difficulty in preparing the large quantities of complex required to ascertain the concentration dependencies of the rate and the nature of the products.

The activation parameters obtained for reduction of complex **1** are quite similar to those for reduction of $[en_2Co(O_2CCH_2NH_2)]^{2+}$ (37) where attack also occurs at the free carbonyl oxygen in an inner-sphere process. Presumably the reaction of complex **1** is slower because of the extra carbon atoms in the electron transfer path. It is known that addition of CH_2 groups in the electron transfer path causes the rate to fall sharply (38). Reduction of $[en_2Co(S(CH_3)$-

[5]It was pointed out in ref. 2 that coordinated aldehyde complexes are difficult to synthesize because the cobalt(III) oxidizes the aldehyde group. This may be a complicating factor in the electron transfer studies.

$CH_2CH_2NH_2)]^{3+}$ is an outer-sphere process and the activation parameters are different from those of the previous two complexes (8).

Complexes of 2-Mercaptobenzothiazole with Cu(II), Ni(II), Co(II), Cd(II), Zn(II), Pb(II), Ag(I), and Tl(I)

I. P. KHULLAR AND U. AGARWALA[1]

Department of Chemistry, Indian Institute of Technology, Kanpur-208016, U.P., India

Received August 21, 1974

I. P. KHULLAR and U. AGARWALA. Can. J. Chem. **53**, 1165 (1975).

The complexes of 2-mercaptobenzothiazole with Cu(II), Ni(II), Co(II), Cd(II), Zn(II), Pb(II), Tl(I), and Ag(I) have been synthesized. Their structures have been assigned on the basis of analytical, spectral (i.r. and visible), and magnetic data.

I. P. KHULLAR et U. AGARWALA. Can. J. Chem. **53**, 1165 (1975).

On a synthétisé les complexes du mercapto-2 benzothiazole avec le Cu(II), Ni(II), Co(II), Cd(II), Zn(II), Pb(II), Tl(I) et Ag (I). On leur a attribué des structures en se basant sur les données analytiques, spectrales (i.r. et visible) et magnétiques. [Traduit par le journal]

The use of 2-mercaptobenzothiazole (**1**) as an analytical reagent (1–4) and of its complexes in industry and medicine has been known for a long time (5, 6). The structures of its complexes with a few metal ions have also been investigated using various physical techniques (7–9). In our laboratory, we have for quite some time now been interested in the complexing properties of the HNCS group (10–13). We felt it worthwhile to attempt investigating the structural aspects of the complexes of **1** with metal ions like Cu(II), Ni(II), Co(II), Cd(II), Zn(II), Pb(II), and also with Ag(I) and Tl(I).

Structure of M(MBT)$_2$

Experimental

The commercially available 2-mercaptobenzothiazole (hereafter referred to as (MBTH)) was recrystallized from hot ethanol before use.

Preparation of Complexes

(i) Bis(2-mercaptobenzothiazolato(1-))copper(II), Cu(MBT)$_2$

A solution of $CuCl_2.2H_2O$ (0.9 g, ~5 mmol) in 50 ml ethanol was added to a solution of ligand (1.7 g, ~10 mmol) in about 80 ml of ethanol. A light yellow compound was immediately precipitated which was digested on a water bath for about an hour. It was cooled, centri-

fuged, washed repeatedly with hot ethanol and ether. The complex was dried in an air-oven at 120 °C.

Anal. Calcd. for $Cu(MBT)_2$: C, 42.5; H, 2.0; N, 7.1; S, 32.4; Cu, 16.1. Found: C, 42.4; H, 1.9; N, 7.2; S, 32.5; Cu, 16.3.

(ii) Bis(2-mercaptobenzothiazolato(1-))nickel(II), $Ni(MBT)_2$

A solution of $NiCl_2.6H_2O$ (1.2 g, ~5 mmol) in 50 ml ethanol was added to a solution of ligand (1.7 g, ~10 mmol) in about 80 ml ethanol neutralized with NH_4OH solution whereby a brown complex precipitated. After about an hour, the precipitate was centrifuged, washed repeatedly with ethanol and ether. It was dried overnight in an air-oven at 120 °C.

Anal. Calcd. for $Ni(MBT)_2$: C, 43.0; H, 2.0; N, 7.2; S, 32.8; Ni, 15.2. Found: C, 42.6; H, 2.0; N, 7.3; S, 32.9; Ni, 14.8.

(iii) Mono(2-mercaptobenzothiazolato(1-))mono chloro cobalt(II), Co(MBT)Cl

$CoCl_2$ (1.2 g, ~5 mmol), in a similar procedure as above (*ii*) gave a green colored complex.

Anal. Calcd. for Co(MBT)Cl: C, 32.3; H, 1.5; N, 5.3; S, 24.6; Co, 22.6. Found C, 32.4; H, 1.7; N, 4.9; S, 24.9; Co, 22.3.

(iv) Bis(2-mercaptobenzothiazolato(1-))cadmium(II), $Cd(MBT)_2$

$CdCl_2$ (0.8 g, ~2.5 mmol) in 50 ml water, in a similar procedure as above (*ii*) gave a cream colored complex.

Anal. Calcd. for $Cd(MBT)_2$: C, 38.4; H, 2.0; N, 5.4; S, 28.6; Cd, 24.7. Found: C, 37.8; H, 1.8; N, 6.3; S, 28.8; Cd, 25.2.

(v) Bis(2-mercaptobenzothiazolato(1-))zinc(II), $Zn(MBT)_2$

$ZnCl_2$ (0.35 g, ~2.5 mmol) in a procedure similar to (*iv*) gave a cream colored complex.

Anal. Calcd. for $Zn(MBT)_2$: C, 42.3; H, 2.0; N, 7.0; S, 32.3; Zn, 16.5. Found: C, 41.8; H, 1.8; N, 6.3; S, 32.5; Zn, 16.9.

(vi) Bis(2-mercaptobenzothiazolato(1-))lead(II), $Pb(MBT)_2$

$Pb(NO_3)_2$ (0.8 g, ~2.5 mmol) in a procedure similar to (*i*) gave a yellow colored complex.

Anal. Calcd. for $Pb(MBT)_2$: C, 32.3; H, 1.7; N, 5.4; Pb, 38.4. Found: C, 31.2; H, 1.5; N, 5.2; Pb, 37.9.

(vii) Mono(2-mercaptobenzothiazolato(1-))silver(I), Ag(MBT)

$AgNO_3$ (0.4 g, ~2.5 mmol) in a procedure similar to (*v*) gave a dark yellow colored complex.

Anal. Calcd. for Ag(MBT): C, 30.7; H, 1.4; N, 5.1; S, 23.4; Ag, 35.5. Found: C, 31.6; H, 1.6; N, 4.8; S, 24.0; Ag, 34.8.

(viii) Mono(2-mercaptobenzothiazolato(1-))thallium(I), Tl(MBT)

$TlNO_3$ (0.3 g, ~2.5 mmol) in a procedure similar to (*vii*) gave a yellow colored complex.

Anal. Calcd. for Tl(MBT): C, 22.7; H, 1.0; N, 3.8; S, 17.3; Tl, 55.1. Found: C, 22.7; H, 0.7; N, 4.6; S, 17.1; Tl, 54.0.

Analysis

The analyses of the metal ions and sulfur were carried out by the standard methods (14, 15). Carbon, hydrogen, and nitrogen analyses were performed by the Microanalytical Section of the Indian Institute of Technology, Kanpur, India.

Infrared Spectra

Infrared spectra of the ligand and of the complexes were recorded with a Perkin–Elmer Model 521 diffraction grating infrared spectrophotometer in the range of 4000–250 cm^{-1}. Samples were prepared as KBr discs. Major bands of the ligand and the complexes are given in Table 1.

Magnetic Susceptibility Measurements

The magnetic susceptibilities of these complexes were determined with the help of a Gouy balance. Mercury tetrathiocyanato cobaltate(II) was used as a magnetic susceptibility standard and the diamagnetic corrections were estimated by a method outlined by Figgis and Lewis (16).

Visible Spectra

The absorption spectra of the ligand and the complexes were recorded on a Beckman DU-2 spectrophotometer in Nujol mull between 250 and 1000 nm.

Results and Discussion

If one assumes that a particular ion adopts its normally preferred geometry in its complexes, the analytical results then suggest the ligand is behaving in a bidentate fashion. Before forming the complex, the ligand may exist either in the thione or in the thiol form. However, it is assumed here that in solution it is behaving as a tautomer rather than in any one particular form.

It is evident that in the ligand molecule, there are only two bonding sites: (*a*) the thiocarbonyl sulfur atom, and (*b*) the nitrogen atom. Since the lone pairs on the sulfur atom present in the skeleton of the ring are involved in the resonating structures of the molecule, it is therefore expected that it should have very weak coordinating ability (17). It is, therefore, assumed that it will not coordinate with the metal ions. As-

TABLE 1. Assignments of the major infrared bands of the ligand and the complexes (cm^{-1})

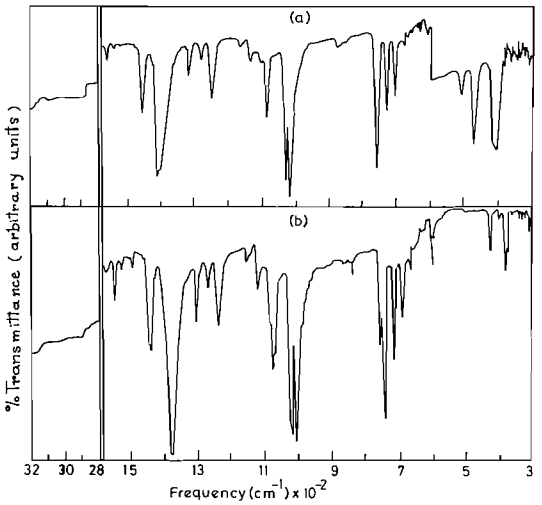

FIG. 2. Infrared spectra of (*a*) $Cu(MBT)_2$, (*b*) $Cd(MBT)_2$.

suming this there remain only two bonding sites on the ligand molecule, the ligand can therefore in some complexes behave as monodentate while in some as bidentate. In order to know the mode of bonding in the complexes, the i.r. studies of these complexes have been made.

Infrared spectra of several heterocyclic systems, in which a 5-membered ring with one or more hetero-atoms is fused to a benzene ring, have been studied and the bands around 1600, 1460, 1390, 1310, 1270, 1250, 1200, 1160, 1100, 1060, 1020, 950, 890, 850, 800, and 750 cm^{-1} have been found to be common to all the systems (18). These bands appear in the spectra of the ligand and the complexes and therefore they have been assigned to the ligand skeletal modes of vibration. Besides these bands, the bands at 3100, 1490, 1010, and 860 cm^{-1} are also present in the spectrum of the ligand. Since the ligand has one HNCS group, one should expect the bands due to N—H stretching mode, thioamide bands, **1**, **2**, **3**, **4** in the regions 3100, 1500, 1300, 1000, and 800 cm^{-1} respectively (19, 20). The bands around 3100, 1490, 1010, 860 cm^{-1} have been assigned to $\nu_{(N-H)}$, thioamide **1**, **3**, and **4** respectively. Undoubtedly the thioamide bands **1**, **3**, **4** will not be purely due to $\delta_{(N-H)}$, $\nu_{(C-N)}$, and $\nu_{(C=S)}$, but they must also be coupled with the other fundamental modes of skeletal vibrations (21). However, it is tacitly assumed that these bands arise due to contributions from $\delta_{(N-H)}$, $\nu_{(C-N)}$, and $\nu_{(C=S)}$. The major contribution from $\nu_{(C=N)}$ should be present in the band at 1318 cm^{-1}.

The direction of shifts in the positions of all the bands in the spectra of the complexes are the same. It indicates that the bonding pattern in the complexes should be similar. The major changes in the spectra of the complexes as compared to that of the ligand are as follows:

(*a*) The bands due to $\nu_{(N-H)}$ and $\delta_{(N-H)}$ are not present in the spectra of complexes. This is what one should expect if the charge balance in the complexes is to be maintained.

(*b*) The position of the band at 1320 cm^{-1} (thioamide band **2**) having major contribution from $\nu_{(C=N)}$ shifts to higher wavenumber ($\sim$1370 cm^{-1}). This shows that the bond order of C=N is increased. It indicates that metal ion is bonded to thiocarbonyl sulfur.

(*c*) The thioamide band (**4**) having major contribution from $\nu_{(C=S)}$ (22) shifts to 700 cm^{-1} region suggesting further that the metal is bonded to sulfur.

(*d*) Two new bands appear around 500 and 300 cm^{-1} in the spectra of the complexes which could be assigned to coupled vibrations having contributions from $\nu_{(M-N)}$ (23) and $\nu_{(M-S)}$ (24).

It is, therefore, concluded from the i.r. spectra (*i*) that metal ions are bonded to thiocarbonyl sulfur atom and (*ii*) that N—H group is not present. It is difficult to say from the i.r. studies if the bonding of the metal ions take place through nitrogen also. However, if in the complexes the ligand molecules take the orientation in such a way that it gives the usually preferred geometry to the metal ion, the ligand molecule should be bidentate. The only other donor atom in the ligand molecule is nitrogen. Hence it is assumed that the metal ions coordinate with the

ligand through both the thiocarbonyl sulfur and the nitrogen atom.

Magnetic and Visible Spectral Studies

The magnetic and the spectral properties of copper, cobalt, and nickel complexes were studied to understand the spatial arrangement of the ligand molecules around the metal ions. The values of magnetic moment corrected for ligand diamagnetism, the position of the electronic absorption bands, and their most probable assignments are given in Table 2.

The magnetic moment of the green cobalt complex is 4.49 B.M. Since the orbital contribution in the tetrahedral Co(II) is much less than that of the octahedral complexes, tetrahedral cobalt(II) complexes have generally lower values of magnetic moments (4.3–4.7 B.M.) (25, 26) as compared to those of octahedral complexes (4.7–5.6 B.M.) (27, 28). The value of magnetic moment (4.49 B.M.) of the complex studied lies well within the range of tetrahedral complexes. The green color of the complex also indicates the tetrahedral geometry of the complex. The electronic spectrum of cobalt(II) complex shows a band at 740 nm. The presence of this band alone cannot distinguish between the tetrahedral and the octahedral geometry. However, the absence of any band around 450 nm suggests the tetrahedral geometry of the complex (29) and therefore, the band at 740 nm is assigned to $^4A_2(F) \rightarrow {}^4T_1(P)$ transition. Thus, on the basis of i.r., magnetic moment, color, and visible spectrum polymeric structure is tentatively proposed for the cobalt(II) complex, **2**. Because of the complete insolubility of the complex in any of the common solvents, it is assumed to be polymeric.

The nickel complex $Ni(MBT)_2$ is diamagnetic. The diamagnetism is very strong indication that the spatial arrangement of the ligand molecules around the nickel ion is square planar, since the other preferred orientations should give the value of the magnetic moment corresponding to two unpaired electrons.

The electronic spectrum of the nickel complex shows four bands at 925, 790, 580, and 440 nm. The intensities of the bands at 925 and 790 nm are relatively weak compared to those at 580 and 440 nm. For the nickel complex the symmetry has been approximated as D_{4h}. For a d^8 system, one should expect in D_{4h} symmetry six bands due to d–d transitions (three singlet → triplet, $^1A_1 \rightarrow {}^3A_2$, ^3E_g, $^3B_{1g}$ and three singlet → singlet, $^1A_{1g} \rightarrow {}^1A_{2g}$, ^1E_g, $^1B_{1g}$ transition (30). Two transition from $^1A_{1g} \rightarrow {}^3B_{1g}$ and $^1B_{1g}$ generally appear in the near u.v. region which may be masked by charge transfer bands present in this region. The other bands which appear in the spectrum of the complex have been assigned as given in Table 2. From the positions of these bands ligand field parameters Δ_1, Δ_2, B, C, and β have been evaluated. These values are also given in Table 2. As expected $\Delta_1 \gg \Delta_2$ since the donor ligand causes a marked destabilization of the b_{1g} ($d_{(x^2-y^2)}$) level while b_{2g} (d_{xy}) level remains practically nonbonding. The values of B (600) and β (0.58) indicate a substantial covalency in the bonds between the ligand donor atoms and the nickel ion. The complex is highly insoluble in all the common solvents. Thus, on the basis of i.r., magnetic moment, and electronic spectral studies square planar polymeric structure is proposed for nickel complex, **3**.

The stoichiometry of the copper complex is $Cu(MBT)_2$. Simple oxidation–reduction experiments showed that in the complex copper is present in +2 oxidation state. This is one of the few copper(II) complexes in which the spin paramagnetism is completely quenched ($\mu_{eff} = 0$) at room temperature. The diamagnetism indicates that there is strong spin–spin interaction between two cupric ions. This may take place either by the formation of a σ or δ bond by the overlap of the two d-orbitals whereby spins of the electrons are paired up or by the formation of extended molecular orbitals by the extended overlap of copper and one of the two ligand donor orbitals. However, in quite a large number of diamagnetic copper(II) complexes, partial or complete quenching is explained by the superexchange mechanism. It is very difficult to decide without complete X-ray work, whether spin–spin interaction takes place because of σ or δ bond formation or by superexchange phenomenon. On the basis of copper carboxylate complexes where quenching of paramagnetism is explained by superexchange phenomenon, the authors also prefer the quenching by superexchange mechanism. This is because of the system  , where the bonding is similar to  .

The spectra of diamagnetic copper carboxylate complexes show three bands in the regions 11 000, 13 500, and 26 000 cm^{-1} (31). Harris *et al.* (32) have proposed structure for the diamagnetic copper(II) complex of diazoaminobenzene in which there is metal–metal interaction and Cu^{2+} ion has square planar geometry. The electronic spectrum of this complex shows two bands at 670 and 530 nm which are assigned to $d_{xy} \rightarrow d_{z^2}$ and $d_{xy} \rightarrow d_{x^2-y^2}$ respectively. The visible spectrum of copper(II) complex shows four bands at 960, 770, 510, and 410 nm. Assuming a square planar arrangement of the ligand molecules around copper(II) ion, the bands at 770 and 510 nm are tentatively assigned to $d_{xy} \rightarrow d_{z^2}$ and $d_{xy} \rightarrow d_{x^2-y^2}$ respectively (Table 2). Tsuchida and co-workers (33, 34) indicated that all the copper complexes in which the paramagnetism is partially or completely quenched absorb around 375 nm region. In our complex, a band at 410 nm appeared which may be a similar band as detected by Tsuchida and co-workers (33, 34). This complex is completely insoluble in all the noncoordinating solvents. Thus, the insolubility in the inorganic and organic noncoordinating solvents, stoichiometry diamagnetism, visible, and i.r. spectral data indicate square-planar polymeric structure for the copper complex, **4**.

Most of the Cd(III), Zn(II), Pb(II) complexes mentioned in the literature are tetrahedral (35). The complexes are diamagnetic, therefore, the tetrahedral arrangement of the ligand molecules around Cd(II), Zn(II) and Pb(II) are assigned to these complexes (structure **4**).

Similarly Ag(I) and Tl(I) complexes are linear. These complexes are also diamagnetic. Therefore, linear structures are proposed for these complexes, **5**.

CARLOS VON CARSTENN-LICHTERFELDE, FERNANDO M. PANIZO, TERESA G. DE QUESADA, BENJAMIN RODRÍGUEZ, SERAFIN VALVERDE, WILLIAM A. AYER, and JO-ANN H. BALL. Can. J. Chem. **53**, 1172 (1975).

The diterpenoids jativatriol (**1**) and sideritol (**2**) have been correlated by transformation of each into *ent*-17-noratis-13-en-1,16-dione (**9**). In the case of jativatriol, a simple procedure is described for transforming the *ent*-15-beyerene derivative into an *ent*-13-atisene derivative.

CARLOS VON CARSTENN-LICHTERFELDE, FERNANDO M. PANIZO, TERESA G. DE QUESADA, BENJAMIN RODRÍGUEZ, SERAFIN VALVERDE, WILLIAM A. AYER et JO-ANN H. BALL. Can. J. Chem. **53**, 1172 (1975).

On a établi une corrélation entre les diterpénoides jativatriol (**1**) et sidéritol (**2**) en les transformant chacun en *ent*-nor-17 atizène-13 dione-1,16 (**9**). Dans le cas du jativatriol, on décrit une procédure simple pour transformer le dérivé *ent*-beyérène-15 en dérivé *ent*-atizène-13.

[Traduit par le journal]

Jativatriol (**1**) (1) and sideritol (**2**) (2) are diterpenoids isolated from *Sideritis angustifolia* Lag. (family *Labiatae*). Sideritol is the first reported diterpenoid of the *ent*-atisane type which does not contain nitrogen as well as the first reported *ent*-atis-13-ene derivative. As noted previously (2) sideritol may be biogenetically related to jativatriol. Rearrangement of the latter as indicated by the arrows in **1** leads to **2**. Conceivably both compounds originate from a common intermediate arising from oxidation of the *ent*-beyer-15-ene skeleton at C-12. In this paper we describe two methods by which jativatriol has been transformed into a derivative of sideritol, confirming our previous conclusions regarding the relationship of these two compounds. In particular, this work firmly establishes the location of the secondary hydroxyl at C-1 in sideritol, a point which had previously been inferred from chemical and spectroscopic data but not directly proven.

3

The transformation of an *ent*-15-beyerene derivative to an *ent*-13-atisene derivative by reductive rearrangement of a 12-tosylhydrazone has recently been reported (3). This same procedure has now been applied to the tosylhydrazone **3** derived (see Experimental) from jativatriol (**1**). The product proved to be a mixture of C-16 epimers, *ent*-1β,17-diacetoxy-16*S*-atis-13-ene (**4**) and ent-1β,17-diacetoxy-16*R*-atis-13-ene (**5**). The stereochemistry at C-16 in these epimers was established by comparing the chemical shifts of the —CH_2OAc protons in **4** and **5** with their respective dihydro deriva-

6 R =

5 R =  ; R′ = 
7 R =

8 R =  ; R′ = 
9 R = O; R′ = O

tives **6** and **7**. The large downfield shift (0.33 p.p.m.) observed for these protons as we go from **4** to **6** indicates that in **4** the acetoxymethyl is *endo* to the double bond (4) and thus has the *ent*-16*S* configuration. In agreement with this result the observed effect (upfield shift of 0.04 p.p.m.) between **5** and **7** indicates the *ent*-16*R* configuration in **5**.

A simpler method of effecting the rearrangement of jativatriol (1) to an *ent*-13-atisene derivative has also been discovered. When a solution of jativatriol in aqueous methanolic HCl is heated under reflux for several hours the aldehyde **8** (as a mixture of C-16 epimers) is obtained in 70% yield. The n.m.r. spectrum of this mixture shows aldehydic signals at δ 9.75 and 9.35 in the ratio of 1:3. Repeated recrystallization from hexane–acetone afforded the epimer displaying the δ 9.35 signal, assigned the stereochemistry shown in **8** on the basis of the upfield shift of the aldehydic signal relative to that of the minor epimer. This assignment was confirmed by reduction ($NaBH_4$) of **8** and subsequent acetylation to give compound **4**.

Oxidative decarbonylation (5) of **8** gave a compound which without further characterization was oxidized with Jones' reagent to the diketone **9**. Oxidation of sideritol (**2**) with excess Jones' reagent gave, in high yield, the same diketone (**9**), thus completing the correlation of the two series and firmly establishing the location of an oxygen function at C-1 in sideritol.

Experimental

Solutions were dried over anhydrous sodium sulfate. Melting points were determined in a Kofler apparatus and are uncorrected. The optical rotations were measured with a Perkin Elmer 141 polarimeter with 1-dm cells. Infrared spectra were recorded on a Perkin Elmer Model 257 spectrometer. Nuclear magnetic resonance spectra were measured using a Perkin Elmer Model R-12 spectrometer or a Varian XL-100 spectrometer in $CDCl_3$ solution and with tetramethylsilane as internal standard and are quoted as δ (number of protons, description of signal assignment). Elementary analyses were carried out in the Instituto de Química Orgánica, Madrid, with the aid of an automatic analyser. Silica gel Merck (60 PF_{254}) was used for preparative layer chromatography.

Preparation of ent-1β,17-Diacetoxy-15-beyeren-12-tosylhydrazone (3)

To a solution of jativatriol-1-monoacetate (1 g), obtained from jativatriol triacetate as described in ref. 1, in anhydrous pyridine (5 ml) was added acetic anhydride (5 ml). The solution was allowed to stand 30 min at 0° and then poured into water and extracted with chloroform. The chloroform layer was dried, filtered, and evaporated leaving a residue which on t.l.c. shows two components. The less polar of these corresponded to jativatriol triacetate, while the other, isolated by preparative t.l.c. (eluent benzene – ethyl acetate 1:1), is a mixture (700 mg) of 1,17- and 1,12-jativatriol diacetates (4:3 ratio according to n.m.r. data). This mixture was dissolved in acetone (20 ml) and mixed with Jones' reagent (1.5 ml). The oxidation was allowed to proceed for 2 h at room temperature. Two products were obtained and these were separated by preparative t.l.c. (eluent benzene – ethyl acetate 3:2):

ent-1β,17-Diacetoxy-15-beyeren-12-one (380 mg): m.p. 145–147° (from aqueous EtOH); $[\alpha]_D^{22}$ −238.1° (*c* 0.44, $CHCl_3$); i.r. (KBr) cm^{-1}: 3080 (olefinic CH); 2980, 2970, 2940, 2920, 2860 (CH stretching vibrations); 1735 (ester); 1710 (ketone); 1235 (C—O of ester); 761 (*cis*-1,2-disubstituted olefin); n.m.r. (δ): 5.91 (2H, AB quartet, *J* 6 Hz, olefinic H-15 and H-16), 4.47 (1H, multiplet, $w_{1/2}$ 18 Hz, axial H-1), 4.19 (2H, AB quartet, *J* 11.3 Hz, H-17), 2.02 and 2.00 (3H each, singlets, two —$OCOCH_3$), C—Me singlets at 0.94, 0.91, and 0.87.

To a solution of the above ketone (300 mg) in absolute ethanol (4 ml) was added tosylhydrazide (167 mg). The solution was then heated under reflux for 10 h. A crystalline precipitate appears on cooling. Crystallization from aqueous ethanol affords pure **3** (360 mg), m.p. 164–167°; $[\alpha]_D^{22}$ −112.3° (*c* 0.52, $CHCl_3$); i.r. (KBr) cm^{-1}: 3110 (—NH—); 3060, 3030, 1600, 758, 738, 685 (aromatic and olefinic); 1720, 1240 (—OAc); 1623 (>C=N—); 1165 (—Ts); n.m.r. (δ): 7.55 (4H, A_2B_2 system, *J* 8.6 Hz, aromatic protons), 5.78 (2H, AB quartet, *J* 6 Hz, olefinic H-15 and H-16), 4.42 (1H, multiplet, $w_{1/2}$ 18 Hz, axial H-1), 4.24 (2H, AB quartet, *J* 12 Hz, H-17), 2.42 (3H, singlet, CH_3—Ph), 2.19 and 1.98 (3H each, singlets, —$OCOCH_3$ on C-17 and C-1 respectively), C—Me singlets at 0.90, 0.86, and 0.85.

Anal. Calcd. for $C_{31}H_{42}O_6N_2S$: C, 65.24; H, 7.42; N, 4.91; S, 5.60. Found: C, 65.41; H, 7.35; N, 4.82; S, 5.71.

$NaBH_4$ Reduction of 3: Compounds 4 and 5

Sodium borohydride (200 mg) was slowly added to a solution of **3** (350 mg) in a 1:1 (v/v) mixture of dioxane – absolute ethanol (10 ml). The solution was then allowed to stir at room temperature for 4 h, diluted with water, and extracted with chloroform. The residue obtained by evaporation of the solvent was then separated into two components by preparative t.l.c. (eluent benzene – ethyl acetate 85:15).

ent-1β,17-Diacetoxy-16*S*-atis-13-ene (**4**): Less polar component, crystallizes from MeOH (133 mg), m.p. 123–125°; $[\alpha]_D^{20}$ +7.3° (*c* 0.72, $CHCl_3$); i.r. (KBr) cm^{-1}: 3040, 3000, 2960, 2930, 2880, 2855, 1728, 1250, 725, 710; n.m.r. (δ): 5.98 (2H, multiplet, olefinic H-13 and H-14), 4.60 (1H, apparent doublet of doublets, axial H-1), 3.61 (2H, doublet, *J* 7.3 Hz, H-17), 2.42 (1H, multiplet, $w_{1/2}$ 12 Hz, allylic H-12), 2.01 and 1.99 (3H each, singlets, two —$OCOCH_3$), C—Me singlets at 0.88, 0.83, and 0.76.

Anal. Calcd. for $C_{24}H_{36}O_4$: C, 74.19; H, 9.34. Found: C, 74.11; H, 9.41.

ent-1β,17-Diacetoxy-16*R*-atis-13-ene (**5**), more polar component, thick oil (49 mg): $[\alpha]_D^{20}$ +30.7° (*c* 0.26, $CHCl_3$); i.r. (NaCl) cm^{-1}: 3030, 2950, 2855, 1740, 1243, 720; n.m.r. (δ): 6.09 (2H, multiplet, olefinic H-13 and H-14), 4.55 (1H, apparent doublet of doublets, axial H-1), 3.99 (2H, octet, J_{gem} 10.6 Hz, J_{vic} 6.6 Hz, H-17), 2.37 (1H, multiplet, $w_{1/2}$ 12 Hz, allylic H-12), 2.04 and 1.99 (3H each, singlets, two —$OCOCH_3$), C—Me singlets at 0.87, 0.83, and 0.78.

ent-1β,17-Diacetoxy-16S-atisane (6)

A solution of compound **4** (100 mg) in EtOH (20 ml) was hydrogenated at room temperature and atmospheric pressure over Pd/C (10%) for 16 h. Filtration and evaporation of the solvent leaves a residue (**6**; 100 mg) which crystallizes from aqueous EtOH, m.p. 99–101°; $[\alpha]_D^{20}$ −45.8° (*c* 0.58, $CHCl_3$); i.r. (KBr) cm^{-1}: 2990, 2950, 2900, 2880, 2855, 1735, 1723, 1250, 1220; n.m.r. (δ): 4.60 (1H, apparent doublet of doublets, axial H-1), 3.94 (2H, doublet, *J* 7.6 Hz, H-17), 2.02 and 1.99 (3H each, singlets, two —$OCOCH_3$), C—Me singlets at 1.11 (3H, H-20) and 0.85 (6H, two Me on C-4).

Anal. Calcd. for $C_{24}H_{38}O_4$: C, 73.80; H, 9.81. Found: C, 73.65; H, 9.80.

ent-1β,17-Diacetoxy-16R-atisane (7)

Compound **5** (40 mg) was hydrogenated in the same manner as described for **4** to give **7** (40 mg): m.p. 98–100° (aqueous EtOH): $[\alpha]_D^{20}$ +1.7° (*c* 0.46, $CHCl_3$); i.r. (KBr) cm^{-1}: 2990, 2965, 2920, 2860, 1750, 1245; n.m.r. (δ): 4.55 (1H, apparent doublet of doublets, axial H-1), 3.95 (2H, doublet, *J* 7.5 Hz, H-17), 2.03 and 2.00 (3H each, singlets, two —$OCOCH_3$), C—Me singlets at 1.11 (3H, H-20), and 0.84 (6H, two Me on C-4).

Anal. Calcd. for $C_{24}H_{38}O_4$: C, 73.80; H, 9.81. Found: C, 73.91; H, 9.68.

Rearrangement of Jativatriol (1) into ent-1β-Hydroxy-16S-atis-13-en-17-al (8)

To a solution of jativatriol (**1**, 400 mg) in absolute MeOH (10 ml), concentrated HCl was added (1.1 ml). The solution was heated under reflux for 7 h, cooled, diluted with water, and extracted with $CHCl_3$. The residue obtained by evaporation of the solvent is a complex mixture from which the main product (280 mg) can be separated by preparative t.l.c. (eluent benzene–ethyl acetate 4:1). Repeated crystallization of the major fraction from *n*-hexane affords pure **8**, m.p. 121–123°; $[\alpha]_D^{22}$ +14° (*c* 0.8, $CHCl_3$); i.r. (Nujol) cm^{-1}: 3535 (—OH); 3065, 3030, 720, 700 (olefin); 2760, 2730, 1716 (—CHO); n.m.r. (δ): 9.35 (1H, doublet, *J* 2 Hz, —*CH*O), 5.96 and 5.92 (1H each, doublet, *J* 4 Hz, H-13 and H-14 olefinic protons), 3.25 (1H, quartet, $J_{aa'}$ 9 Hz, $J_{ae'}$ 5 Hz, axial H-1), 2.86 (1H, multiplet, $w_{1/2}$ 12 Hz, allylic H-12), 2.54 (1H, multiplet, $w_{1/2}$ 20 Hz, H-16), C—Me singlets at 0.86, 0.80, and 0.66. Double resonance shows that the aldehyde proton (9.35 δ) is coupled to a complex signal at δ 2.54. Similarly the olefinic signal appears as a singlet when the allylic proton (δ 2.86) is irradiated. This last proton appears as a quartet (*J* 3.5 Hz) when the olefinic signal is irradiated.

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00. Found: C, 79.55; H, 9.93.

The n.m.r. spectrum of the major fraction before crystallization shows aldehydic signals at 9.75 and 9.35 δ (1:3 ratio). The signal at 9.75 indicates the presence of the *ent*-16*R* isomer in this mixture. These isomers are not distinguished by t.l.c.

Preparation of 4 from 8

An ethanolic solution of compound **8** (50 mg) was reduced with $NaBH_4$ in the usual manner. The crude reduction product was acetylated (Py/Ac_2O) at room temperature to give compound **4**, identical (m.p., m.m.p., i.r., n.m.r., and $[\alpha]_D$) with that described above.

Preparation of ent-17-Noratis-13-en-1,16-dione (9) from 8

To a solution of **8** (47 mg) in DMF (15 ml) was added 1,5-diazabicyclo[4.3.0]non-5-ene (1.5 ml) and cupric acetate – 2,2′-bipyridyl complex (1:1; 9 mg). The solution was heated to 40° and dry air bubbled through the solution for 20 h. The reaction mixture was then diluted with water and extracted with ethyl ether. The residue obtained by evaporation of the ether is predominantly a single product (t.l.c.). This residue was oxidized by the Jones' method and the major component

(**9**) was separated by preparative t.l.c. Compound **9** (20 mg) crystallizes from aqueous EtOH, m.p. 137–138°; $[\alpha]_D^{22}$ +160° (*c* 0.38, $CHCl_3$); i.r. (KBr) cm^{-1}: 3050, 740 (olefin); 3000, 2960, 2860, 1720, 1710 (ketones); n.m.r. (δ): 6.15 (2H, multiplet, H-13 and H-14 olefinic protons), 3.07 (1H, multiplet, $w_{1/2}$ 9 Hz, allylic H-12), C—Me singlets at 1.07, 1.01, and 0.98; mass spectrum *m/e* (% of base peak): 286 (8, calcd. for $C_{19}H_{26}O_2$: 286.1933; found: 286.1944), 244 (36), 139 (100), 91 (35), 41 (34).

Anal. Calcd. for $C_{19}H_{26}O_2$: C, 79.68; H, 9.15. Found: C, 79.48; H. 9.03.

*Preparation of **9** from Sideritol (**2**)*

An acetone solution of compound **2** (70 mg) was oxidized with excess Jones' reagent for 12 h. A single product was obtained (61 mg) identical in all respects with compound **9** prepared from jativatriol.

ARNOLD JARCZEWSKI, PRZEMYSLAW PRUSZYNSKI, and KENNETH T. LEFFEK. Can. J. Chem. **53**, 1176 (1975).

The second-order rate constants, activation parameters, and primary deuterium isotope effects are reported for the proton transfer reaction from di-(4-nitrophenyl)methane to *t*-butoxide ion in a series of solvents containing varying amounts of toluene in *t*-butyl alcohol. Increasing toluene content in the solvent decreases the rate constant and increases the enthalpy of activation, while the entropy of activation becomes less negative. The isotope rate ratio k_H/k_D increases from 7.3 in 10% v/v toluene to 9.4 in 50% v/v toluene at 25 °C, corresponding to a change in $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})$ from 0.46 to 1.0 kcal mol^{-1} and a change in $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$ from −2.4 to −1.1 cal mol^{-1} deg^{-1}. It is suggested that the negative values for $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$ are due to a time lag for solvent reorganization relative to the proton transfer.

ARNOLD JARCZEWSKI, PRZEMYSLAW PRUSZYNSKI et KENNETH T. LEFFEK. Can. J. Chem. **53**, 1176 (1975).

On rapporte les constantes de vitesse du second ordre, les paramètres d'activation et les effets isotopiques primaires du deuterium pour le transfert de proton lors de la réaction du di-(nitro-4 phényl)méthane avec l'ion *t*-butylate dans une série de solvants contenant des quantités variables de toluène dans l'alcool *t*-butylique. L'augmentation du contenu en toluène dans le solvant diminue la vitesse de réaction et augmente l'enthalpie d'activation alors que l'entropie d'activation devient moins négative. A 25 °C, le rapport des vitesses k_H/k_D augmente de 7.3 lorsque l'on a 10% v/v de toluène à 9.4 lorsque l'on a 50% v/v de toluène; cette variation correspond à un changement dans le $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})$ de 0.46 à 1.0 kcal mol^{-1} et un changement dans $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$ de −2.4 à −1.1 cal mol^{-1} deg^{-1}. On suggère que les valeurs négatives pour $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$ sont principalement dues à un retard dans la réorganisation du solvant par rapport à la vitesse du transfert du proton. [Traduit par le journal]

Introduction

The reaction of di-(4-nitrophenyl)methane with alkoxide bases is the proton transfer equilibrium (1–3) shown in eq. 1. The violet color

[1] $(NO_2C_6H_4)_2CH_2 + {}^-OAlK \underset{k_2}{\rightleftharpoons} [(NO_2C_6H_4)_2CH]^- + HOAlK$

due to the anion of the substrate is stable and indicates a molar absorptivity of about 12 000 l mol^{-1} cm^{-1} in the region 510–520 nm.

The previous paper in this series (3) dealt with the primary deuterium isotope effect for the reaction with *t*-butoxide in *t*-butyl alcohol containing 10% v/v toluene. The rate ratio of 7.33 at 25 °C was found to contain an entropy of activation component, $\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger}$, of −2.4 cal mol^{-1} deg^{-1}, corresponding to A_D/A_H = 0.29, which falls well outside the standard zero-point energy approximation theory of isotope effects. Almost simultaneously with this work, Caldin and Mateo (4) discovered large isotope effects for proton transfers from carbon acids to nitrogen bases when the reactions were carried out in toluene solvent.

In this paper, we have investigated the effect of increasing the toluene content of the solvent on the isotope effects in the *t*-butoxide reaction to see whether the Caldin and Mateo phenomenon extends to this type of base and also to test the

hypothesis proposed by Kim and Leffek (3) that the abnormal entropy contribution to the isotope effect is related to solvent composition.

Results and Discussion

Reaction Rates and Activation Parameters

Pseudo first-order rate constants for the reaction of di-(4-nitrophenyl)methane and its deuterated analog with *t*-butoxide were measured as described previously (1), using a substrate concentration of 5×10^{-5} *M* and base concentrations varying between 2.9×10^{-3} and 1.4×10^{-1} *M*. The second-order rate constants, shown in Table 1, were calculated from the slope of the plots of k_1 *vs.* *t*-butoxide concentration.

The activation parameters calculated from the second-order rate constants in Table 1 are presented in Table 2.

It may be seen that the rate constants and activation parameters in solvents containing 20, 50 and 80% v/v toluene in *t*-butyl alcohol form a series with the results in 10% v/v toluene – *t*-butyl alcohol reported earlier (3), in which the changes in these reaction characteristics are smooth. The rate constants decrease as the toluene content of the solvent is increased and are very small for solvents above 80% toluene. This result is opposite to that which we observed for the same reaction in acetonitrile – *t*-butyl alcohol mixtures (3). The second-order rate constant at 25 °C in 50% v/v acetonitrile in *t*-butyl alcohol is almost exactly 100 times faster than that in 50% toluene in *t*-butyl alcohol. However, a change from 50 to 80% acetonitrile increases the rate by a factor of 3, whereas a change from 50 to 80% toluene decreases the rate by a factor of 8. As noted previously (3), the acetonitrile results conform to the Miller–Parker solvation theory (5). The *t*-butoxide ion is a stronger proton abstractor in acetonitrile-rich solvents. If this is true for acetonitrile–alcohol mixtures, and there is a very wide range of rate measurements which support the Miller–Parker theory, it should also be true for toluene–alcohol mixtures and the rates should change in the same way.

We believe that the reason for the observed

*From ref. 2.

decrease in rate with increase in toluene content arises from a second factor, the incomplete dissociation of sodium *t*-butoxide ion pairs. The fraction of sodium *t*-butoxide present as ion pairs must be much greater in toluene – *t*-butyl alcohol mixtures than in acetonitrile – *t*-butyl alcohol mixtures and the increase in the proportion of ion pairs as the toluene content is increased must override the general solvation effect.

An additional factor is that some proton transfer reactions in alcohol solution are known (6, 7) to involve solvent molecules directly in the transfer. If such a mechanism were operating, an increase in the toluene content of the solvent would make the process less favorable and result in a decrease in the rate. Our measurements do not allow a judgement as to whether this mechanism of proton transfer is present, but if it is, its importance cannot be great since the acetonitrile–alcohol mixtures show an opposite rate change. This conclusion is consistent with other work on carbon acid systems (8, 9).

Although the rate changes (*i.e.* free energy changes) for the toluene – *t*-butyl alcohol solvents are opposite to those found for the acetonitrile – *t*-butyl alcohol solvents, the enthalpy and entropy of activation changes are in the same direction. This situation is brought about by the circumstance that in both solvent systems the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ changes are opposed to each other. In going from 50 to 80% toluene in *t*-butyl alcohol the increase in enthalpy outweighs the decrease in the negative entropy by 1.6 kcal mol^{-1} at 300 K, whereas for the same percentage change in the acetonitrile system, the opposite is true by 0.8 kcal mol^{-1} at 300 K.

The changes are accounted for qualitatively by our postulate previously made (3) that the energy required to break one alcohol–alkoxide hydrogen bond would be offset by the formation of a new alcohol–alcohol hydrogen bond and that it would require less energy to break out one alcohol molecule from the solvation shell if the solvent molecule immediately adjacent to it in the next solvent layer is another alcohol molecule. Hence, increase in toluene content increases the activation energy.

Isotope Effects

The isotope effects on the rate constants and activation parameters are summarized in Table 3. The two solvents studied in this work form a series with the 10% v/v toluene – *t*-butyl alcohol solvent reported earlier (2) and the isotope effects are seen to change smoothly with solvent composition, giving larger rate ratios the greater the toluene content. These rate ratios are roughly comparable to those found by Caldin and Mateo (4) for the proton transfer from 4-nitrophenylnitromethane to triethylamine and tri-*n*-butylamine in pure toluene, but very much less than the k_H/k_D of 45 which these authors reported for the same reaction with the base tetramethylguanidine.

The results of Tables 2 and 3 provide additional examples of entropy isotope effects, ($\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger}$), which are negative and correspond to frequency factor ratios, A_D/A_H, of less than unity. The direction of this effect is unusual, although a few have been previously reported (10, 11). We pointed out earlier (3) that the −2.4 cal mol^{-1} deg^{-1} value in 10% toluene – *t*-butyl alcohol could not be explained on standard isotope effect theory which ignores the solvent and postulated that a solvation effect

might be involved. The entropy effects for the other two mixed solvents confirm the experimental validity of our earlier result, in that these measurements were carried out in a different laboratory with different equipment and chemical sources. They also confirm that the phenomenon is a function of solvent composition. Statistically, the results of Table 3 do not prove that the isotope effect on the entropy of activation is different in the three solvents, within a 68% confidence limit. Nevertheless, we believe this to be true, taking into account the fact that the number of measurements made is really too small for reliable statistical analysis. However, all three entropy isotope effects are negative within a 68% confidence limit or better.

In 50% v/v toluene – *t*-butyl alcohol, the isotope effects on the activation parameters fit the zero-point energy approximation for the loss of a C—H or C—D stretching vibration very well but in 10% toluene the results cannot be fitted to the theory at all. Caldin and Mateo (4) have postulated that any solvation changes accompanying proton transfer involving rotation of the solvent molecules will increase the effective mass of the proton and hence reduce the apparent effects of proton tunnelling, *i.e.* reduce k_H/k_D and A_D/A_H. However, A_D/A_H would not be expected to be reduced below a value of one by this mechanism.

The primary kinetic isotope effect gives us a probe to look at the reaction at the site of the proton transfer, in contrast to simply measuring the effect of solvent change on the activation parameters of the normal substrate molecule which include effects arising not only from the substrate molecule itself but also from a quite extensive solvent environment. From the latter type of measurements, we concluded (1) that a large part of the activation parameters seemed to arise from solvation changes in going from the initial to the transition state. Now the isotope effects show that some of this solvation change is very closely associated with the proton transfer site. While the change from C—H to C—D bond breaking cannot change the general characteristics of the solvation shell very far from this site, nevertheless $\Delta S_D^{\ddagger}$ is significantly more negative than $\Delta S_H^{\ddagger}$.

Bell suggested (12) that a time lag between the proton transfer and the reorientation of the solvent molecules could influence the size of the isotope effect. Since the proton is transferred faster than the deuteron, this effect would be larger for proton transfer and would lead to a decrease in k_H/k_D. Caldin (13) developed this idea for proton transfers involving a negative entropy of activation, which is largely controlled by the orientation of solvent molecules. In this case, the solvent molecules are held more extensively in the transition state relative to the initial state and the lag will give a positive contribution to $\Delta S^{\ddagger}$ which will be larger for $\Delta S_H^{\ddagger}$ than for $\Delta S_D^{\ddagger}$. Thus, $\Delta S_D^{\ddagger}$ will be more negative than $\Delta S_H^{\ddagger}$.

Our isotope effects fit the above postulate of Caldin in that solvent lag would be expected to be greater in the more polar solvent of 10% v/v toluene in *t*-butyl alcohol than in the 50% v/v toluene in *t*-butyl alcohol. We observe the largest negative value for $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$ in the more polar solvent and this parameter becomes less negative as the polarity of the solvent is decreased by the addition of toluene. It must be noted, however, that the $\Delta S_H^{\ddagger}$ values themselves are more negative in the more polar solvent and thus do not demonstrate overtly the positive contribution to $\Delta S_H^{\ddagger}$ from solvent lag. Nevertheless, entropies of activation are complex quantities and it is quite possible that the solvent lag effect is masked in the entropy of activation by some other factor which cancels in the isotope effect, $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$. This other factor may be the incomplete dissociation of sodium *t*-butoxide ion pairs.

Experimental

Materials

Di-(4-nitrophenyl)methane was prepared as described previously (1). Deuterated material was prepared from this by exchange with $NaOCH_3$–CH_3OD (3). The exchange process was carried out four times and yielded material 99% isotopically pure according to the n.m.r. spectrum.

Toluene was commercial reagent grade purified by the Walden method (14), with sodium and fractional distillation in the range 110.5 to 111.0 °C. The distillate was protected against moisture and CO_2.

Reagent grade *t*-butyl alcohol was dried over CaO, distilled from sodium metal, and then fractionally distilled at 82.4 °C. The distillate was protected from moisture and CO_2 and stored under dry O_2-free nitrogen.

Kinetic Measurements

Sodium *t*-butoxide was made by dissolving clean sodium metal in a mixture of *t*-butyl alcohol and a small amount of toluene in a flask previously flushed with nitrogen. After the sodium had dissolved, toluene was

added to bring the solvent to the required composition. The concentration of sodium *t*-butoxide was checked by titration with standard HCl using methyl orange indicator.

The proton transfer reaction was followed on a Specord UV-Vis spectrophotometer (Carl-Zeiss Jena) by scanning at a fixed wavelength in the region of 510–520 nm. The reaction cells were maintained at a constant temperature to within ± 0.1 °C. The first-order rate constants were calculated from the absorbance values by the Guggenheim method (15). The second-order rate constants were calculated from the k_1 *vs.* base concentration plots by the method of least squares using an ODRA 204 computer. Example runs have been given in an earlier publication (1).

Received October 28, 1974

ALLAN B. ANDERSON, ROBERT MCCRINDLE, and JAMES K. TURNBULL. Can. J. Chem. **53**, 1181 (1975).

Incubation of 17-norkauran-16-one (**3***b*) and *ent*-17-norkauran-16-one (**2***b*) with *Aspergillus niger* gives the related C-3 equatorial alcohols **3***c* and **2***c*, respectively, whereas 17-norphyllocladan-16-one (**4***b*) gives the 3β-alcohol **4***c* and the corresponding 3-ketone **4***g*. Yields of all of these products are low. Diketone **4***g* is identical with the corresponding compound derived from calliterpenone, thus confirming that calliterpenone should be formulated as **8** rather than **7**.

ALLAN B. ANDERSON, ROBERT MCCRINDLE et JAMES K. TURNBULL. Can. J. Chem. **53**, 1181 (1975).

Les incubations de la nor-17 kauranone-16 (**3***b*) et de l'*ent*-nor-17 kauranone-16 (**2***b*) avec l'*Aspergillus niger* conduisent respectivement aux alcools équatoriaux en position 3 (**3***c* et **2***c*) alors que la nor-17 phyllocladanone-16 (**4***b*) conduit à l'alcool 3β (**4***c*) et au dérivé céto-3 correspondant (**4***g*). Les rendements de tous ces produits sont bas. La dicétone **4***g* est identique avec le composé correspondant obtenu à partir de la calliterpénone; ceci confirme donc que la calliterpénone doit être représentée par la formule **8** plutôt que **7**. [Traduit par le journal]

The gibberellins (2) have attracted a large portion of diterpenoid research mainly because of their influence on the growth and development of plants. All known gibberellins are thought to have the gibbane skeleton (**1**) and to be biosynthesized in plants via *ent*-16-kaurene (**2***a*) or a derivative of this diterpene. Other tetracyclic diterpenes, such as kaurene (**3***a*) and phyllocladene (13β-kaurene; **4***a*) occur (3) naturally and we have been seeking evidence for the occurrence of gibberellin-like compounds derived from these. A study of the gibberellins in plants which produce **3***a* or **4***a* would be an obvious approach in this quest. However, since fresh tissue of such plants has not been obtainable by us[3] in sufficient quantity we have undertaken a less direct attack.

This approach was suggested by observations (6) that although *ent*-kaurene itself has little gibberellin activity, various oxygenated derivatives, all of which contain the ring D *exo*-methylene group, do exhibit significant physiological effects. We planned to submit analogous kaurene and phyllocladene derivatives for testing in bioassays that are specific for gibberellins but since such compounds were not available, synthetic routes from the parent hydrocarbons (**3***a* and **4***a*) were sought. The present paper deals with an investigation of microbial oxygenation as a means of producing the desired derivatives.

Initially, microbial hydroxylation of the more available *ent*-kaurene system was studied as a model. The norketone **2***b* was chosen as a suitable substrate for two reasons. First, carbonyl containing compounds have been successfully used (7, 8) in related steroidal work and second, the C-17 methylene group could be readily reattached by the Wittig reaction. Thus, the norketone **2***b* was incubated with submerged cultures of 13 fungal species (see Experimental) in small scale trial experiments. Transformations of the substrate were detected by t.l.c. com-

parison of the culture extracts of each organism grown in the presence and absence of **2***b*. Five of these fungi, *Calonectria decora*, *Rhyzopus nigricans*, *Fusarium moniliforme*, *Coprinus lagopus*, and *Aspergillus niger*,[4] appeared to effect transformations of **2***b*. Further small scale screening incubations were then carried out with these five fungi using **3***b* and **4***b* as substrates. *Aspergillus niger* was the only organism for which there was clear t.l.c. evidence for the production of derivatives from both of these norketones. On this basis *A. niger* was selected for large scale investigation with **2***b*, **3***b*, and **4***b*.

ent-17-Norkauran-16-one

The ketone (**2***b*, ref. 10) was added in DMF to a submerged culture of *A. niger* (ATCC 26693[5]) which had been growing for 3 days in a full nutrient medium (11) under aerobic conditions. After 5 days the mycelia and aqueous medium were extracted with ethyl acetate. Column chromatography of the extract over silica gel afforded a large fraction of the substrate (**2***b*) and a minor amount of a more polar compound, m.p. 179–181°, which was recognized as a norkauranone from its n.m.r., i.r., and mass spectra. In addition, the n.m.r. spectrum indicated that this transformation product (**2***c*) had resulted from the introduction of a secondary hydroxyl group into **2***b*. The multiplicity of the resonance arising from the carbinol proton (dd, $W_{1/2} = 16$ Hz) revealed the equatorial nature of the hydroxyl group and the presence of only two vicinal protons. This eliminated all but three possible structures for the compound, namely, an *ent*-17-norkauran-16-one with an equatorial (α) hydroxyl group substituted at C-1, C-3, or C-7. A decision in favor of the second of these possibilities was readily made as follows. The hydroxy-*ent*-16-kaurene **2***d*, which was required for biological testing in any case, was prepared from the norketone **2***c* via the acetates **2***e* and **2***f* and its n.m.r. spectrum was recorded in the presence of $Eu(dpm)_3$. The induced shifts of the methyl resonances were in the normalized (12) ratio of 10.0:9.4:4.1 (3 H-19, 3 H-18, and 3 H-20, respectively) which is consistent (13) only with a 3α-hydroxy group. Further, oxidation of **2***d* afforded the corresponding ketone (**2***g*) which gave benzene-induced methyl shifts of the magnitude predicted (14) for a C-3 ketone with ring A in the expected (15) flattened chair conformation. Final confirmation of these structural assignments came from the fact that **2***c*, **2***d*, and **2***e* have identical physical and spectral characteristics with those prepared (16, 17) from diterpenoids of natural provenance.

[4]A group at the University of Western Australia are also studying (9) the metabolism of *ent*-kauranoids by fungi. We thank Professor P. R. Jefferies for discussions of unpublished results.

17-Norkauran-16-one

When the ketone **3***b* was incubated with *A. niger* (ATCC 26693) in a manner similar to that described above for its enantiomer an analogous product mixture was obtained. Much substrate was again recovered along with a small quantity of the related C-3 equatorial alcohol (**3***c*). The latter was characterized as the derived acetate **3***d* and alcohol **3***e* both of which are identical, except in sign of optical rotation, with the corresponding compounds in the *ent*-series (see above).

17-Norphyllocladan-16-one

When norphyllocladanone (**4***b*, ref. 10) was incubated as above with *A. niger*, (ATCC 26693) small amounts of two transformation products were isolated. The major, more polar, product (**4***c*), m.p. 158–160°, was readily formulated as a keto alcohol on the basis of its spectral properties and those of the corresponding acetate (**4***d*), m.p. 156–158°. The multiplicity of the carbinol proton again indicated that it is axial and only coupled to two protons and thus the hydroxyl group must be β-orientated and located at C-1, C-3, or C-7. The eventual assignment of structure **4***c* to the compound rests on the magnitude of the shifts induced by $Eu(dpm)_3$ on the methyl resonances of **5** and **4***e*. The former was produced in our initial attempt to prepare the latter. In this case solutions of phenyl lithium and methyltriphenylphosphine bromide in ether were mixed and then after 10 min at 20° the keto acetate **4***d* was added in the same solvent and the resulting mixture heated to reflux for 2 days. Work-up gave, rather than the desired acetoxy olefin (**4***f*), the unstable diol **6** which was smoothly transformed into the styrene **5** by treatment with toluene-*p*-sulfonic acid in benzene. When the Wittig reaction was repeated, but this time the phenyl lithium – methyltriphenylphosphine bromide solution was heated for 3 h before addition of **4***d*, the expected product **4***f* was formed. The $Eu(dpm)_3$ induced shifts of the methyl resonances in **5** and **4***e* are in the normalized ratios of 10.0:9.3:3.4 and 10.0:9.4:3.9, respectively, values entirely consistent for 3 H-19, 3 H-18, and 3 H-20 in the presence of a 3β-hydroxyl function.

The less polar transformation product, **4***g*, m.p. 187–189°, shows no absorption in the i.r. attributable to OH stretching but gives two strong peaks in the carbonyl region at 1712 and 1749 cm^{-1}. $Eu(dpm)_3$ shifted n.m.r. spectra of this compound suggested the structure **4***g*, a formulation which was readily confirmed by its preparation from **4***c* by oxidation with Jones' reagent.

This investigation provided us not only with **4***e* for biological testing but also with the means of resolving the controversy concerning the structure of calliterpenone. This constituent of *Callicarpa macrophylla* was originally formulated (18) as a substituted kaurane (**7**), an assignment which was subsequently challenged (19). This second group proposed, on much firmer evidence, an alternative structure **8**, based on the phyllocladane skeleton. That the latter assignment is indeed correct was shown by a direct comparison of the diketone **4***g*, prepared in this study, with the corresponding compound[6] derived (19) from calliterpenone. The two samples are identical.

Mechanism

Recently there has been considerable interest in the nature of the interaction between hydroxylating organisms and their substrates during microbial oxidation. Several groups (for leading examples see ref. 8) have pointed out that a knowledge of such interactions for a given organism might allow prediction of the position(s) of oxygenation in any substrate. The oxidations reported in this paper have several notable features relevant to such studies.

It is striking that *A. niger* inserts oxygen only equatorially at C-3 in the three norditerpenoids tested even although these include a pair of enantiomers. Previous studies (20), using other organisms, have shown that the pattern of oxi-

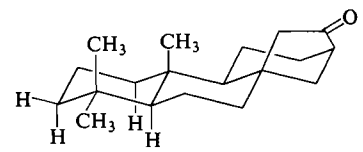
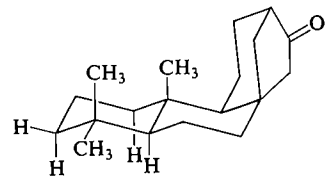
dation of enantiomeric substrates is often different. It has been proposed (8) that polar functional groups such as carbonyls can interact with hydroxylating enzymes in such a way that the site of oxygenation of the substrate bears a fixed geometrical relationship to the carbonyl or other directing group. Certainly the presence of the C-16 carbonyl group in **2***b*, **3***b*, and **4***b* does facilitate hydroxylation with *A. niger*, **2***a* and **4***a* giving no detectable transformation products (see Experimental). Since in each case a reasonable amount of unreacted substrate was recovered from the *filtered* medium it seems likely that **2***a* and **4***a* were present in a physical state suitable for utilization by the organism. It is possible that substrates must contain a polar function to allow their transport through the cellular membrane to a site for hydroxylation within the cell. However, the allylic hydroxylation by *A. niger* of a wide variety of nonoxygenated olefins (21) has been reported and this presumably requires that they diffuse into the cell. Thus, it would appear that the most likely explanation for the absence of oxidation of **2***a* and **4***a* is that the enzymes responsible for remote hydroxylation can react only with substrates which contain a ketone[7] or other polar function.

If the same *A. niger* enzyme is involved in the hydroxylation of **2***b*, **3***b*, and **4***b* then the following model for the role played by the enzyme is attractive in terms of both simplicity and plausibility. First, the hydroxylase "locks on" to the oxygen function at C-16 and then interacts with the flat underside (as drawn in Scheme 1) of **2***b*, **3***b*, and **4***b*. The equatorial proton at C-3 is then singled out for attack. Possibly the enzyme "recognizes" the three axial hydrogens on the underside (Scheme 1) of ring A and allows oxidative displacement of the geminal partner of the one which is most remote from the primary binding site.

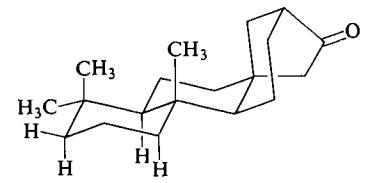
One final aspect of the oxidations of **2***b*, **3***b*, and **4***b* warrants comment, namely that only in the case of norphyllocladanone (**4***b*) was a 3-keto derivative isolated. It has been reported (22) that a strain of *A. niger* oxidizes 3β-hydroxy-5-pregnen-20-one to the 3-ketone while its enantiomer is unaffected. Other 3β-hydroxy steroids are also oxidized (23) to ketones by *A. niger*. Thus it would appear that oxidation of 3β-hydroxy decalin systems which have the same A/B ring junction configuration as that of the naturally occurring steroids is a fairly general property of some strains of this organism. Our failure to detect **3***f* from incubation of the norkauranone **3***b* might have been anticipated in view of the small amount of product **3***c* present and thus available for further transformation. Finally, it appears possible that some strains of *A. niger* may be ineffective for this oxidation of a 3β-hydroxy group to a ketone. In an experiment designed to determine if strains of *A. niger* other than ATCC 26693 can effect hydroxylation of these diterpenoid norketones, **4***b* was incubated with a strain (ATCC 10577) which is well known (7) as an efficient 11α-hydroxylator of steroids. In this case **4***c* was obtained in a yield similar to that from ATCC 26693 but notably no **4***g* could be isolated.



4*b*



3*b*



2*b*

SCHEME I

[7]Some preliminary results involving the interaction of *A. niger* with 15-deuterio derivatives of **2***b* and **2***c* may be taken to indicate the intervention of an enolate, or related, derivative at some stage in the hydroxylation process. For example, **2***b* with an *exo*-deuterium at C-15, after hydroxylation has lost an appreciable proportion of its label while recovered substrate has not. When similarly labelled, **2***c* retains almost all of its deuterium upon exposure for several days to a medium in which *A. niger* has been growing actively.

Experimental

Melting points were determined on a Kofler hot-stage apparatus and are uncorrected. For analytical and preparative t.l.c.. chromatoplates were spread with Kieselgel G. (Merck). Silica gel (Baker) used for column chromatography was 40–140 mesh. Gas–liquid chromatography was carried out with a Varian Aerograph 1200 gas chromatograph using a stainless steel column (1/8 in. × 10 ft packed with 5% SE-30) and nitrogen as carrier gas with a flow rate of 25 ml/min. Light petroleum was of b.p. 30–75°. Infrared solution spectra were recorded in carbon tetrachloride on a Beckman I.R. 12 spectrophotometer. Proton magnetic resonance spectra were run on a Varian Associates A-60A or HA 100 spectrometer, in deuteriochloroform unless otherwise stated, using tetramethylsilane as internal standard. Mass spectra were run on a Varian Associates CH7 instrument. Specific rotations were measured in chloroform unless otherwise stated using a Bellingham and Stanley polarimeter or a Bendix automatic polarimeter. *Aspergillus niger* cultures were maintained on potato dextrose agar slopes at 25°. Submerged cultures of *A. niger* for diterpenoid transformation were grown in presterilized Erlenmeyer flasks each of which was plugged with nonabsorbent cotton wool and contained a full nutrient growth medium (11) and a magnetic stirring bar. The medium was inoculated with *A. niger* under sterile conditions and the cultures were aerated by vigorous magnetic stirring.

Incubations of ent-17-Norkauran-16-one (2b) with Various Fungal Species

The ketone (**2***b*, 20mg) was incubated with 13 fungal species in essentially the fashion described below for one of them, *Aspergillus niger*, transformation being detected by comparison of the culture extract with that of a control on t.l.c. *Calonectria decora, Rhyzopus nigricans, Fusarium moniliforme, Coprinus lagopus*, in addition to *A. niger*, appeared to effect transformations, while *A. nidulans, A. ochraceous*, a *Hypomycetes* species, an *Ostracoderma* species, *Penicillium expansum*, a *Trichoderma* species, *Trichothecium roseum*, and a *Zygorhynchus* species did not.

Incubations of ent-17-Norkauran-16-one (2b) with A. niger (ATCC 26693)

An initial screening incubation was performed as follows. A 3-day-old submerged culture of *A. niger* (100 ml nutrient medium) in a 250-ml Erlenmeyer flask was inoculated with *ent*-17-norkauranone (**2***b*, 20 mg) in DMF (1 ml) and stirred vigorously for 7 days. The culture was then sonicated and the mycelium and medium were extracted with ethyl acetate (3 × 100 ml). Comparison by t.l.c. (ethyl acetate – light petroleum, 1:4) of this extract with one from a control culture inoculated with DMF (1 ml) only, showed a polar spot, in addition to that of substrate (**2***b*), not present in the control extract. Large scale incubations were carried out as follows. Vigorously stirred 3-day-old cultures of *A. niger* (2.5 l nutrient medium) in 4-l Erlenmeyer flasks were incubated with the norketone for 5 days. In a typical run, **2***b* (1.0 g) in DMF (50 ml) was added to the growing culture (5 l). After 5 days the mycelia were removed by filtration and the filtrate was then saturated with NaCl and extracted with ethyl acetate (3 × 1.5 l/2.5 l filtrate). The combined ethyl acetate extracts were evaporated to give an oil (2.8 g). The mycelia were killed by treatment with acetone, which was then allowed to evaporate at ambient temperature and pressure. The resulting tissue was ground with sand and extracted with ethyl acetate. This gave an oil (1.8 g). The two oily residues were then chromatographed separately over silica gel (100 g). The material (2.8 g) from the filtrate on elution with ether – light petroleum (1:4) gave substrate **2***b* contaminated with nonditerpenoid compounds (n.m.r. evidence). Elution with ether – light petroleum (1:1) gave an oil (0.4 g) which consisted of several compounds separable by t.l.c. (acetic acid – ethyl acetate – light petroleum, 2:5:25). One of these was not present in the corresponding fraction from a control culture. Preparative t.l.c. (same solvent, run twice) afforded this component, 3α-hydroxy-*ent*-17-norkauran-16-one (**2***c*, 45 mg). Repeated crystallization from methanol gave pure **2***c* (28 mg), m.p. 179–181° (lit. (16) 179–181°, (17) 192–193°). The material (1.8 g) from the mycelia on chromatography yielded small amounts of pure **2***c* (2 mg) and substrate (**2***b*). All fractions from both columns which contained substrate were combined and crystallized from methanol giving pure **2***b* (0.7 g). Based on substrate not recovered the yield of **2***c* was 9%.

3α-Acetoxy-ent-17-norkauran-16-one (2e)

In later incubations of **2***b* with *A. niger* it was found that **2***c* was more readily separated from column chromatography fractions (see above) as the derived acetate (**2***e*). These fractions were treated with acetic anhydride – pyridine (1:1) at 20° for 12 h and then submitted to preparative t.l.c. (chloroform). This gave the keto acetate **2***e* which on crystallization from methanol had m.p. 194–196° (lit. (17) 186°).

3α-Acetoxy-ent-16-kaurene (2f)

A solution of phenyl lithium was prepared by reacting lithium (160 mg) with bromobenzene (800 mg) in ether (20 ml). A portion (1.8 ml) of the resulting solution was added at 20° to methyltriphenylphosphine bromide (12 mg) in ether (30 ml) under nitrogen and followed 15 min later by **2***e* (45 mg) in ether (10 ml). The mixture was heated to reflux for 65 h and then worked up by treatment with water (50 ml) and extraction into ether (2 × 50 ml). Preparative t.l.c. (ethyl acetate – light petroleum, 3:17) of the product furnished 3α-acetoxy-*ent*-16-kaurene (**2***f*, 40 mg) which crystallized from light petroleum and had m.p. 151–154°; τ 5.20 (br s, 2 H-17), 5.49 (dd, 1 H-3, $w_{1/2}$ = 17 Hz), 7.96 (s, 3H, $-O_2C-CH_3$), 8.95 (s, 3 H-20), and 9.15 (s, 3 H-18 + 3 H-19); $\nu_{C=O}$ 1730 cm^{-1}.

Mol. Wt. Calcd. for $C_{22}H_{34}O_2$: 330.2559. Found (high resolution mass spectrometry): 330.2561.

3α-Hydroxy-ent-16-kaurene (2d)

The acetate (**2***f*, 53 mg) was heated with excess (200 mg) lithium aluminum hydride in refluxing dry ether for 90 min. The reaction was worked up by addition of saturated aqueous sodium sulfate. The crude product was purified by preparative t.l.c. (ethyl acetate – light petroleum, 1:4) and then crystallization from light petroleum. This gave 3α-hydroxy-*ent*-16-kaurene (**2***d*, 38 mg), m.p. 168–169° (lit. (16) 172–173°); τ 5.20 (br s, 2 H-17), 6.78 (dd, 1 H-3, $w_{1/2}$ = 17 Hz), 8.97 (s, 3 H-20), 9.02 (s, 3 H-18), and 9.22 (s, 3 H-19); τ with 0.78 molar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ratio of $Eu(dpm)_3$ to **2***d* 1.25 (s, 3 H-19), 1.73 (s, 3 H-18), 4.80 (br s, 2 H-17), and 5.75 (s, 3 H-20); ν_{OH} 3630 cm^{-1}.

ent-16-Kauren-3-one (2g)

A pyridine (2 ml) solution of alcohol **2***d* (20 mg) was added to a solution of chromium trioxide (0.5 g) in the same solvent (5 ml). After 2 h at 20°, water (80 ml) and ethyl acetate (80 ml) were added and the mixture was stirred for 4 h and then filtered. Evaporation of the ethyl acetate layer gave an oil, the major component of which was separated and purified by preparative t.l.c. (ethyl acetate – light petroleum, 1:9) and crystallization. This yielded *ent*-16-kauren-3-one (**2***g*, 8 mg), m.p. 84–85° (lit. (16) 86–87°); τ 5.20 (br s, 2 H-17), 8.75 (s, 3H, C_4—CH_3), 8.93 (s, 3 H-20), and 8.96 (s, 3H, C_4—CH_3); τ (C_6D_6) 8.80 (s, 3H, C_4—CH_3), 8.99 (s, 3H, C_4—CH_3) and 9.20 (s, 3 H-20); $\nu_{C=O}$ 1710 cm^{-1}.

17-Norkauran-16-one (3b)

(+)-Kaurene (**3***a*, 5.0 g from a *Podocarpus* species[8]) was oxidized with osmium tetroxide – sodium periodate as described previously (10) for its enantiomer. The dark product (4.7 g) was chromatographed over silica gel (200 g) and the fractions eluted with ether – light petroleum (1:8) combined and crystallized from moist methanol. The 17-norkauranone (**3***b*, 2.1 g) obtained had m.p. 116–118° [*cf.* enantiomer, **2***b*, 116–119° (10)], $[\alpha]_D$ +56° (*c*, 1.0); τ 8.91, 9.13, and 9.17 (all s, 3H, quaternary C—CH_3's); $\nu_{C=O}$ 1742 cm^{-1}.

Anal. Calcd. for $C_{19}H_{30}O$: C, 83.15; H, 11.02. Found: C, 83.11; H, 11.00.

Incubations of 17-Norkauran-16-one (3b) with A. niger (ATCC 26693)

Procedures similar to those for *ent*-17-norkauranone were used. In a typical incubation, *A. niger* cultures (4 × 2.5 l) were inoculated with **3***b* (2.0 g) in DMF (50 ml). After 5 days an oil (2.9 g) was recovered from the filtered medium by extraction with ethyl acetate. Chromatography of this oil over a silica gel column (120 g) and elution with ether – light petroleum (1:2) gave fractions containing substrate (see below). Elution with ether gave a complex mixture which contained (t.l.c.) the only component, other than **3***b*, present in the extract from the incubation but absent from that of a control culture. This compound, which had an identical mobility on t.l.c. with that of 3α-hydroxy-*ent*-17-norkauran-16-one (**2***c*) was isolated by repeated preparative t.l.c. (acetic acid – ethyl acetate – light petroleum, 2:25:25 and 2:10:25). The resulting oily 3β-hydroxy-17-norkauran-16-one (**3***c*) (4 mg) could not be induced to crystallize but had $[\alpha]_D$ +30° (lit. (9) enantiomer −45°); τ 6.78 (dd, 1 H-3, $w_{1/2}$ = 17 Hz), 8.89, 8.99, and 9.18 (all s, 3H, quaternary C—CH_3's). The compound was characterized as its acetate (see below).

An extract of the mycelia on chromatography afforded fractions containing substrate but no isolable amounts of **3***c*. All fractions containing substrate from the extracts of the medium and the mycelia were combined and crystallized from methanol. This gave pure **3***b* (1.06 g).

[8]We thank Dr. G. B. Sweet, New Zealand Forest Service, for this material.

3β-Acetoxy-17-norkauran-16-one (3d)

In later incubations of **3***b* with *A. niger*, fractions containing **3***c*, which were obtained by column chromatography over silica gel, were combined and treated with acetic anhydride – pyridine (1:1) at 20° for 14 h. Evaporation of reagents *in vacuo* and purification of the product by preparative t.l.c. (chloroform) and crystallization from light petroleum (b.p. 62–67°) gave the keto acetate **3***d*, m.p. 193–196° (*cf.* **2***e*, m.p. 194–196°), $[\alpha]_D$ +18° (*c*, 0.6); τ 5.50 (dd, 1 H-3, $w_{1/2}$ = 17 Hz), 7.98 (s, 3H, —O_2C—CH_3), 8.90 (s, 3 H-20), and 9.15 (s, 6H, C_4—CH_3's); $\nu_{C=O}$ 1735 cm^{-1}; *m/e* 332 (14%, M^+), 317 (1%), 288 (2%), 273 (26%), 272 (100%), 256 (60%), 228 (26%), and 216 (39%).

Mol. Wt. Calcd. for $C_{21}H_{32}O_3$: 332.2352. Found (high resolution mass spectrometry): 332.2350.

3β-Hydroxy-16-kaurene (3e)

A portion (2.8 ml) of a phenyl lithium solution, prepared from lithium (100 mg) and bromobenzene (800 mg) in ether (20 ml), was added to methyltriphenylphosphine bromide in ether (30 ml) under dry nitrogen. After 2 h at 20° 3β-acetoxy-17-norkauran-16-one (**3***d*, 9 mg) was added in ether (5 ml) and the mixture heated to reflux for 56 h. Decomposition with water, extraction with ether, and evaporation gave an oil (129 mg) which on t.l.c. analysis (ethyl acetate – light petroleum, 1:7) did not contain a compound of the mobility of 3α-acetoxy-*ent*-16-kaurene (**2***f*). It did contain a component of identical R_f with that of 3α-hydroxy-*ent*-16-kaurene (**2***d*). This component, 3β-hydroxy-16-kaurene (**3***e*, 5.3 mg) was recovered by repeated preparative t.l.c. (ethyl acetate – light petroleum, 1:8; chloroform) and had m.p. 168–170° (from methanol; *cf.* **2***d*, m.p. 168–169°), $[\alpha]_D$ +60° (*c*, 0.5); τ 5.20 (br s, 2 H-17), 6.78 (dd, 1 H-3, $w_{1/2}$ = 17 Hz), 8.97 (s, 3 H-20), 9.02 (s, 3 H-18), and 9.22 (s, 3 H-19); ν_{O-H} 3630 cm^{-1}; *m/e* 288 (58%, M^+), 273 (18%), 270 (22%), 255 (52%), 245 (35%), 229 (32%), 227 (53%), 159 (22%), and 91 (100%).

Mol. Wt. Calcd. for $C_{20}H_{32}O$: 288.2453. Found (high resolution mass spectrometry): 288.2454.

Incubations of 17-Norphyllocladan-16-one (4b) with A. niger (ATCC 26693)

The conditions and procedures established for both norkauranone enantiomers (**2***b* and **3***b*) were used for the incubation of **4***b* with *A. niger*. In a typical incubation, cultures (5 × 2.5 l) of *A. niger* were inoculated with the norketone (**4***b*, 2.0 g) in DMF (50 ml). The cultures were harvested after 5 days and gave an oily extract (1.25 g, total from medium and mycelia) which was chromatographed over silica gel (70 g). Elution with ether – light petroleum (1:1) gave substrate (1.36 g), while elution with pure ether gave fractions containing two compounds which were absent from the extract of a control culture. These were isolated by preparative t.l.c. (acetic acid – ethyl acetate – light petroleum, 2:5:25). The less polar transformation product, the diketone (**4***g*, 17 mg, 2.5%) on crystallization from light petroleum had m.p. 187–189°, $[\alpha]_D$ +13° (*c*, 0.8); τ 8.90, 8.95 (each s, 3H, C_4—CH_3's), and 8.99 (s, 3 H-20); τ with a 1.0 molar ratio of $Eu(dpm)_3$ to **4***g* 6.80, 7.08 (each s, 3H, C_4—CH_3's), and 7.84 (s, 3 H-20); $\nu_{C=O}$ 1749 and 1712 cm^{-1}; *m/e* 288 (100%, M^+), 273 (10%), 243 (24%), 232 (40%), 230 (23%), 202 (80%), and 201 (95%).

Mol. Wt. Calcd. for $C_{19}H_{28}O_2$:288.2089. Found (high resolution mass spectrometry):288.2086.

This sample was identical (m.p., mixture m.p., t.l.c., n.m.r., and mass spectra) with **4***g* prepared from calliterpenone (**8**) by Dr. Zaman (19). As obtained from Dr. Zaman **4***g* had m.p. 179–182°, raised to 185–188° by preparative t.l.c. (chloroform) and crystallization from light petroleum.

The more polar transformation product 3β-hydroxy-17-norphyllocladan-16-one (**4***c*, 35 mg, 5.0%), on crystallization from light petroleum had m.p. 158–160°, $[\alpha]_D$ +16° (*c*, 0.7); τ 6.75 (dd, 1 H-3, $w_{1/2}$ = 17 Hz), 7.3 (dd, 1 H-15, J_{obs}, 15α-15β = 19 Hz and 14α-15β = 3 Hz), 9.02, 9.13, and 9.24 (all s, 3H, quaternary C—CH_3's) $\nu_{C=O}$ 1750 cm^{-1}, and ν_{O-H} 3640 cm^{-1}; *m/e* 290 (100%, M^+), 275 (18%), 272 (65%), 258 (62%), 234 (29%), and 230 (24%).

Incubation of 17-Norphyllocladan-16-one (4b) with A. niger (ATCC 10577)

Inoculation of cultures (3 × 2.5 l) of *A. niger* (ATCC 10577) with **4***b* (1.35 g) in DMF (50 ml) and then extraction of the mycelia and medium, as described above, afforded an oil (1.82 g). Chromatography of this oil over silica gel (80 g) and preparative t.l.c. of the resulting fractions gave substrate (**4***b*, 0.81 g) and the keto alcohol **4***c* (27 mg, 5%). Only a trace (< 1 mg) of material with the same R_f on t.l.c. (acetic acid – ethyl acetate – light petroleum, 2:10:25 and 2:6:15) as that of the diketone **4***g* was obtained.

Oxidation of 3β-Hydroxy-17-norphyllocladan-16-one (4c)

The keto alcohol (**4***c*, 4 mg) in acetone (5 ml) was treated with Jones' reagent (0.3 ml). After 30 min at 20° the solution was diluted with water (50 ml) and extracted with ether (2 × 50 ml) to give a compound (3 mg) which was identical by t.l.c., g.l.c. (retention time 10.3 min, 195°), i.r. and mass spectra, with the diketone (**4***g*).

3β-Acetoxy-17-norphyllocladan-16-one (4d)

Treatment of the keto alcohol (**4***c*, 35 mg) with acetic anhydride – pyridine (1:1, 5 ml) for 12 h and then evaporation of the reagents *in vacuo* gave the keto acetate (**4***d*). After preparative t.l.c. (chloroform) and crystallization from light petroleum it (28 mg) had m.p. 156–158°, $[\alpha]_D$ +27° (*c*, 1.0); τ 5.45 (dd, 1 H-3, $w_{1/2}$ = 17 Hz), 7.95 (s, 3H, —O_2C—CH_3), 9.08 (s, 3H, quaternary C—CH_3), and 9.10 (s, 6H, quaternary C—CH_3's); $\nu_{C=O}$ 1735 cm^{-1}.

Mol. Wt. Calcd. for $C_{21}H_{32}O_3$:332.2352. Found (high resolution mass spectrometry):332.2350.

3β-Acetoxy-16-phyllocladene (4f)

A portion (2 ml) of a phenyl lithium solution, prepared from lithium (160 mg) and bromobenzene (800 mg) in ether (20 ml), was added to methyltriphenylphosphine bromide (180 mg) in ether (30 ml) under dry nitrogen and the resulting yellow solution heated to reflux for 3 h. The ketoacetate (**4***d*, 28 mg) in ether (5 ml) was then added and the heating continued for 3 days. Decompositon with water (20 ml), extraction with ether (2 × 50 ml) and evaporation gave an oil (220 mg). This was subjected to preparative t.l.c. (ethyl acetate – light petroleum, 3:17) and gave the acetoxy olefin (**4***f*, 19 mg) which on crystallization from methanol had m.p. 121–123°, $[\alpha]_D$ +41° (*c*, 1.1); τ 5.29 (br s, 2 H-17), 5.52 (dd, 1 H-3, $w_{1/2}$ = 16 Hz), 8.00 (s, 3H, —O_2C—CH_3), 9.05 (s, 3H, quaternary C—CH_3), and 9.17 (s, 6H, quaternary C—CH_3's); $\nu_{C=O}$ 1735 cm^{-1}.

Mol. Wt. Calcd. for $C_{22}H_{34}O_2$:330.2559. Found (high resolution mass spectrometry):330.2560.

Preparation of Diol 6

Phenyl lithium solution (1.6 ml, from 80 mg lithium and 400 mg bromobenzene in 10 ml dry ether) was reacted with methyltriphenylphosphine bromide (120 mg) in ether (30 ml) under dry nitrogen at 20°. After 10 min the keto acetate (**4***d*, 43 mg) was added and the mixture heated to reflux for 48 h. Work-up (as above) gave an oil which on t.l.c. (ethyl acetate – light petroleum, 3:17) showed no trace of the acetoxy olefin **4***f* but only a spot of much lower R_f. The component responsible for this was isolated by preparative t.l.c. (ethyl acetate – light petroleum, 2:3 run twice). This oily diol (**6**, 20 mg) had τ 2.4–2.9 (5H, aromatic protons), 6.80 (dd, 1 H-3, $w_{1/2}$ = 15 Hz), 9.02 (s, 6H, quaternary C—CH_3's), and 9.20 (s, 3H, quaternary C—CH_3); ν_{O-H} 3633 and 3610 cm^{-1}.

Rapid decomposition of **6** to the styrene **5** was taking place and further investigations were limited to **5** (see below).

Dehydration of Diol 6

The diol (**6**, 20 mg) in benzene (20 ml) was treated with toluene-*p*-sulfonic acid (15 mg) in the presence of anhydrous calcium chloride (0.5 g) for 100 min. The drying agent and solvent were removed and the oily residue submitted to preparative t.l.c. (ethyl acetate – light petroleum, 1:4). This gave the styrene **5** (13 mg), which on crystallization from ether had m.p. 177–178°; τ 2.4–2.9 (5H, aromatic protons), 3.75 (s, 1 H-15), 6.75 (dd, 1 H-3, $w_{1/2}$ = 16 Hz), 7.1 (m, 1 H-13), 8.98, 9.20, and 9.22 (all s, 3H, quaternary C—CH_3's); τ with 1.23 molar ratio of Eu(dpm)$_3$ to **5** −0.70 (s, 3 H-19), 0.00 (s, 3 H-18), and 5.90 (s, 3 H-20); λ_{max} 264 (ε 14 600); ν_{O-H} 3650 cm^{-1}.

Mol. Wt. Calcd. for $C_{25}H_{34}O$: 350.2610. Found (high resolution mass spectrometry): 350.2612.

3β-Hydroxy-16-phyllocladene (4e)

A suspension of lithium aluminum hydride (110 mg) in ether (10 ml) was stirred under dry nitrogen at 20° for 1 h. The acetate **4***f* (20 mg) was then added in ether (6 ml) and the reaction heated to reflux for 5 h. Addition, in succession, of water (0.1 ml), aqueous sodium hydroxide (15%, 0.1 ml), and water (0.4 ml) followed by removal of the resulting precipitate and the solvent gave an oil. Preparative t.l.c. (chloroform) of this residue furnished 3β-hydroxy-16-phyllocladene (**4***e*, 18 mg) which crystallized from light petroleum and had m.p. 157–158°, $[\alpha]_D$ +3° (*c*, 0.9); τ 5.30 (br s, 2 H-17), 6.85 (dd, 1 H-3, $w_{1/2}$ = 16 Hz), 9.09 (s, 3 H-18), 9.15 (s, 3 H-20), and 9.29 (s, 3 H-19); τ with 0.4 molar ratio of Eu(dpm)$_3$ to **4***e* 4.25 (s, 3 H-19), 4.49 (s, 3 H-18), 4.95 (br s, 2 H-17), and 7.12 (s, 3 H-20); ν_{O-H} 3638 cm^{-1}.

Mol. Wt. Calcd. for $C_{20}H_{32}O$:288.2453. Found (high resolution mass spectrometry):288.2454.

Incubation of ent-Kaurene (2a) and Phyllocladene (4a) with A. niger (ATCC 26693)

Three cultures (100 ml each) of *A. niger* were grown

for 4 days and then one was inoculated with *ent*-kaurene (**2***a*, 20 mg) in DMF (1.5 ml), another with phyllocladene (**4***a*, 27 mg) in DMF (1.5 ml), and the third with DMF (1.5 ml) only. After incubation for 6 days the cultures were extracted with ethyl acetate as before (see above). The three extracts were compared by analytical t.l.c. (ethyl acetate – light petroleum, 1:9 and 1:2). No trace of products (**2***d*, **4***e*) of axial hydroxylation at C-3 in **2***a* or **4***a* was detected in the appropriate extracts, the three extracts appearing identical except for the presence of unreacted **2***a* and **4***a*. *ent*-Kaurene (**2***a*, 18 mg) and phyllocladene (**4***a*, 24 mg) were recovered by preparative t.l.c. (light petroleum).

We thank the National Research Council of Canada for an Operating Grant (to R.McC.) and a Scholarship (to J.K.T.). We are also indebted to Dr. T. Anthonsen, Trondheim, for the high resolution mass spectra and to Dr. G. L. Barron, University of Guelph for gifts of fungal cultures.

Substituted 5-Allyl-9-oxobenzomorphans. Versatile Intermediates for Investigations in the Field of Analgesics and Narcotic Antagonists. Part 1

IVO MONKOVIC

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q. J5R 1J1

Received October 25, 1974

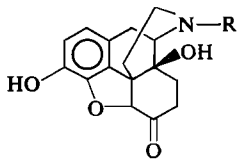
IVO MONKOVIC. Can. J. Chem. **53**, 1189 (1975).

2-Tetralone has been converted to 5-allyl-2-methyl-9-oxo-benzomorphan methobromide (**4**). Thermal dequaternization of **4** afforded tertiary base **5**. Alternatively, **4** was reduced with sodium borohydride to give **7***a* or reacted with methylmagnesium iodide to give **7***b*. Dequaternization of these to tertiary bases (**8***a* and **8***b*) followed by acid-catalyzed cyclization afforded tetrahydrofurano compounds **9***a* and **9***b*, respectively. Bromocyclization of **8***b* afforded bromomethyltetrahydrofurano compound **9***c*, which was further converted to dimethylamino compound **9***d*.

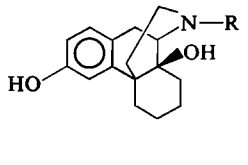
IVO MONKOVIC. Can. J. Chem. **53**, 1189 (1975).

On a transformé la tétralone-2 en méthobromure d'allyl-5 méthyl-2 oxo-9 benzomorphane (**4**). La déquaternisation thermique de **4** conduit à la base tertiaire **5**. Le composé **4** peut aussi être réduit par le borohydrure de sodium pour donner **7***a* ou réagir avec de l'iodure de méthylmagnesium pour conduire à **7***b*. La déquaternisation de ces composés en bases tertiaires (**8***a* et **8***b*) suivie par une cyclisation acido-catalysée fournit respectivement les composés tétrahydrofuranno **9***a* et **9***b*. La bromocyclisation de **8***b* fournit le composé bromométhyltétrahydrofuranno **9***c* qui peut être transformé en composé diméthylamino **9***d*. [Traduit par le journal]

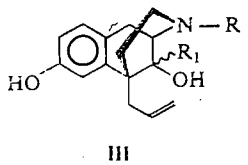
In recent years significant progress has been made in the field of highly potent, pure, and partial narcotic antagonists (nonabusable analgesics) by studying 14-hydroxymorphine-related compounds of general structures **I** (1) and **II** (2),



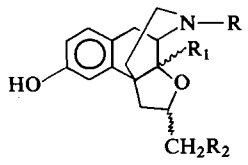
I



II



III



IV

R_1 = H, alkyl; R_2 = H, Br, OH, *N*,*N*-dialkyl.

incorporating various C_3H_5 to C_5H_7 nitrogen substituents. Similar studies in the benzomorphan series have not been conducted, even though synthetic methodology to this end has been available for a number of years (3–5). The lack of interest in the 9-hydroxybenzomorphans may have been due to the finding that replacement of the 9-hydrogen by a hydroxyl group adversely affected agonist activity (Reference 6)

We wished to study the effect of varying the substituent on the nitrogen atom in the 9-hydroxybenzomorphans **III**, while incorporating at C5 a substituent suitably functionalized for the formation of an heterocyclic C-ring in the morphinan series (represented by general structures **IV** and **V**). As a pilot study in this direction, we decided to attempt a synthesis of 5-allyl-9-oxobenzomorphan **5**. At the time of inception of our work, the most promising synthetic approach to **5** appeared to be that of May and co-workers (6, 7). By analogy to their procedure, the allylation of 2-tetralone via the corresponding pyrrolidine enamine afforded allyltetralone **1**. Further alkylation of **1** by reaction with 2-chloro-*N*,*N*-dimethylethylamine and sodium *t*-pentoxide in boiling benzene afforded dialkylated tetralone **2**.

The success of our synthesis was dependent upon a successful selective bromination of ketone **2** in the presence of the double bond. This selectivity has been achieved earlier by utilization of

phenyltriethylammonium tribromide (8) and cupric bromide (9). More recently Awang and Wolfe (10) described a method utilizing pyrrolidone hydrotribromide as a brominating agent. This method was applied in the bromination of **2**, affording a reasonable yield of bromotetralone **3** (57%). The free base of **3** spontaneously cyclized to the quaternary salt **4** (3, 4). Heating a solution of **4** in 1-octanol to reflux for 15 min resulted in a mixture of benzomorphan **5** and two by-products, one of which was identified as an elimination product **6**. Alternatively, **4** was reduced with sodium borohydride in ethanol at room temperature to the 9β-hydroxybenzomorphan **7***a*, which was dequaternized as above, affording a superior yield of tertiary base **8***a* (57% overall yield from **4**), as compared to that of **5**. Similarly treatment of **4** with methylmagnesium iodide, followed by dequaternization as above without prior isolation of **7***b* resulted in tertiary base **8***b*. The stereochemical assignments of the 9-carbinols followed from the method of preparation of **7***b* (3) and from the i.r. spectra of both **8***a* and **8***b*, which exhibited broad maxima at 3400 cm^{-1} (irrespective of concentration) which are characterestic of intramolecular OH–N bonding and have been observed by Kugita and May in 5-methyl homologs (4). Acid-catalyzed cyclizations of **8***a* and *b* (boiling with concentrated hydrochloric acid) afforded the corresponding tetrahydrofuran derivatives **9***a* and **9***b*, respectively. Bromocyclization (11) of **8***b* (addition of a solution of bromine in carbon tetrachloride to a solution of **8***b* in dichloromethane) afforded bromomethyltetrahydrofurano compound **9***c* as the hydrobromide salt. Reaction of **9***c* with dimethylamine in DMF at 100° afforded the corresponding dimethylamino compound **9***d*.

Experimental

The melting points were determined on a Gallenkamp melting point apparatus and are not corrected. The i.r. spectra were recorded on a Unicam Sp-200G grating i.r. spectrometer. The n.m.r. spectra were recorded on a Varian A-60A spectrometer using deuteriochloroform as a solvent. The chemical shifts are expressed in δ values using tetramethylsilane as internal reference. Microanalyses were performed by Micro-Tech Laboratories Inc., Skokie, Ill.

3,4-Dihydro-1-allyl-2(1H)naphthalenone (1)

The 1-allyl-2-tetralone (**1**) was obtained in 78% yield by the procedure described by Murphy *et al.* (7); b.p. 79–83°/0.05 mm; i.r. (neat) 1715 cm^{-1}; n.m.r. δ 7.12 (4H, s), 4.7–6.2 (3H, m), 3.39 (1H, t, J = 6 Hz), 2.2–3.1 (6H, m).

Anal. Calcd. for $C_{13}H_{13}O$: C, 84.29; H, 7.01. Found: C 83.94; H, 7.04.

3,4-Dihydro-1-allyl-1-(2-dimethylaminoethyl)-2(1H)-naphthalenone (2)

A nitrogen atmosphere was maintained throughout this experiment. To a stirred and heated to reflux suspension of sodium hydride (17.0 g of 42.8%, washed with hexene) in benzene (300 ml) was added dropwise during 40 min t-pentyl alcohol (25.0 g), followed by a solution of allyltetralone **1** (67.0 g) in benzene (200 ml) during 30 min. The mixture was heated and stirred for another 30 min, followed by treatment with a solution of 2-chloro-*N*,*N*-dimethylethylamine (50.0 g) in benzene (80 ml) over

a period of 1 h at such a rate as not to cause excessive evolution of hydrogen. After addition was completed, the mixture was heated and stirred for 24 h. After cooling, it was extracted with 2 × 200 ml of 2 *N* hydrochloric acid and the combined extracts were warmed up to 70° to hydrolyze the *O*-alkylated product. The starting material was recovered by extraction with ether, to afford after drying, evaporation of ether, and distillation, 20.1 g of **1**. The acidic layer was basified with ammonium hydroxide and extracted with ether to afford after drying and evaporation of ether 51.8 g of **2** as an oil; i.r. (neat) 1710 cm^{-1}; n.m.r. (CCl_4) δ 7.0–7.3 (4H, m), 4.6–5.8 (3H, m), 2.8–3.2 (2H, m), 2.1–2.8 (4H, m), 1.9 (6H, s), 1.5–2.1 (2H, m). A sample for analysis was purified as the oxalate salt by recrystallization from methanol–acetone; m.p. 118–119°.

Anal. Calcd. for $C_{17}H_{23}NO{\cdot}C_2H_2O_4$: C, 65.69; H, 7.25; N, 4.03. Found: C, 65.47; H, 7.29; N, 4.06.

3-Bromo-1,4-dihydro-1-allyl-1-(2-dimethylamino)-2-(1H)naphthalenone (3)

A freshly prepared hydrogen bromide solution in ether was used to convert free base **2** (14.1 g) in ether at 0–5° to the corresponding hydrogen bromide salt. The ether was decanted and the residue, a heavy oil, was dissolved in a mixture of dichloromethane (100 ml) and THF (200 ml). This solution was stirred vigorously in the dark and to it was added dropwise during 2 h a solution of pyrrolidone hydrotribromide (27–28 g) in THF (300 ml). The mixture was allowed to stand for 3 h and then the separated solid was removed by filtration. The filtrate was concentrated *in vacuo* and the residual solid was recrystallized from 2-propanol, to afford 11.2 g of **3**, m.p. 129–131°. Another crop of 2.1 g was obtained from mother liquors for a total of 13.3 g. Recrystallization from 2-propanol afforded sample for analysis; m.p. 133–135°; i.r. (Nujol) 1735 cm^{-1}; n.m.r. δ 7.0–7.7 (4H), 3.7–5.9 (4H, m), 3.3–3.7 (2H, m), 2.4–3.2 (13H, m).

Anal. Calcd. for $C_{17}H_{22}BrNO{\cdot}HBr$: C, 48.94; H, 5.56; N, 3.36. Found: C, 49.01; H, 5.66; N, 3.21.

5-Allyl-2-methyl-9-oxo-6,7-benzomorphan Methrobromide (4)

A mixture of **3** (8.34 g), water (80 ml), ice (10 g), ether (100 ml), and concentrated ammonium hydroxide (2 ml) was shaken vigorously in a separatory funnel. The ether layer was transferred quickly to a round bottom flask and the aqueous layer was extracted with 2 × 20 ml of ether. The combined ethereal extracts were evaporated to dryness and to the residue was added dichloromethane (20 ml). After 24 h, the separated solid was removed by filtration to afford 5.23 g of **4**, m.p. 189–193°. A sample for analysis was recrystallized from methanol-2-propanol; m.p. 196–197°; i.r. (Nujol) 1735 cm^{-1}; n.m.r. (D_2O) δ 7.48 (4H, s), 5.0–6.3 (3H, m), 3.53 (3H, s), 3.37 (3H, s), 2.5–4.4 (11H, m).

Anal. Calcd. for $C_{16}H_{18}NO{\cdot}CH_3Br$: C, 60.72; H, 6.59; N, 4.17. Found: C, 60.64; H, 6.62; N, 4.23.

In another experiment **4** was obtained in 54% yield directly from **2** without prior isolation of **3**. After addition of pyrrolidone hydrotribromide to **2** was completed, the mixture was allowed to stand overnight, and then it was concentrated to a small volume and the residue was treated with ammonium hydroxide and extracted with ether as above to afford **4**.

5-Allyl-2-methyl-9-oxo-6,7-benzomorphan (5) and 1-Allyl-1-(2-dimethylaminoethyl)-2(1H)naphthalenone (6)

To hot 1-octanol (40 ml) was added quaternary salt **4** (3.36 g) and the mixture was heated to reflux under flow of nitrogen for 15 min. After cooling, to this was added ether (120 ml) and it was extracted with 1 *N* hydrochloric acid (2 × 15 ml) followed by water (5 × 20 ml). The combined extracts were extracted with petroleum ether to remove traces of octanol, basified with ammonium hydroxide, and extracted with ether to afford after drying and concentration 1.98 g of an oil, which showed three spots on t.l.c. This was chromatographed on a silica gel column with ether as eluent, to afford apart from some unidentified less polar impurity, 730 mg of **5** as a white solid, m.p. 65–67°. After treatment with ether and charcoal, the sample showed m.p. 73–75°; i.r. (Nujol) 1725 cm^{-1}; n.m.r. (CCl_4) δ 7.5 (4H, s), 4.8–6.2 (3H, m, $CH_2CH{=}CH_2$), 2.9–3.7 (3H, m, 1-H and 3-H_2), 2.75 (2H, d, J = 6 Hz, $CH_2CH{=}CH_2$), 2.37 (3H, s, N—CH_3), 1.5–2.6 (3H, m, 8-H_2 and 4α-H), 1.37 (1H, d, J = 10 Hz, 4β-H).

A hydrochloride salt crystallized slowly from acetone with ½ mol of water of crystallization; m.p. 190–192°.

Anal. Calcd. for $C_{16}H_{19}NO.HCl{\cdot}\frac{1}{2}H_2O$: C, 67.00; H, 7.38; N, 4.88 Found: C, 67.10; H, 7.31; N, 4.68.

Further elution of the column with methanol afforded 340 mg of crude **6** as an oil, which was purified as oxalate salt by recrystallization from methanol–acetone; m.p. 160–161°; i.r. (free base, neat) 1730 cm^{-1}; n.m.r. (CCl_4) δ 7.2–7.5 (4H, m), 7.25 (1H, d, J = 10 Hz, 4-H), 6.1 (1H, d, J = 10 Hz, 3-H), 4.5–5.7 (3H, m), 1.9 (6H, s), 1.6–3.1 (6H, m).

Anal. Calcd. for $C_{17}H_{22}NO{\cdot}C_2H_2O_4{\cdot}CH_3OH$: C, 63.64; H, 7.21; N, 3.71. Found: C, 63.99; H, 7.51; N, 3.70.

5-Allyl-9β-hydroxy-2-methyl-6,7-benzomorphan Methabromide (7a)

A mixture of **4** (6.73 g) and sodium borohydride (400 mg) in absolute ethanol (50 ml) was stirred for 1 h followed by careful addition of hydrogen bromide (925 mg of 48%) in water (10 ml) and the mixture was heated to 65–70° for 30 min. It was then concentrated *in vacuo* and to the residue was added dichloromethane (25 ml). The mixture was stirred and filtered to remove inorganic salts. The filtrate was evaporated to dryness and to the residue was added acetone (15 ml), causing crystallization. A white solid was removed by filtration to afford 5.54 g of **7***a*; m.p. 206–208° from methanol–acetone; i.r. ($CHCl_3$), 3495 cm^{-1}; n.m.r. ($CDCl_3$) δ 7.1–7.4 (4H, m), 4.7–6.2 (4H, m), 4.0 (3H, s), ˊ.38 (6H, s), 2.4–4.0 (8H, m), 1.4 (1H).

Anal. Calcd. for $C_{16}H_{21}NO{\cdot}CH_3Br$: C, 60.36; H 7.15; N, 4.14. Found: C, 60.73; H, 7.23; N, 4.11.

5-Allyl-9β-hydroxy-2-methyl-6,7-benzomorphan (8a)

A mixture of **7***a* (4.2 g) and 1-octanol (30 ml) was heated to reflux for 45 min. Work-up as above afforded an oil which crystallized from petroleum ether. There was obtained 2.17 g of **8***a*; m.p. 80–81°; i.r. ($CHCl_3$), 3400 cm^{-1}; n.m.r. ($CDCl_3$) δ 7.0–7.5 (4H, m), 4.8–6.2 (3H, m), 3.83 (1H, d, J = 4 Hz), 3.38 (3H, s), 1.9–3.5 (8H, m), 1.12 (1H, d, J = 7 Hz); hydrochloride salt, flakes from methanol–ether; m.p. 228–230°.

Anal. Calcd. for $C_{16}H_{21}NO{\cdot}HCl$: C, 68.68; H, 7.93; N, 5.01. Found: C, 68.77; H, 8.05; N, 4.94.

5-Allyl-9β-hydroxy-2,9α-dimethyl-6,7-benzomorphan (8b)

To a suspension of **4** (3.36 g) in dry ether (5 ml) was added 1.7 *M* solution of methylmagnesium iodide in ether (35 ml) and the mixture stirred for 45 min. The ether was then evaporated and an attempt was made to isolate quaternary salt **7***b*. However, we obtained a heavy oil, which did not crystallize. Therefore, the oil was extracted with chloroform, the extract was dried and evaporated *in vacuo* and the residual oil was pyrrolized in 1-octanol, as described above to afford 2.24 g of **8***b* as an oil; i.r. ($CHCl_3$) 3400 cm^{-1}; n.m.r. (CCl_4) δ 6.9–7.4 (3H, m), 5.8–6.5 (3H, m), 2.37 (3H, s), 1.9–3.1 (8H, m), 1.08 (3H, s), 0.9–1.1 (1H). The oil was dissolved in ether and treated with a solution of oxalic acid in acetone to afford 2.6 g of oxalate salt, m.p. 165–167°. A sample of this was recrystallized from methanol–ether, m.p. 178–180°.

Anal. Calcd. for $C_{17}H_{23}NO{\cdot}C_2H_2O_4$: C, 65.69; H, 7.25; N, 4.03. Found: C, 65.65; H, 7.26; N, 3.89.

Tetrahydrofuranobenzomorphan 9a

A solution of **8***a* (11.05 g) in concentrated hydrochloric acid (10 ml) was heated to reflux for 1 h. After cooling, it was basified with ammonium hydroxide and extracted with ether to afford, after drying and evaporation of ether, 660 mg of **8***a* as an oil. It was dissolved in dry ether and triturated with petroleum ether. The solid impurity was removed by filtration and the filtrate was treated with a solution of oxalic acid in acetone to form the oxalate salt. It crystallized from methanol–acetone with a ½ mol of methanol of crystallization, m.p. 116–118°; n.m.r. (free base, CCl_4) δ 7.0 (4H, s), 4.15–4.7 (1H, m), 3.70 (1H, d, J = 3 Hz), 2.73 (3H, s), 1.26 (3H, d, J = 6 Hz), 1.0–3.6 (9H, m).

Anal. Calcd. for $C_{16}H_{23}NO{\cdot}C_2H_2O_4{\cdot}\frac{1}{2}CH_3OH$: C, 63.59; H, 7.21; N, 4.00. Found: C, 63.27; H, 7.22; N, 4.00.

Tetrahydrofuranobenzomorphan 9b

To a concentrated hydrochloric acid (2 ml) was added oxalate salt of **8***b* (900 mg) and the mixture heated briefly to boiling. Work-up as above afforded 600 mg of **9***b* as a white solid, m.p. 79–82°; n.m.r. (CCl_4) δ 7.0 (4H, s), 4.2–4.8 (1H, m), 2.38 (3H, s), 1.4 (3H, d, J = 6 Hz), 1.0–3.4 (9H, m), 0.97 (3H, s); hydrochloride salt, m.p. 278–280° from methanol–ether.

Anal. Calcd. for $C_{17}H_{23}NO{\cdot}HCl$: C, 69.49; H, 8.23; N, 4.77. Found: C, 69.26; H, 8.24; N, 4.66.

Bromomethyltetrahydrofuranobenzomorphan 9c

To a stirred and cooled (ice bath) solution of **8***b* (2.29 g) in dichloromethane (15 ml) was added dropwise 1 *M* solution of bromine in carbon tetrachloride (8.9 ml). The solvent was then removed *in vacuo* and to the residue was added acetone (12 ml). After 2 h, the solid precipitate was removed by filtration to afford 2.6 g of **9***c*, white crystals, m.p. 228–230° from methanol–acetone; n.m.r. ($CDCl_3$) (free base) δ 7.17 (4H, s), 3.34–5.0 (1H, m), 2.37 (3H, s), 2.0–3.9 (10H, m), 1.12 (1H, d, J = 7 Hz), 1.06 (3H, s).

Anal. Calcd. for $C_{17}H_{22}NO{\cdot}HBr$: C, 48.94; H, 5.58; N, 3.36. Found: C, 49.32; H, 5.63; N. 3.23.

Dimethylaminomethyltetrahydrofuranobenzomorphan 9d

To a solution of dimethylamine in DMF (5 ml) was added the bromohydrobromide **9***c* (1.0 g) and the mixture heated in a steel bomb at 100° for 1 h and after cooling, it was partitioned between benzene and 2 *N* sodium hydroxide (50 ml). Benzene layer was washed several times with water, dried, and evaporated to dryness. The residue was dissolved in ether and extracted with 2 *N* hydrochloric acid (5 ml). The extract was concentrated *in vacuo* and the residue crystallized from methanol acetone to afford 690 mg (71%) of **9***d* as the dihydrochloride salt, with 1 mol of methanol of crystallization, m.p. 278–280°; n.m.r. (free base, CCl_4) δ 7.04 (4H, s), 4.15–4.85 (1H, m), 2.37 (3H, s), 2.23 (6H, s), 1.8–3.1 (8H, m), 1.1 (1H, m), 0.92 (3H, s).

Anal. Calcd. for $C_{19}H_{28}N_2O{\cdot}2HCl{\cdot}CH_3OH$: C, 59.25; H, 8.45; N, 6.9. Found: C, 48.84; H, 8.32; N, 6.96.

A Proton Magnetic Resonance Study of the Ultraviolet Photoproduct of d(TpT) in Aqueous Solution[1]

FRANK E. HRUSKA, DONALD J. WOOD,[2] KELVIN K. OGILVIE, AND JAMES L. CHARLTON

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received August 16, 1974

FRANK E. HRUSKA, DONALD J. WOOD, KELVIN K. OGILVIE, and J. L. CHARLTON. Can. J. Chem. **53**, 1193 (1975).

The p.m.r. data of d(TpT) and its predominant u.v. photoproduct d(T[p]T) in aqueous solution are compared. The data are consistent with the presence of a *cis-syn* cyclobutane ring in d(T[p]T). Consideration of the $H_{1'}$ chemical shifts leads to the conclusion that changes in the sugar–base torsion angle of both nucleotide fragments of the parent molecule are required to bring the thymine bases into alignment for photodimerization. The coupling constants indicate that the conformation of the 5′-terminal fragment is only slightly affected by the cyclobutane ring formation. Photodimerization brings about a distortion of the sugar pucker in the 3′-terminal fragment. In this fragment both the *gauche-gauche* and *gauche-trans* conformers are significantly populated whereas the *trans-gauche* form is excluded.

FRANK E. HRUSKA, DONALD J. WOOD, KELVIN K. OGILVIE et J. L. CHARLTON. Can. J. Chem. **53**, 1193 (1975).

On compare les données de r.m.p., obtenues en solution aqueuse, pour le d(TpT) avec celles de son photoproduit u.v. d(T[p]T) prédominant. Les données sont en accord avec la présence d'un cyclobutane-*cis-syn* dans le d(T[p]T). L'examen des déplacements chimiques du $H_{1'}$ conduit à la conclusion que des changements dans l'angle de torsion sucre–base des deux fragments du nucléotide de la molécule parente sont requis pour amener les bases thymines dans une orientation appropriée pour la photodimérisation. Les constantes de couplage indiquent que la conformation du fragment 5′ terminal n'est que très peu affectée par la formation du noyau cyclobutanique. La photodimérisation amène une distorsion de la molécule de sucre plissée dans le fragment 3′ terminal. Dans ce fragment, les deux conformères *gauche-gauche* et *gauche-trans* existent d'une façon importante alors que la forme *trans-gauche* n'existe pas. [Traduit par le journal]

Introduction

Thymine photodimers possessing a cyclobutane ring are generated by u.v. irradiation of thymine (2–4).[3] In u.v. irradiated DNA the predominant photoproduct is formed from thymines adjacent on a polynucleotide strand and has been shown to possess the *cis-syn* geometry (6–12) with the *trans-syn* form as a minor product (13). Several groups have examined photodimer production in model compounds, particularly the dinucleoside monophosphates (14–17) and the abbreviated dinucleosides (18). Johns *et al.* (16) have isolated two isomeric forms of d(T[p]T), the u.v. photoproduct of d(TpT) (Fig. 1); evidence has been provided for the *cis-syn* cyclobutane geometry in the predominant product and the *trans-syn* in the minor product. Formation of the antiparallel cyclobutane ring systems (*cis-anti* and *trans-anti*) in u.v. irradiated oligo- or polynucleotides is unlikely for steric reasons.

Recently we reported a p.m.r. conformational study of d(TpT) in aqueous solution (19). For the present work we have prepared, according to the methods of Johns *et al.* (16), the predominant photoproduct of d(TpT) and obtained its 100 and 220 MHz spectra. The chemical shift and coupling constant data are shown to be consistent with the presence of a cyclobutane ring structure with the *cis-syn* geometry. Other geometries could not, however, be excluded on the basis of our p.m.r. data alone. The data reveal that thymine dimer formation at the dinucleoside monophosphate level causes distor-

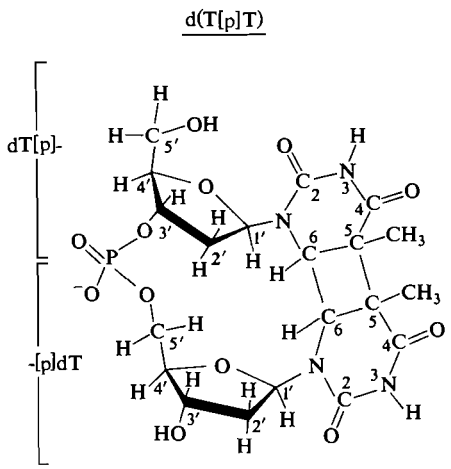

FIG. 1. The structural formula of the ultraviolet photoproduct of 2′-deoxythymidylyl-(3′,5′)-2′-deoxythymidine *i.e.* d(T[p]T). dT[p]- and -[p]dT refer to the nucleotide fragments with the free 5′- and 3′-hydroxyls, respectively.

tion of the sugar–base torsion angle of both nucleoside fragments and perturbs the conformation of the sugar–phosphate backbone. The findings are interesting in the light of evidence that local distortion of secondary structure is a consequence of dimer formation in polynucleotides (20).

Experimental

The procedure of Letsinger *et al.* (21) was used in the synthesis of d(TpT). d(TpT) (75 mg) in water (75 ml) was irradiated under nitrogen through a Pyrex (3 mm) filter with a water-cooled Hanovia 450 W medium-pressure mercury lamp. After 10 h the absorbance (267 nm) dropped to 14% of its original value. The solution was lyophilized and the residue was dissolved in water and applied to Whatmann 3 MM paper which was developed in solvent A (22). The desired photoproduct moved slightly slower than d(TpT). The product was eluted with water and rechromatographed in solvent C (22). The product was again eluted with water and lyophilized to a fine powder. The product was photoreversible to d(TpT) at 254 nm.

An aqueous (D_2O) solution of the photoproduct (0.05 *M*, p*D* = 7.0), containing 0.05 *M* TSP (sodium 3-trimethylsilylpropionate-2,2,3,3-d_4) for internal referencing, was freeze-dried three times, and dissolved in 100% D_2O. Spectra were obtained on Varian HA-100 and HR-220 MHz spectrometers. Calibration of spectra and spin-decoupling experiments were carried out by standard methods. Spectral analysis was carried out with LAME (23). Computer simulations of the spectra were used as the final test of the data. The chemical shift (δ) and coupling constant (J) data are given in Table 1.

Results and Discussion

Spectral Assignment

Figure 2 shows the experimental 220 MHz and calculated spectra of d(T[p]T) at 65 °C. Spectral assignment was carried out by comparison of these spectra with those of dT, 3′dTMP, 5′dTMP, and d(TpT) discussed previously (1, 19). Consideration of the magnetic shielding effects of phosphorylation at the 3′-position of a series of molecules, dT → 3′dTMP (1, 19), d(TpT) → d(TpTp) (24), and d(T[p]T) → d(T[p]Tp) (24), facilitated location of the $H_{2'}$, $H_{2''}$, and $H_{3'}$ bands of the -[p]dT fragment. The reasoning outlined in ref. 19 was used to distinguish the $H_{2'}$ and $H_{2''}$ of the dT[p]- fragment. In this work we argued that, in a 2′-deoxyribose which experiences no unusual distortion, *i.e.* whose conformational and bond angles fall into expected ranges (25–28), the measured values of the coupling constants $J_{2''3'}$ and $J_{3'4'}$ should be identical to within a few tenths of a Hertz. At 18 °C values of 5.7 and 3.7 Hz were obtained for the pair of $H_{2'}$–$H_{3'}$ coupling constants in dT[p]-. By the above arguments the smaller must be $J_{2''3'}$ (and the larger, $J_{2'3'}$) since it is the closer in value to $J_{3'4'}$ (3.1 Hz). The choice of $J_{2''3'}$ = 3.7 Hz and $J_{2'3'}$ = 5.7 Hz allows us to assign $H_{2'}$ to low field of $H_{2''}$ in the 2′,2″ band of dT[p]-. Interestingly, if we apply this same reasoning to the -[p]dT fragment of d(T[p]T) and choose the $H_{2'}$–$H_{3'}$ coupling constant of 3.7 Hz (rather than 8.1 Hz) for $J_{2''3'}$, we arrive at the assignment based on the shielding influence of a 3′-phosphate mentioned above. This supports the contention that our reasoning, based on the near equality of $J_{2''3'}$ and $J_{3'4'}$, is generally applicable to 2′-deoxyribosides with "normal" (25–28) conformations.

Further ambiguity exists in the assignment of the $H_{5'}$ and $H_{5''}$ spectral bands. We have assumed here the Remin and Shugar assignment (29) for ribonucleosides, although there is no justification for assuming that their assignment will hold for our series of molecules. However, wherever relevant, we point out the conformational conclusions which follow from the second choice of $H_{5'}$,$H_{5''}$ assignment.

The Eight Configurational Isomers of d(T[p]T)

Wulff and Fraenkel first listed the four isomeric types of Thy[ ]Thy (4). Actually a total of six configurationally distinct forms exist (Fig. 3) since the *trans-syn* (III) and *cis-anti* (II)

forms exist as a pair of enantiomeric (*d,l*) forms whereas the *cis-syn* (I) and *trans-anti* (IV) forms exist as single (*meso*) diastereomers. Isomers II and III are optically active but their *d,l* labelling remains arbitrary until the optical rotatory properties of the individual enantiomers are determined. By ignoring all steric difficulties which might arise in their actual synthesis, we have been able to construct a total of *eight* configurationally distinct isomers of d(T[p]T),

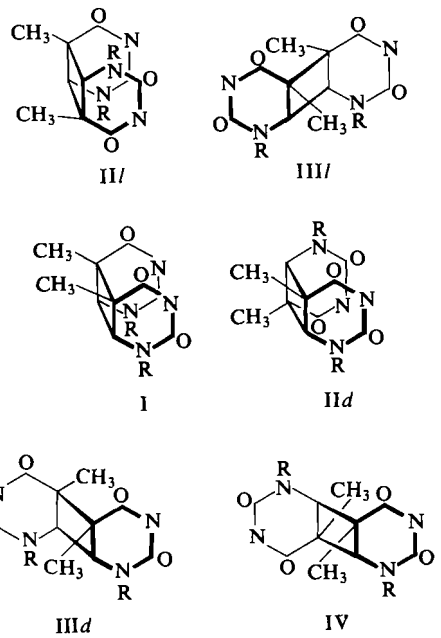

FIG. 3. The six configurational isomers of Thy[ ]Thy. I: *cis-syn*; II*d*, II*l*: *cis-anti*; III*d*, III*l*: *trans-syn*; IV: *trans-anti*. II and III each occur as an enantiomeric pair; their *d,l* labelling is arbitrary.

two for each type of cyclobutane ring. It is inconceivable that any of the four isomers with the antiparallel geometries (II and IV) will ever be synthesized and thus these will not be considered further. The generation of the four diastereomers with geometries I and III can be viewed as follows: (*i*) Configurations with geometry I (designated A_1 and A_2); A_1 will be generated from d(TpT) which has assumed a base-stacked[4] conformation with both the dTp- and -pdT fragments in the ANTI[5] conformation; A_2 is formed if both fragments are SYN. (*ii*) Configurations with geometry III (designated A_3 and A_4); A_3 will be generated from d(TpT) which has assumed a base-stacked conformation with dTp- and -pdT in their SYN and ANTI forms, respectively; A_4 will be generated if dTp- and -pdT are in their ANTI and SYN forms respectively.[6] Note that, whereas A_1 and A_2 possess the same *cyclobutane* geometry (I), A_3 and A_4 differ in that A_3 possesses one of the III*d*, III*l* pair and A_4 the other.

For steric reasons the four isomers are expected to appear in the following order of decreasing importance: $A_1 > A_3 > A_4 > A_2$. This prediction is based *solely* on the expected proportions of d(TpT) with the conformation required to generate A_1, etc. This expectation in turn is based solely on a considerable body of evidence that the ANTI conformation is favored over the SYN in pyrimidine nucleosides, with an even stronger bias for ANTI in pyrimidine-5′-nucleotides due to the repulsion of the 2-keto oxygen and the negatively charged phosphate in the SYN conformation. Interestingly, Weinblum and Johns (6) have shown that the predominant and minor photoproducts possess geometries I and III, respectively. However, since their analysis required liberation of the Thy[ ]Thy from the sugars by hydrolysis, they could not distinguish between the two possibilities for the *intact* predominant product (which we call A_1 and A_2) or for the *intact* minor product (here labelled A_3 and A_4). Our prediction points to A_1 and A_3 as the predominant and minor products observed by Weinblum and Johns.

Evidence for the Cyclobutane Ring

The following observations are consistent with the presence of a cyclobutane ring in d(T[p]T): (*a*) the 0.4 p.p.m. upfield shift of the methyl resonances of d(T[p]T) relative to those of d(TpT) compares favorably with the 0.3 p.p.m. upfield shift observed for the methyl hydrogens in the Thy to *cis-syn* Thy[ ]Thy conversion (4) and with the effect of removal of unsaturation in the propene to propane conversion (30–31); (*b*) the 3.4 p.p.m. upfield shift of the H_6 resonances of d(T[p]T) relative to d(TpT) is in good agreement with the 3.35 p.p.m. shift observed in the Thy to Thy[ ]Thy conversion (4); (*c*) the

[4]In the right-handed helical sense.

[5]ANTI and SYN refer to the conformation about the *N*-glycosyl linkages; *anti* and *syn* refer to the cyclobutane ring geometry.

[6]There is an alternate, but equivalent, way of viewing the formation of the A_1 to A_4 isomers. Viewing a d(TpT) molecule with both fragments in the ANTI conformation from the C_5 to the C_2 positions, we may label the two faces of each base as R (to the right) and L (to the left). The four isomers are generated with the following combination of faces in contact: A_1: R(dTp-), L(-pdT); A_2: L(dTp-), R(-pdT); A_3: L(dTp-), L(-pdT); A_4: R(dTp-), R(-pdT).

appearance of a large J_{66} coupling constant (5.9–6.1 Hz) in d(T[p]T) confirms the presence of covalent links between the bases.

Geometry of the Cyclobutane Ring

The work of Weinblum and Johns (6, 8) on Thy[ ]Thy fragments isolated from d(T[p]T), coupled with later studies (7, 11), provided conclusive evidence for the presence of I in the predominant d(T[p]T) product. Unfortunately, our data cannot provide an independant assignment of ring configuration for the *intact* d(T[p]T) molecule (see below). However, given the *cis-syn* assignment of Weinblum and Johns, we are able to deduce some conformational features of the cyclobutane ring.

With few exceptions crystalline cyclobutane derivatives assume a puckered conformation which confers on the ring substituents quasi-axial (*a*) and quasi-equatorial (*e*) orientations (Fig. 4).[7] The *cis-syn* form of the tetra-*N*-methyl derivative of Thy[ ]Thy, DMT[ ]DMT,[8] is puckered in the crystal state with dihedral angles of 152–153° (11).[9] Available p.m.r. evidence (9, 10) points to a puckered conformation for free *cis-syn* thymine dimers in solution. A $^3J_{66}$ value of 4.8–5.2 Hz was obtained for Thy[ ]Thy (10) and DMT[ ]DMT (9) and, on the basis of studies by Wiberg and Barth (35) and Abraham *et al.* (36), may be translated into an *apparent* dihedral angle of 138°. The 5.9–6.1 Hz values for $^3J_{66}$ suggest a somewhat flatter cyclobutane ring in d(T[p]T) with an apparent dihedral angle of 145°. One cannot, however, distinguish between the two puckered modes on the basis of $^3J_{66}$ values alone.

Nuclear magnetic resonance data for cyclobutane in the nematic phase (37) and for a variety of its derivatives in solution (38) have been interpreted in terms of a rapid interconversion between puckered forms. If one assumes that the 4.8–5.2 Hz $^3J_{66}$ values are consistent with puckered four-membered rings in Thy[ ]Thy and DMT[ ]DMT, then the chemical shift equivalence of corresponding hydrogens on the two halves of each photodimer (9, 10) may be taken as evidence for a rapid interconversion between the two equally populated puckermodes (Fig. 4), since corresponding hydrogens in either puckered form are not related by symmetry. A similar but perhaps somewhat constrained interconversion between puckered modes is also expected for d(T[p]T).

It is unfortunate that the observed $^3J_{66}$ values for d(T[p]T) cannot be used as an independent means for determining the cyclobutane ring configuration; $^3J_{66}$ values of 6.0 Hz are consistent with either puckered form of I (35, 36) or a rapid interconversion between the two modes. In one puckered form of III the 6-hydrogens are *a,a* and a $^3J_{66}$ value of about 10 Hz is expected; in the other they are *e,e* and a $^3J_{66}$ value of about 2.5 Hz is expected. Hence a rapid interconversion between essentially equally populated pucker modes with geometry III can also account for an intermediate (*ca.* 6.0 Hz) value of $^3J_{66}$. Thus little independent configurational information is provided by $^3J_{66}$ values in pyrimidine photodimers.

Several groups (9, 10, 39), in their studies of photodimerized pyrimidine *bases*, have concluded that 5–6 Hz values for J_{66} are consistent only with a vicinal relationship for the two 6-hydrogens. However, *four bond* coupling constants of this magnitude have been observed for hydrogens which constitute an *e,e* pair in other cyclobutane ring systems (35, 36). In this situation the hydrogens are separated by two zigzag (W) coupling paths which favor the appearance of large ^4J values. If one assumes that the same stereochemical rules apply to the pyrimidine photodimers, then a 5–6 Hz J_{66} value does not necessarily preclude the *cis-anti* antiparallel geometry since the two 6-hydrogens are *cis* here and, given the appropriate pucker, may constitute an *e,e* pair. Thus some caution should be exercised in deducing configurational features in the absence of conformational information about the cyclobutane ring. In this regard it is

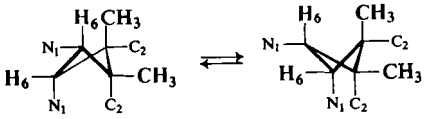

FIG. 4. Puckered forms of the cyclobutane ring.

[7]Centrosymmetrically substituted cyclobutanes may be planar (32); planar centrosymmetrically substituted (*trans-anti*) pyrimidine photodimers have been noted (33, 34).

[8]DMT: 1,3-dimethylthymine.

[9]Defined as the angle between the planes defined by three ring carbon atoms having the transannular distances in common (11).

TABLE 2. Δ(6)[a] values (p.p.m.) for a series of dinucleoside(tide)monophosphates in aqueous solution

18	0.02	0.08	0.08	0.18
65	0.05	0.10	0.03	0.14

[a]Defined as the relative shift between the 6-hydrogens of the two thymine residues.

interesting to point to the absence of an observable $^4J_{66}$ coupling constant in the "low-melting" DMT[ ]DMT isomer (10) which has been shown (40) to have the *cis-anti* geometry and to be puckered with the 6-hydrogens in *a* positions and the methyls in the less crowded *e* positions. If it assumes the same conformation (with the pair of 6-hydrogens rather than the larger methyl groups in the crowded *a,a* positions) in solution, then the absence of any observable $^3J_{66}$ coupling constant is expected.

The Molecular Configuration of d(T[p]T)

Two distinct configurational possibilities exist for d(T[p]T) molecules with the *cis-syn* cyclobutane geometry (see above). Several pieces of evidence suggest that the predominant photoproduct is generated from d(TpT) molecules with ANTI dTp- and -pdT fragments. (*a*) In Table 2 are given Δ(6) values for d(T[p]T) and d(TpT) as well as for d(TpTp) and d(T[p]Tp) from ref. 24; Δ(6) for any dimer is defined as the *relative* chemical shift for the two 6-hydrogens. Comparing the d(TpT) and d(TpTp) entries we note that 3′-phosphorylation enhances the separation of the 6-resonances by 0.05–0.06 p.p.m., whereas for the d(T[p]T) and d(T[p]Tp) entries this enhancement is 0.10–0.11 p.p.m. The enhanced influence of 3′-phosphorylation at the photodimer level seems most consistent with location of the 6-hydrogen of the -[p]dT fragment of d(T[p]T) and the -[p]dTp fragment of d(T[p]Tp) near to the 3′-position. This situation is obtained by rotation of these fragments into an extreme ANTI position (χ, the sugar–base torsion angle $\simeq -160°$) and is possible only when both fragments of the photodimer are ANTI. (*b*) An *endo*-$C_{2'}$ hydrogen should experience a deshielding of about 0.5 p.p.m. upon rotation of a pyrimidine nucleoside from its ANTI to its SYN conformation (41–43). However, in the -pdT to -[p]dT conversion $H_{2'}$ moves upfield by 0.05 p.p.m. Interestingly the $H_{2'}$ hydrogen moves upfield by 0.04 p.p.m. when U (uridine) is converted to diHU (dihydrouridine) by reduction of the C_5—C_6 double bond (44). Thus the 0.05 p.p.m. effect upon $H_{2'}$ is consistent with the disappearance of unsaturation in the C_5—C_6 bond of -[p]dT but not with ANTI to SYN conversion. (*c*) Rotation of a pyrimidine nucleoside into its SYN conformation places the 2-keto oxygen over the sugar ring and should lead to increases of 1.5–2.0 Hz in the sum $J_{4'5'} + J_{4'5''}$ and in the difference $J_{4'5'} - J_{4'5''}$ for the hydroxymethyl group (45, 46). Such changes are not observed for the dTp- to dT[p]- conversion and hence we conclude that photodimerization of d(TpT) does not require ANTI to SYN conversion of the 5′-terminal fragment. We do not think that comparison of *J* and δ values other than those discussed above is meaningful here.

The Sugar–Base Torsion Angles

In the previous section it was suggested that the nucleoside fragments in d(T[p]T) favor the ANTI conformation as in d(TpT). However, our data reveal that some reorientation about the *N*-glycosyl linkages does occur upon conversion of d(TpT) to d(T[p]T). In Fig. 5 the sugar proton chemical shifts for dT, 3′- and 5′-dTMP, d(TpT), and d(T[p]T) are shown. Since $H_{1'}$ is located near to the 2-keto oxygen of ANTI pyrimidine nucleosides, changes in χ should be reflected in δ(1′). Excepting those for d(T[p]T), all δ(1′) entries in Fig. 5 are contained in the narrow range at 6.28 ± 0.05 p.p.m. This was taken as evidence (19) that the χ value distribution for a dT fragment is not drastically affected by 3′- or 5′-phosphorylation or by incorporation into the dimer d(TpT), a contention supported by crystal data. Large upfield shifts, relative to the corresponding δ(1′) in d(TpT), are observed for δ(1′) of dT[p]- ($\simeq$0.52 p.p.m.) and -[p]dT fragments ($\simeq$0.33 p.p.m.). These effects cannot be attributed simply to the removal of the double

[a]In Hz: dT (75 °C) from ref. 24; 3′- and 5′-dTMP (30 °C) from ref. 19; dTp- and -pdT, the fragments of d(TpT), at 18 °C from ref. 32; dT[p]- and -[p]dT, the fragments of d(T[p]T) at 18 °C.

bond character of the C_5—C_6 bond and an accompanying electron density change at $C_{1'}$; upon conversion of U to diHU (44) by reduction of the C_5—C_6 double bond, an upfield shift of only 0.04 p.p.m. is noted in $H_{1'}$. It is more likely that the 0.33 and 0.52 p.p.m. shifts can be traced to the anisotropic magnetic and electric fields associated with the C_2 carbonyls of the thymines, and the χ-dependent orientation of the carbonyls and the 1′-hydrogens. A quantitative evaluation of the χ-value distribution does not seem possible but it seems reasonable to conclude that significant readjustments in the χ angle are required of *both* nucleoside fragments in d(T[p]T).

Conformation of the Sugar Ring

The coupling constants relevant to a discussion of the 2′-deoxyribo rings of d(T[p]T) as well as of dT, 3′- and 5′-dTMP, and d(TpT) are found in Table 3. Considering first the dT[p]- data, we find that the J values are not very different from those of the corresponding monomers (dT, 3′dTMP) and the dTp- fragment of d(TpT). Thus we conclude that this unit is capable of the 2′-*endo* ↔ 3′-*endo* interconversion (26, 27, 45, 46). The data for dT[p]- are consistent with (*a*) a slight increase, relative to dTp-, in the 2′-*endo* bias[10] and (*b*) an increase of about 5° in τ_m (the amplitude of pucker (27)) estimated from the decrease in $J_{1'2''}$ and $J_{2'3'}$. The data do not reveal any significant changes in the pseudorotational parameters P for the dTp- to dT[p]- conversion. At the elevated temperature ($\simeq$65 °C) corresponding J values of dT[p]- and dTp- become more alike, indicating that the conformation of the dT[p]- approaches that of dTp- with increasing temperatures.

Larger effects of photodimerization are indicated for the sugar residue of the -[p]dT frag-

[10]Percentage (3′-*endo*) = $10\,J_{3'4'}$ serves as a useful guide for discussing the conformational weighting of the 2′-*endo* and 3′-*endo* types of pucker (27).

$P_{t'g'}$					5	8	5	9

[a] P_{gg}, P_{gt}, and P_{tg} calculated via eqs. 1–3 and expressed as percentage. $P_{g'g'}$, $P_{g't'}$, and $P_{t'g'}$ calculated via analogous equations given in ref. 19.

ment. This is made particularly clear by the magnitudes of $J_{2',3'}$ (7.6 and 8.1 Hz at 18 and 65 °C) which are the largest such values so far noted in any 2′-deoxyriboside and about 2.5 Hz larger than the corresponding values in dT[p]-. This large $J_{2',3'}$ coupling constant can be interpreted in terms of a flattening of the ring, *i.e.* a reduction in the τ_m of about 10° relative to the value in dT[p]-. The large $J_{1',2'}$ value and small $J_{2'',3'}$ and $J_{3',4'}$ values reveal a preference for the 2′-*endo* conformation though a sizeable contribution from 3′-*endo* must be present since the $J_{2'',3'}$ and $J_{3',4'}$ are comparable to, in fact slightly larger than, the corresponding values for the other molecules listed in Table 3. It is also interesting to note, in view of arguments presented earlier (19), the large differences in the $J_{2'',3'}$ and $J_{3',4'}$ values (0.7 Hz at 18 °C; 1.5 Hz at 65 °C). In all 2-deoxyribosides studied to date, including dT[p]-, this difference is never larger than 0.6 Hz and typically 0.3 Hz. This increase in the $J_{3',4'}$ value relative to $J_{2'',3'}$ could be due to a tendency for the -[p]dT fragment to favor unusually low P_N and/or unusually high P_S values (26, 27) though we cannot discount bond angle distortion in the $C_{2'}$—$C_{3'}$—$C_{4'}$ fragment as a possible interpretation.

Conformation about the $C_{4'}$—$C_{5'}$ Bond

The following relationships which assume a rapid interconversion between staggered conformations are useful for discussing trends in the conformer distribution about the $C_{4'}$—$C_{5'}$ bond (19).

$$[1] \qquad P_{gg} = (13 - \Sigma)/10$$

$$[2] \qquad P_{gt} = (\Sigma - \Delta - 3)/20$$

$$[3] \qquad P_{gg} + P_{gt} + P_{tg} = 1$$

where the P_{ij}'s are the fractional populations of the *gg*, *gt*, and *tg* conformers (Fig. 6), Σ is the observed sum, $J_{4'5'} + J_{4'5''}$, and Δ, the observed difference, $J_{4'5'} - J_{4'5''}$. The calculated values in Table 4 indicate that the dTp- to dT[p]- conversion has no large influence on the $C_{4'}$—$C_{5'}$ population distribution of the free hydroxymethyl group, with a slight bias for *gg* indicated in both instances.

Space-filling molecular models reveal that a d(T[p]T) molecule can reasonably accommodate either the *gg* or *gt* conformer of the -[p]dT fragment but close contact interactions preclude the appearance of the *tg* conformer. Interestingly, if we assume the applicability of eqs. 1–3, we find for -[p]dT significant contributions from *gg* ($\simeq$45%) and from *gt* ($\simeq$55%) but essentially no contribution from *tg* to the overall conformational blend. We must bear in mind that these estimates required us to assume a specific spectral assignment of the 5′,5″ spectral band of the -[p]dT fragment *i.e.* $H_{5'}$ to low field of $H_{5''}$. If the reverse assignment is assumed, then the calculations lead to a *gg* (45%) $\leftrightarrow$ *tg* (55%) interpretation and the exclusion of *gt*. Since the presence of *tg* cannot be easily reconciled with

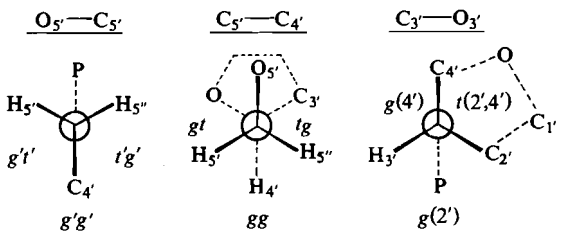

FIG. 6. Definition of the staggered conformers about the $C_{4'}$—$C_{5'}$, $O_{5'}$—$C_{5'}$, and $C_{3'}$—$O_{3'}$ bonds of a nucleotide.

model building, we feel our (Remin and Shugar (29)) assignment is the more reasonable.

Our calculations for the -[p]dT fragment are interesting since in base-stacked helical polynucleotides in the solid state the *gg* form is assumed, exclusive of *gt* and *tg* (25, 28). Thus one conformational consequence of thymine photodimerization appears to be the destabilization of the *gg* rotamer relative to *gt*. The absence of significant effects of the dTp- to dT[p]- conversion on the orientation of the free hydroxymethyl group suggests that distortion may not be transmitted to nucleoside fragments neighboring the damaged photodimer.

Conformation about the $O_{5'}$—$C_{5'}$ and $C_{3'}$—$O_{3'}$ Bonds

The magnitudes of the $^3J_{P5'}$ and $^3J_{P5''}$ coupling constants suggest that the phosphorus atom prefers a *gauche* disposition relative to both the 5′- and 5′′-hydrogens of the -[p]dT fragment (47–51), *i.e.* the *g′g′* conformer (Fig. 6) is preferred as it is in -pdT (32) and all 5′-monophosphates examined to date (25, 28, 51). Conformer populations calculated with equations (19) analogous to [1]–[3] indicate a slight decrease in the *g′g′* conformer of -[p]dT relative to -pdT (Table 4). However, no drastic reorientation about $O_{5'}$—$C_{5'}$ seems required for the -pdT to -[p]dT conversion.

In earlier work (51) correlations between Σ ($=J_{4'5'} + J_{4'5''}$) and Σ'($=J_{P5'} + J_{P5''}$) were discussed; these demonstrate that the population distribution about the $C_{4'}$—$C_{5'}$ and $O_{5'}$—$C_{5'}$ bonds of a 5′-β-nucleotide are interrelated. The interrelationship is such that when the molecule is *gg*, the *g′t′* and *t′g′* conformers are excluded and the *g′g′* state must be assumed; upon rotation out of *gg*, *g′g′* is no longer required and the molecule is allowed to populate the *g′t′* and *t′g′* forms, though *g′g′* remains the predominant form. Steric arguments for this behavior were presented (51). Our studies on d(TpT) (19) and those of Altona (52) indicate that similar correlations and interdependencies hold for the -pN fragment of dinucleoside monophosphates (NpN) as well. Interestingly the Σ,Σ' data for -[p]dT also lie near to the correlation plots in ref. 51. This supports our calculated $C_{4'}$—$C_{5'}$ and $O_{5'}$—$C_{5'}$ rotamer populations in Table 4 and the *gg* ↔ *gt* model for the -[p]dT fragment.

Correlations between Σ and Σ', and the long-range phosphorus-$H_{4'}$ coupling ($^4J_{P4'}$) have been presented (53). They demonstrate that $^4J_{P4'}$ is a simultaneous measure of the conformational distribution about the $C_{4'}$—$C_{5'}$ and $O_{5'}$—$C_{5'}$ bonds of a 5′-nucleotide and support our conclusions based on the Σ,Σ' maps. $^4J_{P4'}$ values of 1.6 Hz (18 °C) and 1.4 Hz (63°C) were revealed in the -[p]dT portion of the d(T[p]T) spectrum. These data also lie near to the $\Sigma,^4J_{P4'}$ and $\Sigma',^4J_{P4'}$ correlation plots, though the deviations seem outside of experimental error. Nevertheless we feel the agreement is adequate and in support of our conformational conclusions based on the three-bond coupling constants.

The $^3J_{P3'}$ coupling constant monitors the conformer distribution about the $C_{3'}$—$O_{3'}$ bond of the dT[p]- fragment. The values of 2.9 Hz (18 °C) and 4.5 Hz (63 °C) argue for a *gauche* orientation of $H_{3'}$ and P (47, 48) (Fig. 6). One could assume an equilibrium blend of rotamers *g*(2′) and *g*(4′). However, *g*(4′) is not compatible with the stacking of bases required for photodimerization and thus can be excluded. These values for $^3J_{P3'}$ in d(T[p]T) are the smallest noted to date. In d(TpT), values of 6.8 and 7.1 Hz were obtained at 18 and 65 °C, respectively. In certain dinucleoside monophosphates (52), $^3J_{P3'}$ values up to 9.5 Hz are noted. This suggests that in d(T[p]T) the *gauche* energy minimum in the H—$C_{3'}$—O—P fragment is nearer to the classically staggered (60°) situation. Furthermore, in contrast with the situation in other dinucleoside monophosphates, $^3J_{P3'}$ changes perceptibly (1.6 Hz) in the temperature interval 18–63 °C. Interestingly in the same interval, substantial changes (~1 Hz) are observed for $J_{3'4'}$ and Σ'. Thus some perceptible rearrangements in the vicinity of the phosphate do occur with changes in temperature. This does not seem to be the case with d(TpT) (19).

In conclusion, p.m.r. data for the predominant u.v. photoproduct of d(TpT) are discussed. The data are consistent with the presence of a puckered cyclobutane ring with the *cis-syn* geometry but do not form an independent basis for configurational analysis. Photodimerization leads to conformational changes in the ribose phosphate backbone with the larger distortions apparent in the 3′-terminal (5′-linked) nucleotide moiety.

NOTE ADDED IN PROOF: Sundaralingam (25) has suggested the symbols ω, ω′, ϕ, ϕ′, ψ, and ψ′

to denote the torsion angles about the P—$O_{5'}$, $O_{3'}$—P, $O_{5'}$—$C_{5'}$, $C_{3'}$—$O_{3'}$, $C_{5'}$—$C_{4'}$, and $C_{4'}$—$C_{3'}$ bonds of a polynucleotide backbone. Rotations were defined to be positive and can be designated as g^+ (*gauche*$^+$), t(*trans*), and g^-(*gauche*$^-$) if the angle lies in the range of staggered conformations possessing the 60, 180, and 300° (−60°) values, respectively. With this nomenclature we have noted (1) an interesting uniformity in the orientations assumed by right-handed helical polynucleotides. Thus for RNA-11 and DNA-A which are 3′-*endo* puckered we have: g^- for the P—O rotations (ω, ω'); t for the C—O rotations (ϕ, ϕ'), and g^+ for the C—C rotations (ψ, ψ'). For DNA-B which is 2′-*endo* the same scheme holds except that ψ' is t rather than g^+. Thus with this uniformity the gross conformational features of right-handed helical polynucleotides (which fall now logically into two classes differing only in pucker) are easily remembered.

Oxidation of five-membered ring (1,3-dioxolan) and six-membered ring (1,3-dioxan) benzylidene acetals by ozone are reported.

PIERRE DESLONGCHAMPS, CLAUDE MOREAU, DANIEL FRÉHEL et ROBERT CHÊNEVERT. Can. J. Chem. **53**, 1204 (1975).

L'oxydation de benzylidène acétals du type dioxolanne-1,3 et dioxanne-1,3 par l'ozone est rapportée.

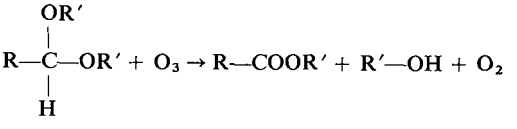
We have reported in a preliminary communication (1), the oxidation of aldehyde acetals to the corresponding esters and alcohols with



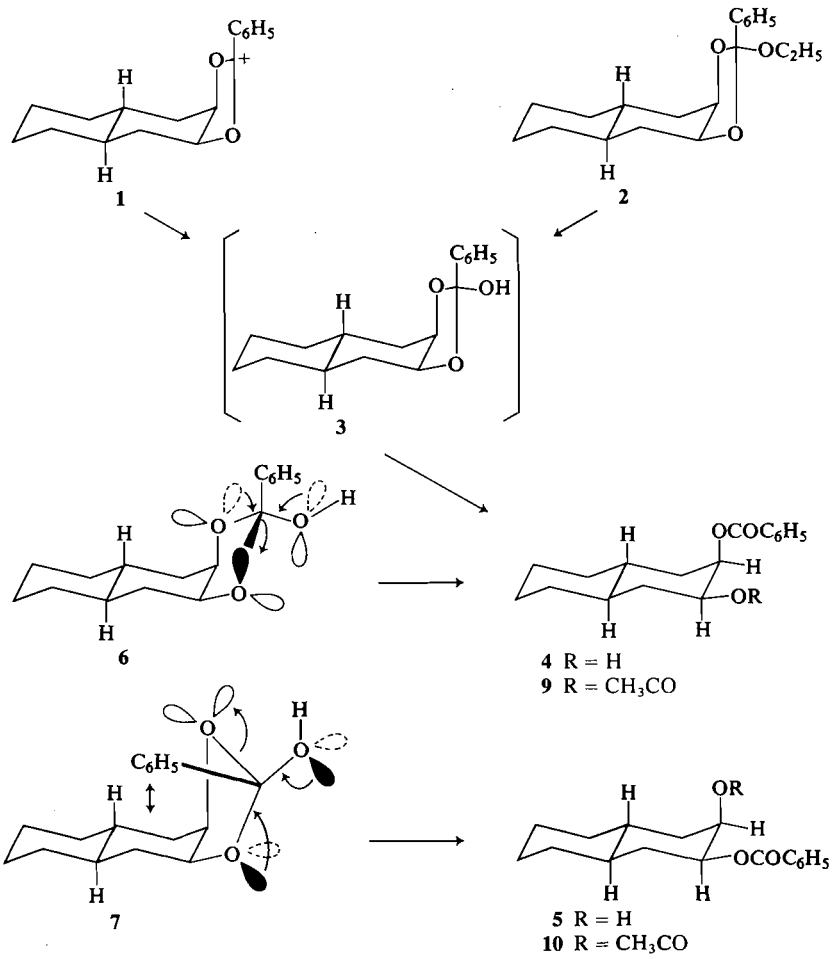
ozone. Further studies on the reactivity of the acetal function in relation to its conformation (2) led us to develop a new stereoelectronic theory for the hydrolysis of esters (3) and amides (4). We have reported in detail (5) the ozonolysis of various types of acetals such as 1,1-dialkoxyheptane, 2-alkyl-1,3-dioxolan, 2-alkyl-1,3-dioxan, 2-alkoxytetrahydropyran, and 2-alkoxytetrahydrofuran as well as α- and β-glycosides. We have also examined the oxidation of benzylidene acetals and we wish to report in detail the result of this work.

We have studied five-membered ring (1,3-dioxolan) and six-membered ring (1,3-dioxan) benzylidene acetals. 1,3-Dioxolan acetals were investigated for two reasons. First, we wanted to obtain evidence that the oxidation of acetals by ozone proceeded through the formation of a tetrahedral hemiorthoester intermediate or its equivalent (3). Secondly, we hoped to demonstrate that the oxidation of these acetals was valuable in the carbohydrate field as an attractive method for the specific esterification of an axial alcohol in conformationally rigid *cis*-1,2-cyclohexanediols. It was also of interest to examine the oxidation of a series of 4,6-*O*-benzylidene derivatives (1,3-dioxan acetals) of glycopyranosides to see if this reaction could be used for the preparation of 6-benzoate-4-hydroxy or 4-benzoate-6-hydroxy derivatives of glycopyranosides. The preparation of such partially esterified sugar derivatives can be important in carbohydrate chemistry. This route is particularly attractive because 4,6-*O*-benzylidene derivatives are normally readily available.

King and Allbutt (6) have described the stereoselective hydrolysis of dioxolenium ions and orthoesters fused to anchored six-membered rings. Mild acid hydrolysis of the dioxolenium salt **1** or the orthoester **2** afforded the axial ester – equatorial alcohol **4** with a very small amount of the isomer **5**. They further established by equilibration studies that the more stable isomer is the expected equatorial benzoate **5**, thus indicating that the formation of the isomer **4** is the result of a kinetically controlled hydrolysis of **1** and **2**. The hydrolysis of **1** and **2** proceeds through the formation of the hemiorthoester tetrahedral intermediate **3**. The intermediate **3** can assume two different conformations **6** and **7** which can give respectively the axial ester **4** and the equatorial ester **5** through an orbital assisted mechanism (3–6). However, conformer **6** is sterically favored over conformer **7** (6) and the axial ester **4** is formed selectively.

The study of the ozonolysis of 1,3-dioxolan benzylidene acetals fused to a rigid six-membered ring was therefore undertaken. If one observes the same stereoselectivity in product formation as seen in the hydrolysis of **1** and **2**, strong indirect evidence will have been obtained that the ozonolysis of acetals proceeds via the formation

[1]To whom all correspondence should be addressed.
[2]Holder of a "bourse postdoctorale France–Québec," 1973–1974.



of an intermediate analogous to a hemiorthoester. Accordingly, oxidation studies on the benzylidenes derivatives **8** of 9β,10α-decalin-2β,3β-diol[3] (6) and **11** of 5α-cholestane-2β,3β-diol (7) were carried out.

Ozonolysis of **8** for 1 h at −78° in ethyl acetate gave a mixture of two isomeric hydroxy benzoates which were separated by preparative thin-layer chromatography. The major isomer (92%) was identified as the axial benzoate **4** ((6), 2β-benzoxy-3β-hydroxy-9β,10α-decalin). The minor isomer (8%) was the equatorial benzoate **5** ((6), 3β-benzoxy-2-β-hydroxy-9β,10α-decalin). The structure of the minor isomer **5** was confirmed by comparison with an authentic sample prepared by benzoylation of 9β,10α-decalin-2β,3β-diol (6).

[3]We are grateful to Professor J. F. King (University of Western Ontario) for his generous gift of this compound.

Analogous results were obtained for the ozonolysis of the cholestane benzylidene derivatives **11**. The major product (92%) was identified as the axial benzoate **12** and the minor product (8%) as the equatorial benzoate **13**. The minor isomer **13** was also compared with an authentic sample prepared by benzoylation of 5α-cholestane-2β,3β-diol (8).

The presence of minor amounts (≃8%) of the equatorial benzoate derivatives (**5** and **13**) in these reactions can be explained in two ways. Either the reaction is simply not completely stereospecific or the reaction is totally stereospecific but the axial benzoate derivatives (**4** and **12**) are converted to some extent into the more stable equatorial isomers (**5** and **13**) by equilibration during the reaction or in the work-up procedure. The second explanation was preferred because we were aware that trace amounts of acetic acid

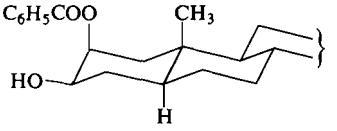
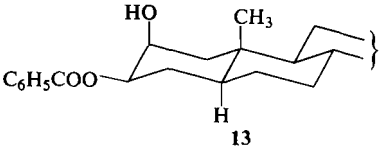
11



12



13

were produced when the ozonolysis reaction was carried out in ethyl acetate. The presence of acid could have catalyzed the isomerization. The ozonolysis of compound **8** was repeated in acetic anhydride containing sodium acetate. This solvent system is known to be useful in transforming *in situ* an alcohol function into an acetate function (5), thus eliminating the possibility of a transesterification during the work-up procedure. As expected, only one product,[4] the axial benzoate – equatorial acetate derivative **9**,[5] was isolated. Thus, the ozonolysis of benzylidene acetal **8** (or **11**) shows the same stereoselectivity as observed in the kinetic decomposition of hemiorthoester **3**. Therefore, it is logical to conclude that this oxidation reaction involves the formation of an intermediate which is either equivalent or identical to a hemiorthoester.

We have also studied the ozonolysis of the following 4,6-*O*-benzylidene derivatives of 2,3-disubstituted methyl α-D-glucopyranosides: 2,3-di-*O*-methyl **14** (m.p. 122–123° (9)), 2,3-di-*O*-acetyl **18** (10), and 2,3-di-*O*-tosyl derivative **22** (11). Ozonolysis of **14** in anhydrous carbon tetrachloride gave a mixture of the 6-*O*-benzoyl derivative **15** (60%) and the 4-*O*-benzoyl derivative **16** (40%) of methyl 2,3-di-*O*-methyl-α-D-glucopyranoside which were separated by preparative thin-layer chromatography. The 4-*O*-benzoyl derivative **16** was further converted into methyl 4-*O*-benzoyl-6-bromo-6-deoxy-2,3-di-*O*-methyl-α-D-glucopyranoside (**17**) (12); an authentic sample of **17** was prepared by oxidation of **14** with *N*-bromosuccinimide (13).

Ozonolysis of the 2,3-di-*O*-acetyl benzylidene derivative **18** in glacial acetic acid gave a mixture of the 6-*O*-benzoyl-2,3-di-*O*-acetyl- (85%) and 4-*O*-benzoyl-2,3-di-*O*-acetyl- (15%) methyl α-D-glycopyranosides (**19** and **20**) which were separated by preparative thin-layer chromatography. The identity of the 4-*O*-benzoyl derivative **20** was established by its transformation into methyl 4-*O*-benzoyl-6-bromo-6-deoxy-2,3-di-*O*-acetyl-α-D-glucopyranoside (**21**) (12). An authentic sample of **21** was prepared by oxidation of compound **18** with *N*-bromosuccinimide (13). The ozonolysis of the 2,3-di-*O*-tosyl benzylidene derivative **22** was also carried out in glacial acetic acid. Methyl 4-*O*-benzoyl-2,3-di-*O*-tosyl-α-D-glucopyranoside (**23**) was the only product isolated. This structure is proposed on the basis of its carbon-13 n.m.r. spectrum (Table 1). Compounds **15** and **16** were used as models. The C-6 of **23** must be part of a CH_2OH group since it is shielded (60.6 p.p.m.) relative to the corresponding carbon in **16** (61.1 p.p.m.). Also, C-6 in **16** is shielded relative to C-6 in **15** (63.7 p.p.m.) (14).

The other possible epimeric benzylidene derivative (m.p. 126–128°) of methyl 2,3-di-*O*-methyl-α-D-glucopyranoside is known (9). If it exists in conformation **24**, it should be inert to ozone; the lone pair orbitals of the two oxygens are not properly oriented to make **24** reactive toward ozone (1, 2, 5). However, it has been proposed that this compound can assume conformation **25** (9). If it does, it should be reactive toward ozone since **25** has proper orbital orientation. The benzylidene epimer (m.p. 126–

[4]Since only product **9** was obtained, one must also conclude that a suspension of sodium acetate in acetic anhydride does not catalyze a possible transesterification to any appreciable extent.

[5]The structure of compound **9** was firmly established by comparison with an authentic sample prepared by acetylation of the axial benzoate derivative **4**. The synthesis of the other possible isomer **10**, the equatorial benzoate – axial acetate derivative, was achieved by acetylation of the equatorial benzoate derivative **5**. This last experiment was carried out to be completely certain that no transesterification reaction occurred prior to the acetylation of the axial benzoate derivative **4**.

25

128°) was found to be reactive toward ozone yielding a mixture of the 6-*O*-benzoyl derivative **15** (40%) and the 4-*O*-benzoyl derivative **16** (60%) of methyl 2,3-di-*O*-methyl-α-D-glucopyranoside. This ozonolysis reaction was carried out with carbon tetrachloride which has been filtered through neutral alumina. The possibility that the epimer (m.p. 126–128°) was first isomerized by traces of acid to the epimer **14** (m.p. 122–123°) prior to the reaction with ozone seems unlikely.

It is known that methyl β-glycopyranoside can be oxidized by ozone (5) but this reaction is slow even at room temperature. Benzylidene acetals are much more reactive; the oxidation is normally completed within 2 h at −78°. Consequently, we think that the oxidation of the benzylidene acetals of alkyl-4,6-*O*-benzylidene-β-glycosides can be carried out without oxidation of the anomeric center. Thus, this new method for the synthesis of partially esterified sugars can be also used with alkyl-β-glycopyranosides.

The oxidation of an ethylidene derivative (**26**) (15) was also attempted. This reaction was carried out in acetic anhydride – sodium acetate, so that the poly-*O*-acetylated product was isolated directly. Methyl 4,6-*O*-ethylidene-2,3-di-*O*-acetyl-α-D-glucopyranoside (**26**) gave methyl 2,3,4,5-tetra-*O*-acetyl-α-D-glucopyranoside (**27**) (16) in excellent yield.

TABLE 1. Carbon-13 n.m.r. spectra (p.p.m.)*

	C-1	C-2	C-3	C-4	C-5	C-6	C=O
 15	97.4	81.6	82.6	69.1	70.1	63.7	166.8
 16	97.7	81.4	80.6	71.3	69.7	61.1	166.5
 23	97.4	76.7	75.8	69.8	68.9	60.6	166.1

*We are grateful to Professor J. K. Saunders for the analysis of the spectra.

We have also studied the ozonolysis of 2-phenyl-4,4,6-trimethyl-1,3-dioxan (**28**). In this reaction, the intermediate **29** should be formed. The orientation of the orbitals of the ring oxygen atoms favors the opening of **29** in both directions equally. However, there is a strong 1,3-diaxial interaction between the OH group and the axial methyl group. The cleavage of **29** to give the secondary ester **30** eliminates this steric interaction whereas the cleavage of **29** to give the corresponding tertiary ester does not. Consequently, we think that this steric compression factor is strong enough to induce a specific cleavage of **29**. The exclusive formation of the secondary ester **30** is thus predicted. This result was confirmed experimentally and it constitutes another piece of evidence for the formation of a hemiorthoester intermediate in the ozonolysis of acetals.[6]

Experimental

The i.r. spectra were taken on a Perkin-Elmer 257 spectrophotometer. Proton n.m.r. spectra (δ value) were recorded on a Varian A-60 spectrometer in solvent indicated. Carbon-13 n.m.r. spectra were taken on a Bruker HX-90 spectrometer equipped with a Nicolet 1083 comp uter. All chemical shifts are recorded relative to internal TMS as standard. The ozonolysis reactions were carried out with a Welsbach Ozonator, model T-816. Organic solutions were dried over anhydrous magnesium sulfate and silica gel was use in all the chromatography. Microanalyses were performed by Dr. C. Daesslé, Organic Microanalyses, and by Mr. J. Tamas, Laboratoire de Microanalyse, Université de Sherbrooke.

[6]For a theoretical study related to this subject, see ref. 17.

Benzylidene Derivative of 9β,10α-Decalin-2β,3β-diol (8)

9β,10α-Decalin-2β,3β-diol ((6) 450 mg, 2.6 mmol) was dissolved in benzaldehyde (30 ml) and mixed with zinc chloride (4 g). The reaction mixture was kept for 18 h at room temperature under nitrogen. Water (50 ml) was then added and the mixture was extracted with ether. After evaporation of the dried ethereal phase, the resulting product was purified by preparative thin-layer chromatography with silica gel. The analytical sample was prepared by sublimation; m.p. 86–80°; n.m.r.: δ($CDCl_3$) 7.40 (5H, multiplet, aromatic hydrogens), 6.13 and 5.86 (1H, two singlets (ratio: 2:1), acetal hydrogen of the isomeric benzylidenes), and 4.16 (2H, multiplet, two >CHOC<).

Anal. Calcd. for $C_{17}H_{22}O_2$: C, 79.03; H, 8.58. Found: C, 79.12; H, 8.81.

Ozonolysis of 2β,3β-O-Benzylidene-9β,10α-decalin (8)

(*a*) Compound **8** (258 mg, 1 mmol) was ozonized in ethyl acetate (100 ml) at −78° (rate of ozone: 1 mmol/min) during 1 h. Residual ozone was removed by flushing the system with nitrogen. The solvent was removed *in vacuo*. The residual material contained the isomers **4** and **5** which were separated by preparative thin-layer chromatography.

2β-Benzoxy-3β-hydroxy-9β,10α-decalin (**4**) (252 mg, 92%); m.p. 105–106° (lit. (6) m.p. 106–107°); i.r.: ($CHCl_3$) 3580, 3460, and 1720 cm^{-1}; n.m.r.: δ($CDCl_3$) 8.1–7.5 (5H, two multiplets, aromatic hydrogens), 5.45 (1H, multiplet, ArCOOCH), and 3.80 (1H, multiplet, C*H*OH).

3β-Benzoxy-2β-hydroxy-9β,10α-decalin (**5**) (17 mg, 6%), m.p. 102° (lit. (6) m.p. 102–103°). An authentic sample of **5** was prepared by benzoylation of 9β,10α-decalin-2β,3β-diol by following the procedure described by King and Allbutt (6).

(*b*) Compound **8** (150 mg, 0.5 mmol) was ozonized (rate of ozone: 1 mmol/min) in acetic anhydride (100 ml) containing sodium acetate (2 g) at room temperature during 1 h. Pyridine was then added to the reaction mixture which was kept at room temperature for 24 h. Solvent was removed *in vacuo*. The resulting material was purified by preparative thin-layer chromatography and was found to be identical with an authentic sample of 3β-acetoxy-2β-benzoxy-9β,10α-decalin (**9**). The isomer **10** could not be detected by thin-layer chromatography.

*3β-Acetoxy-2β-benzoxy-9β,10α-decalin (**9**)*

2β-Benzoxy-3β-hydroxy-9β,10α-decalin (**4**, 80 mg, 0.3 mmol) was dissolved in a mixture of pyridine (10 ml) and acetic anhydride (10 ml). This mixture was kept at room temperature for 15 h. The solvent was removed *in vacuo* and the product was purified by preparative thin-layer chromatography. The analytical sample was prepared by distillation (86 mg, 94%); i.r.: ν_{max} ($CHCl_3$) 1720 cm^{-1}; n.m.r.: δ ($CDCl_3$) 8.1–7.5 (5H, two multiplets, aromatic hydrogens), 5.6 (1H, narrow multiplet, ArCOOCH), 4.98 (1H, broad multiplet, CHOAc), and 1.93 (3H, singlet, CH_3COO).

Anal. Calcd. for $C_{19}H_{24}O_4$: C, 72.13; H, 7.65. Found: C, 72.29; H, 7.29.

*2β-Acetoxy-3β-benzoxy-9β,10α-decalin (**10**)*

3β-Benzoxy-2α-hydroxy-9β,10α-decalin (**5**) was acetylated by the experimental procedure described above. Compound **10** was purified by distillation (92% yield); i.r.: ν_{max} ($CHCl_3$) 1720 cm^{-1}; n.m.r.: δ ($CDCl_3$) 8.0–7.45 (5H, two multiplets, aromatic hydrogens), 5.47 (1H, narrow multiplet, ArCOOCH), 5.10 (1H, broad multiplet, CHOAc), and 2.11 (3H, singlet, CH_3COO).

Anal. Calcd. for $C_{19}H_{24}O_4$: C, 72.13; H, 7.65. Found: C, 72.14; H, 7.71.

*2β,3β-O-Benzylidene-5α-cholestane (**11**)*

Cholestane-2β,3β-diol ((7), 200 mg, 0.5 mmol) was dissolved in benzaldehyde (30 ml) and mixed with zinc chloride (2 g). The reaction mixture was kept for 18 h at room temperature under nitrogen. Ether (500 ml) was added and the organic phase was washed with water. The dried organic phase was evaporated and the residual material was purified by preparative thin-layer chromatography to yield a mixture of the epimeric benzylidenes (**11**) which was recrystallized from acetone; m.p. 126–131°; n.m.r.: δ ($CDCl_3$) 6.12 and 5.76 (1H, two singlets (ratio 1:1), acetal hydrogen of the isomeric benzylidenes), and 4.22 (2H, multiplet, two >CHOC<).

*Ozonolysis of 2β,3β-O-Benzylidene-5α-cholestane (**11**)*

Compound **11** (135 mg, 0.27 mmol) was ozonized in ethyl acetate (50 ml) at −78° (rate of ozone: 1 mmol/min) during 1 h. The solvent was removed *in vacuo*. The residual material contained the isomers **12** and **13** which were separated by preparative thin-layer chromatography.

2β-Benzoxy-3β-hydroxy-5α-cholestane **12** (128 mg, 92%) was recrystallized from acetone; m.p. 141°; i.r.: ν_{max} ($CHCl_3$) 3580, 3460, and 1720 cm^{-1}; n.m.r.: δ ($CDCl_3$) 8.1–7.46 (5H, two multiplets, aromatic hydrogens), 5.42 (1H, narrow multiplet, ArCOOCH), and 3.75 (1H, broad multiplet, C*H*OH).

Anal. Calcd. for $C_{34}H_{52}O_3 \cdot H_2O$: C, 77.51; H, 10.32. Found: C, 77.92; H, 9.89.

3β-Benzoxy-2β-hydroxy-5α-cholestane (**13**) (9 mg, 8%) was recrystallized from acetone, m.p. 213–215°, and was found identical to an authentic sample.

*3β-Benzoxy-2β-hydroxy-5α-cholestane (**13**)*

5α-Cholestane-2β,3β-diol ((7), 115 mg, 0.28 mmol) was dissolved in dichloromethane (25 ml). Pyridine (4.5 ml) and benzoyl chloride (45 mg, 0.3 mmol) was added and the mixture was left at room temperature for 24 h. Ether was added and the organic phase was washed with an aqueous solution of sodium bicarbonate. The dried ethereal solution was evaporated and the residual material was purified by preparative thin-layer chromatography to give the benzoate derivative **13** (104 mg, 90%) which was crystallized from acetone; m.p. 213–215°; i.r.: ν_{max} ($CHCl_3$) 3580, 3460, and 1720 cm^{-1}; n.m.r.: δ ($CDCl_3$) 8.0–7.5 (5H, two multiplets, aromatic hydrogens), 5.08 (1H, broad multiplet, ArCOOCH), and 4.24 (1H, narrow multiplet, C*H*OH).

Anal. Calcd. for $C_{34}H_{52}O_2 \cdot H_2O$: C, 77.51; H, 10.32. Found: C, 77.52; H, 9.99.

Ozonolysis of Methyl 4,6-O-Benzylidene-2,3-di-O-methyl-α-D-glucopyranosides (9)

*(a) Isomer **14** (m.p. 122–123°)*

Methyl 4,6-*O*-benzylidene-2,3-di-*O*-methyl-α-D-glucopyranoside (m.p. 122–123°) (1.556 g, 5.02 mmol) was ozonized (rate of ozone: 0.5 mmol/min) in carbon tetrachloride (filtered through neutral alumina) at room temperature. The reaction was stopped after 30 min and the solvent was evaporated *in vacuo*. The residual material contained the isomers **15** and **16** which were separated by column chromatography with silica gel.

Methyl 6-*O*-benzoyl-2,3-di-*O*-methyl-α-D-glucopyranoside (**15**, 635 mg); m.p. 95–97°; $[\alpha]_{578}^{CHCl_3}$ +42°; n.m.r.: δ ($CDCl_3$) 8.1–7.5 (5H, two multiplets, aromatic hydrogens), 5.23 (1H, doublet, J = 8 Hz, ArCOOCH), 4.96 (1H, doublet, J = 3 Hz, anomeric hydrogen), 3.55 (3H, singlet, OCH_3), 3.53 (3H, singlet, OCH_3), and 3.48 (3H, singlet, OCH_3).

Methyl 4-*O*-benzoyl-2,3-di-*O*-methyl-α-D-glucopyranoside (**16**, 774 mg); m.p. 68–70°; $[\alpha]_{578}^{CHCl_3}$ +107°; n.m.r.: δ ($CDCl_3$) 8.1–7.5 (5H, two multiplets, aromatic hydrogens), 4.87 (1H, doublet, J = 3 Hz, anomeric hydrogen), 4.60 (2H, doublet, J = 3 Hz, CH_2O), 3.66 (3H, singlet, OCH_3), 3.48 (3H, singlet, OCH_3), and 3.43 (3H, singlet, OCH_3).

Anal. Calcd. for $C_{16}H_{22}O_7$: C, 58.88; H, 6.80. Found: C, 59.11; H, 6.92.

*(b) Isomer **24** (**25**) (m.p. 126–128°)*

Methyl 4,6-*O*-benzylidene-2,3-di-*O*-methyl-α-D-glucopyranoside (m.p. 126–128°) was ozonized under the same experimental conditions described for the ozonolysis of isomer **14** (m.p. 122–123°). The isomeric hydroxybenzoates **15** and **16** were isolated in 40 and 60%, respectively.

*Methyl 4-O-Benzoyl-6-bromo-6-deoxy-2,3-di-O-methyl-α-D-glucopyranoside (**17**)*

(*a*) Methyl 4-*O*-benzoyl-2,3-di-*O*-methyl-α-D-glucopyranoside (**16**, 90 mg, 0.3 mmol) and triphenyl phosphine (160 mg, 0.6 mmol) were dissolved in anhydrous dimethylformamide (5 ml). *N*-Bromosuccinimide (110 mg, 0.6 mmol) was then slowly added and the mixture was heated at 60° for 2 h (12). After cooling, water (5 ml) was added and the mixture was extracted with ether. The dried

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

ethereal phase was then evaporated. The residue was purified by preparative thin-layer chromatography to yield pure methyl 4-*O*-benzoyl-6-bromo-6-deoxy-2,3-di-*O*-methyl-α-D-glucopyranoside (**17**, 90 mg, 84%); oil; $[\alpha]_{578}^{CHCl_3}$ +68°; n.m.r.: δ ($CDCl_3$) 8.1–7.5 (5H, two multiplets, aromatic hydrogens), 5.13 (1H, doublet, J = 8 Hz, ArCOOCH), 4.92 (1H, doublet, J = 3 Hz, anomeric hydrogen), 3.53 (3H, singlet, OCH_3), 3.50 (3H, singlet, OCH_3), and 3.46 (3H, singlet, OCH_3).

(*b*) Methyl 4,6-*O*-benzylidene-2,3-di-*O*-methyl-α-D-glucopyranoside (**14**, 320 mg, 1.03 mmol) was dissolved in anhydrous carbon tetrachloride and heated at reflux for 1 h in presence of *N*-bromosuccinimide (280 mg, 1.60 mmol) and barium carbonate (800 mg, 4 mmol) (13). The solution was filtered through Celite and evaporated to dryness. Compound **17** was purified by preparative thin-layer chromatography (247 mg); oil; $[\alpha]_{578}^{CHCl_3}$ +71°. This product was found identical with compound **17** prepared by the procedure described above.

*Ozonolysis of Methyl 4,6-O-Benzylidene-2,3-di-O-acetyl-α-D-glucopyranoside (**18**) (10)*

Compound **18** (165 mg, 0.45 mmol) was ozonized (rate of ozone: 0.3 mmol/min) in glacial acetic acid at room temperature. The reaction was stopped after 1.5 h and the solvent was removed *in vacuo*. The residual material contained the isomers **20** (15%) and **19** (85%) which were separated by preparative thin-layer chromatography. Pure isomer **19** was isolated but isomer **20** was contaminated with a small quantity of the other isomer (**19**).

Methyl 6-*O*-benzoyl-2,3-di-*O*-acetyl-α-D-glucopyranoside (**19**); oil; $[\alpha]_{578}^{CHCl_3}$ +110°; n.m.r.: δ ($CDCl_3$) 8.0–7.4 (5H, two multiplets, aromatic hydrogens), 4.90 (2H, singlet, $ArCOOCH_2$), 3.40 (3H, singlet, OCH_3), and 2.06 (6H, singlet, two CH_3COO).

Anal. Calcd. for $C_{18}H_{22}O_9$: C, 56.53; H, 5.80. Found: C, 56.47; H, 5.97.

Methyl 4-*O*-benzoyl-2,3-di-*O*-acetyl-α-D-glucopyranoside (**20**), oil; n.m.r.: δ ($CDCl_3$) 8.0–7.4 (5H, two multiplets, aromatic hydrogens), 3.43 (3H, singlet, OCH_3), 2.7 (3H, singlet, CH_3COO), and 1.90 (3H, singlet, CH_3COO).

*Methyl 4-O-Benzoyl-6-bromo-6-deoxy-2,3-di-O-acetyl-α-D-glucopyranoside (**21**)*

(*a*) Methyl 4-*O*-benzoyl-2,3-di-*O*-acetyl-α-D-glucopyranoside (**20**, 165 mg, 0.43 mmol) and triphenyl phosphine (230 mg, 0.87 mmol) were dissolved in anhydrous dimethyl formamide (5 ml). *N*-Bromosuccinimide (160 mg, 0.87 mmol) was then added and the mixture was heated at 60° for 2 h (12). After cooling, water (10 ml) was added and the mixture was extracted with ether. The dried ethereal phase was then evaporated. The residue was purified by preparative thin-layer chromatography to yield pure methyl 4-*O*-benzoyl-6-bromo-6-deoxy-2,3-di-*O*-acetyl-α-D-glucopyranoside (**21**, 110 mg); oil; $[\alpha]_{578}^{CHCl_3}$ +61°; n.m.r.: δ ($CDCl_3$) 7.9–7.4 (5H, two multiplets, aromatic hydrogens), 5.0 (2H, singlet, CH_2Br), 3.48 (3H, singlet, OCH_3), 8.05 (3H, singlet, CH_3COO), and 1.86 (3H, singlet, CH_3COO).

(*b*) Methyl 4,6-*O*-benzylidene-2,3-di-*O*-acetyl-α-D-glucopyranoside (**18**, 360 mg, 1.0 mmol) was dissolved in anhydrous carbon tetrachloride and heated at reflux for 1 h in presence of *N*-bromosuccinimide (250 mg, 1.5 mmol) and barium carbonate (800 mg) (13). The solution was filtered through Celite and evaporated to dryness. Compound **21** was purified by preparative thin-layer chromatography (195 mg); oil; $[\alpha]_{578}^{CHCl_3}$ +61°. This product was found identical with compound **21** prepared by the procedure described above.

*Ozonolysis of Methyl 4,6-O-Benzylidene-2,3-di-O-tosyl-α-D-glucopyranoside (**22**) (11)*

Compound **22** (80 mg, 0.136 mmol) was ozonized (rate of ozone: 0.33 mmol/min) in glacial acetic acid at room temperature. The reaction was stopped after 1.5 h and the solvent was removed *in vacuo*. The residue was purified by preparative thin-layer chromatography to give methyl 4-*O*-benzoyl-2,3-di-*O*-tosyl-α-D-glucopyranoside (**23**, 60 mg, 75%); m.p. 85–88°; $[\alpha]_{578}^{CHCl_3}$ −26°; n.m.r.: δ ($CDCl_3$) 8.0–7.0 (13H, multiplets, aromatic hydrogens), 3.36 (3H, singlet, OCH_3), 2.41 (3H, singlet, $ArCH_3$), and 2.25 (3H, singlet, $ArCH_3$).

Anal. Calcd. for $C_{28}H_{30}O_{11}S_2$: C, 55.60; H, 4.99. Found: C, 55.60; H, 5.14.

*Ozonolysis of Methyl 2,3-Di-O-acetyl-4,6-O-ethylidene-α-D-glucopyranoside (**26**) (15)*

Compound **26** (940 mg, 3.09 mmol) was ozonized (rate of ozone: 0.3 mmol/min) in acetic anhydride (100 ml) containing sodium acetate (4 g) at room temperature during 2 h. The reaction mixture was then heated at 100° for 1.5 h. The solvent was removed in *vacuo* then ether was added. The ethereal phase was washed with an aqueous solution of sodium carbonate and brine. The dried organic phase was evaporated *in vacuo* and the residue was purified by column chromatography to yield methyl 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside (**27**, 1.109 g, 98%); m.p. 99–100°; $[\alpha]_{578}^{CHCl_3}$ +129° (lit. (8) m.p. 101–103°; $[\alpha]_{D}^{CHCl_3}$ +130°). This compound was found to be identical to an authentic sample.

*2-Phenyl-4,4,6-trimethyl-1,3-dioxan (**28**)*

Benzaldehyde (10.6 g, 0.10 mol) and 2-methylpentane-2,4-diol (18) (11.8 g, 0.10 mol) were dissolved in dry benzene (150 ml) containing a small quantity of *p*-toluenesulfonic acid. The benzene solution was heated during 3 h and the water was removed with the aid of a Dean-Stark trap. After cooling at room temperature, the reaction mixture was washed with aqueous sodium carbonate and water. The dried organic solution was evaporated and distillation of the crude product gave pure 2-phenyl-4,4,6-trimethyl-1,3-dioxan (19.3 g, 94%); b.p. 73°/150 mm; n.m.r.: δ ($CDCl_3$) 7.50 (5H, multiplet, C_6H_5), 5.81 (1H, singlet, acetal hydrogen), 4.15 (1H, multiplet, —C*H*(CH_3)—O), and 1.41 (11H, multiplet, —CH_2— and CH_3).

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80. Found: C, 75.81; H, 8.91.

*Ozonolysis of 2-Phenyl-4,4,5-trimethyl-1,3-dioxan (**28**)*

(*a*) 2-Phenyl-4,4,6-trimethyl-1,3-dioxan (2.06 g, 0.01 mol) was dissolved in freshly distilled ethyl acetate and cooled at −78°. Ozone (1 mmol/min) was passed through the solution and the end of the reaction was indicated by the appearance of the characteristic blue color of ozone. The excess ozone was swept with a stream of nitrogen and the reaction mixture was allowed to warm up at room temperature. The solvent was evaporated *in vacuo* yielding crude 3-hydroxy-1,3-dimethylbutane benzoate (**30**, 2.18 g, 98%); i.r.: ν_{max} ($CHCl_3$) 3450 and 1710 cm^{-1}; n.m.r.:

δ ($CDCl_3$) 8.15 and 7.60 (5H, two multiplets, C_6H_5), 5.50 (1H, multiplet, $CHOCOC_6H_5$), 2.46 (1H, singlet, OH), 2.1–1.5 (2H, multiplet, CH_2), 1.38 (3H, doublet, $J = 7$ Hz, CH_3), 1.25 (6H, singlet, *gem*-dimethyl).

Acetylation of the crude product with acetic anhydride (100 ml) and sodium acetate (4 g) (reflux for 3 h) gave 4-acetoxy-4-methyl-2-pentyl benzoate (**31**) which was purified by distillation (2.22 g, 84%).

(*b*) 2-Phenyl-4,4,6-trimethyl-1,3-dioxan (2.06 g, 0.01 mol) was dissolved in freshly distilled acetic anhydride (100 ml) and sodium acetate (4 g). Ozone (1 mmol/min) was passed through the solution cooled at −78°. The end of the reaction was indicated by the appearance of the blue color of ozone. The excess ozone was swept away with a stream of nitrogen. The reaction mixture was allowed to be warmed up at room temperature and was refluxed for 3 h. The solvent was removed *in vacuo* and crude product was dissolved in ether (200 ml). The organic phase was washed with aqueous sodium carbonate (5%) and water. The organic phase was dried over magnesium sulfate, filtered, and evaporated to dryness yielding crude 3-acetoxy-1,3-dimethyl butane benzoate (**31**). Distillation *in vacuo* gave the analytical sample (2.13 g, 81%); b.p. 115°/3 mm; i.r.: ν_{max} ($CHCl_3$) 1725 cm^{-1}; n.m.r.: δ ($CDCl_3$) 8.10–7.50 (5H, two multiplets, C_6H_5), 5.46 (1H, multiplet, $CHOCOC_6H_5$), 2.25 (2H, multiplet, CH_2), 1.83 (3H, singlet, CH_3COO), 1.50 (6H, singlet, *gem*-dimethyl), and 1.37 (3H, doublet, $J = 7$ Hz, CH_3).

Anal. Calcd. for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63. Found: C, 67.89; H, 7.59.

Further Studies on the Assignment of Signals in ^{13}C Magnetic Resonance Spectra of Aldoses and Derived Methyl Glycosides[1]

PHILIP A. J. GORIN AND MYTOSK MAZUREK

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan S7N 0W9

Received October 9, 1974

PHILIP A. J. GORIN and MYTOSK MAZUREK. Can. J. Chem. **53**, 1212 (1975).

The ^{13}C signals of most of the more common sugars and their methyl glycosides have been assigned, based on the α-carbon and β-carbon effects that occur on deuterium substitution. For pyranoses having the same hydroxyl configuration, replacement of the CH_2OH substituent at C-5 with CH_3, CO_2H, CO_2Me, or H is accompanied by displacement of the C-4, C-5, and when applicable C-6 signals. The magnitudes of the displacements in the glucopyranose and mannopyranose series are almost identical and were of aid in assigning signals in the ^{13}C spectrum of methyl (methyl α-D-mannopyranuronosid)uronate. The displacements, however, differ from corresponding ones observed in the galactopyranose series. Some assignments are made for the ^{13}C signals of structurally related methyl aldofuranosides.

PHILIP A. J. GORIN et MYTOSK MAZUREK. Can. J. Chem. **53**, 1212 (1975).

On a attribué les signaux en r.m.n. du ^{13}C de la plupart des sucres usuels ainsi que de leurs glycosides de méthyle; ces attributions ont été faites en se basant sur les effets que produisent les carbones α et β des substitutions par du deutérium. Pour des pyrannoses ayant la même configuration des groupes hydroxyles, le remplacement d'un substituant CH_2OH en C-5 par CH_3, CO_2H, CO_2Me ou H s'accompagne par un déplacement des signaux en C-4, C-5 et lorsque c'est possible en C-6. L'amplitude de ces déplacements dans les séries glucopyrannoses et mannopyrannoses sont presque identiques et a été fort utile pour attribuer les signaux dans le spectre r.m.n. du ^{13}C du (α-D-mannopyrannuronoside de méthyle)uronate de méthyle. Les déplacements diffèrent toutefois des déplacements correspondants observés en série galactopyrannose. On a fait quelques attributions pour des signaux de ^{13}C dans des aldofurannosides de méthyle qui leur sont reliés d'une façon structurale. [Traduit par le journal]

In a previous study (1), the carbon-13 magnetic resonance (^{13}c.m.r.) spectra of deuterated derivatives of αβ-D-glucose, αβ-D-mannose, and αβ-D-galactose were interpreted and discussed. With the aid of two suitable deuterated derivatives of each aldose it was possible to make an unambiguous assignment of each signal, since the signals of the ^{13}C nucleus attached to the deuteron (α-carbon) disappeared and those of the adjacent β-carbons were displaced upfield by 0.02–0.10 p.p.m. (1). Since some of the assignments carried out elsewhere have proved to be incorrect, the studies in this laboratory have been extended to most of the frequently encountered monosaccharides and certain derived methyl glycosides. The preparation of the deuterated sugars was rendered easier, in most instances, by synthetic routes previously devised for the undeuterated counterparts.

As in the above study, which was relatively brief, two deuterated derivatives of each sugar were selected and their ^{13}c.m.r. spectra rationalized by observing the expected α-carbon (2) and the β-carbon deuterium isotope effects (1) (Table 1). Although, for the most part, the signal of the α-carbon disappears, in the case of *5-*^2H derivatives of pentoses, or the *6-*^2H derivatives of 6-deoxyhexoses and methyl 6-deoxyhexopyranosides, the α-^{13}C signals appear as triplets at 0.4 p.p.m. upfield (3). The β-carbon effect appeared as an upfield shift of 0.04–0.09 p.p.m. on monodeuteration, 0.07–0.12 p.p.m. on dideuteration, and 0.17 p.p.m. for the C-3 signal of β-D-arabinopyranose-*4,5-*$^2H_3$. The signals of α- and β-anomers of reducing sugars were distinguished by following the mutarotation process by ^{13}c.m.r. spectroscopy, and those of isomeric methyl glycosides, which were components of mixtures, were obtained by reference to appropriate standards.

The assignments made by these approaches are summarized in Tables 2–6. The results obtained on the methyl glycosides can be used in interpreting the ^{13}c.m.r. spectra of polysaccharides and other sugar-containing polymers (4). Also, the following discussion will show that

*α and β subscripts refer to C-1 configuration of sugar.
†Unless otherwise stated, the signals of carbons attached to deuterium disappear.

signal displacements observed on changing certain substituents in structurally related sugars are consistent, so that they may be of aid in interpreting the spectra of other sugars.

The chemical shifts of signals of ^{13}C nuclei of methyl α-D-glucopyranoside may be compared with those of respective nuclei in methyl α-D-aldopyranosides having a Cl conformation and the same configuration at C-2, C-3, C-4, and C-5 (Table 2). On going from methyl α-D-glucopyranoside to methyl 6-deoxy-α-D-glucopyranoside, methyl α-D-glucopyranosiduronic acid, methyl (methyl α-D-glucopyranosid)uronate, and methyl α-D-xylopyranoside, marked differences of shift were not observed for the respective C-1, C-2, C-3, and OCH_3-1 signals. Replacement of CH_2OH at C-5 with CH_3 causes C-4 and C-5 signals to be displaced at +6 p.p.m. (downfield) and −4 p.p.m., respectively.[2] These figures are +1.9 p.p.m. and −0.8 p.p.m., respectively, when comparisons are made with the spectra of

[2]Shifts are measured relative to external Me_4Si, which is always upfield from observed signals.

CO_2H or CO_2CH_3 derivatives. When the spectra of methyl α-D-glucopyranoside and methyl α-D-xylopyranoside, and α-D-glucose and α-D-xylose are compared, respectively, only the shifts of C-5 signals are markedly different (−11 and −10 p.p.m., respectively).

The displacements of the C-4 and C-5 signals recorded for the methyl β-D-aldopyranosides are similar to those recorded above in the α-series, as are those which are obtained when the spectra of the β-anomers of glucose, 6-deoxyglucose, and xylose are compared (Table 3).

A similar approach can be used for comparison of the chemical shifts of the C-4 and C-5 signals of α- and β-D-mannose with those of α- and β-L-rhamnose on one hand and for those of methyl α-D-mannopyranoside and methyl α-L-rhamnopyranoside on the other (Table 4). Again the C-4 and C-5 signal displacements are +.5 p.p.m. and −4 p.p.m., respectively, without appreciable effects on those of C-1, C-2, and C-3. Since the result of replacing a CH_2OH group with a CH_3 group is the same in the glucopyranose and mannopyranose series, little difference would be expected between these two series when a CH_2OH group is replaced with a CO_2CH_3 group. Such a relationship allows a tentative assignment of signals in the ^{13}c.m.r. spectrum of methyl (methyl α-D-mannopyranosid)-uronate, whose deuterated derivatives would be difficult to prepare. Using the CH_2OH to CO_2Me displacements in the glucopyranose series, which are: C-2 (−0.6), C-3 (−0.5), C-4 (+1.8), and C-5 (−0.8), the nearest fit obtained by comparison of signal displacements of methyl α-D-mannopyranoside and the methyl ester are C-2 (−0.8), C-3 (−0.7), C-4 (+1.2), and C-5 (−0.8) (see Table 4).

Comparisons can be made between the shifts of ^{13}C signals of various sugars conformationally and configurationally related to galactose (Table 5). These are between: (*i*) α-D-galactose and 6-deoxy-α-D-galactose, (*ii*) the corresponding β-derivatives, (*iii*) methyl α-D-galactopyranoside and methyl 6-deoxy-α-D-galactopyranoside, and (*iv*) the corresponding β-derivatives. In each comparison the C-5 and C-4 signals are displaced by ~ −4 p.p.m. and ~ +2.5 p.p.m., respectively. The downfield displacement is less than ~ +6 p.p.m. observed in the glucopyranose series, which contains sugars with equatorial rather than axial OH-4 groups. However, on going from (*i*) α-D-galactose to β-L-arabinose, (*ii*) β-D-galactose to α-L-arabinose, (*iii*) methyl α-D-galactopyranoside to methyl β-L-arabinopyranoside, and (*iv*) methyl β-D-galactopyranoside to methyl α-L-arabinopyranoside, the C-5 signals are displaced by −9 to −10 p.p.m. This is of the same order as is observed when the signals of glucose and xylose, or their corresponding methyl pyranosides are compared.

The signals of ^{13}C spectra of some of the pyranose sugars described above and in a previous study (1) have been assigned previously by other methods. The results obtained by Perlin *et al.* (6), who correlated chemical shifts of ^{13}C nuclei with electron densities based on molecular orbital data, agree in most cases. Assignments of ^{13}C signals of αβ-D-glucose, αβ-D-mannose, β-D-galactose, β-D-allose, αβ-D-xylose, α-arabinose, methyl β-D-galactopyranoside, methyl β-D-glucopyranoside, and methyl αβ-D-xylopyranoside were in agreement. In the cases of α-D-galactose, methyl α-D-glucopyranoside, methyl α-D-galactopyranoside, and methyl α-D-mannopyranoside, some were different. Differences were also observed for the C-2, C-3, and C-4 signals of β-arabinose but since they were resolved by only 0.2 p.p.m. and less, the discrepancy may be due to the use of H_2O as solvent in their study and D_2O in ours. The latter solvent was preferred since it appeared to suppress microbial activity and was suitable for ^{1}H–^{13}C decoupling studies.

Less agreement was attained when the present data were compared with the results of Dorman and Roberts (7), who used a system of empirical constants based on steric or proximity effects to estimate chemical shift differences. Agreement was obtained when the assignments of ^{13}C signals of β-D-glucose, αβ-D-mannose, β-D-galactose, α-D-allose, β-D-xylose, αβ-L-rhamnose, β-fucose, and methyl β-D-glucopyranoside were compared. Their assignments of signals of α-D-glucose, α-D-galactose, αβ-arabinose, β-D-allose, α-D-xylose, α-fucose, and methyl α-D-glucopyranoside differed. The disagreement that exists in the cases of α- and β-arabinose can be explained partly by the differing interpretations of the ^{13}c.m.r. spectrum. Dorman and Roberts (7) reported a signal for each anomer that could not be observed by Perlin *et al.* (6) or in the present study. Their discrepancy is likely due to the slowness of recording the spectra, relative to the speed of mutarotation.

TABLE 7. Differences between the ^{13}C chemical shifts of the anomers of D-glucose, and the respective ones of D-mannose and D-galactose, in p.p.m.

C-1	C-2	C-3	C-4	C-5	C-6
		α-D-*Galactose*			
+0.9	−2.3	−2.8	+0.2	−0.4	+1.2
		α-D-*Mannose*			
+2.3	−0.4	−2.1	−2.4	+1.3	+0.8
		β-D-*Galactose*			
+1.2	−1.5	−2.2	−0.2	−0.3	+0.8
		β-D-*Mannose*			
−1.9	−2.5	−2.3	−2.5	+0.6	+0.6

The signal displacements occurring on changing the nature of the substituent at C-5 are confined to C-4, C-5 (and C-6 in some cases). Thus, these effects are over much shorter range than those observed on going from an equatorial to an axial hydroxyl group, for example, β-D-glucose to β-D-galactose or β-D-glucose to β-D-mannose. As far as these longer range effects are concerned, it is evident that on going from β-D-glucose to β-D-mannose, with an axial OH-2 group, and to β-D-galactose with an axial OH-4 group, there is little correlation between signal displacements of carbons in the corresponding positions relative to the axial OH group (Table 7). It, therefore, does not seem profitable to pursue such an approach in predicting ^{13}C chemical shifts of other sugars containing axial OH groups.

A certain number of methyl furanosides were examined and their ^{13}C c.m.r. spectra rationalized. Not surprisingly, the C-1, C-2, C-3, C-4, and OCH_3 signals of methyl β-D-galactofuranoside correspond in their shifts to those of methyl β-L-arabinofuranoside and those of the corresponding β-hexoside to those of the α-pentoside (Table 6). Evidently the CH_2OH and CHOH—CH_2OH substituents are similar in their shielding or deshielding effects and do not give rise to differences of conformation or populations of given conformations.

A few of the deuterated compounds compiled in Table 1 were prepared by routes that have not been described previously. For example, methyl α-L-rhamnopyranoside was treated with phosgene in pyridine to give the 2,3-cyclic carbonate, which was then oxidized with phosphorus pentaoxide in dimethyl sulfoxide to the 2,3-cyclic carbonate of methyl 6-deoxy-α-L-lyxohexopyranosid-4-ulose. Treatment with sodium borohydride provided a mixture containing methyl α-L-rhamnopyranoside which was identified by its ^{13}C c.m.r. spectrum and a larger proportion of another isomer, which although it was not isolated, is probably methyl 6-deoxy-α-L-talopyranoside. The action of sodium borodeuteride on the ketone provided a mixture of the *4-*^2H derivatives of the methyl 6-deoxy-α-L-hexopyranosides, which was used for assigning the ^{13}C signals of methyl α-L-rhamnopyranoside. The mixture of aldoses prepared on hydrolysis contained αβ-L-rhamnose-*4-*^2H, which aided the assignment of ^{13}C signals of αβ-L-rhamnose.

D-Ribose-*5-*^2H was prepared from 1,2-*O*-isopropylidene-α-D-allofuranose by successive periodate oxidation, sodium borodeuteride reduction and hydrolysis. D-Ribose-*3-*^2H was obtained from 1,2-*O*-isopropylidene-α-D-allofuranose-*3-*^2H in a similar fashion, except that sodium borohydride was used as reducing agent.

Experimental

Carbon-13 magnetic resonance spectra were obtained using a Varian XL-100-15 spectrometer with Fourier transform from D_2O solutions (0.85 ml) of compound (20–100 mg) contained in a coaxial glass cylinder fitting snugly within a 12 mm diameter × 8 in. tube maintained at 33°. Larger amounts of solute were dissolved in D_2O (2 ml) contained in the 12 mm × 8 in. tube similar to that described above, except that it was fitted with a Teflon vortex plug. To obtain a complete ^{13}C c.m.r. spectrum the spectral width was 5000 Hz, the acquisition time 0.4 s, and the pulse width 50 μs. In several experiments it was necessary to improve the resolution and the spectral width was narrowed to 500 Hz, with the acquisition time 4 s and the pulse width 117 μs. Under these conditions the extent of the β-carbon deuterium isotope effect could

For personal use only.

be measured by examination of a mixture of deuterated and undeuterated material. Frequently signals were superimposed when a 5000 Hz scan was used and those could be resolved by preparation of two or three spectra with a 500 Hz sweep width and suitable offsets. Signals of CH_2 groups were recognized as triplets in partially decoupled spectra. The chemical shifts are expressed as δ_C in p.p.m., relative to external Me_4Si, whose shift relative to D_2O (lock signal) was obtained in a separate experiment.

Some of the undeuterated chemicals used were obtained commercially and they are listed below with suppliers: α-D-xylose (Fisher Scientific Co., Fair Lawn, N.J.), β-L-arabinose (Nutritional Biochemicals Corp., Cleveland, Ohio), α-L-rhamnose (Aldrich Chemical Co., Milwaukee, Wisc.), α-L-fucose, and α- and β-anomers of methyl D-glucopyranoside and methyl D-galactopyranoside, methyl α- and methyl β-D-xylopyranoside (Sigma Chemical Co., St. Louis, Mo.), α-D-glucose-*2*-^2H (Raylo Chemicals Ltd., Edmonton, Alta.), methyl β-L-arabinopyranoside (K & K Labs Inc., Plainview, N.Y.).

Other compounds were prepared according to procedures described in the appended references. These were: methyl α-L-rhamnopyranoside (8), α- and β-anomers of methyl 6-deoxy-L-galactopyranoside (9), methyl α-D-arabinofuranoside (10), methyl β-L-arabinofuranoside (11), methyl α-L-arabinopyranoside (12), methyl β-D-galactofuranoside and its minor α-anomer which are produced simultaneously (13), α- and β-anomers of methyl D-glucopyranosiduronic acid (14), methyl (methyl α-D-mannopyranosid)uronate (15), and methyl 6-deoxy-α-D-glucopyranoside (16).

The above glucopyranosiduronic acid derivatives were converted to their methyl esters by treatment for 3 h with cold 1% methanolic HCl.

Preparation of Deuterated Sugars

αβ-D-*Xylopyranose-5-*^2H, αβ-D-*Xylopyranose-3-*^2H, *and Derived Methyl* αβ-D-*Xylopyranosides*

α-D-Xylose-*5-*^2H was prepared from 1,2-*O*-isopropylidene-α-D-glucofuranose by successive oxidation with sodium periodate, reduction with sodium borodeuteride, and hydrolysis, as outlined by Isbell *et al.* (17) for the preparation of α-D-xylose-*5-*^3H.

α-D-Xylose-*3-*^2H was similarly prepared from 1,2-*O*-isopropylidene-α-D-glucofuranose-*3-*^2H, obtained from partial acid hydrolysis of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose-*3-*^2H (18).

Mutarotation of each of the deuterated xyloses in D_2O gave αβ-D-xylopyranose.

Each of the αβ-mixtures was treated with refluxing 3% methanolic hydrogen chloride to give methyl αβ-D-xylopyranoside.

4-^2H *and 6-*$^2H_2$ *Derivatives of Methyl* αβ-D-*galactofuranoside and Methyl* αβ-D-*Galactopyranoside*

The *4-*^2H and *6-*^2H derivatives of α-D-galactose (1) were dissolved in 0.5% methanolic hydrogen chloride which was left for 15 h at room temperature (19). The product consisted mainly of methyl αβ-D-galactofuranoside according to the ^{13}c.m.r. spectrum. The signals of methyl αβ-D-galactofuranoside were assigned once the signals of methyl αβ-D-galactopyranoside were accounted for.

The above furanosidic mixtures were converted to deuterated methyl αβ-D-galactopyranosides by refluxing in 3% methanolic hydrogen chloride for 3 h.

5-$^2H_2$ *and 4,5-*$^2H_3$ *Derivatives of* αβ-D-*Arabinopyranose, and Corresponding Deuterated Methyl* αβ-D-*Arabinopyranosides and Methyl* αβ-D-*Arabinofuranosides*

β-D-Arabinopyranose-*5-*$^2H_2$ was prepared from α-D-glucose-*6-*$^2H_2$ (1) by the method used by Isbell *et al.* (20) for the preparation of β-D-arabinopyranose-*5-*^{14}C from α-D-glucose-*6-*^{14}C.

α-D-Glucose-*5,6-*$^2H_3$ was prepared by acid hydrolysis of 1,2-*O*-isopropylidene-α-D-glucofuranose-*5,6-*$^2H_3$ (18) and converted to β-D-arabinopyranose-*4,5-*$^2H_3$ by the same procedure.

Mutarotation of each of the arabinoses in D_2O gave the αβ-pyranosidic mixtures.

Treatment of the anomeric mixture with refluxing 3% methanolic hydrogen chloride for 3 h gave a mixture of methyl αβ-D-arabinopyranoside and methyl αβ-D-arabinofuranoside. In a parallel experiment using undeuterated derivatives, the glycosidic mixture gave a ^{13}c.m.r. spectrum with 23 of the possible 24 signals. Even when a spectral width of 500 Hz was used the signal at δ_C 75.7 from methyl α- and methyl β-D-arabinofuranoside could not be resolved.

*6-Deoxy-*αβ-D-*galactose-6-*^2H, *6-Deoxy-*αβ-L-*galactose-4-*^2H, *Derived Methyl 6-Deoxy-*αβ-L-*galactopyranosides, 6-Deoxy-*αβ-L-*glucose-4-*^2H, *and Methyl 6-Deoxy-*αβ-L-*glucopyranoside-4-*^2H

Using a method analogous to that of Schmid and Karrer (21), who reduced 1,2:3,4-di-*O*-isopropylidene-6-*p*-tolylsulfonyl-α-D-galactopyranose with lithium aluminum hydride to give 1,2:3,4-di-*O*-isopropylidene-α-D-fucopyranose, the *6-*^2H derivative was obtained by using lithium aluminum deuteride.

Heyns *et al.* (22), using Pt/H_2 as reagent, reduced methyl 6-deoxy-α-L-xylohexopyranosid-4-ulose to give methyl 6-deoxy-α-L-galactopyranoside exclusively. Using Pt/D_2 we obtained the *4-*^2H derivative, and when sodium borodeuteride in water was used as a reagent, some methyl 6-deoxy-α-L-glucopyranoside-*4-*^2H was formed also, as shown by the ^{13}c.m.r. spectrum.

Hydrolysis of each deuterated glycoside or glycosides with 0.5 *M* H_2SO_4 at 100° for 6 h gave the appropriate reducing sugars. Each deuterated glycoside was equilibrated with refluxing 3% methanolic hydrogen chloride for 3 h to give the αβ-glycosidic mixture.

αβ-D-*Rhamnose-6-*^2H, αβ-L-*Rhamnose-4-*^2H, *Methyl* α-D-*Rhamnopyranoside-6-*^2H, *and Methyl* α-L-*Rhamnopyranoside-4-*^2H

Haskins *et al.* (23) hydrogenated methyl 2,3,4-tri-*O*-benzoyl-6-deoxy-6-iodo-α-D-mannopyranoside to give methyl 2,3,4-tri-*O*-benzoyl-α-D-rhamnopyranoside using Raney nickel in the presence of diethylamine. They proceeded to prepare methyl α-D-rhamnopyranoside and α-D-rhamnopyranose. The compounds were prepared as *6-*^2H derivatives by substituting deuterium for hydrogen in the reduction step.

To methyl α-L-rhamnopyranoside (6.6 g) in pyridine (30 ml), phosgene (1.2 molar-equiv.) in toluene (20 ml) was added with stirring. After 3 h, the solution was evaporated to a sirup, which was partitioned between chloroform and water. The chloroform layer was washed with water

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and evaporated to a sirup which crystallized. Two recrystallizations from ethanol gave the cyclic 2,3-carbonate of methyl α-L-rhamnopyranoside (1.6 g) with m.p. 158–161° and $[\alpha]_D^{25}$ −40° (*c* 0.8, H_2O).

Anal. Calcd. for $C_8H_{12}O_6$: C, 47.06; H, 5.92. Found: C, 47.02; H, 6.01.

The carbonate (0.50 g) was oxidized in dimethyl sulfoxide (4 ml) – phosphorus pentaoxide (0.20 g) and after 3 days excess chloroform was added and the mixture washed three times with ice-cold water. Evaporation gave a sirup (0.36 g) which crystallized and two recrystallizations from diethyl ether – pentane gave the cyclic 2,3-carbonate of methyl 6-deoxy-α-L-lyxo-hexopyranosid-4-ulose (0.17 g) with m.p. 93° and $[\alpha]_D^{25}$ −120° (*c* 0.6, EtOH).

Anal. Calcd. for $C_8H_{10}O_6$: C, 47.53; H, 4.99. Found: C, 47.25; H, 4.94.

The ketone (0.15 g) in water (5 ml) was treated with sodium borohydride (50 mg) for 3 h and the reaction mixture worked up as outlined above to give a mixture of isomeric methyl 6-deoxy-α-L-hexopyranosides.

Anal. Calcd. for $C_7H_{14}O_5$: C, 47.18; H, 7.92. Found: C, 47.15; H, 8.16.

A mixture of *4-²H* derivatives was prepared using sodium borodeuteride in place of the sodium borohydride. ^{13}C spectroscopy showed that the major product was methyl 6-deoxy-α-L-talopyranose-*4-²H* but the much smaller signals of methyl α-L-rhamnopyranose-*4-²H*, which were recognized by comparison with authentic undeuterated material, were sufficient for the necessary spectral determinations to be made. Hydrolysis with 0.5 *M* H_2SO_4 at 100° for 3 h gave a mixture of 6-deoxy-αβ-L-talose-*4-²H* and αβ-L-rhamnose-*4-²H*, whose ^{13}C n.m.r. spectrum was recorded and compared with that of αβ-L-rhamnose.

2-²H and 5-²H Derivatives of Methyl αβ-D-Glucopyranosiduronic Acid and their Methyl Esters

α-D-Glucose-*2-²H* was treated with refluxing 3% methanolic hydrogen chloride for 6 h to give a mixture which was resolved partially by crystallization from EtOH to give methyl α-D-glucopyranoside-*2-²H* and a mother liquor consisting of a mixture of α- and β-glycoside.

Following the use of the α-anomer to distinguish between the C-2 and C-5 signals of its ^{13}C n.m.r. spectrum, it and its αβ counterpart were oxidized separately with platinum (14) to give methyl α-D-glucopyranosiduronic acid-*2-²H* and its αβ-anomer, respectively.

1,2-*O*-Isopropylidene-α-D-glucofuranose-5,6-$^2H_3$ (18) was similarly treated with MeOH–HCl to give methyl α-D-glucopyranoside-*5,6-²H₃* and sirupy methyl αβ-glucopyranoside-*5,6-²H₃*, which were then converted to methyl α-D-glucopyranosiduronic acid-*5-²H* and the mixed isomeric mixture, respectively.

Each of the four deuterated uronic acid fractions was treated at room temperature in 1% methanolic hydrogen chloride to give the methyl ester.

3-²H and 5-²H Derivatives of Methyl αβ-D-Ribofuranoside

To 1,2-*O*-isopropylidene-α-D-allofuranose (24; 0.50 g) in water (20 ml), sodium metaperiodate (0.75 g) was added and after 18 h the solution was deionized with Amberlite IR120 (H^+ form) and Dowex 1 (HCO_3^- form). The filtrate was evaporated to about 10 ml, sodium borohydride added and after 1 h the solution was acidified with acetic acid and decationized with Amberlite IR120 (H^+ form). The suspension was filtered off and the filtrate evaporated to a sirup to which methanol was added and evaporation carried out, the process being repeated five times. The product (0.35 g) was dissolved in water, the p*H* was adjusted to 2 with H_2SO_4, and the solution kept at 100° for 1 h. The hydrolyzate was neutralized ($BaCO_3$), filtered, and evaporated to a sirup which crystallized from EtOH–EtOAc. A further crystallization gave D-ribose with m.p. and mixture m.p. 84°.

Anal. Calcd. for $C_5H_{10}O_5$: C, 40.00; H, 6.71. Found: C, 40.10; H, 6.80.

A parallel experiment was carried out using sodium borodeuteride instead of sodium borohydride in order to prepare D-ribose-*5-²H*.

1,2:3,4-Di-*O*-isopropylidene-α-D-allofuranose-*3-²H* (18) was converted by the method of Collins (24) to give 1,2-*O*-isopropylidine-α-D-allofuranose-*3-²H* which was converted to D-ribose-*3-²H* by the method outlined above.

A mixture of α- and β-anomers of deuterated methyl D-ribofuranosides was obtained by treating the riboses with 0.5% methanolic hydrogen chloride for 10 h (19). The ^{13}C n.m.r. signals of the β-isomer were characterized by comparison with those of an authentic specimen (25).

6-Deoxy-αβ-D-glucose-6-²H and Methyl 6-Deoxy-αβ-D-glucopyranoside-6-²H

Methyl 6-deoxy-α-D-glucopyranoside-*6-²H* was prepared by lithium aluminum deuteride reduction of methyl 6-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside by using the procedure of Timell *et al.* (16) who used lithium aluminum hydride as reagent.

The αβ-glycosidic mixture was prepared from methyl 6-deoxy-α-D-glucopyranoside by treatment with refluxing 3% methanolic hydrogen chloride for 3 h and 6-deoxy-αβ-D-glucose was prepared from the α-glycoside by using 0.5 *M* H_2SO_4 at 100° for 18 h.

Structure électronique de dérivés sulfures. XI.[1] Thiétanne et dérivés

CLAUDE GUIMON, DANIEL LIOTARD ET GENEVIÈVE PFISTER-GUILLOUZO
Laboratoire de Chimie Structurale – I.U.R.S. – Avenue Philippon – 64016 PAU – France

Reçu le 4 juillet 1974

CLAUDE GUIMON, DANIEL LIOTARD et GENEVIÈVE PFISTER-GUILLOUZO. Can. J. Chem. **53**, 1224 (1975).

Les structures conformationnelles du thiétanne, du thiétanne sulfoxyde et de leurs dérivés mono chlorés en position 3 ont été déterminées théoriquement à l'aide d'un procédé de minimisation de l'énergie par rapport aux facteurs géométriques sur la base de la méthode semi-empirique CNDO/2 étendue à la troisième période.

Les résultats sont en bon accord avec les données expérimentales connues. Les stabilités respectives des différents conformères sont expliquées grâce aux résultats énergétiques partiels obtenus par une partition bicentrique de l'énergie potentielle totale des molécules.

CLAUDE GUIMON, DANIEL LIOTARD, and GENEVIÈVE PFISTER-GUILLOUZO. Can. J. Chem. **53**, 1224 (1975).

The conformations of thietane, thietane sulfoxide, and their 3-chloro derivatives were obtained theoretically by minimization of the energy with respect to geometric parameters using the semi-empirical CNDO/2 method extended to the third period. The results agree well with known experimental data. The respective stabilities of the different conformers are explained by partial energy results obtained by a bicentric partition of the total potential energy of the molecules. [Journal translation]

Durant les dernières années de nombreuses approches théoriques ont été réalisées par différentes méthodes semi-empiriques (Hückel, PPP, EHT, CNDO/2) sur des molécules cycliques comportant un ou plusieurs atomes de soufre. Toutefois, les principaux travaux ont porté sur l'étude de la structure électronique d'hétérocycles conjugués à cinq ou six chaînons en relation avec leur réactivité et leurs propriétés physico-chimiques. A notre connaissance, seuls quelques travaux dispersés ont été effectués sur les cycles saturés présentant un ou plusieurs atomes de soufre. Dans le cadre d'une étude générale sur les problèmes des interactions intramoléculaires consécutives à l'introduction d'un ou de plusieurs atomes de soufre dans un cycle à quatre, cinq ou six chaînons et qui sont à l'origine de la conformation et de la réactivité même de ces composés, nous avons examiné les molécules de thiétanne, de thiétanne sulfoxyde, de chloro-3 thiétanne et de chloro-3 thiétanne sulfoxyde.

Expérimentalement pour ces composés, des études par dipolemétrie et notamment par résonance magnétique nucléaire avaient antérieurement permis de déterminer les conformations privilégiées.

Les calculs ont été effectués à l'aide de la méthode CNDO/2. La paramétrisation adoptée a été présentée antérieurement et appliquée à des sulfures, sulfoxydes et sulfones acycliques (1). Nous rappellerons seulement que les orbitales d ne sont différenciées des orbitales s et p que par le paramètre β^0 intervenant dans l'élément non diagonal de la matrice autocohérente $|\mathbf{F}|$.

On sait que cette méthode sous estime les barrières de rotation et qu'au contraire elle surestime celles d'inversion. Toutefois, ce défaut de la méthode CNDO/2 n'a que peu d'incidence sur les résultats de ce travail à cause des différences énergétiques considérables entre la barrière de torsion du cycle et celle d'inversion du soufre.

Les structures géométriques des différentes molécules et des intermédiaires envisagés lors des processus conformationnels ont été déterminées théoriquement par un procédé de minimisation énergétique (2, 3) utilisant la méthode de plus grande pente (4–7) et mis au point par l'un d'entre nous (D.L.).

Thiétanne

D'après les premiers travaux effectués (8), ce composé semblait présenter une structure plane et appartenir au groupe de symétrie C_{2v}. Ultérieurement plusieurs auteurs ont pu montrer par diverses techniques expérimentales que cette molécule n'était pas plane (symétrie C_S). La bar-

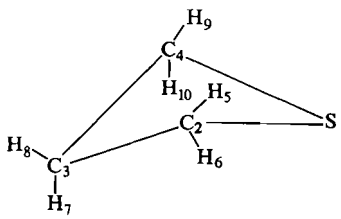
TABLEAU 1. Structures expérimentale (12, 16) et calculées du thiétanne et du chloro-3 thiétanne

	Chloro-3 thiétanne	Thiétanne		
	Géométrie théorique optimisée	Géométrie expérimentale	Géométrie théorique optimisée	Géométrie théorique de la forme plane
Liaisons (Å)				
S–C_2	1.846	1.833	1.842	1.846
C_2—C_3	1.463	1.54	1.463	1.468
C_2—H_5	1.122	1.09	1.121	1.119
C_2—H_6	1.119	1.09	1.123	1.119
C_3—H_7	1.121	1.09	1.122	1.121
C_3—Cl	1.760			
C_3—H_8		1.09	1.124	1.121
Angles (deg)				
θ*	159.1	148.	150.1	180.
C_2SC_4	66.9	79.	69.	68.7
$C_2C_3C_4$	88.1	98.4	91.	90.3
H_5C_2S	108.9		110.8	109.5
H_6C_2S	108.8		111.1	109.5
H_7C_3X†	129.0		124.9	127.3
ClC_3X†	125.8			
H_8C_3X†			130.4	127.3

NOTE: La numérotation des atomes ainsi que le système d'axe sont identiques pour tous les calculs et tous les composés dérivés du thiétanne.
*θ est l'angle dièdre défini par les plans C_2SC_4 et $C_2C_3C_4$.
†X représente l'axe bissecteur de l'angle $C_2C_3C_4$.



rière d'inversion déterminée par micro-ondes (9, 10) et infrarouge lointain (11) est relativement faible (de l'ordre de 274 cm^{-1}) mais plus élevée cependant que celle du triméthylène oxyde qui n'est que de 35 cm^{-1} (12–14). Ces travaux se sont d'ailleurs trouvés confirmés par ceux de Durig et Lord (15).

Compte tenu de ces données expérimentales, nous avons déterminé la forme énergétiquement favorisée pour ce composé par une optimisation complète des divers facteurs géométriques (14 degrés de liberté). La topologie obtenue est reportée dans le tableau 1. On peut noter l'excellent accord entre la structure théorique et celle observée expérimentalement par micro-ondes. En particulier, l'angle dièdre θ entre les plans C_2SC_4 et $C_2C_3C_4$ est calculé à 150.1° pour 148° expérimentalement. Les écarts observés au niveau de la liaison C—C et des angles C_2SC_4 et $C_2C_3C_4$ sont inhérents à la paramétrisation de la méthode CNDO/2 et notamment à l'évaluation des répulsions entre atomes qui sont sous estimées à courte distance.

L'optimisation d'une structure plane (huit degrés de liberté) nous a permis d'évaluer la barrière d'inversion du cycle à 0.317 kcal/mol (111 cm^{-1}). L'ensemble des données énergétiques est rassemblé dans le tableau 2. Nous avons utilisé

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

TABLEAU 2. Différences énergétiques entre les formes plane et non plane du thiétanne (en kcal/mol)

Liaisons	ΔE_l	ΔE_l^T	ΔE_{int}^T	ΔE_{int}^H	ΔE_{at}^T	ΔE_{el}	ΔE_{rep}	ΔE_T
C_2—S	4.099							
C_2—C_3	5.689							
C_2—H_5	0.536							
C_2—H_6	−1.403	12.855	−9.025	0.841	−3.513	125.370	−125.053	0.317
C_3—H_7	−1.906							(111 cm^{-1})
C_3—H_8	−3.081							

NOTE: ΔE_l représente la différence des énergies de liaisons entre les deux formes telles qu'elles ont été définies par Pople (voir texte). Il en est de même pour ΔE_{int} et ΔE_{at}; $\Delta E_l^T = \sum_{liaisons} \Delta E_{liaisons}$; $\Delta E_{int}^T = \sum_{interactions} \Delta E_{interactions}$; $\Delta E_{int}^H = \sum_{interactions}^{hydrogènes} \Delta E_{interaction\ entre\ hydrogènes}$ $\Delta E_{at}^T = \sum_{atomes} \Delta E_{at}$; ΔE_{el} et ΔE_{rep} sont respectivement les différences entre les énergies électroniques et de répulsions des coeurs des deux formes du thiétanne; ΔE_T est l'écart entre l'énergie totale de la forme plane et celle de la forme non plane. Elle représente donc la barrière d'inversion.

la partition bicentrique de l'énergie totale proposée initialement par Pople et Segal (17) et reprise par Gordon (18)

$$E_T = \sum_{A}^{atomes} E_A + \sum_{B>A}^{liaisons} E_{A-B} + \sum_{B>A}^{interactions} E_{A-B}$$

Cette partition est commode car elle rationalise certains concepts chimiques comme les énergies de liaison ou les interactions entre atomes non liés. De plus, ainsi que l'ont remarqué Fischer et Kollmar (19), elle présente l'avantage de répondre à trois critères: la transférabilité, la monotonie et l'importance relativement faible des termes associés aux atomes non liés.

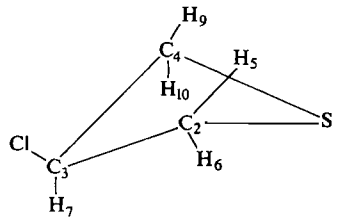
Globalement, si l'énergie totale de répulsion pour la forme plane est bien plus faible que celle de la forme non plane, cet écart est largement compensé par la stabilisation de l'énergie électronique. Rappelons que l'énergie totale est égale à la somme de ces deux énergies qui sont de signes opposés:

$$\Delta E_T = E_{el}(\text{plan}) + E_{rep}(\text{plan}) - |E_{el}(\text{non plan}) + E_{rep}(\text{non plan})| = \Delta E_{el} + \Delta E_{rep}$$

L'analyse des termes E_A et E_{A-B} montre que la stabilité de la forme non plane est due, en partie et comme on pouvait s'y attendre, à une répulsion entre les groupements méthylène plus faible en position "pseudo-staggered" qu'en position "eclipsed," mais surtout à la stabilisation énergétique des liaisons du cycle C—S et C—C et dans une moindre mesure à celle des deux liaisons C_2—H_5 et C_4—H_9.

La matrice densité au premier ordre (tableau 3) montre la faible participation des orbitales de polarisation du soufre au niveau des charges électroniques, ce qui avait été remarqué dans des études antérieures (1) pour des atomes de soufre liés à des atomes de carbone ou d'hydrogène. L'introduction de ces orbitales de polarisation permet néanmoins de traduire correctement le moment dipolaire puisque l'écart entre la valeur théorique et la valeur expérimentale est de l'ordre de 0.1 D.

Chloro-3 thiétanne



La plupart des travaux effectués sur la molécule de thiétanne substituée en 3 ont été réalisés à l'aide de la résonance magnétique nucléaire du proton (22, 23).

Wucherpfennig (22) détermine les déplacements chimiques et les constantes de couplage du thiétanne disubstitué en 3 d'une part par deux groupements méthyle et d'autre part par un groupement méthyle et un groupement hydroxyle. Il conclut dans ce dernier cas que le groupement hydroxyle se trouve en position pseudo-équatoriale. Cette même conformation est proposée pour le chloro-3 thiétanne par Keller *et al.* (23) qui ont analysé la totalité du spectre r.m.n. à l'aide des programmes NMREN et NMRIT. Cette même conformation a également été mise en évidence à partir des données de la dipolemétrie (24).

Ainsi que nous l'avions fait pour le thiétanne nous avons optimisé la structure géométrique du chloro-3 thiétanne, et dans un deuxième temps

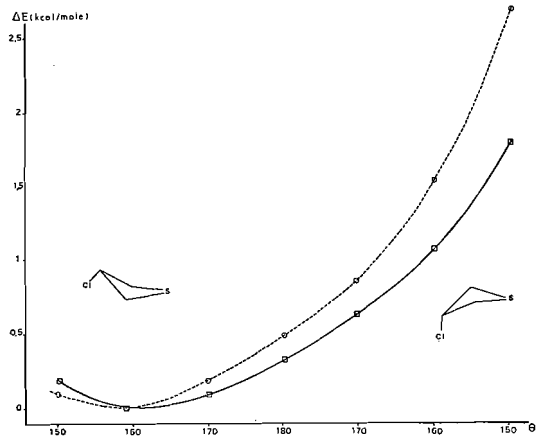

FIG. 1. Energie potentielle totale du chloro-3-thiétanne lors de l'inversion du cycle, à l'état gazeux (trait plein) et solvaté (pointillés).[2]

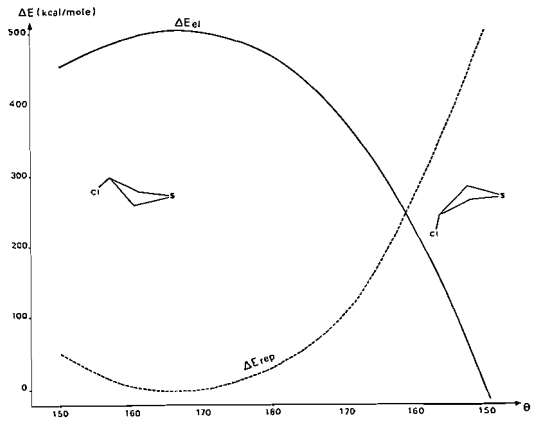

FIG. 2. Energies électronique ΔE_{el} et de répulsion ΔE_{rep} du chloro-3-thiétanne lors de l'inversion du cycle.[2]

les structures de cette molécule en fixant certaines valeurs à l'angle dièdre θ défini par les plans C_2SC_4 et $C_2C_3C_4$. La figure 1 donne les variations de l'énergie potentielle totale du chloro-3 thiétanne en fonction de cet angle θ à l'état gazeux et en solution.

L'énergie de solvatation est calculée selon la formulation proposée par Jano (25) d'après le modèle de Born (26)

$$E_{solv} = -\left(1 - \frac{1}{D_S}\right)\left|\frac{1}{2}\sum_A Q_A{}^2\gamma_{AA} + \sum_{A\neq B}\sum Q_A Q_B \gamma_{AB}\right|$$

Cette relation fait intervenir, outre la constante diélectrique du solvant D_S,[3] la répartition des charges électroniques (Q_A étant la charge nette de l'atome A) et la structure géométrique de la molécule (par les intégrales coulombiennes mono et bi-électroniques γ_{AA} et γ_{AB}).

Comme le suggéraient les données expérimentales, nous observons un seul puit de potentiel pour un angle θ égal à 159.1°, le chlore se plaçant en position pseudo-équatoriale (tableau 1). On peut noter que contrairement aux autres paramètres géométriques qui sont similaires, l'angle dièdre du cycle est nettement plus ouvert que pour le thiétanne non substitué (pour lequel il était à 150.1°). Cette valeur paraît logique si l'on considère l'interaction du chlore avec notamment les carbones des groupements méthylène voisins nettement plus élevée que celle produite par un atome d'hydrogène. Le fait qu'on ne puisse observer de composé à structure pseudo-axiale semble lié à de fortes répulsions entre

[2]L'origine des énergies est prise au point le plus bas des courbes.

[3]Dans tous nos calculs nous avons pris le cas limite: $1 - 1/D_S = 1$ c'est-à-dire $D_S = \infty$.

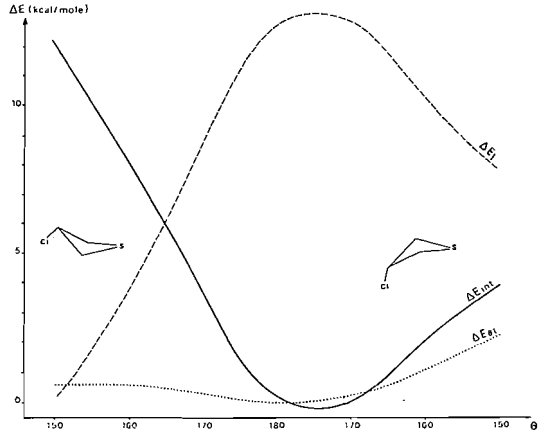

FIG. 3. Energies globales atomique ΔE_{at}, de liaisons ΔE_l et d'interactions entre atomes non liés chimiquement ΔE_{int} lors de l'inversion du cycle du chloro-3-thiétanne.[2]

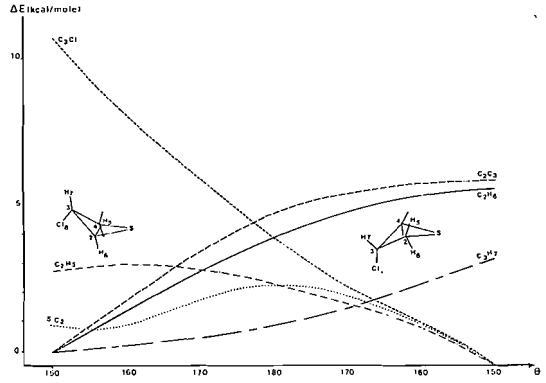

FIG. 4. Energies des liaisons du chloro-3-thiétanne lors de l'inversion du cycle.[2]

atomes (fig. 2) bien qu'on remarque la tendance de l'énergie électronique à stabiliser cette forme.

Les données énergétiques correspondant à la partition bicentrique de l'énergie totale définie précédemment sont reportées dans fig. 3. La courbe représentant les variations globales des énergies de liaison ΔE_l a un maximum pour $\theta \sim 175°$ (forme p-axiale). Les variations de l'énergie associée aux interactions entre atomes non liés chimiquement ΔE_{int} et celles de l'énergie associée aux atomes eux-mêmes ΔE_{at} possèdent un minimum également aux alentours de 175° (forme p-axiale).

Ainsi les énergies de liaisons semblent être à l'origine de la stabilisation d'un conformère par rapport à l'autre. En effet, si l'on examine fig. 4, on note que les liaisons C_2—C_3, C_2—H_6 et

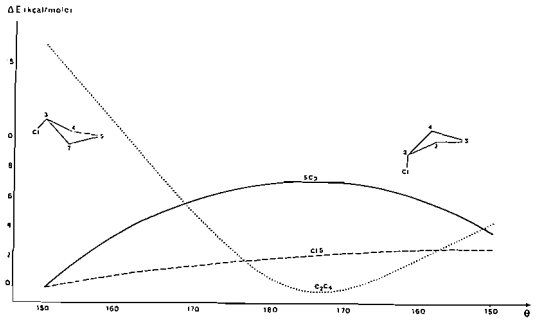

FIG. 5. Energies des principales interactions entre atomes non liés chimiquement du chloro-3-thiétanne lors de l'inversion du cycle.[2]

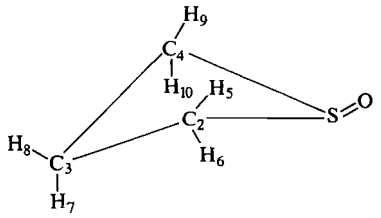
C_3—H_7 sont énergétiquement beaucoup plus liantes dans le dérivé p-équatorial que dans le présumé conformère p-axial alors que les liaisons C_3—Cl et C_2—H_5 sont dans une moindre mesure plus liantes pour la forme p-axiale.

Au contraire comme on peut le voir sur fig. 5, si les interactions entre les atomes de carbone C_3 et de soufre ainsi que celles entre le soufre et le chlore sont attractives dans le dérivé équatorial, ceci est fortement compensé par une diminution notable de l'interaction attractive pour ce composé entre les carbones C_2 et C_4.

La matrice densité au premier ordre (tableau 4) pour la forme privilégiée montre les mêmes caractéristiques générales que pour le thiétanne, c'est-à-dire une légère charge nette négative sur l'atome de soufre et au contraire une charge nette positive pour les autres atomes à l'exception des hydrogènes H_5. Les densités électroniques des orbitales de polarisation sont faibles: 0.147 *e* pour le soufre et 0.064 *e* pour le chlore. Le moment dipolaire calculé à 0.91 D traduit correctement la valeur expérimentale de 1.01 D (24).

Thiétanne sulfoxyde



A l'encontre du thiétanne, le thiétanne sulfoxyde n'a été étudié expérimentalement qu'au travers de ses dérivés substitués. La plupart des travaux effectués ont porté sur des cycles mono-

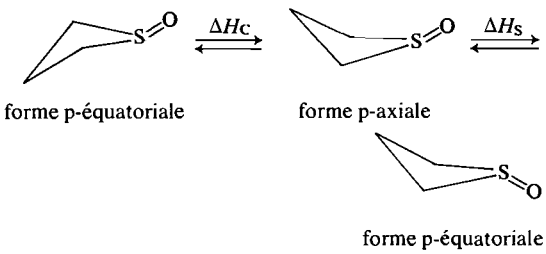
*La charge électronique localisée sur les orbitales d du soufre est de 0.147 *e* alors que celle localisée sur les orbitales d du chlore est de 0.064 *e*.

substitués en position 3 ou disubstitués en 2,4. Il était donc intéressant de rechercher la conformation théorique du dérivé non substitué et les causes principales de sa stabilité avant d'étudier le composé substitué lui-même.

La préférence de l'atome d'oxygène pour la position axiale est bien connue dans le cas des cycles à six chaînons (27–29). Cette préférence, confirmée théoriquement par la méthode Westheimer (30), est remise en question pour les cycles de plus faibles dimensions et en particulier pour le thiétanne sulfoxyde. Wucherpfennig (22) a étudié en résonance magnétique nucléaire du proton les thiétanne, thiétanne sulfoxyde et sulfone disubstitués en position 3 par deux groupements méthyles. Des déplacements chimiques et des constantes de couplage obtenus, il déduit, à l'encontre des cycles à six chaînons, la plus grande stabilité du conformère ayant l'oxygène en position pseudo-équatoriale. On peut donc raisonnablement supposer qu'il en est de même pour le dérivé non substitué.

Comme pour son homologue non oxydé, nous avons effectué une optimisation géométrique des deux conformères possibles. De plus, nous avons calculé d'une part la barrière d'inversion du cycle ΔH_C et d'autre part la barrière d'inversion du soufre ΔH_S.



Dans le tableau 5 sont reportées les structures minimisées des deux conformères p-équatorial et p-axial. Ces structures sont très proches l'une de l'autre puisque sur les longueurs de liaison, l'écart se situe sur la troisième décimale (l'unité étant l'Angström) et que le plus grand écart sur les angles du cycle est de 1° (pour l'angle $C_2C_3C_4$). L'angle dièdre est légèrement plus ouvert dans le cas du conformère p-axial (163.2° contre 158.7°), ce qui semble logique de part l'interaction plus importante dans ce cas entre l'oxygène et les atomes C_3 et H_8. En comparant ces résultats avec les données expérimentales obtenues pour le carboxy-3 thiétanne sulfoxyde (31), il est à noter que si la longueur de la liaison C—S est proche de celle observée expérimentalement, il n'en est pas de même pour les liaisons C—C et surtout S—O. Comme nous l'avions signalé, ces différences par rapport aux valeurs expérimentales sont liées à la méthode, mais seule une optimisation de tous les paramètres géométriques rend fiable les comparaisons énergétiques entre deux conformères. Remarquons d'ailleurs que des études antérieures (18) avaient mis en évidence une meilleure traduction des barrières expérimentales par optimisation des géométries bien que celles-ci soient notablement différentes des valeurs réelles.

Pour évaluer les deux barrières d'inversion ΔH_C et ΔH_S, nous avons choisi des modèles intermédiaires entre les deux formes stables p-équatoriale et p-axiale et nous avons optimisé leur géométrie en gardant constant l'angle dièdre du cycle pour ΔH_C et l'angle XSO pour ΔH_S. Ce mode de calcul ne donne pas en réalité le "vrai chemin" conduisant d'une forme à l'autre, c'est-à-dire la vallée de l'hypersurface énergétique menant du puit de potentiel représentant le conformère p-équatorial à celui associé au conformère p-axial. Il donne un chemin légèrement différent mais qui passe par le même "col." La barrière d'inversion calculée sera donc exacte puisqu'elle est égale à la différence "d'altitude" entre le point le plus bas de l'hypersurface (puit de potentiel le plus profond) et le "col" unique situé entre les deux points.

‡X est l'axe bissecteur de l'angle $C_2C_3C_4$.

Ainsi que le montre fig. 6, les deux conformères ont des énergies potentielles très voisines, la forme équatoriale étant très légèrement plus stable à l'état gazeux. L'énergie de solvatation montre une stabilisation de la forme p-équatoriale en solution. Il est d'ailleurs plus logique de comparer aux données expérimentales les résultats calculés compte tenu de cette énergie de solvatation, les diverses études par dipole métrie ou par r.m.n. ayant été effectuées sur le thiétanne sulfoxyde en solution. Les barrières d'inversion du cycle calculées pour la molécule isolée et solvatée sont néanmoins très proches puisque respectivement égales à 0.36 et 0.39 kcal/mol, différence peu significative. Cette valeur est d'ailleurs du même ordre que celle obtenue pour la molécule de thiétanne (0.32 kcal/mol).

La barrière d'inversion du soufre (fig. 7) par contre est beaucoup plus importante puisque calculée à 47 kcal/mol pour la molécule isolée, elle est de 58 kcal/mol pour le composé solvaté. Le passage d'un conformère à l'autre ne peut donc se faire que par l'inversion du cycle. Comme pour le thiétanne et son homologue substitué, la barrière d'inversion du cycle provient d'une déstabilisation électronique: la courbe ΔE_{el} représentant les différences d'énergie électronique entre les formes intermédiaires lors de l'inversion du cycle présente un maximum pour un angle dièdre θ avoisinant 170° (côté forme p-équatoriale) alors que la grandeur ΔE_{rep} représentant les écarts d'énergie de répulsion entre les coeurs en fonction de l'angle θ, croit lorsque θ diminue et a son minimum pour un angle θ proche de 170° également. Rappelons que ΔE_T (fig. 6) est la somme des termes ΔE_{el} et ΔE_{rep}. Nous n'avons pas rapporté les courbes ΔE_{el} et ΔE_{rep} correspondant à ce composé car elles sont exactement similaires

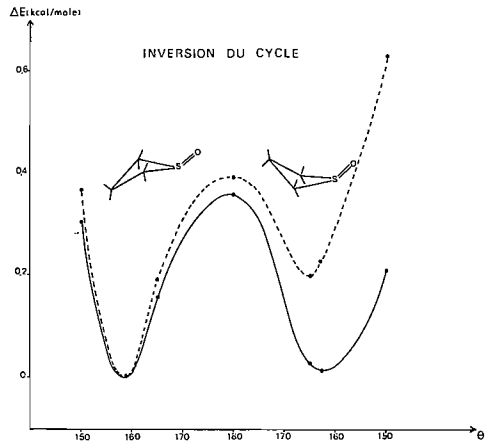

FIG. 6. Energie potentielle totale du thiétanne sulfoxyde lors de l'inversion du cycle à l'état gazeux (trait plein) et à l'état solvaté (pointillés).[2]

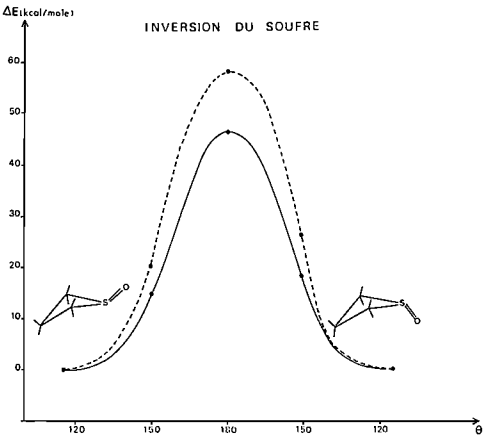

FIG. 7. Energie potentielle totale du thiétanne sulfoxyde lors de l'inversion du groupement sulfoxyde, à l'état gazeux (trait plein) et solvaté (pointillés).[2]

à celles du chloro-3 thiétanne (fig. 2). Il en est de même des variations globales des énergies associées aux atomes, des énergies associées aux liaisons chimiques et de celles associées aux interactions entre atomes non liés chimiquement (fig. 3). On remarque ici aussi que l'allure de la courbe représentant les variations $\Delta E_{\text{liaisons}}$ en fonction de θ est la même que celle représentant ΔE_{el} alors que les courbes ΔE_{at} et $\Delta E_{\text{interactions}}$ sont de même type que ΔE_{rep}, l'ordre de grandeur des variations étant cependant très différent (allant du facteur 1 à 20).

La barrière d'inversion paraît donc liée à l'affaiblissement de certaines liaisons. C'est le cas en particulier pour les liaisons S—O, S—C_2 et C_2—C_3, c'est-à-dire les liaisons formant le cycle (fig. 8), les variations énergétiques des liaisons C_2—H_5 et C_2—H_6 étant en partie compensées par celles en sens contraire de C_3—H_7 et C_3—H_8.

Par contre la destabilisation de la molécule lors de la fermeture de l'angle dièdre θ suit ΔE_{at} et surtout $\Delta E_{\text{interactions}}$.

ΔE_{at} est pratiquement défini par les variations d'énergie de l'atome de soufre (fig. 9), l'ordre de grandeur des autres énergies atomiques étant bien plus faible et celles-ci se compensant les unes les autres.

Enfin $\Delta E_{\text{interactions}}$ est dirigé surtout par l'interaction entre les atomes C_2 et C_4, l'interaction entre les atomes S et C_3 allant en sens

*Le moment dipolaire expérimental du diméthyl-3,3′-thiétanne sulfoxyde est égal à 4.03 D (22).

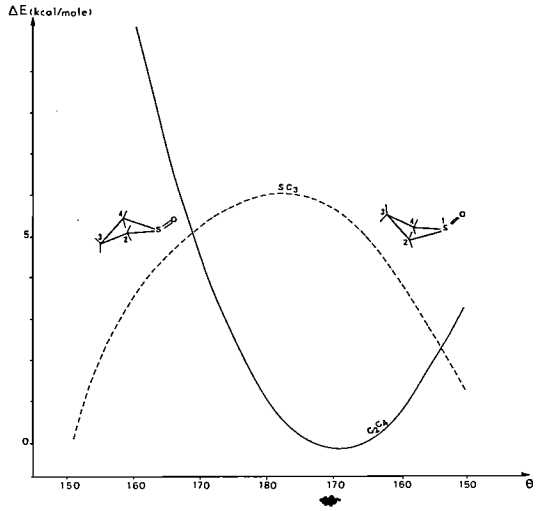

FIG. 10. Energies des principales interactions entre atomes non liés chimiquement du thiétanne sulfoxyde lors de l'inversion du cycle.[2]

contraire, c'est-à-dire vers une déstabilisation de la forme plane (fig. 10). Les interactions entre les autres atomes et en particulier entre les hydrogènes subissent des variations plus faibles. Il en est de même des interactions liantes entre l'atome d'oxygène et les atomes d'hydrogène. L'interaction O–H_5 est plus liante (0.497 kcal/mol) dans le cas du conformère p-équatorial que dans celui du conformère p-axial mais le résultat est inversé pour l'interaction O–H_6 (plus stable de 0.528 kcal/mol dans la forme p-axiale). Enfin les variations des interactions O–H_7 et O–H_8 sont beaucoup plus faibles et assez peu significatives.

En résumé, la déstabilisation du thiétanne sulfoxyde que l'on remarque lors d'une trop grande fermeture de l'angle dièdre θ s'explique par la déstabilisation de l'atome de soufre et par l'augmentation de la répulsion entre les atomes C_2 et C_4. La barrière d'inversion s'explique par l'affaiblissement de l'énergie de la liaison S—O et des énergies de liaison du cycle lorsque celui-ci tend vers une structure plane.

La matrice densité au premier ordre des deux conformères stables et de la forme intermédiaire où le cycle est plan (tableau 6) montre tout d'abord une population notable sur les orbitales d du soufre (0.45 *e*). Cette population s'affaiblit légèrement pour la forme plane du cycle alors qu'au contraire les orbitales 3s et 3p sont un peu plus chargées (notamment les orbitales de type σ). Il faut remarquer cependant que les variations de charge observées pour ces trois formes sont faibles au niveau des atomes lourds et plus sensibles pour les hydrogènes. On note en effet une nette évolution de la charge nette positive des hydrogènes en α et β du groupement sulfoxyde selon l'orientation de ce groupement. Pour le conformère p-équatorial, seul l'hydrogène H_5 a une forte charge nette positive alors que dans le conformère p-axial les deux hydrogènes en α et β en vis à vis de l'oxygène sont fortement positifs. Le moment dipolaire calculé est plus satisfaisant dans le cas de la forme p-équatoriale (4.37 D) pour une valeur expérimentale du diméthyl-3,3′ thiétanne sulfoxyde aux environs de 4 D que dans celui de la forme p-axiale (4.59 D), ce qui est cohérent avec la plus grande stabilité supposée de cette première forme en solution. Enfin pour la forme intermédiaire lors de l'inversion du soufre, on peut noter un net affaiblissement de la polarité de la liaison S—O, due pour la plus grande partie à une densité électronique plus faible sur l'orbitale p_y (p_σ) de l'oxygène. Ceci entraine

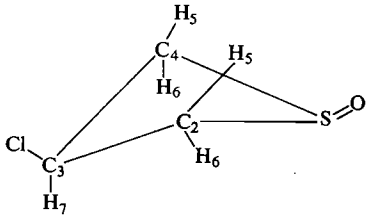
*1 ua = 627.272 kcal/mol.

d'ailleurs un affaiblissement notable de l'énergie de cette liaison qui est à l'origine de la forte barrière observée.

Chloro-3 thiétanne sulfoxyde

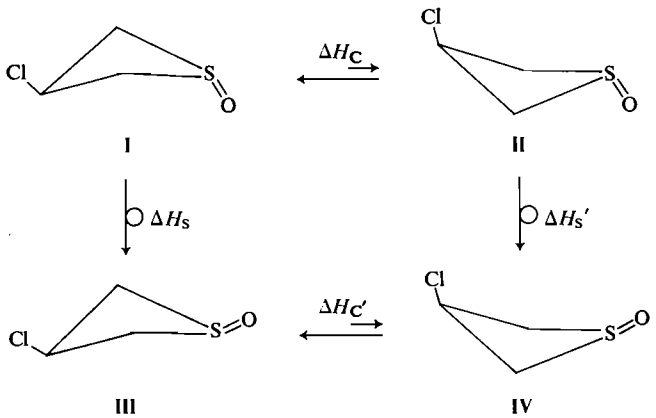


Le chloro-3 thiétanne sulfoxyde peut présenter quatre conformations différentes. Le passage des unes aux autres se fait par l'inversion du cycle (**I** à **II** et **III** à **IV**), ou inversion du soufre (**I** à **III** et **II** à **IV**).

Dans le cas du thiétanne sulfoxyde non substitué nous avions évalué théoriquement la barrière d'inversion du cycle à 0.4 kcal et celle du soufre supérieure à 50 kcal. En supposant que la substitution d'un atome d'hydrogène par un chlore ne modifie pas ou que faiblement l'ordre de grandeur de ces barrières d'inversion, on devrait donc observer dans des conditions normales de température deux formes en équilibre, une *trans* (**I** ou **II**), l'autre *cis* (**III** ou **IV**).

Les études expérimentales effectuées en résonance magnétique nucléaire du proton sur divers dérivés du thiétanne sulfoxyde en position 3 (32–34) confirment cet équilibre. Mais alors que Allenmark (31) met en évidence par rayons X une forme *trans* pour le carboxy-3 thiétanne sulfoxyde et que Arbuzov *et al.* (24) par dipolemétrie conclut à la prédominance de cette même forme pour le chloro-3 thiétanne sulfoxyde, Johnson et Siegl (32, 33), par l'analyse des spectres r.m.n., et après une séparation par chromatographie, mettent en évidence une stabilité supérieure de la forme *cis* pour les dérivés substitués en 3 par un groupement *p*-chlorophényl.

Comme précédemment, nous avons effectué une optimisation complète des structures géométriques des quatre conformères possibles de façon à comparer leur énergie respective. Les résultats de ces calculs sont reportés dans le tableau 3. Il est à noter que l'angle dièdre θ du cycle est voisin de celui calculé pour la chloro-3 thiétanne et qu'il varie relativement peu entre les quatre formes puisqu'il est de 157.2° pour le conformère *trans* avec le chlore en position équatoriale et de 160.3° pour le conformère *cis* diaxial. Cette valeur de 157.2° se rapproche de celle déduite par Arbuzov par dipolemétrie qui



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

TABLEAU 8. Interactions globales et interactions principales entre les atomes de la molécule du chloro-3-thiétanne sulfoxyde dans ses quatre formes possibles (en kcal/mol)

	Energie totale d'interactions	C_2–C_4	S–C_3	S–Cl	O–C_3	O–Cl
I	−107.008	−125.399	−8.205	−4.737	−2.956	3.109
II	−106.109	−126.949	−6.305	−2.487	−2.972	2.833
III	−95.823	−115.416	−8.226	−4.760	−3.013	3.171
IV	−84.224	−102.976	−7.626	−2.594	−3.074	3.463

l'estime à 155.5°. L'introduction d'une liaison polaire sur le cycle thiétanne (S=O ou C—Cl) entraine donc un aplatissement du cycle puisque le thiétanne avait un angle dièdre voisin de 150° alors que les thiétanne sulfoxyde, le chloro-3 thiétanne et le chloro-3 thiétanne sulfoxyde ont un angle dièdre approchant 160°. Par rapport au dérivé non substitué, la différence la plus sensible se situe au niveau de l'angle OSY puisque l'écart avoisine 4°. L'atome d'oxygène se trouve donc un peu plus éloigné du cycle que dans le thiétanne sulfoxyde, ce qui réduit en particulier les interactions entre cet atome et les atomes de carbone C_3 et de chlore.

Les résultats énergétiques globaux (tableau 7) sont en excellent accord avec les données expérimentales. En effet, dans le cas des deux conformères *trans*, la forme la plus stable est celle ayant l'atome d'oxygène en position axiale et l'atome de chlore en position équatoriale. La différence d'énergie entre les deux formes *trans* est de 0.931 kcal/mol en phase gazeuse et de 1.339 kcal/mol à l'état solvaté. Une minimisation énergétique d'une forme intermédiaire (cycle plan) lors de l'inversion du cycle permet d'évaluer la barrière d'inversion entre les deux conformères *trans* à environ 2 kcal/mol, c'est-à-dire une valeur nettement plus élevée que celle du thiétanne (0.32 kcal/mol) et du thiétanne sulfoxyde (0.36 kcal). L'écart énergétique entre les deux formes *cis* est nettement plus élevé, la forme diaxiale étant de loin la moins stable (3.116 kcal/mol en phase vapeur et 4.856 kcal/mol en solution). Par contre, les deux formes énergétiquement les plus stables ont des énergies potentielles voisines, la plus stable étant la forme *trans* (de 0.208 kcal/mol à l'état gazeux et 0.316 kcal/mol à l'état solvaté) ce qui est en accord avec les conclusions d'Arbuzov *et al.* (24) et d'Allenmark (31).

Si l'on examine le tableau 7 on remarque que globalement la stabilité des formes où le chlore est en position équatoriale a son origine dans l'affaiblissement des énergies de répulsions. C'est également ce que nous avions observé pour le chloro-thiétanne et le thiétanne sulfoxyde, le détail des calculs ayant toutefois montré que les répulsions entre atomes liés jouaient un rôle prédominant (les énergies totales des liaisons étant essentiellement à l'origine de la préférence équatoriale tant du chlore que du groupement sulfoxyde).

Par contre lors de la présence de deux groupements polaires (entre **I** et **III**) les interactions entre atomes non liés jouent un rôle prédominant. Ainsi comme on peut le voir par exemple dans le tableau 8, les facteurs qui favorisent la position équatoriale du chlore entre les composés **I** et **II** sont essentiellement les interactions entre atomes non liés. En effet, si les liaisons de la forme **II** sont plus liantes de 10.246 kcal/mol les énergies atomiques sont plus stables de 10.278 kcal/mol pour la forme **I** (tableau 9) (les variations d'énergie atomique provenant en majeure partie des atomes de soufre (6.649 kcal/mol) et de chlore (3.701 kcal/mol)).

Les interactions attractives entre les atomes de chlore et de soufre ainsi que celles entre les atomes de soufre et de carbone C_3 sont bien plus importantes que celles observées pour le chloro-3 thiétanne. Comme pour ce composé, elles favorisent le conformère p-équatorial, mais de

plus compensent largement l'interaction entre les atomes de carbone C_2 et C_4 nettement plus stabilisante pour la forme **II**.

Il faut noter que les interactions O–Cl sont sensiblement voisines.

De la même façon ces interactions stabilisantes $S–C_3$ et S–Cl existent pour le conformère **III** comparativement au conformère **IV** et dans ce cas s'ajoutent à l'interaction $C_2–C_4$ plus importante dans la forme **III**. Remarquons que l'on observe également entre les deux composés une interaction répulsive entre le chlore et l'oxygène du même ordre, ce qui laisse présumer à côté des effets électrostatiques une interaction entre paires libres stabilisante (35).

Si cette analyse met en évidence clairement l'origine de la préférence équatoriale du chlore dans des interactions $S–C_3$ et S–Cl par contre l'orientation privilégiée du groupement sulfoxyde dans une direction axiale semble surtout liée à une interaction stabilisante notable entre les atomes de carbone C_2 et C_4.

Les populations atomiques des quatre conformères du chloro-3 thiétanne sulfoxyde sont reportées dans le tableau 10. Comme pour le thiétanne sulfoxyde, l'atome de soufre est chargé positivement (à l'inverse du chloro-3 thiétanne) et montre un transfert de charge sur les orbitales de polarisation d assez élevé (0.45 *e*). Au contraire, l'atome de chlore possède des orbitales d très peu chargées (0.06 *e*). Il semble donc qu'au niveau de la répartition électronique, on retrouve d'une part du côté du groupement sulfoxyde exactement les mêmes caractéristiques que pour le thiétanne sulfoxyde et d'autre part du côté du chlore celles du chloro-thiétanne. Ce fait traduit d'ailleurs les faibles interactions existant entre l'atome d'oxygène et l'atome de chlore.

De même que nos résultats énergétiques, les valeurs calculées des moments dipolaires vont dans le sens d'une prédominance du conformère *trans* (chlore en position équatoriale) comme l'avait d'ailleurs proposé Arbuzov.

Les conclusions tirées de cette approche théorique sont dans l'ensemble en bon accord avec les données expérimentales connues concernant les préférences conformationnelles des molécules étudiées. Il apparaît donc que malgré ses déficiences le CNDO/2 peut permettre d'aborder de façon raisonnable l'étude conformationnelle des cycles à cinq ou six chaînons comportant des atomes de soufre pour lesquels un traitement *ab initio* est difficilement envisageable. De telles observations avaient déjà été faites par différents auteurs (18, 19, 36); il n'en reste pas moins intéressant de comparer pour le cycle thiétanne ces données semi-empiriques à celles découlant d'un calcul *ab initio* que nous prévoyons d'effectuer.

Les auteurs remercient la Société Nationale des Pétroles d'Aquitaine pour le soutien financier accordé à l'un d'entre eux (C.G.).

The Temperature Dependence of the Ratio k_d/k_c for Ethyl Radicals

D. G. HOOPER, M. SIMON, AND M. H. BACK
University of Ottawa, Ottawa, Canada K1N 6N5

Received October 18, 1974

D. G. HOOPER, M. SIMON, and M. H. BACK. Can. J. Chem. **53**, 1237 (1975).

The ratio of the rate constants for disproportionation and combination for ethyl radicals, k_d/k_c

$$2C_2H_5 \xrightarrow{k_d} C_2H_4 + C_2H_6$$

$$2C_2H_5 \xrightarrow{k_c} C_4H_{10}$$

has been measured over the temperature range 298–173 K in the gas phase. Ethyl radicals were produced by direct photolysis of ethylene followed by addition of hydrogen atoms to ethylene. At low temperatures the only important reactions of the radicals were combination and disproportionation. The ratio k_d/k_c was obtained from measurements of the rates of formation of ethane, butane, and butene. No change in the ratio k_d/k_c was observed over the temperature range studied, leading to the conclusion that $E_d - E_c = 0$, within the experimental error. The significance of this result is discussed in relation to other measurements in both gas and liquid phase and to the nature of the transition state for this reaction.

D. G. HOOPER, M. SIMON et M. H. BACK. Can. J. Chem. **53**, 1237 (1975).

On a mesuré les rapports des constantes de vitesse de dismutation et de combinaison des radicaux éthyles, k_d/k_c

$$2C_2H_5 \xrightarrow{k_d} C_2H_4 + C_2H_6$$

$$2C_2H_5 \xrightarrow{k_c} C_4H_{10}$$

en phase gaseuse à des températures allant de 298–173 K. On a produit les radicaux éthyles par photolyse directe de l'éthylène suivie par l'addition d'atomes d'hydrogène à l'ethylène. A basse température, les seules réactions importantes des radicaux sont les réactions de combinaison et de dismutation. On a obtenu le rapport k_d/k_c à partir des mesures des vitesses de formation de l'éthane, du butane et du butène. On n'a observé aucun changement dans le rapport k_d/k_c dans les limites des températures étudiées; ceci nous amène à conclure que $E_d - E_c = 0$ à l'intérieur des erreurs expérimentales. On discute de la signification de ce résultat en relation avec d'autres mesures en phase gaseuse et en phase liquide et en rapport avec la nature de l'état de transition pour cette réaction. [Traduit par le journal]

Introduction

When two radicals react together two reactions may occur, *viz.* combination, which involves the formation of one bond and one product molecule, and disproportionation, which involves the transfer of a hydrogen atom from one radical to the other forming two product molecules. The ratio of disproportionation to combination in a particular encounter is a characteristic of the radicals involved. Values of k_d/k_c, the rate constant ratio for disproportionation and combination, range from essentially zero for methyl radicals (insofar as this ratio may be observed in this system) to 3.1 for two *t*-butyl radicals (1). The factors determining this ratio have been much discussed but no comprehensive interpretation has yet evolved (2). The most promising empirical relation appears to be the linear dependence of log k_d/k_c on $S_d^0 - S_c^0$, the entropy difference between the products of disproportionation and of combination (3, 4). Even this correlation was shown, however, to require the introduction of a factor, β, to provide agreement with the thermodynamic interpretation of reaction rates (5). Furthermore, as more values of k_d/k_c have become available, it has become evident that the scatter of the data is too large to conclude that all radicals have a common set of linear constants in this relation (6).

If log k_d/k_c is proportional to $S_d^0 - S_c^0$, the difference in activation energy between k_d and k_c, $E_d - E_c$, must be zero or constant (7). Early studies showed that for small radicals the difference was probably zero, but because of the scatter of the data, the small temperature range covered, and the difficulty in distinguishing a temperature-dependence of k_d/k_c from concurrent changes in the mechanism of the reaction, particularly at higher temperatures, some uncertainty remains. The reaction of two ethyl radicals is the system most thoroughly studied. Measurements of k_d/k_c from the photolysis of propionaldehyde showed no change over the range 323–588 K (8). On the other hand Reid and LeRoy found that k_d/k_c increased with temperature in a higher temperature region (9). A study of the photolysis of azoethane both in the gas phase over the range 317–208 K, and in a variety of solvents over the range 358–82 K, showed that k_d/k_c increased with decreasing temperature and that $E_c - E_d$ was approximately 300 cal/mol (10). The authors, however, preferred to attribute the temperature-dependence to a factor T^n, where $n = -0.7$. In a study of the radiolysis of liquid methane in the presence of ethylene over the range 179–92 K Gillis (11) found that k_d/k_c for ethyl radicals increased with decreasing temperature giving $E_c - E_d$ of 290 cal/mol, although the actual values for k_d/k_c were higher than those obtained by Dixon *et al.* (10). In an extension of the experiments with azoethane, Stefani (12) found a heterogeneous contribution to k_d/k_c and concluded that in the gas phase the change in k_d/k_c with temperature was almost within experimental error.

These uncertainties reflect the difficulties in the measurement of a small temperature coefficient of a rate constant ratio in a radical system and the problem of comparing results from studies in the gas phase with those from the liquid phase. In the measurement of such a small temperature coefficient some advantage may be gained by making measurements at low temperatures. To accomplish this with a gas phase reaction we have studied the photolysis of ethylene at 185 nm over the temperature range 298–153 K. Several studies of this reaction (13–16) have shown that at least one primary process involves the formation of a hydrogen atom which rapidly adds to ethylene to form an ethyl radical. Subsequent reactions of the ethyl radical, which at low temperatures are mainly radical–radical reactions, may be studied.

Experimental

Research grade ethylene was obtained from Matheson Co., Whitby, Ont. The ethane impurity of 0.02 mol% was removed by gas chromatography. The cylindrical quartz reaction vessel shown in Fig. 1 was 5 cm in diameter and 114 cc in volume. The window of the vessel formed part of a Dewar flask which was designed so that cooling liquid could cover the vessel completely. To remove mercury vapor, ethylene was admitted to the vessel through two spiral traps maintained at −78 °C. The vessel was isolated by a Hoke bellows-seal stainless steel valve. A low-pressure mercury lamp was constructed of 12 mm o.d. tubing coiled to form a flat spiral. The lamp current was varied between 1 and 6 mA by addition of resistors to the circuit. The lamp was placed about 5 mm from the outside window of the Dewar flask and the lamp and flask were enclosed in a box, through which nitrogen gas was circulated to prevent absorption of light by oxygen.

In the first series of experiments the noncondensable products were separated from the condensable products and collected in a gas burette. They were subsequently analyzed on a 4 m Porapak Q column maintained at 30 °C, using a thermal conductivity detector. The total condensable products were analyzed on a 4 m Porasil A column maintained at 30 °C. In the second series of experiments, for which a flame ionization detector was used, the unreacted ethylene and products were condensed into a small detachable bulb. On warming to room temperature, air was added to bring the total pressure to atmospheric, the mixture was stirred magnetically, and samples were withdrawn with a syringe for analyses. In this analysis system only greaseless Teflon stopcocks and greaseless joints were used. This method had the advantage of giving better separation and permitting duplicate analyses for each experiment but was exact only for ratios of products, not absolute amounts. For calibration, known mixtures of the products were condensed into the bulb and the same procedure followed. A 6 m column of phenylisocyanate on Porasil gave ratios of C_2H_6/C_4H_{10}, C_4H_8/C_4H_{10}, and C_4H_6/C_4H_{10} and a 4 m column of *n*-octane on Porasil (Durapak) gave ratios of

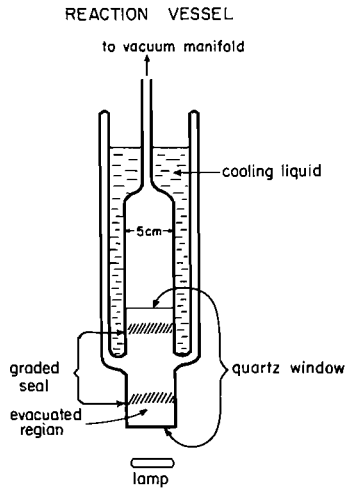

FIG. 1. Diagram of reaction vessel.

For personal use only.

C_4H_8/C_4H_{10}, C_4H_6/C_4H_{10}, C_6H_{14}/C_4H_{10}, and C_6H_{12}/C_4H_{10}. Ratios from duplicate analyses usually agreed within 15%, while analyses on the two columns agreed within 20%, except for hexane, which because of the small amount sometimes had more error.

The photolysis was studied at 298, 195, 173, and 153 K over the range of pressures 16–125 Torr. The cooling liquid at 173 K was ethanol and at 153 K was pentane.

Results and Discussion

The photolysis of ethylene at 185 nm has been shown to involve three primary processes and it has been suggested that at least three excited states of ethylene contribute to these reactions (13). Deactivation without decomposition is also important at 185 nm.

[1] $C_2H_4 + h\nu \rightarrow C_2H_2 + H_2$

[2] $\rightarrow C_2H_2 + 2H$

[3] $\rightarrow C_2H_3 + H$

The hydrogen atoms rapidly add to ethylene and the main reacting species are the vinyl and ethyl radicals. At room temperature radical–radical reactions should predominate.

[4] $H + C_2H_4 \rightarrow C_2H_5$

[5] $C_2H_5 + C_2H_5 \rightarrow C_2H_6 + C_2H_4$

[6] $\rightarrow C_4H_{10}$

[7] $C_2H_3 + C_2H_5 \rightarrow C_2H_4 + C_2H_4$

[8] $\rightarrow C_2H_2 + C_2H_6$

[9] $\rightarrow C_4H_8$

[10] $C_2H_3 + C_2H_3 \rightarrow C_2H_4 + C_2H_2$

[11] $\rightarrow C_4H_6$

The ratio k_5/k_6 should be obtained from the ratio $[C_2H_6]/[C_4H_{10}]$ with a correction for the ethane produced in reaction 8.

The products detected and analyzed were hydrogen, acetylene, butane, ethane, butene-1, 1,3-butadiene, *n*-hexane, and hexene-1. Hydrogen and acetylene were formed directly in the primary processes 1 and 2 while the other products were formed by secondary reactions of the radicals produced in reaction 3. The ratios of the rates of formation of products relative to butane at 298 K are summarized in Table 1, and at 195, 173, and 153 K in Table 2. Typical yield–time plots are given in Fig. 2. The ratio of ethane/butane was constant over the time range studied under all conditions. Methane was not detected except in a few experiments at higher light intensity where small quantities of C_5 products were also observed. Propylene was not detected but propane was not separated from the large quantities of ethylene. The products were identified by comparison of retention time on at least two columns and by addition of small amounts of a particular product into the reaction mixture.

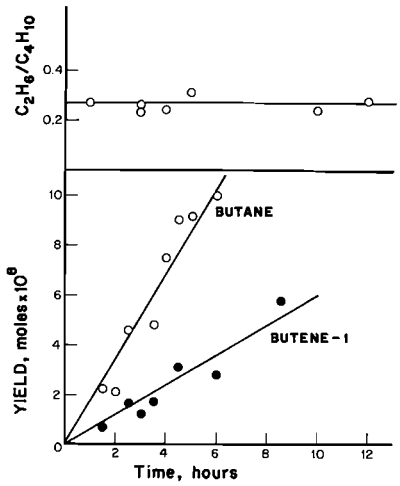

FIG. 2. Variation of the yield of butane and butene with time and of the ratio ethane/butane with time.

In the present experiments the absorbed light intensity at 27 Torr was about 4×10^{14} quanta $l^{-1}\ s^{-1}$, estimated using the value of $\Phi_{H_2} = 0.44$ measured by Glasgow and Potzinger (17). This intensity was much lower than used in previous studies; in particular in the study by Potzinger *et al.* the absorbed intensity was 1.7×10^{17} quanta $l^{-1}\ s^{-1}$ (13). The lower light intensity caused two differences between the mechanism outlined here and that proposed in the latter study. First, reaction 12 is not important in the

[12] $H + C_2H_5 \rightarrow C_2H_6$

present experiments. This is demonstrated by the constancy of the ratio $[C_2H_6]/[C_4H_{10}]$ with a change in light absorbed by a factor of six, illustrated in Figs. 3 and 4. In a second set of experiments in which the absorbed intensity was changed by a factor of four the ratio $[C_2H_6]/[C_4H_{10}]$ was also unchanged. These results are included in Table 1. An increase in absorbed intensity should favor reaction 12 over reaction 4 and hence increase the ratio $[C_2H_6]/[C_4H_{10}]$. If the ratio remains unchanged reaction 12 cannot be important.

Secondly, the formation of *n*-hexane suggests that addition of the ethyl radical to ethylene occurred followed by radical–radical reactions

*The relative yield of acetylene was not reported at room temperature because a small amount of decomposition occurred concurrently by mercury photosensitization at 254 nm. This was negligible at the lower temperatures.

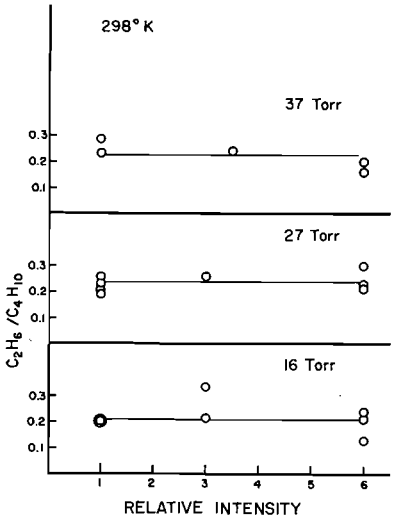

FIG. 3. Variation of the ratio ethane/butane with absorbed light intensity.

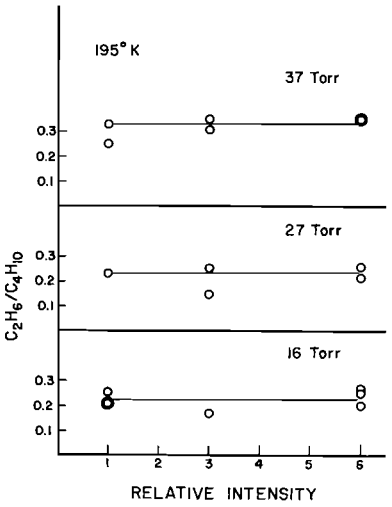

FIG. 4. Variation of the ratio ethane/butane with absorbed light intensity.

of the *n*-butyl radical. Since the ethyl radical is the most abundant radical in the system other radical–radical reactions should be unimportant. Only at very low light intensity would the addition of ethyl radicals to ethylene compete with radical–radical reactions. Hexane was, understandably, not observed in previous studies (13, 16).

[13] $C_2H_5 + C_2H_4 \rightarrow C_4H_9$

[14] $C_4H_9 + C_2H_5 \rightarrow C_4H_8 + C_2H_6$

[15] $\rightarrow C_4H_{10} + C_2H_4$

[16] $\rightarrow n\text{-}C_6H_{14}$

The rates of formation of butane and hexane are given as follows:

$$\text{Rate butane} = k_6[C_2H_5]^2$$

$$\text{Rate hexane} = \frac{k_{16}}{k_{14} + k_{15} + k_{16}} k_{13}[C_2H_5][C_2H_4]$$

Since $[C_2H_5]$ is proportional to $I_a^{1/2}$

[17] $$\frac{\text{Rate hexane}}{\text{Rate butane}} = \frac{k'[C_2H_4]}{I_a^{1/2}}$$

where k' is a composite rate constant. The ratio of hexane/butane as a function of pressure and intensity is shown in Fig. 5. The ratio was roughly linear with ethylene pressure and decreased by a factor of approximately two when

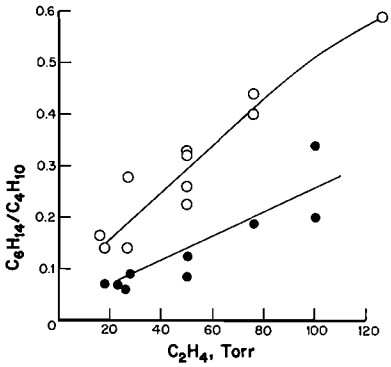

FIG. 5. Variation of the ratio hexane/butane as a function of ethylene pressure: ○, relative intensity = 1.5; ●, relative intensity = 6.

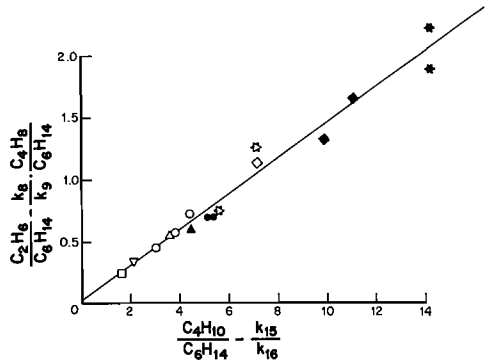

FIG. 6. Plot of eq. 18. Ethylene pressure: ✡, 16 Torr; ◇, 27 Torr; ○, 50 Torr; ▽, 76 Torr; △, 100 Torr; □, 126 Torr. Open symbols denote relative intensity of 1.5; closed symbols relative intensity 6.

the absorbed intensity increased by a factor of four.

Hexene-1 is believed to be formed by a separate primary process not involving hydrogen atoms or ethyl radicals. The kinetics of its formation are discussed in the following paper (18) and will not be further considered here.

Assuming that reactions 5, 6, 8, 9, 14, 15, and 16 account for the formation of ethane, butane, butene, and hexane, the following relation may be derived:

$$[18]\quad \frac{[C_2H_6]}{[C_6H_{14}]} - \frac{k_8[C_4H_8]}{k_9[C_6H_{14}]} = \frac{k_5}{k_6}\left[\frac{[C_4H_{10}]}{[C_6H_{14}]} - \frac{k_{15}}{k_{16}}\right] + \frac{k_{14}}{k_{16}}\left[1 - \frac{k_8}{k_9}\right]$$

where the quantity in brackets refers to the rate of formation of the product. Using measured values for k_{15}/k_{16} and k_{14}/k_{16} (1), the left-hand side of eq. 18 was plotted against

$$\left[\frac{[C_4H_{10}]}{[C_6H_{14}]} - \frac{k_{15}}{k_{16}}\right]$$

A value of k_8/k_9 was chosen so that the slope equalled the accepted value of k_5/k_6 at room temperature. As shown in Fig. 6, a value of $k_8/k_9 = 0.7$ gave a slope of 0.145. The uncertainty in k_8/k_9 was less than ± 0.2. This rather high value of k_8/k_9 means that relatively large amounts of ethane were formed in reaction 8 even though the concentration of vinyl radicals was considerably smaller than the concentration of ethyl radicals. It may be pointed out that high values of k_d/k_c for the reaction of two vinyl radicals have been reported (19, 20).

In their study of the photolysis of ethylene, Hara and Tanaka (16) reported values for the ratios C_2H_6/C_4H_{10} and C_4H_8/C_4H_{10} in excellent agreement with those obtained in the present work. Since hexane was not a product under their experimental conditions they used eq. 19 (see below) to obtain k_5/k_6. By assuming a value of 0.48 for k_8/k_9 they obtained $k_5/k_6 = 0.21$. If the value of k_8/k_9 is taken as 0.7 then from their results $k_5/k_6 = 0.17$, a value in much better agreement with previous measurements.

At 195 K and below hexane was not formed. At these temperatures the addition reaction is considerably slower and the radical–radical reactions can compete successfully. Assuming reactions 5, 6, 8, and 9 now account for the production of ethane, butane, and butene, the following equation may be derived.

$$[19]\quad \frac{[C_2H_6]}{[C_4H_{10}]} = \frac{k_5}{k_6} + \frac{k_8[C_4H_8]}{k_9[C_4H_{10}]}$$

A plot of the ratios $[C_2H_6]/[C_4H_{10}]$ against $[C_4H_8]/[C_4H_{10}]$ obtained over the pressure range 10–128 Torr at 195, 173, and 153 K is shown in Fig. 7. The line represents the values of k_5/k_6 and k_8/k_9 measured at room temperature. It is evident that the ratios measured at lower temperatures are consistent with the values of k_5/k_6 and k_8/k_9 measured at room temperature. Nevertheless for each set of ratios obtained at one temperature a line of lower slope and larger intercept could be drawn. It must be assumed however that both ratios k_5/k_6 and k_8/k_9 would change with temperature in the same direction. Clearly the ratios obtained at

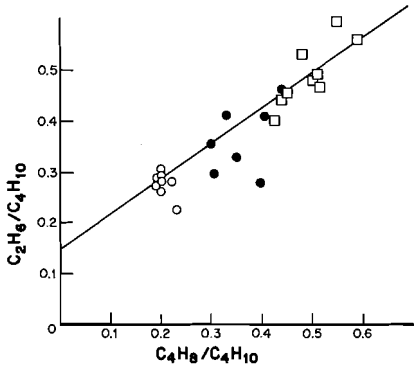

FIG. 7. Plot of eq. 19. ○, 195 K; ●, 173 K; □, 153 K. The line is drawn with intercept = 0.145 and slope = 0.7.

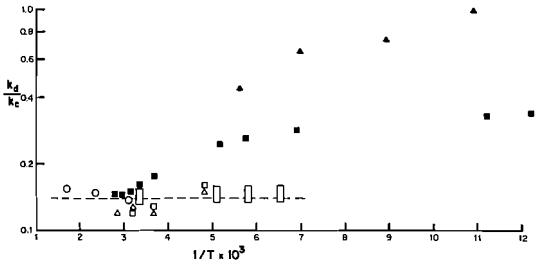

FIG. 8. Values for k_d/k_c as a function of $1/T$. ○, ref. 8; ■ and □, ref. 10; △, ref. 12; ▲, ref. 11; ▯, present work. Open symbols denote results obtained in the gas phase; filled symbols denote results obtained in the liquid phase.

the lower temperatures do not indicate an increase in both the slope and intercept of eq. 19, nor do they indicate a decrease in both these quantities. Our conclusion is that neither ratio, k_5/k_6 nor k_8/k_9, shows any change with temperature within experimental error. Over the temperature range covered by these experiments the present results indicate an upper limit to the activation energy difference for these reactions of about 30 cal/mol.

The ratio C_4H_8/C_4H_{10}, which is proportional to C_2H_3/C_2H_5, increased as the temperature decreased and increased slightly with increasing pressure. The radicals formed in reaction 3 will have some excess energy and a certain fraction may dissociate to acetylene. The exact relation between reactions 2 and 3 has not been clearly established in the photolysis of ethylene. It is not evident, however, why this ratio should depend on temperature. This question is discussed in more detail in the following paper.

In Fig. 8 values of k_d/k_c for ethyl radicals are shown in an Arrhenius plot. The constancy of k_d/k_c with changing temperature observed in the present study is in agreement with the measurements of k_d/k_c by Kerr and Trotman-Dickenson (8) over the temperature range 323–488 K. The results of Dixon *et al.* (10) from the photolysis of azoethane in the gas phase from 298–208 K appear to be in disagreement, since these authors observed an increase in k_d/k_c with decreasing temperature. In a later study of the same system, by Stefani (12), the contribution of a heterogeneous reaction to disproportionation threw some doubt on this interpretation and Stefani concluded that the change in k_d/k_c with temperature was barely significant. The results of many other measurements of k_d/k_c in the temperature range 298–373 K scatter between the values 0.12 and 0.15 (1). None of these results show any tendency for k_d/k_c to decrease above room temperature, as would be expected if the temperature coefficient measured by Dixon *et al.* persisted at higher temperatures. It must be concluded that in the gas phase k_d/k_c for ethyl radicals is independent of temperature within the experimental limits of accuracy.

The measurements by Dixon *et al.* (10) and by Gillis (11) of k_d/k_c for ethyl radicals in the liquid phase do show an increase in the ratio with decreasing temperature. Similar behavior has been observed with other radicals (2). This difference between gas and liquid phases is not easily explained. At room temperature the value of k_d/k_c is virtually the same in the gas phase and in nonpolar liquids. There is therefore no specific solvation effect on the reaction between ethyl radicals and it does not appear that the solvent in any way aids the formation of the disproportionation product. On the other hand the increase in k_d/k_c may be the result of a decrease in k_c, which may occur as rotations in the transition state become increasingly hindered in the liquid phase at low temperature and the reacting pair of radicals may more readily approach and follow the surface leading to disproportionation. An increase in internal pressure of the solvent should show a similar effect and this was observed and discussed by Dixon *et al.* (10). The difference in the volume of activation for disproportionation and combination, measured by Backman *et al.* (21) was also consistent with this interpretation.

The nature of the transition state for dispro-

portionation and combination reactions has been much discussed. The original question concerning the "common" or "separate" transition states was really an attempt to distinguish different types of collisions between the radicals, where one type of collision led to combination and another type to disproportionation. Because of the very loose nature of the collision complex, however, different orientations of the approaching radicals cannot be distinguished (22). Nevertheless within the phase space of the complex two surfaces can be distinguished but because the fraction of the radicals proceeding to disproportionation and combination in the ethyl radical complex appears invariant with temperature, our conclusion is that these two transition states are isoenergetic. Entropy or configurational factors alone must distinguish the two paths even though these factors cannot be described completely by $S_d^0 - S_c^0$, the difference in entropy between the products of disproportionation and combination.

The authors thank the National Research Council of Canada for generous financial support of this research.

The Mechanism of Formation of Hexene-1 in the Photolysis of Ethylene at 185 nm

M. SIMON AND M. H. BACK

Chemistry Department, University of Ottawa, Ottawa, Canada K1N 6N5

Received October 18, 1974

M. SIMON and M. H. BACK. Can. J. Chem. **53**, 1245 (1975).

In the photolysis of ethylene at 185 nm the rate of formation of hexene-1 has been measured. The ratio of the rates of formation of hexene-1 to butane varied from 0.6 to 1.4 at 298 K and fell to about 0.25 at 153 K. It is suggested that hexene-1 is formed by successive additions to ethylene to give hexamethylene which isomerizes to hexene-1.

$$C_2H_4^* + C_2H_4 \rightarrow (CH_2)_4$$
$$(CH_2)_4 + C_2H_4 \rightarrow (CH_2)_6$$
$$(CH_2)_6 \rightarrow C_6H_{12}\text{-}1$$

This interpretation is consistent with the effect of pressure of ethylene and absorbed light intensity on its rate of formation.

M. SIMON et M. H. BACK. Can. J. Chem. **53**, 1245 (1975).

On a mesuré le taux de formation de l'hexène-1 lors de la photolyse de l'éthylène à 185 nm. Les rapports des vitesses de formation de l'hexène-1 par rapport au butane varient de 0.6 à 1.4 à 298 K et tombent à environ 0.25 à 153 K. On suggère que l'hexène-1 se forme par une série d'additions successives à l'éthylène pour donner l'hexaméthylène qui s'isomérise en hexène-1. Les réactions sont

$$C_2H_4^* + C_2H_4 \rightarrow (CH_2)_4$$
$$(CH_2)_4 + C_2H_4 \rightarrow (CH_2)_6$$
$$(CH_2)_6 \rightarrow C_6H_{12}\text{-}1$$

Cette interprétation est en accord avec l'effet sur la vitesse de formation de l'hexène-1, de la pression de l'éthylène et de l'intensité de la lumière absorbée. [Traduit par le journal]

Introduction

In the photolysis of ethylene at 185 nm three primary dissociation processes have been observed (1–5).

[1] $$C_2H_4 + h\nu \rightarrow C_2H_2 + H_2$$

[2] $$\rightarrow C_2H_2 + 2H$$

[3] $$\rightarrow C_2H_3 + H$$

It has been suggested (1) that more than one excited state of ethylene is involved, but the photophysical processes that precede dissociation have not been fully clarified. Previous studies have shown that at room temperature the hydrogen atoms are removed by addition to ethylene and that the products may be accounted for by the subsequent radical–radical reactions of the ethyl and vinyl radicals.

Products of molecular weight higher than C_4 were observed to arise only by secondary reactions of accumulated products. In the present study of the photolysis of ethylene at 185 nm, however, as reported in the preceding paper (6), *n*-hexane and hexene-1 were shown not to be formed in this manner. It was suggested that *n*-hexane was formed by the addition of the ethyl radical to ethylene followed by combination of the resulting *n*-butyl radical with the ethyl radical. By analogy hexene-1 could be formed by combination of the vinyl and *n*-butyl radicals or of the ethyl and butenyl radicals. The kinetics of the formation of hexene-1, however, were not in accord with this mechanism and we have been led to suggest an independent set of reactions involving a consecutive addition of diradicals to ethylene. A somewhat similar mechanism was suggested to account for the formation of the minor product hexene-1 in the mercury-photosensitized decomposition of ethylene (7). The present paper describes the kinetics of the formation of hexene-1 in the direct photolysis of ethylene at 185 nm and discusses the evidence for a diradical mechanism.

Experimental

The apparatus, procedure, and analysis were described in the preceding paper (6). Hexene-1 was identified by coincidence of retention time with pure samples on two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

columns, 4 m × ¼ in. *n*-octane on Porasil C (Durapak) at 40 °C and 3 m × ¼ in. tricresylphosphate on Chromosorb P at 30 °C. Also, small amounts of pure samples were added to the reaction mixture to test for coincidence with the reaction products. 1,5-Hexadiene, *trans*-hexene-2, *trans*-hexene-3, cyclohexane, and methylcyclopentane were well separated from hexene-1 and were shown to be absent from the reaction products.

Results and Discussion

The only two products of any importance of molecular weight higher than C_4 were *n*-hexane and hexene-1. At the highest absorbed light intensity and at long reaction times small amounts of C_5 products and other C_6 products were observed. The ratios of rates of formation of products, listed in Table 1, were obtained under conditions where these minor products were not significant. In Fig. 1 the ratio of hexene-1/butane is shown to be independent of time, and since the rate of formation of butane was previously shown to be independent of time (6) it may be concluded that hexene-1 is not formed by secondary photolysis of a product.

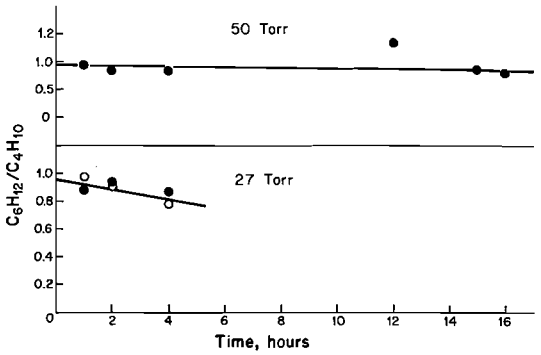

FIG. 1. The ratio of the rates for hexene-1 to butane as a function of time: ○, high intensity; ●, low intensity.

Two arguments may be advanced to show that radical combination reactions are not the main source of hexene. First, the yield of hexene is too large to arise solely from vinyl or butenyl radical reactions. From the relative yields of butane ($C_2H_5 + C_2H_5$), butene ($C_2H_3 + C_2H_5$), and hexane ($C_2H_5 + C_4H_9$) it may be shown that even at the highest pressure of 126 Torr, less than 20% of the hexene-1 produced could have been formed by radical combination reactions, ($C_4H_9 + C_2H_3$ or $C_4H_7 + C_2H_5$) and at lower pressures the fraction was much smaller. Secondly, if hexene were formed by combination of radicals then hexadiene would also be expected as a product from the corresponding combination of vinyl and butenyl radicals, and should be formed in amounts roughly comparable to those of hexane. No trace of hexadiene was observed under any conditions, although such amounts could have been measured easily.

We propose therefore that hexene is formed by a process independent of the formation of hydrogen atoms, which involves instead the successive addition of a diradical to ethylene to form hexamethylene and finally hexene-1.

I_{abs} $\quad C_2H_4 + h\nu \rightarrow C_2H_4(S)$

[1] $\quad C_2H_4(S) \rightarrow C_2H_2 + H_2$

[2] $\quad C_2H_4(S) \rightarrow C_2H_2 + 2H$

[3] $\quad C_2H_4(S) \rightarrow C_2H_3 + H$

[4] $\quad C_2H_4(S) \rightarrow C_2H_4(T)$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[5] $C_2H_4(T) \rightarrow C_2H_3 + H$

[6] $C_2H_4(T) + C_2H_4 \rightarrow 2C_2H_4$

[7] $C_2H_4(T) + C_2H_4 \rightarrow (CH_2)_4$

[8] $(CH_2)_4 + C_2H_4 \rightarrow (CH_2)_6$

[9] $(CH_2)_6 \rightarrow C_6H_{12}$-1

$C_2H_4(S)$ refers to the first excited singlet state of ethylene and $C_2H_4(T)$ to the corresponding triplet state, although this identification is tentative.

If all the hydrogen atoms are converted to ethyl radicals, which in turn disappear by combination,[1] disproportionation, and addition reactions, then the sum $2\alpha R_{C_4H_{10}} + 2\beta R_{C_6H_{14}} + \gamma R_{C_4H_8}$ represents the rate of formation of hydrogen atoms, where α, β, and γ are the corrections for the loss of radicals to disproportionation products. The ratio of this sum to the rate of formation of hexene is shown in Fig. 2 as a function of pressure at each temperature. The data for the rates of formation of products other than hexene-1 were taken from ref. 6. It is clear that the ratio becomes independent of pressure above about 50 Torr, and it must be concluded that above this pressure the excited molecule of ethylene formed in reaction 4 does not undergo any competing first-order reactions, such as reaction 5. Furthermore, the tetramethylene diradical formed in reaction 7 must react quantitatively to yield hexene-1.

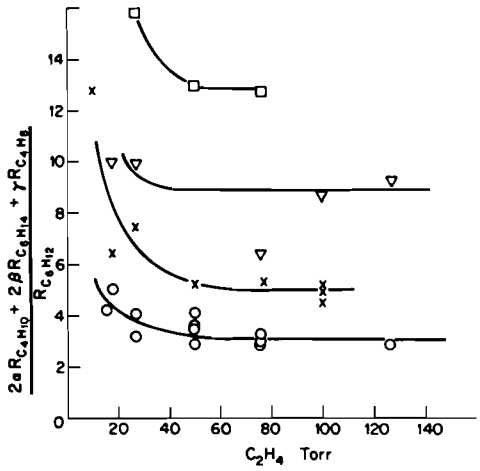

FIG. 2. The ratio $(2\alpha R_{C_4H_{10}} + 2\beta R_{C_6H_{14}} + \gamma R_{C_4H_8})/R_{C_6H_{12}}$ as a function of pressure. ○, 298 K; ×, 195 K; ▽, 173 K; □, 153 K.

[1] $C_2H_5 + C_4H_7$ is neglected.

The results of Potzinger *et al.* (1) provide some confirmation for this assumption. In the mechanism suggested by these authors one of the excited states, designated $C_2H_4^*$, reacts by competing first-order and second-order processes. Using the terminology of these authors

[f] $C_2H_4^* \rightarrow C_2H_2 + 2H$

[g] $C_2H_4 + C_2H_4^* \rightarrow$ deactivation

Reaction g was observed as a deactivation process because hexene was not analyzed by Potzinger *et al.* Higher hydrocarbon products were observed in some experiments but this aspect of the investigation was not pursued. The ratio k_g/k_f was given as 4050 l mol^{-1} at room temperature and at 50 Torr the ratio $k_f/k_g(C_2H_4)$ is approximately 0.1. If the reaction g actually led to formation of hexene then the ratio $k_f/k_g(C_2H_4)$ may be equated to our ratio $k_5/[k_7(C_2H_4)]$ and the ratio of rate constants measured by Potzinger *et al.* is in accord with the pressure-independence observed for the ratio

$$\frac{2\alpha R_{C_4H_{10}} + 2\beta R_{C_6H_{14}} + \gamma R_{C_4H_8}}{R_{C_6H_{12}}}$$

above 50 Torr. The excited molecule designated as $C_2H_4^*$ was not suggested by Potzinger *et al.* to be the triplet state. In our mechanism the triplet state is merely considered to be the most likely state to react in this manner.

It might be questioned why the tetramethylene radical should react entirely by further addition whereas the hexamethylene radical isomerizes to hexene-1. The rates of isomerization of tetramethylene and hexamethylene may be comparable to the isomerization rates of the corresponding alkyl radicals. Isomerization of *n*-butyl radical to *s*-butyl radical, in which a 1,3 hydrogen shift must occur, is much slower than isomerization of 1-hexyl to 2-hexyl, which occurs by a 1,5 hydrogen shift (8–12). By analogy, isomerization of tetramethylene to butene-1 should be slow while isomerization of hexamethylene to hexene-1 should be rapid. If the rate constant for the latter reaction is comparable to that measured for the isomerization of 1-hexyl to 2-hexyl ($\log k\ (s^{-1}) = 9.4 - 11200/2.3RT$) (12), isomerization should be many times faster than addition under the present conditions. It appears reasonable then that the addition reaction of tetramethylene radical could be faster than its

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

isomerization while the reverse could apply to the hexamethylene radical.

In contrast to the behavior of hexene-1, the ratio hexane/butane was found to be linearly dependent on the ethylene pressure (Fig. 5 of ref. 6), as expected from the mechanism involving radical combination reactions. This result also leads to the conclusion that hexene-1 and hexane are formed by entirely different processes.

The effect of absorbed light intensity further supports this conclusion. The ratio

$$\frac{2\alpha R_{C_4H_{10}} + 2\beta R_{C_6H_{14}} + \gamma R_{C_4H_8}}{R_{C_6H_{12}}}$$

was independent of absorbed light intensity when this was changed by a factor of four (Fig. 3). In contrast, the ratio

$$\frac{R_{C_6H_{14}}}{R_{C_4H_{10}}}$$

was inversely proportional to the square root of the absorbed light intensity (Fig. 5 of ref. 6) as expected from the mechanism involving addition of the ethyl radical to ethylene.

Effect of Temperature

The addition of radicals to ethylene is a process which requires an activation energy of several kcal/mol. In previous studies of the photolysis of ethylene at 185 nm this process was not found to be significant. In the present study the absorbed light intensity was sufficiently low that addition of ethyl radicals to ethylene was able to compete with radical–radical reactions at room temperature. At temperatures of 195 K and lower, however, no addition was observed, as indicated by the disappearance of the product *n*-hexane. The product hexene-1, on the other hand, was observed even at the lowest temperature of 153 K, although the yield was reduced. This further substantiates the view that the two products, hexane and hexene, are formed by quite different mechanisms.

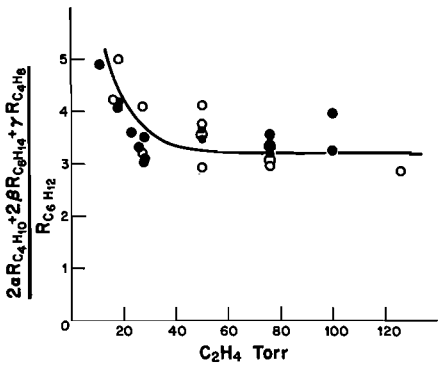

FIG. 3. The ratio $(2\alpha R_{C_4H_{10}} + 2\beta R_{C_6H_{14}} + \gamma R_{C_4H_8})/R_{C_6H_{12}}$ for absorbed intensities different by a factor of four. ●, high intensity; ○, low intensity.

In the pressure-independent region the ratio

$$\frac{2\alpha R_{C_4H_{10}} + 2\beta R_{C_6H_{14}} + \gamma R_{C_4H_8}}{R_{C_6H_{12}}}$$

may be expressed as follows

$$[10] \quad \frac{2\alpha R_{C_4H_{10}} + 2\beta R_{C_6H_{14}} + \gamma R_{C_4H_8}}{R_{C_6H_{12}}} = \frac{2k_2 + k_3}{k_4} \cdot \frac{(k_6 + k_7)}{k_7}$$

and the following equations may be derived.

$$[11] \quad \frac{\gamma R_{C_4H_8} + 2\delta R_{C_4H_6}}{R_{C_6H_{12}}} = \frac{k_3}{k_4} \cdot \frac{(k_6 + k_7)}{k_7}$$

$$[12] \quad \frac{\gamma R_{C_4H_8} + 2\delta R_{C_4H_6}}{2\alpha R_{C_4H_{10}} + 2\beta R_{C_6H_{14}} + \gamma R_{C_4H_8}} = \frac{k_3}{2k_2 + k_3}$$

The ratios in eqs. 11 and 12 were also independent of pressure above about 50 Torr. The values of these three ratios in the plateau region at each temperature are given in Table 2, and the Arrhenius plots are shown in Fig. 4. Because the yield of hexene is relatively large it may be concluded that $(k_6 + k_7)/k_7 \cong 1$ and most of the ethylene formed in reaction 4 produces hexene. The activation energy obtained from the Arrhenius plot of eq. 11 indicates therefore that $E_4 - E_3 \cong 2$ kcal/mol. The final column in Table 2 shows that the ratio $k_3/(2k_2 + k_3)$ is small compared to one and therefore may be approximated to $k_3/2k_2$ only at the highest temperature. A lower limit for $E_2 - E_3$ of about 1.5 kcal/mol may be estimated from the Arrhenius plot of eq. 12 in the region of 298 K. If E_3 is zero these estimates represent the activation energies for reactions 4 and 2 respectively.

A temperature dependence of a primary photodissociation process is unusual. The most probable cause is absorption of some of the incident radiation by vibrationally-excited ethylene, which can lead to an increased vibrational

*The correction factors, α, β, γ, δ are equal to the ratio $(k_d + k_c)/k_c$ for the particular radical–radical reaction. α and β are both well established and equal to 1.15. The value for γ was taken as 1.7, which is the value measured in ref. 6. A range of values has been reported for δ and since the most recent measurement indicates a high value, δ was taken equal to γ, 1.7. It should be emphasized that the variation of the ratios in Table 2 with pressure, absorbed intensity, and temperature is quite insensitive to the values chosen for γ and δ and the conclusions concerning the mechanism are not changed by using other values. Only the actual value of the ratio is affected and these values should therefore be accepted with caution.

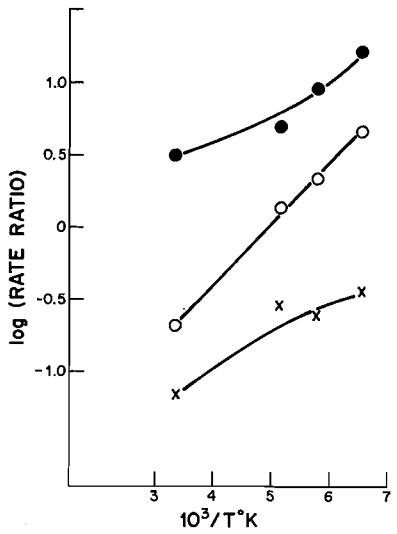

FIG. 4. Arrhenius plots of eqs. 10, 11, and 12: ●, $(2\alpha R_{C_4H_{10}} + 2\beta R_{C_6H_{14}} + \gamma R_{C_4H_8})/R_{C_6H_{12}}$; ○, $(\gamma R_{C_4H_8} + 2\delta R_{C_4H_6}/R_{C_6H_{12}}$; ×, $(\gamma R_{C_4H_8} + 2\delta R_{C_4H_6})/(2\alpha R_{C_4H_{10}} + 2\beta R_{C_6H_{14}} + \gamma R_{C_4H_8})$.

excitation of the upper state. Such "hot band" absorption is usually not appreciable at room temperature and below, but in the long-wavelength tail of a transition involving a large change in geometry, as is the case with ethylene, it can become important.[2] The reason is that a change in geometry may give a more favorable Franck–Condon factor, thus greatly favoring absorption from the vibrationally-excited level. "Hot band" absorption has in fact been observed in ethylene over the temperature range −78 to 100 °C (13). The estimated activation energy for reaction 2 of about 1.5–2.0 kcal/mol corresponds roughly to the energy of the quantum for the torsional vibration of ethylene. The ratio of reaction 2 to 3 could be particularly sensitive to small increments of energy in the upper state since the energy of the absorbed quantum (154 kcal/mol) is not far from the estimated threshold for reaction 3 (145 kcal/mol). Finally it should be noted that a temperature dependence of less than 2 kcal/mol is easily detected only in the low temperature range of the present experiments and would not be apparent in studies in the vicinity of room temperature.

Effect of Oxygen

Some experiments were done with small additions of oxygen to test for a difference in reactivity of the excited molecule producing hydrogen atoms and that giving hexene-1. The effect of oxygen on the products from the hydrogen atoms and on the hexene-1 was almost identical. The rate of formation of ethane, butane, and hexene relative to the rate in the absence of oxygen is shown as a function of oxygen pressure in Fig. 5. The pressure of oxygen required to reduce the yield of hexene by one-half was 2.7×10^{-2} Torr, while the corresponding pressure for ethane was 3.9×10^{-2} Torr. This difference is probably not significant and it may be concluded that oxygen reacts rapidly with the initially-formed singlet state and much slower with other intermediates.

Comparison of Liquid and Gas Phase Photolyses

In a recent study of the photolysis of ethylene at 185 nm in the liquid phase (15) the addition reaction of an excited ethylene molecule with another molecule of ethylene was also observed,

[2]In the A ← X transition of ammonia, a similar case, the 0,0 and 1,1 absorption bands are almost equally intense at room temperature, despite an unfavorable Boltzmann factor of about 10^{-2} for the latter (14).

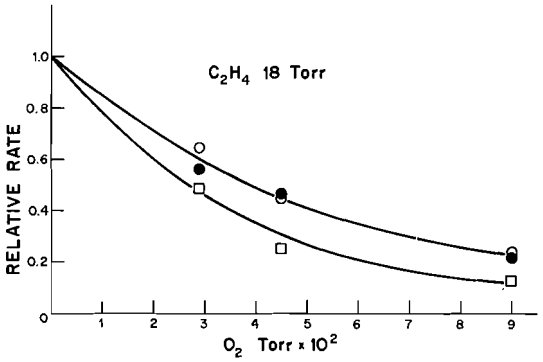

FIG. 5. Rates in the presence of oxygen relative to the rate in the absence of oxygen. ○, C_2H_6; ●, C_4H_{10}; □, C_6H_{12}.

but in this case the products were entirely C_4 molecules, the major portion being butene-1 with smaller amounts of cyclobutane and methylcyclopropane. It was suggested that butene-1 was formed by reaction of the ethylidene radical with ethylene, by either of two possible paths, the ethylidene radical being a possible configuration of the excited state. In the present study the addition reaction was suggested to proceed through a diradical, forming tetramethylene and subsequently hexamethylene. There was no evidence for formation of C_4 products by the addition reaction and the yield of butene-1 was very much smaller than observed in the liquid phase. It seems likely that the lifetime of the ethylidene radical is too short to allow bimolecular reactions to occur in the gas phase and these may be observed only in the liquid phase. Previous attempts to observe reactions of ethylidene in the gas phase have shown that its lifetime is very short and rearrangement to ethylene is very rapid (16).

In the present study the yield of hexene relative to the yield of butene plus butadiene decreased with decreasing temperature (Fig. 4) and by an extrapolation it may be estimated that the hexene formed by the diradical mechanism at −160 °C, where the experiments on liquid ethylene were done, would be only about 10% of the observed yield of hexene in the liquid phase. The diradical addition mechanism would therefore not be important at −160 °C. At this temperature the excited molecules probably undergo a rapid bimolecular reaction before reaction 4 may occur. It may be concluded that two quite distinct photoexcited molecules of ethylene are involved in the addition reaction in the liquid and in the gas phase.

J. T. BULMER and H. F. SHURVELL. Can. J. Chem. **53**, 1251 (1975).

Digitized infrared spectra of nine solutions of trichloroacetic acid in CCl_4 have been studied in the carbonyl stretching region. At all concentrations only two bands are visually apparent. However, factor analysis indicates the presence of four absorbing components. The contour resolution technique gives a monomer band at 1786 cm^{-1}, a dimer band at 1749 cm^{-1}, and a third band close to the dimer frequency at approximately 1735 cm^{-1}. Examination of the changes in Cauchy–Gauss shape ratio of the monomer band with increasing concentration indicates the presence of an unresolved component. The band at 1735 cm^{-1} and the unresolved band near the monomer peak at 1786 cm^{-1} are assigned to absorption of carbonyl groups in linear polymers of trichloroacetic acid. The monomer–dimer equilibrium constant was calculated from the molar absorption coefficients and absorbances of monomer and dimer bands. The average value over the concentration range 0.305 $\times$ 10^{-3} to 0.1603 *M* was 287 l/mol at 33.9 $\pm$ 0.5 °C.

J. T. BULMER et H. F. SHURVELL. Can. J. Chem. **53**, 1251 (1975).

On a étudié, pour la région de vibration du carboxyle, les spectres infrarouges chiffrés de neuf solutions d'acide trichloroacétique dans CCl_4. A toutes les concentrations, il n'y a que deux bandes qui sont apparentes d'une façon visuelle. Toutefois une analyse factorielle indique la présence de quatre composants qui absorbent. La technique de la résolution des contours donne une bande monomère à 1786 cm^{-1}, une bande dimère à 1749 cm^{-1} et une troisième bande près de la fréquence de la bande dimère à environ 1735 cm^{-1}. Un examen des changements dans les rapports des formes Cauchy–Gauss de la bande monomère, lorsque l'on augmente la concentration, indique la présence d'un composant qui n'est pas résolu. On a attribué la bande à 1735 cm^{-1} et la bande non résolue près du pic monomère à 1786 cm^{-1} à l'absorption des groupements carbonyles dans le polymère linéaire de l'acide trichloroacétique. On a calculé les constantes d'équilibre monomère–dimère à partir des coefficients molaires d'absorption et des absorbances des bandes des monomères et dimères. La valeur moyenne sur l'intervalle des concentrations 0.305 $\times$ 10^{-3} à 0.1603 *M* est de 287 l/mol à 33.9 $\pm$ 0.5 °C.

[Traduit par le journal]

Introduction

Infrared band contour resolution together with factor analysis provide a useful approach to the study of equilibria in solution. We have previously reported results of studies of self association of acetic acid (1) and complex formation between chloroform and di-*n*-butyl ether (2) in CCl_4 solutions. Our method is based on well established mathematical techniques. The band contour resolution method using digitized infrared spectra is due to Jones and co-workers (3), while factor analysis has been

applied to spectrophotometric data by a number of authors (4–6). The combination of these two techniques can reveal information not easily obtained by other methods.

Our procedure determines the number of absorbing components in a complex band. If these components can be assigned to the same group vibration in various species in equilibrium, then information on the stoichiometry of the system is available. The method also leads to molar absorption coefficients of the group vibration in hydrogen bonded or complexed molecules, from which equilibrium constants can be calculated. The use of digitized spectra enables an entire band shape to be analyzed rather than using only the positions and heights of the major spectral features.

The present application is to solutions of trichloroacetic acid in CCl_4. Infrared spectra of the carbonyl stretching region show only two bands, while factor analysis indicates that four absorbing components are present. Contour resolution requires two bands at low acid concentrations with a third component at higher concentrations. A careful examination of the shape ratios of the component bands for a Cauchy–Gauss product function, reveals the increasing importance of a Gaussian component associated with the monomer band as the concentration increases.

Experimental

Fisher reagent grade trichloroacetic acid was dried in a drying pistol using P_2O_5. The sample was warmed with refluxing dimethyl ether (b.p. 34.5 °C) and a vacuum of about 0.1 Torr was used. Crystals deposited on the cooler part of the drying pistol. These were collected and stored in a dessicator. Trichloroacetic acid melts at 56.3 °C and has deliquescent crystals. Preliminary results showed that the spectrum of CCl_3COOH is quite sensitive to the presence of water. For this reason all solutions were prepared in a dry box.

Fisher spectroanalyzed carbon tetrachloride was dried over molecular sieves. Dryness was checked by monitoring water bands at 3709 and 3618 cm^{-1}. Ten solutions were prepared in the concentration range 3.05×10^{-4} to 0.1603 *M*.

Spectra were recorded using R.I.I.C. variable pathlength cells on a Perkin–Elmer model 180 spectrometer. The instrument was flushed with dry air and wavenumber calibration was checked using the known frequencies of standard compounds. A cell containing solvent was placed in the reference beam and the absorptions of sample and reference beams were balanced at 1850 cm^{-1}. Pathlengths were determined by the fringe method which only applies to short pathlengths over a small range. However, the high precision with which the R.I.I.C. cells are manufactured ensures accuracy of pathlength over the range used in this work. Details of concentrations and pathlengths of the nine solutions subjected to analysis are given in Table 1.

TABLE 1. Concentrations and pathlengths used for CCl_3COOH solutions in CCl_4

Solution	Concentration (mol/l)	Pathlength (cm)
1	0.00061	0.5019
2	0.00122	0.4827
3	0.00244	0.3101
4	0.00488	0.1327
5	0.00977	0.07037
6	0.02004	0.02242
7	0.04008	0.01043
8	0.08015	0.00564
9	0.16030	0.002281

The spectra were digitized at 0.5 cm^{-1} intervals using the manual technique described previously (7). Digitization was carried out at 301 points over the range from 1850 to 1700 cm^{-1}. Triplicate spectra were compared numerically by a small computer program to check for errors in the manual digitization. The spectra were then averaged before further processing.

Computational Techniques

Band Resolution

The computer programs for band contour resolution were supplied by R. N. Jones and are described fully in ref. 3. The Lorenzian (Cauchy) band shape usually assumed for i.r. bands (8–10) can be written:

$$[1] \qquad A_c(\nu) = X_1[1 + X_3^2(\nu - X_2)^2]^{-1}$$

where $A(\nu)$ = absorbance at wavenumber ν, X_1 = peak height, X_2 = peak position, and X_3 = band width parameter.

Perturbations due to solute–solvent interactions, or absorption by other species such as isomers, isotopic molecules, or in the present case polymeric species add Gaussian character to the i.r. band (11). The Gaussian function can be written

$$[2] \qquad A_g(\nu) = X_1 \exp[-X_4^2(\nu - X_2)^2]$$

where X_1, X_2 are as above and X_4 = Gauss band width parameter.

Equations 1 and 2 can be combined to give a product function

$$[3] \quad A_p(\nu) = X_1\left[\frac{\exp[-X_4^2(\nu - X_2)^2]}{1 + X_3^2(\nu - X_2)^2}\right]$$

The Cauchy–Gauss shape ratio is defined as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[4] $$R_{c/g} = \frac{X_3}{X_3 + X_4}$$

Functions 1 and 3 have been used to fit the observed contours of the carbonyl stretching band of CCl_3COOH in CCl_4 solutions. The fitting procedure involves sequentially increasing the number of absorbing components (NC) until a satisfactory fit is obtained between observed and calculated contours. Infrared absorption is normally recorded as transmittance (T) and this is converted to absorbance by the programs. A good fit is achieved when the function ϕ given by

[5] $$\phi = \sum_i f_i^2$$

where

$$f_i = \left[\frac{T}{T_0}\right]_{\nu(\text{obs})} - \left[\frac{T}{T_0}\right]_{\nu(\text{calcd})}$$

approaches the value of S^2NP, where NP is the number of points in the digitized spectrum and S is the standard deviation in the experimental transmittance measurements. Fluctuation in the wavenumber of the maximum difference between the observed and calculated spectrum (WFM) indicates that the correct number of components (NC) is being used. An invariant WFM indicates the necessity of an additional component at that frequency. In view of the importance of NC and the dependence of the method on an assumed band shape, an independent method for the determination of the number of absorbing components is needed and factor analysis provides this.

Factor Analysis

The mathematical technique known as factor analysis or principal component analysis applies to constitutive properties such as absorbance. The Beer–Lambert law for a single absorbing component at wavenumber ν can be written

[6] $$A(\nu) = \varepsilon(\nu)C$$

where $A(\nu)$ is the absorbance normalized to unit pathlength, $\varepsilon(\nu)$ is the molar absorption coefficient at wavenumber ν, and C is the concentration in mol/l.

For NC absorbing components in NS solutions of different concentrations the Beer–Lambert law for NW wavenumbers over an entire absorption band can be written

[7] $$\mathbf{A} = \mathbf{EC}$$

where $\mathbf{A}$ is the NW × NS normalized absorbance matrix, $\mathbf{E}$ is the NW × NC molar absorption coefficient matrix, and $\mathbf{C}$ is the NC × NS concentration matrix. Also, NW is the number of digitized points in the spectrum, NS is the number of solutions, and NC the number of absorbing components.

The method of factor analysis involves finding the rank of the absorbance matrix. The rank of $\mathbf{A}$ may be interpreted as being equal to the number of absorbing components NC. To find the rank of $\mathbf{A}$, previous workers (4, 5, 12) have formed the matrix $\mathbf{P} = \mathbf{AA}^T$ where $\mathbf{A}^T$ is the transpose of $\mathbf{A}$. This matrix $\mathbf{P}$ is a square matrix of dimension NW × NW and has the same rank as $\mathbf{A}$. The rank of $\mathbf{P}$ however, is the number of nonzero eigenvalues of $\mathbf{P}$. Thus the number of absorbing components also corresponds to the number of nonzero eigenvalues of $\mathbf{P}$. Fortunately, the nonzero eigenvalues of $\mathbf{A}^T\mathbf{A}$ (dimension NS × NS) are identical to those of $\mathbf{AA}^T$ (dimension NW × NW). Since NW is usually several hundred, while NS is about 10, it is obviously easier to handle $\mathbf{A}^T\mathbf{A}$.

In practice, experimental errors and computational procedures, in addition to absorbing components, lead to nonzero eigenvalues of $\mathbf{A}^T\mathbf{A}$. However, statistical tests (1, 4, 5) can be applied to determine which eigenvalues are really nonzero, (*i.e.*, can be attributed to absorbing components). Details of these tests formulated in the present notation have been given in ref. 1. They are: (*i*) A residual standard deviation (r.s.d.) method (5), where the residual standard deviations in the eigenvalues are compared with an estimated average standard deviation (s.d.); (*ii*) The estimation of the square root of the variance of each eigenvalue (4), where eigenvalues larger than the square root of their variances are taken to be nonzero; (*iii*) The χ^2 criterion (4), where the *smallest* number of eigenvalues (m) leading to a value of χ^2 near the expectation value, given by (NW-m)(NS-m) (13), is taken to be NC; (*iv*) An examination of the misfit between the observed absorbance matrix and an absorbance matrix regenerated using only the first m eigenvectors of $\mathbf{A}^T\mathbf{A}$ (4). Here NC is taken to be the *smallest* number of eigenvectors which give a regenerated absorbance matrix with most elements within 3 standard deviations of the corresponding observed points.

Results and Discussion

The spectra of the carbonyl stretching region of three solutions of CCl_3COOH in CCl_4 are shown in Fig. 1. The peak at 1786 cm^{-1} decreases while the peak at 1750 cm^{-1} increases as the concentration increases. At no concentration was there any visual evidence of additional bands, although the 1750 cm^{-1} band does show some asymmetry on the low wavenumber side.

Factor Analysis

Factor analysis of nine spectra of the carbonyl region of CCl_3COOH in CCl_4 solution in the concentration range 0.61×10^{-3} to 0.16 M indicate the presence of four absorbing components.

Inspection of the residual standard deviations in Table 2 indicates that the r.s.d. of the 4th, 5th, and 6th eigenvalues lie in the range of the experimental s.d. However, there is a decrease of an order of magnitude between fourth and fifth eigenvalues, so that four absorbing components are indicated.

Table 2 also compares the eigenvalues of $\mathbf{A}^T\mathbf{A}$ with the square root of the estimated variance for a transmittance error 0.2%. It is seen that only the first four eigenvalues are larger than the square roots of their estimated variances.

The results of the regeneration of the absorbance matrix using from one up to nine eigenvectors of $\mathbf{A}^T\mathbf{A}$ are given in Table 3. Using up to 3 eigenvectors leaves many points with misfits greater than 3 standard deviations. The χ^2 values are also very large. If four eigenvectors are used 2654 out of 2700 data points agree within three estimated transmittance errors. Also $\chi_4^2 = 3107$ is comparable with the expectation value of

1485. The results using five eigenvectors also yield results consistent with a transmittance error of 0.2% and χ_5^2 is closer to the expectation value. However, NC is taken as the *smallest* number of eigenvectors which satisfactorily reproduce the absorbance matrix.

Band Contour Resolution

Visual examination of the spectra at all concentrations between 0.61×10^{-3} and $0.16\ M$ reveals only two bands due to monomer and dimer. However, factor analysis indicates four absorbing components and previous experience with acetic acid leads us to expect two additional absorptions arising from terminal and hydrogen-bonded C=O groups in linear chain structures. The spectra of CCl_3COOH in CCl_4 solution resemble those of acetic acid in the more dilute solutions, where only two bands were apparent.

Two band fits using both Cauchy and Cauchy–Gauss product functions indicated the presence of a third absorption near 1735 cm^{-1} in addition to the monomer at 1780 cm^{-1} and dimer at 1750 cm^{-1}. Details of the results of a three band fit of the spectrum of 0.00488 M CCl_3COOH in CCl_4 using Cauchy functions are given in Table 4. This confirms the necessity for three bands, but does not directly indicate a fourth. However, examination of the Cauchy–Gauss ratio defined in eq. 4 clearly shows the increasing importance of a Gaussian component in the monomer band as the concentration increases. At the same time the dimer band retains a strongly Lorentzian character. Values of the Cauchy–Gauss ratio are listed in Table 5. This is clear evidence for the location of the fourth component predicted by factor analysis and is most likely due to the terminal carbonyl groups of linear chain structures. The 1735 cm^{-1} band is then assigned to hydrogen bonded C=O groups in the linear polymers.

Calculation of Molar Absorption Coefficients and Equilibrium Constants

The calculation of the monomer–dimer equilibrium constant is based on the method of Chiang and Hammaker (14). We have taken the activity coefficients of monomer and dimer to be unity. A linear least squares method is used to obtain the molar absorption coefficients of monomer and dimer from the equation

$$[8] \qquad \frac{A_2}{C_T l} = \varepsilon_2 - \frac{\varepsilon_2}{\varepsilon_1}\left(\frac{A_1}{C_T l}\right)$$

This equation is based on the assumption that only monomer and dimer are present in significant quantities in dilute solutions. The absorbances A_1 and A_2 were obtained from the resolved monomer and dimer bands for the five most dilute solutions, using a two band Cauchy–Gauss product function. The molar absorption coefficients ε_1 and ε_2 were found to be 785 and 1154 l mol^{-1} cm^{-1} for monomer and dimer respectively. An increase in the molar absorption coefficient of the C=O stretching band on hydrogen bonding is usually found and the corresponding values for ε_1 and ε_2 for acetic acid solutions in CCl_4 are 754 and 992 l mol^{-1} cm^{-1} (1).

The equilibrium constant is evaluated using the equation:

$$[9] \qquad K = \frac{1}{2C_1}\frac{A_2}{A_1}\frac{\varepsilon_1}{\varepsilon_2}$$

where

$$[10] \qquad C_1 = C_T\left(\frac{A_1\varepsilon_2}{A_2\varepsilon_1}\right)\Big/\left(1 + \frac{A_1\varepsilon_2}{A_2\varepsilon_1}\right)$$

TABLE 6. Dimerization equilibrium constants of trichloroacetic acid in CCl_4 solution as a function of concentration

Concentration (mol/l × 10^3)	Equilibrium constant (l/mol)
0.305	246
0.610	270
1.22	300
2.44	301
4.88	309
9.77	263
20.0	307
40.1	286
80.2	317
160.3	273

Values of K were obtained using $\varepsilon_1/\varepsilon_2$ from the slope of the line of eq. 8. The results are given in Table 6 for all nine solutions studied. The constant value for the apparent dimerization constant is misleading, since it suggests that only monomer and dimer are present at all concentrations. However the results of factor analysis, band resolution, and the trend in the shape of the monomer band suggest the formation of additional species such as linear polymer chains. A change in equilibrium constant with concentration was observed for acetic acid (1). The apparent absence of this effect here is most likely due to overlap of the bands and our inability to resolve the polymer components.

Conclusions

Factor analysis together with detailed band contour resolution studies indicate the presence of four absorbing components in the carbonyl stretching region of solutions of trichloroacetic acid in CCl_4. Monomeric CCl_3COOH absorbs at 1786 cm^{-1}, while the cyclic dimer absorbs at 1750 cm^{-1}. Linear chain structures, which appear to be less important in CCl_3COOH than in acetic acid in the same solvent, give rise to absorptions due to terminal and hydrogen-bonded carbonyl groups at 1786 and 1735 cm^{-1} respectively.

The apparent equilibrium constant for the monomer–dimer equilibrium does not decrease with increasing concentration in the way observed for acetic acid solutions. This is likely due to our inability to resolve the overlapping monomer/polymer and dimer/polymer bands. The average value for the dimerization equilibrium constant was found to be 287 l mol^{-1} at 33.9 °C. This is compared with previously reported values in Table 7.

It would appear that factor analysis and some detailed features of band contour resolution such as trends in the shape ratio can lead to additional information from spectra. The presence of species other than monomer and dimer in solutions of trichloroacetic in CCl_4 is not detectable from simple band contour analysis alone, nor from the calculated values of the monomer–dimer equilibrium constant at various concentrations.

Thermodynamic Properties of Binary Liquid Acid–Base Mixtures

HORACIO N. SÓLIMO, ROQUE RIGGIO, FRANCO DAVOLIO, AND MIGUEL KATZ

Cátedra de Físico-Química, Facultad de Ciencias Exactas y Tecnología, Universidad Nacional de Tucumán, Tucumán, Argentina

Received October 15, 1974

HORACIO N. SÓLIMO, ROQUE RIGGIO, FRANCO DAVOLIO, and MIGUEL KATZ. Can. J. Chem. **53**, 1258 (1975).

Viscosities, densities, refractive indices, and enthalpies at 25 °C were determined for the systems: propionic acid + aniline (PA + A), propionic acid + *N*,*N*-dimethylaniline (PA + DMA), and propionic acid + pyridine (PA + P). From the experimental results the excess volume, excess viscosity, excess molar free energy of activation, and excess enthalpy were calculated. The deviations from ideality for the excess thermodynamic functions are more important for the systems PA + A and PA + P than for PA + DMA. There is evidence for complex formation between propionic acid and aniline in the following molar relation: 2 $CH_3CH_2COOH \cdot C_6H_5NH_2$.

HORACIO N. SÓLIMO, ROQUE RIGGIO, FRANCO DAVOLIO et MIGUEL KATZ. Can. J. Chem. **53**, 1258 (1975).

On a déterminé, à 25 °C, les viscosités, les densités, les indices de réfraction et les enthalpies des systèmes acide propionique + aniline (AP + A), acide propionique + *N*,*N*-diméthylaniline (AP + DMA) et acide propionique + pyridine (AP + P). On a calculé, à partir de ces résultats expérimentaux le volume d'excès, la viscosité d'excès et l'énergie libre d'activation molaire d'excès et l'enthalpie d'excès. Les déviations de la courbe idéale pour les fonctions thermodynamiques en excès sont plus importantes pour les systèmes AP + A et AP + P que pour le système AP + DMA. Il semble évident qu'il y a formation de complexes entre l'acide propionique et l'aniline dans la relation molaire suivante: 2 molécules acide propionique pour une molécule d'aniline. [Traduit par le journal]

Introduction

Viscosities, densities, refractive indices, and enthalpies of some nonelectrolytes acid–base binary liquid mixtures have been studied to obtain information about the type and degree of interaction between molecules of the components. This is a continuation of our studies about thermodynamic properties (1–3).

The following systems: propionic acid + aniline (PA + A), propionic acid + *N*,*N*-dimethylaniline (PA + DMA), and propionic acid + pyridine (PA + P) were chosen because these four substances have polar characteristics and two of them (A and PA) show hydrogen bonding.

Solutions of nonelectrolytes were classified by Barker and Smith (4) as (*i*) "nonpolar" solutions, (*ii*) "polar" solutions, and (*iii*) "associated" solutions. The first system PA + A could be classified as (*iii*) and the other two systems PA + DMA and PA + P as (*ii*) and (*iii*).

In the present paper, densities, refractive indices, viscosities, and enthalpies of the three systems at different molar fractions were measured at 25 °C. From the experimental results the following thermodynamic functions have been calculated: V^E (excess molar volume), η^E (excess viscosity), G^{*E} (excess molar free energy of activation of flow), and H^E (excess molar enthalpy).

Experimental

Density

Densities were determined with a Robertson specific gravity bottle (5). All weighings were made with an accuracy of ± 0.00005 g cm^{-3}. A thermostatically controlled bath, constant to ± 0.01 °C, was used.

Refractive Index

The refractive indices for the sodium D line of the pure components and mixtures were measured with a Jena dipping refractometer with an accuracy of ± 0.00002.

Viscosity

Viscosities of pure liquids and mixtures have been determined with an accuracy of ± 0.005 cP with a Cannon–Fenske viscosimeter calibrated with doubly distilled water, benzene, and sucrose solutions (6). Kinetic energy corrections were applied to viscosity data. All these experimental methods have been described previously (1).

Calorimetric Measurements

The adiabatic jacketed calorimeter described by Loiseleur (7) was used to determine the change of enthalpy when propionic acid was mixed with aniline, *N*,*N*-dimethylaniline, and pyridine. The following

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

modification was made: Teflon was used instead of nylon in several parts of the calorimeter and a cellophane membrane was used between the two compartments. All measurements were made at 25 ± 1 °C, with an accuracy of ±1%.

Material and Solutions

Propionic acid, Hopkin & Williams, was dried over anhydrous sodium sulfate and fractionally distilled. The fraction distilling at 139–141 °C was collected and refractionated over potassium permanganate. The middle fraction distilling at 140.7 °C at 760 mm was collected. The purification of the other substances was described previously (1, 3).

Mixtures were prepared by mixing weighed amounts of the pure liquids. Caution was taken to prevent evaporation.

Results

In general, values of the densities, viscosities, and refractive indices were in reasonable agreement with data from the literature (8–12).

The excess thermodynamic functions (13) were calculated with the following equations:

$$[1] \qquad \eta^E = \eta - (x_1\eta_1 + x_2\eta_2)$$

$$[2] \qquad V^E = V - (x_1V_1 + x_2V_2)$$

$$[3] \qquad G^{*E} = RT[\ln \eta V - (x_1 \ln \eta_1 V_1 + x_2 \ln \eta_2 V_2)]$$

where η, η_1, and η_2 = viscosity of the mixture and of the pure components; V, V_1, and V_2 = molar volume of the mixture and of the pure components; R = gas constant, and T = absolute temperature. The molar volume V of the mixture is defined by

$$[4] \qquad V = \frac{x_1M_1 + x_2M_2}{\rho}$$

where M_1 and M_2 are the molecular weights of the components and ρ the density of the mixture.

The experimental molar fractions, densities, viscosities, refractive indices, and molar enthalpies for the three systems are listed in Tables 1, 2, and 3.

Each set of results was fitted with a Redlich–Kister form of the type

$$[5] \quad X^E = x_1(1 - x_1) \sum_{j=1}^{n} a_j(1 - 2x_1)^{j-1}$$

where X^E represents the excess property under consideration. The method of least-squares was used to determine the values of the coefficients a_j. In each case the optimum number of coefficients was ascertained from an examination of the variation of the standard error of estimate with n,

$$[6] \quad \sigma_x = [\sum(X_{obs}{}^E - X_{cal}{}^E)^2/(n_{obs} - n)]^{1/2}$$

The values adopted for the coefficients a_j (calculated with a IBM 1620 computer) and the standard error of the estimate σ associated with the use of eq. [5] are summarized in Table 4.

Figures 1, 2, 3, and 4 show the experimental values obtained for the excess property under consideration. The continuous curves for η^E, V^E, and H^E in Figs. 1, 2, and 3 were calculated from eq. [5] using these values for the coefficients.

Discussion

Figure 1 shows positive excess viscosities with well marked maxima. This behavior is an evidence for complex formation (14). The energy necessary to break the hydrogen bonding of the type O—H· · ·O in the propionic acid (9.34 kcal mol^{-1}) (15) is greater than the energy to break the hydrogen bonding N—H· · ·N in the aniline (3–5 kcal mol^{-1}) (16). When they are mixed, a shift of the maximum excess viscosity towards the mole fraction of the component with the most energetic hydrogen bonding is observed. In this case the maximum at $x_1 = 0.66$ is in agreement with what has been said above.

For the other two systems the excess viscosity

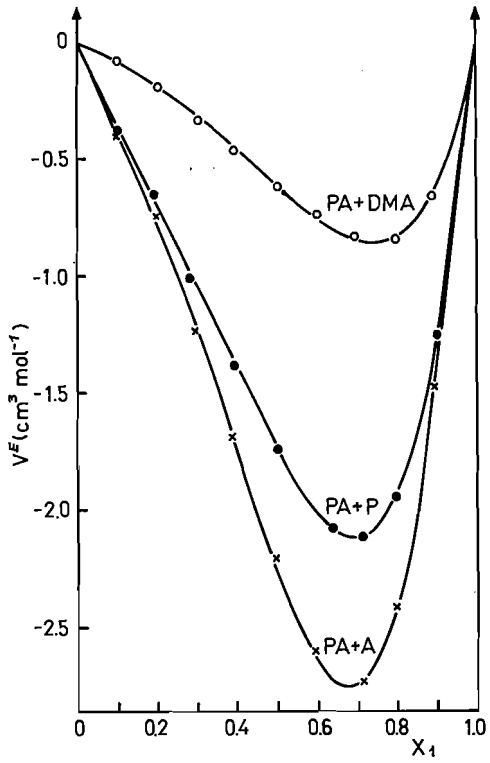

FIG. 2. V^E *vs.* x_1.

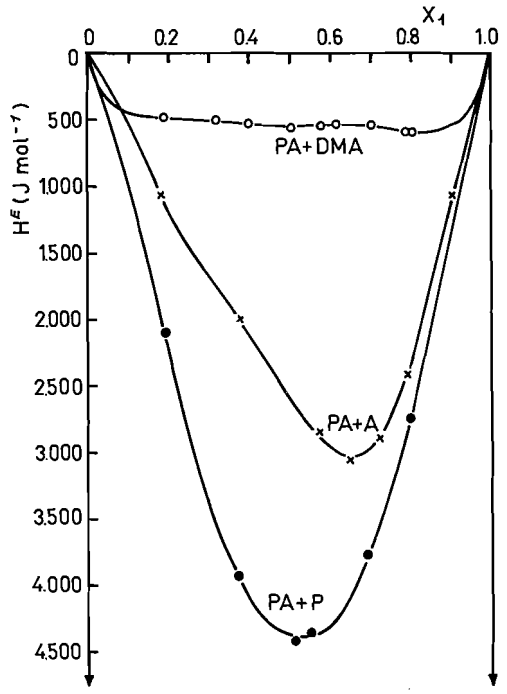

FIG. 3. H^E *vs.* x_1.

becomes less positive and for the PA + P system is meaningful, probably due to the weak bonding N···H of pyridine and the absence of hydrogen bonding in *N*,*N*-dimethylaniline (17).

Fialkov (18) concludes that for systems whose excess viscosity shows well marked maxima, the composition of the compound formed can be fixed, at least to a first examination.

From the analysis of Figs. 1 and 3 we may conclude that for the system PA + A where both components are associated in the pure state, there is evidence for a complex formation in the following molar relation $2CH_3CH_2COOH{\cdot}C_6H_5NH_2$.

For the other two systems we cannot find a molar relation because the maxima do not coincide.

The negative values of V^E in Fig. 2 for the three systems are explained by Prigogine (19) in terms of the different size of the molecules or the dipole–dipole interaction between them. This last effect is more strongly observed in the PA + A system.

Figure 3 shows that H^E for all systems are negative over the whole concentration range. The excess enthalpies of PA + P are greater

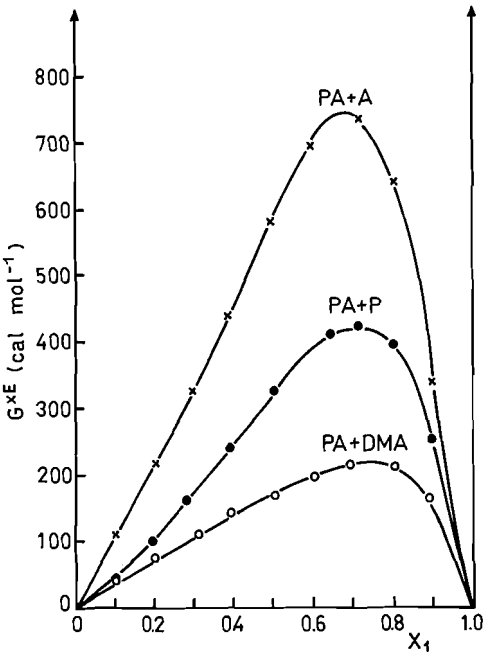

FIG. 4. G^{*E} *vs.* x_1.

than PA + A. The lower negative value for this last system can be explained by the fact that the exothermic effect in complex formation is compensated by the endothermic effect in the rupture of hydrogen bonding in each substance. In the system PA + P there is only an endothermic effect for the propionic acid.

From the analysis of Fig. 4 we may conclude that for the system PA + A more positive G^{*E} values are obtained. This result is in agreement with the expected variation of the ΔH^* and $T\Delta S^*$ functions for nonideal mixtures of the type previously described (20).

The linear variation of the molar refraction for the three systems, calculated from the refractive indices given in Tables 1, 2, and 3 by Lorenz–Lorentz formula, in terms of composition is in agreement with the conclusion of Loiseleur (21) for a large number of ideal and non-ideal systems. Neither the polar characteristics of the substances studied nor the existence of hydrogen bonding in the propionic acid and aniline seem to have any important effect on the linear dependence of this property on concentration.

This work was supported by a SECYT research grant. We are indebted to Miss Silvia Alonso for experimental assistance and to Mr. Eduardo Epstein for help in computation programs.

Electron Mobilities and Ranges in Liquid Ethers: Ion-like and Conduction Band Mobilities[1,2]

JEAN-POL DODELET AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alberta T6G 2E1

Received October 21, 1974

JEAN-POL DODELET and GORDON R. FREEMAN. Can. J. Chem. **53**, 1263 (1975).

The free ion yields in X irradiated ethers are larger than those in alkanes because the dielectric constants of the former liquids are greater than those of the latter. The relative increase of the free ion yield with temperature is smaller in ethers than in alkanes because the dielectric constants decrease more rapidly with increasing temperature in the former. The density normalized penetration range (thermalization length) $b_{GP}d$ of the secondary electrons in dimethyl ether (DME) is 3.5×10^{-7} g/cm^2. As the length of the *n*-alkyl groups on the ether is increased $b_{GP}d$ increases towards the value obtained for long chain *n*-alkanes, 4.5×10^{-7} g/cm^2. Electron mobilities u_e showed two types of behavior: (*i*) at low temperatures u_e approaches a value of about $2u_-$, where u_- is the mobility of the anions formed in the irradiated liquid; (*ii*) at higher temperatures the ratio u_e/u_- increases with temperature, and equals 21 in di-*n*-butyl ether (DBE) at 375 K. The activation energy of electron migration at low temperatures (ion-like mechanism) is similar to that of ion migration, 2–3 kcal/mol, while at high temperatures it increases to ~6 kcal/mol. The larger activation energy is attributed to thermal excitation of electrons from the solvated state into a conduction band, and is equal to one-half of the optical excitation energy of the solvated electrons. Electrons in water, alcohols, and ammonia at 300 K migrate by the ion-like mechanism. Electrons in alkanes migrate almost exclusively by the conduction band mechanism. A plot of the Arrhenius temperature coefficient of electron mobility against mobility in different liquids at a given temperature displays a maximum which is temperature dependent.

JEAN-POL DODELET et GORDON R. FREEMAN. Can. J. Chem. **53**, 1263 (1975).

Les éthers irradiés aux rayons X ont un rendement en ions libres plus grand que les alcanes; ceci est dû à leur constante diélectrique plus élevée. De plus, la diminution sensible de cette constante diélectrique avec l'élévation de température est responsable de la faible augmentation du rendement en ions libres comparativement aux alcanes. Le parcours moyen des électrons secondaires (jusqu'à thermalisation), normalisé pour la densité, $b_{GP}d$, est de 3.5×10^{-7} g/cm^2 pour l'éther diméthylique; il augmente avec l'alongement de la chaîne alkyle tendant vers la valeur 4.5×10^{-7} g/cm^2 obtenue pour le pentane normal. Deux types de mobilité électronique, u_e, ont été observés dans les éthers: (*i*) à basse température, u_e tend vers une mobilité dont la valeur est approximativement deux fois la mobilité anionique, u_-; (*ii*) lorsque l'on augmente la température, le rapport u_e/u_- augmente pour atteindre à 375 K la valeur 21 pour l'éther di-*n*-butylique (DBE). L'énergie d'activation, 2–3 kcal/mol, de la migration électronique à basse température est semblable à celle de la migration ionique tandis qu'à plus haute température elle augmente jusqu'à 6 kcal/mol environ. Cette dernière énergie d'activation est attribuée à l'excitation thermique des électrons depuis l'état solvaté jusqu'à la bande de conduction et vaut la moitié de l'énergie d'excitation optique. Le mécanisme de migration des électrons à 300 K dans l'eau, les alcools et l'ammoniac liquide, est de type ionique. Dans les alcanes les électrons migrent presque exclusivement par un mecanisme de bande de conduction. Le coefficient de température d'Arrhenius pour la mobilité électronique est porté en graphique en fonction de la mobilité électronique dans plusieurs liquides. Un coefficient maximum apparait à une température donnée et varie en fonction de la température.

Introduction

This article reports a continuation of the study of electron transport in dielectric liquids.

Mobilities of thermal electrons in liquid hydrocarbons range over five orders of magnitude, from 510 cm^2 V^{-1} s^{-1} in methane at 118 K to 0.003 cm^2 V^{-1} s^{-1} in ethylene at 170 K (1). The mobility depends greatly upon molecular structure (1–4 and references therein), tending to increase with increasing sphericity of the molecules. A surprising result was that the mobilities ap-

[1]This paper is dedicated to Professor C. A. Winkler of McGill University on the occasion of his sixty-fifth birthday by one of his former students (G.R.F.).

peared to be independent of the magnitudes of small dipole moments, $\mu \leqslant 0.5$ D, possessed by some of the molecules (5). In highly polar liquids such as water (6), alcohols (7, 8), and ammonia (9), electron mobilities are uniformly small, 10^{-3}–10^{-2} cm^2 V^{-1} s^{-1}. The purpose of the present work was to measure electron mobilities in liquids of intermediate polarity. Ethers were a suitable choice because they have moderately high gas phase dipole moments (10) and moderately low liquid phase dielectric constants (11).

The penetration ranges of secondary (~ 10 eV) electrons in ethers were studied for similar reasons. There is an empirical correlation between the mobilities of thermal electrons and the penetration ranges of secondary electrons in liquids (4, 5).

Experimental

Materials

Dimethyl ether (DME) was obtained from Matheson at a purity of 99.87%. Diethyl ether (DEE), dipropyl ether (DPE), dibutyl ether (DBE), tetrahydrofuran (THF), tetrahydropyran (THP), *p*-dioxan (PD), and *m*-dioxan (MD) were obtained from Aldrich Chemical at the highest available purity ($\geqslant$97%).

All the ethers except DME were stirred for several hours under vacuum with lithium aluminum hydride, then distilled onto sodium–potassium alloy and stirred overnight. MD reacted with the alloy, forming a white precipitate over a period of minutes. THF reacted similarly but over a period of many months, hence with a rate $\approx 10^{-5}$–10^{-6} that of MD.

DME has a low boiling point, 250 K, and was used directly from the cylinder.

Techniques

The methods of temperature control, dosimetry, charge clearing, and electron transient conductance measurements were described earlier (4, 12). However, DME, DEE, THF, and THP possessed large intrinsic specific conductivities, $>10^{-12}$ mho cm^{-1} at 300 K, that increased rapidly with temperature. For these compounds the conventional charge clearing measurements could not be made. Instead, the electron and ion conduction transient after a radiation pulse was treated as an a.c. signal, amplified, fed into a Fabritek model 1062 signal averager, and averaged over 512 pulses. Integration under the averaged transient signal gave the collected charge that resulted from an average radiation pulse. This method allowed radiolysis charge clearing measurements to be made in spite of intrinsic conductances up to 3×10^{-11} mho cm^{-1}.

The ion conductance transient obtained in the above manner displayed two portions with decay rates due to ions with different mobilities. At fields >10 kV/cm each decay portion was nearly linear with time (Fig. 1), which permitted the ionic mobilities u to be calculated from eq. 1.

$$[1] \qquad u = l^2/Vt_d$$

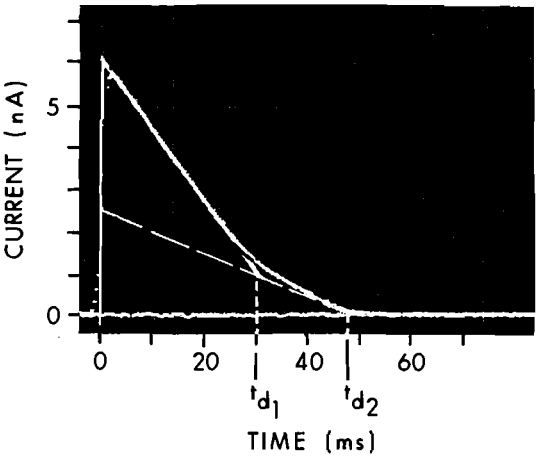

FIG. 1. Oscilloscope trace of ionic drift in di-*n*-propyl ether at 293 K. $l = 0.302$ cm and $V = 4.0$ kV. The triangles were drawn to have equal areas, corresponding to equal amounts of positive and negative charge. The lack of a sharp angle between the fast and slow decay portions is probably due to the presence of two or more slow ions with slightly different mobilities.

where l is the distance between the electrodes, V is the applied voltage, and t_d is the time required for the ion to drift the distance l.

The conductance cell (12) was coated on the outside surface with Aqua Dag (GC. Electronics TV Tube Coat) to minimize electrostatic effects caused by the flowing thermostating gas. Small ghost signals due to these electrostatic effects in uncoated cells were equivalent to an electron mobility $u_e \approx 0.001$ cm^2 V^{-1} s^{-1}, so they interfered with the electron conductance transient when u_e was <0.01 cm^2 V^{-1} s^{-1}. The ghost signals had a half life of 2 μs, so they did not interfere with the ion conductance transients, which had half lives $\sim 10^{-2}$ s.

Physical Properties of the Liquids

The densities d were obtained from the literature (13, 14). The dielectric constants ε were measured as functions of temperature with the aid of an Electro Scientific Industries model 273 capacitance bridge and a General Radio Co. model 1422-CD precision capacitor. The method of measurement and extensive data will be reported elsewhere (15). Values are listed in Table 1. They agree with data in ref. 11 within 1%, in the few cases where comparison is possible.

The intrinsic conductances of the ethers were not accurately recorded, but at 293 K they increase in the following order: PD (10^{-15} Ω^{-1} cm^{-1}) < DBE < DPE ≪ DEE (10^{-11} Ω^{-1} cm^{-1}) < DME ≈ THP < THF < MD ($\sim 10^{-10}$ Ω^{-1} cm^{-1}). The intrinsic conductance of MD was so great that the noise in it was as large as the radiation induced signal. MD also underwent radiation or electrolysis induced polymerization in the cell. The experiment with MD was abandoned.

Results

Free Ion Yields and Electron Ranges

The free ion yields increased with increasing applied electric field strength. Figure 2 shows the field effect for all the ethers that could be measured at 293 K. The curves drawn through the experimental data were calculated on the basis of a single ion pair per spur model (16–19). The probability $\phi(y, E)$ that a thermalized electron–ion pair of initial intrapair separation distance y will escape geminate neutralization in the presence of an applied electric field of strength E is given by eq. 2 (12).

$$[2] \qquad \phi(y, E) = e^{-r/y}\left\{1 + e^{-\beta y}\sum_{n=1}^{\infty}\frac{(\beta y)^n}{(n+1)!}\sum_{j=0}^{n-1}(n-j)\frac{(r/y)^{j+1}}{(j+1)!}\right\}$$

where $r = \xi^2/\varepsilon kT$, $\xi = 4.80 \times 10^{-10}$ e.s.u., ε is the dielectric constant of the fluid, k is Boltzmann's constant, T is the absolute temperature, and $\beta = (\xi E/300kT)$. The free ion yield G_{fi}^E in the presence of an applied field E is given by [3] (12).

$$[3] \qquad G_{fi}^E = G_{tot}\int_0^{\infty}\phi(y,E)F(y)\,dy$$

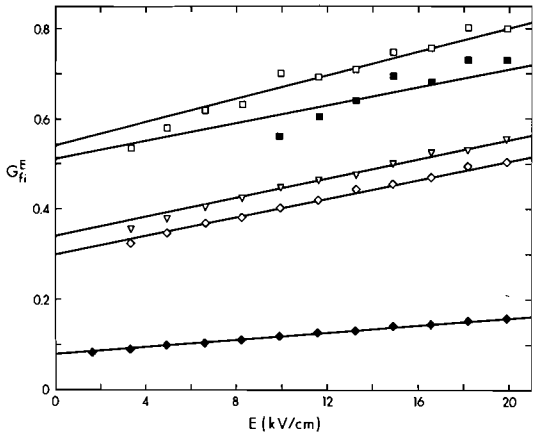

FIG. 2. Free ion yield $G_{fi}{}^E$ at field strength E in ethers at 293 K. □, diethyl ether (DEE); ■, tetrahydropyran (THP); ▽, di-*n*-propyl ether (DPE); ◇, di-*n*-butyl ether (DBE); ◆, *p*-dioxan (PD).

where G_{tot} is the total number of ion–electron pairs generated per 100 eV of energy absorbed by the fluid and $F(y)dy$ is the fraction of pairs with initial separation distances between y and $y + dy$. The distribution function used was YGP, which has a Gaussian body and a power function tail that extends the function to larger y values than would the Gaussian alone (12). The normalized equation for YGP is

$$[4]\quad \begin{cases} F(y) = 0.96\ \mathrm{YG} & y < 2.4b_{GP} \\ F(y) = 0.96\ (\mathrm{YG} + 0.5b_{GP}{}^2/y^3) & y > 2.4b_{GP} \end{cases}$$

with

$$\mathrm{YG} = (4y^2/\pi^{1/2}b_{GP}{}^3)\exp(-y^2/b_{GP}{}^2)$$

where 0.96 is a normalization factor and b_{GP} is the dispersion parameter of the Gaussian and is also the most probable value of the secondary electron range y.

Curves were fit to experimental data by selecting the value of b_{GP} that gave the minimum mean difference between the calculated and experimental free ion yields over the experimental range of field strengths used. The values of b_{GP} obtained for each ether at various temperatures are listed in Table 1. The free ion yields $G_{fi}{}^0$ extrapolated to zero applied field strength were calculated from b_{GP} and are included in Table 1.

The electron ranges in a given liquid are inversely proportional to the liquid density, so the density normalized ranges $b_{GP}d$ are also given in Table 1.

The relative variation of the free ion yield with temperature in ethers is smaller and slightly more complex than in hydrocarbons (4, 12, 20, 21). The difference is due to the relatively greater decrease of ε with increasing T in ethers than in hydrocarbons. The dielectric constant in eq. 2, and hence [3], appears only as a product with T, in r. In hydrocarbons the product εT increases with increasing T, whereas in ethers with relatively high dielectric constants, such as DME and DEE, εT decreases with increasing T. The result is that the relative variation of free ion yield with temperature is smaller in ethers than in hydrocarbons. The $G_{fi}{}^E$ *vs.* E curve for DEE at 195 K crosses the 293 and 328 K curves (Fig. 3); there is a minimum in $G_{fi}{}^E$ at about 250 K.

Ion Mobilities

The measured values of ion mobilities and their activation energies are listed in Table 2. The method does not allow one to distinguish between positively and negatively charged ions, so it is not known for certain that the faster moving ions were anions. Mobilities of cations and anions have been extensively studied in hydrocarbons (for a review see ref. 22). For these liquids the anion mobility was always greater than that of the cations. We assumed the same to be true in ethers. In diethyl ether vapor anion mobilities have been observed to be greater than those of the cations (22). However, the reverse was reported for liquid PD (23), so

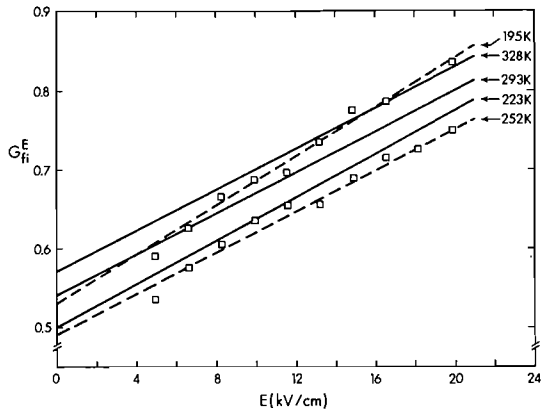

FIG. 3. Free ion yield plotted against field strength in diethyl ether at the temperatures indicated. The curves were calculated using the values of b_{GP} listed in Table 1. Experimental points are only displayed for 195 and 252 K, for clarity; the calculated curves for these two temperatures are dashed for the same reason.

*Reference 13. The values are listed as η^{-1} for direct comparison with the mobilities.

our assignments remain uncertain. The ratio $(u_{fast}/u_{slow}) = 1.7 \pm 0.3$ in all the ethers.

The sum of the separately determined u_+ and u_- values was checked by calculating $(u_+ + u_-)$ from the height of the ion conductance transient, in the manner used for measuring electron mobilities (5). The two methods agreed within 10%.

Electron Mobilities

Electron conductance transients were measured on a microsecond time scale, compared to the millisecond scale used for the ion transients. The shorter time scale used for electrons was due partly to their higher mobilities and partly to their removal by reaction with trace impurities in the ethers. Addition of 10^{-3}–10^{-2} M nitrous oxide to an ether eliminated the electron signal by reacting with the electrons in a time shorter than the response time of the equipment, which was 100 ns.

The electron conductance transient method of determining mobilities (4) yields the sum of the electron and positive ion mobilities $(u_e + u_+)$. The value of u_e was obtained by subtracting u_+ from the sum. The appropriate value of u_+ was obtained by interpolation or extrapolation of data in the previous section.

The electron mobilities are listed in Table 3.

Difficulty was experienced with THF and THP. The mobility measurement involves taking the ratio of the peak magnitude of the electron conductance transient (amps) to the integrated charge collected (coulombs) after a radiation pulse. However in THF and THP the electron conductance transients were small at low temperatures and the radiolytic-charge integration was poor at high temperatures (due to large intrinsic conductances). The mobilities were estimated by measuring the conductance magnitudes at high temperatures and calculating the free ion yields (proportional to the integrated charge collected) at those temperatures by assuming $b_{GP}d$ to be constant. The amount of error introduced by this technique would be $<10\%$ because $b_{GP}d$ was observed to be nearly independent of temperature in the other ethers (Table 1) and in hydrocarbons (1, 2, 12).

mobilities are given in Fig. 4. At low temperatures electron mobilities in some ethers are lower than ion mobilities in others, but at high temperatures the group of electron curves rises above the group of ion curves.

Discussion

Electron Ranges

The density normalized penetration ranges $b_{GP}d$ of the secondary electrons in ethers are smaller than those in the corresponding alkanes (12), compared by exchanging an —O— for a —CH_2—. However, the ether values approach those of the long chain *n*-alkanes (4.5×10^{-7} g/cm^2) as the length of the alkyl groups in the ether is increased. The chain length effect appears to be one of dilution.

The normalized ranges in ethers are larger than those in *trans*- but smaller than those in *cis*-olefins (12), compared by exchanging an —O— for a —CH=CH—.

By considering PD to be a dimer of DME, and

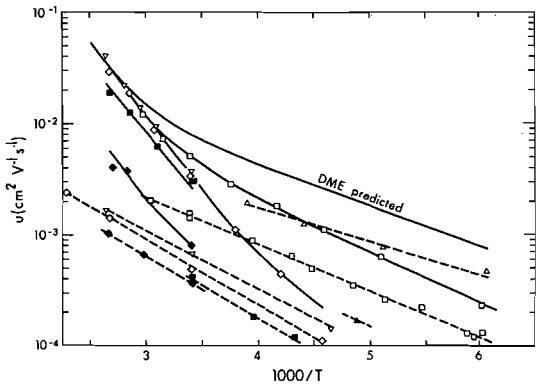

FIG. 4. Electron (—) and anion (---) mobilities in ethers. Open points, di-*n*-alkyl ethers: △, DME; □, DEE; ▽, DPE; ◇, DBE. Full points, cyclic ethers: ◆, PD; ■, THP; ▲, THF. The electron mobility curves were calculated from eqs. 12 and 13, using the parameter values in Table 5.

THF to be a closed ring form of DEE, one may detect small reductions in $b_{GP}d$ that correlate with large increases in molecular dipole moment (Table 4). It had been noted earlier (5) that small changes in molecular dipole moment had negligible effect on the ranges and mobilities of electrons in liquid hydrocarbons. The controlling factors are evidently short range interactions, but their nature is not yet clear. Transfer of electron kinetic energy to molecular vibrations and rotations through transient negative ion formation would be a tempting suggestion if it could accommodate the large difference in behavior of *cis*- and *trans*-butene-2. Of course, different mechanisms may dominate in different systems.

Ion Mobilities

In all of the di-*n*-alkyl ethers from DME to DBE the anion and cation mobilities are related to the liquid viscosity by approximately the same relations

$$[5] \qquad u_- = (2.6 \pm 0.5)10^{-4}\eta^{-1.2}$$

$$[6] \qquad u_+ = (1.5 \pm 0.3)10^{-4}\eta^{-1.2}$$

where u_+ and u_- are in $cm^2\ V^{-1}\ s^{-1}$ and η in cP. The anion mobilities fall in the lowest hatched region of Fig. 5.

The mobility–viscosity relationships are dependent on the type of structure of the solvent molecules. For example, the ions in the cyclic ethers PD and THF have higher mobilities than those in the *n*-alkyl ethers at the same viscosity. They are higher by a factor of about two. However, the viscosity exponent in relations analogous to [5] and [6] was in the range -1.1 to -1.3 in all of the ethers studied. This simply means that the ratio of activation energies of ion mobility and viscous flow has the value $E_\pm/E_\eta = 1.2 \pm 0.1$ in these liquids.

Stokes' law predicts $u \propto \eta^{-1.0}$. Although ion migration is strongly influenced by the solvent viscosity (the ease of solvent molecular translation), the relative difficulty of rotation of the solvent molecules must also be a factor in determining the rate of ion migration in a liquid. Most types of ions do not drag a complete solvation shell with them when they diffuse, but energy requirements would result in the solvation shell of an ion being moderately highly polarized even in the transition state of a diffusion step. Thus solvent molecular rotation should be important in ion diffusion. Rotational motions in polar liquids are usually studied as dielectric relaxation times. Unfortunately, the dielectric relaxation times τ are not known as a function of temperature for any of the present ethers except DEE (24), so an extended correlation with ion mobility cannot be made. However, the activation energy of dielectric relaxation in DEE is $E_\tau = 2.0$ kcal/mol, so $u_- \propto \tau^{-0.95}$ in this liquid.

Electron Mobilities in Ethers

At low temperatures u_e in a particular ether approaches a value of about $2u_-$ in that ether. This behavior is most clearly visible in the DEE results (Fig. 4), but is also observed in those from DBE and PD. At higher temperatures the ratio u_e/u_- increases with temperature, having the value 21 in DBE at 375 K (Fig. 4). Thus the

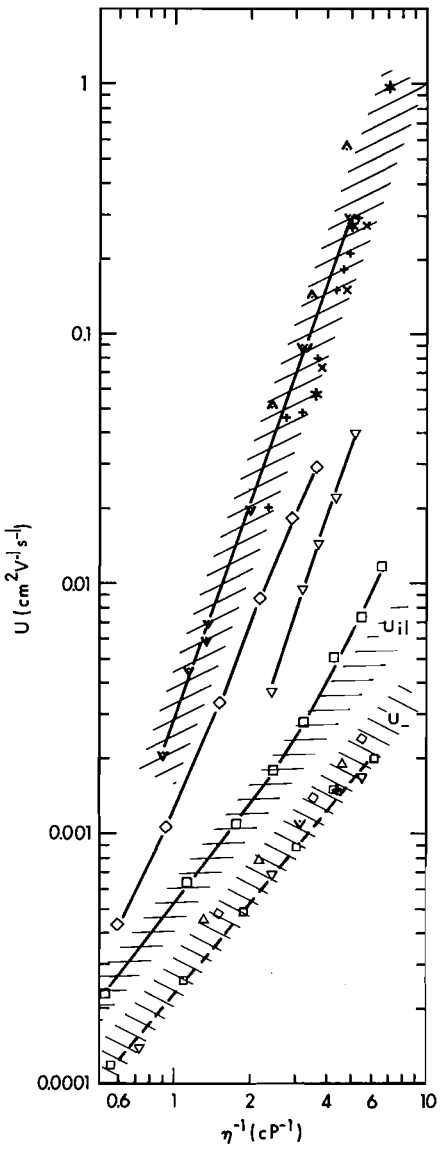

FIG. 5. Electron and anion mobilities in di-*n*-alkyl ethers and *n*-alkanes, plotted against the inverse of the liquid viscosity. The top hatched region refers to electrons in *n*-alkanes, with an inner line drawn through the hexane points for reference. The lowest hatched region refers to anions in the ethers and alkanes, with an inner line drawn through the DEE points for reference. The center hatched region is the expected range of ion-like mobilities for electrons in these liquids. The central lines represent electron mobilities in *n*-alkyl ethers. Solvent: △, DME; □, DEE; ▽, DPE; ◇, DBE; *, ethane; ∧, propane; ×, *n*-butane; +, *n*-pentane; ∨, *n*-hexane. The electron mobilities in hydrocarbons were taken from refs. 1–3 and 45; the ion mobilities in pentane and hexane are from ref. 46. The viscosities were obtained from ref. 13, by extrapolation where necessary.

For personal use only.

activation energy of electron migration in ethers at low temperatures is approximately equal to that of ion migration, 2–3 kcal/mol, while at high temperatures the activation energy of electron migration increases to ~6 kcal/mol, more than double the value for ions. The change of activation energy signifies a change in the mechanism of migration.

The mechanism of electron migration in low temperature ethers apparently resembles that of ion migration. This implies that the diffusive jump distances are short and that solvent rearrangement is involved. Ion mobilities in the present liquids display Arrhenius type temperature dependence (Fig. 4). Thus at low temperatures u_e may be represented by [7].

$$[7] \qquad u_e(\text{low } T) = u_{il}^0 \exp(-E_{il}/RT)$$

where u_{il}^0 and E_{il} are respectively the pre-exponential factor and activation energy for ion-like migration.

Electron migration at high temperatures can be described in terms of thermal excitation from the solvated state into a conduction band. By analogy with the conductance of an n-type semiconductor (25, 26), the average mobility at high temperature is the product of the mobility u_{cb} in the conduction band and the fraction of the electrons that are in the band.

$$[8] \qquad u_e(\text{high } T) = u_{cb} \exp(-E_{cb}/RT)$$

where E_{cb} is the thermal energy barrier between the solvated electron and the conduction band.

The value of u_{cb} is usually considered to have a negative power dependence on temperature (25, 26). For the sake of discussion it will be assumed that u_{cb} in liquid ethers has the $T^{-3/2}$ dependence characteristic of electron scattering by phonons (26).

$$[9] \qquad u_{cb} = u_{cb}^0 T^{-3/2}$$

Solvated electrons do not all reside in traps of the same depth, so eq. 8 must be integrated over the distribution of E_{cb} values. This distribution is not yet known, but some information can be obtained about it by fitting calculated mobilities to the observed mobility *vs.* temperature results. It is particularly interesting to estimate E_{cb} relative to the optical excitation energies that are displayed in the optical absorption spectrum (27, 28). The thermal energies may be lower than the optical energies for a number of reasons (25, 26).

Equation 8 may be written

$$[10] \qquad u_e(\text{high } T) = u_{cb}\chi$$

where

$$[11] \qquad \chi = \frac{\int_0^\infty \exp(-E/RT)N(E)\,dE}{\int_0^\infty N(E)\,dE}$$

and $N(E)dE$ is the relative number of solvated electrons with E_{cb} values between E and $E + dE$.

The mobility at any temperature is

$$[12] \qquad u_e = (1 - \chi)u_{il}^0 \exp(-E_{il}/RT) + \chi u_{cb}$$

The calculations with [12] were systematized through the mobilities in DEE, which were measured over the greatest temperature range (Fig. 4). The mobilities at low temperatures show that $u_{il}^0 = 0.13\ \text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$ and $E_{il} = 2.1$ kcal/mol (0.09 eV/electron) in this liquid. The mobilities at high temperatures give information about $N(E)$ and u_{cb}^0. In preliminary calculations $N(E)$ was approximated by the optical absorption spectrum reported by Jou and Dorfman (27) for electrons in DEE at room temperature (~297 K). The spectrum has an absorption maximum at the energy $E_{am} = 0.54$ eV. It has an approximately Gaussian shape on the low energy side with a dispersion parameter $\sigma = 0.18$ eV, and an approximately Lorentzian (Cauchy) shape on the high energy side with a dispersion parameter $L = 0.30$ eV. The temperature coefficient of the absorption maximum is $dE_{am}/dT \approx -0.0017$ eV/deg, while σ and L are nearly independent of temperature (28). With these parameter values the calculated temperature coefficient of the mobilities was too large, which means that the optical absorption energies are larger than E_{cb}.

In the next series of calculations the activation energy E was reduced by arbitrarily dividing it by $n > 1$, so the Boltzmann exponent in [11] became $(-E/nRT)$. It was demonstrated that this was also equivalent to leaving the Boltzmann exponent as $(-E/RT)$ and reducing the E values in $N(E)$ by dividing E_{am}, σ, and L each by n. Values of n ranging from 1.1 to 5.0 were tried, and $n = 2.0^{+0.5}_{-0.3}$ gave the best agreement with experiment. The best value of u_{cb}^0 was 23 000 $\text{cm}^2\ \text{deg}^{3/2}\ \text{V}^{-1}\ \text{s}^{-1}$, corresponding to $u_{cb} = 4.6\ \text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$ at 294 K. Thus the thermal activation energy for electron mobility in high temperature ethers is equal to one-half of the optical excitation energy.

The value $n = 2$ might be a coincidence, but

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

several mechanisms of thermally activated electron migration in semiconductors lead to an exponential factor $\exp(-E/2RT)$ (26). It is not clear which, if any, of the specific mechanisms might apply to electrons in ethers, but it is tempting to speculate that the great breadth of the optical absorption spectra of solvated electrons is due to a large variation in trap depths, and that most of the observed spectrum in an ether is due to bound–continuum transitions. The possible subdivision of the optical spectra of solvated electrons into bound–bound and bound–continuum transitions has received attention recently (29–32).

The shape of $N(E)$ for thermal excitation might be expected to be different from that of the optical absorption spectrum, but a random set of trap depths could give a Gaussian shape to the low energy side of both. One might also expect the high energy side of both to be more extended than a Gaussian. However, to simplify the calculations for the series of ethers, $N(E)$ was taken to be entirely Gaussian. To facilitate comparison with optical absorption energies the factor $n = 2$ was left in the Boltzmann exponent, although it might actually belong in $N(E)$ as $(E_{am}/2)$ and $(\sigma/2)$. Hence, χ was taken as [13].

$$[13]\quad \chi = \frac{\int_0^\infty \exp\left\{-\frac{E}{2RT} - \left(\frac{E-E_{am}}{\sigma}\right)^2\right\} dE}{\int_0^\infty \exp\left\{-\left(\frac{E-E_{am}}{\sigma}\right)^2\right\} dE}$$

The optical values of E_{am} and σ again gave agreement with the experimental mobilities in DEE, but the required value of u_{cb}^0 was reduced to 13 000 $cm^2\ deg^{3/2}\ V^{-1}\ s^{-1}$. The only effect of decreasing the high energy side of $N(E)$ from a Lorentzian with $L = 0.30$ eV to a Gaussian with $\sigma = 0.18$ eV was to reduce the estimated value of u_{cb}^0 by a factor of 1.8. The high energy side of $N(E)$ contributes negligibly to the *number* of electrons in the conduction band, so reducing the hypothetical population on the high energy side merely increases the apparent *fraction* of electrons on the low energy side and correspondingly decreases the estimated value of u_{cb} (see eqs. 10 and 11). The values of u_{cb} obtained by using [13] are lower limits.

The calculated mobilities are shown in Fig. 4.

The entire set of calculations was repeated with the DBE mobilities and similar conclusions were reached. In both DEE and DBE it appears that $u_{il}^0 \approx 0.13\ cm^2\ V^{-1}\ s^{-1}$ and $E_{il} \approx 1.1\ E_\pm$. The parameters are listed in Table 5 and the calculated curve is shown in Fig. 4.

TABLE 5. Parameters for the calculation of u_e by eq. 12*

Liquid	E_{il} (eV)	u_{cb}^0 ($cm^2\ deg^{3/2}\ V^{-1}\ s^{-1}$)	E_{am}(293 K) (eV)
DME	0.07†	13 000†	0.56†
DEE	0.09	13 000	0.54‡
DPE	0.10	14 000	0.52†
DBE	0.124	12 000	0.50
THF	0.105	13 000	0.59‡
THP	0.12	13 000†	0.53
PD	0.14	13 000†	0.74

*Equation 13 was used for χ. The values $u_{il}^0 = 0.13\ cm^2\ V^{-1}s^{-1}$, $(dE_{am}/dT) = -0.0017$ eV/deg, and $\sigma = 0.33E_{am}$ (293 K) independent of temperature, were assumed for all ethers.
†Assumed.
‡Reference 27.

The calculations using [12] and [13] were then extended to all the ethers. The estimated parameter values are listed in Table 5 and the calculated curves are displayed in Fig. 4. In all cases $u_{il}^0 = 0.13\ cm^2\ V^{-1}\ s^{-1}$ and $E_{il} = (1.1 \pm 0.1)E_\pm$ were consistent with the data. The conduction band mobilities appear to be similar in all the ethers. The value $u_{cb}^0 = 13\,000\ cm^2\ deg^{3/2}\ V^{-1}\ s^{-1}$ corresponds to $u_{cb} = 2.6\ cm^2\ V^{-1}\ s^{-1}$ at 294 K. Not much weight should be given to the absolute value assigned here to u_{cb}^0 because it is highly sensitive to the assumed shape of $N(E)$ and to the temperature coefficient of E_{am}. For example, decreasing (dE_{am}/dT) to -0.0010 eV/deg would increase u_{cb} to 152 $cm^2\ V^{-1}\ s^{-1}$ at 294 K.

The only unusual result in the series is the high value of E_{am} in PD. If the apparent correlation between $N(E)$ and the optical absorption spectrum is real, solvated electrons in PD at 294 K should have an absorption maximum at $E_{am} = 0.74$ eV ($\lambda_{max} = 1.7\ \mu$). This might seem surprising in view of the relatively low dielectric constant of the liquid (Table 1), but is consistent with the observation that E_{am} is greater in polyethers than in monoethers (27). Measurement of the optical spectrum in PD will provide a test of the correlation with $N(E)$.

Experimental difficulties prevented the measurement of u_e in DME, but parameter values were estimated by comparison with those for the other alkyl ethers. The predicted mobilities in DME are shown in Fig. 4.

E_{il} is greater than E_η in all the ethers. In DEE, the only ether for which the activation energy of dielectric relaxation is known (24), $E_{il} = 1.1\ E_\tau$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

This is consistent with the suggestion that solvent molecular rotation makes a major contribution to the ion-like migration mechanism of electrons. Rotational and translational motions of the nonspherical solvent molecules are not independent of each other. The ion-like mechanism of electron migration appears to be governed by migration of the potential well through rotational–translational motions of the dipoles that constitute the well and the medium immediately surrounding it.

The ion-like migration in liquid ethers behaves like the hopping mechanism discussed for amorphous semiconductors (26, 33). A relatively short hopping distance is envisaged in both cases. Whether or not a completely new site is involved in each hop in the liquid depends on whether the hopping distance is greater or less than a molecular diameter.

Electron Mobilities in Other Liquids

Equation 10 was used to estimate the contribution of conduction bands to electron migration in water, alcohols, and ammonia at $\sim$296 K. Values of σ were obtained from known spectra (34–38), and $u_{cb}{}^0$ was taken as $\lesssim 10^5$ cm^2 deg$^{3/2}$ V^{-1} s^{-1}. The contribution of conduction bands in all these liquids was estimated to be negligible at room temperature and below. Electron migration is therefore ion-like, with $u_e/u_- = 2 \pm 1$ in water (6, 39) and alcohols (7, 40). Consistent with this conclusion, the activation energies of viscous flow (13), dielectric relaxation (24), and electron mobility (7, 39) are similar to each other in water or in a given alcohol (41). However, $u_e/u_{Cl^-} = 5$ in ammonia at 240 K (9, 42), so electron migration in this liquid might involve other processes than the simple rotational–translational motions of the solvent molecules. Molecular inversion might make a contribution to electron trap migration. Ammonia molecules invert through a planar ground state with an activation energy of 5.8 kcal/mol (43). It would be informative to measure the temperature dependences of electron migration, viscous flow, and dielectric relaxation in ammonia in the vicinity of 240 K.[3]

[3]NOTE ADDED IN PROOF: The activation energy of electron mobility of dilute solutions of sodium in liquid ammonia near 240 K is $E_u \approx 2.2 \pm 0.5$ kcal/mol, estimated from the data of Kraus (48) and Kraus and Lucasse (49). The activation energy of viscous flow of ammonia near 240 K is $E_\eta = 1.4$ kcal/mol, calculated from data in ref. 50. We now need to know E_τ and a more accurate value of E_u.

By contrast, electron migration in saturated hydrocarbons occurs almost exclusively by the conduction band mechanism. The optical absorption spectra of electrons in saturated hydrocarbons lie at lower energies than those of electrons in ethers (44), and u_e is expected to increase approximately exponentially with decreasing E_{am}. Unfortunately there is not sufficient information about the optical spectra in liquid alkanes to allow quantitative calculations to be done.

To demonstrate that electrons do not migrate to an appreciable extent by the ion-like mechanism in alkanes, the mobilities in five *n*-alkanes (1–3, 45 (*n*-pentane values)) were plotted against the inverse of the liquid viscosity (Fig. 5). The *n*-alkanes were chosen because electron mobilities are lower in these than in branched or cycloalkanes at the same viscosity. Thus the contribution of the ion-like mechanism to electron migration in the *n*-alkanes is greater than that in the other alkanes. The electron mobilities fall in the uppermost hatched region of Fig. 5, while the anion mobilities (46) fall in the lowest hatched region with the anions in *n*-alkyl ethers. The center hatched region represents the expected range of ion-like mobilities for electrons in these liquids, with $u_{il} \approx (2\text{–}3)u_-$. The electron mobilities in alkanes lie well above the ion-like region. Mobilities in ethers are intermediate. Furthermore, the steep slopes of the alkane plots indicate that the activation energy of electron mobility in *n*-alkanes (4 $\pm$ 1 kcal/mol (1–3)) is about 3-fold that of viscous flow. If the correlation between $N(E)$ and the optical spectrum is real, the activation energy is consistent with an optical absorption band centering at $\sim$0.4 eV ($\lambda_{max} \approx 3$ μ) for electrons in *n*-hexane at 300 K.

Furthermore, the mobility $u_e = 10$ cm^2 V^{-1} s^{-1} at 296 K in neohexane, with an activation energy of 1.4 kcal/mol (2), is consistent with an optical absorption band centering at $\sim$0.1 eV ($\lambda_{max} \approx 12$ μ) in that liquid.

The high mobility and low activation energy in neopentane (47) are consistent with electrons being scattered by potential wells of depth $\sim kT$ ($\lambda_{max} \approx 40$ μ) in that liquid.

The values of u_{cb} are not necessarily the same from one type of liquid to another.

Temperature Dependence of Electron Mobility in Liquids

The Arrhenius temperature coefficient E_a of electron mobility passes through a maximum as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

one passes from low to high mobilities. The location and magnitude of the maximum depend on the particular values of u_{i1}^0, E_{i1}, and u_{cb}. To illustrate the effect eq. 14 was taken as an approximation of [12].

$$[14] \quad u_e = 0.1 \exp(-2000/RT) + 100 \exp(-E_{cb}/RT)$$

where u_{i1}^0 and u_{cb} are 0.1 and 100 $cm^2\ V^{-1}\ s^{-1}$, respectively, $E_{i1} = 2000$ cal/mol, and a single "effective" value of E_{cb} was used for a given liquid. Values of u_e were calculated from [14] for a series of values of E_{cb}, at $T = 280$, 300, and 320 K. The values at 280 and 320 K were used to calculate an Arrhenius temperature coefficient E_a from [15].

$$[15] \quad u_e = A_a e^{-E_a/RT}$$

E_a was then plotted against the calculated value of u_e for 300 K (Fig. 6).

With the above choice of parameters E_a has a maximum of 4.6 kcal/mol at $u_e = 0.02\ cm^2\ V^{-1}\ s^{-1}$, with $E_{cb} \approx 5.5$ kcal/mol. For $u_e \geqslant 0.1\ cm^2\ V^{-1}\ s^{-1}$, $E_a = E_{cb}$; values of E_{cb} are marked at several places along the curve in Fig. 6. For $u_e < 0.02\ cm^2\ V^{-1}\ s^{-1}$ E_a decreases with decreasing mobility, reaching $E_a = E_{i1}$ when $E_{cb} = \infty$. However, the parameter values used in this illustration place E_a within experimental error of E_{i1} when $E_{cb} > 8$ kcal/mol (>0.3 eV/electron).

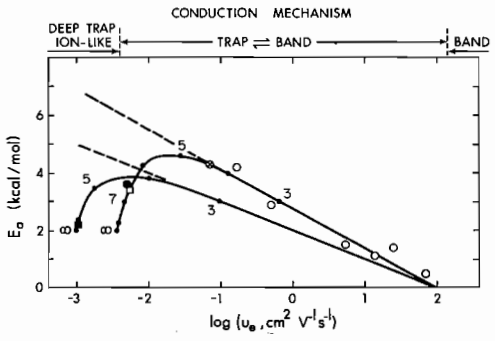

FIG. 6. Variation of the Arrhenius temperature coefficient E_a with electron mobility. The solid curves were calculated from eqs. 14 and 15: upper curve, $T = 300$ K; lower curve, $T = 215$ K. The small dots on the curves represent the points calculated using $E_{cb} = 3$, 4, 5, 6, 7, 8, and ∞ kcal/mol; alternate points are labelled with the value of E_{cb}. The experimental points at 300 K represent: ○, saturated hydrocarbons from refs. 3, 4, and 45; ⊗, n-C_6H_{14} from ref. 47; □, DEE. At 215 K: ●, estimated for n-C_6H_{14} from data in ref. 47: ■, DEE. The dashed lines are extrapolations of $u_e = 100 \exp(-E_{cb}/RT)$.

Experimental values of u_e and E_a at 300 K in a number of hydrocarbons (3, 4, 45, 47) and in DEE (in which u_{i1} agrees approximately with that of eq. 14) are included in Fig. 6. The results are consistent with the model. The scatter of the points about the line represent mainly variations in u_{cb} and experimental error.

The calculations with [14] and [15] were repeated for $T = 200$, 215, and 230 K. The curve for 215 K lies below and to the left of the 300 K curve in Fig. 6. The behavior is consistent with the experimental data available for 215 K.

We are grateful to the staff of the Radiation Research Center for help with the electronics.

Bond Scission in Sulfur Compounds. Part X.[1] The Hydrazinolysis of Methyl *p*-Nitrophenyl Sulfate

ERWIN BUNCEL AND CLAUDIO CHUAQUI

Department of Chemistry, Queen's University, Kingston, Ontario K7L 3N6

Received October 15, 1974

ERWIN BUNCEL and CLAUDIO CHUAQUI. Can. J. Chem. **53**, 1275 (1975).

Reaction of methyl *p*-nitrophenyl sulfate with the hydrazine – hydrazine hydrochloride system in methanol gives rise to different types of behavior depending on the state of ionization of the reagent. For the $H_2NNH_2/H_2NNH_3^+$ combination the observed reaction is conversion of methyl *p*-nitrophenyl sulfate to *p*-nitrophenyl sulfate ion (alkyl–oxygen scission). For the $H_2NNH_3^+/{}^+H_3NNH_3^+$ combination, or with ${}^+H_3NNH_3^+$ alone, one observes the consecutive processes methyl *p*-nitrophenyl sulfate → *p*-nitrophenyl sulfate ion → *p*-nitrophenol (alkyl–oxygen followed by sulfur–oxygen scission). For the alkyl–oxygen scission process, *i.e.* nucleophilic displacement on the alkyl carbon, the observed pseudo first-order rate constant is given by the contributions of several nucleophilic species; $k_{obs} = k_{sol} + k_{Cl^-}[Cl^-] + k_{H_2NNH_3^+}[H_2NNH_3^+] + k_{H_2NNH_2}[H_2NNH_2]$. A method for the dissection of k_{obs} into the constituent terms is given. The sulfur–oxygen scission process is an acid catalyzed reaction and the measured kinetic data have been utilized for the derivation of the pK_a of ${}^+H_3NNH_3^+$ in methanol. Rate data for the conversion of sodium *p*-nitrophenyl sulfate to *p*-nitrophenol in methanol containing HCl have also been determined in this connection.

ERWIN BUNCEL et CLAUDIO CHUAQUI. Can. J. Chem. **53**, 1275 (1975).

La réaction du *p*-nitrophényl sulfate de méthyle avec le système hydrazine – chlorhydrate d'hydrazine dans le méthanol donne lieu à différents types de réaction dépendant de l'état d'ionisation du réactif. Pour la combinaison $H_2NNH_2/H_2NNH_3^+$, la réaction observée est la transformation du *p*-nitrophényl sulfate de méthyle en ion *p*-nitrophényl sulfate (scission alkyle–oxygène). Pour la combinaison $H_2NNH_3^+/{}^+H_3NNH_3^+$ ou avec ${}^+H_3NNH_3^+$ seul, on observe des réactions consécutives allant du *p*-nitrophényl sulfate de méthyle → l'ion *p*-nitrophényl sulfate → *p*-nitrophénol (scission alkyle–oxygène suivie par une scission soufre–oxygène). Pour le processus de scission alkyle–oxygène, *i.e.* le déplacement nucléophile sur le carbone de la chaîne alkyle, la constante de vitesse du pseudo premier ordre qui est observée est obtenue à partir des contributions de plusieurs espèces nucléophiles; $k_{obs} = k_{sol} + k_{Cl^-}[Cl^-] + k_{H_2NNH_3^+}[H_2NNH_3^+] + k_{H_2NNH_2}[H_2NNH_2]$. On donne une méthode pour la dissection du k_{obs} en ses termes constituants. Le processus de scission soufre–oxygène est une réaction acido catalysée et on a pu utiliser les valeurs cinétiques mesurées pour déterminer les valeurs de pK_a du ${}^+H_3NNH_3^+$ dans le méthanol. A cet effet on a aussi déterminé la vitesse de transformation (dans du méthanol contenant du HCl) du *p*-nitrophényl sulfate de sodium en *p*-nitrophénol.

[Traduit par le journal]

Methyl *p*-nitrophenyl sulfate is the first member of the family of mixed alkyl aryl sulfates to be subjected to intensive investigation. This particular substrate offers several possible electrophilic centers in its reactions with nucleophiles: the alkyl carbon, the sulfonyl sulfur, and the aryl carbon. So far we have reported on the neutral and alkaline methanolysis reactions (2) as well as the reaction with some anionic nucleophiles (1). We have now investigated the reaction with the hydrazine – hydrazine hydrochloride system and present here the results of the study, concentrating on the nature of the bond scission processes occurring as well as the reactivity of the various species in this system. Some related compounds which have been examined from a similar point of view are the monoalkyl and aryl sulfates (3–7), the sulfites (8, 9), and the halo sulfates (10–12).

Reactions with the $H_2NNH_2/H_2NNH_3^+$ System

Reactions performed in media containing the H_2NNH_2 and $H_2NNH_3^+$ species have been observed to follow the spectral behavior characteristic of the conversion of methyl *p*-nitrophenyl sulfate to *p*-nitrophenyl sulfate ion. Thus there is a decrease in the absorption maximum at 260 nm due to the reactant, an increase at 283 nm due to product, and a sharp isobestic point occurs at 272 nm. Figure 1 illustrates the spec-

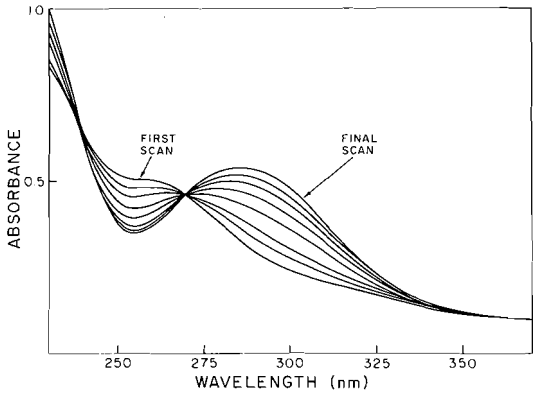

FIG. 1. Spectral scans in typical kinetic run for the conversion of methyl *p*-nitrophenyl sulfate (5.00×10^{-5} *M*) to *p*-nitrophenyl sulfate ion in the reaction with the H_2NNH_2 (7.48×10^{-5} *M*) – $H_2NNH_3^+$ (238.4×10^{-5} *M*) system in methanol at 25°.

tral changes obtained during a typical kinetic run. Plots of log $(A_\infty - A_t)$ *vs.* *t* for data at 283 nm are linear and the slope yields the pseudo first-order rate constant, k_{obs}. The reaction occurring is a nucleophilic displacement on the alkyl carbon center:

[1] $O_2N-C_6H_4-O-\underset{\underset{O}{\|}}{\overset{\overset{O}{\|}}{S}}-O-CH_3 + :Nu \longrightarrow$

$O_2N-C_6H_4-O-\underset{\underset{O}{\|}}{\overset{\overset{O}{\|}}{S}}-O^- + {}^+Nu-CH_3$

The neutral hydrazine species, H_2NNH_2, and the monoprotonated hydrazinium ion, $H_2NNH_3^+$, are both expected to be active nucleophiles towards methyl *p*-nitrophenyl sulfate. In addition, chloride ion, present as the counter ion to $H_2NNH_3^+$, is known to be reactive (1), while methanol should also partake in a neutral solvolytic reaction (2). Thus the overall pseudo first-order rate constant will be the sum of the contributions due to the various constituents, *i.e.*,

$$[2]\quad k_{obs} = k_{sol} + k_{Cl^-}[Cl^-] + k_{H_2NNH_3^+}[H_2NNH_3^+] + k_{H_2NNH_2}[H_2NNH_2]$$

The procedure used for dissection of k_{obs} into the contributing terms is given below.

In Table 1 are given the k_{obs} data obtained for various values of $[H_2NNH_2]$ and $[H_2NNH_3^+]$, while keeping the sum of the concentrations of these species constant (246×10^{-5} *M*). The k_{obs} values when plotted against $[H_2NNH_2]$ yield a linear graph as shown in Fig. 2 (line *1*) with slope 0.394 M^{-1} s^{-1} and intercept on *y* axis 6.34×10^{-4} s^{-1}. One can readily take care of the contribution due to chloride ion since $[Cl^-]$ is known and is in fact constant throughout the series of runs. (This follows from the manner of preparation of the reaction solutions in these runs, namely that a constant quantity of the dihydrochloride salt, $H_2NNH_2 \cdot 2HCl$, was used and variable quantities of CH_3ONa were added in order to generate the H_2NNH_2 and $H_2NNH_3^+$ species, see also Experimental.) Since $k_{Cl^-} = 0.011$ M^{-1} s^{-1} (1) and $[Cl^-] = 4.92 \times 10^{-3}$ *M*, one obtains $k_{Cl^-}[Cl^-] = 0.54 \times 10^{-4}$ s^{-1}, which can then be subtracted from the k_{obs} values throughout the series of runs. The derived values of $k_{obs} - k_{Cl^-}[Cl^-]$ are given in Table 1. The line obtained in plotting $k_{obs} - k_{Cl^-}[Cl^-]$ *vs.* $[H_2NNH_2]$ is of course parallel to the k_{obs} *vs.* $[H_2NNH_2]$ line, *i.e.*, slope 0.394 M^{-1} s^{-1}, intercept on the *y* axis 5.81×10^{-4} s^{-1} (Fig. 2, line *2*). Now this intercept is simply the sum of the terms $k_{sol} + k_{H_2NNH_3^+}[H_2NNH_3^+]$ and since k_{sol} is known (5.28×10^{-4} s^{-1}) from independent measurements in MeOH/$HClO_4$ solutions (1), one obtains $k_{H_2NNH_3^+}[H_2NNH_3^+]$ as equal to $(5.81 - 5.28) \times 10^{-4}$ s^{-1} or 0.53×10^{-4} s^{-1}. Hence the catalytic coefficient $k_{H_2NNH_3^+}$ is given by $k_{H_2NNH_3^+} = 0.53$

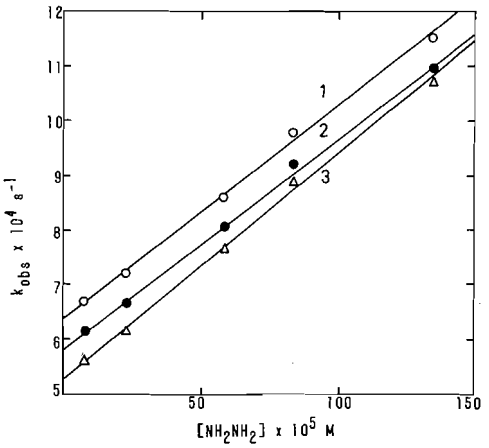

FIG. 2. Plot of rates *vs.* $[H_2NNH_2]$ for reaction of methyl *p*-nitrophenyl sulfate with the H_2NNH_2 – $H_2NNH_3^+$ system in methanol at 25°. Line *1*, k_{obs}; line *2*. $k_{obs} - k_{Cl^-}[Cl^-]$; line *3*. $k_{obs} - k_{Cl^-}[Cl^-] - k_{H_2NNH_3^+}[H_2NNH_3^+]$.

TABLE 1. Kinetic data for the reaction of methyl *p*-nitrophenyl sulfate with the $H_2NNH_2/H_2NNH_3^+$ system in methanol at 25°

$[H_2NNH_2]$ $\times 10^5$ *M*	$[H_2NNH_3^+]$ $\times 10^5$ *M*	k_{obs} $\times 10^4$ s^{-1}	$k_{obs} - k_{Cl^-}[Cl^-]$ $\times 10^4$ s^{-1}	$k_{H_2NNH_3^+}[H_2NNH_3^+]$ $\times 10^4$ s^{-1}	$k_{obs} - k_{Cl^-}[Cl^-] - k_{H_2NNH_3^+}[H_2NNH_3^+]$ $\times 10^4$ s^{-1}	k_{calcd} $\times 10^4$ s^{-1}
7.48	238.4	6.68	6.15	0.52	5.51	6.65
22.82	223.1	7.17	6.64	0.49	6.04	7.25
58.16	187.8	8.60	8.07	0.41	7.56	8.63
83.50	162.4	9.79	9.26	0.36	8.82	9.62
134.17	111.7	11.52	10.99	0.25	10.69	11.59

$\times 10^{-4}/2.46 \times 10^{-3}$ M^{-1} $s^{-1} = 0.022$ M^{-1} s^{-1}, since $[H_2NNH_3^+] = 2.46 \times 10^{-3}$ *M* when $[H_2NNH_2] = 0$ (see Experimental).

The catalytic coefficient due to the neutral hydrazine species can now be obtained readily. For each value of $[H_2NNH_3^+]$ in Table 1 one can calculate the term $k_{H_2NNH_3^+}[H_2NNH_3^+]$ and on subtraction from $k_{obs} - k_{Cl^-}[Cl^-]$ one obtains the data in the last but one column in Table 1. These data when plotted against $[H_2NNH_2]$ yield line *3* of Fig. 2. The slope of this line is now $k_{H_2NNH_2} = 0.412$ M^{-1} s^{-1}.

A check on the above method of calculating rate coefficients may be obtained by reversing the procedure and calculating the sum of the contributions due to the various nucleophilic species in eq. 2, using the values for the catalytic coefficients derived above. The results of this procedure are given in the last column of Table 1 under k_{calcd}. The agreement with the experimental values of k_{obs} is seen to be satisfactory. In addition, it can readily be shown that the difference in the slopes of lines *2* and *3* in Fig. 2 should be simply the catalytic coefficient due to $H_2NNH_3^+$. By this method, $k_{H_2NNH_3^+} = 0.024$ M^{-1} s^{-1}, which compares favorably with the value obtained by the previously outlined procedure.

Reactions with the $H_2NNH_3^+/{}^+H_3NNH_3^+$ System

Reactions performed in media containing the $H_2NNH_3^+$ and $^+H_3NNH_3^+$ species in combination, or the $^+H_3NNH_3^+$ species alone, showed spectral characteristics which were quite different in nature from those in the $H_2NNH_2/H_2NNH_3^+$ system considered above. The spectral changes observed during the course of a kinetic run are illustrated in Fig. 3 and are typical of an A → B → C process (13). In the early stages, before a significant amount of C has formed, the isosbestic point of 272 nm is somewhat poorly defined. Similarly, in the later stages of the run, when the concentration of A is insignificant, a second diffuse isosbestic point at 292 nm is indicative of the B → C process. When all three species are present in significant concentration then isosbestic behavior is lost altogether.

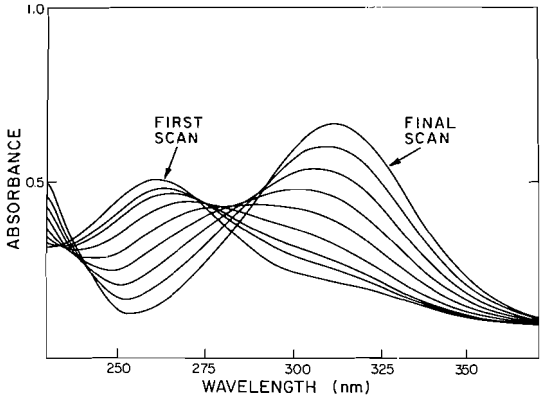

FIG. 3. Spectral scans illustrating the consecutive processes in reaction of methyl *p*-nitrophenyl sulfate (5.00×10^{-5} *M*) with the $H_2NNH_3^+$ (12.9×10^{-5} *M*) − $^+H_3NNH_3^+$ (11.7×10^{-5} *M*) system in methanol at 25°.

For these kinetic runs one can calculate the rate constants, k^A_{obs} and k^B_{obs} respectively, for the A → B and B → C steps by the method described previously (2). One obtains k^A_{obs} by plotting log $(A_\infty - A_t)$ *vs.* *t* for data at 292 nm, which corresponds to the isosbestic wavelength for the B → C conversion. Similarly, one obtains k^B_{obs} by plotting log $(A_t - A_\infty)$ *vs.* *t* at 272 nm, corresponding to the isosbestic wavelength for the A → B conversion (see also footnote 21 in ref. 2). The second plot is linear only in the latter stages of the reaction, when there is no longer a significant concentration of A remaining. The k_{obs} data are given in Table 2. Discussion of these results is deferred so as to allow

prior consideration of the nature of the chemical processes and pertaining matters.

The A → B stage is the nucleophile induced conversion of methyl *p*-nitrophenyl sulfate to *p*-nitrophenyl sulfate ion (*cf.* eq. 1). The B → C stage, namely the conversion of *p*-nitrophenyl sulfate to *p*-nitrophenol, is an acid-catalyzed process (5, 14) as given by eqs. 3 and 4. The SO_3

[3] 
[4] 
formed in eq. 4 will be converted to methyl hydrogen sulfate and, as this should be a strong acid, in the overall reaction of *p*-nitrophenyl sulfate to *p*-nitrophenol no acid is consumed. The A → B → C reaction sequence was also observed in the methanolysis of methyl *p*-nitrophenyl sulfate (2).

As has been noted, the B → C stage is an acid-catalyzed process according to eqs. 3 and 4. In eq. 3, the hydrogen ion (solvated) is derived in part from the neutral solvolytic reaction (eq. 1, Nu = CH_3OH) which generates 1 mol of acid. The second source of hydrogen ion in the present system derives from ionization of $^+H_3NNH_3^+$. Since the magnitude of k^B_{obs} reflects the $[H^+]$ present in the system, one should be able to apply these data towards an indirect determination of the pK_a of $^+H_3NNH_3^+$. There are no literature data for this pK_a pertaining to methanol, though the pK_a in water is known (−0.67) (15). The method used is described below, as it may have more general application.

As a first requirement, the rate of the acid catalyzed conversion of *p*-nitrophenyl sulfate (sodium salt) to *p*-nitrophenol was measured in media of known acidity. Rate data were obtained over a range of [HCl] in methanol and the results are given in Table 3. A plot of k_{obs} *vs.* [HCl] is linear and the slope yields the second-order rate coefficient $k_{HCl} = 1.72\ M^{-1}\ s^{-1}$. If one takes into account the incomplete dissociation of HCl in methanol, via the pK_a value of 1.23 (16), then the corrected value k_{H^+} is given by $1.86\ M^{-1}\ s^{-1}$.

One can now proceed to evaluate the pK_a of $^+H_3NNH_3^+$ in methanol. In the reaction of methyl *p*-nitrophenyl sulfate with $^+H_3NNH_3^+$, using initial reagent concentrations of 24.59×10^{-5} and 49.18×10^{-5} *M* ($[^+H_3NNH_3^+]_0$ in Table 2), one obtains for the B → C process k^B_{obs} values of 2.88×10^{-4} and 4.61×10^{-4} s^{-1}, respectively. Corresponding to these rates one calculates $[H^+]_{total}$ values of 15.52×10^{-5} and 24.85×10^{-5} *M*, respectively, using $k_{H^+} = 1.86\ M^{-1}\ s^{-1}$ as obtained independently (data on HCl-catalyzed reaction of *p*-nitrophenyl sul-

fate). To calculate the pK_a one must consider the hydrogen ion concentration derived from *p*-nitrophenyl hydrogen sulfate formed in the A → B stage.[2] Assuming complete dissociation of $O_2NC_6H_4OSO_3H$, the calculated pK_a values for $^+H_3NNH_3^+$ in the case of the above two sets of data are 3.94 and 3.77, respectively. Or, assuming that $O_2NC_6H_4OSO_3H$ has pK_a 2 in methanol, which is not unreasonable, the derived pK_a's for $^+H_3NNH_3^+$ are now 3.93 and 3.77. Moderate changes in the assumed pK_a for *p*-nitrophenyl hydrogen sulfate lead only to minor variation in the calculated pK_a of $^+H_3NNH_3^+$. Therefore, a reasonable estimate for the pK_a of $^+H_3NNH_3^+$ in methanol is 3.85. This pK_a is defined by eqs. 5 and 6:

$$[5] \qquad {}^+H_3N{-}NH_3^+ \rightleftarrows H_2NNH_3^+ + H^+$$

$$[6] \quad K_a = [H_2NNH_3^+][H^+]/[{}^+H_3NNH_3^+]$$

Though in principle the kinetic method for derivation of pK_a should have general application, in the present system there are two complicating factors. In the first place there is a limitation on observation of the B → C rate, which must not exceed the A → B rate in order to be measurable (*cf.* ref. 17). Secondly the degree of dissociation of *p*-nitrophenyl hydrogen sulfate provides slight uncertainty, which would not be present in the general case (*e.g.* acid-catalyzed ester hydrolysis). It should, however, be readily feasible to devise a suitable system such that the rate of a simple acid-catalyzed reaction would be determined in the presence of the catalyzing acid whose pK_a in the given medium is required.

The catalytic coefficients $k_{H_2NNH_3^+}$ and k_{sol} in the conversion of methyl *p*-nitrophenyl sulfate to *p*-nitrophenyl sulfate ion (eq. 2) can be independently evaluated using the derived value of the pK_a of $^+H_3NNH_3^+$. Thus the equilibrium concentration of the $H_2NNH_3^+$ species, $[H_2NNH_3^+]_{eq}$, will be given by the sum of the initial concentration, $[H_2NNH_3^+]_0$, and the contribution due to the ionization of $^+H_3NNH_3^+$. The latter term is calculated by means of eq. 6. The various data are presented in Table 2. Following the procedure used in Fig. 2, one then plots k^A_{obs} *vs.* $[H_2NNH_3^+]_{eq}$, which gave a linear graph, slope 0.058 M^{-1} s^{-1}, and intercept on the *y* axis 5.63×10^{-4} s^{-1}. Subtraction of the $k_{Cl^-}[Cl^-]$ term gave a second line, the slope yielding $k_{H_2NNH_3^+} = 0.025$ M^{-1} s^{-1}. The intercept on this graph is the neutral solvolytic rate constant, $k_{sol} = (5.32 \pm 0.06) \times 10^{-4}$ s^{-1}. These values substantiate the method for calculation of rate data as given in the previous section.

In conclusion, it has been shown in this study that the nucleophiles $H_2NNH_3^+$ and H_2NNH_2 react with methyl *p*-nitrophenyl sulfate by displacement at the aliphatic carbon with *p*-nitrophenyl sulfate ion as the leaving group. This is analogous to the alkaline methanolysis (2) and the reaction with some common anions (1).

The reactivity ratio, $k_{H_2NNH_2}/k_{H_2NNH_3^+}$, is about 20 in methanol at 25°. A preliminary Bronsted β can be derived for these nucleophiles using the estimated pK_a values 9.2 and 3.9 in methanol for the conjugate acids of these species. Thus $\beta = \Delta pK_a/\Delta \log k_{Nu} = 0.24$. The small value of β is in accord with the good leaving group present and suggests also that "α effects" (18–20) are not significant in this system.

Experimental

Methyl *p*-nitrophenyl sulfate was prepared according to the procedure described previously (21). Hydrazine hydrochloride (BDH reagent grade) was recrystallized before use. Sodium methoxide solutions were prepared by dissolving freshly cut sodium metal in dry methanol. A Bausch and Lomb SP505 spectrophotometer equipped with a thermostatted cell block was used for the spectral measurements.

The procedure used for the kinetic runs recorded in Table 1 may be illustrated for the case of the first run shown in the table. A 0.50 ml aliquot of a 1.50×10^{-2} *M* stock solution of $H_2NNH_2 \cdot 2HCl$ was placed in a 10 mm cuvette. After adding 1.00 ml of 7.73×10^{-3} *M* solution of CH_3ONa/CH_3OH, the volume was made up to 3.00 ml with methanol. The run was started by adding with a syringe 0.050 ml of a stock solution of methyl *p*-nitrophenyl sulfate in ether yielding a solution 5.00×10^{-5} *M* in substrate. The volume of the $H_2NNH_2 \cdot 2HCl$ solution added was kept constant throughout the series of runs, while the volume of CH_3ONa/CH_3OH was varied, with methanol making up the balance in each case for a total of 3.00 ml. Therefore the chloride ion concentration throughout the series was constant at 491.8×10^{-5} *M*. The constancy of the added $H_2NNH_2 \cdot 2HCl$ in this series of runs facilitates the evaluation of catalytic rate constants according to Fig. 2.

For the data presented in Table 2, the experimental design is different from the above in several respects. First, the added $H_2NNH_2 \cdot 2HCl$ is not kept constant but in fact varies throughout the series. Secondly, in the case of the first five runs no CH_3ONa/CH_3OH is added to the

[2]The correction applied is for the acid generated due to the reaction of methanol with the substrate. The competing reaction of $H_2NNH_3^+$, which also generates acid (as well as giving rise to the species $CH_3NHNH_3^+$), has been found to be negligible.

reaction solution. However, for the last two runs the CH_3ONa/CH_3OH solution is added, in an amount equivalent to $[H_2NNH_3^+]_0$.

The procedure used to derive the data of Table 3 for the conversion of *p*-nitrophenyl sulfate ion to *p*-nitrophenol was as follows. A stock solution of the sodium *p*-nitrophenyl sulfate (1.24×10^{-4} *M*) was prepared by reaction of methyl *p*-nitrophenyl sulfate with excess of sodium methoxide in methanol (2). Aliquots of this solution were added to excess of methanolic HCl in the 1 cm cuvette and made up to a total volume of 3 ml with methanol, yielding a final concentration of substrate 4.12×10^{-5} *M* and HCl concentrations as given in Table 3. This procedure circumvents the possibility that commercial *p*-nitrophenyl sulfate could be partially decomposed, as well as providing a mimic of the reaction system used in derivation of the pK_a (*i.e.* $^+H_3NNH_3^+$ + methyl *p*-nitrophenyl sulfate → *p*-nitrophenyl sulfate → *p*-nitrophenol).

A Synthetic Approach to Cadinane- and Amorphane-type Sesquiterpenoids via Annelation of Cyclohexanone Derivatives with (*E*)-2-Methyl-3-hepten-5-one. A Simple Synthesis of (±)-Cadinene Dihydrochloride

EDWARD PIERS AND WYNONA M. PHILLIPS-JOHNSON

Department of Chemistry, University of British Columbia, 2075 Wesbrook Place, Vancouver, Canada V6T 1W5

Received November 18, 1974

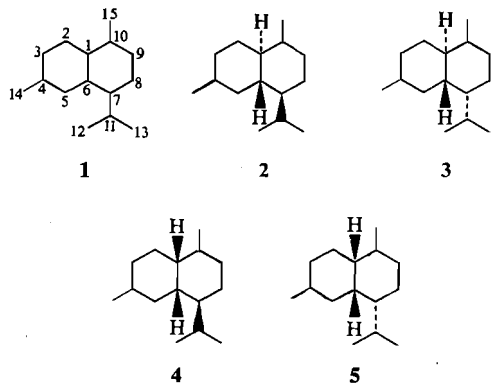
EDWARD PIERS and WYNONA M. PHILLIPS-JOHNSON. Can. J. Chem. **53**, 1281 (1975).

The annelation of the pyrrolidine enamine of cyclohexanone with (*E*)-2-methyl-3-hepten-5-one (**7**) afforded a 7:3 mixture of the octalones **12** and **13**. Lithium–ammonia reduction of the former afforded the *trans*-fused decalone **14**, whereas, in contrast, a similar reduction of **13** gave exclusively the *cis*-fused decalone **16**. Annelation of the pyrrolidine enamine of 4-hydroxycyclohexanone with the unsaturated ketone **7** yielded a 7:3 mixture of the octalones **22** and **23**. The former was converted via a short, efficient synthetic sequence into (±)-cadinene dihydrochloride (**30**).

EDWARD PIERS et WYNONA M. PHILLIPS-JOHNSON. Can. J. Chem. **53**, 1281 (1975).

L'énamine dérivant de la pyrrolidine et de la cyclohexanone soumise à une réaction d'annelation avec la méthyl-2 heptène-3 one-5 (*E*) (**7**) conduit à un mélange 7:3 des octalones **12** et **13**. La réduction par le lithium dans l'ammoniac de **12** conduit à la décalone *trans* **14** alors qu'une réduction similaire de **13** conduit uniquement à la décalone *cis* (**16**). L'énamine dérivée de la pyrrolidine et de l'hydroxy-4 cyclohexanone soumise à une réaction d'annelation avec la cétone non-saturée **7** conduit à un mélange 7:3 des octalones **22** et **23**. Une séquence synthétique courte et efficace permet de transformer **22** en dichlorhydrate de (±)-cadinène (**30**).

The fairly large number of sesquiterpenoids which possess the basic carbon skeleton as shown in **1**[1] have by convention been divided into four classes or subgroups, differing only in the relative stereochemistry at C_1, C_6, and C_7 (1, 2). Thus, the cadinane-type (**2**) and bulgarane-type (**3**) sesquiterpenoids possess *trans*-fused six-membered rings and differ only in the relative stereochemical orientation of the isopropyl or related side chain. On the other hand, in the muurolanes (**4**) and the amorphanes (**5**), the decalin systems are *cis*-fused. Again, these two types differ only in the relative stereochemistry at C_7.



1 **2** **3** **4** **5**

The four sesquiterpenoid classes mentioned above are constituted mainly of olefinic hydrocarbons and alcohols. Structurally speaking, many of the individual members of these classes are very closely related and often differ from one another only in the position of an olefinic double bond and/or in a diastereomeric sense. Because of this, it has often been difficult to separate mixtures of these types of compounds into individual components, and the structural and stereochemical elucidation of the cadinane and related sesquiterpenoids was, in the past, often carried out with impure materials. Consequently, the chemical literature dealing with this area contains many conflicting and erroneous reports. A classic and, perhaps, extreme example of this involves the naturally occurring olefinic alcohol δ-cadinol. Since its isolation in 1922, no fewer than seven different proposals have been put forward regarding the structure and sterochemistry of this compound, the latest (3) being that δ-cadinol is actually a muurolane derivative.

[1]The numbering system shown in structure **1** is that normally used for the cadinane and related sesquiterpenoids.

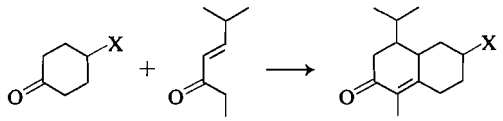
Up to the present time, relatively little work has been reported concerning the synthesis of the cadinane and related sesquiterpenoids.[2] We report in this paper a simple synthetic approach which, with appropriate development and modification, should allow for the efficient synthetic entry into both the cadinane- and amorphane-type sesquiterpenoids.

Of the number of synthetic approaches which we considered and investigated in varying detail (5), the one involving annelation of a substituted cyclohexanone derivative (**6**) with (*E*)-2-methyl-3-hepten-5-one (**7**) appeared, in principle, to be the simplest and most direct (see Scheme 1).



6 **7** **8**

SCHEME 1

Success of this general reaction would introduce, in one step, 14 of the 15 carbon atoms necessary for the synthesis of the cadinane and/or related sesquiterpenoids. An appropriate functional group (X) at C_6 in the annelation product **8** would then presumably allow for the introduction of the final required carbon atom.

The required α,β-unsaturated ketone **7** was prepared as follows (see Scheme 2). Treatment of isobutyraldehyde with the anion of trimethylphosphonoacetate (6) in dimethyl sulfoxide afforded, in 65% yield, the *trans*-olefinic ester **9**. Hydrolysis of the latter with potassium carbonate in aqueous methanol gave the corresponding carboxylic acid **10**. When compound **10** was allowed to react with freshly prepared ethyllithium under carefully controlled conditions (−78°, 2 h), the desired α,β-unsaturated ketone **7** was formed in excellent yield. It should be noted that the success of the latter reaction depended, to a large extent, upon a judicious choice of reaction temperature, reaction time, and reactant concentration. That is, use of reaction temperatures greater than −40°, or use of longer reaction times, resulted in the formation of considerable amounts of alcohol-containing products. On the other hand, milder reaction conditions (more dilute solutions, shorter reaction times, low temperatures) resulted in the recovery of fairly copious amounts of starting material. However, to eliminate the formation of alcohol-containing product, it was necessary to tolerate the recovery of some starting material. The latter could then be recycled and, eventually, the desired unsaturated ketone **7** was obtained in 92% yield.

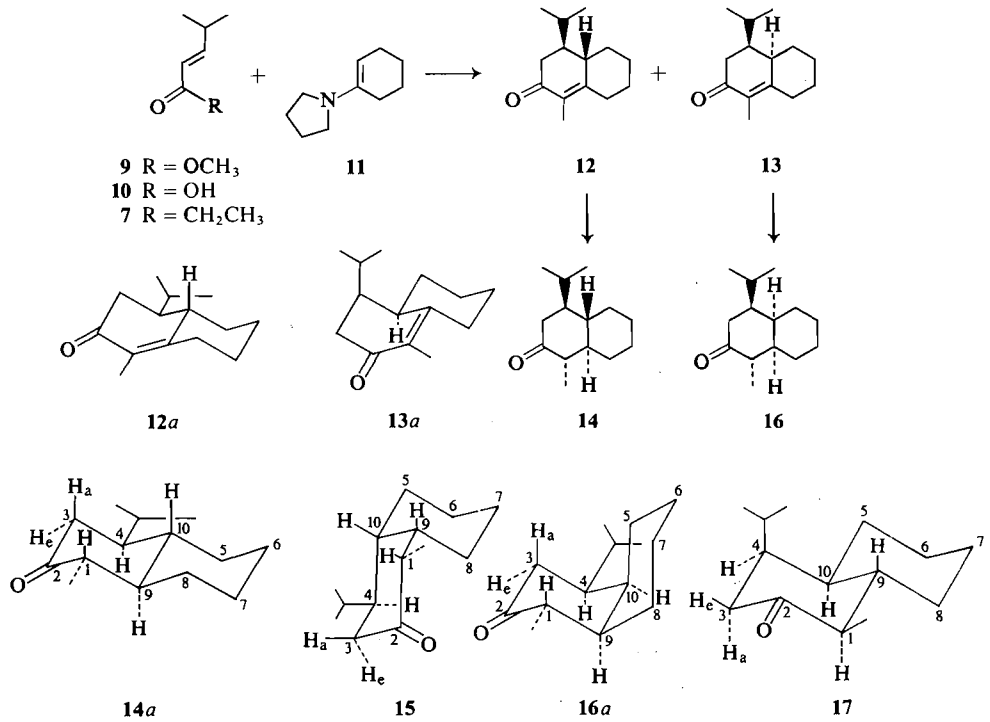
Attempted annelation of cyclohexanone, 2-carbomethoxycyclohexanone, and 2-hydroxymethylenecyclohexanone with the heptenone **7**, using a variety of bases and reaction conditions, proved unsuccessful. However, when the pyrrolidine enamine of cyclohexanone (**11**) was allowed to react with **7** under carefully chosen conditions, the corresponding annelated material was formed in 83% yield (see Scheme 2). Analysis of this material by gas–liquid chromatography (g.l.c.) indicated that it consisted of a mixture of the two epimeric compounds **12** and **13**, in a ratio of approximately 7:3, respectively. Treatment of this mixture with sodium methoxide in refluxing methanol afforded a mixture of the same two components, now in a ratio of 3:1. The two compounds could be separated readily by preparative g.l.c. and spectral and analytical data clearly showed that the two materials were indeed epimers.

On the basis of conformational analysis, one would expect the octalone **12**, containing an equatorially oriented isopropyl group (*cf.* **12***a*), to be more stable than octalone **13**, possessing an axially oriented isopropyl group (*cf.* **13***a*). Hence, the major and minor products obtained from the annelation reaction were assigned structures **12** and **13**, respectively.

In order to obtain additional information regarding the stereochemistry of octalones **12** and **13**, each was subjected to reduction with lithium in liquid ammonia. Reduction of the major annelation product **12** afforded, in 78% yield, the corresponding *trans*-fused decalone **14**. Application of internuclear double resonance (INDOR) techniques (7–9)[3] to a detailed study of the proton magnetic resonance (p.m.r.) spectrum of **14** fully supported the assigned structure and stereochemistry. Specifically, the INDOR studies revealed the following first-order coupling constants: H_{3a}–H_{3e} 12.6 ± 0.4 Hz, H_{3a}–H_4 12.6 ± 0.4 Hz, H_{3e}–H_4

[2]For an excellent and comprehensive review of sesquiterpenoid synthesis, see ref. 4.

[3]We are very grateful to Professor L. D. Hall and Dr. C. W. M. Grant for carrying out the INDOR studies. Details of these experiments will be published elsewhere.



SCHEME 2

3.9 ± 0.4 Hz. It can readily be seen that these first-order coupling constants for compound **14** are fully consistent with the assigned stereochemistry (*cf.* **14***a*). Furthermore, the p.m.r. studies also revealed that the H_1 transitions for compound **14** were spread over at least 32 Hz, indicating that the H_1–H_9 coupling (*cf.* **14***a*) was an axial–axial coupling. If the H_1–H_9 coupling had been axial–equatorial, the H_1 transitions would have been spread over only 22–25 Hz, at most. These facts clearly showed that the lithium–ammonia reduction of the major annelation product (**12**) had not produced a *cis*-fused decalone, which would have had the conformation shown in **15**. The latter structure, although consistent with the observed coupling pattern for the C_3 and C_4 protons, was clearly inconsistent with the observed line width for the H_1 resonance.

Lithium–ammonia reduction of the minor annelation product **13** afforded steroselectively, in 75% yield, the corresponding *cis*-fused decalone **16**. The stereochemistry of the latter was confirmed in two ways. First of all, hydrogenation of the olefinic double bond of **13** would be expected to take place from the side opposite the axially oriented isopropyl group (*cf.* **13***a*) (steric approach control) and also produce the *cis*-fused decalone **16**. Indeed, hydrogenation of **13** over palladium-on-charcoal, followed by equilibration (sodium methoxide in methanol) of the initially formed product, afforded only decalone **16**, identical in all respects with the product obtained from the lithium–ammonia reduction. Secondly, INDOR (7–9)[3] studies on compound **16** again fully supported the assigned stereochemistry. Thus the observed first-order coupling constants (H_{3a}–H_{3e} 13.0 ± 0.4 Hz, H_{3a}–H_4 13.0 ± 0.4 Hz, H_{3e}–H_4 3.9 ± 0.4 Hz) were clearly consistent with structure **16** (*cf.* **16***a*) but were inconsistent with a corresponding decalone possessing a *trans* ring fusion (*cf.* **17**). Furthermore, the p.m.r. studies again showed that the H_1 transitions for compound **16** were spread over at least 33 Hz. As in the case of compound **14**, this fact clearly indicated that the H_1–H_9 coupling (*cf.* **16***a*) was an axial–axial coupling.

It is well known that the alkali metal – ammonia reduction of simply substituted $\Delta^{1(9)}$-2-octalones generally affords, in each case, a high proportion of the corresponding *trans*-fused 2-decalone (10–12). Therefore, the steroselective formation of the *cis*-fused decalone **16** from the

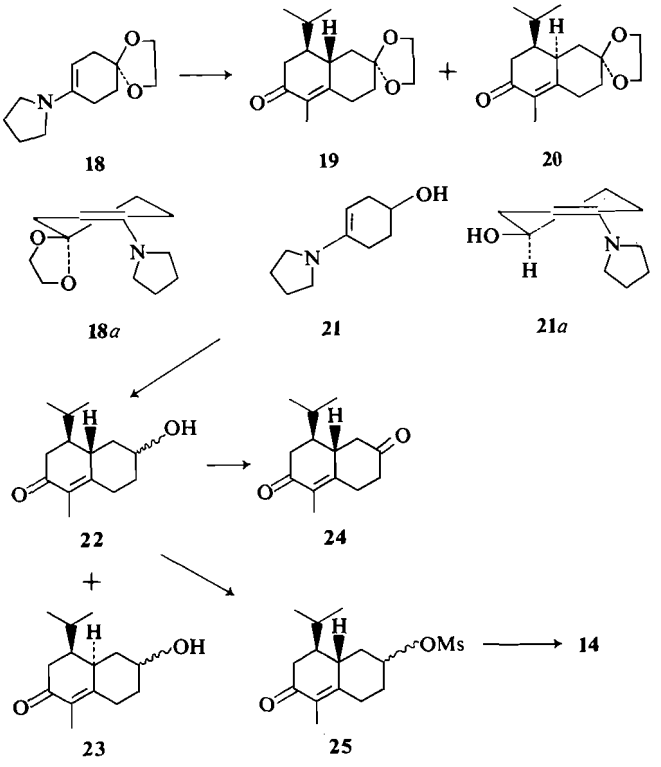


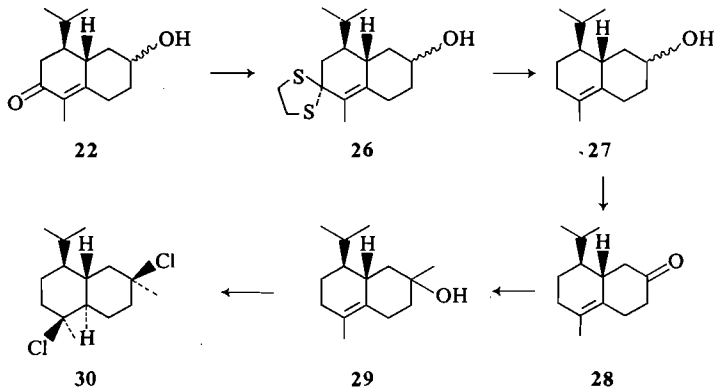
SCHEME 3

lithium–ammonia reduction of octalone **13** was initially surprising and clearly seemed to suggest that the presence of an axially-oriented substituent at the C_4 position of $\Delta^{1(9)}$-2-octalones can exert a profound effect on the stereochemical outcome of the reduction. A more detailed study and discussion of this observation can be found in the accompanying paper (13).

Having successfully realized the annelation of cyclohexanone with the α,β-unsaturated ketone **7**, we next turned our attention to the annelation of a cyclohexanone derivative containing a substituent suitable for the (later) introduction of the last one-carbon unit necessary for the synthesis of cadinane-type (or related) sesquiterpenoids. To this end, the pyrrolidine enamine of 4,4-ethylenedioxycyclohexanone (**18**) (14) was allowed to react with **7** under conditions similar to those used in the above mentioned condensation (see Scheme 3). However, the annelated product, a 4:1 mixture of octalones **19** and **20**, respectively, was obtained in only very poor yield (<10%). Attempts to improve the yield of this reaction by varying the reaction conditions were not successful. It was felt that the ketal functionality, with one of the oxygen atoms necessarily axially oriented (*cf.* **18***a*) could be sterically interfering with the approach of the vinyl ketone **7** to the β-carbon atom of the enamine **18** (anti-parallel attack (15)), thus accounting for the low yield of product. Therefore, it was decided to investigate the use of the pyrrolidine enamine of 4-hydroxycyclohexanone (**21**), which could, presumably, react from a conformation possessing an equatorially oriented hydroxyl group (*cf.* **21***a*). Condensation of **21** with the unsaturated ketone **7** was attempted under a variety of conditions and a 40% yield of a mixture of annelated products was finally realized. The crude product was equilibrated (sodium methoxide in methanol) and then subjected to analysis by g.l.c. and spectral methods. The latter revealed that this material consisted of a mixture of hydroxy octalones **22** and **23** in a ratio of approximately 7:3, respectively. The two compounds were readily separated by preparative g.l.c.

It should be noted that both **22** and **23** actually consisted of a mixture of two epimeric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



SCHEME 4

alcohols. Thus, a careful integration of the p.m.r. spectrum of the major condensation product **22**[4] indicated that the two alcohols possessing axial and equatorial hydroxyl groups were present in a ratio of approximately 3:2, respectively. That compound **22** was indeed a mixture of two epimeric alcohols was shown by chromium trioxide – pyridine oxidation (16) of this material, which produced, in 94% yield, the crystalline dione **24**. The latter, by means of g.l.c. and spectral analysis, was shown to be homogeneous.

Similarly, a careful analysis of the p.m.r. spectrum of the minor condensation product **23**[4] indicated that the epimeric alcohols were present in a ratio of approximately 1:1.

To obtain additional information regarding the relative stereochemistry (at C_4 and C_{10}) of the major and minor condensation products **22** and **23**, it was decided to correlate the former keto alcohol with the previously obtained, and structurally simpler, decalone **14**. Since assignment of the stereochemistry of the latter appeared to be on a firm basis, this correlation would provide corroborative support for the proposed stereochemistry of **22** and, by inference, of **23** as well.

Treatment of the hydroxy octalone **22** with methanesulfonyl chloride in pyridine afforded, in 85% yield, the corresponding keto mesylate **25**. Reaction of the latter with lithium in liquid ammonia containing some ethanol reduced not only the α,β-unsaturated ketone system (11, 12) but also effected hydrogenolysis of the mesylate functionality (17). Oxidation of the resulting crude product with Jones' reagent (18) produced the saturated, *trans*-fused decalone **14**, identical in every respect with a sample of the compound obtained as described previously.

In order to demonstrate the potential use of octalone **22** as an intermediate for the synthesis of cadinane-type sesquiterpenoids, and to fully confirm the stereochemical assignments outlined above, it was decided to convert **22** into racemic cadinene dihydrochloride (**30**) (19–22), the stereochemistry of which has been established unambiguously. To this end, octalone **22** was treated with ethanedithiol in the presence of boron trifluoride etherate to afford the dithioketal **26** (see Scheme 4). Desulfurization of the latter with Raney nickel in refluxing ethanol afforded, in 77% yield, the olefinic alcohol **27**. Oxidation of **27** with chromium trioxide in pyridine (16) gave, in 89% yield, the keto olefin **28**, which in turn was converted, by reaction with methyllithium in ether, into the tertiary alcohol **29** (91% yield). Treatment of the latter compound with anhydrous hydrogen chloride in anhydrous ether at 0° afforded, in 80% yield, racemic cadinene dihydrochloride (**30**). The latter was identical in every respect with an authentic sample of (±)-cadinene dihydrochloride.[5]

The enamine annelation approach to the synthesis of cadinane-type and/or related sesquiterpenoids, as outlined above, is attractive in terms of simplicity and efficiency. However, the general scheme does possess disadvantages. One of these is the production, in the annelation reaction itself, of diastereomeric products (**22**

[4]For the sake of simplicity, this material will subsequently be referred to as one compound.

[5]We are very grateful to Dr. M. D. Sutherland for a generous sample of (±)-cadinene dihydrochloride.

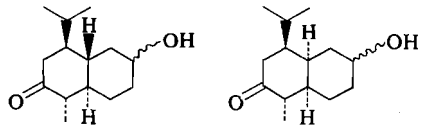
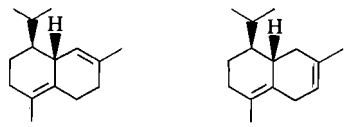
and **23**) which must then be separated at an early stage of the overall synthetic sequence. This complication is, however, at least partially offset by the results obtained from the lithium–ammonia reduction of the initially formed annelation products. That is, on the basis of the work reported in this paper, it is obvious that the lithium–ammonia reduction of a mixture of octalones **22** and **23** would produce a mixture of the corresponding *trans*- and *cis*-fused 2-decalones **31** and **32**, respectively. Separation at this stage of the synthetic sequence would then provide one with two distinct synthetic precursors, one (**31**) potentially convertible into cadinane-type sesquiterpenoids and the other (**32**) potentially convertible into amorphane-type sesquiterpenoids.



31 **32**



33 **34**

Another problem which must as yet be overcome involves the regioselective introduction of olefinic double bonds into various positions of an appropriate synthetic intermediate. For example, conversion of the keto olefin **28** into the natural products δ-cadinene (**33**) and ω-cadinene (**34**) would require the introduction of a methyl group at the carbonyl carbon (of **28**) and the controlled, regioselective introduction of carbon–carbon double bonds into two distinct positions. We are currently investigating methods for carrying out these transformations in a controlled fashion.

Experimental

General[6]

Melting points, which were determined on a Fisher-Johns melting point apparatus, and boiling points are uncorrected. The u.v. spectra were, unless otherwise noted, measured in methanol solution on a Unicam, model SP 800, spectrophotometer. Routine i.r. spectra were recorded on a Perkin-Elmer model 710 spectrophotometer, while comparison spectra were recorded on Perkin-Elmer models 421 or 457 spectrophotometers. The p.m.r. spectra were, unless otherwise noted, taken in deuteriochloroform solution on Varian Associates spectrometers, A-60, T-60 and/or HA-100 or XL-100. Signal positions are given in the Tiers τ scale, with tetramethylsilane as an internal standard. The multiplicity, integrated peak areas, and proton assignments are indicated in parentheses. High resolution mass spectrometric measurements were carried out on an AEI type MS-9 mass spectrometer. Gas–liquid chromatographic analyses were carried out on Varian Aerograph g.l.c. units, models 700 and/or 90-P. The following columns were employed: column A, 10 ft × ¼ in., 8% FFAP on 60–80 mesh Chromosorb G; column B, 10 ft × ¼ in., 20% Carbowax 20M on 60–80 mesh Chromosorb W; column C, 10 ft × ⅜ in., 30% Carbowax 20M on Chromosorb W. The specific column used, along with the column temperature and carrier gas (helium) flow-rate (in ml/min) are indicated in parentheses. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver.

*Methyl (E)-4-Methyl-2-pentenoate (**9**)*

Sodium hydride (4.3 g of a 56% dispersion in mineral oil) was added to 50 ml of dry dimethyl sulfoxide and the resulting suspension was slowly heated under a nitrogen atmosphere to 75° and maintained at that temperature until all frothing had ceased (~45 min). The solution was cooled to room temperature and a solution of 18.2 g of trimethylphosphonoacetate in 30 ml of dimethyl sulfoxide was added. The solution was allowed to stir for 10 min and then a solution of 5.76 g of isobutyraldehyde in 30 ml of dimethyl sulfoxide was added dropwise. After the addition was complete, the reaction mixture was allowed to stir for an additional hour. Water was added and the resulting mixture was extracted thoroughly with petroleum ether (b.p. 30–60°). The combined extracts were successively washed with water and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residue under reduced pressure afforded 6.5 g (65%) of methyl (*E*)-4-methyl-2-pentenoate, b.p. 65°/10 mm (lit. (23) b.p. 74–75°/46 mm); n_D^{25} 1.4309 (lit. (23) n_D^{25} 1.4305); i.r. (film) λ_{max} 5.8, 6.05 μ; p.m.r. τ 8.95 (d, 6H, $-CH(CH_3)_2$, J = 7 Hz), 7.50 (m, 1H, $-CH(CH_3)_2$), 6.30 (s, 3H, OCH_3), 4.25 (d of d, 1H, H-2, $J_{2,3}$ = 16 Hz, $J_{2,4}$ = 1 Hz), 3.05 (d of d, 1H, H-3, $J_{2,3}$ = 16 Hz, $J_{3,4}$ = 7 Hz).

*(E)-4-Methyl-2-pentenoic Acid (**10**)*

To a stirred solution of 34 g of potassium carbonate in 200 ml of methanol–water was added 23 g of methyl (*E*)-4-methyl-2-pentenoate. The reaction mixture was stirred at reflux for 3 h. Most of the methanol was removed under reduced pressure and the residue was diluted with water. The resulting aqueous solution was washed with ether (washings discarded), acidified with dilute hydrochloric acid, and thoroughly extracted with ether. The combined ether extracts were successively washed with water and brine, and dried over magnesium sulfate. Removal of the solvent and distillation of the residue under reduced pressure afforded 17.2 g (82%) of

[6]This general section is applicable to the succeeding, accompanying paper (13), as well as to the present paper.

(*E*)-4-methyl-2-pentenoic acid, b.p. 75°/0.6 mm; n_D^{27} 1.4454; u.v. λ_{max} 217 nm (ε 3630); i.r. (film) λ_{max} 3.1–4.0 (broad), 5.9, 6.1 μ; p.m.r. τ 8.95 (d, 6H, —CH(CH_3)$_2$, J = 6.5 Hz), 7.25–7.8 (m, 1H, —CH(CH$_3$)$_2$), 4.2 (d of d, 1H, H-2, $J_{2,3}$ = 15.5 Hz, $J_{2,4}$ = 1.5 Hz), 2.9 (d of d, 1H, H-3, $J_{2,3}$ = 15.5 Hz, $J_{3,4}$ = 6.5 Hz), −2.15 (s, 1H, —CO_2H).

Anal. Calcd. for $C_6H_{10}O_2$: C, 63.14; H, 8.83. Found: C, 62.85; H, 8.76.

(E)-2-Methyl-3-hepten-5-one (7)

Finely cut lithium wire (25.8 g) was added to 600 ml of anhydrous ether under nitrogen. To the resulting stirred mixture was added dropwise a solution of 120 ml of ethyl bromide (previously distilled from calcium hydride) in 300 ml of anhydrous ether. During the addition the reaction mixture was kept at −10° by application of an external Dry Ice–acetone cooling bath. After the addition was complete the solution was warmed to 0°, kept at this temperature for 1 h, filtered under nitrogen, and used immediately.

A solution of 32 g of (*E*)-4-methyl-2-pentenoic acid in 540 ml of anhydrous ether was cooled to −78° (Dry Ice – acetone) and 600 ml of the previously prepared ethyllithium solution was added dropwise. After the addition was complete, the white slurry was allowed to stir at −78° for an additional hour. The cooling bath was removed and stirring was continued until a clear solution resulted. The latter was poured into rapidly stirred, ice-cold 1 *N* hydrochloric acid. The resulting mixture was thoroughly extracted with ether. The combined ether extracts were washed successively with dilute ammonium hydroxide, water, and brine and then dried over magnesium sulfate. The solvent was removed by careful distillation through a Vigreaux column at atmospheric pressure. Fractional distillation of the residue under reduced pressure yielded 17 g (92%, based on unrecovered starting material) of (*E*)-2-methyl-3-hepten-5-one (**7**), b.p. 54°/10 mm; u.v. λ_{max} 221 nm (a quantitative u.v. spectrum was not obtained, since the material contained a small amount of the corresponding β,γ-unsaturated ketone); i.r. (film) λ_{max} 5.98, 6.14 μ; p.m.r. τ 8.90 (d, 6H, —CH(CH_3)$_2$, J = 7 Hz), 8.95 (t, 3H, —CH_2CH_3, J = 7 Hz), 7.45 (q, 2H, —CH_2—CH_3, J = 7 Hz), 3.98 (d of d, 1H, H-4, $J_{4,5}$ = 16 Hz, $J_{4,6}$ = 1.5 Hz), 3.20 (d of d, 1H, H-5, $J_{4,5}$ = 16 Hz, $J_{5,6}$ = 6 Hz).

Anal. Calcd. for $C_8H_{14}O$: C, 76.19; H, 11.11. Found: C, 76.10; H, 11.12.

Preparation of Octalones 12 and 13

A mixture of 6 g (0.02 mol) of the pyrrolidine enamine of cyclohexanone (**11**) and 2.6 g (0.02 mol) of (*E*)-2-methyl-3-hepten-5-one (**7**) was stirred under nitrogen at 60° for 40 h. Anhydrous dioxan (12 ml) was added and the reaction mixture was refluxed overnight. To the resulting solution was added 1 ml of glacial acetic acid, 2 ml of water, and 0.5 g of anhydrous sodium acetate and refluxing was continued for 4 h. The cooled reaction mixture was diluted with water and the resulting mixture was extracted thoroughly with ether. The combined ether extracts were washed successively with water, dilute hydrochloric acid, water, and brine and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residual material under reduced pressure afforded 3.5 g (83%) of a pale yellow oil, b.p. 100°/0.2 mm. This material was shown by g.l.c. to consist of a 7:3 mixture of octalones **12** and **13**, respectively. Separation of the two components was accomplished by preparative g.l.c. (column A, 200°, 86). The major octalone **12** exhibited u.v. λ_{max} 249 nm (ε 13 600); i.r. (film) λ_{max} 6.0, 6.15 μ; p.m.r. τ 9.21, 9.11 (d, d, 6H, —CH(CH_3)$_2$, J = 7 Hz), 8.26 (s, 3H, vinyl CH_3).

Mol. Wt. Calcd. for $C_{14}H_{22}O$: 206.167. Found (high resolution mass spectrometry): 206.166.

The minor octalone **13** exhibited u.v. λ_{max} 249 nm (ε 13 400); i.r. (film) λ_{max} 6.0, 6.1 μ; p.m.r. τ 9.11 (d, 6H, —CH(CH_3)$_2$, J = 6 Hz), 8.26 (s, 3H, vinyl CH_3).

Mol. Wt. Calcd. for $C_{14}H_{22}O$: 206.167. Found (high resolution mass spectrometry): 206.166.

Lithium–Ammonia Reduction of Octalone 12

To 150 ml of liquid ammonia (distilled from sodium metal) was added 200 mg of finely cut lithium wire. After the lithium had dissolved, a solution of the octalone **12** (450 mg) in 25 ml of anhydrous ether was added dropwise over a period of 30 min. The reaction mixture was allowed to stir for an additional 1.5 h and then ammonium chloride was added to discharge the blue color. The ammonia was allowed to evaporate under a slow stream of nitrogen and the residual material was diluted with water. The resulting mixture was extracted thoroughly with ether. The combined ether extracts were washed successively with water, dilute hydrochloric acid, water, and brine and then dried over anhydrous magnesium sulfate. Removal of the ether, followed by distillation of the residual material under reduced pressure gave 350 mg (78%) of the *trans*-fused decalone **14**, b.p. 125°/0.6 mm. Analysis of the product by g.l.c. (column B, 215°, 110) revealed the presence of only one component. An analytical sample of **14** exhibited i.r. (film) λ_{max} 3.42, 3.51, 5.85 μ; p.m.r. τ 9.23, 9.13 (d, d, 6H, —CH(CH_3)$_2$, J = 7 Hz), 8.99 (d, 3H, secondary CH_3, J = 6.5 Hz).

Anal. Calcd. for $C_{14}H_{24}O$: C, 80.71; H, 11.61. Found: C, 80.48; H, 11.31.

Lithium–Ammonia Reduction of Octalone 13

The lithium–ammonia reduction of the octalone **13** was carried out via a procedure identical with that described above. From 150 mg of **13** there was obtained 115 mg (75%) of the *cis*-fused decalone **16**. Analysis of the product by g.l.c. (column B, 215°, 110) showed the presence of only one component. An analytical sample exhibited i.r. (film) λ_{max} 3.45, 5.85 μ; p.m.r. τ 9.13, 9.09 (d, d, 6H, —CH(CH_3)$_2$, J = 6 Hz), 9.02 (d, 3H, secondary CH_3, J = 6.5 Hz).

Mol. Wt. Calcd. for $C_{14}H_{24}O$: 208.183. Found (high resolution mass spectrometry): 208.182.

Hydrogenation of Octalone 13

A solution of 100 mg of the octalone **13** in 10 ml of freshly distilled ethyl acetate was hydrogenated at atmospheric pressure and room temperature over 10 mg of 10% palladium-on-charcoal. Distillation of the crude product under reduced pressure afforded 96 mg (92%) of a colorless oil, b.p. 125°/0.6 mm. This material was subjected to epimerization with sodium methoxide in refluxing methanol. The resulting product was shown

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

to contain 98% of one component by g.l.c. analysis (column B, 180°, 100). An analytical sample of this material exhibited i.r. and p.m.r. spectra identical with those of the *cis*-fused decalone **16**, obtained as described above.

*Preparation of Octalones **19** and **20***

A solution of 1 g of the pyrrolidine enamine of 4,4-ethylenedioxycyclohexanone (**18**) (24) and 500 mg of (*E*)-2-methyl-3-hepten-5-one (7) in 4 ml of dry dioxan was refluxed for 48 h. A solution of 0.2 g of sodium acetate in 1.1 ml of acetic acid – water (1:2) was added and refluxing was continued for 1.5 h. The cooled reaction mixture was then diluted with water and thoroughly extracted with ether. The combined ether extracts were successively washed with water, aqueous sodium carbonate, water, and brine and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residue under reduced pressure gave 121 mg (8%) of a viscous oil, b.p. 150°/0.1 mm. Gas–liquid chromatographic analysis (column A, 180°, 85) revealed that this material consisted of a mixture of two compounds, in a ratio of 4:1. Analytical samples were collected by preparative g.l.c. The major compound, octalone **19**, exhibited u.v. λ_{max} 243 nm (ε 13 000); i.r. (film) λ_{max} 6.05 μ; p.m.r. τ 9.18, 9.08 (d, d, 6H, —CH(CH_3)$_2$, J = 6.5 Hz), 8.23 (s, 3H, vinyl CH_3), 6.06 (s, 4H, —OCH_2CH_2O—).

Mol. Wt. Calcd. for $C_{16}H_{24}O_3$: 264.172. Found (high resolution mass spectrometry): 264.172.

The minor isomer, octalone **20**, exhibited u.v. λ_{max} 243 nm (ε 18 900); i.r. (film) λ_{max} 6.01, 6.15 μ; p.m.r. τ 9.08, 9.06 (d, d, 6H, —CH(CH_3)$_2$, J = 6.0 Hz), 8.23 (s, 3H, vinyl CH_3), 6.06 (s, 4H, —OCH_2CH_2O—).

Mol. Wt. Calcd. for $C_{16}H_{24}O_3$: 264.172. Found (high resolution mass spectrometry): 264.172.

*Preparation of Hydroxy Octalones **22** and **23***

A solution of 18 g of 4-hydroxycyclohexanone (25) and 20.7 ml of pyrrolidine in 234 ml of benzene was refluxed under a Dean–Stark water separator until no further separation of water occurred. The benzene and excess pyrrolidine were removed under reduced pressure (0.1 mm) to yield a crude, crystalline enamine, i.r. (Nujol) λ_{max} 3.0, 6.1 μ. To this material was added 13.5 g of (*E*)-2-methyl-3-hepten-5-one (7) and the resulting mixture was stirred at 50° for 17 h. At this time, the i.r. spectrum of an aliquot showed the absence of absorptions due to the vinyl ketone. Hence, an additional 5 g of the vinyl ketone 7 was added and stirring was continued for an additional 19 h. Dry dioxan was then added and the resulting solution was refluxed for 16 h. A solution of 5 g of sodium acetate in acetic acid – water (30 ml, 1:2) was added and refluxing was continued for 4 h. The cooled reaction mixture was diluted with water and thoroughly extracted with ether. The combined ether extracts were washed successively with water, dilute hydrochloric acid, water, and brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residue under reduced pressure gave 14 g (40%) of a colorless oil, b.p. 200°/0.1 mm. This material was shown by g.l.c. analysis (column C, 215°, 170) to be a mixture of two components in a ratio of approximately 3:2. Subjection of this mixture to epimerizing conditions (150 ml of 2 *M* sodium methoxide in methanol, reflux 12 h) changed this ratio to 7:3, respectively. The two components were separated by preparative g.l.c. (column C, 230°, 110). The major octalone (**22**) exhibited u.v. λ_{max} 248 nm (ε 10 900); i.r. ($CHCl_3$) λ_{max} 2.75, 2.9, 6.05 μ; p.m.r. τ 9.16, 9.07 (d, d, 6H, —CH(CH_3)$_2$, J = 6.5 Hz), 8.23 (s, 3H, vinyl CH_3), 6.15, 5.82 (unresolved multiplets, 1H, —C*H*OH).

Mol. Wt. Calcd. for $C_{14}H_{22}O_2$: 222.162. Found (high resolution mass spectrometry): 222.162.

The minor octalone (**23**) exhibited u.v. λ_{max} 247 nm (ε 9300); i.r. ($CHCl_3$) λ_{max} 2.75, 2.9, 6.05, 6.15 μ; p.m.r. τ 9.07, 9.04 (d, d, 6H, —CH(CH_3)$_2$, J = 6 Hz), 8.26 (s, 3H, vinyl CH_3), 6.10, 5.78 (unresolved multiplets, 1H, —C*H*OH).

Mol. Wt. Calcd. for $C_{14}H_{22}O_2$: 222.162. Found (high resolution mass spectrometry): 222.162.

*Preparation of Dione **24***

A solution of 60 mg of chromium trioxide in 1.5 ml of dichloromethane containing 0.09 ml of pyridine was allowed to stir at room temperature for 15 min. To this solution was added a solution of 30 mg of octalone **22** in 0.5 ml of dichloromethane. The resulting reaction mixture was allowed to stir at room temperature for 25 min and was then diluted with 8 ml of ether. The ether layer was washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the ether afforded 28 mg (94%) of the dione **24**, m.p. 108–110°. This material showed one peak on g.l.c. analysis (column A, 180°, 86) and exhibited u.v. λ_{max} 247 nm (ε 13 000); i.r. ($CHCl_3$) λ_{max} 5.85, 6.05, 6.15 μ; p.m.r. τ 9.20, 9.07 (d, d, 6H, —CH(CH_3)$_2$, J = 6.5 Hz), 8.12 (s, 3H, vinyl CH_3).

Anal. Calcd. for $C_{14}H_{20}O_2$: C, 76.33; H, 9.15. Found: C, 76.28; H, 9.18.

*Conversion of Hydroxy Octalone **22** into Decalone **14***

To a solution of 225 mg of octalone **22** in 6 ml of dry pyridine at 0° was added 0.15 ml of methanesulfonyl chloride. The reaction mixture was allowed to stir at room temperature for 3.5 h. Ice was added, the mixture was allowed to stir for an additional 10 min, and then was thoroughly extracted with ether. The combined ether extracts were washed with water, dilute sulfuric acid, dilute aqueous sodium bicarbonate, and brine and dried over anhydrous magnesium sulfate. Removal of the solvent afforded 280 mg (85%) of the crude oily methanesulfonate derivative **25**, i.r. (film) λ_{max} 6.0, 7.45, 8.55 μ.

A solution of this material in 1.8 ml of absolute ethanol was added dropwise to a solution of 1.35 g of lithium in 50 ml of liquid ammonia (distilled from sodium metal) at −78°. The mixture was stirred at −78° for 1 h and then at −33° for 1.5 h. Additional ethanol was added until the blue color disappeared. The liquid ammonia was allowed to evaporate, water was added to the residue, and the resulting mixture was thoroughly extracted with ether. The combined ether extracts were washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave 160 mg of a mixture of alcohols. This material was dissolved in 12 ml of acetone (distilled from potassium permanganate) and to the resulting solution was added standard chromic acid solution (18) until the orange color persisted. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

orange color was discharged by addition of isopropyl alcohol and the solvent was removed under reduced pressure. The residue was diluted with water and the mixture was thoroughly extracted with ether. The combined ether extracts were washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residue under reduced pressure afforded 136 mg (85%) of the decalone **14**, b.p. 125°/0.6 mm. This material showed one peak on g.l.c. analysis (column B, 215°, 110) and exhibited spectra (i.r., p.m.r.) identical with those of an authentic sample of the *trans*-fused decalone **14**.

Preparation of the Dithioketal 26

To a cold (0°), stirred mixture of 3.6 g of octalone **22** and 3.0 ml of ethanedithiol was added 1.4 ml of boron trifluoride etherate. The solution was allowed to warm to room temperature and then stirred for an additional 1 h. After dilution with water, the reaction mixture was thoroughly extracted with chloroform. The combined chloroform extracts were washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave 5.2 g of crude material. A benzene solution of the latter was filtered through a short column of Woelm activity I neutral alumina (20 g). The alumina column was eluted with additional benzene. Concentration of the filtrate gave a crystalline solid which, upon recrystallization from ether afforded 3.2 g (66%) of the dithioketal **26**, m.p. 105–110°; i.r. (Nujol) λ_{max} 3.0, 6.1 μ; p.m.r. τ 9.21, 9.02 (d, d, 6H, $-CH(CH_3)_2$, J = 7 Hz), 8.07 (s, 3H, vinyl CH_3), 6.67 (m, 4H, $-SCH_2CH_2S-$), 6.54, 5.86 (unresolved multiplets, 1H, $-CH(OH)-$).

Mol. Wt. Calcd. for $C_{16}H_{26}OS_2$: 298.142. Found: (high resolution mass spectrometry): 298.144.

Preparation of Alcohol 27

To a solution of 700 mg of the dithioketal **26** in 100 ml of absolute ethanol was added 10 g of commercial Raney nickel. The mixture was refluxed for 5 h, cooled, and filtered through a bed of Celite. The filtrate was concentrated and the residual oil was distilled under reduced pressure to afford 350 mg (77%) of the alcohol **27**, b.p. 120°/0.25 mm; i.r. (film) λ_{max} 3.0, 6.0 μ; p.m.r. τ 9.23, 9.09 (d, d, 6H, $-CH(CH_3)_2$, J = 6.5 Hz), 8.40 (s, 3H, vinyl CH_3), 6.36, 5.85 (unresolved multiplets, 1H, $-CH(OH)$).

Mol. Wt. Calcd. for $C_{14}H_{24}O$: 208.183. Found (high resolution mass spectrometry): 208.183.

Preparation of Octalone 28

To an ice-cold solution of 720 mg of chromium trioxide in 18 ml of anhydrous pyridine was added a solution of 350 mg of alcohol **27** in 9 ml of anhydrous pyridine. The solution was allowed to stir at room temperature for 40 h. The reaction mixture was poured into stirred anhydrous ether. Celite was added and the mixture was filtered. The filtrate was thoroughly washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the oily residue under reduced pressure yielded 307 mg (89%) of a colorless oil, b.p. 130°/0.35 mm. This product was shown to be homogeneous by g.l.c. (column B, 180°, 85). An analytical sample exhibited i.r. (film) λ_{max} 5.85 μ; p.m.r. τ 9.21, 9.05 (d, d, 6H, $-CH(CH_3)_2$, J = 6.5 Hz), 8.36 (s, 3H, vinyl CH_3).

Mol. Wt. Calcd. for $C_{14}H_{22}O$: 206.167. Found (high resolution mass spectrometry): 206.168.

Preparation of Alcohol 29

A solution of 230 mg (1.06 mmol) of octalone **28** in 30 ml of anhydrous ether was cooled to 0°. To this solution was added, dropwise, 2 ml of 2.16 *M* methyllithium (4.32 mmol) in ether. After the addition was complete the solution was allowed to stir for 2 h at room temperature and was then poured into a mixture of ice and water. The ether layer was separated and washed with water and brine and dried over anhydrous magnesium sulfate. The solvent was removed and the residual oil was distilled under reduced pressure to afford 224 mg (91%) of a viscous oil, b.p. 130°/0.25 mm. This oil was shown by g.l.c. analysis (column C, 200°, 110) to contain one major component along with trace amounts of unidentified material. The major component, obtained by preparative g.l.c., was a white crystalline substance, m.p. 79–80°; i.r. (Nujol) λ_{max} 3.0, 6.1 μ; p.m.r. τ 9.21, 9.07 (d, d, 6H, $-CH(CH_3)_2$, J = 6.5 Hz), 8.81 (s, 3H, tertiary CH_3), 8.37 (s, 3H, vinyl CH_3).

Mol. Wt. Calcd. for $C_{15}H_{26}O$: 222.198. Found (high resolution mass spectrometry): 222.198.

Preparation of (±)-Cadinene Dihydrochloride (30)

A solution of 100 mg of the crystalline alcohol **29** in 10 ml of anhydrous ether was cooled to 0°. Dry hydrogen chloride gas was bubbled into the solution. At the end of 15 min, the gas flow was stopped and the solution was stirred for an additional hour. The ether was removed under reduced pressure to afford 100 mg (80%) of crystalline (±)-cadinene dihydrochloride (**30**). An analytical sample was obtained by recrystallization from *n*-hexane–methanol to afford white crystals, m.p. 104.5–106°. This sample showed no depression of melting point on admixture with an authentic sample of (±)-cadinene dihydrochloride and its i.r. spectrum was superimposable with that of the authentic sample; i.r. (Nujol), λ_{max} 3.45, 6.95, 8.75, 11.75 μ.

Anal. Calcd. for $C_{15}H_{26}Cl_2$: C, 65.01; H, 9.39. Found: C, 64.75; H, 9.52.

Synthesis and Novel Stereochemical Results in the Lithium–Ammonia Reduction of Some 4-Alkyl-$\Delta^{1(9)}$-2-octalones

EDWARD PIERS, WYNONA M. PHILLIPS-JOHNSON, and CHRISTIAN BERGER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Place, Vancouver, British Columbia V6T 1W5

Received November 18, 1974

EDWARD PIERS, WYNONA M. PHILLIPS-JOHNSON, and CHRISTIAN BERGER. Can. J. Chem. **53**, 1291 (1975).

The 4-alkyl-$\Delta^{1(9)}$-2-octalones **7–11**, inclusive, prepared by conjugate addition of appropriate organocuprate reagents to the cross-conjugated dienones **13** and **14**, were subjected to lithium–ammonia reduction. Interestingly, these reductions produced, in each case, a considerably higher proportion (13–35%) of the corresponding *cis*-fused 2-decalone (**27–31**, inclusive) as compared with that normally formed in the alkali metal – ammonia reduction of $\Delta^{1(9)}$-2-octalones. The results are qualitatively explained in terms of the proposals originally set forth by Robinson.

EDWARD PIERS, WYNONA M. PHILLIPS-JOHNSON et CHRISTIAN BERGER. Can. J. Chem. **53**, 1291 (1975).

On a soumis à une réduction par le lithium dans l'ammoniac les alkyl-4 $\Delta^{1(9)}$ octalones-2 (**7** à **11**) préparées par l'addition 1–4 des réactifs organocuprates appropriés sur les diénones **13** et **14** conjuguées d'une façon croisée. Il est intéressant de noter que ces réductions produisent dans chaque cas une quantité proportionnellement plus élevée (13–35%) de la décalone-2 *cis* correspondante (**27–31** inclusivement) par opposition avec ce qui est normalement obtenu lors de la réduction par les métaux alcalins dans l'ammoniac des $\Delta^{1(9)}$ octalones-2. Les résultats sont expliqués sur une base qualitative en termes des propositions qui ont été originalement mises de l'avant par Robinson. [Traduit par le journal]

The alkali metal – ammonia reduction of α,β-unsaturated ketones is a very useful and frequently employed reaction in organic synthesis. Not only is the reaction normally efficient in terms of product yield but it also produces as the initially formed product an enolate anion, which can then be used in a variety of ways. Furthermore, in those cases where new chiral centers are formed (particularly at the β-carbon), the reaction often proceeds with high stereoselectivity. More explicitly, the latter characteristic is of noteworthy importance in the synthesis of natural products (particularly steroids and terpenoids), in which the transformation illustrated in general terms by **1** → **2** is often a requirement. Indeed, it is well known that the alkali metal – ammonia reduction of $\Delta^{1(9)}$-2-octalone systems of type **1** generally proceeds in a highly stereoselective manner, yielding a large predominance of the corresponding *trans*-fused 2-decalone system **2** (1–3).

The mechanistic details of alkali metal – ammonia reduction of α,β-unsaturated carbonyl compounds have been the subject of many reports in the chemical literature. Of particular note in this regard are the recent papers by House *et al.* (4, 5) and by Kemp and co-workers (6, 7). Furthermore, the reasons underlying the high stereoselectivity of reduction of $\Delta^{1(9)}$-2-octalones and related compounds have been the subject of a number of studies (2, 3, 8) and discussions (9–11*a*). However, there does not as yet appear to be complete agreement as to what the reasons for this high stereoselectivity actually are and a number of different proposals have been put forward. The main source of controversy has been, and appears still to be, related to the question of whether the geometry of the transition state for protonation at the β-carbon is pyramidal (2, 5, 9) or trigonal (3).

In the accompanying paper (12) we reported the preparation and lithium–ammonia reduction of the two epimeric octalones **3** and **4**. It was found that although reduction of **3** proceeded in the "normal" manner and produced only the *trans*-fused 2-decalone **5**, a similar reduction of **4** afforded stereoselectively the *cis*-fused 2-decalone **6**. This novel and initially surprising result led us to initiate an investigation into the stereochemistry of lithium–ammonia reduction of a series of analogous $\Delta^{1(9)}$-2-octalones containing an angular methyl group at C_{10} and various axially oriented alkyl groups at C_4. In particular, we report in this paper the preparation and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

lithium–ammonia reduction of the substituted $\Delta^{1(9)}$-2-octalones **7–11**, inclusive.[1]

Preparation of the 4α-Alkyl-4aβ-methyl-4,4a,5,6,7,8-hexahydro-2(3H)-napthalenones 7–11 (see Scheme 1)

The $\Delta^{1(9)}$-2-octalones chosen for the present study were prepared by conjugate addition of appropriate cuprate reagents (14) to the cross-conjugated dienones **13** (15) and **14** (16). It is now well established that conjugate addition of Grignard reagents (copper catalyzed) or of lithium dialkylcuprate reagents to dienones such as **13** and **14** takes place both regioselectively and stereoselectively to produce the corresponding octalones with an axially oriented alkyl group at C_4 (14, 17–19). In other words, the incoming alkyl group attacks the less hindered β-carbon of the dienone system from the side opposite the already present angular methyl group. Molecular models clearly show that if approach of the reagent were to occur in a stereoelectronically allowed fashion from the other side of the molecule, the incoming alkyl group would, in the transition state, be nearly eclipsed with the angular methyl group. The resulting steric and torsional strain should be a dominant factor and, presumably, ensures that the alternate transition state (α attack at C_4) is favored.

Conjugate addition, under appropriate conditions, of lithium dimethyl-, divinyl-, and diisopropylcuprate to the cross-conjugated dienone **13** afforded, in good yields, the octalones **7**, **12**, and **9**, respectively. In each case, the reaction was highly stereoselective and the spectral properties of the product fully corroborated the assigned structure. The vinyl derivative **12** was found to be quite unstable and was therefore immediately converted, by hydrogenation in the presence of tris(triphenylphosphine)chlororhodium (20), into the corresponding ethyl derivative **8**. In a similar fashion, addition of lithium dimethyl- and diisopropylcuprate to the dienone **14** afforded the octalones **10** and **11**, respectively.

It should be noted that considerable experimentation was done to find optimum conditions for the above-mentioned conjugate additions. Therefore, it is appropriate to make a few general comments regarding these reactions. At the time this work was underway, House and co-workers (21, 22) had already reported a detailed study of the use of lithium dimethylcuprate in conjugate addition to α,β-unsaturated ketones and we therefore experienced no problems in connection with the use of this reagent. However, no analogous information was available for lithium divinyl- or diisopropylcuprate. Initially, therefore, a procedure analogous to that used by House *et al.* (21) for the preparation and use of the dimethyl reagent was also employed for the divinyl and diisopropyl reagents. However, it was found that this procedure gave rise to only a poor yield of conjugate addition product with the divinylcuprate and only recovered starting material or polymeric material in the latter case. In an attempt to enhance the reactivity of the lithium diisopropylcuprate reagent with respect to conjugate addition, the use of various additives was investigated. Indeed, it was found that fair to moderate yields of conjugate addition product could be realized if anhydrous lithium bromide was present in the reaction mixture. However, since these reactions were still rather inefficient as compared with the reactions involving the use of lithium dimethylcuprate, an alternative method of preparing the cuprate reagents was investigated. In this approach, the ether soluble cuprous iodide – tri-*n*-butylphosphine complex (23) was employed instead of cuprous iodide. The solutions of lithium divinyl- and diisopropylcuprates prepared in this manner were homogeneous in contrast to the colloidal appearance of those previously prepared. Fur-

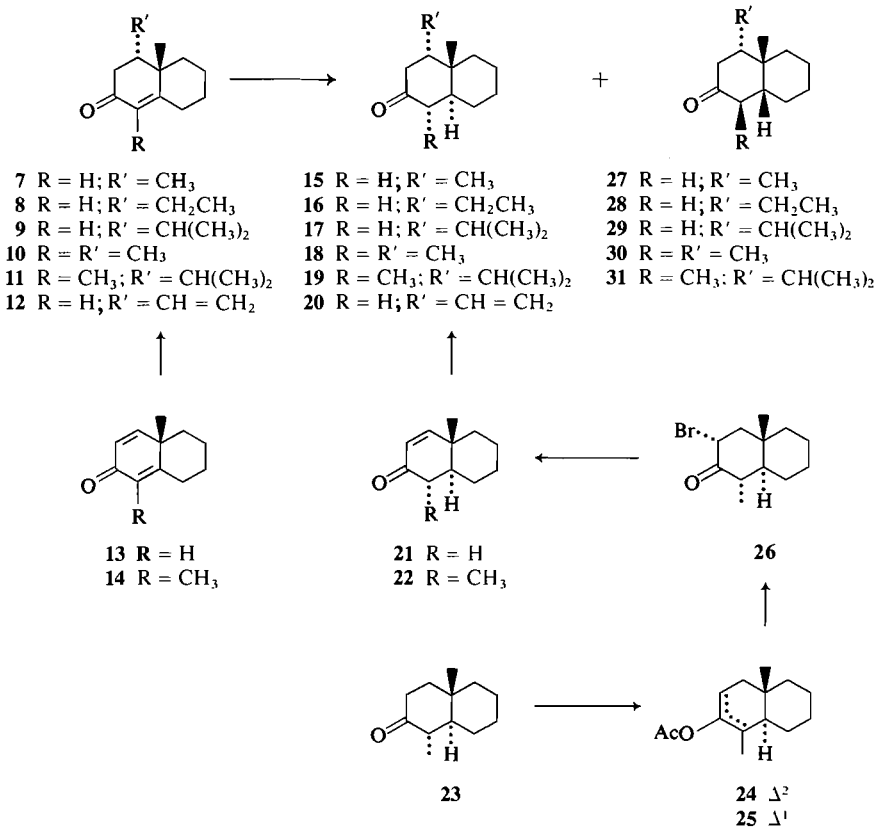

SCHEME 1

thermore, the yields of conjugate addition products were markedly improved, although, in the case of the diisopropyl reagent, the use of anhydrous lithium bromide as an additive again appeared to be advantageous.

In further attempts to improve the yields of conjugate addition products, the effect of other reaction parameters (reaction time, temperature, reactant concentration, and quenching procedure) was investigated. Firstly, it was generally found that product yields obtained upon varying the reaction time from 4 to 36 h appeared to be invariant, although use of reaction times shorter than 4 h generally resulted in the recovery of some starting material. Secondly, repetition of various reactions at different temperatures clearly revealed that the best yields were obtained at low temperatures and most of the conjugate additions were therefore carried out at −78°. Thirdly, attempted additions using a variety of reactant concentrations indicated that optimum yields were obtained when the reaction solutions were between 0.01 and 0.005 *M* in the organocuprate reagents. Finally, it was found advantageous to quench the reactions by dropwise addition of the reaction mixtures to a rapidly stirred solution of aqueous acid (see ref. 24).

It should be noted that recently, subsequent to the time at which the above-described work was carried out, there have appeared a number of reports concerning the use of lithium divinylcuprate (25–29) and related reagents (30–40) in conjugate addition to a variety of α,β-unsaturated ketones.

Preparation of the Lithium–Ammonia Reduction Products (see Scheme 1)

Having realized the efficient and stereoselective synthesis of each of the octalones required for the projected lithium–ammonia reduction studies, it was necessary to unambiguously prepare the products which could be expected from these reductions. Explicitly, this involved the preparation of the *trans*-fused 2-decalones **15–19**, and the *cis*-fused 2-decalones **27–31**. The former

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

compounds (**15–19**) were prepared by the conjugate addition of appropriate organocuprate reagents to the requisite α,β-unsaturated ketone. Thus, when the octalone **21** (41) was allowed to react with each of lithium dimethyl-, divinyl-, and diisopropylcuprate under conditions essentially identical with those outlined previously, the corresponding *trans*-fused 2-decalones (**15**, **20**, and **17**, respectively) were formed in good to excellent yields.[2] Hydrogenation of the vinyl derivative **20** in the presence of palladium-on-charcoal afforded, in 98% yield, the saturated decalone **16**. In a similar fashion, conjugate addition of lithium dimethyl- and diisopropylcuprate to the octalone **22**[3] gave, in excellent yields, the other two required *trans*-fused decalones **18** and **19**, respectively.

The required *cis*-fused decalones (**27–31**) were prepared by hydrogenation of the corresponding $\Delta^{1(9)}$-2-octalones **7–11**. It is well known that, under appropriate conditions, hydrogenation of Δ^4-3-keto steroids and related materials affords mainly the corresponding *cis*-fused decalone-type system. Furthermore, in the case of each of the octalones **7–11**, the presence of an axially oriented alkyl group at C_4 would tend to sterically hinder hydrogenation from the α side. In the event, hydrogenation of compounds **7–11** in 0.3 *N* ethanolic potassium hydroxide over palladium-on-charcoal afforded, in each case, a high yield (≥95%) of product which consisted nearly entirely (≥94%) of the corresponding *cis*-fused 2-decalone (**27–31**). In each case, the minor (≤6%) hydrogenation product exhibited g.l.c. retention times identical with those of the corresponding *trans*-fused 2-decalones (**15–19**).

Lithium–Ammonia Reduction of Octalones 7–11

The lithium–ammonia reduction of each of the octalones **7–11** was carried out under standardized conditions. Thus, a solution of the appropriate substrate in ether was added over a period of 30 min to a solution of lithium in anhydrous ammonia, the reaction mixture was stirred for an additional 2 h, and was then quenched by addition of ammonium chloride. Each reduction was repeated at least twice. The crude product mixtures were distilled and then subjected to analysis by g.l.c. The reduction products, the *trans*- and *cis*-fused 2-decalones, were, in each case, isolated by preparative g.l.c. and were shown to be identical with the corresponding authentic materials prepared as described above.

The composition of the reduction products was determined by integration (disc integrator) of the g.l.c. trace obtained by analysis of the product mixtures. It was found that the molar response factor was, within experimental error, the same for each pair of *cis*- and *trans*-fused 2-decalones. This factor was determined, in each case, by preparing a mixture of authentic *cis*- and *trans*-fused decalones in a ratio very similar to that observed in the lithium–ammonia reduction product. The mixture of known composition was then analyzed by g.l.c. and the ratio of the two components obtained by integration of the g.l.c. trace was found to be within experimental error, the same as the known ratio. This was not unexpected, since it is known that molecules of similar structure and molecular complexity generally have identical molar response factors (43).

The results (yields and product compositions) obtained from several reductions of each individual octalone were averaged and the resultant figures are recorded in Table 1.[4]

As can be seen from an examination of the results summarized in Table 1, small amounts (2–14%) of starting material were recovered from the lithium–ammonia reduction of octalones **7–11**. This was not surprising, since it is well known (3, 4) that alkali metal – ammonia reduction of α,β-unsaturated ketones in the absence of proton donors which are more acidic than ammonia generally leads to the recovery of some starting material. Presumably, this is largely due to the fact that some of the unreduced enone reacts with amide ion (produced when the β-carbon of the substrate is protonated by ammonia) to form either the corresponding enolate anion or the product of conjugate addi-

[2]For a discussion regarding the stereochemistry of this type of reaction, see ref. 41. The decalone **17** had been prepared previously (41) via a somewhat different, although related, method.

[3]This compound was prepared as follows. Conversion of the decalone **23** (42) into a mixture of the enol acetates **24** and **25** (85:15, respectively), followed by bromination of this mixture with bromine in acetic acid, afforded the bromoketone **26**. Dehydrobromination of the latter with anhydrous lithium bromide in hot hexamethylphosphoramide afforded octalone **22**.

[4]The results obtained from three or more reductions of each octalone (**7–11**) were found to be reproducible to within ±2%.

TABLE 1. Stereochemistry of lithium–ammonia reduction of 4-alkyl-$\Delta^{1(9)}$-2-octalones

Experiment No.	Octalone	Yield (%)*	Ratio of *trans*:*cis* decalone	Recovered starting material
1	**3**†	91	>99: 1	—
2	**4**†	80	<1:99	—
3	**7**	93	87:13	2
4	**8**	94	75:25	13
5	**9**	98	69:31	14
6	**10**	90	82:18	8
7	**11**	98	65:35	7

†See ref. 12.

tion (11*b*), both of which would be inert to reduction. This can be avoided by employing an alcohol as a proton source. However, in the presence of an alcohol, the product of reduction is generally the 2-decalol, which must subsequently be oxidized back to the decalone. In the present work, recovery of small amounts of starting material presented no problem to the analysis of product mixtures. That is, in each case, g.l.c. conditions were found in which the starting material (octalone) and the two corresponding products (*cis*- and *trans*-fused decalones) exhibited distinct retention times. Furthermore, the yields of the reduction products were higher when the additional oxidation step could be omitted. Therefore, all of the reductions were carried out in the absence of an alcohol.

From a stereochemical point of view, a number of interesting conclusions can be drawn from the results tabulated in Table 1. Firstly, the results showed that the lithium–ammonia reduction of $\Delta^{1(9)}$-2-octalones possessing an axially oriented alkyl substituent at C_4 afforded, in each case, a much greater proportion of the corresponding *cis*-fused 2-decalone than that normally found in this type of reduction. For example, whereas the parent $\Delta^{1(9)}$-2-octalone was known to afford nearly exclusively *trans*-2-decalone (3, 5), the isopropyloctalone **4** yielded only the corresponding *cis*-fused 2-decalone **6** (Expt. No. 2). Similarly, although less strikingly, the octalones **7–11** afforded upon lithium–ammonia reduction significant amounts (13–35%) of the corresponding *cis*-fused decalones **27–31**, respectively (Expt. Nos. 3–7). In contrast, a similar reduction of the parent 10-methyl-$\Delta^{1(9)}$-2-octalone was known to yield nearly exclusively *trans*-10-methyl-2-decalone (3, 5).

Secondly, the results summarized in Table 1 indicated that the presence (or absence) of an angular methyl group (at C_{10}) in these compounds had a very significant effect on the stereochemical outcome of reduction. Thus, although the C_{10}-unsubstituted octalone **4** afforded only the *cis*-fused product **6** (Expt. No. 2), the 4α-isopropyloctalones **9** and **11**, containing a 10β-methyl group, yielded significantly lower amounts (31 and 35%) of the *cis*-fused decalones (Expt. Nos. 5 and 7). Thirdly, in the case of octalones **7–11**, the results showed that the relative amount of *cis*-fused decalone in the product increased with increasing size of the axially oriented C_4-alkyl group (Expt. Nos. 3–5 and 6, 7). Finally, the results indicated that the presence or absence of a methyl group at C_1 had little or no effect on the stereochemical outcome of the reduction (Expt. Nos. 3, 5–7).

Discussion

It is important to note that, with regards to the lithium–ammonia reduction of octalones **7–11**, the results (Table 1) showed that the energy difference between the transition states leading from the starting material to the Δ^1-enolates (or enols) of the *trans* and *cis*-fused 2-decalones (**32** and **33**) was quite small. Furthermore, the conformational analysis of substituted Δ^1-octalines of the type **32** and **33** has not as yet been put on a quantitative basis and it is thus very difficult to accurately assess the magnitude of the various nonbonded interactions involved in the different conformations of possible intermediates and/or transition states. Therefore, it is difficult to offer, in *quantitative* terms, an explanation for the stereochemical results summarized in Table 1. However, we feel that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

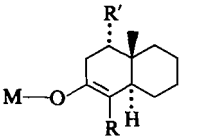
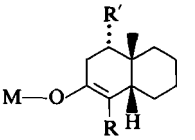
results can be *qualitatively* explained in terms of the proposals originally set forth by Robinson (3).

Briefly, Robinson's conclusions can be summarized as follows. (*a*) The β-carbon of the intermediate anion is planar in shape and the transition state for protonation at the β-carbon should resemble this shape (reactant-like transition state).[5] It was recognized, however, that the planarity is not necessarily perfectly retained in the transition state. (*b*) The intermediate anion can adopt three different conformations (**34**, **35**, **36**),[6] each of which could theoretically lead to protonation transition states to afford **32** and/or **33**. However, considering angle and torsional strain, Robinson concluded that **36** would generally involve too high an energy (large angle strain, lack of planarity of the conjugated system) to be a likely conformation. Of the two remaining conformations, Robinson proposed that **34** would normally be favored and would lead largely to a transition state (resembling **34** in geometry) forming *trans*-fused enolate (or enol) **32**, whereas **35** would normally be more strained (less stable) and would lead mainly to a transition state (resembling **35** in geometry) forming *cis*-fused enolate (or enol) **33**. Therefore, it would be expected that for "normal" $\Delta^{1(9)}$-2-octalones (R′ = H), the transition state arising from **34** (leading to **32**) would be favored over the transition state arising from **35** (leading to **33**), thus accounting for the observed predominance of the *trans*-fused decalone in the product.

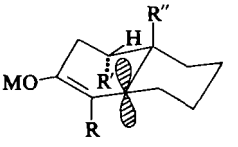
Considering now the stereochemical results obtained from the lithium–ammonia reduction of octalones **4** and **7–11**, inclusive, it is reasonable to propose that the stability gained by changing the conformation of the reduction intermediate from **34** (axial C_4-alkyl group) to **35** (equatorial-like C_4-alkyl group) would at least partially off-set the angle and torsional strain inherent in conformation **35**. If the protonation transition state is reactant like, this would result in a lowering of the energy of the transition state resembling **35** relative to that resembling **34**. Robinson's theory would thus correctly predict a higher proportion of *cis*-fused decalone product in the present examples, relative to that "normally" found.



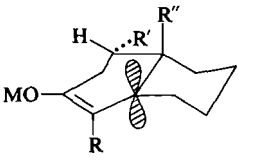
32 M = Li or H



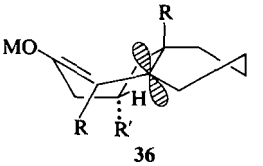
33 = Li or H



34



35



36

The effect of a C_{10} angular methyl group can also be understood in terms of Robinson's theory. In octalones **7–11**, the relative stabilization arising from changing the conformation of the intermediate from **34** to **35** would be somewhat off-set by the increased skew nonbonded interaction between the C_4-alkyl group (R′ in **35**) and the C_{10}-methyl group (R″ = CH_3 in **35**). Hence, in these octalones, the amount of *cis*-fused decalone formed on lithium–ammonia reduction would be expected to be less than in the case of octalone **4**. In the latter, as the conformation of the intermediate changes from **34** (R = R″ = H, R′ = isoPr) to **35**, there is no developing nonbonded interaction between the C_4-isopropyl group and the C_{10}-proton (R″ = H in **35**). Thus, although the magnitude of the effect of changing the C_{10}-substituent from a proton (in **4**) to a methyl group (in **9** and **11**) was not expected *a priori*, the results can be accounted for on a qualitative basis.

Finally, the effect of changing the size of the C_4-alkyl group must be mentioned. As the bulk of the C_4-alkyl group increases, it seems prob-

[5]The reasoning which led to this conclusion will not be reproduced here. However, Robinson has convincingly argued that the transition state for protonation at the β-carbon is not tetrahedral in shape (product-like transition state), since there is no correlation between product ratios and relative product stabilities.

[6]The representations used here differ slightly in detail from those in Robinson's paper. In our representations, we have taken into account the recent mechanistic work of House and co-workers (4, 5).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

able that the stabilization arising from changing the alkyl group from the axial orientation (**34**) to the equatorial-like orientation (**35**) would also increase somewhat. This would make the transition state resembling **35** increasingly more favored and could thus account for the observed fact that as the C_4-alkyl group increases in size, the amount of *cis*-fused decalone obtained also increases.

Experimental[7]

4α,4aβ-Dimethyl-4,4a,5,6,7,8-hexahydro-2(3H)-naphthalenone (7)

To a stirred, ice-cold slurry of 6.84 g of cuprous iodide in 150 ml of anhydrous ether was added 34.3 ml of 2.1 *M* methyllithium in ether. To the resulting clear solution was added dropwise, over a period of 1 h, 1 g (6.2 mmol) of the cross-conjugated dienone **13**. The resulting thick yellow reaction mixture was thoroughly extracted with ether. The combined ether extracts were successively washed with water, dilute ammonium hydroxide, water, and brine and then dried over anhydrous magnesium sulfate. Removal of the solvent followed by distillation of the residue under reduced pressure gave a clear oil, b.p. 124° at 0.3 mm, which was subjected to chromatography on 40 g of silica gel. The fractions eluted with 15% ether – petroleum ether (b.p. 30–60°) contained 900 mg (82%) of the octalone **7** (19, 44), a clear colorless oil which showed a single peak on analysis by g.l.c. (column A, 190°, 86). This material exhibited u.v. λ_{max} 239 nm (ε 14 000); i.r. (film) λ_{max} 6.0, 6.15 μ; p.m.r. τ 9.02 (d, 3H, secondary CH_3, J = 7 Hz), 8.74 (s, 3H, tertiary CH_3), 4.30 (s, 1H, vinyl H).

1,4α,4aβ-Trimethyl-4,4a,5,6,7,8-hexahydro-2(3H)-naphthalenone (10)

The reaction of dienone **14** with lithium dimethylcuprate was carried out by a procedure identical with that described above for the preparation of **7**. From 1 g of dienone **14** there was obtained 1 g (92%) of the trimethyloctalone **10**, b.p. 125°/0.3 mm, which was shown to be homogeneous by g.l.c. (column A, 200°, 86); u.v. λ_{max} 249 nm (ε 13 800); i.r. (film) λ_{max} 6.0, 6.2 μ; p.m.r. τ 9.04 (d, 3H, secondary CH_3, J = 6.5 Hz), 8.74 (s, 3H, tertiary CH_3), 8.25 (d, 3H, vinyl CH_3, J = 1 Hz).

This compound was further characterized as a red 2,4-dinitrophenylhydrazone, recrystallized from ethanol, m.p. 174–175°.

Anal. Calcd. for $C_{19}H_{24}N_4O_4$: C, 61.28; H, 6.50; N, 15.04. Found: C, 60.98; H, 6.42; N, 15.11.

4aβ-Methyl-4α-vinyl-4,4a,5,6,7,8-hexahydro-2(3H)-naphthalenone (12)

A solution of 15 g of tri-*n*-butylphosphine copper(I) iodide (23) in 150 ml of anhydrous ether was cooled to −78° by an external Dry Ice – acetone bath. Addition of 22.8 ml of 3.2 *M* vinyllithium in tetrahydrofuran gave a pale green solution, to which was added, over a period of 1 h, a solution of 1 g of the dienone **13** in 50 ml of dry ether. The resulting thick yellow reaction mixture was allowed to stir at −78° for 4 h. The mixture was allowed to warm to room temperature and was then poured into 250 ml of rapidly stirring 10% hydrochloric acid. The aqueous mixture was thoroughly extracted with ether. The combined ether extracts were washed successively with water, dilute ammonium hydroxide, water, and brine and then dried over anhydrous magnesium sulfate. After removal of the solvent, the desired product was roughly separated from the high boiling material by collecting all material with a boiling point less than 130° at 0.2 mm. The resulting distillate was subjected to chromatography on 100 g of silica gel. The fractions eluted with 10% ether – petroleum ether (b.p. 30–60°) afforded 870 mg (73%) of the desired octalone **12**. The latter showed only one peak by g.l.c. analysis (column A, 195°, 100), and exhibited i.r. (film) λ_{max} 6.0, 6.2, 10.9 μ; p.m.r. τ 8.72 (s, 3H, tertiary methyl), 3.89–5.13 (m, 3H, $-CH=CH_2$), 4.25 (s, 1H, vinyl H). Due to its instability, octalone **12** was not characterized further but was immediately subjected to hydrogenation.

4α-Ethyl-4aβ-methyl-4,4a,5,6,7,8-hexahydro-2(3H)-naphthalenone (8)

The hydrogenation of the octalone **12** (708 mg) was carried out in benzene (50 ml) solution at room temperature and atmospheric pressure using tris(triphenylphosphine)chlororhodium (120 mg) as catalyst. After uptake of hydrogen had essentially ceased, the reaction mixture was filtered through a column of Woelm activity III neutral alumina (20 g). The column was eluted with an additional 100 ml of benzene. Removal of the solvent, followed by distillation of the crude product under reduced pressure afforded 650 mg of a clear colorless oil. Analysis of this material by g.l.c. (column A, 180°, 100) showed that it consisted of a mixture of the decalone **28** (~10%) and the desired octalone **8** (~90%). The mixture was separated by chromotography on 50 g of silica gel. The fractions eluted with 8% ether – petroleum ether (b.p. 30–60°) contained 57 mg of the *cis*-fused decalone **28**, while the fractions eluted with 15% ether – petroleum ether (b.p. 30–60°) contained 413 mg (58%) of the desired octalone **8**; u.v. λ_{max} 239 nm (ε 11 000); i.r. (film) λ_{max} 6.0, 6.2 μ; p.m.r. τ 9.07 (t, 3H, $-CH_2-CH_3$, J = 4 Hz), 8.73 (s, 3H, tertiary CH_3), 4.21 (broad s, 1H, vinyl H).

This compound was further characterized as a red 2,4-dinitrophenylhydrazone derivative, recrystallized from ethanol, m.p. 118–120°.

Anal. Calcd. for $C_{19}H_{24}N_4O_4$: C, 61.28; H, 6.50; N, 15.04. Found: C, 61.07; H, 6.42; N, 15.05.

4α-Isopropyl-4aβ-methyl-4,4a,5,6,7,8-hexahydro-2(3H)-naphthalenone (9)

A solution of 15 g (38 mmol) of tri-*n*-butylphosphine copper(I) iodide and 0.5 g of anhydrous lithium bromide in 150 ml of anhydrous ether was cooled to −78° with an external Dry Ice – acetone bath. A solution of isopropyllithium in pentane (39 ml, 1.86 *M*, 73 mmol) was added, forming first a dark red and then a pale aqua solution. To this solution was added, over a period of 45 min, a solution of 1 g (6.1 mmol) of the dienone **13** in 50 ml of anhydrous ether. The dark red reaction mixture was allowed to stir at −78° for an additional 5 h and was then allowed to warm to room temperature. The reaction mixture was transferred under nitrogen to a dropping funnel and then added slowly to a rapidly stirring solution of

10% hydrochloric acid. The resulting mixture was extracted thoroughly with ether. The combined ether extracts were washed successively with water, dilute ammonium hydroxide, water, and brine and then dried over anhydrous magnesium sulfate. Removal of the solvent and distillation of the residue under reduced pressure afforded an oil which was further purified by chromatography on 25 g of silica gel. The fractions eluted with 20% ether – petroleum ether (b.p. 30–60°) gave 395 mg (95%) of the desired octalone **9**. This material showed one component by g.l.c. (column A, 180°, 86) and exhibited u.v. λ_{max} 240 nm (ε 9400); i.r. (film) λ_{max} 6.0, 6.15 μ; p.m.r. τ 9.20, 9.05 (d, d, 6H, —CH(CH_3)$_2$, J = 6.5 Hz), 8.74 (s, 3H, tertiary CH_3), 4.22 (broad s, 1H, vinyl H).

This compound was further characterized as its 2,4-dinitrophenylhydrazone derivative, recrystallized from ethanol, m.p. 153–155°.

Anal. Calcd. for $C_{20}H_{26}N_4O_4$: C, 62.16; H, 6.78; N, 14.50. Found: C, 62.01; H, 6.80; N, 14.40.

*4α-Isopropyl-1,4aβ-dimethyl-4,4a,5,6,7,8-hexahydro-2(3H)-naphthalenone (**11**)*

The reaction of lithium diisopropylcuprate with the cross-conjugated dienone **14** was carried out via a procedure identical with that described above for the preparation of octalone **9**.

From 2 g of the dienone **14** there was obtained, after chromatography of the crude product on 140 g of silica gel, 2.38 g (95%) of the desired octalone **11**. This material showed one component by g.l.c. (column A, 190°, 86) and exhibited u.v. λ_{max} 294 nm (ε 14 000); i.r. (film) λ_{max} 6.0, 6.2 μ; p.m.r. τ 9.23, 9.04 (d, d, 6H, —CH(CH_3)$_2$, J = 7 Hz), 8.73 (s, 3H, tertiary CH_3), 8.22 (s, 3H, vinyl CH_3).

This compound was further characterized as a red 2,4-dinitrophenylhydrazone derivative, recrystallized from ethanol, m.p. 134–135°.

Anal. Calcd. for $C_{21}H_{28}N_4O_4$: C, 62.98; H, 7.05; N, 13.99. Found: C, 63.13; H, 6.90; N, 13.76.

*3α-Bromo-1α,4aβ-dimethyl-trans-3,4,4a,5,6,7,8,8a-octahydro-2(1H)-naphthalenone (**26**)*

To a solution of 7.9 g (44 mmol) of the dimethyldecalone **23** (42) in 50 ml of isopropenyl acetate was added 0.1 ml of 98% sulfuric acid. The solution was refluxed under an atmosphere of nitrogen for 2.5 h. Most of the isopropenyl acetate was removed under reduced pressure and the residue was diluted with ether. The ether solution was washed successively with water, 5% aqueous sodium bicarbonate, water, and brine and dried over anhydrous magnesium sulfate. Removal of the solvent followed by chromatography of the crude product on 150 g of Woelm activity III neutral alumina, gave 9.5 g of a mixture of enol acetates **24** and **25**, in a ratio of approximately 85:15, respectively. The mixture exhibited i.r. (film) λ_{max} 5.7, 5.95 μ.

The mixture of enol acetates (9.5 g) **24** and **25** was dissolved in 100 ml of glacial acetic acid containing 10 g of anhydrous sodium acetate. To the resulting solution was added, over a period of 1 h, a solution of 7.2 g of bromine in 50 ml of glacial acetic acid. After the addition was complete, the reaction mixture was allowed to stir for an additional 15 min. The glacial acetic acid was removed under reduced pressure, the residue was diluted with water and then thoroughly extracted with ether. The combined ether extracts were washed successively with water, aqueous sodium bicarbonate, water, and brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave a crystalline material which, upon recrystallization from petroleum ether (b.p. 30–60°), afforded 9.2 g (85%) of the bromoketone **26**, m.p. 69–70°; i.r. ($CHCl_3$) λ_{max} 5.8 μ; p.m.r. τ 8.99 (d, 3H, secondary CH_3, J = 6.5 Hz), 8.84 (s, 3H, tertiary CH_3), 5.13 (d of d, 1H, —C(=O)—CH(Br)—, J = 14, 6 Hz).

Anal. Calcd. for $C_{12}H_{19}OBr$: C, 55.60; H, 7.34; Br, 30.89. Found: C, 55.59; H, 7.26; Br, 30.86.

*1α,4aβ-Dimethyl-trans-4a,5,6,7,8,8a-hexahydro-2(1H)-naphthalenone (**22**)*

A solution of 4 g (15 mmol) of the bromoketone **26** and 1.5 g of anhydrous lithium bromide in 35 ml of hexamethylphosphoramide was heated to 120° and kept at this temperature for 3 h. The solution was cooled, diluted with water, and thoroughly extracted with ether. The combined ether extracts were washed thrice with water, once with brine, and dried over anhydrous magnesium sulfate. Removal of the solvent gave an oil which was shown by g.l.c. (column A, 185°, 86) to consist mainly of the desired octalone **22**, contaminated by a small amount of 1,10-dimethyl-$\Delta^{1,9}$-2-octalone. Chromatography of this material on 100 g of silica gel gave, upon elution of the column with 3% ether – benzene, 2 g (72%) of the octalone **22**. The latter exhibited u.v. λ_{max} 229 nm (ε 9200); i.r. (film) λ_{max} 6.0, 6.15 μ; p.m.r. τ 8.93 (s, 3H, tertiary CH_3), 8.92 (d, 3H, secondary CH_3, J = 7 Hz), 4.19, 3.35 (d of d, 2H, —C(=O)—C*H*=CH— and —C(=O)—CH=C*H*—, respectively, J = 9 Hz).

This compound was further characterized as a red 2,4-dinitrophenylhydrazone derivative, recrystallized from ethanol, m.p. 198–199°.

Anal. Calcd. for $C_{18}H_{22}N_4O_4$: C, 60.32; H, 6.19; N, 15.63. Found: C, 60.51; H, 6.11; N, 15.73.

*4α,4aβ-Dimethyl-trans-3,4,4a,5,6,7,8,8a-octahydro-2(1H)-naphthalenone (**15**)*

To a stirred ice-cold slurry of 2.3 g of cuprous iodide in 67 ml of anhydrous ether under nitrogen, was added 11.4 ml of 2.1 *M* ethereal methyllithium. To the resulting clear solution was added dropwise over a period of 30 min, a solution of 328 mg (2 mmol) of the octalone **21** (41) in 40 ml of anhydrous ether. The reaction mixture was allowed to stir at 0° for an additional 1.5 h and was then poured slowly into rapidly stirring 10% aqueous hydrochloric acid. The resulting mixture was thoroughly extracted with ether. The combined ether extracts were washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residue under reduced pressure, afforded 345 mg (98%) of the desired dimethyldecalone **15**, b.p. 110°/0.2 mm (lit. (44) b.p. 133–137°/9 mm). This material showed one component by g.l.c. (column A, 190°, 100) and exhibited i.r. (film) λ_{max} 3.45, 5.85 μ; p.m.r. τ 9.08 (d, H, secondary CH_3, J = 6.5 Hz), 8.87 (s, 3H, tertiary CH_3).

*1α,4α,4aβ-Trimethyl-trans-3,4,4a,5,6,7,8,8a-octahydro-2(1H)-naphthalenone (**18**)*

This compound was prepared by the reaction of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

lithium dimethylcuprate with the dimethyloctalone **22** via a procedure essentially identical with that described above for the preparation of decalone **15**. The crude product obtained from 200 mg (1.2 mmol) of the octalone **22** was subjected to chromatography on silica gel (20 g). The fractions eluted with 5% ether – petroleum ether (b.p. 30–60°) afforded 189 mg (93%) of the desired *trans*-decalone **18**. An analytical sample was obtained by preparative g.l.c. (column A, 190°, 86) and exhibited i.r. (film) λ_{max} 5.85 μ; p.m.r. τ 9.10, 9.02 (d, d, 6H, secondary methyls, J = 7 Hz), 8.77 (s, 3H, tertiary CH_3), 7.97 (d of d, 1H, H-3e, J = 2.2 and 14 Hz), 7.21 (d of d, H-3a, J = 6 and 14 Hz).

This compound was further characterized as an orange 2,4-dinitrophenylhydrazone derivative, recrystallized from ethanol, m.p. 167–168°.

Anal. Calcd. for $C_{19}H_{26}N_4O_4$: C, 60.95; H, 7.00; N, 14.96. Found: C, 60.66; H, 6.87; N, 15.06.

*4aβ-Methyl-4α-vinyl-trans-3,4,4a,5,6,7,8,8a-octahydro-2(1H)-naphthalenone (**20**)*

A solution of tri-*n*-butylphosphine copper(I) iodide (4 g) in anhydrous ether (50 ml) was cooled, under nitrogen, to −78° by means of an external Dry Ice – acetone cooling bath. A solution of 3.1 *M* vinyllithium in tetrahydrofuran (6.4 ml) was added dropwise until the initially formed red solution became colorless. To this solution was added dropwise, over a period of 30 min, a solution of the octalone **21** (328 mg, 2 mmol) in 50 ml of anhydrous ether. The brown reaction mixture was allowed to stir for an additional 5 h at −78° and then allowed to warm slowly to room temperature. The reaction mixture was transferred under nitrogen to an addition funnel and was added dropwise to 100 ml of rapidly stirring 10% hydrochloric acid. The mixture was extracted thoroughly with ether. The combined ethereal extracts were washed successively with dilute ammonium hydroxide, water, and brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave a viscous yellow oil which was subjected to chromatography on 50 g of silica gel. The fractions eluted with 15% ether – petroleum ether (b.p. 30–60°) contained 280 mg (73%) of the desired decalone **20**. This material was distilled (b.p. 130° at 0.15 mm) to afford an oil which showed only one component by g.l.c. (column A, 190°, 100) and exhibited i.r. (film) λ_{max} 5.85, 6.1, 10.9 μ; p.m.r. τ 8.88 (s, 3H, tertiary CH_3), 4.0–5.2 (m, 3H, —CH=CH_2).

This compound was further characterized as a dark red 2,4-dinitrophenylhydrazone derivative, m.p. 186° (from ethanol).

Anal. Calcd. for $C_{19}H_{24}N_4O_4$: C, 61.28; H, 6.50; N, 15.04. Found: C, 60.98; H, 6.41; N, 14.94.

*4α-Ethyl-4aβ-methyl-trans-3,4,4a,5,6,7,8,8a-octahydro-2(1H)-naphthalenone (**16**)*

The hydrogenation of the vinyl-substituted decalone **20** was done at atmospheric pressure and room temperature using 10% palladium-on-charcoal as catalyst and absolute ethanol as solvent. From 675 mg of decalone **20** there was obtained 670 mg (98%) of the ethyl-substituted decalone **16**. The product showed one component by g.l.c. (column A, 180° 86) and exhibited i.r. (film) λ_{max} 5.85 μ; p.m.r. τ 8.88 (s, 3H, tertiary CH_3).

This compound was further characterized as a pale orange 2,4-dinitrophenylhydrazone, m.p. 192–193° (from ethanol).

Anal. Calcd. for $C_{19}H_{26}N_4O_4$: C, 60.95; H, 7.00; N, 14.96. Found: 60.74; H, 6.89; N, 14.92.

*4α-Isopropyl-4aβ-methyl-trans-3,4,4a,5,6,7,8,8a-octahydro-2 (1H)-naphthalenone (**17**)*

To a solution of 4 g of tri-*n*-butylphosphine copper(I) iodide in 60 ml of anhydrous ether at −78° under nitrogen was added 11 ml of 1.86 *M* isopropyllithium in *n*-pentane. To the resulting aqua solution was added dropwise, over a period of 30 min, a solution of 328 mg (2 mmol) of the octalone **21** in 10 ml of anhydrous ether. After the addition was complete, the dark red reaction mixture was allowed to stir for an additional 3h at −78°, was transferred under nitrogen to an addition funnel, and then added dropwise to 50 ml of rapidly stirring 10% hydrochloric acid. The resulting mixture was thoroughly extracted with ether. The combined ether extracts were washed successively with water, dilute ammonium hydroxide, water, and brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave a viscous oil which was distilled under reduced pressure (0.1 mm). All material with b.p. of less than 150° was collected. The distillate was further purified by chromatography over 35 g of silica gel. The fractions eluted with 20% ether – petroleum ether (b.p. 30–60°) contained 297 mg (72%) of the *trans*-fused decalone **17**, which crystallized on standing. Recrystallization of this material from *n*-hexane gave an analytical sample, m.p. 49–50° (lit. m.p. (41) 49–50°); i.r. ($CHCl_3$) λ_{max} 5.87 μ; p.m.r. τ 9.08, 9.17 (d, d, 6H, —CH(CH_3)$_2$, J = 6.8 Hz), 8.89 (s, 3H, tertiary CH_3).

*4α-Isopropyl-1α,4aβ-dimethyl-trans-3,4,4a,5,6,7,8,8a-octahydro-2(1H)-naphthalenone (**19**)*

This compound was prepared by the reaction of lithium diisopropylcuprate with the dimethyloctalone **22** via a procedure essentially identical with that described above for the preparation of decalone **17**. The crude product obtained from 356 mg (2.1 mmol) of octalone **22** was distilled (b.p. 120°/0.3 mm) and the distillate was further purified by chromatography on 20 g of silica gel. Elution with benzene afforded 262 mg (82%) of the desired decalone **19**, which showed one component by g.l.c. analysis (column A, 198°, 86) and exhibited i.r. (film) λ_{max} 5.85 μ; p.m.r. τ 9.21, 9.09 (d, d, 6H, —CH(CH_3)$_2$, J = 6.5 Hz), 9.00 (d, 3H, secondary CH_3, J = 6 Hz), 8.87 (s, 3H, tertiary CH_3); p.m.r. (benzene) τ 7.74 (d of d, 1H, H-3a, J = 15.5, 7.6 Hz), 7.56 (d of d, 1H, H-3e, J = 15.5, 2.4 Hz).

The product was further characterized as a yellow 2,4-dinitrophenylhydrazone derivative, recrystallized from ethanol, m.p. 145–146°.

Anal. Calcd. for $C_{21}H_{30}N_4O_4$: C, 62.67; H, 7.51; N, 13.92. Found: C, 62.55; H, 7.50; N, 13.73.

*4α,4aβ-Dimethyl-cis-3,4,4a,5,6,7,8,8a-octahydro-2(1H)-naphthalenone (**27**)*

A suspension of 20 mg of 10% palladium-on-charcoal in 15 ml of 0.3 *N* ethanolic sodium hydroxide solution was stirred for 1 h under an atmosphere of hydrogen at room temperature. A solution of 122 mg (0.68 mmol) of octalone **7** in 10 ml of ethanol was added by means of a syringe. After the calculated amount of hydrogen had been taken up, the mixture was filtered and the filtrate was concentrated under reduced pressure. The residue was diluted with water and the resulting mixture was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

thoroughly extracted with ether. The combined ether extracts were washed successively with 5% hydrochloric acid, 5% aqueous sodium bicarbonate, water, and brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residue under reduced pressure, gave 119 mg (97%) of the *cis*-fused decalone **27**, b.p. 110°/0.2 mm. This material was shown to be homogeneous by g.l.c. (column A, 190°, 86) and exhibited i.r. (film) λ_{max} 5.85 μ; p.m.r. τ 9.10 (d, 3H, secondary CH_3, J = 7 Hz), 8.95 (s, 3H, tertiary CH_3).

This compound was further characterized as a yellow 2,4-dinitrophenylhydrazone derivative, m.p. 161–162° (from ethanol).

Anal. Calcd. for $C_{18}H_{24}N_4O_4$: C, 59.99; H, 6.71; N, 15.55. Found: C, 59.99; H, 6.80; N, 15.46.

1β,4α,4aβ-Trimethyl-cis-3,4,4a,5,6,7,8,8a-octahydro-2(1H)-naphthalenone (30)

This compound was obtained by hydrogenation of octalone **10** under conditions identical with those used for the preparation of **27**. From 130 mg of **10** there was obtained 125 mg (95%) of a colorless oil, b.p. 115°/0.2 mm, which showed one component by g.l.c. (column A, 180°, 86). Compound **30** exhibited i.r. (film) λ_{max} 5.85 μ; p.m.r. τ 9.08, 9.01 (d, d, 6H, secondary methyls, J = 6.5 Hz), 8.92 (s, 3H, tertiary CH_3), 7.85 (d of d, 1H, H-3e, J = 13, 3.6 Hz), 7.64 (d of d, 1H, H-3a, J = 13, 14.4 Hz), 7.35 (overlapped d of q, 1H, H-1a, J = 13, 6 Hz).

The decalone **30** was further characterized as its 2,4-dinitrophenylhydrazone derivative, m.p. 213–214° (from ethanol).

Anal. Calcd. for $C_{19}H_{26}N_4O_4$: C, 60.95; H, 7.00; N, 14.96. Found: C, 60.85; H, 7.08; N, 14.93.

4α-Ethyl-4aβ-methyl-cis-3,4,4a,5,6,7,8,8a-octahydro-2(1H)-naphthalenone (28)

The hydrogenation of octalone **8** was carried out under conditions identical with those employed for the synthesis of decalone **27**. From 100 mg of octalone **8** there was obtained 96 mg (95%) of a clear colorless oil which was shown by g.l.c. analysis (column A, 180°, 86) to be greater than 95% pure. An analytical sample of the decalone **28** was collected by preparative g.l.c. and exhibited i.r. (film) λ_{max} 5.85 μ; p.m.r. τ 8.90 (s, 1H, tertiary CH_3).

This compound was further characterized as a yellow 2,4-dinitrophenylhydrazone derivative, m.p. 174° (from ethanol).

Anal. Calcd. for $C_{19}H_{26}N_4O_4$: C, 60.95; H, 7.00; N, 14.96. Found: C, 60.81; H, 6.85; N, 14.88.

4α-Isopropyl-4aβ-methyl-cis-3,4,4a,5,6,7,8,8a-octahydro-2(1H)-naphthalenone (29)

Octalone **9** was subjected to hydrogenation under conditions identical with those described previously for the preparation of decalone **27**. From 100 mg of octalone **9** there was obtained 96 mg (96%) of an oil which was shown by g.l.c. analysis (column A, 190°, 86) to consist of two components in a ratio of 95:5. The minor component exhibited a retention time identical with that of the *trans*-fused decalone **17**. An analytical sample of the major component, *cis*-fused decalone **29**, was collected by preparative g.l.c. and exhibited i.r. (film) λ_{max} 5.85 μ; p.m.r. τ 9.19, 9.10 (d, d, 6H, $-CH(CH_3)_2$, J = 6.5 Hz), 8.88 (s, 3H, tertiary CH_3).

This compound was further characterized as an orange 2,4,-dinitrophenylhydrazone derivative, recrystallized from ethanol; m.p. 180–181°.

Anal. Calcd. for $C_{20}H_{28}N_4O_4$: C, 61.84; H, 7.27; N, 14.42. Found: C, 61.86; H, 7.35; N, 14.30.

4α-Isopropyl-1β,4aβ-dimethyl-cis-3,4,4a,5,6,7,8,8a-octahydro-2(1H)-naphthalenone (31)

This compound was prepared by hydrogenation of octalone **11** via a procedure identical with that described for the preparation of decalone **27**. From 100 mg of octalone **11** there was obtained 96 mg (95%) of an oil which exhibited one component by g.l.c. (column A, 180°, 86) and produced the following spectral data: i.r. (film) λ_{max} 5.85 μ; p.m.r. τ 9.19, 9.11 (d, d, 6H, $-CH(CH_3)_2$, J = 6.5 Hz), 9.01 (d, 3H, secondary CH_3, J = 6 Hz), 8.89 (s, 3H, tertiary CH_3), 7.86 (m, 1H, H-3e, J = 14, 3.6 Hz), 7.63 (m, 1H, H-3a, J = 14, 14.3 Hz), 8.30 (m, 1H, H-1a, J = 13, 6 Hz).

This *cis*-fused decalone **31** was further characterized as its 2,4-dinitrophenylhydrazone derivative, m.p. 188–189° (from ethanol).

Anal. Calcd. for $C_{21}H_{30}N_4O_4$: C, 62.67; H, 7.51; N, 13.92. Found: C, 62.46; H, 7.28; N, 14.01.

Lithium–Ammonia Reduction of 4α-Alkyl-4aβ-methyl-4,4a,5,6,7,8-hexahydro-2(3H)-naphthalenones (7, 8, 9) and of 4α-Alkyl-1,4aβ-dimethyl-4,4a,5,6,7,8-hexahydro-2(3H)-naphthalenones (10, 11). General Procedure

To 60 ml of liquid ammonia (freshly distilled from sodium metal) was added 55 mg of finely cut lithium wire. After all the lithium had dissolved, a solution of 0.56 mmol of the appropriate octalone in 10 ml of anhydrous ether was added dropwise over a period of 30 min. The reaction mixture was allowed to stir for an additional 2 h and the blue color was then discharged by careful addition of ammonium chloride. The liquid ammonia was allowed to evaporate and the residue was diluted with water and neutralized by addition of hydrochloric acid. The resulting mixture was thoroughly extracted with ether. The combined ether extracts were washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residual material under reduced pressure afforded an oil which was subjected to analysis by g.l.c. (column A, 160–190°, 86). In each case, g.l.c. conditions were found in which the starting material (octalone), the corresponding *cis*-fused decalone, and the corresponding *trans*-fused decalone exhibited distinct retention times. The percent composition of each product was determined by integration (disc integrator). The products from each reduction were identified by isolation (preparative g.l.c.) and comparison (i.r., p.m.r.) with authentic samples prepared as described previously.

In each case, samples of *cis*-fused and *trans*-fused decalones were carefully weighed and then combined to afford authentic mixtures of known composition approximating that observed in the appropriate lithium–ammonia reduction. Analysis of these authentic mixtures by g.l.c. showed that the observed ratio was, within experimental error, identical with the known ratio; that is, in each case, the g.l.c. molar response factors of the *cis*- and *trans*-fused decalones were, within experimental error, identical.

Each lithium–ammonia reduction was carried out at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

least in triplicate. The results recorded in Table 1 represent average values.

Nucleic Acid Related Compounds. 16. Direct Fluorination of Uracil Nucleotides Using Trifluoromethyl Hypofluorite[1]

MORRIS J. ROBINS, G. RAMANI,[2] AND MALCOLM MACCOSS[3]

Department of Chemistry, The University of Alberta, Edmonton, Alberta T6G 2G2

Received June 3, 1974[4]

MORRIS J. ROBINS, G. RAMANI, and MALCOLM MACCOSS. Can. J. Chem. **53**, 1302 (1975).

Treatment of commercially available uracil nucleotides and dinucleoside phosphates in methanolic solutions with trifluoromethyl hypofluorite in trichlorofluoromethane (Freon 11) gave adducts which were converted into the corresponding 5-fluorouracil nucleotides in basic solution. This procedure circumvents certain problems involved in phosphorylation of the rather inaccessible and expensive 5-fluorouracil nucleosides.

Salts of both 5-fluorouridine-5′-monophosphate (5′-FUMP) and 5-fluorouridine-3′,5′-cyclic monophosphate (cFUMP) were crystallized and fully characterized. The procedure is not readily applicable to dinucleoside phosphates.

MORRIS J. ROBINS, G. RAMANI et MALCOLM MACCOSS. Can. J. Chem. **53**, 1302 (1975).

La réaction de l'hypofluorite de trifluorométhyle en solution dans de la fluorure de trichlorométhyle (Freon 11) avec des solutions méthanoliques de nucléotides et de diphosphates de nucléosides obtenus de sources commerciales donne des adduits qui sont transformés, en solution basique, en nucléotides fluorés en position 5 correspondants. Ce procédé évite certains problèmes rencontrés lors de la formation de phosphates des nucléosides, difficilement accessibles et coûteux, du fluoro-5-uracil.

Les sels des monophosphates-5′ de la fluoro-5-uridine (5′-FUMP) et du monophosphate cyclique-3′,5′ de la fluoro-5 uridine ont été cristallisés et entièrement caractérisés. Ce procédé n'est pas applicable directement aux phosphates de dinucléosides.

Previous extensive studies (1) on 5-fluoropyrimidines and their higher metabolic derivatives had uniformly involved "*de novo*" construction of the fluorinated bases from small aliphatic precursors such as the highly toxic ethyl fluoroacetate (1, 2). Chemical or enzymatic coupling of these base derivatives with a suitably functionalized sugar produced the nucleoside (see for example, 3–7 and references therein). Phosphorylation and/or coupling (with another nucleoside or nucleotide) then gave nucleotide derivatives (see for example, 8–15). Nucleotides of 5-fluorouracil have been evaluated for cytotoxicity (1, 9, 15, 16), as substrates for RNA polymerase (12), as nearest neighbor of associated DNA (17), as substrates for polynucleotide phosphorylase and in investigation of biophysical effects in the resulting homo or copolymers (13, 14), and for ribosome binding and stimulation of amino acid incorporation (14, 18).

Conventional synthetic routes to the final nucleotide products involve specific blocking, phosphorylation and/or coupling, chromatographic separation of the desired nucleotide from unreacted starting materials and polycondensation products, and then deblocking. Often these sequences have been effected in less than satisfactory overall yields. Preliminary communications from our laboratory (19, 20) have described the direct introduction of fluorine at the 5 position of uracil, cytosine, and their nucleosides in high yields using trifluoromethyl hypofluorite in organic solvents.

We now wish to report the synthesis of 5-fluorouracil nucleotides from the commercially available uracil compounds by direct fluorination. Trifluoromethyl hypofluorite in trichlorofluoromethane (CAUTION[5]) was added to

[1]For the previous paper in this series see ref. 24.

[2]Postdoctoral Fellow 1971–1973.

[3]Postdoctoral Fellow 1972–Present.

[4]Revision received December 27, 1974.

[5]CAUTION: Trifluoromethyl hypofluorite (CF_3OF) is a toxic, strong oxidizing agent. We have experienced no problems in the addition of CF_3OF in CCl_3F at $-78°$ to cold (usually $-78°$) solutions of substrates in methanol, chloroform, or aqueous mixtures. However, we have been informed of violent explosions occurring upon direct introduction of gaseous CF_3OF into methanol. Direct addition of CF_3OF to alcohols or other easily oxidizable substrates (especially at room temperature) should not be attempted.

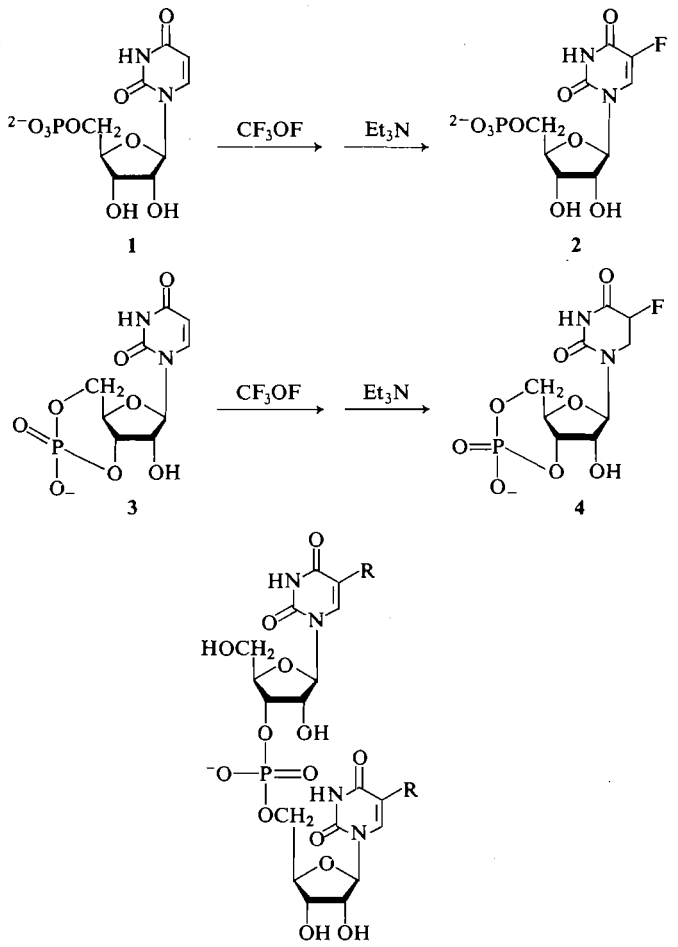

SCHEME 1

cold solutions of the nucleotide tetra-*n*-butylammonium salts in methanol or other salts in aqueous methanol (see Experimental). Reactions proceeded rapidly with loss of u.v. absorption of the uracil chromophore at 260 nm, presumably to give the 5,6-dihydrouracil adduct with fluorine at C_5 and alkoxyl or hydroxyl at C_6. Excess reagent and solvents were evaporated and the adduct residues were treated with aqueous amine solutions to generate the 5-fluorouracil products.

Reactions of the mononucleotides proceeded in good yields as estimated spectroscopically and chromatographically. Both 5-fluorouridine-5′-monophosphate (**2**) and 5-fluorouridine-3′,5′-cyclic monophosphate (**4**) (see Scheme 1) were obtained as analytically pure crystalline salts. Samples of these compounds were hydrolyzed enzymatically to give 5-fluorouridine which was rigorously identified by chromatographic; u.v., ^1H and ^{19}F n.m.r., and mass spectral; and mixture m.p. comparisons with an authentic sample (19).

Although reaction of 5′-UMP (**1**) with trifluoromethyl hypofluorite proceeded readily, quantitative generation of **2** was not observed and varying amounts (~20%) of a non-u.v. absorbing nucleotide product remained after basic treatment. Stronger base or acid treatment of this material did not generate **2** and its

structure is unknown.[6] Also, the presence of tightly associated fluoride was observed with initially precipitated samples of **2** (disodium salt). Analytical values for fluorine were essentially twice the theoretical amount. The ^1H n.m.r. spectrum of this material was in agreement with the structure of **2** and integrated intensities as well as splitting patterns precluded difluorination of the uracil ring. The corresponding ^{19}F n.m.r. spectrum contained a peak with the appropriate splitting for the C_5—F substituent plus broad absorption in the range expected for fluoride anion. A ^{31}P n.m.r. spectrum contained no evidence of P—F bonding. Reprecipitation from aqueous alcoholic solutions failed to reduce the analytical value for fluorine content. Adsorption of the sample on a carbon column, washing the column with 0.1 *N* aqueous sodium chloride solution and then distilled water, elution of the nucleotide with ammonia in ethanol–water, and conversion to the crystalline disodium salt gave **2** with analytical values in agreement with theory.

An analytically pure powder can be obtained readily by applying the reaction product directly to a Dowex 1-X2(HCO_2^-) column, elution of product with formic acid (9), and conversion to the dilithium salt of **2**. Thus, caution should be exercised in assuring that compounds are free from presumably tightly associated fluoride (see ref. 21 for a case of tightly associated mercury ions in nucleoside synthesis).

The dinucleoside phosphates uridylyl-3′ → 5′-uridine (UpU) (**5***a*), uridylyl-3′ → 5′-adenosine (UpA), and adenylyl-3′ → 5′-uridine (ApU) were subjected to this two step procedure. Preliminary studies have indicated that the adenine ring is unreactive toward CF_3OF under these mild conditions. Enzymatic hydrolysis of the product from UpU (**5***a*) using crude snake venom plus bacterial alkaline phosphatase gave 5-fluorouridine as the only u.v. absorbing component (t.l.c. and spectral comparisons). Similarly, UpA and ApU reaction products were found to give adenosine and 5-fluorouridine upon enzymatic hydrolysis. However, more careful examination of the UpU reaction mixture using electrophoresis and anion exchange chromatography on DEAE cellulose columns indicated that free 5-fluorouridine and 5-fluorouridinemonophosphate(s) were present as well as u.v. absorbing products which were not hydrolyzed to 5-fluorouridine by pancreatic ribonuclease. The desired 5-fluorouridylyl-3′ → 5′-5-fluorouridine (FUpFU) was present in less than 20% yield from starting UpU. The ApU and UpA reactions appeared to be equally complex and were not investigated further.

This study extends the convenient direct fluorination of pyrimidine bases using trifluoromethyl hypofluorite (19, 20, 22) to mononucleotides. The feasibility of employing this general method with dinucleotides was briefly investigated and found to be severely limited.

Details of the uracil adduct structure and experimental procedures for various uracil and cytosine nucleosides will be reported shortly.

Experimental

Ultraviolet spectra were determined on Cary 14 or 15 spectrophotometers by dissolving the sample in a few drops of water and then diluting accurately to 100 cc with methanol. Nuclear magnetic resonance spectra were determined in D_2O with TMS as external ^1H reference on Varian A-60, HA-100, and Brüker 90 spectrometers. Evaporations were accomplished using a Büchler rotating evaporator under reduced pressure (aspirator or vacuum pump) at 40° or lower. Mass spectra were determined by the Mass Spectroscopy Laboratory in this Department on an AEI MS-2 spectrometer using a direct probe at 70 eV and 200°.

Alkaline phosphatase (EC 3.1.3.1) (*E. coli* Type III), phosphodiesterase (EC 3.1.4.1) crude venom from *Crotalus adamanteus* (Type VI), ribonuclease (2.7.7.16) (Type I-A), uridine-5′-monophosphate (5′-UMP), uridylyl-3′ → 5′-adenosine (UpA), uridylyl-3′ → 5′-uridine (UpU), and adenylyl-3′ → 5′-uridine (ApU) were purchased from Sigma Chemical Company, St. Louis, Missouri. Trifluoromethyl hypofluorite was purchased from PCR, Inc., Gainsville, Florida. Uridine-3′,5′-cyclic monophosphate (cUMP) was a gift from Dr. R. A. Long, ICN Nucleic Acid Research Institute, Irvine, California.

Descending chromatography was effected using Whatman No. 1 paper and the following solvent systems: *A*, EtOH – 1 *M* NH_4OAc at p*H* 7.2 (7.5:3.0); *B*, 0.0005 *M* sodium borate – isopropyl alcohol (1:2); *C*, EtOH – 1 *M* NH_4OAc at p*H* 7.5 (7:3). Nucleosides obtained by enzymatic dephosphorylation were resolved by t.l.c. on Eastman silica gel sheet No. 13181 using the upper phase of EtOAc–*n*-PrOH–H_2O (4:1:2). Electrophoresis was performed on a Savant flat-plate apparatus (HV-3000A) using Whatman No. 1 paper.

5-Fluorouridine-5′-monophosphate (5′-FUMP) (2)

To a vigorously stirred solution of 0.39 g (0.001 mol) of uridine-5′-monophosphate disodium salt (**1**) (containing 6% H_2O) in 80 ml of H_2O–MeOH (14:66) at −78° was added a solution of 1.4 g (0.013 mol) of CF_3OF

[6]See ref. 23 for discussion concerning the failure of 6-hydroxy-5-fluoro-5,6-dihydrouracil adducts to be converted to 5-fluorouracils in alkaline solution.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

in 10 ml of CCl_3F at −78°. The u.v. absorption of the solution at 262 nm rapidly decreased to a minimum value in ~5 min. After ~10 min further stirring, nitrogen was bubbled through the solution for 25 min to remove excess reagent while the temperature was allowed to rise to room temperature. The solution was then evaporated to dryness and the resulting white solid foam was dissolved in 5 ml of MeOH. A 10 ml portion of Et_3N–MeOH–H_2O (10:45:45) was added and the solution was stirred at room temperature overnight. Evaporation of this solution *in vacuo* gave a white solid foam which was estimated by u.v. spectroscopy to contain ~70% yield of **2**. This material was dissolved in ~5 ml of H_2O and applied to a column (2 × 20 cm) of Dowex 1-X2 (HCO_2^-) resin packed in H_2O. The column was washed with 1250 ml of H_2O and elution was begun with a linear gradient consisting of 2000 ml of H_2O in the mixing chamber and 2000 ml of 1 *N* HCO_2H in the reservoir followed by 1 *N* HCO_2H to completion. The eluate was monitored spectrophotometrically at 254 nm. Product was eluted after 3450 ml of gradient had passed through and the following 1225 ml was pooled and evaporated to dryness. This material was estimated by u.v. spectroscopy to be ~68% yield of **2**. A 60 ml portion of a solution of this solid in 120 ml of H_2O was neutralized to p*H* 7.05 (p*H* meter) with ~1.5 ml of 0.5 *N* LiOH. This solution was concentrated to ~10 ml *in vacuo* and 10 ml of MeOH was added. Acetone (70 ml) was added and the resulting mixture was allowed to stand at −10° for 4 h. The precipitate (0.1 g, 57%) was filtered, washed with acetone and then ether, and dried at 78°/0.1 mm for 3 days over KOH and P_2O_5. R_F 0.39 (*B*).

Anal. Calcd. for $C_9H_{10}FN_2O_9PLi_2$: F, 5.37. Found: F, 5.16.

Comparable results (68.5% of **2** by t.l.c. and u.v. analysis) were obtained by treating a 0.0005 mol sample of the bis(tetra-*n*-butylammonium) salt of **1** (prepared by passing an aqueous solution of disodium **1** through a column of J. T. Baker ANGC-244 (n-Bu_4N^+)) in 45 ml of methanol with 0.6 g of CF_3OF in 5 ml of CCl_3F as described above followed by similar chromophore regeneration.

A sample of **1** was fluorinated in an analogous manner, purified on a carbon column, converted into the disodium salt using a column of J. T. Baker ANGC-244 (Na^+) resin, and crystallized from acetone–water to give needles of 5-fluorouridine-5′-monophosphate disodium salt dihydrate; R_F 0.16 (*A*), 0.39 (*B*); u.v. max 270 nm (ε 9000) min 235 nm (ε 2300); n.m.r. (^1H, D_2O, TMS external) δ 8.28 (d, J_{6-5F} = 6.4 Hz, 1, H_6), (^{19}F, EtOH–H_2O, CCl_3F external) δ 164.1 (d of d, J_{5F-6} = 6.4 Hz, $J_{5F-1'}$ = 1.5 Hz, 1, F_5).

Anal. Calcd. for $C_9H_{10}FN_2O_9PNa_2.2H_2O$: C, 25.61; H, 3.34; F, 4.50; N, 6.64. Found: C, 25.80; H, 2.99; F, 4.56; N, 6.48.

This product was treated with alkaline phosphatase at p*H* 8.5 and 37° to give 5-fluorouridine as the only product as judged by t.l.c. co-chromatography with an authentic sample (19), u.v. spectra, mixture m.p., and superimposable mass spectra (M^+ *m/e* 262).

5-Fluorouridine-3′,5′-cyclic Monophosphate (cFUMP) (4)

To a vigorously stirred solution of 0.25 g (0.00072 mol) of uridine-3′,5′-cyclic monophosphate sodium salt monohydrate (**3**) in 100 ml of H_2O–MeOH (12:88) at −78° was added a solution of 0.30 g (0.003 mol) of CF_3OF in 15 ml of CCl_3F. The u.v. absorption at 261 nm rapidly vanished and excess reagent was removed by bubbling nitrogen through the solution. Solvents were removed by evaporation and the residue was stirred with 15 ml of Et_3N–MeOH–H_2O (10:45:45) for 10 h. This u.v. absorbing solution was evaporated to dryness and the resulting product **4** was dissolved in 1 ml of H_2O and 9 ml of MeOH was added followed by ~1 ml of J. T. Baker ANGC-244 (H^+) resin. The mixture was stirred until strongly acidic (p*H* < 1.5), filtered, and the resin washed with MeOH. To the combined filtrate was added 1 *N* $NaOH_{(aq)}$ dropwise until complete precipitation of the white solid salt occurred. This material was filtered and subjected to two further reprecipitation cycles to give 0.21 g (76%) of crystalline 5-fluorouridine-3′,5′-cyclic phosphate sodium salt dihydrate; R_F 0.63 (*A*), 0.50 (*B*); u.v. max 269 nm (ε 8500), min 235 nm (ε 2100); n.m.r. (^1H, D_2O, TMS external) δ 7.90 (d, J_{6-5F} = 6.4 Hz, 1, H_6), (^{19}F, D_2O, CCl_3F external) δ 164.2 (d of d, J_{5F-6} = 6.4 Hz, $J_{5F-1'}$ = 1.5 Hz, 1, F_5).

Anal. Calcd. for $C_9H_9FN_2O_8PNa{\cdot}2H_2O$: C, 28.29; H, 3.43; F, 4.97; N, 7.33. Found: C, 27.95; H, 3.10; F, 4.99; N, 7.70.

Treatment of this product with excess crude snake venom diesterase plus alkaline phosphatase at p*H* 8.5 and 37° for an extended period of time gave 5-fluorouridine only, which was identified by comparison with an authentic sample (19) as described in the above preparation of **2**.

5-Fluorouridylyl-3′ → 5′-5-Fluorouridine (FUpFU) (5b)

An aqueous solution of UpU (**5a**) was passed through a J. T. Baker ANGC-244 (n-Bu_4N^+) column and the pooled eluate was evaporated to dryness and co-evaporated three times *in vacuo* using 25 ml portions of MeOH. The residue (222 o.d. units) was dissolved in 10 ml of MeOH, cooled to −78°, and treated with 0.27 g of CF_3OF in 2.5 ml of CCl_3F at −78° with vigorous stirring. After 20 min, the solution was evaporated to dryness The residue (u.v. transparent at 260 nm) was dissolved in 15 ml of 15% aqueous ammonia and stirred for 16 h at room temperature. The solution was neutralized with J. T. Baker ANGC-244 (pyridinium$^+$) resin, filtered, and the resin washed well with H_2O. The filtrate was evaporated to dryness, the residue dissolved in a minimum volume of H_2O, and the solution passed through a column (2.2 × 8 cm) of Rexyn 101 (NH_4^+) resin. The pooled aqueous eluate was evaporated to dryness and the residue (103 o.d. units) was dissolved in H_2O. This solution was applied to a column (0.6 × 12.5 cm) of Whatman DE-52 DEAE cellulose (HCO_3^-) packed in H_2O. Elution (16 ml fractions) was begun with H_2O with constant monitoring at 254 nm. Fractions 3–6 contained 10 o.d. units of 5-fluorouridine. At fraction number 18, a linear gradient (1000 ml of H_2O in the mixing chamber and 1000 ml of 0.2 *N* triethylammonium bicarbonate in the reservoir) was begun. Fractions 24–29 contained 5-fluorouridine, 30–34 contained a small quantity of unknown material, 42–54 contained 29.6 o.d. units of two unknown components (paper chromatography, R_F 0.22 and 0.30 (*C*)), 84–94

contained 21.3 o.d. units of FUpFU (*5b*), R_F 0.27 (*C*) as indicated by the following enzymatic hydrolysis.

Compound	Paper chromatography (*C*) R_F	Electrophoretic mobility* Distance (cm)
5′-UMP (**1**)	0.10	17.2
5′-FUMP (**2**)	0.083	20.0
2′(3′)-FUMP	0.13	
cUMP (**3**)	0.42	12.9
cFUMP (**4**)	0.39	18.0
UpU (*5a*)	0.33	11.1
FUpFU (*5b*)	0.27	15.7
Uridine†	0.62	
5-Fluorouridine†	0.61	

*Whatman No. 1 paper; 0.05 *M* glycine p*H* 9.05 (NaOH); 2 kV (37 V/cm), 10–15 mA; 45 min.
†Uridine and 5-fluorouridine are resolved conveniently using the t.l.c. system indicated.

Combined fractions 84–94 were evaporated to dryness and dissolved in 1 ml of H_2O. Ribonuclease (0.5 mg) was added and the solution was allowed to stand at room temperature for 24 h. Paper chromatographic analysis of the concentrated solution showed spots at R_F 0.13 and 0.61 (*C*) corresponding to 5-fluorouridine-2′(3′)-monophosphate and 5-fluorouridine, respectively. These spots were eluted with 0.1 *N* HCl and analyzed by u.v. Three separate enzymatic determinations gave 2′(3′)-FUMP/5-fluorouridine = 0.85/1; 1.15/1; 1.2/1.

Generous support from the National Cancer Institute of Canada, The National Research Council of Canada (A5890), and The University of Alberta is gratefully acknowledged. We also wish to thank Dr. R. A. Long, ICN Pharmaceuticals, for a gift of uridine-3′,5′-cyclic monophosphate.

β-Carbon Shielding Effects in Carbon-13 Nuclear Magnetic Resonance Spectroscopy

H. BEIERBECK AND J. K. SAUNDERS

Département de Chimie, Université de Sherbrooke, Sherbrooke, Québec J1K 2R1

Received August 29, 1974

H. BEIERBECK and J. K. SAUNDERS. Can. J. Chem. **53**, 1307 (1975).

Carbon-13 chemical shifts in saturated hydrocarbons of staggered conformation may be derived from the corresponding resonances in ethane, propane, isobutane, and neopentane in the following way: every H—*C*—C(α)—C(β) *gauche* interaction between an α-hydrogen and a β-carbon deshields a carbon nucleus by *ca.* 4.7 p.p.m. Every exocyclic carbon–carbon *gauche* configuration H—C(α)—*C*—C(α)—C(β)—H has a deshielding effect of *ca.* 1.7 p.p.m., as the result of nonbonded hydrogen–hydrogen γ-interactions. Every nonbonded interaction between an α-hydrogen and a hydrogen on a γ-carbon makes a shielding contribution of *ca.* −4.5 p.p.m.

H. BEIERBECK et J. K. SAUNDERS. Can. J. Chem. **53**, 1307 (1975).

Nous démontrons qu'il est possible de prévoir les déplacements chimiques des carbones des hydrocarbures saturés en se basant sur les déplacements chimiques dans l'éthane, le *n*-propane, le butane tertiaire et le néopentane et en considérant le nombre des interactions *gauches* et interactions non liées de la façon suivante: chaque interaction *gauche* H—*C*—C(α)—C(β) cause un déblindage de 4.7 p.p.m. sur le carbone β. Chaque interaction *gauche* H—C(α)—*C*—C(α)—C(β)—H induit un déblindage de 1.7 p.p.m. sur le carbone β pourvu que ces derniers noyaux aient une configuration telle qu'il y ait une interaction non liée entre les hydrogènes sur les carbones S et γ. Chaque interaction non liée entre un proton α et un proton sur un carbone γ induit un blindage de −4.5 p.p.m. sur le carbone γ.

Introduction

There have been a number of attempts to correlate carbon-13 chemical shifts in saturated hydrocarbons with molecular structural features (1–6). The additivity parameters reported recently by Grant and co-workers (5, 6) appeared to be the best to date, since they were based on conformationally well defined model systems. However, the physical significance of the term β, which these authors interpreted as an inductive shielding contribution (5), seemed questionable since it was difficult to reconcile with the observation that β-substituent effects on carbon-13 chemical shifts are virtually independent of the nature of the substituent (1, 7–14).

In order to resolve this contradiction we have reexamined β-carbon shielding effects in carbon-13 n.m.r. spectroscopy and found that the prediction of carbon-13 chemical shifts with the β-substituent parameters V_g and β of refs. 5 and 6 is numerically equivalent to an interpretation of β-carbon shielding solely in terms of *gauche* interactions.

Results and Discussion

The experimental data used in this study were carbon-13 chemical shifts in saturated hydrocarbons of staggered conformation or parts of molecules which met this criterion. The data in Table 1 are a selection of chemical shifts in rigid decalin derivatives, taken from ref. 5 and those in Table 2 are resonances of carbons in portions of natural product type compounds which consist of cyclohexane rings in the chair form.

In order to extract the β-carbon substituent effects from the data in Tables 1 and 2, the α- and steric shifts were eliminated as follows. Since α-carbon shieldings are nonadditive it is best to use the resonances in ethane, propane, isobutane, and neopentane (1, 2) as references for primary, secondary, tertiary, and quaternary carbons respectively. CH_3CH_3 = 5.9 p.p.m., $CH_2(CH_3)_2$ = 16.1 p.p.m., $CH(CH_3)_3$ = 25.2 p.p.m., $C(CH_3)_4$ = 27.9 p.p.m. Groups which are three or more bonds from the carbon in question make significant shielding contributions only if there are appreciable nonbonded interactions with the hydrogens on that carbon (1,

15). Nonbonded γ-interactions, which are the only steric interactions that need to be considered here, were assumed to make a shielding contribution of −4.5 p.p.m. Little seems to be gained by introducing a new parameter for the second and subsequent γ-interactions, as proposed by Grant and co-workers (5, 6), since the variation of steric shifts with conformational changes is not clearly understood at present.

The derivation of the β-carbon shielding contribution to the chemical shift of C(1) in 17β-hydroxyandrostane may serve as numerical example. C(1) is a secondary carbon and the α-shift is therefore eliminated by subtracting 16.1 p.p.m., the chemical shift of the secondary carbon in propane. There is one nonbonded interaction with a hydrogen on C(11) and a shift increment of −4.5 p.p.m. is subtracted to eliminate this γ-contribution. The β-carbon shielding effect on C(1) in 17β-hydroxyandrostane is therefore

$$\delta(\beta) = 38.8 - 16.1 - (-4.5) = 27.2 \text{ p.p.m.}$$

The β-carbon shielding contributions are included in Tables 1 and 2.

The configuration of the structural unit con-

$$[2c]: \delta(\beta) = n_{CC}(0.91 - 4.43) + n_{\beta}(2 \times 4.43) = n_{CC}(-3.52) + n_{\beta}(8.87)$$

†These agree well with −3.50/8.49 (ref. 5) and −3.38/8.81 p.p.m. (ref. 6).

sisting of a carbon and its α- and β-substituents, in saturated hydrocarbons of staggered conformation, may be described by the number of H—*C*—C(α)—C(β) hydrogen–carbon and C(α)—*C*—C(α)—C(β) carbon–carbon *gauche* interactions, n_{HC} and n_{CC}. Since every β-carbon gives rise to two *gauche* interactions the sum of n_{HC} and n_{CC} is always twice the number of β-carbons, n_{β}.

$$[1] \qquad n_{HC} + n_{CC} = 2n_{\beta}$$

This means that there are three equivalent descriptions of the configuration, namely the parameter sets $\{n_{HC}, n_{CC}\}$, $\{n_{HC}, n_{\beta}\}$, and $\{n_{CC}, n_{\beta}\}$. Since β-carbon substituent effects have been found (5, 6) to correlate with $\{n_{CC}, n_{\beta}\}$, they must also correlate with $\{n_{HC}, n_{CC}\}$ and $\{n_{HC}, n_{\beta}\}$. For instance, the prediction of β-carbon shifts δ(β) in terms of $\{n_{HC}, n_{CC}\}$, with corresponding parameters HC and CC,

$$[2a] \qquad \delta(\beta) = n_{HC}HC + n_{CC}CC$$

may be converted to expressions for δ(β) in terms of $\{n_{HC}, n_{\beta}\}$ or $\{n_{CC}, n_{\beta}\}$, simply by substituting the rearranged eq. 1 into expression 2*a*.

$$[2b] \qquad \delta(\beta) = n_{HC}HC + (2n_{\beta} - n_{HC})CC = n_{HC}(HC - CC) + n_{\beta}(2CC)$$

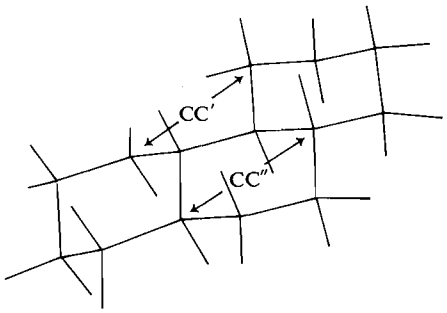
$$[2c] \qquad \delta(\beta) = (2n_{\beta} - n_{CC})HC + n_{CC}CC = n_{CC}(CC - HC) + n_{\beta}(2HC)$$

The coefficients (CC − HC) and (2HC) of n_{CC} and n_{β} in eq. 2*c* correspond to V_g and β of refs. 5 and 6 (Table 3). The results of regression analyses between the β-carbon shifts of Tables 1 and 2 and the three sets of variables $\{n_{HC}, n_{CC}\}$, $\{n_{HC}, n_{\beta}\}$, and $\{n_{CC}, n_{\beta}\}$ clearly show the numerical equivalence of the three predictive schemes [2*a*]–[2*c*]. The root mean squares deviations are identical and the three sets of additivity parameters are interrelated according to eqs. 2*a*–2*c* (Table 3).

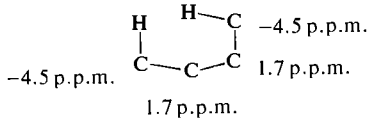
The important result of this demonstration is the conclusion that it is not possible to elucidate the mechanism of β-carbon shielding solely on the basis of correlation studies between observed β-carbon shift increments and structural parameters. However, the observation that β-substituent effects on carbon-13 chemical shifts are rather insensitive to the nature of the substituent (1, 7–14) favors version [2*a*], which corresponds to an interpretation of β-substituent shifts without explicitly invoking inductive effects. For this reason, and because of their interesting implications for conformational studies, the derivation of β-carbon shielding contributions in terms of *gauche* parameters has been chosen here, but with the following modification.

In Tables 1 and 2 the carbon–carbon *gauche* interactions are divided into exocyclic (CC′) and endocyclic (CC″) interactions. A regression analysis with the variable set $\{n_{HC}, n_{CC'}, n_{CC''}\}$ showed that only the parameter $n_{CC'}$ was significant (Table 3). The principal difference between the exocyclic and endocyclic carbon–carbon *gauche* configuration is the steric hydro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

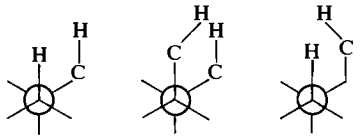


gen–hydrogen interaction H—C(α)—*C*—C(α)—C(β)—H in the exocyclic case. It is therefore possible that the shift increment $n_{CC'}CC'$ is not due to *gauche* interactions between the carbons, but to nonbonded γ-interactions between the hydrogens on these carbons. In other words, it seems that nonbonded γ-interactions shift the signal of the first carbon upfield and that of the second carbon downfield. This then leads to the



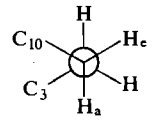
following tentative interpretation of β-carbon shielding effects. *Gauche* interactions H—*C*—C(α)—C(β) between an α-hydrogen and a β-carbon make the major contribution to the β-carbon shift. A second contribution comes from H—C(α)—*C*—C(α)—C(β)—H γ-interactions between hydrogens on an α-carbon and a β-carbon. This shielding term is linked to exocyclic carbon–carbon *gauche* interactions, which are the geometric requirement for steric γ-interactions. The carbon–carbon *gauche* interactions themselves do not seem to affect carbon-13 chemical shifts significantly.

Thus, carbon-13 chemical shifts in saturated hydrocarbons of staggered conformation may be derived from the corresponding resonances in ethane, propane, isobutane, and neopentane in the following way. Every H—*C*—C(α)—C(β) *gauche* interaction between an α-hydrogen and a β-carbon deshields a carbon nucleus by *ca.* 4.7 p.p.m. Every exocyclic carbon–carbon *gauche* configuration H—C(α)—*C*—C(α)—C(β)—H has a deshielding effect of *ca.* 1.7 p.p.m., as the result of nonbonded hydrogen–hydrogen γ-interactions. Every nonbonded interaction between an α-hydrogen and a hydrogen on a γ-carbon makes a shielding contribution of *ca.* −4.5 p.p.m.



4.7 p.p.m. 1.7 p.p.m. −4.5 p.p.m.

The prediction of the chemical shifts of C(1) in androstane may serve as numerical example. Since C(1) is a secondary carbon, the reference shift is the resonance of the secondary carbon in propane (corresponding to the fragment C(2)—C(1)—C(10)). There are a total of five hydrogen–carbon, one exocyclic and two endocyclic carbon–carbon *gauche* interactions about the two bonds C(1)—C(2) and C(1)—C(10). The two endocyclic CC″ interactions do not contribute to the chemical shift.



C_1—C_2

CC′
C(2)—C(1)—C(10)—C(19)
CC″
C(2)—C(1)—C(10)—C(5)

In addition there is one nonbonded γ-interaction with a hydrogen on C(11). Therefore, the chemical shift of C(1) is predicted to be $\delta_{C(1)} = 16.10 + 5 \times 4.73 + 1.74 - 4.50 = 37.0$ p.p.m. The number of *gauche* and nonbonded interactions and the predicted carbon-13 chemical shifts are included in Tables 1 and 2.

Conclusions

Additivity parameters for predicting carbon-13 chemical shifts in saturated hydrocarbons have been proposed, which do not require the explicit assumption of inductive shielding contributions to β-substituent effects. In this interpretation of shielding the hydrogens play a major role, modifying chemical shifts through hydrogen–carbon *gauche* interactions and nonbonded hydrogen–hydrogen γ-interactions. Studies of shielding by functional groups and in conformations, where

dihedral angles differ from 60°, are expected to add further insight into the factors determining carbon-13 chemical shifts.

The Chemical Ionization Mass Spectra of Fluorotoluenes

ALEX. G. HARRISON AND PING-HUANG LIN[1]

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received November 28, 1974

ALEX G. HARRISON and PING-HUANG LIN. Can. J. Chem. **53**, 1314 (1975).

The methane and hydrogen chemical ionization mass spectra of benzyl fluoride, the isomeric fluorotoluenes, and fluorobenzene have been determined. Reaction mechanisms have been elucidated by using CD_4 and D_2 as reagent gases. Both the CH_4 and H_2 spectra of benzyl fluoride show $C_7H_7^+$ as the major ion. In the CH_4 spectra of the fluorotoluenes MH^+ is the only abundant ion resulting from protonation while in the H_2 chemical ionization spectra considerable loss of HF and H_2 occurs from MH^+. There is no evidence for ring expansion to form tropylium type ions. The novel reactions

$$CH_5^+ + FC_6H_4R \rightarrow CH_3C_6H_4R.H^+ + HF$$

$$H_3^+ + FC_6H_4R \rightarrow C_6H_5R.H^+ + HF$$

are important reaction modes for $R = CH_3$ or H and indicate that a long-lived collision complex is formed between CH_5^+ or H_3^+ and the aromatic neutral.

ALEX G. HARRISON et PING-HUANG LIN. Can. J. Chem. **53**, 1314 (1975).

On a déterminé les spectres de masse, par ionisation chimique avec le méthane et l'hydrogène, de fluorures de benzyle. des fluorotoluènes isomères et du fluorobenzène. On a élucidé les mécanismes de réaction en faisant appel à CD_4 et D_2 comme gaz réactifs. Les spectres avec CH_4 et H_2 du fluorure de benzyle montrent la présence de $C_7H_7^+$ comme ion majeur. Dans le spectre des fluorotoluènes ionisés chimiquement par CH_4, MH^+ est le seul ion abondant résultant de la protonation; dans le spectre avec ionisation chimique par H_2, on trouve qu'il y a une perte considérable de HF et de H_2 à partir de MH^+. On ne trouve aucun support pour la présence d'une extention de cycle pour former des ions de type tropylium. Les réactions nouvelles

$$CH_5^+ + FC_6H_4R \rightarrow CH_3C_6H_4R.H^+ + HF$$

$$H_3^+ + FC_6H_4R \rightarrow C_6H_5R.H^+ + HF$$

sont des modes importants de réaction dans les cas où $R = CH_3$ ou H et indiquent qu'un complexe de collision ayant une longue vie se forme entre CH_5^+ ou H_3^+ et la molécule aromatique neutre.

[Traduit par le journal]

It is well established that, in the dissociative electron impact ionization of toluene, and many toluene derivatives, extensive isotopic scrambling occurs (1–3). The early interpretation (2, 3) of ring expansion to form symmetrical tropylium-type ions appears basically correct, although there is now evidence, for some systems, from collisional activation (4) and ion–molecule reaction studies (5) that isomeric ions in addition to tropylium ions (possibly interconverting) are present.

The possible importance of such ring expansion processes in chemical ionization has not been investigated in any detail. Field (6) has shown that, in the methane chemical ionization of toluene, the low abundance $C_7H_7^+$ ($[M—H]^+$) ion originates almost entirely by hydrogen abstraction from the methyl group. This ion probably is formed by a direct hydride abstraction by CH_5^+ and/or $C_2H_5^+$ and in such a direct process one would not anticipate ring expansion. Field's results indicated that protonated toluene, the major ion produced by methane chemical ionization, did not undergo significant fragmentation. In the absence of such fragmentation it is impossible to use isotopic labelling to assess the importance of ring expansion.

As part of a program to assess the role of ring expansion in chemical ionization processes we have determined the chemical ionization mass spectra of benzyl fluoride and the isomeric fluorotoluenes. The significance of the fluorine substituent will be discussed below. The electron

impact mass spectra of benzyl fluoride and the fluorotoluenes are practically identical, the major ions being the molecular ion (*m/e* 110) and the $[M—H]^+$ fragment ion. The appearance potentials for the $FC_7H_6^+$ fragment ions from *m*-fluorotoluene and *p*-fluorotoluene are identical (7) and this has been taken (7) as evidence that ring expansion to a fluorotropylium ion has occurred. In addition, Safe *et al.* (8) recently have measured the ratios of metastable ion intensities for the fragmentation processes

$$[1] \qquad FC_7H_6^+ \rightarrow C_7H_5^+ + HF$$

$$[2] \qquad \rightarrow C_5H_4F^+ + C_2H_2$$

and have observed differences in this ratio of less than 30% for $FC_7H_6^+$ ions generated from the four isomers. Such small differences probably originate from variations in the internal energy distributions of the fragmenting ions (9) rather than from structural differences; these results therefore provide additional support for the earlier suggestion (7) that the same ring-expanded fragment ion is formed by dissociative ionization.

Thus, there is substantial evidence that ring expansion does occur in the electron impact ionization of fluorine-substituted toluenes and it is of interest to consider the possible effect of ring expansion on the chemical ionization of these compounds. In the absence of ring expansion, protonated benzyl fluoride would be expected to show an abundant ion resulting from loss of HF since the product benzyl ion is quite stable. By contrast, in the absence of ring expansion, the loss of HF from the protonated fluorotoluenes will be energetically unfavorable since unstable tolyl ions would be formed; rather the loss of H_2 to form the more stable fluorobenzyl cations should be favored. On the other hand, if ring expansion occurs in the protonated molecules, one would anticipate facile loss of HF for all isomers since a stable tropylium cation can be formed in each case.

We have, therefore, carried out a detailed study of the chemical ionization of benzyl fluoride and the fluorotoluenes using both CH_4 and H_2 as reagent gases. To provide additional information concerning reaction mechanisms we also have used CD_4 and D_2 reagent gases. For comparison purposes the chemical ionization mass spectra of fluorobenzene with the four reagent gases have been determined.

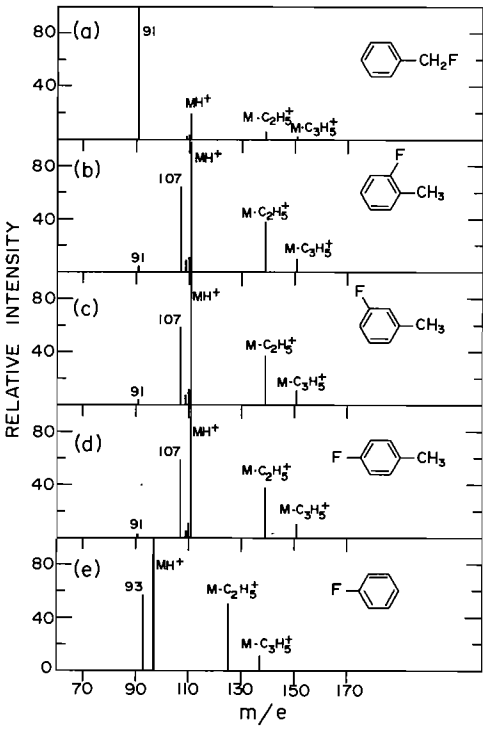

FIG. 1. CH_4 chemical ionization mass spectra of fluorine substituted toluenes and of fluorobenzene.

Methane Chemical Ionization Spectra

The methane chemical ionization mass spectra of benzyl fluoride, the isomeric fluorotoluenes, and fluorobenzene are shown in Fig. 1. For benzyl fluoride, an important peak (19% of base peak) is observed corresponding to the protonated molecule, MH^+, while the base peak is $C_7H_7^+$ at *m/e* 91. The reaction sequence presumably is

$$[3] \qquad \left.\begin{matrix} CH_5^+ \\ C_2H_5^+ \end{matrix}\right\} + C_7H_7F \rightarrow C_7H_7F.H^+ \rightarrow C_7H_7^+ + HF$$

With CD_4 as reagent gas the fragment ion peak did not shift to *m/e* 92 (*cf.* H_2 and D_2 results below) indicating that the added proton is always lost with the HF neutral.[2] In addition, low abundance ions are observed at *m/e* 139 and 151 corresponding to the collision-stabilized clustering of the $C_2H_5^+$ and $C_3H_5^+$ reactant ions with the neutral benzyl fluoride. In contrast

[2]Alternatively one cannot rule out the possibility that the reaction is a direct F^- abstraction reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

to the electron impact spectrum, the $[M—H]^+$ intensity is very low (<2% of base peak).

The spectra of the three fluorotoluenes all show MH^+ as the base peak with only minor formation of $C_7H_7^+$ (2–4% of base peak). The *m/e* 139 and 151 cluster ions are considerably more abundant. In addition the $[M—H]^+$ ions are more abundant than in the benzyl fluoride case but still only 4–8% of the MH^+ intensity. It is probable that, as in the toluene case (6), these ions are formed by hydride abstraction.

The spectra of the three fluorotoluenes are essentially identical and clearly distinguishable from that of benzyl fluoride. As discussed in the previous section the facile loss of HF from protonated benzyl fluoride and the practically negligible loss of HF from the protonated fluorotoluenes provides strong evidence that ring expansion has not occurred in the MH^+ species prior to fragmentation. It is surprising that the loss of H_2 from the protonated fluorotoluenes and from toluene (6) is of only minor importance. The overall reaction

$$[4]\quad CH_5^+ + C_6H_5CH_3 \rightarrow C_6H_5CH_2^+ + H_2 + CH_4$$

is 38 kcal mol^{-1} exothermic[3] and the reaction with the fluorotoluenes would be expected to be similarly exothermic. The low abundance of the $[M—H]^+$ ion suggests either that only a fraction of the exothermicity of the initial proton transfer is retained in the MH^+ ion or that there is an energy barrier additional to the endothermicity for fragmentation of MH^+.

A large ion current is observed at *m/e* 107 in the methane chemical ionization spectra of the fluorotoluenes which shifts to *m/e* 111 when CD_4 is used as reagent gas, indicating incorporation of four deuterium atoms in the product ion. Similarly, in the spectrum of fluorobenzene (Fig. 1*e*) a large ion current is observed at *m/e* 93, shifting to *m/e* 97 with CD_4 as reagent gas. In the fluorobenzene system, Munson and Ridge (13) have shown, using ion cyclotron resonance techniques, that *m/e* 93 is formed by a direct reaction between CH_5^+ and C_6H_5F. The reaction can be written as

$$[5]\quad CH_5^+ + FC_6H_4R \rightarrow CH_3C_6H_4R.H^+ + HF \qquad (R = H \text{ or } CH_3)$$

where it is suggested, although certainly not proven, that the product ion corresponds to the appropriate protonated methyl-substituted benzene. (Rearrangement to tropylium type structures cannot be excluded.) Harrison *et al.* (14) have reported $\Delta H_f(C_7H_9^+) = 224$ kcal mol^{-1} and suggested that the ion may have the protonated toluene structure. Using this heat of formation we calculate that reaction 5 is 35 kcal mol^{-1} exothermic for reaction with fluorobenzene.

The occurrence of reaction 5 is of considerable interest because it indicates that the collision of CH_5^+ with these aromatic molecules does not occur with a simple, direct proton transfer but rather that a collision complex is formed which has a lifetime sufficient for relatively complex bond rearrangements to occur.

Hydrogen Chemical Ionization Mass Spectra

The CH_4 chemical ionization of the fluorotoluenes produces very little fragmentation. To induce further fragmentation we have used H_2 as reagent gas since protonation by H_3^+ is much more exothermic[4] and one might therefore anticipate formation of more highly excited MH^+ ions.

The H_2 and D_2 chemical ionization mass spectra of benzyl fluoride, the fluorotoluenes, and fluorobenzene are displayed graphically in Fig. 2. For benzyl fluoride the MH^+ intensity is extremely small (<2% of base peak), the overwhelming proportion of the ionization being observed as *m/e* 91 ($C_7H_7^+$). In the D_2 spectrum approximately 40% of the ion current moves to *m/e* 92 ($C_7H_6D^+$) indicating that the reaction does not proceed entirely by protonation at the fluorine followed by immediate HF loss (or by direct F^- abstraction) but rather that there is addition of D^+ to the molecule with one of the hydrogens originally bonded to carbon subsequently being eliminated as HF to a significant extent. It should be noted that randomization of all the H/D in $C_7H_7F.D^+$ would lead to 88% HF loss compared to the 40% observed, so that there remains a distinct preference for loss of the added proton (or for F^- abstraction). The results are in contrast to the CD_4 chemical ionization results where no shift to *m/e* 92 was

[3]Calculated using $\Delta H_f(CH_5^+) = 221$ kcal mol^{-1} (10) and $\Delta H_f(C_6H_5CH_2^+) = 213$ kcal mol^{-1} (11). Throughout this paper all thermochemical data not given are taken from ref. 12.

[4]$\Delta H_f(H_3^+) = 264$ kcal mol^{-1} (15) corresponding to p.a.(H_2) = 100 kcal mol^{-1}. $\Delta H_f(CH_5^+) = 221$ kcal mol^{-1} (10) corresponding to p.a.(CH_4) = 127 kcal mol^{-1}.

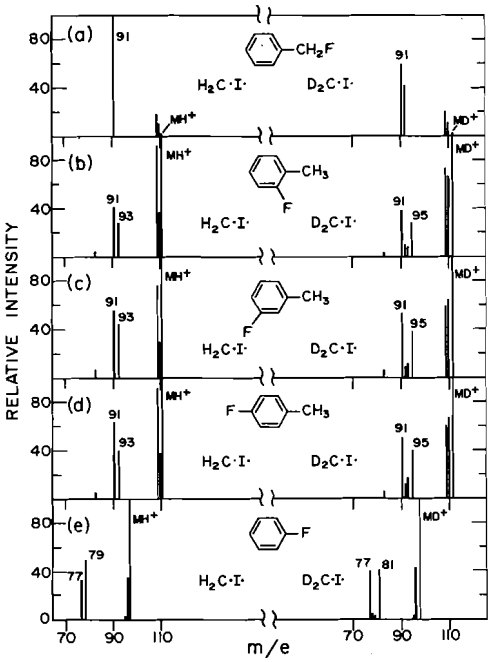

FIG. 2. H_2 and D_2 chemical ionization mass spectra of fluorine substituted toluenes and of fluorobenzene.

observed, indicating no H/D interchange in $C_7H_7F.D^+$ at lower internal energies.

The H_2 chemical ionization mass spectra of the fluorotoluenes are very similar to each other but are distinctly different from the spectrum of benzyl fluoride. As for the CH_4 spectra, the base peak is MH^+, however, much more extensive fragmentation is observed with the $[M—H]^+$ peak being 80–90% of the base peak and the $C_7H_7^+$ peak (*m/e* 91) being 50–65% of the base peak. In addition a significant ion current is observed at *m/e* 110 corresponding to the molecular ion formed by the exothermic charge transfer reaction[5]

[6] $H_3^+ + C_7H_7F \rightarrow C_7H_7F^+ + H_2 + H\cdot$

For each of the fluorotoluenes significant ion currents are observed at *m/e* 93 shifting to *m/e* 95 in the D_2 chemical ionization spectra. Similarly the H_2 chemical ionization of fluorobenzene (Fig. 2*e*) shows a product at *m/e* 79 shifting to *m/e* 81 when D_2 is used as reagent gas. The reaction occurring presumably is the fluorine-displacement reaction 7, analogous to reaction 5 with CH_5^+ as reactant

[7] $H_3^+ + FC_6H_4R \rightarrow HC_6H_4R.H^+ + HF$ (R = H or CH_3)

Assuming the *m/e* 93 product (R = CH_3) is protonated toluene (ΔH_f = 224 kcal mol^{-1}) the overall reaction is ~71 kcal mol^{-1} exothermic. The occurrence of reaction 7 shows that even with H_3^+ as reactant a long-lived complex is formed on collision with the aromatic neutral in a significant fraction of the collisions.

The observation of significant ion currents at *m/e* 91 in the chemical ionization spectra of the fluorotoluenes does not necessarily imply that ring expansion has occurred in the MH^+ ion prior to fragmentation. If this were the case one would anticipate spectra much more similar to that obtained for benzyl fluoride. In addition, any ring expansion process should involve mixing of the H/D in the MD^+ ion, yet the spectra obtained using D_2 as reagent gas show practically no incorporation of D in the fragment ion. (The low intensity peaks at *m/e* 92 and 93 in the D_2 spectra probably arise by loss of H_2 and HD from the *m/e* 95 product.) The H_2 chemical ionization spectrum of fluorobenzene shows an abundant peak at *m/e* 77 ($C_6H_5^+$) corresponding to HF loss from MH^+ and this peak also does not shift when D_2 is used as reagent gas. These results suggest either a direct F^- abstraction reaction or protonation at the fluorine followed by direct loss of HF without hydrogen interchange. The observation of the fluorine-loss peak in the fluorobenzene case provides additional evidence that the *m/e* 91 observed for the fluorotoluenes does not require ring-expansion as an explanation. Although the heat of formation of the phenyl cation is not definitely established a value ≤280 kcal mol^{-1} seems most appropriate (16). Thus the reaction

[8] $H_3^+ + C_6H_5F \rightarrow C_6H_5^+ + HF + H_2$

is calculated to be ≥22 kcal mol^{-1} exothermic and the analogous reaction with the fluorotoluenes to produce tolyl ions should also be exothermic. On the other hand the similar reaction with CH_5^+ as reactant is endothermic.

The $[M—H]^+$ peaks in the H_2 chemical ionization of the fluorotoluenes all are approximately the same intensity relative to the MH^+ base peak. The slightly lower intensity for the *meta* isomer is what would be predicted on the

[5]The recombination energy of H_3^+ is ~9.1 eV (*i.e.* the exothermicity of the reaction $H_3^+ + e \rightarrow H_2 + H$) while the ionization potentials of the fluorotoluenes are in the range 8.8–8.9 eV (12).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

basis of the stability of the respective substituted benzyl ions (7, 17), however, the differences are too small to permit a reliable distinction between the isomers. If the rates of the fragmentation reaction

$$[9] \qquad MH^+ \rightarrow [M—H]^+ + H_2$$

for the various fluorotoluene isomers were controlled by the relative activation energies one would anticipate much greater differences in the $[M—H]^+/MH^+$ ratio since the *p*-fluorobenzyl cation is ~ 10 kcal mol^{-1} more stable than the *m*-fluorobenzyl cation (7, 17). However, the initial protonation reaction by H_3^+ is strongly exothermic and it is more likely that the relative rates are controlled more by the frequency factors than the activation energies at the high internal energies; consequently only slight differences in the extent of fragmentation would be expected.

In the D_2 chemical ionization spectra a significant fraction of the $[M—H]^+$ intensity moves from *m/e* 109 to *m/e* 110 (where it overlaps with $M.^+$), indicating incorporation of one deuterium in the fragment ion. This shows that at least part of the $[M—H]^+$ ion does arise by protonation followed by H_2 elimination, rather than by direct H^- abstraction. In addition it is obvious that considerable H/D interchange occurs prior to fragmentation. These results are in contrast to the results obtained by Field (6) for formation of $[M—H]^+$ in the methane chemical ionization of toluene where only a specific (hydride) abstraction of a methyl hydrogen occurred. In a related study of the reaction of H_3^+ (and D_3^+) with labelled toluenes we have found that both ring and methyl hydrogens are lost in forming the $[M—H]^+$ ion and that considerable hydrogen interchange occurs in MH^+ prior to fragmentation. These results will be reported in detail in a forthcoming publication.

Experimental

The chemical ionization mass spectra were determined using a Dupont 21-490 mass spectrometer equipped with a high-pressure chemical ionization source. The source temperature was ~ 180 °C while the samples were introduced from a heated inlet at ~ 150 °C. The reagent gas pressure cannot be measured accurately with this instrument; however, approximate measurements using a calibrated thermocouple gauge inserted in place of the solid probe indicated reagent gas pressures in the range 0.3 to 0.5 mm. Under these conditions electron impact ionization of the sample was negligible. The spectra presented in the figures are the average of several determinations under the same conditions. Spectra using the nondeuterated and deuterated reagents were obtained under the same operating conditions.

The fluorobenzene, benzyl fluoride, and the fluorotoluenes were commercially available samples and showed no impurities in their mass spectra. Reagent grade CH_4 and H_2 were obtained from Matheson and Company and were used without further purification, as was the CD_4 which was obtained from Merck, Sharp, and Dohme. The D_2 (Matheson and Co.) was passed through a heated palladium thimble prior to use to remove a low-level impurity of mass 28 (probably N_2).

The authors are indebted to the National Research Council of Canada for continued financial support and to Drs. B. Munson and D. Ridge for communication of results prior to publication.

Isotope Effect Studies on Elimination Reactions. X.[1] The Nature of the Transition State for the $E_{CO}2$ Reaction of *Para*-substituted Benzyl Nitrates with Base in 90% by Volume Ethanol–Water

PETER JAMES SMITH[2] AND CAROL AUDREY POLLOCK

Department of Chemistry, Bishop's University, Lennoxville, Quebec J0I 1Z0

AND

ARTHUR NEWCOMBE BOURNS

Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4L8

Received October 28, 1974

PETER JAMES SMITH, CAROL AUDREY POLLOCK, and ARTHUR NEWCOMBE BOURNS. Can. J. Chem. **53**, 1319 (1975).

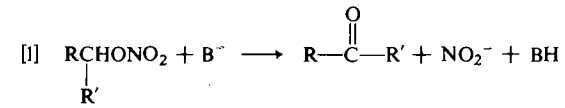
Kinetic isotope effects have been determined for the $E_{CO}2$ reaction of *para*-substituted benzyl nitrates with ethoxide in 90 vol.% ethanol–water at 20°. The nitrogen isotope effect, $(k^{14}/k^{15} - 1)100$ decreased with increasing electron-withdrawing ability of the *para*-substituent; *i.e.* 2.26, 1.95, 1.60, and 0.84 for *p*-CH_3, *p*-H, *p*-CF_3, and *p*-NO_2, respectively. Furthermore, the primary hydrogen–deuterium isotope effects increased also for electron-withdrawing substituents; *i.e.* k^H/k^D = 5.78, 6.06, 6.40, 6.67, and 7.05 for *p*-CH_3, *p*-H, *p*-Br, *p*-CF_3, and *p*-NO_2, respectively. The results are discussed in terms of a recent theoretical treatment dealing with the effect of substituents on the nature of the transition state for a concerted E2 process. The conclusion is reached that any structural change which causes one bond (carbon–hydrogen) to be weakened more at the transition state will have a corresponding effect on the other bond (oxygen–nitrogen).

PETER JAMES SMITH, CAROL AUDREY POLLOCK et ARTHUR NEWCOMBE BOURNS. Can. J. Chem. **53**, 1319 (1975).

On a déterminé les effets isotopiques cinétiques pour la réaction $E_{CO}2$ de nitrates de benzyles substitués en position *para* avec de l'éthylate dans des solutions contenant 90 vol.% éthanol–eau à 20°. L'effet isotopique de l'azote, $(k^{14}/k^{15} - 1)100$ diminue avec l'augmentation du pouvoir électro-affinitaire du substituant *para* à savoir des valeurs de 2.26, 1.95, 1.60 et 0.84 respectivement pour *p*-CH_3, *p*-H, *p*-CF_3 et *p*-NO_2. De plus les effets isotopiques primaires du deuterium par rapport à l'hydrogène augmentent aussi avec les pouvoirs électro-affinitaires des substituants à savoir k^H/k^D = 5.78, 6.06, 6.40, 6.67 et 7.05 respectivement pour *p*-CH_3, *p*-H, *p*-Br, *p*-CF_3 et *p*-NO_2. On discute des résultats en termes d'un traitement théorique récent qui examine l'effet des substituants sur la nature de l'état de transition pour des processus E2 concertés. On arrive à la conclusion que tout changement de structure qui provoque un plus grand affaiblissement d'un lien (carbone–hydrogène) dans l'état de transition aura un effet correspondant sur l'autre lien (oxygène–azote). [Traduit par le journal]

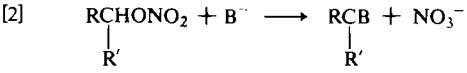
Introduction

An organic nitrate ester, $RCHONO_2$ (R′), can react with base B to produce a carbonyl compound and nitrite ion in a bimolecular carbonyl elimination ($E_{CO}2$), eq. 1. A competing process



[1] $RCHONO_2 + B^- \longrightarrow R{-}C(=O){-}R' + NO_2^- + BH$

is nucleophilic displacement, eq. 2.



[2] $RCHONO_2 + B^- \longrightarrow RCB + NO_3^-$

The reaction of benzyl nitrate, $PhCH_2ONO_2$, with ethoxide in ethanol has been shown (2), using the deuterium exchange test and kinetic isotope effect measurements, to be a concerted one-step process with rupture of both the carbon–hydrogen and oxygen–nitrogen bonds at the transition state.

Subsequently, Pollock and Smith (3) investigated, using kinetic isotope effect measurements, the role of base and solvent in determining transition state geometry for the $E_{CO}2$ reaction of benzyl nitrate. They found that the primary hydrogen–deuterium isotope effect increased with increasing strength of the abstracting base, $k^H/k^D = 5.94$ and 6.41 at 30° for reaction with $EtO^-/EtOH$ and $t\text{-}BuO^-/t\text{-}BuOH$, respectively. The nitrogen isotope effect, $(k^{14}/k^{15} - 1)100$, decreased with increasing strength of the abstracting base; 2.07, 1.82, and 1.54% for reaction with HO^-/40 vol.% EtOH–H_2O, $EtO^-/EtOH$ and $t\text{-}BuO^-/t\text{-}BuOH$, respectively. The conclusion was reached that an increase in the strength of the abstracting base leads to a more reactant-like transition state with decreased rupture of both the carbon–hydrogen and oxygen–nitrogen bonds.

The effect of solvent on the nature of the transition state for the $E_{CO}2$ process was examined by determining rates and nitrogen isotope effects for reaction in various ethanol–water and ethanol – dimethyl sulfoxide mixtures. The nitrogen effect was found to remain essentially constant in solvent mixtures ranging from 65 vol.% EtOH–H_2O on the one hand to 80 vol.% EtOH–DMSO on the other hand where the rate constants differed by a factor of 100-fold. It was concluded that solvent plays only a minor role in determining transition state structure for the concerted elimination reaction of a neutral substrate with base.

An earlier study (1) on the E2 reaction of 2-arylethyltrimethylammonium ions with ethoxide in ethanol showed that electron-withdrawing substituents had the effect of producing a more reactant-like transition state, decreased C—H and $C—N^+$ bond rupture. Accordingly, in the present investigation, both primary hydrogen–deuterium and nitrogen isotope effects have been measured for the reaction of a series of *para*-substituted benzyl nitrates with base in 90 vol.% ethanol–water to examine whether substituents have a similar effect on transition state geometry for the reaction of a neutral substrate, benzyl nitrate with base.

In addition, it was of interest to determine whether Westheimer's curve (plot of k^H/k^D *vs.* the degree of proton transfer to base at the transition state) could be realized for the reaction of the *para*-substituted benzyl nitrates with base by varying the *para*-substituent. The primary hydrogen-deuterium effect of 5.94 (3) observed for the $E_{CO}2$ reaction of the unsubstituted compound is approaching the theoretical maximum[3] of 7 and this suggests that there might be some curvature in the plot of $\log k^H/k^D$ *vs.* $\log k$. The results of the present investigation will be discussed in the light of the theoretical treatment of Thornton (4) on the effect of substituents on the transition state geometry of an E2 reaction.

Results

Hydrogen–Deuterium Isotope Effects

The overall rate constants ($k_{E_{CO}2} + k_{S_N2}$) for reaction of a series of *para*-substituted benzyl nitrates and their α-dideuterated analogs with ethoxide in 90 vol.% ethanol–water are shown in Table 1.

When most of the compounds were reacted with ethoxide in 90 vol.% ethanol–water the carbonyl elimination reaction producing nitrite ion was in competition with an S_N2 process giving nitrate ion; *i.e.* percentage $E_{CO}2 < 100$, Table 1. It is possible, however, using methods described previously (2) to determine the deuterium isotope effect associated with the elimination process. The total rate was followed by acid–base titration and the rate constant for the carbonyl elimination reaction, $k_{E_{CO}2}$, was evaluated from the relative yields of nitrite and nitrate ions determined by the selective reduction of these ions to ammonia. In all cases, the ratio of nitrite to nitrate remained constant during the course of a kinetic run. The primary hydrogen–deuterium effects calculated from the rate data are also given in Table 1.

Hammett plots of $\log k/k_0$ *vs.* σ were obtained for the undeuterated and deuterated series. The slope, ρ, for the former is $+3.89 \pm 0.17$ while the slope of the plot for the α-dideuterated series is $+3.81 \pm 0.16$.

Nitrogen Isotope Effect Results

The results of the nitrogen isotope effect study on the $E_{CO}2$ reaction of *para*-substituted benzyl nitrates with sodium ethoxide in 90 vol.% EtOH–H_2O are shown in Table 2.

The nitrogen isotope effect for the carbonyl elimination reaction of each *para*-substituted benzyl nitrate was obtained by comparing the $^{14}N/^{15}N$ ratio of each substrate of natural

[3]This is assuming that only a stretching vibration is lost at the transition state.

[e]Calculated from values determined at 0° using the equation

$$\log (k^H/k^D)_{T_1} = \log (k^H/k^D)_{T_2} \cdot \frac{T_2}{T_1}.$$

This expression was derived using the assumption that the preexponential terms cancel out; *i.e.*, $A_H = A_D$ and $A_{14} = A_{15}$. The agreement between calculated and experimental results, obtained for other systems, is reasonably good if one considers the standard deviations of the experimental isotope effects.

isotopic abundance with that of nitrite ion formed in the desired reaction of the ester carried to some known extent of completion. Selective reduction of the nitrite ion to ammonia accomplished the separation of the nitrogen of this ion from that of the nitrate ion formed in the simultaneous S_N2 displacement reaction (2). The ammonia was then converted into nitrogen gas which was first purified and then analyzed mass spectrometrically. The isotopic abundance for the reactant was obtained by analysis of the nitrogen gas similarly formed from nitrite plus nitrate produced in a reaction which had been allowed to proceed to completion.

Discussion

The present investigation on the $E_{CO}2$ reaction of the *para*-substituted benzyl nitrates was carried out at 20° with ethoxide in 90 vol.% ethanol–water. It was determined that at this temperature the rate and nitrogen isotope effect measurements could be conveniently performed for all the substrates except for the *p*-NO_2 compound, which was studied at 0°. A more aqueous solvent would lead to a decrease in the $E_{CO}2$ reaction with the solvolysis reaction becoming increasingly important making accurate determinations of both the deuterium and nitrogen isotope effects more difficult.

The kinetically significant abstracting base in solution when ethoxide in ethanol is diluted with water to give a final solution of 90 vol.% ethanol–water is probably ethoxide ion even though it has been shown (7) that the % base present as hydroxide at 25° in 90 vol.% ethanol–water is approximately 35. This view is supported by a nitrogen isotope effect study (3) on the reaction of benzyl nitrate with base in various ethanol–water mixtures where it was found that the isotope effect remained essentially constant for solvent compositions ranging from 100% EtOH to 65 vol.% EtOH–H_2O indicating that the abstracting base remains constant in this solvent composition range. It was found (3) that the nitrogen effect increased for 50 and 40 vol.% EtOH–H_2O mixtures which suggests a weaker abstracting base (4), hydroxide ion, in accordance with our earlier conclusions (1, 3).

The rate constants as well as the primary deuterium and nitrogen isotope effect results for the $E_{CO}2$ reaction of the various substituted benzyl nitrates at 20° are summarized in Table 3. The rate constants, excluding that for the *p*-NO_2 which was determined at 0°, were used to calculate the Hammett ρ value of +3.89. To our knowledge, this value is the second largest that has been determined for an E2 reaction. Only the reaction of *p*-X-phenylethyl methyl sulfoxides with *t*-BuO^-/*t*-BuOH gave a higher value, +4.4, and for this reaction it was concluded (5) that the transition state had substantial carbanion character. It is reasonable to conclude, therefore, that for the $E_{CO}2$ reaction, as well, there is considerable build-up of negative charge at the transition state.

Indeed, the Hammett ρ value of +3.89 together with a large nitrogen effect of 1.95% for reaction of the unsubstituted substrate, suggest a transition state which is carbanionic

with the proton *more than* one-half transferred to base. The only way that a large positive ρ can result in a reaction in which oxygen–nitrogen bond rupture is well advanced would be for the transfer of the proton to be well advanced as well. This conclusion receives support from the fact that the reaction of 2-phenylethyltrimethylammonium ion with ethoxide (7) has smaller values for ρ and the nitrogen effect. For this process, Steffa and Thornton (6) have established that the proton is more than one-half transferred to base at the transition state by determining the secondary effects, k^{OD^-}/k^{OH^-}.

The results of the nitrogen isotope effect study on the $E_{CO}2$ reaction of the *para*-substituted benzyl nitrates, Table 3, show a relationship between the magnitude of the effect and the electron-withdrawing or -donating ability of the *para*-substituent. It is observed that the isotope effect decreases as the *para*-substituent becomes more electron-withdrawing, *i.e.* $(k^{14}/k^{15} - 1)100$ is 2.26 and 0.84 for the *p*-CH_3 and *p*-NO_2 compounds, respectively. In fact, an approximate linear relationship is found from a plot of log $k_{E_{CO}2}$ *vs.* log $(k^{14}/k^{15} - 100)$, Fig. 1, with the smallest nitrogen effect observed for the fastest reaction where the *para*-substituent is the most strongly electron withdrawing.

It is noteworthy that the nitrogen isotope effect obtained for the reaction of the *p*-CH_3 substrate, $(k^{14}/k^{15} - 1)100 = 2.26$, is the largest value obtained for a reaction in solution. In fact, it is approximately 60% of the maximum value of 3.8% calculated on the assumption of complete oxygen–nitrogen bond rupture in the transition state (2).

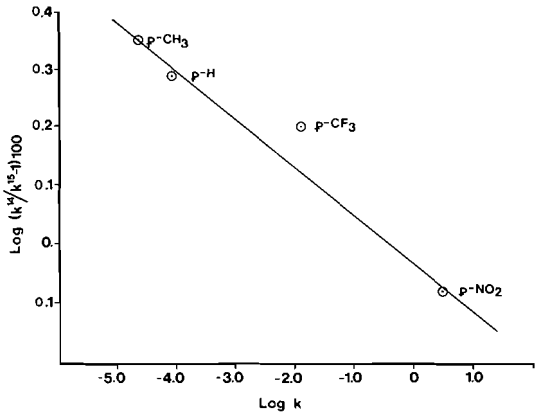

FIG. 1. Plot of log $(k^{14}/k^{15} - 1)100$ *vs.* log $k_{E_{CO}2}$ for the reaction of *para*-substituted benzyl nitrates in 90 vol.% ethanol–water at 20°.

Since the magnitude of the nitrogen effect is considered to depend on the extent to which the composite force constant of the oxygen–nitrogen bond is decreased in going to the transition state, the effect will increase regularly in a reaction series with the extent of bond weakening at the transition state. Consequently, the experimental findings indicate that the extent of O—N bond rupture is decreased in an approximate linear fashion at the transition state as the *para*-substituent becomes more electron withdrawing. Indeed, the sensitivity to substituents and the linear relationship of the nitrogen isotope effect for the elimination process with the free energy of activation makes this isotope effect potentially very useful as a monitor of changes in transition state structure. This is particularly important since it has been noted (8, 9) that the primary hydrogen–deuterium isotope effect is, in some cases, a poor indicator with respect to the degree of carbon–hydrogen bond weakening in the transition state.

A trend in the magnitude of the primary hydrogen–deuterium isotope effects with *para*-substituent is also noted, Table 3. This isotope effect increases with increased electron-withdrawing ability of the *para*-substituent, *i.e.* 5.78 and 7.05 for *p*-CH_3 and *p*-NO_2, respectively. In fact, there appears to be a relationship between the effect of substituents on the reaction rate and their effect on the magnitude of the hydrogen–deuterium isotope effect. This is seen from a plot of log k^H/k^D *vs.* log $k_{E_{CO}2}$, Fig. 2.

An interpretation of the magnitude of the primary hydrogen–deuterium effects, Table 3, in terms of the extent of C—H bond rupture requires a prior knowledge of the nature of the transition state with respect to the degree of proton transfer to base; *i.e.*, whether the proton is more than or less than one-half transferred. As was noted earlier, it is reasonable to conclude that both the large Hammett ρ and nitrogen effect are indicative of a transition state which has considerable carbon–hydrogen bond weakening. The hydrogen–deuterium results, therefore, can be interpreted in the light of Westheimer's treatment (10) with the reasonable assumption that the proton is more than one-half transferred to base at the transition state. Consequently, one can conclude that the reaction of the *p*-NO_2 compound, with the

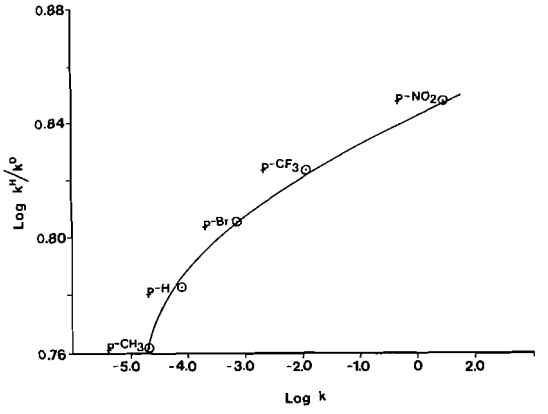

FIG. 2. Plot of log k^H/k^D *vs.* log k_{Eco2} for the reaction of *para*-substituted benzyl nitrates in 90 vol.% ethanol–water at 20°.

largest hydrogen–deuterium isotope effect, has associated with it less C—H bond rupture at the transition state than, for example, the reaction of the *p*-CH_3 compound. It should be noted that the plot of log k_{Eco2} *vs.* log k^H/k^D is similar to Westheimer's curve (plot of k^H/k^D *vs.* the degree of proton transfer to base at the transition state) where it is seen that the magnitude of k^H/k^D appears to be leveling off at a value of approximately 7 for the strong electron-withdrawing substituents, $k^H/k^D = 7.05$ for the *p*-NO_2 compound.

The conclusion that the extent of both C—H and O—N bond rupture at the transition state decreases as the *para*-substituent is made more electron withdrawing is in accord with Hammond's postulate (11) which predicts that the more facile a reaction in a reaction series the more reactant-like its transition state. Also, Thornton's theory (4), dealing with the effects of structural changes in the reactant on the nature of the transition state is consistent with the experimental results. According to this theory the geometrical change for an elimination reaction will be determined largely by the substituent effect on the parallel motion along the reaction coordinate where the relative lengths of the arrows below

represent the relative extent to which each atom has moved when the reacting system has reached the transition state. Thornton predicts, from this reaction-coordinate representation of the transition state, that electron-withdrawing (donating) substituents at carbon should have the same effect on the C—H and O—X bond lengths at the transition state. Thornton showed that the more difficult it is for two atoms to move apart, the greater will be the extent to which they need to separate before arriving at the state of maximum energy which separates reactants and products. He then goes on to point out that an increase in electron withdrawal at carbon should make it easier to remove the proton and therefore, should result in a decrease in the extent of proton transfer to base. This, in turn, will result in shortening of the O—X bond at the transition state since the reaction coordinate motion which results in the separation of H from C also involves a separation of X from O.

It follows from the conclusion that a decrease in C—H bond rupture is accompanied by a decrease in O—N bond rupture that the carbanion character of a transition state is dependent on the *relative* change of each of these bond lengths for a transition state where there is coupling of the motion of the bonds as illustrated by Thornton's representation of the E2 transition state. Thornton (4) considered this situation and suggested that, by making H move more relative to O, and C move more relative to X, the transition state will assume an increasing carbanionic character, that is, will become more Elcb-like, the further its position along the reaction coordinate.

The plot of log k^H/k^D *vs.* log k_{Eco2}, Fig. 2, appears to resemble one-half of Westheimer's curve. It is seen that the magnitude of the hydrogen–deuterium effect becomes less sensitive to changes in the *para*-substituent as the substituent is made more strongly electron withdrawing; *i.e.* for *p*-CF_3 and *p*-NO_2. As a consequence, for the region where k^H/k^D is near the maximum, the magnitude of the isotope effect will not be a good measure of the degree of carbon–hydrogen bond rupture. For this region, nitrogen isotope effects might provide a better measure of changes in transition state geometry.

Experimental

Materials

Nitrate Esters

All the nitrate esters and their α-dideuterated analogs were prepared from the reaction of their respective benzyl halides with silver nitrate in acetonitrile using

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

the procedure described by Buncel and Bourns (2). All of the α-d_2 compounds were shown by n.m.r. to be at least 99% deuterated.

Benzyl nitrate. Benzyl chloride was treated with silver nitrate to give benzyl nitrate (60% yield), b.p. 62.0–62.5°/1 mm (lit. b.p. (2) 45°/0.5 mm).

p-Methylbenzyl nitrate. *p*-Methylbenzyl bromide was treated with silver nitrate to give *p*-methylbenzyl nitrate (42% yield); b.p. 72.0–73.5°/1 mm (lit. (12) 78°/0.6 mm).

p-Bromobenzyl nitrate. *p*-Bromobenzyl nitrate was prepared from the reaction of silver nitrate with *p*-bromobenzyl bromide (74% yield); b.p. 102–103°/1 mm (lit. (12) m.p. 17°).

p-Trifluoromethylbenzyl nitrate. *p*-Trifluoromethylbenzyl bromide was treated with silver nitrate to give *p*-trifluoromethylbenzyl nitrate (57% yield); b.p. 83.5–84.0°/2.5 mm; (lit. (13) 56°/0.3 mm).

p-Nitrobenzyl nitrate. *p*-Nitrobenzyl nitrate was prepared from *p*-nitrobenzyl chloride and silver nitrate (50% yield); m.p. 67.0–68.0° (lit. (12) 68.2°).

Absolute Ethyl Alcohol

This solvent was dried by the method of Lund and Bjerrum (14) and stored under anhydrous conditions.

Sodium Ethoxide

Sodium ethoxide was prepared by the action of sodium with anhydrous ethanol under strictly anhydrous conditions in a nitrogen atmosphere. The base solution was prepared by diluting the ethoxide solution with water to give the desired solvent by percentage volume to volume. The water used in the dilutions was CO_2 free.

Kinetic Measurements

The rate constants for the overall reactions as well as the rate constants for elimination were determined as described by Buncel and Bourns (2).

Nitrogen Isotope Effects

Complete Reaction and Collection of Ammonia

A sample of benzyl nitrate was added to a sodium ethoxide solution and the reaction was allowed to proceed to completion. A 5 ml aliquot of the reaction mixture was extracted with ether and the aqueous layer was added to a Kjeldahl distillation where the nitrite and nitrate were reduced by the procedure described by Buncel (2) and the ammonia was distilled into the same flask containing excess sulfuric acid. The acid was back-titrated with standard alkali, using bromocresol green as indicator, followed by the immediate addition of 3 ml of 0.01 N H_2SO_4 to prevent loss of ammonia. The titration gave the total number of moles of product formed which was usually greater than 99% of the number of moles of reactant.

Partial Reaction

The concentration of benzyl nitrate was such that when the reaction had proceeded to the desired extent of reaction, the nitrite produced would yield a volume of nitrogen of approximately 3 ml at standard conditions. The substrate was weighed into a reaction flask which was placed in a constant temperature bath and allowed to equilibrate. Similarly, the base solution of desired concentration was placed in the constant temperature bath. After approximately 30 min, the reactants were mixed and the reaction was allowed to proceed for a predetermined time, as calculated from the kinetic data. The reaction flask was then removed from the bath and its contents emptied into a separatory funnel containing ice, water, and diethyl ether. The aqueous layer was extracted four times with ether. The combined ether extracts were then washed four times with water and these washings were added to the aqueous layer which was then concentrated to a small volume, 25 ml, on a rotary evaporator.

The concentrated solution was then added to a Kjeldahl distillation flask and the nitrite ion converted into ammonia which was distilled into excess standard sulfuric acid and back-titrated as described for the preparation of the complete samples. The resulting ammonium sulfate solution was concentrated to 3 ml in preparation for its conversion to ammonia.

In all of the partial reactions where the nitrite ion was reduced to ammonia in preparation for its conversion to nitrogen gas and mass spectrometric analysis, the amount of nitrite ion was determined by the procedure described above, so that the ratio $[NO_2^-]/([NO_2^-] + [NO_3^-])$ could be used in the evaluation of nitrogen isotope effect for the $E_{CO}2$ process. The ammonium sulfate solutions were converted to nitrogen by the procedure described by Buncel and Bourns (2).

For the reaction of the *p*-nitrobenzyl nitrate at 0°, the usual method of quenching was unsatisfactory due to the fast rate of reaction. In this case, the desired extent of reaction was achieved by adding the appropriate amount of base, corresponding to the extent of reaction required, and allowing the reaction to proceed for 30 half-lives. In these cases, the concentration of the reactants was sufficiently low so that no more than 1% reaction occurred during the mixing of the reacting solutions.

The kinetic isotope effect was calculated by using the expression suggested by Baliga and Bourns (15),

$$\frac{k^{14}}{k^{15}} = \frac{\ln 1 - \dfrac{f'(1-p)}{1-f'p}}{\ln 1 - \dfrac{rf'(1-p)}{1-f'p}}$$

where f' is the mol fraction of the ester which has undergone reaction, p is the fraction of the total reaction which is substitution and r is $(^{14}N/^{15}N)_{reactant}/(^{14}N/^{15}N)_{NO_2^-}$. This is a modification of an expression derived by Stevens and Attree (16), and takes into account the fact that the reactant is being consumed by reactions other than those where the isotope effect is being measured.

Synthesis and Fungicidal Activity of *N,S*-Substituted α-Thio-β-aminocrotonanilides

JAMES BENJAMIN PIERCE, ROBERT JAMES FANNING, AND ROBERT ALLAN DAVIS

Uniroyal Ltd. Research Laboratories, Guelph, Ontario and Uniroyal Chemical, Division of Uniroyal Inc., Naugatuck, Connecticut

Received November 5, 1974

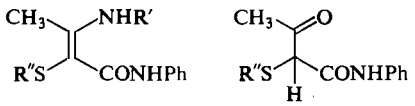
JAMES BENJAMIN PIERCE, ROBERT JAMES FANNING, and ROBERT ALLAN DAVIS. Can. J. Chem. **53**, 1327 (1975).

A number of *N,S*-substituted α-thio-β-aminocrotonanilides have been synthesized. Their fungicidal activity on a number of organisms has been studied and in general it has been found that it is inferior to that of the 1,4-oxathiins to which these compounds bear some structural similarities.

JAMES BENJAMIN PIERCE, ROBERT JAMES FANNING et ROBERT ALLAN DAVIS. Can. J. Chem. **53**, 1327 (1975).

On a synthétisé un certain nombre d'α-thio β-aminocrotonanilides substitués sur l'azote et le soufre. On a étudié leur activité fungicide sur un certain nombre d'organismes et on a trouvé qu'en général ces composés sont moins actifs que les oxathiinnes-1,4 avec lesquels ils sont reliés par leur structure. [Traduit par le journal]

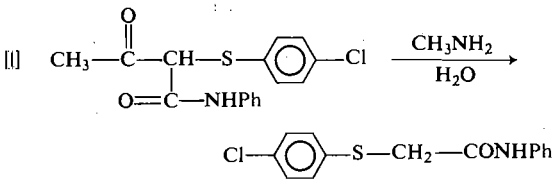
The discovery that certain 1,4-oxathiins and more particularly 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxanilide (Vitavax®) possess systemic fungicidal activity (1) has led us to study this and other closely related systems with the expectation that they too might exhibit biological activity (2). Among the compounds that we have synthesized and tested are the *N,S*-substituted α-thio-β-aminocrotonanilides (**I**). These compounds are derivatives of acetoacetanilide α-thioethers (**II**), a group which includes the intermediate compounds often used to produce the systemic 1,4-oxathiins (1).



I **II**

After this work had begun a report by Mattsson and Bertilsson (3) appeared which described the synthesis and fungicidal properties of some compounds of type **I** and in particular 2-(2-hydroxyethylthio)-3-pentylamino crotonanilide which can be made by treating Vitavax with pentylamine. We wish to record here our syntheses of compounds of type **I** and our findings about their biological activities.

We have synthesized the compounds **I** by one of two routes as shown in Scheme 1. The choice of route depended largely upon the nature of the amine as it was found that in some cases the intermediate **II** underwent undesired side reactions. Thus treatment of α-(4-chlorophenylthio)acetoacetanilide (**II**, R″ = 4-chlorophenyl) with aqueous methylamine gave the deacetylated product α-(4-chlorophenylthio)acetanilide (eq. 1). The desired product **I** (R″ = *p*-chlorophenyl; R′ = CH_3) could be prepared, however, using **III** (R′ = CH_3) (4) and *p*-chlorothiophenol. Deacetylations such as that shown in equation (1) have previously been shown to occur when α-cyano (5), α,α-dichloro (6), and other α-sulfur substituted (2) acetoacetanilides are treated with base.



While deacetylation reactions such as the above are not too surprising, in one case of attempting to convert **II** to **I** we did discover a rather unique reaction. Thus treatment of **II** (R″ = 2-benzothiazolyl) with 40% aqueous methylamine led not to the expected **I** (R′ = CH_3; R″ = 2-benzothiazoyl) but to 2-anilinobenzothiazole in high yield (eq. 2). The product was identified by comparison of its melting point and i.r. spectrum with those of authentic ma-

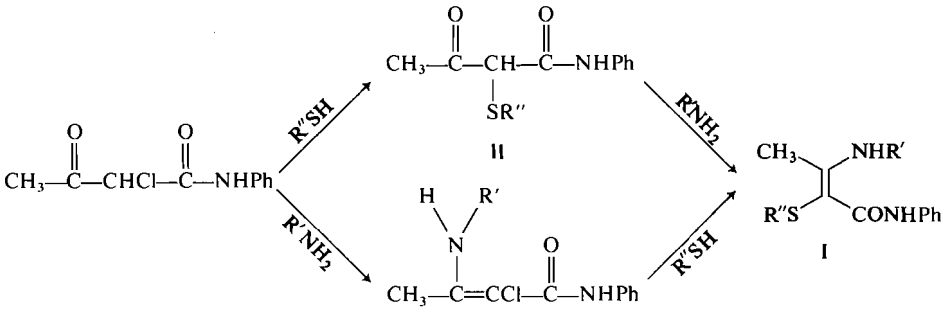

SCHEME 1

[2] 
terial made by the method of Hofmann (7). At present we have no evidence concerning the mechanism of this reaction but it is hoped to study it further in the near future.

In this connection it should be mentioned that whereas the reaction of mercaptans with α-chloroacetoacetanilide in general gives excellent yields of the compounds **II**, reaction with hydrogen sulfide results predominantly in production of acetoacetanilide and sulfur (eq. 3).

[3] 
Thus repetition of the experiment of Mattsson and Bertilsson (3) in which 2-mercaptoacetoacetanilide (**II**, R″ = H) is claimed, in our hands, gave only a 78% yield of acetoacetanilide. The product, m.p. 78–84 °C, gave an i.r. spectrum identical in every way to that of authentic material. The above reaction may well proceed via the expected 2-mercaptoacetoacetanilide which then eliminates sulfur by further reaction with sodium hydrogen sulfide or sodium hydroxide (eq. 4).

In Tables 1 and 2 we have listed the compounds **I** that have been prepared for this study. Table 1 gives those prepared via intermediates

[4] 
II (Scheme 1) and Table 2 those prepared via intermediates **III** (Scheme 1). The melting points, analyses, and yields obtained in going from **II** or **III** to **I** are also recorded.

We have found the fungicidal activity of these compounds to be much inferior to that of oxathiins such as Vitavax. The activity of the compounds α-(2-hydroxyethylthio)-β-aminocrotonanilide (**I**, R′ = H; R″ = HO—CH_2—CH_2—), α-(2-hydroxyethylthio)-β-methylaminocrotonanilide (**I**, R′ = Me; R″ = HO—CH_2—CH_2—), and α-(2-hydroxyethylthio)-β-anilinocrotonanilide (**I**, R′ = Ph; R″ = HO—CH_2—CH_2—) were of particular interest to us because of their close relationship to Vitavax and the intermediate used to produce Vitavax (1). However, in *in vitro* tests these compounds did not control *Alternaria solani*, *Fusarium oxysporum*, *Pythium* Spp., or *Rhizoctonia solani* at 500 p.p.m. This is in contrast to Vitavax which gives excellent control of most basidiomycetes such as *Rhizoctonia solani* and is also active on the other fungal species (8). In addition *in vivo* greenhouse tests on tomato early blight and powdery mildew on beans at 500 p.p.m. also showed these com-

pounds to have little activity compared to the activity of Vitavax under these conditions.

Some of the compounds listed in Tables 1 and 2 did show some *in vitro* fungicidal activity. These activities are recorded in Table 3. The activities recorded for these crotonanilides all fell rapidly as the dosage of the chemical was lowered. Thus on the basis of our tests we have concluded that the fungicidal activity of these compounds is much inferior to that of oxathiins.

Experimental

The experiments described below were chosen as typical of the preparation of *N,S*-substituted α-thio-β-amino-crotonanilides (**I**) via intermediates **II** and **III**. Spectral data are given for the compounds described in these typical preparations; spectral data for the other compounds shown in Tables 1 and 2 were in full accord with their proposed structures.

acetanilide (12.7 g, 0.05 mol) (2), 4-ethoxyaniline (6.9 g, 0.05 mol), 4-toluenesulfonic acid (0.1 g), and benzene (100 ml) was brought to reflux and the water formed was removed azeotropically. After 2.5 h the reaction mixture was filtered to remove a small amount of 4-ethoxyanilinium-4-toluenesulfonate salt and the benzene was then removed from the filtrate. The crude oil crystallized upon standing and was recrystallized from isopropanol to give 16.8 g or 90% of product, m.p. 113.5–115 °C; n.m.r. (DMSO-d_6): 1.30 (3H, t, J = 6 Hz), 2.33 (3H, S), 2.65 (2H, t, J = 5 Hz), 3.30–3.80 (2H, m), 3.95 (2H, q, J = 6 Hz), 5.11 (1H, t, J = 5 Hz exchange), 6.70–7.80 (5H, m), 9.78 (1H, S, exchange); i.r. (KBr): 3350, 3260, 1600, 1560, 1500, 1430, 1210 cm^{-1}.

α-(2-Benzothiazolyl)acetoacetanilide

A mixture of 2-mercaptobenzothiazole (34.4 g, 0.21 mol), 2-chloroacetoacetanilide (43.2 g, 0.21 mol), benzene (150 ml), sodium bicarbonate (17.6 g, 0.21 mol), and water (100 ml) was brought to reflux for 4 h. The phases of the hot mixture were separated and the product crystallized from the benzene phase upon cooling. Thus were obtained 51.9 g or 74% of the title compound, m.p. 123–124.5 °C.

α-(2-Benzothiazolyl)-β-(4-phenylaminoanilino)-crotonanilide

A mixture of α-(2-benzothiazolyl)acetoacetanilide (prepared as above) (17.1 g, 0.05 mol), 4-(phenylamino)-aniline (9.2 g, 0.05 mol), 4-toluenesulfonic acid (0.1 g), and benzene (125 ml) was refluxed and the water was removed azeotropically. After 2.5 h the benzene was removed and the dark residue was crystallized from ethanol giving 20.5 g or 81% of product, m.p. 166–168.5 °C; n.m.r. ($CDCl_3$): 2.32 (3H, S), 5.88 (1H, S, exchange), 6.85–7.90 (18H, m), 8.70 (1H, S, exchange), 12.77 (1H,

S, exchange); i.r. (KBr): 1555, 1600, 1435, 1425, 1300, 1210 cm^{-1}).

Preparation via Intermediate III

α-(2-Hydroxyethylthio)-β-(methylamino)crotonanilide

A solution of 2-mercaptoethanol (3.7 g, 0.045 mol), triethylamine (6.3 ml, 0.045 mol), and benzene (50 ml) was added to a solution of α-chloro-β-(methylamino)-crotonanilide (10 g, 0.045 mol) (4) in benzene (100 ml). After refluxing for 15 min a precipitate of triethylamine hydrochloride began to separate. The mixture was refluxed for 2.5 h, cooled, and extracted with water. The benzene was removed from the organic layer and the residue crystallized from isopropanol giving 9.0 g or 75% of the product, m.p. 74–77 °C; n.m.r. ($CDCl_3$): 2.30 (3H, S), 2.49 (2H, t, J = 6 Hz), 2.83 (3H, d, J = 6 Hz), 3.58 (2H, t, J = 6 Hz), 3.40 (1H, bs), 6.9–7.6 (5H, m), 9.30 (1H, S, exchange), 10.55 (1H, q, J = 6 Hz, exchange); i.r. (CCl_4): 3325, 1615, 1580, 1510, 1435, 1310, 1200 cm^{-1}.

α-(N,N-Diethyldithiocarbamoyl)-β-aminocrotonanilide

A mixture containing α-chloro-β-aminocrotonanilide (15 g, 0.071 mol), (4) the sodium salt of *N,N*-diethyldithiocarbamate trihydrate (16.1 g, 0.071 mol), and dimethylsulfoxide (50 ml) was warmed on a steam bath for 0.5 h and then poured into 500 ml of water. The precipitate was separated by filtration and recrystallized from ethanol to give 20.1 g or 87% of product, m.p. 124–126 °C; n.m.r. ($CDCl_3$): 1.28 (6H, m), 2.03 (3H, S), 3.85 (4H, m), 7.30 (5H, m), 8.08 (1H, S); i.r. ($CHCl_3$): 3490, 3375, 2975, 1625, 1580, 1500, 1430, 1310, 1270 cm^{-1}.

Reaction of α-(2-Benzothiazolyl)acetoacetanilide with Methylamine

A solution of α-(2-benzothiazolyl)acetoacetanilide (2.0 g, 0.0059 mol) in 30 ml of 40% aqueous methylamine was allowed to sit at room temperature for 4 days. Long white needles of 2-anilinobenzothiazole were gradually formed. These were filtered off, washed with a little fresh methylamine solution and air dried. Thus were obtained 1.2 g or 90.8% of 2-anilinobenzothiazole, m.p. 157–159 °C, identical in every way with an authentic sample made by the method of Hofmann (7).

Reaction of α-(4-Chlorophenylthio)acetoacetanilide with Methylamine

A sample of α-(4-chlorophenylthio)acetoacetanilide (10 g, 0.031 mol) was dissolved in 150 ml of 40% aqueous methylamine. The solution was allowed to stand at room temperature for 2.5 h and then filtered to remove the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

product. A second crop was also obtained from the filtrate. The product was recrystallized from ethanol yielding 4.7 g or 51.5% of α-(4-chlorophenylthio)acetanilide, m.p. 108–110 °C. The identity of the product was proved by comparison with an authentic sample made by the reaction of α-chloroacetanilide with 4-chlorothiophenol.

Attempted Preparation of α-Mercaptoacetoacetanilide

The method of German Offen. 2,133,450 (3) was followed. Thus a solution of sodium hydroxide (8 g) in water (100 ml) was saturated with hydrogen sulfide and to this solution was added dropwise a solution of α-chloroacetoacetanilide (42.3 g) in methanol (150 ml) and benzene (150 ml). When the addition was complete (about 1 h) the mixture was stirred an additional 15 min and then filtered to remove 4.0 g or 62.5% of sulfur, m.p. 120 °C, burning with a blue flame smelling strongly of sulfur dioxide. The filtrate consisted of two phases. These were separated and the lower phase was extracted with 2 × 100 ml of ether and these ether phases combined with the upper phase. These organic phases were dried with anhydrous sodium sulfate and the solvents were then removed. The residue was recrystallized from toluene to give 28.5 g or 77.5% of acetoacetanilide, m.p. 78–84 °C. The identity of the product was confirmed as being acetoacetanilide rather than 2-mercaptoacetoacetanilide by comparison of its i.r. spectrum with that of authentic material.

A New Method of Preparing Hydrazonyl Halides

PEDER WOLKOFF

Department of General and Organic Chemistry, H. C. Ørsted Institute, University of Copenhagen, Universitetsparken 5, DK-2100 Copenhagen Ø, Denmark

Received September 9, 1974

PEDER WOLKOFF. Can. J. Chem. **53**, 1333 (1975).

The triphenylphosphine – carbon tetrahalide (Br, Cl) system transforms *N'*-benzoyl-*N*-arylhydrazines (**1**), *N,N*-dimethyl-, and *N*-methyl-*N*-phenyl-*N'*-benzoylhydrazines (**3**) into the corresponding hydrazonyl halides **2** and **4**.

Tribromomethyltriphenylphosphonium bromide (**7**), formed by reacting triphenylphosphine with carbon tetrabromide, is capable of transforming *N'*-benzoyl-*N*-phenylhydrazine (**1***a*) into the corresponding hydrazonyl bromide (**2***b*) in the presence of triphenylphosphine.

PEDER WOLKOFF. Can. J. Chem. **53**, 1333 (1975).

Le couple triphénylphosphine – tétrahalogénure de carbone (Br, Cl) transforme les *N'*-benzoyl *N*-arylhydrazines (**1**) ainsi que les *N,N*-diméthyl- et *N*-phényl *N'*-benzoylhydrazines (**3**) en halogénures (**2** et **4**) d'hydrazonyle correspondants.

Le bromure de tribromométhyltriphénylphosphonium (**7**) obtenu par réaction de la triphénylphosphine avec le tétrabromure de carbone peut transformer, en présence de triphénylphosphine, la *N'*-benzoyl *N*-phénylhydrazine (**1***a*) en bromure d'hydrazonyle correspondant (**2***b*).

[Traduit par le journal]

The two most important methods for the preparation of aromatic hydrazonyl halides (α-halogenobenzaldehyde arylhydrazones, **2**) are the action of phosphorus pentachloride on *N'*-benzoyl-*N*-arylhydrazines (**1**) and the halogenation of benzaldehyde arylhydrazones. The applicability of these methods is limited; the first can only be applied to hydrazonyl chlorides and the latter is generally accompanied by halogenation in the *N*-aryl part of the hydrazone (*cf.* ref. 1).

The recent work by Appel *et al.* (2) in transforming secondary amides (RCONHR') into the corresponding imidoyl halides (RCXNR') by use of the triphenylphosphine – carbon tetrahalide system (Ph_3P–CX_4) has prompted us to examine the applicability of this method also to the hydrazonyl system.

Applying the Ph_3P–CX_4 system to **1** affords **2** (see eq. 1) in 40–65% yield.

[1] $\underset{\mathbf{1}}{PhCONHNHAr} \xrightarrow{Ph_3P\text{–}CX_4} \underset{\mathbf{2}}{PhCX{=}NNHAr}$

a Ar = Ph; X = Cl
b Ar = Ph; X = Br
c Ar = 2-$NO_2C_6H_4$; X = Cl
d Ar = 3-$NO_2C_6H_4$; X = Cl
e Ar = 4-$NO_2C_6H_4$; X = Cl

Typically, CCl_4 (1 equiv.) was added to a stirred suspension of **1***a* (1 equiv.) and Ph_3P (1.25 equiv.) in dry CH_3CN. After 6 h the precipitate was filtered off and recrystallized to give **2***a* in 58% yield. The previously unknown α-bromobenzaldehyde phenylhydrazone (**2***b*, 33%) was prepared in a similar manner; the yield of **2** was increased slightly when the reaction time was extended to 20 h. The method is not limited to aromatic hydrazonyl halides but may also be applied to the preparation of aliphatic hydrazonyl halides of type **4** (see eq. 2).

[2] $\underset{\mathbf{3}}{PhCONHN(CH_3)R} \xrightarrow{Ph_3P\text{–}CX_4} \underset{\mathbf{4}}{PhCX{=}NN(CH_3)R}$

a R = Ph; X = Cl
b R = CH_3; X = Cl
c R = CH_3; X = Br

Thus reacting the Ph_3P–CBr_4 system with *N,N*-dimethyl-*N'*-benzoylhydrazine (**3***b*) affords after 2 h α-bromobenzaldehyde dimethylhydrazone (**4***c*; 39%), which has previously been prepared (but not isolated) by *in situ* bromination of the corresponding hydrazone ($PhCHNN(CH_3)_2$) (3). A mass spectrum taken of the reaction mixture confirmed the presence of bromoform and triphenylphosphine oxide.

The active reagents, transforming **1** and **3** into **2** and **4**, respectively, may be the charge–transfer complex (**5**), and the dihalogeno triphenylphosphorane (**6**), as shown by Appel *et al.* (2) in the transformation of amides into imidoyl halides.

$$\overset{+\delta}{Ph_3P} \ldots X \ldots \overset{-\delta}{CX_3} \qquad Ph_3PX_2$$
5 **6**

The sparingly soluble tribromomethyltriphenylphosphonium bromide (**7**) precipitated out instantly (88%) in dry CH_3CN by mixing CBr_4 (1 equiv.) with Ph_3P (1 equiv.) in the absence of **1** or **3** (see eq. 3); with 2 equiv. of Ph_3P the yield

[3] $$CBr_4 + Ph_3P \rightarrow (Ph_3PCBr_3)Br$$
7

of **7** was reduced to 69%. This shows that under these experimental conditions only a certain part of the Ph_3P–CBr_4 system is converted to **6** (X = Br) and dibromomethylene triphenylphosphorane (**8**) (4). Compound **7** itself was capable of transforming **1***a* into the corresponding hydrazonyl bromide **2***b* (42% after recrystallization) only in the presence of Ph_3P (see eq. 4).

[4] $$\underset{\textbf{1}a}{PhCONHNHPh} \xrightarrow{(Ph_3PCBr_3)Br + Ph_3P} \underset{\textbf{2}b}{PhCBr{=}NNHPh}$$

The formation of **2***b* may then be explained in terms of the action of **6** (X = Br) on **1***a*, where **6** (X = Br) is formed according to reaction 5, which has been proposed by Appel *et al.* (2) in accordance with the observations by Ramirez *et al.* (4) and Rabinowitz and Marcus (5) on the reaction of Ph_3P with CBr_4 and CCl_4, respectively; (see ref. 6 for a general review).

[5] $$\underset{\textbf{7}}{(Ph_3PCBr_3)Br} + Ph_3P \rightarrow \underset{\textbf{6}}{Ph_3PBr_2} + \underset{\textbf{8}}{Ph_3P{=}CBr_2}$$

This is further substantiated by the observation that dibromomethyltriphenylphosphonium bromide (**9**) is formed in 52% yield (after recrystallization), by refluxing compound **7** (1 equiv.) with Ph_3P (1 equiv.) in wet CH_3CN (see eq. 6).

[6] $$\underset{\textbf{7}}{(Ph_3PCBr_3)Br} + Ph_3P \xrightarrow[CH_3CN,\ H_2O]{} \underset{\textbf{9}}{(Ph_3PCHBr_2)Br}$$

The formation of **9** may be explained as an addition of HBr to the ylide **8** (**8** + HBr → **9**), where **8** is formed according to reaction 5. Similarly the reduction of bromomethyltriphenylphosphonium bromide to methyltriphenylphosphonium bromide by the action of Ph_3P has been reported (7).

Experimental

All melting points were taken on a Reichert melting point microscope. The aromatic hydrazonyl halides were normally recrystallized from acetonitrile.

α-Halogenobenzaldehyde Arylhydrazones

Carbon tetrachloride (1.95 ml, 20.0 mmol) was added to a stirred suspension of compound **1***a* (4.24 g, 20.0 mmol) and Ph_3P (6.55 g, 25.0 mmol) in CH_3CN (40 ml, dried by passage through an alumina column and introduced directly from the columm into the reaction flask). After 6 h the solution was cooled, crystallization was initiated by scratching, and the product filtered off. Recrystallization gave compound **2***a* in 58% yield, m.p. 128–131° (lit. (8) 129.5–130.5°). Extension of the reaction time to 20 h increased the yield of **2***a* to 64%.

Compound **1***c* (reaction time 20 h) gave **2***c* (59%), m.p. 162–164°.

Anal. Calcd. for $C_{13}H_9ClN_3O_2$: C, 56.69; H, 3.66; N, 15.24. Found: C, 56.85; H, 3.97; N, 15.48.

Compound **1***d* (reaction time 20 h) gave **2***d* (60%), m.p. 162–165°.

Anal. Found: C, 56.40; H, 3.86; N, 15.45.

Compound **1***e* (reaction time 20 h) gave **2***e* (55%), m.p. 189–192° (acetonitrile–acetone, 1:1) (lit. (9) 189–191°).

Carbon tetrabromide (6.03 g, 20.0 mmol), compound **1***a* (20.0 mmol), and Ph_3P (25.0 mmol) were mixed. After 6 h the clear solution was evaporated to dryness and extracted four times with ether, the ether was removed *in vacuo* and the residue recrystallized from ethanol to give compound **2***b* (33%), m.p. 109–111°. Extension of the reaction time to 20 h increased the yield of **2***b* to 40%.

Anal. Calcd. for $C_{13}H_{11}BrN_2$: C, 56.22; H, 4.03; N, 10.24. Found: C, 56.74; H, 4.03; N, 10.18.

α-Halogenobenzaldehyde N-Methyl-N-phenyl- and N,N-Dimethylhydrazones

Carbon tetrachloride (1.95 ml, 20.0 mmol) was added to a stirred suspension of compound **3***a* (4.52 g, 20.0 mmol) and Ph_3P (6.55 g, 25.0 mmol) in CH_3CN, (40 ml; dried as described above) with the exclusion of moisture. After 2 h, the solution was evaporated. The solid material was extracted four times with ether and the ether was removed *in vacuo*; this was followed by distillation to give **4***a* (77%), b.p. 138–143°/0.05 mm; δ 3.39 (CH_3, in $CDCl_3$) (lit. (10) δ 3.40).

Carbon tetrachloride (20.0 mmol), compound **3***b* (11) (3.28 g, 20.0 mmol), and Ph_3P (25.0 mmol) (reaction time 2 h) gave compound **4***b* (58%), b.p. 58–60°/0.05 mm; δ 2.84 (CH_3) ($CDCl_3$).

Anal. Calcd. for $C_9H_{11}ClN_2$: C, 59.18; H, 6.07; N, 15.34. Found: C, 58.78; H, 6.18, N, 15.34.

Carbon tetrabromide (20.0 mmol), compound **3***b* (20.0 mmol), and Ph_3P (25.0 mmol) (reaction time 2 h) gave compound **4***c* (39%), b.p. 82–85°/0.5 mm; δ 2.80 (CH_3) ($CDCl_3$). A mass spectrum of the reaction mixture showed both the presence of bromoform (*m/e* 254/256) and triphenylphosphine oxide (*m/e* 278).

Anal. Calcd. for $C_9H_{11}BrN_2$: C, 47.59; H, 4.88; N, 12.34. Found: C, 48.02; H, 5.23; N, 12.38.

The Reaction of Triphenylphosphine with Carbon Tetrabromide

Carbon tetrabromide (6.03 g, 20.0 mmol) was added to a stirred suspension of Ph_3P (5.25 g, 20.0 mmol) in

CH_3CN (25 ml; dried as described above). After 15 min the solution was filtered and washed carefully with ether to give compound **7** (88% yield), m.p. 230–232° (lit. (4) 246–247°).

Anal. Calcd. for $C_{19}H_{15}Br_4P$: C, 38.42; H, 2.55. Found: C, 38.57; H, 3.00.

Compound **7** crystallized from ethanol as a solvate, m.p. 242–244°.

Anal. Calcd. for $C_{19}H_{15}Br_4P \cdot C_2H_5OH$: C, 39.41; H, 3.31; Br, 49.95. Found: C, 39.20; H, 2.90; Br, 51.27.

Recrystallization of the solvated form from nitromethane gave m.p. 236–238°.

Anal. Found: C, 38.28; H, 2.95.

Carbon tetrabromide (20.0 mmol) was added to a stirred suspension of Ph_3P (10.50 g, 40.0 mmol) in CH_3CN (25 ml; dried as described above). This gave after 15 min **7** (69%), m.p. 228–230°.

Anal. Found: C, 38.91; H, 2.95.

The Reaction of N'-Benzoyl-N-phenylhydrazine with Tribromomethyltriphenylphosphonium Bromide

Compound **1***a* (2.12 g, 10.0 mmol), crude **7** (5.94 g, 10.0 mmol), and Ph_3P (2.62 g, 10.0 mmol) were stirred together under dry conditions at room temperature for 3 days in CH_3CN (20 ml; dried as described above). The mixture was evaporated to dryness, the residue extracted four times with ether, and the ether removed *in vacuo*; this was followed by recrystallization from ethanol to give compound **2***b* (42%), m.p. 108–110°; i.r. identical to that of **2***b* prepared above.

Compound **2***b* was not isolated nor detected (t.l.c.) by repeating the foregoing experiment in the absence of Ph_3P.

The Reaction of Tribromomethyltriphenylphosphonium Bromide with Triphenylphosphine

Crude **7** (2.97 g, 5.0 mmol) and Ph_3P (1.31 g, 5.0 mmol) were refluxed together for 30 min in CH_3CN (10 ml). The red solution was allowed to cool to room temperature and then filtered. The solid obtained (2.32 g) was recrystallized to give compound **9** (52%). Compound **9** crystallized from acetonitrile as a solvate, m.p. 144–147°.

Anal. Calcd. for $C_{19}H_{16}Br_3P \cdot CH_3CN$: C, 45.35; H, 3.44; N, 2.52; Br (ionic), 14.37. Found: C, 45.18; H, 3.76; N, 2.96; Br (ionic), 14.37.

Heating compound **9** at 170° overnight gave m.p. 235–238° (lit. (12) 235°).

Anal. Calcd. for $C_{19}H_{16}Br_3P$: C, 44.30; H, 3.13. Found: C, 44.30; H, 3.19.

The Preparation and Properties of Some 2,1-Benzisoxazole and 2,1-Benzisothiazole Derivatives

MOHINDER S. CHAUHAN AND DAVID M. MCKINNON

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received November 12, 1974

MOHINDER S. CHAUHAN and DAVID M. MCKINNON. Can. J. Chem. **53**, 1336 (1975).

A number of 2,1-benzisoxazole and 2,1-benzisothiazole compounds containing alkoxy or amino substituents in the 3-position and carboxy substituents in the 7-position, and potentially capable of valency tautomerism have been synthesized by reduction or oxidation, respectively, of suitable 2-nitro- or 2-aminoisophthalic acid derivatives. Thionation of 2-aminoisophthalic esters gave benzothiazaphosphorine derivatives. A temperature dependent n.m.r. study of the benzisoxazole and benzisothiazole derivatives indicates that in only one case, for methyl 3-methoxy-2,1-benzisothiazole-7-thionocarboxylate is there evidence for tautomerism at 200°.

MOHINDER S. CHAUHAN et DAVID M. MCKINNON. Can. J. Chem. **53**, 1336 (1975).

On a synthétisé un certain nombre de dérivés du benzisoxazole-2,1 et du benzisothiazole-2,1 contenant des substituants alkoxy et amino en position 3 et des substituants carboxy en position 7; ces composés qui sont susceptibles de présenter de la tautomérie de valence, ont été respectivement obtenus par réduction ou oxydation des dérivés appropriés des acides nitro-2 ou amino-2 isophtaliques. La thionation des esters de l'acide amino-2 isophtalique donne les dérivés benzothiaphosphorines. On a examiné les spectres r.m.n. des dérivés du benzisoxazole et du benzisothiazole à différentes températures; on n'a trouvé qu'un seul cas, celui du méthoxy-3 benzisothiazole-2,1 thiono-7 carboxylate de méthyle où de la tautomérie de valence existe à 200°. [Traduit par le journal]

2,1-Benzisoxazole (anthranil) derivatives, particularly certain 7-substituted compounds, are of interest in studies on valency tautomerism (1). The ease with which the process occurs, however, appears to depend in some measure on the solvent used (1, 2). To obtain more information on these compounds we have therefore attempted the synthesis of some other 2,1-benzisoxazoles and studied their properties. It was also of interest to compare the properties of such 7-acyl-2,1-benzisoxazoles (**1**) with the corresponding 7-thioacyl-2,1-benzisothiazoles (**2**) to determine the relative effects, if any, of the sulfur and oxygen atoms in the valency tautomerism of the compounds, since the compounds **2**, more so than **1**, parallel the structure of a benzo-1,2-dithiolium derivative (3) which demonstrates magnetic equivalence of substituents on the 3- and thioacyl positions. These comparisons were frustrated in an earlier study (1) by the lability of an aliphatic thione substituent. In this work therefore, studies were directed towards the synthesis of esters and amides possessing the required potential symmetry. The sulfur analogs of these would be expected to be sufficiently stable to provide an adequate comparison.

b $R_1 = R_2 = NMe_2$

Syntheses were based on two methods, the reduction of *o*-nitrocarbonyl compounds or the oxidation of *o*-amino compounds. While both methods have been used for the conversion of suitable aldehydes and ketones to 2,1-benzisoxazoles (4) and are also applicable to the conversion of suitable thiocarbonyl compounds to 2,1-benzisothiazoles (5), they have not been used for the conversions of *o*-nitro- or *o*-aminoesters or thionoesters to 3-alkoxy-2,1-benzisoxazoles or 2,1-benzisothiazoles. Indeed such compounds appear to be unknown. 3-Amino-2,1-benzisoxazoles are available (6, 7) by reduction of suitable *o*-nitrobenzoic acid derivatives.

Methyl 2-nitroisophthalate (**3***a*) was reduced by stannous chloride in hydrochloric acid to methyl 2-aminoisophthalate (**3***b*). Treatment of this with hydrogen peroxide in acetic acid regenerated **3***a* but with Caro's acid 3-methoxy-2,1-benzisoxazole-7-carboxylic acid (**1***a*) was produced. Hydrolysis of an ester group had obviously accompanied the oxidative cyclization. We were unsuccessful in intercepting the required 2,1-benzisoxazole ester and other reductive methods were unsuccessful. The acid **1***a* treated with diazomethane afforded the desired ester **1***b* which has a structure of the required potential symmetry. The azide **3***c*, prepared from the amine **3***b*, failed to give **1***b* on either thermolysis or photolysis, although a similar reaction succeeded for 2,6-diacetylazidobenzene **3***d*, giving **1***c*.

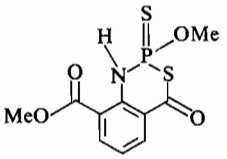
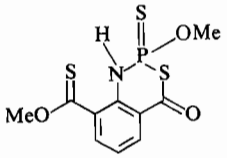
Thionation of **1***b* by phosphorus pentasulfide in toluene gave the 2,1-benzisothiazole **2***a* accompanied by the partially thionated compound **4** and the isomeric methyl 3-methoxy-2,1-benzisothiazole-7-carboxylate (**5**). The latter appears to be derived from **2***a* by hydrolysis of the thionoester function on the silica gel chromatogram used in separation but **2***a* appears to be otherwise stable. The ring sulfur in **2***a* is probably derived from the thionoester group in the initially thionated product **4** by valency tautomerism, similarly to a previously described example (1).

We also treated *N,N,N′,N′*-tetramethyl-2-nitroisophthalamide (**3***e*) with stannous chloride in hydrochloric acid. Two products were obtained, 3-dimethylamino-2,1-benzisoxazole-7-carboxylic acid (**1***d*) and the amine **3***f*. No 2,1-benzisoxazole **1***e* could be intercepted and other reductive methods failed to yield the desired product. The acid **1***d* was also converted by diazomethane into methyl 3-dimethylamino-2,1-benzisoxazole-7-carboxylate (**1***f*) but various attempts to form **1***e* from this by suitable chemical conversions were unsuccessful. The compound **1***f* is, however, suitable for study since it is potentially capable of valency tautomerism.

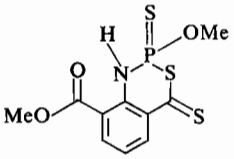
N,N,N′,N′-Tetramethyl-2-nitroisophthalamide (**3***e*) was smoothly thionated to the bisthioamide **3***g* which was reduced with stannous chloride to form a mixture of the desired *N,N*-dimethyl-3-dimethylamino-2,1-benzisothiazole-7-thiocarboxamide (**2***b*) and the amine **3***h* which were separated by fractional crystallization. The amine, as with many such structures (8), could be reoxidized to the benzisothiazole by peracetic acid.



6



7



8

Methyl 2-nitroisothiolphthalate (**3***i*), prepared by treatment of 2-nitroisophthaloyl chloride with methanethiol, gave on stannous chloride reduction only methyl 2-aminoisothiolphthalate (**3***j*). No 2,1-benzisoxazole could be intercepted. The ester **3***j* could not be reoxidized to the desired 2,1-benzisoxazole by any method tried. The nitro compound **3***i* was slowly thionated by phosphorus pentasulfide in toluene to yield methyl 2-nitrotetrathioisophthalate **3***k* but this only gave what appears to be a hydrolysis product on attempted reduction. The failure to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

effect suitable reduction of **3***k* in contrast to **3***i* or **3***a* is disappointing but it is probable that the nitro group is sterically hindered by the bulky sulfur functions. It is interesting that in contrast to the other compounds, which exhibit a low field displacement of aromatic protons *ortho* to the carbonyl or thiocarbonyl groups because of the electron withdrawing and anisotropic effects, the aromatic protons in **3***k* appear as a singlet.

The direct thionation of methyl 2-aminoisophthalate **3***b* with phosphorus pentasulfide gave two products, both of which contained phosphorus. The analysis, mass spectral data, and n.m.r. of one of these were in accord with the benzothiazaphosphorinethione structure **6**. This structure is analogous to some obtained by Legrand and Losac'h (9) by thionation of *N*-substituted anthranilic esters. The other compound, which was dark green, had one oxygen atom replaced by sulfur. Since a peak at 1700 cm^{-1} in **7**, due to the ester carbonyl frequency, was absent, we tentatively assign to this compound the thionoester structure **7** rather than the isomeric phosphorinedithione structure **8**.

Nuclear magnetic resonance spectra were performed in dimethyl sulfoxide. Earlier work (2) had indicated that this was a satisfactory solvent. Over the temperature range studied (40–200°) the methyl groups in **1***b* were nonequivalent, although some approach of τ values and line broadening was evident. The corresponding 2,1-benzisothiazole **2***a* exhibited coalescence at 200°. For the thioamide **2***b*, at 40° three methyl signals were observed due to the equivalent amine methyls and the nonequivalent thioamidic methyls. At 200° the latter had become equivalent but were still different from the former, two singlets being observed. These results are consistent with values for rotational barriers in thioamides (10). The net result of the alkoxy- or dimethylamino groups on the system appears to be to reduce the ease of tautomerism. The small enhancement by sulfur that is evident by comparison of the compounds **1***b* and **2***a* is expected (11) in view of the generally lower free energy of activation of reactions at sulfur atoms.

While methyl 3-dimethylamino-2,1-benzisoxazole-7-carboxylate (**1***f*) is potentially capable of tautomerism to *N*,*N*-dimethyl-3-methoxy-2,1-benzisoxazole-7-carboxamide (**1***g*), no evidence for this was obtained under the conditions studied. At 40° the amine methyl groups were nonequivalent but coalescence of their signals occurred on warming to 120°. At 200° only two signals, due to the amine and ester methyls, were apparent. It is interesting in that whereas the amine methyls in **1***f* were nonequivalent at room temperature, those in the 2,1-benzisothiazole **2***b* demonstrated equivalence in any solvent tried. The differences may be due to the greater electronegativity of the oxygen atom over sulfur in the heterocyclic ring affecting the amount of double bond character in the exocyclic carbon to nitrogen band. It is also likely that there is a significant effect of the carbonyl or thiocarbonyl group in the 7-position.

The amino methyl groups in the acid **1***d*, in contrast to the ester **1***f*, are equivalent due to its existence as the zwitterionic structure **1***h* akin to normal amino acids. The i.r. spectrum indicated a band at 2350 cm^{-1}, typical of protonated amines. When the compound was treated with sodium bicarbonate solution, to suppress protonation, the n.m.r. indicated nonequivalence of the methyl groups.

Experimental

The i.r. spectra were performed on a Perkin-Elmer model 337 spectrophotometer in liquid paraffin mulls. The n.m.r. spectra were obtained on a Varian model 56/60A spectrometer and, unless otherwise stated, in deuteriochloroform at 40°, using tetramethylsilane as an internal standard. Chromatography was performed using Camag silica gel, type D.S.F.5., supplied by Terochem Laboratories. Development of plates was carried out using benzene, with increasing proportions of chloroform, unless otherwise stated. Melting points were obtained on a precalibrated Thermopan apparatus.

Preparation of Methyl 2-Nitroisophthalate (3a)

A mixture of 2-nitroisophthaloyl chloride (9.92 g, 40 mmol) (1) and methanol (150 ml) was refluxed for 30 h. Excess methanol was removed by evaporation and the residue crystallized from a benzene – petroleum ether, 1:1 mixture, as colorless plates m.p. 133–134° (98%).

Anal. Calcd. for $C_{10}H_9NO_6$: C, 50.21; H, 3.76; N, 5.85. Found: C, 50.38; H, 3.86; N, 5.93.

The i.r. spectrum, 1735 cm^{-1} (C=O str). The n.m.r. spectrum, 6.49 (6H singlet, the methyl protons) 2.85–2.09 τ (3 H bands the aromatic protons). The mass spectrum, M^+ Calcd.: 239. Found: 239.

Preparation of 2,6-Diacetylazidobenzene (3d)

2,6-Diacetylaniline (1.77 g, 10 mmol) in 20% hydrochloric acid (20 ml) was diazotized at 0° with sodium nitrite (0.69 g). The mixture was filtered and added to sodium azide (1.5 g) in water (10 ml) and allowed to stand 16 h. The crystalline precipitate was collected,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

washed, and recrystallized from petroleum ether. Colorless needles m.p. 48° were obtained (76%).

Anal. Calcd. for $C_{10}H_9N_3O_2$: C, 59.15; H, 4.44; N, 20.69. Found: C, 59.01; H, 4.52; N, 20.70.

The i.r. spectrum, 2151 cm^{-1} (N_3). The n.m.r. spectrum, 7.35 τ (6H singlet, the methyl protons), 2.13–2.84 τ (3H bands, the aromatic protons). The mass spectrum M^+ Calcd.: 203. Found: 203 (M^+), 175 ($M^+ - N_2$).

Preparation of 7-Acetyl-3-methyl-2,1-benzisoxazole (1c)

2,6-Diacetylazidobenzene (0.51 g, 2.5 mmol) in *o*-dichlorobenzene (5 ml) was refluxed 20 min. The solution slowly acquired a purple color. Evaporation and chromatography indicated a number of products but the yellow and orange bands on work-up gave a crude crystalline product which was recrystallized from petroleum ether – benzene, 1:1 mixture, as colorless needles m.p 103°, identical (mixture m.p. and i.r.) with an authentic sample (1).

Reduction of Methyl 2-Nitroisophthalate to form Methyl 2-Aminoisophthalate (3b)

Methyl 2-nitroisophthalate (2.86 g, 12 mmol) was slowly added over 10 min to a stirred solution of stannous chloride dihydrate (12 g) in concentrated hydrochloric acid (36 ml) at 25° under a nitrogen atmosphere. The mixture was stirred 1.5 h then diluted with water (100 ml). The precipitate was filtered and recrystallized from a mixture of benzene – petroleum ether, 1:1, to give the desired amine as colorless needles m.p. 102–103°. The yield was virtually quantitative.

Anal. Calcd. for $C_{10}H_{11}NO_4$: C, 57.45; H, 5.26; N, 6.70. Found: C, 57.57; H, 5.41; N, 6.82.

The i.r. spectrum 1705 cm^{-1} (C=O str). The n.m.r. spectrum, 6.17 (6H singlet, the methyl protons), 3.45 and 1.92 τ (1H triplet and 3H doublet, the aromatic protons), and 1.89 τ (2H band, the amine protons, exchanged in D_2O). The mass spectrum M^+ Calcd.: 209. Found: 209.

Oxidation of Methyl 2-Aminoisophthalate

(a) With Caro's Acid

A mixture of the amine (313 mg, 15 mmol) and Caro's acid (prepared by stirring a mixture of potassium persulfate (10 g), concentrated sulfuric acid (7 ml), and ice (50 g)) was stirred at 30° for 5 h. The mixture was diluted with water, filtered, and the residue extracted with hexane (4 × 20 ml). The combined extracts on evaporation gave starting material. The residue was crystallized from a mixture of chloroform and petroleum ether to give 3-methoxy-2,1-benzisoxazole-7-carboxylic acid (43%) as colorless needles, m.p. 160–161°. Further small amounts of products were obtained by extraction of the aqueous filtrate with methylene chloride.

Anal. Calcd. for $C_9H_7NO_4$: C, 55.95; H, 3.63; N, 7.26. Found: C, 55.79; H, 3.63; N, 7.37.

The i.r. spectrum, 1751 cm^{-1} (C=O str). The n.m.r. spectrum 6.01 (3H singlet, the methyl protons), 2.95–1.75 τ (3H bands, the aromatic protons). The mass spectrum M^+ Calcd.: 193. Found: 193.

(b) With Hydrogen Peroxide

A mixture of the amine (170 mg, 8 mmol), glacial acetic acid (5 ml), and 50% aqueous hydrogen peroxide, 1.0 ml) was left at 30° for 70 h. Work-up afforded methyl 2-nitroisophthalate (63%).

Preparation of Methyl 3-Methoxy-2,1-benzisoxazole-7-carboxylate (1b)

To a solution of diazomethane (40 mg) in ether (30 ml) was added a solution of 3-methoxy-2,1-benzisoxazole-7-carboxylic acid (58 mg, 3 mmol) in ether (20 ml). Immediate evolution of gas was evident. After ½ h, the mixture was evaporated to yield the ester, which was recrystallized from hexane as colorless needles, m.p. 134–135° (96%). The compound exhibited a strong blue fluorescence in u.v. light.

Anal. Calcd. for $C_{10}H_9NO_4$: C, 57.95; H, 4.45; N, 6.77. Found: C, 57.89; H, 4.40; N, 6.78.

The i.r. spectrum, 1764 cm^{-1} (C=O str). The n.m.r. spectrum, 6.45 (3H singlet, the ester methyl), 6.02 (3H singlet, the methoxyl protons) 2.80–1.54 τ (3H bands, the aromatic protons). The mass spectrum M^+ Calcd.: 207. Found: 207.

Preparation of Methyl 2-Azidoisophthalate (3c)

To a stirred suspension of methyl 2-aminoisophthalate (1.67 g, 8 mmol) in 50% hydrochloric acid (10 ml) was added dropwise at 0° a solution of potassium nitrite (0.7 g) in water (10 ml). The solution was stirred a further 10 min and filtered. To the stirred filtrate was added a solution of sodium azide (2.0 g) in water (15 ml). A colorless precipitate was produced. The mixture was stirred a further 2 h then the precipitate collected and recrystallized from a benzene – petroleum ether, 1:1 mixture, as colorless plates m.p. 67° (88%).

Anal. Calcd. for $C_{10}H_9N_3O_4$: C, 51.10; H, 3.83; N, 17.85. Found: C, 51.13; H, 3.96; N, 17.81.

The i.r. spectrum, 1737 (C=O str) and 2163 cm^{-1} (N_3). The n.m.r. spectrum, 6.04 (6H singlet, the methyl protons), 2.84–1.92 τ (3H bands, the aromatic protons). The mass spectrum M^+ Calcd.: 235. Found: 235.

Attempted Conversion of Methyl 2-Azidoisophthalate to Methyl 3-Methoxy-2,1-benzisoxazole-7-carboxylate

Pyrolysis of the azide (156 mg, 0.65 mmol) in boiling *o*-dichlorobenzene or photolysis of the azide (235 mg, 1 mmol) dissolved in dry benzene (350 ml) under nitrogen with a medium pressure mercury lamp in a quartz reactor for 1 h yielded traces of methyl 2-aminoisophthalate and much polymeric material.

Thionation of Methyl 3-Methoxy-2,1-benzisoxazole-7-carboxylate

The ester (250 mg, 1.2 mmol) and phosphorus pentasulfide (420 mg) in dry toluene (20 ml) were refluxed 5 h. The solvent was removed under reduced pressure and the residue treated with 5% aqueous sodium bicarbonate solution. The mixture was extracted with ether (4 × 100 ml) and the extract washed, dried, and evaporated gave a crude product which was separated by chromatography using a 1% methanol solution in chloroform as an eluent to give methyl 3-methoxy-2,1-benzisothiazole-7-thionocarboxylate as yellow plates, m.p. 128–129°, from petroleum ether (7%).

Anal. Calcd. for $C_{10}H_9NO_2S_2$: C, 50.21; H, 3.77; N, 5.86; S, 26.75. Found: C, 50.35; H, 3.89; N, 5.93; S, 26.60.

The mass spectrum M^+ Calcd.: 239. Found: 239.

Methyl 3-methoxy-2,1-benzisoxazole-7-thionocarboxylate, yellow prisms, m.p. 123–124°, from petroleum ether (4%), was also separated by chromatography.

Anal. Calcd. for $C_{10}H_9NO_2S$: C, 53.81; H, 4.03; N.

6.27; S, 14.35. Found: C, 53.71; H, 4.18; N, 6.10; S, 14.49.

The n.m.r. spectrum, 4.22 and 4.00 (two 3H singlets, the methyl protons), 2.72–1.52 τ (3H bands, the aromatic protons). The mass spectrum M^+ Calcd.: 223. Found: 223.

A small quantity of pale yellow material tentatively methyl 3-methoxy-2,1-benzisothiazole-7-carboxylate (0.5%) was also isolated. The mass spectrum M^+ Calcd.: 223. Found: 223. The i.r. spectrum, 1765 cm^{-1} (C=O str).

Preparation of N,N,N′,N′-Tetramethyl-2-nitroisophthalamide (3e)

2-Nitroisophthaloyl chloride (24.8 g, 0.1 mol) was dissolved in dry benzene (200 ml) and 40% aqueous dimethylamine solution (20 ml) was added slowly. The mixture was stirred for 3 h at 50°. The benzene layer separated, washed with saturated sodium chloride solution, dried, and evaporated gave a pale yellow product which was recrystallized from a benzene – petroleum ether, 1:1 mixture, as colorless plates, m.p. 151–152° (83%). The product was stable but turned red on prolonged exposure to light.

Anal. Calcd. for $C_{12}H_{15}N_3O_4$: C, 54.34; H, 5.65; N, 15.82. Found: C, 54.33; H, 5.70; N, 15.68.

The i.r. spectrum, 1640 cm^{-1} (C=O str). The n.m.r. spectrum 7.08 and 6.92 (two 6H singlets, the methyl protons), 2.72–2.14 τ (3H bands, the aromatic protons). The mass spectrum M^+ Calcd.: 265. Found: 265.

Reduction of N,N,N′,N′-Tetramethyl-2-nitroisophthalamide

The nitro compound (2.99 g, 12.5 mmol) was added to a stirred solution of stannous chloride (12.0 g) in concentrated hydrochloric acid (36 ml) under nitrogen. The solution was stirred 1½ h at 0°, saturated sodium chloride solution (150 ml) added, and the mixture extracted with chloroform (3 × 150 ml). Work-up of the combined chloroform extracts yielded a crystalline residue which was recrystallized from benzene to give 3-dimethylamino-2,1-benzisoxazole-7-carboxylic acid as colorless needles, m.p. 164–165° (70%).

Anal. Calcd. for $C_{10}H_{10}N_2O_3$: C, 58.25; H, 4.85; N, 13.59. Found: C, 58.32; H, 4.95; N, 13.74.

The i.r. spectrum, 1602 (tentatively asym. CO_2^- str) and 2350 cm^{-1} (N^+—H str). The n.m.r. spectrum in $CDCl_3$ 6.86 (6H singlet, the methyl protons), 2.94–2.22 (3H bands, the aromatic protons), −1.10 τ (broad 1H band, exchanged in D_2O (the acidic proton)). In D_2O saturated with $NaHCO_3$ the methyl protons were evident as two peaks at 6.94 and 7.08 τ.

Neutralization of the aqueous layer from above with sodium bicarbonate and chloroform extraction gave on evaporation a crystalline product which was recrystallized from benzene – petroleum ether, 1:1 mixture, to give *N,N,N′N′*-tetramethyl-2-aminoisophthalamide as colorless needles, m.p. 177–178° (15%).

Anal. Calcd. for $C_{12}H_{17}N_3O_2$: C, 61.27; H, 7.23; N, 17.87. Found: C, 61.19; H, 7.48; N, 17.69.

The i.r. spectrum, 1661 cm^{-1} (C=O str). The n.m.r. spectrum, 6.95 (12H singlet, the methyl protons), 3.25–2.65 τ (3H bands, the aromatic protons).

Preparation of Methyl 3-Dimethylamino-2,1-benzisoxazole-7-carboxylate (1f)

3-Dimethylamino-2,1-benzisoxazole-7-carboxylic acid (248 mg, 1.2 mmol) in dry ether (300 ml) was added to the calculated amount of diazomethane in dry ether (50 ml). The solution was left at room temperature for 5 h then the ether was removed by evaporation. The residue was crystallized from a benzene – petroleum ether, 1:1 mixture, as colorless needles m.p. 105–106° (98%).

Anal. Calcd. for $C_{11}H_{12}N_2O_3$: C, 60.00; H, 5.45; N, 12.73. Found: C, 60.04; H, 5.43; N, 12.72.

The i.r. spectrum, 1761 cm^{-1} (C=O str). The n.m.r. spectrum 7.06 and 6.84 (two 3H singlets, the amine methyls), 6.73 (3H singlet, the ester methyl), 2.72–1.98 τ (3H bands, the aromatic protons). The mass spectrum M^+ Calcd.: 220. Found: 220.

Preparation of N,N,N′,N′-Tetramethyl-2-nitroisothiophthalamide

A mixture of *N,N,N′N′*-tetramethylisophthalamide (7.0 g, 2.66 mmol) and phosphorus pentasulfide (10.0 g) in toluene (50 ml) was refluxed for 3 h. The solvent was evaporated and the residue treated with 5% sodium bicarbonate solution and extracted with chloroform (3 × 100 ml). The combined extracts were washed with water and evaporated. The residue was crystallized from benzene to give the product as yellow plates m.p. 204–205° (88%).

Anal. Calcd. for $C_{12}H_{15}N_3O_2S_2$: C, 48.48; H, 5.05; N, 16.14; S, 21.55. Found: C, 48.64; H, 5.05; N, 14.11; S, 21.66.

The n.m.r. spectrum 6.73 and 6.43 (two 6H singlets, the methyl protons), 2.96–2.41 τ (3H bands, the aromatic protons). The mass spectrum M^+ Calcd.: 297. Found: 297.

Reduction of N,N,N′,N′-Tetramethyl-2-nitroisothiophthalamide

To a solution of stannous chloride (2.5 g) in concentrated hydrochloric acid (15 ml) was added the thioamide (1.435 g, 5 mmol) and the mixture stirred under nitrogen 3 h. The mixture was filtered and the residue washed with water then dissolved in benzene. The benzene solution was washed with 50% aqueous sodium hydroxide solution, washed with water, dried, and evaporated to give a crude product which was separated by chromatography using 1% methanol in chloroform as an eluant to give starting material and a mixture of *N,N,N′,N′*-tetramethyl-2-aminoisothiophthalamide (80%) and *N,N*-dimethyl-3-dimethylamino-2,1-benzisothiazole-7-thiocarboxamide (16%). These were separated by fractional crystallization from benzene, in which the isothiazole is more soluble, to give products m.p. 207–208 and 202°, respectively.

For the amine, Anal. Calcd. for $C_{12}H_{17}N_3S_2$: C, 53.93; H, 6.37; N, 15.71; S, 24.00. Found: C, 53.63; H, 6.28; N, 15.53; S, 24.02.

The n.m.r. spectrum 6.84 and 6.46 (two 6H singlets, the methyl protons), 5.90 (broad band, exchangeable in D_2O, the amine protons), 2.11–1.54 τ (3H bands, the aromatic protons). The mass spectrum, M^+ Calcd.: 267. Found: 267. Rigorous drying was necessary for proper analysis.

For personal use only.

2.19–2.04 τ (3H bands, the aromatic protons). The mass spectrum M^+ Calcd.: 265. Found: 265.

Oxidation of N,N,N′,N′-Tetramethyl-2-aminoisothiophthalamide with Hydrogen Peroxide in Acetic Acid

The thioamide (80 mg, 0.3 mmol) in acetic acid (5 ml) was treated with 30% hydrogen peroxide (0.03 ml) and the solution heated at 50° for 1 h. The solution was diluted with water, extracted with chloroform, and the chloroform layer washed with saturated sodium bicarbonate solution. Evaporation yielded a yellow oil which on examination by chromatography, using repeated development with chloroform, yielded three yellow bands. The second of these on elution gave *N,N*-dimethyl-3-dimethylamino-2,1-benzisothiazole-7-thiocarboxamide, identical (mixture m.p. and mass spectrum) to a sample prepared above (10%).

Preparation of Methyl 2-Nitroisothiolphthalate (3i)

A mixture of 2-nitroisophthaloyl chloride (12.4 g, 50 mmol), dry benzene (150 ml), and methanethiol (19.2 g) was treated with triethylamine (30 g), and the mixture stirred 3 h. The mixture was warmed to 60° to remove excess methanethiol, then poured into water. The benzene layer was extracted with dilute sodium hydroxide and dilute hydrochloric acid, dried, and evaporated under reduced pressure to give the crude ester, which was recrystallized from a mixture of benzene and petroleum ether as colorless plates m.p. 130–131°.

Anal. Calcd. for $C_{10}H_9NO_4S_2$: C, 44.28; H, 3.32; N, 5.16; S, 23.61. Found: C, 44.44, H, 3.35, N, 5.21; S, 23.79.

The i.r. spectrum, 1635 cm^{-1} (C=O str). The n.m.r. spectrum, 7.52 (6H singlet, the methyl protons), 2.46–1.82 τ (3H bands, the aromatic protons). The mass spectrum M^+ Calcd.: 271. Found: 271.

Reduction of Methyl 2-Nitroisothiolphthalate with Stannous Chloride

A mixture of methyl 2-nitroisothiolphthalate (4.06 g, 1.5 mmol), stannous chloride dihydrate (36 g), and concentrated hydrochloric acid (100 ml) was heated at 60° for 16 h under nitrogen. Water (300 ml) was added to the reaction mixture and the precipitate filtered. The residue was extracted with boiling petroleum ether which on concentration and cooling gave methyl 2-aminoisothiolphthalate. The product was recrystallized from petroleum ether as lemon yellow plates, m.p. 93–94°, (63%).

Anal. Calcd. for $C_{10}H_{11}NO_2S_2$: C, 49.79; H, 4.56; N, 5.81; S, 26.55. Found: C, 49.69; H, 4.63; N, 5.79; S, 26.74.

The i.r. spectrum, 3300 and 3405 (NH_2 str), 1655 cm^{-1} (C=O str). The n.m.r. spectrum, 7.63 (6H singlet, methyl protons), 3.56 and 1.80 (1H triplet, 2H doublet, the aromatic protons), and 1.80 τ (2H band, the amine protons). The mass spectrum M^+ Calcd.: 241. Found: 241.

Thionation of Methyl 2-Nitroisothiolphthalate to form 3k

A mixture of methyl 2-nitroisothiolphthalate (4.06 g, 15 mmol), phosphorus pentasulfide (12.0 g), and toluene (2.50 ml) was refluxed 3 days. The mixture was filtered, washed with sodium bicarbonate solution, and evaporated to yield a brown residue. Crystallization from a benzene, petroleum ether mixture gave the tetrathioester as orange plates, m.p. 138–139°, (71%).

Anal. Calcd. for $C_{10}H_9NO_2S_4$: C, 39.60; H, 2.97; N, 4.62; S, 42.24. Found: C, 39.67; H, 3.08; N, 4.69; S, 42.48.

The n.m.r. spectrum, 7.26 (6H singlet, the methyl protons) and 2.48 τ (3H singlet, the aromatic protons). This absorption remained a singlet when the compound was dissolved in hexadeuteriobenzene. The mass spectrum M^+ Calcd.: 303. Found: 303.

Attempted Reduction of Methyl 2-Nitroisotetrathiophthalate with Stannous Chloride

A mixture of the tetrathioester (1.0 g), stannous chloride (9.0 g), and concentrated hydrochloric acid (27 ml) was heated at 60–70° for 4 h. Work-up afforded mainly starting material and traces of hydrolyzed products.

Reaction of Methyl 2-Aminoisophthalate with Phosphorus Pentasulfide

A mixture of the ester (418 mg, 2 mmol), phosphorus pentasulfide (600 mg, 1.35 mmol), and toluene (25 ml) was refluxed for 8 h. The mixture was filtered and the residue washed with benzene and the benzene washings united with the toluene. The solvent was removed *in vacuo* and the residue treated with sodium bicarbonate solution. An ether extract was dried and evaporated to yield green material which was separated by chromatography in benzene to give **7** as dark green prisms m.p. 99–100° (58%) and **6** as greenish yellow prisms m.p. 150–152° (11%).

For **7**, Anal. Calcd. for $C_{10}H_{10}NO_3PS_3$: C, 37.61; H, 3.13; N, 4.39; P, 9.71; S, 30.09. Found: C, 37.79; H, 3.25; N, 4.50; P, 9.93; S, 30.06.

The i.r. spectrum, 1675 cm^{-1} (C=O str). The n.m.r. spectrum, 6.33 (3H doublet, $J = 16$ Hz, the methoxy protons, split by phosphorus) and 5.98 τ (3H singlet, the ester methyl). The mass spectrum M^+ Calcd.: 319. Found: 319.

For **6**, Anal. Calcd. for $C_{10}H_{10}NO_4PS_2$: C, 39.60; H, 3.30; N, 4.02; P, 10.23; S, 21.12. Found: C, 39.68; H, 3.22; N, 4.68; P, 10.03, S, 21.11.

The i.r. spectrum, 1695, 1660 cm^{-1} (C=O str). The n.m.r. spectrum, 6.33 (3H doublet, $J = 16$ Hz, the methoxy protons, split by phosphorus), 6.08 τ (3H singlet, the ester methyl). The mass spectrum M^+ Calcd.: 303. Found: 303.

Nuclear Magnetic Resonance Spectral Data

These were obtained on samples dissolved in hexadeuteriodimethyl sulfoxide in degassed sealed tubes and over the temperature range 40–200°.

Methyl 3-methoxy-2,1-benzisoxazole-7-carboxylate. At 40° two singlets at 6.70 and 6.21 τ were evident. At 200°, two singlets, separated by 0.52 τ were still observed, although some line broadening was evident.

Methyl 3-methoxy-2,1-benzisothiazole-7-thionocarboxylate. At 40° two singlets were observed at 6.54 and 6.20 τ. At 200° these had coalesced into a broad singlet at 6.30 τ.

Methyl 3-dimethylamino-2,1-benzisoxazole-7-carboxylate. At 40° this exhibited three methyl absorptions. Two at 7.28 and 7.10 τ were assigned to the amine methyl and one at 6.89 τ to the ester methyl. At 120° the former became equivalent but even at 200° there was no evidence for the valency isomerism.

N,N-Dimethyl-3-dimethylamino-2,1-benzisothiazole-7-thiocarboxamide. At 40°, this exhibited three methyl signals, at 7.07 and 6.54 τ, the amidic methyls, and at 6.72 τ, the equivalent amino methyls. At 180° the peaks were still discrete. At 200° the amidic methyl peaks had collapsed to a singlet but were still nonequivalent to the amine methyl. An attempt to study the temperature dependent rotational equivalence of the amine methyls in chloroform or acetone was unsuccessful as the compound was too insoluble in these solvents below −20°.

We wish to thank the National Research Council of Canada for financial support of this research. We also wish to thank Mr. M. Arneson and Mr. R. Simanavicius for preparation of spectra.

The Electronic Structure and Localized Molecular Orbitals in S_4N_4 by the CNDO/BW Theory

M. S. GOPINATHAN AND M. A. WHITEHEAD[1]

Theoretical Chemistry Department, 1 South Parks Road, Oxford, England

Received September 24, 1974

M. S. GOPINATHAN and M. A. WHITEHEAD. Can. J. Chem. **53**, 1343 (1975).

The energies calculated for tetranitrogen tetrasulfide, S_4N_4, by the CNDO/BW theory favor a structure with coplanar nitrogen atoms and not a structure with coplanar sulfur atoms. Both structures have been proposed from experimental studies. Localized molecular orbitals are calculated for S_4N_4 and used to choose the appropriate Lewis structure for the molecule. The hybridization at the nitrogen and sulfur atoms is discussed. There is electron delocalization in the molecule, the S—N bond is a bent bond involving pure p-orbitals on the sulfur and nitrogen atoms and there is a pure p-bent bond between the sulfur atoms on the same side of the coplanar nitrogen atoms. There is no N—N bond in S_4N_4.

M. S. GOPINATHAN et M. A. WHITEHEAD. Can. J. Chem. **53**, 1343 (1975).

Les énergies calculées pour le tétrasulfure de tétrazote, S_4N_4, par la théorie CNDO/BW favorisent une structure avec des atomes d'azote coplanaires et non pas une structure avec des atomes de soufre coplanaires. Les deux structures avaient été proposées à partir d'études expérimentales. Les orbitales moléculaires localisées peuvent être calculées pour S_4N_4 et utilisées pour choisir la structure de Lewis appropriée pour la molécule. On discute de l'hybridisation aux atomes d'azote et aux atomes de soufre. Il y a une délocalisation des électrons dans la molécule; le lien S—N est un lien courbé impliquant des orbitales p pures sur les atomes de soufre et les atomes d'azote et il y a un lien p courbé entre les atomes de soufre sur le même côté des atomes d'azote coplanaires. Il n'y a pas de lien N—N dans le S_4N_4.

[Traduit par le journal]

Introduction

The molecular structure and chemical bonding in tetranitrogen tetrasulfide, S_4N_4, are unresolved (1, 2). X-Ray and electron diffraction studies (3) and vibrational (4) and electronic (5) spectral studies lead to two proposed molecular structures, **1** and **2**, (Figs. 1 and 2). In structure **1** the four nitrogen atoms are coplanar with two sulfur atoms above and two below the plane, while structure **2** has coplanar sulfur atoms with the nitrogen atoms above and below the plane. Both structures have D_{2d} molecular symmetry. An extended Hückel theory study (6) of the energies of the two structures predicted structure **1** to be more stable. The same structures are here studied using SCFMO wavefunctions of the CNDO/BW theory (7).

There is also the problem of the electronic structure of S_4N_4. Many Lewis structures (Fig. 3, **A** to **G**) have been proposed for S_4N_4, which differ in the type of bonds present, the charge on the atoms, the number of lone-pair electrons on each atom, and the presence or absence of S—S

and N—N bonds. Experimental and theoretical studies have not provided a unique atomic orbital description. From vibrational spectra, Lippincott and Tobin (4) proposed structure **2** with N—N bonds but no S—S bonds. The electronic spectrum was explained (5) using a weak S—S bond, structure **1**. A free electron treatment (8) suggested the presence of both N—N and S—S bonds, while Lindqvist (9) proposed formula **B**. From an empirical correlation between S—S bond length and s-character of the sulfur hybrid orbitals in other molecules, it was argued that a single bond involving pure po orbitals exists in S_4N_4 (9). Extended Hückel calculations (6) gave a negative bond order between the nitrogen atoms and indicated a weak S—S bond of the pσ type. The dispute over the existence of an S—S bond arises from the fact that the observed S—S distance in S_4N_4 is 2.58 Å which is longer than the normal single bond length, of 2.08 Å, and shorter than the sum of the van der Waals radii, 3.70 Å (7). A pure pσ bond between sulfur atoms does not fit (3) with the "double bond character" of the N—S bond inferred from the bond length of 1.616 Å, which is shorter than a "pure single (sp^3)" bond length of 1.764 Å. However this N—S double bond character is not consistent with the observed angles of 113° at nitrogen and 105° at sulfur. Any bonding scheme for the molecule also has to explain the electron delocalization in the S—N ring, indicated by the electronic spectrum (5), and the ^{14}N n.m.r. chemical shifts (10) and explain the unstable nature of the compound.

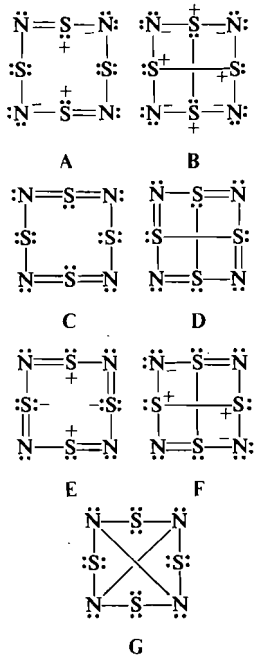

FIG. 3. Possible Lewis structures for S_4N_4.

The conventional form of molecular orbital wavefunctions cannot answer the above questions since the wavefunctions are delocalized over the entire molecular frame, and do not correspond to chemical bonds, lone pairs, etc. However, a single determinantal wavefunction, such as the CNDO/BW wavefunction, is invariant to orthogonal transformation of the occupied molecular orbitals out of which it is formed. Therefore the delocalized molecular orbitals can be transformed into Localized Molecular Orbitals (LMO's) which correspond to chemical bonds and lone pairs. Several criteria have been used to determine the transformation matrix (11) but the most successful and theoretically attractive method is that of Lennard-Jones (12), extensively applied by Ruedenberg and co-workers (13). This method uses the theory that the two electrons forming a localized bond have maximum self-repulsion. This is an intrinsic criterion (14) and does not involve any preconceived model for the electron density distribution. The method successfully describes the electronic structure of a wide variety of molecules including electron deficient molecules (15, 27), and has been applied to the CNDO/BW wavefunctions for S_4N_4 to obtain a quantitative description of the nature of the bonding.

Method of Calculation

The CNDO/BW theory is specifically parameterized to yield the correct equilibrium molecular geometry (7). The parameter set III of Boyd and Whitehead (7) has been used, together with the experimental molecular geometry: structure **1**: N—S 1.616 Å, ∠SNS 113°, ∠NSN 105° (ref. 3); structure **2**: N—S 1.74 Å, ∠SNS 98.2°, ∠NSN 79.25° (ref. 4). Only 2s and 2p functions were used in the basis set; the possibility of d-orbitals on sulfur is discussed later. The localization procedure followed that of CNDO type wavefunctions given by Gopinathan and Narasimhan (16).

Results and Discussion

Geometrical Structure

The total molecular energy calculated by the

*N_s coefficient of atomic orbtal a on nitrogen.
†S_b coefficient of atomic orbital b on sulfur. The delocalization is given by $d = (1 - \sum_i c_{iTLMO}^2) \times 100\%$. Thus the delocalization of the N_1 lone pair is $(1 - \sum_{s,p_x,p_y,p_z} c_{N_1TLMO}^2)$, and the amount of delocalization other than to the adjacent S_2 and S_3 is given by $(1 - \sum_{\text{nitrogen orbitals}} c_i^2 - \sum_{\text{sulfur orbitals}} c_i^2)$.

CNDO/BW method is −64.72827 a.u. for structure **1** and −64.39302 a.u. for structure **2**. The average calculated S—N bond energy is 70 kcal mol^{-1} for structure **1** and 50 kcal mol^{-1} for structure **2**. Thus the coplanar nitrogen structure is more stable than the coplanar sulfur structure by 0.33525 a.u. (~200 kcal mol^{-1}). Qualitatively similar results were obtained from extended Hückel calculations (6). The latest three-dimensional X-ray diffraction study (3) also supports structure **1**. These results show structure **1** to be the correct one; structure **2** is not considered further.

Electronic Structure

There are 44 valence electrons in S_4N_4 in 22 occupied molecular orbitals. The localized CNDO/BW molecular orbitals for S_4N_4 are highly localized. The degree of delocalization of LMO can be obtained as follows.

While a given LMO approximates a given bond or lone pair in a molecule, it contains coefficients of atomic orbitals on atoms which are not those forming a localized bond or lone pair. If all the coefficients of atomic orbitals, other than those chemically considered to be involved in the bond or lone pair, are neglected, a *Truncated Localized Molecular Orbital*, TLMO (Ψ_{TLMO}) is obtained. This TLMO is not renormalized. The original LMO is normalized, and the difference

$$1 - \int \Psi_{TLMO}^2 \, d\tau$$

measures the delocalization of the original LMO. If the LMO is completely localized it equals the TLMO and the above difference is zero. Within the CNDO/BW theory, where differential overlap is neglected, this difference becomes

$$d = \left(1 - \sum_i c_{iTLMO}^2\right) \times 100$$

as a percentage of delocalization, and d goes to 0% when the LMO represents a completely localized lone pair or bond, and hence is identical to the TLMO.

The LMO's in S_4N_4 belong to five types, Table 1 and Fig. 4.

(1) Nitrogen Lone Pair (I)

This is a nitrogen 2s orbital, with 99.1% s-character. Thus there is no hybridization at the nitrogen atoms in S_4N_4. The delocalization index, d, is 1.02%; this lone pair is highly localized.

(2) Sulfur Lone Pair

This is predominantly a sulfur 2s orbital, with 80.45% s-character. The d value is 0.85%; the lone pair is highly localized.

(3) N—S Bond

The d value is 2.76%; the bond is highly localized. It is a single bond between almost pure p-orbitals on nitrogen and sulfur. The s-characters of the nitrogen and sulfur orbitals are 3.82 and 9.83% respectively. These orbitals are not directed along the N—S internuclear axis. The p-vector corresponding to the nitrogen orbital (having the x, y, z components given in Table 1) makes an angle of 6.03° with the NS axis at 21.17° to the NSS plane and the corresponding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

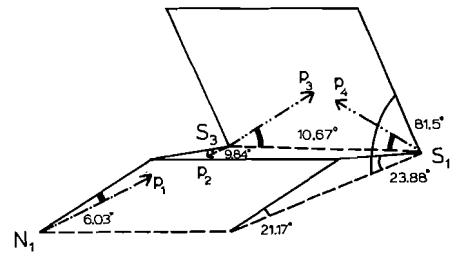

FIG. 4. Atomic orbital representation (schematic) of N—S and S—S bonds in S_4N_4 obtained from LMO's. Only one N—S bond (N_1S_3) and one S—S bond (S_1—S_3) are shown. The angles represent the deviation of the atomic hybrids from the internuclear axes and from the NSS plane. Note that the overlap occurs inside the nuclear frame, as in ref. 27 for the center bond of 1,2-$C_2B_4H_6$. Angle between p_1 and N_1—S_3 axis = 6.03°; p_1 and N_1—S_3—S_1 plane = 21.17°; p_2 and N_1—S_3 axis = 9.84°; p_2 and N_1—S_3—S_1 plane = 23.880°; p_3 and S_3—S_1 axis = p_4 and S_3—S_1 axis = 10.67°; p_3 and N_1—S_3—S_1 plane = p_4 and N_1—S_3—S_1 plane = 81.5°; where p_1 = p-orbital vector on N_1 involved in the N_1—S_3 bond, p_2 = p-orbital vector on S_3 involved in the N_1—S_3 bond, p_3 = p-orbital vector on S_3 involved in the S_3—S_1 bond, and p_4 = p-orbital vector on S_1 involved in the S_3—S_1 bond.

sulfur orbital makes an angle of 9.84° with the NS axis at 23.88° to the NSS plane (Fig. 4). Thus, maximum overlap occurs off the internuclear axis; the N—S bond is bent (17).

(4) S—S Bond

The delocalization index is 6.7% and is over the whole molecule. The orbitals in this LMO are almost pure p-orbitals on sulfur, with 2.0% s-character; the bond is between two sulfur atoms on the same side of the nitrogen plane. The S—S bond is bent, the sulfur p-orbital vectors in this LMO make angles of 10.67° with the S—S axis at 81.5° to the NSS plane.

(5) Nitrogen Lone Pair (II)

The *d* value is 14.82%. The delocalization is mainly (9.89%) to the p-orbitals of the two sulfur atoms to which the nitrogen is bonded. The remaining 5% is to all other atoms. This is a pure p-orbital lone pair on nitrogen, but more delocalized than the nitrogen s-lone pair (I) described above.

These are the only LMO's in S_4N_4. No LMO corresponds to an N—N bond; there is no N—N bond in the molecule, agreeing with the reduction products of S_4N_4 never containing N—N bonds. The LMO's show the molecule to be adequately described by the Lewis structure **B**, suggested by Lindqvist (9).

The atomic charges at nitrogen and sulfur from the present calculations are −0.329 and +0.329 respectively, again supporting structure **B** which has been shown to be consistent with the electronic spectrum of S_4N_4 (5) which requires a polar structure.

The N—S and S—S bonds are bent bonds between almost pure p-orbitals; they are weaker than normal straight bonds involving sp^n hybrids, which explains the classical "strain" in S_4N_4 and its unstable nature (4). Thus S_4N_4 is analogous to P_4 (17) where bent bonding occurs between essentially p-orbitals. The difficulty in reconciling the observed N—S and S—S bond lengths with the valence angles at nitrogen and sulfur disappears; bond lengths are not simply a function of double bond character or bond order. Thus while the N—S bond length in H_3—N—SO_3 is 1.764 ± 0.020 Å, and is assumed to be a single sp^3 bond (3), the observed N—S distance in S_4N_4 is 1.616 ± 0.010 Å. But this does not imply double bond character in the N—S bond in S_4N_4 (bond order greater than 1) nor sp^2 hybrids. The nature of a chemical bond between two atoms is determined by, (*1*) the s and p character of the bonding atomic hybrids, (*2*) the bent or straight overlap of these hybrids, and (*3*) the delocalization of these hybrids to other atoms. The S—S bond in S_4N_4 illustrates these points. The LMO shows pure p-orbitals in the bond, a considerably bent bond, and a delocalization of 6.7% to other atoms in the molecule, causing a considerable weakening of the bond even though it is a two electron single bond. This result agrees with Lindqvist's (9) prediction of a pure p-orbital bond from the correlation of observed S—S distances in S_8, $S_2O_6^{2-}$, $S_2O_4^{3-}$, and S_4N_4 with the s-character of the sulfur hybrid.

There is no satisfactory definition of bond index to measure the strength of a bond in SCFMO theory (18, 19). However, the bond order index of Wiberg (20, 21) may be used as a measure of bond strength. The index is the sum of the squares of the first-order density matrix elements between orbitals on two atoms. The Wiberg index for the N—S and S—S bonds in S_4N_4, has been calculated using the LMO's in Table 1. For the N—S bond the value is 0.907; there is an additional contribution to the N—S bond order from the delocalized N lone pair (II) of 0.16. Thus the total bond order for the N—S bond is 1.067; that for the S—S bond is 0.869. The N—S bond has little double bond character, and the S—S bond is weaker than a normal single S—S bond.

The diamagnetic ring current in S_4N_4 (10) suggests electron delocalization around the SN ring. From the LMO's the diamagnetic ring current is obviously due to the p-orbital lone pair electrons on nitrogen delocalizing into the p-orbitals on the sulfur atoms to which it is directly bonded. A recent CNDO/2 calculation of the Wiberg bond order for the S—N bonds in $N_4S_4F_4$ and S_4N_4 by Cassoux *et al.* (22) gave the values 1.3 and 1.87 for the two types of bonds in $N_4S_4F_4$ and 1.49 for the bond in S_4N_4. These authors interpreted the bond order in S_4N_4 intermediate between the values for $N_4S_4F_4$, as evidence for electron delocalization in N_4S_4. This is not true; their result is a consequence of using uniform S—N bond lengths in S_4N_4 intermediate between the two S—N bond lengths in $N_4S_4F_4$.

The present LMO picture of the molecule obtained using only s and p functions on sulfur shows electron delocalization in the molecule, and hence it is not necessary to use d-orbitals on sulfur to explain the ring current (10, 15). Turner and Mortimer's extended Hückel theory calculations (6), specifically included d-orbitals on sulfur and showed that d-orbitals do not play any role in the molecular description of S_4N_4. Similarly X_α calculations on SO_4^{2-} and SF_6 (23) have shown that there is no sulfur 3d orbital contribution to the electronic structure of these molecules. Similar conclusions have been reached by Koutecky and Musher (24) from CNDO/2 calculations on sulfur compounds of different valence states.

Conclusion

S_4N_4 has a molecular structure with coplanar nitrogen atoms. The electronic formula for the molecule is the polar Lewis structure **B**. There is no s–p hybridization at nitrogen or sulfur. The N—S and S—S bonds are bent single bonds involving pure p-orbitals. There is no N—N bond. Electron delocalization occurs by delocalization of the p-electrons in a nitrogen lone pair to the p-orbitals on the sulfur atoms to which the nitrogen is bonded. The field gradient direction at the nitrogen atom, and the relation to recent n.q.r. field gradient measurements (25) will be considered in a paper on the n.q.r. field gradients of various SN ring systems (26).

The Origin of the Methyl Radical in the Photolysis of Propane at 123.6 nm

JANUSZ GAWŁOWSKI,[1] JAN A. HERMAN, AND PIERRE GAGNON

Groupe de Dynamique Moléculaire, Département de Chimie, Université Laval, Québec, Québec G1K 7P4

Received November 8, 1974

JANUSZ GAWŁOWSKI, JAN A. HERMAN, and PIERRE GAGNON. Can. J. Chem. **53**, 1348 (1975).

The isotopic composition of methane formed in photolysis at 123.6 nm of propane-*1,1,1-d*$_3$ under high pressure and in the presence of NO or H_2S was investigated. The results indicate that the main source of methyl radicals are the dissociation of propane and propyl radicals

$$C_3H_8 \xrightarrow{h\nu} CH_3^{\cdot} + C_2H_5^{\cdot}$$

$$C_3H_8 \xrightarrow{h\nu} H^{\cdot} + C_3H_7^{*} \rightarrow H^{\cdot} + CH_3^{\cdot} + C_2H_4$$

JANUSZ GAWŁOWSKI, JAN A. HERMAN et PIERRE GAGNON. Can. J. Chem. **53**, 1348 (1975).

On a étudié la composition isotopique du méthane formé lors de la photolyse à 123.6 nm et à presssion élevée du trideutéro-*1,1,1* propane et en présence du NO et H_2S. Les résultats indiquent que les radicaux méthyls viennent principalement de la dissociation du propane et du radical propyl

$$C_3H_8 \xrightarrow{h\nu} CH_3^{\cdot} + C_3H_5^{\cdot}$$

$$C_3H_8 \xrightarrow{h\nu} H^{\cdot} + C_3H_7^{*} \rightarrow H^{\cdot} + CH_3^{\cdot} + C_2H_4$$

Introduction

The photolysis of propane in the vacuum ultraviolet region was extensively investigated in the last decade (1–6). However, agreement relative to the primary and secondary decomposition processes of propane has not yet been achieved. The authors of refs. 1–4 and 6 consider the following five primary processes:

$$[1] \quad C_3H_8 \xrightarrow{h\nu} C_3H_6 + H_2$$

$$[2] \quad \rightarrow C_2H_4 + CH_4$$

$$[3] \quad \rightarrow C_2H_6 + CH_2^{\cdot}$$

$$[4] \quad \rightarrow C_3H_7^{\cdot} + H^{\cdot}$$

$$[5] \quad \rightarrow C_2H_5^{\cdot} + CH_3^{\cdot}$$

The fragments produced from processes 1–5 are usually highly excited and can dissociate further:

$$[6] \quad C_3H_7^{*} \rightarrow C_3H_6 + H^{\cdot}$$

$$[7] \quad \rightarrow C_2H_4 + CH_3^{\cdot}$$

$$[8] \quad C_2H_5^{*} \rightarrow C_2H_4 + H^{\cdot}$$

$$[9] \quad C_2H_4^{*} \rightarrow C_2H_2 + H_2$$

Vorachek and Koob (5) have proposed another mechanism for the photolysis of propane at 123.6 nm: (*a*) they postulate only three primary processes 1–3, (*b*) the methyl radical originates in dissociation of excited methane

$$[10] \quad CH_4^{*} \rightarrow CH_3^{\cdot} + H^{\cdot}$$

(*c*) the hydrogen atoms are formed only by dissociation of excited fragments, mainly in processes 10 and 11

$$[11] \quad H_2^{*} \rightarrow H^{\cdot} + H^{\cdot}$$

The purpose of this work is to examine which of the two proposed mechanisms, [5] and [7] or [10], are the origin of the methyl radicals produced in the photolysis of propane at 123.6 nm.

Experimental

Carefully degassed partially deuterated propane, $CD_3CH_2CH_3$, from Merck, Sharp and Dohme was used in the experiments. Its isotopic purity was better than 98%. Hydrogen sulfide and nitric oxide (Matheson Co.) were used after purification by standard methods. The mixtures of gases were irradiated with a krypton resonance lamp equipped with a CaF_2 window allowing only the transmission of the 123.6 nm wavelength photons. The construction of the lamp is already described in the literature (7). After irradiation the gases were frozen at liquid nitrogen temperature (−195 °C) and the volatile residual gases were introduced directly into a Varian

Atlas CH 7 mass spectrometer. The analyses of isotopic methanes were done at mass resolution $m/\Delta m \approx 2000$ to differentiate between m/e of interest from those originating from water, nitrogen, and oxygen.

Results and Discussion

The isotopic composition of methane formed during photolysis of pure propane-*1,1,1*-d_3 at 16.6 Torr and at 270 and 380 Torr in the presence of suitable scavengers is presented in Table 1. The first two entries in Table 1 represent results of two different experiments done under identical conditions, the first one (at 16.6 Torr) by us, the second (at 16.8 Torr) by Okabe and McNesby (1). Both sets of results show CD_3H and CH_4 to be the main products (about 90% of the total methane), but we find the CD_3H/CH_4 ratio to be practically the inverse of the ratio found by the workers of ref. 1. The reasons for this discrepancy are not clear yet. Isotopic composition differences for experiments at 270 and 380 Torr and for each scavenger are within experimental errors.

These results allow us to calculate approximately the isotopic composition of methyl radicals. In the presence of NO, methane is formed only in molecular processes, mainly in reaction 2. On the other hand, H_2S reacts very efficiently with free radicals, and therefore in its presence methane will be formed not only in molecular processes, but also from $CH_3^\cdot$ (3) and $CH_2^\cdot$ (8) radicals

$$[12] \qquad CH_3^\cdot + H_2S \rightarrow CH_4 + HS^\cdot$$

$$[13] \qquad CH_2^\cdot + 2H_2S \rightarrow CH_4 + 2HS^\cdot$$

On the assumption that (*1*) the quantum yields of molecular methane, methyl, and methylene radicals are identical for photolysis of C_3H_8 and $CD_3CH_2CH_3$ and (*2*) that methylene radical is generated with equal efficiency from both carbon ends in propane-*1,1,1*-d_3 (this is an oversimplification, because the isotope effect is not taken into account), one can estimate from the present results and from Vorachek and Koob's data (5) at 380 Torr ($\Phi_{CH_4} = 0.152$, $\Phi_{CH_3} = 0.339$, and $\Phi_{CH_2} = 0.035$)[2] the isotopic composition of methyl radicals. The calculation gives the following isotopic composition for the methyl radical: $CD_3^\cdot$, 42%; $CD_2H^\cdot$, 5%; $CDH_2^\cdot$, 4%; and $CH_3^\cdot$, 49%. The fact that more than 90% of the scavengeable methane is formed from $CH_3^\cdot$ and $CD_3^\cdot$ radicals shows clearly that processes 5 and 7 are the main sources of the methyl radical. If the assumptions of Vorachek and Koob were true, then the methyl radical should be composed mainly of CD_2H and CDH_2. Ausloos *et al.* have shown in the photolysis of $CD_3CH_2CD_3$ + NO system at 123.6 nm that the yields of CD_3H and C_2D_3H are practically equal, but the yield of $C_2D_2H_2$ is about 10-fold greater than that of CD_4 (6). Therefore, the dissociating methane in reaction 10 could only arise from the end carbon atoms in propane, and in our experiments this should correspond to CD_3H and CDH_3, which means that

$$[14a] \qquad CD_3H^* \rightarrow CD_3^\cdot + H^\cdot$$

$$[14b] \qquad \rightarrow CD_2H^\cdot + D^\cdot$$

[2]We assume that only methylene radicals in the triplet state react with H_2S. This is inferred from the results of Ausloos *et al.* relative to the yield of butanes in the propane photolysis (3). They found that this yield was practically the same in the presence of 12.9% H_2S or 5% NO. Since the precursor of butanes in the C_3H_8 + NO system is the singlet methylene radical on account of its low reactivity towards NO, we conclude that similar yield of butanes obtained by Ausloos *et al.* in the C_3H_8 + H_2S system indicate that $^1CH_2$ is no more reactive towards H_2S than it is towards NO. From Vorachek and Koob's data at 380 Torr of C_3H_8 + 5% O_2 we get: $\Phi^3_{CH_2} = \Phi_{C_2H_6} - \Phi_{\Sigma C_4H_{10}} = 0.035$.

[15*a*] $CDH_3^* \rightarrow CDH_2^{\cdot} + H^{\cdot}$

[15*b*] $\rightarrow CH_3^{\cdot} + D^{\cdot}$

In partially deuterated hydrocarbons the isotope effect favors the C—H bond dissociation compared to that of the C—D bond (9), we would then expect the following values for the ratio of the yields of the methyl radicals generated in reactions 14*a* and *b* and 15*a* and *b*: $CD_2H/CD_3 < 3$ and $CDH_2/CH_3 > 3$. The corresponding experimental values for these ratios from our results are $CD_2H/CD_3 \approx 0.12$ and $CDH_2/CH_3 \approx 0.08$. The comparison of expected with experimental CD_2H/CH_3 ratios shows clearly that the breakdown of methane in reaction 10 cannot be the main source of methyl radicals in the photolysis of propane. The calculated contribution of partially deuterated radicals $CD_2H^{\cdot}$ (5%) and $CDH_2^{\cdot}$ (4%) (Table 1) can result from accumulated experimental error and assumptions relative to the isotopic calculations; it can also originate from isotopic impurities in the reactant gas. Although one cannot eliminate reaction 10 from the mechanism its contribution to the methyl radical formation cannot exceed 10%.

^{13}C Nuclear Magnetic Resonance Studies. Part 48. ^{13}C Spectra of a Variety of Bicyclic Ketones[1]

S. H. GROVER, D. H. MARR,[2] J. B. STOTHERS, AND C. T. TAN
Department of Chemistry, University of Western Ontario, London N6A 5B7

Received November 1, 1974

S. H. GROVER, D. H. MARR, J. B. STOTHERS, and C. T. TAN. Can. J. Chem. **53**, 1351 (1975).

The ^{13}C n.m.r. spectra of a series of 37 bicyclic ketones have been recorded to examine the variations in ^{13}C shieldings with structure and with methyl substitution. Several examples of six skeletal types were included: bicyclo[4.4.0]decanones, bicyclo[4.1.0]heptanones, bicyclo-[3.1.0]hexanones, bicyclo[3.2.2]nonanones, bicyclo[3.2.1]- and -[3.3.0]octanones as well as bicyclo[2.1.1]hexan-2-one, nopinone (6,6-dimethylbicyclo[3.1.1]heptan-2-one), and two methyl derivatives of the latter. The observed trends associated with methyl substitution follow well-defined patterns and offer further support for the application of ^{13}C shieldings as aids for stereochemical assignments especially through the well known γ effects. The variation in the shieldings of the carbonyl carbons in these systems suggested that bond eclipsing interactions have an important influence on this parameter. With this notion, the heretofore puzzling variations observed for the cycloalkanones are readily interpretable in terms of their favored conformations.

S. H. GROVER, D. H. MARR, J. B. STOTHERS et C. T. TAN. Can. J. Chem. **53**, 1351 (1975).

On a déterminé les spectres r.m.n. du ^{13}C d'une série de 37 cétones bicycliques pour examiner les variations du blindage du ^{13}C en fonction de la structure et de la substitution par des groupements méthyles. Plusieurs exemples de six types de squelettes sont inclus: bicyclo-[4.4.0]déconones, bicyclo[4.1.0]heptanones, bicyclo[3.1.0]hexanones, bicyclo[3.2.2]nonanones, bicyclo[3.2.1] et [3.3.0]octanones de même que bicyclo[2.1.1]hexanone-2, nopinone (diméthyl-6,6 bicyclo[3.1.1]heptanone-2) de même que deux dérivés méthylés de cette dernière. Les tendances observées, associées avec la substitution du méthyle, suivent des patrons bien définis et offrent un support supplémentaire pour l'application des blindages du ^{13}C comme aide pour l'attribution stéréochimique spécialement grâce aux effets γ bien connus. La variation dans les blindages du groupe carbonyle dans ces systèmes suggère que des interactions provenant des éclipsages des liens ont une influence importante sur ce paramètre. Avec cette notion, les variations un peu surprenante observées jusqu'à maintenant dans les cycloalcanones sont facilement interprétables en termes des conformations les plus favorisées.

[Traduit par le journal]

Introduction

One of the most important and interesting features of ^{13}C nuclear shieldings is their remarkable sensitivity to stereochemical environment. Although this has been recognized for several years (1), a satisfactory theoretical interpretation has yet to be presented. Nevertheless, stereochemical assignments for a wide variety of systems have been obtained empirically (2) through the knowledge that the relative orientation of vicinal carbons, or of a carbon vicinal to a heteroatom, has a pronounced effect on the observed shieldings, attributed to 1,4-nonbonded interactions. The general trends and relative magnitudes of these shifts, termed γ effects, have been determined through systematic studies of series of model compounds, primarily, in cyclic systems. Much of the attention has been focussed on mono- and polycyclic six-membered ring systems because of their well-defined geometries although several bicyclic systems with other ring sizes are also attractive models. Of the latter, however, only the bicyclo[2.2.1]heptanes (ref. 3 and references therein) and bicyclo[2.2.2]octanes (4) have been examined in some detail. In these studies, a common approach has been to examine the effects of methyl substitution on the shieldings of the skeletal carbons as a function of methyl orientation since the latter is well defined. In this way, the influence of molecular geometry on the ^{13}C shieldings can be determined with minimum alteration of the bonding contributions.

Another aspect of stereochemical effects in ^{13}C spectra concerns the variation of carbonyl carbon shieldings with ring size. While the trend was

illustrated several years ago (5), no satisfactory explanation has been put forward although a conformational origin may be suspected. The relative rigidity of bicyclic skeletons, however, provides a means whereby potential conformational contributions can be controlled and tested.

For these reasons, a series of 37 bicyclic ketones, embracing 8 skeletal types, **1–8**, was selected for ^{13}C n.m.r. examination. We wish to report the ^{13}C shieldings for this series for comparison of the methyl substituent effects with other well-defined systems. The carbonyl shieldings for this series have led to an interpretation of the variation of carbonyl shieldings in the cycloalkanones (C_4–C_{17}) in terms of their preferred conformations. Both features have potential application for stereochemical elucidations.

Experimental

Materials

Apart from bicyclo[3.2.1]octan-2-one, *trans*-decal-1- and -2-one which were commercially available, the ketones were prepared by published procedures. These include bicyclo[3.1.0]hexan-3-one by CrO_3 oxidation of bicyclo[3.1.0]hexan-3-ol (6), 6,6-dimethylbicyclo[3.1.1]-heptan-2-one (nopinone) by ozonolysis of β-pinene (7), *cis*-bicyclo[3.3.0]octan-2-one (8), bicyclo[3.2.1]octan-3-one (9) and -6-one (10). Several samples were available from earlier work in this laboratory: the bicyclo[3.1.0]hexan-2-ones (11), the bicyclo[4.1.0]heptan-2-ones (11), and the 10-methyldecalones (12). Professors R. R. Fraser and J. L. Charlton kindly provided samples of bicyclo[3.2.2]nonan-6-one and bicyclo[2.1.1]hexan-2-one, respectively. 3,3-Dimethylbicyclo[3.3.0]octan-2-one was isolated as the rearrangement product obtained by homoenolization of 3,3-dimethylbicyclo[3.2.1]octan-2-one (13). Ring expansion of norcamphor with diazoethane furnished *endo*-2-methylbicyclo[3.2.1]octan-3-one (14) which upon equilibration with trifluoroacetic acid gave a mixture of the *exo* and *endo* isomers (37:63). This ring expansion reaction also gave *exo*-3-methylbicyclo[3.2.1]octan-2-one but, contrary to the original report, attempted epimerization with sodium methoxide failed to produce detectable amounts of the *endo*-3-methyl isomer. To confirm enolate formation under these conditions, an experiment with MeO^-/MeOD was carried out giving only the *endo*-3-deuterio-*exo*-3-methyl isomer in high yield. Norcamphor also served as the starting material for 2,2-dimethylbicyclo[3.2.1]octan-3-one which was generated from the 2-methyl-2-chloromethyl derivatives (15) by reduction with *t*-BuO^-/*t*-BuOH followed by CrO_3 oxidation to furnish the desired ketone identical to that reported by another route (16). The remaining examples were obtained by methylation using the sodamide – methyl iodide procedure (17). The mono- and dimethyl derivatives were, in most cases, readily separated by g.c. on SE-30 columns. The preparations and physical constants of the new compounds obtained in this work are described below.

3,3,6,6-Tetramethylbicyclo[3.1.1]heptan-2-one

Methylation of nopinone using sodamide and methyl iodide (17) afforded a mixture (550 mg) of three ketones. Gas chromatographic analysis and separation on SE-30 columns showed the mixture to contain nopinone (52%), *cis*-nopinone, the *exo*-3-methyl derivative (34%), and the desired 3,3-dimethylnopinone (14%). A sample of *cis*-nopinone, *exo*-3,6,6-trimethylbicyclo[3.1.1]heptan-2-one, exhibited the same i.r. and n.m.r. spectra as those reported (18).

Mol. wt. Calcd. for $C_{10}H_{16}O$: 152.1200. Found (*m/e*): 152.1199.

A sample of 3,3,6,6-tetramethylbicyclo[3.1.1]heptan-2-one had the following properties: $\nu_{max}(CCl_4)$ 1700 cm^{-1}; ^1H n.m.r. 0.84 (s, 3H), 1.24 (s, 3H), 1.31 (s, 3H), 1.33 p.p.m. (s, 3H).

Mol. wt. Calcd. for $C_{11}H_{18}O$: 166.1357. Found (*m/e*): 166.1359.

2,4-Dinitrophenylhydrazone, m.p. 117.5–118.5°.

7,7-Dimethylbicyclo[3.2.2]nonan-6-one

Methylation of bicyclo[3.2.2]nonan-6-one using $NaNH_2$–CH_3I (17) gave a mixture containing unreacted starting material (20%), the monomethyl ketones (43%), and 7,7-dimethylbicyclo[3.2.2]nonan-6-one (37%). The latter was isolated by preparative g.c. on a SE-30 column and found to have the following properties: $\nu_{max}(CCl_4)$ 1711 cm^{-1}; ^1H n.m.r. 1.14 p.p.m. (s, 6H); m.p. 89–90°.

Anal. Calcd. for $C_{11}H_{18}O$: C, 79.46; H, 10.91. Found: C, 79.56; H, 10.78.

The 7-methylbicyclo[3.2.2]nonan-6-ones, however, could not be separated but the mixture gave methyl signals in its ^1H spectrum at 1.16 (d, $J \sim 7.5$ Hz) and 1.13 p.p.m. (d, $J \sim 6.5$ Hz) assigned to the *exo* and *endo* isomers on the basis of the ^{13}C spectrum (see Discussion) which indicated that the two ketones were present in a 2:3 (*exo/endo*) ratio.

Anal. Calcd. for $C_{10}H_{16}O$: C, 78.89; H, 10.59. Found: C, 78.85; H, 10.64.

endo-7-Methylbicyclo[3.2.1]octan-6-one

The usual methylation procedure employed for this series gave only 4% of the *endo*-7-methyl derivative of bicyclo[3.2.1]octan-6-one. The major monomethyl derivative was found to be identical to that described by Kubota *et al.* (19) and subsequently shown to be the 7-*exo*-methyl isomer. A sample of the latter (400 mg) was dissolved in 10 ml of 3% sodium methoxide in methanol and the solution refluxed for 7 h in a nitrogen atmosphere. After dilution with 15 ml of ice water, the ketone product was isolated by pentane extraction. Gas chromatographic analysis on 20% Carbowax 4000 showed that the mixture (400 mg) contained 45% of the *exo*-7-methyl isomer and 55% of the desired *endo*-7-methylbicyclo[3.2.1]octan-6-one. Separation by preparative g.c. gave a sample of the latter having the following properties: $\nu_{max}(CCl_4)$ 1710 cm^{-1}; ^1H n.m.r., 1.10 p.p.m. (d, 3H, $J \sim 7$ Hz); 2,4-dinitrophenylhydrazone, m.p. 203.5–204.5°.

Anal. Calcd. for $C_{15}H_{18}N_4O_4$: C, 56.59; H, 5.70; N, 17.60. Found: C, 56.63; H, 5.88; N, 17.42.

As an aid for some of the assignments, several of the ketones were refluxed with 5% MeO^-/MeOD to exchange the α-protons. Specific examples are noted in the Results section. In each case, the ketone was recovered in high yield.

Spectra

Proton spectra were recorded with either Varian T-60 or HA-100 spectrometers while ^{13}C spectra were ob-

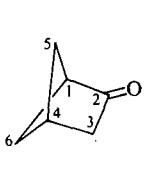
For personal use only.

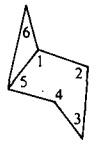
tained using a Varian XL-100-15 system operating in the Fourier transform mode, as described previously (3). The data were determined for $CDCl_3$ solutions (5–15% w/v) containing a few drops of TMS as an internal standard in 5 mm sample tubes. Peak positions were measured relative to TMS to within ±1 Hz; thus the shieldings have precisions greater than 0.1 p.p.m.

Results

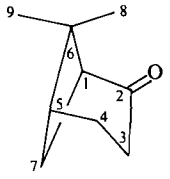
The shielding data for this series of ketones are collected in Table 1. In each case, both noise and off-resonance decoupled spectra were obtained to distinguish between carbon types, the first step for the assignments. The carbonyl carbons were readily assigned from their characteristic low-field positions (1) and in the parent systems, the



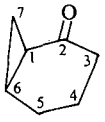
1



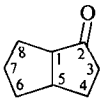
2



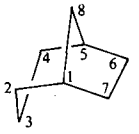
3



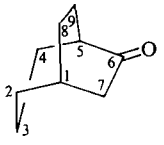
4



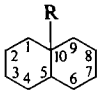
5



6



7



8

nonequivalent bridgehead carbons could be distinguished readily since that closer to the carbonyl is consistently less shielded. For the symmetrical compounds, the relative intensities led to straightforward assignments. From these features, the assignments for 2-oxo-**1**, 3-oxo-**2** and -**6** were completed.

The 2-oxo-**2** derivatives each have three methylene carbons which were distinguished in the monomethyl derivatives by deuterium exchange of the α-methylene protons. In the spectra of the dideuterated derivatives, one methylene signal essentially disappeared, one was shifted to higher field by ~0.2 p.p.m., by the geminal isotope effect, while the third was unaffected, establishing these as the C-3, C-4, and C-6 signals, respectively (3). From the methyl shieldings for the monomethyl derivatives, it followed that the more shielded methyl signal for the 1,5-dimethyl derivative was due to the 1-methyl carbon. In a similar manner, the assignments for the **4** derivatives were completed, again, utilizing the results for the 3,3-dideuteriomonomethyl isomers to identify the different methylene signals.

To aid the assignment for nopinone (**3**) and its derivatives, the ^{13}C spectra of apopinane (**9***a*), *cis*-pinane (**9***b*), and the nopinols (**9***c* and *d*) were also recorded; these data appear in Table 2. For **9***a*, the C-1, -2, -4, -5, and -6 assignments were straightforward and it remained to distinguish the C-3 from the C-7 signal and the *gem*-dimethyl resonances. The consistent appearance of a methylene signal near 26 p.p.m. in all spectra of the [3.1.1] series led to its assignment as C-7 since C-2 substitution could be expected to have little effect at this position. Since C-8 is essentially axial with respect to the six-membered ring and C-9 is equatorial, it was expected that C-8 would be the more shielded of the *gem*-dimethyl carbons. This was supported by an examination of the relative shifts in **3** upon addition of $Eu(fod)_3$, since the higher field methyl signal exhibited a greater downfield shift. With two methyl signals near 23 p.p.m. for **9***b* the assignments of C-8 and

[b]From ref. 12.
[c]From ref. 20; the methyl shielding is 15.7 p.p.m.

C-10 are uncertain and for 3,3,6,6-tetramethyl-**3** the methyl assignments may not be correct; the present assignments are discussed more fully later.

As noted earlier, 3,3-dimethyl-*cis*-bicyclo-[3.3.0]octan-2-one was obtained by homoenolization of 3,3-dimethylbicyclo[3.2.1]octan-2-one. Deuterium exchange under homoenolization conditions, coupled with ^2H n.m.r. examination, permitted unequivocal identification of C-6, -7, and -8 (13) in the ^{13}C spectrum and completed the assignments, from which those for **5** and its trimethyl derivative followed readily.

In the [3.2.1] series, the parent hydrocarbon was also examined (Table 2). For the 2-oxo compounds, the spectra of the 3,3-dideuterio, 3-deuterio-3-methyl, and 1,7,7,9,10-pentadeuterio-3,3-dimethyl derivatives were also determined; the latter isomer was obtained from homoenolization experiments (13). With these data the assignments for the 2-oxo derivatives were readily completed. For the 3-oxo derivatives, the well-separated methine signals permitted straightforward assignments while the C-6 and C-7 methylene resonances were identified on the basis of an expected shielding influence of an *endo*-2-methyl at C-7 but for the *exo*-2-methyl isomer these methylene signals were not so readily assigned. By analogy with *exo*-3-methylnorcamphor (3), however, one may predict that the *exo*-2-methyl group would tend to deshield C-7 slightly and, on this basis, the C-6 and C-7 signals were taken to be those at 28.5 and 30.1 p.p.m., respectively. A comparison of the data for the 6-oxo series with that for the parent hydrocarbon led to the assignments given in Table 1 for these four derivatives. A sample of 7,7-dimethylbicyclo[3.2.1]octan-6-one containing deuterium at C-3, -4, -5, and -9 was available from homoenolization studies (20) to confirm its assignments and provide supporting evidence for those for the other 6-oxo derivatives.

For the bicyclo[3.2.2]nonan-6-ones, the spectra of the 7,7-dideuterio, 7-deuterio-7-*exo*-methyl, and 7-deuterio-7-*endo*-methyl derivatives as well as the parent hydrocarbon (Table 2) were also recorded. This permitted a ready distinction between the methine signals for the monomethyl cases. Since one signal was essentially eliminated, one was shifted upfield by 0.1 p.p.m. while the third methine signal was unaffected in the spectra of the deuterated compounds, these arose from C-7, C-1, and C-5, respectively. In addition, one of the methylene signals in each was significantly broadened, identifying the vicinal methylene carbon *anti* to the deuterium (21). Of the remaining methylene peaks, the highest field signal, ~21 p.p.m., was assigned to C-3 in the four ketones because of its similarity with C-3 in the hydrocarbon and the fact that it should be little affected by 7-substitution. All four ketones exhibited methylene absorption near 31 p.p.m. which was assigned to C-4 since this carbon should be little affected by 7-substitution. Supporting this assignment, the spectrum for 7,7-dideuteriobicyclo-[3.3.2]octan-6-one showed broadening due to vicinal C–D coupling for the 24.4 and 34.1 p.p.m. resonances. Thus it also followed that C-9 gave rise to the signal near 23 p.p.m. in the four ketones.

For the *trans*-decalones, the methylene assignments were made by comparison with the results for *trans*-decalin and 10-methyl-*trans*-decalin (Table 2) in a manner analogous to that described for the decalols (12) and some more highly substituted decalones (22). In the 2- and 3-oxo derivatives, the carbonyl group has little effect on the C-6, -7, -8, and -9 shieldings while the α-meth-

ylene carbons were readily identified by their characteristic shifts to lower field. In the 1- and 4-oxo derivatives, the *gauche* vicinal methylene carbon (C-9 and C-6, respectively) was characterized by its upfield shift caused by the γ effect of the carbonyl oxygen while the remaining methylene carbons in the unsubstituted ring are essentially unaffected (22), as are the β- and γ-methylene carbons in the substituted ring. Thus, the assignments for these decalones were readily completed.

Discussion

In one of the first systematic studies of substituent effects in alicyclic systems, Dalling and Grant (23) showed the remarkable reproducibility and stereochemical dependence of the effects of methyl groups on the shieldings of cyclohexane ring carbons. Similar results were subsequently obtained for the norbornane system by Roberts and co-workers (24) and in this laboratory (3) for the bicyclo[2.2.2]octanones (4*b*) and for several cyclohexanones and cyclopentanones (25). In each case, the carbons γ to the site of substitution are significantly shielded if *gauche* to the methyl group and tend to be deshielded slightly, if *anti*. To examine the trends for α-methyl substitution in the present ring systems, some pertinent data are given in Table 3, which contains the shifts observed for the skeletal

carbons in the monomethyl derivatives from their positions for the parent ketones. The first seven entries have the carbonyl in a two-carbon bridge with the α-methyl *gauche*, or approximately so, to either a one- or two-carbon bridge. It is apparent that the latter arrangement produces the larger upfield shift, as might be expected because of the smaller dihedral angle between the two γ centers; the relative shieldings of the methyl carbons exhibit the same trend. For each *exo*/*endo* pair, the β effects are somewhat diminished in the isomer having the greater negative γ shift. The last three entries in the first column of Table 3 have an equatorial α-methyl nearly eclipsed with the carbonyl group, with only one having a *gauche* γ interaction, which presumably accounts for the attenuated β effect at the adjacent bridgehead carbon. It has been generally found that the shielding of all carbons in the γ *gauche* fragment are upfield from those in the corresponding arrangement lacking the *gauche* interaction (1, 2). The remaining six entries in Table 3 are closely related, each having the methyl group in an axial orientation on a six-membered ring. The variety of γ *gauche* effects are consistently upfield for sp^3 carbons while the carbonyl carbon is much less affected. It is interesting that with three or four γ *gauche* interactions the methyl group no longer deshields the carbon to which it is bonded; also the β effects at the methine carbons are very much less than those at the methylenes. From Table 1, it is apparent that methyl substitution at the ring junctions in the [3.1.0] and [4.1.0] systems does not produce distinctive upfield shifts for the γ-carbons. This is consistent with the relatively large dihedral angles, ~120°, relating these centers. The γ shielding interactions between the nearly eclipsed vicinal methyls in the dimethyl derivatives, however, are clearly evident from the methyl carbon shieldings.

To examine the effect of the carbonyl group on the shieldings of the neighboring carbons, the relevant data are listed in Table 4, obtained by comparison of the results for the unsubstituted ketones with those for the parent hydrocarbons. The earlier data for norcamphor (3) and bicyclo[2.2.2]octanone (4*b*)[3] are included. In general, the α-methylene carbons are more strongly deshielded in the bicyclic systems than in cyclopentanone or cyclohexanone. It is also interesting that the carbonyl group tends to shield the γ-carbons in all cases. There seems to be no ready explanation for either of these trends. The upfield shifts exhibited by the β-methylene carbons, however, are consistent with γ interactions involving the carbonyl oxygen and, as expected, the effects are larger with smaller dihedral angles such that a trend is discernible. The maximum upfield shifts are found for the three decalones having the carbonyl group at either C-1 or C-4, in which cases the carbonyl oxygen must be nearly eclipsed with C-9 or C-6, respectively. The smallest shifts occur in the systems for which the carbonyl oxygen and β-methylene carbon are separated by relatively large dihedral angles, ~120°. Presumably the interaction producing these upfield shifts involves the hydrogen bonded to the affected carbon. For the β-bridgehead carbons, the bridgehead hydrogen and carbonyl oxygen are much too far apart to interact and there is no apparent trend in these data. It may be noted that in two cases the quaternary β-carbons are markedly deshielded by the carbonyl groups but this is probably a result of the elimination of a *gauche* γ interaction of the angular methyl bonded to the quaternary carbon by placement of the carbonyl at C-2 or C-4 in the decalone skeleton.

The variation of the carbonyl carbon shieldings in this series of bicyclic ketones seems particularly interesting. The values span a range of 14 p.p.m., δ_C 208.7–223.0 for the parent ketones, and there appears to be a trend which may account for the well-known but unexplained, variation of carbonyl shieldings in the monocyclic series (5). The remarkable sensitivity of this shielding to ring size has only been attributed to conformational factors in the most general terms. Although most of these bicyclic ketones can be regarded as either substituted cyclohexanones or cyclopentanones, the observed carbonyl shieldings seem to depend primarily on features other than ring size. For the simple five- and six-membered rings the carbonyl shieldings differ by 8 p.p.m. (5, 25), 220.5 and 212.0 p.p.m., respectively, in $CDCl_3$ but in **1** and **3** this absorption is near 214 p.p.m., even though their carbonyl groups are in different sized rings. As a possible explanation, it can be suggested that the number of α-bond eclipsing interactions present in each case is the more important feature. Cyclohexanone has two bond eclipsing interactions, whereas **1** and **3** have one, and cyclopentanone can be viewed as lacking such inter-

[3]The methylene shielding for bicyclo[2.2.2]octane is incorrect in the earlier paper and should read 26.1 p.p.m.

actions, since its favored conformation is the half-chair (26). Inspection of molecular models indicates that α-bond eclipsing interactions should be minimal in **5** and 6-oxo-**6** and their carbonyl shieldings of 223.0 and 221.4 p.p.m., respectively, are comparable to the cyclopentanone value. The carbonyl shieldings for 3-oxo-**6** and five of the six decalones (210.5–211.9 p.p.m.) are essentially the same as that of cyclohexanone and each of these has comparable bond eclipsing. In *trans*-10-methyl-1-decalone, the somewhat lower carbonyl shielding of 215.6 p.p.m. may result from a greater degree of flattening in the ring containing the carbonyl group which would tend to reduce the *syn* axial interaction of the angular methyl at C-2. Ring flattening increases the dihedral angle between the α C—H bond and the carbonyl π-bond, thereby reducing the eclipsing interaction. The fact that the γ effect of the angular methyl group at C-2 (Table 3) is significantly less than that at C-4 and C-6 is consistent with this interpretation. The carbonyl shieldings of **7**, bicyclo[2.2.2]octanone (4*b*), and norcamphor (3) are 216.2, 216.7, and 217.4 p.p.m., respectively, which on the basis of the present proposal suggest that the carbonyl group has a single bond eclipsing interaction somewhat smaller than that in the more rigid **1** skeleton. Again, molecular models indicate that this is a reasonable interpretation. On similar grounds, the carbonyl absorption of 214.0 p.p.m. for 2-oxo-**6** can be interpreted in terms of **10** as the favored conformation having the 3-carbon bridge nearly planar.

For the ketones containing a three-membered ring, an earlier study (11) of the carbonyl shieldings led to the conclusion that cyclopropylcarbonyl conjugation could be a contributing

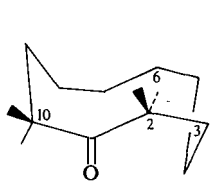
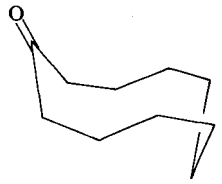
[a]1 *M* solutions in $CDCl_3$.

factor. This still seems reasonable for bicyclo-[4.1.0]heptan-2-one since its carbonyl signal at 208.7 p.p.m. is at appreciably higher field than that for cyclohexanone. For bicyclo[3.1.0]hexan-2-one, however, the observed shielding of 215.1 p.p.m. is also consistent with the presence of one bond eclipsing interaction, which on the basis of the foregoing, would tend to increase the carbonyl shielding from that found for cyclopentanone, as is observed. In bicyclo[3.1.0]hexan-3-one, the absorption at 217.9 p.p.m. is not so greatly different from cyclopentanone but could conceivably represent the shielding for the envelope conformation **11** since the three-membered ring probably precludes the half-chair conformer and in **11** bond opposition strain between the C-3 (C-4) and C-2 (C-5) hydrogens is minimized. The alternative envelope conformer maximizes this contribution.

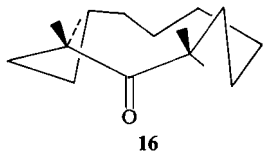
Since the variations in the carbonyl shieldings in these bicyclic systems are explicable in terms of the number of bond eclipsing interactions it seems reasonable to reexamine the trends found several years ago for the monocyclic ketones (5). The data for 1 *M* solutions in $CDCl_3$ are listed in Table 5 from which it is apparent that the carbonyl carbons in 8- and 9-membered rings are appreciably deshielded relative to cyclohexanone, whereas the 7-, 10-, and 11-membered ring examples are somewhat less shielded than cyclohexanone. For the larger rings the carbonyl shieldings are essentially the same as cyclohexanone. These trends are identical to those originally reported (5) but in $CDCl_3$ the carbonyl carbons are deshielded by *ca.* 3 p.p.m., relative to the values for CS_2 solutions, presumably because of hydrogen bonding in $CDCl_3$. On the basis of bond eclipsing contributions to the carbonyl shieldings, the observed values for cyclooctanone and cyclononanone indicate that these favor conformations with one eclipsing interaction such as **12** and **13**, respectively. These are boat-chair (BC) conformations with **13** somewhat distorted to relieve bond opposition strain at C-3 and C-4. Anet and his co-workers have established that **12** is the favored conformation for cyclooctanone (27) and have shown that cyclononanone very likely exists in a single conformation of the same symmetry (28). For cyclodecanone, two of the possible boat-chair-boat (BCB) conformations are **14** and **15**. If **15** were



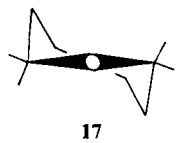
14 (BCB-3)



15 (BCB-1)



16



17

favored, one could anticipate a carbonyl shielding essentially the same as that for cyclohexanone whereas in **14** transannular interactions tend to maximize the separation between closely approaching hydrogens (*e.g.* on C-2 and C-6 in **14**) thereby reducing the bond eclipsing interactions of the carbonyl group (*i.e.* with the C_2—C_3 bond

and one of the α-hydrogens at C-10) and decreasing the carbonyl shielding. The observed shielding of 214.7 p.p.m. is significantly less than the cyclohexanone value of 212.0 p.p.m. The remaining BCB-2 conformation for cyclodecanone has the carbonyl group in an environment very similar to that for cyclohexanone, always eclipsed with two hydrogens on the α- and α′-carbons. Thus the carbonyl shielding results favor **14** as the preferred conformation. Anet *et al.* (28) have recently presented evidence that cyclodecanone strongly favors **14** (BCB-3) over the BCB-2 conformer and their results clearly eliminate **15** as a major contributor. Since the carbonyl shielding of cycloundecanone (214.3 p.p.m.) is very close to that for cyclodecanone, a similar preferred conformation is indicated and it has been shown that the 11-membered ring ketone probably exists as a single conformer in solution (28). The conformation of the crystalline state has recently been established (29). Anet *et al.* have also shown that cyclododecanone very probably has the same ring skeleton as cyclododecane, a "square" D_4 form, as represented by **16** with the carbonyl group at a noncorner position (28). This conformation has two bond eclipsing interactions for the carbonyl group and the observed shielding of 212.7 p.p.m. fits very well with the present interpretation. Finally it may be noted that the bond eclipsing for the carbonyl group in a twist-chair seven-membered ring (**17**) would appear to be less than that for cyclohexanone, as judged by inspection of molecular models, and the observed shielding of 215.2 p.p.m. seems very reasonable.

Although the notion that bond eclipsing interactions are important factors governing carbonyl carbon shieldings is speculative, the favored conformations indicated by the observed shieldings for the cycloalkanones are in excellent agreement with those deduced on the basis of much more rigorous information. This suggests that carbonyl shielding data may be helpful for conformation assignments in a variety of systems.

We are grateful to the National Research Council of Canada for financial support of this work. We wish to thank Inara Grikis for technical assistance and Dr. A. L. Johnson for the preparation of bicyclo[3.3.0]octan-2-one.

Studies on the Synthesis of Novel Carbohydrates with Sulfur in the Ring. Part III. The Synthesis of Derivatives of 2,6-Dithio-hex-4-en-2-ulopyranosidononitriles

DOLATRAI M. VYAS AND GEORGE W. HAY[1]

Department of Chemistry, Queen's University, Kingston, Ontario K7L 3N6

Received September 23, 1974

DOLATRAI M. VYAS and GEORGE W. HAY. Can. J. Chem. **53**, 1362 (1975).

The *cis*-hydroxylation of 3,6-dihydro-3-methoxy-2-methylthio-2*H*-thiopyran-2-carbonitrile and of 3-*exo*-cyano-3-methylthio-2-thiabicyclo[2.2.1]hept-5-ene by treatment with OsO_4–pyridine afforded sulfur analogs of two new types of carbohydrates. The Diels–Alder reaction of *trans,trans*-1,4-diacetoxy-1,3-butadiene with methyl cyanodithioformate gave a one-step synthesis of methyl 3,6-di-*O*-acetyl-4,5-dideoxy-2,6-dithio-α-DL-*threo*-hex-4-en-2-ulopyranosidononitrile.

DOLATRAI M. VYAS et GEORGE W. HAY. Can. J. Chem. **53**, 1362 (1975).

L'hydroxylation *cis*, par traitement avec OsO_4 dans la pyridine, du dihydro-3,6 méthoxy-3 méthylthio-2 2*H*-thiopyrancarbonitrile-2 et de l'*exo* cyano-3 méthylthio-3 thia-2 bicyclo[2.2.1]-heptène-5 conduit aux analogues sulfurés de deux nouveaux types de carbohydrates. La réaction de Diels–Alder entre le diacétoxy-1,4 butadiène-1,3 *trans,trans* et le cyanodithioformate de méthyle fournit une synthèse en une étape du di-*O*-acétyl-3,6 didésoxy-4,5 dithio-2,6 α-DL-*thréo*-hexène-4 ulopyrannosidononitrile-2. [Traduit par le journal]

Introduction

Previous reports (1, 2) from this laboratory have described the synthesis of 3,6-dihydro-3-methoxy-2-methylthio-2*H*-thiopyran-2-carbonitrile (**1**) (2*a*) and 3-*exo*-cyano-3-methylthio-2-thiabicyclo[2.2.1]hept-5-ene (**2**)[2] (2*b*, *c*) by facile Diels–Alder reactions between methylcyanodithioformate (MCDF) and 1-methoxy-1,3-butadiene and cyclopentadiene, respectively. These compounds are useful precursors for the synthesis of more highly substituted novel carbohydrates with sulfur in the ring. Of particular interest is compound **2** which affords access to a series of bicyclic sugars distinct from those previously synthesized (3–5).

The sulfur atoms are the most nucleophilic centers in compounds **1** and **2**, and they react preferentially with most of the electrophilic reagents commonly used to add to carbon–carbon double bonds. Thus, in studies of a series of 3,6-dihydro-2*H*-thiopyrans reported previously (1, 2), attempts to achieve *trans*-hydroxylations by epoxidation with a variety of peracids or *cis*-hydroxylation with such normally effective reagents as neutral $KMnO_4$ or OsO_4–H_2O_2–*t*-BuOH led only to the oxidation of the sulfur atoms and the concomitant stabilization of the cyclic double bond[3] towards further addition. However, the *cis*-hydroxylation of carbon–carbon double bond can be achieved by OsO_4–pyridine, a system which is unreactive towards sulfur (8). Furthermore, Brown and his co-workers (9) have demonstrated the sensitivity of osmic acid to steric control during the hydroxylation of 2-methoxy-5,6-dihydro-2*H*-pyran and *cis*-2,5-dimethoxy-5,6-dihydro-2*H*-pyran; similar results have been reported by Banasek and Zamojski (10).

This paper describes the products of the osmic acid hydroxylation of **1** and **2**, and the synthesis of methyl 3,6-di-*O*-acetyl-4,5-dideoxy-2,6-dithio-α-DL-*threo*-hex-4-en-2-ulopyranosidononitrile (**3**). The conformations and structures assigned to these unusual carbohydrates were based primarily on the p.m.r. spectroscopic data.

[1]To whom inquiries should be addressed. This research was sponsored by Operating Grant A1921 from the National Research Council of Canada.

[2]Heterocyclic nomenclature has been employed arbitrarily. Alternative names (6) are: methyl 4,5-dideoxy-3-*O*-methyl-2,6-dithio-β-DL-*glycero*-hex-4-en-2-ulopyranosidononitrile (**1**) (1); methyl 3,4,5-trideoxy-3,6-*C*-methylene-2,6-dithio-α-DL-*threo*-hex-4-en-2-ulopyranosidononitrile (**2**). The structural formula of only one stereoisomer is given in the text.

[3]The rationalization of the unreactivity of this double bond in the oxidized products in terms of inductive, field, and/or conformational effects will be reported in a succeeding paper (*cf.* ref. 7).

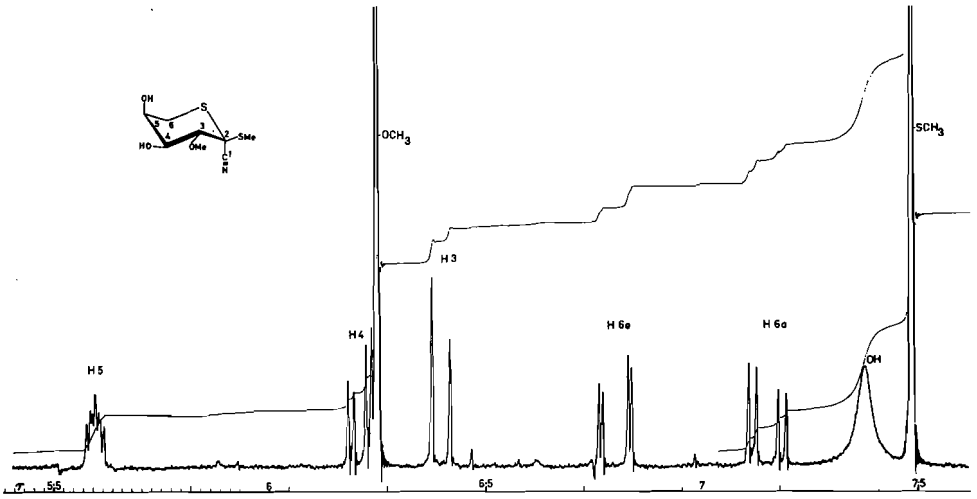

FIG. 1. The 220 MHz p.m.r. spectrum of compound **4** in chloroform-*d*.

Results and Discussion

Osmic acid reacted with **1** to give 80% yield of product, the analysis of which by t.l.c. revealed the presence of only two compounds, one in trace amounts. The major product (**4**) was obtained in a pure crystalline form in 70% overall yield by recrystallization from acetone – petroleum ether. The infrared spectrum of **4** revealed no oxidation of the sulfur but exhibited a strong absorption (3333 cm^{-1}) due to OH.

The structure and conformation of **4** were deduced from the 220 MHz p.m.r. spectrum (Fig. 1); on this evidence compound **4** was designated as methyl 3-*O*-methyl-2,6-dithio-α-DL-*arabino*-2-hexulopyranosidononitrile.

The one-proton doublet at τ 6.40 was assigned to the H-3 proton, J = 9.2 Hz, a value typical of coupling between vicinal diaxial protons. The C-6 methylene protons formed the MX portion of an AMX system centered at τ 6.98. The MX moiety had $J_{6a,5e}$ = 4 Hz, and $J_{6e,5e}$ = 2 Hz. The A portion of the system was the one-proton multiplet centered at τ 5.60 and was assigned to H-5. The one-proton quartet centered at τ 6.21 was attributed to H-4 with $J_{3a,4a}$ = 9.2 Hz, and $J_{4a,5e}$ = 3 Hz. These p.m.r. data are consistent with an attack by OsO_4 on the olefinic bond in **1** from the side opposite to the quasi-equatorial methoxyl group. The p.m.r. coupling constants also indicate that **4** occurs exclusively in the $^5C_2$(L) conformer in chloroform-*d* solution. This preference may reflect the stabilization resulting from the fewer 1,3-nonbonded interactions in the $^5C_2$(L) as compared to the $^2C_5$(L) conformer. Moreover, the recently reported destabilizing "hockey stick" effect (11), arising from orbital repulsion

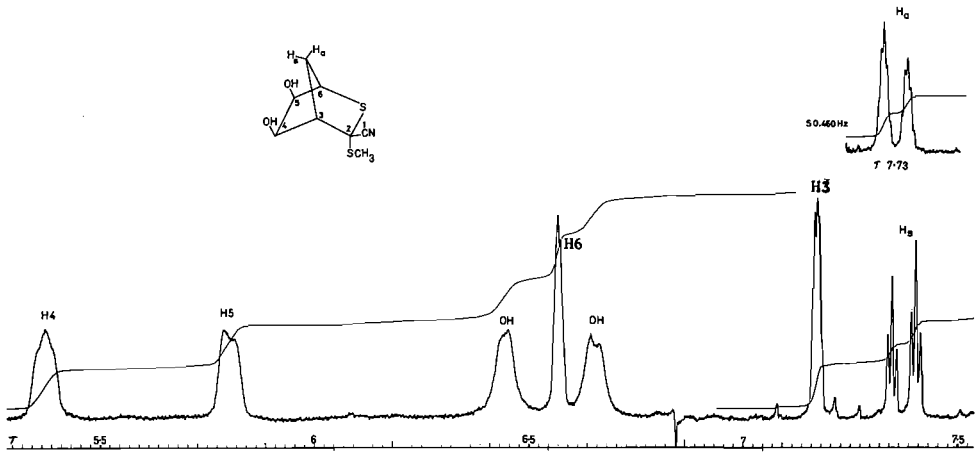

FIG. 2. The 220 MHz p.m.r. spectrum of compound **5** in chloroform-*d*.

between a sulfur atom in the ring and a β axial heteroatom-containing substituent (*e.g.*, OMe) present in the $^2C_5$ conformation of **4**, would add to the instability of that conformer. In the case of compound **1** it was revealed that of the two anomeric substituents the cyano group had the dominant "anomeric effect" (12) and showed a greater tendency to be axially disposed. This phenomenon in compound **4** may account further for the preponderance of the $^5C_2$ over the $^2C_5$ conformer.

The OsO_4–pyridine hydroxylation of **2** afforded one pure crystalline product (**5**). The elemental analysis and the i.r. spectral data for **5** were consistent with the proposed structure.

Steric considerations for this reaction strongly favor the osmic acid attack on the olefin from the less hindered *exo* side, since the hydroxylation proceeds via the osmate ester of the glycol (13). On this assumption compound **5** was tentatively designated as methyl 3-deoxy-3,6-*C*-methylene-2,6-dithio-α-DL-*talo*-hex-2-ulo-pyranosidononitrile. A similar rationale has been offered by Daniels and Fischer (14) to explain the OsO_4-catalyzed hydroxylation of the furan – maleic anhydride Diels–Alder adduct.

Analysis of the 220 MHz spectrum of **5** (Fig. 2) corroborated the stereoselectivity of the osmic acid attack on **2**. The methylene bridge hydrogens exhibited a complex AB system centered at τ 7.56. The coupling pattern revealed that the A portion centered at τ 7.38, resulted from the geminal coupling of 12 Hz and equal vicinal couplings of 2 Hz with two other protons. The B portion, centered at τ 7.73, showed the geminal coupling of 12 Hz and also coupling with more than two protons, thus accounting for the unresolved multiplet character of the signal. This could be rationalized in terms of a "W"-type long range coupling (15) between the *anti*-proton of the methylene bridge and H-5 and H-4 which, in this case, must be *endo*. Such long range couplings have been observed in several bicyclic systems (7, 16). On this basis the A and B portions of the signal were assigned to the *syn* and *anti* protons of the methylene bridge, respectively. This analysis of the AB system further corroborated the postulated control of the approach of osmic acid to compound **2**. Other signal assignments are documented in Table 1. These were made through proton decoupling experiments on the assumption that the H-6 proton in **5** should resonate at lower field than the H-3 proton. This assumption has been verified experimentally in the 2-thiabicyclo[2.2.1]heptane system (17), where the bridgehead proton on the carbon α to sulfur resonates at lower field than the other bridgehead proton. On account of the highly coupled nature of the spectrum of **5** proton decoupling experiments did not result in any drastic simplification of signals but only slight sharpening of the peaks was observed. Signals due to the hydroxyl protons were readily identified since they showed considerably different chemical shifts at different sample concentrations.

The reaction of *trans,trans*-1,4-diacetoxy-1,3-butadiene with MCDF in refluxing benzene afforded one crystalline product (**3**) which was

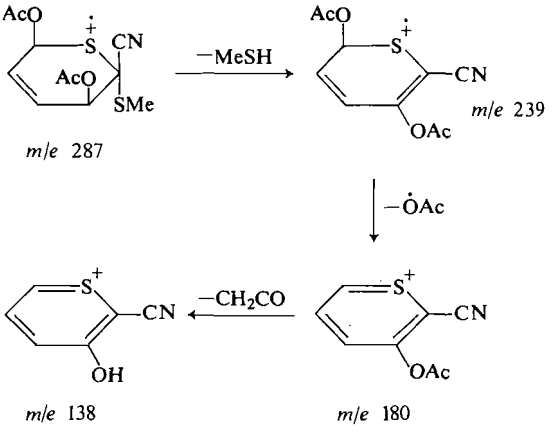
‡60 MHz p.m.r. data.

characterized from its p.m.r. (Fig. 3; Table 1) and mass spectra. The possibility of compound **3** being a 1,2-cycloaddition adduct (**6** or **7**) was ruled out on the basis of its 60 MHz p.m.r. chemical shift data. The two one-proton resonances at τ 4.05 and 4.30 are consistent only with the allylic hydrogen signals in **3**, as the allylic protons in **6** and **7** would resonate at approximately τ 5.5 (18) and 7.0 (19), respectively. This structural assignment was substantiated by the mass spectral data of **3** which revealed a fragmentation pattern which is consistent only with the normal Diels–Alder adduct **3**. The *m/e* peaks at 170, 128, and 86 can be attributed to [1,4-diacetoxy-1,3-butadiene $(C_8H_{10}O_4)]^{+\cdot}$, $[C_8H_{10}O_4–CH_2CO]^{+\cdot}$, and $[C_8H_{10}O_4–2CH_2CO]^{+\cdot}$, respectively. 1,4-Diacetoxy-1,3-butadiene arises from the retro Diels–Alder fragmentation of **3**. Such a fragmentation for compounds **6** and **7** was considered to be less likely. However, further convincing evidence for structure **3** is provided by *m/e* peaks at 239, 180, and 138 which could only be attributed to the following fragmentation pattern resulting from the six-membered ring adduct **3**.



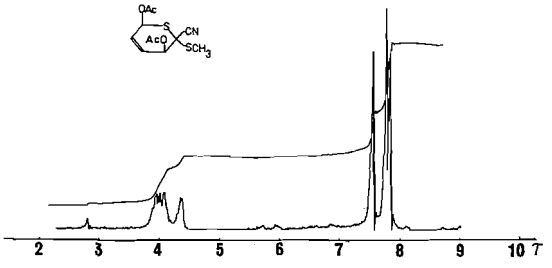


FIG. 3. The 60 MHz p.m.r. spectrum of compound **3** in chloroform-*d*.

Because Diels–Alder reactions are stereospecific (20), leading exclusively to *cis* adducts when the diene has *trans,trans* geometry, the relative stereochemistry at C-3 and C-6 in **3** was assigned as *cis*. The configuration at the anomeric center was assumed to be α on the basis that the *endo* rule with respect to the cyano function was obeyed; open-chain dienes are known to obey the *endo* rule at low temperatures (20). Moreover theoretical studies by Hoffmann and Woodward (21) have shown that, for dienophiles having a conjugated π system, the *endo* addition to the diene is energetically more favorable.

Experimental

General Procedures

Melting points were determined with a Fisher-Johns

melting point block and are uncorrected. Evaporations were conducted at 40° under reduced pressure (25 mm Hg) in a rotary evaporator. Infrared spectra were recorded on a Perkin-Elmer Model 180 spectrometer. Proton magnetic resonance spectra were obtained using a Varian T60 or a Varian HR 200 spectrometer with tetramethylsilane (TMS) (τ 10.00) as internal standard. Mass spectra were determined with a JOEL-JMS 01SC double focussing spectrometer at 75 eV and 100 nA. Thin-layer chromatography (t.l.c.) was performed on Eastman silica gel 'Chromagram' sheets and components were detected by using an iodine chamber.

Reaction of 3,6-Dihydro-3-methoxy-2-methylthio-2H-thiopyran-2-carbonitrile (1) with Osmic Acid

Osmium tetroxide (1g) in 4 ml dry pyridine was added to a solution of compound (**1**) (0.66 g) in 6 ml dry pyridine. The reaction mixture was stirred at room temperature for 21 h whereupon 1.8 g of sodium bisulfite (20 ml pyridine + 30 ml H_2O) was added and stirred for an additional 4 h. This was followed by extraction with CH_2Cl_2 (6 × 25 ml) and dried over $MgSO_4$. Evaporation of the solvent afforded a thick syrup (0.62 g), which showed two spots on t.l.c. (1:9 EtOAc–CH_2Cl_2); the component with greater R_f was only present in trace quantities. On crystallization from acetone and petroleum ether (b.p. 60–80°) 0.5 g of pure crystalline material (**4**) was obtained, which gave one spot on t.l.c., m.p. 132°; ν_{max} (KBr disc) 3333 (OH) and 2222 cm^{-1} (C≡N); τ ($CDCl_3$), see Table 1.

Anal. Calcd. for $C_8H_{13}NO_3S_2$: C, 40.83; H, 5.57. Found: C, 40.79; H, 5.68.

Osmic Acid Cis Hydroxylation of Compound 2

To 0.71 g of adduct **2** in 6 ml dry pyridine was added 1.0 g of OsO_4 in 5 ml of dry pyridine. The reaction mixture was stirred at room temperature for 18 h, followed by a work-up similar to that of the preceding case resulted in a white solid which upon recrystallization (methylene chloride – petroleum ether, b.p. 110–125°), afforded 0.6 g **5** as colorless crystals, m.p. 105–106°; ν_{max}(KBr disc) 3448 (OH) and 2222 cm^{-1} (C≡N); τ ($CDCl_3$), see Table 1.

Anal. Calcd. for $C_8H_{11}NO_2S_2$: C, 44.22; H, 5.10. Found: C, 44.36; H, 5.43.

trans,trans-1,4-Diacetoxy-1,3-butadiene

This compound was prepared in 56% yield from 25 g of cyclooctatetraene by the published procedure of Hill and Carlson (22), m.p. 100–102° (lit. (22) m.p. 103–104°).

Reaction of MCDF with trans,trans-1,4-Diacetoxy-1,3-butadiene

Diene (0.49 g) was refluxed for 24 h with MCDF (prepared from 1.8 g *N,N,N,N*-tetraethylammonium cyanodithioformate) in 20 ml benzene. The solution was concentrated to approximately 5 ml, which upon standing afforded analytically pure crystals (0.23 g), m.p. 68–70°; ν_{max}(KBr disc) 2222 (C≡N), 1748 (C=O), and 1667 cm^{-1} (C=C); τ ($CDCl_3$), see Table 1; *m/e* 287($M^{+\cdot}$)(7), 239(5), 180(5), 170(88), 138(25), 128(90), 86(73), and 43 a.m.u. (100).

Anal. Calcd. for $C_{11}H_{13}NS_2O_4$: C, 45.99; H, 4.56; S, 22.30. Found: C, 45.73; H, 4.68; S, 22.26.

The n.m.r. of the mother liquor was identical to that of the crystalline material; no other cycloaddition product was detected.

Secondary Deuterium Isotope Effects on Carbonyl Ylide Intermediates

VESNA VUKOV AND ROBERT J. CRAWFORD
Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received September 11, 1974

VESNA VUKOV and ROBERT J. CRAWFORD. Can. J. Chem. **53**, 1367 (1975).

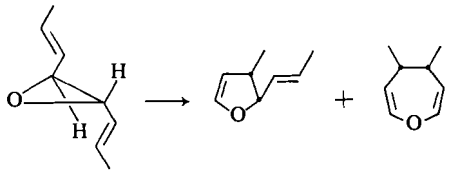
The formation of vinyldihydrofuran (**6**) and dihydrooxepine (**5**) is sensitive to deuterium substitution at the terminal methylene of 2,3-divinyloxirane. Intra- and intermolecular isotope effects have been examined and suggest that **5** is produced on a competitive basis with **6** from a common intermediate.

VESNA VUKOV et ROBERT J. CRAWFORD. Can. J. Chem. **53**, 1367 (1975).

La formation du vinyldihydrofurane (**6**) et de la dihydrooxépine (**5**) est sensible à l'introduction de deutérium dans le méthylène terminal du vinyl-2,3-oxirane. On a déterminé les effets isotopiques intra- et intermoléculaires et ceux-ci suggèrent que **5** est produit en competition avec **6** à partir d'un intermédiaire commun.

Introduction

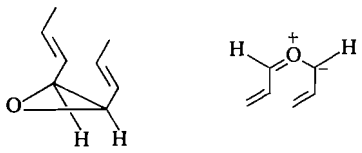
Scheme 1 has been suggested (1, 2) to explain the racemization of (+)-2,3-divinyloxirane (**1**) along with its isomerization to 3-vinyl-2,3-dihydrofuran (**6**) and 4,5-dihydrooxepine (**5**). A sigmatropic ($\sigma^2a + \pi^2s$) process for the production of **6** was ruled out on the basis of the negligible rotation of **6** produced from (+)-**1**. The planar carbonyl ylide **2** was thus adopted as a common intermediate. Chuche and coworkers (2) have demonstrated that the thermal isomerization of **7** gives rise to only **8** and **9**.



7 **8** **9**

Orbital symmetry considerations (3) suggest that **8** was produced by a five-center (6π) disrotatory ring closure of a carbonyl ylide analogous to **3**. It was suggested that a three-center (4π electron) conrotatory ring closure generated the *cis*-oxirane (**10**) which undergoes a rapid boat-like Cope rearrangement to **9**. The independently synthesized oxirane **10** produced only **9** upon thermolysis at 70° (2).

The carbonyl ylide **3** can be produced in more than one way in that it may be the result of a nonallowed disrotatory ring opening of **1**, the racemization being favored by 5.2 kcal mol^{-1} over the rearrangement process (1). It may also be produced by an isomerization of the carbonyl



10 **11**

ylide **2** into the carbonyl ylide **3** by rotation about the carbon–oxygen bond of the ylide as shown in Scheme 1. The possibility of a conrotatory ring opening directly from the *trans*-oxirane (**1**) to a carbonyl ylide such as **11** for the production of **5** and **6** (or **8** and **9** from **7**) has been ruled out on both kinetic (4) and stereochemical grounds (2).

Dolbier and Alonso (5) have examined thermal reactions wherein the product determining step has demonstrated a secondary deuterium kinetic isotope effect of greater than unity ($k_H/k_D > 1.0$) in processes in which a new bond is being formed to the isotopically substituted center. Generally such bond forming processes result in inverse isotope effects ($k_H/k_D < 1.0$). They have suggested that "such isotope effects are derived from the rotation of a methylene group of a conjugated system to a nonconjugated, orthogonal conformation in the transition state." They suggested that the dramatic lowering of the torsional force constant of the methylene twisting motion is primarily responsible for the observed isotope effects (5, 6) in reactions involving "the product forming destruction of resonance stabilized biradicals." The carbonyl ylides are examples of resonance stabilized biradicals (7) and it is the

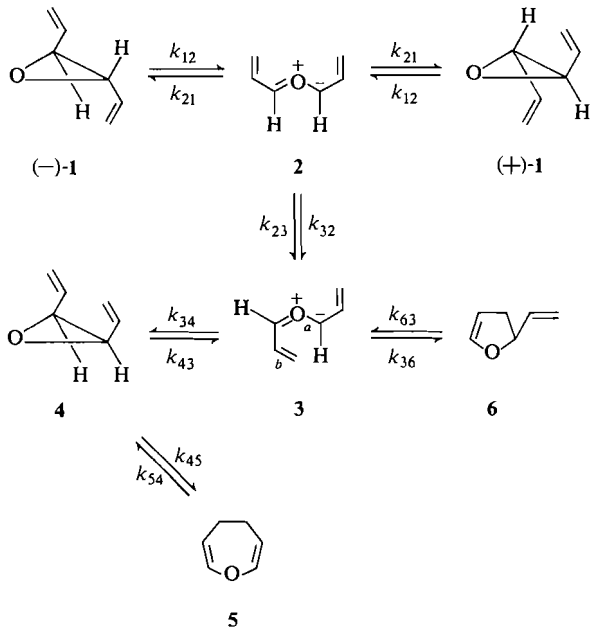
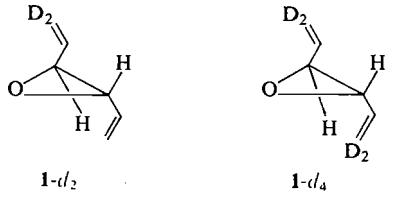


SCHEME 1

purpose of this paper to determine the magnitude of the isotope effects of the reactions in Scheme 1, and to compare these with those observed by Dolbier (5) for the purpose of examining the generality of their suggestion. Generally the isotope effects are rationalized in terms of the changes in force fields caused by the creation of new isotopically sensitive normal modes (6, 8). Seltzer (9) has demonstrated that for addition reactions where an olefinic methylene is transformed to a tetrahedral carbon that an inverse isotope effect ($k_H/k_D < 1.0$) is observed whereas in the reverse of this the normal isotope effect is encountered (10). The generalization that the transformation of an sp^2 methylene to an sp^3 methylene resulted in inverse isotope effects whereas an $sp^3 \rightarrow sp^2$ transformation gave the normal isotope effect has been widely used in the interpretation of secondary deuterium isotope effects; although not rigorously accurate, it provides a useful guide since it does correspond to the introduction of, or elimination of, new normal modes.

Results and Discussion

The secondary deuterium kinetic isotope effect upon the initial step, k_{12}, of Scheme 1 is most readily obtained by comparing k_α (where $k_\alpha = 2k_{12}$) the rate of racemization of (−)-**1** with that of k_α'[1] the rate of racemization of (−)-**1**-d_4. This material was synthesized as outlined in Scheme 2. The racemization rates were



measured, in the gas phase, at 150.04 ± 0.02° with samples of (−)-**1** and (−)-**1**-d_4 being heated concurrently. For **1**, k_α is (5.18 ± 0.07) × 10^{-5} s^{-1} and for **1**-d_4, k_α' is (4.78 ± 0.04) × 10^{-5} s^{-1}. Thus k_H/k_D for the first step (**1** → **2**) is 1.08 ± 0.02, or in terms of the free energy change per deuterium, $\delta\Delta G^{\ddagger}/n$, is 16 ± 4 cal mol^{-1}, much smaller in magnitude and of opposite sign, than the 80–120 cal mol^{-1} frequently observed when a new bond is being formed at the isotopically substituted center.

Since **4** gives only **5** (12) and both **5** and **6** are stable under the reaction conditions then we know that k_{54}, k_{43}, and k_{63} are small relative

[1]In this paper all of the rate constants primed refer to reactions with the tetradeuterated substrate whereas the unprimed rate constants (k_x) refer to the nondeuterated system.

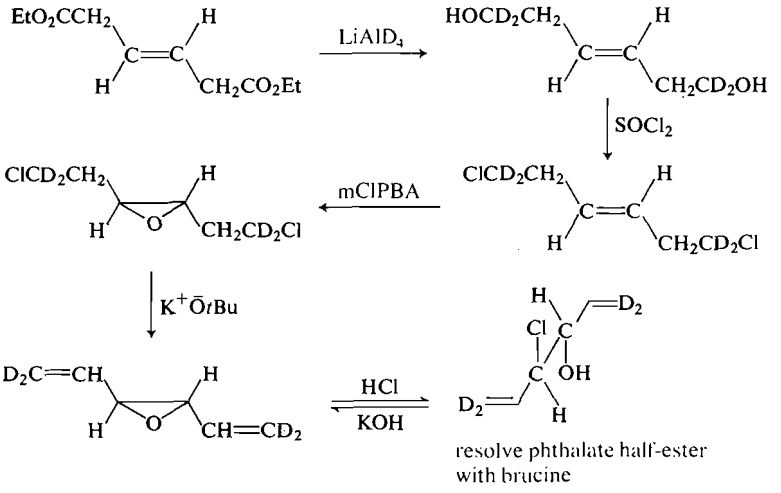


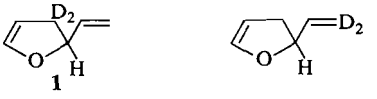
SCHEME 2

TABLE 1. Steady-state rate expression for Scheme 1 and measured rate constants at 192.45°

Reaction	k	$10^5 k$ (s^{-1})
1 → **5**	$\frac{2k_{12}k_{23}k_{34}}{(2k_{21}+k_{23})(k_{32}+k_{34}+k_{36}) - k_{32}k_{23}}$	7.32±0.02
1-d_4 → **5**-d_4	$\frac{2k_{12}'k_{23}'k_{34}'}{(2k_{21}' + k_{26}')(k_{32}'+k_{34}'+k_{36}') - k_{32}'k_{23}'}$	6.31±0.05
1 →**6**	$\frac{2k_{12}k_{23}k_{36}}{(2k_{21}+k_{23})(k_{32}+k_{34}+k_{36}) - k_{32}k_{23}}$	2.99±0.02
1-d_4 → **6**-d_4	$\frac{2k_{12}'k_{23}'k_{36}'}{(2k_{21}'+k_{23}')(k_{32}'+k_{34}'+k_{36}') - k_{32}'k_{23}'}$	2.69±0.02

to other competing processes and they can be omitted from steady state calculations. Using the steady-state approximation for the intermediates **2**, **3**, and **4** the rate expressions, for Scheme 1, are given in Table 1. The rate constants for the production of **5**-d_4 and **6**-d_4 from **1**-d_4 are listed in Table 1 with those measured concurrently for **1** going to **5** and **6** at 192.43 ± 0.02°. The product ratio **6**/**5** was assessed by analytical gas chromatography (g.c.) to be 2.45 ± 0.04. The yield of oxepine was slightly increased on deuteration to produce the ratio **6**-d_4/**5**-d_4 of 2.36 ± 0.03.

The intramolecular isotope effect upon the production of **6** was measured by n.m.r. analysis of the vinyldihydrofuran produced on the isomerization of a sample of **1**-d_2 at 192.43 ± 0.02°.



6-d_2-A **6**-d_2-B

The **6**-d_2 produced proved to be a 52:48 mixture of A:B giving an intramolecular isotope effect of 0.92 ± 0.02. Such an intramolecular isotope effect is rationalized readily in the conventional sense that the creation of new bending modes at the isotopically substituted center brings about a greater decrease in the transition states zero-point energy on going to **6**-d_2-A than for that proceeding to **6**-d_2-B. The change in free energy per deuterium ($\delta\Delta G^{\ddagger}/n$) of −38 ± 10 cal mol^{-1} is somewhat smaller than is normally expected but may be a reflection of the transition state being similar in character to the inter-

For personal use only.

mediate and that as a consequence bond formation has not progressed very significantly. There should be little, or no, difference between this intramolecular isotope effect and the corresponding intermolecular isotope effect measured by comparing the rate of formation of **6** *vs.* **6**-d_4 (13); however, as a post-transition state intermediate this cannot be obtained directly from the kinetic data. Using the product proportions obtained from the infinity tubes on the steady-state rate constants it can be shown that:

$$\frac{d[\mathbf{6}]}{d[\mathbf{5}]} = \frac{k_{36}}{k_{34}} = 2.45 \pm 0.04$$

and

$$\frac{d[\mathbf{6}\text{-}d_4]}{d[\mathbf{5}\text{-}d_4]} = \frac{k_{36}'}{k_{34}'} = 2.36 \pm 0.03$$

Dividing the former by the latter we obtain:

$$\frac{k_{36}}{k_{34}}\frac{k_{34}'}{k_{36}'} = 1.04 \pm 0.03$$

Using the intramolecular value for the reaction **3** → **6** of 0.92 we obtain a value for k_{34}/k_{34}' of 0.89 ± 0.05. Such an inverse isotope effect suggests that the isotopically substituted methylenes are undergoing, in the course of the reaction, a large increase in the force field caused by the creation of new isotopically sensitive normal modes (6, 8). This does not seem reasonable in terms of the process **3** → **4**, an alternative more compatible with the isotope effect is that **5** is being formed directly from **3**. Rotation about the carbon–oxygen bond *a* in **3** produces **5**. This motion is symmetry allowed if it occurs in a conrotatory fashion with respect to rotation about the double bond *b* of **3**. This is consistent with the stereochemical observation of Pommelet *et al.* (2) that **7** produces **9** upon heating, and that no *trans*-4,5-dimethyl-4,5-dihydrooxepine is observed.

Arnold and Karnischky (14) have demonstrated that the disrotatory ring opening of a 5-oxabicyclo[2.1.0]pentane can occur at 120°, thus demonstrating that this motion may be more available than expected from orbital symmetry considerations. Recent theoretical considerations by Berson and Salem (15) suggest that such "forbidden" processes may in fact be concerted and stabilized by subjacent orbital effects. With these factors in mind we propose as an alternative Scheme 3 which is equally capable of rationalizing all of the stereochemical and kinetic data for the 2,3-divinyloxiranes. Table 2 lists the isotope effects observed here in terms of Scheme 3.

We conclude from this work that the secondary deuterium isotope effects observed for the system under investigation are readily rationalized in the conventional sense (11) where the introduction of new bonds to the isotopically labelled position results in an inverse isotope effect, and that transformations such as 1 → 2 and 1 → 3 which do not involve changes in bonding to the isotopically labelled center result in small normal isotope effects. Our data also indicate that a major portion of the dihydrooxepine formed from *trans*-1,2-divinyloxirane does so in a step that is directly competitive with the formation of vinyldihydrofuran rather than arising exclusively from *cis*-2,3-divinyloxirane. Whereas we had anticipated that the transformation of **3** → **5** would give a normal isotope effect, by analogy with the observations of Dolbier and Alonso (5), the inverse isotope effect was observed. This may be reconciled if the transformation **3** → **5** requires little or no twisting of the terminal methylene, a factor which Dolbier suggests is important to his cases where the normal isotope effect is observed in reactions where new force bending constants are created. As indicated earlier the free energy change for **3** → **5**, $\delta\Delta G^{\neq} = -38 \pm 4$ cal mol^{-1}, is small and its attenuated nature may in fact be due to some contribution from the methylene twisting. It should be noted that the carbonyl ylide intermediates are expected to be more stable, on the basis of successful trapping experiments and spectroscopic observations (7, 14), than the putative diradical intermediate of the 1,1-divinylcyclopropane to vinylcyclopentene rearrangement (5).

TABLE 2. Secondary deuterium isotope effects for rates as labelled in Scheme 3

Reaction	n*	k_H/k_D	$\delta\Delta G^{\neq}/n$ (cal mol^{-1})
(−)-**1** → (±)-**1**	4	1.08±0.02	16±4
1 → **3**	4	1.15±0.02	32±4
3 → **5**	2†	0.92±0.02	−38±4
3 → **6**	4	0.88±0.04	−30±10

*Where n is the number of deuteriums involved.

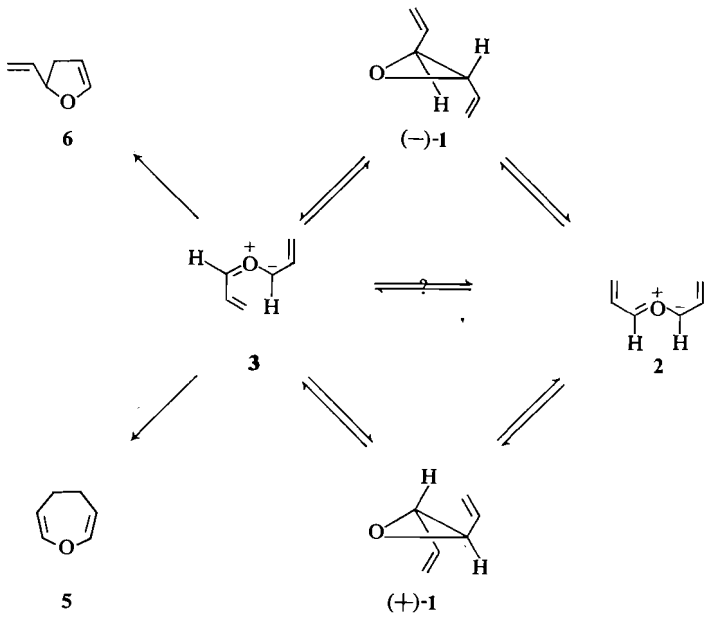

SCHEME 3

Experimental

The n.m.r. spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The analytical g.c. was carried out using a Perkin-Elmer 900 GE equipped with capillary columns and a Hewlett-Packard 3370A Electronic Integrator. Mass spectra were determined on an AEI MS-9 double focussing high resolution spectrometer.

Preparation of trans-3-Hexene-1,6-diol-1,1,6,6-d_4

Diethyl *trans*-3-hexenedioate (29 g, 145 mmol) was dissolved in dry ether and added dropwise to a solution of lithium aluminum deuteride (7 g, 166 mmol) in ether (300 ml) which was maintained at 0°. The reaction was then allowed to warm to room temperature and stirred overnight. The excess reducing agent was destroyed by the careful addition of wet ether followed by a saturated solution of sodiumpotassium tartarate (200 ml). The organic layer was separated and the aqueous portion was subjected to continuous ether extraction, 12 h. The combined ether solutions were dried and the solvent removed. The diol was then subjected to silica gel chromatography 10.2 g (67%).

The n.m.r. spectrum, δ TMS ($CDCl_3$) 5.5 (multiplet, 2H), 3.6 (singlet, 2H), and 3.3 (broad doublet, 4H).

Preparation of trans-1,6-Dichloro-3-hexene-1,1,6,6-d_4

trans-3-Hexene-1,6-diol-*1,1,6,6-d_4* (9.77 g, 81 mmol) was added dropwise to freshly distilled, stirred thionylchloride (24 g, 203 mmol) maintained at 0°. Stirring was continued for an additional 2 h followed by the addition of a few drops of pyridine. The mixture was then warmed to 60° for 3 h. Water was added and the mixture extracted with chloroform. The organic layer was washed once with 2 *N* hydrochloric acid, then with saturated sodium carbonate. After drying over molecular sieves (4 Å) the solvent was removed and the residue distilled 9.3 g (74%) at 64°/5 Torr, (lit. (16) value of nondeuterated material 80°/13 Torr).

Preparation of trans-1,6-Dichloro-3,4-epoxyhexane-1,1,6,6-d_4

The freshly distilled dichloride (9 g, 57 mmol) was dissolved in methylene chloride (100 ml) and added dropwise to a solution of *m*-chloroperbenzoic acid (14.6 g, 84 mmol) in methylene chloride (200 ml). The solution was stirred and maintained at room temperature overnight. The *m*-chlorobenzoic acid was removed by filtration and the solvent removed on a rotary evaporator. Ether was then added to the residue and the solution was washed with a 10% solution of sodium sulfite until a negative KI – starch paper test was achieved. After washing with saturated sodium carbonate the ether solution was dried over molecular sieves (4 Å). Upon removal of the ether the residue was vacuum distilled at 65°/4 Torr, to give 8.8 g (89%).

The n.m.r. spectrum, δ TMS ($CDCl_3$), 3.0 (doublet, 4H), 1.05 (triplet, 2H).

*Preparation of 2,3-Divinyloxirane-d_4 (**1**-d_4)*

Potassium *t*-butoxide (11.2 g, 110 mmol) was added to a solution of *trans*-1,6-dichloro-3,4-epoxy-hexane-*1,1,6,6-d_4* (8.8 g, 50 mmol) in absolute ether (100 ml) and the mixture was stirred overnight at room temperature. Moisture was rigorously excluded. The mixture was then filtered and the solid washed with fresh ether. The combined filtrates were washed with water and dried over anhydrous sodium sulfate. The ether solution was used directly for the next step. An aliquot of this solution was subjected to preparative g.c. (β,β′-oxydipropionitrile on Chromosorb at 60°) and an n.m.r. spectrum taken and was found consistent with the spectrum of the nondeuterated material (1).

*Resolution of **1**-d_4*

The oxirane **1**-d_4 was converted to *threo*-4-chloro-1,5-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

hexadiene-3-ol-*1,1,6,6-d*$_4$ and converted to the phthalate half-ester followed by resolution of the brucine salt. The conversion to **1**-*d*$_4$ was achieved in the same manner as described for the nondeuterated material (1).

The n.m.r. spectrum of the isolated (−)-**1**-*d*$_4$ displayed less than 1% absorption in the region assigned to the terminal methylene. The integration ratio of the low field vinyl protons at δ 5.6 to the oxirane ring protons at δ 3.25 was 1.01:1.00.

Preparation of Monoethyl trans-3-Hexenedioate

A solution of diethyl *trans*-3-hexenedioate (10 g, 50 mmol), *trans*-3-hexenedioic acid (17.4 g, 120 mmol), and 95% ethanol (10.3 ml) in butyl ether (6.2 ml) with concentrated hydrochloric acid (3 ml) was refluxed for 2 h. The volatile components were then removed on a rotary evaporator and the residue fractionated. The first fraction, b.p. 115°/4 Torr, consisted mainly of the diester; second fraction, b.p. 130°/4 Torr, is the half-ester. Further purification was achieved by extracting an ethereal solution of the second fraction with a 5% sodium bicarbonate solution followed by acidification and ether extraction. After drying and removal of ether the half-ester was distilled, b.p. 118°/0.3 Torr, 9 g (46%).

The n.m.r. spectrum, δ TMS ($CDCl_3$) 10.45 (singlet, 1H), 5.8 (multiplet, 2H), 4.2 (quartet, 2H), 3.15 (broad multiplet, 4H), 1.25 (triplet, 3H).

Preparation of trans-6-Hydroxy-3-hexenoic Acid

Sodium (6.6 g, 0.23 g-at.) was added in small portions to a solution of monoethyl *trans*-3-hexenedioate (15 g, 87 mmol) in liquid ammonia (450 ml) containing absolute ethanol (14.4 ml) (17). After completion of addition a small amount of ethanol was added to remove the blue color. The solution was stirred overnight and the ammonia allowed to evaporate. Upon addition of water and acidification, the solution was continuously extracted using ether. The ether layer was dried and concentrated to give 5.3 g (45%) of crude hydroxy acid. The compound was difficult to purify and thus was used directly for the next step.

Preparation of trans-3-Hexene-1,6-diol-1,1-d$_2$

The crude hydroxy acid (5.3 g, 41 mmol) from the above experiment was dissolved in ether (75 ml) and added to a slurry of lithium aluminum deuteride (1.88 g, 45 mmol) in ether (75 ml). The reaction mixture was kept under nitrogen and stirred for 2 h. Excess reducing agent was destroyed by the addition of wet ether and the diol was worked up as described above for the tetradeuterated diol.

The n.m.r. spectrum, δ TMS ($CDCl_3$) 5.5 (multiplet, 2H), 4.6 (triplet, 2H), 3.7 (singlet, 2H), 2.25 (multiplet, 4H).

Preparation of trans-3,4-Epoxy-1,5-hexadiene-1,1-d$_2$ *(1-d*$_2$*)*

The conversion of the diol of the previous preparation to the dichloride was accomplished in the same manner as that described earlier for the tetradeuterio compound. Epoxidation was carried out as described above followed by dehydrohalogenation using potassium *t*-butoxide. The pure **1**-*d*$_2$ was isolated by preparative g.c.

A 100 MHz n.m.r. spectrum δ TMS ($CDCl_3$) 6.8–5.2 (multiplet), 3.2 (doublet). Careful integration gave intensities of 2.02:1.00.

Conversion of 1-d$_2$ *to 6-d*$_2$*-A and 6-d*$_2$*-B*

Pure epoxide, **1**-*d*$_2$, was placed in break-seals such that the pressure at 192° was 600 Torr. These degassed samples were then heated to 192° for 22 h. The cooled samples were then reattached to the vacuum line and the product transferred to a sample vial. Ether was added and the mixture was separated by preparative g.c. (20% Carbowax 1500 at 40°). The vinyldihydrofuran-*d*$_2$ was placed in an n.m.r. sample tube, $CDCl_3$ and TMS added, and the sample degassed before analysis.

Careful integration of the low and high field signals gave a ratio (R) of 5.28 ± 0.11. The mol fraction n of **6**-*d*$_2$-A present is given by the equation $n = (R - 2)/(1 + R)$ and thus 0.522 ± 0.008.

Kinetic Measurements

The kinetic measurements were carried out as described previously except that in each case samples of the nondeuterated oxirane **1** were measured concurrently.

The Extraction of Mercury and Methylmercury by Diphenylthiocarbazone-treated Polyurethane Foams

ARTHUR CHOW AND DANIEL BUKSAK
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2
Received November 15, 1974

ARTHUR CHOW and DANIEL BUKSAK. Can. J. Chem. **53**, 1373 (1975).

Dithizone-treated polyurethane foams which are easily prepared in the laboratory, are shown to efficiently extract mercury(II) and methylmercury(II) chloride from aqueous solution over a wide p*H* range for mercury concentrations below 10 p.p.m. The mercury is firmly held but can be recovered for analysis by eluting with acetone if desired. The extraction of both forms of mercury from domestic water, river water, raw sewage, and secondary-treated sewage is shown to be acceptable.

ARTHUR CHOW et DANIEL BUKSAK. Can. J. Chem. **53**, 1373 (1975).

Des mousses de polyuréthane, traitées par le dithizone, peuvent être facilement préparées au laboratoire et on montre qu'elles peuvent extraire d'une façon efficace le mercure(II) et le chlorure de méthylmercure(II) de solutions aqueuses à des p*H* très variés et pour des concentrations de mercure en bas de 10 p.p.m. Le mercure est fortement retenu mais si on le désire il peut être récupéré pour analyse par élution avec de l'acétone. On montre qu'il y a une extraction acceptable des deux formes de mercure provenant d'eaux domestiques, d'eaux de rivière, d'eaux d'égout brutes et d'eaux d'égout traitées d'une façon secondaire.
[Traduit par le journal]

The extraction of inorganic pollutants from aqueous solutions has been accomplished with a variety of techniques for many elements. Methods such as ion exchange (1), coprecipitation (2), freeze concentration (2), gas chromatography (3), and others have been applied to specific problems but often have limited applicability because of nonselectivity or because of a necessary, extensive pretreatment.

Mercury has been recovered from brine solutions by extraction with high molecular weight amines (4) although this was not specific for only mercury. Some agricultural products and by-products have been shown (5) to adsorb nonquantitatively some mercury(II) chloride and methylmercury(II) chloride. In a previous paper (6) SH-treated polyurethane foam was used to extract mercury(II) and methylmercury(II) chloride from solution but this technique was not fully acceptable because of the low capacity and the complex preparation of the foam.

Diphenyldithiocarbazone (dithizone) has been used as a complexing agent for mercury with the complex being extracted into carbon tetrachloride (7, 8) and other solvents (9). Solvent extraction methods have a distinct disadvantage because of the limited sample volume that can be conveniently handled. Because of this and other difficulties, several attempts have been made to immobilize the dithizone on some form of matrix. Pierce and Peck (10) used dithizone on silica gel for a column chromatographic separation of mercury. Ueno and co-workers (11, 12) prepared hydrophobic gel particles containing dithizone by two methods and showed that a column of these could extract about 1 to 2 mg per 10 ml of material. Mercury was recovered and the column regenerated by using a sulfuric acid – potassium bromide solution. Braun and Faraq have used polyurethane foam which had been treated with zinc diethyldithiocarbamate or zinc dithizonate in a plastizer such as tributylphosphate to extract mercury (13) and other metals (14). These foams were shown to be efficient for collecting mercury(II) from solutions ranging in concentration from 0.72 to 72 p.p.b. Mercury could be removed from the column by using sodium thiosulfate solution. The effect of other metals in the solution on the extraction of mercury was not indicated. The application to methylmercury(II) or to real samples was not discussed.

Polyurethane foam has been used previously as an extraction medium for cigarette filters (15), oil spills (16, 17), phenol adsorption (18), polychlorinated biphenyls (19), and for mercury (6) and other metals.

It was felt that because of the wide concern

about mercury in the environment (20), a simple extraction method which would permit the removal of trace amounts of mercury(II) and methylmercury(II) chloride from aqueous samples would be useful. This would be especially useful if it permitted the extraction to be carried out in the field and the analysis to be done in the laboratory. Polyurethane foam constitutes an easily-available material which is quite inert to most solvents and is easily manipulated. Dithizone is a good complexing agent for mercury although it is not completely specific (9), and can function over a wide range of acidities. For these reasons, a detailed study of the direct use of dithizone with flexible polyurethane foam was undertaken.

Experimental

Apparatus and Reagents

A Baird Atomic Model 530 γ spectrometer with a Model 810C well-type NaI (Tl) detector was used to measure the radioactivity of the samples. A Coleman Model 38A p*H* meter was used to determine the acidity of the samples. All chemicals used were reagent grade and all water used was double distilled and deionized unless otherwise indicated. Methylmercury-203(II) chloride and mercury-203(II) chloride were obtained from ICN Research Products, Montreal and NEN Canada, Dorval, respectively. The flexible polyurethane foams were obtained as cylindrical plugs, 2.2 × 4.0 cm (DisPo brand, Canlab, Winnipeg) which fit snugly into glass columns 20 cm in length which were equipped with a Teflon stopcock.

Procedure

The polyurethane foams were soaked in a solution of 0.1 mg/ml dithizone in acetone for 1 h, drained, and then left to dry overnight in a vacuum dessicator. Two dithizone-treated foams were placed in each glass column with enough water to completely immerse them. Any air in the foams was removed by compressing them several times with a glass plunger. The column was now ready for use. Prior to the addition of a sample, the water was drained from the column, the foams compressed several times, and any residual water removed by blowing air through the foams.

Samples were prepared by taking an appropriate aliquot of the required radioactive mercury tracer, adding the desired amount of a solution of the inactive mercury compound, and diluting it to 100 ml at the appropriate acidity. The radioactivity of each individual sample in a beaker was counted five times on the γ spectrometer for 50 s, and the average taken. The sample was then transferred to a column containing two foams and the empty beaker counted again to permit the most accurate estimate of the actual radioactivity used. Normal samples had an activity of about 1000 ± 4 c.p.s. which corresponded to roughly a 0.002 p.p.b. mercury solution; the background was about 20 ± 1.5 c.p.s. The air was removed from the foams by compressing them several times and the sample then permitted to flow through the column by compressing the foams and then blowing air through them. The radioactivity of the recovered sample was compared with that of the original added sample to determine the percentage of mercury extracted by the foams. Since the radio activity *not* extracted was used for calculation and this was often quite small, the precision of the measurement of the extraction was about ±0.3%. Where multiple samples were used, the average has been reported and an average deviation was obtained of about ±0.5% of the percentage extraction. Although a much simpler format could be used in practice, the above procedure allowed a more precise evaluation in the laboratory.

Results

The effect of various acidities was evaluated for extraction by dithizone-treated foams for both mercury(II) and methylmercury(II) chloride using 100 ml samples containing tracer only at flow rates of 1 and 3 ml per min. The results are recorded in Table 1. Both mercury compounds were extracted from the aqueous phase at the slower flow rate with 94% or greater efficiency between p*H* 1 to 10. The faster flow rate gave more variable results and was less quantitative. Other experiments have shown a change in the extraction from 89% at 5 ml per min to 98.5% at 0.5 ml per min at p*H* 5.5 for similar solutions. Mercury(II) chloride was efficiently extracted at about p*H* 5 to 10 while methylmercury(II) chloride was best extracted at p*H* 1.2.

The amount of mercury used in these experiments was extremely small with respect to the amount of dithizone held by the foam and so

TABLE 1. Effect of p*H* and flow rate on extraction of mercury

Compound	p*H*	Extraction (%) Flow rate, 1 ml/min	Flow rate, 3 ml/min
$HgCl_2$ (0.002 p.p.b.)	0	98.6	—
	1.3	95.1	89.2
	3.8	96.0	94.7
	5.0	96.5	—

the reaction should strongly favor complex formation if the reaction is possible. Some dithizone was washed from the foams during the passage of the samples but no attempt was made to correlate the amount with the acidity of the solution.

The working range for mercury compounds was evaluated using a series of solutions varying in mercury concentration from 400 and 10 p.p.m. to the lower limit of the diluted tracer alone without nonradioactive carrier. This lower limit was calculated to be roughly 2×10^{-10} g per 100 ml sample on the basis of the measured radioactivity. It can be seen from the results shown in Table 2 that almost quantitative recovery of both mercury compounds was obtained up to a concentration of 5 or 10 p.p.m. *i.e.* a total amount of 0.5 or 1.0 mg. From the values for mercury(II) chloride, it can be seen that the total capacity of the dithizone-treated foams was much greater but that at high concentrations quantitative extraction would not occur. The more significant data indicate that even the most minute amounts of both mercury compounds were quantitatively removed from aqueous solution by the dithizone-treated foams. Additional experiments have shown that the treated foams were able to concentrate 96 and 99% of mercury(II) and methylmercury(II) chloride even when the samples were diluted by a factor of 10 to 1000 ml of 0.0002 p.p.b. solutions at p*H* 5.5 and 1.3 respectively.

TABLE 2. Effect of concentration on extraction of mercury

Compound	Concentration of sample	Extracted by foam (%)	p*H* of sample
$HgCl_2$	0.002 p.p.b.	98.4	5.5
$HgCl_2$	4 p.p.b.	98.5	5.5
$HgCl_2$	40 p.p.b.	99.1	5.5
$HgCl_2$	400 p.p.b.	97.2	5.5
$HgCl_2$	4 p.p.m.	99.7	5 5
$HgCl_2$	40 p.p.m.	62.3	5.5
$HgCl_2$	400 p.p.m.	33.4	5.5
CH_3HgCl	10 p.p.b.	99.7	1.3
CH_3HgCl	100 p.p.b.	99.7	1.3
CH_3HgCl	500 p.p.b.	99.9	1.3

CH_3HgCl	0.2 p.p.b.	99.3	5.5
CH_3HgCl	0.002 p.p.b.	99.4	5.5

After the extraction of mercury(II) and methylmercury(II) chloride by dithizone-treated foams, the complex was shown to be firmly held by attempting elution with water. In all cases 100 ml of water removed none of the mercury activity and a few experiments showed that 400 ml of water removed less than 0.1% with no dithizone color being seen in the eluant. Hydrochloric acid at 1 and 3 *M* removed less than 5% of the mercury but up to 50% of the methylmercury chloride. Attempts to recover the mercury using 0.1 *M* sodium thiosulfate solution with a 1 ml per min flow rate were unsuccessful with only 55% of the radioactivity being extracted. Mercury could however, be quantitatively removed from the foams by simply extracting with 100 ml of acetone. This procedure removes both the dithizone and the mercury simultaneously. The determination of the recovered mercury was made by counting the radioactive tracer for these experiments so that the same analytical method could be used for all the concentrations studied and so that the most minute amounts could be determined. In practice, the recovered mercury would be determined by the established techniques of X-ray fluorescence, spectrophotometry, atomic absorption or flameless atomic absorption spectroscopy, etc. as was required for the particular amount anticipated.

The recovery of the complexed mercury with 100 ml of acetone resulted in an increase in the concentration of the metal by a factor of ten for the 1 l samples. For the other samples, no attempt was made to increase the mercury concentration although much smaller volumes of acetone would provide a significant recovery of the complexed mercury. The results indicate that much larger concentration factors could be obtained for large volumes of dilute solutions since these foams have a significant mercury capacity and there was no significant loss of complex during the passage of water.

For comparison with the foregoing data, foams which had not been treated with dithizone were examined for the extraction of the mercury compounds under similar conditions. It was found that the plain foams would extract more than 60% of the mercury(II) chloride tracer but that 40% of this extracted mercury was washed off with the passage of 100 ml of water. Similarly,

45% of methylmercury(II) chloride was extracted and 40% of this was washed off with the first 100 ml of water to pass through the foam. An additional 100 ml removed 13% more of the extracted radioactivity. Thus it can be seen that the addition of dithizone to the foams greatly increased the ability of the foam both to extract and retain mercury.

The ability of dithizone-treated foams to extract mercury from a variety of matrices was considered very important to possible applications. Initial studies showed that a concurrent 10 or 100 p.p.m. concentration of copper, magnesium, calcium, aluminum, iron, or zinc did not appreciably influence the quantitative extraction of 0.002 p.p.b. solutions of mercury(II) or methylmercury(II) chloride where at least 96% mercury extraction was achieved. These metals were chosen because they are the most concentrated ones which occur in both the local water and sewage where they are present at 0.1 to 35 p.p.m. levels.

Natural samples contain a wide variety of components and because of this, several aliquots were taken of tap water, river water, raw sewage, and secondary-treated sewage. These sewage samples had been analyzed previously in this laboratory and were known to contain calcium, magnesium, aluminum, iron, zinc, chromium, lead, copper, manganese, nickel, silver, lithium, and bismuth, of which only the first four were above the 1 p.p.m. level.

Only minor amounts of copper, silver, zinc, and lead were present which might possibly interfere with the complexation of mercury. These metals should not affect the extraction of mercury other than to slightly lower the capacity of the foams for mercury, unless saturation was approached. These samples were spiked with the radioactive mercury tracers to provide a means to evaluate the efficiency of the extraction from these complex matrices. The results of this study which are shown in Table 3, indicated that in comparison to the extraction from distilled water, the extraction of mercury(II) chloride is somewhat less effective with about 80 to 90% being extracted at about p*H* 1. At the natural p*H* of the samples taken, it was found that approximately 10% less mercury was removed. For methylmercury(II) chloride, however, almost quantitative recovery was achieved from all the samples at both the natural and the adjusted acidities. No attempt was made to increase the extraction efficiency by using masking agents for the wide variety of diverse ions known to be present since in practice, the exact matrix would probably be only vaguely known and any addition might be unwieldy for the separational system. Thus it can be seen that both mercury compounds can be extracted from complex matrices with good efficiency using the dithizone-treated foams, without extensive treatment of the samples.

TABLE 3. Extraction of mercury from various matrices

Compound	Matrix	p*H*	Extraction (%)
$HgCl_2$	Double-distilled H_2O	5.5	97.1
	Double-distilled H_2O	3.8	96.0
	Tap H_2O	6.5	88.5
	Tap H_2O	7.2	70.4
	Tap H_2O	1.3	98.3
	River H_2O*	8.1	78.7
	River H_2O	1.3	84.3
	Raw sewage	6.9	63.7
	Raw sewage	1.2	77.8
	Treated sewage	7.4	71.1
	Treated sewage	0.9	83.5

Conclusions

The preparation of polyurethane foam containing dithizone may be easily carried out in the laboratory. These dithizone-treated foams efficiently absorb mercury(II) and methylmercury(II) chloride over a wide p*H* range at various flow rates. Both of the mercury compounds are quantitatively extracted from the most dilute solutions up to 10 p.p.m. and are retained strongly enough by the foam to permit the passage of excess water without significant loss. The mercury can be totally recovered from the foams by simple extraction with acetone.

The dithizone-treated foams provide a simple means of extracting methylmercury(II) and mercury(II) chloride from both simple and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

complex aqueous systems. The technique permits the use of a wide variety of conditions and has been demonstrated to function well even for complex, real samples.

The use of dithizone-treated foams thus offers a new and efficient method for the extraction and concentration of both methylmercury(II) and mercury(II) chloride which may prove useful especially for trace amounts both in the laboratory and in the field. The application of similar techniques for other metals is presently being investigated.

The Vibrational Spectra and Structure of Dimethyl Carbonate and its Conformational Behavior[1]

J. E. KATON AND M. D. COHEN

Department of Chemistry, Miami University, Oxford, Ohio 45056

Received October 28, 1974

J. E. KATON and M. D. COHEN. Can. J. Chem. **53**, 1378 (1975).

The infrared spectra of dimethyl carbonate in the liquid and solid phases and the Raman spectrum of the liquid phase are reported. The evidence suggests that dimethyl carbonate exists as an equilibrium mixture of at least two conformers in the liquid state. An experimental value for the enthalpy difference of the two conformers of 2.6 ± 0.5 kcal/mol is obtained from the temperature dependency of the infrared spectrum.

Dimethyl carbonate crystallizes as an oriented polycrystalline film and polarized infrared spectra of the solid have been obtained. These have been utilized, along with the liquid phase data to obtain an improved vibrational assignment. There appears to be a solid–solid phase change in dimethyl carbonate in the vicinity of 140 K, but the details of this change are not known.

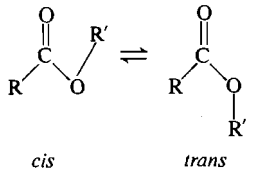
J. E. KATON et M. D. COHEN. Can. J. Chem. **53**, 1378 (1975).

On rapporte le spectre infrarouge du carbonate de diméthyle dans les phases liquide et solide et le spectre Raman de la phase liquide. Les données suggèrent que le carbonate de diméthyle existe sous forme d'un mélange à l'équilibre d'au moins deux conformères dans l'état liquide. On obtient une valeur expérimentale pour la différence d'enthalpie entre les deux conformères de 2.6 ± 0.5 kcal/mol à partir de la dépendance sur la température des spectres infrarouges.

Le carbonate de diméthyle cristallise sous forme de film polycristallin orienté et on a pu obtenir les spectres infrarouges polarisés du solide. On a utilisé ceux-ci de même que les données en phase liquide pour obtenir des attributions vibrationnelles améliorées. Il semble qu'il y a un changement de phase solide–solide dans le carbonate de diméthyle à proximité de 140 K, mais on ne connait pas les détails de ce changement. [Traduit par le journal]

Introduction

Ever since the concept of hindered internal rotation about single bonds was established, it has been expected that esters of simple carboxylic acids might exist in a conformational equilibrium in their fluid states. Such an equilibrium is expected, on theoretical grounds, to involve the two planar conformations shown below.



cis *trans*

The nomenclature used here is probably the most common, although many other investigators use the reverse notation of *cis* and *trans*.

Very many investigators have sought experimental evidence for the existence of such an equilibrium, but conclusive results have been very difficult to obtain. Jones and Owen (1) have recently written a very comprehensive review of this previous work. The conclusion which must be drawn from this previous work is that there has not appeared in the literature any report of the experimental confirmation of the existence of *trans* conformers of esters except "when ring-formation dominates the molecular structure (lactones) and possibly when the alkyl group R′ becomes too large to be accommodated in the space allowed by the *cis* structure" (1). The latter case has been discussed in more detail by Oki and Nakanishi (2, 3) and George *et al.* (4). Both of these groups have observed the presence of a conformational equilibrium in *t*-butyl formate (but not in *t*-butyl acetate). Their results indicate that the *cis* structure is the more stable, but whereas Oki and Nakanishi reported the enthalpy difference between conformers to be 2.2 ± 0.7 kcal/mol by n.m.r. methods, George *et al.* found the value to be 150 ± 20 cal/mol by infrared methods. In addition, Oki and Nakanishi (3) have reported that methyl *t*-butyl carbonate exists as a conformational

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

equilibrium in which the most stable conformer is the one in which the methyl group has the *cis* conformation while the *t*-butyl group possesses the *trans* conformation. Their data are not very conclusive, however.

It would appear that the ideal simple compound for investigation of such a conformational equilibrium is dimethyl carbonate. In the case of dimethyl carbonate the only possible conformers are those which differ by internal rotation about the C—O bonds. In addition, there is a statistical weight factor of two in dimethyl carbonate which is not possessed by other simple esters such as methyl formate or methyl acetate. This leads to higher populations of the *cis–trans* conformer, thereby making it easier to detect experimentally (the nomenclature used here arises from the possibility of two ester groups orienting in either the *cis* or *trans* conformation). As Jones and Owen (1) point out, the barrier to rotation in dimethyl carbonate should be lower than that in other esters due to greater electron delocalization. This has no direct bearing on the equilibrium, but does have implications with regard to the experimental approach.

The temperature dependence of the dipole moment of dimethyl carbonate has been reported by Mizushima and Kubo (5) and the results interpreted in terms of one conformer only, the *cis–cis*. Collingwood *et al.* (6) have studied the vibrational spectra of the compound and report that they found no evidence for the existence of a second conformer. They conclude that the structure is the *cis–cis* conformer on the basis of the contours of the vapor phase infrared spectrum and the small number of polarized Raman bands in the liquid phase. The latter is evidence for a C_{2v} structure and the *trans–trans* form is too sterically hindered to be considered seriously.

We have previously given a preliminary report (7, 8) of the results of a thorough study of the vibrational spectra of dimethyl carbonate and the evidence that it exists in a conformational equilibrium mixture in the liquid phase. We report the details and complete results herewith.

Experimental

Dimethyl carbonate was purchased from Aldrich Chemical Company, Incorporated, and fractionally distilled. The constant boiling fraction (90 °C/760 mm Hg) was used for spectral studies. Although the infrared spectrum of the redistilled material was identical to the original, it was found that the solid–solid phase change discussed later could only be readily observed with the redistilled material.

Infrared spectra in the 4000–250 cm^{-1} region were recorded on a Perkin–Elmer Model 180 infrared spectrophotometer and those in the 300–50 cm^{-1} region on a Digilab, Inc., Model FTS-14, Fourier Transform spectrometer. Raman spectra were recorded on a Cary Model 81 Raman spectrometer using an argon ion laser source.

Low temperature infrared spectra were obtained utilizing a conventionally designed low temperature infrared cell mounted in an evacuable chamber fitted with windows for the passage of the infrared beam. The cell was cooled by a stream of nitrogen gas which had been previously cooled by passing through a copper coil immersed in liquid nitrogen and whose flow rate could be controlled by a needle valve. The temperature was monitored by a thermocouple in contact with one of the cell windows. Nominal temperatures as low as 120 K could be reached by controlling the flow of nitrogen gas.

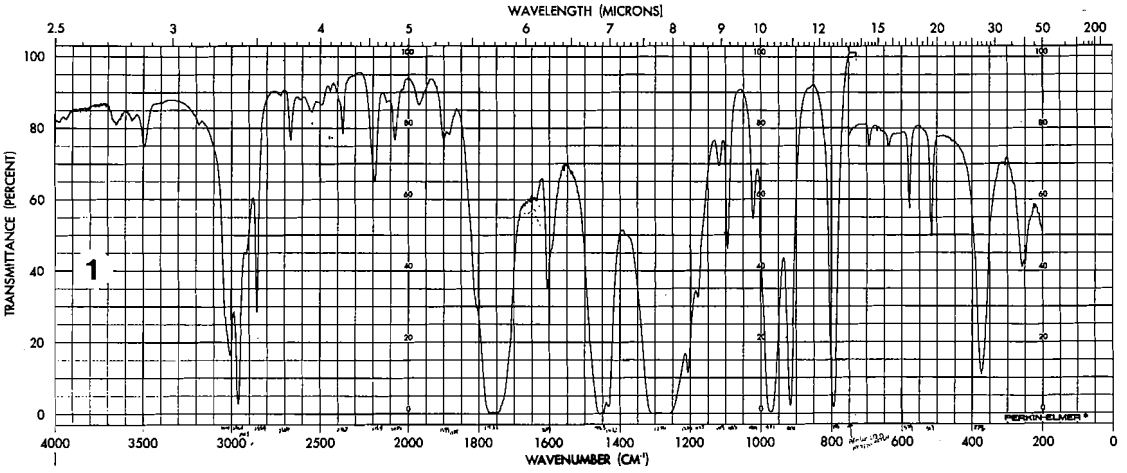
Polarized infrared spectra were obtained utilizing the standard Model 180 polarizer accessory consisting of a gold wire grid mounted on a silver bromide substrate. Oriented polycrystals were obtained by simply cooling the sample below the freezing point, usually fairly rapidly (about 10°/min). No annealing was necessary.

The liquid phase infrared and Raman spectra of dimethyl carbonate are reproduced in Figs. 1 and 2. Typical polarized infrared spectra of crystalline dimethyl carbonate at nominal temperatures of 253 K have been previously published (8) and those at 120 K are reproduced in Figs. 3 and 4. The observed infrared and Raman bands of the liquid and high temperature solid phase are given in Table 1. The frequency accuracy is expected to be ± 4 cm^{-1} in the Raman spectrum and ± 2 cm^{-1} in the infrared spectra, at the worst.

Results

Conformational Behavior

If one studies the liquid phase Raman spectrum of dimethyl carbonate carefully, one is led to the conclusion that it is a rather unusual spectrum for a single compound in a single conformation. Overtones and combination bands are nearly always absent in the Raman spectrum unless they are intensified by Fermi resonance. As a result, one usually sees a few less Raman lines than the number of fundamental modes of vibration predicted for the molecule in question. This is generally true due to the fact that a few fundamental modes are usually weak or so closely spaced that they are unresolvable. Whatever the structure of dimethyl carbonate, it should have 30 fundamental modes of vibration active in the Raman spectrum. Although there are 28 distinct Raman bands, it is clear that not all of the fundamental modes are being resolved. In the CH stretching region there are six ob-



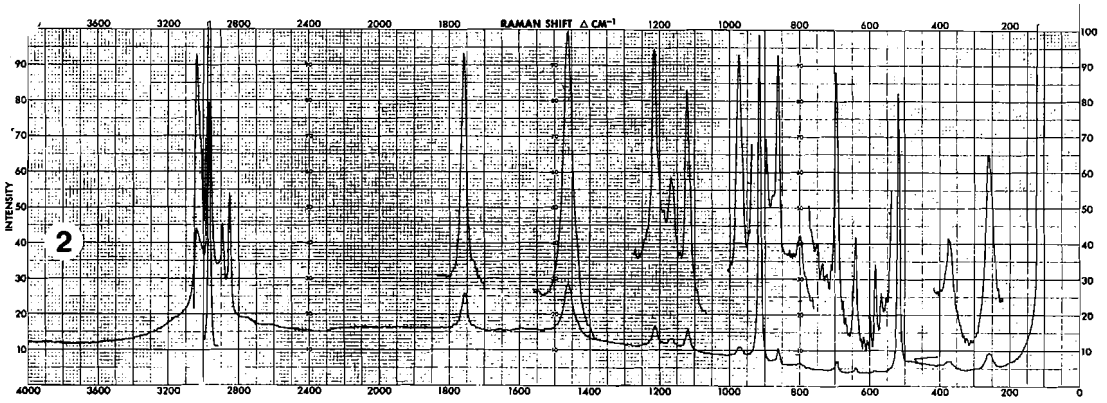


FIG. 1. The infrared spectrum of dimethyl carbonate (liquid, nominal path length 0.05 mm).
FIG. 2. The Raman spectrum of liquid dimethyl carbonate.

served bands, but three are obviously too low in frequency for fundamental modes of methyl esters. Two can be readily assigned as overtones of two CH_3 bending modes in Fermi resonance with the fundamentals. These are very typical features in the spectra of many compounds containing methyl groups. The third is a weak shoulder which can be assigned as a combination band. We are therefore failing to resolve three fundamentals in this region. A similar behavior occurs in the 1400–1500 cm^{-1} region where one expects six CH_3 bending modes. Only two Raman bands can be observed here, however, and they are not well-resolved. It is then clear that the Raman spectrum has more bands than are expected for a single compound in a single conformation. This immediately leads one to suspect a conformational equilibrium. Comparison with the liquid phase infrared spectrum indicates that nearly all of the Raman bands have infrared counterparts (although this is formally not expected for a C_{2v} molecule, it is quite reasonable in view of the nature of the A_2 modes and is discussed later). Several of the observed bands disappear, however, when the sample is cooled and the infrared spectrum of the crystal recorded. This is still further evidence for the existence of a conformational equilibrium in the liquid phase. All of these bands that disappear on cooling are quite weak in *either* the infrared or Raman spectrum, however, and this is probably the reason that Collingwood *et al.* failed to recognize the existence of a second conformer. This behavior is illustrated by the bands at 1095, 863, 640, and 583 cm^{-1}. The first and last are very weak in the Raman but relatively

strong in the infrared while the second and third show the reverse behavior. A fifth band at 2189 cm^{-1} in the infrared spectrum of the liquid disappears on crystallization. This band can be readily assigned as the overtone of the 1095 cm^{-1} band, of course. There are other minor features in the spectra that behave similarly.

As a final test of a conformational equilibrium, the temperature dependence of the relative infrared absorbances of two bands, one of which disappears in the crystal spectrum, were measured. Since relatively long path lengths were required for these measurements, the 1095 cm^{-1} band overlapped the 1120 cm^{-1} band rather strongly. Therefore the 580/518 cm^{-1} pair were chosen for the measurements since they were relatively well isolated. Their weakness leads to relatively large absorbance errors, however. The relative absorbances of the 580/518 cm^{-1} bands as a function of temperature over the range 13–47 °C were measured. The graph of the logarithm of these ratios versus the reciprocal of the absolute temperature has a good deal of scatter due to inherent lack of accuracy, but it generally shows the trend expected for bands due to different conformers (8). The line was obtained by least squares analysis and treatment of the data in the standard way (9) yields

a value of ΔH of 2.6 ± 0.5 kcal/mol. These results, taken together, suggest that the liquid phase of dimethyl carbonate exists as a conformational equilibrium of at least two conformers.

Vibrational Assignment

Collingwood *et al.* (C.L.W.) have published an assignment based on vapor phase infrared contours and Raman polarization data. The assignment assumes, however, that only the *cis–cis*, C_{2v}, structure is present. Their lack of infrared spectra of the crystal has therefore led to certain misassignments. In addition, we find ourselves in disagreement with C.L.W. in regard to the experimental observation of a number of weak bands. Finally, we have assigned two of the A_2 modes from our low temperature solid phase infrared spectrum under the assumption that the site symmetry of dimethyl carbonate in this phase is lower than C_{2v}. This assumption is discussed further in the next section. The assignments of the fundamental modes are compared in Table 2.

In the CH stretching region our assignment of the liquid phase spectrum is essentially identical with that of C.L.W. There are three accidental degeneracies (ν_1 with ν_{16}, ν_2 with ν_{17}, and ν_{11} with ν_{25}). In the 120 K spectrum, however, the latter two degeneracies are split.

The first assignment disagreement between C.L.W. and ourselves occurs in the CH_3 bending region. This is a very difficult region because six fundamental modes occur here and there is a great deal of accidental degeneracy. Although our liquid infrared data agrees with that of C.L.W., our Raman data does not. C.L.W. observe Raman bands at 1456 and 1414 cm^{-1}. We have searched for the 1414 cm^{-1} band, but are unable to find it. We do observe a shoulder at 1453 cm^{-1}, however, on a major band at 1461 cm^{-1}. Since our infrared spectrum has bands at 1458 and 1436 cm^{-1}, it seems clear that the 1453 cm^{-1} shoulder must be the A_2 CH_3 antisymmetric bending mode, ν_{12}. Since symmetric methyl bending modes are almost invariably lower in frequency than the corresponding antisymmetric modes, we prefer to assign 1436 cm^{-1} as ν_4 and ν_{18} and the 1458 cm^{-1} band as ν_5, ν_{19}, and ν_{26}. At 120 K, the degeneracy between ν_4 and ν_{18} is split, but that between ν_5 and ν_{19} is not. In addition, we observe two bands at 1452.7 and 1451.0 cm^{-1} of opposite polarization in the oriented crystal at

120 K. These bands, which can only be resolved by utilizing the polarizer, are assigned to ν_{12} and ν_{26}.

The CH_3 rocking modes are all assigned in the 1150–1250 cm^{-1} region, but our data are quite different from that reported by C.L.W. They observed no infrared vapor bands in this region, but did observe liquid phase bands at 1162, 1176, and 1210 cm^{-1}. They assigned the four methyl rocking modes from their Raman spectra with the four bands and their relative intensities being 1160 (2), 1195 (4), 1210 (1), and 1234 (1). The 1195 cm^{-1} band was reported to be polarized. We do not observe the 1234 cm band, the 1215 cm^{-1} band is the strongest Raman band in this region and we find it to be polarized, the 1190 cm^{-1} band is very weak, and the 1165 cm^{-1} is the second strongest in the region. A liquid phase infrared band is found corresponding to the 1215 band, but not to the 1165 and 1190 cm^{-1} bands. The crystal infrared spectrum has bands at 1190 and 1158 cm^{-1}, however. This assignment requires that two of the methyl rocks remain accidentally degenerate and ν_6 and ν_{21} have been chosen as corresponding to the strongest Raman and infrared band observed. The choice for ν_{13} and ν_{27} is then arbitrary and we have chosen the highest frequency as ν_{13}.

The four skeletal stretching modes involving the ether-like bonds present no difficulty and we agree with C.L.W. as to their assignment.

The only fundamentals remaining to be assigned are the skeletal bending modes. These are expected below 900 cm^{-1}, where the remaining nonassigned bands are found. Because

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of a lack of crystal spectra, C.L.W. assigned as fundamentals bands at 857, 634, and 579 cm^{-1}. These correspond to a second conformer, however, as we have previously discussed. They then assigned five Raman bands between 500–198 cm^{-1} as difference bands, the lowest of the ground states being 792 cm^{-1}. This must certainly be incorrect since at room temperature such a high level could not be significantly populated.

The two OCO_2 rocking modes are expected to be the highest in frequency of the skeletal bending modes and C.L.W. have assigned ν_{28} by infrared vapor phase contours. We therefore agree in our assignment of ν_{28}, but assign ν_{23}, the in-plane rocking mode to the next highest frequency found in the solid, 692 cm^{-1}.

There are three more nontorsional skeletal bending modes and three major bands remaining in both the infrared and Raman spectra. Two of these Raman bands are polarized and therefore correspond to the two remaining A_1 modes, ν_9 and ν_{10}. The higher frequency one is chosen as δOCO and the lower as δCOC since the former could be expected at a higher frequency. The remaining depolarized Raman band is then assigned as the B_1, δCOC bending mode.

In a number of studies of compounds containing methoxy groups (10–12), it has been reported that methoxy torsions occur in the range 170–215 cm^{-1} and the corresponding methyl torsions at 130–150 cm^{-1}. We therefore assign the two methoxy torsions, ν_{14} and ν_{29}, as being accidentally degenerate at 198 cm^{-1} and the two methyl torsions as being accidentally degenerate at 136 cm^{-1}.

Crystal Spectra

We have earlier reported (7, 8) that dimethyl carbonate can be crystallized between alkali halide windows as a highly oriented film. We have earlier reported that this phenomenon is rather general with other compounds (13). It is therefore feasible to study the polarized infrared spectra of dimethyl carbonate at low temperatures. Unfortunately, the crystal structure of dimethyl carbonate has not been reported and the results of a polarized infrared spectral study are therefore not unambiguously interpretable. Nevertheless, some information can be drawn from such low temperature studies.

If the sample used is one that has been purified, there appears to be a solid–solid phase change at a nominal temperature of about 140 K. The orientation of the crystals is not destroyed by this phase change since strong polarization effects are noted in the spectra of both phases. Comparison of the spectra in Figs. 3 and 4 with those published earlier (8) leads to the conclusion that the low temperature phase spectra are much more complicated than those of the higher temperature phase, with a great deal of band splitting and sharpening. The change in the spectra is a sudden one, however, and therefore indicates an actual change in crystal or molecular structure. The high temperature solid phase spectra have no significant temperature dependency, but the low temperature solid phase spectra do. In general, the splittings observed in the spectra of the low temperature phase increase as the temperature is lowered. This behavior is typical of crystal splittings in organic crystals, due probably to lattice contraction effects.

The three A_2 modes which are above the low frequency transmission limit of the windows are all methyl modes which might be expected to be accidentally degenerate with other methyl modes of the same type but of different symmetry. This appears to be true with ν_{11}, but ν_{12} and ν_{13} do appear to be resolved in the Raman spectrum of the liquid. In the high temperature solid phase infrared spectrum ν_{12} and ν_{13} also appear, but ν_{11} does not. If the assignment is correct, this indicates that the site symmetry of the high temperature crystal is less than C_{2v}. In the low temperature solid phase infrared spectra a new band appears which can be assigned to ν_{11}. It must be noted, however, that this assignment is quite arbitrary. The band may simply be due to crystal splitting, *i.e.* the same molecular mode split by intermolecular interactions. Nevertheless, ν_{11}, ν_{12}, and ν_{13} must occur very near their present assignment frequencies.

Conclusions

The spectral data for dimethyl carbonate are all consistent with the existence of a conformational equilibrium in the liquid state. In view of previous structural studies, the major conformer must be the *cis–cis*, C_{2v} structure. The second structure would be expected, on theoretical grounds, to be the *cis–trans* C_s structure. There is no experimental evidence confirming this structure as a second conformer, however.

The ΔH value obtained experimentally is quite high, but is in the range predicted for ester conformations (1). It corresponds to a relative concentration of the second conformer of about 1% at ambient temperatures in the absence of a statistical weight factor. If the second conformer is the *cis–trans* structure it would possess a statistical weight factor of two, doubling its relative concentration. If the second conformer is one in which one methyl group is not coplanar with the remainder of the molecule, however, the statistical weight factor would be four.

The recording of the solid state infrared spectra of dimethyl carbonate has, in addition to providing evidence for the conformational equilibrium, allowed improvements in the assignment of the fundamental modes of vibration. Collingwood *et al.* have assigned second conformer bands as fundamentals of the *cis–cis* conformer and these assignments have been corrected.

Dimethyl carbonate crystallizes as an oriented polycrystalline film and polarized infrared spectra may be obtained. In the absence of a known crystal structure, these cannot be fully interpreted. Nevertheless, they indicate that the site symmetry is lower than C_{2v}. It appears that dimethyl carbonate undergoes a solid–solid phase transition in the neighborhood of 140 K, but the exact nature of this transition is not known.

We wish to express our appreciation to Dr. G. L. Carlson of Carnegie–Mellon University and Mr. R. J. Jakobsen of Battelle–Columbus for making their Cary 81 Laser Raman spectrometer and Digilab FTS-14 Infrared Fourier Transform Spectrometer available to us.

Vibrational Spectra of $N_2H_5HC_2O_4$ and $N_2D_5DC_2O_4$

R. SAVOIE AND M. GUAY

Département de Chimie, Université Laval, Québec, Québec G1K 7P4

Received November 15, 1974

R. SAVOIE and M. GUAY. Can. J. Chem. **53**, 1387 (1975).

Infrared and Raman spectra of $N_2H_5HC_2O_4$ and $N_2D_5DC_2O_4$ have been recorded at various temperatures between 77 and 300 K. The results at 300 K are consistent with the known crystal structures of these solids. A phase transition has been detected at ~240 K in $N_2D_5DC_2O_4$ and although there are similarities between the two stable solid phases of this compound, the low-temperature form appears to be centrosymmetric and to have a larger unit cell than the high-temperature modification.

R. SAVOIE et M. GUAY. Can. J. Chem. **53**, 1387 (1975).

Les spectres de vibration du composé $N_2H_5HC_2O_4$ et ceux de son analogue deutérié ont été obtenus à diverses températures entre 77 et 300 K. Les résultats à 300 K s'interprètent bien d'après les structures cristallines connues de ces espèces. On a par ailleurs mis en évidence une transition cristalline à ~240 K dans $N_2D_5DC_2O_4$. Même si les deux phases solides de ce dernier composé sont assez semblables, les spectres suggèrent pour la modification stable aux plus basses températures une structure centrosymétrique et une maille élémentaire augmentée par rapport à celle de la phase stable à température ambiante.

Introduction

Proton magnetic resonance investigations of hydrazinium hydrogen oxalate ($N_2H_5HC_2O_4 \equiv$ HyHOx) have shown this crystal to consist of $N_2H_5^+$ and $HC_2O_4^-$ ions (1). This has been confirmed by an X-ray diffraction structure determination (2) followed by a neutron diffraction study (3). The crystal was found to belong to the $P2_1/m$ (C_{2h}^2) space group of the monoclinic system, with two formula units per unit cell. In this structure, the $N_2H_5^+$ ions are required by symmetry to have a perfectly staggered configuration since they are located in mirror planes (at $y = \frac{1}{4}, \frac{3}{4}$), where they are linked together into zigzag chains by in-plane $NH^+\cdots N$ hydrogen bonds. Other hydrogen atoms are involved in bifurcated and trifurcated bonds with the cross-linking oxalate ions which form planar chains through very short (0.245 nm) and symmetrical or statistically disordered hydrogen bonds. The oxalate chains run parallel to each other in the $y = 0, \frac{1}{2}$ planes.

Two independent vibrational studies of HyHOx have already been reported. Selvarajan (4) has published the room-temperature infrared spectrum of the solid in a KBr matrix and the Raman spectrum of the powder, the latter of poor quality due, in part, to the weakness of the exciting source (He–Ne laser). Lindgren *et al.* (5), from a comparative infrared study of HyHOx and its deuterated analog (DyDOx) at liquid-nitrogen temperature, concluded that the $O\cdots H\cdots O$ bonds become asymmetrical when hydrogen is substituted by deuterium in this compound. This prompted an X-ray diffraction study of both crystalline HyHOx and DyDOx, by Thomas (6), who confirmed the noncentrosymmetric structure of the latter (space group: $P2_1(C_2^2)$, $Z = 2$). Still not definitely established, however, is the exact location of the H or D atoms linking the oxalate ions in these solids.

The present study was initiated for the purpose of complementing the diffraction studies and to gather information on the crystal structures of HyHOx and DyDOx at low temperature, as the occurrence of a crystalline phase change had already been indicated in HyHOx by low-temperature X-ray photographs (3).

Experimental

The HyHOx used in this study was prepared as described by Turrentine (7), by mixing warm solutions of hydrazine and oxalic acid (reagent grade, Fisher Scientific Co.). The deuterated product was prepared in a similar manner, from N_2D_4 (97% atom D) in heavy water (99.7% atom D) from Merck, Sharp, and Dohme, and $D_2C_2O_4$ obtained by reacting D_2SO_4 with CaC_2O_4. From the relative intensities of infrared bands attributable to mixed isotopic species, it is estimated that the degree of deuteration of the final product was ~95%.

The Raman spectra of polycrystalline samples were obtained from powders placed in a Dewar-type cryostat with flat windows at the end and cooled by a flow of cold nitrogen gas. In the infrared, Nujol and Fluorolube mulls were used. They were held between CsI (for the mid-infrared)

or crystalline quartz (for the far-infrared) windows in a conventional liquid nitrogen cryostat.

The single crystals of HyHOx for the Raman polarization study were grown by slow evaporation of saturated aqueous solutions. The location of the crystallographic axes in the crystals studied (1.5 × 1 × 5 mm) was found by X-ray diffraction. Raman spectra were recorded with the laser beam entering the crystal along the crystallographic *b* axis, the latter being perpendicular to a pair of parallel crystal faces. However, since the crystal shape was such that the axis of observation (*a* or *c* crystal axis) was not perpendicular to a crystal face, extinction of the Raman bands was never complete when expected. The polarization effects were nevertheless sufficiently pronounced to characterize unambiguously different vibrational species.

A Spex (Model 1400) and a Jarrell–Ash (Model 25-100) spectrometer with a CRL (Model 52A) argon laser were used for the Raman experiments. The infrared spectra were obtained with a Perkin–Elmer (Model 621) spectrophotometer (200–4000 cm^{-1} region) and a RIIC (Model FS-720) interferometer coupled to a FTC-100 Fourier transform computer for the 20–400 cm^{-1} region. The slit widths of the spectrometers were generally adjusted so as to get a resolution of 2 cm^{-1} or better and the frequencies reported later are probably accurate within ±2 cm^{-1} in the case of sharp peaks.

Results and Discussion

The low-frequency (20–600 cm^{-1}) infrared and Raman spectra of HyHOx and DyDOx at low and room temperatures are reproduced in Figs. 1 and 2. Complements of the Raman spectra are shown in Fig. 3. The corresponding infrared spectra (600–3500 cm^{-1}) are not reproduced, being essentially similar to those already reported (4, 5). To facilitate the discussion, the spectra of crystalline HyHOx will be analyzed first, using the closely resembling room-temperature spectra of the deuterated compound. The low-temperature spectra of DyDOx will be discussed separately since they differ appreciably from those at room temperature.

HyHOx

The vibrational correlation diagrams for the $N_2H_5^+$, $C_2O_4^{2-}$, and H^+ ions in crystalline HyHOx are given in Table 1, for the centrosymmetric $P2_1/m$ (C_{2h}^2) structure deduced from the diffraction studies.

The correlation diagram for the $H_2N—NH_3^+$ ion indicates that the fundamental vibrations of this species, whether they are symmetric (*A'*) or not (*A''*) with respect to the symmetry plane at the site, should give in each case one Raman and one infrared-active component ($A_g + B_u$ or $B_g + A_u$) in the crystal. This is effectively the case for the two fundamental stretching vibrations of the NH_2 group responsible for the 3292/3293 and 3357/3364 cm^{-1} infrared/Raman pairs of bands (in the room-temperature spectra), the latter pair belonging to the asymmetric stretch since the vibration at 3364 cm^{-1} has B_g symmetry (Fig. 3*A*).

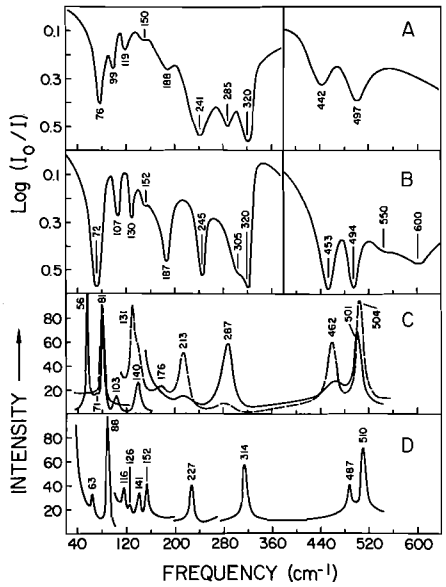

FIG. 1. Infrared spectra of polycrystalline $N_2H_5HC_2O_4$ at (*A*) 300 K and (*B*) 77 K. Polarized Raman spectrum of a single crystal at (*C*) 300 K (—A_g and ···B_g species). Raman spectrum of the powder at (*D*) 77 K.

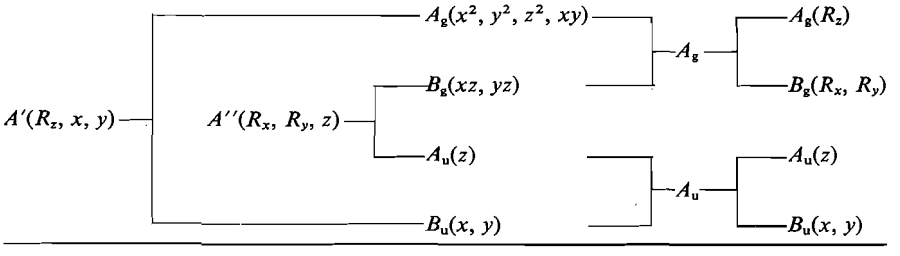
TABLE 1. Vibrational correlation diagrams for the $N_2H_5^+$, H^+, and $C_2O_4^{2-}$ ions in crystalline hydrazinium hydrogen oxalate



Similarly, the N—N stretching mode is characterized by the 968(infrared)/967(Raman) pair, the Raman-active mode having A_g symmetry as it arises from a symmetric (*A'*) vibration in the free ion.

Bands due to the vibrations of the hydrazinium ions are readily identified from the spectra of the deuterated compound and those of the hydrazinium halides (8). They do not reflect the crystal structure very well because some of them are very weak or nearly degenerate. For instance, only three Raman bands at 1416, 1606, and 1610 cm^{-1}, with infrared counterparts at 1412 and 1609 cm^{-1}, can be attributed to the four H—N—H

bending modes. The Raman spectrum of DyDOx, however, shows four peaks in the 1096–1193 cm^{-1} region. Similarly, the four N—N—H bending vibrations (wagging and rocking modes) are characterized by two infrared peaks only (at 1084 and 1120 cm^{-1}). As for the torsion about the N—N axis, expected to occur in the 500–650 cm^{-1} region as in $(N_2H_5)_2SO_4$ (4) and the hydrazinium halides, it has not been detected.

The fundamental vibrations of the $C_2O_4^{2-}$ ions in crystalline hydrazinium hydrogen oxalate are either symmetrical with respect to the center of inversion located midway between the two carbon atoms (A_g species), in which case they are predicted (see Table 1) to give a doublet in the Raman spectrum of the crystal ($A_g + B_g$), or asymmetrical with respect to it (A_u species), in which case they should be characterized by an infrared-active doublet ($A_u + B_u$). This pattern is readily recognized in the spectra, although the predicted factor-group splitting of the infrared-active vibrations is not apparent. For example, two of the four CO stretching modes are infrared-active only (1343 and 1727 cm^{-1}), whereas the remaining two occur as doublets in the Raman spectrum, at 1439 ($A_g + B_g$) and 1702(B_g)/1714(A_g). Similarly, the C—C stretching vibration is Raman-active only, the A_g and B_g vibrational components in the crystal having identical frequencies at room temperature (either 856 or 897 cm^{-1}, one of the two peaks being presumably due to a combination mode), as shown in the polarized Raman spectrum (Fig. 3*A*).

The other vibrations of the oxalate ions are nearly frequency coincident with the corresponding modes in $NaHC_2O_4$ and in $NaHC_2O_4 \cdot H_2O$ (9), in which the $HC_2O_4^-$ network is quite similar to that in HyHOx. The infrared bands at 241 and 320 cm^{-1} are thus assigned to the normally infrared-active rocking and wagging (symmetric C—C—O_2 bending) modes, whereas that at 497 cm^{-1} belongs to the asymmetric O—C—O bending mode. The corresponding symmetric vibration is responsible for the 501(A_g)/504(B_g) cm^{-1} Raman doublet. However, the two Raman-active rocking and wagging modes were not detected. Finally, the weak infrared band at 150 cm^{-1} is tentatively assigned to the torsional mode.

Although the number of optically active lattice modes (at $k = 0$) in crystalline HyHOx is expected from Table 1 to be rather large, the low-frequency region of the spectra can be reasonably well interpreted, using polarization data and frequency shifts upon deuteration. The librational modes of the $N_2H_5^+$ ions, in particular, are easily identified. Oscillations about the N—N axis, involving mainly the hydrogen atoms, are characterized by the 442/462 cm^{-1} infrared (A_u)/Raman (B_g) pair of bands, which are strongly temperature dependent and are shifted by a factor of 1.32 upon deuteration (462 → 351 cm^{-1}). Other librational motions of the hydrazinium ions take place in planes of symmetry of the crystal (285(B_u)/287(A_g) cm^{-1}), or perpendicular to them (188(A_u)/213(B_g) cm^{-1}).

The librational modes of the oxalate ions should be Raman-active only and occur as a series of doublets (A_g/B_g species) with mean frequency in the ratio 1:1.3:1.6 (assuming the frequency to be inversely proportional to the square root of the moment of inertia). Observed Raman bands at 81 cm^{-1} ($A_g + B_g$), 103 cm^{-1} (A_g), and 131/140 cm^{-1} (B_g/A_g) fit this pattern very well, except that the B_g counterpart of the 103 cm^{-1} mode has not been detected. Also expected in this region are three bands due to translational modes ($2A_g + B_g$) of the hydrazinium ions, which are probably strongly coupled to the librational motions of the oxalate ions. The two A_g modes involve layers of hydrazinium ions oscillating between layers of oxalate ions and are expected to have relatively low frequencies. The strong Raman band at 56 cm^{-1} likely accounts for at least one of these two vibrations. The B_g mode in which the hydrazinium ions move against the $HC_2O_4^-$ layers, in the general direction of the NH···O bonds, is expected to have a higher frequency. The remaining peak at 176 cm^{-1} in the Raman spectrum is tentatively assigned to this vibration. The other translational modes in HyHOx should be infrared active only ($6A_u + 6B_u$). Some of these involve mainly the H^+ ions and are responsible for the very broad absorption feature with maximum near 650 cm^{-1} in the infrared spectrum (5). Others involve mostly the heavier ions since they must account for the very low-frequency infrared-active modes at 76, 99, and 119 cm^{-1}.

The vibrational spectra of crystalline HyHOx, which can be well interpreted on the basis of the centrosymmetric crystal structure deduced from the diffraction studies, show no sudden change as the temperature is lowered to 77 K. This, however, does not necessarily mean that the phase transition detected below about 173 K by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

X-ray diffraction (3) is not real. The suggested doubling of the *c* unit cell dimension at low temperature can occur with only minor modifications of the actual crystal structure and result in essentially similar vibrational spectra. In any case, it seems that the O···H···O bonds remain the same as the temperature is lowered, since the characteristic broad absorption band in the 300–1500 cm^{-1}, as well as the narrow transmission peak (10) near 720 cm^{-1}, are still present in the infrared spectrum at 77 K.

DyDOx

The neutron diffraction study of Thomas (6) has shown that the crystal structure of N_2D_5-DC_2O_4 at room temperature is best described by the noncentrosymmetric space group $P2_1$ (C_2^2). In this structure, the various ions are all located on general positions of the unit cell, so that all vibrational components in the solid, instead of being either Raman or infrared-active only, should be active in both types of spectra. This prediction is generally not verified in this case, most likely because the crystal structure departs only slightly from that of HyHOx. The weak infrared activity of the C—C stretching mode (at 853 or 888 cm^{-1}) in DyDOx nevertheless confirms the lowering of symmetry of the oxalate ions upon deuteration.

In the course of the present study, it was early realized that the vibrational spectra of DyDOx at liquid-nitrogen temperature could not be interpreted on the same basis as those at room temperature. The low and high-frequency regions in particular differed markedly at these two temperatures (see Figs. 2 and 3). A careful temperature dependence study indicated that the changes observed in the spectra upon cooling the samples occurred over an extended temperature range, approximately from 240 to 200 K, whereas the reverse transformation took place from 240 to 275 K upon warming. The marked spectral changes in DyDOx near 240 K indicate the occurrence of a genuine phase transition in this solid.

The average vibrational frequencies of the oxalate ions in DyDOx are almost identical in the two solid phases, which suggests that the structural parameters of these ions in the DOx···DOx··· chains remain essentially unchanged in the low-temperature phase (phase II). However, it should be noted that splitting of infrared bands due to the Ox ions occur at the transition (for example, $222 \rightarrow 212 + 236\ cm^{-1}$, $310 \rightarrow 305 + 326\ cm^{-1}$...). Such splittings were predicted above for HyHOx and DyDOx in phase I (high-temperature phase), but were not observed in the infrared spectra of these solids. This apparent lack of vibrational coupling can be explained by the fact that two Ox ions in any primitive cell are separated by Hy^+ or Dy^+ ions. If this interpretation is correct, observed splittings in DyDOx phase II could result from adjacent Ox ions being orientationally different. For example, alternate DOx ions in a chain could have their C_2O_4 planes oriented in different directions. This would of course imply a doubling of the unit cell, which would be consistent with the increased number of bands in the spectra (particularly in the Raman spectrum) of phase II.

The spectra of the $N_2D_5^+$ ions also reflect the phase transition, as shown by the 2400 cm^{-1} region of the Raman spectra (Fig. 3), where the characteristic doublet of the NH_2 group at 2422/2516 cm^{-1} in phase I is replaced by that at 2356/2485 cm^{-1} in phase II. The corresponding frequencies in the room-temperature infrared spectrum of HyHOx are 3292/3357 cm^{-1}. The frequency of the NH stretching vibration of $NHDND_3^+$ species isolated in DyDOx, 3320 cm^{-1}, is very nearly the average of the latter two. The presence of a singlet in this region indicates that the H atoms in the NHD—ND_3^+ and NDH—ND_3^+ species are equivalent. This is consistent with the X-ray diffraction findings that the two D atoms of the ND_2 groups of the ND_2—ND_3^+ ions are nearly equivalent in phase I. In the low temperature modification, the doublet at 3320/3328 cm^{-1} is indicative of a more pronounced departure from planar symmetry of the Dy^+ ions. The possibility of disorder in the relative orientations of the oxalate chains in DyDOx, as suggested by Thomas (6), should therefore be considered, especially since the phase transition in the solid could result from an ordering of the system. The fact that the bands attributable to the oxalate ions in the room-temperature vibrational spectra of DyDOx are somewhat broader than the corresponding ones in HyHOx could be due to orientational disorder of the Ox chains in the deuterated compound. It seems extremely unlikely, however, that the changes in the spectra at ~240 K are caused solely by an ordering of the Ox chains, although it is possible that more important structural changes are triggered by such a process. Whatever the situation in phase I, the sharpness of the bands in the low-tempera-

ture vibrational spectra is indicative of an ordered crystal. Furthermore, the obvious tendency for the infrared and Raman bands to have different frequencies suggests a centrosymmetric structure for phase II, which would require that adjacent chains (or chains in alternate layers) be oriented in opposite directions in the low-temperature form.

The authors gratefully acknowledge financial support of this work by the National Research Council of Canada. We are also indebted to Professor A. Cabana (Université de Sherbrooke) for temporary use of his Raman spectrometer, and to Professor A. Beauchamp (Université de Montréal) and Dr. R. Dubey for their help in locating the crystallographic axes in monocrystals of hydrazinium hydrogen oxalate.

Crystal and Molecular Structure of *B*-Phenyl-*diptych*boroxazolidine, $C_6H_5BN(CH_2CH_2O)_2$

STEVEN J. RETTIG AND JAMES TROTTER

Department of Chemistry, University of British Columbia, Vancouver, British Columbia V6T 1W5

Received November 8, 1974

STEVEN J. RETTIG and JAMES TROTTER. Can. J. Chem. **53**, 1393 (1975).

Crystals of *B*-phenyl-*diptych*boroxazolidine are monoclinic, $a = 8.4977(4)$, $b = 9.0617(5)$, $c = 7.0105(3)$ Å, $\beta = 111.627(3)°$, $Z = 2$, space group $P2_1$. The structure was solved by direct methods and was refined by full-matrix least squares procedures to a final R of 0.040 for 967 reflections with $I \geq 3\sigma(I)$. The bond lengths involving nonhydrogen atoms have been corrected for thermal motion. Bond lengths are: B—O, 1.460(3) and 1.474(3), B—N, 1.666(3), B—C, 1.613(3), C—O, 1.411(3) and 1.419(3), C—N, 1.485(3) and 1.486(3), $C(sp^3)$—$C(sp^3)$, 1.514(4) and 1.524(4), C—C(ar), 1.384–1.400(4–6), mean C—H, 0.98(4), and N—H, 0.87(5) Å. The crystal structure consists of discrete molecules of *B*-phenyl-*diptych*boroxazolidine each linked to two others by N—H. . .O hydrogen bonds (O. . .N = 2.914(3) Å) to form continuous spirals along *b*.

STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **53**, 1393 (1975).

Les cristaux de la *B*-phényl-*diptych*boroxazolidine sont monocliniques $a = 8.4977(4)$, $b = 9.0617(5)$, $c = 7.0105(3)$ Å, $\beta = 111.627(3)°$, $Z = 2$, groupe d'espace $P2_1$. La structure a été résolue par la méthode directe et affinée par les méthodes des moindres carrés (matrice complète) avec une valeur finale de R de 0.040 pour 967 réflections avec $I \geq 3\sigma(I)$. Les longueurs des liaisons impliquant des atomes autres que l'hydrogène sont corrigées pour les mouvements thermiques. Les longueurs des liaisons sont B—O, 1.460(3) et 1.474(3), B—N, 1.666(3), B—C, 1.613(3), C—O, 1.411(3) et 1.419(3), C—N, 1.485(3) et 1.486(3), $C(sp^3)$—$C(sp^3)$, 1.514(4) et 1.524(4), C—C(ar) 1.384–1.400(4–6) valeur moyenne C—H, 0.98(4) et N—H 0.87(5) Å. [Traduit par le journal]

Introduction

The cyclic structures of *triptych*boroxazolidine, **1**, (triethanolamine borate (1)) and two ethanolamine diarylborinates (*B*,*B*-diphenylboroxazolidine, **2***a*, (2) and *B*,*B*-bis(*p*-fluorophenyl)-boroxazolidine, **2***b*, (3)) featuring intramolecular N → B coordination, as first proposed by Brown and Fletcher (4), have recently been established by X-ray crystallography. This report describes the structure of the diethanolamine ester of phenylboronic acid, *B*-phenyl-*diptych*boroxazolidine (**3**). The N → B interaction in each of these three types of boron esters was supported by a good deal of chemical evidence (5). With this report, conclusive proof of the existence of the N → B interaction has been presented for each type of boroxazolidine.

Experimental

B-Phenyl-*diptych*oboroxazolidine was prepared as previously described (6, 7). Recrystallization from ethanol–acetone gave colorless needles, elongated along *b*. The crystal chosen for study was mounted with *b* parallel to the goniostat axis and had dimensions of *ca.* 0.3 × 0.7 × 0.3 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least squares treatment of $\sin^2\theta$ values for 24 reflections measured on a diffractometer with CuK_α radiation. Crystal data are:

$C_{10}H_{14}BNO_2$ f.w. = 191.0

Monoclinic, $a = 8.4977(4)$, $b = 9.0617(5)$, $c = 7.0105(3)$ Å, $\beta = 111.627(3)°$, $V = 501.83(4)$ Å^3, $\rho_m = 1.266$ (flotation in aqueous KI), $Z = 2$, $\rho_c = 1.2642(1)$ g cm^{-3}, $F(000) = 204$ (23 °C; CuK_α, $\lambda = 1.5418$ Å, $\mu = 7.0$ cm^{-1}). Absent reflections: $0k0$, $k \neq 2n$, space group $P2_1$ (C_2^2, No. 4).

Intensities were measured on a Datex-automated General Electric XRD 6 diffractometer, with a scintillation counter, CuK_α (nickel filter and pulse height analyzer), and a θ–2θ scan at 2° min^{-1} over a range of $(1.80 + 0.86 \tan\theta)°$ in 2θ, with 10 s background counts being measured at each end of the scan. Data were measured to $2\theta = 145°$ (minimum interplanar spacing 0.81 Å). The r.m.s. deviation of the intensity of the check reflection, measured every 40 reflections throughout the data collection, from its mean value was 0.9%. The final intensity was 1.012 times the initial value. Lorentz and polarization corrections and check reflection scaling were applied, and the structure amplitudes were derived. No absorption correction was made in view of the low value of μ. Of the 1062 independent reflections measured, 84 had intensities less than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time-averaged background count. These reflections were given zero weight in the refinement but were included in the structure factor calculations.

Structure Analysis

The systematic absences allow space groups $P2_1$ or $P2_1/m$. The noncentrosymmetric space group $P2_1$ was indicated by the E statistics. The structure was solved by direct methods, 189 reflections with normalized structure factor $|E| \geq 1.35$ being used in the symbolic addition procedure for noncentrosymmetric crystals (8). The phases of the 5 0 −5, 8 0 −1, and 8 1 −2 reflections were fixed to define the origin. During a manual expansion carried out among those 56 reflections with $|E| \geq 1.85$, symbol phases were assigned to the 2 9 −2, 4 7 −2, 3 9 −2, and 7 0 −8 reflections and the phase of 6 0 2 was strongly indicated to be 500 mc. These eight planes comprise the basic set of reflections given in Table 1.

8	1	−2	2.10	0 } origin determining
6	0	2	2.06	500 fixed
2	9	−2	2.62	*e*
4	7	−2	2.72	*a*
3	9	−2	2.40	*b*
7	0	−8	2.76	*c*

The phase of the 2 9 −2 reflection was indicated to be ±250 mc. The enantiomorph was set by allowing this symbol phase (*e*) to have only one starting value of +250 mc, thus constraining the phase of this reflection to lie between 0 and 500 mc. The basic set of reflections was split into eight starting sets by allowing symbols *a*, *b*, and *c* two starting values each. These eight starting sets were used as input to a computer program which determines phases using the tangent formula (9–10). The values of overall *t*, overall α, Q, and Rk on the final cycle for each set of phases are given in Table 2.

An *E*-map calculated from set 6, which had the lowest value of Rk and greatest number of phases determined, clearly gave the structure, the 14 highest peaks accounting for the 14 nonhydrogen atoms. Two cycles of full-matrix least squares refinement of the positional and isotropic thermal parameters of the nonhydrogen atoms gave R 0.17. The y coordinate of O(1) was fixed to define the origin. Four cycles of anisotropic refinement reduced R to 0.075 and a difference map revealed the positions of the hydrogen atoms. The entire structure (H atoms with isotropic thermal parameters) was refined for six cycles giving a final R of 0.040 for 967 reflections with $I \geq 3\sigma(I)$ (11 reflections which had $|F_o - F_c| > 3\sigma(F)$ were removed from the data set in the final stages of refinement).

The least squares refinement was based on the minimization of $\Sigma w[|F_o| - |F_c/(1 + qI)|]^2$ where q is the extinction parameter and I the uncorrected intensity. The final value of q was 9.00×10^{-7} e^{-2}. The scattering factors of ref. 11 were used for the nonhydrogen atoms and those of ref. 12 for the hydrogen atoms. Anomalous scattering factors from ref. 13 were used for the nonhydrogen atoms. The anisotropic thermal parameters employed in the refinement are U_{ij} in the expression

$$f = f^0 \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c^*)]$$

where f^0 is the tabulated scattering factor and f is that corrected for thermal motion. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

The absolute configuration of the molecule (for the particular crystal used) has been determined through the anomalous scattering of the nonhydrogen atoms. Enantiomorph A is represented by the coordinates in

TABLE 3. Results of Hamilton's test

Parameter compared	Enantiomorph A	Enantiomorph B	B/A	Significance level*
Conventional $R \times 100$ (3σ data)	4.069	4.077	1.0020	>90
Conventional $R \times 100$ (all F)	4.363	4.372	1.0019	>90
Weighted† $R \times 100$ (3σ data)	5.327	5.343	1.0029	>95
Weighted $R \times 100$ (all F)	5.492	5.507	1.0027	>95

*This is the % probability that enantiomorph A is the correct absolute configuration.
†Weighted $R = \Sigma w(|F_o| - |F_c|)^2 / \Sigma w|F_o|^2$.

Table 4 referred to a right-handed axial system and enantiomorph B, the mirror image of A, was generated by changing the y coordinates of A to $1 - y$. Both enantiomorphs were refined and Hamilton's test (14) applied to the resulting R factor ratios. The results of this test, compiled in Table 3, strongly indicate that enantiomorph A is the correct one (the R values in Table 3 are not from the final cycle of refinement).

On the final cycle of refinement the largest parameter shift was 0.09σ. The mean error in an observation of unit weight was 1.44. A final difference map showed maximum fluctuations of ± 0.2 e Å^{-3}. The final positional and thermal parameters appear in Tables 4 and 5 respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

Thermal Motion and Correction of Molecular Geometry

The ellipsoids of thermal motion for the nonhydrogen atoms are shown in Fig. 1. The thermal motion has been analyzed in terms of the rigid-body modes of translation (T), libration (L), and screw (S) motion (15) using the computer program MGTLS. The r.m.s. standard deviation in the temperature factors U_{ij} is 0.0013 Å^2 indicating that the molecule as a whole (r.m.s. $\Delta U_{ij} = 0.0044$ Å^2) is not a good

[1]The structure factor table is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

rigid body. Examination of the individual ΔU_{ij} revealed considerable independent motion of the oxygen atoms. Two different 7-atom groups: C(5)–C(10) and B (r.m.s. $\Delta U_{ij} = 0.0019$ Å^2); and C(1)–C(5), N, and B (r.m.s. $\Delta U_{ij} = 0.0024$ Å^2) were adequately described by the rigid body thermal parameters given in Table 6.

The appropriate bond distances and angles have been corrected for libration (16, 17), using shape parameters q^2 of 0.08 for all atoms involved. Both corrected and uncorrected bond

lengths appear in Table 7. The changes in the bond angles were insignificant, thus only the uncorrected values are given in Table 8.

Results and Discussion

Figure 1 shows a general view of the molecule and the crystallographic numbering scheme. Figure 2 shows the packing arrangement viewed down c^*. Intraannular dihedral angles defining the conformations of the fused five-membered rings are listed in Table 9 and the weighted least squares mean plane in Table 10. Nonbonded inter- and intramolecular distances and details of the hydrogen bonding scheme appear in Table 11.

The crystal structure consists of discrete molecules of *B*-phenyl-*diptych*oroxazolidine, each linked to two others by N—H. . .O hydrogen bonds (N. . .O = 2.914(3) Å) to form continuous spirals about a 2_1 axis along *b*. The O. . .N distance is between the values of 2.874(2) and 2.941(3) Å for similar hydrogen bonds in **2***a* and **2***b* respectively. Aside from the hydrogen bond, there is only one intermolecular distance which is significantly shorter than the sum of van der Waals radii, C(6). . .H(3*a*), 2.60(4) Å. All other intermolecular contacts, the shortest of which are listed in Table 11, correspond to normal van der Waals interactions.

The conformations of the two five-membered rings are significantly different as shown in Table 9. This is due in part to intermolecular steric forces of which the O(1). . .H(N)—N hydrogen bond and the C(6). . .H(3*a*) contact

(*b*) Bonds involving hydrogen atoms

Bond	Distance	Bond	Distance
N—H(N)	0.87(5)	C(4)—H(4*a*)	1.02(4)
C(1)—H(1*a*)	0.97(5)	C(4)—H(4*b*)	0.94(4)
C(1)—H(1*b*)	0.96(5)	C(6)—H(6)	0.99(4)
C(2)—H(2*a*)	0.91(5)	C(7)—H(7)	1.03(5)
C(2)—H(2*b*)	1.01(4)	C(8)—H(8)	0.98(5)
C(3)—H(3*a*)	1.03(4)	C(9)—H(9)	0.92(5)
C(3)—H(3*b*)	1.00(4)	C(10)—H(10)	0.96(4)

*These bonds have been corrected for independent motion as well as libration.

are most important. The observed dihedral angles in the rings are in good agreement with those obtained for free cyclopentanes from energy minimization calculations (18) for $\omega_1 = 20.0°$ (B—O(1)—C(1)—C(2)—N) and $\omega_1 = -35.0°$ (B—O(2)—C(3)—C(4)—N), also shown in Table 9. The observed magnitudes of the dihedral angles are larger than the calculated values since the mean valence angles in the rings, 105.3° for the O(1) ring and 105.4° for the O(2) ring, are slightly greater than the calculated value of 104.2° (18). Bond angles in the five-membered rings range from 101.0(2)° for O(1)—B—N to 111.4(2)° for B—O(2)—C(3).

The C—N, C—O, and C—C distances in the fused five-membered rings do not differ significantly from corresponding bonds in the other boroxazolidines **1**, **2***a*, and **2***b* (1–3). As in **2***a* and **2***b*, the C—C distances (C(1)—C(2), 1.514(4), and C(3)—C(4), 1.524(4) Å) are significantly shorter than the value of 1.537 Å expected for a $C(sp^3)$—$C(sp^3)$ single bond while the C—N distances (C(2)—N, 1.485(3), and C(4)—N, 1.486(3) Å) correspond to normal $C(sp^3)$—$N(sp^3)$ single bonds. The two B—O bonds, B—O(1), 1.474(3), and B—O(2), 1.460(3) Å, are significantly different. This difference appears to be due to the fact that O(1) is involved in the N—H. . .O hydrogen bond while O(2) is not. The B—O(1) distance compares well with the B—O distances of 1.484(3) Å in **2***a* and 1.471(4) in **2***b* which both involve hydrogen-bonded O atoms. The B—O distances in this compound, as well as in **2***a* and **2***b*, are somewhat longer than in **1**, where all three B—O distances were found to be 1.43(1) Å. The B—N bond, 1.666(3) Å, is similar to the values of 1.647(9) for **1**, 1.653(3) for **2***a*, and 1.652(4) Å for **2***b*.

The phenyl ring is planar within experimental error (see Table 10). None of the phenyl hydrogen atoms is significantly displaced from the mean plane but the B atom is displaced by a small, but significant 0.07 Å (23σ) from the phenyl ring mean plane. Small, but significant, displacements of the B atom from phenyl mean planes were also noted in the structures of **2***a* and **2***b*. This deviation represents a folding of the phenyl group away from the B—N bond and, as can be seen in Fig. 2, probably results from intermolecular steric effects. The phenyl ring is oriented such that it is slightly twisted about the B—C(5) bond with respect to the two O atoms, the dihedral angles are: O(1)[B—

C(5)]C(6), 18.9°, and O(2)[B—C(5)]C(10), −33.2(3)°.

The C—C bond lengths in the phenyl ring range from 1.379–1.400 Å with a mean value of 1.392 Å. The difference between the extreme values is significant. The bond distances in the ring decrease as they are removed from the boron substituent, an effect noted also for the phenyl rings of compounds **2***a* and **2***b* where it is slightly more pronounced. The mean values for the three groups are 1.399, 1.396, and 1.382 Å corresponding to values of 1.403, 1.394, and 1.380 for **2***a* and 1.403, 1.391, and 1.378 Å for **2***b*. The B—C bond length of 1.613(3) Å is similar to the mean values of 1.616 and 1.621 Å for **2***a* and **2***b* but shorter than the values of 1.631–1.648(8) Å in the tetraphenylborate anion (19).

The angles in the phenyl ring range from 116.6(2) to 122.0(3)°, showing some significant deviations from 120°. The angle at C(5), carrying the boron substituent, is 116.6(2)° and the other angles (mean values are given for equivalent pairs) are 121.9, 120.2, and 119.5° for atoms *ortho*, *meta*, and *para* to C(5). A similar variation is noted for the unsubstituted phenyl groups of **2***a* where the corresponding angles have mean values of 115.9, 122.3, 120.0, and 119.7°. The small angle at C(5) indicates that the B substituent is electron releasing (20), which would result in a small residual negative charge on the aromatic π system.

The mean C—H, mean C(ar)—H, and N—H bond lengths of 0.98(4), 0.98(4), and 0.87(5) Å are as expected for X-ray data. The bond angles involving the hydrogen atoms (Table 8) are generally as expected. There is one angle, C(3)—C(4)—H(4*b*), 120(3)°, which is significantly different from the expected value. This probably results from intramolecular steric interactions, the nonbonded contacts C(2). . .H-(4*b*), H(N). . .H(4*b*), and H(2*b*). . .H(4*b*) are all less than the sum of van der Waals radii.

We would like to thank Dr. A. Storr for preparing the sample, the National Research Council of Canada for financial support, and the University of British Columbia Computing Centre for assistance.

Homogeneous Catalysis of Hydrogen Isotope Exchange between D_2 and Ethanol by Dichlorotris(triphenylphosphine) Ruthenium(II)[1]

GRAEME STRATHDEE AND RUSSELL GIVEN

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba R0E 1L0

Received November 22, 1974

GRAEME STRATHDEE and RUSSELL GIVEN. Can. J. Chem. **53**, 1442 (1975).

Rates of D_2–ethanol exchange catalyzed by solutions of dichlorotris(triphenylphosphine) ruthenium(II) in 1:1 benzene–ethanol are reported as a function of the concentrations of ruthenium, deuterium, triphenylphosphine, and HCl. The rates were extremely fast, and approached 10^{-3} mol D_2 l^{-1} s^{-1} at 333 K with 1.3 mmol/l Ru. Over the temperature range 263 to 303 K, the apparent activation energy was 85 kJ/mol. The kinetics have been interpreted in terms of a mechanism in which activation of D_2 by $RuCl_2L_3$ is rate-controlling. A comparison is made between the characteristics of this homogeneous catalyst and those of the related $RhClL_3$.

GRAEME STRATHDEE et RUSSELL GIVEN. Can. J. Chem. **53**, 1442 (1975).

On rapporte les vitesses de l'échange D_2–éthanol catalysé par des solutions de dichlorotris-(triphénylphosphine) ruthenium(II) dans des solutions 1:1 benzène–éthanol; ces vitesses ont été déterminées en fonction des concentrations de ruthenium, de deuterium, de triphénylphosphine et de HCl. Les vitesses sont extrêmement rapides et s'approchent de 10^{-3} mol D_2 l^{-1} s^{-1} à 333 K avec 1.3 mmol/l Ru. Entre les températures de 263 et 303 K, l'énergie d'activation apparente est de 85 kJ/mol. On a interprété la cinétique en terme d'un mécanisme dans lequel l'activation du D_2 par $RuCl_2L_3$ est déterminante pour la vitesse de la réaction. On fait une comparaison entre les caractéristiques de ce catalyseur homogène et celles du composé similaire $RhClL_3$. [Traduit par le journal]

Introduction

Dichlorotris(triphenylphosphine)ruthenium-(II) is a highly effective homogeneous catalyst for the hydrogenation of olefins and acetylenes in ethanol–benzene solution (1). Catalytic activity has been attributed to the formation of the monohydride, $RuHClL_3$ (L = triphenylphosphine)

[1] $$RuCl_2L_3 + H_2 \rightleftarrows RuHClL_3 + HCl$$

followed by olefin insertion into the Ru—H bond (2, 3). James has reviewed this topic in detail (4).

Because the component reactions of equilibrium 1 are fast (2), $RuCl_2L_3$ was of interest to us as a catalyst for D_2 – protic solvent exchange, with potential applicability in processes for the enrichment of deuterium. Since each cleavage of D_2 by $RuCl_2L_3$ would lead to exchange, this complex was potentially more effective than, say, $RhClL_3$ in benzene–ethanol where the slow deuterium transfer to the solvent was preceded by oxidative addition of D_2 to $RhClL_3$ (5).

In this work, we have studied the kinetics of D_2–ethanol exchange catalyzed by $RuCl_2L_3$ in 1:1 benzene–ethanol solution. A mechanism is proposed in which $RuCl_2L_3$ is the active catalyst species. A comparison has been made with the function of the closely related rhodium catalyst $RhClL_3$.

Experimental

The $RuCl_2L_3$ was purchased from Strem Chemicals and used as received.

Anal. Calcd. for $C_{54}H_{45}P_3RuCl_2$: C, 67.6; H, 4.7; P, 9.7; Ru, 10.5; Cl, 7.4. Found: C, 67.6; H, 4.7; P, 9.7; Ru, 9.1; Cl, 8.3.

Benzene and ethanol were each percolated through beds of activated Linde 4A molecular sieves to remove water. Each was distilled in a stream of flowing nitrogen, flushed with N_2 for at least 0.5 h, and stored in an N_2-purged glove box (typically 20 p.p.m. O_2). The N_2-saturated solvents were transferred by syringe to the reaction flask.

The deuterium gas (Matheson) was purified as previously described (6). Other reagents were used as received. The absence of triphenylphosphine oxide in the triphenylphosphine (Alpha Inorganics) was confirmed by infrared and n.m.r. spectrometric analyses.

Hydrogen isotope exchange reactions were conducted in a 93 ml glass gas–liquid contactor with efficient mag-

netic stirring as previously outlined (5). Initial D_2 exchange rates were calculated with the relation

$$[2] \qquad -d[D_2]/dt = \ln [(n_0 - n_e)/(n_t - n_e)]A/t$$

where n_0, n_t, and n_e were the mol% D_2 in the gas phase at $t = 0$ and $t = t$ s, and at equilibrium, and A was the gas:liquid mole ratio given by A = initial D_2 (mol) ÷ solution volume (l). Plots of log D_2 against t were linear over several half-lives.

Since the D_2 exchange reaction rates were relatively rapid, about 10^{-4} mol l^{-1} s^{-1}, it was necessary to demonstrate that rate measurements were not D_2-mass-transfer-limited. In our 93 ml capacity reaction cell, the D_2 exchange rates were independent of stirring speed above about 1000 r.p.m. for D_2 = 2.73 mmol/l, Ru = 1.3 mmol/l in 20 ml solution. The catalyst solution was generally stirred at 3000 r.p.m. to generate the gas–liquid dispersion.

The effect of additives on the D_2 exchange rate was determined after injection of gaseous reagents by syringe, or by dissolution of the solids and addition as solutions in the ethanol. In some experiments, the reference D_2 exchange rate was followed for two half-lives before the additive was introduced.

Hydrogen solubility in 1:1 benzene–ethanol was measured with a precision of ±2% at 273, 298, and 323 K by a modified gas stripping technique (7). Within this temperature range, the solubility of H_2 (at 101 kPa) is given by

$$[3] \quad [H_2] = 2.42 \times 10^{-3} \exp\left[\frac{2.22}{R}\left(\frac{1}{T} - \frac{1}{273}\right)\right]$$

where R = gas constant (kJ/mol), T = temperature, K.

The dependence of [HCl] on $[H_2]$ and [Ru] was determined with the cell shown in Fig. 1. The glass–AgCl/Ag electrode couple was used to detect and measure the concentration of HCl by use of the calibration curve

$$[4] \qquad [HCl] = \exp 0.0428 \text{ [e.m.f. (mV)} - 604.5]$$

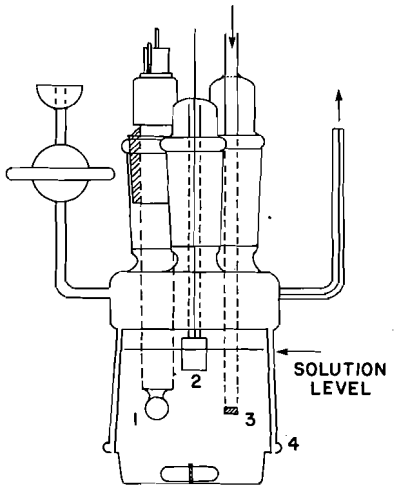

FIG. 1. Apparatus for measurement of HCl released as a function of H_2 pressure: 1, glass electrode; 2, AgCl/Ag electrode; 3, porous glass sparger; 4, T/S 60/50.

obtained by separate experiments with HCl solutions in 1:1 benzene–ethanol. Hydrogen, or an H_2–N_2 mixture, was presaturated with solvent vapor and was slowly bubbled through the cell until no further increase in cell e.m.f. was noted. Purging the vessel with N_2 reversed the reaction, and [HCl] became negligible. Other experiments showed that dissolved HCl was not stripped from solution by the gas stream.

Results

A set of data from a typical experiment are shown in Fig. 2. The overall isotope exchange reactions

$$[5] \qquad D_2 + C_2H_5OH \rightarrow HD + C_2H_5OD$$

$$[6] \qquad HD + C_2H_5OH \rightarrow H_2 + C_2H_5OD$$

commenced with the injection of the ethanol. No significant induction period occurred with solutions of $RuCl_2L_3$ alone. However, if excess triphenylphosphine, L, was initially added to the system, or if the temperature was below about 293 K, a slow increase to a limiting reaction rate was observed. In these cases, the final slopes of plots of log D_2 *vs.* t were used to calculate initial rates.

First-order decay plots for D_2 and HD were usually linear over several half-lives. From the data in Fig. 2, the apparent isotope effect $2k_{HD}/k_{D_2}$ = 1.13 was calculated, both from the maximum mol% HD and directly from the ob-

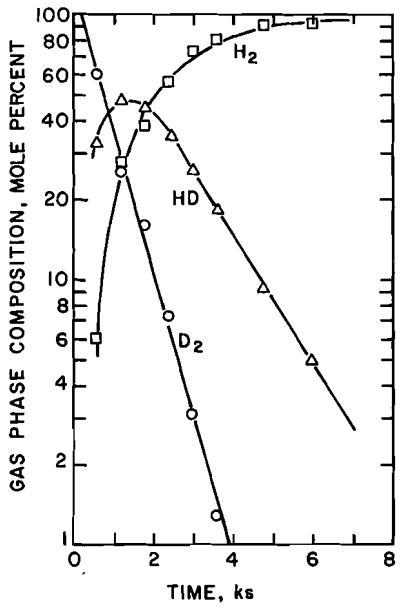

FIG. 2. Data for a typical exchange reaction. [Ru], 1.3 mmol/l; $[D_2]_0$, 2.7 mmol/l; T, 298 K.

served rates of disappearance of HD and D_2 (5). Experimental half-lives were typically 600 s in our reaction cell, but were as short as 60 s at the highest Ru concentrations. In runs with low partial pressures of D_2, care was taken to add sufficient N_2 to avoid admission of O_2 to the cell.

The Effect of D_2 and Ru Concentration on Initial Exchange Rates

Figure 3 shows the effect of D_2 concentrations between 0.4 to 2.90 mmol/l (D_2 partial pressures from 13 to 93 kPa) and ruthenium concentrations from 0.52 to 5.2 mmol/l on initial D_2 exchange rates in 1:1 (by volume) benzene–ethanol.

The form of these data is similar to that obtained for olefin hydrogenation reactions catalyzed by $RuCl_2L_3$ (3). The maximum rate for each $[Ru]_0$ may be calculated from the intercepts of plots of (Rate of D_2 exchange)$^{-1}$ *vs.* $[D_2]_0{}^{-1}$. The slopes and intercepts for the best straight lines through the data plotted in this way are listed in Table 1.

The experimental half-life for the D_2 exchange reaction was short (less than 100 s) at high [Ru]. Because D_2 uptake by $RuCl_2L_3$ occurred during a significant portion of this interval, we consider our measurements of these fast exchange rates to be somewhat low. This conclusion is supported by the fact that lines through plots of (D_2 exchange rate)$^{-1}$ *vs.* $[Ru]_0{}^{-1}$ were found to intercept the ordinate at positive values instead of at the origin.

TABLE 1. Parameters for best straight lines through $[Ru]_0$/Rate *vs.* $1/[D_2]$ data

$[Ru]_0$ (mmol/l)	Slope ($\times 10^3$) (mol s l^{-1})	Intercept (s)
1.3	7.77	5.09
2.5	7.35	5.18
4.0	12.2	3.71
5.6	16.9	2.09

Errors on experimental rates were estimated to be $\pm 5\%$, except at the highest [Ru] when the errors may have been $\pm 15\%$. There was no exchange of D_2 in blank experiments in which $RuCl_2L_3$ was omitted. Also, neither $RuCl_3 \cdot xH_2O$, nor 1% Al_2O_3-supported Ru metal, catalyzed D_2 exchange under our conditions. Therefore, there was no residual reaction rate due to the presence of these potential trace contaminants.

Temperature Dependence

The effect of temperature on the rate of D_2 exchange was determined between 263 and 333 K. These data are plotted in Fig. 4 as 1/rate *vs.* $1/T$. Pronounced curvature is evident below 3.3×10^{-3} K^{-1} (above 30°C). Since the temperature-dependence of the solubility of H_2 in 1:1

benzene–ethanol was slight between 273 and 323 K, Fig. 4 reflects the variation in the equilibrium distribution of catalytically active Ru species, and the influence of the D_2-mass-transport on the exchange rate.

From the slope of the best straight line through the data in Fig. 4 between 263 and 303 K, an apparent activation energy, E_a, for the D_2 exchange reaction was calculated to be 85 kJ mol^{-1}.

At lower reaction temperatures, longer times were required to approach the maximum limiting values reported in Fig. 4. For example at 273 K ($[D_2]_0$ = 2.52 mmol/l, [Ru] = 1.3 mmol/l), no change in the gas phase composition was observed during the first 1.8 ks of contact. This effect arose because the active catalyst species required more time to equilibrate at these temperatures, and was probably an indication that the initial rate of D_2 activation was slow. In this case, the catalyst solution required about 1 ks to change from the brown color characteristic of $RuCl_2L_3$ in benzene to the red-violet of $RuHClL_3$ in H_2-saturated benzene–ethanol. At 303 K, the color change occurred within a few seconds.

Effects of Additives

These experiments were conducted under the standard conditions: temperature, 298 K; $[D_2]_0$ = 2.74 mmol/l; [Ru] = 1.3 mmol/l.

Triphenylphosphine

Addition of L increased the final rate of D_2 exchange as shown in Fig. 5. However, L initially inhibited the reaction. For example with a 10:1 excess of L:Ru, the exchange rate accelerated for about 2 ks before the maximum rate was established. This phenomenon is illustrated in Fig. 6.

If this behavior is related to the L ligand dissociation equilibrium reported by James and Markham (8)

[7] $$RuCl_2L_3 \rightleftarrows RuCl_2L_2 + L$$

and if the rate constant for the activation of D_2 for exchange is greater for $RuCl_2L_3$ than for $RuCl_2L_2$, then addition of L would be expected to increase the final rate as shown in Fig. 5. The initial inhibition of D_2 exchange by excess L cannot be explained in a similar way, since one would predict from reaction 7 that excess L would always enhance the rate of D_2 exchange. This topic is discussed further in the section on reaction mechanism.

Anhydrous HCl and Chloride Ion

The rate of exchange was enhanced by addition of anhydrous HCl. This effect was slightly greater than with L. The data are also included in Fig. 5.

If the rate determining step in the overall D_2 exchange reaction was the cleavage of D_2 by

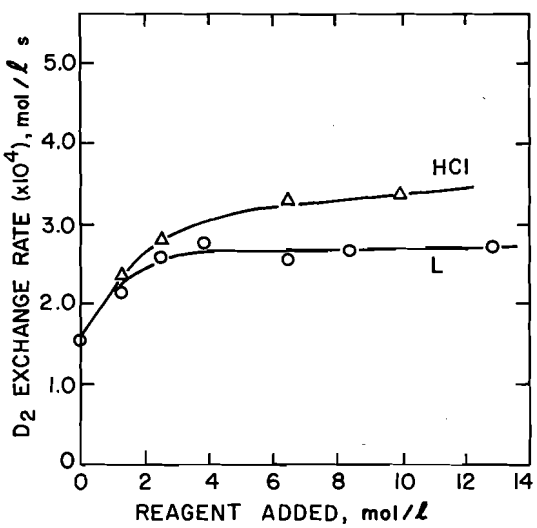

FIG. 5. The effect of excess L and HCl on the rate of D_2 exchange.

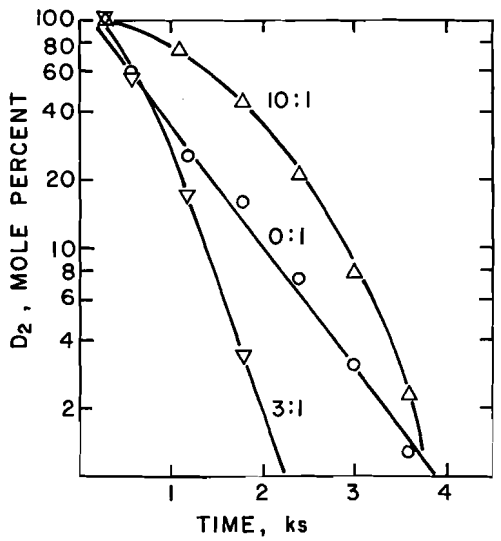

FIG. 6. The characteristic initial inhibition of D_2 exchange by excess L, as a function of the L:Ru ratio.

$RuCl_2L_3$ (3)

[8] $RuCl_2L_3 + D_2 \rightleftarrows RuDClL_3 + DCl$

then the exchange rate would have been expected to increase as equilibrium 8 was shifted to the left by excess HCl. Chloride ion, added as LiCl, had no effect on the rate of exchange, but this may have been due to a low activity of Cl^- because of ion-pair dimer formation (9) to yield Li_2Cl_2 in 1:1 benzene–ethanol. If Cl^- was added as $(CH_3)_4NCl$, a slight increase in the D_2 exchange rate was observed in agreement with the results for HCl.

If Cl^- dissociation occurred from Ru-containing species in solution, the effect of added Cl^- would be less than expected. A 10:1 excess of LiBr had no effect on the D_2 exchange rate, although the catalyst solution was maroon rather than the normal red-violet. Some halide exchange likely occurred with the active catalyst. The extent of Cl^- dissociation from either $RuCl_2L_3$ or $RuHClL_3$ has not been found to be great (8, 10).

When a 75:1 excess of HCl was added to the Ru catalyst, the solution turned bright yellow. Both the absorption maxima at 360 and 520 nm, characteristic of $RuCl_2L_3$ solutions containing $RuHClL_3$, were absent under these conditions although D_2 exchange remained fast. This indicated that the distribution of catalytically active species differs in strongly acidic media. The monohydride, $RuHClL_3$ is known to be unstable in the presence of excess HCl (11).

Bases

Ammonia, methylamines, and LiOH all inhibited the D_2-exchange reaction. A 4-fold excess of each base (:Ru) reduced the rate by two orders of magnitude under the usual conditions. Undoubtedly, neutralization of the DCl produced by reaction 8 drove the equilibrium to the right thereby lowering the concentration of catalytically active $RuCl_2L_3$. This result was expected, since the monohydride has been synthesized in nonbasic aprotic solvents by a related procedure (3).

Oxygen

If added O_2 exceeded 10 O_2:1Ru the D_2 exchange reaction ceased. Less O_2 reduced the rate for a short period (300 s) after which it returned to the original value. The capability of these solutions to recover from the effect of admission of small amounts of O_2 is highly desirable from the practical point of view, and is undoubtedly related to the activity of $RuCl_2L_3$ for the $2H_2 + O_2$ recombination reaction reported by Vaska and Tadros (12). Oxidation of L either to triphenylphosphine oxide (13), or to Ru-containing species, presumably occurs at higher O_2 concentrations at which the rate of activation of O_2 by the complexes must exceed the rate of H_2 cleavage. Retention of catalytic activity by $RuCl_2L_3$ in the presence of O_2 is not novel, since Lyons has observed isomerization of olefins under such conditions (14).

Carbon Monoxide

The Ru catalyst was immediately and irreversibly poisoned for D_2 exchange by CO. A stable Ru–carbonyl complex was likely formed. Stephenson and co-worker have discussed these reactions (15).

The Hydrogen-uptake Equilibrium

The electrochemical cell:

[9] Glass | HCl (1:1 C_6H_6–C_2H_5OH) | AgCl, Ag

was employed to measure HCl released upon cleavage of H_2 by the overall reaction 1. Because the slope of the calibration curve (cell e.m.f. *vs.* log [HCl]) was low (*cf.* eq. 4) small errors in the measurement of e.m.f. resulted in large errors in the interpolated values of [HCl]. For example, at 1 mmol/l the error was estimated to be 5%/mV. Our data are shown in Fig. 7 for [HCl] as a function of [Ru] and equilibrium [H_2]. Even at 100 kPa partial pressure of H_2, the conversion of $RuCl_2L_3$ to $RuHClL_3$ was only partially complete.

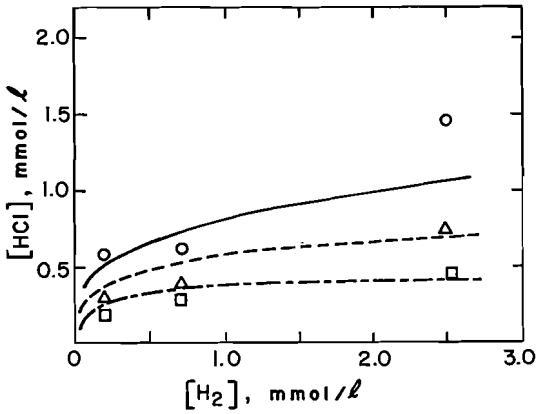

FIG. 7. The dependence of the equilibrium concentration of HCl on the concentrations of H_2 and total Ru. [Ru], mmol/l: □, 0.49; △, 0.98; ○, 2.0.

Discussion

Species in Solution

Many previous studies of the catalytic activity of solutions of $RuCl_2L_3$ have been directed towards understanding the mechanisms of hydrogenation of unsaturated organics, particularly terminal olefins and acetylenes. The hydrogen activation step itself, reaction 1, has not been studied in detail. Since James and Markham have reported that $RuCl_2L_3$ was extensively dissociated in both benzene and dimethylformamide solutions, it was of interest to determine if this complex or the species $RuCl_2L_2$ formed by reaction 7 dominated the rate law.

The major species present in hydrogenated solutions of $RuCl_2L_3$ are known to be $RuCl_2L_3$, $RuCl_2L_2$, $RuHClL_3$, and $RuHClL_2$ (3, 4, 10, 16). The deuterium exchange rates discussed above were generally measured under conditions at which the concentrations of these species had reached equilibrium. These rates could therefore be used as a direct measure of the concentration of species which activated D_2 or HD and promoted D-transfer to the protic solvent. A deuteron (as DCl) is released in the cleavage of the D_2 molecule by $RuCl_2L_3$ (*cf.* reaction 8), and the rate of D^+ transfer to the ethanol hydroxyl pool is effectively instantaneous (17) and irreversible

[10] $\quad DCl + C_2H_5OH \rightarrow C_2H_5OD + HCl$

Thus each D_2-activation event resulted in detectable exchange. Only $RuCl_2L_3$ and $RuCl_2L_2$ may cleave D_2 and promote D-transfer to the protic solvent. In a separate study (11) we have discussed the kinetics and mechanism of H_2–D_2 exchange catalyzed by $RuHClL_3$. The monohydride does not promote D_2–C_2H_5OH exchange at a significant rate. For example, at $[RuHClL_3] = 1.1$ mmol/l, $[D_2] = 2.7$ mmol/l, and 298 K the exchange rate was only 4 μmol D_2 l^{-1} s^{-1}, about a factor of 35 lower than with $RuCl_2L_3$.

Reaction Mechanism

The reaction scheme summarized in Table 2 may be used to explain the kinetics of the exchange reaction at low degrees of D_2 conversion. Equilibria involving HD and H_2 have been omitted. If it is assumed that the rate law has the following form (note that the labelling system of Table 2 has been used)

TABLE 2. Mechanism of D_2–ethanol exchange catalyzed by $RuCl_2L_3$ (L = triphenylphosphine)

[7]	$RuCl_2L_3$	$\overset{K_7}{\rightleftarrows}$	$RuCl_2L_2 + L$
[8]	$RuCl_2L_3 + D_2$	$\overset{k_8}{\rightarrow}$	$RuDClL_3 + DCl$
[11]	$RuCl_2L_2 + D_2$	$\overset{k_{11}}{\rightarrow}$	$RuDClL_2 + DCl$
[10]	$DCl + C_2H_5OH$	$\overset{k_{10}}{\rightarrow}$ fast	$HCl + C_2H_5OD$
[−8]	$RuDClL_3 + HCl$	$\overset{k_{-8}}{\rightarrow}$	$RuCl_2L_3 + HD$
[−11]	$RuDClL_2 + HCl$	$\overset{k_{-11}}{\rightarrow}$	$RuCl_2L_2 + HD$
[12]	$RuDClL_3$	$\overset{K_{12}}{\rightleftarrows}$	$RuDClL_2 + L$

$$[13] \quad -d[D_2]/dt = (k_8[RuCl_2L_3] + k_{11}[RuCl_2L_2])[D_2]$$

Then from the mass balance expression for total ruthenium

$$[14] \quad [Ru]_0 = [RuCl_2L_3] + [RuCl_2L_2] + [RuDClL_3] + [RuDClL_2]$$

the following may be derived

$$[15] \quad -d[D_2]/dt = \frac{(k_8 + k_{11}K_7/[L])[Ru]_0[D_2]}{1 + \frac{K_7}{[L]} + \frac{K_8[D_2]_0}{[HCl]} + \frac{K_8K_{12}[D_2]_0}{[L][HCl]}}$$

Addition of excess $[L]:[Ru]_0$ has been shown to increase the exchange rate, therefore $k_8 > k_{11}K_7/[L]$. If the rate law 15 is then dominated by the term

$$[16] \quad -d[D_2]/dt = k_8[RuCl_2L_3][D_2]$$

expression 13 becomes approximately

$$[17] \quad -d[D_2]/dt = \frac{k_8[Ru]_0[D_2]}{1 + \frac{K_7}{[L]} + \frac{K_8[D_2]_0}{[HCl]} + \frac{K_8K_{12}[D_2]_0}{[L][HCl]}}$$

Qualitatively, eq. 17 predicts that the D_2 exchange rate will increase with both added L and HCl, as observed.

Values for the rate constant k_8 and equilibrium constant K_7 may be calculated in the following way. By use of the data in Fig. 7, the sum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$[RuCl_2L_3] + [RuCl_2L_2]$ is given by $[Ru]_0 - [HCl]$ at a fixed $[H_2]$ (or $[D_2]$). Since the slopes of plots of $[Ru]_0$/Rate *vs.* $1/[D_2]$ (*cf.* Table 1) yield values for $(1 + K_7/[L])/k_8$, two equations in K_7 and k_8, for example at $[Ru]_0 = 1.3$ and 2.5 mmol/l, may be solved simultaneously to yield $K_7 = 1.3 \times 10^{-4}$ mol/l and $k_8 = 210$ l mol^{-1} s^{-1}.

The intercepts of those plots at $1/[D_2] = 0$ correspond to $(K_8/[HCl] + K_8K_{12}/[L][HCl])/k_8$. By assuming that dissociation of L from $RuHClL_3$ is slight, *i.e.* $K_{12} \doteq 0$, then $[Ru]_0$/Rate $= K_8/k_8[HCl]$. At that limiting condition of high $[D_2]$, $[HCl] \doteq [Ru]_0$, therefore Rate $= k_8[Ru]_0^2/K_8$. A plot of the limiting rates at $1/[D_2] = 0$ against $[Ru]_0^2$ gives a straight line of slope $k_8/K_8 = 80$ l mol^{-1} s^{-1}. Constant K_8 is therefore calculated to be 2.6.

The low value of K_7 suggests that the dissociation of L from $RuCl_2L_3$ in 1:1 benzene–ethanol is not as extensive as in benzene alone or in DMF (8). However, it explains the relative insensitivity of the overall exchange reaction rate to the addition of excess L. Our evaluation of the magnitude of K_8 was determined primarily by the form of the data reported in Fig. 7, and is the first reported in the literature.

The rate constant k_8 is large, but is consistent with the efficiency with which $RuCl_2L_3$ activates molecular hydrogen (or D_2) in this solvent system. If the species $RuCl_2L_2$ is active at all, k_{11} is probably less than 10% of k_8, *i.e.* 21 l mol^{-1} s^{-1}, however, we have been unable to demonstrate this conclusively.

We have no satisfactory explanation for the initial inhibition of D_2 exchange by excess L. It was pointed out in the section Effects of Additives that experiments with excess L would always be expected to yield higher D_2 exchange rates than if no excess L was added. The slow initial exchange can be accounted for if equilibrium 18 is significant under our conditions,

[18] $$RuCl_2L_3 + L \rightleftarrows RuCl_2L_4$$

providing that the component reaction rates are slow with respect to the rate of deuterium uptake by $RuCl_2L_3$. We do not favor this possibility, since Caulton has shown by ^{31}P n.m.r. experiments that dissociation of L from $RuCl_2L_4$ to yield $RuCl_2L_3$ is essentially complete in $CHCl_3$ at 303 K (16).

Comparison of $RuCl_2L_3$ with $RhClL_3$

This study has provided evidence that $RuCl_2L_3$ cleaves molecular hydrogen at a specific rate which is greater than that for the dissociated species $RuCl_2L_2$. The thorough investigations of solutions of the isoelectronic rhodium catalyst $RhClL_3$ by Halpern and Wong (18) and by Tolman *et al.* (19) have shown that the specific rate of activation of H_2 by $RhClL_2$ was at least 10^4 greater than by $RhClL_3$. In the ruthenium system, it may be essential to have Ru(II) stabilized by three L to provide the metal with sufficient electron density to promote D—D cleavage. The complex $RuCl_2L_3$ would possess 16 metal valence shell electrons, whereas $RuCl_2L_2$ would contain only 14. Although $RhClL_3$ and $RhClL_2$ are isoelectronic with $RuCl_2L_3$ and $RuCl_2L_2$ respectively, the detailed mechanisms of D_2-cleavage are dissimilar. In the rhodium case, oxidative addition of D_2 to the Rh atom is favored presumably because Rh(I) to Rh(III) conversion is more facile in $RhClL_2$ compared to $RhClL_3$. In the ruthenium system, no overall Ru-oxidation state change is required, (*cf.* reaction 8) although the formation of $RuHClL_3$ via a seven-coordinate Ru(IV) intermediate $RuH_2Cl_2L_3$ as proposed by Harrod *et al.* (20) has not been disproven. Apparently, reduction in the coordination number of the Ru metal ion is not accompanied by enhanced reactivity towards molecular hydrogen. It follows that access of H_2 is not impeded by the stereochemical requirements of the ligands in $RuCl_2L_3$.

Applicability of $RuCl_2L_3$ to Deuterium Enrichment

This catalyst is among the most active which we have studied for the exchange of deuterium between hydrogen gas and protic solvents. It has the desirable characteristic that the rapid hydrogen activation reaction is also rate-controlling for the exchange. In contrast, when the activation of D_2 is slow, or is not rate-determining, such as with complexes of the type $RhXL_3$ or $IrX(CO)L_2$ (X = halogen, L = alkyl or arylphosphine), then optimum deuterium exchange rates cannot be realized.

Although the D_2 conversion rates with $RuCl_2L_3$ were rapid in terms of the capability of typical stirred-tank experimental reactors, an improvement in rate of approximately two orders of magnitude would be required to make

the catalyst attractive for D enrichment purposes. Since the solubility limit of this complex is low, and since the D_2 conversion rates fall off with increasing gas pressure, $RuCl_2L_3$ is unsatisfactory for this application.

The authors wish to thank their colleagues for helpful discussions, particularly M. Tomlinson and Dr. N. H. Sagert, and D. Bell and his assistants of the Analytical Science Branch for the deuterium analyses.

Thermodynamics of Mixed Electrolyte Solutions

JAMES SANGSTER AND FABIO LENZI

Département du Génie Chimique, Ecole Polytechnique, Université de Montréal, Montréal, Québec H3C 3A7

Received August 16, 1974

JAMES SANGSTER and FABIO LENZI. Can. J. Chem. **53**, 1410 (1975).

A general thermodynamic expression has been derived for the deviation Δ from Zdanovskii's rule. Conditions have been deduced under which Δ vanishes, and examples given. For nonzero values of Δ it has been shown by means of an example that Δ may be evaluated in some cases by the introduction of empirical assumptions, such as Harned's rule. The use of Zdanovskii's rule in facilitating the integration of the McKay–Perring equation has been discussed briefly.

JAMES SANGSTER et FABIO LENZI. Can. J. Chem. **53**, 1410 (1975).

Une expression générale thermodynamique a été dérivée pour la déviation Δ de la règle de Zdanovskii. Des conditions ont été déduites, avec exemples à l'appui, sous lesquelles Δ devient zéro. Pour les valeurs de Δ différentes de zéro, il a été démontré, au moyen d'un exemple, que le Δ peut être évalué dans certains cas en introduisant des suppositions empiriques, telles que la règle de Harned. L'utilité de la règle de Zdanovskii pour faciliter l'intégration de l'équation de McKay–Perring a été brièvement examinée.

Introduction

Zdanovskii (1) in 1936 proposed a simple empirical rule relating the concentrations of aqueous salt solutions under isopiestic conditions (that is, at the same water activity, a_w). Suppose that a ternary solution of electrolytes 1 and 2 at molalities m_1 and m_2 is in isopiestic equilibrium with two binary solutions at molalities m_{10} and m_{20}. The rule states that

$$[1] \qquad 1/m = y_1/m_{10} + y_2/m_{20}$$

where $m = m_1 + m_2$, $y_1 = m_1/m$, and $y_2 = m_2/m$. An alternative form of the rule may be obtained by multiplying eq. 1 by m

$$[2] \qquad 1 = m_1/m_{10} + m_2/m_{20}$$

Equation 1 is an approximation to actual behavior, and Kirgintsev and Luk'yanov (2) measured deviations from Zdanovskii's rule for a large number of electrolyte pairs. They proposed the equation

$$[3] \qquad 1/m = y_1/m_{10} + y_2/m_{20} + by_1y_2$$

where b is an empirical parameter.

Zdanovskii's rule, eq. 1 or 2, has proved to be a useful relation for estimating the water activity of multicomponent aqueous solutions up to high concentration (3), and of supersaturated single-solute solutions (4). It has also been used to simplify the integration of the McKay–Perring equation for obtaining activity coefficients in mixed electrolyte solutions (2, 5).

Until recently, no theoretical justification of this empirical rule had been attempted. In this paper we shall derive a general thermodynamic expression for the deviation from Zdanovskii's rule, and examine a number of particular cases in which it vanishes or may be calculated with the help of empirical assumptions.

General Treatment

The general condition for isopiestic equilibrium among binary and ternary aqueous electrolyte solutions is

$$[4] \qquad \nu_1 m_{10}\phi_{10} = \nu_2 m_{20}\phi_{20} = \bar{\nu} m \phi_{12}$$

where ν_1 and ν_2 are the numbers of ions per molecule of electrolytes 1 and 2 respectively, $\bar{\nu} = \nu_1 y_1 + \nu_2 y_2$, ϕ_{10} and ϕ_{20} are the osmotic coefficients of the binary solutions, and ϕ_{12} the osmotic coefficient of the ternary solution.

After a few steps, eq. 4 can be rewritten as

$$[5] \qquad 1 = m_1/m_{10} + m_2/m_{20} + \Delta$$

where Δ is the Zdanovskii deviation term, given by

$$[6] \qquad \Delta = (\bar{\nu}\phi_{12} - \nu_1 y_1 \phi_{10} - \nu_2 y_2 \phi_{20})/\bar{\nu}\phi_{12}$$

Equation 6 is an explicit expression for Δ in terms of osmotic coefficients; for the analysis of special cases later in this paper, we need Δ in terms of activity coefficients. We use the following relation (ref. 6, eq. 34-33) for ϕ_{12}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

$$[7]\quad \phi_{12} = 1 + \frac{\nu_1 y_1}{\bar{\nu} m}\int_0^m m\mathrm{d}(\ln\gamma_1) + \frac{\nu_2 y_2}{\bar{\nu} m}\int_0^m m\mathrm{d}(\ln\gamma_2)$$

and the following relation (ref. 6, eq. 23-22) for ϕ_{i0}

$$[8]\quad \phi_{i0} = 1 + \frac{1}{m_{i0}}\int_0^{m_{i0}} m_{i0}\mathrm{d}(\ln\gamma_{i0})$$

where $i = 1, 2$. In these equations γ_1 and γ_2 are activity coefficients of component electrolytes in the mixed solution, and γ_{10} and γ_{20} are activity coefficients in the isopiestic single-salt solutions.

Cases in which $\Delta = 0$

(*i*) At infinite dilution all osmotic coefficients approach unity, and it can be seen from eq. 6 that in this case Δ vanishes. Mikhailov (7) attempted to show this by assuming the Debye–Hückel limiting law expressions for the osmotic coefficients of mixed and single electrolyte solutions. He derived the equation

$$[9]\quad 1/m = y_1/m_{10} + y_2/m_{20} + Q/(-\ln a_w)^{\frac{1}{2}}$$

for solutions under isopiestic equilibrium. In this equation Q is a function of the Debye–Hückel limiting law slope, conversion factors, y, ionic charges, and valence types of the electrolytes in the mixed solution. The function Q is independent of concentration, identically zero for symmetrical mixtures, and positive and finite for unsymmetrical mixtures. Mikhailov concluded that at low concentrations Zdanovskii's rule (eq. 1) and its improved version (eq. 3) contradict the Debye–Hückel theory in the case of unsymmetrical mixtures.

This is an error in interpretation, for actually there is no contradiction. We need only throw eq. 9 into the alternative form of eq. 2. We make the substitution $-\ln a_w = 1000\bar{\nu} m\phi_{12}/M_w$, where M_w is the molar mass of water. Multiplying the resulting equation by m, we obtain

$$[10]\quad 1 = m_1/m_{10} + m_2/m_{20} + Q' m^{1/2}$$

where Q' combines terms which are independent of concentration. Thus as $m \to 0$, Δ vanishes, and eq. 2 represents the zero concentration limiting behavior of all electrolyte mixtures.

(*ii*) Although at finite concentrations osmotic coefficients may be different from unity, we found (*3a*) that there are some mixtures, symmetrical or not, which conform exactly to Zdanovskii's rule. An example is the system $NaCl–BaCl_2–H_2O$, for which representative data are given in Table 1; $\Delta = 0$ for this system within experimental uncertainty.[1] Thus for systems such as this one, we have the simple relation (from eq. 6)

$$[11]\quad \bar{\nu}\phi_{12} = \nu_1 y_1 \phi_{10} + \nu_2 y_2 \phi_{20}$$

i.e., ϕ_{12} is a linear function of composition under isopiestic conditions.

Cases in which $\Delta \neq 0$

When neither of the previous conditions (*i*) or (*ii*) holds, the integrals in eqs. 7 and 8 must be evaluated in order to obtain an expression for Δ. These require expressions for activity coefficients in mixed and single electrolyte solutions. For simplicity we will examine the case of two 1:1 electrolytes and use data for the system NaCl(1)–KCl(2)–H_2O at 25 °C as an example.

For γ_1 and γ_2 we use the Harned-type relations (ref. 6, eq. 34-27)

$$[12]\quad \log\gamma_1 = \log\gamma_{1(0)} - \alpha_{12} m_2$$

$$[13]\quad \log\gamma_2 = \log\gamma_{2(0)} - \alpha_{21} m_1$$

which are assumed to be valid for systems at constant total molality m. In these equations α_{12} and α_{21} are independent of composition at a given m, but may otherwise vary with m; $\gamma_{1(0)}$ and $\gamma_{2(0)}$ are activity coefficients of the electrolytes in their own solutions at molality m. For $\gamma_{1(0)}$ and $\gamma_{2(0)}$ we use the Guggenheim-type expressions (ref. 6, eq. 22-20)

$$[14]\quad \log\gamma_{1(0)} = -A_\gamma m^{1/2}/(1 + m^{1/2}) + B_1 m$$

$$[15]\quad \log\gamma_{2(0)} = -A_\gamma m^{1/2}/(1 + m^{1/2}) + B_2 m$$

where A_γ is the Debye–Hückel limiting slope and B_1 and B_2 are empirical parameters. If now we substitute eqs. 12–15 in eq. 7, the final result is (ref. 6, eq. 23-39)

$$[16]\quad \phi_{12} = 1 - 2.303\{A_\gamma m^{1/2}\,\sigma(m^{1/2})/3 - [\bar{B} - y_1 y_2(\alpha_{12} + \alpha_{21})]m/2\}$$

where $\bar{B} = y_1 B_1 + y_2 B_2$ and $\sigma(m^{1/2})$ is a simple function of molality (ref. 6, eq. 23-40). The expressions for ϕ_{10} and ϕ_{20} are obtained from eq. 8 and those analogous to eqs. 14 and 15. The result is

[1] If the error in the molalities measured at isopiestic equilibrium is ± 0.0005, this will cause an uncertainty of a few units in the fourth decimal place of Δ.

4.3226	3.9968	4.5514	0.0119	0.0113

*From eq. 5 and experimental data of ref. 11.

[17] $$\phi_{i0} = 1 - 2.303[A_\gamma m_{i0}^{1/2} \sigma(m_{i0}^{1/2})/3 - B_1 m_{i0}/2]$$

where $i = 1, 2$. We may now compare calculated and experimental values of Δ for the system NaCl–KCl–H_2O. This is shown in Table 2, where Δ has been calculated from eqs. 6, 16, and 17; the α's were those of Robinson (9) and the B's were taken from a standard reference (ref. 6, pp. 644–645). The experimental and predicted values of Δ agree within experimental uncertainty.[1]

Evaluation of the McKay–Perring Integral

The essential step in the McKay–Perring method (10) of calculating activity coefficients is the evaluation of an integral of a function $f(y)$ expressing the variation of the total molality m with composition under isopiestic conditions. In particular cases, $f(y)$ assumes simple analytical forms; these cases are based on deviations from Zdanovskii's rule, though not always explicitly.

In the simplest case $\Delta = 0$ and therefore the integral is zero also (2). When $\Delta \neq 0$, Kirgintsev and Luk'yanov (2) and Allakhverdov and Stepin (5) use a $f(y)$ defined in the manner of eq. 3; their equations differ only in the form of the deviation term by_1y_2. Robinson (9) uses the "isopiestic ratio" $R \equiv m_{10}/m$, which in some cases can be represented by $R = 1 - cy_2 - dy_2^2$, where c and d are empirical constants. The integrand then becomes d/m_{10}; this quantity is identical with the b of Kirgintsev and Luk'yanov (7). Thus Zdanovskii's rule, and deviations from it, constitute the basis of these evaluations of the McKay–Perring integral.

We wish to thank a referee for much helpful advice in the preparation of the final form of this paper.

Raman Spectral Studies of Cadmium–Nitrite Interactions in Aqueous Solutions and Crystals[1]

DONALD E. IRISH AND RODERICK V. THORPE[2]

Department of Chemistry, University of Waterloo, Waterloo, Ontario N2L 3G1

Received November 14, 1974

DONALD E. IRISH and RODERICK V. THORPE. Can. J. Chem. **53**, 1414 (1975).

Raman spectra of aqueous solutions containing Cd^{2+} and NO_2^- clearly reveal the presence of solvated nitrite ion and of complexes. A band at 861 cm^{-1} is characteristic of the latter. The free nitrite concentration was measured from the intensity of the 817 cm^{-1} line and the average ligand number was evaluated for solutions with composition prescribed by the mole-ratio method. Four cumulative formation constants were deduced: $\beta_1 = 61.6$; $\beta_2 = 993$; $\beta_3 = 2390$; $\beta_4 = 1899$. Evidence that nitrite chelates Cd^{2+} through the two oxygen atoms is presented. The diagnostic spectral evidence consists of a high intensity, high frequency deformation mode and low intensity N—O stretching Raman bands with frequencies almost identical to those of the solvated nitrite ion. Data are also presented for solid $Cd(NO_2)_2$ and $K_{x-2}Cd(NO_2)_x$ ($x = 3, 4, 5$).

DONALD E. IRISH et RODERICK V. THORPE. Can. J. Chem. **53**, 1414 (1975).

Les spectres Raman de solutions aqueuses contenant du Cd^{2+} et du NO_2^- montrent clairement la présence d'ions nitrites solvatés de même que la présence de complexes. Une bande à 861 cm^{-1} est caractéristique de ces derniers. On a mesuré la concentration en nitrite libre à partir de l'intensité de la bande à 817 cm^{-1} et on a évalué le nombre moyen de ligands pour des solutions ayant une composition prescrite par la méthode des rapports molaires. On a déduit quatre constantes de formation cumulative: $\beta_1 = 61.6$; $\beta_2 = 993$; $\beta_3 = 2390$; $\beta_4 = 1899$. On présente des résultats indiquant que le nitrite se chélate au Cd^{2+} par l'intermédiaire des deux atomes d'oxygène. Cette conclusion, basée sur les spectres, est obtenue en se basant sur un mode de déformation de haute intensité et de haute fréquence et sur des bandes d'élongation N—O en spectroscopie Raman qui sont de basse intensité et qui ont des fréquences pratiquement identiques à celles des ions nitrites solvatés. On présente aussi des données pour le $Cd(NO_2)_2$ et le $K_{x-2}Cd(NO_2)_x$ ($x = 3, 4, 5$) à l'état solide.

[Traduit par le journal]

Raman spectra of aqueous solutions of alkali metal nitrites only exhibit lines characteristic of the solvated nitrite ion; no lines characteristic of the nitrite ion bonded to a cation are observed despite the very high solubilities of these salts (1). In contrast, divalent cations such as Ni^{2+}, Mg^{2+}, Ca^{2+}, and Zn^{2+} form complexes with nitrite ion and Raman lines attributable to both the bound and free forms of the anion are observed (2, 3). From measurement of the relative integrated intensities of the lines in the deformation region it was possible to evaluate stepwise stability constants for the species $ZnNO_2^+$ and $Zn(NO_2)_2$; values of 1.4 and 0.9 mol^{-1} l at 25° were obtained for K_1 and K_2 (3). That work has now been extended to a study of the species formed between Cd^{2+} and NO_2^- in water. In addition to a determination of the stability constants for four mononuclear complexes, structures of the species are proposed consistent with the parameters of the vibrational lines. Spectra of related solids are also reported.

Experimental

In preliminary experiments eleven solutions were prepared in accordance with the Job method of continuous variations (4, 5). A stock solution of $Cd(ClO_4)_2$ was prepared by reacting weighed amounts of CdO (J. T. Baker Analyzed Reagent grade, 99.2%) with the stoichiometric amount of $HClO_4$. The p*H* was adjusted to between 6 and 6.8 with 1 *M* NaOH and weighed quantities of $NaNO_2$ (Baker and Adamson, A.C.S. Reagent Grade) were added. The sum of the concentrations $[Cd^{2+}] + [NO_2^-]$ was kept constant at 1.43 mol l^{-1} and the Job variable ($f = [NO_2^-]/1.43$) varied from 0.26 to 1.0.

Stability constants were evaluated from data obtained from four series of solutions prepared as above but with compositions in accord with the mole-ratio method (5).

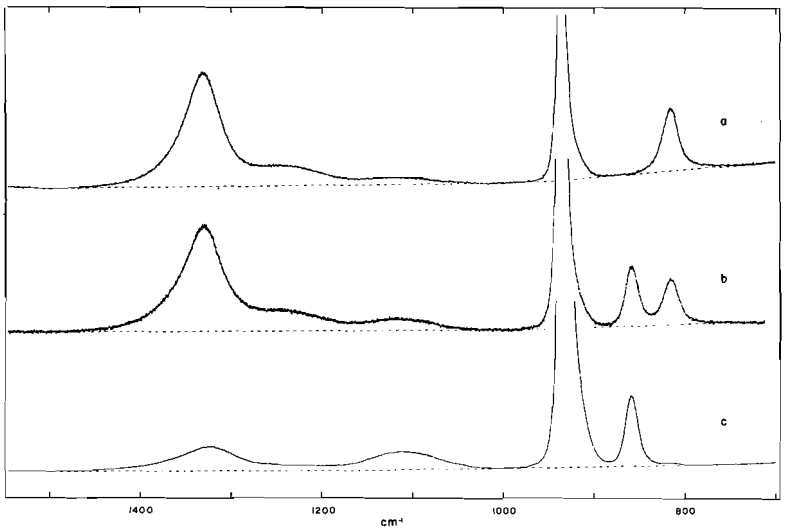

FIG. 1. Comparison of Raman spectra of $NaNO_2$ and Cd^{2+}–NO_2^- solutions from 700 to 1500 cm^{-1}: (*a*) 1.475 *M* $NaNO_2$; (*b*) 0.400 *M* Cd^{2+}, 3.62 *M* NO_2^-; (*c*) 0.896 *M* Cd^{2+}, 1.852 *M* NO_2^-.

These solutions were analyzed for NO_2^- by permanganate titration (6). Concentrations of Cd^{2+} and ClO_4^- were obtained from the weights of materials used. All solutions were filtered through a Millipore 0.100 μ filter prior to spectral measurements.

Raman spectra, excited by the 514.5 nm line of a Coherent Radiation Model 52G argon ion laser, were recorded on a Cary 81 spectrophotometer, modified as described previously (7). Samples were at the ambient temperature of the sample compartment (approximately 25 °C). All band intensities, measured as areas, were ratios relative to the intensity of the 935 cm^{-1} line of ClO_4^-. The use of this internal standard compensated for possible refractive index or color effects. Raman spectra of $Cd(ClO_4)_2$ and $NaClO_4$ solutions were used to establish the baseline. Band contours were resolved into components by a modification of the computer procedure, CURVER, described elsewhere (8). Initially the spectra, recorded repeatedly and at slow scan, were digitized using a model 21, Ruscom Logics Limited digitizer which transferred the *x* and *y* coordinates of points on a band contour to a magnetic tape via a Digi-Data Corporation tape drive unit. These data, in proper format, were used in conjunction with a PDP-11 model 20 computer and a modified CURVER program. An empirical line shape (7) which most closely fitted the symmetrically-shaped nitrite bands was employed. The line intensity of particular importance for evaluation of equilibrium constants, *viz.* the 817 cm^{-1} line, overlaps with other lines to only a small extent and thus accurate intensity measurements could be made.

Anhydrous $Cd(NO_2)_2$ was prepared from barium nitrite and cadmium sulfate as suggested by Rây (9). The purest compound prepared was analyzed for NO_2^- and showed 44.59% (predicted, 45.01%). The analysis and spectra of the solid were recorded after careful dehydration in a vacuum oven at 70 °C for several hours. The salt partially decomposed when placed in water or ethanol. Salts of the general formula $K_{x-2}Cd(NO_2)_x$, where *x* is 3, 4, or 5, were prepared by partial dehydration of solutions containing the requisite amount of KNO_2 and $Cd(NO_2)_2$ and were dried *in vacuo* at 70°. When *x* was 5, nitrite analysis gave 50.72% (predicted, 50.03%). This solid did not noticeably decompose when placed in water. Raman spectra of the powders were obtained as previously described (10). A few spectra were obtained with a Jarrell-Ash Model 100 double monochromator equipped for photon counting with an S.S.R. 1105 data converter. Infrared spectra were obtained on a Beckman IR-9 spectrophotometer fitted with a Wilks model-9 multiple internal reflectance attachment and a 60° KRS-5 prism (10, 11).

Results and Discussion

Spectral Features

The nitrite ion (C_{2v} symmetry) generates three coincident infrared and Raman lines. For 5.8 mol l^{-1} aqueous $NaNO_2$ solutions these are: $\nu_1(A_1)$, 1331 cm^{-1}, symmetric stretch; $\nu_2(A_1)$, 817 cm^{-1}, deformation; $\nu_3(B_1)$, 1242 cm^{-1}, antisymmetric stretch. They are illustrated in Fig. 1*a*. Two lines of ClO_4^-, the internal standard, are also seen in that figure at 935 and 1116 cm^{-1}. On addition of Cd^{2+} a new polarized line appears at 861 cm^{-1} (Fig. 1*b*) and grows in intensity at the expense of the 817 cm^{-1} line as the $[Cd^{2+}]/[NO_2^-]$ ratio increases (Fig. 1*c*). Less distinctive changes occur in the 1200–1400 cm^{-1} region; lines characteristic of the new species occur almost at the same positions as those of solvated NO_2^- and differ largely in molar intensity (Fig.

1*c*). This region will be discussed in more detail below.

The intensity measurements from the Job experiment (peak-height intensities; half-width was found to be constant to ± 1 cm^{-1}) are illustrated in Fig. 2. The unsymmetrical appearance of the plot and the maximum at approximately $f = 0.72$ suggest the presence of complexes of higher order than 1 : 1. The maximum is not very sharp and thus the complexes are not expected to have extremely high formation constants. For $f < 0.8$ the intensity of the 817 cm^{-1} line is very small and its molar intensity is also much less than that of the 861 cm^{-1} line. On this line-height scale (relative to 1 mol l^{-1} ClO_4^-) the ratio of molar intensities is about 0.7, estimated at $f = 0.72$.

Stability Constants from Mole-ratio Experiments

The mole-ratio method was applied to determine the identity of complexes formed by cadmium and nitrite in aqueous solution and to evaluate their formation constants. Solutions were prepared with metal concentrations, in four different series, of 1.00, 0.90, 0.40, and 0.30 mol l^{-1} respectively. The Raman spectrum of each solution was recorded in the 730 to 1000 cm^{-1} region and for selected solutions, also in the 1000 to 1520 cm^{-1} region. Because of overlap between the 817 and 861 cm^{-1} nitrite deformation bands, all spectra were digitized and curve resolved as described above. During the curve resolving, an extra component band had to be invoked, *ca.* 845 cm^{-1}, to fit the band contour of the 730 to 907 cm^{-1} region (Fig. 3).

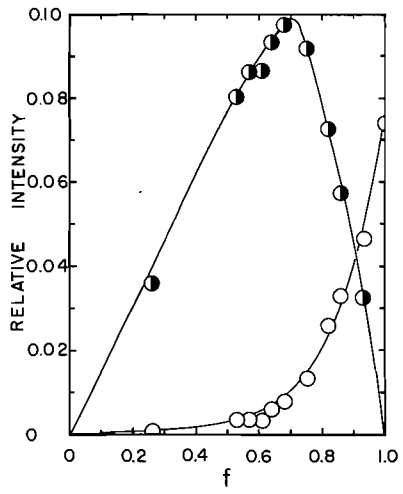

FIG. 2. Job method of continuous variations plot of relative intensity against f: ◑, relative intensity of 861 cm^{-1} bound nitrite band; ○, relative intensity of 817 cm^{-1} free nitrite band.

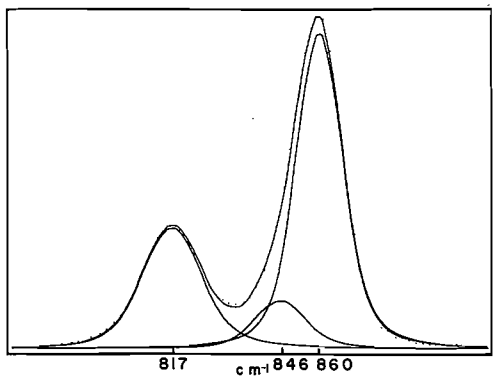

FIG. 3. Curve resolving of the nitrite deformation spectral region of a Cd–NO_2 aqueous solution ($\bar{n} = 3.48$).

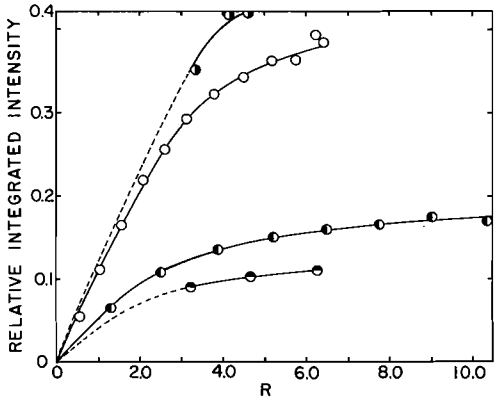

FIG. 4. Relative integrated intensity of the 861 cm^{-1} band against nitrite-to-cadmium mole ratio: ◑, 1.00 *M* Cd^{2+}; ○, 0.90 *M* Cd^{2+}; ◐, 0.40 *M* Cd^{2+}; ◓, 0.30 *M* Cd^{2+}.

Figure 4 is a plot of the relative intensity of the combined 861 and 845 cm^{-1} bands against R, the ratio of the concentrations of the total nitrite-to-cadmium for the four series. The steep slopes (increasing as cadmium concentration increases from one series to the next) and gradual levelling off at relatively low ligand-to-metal ratios (10 or less), again manifest the fairly high stability of the cadmium nitrite complexes formed. The difficulty of determining the molar intensities of the components of the band contour of bound nitrite led to the decision to determine stability constants from measurements of the 817 cm^{-1}, free nitrite band intensity. The molar intensity of this line was obtained from measurements on $NaNO_2$

solutions. A plot of relative integrated intensity of the free nitrite 817 cm^{-1} band against nitrite concentration is linear (Fig. 5). A least squares calculation was performed and gave a molar intensity, J_F, of 0.068 l mol^{-1}.

Using the measured J_F value for the free nitrite 817 cm^{-1} band, the free nitrite concentrations in the solutions were found from the curve resolved intensities by the simple relation

$$[1] \qquad C_F = I_F/J_F$$

Therefore, $\bar{n}$, the average ligand number of the complexes, was found using the total nitrite and metal concentrations

$$[2] \qquad \bar{n} = (C_T - C_F)/C_M$$

$\bar{n}$ was found to have a maximum value of 3.59 in the concentration ranges studied; thus, substantial concentrations of complexes of higher order than 1:4 were not anticipated. Only mononuclear complexes are indicated because the data from four different molar ratio experiments lie on the same curve of $\bar{n}$, as derived from eq. 2, plotted against observed free nitrite concentration (Fig. 6).

The GAUSS-Z least squares method (12) was employed in an IBM 360-75 computer program (13) to calculate β, the cumulative formation constants. Using initial guesses of β (with literature values as a guide), the program calculates new $\bar{n}$ by the equation

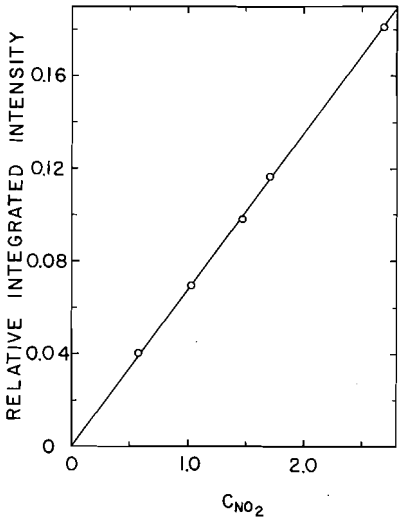

FIG. 5. Relative integrated intensity of the 817 cm^{-1} band against total nitrite concentration for standard $NaNO_2$ solutions.

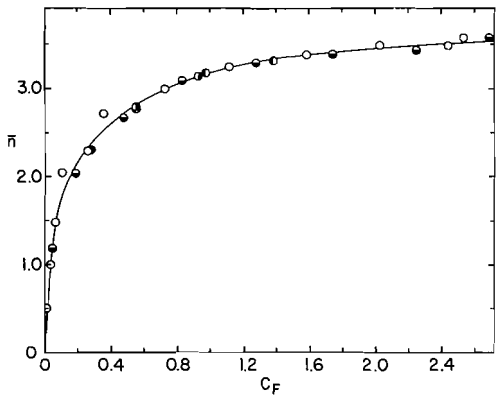

FIG. 6. $\bar{n}$ against free nitrite concentration for mole-ratio experiments: ◐, 1.00 *M* Cd^{2+}; ○, 0.90 *M* Cd^{2+}; ◒, 0.40 *M* Cd^{2+}; ◑, 0.30 *M* Cd^{2+}.

$$[3] \qquad \bar{n} = \frac{\beta_1 C_F + 2\beta_2 C_F^2 + ...}{1 + \beta_1 C_F + \beta_2 C_F^2 + ...}$$

The $\bar{n}$ are then refined in an iterative procedure to minimize the sum of the square of the difference between $\bar{n}_{calcd}$ (calculated by eq. 3) and $\bar{n}$ (initially calculated by eq. 2). The final value of the residual $R = \sum |\bar{n} - \bar{n}_{calcd}| / \sum \bar{n}$ was 1.65%. The results are presented in Table 1. Except for the first six points, for which the intensity of the free nitrite 817 cm^{-1} band is low, all solutions have values of ΔC_F less than 5% of the C_F values observed experimentally.

The logarithms of the cumulative stability constants, β_1, β_2, β_3, and β_4 are 1.79, 3.00, 3.38, and 3.28 respectively when concentrations are expressed in mol l^{-1}; the standard deviations in the logarithms are 0.053, 0.032, 0.024, and 0.011 respectively, and the unweighted sum of the squares of the deviations is 0.0948. The stepwise constants K_1 to K_4 are 61.6, 16.1, 2.41, and 0.79. Following the usual conventions (14) the log β values are compared with those obtained by other methods in Table 2. Curves of the degree of formation of each species, $\alpha = C_i/C_M$, are illustrated in Fig. 7. Extrapolations were made to lower concentrations using the computed β_1 because as log C_F becomes smaller than −2.6 only one complex species concentration is significant, *viz.* $[CdNO_2^+]$.

The Raman spectrum of one solution was examined from 710 to 1000 cm^{-1} at 31 and 61.5 °C and at 28.5 and 71 °C. The small changes in the relative intensities of the 817 and 861 cm^{-1} bands indicated a slight decrease in the concen-

tration of bound nitrite with 30 and 40° temperature increases. These results imply that the net complex formation for the concentrations of species examined is slightly unstable with respect to temperature increases.

Comparing the different results in Table 2 there seems to be general agreement that log β_1 is about 1.8. Ultraviolet spectrophotometry to date has not made possible evaluation of the number of complexes or their formation constants (20, 21). Garnier (22) has pointed out, however, that the spectrophotometric results are not inconsistent with the presence of four complexes. The absorption (*ca.* 31 000 cm^{-1}) is a colligative property of bound nitrite ion, independent of the number of nitrite ions bound to the metal ion. The polarographic study of Jain and Gaur (17) failed to make allowance for the competitive complexing between cadmium and nitrate ions (23). The results of Swinarski and Grodzicki (19) are more in

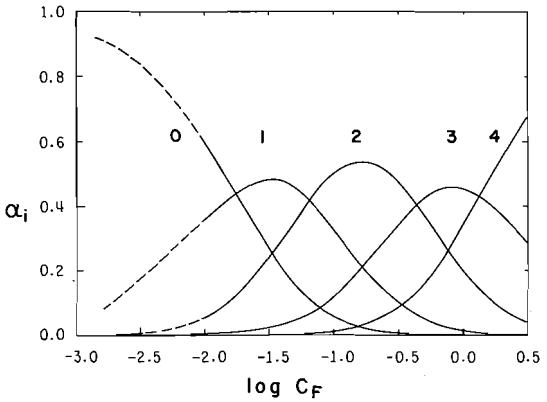

FIG. 7. Formation curves: α against log free nitrite concentration.

accord with the present work. The best agreement, however, is with the e.m.f. study of Leden (15). Gerding (16) also favored Leden's constants; he used them as starting values and adjusted them to give the best fit to his calorimetric data. He evaluated only three constants but noted that his data indicated a fourth complex. Possibly its detection has been sporadic because solution compositions have not spanned a sufficiently wide composition range.

Assignments and Structure

As noted previously, the symmetric stretching mode is observed *ca.* 1331 cm^{-1} and the antisymmetric stretching mode occurs *ca.* 1242 cm^{-1} for free nitrite. Upon addition of cadmium to a solution of sodium nitrite, no additional bands are evident in the 1000 to 1520 cm^{-1} Raman spectral region (*cf.* ref. 1). However, a noticeable decrease occurs in the molar intensity of the nitrite stretching bands. This can be noted by referring to Fig. 1. To convert the three spectra in the figure to the same scale as spectrum *a*, it is necessary to multiply the intensity of spectrum *b* by approximately two and that of spectrum *c* by approximately 2.5. Even with this conversion it is evident that the Raman molar intensities of the stretching modes of bound nitrite are less than half those of free nitrite.

The half-width of the 1331 cm^{-1} band increases from about 43 cm^{-1} for 5.8 mol l^{-1} $NaNO_2$ to about 66 cm^{-1} when the ratio of bound-to-free nitrite is 6.5. The results suggest that a bound nitrite stretching mode is nearly coincident ($\pm$10 cm^{-1}) with the 1330 cm^{-1} free nitrite stretching mode. Because of low intensity and overlap with the ν_3 line of perchlorate no significant trend was observable in the 1240 cm^{-1} region.

The digitized data facilitated another comparison of the band contours of free and bound nitrite. Point by point intensities were converted to a scale relative to 1 mol l^{-1} perchlorate and are plotted in Fig. 8 for a cadmium nitrite solution and sodium nitrite solution having equivalent concentrations of free nitrite. Although significant errors in the plot may exist, especially near the low intensity contour of the *ca.* 1116 cm^{-1} perchlorate band, a difference intensity contour, with maxima *ca.* 1337, 1249, and 1115 cm^{-1}, is evident. The occurrence of the largest intensity at about 1337 cm^{-1} further supports the contention that at least one bound nitrite stretching mode occurs within 10 cm^{-1} of the symmetric stretching mode of free nitrite. The difference intensity maximum *ca.* 1115 cm^{-1} is probably not real since large errors are inherent in measuring the difference between two low intensity contours. This postulate is substantiated by the fact that no intensity was observed at *ca.* 1115 cm^{-1} in the spectra of cadmium nitrite solutions not containing perchlorate. The difference intensity *ca.* 1249 cm^{-1} is apparently genuine since intensity is observed in this region for cadmium nitrite solutions containing a very low concentration of free nitrite.

None of the common types of coordination of

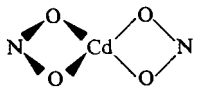
nitrite ligand to a cation would produce the observed spectral results. Observed N-bonded complexes have the bound antisymmetric stretch raised to approximately 1345 to 1497 cm^{-1}, whereas in O-bonded and bridged complexes, this band occurs at even higher frequencies (22, 24–28). The symmetric stretching frequency may rise or remain unshifted in N-bonded complexes but upon O-bonded coordination this band generally shifts to much lower frequency. Garnier (22) reports infrared and Raman spectra of a saturated aqueous solution of $K_2Cd(NO_2)_4$ which are similar to some of the spectra observed here. His infrared spectra show that the antisymmetric stretch of bound nitrite occurs *ca.* 1230 cm^{-1} or essentially unchanged from that of free nitrite. His postulate to explain the observed spectra is that the complexes contain bidentate-coordinated O-bonded linkages. Intuitively, this explanation is reasonable, since a molecular orbital approach would predict a lowering of the bond order with this coordination, lowering the nitrite stretching frequency, but the ring rigidity tends to increase the force constant for stretching, so that the frequency lowering effect is partly cancelled. It is possible then that little shifting of the N—O stretching frequencies will occur on the basis of his proposal. The decreased electron density in the N—O bonds would contribute to a decreased polarizability and an increased bond dipole; thus low Raman intensity and high infrared intensity can be rationalized. Raman resonance is not an acceptable explanation because the absorbance is negligible at the wavelength of the exciting line. Depolarization studies of cadmium nitrite solutions did not reveal any new information because of the high depolarization ratio of the symmetric stretch and considerable band overlap in this region.

The relatively high frequency, 861 cm^{-1}, of the deformation mode also supports bidentate O-bonding. Structures containing either N-bonded or O-bonded ligands have been reported and the deformations are lower than about 850 cm^{-1} (24–29). On the other hand bridging or chelation gives a higher frequency, >860 cm^{-1} (28, 30). The ring rigidity in the proposed bidentate structure would also force the deformation mode to higher frequency. The curve resolved spectra (Fig. 3) suggested two bands in this region at 846 and 861 cm^{-1}. These positions are reminiscent of those observed on dehydration of $LiNO_2 \cdot H_2O$ (842 and 872 cm^{-1}) (31). Their existence for the $Cd(NO_2)_x^{2-x}$ species may imply that whereas the nitrite ions for the most part chelate the Cd^{2+} giving rise to the 861 cm^{-1} line, a smaller fraction are oriented in monodentate fashion, possibly in the higher complex, giving the 846 cm^{-1} line.

The oxygen–cation bonds probably have high ionic character (22); a broad, weak polarized line at 240 cm^{-1} is assigned to the symmetric stretch and depolarized lines at 324 and 446 cm^{-1} are assigned to rocking and wagging modes respectively (24). The bonding of possibly eight-coordinated cadmium(II) can be understood in terms of three-center bonds discussed by Bullock and Tuck (32) for $[Hg(NO_2)_4]^{2-}$ (*vide post*).

Spectra of Related Solids

The Raman and infrared lines from the deformation and stretching modes of NO_2^- in several solids are presented in Table 3. The positions of the weak, broad bands above 1200 cm^{-1} are estimated to ± 5 cm^{-1}. The spectrum of $Cd(NO_2)_2$ is particularly interesting. The 874 cm^{-1} deformation is high in frequency and intensity. The stretching modes are weak in comparison and also when compared to the lines of $NaNO_2$; and yet they are not markedly shifted from the positions observed for alkali metal nitrites (30). These observations and those to follow suggest that also in the solid state nitrite ion chelates Cd^{2+}. The structure is represented by



D_{2d} symmetry would account for coincidence of Raman and i.r. spectral lines. Raman lines at 347 and 382 cm^{-1} are believed to arise from cadmium–oxygen stretching motions. Lines observed at 48, 62, 71, 85, 94, 120–135, and 190 cm^{-1} are mostly lattice modes.

The solid $K_2Cd(NO_2)_4$ has been examined previously (22, 29, 33). Goodgame and Hitchman (33) have demonstrated that $K_2Cd(NO_2)_4$ and $K_2Hg(NO_2)_4$ are isomorphous. They argued that NO_2^- chelates the group 2B metal ions in both of these compounds and a structure similar to the coordination polyhedron inferred from X-ray and neutron scattering data for $K_3[Hg(NO_2)_4]NO_3$ results (34, 35). The infrared spectral data of Bullock and Tuck (32), Garnier (22), and Good-

game and Hitchman (33) confirmed that $K_3[Hg(NO_2)_4]NO_3$ and $K_2Hg(NO_2)_4$ contain the same $[Hg(NO_2)_4]^{2-}$ unit. Consequently the evidence is quite strong for bidentate O-bonded coordination (although not for equal Cd—O distances) for the complexes studied in this work. The higher frequency of the deformation band of $Cd(NO_2)_2$, compared with $K_2Cd(NO_2)_4$, is attributable to a more symmetrical arrangement with stronger Cd—O bonds. Greater overlap between sp^3 hybrid orbitals of Cd^{2+} and nonbonding sp^2 hybrid orbitals of each oxygen would result in stronger bonds for the four-coordinated species than the eight-coordinated species (*cf.* ref. 32).

The crystals formed from compositions $x = 3$ and $x = 5$ are probably double salts containing KNO_2 and $K_2Cd(NO_2)_4$. The lines at 828, 1230, and the markedly higher intensity at 1326 cm^{-1} suggest uncoordinated nitrite. The weak 1048 cm^{-1} line is attributable to NO_3^- resulting from slight decomposition.

In conclusion we infer that Cd^{2+} is chelated by nitrite ion in the solids and in aqueous solution. The mode of attachment is particularly favorable for the first two complexes in solution; monodentate O-bonding occurs to some extent in the third or fourth complex. The diagnostic spectral features of the chelation are low-intensity Raman bands in the N—O stretching region with frequencies almost identical to those of the solvated nitrite ion and a high intensity, high frequency deformation mode. The infrared intensities will be intense in the stretching region because of the increased bond polarity. These conclusions lead us to believe that Zn^{2+} in aqueous solution is also chelated by nitrite ion. The deformation occurs at 867 cm^{-1} and the observations in the stretching region (3) appear to meet the conditions specified above. $Zn(NO_2)_2$ is the highest complex in aqueous solution; it should also have D_{2d} symmetry as described above for the unit in solid $Cd(NO_2)_2$. The bonding would involve overlap of sp^3 hybrid orbitals of Zn^{2+} and sp^2 nonbonding orbitals of the oxygen atoms. But the smaller size of the Zn^{2+} ion precludes higher coordination of this type. Although higher complexes do not form in solution, $Cs_2Zn(NO_2)_4$ can form in the crystalline state. Then the nitrite ions are forced to coordinate in monodentate arrangement and the deformation drops to 847 cm^{-1} while ν(N—O) occurs at 1167 cm^{-1} and ν(N=O) at about 1380 cm^{-1} (22, 33).

Received November 1, 1974

R. GEORGE S. RITCHIE, NATSUKO CYR, BRIAN KORSCH, HANS J. KOCH, and ARTHUR S. PERLIN. Can. J. Chem. **53**, 1424 (1975).

Assignments for the ^{13}C chemical shifts of methyl aldopento- and hexofuranosides and of cyclopentane polyols are reported, and these chemical shifts are evaluated with respect to all combinations of configurational arrangements of the ring substituents. A *cis* configuration of vicinal substituents is generally associated with a substantial increase in shielding, as compared with the *trans* analog. Among the furanosides, however, changes in configuration involving O-3 and C-5 are accompanied by a complex shielding pattern: *e.g.*, effects on C-3 are minor, C-4 is more shielded in *cis* than in *trans* isomers, and C-4 and C-5 of hexosides are more shielded than those of pentosides. Variations in shielding attributable to *cis* or *trans* arrangements of substituents in a 1,3-relationship are encountered in only a few instances; however, it is noteworthy that C-4 is *less* shielded when O-1 and O-3 are *cis* than when *trans*. These diverse effects are considered also in relation to steric interactions and to conformational influences on ^{13}C chemical shifts in the five-membered ring series.

R. GEORGE S. RITCHIE, NATSUKO CYR, BRIAN KORSCH, HANS J. KOCH et ARTHUR S. PERLIN. Can. J. Chem. **53**, 1424 (1975).

On rapporte les attributions de déplacements chimiques du ^{13}C pour les aldopento- et hexofurannosides de méthyle et pour une série de cyclopentanepolyols; on évalue ces déplacements chimiques par rapport à toutes les combinaisons d'arrangements configurationnels des substituants du noyau. Par opposition aux analogues *trans*, on associe généralement une augmentation substantielle du blindage avec une configuration *cis* des substituants vicinaux. Toutefois parmi les furannosides, les changements de configuration impliquant O-3 et C-5 sont accompagnés par un patron de blindage complexe, *e.g.* les effets sur C-3 sont mineurs, C-4 est plus blindé dans les isomères *cis* que dans les isomères *trans* et C-4 et C-5 des hexosides sont plus blindés que ceux des pentosides. On ne rencontre que quelques cas où des variations dans le blindage sont attribuables aux arrangements *cis* et *trans* des substituants en position 1,3; toutefois il est à noter que C-4 est moins blindé quand O-1 et O-3 sont *cis* que lorsqu'ils sont *trans*. On considère aussi ces divers effets en relation avec les interactions stériques et les influences conformationnelles sur les déplacements chimiques du ^{13}C dans une série de cycles à cinq membres. [Traduit par le journal]

Introduction

Earlier studies (1–6) have dealt with configurational and conformational effects on ^{13}C n.m.r. chemical shifts in the pyranose series of carbohydrates and selected substituted cyclohexanols. The recognition of such steric effects in the spectra of these compounds proved to be relatively straightforward because of the unique geometry of the six-membered ring: namely, the existence of two chair conformations, in which the substituents are either axial or equatorial. By contrast, the furanose and cyclopentane rings are more flexible structures, conformers of which may differ relatively little in energy and hence readily interconvert as envelope and twist forms; *i.e.*, those conformations in which one and two atoms, respectively, are out of the plane of the ring. Therefore, a representative conformer may be difficult to define for a given substituted five-membered ring. The value of ^{1}H–^{1}H coupling in this context has, of course, long been recognized (7). However, ^{13}C n.m.r. data, by providing complementary stereochemical information, should enhance the reliability of conformational analysis in this area.

As described in a preliminary report (8), configurational differences between isomeric furanoses are readily recognizable by variations

in ^{13}C chemical shifts. A more definitive analysis of chemical shift data for these compounds and a fuller account of the shielding influences observed is contained here, together with a comparative study on cyclopentanols. Configurational inversion rarely introduces a large change in the conformation of pyranoses but might lead to a gross effect on the pseudorotational itinerary of furanoses (*e.g.*, ref. 9). Hence, the influences on shielding noted below are ascribed empirically to known changes in configuration, although it is clear that an unknown conformational factor is included and may even make a major contribution to shielding.

Results and Discussion

Cyclopentanols

Because there are close analogies between the spectral characteristics of pyranoses and cyclohexanes, it is of interest to study data on cyclopentanols in conjunction with the furanosides. As in the cyclohexane series (10, 11) steric hindrance (due to CH_3–CH_3 and CH_3–OH interactions) in cyclopentanes is associated with upfield shifts (12), at least for the substituted ^{13}C nuclei when two related isomers are compared. For example, C-1 and C-2 of *cis*-1,2-dimethylcyclopentane and -2-methylcyclopentanol are more shielded than those of their *trans* isomers (12). When there are two or more hydroxyl groups on the ring, the interactions become more complex. Studying these effects in the cyclopentane series should facilitate the unravelling of the ^{13}C chemical shifts of furanosides.

Since numerous cases of the consistent additivity of substituent effects have been found (13, 14) for various types of ^{13}C nuclei, the validity of these effects in the cyclopentanol series has been studied. Thus, some disubstituted cyclopentanes were compared with cyclopentanol to determine the influence on C-1 of a hydroxyl group or a methyl group at various positions in the ring. The data are summarized in Table 1 for all combinations of diols and, for comparison, the methylcyclopentanols reported by Christl *et al.* (12). When one compares the primary carbinol signals of the following alcohols, where steric effects are minimal, values[2] similar to those observed for the *trans* examples of Table 1 are obtained; this suggests that the *trans* arrangement *per se* makes little contribution to the chemical shift.[3]

$$\overset{*}{C}H_3CH_2OH \rightarrow HOCH_2\overset{*}{C}H_2OH \qquad +4.6 \text{ p.p.m.}$$

$$\overset{*}{C}H_3CH_2\overset{*}{C}H_2OH \rightarrow HOCH_2CH_2\overset{*}{C}H_2OH \qquad -1.9 \text{ p.p.m.}$$

The substituent effect of a methyl group is distinctly different from that of a hydroxyl: carbon-1 in *cis*-2-methylcyclopentanol is deshielded relative to that of cyclopentanol, whereas the corresponding *cis*-diol is slightly more shielded. This is difficult to reconcile only on the basis of steric effects. Similarly, for the C-3-methyl compounds, C-1 is essentially unaffected, whereas it is more strongly shielded in the related *cis*- and *trans*-1,3-diols. That the γ

[2]Using TMS as the standard for ^{13}C chemical shifts, a negative value refers to increased shielding, and a positive one to a downfield shift.

[3]As a referee has noted, these comparisons may not be entirely valid because the *gauche* conformer of ethylene glycol should be important as a result of intramolecular hydrogen bonding.

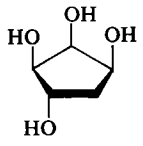
TABLE 2. Experimental chemical shifts for cyclopentane polyols and their deviations (in parentheses) from those calculated using substituent parameters for cyclopentanols

Cyclopentanols	C-1	C-2	C-3	C-4	C-5
1,2,3-Triol	72.8 (−0.3)	74.8 (+0.3)	—	29.9	—
1,3/2-Triol	76.6 (−1.4)	85.1 (+0.8)	—	29.1	—
1,2/3-Triol	72.5 (−0.4)	79.9 (+0.5)	76.8 (−1.0)	29.0	29.0
1,4/2-Triol	78.4 (−0.4)	78.2 (−0.4)	41.8[a]	70.1 (−1.4)	41.9[a]
1,2,3/4-Tetrol	70.7 (−0.5)	74.2 (+1.6)	79.3 (1.6)	76.4 (+0.5)	39.1
1,2,4/3-Tetrol	69.9 (−1.3)	76.9 (−0.8)	82.5 (+0.1)	74.0 (−2.3)	38.4
1,2/3,4-Tetrol	69.5 (−1.5)	77.1 (−0.6)	—	—	39.2
1,3/2,4-Tetrol	74.1 (−2.0)	83.0 (+0.4)	—	—	38.4
1,4/2,3-Tetrol	75.8 (−0.3)	78.6 (+0.9)	—	—	38.8
1,2,3,4/5-Pentol	76.5 (+0.5)	72.0 (+1.1)	—	—	84.1 (+3.2)

[a]May be interchanged.

effect of the hydroxyl group is greater than that of the methyl has been noted in other systems (11, 13*a*, 14). Only with the 1,2-*cis*- and 1,2-*trans*-cyclopentane diols is the expected stronger shielding of C-1 of the former than of the latter noted.

It was found that the empirical substituent effects given in Table 1 are useful for predicting the chemical shifts of each substituted carbon nucleus of polyols of cyclopentane. The reasonably good agreement obtained for some triols, tetrols, and a pentol with the experimental values is demonstrated in Table 2. A typical calculation is shown below using the values in parentheses in Table 1.



1.2.3/4-Tetrol

C-1: 75.1 + (−0.3) + (−1.7) + (−1.9) = 71.2

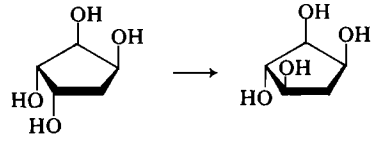
C-2: 75.1 + (−0.3) + (−0.3) + (−1.7) = 72.8

C-3: 75.1 + (−1.7) + (−0.3) + (+4.6) = 77.7

C-4: 75.1 + (−1.9) + (−1.9) + (+4.6) = 75.9

The deviations (shown in parentheses in Table 2) are the experimental chemical shifts minus the calculated values. In most cases, the error is small enough to confirm the assignment of each carbon signal, although it appears to increase as more and more hydroxyls are added. This suggests that the ^{13}C chemical shift depends to a small extent on interactions which are not considered here.

The change from the *trans*-1,2-diol arrangement to the *cis*, involves an increase in shielding of 4.6 p.p.m., whereas 1,3-interactions seem relatively unimportant (~0.2 p.p.m.) when comparing members of the same set. Hence, given one member of a series for which the assignments are known, such as a cyclopentanetetrol, it is to be expected that the spectrum of all other members can be estimated by using only the vicinal *cis–trans* conversions. The experimental chemical shifts of the triols and tetrols (Table 2) were then tested for the consistency of this approach. For the triols, 1,2-effects ranged from 3.8–5.2 p.p.m. (average 4.6), whereas they were slightly worse for the tetrols: 3.4–6.3 p.p.m. (average 4.8 p.p.m.). A sample conversion test is as follows:



1.2/3.4-Tetrol 1.2.4/3-Tetrol

1,3-arrangements
C-1: +0.4 p.p.m.
C-2: −0.2 p.p.m.

1,2-arrangements
C-3: +5.4 p.p.m.
C-4: +4.5 p.p.m.

This illustrates further that nonvicinal effects are small. However, as will be seen in conjunction with furanosides (below), such effects may sometimes be substantial.

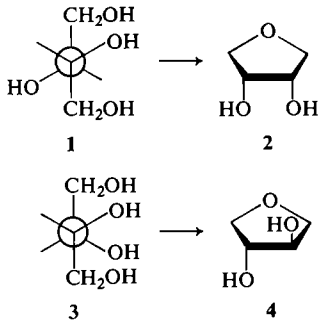
Effect of Ring Closure on α,ω-Butanols

Dehydration of derivatives of butane-1,4-diol gives the corresponding saturated, five-membered heterocycles. The chemical shift patterns of these compounds illustrate important features to be found in the furanoside spectra. For example, the carbons bonded to the ring oxygen are more deshielded (6–10 p.p.m.) than those in the open-chain polyols, as shown by the data in Table 3. Similar deshielding effects are observed when carbinol groups are methylated (4, 5), so that ring closure amounts to an internal *O*-alkylation. The most dramatic case is for 1,4-anhydroerythritol (**2**),[4] in which the α-carbons are at lower field than the β-carbons. The latter, being incorporated in the *cis*-2,3-diol arrangement, experience an increase in shielding, just as in the cyclopentanol series; in 1,4-anhydro-D-threitol (**4**) because of the *trans*-2,3-diol arrangement these ^{13}C nuclei follow the usual order: secondary less shielded than primary (13*a*).



These anhydrides may be considered in relation to their parent polyols. Thus, when the secondary hydroxyl groups of erythritol (**1**), favoring an *anti* orientation, are brought into a vicinal *cis* relationship on ring closure (**2**) an upfield shift of 1.2 p.p.m. is observed for C-2 (and C-3). On the other hand, the hydroxyl groups of threitol are expected to be *gauche* (**3**) but should more closely approach an *anti* disposition on ring closure (**4**), which should contribute to the deshielding of 4.5 p.p.m. observed. Deshielding (by 5.4 p.p.m.) is also found for C-2 (and C-3) in the *cis* to *trans* configurational change in going from **2** to **4**, an effect comparable to that observed with the cyclopentanols (Table 1).

[4]Chemical shifts for this, and other 1,4-anhydro derivatives, have been reported recently by Que and Gray (15).

TABLE 3. Effects of ring closure of butane α,ω-diols: ^{13}C chemical shifts of tetrahydrofuran rings and related systems in D_2O (p.p.m. from TMS)

	C-1	C-2
Butane-1,4-diol	62.6	29.2
Tetrahydrofuran	68.6	26.2
meso-Erythritol (**1**)	63.9	73.2
1,4-Anhydroerythritol (**2**)	72.7	72.0
D-Threitol (**3**)	63.9	72.8
1,4-Anhydrothreitol (**4**)	73.8	77.4

Methyl Tetrofuranosides

In extending this study to the methyl glycofuranosides, additional effects due to the methoxyl and alkyl groups were assessed. The alternating *trans* configuration of methyl α-threoside (**9**, R = H) is considered first, as it has the least number of steric interactions. Carbon-1 now has two electronegative oxygens, both of which are "alkylated," and therefore is the least shielded of the nuclei. Carbon-2 also experiences more deshielding: a "β-effect"; *i.e.*, in a series of alkanes, where one hydrogen is replaced by an OH group, there is not only a shift downfield for the α-carbon (36–51 p.p.m.) but a smaller shift (5–10 p.p.m.) of the β-carbon (13*b*, 14). By analogy, this extra oxygen on C-1 in furanoses (relative to a 1,4-anhydrotetritol) causes C-2 to shift to lower field than C-3. As alkylation of the extra oxygen on C-1 would only promote an upfield shift for C-2 of $\sim 1.7 \pm 0.7$ p.p.m. (13*c*) the signal of the latter will always occur at lower field than C-3, even for the glycosides. When **9** (R = H) is compared with 1,4-anhydro-D-threitol (**4**), there is little change at C-3 and C-4. Since C-4 (and C-1) is more shielded than C-3 (and C-2) in compound **4**, the same order should be expected for **9** (R = H). Hence the shielding order for tetroside **9**: C-1 ≪ C-2 < C-3 < C-4 < OMe. A partial spectrum of methyl α-D-threoside is represented by Fig. 1, in comparison with the remaining tetrosides and compound **4**.

The β-anomer **10** (R = H) has a *cis* 1,2-interaction, so that C-1 and C-2 become more shielded (5.6 and 3.1 p.p.m., respectively) than in **9** (R = H). As the 1,3-interaction differences are assumed to be small, the chemical shifts of the other nuclei should not be materially changed. Experimentally, this trend is observed but the numerical differences for C-3 and C-4

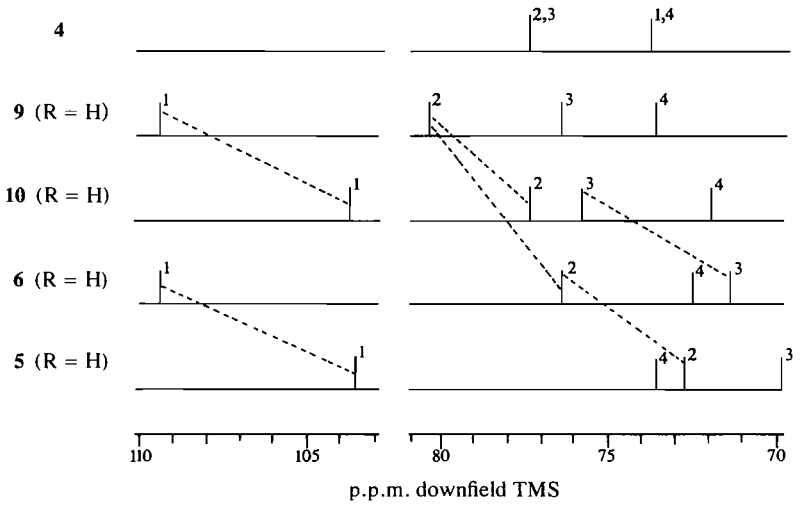


FIG. 1. Correlation of the ^{13}C chemical shifts of the ring carbons in the methyl tetrofuranosides and 1,4-anhydro-D-threitol.

are much larger than found for the cyclopentane triols, possibly due to the presence of the ring oxygen.

When comparing **6** (R = H) with **9** (R = H), the *cis* 2,3-interaction generates comparable shieldings for both C-2 and C-3. Now signal C-3 appears at higher field than C-4 in **6** (R = H) and the chemical shift for C-2 is similar to that in compound **10** (R = H). On proceeding to **5** (R = H), a compound containing all groups on the same side of the ring, C-2, flanked by two *cis* groups (OH, OMe), shifts to higher field than C-4. (The assignments of the C-4 signals were confirmed by reference to the proton-coupled spectra.) Carbon-3 in compound **5** (R = H) appears to be abnormally strongly shielded, for its position should be essentially that found in **6** (R = H), based on the cyclopentanol data. In this series, C-4 of the β-anomer is more shielded than that of the α-anomer; however, wide variations in the chemical shifts for C-4 of the higher homologs do not make this a general rule. Finally, the chemical shift of C-1 is *not* an indicator of anomeric character, as it generally is in the pyranoside series, but is a relative quantity, dependent upon the orientation of the group at C-2 (see also ref. 16).

Methyl Aldopento- and Hexofuranosides

Replacement of an α-H with a primary carbinol group, causes strong deshielding:

$\overset{*}{C}H_3OH \rightarrow HOCH_2\overset{*}{C}H_2OH$	12.6 p.p.m.
$CH_3\overset{*}{C}H_2OH \rightarrow CH_3\overset{*}{C}HOHCH_2OH$	11.6 p.p.m.
$\overset{*}{C}H_4 \rightarrow \overset{*}{C}H_3CH_2OH$	20.0 p.p.m. (13*d*)
$CH_3\overset{*}{C}H_3 \rightarrow CH_3\overset{*}{C}H_2CH_2OH$	20.2 p.p.m. (13*d*)

Hence, replacement of a 4-hydrogen in tetroside **9** by CH_2OH causes such a large downfield shift for the C-4 signal of the pentosides, that it resonates at lower field than any of the other secondary (and primary) ^{13}C nuclei. Thus, the shielding order for the alternating *trans* compound, pentoside **9**, is C-1 ≪ C-4 < C-2 < C-3 < C-5 < OMe.

Chain extension to the hexosides (R = $CHOHCH_2OH$) does little to change the chemical shifts of the ring carbons but C-5 becomes deshielded. Since C-2, in open-chain compound **1** (Table 3), is more shielded than that in the all *trans*-cyclopentane 1,3/2,4-tetrol (Table 2), it is to be expected that C-5 of a hexoside, which is a part of a side chain, will be more shielded than C-3. Thus, the shielding order for methyl β-D-galactofuranoside (**9**) must be C-1 ≪ C-4 < C-2 < C-3 < C-5 < C-6 < OMe.

When one correlates the chemical shifts of pentosides and hexosides, as for the tetrosides (Fig. 1), using the adjacent *trans–cis* conversions, one arrives at the assignments given in Table 4.

6 8 10 12

In helping to unequivocally define those assignments of signals which are close together, the anomers of methyl D-*gluco*- and D-*allo*-hexofuranoside-3*d* and -4*d* were prepared. The spectra of the deuterated compounds were essentially the same as those of the nondeuterated species, save for the facts that: the signal for the deuterated carbon was usually not observed above the background noise and nuclei β to the deuterium were barely perceptively more shielded (~0.05 p.p.m.) than those of the nondeuterated compounds. This approach has already been utilized for pyranosides (2, 6, 18).

Assignments were also greatly facilitated by analyses of the proton coupled ^{13}C spectra (see Experimental).

Analysis of Shielding Factors in Furanosides

Variations in shielding associated with configurational changes were evaluated for all combinations of the different *cis–trans* arrangements of ring substituents (OH, OCH_3, R).

C-5	0.6	−0.8	1.0	0.2	−0.1	−2.5

For this purpose it was assumed (*a*) that the chemical shift of a given ^{13}C nucleus is affected by the sum of all 1,2-, and 1,3-*trans* and -*cis* arrangements,[5] and (*b*) that the shielding influence on a carbon in a given *cis* or *trans* arrangement is a constant for the same configuration in all of the isomeric compounds. Using the chemical shift data of Table 4, shielding contributions associated with individual arrays of substituent pairs were then calculated (see Experimental), and are listed in Table 5. This table also includes data for the cyclopentane tetrols and, in addition, values calculated from ^{13}C chemical shifts reported (15) for 1,4-anhydropentitols. The following comments summarize these findings, and other information contained in Table 4, for each of the ^{13}C nuclei:

(*a*) Only the *cis*-1,2 arrangement introduces an important contribution for C-1, because the latter is uniformly about 6 p.p.m. more shielded in the *cis*, than in the *trans*, anomer.

(*b*) For C-2 both the *cis*-1,2 and -2,3 configurations are consistently associated with greater shielding than their *trans* counterparts, the *cis*-1,2 being characterized by less of an impact (by about 1.5 p.p.m.) than the *cis*-2,3.

(*c*) Stronger shielding of C-3 is also ascribable to the *cis*-2,3 as compared with the *trans*-2,3 configuration. In marked contrast, however, a *cis* arrangement of O-3 and C-5 differs relatively little from the *trans* in its apparent effect on the chemical shift of C-3. This is analogous to earlier observations (8) on *cis* and *trans* arrangements of O-3 and C-1 in ketofuranoses.

(*d*) In almost all *cis* and *trans* combinations of O-3 and C-5 a shielding influence on C-4 is attributable to the *cis* configuration of these nuclei, although the increase in shielding is more marked in the hexoside than in the pentoside or 1,4-anhydropentitol series. This

[5]That is, in a transformation such as α-anomer → β-anomer, C-1 is expected to be affected not only by the configurational change of O-1 with respect to O-2 but also by the accompanying changes in the disposition of O-1 relative to O-3 and O-5.

suggests that the greater steric perturbation expected from C-5 in the structure —C(5)-HOH—C(6)H_2OH as compared with —C(5)-H_2OH, is a possible source of the stronger shielding observed.

(*e*) Whereas C-5 of the pentosides exhibits little change in shielding due to a *cis*, as compared to a *trans*-O-3,C-5 arrangement, an increase (by ~2.5 p.p.m.) in the shielding of C-5 of the corresponding hexoside is evident. As just noted with respect to C-4, this difference also might be attributable to the expected increase in steric crowding around C-5 of the hexoside. Nevertheless, an effect similar to those on C-4 and C-5 associated with this extension of the carbon chain is not noticeably transmitted to C-3 as well.

(*f*) In general, *cis* substituents bearing a 1,3-relationship differ little from the *trans* isomers in their effect on shielding. However, a unique type of influence is indicated by the fact that C-4 of pento- or hexofuranosides is *deshielded* (by 2 p.p.m.) when there is a *cis*, in contrast to a *trans*, arrangement of O-1 and O-3. This means, for example, that in comparing each of the α,β anomeric pairs having the *gluco*, *manno*, and *allo* configurations the C-4 shielding differences for these pairs are observed to be −3.5, ~0, and +2.5 p.p.m., respectively, although no such variation should be expected if the vicinal O-3,C-5 configuration inversion is the sole factor.

(*g*) The anomeric *O*-methyl carbons and C-6 are affected to only a small degree by these diverse changes in configuration (Table 4). Perhaps consistent with such characteristics, is the likelihood that rotational isomerism about the C-1,O-1 or C-4,C-5 bond will tend to favor a disposition for OCH_3 or C-6 that is furthest removed from other nuclei of the molecule. Although, seemingly by contrast, axial anomeric OCH_3 substituents in the pyranoside series are more shielded than equatorial ones (4), this difference is not related to the relative arrangement of OCH_3 and O-2, because the same axial:equatorial difference is found for the *manno* (OCH_3 and O-2 *anti*) as for the *gluco* (*gauche*) configuration.

Conformational Influences

Although a wide array of shielding effects on the different ^{13}C nuclei is evident among the foregoing data, chemical shifts calculated by reference to Table 5 generally agree with the observed values to better than ±0.6 p.p.m. Hence the shielding associated with a given modification appears to be a consistent, characteristic quantity.[6] As noted at the outset, such a steric change is expected to include a conformational component, information about which is a prime objective of these studies.

Some measure of how conformational changes influence shielding may be gained from the estimates made earlier (8) of diamagnetic contributions to the chemical shifts. Thus, various possible forms of β-ribofuranose have been considered relative to β-ribopyranose, in the light of the fact that most ^{13}C nuclei of the latter are more shielded than those of the furanose.[7] It is found that if C-3, for example, is above the plane of the ring (envelope form E^3 (9)) less shielding of most ^{13}C nuclei of the furanose than of the pyranose molecule is indeed to be anticipated, whereas if C-3 were down (E_3), only relatively small chemical shift differences between these isomers might be expected. It may be noted also that such estimates (8) of diamagnetic contributions suggest that a *cis–trans* configurational change at C-3 and C-4, *e.g.*, β-ribofuranose to β-xylofuranose, *need not* be accompanied by a large change in shielding at C-3. This possibility is of particular interest in the light of the experimental finding (Table 5) that the shielding effect on C-3 in such circumstances is very small.

The current data, by themselves, do not provide an obvious basis for defining conformation. However, when viewed together with ^1H–^1H and ^{13}C–^1H coupling constants, these chemical shift values and shielding analyses should help to substantially reduce the number of pseudorotational forms that need be considered for a given molecule.

^{13}C Shielding and Steric Interactions

Steric compression appears in many in-

[6]The four aldopentose configurations are represented here, and four of the eight in the aldohexose series. Since the chemical shifts of configurationally related pentosides and hexosides are closely similar (aside from the increased shielding of C-4 and C-5 of the hexosides) (Table 5), it is likely that analogous results will be found for furanosides of the other aldohexoses: *i.e.*, close similarities between the *xylo* and *ido*, *arabino* and *altro*, etc., isomers.

[7]This shielding difference is general for configurationally-related five- and six-membered ring isomers (8, 19).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

stances to be associated with an increase in the shielding of ^{13}C nuclei (10, 13, 14). Thus, a comparison of chemical shift differences between diastereoisomeric cyclohexane derivatives (10, 20, 21) and pyranoses (4, 5) shows that as free energy increases within the series so also, in a relatively consistent fashion, does ^{13}C shielding. A similar trend is found among the current data (Table 4); average chemical shift values (as a measure of the state of overall ^{13}C shielding within each of the molecules (4, 21)) form the following sequences.

tetrosides: **9 < 6 < 10 < 5**

pentosides: **9 < 12 < 7 < 10 < 11 ≈ 6 < 8 ≈ 5**

hexosides: **9 < 12 < 10 < 6 < 7 < 11 < 5 < 8**

That is, those furanosides that have an all-*trans* arrangement of substituents (**9**) and are expected to be most stable (22–24), also possess on the average the least shielded ^{13}C nuclei. Similarly, the introduction of *cis* substituents is accompanied by upfield shifts, and a high incidence of *cis* substituents (**5** or **8**) is associated with the most strongly shielded ^{13}C nuclei.

Hence, as with six-membered ring compounds, it appears reasonable to regard the configurational influences on ^{13}C chemical shifts described here as a reflection of destabilizing steric interactions.

Experimental

^{13}C Nuclear Magnetic Resonance Spectra

^{13}C magnetic resonance spectra of the glycosides were measured at a frequency of 22.63 MHz with a Bruker, WH-90 FT spectrometer, employing a ^{2}H-lock. Deuterium oxide was used as solvent and the signal of tetramethylsilane (in a coaxial tube) served as an external standard. ^{13}C spectra of the cyclopentanols, in water, were recorded with a Varian HA-100 CW spectrometer operating at 25.15 MHz, using the signal of ^{13}C-enriched methyl iodide in a coaxial capillary for the homonuclear field-frequency lock.

Support for some of the signal assignments in the glycofuranoside series was obtained by reference to ^{1}H-coupled spectra of these compounds. Thus, since C-2 can couple with fewer protons (across two and three bonds) than C-3 or C-4 it was expected to account for the least complex signal of the three in a coupled spectrum, and C-4 to give the most complex signal because it can interact with the largest number of protons. A distinction between the C-5 signal of a hexofuranoside and the C-2 or C-3 signal was provided by the finding (assumed to apply generally) that direct coupling ($^{1}J_{C,H}$) for the latter two nuclei is about 10 Hz larger than that for exocyclic C-5. In a number of instances, the conclusions reached on the basis of the comparisons cited above were cross-checked by reference to the coupled spectra of the specifically deuterated compounds, since this verified sources of the two- and three-bond ^{1}H couplings. Signals produced by primary carbons (C-5 of pentosides, C-6 of hexosides) were readily assigned from their triplet appearance (due to directly bonded ^{1}H-coupling).

Numerical Analysis of ^{13}C Chemical Shifts

A comparison of chemical shifts was made between a compound selected as a reference within a given series and each isomer (m) of the series. The observed difference (D_m^k) in the chemical shift of carbon k in the isomer (m = 1, 2, etc.) relative to that of the reference was expressed as the algebraic sum of the individual shielding terms (X_n^k), one for each arrangement of a substituent pair. Then, for carbon k:

$$D_m^{\,k} = \sum_{1}^{n} X_n^{\,k}\, C_{mn}$$

where C = 1 for a *trans* → *cis* interconversion, −1 for *cis* → *trans*, or 0 for no change in configuration.

As an example, the comparison of C-1 of methyl β-alloside (6) with that of the (arbitrary) reference compound, methyl α-alloside (**5**), involves conversion of a *trans* anomer (**6**) into a *cis* (**5**). Hence

$$D_m^{\,1} = 103.8(\delta_{C\text{-}1} \text{ of } \mathbf{5}) - 109.0(\delta_{C\text{-}1} \text{ of } \mathbf{6}) = -5.2$$

Therefore,

$$-5.2 = X_1(1) + X_2(1) + X_3(-1) + X_4(0) + X_5(0) + X_6(0)$$

where X_1, X_2, etc. describe shielding contributions from the six *cis–trans* arrangements of the ring substituents, (1,2) (1,3) (1,4) (2,3) (2,4) (3,4), respectively. Hence, for each carbon (k) of the pento- and hexofuranosides there are six unknowns (X_n^k) and eight compounds (Table 4) for comparison. From the resulting set of seven simultaneous equations, a least-squares fit for the solutions to the six unknowns was determined. Calculations performed with an IBM-360 computer using the double precision IMSL subroutine LLSQAR gave the results recorded in Table 5.

The maximum deviation obtained in recalculating the shift differences from these numbers was ±0.6 p.p.m.

Preparation of Glycosides

Methyl glycofuranosides were prepared by the Fischer reaction (25), *i.e.*, by reaction of the sugars with methanol in the presence of an acid catalyst. The conditions used were varied according to the individual sugar and, in general, correspond to experimental procedures described by various earlier workers, and summarized by Green (26). Mixtures of glycosides were fractionated by conventional preparative chromatographic methods. The ^{13}C n.m.r. spectra described here, as well as the p.m.r. spectra, furnished additional checks on the purity and identity of the various glycosides.

1,2:5,6-Di-O-isopropylidene-α-D-allofuranose-4-d

1,2:5,6-Di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (27) (2.5 g) in D_2O (10 ml) and pyridine (50 ml) was heated for 5 min at 95° and then kept at ambient

temperature for 18 h. The solvents were removed *in vacuo* and the deuterium exchange procedure repeated three times.[8] This was followed by reduction with aqueous borohydride. A solution of the final product in hot petroleum ether (65–110°) was clarified with charcoal and, upon cooling, deposited crystals of the title compound; m.p. 70–73°; deuterium content estimated by n.m.r. spectroscopy, > 95%.

1,2:5,6-Di-O-isopropylidene-α-D-glucofuranose-4-d

Prepared from 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose-4-*d* (above) by inversion at C-3, as described for preparation of the 3-deuterio analog (5).

D-*Glucose-4-d and* D-*Allose-4-d*

Prepared by hydrolysis of the two foregoing di-*O*-isopropylidene derivatives, respectively, in aqueous solution in the presence of Amberlite 1R-120 (H^+) resin.

2-Deacetylchelocardin: A Degradation Product of Chelocardin

DANIEL T. W. CHU, D. L. GARMAISE, AND E. BERNSTEIN

Department of Research, Abbott Laboratories, Limited, P.O. Box 6150, Montreal, Quebec H3C 3K6

Received August 2, 1974

DANIEL T. W. CHU, D. L. GARMAISE, and E. BERNSTEIN. Can. J. Chem. **53**, 1434 (1975).

A novel chemical transformation is described in which chelocardin **1**, under normal ketalization conditions, is converted with elimination of the 2-acetyl group, to the bisdioxolane **2**. Hydrolysis of **2** yields 2-deacetylchelocardin **4**. The properties of the tricarbonylmethane system in **1** and of the 1,3-cyclohexanedione system in **4** are found to be profoundly modified by the presence of the 4-amino and the 12*a*-hydroxyl group.

DANIEL T. W. CHU, D. L. GARMAISE et E. BERNSTEIN. Can. J. Chem. **53**, 1434 (1975).

On décrit une nouvelle transformation chimique au cours de laquelle la chélocardine **1**, sous les conditions normales d'acétalisation, est transformée, par une élimination du groupe acétyle en position 2, en bisdioxolanne **2**. L'hydrolyse de **2** conduit au déacétyl-2 chélocardine **4**. On trouve que les propriétés du système tricarbonylméthane de **1** et du système cyclohexanedione-1,3 de **4** sont affectés d'une façon profonde par la présence d'un groupe amino en position 4 et d'un groupe hydroxyle en position 12*a*. [Traduit par le journal]

Chelocardin, a potent broad spectrum antibiotic produced by *Nocardia sulphurea* (NRRL-2822), was isolated in 1956 and was first described in 1962 (1, 2). Its structure was established by Mitscher *et al.* as **1** (3).

The 2-acetyl-1,3-cyclohexanedione system in ring A suggests a parallel with the tricarbonylmethane antibacterial agents. The purpose of this work was to investigate the chemical behavior of this triketone system and to compare it with the properties of model compounds.

It has been reported that the acetyl group of 2-acetyldimedone is readily split by refluxing dilute sulfuric acid (4). Chelocardin would not withstand such conditions but it was found that a compound later shown to be 2-deacetylchelocardin (**4**) was formed, unreproducibly and in very low yield, when chelocardin was heated with hydrochloric acid in glacial acetic acid.[1] However, a novel transformation of chelocardin (**1**) into 2-deacetylchelocardin (**4**) has been developed as illustrated in Scheme 1.

Ketalization of chelocardin hydrochloride in benzene in the presence of a large excess of ethylene glycol and *p*-toluenesulfonic acid gave an 80% yield of the 1,3-bisdioxolane derivative **2** in which the 2-acetyl group has been eliminated. Its n.m.r. spectrum possesses only two singlets corresponding to the C-6 and C-9 methyl groups. The absence of another singlet signal in the region of δ 0.7–2 (corresponding to the methyl group of the ketalized 2-acetyl group) and the disappearance of the acetyl singlet (δ 2.56 in the parent compound) indicates the loss of the 2-acetyl side chain. This is further substantiated by the disappearance of the band at 1690 cm^{-1} (which represents one of the carbonyl groups in the tricarbonylmethane system) in its i.r. spectrum. All the other n.m.r. signals are consistent with the assigned structure.

Further confirmation of the structure was obtained by converting it to a carbobenzoxy derivative **3**. The i.r. spectrum of **3** showed carbamate absorption at 1720 cm^{-1}. Its n.m.r. spectrum showed the characteristic methylene protons as doublets at δ 1.87 and 2.50, with $J = -15$ Hz, and two sharp singlets for the 6- and 9-methyl groups at δ 2.33 and 2.36, respectively. All the other signals were consistent with the assigned structure.

Hydrolysis of **2** in hydrochloric acid – acetone solution gave 2-deacetylchelocardin (**4**) in 72% yield. Its n.m.r. spectrum showed two singlets at δ 2.15 and 2.35 (6- and 9-methyl groups) and a doublet at δ 5.6 for the H_4 proton indicating that there was no epimerization of the C_4 hydrogen.

This novel chemical transformation (**1** → **4**) can also be achieved by using other diols. For example, treatment of the chelocardin with 1,2-propanediol, under the same reaction conditions, gave the bisdioxolane derivative **5** which was then transformed to the corresponding carbobenzoxy derivative **6** upon treatment with

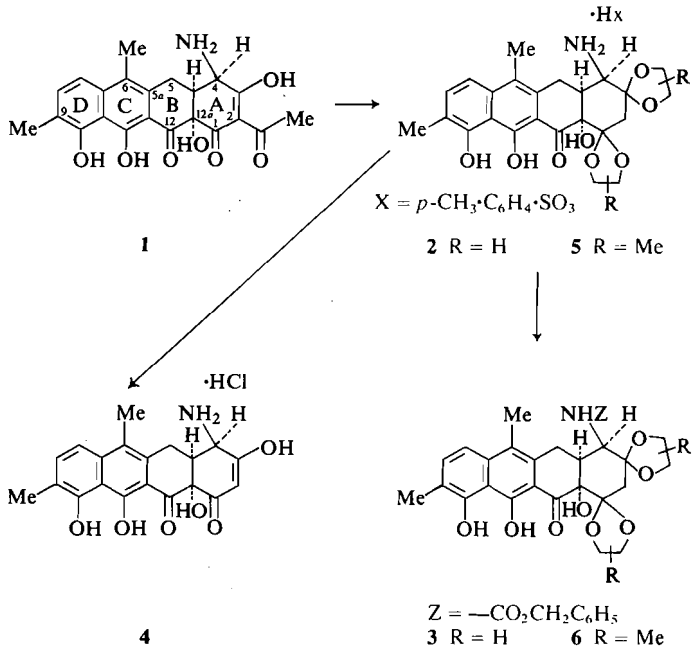
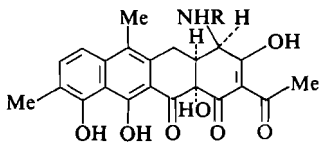


SCHEME 1

carbobenzoxy chloride. Hydrolysis of **5** gave again 2-deacetylchelocardin (**4**).

The elimination of the acetyl group could not be achieved by using ethanol in place of a 1,2-diol or by simple reflux with *p*-TSA in benzene. Additionally, *N*-carbobenzoxychelocardin (**7***a*) and *N*-acetylchelocardin (**7***b*) were recovered unchanged on treatment with ethylene glycol under the same ketalizing conditions.



7
a R = —$CO_2CH_2C_6H_5$
b R = —Ac

It appears then that the unaltered 4-amino group and the presence of a 1,2-diol are required for the reaction to proceed. The importance of the 4-amino group was substantiated further by the observation that 2-acetyldimedone was recovered unchanged when treated with ethylene glycol and *p*-TSA in refluxing benzene.

Unfortunately, other simple triacetyl compounds with a 4-amino group, either with or without the 12*a* hydroxyl group, are not readily available and hence it is not possible to determine whether the presence of the 12*a* hydroxyl is necessary for this transformation. In the absence of further experimental evidence, it is difficult to be definite about the mechanism of this cleavage reaction. At the present moment, we favor the reaction course illustrated in Scheme 2.

The primary approach by the diol is to the exocyclic carbonyl group in the tautomeric form **1***a*. The C-3 carbonyl group serves as the electron sink, owing to the slightly positive charge created by the hydrogen bonding with the 4-amino group. There is other experimental evidence showing that the exocyclic carbonyl group is the most reactive center of the three carbonyl groups and this will be reported later. The initial Michael reaction yields the hemiacetal **8**, which cyclizes by attacking either the C-1 or C-3 to give **9** or **10**. These intermediates are stabilized by elimination of the 2-acetyl group to form **11** or **12** by a retrograde aldol reaction after protonation of C_1 or C_3 carbonyl group. Compound **11** (or **12**) upon the elimination of a molecule of acetic acid gives the intermediate **11***a* (or **12***a*) which is subsequently converted into the bisdioxolane **2**. It has been reported that 1,3-cyclohexanedione and 2-bromo-5,5-dimethylcyclohexanedione-1,3 under the same

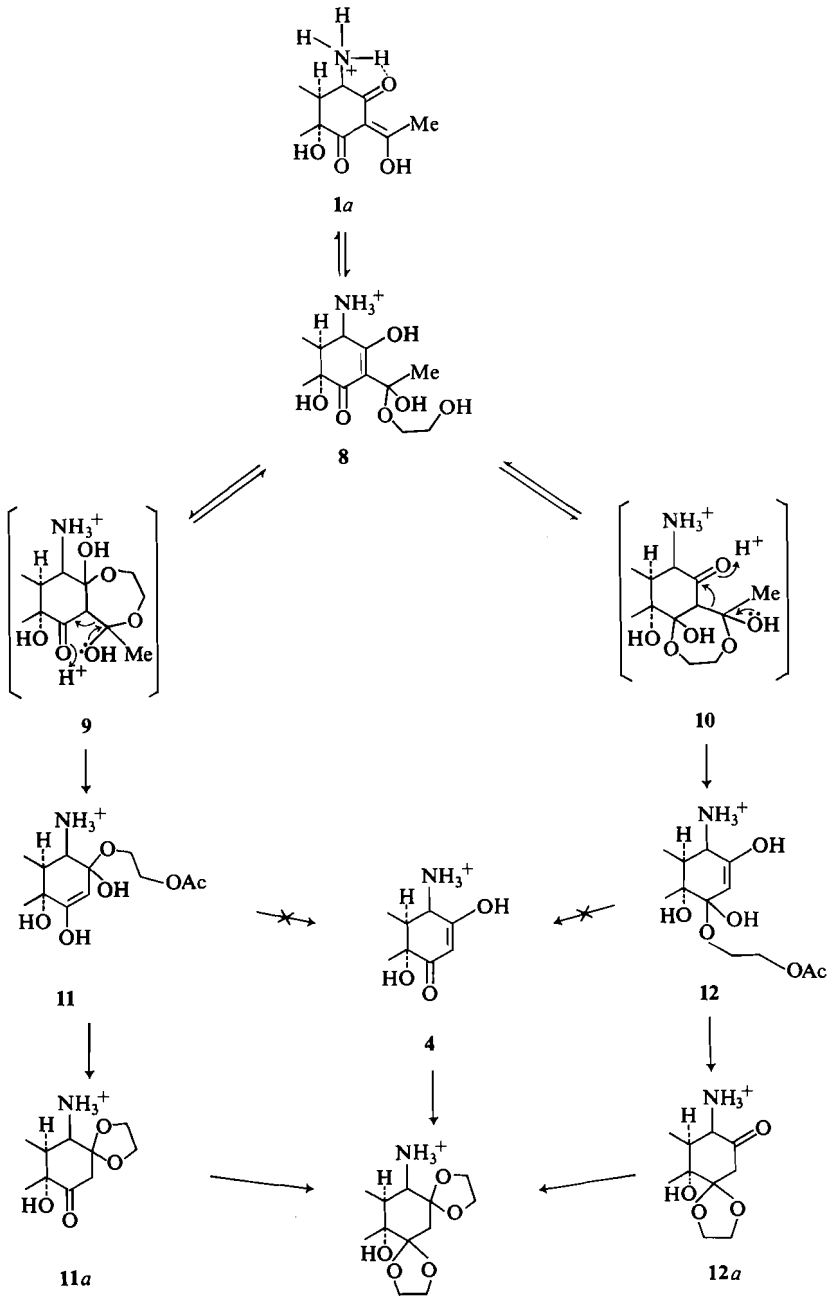

SCHEME 2

ketalization conditions gave the corresponding bisdioxolane (5, 6). We have found that **4** obtained by hydrolysis of the bisdioxolane **2** gives **2** in good yield when treated with ethylene glycol and *p*-TSA. It would be tempting to propose an alternative scheme (**11** → **4** → **2**) involving compound **4** as an intermediate which then would be converted to **2**. But during the course of the reaction, no such intermediate **4** was observed by t.l.c. Since the transformation of **4** into **2**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

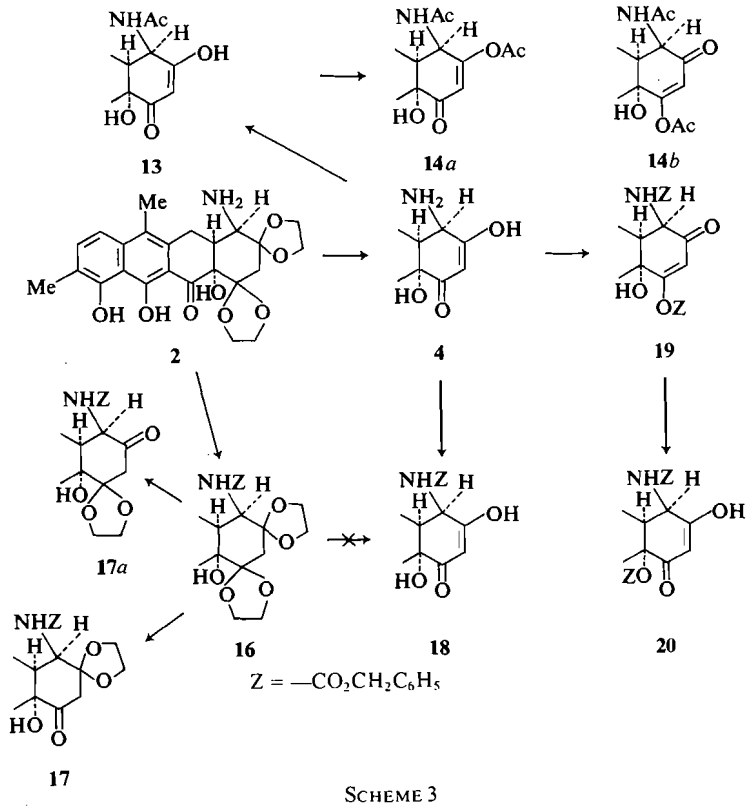


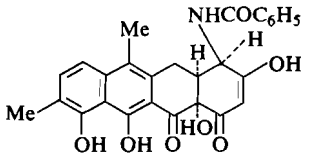
SCHEME 3

under similar conditions required more than 10 h to complete, it is unlikely that the elimination ketalization involves **4** as an intermediate.

Reactions of Deacetylchelocardin

The acylation and alkylation of deacetylchelocardin did not follow the course which might have been expected from model compounds. The unusual behavior of ring A of 2-deacetylchelocardin (**4**) is illustrated in Scheme 3.

Cautious treatment of **4** with acetic anhydride gave the *N*-monoacetyl derivative **13** which was converted on further acetylation to a mixture of *N,O*-diacetyl derivatives **14***a* (or **14***b*) and an *N,O,O*-triacetyl derivative. The diacetyl and triacetyl derivatives were readily hydrolyzed back to the *N*-monoacetyl compound **13**, indicating that there was no trace of *C*-acylation at the 2-position. The addition of sodium acetate to the reaction mixture did not affect this result and none of the *O*-acetyl groups could be rearranged to the 2-position. In contrast, cyclohexane-1,3-dione and dimedone have been converted to the 2-acetyl derivatives by heating with acetic anhydride in the presence of sodium acetate (4, 7). Cyclohexane-1,3-diones yield 2-alkyl derivatives exclusively when treated with α-haloketones (8) but when *N*-benzoyldeacetylchelocardin (**15**) was treated with chloroacetone in refluxing tetrahydrofuran or in refluxing aqueous methanol, the starting material was recovered unchanged.



15

Although the C-2 alkylation of acyclic 1,3-diones is readily effected via the thallium salt (9) and can also be achieved, in lower yields, with cyclic 1,3-diones (10), deacetylchelocardin (**4**) yielded only *O*-alkyl derivatives.

The bisdioxolane **2** yielded an *N*-carbobenzoxy derivative **16**, which on hydrolysis yielded a monoketone-monodioxolane **17** (which may also be represented as the 3-keto-1-dioxolane

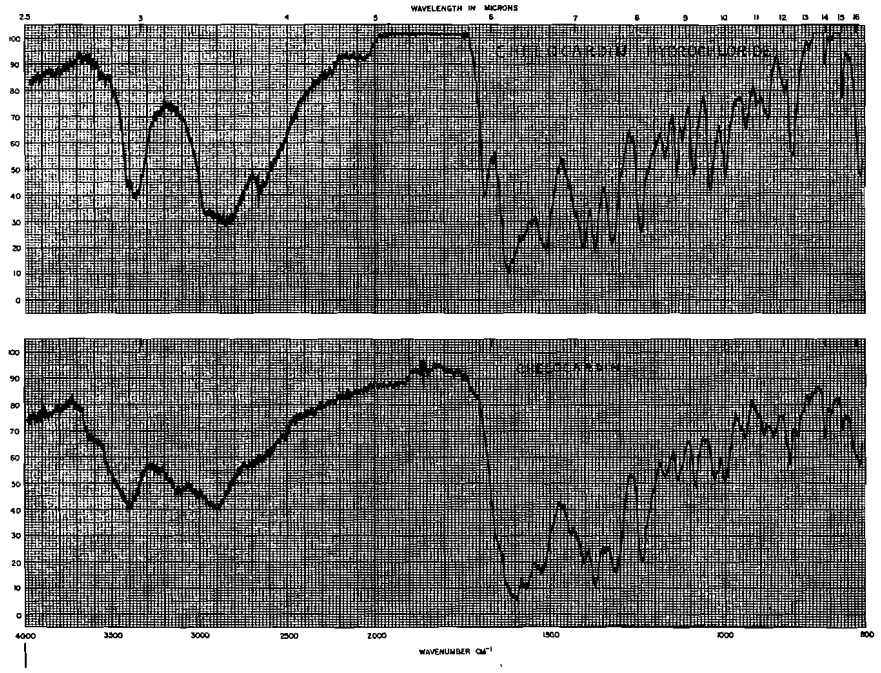

FIG. 1. Infrared spectra of chelocardin and chelocardin hydrochloride as KBr dispersion.

17*a*) and not the 2-deacetylcarbobenzoxy derivative **18**.

Deacetylchelocardin yielded a monocarbobenzoxy derivative **18** and a monobenzoyl derivative **15** when treated cautiously with 1 equiv. of the appropriate reagent. On treatment with excess carbobenzoxy chloride, a dicarbobenzoxy derivative **19** was formed. This substance, on treatment with base, did not hydrolyze to the monocarbobenzoxy derivative but instead rearranged to a stable isomeric dicarbobenzoxy compound, which is formulated as **20**.

The relative ease of this rearrangement (presumably caused by the participation of the neighboring 12*a* hydroxyl group) together with the steric hindrance due to the *N*-carbobenzoxy group at the 4-position, makes it unlikely that the carbobenzoxy group would be in the 3-position.

In summary, we have observed that the presence of the 4-amino and 12*a*-hydroxyl groups profoundly modified the behavior of the tricarbonylmethane system in chelocardin (**1**) and the 1,3-dione system in deacetylchelocardin (**4**).

Experimental Section

The i.r. spectra were recorded on Beckman model IR8 infrared spectrophotometer. The n.m.r. spectra were recorded on Varian Associates A-60 and HA-100 spectrometers in deuterated solvents; resonance positions are given on the δ scale (p.p.m.) relative to internal tetramethylsilane. The n.m.r. peaks were designated as follows: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; b, broad. The high resolution mass spectra were determined on Associated Electrical Industries MS-902 Double Focussing mass spectrometer and were processed on an IBM 1800 computer.

The i.r. absorption spectra of chelocardin and its hydrochloride are shown in Fig. 1. Since the various derivatives reported here have the basic β-hydroxy-α,β-unsaturated carbonyl function which would have a similar absorption to the β-diketone system, very little change in the carbonyl absorption region (1580–1680 cm^{-1}) was observed. However, the changes in relative intensity of the carbonyl absorptions correlated with the structural changes. Thus, only the relevant difference in absorption bands will be mentioned in the experimental section.

2-Deacetylchelocardin-1,3-bisdioxolane (2)

p-Toluenesulfonic acid (6 g; 35 mmol) was added to a suspension of β-chelocardin hydrochloride (14.5 g; 32.4 mmol) in benzene (1500 ml) and followed by the addition of ethylene glycol (17 g; 0.27 mol). The mixture was then refluxed for 48 h with vigorous stirring and azeotropic removal of water. The benzene was decanted. *p*-Toluenesulfonic acid (0.5 g; 3.8 mmol) and ethylene glycol (3 g; 50 mmol) were then added to the benzene portion and the solution refluxed for an additional 3 h. The solution was then evaporated under reduced pressure nearly to dryness. After the addition of ethanol (25 ml), the solution was slowly poured with stirring into ether (1200 ml). The mixture was then filtered and the residue washed with ether yielding 9.5 g solid material.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The solid residue left earlier (after decantation of the benzene) was suspended in 1000 ml of benzene. After the addition of *p*-toluenesulfonic acid (1 g; 6.5 mmol) and ethylene glycol (7 g; 0.11 mmol) this mixture was refluxed for an additional 40 h with removal of water. The second reaction was worked up in a similar manner to the prior ketalization using 15 ml ethanol and 800 ml ether to give 6.5 g solid. Thin-layer chromatographic analysis of the above two solid materials showed one homogeneous spot. The combined product was 16 g (80%) which showed a loss of the 1690 cm^{-1} band in the i.r. spectrum and an n.m.r. spectrum completely consistent with the assigned structure as **2**. (The n.m.r. spectra obtained from chelocardin derivatives in which the 4-amino group is not converted to an amide are usually of poor resolution.) During the course of the reaction, t.l.c. did not show the presence of compound **4**.

Transformation of 2 into 3

Water (25 ml) was added to a solution of **2** (450 mg; 0.72 mmol) in methanol (25 ml) and the mixture was cooled to 3–5 °C. After the addition of sodium bicarbonate (0.5 g; 5.9 mmol) benzylchloroformate (1.3 g; 8 mmol) was added slowly. The ice bath was removed after 5 min and the reaction stirred for an additional 1½ h. The p*H* was adjusted to approximately 1 by the addition of dilute hydrochloric acid at ice temperature and the mixture extracted with chloroform. The organic phase was dried over sodium sulfate, filtered, and evaporated under reduced pressure almost to dryness. After the addition of a small amount of ether the solution was poured with stirring into hexane. Evaporation to a smaller volume and filtration gave a residue which after drying yielded 400 mg (96%) of carbobenzoxy deacetylchelocardin dioxolane **3**. The i.r. spectrum showed a carbamate absorption at 1720 cm^{-1}; n.m.r. ($CDCl_3$): δ 1.87 (d, 1H, C_2-*H*, $J_{ab} = -15$ Hz), 2.33 (s, 3H, C_6-CH_3), 2.36 (s, 3H, C_9-CH_3), 2.50 (d, 1H, C_2-*H*), 3.77 (m, 10H, C_5-*H*; —O—CH_2CH_2—O—), 4.29 (s, 1H, C_{12a}-O*H*), 4.71 (m, 1H, C_{4a}-*H*), 5.17 (s, 2H, —O—CH_2 C_6H_5), 5.21 (d, 1H, C_4-*H*), 7.37 (m, 7H, C_7-*H*, C_8-*H*, and C_6H_5), 10.11 (s, 1H, C_{10}-O*H*), 15.95 (s, 1H, C_{11}-O*H*); *m/e* 591.2097 (calcd.: 591.2105).

Anal. Calcd. for $C_{32}H_{33}NO_{16}$: C, 64.97; H, 5.58; N, 2.37; O, 27.07. Found: C, 64.86, H, 5.39; N, 2.41; O, 26.77.

2-Deacetylchelocardin (4)

The bisdioxolane **2** (10 g; 16 mmol) was dissolved in acetone (500 ml) and 30% hydrochloric acid (500 ml) and the solution was heated at 50 °C for 45 h. An equal volume of saturated sodium carbonate solution was added slowly (to a p*H* of 2–3) and the mixture was then shaken with chloroform. A precipitate was thrown down and this was isolated by filtration. The filtrate was separated into two layers and the chloroform fraction was decanted. The aqueous layer was reextracted with *n*-butyl alcohol. The alcohol portion was then washed with water twice, dried over magnesium sulfate, and filtered. After evaporation under reduced pressure, the crude product was dissolved in ethanol and the solution poured with stirring into ether. The resulting precipitate was collected by filtration to give a total yield of solid of 6 g. The product was further purified by filtration through Sephadex LH20 using 0.01 *M* HCl in methanol as eluent giving 4.6 g (72%) pure 2-deacetylchelocardin hydrochloride (**4**); n.m.r. ($(CD_3)_2SO$): δ 2.15 (s, 3H, C_6-CH_3), 2.35 (s, 3H, C_9-CH_3), 3.25 (m, 5H), 5.6 (d, 1H, C_4-*H*), 7.32 (d, 1H, C_7-*H*, $J_{7,8} = 8.5$ Hz), 7.58 (d, 1H, C_8-*H*), 8.81 (b, 1H, O*H*); *m/e* 369.1211 (calcd.: 369.1207).

Preparation of Substituted Bisdioxolane 5

β-Chelocardin hydrochloride (570 mg; 1.2 mmol) was suspended in benzene (70 ml). After the addition of *p*-TSA (0.12 g; 1.5 mmol) propylene glycol (340 mg; 4.4 mmol) was added. The mixture was then refluxed with azeotropic water removal for 64 h. After concentration under reduced pressure to a small volume, the residue was poured with stirring into *n*-hexane. Filtration yielded 650 mg of the title compound (**5**).

Conversion of 5 to Carbobenzoxy Derivative 6

Compound **5** (300 mg; 0.46 mmol) was dissolved in 50% aqueous methanol (30 ml) and was cooled to 5 °C. Sodium bicarbonate (100 mg; 1.2 mmol) was added, followed by the addition of benzyl chloroformate (300 mg; 0.2 mmol). After stirring for 2 h at room temperature, the reaction mixture was diluted with water and extracted with chloroform. The organic phase was dried, filtered, and evaporated under reduced pressure to a very small volume. Addition dropwise to well stirred hexane gave solid **6** which was isolated by filtration, yielding 290 mg (98%). The i.r. spectrum showed a carbamate absorption at 1720 cm^{-1}; n.m.r. ($CDCl_3$): δ 1.20 (m, 6H, —OCH_2CH(CH_3)—O), 1.97 (m, 1H, C_2-*H*), 2.34 (s, 3H, C_6-CH_3), 2.37 (s, 3H, C_9-CH_3), 2.60 (m, 1H, C_2-*H*), 3.81 (m, 8H, C_5-CH_2; —OCH_2—CH—O), 4.24 (m, 1H, C_{12a}-O*H*), 4.66 (m, 1H, C_{4a}-*H*), 5.15 (s, 2H, —O—$CH_2C_6H_5$), 5.20 (m, 1H, C_4-*H*), 7.36 (m, 7H, C_7-*H*; C_8-*H* and C_6H_5), 10.13 (s, 1H, C_{10}-O*H*), 15.96 (s, 1H, C_{11}-O*H*).

Anal. Calcd. for $C_{34}H_{37}NO_{10}$: C, 65.90; H, 5.98; N, 2.26; O, 25.85. Found: C, 66.00; H, 6.20; N, 2.21; O, 25.30.

Acetylation of 2-Deacetylchelocardin (4)

Deacetylchelocardin hydrochloride (**4**) (100 mg; 0.25 mmol) was added to a stirred solution of sodium acetate (20 mg; 0.25 mmol) in acetic anhydride (4 ml). After 10 min, the starting material was completely converted to a mixture of two products A and B. After 1 h, the reaction mixture consisted of two products B and C with the loss of A. The R_f values of A, B, and C (developed on silica gel using a solvent system of hexane – ethyl acetate – formic acid 40:60:5) were 0.30, 0.41, and 0.63, respectively. The reaction was worked up after an additional 1 h by pouring into 20 ml ice cold water and stirring for 30 min. The solvents were removed by filtration and the solid was taken up in chloroform, washed twice with water, and dried. Evaporation of the solvent under reduced pressure gave 119 mg crude mixture. Forty milligrams of this was eluted from a silica gel column giving 10 mg sample of a *N,O,O*-triacetylated product C confirmed by mass spectroscopy. The product B was isolated by gel filtration through Sephadex LH20 column using methanol as eluent. Its structure was confirmed to be *N,O*-diacetylated product **14***a* or *b* confirmed by mass spectroscopy. The presence of normal fragmentation pattern excluded the presence of a phenolic acetate group. Compound A could be prepared in high purity by following the reaction by t.l.c. and stopping the reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

after a short time even though the starting material was still present. The i.r. and n.m.r. spectra of the pure sample were consistent with the assigned structure of the *N*-monoacetyl derivative (**13**).

*N-Benzoyldeacetylchelocardin (**15**)*

Benzoyl chloride (34.6 mg; 0.25 mmol) dissolved in tetrahydrofuran (2 ml) was added dropwise to a stirred solution of 2-deacetylchelocardin hydrochloride (**4**) (100 mg; 0.25 mmol) in 12 ml of 30% aqueous THF. The p*H* was adjusted to between 8 and 8.5 with 7% sodium hydroxide solution. When the addition was completed, the stirring was continued for ½ h at room temperature and the aqueous solution acidified to p*H* ~ 2 with 5% hydrochloric acid. After the addition of more water, the precipitate was filtered, washed with water and a small amount of ether, then dried, yielding 84 mg product. The i.r. spectrum showed a carbamate absorption at 1720 cm^{-1} (weak). The n.m.r. spectrum was consistent with the assigned structure **15**. Its mass spectrum had a *m/e* peak at 473.1470 (calcd. for $C_{27}H_{23}NO_7$ 473.1474).

*N-Carbobenzoxydeacetylchelocardin (**18**)*

To a solution of deacetylchelocardin hydrochloride (**4**) (200 mg; 0.49 mmol) in 20 ml of 30% aqueous THF (adjusted to a p*H* 8.5 with 7% sodium hydroxide) carbobenzoxy chloride (84 mg; 0.49 mmol) in tetrahydrofuran (5 ml) was added dropwise over a 30 min period. At the end of the reaction the p*H* was 7 and the starting material was converted completely into two products, one major. Water (500 ml) was then added, the p*H* adjusted to 2, and the product extracted with ether (2 × 50 ml) which was dried and evaporated under reduced pressure to dryness. Recrystallization from benzene followed by glacial acetic acid afforded a pure product m.p. 223–226 °C; *m/e* was found to be 503.1572 (calcd. for $C_{28}H_{27}NO_8$ 503.1580). The i.r. spectrum showed a carbamate absorption at 1720 cm^{-1}; n.m.r. ($CDCl_3$): δ 2.24 (s, 3H, C_6-C*H*$_3$), 2.32 (s, 3H, C_9-C*H*$_3$), 3.25 (m, 1H, C_5-*H*), 3.46 (d, 1H, C_2-*H*, $J_{ab} = -15$ Hz), 4.44 (d, 1H, C_2-*H*), 5.16 (s, 2H, —C*H*$_2$—C_6H_5), 5.39 (m, 1H, N*H*), 5.88 (m, 1H, C_4-*H*), 7.45 (m, 8H, C_7-*H*; C_8-*H*; C_6H_5; O*H*), 15.0 (bs, 1H, O*H*).

*Preparation of Monodioxolane (**17**)*

The carbobenzoxybisdioxolane **16** (110 mg; 0.2 mmol) was dissolved in a mixture of acetone (11 ml) and hydrochloric acid (5.5 ml, 30%). After heating at 50 °C for 5½ h, water (55 ml) was added and the mixture filtered. The solid was purified by dry column chromatography on silica gel using ethyl acetate as eluent yielding 85 mg (84%) monodioxolane **17** (or **17***a*). Its mass spectrum showed the *m/e* at 547.1856 (calcd. for $C_{30}H_{29}NO_9$ 547.1842); n.m.r. ($CDCl_3$): δ 2.27 (s, 3H, C_6-C*H*$_3$), 2.33 (s, 3H, C_9-C*H*$_3$), 2.75 (m, 2H, C_2-C*H*$_2$), 3.52 (m, 7H, —OC*H*$_2$C*H*$_2$—O; C_5-C*H*$_2$, N*H*), 4.50 (m, 1H, C_5-*H*), 4.68 (sb, 1H, C_{12a}-O*H*), 5.13 (s, 2H, OC*H*$_2$—C_6H_5), 5.87 (d, 1H, C_4-*H*), 7.35 (m, 7H, C_7-*H*; C_8-*H*; C_6H_5), 10.17 (s, 1H, C_{10}-O*H*), 15.75 (bs, 1H, C_{11}-O*H*).

*Preparation of Dicarbobenzoxy Derivative **19***

2-Deacetylchelocardin hydrochloride (**4**) (190 mg; 0.47 mmol) was dissolved in a mixture of methanol (10 ml) and ether (10 ml). Sodium bicarbonate (190 mg; 2.4 mmol), followed by carbobenzoxy chloride (500 ml; 3 mmol) was added and the mixture was stirred at ice temperature for ½ h. After stirring at room temperature for a further 2 h, the p*H* of the mixture was adjusted to 3 by the addition of dilute hydrochloric acid solution. The mixture was then extracted with chloroform which was subsequently filtered and evaporated to give a solid residue. A small quantity of ethanol was added to dissolve this solid, which was subsequently reprecipitated by the addition of a small amount of ether and then a large amount of hexane. Filtration gave 190 mg of pure **19** (64%). Its i.r. spectrum showed an enol carbonate absorption at 1775 cm^{-1}. Its n.m.r. spectrum contained a characteristic singlet at δ 5.15 having an intensity corresponding to four protons when compared to the two aromatic methyl signals and was assigned to the four methylene protons of the benzyl groups. Mass spectrum showed *m/e* at 637.1935 (calcd. 637.1948).

Anal. Calcd. for $C_{36}H_{31}NO_{10}$: C, 67.82; H, 4.87; N, 2.20; O, 25.12. Found: C, 67.60; H, 5.03; N, 2.34; O, 25.48.

*Base Treatment of **19***

Compound **19** (130 mg; 0.2 mmol) was added to a mixture of ethanol (10 ml) and aqueous saturated sodium carbonate solution (2 ml). After stirring for 30 min, the p*H* of the mixture was adjusted to 3 followed by extraction with chloroform, which was washed subsequently, dried, filtered, and evaporated to dryness under reduced pressure. The residue was purified by gel filtration through Sephadex LH20 using 0.01 *M* HCl in methanol as eluent; 75 mg of pure **12***a* carbonate derivative **20** was isolated. Its i.r. spectrum showed a carbonate absorption at 1755 cm^{-1} and carbamate absorption at 1720 cm^{-1}.

Anal. Calcd. for $C_{36}H_{31}NO_{10}$: C, 67.82; H, 4.87; N, 2.20; O, 25.12. Found: C, 67.68; H, 4.91; N, 2.41; O, 25.19.

*Transformation of 2-Deacetylchelocardin (**4**) into **2***

2-Deacetylchelocardin (**4**) (40.5 mg; 0.1 mmol) was dissolved in benzene (10 ml). *p*-Toluenesulfonic acid (22 mg; 0.19 mmol) was added to the solution and followed by the addition of ethylene glycol (34 mg; 0.54 mmol). The mixture was then refluxed with vigorous stirring and azeotropic removal of water. The progress of the reaction was monitored by t.l.c. and the reaction was nearly complete in about 11 h. After refluxing for 16 h, the benzene solution was then evaporated under reduced pressure nearly to dryness. After the addition of ethanol (1 ml), the solution was added slowly with stirring into ether (50 ml). The mixture was filtered and the residue was washed with ether yielding 45 mg solid material (91%) which gave i.r. and n.m.r. spectra identical to those of 2-deacetylchelocardin-1,3-bisdioxolane (**2**).

We thank R. S. Egan and M. I. Levenberg of Abbott Laboratories for the n.m.r. and mass spectra, respectively, and the staff of the microanalytical department of Abbott Laboratories for the elemental analysis.

Kinetics of the Fully Inhibited Thermal Decomposition of Bistrifluoromethyl Peroxide, CF_3OOCF_3[1]

BERNARD DESCAMPS AND WENDELL FORST

Molecular Dynamics Group, Department of Chemistry, Université Laval, Québec, Québec G1K 7P4

Received December 2, 1974

BERNARD DESCAMPS and WENDELL FORST. Can. J. Chem. **53**, 1442 (1975).

The pyrolysis of CF_3OOCF_3 (BTMP) was studied in the gas phase from 5 to 100 Torr BTMP pressure and between 197 and 244 °C in a clean nickel reactor by the static method. CF_3O radicals, due to the initial split $CF_3OOCF_3 \xrightarrow{[1]} 2CF_3O$, were scavenged by SO_3F radicals produced *in situ* by the thermal decomposition of their dimer $S_2O_6F_2$. Under these conditions, CF_3OOSO_2F is the only product of BTMP pyrolysis, as shown by gas chromatographic analysis. Thus the BTMP pyrolysis becomes fully inhibited and the rate of accumulation of CF_3OOSO_2F is a measure of k_1. The rate constant k_1 turns out to be pressure-insensitive under the experimental conditions, from which it is inferred that k_1 is actually $k_{1\infty}$, the limiting high-pressure unimolecular rate constant for reaction 1. Its temperature dependence yields the result

$$k_{1\infty}\ (s^{-1}) = 10^{15.9\pm0.23} \exp\{-(46.2 \pm 0.5\ \text{kcal/mol})/RT\}$$

This result is compared with other values of the O—O bond dissociation energy in BTMP. The experimental expression for $k_{1\infty}$ is used to construct the pressure falloff of k_1 following the procedure of Forst. The calculation confirms that falloff begins only below 10 Torr.

BERNARD DESCAMPS et WENDELL FORST. Can. J. Chem. **53**, 1442 (1975).

La pyrolyse du CF_3OOCF_3 (BTMP) a été étudiée en phase gazeuse par la méthode statique à des pressions de 5 à 100 Torr de BTMP, et des températures variant entre 197 et 244 °C, dans un réacteur "propre" en nickel. Les radicaux CF_3O, provenant de la scission initiale $CF_3OOCF_3 \xrightarrow{[1]} 2CF_3O$, ont été captés par les radicaux SO_3F produits *in situ* par la décomposition thermique de leur dimère $S_2O_6F_2$. Sous ces conditions, CF_3OOSO_2F est le seul produit de la pyrolyse du BTMP, comme nous l'avons démontré par analyse chromatographique. Ainsi la pyrolyse du BTMP devient totalement inhibée et la vitesse d'accumulation du CF_3OOSO_2F est la mesure de k_1. La constante de vitesse k_1 s'avère être insensible à la pression sous nos conditions expérimentales, d'où nous concluons que k_1 est en fait $k_{1\infty}$, la constante de vitesse monomoléculaire de la réaction 1 dans la limite des hautes pressions. Sa dépendance de température donne

$$k_{1\infty}\ (s^{-1}) = 10^{15.9\pm0.23} \exp\{-(46.2 \pm 0.5\ \text{kcal/mol})/RT\}$$

On compare ce résultat à d'autres valeurs de l'énergie de la liaison O—O dans le BTMP. L'expression expérimentale pour $k_{1\infty}$ est ensuite utilisée pour la reconstitution de la courbe de la chute de k_1 avec la pression, suivant la procédure de Forst. Ce calcul confirme que k_1 ne chute qu'au dessous de 10 Torr.

Introduction

The pyrolysis of bistrifluoromethyl peroxide CF_3OOCF_3 (BTMP) is a complex reaction initiated by CF_3O radicals (1).[2] Even initial rate measurements yield an overall rate constant that actually involves, in our interpretation (1), rate constants for three different reaction steps, two of which are the initial split of BTMP into two radicals and their recombination

$$CF_3OOCF_3 \underset{[2]}{\overset{[1]}{\rightleftharpoons}} CF_3O + OCF_3$$

Thus the rate of the unimolecular dissociation of BTMP into two CF_3O radicals is not directly accessible to measurement. Because of the intrinsic interest of simple bond-fission unimolecular reactions, it seemed worthwhile to attempt to modify the course of the pyrolysis in such a way that only reaction 1 would occur, which can be accomplished by scavenging all CF_3O radicals.

[1]This paper is dedicated to Professor C. A. Winkler of McGill University on the occasion of his sixty-fifth birthday by one of his former students (W.F.).

Several compounds, *e.g.* SF_4, O_2, and CF_4 are known (2) to form adducts with CF_3O radicals, but these adducts generally are not stable above 200 °C, the temperature of BTMP pyrolysis. Schumacher and co-workers (3) have found that the fluorosulfate free radical SO_3F is not only an efficient scavenger for CF_3O radicals via the reaction

[3] $$SO_3F + CF_3O \rightarrow CF_3OOSO_2F$$

but the trifluoromethyl peroxyfluorosulfonate CF_3OOSO_2F (TPS) so formed is stable around 230 °C. As a result, they were able to use reaction 3 to successfully scavenge CF_3O radicals produced in the process $CF_3OF \rightarrow CF_3O + F$.

The purpose of this work is to use reaction 3 to scavenge all CF_3O radicals produced in reaction 1. Hopefully, the BTMP pyrolysis thus becomes fully inhibited, making it possible to determine k_1, the rate constant for the unimolecular fission of BTMP into two CF_3O radicals.

Experimental

Materials

Peroxydisulfuryl difluoride $S_2O_6F_2$, the source of SO_3F radicals, was prepared by the method of Shreeve and Cady (4) from Sulfan-B (Baker & Adamson) and F_2. The method produces as byproduct substantial amounts of SO_3F_2 which were removed by distillation. Purity of $S_2O_6F_2$ was checked by infrared, but this method does not reveal traces of the fluorine fluorosulfate SO_3F_2 impurity because of the similarity of their infrared spectra (5).

Other materials were as described before (1).

Apparatus

The same static system described previously (1) was employed, with the same "clean" nickel reactor. The reactor was conditioned with 5–6 Torr of BTMP for several minutes immediately prior to a run.

Analysis

Analysis was done by gas chromatography with a gas density detector. The analytical problem was a difficult one and is described elsewhere (6). While we estimate the precision of successive analyses done on the same day to be about 5%, the actual accuracy over the several months it took to complete this work was only within 10 or 15% because of temperamental behavior of the chromatographic column. Consequently experimental error in the reported *individual* rate constants is somewhat larger than it would be in a better-behaved system. However these individual errors seem to average out in a *collection* of rate constants obtained at the same temperature because an excellent Arrhenius plot is obtained (Fig. 4 and eq. 9).

Infrared analysis was used for the determination of COF_2.

It is the property of the gas density detector that weight of component x is proportional to corrected peak area $S_x = F_x S_x'$. Here (7) S_x' is the actual peak area corresponding to component x and F_x is a correction factor given by $M_x/(M_x - M_c)$, where M_x = molecular weight of component x, M_c = molecular weight of carrier gas (28.013 since nitrogen was used). Thus $F_x = 1.19728$ for BTMP, 1.17951 for TPS, and 1.16468 for $S_2O_6F_2$.

Procedure

Mixtures of BTMP and $S_2O_6F_2$, prepared in a standard gas-handling system, were introduced into the reactor by expansion from a reference volume. Because both compounds are heavy gases, they mix by diffusion only very slowly and a magnetic mixer had to be used to insure proper mixing. Inasmuch as $S_2O_6F_2$ tends to be strongly adsorbed on the walls, the mixing vessel (and also the reference volume) was heated to 100 °C. Analysis of mixtures after prolonged mixing at 100 °C or condensing in liquid air always showed that composition had remained unchanged; in particular, analysis established the absence, even in trace amounts, of compounds other than BTMP and $S_2O_6F_2$.

The total pressure in the reactor was monitored by a pressure transducer. After a predetermined reaction time, corresponding to no more than ~5% decomposition of BTMP, the contents of the reactor were condensed in a liquid nitrogen trap, and after warm-up and remixing an aliquot was analyzed by gas chromatography.

On introduction into the reactor, the equilibrium between $S_2O_6F_2$ and SO_3F radicals is established practically instantaneously (see Preliminary Results), so that the initial partial pressure of BTMP (P_0) must be calculated from the measured total pressure inside the reactor (P_t). Suppose a gas mixture containing, at room temperature, a mol of BTMP and b mol of $S_2O_6F_2$, was introduced into the reactor. At reactor temperature, x mol of $S_2O_6F_2$ dissociate to form $2x$ mol of SO_3F radicals; thus the total number of mol in the reactor is $a + b + x$. The partial pressures of the radicals and their dimer are $P_{SO_3F} = 2xP_t/(a + b + x)$, $P_{S_2O_6F_2} = (b - x)P_t/(a + b + x)$, and the equilibrium constant is $K_p = 4x^2P_t/(a + b + x)(b - x)$. Since K_p is known (eq. 6), x can be calculated. Then $P_0 = aP_t/(a + b + x)$.

$S_2O_6F_2$ condenses easily (b.p. ~ 67 °C), so that the highest pressure attainable in the reference volume before condensation took place limited the maximum pressure in the reactor to about 250 Torr.

Preliminary Results

The fluorosulfate free radicals SO_3F were generated *in situ* by the thermal homolytic cleavage of their dimer, the peroxydisulfuryl difluoride $S_2O_6F_2$, a well-known reaction (8–11)

$$S_2O_6F_2 \underset{[5]}{\overset{[4]}{\rightleftharpoons}} 2SO_3F$$

The equilibrium constant for this reaction in the gas phase was measured as a function of temperature by Dudley and Cady (8) who give

[6] $$\log_{10} K_p\,(\text{atm}) = 7.981 - 4.785 \times 10^3\, T^{-1}$$

To be useful for inhibition purposes, the equilibrium between the fluorosulfate free radical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and its dimer must be established in a time that is short compared with the time it takes for BTMP to yield measurable amounts of products at the reaction temperature (~250 °C); in addition, neither the radical nor its dimer must decompose themselves. To check this, 90 Torr of dimer $S_2O_6F_2$ was introduced into the reactor at 253.5 °C. The dissociation of the dimer increases the number of molecules, and from eq. 6 about a 50% pressure increase could be expected at 254 °C; however, after a brief initial pressure disturbance in the reactor due to the introduction of the gas and its heat-up, no pressure change was noted in the reactor, suggesting that the equilibrium between SO_3F and its dimer is established practically instantaneously. At this temperature, the half-life of the (uninhibited) BTMP pyrolysis at initial pressures of 20 Torr or higher is about 2 h, as determined from initial rates (1), so that the dimer $\rightleftharpoons 2SO_3F$ equilibrium is certainly established quickly enough. After 37 min at 253.5 °C, the contents of the reactor were trapped out and analyzed by chromatography. The initial amount of the dimer was recovered *in toto* and no other compounds were detected, indicating that no measurable degradation of the dimer or of the radical had occurred. Clearly then the dimer $\rightleftharpoons 2SO_3F$ equilibrium has all the useful properties for inhibition purposes.

If a mixture of BTMP and $S_2O_6F_2$ is introduced into the reactor, only reactions 1, 3, 4, and 5 will take place if all CF_3O radicals are scavenged. If not, other reactions of CF_3O radicals will occur (1), leading ultimately to the formation of COF_2 and CF_3OF. Of the two products, which are produced in equimolar amounts, COF_2 is very easily determined by infrared, and therefore we have used COF_2 as indicator of the degree of scavenging. The practical problem is to determine the $S_2O_6F_2$:BTMP ratio necessary to cause the disappearance of COF_2; we refer here to "cold" dimer, as measured out during the preparation of gas mixtures, and not to the actual amount of dimer present at reactor temperatures. The results are shown in Fig. 1 from which it may be deduced that about a twofold excess of (cold) $S_2O_6F_2$ over BTMP is necessary for complete disappearance of COF_2 (it can be calculated from eq. 6 that at 233 °C between 50 to 75% of the dimer is dissociated, depending on pressure). However even if the $S_2O_6F_2$:BTMP ratio is unity, only about 0.5% of BTMP ends up as COF_2, an amount that is quite clearly unimportant because the rate constant k_1 remains unchanged (Fig. 1).

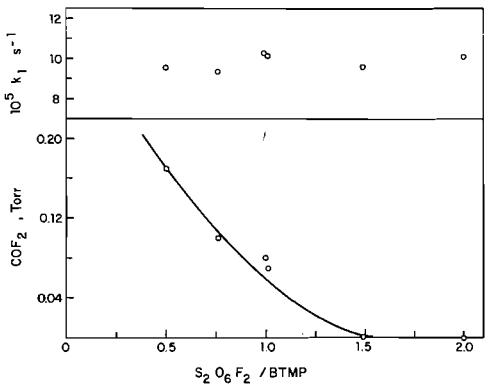

FIG. 1. Effect of varying $S_2O_6F_2$/BTMP ratio at 233.3 °C. $S_2O_6F_2$/BTMP is the ratio of pressures of the two compounds in cold mixtures. Initial pressure of BTMP in reactor constant at $P_0 \sim 17.5$ Torr. Upper portion, rate constant k_1 as a function of $S_2O_6F_2$/BTMP; lower portion, COF_2 produced in the reactor as a function of $S_2O_6F_2$/BTMP.

Results

Preliminary results show that in gas mixtures containing (at room temperature) at least equal amounts of $S_2O_6F_2$ and BTMP, the overall reaction around 250 °C is simply

[7] $CF_3OOCF_3 + S_2O_6F_2 \rightarrow 2CF_3OOSO_2F$

This can be interpreted as the result of the sequence of reactions

[1] $CF_3OOCF_3 \rightarrow 2CF_3O$ (rate-determining)

[3] $CF_3O + SO_3F \rightarrow CF_3OOSO_2F$

Reaction 3, like every reaction between two radicals, can be reasonably expected to have a large rate constant, of the order of the collision number; reaction 1, on the other hand, must be a rather slow process because it will have an appreciable activation energy. In our system, the concentration of SO_3F radicals in equilibrium with their dimer is fairly high, of the order of the concentration of BTMP itself, so that we have $k_3[SO_3F] \gg k_1$; thus reaction 1 is rate-determining. Since the equilibrium dimer $\rightleftharpoons 2SO_3F$ is established practically instantaneously, the CF_3O radicals, which are produced at a comparatively slow rate, encounter a SO_3F radical before they have a chance to encounter one of their own kind, and are effectively removed via reaction 3, the product TPS having

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

been shown to be stable at the temperature of the experiment. Such efficient scavenging of CF_3O radicals means that their steady-state concentration is very low, which insures that the reverse reaction 2 is suppressed, in addition to all the other reactions of CF_3O radicals mentioned in ref. 1.

Consequently the rate of formation of TPS can be taken to be a measure of the rate of reaction 1, the unimolecular fission of BTMP into two CF_3O radicals. Let the initial pressure of BTMP in the reactor at time t_0 be P_0, and let ΔP represent the amount of BTMP decomposed in the time interval Δt; then the ratio of concentrations (or pressures) of product and reactant at time $t = t_0 + \Delta t$ is r = [TPS]/[BTMP] $= 2\Delta P/(P_0 - \Delta P)$, whence $\Delta P = rP_0/(r + 2)$. The ratio r is obtained directly from gas chromatographic peaks as $r = (S_{TPS}/S_{BTMP}) \times (M_{BTMP}/M_{TPS})$, where S_x and M_x are the corrected peak area (see Experimental) and molecular weight, respectively, of component x. The first-order rate constant k_1 is then given by

$$[8] \qquad k_1 = \frac{1}{P_0 - \Delta P/2}\frac{\Delta P}{\Delta t} = \frac{2r}{\Delta t(r + 4)}$$

where $P_0 - \Delta P/2$ is the mean pressure of BTMP during the interval Δt.

Calculation of k_1 by eq. 8 assumes that ΔP rises linearly with Δt. Figure 2 shows that this is indeed the case, except that some curvature appears at very small Δt, corresponding to about 0.5% decomposition of BTMP. The reasons for this are not quite clear; analytical difficulties at such small conversions, or possibly a slight delay in the establishment of complete equilibrium between the SO_3F radicals and their dimer, may be a factor. The latter possibility seems more probable since the length of the curved portion appears to be more related to the absolute value of the time interval than to the amount of conversion. The consequence is that our practice to calculate k_1 from the amount of TPS present at ~5% decomposition may lead to a slight underestimation of k_1, although we believe it to be smaller than the fluctuation in k_1 due to experimental error (Table 1).

Figure 3 shows k_1 as a function of total pressure P_t in the reactor, at fixed initial pressure P_0 of BTMP. Clearly there is no discernible effect within experimental error; the same conclusion emerges from the complete results at five temperatures shown in Table 1. The manifest constancy of k_1 (within experimental error) at any one temperature, regardless of P_0, revealed at the same time in Table 1, shows that the reaction is in fact of the expected first order. If the reaction were some kind of second-order bimolecular process (between BTMP and $S_2O_6F_2$ or SO_3F) giving TPS directly, we would have $\Delta P/\Delta t = kP_0(P_t - P_0)$. Since P_t in our experiments is constant (Table 1), $P_t - P_0$ is proportional to the concentration of $S_2O_6F_2$ or SO_3F. Then $k_1 \sim \Delta P/P_0\Delta t = k(P_t - P_0)$, or, in other words, k_1 should *decrease* with increasing P_0, whereas for a unimolecular process k_1 can only

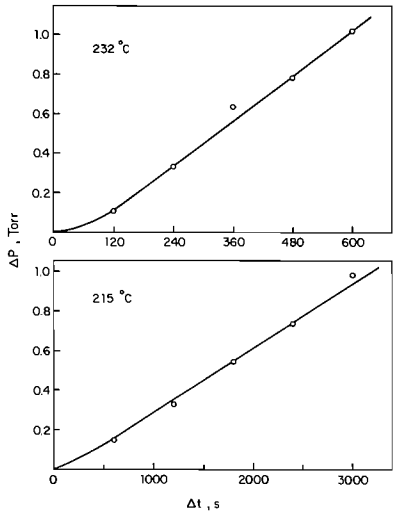

FIG. 2. Amount of BTMP decomposed (ΔP) as a function of reaction time (Δt) at two temperatures. Initial pressure of BTMP in reactor is P_0 = 17.5 Torr in both cases; thus ΔP = 1 Torr represents 5.7% decomposition. Each experimental point represents a separate experiment.

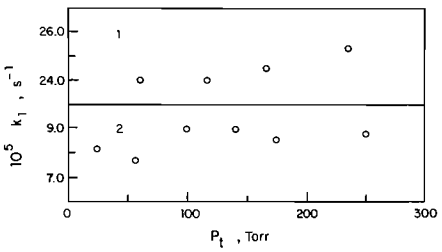

FIG. 3. Rate constant k_1 as a function of total pressure P_t in reactor: (*1*) 244.0 °C, P_0 constant at ~19 Torr; (*2*) 233.4 °C, P_0 constant at ~9 Torr. P_t is the sum of partial pressures of BTMP, SO_3F, and $S_2O_6F_2$. P_0 is the initial partial pressure of BTMP in the reactor.

*Mole fraction of BTMP in cold (BTMP + $S_2O_6F_2$) mixtures.
†Last decimal not significant.

increase or remain constant. The fact that our k_1 is constant under our experimental conditions shows that it is actually $k_{1\infty}$, the limiting high-pressure unimolecular rate constant for reaction 1.

The average rate constant at each of the five temperatures, as given in Table 1, is denoted $k_{1\infty}$ and is plotted in Fig. 4 in the form of an Arrhenius plot which yields the activation energy $E_{1\infty} = 46.2$ kcal/mol. The full least squares result is

$$[9] \quad k_{1\infty} = 10^{15.94\pm0.23} \exp\{-(46\,200 \pm 510)/RT\}\ s^{-1}$$

As a first approximation, we may take $E_{1\infty}$ to be equal to $D(CF_3O—OCF_3)$, the strength of the O—O bond in BTMP. In fact, the value $D(CF_3O—OCF_3) = 46.2$ kcal/mol appears to fit in quite well with other information, thermochemical and kinetic, available about the uninhibited pyrolysis (1) of BTMP.

Levy and Kennedy (12) first reported $D(CF_3O—OCF_3) = 40.6 \pm 5$ kcal/mol, based on measurements of the equilibrium $CF_3OOCF_3 \rightleftharpoons CF_3OF + COF_2$, and later (13) determined $D(CF_3O—OCF_3) = 46.2 \pm 0.33$ from the temperature dependence of initial rate in BTMP pyrolysis. Our value for the O—O bond strength

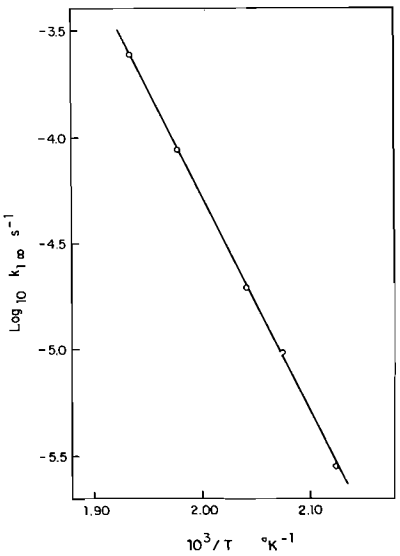

FIG. 4. Arrhenius plot for average k_1 of Table 1 (denoted as $k_{1\infty}$). The activation energy is $E_{1\infty} = 46.2 \pm 0.5$ kcal/mol.

thus agrees exactly with their second determination, an agreement that is no doubt entirely fortuitous. Not only does our interpretation of the (uninhibited) pyrolysis (1) differ fundamentally from theirs, but we also find the temperature dependence of the initial rate yields an activation energy 3.5 kcal/mol higher than theirs (49.7 kcal/mol).

Equation 9 shows that reaction 1 has a rate constant with the expected "high" pre-exponential factor (A_∞) typical of simple bond-fission unimolecular reactions (ref. 14, p. 178). For example, in the pyrolysis of hexafluoroazomethane, a very similar molecule, experiment gives (15) $A_\infty = 10^{16.2}$. If it is assumed that randomization of internal energy precedes decomposition, *i.e.* that the decomposition of BTMP is statistical, the information contained in eq. 9 can be used to reconstruct the thermal falloff curve for k_1 following the deconvolution procedure of Forst (ref. 14, chapt. 11, sect. 2). The usefulness of this procedure has been demonstrated in a number of instances (16–25). Briefly, the procedure consists of showing that if k_∞ in a thermal system is known in the form $k_\infty = A_\infty \exp(-E_\infty/RT)$, the microcanonical unimolecular rate constant of specified energy $k(E)$ can be written (neglecting centrifugal effects)

$$[10] \quad k(E) = A_\infty N(E - E_\infty)/N(E) \qquad (E \geqslant E_\infty)$$

where $N(E)$ and $N(E - E_\infty)$ are the densities of states of the reactant molecule at energies E and $E - E_\infty$, respectively. Thus only the experimental k_∞ and properties of the reactant molecule are necessary; no transition state need be postulated since no transition state properties are involved in eq. 10. The rate constant $k(E)$ of eq. 10 can then be substituted into the usual (statistical, or RRKM) rate constant integral to yield

$$[11] \quad k/k_\infty = \frac{1}{Q}\int_0^\infty \frac{N(x)e^{-x/RT}\,dx}{1 + \dfrac{A_\infty N(x)}{ZPN(x + E_\infty)}}$$

where Q = partition function, Z = collision number, and P = pressure. Numerical evaluation of the integral for several values of P then gives the falloff curve.

Figure 5 shows the result of calculations done for BTMP at the midpoint of the temperature range investigated, in the form of the usual $\log(k_1/k_{1\infty})$ *vs.* $\log P_0$ plot obtained by numerical integration of eq. 11. It can be seen that the falloff is quite slow, even for a molecule the size of BTMP, because of its low vibrational frequencies. Figure 5 thus bears out our experimental results which show that the rate constant k_1 is virtually pressure-independent above $P_0 \sim 10$ Torr. This conclusion would not be modified by some other reasonable choice of the collision diameter. In this instance, the

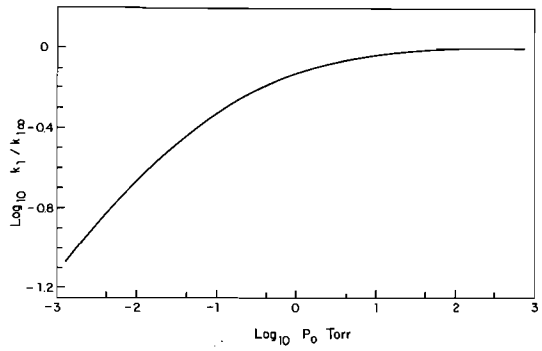

FIG. 5. Calculated fall-off curve for k_1 at 216.4 °C. Values of $k_1/k_{1\infty}$ obtained from eq. 11. Densities of states calculated by the method of steepest descents (ref. 14, append. p. 395 ff.). Vibrational frequencies of BTMP used (26) (in cm^{-1}): 64, 94, 134, 211, 228, 340, 445, 490, 558, 610, 627, 634, 673, 713, 975, 1065, 1125, 1166, 1191, 1240, 1265, 1287. Crystal Structure of and Electron Paramagnetic Resonance of Mn^{2+} in $Cd_2(NH_4)_2(SO_4)_3$

HOK NAM NG AND CRISPIN CALVO

Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

Received September 24, 1974

HOK NAM NG and CRISPIN CALVO. Can. J. Chem. **53**, 1449 (1975).

The room temperature structure of $Cd_2(NH_4)_2(SO_4)_3$ (CAS), isotypic with the mineral langbeinite $K_2Mg_2(SO_4)_3$ has been refined by full-matrix least squares methods. The structure is cubic with $a = 10.362(7)$ Å and space group $P2_13$. There are two inequivalent sites for the cation Cd^{2+} and e.p.r. spectra of doped Mn^{2+} show that Cd^{2+} was substituted in both sites with preferential occupancy by Mn^{2+} in a 1:3 ratio. Refinement of X-ray data on a mixed crystal of the stoichiometry $Cd_{0.84}Mn_{1.16}(NH_4)_2(SO_4)_3$ shows that site I contains 82% Mn^{2+} while site II has 38%. The zero-field splitting parameter D was calculated for Mn^{2+} in two sites using a point-charge model and confirms that Mn^{2+} substitutes into site I with greater preference. Although a monoclinic ferroelectric phase of CAS has been suggested below 90 K, no change in space group symmetry could be detected at 80 K. The proton second moment, calculated by the van Vleck's formula, and compared with the experimental values, suggests a tunneling motion of the protons among the four vertices of the ammonium tetrahedron.

HOK NAM NG et CRISPIN CALVO. Can. J. Chem. **53**, 1449 (1975).

La structure, telle qu'elle existe à la température ambiante, de $Cd_2(NH_4)_2(SO_4)_3$ (CAS), isostructural du minéral langbeinite $K_2Mg_2(SO_4)_3$, a été affinée par moindres carrés (matrice complète). La structure est cubique avec $a = 10.362(7)$ Å et appartient au groupe d'espace $P2_13$. Le cation Cd^{2+} occupe deux sites non-équivalents; le spectre r.p.e. du composé additionné de traces de Mn^{2+} montre que Cd^{2+} est substitué dans les deux sites par Mn^{2+} avec une occupation préférentielle dans le rapport de 1 : 3. L'affinement des données de rayons-X d'un cristal mixte de stoichiométrie $Cd_{0.84}Mn_{1.16}(NH_4)_2(SO_4)_3$ montre que le site I contient 82% de Mn^{2+} alors que le site II n'en contient que 38%. Le paramètre de couplage D à champ nul a été calculé pour Mn^{2+} dans chacun des sites utilisant un modèle de charge ponctuelle et confirme que Mn^{2+} se substitue dans le site I avec une préférence plus grande. Quoiqu'il a été suggéré que le CAS existe dans une phase monoclinique ferroélectrique à des températures inférieures à 90 K, on n'a pas pu détecter de changement de groupe d'espace à 80 K. Le "moment secondaire du proton", calculé par la formule de van Vleck et comparé avec les valeurs expérimentales, suggère un mouvement du à un effet tunnel des protons parmi les quatre sommets du tétraèdre de l'ammonium. [Traduit par le journal]

Introduction

A large number of double sulfates with the general formula $A_2B_2(SO_4)_3$ (where A is a monovalent metal or ammonium and B is a divalent metal) are isostructural with the mineral langbeinite $K_2Mg_2(SO_4)_3$. These crystals are cubic with the space group $P2_13$ and contain four formula units per unit cell. One of them, $Cd_2(NH_4)_2(SO_4)_3$ (CAS), has been known for a long time to undergo a phase transformation and become ferroelectric below 90 K (1, 2). Recently another member of the family, $Cd_2Tl_2(SO_4)_3$ (CTS) was reported to have a ferroelectric phase below 130 K (3). The ferroelectric phase of both crystals is believed to have the space group $P2_1$. The dielectric anomaly of CAS has aroused considerable interest in the nature of this ferroelectric phase transformation (4–6). While Dvořák (6) predicts from group theoretical considerations that the ferroelectric phase should have new unit cell vectors, $a_1' = a_1 - a_2$, $a_2' = a_1 + a_2$, and $a_3' = a_3$ with the cell volume doubled, Aizu (5) suggests that the primitive cell is tripled as a result of the condensation of triply degenerate pairs of conjugate lattice vibration modes with wave length three times the lattice constant. Since no accurate atomic parameters for CAS have been published, we have obtained more structural information on this compound by X-ray diffraction and electron paramagnetic resonance (e.p.r.). Some preliminary e.p.r. results for Mn^{2+} in CAS were reported by Tatsuzaki (7).

Experiments

Crystals of CAS were grown by slow evaporation at 85 °C of a solution containing $3CdSO_4.8H_2O$ and $(NH_4)_2SO_4$ in the proper stoichiometric ratio. A good quality single crystal was selected and ground into a

sphere of 0.30 mm diameter for X-ray intensity measurements. For e.p.r. studies about 0.2 mol% of $MnSO_4.4H_2O$ was added to the starting solution, and tetrahedrally shaped crystals with edges of about 1 mm were used. X-Ray intensity data were collected on a Syntex $P\bar{1}$ automatic diffractometer using graphite monochromatized MoKα radiation and θ–2θ scan at variable rate. Reflections whose intensities, corrected for background, were less than three times their standard deviation were considered unobserved. A total of 294 symmetry independent reflections were collected within $2\theta \leq 45°$, of which 257 were considered observed. The data were corrected for Lorentz, polarization, and absorption effects ($\mu R = 0.66$). The lattice constant was determined by a least squares fit to fifteen 2θ values measured with the automatic diffractometer. The crystal data are shown in Table 1.

A Varian V-4503 spectrometer with a 12 in. rotatable magnet was used for e.p.r. measurements. The microwave cavity was operated at 35 GHz in the cylindrical TE_{011} mode. A Varian Fieldial unit was used for regulating and measuring the magnetic field. The crystals were aligned by X-ray technique and spectra were recorded by rotating the magnetic field around crystals mounted along either the [110] or [111] axes.

Results

Refinement of the X-ray data was performed on a CDC 6400 computer with a full-matrix least squares program. The final coordinates of $K_2Mg_2(SO_4)_3$ (8) were used as initial parameters for the refinement. The scattering curves for Cd^{2+}, N, S, and O were taken from the *International Tables for X-Ray Crystallography* (9) and those for Cd and S were corrected for anomalous dispersion. A weighting function $\omega = (A + B|F_o| + C|F_o|^2)^{-1}$ was used with coefficients chosen so that $\omega(\Delta F^2)$, involving the square of the difference between the observed and calculated structure factors, would be independent of the local average of $|F_o|$. Unobserved reflections whose observed structure factors are larger than the calculated value were given zero weight, otherwise they were given a value 0.9 times the local minimum of $|F_o|$. Refinement was terminated when all the calculated shifts were less than 0.3 of the errors. The final R value is 0.016 and the weighted R value

$$R_\omega = \left[\frac{\sum\omega(|F_o| - |F_c|)^2}{\sum\omega|F_o|^2}\right]^{1/2}$$

is 0.020. The coefficients of the weighting function are 4.16, −0.0826, and 0.0008 for A, B, and C respectively. The final positional and thermal parameters are listed in Table 2. The observed and calculated structure factors (with no H atoms) are listed in Table 3.[1]

TABLE 1. CAS crystal data

Proton magnetic resonance (p.m.r.) data indicate the existence of general reorientation of the ammonium ions at room temperature (10, 11). Goc *et al.* suggest a "tunneling" motion in which each proton is distributed with equal probability over the four vertices of the ammonium tetrahedron (12). For each of the two inequivalent ammonium groups in CAS, one hydrogen atom should be on a threefold axis and may be considered as the apex of the tetrahedron, while the other three hydrogen atoms are related by this threefold axis. Four possible configurations of these ammonium groups may be envisaged: (*1*) both apices pointing in the [111] direction, (*2*) both along the [$\bar{1}\bar{1}\bar{1}$] direction, (*3*) the nearest neighbors pointing towards each other, and (*4*) the nearest neighbors pointing away from each other. Model *3* results in the hydrogen atoms at the apices being 2.0 Å apart and therefore was rejected. Standard hydrogen atomic scattering factors were used (9). The other models were tested against the X-ray data by rotating each NH_4 group as a rigid tetrahedral group around the N—H bond along the threefold axis so that reasonable O...H distances could be found for hydrogen bonding. Model *1* consistently gave an R value of 0.023. One configuration of model *4* gave an R value of 0.018 and one other configuration of model *2* gave an R value of 0.017. Although models *1* and *3* may be rejected for the orientation of the ammonium groups, it is not possible to determine the positions of the hydrogen atoms based on X-ray data and the R values. The estimated standard deviations for these positions amount to 0.03 fractional coordinates for both models *2* and *4*, which corresponds to an estimated error of the order of 0.4 Å for the N—H bonds. A dynamic model for the hydrogen atoms appears to be

*Calculated from $\beta_{ij} = 2\pi^2 b_i b_j U_{ij}$ where $T = \exp[-(\beta_{11}h^2 + 2\beta_{12}hk + \ldots)]$ is the thermal factor appearing in the structure factor expression and b_i's are reciprocal lattice vectors.

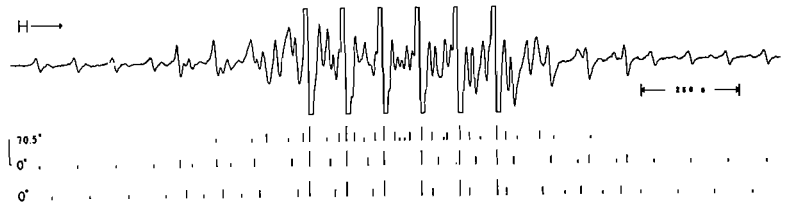

FIG. 1. Electron paramagnetic resonance spectrum of Mn^{2+} in CAS with H ∥ [111] (analysis is shown below the spectrum. Lines unaccounted for in the analysis are attributed to the 70.5° spectrum of site II.)

very likely and the final answer must await a single crystal neutron diffraction study.

Electron paramagnetic resonance spectra of CAS doped with Mn^{2+} were taken at room temperature by rotating the magnetic field around the [110] and [111] axes of the crystals. Spectral resolution was generally poor due to the large number of resonance lines. However, a few observations may be made from these complex spectra. First there exist two inequivalent sites of Mn^{2+} with the intensity ratio of their resonance lines about 1:3. Secondly, the crystalline field around both sites is axially symmetric with the symmetry axis (the z-axis) parallel to the body diagonal of the cubic unit cell, as Tatsuzaki observed (7). It may be concluded that the Mn^{2+} substitutes at both sites of the Cd^{2+}. The simplest spectral pattern (Fig. 1) was found when the magnetic field was along the [111] axis. There are four symmetry equivalent sites related by the twofold screw axes for each of the two inequivalent Mn^{2+}. The direction of the static magnetic field in this case is parallel to the z-axis of one site while it makes an angle of 70.5° with the z-axis of the other three sites. The result is that two sets of spectra are observed and each set consists of two Mn^{2+} spectra with an intensity ratio of 1:3. The two sets of spectra shown in Fig. 1 have again an intensity ratio of about 1:3, suggesting preferential occupation of the two inequivalent sites by the Mn^{2+}. Also, the 70.5° spectrum in each set should have a zero-field splitting ($3\cos^2\theta - 1$) times that for the 0° spectrum, as observed (Fig. 1).

The spectra were analyzed by using the equations for resonance fields by Bleaney and Trenam (13). The hyperfine splitting due to ^{55}Mn was found to be almost isotropic at 97 ± 5 G. The spectral parameters are given in Table 4.

It is not possible to establish from e.p.r. experiments alone which spectrum belongs to which one of the two inequivalent sites of Mn^{2+} since the site symmetries are the same, *i.e.* trigonal. The fact that greater concentration of Mn^{2+} was found in one site implies that the Mn^{2+} may also prefer the same site even at higher concentration levels. Consequently, crystals of the stoichiometry $Mn_xCd_{2-x}(NH_4)_2(SO_4)_3$ were grown by using a 1:1 ratio of Cd and Mn in the starting solution. The Mn content of the sample was analyzed colorimetrically by oxidation of Mn^{2+} to MnO_4^- with KIO_4. The value of x was found to be 1.16 ± 0.05. X-Ray data were collected on a spherical crystal (radius = 0.018 cm) and the structure was assumed to be isomorphous with CAS. The data were corrected as above and the model was refined by using a full-matrix least squares program with the site occupancy as an additional variable. The structure, with a = 10.262(8) Å, refined to a final R value of 0.051 and R_ω of 0.052. The result shows that cation site I contained 0.82 ± 11 Mn while site II contained 0.38 ± 11. The total Mn content of x = 1.2 agrees well with our chemical analysis. If we assume that the site preference of Mn^{2+} is the same at both low and high concentration the set of e.p.r. spectra with the higher intensity and larger D-splitting would correspond to Mn^{2+} in site I.

The solution to the question of site occupancy may be sought in another way. The various mechanisms giving rise to the zero-field splitting

of a ^6S state ion in trigonal symmetry have been discussed by Sharma, who derived expressions relating the zero-field splitting parameter D to the crystal field (14). The results were applied by Sharma to the case of Mn^{2+} in $CdCl_2$. We performed a similar calculation for Mn^{2+} in CAS by direct lattice summation to a maximum radius of 30 Å. The atomic coordinates from the structure refinement were used and the atoms were treated as point charges whose magnitude was equal to their formal charge. Using a 10 Dq value of 9000 cm^{-1} and a spin–orbit coupling constant of 300 cm^{-1} for Mn^{2+}, we obtained a value of $D = -214$ G for Mn^{2+} in site I and $D = -168$ G for site II. It is conceivable that the lattice may distort in the immediate vicinity of the site due to substitution by a cation of different size. The positions of the nearest oxygen atoms around each site were then altered in such a way that the average Mn—O distance was 2.19 Å but with O—Mn—O angles the same as in the case of Cd^{2+}. D changes by -3 G for both site I and site II. Comparison with the experimental values in Table 4 indicates that the assignment of site for the Mn^{2+} is correct.

We also attempted to verify that the space group of CAS in the ferroelectric phase below 90 K is $P2_1$, and to clarify whether the cell is doubled or tripled by taking precession photographs of the crystal at 80 K. Unfortunately neither the change in space group nor doubling or tripling of the cell constant could be detected at this temperature. Application of a static electric field up to 1.2 kV/cm along a cube axis of the crystal, in order to maintain a single-domain crystal in the ferroelectric phase, also proved to be of no avail in detecting those changes. Electron paramagnetic resonance spectra were also recorded at 77 K. A definite change of the spectral pattern was observed with the appearance of more Mn^{2+} sites than at room temperature, thus indicating a phase transition to a space group of lower symmetry. However, the spectra proved to be too complex to permit an unambiguous analysis.

Discussion

The room temperature structure of CAS projected along the [001] axis is shown in Fig. 2. The important bond lengths and bond angles are listed in Table 5. The structure is essentially the same as that of langbeinite ($K_2Mg_2(SO_4)_3$) (8). The sulfate group is slightly distorted with an

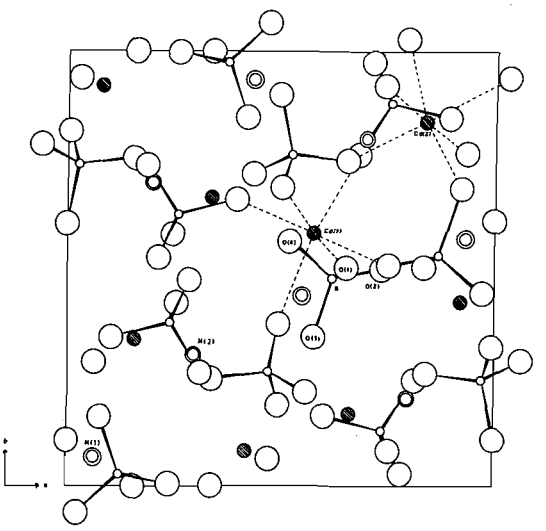

FIG. 2. Structure of CAS projected along [001].

average S—O bond length of 1.458 Å. Both Cd^{2+} ions have a distorted octahedral environment with the major distortion along the threefold axis. The shorter average cation–oxygen distance in site I is consistent with the observation that occupation of this site is preferred by Mn^{2+}, whose ionic radius is slightly smaller than that of Cd^{2+}. Each oxygen atom from a sulfate group is bonded to only one cation. The two ammonium groups have irregular environments, the first has a coordination number of 12 and the second has a coordination number of 9. The K^+ ions in langbeinite are coordinated in a similar fashion.

Goc *et al.* investigated the n.m.r. linewidths of CAS and concluded that the intramolecular contribution to the proton second moment was reduced to zero due to general reorientation of protons in the ammonium groups (12). They obtained a second moment of 0.80 G^2 for the powdered sample. The theoretical second moment for molecular reorientation of the ammonium groups by the van Vleck's formula (15), in the case of powdered CAS, is

$$S = 358.08 \sum r_{ij}^{-6}$$

where r_{ij} is the distance between centers of the groups. Using the results of our structural refinement and summing over $r_{ij} \leq 15$ Å, we obtained a value of 1.54 G^2. (Goc *et al.* reported a calculated value of 0.81 G^2 by using the atomic positions of langbeinite while we obtained a

*The number following the atom identification designates the symmetry operation in the order listed in the *International Tables of X-Ray Crystallography*; thus O(2)4 is generated from the position of O(2) in Table 2 by the symmetry operation $\frac{1}{2} + x, \frac{1}{2} - y, -z$.

value of 1.61 G^2 with these coordinates.) While the value of 1.54 G^2 is high compared with the experimental values of 0.80 G^2, Andrew and Eades (16) pointed out that for general molecular reorientation about the center of gravity, the intermolecular contribution to the second moment was further reduced and r_{ij}^{-6} should be replaced by ξG_{ij}^2 where

$$G_{ij} = \frac{1}{4r_{ij}R_1R_2} \ln\left[\frac{r_{ij}^2(R_1 - R_2)^2}{r_{ij}^2 - (R_1 + R_2)^2}\right]$$

and R_1 and R_2 are the distances of the protons from the centers of gravity of the groups and ξ was given a value of 0.63. Using these reduced interproton vectors the second moment of powdered CAS was calculated to be 1.17 G^2. Although there might be some contribution to the second moment from nuclei other than protons, this contribution is expected to be much smaller than the 0.1 G^2 found for NH_4Cl (17) since ^{16}O has zero nuclear magnetic moment. We also calculated the angular dependence of the second moment for a single crystal CAS. The results are plotted in Fig. 3. Although the shape of the

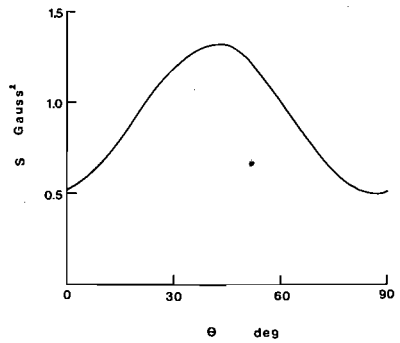

FIG. 3. Calculated angular dependence of proton second moment of CAS. ($\theta = 0°$ corresponds to H ∥ [100] and $\theta = 90°$ corresponds to H ∥ [010]).

curve and the values of the extrema (0.51 and 1.32 G^2) agree well with the experiments of Goc *et al.*, there is a difference in phase by 45°, *i.e.*, the theoretical minimum of S is to be found with the magnetic field along a cube axis and not along the [110] axis as they reported. Since the intramolecular proton contribution appears to be zero, the calculated second moment is inde-

pendent of the positions of the hydrogen atoms obtained from diffraction experiments, which must be taken as "statistical average" positions.

We conclude from these studies that CAS has the langbeinite structure at room temperature with redistribution of the hydrogen atoms among the vertices of the ammonium groups. Previous n.m.r. studies (10, 11) indicate that there is negligible change in linewidth or relaxation time of the proton resonance in going from room temperature to 77 K. This together with the observation of a similar phase transformation of $Cd_2Tl_2(SO_4)_2$ at 130 K by Brezina and Glogarová suggests that motion of the NH_4 groups in CAS is not "frozen-in" and is not responsible for the ferroelectric phase transformation, as it was found to be the case in many other ammonium salts. Some motional change of the sulfate group may be responsible for bringing about the structural change of CAS and CTS.

Photolysis of Pyridazine in the Gas Phase

JAMES R. FRASER, L. H. LOW, AND NEIL A. WEIR
Chemistry Department, Lakehead University, Thunder Bay, Ontario P7B 5E1

Received October 11, 1974

JAMES R. FRASER, L. H. LOW, and NEIL A. WEIR. Can. J. Chem. **53**, 1456 (1975).

Pyridazine was photolyzed with long wave ultraviolet radiation (3650–3663 Å) over the temperature range 100–160 °C. Nitrogen and vinylacetylene were the main products, their quantum yields at 110 °C being 0.12 ± 0.05 and 0.09 ± 0.04, respectively. Nitrogen formation is not significantly inhibited by the presence of oxygen and no isomerization of *cis*-but-2-ene was observed during photolyses. It appears that some reaction occurs from the excited singlet, S (n → π*) A, but this state is efficiently deactivated photophysically. It is suggested that vinylacetylene is formed from a C_4H_4 diradical by means of a 1,3 H-atom migration, and isotope effects observed for the photolysis of pyridazine-d_4 support C—H bond fission.

JAMES R. FRASER, L. H. LOW et NEIL A. WEIR. Can. J. Chem. **53**, 1456 (1975).

On a photolysé la pyridazine avec une radiation ultraviolette de grande longueur d'onde (3650–3663 Å), à des températures allant de 100–160 °C. L'azote et le vinyl-acétylène sont les produits principaux et leurs rendements quantiques à 110 °C sont respectivement de 0.12 ± 0.05 et 0.09 ± 0.04. La formation d'azote n'est pas inhibée d'une façon significative par la présence d'oxygène et on n'a pas observé d'isomérisation du butène-2 *cis* durant les photolyses. Il semble que quelques réactions se produisent à partir d'un état excité singulet, S (n → π*) A ; cet état est toutefois désactivé d'une façon efficace par des processus photo-physiques. On suggère que le vinyl-acétylène se forme à partir du radical C_4H_4 par l'intermédiaire d'une migration 1,3 d'un atome d'hydrogène; les effets isotopiques observés lors de la photolyse de la pyridazine-d_4 sont en accord avec une fission du lien C—H. [Traduit par le journal]

Introduction

The photochemistry of a number of 1,4-diazines has been studied in detail, and relationships between excited states and mechanisms of isomerization have been elucidated (1–4). By comparison, knowledge of the photochemistry of 1,2-diazines is very limited, although a considerable amount of data related to photophysical processes occurring in these molecules has been amassed (5–9).

Electron impact induced fragmentation of pyridazine results in the production of nitrogen and another ionic species, $C_4H_4^{2+}$, which, on the basis of metastable ion detection, was tentatively assigned the cyclobutadienyl dication structure (10).

The diazines have chemical structures similar to those of diazirines which undergo photolytic and thermolytic isomerizations or decompositions into nitrogen and a number of small hydrocarbons (11, 12). Some evidence has been obtained for the production of carbenes as intermediates and a transition state involving simultaneous rupture of two C—N bonds has been postulated (13).

1-Pyrazolines and substituted 1-pyrazolines undergo similar photochemical decompositions into nitrogen and vibrationally excited cyclopropanes which subsequently isomerize (14, 15) an intermediate excited singlet methylene produced by two simultaneous C—N bond fissions, rapidly undergoing ring closure (16).

Pyridazine is of particular interest, since it can be seen that an analogous decomposition would produce a diradical which could conceivably ring close to yield cyclobutadiene. The object of this work was to investigate the photoreactions of pyridazine.

Experimental

Photolyses were carried out in a conventional "static" system using a Pyrex reaction vessel (120 cm^3) which had been "aged" by the pyrolysis of hexamethyldisiloxane at 500 °C for 16 h. The associated vacuum system and analytical train incorporated greaseless stopcocks. The reaction vessel was housed in a coaxial furnace, the temperature of which was maintained to ±0.1 °C. Analyses were carried out by gas chromatography (Hewlett Packard Research Chromatograph) the products from the reaction vessel being divided into two fractions, one condensable and the other noncondensable at −205 °C (pumped liquid N_2), which were subsequently transferred to a temperature programmed 10 ft column containing Celite coated with 12% Carbowax and to a 6 ft molecular sieve column (5A) at 30 °C respectively. The Carbowax column effluent passed through a f.i.d., while the molecular sieve column was used along with a katharometer and helium was the carrier gas. The nature of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

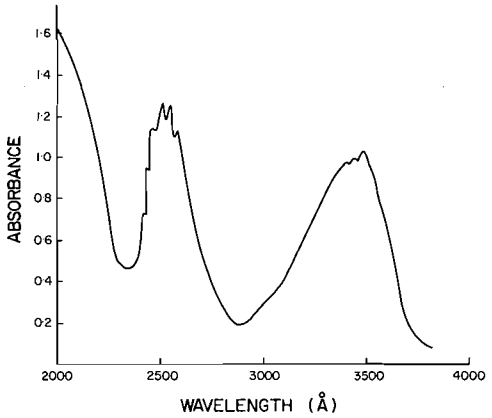

FIG. 1. Ultraviolet spectrum of pyridazine; pressure 23 Torr at 95 ± 1 °C, path length 1 cm.

the gases was confirmed by mass spectrometry, small samples of the column effluent being introduced directly into the R.MU7 mass spectrometer. Unreacted pyridazine was separated at −20 °C (salt bath) and determined, after expansion into a standard volume, by pressure measurement of 60 °C. The ultraviolet source was a medium pressure 100 W Hg arc (Hanovia).

Light from the arc passed through a standard filter to isolate the 3650–3663 Å band (17) and was focused by means of a lens into a parallel beam which traversed the reaction vessel.

Quantum yields were determined by potassium ferrioxalate actinometry (18). Solutions (0.006 *M*) were irradiated at 20 °C under the same conditions as the above reaction vessel, and were stirred by bubbling through them a stream of pure N_2. The quantum yield of Fe^{2+} formation was assumed to be 1.21 (18), and the fraction of light absorbed by a solution was determined using a phototube (R.C.A. Type 1P28) powered by a 120 V d.c. (Dry Cell) power supply. The output of the phototube was measured using a microvolt meter (Keithley Model 155).

The ultraviolet spectrum of gaseous pyridazine (pressure 23 Torr) shown in Fig. 1, was measured at 95 ± 1 °C using a Cary 14 spectrophotometer, fitted with a heated sample holder, which contained a quartz cell (Rho Scientific Anaerobic cell) with a path length of 1 cm. The cell was filled after evacuation by molecular distillation of pyridazine at 10^{-5} Torr.

Pyridazine (Aldrich) was dried over anhydrous $MgSO_4$ for 24 h and repeatedly distilled under reduced pressure in presence of nitrogen. Gas chromatographic analyses on two columns showed only one peak. Pyridazine-d_4 (Merck, Sharp and Dohme) was used without further purification.

Results

Pyridazine was photolyzed over the temperature range 100–160 °C (the vapor pressure being insufficiently high at temperatures below 100 °C). The noncondensable fraction yielded one product which was identified as nitrogen, and only one product could be separated from the condensable fraction. This product was subjected to the following analyses, the results of which are shown below.

(*a*) Infrared gas phase spectra showed the following main bands: 3300 (s), 2990 (s), 2120 (w), 1670 (w), 1450 (s), 1300 (m), 970 cm^{-1} (w).

(*b*) Mass spectrometry indicated a molecular weight of 52 which corresponds to the mass of a molecule formed by the loss of nitrogen from pyridazine. The molecular ion had the highest relative abundance and high resolution measurements indicated an *m/e* value of 52.0312 which would correspond to a C_4H_4 entity ($C_4H_4 \equiv$ 52.0313).

(*c*) Nuclear magnetic resonance analyses in deuterated chloroform showed two main bands, a sharp singlet at τ 7.2 p.p.m., and a multiplet centered at τ 4.65 p.p.m.

(*d*) The ultraviolet spectrum of a gaseous sample showed a broad band extending to 2500 Å. It was noted, however, that after standing at room temperature for a short period, the sample underwent polymerization, a yellow deposit forming on the walls of the gas cell. The u.v. spectrum of samples then showed a large bathochromic shift.

The C_4H_4 fragment could conceivably have one of three structures (cyclobutadiene omitted), *i.e.*, butatriene, vinylacetylene, or methylene cyclopropene. The above i.r. and n.m.r. data appear to favor vinylacetylene (*e.g.* the singlet at τ 7.2 p.p.m. and the peaks at 3300 and 2120 cm^{-1} suggest the presence of the —C≡CH group). The above spectral measurements were made on an authentic sample of vinylacetylene, and similar data obtained (*e.g.* a singlet at τ 7.15 p.p.m., a multiplet centered on τ 4.55 p.p.m., i.r. absorptions at 3300, 2980, and 2130 cm^{-1}). No evidence for the allene or the *exo*-double bond structures could be obtained, and it is concluded that the major products of photolysis of pyridazine are nitrogen and vinylacetylene; other products, if formed, were present in insufficient quantities for i.r. spectral estimation.

The stoichiometry of the decomposition is shown in Fig. 2 and it can be seen that while there is a good correspondence between pyridazine depletion and nitrogen formation, the vinylacetylene yield was consistently lower, possibly on account of the polymerization which occurs during the analysis. (Vinylacetylene is known to polymerize readily at room tempera-

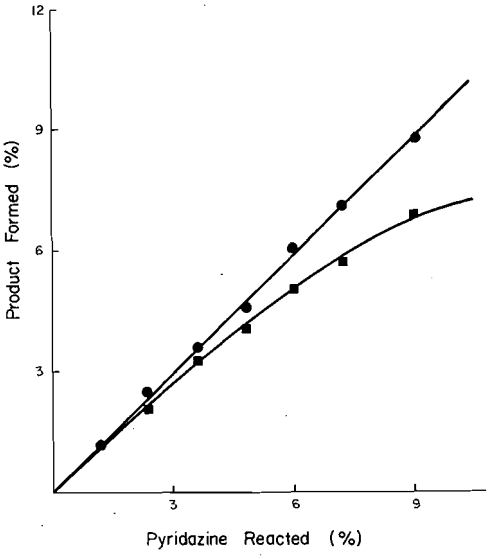

FIG. 2. Demonstration of the stoichiometry of the reaction at 110 °C, pyridazine pressure 25 Torr: ○, nitrogen produced; □, vinylacetylene produced (both as percent of initial reactant).

ture, but no polymer was observed in the reaction vessel.) Beyond about 20% decomposition Fig. 2 becomes curved, presumably due to decreasing pyridazine concentration (and hence light absorption).

Studies of the reaction were therefore restricted to the first 5% of the pyridazine decomposition. The effect of surfaces on the reaction was investigated and identical runs were carried out in an unpacked and in a packed (with Pyrex tubes) vessel, both of which had been aged as previously described and had surface–volume ratios of 1.2 and 8.3 cm^{-1} respectively. The rates of nitrogen and vinylacetylene formation for the unpacked vessel were 2.4×10^{-8} and 2.0×10^{-8} mol l^{-1} s^{-1} respectively and for the packed vessel were 2.5×10^{-8} and 1.86×10^{-8} mol l^{-1} s^{-1}, respectively. It is concluded that the reaction is homogeneous.

The extent of the purely thermal decomposition of pyridazine was investigated over the temperature range 100–160 °C and no detectable amounts of either product of the photoreaction were obtained.

The rate of nitrogen formation was found to be directly proportional to the pyridazine pressure (as would be expected for low extents of absorption) and to the light intensity (Table 1).

TABLE 1. Photolysis of pyridazine (26 Torr) at 102 °C with varying u.v. (3650–3663 Å) intensities

$R_{N_2} \times 10^8$ (mol l^{-1} s^{-1})	I (%)	R_{N_2}/I
2.66	100	0.026
2.37	81.7	0.029
1.54	64.3	0.024
1.26	46.6	0.027
0.81	33.4	0.024
0.506	22.0	0.023

Vinylacetylene formation conforms to a similar relationship, but the data are more scattered.

Quantum yields for nitrogen formation were almost invariant, with values of 0.12 ± 0.05 over the pyridazine pressure range 5–45 Torr, but those for vinylacetylene decreased with increasing pressure, *e.g.* at 5 Torr, $\Phi = 0.09 \pm 0.04$ and at 50 Torr, $\Phi = 0.06 \pm 0.02$ (measured at 110 °C).

It would appear from these results and from the light intensity data that chain decompositions are not involved.

Photolysis of pyridazine-d_4 under identical conditions at 110 °C yielded nitrogen and C_4D_4 (presumably vinylacetylene-d_4). No significant isotope effect was observed for nitrogen formation; $(R_{N_2})_H/(R_{N_2})_D = 1.04 \pm 0.01$ but for vinyl acetylene (v) the ratio $(R_v)_H/(R_v)_D$ was 1.65 ± 0.2, these measurements being made at 3% decomposition.

The photolysis was carried out in the presence of a number of added gases, and the results are shown in Fig. 3.

It can be seen that the inhibiting effects of CO_2, O_2, and *cis*-but-2-ene are comparable. The O_2 pressure had to be limited to 30 Torr to minimize explosion hazards. The effects of argon and CO_2 on vinylacetylene formation are very similar to those shown in Fig. 3, but both O_2, and to a lesser extent, *cis*-but-2-ene depress vinylacetylene yields and appear to react with small amounts of vinylacetylene and/or its precursor, a number of additional products, of which only acetylene was positively identified, being formed.

No evidence for isomerization of the *cis*-but-2-ene was obtained.

Discussion

The following scheme qualitatively accounts for the experimental data.

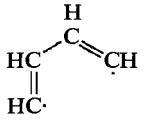
$$[\cdot C_4H_4\cdot]^* \rightarrow CH{\equiv}C{-}CH{=}CH_2$$

Absorption of light produces an excited pyridazine molecule which by analogy with previous data (13) could be a diradical with the structure



No evidence was obtained for a two-step decomposition. However the lifetime of a diazomethane type intermediate monoradical would be very short at temperatures above 100 °C. The diradical subsequently isomerizes by means of a 1,3-H atom migration to produce vinylacetylene.

Due to the presence of two filled nonbonding molecular orbitals in pyridazine, two n → π* transitions are possible; however, one of these, is symmetry forbidden. Absorption of ultraviolet radiation (λ = 3650–3663 Å) yields the vibrationally excited singlet, S* (7, 8) which is symmetry allowed [S (n → π*) A]. This species undergoes vibrational relaxation on collision with added gas molecules and this is reflected in decreased product yields (Fig. 3).

Pyridazine is anomalous in that the photophysical deactivation of the S (n → π*) A state is very facile (7). In addition to fluorescence of low intensity, rapid internal conversion to the symmetry forbidden singlet, S (n → π*) F, vibrational relaxation to the S_0 state and intersystem crossing to the triplet T (n → π*) occur. Since the energy of the triplet lies close to that of the S (n → π*) F state, further rapid intersystem crossing to this singlet occurs, the singlet subsequently returning to the ground state by internal conversion (the triplet lifetime is less than 10^{-6} s) (7) before appreciable numbers of encounters are made with oxygen and *cis*-but-2-ene molecules; a similar conclusion was reached by Srinivasan (19) regarding the photodecomposition of cycloheptanone. A plausible reaction scheme is summarized as follows.

$$[2] \quad \text{Pyridazine } (S_0) \xrightarrow{h\nu} S_1^*[S\ (n \rightarrow \pi^*)\ A]$$

$$[3] \quad S_1^* + M \rightarrow S_1 + M \text{ (M is a molecule which removes vibrational excitation on collision)}$$

$$[4] \quad S_1^* \rightarrow T_1^*$$

$$[5] \quad S_1^* \rightarrow \text{products } (N_2 + C_4H_4)$$

$$[6] \quad S_1 \rightarrow T_1 \rightarrow S\ (n \rightarrow \pi^*)\ F \rightarrow S_0$$

$$[7] \quad S_1 \rightarrow S\ (n \rightarrow \pi^*)\ F \rightarrow S_0$$

The low photochemical quantum yields are consistent with efficient partitioning of energy into photophysical processes.

The data shown in Fig. 3 could be interpreted in terms of some decomposition occurring from vibrationally excited pyridazine, the added gases removing vibrational energy by collision, and hence reducing the N_2 yield.

The excited singlet is undoubtedly formed (7), and since intersystem crossing is rapid, the excited triplet could also be present; both could yield the products.

The results obtained from reactions carried out in presence of O_2 and *cis*-but-2-ene would suggest that if triplets are indeed involved, they must be short lived excited species which decompose before significant amounts of quenching by either O_2 or *cis*-but-2-ene can take place.

From previous studies (19), it would appear that the concentrations of O_2 used in the present work would be sufficient to quench a large proportion of pyridazine triplets, and the observation that the deactivating effect of O_2 is com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

parable with that of CO_2 would suggest that no such quenching takes place.

In addition, the absence of a detectable extent of isomerization of *cis*-but-2-ene would support the above conclusions.

Because of the apparent complexity of the reactions in which O_2 and *cis*-but-2-ene are present, it was not possible to obtain unequivocal information regarding either the nature or electronic multiplicity of the C_4H_4 precursor of vinylacetylene. There is evidence that the singlet state is predominant in tetramethylene diradicals derived from the photodecomposition of saturated six-ring azo compounds (20), and the inhibiting effects of argon and CO_2 on vinylacetylene formation suggest that a vibrationally excited species is involved. Such excited diradicals frequently ring-close to form the corresponding alicyclic compounds which isomerize to form unsaturated open chain molecules (21). By analogy, the C_4H_4 diradical would yield excited cyclobutadiene and/or excited methylene cyclopropene, neither of which would be expected to have more than transitory existence, and vinylacetylene would be formed by isomerization.

An alternative mechanism involves a unimolecular isomerization of C_4H_4, the H-atom undergoing a 1,3 migration. Such reactions have been observed for vibrationally excited (40 kcal mol^{-1}) alkyl radicals (22) and probably involve cyclic transition states, there being sufficient excitation in the bending modes to ensure repeated encounters of the two ends of the radicals. A qualitatively similar mechanism of formation of vinylacetylene from excited butadiene was suggested by Lossing and co-worker (23), a H-atom on the 2 C-atom interacting with the double bond between C-atoms 3 and 4, the encounter being facilitated by the excited bending modes of the 2–3 bond.

The significant deuterium isotope effect qualitatively supports the rupturing of a C—H bond as a prerequisite for hydrogen migration. However, the effect is considerably less than would be expected for a purely thermally activated process, confirming to some extent the involvement of a vibrationally excited C_4H_4 species.

The authors gratefully acknowledge the technical assistance of Mr. D. Corbett and Mr. S. Spivac and the financial assistance of the National Research Council of Canada.

Etude spectroscopique de l'aniline dans les solvants

P. MÉALLIER, A. BERTHELON ET B. POUYET

Laboratoire de photochimie, laboratoire associé au département de chimie organique, Université Claude Bernard Lyon I, Villeurbanne, France

Reçu le 9 mai 1974[1]

P. MÉALLIER, A. BERTHELON et B. POUYET. Can. J. Chem. **53**, 1461 (1975).

L'influence des solvants sur la position et l'intensité des bandes d'absorption a été étudiée entre 200 et 400 nm. Nous nous sommes intéressés plus particulièrement au moment spectroscopique et au déplacement de la bande située à 280 nm.

Alors qu'avec les solvants hydroxylés, la bande d'absorption de l'amine est déplacée vers les courtes longueurs d'onde, que la valeur du moment dipolaire diminue en passant de l'état fondamental à l'état excité, nous avons le phénomène inverse avec les solvants non hydroxylés.

L'importance du transfert de charge, la structure de la molécule ainsi que le comportement des diverses solutions lors d'une photooxydation sont précisées.

P. MÉALLIER, A. BERTHELON, and B. POUYET. Can. J. Chem. **53**, 1461 (1975).

The effect of change of solvent on the positions and intensities of absorption bands of some aromatic amines between 200 and 400 nm has been examined. In particular, the behavior of the band at 280 nm has been studied.

In hydroxylic solvents, this band is displaced towards shorter wavelengths, and the dipole moment in the excited state of the molecule is smaller than in the ground state. The opposite effects are found when nonhydroxylic solvents are used.

The results show how the molecular structure is altered by charge transfer effects and can explain how different solvents affect photochemical oxidation processes.

Introduction

L'aniline et les toluidines présentent dans le domaine de longueurs d'onde compris entre 200 et 400 nm deux bandes d'absorption. Pour étudier l'oxydation photochimique de ces amines, il faut donc choisir une source qui émette soit à 230, soit à 280 nm.

Afin de faciliter les conditions expérimentales lors de l'oxydation, nous avons choisi la bande d'absorption située vers les plus grandes longueurs d'onde.

L'étude spectroscopique préliminaire se rapporte donc au comportement de cette bande d'absorption, c'est-à-dire aux variations d'intensité et aux variations de longueurs d'onde dans différents solvants.

A l'aide de ces résultats, nous nous proposons également de préciser la nature de la transition qui est tantôt définie comme une bande caractéristique du benzène (1), tantôt comme une bande nouvelle due au substituant.

Kimura *et al.* (2), par une étude théorique, laissent prévoir que l'on est en présence "d'une bande de transfert, caractéristique d'un transfert de l'électron entre les substituants et le cycle". C'est cette bande située vers 280 nm que nous nous proposons d'étudier.

Notre travail comprendra donc deux parties: (*1*) étude de l'intensité (moment spectroscopique); (*2*) étude de la position des maxima d'absorption en fonction de la nature des solvants.

Appareillage

Toutes nos expériences ont été réalisées sur un spectrophotomètre SP 800 A muni du dispositif d'expansion d'échelle SP 820. La précision des mesures est d'environ ± 1 Å, soit $\pm 10\ cm^{-1}$ dans le domaine de longueur d'onde considéré.

Etude du moment spectroscopique

Afin de définir l'influence des substituants sur un cycle benzénique, Sklar (3) et Platt (4) ont introduit la notion de "moment spectroscopique" ou "moment de migration".

Suivant la répartition des charges envisagées par Platt, nous avons attribué: le signe + au carbone portant le groupement amino; le signe − au carbone portant le groupement en position *ortho*; le signe + au carbone portant le groupement en position *méta*; le signe − au carbone portant le groupement en position *para*.

TABLEAU 1. Valeurs des moments spectroscopiques mesurés dans différents solvants

Solvant	Aniline	*o*-Toluidine	*m*-Toluidine	*p*-Toluidine
Hexane	48.7	58.2	49.7	49
Cyclohexane	50.3	59.2	51.4	50.2
Benzène	51.3	62.2	53.7	54.7
Ether éthylique	54.3	62.5	53.7	53.2
Acétate d'éthyle	53.2	63.2	52.7	53.2
Dioxanne	63	65.2	54.7	53.7
THF	52.5	65.2	54.2	53.7
DMF	76	65.2	57.2	54.2
DMSO	57.7	67.2	57.5	56
Décaline	50.7	61	52	47.7
$CHCl_3$	44.5	56.2	47	48.2
CCl_4	60.7	75	58.2	61.2
Butanol	43	51.2	44	43
Propanol	42	54.2	43.8	45.5
Ethanol	43	51.2	44.2	45.5
Méthanol	42	48.2	42	41.2
Eau	39	44.2	39.8	40

TABLEAU 2. Moments spectroscopiques pour la bande située à 2800 Å exprimés en $(\text{cm mol/l})^{1/2}$

		m		
Molécule	ε_{max}	Calculé	Mesuré	$\Delta m = m_{mes} - m_{calc}$
Aniline	1700		48.7	
o-Toluidine	2070	34	58	+24
m-Toluidine	1740	34	49.7	+15.7
p-Toluidine	1760	47	50.2	+3.2

Les groupements CH_3 et NH_2 étant donneurs d'électrons, nous obtenons les relations suivantes: l'*o*-toluidine, moment $= k(m_a^2 + m_b^2 - m_a \cdot m_b)^{1/2}$; la *m*-toluidine, moment $= k(m_a^2 + m_b^2 - m_a \cdot m_b)^{1/2}$; la *p*-toluidine, moment $= k(m_a^2 + m_b^2 + 2m_a \cdot m_b)^{1/2}$. m_a et m_b étant les modules des moments spectroscopiques des groupements NH_2 et CH_3.

On prend $k = 1$ afin d'obtenir les résultats en $(\text{cm mol/l})^{1/2}$. Le moment spectroscopique ainsi défini permet de connaître théoriquement la variation d'intensité qu'entraîne la substitution d'un groupement à un autre. Ballester *et al.* (5) ont relié ce concept à l'expérience à l'aide d'une relation empirique:

$$\varepsilon_{max} = 40 \sum_{1}^{6} m_i - 250$$

en prenant zéro pour le moment spectroscopique du benzène et en ne considérant que les transitions pour lesquelles $\varepsilon_{max} \geqslant 350$. ε_{max} = coefficient d'absorption moléculaire à la longueur d'onde où l'absorption est maximale. m_i = moment spectroscopique de chaque substituant.

En appliquant à la relation précédente les valeurs des coefficients d'absorption moléculaire que nous avons mesurés, nous avons obtenu les résultats consignés dans les tableaux 1 et 2.

Dans le tableau 2, nous avons comparé les résultats expérimentaux aux résultats théoriques en utilisant l'hexane comme solvant et en prenant respectivement pour les moments spectroscopiques des groupements CH_3 et NH_2, les valeurs +9 et +38 (6).

Ainsi que Platt le signale dans sa publication, le calcul théorique du moment spectroscopique d'une amine aromatique diffère notablement d'une mesure expérimentale. Cette différence est due à l'interaction très forte entre noyau aromatique et substituant. L'écart maximum étant obtenu pour l'*o*-toluidine, où la déformation du cycle entraîne les modifications de symétrie les plus importantes (7).

Nous ne pouvons donc espérer aucune indication quant aux densités électroniques du cycle aromatique à partir de ces résultats.

TABLEAU 3. Caractéristiques des solvants utilisés

Solvant	n_D^{25C}	D^{25C}	$\frac{n_D^2-1}{2n_D^2+1}$	$\frac{D-1}{D+2}-\frac{n_D^2-1}{n_D^2+2}$
Hexane	1.372	1.890	0.1861	0.0001
Octane	1.395	1.948	0.1940	0.0004
Cyclohexane	1.424	2.023	0.2016	0.0018
Chloroforme	1.442	4.806	0.2104	0.2927
trans-Décaline	1.466	2.172	0.2170	0.064
Tétrachlorure de carbone	1.459	2.238	0.2159	0.168
Ether éthylique	1.351	4.335	0.1765	0.3120
Benzène	1.498	2.284	0.2275	0.0051
Dioxanne	1.417	2.209	0.2005	0.0363
Acétate d'éthyle	1.369	6.02	0.1835	0.398
Tétrahydrofurane	1.404	7.39	0.1965	0.436
DMF	1.427	37.6	0.2042	0.667
DMSO	1.478	48.9	0.2206	0.674
Butanol	1.397	17.8	0.1940	0.6066
Propanol	1.375	20.1	0.1862	0.6299
Ethanol	1.359	24.3	0.1804	0.6641
Méthanol	1.326	33.62	0.1678	0.7113
Eau	1.332	80.37	0.1701	0.7585

Cependant, si l'on considère une molécule donnée, mise en solution dans différents solvants, il sera possible de suivre l'évolution du moment spectroscopique de cette molécule en fonction des solvants choisis.

Ainsi la variation du moment spectroscopique de chaque amine au cours de l'étude a été de: 37 pour l'aniline; 30.8 pour l'*o*-toluidine; 18.4 pour la *m*-toluidine; 21.2 pour la *p*-toluidine.

Ces variations sont importantes avec les solvants non hydroxylés, faibles avec les solvants hydroxylés.

Etude du déplacement du maximum d'absorption

Pour suivre le déplacement du maximum d'absorption, nous avons utilisé l'équation de McRae et Basu (8–10). Cette relation fait intervenir les effets suivants: effet de dispersion; effet d'induction (dû au soluté); effet Starck (dû au solvant); effet d'orientation. La variation générale est égale à la somme de ces quatre effets.

$$\bar{\nu}_{\text{vapeur}} - \bar{\nu}_{\text{solution}} = \Delta\bar{\nu}_{\text{dispersion}} + \Delta\bar{\nu}_{\text{induction}} + \Delta\bar{\nu}_{\text{Starck}} + \Delta\bar{\nu}_{\text{orientation}}$$

avec pour chaque terme les relations suivantes:

$$\Delta\bar{\nu}_{\text{dispersion}} = \frac{2}{hca^3}\left(\frac{n_D^2-1}{n_D^2+2}\right)\frac{E}{\varepsilon+E} \times (|\bar{M}_{ef}|^2 + \varepsilon(\alpha_g - \alpha_e))$$

$$\Delta\bar{\nu}_{\text{induction}} = \frac{1}{hca^3}\frac{n_D^2-1}{2n_D^2+1}(\mu_e^2 - \mu_f^2)$$

$$\Delta\bar{\nu}_{\text{Starck}} = \frac{6}{hca^6}\mu_f^2(\alpha_f - \alpha_e) \times \left(\frac{D-1}{D+2} - \frac{n_D^2-1}{n_D^2+2}\right)^2$$

$$\Delta\bar{\nu}_{\text{orientation}} = \frac{2}{hca^3}\mu_f(\mu_e - \mu_f) \times \left(\frac{D-1}{D+2} - \frac{n_D^2-1}{n_D^2+2}\right)$$

où h = constante de Planck, c = vitesse de la lumière, a = rayon d'Onsager du soluté, μ_f = moment dipolaire à l'état fondamental, μ_e = moment dipolaire à l'état excité, α_f = polarisabilité du soluté à l'état fondamental, α_e = polarisabilité du soluté à l'état excité, M_{ef} = moment de transition de la bande du soluté, ε = énergie d'excitation moyenne du soluté, E = énergie d'excitation du solvant, n_D = indice de réfraction en utilisant la raie D du sodium et D = constante diélectrique.

Les caractéristiques des solvants utilisés sont consignées dans le tableau 3.

Le déplacement du maximum d'absorption, noté dans le tableau 4, est déterminé en prenant comme référence le spectre de l'amine à l'état vapeur. Le signe plus (+) étant pris lorsqu'il y a déplacement de la bande vers les grandes

Tétrahydrofurane	660	729	714	851
DMF	1012	1082	1060	1293
DMSO	1125	1198	1173	1390
Butanol	0	360	180	180
Propanol	−151	246	120	118
Ethanol	−246	180	60	
Méthanol	−528	0	−61	−60
Eau	−749	−503	−557	−538

longueurs d'onde, le signe moins (−) lorsqu'il y a déplacement inverse.

Effets de dispersion et d'induction

Pour déterminer l'importance de ces deux effets, nous avons tracé les spectres d'absorption des anilines en utilisant des solvants apolaires. Nous avons obtenu les résultats suivants, fig. 1.

Ce déplacement, dû à la somme des deux effets, peut, en première approximation, être considéré comme constant pour l'ensemble des solvants. Ceci à condition que la variation du rapport $n_D^2 - 1/(2n_D^2 + 1)$ pour les solvants polaires, soit comprise dans l'intervalle de variation de ce même rapport pour les solvants non polaires utilisés dans la relation (11)

$$\Delta\bar{\nu} = f\left(\frac{n_D^2 - 1}{2n_D^2 + 1}\right)$$

Nous obtenons donc pour ces derniers, les déplacements suivants:

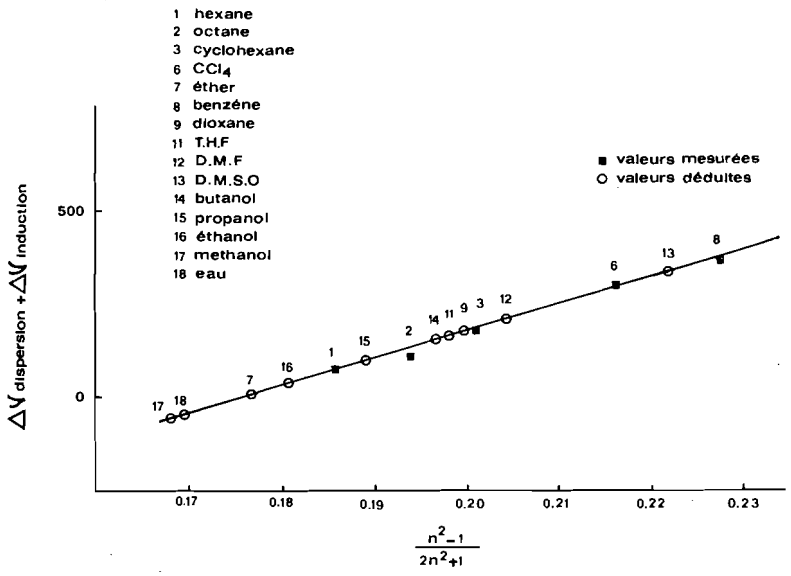

FIG. 1. Effets de dispersion et d'induction pour les solvants étudiés.

Solvant	Déplacement (cm^{-1})
Ether éthylique	10
Acétate d'éthyle	58
THF	144
DMF	195
DMSO	311
Dioxanne	180
Butanol	125
Propanol	90
Ethanol	35
Méthanol	−65
Eau	−50

Effet d'orientation

L'effet Starck, toujours très faible, peut être négligé, ce qui nous conduit à un déplacement dû aux forces d'orientation, égal à:

Solvant	Déplacement (cm^{-1})
Ether éthylique	353
Acétate d'éthyle	481
THF	516
DMF	817
DMSO	814
Dioxanne	303
Butanol	−125
Propanol	−241
Ethanol	−280
Méthanol	−463
Eau	−729

Ce qui nous donne la fig. 2, où nous remarquerons une pente positive pour les solvants non hydroxylés, une pente négative pour les solvants hydroxylés.

Discussion

Dans certains solvants, le moment dipolaire de l'aniline à l'état fondamental est connu (12–14), nous pouvons alors calculer la valeur du moment dipolaire lorsque la molécule est à l'état excité.

Nous avons effectué ce calcul pour l'aniline en solution dans le dioxanne et dans l'éther éthylique, à partir de la relation

$$\Delta\bar{\nu}_{\text{orientation}} = f\left(\frac{D-1}{D+2} - \frac{n^2-1}{n^2+2}\right)$$

La pente de la droite obtenue est

$$\text{pente} = \frac{2}{hca^3}\,\mu_f(\mu_e - \mu_f) = 1280$$

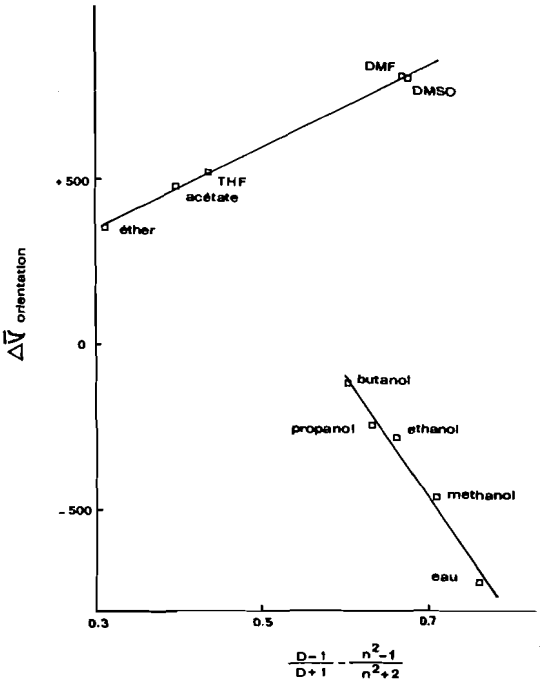

FIG. 2. Effets d'orientation pour les solvants étudiés.

avec $h = 6.62 \times 10^{-34}$; $c = 3 \times 10^8$ m/s; $a = 3.3$ Å ce qui conduit à $\mu_e = 4.4$ D (éther éthylique) et $\mu_e = 4.3$ D (dioxanne).

Ce calcul n'est pas possible pour l'aniline en solution dans l'eau ou dans les alcools. Dans ce cas, nous ne pouvons déterminer que la variation du moment dipolaire au cours de la transition.

En appliquant la relation précédente, nous avons trouvé pente de la droite = −4100 ce qui conduit à $\mu_e < \mu_f$.

Nous remarquons donc un comportement différent entre amine et solvant, selon qu'il existe ou non des groupements non hydroxylés dans ce dernier. Nous avons en effet, avec les solvants non hydroxylés: augmentation du moment spectroscopique et du moment dipolaire de l'amine à l'état excité lorsque la constante diélectrique du solvant augmente. Avec les solvants hydroxylés, nous avons le phénomène inverse. Une étude sur l'association soluté–solvant, en appliquant la méthode de calcul signalée par Gosh et Basu (15), nous a permis de mettre en évidence la formation de complexes 1:1 entre amine et solvant. A partir des valeurs obtenues pour la constante d'équilibre, nous avons calculé les variations d'enthalpies accompagnant cette complexation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

L'existence de ces liaisons soluté-solvant explique le déplacement de la bande d'absorption vers les grandes longueurs d'onde avec les solvants non hydroxylés, le déplacement vers les courtes longueurs d'onde avec les solvants hydroxylés.

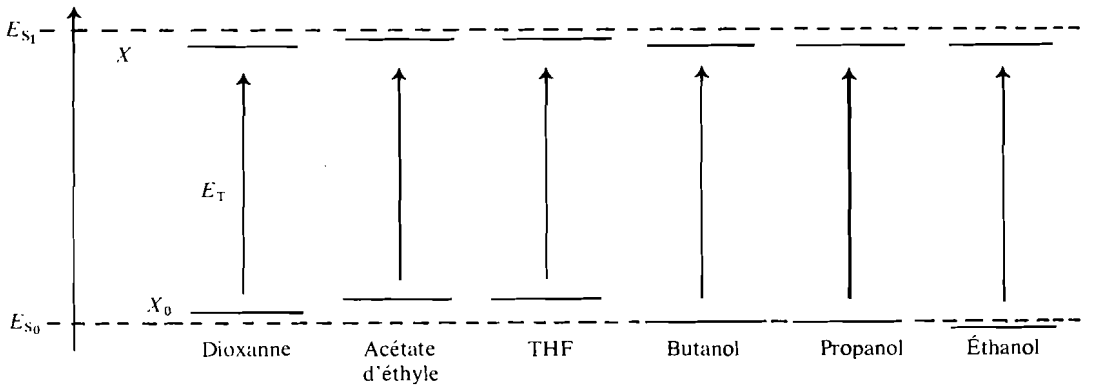
En effet, si nous appelons: E_T = l'énergie de transition de l'aniline dans différents solvants; E_{S_0} = l'énergie de la molécule d'aniline dans son état fondamental; E_{S_1} = l'énergie de la molécule d'aniline dans son premier état singulet excité; X_0 = l'énergie de la molécule d'aniline associée au solvant, (état fondamental); X = l'énergie de la molécule d'aniline associée au solvant (état excité).

La connaissance de $X_0 - E_{S_0}$ nous permet de situer le niveau énergétique de l'état fondamental de l'amine associée par rapport à l'amine à l'état vapeur ou dans un solvant inerte. $X = X_0 + E_T$ = valeur énergétique du premier singulet excité de l'amine en solution. $X - E_{S_1}$: permet de situer le niveau énergétique de l'état S_1 de l'amine associée, par rapport à l'amine à l'état vapeur ou dans un solvant inerte.

L'expression $X_0 - E_{S_0}$ représente en fait l'énergie de solvatation de l'amine, valeur que nous avons précédemment calculée (16). Les valeurs de E_T pour l'aniline ont été déterminées pour la bande O—O, grâce aux courbes de fluorescence réalisées au laboratoire (17). L'énergie de transition prise comme référence correspond à une solution d'aniline dans l'hexane.

On obtient les résultats suivants:

	E_T	$X_0 - E_{S_0}$ (kcal/mol)	$X - E_{S_1}$ (kcal/mol)
Référence	94.347		
Dioxanne	91.488	0.575	−2.28
Acétate d'éthyle	91.633	2.081	−0.63
Tétrahydrofurane	91.339	1.945	−1.06
Butanol	91.773	0	−2.57
Propanol	91.928	0.20	−2.62
Éthanol	91.928	0.50	−2.82



Résultats non surprenants où l'on constate que la différence entre les énergies $X - E_{S_1}$ augmente avec la polarité du solvant. Il y a une exception toutefois avec le dioxanne dont nous avons déjà signalé le comportement particulier lorsqu'on l'utilise comme solvant de l'aniline (16).

On remarquera d'une part, pour les solvants non hydroxylés: l'énergie de l'aniline à l'état fondamental est plus élevée lorsqu'il y a association que lorsque cette même molécule est libre; que l'énergie nécessaire à la transition varie dans le même sens.

Si cette dernière remarque reste valable avec les solvants hydroxylés, par contre l'état énergétique du complexe soluté-solvant se situe à un niveau inférieur.

Les liaisons conduisant à des effets opposés, nous avons pensé qu'elles devaient donner au soluté tantôt un rôle d'accepteur d'électrons, tantôt un rôle de donneur d'électrons.

Cette hypothèse nous conduit à la représentation suivante. Solvants non hydroxylés (type dioxanne)

[i] 
Solvants hydroxylés

[2] 
Dans le premier cas, l'association amine–solvant favorise la migration des électrons libres de l'azote sur le cycle, dans le second cas, la liaison hydrogène localise les électrons libres de l'azote et diminue la résonance.

Ce résultat est confirmé par l'étude des *NN'*-méthyl aniline et *NN'*-éthyl aniline, où les variations du moment spectroscopique (Δm) deviennent très faibles. Dans ce cas, la possibilité de liaisons hydrogènes entre les groupements portés par l'azote et les atomes d'oxygène des solvants étant pratiquement nulle, nous trouvons *N,N'*-méthyl aniline, $\Delta m = 2.1$; *N,N'*-éthyl aniline, $\Delta m = 3.1$, alors que pour l'aniline, nous avons $\Delta m = 37$.

L'existence des liaisons hydrogène, telles que nous les avons représentées, nous permet également de vérifier l'hypothèse de Kimura *et al.* (2), à savoir la possibilité d'un transfert de charge, ce transfert de charge pouvant augmenter de 22% l'intensité de la bande d'absorption.

Dans notre cas, nous aurions possibilité maximale de transfert avec les solvants non hydroxylés, possibilité minimale de transfert avec les solvants hydroxylés, le transfert pouvant être considéré comme constant lorsque l'on passe de l'état vapeur à l'amine en solution dans l'hexane solvant inerte (18).

En appelant ε_h = coefficient d'absorption molaire de l'aniline dans l'hexane et ε_e = coefficient d'absorption molaire de l'aniline dans l'eau, nous devons avoir

$$\varepsilon_h - 0.22\varepsilon_h = \varepsilon_e$$

Le calcul nous donne, $\varepsilon_e = 1326$; l'expérience, $\varepsilon_e = 1300$.

Conclusion

L'étude spectroscopique de l'aniline dans différents solvants nous a permis de mettre en évidence:

L'existence de liaisons soluté–solvant où selon la nature de celui-ci, le soluté se comportera soit en accepteur d'électrons, soit en donneur d'électrons au sein du complexe 1:1 formé.

D'expliquer les variations d'intensité de la bande d'absorption considérée, ainsi que les déplacements de sa longueur d'onde maximale d'absorption.

D'attribuer à la molécule d'aniline une configuration plane, seule compatible avec l'existence d'un transfert de charge azote-cycle.

Enfin de prévoir un rendement chimique plus élevé lors d'une oxydation photochimique dans un solvant non hydroxylé, que dans un solvant hydroxylé, si, comme on peut le supposer, le mécanisme d'oxydation fait intervenir la molécule d'amine dans son état excité.

Received December 23, 1974

EDMUND MALINSKI, ANTONINA PIEKOS, and TOMASZ A. MODRO. Can. J. Chem. **53**, 1468 (1975).

The nitration of some tertiary phosphine oxides $ArP(O)R_2$ in aqueous sulfuric acid has been investigated. All compounds studied react as conjugate acids. When the phosphinyl group is bonded directly to the benzene ring, high deactivation and *meta*-orientation is found, accompanied in most cases by some substitution at the *ortho* position. The substituent effects of the "quasiphosphonium" group $P(OH)R_2^+$ are compared with those of structurally related systems and are discussed in terms of p_π–d_π interactions of the oxygen and the phosphorus atom.

EDMUND MALINSKI, ANTONINA PIEKOS et TOMASZ A. MODRO. Can. J. Chem. **53**, 1468 (1975).

On a étudié la nitration de quelques oxydes de phosphines tertiaires, $ArP(O)R_2$, dans l'acide sulfurique aqueux. Tous les composés étudiés réagissent sous forme d'acides conjugués. Quand le groupe phosphinyle est lié directement au noyau benzénique, on trouve que le noyau est désactivé et l'orientation se fait principalement en *meta*; dans la plupart des cas il y a un peu de substitution en position *ortho*. On compare les effets de substituant du groupe "quasiphosphonium" $P(OH)R_2^+$ avec ceux de systèmes qui lui sont reliés d'une façon structurale et on discute de ces effets en terme d'interactions p_π–d_π de l'oxygène et de l'atome de phosphore.
[Traduit par le journal]

We have recently demonstrated (1) that the deactivating effect of the phosphorus positive pole in aromatic nitration is drastically decreased when the "classical" phosphonium substituent PMe_3^+ is replaced by the "quasiphosphonium" $P(OH)_3^+$ obtained by protonation of phosphonic acid group. This change in reactivity was attributed to back-donating interactions between oxygen atoms and phosphorus, resulting in a high degree of charge delocalization in the $P(OH)_3^+$ substituent.

In terms of the availability of the oxygen nonbonding electrons for the p_π–d_π interactions with phosphorus atom, protonated tertiary phosphine oxides of the type $Ph—P(OH)R_2^+$ occupy an intermediate position between the quaternary phosphonium ions $Ph—PR_3^+$ and the protonated aromatic phosphonic acids, $Ph—P(OH)_3^+$. Quantitative comparison of the reactivities in these structurally related series should provide further information on the detailed nature of the factors influencing substituent effects in such systems. We have therefore studied the nitration of some tertiary phosphine oxides of the type $Ph(CH_2)_nP(O)R_2$, differing in alkyl groups R and in ring – phosphorus atom distance (n = 0, 1, 2), and compared these results with previous data obtained for various aromatic systems containing phosphorus atom in a side chain.

Experimental

Solvents were purified by conventional methods. Melting and boiling points are uncorrected. Thin-layer chromatography was carried out on standard glass plates covered with Kieselgel G (E. Merck) and developed by iodine vapors. Column chromatography was performed using Kieselgel 60 (E. Merck); for all chromatographic experiments solvent system benzene – chloroform – isopropyl alcohol (2:1:1) was used. Solutions of sulfuric acid were obtained by diluting AnalaR sulfuric acid (d 1.83) with distilled water and standarized with aqueous NaOH. AnalaR nitric acid (d 1.42) was distilled from an equal volume of concentrated H_2SO_4 immediately before use.

The u.v. spectra were recorded using a Perkin–Elmer 402 or a Carl Zeiss–Jena VSU-2 spectrophotometer; n.m.r. spectra were obtained with a Tesla BS-487 (80 MHz) spectrometer with TMS or HMDSO as internal

standards. Infrared spectra were recorded on a Unicam SP-200 spectrophotometer.

Substrates

Phenyldimethyl- (**1**), phenyldiethyl- (**2**), and phenyldiisopropylphosphine (**3**) oxides were prepared by oxidation of the corresponding phosphines (ref. 2, p. 34), according to the reported procedure (ref. 2, p. 144). Phenyldi(chloromethyl)phosphine oxide (**4**) was synthesized according to Yagupolskii and Yufa (4) by reaction of $PhPCl_4$ with diazomethane. Benzyldiethylphosphine oxide (**5**) was prepared from diethyl phosphite by reaction with ethylmagnesium bromide followed by benzyl bromide (5); β-phenylethyldiethylphosphine oxide (**6**) was obtained by degradation of the quaternary β-phenylethyldiethylphenylphosphonium bromide, following the procedure reported by Meisenheimer *et al.* (6) for the dimethyl derivative. The purity of substrates was controlled chromatographically (single spot on the t.l.c. plate). Since all phosphine oxides studied save compound **4** are highly hygroscopic, they were dried under reduced pressure over P_2O_5 until no absorption band due to water molecules could be found in their i.r. spectra. The properties of compounds **1–6** are collected in Table 1.

Kinetics

Rate measurements were carried out as described before (1). The extent of reaction was determined from the variation in the absorbance at 260–280 nm in samples of the reaction mixture, quenched at suitable times in large volumes of water. In all cases good second-order kinetics during individual kinetic runs were observed.

Product Determination

Substrate, **1–4**, (5×10^{-3} mol) was added slowly to a 10-fold excess of nitric acid (d 1.5)[3] at 0°, then kept at room temperature for 24 h. Nitric acid was evaporated under reduced pressure at room temperature and the residue dried in vacuum over KOH. The nitration product (quantitative yield) was then examined chromatographically (t.l.c.) and spectroscopically (n.m.r., i.r., u.v.). Substrate **4** gave single-component nitration product; in case of **1–3** two products were present in the reaction mixture. Reaction products formed in nitration of compounds **1–3** were separated by column chromatography and the following pure mononitroderivatives were obtained:

From substrate **1**:

(3-nitrophenyl)dimethylphosphine oxide, 90%, m.p. 183–184° (from acetone–hexane); λ_{max} 263 nm; ε 7200; R_f 0.44.

(2-nitrophenyl)dimethylphosphine oxide, 10%, m.p. 79–81°; λ_{max} 270 nm; ε 4300; R_f 0.53.

From substrate **2**:

(3-nitrophenyl)diethylphosphine oxide, 93%, m.p. 112–113° (from acetone–hexane); λ_{max} 263 nm; ε 6900; R_f 0.60.

(2-nitrophenyl)diethylphosphine oxide, 7%, oil; λ_{max} 270 nm; ε 3700; R_f 0.66.

From substrate **3**:

(3-nitrophenyl)diisopropylphosphine oxide, 99%, m.p. 152–153° (from acetone–hexane); λ_{max} 263 nm; ε 6200; R_f 0.71.

(2-nitrophenyl)diisopropylphosphine oxide, *ca.* 1%, oil; λ_{max} 270 nm; ε 4400; R_f 0.76.

From substrate **4**:

(3-nitrophenyl)di(chloromethyl)phosphine oxide, 100%, m.p. 152–154° (lit. (4) m.p. 154–155°); λ_{max} 266 nm; ε 6900; R_f 0.72.

For the (3-nitrophenyl)dimethylphosphine oxide the following n.m.r. spectrum was obtained ($CDCl_3$): 1.76 (d, 6H), $J_{CH_3,P}$ = 14 Hz; 7.66 (triplet of doublets, 1H), $J_{H_5,H_{4,6}}$ = 7 Hz; $J_{H_5,P}$ = 3 Hz; 7.87–8.37 (m, 2H); 8.47 (doublet of triplets, 1H), $J_{H_2,P}$ = 13 Hz; $J_{H_2,H_{4,6}}$ = 2 Hz.

Nuclear magnetic resonance spectrum of the (2-nitrophenyl)dimethylphosphine oxide showed: 1.85 (d, 6H), $J_{CH_3,P}$ = 14 Hz; 7.50–7.95 (m, 2H); 8.14 (quartet of doublets, 1H), J_{H_3,H_4} = 7 Hz; $J_{H_3,P}$ = 3 Hz; J_{H_3,H_5} = 2 Hz; 8.47 (quartet of doublets, 1H), $J_{H_6,P}$ = 13 Hz; J_{H_6,H_5} = 7 Hz; J_{H_6,H_4} = 2 Hz.

Structural assignments for the nitration products of compounds **2–4** were obtained in the same manner.

[3]For isolation purposes nitric acid is a better reaction medium than sulfuric acid. We have found that this change of the medium has no effect on the product composition.

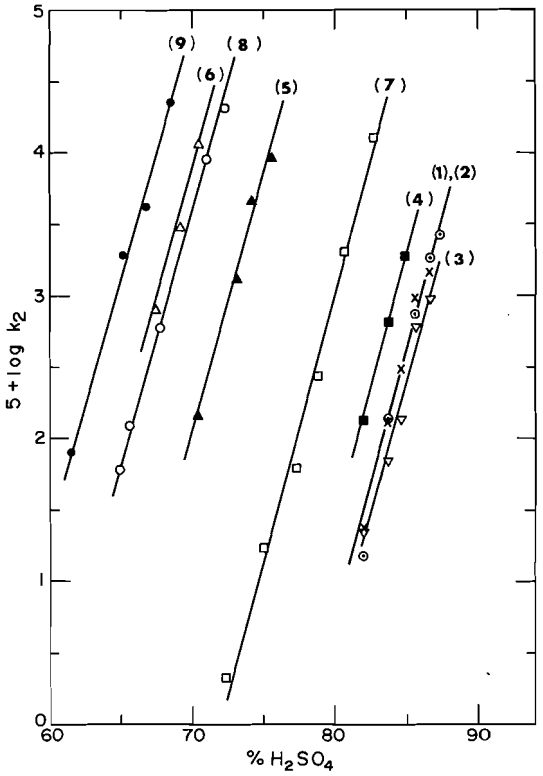

FIG. 1. Variation of rate coefficients (l mol^{-1} s^{-1}) with acidity for nitration in sulfuric acid; (**1**), PhP(O)Me_2; (**2**), PhP(O)Et_2; (**3**), PhP(O)*i*-Pr_2; (**4**), PhP(O)$(CH_2Cl)_2$; (**5**), $PhCH_2P(O)Et_2$; (**6**), $PhCH_2CH_2P(O)Et_2$; (**7**), $PhPO_3H_2$; (**8**), $PhCH_2PO_3H_2$; (**9**), $PhCH_2CH_2PO_3H_2$.

Results and Discussion

Second-order rate constants for nitration in sulfuric acid are listed in Table 2. Rate profiles are shown in Fig. 1; included are data (10) for $Ph(CH_2)_nPO_3H_3^+$ (n = 0, 1, 2) system for comparison.

All plots of log k_2 *vs.* acidity are satisfactorily linear ($r > 0.99$) and to a first approximation parallel to each other (slope values = 0.34–0.40). According to arguments presented before (1), this type of rate–acidity dependence obtained for nitration proves that for a given acidity range all substrates react entirely as protonated species. In all cases, the reactivity data reflect therefore the effect of the substituent of the "quasiphosphonium" structure, $-\overset{|}{\underset{|}{P}}(OH)^+$. The parallelism of the rate profiles allowed an evaluation of relative reactivities by standard overlap technique. The pertinent data related to the reactivity of benzene are collected in Table 3.

Table 3 shows clearly that in the protonated phosphine oxides the substituent $P(OH)R_2^+$ deactivates the ring to a much higher extent than does the protonated phosphonic group $P(OH)_3^+$, the ratio of reactivities $k_{rel(PO_3H_3^+)}/k_{rel(PEt_2OH^+)}$ for the series $Ph(CH_2)_nX$ being equal to 200, 25, and 10 for n = 0, 1, and 2, respectively. In fact, the $P(OH)Me_2^+$ group, when bonded directly to the benzene ring, shows a slightly stronger deactivating effect (by a factor of three) than the "pure" trimethylphosphonium pole. This is in agreement with results of Eaborn and co-workers (13), who found that in the protodetrimethylsilylation reaction, involving fully protonated substrates, deactivation decreases in the same order. The observed order of reactivities suggests that the back-donation of electrons due to a single oxygen atom in the protonated phosphinyl group is too weak to outweigh the −I effect of the OH group. The effect of successive methylene groups introduced between the ring and the substituent (compounds **5** and **6** in Table 3), when considered in terms of the approach discussed previously (10), shows again the close resemblance of the substituent effects of the $P(OH)R_2^+$ and PMe_3^+ groups.[4] In the extreme case of the protonated phosphonic acid group, on the other hand, three equivalent resonance structures of type **B** contribute significantly to the charge distribution and therefore decrease effectively the total electron-withdrawing properties of the substituent:

$$\underset{\mathbf{A}}{-\overset{|}{\underset{|}{P^+}}-OH} \leftrightarrow \underset{\mathbf{B}}{-\overset{|}{\underset{|}{P}}=OH^+}$$

The behavior of phenyldi(chloromethyl)phosphine oxide (**4**) is of some interest. Despite the presence of two strongly electronegative atoms, this compound is more reactive (by a factor of five) than the corresponding dimethyl derivative (**1**). This result, seemingly contradictory to the usual structural effects on the net polarity of substituents, remains however in excellent agreement with some conclusions obtained from

[4]The ratio log $(k_{rel}^{CH_2X}/k_{rel}^{X})/-\log k_{rel}^{X}$, considered as a measure of the relative contributions of the inductive and mesomeric interactions to the net polar effect of substituent X, has almost the same value for X = PMe_3^+ and X = $P(OH)Et_2^+$.

n.m.r. spectroscopic investigations concerning the detailed nature of bonding in phosphorus-containing systems. An increase in shielding of the phosphorus atom by electron-withdrawing groups caused by an increase in p_π–d_π conjugation is generally observed (14); for example, replacement of methyl by chloromethyl at the phosphoryl function $—\overset{|}{\underset{|}{P}}=O$ results in an upfield ^{31}P chemical shift, and also the contributions to shielding of the tetravalent phosphorus atom from directly bonded groups were found to decrease in the order $Ph \geqslant CH_2Cl > CH_3$ (15). Van Wazer and Letchner demonstrated (16) that the π-bonding order for the PO bond in OPZ_3 type molecules increases from 0.35 to 0.50 when $Z = CH_3$ is changed to $Z = CH_2Cl$. These authors found also that for $Z = t$-Bu, the π-bonding is virtually nonexistent, and explained this result in terms of the large value of the Z—P—Z angle, inhibiting π-electron feedback from the oxygen. This interpretation could also be applied to explain why the phenyldiisopropylphosphine oxide (**3**) exhibits the lowest reactivity among the phosphine oxides studied in this work. The observed relative deactivating effects in substrates **1** and **4** to our knowledge represent the first example in which electronegative groups modify the p_π–d_π bonding order at phosphorus to the extent that is reflected in the increase of the reactivity of the adjacent system in an electrophilic reaction.

Preparative nitration of tertiary arylphosphine oxides has not been extensively studied; in the reported cases exclusive *meta*-substitution with respect to the phosphinyl group was observed (17). Since we found an unusually high discrimination between *ortho* and *para* positions during nitration of benzenephosphonic acid (1) (18% *ortho* and no *para* substitution), we have determined the product composition for nitration of compounds **1–4** in order to establish how far this intramolecular selectivity is general for the "quasiphosphonium" systems.

The nitration of phenyldimethylphosphine oxide (**1**) resulted in formation of two products, easily demonstrated by t.l.c. and p.m.r. of the reaction mixture. When separated by column chromatography, two mononitroderivatives of **1** (in 90% and 10% yield) were obtained. On the basis of spectroscopic characteristics, the main product was recognized as (*m*-nitrophenyl)-dimethylphosphine oxide, such a result being in full agreement with the general directing pattern of phosphonium and "quasiphosphonium" substituted benzene derivatives. The second product was identified as the corresponding *ortho*-nitrocompound. The proton resonance of the methyl groups in this isomer occurs at 0.09 p.p.m. (in $CDCl_3$) to low field of the corresponding doublet of the *meta*-isomer. In the aromatic region, the low-field C_6-hydrogen (*ortho* to phosphorus, $\delta = 8.47$) and C_3-hydrogen (*ortho* to NO_2, $\delta = 8.14$) can be easily distinguished from the C_4 and C_5-hydrogen signals and show the pattern expected for the 1,2-disubstituted structure. The same analysis showed that the minor product formed in nitration of **2** (7%), as well as of **3** (*ca.* 1%) are *ortho*-nitroderivatives; no sign of the A_2B_2 pattern expected for the *para*-nitroproduct was observed. The *ortho* structure of the isolated minor components of nitration products was also supported by their i.r. and u.v. characteristics. The i.r. spectra of the individual products showed at the region of 800–900 cm^{-1} (out-of-plane C—H deformation vibrations) absorption bands expected for the 1,3 and 1,2 substitution patterns, respectively. The intensity of the absorption in the u.v. region was considerably lower for the side-products than for the main products, which is in agreement with the previously observed decrease in intensity in the order $\varepsilon_p > \varepsilon_m > \varepsilon_o$ for all such nitro-substituted benzene derivatives containing phosphorus.

TABLE 4. Partial rate factors for nitration in aqueous sulfuric acid, 25.0°

Substituent	$f_o \times 10^7$	$f_m \times 10^7$	f_p	$\delta\Delta G_o^{\neq}/\delta\Delta G_m^{\neq}$
$P(OH)Me_2^+$	0.16	1.48	—	1.14
$P(OH)_3^{+*}$	60	270	—	1.14
$P(OH)_2H^{+*}$	10	50	—	1.13

*Taken from ref. 1.

In agreement with results reported by Yagupolskii and Yufa (4), nitration of phenyldi-(chloromethyl)phosphine oxide (**4**) gave a single product which was identified as pure *meta*-nitroderivative; no isomeric substitution products could be detected.

The decreasing proportion of the *ortho*-nitration with the increase in the size of the alkyl groups in $P(OH)R_2^+$ substituent (10%, 7%, *ca.* 1% for R = Me, Et, *i*-Pr, respectively) clearly results from the increase of the steric hindrance for the attack at *ortho* positions. More important however is that in all cases the products of *para*-substitution are formed in negligible amounts if at all. This pattern of intramolecular selectivity follows closely the orientation found in nitration of benzenephosphonic (protonated and unprotonated) and benzenephosphonous ($Ph—PO_2H_2$) acids (1). Since it seems reasonable to assume that steric requirements of the $P(OH)_3^+$, $P(OH)_2H^+$, and $P(OH)Me_2^+$ substituents are similar, the values of partial rate factors for these systems can be directly compared also with respect to the reactivity of the *ortho* positions (Table 4). Although the reactivities of the given position in these substrates differ significantly, the ratio of the substituent effects on the free energy of activation at the *ortho*- and *meta*-positions, $\delta\Delta G_o^{\neq}/\delta\Delta G_m^{\neq}$ has the same value. This can be considered as an indication of a common mechanism for intramolecular selectivity operating in all systems in which phosphorus atom, bonded to at least one oxygen, is attached to the aromatic ring.

Substituents of the −I, −M type are known to give in nitration an *o*/*p* ratio usually >2 (ref. 18, chapt. 9.1.3); however the discrimination of the *para* position in electrophilic substitution of the "quasiphosphonium" type of benzene derivatives seems to be much more pronounced.[5] The possibility must therefore be considered that with these substituents, when there is no steric hindrance, the initial specific interaction with the electrophile species occurs at the substituent, followed then by a selective transfer of the electrophile to the *ortho* position of the ring. The nature of such specific effects is not clear, as in other cases when the specific electrophile–substituent interactions are taken into account (ref. 18, chapt. 5.3.4). However, summarizing the evidence presented in this and previous papers, we feel it reasonable to consider organophosphorus groups of the structural type $—\overset{|}{\underset{|}{P(O)}}$ or $—\overset{|}{\underset{|}{P(OH)^+}}$ as a rather unusual group of substituents, which deactivate the ring in electrophilic substitution with distinctive *meta*/*ortho* orientation and rigorous discrimination of the *para*-substitution. It is worth mentioning that nitration of phenylboronic acid in strongly acidic media (19) provides an example which probably resembles most closely this pattern of substituent effects.

[5]We have recently observed a similar pattern of *meta*/*ortho* orientation with negligible *para*-substitution for positive bromination of tertiary aromatic phosphine oxides (20).

Reactions of OH, CH_2OH, Br_2^-, and $(CNS)_2^-$ Free Radicals with Cysteine at p*H* 5.3

GREESH CHAND GOYAL[1] AND DAVID ANTHONY ARMSTRONG
Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received November 4, 1974

GREESH CHAND GOYAL and DAVID ANTHONY ARMSTRONG. Can. J. Chem. **53**, 1475 (1975).

The products of radiolysis of cysteine in nitrous oxide saturated solutions at p*H* 5.3 have been investigated both in the absence of other solutes and in the presence of 1 *M* methanol, 0.5 *M* KBr, and 0.2 *M* NaCNS. The results can be explained by a mechanism in which the free radicals •OH, $•CH_2OH$, $•Br_2^-$, and $•(CNS)_2^-$ all react with the cysteine (CysSH) sulfhydryl group to form CysS• as a major intermediate product. Minor yields (0.2 molecules per 100 eV) of ammonia observed in the case of attack by $•Br_2^-$ may result from attack on the NH_3^+ group or α-hydrogen by this species. Cysteine trisulfide was observed in all systems with a yield 0.12 ± 0.03 molecules per 100 eV and is probably formed from minor secondary reactions of CysS• radicals. In agreement with previous conclusions based on the analysis of products from deaerated solutions the majority of CysS• radicals form CysSSCys.

GREESH CHAND GOYAL et DAVID ANTHONY ARMSTRONG. Can. J. Chem. **53**, 1475 (1975).

On a examiné les produits de radiolyse de la cystéine dans des solutions saturées en oxyde nitreux à un p*H* de 5.3 en l'absence d'autres solutés de même qu'en présence de méthanol 1 *M*, de KBr 0.5 *M* et de NaCNS 0.2 *M*. Les résultats peuvent être expliqués par un mécanisme dans lequel les radicaux libres •OH, $•CH_2OH$, $•Br_2^-$ et $•(CNS)_2^-$ réagissent tous avec le groupe sulfhydryle de la cystéine pour former le radical CysS• comme un produit intermédiaire majeur. Les rendements mineurs (0.2 molécules par 100 eV) d'ammoniac observés dans le cas de l'attaque par $•Br_2^-$ peuvent provenir d'une attaque, par cette espèce, soit sur le groupe NH_3^+ soit sur l'hydrogène en α. Dans tous les cas, on a observé la formation de trisulfure de cystéine et le rendement est de 0.12 ± 0.03 molécules par 100 eV; ce composé se forme probablement à partir de réactions secondaires mineures des radicaux CysS. La majorité des radicaux CysS• forment CysSSCys; cette conclusion est en accord avec d'autres énoncés précédemment et qui étaient basés sur l'analyse des produits provenant de solutions desquelles l'air avait été enlevée.
[Traduit par le journal]

Introduction

Previous studies of the γ (1, 2) and pulse radiolysis (3, 4) of aqueous oxygen free solutions of cysteine ($HSCH_2CH(NH_3^+)CO_2^-$) and the related molecule cysteamine ($HSCH_2CH_2NH_3^+$) (5) have shown that the major products can be explained by the following mechanism, in which the abbreviation CysSH is used for the cysteine structure:

[1] $H_2O \rightsquigarrow •OH\ •H\ e_{aq}^-\ H^+\ H_2O_2\ H_2$

[2] $•OH + CysSH \rightarrow CysS• + H_2O$

[3] $•H + CysSH \rightarrow CysS• + H_2$

[4] $•H + CysSH \rightarrow Cys• + H_2S$

[5] $e_{aq}^- + H^+ \rightarrow •H$

[6] $e_{aq}^- + CysSH \rightarrow Cys• + SH^- \ (\xrightarrow{H^+} H_2S)$

[7] $Cys• + CysSH \rightarrow CysH + CysS•$

[8] $CysSH \rightleftharpoons CysS^- + H^+$

[9] $CysS• + CysS^- \rightleftharpoons CysS\overset{\bullet}{S}^-Cys$

[10] $CysS• + CysS• \rightarrow CysSSCys$

[11] $CysS• + CysS\overset{\bullet}{S}^-Cys \rightarrow CysS^- + CysSSCys$

[12] $H_2O_2 + 2CysSH \rightarrow CysSSCys + 2H_2O$

More recently Purdie *et al.* (6) have investigated the radiolysis of penicillamine ($HSC(CH_3)_2CH(NH_3^+)CO_2^-$ = HSPen) and have found clear evidence for the production of a significant yield of penicillamine trisulfide (PenSSSPen). Since this behavior is quite different from previous observations of cysteine radiolysis and may have implications for an understanding of differences in their abilities as protectors (6), we have reinvestigated the cysteine system to determine whether any trisulfide is in fact formed. We have also broadened the scope of our study to determine the products resulting from the reactions of $•(Br_2)^-$, $•(CNS)_2^-$, and $•CH_2OH$ with cysteine. Pulse

radiolysis experiments (7) show that the rate constants for reaction with CysSH by the former two radicals increase markedly in the pH region where —SH ionizes (pK CysSH 8.3 (8)) and above pH 8 they are assumed to react preferentially with $CysS^-$ (7), presumably to cause oxidation to CysS. Our present interest lay in determining the mechanism of reaction at pH 5.3, where the rate constants are still appreciable (see Table 1) even though CysSH is un-ionized.

In the case of the $\cdot CH_2OH$ radical two reactions are conceivable, since alcohol radicals may

[13] $CysSH + \cdot CH_2OH \rightarrow CysS\cdot + CH_3OH$

[14] $CysSH + \cdot CH_2OH \rightarrow Cys\cdot + CH_2O + H_2S$ (or $SH^- + H^+$)

behave as hydrogen atom acceptors (9) or as reducing agents (10, 11). The prior observation (9) of a pseudo first-order build up of —S$\dot{S}^-$— anions in the pulse radiolysis of N_2O-saturated solutions containing 1.13 mM cysteamine and higher concentrations of methanol was taken as evidence for the cysteamine analogs of reactions 13 and 9, the former being rate controlling. While vitiating the possibility of reaction 14 for the cysteamine system, this evidence does not completely exclude it since minor contributions of —S$\dot{S}^-$— from the sequence of reactions 14, 7, and 9 may not alter the rate of production significantly from that expected for reactions 13 and 9 alone. In the present system the yield of reaction 14 can be determined from the alanine yield.

Experimental

Potassium bromide and sodium thiocyanate from the Baker Chemical Company and L-cysteine from Mann Research Laboratories were used without further purification. The methanol was A.C.S. certified reagent grade. High purity nitrous oxide from the Matheson Co. was freed from traces of NO and other noncondensible gases by several cycles of sublimation, condensation, and pumping at −196 and −132 °C. After this it was stored in a bulb on the vacuum line. Cysteine solutions of pH 5.3 were prepared in fresh, triply distilled water containing the solutes needed for the production of the radicals being investigated. Following this 5 ml aliquots were transferred to the carefully cleaned pyrex cells and attached to the vacuum line. After thorough degassing (2) the samples were equilibrated with N_2O at 760 mm and sealed. Prior to irradiation they were stored in a refrigerator. Immediately after irradiation the analysis for amino-containing products was performed on a Technicon amino acid analyzer. Norleucine was used as an internal standard and elution buffers of pH 3.10, 3.30, and 4.50 were employed in succession for periods of 50, 60, and 50 min, respectively. A final buffer of pH 5.0 was used to elute ammonia. Standardization procedures and other details of the amino acid analyses may be found in ref. 2.

All irradiations were performed at 23 °C in a "Gamma Cell 220" purchased from Atomic Energy of Canada. The dose rate, which was determined by ferrous sulfate dosimetry assuming $G(Fe^{3+}) = 15.6$ (p. 217 of ref. 12), was 4.5×10^{16} eV ml^{-1} min^{-1}.

Results

Chromatograms of the irradiated solutions exhibited clearly resolved peaks due to residual cysteine and to alanine, cystine, cysteine trisulfide, norleucine (internal standard), and ammonia in the order given. The cysteine trisulfide was a minor product in all solutions, while ammonia was only detectable in the KBr solutions. In solutions containing methanol a small unidentified peak appeared before the residual cysteine. It corresponded to a G of about 0.1, assuming a ninhydrin sensitivity equal to that of alanine. No other peaks of any significance were observed.

Experiments with each solute system were performed at several doses in the range 1.0 to 6.0×10^{18} eV ml^{-1}. Yield–dose plots calculated

TABLE 2. G values of amino-containing products and nitrogen balance from N_2O-saturated 10^{-2} M cysteine solutions with added solutes at pH 5.3

	No added solute		1 M CH_3OH		0.5 M KBr		0.2 M NaCNS	
Product	G value	G(N)	G value	G(N)	G value	G(N)	G value	G(N)
CySSCy	3.25±0.25	6.50	3.05±0.2	6.10	3.43±0.3	6.86	3.48±0.2	6.96
CyH	0.88±0.05	0.88	0.89±0.06	0.89	0.83±0.05	0.83	0.77±0.06	0.77
CySSSCy	~0.14	0.28	~0.12	0.24	~0.15	0.30	~0.10	0.20
NH_3					0.20±0.04	0.20		
Total N		7.65		7.25		8.2		7.95
−CySH[a]	7.9±0.5		7.3±0.5		8.5±0.5		8.1±0.5	

[a]Determined from the decrease in the cysSH peak.

from the peak areas were linear, both for the products and for residual cysteine. The G values calculated from their slopes are presented in Table 2. In each case there is an excellent nitrogen balance, showing that the overall stoichiometry:

$$[15]\quad G(-\mathrm{CysSH}) = 2G(\mathrm{CysS})_2 + 2G(\mathrm{CysSSSCys}) + G(\mathrm{CysH})$$

holds. Thus one can conclude that all significant products, other than H_2S which was previously found to follow the alanine yield closely (2), have been determined.

Discussion

The amount of cystine formed from hydrogen peroxide would be negligible here since reaction 12 has a half life of ~10 h (2*b*) and our solutions were analyzed immediately after the radiolyses, which were themselves of less than 2 h duration. Hence only reactions initiated by ·H, ·OH, and e_{aq}^- or by the solute radicals formed from them need be considered. Table 1 gives the yields of primary radicals estimated for our conditions from data in the literature. From the concentration of N_2O (2.8×10^{-2} *M*) and the rate constants for reactions 6 ($9 \times 10^9\ M^{-1}\ s^{-1}$ (1, 2)) and 16 ($9 \times 10^9\ M^{-1}\ s^{-1}$, average of two values on p. 55 of ref. 12):

$$[16]\quad e_{aq}^- + N_2O + (H_2O) \rightarrow N_2 + OH + OH^-$$

we calculate that 0.78 e_{aq}^- per 100 eV would undergo reaction 6. Since $G_H = 0.6$ (ref. 12, p. 140) in the absence of solutes and $k_3/k_4 = 3.5$ (2*a*), a further yield of 0.13 alanyl radicals per 100 eV would be formed in reaction 4, giving a total yield of alanine molecules from reaction 7 of ~0.9 per 100 eV. This is in excellent agreement with the yield reported in Table 2 for solutions with only N_2O and cysteine. The alanine yield in the 1 *M* CH_3OH solutions is the same, showing that reaction 13 is in fact the only important mode of $\cdot CH_2OH$ attack on CysSH at p*H* 5.3. From Table 1 the yields of G_H in 0.5 *M* KBr and 0.2 *M* NaCNS are expected to be lower and this also appears to be reflected in the smaller alanine yields for these solutions in Table 2.

From the rate constants in column two of Table 1 and k_2 in column four it can be shown that 8, 24, and 17% of the OH radicals react directly with CysSH in the CNS^-, Br^-, and CH_3OH solutions, respectively. The remainder are converted to $\cdot(CNS)_2^-$, $\cdot Br_2^-$, and $\cdot CH_2OH$ by reactions 17–18, 19–20, and 21, respectively:

$$[17]\quad OH + CNS^- \rightarrow OH^- + \cdot CNS$$

$$[18]\quad \cdot CNS + CNS^- \rightleftharpoons \cdot(CNS)_2^-$$

$$[19]\quad \cdot OH + Br^- \rightarrow OH^- + \cdot Br$$

$$[20]\quad \cdot Br + Br^- \rightleftharpoons \cdot Br_2^-$$

$$[21]\quad \cdot OH + CH_3OH \rightarrow H_2O + \cdot CH_2OH$$

The ubiquitous occurrence of trisulfide in a yield of 0.1–0.15 molecules per 100 indicates that it is not a product of specific reactions of any one radical, for example:

$$[22]\quad \mathrm{CysSH} + OH \rightarrow \mathrm{Cys}\cdot + \mathrm{HSOH} \rightarrow S + H_2O$$

$$[23]\quad S + \mathrm{CysSSCys} \rightarrow \mathrm{CysSSSCys}$$

In fact the relative constancy of the disulfide and trisulfide yields in Table 2 is best explained if all four radical species attack CysSH to produce CysS· through reactions 2, 13, 24, and 25:

$$[24]\quad \mathrm{CysSH} + \cdot Br_2^- \rightarrow \mathrm{CysS}\cdot + 2Br^- + H^+$$

$$[25]\quad \mathrm{CysSH} + \cdot(CNS)_2^- \rightarrow \mathrm{CysS}\cdot + 2CNS^- + H^+$$

and CysSSSCys arises from secondary reactions of CysS·. One possibility is the cleavage of sulfenium radicals formed in reaction 26, *viz*:

$$[26]\quad \mathrm{CysS}\cdot + \mathrm{CysSH} \rightleftharpoons \mathrm{CysS}\overset{\cdot}{\underset{H}{S}}\mathrm{Cys}$$

$$[27]\quad \mathrm{CysS}\overset{\cdot}{\underset{H}{S}}\mathrm{Cys} \rightarrow (\mathrm{CysSSH} + \mathrm{Cys}\cdot)_{\text{solvent cage}} \rightarrow (\mathrm{CysSS}\cdot + \mathrm{CysH})_{\text{solvent cage}} \rightarrow \mathrm{CysSS}\cdot + \mathrm{CysH}$$

followed by:

$$[28]\quad \mathrm{CysSS}\cdot + \cdot\mathrm{SCys} \rightarrow \mathrm{CysSSSCys}$$

Tung and Stone (18) have proposed reaction 29

$$[29]\quad \mathrm{CysS}\overset{\cdot}{S}^-\mathrm{Cys} + H_2O \rightarrow \mathrm{CysSS}\cdot + \mathrm{CysH} + OH^-$$

above p*H* 7 and an analogous reaction has been postulated in penicillamine (6). However, further work will be required to confirm the occurrence of reaction 27 for the protonated form of the anion. The important point here is that, in accord with previous conclusions (1–5), cysteine trisulfide is a relatively minor product. Thus the significant difference between the radiation chemistry of penicillamine and cysteine in this respect is confirmed.

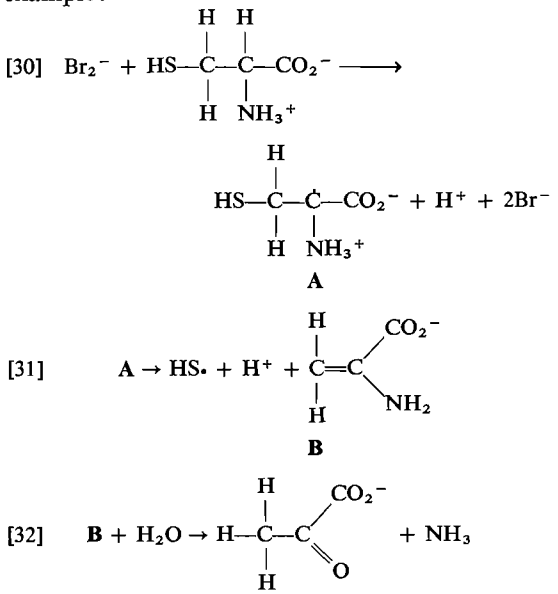
The relatively minor pathway responsible for the small yield of ammonia in the $\cdot Br_2^-$ system is not at present understood. However, one may note that the attack of $\cdot Cl_2^-$ on cystine produces ammonia in an even larger yield (19). Possibly the negative charge and strong oxidizing power of these radicals facilitates their attack at the NH_3^+ group (*cf.* ref. 19) or the adjacent α-hydrogen, causing hydrolysis and deamination, for example:



From the major reactions proposed the following radical balance equation should hold:

$$[33]\quad 2[G(\mathrm{CysS})_2 + G(\mathrm{CysSSSCys})] = G_{\mathrm{H}} + G_{\mathrm{OH}} + G_{e_{aq}^-}$$

Reference to Table 1 substantiates its validity within the experimental uncertainty of ±0.5 per 100 eV for all of the solute systems.

JEAN-ROCK BRINDLE and JEAN-LOUIS LIARD. Can. J. Chem. **53**, 1480 (1975).

Sulfurated sodium borohydride reacts with benzylic halides to give high yields of α-toluenethiol or benzylic polysulfides depending upon the experimental conditions and the mode of hydrolysis.

Aliphatic halides and dibenzylic halides react in the same manner as benzylic halides for a given experimental condition whereas benzylic halides substituted with other groups can be totally or partially reduced depending on the stability of the substituent towards $NaBH_2S_3$.

Halogens directly attached on the aromatic ring do not react with $NaBH_2S_3$.

JEAN-ROCK BRINDLE et JEAN-LOUIS LIARD. Can. J. Chem. **53**, 1480 (1975).

La réaction de $NaBH_2S_3$ avec les halogénures benzyliques conduit à une production quantitative d'α-toluènethiol ou de polysulfures benzyliques dépendant des conditions expérimentales employées et du mode d'hydrolyse choisi.

Les halogénures aliphatiques et les halogénures dibenzyliques réagissent de la même manière que les halogénures benzyliques sous des conditions expérimentales similaires, alors que les halogénures benzyliques substitués par d'autres groupes, peuvent être réduit totalement ou partiellement dépendant de la stabilité du deuxième groupe vis-à-vis $NaBH_2S_3$.

Les halogénures directement fixés sur un noyau benzénique ne réagissent pas avec $NaBH_2S_3$.

Martin and Greco (1) and Tsurugi and Nakabayaski (2) have already reported the synthesis of thiols (1) and sulfides (2) from benzylic halides in very moderate yields. This report describes a significant improvement of the existing synthetic procedures resulting from the use of sulfurated sodium borohydride (3) as a new reagent for the preparation of thiols or sulfides from halogenated compounds.

From Table 1, it can be seen that after treatment with $NaBH_2S_3$, the predominance of a given benzylic sulfurated compound depends largely upon the method of hydrolysis and the experimental conditions used. Considering benzyl chloride as a typical case, we notice that hydrolysis with sodium hydroxide favors greatly the production of sulfides in every case except when a high temperature and an excess of reducing agent are used. At constant temperature, an increase in the molar ratio of the sulfurated hydride increases the production of thiols and the same effect is observed when there is an increase in temperature at constant molar ratio. From these observations it is normal to find very high yields of thiols when an excess of reducing agent and high temperature are used, this effect being independant of the method of hydrolysis. Experimental conditions avoiding large excess of $NaBH_2S_3$ give moderate yields of thiols and sulfides when acidic hydrolysis is used but give high yields of sulfides when hydrolysis is made with a 10% sodium hydroxide solution.

Table 2 shows the reactivity of different organic iodides, chlorides, or bromides and shows that the general trend previously observed with benzyl halides is also verified with other benzylic and aliphatic halides. Methyl iodide reacts the same way as benzyl iodide under similar experimental conditions yielding mainly the corresponding thiol. For aliphatic chlorides, such as *t*-butyl chloride and 2-(chloroethyl)benzene, it appears that the same type of reactivity is obtained except when steric hindrance is important enough to inhibit reaction as seems to be the case with *t*-butyl chloride. 1-(Bromoethyl)benzene reacts in a fashion similar to benzylic bromide yielding similar proportions of the corresponding thiol and polysulfides. *p*-Dibenzylic chlorides give excellent yields of the corresponding dithiols. With substituted benzylic chlorides, such as *p*-nitrobenzyl chloride, the reaction proceeds normally under mild experimental conditions

to give nitrated thiols and polysulfides. With stronger reaction conditions, the reaction proceeds further to transform the nitro group into the amino group.

From the already known selectivity of $NaBH_2S_3$, it can be said that substituted benzylic chlorides would react normally to give the corresponding thiols and sulfides especially if the substituted group is inert to $NaBH_2S_3$, as is the case for ester, acid, ether, or olefinic groups. The same conclusion may be applied to *p*-nitrobenzyl bromide as shown by the results of Table 2.

In conclusion it is important to note that aromatic halides are inert to $NaBH_2S_3$ as shown in Table 2 whereas aliphatic and benzylic halogenated compounds give excellent yields of the corresponding sulfurated products. Actually, the main advantage of sulfurated sodium borohydride over the older reagents for the production of thiols and sulfides from halogenated compounds, is that $NaBH_2S_3$ generally leads to an almost quantitative yield of thiols or sulfides depending essentially upon the choice of the reaction conditions and the mode of hydrolysis, whereas older methods (1, 2) give more moderate yields and call for specific reagents in order to assure the production of thiols or of sulfides.

Experimental

The n.m.r. measurements were made with a Perkin-Elmer R-12A apparatus. The i.r. measurements were made with a Pye Unicam SP 200G spectrophotometer.

Typical Procedures for the Reaction of $NaBH_2S_3$ and Organic Halides

The experimental conditions for the reductions have been described in earlier works (4, 5) and the separation of the reaction products has been made by evaporation or distillation of α-toluenethiol followed by separation over column chromatography using silica gel and a mixture of hexane–CCl_4 as eluant, in order to isolate the sulfides. The identification of these sulfurated compounds has been confirmed by a comparative study of the n.m.r. chemical shifts with the authentic products as mentioned by Grant and Van Wazer (6).

Optimal Conditions for the Reaction of Benzyl Chloride

To a suspension of 0.20 mol (26.40 g) of $NaBH_2S_3$ prepared as described by Lalancette (3) in 200 ml of tetrahydrofuran, 0.05 mol (6.33 g) of benzyl chloride in 100 ml of tetrahydrofuran was added dropwise. The reaction mixture was stirred and refluxed for 16 h and was then evaporated to dryness, under reduced pressure, at room temperature. The residual solid was covered with 200 ml of ethyl ether and 10% hydrochloric acid was added until the p*H* of the reaction mixture was 1.0. The precipitated sulfur was filtered off and the filtrate washed repeatedly with ethyl ether. The organic fraction was then dried over $MgSO_4$ and the evaporation of ether gave a 99% yield of α-toluenethiol. A similar reaction using equimolar quantities of $NaBH_2S_3$ and benzyl chloride at 65° for 16 h was hydrolyzed with a 10% sodium hydroxide solution until the p*H* of the reaction mixture was 11.0. The ethereal fraction was dried over $MgSO_4$ and the evaporation of ether gave a mixture of thiol and sulfides. After evaporation of the α-toluenethiol (13%), the residual solid was analyzed by a column chromatography study using a silica gel column and a mixture of hexane–CCl_4 as eluant. The separation gave 59% of benzyl sulfide and 29% of benzyl disulfide.

The positive identification of all products was made by a comparative n.m.r. study with authentic samples.

The Rearrangement of Aryl Thiohydrazonates

ARTHUR J. ELLIOTT

Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

AND

PATRICK D. CALLAGHAN, MARTIN S. GIBSON, AND STEVEN T. NEMETH

Department of Chemistry, Brock University, St. Catharines, Ontario L2S 3A1[1]

ARTHUR J. ELLIOTT, PATRICK D. CALLAGHAN, MARTIN S. GIBSON, and STEVEN T. NEMETH. Can. J. Chem. **53**, 1484 (1975).

Rearrangement and cyclization of a series of *p*-nitrophenyl and heteroaryl thiohydrazonates ArSCAr′ = $NNHC_6H_3XY(2,4)$, where the displaced substituent X is Br or F and the remaining substituent Y is Br or NO_2, occurs under suitable basic conditions to the corresponding 7-substituted 2-aryl-4-*p*-nitrophenyl- and -4-heteroaryl-4*H*-1,3,4-benzothiadiazines, *e.g.* **13** → **19**. Under these or suitable acidic conditions, the 4,6-dimethyl-2-pyrimidinyl thiohydrazonate rearranges to the thiohydrazide $Ar'CSNHNArC_6H_3XY(2,4)$, apparently the first case of thiohydrazonate-thiohydrazide rearrangement; such acidic treatment produces cleavage of some other heteroaryl thiohydrazonates.

Independent syntheses of two of the 4-heteroaryl-substituted benzothiadiazines are reported.

ARTHUR J. ELLIOTT, PATRICK D. CALLAGHAN, MARTIN S. GIBSON et STEVEN T. NEMETH. Can. J. Chem. **53**, 1484 (1975).

Le réarrangement et la cyclisation d'une série de thiohydrazonates de *p*-nitrophényles et d'hétéroaryles ArSCAr′ = $NNHC_6H_3XY(2,4)$ dans lesquels le substituant déplacé X est Br ou F et l'autre substituant Y est Br ou NO_2 se produit dans des conditions basiques appropriées pour conduire aux aryl-2 *p*-nitrophényl-4 et aux hétéroaryl-4 4*H*-benzothiadiazines-1,3,4 substituées en position 7, *e.g.* **13** donne **19**. Dans ces conditions et/ou dans des conditions acides appropriées, le thiohydrazonate de diméthyl-4,6 pyrimidinyle-2 se réarrange pour fournir le thiohydrazide $Ar'CSNHNArC_6H_3XY(2,4)$ et ceci est apparamment le premier cas d'un réarrangement thiohydrazonate en thiohydrazide; un tel traitement acide produit généralement une coupure d'autres thiohydrazonates d'hétéroaryles.

On rapporte des synthèses indépendantes de deux des benzothiadiazines substitués par des hétéroaryles-4. [Traduit par le journal]

Huisgen *et al.* (1) have noted that whereas thermolysis of 2,5-diphenyltetrazole in phenol gave *N′*,*N′*-diphenylbenzohydrazide, the corresponding reaction in thiophenol gave phenyl *N*-phenyl(thiobenzohydrazonate) (**1**); the corresponding *p*-tolyl thiohydrazonate was prepared similarly. Both thiohydrazonates were stable under the conditions of formation at 160–170°. Thermal rearrangement of **1** to *N′*,*N′*-diphenyl-(thiobenzohydrazide) (**2**) under conditions where oxygen analogs (aryl hydrazonates) rearrange satisfactorily to *N′*,*N′*-diarylhydrazides was attempted later by Hegarty *et al.* (2) but without success.

$PhC(SPh)=NNHPh$ (**1**) $\qquad$ $PhCSNHNPh_2$ (**2**)

Our approach to the problem of rearrangement of aryl thiohydrazonates has involved two considerations: (*i*) the *S*-aryl ring should be made electron deficient by substitution and/or incorporation of heteroatom(s); (*ii*) rearrangement should be further facilitated by employing basic conditions to increase the nucleophilicity of the terminal nitrogen of the hydrazonyl system or, where the *S*-aryl group is basic, by employing acidic conditions to increase the electrophilicity of that group. In most cases substituents in the *N*-aryl group were chosen with a view to synthesis of 4*H*-1,3,4-benzothiadiazine derivatives as indicated below.

Initially the hydrazonyl bromide **3** was treated with *p*-nitrothiophenol in ethanol (EtOH) in presence of triethylamine (NEt_3) to give the thiohydrazonate **13**. By contrast with the corresponding reaction of **3** with thioacetate ion, there was apparently no conversion of **3** to hydrazonyl sulfide (3); also, neither *p*,*p*-dinitrodiphenyl sulfide nor *p*,*p*-dinitrodiphenyl disulfide was detected in the reaction mixture. Other

hydrazonyl halides were similarly converted to corresponding *p*-nitrophenyl thiohydrazonates **14–18**, except in the case of **8** where competing reaction of *p*-nitrothiophenoxide ion with the thiocyanato group occurred leading to a complex mixture, possibly containing disulfides (4), from which a small yield of **17** was isolated (Scheme 1). The structures of the thiohydrazonates were confirmed by examination of mass spectra which revealed characteristic loss of the elements of *p*-nitrothiophenol from the molecular ions (5).

When the thiohydrazonate **13** was treated with EtOH–NEt_3 at reflux, the product isolated was not the isomeric *N'*,*N'*-diaryl(thiobenzohydrazide) (product of rearrangement) but the thiadiazine **19** (product of rearrangement and cyclization). Thiohydrazonates **15**, **16**, and **18** similarly gave thiadiazines **20**, **21**, and **22**, respectively, but no thiadiazine was obtained from **17**, a result consistent with earlier observations (3). The primary product from **10** and *p*-nitrothiophenol, presumably the thiohydrazonate, similarly was converted to **23**, whilst the conversion of **14** to **19**, sluggish in EtOH–NEt_3, was achieved readily by employing the perhaps unnecessarily forcing conditions of reflux with sodium hydroxide and NEt_3 in dimethylformamide (DMF).

These reactions differ from the rearrangement of aryl hydrazonates which lead to *N'*,*N'*-diarylhydrazides (2, 5) and resemble rather those reactions of hydrazonyl halides with thioacetate ion in which a hydrazonyl thioacetate, presumed as intermediate, undergoes rearrangement and cyclization by displacement of transiently activated *o*-halogen to a 4-acetyl-4*H*-1,3,4-benzothiadiazine (3). In the absence of definite evidence for involvement of an intermediate *N'*,*N'*-diaryl(thiobenzohydrazide) in thiadiazine formation, it is reasonable to assume that such an intermediate is consumed as it is formed.

A group of heteroaryl thiohydrazonates (**24–29**, **30***a*, and **31***a*) was next prepared by treatment of **4** with (*i*) the appropriate thiol in EtOH–NEt_3 or (*ii*) the sodium salt of the thiol; **30***b* and **31***b* were prepared similarly from the appropriate thiols and hydrazonyl halides **3** and **12**, respectively (Scheme 2). As in the above preparations of *p*-nitrophenyl thiohydrazonates, no hydrazonyl sulfides were detected in the reaction mixtures. Also, as with the *p*-nitrophenyl analogs, loss of the elements of the heterocyclic thiol from the molecular ions was a characteristic feature of the mass spectra of these heteroaryl thiohydrazonates.

It had been reported that **1** undergoes hydrolysis to PhCONHNHPh in concentrated hydrochloric acid – methanol (1) and that the analogous hydrazonate behaves similarly (2). Such conditions should presumably be avoided for the heteroaryl thiohydrazonates if rearrangement is desired. After experimentation, it was noted that **16** and an analogous hydrazonate (**14**; O instead of S in formula) were stable in concentrated hydrochloric acid – benzene under certain conditions and this system was adopted for the work in hand. When the pyrimidinyl thiohydrazonate **24** was so treated, the isomeric thiohydrazide **32** was obtained in 55% yield, providing the first instance in this work of a

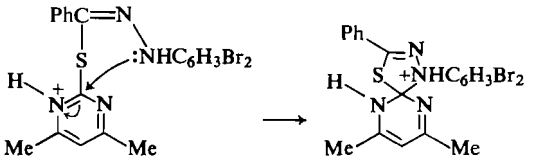
SCHEME 2

thiohydrazonate → thiohydrazide rearrangement which was not complicated by subsequent reactions. However, with the tetrazolyl thiohydrazonate **25**, it was noted that acidic cleavage supervened to give the corresponding thiol and hydrazonyl chloride **11**, providing incidentally further evidence for structural assignment **25**; the presence of the hydrazide ($PhCONHNHC_6H_3Br_2$) was also indicated (t.l.c.), suggesting that some hydrolysis was occurring. Compound **25** could be reconstructed from the component thiol and **11** in EtOH–NEt_3. Acidic cleavage was also implicated in the more complex reaction of the quinoxalinyl thiohydrazonate **26** from which **11** was obtained, although none of the corresponding thiol was isolated. Compound **27** also gave a complex mixture under these conditions; no single product was isolated but there was some indication (p.m.r.) that the isomeric thiohydrazide was present. Compounds **28** and **29** were stable under these conditions.

The acid-catalyzed hydrolysis of hydrazonates has been interpreted in terms of protonation of the hydrazonate oxygen atom (2) and similar considerations can be applied to acidic cleavage and hydrolysis of thiohydrazonates, *i.e.* protonation of the thiohydrazonate sulfur atom and subsequent reaction involving chloride ion or water. However, with the present cases, alternative protonation of heteroatom(s) of the heteroaryl ring may occur, some of which would create a situation conducive to rearrangement, and the reaction course is presumably regulated by competition between these possibilities. The acid-catalyzed rearrangement **24** → **32** would thus proceed as follows:



Attention was next turned to the behavior of heteroaryl thiohydrazonates under basic conditions. In view of the above results with *p*-nitrophenyl analogs, it was considered likely that thiadiazines would result if S → N heteroaryl migration occurred. When the heteroaryl thiohydrazonates were treated with EtOH–NEt_3 at reflux, the corresponding thiadiazines were obtained in the following cases: **26** → **33**, **27** → **34**, **29** → **35**, **30***a* and *b* → **36**. With **30***a* there was evidence (t.l.c.) for the involvement of an intermediate, possibly the isomeric thiohydrazide, in the conversion to **36**. Under these reaction conditions, **24** rearranged to the thiohydrazide **32** after which decomposition slowly set in, whilst **25** was decomposed extensively. Unlike **27**, no reaction was observed with **28** and no reaction was observed with **31***a* or *b*, the latter having been chosen as a case where

any rearrangement could not be followed by thiadiazine formation. When treated with sodium hydroxide and NEt_3 in DMF, however, **31***a* gave **37** but the yield was poor owing to hydrolysis of the benzoxazole ring. Finally, the structures of two of the thiadiazines (**33** and **34**) were confirmed by alternative syntheses from **38** and 2-chloroquinoxaline and 2-chloro-5-nitropyridine, respectively.

It is interesting that so few instances of simple rearrangement of aryl thiohydrazonates to thiohydrazides have been observed but it would seem likely that more examples could be found along the lines of this work. It may be that in many cases equilibrium favors the aryl thiohydrazonate (unlike similar aryl hydrazonates) rather than the thiohydrazide under the conditions which have been employed and that thiadiazine formation constitutes a process for displacement of equilibrium. Regardless, however, of whether the thiohydrazide is involved as intermediate, the S → N aryl migration taking place in formation of thiadiazines can be seen as a Smiles-type rearrangement. For migrating heterocyclic rings, such rearrangements have been studied principally in the pyridine (6) and *s*-triazine (7) series, although there are clearly many other possibilities.

Experimental

Proton magnetic resonance spectra ($CDCl_3$) were recorded on Varian A-60 and T-60 spectrometers using tetramethylsilane as internal standard; the presence of exchangeable protons was confirmed by use of D_2O. Mass spectra were recorded on Hitachi Perkin-Elmer RMU-6A and AEI-MS902 spectrometers; data are quoted as *m/e* values for the lowest isotopic species, bromine excepted (^{81}Br and ^{79}Br).

Hydrazonyl halides were prepared by published methods (3, 5, 8), as were 4,6-dimethylpyrimidine-2-thiol (9), quinoxaline-2-thiol (10) (from 2-chloroquinoxaline (11)), and 5-nitropyridine-2-thiol (12).

DMF and NEt_3 were stored over NaOH for at least 4 days before use.

Preparation of p-Nitrophenyl Thiohydrazonates

As general procedure, the hydrazonyl halide (0.01 mol) and *p*-nitrothiophenol (0.01 mol) were stirred together in EtOH (25 ml) and NEt_3 (1 ml) at room temperature for 2 h; for **3** and **4** the quantities of EtOH and NEt_3 were 40 ml and 3 ml, respectively, and reaction time was 1 h. The product was filtered off, washed, dried, and purified by crystallization.

Compound **3** gave *p-nitrophenyl N-4-bromo-2-fluorophenyl(thiobenzohydrazonate)* (**13**) (3.0 g, 67%) as orange prisms, m.p. 153–155° (from benzene–ethanol); i.r. (Nujol) 3280 cm^{-1} (NH).

Anal. Calcd. for $C_{19}H_{13}BrFN_3O_2S$: C, 51.12; H, 2.91; Br, 17.94; N, 9.42. Found: C, 51.4; H, 3.1; Br, 18.0; N, 9.1.

Compound **4** gave **14** (4.5 g, 90%) as yellow plates, m.p. 173–175° (from benzene–ethanol).

Anal. Calcd. for $C_{19}H_{13}Br_2N_3O_2S$: C, 44.97; H, 2.56; N, 8.28; S, 6.31. Found: C, 45.23; H, 2.79; N, 8.56; S, 6.16.

Compound **5** gave **15** (3.1 g, 57%) as yellow needles, m.p. 164° (from ethanol); p.m.r. δ 9.1 (s, NH), 8.0 (A), and 7.0 (B) (A_2B_2q, J = 9.0 Hz), 8.25–7.3 (m, 7H), and 3.9 (s, 3H); mass spectrum (70 eV) *m/e* 539/537/535 (M^+), 457/455 (M^+ − HBr), 384/382/380 (M^+ − $NO_2C_6H_4SH$), 304/302, 278/276, 277/275, 252/250/248 ($Br_2C_6H_3NH$), 225/223/221, 198/196, 171/169, 170/168, 155 ($NO_2C_6H_4SH$), 151, 133, 90, and 63.

Anal. Calcd. for $C_{20}H_{15}Br_2N_3O_3S$: C, 44.70; H, 2.79; Br, 29.80. Found: C, 44.52; H, 2.68; Br, 29.83.

Compound **6** gave **16** (3.4 g, 63%) as yellow needles, m.p. 158–160° (from benzene–hexane).

Anal. Calcd. for $C_{19}H_{12}Br_2ClN_3O_2S$: C, 42.11; H, 2.22; N, 7.76. Found: C, 42.27; H, 2.25; N, 7.69.

Compound **7** gave **17** (2.62 g, 62%) as yellow needles, m.p. 159° (from ethanol).

Anal. Calcd. for $C_{19}H_{14}BrN_3O_2S$: C, 53.27; H, 3.27; N, 9.81. Found: C, 53.7; H, 3.4; N, 10.0.

Compound **8** (2.09 g, 0.005 mol) reacted under the normal conditions with evolution of HCN to give an orange-yellow solid. Chromatography on Florisil and elution with hexane–ether (4:1) gave **17** which crystallized from EtOH as yellow needles (0.4 g, 18%), m.p. 159°, identical with the foregoing sample of **17**. Further elution gave yellow tarry material from which no solid product was obtained.

Compound **9** gave **18** (2.8 g, 55%) as yellow needles, m.p. 170° (from ethanol).

Anal. Calcd. for $C_{17}H_{10}Br_3N_3O_2S_2$: C, 34.46; H, 1.69; Br, 40.54; N, 7.09. Found: C, 34.68; H, 1.74; Br, 40.51; N, 6.99.

Rearrangement of p-Nitrophenyl Thiohydrazonates and Formation of Substituted 4H-1,3,4-Benzothiadiazines

Compound **13** (1.0 g), EtOH (15 ml), and NEt_3 (15 ml), were boiled under reflux for 2.75 h. *7-Bromo-4-p-nitrophenyl-2-phenyl-4H-1,3,4-benzothiadiazine* (**19**) crystallized slowly from the reaction mixture and was isolated, after cooling, as orange prisms (0.75 g, 79%), m.p. 228–229°.

Anal. Calcd. for $C_{19}H_{12}BrN_3O_2S$: C, 53.52; H, 2.82; Br, 18.78; N, 9.86. Found: C, 53.3; H, 2.9; Br, 18.8; N, 9.8.

Compound **14** (1.0 g), NaOH (0.1 g), DMF (10 ml), and NEt_3 (2.5 ml) were boiled under reflux for 2 h. When cool, the crystalline precipitate (0.77 g, 90%) m.p. 225–227°, was collected; crystallization from benzene gave **19** as orange prisms, m.p. 227–229°, identical with the previous sample of **19**.

Compound **15** (2.0 g), EtOH (20 ml), and NEt_3 (20 ml) were boiled under reflux for 2 h. The solution was concentrated *in vacuo* and the orange solid was collected, washed, and dried. Crystallization from benzene gave the *thiadiazine* (**20**) (1.2 g, 74%) as orange prisms, m.p. 217° (dec.).

Anal. Calcd. for $C_{20}H_{14}BrN_3O_3S$: C, 52.63; H, 3.07; Br, 17.54. Found: C, 52.54; H, 2.97; Br, 17.65.

Compound **16** (2.0 g), treated as for **15** above, gave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

21 (0.7 g, 40%) as orange-yellow needles, m.p. 253–254° (dec.) (from benzene).

Anal. Calcd. for $C_{19}H_{11}BrClN_3O_2S$: C, 49.51; H, 2.39; N, 9.12. Found: C, 49.47; H, 2.41; N, 8.96.

Compound **17** (0.5 g), treated as for **15** above, gave a yellow gum which contained at least four components (t.l.c.), none of which was **17** or was fluorescent. Attempts to isolate solid products were unsuccessful.

Compound **18** (1.5 g), EtOH (15 ml), and NEt_3 (15 ml) were boiled under reflux for 4 h, cooled, and the product was filtered off. Compound **22** (0.8 g, 64%) crystallized from benzene–hexane as orange-brown prisms, m.p. 213°.

Anal. Calcd. for $C_{17}H_9Br_2N_3O_2S_2$: C, 39.92; H, 1.76; Br, 31.31; S, 12.52. Found: C, 39.62; H, 1.75; Br, 31.50; S, 12.65.

Compound **10** (3.10 g) was treated with *p*-nitrothiophenol in the manner described above for **5**. A sample (1.0 g) of the crude product was boiled under reflux with EtOH (10 ml) and NEt_3 (10 ml) for 4 h and the solution was then concentrated. The solid was collected, triturated with boiling acetone and benzene, and then crystallized from dioxan to give **23** as red prisms (0.37 g, 45% overall from **10**), m.p. 274° (dec.).

Anal. Calcd. for $C_{19}H_{12}N_4O_4S$: C, 58.16; H, 3.06; N, 14.29. Found: C, 58.6; H, 3.1; N, 14.0.

Preparation of Heteroaryl Thiohydrazonates

(i) The hydrazonyl halide (0.01 mol) and the thiol (0.01 mol) were stirred together in EtOH (30 ml) and NEt_3 (1 ml) at room temperature for 2 h; for preparations of **30** (*a* and *b*) and **31** (*a* and *b*), reaction times were 1 and 3 h, respectively, and the quantity of NEt_3 was increased to 3 ml. The product was filtered off (after dilution with water in the case of **27**), washed, dried, and purified by crystallization.

Compound **4** and quinoxaline-2-thiol gave the *thiohydrazonate* (**26**) (3.2 g, 63%) as yellow prisms, m.p. 142–143° (from hexane–toluene); p.m.r. δ 9.18 (s, NH), 8.52 (s, 1H) ,and 8.1–7.1 (m, 12H); mass spectrum *m/e* 516/514/512 (M^+), 435/433, 434/432, 381/379/377 ($Br_2C_6H_3NHC_8H_5N_2$), 354/352/350 ($M^+ - C_8H_5N_2SH$), 300/298, 251/249/247, 219, 170/168, 162 ($C_8H_5N_2SH$), 129, 121, 118, 103, and 91.

Anal. Calcd. for $C_{21}H_{14}Br_2N_4S$: C, 49.03; H, 2.72; Br, 31.13. Found: C, 49.01; H, 2.63; Br, 31.35.

Compound **4** and 5-nitropyridine-2-thiol gave **27** (3.4 g, 83%) as yellow plates, m.p. 144–145° (from ethanol – ethyl acetate). Analytical figures were discrepant. Proton magnetic resonance δ 9.25 (s, NH), 9.25 (d, 1H, $J = 2.5$ Hz), 8.4–7.98 (m, 3H), and 7.65–7.3 (m, 7H); mass spectrum *m/e* 510/508/506 (M^+), 477/475/473, 429/427, 428/426, 376/374/372 ($Br_2C_6H_3NC_5NH_3NO_2$), 354/352/350 ($M^+ - NO_2C_5H_3NSH$), 347, 309/307/305, 305/303, 295/293/291, 251/249/247 ($Br_2C_6H_3N$), 241, 198, 170/168, 155 ($NO_2C_5H_3NS$), 121, 103, and 76.

Compound **4** and benzothiazole-2-thiol gave **30***a* (4.8 g, 93%) as cream prisms, m.p. 128–130° (from benzene–ethanol).

Anal. Calcd. for $C_{20}H_{13}Br_2N_3S_2$: C, 46.24; H, 2.50; Br, 30.83; N, 8.09. Found: C, 46.5; H, 2.7; Br, 30.6; N, 8.0.

Compound **3** and benzothiazole-2-thiol gave **30***b* (1.4 g, 31%) as cream prisms, m.p. 100–102° (from ethanol).

Anal. Calcd. for $C_{20}H_{13}BrFN_3S_2$: C, 52.40; H, 2.84; N, 9.17; S, 13.97. Found: C, 52.1; H, 2.6; N, 8.9; S, 14.0.

Compound **4** and benzoxazole-2-thiol gave **31***a* (3.5 g, 69%) as reddish prisms, m.p. 136–138° (from benzene–hexane).

Anal. Calcd. for $C_{20}H_{13}Br_2N_3OS$: C, 47.71; H, 2.58; N, 8.35. Found: C, 48.27; H, 2.87; N, 8.20.

Compound **12** and benzoxazole-2-thiol gave **31***b* (2.5 g, 72%) as yellowish prisms, m.p. 116–117° (from benzene–hexane).

Anal. Calcd. for $C_{20}H_{15}N_3OS$: C, 69.57; H, 4.35; N, 12.17. Found: C, 59.76; H, 4.47; N, 12.03.

(ii) Sodium salts of thiols were prepared by addition of 1 equiv. of sodium to the thiol in EtOH and were then precipitated by addition of dry ether, collected, and stored *in vacuo*. The hydrazonyl halide **4** (0.01 mol) and the sodium salt of the thiol (0.01 mol) were stirred together in dry acetonitrile (30 ml) for 2 h, and the product was then filtered off, washed, dried and purified by crystallization. For preparation of **25**, EtOH (30 ml) was used as solvent and the product was collected after pouring the reaction mixture into water.

The sodium salt of 4,6-dimethylpyrimidine-2-thiol gave the *thiohydrazonate* (**24**) (3.7 g, 75%) as colorless needles, m.p. 118° (from hexane); i.r. (Nujol) 3280 cm^{-1} (NH); p.m.r. δ 9.15 (s, NH), 8.1–7.95 (m, 2H), 7.55–7.1 (m, 6H), 6.62 (s, 1H) and 2.32 (s, 6H); mass spectrum *m/e* 494/492/490 (M^+), 461/459/457, 413/411, 359/357/355 ($Br_2C_6H_3NHC_6H_7N_2$), 354/352/350 ($M^+ - C_6H_7N_2SH$), 310/308, 278/276, 251/249/247, 225, 170/168, 140 ($C_6H_7N_2SH$), 121, 103, 82, 77, and 67.

Anal. Calcd. for $C_{19}H_{16}Br_2N_4S$: C, 46.34; H, 3.25; Br, 32.52; N, 11.38. Found: C, 46.4; H, 3.4; Br, 32.6; N, 11.7.

The sodium salt of 1-phenyltetrazole-5-thiol gave **25** (4.7 g, 89%) as fawn needles, m.p. 171–172° (dec.) (from hexane–toluene); p.m.r. δ 9.05 (s, NH) and 7.9–7.25 (m, 13H).

Anal. Calcd. for $C_{20}H_{14}Br_2N_6S$: C, 45.28; H, 2.64; N, 15.85. Found: C, 45.53; H, 2.61; N, 15.75.

The sodium salt of pyridine-2-thiol gave **28** (3.5 g, 76%) as colorless needles, m.p. 131° (from hexane–toluene).

Anal. Calcd. for $C_{18}H_{13}Br_2N_3S$: C, 46.65; H, 2.81; Br, 34.56; N, 9.07. Found: C, 47.0; H, 3.1; Br, 34.8; N, 8.8.

The sodium salt of 4-methylquinoline-2-thiol gave **29** (3.8 g, 73%) as pale yellow prisms, m.p. 117–118° (from hexane–toluene).

Anal. Calcd. for $C_{23}H_{17}Br_2N_3S$: C, 52.37; H, 3.23; Br, 30.36; N, 7.97. Found: C, 52.3; H, 3.4; Br, 30.3; N, 7.9.

Behavior of Heteroaryl Thiohydrazonates under Acidic Conditions

(i) Compound **24** (1.0 g) was dissolved in warm benzene (30 ml) and concentrated HCl (10 ml) was added. The two-phase mixture was heated without agitation on a steam bath for 1 h and then cooled. The benzene layer was separated, washed with aqueous $NaHCO_3$ solution and water, and then dried and evaporated *in vacuo*. Crystallization from hexane–toluene gave the *thiobenzohydrazide* (**32**) (0.55 g, 55%) as bright yellow prisms, m.p. 142°; i.r. (Nujol) 3340 cm^{-1} (NH); p.m.r. δ 9.7 (s, NH), 8.1–7.15 (m, 8H), 6.47 (s, 1H), and 2.3 (s, 6H); mass

spectrum *m/e* 494/492/490 (M^+), 461/459/457, 413/411, 359/357/355, 310/308, 278/276, 251/249/247, 225, 197, 170/168, 121, 103, 77, and 67.

Anal. Calcd. for $C_{19}H_{16}Br_2N_4S$: C, 46.34; H, 3.25; Br, 32.52; N, 11.38. Found: C, 46.4; H, 3.2; Br, 32.5; N, 11.6.

(ii) Compound **25** (2.0 g) in benzene (50 ml) and concentrated HCl (20 ml) was treated as above. The benzene layer was washed with 2 *M* NaOH (50 ml) and the alkaline solution was acidified with concentrated HCl to precipitate a white solid which was filtered off and dried *in vacuo*. Crystallization from toluene gave 1-phenyltetrazole-5-thiol (0.4 g, 60%) as needles, m.p. 157° (dec.) (lit. (13) m.p. 147–150° (dec.)).

Anal. Calcd. for $C_7H_6N_4S$: C, 47.19; H, 3.37; N, 31.46; S, 17.98. Found: C, 47.38; H, 3.24; N, 30.98; S, 17.98.

The benzene solution was evaporated and the residue chromatographed on Florisil (toluene as eluant) to give **11** (0.6 g, 41%) as needles, m.p. 105–108° (from hexane) (lit. (3) m.p. 109–110°); p.m.r. δ 8.05 (s, NH), 7.6–7.4 (m, 2H), and 7.2–6.85 (m, 6H); mass spectrum *m/e* 390/388/386 (M^+), 354/352/350 (M^+ − HCl), 273/271, 251/249/247, 237/235/233, 225/223/221, 171/169, 170/168, 143/141, 119/117, 103, 89, 77.

Thin-layer chromatography indicated that the only other product from the reaction was almost certainly $PhCONHNHC_6H_3Br_2$.

Compound **11** (0.38 g) and 1-phenyltetrazole-5-thiol (0.18 g) isolated from the above reaction were stirred together with EtOH (5 ml) and NEt_3 (0.2 ml) for 2 h at room temperature and the mixture was then poured into water. Isolated by means of ether, compound **25** (0.05 g) crystallized from toluene as needles, m.p. and mixture m.p. 171–172° (dec.).

(iii) Compound **26** (2.0 g) in benzene (50 ml) and concentrated HCl (20 ml), treated as above, gave a mixture of at least eight components (t.l.c.); compound **11**, separated by chromatography (Florisil, hexane–toluene), crystallized from hexane as needles (0.2 g, 13%), m.p. 104–108°, identical with the previous sample.

(iv) Compound **27** (2.0 g), treated with concentrated HCl as above, gave a mixture of at least eight components, none of which could be separated in crystalline form. The product had the following spectral characteristics; i.r. (CCl_4) 3320 cm^{-1} (NH); p.m.r. δ 9.9 (s, NH), 9.02 (d, 1H, J = 2.5 Hz), 8.4–7.25 (m, *ca.* 10H), and 6.7 (d, 1H, J = 9.0 Hz).

The following compounds were unaffected by treatment with concentrated HCl – benzene under the above conditions: **28** and **29**, and **16** and an analogous hydrazonate (**14**; O instead of S).

Behavior of Heteroaryl Thiohydrazonates under Basic Conditions; Formation of Substituted 4H-1,3,4-Benzothiadiazines

(i) Compound **27** (2.0 g), EtOH (10 ml), and NEt_3 (10 ml) were boiled under reflux for 2 h, cooled, and the product was filtered off, washed, and dried. Crystallization from benzene gave *7-bromo-4-(5-nitro-2-pyridinyl)-2-phenyl-4H-1,3,4-benzothiadiazine* (**34**) (1.31 g, 79%) as yellow needles, m.p. 223°.

Anal. Calcd. for $C_{18}H_{11}BrN_4O_2S$: C, 50.59; H, 2.58; N, 13.11. Found: C, 50.8; H, 2.8; N, 12.9.

Compound **26** (2.57 g), EtOH (10 ml), and NEt_3 (10 ml) were boiled under reflux for 2 h. The solution was cooled, poured into 5% acetic acid (700 ml), and the product was filtered off, washed, and dried. Crystallization from benzene gave **33** (2.03 g, 94%) as yellow needles, m.p. 211–212°.

Anal. Calcd. for $C_{21}H_{13}BrN_4S$: C, 58.20; H, 3.00; Br, 18.48. Found: C, 58.05; H, 2.92; Br, 18.66.

Compound **29** (2.0 g), EtOH (10 ml), and NEt_3 (10 ml) were boiled under reflux for 2 h, cooled, and the product was filtered off, washed, and dried. The product was chromatographed on Florisil and the fraction containing the yellow fluorescent component (eluted with $CHCl_3$) was collected and evaporated. Crystallization from benzene gave **35** (0.2 g, 16%) as yellow needles, m.p. 204°; mass spectrum *m/e* 447/445 (M^+), 348, 315, 284, 283, 278, 263, 223, 177/175, 176/174, 159, 149, 142, 140, 130, 115, 103, 89, and 79.

Anal. Calcd. for $C_{23}H_{16}BrN_3S$: C, 61.88; H, 3.59; Br, 17.94; N, 9.42. Found: C, 61.6; 59.0; H, 4.2, 3.6; Br, 17.8, 18.0; N, 8.5.

Compound **30***a* (1.0 g), EtOH (20 ml), and NEt_3 (20 ml) were boiled under reflux for 3.5 h, cooled, and the product was collected. Crystallization from benzene gave **36** as yellow needles (0.43 g, 51%), m.p. 196–197°; compound **30***b* similarly gave **36** (80%), m.p. and mixture m.p. 196–197°.

Anal. Calcd. for $C_{20}H_{12}BrN_3S_2$: C, 54.79; H, 2.74; Br, 18.26; N, 9.59. Found: C, 54.9; H, 2.6; Br, 18.1; N, 9.7.

Compounds **28**, and **31***a* and *b* were unaffected after 2 h under the above conditions, whilst **25** was extensively decomposed. Compound **24** rearranged to **32**, reaction being virtually complete after 30 min (t.l.c.); the product (**32**) isolated after 2 h was contaminated with at least three other substances (t.l.c.) and could not be obtained pure.

(ii) Compound **31***a* (2.0 g), NaOH (0.2 g), DMF (15 ml), and NEt_3 (2.5 ml) were boiled under reflux for 3 h. The dark mixture was concentrated *in vacuo* to half bulk, chilled, and the brown solid was collected, washed with EtOH, and dried. After crystallization from cyclohexane, **37** (0.4 g, 24%) was obtained as pale green prisms, m.p. 158–161°.

Anal. Calcd. for $C_{20}H_{12}BrN_3OS$: C, 56.87; H, 2.84; N, 9.95. Found: C, 57.02; H, 2.94; N, 9.76.

Alternative Syntheses of Thiadiazines 33 and 34

Compound **38** (3) (1.02 g), 2-chloroquinoxaline (0.54 g), acetonitrile (20 ml), and NEt_3 (3 ml) were boiled under reflux for 4 h. Solvent was removed *in vacuo* and the solid was washed with water and dried. Crystallization from benzene gave **33** (0.9 g, 62%), m.p. and mixture m.p. 211–212°.

Compound **38** (1.02 g) and 2-chloro-5-nitropyridine (0.53 g) similarly gave **34** (1.1 g, 76%), m.p. and mixture m.p. 223°.

Under these conditions, **38** did not react with 2-chloro-4,6-dimethylpyrimidine or with 2-chloropyridine.

We thank the National Research Council of Canada for financial support, and Imperial Chemical Industries Ltd. for samples of pyridine-2-thiol and 4-methylquinoline-2-thiol.

Tetrafluoro- and Octafluoro[4.2]paracyclophanes

ROBERT FILLER AND EUI W. CHOE

Department of Chemistry, Illinois Institute of Technology, Chicago, Illinois 60616

Received August 19, 1974

ROBERT FILLER and EUI W. CHOE. Can J. Chem. **53**, 1491 (1975).

Synthetic sequences for the preparation of 6,7,9,10,14,15,17,18-octafluoro[4.2]paracyclophane (**1**) and 6,7,9,10-tetrafluoro[4.2]paracyclophane (**2**) are outlined. The u.v. absorption of compound **1** is hypsochromically shifted more than 20 nm from the long wavelength band (286–291 nm) characteristic of the [2.2]paracyclophanes.

ROBERT FILLER et EUI W. CHOE. Can. J. Chem. **53**, 1491 (1975).

On décrit les séquences de la synthèse de l'octafluoro 6,7,9,10,14,15,17,18[4.2]paracyclophane (**1**) et du tétrafluoro 6,7,9,10[4.2]paracyclophane. Le spectre d'absorption ultraviolet du composé **1** est déplacé d'une façon hypsochrome par plus de 20 nm par rapport à la bande à longueur d'onde longue (286–291 nm) caractéristique des [2.2]paracyclophanes.

For personal use only.

In previous papers we described the syntheses and properties of octafluoro[2.2]paracyclophane (1) and tetrafluoro[2.2]paracyclophane (2). We report here the syntheses of 6,7,9,10,14,15,17,18-octafluoro[4.2]paracyclophane (**1**) and its tetrafluoro analog (**2**), as outlined in Schemes 1 and 2, respectively.

While compound **1** was obtained in pure form after an arduous separation from its open-chain analog, *p*-$CH_3C_6F_4(CH_2)_4C_6F_4CH_3$-*p*, **2** could not be separated cleanly from the corresponding open-chain compound, which was also formed in the final reaction to give a 50:50 mixture (by p.m.r. spectral analysis).

We have discussed previously (2) the influence of polyfluoroaryl rings on the u.v. spectra of [2.2]paracyclophanes and speculated on the possible roles of attractive and repulsive transannular interactions. In the present study we observed the effect of bridge length by comparing the spectra of the octafluoro[2.2]- and [4.2]-paracyclophanes (Fig. 1). When the value of *m* decreases from 4 to 2, a large bathochromic shift (269 nm → 291 nm) occurs, which may reflect enhanced ring distortions with increased proximity of the fluoroaromatic nuclei. This argument requires further scrutiny in light of recent studies on [6]paracyclophane (3). The spectrum of **1** more closely resembles that of its open-chain model (Fig. 1). A similar, though less pronounced, behavior has been observed in the corresponding nonfluorinated analogs (4).

Experimental

All melting points are uncorrected. Infrared spectra were measured on a Perkin-Elmer Model 257 spectrophotometer or a Beckman IR-8 i.r. spectrometer using sodium chloride cells with a path length of 0.1 mm. Ultraviolet spectra in cyclohexane were obtained on a Beckman DK-2 spectrophotometer.

Proton magnetic resonance spectra were obtained on a Varian A-60 n.m.r. spectrometer. Chemical shifts are reported in p.p.m. relative to tetramethylsilane as internal standard. Fluorine magnetic resonance spectra were obtained on a Varian DA-60-IL spectrometer operating at 56.44 MHz in the high resolution mode. Chemical shifts were measured by the sideband technique and are reported in p.p.m. upfield or downfield from hexafluorobenzene as internal standard. Unless otherwise noted, all spectra were obtained at approximately 15% concentration in carbon tetrachloride.

Elemental analyses were conducted by Micro-Tech Laboratories, Inc., Skokie, Illinois and M-H-W Laboratories, Garden City, Michigan.

1,4-Bis(pentafluorophenyl)-2-butene

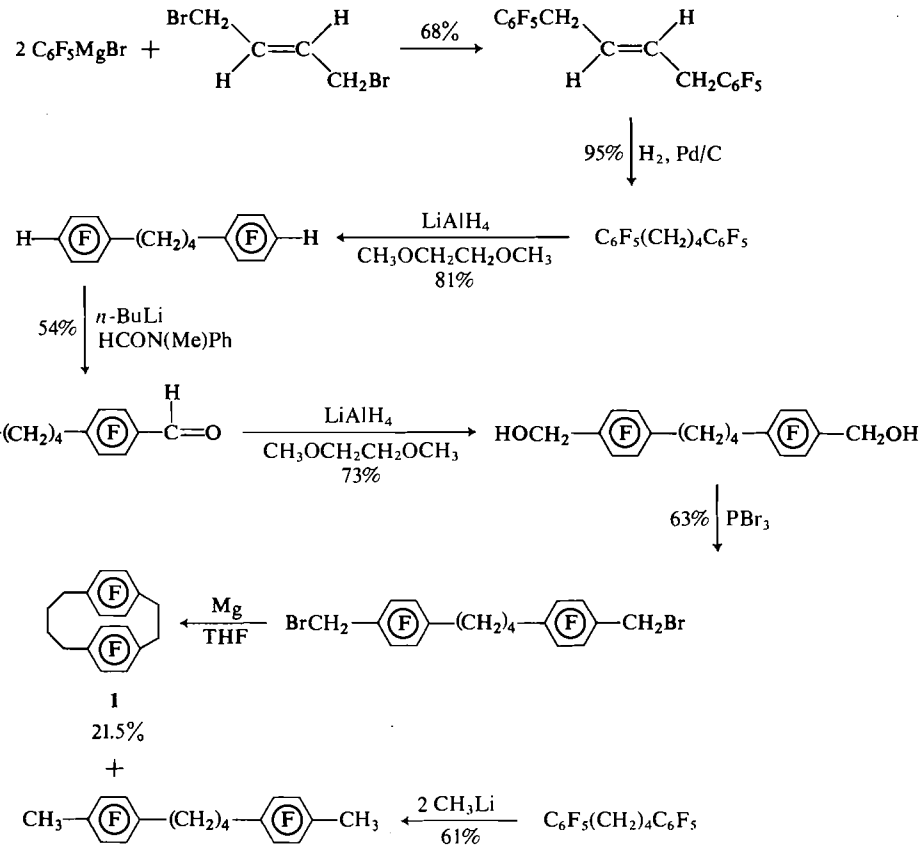
To the solution of pentafluorophenylmagnesium bromide, prepared under nitrogen by treating 6.08 g (0.25 g-atom) of magnesium with 61.8 g (0.25 mol) of bromopentafluorobenzene in 125 ml of anhydrous ether at 15°, was added 26.82 g (0.125 mol) of *trans*-1,4-dibromo-2-butene in 100 ml of anhydrous ether at a moderate rate. The resulting mixture was stirred for 28 h at reflux temperature and hydrolyzed by adding crushed ice and 150 ml of Jilute hydrochloric acid. The ether layer was separated, washed with water and a saturated ammonium chloride solution, dried ($MgSO_4$), and evaporated *in vacuo* to give a brown solid. Recrystallization from 95% ethanol with 8 g of activated charcoal afforded 33 g (67.8%) of white needles; m.p. 94–94.5°; n.m.r. (CCl_4): δ 5.64 (m, 2, vinylic) and 3.42 (m, 4, methylene).

1,4-Bis(pentafluorophenyl)butane

Hydrogenation of 1,4-bis(pentafluorophenyl)-2-butene was conducted in ethyl acetate solution in a Parr apparatus using 5% palladium-on-charcoal to give 87% of the desired product, m.p. 71.5–74°.

1,4-Bis(2',3',5',6'-tetrafluorophenyl)butane

To a solution of lithium aluminum hydride (10 g, 0.264 mol) in 240 ml of 1,2-dimethoxyethane, was added slowly



SCHEME 1

at 15°, 30 g (0.075 mol) of the bis(pentafluorophenyl)-butane. The resulting mixture was refluxed for 16 h. After decomposition of excess lithium aluminum hydride by adding a few drops of water followed by hydrolysis with dilute sulfuric acid, the mixture was poured into 2 l of water and a white solid precipitated. After decantation, the water layer was extracted with ether. The ether extract was used to dissolve the white solid, the solution was dried ($MgSO_4$), and evaporated *in vacuo* to give a white solid. Recrystallization from 95% ethanol afforded 22 g (81.3%) of product: m.p. 81.5–83°; n.m.r. δ 6.88 (triplet of triplet, 2, aromatic), 2.81 (m, 4, benzylic), and 1.71 (q, 4, J_{HH} = 3.38 Hz, methylene).

1,4-Bis(4′-formyl-2′,3′,5′,6′-tetrafluorophenyl)butane

To a solution of 0.12 mol *n*-butyllithium (75.4 ml of 15% *n*-butyllithium in hexane) cooled to −78°, was added slowly 21.2 g (0.06 mol) of the bis(tetrafluorophenyl)-butane in 400 ml of anhydrous ether. The resulting milky solution was allowed to react for 2 h. *N*-Methylformanilide (16.24 g, 0.12 mol) in 160 ml of ether was added and stirred for 3 h. After hydrolyzing with 100 ml of water and 100 ml of 6 *N* hydrochloric acid, the mixture was extracted with 1 l of ether. The ether extract was washed, dried ($MgSO_4$), and evaporated *in vacuo* to give a white solid. Trituration of this solid with 30 ml of ether and filtration gave 13.25 g (53.9%) of the bisaldehyde, m.p. 128–129°; i.r. ($CHCl_3$) 2770 (aldehyde C—H), 1705 (C=O), and 1485 cm^{-1} (polyfluoroaromatic ring); p.m.r. ($CDCl_3$) showed a triplet at δ 10.3, J_{HCCF} = 1.1 Hz (2H, —C_6F_4—CHO), a complex multiplet centered at 2.88 (4H, benzylic protons), and a quintet centered at 1.80, J_{HH} = 3.38 Hz (4H, methylene protons).

1,4-Bis(4′-hydroxymethyl-2′,3′,5′,6′-tetrafluorophenyl)-butane

To a solution of 1.52 g (0.04 mol) of lithium aluminum hydride in 250 ml of 1,2-dimethoxyethane, 20.5 g (0.05 mol) of bisaldehyde in 250 ml of 1,2-dimethoxyethane was added slowly at 15° and the mixture was stirred for 90 min. After addition of 100 ml of dilute hydrochloric acid, the mixture was poured into 3 l of water. The white solid was filtered and washed with water. Recrystallization from benzene gave 15 g (72.5%) of the diol, m.p. 172–174°; i.r. (CCl_4) 3400 and 3330 cm^{-1} (O—H).

1,4-Bis(4′-bromomethyl-2′,3′,5′,6′-tetrafluorophenyl)-butane

A mixture of 23.3 g (0.0563 mol) of bisdiol and 30.54 g (0.1126 mol, 10.71 ml) of phosphorus tribromide was heated at 140° for 5 h and then cooled and poured into 500 ml of water. The yellow solid was filtered, washed successively with water, a 5% sodium carbonate solution, then water, and dried in air. Recrystallization from carbon

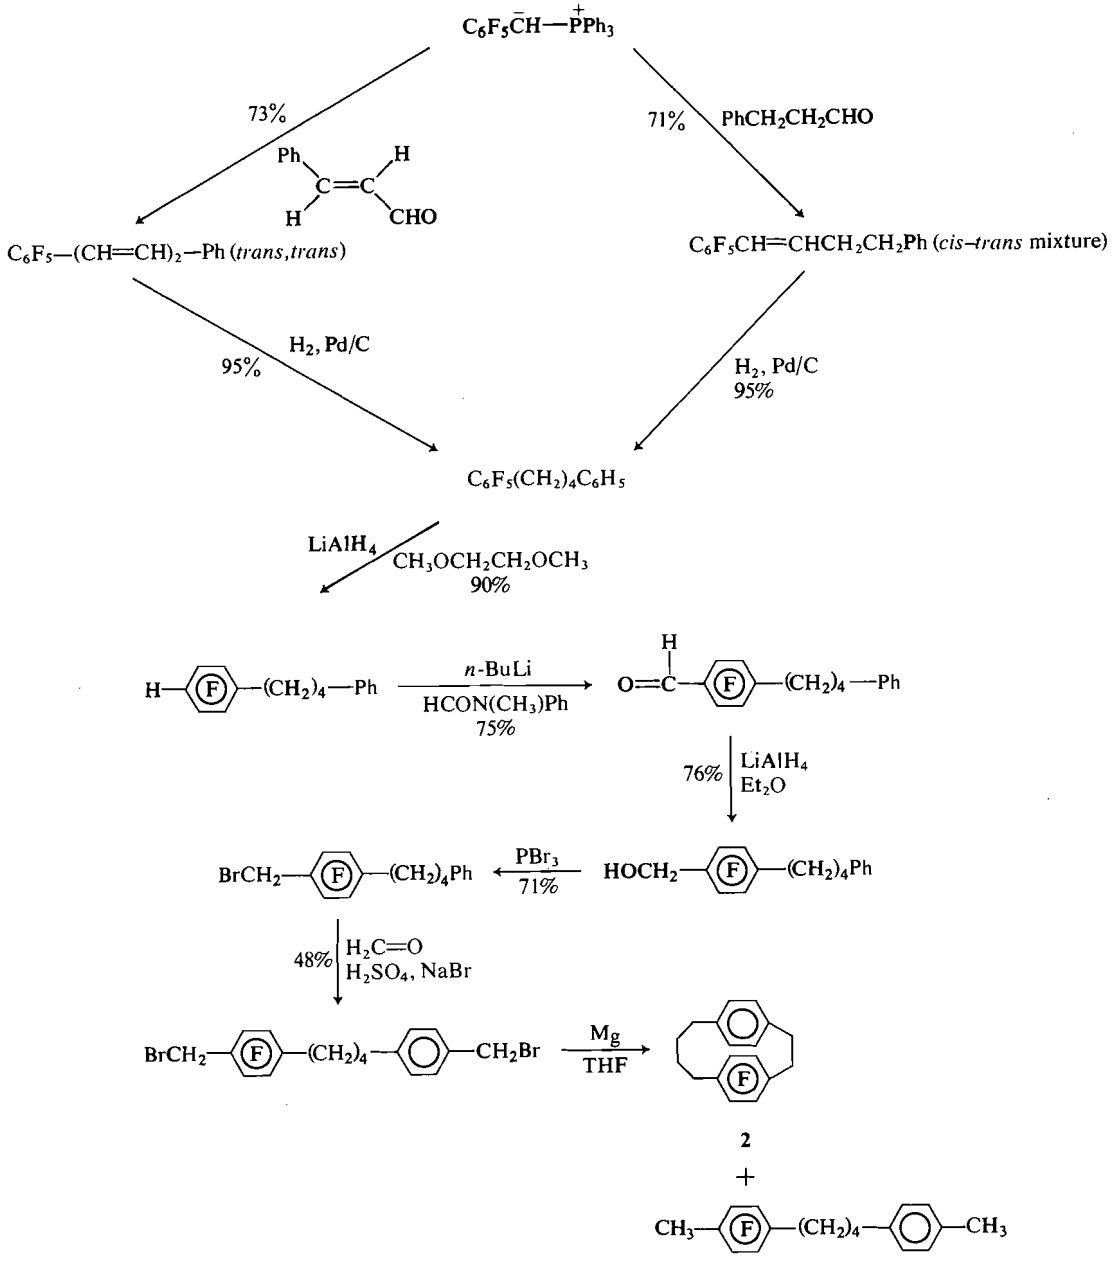

SCHEME 2

tetrachloride (400 ml) afforded 19.0 g (62.5%) of product as white needles. Sublimation at 150° (0.1 Torr) gave white crystals, m.p. 163.5–165°.

Anal. Calcd. for $C_{18}H_{12}Br_2F_8$: C, 40.03; H, 2.24. Found: C, 40.34; H, 2.26.

6,7,9,10,14,15,17,18-Octafluoro[4.2]paracyclophane (1)

To one-half of 0.3648 g (0.015 g-atom) of magnesium metal in 5 ml of tetrahydrofuran and a few crystals of iodine in a 250 ml three-necked flask, was added one-half of a tetrahydrofuran solution (105 ml) of 6.6 g (0.0122 mol) of the bisbromomethyl compound. After the mixture was stirred vigorously for 2 h, the Grignard reagent started to form. After two-thirds of the original magnesium had been consumed, the other half of magnesium and the solution of the starting material were added. After stirring for 72 h, 40 ml of tetrahydrofuran was added and the mixture stirred for an additional 60 h. The mixture was acidified with 150 ml of water and 60 ml of dilute hydrochloric acid. Filtration and air drying, followed by

sublimation (410° (0.1 Torr)) of the resulting white solid, gave 2.5 g of white sublimate. Analysis of the p.m.r. (CCl_4) spectrum of this sublimate revealed the presence of 16% of starting material, 39% of octafluoro[4.2]paracyclophane (**1**), and 43% of reduction product, 1,4-bis(4′-methyl-2′,3′,5′,6′-tetrafluorophenyl)butane. The yield of **1** was estimated to be 1 g (21.5%). The residue from the sublimation was 2.7 g of polymeric material.

Recrystallization of the sublimate from pentane gave 0.42 g of starting material. The pentane-soluble portion was chromatographed with a 90:10 mixture of pentane–benzene on 1300 g of neutral alumina using a 5 ft column, to give about 1.0 g of material. Recrystallization from 95% ethanol gave 0.42 g of the reduced product, 1,4-bis(4′-methyl-2′,3′,5′,6′-tetrafluorophenyl)butane, m.p. 141–143° (no depression when admixed with an authentic sample); n.m.r. δ 2.27 (t, 6, $^4J_{HF}$ = 2.25 Hz, methyl), 2.75 (4, m, benzylic), and 1.67 (4, m, methylene β to C_6F_5). Evaporation of the ethanol-soluble portion gave a white solid which was recrystallized from 8 ml of 95% ethanol to give 80 mg of reduced product. Evaporation of the ethanol-soluble portion and recrystallization of the residue from 0.75 ml of methylcyclohexane gave 20 mg of white crystals of pure **1**. Sublimation at 125° (0.05 Torr) gave an analytical sample, m.p. 174.5–175.5°; n.m.r. (CCl_4) δ 3.27 (m, 4, —C_6F_4—CH_2CH_2—C_6F_4—), 2.57 (m, 4,—C_6F_4—CH_2—CH_2—CH_2—CH_2—C_6F_4—), and 1.70 (m, 4, —C_6F_4—$CH_2CH_2CH_2CH_2$—C_6F_4—); u.v. λ_{max} (cyclohexane) 222 shoulder and 269 nm (log ε, 3.87 and 3.16); mass spectrum *m/e* (relative intensity) 380 (51.3) (m^+), 204 (18.9) (CH_2—C_6F_4—$CH_2CH_2^+$), 176 (100) (CH_2—C_6F_4—CH_2^+), 28 (91) ($CH_2CH_2^+$).

1,4-Bis(4′-methyl-2′,3′,5′,6′-tetrafluorophenyl)butane

To an ethereal solution (20 ml) of 5 g (0.0128 mol) of 1,4-bis(pentafluorophenyl)butane, 15.85 ml of 5% methyllithium in ether was added sufficiently slowly to allow a gentle reflux under nitrogen. The resulting mixture turned light yellow, was stirred for 15 h, and hydrolyzed by adding ice and 6 *N* hydrochloric acid. Additional ether was required to extract the mixture. The ether layer was separated, dried ($MgSO_4$), and evaporated *in vacuo* to give a light yellow solid. Recrystallization from 95% ethanol, followed by two recrystallizations from Skelly B, with charcoal, gave 3 g (61.3%) of product, m.p. 141–145°. Sublimation at 140° (0.05 Torr) gave pure material, m.p. 141.5–143°.

Anal. Calcd. for $C_{18}H_{14}F_8$: C, 56.55; H, 3.69. Found: C, 56.60; H, 3.74.

2,3,4,5,6-Pentafluorobenzyltriphenylphosphonium Bromide

A mixture of 26.2 g (0.1 mol) of triphenylphosphine and 26.1 g (0.1 mol) of pentafluorobenzyl bromide in 180 ml of *p*-xylene was heated under reflux for 20 h. A white solid began to separate within ½ h. The white solid was collected and washed with 100 ml of *p*-xylene. Recrystallization from a 95:5 mixture of ether–methanol gave 51 g (97.5%) of the phosphonium salt: m.p. 240–241°; n.m.r. ($CDCl_3$) δ 8.15–7.60 (m, 15, aromatic) and two multiplets separated by 14 Hz, centered at 5.58 (2, C_6F_5—CH_2—P—).

Anal. Calcd. for $C_{25}H_{17}F_5BrP$: C, 57.38; H, 3.27. Found: C, 57.27; H, 3.11.

1-Pentafluorophenyl-4-phenylbutane

In a 1-l three-necked flask, equipped with a magnetic stirrer, a reflux condenser, a pressure equalizing dropping funnel connected to a nitrogen supply, and a 125 ml Erlenmeyer flask connected to the reaction flask with Gooch tubing for solid addition, was placed 0.12 mol of *n*-butyllithium (75.36 ml of 15% *n*-butyllithium in hexane, Foote Mineral Co.) in 400 ml of dry benzene. To this solution, cooled to 15° by a water bath, was added 62.76 g (0.21 mol) of 2,3,4,5,6-pentafluorobenzyltriphenylphosphonium bromide in an Erlenmeyer flask disposed in a dive position, over a period of 10 min. The resulting orange-yellow solution was stirred for 1 h at room temperature and then brought to reflux. To the hot phosphorane solution, was added slowly 0.132 mol of hydrocinnamaldehyde or *trans*-cinnamaldehyde. The red color disappeared and the resulting mixture was heated under reflux for 14 h and filtered. The filter cake was washed with additional benzene, with water, 50 ml of ether, and then dried to give 30 g (90%) of triphenylphosphine oxide.

The filtrate (benzene layer) was evaporated *in vacuo* to give a mixture of *cis* and *trans* isomers of 1-pentafluorophenyl-4-phenyl-1-butene (70.9%) (b.p. 104–108° (0.05 Torr)), or *trans,trans*-1-pentafluorophenyl-4-phenyl-1,3-butadiene (73%), respectively. The butadiene: m.p. 145–147°; i.r. ($CHCl_3$) 1515, 1494, 1000, and 965 cm^{-1}; n.m.r. ($CDCl_3$) δ 7.6–6.3 (m, ArH and vinyl). The *trans,trans* configuration was supported by the presence of λ_{max} (EtOH) 327 and a shoulder at 314 nm (5) and by the ab-

1-(4′-Bromomethyl-2′,3′,5′,6′-tetrafluorophenyl)-4-phenylbutane

This compound was prepared via the same series of reactions and procedures described earlier in the synthesis of octafluoro[4.2]paracyclophane. Pertinent data are collected in Table 1.

1-(4′-Bromomethyl-2′,3′,5′,6′-tetrafluorophenyl)-4-(4″-bromomethylphenyl)butane

This compound was prepared from its precursor above by a bromomethylation procedure described previously (7). The relevant data are found in Table 1.

6,7,9,10-Tetrafluoro[4.2]paracyclophane (2)

The mono Grignard reagent, prepared by reaction of 6.02 g (0.015 mol) of 1-(4′-bromomethyl-2′,3′,5′,6′-tetrafluorophenyl)-4-(4″-bromomethylphenyl)butane in 60 ml of tetrahydrofuran and 0.40 g (0.0165 g-atom) of magnesium turnings, was stirred for 48 h under a nitrogen atmosphere. The resulting mixture was acidified with 100 ml of water and 40 ml of dilute hydrochloric acid, filtered, and washed with water. Sublimation of the white solid at 150° (0.1 Torr) gave 0.28 g of sublimate whose p.m.r. spectrum revealed that this substance was about a 50:50 mixture of the intramolecularly cyclized product, **2** (δ's similar to those for compound **1**), and its open-chain analog, *p*-$CH_3C_6F_4CH_2CH_2CH_2CH_2C_6H_4CH_3$-*p*, (—$C_6F_4$-$CH_3$), δ 2.27 (t), $^4J_{HF}$ = 2.25 Hz. Efforts to separate the two components by column chromatography on alumina, followed by fractional crystallizations from various solvents, *e.g.*, acetone, hexane, methylcyclohexane, acetic acid, and ethanol, were unsuccessful.

Reaction of 2,5-Dimethylfuran with Ethyl Propiolate: The Chemistry of Ethyl 1,4-Dimethyl-7-oxabicyclo[2.2.1]hepta-2,5-diene-2-carboxylate[1]

ARCHIBALD WILSON MCCULLOCH AND ALISTER GAVIN MCINNES

Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia B3H 3Z1

Received December 9, 1974

ARCHIBALD WILSON MCCULLOCH and ALISTER GAVIN MCINNES. Can. J. Chem. **53**, 1496 (1975).

Thermal reaction of 2,5-dimethylfuran (**1**) and ethyl propiolate (**2**) affords the Diels–Alder adduct (**3**) and seven additional products, all of which are derived from **3**. The major products, depending on the conditions, are the *endo-exo* 2:1 diadducts (**4** and **5**) and two nortricyclenes (**8** and **10**). The last two products arise by homo Diels–Alder type dimerization of **3** (to give **10**) and subsequent Diels–Alder retrogression (to give **8**). The minor reaction products include a third nortricyclene (**9**), isomeric with **8**.

ARCHIBALD WILSON MCCULLOCH et ALISTER GAVIN MCINNES. Can. J. Chem. **53**, 1496 (1975).

La réaction thermique du diméthyl-2,5 furanne (**1**) et du propiolate d'éthyle (**2**) conduit à l'adduit de Diels–Alder (**3**) et à sept produits additionnels qui sont tous dérivés de **3**. Les produits majeurs, dépendant des conditions expérimentales, sont les diadduits *endo-exo* 2:1 (**4** et **5**) et les deux nortricyclènes (**8** et **10**). Les deux derniers produits proviennent d'une dimérisation du type homo Diels–Alder de **3** (pour donner **10**) et d'une rétrogration Diels–Alder subséquente (pour donner **8**). Les produits mineurs de la réaction incluent un troisième nortricyclène (**9**) isomère de **8**. [Traduit par le journal]

Introduction

Although Diels–Alder reactions of substituted furans with esters of acetylenedicarboxylic acid have been thoroughly investigated (1–3), the corresponding reactions utilizing propiolic acid esters have received little attention. In recent communications we have described $AlCl_3$ acceleration of the reactions of 2-methyl-, 2-phenyl-, 2,5-dimethyl-, and 2,5-diphenylfuran with the latter type of dienophile. The adducts produced in this way were shown to rearrange readily *in situ* to substituted phenolic compounds (4, 5). In the present communication we wish to describe the results of an investigation of the thermal reaction of 2,5-dimethylfuran **1** and ethyl propiolate **2**: this has revealed the high reactivity of the 2-carbethoxyoxanorbornadiene system.

Results and Discussion

The reaction of **1** and **2** at 95° proceeds slowly. In addition to the expected oxanorbornadiene adduct **3** we have isolated *seven* other products. These are the 2:1 diadducts **4** and **5**, the cyclobutene **6**, the β-carbethoxyfuran **7**, and the nortricyclene derivatives **8**, **9**, and **10**. The product composition is dependent on the initial reactant ratio, as well as reaction time and temperature (Table 1).

Adducts of type **3** are difficult to obtain. In fact **3** is the only 1:1 adduct of any furan with **2** as yet isolated. We have previously reported its formation (15%) via the $AlCl_3$-promoted reaction of **1** and **2** at −60° (5). The problem in obtaining such compounds is due to the lesser dienophilic reactivity of propiolate esters compared to esters of acetylenedicarboxylic acid and the susceptibility of the adducts to further reaction, as evidenced by their facile $AlCl_3$-catalyzed aromatization (5).

The results from Table 1, together with those derived from monitoring (p.m.r.) reactions between **1** and **2**, and from several additional independent experiments (see Experimental), showed that the formation of all seven products in the present study can be traced to the initially formed Diels–Alder adduct **3**. The reaction pathways involve (*i*) further Diels–Alder reaction of **3** with **1** (to give **4** and **5**); (*ii*) homo Diels–Alder reaction of **3** with itself (to give **10**) or with **2** (to give **8** and/or **9**?); (*iii*) Diels–Alder retrogressions of **3** (to give **7**) or of product **10** (to give **8**); and (*iv*) 2 + 2 cycloaddition of **2** to **3** (to give **6**). These transformations are summarized in Scheme 1. It is noteworthy that product **8** arises predominantly via dimerization

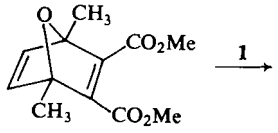
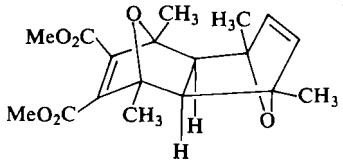
of **3** to **10** and subsequent Diels–Alder retrogression, rather than by direct reaction of **3** with **2**. Compound **10**, incidentally, is not formed at 95° by Diels–Alder addition of **1** to **8**.

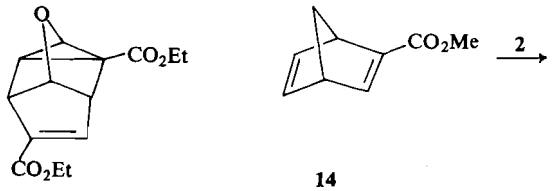
Formation of diadducts **4** and **5** is not surprising since Diels–Alder additions of furans to oxanorbornadienes are well known (6–8). Thus, initial reaction of **3** with **1** affords **4**, derived by addition at the activated double bond of **3**. (Diadduct **4** is thermally unstable and when heated alone at 95° undergoes partial retrogression to **3** and **1**.) Addition of **1** to **3** under more forcing conditions (120°) occurs at the less substituted double bond of **3** to give **5**. Such behavior would be anticipated (see below) on the basis of previous work on related systems (6). An unexpected aspect of these additions, however, is their regioselectivity; we could not



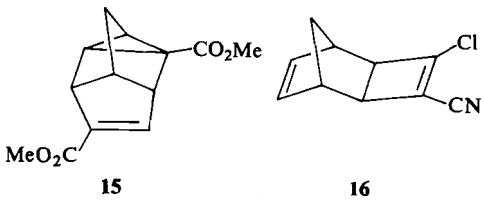
11



12



13 **14**



15 **16**

detect any stereoisomers of **4** or **5**. Slee and LeGoff (8) have recently reported that analogous addition of **1** to oxanorborandiene **11** at 100° gives a low yield (10%) of diadduct **12** only.

The nortricyclenes **8**, **9**, and **10** (and the structurally related derivative **13**, isolated from the thermal reaction of furan with **2** (7)), are the first such compounds to be derived from the oxanorbornadiene system, although similar compounds have been produced from norbornadienes (9–11). Although the most important route to **8** obviously involves dimerization of **3** to **10**, we cannot completely rule out the possibility of direct homo Diels–Alder addition of **2** to **3**. It may be that the minor isomer **9** is the product of such addition.[2] Direct 2,6-addition (107°/7 days) of **2** to methyl bicyclo[2.2.1]hepta-2,5-diene-2-carboxylate **14** has been reported to give a 30% yield of **15** (9). This latter product may actually arise via an intermediate analogous to **10**.

The 2 + 2 cycloadduct structure **6** has been tentatively assigned to one of our minor products on the basis of spectral evidence (see below). Its formation may be accounted for by an ionic cycloaddition mechanism similar to that proposed by Sasaki *et al.* (11) to explain their isolation of the cyclobutene **16** as a by-product (6%) from the reaction of norbornadiene with chlorocyanoacetylene.

Structures

The elucidation of the structures of the various reaction products was based primarily on their p.m.r. (Tables 2 and 3), i.r., and mass spectral properties (see Experimental). The monoadduct **3** has been isolated and characterized previously (5).

Diadducts 4 and 5

The p.m.r. spectrum (Table 2) of each of these compounds shows signals for one carbethoxyl and four methyl groups and for five other hydrogens, indicating an overall diadduct structure. In the case of **4** there are four olefinic (two AB quartets) and one methine hydrogen, indicating a diadduct formed by addition of **1** to the activated double bond of **3**. In the spectrum of **5**, on the other hand, there are signals for three olefinic (one at low field, deshielded by the carbethoxyl) and two methine (AB quartet) protons, an arrangement compatible only with a diadduct formed by addition of **1** to the less substituted double bond of **3**.

No molecular ion is observed in either mass spectrum. The base peak in each case is at *m/e*

[2]We were unable to detect any product analogous to **10** which could be postulated as a precursor of **9**.

96, reflecting the overwhelming tendency of these compounds to eliminate **1** by Diels–Alder retrogression.

The assignment of *endo-exo* stereochemistry to both **4** and **5** was based on their p.m.r. spectra and the fact that such additions are kinetically favored (6). The expected mode of addition of **1** to either double bond of **3** is to the oxygen-bridged face of the latter (12). Thus two product configurations are likely in each case, namely *endo-endo* **17***a* (or *b*) and *endo-exo* **4** (or **5**). The presence of signals for four nonequivalent olefinic hydrogens in the spectrum of **4** eliminates the symmetrical *endo-endo* isomer **17***a* in this case. It is impossible to assign *endo-endo* or *endo-exo* stereochemistry unequivocally to isomer **5** on the basis of its p.m.r. spectrum, which is compatible with either. However, all previous work in this (6, 7) and other (8) laboratories indicates that the kinetically favored diadducts possess *endo-exo* stereochemistry. Supporting evidence for this assignment in the case of **5** is derived from the chemical shift of the ring-junction hydrogens (quartet, $\Delta\nu_{ab} = 6.6$ Hz, centered at 2.55 δ), which is close to that (2.72 δ) of the corresponding hydrogens in **12** (8).

*Nortricyclenes **8**, **9**, and **10***

The mass and p.m.r. spectra of **8** indicate a product derived from one molecule of **1** and two of **2**. The p.m.r. spectrum (Table 3) shows signals for four single hydrogens, only one of which appears in the olefinic region. The chemical shifts of the three methine protons are in accord with those of similar hydrogens in related compounds (7, 9, 11). Two of these protons have approximately the same chemical shift, suggesting that they occupy similar environments (H-1, H-5), while the third is located at high field, consistent with it being on a cyclopropane ring. Moreover, the chemical shift of the vinylic hydrogen is consistent with deshielding by a carbethoxyl group and is very similar to that of the corresponding proton in **15** (9). In addition it is vicinally coupled to only one hydrogen. As expected, the chemical shifts of the two bridgehead methyl groups are significantly different. Verification of the structure was provided by the ^{13}C n.m.r. spectrum. We have reported full ^{13}C data for **8** (and **13**) elsewhere (7).

The spectral properties of compound **9** are, as expected, very similar to those of its isomer **8**. The main points of difference, leading to the assignment of structure **9** are in the chemical shifts and multiplicities of H-1 and H-5 (Table 3). These changes reflect the new position of the olefinic proton in **9**. The hydrogen at C-1, now subject to the deshielding effect of a second carbethoxyl group and no longer vicinal to any other hydrogen, appears as a narrow triplet at 3.49 δ (a downfield shift relative to the same

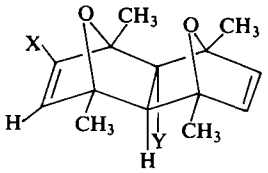
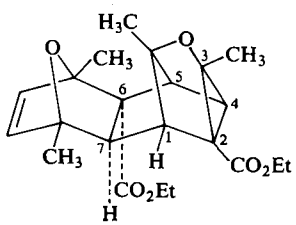
proton in **8** of 0.59 p.p.m.). The hydrogen at C-5, on the other hand, which is now coupled vicinally to two other hydrogens but is no longer deshielded by an adjacent carbethoxyl, is observed as a broad multiplet centered at 2.24 δ (an upfield shift of 0.83 p.p.m.).

The weak molecular ion at *m/e* 388 and base peak at *m/e* 96 indicate that compound **10** is a 2:2 product from which **1** may be readily lost. Infrared absorptions at 1737 and 1718 cm^{-1} suggest two quite different types of ester group. The p.m.r. spectrum of **10** (Table 3) shows signals for two carbethoxyl and four *C*-methyl groups, an AB quartet for two olefinic hydrogens, and signals for four single methine hydrogens (at 1.75, 2.36, 2.50, and 3.02 δ). The signal at highest field was assigned to the cyclopropyl hydrogen H-4: this is coupled (J = 1.8 Hz) to the hydrogen resonating at 2.36 δ which can therefore be assigned to H-5. Since H-1 and H-5 are located in similar environments, the remaining signals may be assigned to H-1 (2.50 δ) and the ring-junction hydrogen (3.02 δ). The lack of coupling between the latter two protons necessitates that the dihedral angle between them approximates 90° and allows assignment of stereochemistry **18** or **19**. The latter configuration, however, would require approach of the diene component to the face of the dienophile opposite to the oxygen bridge. Such an approach is unlikely on steric grounds (6, 12).

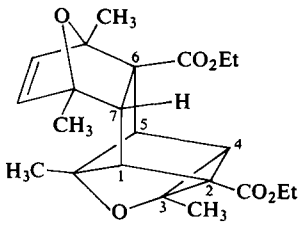


17

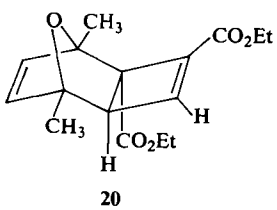
a X = H; Y = CO_2Et
b X = CO_2Et; Y = H



18



19



20

Compound 6

The molecular ion of this compound is at *m/e* 292 indicating a 1:2 product. The p.m.r. spectrum (Table 2) shows two nonequivalent carbethoxyl groups and two nonequivalent *C*-methyl groups, together with an AB quartet for two olefinic hydrogens and two one-proton doublets ($J \approx 0.8$ Hz), one due to a methine (2.95 δ) and the other to an olefinic (7.20 δ) hydrogen. The i.r. spectrum shows absorptions in the carbonyl region at 1727 and 1737 cm^{-1}, in accord with the presence of both conjugated and saturated ester groups. The cyclobutene ring is assigned an *exo* relationship to the bridged ring since approach in this direction is known to be least sterically hindered (12). The available evidence is equally consistent with cyclobutene structure **20**. However, the requirements of the proposed ionic cycloaddition mechanism (*cf.* 11) would favor **6**.

Compound 7

The mass spectrum indicates a molecular weight of 168 and the p.m.r. spectrum (Table 2) shows characteristic signals for one carbethoxyl and two *C*-methyl groups, and for one single hydrogen in the olefinic region. Confirmatory evidence for the furan structure is provided by the chemical shifts of the hydrogens of the two ring methyl groups and the magnitude of the coupling (~1 Hz) between the hydrogens of one of these groups (2.25 δ) and the adjacent ring hydrogen (6.24 δ).

Experimental

The p.m.r. spectra were recorded on a Varian A-60A spectrometer equipped with a V-6058A spin decoupler, using tetramethylsilane as internal standard. The i.r. spectra were obtained in CCl_4 solution on a Perkin-Elmer 521 spectrometer and the mass spectra with a

Dupont-C.E.C. 21-491 spectrometer. Unless stated otherwise the source of heat used in all reactions was a steam bath. Column chromatography was performed on Mallinckrodt silicic acid, 100 mesh, using $CHCl_3$ to elute. For preparative thin-layer chromatography (p.l.c.) Merck silica gel HF-254 (1.5 mm layers) was used, with $CHCl_3$ to elute.

Reaction of 2,5-Dimethylfuran **1** *with Ethyl Propiolate* **2**

General Procedure

The reaction of **1** and **2** was carried out under varying conditions (Table 1) using the following procedure. A mixture of **1** and **2** was heated and at the end of the desired reaction period unreacted starting materials were removed by azeotroping with EtOH. The oily residue obtained was then submitted to column chromatography. The products eluted in the following order: **7**, **8**, **3**, **9**, **6**, **10**, **5**, and **4**.

(*A*) A reaction mixture of **1** (6.98 g, 0.073 mol) and **2** (3.67 g, 0.037 mol) was maintained at reflux for 48 h (heating mantle). Obtained as products. (*i*) *compound* **7** as a pale yellow oil (0.060 g, 1%), n_D^{23} 1.4690; parent ion at *m/e* 168 (51%) ($C_9H_{12}O_3$ requires 168), base peak at *m/e* 43, strong ions at *m/e* 139 (77%) and 123 (70%); ν_{max} 1717 cm^{-1}; (*ii*) *compound* **8** as a pale yellow oil (3.34 g, 62%), n_D^{25} 1.4844; parent ion at *m/e* 292 (5%) ($C_{16}H_{20}O_5$ requires 292), base peak at *m/e* 43, strong ions at *m/e* 249 (17%), 247 (11%), 246 (12%), 221 (12%), 219 (22%), 218 (11%), 204 (10%), 176 (7%), 175 (9%), 173 (10%), 152 (13%), 147 (12%), 139 (13%), 96 (32%), and 77 (16%); ν_{max} 1715, 1721 cm^{-1}; (*iii*) an oil (2.40 g), containing *ca.* 90% *compound* **5** (*ca.* 19%). The pure compound was obtained by repeated p.l.c. as a pale yellow oil, n_D^{26} 1.4813. No parent ion was observed, base peak at *m/e* 96, strong ions at *m/e* 168 (7%), 139 (7%), and 43 (29%); ν_{max} 1713 cm^{-1}.

(*B*) From a reaction of **1** (9.6 g, 0.10 mol) and **2** (19.6 g, 0.20 mol) at 95° for 7 days were obtained: (*i*) an oil (1.14 g), mainly **8**, contaminated by a small amount of **7**; (*ii*) pure **8** (1.90 g); (*iii*) an oil (6.01 g), mainly **8** but contaminated by **3**; (*iv*) an oil (0.340 g), which on p.l.c. gave *compound* **9** as a pale yellow oil (0.076 g, 0.3%), n_D^{26} 1.4888; parent ion (very weak) at *m/e* 292 ($C_{16}H_{20}O_5$ requires 292), base peak at *m/e* 43, strong ions at *m/e* 249 (23%), 246 (27%), 221 (18%), 200 (53%), 175 (16%), 173 (23%), and 77 (23%); ν_{max} 1717 (sh), 1721 cm^{-1}; (*v*) an oil (1.128 g), which on repeated p.l.c. gave *compound* **6** (0.368 g, 1.3%) as a pale yellow oil, n_D^{26} 1.4911; parent ion at *m/e* 292 (48%) ($C_{16}H_{20}O_5$ requires 292), base peak at *m/e* 218, strong ions at *m/e* 248 (16%), 247 (25%), 219 (26%), 203 (68%), 190 (30%), 175 (48%), 173 (68%), 96 (74%), and 43 (74%); ν_{max} 1727, 1737 (sh) cm^{-1}. This fraction also afforded compounds **9** (0.061 g, 0.2%) and **10** (0.418 g, 2.2%); (*vi*) *compound* **10** (1.774 g, 9.1%) as a pale yellow oil, n_D^{25} 1.6553; parent ion (very weak) at *m/e* 388 ($C_{22}H_{28}O_6$ requires 388), base peak at *m/e* 96, strong ions at *m/e* 249 (30%), 227 (13%), 178 (33%), and 43 (88%); ν_{max} 1718, 1737 cm^{-1}; (*vii*) an oil (0.765 g), which on p.l.c. gave a mixture (0.599 g, 4.2%) of **4** and **5** in an approximate ratio of 3:5.

(*C*) From a reaction of **1** (6.98 g, 0.073 mol) and **2** (3.67 g, 0.037 mol) at 95° for 48 h were obtained: (*i*) a yellow oil (3.68 g), repeated p.l.c. of which gave (*a*) compound **8** (0.342 g, 6%), (*b*) compound **3** (0.260 g, 3.6%), identical to material obtained previously (5), and (*c*) *compound* **4** (1.634 g, 15%) as an oil which gradually crystallized, m.p. 40–43°; no parent ion was observed, ion of highest mass at *m/e* 217 (3%) ($M - CO_2Et$), base peak at *m/e* 96, strong ions at *m/e* 201 (3%), 159 (3%), 152 (4%), 149 (3%), 81 (6%), 77 (4%), and 43 (39%); ν_{max} 1711, 1738 cm^{-1}; (*ii*) an oil (2.06 g), p.l.c. of which gave (*a*) compound **10** (0.162 g, 2%) and (*b*) a mixture of **4** and **5** (1.14 g, 11%) in a ratio of 7:4.

(*D*) Two other reactions were performed, both at 95°. One used a 1:1 (2 days) and the other a 2:1 (7 days) reactant ratio. The product compositions of these and of reactions *A–C* above were estimated by integration of the appropriate p.m.r. signals in the various column fractions and are summarized in Table 1.

(*E*) A reaction of **1** (9.6 g, 0.1 mol) and **2** (19.6 g, 0.2 mol) at 95° was monitored daily by p.m.r. for 1 week. This showed that **3** and **4** were the major products initially, and that the amounts of **8** and **10** increased with time, at the expense of **3** and **4**.

Retrogression of Compound **4**

A sample of pure **4** was heated at 95°. Thermal breakdown to a mixture of **3** and **1** of 12% (1 h) and 25% (4 h) was observed (p.m.r.).

Attempted Reaction of **8** *with* **1**

Equimolar amounts of **8** and **1** were heated at 95° for 48 h. Compound **8** remained unreacted, the only change being some oxidative breakdown of **1**.

Dimerization of **3** *to Compound* **10**

(a) Attempted Reaction of **3** *with* **2**

Equimolar amounts of **3** and **2** were heated at 95°; p.m.r. showed that **2** remained unreacted while **3** was converted to **10** (**10**:**3** = 1:1 after 3 h, = 3:1 after 9 h). Small amounts of **8** were also formed. There was also evidence of considerable polymerization.

(b) Reaction of **3** *with* **1**

Equimolar amounts of **3** and **1** were heated at 95°. After 2.5 h the molar ratio of products (p.m.r.) was **3**:**4**:**10** = 7:2:4. No **5** was observed. After 7 h only a trace of **3** remained, the major products being **10** and **4** (approximate ratio 2:1).

(c) Direct Thermolysis of **3**

A 100 mg sample of **3** was heated at 95° for 21 h. Repeated p.l.c. (1% MeOH–$CHCl_3$) gave compounds **8** (10 mg) and **10** (27 mg, 27%).

Retrogression of **10**: *Formation of Compound* **8**

A pure sample of **10** was heated on an oil bath maintained at 120°. Smooth conversion to **8** (20% in 2 h, 50% in 6 h, 80% in 12 h) was observed (p.m.r.). The reaction was significantly slower at 95°.

We gratefully acknowledge the very useful contributions made to this work by R. Richard (NRCC summer student, 1972) and D. Ettinger (research assistant, 1972–1973). Our thanks go also to P. F. Seto for the i.r. spectra.

Synthesis of Substituted Hydrindanes. Part I. Products Arising from the Cyclization of Acetonyl Cyclohexanones and Acetonyl Cyclohexadiones

ANDRÉ BETH, JACQUES PELLETIER, ROBERT RUSSO, MARCEL SOUCY, AND ROBERT H. BURNELL[1]

Received July 23, 1974

ANDRÉ BETH, JACQUES PELLETIER, ROBERT RUSSO, MARCEL SOUCY, and ROBERT H. BURNELL. Can. J. Chem. **53**, 1504 (1975).

The preparation and cyclizations of certain 1,4-diketones have been studied as a route to substituted hydrindan-2-one systems. Other types of products encountered are also described.

ANDRÉ BETH, JACQUES PELLETIER, ROBERT RUSSO, MARCEL SOUCY et ROBERT H. BURNELL. Can. J. Chem. **53**, 1504 (1975).

On a étudié la préparation de certaines dicétones-1,4 ainsi que leur cyclisation comme moyen d'arriver au système hydrindanone-2 substitué. On décrit aussi d'autres types de produits qui ont été rencontrés. [Traduit par le journal]

While investigating synthetic routes which could lead to both *Lycopodium* alkaloids possessing the fawcettimine skeleton and certain terpenes we have investigated the preparation of several hydrindan-2-one systems. We were particularly interested in models of type **1** in which R_3 and R_4 would represent either a nine-membered nitrogen containing ring or sidechains susceptible to cyclization to this medium-sized ring.

We decided that cyclohexa-1,3-diones offered certain advantages of reactivity and availability as starting materials and for most of the trial series we chose the readily available dimedone although some sequences have started from dihydroorcinol. Acrylonitrile condenses readily with dimedone in the presence of triethylamine (1) and we have found that by careful adjustment of the p*H* after the reaction, the pure monocyanoethyl derivative **2***a* is obtained directly in yields exceeding 70%. Alkylation of the latter with ethyl β-bromolevulinate in the presence of sodium hydride in dimethoxyethane gave only a poor yield of the triketo ester **3***a*. A similar compound, **3***b* was prepared from 2-allyldihydroorcinol **2***b*, again in low yield but the conditions necessary to cyclize these multifunctional compounds (to give **4***a* and **4***b*) were never achieved. The number of possible reactions of each compound (**3***a* and **3***b*) in reagents normally favoring cyclization, prohibited a meaningful analysis of the products.

To further investigate the formation of the five-membered ring, simpler models were sought containing as essential elements the "quaternary" carbon atom and a side chain possessing only one carbonyl residue. Consequently cyanoethyldimedone **2***a* was alkylated in high yield with propargyl bromide to give **5***a*, forming the quaternary center and a less enolizable symmetrical 1,3-diketone. The triple bond was hydrated in virtually quantitative yield to the triketo-

nitrile **6***a* which did not cyclize under basic conditions but afforded only the triketone **6***c* arising from a retro-Michael reaction while acidic conditions tended to open the six-membered ring (retro-Claisen) before effecting the closure, the major product being the cyclopentenone **7**. The analogous allyl-triketone **6***b*, prepared via compound **5***b* (propargylation of **2***c*) and hydration of the triple bond, was more resistant but again the only products isolated in attempted cyclizations were those resulting from expulsion of one of the side chains.

The vulnerability of the β-diketo system to cleavage suggested that internal alkylation might be more rewarding than internal condensation. To convert one of the carbonyl groups in the cyano-diketone **5***a* to a potential leaving group we reduced selectively one of the carbonyl groups and the product (**8***a*) was transformed to both the tosyl and acetyl derivatives (**8***b* and *c*, respectively). Later we found that even under forcing conditions the second carbonyl is quite resistant to sodium borohydride reduction. Since the best method we had found for hydrating the triple bond in the propargyl residue involves a methanolic solution containing a trace of trichloroacetic acid, we felt that it might be possible to isolate the diketone as the corresponding diketal providing the reaction mixture is not decomposed in water. After hydrating the triple bond in the tosyl derivative **8***b*, the volatile products were simply evaporated at or below room temperature *in vacuo* and the crystalline product shows no carbonyl absorption in the i.r. spectrum. Since mild hydrolysis of this material (or just recrystallizing from less than anhydrous solvents) affords the diketone **10***b*, the addition to the triple bond did take place. Elemental analysis of the ketal, with other spectral characterization, showed it to be the cyclic ketal **9**.

The normal procedure for hydrating the triple bonds in all three compounds **8***a*, *b*, and *c* was without consequence affording the corresponding diketones **10***a*, *b*, and *c*. Attempts to cyclize these compounds gave different results. The alcohol **10***a* suffers ring-opening by retroaldolization under all but the mildest conditions; certainly neither the cyclopentenone **11***a* which could arise by condensation nor the internal alkylation product, cyclopentanone **11***b* was isolated. The tosylate **8***b* cyclizes rapidly at room temperature in methanolic sodium methoxide but forms the (predicted?) substituted cyclopropane **12**. Varying the conditions had no apparent effect on the direction of enolization or carbanion formation and only in one reaction, in *t*-butyl alcohol containing sodium *t*-butoxide, was a different product obtained. We tentatively postulate the latter to be the substituted spiro[4.4.0.$0^{1,7}$]tricyclodecane **13** (see Experimental). The acetyl derivative **8***c* was recovered unchanged from several attempted cyclization reactions, but in one case afforded the spiro[5.4.1]-bicyclodecane system **14**.

One further type of ring closure was tried on molecules containing virtually the same functional groups. Alkylation of cyanoethyldimedone **2***a* with 2,3-dichloropropene afforded the chloro-alkene **15***a* which was reduced to the keto-alcohol **15***b* now suitably functionalized to

attempt cyclization in concentrated acids, as described by Lansbury (2). We had previously failed to prepare enol esters or ethers with the terminal double bond. It was felt that this chloro-alkene (**15***b*) should form the five-membered ring but in cold sulfuric acid the reaction was extremely complex and the nitrile appeared to be the most susceptible function. In refluxing formic acid the molecule (**15***b*) was surprisingly stable affording only the *O*-formyl derivative **15***c*. While this type of cyclization is feasible, most examples in the literature involve benzylic or allylic hydroxyl groups.

The attractiveness of the synthetic route from cyclohexa-1,3-diones lay in the fact that the formation of the quaternary center isolates the two carbonyl groups while preserving a symmetrical molecule: one carbonyl serving as the means to cyclize the five-membered ring while the other is suitably placed for the final synthetic goal or for modifying the six-membered ring. The difficulties encountered in performing the cyclization forced a reassessment of the route. By eliminating one of the two oxygen functions (the hydroxyl in **8***a* for instance) the ring closure should be relatively facile since the competing reactions (retroaldol and retro-Michael) are either impossible or considerably less probable. For certain syntheses, however, an additional problem is introduced, that of reestablishing the oxygen function at the carbon atom adjacent to the quaternary center with acceptable selectivity.

Of several methods tried, the dehydration of the keto-alcohol **8***a* was best accomplished with phosphorus oxychloride in pyridine but the quality of the reagents affects the yield of olefin **16***a* drastically. As in previous series boron trifluoride – trichloroacetic acid catalyzed hydration of the triple bond affords the diketone **16***b*. Cycloaldolization of the latter in methanolic potassium hydroxide is rapid, as is the hydrolysis of the nitrile and the acidic product from the reaction is cyclopentenone **17***a*.

Our first attempt to cyclize the diketo-olefin **16***b* was with sodium hydride in dimethoxyethane (reflecting perhaps previous difficulties) and this reaction had produced three products, the major being an acid isomeric with **17***a* and with quite similar spectral characteristics. We felt at the time that this might be the desired cyclization product and that the smaller quantity of a neutral material from this same reaction was

the nitrile **17***c*. When hydrolysis of the nitrile afforded the cyclized acid **17***a*, identical with that from the easier hydroxide cyclization, we were forced to reexamine the anomalous sodium hydride cyclization product. The u.v. spectrum of the latter (λ_{max} 221 nm, ε 6900) suggested an α,β-unsaturated acid rather than a conjugated five-membered ring ketone such as **17***a* (λ_{max} 233 nm, ε 13 000). Other spectral considerations (see Experimental) imply that the anomalous product has the structure **18***a* and its formation can be imagined as combined aldolization and Claisen-type ring closures followed by β-diketone cleavage. The third product from this cyclization was also a nitrile but contained a hydroxyl group. Spectral data, analysis, and con-

sideration of the reactions likely to occur suggest that this new material is the alternate aldolization product **19**.

The analogous series starting with allyl- (**2***c*) rather than cyanoethyldimedone (**2***a*) was also carried through to the cyclized material by the methods already discussed. Thus allyldimedone (**2***c*) is propargylated to afford the diketone **5***b* in which one carbonyl group is then selectively reduced to give the ketol **20**. While we separated the predominant solid isomer in which the hydroxyl group is equatorial both isomers separately or as a mixture are dehydrated to the olefin **16***c*. Hydration of the triple bond affords the diketone **16***d* which cyclizes to the conjugated enone **17***d*. In this compound we assume the three olefinic double bonds (terminal, cyclic, and conjugated) to be sufficiently different to allow selective modification.

Another approach to compounds of type **1** might be to introduce R_3 and R_4 by a Diels–Alder reaction should enediones such as **1***a* show sufficient reactivity as dienophiles. Not finding products of this nature in the literature, we attempted to prepare them. The fact that hydrindenone **22***a* can be readily prepared from indene (3) prompted a few experiments aimed at functionalizing the allylic methylene group but these failed due to the superior reactivity of the angular methine. To exclude this possibility we synthesized compounds with angular ester functions (**22***c* and *d*). The carbomethoxy groups could be readily eliminated after cyclization (vinylogous β-keto esters) and since synthesis from indene was no longer advantageous we prepared these keto esters from α-carboalkoxycyclohexanones. Alkylation with propargyl bromide (giving **23***a*, *b*, and *c*), hydration of the triple bond (affording **24***a*, *b*, and *c*), and cyclization of the diketo esters lead to the enones **22***c* and *d* in satisfactory yields. Varying the conditions of the ring formation also gave the decarboxylated enones **22***a* and *b*. Our Experimental was adapted from methods described by Raphael (4). The allylic functionalization proved equally unsatisfactory with the angular substituent and a variety of conditions (see Experimental) affecting allylic oxidations afforded starting material as the only tractable product.

One experiment was performed to introduce an angular substituent in compound **22***a* by conjugate addition to the enone system. Treatment

of the latter with tetrakis(iodotri-*n*-butylphosphine) copper and vinyl lithium (5) affords the vinylhydrindanone **25** in modest yield. We hope to use this reaction later in another synthesis.

It had become evident that while the five-membered ring is easily grafted onto the cyclohexanone, the second ketone (perhaps as a latent substituent) would be best introduced at the outset. Arylidene or alkylidene residues, which could later be transformed into carbonyl groups by ozonolysis proved cumbersome and the yields in some steps were extremely poor. Finally the ketone was protected as the dioxalane by the following route.

α-Benzylidene or α-ethylidene cyclohexanones are converted to their spiro-ketals (**26***a* and *b*) and then cleaved by ozonolysis to give the monoketals of the corresponding α-diketones (**27***a* and *b*). Direct alkylation gives largely the dialkylated product **28***a*, the presence of which is easily revealed in the n.m.r. spectrum of the material (**28***b*) arising from the hydrogenation of the triple bonds. By first preparing the hydroxymethylene derivatives then alkylating, the monopropargylated products (**28***e* and *f*) are obtained in satisfactory yield and the hydration of the triple bond can be performed without hydrolysis of the spiro-ketal after slight modification of the conditions. Both diketones **28***g* and *h* were prepared but only the latter was cyclized to the enone **29**, which is a protected form of the desired enedione **21***a*. However, despite numerous attempts to remove the dioxolane moiety

none was successful, in most cases hydrolysis destroyed the molecule beyond recognition. The enone spiro-ketal **29** showed great reluctance to undergo Diels–Alder cycloadditions.

As a variant to the method described above and to avoid the hydrolysis of the spiro-ketal during hydration of the triple bond (in **28***e* and *f*) we investigated a parallel route involving allylation of the activated keto-ketal **28***d*. The nature of this product (**28***i*) was confirmed by preparing a sample from the propargyl containing analog **28***f* by hydrogenation over Lindlar catalyst. The hydroxylation of the double bond using mercuric acetate followed by sodium borohydride also reduces the existing ketone moiety to give the diol **30** which is oxidized (Sarett reagent) to the diketo-ketal **28***h*. The latter on reduction with sodium borohydride also affords the diol **30**. This route however offers no advantage, either in yield or ease of manipulation.

Experimental

The normal conditions and instruments for the spectra quoted are: u.v. ethanol solutions, Beckman DK-1A; i.r. Perkin Elmer 457 and Beckman IR 12; n.m.r. Varian A60 and Bruker HX 90, internal TMS standard, coupling constants are given in parentheses; mass spectra, Varian M66. Elemental analyses were performed by Mr. R. Dulude, Chemistry Department, Université Laval and by Dr. F. Pascher, Bonn.

2-Cyanoethyl-5,5-dimethylcyclohexa-1,3-dione (2a)

Dimedone (7 g) is added to a solution of isopropanol (15 ml) and triethylamine (5 ml) in water (15 ml) under nitrogen. Freshly distilled acrylonitrile (3.5 ml) is introduced and the mixture refluxed for 3 h then cooled in ice (*ca.* 2 h) to crystallize the 2,2-bis(2-cyanoethyl)-5,5-dimethylcyclohexa-1,3-dione, m.p. 145° (1.5 g, 12%) (lit. (6) m.p. 146–147°). The filtrate is acidified (dilute hydrochloric acid) to p*H* 6, precipitating the cyanoethyldimedone **2***a* (6.7 g, 70%), m.p. 153–154°; λ_{max} 262 (16 100) and 290 (sh. 7400) nm; ν_{KBr} 2550, 2260, 1640, and 1565 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl s 1.1, $-CH_2CO$ s 2.4, $-CH_2CH_2CN$ m 2.5, and OH (enol) s 8.15.

Anal. Calcd. for $C_{11}H_{15}NO_2$: C, 68.3; H, 7.8; N, 7.3. Found: C, 68.5; H, 7.9; N, 7.6.

2-Allyl-5-methylcyclohexa-1,3-dione (2b)

This was prepared following essentially the method of Rosenmund (7), m.p. 135–136°.

Anal. Calcd. for $C_{10}H_{14}O_2$: C, 72.3; H, 8.5. Found: C, 72.1; H, 8.4.

2-Allyl-5,5-dimethylcyclohexa-1,3-dione (2c)

This was prepared by the method of Rosenmund (7), m.p. 145–146° (lit. 145–146°); λ_{max} 262 (13 800) nm; ν_{KBr} 3080, 3010, 2600, 1638, and 1560 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl s 1.07, $-CH_2CO-$ s 2.37, $-CH_2-CH{=}CH_2$ d(6.0) 3.12, m 5.0 and m 5.8; *m/e* 180 (M+), 165, 124, 109, 97, 96, 95, 83 (base), and 81.

Ethyl 3-[1-(2-Cyanoethyl)-4,4-dimethyl-2,6-dioxocyclohexyl]-4-oxopentanoate (3a)

Sodium hydride (2.35 g) washed free of mineral oil, is suspended in dimethoxyethane (100 ml) under nitrogen. The cyanoethyldimedone **2***a* (4.8 g) is added and after 2 h, ethyl β-bromolevulinate (5.58 g) is introduced dropwise and the mixture is stirred at 48° for 12 h. The reaction mixture is decomposed in water and ether extraction affords a neutral oil (2.5 g) and starting material (3.4 g) from the aqueous phase on acidification. The oil is chromatographed over Florosil. The benzene – 4% ether eluate is the ester **3***a* (0.5 g), m.p. 123–124°; ν_{KBr} 2260, 1740, 1725, 1715, 1695 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl s 0.8, CH_3CH_2O t(7.2) 1.21, and q(7.2) 4.1, CH_3CO s 2.16, $CO-CH-CH_2COOR$ d of d (2.5 and 10.5) 3.70, d of d(8.5 and 10.5) 3.11 and d of d (8.5 and 2.5) 2.51; *m/e* 335 (M+), 290, 262, 248 (base), 220, 207, and 83.

2-Acetonyl-2-(2-cyanoethyl)-5,5-dimethylcyclohexa-1,3-dione (6a)

To the propargyl derivative **5***a* (4 g) in methanol (150 ml) and ethoxyethanol (5 ml) is added aqueous sulfuric acid (0.3 ml of 1 *N*) and Dowex 50W-X4 resin (0.9 g) charged with mercuric ions (8). The mixture is stirred for 18 h and after neutralizing with ammonia, the resin is filtered and the solvents evaporated. The residue (**6***a*) crystallizes on contact with acetone (4.5 g, quantitative), m.p. 115–116°; ν_{KBr} 2260, 1730, 1705, 1700 cm^{-1}; $\delta_{acetone\text{-}d_6}$ *gem*-dimethyl s 1.17, CH_3COCH_2 s 2.08, and —CH_2CO s 3.08; *m/e* 249 (M+), 234, 207 (base), 206, 190, 179, 178, 167, 164, 109, and 108.

Anal. Calcd. for $C_{14}H_{19}NO_3$: C, 67.4; H, 7.7; N, 5.6. Found: C, 67.2; H, 7.6; N, 5.6.

NOTE: Owing to a certain loss of activity of the treated resin on standing, this hydration is more reproducible using the boron trifluoride – trichloroacetic acid method described later (see **10***c*).

Cyclization of the Triketonitrile 6a

(a) With Potassium t-Butoxide (retro-Michael)

Potassium (180 mg) is dissolved in *t*-butyl alcohol (10 ml) under nitrogen and after cooling 2-acetonyl-2-cyanoethyldimedone (**6***a*) (1.4 g) is added and stirring continued for 35 min. The reaction mixture is poured into ice water and acidified with hydrochloric acid (28 ml, 2 *N*). Extraction affords an oil (1.2 g) from which *2-acetonyldimedone* (**6***c*) crystallizes, m.p. 134–135° (lit. (9) 132–133°); λ_{max} 263 (14 400) and λ_{max} (NaOH) 289 (24 600) nm; ν_{KBr} 1723, 1650, and 1570 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl s 1.10, CH_3COCH_2 s 2.17 and s 3.44, ring CH_2CO s 2.35, OH(enol) 9.67.

Anal. Calcd. for $C_{11}H_{16}O_3$: C, 67.3; H, 8.2. Found: C, 67.5; H, 8.2.

(b) With Ethanolic Hydrochloric Acid (retro-Claisen etc.)

To the triketone **6***a* (1.39 g) in dry ethanol (30 ml) is added concentrated hydrochloric acid (1 ml) and the mixture is refluxed for 24 h. After decomposition in ice water, the product (**7**) (1.2 g) is obtained by extraction and purified by molecular distillation (cold finger): λ_{max} 224 (6000) nm; ν_{film} 2260, 1740 (ester), 1705, and 1640 (conjugated cyclopentenone) cm^{-1}; δ_{CCl_4} *gem*-dimethyl s 1.05, CH_3CH_2O t(7.3) 1.26, and q (7.3) 4.15, CH_2COOR s 2.21, =CH—CO broad s 5.97; *m/e* 277 (M+), 247, 231, 189, 164, 163, 149, 148 (base), and 108.

2-Propargyl-2-(2-cyanoethyl)-3-hydroxy-5,5-dimethylcyclohexanone (8a)

Sodium borohydride (135 mg) is added to a solution of 2-propargyl-2-cyanoethyldimedone (**5***a*) (1.15 g) in methanol (80 ml) and the mixture stirred at room temperature for 4 h. Water (10 ml) is added and the mixture concentrated to about one-third volume before pouring into water and extracting with chloroform. The equatorial hydroxy-ketone **8***a* (1.05 g, 90%) crystallizes from methanol, m.p. 178–179°; ν_{KBr} 3420, 3280, 2260, 1705 cm^{-1}; $\delta_{pyridine\text{-}d_5}$ (90MHz) *gem*-dimethyl two s 0.91 and 1.00, —CHOH d of d(10.0 and 5.5) 4.72 and s 5.0; *m/e* 233, 216, 159, 158 (base), 135, 130, 116, and 101.

Anal. Calcd. for $C_{14}H_{19}NO_2$: C, 72.1; H, 8.2; N, 6.0. Found: C, 72.2; H, 8.3; N, 6.2.

The hydroxy-ketone gives the *O-tosyl derivative* **8***b* (88% yield) on treatment with tosyl chloride in pyridine. The product crystallizes on pouring the reaction mixture into ice water, m.p. 165° (from methanol); ν_{KBr} 3280, 2260, 1715, 1605, 1195, and 1185 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl two s 0.95 and 1.10, —CH_2CO s 2.27 (broad), tosyl s 2.5 and ABq (J_{AB} = 8.5 Hz) 7.6, C*H*OTs d of d(9.0 and 7.5) 5.30; *m/e* 387 (M+, weak) 216, 215, 200, 188, 173, 159, 158, 155, 133, and 119.

Anal. Calcd. for $C_{21}H_{25}NSO_4$: C, 65.1; H, 6.5; N, 3.6. Found: C, 64.8; H, 6.4; N, 3.7.

Acetylation of hydroxy-ketone **8***a* in acetic anhydride – pyridine on a steam bath for 2 days affords the *O-acetyl derivative* **8***c* (78% after recrystallization), m.p. 129–130°; ν_{KBr} 3310, 2260, 2140, 1735, 1710, 1250, 1240 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl two s 0.99 and 1.11, HC≡C—CH_2—*t*(2) 1.83 and d(2.0) 2.53, CH_3CO s 2.08, C*H*—O—Ac d of d(9.0 and 7.0) 5.63.

Anal. Calcd. for $C_{16}N_{21}NO_3$: C, 69.8; H, 7.7; N, 5.1. Found: C, 69.9; H, 7.7; N, 5.1.

2-Acetonyl-2-(2-cyanoethyl)-3-hydroxy-5,5-dimethylcyclohexanone (10a)

Hydration of the triple bond was accomplished by the Dowex resin method (see **6***a*) but yields were more reproducible using the following (in all three cases superior to 80%).

The *O*-acetyl derivative **8***c* (420 mg) is dissolved in warm methanol (35 ml) and without cooling mercuric oxide (21 mg), trichloroacetic acid (2 mg), and boron trifluoride etherate (1 ml) are added. After stirring for 2 h and pouring into dilute sulfuric acid, the methyl-ketone **10***c* (358 mg, 80%) was obtained by chloroform extraction.

The hydroxy-ketone **10***a*, m.p. 84–85°; ν_{KBr} 3420, 2260, 1710, and 1705 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl two s 1.03 and 1.08, CH_3CO s 2.21, CHOH d of d(10.0 and 7.0) 4.43 and s 3.2; *m/e* 239 (M+), 208, 194 (base), 191, 164, 148, and 108.

Anal. Calcd. for $C_{14}H_{21}NO_3$: C, 66.9; H, 8.4; N, 5.6. Found: C, 67.0; H, 8.6; N, 5.6.

The tosylate **10***b*, m.p. 135–136°; ν_{KBr} 2260, 1725, 1715,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

1605, 1195, 1185 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl two s 0.99 and 1.05, CH_3COCH_2 s 2.05 and ABq (J_{AB} = 18.0 Hz) 2.76, CH_3-aromatic s 2.47, CH—O—Ts d of d(5.32) 5.39, aromatic H ABq (J_{AB} = 8.2 Hz) 7.36.

Anal. Calcd. for $C_{21}H_{27}NSO_5$: C, 62.2; H, 6.7; N, 3.5. Found: C, 62.1; H, 6.9; N, 3.9.

The acetate **10c**, m.p. 143–144°; ν_{KBr} 2260, 1735, 1710, 1700, 1255, 1245 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl two s 1.16 and 1.23, CH_3CO two s 2.12 and 2.29, CHOAc d of d(10.0 and 8.0) 5.77.

Anal. Calcd. for $C_{16}H_{23}NO_4$: C, 65.5; H, 7.9; N, 4.8. Found: C, 65.5; H, 7.9; N, 4.8.

2,8-Dimethoxy-4-tosyloxy-9-cyanoethyl-2-methyl-perhydrobenzfuran (9)

The *O*-tosyl derivative **8b** (3.9 g) is hydrated as above but instead of pouring into dilute acid, the reaction mixture is evaporated *in vacuo* affording a white solid (3.7 g by filtration), m.p. 93–94°; ν_{KBr} 2260, 1605, 1198, and 1185 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl s 1.00, $CH_3C(OCH_3)$ s 1.40, CH_3 aromatic s 2.47, 2 × CH_3O two 2 3.18 and 3.32, C*H*OTs d of d(10.0 and 7.0) 5.32, aromatic ABq (J_{AB} = 8.5 Hz) 7.70; *m/e* 451 (M+).

Anal. Calcd. for $C_{23}H_{33}O_6SN$: C, 61.2; H, 7.4; N, 3.1. Found: C, 61.3; H, 7.4; N, 3.2.

Cyclizations of Diketo-tosylate 10b

(a) 1-(2-Cyanoethyl)-4,4-dimethyl-7-acetobicyclo-[4.1.0]heptan-2-one (12)

To a methanolic solution of sodium methoxide (sodium (11.5 mg) in methanol (20 ml)), the diketo-tosylate **10b** (202 mg) is added and the mixture stirred at room temperature for 2.5 h. Chloroform extraction, after pouring the mixture into ice water, gives a clear oil (130 mg) which is chromatographed over alumina III. The benzene – 10% ether eluate is the substituted cyclopropane **12** (85 mg, 73%), m.p. 85–86°; λ_{max} 210 (8300) nm; ν_{KBr} 3060, 2260, 1703 (broad) cm^{-1}; δ_{CDCl_3} *gem*-dimethyl two s 0.90 and 1.00, CH_3CO s 2.33, *no* vinyl or aromatic protons; *m/e* 233 (M+), 218, 193, 191, 190, 176, 160, 151, 149, 148 (base). A sample is sublimed for analysis.

Anal. Calcd. for $C_{14}H_{19}NO_2$: C, 72.1; H, 8.2; N, 6.0. Found: C, 72.0; H, 8.1; N, 6.0.

This same product (**12**) is obtained by refluxing the tosylate **10b** and pyrrolidine in benzene with a Dean–Stark water separator.

(b) 9-Cyano-8-hydroxy-2-oxo-4,4,8-trimethyl-tricyclo[4.4.0.0^{1,7}]decane (13)

To a cold solution of sodium *t*-butoxide (sodium (18.6 mg) in *t*-butyl alcohol (20 ml)), is added the diketo-tosylate **10b** (325 mg) and stirring continued for 3 h at room temperature. The reaction is stopped by pouring into ice water and extracting with ether gives a viscous oil (219 mg) which crystallizes on contact with benzene to afford the spiro compound **13** (175 mg, 75%), m.p. 159–160°; ν_{KBr} 3410, 3045, 2265, 1685 cm^{-1}; δ_{CDCl_3} (90 MHz) *gem*-dimethyl two s 0.90 and 0.97, $CH_3C(OH)$ s 1.46, —CH—CN t (1.5) 2.62, no vinyl or aromatic protons; *m/e* 233 (M+) 218, 190, 177, 176, 134, 125 (base) 107, 106.

Anal. Calcd. for $C_{14}H_{19}NO_2$: C, 72.1; H, 8.2; N, 6.0. Found: C, 72.1; H, 8.1; N, 5.8.

Cyclization of Diketo-acetate 10c

Potassium (40 mg) is dissolved in *t*-butyl alcohol (30 ml) and to this solution is added the diketo-acetate **10c** (293 mg). After 12 h at 40° the reaction mixture is decomposed in ice water and the neutral products (202 mg) obtained by extraction. Chromatography over alumina III gave a *keto-nitrile* **14** (30 mg), m.p. 141–142°; ν_{KBr} 3390, 1740, and 1710 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl two s 0.92 and 1.13, —CH(OH)— m 4.0 and s (broad) 3.25; *m/e* 210 (M+) 195, 182, 154, 149, 126 (base), 125, 110, and 109.

Anal. Calcd. for $C_{12}H_{18}O_3$: C, 68.5; H, 8.6. Found: C, 68.7; H, 8.7.

Other attempted cyclizations either gave back the starting material or in one case (concentrated hydrochloric acid in ethanol) hydrolyzed the product to the alcohol **10a**.

2-(2-Chloropropen-2-yl)-2-(2-cyanoethyl)-5,5-dimethylcyclohexa 1,3-dione (15a)

To a solution of cyanoethyldimedone **2a** (1.93 g) in dimethylformamide (distilled from sodium hydride) under nitrogen, is added sodium hydride – mineral oil (2 g). After warming at 60° for 17 h, 2,3-dichloropropene (5 ml) is added dropwise and heating continued for 6 h. The crude product obtained by extraction is chromatographed over alumina III affording the crystalline chloroalkene **15a** (1.34 g, 50%), m.p. 116–117° (from ether); ν_{KBr} 3120, 2260, 1730, 1700, 1645, and 900 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl two s 0.84 and 1.21, $—CH_2—CCl=CH_2$ ABq (J_{AB} = 14.5 Hz) 2.74 and two s 5.32 and 5.47; *m/e* 269 and 267 (M+), 232, 231, 229, 227, 218, 201, 199.

Anal. Calcd. for $C_{14}H_{18}NO_2Cl$: C, 62.8; H, 6.8; N, 5.2. Found: C, 63.2; H, 6.7; N, 5.3.

NOTE: vacuum sublimation of **15a** gives the propargyl derivative **5a**.

2-(2-Chloropropen-2-yl)-2-(2-cyanoethyl)-3-hydroxy-5,5-dimethylcyclohexanone (15b)

The diketone **15a** (566 mg) is reduced with sodium borohydride (56 mg) in methanol (50 ml). The colorless oil obtained crystallizes on contact with ether to give the hydroxy-ketone **15b** (505 mg, 90%), m.p. 97–98°; ν_{KBr} 3440, 3010, 2260, 1690, 1645, and 900 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl two s 0.95 and 1.14, $CH_2—CCl=CH_2$ ABq (J_{AB} = 14.5 Hz) 2.87 and s 5.42, —CH(OH)— m 4.35 and s 3.0.

Anal. Calcd. for $C_{14}H_{20}NO_2Cl$: C, 62.3; H, 7.5; N, 5.2. Found: C, 62.7; H, 7.6; N, 5.2.

Cyclizations attempted in concentrated sulfuric acid gave intractable products and refluxing in 97% formic acid afforded the *O-formate* **15c**, m.p. 122–123°; ν_{KBr} 2260, 1730, 1710, 1635, 1180, 1165, and 900 cm^{-1}; δ_{CDCl_3} very similar to **15b** but no OH proton, —OC*H*O s 8.14; *m/e* 299 and 297 (M+, weak) 262 (base), 211, 209, 190, 174, 134, 133, 132.

Anal. Calcd. for $C_{15}H_{20}O_3NCl$: C, 60.5; H, 6.8; N, 4.7. Found: C, 60.8; H, 6.8; N, 4.7.

2-Propargyl-2-(2-cyanoethyl)-5,5-dimethylcyclohex-3-enone (16a)

The hydroxy-ketone **8a** (2.33 g) is dissolved in pyridine (50 ml, freshly distilled from calcium hydride). After cooling to 0°, fresh phosphorous oxychloride (9 ml) is added and the solution allowed to warm to room temperature and then heated at 60° for 20 h. The reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

mixture is poured very slowly into stirred ice water affording the crystalline unsaturated ketone **16***a* (1.46 g, 68%), m.p. 86–87°; ν_{KBr} 3260, 3030, 2260, 2120, 1715, and 780 cm^{-1}; δ_{CDCl_3} (90MHz) *gem*-dimethyl two s 1.06 and 1.10 —CH=CH— ABq (J_{AB} = 10.0 Hz) 5.7 (broadened by W coupling); *m/e* 215 (M+), 176, 173, 159, 158, 135 (base), 133, 132, 131, 119, 117, and 105.

Anal. Calcd. for $C_{14}H_{17}NO$: C, 78.1; H, 8.1; N, 6.5. Found: C, 78.1; H, 8.0; N, 6.6.

NOTE: The yield in this elimination varied greatly with the duration of the reaction (19 h, 68%; 23 h, 45%; and 44 h, 20%) and the quality of the reagents. An alternative method employing tosyl chloride in pyridine (65° for 2 days) never gave more than 52% and then only after column chromatography (alumina III).

*2-Acetonyl-2-(2-cyanoethyl)-5,5-dimethylcyclohex-3-enone (**16***b*)

The triple bond in **16***a* (1.36 g) is hydrated as given above for **10***a* affording the methyl-ketone **16***b* (1.05 g, 71%) after column chromatography. Although pure, as shown by t.l.c., this product has never crystallized; ν_{KBr} 3020, 2260, 1715, 1705, and 1365 cm^{-1}; δ_{CDCl_3} (90MHz) *gem*-dimethyl two s 1.06 and 1.14, CH_3-$COCH_2$— s 2.09 and ABq (J_{AB} = 16.5 Hz) 2.75, ring —CH_2CO— ABq (J_{AB} = 14.5 Hz) 2.46, —CH≡CH— ABq (J_{AB} = 10.0 Hz) 5.63. To characterize this product the solid intermediate cyclic acetal is isolated (like **9** but double bond and no *O*-tosyl), m.p. 71–72°; ν_{KBr} 3010, 2260, 1075 cm^{-1}.

Anal. Calcd. for $C_{16}H_{25}O_3N$: C, 68.8; H, 9.0; N, 6.0. Found: C, 69.0; H, 9.0; N, 6.0.

Hydrolysis of this derivative affords the diketone **16***b* quantitatively.

*Cyclization of **19**b*

(a) With Potassium Hydroxide

Under nitrogen, the diketone **16***b* (0.7 g) is boiled in "previously boiled" water and a solution of potassium hydroxide (1.0 g) in "boiled" water (2.7 ml) is added. Refluxing is continued for 12 h and after cooling, diluting with water, salt, and ice the solution is extracted to remove a small quantity of neutral material (23 mg). Acidification of the aqueous solution at 0° and chloroform extraction affords the cyclized acid **17***a* (530 mg, from ether – petroleum ether), m.p. 87–88°; λ_{max} 233 (13 000) nm; ν_{KBr} 3300–2500 (broad), 3010, 1725, 1670, 1620 cm^{-1}; δ_{CHCl_3} 1710, 1688, and 1625 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl two s 0.93 and 1.18, —$COCH_2$— ABq (J_{AB} = 18.0 Hz) 2.27, —CH_2—C(=CH)— s (broad) 2.53 and s (broad) 5.97, —CH=CH— ABq (J_{AB} = 9.5 Hz) 5.50, COOH s (broad) 9.9; *m/e* 234 (M+), 162, 161 (base), 133, 118, 117.

Anal. Calcd. for $C_{14}H_{18}O_3$: C, 71.8; H, 7.8. Found: C, 72.1; H, 7.8.

Treating the acid **17***a* with excess ethereal diazomethane at room temperature gave the *methyl ester* **17***b*, b.p. 97–98° at 0.03 nm; similar properties to the acid: ν_{film} 3010, 1738, 1710, 1625 cm^{-1}; *m/e* 248, 175, 162, 161 (base), 159, 133, 119, 117.

*(b) With Sodium Hydride (**18***a*, **17***c*, *and **19**)*

Under nitrogen, sodium hydride (275 mg; mineral oil suspension) is introduced into dimethoxyethane (50 ml, distilled from sodium hydride). After 20 min, the diketone **16***b* (1.4 g) in dimethoxyethane (15 ml) is added drop by drop. The solution becomes red and is stirred overnight at room temperature. Dilution with ice water and extraction gives a neutral fraction (660 mg) containing several products as shown by t.l.c. (see below). Acidification and extraction of the aqueous phase affords the unsaturated acid **18***a* ([6-(4,4-dimethyl)spiro[5.4]dec-2-en-8-on]ylidene acetic acid) as a yellow solid (541 mg) which is crystallized from petroleum ether – benzene and finally sublimed, m.p. 123–124°; λ_{max} 221(6900) nm; ν_{KBr} 3500–2500 (broad), 3030, 1745, 1690, 1660, 1613, 1268, and 1250 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl two s 1.0 and 1.04, —CH_2—C(=CH—COOH ABq (J_{AB} = 13.0 Hz, allylic coupling 1 Hz) 2.3 and s (broad) 5.80, —CH=CH— ABq (J_{AB} = 9.5 Hz) 5.53; *m/e* 234, 216, 163, 160 (base), 145, 133, 132, 117, and 105.

Anal. Calcd. for $C_{14}H_{18}O_3$: C, 71.8; H, 7.4. Found: C, 71.3; H, 7.7.

The *methyl ester* **18***b* is prepared quantitatively using diazomethane.

The neutral fraction from the reaction above (660 mg) is chromatographed over neutral alumina (II). Elution with benzene gave an unidentified mixture (110 mg) but benzene–ether eluted the *nitrile* **17***c* (118 mg) which could not be induced to crystallize; λ_{max} 232 (13 250) nm: ν_{film} 3020, 2260, 1710, and 1625 cm^{-1}; δ_{CDCl_3} (90MHz) *gem*-dimethyl two s 0.94 and 1.20, —CH_2—CO— ABq 2.26, —CH_2—C(=CH— s (broad) 2.53 and s (broad) 5.98, —CH=CH— ABq (J_{AB} = 10.0 Hz) 5.28. Hydrolysis (6 h in 5% aqueous sodium hydroxide) afforded the acid **17***a*, m.p. 87–88° identical with the sample above.

Further elution (ether–chloroform) gives another *nitrile* **19** m.p. 114–115°; ν_{KBr} 3440, 3030, 2260, 1710, and 785 cm^{-1}; δ_{CDCl_3} *gem*-dimethyl two s 1.02 and 1.06, $CH_3C(OH)$—CH_2— s 1.51 and ABq (J_{AB} = 14.5 Hz) 2.03, —COC*H*—C(—OH s 2.35, —CH=CH— ABq (J_{AB} = 10.0 Hz) 5.73; *m/e* 233, 191 (base), 180, 165, 137, and 109.

Anal. Calcd. for $C_{14}H_{19}O_2N$: C, 72.1; H, 8.2; N, 6.0. Found: C, 72.2; H, 8.2; N, 6.0.

*2-Allyl-2-propargyl-5,5-dimethylcyclohexa-1.3-dione (**5b**)*

Prepared from 2-allyldimedone (**2***c*) (24 g) by essentially the method described above for **5***a*. The propargyl derivative crystallizes from *n*-pentane (25.8 g, 89%), m.p. 58–59°; ν_{KBr} 3290, 3080, 2115, 1718, 1680, 1638 cm^{-1}; δ_{CDCl_3} (90MHz) *gem*-dimethyl two s 0.96 and 1.11, HC≡C—CH_2— t(2.7) 1.92 and d(2.7) 2.62, —CH_2-CH=CH_2 d(7.1) 2.65, q of t(18.0, 8.0, 7.1) 5.55 and m(18.0, 8.0) 5.05; *m/e* 218 (M+), 203, 179, 177, 175, 135, 134 (base), and 121.

Anal. Calcd. for $C_{14}H_{18}O_2$: C, 77.0; H, 8.3. Found: C, 77.1; H, 8.3.

*2-Allyl-2-propargyl-3-hydroxy-5,5-dimethylcyclohexanone (**20**)*

Sodium borohydride (2.02 g) reduction of the diketone **5***b* (16.46 g) in methanol (150 ml) affords the crude hydroxy-ketone **20** (16.4 g, 98%) which from the n.m.r. spectrum and t.l.c. is a mixture of epimeric alcohols but

the equatorial isomer, the major product (4.04 g) crystallizes in part from ether – petroleum ether and the spectral and other characteristics quoted refer to this epimer, m.p. 75–76°; ν_{KBr} 3420, 3250, 2080, 2110, 1700, and 1640 cm^{-1}; δ_{CDCl_3} (90MHz) *gem*-dimethyl two s 0.89 and 1.08, $HC{\equiv}C{-}CH_2{-}$ t(2.5) 2.08 and d(2.5) 2.54, $-CH_2{-}CH{=}CH_2$ d(7) 2.56, q of t(18.0, 9.0, 7.0) 5.45, and m(18.0, 9.0) 5.1, $-CHOH$ d of d(10.5 and 6.5) 4.32; (in the crude product the axial hydroxyl $-CHOH$ gives d of d(6.5 and 6.0) 4.16).

Anal. Calcd. for $C_{14}H_{20}O_2$: C, 76.3; H, 9.2. Found: C, 76.4; H, 9.3.

The *tosylate* was prepared in pyridine with tosyl chloride, m.p. 112–113° (from ether); ν_{KBr} 3280, 1710, 1640, 1600, 1192, and 1180 cm^{-1}.

Anal. Calcd. for $C_{21}H_{26}O_4S$: C, 67.4; H, 7.0. Found: C, 67.2; H, 7.0.

2-Propargyl-2-allyl-5,5-dimethylcyclohex-3-en-1-one (16c)
