The Photochemical Reactivity of Some Benzoylthiophenes. III. The Effect of an Adjacent Methyl Group on the Excited State Reactivity of 2-Benzoylthiophene[1]

D. R. ARNOLD[2] AND B. M. CLARKE, JR.

Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ontario N6A 3K7

Received July 31, 1974

D. R. ARNOLD and B. M. CLARKE, JR. Can. J. Chem. **53**, 1 (1975).

The ultraviolet absorption and phosphorescence emission spectra of 2-(2-methylbenzoyl) thiophene (**1**), 2-benzoyl-3-methylthiophene (**2**), 2-benzoyl-4-methylthiophene (**3**), and 2-benzoyl-5-methylthiophene (**4**) are reported and analyzed. Partial energy diagrams are constructed. The lowest triplet is assigned as a π,π^* state of the 2-thienoyl chromophore in every case. Photocycloaddition of isobutylene to the carbonyl group was observed with **1** and **2**. The oxetanes are thermally unstable; olefins 1-(2-thienyl)-1-(2-methylphenyl)-2-methylpropene (from **1**) and 1-phenyl-1-(2-(3-methylthienyl))-2-methylpropene (from **2**) were formed and characterized. Irradiation of **1** and **2** in *O*-deuteromethanol did not lead to incorporation of deuterium; no reaction was observed. These results are discussed in terms of the existing generalizations potentially useful for predicting photochemical reactivity.

D. R. ARNOLD et B. M. CLARKE, JR. Can. J. Chem. **53**, 1 (1975).

On rapporte et analyse les spectres d'absorption ultraviolet et d'émission de phosphorescence des (méthyl-2 benzoyl)-2 thiophène (**1**), benzoyl-2 méthyl-3 thiophène (**2**), benzoyl-2 méthyl-4 thiophène (**3**) et benzoyl-2 méthyl-5 thiophène (**4**). Des diagrammes partiels d'énergie sont rapportés. Dans chaque cas, on assigne l'état triplet le plus bas à un état π,π^* du chromophore thiénoyl. On observe la photocycloaddition de l'isobutylène sur le groupement carbonyle des produits **1** et **2**. Les oxétanes sont thermiquement instables; les oléfines (thiényl-2)-1 (méthyl-2 phényl)-1 méthyl-2 propène (à partir de **1**) et de phényl-1 ((méthyl-3 thiényl)-2)-1 méthyl-2 propène (à partir de **2**) se forment et ont été caractérisées. L'irradiation de **1** et de **2** dans le méthanol-OD ne conduit pas à l'incorporation du deutérium; on n'observe aucune réaction. On discute de ces résultats en termes des généralisations existantes et qui peuvent s'avérer utiles pour prédire la réactivité photochimique. [Traduit par le journal]

Introduction

One photochemical reaction which could be particularly useful for synthesis, if it were general or at least predictable, is that which can formally be viewed as a γ-hydrogen abstraction by the oxygen atom of an α,β-unsaturated carbonyl compound. The resulting intermediate(s), if there is one (are any), may subsequently lead to the cyclobutenol or dienol. These products may be of interest in their own right, or may undergo further reactions.

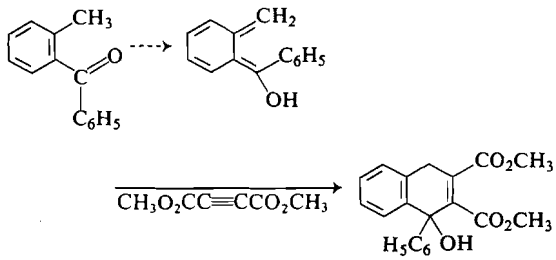
There are now several examples of this type of reaction (1, 2) and a considerable interest in the mechanism(s). There is, to our knowledge, only one example (3) of a planned synthetic sequence which takes advantage of this reactivity.[3] This will probably remain the case, the synthetic utility will not be fully realized, until the generality of the reaction is known and until it is possible to predict when reactions of this type will occur.

An early example of this reaction (4*a*), which has been extensively studied (4), is the irradiation of *o*-methylbenzophenone, where irradiation in benzene solution gave the photoenol which could be trapped with dienophile, ultimately resulting in formation of the naphthalene derivative. The excited state responsible for this reaction has been shown to be the n,π* triplet.



Diagnostic of formation of the photoenol was incorporation of deuterium in the methyl group upon irradiation in *O*-deuteromethanol. This intramolecular hydrogen abstraction from the *o*-methyl group is believed to be the cause of the greatly diminished photochemical reactivity of this compound toward intermolecular hydrogen abstraction leading to pinacol formation, and toward photocycloaddition with olefins to give the oxetane (4*k*). In fact, this ketone has been used as a stabilizer against ultraviolet irradiation in, for example, plastics.

Intramolecular and intermolecular hydrogen abstraction and photocycloaddition to give the oxetane are reactions expected of an n,π* singlet or triplet state. The observed product, following formation of these reactive states, is a function of the relative rates of these competing reactions. With *o*-methylbenzophenone, the intramolecular reaction usually competes favorably. For the general case, therefore, if a carbonyl compound is known to abstract hydrogen intermolecularly, or to undergo photocycloaddition to give an oxetane, it should follow that substitution by an alkyl group (or any other group from which hydrogen could be abstracted) in a position which would allow intramolecular hydrogen abstraction should not only inhibit the intermolecular reactions, but should lead to the photoenol instead. This prediction of course assumes that the substitution by the alkyl group will not significantly alter the nature of the excited states, an assumption which is commonly made, albeit with little justification.

Furthermore, if intermolecular and intramolecular hydrogen abstraction and photocycloaddition to give the oxetane are characteristic of the carbonyl n,π* triplet, one might except a correlation between reactivity in these reactions and the nature of the lowest triplet, as determined by phosphorescence emission studies.

We have recently shown that, although 2-benzoylthiophene emits from a triplet with π,π* character, photocycloaddition of olefins to the carbonyl group does occur (5). We were, therefore, interested in the photochemical reactivity of the methyl substituted 2-benzoylthiophenes, particularly those with the methyl present in the *ortho-* position of the benzoyl group (2-(2-methylbenzoyl)thiophene, **1**) and in the adjacent position of the thiophene (2-benzoyl-3-methylthiophene, **2**).

We ask the following questions:

(*1*) Does the methyl group significantly alter the positioning of the available excited states as determined by a spectroscopic study? While it is sometimes assumed that alkyl substitution does not appreciably (?) influence the excited state(s), this need not be the case. Particularly when the states are close in energy, an upper state in the unsubstituted molecule may become the lowest state upon addition of the alkyl substituent. For this reason we are interested not only in the spectroscopic characterization of the excited states in **1** and **2** but also of 2-benzoyl-4-methylthiophene (**3**) and 2-benzoyl-5-methylthiophene (**4**) as well.

(*2*) Will the adjacent methyl group inhibit the photocycloaddition reaction? Prediction, based on analogy with *o*-methylbenzophenone, would be yes. However, the photocycloaddition reaction with 2-benzoylthiophene may involve a state other than the n,π* state, particularly since the phosphorescence emission spectrum of 2-

[3]Since the absorption spectrum of the photoenol is usually drastically different from that of the ketone, this reaction has received attention as a photochromic system (2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

benzoylthiophene reveals the lowest triplet has π,π^* character. If some other excited state is involved, perhaps with this state, hydrogen abstraction does not compete with photocycloaddition.

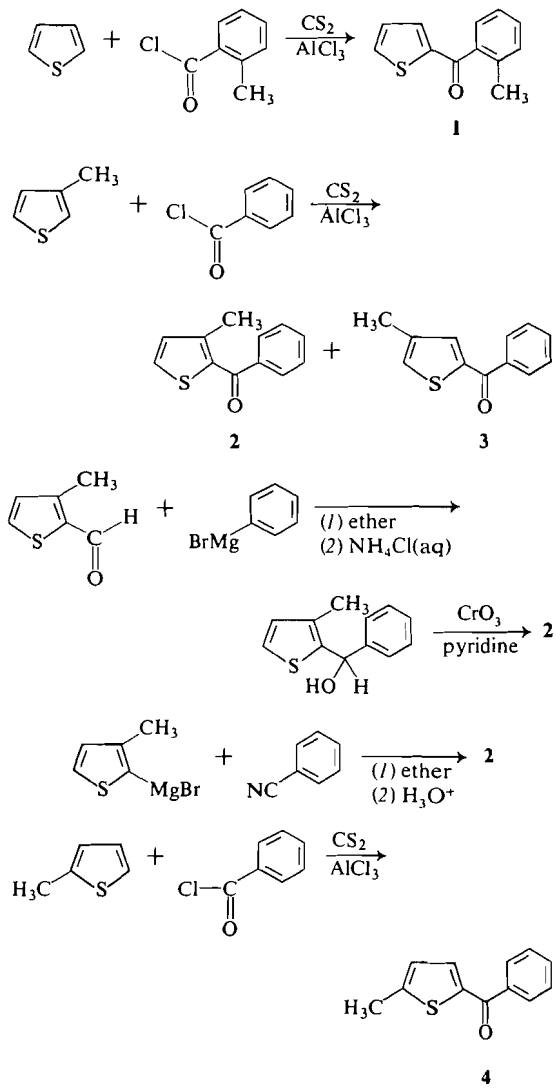
(*3*) Will the photoenol form? If the photoenol of **2** forms, this reaction would afford a convenient route to this reactive intermediate, potentially useful in a wide variety of syntheses.

Answers to these questions might lead to some conclusion with regard to our more general objective, which is to define on what basis photochemical reactivity can be predicted. This may be based on an analogy with the reactivity of related model compounds (*e.g.* benzophenone and *o*-methylbenzophenone); it may be based on the knowledge of the electronic configuration and energy of the lowest excited states gleaned from spectroscopic studies; or extrapolation of one type of "characteristic" photoreactivity to another.

Results

The ketones (**1–4**), required for this study, were prepared by the Friedel–Crafts procedure; **1** has been prepared previously (6), **2–4** are new compounds. The reaction of 3-methylthiophene with benzoyl chloride gave a mixture of two benzoylated products in the ratio 6:1. This mixture was easily separated by preparative vapor phase chromatography. Expectations, based on analogy with other electrophilic substitution reactions of 3-methylthiophene, suggest the major product should have structure **2** (7). This assignment is consistent with the n.m.r. spectra which show the methyl protons in the major product at somewhat lower field than for the minor product, the result of deshielding by the adjacent benzoyl group. Furthermore, the larger coupling observed for the proton in the 5 position of the major product is consistent with **2**, where the coupling results from an adjacent proton.

Confirmation of this structural assignment was provided by alternative synthesis of **2**. Two sequences, involving the Grignard reaction, were utilized: one, using the Grignard reagent from bromobenzene reacting with 3-methyl-2-thiophene carboxaldehyde followed by oxidation of the resulting alcohol; and the other used the reaction of the Grignard reagent from 2-bromo-3-methylthiophene with benzonitrile followed by hydrolysis of the imine. The latter approach gave the better yield of **2**. These reactions are



SCHEME I

shown in Scheme 1. The chemical shifts and coupling constants for the protons on the thiophene ring are summarized in Table 1.

The ultraviolet absorption spectra of ketones **1–4** were taken in hexane solution and are shown in Fig. 1. The phosphorescence emission spectra of **1–4** were taken in ethanol:methanol (4:1) glass at 77 °K. The gross vibrational, rotational features of these emission spectra are superficially similar to one another and to that observed from 2-benzoylthiophene (*5a*); however, the O—O band is significantly shifted depending upon the position of the methyl group on the thiophene ring. The triplet energy,

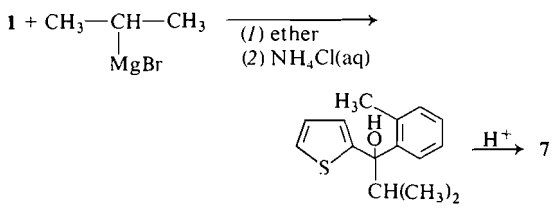
No evidence was obtained for addition of isobutylene to the thiophene ring; however, the material balance indicates considerable starting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

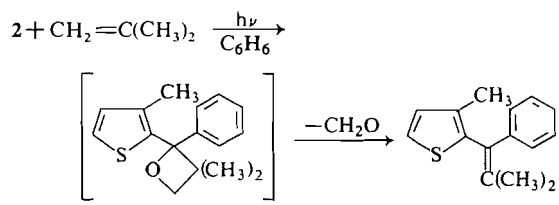
ketone has not been accounted for and the n.m.r. spectrum of the crude reaction mixture suggests several other products form in small amounts. There was no indication of photochemical rearrangement of the starting ketone.

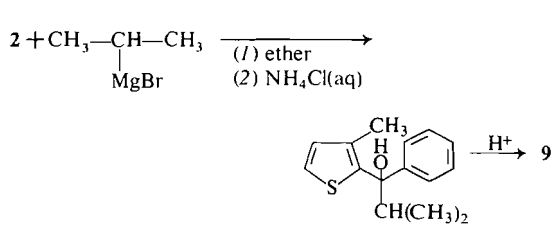
The structure assigned to olefin **7** was suggested by the n.m.r. spectrum which shows methyl protons absorbing at 1.56, 2.08, and 2.11 p.p.m.; the vinyl methyls of 1-phenyl-1-(2-thienyl)-2-methylpropene occur at 1.98 and 1.68 p.p.m. (*5b*). Confirmation of this assignment was obtained by synthesis of the identical material by dehydration of the alcohol prepared by the Grignard reaction of the ketone **1** with isopropylmagnesium bromide.

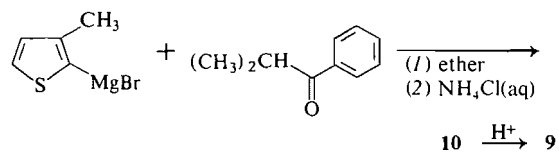


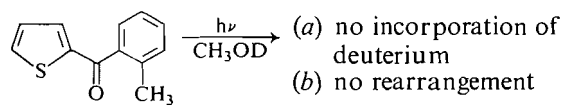
When ketone **2** was irradiated in benzene solution containing isobutylene, the n.m.r. spectrum of the crude reaction mixture gives no indication for the presence of an oxetane; however, peaks at 1.74, 1.85, and 2.09 p.p.m. attributable to olefin **9** are present along with complex absorption due to the formation of other minor products. The olefin **9** was isolated from the crude reaction mixture by column chromatography. The structural assignment was confirmed by synthesizing identical material by dehydrating the alcohol **10** prepared by the Grignard reaction of ketone **2** with isopropylmagnesium bromide or by the Grignard reaction of 3-methyl-2-thienyl magnesium bromide with isobutyrophenone. There was no indication of photochemical rearrangement of the starting ketone **2**.

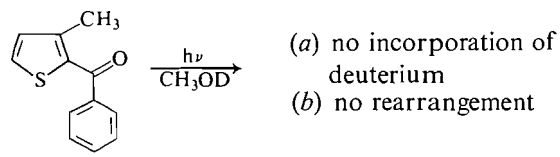
Ketones **1** and **2** were irradiated in *O*-deuteromethanol. There was no evidence for any photochemical reaction occurring in either case. The starting material could be recovered essentially pure (i.r., n.m.r.) by evaporating the solvent. No isomerization of the thiophene was observed. No deuterium was incorporated in the methyl group since there was no decrease in the integrated n.m.r. signal due to the protons of the methyl. Furthermore, the mass spectra of the recovered starting materials showed no increase in the parent-plus-one mass peak. A control experiment, using *o*-methylbenzophenone, showed rapid incorporation of deuterium in the methyl group, under these conditions.











Discussion

Since intermolecular and intramolecular hydrogen abstraction and photocycloaddition to give the oxetane are usually considered to be characteristic reactions of the carbonyl n,π* triplet, and since there frequently is a correlation between photochemical reactivity and the nature of the lowest triplet determined by phosphorescence emission studies,[4] we will first interpret the ultraviolet absorption and phosphorescence emis-

[4]It must be kept in mind that the conditions used in these two types of experiments are very different (*i.e.*, room temperature in fluid solution *vs.* 77 °K in a rigid medium); exceptions are, therefore, not unexpected.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

sion spectra, construct energy diagrams, and discuss the observed reactivity in terms of this generalization.

The ultraviolet absorption spectra of 2-benzoylthiophene (**5**) and several derivatives, mostly substituted in the thiophene 5-position, have been analyzed in some detail (5*a*, 8). The total absorption spectrum is a composite of transitions involving five more or less independent chromophores, Fig. 2. With 2-benzoylthiophene (hexane solution) a maximum occurs at 245 nm which includes transitions of the benzoyl and thienyl chromophores. The $\pi \rightarrow \pi^*$ transition of the 2-thienoyl chromophore causes a maximum at 275 nm. Weak, long wavelength, structured absorption, with a O—O band near 380 nm is due to the carbonyl $n \rightarrow \pi^*$ transition. The gross features of the spectrum of **1** are similar to **5**, with maxima slightly shifted to 261 and 285 nm. The spectra of **1** and **5** are even less different when ethanol is the solvent (λ_{max} 264 and 292 nm for both **1** and **5**) (8).

The absorption spectra of **2** is similar to that of **1** (and **5**); the thienoyl transition at 282 nm is relatively unaffected. This can be taken as evidence that the thienoyl moiety remains essentially planar in spite of the potential increase in steric interaction. The decrease in intensity of the maximum at 250 nm in **2** relative to **5** (ε = 10 800 and 12 300 for **2** and **5** respectively) may in fact result from decreased planarity of the benzoyl moiety because of the methyl group.

The absorption spectra of **3** and **4** show a pronounced bathochromic shift of the band assigned to the thienoyl chromophore; 20 nm relative to that of **5**, a difference in energy of *ca.* 7 kcal mol^{-1}. Obviously, the effect of a methyl group cannot be ignored when predicting the relative positions of the excited states of a molecule.

The 2-thienoyl chromophore has been compared with the α,β- γ,δ-unsaturated carbonyl chromophore. It is therefore interesting to note the similarity of the effect of alkyl substitution on these two systems. The effect of alkyl substitution in the γ or δ position is similar, 18 nm for α,β- γ,δ-unsaturated carbonyl compounds. On the other hand, alkyl substitution in the β-position of the unsaturated carbonyl chromophore (analogous to **2**) causes a much larger effect (12 nm bathochromic) than observed for this transition in **2**.

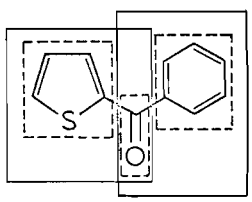

FIG. 2. The ultraviolet absorption spectrum of 2-benzoylthiophene is a composite of transitions involving five, more or less independent chromophores.

The weak absorption at long wave lengths (hexane solution) for **1**–**5** is attributed to the carbonyl $n \rightarrow \pi^*$ transition. It is essentially unaffected (O—O band *ca.* 380 nm) by methyl substitution.

The gross features of the phosphoresence emission spectra from **1**–**4** are similar to one another and to that of **5**. However, the triplet energies, calculated from the position of the short wave length maximum, show significant differences (Table 2). The similarity in the shape of the spectra and the phosphorescence lifetimes (relatively long) indicates the same state is involved in all cases, the π,π^* thienoyl triplet. The progression of triplet energies **1** > **2** > **3** > **4** is interesting. This progression is not observed in the singlet transition (λ_{max}) for this chromophore.

This spectral information is summarized in the partial energy diagrams shown in Fig. 3. The π,π^* singlet energy levels are taken from the maximum of the absorption spectra, they are, therefore, maximum values but are useful for comparison. The n,π^* singlet energies are taken from the O—O band of the absorption spectrum. The π,π^* triplet energies are taken as the O—O band of the emission spectrum and the n,π^* triplet energies are estimated assuming a typical $(n,\pi^*)S$–$(n,\pi^*)T$ separation of 2000 cm^{-1}.

The generalization of photochemical reactivity based upon the nature of the lowest triplet and attributing rapid (and frequently efficient) hydrogen abstraction and photocycloaddition to reactions of the n,π^* triplet would predict **1** and **2** should be unreactive. Thermal equilibration and vibronic mixing of the lower energy π,π^* triplet with the more reactive n,π^* triplet should also be negligible in view of the rather large (>6 kcal mol^{-1}) separation between these states (9). Reaction of the n,π^* singlet is possible; however, the ordering of states, with a π,π^*

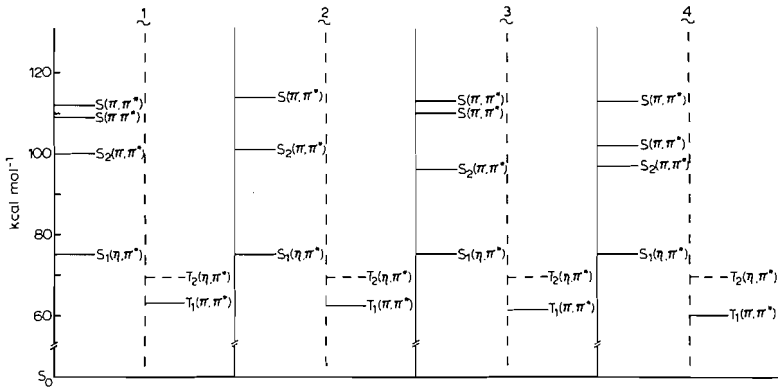

FIG. 3. Partial energy diagrams for some 2-benzoylthiophenes.

triplet below the lowest n,π* singlet, should result in rapid intersystem crossing (10). Therefore, the lack of deuterium exchange in **1** and **2** is predictable based on the knowledge summarized in the partial energy diagrams (Fig. 3). The photocycloaddition is unexpected, not only from the consideration of positioning of the excited states, but, the adjacent methyl does not quench the reaction as it does in the case of *o*-methylbenzophenone.

There is a considerable amount of recent evidence indicating that oxetane formation cannot simply be viewed as requiring the carbonyl n,π* state in a reaction analogous to alkoxy radical addition to an olefin, but that the first step toward oxetane formation is formation of a complex (11). Furthermore, this complex can be formed from either an n,π* or π,π* state and with a rate competitive with intersystem crossing. Obviously several sets of generalizations will be required to predict reactivity in this reaction.

Since it seems unlikely that an n,π* state is involved in the observed photocycloaddition of **1** and **2**, intramolecular hydrogen abstraction does not inhibit this reaction with the state that *is* involved. We cannot, with the information available at this time, assign this reaction to a state; however, we favor the lowest π,π* triplet as the most likely candidate. Sensitization and quenching studies which would make possible an assignment are difficult in this case because of the low yield (the reaction mixture turns dark) and low quantum yield (estimated <0.05).

If generalizations of photochemical reactivity can be based upon characteristic reactivity in different types of reactions, the lack of intramolecular hydrogen abstraction with **1** and **2** is relevant to the question of intermolecular hydrogen abstraction with these ketones and with **5**. The n,π* triplet of *o*-methylbenzophenone can undergo competitive intramolecular and intermolecular hydrogen abstraction. The product obtained following intermolecular hydrogen abstraction from isopropyl alcohol is the pinacol (33% yield) (4*d*). The quantum yield for pinacol formation is low, approximately 0.1 that for pinacol formation from benzophenone, which illustrates the pronounced preference for intramolecular hydrogen abstraction (4*a*, *b*, *d*). Therefore, the prediction can be made that **1** and **2** will not be reduced upon irradiation in isopropyl alcohol. Obviously, the reported (12) reduction of **5**, upon irradiation in isopropanol, which presumed pinacol formation is inconsistent with these results.

We have now turned our attention to the methyl substituted 3-benzoylthiophene derivatives. Since 3-benzoylthiophene emits from an n,π* triplet (5*a*) we predict intramolecular hydrogen abstraction will occur from an adjacent methyl in these cases. The report of this study will constitute Part IV of this series.

Experimental

General

A description of the apparatus used and the general experimental approach was similar to that reported in Parts I and II (5).

Irradiations were carried out using a Hanovia 450-W medium-pressure mercury vapor lamp (679 A36) in a quartz cooling jacket which was immersed in a constant temperature bath at 10°. The samples, contained in sealed quartz or Pyrex tubes (20 mm diameter) having a volume of 40 ml, were arranged around the lamp at a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

distance of 25 mm; they were not degassed unless stated otherwise.

The n.m.r. spectra were run in 1–2 *M* solutions in deuterochloroform using tetramethylsilane as an internal reference. The spectra were obtained on a Varian HA-100 spectrometer. The chemical shifts are taken as the center of multiplets and the reported coupling constants are the result of first-order analysis. Coupling was confirmed by double irradiation experiments.

The emission spectra were obtained as previously reported (Part I) (*5a*) with the exception that ethanol: methanol (4:1) was used as the solvent instead of diethyl ether:isopentane:ethanol (5:5:2).

Preparative v.p.c. separations were carried out using a F and M Scientific preparative gas chromatograph, Model 776.

Methylthiophene-2 and -3 and 3-methyl-2-thiophenecarboxaldehyde were obtained from Aldrich Chemical Co.

2-(2-Methylbenzoyl) Thiophene(1)

This ketone was prepared by the Friedel–Crafts reaction (6). Treatment of 2-methylbenzoic acid (34.0 g, 0.23 mol) with thionyl chloride (25 ml) at reflux for 1 h gave, after evaporation of excess thionyl chloride, 2-methylbenzoyl chloride (36.4 g, 94%) which was purified by distillation (b.p. 94–96°, 20 mm; lit. (13) 110–111°, 29 mm).

Thiophene (9.0 g, 0.1 mol) and 2-methylbenzoyl chloride (15.4 g, 0.1 mol) were dissolved in carbon disulfide (125 ml) with exclusion of moisture. Anhydrous aluminum chloride (13.2 g, 0.1 mol) was added in 3 g portions over ½ h. This mixture was refluxed 1½ h, cooled, poured into 3 l water, and stirred until the black residue dissolved. The layers were separated, the aqueous layer was extracted (4 × 500 ml) with carbon disulfide, the combined carbon disulfide solutions were washed with 10% aqueous sodium hydroxide (1 × 500 ml) and water (1 × 500 ml) and finally dried over anhydrous sodium sulfate. Filtration, evaporation of the solvent, and distillation gave 2-(2-methylbenzoyl) thiophene (12.5 g, 58%) as a colorless oil (b.p. 101–104°, 0.01 mm). A sample was triply distilled (b.p. 124°, 0.17 mm) for analysis and spectral studies: i.r. ν_{max}^{neat} 1645, 1425, 1315, 1285, 740 cm^{-1}; u.v. λ_{max}^{hexane} 262 nm (ε = 14 600), 283 nm (ε = 13 300).

Anal. Calcd. for $C_{12}H_{10}OS$: C, 71.28; H, 4.99. Found: C, 71.08; H, 5.14.

These physical and spectral properties agree satisfactorily with those reported for this compound (8, 14).

2-Benzoyl-3-methylthiophene (2) and 2-Benzoyl-4-methylthiophene (3) (Friedel–Crafts Reaction)

Treatment of 3-methylthiophene (9.8 g, 0.1 mol) with benzoyl chloride (14.0 g, 0.1 mol) and anhydrous aluminum chloride (26.6 g, 0.2 mol) in carbon disulfide (500 ml), following the same reaction and work-up procedure used for the preparation of 2-(2-methylbenzoyl)thiophene, gave a 6:1 mixture of 2-benzoyl-3-methylthiophene and 2-benzoyl-4-methylthiophene. This mixture was separated by preparative v.p.c. using a 5 ft × 3/4 in. column packed with 5% QF-1 on 60/80 mesh Chromosorb W. Using an injector and column temperature of 150° and a carrier gas (N_2) flow rate of 12 cc/min, the retention time for 2-benzoyl-3-methylthiophene was 1.5 min and for 2-benzoyl-4-methylthiophene, 17.5 min.

2-Benzoyl-3-methylthiophene is a colorless oil: i.r. ν_{max}^{neat} 1630, 1400, 1265, 900 cm^{-1}; u.v. λ_{max}^{hexane} 250 (ε = 10 800), 282 (ε = 14 800).

Anal. Calcd. for $C_{12}H_{10}OS$: C, 71.28; H, 4.99. Found: C, 71.27; H, 5.16.

2-Benzoyl-4-methylthiophene is colorless crystals (m.p. 88–90°, from hexane): i.r. $\nu_{max}^{CCl_4}$ 1641, 1421, 1286, 856, 706 cm^{-1}; u.v. λ_{max}^{hexane} 252 (ε = 11 400), 296 (ε = 8100).

Anal. Calcd. for $C_{12}H_{10}OS$; C, 71.28; H, 4.99. Found: C, 71.00; H, 4.98.

2-Benzoyl-3-methylthiophene (3) (The Grignard Route)

Two different approaches, utilizing the Grignard reaction, were tried; the route from 2-bromo-3-methylthiophene was found to be the best (15).

Via the Aldehyde

A solution of the Grignard reagent prepared from bromobenzene (1.57 g, 10 mmol) and magnesium (240 mg, 1 equivalent) in dry ether (20 ml) was treated dropwise with 3-methyl-2-thiophene carboxaldehyde (1.26 g, 10 mmol). The solution was stirred vigorously during the addition and was then refluxed for 3 h. An aqueous ammonium chloride solution (50 ml, 10%) was added to the reaction mixture. The layers were separated, the aqueous layer extracted with ether (2 × 100 ml) and the combined ether layers were dried over magnesium sulfate. Evaporation of the solvent left a yellow oil (1.76 g, 85%) n.m.r.; δ 2.15 p.p.m. (s, 3H, methyl), 3.25 (broad, 1H, hydroxyl), 5.90 (broad, 1H, benzylic), presumed to be 2-(3-methylthienyl) phenylcarbinol, which was not further purified, but oxidized with Cornforth's reagent (chromium trioxide in pyridine, water) (16).

A pyridine (5.8 ml) solution of chromium trioxide (580 mg) and water (0.58 ml) was prepared and added dropwise to a benzene (20 ml) solution of the carbinol (1.76 g). The resulting mixture was stirred for 3 h and then poured into water/ether. The layers were separated, the aqueous layer was extracted with ether (150 ml) and the combined ether layers were washed with dilute hydrochloric acid (200 ml, 5%), sodium bicarbonate solution (200 ml, 5%), and water. The resulting extract was dried over magnesium sulfate, the ether was evaporated, and the residue chromatographed on alumina. 2-Benzoyl-3-methylthiophene, identical (i.r., n.m.r.) with that obtained from the Friedel–Crafts procedure given above, was eluted from the column using ether. The yield from the crude carbinol was 38% (470 mg).

Via 2-Bromo-3-methylthiophene

To a mixture of magnesium (1.2 g, 1 equivalent) in dry tetrahydrofuran (10 ml, distilled from CaH_2) was added 2-bromo-3-methylthiophene (17) (1 g) and a small crystal of iodine. An exothermic reaction started after approximately 5 min and the mixture began to reflux. The mixture was stirred with a magnetic stirring bar and additional 2-bromo-3-methylthiophene (7.85 g total, 0.05 mol) in 10 ml of dry tetrahydrofuran was added at a rate such that reflux was maintained. After the addition the mixture was heated under reflux for ½ h and then cooled to room temperature. Benzonitrile (5.1 g, 0.05 mol) was added to this solution and the mixture refluxed for 30 h. The resulting mixture was cooled in an ice bath and aqueous hydrochloric acid (20 ml, 10%) was slowly added. The tetrahydrofuran was now removed on a rotary evaporator, the aqueous solution was diluted with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

water (300 ml) and extracted with ether (3 × 200 ml). The combined ether layers were washed with saturated aqueous sodium bicarbonate and dried over magnesium sulfate (anhydrous). Evaporation of the ether followed by vacuum distillation gave a product (b.p. 120°, 0.15 mm; 4.4 g, 45%) which was identified, by spectral analysis, as the imine: i.r. ν_{max}^{neat} 3231, 1591, 1571, 1426, 1341, 1191, 881, 836, 706 cm^{-1}; n.m.r. δ (p.p.m.) 2.05 (s, 3H, methyl protons), 7.75–6.78 (complex, 8H, aromatic protons). The imine was refluxed with a mixture of benzene (20 ml) and aqueous hydrochloric acid (20 ml, 10%) for 10 h. The benzene layer was separated, washed with aqueous sodium bicarbonate solution, dried over sodium sulfate (anhydrous), and the solvent was removed. The resulting orange oil was vacuum distilled to give 2-benzoyl-3-methylthiophene (b.p. 104–108°, 0.05 mm; 3.5 g, 71%) identical (i.r., n.m.r.) with that obtained by the Friedel–Crafts route.

*2-Benzoyl-5-methylthiophene (**4**)*

To a stirred solution of 2-methylthiophene (9.7 g, 0.1 mol) and benzoyl chloride (13.8 g, 0.1 mol) in carbon disulfide (500 ml), anhydrous aluminum chloride (26.4 g, 0.22 mol) was added in portions over 1 h. The resulting mixture was stirred for 3 h and then was poured onto ice (500 g). After the ice melted, the layers were separated, the aqueous layer was extracted with carbon disulfide (500 ml) and the combined carbon disulfide layers were washed with sodium hydroxide (250 ml, 10%) and water (250 ml). This extract was dried over sodium sulfate (anhydrous). The solvent was evaporated and the 2-benzoyl-5-methylthiophene was purified by vacuum distillation (b.p. 130°, 0.06 mm, 16.34 g, 81%). A small sample was bulb-to-bulb distilled prior to spectral analysis: i.r. ν_{max}^{neat} 1630, 1450, 1295, 710 cm^{-1}; λ_{max}^{hexane} 253 (ε = 10 200), 280 (ε = 9650), 295 (ε = 13 000).

Anal. Calcd. for $C_{12}H_{10}OS$: C, 71.28; H, 4.99. Found: C, 71.13; H, 4.86.

*Irradiation of 2-(2-Methylbenzoyl)thiophene (**1**) in the Presence of Isobutylene*

2-(2-Methylbenzoyl)thiophene (2 g) was dissolved in a 25% solution of isobutylene in benzene (35 ml) and was irradiated in a quartz irradiation vessel, sealed with a rubber serum cap, for 190 h. The excess isobutylene and benzene were evaporated and the n.m.r. of the resulting yellow–brown oil was taken. Peaks at δ (p.p.m.) 1.55, 2.05, and 2.10, characteristic of the olefin were observed, along with complex absorption between 0.8–1.85. No absorption was apparent in the region expected for the oxetane methylene protons. This crude reaction mixture was chromatographed on neutral alumina (Shawinigan, activity 1) and a product (58 mg) was eluted, with hexane:benzene (4:1), which was identical (i.r., n.m.r.) with 1-(2-thienyl)-1-(2-methylphenyl)-2-methylpropene (7) prepared by the Grignard method given below. Further elution with benzene gave recovered starting material (1.15 g); so, the yield of olefin was 26%. Similar results were obtained using a Pyrex irradiation vessel.

*Irradiation of 2-Benzoyl-3-methylthiophene (**2**) in the Presence of Isobutylene*

2-Benzoyl-3-methylthiophene (775 mg) was dissolved in a 25% solution of isobutylene in benzene (35 ml) and was irradiated in a Pyrex irradiation vessel, sealed with a rubber serum cap, for 170 h. Evaporation of the excess isobutylene and benzene left a dark oil. The n.m.r. spectra had complex absorption between δ (p.p.m.) 2.2–0.8 including singlets at 2.17, 1.81, and 1.76 characteristic of the olefin and a singlet at 2.42 due to the starting ketone; there was no indication of oxetane being present. The crude reaction mixture was chromatographed on neutral alumina (Shawinigan, activity 1). Elution with hexane:benzene (4:1) gave a product (20 mg) identical (i.r., n.m.r.) with 1-(2-(3-methylthiophene))-1-phenyl-2-methylpropene (**9**) prepared by the Grignard method given below. Further elution with benzene afforded starting material (342 mg); so, the yield of product was 4%. Essentially the same result was obtained when a quartz irradiation vessel was used.

1-(2-Thienyl)-1(2-methylphenyl)-2-methylpropene (7)

To a solution of the Grignard reagent prepared from 2-bromopropane (1.23 g, 0.01 mol) and magnesium (0.24 g, 1 equivalent) in dry ether (10 ml) was added 2-(2-methylbenzoyl)thiophene (0.27 g, 0.023 mol) and the resulting solution was refluxed for 17 h. This reaction mixture was poured into aqueous ammonium chloride (50 ml, 10%), the resulting layers were separated, and the aqueous layer extracted with ether (2 × 50 ml). The combined ether extracts were dried over magnesium sulfate (anhydrous). Evaporation of the solvent left a yellow oil, presumed to contain the alcohol. This oil was dissolved in benzene (25 ml), 4-toluenesulfonic acid (trace) was added, and the solution refluxed for 5 h. The solvent was evaporated, the oil was dissolved in ether and washed with aqueous sodium carbonate (10 ml, 10%), and dried over magnesium sulfate (anhydrous). Evaporation of the solvent left a dark oil which was chromatographed on silica gel (E. M. Reagents, 7733). The product (22 mg, 7.2%) was eluted with 5% hexane in benzene. A sample was distilled, bulb-to-bulb under vacuum, for spectral characterization and analysis: i.r. $\nu_{CHCl_3}^{max}$ 1715, 1595, 1380, 1370, 1280, 905 cm^{-1}; n.m.r. δ (p.p.m.) 1.65(s), 2.13(s), 2.18(s), (methyl protons), 7.35–6.70 (complex), (phenyl and thienyl protons).

Anal. Calcd. for $C_{15}H_{16}S$: C, 78.92; H, 7.06. Found: C, 79.11; H, 7.27.

*1-Phenyl-1-(2-(3-methylthienyl))-2-methylpropene (**9**)*

Two different procedures, involving the Grignard reaction, were used for the preparation of this olefin. The procedure utilizing 2-bromo-3-methylthiophene was found to give the best yields.

The Grignard Reaction of 2-Propyl Magnesium Bromide with 2-Benzoyl-3-methylthiophene

To a solution of the Grignard reagent prepared from 2-bromopropane (280 mg, 0.022 mol) and magnesium (56 mg, 1 equivalent) in anhydrous ether (20 ml) was added 2-benzoyl-3-methylthiophene (470 mg, 0.023 mol) dissolved in ether (20 ml). The reaction was stirred overnight and then was poured into aqueous ammonium chloride (50 ml, 10%). The resulting layers were separated and the aqueous layer extracted with ether (100 ml). The combined ether extract was dried over magnesium sulfate (anhydrous) and the solvent evaporated to obtain a yellow oil. This oil, presumably the alcohol, was not characterized but was dissolved in benzene (25 ml), 4-toluenesulfonic acid (trace) was added, and the resulting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solution refluxed for 24 h. The resulting mixture was washed with sodium bicarbonate solution (20 ml, 10% aqueous), dried over magnesium sulfate (anhydrous), and the solvent was evaporated to give a dark oil which was chromatographed on neutral alumina (Shawinigan, activity 1). The first fractions, eluting with hexane: benzene, contained the olefin (58 mg, 9%).

Reaction of the Grignard reagent from 2-Bromo-3-methylthiophene with Isobutyrophenone

To a mixture of 2-bromo-3-methylthiophene (17) (1 g) and magnesium turnings (0.324 g, 1 equivalent) in dry tetrahydrofuran (10 ml) a crystal of iodine was added. After several minutes a vigorous reaction started and additional halide (totaling 2.39 g, 0.013 mol) in tetrahydrofuran (20 ml) was added at such a rate as to maintain reflux. The mixture was heated under reflux for 2 h and cooled to room temperature. A solution of isobutyrophenone (2 g, 0.013 mol) in tetrahydrofuran (10 ml) was then added dropwise and the reaction mixture refluxed for 5 h, cooled in an ice bath, and treated with hydrochloric acid (10 ml, 10%). The tetrahydrofuran was removed on a rotary evaporator and replaced by ether. The ether layer was separated and the aqueous layer extracted with ether (2 × 100 ml). The combined ether extracts were dried over magnesium sulfate (anhydrous) and, after removal of the solvent, a dark oil was obtained which, by n.m.r., was approximately half the desired alcohol and the remainder, starting ketone. The alcohol was not further characterized, but was dissolved in benzene (20 ml) with a trace of 4-toluenesulfonic acid and refluxed for 20 h. After evaporation of the solvent the product (1.14 g, 40%, based on unrecovered starting ketone) was obtained by vacuum distillation (b.p. 80–83°, 0.05 mm): i.r. ν_{max}^{neat} 2986, 2912, 2861, 1602, 1496, 1446, 1376, 762, 709 cm^{-1}; n.m.r. δ (p.p.m.) 1.82 (s, 3H, methyl), 1.90 (s, 3H, methyl), 2.12 (s, 3H, methyl), 7.55–6.65 (complex, 7H, aromatic and thienyl).

Anal. Calcd. for $C_{15}H_{16}S$: C, 78.92; H, 7.06. Found: C, 78.93; H, 7.22.

Irradiation of 2-(2-Methylbenzoyl)thiophene (1) in O-Deuteromethanol

A Pyrex n.m.r. tube, containing 2-(2-methylbenzoyl)-thiophene (121 mg) in CH_3OD (3.25 ml) was degassed by three freeze–pump–thaw cycles, sealed, and irradiated for 30 h. Comparison of the integrated area and heights of the n.m.r. peaks due to the methyl group and aromatic protons before and after irradiation indicate little or no deuterium incorporation, (aromatic region/methyl peak, integrated area, calcd. (2.34), observed before irradiation (2.46), observed after irradiation (2.58). Evaporation of the solvent gave recovered starting material which had an essentially identical ratio of $M^+/(M + 1)^+$ peak in the mass spectrum with starting material; starting material, $M^+/(M + 1)^+$ (0.158); recovered starting material (0.161).

A control experiment, using 2-methylbenzophenone under these conditions led to rapid and essentially complete exchange of the methyl protons in a few hours.

Irradiation of 2-Benzoyl-3-methylthiophene (2) in O-Deuteromethanol

A Pyrex n.m.r. tube, containing 2-benzoyl-3-methyl-thiophene (0.1 g) and CH_3OD (1 ml) was degassed by three freeze–pump–thaw cycles, sealed, and irradiated for 45 h. Comparison of the integrated area and heights of the n.m.r. peaks due to the methyl group and aromatic protons before and after irradiation indicate little or no deuterium incorporation (aromatic region/methyl peak, integrated area; calcd. (2.34), observed before irradiation (2.81), observed after irradiation (2.62)). Evaporation of the solvent gave recovered starting material which had an essentially identical ratio of $M^+/(M + 1)^+$ peak in the mass spectrum with starting material; starting material, $M^+/(M + 1)^+$, (0.186); recovered starting material (0.188).

This work was supported by a grant from the National Research Council of Canada. We gratefully acknowledge the assistance of H. Schroeder in obtaining the 100 MHz n.m.r. spectra.

Hydrothermal Formation of Ferrite Spinels

ALAN ROSS GAINSFORD, MARGARET JOY SISLEY, AND THOMAS WILSON SWADDLE[1]

Department of Chemistry, The University of Calgary, Calgary, Alberta T2N 1N4

AND

PETER BAYLISS

Department of Geology, The University of Calgary, Calgary, Alberta T2N 1N4

Received August 19, 1974

ALAN ROSS GAINSFORD, MARGARET JOY SISLEY, THOMAS WILSON SWADDLE, and PETER BAYLISS. Can. J. Chem. **53**, 12 (1975).

The possibility of forming spinel-type ferrites MFe_2O_4 from $M(OH)_2$ or MO and α-FeO(OH) (goethite) or α-Fe_2O_3 (hematite) under hydrothermal conditions up to 350° has been investigated experimentally for M = Mg, Ca, Mn, Co, Ni, Cu, and Zn. Formation of MFe_2O_4 was observed for M = Mn (jacobsite), Co, Ni (trevorite), and Zn (franklinite), and was in general favored by high temperatures, high p*H*, and the presence of $NaNO_3$ or, especially, NaCl in solution. α-FeO(OH) is more reactive than α-Fe_2O_3, but generally converts to the latter at 220–260°, independently of p*H*, in neutral or alkaline media. Interpretation of the results is complicated by the ion-exchanging properties and varying degrees of crystallinity of $M(OH)_2$, and by the tendency of $M(OH)_2$ to decompose to MO or to be oxidized at the higher temperatures. Nevertheless, the order of reactivity M = Co ≥ Mn > Ni > Zn > (Mg, Ca, Cu) in MFe_2O_4 formation is generally valid. The formation of MFe_2O_4 is limited by kinetic rather than thermodynamic factors for the various M listed (except Cu).

ALAN ROSS GAINSFORD, MARGARET JOY SISLEY, THOMAS WILSON SWADDLE et PETER BAYLISS. Can. J. Chem. **53**, 12 (1975).

On étudie expérimentalement la possibilité de former des ferrites MFe_2O_4 du type spinelle à partir de $M(OH)_2$ ou de MO et de α-FeO(OH) (goethite) ou de α-Fe_2O_3 (hématite) par réaction hydrothermique allant jusqu'à 350°, pour M = Mg, Ca, Mn, Co, Ni, Cu et Zn. On observe la formation de MFe_2O_4 pour M = Mn (jacobsite), Co, Ni (trévorite) et Zn (franklinite); cette réaction est généralement favorisée par de hautes températures, un p*H* élevé et la présence de $NaNO_3$ ou, spécialement NaCl en solution. α-FeO(OH) est plus réactif que α-Fe_2O_3, mais en général, il se transforme en ce dernier à 220–260°, indépendamment du p*H*, en milieu neutre ou alcalin. L'interprétation des résultats se complique à cause des propriétés d'échange d'ions, des degrés variables de cristallinité de $M(OH)_2$, ainsi que de la tendance de $M(OH)_2$ à se décomposer en MO ou à s'oxyder à des températures plus élevées. Néanmoins, l'ordre de la réactivité de M = Co ≥ Mn > Ni > Zn > (Mg, Ca, Cu) pour la formation de MFe_2O_4 est généralement valable. La formation de MFe_2O_4 est limitée par des facteurs cinétiques plutôt que thermodynamiques pour tous les éléments M de la liste à l'exception du Cu. [Traduit par le journal]

Introduction

The heat transfer systems of water-cooled nuclear power reactors are usually operated using liquid H_2O or D_2O under pressure at about 250–300° (523–573 K), with a hydroxide ion concentration of about 3×10^{-4} mol kg^{-1} and an excess pressure of hydrogen so as to minimize corrosion of the structural materials. The chief corrosion product of mild steel under these conditions is magnetite ($Fe^{II}Fe^{III}_2O_4$), which may be regarded as an iron(II) ferrite having the inverse spinel structure. However, if in-core boiling is permitted, oxidizing conditions may develop locally, leading to the formation of hematite (α-Fe_2O_3) and possibly goethite (α-FeO(OH)) rather than lepidocrocite (γ-FeO(OH)) which is the chief constituent of rust formed at ambient temperatures (1).

Replacement of Fe^{2+} by Co^{2+} in the magnetite structure to give $Co_xFe_{3-x}O_4$ ($0 < x \leq 1$) presents a technological problem, since this appears to be the vehicle for the development of strong ^{60}Co radiation fields in certain locations in the coolant circuits outside the reactor core. Nickel(II) is also often present in the corrosion products as $Ni_xFe_{3-x}O_4$. A direct investigation of the mechanism of incorporation of cobalt(II) or nickel(II) into the magnetite lattice would

require strict maintenance and control of a hydrogen pressure, since, at the temperatures and pH values of interest, the $Fe(OH)_2$ produced in the formal reaction

[1] $M(OH)_2 + Fe_3O_4 = MFe_2O_4 + Fe(OH)_2$

would decompose to magnetite and hydrogen (2), the net reaction being

[2] $3M(OH)_2 + 2Fe_3O_4 = 3MFe_2O_4 + 2H_2O + H_2$

In our exploratory studies of hydrothermal spinel-type ferrite formation, we have considered instead the reactions of divalent metal oxides MO or hydroxides $M(OH)_2$ with iron(III) hydroxide, goethite, or hematite in nonreducing conditions, which may have direct relevance to anticipated corrosion-related problems in water-cooled reactors presently under construction which will utilize in-core boiling.

Thermodynamic calculations (3, 4) indicate that the reactions

[3] $MO + \alpha\text{-}Fe_2O_3 \rightarrow MFe_2O_4$

are favored, over the range 25–1000° at least, for M = Mg, Ni, Fe, and Co, the free energy change being increasingly negative in that order and not strongly temperature-dependent. Reference to thermodynamic data for $M(OH)_2$ and MO (5) shows that the corresponding reactions

[4] $M(OH)_2 + \alpha\text{-}Fe_2O_3 \rightarrow MFe_2O_4 + H_2O$

should also proceed spontaneously at 25° for M = Ni, Fe, and Co at least, and presumably this also applies at elevated temperatures. Langmuir (6) has established that goethite is thermodynamically unstable with respect to hematite and liquid water (at its saturation vapor pressure) above 81°, for coarse-grained crystals at least, so that reactions 5 and 6 are also thermodynamically possible under hydrothermal conditions, for M = Ni, Fe, and Co at least.

[5] $MO + 2\alpha\text{-}FeO(OH) \rightarrow MFe_2O_4 + H_2O$

[6] $M(OH)_2 + 2\alpha\text{-}FeO(OH) \rightarrow MFe_2O_4 + 2H_2O$

Ferrites MFe_2O_4 are known to form when iron(III) hydroxide is coprecipitated at 100° with various $M(OH)_2$ by addition of alkali to solutions containing stoichiometric amounts of M(II) and Fe(III) salts (7, 8). The product is too poorly crystalline to be detected by X-ray diffraction unless the suspended precipitate is maintained for many hours at 100° under neutral conditions or for shorter times at pH_{25} 12–14.[2] However, in the present context, we are concerned with the reactions of M(II) and Fe(III) species released into a high-temperature aqueous environment which is already alkaline, and the question arises as to whether iron(III) hydroxide plays a significant role in ferrite formation under hydrothermal conditions. Christensen and co-worker (9, 10) report that the products of decomposition of iron(III) hydroxide suspensions in aqueous alkali at 100–200° are pure goethite at pH_{25} 10.5–10.8, and various mixtures of goethite and hematite between pH_{25} 8.0 and 10.0. However, unpublished preliminary work by Gainsford in our laboratories, using titanium–palladium or stainless steel autoclaves, has shown that while goethite is indeed the sole product at pH_{25} 13–14 up to 100°, hematite is also formed at higher temperatures, comprising 95% of the product after 24 h at 200° (the effective reaction temperature was probably less than this, since the reaction was probably faster than thermal equilibration), and at pH_{25} 10.6 the percentage of hematite recovered rose from 5 at 100° to 95 at 200°. The exact form of the rate law for the conversion of iron(III) hydroxide to goethite at pH_{25} 13–14 at 60–75° depends on the nature of the reaction vessel and the temperature; however, with reference to the reagents and methods used in the present study, it can be said that the time for 50% conversion of iron(III) hydroxide is about 5 h in 1.0 M NaOH at 75°, is roughly proportional to $[OH^-]^2$, and decreases about threefold for a 10° rise in temperature. Thus, the survival time of iron(III) hydroxide is negligible in the conditions of spinel synthesis reported here, especially at $pH_{25} < 13$, and a series of trial experiments showed that direct reaction of iron(III) hydroxide with $M(OH)_2$ is impeded by its decomposition to goethite and particularly hematite at temperatures of the order of 200°.

Accordingly, the present report is concerned primarily with reactions 3–6. Laudise (11) reports some hydrothermal syntheses of $NiFe_2O_4$ and $ZnFe_2O_4$ via reaction 3 under supercritical conditions (470–480° at ~120 MNm^{-2} in 0.5 m NH_4Cl, and ~400° at ~200 MNm^{-2} in ~1.0 m NaOH respectively), but there is little information on the effect of varying the reaction conditions,

[2]In this article, pH values are expressed in terms of measurements at 25°, since the auto-ionization of water is strongly temperature-dependent. Concentrations are expressed on the molal scale (m), mol kg^{-1}.

and in any event we are concerned in the present context with subcritical aqueous systems. The interpretation of our results is complicated by the conversion of goethite to hematite, the decomposition of $M(OH)_2$ to MO or M(III) compounds, the ion-exchanging properties of $M(OH)_2$, uncertainties arising from the variable degrees of crystallinity of the reactants, pH changes in the course of reaction, and limitations imposed by the corrosiveness of the hydrothermal media and the lack of a corrosion-proof stirred autoclave. However, several useful generalizations can still be made regarding the effects of pH, temperature, and dissolved electrolytes on the progress of reactions 3–6 under hydrothermal conditions.

Experimental

Apparatus

Except where otherwise indicated, reactions were carried out in unlined 62 cm^3 titanium – 0.2% palladium alloy pressure vessels described previously (2). The interior surfaces of these vessels were preoxidized by autoclaving dilute H_2O_2 in them, and were in general resistant to attack by dilute alkaline solutions under the experimental conditions. However, 1.0 *m* NaOH at temperatures above 200° was found to attack freshly sand-blasted titanium alloy vessels appreciably, forming hydrogen which caused partial reduction of goethite (though not hematite) to magnetite. This was not a serious problem with vessels having well-oxidized interiors, but it does place a limit on the usefulness of this otherwise highly corrosion-resistant alloy, especially since hydrogen embrittles titanium. Autoclaves of type 316 stainless steel are fairly resistant to attack by hot aqueous alkali, but were not widely used because the constituent elements of the steel are among those of the reactants being studied. Silica liners are severely attacked by alkali at high temperatures, and also react hydrothermally with metal hydroxides or oxides to form silicates (12), *e.g.*, α-FeO(OH) in a silica liner with 0.01 *m* NaOH at 230–270° yielded the pyroxene *acmite*, $NaFeSi_2O_6$. Machined Teflon liners are expensive, difficult to clean, and soften above 300°.

Materials

Fisher Certified reagents were used throughout, and distilled water was passed through Barnstead de-ionizer and organic removal cartridges before use. Goethite, free of hematite, was prepared by treating a stirred solution of $Fe(NO_3)_3 \cdot 9H_2O$ (60.6 g) in 1500 cm^3 water with 48 g solid NaOH pelletwise, maintaining the stirred mixture at 75° for 22 h. The product was filtered, then washed with water, 3 *M* HNO_3 (to remove any residual iron(III hydroxide), more water, and finally acetone, and was dried at 70° (13.2 g, 99%).

Procedures

Reaction mixtures were made up as follows.

(a) Hydrothermal Conversion of Goethite to Hematite

Goethite samples (0.444 g, 5.0 mmol) were heated for selected periods in the autoclaves with 40 g water or aqueous NaOH, using a Blue M Conwate CW-160HF-1 forced convection oven ($\pm$ <5°). The goethite–hematite ratios of the dried solid products were determined by X-ray diffractometry from the relative intensities of the goethite *110* (0.418 nm) and hematite *211* (0.366 nm) reflections, with reference to a calibration curve prepared from standard samples.

(b) Reactions of $M(OH)_2$ with Goethite or Hematite in Media Containing Sodium Chloride or Nitrate

Solutions (2 *m*) of MCl_2 or $M(NO_3)_2$ (10.0 mmol) and of NaOH (20.0 mmol) were mixed and made to 40 cm^3 with water or aqueous NaOH to obtain the desired initial pH_{25}, and goethite or hematite (20.0 mmol) was mixed in. The mixtures were sealed in the autoclaves under nitrogen at 0.1 MNm^{-2} pressure and maintained at the desired temperature for 24 h. The pH_{25} of the solution phase was measured before and after each experiment. The solid products were washed with water and acetone, air dried, and identified by X-ray diffractometry with the aid of the JCPDS data files.

(c) Reactions of $M(OH)_2$ with Goethite or Hematite in Media Containing no Solutes other than NaOH

$M(OH)_2$ was made from $M(NO_3)_2$ solution as in (*b*), but was filtered and washed several times with dilute NaOH and then with water before transfer to the autoclave as a slurry in water or NaOH solution of the desired pH. The procedure was then as in (*b*).

Results

The following observations refer to a standard reaction time of 24 h, unless otherwise indicated.

Conversion of Goethite to Hematite

The beginnings of this reaction in a 24 h period were first observed at essentially the same temperature, 220 $\pm$ 10°, whether the initial pH_{25} was 7, 9, 12, or 14, and in all cases the reaction was complete within 24 h at 260°. In a few instances, *e.g.*, one involving pH_{25} 12 at 270°, a small amount of β-$NaFeO_2$ was recovered; the conditions favoring the formation of this compound were not obvious, but seemed to reflect the condition of the vessel wall, *i.e.*, nucleation of β-$NaFeO_2$ crystallization was probably the key factor. In no case was any evidence obtained for the rehydration of hematite to goethite.

The rate of conversion of goethite to hematite was slow initially, but later proceeded rapidly to near-completion. Thus, when samples of goethite were heated at 270° in 1.0 *m* NaOH for various times, the fraction of goethite recovered was still 100% after 70 min and 98% after 80 min, but only 12% after 90 min and progressively less thereafter (the half-time for thermal equilibration in the autoclaves was 7 min).

Conversions of $M(OH)_2$ during Spinel Synthesis

The crystallinity of $M(OH)_2$ improved during hydrothermal treatment. However, species other than $M(OH)_2$ and MFe_2O_4 were often detected by X-ray diffractometry after attempted spinel syntheses, and these conversions are outlined in Tables 1 and 2.

Cobalt(II) hydroxide was generally recovered as the pink β-form, which has the brucite structure, but at 250° and above it tends to

dehydrate to CoO. At pH_{25} 7, small amounts of Co^{2+} (more than could be accounted for by the solubility of $Co(OH)_2$ itself) were observed in the solution phase after hydrothermal treatment, which indicates that the freshly precipitated "$Co(OH)_2$" contains some small fraction of Cl^- or NO_3^- in place of hydroxide, so $CoCl_2$ or $Co(NO_3)_2$ is released into solution as hydrothermal recrystallization of the $Co(OH)_2$ proceeds. The tendency of Co(II) to form $Co_2(OH)_3Cl$ (13) in chloride media at pH 7–10.5 is a manifestation of this ion-exchanging property of $Co(OH)_2$. Spontaneous hydrothermal oxidation of Co(II) to Co_3O_4 at near-neutral pH values has been reported previously (12).

The conversions of $Ni(OH)_2$ were closely similar to those of $Co(OH)_2$, except that oxidation to Ni(III) did not occur. The transformation of $Ni(OH)_2$ to NiO (bunsenite) occurred generally at temperatures above 250°, but also at 200° at pH_{25} 14 in several cases. The latter observation shows that Aia's purported phase relationship diagram (14), according to which $Ni(OH)_2$ decomposes to NiO in water at 285 ± 5°, may have kinetic, but no thermodynamic, significance.

The oxidation of $Mn(OH)_2$ presented problems of product identification, since the X-ray diffraction patterns of γ-Mn_2O_3 and γ-Mn_3O_4 (hausmannite) are almost identical (15), while the existence of variously hydrated forms and poly-

morphs of MnO(OH), Mn_3O_4, or Mn_2O_3 (16) makes positive identification difficult, especially in mixtures. However, the tentative identification of the Mn(III)-containing products as γ-MnO(OH) (manganite) at the lower temperatures, γ-Mn_2O_3 under most intermediate conditions, and α-Mn_2O_3 (bixbyite) at 350° in one instance follows a logical pattern. The α form of Mn_2O_3 is the more thermodynamically stable, and γ-Mn_2O_3 reverts to it *in vacuo* at 500° in 2 days, or at 25° in about 1 year (15).

Zinc hydroxide invariably decomposed to ZnO (zincite) under hydrothermal conditions, whereas $Mg(OH)_2$ (brucite) and $Ca(OH)_2$ (portlandite) were unchanged. Copper hydroxide was recovered as CuO (tenorite) under all conditions except in chloride media at pH_{25} 7–10.5 at 100–200°, in which circumstances paratacamite ($Cu_2(OH)_3Cl$) was formed instead.

The suppression of the oxidation of $Mn(OH)_2$ and $Co(OH)_2$ at pH_{25} 14 was probably a direct p*H* effect, but there is the possibility that the (II) oxidation state was maintained by the presence of some small amount of hydrogen produced by corrosion of the metal of the autoclave by aqueous alkali or steam (the latter explanation may also explain the reduction of aqueous $CuCl_2$ to CuCl reported previously (12)). However, corrosion of the vessel walls was not extensive, nor was goethite reduced to magnetite in these particular cases, so that the first explanation is to be preferred.

The pH_{25} of the hydrothermal media did not change significantly over the 24 h reaction period when the initial pH_{25} was 7.0 or 14.0. However, a fall of about 1.0 p*H* unit and sometimes more was generally observed for initial pH_{25} 10.5 after 24 *h* of hydrothermal treatment. A similar phenomenon was reported by Christensen and Fregerslev (10) for the hydrothermal decomposition of iron(III) hydroxide. Experiments using Teflon liners showed that this loss of OH^- was not due to corrosion of the titanium alloy of the autoclave walls, but rather to interaction between the fresh $M(OH)_2$ precipitate (and, to a lesser extent, the hematite or goethite) and OH^- in solution. This effect may be attributed to the ion-exchanging properties of the initial $M(OH)_2$ precipitates referred to above; as $M(OH)_2$ becomes more crystalline under hydrothermal treatment, the replacement of residual Cl^- or NO_3^- in the precipitate by OH^- from solution will cause a fall in the pH_{25} toward 7. As little as 0.1% residual Cl^- or NO_3^- in $M(OH)_2$ would account for the observed decreases in p*H*. Nevertheless, the marked differences in the outcome of many experiments run at initial pH_{25} 10.5 relative to those at 7.0 affirm that it is the initial, rather than the final, pH_{25} value that is significant from the standpoint of spinel formation.

Formation of MFe_2O_4

The salient features of these reactions are summarized in Tables 1 and 2. The percentage yields of MFe_2O_4 are rough estimates based upon the intensities of X-ray reflections characterizing MFe_2O_4 and the residual reactants or their derivatives.

Discussion

Although the interpretation of the data of Tables 1 and 2 is complicated by the factors listed in the Introduction, the following generalizations can be made.

(*a*) In the absence of solutes other than NaOH, hydrothermal spinel formation according to reactions 3–6 is negligible in 24 h at pH_{25} 7 over the range 100–350°, and becomes significant for M = Co, Ni, and Zn only at 350° at pH_{25} 10.5. However, at pH_{25} 14, spinel formation via reaction 4 proceeds at a significant rate at 200° or less for M = Co and Mn, though $NiFe_2O_4$ (trevorite) was detected only at 300° and above, and Cu, Mg, and Ca ferrites were not detected under any hydrothermal conditions up to 350°. Since highly alkaline conditions favor MFe_2O_4 formation, it presumably occurs through the solution phase by dissolution of $M(OH)_2$ or MO and goethite or hematite as $M(OH)_3^-$, $Fe(OH)_4^-$, or similar species. The detection of some solid β-$NaFeO_2$ in several instances when the goethite–hematite transformation was being examined at pH_{25} 12 strongly suggests the presence of $Fe(OH)_4^-$ ($\equiv FeO_2^-$) in solution in small concentrations in alkaline media, as proposed by Lengweiler *et al.* (17). The kinetic reactivity sequence M = Co ≥ Mn > Ni ≥ Zn > (Mg, Ca, Cu) parallels the thermodynamic reactivity sequence M = Co > Ni > Mg > Cu for reaction 3 (3, 4). Indeed, $CuFe_2O_4$ is not expected to form by reaction 3 under hydrothermal conditions for thermodynamic reasons (3), and this presumably reflects the Jahn–Teller distortion of the spinel structure originating in the $3d^9$ electronic configuration of Cu^{2+} (18).

(*b*) The presence of 0.5 *m* chloride or nitrate ion facilitates MFe_2O_4 formation, although high p*H* is still necessary for optimum effect. This may be attributed to solubilization of M(II) or Fe(III) by anion–cation complexing, which becomes increasingly effective in hydrothermal systems as the temperature increases (2, 12, 19). Chloride is more effective than nitrate in catalyzing reactions 3–6, as expected if anion–cation complexing is involved (20). The greater catalytic power of Cl^- was established early in this investigation, so that in many later experiments the effect of NO_3^- was not investigated at temperatures and p*H* values at which chloride-containing systems produced no MFe_2O_4. Nitrate has a disadvantage in that it facilitates the oxidation of Mn(II) and Co(II), whereas chloride, though nonoxidizing, tends to form compounds of the type $M_2(OH)_3Cl$ by reaction with $M(OH)_2$.

(*c*) Reactions 3–6 in hydrothermal conditions are favored by increasing the temperature, as expected for thermodynamically possible processes which are inhibited kinetically. In principle, the relative yields of the various MFe_2O_4 listed in Tables 1 and 2 should provide an index of the relative kinetic reactivities of M in $M(OH)_2$ or MO, since most of these hydroxides and oxides have exactly analogous crystal structures (brucite structure in $M(OH)_2$ where M is Mn, Co, Ni, Mg, or Ca, and halite structure for the corresponding MO (18)), as do the MFe_2O_4 products (spinel structure). However, the picture is confused by the depletion of $M(OH)_2$ reservoir by oxidation or conversion to MO in some cases, by the formation of $M_2(OH)_3Cl$ in chloride media in others, and by the increase in crystallinity of the sundry $M(OH)_2$ to various degrees as the severity of the hydrothermal conditions is increased. A detailed kinetic study of reactions 3–6 would have to take these factors into account, as well as to examine the effect of stirring and to maintain constant p*H*. Nevertheless, the data of Tables 1 and 2 afford a useful qualitative insight into the kinetics and mechanism of ferrite formation.

(*d*) Goethite is markedly more reactive than hematite in the hydrothermal reactions 3–6, as anticipated on thermodynamic grounds (6). The operative factor is probably the solubility or, more specifically, the *rate* of dissolution of goethite and hematite in the hydrothermal media. The conversion of goethite to hematite becomes kinetically significant above about 220° in all cases (and is evidently somewhat catalyzed by $Mn(OH)_2$ and $Co(OH)_2$ at pH_{25} 12.5 at least). In no case was the rehydration of hematite to goethite observed; as Langmuir (6) pointed out, this is thermodynamically possible below 80°, or above this temperature for hematite of very small grain size, but it is unlikely to be observed for kinetic reasons (however, in soils, hematite may be dissolved by complexing and/or reduction by organic anions followed by reprecipitation as goethite (21, 22)). The temperature range found in the present studies for the goethite–hematite conversion agrees with that reported by several other investigators (23–26) for the reaction both in water and in air (which supports our assertion that the reaction does not involve the solution phase), but lower decomposition temperatures have been recorded (1, 27–35). These lower decomposition temperatures could be associated with small particle size, the importance of which was stressed by Langmuir (6), or with the presence of impurities, since we have found that $Co(OH)_2$ and $Mn(OH)_2$ accelerate the reaction significantly. Conversion of goethite to hematite by Tunnell and Posnjak (30) at 100° in 0.1 *M* HCl over several weeks undoubtedly occurred via iron(III) aquo and chloro complexes in solution. Goethite decomposition temperatures of as high as 290–375° have been recorded in differential thermal analysis (35), but in this case the heating rate is an important variable.

(*e*) The position of Ni in the general reactivity order in reactions 3–6 ($M = Co \geq Mn > Ni > Mg$) contrasts with the sequence established (2) for the analogous formation of MCr_2O_4 ($M = Mn > Co > Mg \gg Ni$). An important difference between the chromites and the ferrites is that the former are normal spinels (Cr^{3+} in octahedral sites only, M^{2+} in tetrahedral sites in the face-centered-cubic oxide array) whereas the ferrites considered here are generally inverse spinels (Fe^{3+} in both octahedral and tetrahedral sites, M^{2+} in octahedral sites only) (36). M^{2+} ions in MO with the NaCl structure or in $M(OH)_2$ with the brucite structure are already octahedrally coordinated by oxygen ions, and consequently crystal field effects are not expected to influence the energetics of reactions 3–6 in these cases. However, crystal field stabilization energy losses will be large (8.45 *Dq*, ≡ 100 kJ mol^{-1}) for the $3d^8$ ion Ni^{2+} in the formation of $NiCr_2O_4$ from NiO or $Ni(OH)_2$, relative to Co^{2+} (2.67 Dq), Mn^{2+} (zero), or Mg^{2+} (zero), and these are

reflected in the changes in the reactivity order on going from MFe_2O_4 formation to MCr_2O_4 syntheses.

Ring C Functionalized Diterpenoids. Part IV.[1] Minor Products from the Cleavage of the Cyclopropane Ring in Methyl *ent*-Trachyloban-19-oate with Thallic Acetate

HELEN MARGARET CAMPBELL, PATRICK ALISTAIR GUNN, ALAN JAMES MCALEES, AND ROBERT MCCRINDLE[2]

Chemistry Department, University of Guelph, Guelph, Ontario N1G 2W1

Received June 25, 1974

HELEN MARGARET CAMPBELL, PATRICK ALISTAIR GUNN, ALAN JAMES MCALEES, and ROBERT MCCRINDLE. Can. J. Chem. **53**, 20 (1975).

Structures are assigned to seven minor products (**6***b*, **9**, **11***b*, **12***b*, **13***b*, **16**, and **25***b*) obtained from treatment of methyl *ent*-trachyloban-19-oate (**1**) with thallic oxide in acetic acid. The mechanism of the oxidative cleavage is discussed. Formation of the major products, described earlier, and all but one (**25***b*) of the minor products may be rationalized in terms of initial scission of the C_{13}—C_{16} bond.

HELEN MARGARET CAMPBELL, PATRICK ALISTAIR GUNN, ALAN JAMES MCALEES et ROBERT MCCRINDLE. Can. J. Chem. **53**, 20 (1975).

Des structures sont assignées à sept produits mineurs (**6***b*, **9**, **11***b*, **12***b*, **13***b*, **16** et **25***b*) obtenus par la réaction du trachyloban-*ent*-oate-19 de méthyle (**1**) avec l'oxyde thallique dans l'acide acétique. Le mécanisme du clivage oxidant est discuté. La formation des produits majeurs, décrite précédemment, et des produits mineur à l'exception de (**25***b*) peut être rationnalisée en termes d'une scission initiale de la liaison C_{13}—C_{16}. [Traduit par le journal]

In an earlier paper (2) we have assigned structures to the major components (**2**–**5**) of the very complex mixture obtained by oxidative cleavage of the cyclopropane ring in methyl *ent*-trachyloban-19-oate (**1**). The formation of these compounds involves scission of the C_{13}—C_{16} bond in **1**. The present paper is devoted to the minor products of this reaction and a more detailed consideration of the mechanism of the reaction.

Results

Seven new compounds have been isolated, six from the monoacetate fraction (2) and one from the diacetate fraction. Structures have been assigned to the first six on evidence which is outlined below. The structure suggested for the diacetate is tentative and based mainly on mechanistic considerations.

The monoacetate fraction was separated (2) into two parts, the more polar of which consisted largely of the major components **2** and **5**,[3] while the less polar contained a very complex mixture of products. The least polar of these, **6***b*, was isolated only with considerable difficulty. Since the material thus obtained contained residual impurities it was converted into the corresponding alcohol (**6***a*), m.p. 148–150°, which gave n.m.r. resonances attributable to a carbinyl proton (τ 6.43, d), an olefinic proton (τ 4.60, br s), and a methyl group on a double bond (τ 8.31, d). The principal evidence for the structures of **6***a* and *b* is the observation that the former is formed on aqueous treatment of the *p*-toluenesulfonate **7**. The multiplicities of the resonances due to the carbinyl and olefinic protons in **6***a* allowed us to discount the alternative structure **8**. The assignment of the α-orientation to the hydroxy group in **6***a*, which is predicted on both mechanistic (see below) and steric grounds, is supported by the observation that the carbinyl proton shows no appreciable 'W' coupling to αH-11 (3).

The next compound, **9**, m.p. 101–104°, proved to be a ketone, the n.m.r. spectrum of which shows sharp singlets at τ 9.34 (3 H-20), 8.85 (3 H-18), 7.97 (3 H-17), and 7.67 (2 H-15), and a broad singlet at 4.92 (H-12 + H-13). The ready reduction of **9** with sodium borohydride to **10** (probably a mixture of diastereoisomers), m.p. 79°, showed that the signal at

τ 7.97 in **9**, which is replaced by a doublet at τ 8.87, $J = 6$ Hz, in **10**, is due to a methyl ketone rather than an acetate. In addition, integration of the allylic proton region of the n.m.r. spectrum of **10** shows the presence of four allylic protons, thus establishing the position of the double bond in **10** and hence also in **9**.

As further components of the less polar monoacetate fraction could not be separated directly, the remaining mixture was subjected to mild base hydrolysis, which gave the corresponding alcohols without affecting the axial C-19 ester function. Preparative t.l.c. of the alcohols gave three significant fractions. In contrast to our findings for all the other products obtained, the n.m.r. spectrum of the least polar alcohol, **11***a*, m.p. 142–145°, isolated from this mixture showed no resonances attributable to olefinic or carbinyl protons. It did however reveal the presence of three methyl groups, two attached to quaternary carbon atoms and one on a carbon atom which carried a hydroxyl group. This led us to consider that **11***a* was simply the product of acid-promoted opening of the cyclopropane ring in **1**, and indeed, comparison of the physical constants of **11***a* with those published (4) for methyl 16β-hydroxy-*ent*-atisan-19-oate ratified the identity of these two. As anticipated, when **1** was treated with acetic acid alone at 75° for 5 days, it suffered partial conversion into the acetate **11***b*, m.p. 143–144°.

The second alcohol isolated, **12***a*, is also tertiary and has a particularly characteristic n.m.r. spectrum. This reveals the presence of a *cis*-disubstituted double bond, one olefinic proton of which is further coupled to an adjacent methine proton. In addition, the orientation of this double bond is such as to cause a marked shielding of the C-20 methyl group which resonates at τ 9.62. The absence of absorption attributable to OH—π bonding in the i.r.

spectrum of **12***a* allows assignment of the configuration at C-16 as shown.

The next component is also an olefinic tertiary alcohol, **13***a*, m.p. 120–121°, as evidenced by peaks in the n.m.r. spectrum at τ 4.82 (m, *1* H-7), 8.70 (s, 3 H-17), 8.83 (s, 3 H-18), and 9.36 (s, 3 H-20). The assignment of structure **13***a* to this compound rests largely on the observation of a particularly intense peak in its mass spectrum of *m/e* 146, attributable to a fragment derived by the retro-Diels–Alder fission and dehydration depicted in Fig. 1. The relatively high field position of the C-10 methyl resonance is similar to that observed (5) for rimuene, **14** (τ 9.38) but contrasts with that observed (6, 7) for **15** (τ 9.23, 9.25) although the latter, at first sight, might be expected to provide a closer analogy. However, examination of molecular models suggests that the 16β-substituent in **13***a* interacts sufficiently with H-9 to cause a slight flattening of rings B and C. As a result of this, the C-10 methyl group rotates towards the shielding cone of the C-7 double bond. Flattening of rings A and B in rimuene, **14**, which reduces various nonbonded interactions, could account for the upfield shift of the C-9 methyl resonance. In contrast, flattening of rings B and C in **15** does not lead to a comparable reduction in nonbonded strain.

A further product, **16**, m.p. 128–131°, has been isolated from the more polar monoacetate fraction (2) by preparative t.l.c. over silver nitrate – silica gel. The n.m.r. of **16** shows only two quaternary methyl groups at τ 8.82 (3 H-18) and 9.23 (3 H-20). A broad singlet at τ 5.20, which integrates for three protons, is ascribed to 2 H-17 + H-13. In addition, the hydrogenation of **16** gave a single product **17***b*, which was identical (t.l.c., g.l.c., and n.m.r.) with the single product obtained by hydrogenation of the isomer **2**. Since **17***b* was obtained as an oil which could not be induced to crystallize, final confirmation of its structure was achieved by converting it into the corresponding alcohol, **17***a*, m.p. 134–135°, which had been obtained previously (2).

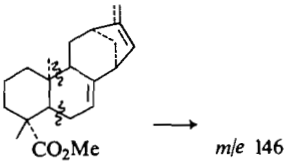

Fig. 1. Mass spectral fragmentation pattern.

Discussion

All but one (discussed below) of the products isolated from the cleavage of **1** with thallic acetate can be most readily envisaged as deriving from initial attack[4] at the C_{13}—C_{16} bond (**18** arrows) with development of considerable carbonium ion character at C-16 (**19**). Preferential cleavage of the C_{13}—C_{16} bond is anticipated on the basis of earlier reports on the cleavage of trachylobanes with acids (8–10).[5] Indeed, it is consistent with the results of cleavage of simple bicyclo[*n*.1.0.] alkanes by thallic acetate (12), where it is found that the relative ease of internal (O bridge) bond cleavage increases with decreasing *n*. The structures of the products isolated suggest that at least three competing processes determine the eventual fate of carbonium ion **19** (Scheme 1).

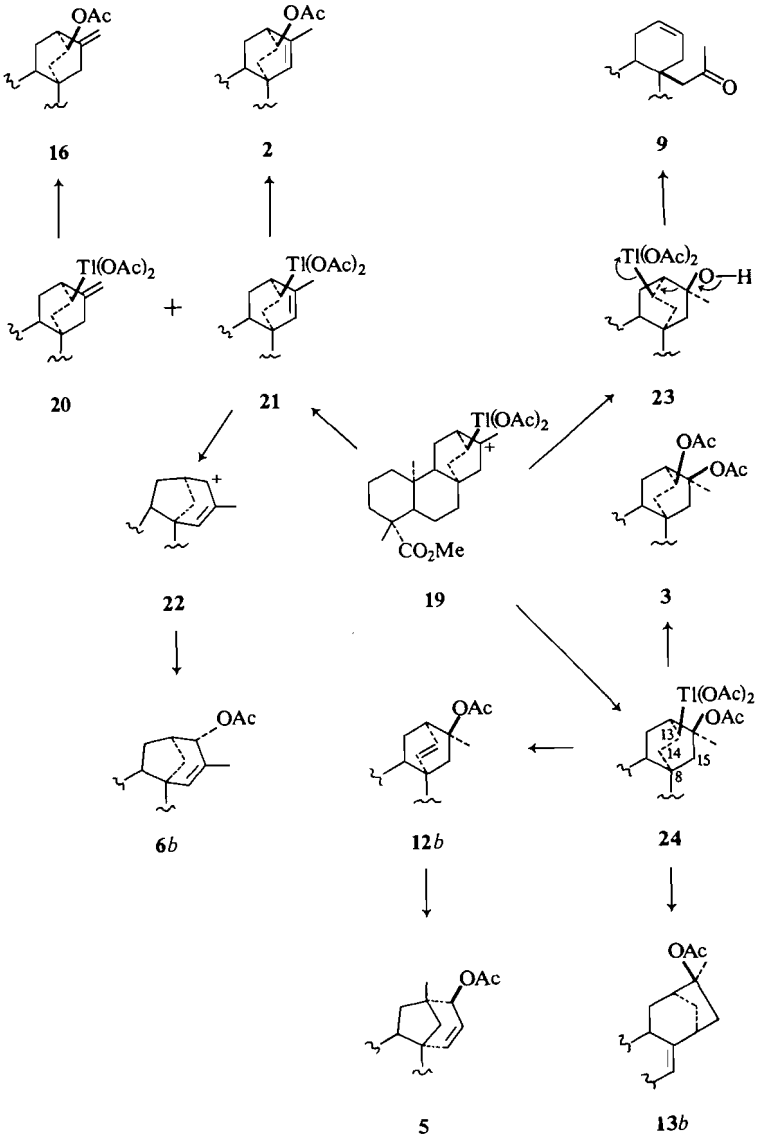
First, elimination of a proton can give **20** and **21**, from which the olefinic monoacetates **2** and **16** may derive. The stereochemistry of these products requires that the replacement of the —$Tl(OAc)_2$ group with —OAc proceed with retention (2). Migration of the C_{11}—C_{12} bond to C-13 upon heterolysis of the —$Tl(OAc)_2$ group in **21** would produce the allylic cation **22** and thence **6***b*. Diacetate **4** probably results from allylic oxidation of **2** and/or **16**.

Second, attack on the β-face (see below) of **19** by water generated in the formation of $Tl(OAc)_3$ from Tl_2O_3 may produce the tertiary alcohol **23**. This would be expected to fragment as shown (**23** arrows), furnishing the ketone **9**.

Third, attack by solvent (acetic acid) on **19** would give the tertiary acetate **24**, the stereochemistry of which is that expected (12) on the basis of *trans* opening of the cyclopropane ring. It has been suggested (12) that this cleavage involves 'a closely timed sequence in which the addition of metal salt and solvent occur in such a fashion as to preclude loss of stereochemistry.' In the present instance, even if addition of solvent were not concerted with

[4]Since our results do not allow us to draw any conclusions as to the nature of the electrophilic species involved, we have used $Tl(OAc)_3$ in **18** for convenience (*cf.* ref. 13).

[5]The relatively large amounts of beyeranes found in one of these studies (10) are probably obtained by rearrangement of an initially formed atisane carbonium ion (1, 11).



SCHEME 1

ring opening, attack at C-16 would still be expected to take place preferentially on the β-face since α-attack would be severely hindered by the bulky —$Tl(OAc)_2$ substituent at C-13. Several pathways can be invoked to account for the subsequent fate of **24**. Thus, internal nucleophilic substitution gives the diacetate **3**. Alternatively, heterolysis of the —$Tl(OAc)_2$ group with (*a*) loss of a proton from the neighboring carbon (C-14) or (*b*) hydride shift from C-14 to C-13, migration of the C_8—C_{15} bond to C-14, and elimination of a proton from C-7, leads to the olefinic tertiary acetates **12***b* and **13***b*, respectively. The isolation of alcohol **12***a* lends credence to our previous suggestion (2) that **5** might be formed by rearrangement of acetate **12***b*. Ionization of the tertiary acetate function in **12***b* may be assisted by homoallylic participation (14).

Finally, one minor product, the diacetate of intermediate polarity (2) appears to have structure **25***b*. The n.m.r. spectrum shows singlets at τ 9.18 (3 H-20), 8.86 (3 H-18), 8.52 (3 H-17), and 8.12 (6H, 2 —OCOCH_3) and a multiplet

25 **26**

a $R^1 = R^2 = OH$
b $R^1 = R^2 = OAc$
c $R^1 = OAc$; $R^2 = Tl(OAc)_2$

at τ 5.10 (dd, J_{obs} = 3 and 6 Hz). The multiplicity of the last rules out the possibility that the diacetate is a 12α- or β-substituted kaurane or a 13α- or β-substituted atisane since its coupling pattern is very different from theirs (15). This, and the indication from its n.m.r. spectrum that the moiety $H_3C—C—OAc$ (τ 8.52) is present, leads to structures such as **25***b*. Support for structure **25***b* comes from the i.r. absorption of the derived diol, **25***a*, m.p. 195–197°, and a consideration of reaction pathways emanating from **1** which are satisfying on mechanistic grounds. Thus, the diol shows strong hydrogen bonding, $\Delta\nu_{OH} = 95\ cm^{-1}$, a value considerably larger than those recorded for simple cyclohexane vicinal diols but similar to those for certain related bridged systems (16). In addition, the following mechanistic pathway would account for the formation of **25***b*. Attack of the metal salt on the $C_{12}—C_{13}$ bond of **1** and attachment of the thallium substituent to C-13 would give the ion **26**. Wagner–Meerwein rearrangement with transfer of carbonium ion character to C-16 (see **26** arrows) and then capture of solvent at C-16 would give **25***c*. Steric and mechanistic arguments predict capture on the α-face. The diacetate **25***b* would then be generated from **25***c* with retention of stereochemistry (2) at C-13.

Experimental

Melting points were determined on a Kofler hot-stage apparatus and are uncorrected. For normal analytical and preparative t.l.c., chromatoplates were spread with Kieselgel G (Merck), while silver nitrate – silica gel chromatoplates in addition contained 12% of the former. Gas–liquid chromatography was carried out at 200° with a Varian Aerograph 1200 gas chromatograph using a stainless steel column (1/8 in. × 10 ft packed with 5% SE-30) and nitrogen as carrier gas with a flow rate of 25 ml/min. Light petroleum was of b.p. 60–80°. Proton magnetic resonance spectra were run on a Varian Associates A-60A or HA100 spectrometer in carbon tetrachloride unless otherwise stated using approximately 0.3 *M* solutions and tetramethylsilane as internal standard. Infrared spectra were recorded in carbon tetrachloride on a Beckman I.R.12 spectrophotometer. Microanalyses were by Mr. S. McKinnon, Guelph. Routine mass spectra were run on a Varian Associates CH7 instrument and high resolution mass spectra on an AEI MS 902 instrument equipped with a PDP8 computer at the N.T.H., Trondheim, Norway.

Separation of Further Products from the Oxidative Cleavage

The products (3.60 g) from the oxidative cleavage of **1** (3.40 g) were chromatographed over alumina (2). Seven fractions (1.227 g total) were collected using light petroleum – ethyl acetate (24:1) as eluant. The last three of these were combined (556 mg) and a minor component (**16**, 42 mg) separated by preparative t.l.c. over silver nitrate – silica gel (ethyl acetate – light petroleum) before isolation (2) of the alcohols corresponding to **2** and **5** from the rest of this material. This new acetate (**16**) crystallized from light petroleum and had m.p. 128–131°; τ 5.20 (br s, 3H, 2 H-17 + H-13), 7.98 (s, 3H, —OCOCH_3), 8.82 (s, 3 H-18), and 9.23 (s, 3 H-20).

Anal. Calcd. for $C_{23}H_{34}O_4$: C, 73.76; H, 9.15. Found: C, 73.55; H, 9.04.

The other four fractions (of the seven) from the alumina column were also combined (671 mg) and subjected to preparative t.l.c. (ethyl acetate – light petroleum, 3:97, run four times). The fractions obtained by this procedure were then subjected to further preparative t.l.c. this time on silica gel – silver nitrate (ethyl acetate, 3:97, run four times). This yielded a pure sample of **9** (82 mg) and a second component (**6***b*) in almost pure form. The remaining fractions were recombined and hydrolyzed with excess sodium hydroxide (0.5 g) in refluxing aqueous methanol (20 ml, 1:1) for 1 h. The hydrolysis mixture was separated by preparative t.l.c. first on silica gel (ethyl acetate – light petroleum, 1:10, run thrice) and then on silver nitrate – silica gel (ethyl acetate – light petroleum, 1:10, run thrice). This sequence afforded **11***a* (20 mg), **12***a* (74 mg), and **13***a* (41 mg).

Ketone **9** crystallized from light petroleum and had m.p. 101–104°; τ 4.92 (br s, 2H, H-12 + H-13), 7.67 (s, 2 H-15), 7.97 (s, 3 H-17), 8.85 (s, 3 H-18), and 9.34 (s, 3 H-20); *m/e* 332 (M).

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70. Found: C, 75.88; H, 9.76.

Acetate **6***b*, which had τ 4.58 (br s, 1 H-15), 5.31 (d, 1 H-12, J = 3 Hz), 8.03 (s, 3H, —OCOCH_3), 8.43 (br s, 3 H-17), 8.83 (s, 3 H-18), and 9.36 (s, 3 H-20), failed to crystallize and was hydrolyzed with excess sodium hydroxide (0.1 g) in refluxing aqueous methanol (10 ml, 1:1) for 1 h. The alcohol (**6***a*, 44 mg) was recovered from the reaction mixture by preparative t.l.c. (ethyl acetate – light petroleum, 1:10, run thrice). After crystallization from light petroleum it had m.p. 148–150°; τ 4.60 (br s, 1 H-15), 6.43 (d, 1 H-12, J = 3 Hz), 8.31 (br s, 3 H-17), 8.82 (s, 3 H-18), and 9.31 (s, 3 H-20).

Mol. Wt. Calcd. for $C_{21}H_{32}O_3$: 332.2352. Found (high resolution mass spectrometry): 332.2356.

The known (4) alcohol **11***a* had m.p. 142–145° (lit. (4) m.p. 148°) on crystallization from light petroleum;

τ 8.71 (s, 3 H-17), 8.83 (s, 3 H-18), and 9.22 (s, 3 H-20). Alcohol **12***a* was obtained as an oil; τ 3.82 (m, 1 H-14), 4.00 (m, 1 H-13), 8.83 (s, 3 H-18), 8.91 (s, 3 H-17), and 9.62 (s, 3 H-20); in the presence of 0.4 *M* ratio of Eu(DPM)$_3$ to **12***a* τ 2.90 (m, 1 H-14), 3.22 (m, 1 H-13), 6.25 (s, 3 H-17), 8.50 (s, 3 H-18), 8.85 (s, 3 H-20); ν_{max} 3620 and 1740 cm^{-1}.

Mol. Wt. Calcd. for $C_{21}H_{32}O_3$: 332.2352. Found (high resolution mass spectrometry): 332.2353.

Alcohol **13***a* after crystallization from light petroleum had m.p. 120–121°; τ 4.82 (m, 1 H-7), 8.70 (s, 3 H-17), 8.83 (s, 3 H-18), and 9.36 (s, 3 H-20); *m/e* 146 (M − 18 − 168).

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70. Found: C, 75.88; H, 9.76.

Fractions from the original alumina column eluted with light petroleum – ethyl acetate (23:2) were combined (966 mg total) and subjected to preparative t.l.c. (ethyl acetate – light petroleum, 1:9, run thrice). This yielded (2) **3** and **4** and a compound (**25***b*, 109 mg) of intermediate polarity. The last even after repeated preparative t.l.c. contained traces of **4**. This material (84 mg) which had τ 5.10 (dd, 1 H-13, J_{obs} = 3 and 6 Hz) 8.52 (s, 3 H-17), 8.86 (s, 3 H-18), and 9.18 (s, 3 H-20) was hydrolyzed with sodium hydroxide (0.4 g) in refluxing aqueous methanol (20 ml, 1:1) for 3 h. The product mixture (72 mg) was subjected to preparative t.l.c. (ethyl acetate – light petroleum, 1:4) and afforded substrate (15 mg) and diol **25***a* (26 mg). The latter on crystallization from benzene – light petroleum had m.p. 195–197°; τ ($CDCl_3$) 6.18 (dd, 1 H-13, J_{obs} = 3.5 and 5 Hz), 8.75 (s, 3 H-17), 8.83 (s, 3 H-18), and 9.22 (s, 3 H-20); ν_{OH} (2 mg/ml) 3610, 3515, 3348 cm^{-1}; ν_{OH} (0.5 mg/ml) 3610 and 3515 cm^{-1}.

Anal. Calcd. for $C_{21}H_{34}O_4$: C, 71.96; H, 9.78. Found: C, 71.89; H, 9.69.

Solvolysis of the Tosylate 7

The alcohol (35 mg) derived (2) from **2** was treated with excess *p*-toluenesulfonyl chloride (30 mg) in pyridine (2 ml) overnight. The reaction mixture (one spot on t.l.c., less polar than substrate) was diluted with ether and washed twice with chilled hydrochloric acid (1 *M*) and then water. The product (31 mg, 89%) was purified by preparative t.l.c. (ethyl acetate – light petroleum, 1:9 run twice) and shown to be identical with **6***a* by m.p., mixture m.p., t.l.c., and n.m.r.

*Reduction of the Ketone **9** with Sodium Borohydride*

The ketone **9** (22 mg) was treated with excess sodium borohydride (25 mg) in ethanol (5 ml) at 20° for 3 h. The alcohol **10** formed, was purified by preparative t.l.c. (ethyl acetate – light petroleum, 1:5) and then crystallization from light petroleum. It (16 mg) had m.p. 79°; τ 4.47 (br s, 2H, H-12 + H-13), 7.5–8.15 (m, 4H, 2H-11 + 2H-14), 8.85 (s, 3 H-18), 8.87 (d, 3 H-17, J = 6 Hz), and 9.33 (s, 3 H-20).

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.41; H, 10.25. Found: C, 75.53; H, 10.13.

*Hydrogenation of Acetate **16***

Hydrogenation of **16** (25 mg) in ethyl acetate (10 ml) over palladized charcoal (5%, 15 mg) for 30 min afforded a single product which was purified by t.l.c. on silver nitrate – silica gel (ethyl acetate – light petroleum, 1:10, run thrice). This oil (18 mg) was shown by n.m.r., t.l.c., and g.l.c. to be identical with the major product, **17***b*, obtained by hydrogenation of **2**. Hydrolysis of the oil with sodium hydroxide (0.1 g) in refluxing aqueous methanol (10 ml, 1:1) for 3 h yielded **17***a* (14 mg, 88%), which crystallized from ethyl acetate – light petroleum. This alcohol had m.p. 132–134° and was identical (m.p., mixture m.p., t.l.c., and n.m.r.) with an authentic sample (2) of **17***a*.

*Treatment of Methyl ent-Trachyloban-19-oate (**1**) with Acetic Acid*

The ester **1** (100 mg) was heated in 20 ml glacial acetic acid at 75° for 5 days. The solvent was evaporated and the residue separated by preparative t.l.c. (ethyl acetate – light petroleum, 1:5 run thrice). One major product (**11***b*, 23 mg, 19%) was recovered. It crystallized from light petroleum and had m.p. 143–144°; τ 8.05 (s, 3H, —OCO*CH*$_3$), 8.46 (s, 3 H-17), 8.84 (s, 3 H-18), and 9.22 (s, 3 H-20).

Anal. Calcd. for $C_{23}H_{36}O_4$: C, 73.37; H, 9.64. Found: C, 73.34; H, 9.77.

The Determination of the Preferred Stereochemistry and the Magnitude of the Hydrogen Isotope Effect for 1,3 Elimination in the Locked Norbornyl System Methyl *exo*-2-Bromo-1-norbornanecarboxylate-*endo,endo*-5,6-d_2[1]

NICK HENRY WERSTIUK

Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

Received June 24, 1974

NICK HENRY WERSTIUK. Can. J. Chem. **53**, 26 (1975).

Methyl *exo*-2-bromo-1-norbornanecarboxylate-*endo,endo*-5,6-d_2 (**1***b*) has been prepared and solvolyzed at 112° in 80:20 EtOH-H_2O buffered with NaOAc. The loss of 85–90% of the deuterium available on the front face of **1***b* in the formation of the tricyclic ester **6**D coupled with a novel analysis established that the *endo*:*exo* preference for 1,3 elimination is at least 15:1 to 20:1. A comparison of the solvolytic kinetic isotope effect (1.18 ± 0.04) for **1***b* and the 1,3-elimination kinetic isotope effect (1.45–1.6) with data for 1,2 eliminations indicates that elimination occurs from the classical, perhaps 1,3 hyperconjugatively stabilized carbocation **20**. The *endo*:*exo* preference established in this study is used to reinterpret 1,3-elimination data determined by Collins in the solvolysis of deuteriohydroxyphenyl norbornyl tosylates.

NICK HENRY WERSTIUK. Can. J. Chem. **53**, 26 (1975).

On a préparé et solvolysé l'ester méthylique de bromo-2-*exo* norbornanecarboxylique-1 *endo,endo*-5,6-d_2 (**1***b*) à 112° avec une solution tamponnée de 80:20 EtOh–H_2O avec NaOAc. La perte de 85–90% du deutérium disponible sur la face avant de **1***b* dans la formation de l'ester tricyclique **6**D couplée avec une analyse nouvelle établit que la préférence *endo*:*exo* pour une élimination 1,3 est au moins de 15:1 à 20:1. Une comparaison de l'effet isotopique solvolytique et cinétique (1.18 ± 0.04) pour **1***b* et de l'effet isotopique pour la cinétique de l'élimination 1,3 (1.45–1.6) avec les résultats pour les éliminations 1,2 indique que l'élimination se produit d'une façon classique, peut-être par une carbocation stabilisé par hyperconjugaison 1,3 **20**. La préférence *endo*:*exo* établie dans cette étude est utilisée pour réinterpréter les résultats de l'élimination 1,3 déterminés par Collins dans la solvolyse des tosylates de deutériohydroxyphényl norbonyle.

[Traduit par le journal]

Introduction

The intricacies of the mechanisms of 1,2 (β) elimination have been probed extensively through kinetic and solvent isotope effect studies, through changes in base strength, leaving group and solvent polarity, and studies on stereospecifically deuterium labelled substrates. Many substantial reviews are available presently on this subject (2–9). However, 1,3- and 1,4-elimination reactions have not been studied as extensively, although there is presently activity in the area of 1,3 eliminations, prefaced by the work of Nickon and Werstiuk (*10*).

1,3 Elimination occurs in acyclic and alicyclic systems through E1cb-like, E-2-like, and E-1-like transition states. For example, there are a multitude of three-membered ring-forming reactions both in acyclic and alicyclic systems which involve prior anion formation followed by 1,3 displacement of the leaving group. A recent publication by Bordwell and Jarvis (11) describes some of the latest mechanistic information that has been accumulated on these E1cb-like 1,3 eliminations. An example of a fully concerted E-2-like 1,3 elimination has not yet been documented but studies under selected conditions on 5-*oxo*-*exo*-2-norbornyl derivatives (12) may prove fruitful. There are many examples documented in the literature (12–21) of E-1-like 1,3 elimination especially in bicyclo[2.2.1]heptyl derivatives. However, little mechanistic detail has been established for these 1,3 processes.

This paper describes in detail a study of 1,3 elimination in the norbornyl system methyl *exo*-2-bromo-1-norbornanecarboxylate (**1***a*). The study was undertaken to establish the preferred stereochemistry for the E-1-like 1,3 elimination in this locked norbornyl substrate, where the ubiquitous 1,2 Wagner–Meerwein rearrangement and/or norbornonium ion formation which scrambles C—H stereochemistry at C-6 is precluded or at least diminished. The results of this study would then serve as a basis for the interpretation of the stereochemical preference

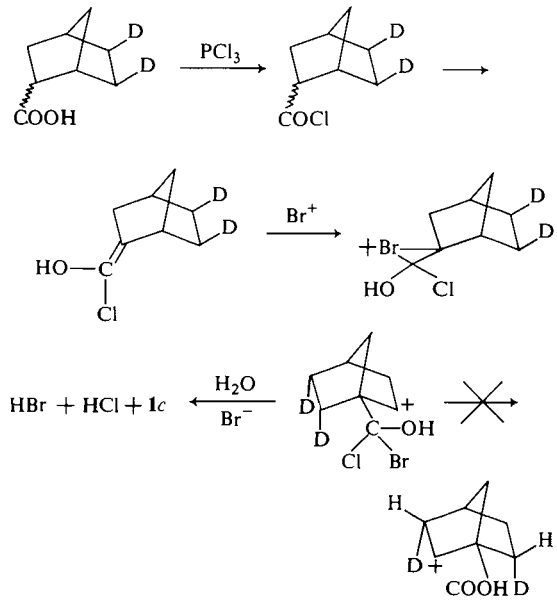
data for 1,3 elimination in norbornyl systems in general. A specific case that deals with the work of Collins and Benjamin (15) will be discussed subsequently in the text of this paper. Also, the present study would establish both product and solvolysis kinetic isotope effects for the purpose of providing a comparison with those of 1,2 effects. Eventually, it would be desirable to decide through the magnitude of the effects whether or not the *exo* or *endo* C—H bonds at C-6 participate directly in a 1,3 manner in the ionization step during solvolysis. The bromoester **1***a* was chosen for the study because it is a locked system (1) that yields 43% of tricyclic material on solvolysis (13) and the synthesis of the deuterated substrate **1***b* is straightforward.

Preparation of Substrates: Determination of Stereochemical Purity

Compound **1***a* was prepared by the method of Boehme (22, 23). The dideuterated bromoester **1***b* was prepared by using a 1,2 Wagner–Meerwein shift to move *exo* deuterium to the *endo* position (24). Reduction of 5-norbornene-2-carboxylic acid (**2**) (80% *endo*, 20% *exo*) both with dideuteriodimide and deuterium on palladium-on-charcoal gave good yields of a mixture of *exo*-2- and *endo*-2-norbornanecarboxylic-*exo*, *exo*-5, 6-d_2 acid (**3**). Bromination of the acid gave *exo*-2-bromo-1-norbornanecarboxylic-*endo*,*endo*-5,6-d_2 acid (**1***c*) that was esterified with diazomethane. Although the mechanism of the bromination rearrangement sequence for the conversion of **3** → **1***c* has not been established, undoubtedly, the Hell–Volhard–Zelinsky reaction involves enolization of the acid chloride followed by electrophilic attack of bromine on the enol. As charge is developed at C-2, rearrangement occurs to the 1-carboxy system that is captured by bromide ion. Interestingly, a 6,2 hydride (deuteride) shift does not occur significantly in this case. This was established by n.m.r. integration analysis (Fig. 1) of the olefinic region of methyl 1-norbornenecarboxylate-*endo*,*endo*-5,6-d_2 isolated from NaOMe-catalyzed elimination of HBr from **1***b*. Since 1,2 elimination of HBr from **1***b* is specifically *cis-exo* (25) the bromoester, in which a 6,2 deuteride shift has occurred, would give olefin in which a hydrogen at C-3 is replaced by deuterium. From integration analysis an upper limit of 5% is set on the extent of deuteride shift. The presence of a deuteride shifted product,



SCHEME I

however, does not affect the interpretation of the stereochemistry studies since the deuterium must necessarily remain 1,3 and *endo* with respect to the bromine.

It is of interest that the 1,2-elimination product is the major component (80%) of the reaction of **1***b* under E-2 conditions. Three other products, listed in order of increasing retention time, were tricyclic ester (8%), unknown (4%), and methyl 2 methoxy-1-norbornanecarboxylate (8%). That methyl 2 methoxy-1-norbornanecarboxylate was one of the minor components (isolated by preparative g.l.p.c.) was established by mass spectrometry which showed a parent ion at *m/e* 186

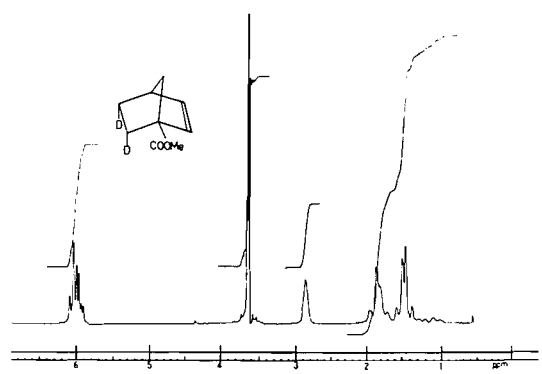


FIG. 1. Nuclear magnetic resonance spectrum (100 MHz; CCl_4) of 4D obtained from NaOMe-catalyzed elimination of HBr from **1***b*.

($C_{10}H_{14}O_3D_2$) and a fragmentation pattern consistent with the proposed structure. The methoxy group is likely situated *exo* at C-2. That the 1,2-elimination product predominates under E-2 conditions supports our claim that under solvolysis conditions 1,3 elimination is E-1-like and is preceded by ion pair formation. The integration analysis on the olefin **4D** obtained from base-catalyzed elimination also established that the deuterium in the bromoester was at least 95% stereochemically pure *endo* at C-5 and C-6. This reflects the stereospecific *exo* reduction of the norbornenecarboxylic acid which is expected for the system (26). The multiplets centered at 1.8 and 1.5 δ (Fig. 1) are what would be expected for the *exo*-5,6 and C-7 hydrogens, respectively, in the [2.2.1] system (24, 26). The residual of the *endo* hydrogens is centered at around 1.1 δ. Further support for the stereochemistry of the deuterium is obtained from the proton n.m.r. spectrum (Fig. 2) of methyl 2-norbornene-2-carboxylate-*exo*,*exo*-5,6-d_2 (**5***b*) obtained from CH_2N_2 esterification of the product obtained from elimination of HBr from the carboxylic acid **1***c*. Since the rearrangement to **5***a* shifts *endo* deuterium to the *exo* position, the relative intensities of the peaks at around 1.8 and 1.1 δ should interchange. The n.m.r. spectrum (Fig. 2) of **5***b* indicates this to be the case.

Results

Solvolysis of **1***a* and **1***b* in 80:20, v/v, EtOH–H_2O buffered with NaOAc gave the products **4**H, **6**H, **7**H, **8**H, and **4**D, **6**D, **7**D, **8**D respectively as described in Table 1. The deuterium content of both **1***b* and tricyclic material was established by mass spectrometry and n.m.r. spectroscopy

(Fig. 3). As indicated in Table 1 an isotope effect operates in the elimination to decrease the quantity of tricyclic material and increase the amount of the other products. This, coupled with the loss of approximately 90% of the deuterium available on the front face of **1***b*, establishes a large preference for cleavage of the *endo*-C—H bond over the *exo*-C—H bond at C-6 in the 1,3 elimination. The γ-kinetic isotope effect (Table 2) for solvolysis of **1***a* and *b* is 1.18 ± 0.04 in the range of 115°. The data for run 3 is plotted in Fig. 4. The rate constant of 1.04×10^{-5} s^{-1} at 115° for **1***a* (0.03 *M* **1***a*; 0.09 *M* NaOAc) compares favorably with the rate constants of 0.85×10^{-5} s^{-1} (112.6°) and 1.28×10^{-5} s^{-1} (119.5°) reported for **1***a* (0.01–0.04 *M* **1***a*; 0.01–0.04 *M* NaOAc) by Wilt (13). The increased rate

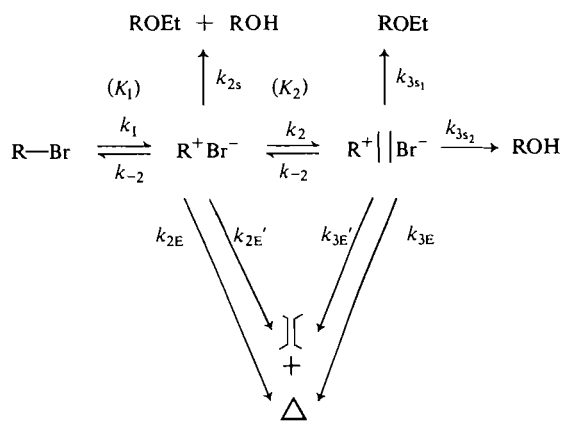
3	0.05 *M* **1***a*,**1***b* 0.14 *M* NaOAc 116.10 ± 0.04°	1.86 ± 0.02	1.54 ± 0.02	1.20 ± 0.04
	Mean			1.18 ± 0.04

*Five additional preliminary runs were used to establish the validity of the kinetic procedure. Compounds **1***a* and **1***b* were run simultaneously in the same constant temperature bath and aliquots were removed at the same time.
†The rate constants were obtained by least-squares analysis of the data; the standard deviation of the slope was taken as the error in the slope.

High Pressure Liquid Chromatograph. The solvent system 15–20% $CHCl_3$ – 85–80% hexane (v/v) was used with a 3/8 in. × 3 ft Porasil A column (column volume 34 ml). A flow rate of 0.7 ml/min was used with the pressure being 800 p.s.i. The bromoester was eluted after approximately 80 ml of flow. Although there was some tailing when a 60–70 mg (45 μl neat liquid) sample was injected, careful g.l.p.c. and n.m.r. analysis of the tail fraction showed that no other compound was present. Also, a l.c. analysis of a 4 μl sample showed a symmetrical peak. After a total of 10–12 samples each of **1***a* and *b* were injected and collected, the appropriate fractions were combined and the solvent was taken off on the rotatory evaporator. The residue was distilled under vacuum bulb to bulb twice for final purification. In this case l.c. is far superior to gas chromatography in terms of degree of separation, ease of handling and recovery of materials. This is however offset to some degree by the somewhat lengthy period required to establish conditions.

Discussion

When an ion pair scheme is considered for the solvolysis (Scheme 2) and the formation of products from tight ion pairs (TIP) and solvent separated ion pairs (SSIP) is describable on the basis of pseudo first-order processes, the following analysis can be made.[2] Since it has been established that k_{2S} is negligible in the



SCHEME 2

[2.2.1] system (27), attack of solvent on TIP to give ether and alcohol products is not important in the solvolysis of **1***a*. If the steady state approximation can be applied in this case, then in the scheme, K_1 would be affected by deuterium substitution but K_2 would not, since k_{2H}/k_{-2H} and k_{2D}/k_{-2D} should remain constant. This is so because the electronic and hybridization changes at C-6 (compared to R_H-Br) in R_H^+ in the $SSIP_H$ should be essentially identical to those in R_H^+ in TIP_H. Also, the changes at C-6 (from R_D-Br) in R_D^+ in $SSIP_D$ should be essentially identical to those for R_D^+ in TIP_D. Therefore, since $[TIP]_H/[SSIP]_H \simeq [TIP]_D/[SSIP]_D \simeq$ constant, the difference in the relative amounts of products from **1***a* and *b* would be governed by the relative magnitudes of the product rate constants and not by a variation in

[2]A hydride shift sequence is omitted from the scheme since the ion which results from an $H^-(D^-)$ shift should exhibit the reactivity of a SSIP even in the case of **1***b*.

the magnitude of K_2. This is reasonably important since it is not yet established which of k_{2E} and k_{3E} is most important or whether they both contribute equally to the 1,3 elimination. However, it is likely that for an E-1-like elimination k_{2E} and k_{3E} are of comparable magnitude since the force constant changes in the TIP and SSIP at C-6 should be essentially identical (28). For the same reason, the elimination isotope effects should also be identical for both species. Thus, k_{2E} and k_{3E} (1,3 elimination) are combined into $k_{E\ total}$.[3] Therefore, assuming the equilibrium between TIP and SSIP is fast

$$\frac{k_{HE\ total}}{k_{H3S_1} + k_{H3S_2}} \simeq \frac{6H}{7H + 8H}$$

and

$$\frac{k_{DE\ total}}{k_{D3S_1} + k_{D3S_2}} \simeq \frac{6D}{7D + 8D}$$

On the assumption that the isotope effect for capture of SSIP by solvent is negligible so that $k_{H3S_1} + k_{H3S_2} \simeq k_{D3S_1} + k_{D3S_2}$

$$\frac{k_{HE\ total}}{k_{DE\ total}} \simeq \frac{\dfrac{6H}{7H + 8H}}{\dfrac{6D}{7D + 8D}} \simeq 1.6$$

If an isotope effect does indeed operate on k_{3S} then it is likely inverse (28). Since there is no information available on the magnitude of such a γ-effect, only an estimate is possible presently based on a β-isotope effect. Humski *et al.* (28) have recently reported a value of 0.90 for the β-isotope effect for the collapse of cyclopentyl-*cis*-β-*d* brosylate ion pairs in 80:20 ethanol–water. If this is considered as the maximum value for a collapse isotope effect then $k_{D3S} \simeq 1.10\ k_{H3S}$. Substituting this in the expression for $k_{HE\ (total)}/k_{DE\ (total)}$, a value of 1.45 is obtained for the elimination isotope effect. The value of 1.45–1.60 compares favorably with the values reported for 1,3 elimination in the [2.2.1] system (10).

[3]The sum of k_{3S_1} and k_{3S_2} is used since the elimination process likely also involves both solvent bases. This comparison is an attempt to take into account the pseudo first-order nature of the product steps involving both EtOH and H_2O.

A novel analysis[4] that combines in [1] the initial distribution of deuterated species, the elimination isotope effect (1.6), the stereochemical purity (95–98%), an assumed preference, and the amount of tricyclic material (43%) formed from **1***a*, is used to predict the yield and the distribution of deuterated species of tricyclic material from **1***b*. The data in Table 3 clearly validate the method and establish that for a stereochemical purity of 98–95% there is at least a 15:1 to 20:1 preference for cleavage of the *endo*-C—H bond at C-6.

[4]Described herein is a sample calculation (assumed preference 20:1; isotope effect 1.6) that uses [1] for analysis of *endo vs. exo* cleavage for **1***b* (73.7% d_2, 24.5% d_1, 1.8% d_0) in which the deuterium is taken to be 95% stereochemically pure *endo* and the secondary isotope effect for cleavage of a C—H bond is assumed to be negligible.

endo,endo-5,6-d_2 component

endo cleavage $\left(\frac{73.7}{100}\right)(0.95)\left(\frac{20}{20}\right)\left(\frac{1}{1.6}\right)(43) = 18.80\ d_1$

exo cleavage $\left(\frac{73.7}{100}\right)(0.95)\left(\frac{1}{20}\right)(43) = 1.51\ d_2$

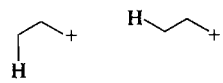
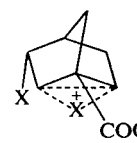
The *endo* preference for elimination from **1***a* establishes that the semi-U pathway (**A**) (10) is preferred for an E-1-like 1,3 process in locked [2.2.1] systems with $\Delta G^{\ddagger}$ being a *minimum* of 1.5–2 kcal/mol less than that for the semi-W pathway (**B**). Whether or not a symmetrical

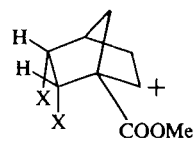


A B

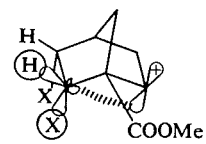
edge-protonated nortricyclane (**9**H, **9**D) is an intermediate from which loss of a proton (deuteron) occurs is a point of interest. This problem is discussed in more detail subsequently in the text. That is, the ion **10**H (**10**D) may be the intermediate and **9**H (**9**D) represents only a transition state for the elimination and $H^-(D^-)$ shift. That a hydride (deuteride) shift does occur during solvolysis of **1***a* (**1***b*) is supported by the following facts. Nuclear magnetic resonance integration analysis of the olefinic region of **4**D, obtained from solvolysis of **1***b*, showed that deuterium was located at C-3 and established that 10–20% of the olefin arises after a deuteride shift occurs. Furthermore, partial collapse of the *endo*-2-C–H multiplet in the n.m.r. spectrum (Fig. 5) of **7**D



9*H* X = H
9*D* X = D

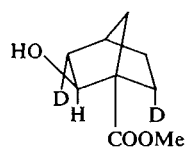


10*H* X = H
10*D* X = D

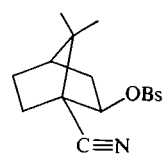


11*H* X = H
11*D* X = D

is consistent with loss of *cis–endo* coupling (29) which would be expected from **12**. That a hydride (deuteride) shift would be expected in this system is supported by Muneyuki's (19) study on the acetolysis of optically active **13** which established that the product acetate racemized partially.



12



13

The *endo* preference established in this study shows conclusively that the overlap of the back-lobe of *exo*-C-6—H with the p-orbital at C-2 as described in **11**H (**11**D) *does not* play an important role in the stereochemical outcome of an E-1-like 1,3 elimination in the [2.2.1] system.

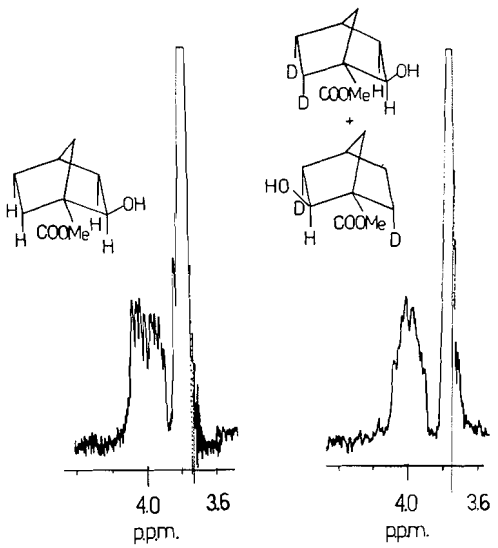

FIG. 5. Nuclear magnetic resonance spectra (60 MHz; $CDCl_3$) (sweep width 250 Hz) of 7H and D obtained from solvolysis of **1***a* and *b*.

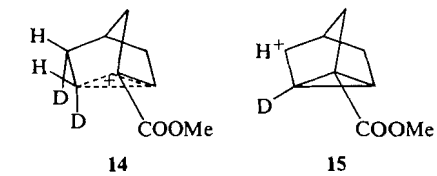
This is of interest for two reasons. Farnum and Mehta (30) and Olah and co-workers (31, 32) have reported that this type of overlap operates in the norbornyl system and is the cause of the deshielding of the *exo* over the *endo* proton at C-6 in norbornyl cations generated in strong acids. Apparently, this overlap is not sufficient to preferentially activate *exo*-C—H over *endo*-C—H for 1,3 elimination. Also, *exo* approach of reagents to the [2.2.1] system is preferred, especially for proton transfer in homoenolization and homoketonization (33) processes.

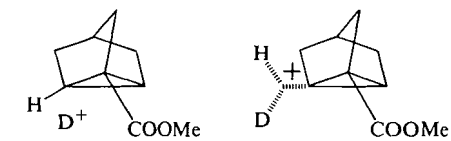
The magnitude (1.45–1.6) of the primary 1,3-elimination isotope effect established in this study parallels closely the few examples documented in the literature (10, 15, 21, 34–38) for E-1 1,2 and 1,3 eliminations (Table 4).

Since the magnitude of the isotope effect for an E-2-like 1,3 elimination has not been determined because there is as yet no experimental support for a concerted 1,3 elimination and no theoretical studies have been carried out on 1,3 processes the usual correlation between the magnitude of the isotope effect and concertedness is difficult to establish in this case. However, the low value observed for **1***b* does fall in the range for 1,2 eliminations and 1,3 eliminations from carbocations (*vide supra*).

The γ-kinetic isotope effect is of interest since the presence of the carbomethoxy group should preclude significant neighboring group (nonvertical) participation of C-1—C-6 bond via **14**. Thus, the γ-effect may arise from any one, or some combination of the three effects. Possibly, 1,3 hyperconjugation to both the *exo*- and *endo*-C—H bonds at C-6 as described by the

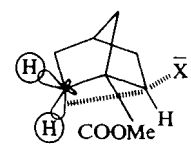


14 **15**



16 **17**

limiting forms **15** and **16** is important in the ionization step. Perhaps the sum of **15** and **16** is equivalent to the H-nortricyclonium ion **17**, the unsubstituted form of which Olah has proposed as a contributor to the structure of the norbornyl cation. Also likely is the direct involvement, as described by **18**, of only the *endo*-C—H(D) bond in the ionization step. Presently, the relative importance of each effect cannot be established although **15** + **16** = **17** may be important in the solvolysis of 7-chloro-*exo*-2-norbornyl- 6-*endo*-*d* and -*exo*,*exo*-5,6-d_2 brosylates (21). Lastly, it is possible that the



18

kinetic isotope effect is a manifestation of the elimination isotope effects only. If the ion pair scheme (Scheme 2, *vide supra*) is considered and the steady state approximation is applied, then it can be shown that when $k_{2S} = 0$ (27)

$$\left(\frac{k_H}{k_D}\right)_{obs} = \left(\frac{k_{H1}}{k_{D1}}\right)\left(\frac{1 + Y_D}{1 + Y_H}\right) \times \frac{\frac{k_{H2E}}{k_{H2}} + \left[\left(\frac{k_{H3E}}{k_{H3S}} + 1\right)\left(\frac{1}{1 + Z_H}\right)\right]}{\frac{k_{D2E}}{k_{D2}} + \left[\left(\frac{k_{D3E}}{k_{D3S}} + 1\right)\left(\frac{1}{1 + Z_D}\right)\right]} = (IIE)(R)(S)$$

TABLE 4. Tabulation of β-kinetic isotope effects and 1,2 and 1,3 elimination isotope effects for solvolysis reactions

Entry	Deuterated substrate	Conditions	Kinetic isotope effect per D	Primary isotope effect for olefin formation	Reference No.
1		80:20 EtOH–H_2O 25°	1.19	1.8	34

*The value of 1.14 is based on the *exo* and *endo* effect being identical. The value of 1.28 is the total observed kinetic effect.
†Based on the ratio of olefin fraction from H substrate and D substrate.
‡The value of 1.2 is obtained from the ratio of 2-methylbutene-2 fractions. The value of 1.6 is obtained using the tertiary acetate ratio as well as the olefin ratio in the analysis developed in this paper.
§This is the isotope effect for nortricyclane formation.

where

$$Y = \frac{k_{-1} + k_{2E}}{k_2}$$

and

$$Z = \frac{k_{-2} + k_{3E}}{k_{3S}}$$

If the ionization isotope effect (IIE) $k_{H1}/k_{D1} \simeq 1.0$ then through a consideration of the effect of deuterium substitution on the rate constants k_{2E}, k_2, k_{-2}, k_{3E}, and k_{3S} it is seen that $k_{H2E} > k_{D2E}$, $k_{H2} \simeq k_{D2}$, $k_{H-2} \simeq k_{D-2}$, $k_{H3E} > k_{D3E}$, and $k_{H3S} \simeq k_{D3S}$. Therefore, the R and S terms could control the observed isotope effect but with some mutual attenuation since $1 + Y_D$ is $< 1 + Y_H$ in the R term and the numerator is larger than the denominator in the S term. That the observed kinetic isotope effect can vary with the amount of elimination has been established by Humski (38) through studies on the solvolysis of 1,2-dimethyl-*exo*-2-norbornyl-*p*-nitrobenzoate. This however is not general since in the solvolysis of cyclopentyl brosylate-*trans*-β-*d* in ethanol–water the kinetic isotope effect does not vary significantly with a change in the amount of olefin formed and in fact in trifluoroethanol–water actually increases slightly as the amount of olefin decreases (28).

Nevertheless, 1,3 elimination at some point would involve a transition state which resembles

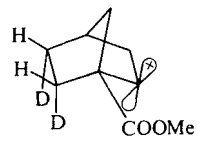
an edge-protonated nortricyclane[5], the overall process being characterized by an isotope effect of 1.45–1.6. If the kinetic isotope effect (1.18 ± 0.04) in fact predominantly reflects the ionization isotope effect then that k_H/k_D (elim) > k_H/k_D (kinetic) indicates that the C—H bonds at C-6 undergo a force constant change during ionization either through **15** + **16** = **17** or **18** or both but the change does not approach that in **9**D. That is, if involvement of the endo-C—D bond at C-6 at ionization approached the extent depicted in **9**D then k_H/k_D (kinetic) > k_H/k_D (elim). There is some support for this concept available in the literature at least for 1,2 eliminations. For example, in Table 4 in entries 1, 3, and 4 where k_H/k_D (obs) > k_H/k_D (elim), elimination is considered to occur from classical species with the β-C—H bonds being perturbed only through hyperconjugation (vertical participation). It must be pointed out here that it is understood that the primary elimination isotope effects are inflated somewhat in entries 1, 2, and 3 because a secondary effect (≃ 1.2) operates in each case as well. However, k_H/k_D (obs) would still be less than k_H/k_D (elim). In the solvolysis of 2-substituted-2,3-dimethylbutanes (entry 5), however, k_H/k_D (obs) > k_H/k_D (elim). In the case of the solvolysis of the tosylate in entry 6, Winstein and Takahashi (36) proposed that neighboring group participation (nonvertical participation) of the C—H(D) leading to an ethonium ion was important. In this case it is reasonable that k_H/k_D (obs) > k_H/k_D (elim) since elimination should now occur from an ethonium ion. The isotope effect for loss of D^+ from such a species would be expected to be less than that for loss of D^+ from a classical ion since the C—H(D) force constants in the former are already lowered substantially. Significantly, Cram and Tadanier (40) proposed that the ethonium ion was formed in the solvolysis of 3-cyclohexyl-2-butyl tosylate where k_H/k_D (obs) is in the order of 1.7–1.8. Unfortunately the olefin ratios were not reported for the deuterated compounds so that an elimination isotope effect cannot be evaluated. However, this author predicts that k_H/k_D (obs) should be greater than k_H/k_D (elim).

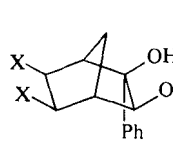
Thus from the stereochemical preference data, the relative magnitudes of the kinetic and elimination isotope effects the author proposes that 1,3 elimination in **1***b* occurs from a species which closely resembles the classical ion **20** where the C—H, C—D bonds at C-6 may be involved in 1,3 hyperconjugative stabilization



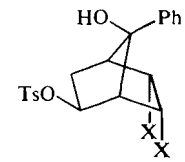
20

but that the transition state for 1,3 elimination and the 6,2 H(D) shift resembles an edge-protonated nortricyclane, the isotope effect for the 1,3 process being around 1.6.

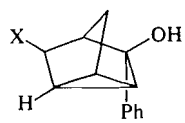
That the semi-U pathway is preferred for E-1-like 1,3 elimination in the [2.2.1] system where rearrangement is precluded provides a basis for the reinterpretation of other 1,3 preference data (15). Collins found that the tosylates **21**H and **22**H gave essentially identical product compositions including the nortricyclanol



21*H* X = H
21*D* X = D



22*H* X = H
22*D* X = D



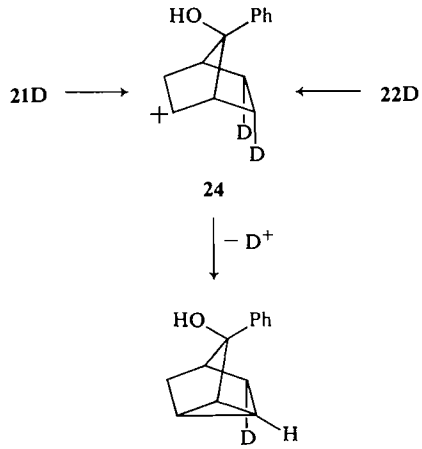
23*H* X = H
23*D* X = D

23H (26%). When **21**D and **22**D were solvolyzed in each case one deuterium atom was lost in the formation of **23**D. That the product composition

[5]E-1-like 1,3 elimination in the [2.2.1] system should be essentially the reverse of the protonation of the appropriately substituted nortricyclane. Although **6**H has not been opened with D^+ to check this, the D^+

opening of nortricyclyl chloride occurs by edge-protonation of bond *a* (39). This correlates very well with the finding that cleavage of *endo*-C—H(D) at C-6 is preferred for 1,3 elimination in solvolysis of the 7-chloro-*exo*-2-norbornyl-6-*endo-d* brosylate (21).

was identical within experimental error from **21**H and **22**H indicated that common intermediates were involved. The authors interpreted the deuterium loss data on the basis of elimination of *exo* deuterium from **21**D and *endo* deuterium from **22**D and stated that the solvolysis results could be accounted for on the basis of either nonclassical or classical ions and that the edge-protonated nortricyclane could be either an intermediate or transition state. On the basis of previous discussion (*vide supra*) the results can be accounted for in the following manner.



Cleavage of the C—OTs bond in **21**D followed by a 1,2 alkyl shift gives **24**. Solvolysis of **22**D gives **24** directly. In this case the hydroxyl and phenyl groups provide the necessary lock through an inductive effect and perhaps OH-4 participation for the former and an inductive and steric effect for the latter. Ion **24** need be classical and stabilized only through 1,3 hyperconjugation (*vide supra*). Reaction of **24** with an *endo* preference as expected would then lead directly to **23** with a loss of one deuterium in both cases. The point here is that the C—D bond originally *exo* in **21**D is cleaved as an *endo* bond in **24**. That **24** resembles a classical ion and elimination occurs from this species is supported by value of 1.8 for magnitude of the elimination isotope effect which was evaluated from Collins' product data by the method described previously in this paper.

Experimental

General

Melting points were taken on a Kofler hot stage melting point apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer Model 337 spectrometer. The n.m.r. spectra were recorded on Varian A-60, T-60 and HA-100 spectrometers on solutions in CCl_4 or $CDCl_3$ with tetramethyl silane as internal standard. Mass spectra were obtained on a Hitachi Model RMU6-A spectrometer. Preparative and analytical gas liquid chromatography was carried out on Varian 90-P-3 and 204 instruments, respectively, with He as carrier gas. High pressure liquid chromatography was accomplished on a Waters Model 200 liquid chromatograph. All solutions were dried over anhydrous Na_2SO_4 or $MgSO_4$.

Dipotassium Azodicarboxylate

To a vigorously stirred solution of 600 ml of 40% KOH maintained at 0–3° was added azodicarbonamide (110 g) portionwise. After the addition was complete the mixture was stirred for 1 h and the salt was filtered through a sintered glass funnel. The salt was washed with 8 l of anhydrous methanol, cooled to 0–5°, and vacuum dried (rotatory pump) for 2 days. The salt that was used for the deuterations was washed with (2 × 50 ml; 1 × 75 ml) MeOD and pumped on for 2 days.

Dideuteriodimide Reduction of Norbornenecarboxylic Acid

Norbornenecarboxylic acid (14 g, 80:20 *endo*:*exo*) was added to a slurry of dipotassium azodicarboxylate (54 g) in MeOD (300 ml, 95%-O-*d*) contained in a three-necked 1-l flask equipped with a condenser, dropping funnel, and stirrer. To the vigorously stirred mixture was added DOAc (26 g, 95–97%-O-*d*) in MeOD (30 ml) over a period of 1 h. After the addition was complete the mixture was stirred for an additional 1.5 h at room temperature. An aliquot was worked up and analyzed by infrared spectroscopy. The absence of an initially strong band at 710 cm^{-1} showed that the reduction was at least 98–99% complete. The MeOD was recovered by distillation through a 14 in. glass helices column to yield a viscous residue of approximately 75 ml. Ether (100 ml) and water (175 ml) were added and after shaking the ether layer was drawn off. The aqueous layer was extracted with additional ether (10 × 50 ml). The combined ethereal layers were washed with water, dried, and the ether was distilled off. Distillation of the residue gave 9 g of the dideuterioacid, b.p. 103–104° (1–8 mm), which solidified to a viscous mass on standing. Nuclear magnetic resonance (60 MHz, $CDCl_3$) δ 11.0 (bs, 1H, COOH), 2.75 (bm, 1H, C-2—*exo*-H), 2.55 and 2.25 (m, 2H, bridgehead C—Hs), 1.8–1.1 (norbornyl envelope, approximately 6H).

Deuteration of Norbornenecarboxylic Acid

Norbornenecarboxylic acid (30 g, 0.218 mol, Aldrich Chemical Co., 80:20 *endo*:*exo*) was dissolved in anhydrous methanol (125 ml) in a 250 ml conical flask. Palladium (10%) on charcoal (4 g) was added and the mixture was connected to a gas burette. The mixture was stirred vigorously while approximately 5 l of D_2 was taken up by the warm solution. The mixture was stirred for 4 h longer and the catalyst was filtered off. The methanol was distilled off through a 12 in. Vigreux column. The residue which remained was distilled under vacuum as above to give 26 g of the dideuteriocarboxylic acid. Nuclear magnetic resonance (60 MHz, CCl_4) δ 12.0 (s, 1H, COOH), 2.88 (m, approximately 1H, C-2—*exo*-H), 2.70 (m, 1H, bridgehead C—H), 2.35 (m, 1H, C-4—H), 1.75 (m, 2H, *syn*- and *anti*-7-H), 1.5 (bs, approximately 4H, norbornyl envelope).

Dimide Reduction of Norbornenecarboxylic Acid

To a slurry of dipotassium azodicarboxylate (36 g, freshly prepared) in methanol (distilled from sodium) was added norbornenecarboxylic acid (10 g, 80:20 *endo*:*exo*). To the vigorously stirred solution was added glacial acetic acid (17.5 g, in 20 ml of dry methanol) over a period of 1.5 h. After the addition was complete analysis of an aliquot by i.r. showed the absence of an intense peak at 710 cm^{-1} and indicated that the reduction was complete. Ether was added (700 ml) and the KOAc which precipitated was filtered off. The solvent was distilled off to a volume of 20 ml, then water was added (150 ml) and the solution was extracted with ether (1 × 200 ml; 3 × 50 ml). The ethereal solution was dried and the solvent evaporated. Vacuum distillation of the residue gave 7.6 g of 2-norbornanecarboxylic acid (b.p. 108–109°/2 mm) which solidified to a semi-solid on standing. Nuclear magnetic resonance (60 MHz, $CDCl_3$) δ 12.0 (s, 1H, COOH), 2.75 (bm, < 1H, C-2—*exo*-H), 2.58 (bs, 1H, C-1—H), 2.26 (bs, 1H, C-4—H), 1.45 (norbornyl envelope, 8H). There was no detectable olefinic signal in the n.m.r.

Bromination of 2-Norbornanecarboxylic Acid

The 2-norbornanecarboxylic acid (6.4 g, > 95% pure) was heated on the steam bath with bromine (8.8 g) and PCl_3 (0.1 ml) for 7 h. After the initial time an additional amount of bromine was added (4.0 g) and the mixture was heated for an additional 3 h. The mixture was poured onto water (250 ml) and ether (50 ml). An additional amount of ether was added (100 ml) followed by 6 g of $Na_2S_2O_4$. The ethereal layer was washed with water (50 ml) and dried. The ether was concentrated and the solid mass (5.0 g) was crystallized from toluene to give 3.9 of the bromoacid, m.p. 148–150° (lit. (22, 23) 150–151°).

Bromination of 2-Norbornanecarboxylic-exo,exo-5,6-d_2 Acid

Run 1. The deuteriocarboxylic acid (2.0 g, 0.014 mol), obtained from the dideuteriodimide reduction, was mixed with Br_2 (2.7 g, 0.016 mol) and PCl_3. The mixture was heated on the steam bath for 9 h, then poured into a dilute aqueous solution of $Na_2S_2O_4$, extracted with ether (1 × 100, 2 × 50 ml) and decolorized with charcoal. The residue was recrystallized from toluene to give 1.1 g of the deuterated *exo*-2-bromo-1-norbornanecarboxylic acid, m.p. 148–150°. Nuclear magnetic resonance ($CDCl_3$) δ 11.63 (s, COOH, 1H), 4.19 (m, H—C—Br, 1H), 2.5–1.4 (m, norbornyl envelope, 7.2 H). The n.m.r. showed considerable simplification in the region of 1.5–1.6 δ when compared to that of **1*d***, consistent with the replacement of *endo*-5,6-C—H with deuterium. Mass spectrum (80 eV), *m/e* 218–223 (M^+), 189–192 ($M^+ - C_2H_2D_2$), 139–141 ($M^+ - Br$).

Run 2. The acid (16 g, > 95% pure) prepared by catalytic deuteration of norbornenyl carboxylic acid was heated on the steam bath for 8 h with 1 ml of PCl_3 and 20 g of Br_2 as described previously. An additional 10 g of Br_2 were added and the mixture was heated for an additional 4 h at 75–80°. The reaction mixture was worked up as described previously and recrystallized from toluene to give 6.7 g of the dideuteriobromoacid, m.p. 150–152°.

*Esterification of the Dideuteriobromoacid **1c***

Run 1. The deuterated acid obtained from dideuteriodimide reduction (0.9 g, 0.004 mol, m.p. 148–150°) was dissolved in ether (50 ml) and treated with an ether solution of CH_2N_2 prepared from Diazald. The ether was evaporated and the viscous oil was purified by a bulb-to-bulb distillation at 5 mm to give 0.60 g of the bromoester. Analytical gas chromatography showed the ester to be > 98% pure; n.m.r. ($CDCl_3$) δ 4.18 (m, H—C—Br, 1H) 3.73 (s, —COOMe, 3H), 2.4–1.3 (m, norbornyl envelope, 7.3 H). The n.m.r. showed considerable simplification of the spectrum in the region of 1.7 δ as compared to the nondeuterated ester consistent with the replacement of *endo*-5,6-C—H with deuterium. Mass spectrum (80 eV), *m/e* 232–237 (M^+), 201–206 ($M^+ -$ OMe), 173–178 ($M^+ -$ COOMe), 153–157 ($M^+ - Br$). Analysis of the $M^+ - Br$ peaks at 10 eV showed that the ester was composed of 73.7% d_2, 24.5% d_1, and 1.8% d_0 species, a total of 1.72 excess D per molecule.

Run 2. The bromoacid (3.8 g) obtained from the Pd-on-charcoal reduction was esterified with diazomethane as described previously. Analytical g.l.p.c. on 10 ft × 1/8 in. 10% Carbowax on Chromosorb W at 175° showed the ester to be > 98% pure with two minor components, one (< 1%) of slightly shorter retention time and another (< 1%) of longer retention time. Mass spectrum (14 eV, sample purified by preparative g.l.c.) 2.3% d_3, 84.2% d_2, 11.2% d_1, and 2.5% d_0 species; 1.87 excess D per molecule.

*Esterification of the Bromoacid **1d***

Run 1. The bromoacid (0.14 g) was treated with an ether solution of diazomethane prepared in the usual manner and after work-up gave the methyl ester. Nuclear magnetic resonance ($CDCl_3$) δ 4.20 (m, H—C—Br, 1H), 2.80 (s, COOMe, 3H), 2.5–1.2 (m, norbornyl envelope, 9H). Mass spectrum (80 eV, sample purified by preparative g.l.p.c.) 232–235 (M^+), 201–204 ($M^+ -$ OMe), 173–176 ($M^+ -$ COOMe) 153–154 ($M^+ - Br$). Analysis of $M^+ - Br$ peak at 10 eV established that 153 and 154 were 9.45 and 0.80% of the 152 peak, respectively.

Run 2. The bromoacid (3.5 g, m.p. 148–150°) was esterified as described previously. Gas chromatographic analysis on a 10 ft × 3/8 in. 10% SE-30 on Chromosorb W column at 160° showed the ester to be 95–97% pure with two minor components present.

*Solvolysis of the Dideuteriobromoester **1b***

Run 1. The deuteriobromoester (0.16 g, purified by preparative g.l.p.c.) obtained from dideuteriodimide reduction sequence was dissolved in EtOH (4 ml) and H_2O (1 ml) containing NaOAc (0.065 g) and the mixture was sealed in a tube which was suspended in refluxing toluene (112°) for 4 days. The tube was opened, the contents poured into water (50 ml), and extracted with pentane (1 × 25 ml, 2 × 15 ml). The dried solution was analyzed by analytical g.l.p.c. with electronic area integration on a 5 ft × 1/8 in. 5% SE-30 Chromosorb W column with temperature programming from 100–150° at 80 min. The following product distribution, listed in order of increasing retention time, was established; methyl deuterio-1-norbornenecarboxylate 9.9%, methyl deuterio-1-nortricyclanecarboxylate 32.0%, methyl deuterio-*exo*-2-hydroxynorbornane-1-carboxylate 16.7%, methyl deuterio-*exo*-2-ethoxynorbornane-1-carboxylate 38.4%, unknown 1.6%, unknown 1.4% (entry 2, Table 1). The pentane was distilled off to yield an oily residue which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

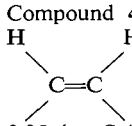
was separated into the four major components by preparative gas chromatography on a 5 ft × 1/4 in. 20% SE-30 on Chromosorb W column at 155°. Nuclear magnetic resonance (CCl_4) (Fig. 3) methyl deuterio-1-nortricyclanecarboxylate: δ 3.60 (s, COOMe, 3H), 2.06 (m, C-4—H, 1H), 1.78 (m, C-7, 2H) 1.47 (d, C-2, C-6—H, <2H), 1.37 (m, C-3, C-5—H, >3H). Mass spectrum methyl 1-nortricyclanecarboxylate (10 eV); a composite of 8.6% d_2, 79.4% d_1, and 12.0 d_0 species, corresponding to 0.97 excess D per molecule.

Nuclear magnetic resonance integration analysis (average of two integrations) utilizing the ester methyl and the total of the signals at 1.47 and 1.37 established that essentially only one deuterium remained in the nortricyclane with reduction of the signal at 1.37 being pronounced. A slight decrease in the relative intensity of the signal at 1.78 was consistent with some deuterium positioned on the cyclopropane ring (Fig. 3).

Run 2. The deuteriobromoester (0.080 g) obtained from the dideuteriodimide reduction sequence and purified by preparative g.l.p.c. was dissolved in EtOH (4 ml) and H_2O (1 ml) and anhydrous NaOAc (0.043 g) was added. The mixture was refluxed for 4 days and poured into water (10 ml) and extracted with ether (3 × 10 ml). The ether was distilled off after drying and the oily residue was separated by preparative gas chromatography on a 5 ft × 1/4 in. 20% SE-30 on Chromosorb W column at 140° into the four major products, in the following order of elution; methyl deuterio-1-norbornenecarboxylate, methyl deuterio-1-nortricyclanecarboxylate, methyl deuterio-*exo*-2-hydroxynorbornanecarboxylate, and methyl deuterio-1-*exo*-2-ethoxynorbornanecarboxylate. Mass spectrum methyl deuterio-1-nortricyclanecarboxylate (80 eV): *m/e* 153 (M^+, $C_9H_4O_2D$); analysis at 10 eV of M^+ showed the tricyclic material to be a composite of 5.7% d_2, 81.0% d_1, and 13.3% d_0 species, a total of 0.92 excess D per molecule.

Large Scale Solvolysis of the Dideuteriobromoester 1b

The dideuteriobromoester (1.5 g, >98% pure) prepared by CH_2N_2 esterification of the dideuterio acid obtained by catalytic deuteration was dissolved in 20 ml of 80:20, v/v, EtOH–H_2O (0.35 *M* in NaOAc) and the solution was sealed in a tube and suspended in refluxing toluene. After 14 days the tube was removed and the contents were poured into water (50 ml, saturated with NaCl) and the mixture was extracted with purified pentane (1 × 20 ml, 2 × 10 ml). The aqueous layer was then extracted with ether (1 × 20, 2 × 10 ml). The two solutions were washed with water and dried. Distillation of the solvent in each case through a 2 ft helices packed column gave 1–1.5 ml of residue in each case. The products were isolated by preparative g.l.p.c. (5 ft × 1/4 in., 20% Carbowax on Chromosorb W, 180°). The norbornenyl ester which was difficult to collect because of its volatility was collected with the aid of a collector that contained glass wool in the inlet and $CDCl_3$ in a bulb at the bottom. After every collection the tube was inverted carefully in order to dissolve the collected ester. Compound **4D** n.m.r. (60 MHz, $CDCl_3$) δ 6.18 (m,

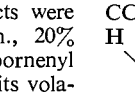


, 1.90 ± 0.10 H), 3.70 (s, —O—Me, 3.0 H), 2.95 (m, C-4—H, 1.0 H) 1.90 (unresolved quartet with fine structure, C-6, C-5 *exo*-H, *ca.* 2.0 H), 1.55 (m, C-7-*syn*- and *anti*-H, 2.0 H). The other products were also collected with a V-tube in which glass wool was placed in the part of the collector that was inserted into the preparative g.l.c. Compound **6D**; n.m.r. (60 MHz, CCl_4) δ 3.72 (s, —OMe, 3.0 H) 2.15 (m, C-4—H, 1.0 H), 1.90 (s, C-2; C-6—H, 1.90 H), 1.58 (d, C-7—H, 2.0 H), 1.45 (s, C-3; C-5—H, approximately 3H). Compound **7D** n.m.r. δ 3.70 (s, COOMe, 3H), 3.5 (m, H—C—O—CH_2—, 3H), 2.5 (m, C-4—H, 1H), 1.6 (m, norbornyl envelope, approximately 6H), 1.10 (t, —CH_3, 3H). Compound **8D** n.m.r. δ 4.0 (m, H—C—OH, 1H), 3.80 (s, COOMe, 3H), 3.0 (bs, —O—H, 1H), 2.30 (m, C-4—H, 1H), 2.0–1.1 (m, norbornyl envelope, approximately 6H). There was considerable simplification of the H—C—OH signal at 4.0 δ (Fig. 5) indicating that a deuteride shift results in the positioning of a deuterium *endo* at C-3. Compound **6D** mass spectrum (14 eV) 1.0% d_3, 13.4% d_2, 76.5% d_1, 9.3% d_0; 1.06 excess D per molecule.

Solvolysis of the Bromoester 1a

Run 1. The bromoester (0.1 g) was mixed with EtOH (4 ml), H_2O (1 ml), and NaOAc (0.040 g) and sealed in a tube. The tube was heated in refluxing toluene (112°) for 4 days and the contents were poured into water (50 ml) and extracted with pentane (1 × 25 ml, 2 × 15 ml). Analytical g.l.p.c. analysis on a 5 ft × 1/8 in. 5% SE-30 on Chromosorb W column with temperature programming (100–150° at 8°/min) and electronic area integration established the product distribution; methyl 1-norbornenecarboxylate 7.4%, methyl 1-nortricyclanecarboxylate 43.0%, unknown 0.2%, methyl *exo*-2-hydroxynorbornane-1-carboxylate 13.8%, methyl *exo*-2-ethoxynorbornane-1-carboxylate 31.8%, unknown 3.0%, unknown 0.6%, unknown 0.2%.

Run 2. The bromoester (1.24 g, 95–97% pure) was dissolved in 30 ml of solvolysis solution (EtOH 80 ml, H_2O 20 ml, NaOAc 1.6 g) and the solution (0.18 *M* ester, 0.2 *M* NaOAc) was sealed in a tube and heated on the steam bath (95°) for 6 days. The contents were poured into water (100 ml) saturated with NaCl and extracted with pentane (2 × 30, 3 × 20 ml). Analytical g.l.p.c. analysis on the 5 ft, 5% SE-30 column showed the four major products and *ca.* 15% starting material. The pentane layers were dried and distilled through a 1.5 ft helices packed column. Preparative g.l.p.c. on a 5 ft × 1/4 in. 20% SE-30 on Chromosorb W column at 165° gave the pure norbornenyl and nortricyclyl esters. The ether and alcohol were collected together then separated on a 10 ft × 3/8 in. 15% Carbowax on Chromosorb W column at 190°. Nuclear magnetic resonance (60 MHz, CCl_4): methylnorbornene-1-carboxylate, δ 6.05 (m,



, 2H), 3.70 (s, COOMe, 3H), 2.90 (m, C-4—H, 1H), 1.9 (m, C-5, C-6—*exo*-H, 2H), 1.5 (m, C-7-H, 2H), 1.1 (m, C-5, C-6—*endo*-H, 2H); methyl 1-nortricyclane-1-carboxylate δ 3.70 (s, COOMe, 3H), 2.10 (m, C-4—H, 1H), 1.90 (s, C-2, C-6—H, 2H), 1.5 (d, C-7—H, 2H), 1.20 (s, C-3, C-5-H, 4H); methyl *exo*-2-ethoxynorbornane-1-carboxylate δ 3.70 (s, COOMe, 3H), 3.3 (m, H—C—O—Et, 3H), 2.25 (m, C-4—H, 1H), 2.0–1.2 (m, norbornyl envelope, 8H), 1.10 (t, —O—CH_2—CH_3, 3H); methyl *exo*-2-hydroxynorbornane-1-carboxy-

late δ 4.0 (m, H—C—OH, 1H), 3.0 (bs, —O—H, 1H), 2.30 (m, C-4-H, 1H), 2.1–1.0 (m, norbornyl envelope, 8H).

Methoxide-catalyzed Elimination of HBr from ***1b***

The bromoester obtained via dideuteriodimide reduction (0.23 g, 0.00096 mol) was dissolved in 10 ml of a saturated solution of NaOMe in MeOH and the solution was refluxed for 24 h. The mixture was poured into water (30 ml) and extracted with ether (2 × 30 ml). The aqueous layer was acidified with dilute aqueous HCl and extracted with ether (2 × 30 ml). The ethereal layers were dried and the solvent was taken off on the rotatory evaporator to yield a solid. The solid was taken up in ether and treated with diazomethane. Analytical g.l.p.c. of the solution showed that the product ester had the same retention time as the material obtained from extraction of the basic solution. The two ethereal solutions were combined and the volume was reduced to *ca.* 3 ml by distillation through a 1-ft helices packed column. The methyl deuterionorbornene-1-carboxylate (0.075 g) was isolated by preparative g.l.p.c. In addition to the norbornenyl ester there were three minor products, the deuterionortricyclyl ester < 8%, unknown 4%, and *exo*-2-methoxynorbornyl ester < 8%. The latter product was isolated and its structure inferred from the mass spectrum (80 eV): *m/e* 186 (M^+, $C_{10}H_4O_2D_2$). Compound **4D** (Fig. 1) n.m.r. (100 MHz, CCl_4): δ 6.18 (d, C-2-H, J = 5 Hz), 6.03 (pair of doublets, C-3-H, J = 5.3 Hz), 3.70 (s, COOMe, 3H), 2.95 (m, C-4-H, 1H), 1.87 (A, B quartet with fine structure with higher field position coupled more than low-field position, C-6,C-5—*exo*-H's, respectively, < 2H), 1.5 (A, B quartet with fine structure, C-7-*syn*- and *anti*-H's, 2H), 1.2 (m, C-5, C-6-*endo*-H's < 0.3 H). Area integration analysis of the olefinic and methyl ester protons (average of 8 integrals) showed that there was only 1.95 hydrogens at C-2, C-3. This establishes that a deuteride shift occurs only to the extent of 5% during bromination of the dideuterionorbornylcarboxylic acid.

t-Butoxide-catalyzed Elimination of HBr from ***1c***

The deuteriobromoacid (0.25 g, m.p. 144–146°) was dissolved in a saturated solution of KO*t*Bu in *t*-BuOH (30 ml) and the mixture was refluxed for 7 h. The mixture was poured into water (25 ml) and acidified with dilute aqueous hydrochloric acid and extracted with ether (1 × 50, 2 × 25 ml). The ethereal layer was dried and treated with diazomethane. Analytical g.l.p.c. 5 ft × 1/8 in. 5% SE-30 on Chromosorb W column with temperature programming (100–150°) at 10°/min showed in order of increased retention time, methyl deuterio-2-norbornene-1-carboxylate (20%), unknown < 1%, methyl deuterio-2-norbornene-2-carboxylate 60%, unknown 1%, unknown 10%, unknown 10% as well as 3% of bromoester. The ester **5D** was isolated by preparative g.l.p.c. on a 5 ft × 1/4 in. 20% SE-30 on Chromosorb W column maintained at 160°. The n.m.r. spectrum (60 MHz, CCl_4) showed signals at δ 6.83 (d,  , J = 3.5 Hz, 1H), 3.70 (s, COOMe, 3H), 3.26 (m, C-1—H, 1H), 3.03 (m, C-4—H, 1H), 1.77 (m, C-5,C-6—*exo*-H's, 0.3 H), 1.42 (m, C-7-*syn*-H, 1H), 1.15 (m, C-7—*anti*-H, 1H), 1.09 (m, C-5, C-6—*endo*-H's, 1.86 H). Integration analysis of the methyl ester signal at 3.70 and the signals at 1.77 (*exo*-C—H) and 1.09 (*endo*-C—H) gave ratios which were consistent with the deuterium being 95% stereochemically pure *exo*.

Kinetic Procedure

Sample tubes were made from 10 mm pyrex tubing and washed exhaustively with distilled water and absolute ethanol and dried in an oven. The bromoesters used for the exploratory runs and run 1 (Table 2) were purified by preparative g.l.p.c. on a 5 ft × 1/4 in. 20% SE-30 on Chromosorb W at 170–180°. The bromoesters used in runs 2 and 3 (Table 2) were purified by high pressure liquid chromatography using a Waters Model 200 Chromatograph. The solvent system 15–20% $CHCl_3$ – 85–80% hexane (v/v) was used with a 3/8 in. × 3 ft Porasil A column (column volume 34 ml). At a flow rate of 0.7 ml/min (800 p.s.i.) the bromoester was eluted after approximately 80 ml of flow. After 10–12 injections of 45 μl of neat liquid the appropriate fractions were combined and the solvent was removed on the rotatory evaporator. Final purification was achieved by two bulb-to-bulb vacuum distillations. The 0.09 and 0.135 *M* NaOAc in 80:20 EtOH–H_2O solvolysis solutions were prepared by dissolving 0.68 g of NaOAc·$3H_2O$ and 0.79 g of anhydrous NaOAc, respectively, in 100 ml of 80:20 EtOH–H_2O solution which was 0.04 *M* in NaOAc. The water used in the EtOH–H_2O solution was distilled then doubly distilled from $KMmO_4$. The absolute ethanol was distilled prior to use. In a typical kinetic run 0.10–0.17 g of each ester was dissolved in 15.00 ml of solvolysis solution transferred by means of 10 and 5 ml volumetric pipettes. The solution was mixed and approximately 1.2 ml of the solution of each of the esters was transferred to the ampoules (10–12) which were flushed with dry nitrogen. The ampoules containing the deuterated and non-deuterated esters were sealed and simultaneously submerged completely in a Haake Model NBe bath maintained at around 115.00 ± 0.03° with ethylene glycol as solvent. Both deuterated and nondeuterated aliquots were withdrawn simultaneously at appropriate intervals and stored in the freezer. After the kinetic run was complete and infinity samples were obtained by suspending two samples in refluxing toluene for 1–2 weeks, the samples were removed and equilibrated to room temperature. An exact portion (1.00 ml) was removed from each aliquot, distilled water (1.0 ml), and 6 *N* HOAc (1.0 ml) and 2 drops of 0.1% eosin in 95% EtOH was added and the aliquot was titrated to a pink end point (41) with 0.0100–0.0150 *N* $AgNO_3$ using a 5.00 ml burette. Titers ranged from 0.4 to 3.5 ml. The results were subjected to least-squares analysis. An example of the data is described in Fig. 4.

Biosynthesis of Lycopodine. The Question of the Intermediacy of Piperidine-2-acetic Acid

W. D. MARSHALL, T. T. NGUYEN, D. B. MACLEAN, AND IAN D. SPENSER
Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1
Received August 12, 1974

W. D. MARSHALL, T. T. NGUYEN, D. B. MACLEAN, and IAN D. SPENSER. Can. J. Chem. **53**, 41 (1975).

In *Lycopodium tristachyum* lycopodine is derived from L-lysine whereas pipecolic acid is derived from D-lysine. Malonic acid serves as a specific precurser of the non-lysine derived segments of lycopodine. Piperidine-2-acetic acid is not incorporated into the alkaloid.

W. D. MARSHALL, T. T. NGUYEN, D. B. MACLEAN et IAN D. SPENSER, Can. J. Chem. **53**, 41 (1975).

Dans le *Lycopodium tristachyum*, la lycopodine dérive de la L-lysine alors que l'acide pipécolique dérive de la D-lysine. L'acide malonique sert de précurseur spécifique pour les segments de la lycopodine ne dérivant pas de la lysine. L'acide piperidine-2 acétique n'est pas incorporé dans l'alkaloïde. [Traduit par le journal]

Introduction

In the course of our studies of the biosynthesis of the *Lycopodium* alkaloids (1–6) it was found that acetate (2), lysine (**1**) (1, 2), cadaverine (**2**) (2, 6), Δ^1-piperideine (**3**) (4, 6), and pelletierine (**7**) (3, 4) serve as specific precursors of lycopodine (**8**). Activity from radioactively labelled samples of all these substrates is incorporated nonrandomly into the alkaloid. Radioactivity from all except pelletierine (**7**) is incorporated in such a manner that the two 'halves' of lycopodine, *i.e.*, the C_8 chains, C-1 to -8 and C-9 to -16, respectively, each contain 50% of the label. Pelletierine, which in another plant species is itself derived from lysine, cadaverine, Δ^1-piperideine, and acetate (7–9), enters only one of the 'halves' of lycopodine, the C_8 chain, C-9 to -16 (3, 4), of which it is an obligatory precursor (6). Pelletierine does not enter the C_8 chain, C-1 to -8, of lycopodine. To account for the apparent anomaly that pelletierine enters only one of the 'halves' of the lycopodine molecule whereas lysine, cadaverine, Δ^1-piperideine, and acetate, from which pelletierine is apparently derived, enter both halves, we proposed the biogenetic model outlined in Scheme 1 (6). The salient features of this scheme are that pelletierine (**7**), the precursor of the C_8 chain, C-9 to -16, of lycopodine, is derived from piperidine-2-acetoacetate (**6**) in an irreversible decarboxylation, that the piperidine-2-acetoacetate (or its coenzyme A derivative (**5**)) is the precursor of the C_8 chain, C-1 to -8, of lycopodine, and that a CO_2 unit is expelled from the system at some stage after combination of piperidine-2-acetoacetate with pelletierine. Provided the steady state concentration of pelletierine is small compared to that of its postulated precursor, piperidine-2-acetoacetate, all experimental observations (1–4, 6) are accounted for by this hypothesis (6).

Piperidine-2-acetoacetate (**6**) could, in turn, be derived from Δ^1-piperideine (**3**) by stepwise condensation with two units of malonyl coenzyme A. The coenzyme A derivative (**4**) of piperidine-2-acetate is predicted to be a stage on this proposed route to lycopodine. Since malonyl coenzyme A originates by carboxylation of acetyl coenzyme A (10) and since Δ^1-piperideine is likely to be derived, via cadaverine, from L-lysine (9), the previously observed incorporation pattern (1–4) would be accounted for.

In the present study several aspects of the biogenetic model outlined in Scheme 1 were examined experimentally. It is shown that, as predicted, malonate enters lycopodine. It is demonstrated that, as predicted, lycopodine is derived from L-lysine and not from D-lysine. It is shown that, contrary to prediction, piperidine-2-acetate is not an intermediate in the biosynthesis of lycopodine.

Results and Discussion

In principle, there are a number of ways in which the hypothesis outlined in Scheme 1

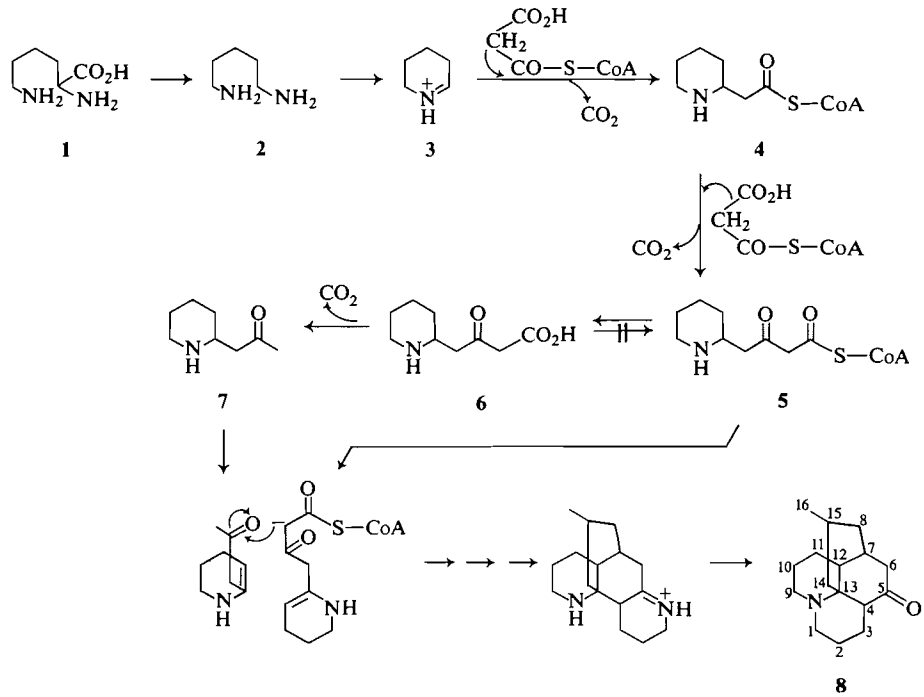

SCHEME 1. The biosynthesis of lycopodine. A hypothetical pathway consistent with published experimental evidence (1–4, 6).

could be tested by means of tracer experiments. The most direct approach, by an experiment with piperidine-2-acetoacetate which is predicted to enter the C_8 unit, C-1 to -8, as well as the pelletierine derived C_8 unit, C-9 to -16, of lycopodine, has not yet been feasible since the required substrate has not been described.[1] Several other approaches were therefore attempted.

Piperidine-2-acetoacetate (**6**) is postulated to arise by condensation of malonyl coenzyme A with piperidine-2-acetyl coenzyme A (**4**) and the latter, in turn, by addition of malonyl coenzyme A to Δ^1-piperideine (**3**), an established intermediate in lycopodine biosynthesis (4, 6).

The present work therefore focussed on testing the intermediacy of malonate and of piperidine-2-acetate in lycopodine biosynthesis.

The first set of the present experiments, aimed at the attempted demonstration that piperidine-2-acetic acid (**13**) serves as a precursor of lycopodine, gave an inconclusive result. Piperidine-2-acetic acid or, more precisely, its coenzyme A ester (**4**), is postulated by the hypothesis to be a precursor of piperidine-2-acetoacetic acid (**6**), and should, like the latter, be incorporated into both 'halves' of lycopodine. It should serve as a source of the C_7 units, C-1 to -7 and C-9 to -15. A sample of (±)-[*carboxyl*-^{14}C]piperidine-2-acetate was prepared in 57% radiochemical yield by the conventional steps, outlined in Scheme 2, which are fully described in the Experimental section. A sample of this compound (100 μCi) was administered to cuttings of *Lycopodium tristachyum* (Experiment 18). The lycopodine which was isolated showed radioactivity but the specific activity of the alkaloid after rigorous purification was too low (approximately 3 d.p.m./mg above background) to permit conclusions to be drawn, since the low activity precluded degradation of the sample.

In another experiment (Experiment 19) a sample of the (±)-[*carboxyl*-^{14}C]piperidine-2-acetate (20 μCi) was administered to *L. tristachyum* cuttings in admixture with DL-[*4*-^3H]-lysine (100 μCi). The lycopodine which was

[1]The ethyl ester of the corresponding carbinol has now been prepared (I. Noguchi and D. B. MacLean, unpublished work, 1973) and the synthesis of a ^{14}C-labelled sample is in hand.

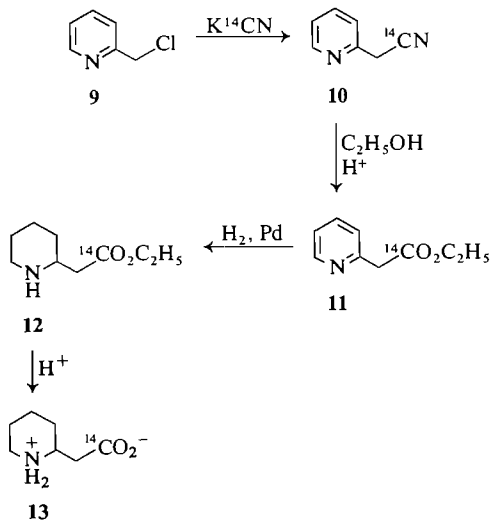


SCHEME 2. Synthesis of [*carboxyl-*^{14}*C*]piperidine-2-acetic acid.

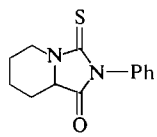
isolated showed a specific activity relative to ^{14}C (approximately 2 d.p.m./mg) not greatly different from that of the sample obtained in the earlier experiment.

The high ^{3}H/^{14}C ratio of the sample of lycopodine (^{3}H/^{14}C = 82 ± 3) indicated that biosynthesis of the alkaloid had taken place during the experiment and that lysine (*i.e.*, ^{3}H) had been incorporated *ca.* 17 times as efficiently as (±)-piperidine-2-acetate (*i.e.*, ^{14}C). This result raised further doubts regarding the intermediacy of this compound.

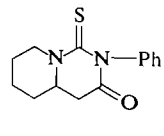
A second approach to test the hypothesis outlined in Scheme 1 was based on the predicted intermediacy of malonate. If ^{14}C-labelled malonate were incorporated into lycopodine, the labelling pattern to be expected would be identical with that found after administration of correspondingly labelled [^{14}*C*]acetate (2). Activity from [*1-*^{14}*C*]malonate should thus be equally distributed among C-7 and -15 of lycopodine, each of these containing 50% of the total activity of the alkaloid. Activity from [*2-*^{14}*C*]malonate should be equally distributed among C-6, -8, -14, and -16 of lycopodine, each of these containing 25% of the total activity of the alkaloid.

Activity from [*1-*^{14}*C*]malonate was indeed incorporated into lycopodine (Experiment 20). Consistent with prediction, half of this activity was located at C-15 of the lycopodine (Kuhn–Roth acetate (C-15, -16) minus Schmidt methylamine (C-16), Table 3). As in the last experiment, the ^{14}C tracer (250 μCi) was administered in admixture with DL-[*4-*^{3}*H*]lysine (1 mCi).[2] It is of interest that in this experiment it was the malonate (*i.e.*, ^{14}C) which was incorporated into the lycopodine (^{3}H/^{14}C = 0.74 ± 0.01) *ca.* 14 times[3] as efficiently as the lysine (*i.e.*, ^{3}H).

If piperidine-2-acetate were a precursor of lycopodine, its formation from lysine and malonate, at a time when these are incorporated into lycopodine, would be mandatory. It should then be present in the system from which ^{3}H,^{14}C-labelled lycopodine was isolated after administration of a mixture of [^{3}*H*]lysine and [^{14}*C*]malonate, and should, under these conditions, show a ^{3}H/^{14}C ratio identical with that of lycopodine. Piperidine-2-acetic acid was isolated from the plant material from this experiment (Experiment 20) by carrier dilution. After purification by column chromatography (Dowex 50W-X4, H^+) and derivatization by reaction with phenylisothiocyanate, the sample contained tritium (specific activity 3.0 (±0.1) × 10^4 d.p.m./mmol) but no ^{14}C. Even though it appeared to be present in the system,[4] piperidine-2-acetate clearly did not play a part in the biosynthesis of lycopodine, since it did not show a ^{3}H/^{14}C ratio identical with that of the product.



14



15

[2]Incorporation into lycopodine of tritium from DL-[*4-*^{3}*H*]lysine, without loss relative to C-6 of lysine, was demonstrated by a separate experiment (Experiment 22, *vide infra*).

[3]Since in the course of incorporation one of the carboxyl groups of malonate is expelled, one half of the activity administered as malonate must be lost as carbon dioxide.

[4]Piperidine-2-acetic acid does not appear to have been isolated from natural sources. The natural occurrence of the compound, apparently indicated by the tritium content of the trapped sample of piperidine-2-acetic acid must be regarded as questionable on the basis of the absence of ^{14}C.

It is very likely that tritium activity of the sample was due to contamination by traces of pipecolic acid. The method adopted to re-isolate piperidine-2-acetate from the plant extract to which piperidine-2-acetate had been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Having obtained inconclusive results concerning the intermediacy of piperidine-2-acetate in lycopodine biosynthesis by direct feeding experiments (Experiments 18 and 19) and having found strong indication against its involvement by a trapping experiment, we made a further attempt to obtain a conclusive result.

With the demonstration that malonate, like acetate, served as a specific precursor of lycopodine, [2-^{14}C]malonate was employed in this third approach to test the biosynthetic intermediacy of piperidine-2-acetate.

Activity from [2-^{14}C]malonate should enter lycopodine in the same manner as activity from [2-^{14}C]acetate, supplying C-6, -8, -14, and -16, each of which should contain 25% of the activity of intact lycopodine. If piperidine-2-acetate were an intermediate in lycopodine biosynthesis according to Scheme 1, two of these carbon atoms, C-6 and -14, would originate from malonate via the α-methylene group of piperidine-2-acetate. The other two carbon atoms, C-8 and -16, would arise more directly from malonate. It follows that in a tracer experiment with [2-^{14}C]malonate, incorporation of activity into C-6 and -14 of lycopodine but not into C-8 and -16 should be suppressed in the presence of inactive piperidine-2-acetate, if this were an intermediate.

Thus, if piperidine-2-acetate were not an obligatory intermediate, addition of unlabelled piperidine-2-acetate would not affect entry of ^{14}C from [2-^{14}C]malonate into the four carbon atoms, C-6, -8, -14, -16. Each of these would contain one quarter of the label of the intact lycopodine derived from [2-^{14}C]malonate, regardless of whether inactive piperidine-2-acetate were added to the system or not.

However, if piperidine-2-acetate were an obligatory intermediate on the route from malonate into lycopodine, addition of inactive piperidine-2-acetate to the system would suppress entry of label from [2-^{14}C]malonate into the two carbon atoms, C-6 and -14, but not into the two carbon atoms, C-8 and -16. It follows that under these conditions, the four carbon atoms in question, derived from [2-^{14}C]malonate, would no longer be equally labelled.

The two carbon atoms, C-6 and -14, each should contain less activity than the two carbon atoms, C-8 and -16. In the limit, suppression of incorporation of label into C-6 and -14 by carrier piperidine-2-acetate would be complete, so that all activity from [2-^{14}C]malonate would be equally divided between C-8 and -16, each of which would now contain 50% of the activity of intact lycopodine.

Thus, if the lycopodine, derived from an experiment in which [2-^{14}C]malonate were administered in the presence of excess inactive piperidine-2-acetic acid, yielded Kuhn–Roth acetate (C-15, -16) and Schmidt methylamine (C-16), each containing one quarter of the activity of the intact alkaloid, piperidine-2-acetate is not an intermediate of lycopodine biosynthesis. If Kuhn–Roth acetate and Schmidt methylamine were obtained containing more than one quarter and up to one half of the activity of the intact alkaloid, the intermediacy of piperidine-2-acetate would be established.

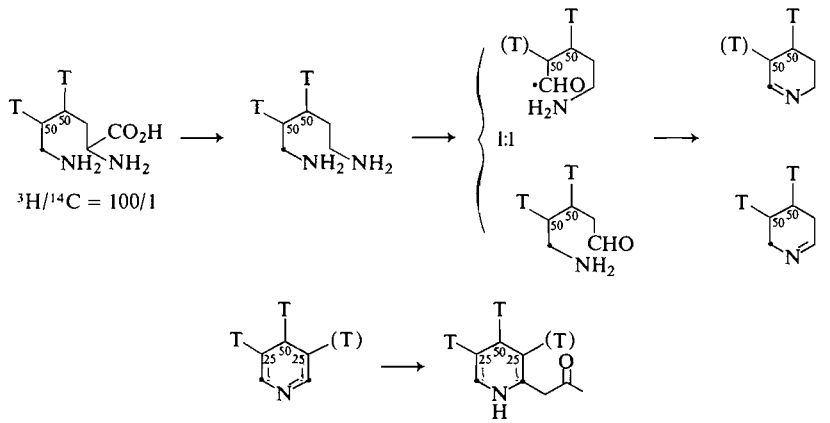
In the event, lycopodine, isolated from an experiment in which [2-^{14}C]malonate was administered in the presence of inactive piperidine-2-acetic acid (Experiment 21), contained one quarter of its activity at the *C*-methyl group (C-16, methylamine) (Table 3). Thus, piperidine-2-acetate cannot be an intermediate.

A fourth approach which was followed con-

---

added as carrier (see Experimental), is not specific for this compound but is an adaptation of a general method for the isolation of secondary amino acids. Pipecolic acid, among other compounds, is also separated by this procedure.

The two compounds were isolated in the form of their crystalline condensation products with phenylisothiocyanate (**14** and **15**). These can be readily differentiated by physical methods (see Experimental) but persistent attempts to achieve chromatographic separation failed. The presence of contaminating pipecolic acid in the trapped sample of piperidine-2-acetic acid could thus not be detected by radiochromatography. A further trapping experiment strongly suggested that activity was due mainly, if not entirely, to pipecolic acid. An inactive sample of the phenylisothiocyanate adduct of pipecolic acid (**14**) (10 mg) was added to the mother liquors from the crystallization of the ^{3}H-containing sample of the piperidine-2-acetic acid adduct (**15**). The pipecolic acid derivative (**14**) was then re-isolated. After repeated crystallization of the two derivatives, (**14**) and (**15**), the pipecolic acid derivative (**14**) showed a specific activity two orders of magnitude higher (2×10^4 d.p.m./mg) than the derivative of piperidine-2-acetic acid (**15**) (1.1×10^2 d.p.m./mg). It is very likely, therefore, that the activity associated with the sample of piperidine-2-acetic acid found in Experiments 20 was due to contamination with traces of pipecolic acid, and that piperidine-2-acetic acid does not occur naturally in *L. tristachyum*.



SCHEME 3. Predicted mode of incorporation of [4,5-$^3H_2$,6-^{14}C]lysine into lycopodine (2).

currently with the above experiments to evaluate the hypothesis, that piperidine-2-acetate was an intermediate of lycopodine biosynthesis, was based on stereochemical considerations. Its primary objective was to investigate whether the same enantiomer of lysine was incorporated into both.

It is known that the piperidine nucleus of several piperidine alkaloids is derived from L-lysine whereas pipecolic acid, isolated from the same sources, is derived from D-lysine (8). This was demonstrated by a new technique whereby the chirality of a precursor–product relationship can be determined by tracer experiments with doubly labelled substrate. Provided intact incorporation of ^3H,^{14}C-labelled racemate of a substrate into a product has been shown to take place with maintenance of the $^3H/^{14}C$ ratio, it is possible to determine, by the use of a multiply labelled substrate in which one enantiomer is labelled with tritium while the other is labelled not only with tritium but also with ^{14}C, which of the enantiomers of the substrate is incorporated into the product (8).

Before this technique could be applied to the study of the chirality of the conversion of lysine into lycopodine, incorporation of activity from a ^3H,^{14}C-labelled sample of DL-lysine into lycopodine without change in $^3H/^{14}C$ ratio had to be demonstrated. The entry into lycopodine of an intact C_5 fragment (C-2 to -6 of lysine), derived from lysine by decarboxylation, may be inferred from earlier work on the incorporation of DL-[2-^{14}C]- and DL-[6-^{14}C]-lysine, [1-^{14}C]cadaverine, and [2-^{14}C]- and [6-^{14}C]-Δ^1-piperideine (1, 2, 4, 6).

In an earlier feeding experiment with a doubly labelled sample of lysine, DL-[4,5-$^3H_2$,6-^{14}C]lysine, incorporation into lycopodine was accompanied by 22% loss of tritium, relative to ^{14}C (Experiment 5) (2). A maximum loss of 25% of tritium, relative to ^{14}C, may be accounted for, without breakdown of the carbon skeleton of lysine other than loss of the carboxyl group, by removal of tritium from C-5 of lysine, as shown in Scheme 3 (2).

It can be predicted on the basis of this scheme, that a sample of DL-[4-^3H,6-^{14}C]lysine should enter lycopodine without change in $^3H/^{14}C$-ratio. That this is indeed the case is shown by

the result of Experiment 22 (Table 2) in which a sample of DL-[4-^3H,6-^{14}C]lysine[5] ($^3H/^{14}C$ = 12.5 ± 0.2) was administered to *L. tristachyum* cuttings. The lycopodine ($^3H/^{14}C$ = 13.0 ± 0.1) as well as the pipecolic acid ($^3H/^{14}C$ = 12.9 ± 0.1) which were isolated from this plant material were found to maintain the $^3H/^{14}C$ ratio of the substrate.

This finding confirms the view (2) that the change in the $^3H/^{14}C$ ratio, observed in the earlier experiment with DL-[4,5-$^3H_2$,6-^{14}C]lysine (Experiment 5) (2), was due entirely to loss of tritium from C-5 of lysine in the course of its incorporation into lycopodine.

With the demonstration that DL-[4-^3H,6-^{14}C]-lysine enters lycopodine without change in $^3H/^{14}C$ ratio, together with the earlier evidence on the mode of incorporation of lysine into lycopodine, the necessary conditions have been met to determine the chirality of the precursor–product relationship by means of the tracer method referred to earlier.

Samples of DL-[4,5-$^3H_2$]/D-[6-^{14}C]lysine and of L-[4,5-$^3H_2$]/DL-[6-^{14}C]lysine were administered in separate experiments to cuttings of *L. tristachyum* (Experiments 23 and 24), and lycopodine and pipecolic acid were isolated from the plants (Table 2). Comparison of the $^3H/^{14}C$ ratios of substrate and products[6] (Table 4) clearly indicates that lycopodine is derived from L-lysine whereas pipecolic acid is derived largely, if not exclusively, from D-lysine. These results are analogous to those obtained with other plant species in which piperidine alkaloids are derived entirely from L-lysine while L-pipecolic acid is generated almost totally from D-lysine (8).

[5]That the labelled components of this substrate, [4-^3H]lysine and [6-^{14}C]lysine, used in Experiment 22, were indeed racemates was shown in a separate experiment (8). A mixture of the two labelled samples ($^3H/^{14}C$ = 8.1 ± 0.1) was subjected to the action of L-lysine decarboxylase (*ex Bacillus cadaveris*, Sigma Chemical Co.). The resulting cadaverine ($^3H/^{14}C$ = 7.7 ± 0.1), originating by decarboxylation of L-lysine, and the unreacted D-lysine which was recovered ($^3H/^{14}C$ = 8.1 ± 0.1), each maintained the $^3H/^{14}C$ ratio of the original mixture, within experimental error. This shows that each of the labelled components of the [4-^3H,6-^{14}C]lysine used as the substrate in Experiment 22 had indeed been a racemic mixture.

[6]A correction factor was applied to the observed $^3H/^{14}C$ ratio of lycopodine, to allow for the established loss of ^3H (~22%) in the course of the incorporation of [4,5-$^3H_2$]lysine into lycopodine, now shown to be from C-5 by the results of Experiments 22 and 5.

Since lycopodine is derived exclusively from L-lysine, intermediates of lycopodine biosynthesis must also be derived from L-lysine. It follows that a condition for the intermediacy of piperidine-2-acetate in lycopodine biosynthesis was its derivation from L-lysine. Experiments to test this condition were not attempted when it emerged from the other evidence, described earlier, that piperidine-2-acetate was not an intermediate in the biosynthesis of lycopodine.

It is clear that the hypothesis of lycopodine biosynthesis outlined in Scheme 1 requires modification. If piperidine-2-acetoacetate does serve as an intermediate, its derivation from L-lysine and malonate (or acetate) cannot proceed by way of free piperidine-2-acetate.

Experimental

Labelled Compounds

Sodium [1-^{14}C]malonate (Experiment 20), sodium [2-^{14}C]malonate (Experiment 21), DL-[4-^3H]lysine (Experiments 19, 20, 22), DL-[4,5-$^3H_2$]lysine (Experiment 23), L-[4,5-$^3H_2$]lysine (Experiment 24) and DL-[6-^{14}C]lysine (Experiments 22, 24) were commercial products (see Tables 1 and 2). D-[6-^{14}C]Lysine was prepared from DL-[6-^{14}C]lysine by destruction of the L-enantiomer by means of L-lysine decarboxylase (8). (±)[carboxyl-^{14}C]-Piperidine-2-acetic acid was prepared from potassium [^{14}C]cyanide, as described below. The intermolecularly doubly labelled samples of lysine which were used in Experiments 22–24 were prepared by mixing suitable quantities of the above tracers. Nominal total activities, and the $^3H/^{14}C$ ratios of the doubly labelled samples, determined by liquid scintillation counting, are given in Tables 1 and 2.

*(±)-[carboxyl-^{14}C]Piperidine-2-acetic Acid (**13**)*

*[cyano-^{14}C]Pyridine-2-acetonitrile (**10**) (**11**)*

2-Chloromethylpyridine hydrochloride (**9**) (270 mg) (2-picolyl chloride, Aldrich Chemical Co., recrystallized from ethanol–ether, m.p. 128–130°) was dissolved in a little water, sodium bicarbonate solution (10% w/v) was added and the free base was extracted into chloroform (3 × 5 ml). The chloroform solution was dried (anhydrous sodium sulfate) and filtered, and the solvent was evaporated, leaving 2-chloromethylpyridine (200 mg) as an oily liquid. Potassium cyanide (1.2 mg, nominal total activity 1 mCi, nominal specific activity 54 mCi/mmol, Amersham Searle) was washed into the reaction flask with aqueous ethanol (5 ml, 60% v/v). Nonradioactive potassium cyanide (113 mg) was added as carrier, together with potassium iodide (12 mg). The mixture was refluxed with stirring. A drying tube containing solid potassium hydroxide was attached to the condenser during this operation to absorb any gaseous hydrogen [^{14}C]cyanide which might be liberated. The mixture was kept overnight and was then concentrated with repeated addition of water until all ethanol had been distilled off. Saturated aqueous sodium carbonate (5 ml) was added and the mixture continuously extracted with ether for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

24 h and then for another 24 h with a new portion of ether. The combined ether extract was evaporated with a stream of nitrogen. The residue was distilled at 60° and 10^{-2} mm yielding a liquid whose R_f value (t.l.c., silica gel 0.2 mm, ether–chloroform, 1:1, R_f 0.56) was identical with that of an authentic sample of inactive pyridine-2-acetonitrile (11); n.m.r. spectrum, δ 3.8 (s, 2H), 7.4 p.p.m. (m, 4H); i.r. spectrum, 2230 cm^{-1} (CN).

*Ethyl [carboxyl-^{14}C]Pyridine-2-acetate (**11**) (11)*

The above nitrile was dissolved in ethanol, the solution was cooled to −20° and kept at that temperature with stirring, while a stream of dry hydrogen chloride gas was passed through it. The mixture was refluxed overnight, ethanol was distilled off, the residue was dissolved in water (10 ml), the solution transferred into a liquid–liquid extractor, basified with saturated aqueous sodium carbonate (10 ml) and extracted 2 × 24 h with ether. The ether extract was evaporated in a stream of nitrogen and the residue distilled at 90° and 10^{-2} mm, yielding an oil which was identical on t.l.c. (silica gel 0.2 mm, ether–chloroform, 1:1, R_f 0.60) with an authentic sample of inactive ethyl pyridyl-2-acetate (11); n.m.r. spectrum, δ 3.9 (s, 2H), 7.4 (m, 4H), 1.4 (t, 3H) 4.3 p.p.m. (q, 2H).

*[carboxyl-^{14}C]Piperidine-2-acetic Acid (**13**) (12)*

The above ester was transferred into a 50 ml hydrogenation flask and hydrochloric acid (10%, 10 ml) and Adams' catalyst (40 mg) was added. Hydrogenation was carried out at room temperature and atm. pressure for 15 h. The catalyst was filtered off, rinsed with hydrochloric acid (10%, 20 ml) and the combined filtrate refluxed for 10 h. The solvent was evaporated *in vacuo* and the residue sublimed at 120° and 10^{-2} mm. The sublimate was recrystallized from methanol–ether. [*carboxyl*-^{14}C]-Piperidine-2-acetic acid hydrochloride (158 mg) was obtained as colorless needles. The purity of the product was checked by thin-layer radiochromatography (silica gel, 0.2 mm, 1-butanol – acetic acid – water, 4:2:1). A single radioactive peak, R_f 0.4, appeared which was identical in R_f value with that given by an authentic specimen of the product (*vide infra*). The specific activity of the product was 0.63 mCi/mmol, its total activity 0.57 mCi (57% radiochemical yield).

Piperidine-2-acetic Acid

(*i*) By chromic acid oxidation of 2-(2-piperidine)ethan-1-ol (13): A mixture of chromium trioxide (20 g), concentrated sulfuric acid (40 g) and water (300 ml) was added dropwise with stirring to an ice-cooled solution of 2-(2-piperidine)ethan-1-ol (10 g) (2-piperidineethanol, Aldrich Chemical Co.) in water (10 ml). Addition was completed after 1 h and stirring continued for 3 h at room temperature. The solution was basified with saturated barium hydroxide solution, excess barium precipitated with carbon dioxide and the mixture filtered through celite. The filtrate was evaporated and the residue was dissolved in methanol. On addition of ether the product, (±)-piperidine-2-acetic acid (8 g, 72%) crystallized in colorless needles; m.p. 217–218° (lit. (12) m.p. 212°); (mass spectrum, molecular ion *m/e* 143). A small sample was converted into the *hydrochloride salt* which was purified by sublimation at 120° and 10^{-2} mm; m.p. 180–182° (lit. (13) m.p. 180–182°; (12) 182–185°); i.r. spectrum, 1730 cm^{-1} (C=O), 2800–3300 cm^{-1} (NH_2^+).

(*ii*) By hydrogenation of ethyl pyridine-2-acetate (**11**) (12): Ethyl pyridine-2-acetate (165 mg) was hydrogenated in aqueous hydrochloric acid (10 ml, 6 *M*) in the presence of Adams' catalyst at room temperature and atm. pressure for 10 h. The mixture was filtered, the filtrate neutralized with aqueous sodium bicarbonate and the product extracted into chloroform. The extract was dried (anhydrous sodium sulfate) the solvent evaporated and the residue distilled at 80° and 10^{-2} mm. Ethyl piperidine-2-acetate (**12**) (150 mg, 88%) was obtained as a yellow oil; mass spectrum, molecular ion *m/e* 171; n.m.r. spectrum δ 1.3 (t, 3H), 4.1 (q, 2H), 1.9 p.p.m. (s, 1H); i.r. spectrum, 1730 cm^{-1} (ester). Acid hydrolysis of a small sample of the ester gave piperidine-2-acetic acid (**13**), identical with the sample prepared by method *i*.

Tracer Experiments

In each of the seven feeding experiments radioactive tracer was administered to excised shoots of *Lycopodium tristachyum*. The method has been described in earlier papers (2, 6). The details of the seven experiments are summarized in Tables 1 and 2.

Isolation of Lycopodine, Pipecolic Acid, and Piperidine-2-acetic Acid

The shoots of *L. tristachyum* were dried and ground to a fine powder in a blender. The powder was continuously extracted with methanol for 48 h. Solvent was changed after 24 h. The extract was concentrated to remove all methanol, dilute hydrochloric acid (5%, 200 ml) was added, the mixture stirred for 2 h, and filtered through celite. The filtrate was washed with ether (3 × 50 ml) and was then basified with dilute ammonia and extracted with chloroform (3 × 150 ml). Lycopodine was isolated from the chloroform extract, pipecolic and piperidine-2-acetic acid from the aqueous layer.

Lycopodine (6)

The chloroform extract was dried and evaporated, the residue extracted repeatedly with hexane, the extract was dried (anhydrous sodium sulfate) and evaporated. The residue was dissolved in benzene and applied to a short column of alumina. Lycopodine was eluted with benzene and was purified to constant activity by crystallization from hexane followed by sublimation at 110° and 5 × 10^{-3} mm.

Pipecolic Acid (8)

The basified filtrate from which lycopodine had been removed by chloroform extraction was concentrated on the steam bath after inactive DL-pipecolic acid (100 mg) had been added as carrier. The residue was redissolved in water, a little charcoal was added, the suspension filtered through cotton and the filtrate applied to a column (18 × 1.5 cm) of Dowex 50W-X4 (H^+ form). The column was eluted with water until the eluate no longer contained carbohydrates as detected by the Molisch test (α-naphthol – concentrated sulfuric acid). Amino acids were eluted from the washed column with 1 *M* ammonia (approximately 200 ml). Pipecolic acid, m.p. 280–281°, 15–20 mg, was isolated from the eluate by the nitrosation method described earlier (8).

*Phenylisothiocyanate Condensation Product of Pipecolic Acid (Perhydro-3-oxo-2-phenyl-1-thioimidazo[1,5-a]pyridine) (**14**)*

Pipecolic acid (20 mg) was dissolved in aqueous pyridine (50% v/v, 3 ml) and the p*H* of the mixture adjusted

TABLE 3. Incorporation of malonate into lycopodine

[a]See ref. 8. In an experiment with DL-[^{3}H]/D-[^{14}C]substrate, % of product derived from D-substrate = $50 \times \frac{^3H/^{14}C \text{ in substrate}}{^3H/^{14}C \text{ in product}}$.
[b]See ref. 8. In an experiment with L-[^{3}H]/DL-[^{14}C]substrate, % of product derived from L-substrate = $50 \times \frac{^3H/^{14}C \text{ in product}}{^3H/^{14}C \text{ in substrate}}$.
[c]These values for the $^3H/^{14}C$ ratio of lycopodine are the observed values (Table 2), corrected for loss of tritium from C-5 of lysine in the course of its incorporation into lycopodine. The correction factor is (10.7 ± 0.2)/(8.4 ± 0.1) (see Expts. 5 and 22, and footnote 6).

to p*H* 8.6 with sodium carbonate. Freshly distilled phenylisothiocyanate (4 drops) was added and the mixture heated 2 h at 40°. The mixture was acidified with dilute hydrochloric acid and extracted with chloroform (2 × 2 ml). The extract was concentrated, the oily residue dissolved in methanolic hydrochloric acid (1 *M*, 5 ml) and the solution heated 1 h at 80°. Solvent was evaporated and the title product (25–35 mg) crystallized from methanol; m.p. 162–163°; i.r. spectrum, 1740 cm^{-1} (C=O), 1210 cm^{-1}, no absorption above 3100 cm^{-1}; mass spectrum, molecular ion *m/e* 246 (base peak), M − 29, M − 33, M − 111.

Anal. Calcd. for $C_{13}H_{14}N_2OS$: C, 63.4; H, 5.7; N, 11.4. Found: C, 63.3; H, 5.9; N, 11.3.

Piperidine-2-acetic Acid

DL-Piperidine-2-acetic acid (50 mg) was added to the basified aqueous filtrate from the plant extract from which lycopodine had been removed by extraction with chloroform. The re-isolation procedure of piperidine-2-acetic acid was similar to that for the isolation of pipecolic acid. The mixture was concentrated, treated with charcoal, and applied to a column of Dowex 50W-X4 (H^+ form). The column was washed, amino acids eluted with 1 *M* ammonia, the eluate evaporated, the residue acidified with hydrochloric acid (6 *M*, 5 ml) and sodium nitrite (1 g) was added in small portions. After 1 h the solution was extracted with ether (4 × 15 ml), the extract dried (anhydrous sodium sulfate) and evaporated. The residue, containing nitroso derivatives of secondary amino acids, was heated 15 min with concentrated hydrochloric acid (2 ml). The solution was evaporated and the residue applied to a second column (10 × 1 cm) of Dowex 50W-X4 (H^+ form) which was washed with water. The product was eluted with 1 *M* ammonia, eluate being collected until no more radioactivity emerged from the column.

The ammoniacal eluate was evaporated, the residue dissolved in aqueous pyridine (50% v/v, 5 ml) and the p*H* adjusted to 8.6 with sodium carbonate. Freshly distilled

phenylisothiocyanate (5 drops) was added, the mixture was heated 2 h at 40°, acidified and extracted with chloroform (2 × 2 ml). The extract was dried and evaporated, the residual oil hydrolyzed by heating 1 h at 80° with hydrochloric acid (1 *M*) in aqueous methanol. The solvent was evaporated and the phenylisothiocyanate condensation product of piperidine-2-acetic acid (perhydro-3-oxo-2-phenyl-1-thiopyrido[1,2-*c*]-pyrimidine) (**15**) (7 mg), recrystallized from methanol; m.p. 195–196°; i.r. spectrum 1715 cm^{-1} (C=O), 1210 cm^{-1}, no absorption above 3100 cm^{-1}; mass spectrum: molecular ion *m/e* 260 (base peak), M − 29, M − 43, M − 125.

Mol. Wt. Calcd. for $C_{14}H_{16}N_2OS$: 260.098. Found (high resolution mass spectrum of molecular ion): 260.099.

Anal. Calcd. for $C_{14}H_{16}N_2OS$: C, 64.6; H, 6.2; N, 10.8; S, 12.3. Found: C, 64.6; H, 6.3; N, 10.8; S, 12.2.

Degradation of Lycopodine

Carbons-15 and -16 as Acetic Acid

The Kuhn–Roth oxidation of lycopodine was carried out essentially as described in an earlier paper (2) and the resulting acetic acid converted into acetyl-α-naphthylamide, m.p. 157–159°.

Carbon-16 as Methylamine

The Kuhn–Roth acetate was further degraded to methylamine by the Schmidt reaction, as described in an earlier publication (14). The methylamine so obtained has converted into the β-naphthoyl derivative, m.p. 111–112° (sealed capillary).

Determination of Radioactivity

Radioactivity was determined by liquid scintillation counting (Mark I Liquid Scintillation Computer, Nuclear Chicago Corp., Model 6860). Activity due to ^3H and ^{14}C was determined simultaneously, by external standardization counting with ^{133}Ba.

'Aquasol' (New England Nuclear Corp.) (10 ml) was used as the counting medium. Triplicate samples of each compound were counted under comparable conditions of quenching. Confidence limits shown in the results are standard deviations of the mean. For highly quenched samples the confidence limit of the quench correction curves were ±5%.

We thank Dr. A. I. Meyers, Louisiana State University of New Orleans, for a generous sample of DL-piperidine-2-acetic acid. This work was supported by a grant from the National Research Council of Canada.

Infrared Studies of Water in Crystalline Hydrates: $K_2FeCl_5 \cdot H_2O$ (Erythrosiderite) and Related Aquopentachloroferrates(III)[1]

MICHAEL FALK AND CHUNG-HSI HUANG

Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia B3H 3Z1

AND

OSVALD KNOP

Department of Chemistry, Dalhousie University, Halifax, Nova Scotia B3H 4J3

Received July 22, 1974

MICHAEL FALK, CHUNG-HSI HUANG, and OSVALD KNOP. Can. J. Chem. **53**, 51 (1975).

Infrared spectra of $M_2[FeCl_5(H_2O)]$ (M = K, Rb, NH_4) at different degrees of deuteration were recorded, between 4000 and 300 cm^{-1}, at 30 and −160 °C. The spectra of the three compounds were closely similar, as was that of natural $K_2[FeCl_5(H_2O)]$ (*erythrosiderite*). They indicate the existence of only one type of water molecule in the structure. The water molecules are symmetric, well separated from one another, and engage in O—H . . . Cl bonds with O . . . Cl distances of about 3.22 Å, as estimated from the OH and OD stretching frequencies. These conclusions support the structure proposed for $K_2[FeCl_5(H_2O)]$ by Bellanca and lead to approximate location of the H atoms. The observed mixing of the librational and translational modes, which occurs when the frequencies of translational modes are high, may be characteristic of H_2O molecules coordinated to cations of high charge.

MICHAEL FALK, CHUNG-HSI HUANG et OSVALD KNOP. Can. J. Chem. **53**, 51 (1975).

Les spectres infrarouge de $M_2[FeCl_5(H_2O)]$ (M = K, Rb, NH_4) ont été enregistrés, entre 4000 et 300 cm^{-1}, à 30 et −160 °C et à différents degrés de deutération. Ces spectres, comme celui du $K_2[FeCl_5(H_2O)]$ naturel (*érythrosidérite*), se ressemblent d'une manière frappante. Ils indiquent que la structure cristalline ne contient qu'un seul type de molécule d'eau. Les molécules d'eau sont symétriques, bien isolées les unes des autres, et forment des liaisons hydrogène O—H . . . Cl, dont la distance interatomique O . . . Cl, estimée à partir des valeurs des fréquences OH et OD, est proche de 3.22 Å. Ces résultats corroborent la structure proposée pour $K_2[FeCl_5(H_2O)]$ par Bellanca. Ils permettent aussi d'estimer les positions des atomes d'hydrogène. Les modes mixtes de libration et de translation, observés pour ces composés, et qui sont dus à de hautes fréquences des modes de translation, peuvent être charactéristiques de molécules d'eau coordonnées à des cations de charge élevée.

The spectroscopic properties of water molecules strongly coordinated to cations of high charge have received relatively little systematic attention. For example, not much reliable information exists on the effect of cationic size and charge on the strength and geometry of the hydrogen bonds formed by such H_2O molecules (1). To extend our knowledge of the behavior of H_2O in aquocomplexes of this type we have studied the i.r. spectra, between 4000 and 300 cm^{-1}, of polycrystalline $M_2FeCl_5.H_2O$ = $M_2[FeCl_5(H_2O)]$ (M = K,[2] Rb, NH_4) at different temperatures and degrees of deuteration. The low water content and the favorable crystallographic features make these compounds well suited for a detailed investigation. The region below 600 cm^{-1} in the spectra of all three compounds (undeuterated and fully deuterated) was previously investigated by Adams and Lock (2) in the i.r. and by Adams and Newton (3) in the Raman (below 400 cm^{-1}); the Raman spectrum of the NH_4 compound was reported also by Cotton and Gibson (4). However, the frequencies above 600 cm^{-1} do not appear to have been studied in any compounds of the general formula $M_2[XCl_5(H_2O)]$.

Experimental

Ruby-red crystals of $K_2FeCl_5.H_2O$ were obtained by slow evaporation of mixed aqueous solutions of $FeCl_3$ and KCl, acidified with HCl, at about 40 °C.

Anal. Calcd. for $K_2FeCl_5.H_2O$: Fe, 16.96; Cl, 53.83; H_2O, 5.47. Found: Fe, 16.94(5); Cl, 53.50(13); H_2O, 5.43(4).

Deuterated crystals were prepared in a similar manner using mixtures of H_2O and D_2O, or by recrystallization of

[1]NRCC No. 14310.

[2]$K_2FeCl_5.H_2O$ occurs in nature as the mineral *erythrosiderite*.

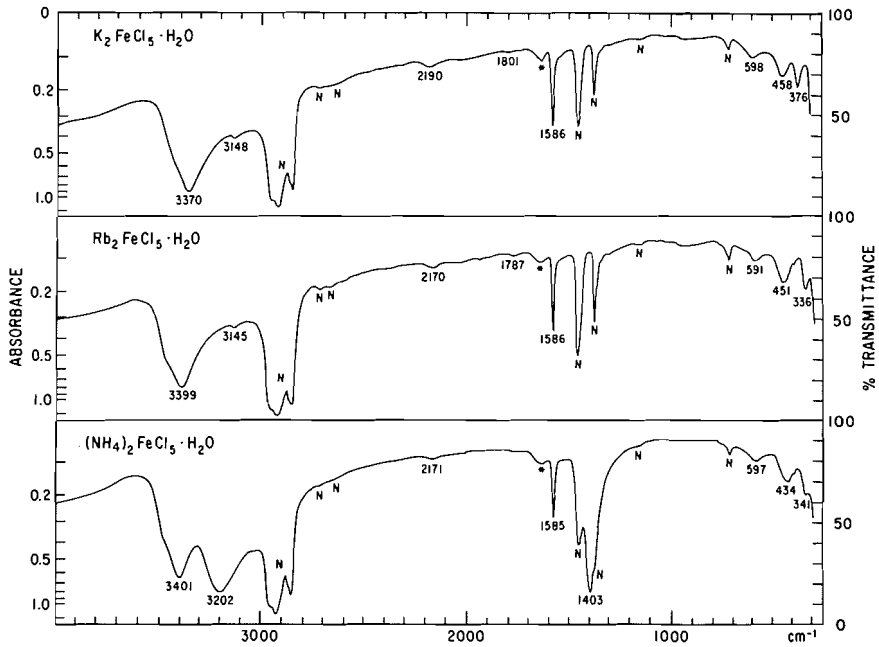

FIG. 1. Survey spectra of undeuterated $M_2FeCl_5.H_2O$ (M = K, Rb, NH_4) at room temperature (Nujol mulls, CsBr windows). *N* denotes Nujol bands, asterisks denote spurious bands.

the undeuterated material from such acidified isotopic mixtures. To obtain the highest degree of deuteration (about 95%), anhydrous $FeCl_3$ was dissolved in D_2O acidified with DCl, and the solution was allowed to crystallize in a stream of dry nitrogen in a dry-box. The Rb and NH_4 compounds were prepared in an analogous manner.

A specimen of natural *erythrosiderite* from the Vesuvius (R 1364, Washington A. Roebling Collection) was obtained from the U.S. National Museum, Washington, D.C.

Infrared spectra of polycrystalline samples were recorded between 4000 and 300 cm^{-1} at 30 and −160 °C on a Perkin–Elmer model 521 spectrophotometer purged with dry N_2. The use of automatic frequency marker and careful calibration made it possible to measure the frequencies of sharp peaks to within 0.5 cm^{-1}. Finely ground sample powders were mulled with Nujol or Fluorolube, and the mulls were mounted between KBr or CsBr plates. Deuterated samples were handled in a dry-box. KCl-pellet technique was also used, but it was found impossible to prevent small amounts of atmospheric moisture from being introduced into the pellets.

Results

The spectra of typical Nujol mulls of undeuterated $K_2FeCl_5.H_2O$ and its Rb and NH_4 analogs at room temperature are shown in Fig. 1 in a form suitable for identification purposes.[3] The frequencies of the major H_2O bands are listed in Table 1. The spectrum gradually sharpened upon cooling to liquid-nitrogen temperature; the frequencies quoted in the following will normally be those obtained from the low-temperature spectra. No evidence of a phase transition on cooling was observed.

A pellet of $K_2FeCl_5.H_2O$ in KCl and a pellet obtained by pressing $FeCl_3$ with a large excess of *nearly* anhydrous KCl (*cf.* ref. 6) produced essentially the same spectra as the mull. The spectrum of the erythrosiderite sample differed only by the presence of additional bands between 1250 and 850 cm^{-1} attributable to an admixture of sulfate.

The frequencies of the major H_2O, HDO, and D_2O bands of $K_2FeCl_5.H_2O$ are listed in Table 2. Figure 2 shows the spectrum in the region of the OH and OD stretching fundamentals at different D contents at liquid-nitrogen temperature. Although in the room-temperature spectrum the two H_2O stretching

[3]The survey spectrum of the undeuterated NH_4 compound at room temperature reproduced in the collection of spectra by Nyquist and Kagel (5) agrees well with ours, but their spectrum of the K compound is of very low quality.

fundamentals, ν_1 and ν_3, were not resolved (Fig. 1), they were well resolved at liquid-nitrogen temperature. The frequency separation of ν_1 and ν_3, which is about 100 cm^{-1} for the H_2O molecule in the vapor and in inert solvents, tends to decrease when these frequencies shift downward as a consequence of H-bonding (7); its value in $K_2FeCl_5.H_2O$ and in the related hydrates (Table 1) appears to be the smallest on record. The corresponding fundamentals

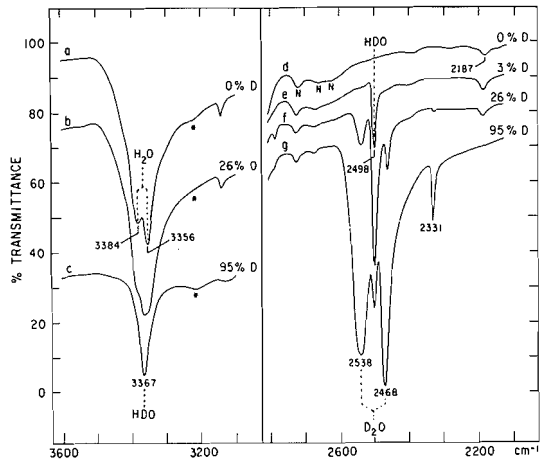

FIG. 2. Spectra of $K_2FeCl_5.H_2O$ at $-160\,°C$ (Nujol mulls, KBr windows): regions of OH and OD stretching fundamentals of water at different degrees of sample deuteration. The vertical scale refers to curves *b* and *f*; the other curves have been displaced for clarity.

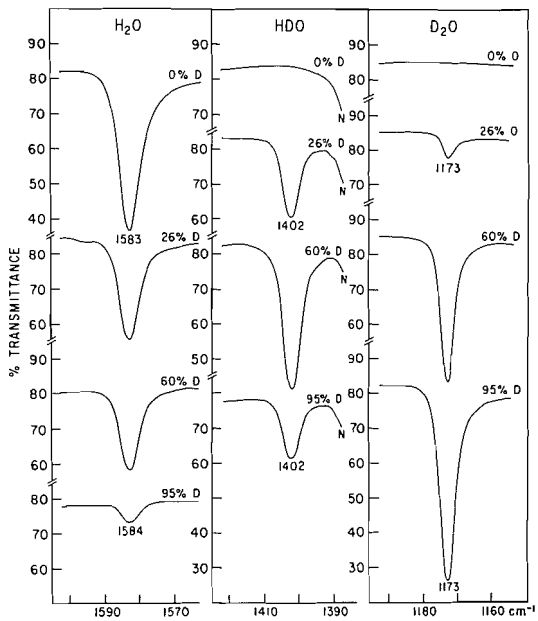

FIG. 3. Spectra of $K_2FeCl_5.H_2O$ at $-160\,°C$ (Nujol mulls, KBr windows): bending fundamentals of H_2O, HDO, and D_2O at different degrees of sample deuteration.

of D_2O were well resolved even at room temperature. This is because of the well-known narrower band width and greater ν_1–ν_3 separation for D_2O. In assigning these two fundamentals we have assumed that $\nu_3 > \nu_1$; this relation generally holds for the water molecule.

The vibrationally isolated OH stretching fundamental of isotopically dilute HDO gives rise to a singlet at 3367 cm^{-1}. The absence, at intermediate D contents, of distinct spectral features arising from pairs of water molecules of the same isotopic species indicates that such pairs vibrate at frequencies approaching those of the isotopically isolated molecules. Vibrational coupling of the stretching fundamentals of neighboring molecules is thus negligible.

The bending fundamentals of H_2O, HDO, and D_2O at liquid-nitrogen temperature were all singlets (Fig. 3). Their frequencies did not change with the D content of the sample, showing that vibrational coupling of the bending fundamentals is also negligible.

Three bands due to H_2O were observed in the region 650 to 300 cm^{-1} (Fig. 4). Their frequencies agree reasonably well with those reported by Adams and Lock (2), who assigned the band at *ca.* 600 cm^{-1} to the wagging libration, the band at *ca.* 456 cm^{-1} to the rocking vibration, and the band at *ca.* 395 cm^{-1} to a translation of the H_2O molecule in the direction of the Fe—OH_2 bond. In this assignment the frequencies of the two librations are reversed from the usual sequence rock > wag (*cf.* ref. 1); the i.r. *intensities* are usually larger for wagging than for rocking (1), and this also is reversed in the spectrum of $K_2FeCl_5.H_2O$. The correctness of the assignment of Adams and Lock is supported by the following consideration based on the present results. Under the site symmetry C_s the Fe—O stretching (A') may, in principle, mix with the wagging libration (A') but not with the rocking libration (A'') (Fig. 5). Values of the H_2O/D_2O frequency ratio of bands believed to correspond to purely librational (unmixed) motions fall in the range 1.35–1.41 (*cf.* for example ref. 8). The ratio for the 456 cm^{-1} band is 456/338 = 1.35, that for the 600 cm^{-1} band is 600/469 = 1.28. Hence the more intense lower-frequency band corresponds to an essentially pure libration and thus to rocking. The reversals may be characteristic of the spectra of water molecules strongly coordinated to one metal atom, as in the aquopentachloroferrates(III).

The twisting libration is expected to be of very low intensity in the i.r. spectrum (1). Bands corresponding to the other two transla-

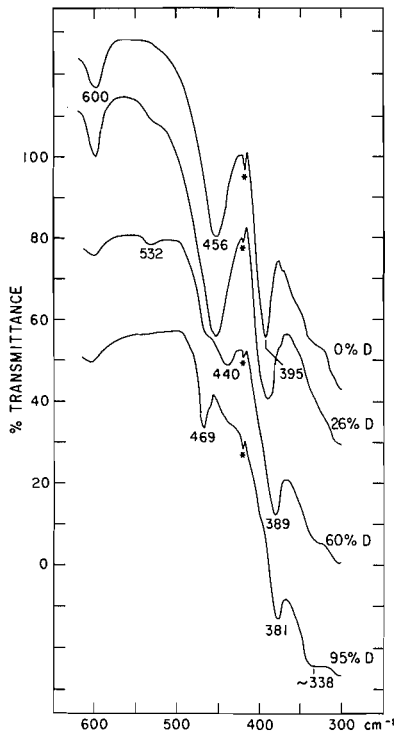

FIG. 4. Spectra of $K_2FeCl_5.H_2O$ at −160 °C (Nujol mulls, KBr windows): bands in the region of libration and translation of water molecules at different degrees of sample deuteration. The vertical scale refers to the curve for 26% D; the other curves have been displaced for clarity.

tions of the water molecule are to be looked for at frequencies lower than 300 cm^{-1}.

Our assignment of the 376 cm^{-1} H_2O band in the room-temperature i.r. spectrum to the Fe—OH_2 stretching is supported by the existence of a corresponding A_g band at 384 cm^{-1} in the Raman spectrum (3). Furthermore, a corresponding band is observed, at 387 cm^{-1}, in the i.r. spectrum of $Cs_2[RhCl_5(H_2O)]$, but it is absent in the spectrum of $Cs_3[RhCl_6].H_2O$ (footnotes 4 and 5 of ref. 9). If the Fe—OH_2 stretching mixed only with the wagging libration, an H_2O/D_2O frequency ratio greater than $(20/18)^{1/2} = 1.054$ (pure translation) could be expected for the stretching. However, the observed value is lower, 395/381 = 1.037.[4] This indicates further mixing of this mode, presumably with vibrations of lower frequencies involving the chlorine atoms.

[4]Low-temperature frequencies.

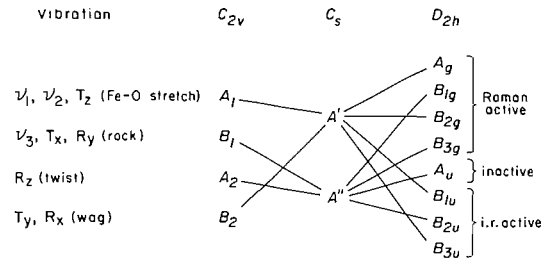

FIG. 5. Correlation of the symmetry species of the molecular group (C_{2v}; $C_2 = z'$, plane containing H_2O = $x'z'$ plane), the site group (C_s; mirror plane = $y'z'$ plane of H_2O || xz plane of the unit cell), and the factor group (D_{2h}). The coordinates x', y', z' are the conventional internal coordinates of the water molecule, while x, y, z are the unit-cell coordinates ($x' = y$, $y'z'$ || 010 (= xz plane); *cf.* Table 3).

No evidence of measurable vibrational coupling was detected for any of the observed fundamentals. For the three internal vibrations (ν_1, ν_2, ν_3) and for the wagging libration there was clear absence of frequency shifts with changing D content of the sample; the severe overlap of the H_2O, HDO, and D_2O absorptions between 500 and 300 cm^{-1} precluded observation of possible shifts for the rocking and the Fe—OH_2 stretching (translation). The doubling of the ν_1, ν_2, wagging and T_z fundamentals, required by the rules of factor-group splitting (Fig. 5), was not observed, and so the magnitude of the splitting must be very small. This can be taken to indicate that at least the ν_1, ν_2, ν_3, and the wagging vibration of each water molecule in this hydrate occur nearly independently of those of its neighbors.

The frequencies of the ammonium compound are very similar to those of the K compound (Table 1), and as the two compounds are isostructural (10), a separate analysis of the spectrum of H_2O in $(NH_4)_2FeCl_5.H_2O$ is not required. The frequencies (in cm^{-1}) of the NH_4 and NH_3D groups are as follows:

Vibration		Frequency (cm^{-1}) 30 °C	−160 °C
NH_4:	NH stretch	3202	3214, 3172
	NH_2 bend	1403	1402
NH_3D:	NH stretch	2352	2370, 2334
	NHD bend	1247	1254, 1243

No crystallographic information is available

TABLE 3. Positional parameters* and site symmetries of atoms in $K_2FeCl_5.H_2O$ (*Pnma*, No. 62; $Z = 4$) (11)

Atom	Equipoint	Site symmetry	x	y	z
Fe	4(*c*)	*m*	0.111	¼	0.302
K	8(*d*)	*1*	0.356	0.003	0.339
Cl(1)	4(*c*)	*m*	0.004	¼	0.030
Cl(2)	4(*c*)	*m*	0.251	¼	0.071
Cl(3)	4(*c*)	*m*	0.226	¼	0.561
Cl(4)	8(*d*)	*1*	0.111	0.003	0.302
O	4(*c*)	*m*	0.996	¼	0.490

*The unit-cell dimensions quoted by Bellanca (11) are $a = 13.75(2)$ Å, $b = 9.92(2)$ Å, $c = 6.93(2)$ Å. The compounds $(NH_4)_2FeCl_5.H_2O$, $K_2RuCl_5.H_2O$, $Cs_2TlCl_5.H_2O$, $M_2VCl_5.H_2O$ (M = K, Rb, NH_4), and $M_2InCl_5.H_2O$ (M = K, Rb, Cs, Tl, NH_4) have been reported to be isostructural with $K_2FeCl_5.H_2O$ (12–14).

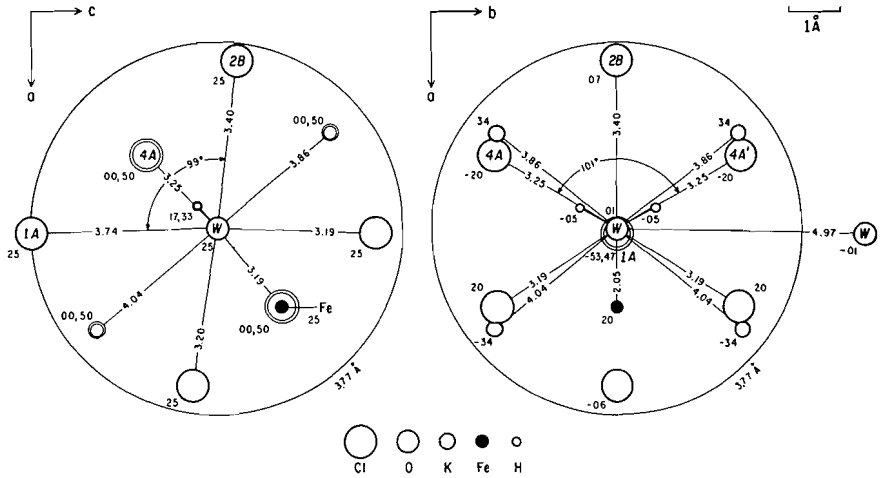

FIG. 6. Immediate environment of an oxygen atom (*W*) in $K_2FeCl_5.H_2O$ according to ref. 11. The fractional coordinates have been multiplied by 100; the interatomic distances are in Å. Double circles represent atoms related by a mirror plane || 010. *Left*, projection on 010; *right*, projection on 001. The hydrogen atoms are placed midway between positions *a* and *b* discussed in text.

for the Rb compound, but as its frequencies are closely similar to those of the ammonium compound (Table 1) and the effective radii of the NH_4^+ and Rb^+ ions are not very different, it is reasonable to assume that the Rb compound too is isostructural with $K_2FeCl_5.H_2O$.

Discussion

In the structure proposed for $K_2[FeCl_5(H_2O)]$ by Bellanca (11) (Table 3) the four oxygen atoms in the unit cell lie on mirror planes parallel to 010 and are all equivalent; the hydrogen atoms were not located. In view of the large separation of the neighboring oxygens, *ca.* 4.97 Å (Fig. 6), hydrogen bonding in this crystal can only be of the O—H. . .Cl type. Each oxygen atom has eight Cl neighbors at distances shorter than 3.77 Å, the upper limit postulated for effective O—H. . .Cl bonding (1). The reported Fe—O distance, 2.05 Å, agrees well with the average Fe^{3+}—OH_2 distance of 2.06 Å in crystalline hydrates (1).

Only two of the orientations of the water molecule that are possible in Bellanca's structure yield acceptable geometries (*cf.* ref. 1):

(*i*) The H_2O molecule is *in* the mirror plane, each H atom belongs to a different 4(*c*) equipoint, and both hydrogen bonds are normal (*i.e.* not bifurcated): $Cl(2)^B$. . .H—O—H′. . .$Cl(1)^A$, corresponding to an O. . .$Cl(2)^B$ distance of 3.40(4) Å, an O. . .$Cl(1)^A$ distance of 3.74(4) Å, and a Cl. . .O. . .Cl angle of *ca.* 99°.

(*ii*) The plane of the water molecule is at right angles to the mirror plane, both H atoms belong to the same equipoint 8(*d*), and only one possibility of hydrogen bonding exists:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$Cl(4)^4$. . .H—O—H′. . .$Cl(4)^{4'}$, corresponding to an O. . .Cl distance of 3.25(4) Å and a Cl. . .O. . .Cl angle of *ca.* 101°.

In (*i*) one of the hydrogen bonds is weak and the other very weak; probably only one of the two H atoms is engaged in hydrogen bonding. In (*ii*) the two hydrogen bonds are equivalent and relatively strong.

The essential correctness of Bellanca's structure is supported by evidence from the i.r. spectra to this extent: (*1*) The H_2O (and D_2O) fundamentals are single, hence there is only *one* type of water molecule in the unit cell. (*2*) Coupling of internal vibrations is negligible, hence the water molecules are "far apart" (*cf.* last paragraph of ref. 6).

The i.r. evidence leads further to new information about the water molecule: (*3*) The water molecule is symmetric, as only singlet HDO bands are observed. This eliminates (*i*) and establishes (*ii*) as the correct alternative. (*4*) The value of the stretching frequency (2508 cm^{-1} for isolated OD stretch at room temperature) corresponds to a hydrogen-bonded O. . .Cl distance of 3.22(4) Å (*cf.* the *R*–ν correlation of ref. 1). This is in good agreement with the value calculated from Bellanca's structure for case (*ii*), 3.25(4) Å.

The orientation of the water molecule may be expected to be the result of a compromise between (*a*) a tendency to minimize the H. . .Fe repulsions, which are minimum when the bisector of the HOH angle points along the Fe. . .O direction, and (*b*) a tendency to maximize the H. . .Cl attractions, which are maximum when the H atoms are in the Cl. . .O. . .Cl plane. Since the Fe atom is only about 0.18 Å from this plane, the orientations corresponding to the requirements (*a*) and (*b*) are not very different. Assuming that the internal geometry of the H_2O molecule in $K_2[FeCl_5(H_2O)]$ is the average geometry of H_2O in crystalline hydrates, with OH distances of 0.98 Å and an HOH angle of 108° (1), the approximate fractional coordinates (*cf.* Table 3) of the H atoms are calculated to be (0.036, 0.830, 0.457) for (*a*) and (0.034, 0.830, 0.452) for (*b*) (Fig. 6). The distance between these two positions is only 0.04 Å, which is comparable with the uncertainty in the positions of the Fe, Cl, and O atoms in Bellanca's structure.

The frequencies of the isolated OD stretch in the NH_4 and Rb analogs are about 20 cm^{-1} higher (Table 1), pointing to a small decrease in the H-bond strength with increasing size of the M^+ ion. Discussion of the variation of H-bond strength with *X* in compounds containing the aquo complex $[XCl_5(H_2O)]^{2-}$ is not possible at present, the above three $M_2[FeCl_5(H_2O)]$ compounds being the first of this type in which the H_2O vibrations have been studied in detail.

In hydrates studied so far mixing of librations and translations of the water molecule is rarely evident; translational frequencies lie generally well below 300 cm^{-1}, while librational frequencies usually are found above 450 cm^{-1} for H_2O and above 350 cm^{-1} for D_2O. Mixed modes can be expected when the higher translational modes attain frequencies comparable with the librational frequencies, as in the aquopentachloroferrates(III). This situation is probably characteristic of water molecules strongly coordinated to cations and may be expected of other hydrates in which H_2O is coordinated to cations of high charge.

We wish to thank Professor W. H. Baur for supplying us with a copy of his program CALPHO (Calculation of Hydrogen Positions in Crystal Structures), Dr. John S. White, Jr. for the sample of natural erythrosiderite, and Miss Gwen H. Thomas and Mr. P. F. Seto for assistance with the experimental work.

Synthesis and Crystal and Molecular Structures of the *N,N*-Dimethylethanolaminogallane and *N,N*-Dimethylethanolaminogallium Dimethyl Dimers

STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, Vancouver, British Columbia V6T 1W5

Received July 30, 1974

STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **53**, 58 (1975).

Crystals of the *N,N*-dimethylethanolaminogallane dimer **1***a* are monoclinic, $a = 8.540(1)$, $b = 7.0433(7)$, $c = 12.227(6)$ Å, $\beta = 92.94(3)°$, $Z = 2$, space group $P2_1/c$ and crystals of the *N,N*-dimethylethanolaminogallium dimethyl dimer **1***b* are orthorhombic, $a = 15.608(3)$, $b = 11.655(2)$, $c = 10.266(2)$ Å, $Z = 4$, space group *Pccn*. Both structures were determined by Patterson and Fourier syntheses and were refined by full-matrix least-squares procedures to final *R* values of 0.039 and 0.053 for 1062 and 1155 reflections with $I \geq 3\sigma(I)$ respectively. Both structures feature well-separated centrosymmetric dimeric units occurring via the formation of four-membered Ga_2O_2 rings. The five-coordinate gallium atoms have distorted trigonal bipyramidal geometry. Steric interactions between methyl groups in **1***b* are believed responsible for the lengthening of the axial Ga—N distance from 2.279(3) in **1***a* to 2.471(4) Å in **1***b*. Other bond distances are: for **1***a*; Ga—O (axial), 2.053(3), Ga—O, 1.911(3), Ga—H, 1.50(7) and 1.73(5), O—C, 1.369(5), N—C, 1.466–1.485(6), C—C, 1.512(7), and mean C—H, 1.05; for **1***b*; Ga—O (axial), 2.078(3), Ga—O, 1.913(3), Ga—C, 1.936(6) and 1.948(7), O—C, 1.382(7), N—C, 1.452–1.482(7–8), C—C, 1.516(9), and mean C—H, 1.01 Å.

STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **53**, 58 (1975).

Les cristaux du dimère du *N,N*-diméthyléthanolaminogallane sont monocliniques, $a = 8.540(1)$, $b = 7.0433(7)$, $c = 12.227(6)$ Å, $\beta = 92.94(3)°$, $Z = 2$, groupe d'espace $P2_1/c$; les cristaux du dimère du *N,N*-diméthyléthanolamino diméthyl gallium sont orthorhombiques, $a = 15.608(3)$, $b = 11.655(2)$, $c = 10.266(2)$ Å, $Z = 4$, groupe d'espace *Pccn*. On détermine les deux structures par les synthèses de Patterson et de Fourier et on procède à un raffinement par la méthode de moindres carrés (matrice complète) pour 1062 et 1155 réflexions jusqu'à des facteurs d'accord *R* de 0.039 et 0.053 avec $I \geq 3\sigma(I)$. Les deux structures sont caractérisées par des unités dimériques centrosymétriques bien séparées qui proviennent de la formation de noyaux Ga_2O_2 à quatre membres. Les atomes de gallium de coordination cinq ont la géométrie d'une bipyramide trigonale déformée. On croit que les interactions stériques entre les groupes méthyles dans **1***b* sont la cause de l'allongement de la distance axiale Ga—N de 2.279(3) dans **1***a* à 2.471(4) Å dans **1***b*. On établit que les autres longueurs de liaisons sont: pour **1***a*; Ga—O (axial), 2.053(3); Ga—O, 1.911(3); Ga—H, 1.50(7) et 1.73(5); O—C, 1.369(5); N—C, 1.466–1.485(6); C—C, 1.512(7) et C—H moyen, 1.05; pour **1***b*; Ga—O(axial), 2.078(3); Ga—O, 1.913(3); Ga—C, 1.936(6) et 1.948(7); O—C, 1.382(7); N—C, 1.452–1.482(7–8); C—C, 1.516(9) et C—H moyen, 1.01 Å.

[Traduit par le journal]

Introduction

A previous report (1) characterized the *N*-methyldiethanolaminogallane dimer, $[MeN(CH_2CH_2O)_2GaH]_2$, as the first crystallographic example of a five-coordinate gallium complex, the gallium atoms having trigonal bipyramidal coordination, with an angle of 151.2° between the axial substituents. It was postulated at that time that similar derivatives employing the *N,N*-dimethylethanolamino, "$Me_2NCH_2CH_2O$", moiety as a ligand might also provide examples of five-coordinate gallium atoms in crystalline samples. The present report deals with the preparations and crystal structures of two such complexes, $[Me_2NCH_2CH_2OGaH_2]_2$ and $[Me_2NCH_2CH_2OGaMe_2]_2$. In both compounds the four-membered Ga_2O_2 ring encountered in the previous work (1) is again the central feature, and in addition coordination of the nitrogen atom is also involved to give the predicted five-coordinate gallium atoms in both structures **1**. Steric interactions in the dimethylgallium derivative (**1***b*) make the Ga—N link weaker than that in the corresponding gallane compound $[Me_2NCH_2CH_2OGaH_2]_2$ (**1***a*). The Ga—H bonds in the latter compound are significantly different and an interaction between one of the hydrogen atoms and the bridging oxygen atom is postulated.

b; R = Me

Experimental

Starting Materials

N,N-Dimethylethanolamine was refluxed over anhydrous $CaSO_4$ and distilled prior to use. Trimethylaminegallane (2) and gallium trimethyl (3) were prepared as previously described. All materials were handled in a glove-box filled with dry nitrogen or on a standard high-vacuum line.

N,N-Dimethylethanolaminogallium Dimethyl Dimer, $[Me_2NCH_2CH_2OGaMe_2]_2$

This was prepared by reacting *N,N*-dimethylethanolamine (0.585 g, 5.91 mmol) with gallium trimethyl (0.679 g, 5.91 mmol) in refluxing benzene solvent. After removal of solvent the product was isolated as a moisture-sensitive white solid which was recrystallized from toluene to yield colorless crystals, m.p. 81 °C.

Anal. Calcd. for $[Me_2NCH_2CH_2OGaMe_2]_2$: Ga, 37.1; C, 38.3; H, 8.5; N, 7.5. Mol. wt. 376. Found: Ga, 37.0; C, 38.0; H, 8.6; N, 7.2. Mol. wt. 372.

N,N-Dimethylethanolaminogallane Dimer, $[Me_2NCH_2CH_2OGaH_2]_2$

Trimethylaminegallane (0.440 g, 3.34 mmol) was reacted with *N,N*-dimethylethanolamine (0.297 g, 3.34 mmol) in benzene solvent and the hydrogen evolved measured (75 ml, 3.35 mmol)

$$2Me_3NGaH_3 + 2Me_2NCH_2CH_2OH \rightarrow [Me_2NCH_2CH_2OGaH_2]_2 + 2H_2 + 2Me_3N$$

After removal of solvent the product remained as an air-sensitive white solid which was recrystallized from toluene to give colorless crystals.

Anal. Calcd. for $[Me_2NCH_2CH_2OGaH_2]_2$: Ga, 43.6; hydrol. H, 1.25. Mol. wt. 320. Found: Ga, 43.5; hydrol. H, 1.24. Mol. wt. 315.

Crystallographic Studies of the N,N-Dimethylethanolaminogallane Dimer (1a)

The crystal chosen for study was mounted with c^* parallel to the goniostat axis and had dimensions of *ca.* 0.31 × 0.30 × 0.30 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least-squares treatment of $\sin^2\theta$ values for 26 reflections measured on a diffractometer with CuK_α radiation. Crystal data are:

$C_8H_{24}Ga_2N_2O_2$ f.w. = 319.7

Monoclinic, $a = 8.540(1)$, $b = 7.0433(7)$, $c = 12.227(6)$ Å, $\beta = 92.94(3)°$, $V = 734.5(4)$ Å^3, $Z = 2$, $\rho_c = 1.446(1)$ g cm^{-3}, $F(000) = 328$ (20 °C, CuK_α, $\lambda = 1.5418$ Å, $\mu = 47$ cm^{-1}). Absent reflections: $0k0$, $k \neq 2n$ and $h0l$, $l \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured on a Datex-automated General Electric XRD 6 diffractometer, with a scintillation counter, CuK_α (nickel filter and pulse height analyser), and a θ–2θ scan at 2° min^{-1} over a range of (1.80 + 0.86 tan θ) deg in 2θ, with 20 s background counts being measured at each end of the scan. Data were measured to $2\theta = 145°$ (minimum interplanar spacing 0.81 Å). A check reflection was monitored every 40 reflections throughout the data collection. The r.m.s. deviation of the intensity of the check reflection from its initial value was 2.0% and the final intensity was 1.03 times the initial intensity. Lorentz and polarization corrections were applied, and the structure amplitudes were derived. No absorption correction was made due to irregularities of the crystal surface. Of the 1454 independent reflections measured, 369 had intensities less than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time averaged background count. These reflections were given zero weight in the refinement.

The position of the gallium atom was determined from the three-dimensional Patterson function. Two cycles of full-matrix least-squares refinement of the positional and isotropic thermal parameters of the gallium atom gave $R = 0.31$. A difference map at this point revealed the positions of the O, N, and C atoms. Two cycles of refinement with the gallium atom anisotropic and the O, N, and C atoms isotropic followed by two cycles with all non-hydrogen atoms anisotropic gave $R = 0.070$. The positions of all 12 hydrogen atoms were revealed by a difference map at this point. The hydrogen atoms were included in all subsequent refinement with isotropic thermal parameters. The refinement was concluded after four cycles with $R = 0.039$ for 1062 reflections with $I \geq 3\sigma(I)$ (23 planes with $|F_o - F_c| > 3\sigma(F)$ were given zero weight in the final stages of refinement).

The least-squares refinement was based on the minimization of $\Sigma w(F_o - F_c)^2$. The scattering factors of ref. 4 were used for the non-hydrogen atoms and those of ref. 5 for the hydrogen atoms. Anomalous scattering corrections (6) were applied for Ga, O, N, and C atoms. The anisotropic temperature factors employed in the refinement are U_{ij} in the expression

$$f = f^0 \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c^*)]$$

where f^0 is the tabulated scattering factor and f is that corrected for thermal motion. The weighting scheme: $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave constant average values of $w(F_o - F_c)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. The mean error in an observation of unit weight was 1.04. In the final stages of refinement an extinction parameter was refined, the final value being 8.74×10^{-7}.

On the final cycle of refinement the mean parameter shift was 0.15σ, the largest shift being 1.3σ for the temperature factor of H(1B).

Crystallographic Studies of the N,N-Dimethylethanolaminogallium Dimethyl Dimer (1b)

Experimental details for **1b** are the same as for compound **1a** except where noted. Two crystals were used for the data collection. The first crystal was mounted with [011] parallel to the goniostat axis and had dimensions of *ca.* 0.3 × 0.5 × 0.6 mm. The second crystal was mounted with [032] parallel to the goniostat axis and had dimensions of *ca.* 0.4 × 0.4 × 0.7 mm. 20 reflections measured with CuK_α radiation were employed in the refinement of the unit-cell parameters. Crystal data are:

$C_{12}H_{32}Ga_2N_2O_2$ f.w. = 375.8

Orthorhombic, $a = 15.608(3)$, $b = 11.655(2)$, $c = 10.266(2)$ Å, $V = 1867.7(7)$ Å^3, $Z = 4$, $\rho_c = 1.337(1)$ g cm^{-3}, $F(000) = 784$ (20 °C, CuK_α, $\mu = 38$ cm^{-1}). Absent reflections: $0kl$, $l \neq 2n$, $h0l$, $l \neq 2n$, and $hk0$, $h + k \neq 2n$ define uniquely the space group $Pccn$ (D_{2h}^{10}, No. 56).

The r.m.s. deviations of the intensities of the check reflections from their mean values were 0.6% for crystal *1* and 2.2% for crystal *2*. The first 1009 intensities were measured with crystal *1* before it shattered inside the sealed glass capillary tube. The remaining data were collected with the second crystal. Of the 1852 independent reflections measured, 675 had intensities less than $3\sigma(I)$ above background.

The position of the gallium atom was determined from the three-dimensional Patterson function. Two cycles of isotropic refinement gave $R = 0.27$. The positions of the O, N, and C atoms were then taken from a difference map. Two cycles of refinement with the gallium atom anisotropic and the O, N, and C atoms isotropic followed by two cycles with all the non-hydrogen atoms anisotropic gave $R = 0.074$. A difference map at this point gave positions for 15 of the 16 hydrogen atoms, the remaining hydrogen atom was located on a subsequent difference map. The hydrogen atoms were included in the final cycles of refinement with isotropic thermal parameters. The refinement was concluded after six more cycles with $R = 0.053$ for 1155 reflections with $I \geq 3\sigma(I)$ (22 planes with $|F_o - F_c| > 3\sigma(F)$ were given zero weight in the final stages of refinement). The mean error in an observation of unit weight was 1.21 and the final value of the extinction parameter was 3.13×10^{-7}.

On the final cycle of refinement the mean parameter shift was 0.12σ, the largest shift being 0.87σ for the y coordinate of methyl hydrogen atom H (3A).

The final positional parameters for both **1a** and **1b** are given in Table 1 and the thermal parameters in Table 2. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The thermal motions of both **1a** and **1b** have been analyzed in terms of the rigid-body modes of translation and libration using the computer program MGTLS (7). The analysis of **1a** was unsuccessful while the thermal motion of the entire dimeric molecule of **1b** was adequately described by the derived rigid-body parameters (r.m.s. $\Delta U_{ij} = 0.0115$ Å^2, r.m.s. $\sigma U_{ij} = 0.0039$ Å^2). The appropriate bond distances for **1b** have been corrected for libration (8, 9) and appear along with the uncorrected distances in Table 3.

[1]The structure factor table is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

additional crystallographic examples of this type of coordination and further information on Ga—H bond lengths. The crystallographic numbering schemes and 50% probability thermal ellipsoids for the two molecules are shown in Fig. 1. Figure 2 shows the structure of $[Me_2NCH_2CH_2OGaH_2]_2$ (**1***a*) viewed along *b* and Fig. 3 shows the structure of $[Me_2NCH_2CH_2OGaMe_2]_2$ (**1***b*) viewed along *c*. Bond lengths and angles are given in Tables 3 and 4 respectively. Table 5 gives the intraannular dihedral angles defining the conformations of the five-membered GaOCCN rings and selected inter- and intramolecular non-bonded contacts are listed in Table 6. Throughout the discussion the uncorrected bond lengths for **1***b* will be employed for direct comparison to **1***a* and atoms marked with an asterisk are related to those in Table 1 by the crystallographic center of symmetry.

The molecules exhibit the structures predicted on the basis of the previous study of the dimer, $[MeN(CH_2CH_2O)_2GaH]_2$ (1), and contain gallium atoms with distorted trigonal bipyramidal geometry. The monomer units (containing

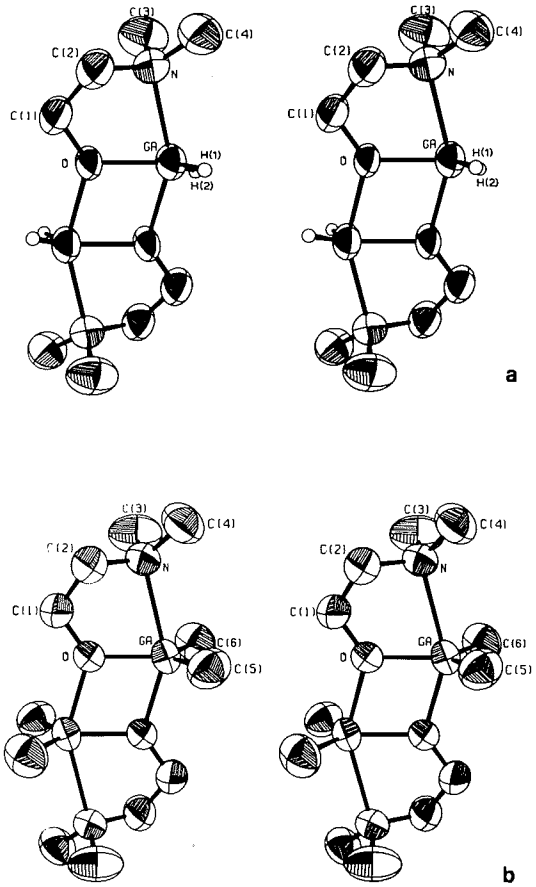

FIG. 1. Stereoscopic views of (*a*) $[Me_2NCH_2CH_2OGaH_2]_2$ (**1***a*) and (*b*) $[Me_2NCH_2CH_2OGaMe_2]_2$ (**1***b*) showing the atom numbering scheme and 50% probability thermal ellipsoids. Methylene and methyl hydrogen atoms have been omitted for clarity.

tetrahedrally coordinated gallium atoms) which might be predicted by comparison with similar boron compounds (11, 12), dimerize via the formation of four-membered Ga_2O_2 rings to form centrosymmetric molecules featuring a system of three fused rings. The $[MeN(CH_2CH_2O)_2GaH]_2$ dimers (1) have C_2 symmetry while the present molecules both have crystallographically imposed $\bar{1}$ (C_i) symmetry. The gallium coordination spheres have nitrogen atoms occupying axial positions and the oxygen atoms occupying an equatorial site on one gallium and an axial position on the second gallium atom. The two remaining equatorial positions are occupied by hydrogen atoms in **1***a* and by methyl groups in **1***b*.

The importance of steric interactions is emphasized by the Ga—N bond distances in the two compounds. In the gallium dimethyl derivative (**1***b*) there is steric interaction between the methyl groups [C(3) ... C(6), C(4) ... C(5)] and as a consequence the Ga—N link is rather long at 2.471(4) Å. In contrast the gallane derivative (**1***a*) experiences much less severe steric interactions and the Ga—N bond length is reduced considerably to 2.279(3) Å, nearer the corresponding mean axial Ga—N distance of 2.193 Å in $[MeN(CH_2CH_2O)_2GaH]_2$.

The rather long and consequently weak Ga—N bond in $[Me_2NCH_2CH_2OGaMe_2]_2$ (**1***b*) may explain the chemical evidence which led to the original prediction of a four-coordinate gallium structure for the dimer, involving the four-membered Ga_2O_2 ring, but lacking any involvement of nitrogen atoms in the gallium coordination sphere. Thus Coates and Hayter (13), on the basis of the formation of a dimethiodide from the reaction of methyl iodide with $[Me_2NCH_2CH_2OGaMe_2]_2$, concluded that the nitrogen atoms were not utilized in the dimer bonding scheme. On the present structural evidence it seems probable that in solution the methyl iodide reagent may quite well break the weak Ga—N link and produce a dimethiodide thus indicating the presence of tercovalent nitrogen atoms in the dimer units.

The equatorial Ga—O bond lengths in **1***a* and **1***b*, 1.911(3) and 1.913(3) Å respectively, are equal within experimental error, while the axial Ga—O bond lengths, 2.053(3) in **1***a* and 2.078(3) Å in **1***b*, are significantly different. These distances also differ from those in $[MeN(CH_2CH_2O)_2GaH]_2$ where the bridging equatorial and axial Ga—O distances are 1.960(8) and 2.018(2) and the "free" equatorial Ga—O distance is 1.847(2) Å. The mean Ga—O distances for tetrahedrally and octahedrally coordinated gallium atoms are both 1.96 Å (14–16). On the basis of hybridization effects alone the equatorial bonds would be expected to be shorter and axial bonds longer than this value which is indeed the case in each of the three five-coordinate structures. In compound **1***a* the two equatorial Ga—H distances are 1.50(7) and 1.73(5) Å while the equatorial Ga—H distance in $[MeN(CH_2CH_2O)_2GaH]_2$ is 1.41(7) Å. There appears to be an interaction of H(2) with O*, the distance O* ... H(2) (2.28(7) Å) being shorter than a normal van der

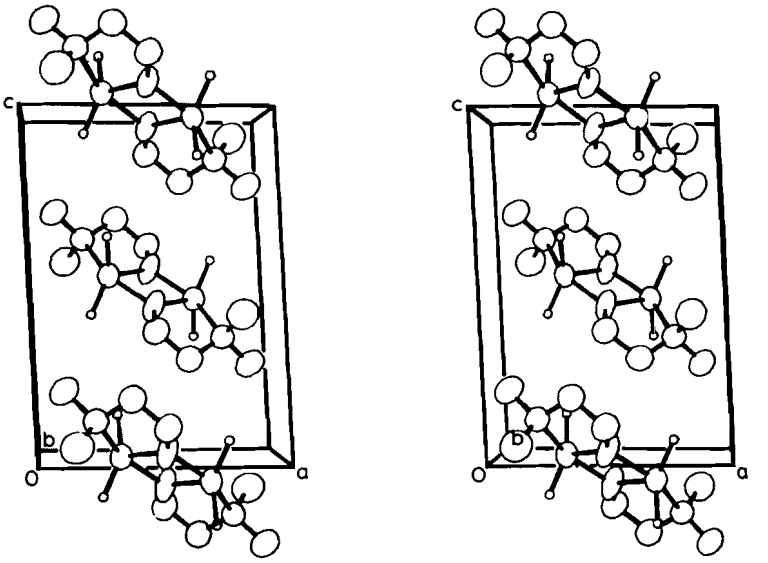

FIG. 2. The structure of $[Me_2NCH_2CH_2OGaH_2]_2$ (1*a*) viewed along *b*.

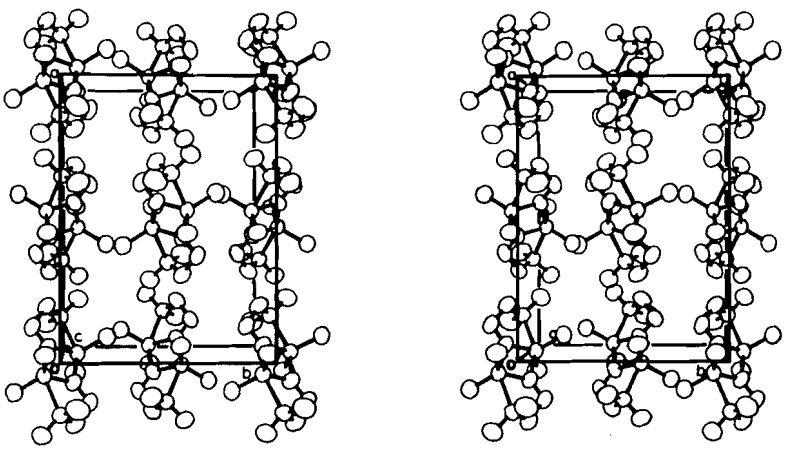

FIG. 3. The structure of $[Me_2NCH_2CH_2OGaMe_2]_2$ (1*b*) viewed along *c*.

Waals contact. The three remaining O ... H contact distances in the gallium coordination sphere range from 2.92–2.96 Å (see Table 6).

The distortion of the trigonal bipyramids occurs as a deformation of the angles between the axial substituents from the ideal value of 180° to 152.4(1) in **1***a* and 150.0(1)° in **1***b*. These values are similar to that of 151.2(4)° for the corresponding angle in $[MeN(CH_2CH_2O)_2GaH]_2$. This deformation appears to result directly from the steric constraints associated with the formation of the four-membered Ga_2O_2 rings in all three compounds. Unlike $[MeN(CH_2CH_2O)_2GaH]_2$, these compounds both have slightly nonplanar equatorial groups. The dihedral angles between normals to the mean planes of the equatorial groups and the planes of the Ga_2O_2 rings are 100.4 in **1***a* and 87.9° in **1***b*. Angular distortions occur in the gallium coordination spheres as a result of steric forces. In both compounds the angles within the equatorial groups as well as the axial–Ga–equatorial angles show some considerable deviations from their "ideal" values (see Table 4).

tween axial and equatorial Ga—O distances than in the present structures. The octahedral complex $[Ga_2(OH)_2Cl_2(C_{14}H_{17}N_3)_2]Cl_2 \cdot H_2O$ (15) also exhibits a planar centrosymmetric Ga_2O_2 ring with Ga—O distances of 1.908 and 2.017 Å.

The dihedral angles in the five-membered GaOCCN chelate rings are compared with those obtained from energy minimization calculations (17) in Table 5. The ring conformations in **1***a* and **1***b* are different, that in **1***a* having a conformation closest to that calculated for $\omega_1 = 20°$ and **1***b* nearest to that calculated for $\omega_1 = 25°$. These conformations are similar to that of the "free" (not containing the bridging oxygen atom) chelate rings in $[MeN(CH_2CH_2O)_2GaH]_2$ rather than the corresponding rings containing the bridging oxygen atoms. The mean angles in the five-membered rings of 104.2 for **1***a* and 103.8 for **1***b* compare well with the calculated value of 104.2 (17), values of 104.8 and 103.8 for the "bridging" and "free" rings in $[MeN(CH_2CH_2O)_2GaH]_2$, and values of 104.8 and 104.9° in the BOCCN rings in related compounds $Ph_2BOCH_2CH_2NH_2$ (11) and $(p\text{-}FC_6H_4)_2BOCH_2CH_2NH_2$ (12). The C—O, C—C, and C—N distances in the chelate rings (Table 3), which are sensitive to conformational and electronic differences, are slightly, but not significantly, different in the two compounds. The corresponding C—O, C—C, and C—N distances in related structures are: 1.427(3), 1.507(6), and 1.477(2) in the "bridging" and 1.412(3), 1.534(1), and 1.468(4) Å in the "free" rings of $[MeN(CH_2CH_2O)_2GaH]_2$, and the mean values for the two boron compounds (11, 12) are 1.416(3), 1.500(6), and 1.488(3) Å. The N—C(methyl) distances are as expected. The mean valence angles at the quaternary nitrogen atoms are 109.5 in **1***a* and 109.4 in **1***b* with the smallest angles occurring in the five-membered rings. The geometry involving the hydrogen atoms is as expected.

Both crystal structures (see Figs. 2 and 3) consist of discrete dimeric units separated by normal van der Waals distances, the shortest of which are listed in Table 6. Nonbonded contacts in the gallium coordination spheres and other intramolecular contacts which correspond to steric interactions are also given in Table 6.

The low frequency infrared spectra of the two compounds again display a number of absorptions attributable to "Ga—O", "Ga—N", and ring modes. Compound **1***a* has three bands in this region (530 s, 508 vs, and 420 s) and in addition displays the characteristic Ga—H stretch (at 1830 vs) and Ga—H deformation (at 750 s) modes. Compound **1***b* exhibits three absorption bands in positions close to those in **1***a* (525 s, 507 vs, and 425 s) and in addition a characteristic Ga—C stretch (at 570 s).

Extension of this work on five-coordinate gallium complexes to include other aminoalcohols and related chelating ligands is in progress.

We thank the National Research Council of Canada for financial support and the University of British Columbia Computing Centre for assistance.

The synthesis and pyrolysis of the methyl phthalate esters of diphenylmethylsilyl, *t*-butylsilyl, benzyldiphenylsilyl, and optically active 2-octanol yielded corresponding silyl ethers and phthalic anhydride. In the case of the latter compound, almost complete retention of configuration was observed about the asymmetric carbon atom. A mechanism is proposed for this rearrangement.

La synthèse et la pyrolyse des phtalates de méthyle et de diphénylméthylsilyle, de *t*-butylsilyle, de benzyldiphénylsilyle et de l'octyl-2 optiquement actif conduit aux éthers silylés et à l'anhydridre phtalique. Dans le cas du dernier ester, on a observé une rétention pratiquement complète de la figuration autour du carbone asymétrique. On propose un mécanisme pour ce réarrangement. [Traduit par le journal]

Introduction

Over the past several years, our laboratory has been engaged in an exhaustive study on the pyrolysis of tertiary hydrogen phthalate esters which at abnormally low temperatures (below 150°) decompose to afford near quantitative yields of olefins and phthalic acid (1). Mechanistic studies have shown that the decomposition of such esters occurs through a reversibly formed ion pair with *ortho*-carboxylate hydrogen participation, followed by a kinetically controlled elimination of phthalic acid and olefin (2, 3). A natural extrapolation would be to study the pyrolysis of tertiary silyl hydrogen phthalates which presumably might lead to a stable Si=C system especially if these derivatives decomposed at low temperatures and contained within the compounds resonance and/or steric stabilization.

There is a scarcity of such derivatives in the literature. Gilman and co-workers (4) recorded an unsuccessful attempt at the preparation of a silyl hydrogen phthalate upon reacting triphenylsilanol with phthalic anhydride. A patent reference (5) reports the chloroplatinic acid catalyzed preparation of silyl derivatives of dicarboxylic acids, including phthalic acid, although the report indicates that a mixture of silyl hydrogen phthalate and disilyl ester was produced. We were not successful in obtaining pure monosilyl derivatives from the reaction of potassium phthalate with several tertiary silyl chlorides. The disilyl esters were the predominating products. It is interesting to report that an attempt to prepare the monosilver hydrogen phthalate salt using an obvious exchange reaction of the corresponding monopotassium salt and silver nitrate gave only the disilver salt in quantitative yield. Although silver salts of acids are generally water insoluble, it appears that this salt has sufficient solubility to allow further selective reaction with silver nitrate under more homogeneous conditions. In any event, a preparation of silver hydrogen phthalate does not appear in the literature.

The reaction of phthalic acid with tertiary silyl chlorides (pyridine catalysis) under homogeneous conditions, again lead to mixtures. The procedure of Sommer and co-workers (ref. 6 and references cited therein) which involves the treatment of an organosilicon hydride with an organic acid in the presence of 10% palladium on carbon to yield esters did not prove fruitful with phthalic acid and diphenylmethylsilane. Here again, mixtures were obtained.

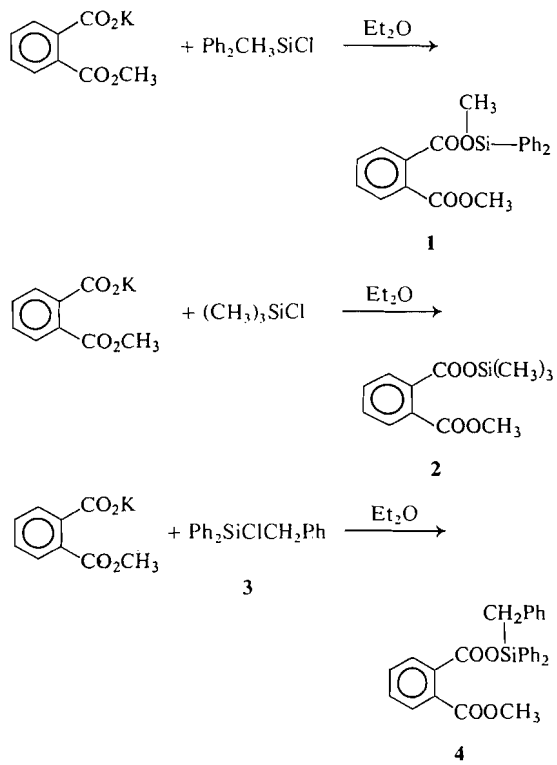
It was decided to prepare *t*-silyl methyl phthalate esters for pyrolytic studies to circumvent the problems previously encountered with the preparation of the monosilyl derivatives. Thus methyldiphenylsilyl, trimethylsilyl, and benzyldiphenylsilyl methyl phthalates (**1**, **2**, and **4**) were prepared in excellent yields from anhydrous potassium methyl phthalate with the appropriate silyl chloride (Scheme 1).

Thermal decomposition of **1** was effected only very slowly at 250° to give phthalic anhydride (**5**) and diphenylmethylmethoxysilane (**6**) as the major products. A more rapid decomposition was realized at 400°. The silyl ester (**2**) decomposed in a similar manner over the temperature range 400–470° to give **5** and methoxytrimethylsilane (**7**). Decomposition of **4** at 400° yielded **5** and benzyldiphenylmethoxysilane (**8**). No silicoolefin nor products which could be construed as arising from such an intermediate were observed.

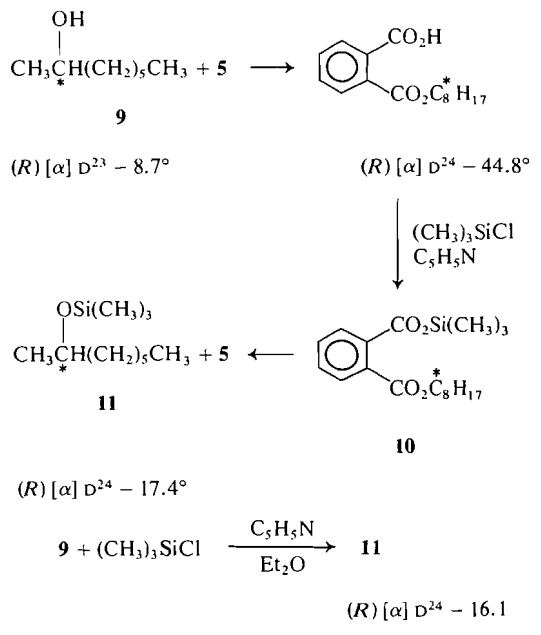
Isolation of silyl ethers (**6**, **7**, and **8**) from the pyrolysis of **1**, **2**, and **4** contrasts with the pyrolysis of methyl alkyl phthalates which give the appropriate alkene, methanol, and **5** (7). The reaction is postulated to initially involve the formation of alkenes and methyl hydrogen phthalate, followed by decomposition of this acid ester to methanol and **5** (8).

In order to provide some idea of the stereochemical aspects of our results, optically active trimethylsilyl-2-octyl phthalate (**10**) was prepared and subjected to pyrolysis. The synthesis of **10**, the pyrolysis, and proof of retention of configuration about the asymmetric carbon atom is shown in Scheme 2.

It is proposed then that the reaction proceeds in a concerted manner as indicated in Scheme 3 with essentially complete retention of configuration about the asymmetric carbon atom.



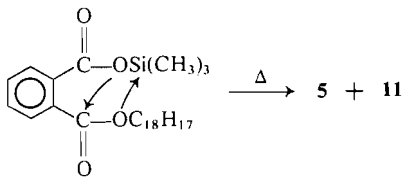
SCHEME 1. Synthesis of diphenylmethylsilyl, trimethylsilyl, and diphenylbenzylsilyl methyl phthalates (**1**, **2**, and **4**).



SCHEME 2. Synthesis and pyrolysis of optically active trimethylsilyl-2-octyl phthalate (**10**) and synthesis of optically active trimethylsilyl-2-octanol (**11**)

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Infrared spectra were recorded on Beckman IR-10 and IR-12 spectrometers in chloroform or deuterochloroform solutions unless otherwise noted. Nuclear magnetic resonance spectra were obtained with a Jeolco C-60 HL spectrometer in deuterochloroform with methylene chloride as an internal standard (τ 4.70) unless otherwise specified. Optical rotation measurements were determined with a Rudolph Model 80 polarimeter equipped with a sodium lamp (λ 589 nm) using 2 dm polarimeter tubes. Gas chromatography (g.c.) was performed on Hewlett Packard 720 and 5750 instruments. Columns utilized were as follows: 6 ft × 1/4 in. 10% SE 30 on 60–80 Chromosorb W, 8 ft × 1/4 in. 20% SE 30 on 60–80 Chromosorb W, 8 ft × 3/8 in.



10

SCHEME 3. Postulated thermal decomposition pathway for *t*-silyl alkyl phthalates.

10% SE 30 on 60–80 Chromosorb W, and 6 ft × 1/4 in. 10% Dexsil 300 on 60–80 Chromosorb W. All nonaqueous reactions were run in dried apparatus under an atmosphere of nitrogen and the silyl chlorides utilized were distilled prior to use. All ethereal solvents were purified by distillation from lithium aluminum hydride and pyridine was distilled from calcium hydride. Anhydrous sodium sulfate was used for all drying operations unless otherwise noted. Microanalyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, N.Y. and A. B. Gygli Microanalyses Laboratory, Toronto, Ontario.

*Methyldiphenylsilyl Methyl Phthalate (**1**)*

To 1.09 g (5 mmol) of potassium methyl phthalate in 50 ml of ether was added 0.83 g (4 mmol) of diphenylmethylsilyl chloride. The resultant heterogeneous mixture was vigorously stirred for 4 h at room temperature and then allowed to stand for an additional 4 h. The mixture was filtered through Super Cel under an atmosphere of nitrogen and concentrated overnight at 35° (1 mm) to give 1.2 g (82%) of **1** as a pale yellow viscous liquid: i.r. 5.78, 5.85, and 8.93 μ (PhSi); n.m.r. 2.4 (m, 14), 6.34 (s, 3, OCH_3), and 8.98 (s, 3, CH_3Si).

Anal. Calcd. for $C_{22}H_{20}O_4Si$: C, 70.18; H, 5.35; Si, 7.46. Found: C, 70.13; H, 5.41; Si, 7.45.

*Trimethylsilyl Methyl Phthalate (**2**)*

To 3.27 g (15 mmol) of potassium methyl phthalate in 80 ml of ether was added 1.53 g (12 mmol) of chlorotrimethylsilane and the mixture was vigorously stirred for 4 h. The mixture was filtered through Super Cel under an atmosphere of nitrogen and concentrated overnight at 40° (0.5 mm) to give 2.4 g (80%) of **2** as a yellow liquid: i.r. 5.78, 5.85, and 11.7 μ (CH_3Si); n.m.r. 2.4 (m, 4), 6.1 (s, 3, OCH_3), and 9.61 (s, 9, CH_3Si).

Anal. Calcd. for $C_{12}H_{16}O_4Si$: C, 57.11; H, 6.39; Si, 11.13. Found: C, 57.48; H, 6.55, Si, 11.21.

*Benzyldiphenylchlorosilane (**3**)*

Benzylmagnesium chloride (200 mmol) in 150 ml of ether and chlorodiphenylsilane (53.2 g, 210 mmol) in 125 ml of ether were stirred for 15 min at 0° and then refluxed for 2 h. Upon cooling, the solution was filtered through Super Cel under a nitrogen atmosphere with the aid of another 150 ml of ether and the filtrate was concentrated *in vacuo*. Methylene chloride (50 ml) was added and the solution was refiltered and concentrated to a pale yellow liquid. Short-path distillation gave 40.9 g (66%) of the chlorosilane: b.p. 147–150° (0.003 mm); m.p. 52–57°; n_D^{25} 1.6085; i.r. 7.0, 8.97, and 19.0 μ (SiCl); n.m.r. 2.7 (m, 15) and 7.2 (s, 2).

Anal. Calcd. for $C_{19}H_{17}SiCl$: C, 73.87; H, 5.54; Cl, 11.47. Found: C, 73.76; H, 5.58; Cl, 11.38.

*Benzyldiphenylsilyl Methyl Phthalate (**4**)*

To 1.09 g (5 mmol) of potassium methyl phthalate in 50 ml of ether was added 1.23 g (4 mmol) of **3** in 1 ml of ether and the mixture was stirred for 4 h and then allowed to stand without stirring for 4 h. The mixture was filtered through Super Cel under an atmosphere of nitrogen and concentrated overnight at 45° (0.3 mm) to give 1.4 g (78%) of **4** as a pale yellow viscous liquid: i.r. 5.78, 5.84, and 8.90 μ (PhSi); n.m.r. 2.6 (m, 19), 6.38 (s, 3, OCH_3), and 6.85 (s, 2, CH_2Ph).

Anal. Calcd. for $C_{28}H_{24}O_4Si$: C, 74.30; H, 5.34; Si, 6.20. Found: C, 74.48; H, 5.45; Si, 5.90.

*(R)-(−)-Trimethylsilyl-2-octyl Phthalate (**10**)*

(*R*)-(−)-2-octanol (**9**), $[\alpha]_D^{23}$ − 8.7° was reacted with **5** according to the procedure of Kenyon (9) to give 26 g (74%) of (*R*)-(−)-2-octyl hydrogen phthalate; m.p. 69–70°; $[\alpha]_D^{24}$ − 44.8° (C 3.4, abs. ethanol) [lit. (7) m.p. 75°; $[\alpha]_D^{24}$ − 48.4°]. The trimethylsilyl derivative **10** was prepared from the potassium salt according to the procedure described for **1** to obtain **10** (72%) as a colorless liquid, i.r. 5.83 and 11.7 μ; n.m.r. ($CDCl_3$–*p*-dioxane), 8.7 (m, 16), and 9.6 (m, 9, CH_3Si).

Anal. Calcd. for $C_{19}H_{30}O_4Si$: C, 65.10; H, 8.62. Found: C, 65.24; H, 8.50.

*(R)-(−)-2-Octyltrimethylsiloxane (**11**)*

This was prepared in 64% yield by the method of Fertig *et al.* (10) using ether as a solvent: b.p. 99.0–99.5° (30 mm); n_D^{20} 1.4124; $[\alpha]_D^{24}$ − 16.1°.

*Diphenylmethylmethoxysilane (**6**)*

Diphenylmethylchlorosilane (**3**) was converted by the procedure of Sommer *et al.* (11) into **6** (53%): b.p. 87–90° (0.075 mm); n_D^{25} 1.5531 [lit. (11) n_D^{25} 1.5510].

*Trimethylmethoxysilane (**7**)*

Chlorotrimethylsilane was converted by the method of Sauer (12) into 7 (18%): b.p. 57.5°; n_D^{20} 1.3675 (lit. (12) b.p. 57°, n_D^{20} 1.3678).

*Benzyldiphenylmethoxysilane (**8**)*

Benzyldiphenylchlorosilane (**3**) (5.17 g) was converted by the method of Sauer (12) into **8** (3.9 g, 76%): b.p. 142–144° (0.005 mm); n_D^{25} 1.5923; i.r. 3.52, 7.0, 8.93, and 9.17 μ; n.m.r. 2.7 (m, 15), 6.42 (s, 3), and 7.24 (s, 2).

Anal. Calcd. for $C_{20}H_{20}OSi$: C, 78.89; H, 6.62, Si, 9.22. Found: C, 78.55; H, 6.78; Si, 8.90.

General Pyrolysis Procedure

The thermal rearrangements were effected by a calibrated variac controlled heating mantle or by the use of a bunsen flame (the results were not altered by this method). The sample was placed in a dried single-necked flask which was attached to a cooled flask for trapping of volatile products. All pyrolyses were conducted under an atmosphere of nitrogen. After the pyrolysis assembly cooled, pentane was added and the insoluble phthalic anhydride was filtered, washed with pentane, dried, and identified by comparison of its infrared spectrum and its melting point with authentic material. The combined pentane fractions were concentrated to yield oils. The components which constituted the oils were identified by i.r., n.m.r., and g.c. (retention time) comparison with authentic material and the relative amounts were calculated by n.m.r. integration.

For personal use only.

Pyrolysis of Diphenylmethylsilyl Methyl Phthalate (1)

Pyrolysis of 1.1 g of **1** with a bunsen flame for 15 min and then for 3 min (0.5 mm) to remove volatile material from the reaction flask gave **5** (0.4 g, 88%) and a yellow oil (0.64 g) which contained four components as indicated by i.r. and n.m.r. inspection. The components were identified as diphenylmethylmethoxysilane (**6**, 85%), sym-tetraphenyldimethyldisiloxane (7%), m.p. 45–46° (lit. (13), m.p. 50°), methyl hydrogen phthalate, and undecomposed **1** (6%). Pyrolysis of **1** at 250° indicated *ca.* 90% decomposition at the end of 6 h.

Pyrolysis of Trimethylsilyl Methyl Phthalate (2)

Pyrolysis of 2.3 g of **2** at 400° and then at 470° (0.5 h) gave **5** (0.75 g, 48%) and methoxytrimethylsilane (**7**) (0.37 g, 38%). The remaining material (0.87 g) from concentration of the pentane layer, was shown by i.r. and n.m.r. inspection to consist of methyl hydrogen phthalate along with small amounts of trimethylsilanol, hexamethyldisiloxane, undecomposed **2** as well as **5**.

Pyrolysis of Benzyldiphenylsilyl Methyl Phthalate (4)

Pyrolysis of 0.96 g of **4** at 400° (1 h) and then with a Bunsen flame for 3 min (0.5 mm) gave **5** (0.28 g, 90%) and a yellow oil (0.24 g) which was identified as **8** along with trace amounts of starting material.

Pyrolysis of (R)-(−)-Trimethylsilyl-2-Octyl Phthalate (10)

Pyrolysis of 5.5 g of **10** at 400° (1.5 h) and then at 470° (0.5 h) gave **5** (2.2 g, 93%) and a colorless volatile liquid (2.6 g) which contained five components by g.c. analysis. The products were separated by preparative g.c. and were identified by spectral comparison and retention time with authentic samples. The first two components were identified as trimethylsilanol (1%) and hexamethyldisiloxane (2%). The third peak (4%) consisted of at least three components tentatively identified as a mixture of octenes by g.c. and spectral comparison with an authentic sample of 1-octene. The fourth component (10%) was identified as 2-octanol (**9**): $[\alpha]_D^{24} - 8.8°$ (C, 1.7, abs. ethanol). The last component (83%) was identified as the (*R*)-(−)-2-octyltrimethylsilyl ether **11**: $[\alpha]_D^{24} - 17.4°$ (C, 3.4, isooctane).

The authors wish to thank Dr. A. G. Brook of the University of Toronto, Toronto, Ontario and Dr. M. Rabin of Wayne State University, Detroit, Michigan, U.S.A. for many helpful discussions during the course of this work. Financial support by the National Research Council of Canada and by the Petroleum Research Fund (Grant No. 1575-A4) administered by the American Chemical Society is gratefully acknowledged.

The Far Infrared Spectra and X-Ray Powder Diffraction Patterns of the Structure I Hydrates of Cyclopropane and Ethylene Oxide at 100 °K

JOHN E. BERTIE, FRANCES E. BATES, AND DAVID K. HENDRICKSEN
Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2E1

Received August 19, 1974

JOHN E. BERTIE, FRANCES E. BATES, and DAVID K. HENDRICKSEN. Can. J. Chem. **53**, 71 (1975).

This paper presents the far-infrared spectrum and X-ray powder diffraction pattern of the structure I hydrate of cyclopropane at 100 °K, and the powder diffraction pattern of the isostructural ethylene oxide hydrate at 100 °K. Between 360 and 100 cm^{-1} the absorption by cyclopropane hydrate is essentially identical to that by ethylene oxide hydrate, but is shifted to low frequency by about 2%. This shift is undoubtedly related to the hydrogen bonds being slightly longer in cyclopropane hydrate, whose cubic lattice parameter is 11.98 ± 0.02 Å compared to 11.89 ± 0.02 Å for ethylene oxide hydrate, both at 110 ± 20 °K. The absorption by cyclopropane hydrate below 100 cm^{-1} decreases rapidly with decreasing frequency; this confirms that the absorption plateau observed for ethylene oxide hydrate between 100 and about 50 cm^{-1} is due to primarily rotational vibrations of ethylene oxide. A recent statement, that the orientational disorder of the water molecules need not be invoked to explain the far infrared spectrum of ice 1h, is disputed.

JOHN E. BERTIE, FRANCES E. BATES et DAVID K. HENDRICKSEN. Can. J. Chem. **53**, 71 (1975).

Dans cette publication, on présente les spectres infrarouges lointains et les patrons de diffraction au rayon-X des poudres de l'hydrate de structure I du cyclopropane à 100 °K et les patrons de diffraction des poudres, aussi à 100 °K, de l'hydrate d'oxyde d'éthylène qui lui est isostructural. Entre 360 et 100 cm^{-1}, l'absorption de l'hydrate de cyclopropane est pratiquement identique à celle de l'hydrate d'oxyde d'éthylène mais le spectre est déplacé vers les basses fréquences par environ 2%. Ce déplacement est sans doute relié au fait que les ponts hydrogène sont légèrement plus longs dans l'hydrate de cyclopropane dont les paramètres de mailles cubiques sont de 11.98 ± 0.02 Å comparé à 11.89 ± 0.02 Å pour l'hydrate d'oxyde d'éthylène; les deux à 110 ± 20 °K. L'absorption de l'hydrate de cyclopropane en bas de 100 cm^{-1} diminue rapidement à mesure que la fréquence diminue; ceci confirme que le plateau d'absorption observé dans le cas de l'hydrate de l'oxyde d'éthylène entre 100 et environ 50 cm^{-1} est principalement dû à des vibrations rotationnelles de l'oxyde d'éthylène. On conteste une affirmation récente à l'effet que le désordre dans l'orientation des molécules d'eau n'est pas nécessaire pour expliquer le spectre infrarouge lointain de la glace 1h. [Traduit par le journal]

Introduction

Cyclopropane forms clathrate hydrates with both of the common structures, I and II (1–4). Its structure I hydrate is isostructural with ethylene oxide hydrate (5) but, due to their larger size, cyclopropane molecules only occupy the tetrakaidecahedral cages (2, 4) whereas some ethylene oxide molecules also occupy the smaller dodecahedral cages (5). In both cases the water molecules are orientationally disordered and reorient extremely slowly at about 100 °K (3, 4, 6), while the guest molecules reorient rapidly at this temperature (3, 4, 6, 7). The far-infrared spectrum of ethylene oxide hydrate has been reported (8), and no firm assignment could be made of the absorption below 100 cm^{-1} to vibrations of the water molecules or to those of the ethylene oxide molecules. The intensity of the absorption by the ethylene oxide molecules is undoubtedly mainly due to the molecular dipole moment (8), so a comparison of the spectra of the structure I hydrates of ethylene oxide and the non-dipolar cyclopropane should clarify the assignment.

Experimental

The experimental methods have been described previously (8) except for the preparation of the structure I cyclopropane hydrate. About 3 ml of outgassed distilled water were maintained at 5 °C in contact with the equilibrium vapor pressure of cyclopropane at 5 °C, about 3000 Torr (2). The hydrate usually formed within 10 min sufficiently to prevent a steel rod or ball in the water from rattling, and the apparatus was left for about 2 days at

5 °C to ensure complete formation of the hydrate. The hydrate was cooled to −80 °C and the excess cyclopropane was removed under vacuum, then the hydrate was cooled in liquid nitrogen, transferred to glass storage vials in the dry gas above boiling liquid nitrogen, and was stored under liquid nitrogen. For infrared and X-ray samples, the hydrate was ground by hand, using a stainless steel pestle and mortar at 77 °K, because the mechanical grinding used successfully for ethylene oxide hydrate (8) converted most of the cyclopropane hydrate to ice 1h. In this work the infrared samples were held at 100 ± 10 °K and the X-ray samples at 110 ± 20 °K.

Results and Discussion

The finely ground cyclopropane hydrate used for the infrared samples was shown to be the structure I hydrate, free from ice and solid cyclopropane, by its X-ray powder pattern. This is shown in Table 1 together with the powder pattern of ethylene oxide hydrate at 110 ± 20 °K and the intensities calculated (9), for all of the lines that should be seen, from the structure factors of ethylene oxide hydrate at −25 °C (5). The program DREFINE (10) was used to fit the 2θ values shown in Table 1, and gave a = 11.975 ± 0.004 Å for cyclopropane hydrate and a = 11.891 ± 0.003 Å for ethylene oxide hydrate. The 2θ values varied by ±0.1° for different samples, and the average of at least 6 determinations gave a = 11.98 ± 0.02 Å for cyclopropane hydrate and 11.89 ± 0.03 Å for ethylene oxide hydrate. The flat-plate powder camera was calibrated by comparing the lattice parameters of ice 1h determined as described above with those of Brille and Tippe (11). The parameter determined for ethylene oxide hydrate is about 0.05 Å lower than the probable value extrapolated from the data of McIntyre and Petersen for flash-frozen samples (12). It is clear that the lattice parameter for cyclopropane hydrate is

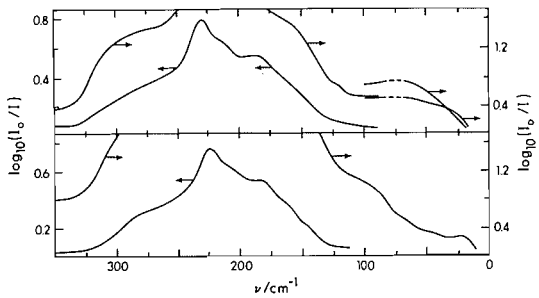

FIG. 1. The far-infrared spectra of the structure I hydrates of cyclopropane (lower box) and ethylene oxide (upper box), mulled in propane, at 100 °K. The arrows indicate the appropriate absorbance scale.

about 0.75% greater than that of ethylene oxide hydrate, which means that the hydrogen-bonded O---O distances are about 0.02 Å longer in cyclopropane hydrate, assuming a proportional lengthening of each hydrogen bond. The lattice parameters of cyclopropane and ethylene oxide hydrates have been given as 12.14 ± 0.1 Å at +5 °C (2, 3) and 12.03 ± 0.01 Å at −25 °C (3, 5), respectively. If the 12.14 Å is taken to be correct, it is also clear that the thermal expansion of both hydrates is considerably greater than that of ice 1h (11). This result is qualitatively consistent with the greater deviation from harmonicity found (8) for the translational vibrations of the water molecules in ethylene oxide hydrate than for those in ice I.

The far infrared spectrum of cyclopropane hydrate at 100 °K is shown in Fig. 1 and the frequencies of the features are given in Table 2. The corresponding data for ethylene oxide hydrate are included for comparison. The absorption above 100 cm^{-1} is very similar to that by ethylene oxide hydrate, which confirms the previous (8) conclusion that it is due to the translational vibrations of the water molecules. It is assigned to the density of vibrational states, modified by an intensity function which very crudely approximates the square of the frequency, through the theory for absorption by translational vibrations in orientationally disordered crystals (13, 14). The density of states curve for cyclopropane hydrate deduced from the spectrum above 100 cm^{-1} is essentially the same as that deduced for ethylene oxide hydrate (8), which is expected since the two water lattices are isostructural, but is shifted to low frequency by about 2%. This shift is undoubtedly related to the longer lattice parameter and, therefore, hydrogen bonds in

cyclopropane hydrate. Qualitative support for the density of states curve deduced from the spectra (8) is obtained from an inelastic neutron scattering study of the isostructural sulfur dioxide hydrate at 248 °K (15). The density of water molecule vibrational states obtained in that work shows a broad maximum from 100 to 300 cm^{-1}, with peaks at about 150, 184, and 244 cm^{-1}. The frequency increase on cooling to 100 °K is probably about 20 cm^{-1}, which places the neutron scattering results in fair agreement with the spectroscopic results. However, the vibrations above about 230 cm^{-1} are stronger in the neutron spectra than in the infrared spectra, as has been found for ice 1h (16–18). A more detailed assignment of the spectrum above 100 cm^{-1} must await a calculation of the density of states curve.

The neutron scattering spectra (15) of sulfur dioxide hydrate show that the first maximum in the density of vibrational states of the water molecules lies about 20 cm^{-1} higher than in ice 1h at 248 °K. This places the maximum at 80–85 cm^{-1} at 100 °K (8) if the 20 cm^{-1} difference holds true at this temperature. Further, preliminary calculations of the density of states of the translational vibrations of the water molecules in structure I hydrates have been made (19), using nearest-neighbor O...O stretching and O...O...O angle-bending force constants. They indicate that the same angle-bending force constant that places the first maximum at 60

cm^{-1} in ice 1h places it between 80 and 90 cm^{-1} in the hydrate. Thus the broad shoulder at about 88 cm^{-1} in the spectrum of cyclopropane hydrate can be assigned to the first maximum in the density of states of the translational vibrations of the water molecules.

This interpretation of the absorption by translational lattice vibrations in crystals formed by orientationally disordered water molecules has recently been questioned by Zerbi and co-workers (20). These authors deny that the breadth of the features observed for ice 1h (18) is evidence of the influence of the disorder. They prefer to assign the features to vibrations which are infrared-active under the factor group of a fully ordered structure, whose symmetry is reduced from the known diffraction symmetry by placing the hydrogen atoms in ordered positions. We cannot agree with their interpretation for several reasons. As Zerbi and co-workers point out, ice 1h does not have the ordered structure that they assume, but is disordered apart from short-range correlation effects (18). Therefore, since Zerbi and co-workers rely upon the activation of vibrations by the reduction in the diffraction symmetry that they impose by their model, it seems illogical to deny that the much greater reduction in symmetry to the actual structure of ice 1h activates all of the vibrations, which are, thus, activated by the disorder. Further, Zerbi and co-workers predict 7 infrared-active vibrations for ice 1h which they calculate to lie between 47 and 284 cm^{-1}, and one infrared-active vibration for ice 1c which they assign at 225 cm^{-1}. They then say that these predictions account for the identity of the spectra of ices 1h and 1c (18). We cannot agree that they do. Finally, the number of vibrations which are infrared-active under the factor groups of the ordered forms of ice, ices II and IX, exceeds the number predicted for ice 1h under the model of Zerbi and co-workers, yet the far-infrared absorption by ices II and IX consists of sharp discrete lines (21). The only conclusion that we can logically draw from this evidence is that the continuous broad absorption observed for the disordered forms of ice (18, 21, 22) and the clathrate hydrates ((8) and this work) is due to the activation of all of the vibrations by the known disorder.

The absorption by cyclopropane hydrate below 100 cm^{-1} (Fig. 1) decreases rapidly with decreasing frequency, in marked contrast to the absorption plateau between 100 and 50 cm^{-1} observed for ethylene oxide hydrate (8). This plateau must, therefore, be associated with the dipole moment of the guest molecule through the rotational–translational vibrations of the guest. It was noted previously (8) that approximate calculations based on the dielectric constants (3) place the rotational vibrations of ethylene oxide near 35 cm^{-1} at 4 °K, but at 100 °K they clearly influence the absorption up to 100 cm^{-1} and yield broad absorption which is similar to that in liquids (8). Klug and Whalley (23) have shown that similar, but rather more structured, absorption by the structure II hydrate of tetrahydrofuran at 80 °K develops into bands at 25 and 38 cm^{-1} at 17 °K, compared with about 15 and 20 cm^{-1} predicted (3) from the dielectric constants. It is possible that the weak features at 23 and 46 cm^{-1} shown in Fig. 1 are corresponding absorptions in cyclopropane hydrate. A study of the absorption below 100 cm^{-1} by ethylene oxide and cyclopropane hydrates and deuterates between 100 and 4 °K has been initiated, to try to reliably determine the vibrational frequencies of the guest molecules.

We thank the National Research Council of Canada for financial support and for the award of a scholarship to F.E.B. We are grateful to Dr. F. W. Birss for permission to quote unpublished results from his laboratory.

Electrochemiluminescence of Phenanthrene-d_{10}: A Possible Case of Efficient Triplet–Triplet Annihilation

N. PERIASAMY AND K. S. V. SANTHANAM

Chemical Physics Group, Tata Institute of Fundamental Research, Homi Bhabha Road, Bombay-400005, India

Received July 11, 1974

N. PERIASAMY and K. S. V. SANTHANAM. Can. J. Chem. **53**, 76 (1975).

Electrochemiluminescence (e.c.l.) of mixed phenanthrene(Ph)-d_{10}-oxidant and Ph-h_{10}–oxidant systems have been studied. Emission from excited singlet state of Ph-d_{10} or Ph-h_{10} is observed. On the basis of energetics of the electron transfer reaction, triplet–triplet annihilation is postulated to give the excited singlet state of Ph. Comparison of these results with photoluminescence of Ph-d_{10}, shows efficient triplet–triplet annihilation occurs in e.c.l.

N. PERIASAMY et K. S. V. SANTHANAM. Can. J. Chem. **53**, 76 (1975).

On étudie l'électrochimiluminescence (e.c.l.) de systèmes mixtes de phénanthrène (Ph)-d_{10}–oxydant et Ph-h_{10}–oxydant. On observe une émission de l'état singulet excité de Ph-d_{10} ou Ph-h_{10}. A partir des énergies de la réaction de transfert d'électrons, on suppose que l'annihilation triplet–triplet donne l'état singulet excité de Ph. La comparaison de ces résultats avec la photoluminescence de Ph-d_{10} montre l'apparition de l'annihilation triplet–triplet efficace en e.c.l. [Traduit par le journal]

Introduction

Although several previous reports of electrochemiluminescence (e.c.l.) systems containing phenanthrene (Ph) alone (1, 2) have appeared, there are no studies reported of mixed Ph-h_{10}–oxidant or Ph-d_{10} (deuterated phenanthrene)–oxidant systems. With mixed systems, it has been possible to choose stable oxidants for the e.c.l. reactions and hence complexity arising from the decomposition products of the oxidant is less with these systems (2); Ph cation used as the oxidant in e.c.l. of Ph is unstable under the conditions employed in e.c.l. We wish to report here a detailed consideration of the energetics of the e.c.l. reactions of the mixed Ph–oxidant systems which suggest that triplet intermediates are involved in the e.c.l. reactions. The observed emission from the excited singlet state of Ph can be most reasonably explained as due to triplet–triplet annihilation. Earlier studies (3, 4) on Ph-d_{10} by photoluminescence indicated the absence of excited singlet state formation via triplet–triplet annihilation (delayed fluoresence) in spite of the triplet formation efficiency, ϕ_t of 0.93. Under similar conditions Ph-h_{10} (ϕ_t = 0.88) is known to give delayed fluorescence (5). The present investigation by e.c.l. suggests efficient triplet–triplet annihilation occuring in both Ph-h_{10} and Ph-d_{10} systems.

Magnetic field has been shown to alter the e.c.l. emission intensity of systems where triplet intermediates are involved in the formation of excited singlet state (6–8). Mixed Ph–oxidant systems show magnetic field enhancement and these results are also presented herewith.

Experimental

Ph-h_{10} (99%) was obtained from GMBH & Co. (Germany). The sample was purified by zone refining. Ph-d_{10} (~98%) (Merck) was zone refined before use. *p*-Phenylenediamine (PPD), and *N'N'*-tetramethyl-*p*-phenylenediamine (TMPD) (BDH), were purified by vacuum sublimation. Tri-*p*-tolylamine (TPTA) used in these studies were obtained from Dr. Zachariasse. Polarographic grade tetra-*n*-butyl ammonium perchlorate (TBAP) (South Western Analytical Chemicals) was used as the supporting electrolyte. The TBAP sample was dried *in vacuo* at 100 °C for 24 h and stored in a desiccator. 1,2-Dimethoxyethane (DME) (Fluka) was purified by distillation after drying it over freshly cut sodium pieces for 24 h. The distillate was vacuum redistilled over $LiAlH_4$ and the middle fraction was stored under vacuum over sodium anthracenide. About 2–3 ml of DME is distilled into the e.c.l. cell from the storage vessel.

Fluorescence and e.c.l. spectra were recorded with Hilger-Watts D-292 monochromators. The procedure for electrochemical measurements and the cells used have been described (9). The i.r. effect in the cyclic voltammetric curves were reduced by a positive feed back in the potentiostatic circuit. Magnetic field experiments were conducted according to the procedure described earlier (8). The field effects were examined on the singlet and excimer components by using Corning filters CS-7-59, CS-3-68, and Ilford 520.

Results and Discussion

The oxidants employed in the present e.c.l. studies are the cations of PPD, TMPD, and TPTA. The cyclic voltammetric cathodic peak potentials (E_{pc}) for reduction of Ph-d_{10} or -h_{10} to the anion radical

$$[1] \qquad Ph + e \rightarrow Ph^-$$

has been obtained with solutions containing 1.0 m*M* Ph and 1.0 m*M* PPD or TMPD or TPTA in DME to be -2.63 V *vs.* s.c.e. (practically no shift in E_{pc} was observed between Ph-d_{10} and Ph-h_{10}), while oxidation of PPD or TMPD or TPTA (represented by R) to the cation radical

$$[2] \qquad R - e \rightarrow R^+$$

occurs at $E_{pa} = +0.24$, $+0.22$, or $+0.91$ V. The enthalpies of the radical ion electron transfer reactions, calculated from the relation

$$[3] \qquad \Delta H^0 = E_{\frac{1}{2}(Ph/Ph^-)} - E_{\frac{1}{2}(R/R^+)} + 0.10$$

are 2.71 eV with PPD^+, 2.69 eV with $TMPD^+$, and 3.38 eV with $TPTA^+$. The singlet (E_s) and triplet (E_t) states of Ph-d_{10} are located at 3.60 and 2.69 eV (10). The enthalpies of the electron transfer reactions are thus enough to form the triplet state of Ph-d_{10} but are insufficient to form the singlet state of Ph-d_{10}. A similar argument may be extended to Ph-h_{10} where the singlet and triplet levels are expected to be close to the values of Ph-d_{10} (10). The electron transfer reaction with a typical oxidant like PPD^+ thus leads to

$$[4] \qquad Ph^- + PPD^+ \rightarrow {}^3Ph + PPD$$

The e.c.l. spectrum of Ph (-d_{10} or -h_{10}) has maximum at 25 000 cm^{-1} and agrees with the fluorescence spectrum[1] of Ph. Thus the e.c.l. emission comes from

$$[5] \qquad {}^3Ph + {}^3Ph \rightarrow {}^1Ph^* + Ph$$
$$\swarrow$$
$$Ph + h\nu$$

Consideration of the above energetics shows that the electron transfer reaction cannot produce the excited singlet or triplet states of PPD or TMPD located at $E_s = 3.60$ eV and $E_t = 2.90$ eV, and $E_s = 3.52$ eV and $E_t = 2.83$ eV respectively. The location of $E_s = 3.51$ eV and $E_t = 2.96$ eV for TPTA shows that the enthalpy of the e.c.l. reaction is sufficient to form the triplet state of TPTA directly. The e.c.l. emission spectrum generated with $TPTA^+$ as oxidant has a tailing in the region of fluorescence of TPTA, suggesting the emission is coming from the excited singlet state of TPTA also.

In addition to the emission from the excited singlet state of Ph, a broad structureless emission is observed at longer wavelengths with TPTA (21 500 cm^{-1}) or TMPD (16 700 cm^{-1}). This structureless emission observed with pure Ph system (19 379 cm^{-1}) in e.c.l. is due to the products of decomposition of Ph^+ (2) or emission attributed to triplet of Ph (1). Under the present experimental conditions the cations of TMPD or TPTA are highly stable and emission coming from the decomposition products is absent. The emission coming from Ph triplet in the present studies is unlikely due to differences in emission wavelengths with oxidants. It is suggested that the longer wavelength emission is due to heteroexcimer as proposed by Weller and Zachariasse (11*a*) for chemiluminescent systems. The relative amounts of singlet to excimer components obtained in e.c.l. are presented in Table 1.

No pre-annihilation e.c.l. is observed with either Ph-h_{10}–oxidant or Ph-d_{10}–oxidant systems in the present investigation. Such a pre-annihilation e.c.l. is observed with Ph-h_{10} alone in solvents like *N*,*N*-dimethylformamide (1).

TABLE 1. Electrochemiluminescence data for phenanthrene in DME

System	Emission (%) Singlet*	Excimer†
Ph-h_{10}–PPD	100	—
Ph-d_{10}–PPD	100	—
Ph-h_{10}–TMPD	95	5
Ph-d_{10}–TMPD	12	88
Ph-h_{10}–TPTA	20	80
Ph-d_{10}–TPTA	33	67

*The percentage singlet emission was calculated from the e.c.l. spectrum with maximum at 25 000 cm^{-1} from the total singlet and excimer emissions. Integrated areas have been used in the calculations. Errors in the values reported are ±10%.

†The percentage excimer emission was based on the emission at longer wavelength, from the total singlet and excimer emissions.

[1]The fluorescence spectrum of Ph in ethanol shows maxima at 360, 380, and 400 nm.

Changes occurring in the e.c.l. emission intensity in the external magnetic field has been taken as an indication of the presence of triplet intermediates (6–8). The recorded enhancement of emission intensities in the magnetic field for Ph–oxidant systems are presented in Table 2. These results support the above conclusions of triplet intermediates formed in the e.c.l. reactions involving Ph–oxidant systems. The excimer emission does not show a magnetic field effect. This suggests excimer is formed directly in the electron transfer reaction (11).

The difference in behavior (in terms of relative production of excimer) exhibited by Ph-h_{10} and Ph-d_{10} probably arises from the relative rates of heteroexcimer formation and triplet production and the decomposition of the heteroexcimer in the reaction

$$[6] \qquad Ph^- + TMPD^+ \begin{cases} \nearrow (a)\ {}^1(TMPD^+Ph^-) \\ \searrow (b)\ {}^3Ph + TMPD \end{cases}$$

(for reaction 6*a*, see footnote 1). The heteroexcimer cannot be formed via ^{3}Ph and ^{3}TMPD as indicated by the absence of magnetic field effect on the e.c.l. intensity of the mixed systems.

Absence of delayed fluorescence in Ph-d_{10} was reported (3) during photoluminescence studies. In e.c.l., since the emission from the excited singlet state of Ph-d_{10} is observed via triplet–triplet annihilation it may be possible that efficient production of triplet state of Ph-d_{10} may be the cause for observing emission from the excited singlet state.[2]

[2]Rate of production of triplets in e.c.l. is proportional to concentrations of the free radicals. For a solution with 1.0 mM phenanthrene-d_{10} and 1.0 mM PPD and a rate constant of 10^9 l M^{-1} s^{-1} (12), the rate would be in the range of 1.0–10.0 M l^{-1} s^{-1}. In photoluminescence the rate of production of the triplets is equal to $I_a\phi_t$ where I_a is the rate of light absorption which is in the range of 10^{-5}–10^{-6} einstein l^{-1} s^{-1} and ϕ_t is 0.93. The rate of production of triplets in the latter case is thus small by orders of magnitude.

TABLE 2. Enhancement of intensity in the magnetic field

Field (kG)	Enhancement (%)	
	Ph-h_{10}–TMPD*	Ph-d_{10}–PPD
1.0	8	5
3.0	11	7
8.0	11	9

*The intensity of the excimer component is not affected by the field.

Authors wish to thank Professor Weller and Dr. Zachariasse for the gift of TPTA, Dr. Prasad for Ph-d_{10} and Professor Bard for a preprint of his work on Marcus' theory. We wish to thank Professor B. Venkataraman for helpful discussions and Mrs. Shah for assistance.

CHUNG-HSI HUANG, OSVALD KNOP, DAVID A. OTHEN, FRANK W. D. WOODHAMS, and R. ALLAN HOWIE. Can. J. Chem. **53**, 79 (1975).

Cubic $M^{4+}P_2O_7$ pyrophosphates of Ti, Zr, Hf, Sn, and Pb have been examined by X-ray powder diffractometry and by infrared, Raman, and Mössbauer ^{119}Sn spectroscopy. The tin compound appeared to be of Chaunac's type *I* (with P_2O_7 groups oriented at random) and could be converted to type *II* (with ordered P_2O_7 groups) by heating to high temperatures. All the other preparations were of Chaunac's type *II*. Evidence from lattice parameters and intensity features of the Raman spectra suggests that the cubic MP_2O_7 pyrophosphates fall in two groups, one containing the compounds of the typical elements (Ge, Sn, Pb) and the other, the compounds of the transition elements. No support has been found for the view that the P—O—P groupings of the pyrophosphate anion in these compounds are linear. The ^{119}Sn chemical shift in SnP_2O_7 is only slightly less negative than the shift in $CuSnF_6.4H_2O$, which makes SnP_2O_7 one of the most ionic compounds of tetravalent tin known. The observed quadrupole splitting in the Mössbauer spectrum of SnP_2O_7 arises largely from the contribution of the valence term to the electric field gradient at the Sn atom.

CHUNG-HSI HUANG, OSVALD KNOP, DAVID A. OTHEN, FRANK W. D. WOODHAMS et R. ALLAN HOWIE. Can. J. Chem. **53**, 79 (1975).

On a examiné les diffractogrammes X de poudre et les spectres infrarouge, Raman et Mössbauer (^{119}Sn) des pyrophosphates $M^{4+}P_2O_7$ cubiques de Ti, Zr, Hf, Sn et Pb. Le composé d'étain, qui était du type Chaunac *I* (à l'orientation aléatoire des groupes P_2O_7), a pu être converti par chauffage à hautes températures en type *II* (à groupes P_2O_7 ordonnés). Les autres préparations étaient du type *II*. Les paramètres de mailles élémentaires et les caractères d'intensité des spectres Raman suggèrent que les pyrophosphates MP_2O_7 cubiques se divisent en deux groupes, l'un contenant les composés des éléments typiques (Ge, Sn, Pb) et l'autre, les composés des éléments de transition. Aucune indication de linearité n'a été trouvée pour les groupements P—O—P des anions $P_2O_7^{4-}$ dans ces composés. La valeur négative du déplacement isomère de ^{119}Sn dans SnP_2O_7 est légèrement inférieure à celle du $CuSnF_6.4H_2O$, ce qui rend SnP_2O_7 un des composés les plus ioniques connus de l'étain quadrivalent. C'est le terme de valence du gradient de champ éléctrique sur l'atome d'étain qui est largement responsable du dédoublement quadrupolaire observé dans le spectre Mössbauer de SnP_2O_7.

The cubic pyrophosphates of tetravalent elements, MP_2O_7, are of interest for several reasons. These refractory compounds span the entire range of tetravalent elements from Si to Th, SiP_2O_7 being one of the few compounds that contain silicon in 6-coordination, but it is not known to what extent they are isostructural. The configuration of the P—O—P group of the $P_2O_7^{4-}$ anion in these phosphates has been the subject of controversy and conjecture (1–12) ever since the appearance of the paper of Levi and Peyronel (13), largely because of the uncertainty as to the true size of the MP_2O_7 unit cells. McGeachin (1) has pointed out that the description of Levi and Peyronel (the "LP cell": $a \sim 8$ Å, $Pa3$, $Z = 4$) would necessitate a *linear* P—O—P group, but this geometry is not encountered in other pyrophosphates. Insight into the complexities of the crystal chemistry of the cubic MP_2O_7 has been gained only recently through the efforts of Chaunac and co-workers (2, 3) and Tillmanns *et al.* (14). Their principal results, which are essential for our dis-

[1]INCO Graduate Research Fellow, 1968–1970. This paper is based in part on the M.Sc. thesis submitted by C.-H. Huang to the Department of Chemistry, Dalhousie University (34). Present address: Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland.

cussion of the problem, can be summarized as follows.

An X-ray and i.r. study of ZrP_2O_7 has enabled Chaunac and co-workers to distinguish three forms, all of cubic symmetry. *Form I* ($a \sim 8.25$ Å; the LP cell) is obtained when ZrO_2 or hydrated Zr oxide is heated with H_3PO_4 to temperatures not exceeding about 250 °C. The P—O—P groups are bent, but their orientations relative to the trigyres containing the P—P pairs are disordered. Averaging the positions of the oxygen atoms over the crystal thus simulates the linear P—O—P groups and the D_{3d} symmetry of the anion demanded by the diffraction symmetry *Pa*3.[3] The orientation disorder is attributed to frozen-in stacking faults produced during the crystal growth at the relatively low temperatures.

Form II is obtained from ZrO_2 or hydrated Zr oxide and H_3PO_4 by heating above *ca.* 250 °C, or directly from *I* by heating to these temperatures; the transformation $I \rightarrow II$ is irreversible. The lattice parameter *a(II)* is three times that of *I*. This large unit cell results from ordering of the P_2O_7 anions. The P—P vectors of the P—O—P groups are no longer required to coincide with the trigyres, and in the absence of constraints imposed by space-group symmetry the P—O—P groups assume their natural bent configurations and their equilibrium orientations in the crystal.

Form III ($a(III) \sim 8.27$–8.28 Å) exists only above 300 °C and has the space-group symmetry *Pa*3. In contrast to *I*, this symmetry is not "statistical" but true. The P—P vectors are on the trigyres, but the oxygen atoms are "thermally disordered", *i.e.* their abnormally high amplitudes of thermal motion result in *dynamic* (time-averaging) simulation of linear P—O—P groupings. The transformation $II \rightarrow III$ is reversible and is confirmed by independent dilatometric evidence (28); the enthalpy change associated with the process between 530 and 575 °K has been estimated as 130 cal/mol (3).

It seems that this polymorphism exists in all the cubic MP_2O_7. Chaunac and co-workers (3; *cf.* also ref. 15) state that TiP_2O_7 behaves in an analogous manner, and X-ray diffraction evidence of the tripled cell has been reported for the Si (15–17), Ge (15, 16), Sn (15), Pb (15), Hf (15), α-U (15, 18), and probably also Ce (15) compounds. Dilatometric evidence of similar transitions in the U and Th compounds has also been reported (19, 20). Independent supporting evidence for the existence of form *III* comes from the relatively weak band at 740 cm^{-1} in the i.r. spectra of $ZrP_2O_7(I)$ and $ZrP_2O_7(II)$. This band, which is absent, or at least extremely weak, in spectra of ZrP_2O_7 at 320 °C (3), was considered to be characteristic of bent X_2O_7 groups by Lazarev *et al.* (4–6), and of diagnostic importance. A weak band at 490 cm^{-1} in the spectrum of $ZrP_2O_7(I)$ seems to be characteristic of form *I* (3).

The structural features postulated by Chaunac for $ZrP_2O_7(II)$ have been reported to exist in $SiP_2O_7(II)$ (or SiP_2O_7AI according to ref. 17). Because of the complexity of the problem (a cubic unit cell having a volume of 11267 $Å^3$), Tillmanns *et al.* (14) generated a trial structure by computer simulation from assumed interatomic distances and bond angles, starting from values that had been obtained by refining the LP substructure in *Pa*3. The trial structure was then refined in *Pa*3, using individual isotropic temperature factors, to an *R* of 30.8%, with more than 50% of the reflections unobserved ($|F_o| = 0$). The 108 P_2O_7 groups in the unit cell fall into six sets of configurations: four of these, each accounting for 24/108 = 22.2% of the total, have bent P—O—P bridges (O_{bridge} in 24(*d*)) and staggered PO_3 groups. The remaining 12/108 = 11.1% contain *linear* P—O—P groupings: one third (= 3.7%) are of symmetry D_{3d} (O_{bridge} in 4(*b*)), while the other two thirds have a *gauche* configuration of symmetry C_3 (O_{bridge} in 8(*c*)). However, the temperature factors of the O_{bridge} atoms in the linear P—O—P groupings were, respectively, about twice and three times the average of the temperature factors of *all* the oxygens in the unit cell, and their estimated standard deviations were 2.5 times those for all the other oxygen atoms; one of the PO_3 oxygens had a *B* of 0.0(2) $Å^2$. In the circumstances the linearity of the 11.1% of the P—O—P groupings cannot be viewed as established. The authors themselves recognize the desirability of an anisotropic temperature factor refinement.

Useful as these results are, they do not indicate which other compounds have properties *strictly* analogous to those of $SiP_2O_7(II)$ and ZrP_2O_7.

[3]Refinement from photographic Weissenberg intensities (2) in both *Pbca* and *Pa*3 gave similar results, with characteristically large thermal parameters and abnormally short P—O distances.

The Si atom is too small for SiP_2O_7 to be considered a "typical" representative of the cubic MP_2O_7 group (*cf.* the variety of non-cubic polymorphs reported for SiP_2O_7 but not for the other compounds, refs. 17, 21, and 22), and some differences may be expected to occur when going from the small Ge to the large Th atom. The question of isomorphism can be properly answered only when the crystal structures of the individual compounds are known, but it ought to be possible to increase our understanding of these pyrophosphates from lesser evidence. To this end we have prepared the polycrystalline Ti, Zr, Hf, Sn, and Pb compounds and re-examined them by X-ray diffraction and i.r. spectroscopy. The laser Raman spectra of these compounds are being reported here for the first time, as is also the Mössbauer ^{119}Sn spectrum of SnP_2O_7.

Experimental

Chemicals of reagent-grade or better purity were used in the preparations. The phosphoric acid was 85%.

ZrP_2O_7 was prepared in two ways. (*i*) An excess of freshly prepared 10% solution of $(NH_4)_2HPO_4$ was added to a sulfuric acid solution of zirconyl sulfate. The mixed solution was digested at 50 °C, cooled, and filtered. The precipitate was washed with a cold 5% solution of NH_4NO_3 until the excess phosphate was removed, dried in a Pt crucible, and calcined for 12 h at 900 °C. (*ii*) An excess of H_3PO_4 was added slowly to 500 ml of a solution containing 5 g of $ZrO(NO_3)_2$. After decantation the precipitate was transferred to a Pt crucible, calcined at 350 °C for 1 h and quenched in CCl_4. The product was washed with water, filtered and dried, and fired subsequently for 12 h at 900 °C. The X-ray powder patterns of products obtained by (*i*) and (*ii*) were identical.

HfP_2O_7 also was prepared by two methods. (*i*) The precipitate of $HfP_2O_7 \cdot 2H_2O$ prepared from $HfOCl_2 \cdot 8H_2O$ according to ref. 23 was calcined for 3 h at 1200 °C. (*ii*) A mixture of $1HfO_2 + 3H_3PO_4$ was heated for 1 h to 400 °C, cooled, and the resulting solid treated as under (*ii*) for ZrP_2O_7. The product of (*ii*) gave a sharper X-ray powder pattern than that of (*i*), for which the high-angle lines were weak and diffuse.

The Ti, Sn, and Pb pyrophosphates were prepared as under (*ii*) for HfP_2O_7 using TiO_2, $SnCl_4.5H_2O$, and PbO_2 instead of HfO_2 (Table 1).[4] All the pyrophosphates were very fine white powders.

The oxygen contents of the preparations were determined by vacuum fusion. Density of the powders was determined, in duplicate, by double weighing as in ref. 24.

The lattice parameters, oxygen contents, and densities of the products are compared in Table 1 with results reported by other workers.

[4]Copies of Table 1 are available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Infrared and Raman Spectra

Infrared spectra were obtained as described in ref. 31. Raman spectra were obtained using the 4880 Å line of a Carson Ar^+ laser in conjunction with a Spex 1401 double monochromator and a SSR photon counter. The instrumental frequencies were calibrated using CCl_4 lines; furthermore, when the exciting line was not filtered, calibration against the argon plasma lines present in the sample spectra was possible (32). The pyrophosphate powders were contained in glass capillaries. The instrumental resolution for the survey spectra shown (Figs. 3 and 4) was better than 5 cm^{-1}, but frequencies were measured from *expanded* spectra taken at 2 cm^{-1} resolution and averaged to give the tabulated results (Table 4).

Both capillaries and pressed powders were used for the Sn compounds, whose Raman spectra were much weaker than those of the other pyrophosphates. With pellets the instrumental resolution was 7 or 9 cm^{-1}. This lower resolution did not affect the spectra; most bands had half-widths of about 10 cm^{-1} and hence the positions of the peak maxima were difficult to ascertain, but the spectra had much better signal-to-noise ratios than when the capillaries were used. The frequencies quoted for the Sn compounds are from the pellet spectra.

For all samples the frequencies of the stronger Raman features are accurate to ± 2 cm^{-1} and of the weaker features, to about ± 5 cm^{-1}.

Mössbauer ^{119}Sn Spectra

The details of apparatus and procedure are described in ref. 35. The chemical shifts δ in Table 5 are quoted with respect to $BaSnO_3$ at room temperature; values relative to β-Sn are obtained by subtracting 2.570 mm/s and to α-Sn, by subtracting 1.92 mm/s (33).

Other Methods

Thermogravimetric (TGA) curves were obtained as described in ref. 31. Typically a 0.5 g sample was placed in a recrystallized-alumina crucible and heated in stagnant air at a rate of 6 °C/min.

Collection of integrated X-ray diffractometer intensities (CuKα) and details of X-ray diffraction are described in ref. 31. As_2O_3 or Si were used as internal standards for Guinier photographs (CuKα and $CuK\alpha_1$). The a_0 values were determined from powder photographs obtained in 114.6 mm diameter cameras except for $a_0(TiP_2O_7)$, which was determined from a Guinier photograph.

Characterization of the Products

The anhydrous Ti, Zr, and Hf compounds did not undergo any change in weight when heated to 1300 °C (TGA in stagnant air), indicating that no significant loss, if any, of P_2O_5 occurred.[5] The slope of the TGA curve of $HfP_2O_7.2H_2O$ prepared by (*i*) was practically zero above 700 °C.

[5]According to ref. 28 ZrP_2O_7 lost P_2O_5 rather readily when heated at 1550 °C for 4 h and was converted to $(ZrO)_2P_2O_7$, the latter being stable to at least 1600 °C. In another paper (18) ZrP_2O_7 is reported to be stable up to 1500 °C, above which temperature $(ZrO)_2P_2O_7$ (stated to be stable up to about 1700 °C) begins to appear.

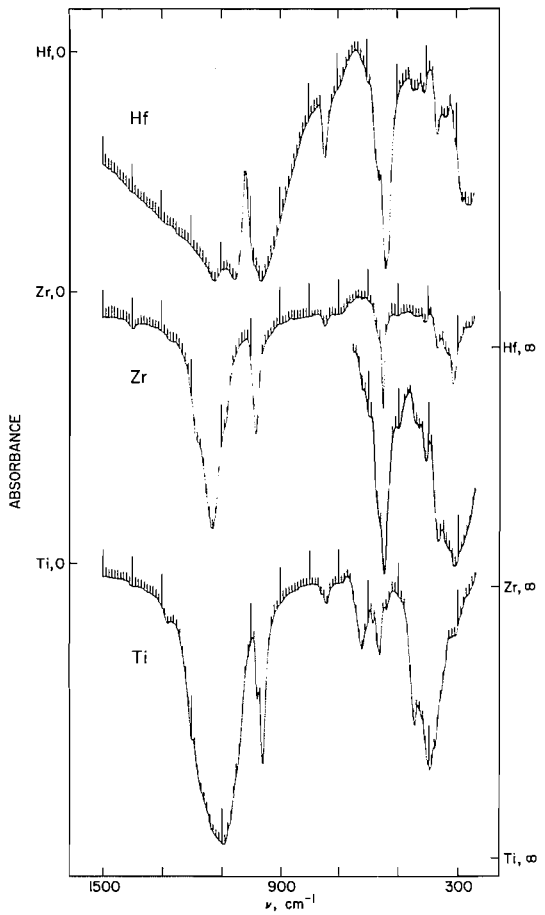

FIG. 1. Infrared spectra of cubic MP_2O_7 (M = Ti, Zr, Hf) pyrophosphates in the region 1500–250 cm^{-1} (compensated KBr pellets). The detail shown is for the Zr compound.

PbP_2O_7 began to lose weight at about 400 °C. The TGA curve quickly reached a plateau extending from *ca.* 580 °C (*cf.* ref. 27). The sample fused to a transparent light-amber-colored glass. The loss of weight, which corresponded to one oxygen per PbP_2O_7, is compatible with the reduction of Pb^{4+} to Pb^{2+} and formation of a Pb^{2+} phosphate (possibly metaphosphate, *cf.* ref. 27). The i.r. spectrum of the glass was quite different from that of PbP_2O_7, although there was absorption in the 740 cm^{-1} region.

The TGA curve obtained with SnP_2O_7 in an alumina crucible indicated progressive loss of weight (34). The loss began to be perceptible in the 550–600 °C range. The sample continued to lose weight up to *ca.* 930 °C, after which the weight remained constant to about 1060 °C. The total weight loss corresponded to about one oxygen per SnP_2O_7. The sample fused to a transparent colorless glass which was not investigated further. It is likely that the glass was formed by reaction with the crucible material. Heating SnP_2O_7 in a Pt crucible to 1200 °C for 1 d followed by quenching in air resulted in a weight loss of *ca.* 16%. The product had the same appearance as the initial material, but small amounts of a colorless glassy material adhered to the crucible where the metal was in contact with the sample powder. The glassy material dissolved in hot water, suggesting that it may have been P_2O_5 or phosphate glass. The powder diffraction photograph of the bulk of the product was almost identical with that of the original SnP_2O_7 except for a small contraction of the unit cell (a_0 = 7.943(2) Å, *i.e.* about 0.4%) and a few very weak extra lines. Compared with the initial material the i.r. spectrum of the product showed significant differences in the 600–300 cm^{-1} region (Fig. 2). In the following the original SnP_2O_7 will be referred to as $SnP_2O_7(1)$ and the product of heating *1* to 1200 °C, as $SnP_2O_7(2)$.

With the exception of SnP_2O_7 the Guinier photographs of the pyrophosphates revealed numerous very weak but mostly well-defined lines which could not be accounted for on the LP cell but were indexable on the 27LP cell. Some of the stronger "extra" lines appeared also in standard powder photographs and in the diffractometer patterns, the 310 line of ZrP_2O_7 being the most clearly visible. The i.r. spectra of *all* these compounds (Figs. 1 and 2) contained the band near 740 cm^{-1} characteristic of bent P—O—P groupings. The products must thus have been of type *II*. The PbP_2O_7 preparation may have contained slight impurity.

$D(I)$					1000[e]	1007[e]	

[a]The xyz coordinates of ref. 2 have been permuted cyclically to match those of ref. 16; those of ref. 13 (obtained from FeKα data) are quoted without change. $D(\Delta I) = 100\,\Sigma|\Delta I|/\Sigma I_o$, $D(I) = 1000\,\Sigma I_c/\Sigma I_o$.
[b]F-refinement of $Zr^{4+}P_2{}^0O_6{}^0O^0$ from 23 out of the 27 single reflections possible in *Pa*3 up to and including 10.2.2+666; weighting scheme W3 of ref. 39.
[c]I-refinement of $Zr^{4+}P_2{}^0O_6{}^0O^0$ from 66 out of the 127 I_0 possible in *Pa*3 up to and including 10.2.2+666; $w(hkl) = \sigma^{-1}[I_o(hkl)]$.
[d]I-refinement of $Sn^{4+}P_2{}^0O_6{}^0O^0$ from 47 out of the 82 I_o (monochromator after the specimen) possible in *Pa*3 up to and including 731+371+553; $w(hkl) = \sigma^{-1}[I_o(hkl)]$.
[e]Includes only reflections used in the refinement.
[f]This R appears to refer to an F^2-refinement (MoKα).

The Guinier photographs of SnP_2O_7 contained only a few, relatively diffuse "extra" lines, and the i.r. spectrum of $SnP_2O_7(I)$ contained an additional band at 499 cm^{-1}. This seemed to correspond to the 490 cm^{-1} band in Chaunac's room-temperature spectrum of $ZrP_2O_7(I)$. On the strength of this evidence $SnP_2O_7(I)$ was taken to be of type *I* and $SnP_2O_7(2)$, of type *II*.

Results

Structure Refinement of $ZrP_2O_7(II)$ and $SnP_2O_7(I)$

The integrated diffractometer LP-subcell intensities were used in full-matrix refinements in *Pa*3 with individual isotropic temperature factors and *ad hoc* programs. A number of models were tried in both *F*- and *I*-refinements employing different combinations of the scattering factors for Zr^{4+} and Sn^{4+} (36); P, O, O^-, and O^{2+} (37); and O^{2-} (38). The results for $Zr^{4+}P_2{}^0O_6{}^-O^0$ and $Sn^{4+}P_2{}^0O_6{}^0O^0$ are shown in Table 2. The refined parameter values are not very accurate, though they compare with those from similar refinements of $ZrP_2O_7(II)$ (16) and $ZrP_2O_7(I)$ (2) from single-crystal data. The largest correlation coefficients were, typically, $B(Zr) - K$ (0.68), $x - z$ (−0.51), and $z - B(O_{outer})$ (0.49); the $x - B(O_{outer})$ and $y - B(O_{outer})$ values were only −0.07 and 0.17 respectively. Refinements designed to determine the effective scattering factors $n_i f_i$ were inconclusive because of the large standard deviations of the refined values of n_i. They indicated, however, a high degree of correlation of n_i and B_i for P, O_{outer}, and O_{bridge}, the $n_i - B_i$ terms in the correlation matrices having values greater than |0.8|.

The results of our *I*-refinements of $ZrP_2O_7(II)$ are quite similar to those obtained for $ZrP_2O_7(I)$ by Chaunac from single-crystal data, in spite of the fact that the assumed structure and the space group *Pa*3 are *statistically correct* for form *I* but only subcell approximations for form *II*. The refinement of $SnP_2O_7(I)$ also gave results strikingly similar to those for $ZrP_2O_7(I)$ of ref. 2. The large B(oxygen) values support Chaunac's model for form *I*. Refinements of form *I* structures cannot thus provide information about the geometry of the P_2O_7 ion.

Infrared Spectra

Infrared spectra of cubic MP_2O_7 have been reported by Steger and Leukroth (26) for M = Ti, Zr, Si, Sn; by Lecomte *et al.* (9) for Zr, Si, Ge; by Haider (40) for Zr; and by Hubin and Tarte (8) for Ti, Zr, Hf, U, Si, Sn, and Pb. There is general agreement between those frequencies that are listed both in Table 2 and in ref. 8; the few values that differ by more than the stated uncertainty are identified in Table 2. However, comparison of the list of Hubin and Tarte with the spectra shown in their paper reveals that the spectra are more complex than the list of frequencies corresponding to the most prominent bands would indicate. This is shown even more clearly in our Figs. 1 and 2, in which the *original* (not redrawn) traces are reproduced. While

[a]Compensated KBr pellets. S, shoulder.
[b]This frequency differs from the value quoted in ref. 8 by more than the stated uncertainty.

Table 2 contains the frequencies of all the minor features that can be detected in our spectra with reasonable confidence, many of the band profiles suggest the existence of further, unresolved peaks.

The weak or very weak band or shoulder at *ca.* 690 cm^{-1} was present in all the i.r. spectra of Table 3 but has not been reported by other authors (8, 26). If it is present in the Raman spectra, it must be very weak. The possibility cannot be ruled out that this feature is spurious, although we cannot offer an explanation for its presence.

The strong band at *ca.* 300 cm^{-1} is present in the i.r. spectra of SnP_2O_7 as well as in that of SnO_2 (41). It very likely corresponds to a deformation mode of the SnO_6 octahedron. The very intense SnO_2 band with a maximum at *ca.* 630 cm^{-1} is, however, seen in neither spectrum of SnP_2O_7; the vvw shoulder at *ca.* 635 cm^{-1} in the spectrum of $SnP_2O_7(2)$ occurs in the region of grating change-over of the spectrometer used and may not be real.

The main difference between the i.r. spectra of $SnP_2O_7(1)$ and $SnP_2O_7(2)$ is the sharpening of the bands at *ca.* 536 and 1010 cm^{-1} in *2* and the disappearance, or at least a great weakening, of the 1400 and 499 cm^{-1} bands of *1*. This last

difference is less evident in the Raman spectra. The increasing sharpness of the bands may be attributed to an improvement in crystallinity on firing. However, the band at 499 cm^{-1} appears to correspond to the 490 cm^{-1} i.r. band reported in ref. 3 for $ZrP_2O_7(I)$ but absent in the spectra of $ZrP_2O_7(II)$ and $ZrP_2O_7(III)$. While the 740 cm^{-1} band of the $ZrP_2O_7(I)$ spectrum reappears when *III* changes to *II* on cooling, the 490 cm^{-1} band does not, although Chaunac and co-workers (3) mention that the latter has been seen to reappear, partially, on cooling after *I* had been heated *very briefly* to 300 °C. The 490 cm^{-1} band could accordingly be considered to be characteristic of form *I*; its presence in the i.r. spectrum of $SnP_2O_7(1)$ suggests that $SnP_2O_7(1)$ was in fact $SnP_2O_7(I)$. The 469 cm^{-1} band in the i.r. spectrum of $SnP_2O_7(2)$ has its counterpart at 468 cm^{-1} in the spectrum of PbP_2O_7, but a similar band appears to be absent in the i.r. spectra of the Ti, Zr, and Hf compounds. The slight difference in the values of some of the i.r. frequencies of $SnP_2O_7(1)$ and $SnP_2O_7(2)$ (Table 3) may well arise from the better definition of the spectrum of *2*, though for the 1168, 1010, and 305 cm^{-1} bands the differences are probably real.

Raman Spectra

The photographic spectrum of ZrP_2O_7 reported in ref. 26 is grossly incomplete and the band frequencies are inaccurate, largely because of the weak intensities of most of the bands. The laser spectra (Figs. 3 and 4, Table 4) also suffer from the general weakness of the spectrum. Because of this and the uncertainty in the frequencies of weak shoulders and poorly resolved bands, it is difficult to establish with certainty which i.r. and Raman bands correspond and so to determine which modes are active in both spectra. These factors are also responsible for the often unsatisfactory agreement of i.r. and Raman frequencies which otherwise appear to correspond.

A further complication arose with the spectra of the Sn pyrophosphates. It was found that a spectrum of a pellet of $SnP_2O_7(1)$ obtained after the pellet had been exposed to laser light for about 6 h (Fig. 4*B*) differed from that of a freshly prepared, unirradiated pellet (Fig. 4*A*). It resembled more closely that of a freshly prepared pellet of $SnP_2O_7(2)$ (Fig. 4), except that the high scatter associated with sample *1* was still present. These differences are genuine, since the resolution of the sample *1* spectra is higher (7 cm^{-1}) than the resolution of the sample *2* spectrum (9 cm^{-1}). It seems therefore possible that the blue laser light causes a change from form *I* to form *II* on the surface of the pellet. However, the high scatter of spectrum 4*B* probably indicates that the crystallinity of the material was not changed, while the smoother spectrum of sample *2* is indicative of the improved crystallinity on prolonged firing. Further investigation would be required to verify these hypotheses.[6]

The spectra of the Ti, Zr, and Hf compounds (Fig. 3) are dominated by the very strong multiple bands in the 1200–1000 cm^{-1} region generally ascribed to P—O stretching modes. While these bands are prominent in all the spectra, in the spectra of the Sn and Pb compounds (Fig. 4) they are less intense than the band groups at *ca.* 340 cm^{-1} characteristic of MO_6 deformation modes.

Mössbauer ^{119}Sn Spectrum of SnP_2O_7

The spectra of $SnP_2O_7(1)$ appeared to consist of a single resonance absorption in the Sn(IV) velocity region, with no asymmetry or fine structure. There was no change in the appearance of the spectrum on cooling the absorber to 4.2 °K. The spectrum of $SnP_2O_7(2)$ was identical to that of $SnP_2O_7(1)$. No evidence of any Sn(II) absorption was found in spectra taken on a larger velocity scale.

All spectra were fitted to two models, (*a*) a single line and (*b*) a pair of lines of equal widths and intensities. The assumed line-shape was Lorentzian; for details of the fitting see ref. 24. The χ^2 of an acceptable fit was required to lie between the 1 and 99% limits of the χ^2 distribution, *i.e.* between about 150 and 242 for spectra with 194 degrees of freedom.

The Mössbauer parameters are listed in Table 5. The two-line fits (*b*) always gave substantially lower χ^2 than the one-line fits (*a*) and more acceptable values for the line width.[7] Indeed the

[6]It is likely that the small decrease in a_0 on firing $SnP_2O_7(1)$ (see Experimental) also reflects improved crystallinity of $SnP_2O_7(2)$. Shrinkage of the lattice parameters with increased firing temperature or time or both is a well-known occurrence in preparative solid-state reactions at high temperatures.

[7]The χ^2 values for fit (*b*) to the $SnP_2O_7(1)$ spectrum at 77 °K (Table 5) are too high. However, this spectrum was obtained to very high statistics and the untypically high χ^2 values may reflect the inadequacy of fitting to strictly Lorentzian shapes.

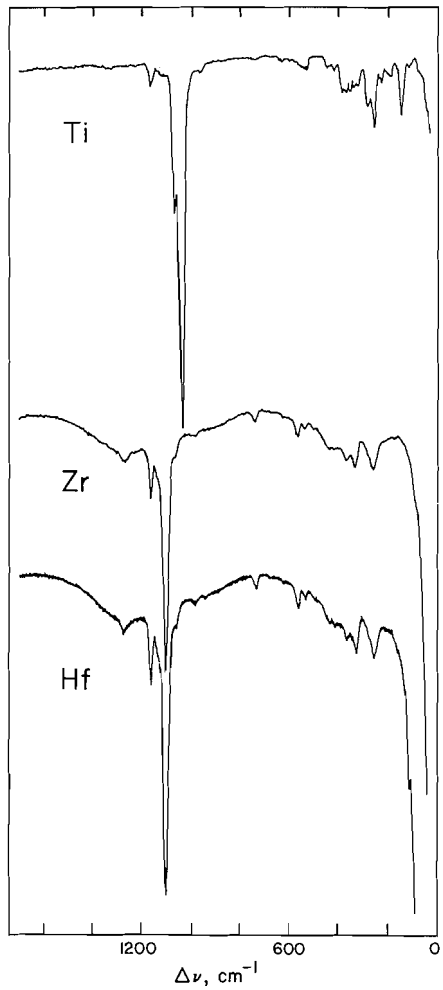

FIG. 3. Raman spectra of cubic MP_2O_7 (M = Ti, Zr, Hf) pyrophosphates in the region 1600–50 cm^{-1} (arbitrary intensity scale).

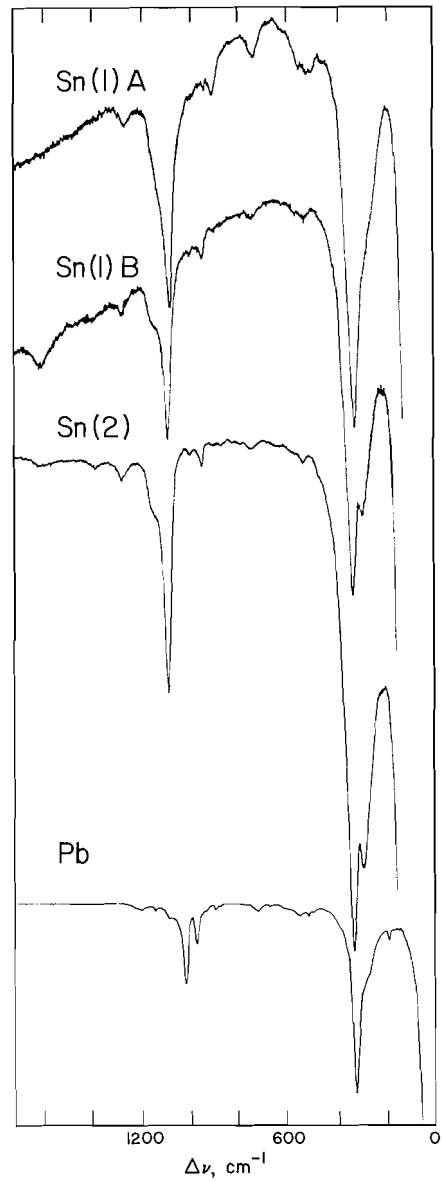

FIG 4. Raman spectra of cubic MP_2O_7 (M = Sn, Pb) pyrophosphates in the region 1600–50 cm^{-1} (arbitrary intensity scale). Sn(*1*)*A*, freshly prepared, unirradiated pellet; Sn(*1*)*B*, spectrum taken after *ca.* 6 h exposure to the laser beam and two months standing.

one-line χ^2 are not statistically acceptable. This may be taken as good evidence that the spectra consist at least of a pair of unresolved lines. The accuracy of the Δ and Γ values does not permit definite conclusions to be made about the effect of temperature lowering.

Discussion

Are the Cubic $M^{4+}P_2O_7$ Isostructural?

Only a complete determination of the individual crystal structures can provide a definitive answer. The crystallographic results will have to explain, or at least be compatible with, (*1*) the observed inconsistencies in the a_0 *vs.* $r^{vi}(M^{4+})$ plot (Fig. 5), and (*2*) the dissimilarities of some of the principal features of the Raman spectra (Figs. 3 and 4).

(*1*) Völlenkle *et al.* (15) accommodated the points of their a_0 *vs.* $r(M^{4+})$ plot on two separate curves, one containing Si, Ge, Sn, Pb and the other, the transition elements. An amended set of the Ahrens radii appears to have been

used. Replotting the available $a_0(I)$ or $a_0(II)/3$ values (Table 1) against the most recent set of $r^{vi}(M^{4+})$ values (42) produces a less clear-cut result (Fig. 5): the points for Ge, Sn, and Pb are significantly below the straight line defined by the set Si, Ti, Hf, Zr, Pu, Ce, Th and do not fall on a straight line of their own. The spread does not seem to be ascribable to experimental inaccuracies. When more than one a_0 value have been reported for a particular M, the agreement is usually reasonable (Table 1), and the differences between $a_0(I)$ and $a_0(II)/3$ are quite small.

(*2*) The relative intensity of the Raman bands in the 340 cm^{-1} region, characteristic of MO_6 deformation modes, is considerably higher for Sn and Pb than for Ti, Zr, and Hf (Fig. 4), despite the general weakness of the Sn and Pb spectra. The difference, which is not evident in the i.r. spectra, can be explained as due to the greater polarizability of the Sn and Pb ions com-

[a]δ, chemical shift relative to $BaSnO_3$ at room temperature; |Δ|, quadrupole splitting; Γ, line width. All values are in mm/s. The parameters are the averages of the two mirror-image spectra (see text). The two χ^2 values refer to the spectra accumulated in channels 0–199 and 200–399 respectively.

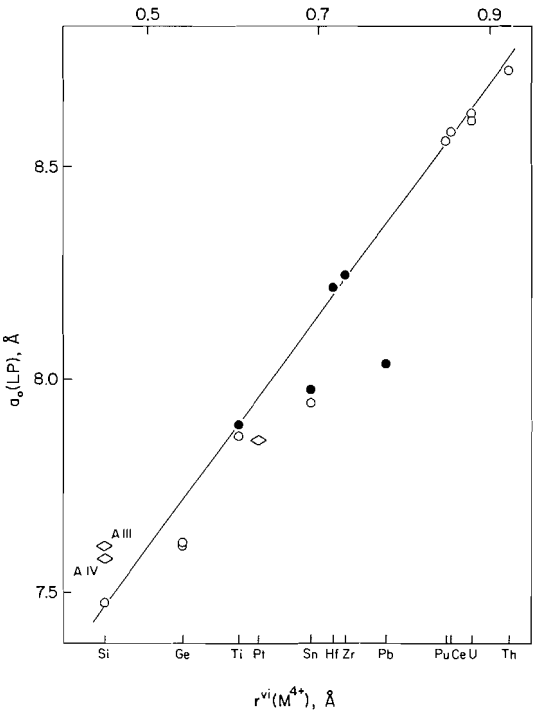

FIG. 5. Lattice parameters a_0(LP) of MP_2O_7 *vs.* empirical ionic radii of M^{4+} for 6-coordination (42). Full circles, this work; open circles, literature values (see Table 1). The $(V_{u.c.})^{1/3}$ values for the monoclinic SiP_2O_7*AIII* (21), SiP_2O_7*AIV* (22), and PtP_2O_7 (43) pyrophosphates are shown for comparison (rhombs).

pared with Ti, Zr, and Hf. Stated differently, it is due to the higher degree of covalency of the M—O bonds in the pyrophosphates of the typical elements (*cf.* also the isomer shift in SnP_2O_7, below). The consequence of increased covalency would be a shortening of the M—O distances, which in turn would be reflected in a reduction of the lattice parameter.

It would appear that the failure of the points for Ge, Sn, and Pb to fall on the straight line of Fig. 5 has some foundation in differences in the electronic configurations of the M^{4+} atoms. Ge, Sn, and Pb have d^{10} configurations, whereas the M^{4+} with points on the straight line do not contain, formally, electrons beyond the inert-gas cores.

Infrared and Raman Spectra

Some of the existing partial, approximate assignments of the i.r. frequencies (7–12) are based on normal-coordinate analysis of the P_2O_7 ion under the symmetry D_{3d} (7) or D_{3h} (in $M_2^{2+}P_2O_7$, *cf.* ref. 10). However, the X-ray evidence leads to the conclusion that forms *I* and *II* contain nonlinear P—O—P groupings and so the spectra must be interpreted on the assumption that the anion has a lower symmetry, *viz.*, C_{2v}, C_s, C_2, or C_1. Even if one accepts that 11% of the P—O—P bridges in SiP_2O_7(*II*) are linear, and assuming that all the MP_2O_7(*II*) are strictly isostructural with SiP_2O_7(*II*), the dominant contribution to the spectrum will be from P_2O_7 having configurations of symmetries other than trigonal.

Since form *I* contains a large number of P_2O_7 rotational orientations about the P—P vectors and these orientations are at random, there will be a quasi-continuous distribution of frequencies about a mean for each vibrational mode of the anion; this will appear as line broadening. The frequency density of such a distribution will be higher than in form *II*, where ideally (assuming analogy with SiP_2O_7(*II*)) only six distinct P_2O_7 configurations and environments would be expected. Comparison of the spectra of SnP_2O_7-(*I*) and SnP_2O_7(*II*) (Fig. 2), however, shows only minor differences between the two. The crystal structure of *I* is in principle indeterminate, except in the statistical (space-averaging) sense. Hence even if the structures of the form *II* com-

pounds were known in detail, the possibility of a *detailed* interpretation of the spectra appears remote.

The number of bands between *ca.* 1300 and 400 cm^{-1} in some of the spectra (Ti, Pb; Table 3) is compatible with the symmetries C_2, C_s, and C_1, for which 21 i.r. active fundamentals would be expected; in *all* the spectra it is greater than the number (ten) of i.r. active fundamentals that would be expected if the anion were of symmetry D_3, and the complicated band shapes indicate the existence of unresolvable component bands of closely spaced frequencies.[8] Numerous similarities in the frequency values for the cubic MP_2O_7 and the pyrophosphates of Mg(α), Ca, Sr, and Ba provide further circumstantial support for the anion having a symmetry lower than trigonal, for the anion is known to be bent in α-$Mg_2P_2O_7$ (44). However, the principal band assignments made under symmetry D_{3d} (and also under D_{3h}) do go some way toward an understanding of the spectra in a general way.

In view of the complexity of the structures of *I* and *II* the real nature of Lazarev's "diagnostic" band at 740 cm^{-1} is not clear. Lazarev assigns this band to the symmetric stretching fundamental of the P—O—P group, which should be i.r. inactive if the anion were of symmetry D_{3d} or D_{3h}. Hubin and Tarte (8) interpret this band as arising from the antisymmetric stretching vibration of the P—O—P group, but as pointed out by Chaunac and coworkers (3; *cf.* also ref. 7), this can hardly be correct in view of the temperature dependence of the intensity of this band. Lazarev's assignment, which is consistent with other evidence presented by Mooney and Goldsmith (7), was adopted by these authors in their calculation of force constants of P_2O_7 in cubic MP_2O_7 from the experimental i.r. frequencies of Hubin and Tarte; the assumption of the D_{3d} symmetry for the anion unfortunately renders the calculation unrealistic. If the 740 cm^{-1} band does correspond to the symmetric stretching fundamental, its width should reflect the effect of the distribution of P_2O_7 geometries, but as comparison of the spectra of $SnP_2O_7(I)$ and $SnP_2O_7(II)$ shows, the difference for the two forms is not readily discernible. This is perhaps a manifestation of the relative insensitivity of the frequencies to changes in the geometry of the ion.

[8]Because of their general weakness the Raman spectra (Table 4, Figs. 3 and 4) are less well suited for arguments based on the observed number of bands.

The ^{119}Sn Chemical Shift in SnP_2O_7

The chemical shift in SnP_2O_7 lies, at room temperature as well as at 77 °K (Table 5), between those of Cs_2SnF_6 and $K_2SnF_6.H_2O$ (35). It is close to the most negative δ value reported to date, that for $CuSnF_6.4H_2O$ (35):

	δ value (mm/s)	
Compound	Room temperature	77 °K
Cs_2SnF_6	−0.374(8)	−0.281(10)
$K_2SnF_6.H_2O$	−0.413(8)	−0.390(6)
$CuSnF_6.4H_2O$	−0.456(10)	−0.415(10)

Lees and Flinn (33) regarded the Sn atom in K_2SnF_6 as being close to the ideal Sn^{4+} and used its δ value to define the $4d^{10}$ point in their chemical-shift calibration equation. SCFMO calculations of Greenwood *et al.* (45) have, however, shown that in the SnF_6^{2-} ion there is appreciable occupation of the 5s and 5p orbitals of the Sn atom, *viz.*, ~0.7 and 1.3 electrons respectively. A linear relation between δ and the 5s orbital occupation number was also found. In view of the closeness of the δ values for $SnP_2O_7(I)$ and the hexafluostannates the electron densities at the Sn atom in these structures must then be very similar but quite different from that in SnO_2. This difference is not unexpected. In the SnP_2O_7 structure each tin atom is surrounded by six oxygen neighbors as in SnO_2, but unlike in the oxide each of the oxygen atoms has a phosphorus nearest neighbor. The electron charge density on these oxygens will be reduced owing to formation of a strong covalent bond with the P atom. This in turn will reduce the degree of covalency between the oxygens and the Sn^{4+} ion and lead to a decrease in s-electron density from that in SnO_2, as observed. It is also noted that the chemical shift of Sn(II) pyrophosphate is close to that of SnF_2 (33).

Jørgensen (46) has shown that the nephelauxetic ratio β may be factored into a metal-ion parameter and a ligand parameter *h*. Duffy and Ingram (47) have recently discussed covalency in molten salts and glasses in terms of this *h* factor and shown that a linear relation exists between *h* and the splitting between the s and p levels of the metal ion as measured optically.

This splitting is expected to decrease with increasing covalency. It is thus reasonable to conclude that there is an approximate correlation between covalency and the h factor. The values of h for phosphate, fluoride, and oxide ligands are ~ 1.0, 0.8, and 2.4 respectively (46), so that the degree of covalency of the pyrophosphate is much closer to that of the fluoride than that of the oxide, as observed. SnP_2O_7 must thus be regarded as one of the most ionic compounds of tetravalent tin known.

Quadrupole Splitting in SnP_2O_7

Mössbauer ^{119}Sn spectra are expected to show quadrupole splitting for Sn atoms in sites of symmetry lower than cubic. This is the situation encountered in $SnP_2O_7(I)$. Because of the random orientations of the P_2O_7 anions the symmetry of the SnO_6 octahedra will be at most $\bar{3}$. If *all* the octahedra were equivalent and of symmetry $\bar{3}$ (the case of the LP structure), the quadrupole-split spectrum would be symmetric and simple, and the observed separation of the components of the doublet would measure the value of the splitting Δ uniquely.[9] However, in $SnP_2O_7(I)$ the majority of the octahedra will have symmetries lower than $\bar{3}$, mostly non-axial, and even octahedra having the same point-group symmetry may be expected to be metrically different. Such a distribution of geometries will be reflected in a distribution of Δ values, and instead of a simple spectrum a composite spectrum consisting of a pair of broadened, possibly non-Lorentzian-shaped lines will be observed. The widths of the lines of model *b* (Table 5), however, are of the same order as those observed in cubic hexafluostannates (35) for comparable absorber thickness. Hence we conclude that the distribution about the mean of electric field gradient (e.f.g.) values arising from the distribution of SnO_6 geometries is too small to give rise to any appreciable line broadening, and so the observed separation, ~ 0.32 mm/s, may be taken to be the unique value of Δ.

This insensitivity of Δ to variations in SnO_6 geometry present in $SnP_2O_7(I)$ is further manifested on comparing the spectra of $SnP_2O_7(I)$ and $SnP_2O_7(II)$: although only a small number of distinct types of SnO_6 octahedra is expected to be present in *II* (six if *II* is isostructural with $SiP_2O_7(II)$) compared with the quasi-continuous distribution in *I*, the spectra are indistinguishable. In these circumstances it is reasonable to attempt an estimate of the relative contributions made to the observed Δ by the two components of the e.f.g. at the Sn atom, $q_{\text{latt.}}$ and $q_{\text{val.}}$. Assuming the symmetry of the SnO_6 octahedron to be $\bar{3}$, $\Delta = \frac{1}{2}e^2qQ$, $a = (1 - R)q_{\text{val.}} + (1 - \gamma_\infty)q_{\text{latt.}}$, where R and γ_∞ are the Sternheimer antishielding factors for the valence (val.) and lattice (latt.) contributions respectively. An estimate of $q_{\text{latt.}}$ can then be obtained from a point-charge model. A calculation using the average positional parameters of the Sn, P, and O atoms as determined from the structure refinement in $Pa3$ (Table 2), and assuming formal charges of 4+, 5+, and 2− respectively, gave $q_{\text{latt.}} = 0.384 \times 10^{14}$ e.s.u./cm^3. Taking $Q(\text{Sn}) = -0.07 \times 10^{-24}$ cm^2 (48) and $\gamma_\infty = -10$ (49) leads to an expected Δ of only about 0.05 mm/s, *i.e.* about six times smaller than the observed value and only about 1/20 the resonance line-width. Covalency and polarization factors will necessitate reduction of the formal charges on the ions which in turn will reduce $q_{\text{latt.}}$ still further. When the computation was repeated for the formal charges of 4+, 1.5+, and 1−, the resulting values were 0.135×10^{14} e.s.u./cm^3 for $q_{\text{latt.}}$ and 0.02 mm/s for Δ. It can thus be argued that a significant, possibly the dominant, contribution to the observed Δ comes from $q_{\text{val.}}$. A nonzero $q_{\text{val.}}$ term implies nonzero occupancy of the valence orbitals on the Sn atom, *i.e.* the "Sn^{4+} ion" is not ideal (*cf.* preceding section). When the symmetry of the Sn site is lowered from $m3m$ to $\bar{3}$, the t_{1u} orbitals, formed from the 5p atomic orbitals of Sn and ligand-group orbitals, are split into a doublet E_u (p_x, p_y character) and a singlet A_u (p_z character). The e.f.g. then arises from differences in p-character of this doublet and singlet. The $q_{\text{val.}}$ term cannot be calculated as the distribution of the valence electrons on the Sn atom is not known.

[9]In principle a distribution of environments of the Sn atom would produce a distribution of chemical shift values, which too might falsify evaluation of Δ from the experimental spectrum. However, in SnP_2O_7 the δ distribution must be completely negligible; in the cubic pyrochlores $Ln_2Sn_2O_7$ (Ln = La to Lu) the progressive distortion of the SnO_6 octahedron of symmetry $\bar{3}m$ increases Δ from ~ 0.42 to ~ 0.80 mm/s, yet δ remains constant (50, 51).

We wish to express our gratitude to Dr. L. D. Calvert for obtaining the Guinier photographs; Dr. J. A. Duffy for many helpful discussions; Dr. M. Falk for the use of

his i.r. spectrometer; Dr. C. R. Masson and Mr. J. Uher for the oxygen analyses by vacuum fusion; Dr. W. G. Parker for obtaining the low-temperature Mössbauer spectra of SnP_2O_7; and Mr. P. F. Seto for obtaining some of the i.r. spectra. Award of an INCO Graduate Research Fellowship to one of the authors is gratefully acknowledged.

This investigation was supported by a grant in aid of research from the National Research Council of Canada.

SHINGO MATSUOKA, TAKAAKI TAMURA, KEICHI OSHIMA, and YUNOSUKE OSHIMA. Can. J. Chem. **53**, 92 (1975).

Ionic reactions in the radiolysis of *n*-butane were studied at temperatures ranging from 17 to 548 °C. Ionic chain reactions were found for the first time to take part in the radiation-sensitized thermal cracking mechanism of hydrocarbon system.

The isobutane and isobutene yields increased with increasing temperature and at 548 °C their *G*-values reached 31.2 and 12.1, respectively, though they were not formed by the thermal cracking of *n*-butane. The formation was completely suppressed by the addition of 0.15 mol% ammonia. They were produced with high yields irrespective of the kind of wall of the irradiation cells. It was concluded from these results that isobutane and isobutene were formed by homogeneous ionic chain reactions with activation energies. Part of the propane product was also found to have been formed by ionic chain reactions. From the effect of adding *n*-pentane on the yields of the ionic products, $C_4H_9^+$ ion was inferred as the carrier ion.

In the vicinity of room temperature, formation by ionic reactions of polymers with more than 14 carbon atoms was inferred from the material balance of the products from H_2 to C_{14}.

SHINGO MATSUOKA, TAKAAKI TAMURA, KEICHI OSHIMA et YUNOSUKE OSHIMA. Can. J. Chem. **53**, 92 (1975).

On a étudié les réactions ioniques de la radiolyse du *n*-butane dans un intervalle de température de 17 à 548 °C. Les réactions ioniques en chaîne ont été observées pour la première fois dans le mécanisme de craquage thermique, sensibilisé par les radiations, d'un système d'hydrocarbure.

Les rendements pour l'isobutane et l'isobutène augmentent avec l'élévation de température, et à 548 °C les valeurs *G* atteignent respectivement 31.2 et 12.1, même s'ils ne sont pas formés par le craquage thermique du *n*-butane. La formation a été entièrement supprimée par l'addition de 0.15 mol% d'ammoniac. On les a obtenu avec de hauts rendements sans tenir compte de la sorte de paroie des cellules servant à l'irradiation. Ces résultats indiquent que l'isobutane et l'isobutènes sont formés par des réactions ioniques en chaîne homogène ayant des énergies d'activation. On a trouvé qu'une partie de propane s'est formée par des réactions ioniques en chaîne. L'effet produit par addition de *n*-pentane sur les rendements en produits ioniques indique que l'ion $C_4H_9^+$ est impliqué comme ion vecteur.

Au voisinage de la température ambiante, la formation par des réactions ioniques de polymères, ayant plus de 14 atomes de carbone est déduite du bilan matériel des produits de H_2 à C_{14}.

[Traduit par le journal]

Introduction

The radiation-sensitized thermal cracking (r.t.c.) of hydrocarbons has been studied by many workers mainly from the viewpoint of industrial interest (1–6). Its reaction mechanism, however, has not been subjected to close investigation, since a radiation-initiated radical chain mechanism which is similar to the well-known radical chain mechanism for the thermal cracking of hydrocarbons has been taken for granted.

On the other hand, Bansal and Freeman (7) and van der Linde and Freeman (8) carried out a detailed study of the r.t.c. of alcohols, and have discovered that ionic chain reactions take part in the reaction system. These ionic chain

reactions involve formation of a protonated cluster of alcohols and its subsequent thermal decomposition. Nakagawa *et al.* have observed the large yields of benzene ($G = 28.5$) and cyclohexene ($G = 14.0$) in the radiolysis of 1,4-cyclohexadiene vapor at room temperature and a pressure of 42 Torr, and have interpreted these products in terms of an ionic chain mechanism (9, 10).

In a previous paper (11), we reported the behavior of radical products from the r.t.c. of *n*-butane. The present paper is concerned with the behavior of several ionic products and describes especially a participation of ionic chain reactions in the r.t.c. mechanism.

Experimental

The apparatus and techniques used for the experiments were described in detail in the previous paper (11). Experiments were carried out in both static and flow systems. The cylindrical Pyrex irradiation cells with 0.3 mm thick electron admission windows (105 mm long and 16.5 mm i.d.) were used for the static experiments and the copper irradiation cell with a 0.04 mm thick stainless steel window (124 mm long and 17 mm i.d.) for the flow experiments, unless otherwise stated.

Irradiations were performed with a collimated 1.5 MeV electron beam from a Hitachi Cockcroft–Walton type accelerator. The absorbed dose in the static experiments was measured by the ethylene dosimeter assuming $G(H_2) = 1.31$ (12), and in the flow experiments it was determined on the basis of the acetylene yield of $G(C_2H_2) = 2.45$ from the radiolysis of ethylene (11). The product yields from the r.t.c. of *n*-butane-additive mixtures were calculated on the basis of the energy absorbed only in the *n*-butane. The dose rate distribution curve along the length of the cell was shown previously.

The total gas pressure of the samples used in the static experiments was 400 mm Hg at 0 °C, and in the flow experiments it was constant at atmospheric pressure irrespective of reaction temperature.

The reactants *n*-butane, ethylene, propylene, and ammonia were the same as those used before. GR grade *n*-pentane (99.99%) obtained from Tokyo Kagaku Seiki Co. was dried with molecular sieve 3A before use.

The products hydrogen and hydrocarbons from C_1 to C_8 were analyzed by gas chromatography (11). For some samples, the C_9–C_{14} products were also analyzed by gas chromatography, using a 25 m Apiezon-L capillary column (0.25 mm i.d.) at 150 °C.

Results and Discussion

(A) Formation of Isobutane and Isobutene

(i) Effect of Temperature

The yields of isobutane and of isobutene from the radiolysis of *n*-butane were measured at temperatures between 17 and 548 °C. Arrhenius plots of them are shown in Fig. 1.[2] To investigate the effect of the wall of the irradiation cell on these products, several kinds of walls were used. In the static experiments, Pyrex cells and internally silver-coated Pyrex cells were compared under the following reaction conditions: dose rate = 1.17×10^{18} eV/g s, dose[3] = 3.41×10^{20} to 3.10×10^{19} eV/g, conversion of *n*-butane = 0.101 to 2.00%. In the flow experiments, the quartz and the copper cells were used under these conditions: dose rate = 9.3×10^{17} eV/g s for the copper cell, 1.30×10^{18} eV/g s for the quartz cell, contact time = 16.6 to 24.0 s, conversion = 0.055 to 5.0%.

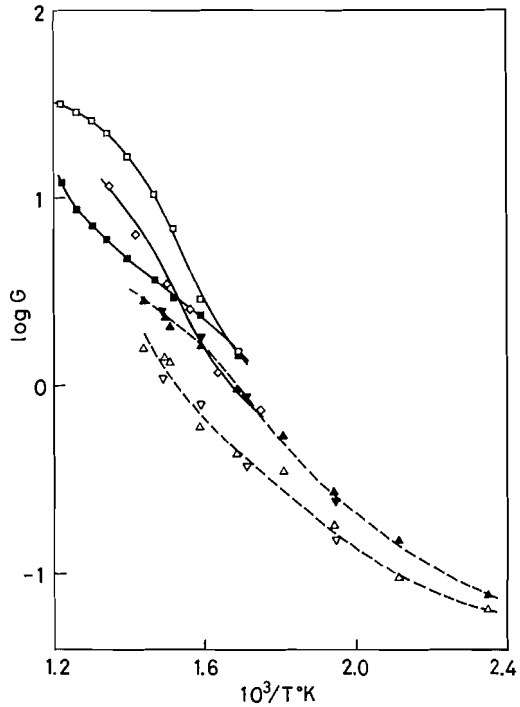

FIG. 1. Arrhenius plots for the formation of isobutane (open points) and of isobutene (filled points) in the various irradiation cells: (△, ▲) Pyrex cell and (▽, ▼) internally silver-coated Pyrex cell, in the static experiments; (◇) quartz cell and (□, ■) copper cell, in the flow experiments.

The *G*-values of isobutane and isobutene

[2]The isobutane yield in the flow system increased, finally reaching the asymptotic value, as the time of passing the feed gas through the flow line became longer. This increase is probably due to the dessication of the flow line (see later). The yields reported were measured after a sufficient aging time of the flow line.

[3]Dose was varied corresponding to reaction temperature.

TABLE 1. Effect of varying amount of ammonia on the yields of several products from the r.t.c. of *n*-butane at 393 °C, in the static experiments with Pyrex cells

Products	G-values with amount of NH_3 (mol%) = 0	0.021	0.146	0.99	2.48	10.1	20.0

increased with increasing temperature and in the copper cell reached 31.2 and 12.1, respectively, at 548 °C. Their yields from the thermal cracking (t.c.) at 548 °C did not amount to even 0.5% of those from the r.t.c., even when the t.c. reaction proceeded to the same conversion as the r.t.c. reaction did. The apparent activation energies for the formation of isobutane and isobutene varied with temperature, and at 400 °C they were about 15 and 8 kcal/mol, respectively.

(ii) Effect of Adding Ammonia

Table 1 shows the effect of ammonia added in varying amounts on the yields of several products related to ionic reactions. The experiments were carried out in the static system under the following conditions: temperature = 393 °C, dose rate = 1.24×10^{18} eV/g s, dose = 3.72×10^{19} eV/g, conversion = 1.1%.

The effect of adding 11.4 mol% ammonia at 449 °C, obtained in the flow system is presented in Table 2. The dose rate was 9.8×10^{17} eV/g s, the contact time 16.2 to 14.5 s, and the conversion 1.2%.

The striking suppression of the formation of isobutane and isobutene, caused by the addition of ammonia is seen from Tables 1 and 2.

(iii) Effect of Adding Propylene

Isobutane and isobutene were formed as minor products; for instance, at 548 °C they constituted only 0.47 and 0.18 mol% of the total products, respectively. We studied the effect of propylene, one of the major products, on the formation of the isomerized C_4 products (in the flow system).

TABLE 2. Effect of ammonia addition on the yields of several products from the r.t.c. of *n*-butane at 449 °C, in the flow experiments with the quartz cell

Products	*G*-values with amount of NH_3 (mol%) = 0	11.4
$-n$-B	800	870
Pr	7.9	4.0
cyclo-Pr	—	0.053
iso-B	8.4	0.097
iso-B$^=$	3.7	0.085
1-B$^=$	5.1	6.0
trans-2B$^=$	5.3	5.6
cis-2B$^=$	3.30	3.48
Higher paraffins	1.58	1.11
Higher olefins	2.00	1.92

The results are given in Fig. 2*A*. The amount of propylene in Fig. 2*A* is the sum of the added propylene and a half of the product propylene. The experimental conditions used were as follows: temperature = 449 °C, dose rate = 9.8×10^{17} eV/g s, contact time = 13.4 to 15.8 s, conversion = 1.17 to 0.24%.

The isobutene formation is seen to be sensitized by propylene and on the contrary the isobutane formation to be suppressed.

(iv) Effect of Adding n-Pentane

Figure 2*B* shows the effect of adding *n*-pentane (0 to 3.6 mol%) on the yields of the isomerized C_4 and C_5 products. The *n*-pentane added contained 2-methylbutane, 2-methyl-1-butene, and 2-methyl-2-butene as impurities, and the yields in Fig. 2*B* were corrected for these

For personal use only.

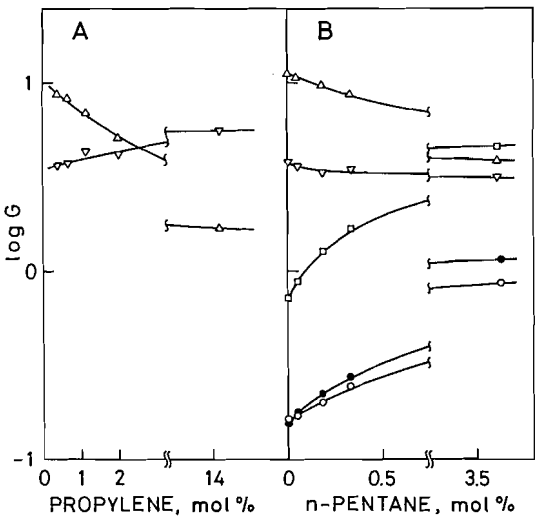

FIG. 2. The effects of the additives on the yields of (△) isobutane, (▽) isobutene, (□) 2-methylbutane, (○) 2-methyl-1-butene, and (●) 2-methyl-2-butene from the r.t.c. of *n*-butane at 449 °C in the flow experiments with the quartz cell.

impurities; the maximum corrections were 2.9, 44, and 44% respectively. The experimental conditions were the same as used in the experiments on the effect of propylene addition.

As seen in Fig. 2*B*, the yields of isobutane and isobutene decreased with increasing *n*-pentane and on the contrary, the yields of 2-methylbutane, 2-methyl-1-butene, and 2-methyl-2-butene, which were not formed by radical reactions, increased.

Formation Mechanism

The following results indicate that isobutane and isobutene were formed by homogeneous ionic chain reactions. (*a*) The *G*-values of isobutane and isobutene both exceeded 10 at high temperatures (Fig. 1). (*b*) They were not formed by the t.c. of *n*-butane and their formation by the r.t.c. was completely inhibited by the addition of ammonia. (*c*) Their formation is not due to the radiation-sensitized wall effect, because they were produced with high yields in all kinds of walls studied. (*d*) At the dose rates used in the present experiments, the ions formed in the gas-phase are considered to react according to homogeneous kinetics (13).

In the present system, the primary ions formed by ionizing radiation change mostly into $C_4H_9^+$ ions by ion–molecule reactions (14, 15). If we assume that the precursor ion for the isomerized C_4 products is $C_4H_9^+$, the decrease of the yields of these products by the addition of *n*-pentane (Fig. 2*B*) is explained by the following hydride ion transfer reaction.

[1] $C_4H_9^+ + n\text{-}C_5H_{12} \rightarrow C_5H_{11}^+ + C_4H_{10}$

The newly formed $C_5H_{11}^+$ ion is probably the precursor of the isomerized C_5 products, in agreement with the experimental observation.

We propose a following mechanism for the isobutene formation.

[2] $s\text{-}C_4H_9^+ + C_3H_6 \rightarrow C_7H_{15}^+$

[3] $C_7H_{15}^+ \rightarrow C_7H_{15}'^+$ (isomerization)

[4] $C_7H_{15}'^+ \rightarrow C_3H_7^+ + \text{iso-}C_4H_{10}$

[5] $C_3H_7^+ + n\text{-}C_4H_{10} \rightarrow s\text{-}C_4H_9^+ + C_3H_8$

The reactant propylene in reaction 2 is produced as a major product of the radical chain reactions (11). Although Abramson and co-worker have reported that reaction 2 did not proceed at 0.005 Torr (16), at higher pressures as in our system this reaction probably proceeds. As shown in Table 1, the heptene yield increased from 0.63 to 1.44 by the addition of 0.021 mol% ammonia, but as more ammonia was added the yield decreased to 0.41. This can be explained by the competitive reactions between reactions 2–8.

[6] $C_3H_7^+ + NH_3 \rightarrow C_3H_6, \ldots .$

[7] $s\text{-}C_4H_9^+ + NH_3 \rightarrow C_4H_8, \ldots .$

[8] $C_7H_{15}^+ + NH_3 \rightarrow C_7H_{14}, \ldots .$

The participation of reaction 2 is also supported by the increase of the isobutene yield by the addition of propylene (Fig. 2*A*).

$C_7H_{15}^+$ or $C_7H_{15}'^+$ ion is much more stable in our system than $C_3H_7^+$ and $s\text{-}C_4H_9^+$ ions, and therefore reaction 3 or 4 competes with the corresponding neutralization reaction. The participation of the stable ion in the chain mechanism explains that only 0.15 mol% ammonia inhibits the isobutene formation, and is also consistent with the result that the isobutene formation has an activation energy.

Ionic chain reactions 2–5 produce propane in addition to isobutene. This is consistent with the results; that is, at temperatures where ionic chain reactions proceeded significantly, the decrement of $G(C_3H_8)$ caused by the addition of 20 mol% ammonia exceeded 1.1 (Tables 1 and 2) which was the decrement at temperatures where ionic chain reactions did not occur.

The initial increase and subsequent decrease of the yields of the straight chain butenes with increasing ammonia (Table 1) is also explained by reactions 2–8, and this trend agrees with the results obtained at room temperature (17). As seen in Table 1, the change of the yield of 1-butene is prominent among the straight butenes. This suggests that reaction 7 favorably produces 1-butene.

The inhibition of the isobutane formation by 0.021 mol% ammonia (Table 1) also suggests the participation of a stable ion in the chain mechanism. This stable ion may be scavenged by traces of water existing in the system, analogous to the reaction between $C_3H_7^+$ and H_2O to produce $C_3H_7 \cdot H_2O^+$ (18), explaining the sensitivity of the isobutane yield to the dessication of the flow line.[4]

The isobutane yield, however, decreased by propylene addition. The same decrease was observed by adding the products from the t.c. of *n*-butane instead of adding propylene. Further, as the addition of 11.4 mol% ammonia caused only a slight change of the yields of higher paraffins, higher olefins, and the straight chain butenes (Table 2), the participation of the accumulated products in the chain mechanism of the isobutane formation may be excluded. If we assume that isobutane is formed by a usual hydride ion transfer reaction of $C_4H_9^+$ with *n*-butane molecule, $C_4H_9^+$ must be a protonated methylcyclopropane or isobutyl cation to secure an exothermicity of the reaction (19, 20). However, Lias *et al.* have reported that the isobutyl cation formed as a fragment ion from the radiolysis of isopentane at 27 °C isomerizes promptly to *t*-butyl cation before it undergoes a hydride ion transfer reaction (21). A further study is necessary to construct a mechanism leading to the isobutane formation.

The observed activation energies for the formation of isobutane and isobutene should not be attributed to the increase of the quantity of the accumulated propylene, one of the reactants, with increasing temperature, since the isobutane formation was suppressed by propylene and the isobutene formation was only slightly sensitized by the addition of a large amount of propylene. They should be attributed to the activation energy of elementary reactions such as reactions 3 and 4.

(B) Formation of Polymer (Material Balance of the Products)

In Fig. 3 are given the temperature dependence curves of the ratio of the sum of hydrogen atoms to that of carbon atoms in the products from H_2 to C_8, *H/C*, obtained by the static experiments with and without the addition of 20 mol% ammonia. Also presented are Arrhenius plots of the decomposition *G*-values of *n*-butane calculated on the basis of numbers of C atoms in the products. The *H/C* values obtained from the radiolysis of *n*-butane in the internally silver-coated Pyrex cells and those from the radiolysis of *n*-butane containing 0.72 mol% of 3-methylheptane in the Pyrex cells are also plotted. In some samples, the *G*-values for C_9–C_{14} products were determined; they were all less

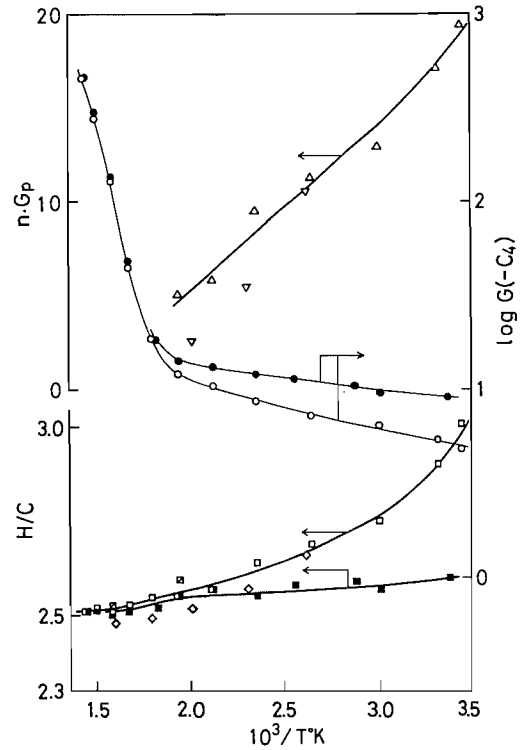

FIG. 3. The temperature dependence curves of (□)*H/C*, (△)$n \cdot G_p$, and (○)$G(-C_4)$ from the r.t.c. of *n*-butane in Pyrex cells; (◪)*H/C* in internally silver-coated Pyrex cells; (◇)*H/C* and (▽)$n \cdot G_p$ from the r.t.c. of *n*-butane containing 0.72 mol% 3-methylheptane in Pyrex cells. Filled marks correspond to the r.t.c. in the presence of 20 mol% ammonia.

[4]The lower yields of isobutane in the static system than in the flow system (Fig. 1) are probably ascribed to the difference in the residual water concentration between the two systems.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

than 0.02. Thus the contribution of the products from C_9 to C_{14} to the H/C is negligible. The experimental conditions are given in $(A)(i)$.

The H/C values from the radiolysis of pure *n*-butane deviated significantly at near room temperature from that of the feed *n*-butane, 2.5. For instance, the H/C was calculated to be 3.0 at 17 °C. Since the same deviation was observed in the experiments with the internally silver-coated Pyrex cells, this cannot be ascribed to the selective adsorption of products by Pyrex wall. The H/C value, however, approached 2.5 by the addition of 20 mol% ammonia. Therefore, this deviation is presumably ascribed to the formation of polymer, having more than 14 carbon atoms, by an ionic mechanism. A slight deviation from 2.5 of the H/C value obtained in the presence of ammonia may be explained by the formation of hydrogen and amines from the ammonia decomposition. The polymer formation has also been reported in the gas-phase radiolysis of methane (22) and in the solid-phase radiolysis of methane, ethane, and propane (23).

Assuming the chemical formula of the polymer to be $(CH_2)_n$ (23) and denoting its G-value by G_p, we can determine the values of nG_p so as to adjust the H/C value to 2.5. The temperature dependence curve of nG_p is also plotted in Fig. 3. The polymer formation has an apparent negative activation energy.

The addition of 0.72 mol% 3-methylheptane caused a slight decrease of the yields of polymer from the radiolysis of *n*-butane (at about 0.1% conversion) and did not change the yield of 3,4-dimethylhexane (one of the major products at temperatures below 280 °C). Considering that the final concentration of the 3,4-dimethylhexane product was less than 150 p.p.m. in our experiments, this result indicates that the consumption of higher paraffin products through hydride ion transfer reaction can be neglected. This suggests that the *n*-butane molecule is one of the reactants for the polymer formation, as in the case of the radiolysis of methane (22, 23).

The authors would like to express their sincere thanks to Professor Yoneho Tabata of the University of Tokyo for his helpful discussions and encouragement. The authors are also deeply indebted to Mr. Keiichi Yotsumoto and Mr. Hiromi Sunaga of Japan Atomic Energy Research Institute for their valuable assistance.

Etude des succinates simples et complexes de cobalt(II)

PATRICK SHARROCK ET THEOPHILE THEOPHANIDES
Département de chimie, Université de Montréal, Montréal, Québec H3C 3V1

Reçu le 22 mai 1974

PATRICK SHARROCK et THEOPHILE THEOPHANIDES. Can. J. Chem. **53**, 98 (1975).

Le succinate de cobalt(II) tétrahydraté, $CoC_4H_4O_4 \cdot 4H_2O$, ainsi que le sel anhydre amorphe et cristallisé ont été préparés et étudiés par spectroscopie i.r., u.v.–visible, susceptibilité magnétique, thermogravimétrie et par diffraction de rayons X. Les sels alcalins du succinate de cobalt $M_2Co_2(C_4H_4O_4)_3$, où $M = K^+$ et NH_4^+ ont été synthétisés pour la première fois. Les conformations, alternée *gauche* et alternée *trans* de l'acide succinique ont été trouvées dans ces complexes. Les succinates du cobalt étudiés ici n'ont pas la structure-cage.

PATRICK SHARROCK and THEOPHILE THEOPHANIDES. Can. J. Chem. **53**, 98 (1975).

Cobalt(II) succinate tetrahydrate, $CoC_4H_4O \cdot 4H_2O$ and anhydrous (amorphous and crystalline) have been prepared and studied by i.r. and u.v.–visible spectroscopy, magnetic susceptibility, thermogravimetry, and by X-ray diffraction. The alkaline salts of cobalt succinate $M_2Co_2(C_4H_4O_4)_3$, where $M = K^+$ and NH_4^+ have also been prepared for the first time. The staggered *gauche* and *trans* conformations of succinic acid have been found to be present in the complexes. The cage-like structure has not been found in any of the Co(II) carboxylates studied here.

Introduction

L'acide succinique est un acide α,ω-dicarboxylique et sa structure cristalline présente de longues chaînes dans lesquelles les molécules sont en conformation *trans* et forment des ponts hydrogènes entre elles (1). L'acide succinique avec les éléments de transition forme des complexes polymères ou des chélates (2). On a trouvé par spectroscopie infrarouge (3) que le succinate de sodium, de symétrie C_{2h} a une conformation alternée *trans* (voir fig. 1).

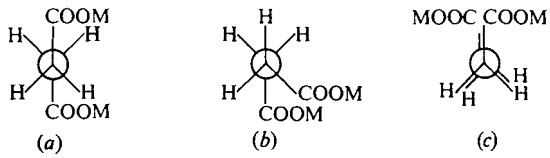

FIG. 1. Les trois rotamères de l'acide succinique complexé. (*a*) Alternée *trans*: $M = H^+$, Na^+, K^+, NH_4^+, Co^{2+}. (*b*) Alternée *gauche*: $M = Co^{2+}$. (*c*) Eclipsée *cis*: $M = Cu^{2+}$, Cr^{2+}.

Les structures des complexes succinates polymères du cuivre(II) et chrome(II) sont connues (4) et leurs spectres infrarouges sont caractéristiques de la conformation éclipsée *cis*. Par contre la conformation alternée *gauche* a été trouvée dans les complexes $M_2[Co_2(\text{succinate})_3]$, où $M = K^+$ et NH_4^+, présentés dans ce travail. Le $K_2[Co_2(\text{succinate})_3]$ a été étudié antérieurement par "hétérométrie" (5). L'acide succinique forme des structures cages (6) avec le Cu(II) et le Cr(II). Par contre, le présent travail n'indique pas la présence de liens métal–métal ou de structures cages pour les succinates de Co(II).

Partie expérimentale

Succinates simples de cobalt(II)

Le succinate de cobalt(II) tétrahydraté a été préparé d'après la méthode publiée précédemment (7). Le succinate de Co(II) anhydre et amorphe est préparé en déshydratant le tétrahydraté dans une étuve à 100 °C à pression atmosphérique. En tirant sous vide et en chauffant entre 280 et 290 °C pendant plus d'une heure, on obtient le succinate de Co(II) anhydre et cristallin. Les réactions procèdent comme suit

$$Co(OH)_2 \cdot 6H_2O + HOOC{-}CH_2CH_2{-}COOH \xrightarrow[H_2O]{\Delta(60\,^\circ C)} CoC_4H_4O_4 \cdot 4H_2O$$

$$CoC_4H_4O_4 \cdot 4H_2O \xrightarrow[1\ atm]{100\,^\circ C} CoC_4H_4O_4\ (\text{amorphe}) \xrightarrow[\text{sous vide}]{285\,^\circ C} CoC_4H_4O_4\ (\text{cristallin})$$

Le succinate de cobalt deutéré, $CoC_4H_4O_4 \cdot 4D_2O$, a été obtenu en recristallisant le produit amorphe dans le D_2O.

Succinates complexes de cobalt (II)

Les sels alcalins de succinates de Co(II) ont été synthétisés pour la première fois en utilisant la méthode suivante.

Le sel d'ammonium-succinate cobalt(II)

A une solution de 5 g de succinate d'ammonium dans 5 ml d'eau on ajoute 30 ml de *t*-butanol qui restent sur

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

une phase supérieure. On ajoute ensuite 15 ml d'une solution de 1.5 g de $CoCl_2 \cdot 6H_2O$ dans l'éthanol à 90%. On mélange vigoureusement sur agitateur magnétique. L'addition de 50 ml de méthanol rend homogène les deux phases et le sel d'ammonium succinate cobalt(II) précipite. Le précipité, lavé avec 5 portions de 75 ml d'un mélange 90% CH_3OH – 10% est rincé au méthanol pur et séché. On obtient 1.4 g de produit bleu (44.5%).

Anal. calc. pour $(NH_4)_2Co_2(C_4H_4O_4)_3$: C, 26.69; H, 4.46; N, 5.22. Trouvée par Chemalytics Inc., Tempe, Arizona: C, 26.51; H, 3.85; N, 5.18.

Le sel d'ammonium succinate cobalt(II) se disproportionne lentement dans le méthanol contenant 10% d'eau pour donner du succinate d'ammonium et du succinate de cobalt, comme suit

$$(NH_4)_2[Co_2(\text{succinate})_3] \xrightarrow{H_2O} 2Co(\text{succinate}) \cdot 4H_2O + (NH_4)_2(\text{succinate})$$

Le sel de potassium succinate cobalt(II)

La présence de deux phases n'est pas nécessaire pour commencer cette préparation. A 50 ml d'une solution saturée de succinate de potassium dans l'éthanol à 90% on ajoute goutte à goutte une solution saturée de $CoCl_2$ dans le même solvant. Il se forme un précipité huileux qui se sépare dans une phase inférieure. Ce précipité se coagule lentement et on arrête l'addition de Co^{2+} lorsqu'une suspension poudreuse est obtenue. On filtre et on lave le précipité de couleur mauve avec 250 ml de méthanol contenant 10% d'eau pour éliminer le chlorure de potassium qui se forme durant la réaction

$$2CoCl_2 \cdot 6H_2O + 3K_2C_4H_4O_4 \xrightarrow{EtOH\ 90\%} K_2Co_2(C_4H_4O_4)_3 + 4KCl + 6H_2O$$

Le produit est rincé au méthanol et séché à l'air.

Anal. calc. pour $K_2Co_2(C_4H_4O_4)_3$: C, 26.48; H, 2.21. Trouvée: C, 26.43; H, 1.73.

Le sel de potassium succinate cobalt(II) se disproportionne dans le méthanol contenant 30% d'eau et semble être plus stable que le sel analogue d'ammonium. Le succinate de lithium réagit, dans les mêmes conditions, pour former un complexe bleu, mais le succinate de sodium n'a pas donné de complexe bleu malgré de nombreuses tentatives. Dans chaque cas, il se formait un précipité rose de succinate de cobalt simple.

Tous les diagrammes de poudres ont été pris dans une caméra Debye–Scherrer (114.56 mm de diamètre) en utilisant les radiations filtrées du cuivre et du chrome (λ $CuK_{\bar{\alpha}}$ = 1.5418 Å et λ $CrK_{\bar{\alpha}}$ = 2.2909 Å). Les échantillons finement broyés ont été introduits dans les capillaires de quartz de 0.3 mm de diamètre. Les intensités des raies ont été estimés visuellement.

Les spectres infrarouges ont été enregistrés avec un spectrophotomètre Perkin–Elmer 621 entre 4000 et 250 cm^{-1}. L'échantillon a été broyé dans le Nujol et son spectre a été enregistré à l'aide d'un compensateur.

Les analyses thermogravimétriques ont été effectuées sur des échantillons de 50 mg environ, dans un panier en aluminium. La température était contrôlée par un programmeur et suivie sur papier graphique à l'aide d'un thermocouple. Le poids a été mesuré par une électrobalance de Cahn enregistré sur le même graphique à l'aide d'une plume Graphispot. Le panier était dans un long tube en verre, qui nous a permis de faire des mesures sous vide.

Résultats et discussion

Les succinates de cobalt(II) simples sont connus depuis quelques temps (7). Les diagrammes thermogravimétriques des échantillons de 60 à 80 mg avec un taux de chauffage de 3.5 °C/min ne révèlent pas de composé hydraté intermédiaire défini. Ceci concorde avec les travaux antérieurs où la perte d'eau, avec chauffage lent sous vide se traduit par un seul pic endothermique dans le diagramme thermodifférentiel (7). La perte observée de 29.12% correspond à celle calculée de 29.18% pour quatre molécules d'eau. Les quatre molécules d'eau du succinate semblent être équivalentes. Dans l'acétate de nickel tétrahydraté, isostructural avec l'acétate du cobalt(II) on trouve deux sortes de molécules d'eau qui diffèrent par leur nombre de liens hydrogènes (8). Ceci explique les spectres infrarouges (9) et les diagrammes thermogravimétriques (10) de l'acétate de cobalt(II) tétrahydraté. Le succinate de cobalt(II) ne se décompose pas comme l'acétate (11), sa stabilité provenant de la structure polymère du composé et de la non volatilité de l'acide succinique. La détermination de sa structure tridimensionnelle serait intéressante pour expliquer l'équivalence des 4 molécules d'eau. Au-dessus de 330 °C, le succinate anhydre se décompose pour donner du CoO (perte de poids calc., 40.4%; obs.; 39.8%).

Les travaux antérieurs ont permis de détecter une forme cristalline du succinate de cobalt(II) anhydre, obtenue en chauffant le composé amorphe sous vide et au-dessus de 280 °C. Les échantillons du produit cristallin ont donné des diagrammes X en bon accord avec ceux obtenus par la radiation $CoK_{\bar{\alpha}}$ et $CrK_{\bar{\alpha}}$ (tableau 1).

Les spectres visibles sont représentés dans la fig. 3. Le succinate tétrahydraté de couleur rose a une bande à λ_{max} = 19 550 cm^{-1} avec un épaulement à 21 300 cm^{-1}, en solution. A l'état solide on a deux bandes à λ_{max} = 19 680 et 21 880 cm^{-1}. Il est analogue au spectre de l'acétate de cobalt tétrahydraté (λ_{max} = 18 900 cm^{-1} avec épaulement à 20 200 cm^{-1}) et vérifie la géométrique octaédrique autour du cobalt (fig. 2*b*). Les molécules d'eau occupent 4 positions de coordination. L'absorption faible (car interdite par symétrie) de la transition $^4T_{1g}(P) \leftarrow {}^4T_{1g}(F)$, est caractéristique de la coordination

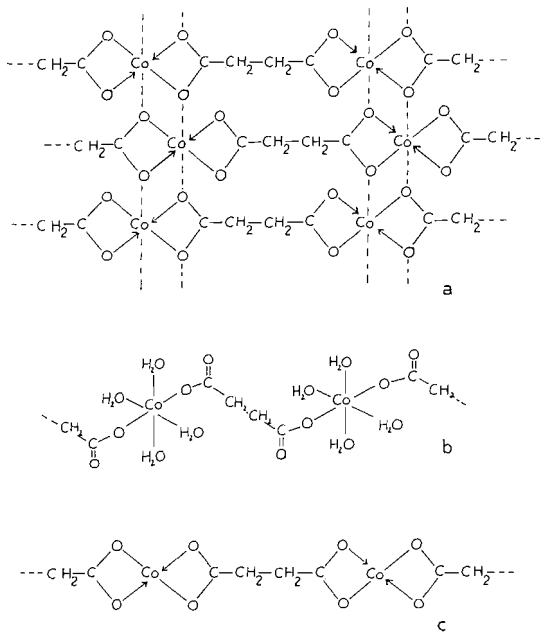

FIG. 2. Structures proposées les succinates de cobalt(II) simples: (*a*) Co(succinate), anhydre cristallin, (*b*) Co(succinate)·$4H_2O$ et (*c*) Co(succinate) anhydre amorphe.

octaédrique et l'épaulement vers les longueurs d'ondes plus courtes est une conséquence du couplage spin–orbite de l'état excité $^4T_{1g}(P)$.

Le succinate de cobalt anhydre et amorphe est bleu. L'absorption intense vers $\lambda_{max} = 18\,525$ cm^{-1} est due à la transition $^4T_1(P) \leftarrow {}^4A_2$. Le couplage spin–orbite dédouble l'état $^4T_1(P)$ et permet à la transition $^2G \leftarrow {}^2F$ (12) d'augmenter en intensité. Le calcul théorique prévoit une absorption près de 18 900 cm^{-1}, mais généralement on observe une bande complexe vers 15 000 cm^{-1}. Le spectre visible du succinate anhydre et amorphe désigne la géométrie tétraédrique proposée dans la fig. 2*c* pour le Co(II). Le succinate anhydre et cristallin a une absorption vers $\lambda_{max} = 21\,010$ cm^{-1} avec un épaulement à 18 875 cm^{-1}.

Le Co(II) de configuration d^7 avec trois électrons célibataires donne un moment magnétique, $\mu = 3.87$ M.B. Cependant, le couplage spin orbite cause un éclatement des états avec différents J de l'ordre de grandeur kT. Le calcul prévoit $\mu = 5.21$ M.B. pour le Co(II) octaédrique (13) et les moments magnétiques généralement observés sont compris entre 4.7 et 5.3 M.B. Les succinates tétrahydratés et cristallins ont respectivement, un moment magnétique à 22 °C de 4.88 et 5.11 M.B. Les mesures de suceptibilité magnétique suggérent aussi les structures déduites à l'aide des spectres visibles. Ces valeurs sont proches de celles observées pour des carboxylates analogues: $Co(CH_3COO)_2(H_2O)$, fraîchement recristallisé, $\mu = 4.84$ M.B. et $\mu = 5.16$ M.B. (14); $Co(CH_3COO)_2(D_2O)_2$, $\mu = 4.906$ M.B. et $Co(C_4H_4O_4)\cdot 4D_2O$, $\mu = 4.90$ M.B.

Lorsque le Co(II) est dans un environnement tétraédrique, le moment magnétique se situe généralement entre 4.4 et 4.8 M.B. Le succinate $CoC_4H_4O_4$ amorphe a un moment assez élevé avec $\mu = 4.89$ M.B. Ceci élimine la possibilité d'avoir une structure plan carré ou tétragonale car dans ces cas μ serait entre 2.4 et 2.8 M.B. (15). Puisque les spectres visibles montrent que le Co a un nombre de coordination de quatre, le succinate amorphe doit être tétraédrique, bien que la mesure de la susceptibilité magnétique soit dans l'intervale ordinaire du Co(II) octaédrique.

Les spectres infrarouges donnent des renseignements surtout sur la conformation adoptée par l'acide succinique dans les complexes. Les fréquences et les attributions sont rassemblées dans le tableau 2. Toutes les absorptions observées (fig. 4) pour le succinate tétrahydraté se retrouvent dans le spectre du succinate de sodium ou d'ammonium. La conformation est

*Present travail.

donc alternée *trans* (fig. 1*a*). Le succinate amorphe a des bandes assez larges, comme attendu pour un produit amorphe et les absorptions ν_sCOO et ν_aCOO n'ont pas une structure fine. Par contre, dans le succinate cristallin ces deux bandes sont dédoublées. De plus, quatre bandes caractéristiques ν_{C-C} et CH_2 de la conformation éclipsée *cis* (fig. 1*c*) apparaissent vers 900 et 1050 cm^{-1}. Les bandes de torsion et de balancement hors du plan du CH_2 sont complexes, mais ces massifs ressemblent dans cette région le spectre de l'anhydride succinique (fig. 4). Le sel amorphe a donc une conformation distordue, compatible avec la structure proposée (fig. 2*c*).

Les sels de potassium et d'ammonium du succinate de Co(II) présentent des spectres intéressants qui sont presque identiques. Les bandes ν_sCOO et ν_aCOO sont complexes. Les fréquences en dessous de 1400 cm^{-1} correspondent aux absorptions caractéristiques de la conformation alternée *trans* seulement légèrement déplacées et facilement reconnaissables d'après leur intensité (ces bandes sont indiquées avec des flèches dans la fig. 4). De plus, certaines fréquences typiques de la conformation *cis* sont présentes dans les spectres et sont indiquées par des astériques. Contrairement aux bandes caractéristiques de la conformation alternée *trans*, on ne retrouve pas intégralement toutes les fré-

quences typiques de la conformation *cis*. C'est pourquoi nous proposons que la forme alternée *gauche* est présente dans les sels alcalins de succinate de Co(II) et donne les huit absorptions qui restent, après avoir éliminé celles qui proviennent de la conformation alternée *trans*. Les deux conformations de l'acide succinique sont donc alternées *trans* et *gauche*. La structure proposée pour $M_2[Co_2(\text{succinate})_3]$ est représentée sur la fig. 5. Les ponts simples d'acide succinique alternent avec les ponts doubles. Dans la fig. 5 la conformation alternée *trans* de plus basse énergie correspond aux ponts simples comme dans le cas du succinate tétrahydraté. La conformation alternée *gauche* correspond aux ponts doubles et sera décrite dans la conclusion. La présence des deux conformations dans les sels alcalins de succinate de Co(II) se trouve vérifiée aussi par les trois fréquences ν_{CH} observées. En effet, les succinates de sodium et de cuivre ne présentent que deux bandes chacun dans cette région.

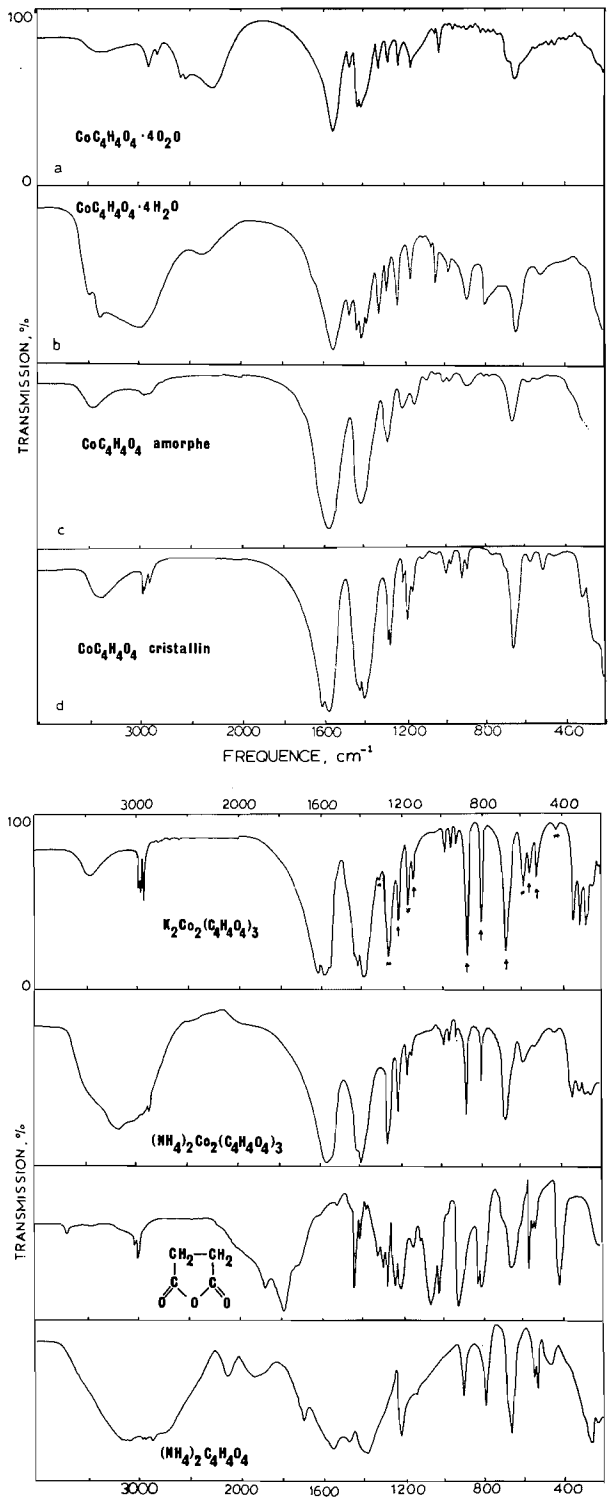

FIG. 4. Spectres infrarouges des succinates de cobalt(II) de l'anhydride succinique et du succinate d'ammonium.

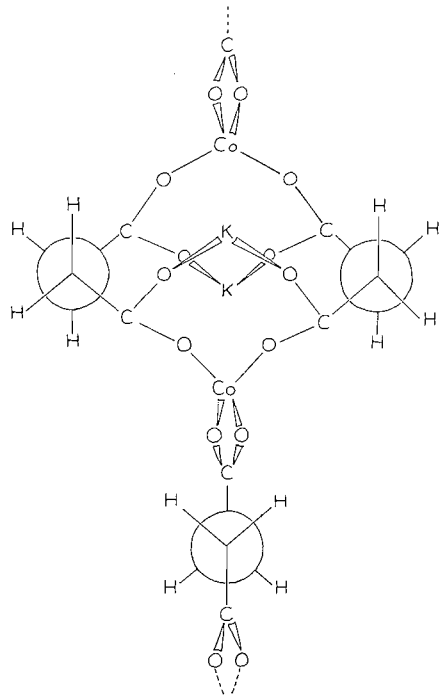

FIG. 5. Structure proposée pour le complexe K_2Co_2-(succinate)$_3$.

Les sels complexes $M_2[Co_2(\text{succinate})_3]$ sont de couleur mauve foncé et ont un spectre visible très simple avec deux absorptions d'intensité à peu près égale: $\lambda_{max} = 558$ et 522 nm pour $M = K^+$ et $\lambda_{max} = 588$ et 520 nm pour $M = NH_4^+$. Ceci appuie la structure proposée, où le métal est dans un environnement tétraédrique. Le moment magnétique observé de 5.36 M.B. pour $K_2[CO_2(\text{succinate})_3]$ est raisonnable et le diagramme X montre des distances réticulaires différentes.

Conclusion

La structure cage n'a été trouvée dans aucune des trois formes de succinate de cobalt(II) dans cette étude. Ceci démontre la tendance du cobalt(II) à former des environnements, soit octaédriques, soit tétraédriques et des polymères sans lien métal–métal. La formation des liens métal–métal n'est pas essentielle pour obtenir la structure cage dans le succinate de cuivre. Cependant, le présent travail indique que la géométrie autour du métal joue un rôle important dans la structure des carboxylates. Ainsi, dans le cas du Cu(II) et du Cr(II), la préférence marquée de la géométrie plan-carré permet le rapprochement des deux métaux et la formation subséquent d'une structure cage. L'influence des ligands en position axiale dans le case des carboxylates dinucléaires du Cu(II) est connue (16). L'étude des structures cages doit inclure, les ligands axiaux, le métal et sa géométrie habituelle, la présence d'un lien métal–métal (17) et les substituants en α des groupes carboxyliques (18). Le seul carboxylate de Co(II) à structure cage est le benzoate de cobalt, stabilisé avec la monoquinoline en position axiale (19).

L'acide succinique donne des complexes polymères stables et permet d'étudier le comportement des groupes carboxyliques et la conformation des chaînes organiques. La conformation alternée *gauche* proposée pour les ponts doubles dans $M_2[Co_2(\text{succinate})_3]$ est trouvée reliée à une structure pseudo-cage, où deux groupes COO forment deux ponts entre un cobalt et un potassium. Dans une vraie structure cage, quatre groupes COO forment quatre ponts entre deux métaux identiques. La structure pseudo-cage est par ce fait plus souple et permet au cobalt d'adopter une géométrie tétraédrique. Il est intéressant de remarquer que les sels alcalins du succinate de cuivre ont la composition $M_2[Cu(\text{succinate})_2]$, qui diffère de celle du $M_2[Co_2(\text{succinate})_3]$. L'acide succinique forme donc avec le cobalt et le potassium, un sel complexe analogue à celui formé avec l'acide acétique de composition $K_2Co_2(CH_3COO)_6 \cdot 4H_2O$ (20).

The Kinetics and Mechanism of H_2–D_2 Exchange Catalyzed by Hydridochlorotris(triphenylphosphine)ruthenium(II)[1]

GRAEME STRATHDEE AND RUSSELL GIVEN

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba R0E 1L0

Received August 15, 1974

GRAEME STRATHDEE and RUSSELL GIVEN. Can J. Chem. **53**, 106 (1975).

The H_2–D_2 exchange reaction is catalyzed extremely efficiently by solutions of hydridochlorotris(triphenylphosphine)ruthenium(II) in benzene between 279 and 298 K. Rates of exchange were partly controlled by the mass transport of hydrogen. A mechanism involving formation of di- and tetrahydride ruthenium species has been employed to explain the rapid H–D exchange without the participation of the original Ru—H bond of $RuHCl(PPh_3)_3$. Nuclear magnetic resonance and infrared experiments showed that the rate of exchange of Ru—H with D_2 was insignificant with respect to the rate of the H_2–D_2 equilibration process.

GRAEME STRATHDEE et RUSSELL GIVEN. Can. J. Chem. **53**, 106 (1975).

La réaction d'échange H_2–D_2 est catalysée d'une façon très efficace par des solutions d'hydridochlorotris (triphénylphosphine) de ruthenium(II) dans le benzène entre 279 K et 298 K. Les vitesses d'échange sont en partie contrôlées par le transport de masse de l'hydrogène. On a utilisé un mécanisme impliquant la formation d'espèces di- et tétrahydrure de ruthénium pour expliquer l'échange rapide H–D sans participation du lien original Ru—H du $RuHCl(PPh_3)_3$. Des expériences de r.m.n. et d'infrarouge montrent que le taux d'échange de Ru—H avec D_2 est très faible par rapport au taux d'équilibration de H_2 avec D_2. [Traduit par le journal]

Introduction

Hydrogen–deuterium exchange between D_2 and metal complexes in aprotic solvents has been used to show that metal hydride complexes can undergo intermolecular H–D transfer. Schunn has reviewed this subject in considerable detail (1). Often, metal complexes which participate in these reactions also catalyze H_2–D_2 equilibration to yield HD. This conversion has unique requirements: hydrido-complexes with one or more labile M—H bonds must have the capability to oxidatively add H_2 and D_2 either sequentially or simultaneously so that H and D scrambling may occur at the metal atom. The former route, sequential oxidative addition to the metal hydride containing an exchangeable metal–hydrogen bond, is probably favored in most cases, for example $RhH(CO)(PPh_3)_3$ (2), $FeH_2[P(O\text{-}i\text{-}C_3H_7)_3]_4$ (3), $CoH_3(PPh_3)_3$ (4), and $IrH_3(CO)(PPh_3)_2$ (5), likely function in this way. Eberhardt and Vaska have suggested that $Ir(CO)Cl(PPh_3)_2$ promotes H_2–D_2 exchange via an eight-coordinate intermediate, that is, by the second mechanism (6). Siegel has compared heterogeneous with homogeneous catalysts for the H_2–D_2 reaction (7). A detailed study of the kinetics of the H_2–D_2 exchange reaction has not been reported in any of these cases.

The possibility that this equilibration occurred extremely rapidly in the presence of $RuHCl(PPh_3)_3$ was suggested by our detailed study of the $RuCl_2(PPh_3)_3$ catalysis of D_2–C_2H_5OH exchange in 1:1 C_6H_6–C_2H_5OH (8). The gas phase composition was determined at all times by K_1 (9) for the reaction

$$[1] \qquad D_2 + H_2 \rightleftarrows 2HD$$

The present study of the kinetics of reaction 1 catalyzed by $RuHCl(PPh_3)_3$ has confirmed this hypothesis. In addition, it has been found that the original Ru—H bond does not participate in the exchange mechanism in C_6H_6 solution. The inplications of this unexpected behavior for other reactions catalyzed by $RuHCl(PPh_3)_3$ are discussed.

Experimental

The monohydrido complex, $RuHCl(PPh_3)_3$, was prepared by reaction of a benzene solution of $RuCl_2(PPh_3)_3$, obtained from Strem Chemicals Inc., with sodium borohydride in water (10). The dihydride, $RuH_2(PPh_3)_4$, was obtained by the method of Levison and Robinson (11).

Benzene was purified by slow percolation through a 0.2 m × 0.03 m column of activated Linde type 4A molecular sieve followed by distillation in a dry nitrogen atmosphere. All materials were stored and handled in a

N_2-filled glove box which was continuously purged with nitrogen containing less than 20 p.p.m. of oxygen.

The H_2–D_2 exchange reactions were always performed with freshly prepared solutions of $RuHCl(PPh_3)_3$. The reaction flask of total volume 93.3 ml was evacuated and filled with an H_2–D_2 mixture obtained from Matheson of Canada Ltd. Mass spectrometric analysis gave (mol %): H_2, 49.4; HD, 0.75; D_2, 49.8. The exchange reaction commenced with the rapid injection of 20.0 ml of the catalyst solution. The gas–liquid dispersion was magnetically stirred at about 2800 r.p.m. and the temperature was controlled to ± 0.1 K. Gas samples (1.0 ml) were removed by syringe and retained in glass bombs for mass spectrometric analysis. No exchange was observed in blank experiments without $RuHCl(PPh_3)_3$. No hydrogenation of C_6H_6 was detected by v.p.c. analysis, therefore no Ru metal was present.

Rates of equilibration are reported as rates of disappearance of D_2

$$[2] \qquad -d[D_2]/dt = \ln [(n_0-n_e)/(n_t-n_e)]A/t$$

where n_0, n_t, and n_e represent the mol% D_2 at $t = 0$, $t = t$ s and at equilibrium, respectively. A is the gas:liquid ratio in mol D_2 per l defined as: total initial D_2 in moles ÷ volume of solution in liter.

Nuclear magnetic resonance spectra were recorded with a Perkin Elmer R12A spectrometer which thermoregulated samples at 311 K.

Results

H_2–D_2 Exchange

Rate Measurements

A typical set of experimental data is shown in Fig. 1. These exchange reactions were extremely rapid even at low temperature in dilute solutions of the catalyst. Half-lives for the disappearance of D_2 (or H_2) were generally 100–300 s. If the reaction was not followed for a sufficiently long period to establish the equilibrium concentration of D_2, then n_e was calculated using the values for the equilibrium constant K for [1] given by Bond (9). There was no detectable change in the atom-fraction of D in the gas phase during these experiments, therefore no significant transfer of D to ligand or solvent C—H bonds occurred.

The dependence of the rate of the H_2–D_2 exchange reaction at 297 K on dissolved deuterium and total ruthenium concentrations is illustrated in Fig. 2. From the slopes of the lines through each data set, it was calculated that

$$[3] \qquad -d[D_2]/dt = k[D_2]^{1.5}\,[Ru]^{0.38}$$

The activation energy for the H_2–D_2 exchange reaction was evaluated from the data presented in Fig. 3. The slope of the line through the data plotted as log (rate) against $1/T$ gave $E_a = 25.9$ kJ/mol.

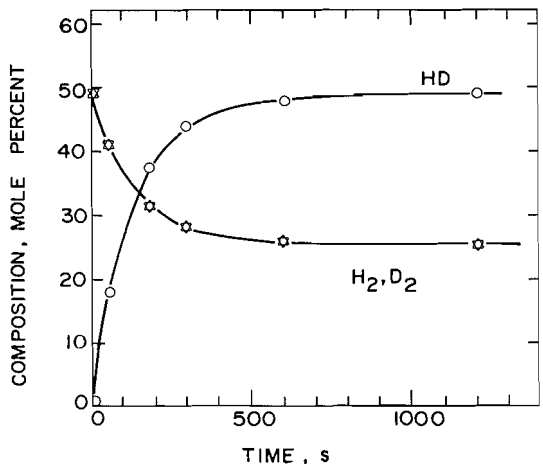

FIG. 1. Typical set of experimental data. △, D_2; ▽, HD; ○, H_2. Conditions: total ruthenium: 1.1×10^{-4} mol/l; initial pressure of D_2: 38.5 kPa; temperature: 278.1 K; solvent: C_6H_6.

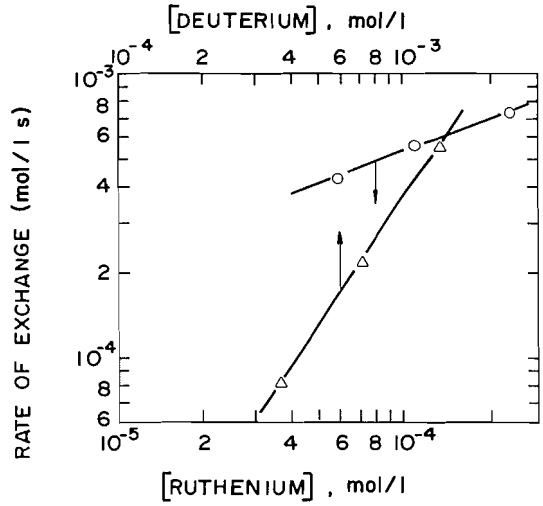

FIG. 2. Dependence of H_2–D_2 exchange rate on the concentrations of deuterium and total ruthenium. Temperature 278.1 K.

It may be seen in Fig. 2 that the rates of these reactions were extremely high: about 5×10^{-3} mol D_2/l s at 10^{-4} mol/l Ru. Since E_a was low, the possibility that the exchange rates were D_2-mass-transport-limited was tested by varying the stirring speed. Reduction in agitation rate by a factor of two decreased the reaction rate by a factor of approximately two, with [Ru] = 10^{-4} mol/l and [D_2] = 1.35×10^{-3} mol/l at 279 K. This suggested that the measured D_2 exchange rates were partly affected by the gas–liquid

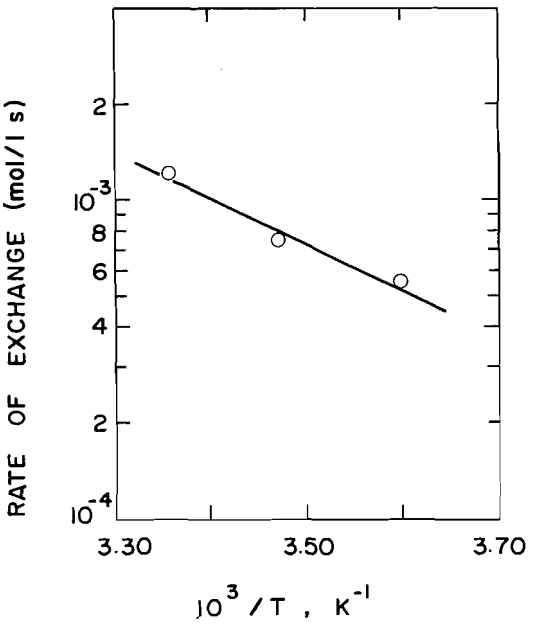

FIG. 3. Effect of temperature on the H_2–D_2 exchange rate.

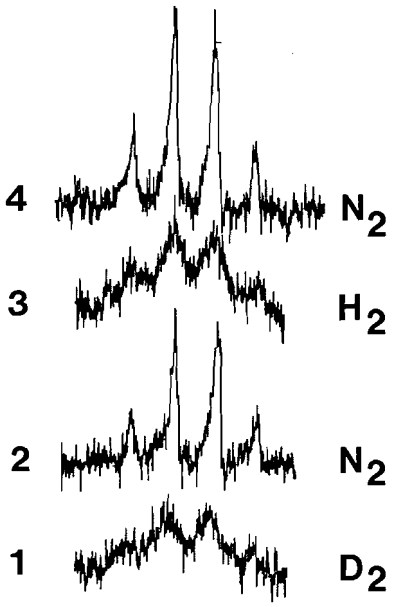

FIG. 4. Nuclear magnetic resonance spectra of a 0.1 *M* solution of $RuHCl(PPh_3)_3$ in $DCCl_3$: *1*, after 5 min D_2 purge; *2*, after 5 min N_2 purge; *3*, after 5 min H_2 purge; *4*, after 2.5 min N_2 purge.

diffusion rate. It was not feasible to increase gas–liquid transfer of D_2, HD, and H_2 by raising the stirring power since cavitation of the stirring bar occurred in the dispersion. Neither was it possible to reduce the temperature below 279 K in benzene (m.p. 278.6 K) nor to further dilute the catalyst solution below 5×10^{-5} mol/l Ru without increasing the effects of trace impurities such as O_2. The effect of partial diffusion control of the reaction rates on the kinetic parameters quoted above is considered in the discussion.

Effect of Added Reagents

PPh_3: Addition of a 5:1 excess to a C_6H_6 solution 1.2×10^{-4} mol/l in $RuHCl(PPh_3)_3$ and 1.3×10^{-3} mol/l in both H_2 and D_2 caused no change in the H_2–D_2 exchange rate. Since PPh_3 did not inhibit this reaction, generation of the catalytically active species did not require dissociation of PPh_3 from the complex.

O_2: Dissolution of $RuHCl(PPh_3)_3$ in C_6H_6 under oxygen yielded an oxidized green solution which was inactive for H_2–D_2 exchange. Since ruthenium metal is known to be an effective catalyst for this reaction, any trace amounts of Ru metal formed during the borohydride reduction of $RuCl_2(PPh_3)_3$ to yield $RuHCl(PPh_3)_3$ would have catalyzed H_2–D_2 exchange at a measurable rate. The lack of activity under O_2 confirmed that no metallic ruthenium had been formed during the preparation of $RuHCl(PPh_3)_3$.

Identification of the Catalytically Active Species

Because the rates of the H_2–D_2 reactions were rapid with respect to the rates of olefin hydrogenation using $RuHCl(PPh_3)_3$ (10), it was essential to establish if this hydrido–ruthenium complex, or another species derived from it, was catalytically active.

Nuclear Magnetic Resonance Analyses

Solutions of $RuHCl(PPh_3)_3$, up to 0.1 mol/l in $DCCl_3$, were purged in succession with D_2, N_2, H_2, and N_2 again. A typical set of spectra in the region of the high-field resonance of Ru—H is shown in Fig. 4. The initial spectrum under N_2 is not shown, but it was a well-defined quartet centered at 27.5 τ *vs.* TMS, with J(P—H) of 26 Hz, due to coupling of Ru—H with three equivalent P nuclei similar to scan 2 in Fig. 4. It may be seen that in either D_2- or H_2-saturated solution, the Ru—H quartet was considerably broadened. In every case, the sharp resonance was restored by purging with N_2. It is also important to note that rapid exchange (comparable to that for the H_2–D_2 reaction) of the Ru—H bond with D_2 did not occur.

Addition of 1 mole of anhydrous HCl per mole of $RuHCl(PPh_3)_3$ destroyed the quartet and yielded a broad resonance at 20.5 τ which decreased in intensity with time. This was likely due to production of $RuCl_2(PPh_3)_3$ with release of H_2 from the solution.

These data suggest that there was a fast ligand exchange process at the Ru atom, due either to weak complex formation between $RuHCl(PPh_3)_3$ and H_2 or D_2 without deuterium transfer to the Ru—H bond, or to slight but rapid dissociation of HCl from $RuHCl(PPh_3)_3$ occurring in the presence of H_2 or D_2.

Infrared Spectra

A comparison of the relative intensities of the ν(Ru—H) band at 2015 cm^{-1} (10) with the ν(C—H) band at 3055 cm^{-1} of $RuHCl(PPh_3)_3$ before and after exposure to D_2 gas in C_6H_6 solution for 5 min confirmed the n.m.r. observation that no significant Ru—H exchange with D_2 occurred on this time-scale.

Weak H_2 – Adduct Formation

By using the gas chromatographic H_2-stripping technique developed by us (12) to determine H_2-uptake equilibria with metal complexes, we detected a small but significant absorption of H_2 by a 2.5 mmol/l solution of $RuHCl(PPh_3)_3$ in C_6H_6. The ratio H_2:Ru was 0.056 ± 0.020 (σ). This is direct evidence for a weak interaction between $RuHCl(PPh_3)_3$ and H_2.

Experiments with $RuH_2(PPh_3)_4$

This dihydride was of interest as a potential catalytically active intermediate during H_2–D_2 exchange. The ability of this complex to absorb an additional mole of H_2 has been described by Knoth (13).

A bright yellow benzene solution, 1.1 mmol/l in $RuH_2(PPh_3)_4$, gave an H_2–D_2 exchange rate of only 2×10^{-4} mol D_2/l s at $[D_2] = 1.3$ mmol/l and 279 K. However, after sitting overnight under hydrogen, the solution had turned red. Under identical conditions, the H_2–D_2 exchange rate with this solution was then found to be 7.2×10^{-4} mol D_2/l s, that is, it had increased by a factor of 3.5. This enhanced rate may have been due to the formation of either the potentially more catalytically active $RuH_2(PPh_3)_3$ by loss of one PPh_3 ligand, or the red solvated cationic species $[Ru(PPh_3)_3]^{2+}$ reported by Mitchell *et al.* (14). The improved rate obtained with this $RuH_2(PPh_3)_4$ solution was about half that predicted for $RuHCl(PPh_3)_3$ at 1.1 mmol/l by extrapolation of the data in Fig. 2. Thus, the activities of these two solutions were comparable.

Discussion

Mechanism of the H_2–D_2 Exchange Reaction

Our observations that the specific rate of H_2–D_2 exchange is extremely rapid, and that the exchange of D_2 with the Ru—H bond of $RuHCl(PPh_3)_3$ is slow in comparison, may be accounted for if the following equilibria are considered

$$[4] \quad RuHCl(PPh_3)_3 + D_2 \overset{K_4}{\rightleftarrows} RuD_2(PPh_3)_3 + HCl$$

$$[5] \quad RuD_2(PPh_3)_3 + H_2 \overset{K_5}{\rightleftarrows} RuH_2D_2(PPh_3)_3 \overset{K_5'}{\rightleftarrows} RuHD(PPh_3)_3 + HD$$

$$[6] \quad RuD_2(PPh_3)_3 + N_2 \overset{K_6}{\rightleftarrows} RuD_2(N_2)(PPh_3)_3$$

The dependence of the apparent rate law, eq. 3, on $[D_2]^{1.5}$ and $[Ru]^{0.38}$ may be explained if the rate limiting step is the uptake of a second molecule of hydrogen by $RuD_2(PPh_3)_3$, that is, the forward step of equilibrium 5 with rate constant k_5.

It should be noted that other similar equations may be written by replacement of H by D and D by H as appropriate to take into account the additional possibilities of isotopic substitution. These will not be entirely equivalent expressions since the relative magnitude of the equilibrium constants will depend on different thermodynamic isotope effects (15). However, for the purpose of this discussion, H and D will be regarded as interchangeable and equilibrium H—D isotope effects will be ignored.

In the following discussion, the chemical aspects of H_2–D_2 exchange catalyzed by $RuHCl(PPh_3)_3$ are examined, and derivations of expressions which account for the observed dependence of the equilibration rate on $[D_2]$ and [Ru] are presented. The effect of D_2 and H_2 mass transport control are also discussed.

Chemical Aspects of the H_2–D_2 Exchange Mechanism

The validity of reaction 4 is supported by our n.m.r. and infrared data. It is clear that rapid chemical exchange at the Ru atom does not occur in the absence of H_2 (or D_2). In the presence of D_2, exchange of $RuHCl(PPh_3)_3$ in either $CDCl_3$ or C_6H_6 solution is very slow

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

between 279 and 298 K (10). Since the rate of H_2–D_2 exchange catalyzed by C_6H_6 solutions of $RuHCl(PPh_3)_3$ is fast in comparison, then the Ru—H bond cannot participate directly by a route involving alternate oxidative activation of H_2 and D_2, and exchange with, the monohydride. Also, because the atom-fraction of D in the gas-phase did not change during H_2–D_2 exchange experiments with $RuHCl(PPh_3)_3$, no significant transfer of D occurred to other proton pools such as the ortho-protons of the triphenylphosphine ligands.[2] This reaction rate is several orders of magnitude slower than that for the H_2–D_2 exchange discussed here (16, 17).

Dissociation of HCl from $RuHCl(PPh_3)_3$ must occur to allow formation of the di- and tetrahydrido species (reactions 4, 5). Activation of both H_2 and D_2 by $RuHCl(PPh_3)_3$ without loss of HCl or PPh_3 would violate the 16 and 18 electron rule as formulated by Tolman for homogeneous metal catalysts (18), since the potential pentahydrido intermediate would contain 20 valence shell bonding and non-bonding electrons. Our observation that excess PPh_3 did not retard the H_2–D_2 exchange reaction shows that PPh_3 dissociation is not a contributary step in the exchange.

The monohydride, $RuHCl(PPh_3)_3$, is thermodynamically stable with respect to loss of HCl. No $RuH_2(PPh_3)_3$ or $RuH_4(PPh_3)_3$ was evident in the n.m.r. spectrum of $CDCl_3$ solutions of $RuHCl(PPh_3)_3$ under 1 atm of H_2. Also, addition of 1:1 HCl to $RuHCl(PPh_3)_3$ readily yielded $RuCl_2(PPh_3)_3$ with loss of H_2. During this reaction, the high-field Ru—H quartet broadened and shifted to about 20 τ, and decayed with time as H_2 was evolved from solution. The dihydride is also unstable in the presence of HCl (13). The data above suggest that in reaction 4, the dihydrido species concentration is no greater than 5% of $[RuHCl(PPh_3)_3]$. Therefore K_4 is low (≤ 0.08).

The uptake of either H_2 (or D_2) or N_2 by $RuH_2(PPh_3)_3$ is well known (13, 19), although the equilibrium constants for reactions 5 and 6 have not been determined. Harris *et al.* have also shown that the conversion of $RuH_2(PPh_3)_4$ to $RuH_4(PPh_3)_3$ is facile. The reaction of $RuH_2(N_2)(PPh_3)_3$ with H_2 occurs readily as well to yield the tetrahydride (13, 19). Knoth's n.m.r. data (13) suggest that H_2 dissociation occurs from the related tetrahydridotris(tri-*p*-tolyl) phosphine ruthenium complex and the component reactions are rapid, but under 1 atm of H_2 this species appears to be somewhat more stable than the dihydrido adduct. In the hydrogen-saturated C_6H_6 solution of $RuHCl(PPh_3)_3$, the monohydride is thermodynamically the most stable Ru-complex.

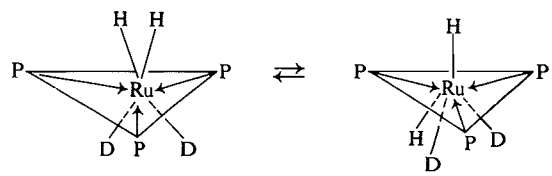
Relatively low H_2–D_2 exchange rates were obtained with $RuH_2(PPh_3)_4$ as the catalyst. Presumably, the extent of PPh_3 dissociation from this complex to yield the catalytically active $RuH_2(PPh_3)_3$ is small. This is certainly true for the closely related dihydride $RuH_2(CH_3PPh_2)_4$ (20). A detailed investigation of reaction 7 has not been reported in the literature, but

$$[7] \qquad RuH_2(PPh_3)_4 \rightleftharpoons RuH_2(PPh_3)_3 + PPh_3$$

if this equilibrium is established slowly, and lies well to the left, the enhancement of the H_2–D_2 exchange rate with time (*c.f.* section under Experiments with $RuH_2(PPh_3)_4$) could be explained in terms of an increase in the concentration of the catalytically active dihydride.

H–D Exchange on $RuH_2D_2(PPh_3)_3$

Nuclear magnetic resonance experiments have not exclusively related the broad Ru—H resonance either to rapid chemical exchange of $RuH_4(PPh_3)_3$ with hydrogen or to stereochemical non-rigidity. If mechanism I is correct, then the occurrence of fast H_2–D_2 exchange suggests that either three or four metal–hydrogen bonds are chemically equivalent for at least a fraction of their mutual lifetime on Ru. Also, the tetrahydride must be non-rigid, since addition and dissociation of H_2 and D_2 could otherwise occur without randomization and H_2–D_2 exchange. These criteria may be met if one or more of the Ru—H bonds moves through the plane of the three P atoms, *e.g.*



1 **2**

or if a structure similar to **2** is dominant. An equilibrium of this type may also account for the chemical reactivity of 1 mole of H_2 per mole

[2]The deuterium analyses would detect the loss of 5 microequivalents of D from the gas phase.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of Ru in the tetrahydride (13, 19, 21). In comparison to the free energies of activation for intramolecular rearrangement of dihydrides of the type RuH_2L_4 (L = phosphines, phosphites) which fall in the range 75 ± 9 kJ mol^{-1} (22), the free energies of activation for the proposed intramolecular process of $RuH_4(PPh_3)_3$ must be comparatively small because the overall $E^{\ddagger}$ for H_2–D_2 exchange was found to be only 26 kJ mol^{-1}.

Evaluation of H_2–D_2 Exchange Reaction Mechanisms

Three possible routes are considered, based on reactions 4–6, for which the rate-determining steps are: (*I*) activation of D_2 (or H_2) by $RuH_2(PPh_3)_3$ or $RuD_2(PPh_3)_3$; (*II*) uptake of H_2 by $RuHCl(PPh_3)_3$; and (*III*) activation of H_2 by $Ru(PPh_3)_3$. Mechanism I is favored.

Mechanism I

Assuming that the ruthenium complex species in solution are $RuHCl(PPh_3)_3$, $RuH_2(PPh_3)_3$, $RuH_4(PPh_3)_3$, and $RuH_2(N_2)(PPh_3)_3$ and their deuterated equivalents, and the rate-determining step is

$$[8]\quad (\text{Rate})_0 = -\text{d}[D_2]_0/\text{d}t = k_5[D_2]_0[RuH_2]$$

then initial rates are given by

$$[9]\quad (\text{Rate})_0 = \frac{2k_5K_4[D_2]_0^2[Ru]_0}{([HCl] + K_4[H_2]_T + K_4K_6[H_2]_T[N_2] + K_4K_5[H_2]_T^2)}$$

where $[D_2]$, $[Ru]_0$, and $[H_2]_T$ are the concentrations of initial D_2, total ruthenium, and total hydrogen, *i.e.*, H_2 + HD + D_2 respectively. If $[RuH_2]$, $[RuH_2(N_2)]$, and $[RuH_4]$ (the PPh_3 ligands have been omitted) are small with respect to [RuHCl], then the limiting case of eq. 9 becomes

$$[10]\quad (\text{Rate})_0 = \frac{2k_5K_4[D_2]_0^2[Ru]_0}{[HCl]}$$

But, since $[HCl] \doteqdot (K_4[H_2]_T\ [RuHCl])^{1/2}$ *c.f.* eq. 4, then at constant $[H_2]_T$, [HCl] varies approximately as $[Ru]_0^{1/2}$ and expression 10 yields

$$[11]\quad (\text{Rate})_0 = k_5(2K_4)^{1/2}[D_2]_0^{1.5}[Ru]_0^{0.5}$$

Depending on the magnitudes of constants K_4, K_5, and K_6, it may be seen from eq. 9 that the apparent rate law will have the form

$$[12]\quad (\text{Rate})_0 = (\text{Constant})\,[D_2]_0^{<2}[Ru]_0^{0.5\text{ to }1.0}$$

A rigorous test of eq. 9 could not be made, because it was not clear what effect diffusion had on the observed exchange rates. However, alternative rate-limiting steps based on the equilibria described by reactions 4–6 cannot account for the observed $[D_2]$ and [Ru] dependence, therefore this scheme is preferred.

Mechanism II

If uptake of D_2 by $RuHCl(PPh_3)_3$ is rate-controlling, *i.e.*,

$$[13]\quad (\text{Rate})_0 = -\text{d}[D_2]_0/\text{d}t = k_4[D_2]_0\ [RuHCl(PPh_3)_3]$$

then one may derive the expression

$$[14]\quad (\text{Rate})_0 = \frac{k_4[D_2]_0[Ru]_0[HCl]}{([HCl] + K_4[H_2]_T + K_4K_5[H_2]_T^2 + K_1K_3[H_2]_T[N_2])}$$

Using arguments similar to those presented above, the observable H_2–D_2 exchange reaction orders in $[D_2]_0$ and $[Ru]_0$ would be ≤ 1 and 1, respectively.

Mechanism III

If loss of HCl from $RuHCl(PPh_3)_3$ occurred rapidly and dissociatively to yield a Ru(0) intermediate such as $Ru(PPh_3)_3$

$$[15]\quad RuHCl(PPh_3)_3 \rightleftarrows Ru(PPh_3)_3 + HCl$$

and the rate-determining step was uptake of H_2 (or D_2) by this species

$$[16]\quad Ru(PPh_3)_3 + D_2 \xrightarrow{k_{16}} RuD_2(PPh_3)_3$$

Then one would obtain

$$[17]\quad (\text{Rate})_0 = \frac{k_{16}[D_2]_0[Ru]_0}{\left(\frac{[HCl]}{K_{13}} + 1 + K_{14}[H_2]_T + K_5[H_2]_T^2 + K_5K_6[H_2]_T[N_2]\right)}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In this case, the H_2–D_2 exchange reaction orders in $[D_2]_0$ and $[Ru]_0$ would be ≤ 1 and 0.5 to 1.0 respectively, depending on the magnitudes of K_5, K_6, K_{15}, and K_{16}. The n.m.r. evidence suggests that this route is highly unlikely, because rapid dissociation of HCl from $RuHCl(PPh_3)_3$ is not observed in the absence of H_2 (or D_2).

The Effect of Mass Transfer Resistance

To justify the selection of eq. 9 over eq. 14, it is necessary to consider the possible influence of the interfacial mass transport of hydrogen on the apparent H_2–D_2 exchange reaction kinetics.

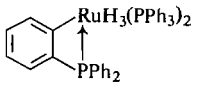
Gessner (23) has summarized the rate expressions and reaction orders for four different chemical reaction rate regimes. The two extreme cases are those in which the chemical reaction rate is either extremely fast (his regime I) or very slow (regime IV) with respect to the gas–liquid mass transfer rate. It appears that the present H_2–D_2 exchange system is a regime II case (*i.e.*, moderately fast reaction), since the reaction orders with respect to $[D_2]_0$ and $[Ru]_0$ would be 0 and 1 in regime I (very fast reaction) and 1 and 0 in regime III (slow reaction), respectively. Recall that these orders were found to be 1.5 and 0.38, respectively. In regime II, theory would predict these values to be $(\alpha + 1)/2$ and $\beta/2$ where α and β are the true chemical orders in $[D_2]_0$ and $[Ru]_0$. If $\alpha = 1.5$ and $\beta = 0.5$ as given by eq. 11, then the apparent reaction orders would be $[D_2]_0^{1.25}$ and $[Ru]_0^{0.25}$. In the case of mechanism II, from eq. 13, $\alpha \leq 1 = \beta$, therefore in regime II, the observed dependence would be $[D_2]_0^{\leq 1}$ and $[Ru]_0^{0.5}$. The exponents for mechanism I are closer to the observed values than are those for mechanism II. Extension of these calculations to obtain rate and equilibrium constants cannot be justified in view of the uncertainties associated with the control of deuterium exchange by mass transfer.

Implications of the Present Results for Other Reactions Catalyzed by "$RuHCl(PPh_3)_3$"

Since we have demonstrated that extremely rapid H_2–D_2 exchange can occur in solutions of $RuHCl(PPh_3)_3$ without participation of the original Ru—H bond, the possibility should be considered that this monohydride is also catalytically inactive in other hydrogen-transfer reactions under H_2. These include olefin hydrogenation and isomerization, H–D exchange with olefins, or *ortho*-hydrogens of ligand PPh_3.

Hallman, McGarvey, and Wilkinson proposed that the active catalyst for olefin hydrogenation was $RuHCl(PPh_3)_2$, formed by PPh_3 dissociation (10). However, because of doubt about the independence of their hydrogenation rate data from H_2-mass transfer control, they were unable to directly test their proposed mechanism (insertion of the activated olefin into the Ru—H bond followed by H_2 addition to the alkyl complex and alkane elimination). James has discussed this matter in detail (24). Since Pennella has reported that toluene solutions of $RuH_4(PPh_3)_3$ are highly active for pent-1-ene isomerization and reduction (21, 25), we suggest that this species is also generated and is catalytically active in solutions of $RuHCl(PPh_3)_3$ in the presence of olefins. A pentene-coordinated hydrido-complex $RuH_2(C_5H_{10})(PPh_3)_3$ has been tentatively identified by Pennella (21), although Harris *et al.* detected no adduct formation between C_2H_4 and $RuH_2(PPh_3)_4$ in C_6H_6 under mild conditions (19). Since Hallman *et al.* (10) found that significant $Ru(C_2H_5)Cl(PPh_3)_3$ formation from $RuHCl(PPh_3)_3$ and C_2H_4 required 35 atm pressure, the instability of alkene adducts of the dihydride is not surprising. In the absence of a definitive study of the chemical kinetics of olefin hydrogenation by "$RuHCl(PPh_3)_3$" the currently accepted explanation for the activity of these solutions is questionable. Hydrogenation may equally well proceed via spectroscopically undetectable intermediates of the type $RuH(alkyl)(PPh_3)_3$ or $RuH_3(alkyl)(PPh_3)_3$.

The D_2–$RuHCl(PPh_3)_3$ exchange observed by Schunn (16), which included deuteration of the *ortho*-hydrogens of the both free and complexed PPh_3, may have involved species of the type



However, those H–D exchange experiments conducted with olefins in the absence of H_2 (or D_2) undoubtedly occurred by the monohydride route (16, 26) because reaction 4 could not occur. Similarly, the polymerization or either ethylene or butadiene catalyzed by solutions of $RuHCl(PPh_3)_3$ in *N,N*-dimethylacetamide (27) must occur via $RuHCl(PPh_3)_2$.

Summary

Solutions of $RuHCl(PPh_3)_3$ in C_6H_6 have been found to promote extremely rapid H_2–D_2 exchange. The rate data were shown to be affected by mass-transfer of hydrogen across the gas–liquid phase boundary. A mechanism involving formation of di- and tetrahydrido ruthenium species was invoked to explain the lack of participation by the Ru—H bond of the precursor of the active catalyst.

The authors wish to thank Dr. N. H. Sagert and M. Tomlinson for useful discussions, and D. Bell, Analytical Science Branch, for the deuterium analyses.

Crystal Structures of K_2MgCl_4 and Cs_2MgCl_4

CYRIL S. GIBBONS,[1] VINCENT C. REINSBOROUGH, AND W. ALEXANDER WHITLA[2]

Department of Chemistry, Mount Allison University, Sackville, New Brunswick E0A 3C0

Received July 10, 1974

CYRIL S. GIBBONS, VINCENT C. REINSBOROUGH, and W. ALEXANDER WHITLA. Can. J. Chem. **53**, 114 (1975).

Supporting evidence for complex ion formation in $MgCl_2$ alkali chloride melts was sought from a single crystal X-ray analysis of the title compounds. Crystals of K_2MgCl_4 are tetragonal, a = 4.94, c = 15.58 Å, Z = 2, space group $I\,4/mmm$. The compound is isostructural with K_2NiF_4, and was determined with MoKα diffractometer data and refined by full-matrix least-squares to R = 0.046 for 180 reflections.

Crystals of Cs_2MgCl_4 are orthorhombic, a = 9.777, b = 7.514, c = 13.234 Å, Z = 4, space group *Pnma*. The compound is isostructural with β-K_2SO_4, and was determined with MoKα diffractometer data and refined by full-matrix least-squares to R = 0.074 for 1084 reflections. The K_2MgCl_4 structure contains an infinite two-dimensional array of $MgCl_6$ octahedra sharing edges. The Cs_2MgCl_4 structure contains discrete $MgCl_4^{2-}$ anions which likely continue to exist in the melt close to the melting point.

CYRIL S. GIBBONS, VINCENT C. REINSBOROUGH et W. ALEXANDER WHITLA. Can. J. Chem. **53**, 114 (1975).

On a cherché par diffraction des rayons-X de cristaux uniques des composés mentionnés dans le titre, l'existence d'ions complexes dans les produits de fusion de $MgCl_2$ avec des chlorures alcalins. Les cristaux de K_2MgCl_4 sont tétragonaux, a = 4.94, c = 15.58 Å, Z = 2, groupe d'espace $I\,4/mmm$. Le composé est isostructural avec K_2NiF_4 et sa structure a été déterminée avec des données du diffractomètre mesurées avec MoKα et affinée par moindres-carrés (matrice complète) jusqu'à une valeur R de 0.046 pour 180 réflexions.

Les cristaux de Cs_2MgCl_4 sont orthorhombiques, a = 9.777, b = 7.514, c = 13.234 Å, Z = 4, groupe d'espace *Pnma*. Le composé est isostructural avec le β-K_2SO_4 et sa structure a été déterminée à l'aide des données diffractomètriques mesurées avec MoKα et affinée par moindres-carrés (matrice complète) jusqu'à une valeur de R de 0.074 pour 1084 réflexions. La structure de K_2MgCl_4 contient un arrangement bidimensionnel infini d'octaèdres $MgCl_6$ liés par deux côtés. La structure de Cs_2MgCl_4 contient des anions $MgCl_4^{2-}$ individuels qui continuent vraisemblablement d'exister près du point de fusion. [Traduit par le journal]

Introduction

The controversy over complex ions in molten salts most often centers upon the binary MCl_2 – alkali metal chloride melts where deviations from additivity or ideality in transport and thermodynamic properties are extreme at stoichiometrically appropriate mole fractions (1, 2). Flood and Urnes (3) were the first to suggest the tetrahedral MCl_4^{2-} as being the principal complex species in these systems and recent calorimetric (4–7) and Raman investigations (8, 9) concur in this assessment. Postulated ions have ranged from the pyramidal MCl_3^- to larger and more highly charged species such as MCl_6^{4-}. Direct evidence for these complex species in melts is difficult to obtain so that mass spectrometric or vapor pressure studies are often performed on the vapors above the melts in hopes of obtaining some hint of what species are in the liquid state (10). As far as is known, the approach from the solid state has never been employed for these binary systems although it has long been recognized that the solid structure is maintained to some extent in the melt (11). Recent Raman work confirms this view (12). In the present work, single crystal X-ray analyses of the compounds K_2MgCl_4 and Cs_2MgCl_4 obtained from melts of the appropriate stoichiometry were undertaken to provide details of the magnesium ion coordination in the solid state.

Experimental

The phase diagrams indicate that both K_2MgCl_4 and Cs_2MgCl_4 are congruently melting compounds (13, 14). To obtain single crystals suitable for X-ray diffraction analysis, a modified Bridgman technique was used in which the ampoule containing a molten mixture

of the salts in the correct stoichiometric proportions was withdrawn at a rate of 3 mm per hour from a Stanton–Redcroft furnace equipped with a Eurotherm temperature controller. All materials were dried prior to use and manipulated in a drybox. Exact stoichiometry was achieved by weighing the sealed container of the salts on an analytical balance and adjusting the weight of the nonhygroscopic salt (CsCl or KCl). The resulting complexes were hygroscopic and were examined under a binocular microscope sealed inside a glove bag. Samples of the appropriate size were chipped from the mass of the solid and sealed inside quartz capillaries for X-ray examination. The fragments did not show any well-defined cleavage planes for either of the compounds studied.

The unit cell parameters and space group were determined from Weissenberg and precession photographs and diffractometer data, the unit cell parameters being refined by the least-squares procedure of the Picker FACS I system for 9 (K_2MgCl_4) and 11 (Cs_2MgCl_4) reflections with MoKα radiation. Crystal data are:

K_2MgCl_4 f.w. = 244.3
Tetragonal, $a = 4.94(1)$, $c = 15.58(4)$ Å, $V = 380.2$ Å^3, $Z = 2$, $\rho_c = 2.13$, $F(000) = 236$. MoKα, $\lambda = 0.7107$ Å, $\mu = 25.7$ cm^{-1}. Space group $I\,4/mmm$.

Cs_2MgCl_4 f.w. = 431.9
Orthorhombic, $a = 9.777(4)$, $b = 7.514(3)$, $c = 13.234(6)$ Å, $V = 972.2$ Å^3, $Z = 4$, $\rho_c = 2.95$, $F(000) = 760$. MoKα, $\lambda = 0.7107$ Å, $\mu = 86.8$ cm^{-1}. Space group *Pnma*.

The intensities of all reflections with $2\theta(\text{MoK}\alpha) \leq 60°$ (minimum interplanar spacing, 0.71 Å) for K_2MgCl_4 and $2\theta(\text{MoK}\alpha) \leq 55°$ (minimum interplanar spacing, 0.77 Å) for Cs_2MgCl_4 were measured on a Picker FACS I diffractometer system with a scintillation counter, approximately monochromatic MoKα radiation (graphite monochromator and pulse-height analyzer), and a θ–2θ scan of 1° min^{-1} in 2θ. Background counts were made at the beginning and end of the scan, and a check reflection was measured every 25 reflections and used to scale the data.

The crystals used for data collection were irregular cleavage fragments of average cross-section 0.3 mm. The K_2MgCl_4 crystal was initially mounted with a parallel to the ϕ axis of the goniostat, but was displaced slightly in ϕ and χ for the data collection. The Cs_2MgCl_4 crystal was similarly displaced from its b axis setting for the data collection. No absorption corrections were made. Lorentz and polarization factors were applied, and the structure amplitudes derived. For K_2MgCl_4, 180 reflections of the 196 measured (92%) were classified as observed, and for Cs_2MgCl_4, 1084 of the 1200 measured (90%) were classified as observed. Reflections were classified as observed if the net count was greater than 7% of the scaled background count. Unobserved reflections were given zero weight in the refinement of the structures.

Differential thermal analyses (Deltatherm model D2000-16) were carried out on both compounds and indicated no major phase changes from room temperature to the melting point. Precession photographs were obtained for K_2MgCl_4 at approximately 250 °C, and were identical to the room temperature photographs, except for a slight expansion of the lattice parameters. Since the DTA apparatus did not allow completely anhydrous conditions, minor deflections below 200 °C on the DTA trace were ascribed to the evolution of adsorbed water. Therefore we are confident that the room temperature structures are maintained up to the melting point.

All crystallographic calculations were made on an IBM 1130 computer using programs written by W.A.W. Standard test data (15) were used to confirm the reliability of the programs.

Structure Analysis

K_2MgCl_4

Consideration of the space group and unit cell data indicated possible isomorphism with the known K_2NiF_4 structure (16, 17), and this was verified by the Patterson function. With the atomic positions of ref. 16, scattering factors from ref. 18, and isotropic temperature factors $B = 1.0$ Å^2, a structure factor calculation gave $R = 0.36$. Two cycles of full-matrix least-squares with unit weights reduced R to 0.16. To complete the refinement, all atoms were assigned anisotropic thermal parameters, and with $\sqrt{w} = 1.0$ for $|F_o| \leq 20$, $\sqrt{w} = 20/|F_o|$ for $|F_o| > 20$, five cycles of refinement resulted in a final R of 0.045 for the 180 observed reflections. The maximum parameter shift in the final cycle was 1.3σ, and a final difference map showed no spurious detail.

Cs_2MgCl_4

The space group and unit cell data indicated that the structure was of the K_2SO_4 type, but initial parameters used were averages of K_2SO_4 and the isomorphous Cs_2CuCl_4 (16), to allow for the differences in ionic size. With these initial coordinates, scattering factors from ref. 18, and isotropic temperature factors $B = 2.0$ Å^2, a structure factor calculation gave $R = 0.42$. A subsequent Fourier map was computed, and the positional coordinates adjusted. At this point, R was 0.32, and two cycles of full-matrix least-squares refinement with unit weights reduced R to 0.17. All atoms were then assigned anisotropic temperature factors, and four further cycles of least-squares refinement with $\sqrt{w} = 1.0$ for $|F_o| \leq 50$, $\sqrt{w} = 50/|F_o|$ for $|F_o| > 50$, gave a final R of 0.074 for the 1084 observed reflections. The maximum parameter shift in the final cycle was 0.09σ, and a final difference map showed only minor peaks around the heavier atoms, probably due to series-termination errors.

Final positional and thermal parameters are listed in Tables 1 and 2, and interatomic distances and angles in Table 3. Figures 1 and 2 show the packing arrangements in K_2MgCl_4 and Cs_2MgCl_4 respectively.

Observed and final calculated structure factors are given in Table 4.[3]

Discussion

The structure of K_2MgCl_4 is of the K_2NiF_4 type (16, 17) and is illustrated in Fig. 1. The two independent Mg—Cl distances are 2.470 and

[3]Photocopies of Table 4 are available upon request, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

2.491 Å, and all angles at Mg are constrained to 90° by symmetry. The $MgCl_6$ octahedra share four corners to form infinite layers parallel to (001) separated by $c/2$, with the potassium ions situated in the "valleys" formed by the faces of the octahedra. K ... Cl contacts are 3.331(1) and 3.503(1) Å in the one layer, and 3.071(2) Å to the unshared corner of the octahedron in the next layer.

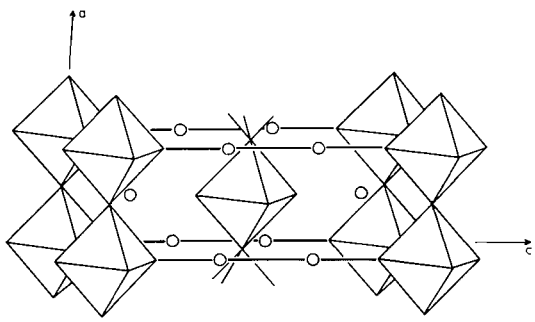

FIG. 1. General view of the unit cell contents of K_2MgCl_4. The circles represent potassium ions.

Cs_2MgCl_4 is isostructural with β-K_2SO_4 (16, 19) and consists of cesium cations and discrete $MgCl_4^{2-}$ tetrahedra (Fig. 2). Distortion of the tetrahedron is only slight as indicated by the bond lengths and angles of Table 3, and compares with that found in Cs_2ZnCl_4 (20). There

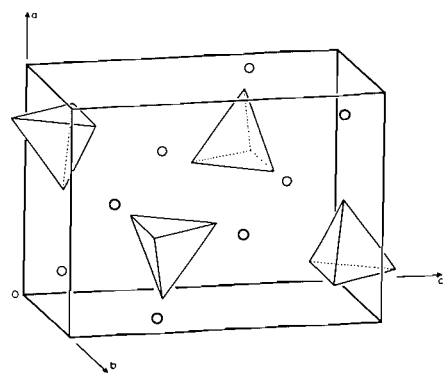

FIG. 2. General view of the unit cell contents of Cs_2MgCl_4. The heavier circles are cesium ions at $\frac{3}{4}b$ while the lighter ones are at $\frac{1}{4}b$.

are two independent cesium ions in the structure with slightly different coordination. Each ion has seven contacts between 3.47 and 3.84 Å with one additional contact at 3.97 Å in this case and two, at 3.96 Å in the other. In both situations, the cesium ions have no unusual features. Further discussion of these structures is unnecessary as many isostructural compounds have already been described in the literature.

To extend these solid state structures to the structure of the melt is necessarily tenuous. The liquid state will not have the long term ordering characteristic of the solid state and thus the K_2MgCl_4 structure, with an infinite array of octahedra sharing corners, probably has little relationship to the liquid state. However, the Cs_2MgCl_4 structure contains the $MgCl_4^{2-}$ anion which can retain its existence in the liquid state and thus it is reasonable to propose that discrete $MgCl_4^{2-}$ anions exist in the liquid cesium salt at least near the melting point.

The crystal structures of the 1:1 complexes $KMgCl_3$ (21) and $CsMgCl_3$ (22) are also known with octahedra sharing edges in the former and octahedra sharing faces in the latter. No discrete anionic complexes have been observed in either, and no conclusions regarding complex species in the corresponding melts can be made. However, it is interesting to note that both the enthalpy and the entropy of fusion for Cs_2MgCl_4 are substantially lower than those for the other three compounds mentioned above (23). This is consistent with a smaller degree of reorganization of the solid on melting for Cs_2MgCl_4 which would occur if the $MgCl_4^{2-}$ ions were essentially unaltered on melting. This does not however preclude the presence of other ions which could exist as well.

It is evident from these two structures that the ionic size and charge density of the alkali metal ion is a factor affecting the coordination of the magnesium ion. From melts of the same stoichiometric ratio, $2KCl{\cdot}MgCl_2$ forms a two dimensional infinite array with the potassium ion coordinated by two adjacent layers, while the cesium compound forms a loosely packed structure containing discrete $MgCl_4^{2-}$ tetrahedra. Also, the potassium ion has a distorted nine coordination by chloride ions whereas the cesium coordination is more regular. The larger, more easily polarized cesium ion must interfere with the tendency in the solid for the magnesium ion to coordinate six ligands. Since potassium is more polarizing than cesium, the ionic size may be the dominant factor in the change. Further studies on related systems are being undertaken to clarify this point.

A general cyclization route to pyrazolo[1,5-*a*]pyrimidines from 3-aminopyrazole and 1,3-dicarbonyl compounds is applied to synthesis of the parent ring system. In nitration of this species the orientation of substitution is strongly reagent dependent. Mixed nitric and sulfuric acids yield the 3-nitro compound, whereas nitric acid in acetic anhydride yields the 6-nitro compound. Brominations yield 3-bromo and 3,6-dibromo species.

The majority reacting species in the strongly acidic medium is identified as the 1-protonated entity by conjoint use of approximate molecular orbital calculations and the variation of coupling constant patterns accompanying protonation. The molecular orbital calculations predict successive 3- and 6-substitution by electrophiles in pyrazolo[1,5-*a*]pyrimidine and its conjugate acid, and an addition–elimination sequence is proposed to account for the observed 6-nitration.

BRIAN MAURICE LYNCH, MISBAHUL AIN KHAN, SURESH CHANDRA SHARMA et HUK CHIA TEO. Can. J. Chem. **53**, 119 (1975).

Une méthode générale de cyclisation conduisant aux pyrazolo[1,5-*a*]pyrimidines, à partir des amino-3 pyrazole et des composés dicarbonylés 1,3, est appliquée à la synthèse de ces systèmes cycliques fondamentaux. Lors de la nitration de ces espèces, l'orientation de la substitution dépend beaucoup de la nature du réactif. Un mélange d'acides nitrique et sulfurique conduit au composé portant un groupe nitro en position 3 alors que l'acide nitrique dans l'anhydride acétique conduit au composé portant un groupe nitro en position 6. La bromuration conduit aux dérivés bromo-3 et dibromo-3,6.

On a identifié les espèces réagissant d'une façon prédominante dans les milieux fortement acide comme étant les entités protonées en position 1; cette conclusion a été établie par l'utilisation à la fois de calcul d'orbitales moléculaires approché et la variation de patron de constante de couplage accompagnant la protonation. Les calculs d'orbitales moléculaires prédisent des substitutions électrophiles successives en position 3 et 6 pour les pyrazolo [1,5-*a*]pyrimidines et leurs acides conjugués et l'on propose une séquence d'addition et d'élimination pour tenir compte de la nitration observée en position 6. [Traduit par le journal]

Introduction

As part of a systematic synthesis program for fused-ring species derived from pyrazole (1, 2), we communicated in 1970 (1) a brief account of routes to pyrazolo[1,5-*a*]pyrimidine **1** and some 3-substituted derivatives. Patent claims to a similar synthetic route (3) and reports of enzyme-inhibitory activity for 3-substituted 5,7-dimethylpyrazolo[1,5-*a*]pyrimidines (4 and references therein) prompt us to provide details of the synthesis of **1**, and to report and analyze the patterns revealed in its common electrophilic substitutions and in its p.m.r. spectra, using an interpretive framework of π-electron (HMO) and all-valence-electron (CNDO/2) quantum chemical calculations.

Results

The parent species **1** is available in excellent yield by a sequential condensation and electrophilic cyclization, employing 1,1,3,3-tetramethoxypropane (malondialdehyde tetramethylacetal) and 3-aminopyrazole (generated by thermal decarboxylation of the commercially available 3-aminopyrazole-4-carboxylic acid) with zinc chloride in refluxing ethanolic solution. This route is based on related precedents in the Russian literature (5) and we have also applied

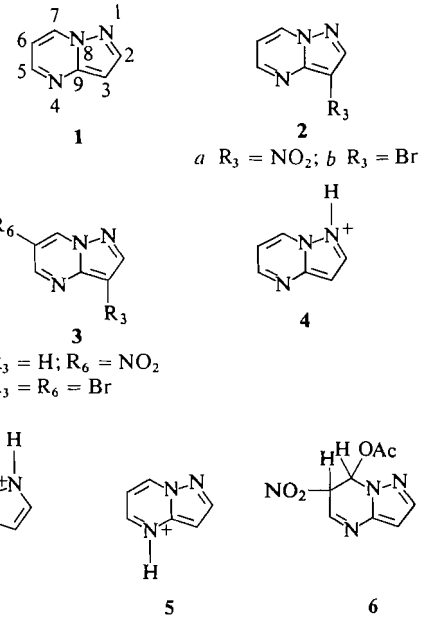
it to construction of compounds in the isomeric pyrazolo[3,4-*b*]pyridine series (1, 6).

One of our purposes in examining the patterns of electrophilic substitution of **1** was to seek further examples of *reagent-dependent orientation* (as explored previously for brominations and nitrations of arylpyrazoles (7, 8), acetanilides (9), and arylpyrimidines (10)). In considering such substitutions, the actual reacting species could be either the free base **1** or a conjugate acid species, and the favored positions of substitution might differ for attack on each entity. The expectation of reagent-dependent orientation was fulfilled for nitration reactions: treatment of **1** with mixed concentrated nitric and sulfuric acids at 0 ± 5° (standard conditions for mononitration of arylpyrazoles (7, 8)) gave the 3-nitropyrazolo[1,5-*a*]pyrimidine **2***a*, whereas corresponding treatment with nitric acid – acetic anhydride gave the 6-nitropyrazolo-[1,5-*a*]pyrimidine **3***a*, with each reaction being regiospecific.

In contrast, brominations under a variety of conditions (6) provided the 3-bromopyrazolo-[1,5-*a*]pyrimidine **2***b* and/or 3,6-dibromopyrazolo[1,5-*a*]pyrimidine **3***b* but there was no indication of initial 6-substitution.

The formation of **2***a* in nitration of **1** corresponds to the orientation in mononitration of pyrazolo[1,5-*a*]pyridine (2), whereas the 6-nitration to **3***a* has precedent in the nitration of tetrazolo[1,5-*a*]pyridine (11).



Discussion

Explanation of the Regioselective Nitrations

The remarkable feature of the nitration results is that their sense is opposite to that observed in the nitrations of arylpyrazoles (7, 8) and pyrazolo[1,5-*a*]pyridine (2), where we found that the nitric acid – acetic anhydride reagent favors attack in the pyrazole moiety. A necessary starting point for an explanation is a definition of the majority reacting species in the nitration media. The pK_a of the conjugate acid derived from **1** is 2.30 (determined potentiometrically (6)), suggesting very strongly that the majority species in the mixed acid nitrations of **1** will be this conjugate acid (compare pyrazole and 1-arylpyrazoles, of similar basic strength to **1**, where kinetic proof of nitration via the conjugate acid species has been given (12, 13).

The species **1** could undergo either 1-protonation (to entity **4**) or 4-protonation (to entity **5**) and it is difficult to decide between these potential basic centers (the 1- or the 4-nitrogen). The results of quantum-chemical calculations favor **4**: thus the π-electron distribution from a HMO calculation on **1** (Fig. 1) indicates that position 1 would be protonated first (accepting that a proton would attach itself most readily to the nitrogen atom of highest π-electron density (*cf.* 14), and HMO calculations of the π-electron binding energies of assumed models of **4** and **5** (which give respective values of 13.353 and 13.297 β) indicate that **4** is the more stable entity. The all-valence-

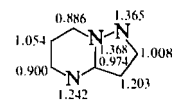


FIG. 1. HMO π-electron densities for species **1**

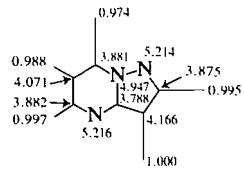

FIG. 2. CNDO/2 electron densities for species **1**.

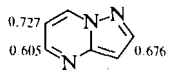

FIG. 3. HMO π-bond orders for species **1**.

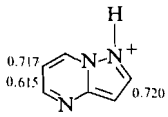

FIG. 4. HMO π-bond orders for species **4**.

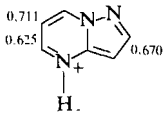

FIG. 5. HMO π-bond orders for species **5**.

electron CNDO/2 calculation for **1** (Fig. 2) yields virtually identical total electron densities (5.214 at nitrogen-1, 5.216 at nitrogen-4) but the 2s electron populations (corresponding to the lone-pair basic center) strongly favor protonation at nitrogen-1 (the 2s electron populations are 1-nitrogen, 1.520; 4-nitrogen, 1.458).

Furthermore, conjoint comparison of the calculated HMO π-bond orders for **1**, **4**, and **5** (see Figs. 3–5) with changes in the magnitudes of interproton couplings accompanying protonation of **1** (as revealed by the comparison of p.m.r. spectra in deuteriochloroform and in trifluoroacetic acid-*d*, see Table 1) favors **4** as majority species. The calculated bond orders for the 2–3 bond in **4** as compared with **1** increase significantly (from 0.676 to 0.720), with but little change in the bond orders on the periphery of the pyrimidine moiety; for the model comparison of **5** with **1**, the bond orders where proton–proton coupling would be detectable are closely similar for each species.

The changes in coupling constants accompanying protonation are confined to an increase in J_{23} from 2.0 to 3.0 Hz, whereas J_{56} and J_{67} are unaffected; in view of previously demonstrated bond order – coupling constant relationships (15, 16), this pattern is consistent with **4** but not with **5**. The increase in bond order between atoms 2 and 3 may be understood in resonance formalism by considering the contribution of structure **4***a*. Related evidence supporting position 1 as the protonation site is provided by the lanthanide-induced shifts of the protons in **1**, where the pattern of shifts indicates almost exclusive complexation at nitrogen-1 (unpublished work with Mr. Philip Smith).

Accepting that the predominant conjugate acid species of **1** is **4**, we have modelled the expected site of electrophilic substitution in **4** by evaluating the HMO localization energies for substitution at positions 3 and 6, taking cation–cation repulsion into account by a summation procedure (17, 18). 3-Substitution is strongly favored (the localization energies are 2.04 β for 3-substitution and 2.39 β for 6-substitution) and although the cation–cation repulsions favor 6- over 3-substitution the difference in repulsions is only *ca.* 20 kJ M^{-1} and is not sufficient to counterbalance the difference in σ-complex energies. Similarly, the higher-level CNDO/2 calculations of the relative binding energies for 3- and 6-proton exchange intermediates (σ-complexes for proton exchange) involving each of the species **1** and **4**, give energy differences of 107 kJ M^{-1} favoring

3-substitution in species **1** and 35 kJ M^{-1} favoring 3-substitution in species **4**. Both theoretical approaches agree in suggesting that 3-substitution will be the normal pattern for electrophilic substitution in pyrazolo[1,5-*a*]-pyrimidine, for reaction through either the conjugate acid **4** or the free base **1**.

This leads to the conclusion that the 6-nitration observed using the nitric acid – acetic anhydride reagent is not a simple displacement of a proton by nitronium ion. Since it is known that this reagent often adds the elements of nitronium acetate to bonds of high order in olefinic and heteroaromatic species (10, 19), we propose that formation of the 6-nitro compound **3***a* results from rapid addition of nitro and acetate moieties to the 6—7 bond of **1** to yield the adduct **6** (reaction through the free base **1** is suggested since this will be present in significant proportions in the reaction medium); **6** is postulated to yield **3***a* by elimination of acetic acid during work-up. The rate of formation of **6** from pyrazolo[1,5-*a*]pyrimidine is postulated to be faster than the encounter rate of nitronium ion with substrate, in order to account for the absence of 3-nitration. Evidence supporting the postulated intermediacy of **6** is cited in the Experimental section.

Proton Magnetic Resonance Spectra

The data assembled in Table 1 for the various pyrazolo[1,5-*a*]pyrimidines reveal that the 3- and 6-protons in **1** have characteristic chemical shifts and interprotonic couplings: species carrying substituents at these positions lack these characteristic signals. The nitro group in **2***a* and **3***a* exerts the expected deshielding influence on vicinal protons (20), whereas bromo substituents (as in **2***b* and **3***b*) have little effect on the shifts of the remaining protons, again in accord with expectation (20).

The sequence of chemical shifts for the protons of pyrazolo[1,5-*a*]pyrimidine in trifluoroacetic acid-*d* follows the order of calculated HMO π-electron densities for the 1-protonated species **4** if the shifts are corrected for ring-current and anisotropy effects (*cf.* 21): the equation linking these quantities is

$$\delta = 15.31 - 6.92q_\pi$$

$$(n = 5, r = 0.968)$$

and the response in p.p.m./electron is in the range typical of aromatic protons (21).

Experimental

Microanalyses were carried out using a Hewlett-Packard Model 185 Analyzer. Melting points were measured on a Kofler Heizbank and are corrected with reference to standard samples. The p.m.r. spectra were recorded with a Varian A-60D spectrometer, equipped with a V-6040 variable temperature controller. Infrared spectra were obtained on a Beckman Acculab 4 spectrometer.

Synthesis of Pyrazolo[1,5-a]pyrimidine, 1

3-Aminopyrazole-4-carboxylic acid (Aldrich Chemical Co.) (5 g) was decarboxylated by heating at *ca.* 170° until evolution of carbon dioxide ceased. The decarboxylation product was dissolved in ethanol (75 ml) and to this solution was added 10 *M* hydrochloric acid (5 ml) and zinc chloride (2.5 g). The mixture was heated to reflux and a solution of 1,1,3,3-tetramethoxypropane (6.6 g) in ethanol (10 ml) was added; heating under reflux was continued for 1 h. The reaction mixture was poured onto ice water (500 g), neutralized with aqueous ammonia, and extracted with chloroform (4 × 100 ml). Removal of the chloroform under reduced pressure, followed by vacuum sublimation at *ca.* 80°, provided pyrazolo[1,5-*a*]pyrimidine **1**, m.p. 105° (4.0 g, 86% based on 3-aminopyrazole-4-carboxylic acid).

Anal. Calcd. for $C_6H_5N_3$: C, 60.50; H, 4.23; N, 35.27. Found: C, 60.60; H, 4.25; N, 35.15.

Nitrations

To 3-Nitropyrazolo[1,5-a]pyrimidine, 2a

Pyrazolo[1,5-*a*]pyrimidine (1.19 g, 0.01 mol) was dissolved in concentrated sulfuric acid (*d* 1.84, 10 ml) at 20°, cooled to −5°, and treated at this temperature with a mixture of concentrated sulfuric acid and fuming (90%) nitric acids (1:1 v/v; 4 ml). The reaction mixture was kept at 0° for 15 min and at 5° for 15 min, and poured onto ice. The precipitated light yellow solid was collected by filtration, washed with cold water, and crystallized from water, yielding 623 mg 3-nitropyrazolo[1,5-*a*]-pyrimidine **2***a*, m.p. 259–260°.

Anal. Calcd. for $C_6H_4N_4O_2$: C, 43.91; H, 2.45; N, 34.14. Found: C, 43.59; H, 2.36; N, 33.82.

Extraction of the filtrate with chloroform, followed by evaporation of the extract, yielded recovered pyrazolo-[1,5-*a*]pyrimidine (170 mg); the yield of isolated, crystallized product based upon the apparent conversion is 44%. Monitoring of the p.m.r. spectra of model reaction mixtures using deuterated nitrating media indicated no organic species other than the 3-nitro compound **2***a* and unreacted **1**.

To 6-Nitropyrazolo[1,5-a]pyrimidine, 3a

Pyrazolo(1,5-*a*)pyrimidine (510 mg, 0.005 mol) in acetic anhydride (10 ml) was nitrated by dropwise addition of fuming (90%) nitric acid (5 ml) over 1 h at 0–5°. The reaction mixture was poured onto crushed ice and allowed to stand overnight. The precipitate was collected and crystallized from methanol, yielding 6-nitropyrazolo-[1,5-*a*]pyrimidine **3***a*, m.p. 180° (300 mg, 43% of crystallized product).

Anal. Found: C, 43.50; H, 2.71; N, 34.30.

The p.m.r. spectrum of the crude product showed no indication of the presence of the 3-nitro compound **2***a*. Marginally successful efforts were made to demonstrate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the intermediacy of the addition product **6** in yielding **3***a*, as follows: removal of the volatile materials from an aliquot portion of a reaction mixture by low-temperature vacuum distillation left yellow oily material, which was extracted with chloroform-*d* at 5°; the extract was washed repeatedly with ice-cold aqueous sodium hydrogen carbonate, dried overnight over anhydrous magnesium sulfate at 5°, and concentrated at 5° under reduced pressure. The p.m.r. spectrum of the concentrate was recorded using a probe temperature of 0°; it showed signals of similar intensity at δ 7.90 and 7.84, assigned, respectively, to acetate methyl groups in residual acetic acid (or acetic acid from the decomposition of **6**) and to the species **6** (*cf.* the chemical shift of acetate methyl signals in a related adduct isolated in the acetyl nitrate nitration of 4-phenylpyrimidine (10)). The aromatic region showed 17 signals between 400 and 600 Hz from tetramethylsilane, consistent with the presence of **1**, **3***a*, and **6**; resolution was limited by peak half-widths of 2–3 Hz but subtraction of signals assignable by inspection to **1** and **3***a* (compare Table 1) suggested the following chemical shifts for the protons of **6**: δ 8.4 (2-proton), 7.3 (3-proton) 9.5 (5-proton), 8.0 and 8.2 (6- and 7-protons). After standing overnight, the p.m.r. spectrum of this sample indicated the presence of **1**, **3***a*, and acetic acid. A further portion of the chloroform-*d* concentrate was used to obtain a rapid-scan i.r. spectrum. By comparison with spectra of authentic samples of **1** and **3***a*, it was evident that these were major components but carbonyl absorptions were also present at 1750 (s) and 1700 cm^{-1} (vs); the high-frequency peak is in the region expected (*cf.* (10)) for the *C*-acetate group of **6** (the 1700 cm^{-1} absorption is due to the acetic acid).

Brominations

To 3-Bromopyrazolo[1,5-a]pyrimidine, 2b

Pyrazolo[1,5-*a*]pyrimidine (1.19 g, 0.01 mol) was brominated using a stoichiometric amount of bromine in chloroform at room temperature for 1 h. The reaction mixture was washed with aqueous sodium hydrogen carbonate and the chloroform layer was separated and evaporated, leaving crude 3-bromopyrazolo[1,5-*a*]pyrimidine, which was crystallized from water to give pure **2***b*, m.p. 158–159° (1.00 g, 50%).

Anal. Calcd. for $C_6H_4BrN_3$: C, 36.36; H, 2.02; N, 21.21. Found: C, 36.05; H, 2.05; N, 21.40.

To 3,6-Dibromopyrazolo[1,5-a]pyrimidine, 3b

To a stirred solution of pyrazolo[1,5-*a*]pyrimidine (1.19 g, 0.01 mol) in ethanol (25 ml) was added, dropwise, a saturated aqueous solution of bromine (50 ml). During the addition, nitrogen gas was bubbled slowly through the solution. After addition of the bromine reagent was complete (2 h), the reaction mixture was made basic with aqueous sodium hydroxide, and the precipitated solid was collected. The aqueous filtrate was extracted with chloroform (3 × 100 ml), the chloroform extracts were combined, dried (anhydrous sodium carbonate), and evaporated. The residue was added to the precipitated solid, and the entire material was crystallized from ethanol, yielding 3,6-dibromopyrazolo[1,5-*a*]-pyrimidine **3***b*, m.p. 198–200° (1.40 g, 50%).

Anal. Calcd. for $C_6H_3Br_2N_3$: C, 26.02; H, 1.09; N, 15.18. Found: C, 26.00; H, 1.03; N, 15.09.

Molecular Orbital Calculations

The calculations using the simple Hückel method (HMO) were made using a standard program (10, 21) with an IBM 1130 computer. The electronegativity parameters h for various types of nitrogen were: pyrroloid, $h = 1$; pyridinoid, $h = \frac{1}{2}$. Electrostatic corrections to the localization energies were taken into account as follows (18): the interaction energy between the incoming electrophile and the charge-field of the cationic heterocyclic substrate was calculated for slightly polarized models of the substrate (the Coulomb integral of the carbon under attack was increased from α to $\alpha + \frac{1}{2}\beta$). Corrections were evaluated by summation of the terms q_i/r_i for each atom, using the HMO π-electron densities (q_i is the net charge at a particular atom and r_i its distance from the incoming electrophile, which was assumed to be normal to the aromatic ring plane and 0.3 nm directly above the site of attack).

CNDO/2 calculations were made using a version of Quantum Chemistry Program Exchange Program 91 modified for operation on a Hewlett-Packard 3000 Computer. The bond lengths chosen were as follows: for **1** (bond, bond length) 1—2, 0.132 nm; 2—3, 3—9, 4—9, 4—5, 5—6, 6—7, 0.14 nm; 7—8, 8—9, 0.134 nm; 8—1, 0.145 nm; and for the conjugate acid species **4** and **5**, 1—2, 0.130 nm; 8—1, 0.150 nm; all other ring bonds, 0.140 nm. All aromatic C—H bonds are 0.108 nm; the N—H bond, 0.100 nm. All C—H bonds and the N—H bond bisect the bond angles linking the C or N atoms to the ring system. Bond angles were as follows: for **1** (angle defined by constituent atoms, angle) 9—8—1, 105°; 8—1—2, 112°; 1—2—3, 107°; 2—3—9, 109°; 3—9—8, 109°; 8—4—9, 115°; 9—4—5, 4—5—6, 5—6—7, 6—7—8, 120°; 7—8—9, 125°; and for the conjugate acid species, 9—8—1, 108°, 8—1—2, 106°, 1—2—3, 110°; 2—3—9, 3—9—8, 108°; all other ring angles, 120°.

The σ-complexes from attachment of protons to the 3 or 6 positions of **1** and the conjugate acid **4** were modelled by changing the bond lengths linking the site of proton attachment to the other ring atoms to 0.150 nm, assuming equivalent C—H bonds of length 0.109 nm, and a tetrahedral H—C—H angle; the other angles in the affected ring were adjusted to reform the ring, without variation of bond lengths.

The molecular geometries chosen are based upon those used for a previous study (2) of a closely related condensed pyrazole species, where the choice gave good correspondence with observed dipole moments. Variations for conjugate acid species and for σ-complex models used the standard set of bond lengths and bond angles recommended for the CNDO/2 program.

We thank the following persons for analytical and computational assistance: Messrs. E. Schuegraf and B. A. Dawson, and Mesdames L. Graham and K. von Reubendale. The program of research of which this paper is one part was supported generously by the National Cancer Institute of Canada, the National Research Council of Canada, and the Saint Francis Xavier University Council for Research. We thank Drs. R. K. Robins and D. E. O'Brien (ICN Nucleic Acid Research Institute, Irvine, California) for their courtesy in discussion of unpublished results.

A Synthesis of (±)-Cularicine

ISAO NOGUCHI AND DAVID B. MACLEAN

Department of Chemistry, McMaster University, Hamilton, Ontario L8S 4M1

Received July 5, 1974

ISAO NOGUCHI and DAVID B. MACLEAN. Can. J. Chem. **53**, 125 (1975).

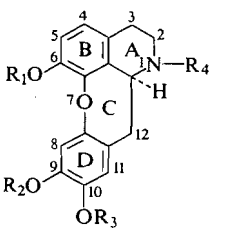
A synthesis of (±)-cularicine is reported. 2-(2′-Benzyloxyphenoxy)-4,5-methylenedioxyphenylacetic acid was converted in four steps to 6-benzyloxy-2,3-methylenedioxy-10,11-dihydrodibenz[*b*,*f*]oxepin-10(11*H*)-one. A modified Pomeranz–Fritsch reaction was applied to this ketone to add the two carbon atoms and one nitrogen atom required to complete the carbon skeleton of cularicine. The norcularicine derived from this reaction was *N*-methylated with formaldehyde and sodium borohydride.

ISAO NOGUCHI et DAVID B. MACLEAN. Can. J. Chem. **53**, 125 (1975).

On rapporte une synthèse de la (±)-cularicine. L'acide (benzyloxy-2′ phénoxy)-2 méthylènedioxy-4,5 phénylacétique est transformé en quatre étapes en 11*H*-benzyloxy-6 méthylènedioxy-2,3 dihydro-10,11 dibenz[*b*,*f*]oxepinone-10. On a soumis cette cétone à une forme modifiée de la réaction de Pomeranz–Fritsch. Afin d'ajouter les deux atomes de carbone et l'atome d'azote nécessaire pour compléter le squelette carboné de la cularicine. La norcularicine obtenue par cette réaction a été *N*-méthylée avec de la formaldéhyde et du borohydrure de sodium.

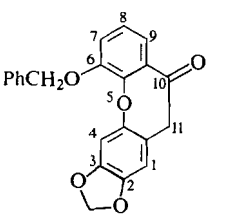
[Traduit par le journal]

(+)-Cularicine (**1**, $C_{18}H_{17}NO_4$), an alkaloid of *Corydalis claviculata* (L.) DC, was isolated by Manske (1, 2), who elucidated its structure (2) by converting it into cularine (**2**), an alkaloid of established structure (3, 4). Besides **1** and **2** only two other alkaloids of this type have been isolated, cularimine (3) and cularidine (4). The absolute configuration of cularine, shown in the accompanying structure, has recently been established by relating it chemically to *S*-laudanosine (5) and by X-ray analysis of its methiodide (6). Since **1**, **3**, and **4** have all been converted to cularine their configuration is also known (3, 4).



1 (cularicine) $R_1 = H$; $R_2 + R_3 = CH_2$; $R_4 = Me$
2 (cularine) $R_1 = R_2 = R_3 = R_4 = Me$
3 (cularimine) $R_1 = R_2 = R_3 = Me$; $R_4 = H$
4 (cularidine) $R_1 = H$; $R_2 = R_3 = R_4 = Me$

Several successful approaches to the synthesis of cularine have been reported. In two of these the diphenyl ether linkage was formed in an Ullmann reaction in the initial stages of the synthetic scheme and rings A and C were subsequently constructed from the appropriately substituted diphenyl ether (7, 8). In another approach, substituted benzylisoquinolines were synthesized and the diphenyl ether linkage was introduced in a late stage of the synthetic scheme either through oxidative coupling (9–11) or through an intramolecular Ullmann reaction (12, 13). Resolution of synthetic (±)-cularine has been effected (14). Initial attempts to synthesize cularidine (15, 16) led only to derivatives that were not convertible into the racemic phenolic base. More recently, however, the intramolecular Ullmann reaction has been applied to the synthesis of cularidine (17) and of cularicine (18). Here we describe another synthesis of (±)-cularicine by a method that should serve equally well for the synthesis of (±)-cularidine.



5

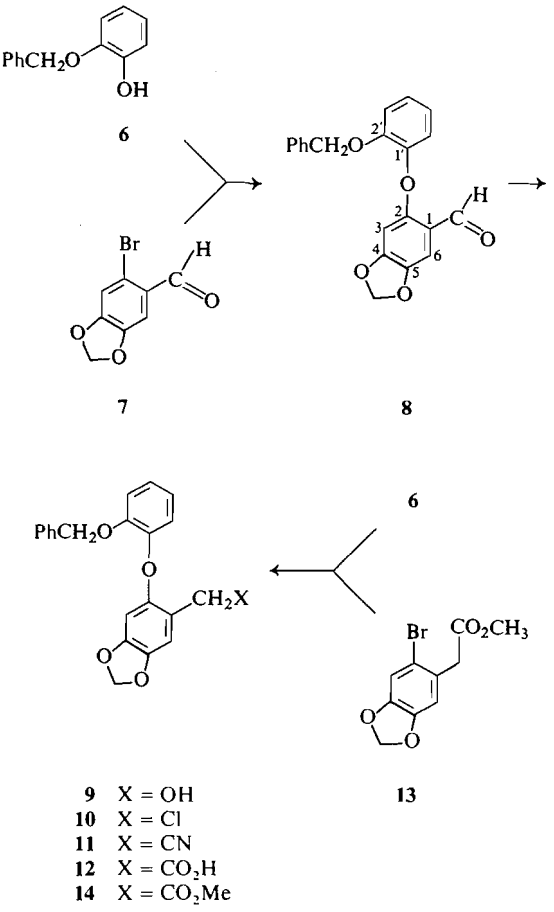

SCHEME 1

The first objective of our synthesis was the oxepinone (**5**) containing three of the four rings of cularicine with the potential phenolic group at C-6 of cularicine suitably protected. The synthesis of **5** was brought about in the manner shown in Schemes 1 and 2. Ullmann condensation of *o*-benzyloxyphenol (**6**) (19) with 6-bromopiperonal (**7**) (20) in the presence of copper and cupric oxide gave the diphenyl ether (**8**), in 53% yield, which was reduced to the alcohol (**9**) in quantitative yield. Treatment of **9** with thionyl chloride yielded the chloride (**10**) that was converted directly to the cyanide (**11**) with sodium cyanide in methyl ethyl ketone. Base-catalyzed hydrolysis of **11** led to the acid **12** in good yield. Compound **12** was also prepared by fusion of **6** with methyl 6-bromohomopiperonylate (**13**) in the presence of copper and cupric oxide at 140° for 8 h. The methyl ester (**14**) so obtained was hydrolyzed directly to the acid (**12**). These experiments are summarized in Scheme 1. Up to this point our synthetic scheme is analogous to that used in the original synthesis of cularine (7).

Attempts to cyclize **12** in various acidic media led to failure. Similarly, cyclization of the acid chloride (**15**) under a variety of Friedel–Crafts conditions gave uncharacterized products apparently resulting from debenzylation of the ether by the Lewis acid catalysts. At length it was found that the amide (**16**) cyclized to the enamine (**17**) on treatment with phosphoryl chloride in a mixture of benzene and toluene at reflux. To our knowledge this method of cyclization is unique. However, it has an analogy in the Bischler–Napieralski cyclization of phenylethyl amides to dihydroisoquinolines. The general utility of this cyclization for the preparation of ketones will be investigated further. The structure of **17** follows from an examination of its spectroscopic properties and from its hydrolysis to the oxepinone (**5**). The spectroscopic properties of **5** are in accord with the structure assigned. These transformations are outlined in Scheme 2.

The introduction of two carbon atoms and a

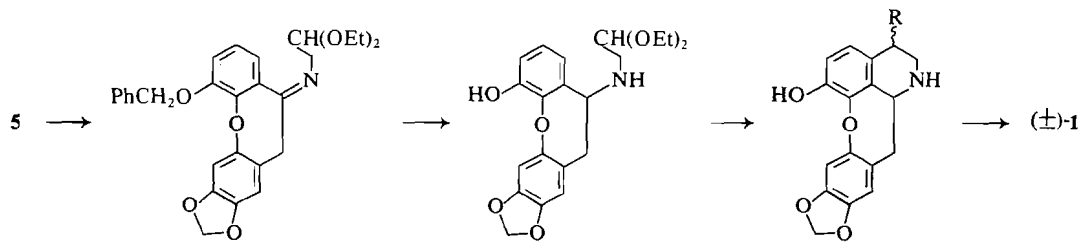

SCHEME 3

nitrogen atom was now necessary to complete the ring system of cularicine. To bring this about, we turned to the modified Pomeranz–Fritsch procedure developed by Bobbitt *et al.* (21) and eventually worked out satisfactory conditions to prepare a Schiff base and to effect the cyclization of its dihydro derivative (Scheme 3).

The oxepinone (**5**) was condensed with aminoacetaldehyde diethyl acetal to the Schiff base (**18**) which was converted directly to the phenolic amino acetal (**19**). The protecting benzyl group was removed by hydrogenolysis simultaneously with the reduction of the carbon–nitrogen double bond. The acetal (**19**) was converted in 6 *N* ethanolic hydrochloric acid into the cyclized compound (**20**). The formation of an ethoxy rather than the usual hydroxy compound in the Bobbit cyclization appears to be without precedent in the literature (22, and references cited therein). The 3-ethoxynorcularicine (**20**) obtained in this reaction represents one of a pair of racemates but its relative configuration was not established. In an analogous reaction Dalton *et al.* (23) also obtained only one of a pair of possible racemates. The ethoxy group of **20** was removed by hydrogenolysis over Pt in ethanolic hydrochloric acid yielding racemic norcularicine (**21**). Treatment of the mother liquor, remaining after the separation of **20**, with hydrogen over Pt also led to the recovery of (±)-norcularicine.

Finally, *N*-methylation was brought about with formaldehyde and sodium borohydride. The product of this reaction, (±)-cularicine, had spectral properties in solution that were identical with those of a sample of natural (+)-cularicine obtained from Professor R. H. F. Manske. The melting point of our product differs from that reported (18) but the spectral properties agree within experimental error.

Experimental

Apparatus, Methods, and Materials

Infrared spectra were recorded on a Beckmann IR-5 spectrometer in KBr, in liquid film or in solution as stated. The data are reported in $\nu\,cm^{-1}$.

Proton magnetic resonance spectra were recorded on Varian HA-100 or A-60 spectrometers. All spectra were recorded at ambient temperature in solution in the solvent specified with tetramethylsilane (TMS) as internal standard. Chemical shifts are reported relative to TMS = 0.0 δ. The symbols s, d, t, m, refer to singlet, doublet, triplet, and multiplet, respectively.

Mass spectra were determined on a C.E.C. 21-110B mass spectrometer. Samples were introduced through a direct inlet system. Relative intensity data were obtained from low resolution spectra recorded under identical conditions at an ionization voltage of 70 eV, a trap current at 140 μA, and at 200 °C or at the source temperature specified. Relative intensities of individual ions are placed in parenthesis after the *m/e* value.

Melting points are uncorrected.

2-(2′-Benzyloxyphenoxy)-4,5-methylenedioxybenzaldehyde (8)

A mixture of *o*-benzyloxyphenol (19) (**6**, 5.0 g), 6-bromopiperonal (20) (**7**, 5.5 g), potassium carbonate (12.0 g), copper powder (10.0 g), cupric oxide (5.0 g) and pyridine (15 ml) was heated at 110–115° with vigorous stirring for 20 h. The product was extracted with chloroform, and the extract was filtered and washed with 10% HCl and 5% NaOH. It was then dried over potassium carbonate and evaporated to leave a dark syrup. Purification was effected by column chromatography on silica gel using chloroform as eluent to give 2-(2′-benzyloxyphenoxy)-4,5-methylenedioxybenzaldehyde (**8**, 4.6 g, 52.9%) as colorless needles melting at 104–105° after recrystallization from ethanol; i.r. (KBr): 1670 (CO), 935 (OCH_2O), 735, 695 (monosubstituted benzene); p.m.r. ($CDCl_3$): 10.14 (1 H, s, —C*H*O), 7.35–6.92 (10 H, m, Ar—H), 6.25 (1 H, s, H-3), 5.92 (2 H, s, OCH_2O), 5.05 (2 H, s, OCH_2Ph).

Anal. Calcd. for $C_{21}H_{16}O_5$: C, 72.40; H, 4.63. Found: C, 72.52; H, 4.74.

2-(2′-Benzyloxyphenoxy)-4,5-methylenedioxybenzyl Alcohol (9)

Sodium borohydride (10.0 g) was added in portions to a stirred solution of the aldehyde (**8**) (20.0 g) in methanol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

(600 ml) at room temperature. After stirring the mixture for a further 2 h, the solvent was removed to leave a colorless viscous residue which was diluted with water and extracted with benzene. The extract gave on evaporation the alcohol (**9**), (19.4 g, 97%) as colorless needles melting at 84–85° after crystallization from chloroform–hexane; i.r. (KBr): 3250 (OH), 935 (OCH_2O), 745, 695 (monosubstituted benzene); p.m.r. ($CDCl_3$): 7.27 (5 H, s, C_6H_5), 7.15–6.90 (4 H, m, Ar—H), 6.85 (1 H, s, H-6), 6.34 (1 H, s, H-3), 5.83 (2 H, s, OCH_2O), 5.02 (2 H, s, OCH_2Ph), 4.58 (2 H, CH_2OH), 2.48 (1 H, broad s, OH).

Anal. Calcd. for $C_{21}H_{18}O_5$: C, 71.99; H, 5.18. Found: C, 71.99; H, 5.23.

*2-(2′-Benzyloxyphenoxy)-4,5-methylenedioxybenzyl Cyanide (**11**)*

Thionyl chloride (40 ml) was added dropwise to a stirred solution of alcohol (**9**) (20 g) in benzene (300 ml) at 5–10° and the mixture was then heated under reflux for 1 h. Removal of the solvent yielded the chloride (**10**) which was used in the next step without further purification. The chloride (**10**) in benzene (100 ml) was added dropwise to a stirred mixture of methyl ethyl ketone (500 ml), sodium cyanide (20 g), and sodium iodide (15 g) at room temperature. This mixture was warmed to 60–70° and stirred for a further 8 h at the same temperature. Water (100 ml) was then added to the reaction mixture, and the organic layer was separated, washed with a small amount of water, and dried over potassium carbonate. The extract was worked up to give the crude cyanide (**11**) which crystallized from ethanol to afford colorless needles melting at 108–109°; yield, 19.2 g (93.2% based on **9**); i.r. (KBr): 2255 (weak, CN), 935 (OCH_2O), 735, 695 (monosubstituted benzene); p.m.r. ($CDCl_3$): 7.29 (5 H, broad s, C_6H_5), 6.9–7.2 (4 H, m, Ar—H) 6.88 (1 H, s, H-6), 6.34 (1 H, s, H-3), 5.91 (2 H, s, OCH_2O), 5.04 (2 H, s, OCH_2Ph), 3.67 (2 H, s, CH_2CN).

Anal. Calcd. for $C_{22}H_{17}NO_4$: C, 73.53; H, 4.77; N, 3.90. Found: C, 73.74; H, 4.81; N, 3.75.

*2-(2′-Benzyloxyphenoxy)-4,5-methylenedioxyphenylacetic Acid (**12**)*

A mixture of the cyanide (**11**) (19.5 g), ethanol (500 ml), potassium hydroxide (40 g), and water (100 ml) was refluxed for 48 h. After removal of solvent from the mixture, the brown residue was diluted with water, washed with ether, and then acidified with hydrochloric acid to afford a precipitate which was extracted with chloroform. The extract was dried over magnesium sulfate, and evaporated to leave a slightly colored syrup which crystallized from chloroform–hexane yielding the acid (**12**) (14.3 g, 70.0%) as colorless needles melting at 128–129°; i.r. (KBr): 3300–2550 (OH), 1720 (CO), 750, 700 (monosubstituted benzene); p.m.r. ($CDCl_3$): 7.30 (5 H, broad s, C_6H_5), 7.15–6.85 (4 H, m, Ar—H), 6.75 (1 H, s, H-6), 6.37 (1 H, s, H-3), 5.90 (2 H, s, OCH_2O), 5.08 (2 H, s, OCH_2Ph), 3.63 (2 H, s, CH_2COOH).

Anal. Calcd. for $C_{22}H_{18}O_6$: C, 69.83; H, 4.80. Found: C, 69.90; H, 4.66.

*Methyl 2-(2′-Benzyloxyphenoxy)-4,5-methylenedioxyphenylacetate (**14**)*

A mixture of methyl 6-bromohomopiperonylate (24) (**13**, 5.6 g), *o*-benzyloxyphenol (**6**, 6.0 g), potassium carbonate (5.6 g), copper powder (6.0 g), cupric oxide (2.0 g), and pyridine (8 ml) was heated at 140° under vigorous stirring for 8 h. The product was exhaustively extracted with chloroform and the extract was filtered to remove suspended material. The chloroform filtrate was then washed with 10% HCl, dried over magnesium sulfate, and evaporated, yielding a dark colored syrup. Purification of the crude product by column chromatography on silica gel using chloroform as eluent gave the diphenyl ether (**14**) (6.7 g, 58.1%) as a slightly colored syrup; i.r. (liquid film): 1730 (CO), 925 (OCH_2O), 745, 680 (monosubstituted benzene); p.m.r. ($CDCl_3$): 7.33 (5 H, broad s, C_6H_5), 7.15–6.85 (4 H, m, Ar—H), 6.77 (1 H, s, H-6), 6.39 (1 H, s, H-3), 5.89 (2 H, s, OCH_2O), 5.08 (2 H, s, OCH_2Ph), 3.63 (2 H, s, $—CH_2COOCH_3$), 3.57 (3 H, s, OCH_3).

*Hydrolysis of **14***

The methyl ester (**14**) (6.5 g) was dissolved in a mixture of ethanol (150 ml) and 20% NaOH (80 ml) and refluxed for 2 h. The residue obtained after removal of solvent was diluted with water, washed with ether, and acidified with hydrochloric acid to afford a colorless precipitate. Extraction of the precipitate with chloroform gave the phenylacetic acid (**12**) (5.4 g, 96.3%) obtained as colorless needles melting at 128–129.5° after crystallization from chloroform–hexane. This compound was identical with the sample prepared above.

*N-[2-(2′-Benzyloxyphenoxy)-4,5-methylenedioxyphenacetyl]morpholine (**16**)*

Thionyl chloride (60 ml) was added dropwise to a cooled solution of the acid (**12**) (20.0 g) in dry benzene (300 ml) and the mixture was gently refluxed for 1.5 h. Removal of the solvent gave the acid chloride (**15**) which was dissolved in 30 ml of chloroform and used in the next reaction without purification.

To a stirred mixture of triethylamine (24 ml), morpholine (36 g), and chloroform (240 ml) the acid chloride solution, prepared above, was added dropwise at 0–10°. The mixture was stirred for 3.5 h at room temperature and was then washed with 10% NaOH and 10% HCl. The chloroform solution was dried over potassium carbonate and evaporated to yield the amide **16**, (21 g, 88.9%) as a slightly colored syrup; i.r. (liquid film): 1660 (CO), 935 (OCH_2O), 750, 700 (monosubstituted benzene); p.m.r. ($CDCl_3$): 7.33 (5 H, broad s, C_6H_5), 7.10–6.80 (4 H, m, Ar—H), 6.90 (1 H, s, H-6), 6.38 (1 H, s, H-3), 5.92 (2 H, s, OCH_2O), 5.08 (2 H, s, OCH_2Ph), 3.63 (2 H, s, CH_2CON), 3.58–3.23 (8 H, m, morpholine hydrogens).

*10-N-Morpholino-6-benzyloxy-2,3-methylenedioxydibenz[b,f]oxepin (**17**)*

A mixture of the amide (**16**) (20 g), dry toluene (120 ml), dry benzene (60 ml), and phosphoryl chloride (51 ml) was gently refluxed for 3.5 h. The reaction mixture was poured into a large volume of hexane and yielded

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

a precipitate which was collected by filtration. The crude product was basified by adding it in portions to a stirred mixture of chloroform and aqueous ammonia. The chloroform layer was separated, and worked up in the usual manner to give a dark colored viscous residue. Purification by column chromatography on silica gel using chloroform gave the enamine (**17**) (3.84 g, 20.0%) as yellow prisms melting at 175–177° after recrystallization from ether; i.r. (KBr): 1630 (weak, C=C), 945 (OCH_2O), 745, 695 (monosubstituted benzene); p.m.r. ($CDCl_3$): 7.65–6.95 (8 H, m, Ar—H), 6.82 (1 H, s, H-1), 6.60 (1 H, s, H-4), 5.93 (1 H, s, H-11), 5.90 (2 H, s, OCH_2O), 5.19 (2 H, s, OCH_2Ph), 3.86 (4 H, t, J = 4.0 Hz, ), 2.98 (4 H, t, J = 4.0 Hz, ); mass spectrum: *m/e* 429 (M^+).

Anal. Calcd. for $C_{26}H_{23}NO_5$: C, 72.71; H, 5.40; N, 3.26. Found: C, 72.77; H, 5.64; N, 3.26.

*6-Benzyloxy-2,3-methylenedioxy-10,11-dihydrodibenz-[b,f]oxepin-10(11H)-one (**5**)*

A stirred solution of the enamine (**17**) (1.5 g) in tetrahydrofuran (43 ml) was treated dropwise with 1 *M* sulfuric acid (50 ml) and the mixture stirred for 4 h at room temperature. The reaction mixture was extracted with chloroform, the extract dried over magnesium sulfate and potassium carbonate, and evaporated to give a brown syrup. Crystallization from ether gave the dihydrodibenzoxepinone (**5**) (0.91 g, 72.2%) as yellow prisms melting at 131–132°; i.r. (KBr); 1680 (CO), 935 (OCH_2O), 735, 700 (monosubstituted benzene); p.m.r. ($CDCl_3$); 7.69 (1 H, pair of doublets, J = 2.5 and 7.5 Hz, H-7 or H-9), 7.55–7.05 (7 H, m, Ar—H), 6.86 (1 H, s, H-1 or H-4), 6.75 (1 H, s, H-4 or H-1), 5.98 (2 H, s, OCH_2O), 5.26 (2 H, s, OCH_2Ph), 4.02 (2H, s, CO-CH_2); mass spectrum; *m/e* 360 (M^+).

Anal. Calcd. for $C_{22}H_{16}O_5$: C, 73.32; H, 4.48. Found: C, 73.43; H, 4.34.

*10-(2′,2′-Diethoxyethylamino)-6-hydroxy-2,3-methylenedioxy-10,11-dihydrodibenz[b,f]oxepin (**19**)*

A mixture of **5** (1.6 g), dry toluene (50 ml), aminoacetaldehyde diethyl acetal (3.5 ml), and pyridine (6 drops) was allowed to stand at room temperature for 10 h and then refluxed using a Dean–Stark apparatus for 20 h. Most of the solvent was removed, fresh toluene (40 ml) and aminoacetaldehyde diethyl acetal (3.5 ml) were added and reflux was continued for a further 8 h. The solvent was removed leaving the Schiff base **18** as a slightly colored syrup. This residue was dissolved in ethanol (100 ml) and hydrogenated over platinum at 20 p.s.i.g. for 15 h. The filtrate, after removal of catalyst, was hydrogenated again in the presence of 10% palladium-on-charcoal at 40 p.s.i.g. for 20 h. The catalyst was filtered off and the solvent was evaporated to give a pale yellow syrup. The residue, dissolved in ether, was treated with ether saturated with dry hydrogen chloride yielding the hydrochloride of **19** (0.91 g). Attempts to crystallize the hydrochloride from ethanol–ether gave only an amorphous material melting at 118° (dec.); i.r. (KBr): 3200 (OH), 2800–2500 ( ), 930 (OCH_2O). Crude **19** was used in the next reaction without purification.

*Cyclization of **19***

A stirred solution of the hydrochloride of **19** (0.85 g) in ethanol (6 ml) was treated dropwise with 6 *N* ethanolic hydrochloric acid solution (40 ml) at 5–10° and the mixture was stirred for 20 h at room temperature. The colorless precipitate, which separated, was collected by filtration, and recrystallized from ethanol–ether to afford 3-ethoxy-norcularicine (**20**) hydrochloride (0.75 g, 88.1%) as colorless needles melting at 236° (dec.); i.r. (KBr): 3200 (OH), 2450 ( ), 925 (OCH_2O); p.m.r. (DMSO-d_6): 6.96, 6.85 (each 1 H, d, J = 8.2 Hz, H-4 and H-5), 6.95, 6.71 (each 1 H, s, H-8 and H-11), 5.92 (2 H, s, OCH_2O), 4.73–4.40 (2 H, m, H-12a and H-3), 3.60–3.00 (7 H, m, 3 × CH_2 and NH), 0.97 (3 H, t, J = 7.0 Hz, CH_2CH_3).

Anal. Calcd. for $C_{19}H_{19}NO_5 \cdot HCl$: C, 60.40; H, 5.33; N, 3.70. Found: C, 60.50; H, 5.36; N, 3.79.

The free base was liberated from the hydrochloride by ammonia. It melted at 176–178° (dec.) after crystallization from chloroform–hexane; i.r. (KBr): 3290 (NH), 930 (OCH_2O); p.m.r. (DMSO-d_6): 7.01, 6.64 (each 1 H, s, H-8 and H-11), 6.91, 6.71 (each 1 H, d, J = 8.2 Hz, H-4 and H-5), 5.92 (2 H, s, OCH_2O), 4.38 (1 H, pair of doublets, J = 10.0 and 7.0 Hz, H-12a), 4.07 (1 H, m, H-3), 3.46 (2 H, m, CH_2CH_3), 3.08–2.85 (4 H, m, 2 × CH_2), 1.08 (3 H, t, J = 7.0 Hz, CH_2CH_3); mass spectrum *m/e*: 341 (M^+, 100), 324 (7), 311 (7), 294 (41), 283 (33), 278 (13).

The mother liquor from the separation of **20** was treated with hydrogen over platinum at 25 p.s.i.g. for 6 h. The filtrate, after removal of catalyst, was concentrated to 5 ml, cooled with ice, carefully basified with ammonia, and then extracted with chloroform. The extract gave on evaporation a brown gum which was purified by preparative thick-layer chromatography on silica gel (chloroform–benzene–methanol, 1:3:1) to give (±)-*N*-norcularicine (**21**) (72 mg, 7.0% based on **19**) as a glass which crystallized from methanol yielding colorless prisms melting at 99° with softening and some decomposition at 92°. The crystals are probably solvated. Mass spectrum (270°), *m/e*: 297 (M^+, 100), 296 (46), 280 (47), 268 (16), 267 (21), 148.5 (M^{2+}, 7), 147 (20); i.r. (KBr): 3400–3300 (NH and OH), 935 (OCH_2O). Compound **21** was recrystallized from acetone yielding colorless needles melting at 96–99°. These crystals were also solvated; i.r. (KBr): 3400–3300 (NH and OH), 935 (OCH_2O), 1710 (acetone carbonyl); p.m.r. (CD_3OD):[1] 6.92, 6.58 (each 1 H, s, H-8 and H-11), 6.74 (2 H, s, H-4 and H-5), 5.90, 5.88 (each 1 H, d, J = 1.0 Hz, O—CH_2—O), 4.33 (1 H, pair of doublets,

[1]The sample for p.m.r. analysis was prepared in the following manner. The crystals obtained from the crystallization in acetone were dissolved in an excess of methanol, the solution evaporated to dryness, and the residue taken up in CD_3OD.

J = 11.0 and 4.0 Hz, H-12a), 3.25–2.60 (6 H, m, 3 × CH_2). Compound **21** formed a picrate as yellow needles melting at 241° (dec.); i.r. (KBr): 3410 (OH), 1570, 1320 (NO_2), 935 (OCH_2O).

Anal. Calcd. for $C_{17}H_{15}NO_4 \cdot C_6H_3N_3O_7$: C, 52.47; H, 3.45; N, 10.64. Found: C, 52.59; H, 3.65; N, 10.41.

Acid-catalyzed Hydrogenolysis of 20

3-Ethoxynorcularicine hydrochloride (**20**, HCl, 320 mg) was dissolved in 3 *N* ethanolic hydrochloric acid solution (60 ml) and treated with hydrogen over platinum at 25 p.s.i.g. for 15 h. The filtrate, after removal of catalyst, was concentrated to 15 ml, basified with ammonia, and extracted with chloroform. The extract was dried over magnesium sulfate, and evaporated to leave a brown residue. This was purified by preparative thick-layer chromatography on silica gel (chloroform–benzene–methanol, 1:3:1) to give (±)-*N*-norcularicine (**21**, 104 mg, 41%) as a colorless glass which crystallized from methanol to give colorless prisms melting at 101°. The mass spectrum of this sample was the same as that described above for **21**. Recrystallization from acetone gave a sample melting at 97–101°. The i.r. spectrum of this sample was superimposable on that described in the preceding section for the sample of (±)-norcularicine crystallized from acetone.

(±)-Cularicine (1)

A mixture of (±)-*N*-norcularicine (**21**) (60 mg), methanol (6 ml), and 37% formalin (1.0 ml) was warmed at 40–45° for 30 min. The mixture was cooled and sodium borohydride (0.7 g) was then added in portions. The solvent was removed *in vacuo* and the residue obtained was treated with water and extracted with chloroform. The extract, after drying over magnesium sulfate, was evaporated to leave a slightly colored syrup which was purified by preparative thick-layer chromatography on silica gel (chloroform–benzene–methanol, 1:3:1) to give (±)-cularicine (**1**, 45 mg, 71%) as a glass which crystallized from methanol yielding solvated crystals melting at 95–96°; i.r. (KBr): 3150 (OH), 935 (OCH_2O); mass spectrum (270°), *m/e*: 311 (M^+, 100), 310 (16), 294 (58), 282 (10), 267 (9), 161 (18), 155.5 (M^{2+}, 5).

Recrystallization of **1** from acetone gave a colorless crystalline mass melting at 81–82°; i.r. (KBr): 3400 (OH), 935 (OCH_2O), 1710 (acetone carbonyl). The presence of acetone of crystallization was also apparent when the mass spectrum of this sample was recorded.

Compound **1**, obtained from acetone, was dissolved in chloroform and evaporated to dryness yielding a glass that was used to measure the i.r. and p.m.r. spectra; p.m.r. ($CDCl_3$): 6.80 (2 H, s, H-4 and H-5), 6.67, 6.53 (each 1 H, s, H-8 and H-11), 5.91, 5.89 (each 1 H, d, J = 1.3 Hz, OCH_2O), 4.23 (1 H, pair of doublets, J = 10.0 and 4.0 Hz, H-12a), 3.20–3.75 (6 H, m, 3 × CH_2), 2.53 (3 H, s, N—CH_3); i.r. ($CHCl_3$): 3550 (OH), 2820 (N—CH_3), 940 (OCH_2O). The i.r. spectrum in chloroform and the p.m.r. spectrum in deuteriochloroform were identical with those of natural (+)-cularicine. When recrystallized from ether racemic **1** gave colorless needles melting at 155–156°. Mass spectrum (270°), *m/e*: 311 (M^+, 100), 310 (21), 294 (65), 282 (12), 268 (5), 267 (11), 174 (10), 161 (24), 155.5 (M^{2+}, 7); t.l.c. of racemic **1** in a variety of solvent systems showed the same behavior as natural (+)-cularicine.

Compound **1** formed a hydrochloride as colorless needles melting at 255–257° (dec.), (MeOH–Et_2O); i.r. (KBr): 3150 (OH), 2750–2400 ($\overset{+}{\underset{/}{\backslash}}$NH, 935 ($OCH_2O$).

Anal. Calcd. for $C_{18}H_{17}NO_4 \cdot HCl$: C, 62.16; H, 5.21; N, 4.02. Found: C, 62.31; H, 5.36; N, 4.02.

We thank the National Research Council of Canada for support of this work and Dr. R. H. F. Manske for a sample of (+)-cularicine.

C-Nucleosides and Related Compounds. IV. The Synthesis and Chemistry of D,L-2,5-Anhydroallose Derivatives

GEORGE JUST, ALAIN MARTEL, KARL GROZINGER, AND MOHABIR RAMJEESINGH
Department of Chemistry, McGill University, Montreal, Quebec H3C 3G1

Received July 11, 1974

GEORGE JUST, ALAIN MARTEL, KARL GROZINGER, and MOHABIR RAMJEESINGH. Can. J. Chem. **53**, 131 (1975).

Methyl β-nitroacrylate (**1**) reacted with furan to give the corresponding Diels–Alder adduct, which was converted to D,L-3,4-di-*O*-isopropylidene-2,5-anhydroallose (**9**) in a five-step sequence in 14% yield, based on **1**. The conversion of **9** to its oxime, semicarbazone, and thiosemicarbazone is described, as well as the synthesis of the free aldehyde **15**, and of the Wittig reaction product **14**.

GEORGE JUST, ALAIN MARTEL, KARL GROZINGER et MOHABIR RAMJEESINGH. Can. J. Chem. **53**, 131 (1975).

Le β-nitroacrylate de méthyle (**1**) réagit avec le furanne pour conduire au produit d'addition de Diels–Alder correspondant; ce dernier peut être transformé en cinq étapes, avec un rendement global de 14% basé sur **1**, en D,L-di-*O*-isopropylidène-3,4 anhydro-2,5 allose (**9**). On décrit la transformation de **9** en oxime, semicarbazone et thiosemicarbazone, de même que la synthèse de l'aldéhyde **15** et du produit **14** provenant de la réaction de Wittig. [Traduit par le journal]

In a preliminary communication, we reported (1) on the synthesis of 3,4-isopropylidene-2,5-anhydroallose (**9**). We wish to give a full account of this and related work.

Treatment of methyl β-nitroacrylate (**1**) (2, 3) with an excess of furan at room temperature gave in quantitative yield a mixture of **2***a* and **2***b*, from which *endo*-nitro ester **2***b* could be obtained crystalline, and **2***a* as an oil. This separation allowed the analysis of the n.m.r. spectra of the isomers. However, the stereochemistry of the isomers was assigned based on spectral data of the hydroxylation products **3** and **4**. Hydroxylation of **2***a* or **2***b* with hydrogen peroxide and a catalytic amount of osmium tetroxide gave diols **3** and **4**, respectively. Alternatively, the mixture of **2***a* and *b* was hydroxylated and diols **3** and **4** were separated by crystallization. There is ample precedent for the preferential *exo*-hydroxylation of bicyclo[2.2.1] systems of type **2**, leaving little doubt as to the correctness of the stereochemical assignment of the hydroxy groups (4).

It is known that the coupling constant of *endo*-protons with the bridgehead proton in bicyclo-[2.2.1]heptane derivatives is close to zero (5), whereas the coupling constants of an *exo*-proton with the bridgehead proton and with the adjacent *endo*-proton should be of comparable order of magnitude ($J \cong 4$ Hz, (5)). One would therefore expect that the low-field proton α to nitro group in **3** should appear as a doublet and in **4** as a doublet of doublets or a triplet. The structures of **2***a*, **2***b*, **3**, and **4** have been assigned accordingly. The structure of **2***a* was further confirmed by chemical transformations leading to lactone **17**.[1]

Treatment of **3** and **4** with acetone–dimethoxypropane in the presence of *p*-toluenesulfonic acid for several hours gave a good yield of the corresponding isopropylidene derivatives **3***a* and **4***a*. Elimination of nitrous acid by means of diazabicyclo[5.4.0]undec-5-ene (DBU) in cold or boiling ether or methylene chloride from the *exo*-nitro ester **3***a* proceeded in good yield. A small amount of dimer **7** was also formed in this reaction. In the case of *endo*-nitro ester **4***a*, the dimer became the major product (48%) when the elimination was carried out with DBU in ether at 0°, olefin **6** being produced in 28% yield. By carrying out the reaction under reflux, the desired olefin **6** became the major reaction product.

Dimer **7** is formed by Michael addition of the carbanion generated by abstraction of the proton α to the nitro group of **4** to olefin **6**, followed by elimination of nitrous acid. The structure of dimer **7** was based on its spectral data and those of its dihydro derivative $\mathbf{7}\cdot H_2$ obtained by catalytic hydrogenation.

Olefin **6** was characterized by cleaving the

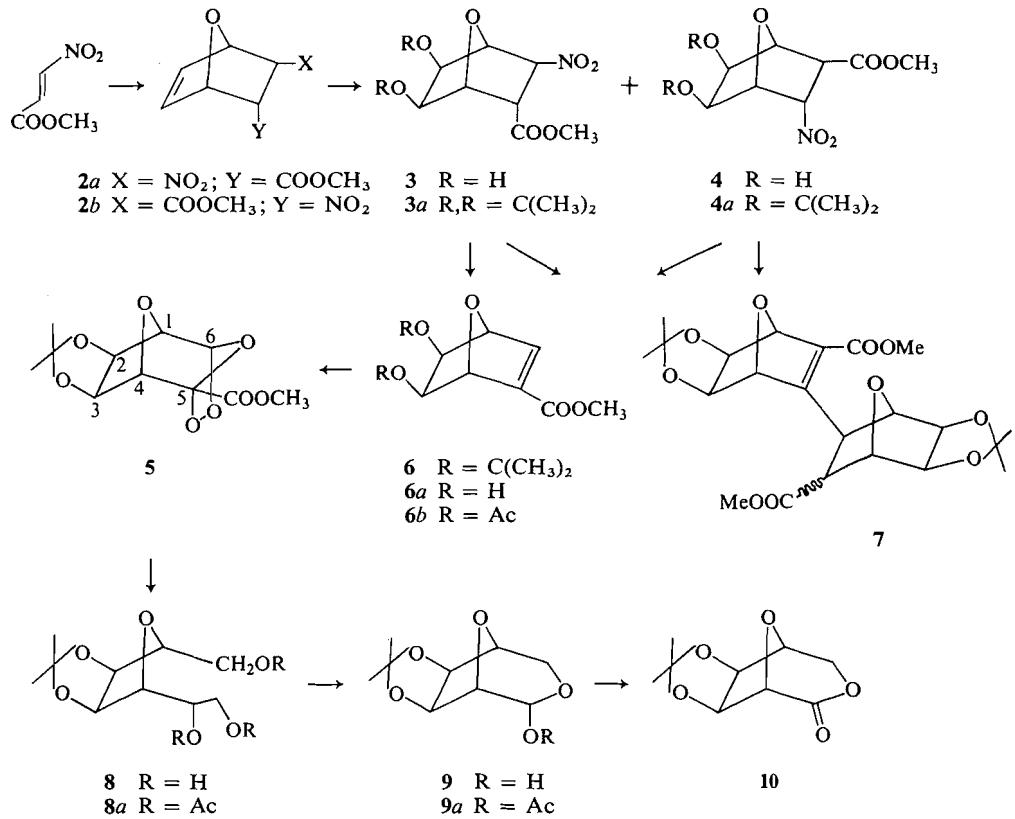
For personal use only.



isopropylidene group with aqueous trifluoroacetic acid and acetylating the resulting diol **6***a* to diacetate **6***b*.

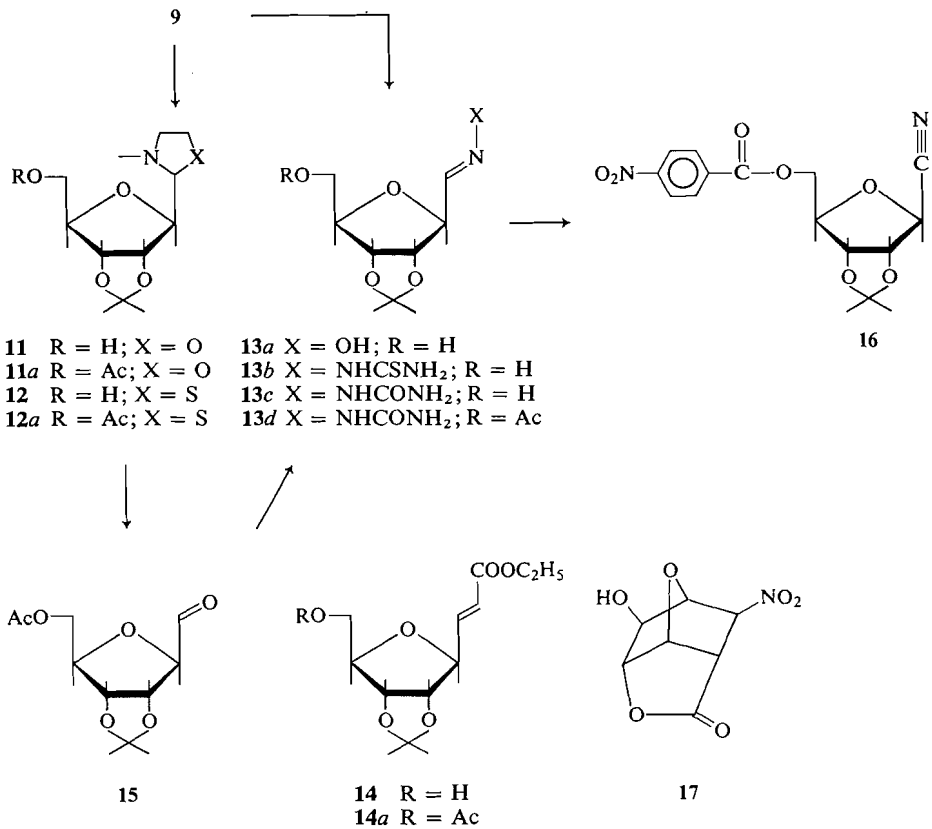
Ozonolysis of **6** gave a single oily ozonide, to which structure **5** was assigned, based on the following arguments. Protons H_2 and H_3 appear as a singlet at 5.25 p.p.m., so that the carbomethoxy group does not influence their chemical shift. Proton H_1 is coupled with H_4 (*w*-coupling; $J = 2$ Hz) and with H_6, which appears as a doublet ($J = 5.5$ Hz). Models indicate that in structure **6**, the dihedral angle between H_1 and H_6 is 0°, whereas in the corresponding isomeric ozonide, it is approximately 35°. Comparison with sugar derivatives having a similar degree of substitution (6–9) suggest that a coupling constant of 5.5 Hz is more appropriate for a dihedral angle of 0°, rather than 35°, so that structure **5** is preferred for the ozonide.

Sodium borohydride reduction of ozonide **5** gave triol **8**, in 36% yield. It was characterized as its acetate **8***a*. When the borohydride reduction mixture was evaporated and acetylated *in situ*, triacetate **8***a* was obtained in 79% yield. Reaction of triol **8** with periodate (10) converted it nearly quantitatively to D,L-3,4-isopropylidene-2,5-anhydroallose, **9**, m.p. 185–186°. The sodium borohydride reduction mixture could also be acidified with aqueous acetic acid and the mixture directly submitted to periodate cleavage. In that instance, the yield of the anhydroallose **9**, based on olefin **6**, was 61%. Anhydroallose **9** was characterized by making its 1-*O*-acetyl derivative **9***a* and by oxidizing it to lactone **10** with Fetizon's reagent (11).

Treatment of lactol **9** with semicarbazide gave the crystalline semicarbazone **13***c*, which was further converted to acetate **13***d*. Similarly, a crystalline thiosemicarbazone **13***b* could be obtained from **9**. In each case, only one geometric isomer was obtained. Upon oximation, an oily oxime **13***a* consisting of a mixture of the *syn*- and *anti*-isomer was obtained. Treatment of the oxime **13***a* with *p*-nitrobenzoyl chloride in pyridine gave the crystalline *p*-nitrobenzoate nitrile **16**.

Lactol **9** reacted with carbethoxymethylene triphenylphosphorane to give the α,β-unsaturated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



trans-ester **14** in good yield and purity. Acetylation transformed it to **14***a*.

Reaction of lactol **9** with unstabilized Wittig reagents gave starting material only. Since this lack of reactivity severely curtailed the synthetic utility of **9**, free aldehyde **15** was prepared in the following manner. Compound **9** was treated with *N*-methylethanolamine in boiling benzene with continuous removal of water. The resulting oxazolidine **11** could not be purified and was converted to its acetate **11***a*, which was equally unstable to purification by chromatography. Hydrolysis of **11***a* with aqueous acetic acid gave the equally unstable aldehyde **15**. Its semicarbazone proved to be identical to **13***d*, obtained via the sequence **9** → **13***c* → **13***d*. As will be reported later, aldehyde **15** reacted with unstabilized Wittig reagents in the expected manner.

Reaction of **9** with *N*-methylthioethanolamine gave the stable thiazolidine **12**, which was further converted to acetate **12***a*. Since **12***a* is much more stable than **11***a*, it might be the preferred precursor to aldehyde **15**. However, the relative inconvenience of preparing *N*-methylthioethanolamine, coupled with the fact that aldehyde **15** obtained via **11** was of sufficient purity to undergo clean Wittig reactions, made this second pathway relatively unattractive.

Experimental

Melting points were determined on a Gallenkamp block and are uncorrected. Mass spectra were obtained on an AE1-MS-902 mass spectrometer at 70 eV using a direct-insertion probe. Nuclear magnetic resonance spectra were recorded on a Varian Associates T-60 spectrometer. Infrared spectra were obtained on a Unicam SP1000 and a Perkin–Elmer 257 i.r. spectrophotometer. Ultraviolet spectra were determined with a Unicam SP-800 spectrophotometer. Microanalyses were carried out by C. Daessle, Montreal.

Methyl trans-7-Oxabicyclo[2.2.1]hept-5-ene-2(3)-nitro-3(2)-carboxylate (2)

3-Nitroacrylate (**1**, 120 g) and 125 g (2 equiv.) of furan were stirred overnight. During the course of the reaction crystals separated out. After refrigeration, the product was collected and crystallized from ether to give 31 g (17%) of *endo*-nitro compound **2***b*, m.p. 66–67°. Upon evaporation of the filtrate 100 g (55%) of the *exo*-nitro **2***a* isomer was obtained as an oil.

Exo-nitro isomer **2***a*: i.r. (film) 1735 (C=O), 1550 (NO_2), 875 cm^{-1} (C—N); n.m.r. ($CDCl_3$) δ 3.70 (s, 3H),

Elimination of nitrous acid using the *endo*-nitro isomer gave **6** in a 72% yield.

*Dimer **7***

An ether solution of *endo*-nitro ester **4***a* (18.0 g) was treated with 14.5 g DBU at 0° for 1 h. After work-up, the crystalline residue was chromatographed on silicic acid using benzene – ethyl acetate (95:5) as an eluent. The first fraction (4.2 g, 28%) was identified as olefin **6**. The major product, which was eluted later, consisted of colorless plates, m.p. 169–171° (6.8 g) of the dimer **7**.

Using the above reaction conditions on *exo-nitro* ester **3***a*, a mixture of olefin **6** (60%) and dimer **7** (8%) was obtained. The dimer proved to be in all respects identical with the sample obtained from the *endo-nitro* ester **4***a*; i.r. (KBr) 1735, 1720 (C=O), 1640 (C=C), 1370, 1380 (*gem*-dimethyl), 1070, 1075 cm^{-1} (C—O—C); n.m.r. ($CDCl_3$) δ 1.30 (s, 3H), 1.35 (s, 3H), 1.45 (s, 3H), 1.50 (s, 3H), 2.98 (t, J = 6 Hz, 1H), 3.78 (s, 6H), 3.85 (s, H), 4.20 (s, 1H), 4.42 (s, 2H), 4.45 (s, 2H), 4.70 (d, J = 6 Hz, 1H), 4.97 (s, 2H); u.v. λ_{max}(EtOH) 237 nm, ε 5700.

For personal use only.

t.l.c. on silicagel, the oily diacetate **6***b* in 56% yield; i.r. (KBr film) 1755 (C=O), 1735 (C=O) 1625 (C=C), 1255 cm^{-1} (C—O—C); n.m.r. ($CDCl_3$) δ 2.08, 2.10 (2s, 6H), 3.75 (s, 3H), 4.88 (s, 2H), 5.00 (d of d, J = 2 Hz, 1H), 5.08 (d, J = 2 Hz, 1H), 7.07 (d, J = 2 Hz, 1H).

*Ozonide **5** of the Olefin (**6**)*

The olefin **6** (100 mg), dissolved in ethyl acetate, was treated with ozone at −78°. Evaporation of the solvent gave a quantitative yield of pure ozonide **5**; i.r. (KBr film) 1760 (C=O), 1390, 1380 (*gem*-dimethyl), 1020, 1055, 1085 cm^{-1} (ozonide); n.m.r. ($CDCl_3$) δ 1.40 (s, 3H), 1.54 (s, 3H), 4.10 (s, 3H, OCH_3), 4.58 (dd, J_{AM} = 5.5 Hz, J_{MX} 2 Hz, 1H), 4.85 (d, J = 2 Hz, 1H), 5.28 (s, 2H), 6.33 (d, J = 5.5 Hz, 1H).

*3,4-O-Isopropylidene-2β-(1′,2′-dihydroxyethyl)-5β-hydroxymethyl tetrahydrofuran-3α,4α-diol [**8**]*

Ozonide **6**, obtained from olefin **5** (400 mg), was treated with sodium borohydride in refluxing isopropanol for 4 h. To the reaction mixture previously cooled down to 0° was added 50% aqueous acetic acid (6 ml). After evaporation of the solvent, the solid residue was extracted with ethyl acetate to give the triol **8** in 35% yield; i.r. (KBr film) 3500, 3300 (OH), 1390, 1380 (*gem*-dimethyl), 1080, 1050 cm^{-1} (C—O); n.m.r. ($(CD_3)_2CO$) δ 1.31 (s, 3H), 1.48 (s, 3H), 3.70 and 4.00 (10H), 4.72 (b.s., 2H); mass spectrum (70 eV) *m/e* 219 ($M^+ - CH_3$), 189 ($M^+ - CH_3 - CH_2O$).

*3,4-O-Isopropylidene-2β-(1′,2′-diacetoxyethyl)-5β-acetoxymethyltetrahydrofuran-3α,4α-diol (**8***a*)*

To the ozonide **6** (200 mg) in isopropanol (15 ml) was added sodium borohydride (400 mg) and the mixture was then refluxed for 3 h. After acidification of the reaction mixture at 0° and evaporation of the solvent to dryness *in vacuo*, the solid residue was treated with a mixture of acetic anhydride – pyridine (4:6 ml) overnight. After evaporation *in vacuo*, the solid residue was extracted with methylene chloride. The pure acetate **8***a* was obtained in 79% yield; i.r. (KBr film) 1750 (C=O), 1380 (*gem*-dimethyl), 1230 cm^{-1} (CH_3COO); n.m.r. ($CDCl_3$) δ 1.37 (s, 3H), 1.56 (s, 3H), 2.05 and 2.12 (2s, 9H), 4.20 (m, 6H), 4.54 (m, 2H), 5.22 (m, 1H); mass spectrum (70 eV) *m/e* 345 ($M^+ - CH_3$), 303 ($M^+ - CH_3 - CH_2CO$), 285 ($M^+ - CH_3 - CH_3COOH$).

D,L-*2,5-Anhydro-3,4-O-isopropylideneallose (**9**)*

Ozonide **6** from 550 mg of olefin **5** was treated in isopropanol with sodium borohydride (900 mg) at 0° and then refluxed for 4 h. After cooling, the mixture was stirred for 30 min with 50% aqueous acetic acid (8 ml) and then evaporated down and the residue azeotroped with ethyl alcohol and benzene. The solid residue was then dissolved in 50% aqueous methanol (20 ml), sodium periodate (600 mg) was added and the solution stirred 1 h. The resulting precipitate was filtered off and the filtrate extracted with chloroform. The organic layer was dried over sodium sulfate and evaporated to give 61% yield of **11**, m.p. 185–186°; i.r. (Nujol) 3480, 3420, 3200 (OH), 1095, 1075, 1055 cm^{-1} (C—O); n.m.r. ($(CD_3)_2CO$) δ 1.30 (s, 3H, CH_3), 1.38 (s, 3H, CH_3), 2.76 (s, OH), 3.42 (m, 1H), 4.00 (m, 3H), 4.75 (m + s, 3H); mass spectrum (70 eV) *m/e* 187 ($M^+ - CH_3$) 173.

Anal. Calcd. for $C_9H_{14}O_5$: C, 53.45; H, 6.98. Found: C, 53.86; H, 7.06.

*1-O-acetyl-2,5-anhdro-3,4-O-isopropylidene-*D,L-*allose (**9***a*)*

The hemiacetal **11** (30 mg) was acetylated overnight with 2 ml of acetic anhydride and 3 ml of pyridine. Work-up of the mixture gave a quantitative yield of the crystalline acetate **11***a*, which was recrystallized from a mixture of methanol–acetone–hexane, m.p. 138.5–139.5°; i.r. ($CHCl_3$) 1750 (OAc), 1385 (*gem*-dimethyl), 1230 cm^{-1} (OAc); n.m.r. ($CDCl_3$) δ 1.38 (s, 3H, C—CH_3), 1.51 (s, 3H, C—CH_3), 2.18 (s, 3H, OAc), 3.50 (d, 1H), 4.23 (m, 3H), 4.88 (s, 2H), 5.72 (s, 1H); mass spectrum (70 eV) *m/e* 229 ($M^+ - CH_3$).

D,L-*2,5-Anhydro-3,4-O-isopropylideneallonic Acid Lactone (**10**)*

Fetizon reagent (9 mequiv.) (11) was added to 400 mg (2 mmol) of **9** in 70 ml of dry benzene. The mixture was heated to reflux for 36 h. The solution was then filtered through Celite and evaporated. The crude product (275 mg) was purified by chromatography on a silica gel column (activity I). Elution with benzene–ether (1:1) gave colorless platelets of **10**, m.p. 122–124°, yield 70%; i.r. ($CHCl_3$ solution) 1770 (lactone), 1385 cm^{-1} (*gem*-dimethyl); n.m.r. ($CDCl_3$) δ 1.3 (s, 3H), 1.5 (s, 3H), 4.45 (α, 1H), 4.62 (s, 1H), 4.0–4.7 (m, 2H), 4.85 (s, 2H); mass spectrum (70 eV) *m/e* 185 ($M^+ - CH_3$), 143, 99, 97, 69, 59.

*N-Methyl-2(3α,4α-dihydroxy-di-O-isopropylidene-5β-hydroxymethyl-furan-2β-yl)oxazolidine (**11**)*

Anhydroallose (**9**) (202 mg, 1 mmol) was dissolved in 50 ml of dry benzene containing *N*-methylethanolamine (150 mg, 2 mmol). The mixture was refluxed with a Dean–Stark trap filled with molecular sieves (type 3A) for 36 h. The reaction mixture was then evaporated off under high vacuum leaving 275 mg of the crude oily oxazolidine. Attempts at purification by chromatography led to decomposition of the product; i.r. (film) 3500 (O—H), 2810 (N—CH_3), 1470, 1380 cm^{-1} (*gem*-dimethyl); n.m.r. ($CDCl_3$) δ 1.28 (s, 3H), 1.42 (s, 3H), 2.38 (s, 3H), 2.6 (m, 1H), 3.2 (m, 1H), 3.4–4.2 (m's 8H), 4.5 (d, 2H); mass spectrum (70 eV) *m/e* 259 (M^+), 244 ($M^+ - CH_3$), 228 ($M^+ - CH_2OH$), 189, 152, 86.

*6-O-Acetyl-2,5-anhydro-3,4-O-isopropylidene-*D,L-*allose (**15**)*

Oxazolidine **11** (275 mg), was stirred for 14 h with pyridine (5 ml) and acetic anhydride (3 ml). Evaporation of the solution gave the crude acetate which was dissolved in 10 ml of 50% aqueous acetic acid and stirred for 45 min at room temperature. The aqueous solution was extracted with 3 × 15 ml of methylene chloride and the organic layer dried over sodium sulfate and evaporated to give 200 mg of unstable aldehyde **15**; i.r. ($CHCl_3$) 1750 (acetate), 1720 (aldehyde), 1380 cm^{-1} (*gem*-dimethyl); n.m.r. ($CDCl_3$) δ 1.27 (s, 3H), 1.47 (s, 3H), 2.0 (s, 3H), 4.0 (m, 2H), 4.4–4.2 (m's, 2H), 4.45 (m, 1H), 4.7 (m, 1H), 9.22 (2, 1H).

The aldehyde (200 mg) was characterized as the semicarbazone **13***d* (12). It crystallized from the reaction mixture after standing for several days in the refrigerator,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

giving 160 mg of product, m.p. 146–148°. Compound **13***d* was obtained in 55% yield, based on anhydroallose **9**. This compound was identical in every respect to that prepared by the other route.

Anal. Calcd. for $C_{12}H_{19}O_6N_3$: C, 47.83; H, 6.36; N, 13.95. Found: C, 47.56; H, 6.29; N, 13.86.

N-Methyl-2(3α,4α-dihydroxy-di-O-isopropylidene-5β-hydroxymethyl-furan-1β-yl)thiazolidine (12)

Anhydroallose (**9**) (150 mg, 0.75 mmol) was heated to reflux in 20 ml of dry benzene containing *N*-methyl thioethanolamine (182 mg, 2 mmol) with a Dean–Stark condenser containing molecular sieves (type 3A) for 36 h. Evaporation and separation on a 20 × 20 silica gel plate, using ethyl ether as a solvent system, gave 115 mg of **12** as a clear oil (R_f = 0.25), yield 55%; i.r. (film) 3400 (O—H), 2800 (N—CH_3), 1460, 1380 (*gem*-dimethyl), 1215 cm^{-1}; n.m.r. ($CDCl_3$) δ 1.32 (s, 3H), 1.52 (s, 3H), 2.48 (s, 3H), 3.10 (m's, 5H), 3.65 (d, 2H), 3.8–4.2 (m's, 3H), 4.6 (m, 2H); mass spectrum (70 eV) *m/e* 275 (M^+), 274 ($M^+ - 1$), 260 ($M^+ - CH_3$), 228, 200, 168, 102.

Analysis was made on the acetate derivative (**12***a*).

N-Methyl-2(3α,4α-dihydroxy-di-O-isopropylidene-5β-acetoxymethyl-furan-1β-yl)thiazolidine (12a)

The thiazolidine **12** (100 mg, 0.36 mmol), was acetylated with pyridine – acetic anhydride in the usual way. The crude product was chromatographed on a silica gel column (activity III). Elution with ethyl ether gave the acetate derivative as a colorless oil in quantitative yield; i.r. (film) 2600 (N—CH_3), 1760 (acetate), 1385 cm^{-1} (*gem*-dimethyl); n.m.r. ($CDCl_3$) δ 1.25 (s, 3H), 1.45 (s, 3H), 2.05 (s, 3H), 2.35 (s, 3H), 3.0 (m's, 4H), 3.5 (m, 1H), 4.02 (d + m, 2H), 4.18 (broad s, 2H), 4.5 (d, 2H); mass spectrum (70 eV) *m/e* 317 (M^+), 316 ($M^+ - 1$), 302 ($M^+ - CH_3$), 270 ($M^+ - CH_3 - S$), 259, 229, 182, 139, 102.

*2,5-Anhydro-3,4-O-isopropylidene-*D,L*-allose Semicarbazone (13c)*

Anhydroallose **9** (202 mg, 1 mmol) was dissolved in 30 ml of methanol containing semicarbazide (82.5 mg, 1.1 mmol). The solution was refluxed with a Dean–Stark trap for 5 h by which time no allose could be detected by t.l.c. Evaporation and separation of the residue on 20 × 20 silica gel plates using methanol – ethyl acetate (3:7) as a solvent system gave 180 mg of the crystalline product (R_f = 0.65), yield 70%. Recrystallization from acetone – ethyl ether gave small cubic crystals, m.p. 136–137°; i.r. (KBr disc) 3500 to 3200 (multiple bands, NH_2, NH, OH) 1690 (semicarbazone), 1640 (C=N), 1385 cm^{-1} (*gem*-dimethyl); n.m.r. ($(CD_3)_2CO$) δ 1.24 (s, 3H), 1.40 (s, 3H), 2.82 (1H, OH), 3.4 (2H), 3.82 (m's, 2H), 4.20 (dd, J = 6 Hz, J = 3 Hz), 4.5 (m's, 2H), 5.82 (NH_2), 6.8 (d, 1H, J = 6 Hz), 9.05 (1H, NH); mass spectrum (70 eV) *m/e* 259 (M^+), 244 ($M^+ - CH_3$), 201 (244 – CONH), 185 (244 – NH_2CONH), 158 (244 – CH:NNHCONH$_2$), 116, 86.

Anal. Calcd. for $C_{10}H_{17}O_5N_3$: C, 46.32; H, 6.61; N, 16.21. Found: C, 46.11; H, 6.75; N, 16.01.

*6-O-Acetyl-2,5-anhydro-3,4-O-isopropylidene-*D,L*-allose Semi-carbazone (13d)*

The semicarbazone derivative (**13***c*) (100 mg, 0.4 mmol) was dissolved in 3 ml of pyridine and 2 ml of acetic anhydride. The solution was stirred for 10 h. Evaporation of the excess pyridine – acetic anhydride left an oily brown residue which was chromatographed on a 20 × 20 silica gel plate. Elution with methanol–ethyl acetate (1:4) gave 95 mg of colorless oil (R_f = 0.8), yield 90%. The product was crystallized from methanol – petroleum ether, m.p. 148°; i.r. (KBr disc) 3490 (NH), 1760 (acetate), 1700 (amide), 1640 (C=N), 1390 cm^{-1}; n.m.r. ($CDCl_3$) δ 1.40 (s, 3H), 1.60 (s, 3H), 2.05 (s, 3H), 3.50 (1H, OH), 4.28 (b.s, 2H), 4.30 (m, 1H), 4.68 (m, 2H), 4.90 (m, 1H), 5.80 (2H, NH_2), 7.20 (d, 1H, J = 6 Hz), 10.0 (1H, NH); mass spectrum (70 eV) *m/e* 301 (M^+), 286 ($M^+ - CH_3$), 269, 258 ($M^+ - NHCO$), 243, 226, 215, 171, 86, 69.

Anal. Calcd. for $C_{12}H_{19}O_6N_3$: C, 47.83; H, 6.36; N, 13.95. Found: C, 48.04; H, 6.28; N, 13.81.

Ethyl trans-3-(5β-Hydroxymethyl-3α,4α-dihydroxy-di-O-isopropylidene-furan-1β-yl)acrylate (14)

Carbethoxymethylene triphenylphosphorane (600 mg, 1.725 mmol) was added to the anhydroallose (**9**) (300 mg, 1.48 mmol) in 15 ml of dimethylformamide. The solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was heated at 95 °C for 6 h, cooled, and stripped of solvent by evaporation under high vacuum. The residue was triturated with ether and the white crystalline material that precipitated was filtered off. The filtrate was evaporated to dryness and chromatographed on 20 × 20 silica gel plates. Elution with methylene chloride – ether (2:3) gave 250 mg of colorless oily product, yield 66%; i.r. (film) 3500 (OH), 1730 (ester), 1670 (C=C), 1380 cm^{-1} (*gem*-dimethyl); n.m.r. ($CDCl_3$) δ 1.20 (t, 3H, J = 7 Hz), 1.30 (s, 3H), 1.52 (s, 3H), 2.02 (s, O—H), 3.5 to 4.52 (m's, 8H), 5.73 (d, 1H, J = 14 Hz), 6.70 (dd, 1H, J = 14 Hz, J = 4 Hz); mass spectrum (70 eV), *m/e* 272 (M^+), 257 ($M^+ - CH_3$), 227 ($M^+ - CH_3 - CH_2O$), 214 ($M^+ - CH_3 - CH_3COO$), 167, 129, 85.

Anal. Calcd. for $C_{13}H_{20}O_6$: C, 57.35; H, 7.35. Found: C, 56.61; H, 7.66.

*Ethyl trans-3-(5β-Acetoxymethyl-3α,4α-dihydroxy-di-O-isopropylidenefuran-1β-yl)acrylate (**14a**)*

Crude or pure ester **14** (200 mg) was acetylated using 5 ml of acetic anhydride in 6 ml of pyridine stirring for 6 h at room temperature. The mixture was then evaporated to dryness under high vacuum. The oil product was purified on a silica gel column (activity III), eluting with ether–hexane (1:1). When intermediate **14** was not isolated, overall yield based on **9** is 80%; i.r. (film) 1745 (acetate), 1725 (ethyl ester), 1660 (C=C), 1380 cm^{-1} (*gem*-dimethyl); n.m.r. ($CDCl_3$) δ 1.24 (t, 3H, J = 7 Hz), 1.33 (s, 3H), 1.55 (s, 3H), 2.10 (s, 3H), 4.0–4.52 (m's, 8H), 6.18 (d, 1H, J = 16 Hz), 6.95 (dd, 1H, J = 16 Hz, J = 5 Hz); mass spectrum (70 eV) *m/e* 314 (M^+), 299 ($M^+ - CH_3$), 256 (299 − CH_3CO), 211, 196, 86.

*9β-Cyano-5β-p-nitrobenzoylmethyl-(3α,4α-dihydroxy-di-O-isopropylidene)furan (**16**)*

The oily oxime **13***a* (150 mg, 0.7 mmol), dissolved in 5 ml of pyridine containing *p*-nitrobenzoyl chloride (400 mg, 2.16 mmol) was stirred for 14 h at room temperature. *p*-Nitrobenzoic acid was then filtered off and the solution evaporated under high vacuum. Chromatography of the oily mixture on 20 × 20 silica gel plates, eluting with ether–hexane (1:1), gave 190 mg of the crystalline nitrile **16** (R_f = 0.45), yield 75%. Recrystallization of the product from chloroform–hexane at room temperature gave small needle-like crystals, m.p. 118–120°; i.r. (Nujol) 2230 (C=N), 1740 (nitro benzoate), 1380 cm^{-1} (*gem*-dimethyl); n.m.r. ($CDCl_3$) δ 1.40 (s, 3H), 1.50 (s, 3H), 4.62 (b.s., 3H), 4.82 (d, 2H, J = 8 Hz), 5.18 (dd, 1H, J = 8 Hz, J = 2 Hz); mass spectrum (70 eV) *m/e* 333 ($M^+ - CH_3$), 303 ($M^+ - CH_3 - NO$), 275 (303 − CO), 226 ($M^+ - C_6H_5NO_2$), 208, 166, 150, 131, 120.

Synthesis of 6-Hydroxyfulvenes. II. Isomerization of 7-Oxanorbornadienes and 3-Oxaquadricyclanes[1]

RAJ KUMAR BANSAL,[2] ARCHIBALD WILSON MCCULLOCH, PAUL WAYNE RASMUSSEN, AND ALISTER GAVIN MCINNES

Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia B3H 3Z1

Received July 24, 1974

RAJ KUMAR BANSAL, ARCHIBALD WILSON MCCULLOCH, PAUL WAYNE RASMUSSEN, and ALISTER GAVIN MCINNES. Can. J. Chem. **53**, 138 (1975).

Substituted 7-oxanorbornadienes (**1***a–e*) isomerize in good yield in the presence of iodine to 6-hydroxyfulvenes (**2***a–e*): the reaction is catalyzed by light. Oxaquadricyclanes having bridgehead methyl substituents (**3***b*, *c*) also undergo slow photoisomerization (2537 Å) to the same fulvenes. Irradiation of the oxanorbornadienes with bridgehead phenyl substituents (**1***d*, *e*) resulted in oxepines (**7***d*, *e*). Phenyl substituted oxaquadricyclanes could not be isolated.

RAJ KUMAR BANSAL, ARCHIBALD WILSON MCCULLOCH, PAUL WAYNE RASMUSSEN et ALISTER GAVIN MCINNES. Can. J. Chem. **53**, 138 (1975).

En présence d'iode, les oxa-7 norbornadiènes substitués (**1***a–e*) s'isomérisent avec de bons rendements pour conduire aux hydroxy-6 fulvènes (**2***a–e*); la réaction est catalysée par la lumière. Les oxaquadricyclanes possédant les substituants méthyles en tête de pont (**3***b*, *c*), subissent aussi une photoisomérisation lente (2537 Å) conduisant aux mêmes fulvènes. L'irradiation d'oxanorbornadiènes possédant des groupements phényles en tête de pont (**1***d*, *e*) fournit les oxépines (**7***d*, *e*). On n'a pas pu isoler d'oxaquadricyclanes substitués par des groupes phényles.

[Traduit par le journal]

Recent reports on the photoisomerization of 7-oxanorbornadienes and the transition metal promoted isomerizations of 7-oxanorbornadienes and 3-oxaquadricyclanes to 6-hydroxyfulvenes (1, 2) have prompted us to report our observations on these systems.

Stusche and Prinzbach have reported that the 6-hydroxyfulvenes **2***a*, *c*, *f* are formed upon direct or sensitized excitation of oxanorbornadienes **1***a*, *c*, *f* or by Cu^{I} or Ag^{I} catalyzed isomerization of the corresponding oxaquadricyclanes **3***a*, *c*, *f* (1). Bruggink and Hogeveen found that **1***a–c* and **3***a–c* are converted under the influence of $[Rh(CO)_2Cl]_2$ to **2***a–c* (2).

We have found that oxanorbornadienes **1***a–e* isomerize rapidly to **2***a–e* in the presence of *iodine*. The reaction is catalyzed by light. With the exception of **2***a* (33%) yields were $\geq 75\%$. The iodine-promoted conversion of **1** to **2** is characterized by a very fast rate and a high degree of regioselectivity. Thus, isomerization of **1***b* affords *two* fulvenes, **2***b* and **4**, but in a molar ratio of 12:1.

The reaction proceeds equally well in ether, benzene, CCl_4, or *n*-heptane. It does not, how-

ever, appear to be applicable to norbornadienes which lack a bridge heteroatom. Under the same conditions compound **5** was converted to a mixture of stereoisomeric diiodonortricyclenes **6**.[3] The iodine-assisted isomerization is moreover not applicable to the oxaquadricyclane system: under the same conditions **3***b*, *c* rapidly gave complex mixtures of products containing only small amounts of **2***b*, *c*.

Stusche and Prinzbach have observed low-yield photoisomerization of **1** to **2** on direct excitation with light of wavelength >2800 Å (1). We have found that isomerization of **3***b*, *c* (prepared by irradiation of **1** at 3000 Å) to **2***b*, *c* may be achieved slowly (30–40% in 24 h) upon irradiation of the former at 2537 Å. The latter conversions are best explained by the equilibrium (1 ⇆ 3) shown in Scheme 1 (*cf.* 3, 4).

The regioselectivity observed in both the iodine-assisted conversion of **1***b*, and the photoconversion of **3***b*, to **2***b*, is strongly suggestive of closely related pathways. We believe that the iodine-promoted conversion can best be interpreted by a radical pathway. A possible mechanism is outlined in Scheme 1.

[3]A. W. McCulloch, D. G. Smith, J. A. Walter, and A. G. McInnes. Unpublished work.

It is known that tertiary radicals are more stable than secondary by about 4 kcal (5). The observed regioselectivity of the reaction (product ratio **2***b*:**4**, 12:1) can thus be rationalized in terms of the energy difference between the radical intermediates **8***a* and **8***b*. We have derived pseudo first-order rate constants for the conversions of **1***a–c* to **2***a–c* (Table 1). The fact that increasing methyl substitution at the bridgehead positions leads to increasing rates of isomerization is consistent with the proposed mechanism. The iodine-promoted reaction, although slowed by a factor of two or three, proceeds also in the dark, presumably initiated by thermal homolytic fission of the iodine.

We were unable to isolate the phenyl-substituted oxaquadricyclanes **3***d*, *e* since irradia-

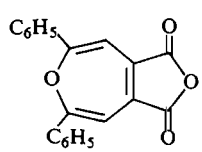
9



10

d $R_1 = C_6H_5$; $R_2 = H$
e $R_1 = R_2 = C_6H_5$

tion of **1***d*, *e* at 3000 Å led directly to the oxepines 7*d*, *e* (~60% in 24 h at 30°).[4] The thermal instability of oxaquadricyclanes and their isomerization to oxepines is well known (6–8). The latter process is highly dependent on substitution (9); it clearly is favored when aryl substituents occupy the bridgehead positions.

The structures of oxanorbornadienes **1***d*, *e* follow from their mode of formation and comparison of their spectral properties with those of the corresponding ethyl esters (10).

Compounds **2***d* and **2***e* both show infrared absorptions for the strongly bonded hydroxyl (~2950 cm^{-1}) and carbomethoxy carbonyl (~1600 cm^{-1}) groups characteristic of 1-carbomethoxy-6-hydroxyfulvenes. This is confirmed by the low-field shift of the enolic hydroxyl (~16.3 δ). The chemical shifts and multiplicities of the ring hydrogens in these compounds are comparable to those observed for the analogous methylated compounds **2***b* and **2***c*.

Although fulvene **4** could not be isolated, its p.m.r. spectral characteristics provide strong evidence for the assigned structure. The low-field hydroxyl proton and H-6 form a very distinctive AX system ($J = 13.1$ Hz), similar to that observed in the spectrum of **2***a* (2). The coupling between the ring proton and the ring methyl hydrogens is identical to that between H-4 and the *C*-methyl at C-3 in **2***c*.

Compounds 7*d* and 7*e* show infrared absorption for unsaturated ester carbonyl groups near 1720 cm^{-1} and strong ultraviolet maxima (see Experimental) compatible with oxepine structures. Their spectral properties are consistent with either 7*d*, *e* or 9*d*, *e*. Conclusive proof that the carboxylate groupings are located at C-4 and C-5, as in **7**, was provided by facile conversion of 7*e* to the cyclic anhydride **10**, the structure of which could be readily deduced from its mass, i.r., u.v., and p.m.r. spectra. The 3,6-diphenyl isomer of 7*e* has been shown to exist as the benzene oxide tautomer (11). Our p.m.r. data for 7*d*, *e* clearly indicate oxepine structures, at least at ambient temperature. It should be noted that

[4]We did not detect 3*d*, *e* in the products of irradiation at 0° and did not attempt their isolation at even lower temperatures.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

tautomerism of **7***d*, *e* to the benzene oxide forms would result in decreased conjugation.

Our physical data for **2***a–c* are identical to those previously reported (1, 2, 12). Proton magnetic resonance data for **1***d*, *e*, **2***d*, *e*, **4**, **7***d*, *e*, and **10** are given in Table 2.

Experimental

The p.m.r. spectra were obtained on a Varian A-60A spectrometer equipped with a V-6058 spin-decoupler, using $CDCl_3$ as solvent (unless stated otherwise) and tetramethylsilane as internal standard. Infrared spectra were recorded on a Perkin–Elmer 521 spectrometer, u.v. spectra (in EtOH) on a Unicam SP 8000 instrument, and mass spectra on a Dupont-CEC 21–491 spectrometer. Ultraviolet irradiation experiments were conducted in a Rayonet photochemical reactor. All column chromatography was carried out using Mallinckrodt silicic acid (100–150 mesh); preparative t.l.c. employed Merck silica gel HF-254.

2,3-Dicarbomethoxy-7-oxabicyclo[2.2.1]hepta-2,5-dienes (1a–d)

Adducts **1***a–d* were prepared by conventional thermal Diels–Alder reaction (100°) of the appropriate furan with dimethyl acetylenedicarboxylate (DMAD) and were purified by column chromatography ($CHCl_3$). Adduct **1***d* was obtained as a yellow oil, n_D^{24} 1.5312.

2,3-Dicarbomethoxy-1,4-diphenyl-7-oxabicyclo[2.2.1]hepta-2,5-diene (1e)

A solution of 2,5-diphenylfuran (14.30 g, 0.065 mol) in CH_2Cl_2 (75 ml) was added to a stirred mixture of DMAD (9.24 g, 0.065 mol) and $AlCl_3$ (8.67 g, 0.065 mol) in CH_2Cl_2 (250 ml), both solutions being cooled to −20° before mixing. Stirring was continued for 1 h at −20°. The reaction mixture was then washed with water, dried (Na_2SO_4), and evaporated. Trituration of the residue with ether–petroleum ether gave **1***e* as cream-coloured prisms (3.84 g, 16%), m.p. 120–121°.

Isomerization of 1 to 2

General procedure

An ether solution of the oxanorbornadiene **1** and iodine was irradiated (3000 Å in Rayonet reactor, or exposure to daylight) for 15 min at 25–30°. The mixture was washed with sodium bisulfite solution, then H_2O, dried (Na_2SO_4), and evaporated. The 6-hydroxyfulvene was obtained by purification of the residue.

1,2-Dicarbomethoxy-6-hydroxyfulvene (2a)

The general procedure was modified in that a solution of **1***a* (1.2 g, 0.006 mol) and I_2 (2.89 g, 0.011 mol) in Et_2O (150 ml) was irradiated (3000 Å) for 90 min. Column chromatography of the oily product gave **2***a* as a yellow oil (400 mg, 33%), n_D^{25} 1.6554; molecular ion at *m/e* 210 ($C_{10}H_{10}O_5$ requires 210).

1,2-Dicarbomethoxy-6-methyl-6-hydroxyfulvene (2b) and 1,2-Dicarbomethoxy-3-methyl-6-hydroxyfulvene (4)

Reaction of **1***b* (0.4 g, 0.002 mol) and I_2 (0.045 g, 0.0002 mol) in Et_2O (100 ml) gave a product shown by p.m.r. (see Table 2) to contain **2***b* and **4** in a ratio of 12:1. Crystallization from petroleum ether gave **2***b* as yellow needles (0.31 g, 78%), m.p. 84–85°; molecular ion at *m/e* 224 ($C_{11}H_{12}O_5$ requires 224); ν_{max} (CCl_4) 2955, 1730 cm^{-1}; ν_{max} (KBr) 2955, 1720, 1610 cm^{-1}; λ_{max} (ε) 238 (12 300), 326 nm (21 700). All attempts to isolate **4** by chromatography were unsuccessful.

1,2-Dicarbomethoxy-3,6-dimethyl-6-hydroxyfulvene (2c)

Column chromatography ($CHCl_3$) of the crude product from reaction of **1***c* (4.0 g, 0.017 mol) and I_2 (0.100 g, 0.0004 mol) in Et_2O (400 ml) gave **2***c* as a yellow oil (3.21 g, 80%), identical to the material obtained previously by acid-catalyzed rearrangement of **3***c* (11). The conversion of **1***c* also proceeded readily in benzene, CCl_4, or *n*-heptane.

1,2-Dicarbomethoxy-6-phenyl-6-hydroxyfulvene (2d)

The oily product obtained from reaction of **1***d* (0.6 g, 0.002 mol) and I_2 (0.05 g, 0.0002 mol) in Et_2O (150 ml) was submitted to preparative t.l.c. ($CHCl_3$). This gave **2***d* as a viscous yellow oil (0.45 g, 75%), which slowly crystallized as needles, m.p. 92–94°; molecular ion at *m/e* 286 ($C_{16}H_{14}O_5$ requires 286); ν_{max} (liquid film) 2950, 1715, 1605, 1563 cm^{-1}; λ_{max} (ε) 230 (11 100), 270 (5400), 347 nm (12 000).

1,2-Dicarbomethoxy-3,6-diphenyl-6-hydroxyfulvene (2e)

Crystallization (EtOH) of the crude product from reaction of **1***e* (2.00 g, 0.0055 mol) and I_2 (0.050 g, 0.0002 mol) in Et_2O (300 ml) gave **2***e* as bright orange needles (1.80 g, 90%), m.p. 141–142°; molecular ion at *m/e* 362 ($C_{22}H_{18}O_5$ requires 362); ν_{max} (CCl_4) 2955, 1732 cm^{-1}; ν_{max} (KBr) 2950, 1725, 1620, 1608, 1588, 1567 cm^{-1}; λ_{max} (ε) 237 (15 500), 273 (21 100), 345 nm (14 800).

Rate Studies

Stirred CCl_4 solutions 0.0155 *M* in adduct **1***a*, *b*, or *c*, and 0.00465 *M* in I_2 were allowed to react at 27° in the dark and under illumination from a 15 W bulb filtered through an Ilford F-904 red filter. Disappearance of the adduct was followed by gas chromatography assay (benzophenone internal standard) of aliquots after passage through a column of 8:1 $NaHSO_3$:celite 545. Values of $\log_e A_0/A$, where A_0 = ratio of adduct to benzophenone at zero time, and A = ratio of adduct to benzophenone at time t, were then plotted against time to give in each case over the first 5 min of reaction a straight line from which a pseudo first-order rate constant could be determined (Table 1).

2,3-Dicarbomethoxy-3,6-diiodonortricyclenes (6)

A solution of 2,3-dicarbomethoxybicyclo[2.2.1]hepta-2,5-diene **5** (7.16 g, 0.034 mol) and I_2 (10.13 g, 0.040 mol) in Et_2O (400 ml) was exposed to daylight for 4 h at room temperature, and was then washed with bisulfite, then H_2O, and dried (Na_2SO_4). The residue (13.62 g) obtained on evaporation was shown by n.m.r. studies to be predominantly a mixture of two stereoisomeric nortricyclenes of overall structure **6**.[3]

Oxaquadricyclanes 3b and 3c

These compounds were prepared by irradiation of Et_2O solutions of **1***b* and **1***c* at 3000 Å for 6 h at 30°.

Isomerization of 3 to 2

Reactions of **3***b* or **3***c* with I_2 using the standard procedure employed above for the conversion of **1** to **2** resulted in complex mixtures of products containing only small amounts of **2***b* and **2***c*.

Irradiation of Et_2O solutions of **3***b* or 3*c* at 2537 Å for 24 h at 30° caused 30–40% conversion (p.m.r.) to **2***b* and **2***c*.

Isomerization of 1 to 7

4,5-Dicarbomethoxy-2-phenyloxepine (7d)

A solution of **1***d* (2.00 g) in Et_2O (200 ml) was irradiated at 3000 Å for 24 h at 30°. The residue obtained on evaporation of solvent[5] was chromatographed ($CHCl_3$). Pure **7***d* was collected as a yellow oil (0.36 g, 18%), n_D^{24} = 1.5940; molecular ion at *m/e* 286 ($C_{16}H_{14}O_5$ requires 286); ν_{max} (liquid film) 1723 cm^{-1}; λ_{max} (ε) 249 (14 900), 325 (5100), 345 nm (6100).

4,5-Dicarbomethoxy-2,7-diphenyloxepine (7e)

A solution of **1***e* (2.40 g) in Et_2O (425 ml) was irradiated at 3000 Å for 24 h at 30°. Evaporation of the solvent and crystallization of the residue from EtOH gave **7***e* as bright yellow prisms (1.44 g, 60%), m.p. 113–114°; molecular ion at *m/e* 362 ($C_{22}H_{18}O_5$ requires 362); ν_{max} (KBr) 1716, 1603 cm^{-1}; λ_{max} (ε) 268 (37 500), 325 (8500), 365 nm (8300).

4,5-Dicarbethoxy-2,7-diphenyloxepine, prepared in the same way from 2,3-dicarbethoxy-1,4-diphenyl-7-oxabicyclo[2.2.1]hepta-2,5-diene, crystallized as yellow-orange prisms, m.p. 108.5–109.5°; molecular ion at *m/e* 390.

2,7-Diphenyloxepine-4,5-dicarboxylic Anhydride (10)

A solution of **7***e* (250 mg) in 1 *N* methanolic KOH (15 ml) was refluxed for 75 min. The precipitated salt (bronze coloured leaflets) and supernatant were concentrated and the residue dissolved in H_2O. The yellow aqueous solution was extracted with Et_2O (colourless extract → no material) and then acidified with HCl. The acid solution was extracted with Et_2O until colourless: evaporation of solvent gave crude **10** as an orange solid (225 mg), m.p. 160–167°, which gave no effervescence with bicarbonate. A sample of the pure anhydride was obtained by preparative t.l.c. ($CHCl_3$) as bright orange-red rosettes, m.p. 168–170°; molecular ion at *m/e* 316 ($C_{20}H_{12}O_4$ requires 316); ν_{max} (KBr): 1840, 1815, 1800, 1755, 1297, 1246 cm^{-1}; λ_{max} (ε) 271 (30 200); 326 (5400), 364 nm (5500).

[5]Proton magnetic resonance examination of the crude product indicated a conversion to **7***d* of the order of 50–60%. The low yield after chromatography must be due to partial decomposition of the oxepine on the column.

We thank Mrs. M. G. Flack for her excellent technical assistance and Mr. P. F. Seto for the i.r. spectra.

Conversion of Bicyclo[2.2.2]octane Systems into Tricyclo[3.2.1.$0^{2,7}$]octanes: A Third Synthesis of the Diterpenoid Trachylobane

RONALD B. KELLY, BARRY A. BECKETT, JENO EBER, HING-KWOK HUNG, AND JIRI ZAMECNIK

Department of Chemistry, University of New Brunswick, Saint John, New Brunswick

Received August 20, 1974

RONALD B. KELLY, BARRY A. BECKETT, JENO EBER, HING-KWOK HUNG, and JIRI ZAMECNIK. Can. J. Chem. **53**, 143 (1975).

The cyclization of bicyclooctane systems to tricyclooctane systems is discussed with particular reference to stereochemical aspects as encountered during the total syntheses of ishwarane and trachylobane. Of special interest are the homoallylic cyclizations. A third, convenient synthesis of trachylobane via a reductive homoallylic cyclization is reported.

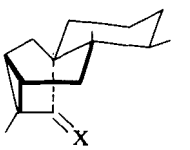
RONALD B. KELLY, BARRY A. BECKETT, JENO EBER, HING-KWOK HUNG et JIRI ZAMECNIK. Can. J. Chem. **53**, 143 (1975).

On discute de la cyclisation des systèmes bicyclooctane en systèmes tricyclooctane; on s'intéresse particulièrement aux aspects stéréochimiques rencontrés durant les synthèses totales de l'ishwarane et du trachylobane. Les cyclisations homoallyliques sont d'un intérêt spécial. On rapporte une troisième synthèse très pratique du trachylobane par l'intermédiaire d'une cyclisation homoallylique réductrice. [Traduit par le journal]

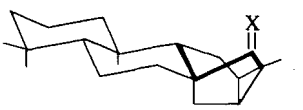
Formerly, we have described a total synthesis of the sesquiterpenoid ishwarane (**1**) (1) and two synthetic routes to the diterpenoid trachylobane (**2**) (2). A novel structural feature common to both of these terpenoids is a tricyclo[3.2.1.$0^{2,7}$]-octane system. Consequently, during our work on the synthesis of ishwarane and trachylobane, we became interested in devising methods for converting bicyclo[2.2.2]octane systems, readily available by synthesis, into tricyclo[3.2.1.$0^{2,7}$]-octane systems.

We have already described (1, 2) two methods for achieving such conversions. We now wish to report the application of yet another method which has resulted in a third, convenient synthesis of trachylobane (**2**). Also, we wish to discuss some recently observed stereochemical aspects of the cyclization of bicyclooctane systems to tricyclooctane systems and to present some experimental details of our work which have not yet been published.

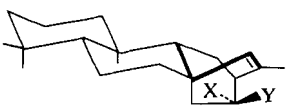
Very recently we were successful in converting the synthetic mesylate **3** directly into trachylobane (**2**) in 60% yield by reduction with lithium aluminum hydride under mild conditions. Since **3** (*2b*) and the corresponding alcohol **4** (*2a*) are intermediates in our previously described syntheses of trachylobane, the conversion **3** → **2** constitutes a third and, so far, the most convenient synthesis of trachylobane.

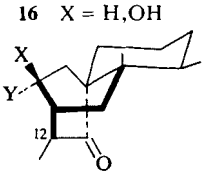


1 X = H,H
8 X = O

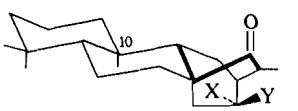


2 X = H,H
10 X = O
16 X = H,OH





3 X = OMs; Y = H
4 X = OH; Y = H
5 X = H; Y = OMs
6 X = H; Y = OH
7 X = OTs; Y = H
11 X = H; Y = OTs
12 X = O—$\overset{+}{S}(CH_3)_2$; Y = H



9 X = OTs; Y = H
13 X = H; Y = OTs
14 X = O—$\overset{+}{S}(CH_3)_2$; Y = H
15 X = H; Y = OH

With regard to the conversion **3** → **2** by lithium aluminum hydride, it should be mentioned that there is precedent (3) for such reductive homoallylic cyclizations which are understandable in

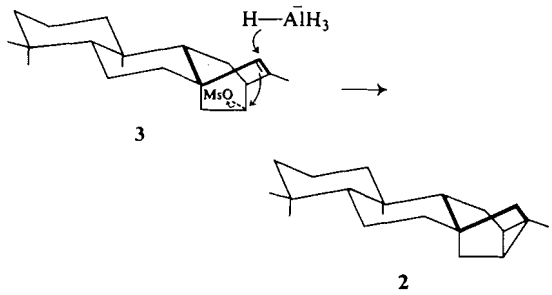

SCHEME 1

terms of the mechanism shown in Scheme 1. As might be expected from precedent (3), treatment of the epimeric *syn*-mesylate **5** of the alcohol **6** (2*a*) with lithium aluminum hydride (as above) produced a mixture of intractable olefinic material possibly containing skeletally rearranged olefin (3).

Our original method for converting bicyclooctane systems into tricyclooctane systems depended on an S_N2i displacement of tosylate by a carbanion as exemplified by the cyclization of **7** to **8** in 70% yield (1) and **9** to **10** in 52% yield (2*a*). These cyclizations, which were achieved by heating the keto tosylates with methylsulfinyl carbanion (4) in dimethyl sulfoxide at 60°, may be regarded as stereochemically unexceptional because, in both instances, the tosylate function is favorably aligned (*anti*) for an S_N2i displacement by the carbanion.

Surprisingly, however, it was found that the *syn*-keto tosylate **11** also cyclized in 60% yield under the same conditions. A mechanism proposed (1) for this cyclization invoked an S_N2 displacement of tosylate by dimethyl sulfoxide to give the intermediate **12** which, being favorably aligned, underwent S_N2i displacement of dimethyl sulfoxide by the carbanion at C-12 to give **8**.

In view of the cyclization of **11**, it was of interest to investigate the behavior of the *syn*-keto tosylate **13** under cyclization conditions identical to those employed in the case of **11** (these conditions were also employed for the cyclizations **7** → **8** and **9** → **10**). In the event, **13** did indeed cyclize to **10** but in only 21% yield. The low yield of **10** suggests that stereochemical factors play an important role in this type of reaction.[1]

A plausible explanation for the low yield of **10** from **13** can be adduced on the basis of stereochemical considerations applied to the proposed double-displacement mechanism (*vide supra*). Thus, models show that the approach of dimethyl sulfoxide during an S_N2 displacement of tosylate in **13** to give the postulated intermediate **14** is hindered by the methyl group at C-10. Consequently, the proposed double-displacement mechanism via the intermediate **14** cannot operate as effectively as in the cyclization **11** → **8**. In the latter the approach of dimethyl sulfoxide required for an S_N2 displacement of tosylate is relatively unhindered. These observations lend support to the proposed double-displacement mechanism.

The key step in our second synthetic route to trachylobane (2*b*) was a homoallylic cyclization of the mesylate **3** of the alcohol **4** (*cf.* ref. 6). Thus, when **3** was heated at 60° in dimethyl sulfoxide containing methylsulfinyl carbanion it was converted to a ketone (60% from **4**) and an alcohol (30% from **4**).

The ketone was identified as the cyclopropyl ketone **10**, the immediate precursor of trachylobane (**2**) in our original synthesis of this diterpenoid (2*a*). The crystalline alcohol possessed properties consistent with structure **16**; the i.r. spectrum showed hydroxyl absorption at 3240 cm^{-1} and the n.m.r. spectrum was devoid of signals attributable to vinylic protons and vinylic methyl but exhibited a singlet (1H) at δ 3.25 due to the *H*—C—OH group. Also consistent with structure **16** was the fact that it could be oxidized in 70% yield with Jones' reagent (5) to the cyclopropyl ketone **10**.

The ketone **10** was also obtained in 70% yield from **4** by direct oxidation of the crude cyclization product with Jones' reagent (5). In our original synthesis of trachylobane (2*a*) the conversion of **4** into **10** required six steps and was accomplished in 14% yield. The conversion of **4** into **10** by the method just described therefore completes a synthesis of trachylobane which is a significant improvement over the original synthesis.

A plausible mechanism for the cyclization of **3** to **10** and **16**, shown in Scheme 2, involves the intermediate **17** which arises by the homoallylic mechanism indicated. Elimination of the proton at C-14 of the intermediate **17** would give the cyclopropyl ketone **10** (*cf.* ref. 7) whereas hydrolysis of **17** would produce the alcohol **16**.

Lately we have subjected the *syn*-mesylate **5**,

[1]The synthesis of the alcohol **15**, corresponding to the tosylate **13** is described in the sequel.

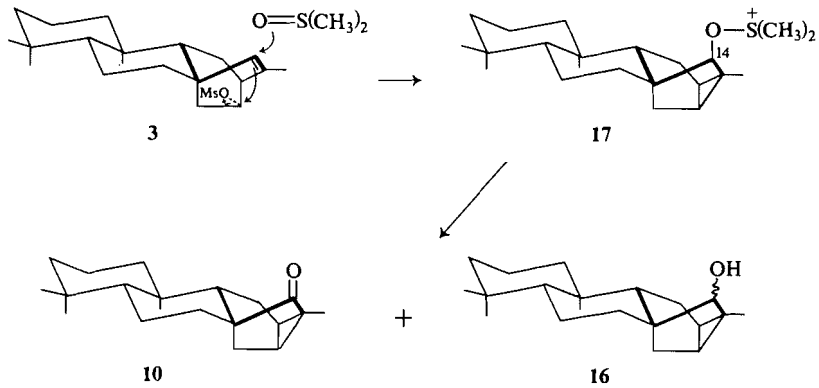
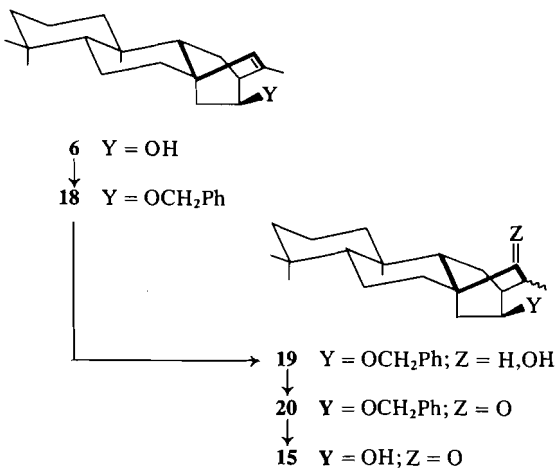


SCHEME 2

epimeric with the mesylate **3** at C-16, to the identical conditions whereby **3** underwent cyclization to **10** and **16**. In contrast with **3**, the mesylate **5** was recovered quantitatively. Thus, it would appear that the stereochemical requirements for homoallylic cyclizations are critical. This is demonstrated by the fact that, whereas **3** underwent reductive homoallylic cyclization to trachylobane **2** (*vide supra*) and cyclized to the cyclopropyl ketone **10** and the cyclopropyl alcohol **16** as just described, the epimeric mesylate failed to cyclize under identical conditions.

The synthesis of the keto alcohol **15** is outlined in Scheme 3. The starting material for this synthesis was the totally synthetic enol **6**, encountered during our original synthesis of trachylobane (*2a*). This was converted in 69% yield to the crystalline benzyl ether **18** which, on hydroboration followed by oxidation with peroxide, afforded the crystalline benzyl ether alcohol **19**. The spectral properties of the hydroboration–oxidation product were consistent with structure **19**; the i.r. spectrum showed hydroxyl absorption at 3490 cm^{-1} and the n.m.r. spectrum showed a singlet (3H) at δ 0.81 and two superimposed singlets (6H) at 0.88 due to tertiary methyl groups, a doublet (3H) at 1.33 due to the secondary methyl, a single-proton doublet at 3.00 due to *H*—C—OH, a multiplet (1H) at 3.64 due to *H*—C—O, a 2-proton multiplet at 4.48 due to benzylic protons and a multiplet (7H) at 7.32 due to aromatic protons.

Oxidation of **19** with the Sarett reagent (8) afforded, in 87% yield, the crystalline keto benzyl ether **20** (i.r. 1705 cm^{-1} (ketone)). Removal of the benzyl group of **20** by hydrogenolysis gave the crystalline keto alcohol **15** in 80% yield (i.r. 3450 cm^{-1} (OH), 1705 cm^{-1} (ketone); n.m.r. δ 4.10 (m, 1H, *H*—C—OH), devoid of signals for aromatic protons).



SCHEME 3

Experimental

Instrumentation,[2] *Methods, and Materials*

The n.m.r. chemical shifts are expressed in p.p.m. (δ values) downfield from the signal for tetramethylsilane which is used as an internal standard.

Reaction products were isolated by the following procedure. The product was extracted into the specified solvent and the extract was washed three times with appropriate aqueous solutions as indicated. The original aqueous layer (if any) and the aqueous washings were extracted three times with the solvent and the combined extracts were dried over anhydrous magnesium sulfate, filtered and evaporated *in vacuo* on a rotary evaporator.

[2]Information about instrumentation may be obtained by consulting ref. *2a*.

Petroleum ether refers to the fraction with b.p. 30–60°. Brine refers to a saturated solution of sodium chloride.

*Conversion of Mesylate **3** Directly to Trachylobane with Lithium Aluminum Hydride*

A solution of 50 mg of the enol **4** in 3 ml of pyridine was cooled to 0° then treated with 0.1 ml of methanesulfonyl chloride. The solution was left, under nitrogen, at −14° for 62 h then at 10° for a further 10 h. Ice was added to the reaction mixture and the resulting aqueous solution was worked up in the usual manner with cold 1 *N* hydrochloric acid and brine. Evaporation of the dried ether extracts gave 64 mg of mesylate **3** which was used in the next step without further purification.

The following reaction was carried out in a dry nitrogen atmosphere. A solution of 64 mg of the mesylate **3** in 3 ml of ether was added slowly over a period of 30 min to a stirred suspension of 38 mg of lithium aluminum hydride in 3 ml of ether. The mixture was then refluxed for 5 h. The cooled reaction mixture was treated with 0.3 ml of brine, stirred for 5 h, dried with anhydrous sodium sulfate and filtered. Evaporation of the filtrate and purification of the residue by t.l.c. on silica gel with pentane as solvent afforded 28 mg (60%) of (±)-trachylobane. This synthetic sample of trachylobane was identical with a sample of authentic trachylobane obtained from natural sources (i.r. and n.m.r. spectra, a single peak on v.p.c. when coinjected with the authentic sample).[3]

Anal. Calcd. for $C_{20}H_{32}$: C, 88.16; H, 11.84. Found: C, 88.31; H, 12.01.

*Homoallylic Cyclization of Mesylate **3** to Cyclopropyl Ketone **10** and Cyclopropyl Alcohol **16***

The enol **4** (75 mg) was converted to the mesylate **3** by the procedure described in the preceding experiment and the mesylate was treated as follows in a dry nitrogen atmosphere. A solution of 95 mg of **3** in 2.6 ml of dry dimethyl sulfoxide was treated with 0.51 ml of a 0.5 *M* dimethyl sulfoxide solution of methylsulfinyl carbanion (4). The solution was heated at 60° for 1.5 h then cooled and treated with 0.5 ml of water. The reaction solution was worked up with ether, brine, and water in the usual manner. The product, obtained by evaporation of the ether extracts, was separated into two fractions by t.l.c. on silica gel with chloroform as solvent.

Crystallization of the faster moving fraction from petroleum ether afforded 45 mg (60%) of the *cyclopropyl ketone **10***, m.p. 88°; identical (mixture m.p., u.v., i.r., and n.m.r. spectra) with the same cyclopropyl ketone previously obtained by a different method (*2a*).[3]

Anal. Calcd. for $C_{20}H_{30}O$: C, 83.86; H, 10.56. Found: C, 84.20; H, 10.61.

Crystallization of the slower moving fraction from ether – petroleum ether afforded 23 mg (30%) of the *cyclopropyl alcohol **16***, m.p. 118–119°; ν_{max} (Nujol) 3240 cm^{-1} (OH); n.m.r. ($CDCl_3$), *ca.* δ 0.60 (m, 2H, protons on cyclopropane ring), 0.79, 0.83, 0.97, and 1.19 (s, 3H each, tertiary methyls), 3.25 (s, 1H, *H*—C—OH), devoid of signals for vinylic protons and vinylic methyl.

Anal Calcd. for $C_{20}H_{32}O$: C, 83.27; H, 11.25. Found: C, 83.25; H, 11.02.

In a separate experiment, 100 mg of **4** was converted to the mesylate **3** and treated with methylsulfinyl carbanion (4) in dimethyl sulfoxide as above. A solution of the crude cyclization product (120 mg) in 12 ml of ether was cooled on an ice bath and treated dropwise with 8 *N* Jones' reagent (5) until a persistent orange color was observed. After the addition of 1 ml of methanol, the reaction mixture was worked up in the usual manner with ether, sodium carbonate solution and brine. Crystallization of the product from petroleum ether afforded 69 mg (70%) of the *cyclopropyl ketone **10***, m.p. 88°; identical (mixture m.p., u.v., i.r., and n.m.r. spectra) with the cyclopropyl ketone obtained in a preceding section of this experiment.[3]

*Oxidation of the Cyclopropyl Alcohol **16** to the Cyclopropyl Ketone **10***

Oxidation of 117 mg of the cyclopropyl alcohol **16** with Jones' reagent (5) by the procedure described in the preceding experiment afforded 81 mg (70%) of the cyclopropyl ketone **10**, m.p. 88°; identical (mixture m.p., u.v., i.r., and n.m.r. spectra) with the cyclopropyl ketone obtained in the preceding experiment.[3]

*Benzyl Ether **18***

A mixture of 546 mg of the enol **6** (*2a*), 546 mg of sodium hydride and 45 ml of benzene was refluxed under a dry nitrogen atmosphere for 5 h. Benzyl chloride (2.28 ml) was then added and reflux was continued for an additional 17 h. After cooling, the reaction mixture was treated dropwise with 5 ml of methanol then added to 100 ml of water. The benzene layer was separated and the aqueous layer was extracted with ether. The benzene layer and the ether extracts were combined and evaporated *in vacuo*. The residual oil was chromatographed on a column of 90 g of silica gel with 2% of ether in petroleum ether as solvent. The material eluted from the column was rechromatographed on a column of 30 g of silica gel impregnated with 20% of silver nitrate. Elution of the column with 1% of ether in petroleum ether and crystallization of the eluted product from pentane afforded 500 mg (69%) of **18**, m.p. 47°; ν_{max} (smear) 3030–3000, 2000–1600, and 800–680 (multiple bands, aromatic) and 1650 cm^{-1} (olefin); n.m.r. ($CDCl_3$), δ 0.79 (s, 3H, tertiary methyl), 0.84 (s, 6H, superimposed signals for two tertiary methyls), 3.55 (m, 1H, *H*—C—O), 4.47 (s, 2H, benzylic methylene), 5.61 (m, 1H, vinylic proton), 7.27 (m, 5H, aromatic protons).

Anal. Calcd. for $C_{27}H_{38}O$: C, 85.66; H, 10.12. Found: C, 85.82; H, 10.31.

*Benzyl Ether Alcohol **19***

A solution of 188 mg of the benzyl ether **18** in 1.6 ml of dry tetrahydrofuran was treated, while cooled on an ice bath, with 0.62 ml of a 1 *M* tetrahydrofuran solution of borane. The reaction solution was allowed to warm to room temperature and kept under dry nitrogen for 16 h. After the addition of 0.3 ml of water, the reaction solution was treated with 1 ml of 3 *M* sodium hydroxide followed by 1 ml of 30% hydrogen peroxide. The mixture was stirred at 40° for 45 min then worked up in the usual manner with ether and brine. Purification of the product by t.l.c. on silica gel with ether – petroleum ether as solvent followed by crystallization from pentane gave 105 mg (54%) of **19**, m.p. 106–107°; ν_{max} (Nujol) 3490 cm^{-1}; n.m.r. ($CDCl_3$), δ 0.81 (s, 3H, tertiary methyl),

[3]For the spectral properties of trachylobane and the cyclopropyl ketone **10** see ref. *2a*.

0.88 (s, 6H, superimposed signals for two tertiary methyls), 1.33 (d, J = 6.5 Hz, 3H, secondary methyl), 3.00 (d, J = 3.0 Hz, 1H, *H*—C—OH), 3.64 (m, 1H, *H*—C—O), 4.48 (m, 2H, benzylic protons), 7.32 (m, 5H, aromatic protons).

Anal. Calcd. for $C_{27}H_{40}O_2$: C, 81.76; H, 10.17. Found: C, 81.27; H, 10.45.

Keto Benzyl Ether ***20***

A solution of 134 mg of the benzyl ether alcohol **19** in 2.5 ml of pyridine was added to 240 mg of chromic anhydride suspended in 2.5 ml of pyridine. The mixture was stirred in the dark at room temperature for 4 h. The pyridine was evaporated *in vacuo*, the residue suspended in water and the product extracted into ether. The ether extracts were worked up in the usual manner with brine. Crystallization of the product from methylene chloride – ether afforded 116 mg (87%) of **20**, m.p. 154°; ν_{max} (Nujol) 1705 cm^{-1} (ketone); n.m.r. ($CDCl_3$) δ 0.83, 0.86 and 0.96 (s, 3H each, tertiary methyls), 1.31 (d, J = 6.5 Hz, 3H, secondary methyl), 3.78 (m, 1H, *H*—C—O), 4.50 (s, 2H, benzylic protons), 7.27 (m, 5H, aromatic protons).

Anal. Calcd. for $C_{27}H_{38}O_2$: C, 82.18; H, 9.71. Found: C, 82.49; H, 9.66.

Keto Alcohol ***15***

The keto benzyl alcohol **20** in 38 ml of ethanol was hydrogenated at *ca.* 2 atm. pressure over 75 mg of palladium–charcoal catalyst (10% Pd) for 15 h. Removal of the catalyst by filtration, evaporation of the solvent *in vacuo* and crystallization of the residue from ether – petroleum ether afforded 83 mg (80%) of **15**, m.p. 161–162°; ν_{max} (Nujol) 3450 (OH) and 1705 cm^{-1} (ketone); n.m.r. ($CDCl_3$), δ 0.84, 0.87, and 0.97 (s, 3H each, tertiary methyls), 1.30 (d, J = 6.5 Hz, 3H, secondary methyl), 4.10 (m, 1H, *H*—C—OH).

Anal. Calcd. for $C_{20}H_{32}O_2$: C, 78.89; H, 10.60. Found: C, 79.12; H, 10.88.

Carbon-13 Fourier Transform Nuclear Magnetic Resonance. IX.[1] Complete Assignments of some Prodigiosins. Bioincorporation of Label

ROBERT J. CUSHLEY,[2] RICHARD J. SYKES, C.-K. SHAW, AND HARRY H. WASSERMAN

Department of Chemistry, Yale University, and Section of Physical Sciences, Yale University School of Medicine, New Haven, Connecticut 06520

Received July 15, 1974

ROBERT J. CUSHLEY, RICHARD J. SYKES, C.-K. SHAW, and HARRY H. WASSERMAN. Can. J. Chem. **53**, 148 (1975).

A comprehensive study has been made of the carbon-13 chemical shifts of substituted pyrroles. The data, together with perdeuteration, single resonance, and off-resonance techniques, formed the basis for the complete interpretation of the carbon-13 spectra of the prodigiosins. Based on these assignments the biosynthetic origin of the prodigiosin carbons was elucidated, with further biosynthetic studies to be reported.

Carbon-13 chemical shifts are shown to be an effective means of determining sites of protonation.

ROBERT J. CUSHLEY, RICHARD J. SYKES, C.-K. SHAW et HARRY H. WASSERMAN. Can. J. Chem. **53**, 148 (1975).

On a fait une étude exhaustive des déplacements chimiques du carbone-13 de pyrroles substitués. Ces données, accompagnées de la perdeutération et des techniques de résonance simple et d'irradiation hors résonance (off-resonance, permettent une interprétation complète du spectre de carbone-13 des prodigiosines. Sur la base de ces attributions, on a élucidé l'origine biosynthétique des carbones de la prodigiosines; on a fait aussi appel à d'autres études biosynthétiques qui seront rapportées.

Les déplacements chimiques en carbone-13 sont des moyens efficaces de déterminer les sites de protonation. [Traduit par le journal]

Introduction

The prodigiosins are red bacterial pigments, unique in nature as the only known polypyrroles that are biosynthetically unrelated to the porphyrins. Six prodigiosins are known, all having in common a methoxybipyrrolepyrrolemethane skeleton. A listing of the recent literature on these pigments was given in the communication of this work (2), which described the biological incorporation of [1-^{13}C]- and [2-^{13}C]-acetate into prodigiosin (**17**).[3]

A number of studies have been published recently on the ^{13}C n.m.r. of porphyrins and corrinoid compounds especially of vitamin B_{12} (3), including studies of samples biosynthetically enriched with ^{13}C (4). Because of the importance attached to the pyrrole moiety, and in order to assign the ^{13}C spectra of several prodigiosins, we have made a systematic study of the ^{13}C chemical shifts of a number of pyrrole derivatives by Fourier transform n.m.r. Unambiguous assignments for the prodigiosins was critical since it formed the basis for biosynthetic studies.

Experimental

Carbon-13 spectra were determined using a computer controlled Fourier transform n.m.r. system consisting of an on-line IBM 1800 computer with 24K of 4 μs core and a 21.5 kGauss Bruker HFX-3 spectrometer (5). The computer is remotely controlled through an 1816 typewriter, interrupts, and digital input at the n.m.r. console. The 1800 is capable of sampling up to 8192 FID double precision or 16 384 single precision data points at rates up to 20 KHz (11 bit ADC for both one- and two-word integers). The r.f. excitation pulse is created at a set of H-P 10514 mixers by logic levels from the IBM 1800 Electronic Contact Operate (ECO). Pulses are amplified using a commercially available power amplifier. After amplification and phase detection, the FID signal is conditioned for the ±5 V input level of the 1800 ADC Multiplexer with an HP-8875A Differential Amplifier followed by a four-pole Tchebyscheff active filter with selectable cutoff frequencies (automatically set by the controlling program) for use at

several sampling rates. A 4096 channel hard-wired computer which has been modified to accept digital data serves as an on-line buffered CRT-plotter for data presentation.

Unless otherwise indicated in the text, ^{13}C spectra were run using the following conditions: digitizing rate = 10 KHz; pulse width = 50 μs; receiver skip = 100 μs; ISKIP (5) = 0 s.

When a 4K data set was obtained, chemical shifts are quoted to the nearest tenth ±0.1 p.p.m.; 8K data set quoted to the nearest hundredth ±0.05 p.p.m.

Materials

Compounds **1–8**, **10**, and **11** are commercially available from the Aldrich Chemical Company. Compound **9** was obtained by pyrolysis of **17** (6). Sources for the remaining compounds were: **12–14** (7); **15** (8); **16** (9); **17** (10); **19** (11), and **21** (12).

Perdeuterioprodigiosin (Typical Run)

Prodigiosin hydrochloride (**18** 2.5 g, 7.5 mmol) was dissolved in 100 ml deuteriochloroform in a 300 ml round bottomed flask; 6 *N* DCl in D_2O (25 ml) was added and the flask was shaken vigorously for 48 h. The chloroform layer was filtered and finely powdered sodium carbonate (anhydrous) was added to neutralize the bulk of the excess acid; after a further filtration the chloroform solution was washed with 1 *N* KOH–D_2O until the pigment had been converted to the free base. The chloroform layer was separated and the chloroform removed *in vacuo*. The residue was dissolved in methylene chloride and this solution was washed with 0.1 *N* DCl–D_2O. The methylene chloride was removed on the rotovac and the residue thoroughly dried in high vacuum. A single recrystallization gave clean crystals of perdeuterio **18** (1.8 g, 70% yield). The proton n.m.r. spectrum showed only two aromatic absorptions, both sharp singlets, the high field one of which became a doublet on washing the n.m.r. solution with H_2O: δH 6.19 p.p.m. (A4) and δH 6.71 p.p.m. (1′′).

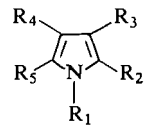
Biosynthetic Experiments

The bioincorporation experiment consisted of feeding sodium [1-^{13}C]- and [2-^{13}C]-acetate (Prochem Ltd., 62% ^{13}C) in two separate experiments at 10 mmol/l in a Bactopeptone and glycerol medium in agar gel. The ^{13}C Fourier transform spectra of isolated prodigiosin (**17**) showed levels of labeled carbons of ~8 and ~11%, respectively (2).

Results and Discussion

Pyrroles

The ^{13}C spectra of pyrrole (**1**) and two alkyl pyrroles (**3**, **5**) have been published by Grant and co-workers (13) and Roberts and co-workers (14). Lippmaa *et al.* (15) have reported ^{13}C spectra of a number of nitropyrroles. Our list of pyrroles includes some with electron withdrawing and electron donating substituents, and two bipyrroles.



1 R_1–R_5 = H
2 R_1 = CH_3; R_2–R_5 = H
3 R_2 = CH_3; R_1, R_3–R_5 = H
4 R_1, R_2 = CH_3; R_3–R_5 = H
5 R_2, R_5 = CH_3; R_1, R_3, R_4 = H
6 R_1, R_2, R_5 = CH_3; R_3, R_4 = H
7 R_2, R_4 = CH_3; R_1, R_3, R_5 = H
8 R_2, R_4 = CH_3; R_3 = Et; R_1, R_5 = H
9 R_2 = CH_3; R_3 = *n*–Amyl; R_1, R_4, R_5 = H
10 R_2 = CHO; R_1, R_3–R_5 = H
11 R_1 = CH_3; R_2 = CHO; R_3–R_5 = H
12 R_2 = COOMe; R_1, R_3–R_5 = H
13 R_2 = COOEt; R_5 = CH_3; R_1, R_3, R_4 = H
14 R_2 = COOEt; R_3 = OMe; R_5 = CH_3; R_1, R_4 = H

The ^{13}C chemical shift assignments of these pyrroles and bipyrroles are given in Table 1. Spectra were run with 20% solutions of the pyrroles in a $CHCl_3$–C_6F_6–HMDS[4] mixture (3:1:1) with proton noise decoupling. In addition, the normal ^{13}C spectrum of **8** (single resonance spectrum) and off-resonance spectra of **7** and **12** were determined to aid in the assignment and INDOR ^{13}C spectra were measured from the C–H satellites in the proton n.m.r. spectra of **10** and **15**.

The aromatic absorptions of the eight alkyl pyrroles (**2–9**) all fell in the region δ_C 105–135 p.p.m. Assignments were made, in part, by assuming that a free α-carbon should absorb downfield of a free β-carbon, and that a substituted α-carbon would be more deshielded than a substituted β-carbon. Table 2 shows the effect at each aromatic carbon of alkyl substitution at the *N*-, 2-, and 3- positions: the change in chemical shift at each of the four aromatic carbons is approximately additive, as has been noted by Grant and co-workers (13) for 2-methyl and 2,5-dimethyl five-membered heterocycles.

The strong deshielding (~10 p.p.m.) of the directly methylated carbon (Table 2) is frequently observed in ^{13}C n.m.r. (16). *N*-Methylation reduces the magnitude of this effect to about 7 p.p.m. in pyrrole. Upon α-alkylation, the *ortho* β-carbon is shielded by about 2 p.p.m.: similarly on β-alkylation, the *ortho* α-position

[4]Hexamethyldisilane (HMDS) (b.p. 113°) was chosen as the internal reference as TMS (b.p. 27°) evaporated too easily from the sample under noise decoupling conditions; $\delta_{THS} = \delta_{HMDS} - 2.34$ p.p.m.

[a]Run as 20% solutions in chloroform–HMDS–C_6F_6 (3:1:1) mixture except **13**, **14**, which were run as 5% solutions, and **15**, **16**, which were run as saturated solutions in DMSO with external C_6F_6.
[b]Chemical shifts downfield from HMDS.[4] Samples run in DMSO; chemical shifts were converted to HMDS scale using $\delta_{HMDS} - \delta_{DMSO} = 43.85$ p.p.m.

is shielded by 2.5–4.5 p.p.m. (while the *ortho* β-carbon is deshielded). This shielding of the *ortho* position has been noted by Roberts and co-workers (14) and by Grant and co-workers (13) for the α-methylation of furan and thiophene, and in the case of the methyl indoles (17). However, while 2-alkylation of pyridines results in a small (1 p.p.m.) shielding of the *ortho* 3-carbon, 3- and 4-alkylation shows a small deshielding of the carbons *ortho* to the site of alkylation (18). This is also the case for substituted benzenes as Lauterbur has reported a 0.2–1.0 p.p.m. deshielding *ortho* to the site of methylation (19).

In both pyridines and benzenes, alkylation generally results in the shielding (2.5–3.0 p.p.m.) of the aromatic carbon *para* to the site of alkylation: in pyrroles there is a 1.0–2.0 p.p.m. shielding of the 5-carbon on alkylation of the 2-carbon.

Methyl groups bonded directly to the pyrrole nucleus absorb in the range δ_C 13–16 p.p.m. This shows a substantial shielding of the methyl groups when compared to methyl groups bonded to benzenes (δ_C 23–25 p.p.m.) (19) and pyridines (δ_C 21–28 p.p.m.) (18, 20) and is in the same region as methyls bonded to the hetero-ring of indole (17).

On the basis of the data available for compounds **8** and **9**, the β and γ effects of pyrrole substitution on an alkane chain fit the pattern observed for most other polar functionalities (16): a deshielding of the β-carbon by 8–10 p.p.m. and a smaller shielding of the γ-carbon by 2–4 p.p.m.

Pyrroles **10–14** all carry carbonyl substituents. The ^{13}C chemical shifts of the three unsubstituted aromatic carbons of pyrrole 2-carboxaldehyde (**10**) were measured by INDOR spectroscopy in order to provide an unam-

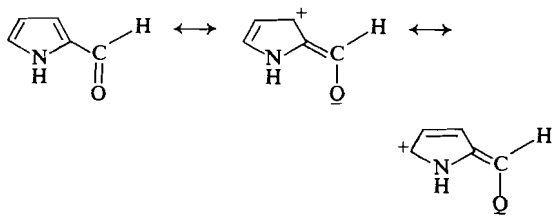
[a]The position of alkylation is indicated in italics. Thus 2.4-diMe-*3*-Et-pyrrole indicates that the data given on that line refers to the effect of placing an ethyl group on the 3-position of 2,4-dimethylpyrrole.
[b]Positive shifts are upfield (shielded) and negative shifts are downfield (deshielded).
[c]For example, 2,4-dimethylpyrrole.

biguous assignment of the Fourier transform spectrum of this key compound.

Compared to free pyrrole, the aldehyde exhibits strong deshielding of carbons 3 and 5 of −14.2 and −9.5 p.p.m., respectively, while carbon 4 is deshielded by only −3.3 p.p.m. A similar phenomenon has been noted in the proton n.m.r. spectra of pyrroles α-substituted with strong electron withdrawing groups (21). It reflects the reduction of π-electron density at positions 3 and 5:



When pyrrole is substituted with a 2-carboxaldehyde group, the deshielding of each of the aromatic ring carbons is substantially greater than the aromatic ring deshielding observed on formation of benzaldehyde (22) or the pyridine carboxaldehydes (20*a*, *b*).

By comparison, 2-carbmethoxypyrrole (**12**) shows a very much smaller deshielding of the 3 and 5 carbons, and an especially small deshielding (only 5 p.p.m. compared to free pyrrole) of the substituted 2-carbon.

The ^{13}C spectrum of 5-methyl-2-carbethoxypyrrole (**13**) includes two substituted carbons at δ_C 124.0 and 136.6 p.p.m. Comparison with the observed α-carbon absorptions in 2-carbmethoxypyrrole (**12**) (δ_C 125.3 and 126.3 p.p.m.) lead to the assignment of the lowest field peak (δ_C 136.6 p.p.m.) to the 5-carbon. The changes in chemical shift between **12** and **13** then fit the established pattern for the effects of 2-alkylation: the substituted carbon is deshielded by 10.7 p.p.m. and the *ortho* β-carbon is shielded by 1.7 p.p.m. (Table 2). Thus, the most deshielded substituted carbon is not the carbon carrying the carbethoxy group but the carbon carrying the methyl group.

Introduction of the 3-methoxyl group into **13** to give **14** radically alters the ^{13}C spectrum. The new low field substituted aromatic carbon (δ_C 156.7 p.p.m.) is assigned to carbon 3 by analogy with the strongly deshielded aromatic carbon of anisole (δ_C 163.4 p.p.m.) (22, 23). The downfield shift reflecting the inductive effect of the oxygen. The one unsubstituted aromatic carbon in **14** (carbon 4) absorbs at δ_C 97.95 p.p.m. suggesting strong mesomeric electron donation from the oxygen lone pair. An *ortho* shielding of similar magnitude (about 14 p.p.m.) is seen when anisole is compared to benzene (22, 23). On this basis, the other *ortho* position, the 2-carbon, was assigned to the high field substituted carbon absorption at δ_C 108.4 p.p.m.: this represents a shielding of about 16 p.p.m. over the analogous position in **13**. The remaining substituted carbon, at position 5, is only very slightly shielded by the methoxyl substituent (1.5 p.p.m.).

The carbonyl groups of pyrrole-2-carboxaldehyde (**10**) and its 2-methyl derivative, **11**, show the same shielding effect noted for alkyl substituents (*vida supra*) being 10 p.p.m. to higher field than carbonyls of benzaldehyde (22) or pyridine-2-carboxaldehyde (20*b*). The carbonyl resonance signals of the two carbalkoxy pyrroles **12** and **13** are found 2–5 p.p.m. to higher field than the corresponding benzoate carbonyl (24). Aromatic substitution with a strong electron releasing group (OMe in **14**) has no effect on the carbonyl absorption, in keeping with the results of Stothers and Lauterbur who found a similar effect in *para*-substituted benzaldehydes, acetophenones, and benzoates (25).

Bipyrroles

The ^{13}C n.m.r. spectrum of bipyrrole (**15**) in DMSO showed four absorptions, the lowest field signal (δ_C 129.4 p.p.m.) being due to the substituted carbon. The free α-carbon absorbed at δ_C 120.2 p.p.m. One of the two β-carbons absorbed at relatively high field (δ_C 106.0 p.p.m.) and was assigned as carbon 3, since, from the above discussion, this carbon should be the most sensitive to any mesomeric electron donation by the neighboring α-substituent, a pyrrole ring. The other β-carbon (carbon 4) absorbed at δ_C 111.5 p.p.m.

The ^{13}C n.m.r. spectrum of the 3-methoxybipyrrolecarboxaldehyde **16** was also determined in DMSO. INDOR spectra were measured for carbons A3, A4, A5, and B4: in each case they coincided in the FT spectrum with those absorptions that showed Overhauser enhancements. The B4 position showed the same shift to high field observed in the model methoxy pyrrole **14**. By analogy with the 3-carbon in **14**, the low field absorption at δ_C 161.8 p.p.m. in **16** was assigned to B3.

Comparison of the chemical shifts measured for **10** and **12** indicates that conversion of a 2-carbalkoxy function to a 2-carboxaldehyde function results in a deshielding of the 2-carbon by some 10 p.p.m. and of the 3-carbon by some 7 p.p.m. The chemical shifts observed in bipyrrole (**15**) suggest that the pyrrole ring is similar to the methyl group in its substituent effect on the pyrrole ring, except that the β-carbon *ortho* to the site of substitution is somewhat more strongly shielded. Assuming that an approximate additivity of chemical shifts exists between the pairs of pyrroles **10,12** and **14,16**, then the B2 carbon of **16** is predicted to absorb around δ_C 118 p.p.m., and the B5 carbon of **16** at around δ_C 135 p.p.m. On this basis, the substituted absorption at δ_C 120.9 p.p.m. was assigned to B2 and the substituted absorption at δ_C 126.8 p.p.m. was assigned to A2: this carbon is thus some 2.6 p.p.m. more shielded in **16** than in bipyrrole (**15**).

Long-range ^{13}C–^{1}H Coupling

Both long-range cross-ring and ring to side-chain couplings proved to be of importance in the assignment of the ^{13}C spectra of the prodigiosins. Generally, the limiting resolution (1.2 Hz) of the single resonance spectra determined using an 8K data set proved insufficient to resolve the complex multiplets in the single resonance spectra of the prodigiosins and pyrroles, and hence, half-band widths were measured. While cross-ring coupling has been reported for pyrrole (**1**) and 2,5-dimethylpyrrole (**4**) by Weigert and Roberts (14), no data were reported for side-chain to ring ^{13}C–^{1}H coupling. Therefore, we studied 1,5-dideuterio-2,4-dimethyl-3-ethylpyrrole (**8**-d_2), prepared by acid catalyzed exchange of **8** with D_2O–DCl. Single resonance and proton noise decoupled spectra were determined and the half-band widths are given in Table 3.

The substantial increase in the half-band widths ($\Delta_{1/2}$) of each aromatic carbon upon removal of proton decoupling is firm proof of side-chain to ring coupling in **8**-d_2. The ^{13}C peaks of carbons 2 and 3 of **8**-d_2 were well-defined sextets with splittings of 5.4 Hz. Carbon 4, on the other hand showed extra splittings which we interpret as three, or more, bond coupling of carbon 4 with the protons of the side chains. In addition, carbon 5, which is deuterated and shows an isotope shift of 0.34 ± 0.05 p.p.m., showed substantial broadening in the single resonance spectrum, while $\Delta_{1/2}$ in the proton noise decoupled spectrum was identical with that of the tertiary carbons. This indicates no detectable long-range deuterium coupling, and a coupling of carbon 5 with the alkyl substituent protons three or more bonds away.

Prodigiosins

Prodigiosin hydrochloride (**18**)

Our original report on the biosynthetic incorporation of ^{13}C-enriched acetate into prodigiosin outlined the assignment of the

^{13}C n.m.r. spectrum of prodigiosin hydrochloride (**18**) (2). The ^{13}C assignments of **18** are shown in Table 4 referenced to external HMDS.[4] The proton noise-decoupled spectrum of **18** showed seven resonance signals upfield of $CHCl_3$ (δ_C 80.0 p.p.m.). The methoxyl carbon was assigned to the peak at δ_C 61.3 p.p.m. on the basis of chemical shift data. The C2 and 5′ methyls were assigned to the absorptions at δ_C 14.8 and 16.5 p.p.m., respectively, on the basis of INDOR measurements. An off-resonance experiment with the cw decoupling frequency placed at the center of the methylene region delineated carbons 2′, 3′ and 4′, whose ^{13}C absorptions were sharp singlets, from 1′, whose absorption at δ_C 27.8 p.p.m. was a broad triplet, ($\Delta_{1/2}$ 8 Hz). Of the three carbons 2′, 3′, and 4′, carbon 4′ was assigned to the resonance signal at δ_C 25.0 p.p.m. by analogy with the known range of ^{13}C shifts for β-

[a]Chemical shifts are given relative to HMDS[4] and are calculated from the solvent peak $CHCl_3$ (δ_C 80.0 p.p.m.). Since chloroform does show solvent effects of several tenths of a part per million, all data has been rounded off to the nearest 0.1 p.p.m.
[b]These carbons are reversed from original assignment (2).
[c]These carbons are reversed from original assignment (2).

carbons of straight chain alkanes (δ_C 25.0–26.0 p.p.m.) (1, 26). Carbons 2' and 3' were resolved by studying the ^{13}C n.m.r. spectrum of a sample of **18** biosynthetically enriched with ^{13}C from [1-^{13}C]-acetate (2). Of the alkyl carbons, 4' and *either* 2' or 3' were enriched with ~10% ^{13}C. Hence, the absence of any detectable ^{13}C–^{13}C coupling in the spectrum assigned the absorption at δ_C 32.2 p.p.m. to 2', and the absorption at δ_C 34.0 p.p.m. to 3'.

The 13 aromatic carbons of **18** have only 12 absorptions downfield of chloroform because of the overlap of two absorptions at δ_C 130.8 p.p.m. INDOR measurements assigned the following secondary carbons: A3 at δ_C 119.8; A4 at δ_C 114.3; A5 at δ_C 129.0; B4 at δ_C 95.5; C4 at δ_C 130.8; and 1'' at δ_C 118.2 p.p.m. In the off-resonance experiment, the absorption at δ_C 130.8 p.p.m. became a triplet, indicating the overlap of the absorption of a substituted aromatic carbon with the absorption of the unsubstituted aromatic carbon, C4.

Carbon B3, substituted with —OMe, was assigned the lowest field resonance (δ_C 168.3 p.p.m.) by analogy with the methoxypyrroles **14** and **16**.

A sample of **18** biosynthetically enriched with [1-^{13}C]-acetate gave a spectrum indicating that three aromatic substituted carbons, including B3 were enriched (2). Compound **18** was degraded to **9** (6) which showed enrichment at carbons 3 and 5. Thus, the C3,C5 pair was assigned to the peaks at δ_C 130.8 and 127.6 p.p.m.

Perdeuteration of **18** gave a compound in which only A4 and 1'' of the aromatic carbons remained protonated. A single resonance spectrum of perdeuterio-**18** assigned C3 at δ_C 130.8 p.p.m. (peak broadened due to long range coupling with the alkyl side chain; $\Delta_{1/2}$ = 18.5 Hz), and C5 to δ_C 127.6 p.p.m. (sharp singlet; $\Delta_{1/2}$ = 5 Hz). Carbon A2 was assigned to the narrow doublet at δ_C 124.7 p.p.m. (J = 8 Hz; cross-ring coupling with A4-*H*), while C2 could be assigned to the broad peak at δ_C 148.8 p.p.m. ($\Delta_{1/2}$ = 11.5 Hz, coupling with C2-*Me*). Carbons B2 and B5 both ap-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

peared as sharp singlets ($\Delta_{1/2}$ = 4 Hz), while B3 was broadened ($\Delta_{1/2}$ = 11.5 Hz) by long-range coupling with the methoxyl protons.

Proof of these assignments was obtained in a study of **18** biosynthetically enriched with ^{13}C at 1″ and B2 (23% ^{13}C) (27). An AB pattern (J = 75 Hz) was found for 1″ and B2. As well, the natural abundance signal for B4 showed a coupling of 68 Hz with B5 when the B5 carbon was enriched (28% ^{13}C) (27).

^{13}C Fourier transform n.m.r. studies of samples of **18** biosynthetically enriched with ^{13}C from [1-^{13}C]- and [2-^{13}C]-acetate allowed the first details of the biosynthesis of this pigment to be elucidated (2). Spectra of both samples showed primary incorporation of acetate at five sites in the molecule. Feeding [1-^{13}C]-acetate led to the enrichment of aromatic carbons B3, C3, and C5, and alkyl carbons 2′ and 4′, while feeding [2-^{13}C]-acetate led to the enrichment of two aromatic carbons, B4 and C4, and three carbons in the amyl side chain, 1′, 3′, and 5′ (Fig. 1). Thus, we showed the C ring is constituted from an eight carbon polyacetate chain, while ring B includes one further acetate unit, at B3–B4. No primary incorporation of acetate was found in ring A. Our further studies, using ^{13}C enriched substrates, have elucidated the origin of ring A as proline. As well, the remaining carbons of **18** were shown to be constituted from serine, glycine, and methionine (27). Results of the study on the biosynthetic origin of undecyl **19** and metacyclo **21** have also been completed and form the substance of a separate communication (28).

Prodigiosin (**17**)

The ^{13}C spectrum of the free base of prodigiosin (**17**) was assigned by a very similar approach. The seven alkyl carbons were assigned by analogy with the alkyl carbons of **18**. While C2-*Me* is 2 p.p.m. more shielded in **17** than **18** the remaining alkyl absorptions in **17** are all within 0.5 p.p.m. of the equivalent absorptions of **18**.

INDOR measurements on **17** specifically assigned 1″ (δ_C 118.7 p.p.m.), C4 (δ_C 123.8 p.p.m.), and B4 (δ_C 98.2 p.p.m.), as well as the pair of carbons A3 and A5, whose ^{13}C–^{1}H satellites overlapped. A3 was assigned to the higher field absorption (δ_C 115.3 p.p.m.) and A5 to the lower field absorption (δ_C 125.4 p.p.m.) as the pyrrole α carbon is always found to low field of the pyrrole β carbon (Table 1). The residual couplings in an off-resonance spectrum supported this assignment (A5, J_r = 44 Hz, J = 187.5 Hz; A3, J_r = 41.5 Hz, J = 167.5 Hz). The remaining secondary aromatic carbon, A4, was then assigned to δ_C 112.6 p.p.m.

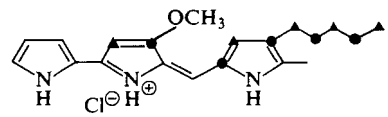

FIG. 1. Pattern of biosynthetic incorporation of ^{13}C label into prodigiosin.

The seven substituted carbons were assigned by exactly the same procedure of perdeuteration and single resonance spectroscopy used to make their assignments in the hydrochloride salt, **18**. The long range couplings measured in **17** were, within experimental error, identical to those measured for **18**.

Undecylprodigiosin Free Base (**19**)

The ^{13}C n.m.r. spectrum of **19**, is shown in Fig. 2. The assigned chemical shifts are listed in Table 4.

Of the alkyl absorptions, 11′ (δ_C 16.8 p.p.m.), 10′ (δ_C 25.4 p.p.m.) and 9′ (δ_C 34.7 p.p.m.) were assigned by analogy with the chemical shifts of the equivalent carbons in *n*-undecane (carbons 11 δ_C 16.1 p.p.m., 10 δ_C 25.0 p.p.m., 9 δ_C 34.3 p.p.m. (26)). 1′ was assigned to the absorption at δ_C 30.1 p.p.m. by comparison with the similarly shielded methylenes of **17** (1′ in **17**, δ_C 28.3 p.p.m.) and the model 2-*n*-undecylpyrrole (δ_C 30.3 p.p.m.). The remaining alkyl methylenes (2′–8′) all absorb in the intense peaks at δ_C 32.4 and δ_C 32.1 p.p.m. The methoxyl carbon is found at δ_C 61.0 p.p.m. (compared with δ_C 61.0 and 61.3 p.p.m. in **17** and **18**, respectively).

Quantitative measurements of the peak intensities in a spectrum of **19**, accomplished using a delay between pulses (ISKIP = 2 s (5), showed that the absorption at δ_C 131.2 p.p.m. was due to two carbons. An off-resonance spectrum showed that the seven protonated aromatic carbons all absorbed upfield of the six substituted aromatic carbons (insert in Fig. 2).

By analogy with previous assignments (pro-

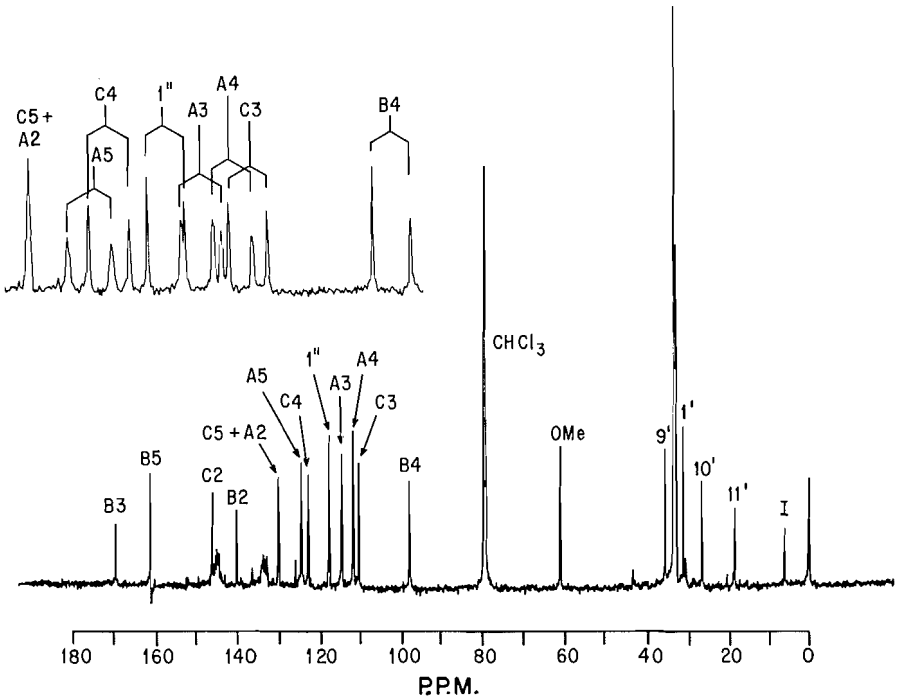

FIG. 2. Proton noise decoupled ^{13}C Fourier transform spectrum of 1 *M* undecylprodigiosin base (**19**) in $CHCl_3$ using an external C_6F_6 lock. Insert: off-resonance spectrum of portion 95.8–133.4 p.p.m. downfield from HMDS.

digiosin **17**, prodigiosin hydrochloride **18**, and two model pyrroles **14** and **15**), B3 (inductively deshielded by the methoxyl substituent) was assigned to the lowest field absorption (δ_C 171.9 p.p.m.), and B4 (mesomerically shielded by the methoxyl group) to the highest field absorption (δ_C 98.4 p.p.m.); B3 and B4 in **19** both absorb within 0.2 p.p.m. of B3 and B4 in **17**. As expected, the change in alkyl substitution in ring C does not affect the chemical shifts in ring B significantly.

Comparison of ring C in **19** with ring C in **17** shows that the gross structural differences are the removal of the *n*-amyl from C3, and extension of the methyl group at C2 into a polymethylene chain. Thus, C3 changes by removal of α (−10 p.p.m., Table 2), β (−9 p.p.m. (26)), and γ (+3 p.p.m. (1, 26))[5] substituent shifts. C2 undergoes a β and γ substituent shift due to extension of C2—CH_3 to C2—$(CH_2)_{10}CH_3$, plus removal of a C3-substituent shift, Table 2. From Table 2, the remote substituent effects are small and this is common to other alkylated aromatics such as benzenes, (19, 24), pyridines (18, 20), and indoles (17). The C-ring chemical shifts fit the predicted shifts closely in both sign and magnitude (number in parenthesis is chemical shift **17** → **19**): C2 δ_C 147.4 p.p.m. (−7.8 p.p.m.); C3 δ_C 111.4 p.p.m. (+15.1 p.p.m.); C4 δ_C 124.0 p.p.m. (+0.2 p.p.m.); C5 δ_C 131.2 p.p.m. (−1.1 p.p.m.).

Perdeuteration of **19** resulted in exchange of all protons except A4-*H*, 1″-*H*, and C4-*H*, thus assigning A4, 1″, and C4. A single resonance experiment confirmed these assignments yielding the following ^{13}C–^{1}H coupling constants: J_{A4-H} = 172.8 Hz, $J_{1''-H}$ = 154.8 Hz and J_{C4-H} = 171.0 Hz. In the single resonance spectrum of perdeuterio-**19**, B2 and B5 are sharp singlets, B3 a broadened singlet ($\Delta_{1/2}$ 9 Hz) due to long-range coupling to —O*C*H_3 and C2 a broad peak ($\Delta_{1/2}$ 19 Hz) due to cross-ring coupling and long-range coupling to the alkyl protons. A2 and C5 remained overlapping doublets ($J \sim 7$ Hz).

Undecylprodigiosin Hydrochloride (**20**)

The hydrochloride was assigned similarly by chemical shift, perdeuteration, and off-resonance techniques. By taking chemical shift

[5]Alkyl carbons are designated: ω, terminal; ω − 1, penultimate; etc.

For personal use only.

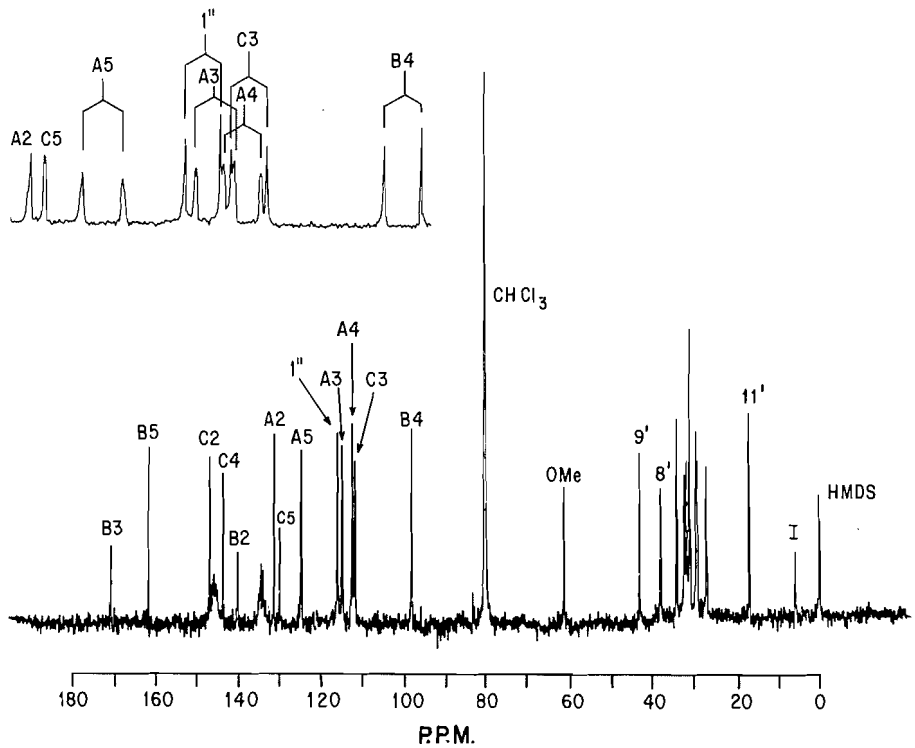

FIG. 3. Proton noise decoupled ^{13}C Fourier transform spectrum of 1 *M* metacycloprodigiosin base (**21**) in $CHCl_3$ (external C_6F_6 lock). Insert: off-resonance spectrum of portion 95.8–133.4 p.p.m. downfield for HMDS.

differences of specific carbons in **18** compared with **17**, the shift differences for the **20**,**19** pair are predicted to within ≤ 0.7 p.p.m. with the exception of C2 (1.3 p.p.m.) (See Table 4).

As found with **18**, B2 undergoes a large upfield shift of 17.3 p.p.m. upon salt formation and was distinguished from A2 (Fig. 4) since the latter is a doublet ($J \sim 7$ Hz) in the single resonance spectrum of perdeuterio-**20**. An interesting case is the shift crossover (Fig. 4) of A5 and C4 on going from base (**19**) to hydrochloride (**20**). Since both A2 and C5 both are identical doublets in the single resonance spectrum of perdeuterio-**20**, they were distinguished by secondary incorporation of ^{13}C when [2-^{13}C]-acetate was used as precursor (28). Such a secondary pathway of ^{13}C incorporation at A2 is consistent with the known biological pathway of acetate to proline.

Metacycloprodigiosin Free Base (**21**)

All 13 aromatic absorptions are resolved in the ^{13}C n.m.r. spectrum of **21**, as are 9 of the 11 carbons of the cyclic alkane chain (Fig. 3). The resolution of alkane absorptions provides a striking contrast with the lack of resolution of the alkane carbons in **19** (Fig. 2).

The alkyl absorption at δ_C 15.3 p.p.m. can be assigned to 11′ as the only alkyl methyl in **21**. Compared to terminal methyl groups of γ-branched alkanes (29), 11′ is somewhat deshielded (the terminal methyl of 3-ethylheptane absorbs at δ_C 12.9 p.p.m.). The low field alkyl absorption at δ_C 42.1 p.p.m. can be assigned to 9′ since it becomes a doublet in off-resonance spectra and the shift is in the range typical for tertiary alkane carbons (the 3-carbon of 3-ethylheptane absorbs at δ_C 43.0 p.p.m. (26)). Similarly, carbons at the $\omega - 3$ position[5] of alkanes which are adjacent to a tertiary center absorb at δ_C 35–39 p.p.m. (26), hence, the resonance at 36.9 p.p.m. was assigned to 8′.

A detailed assignment of the remaining alkyl absorptions is not possible at present. Several factors may help explain the resolution of the cycloalkane carbons. There will be steric (1) and linear electric field (1) interactions between the ethyl sidechain and neighboring

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

carbons. A study of space filling models of **21** shows that the cycloalkane chain is somewhat strained and inflexible, hence, cross-ring effects may be important. Finally, steric and electric field effects (29) due to the unsaturated ring will contribute to the polymethylene carbon shifts.

An interesting effect is seen for the bridgehead carbon, 1″. The 1″ shift for metacyclo compounds is, on the average, 2.6 p.p.m. to higher field than for prodigiosin and undecyl compounds (Table 4). Such an upfield shift can be attributed to γ interaction between 1″ and 9′. The results indicate the stereochemistry about the 1″—B2 bond and the configuration of the 9′-ethyl are substantially as indicated in the structural formula for **21**, shown above.

The six unsubstituted aromatic carbons in **21** were distinguished in an off-resonance spectrum (insert in Fig. 3); as in **17** and **19**, they all absorb upfield of the seven substituted aromatic carbons. B3 (δ_C 171.7 p.p.m.) and B4 (δ_C 98.1 p.p.m.) were assigned as the most deshielded and most shielded aromatic absorptions; they both absorb within 0.2 p.p.m. of the equivalent carbons of **17**. Of the remaining carbons in rings A and B, B5, B2 and A5 can be assigned unambiguously; each absorbs within 0.4 p.p.m. of the equivalent carbon in **17** (see Fig. 4).

The absorption at δ_C 116.1 p.p.m. gave a residual splitting of 71 Hz in the off-resonance spectrum, while the absorption at δ_C 115.0 p.p.m. had a residual splitting of 78 Hz. $J_{^{13}C-^{1}H}$ for 1″, measured in the proton spectrum of **21**, is 156 Hz. Because the proton absorptions for A3-*H* and A5-*H* overlap, $J_{^{13}C-^{1}H}$ cannot be measured exactly for either carbon, but it is greater than 174 Hz and less than 184 Hz. Therefore, since the absorption at δ_C 116.1 p.p.m. shows the smaller residual splitting, it was assigned to 1″, and A3 was assigned to the absorption at δ_C 115.0 p.p.m.

Compound **21** can be regarded as a derivative of **19** in which the *n*-undecyl chain of **19** has been cyclized onto C4. The chief consequence of this should be a very strong deshielding of C4 (since the substituting group is α-branched), C5 should be slightly shielded, and C2 and C3 should be relatively little affected (see Table 2). On this basis, unambiguous assignments can be made for C2 at δ_C 147.2 p.p.m., and C4 at δ_C 144.0 p.p.m. C5 is assigned to δ_C 130.2 p.p.m. (1.0 p.p.m. shielded from C5 in **19**); and A2 can be assigned to δ_C 131.6 p.p.m., which is very similar to the position of absorption of A2 in **19** (δ_C 131.2 p.p.m.) and in **17** (δ_C 131.4 p.p.m.).

Perdeuteration of **21** gave a triprotonated compound (1″-*H*, B4-*H*, and C3-*H*) thus obviating any difficulty due to small shift differences between A4 (112.6 p.p.m.) and C3 (111.9 p.p.m.). The A2-C5 pair (Fig. 4) were distinguished using the bioenrichment scheme outlined above for **20**.

Metacycloprodigiosin Hydrochloride (**22**)

Assignments for **22** were made identical to the methods used for **20** and are listed in Table 4. Of the carbons possible of misassignment, Fig. 4, a clear distinction of A5 from C5 was made possible when a sample of **22** was enriched using [1-^{13}C]-acetate. Sharp singlets were observed for C2, C4, and A5, thus C5 δ_C = 128.7 p.p.m. while A5 δ_C = 129.4 p.p.m. Since the bridgehead, 1″, always has the smallest C–H coupling, it was assigned δ_C 116.0 p.p.m. ($J_{1''-H}$ = 155 Hz) and A4 was therefore assigned δ_C 114.4 p.p.m. (J_{A4-H} = 175.5 Hz).

From Fig. 4 the striking shift continuity in the prodigiosin series is apparent, first, in the comparison of free base – hydrochloride pairs and, second, in the comparisons of series of free bases or series of hydrochlorides. For instance, in the free base series **17**, **19**, and **21** the ring A carbons all absorb within ±0.4 p.p.m. of **17**. Similarly, the ring B carbons absorb within ±0.3 p.p.m. of **17** except for B5 (±0.8 p.p.m.).

Both *in vivo*, and *in vitro*, prodigiosin (**17**) is formed by the condensation of 2-methyl-3-amylpyrrole (**8**) and the 3-methoxybipyrrole-carboxaldehyde (**15**) (30). If the ^{13}C chemical shifts of the aromatic carbons of **8** and **15** are compared with the equivalent carbons of prodigiosin free base (**17**), it is clear that formation of the bipyrropyrromethane system results in a deshielding of every aromatic carbon. The deshielding is most marked at carbons B2 (−21.9 p.p.m.) and B5 (−28.1 p.p.m.).

Protonation of Prodigiosins

Because of the wide dispersion of chemical shifts observed, ^{13}C n.m.r. provides an effective means of determining sites of protonation. In Fig. 4, the ^{13}C chemical shifts of the free base

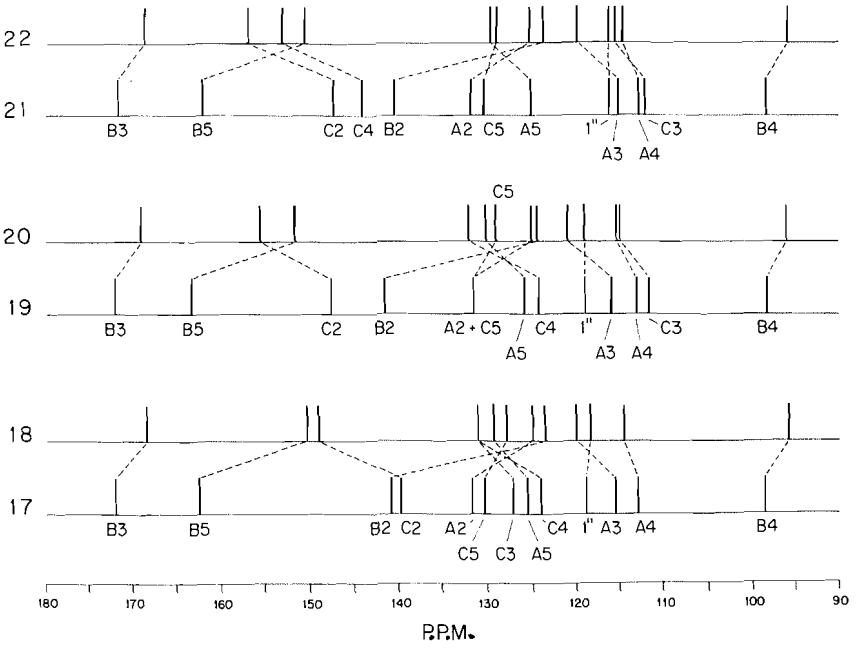

FIG. 4. Comparison of aromatic ^{13}C chemical shifts for the prodigiosin series.

of prodigiosins **17**, **19**, and **21** are compared with the chemical shifts of prodigiosin hydrochlorides **18**, **20**, and **22**. All of the carbons in ring B shift sharply to higher field, while the carbons of ring A (except A2) and ring C (except C5) shift downfield upon protonation.

Pugmire and Grant have reported that carbons α to the nitrogen in various five-membered nitrogen heterocycles are strongly *shielded* on protonation of the nitrogen, by about 9.0 p.p.m. (31). Explanations of this phenomenon differ; Grant has proposed a change in the N—C bond order, while Adam *et al.* have considered changes in the average excitation energy (32). Whatever the explanation, the strong shielding of carbons B2 (+17.4 p.p.m.) and B5 (+12.2 p.p.m.) suggests that the additional positive charge is highly localized in the B ring. The ^{13}C chemical shifts of the A and C rings of the hydrochlorides support this contention.

The Structure of the Dimethylthallium Ion Oriented in a Lyotropic Nematic Phase

YUNKO LEE AND LEONARD W. REEVES

Department of Chemistry, University of Waterloo, Waterloo, Ontario N2L 3G1

Received August 30, 1974

YUNKO LEE and LEONARD W. REEVES. Can. J. Chem. **53**, 161 (1975).

The proton magnetic resonance spectra of dimethylthallium ion has been studied in both anionic and cationic detergent nematic phases. The spectra were analyzed to derive the values of inter- and intramethyl proton–proton dipolar coupling and the intermethyl scalar coupling constants. The degree of orientation of the dimethylthallium cation is much higher in the anionic nematic phase than in the cationic phase. It is proposed that electrostatic interactions play a significant role in the orientation of complex ions in ionic detergent nematic phases.

YUNKO LEE et LEONARD W. REEVES. Can. J. Chem. **53**, 161 (1975).

On a étudié les spectres de résonance magnétique du proton de l'ion diméthylthallium dans des phases nématiques de détergents anionique et cationique. On a analysé les spectres pour déterminer les valeurs des couplages dipolaires proton–proton inter- et intraméthyle et les constantes de couplage scalaire interméthyle. Le degré d'orientation du cation diméthylthallium est beaucoup plus élevé dans la phase nématique anionique que dans la phase cationique. On suggère que les interactions électrostatiques jouent un rôle important dans l'orientation des ions complexes dans des phases nématiques de détergents ioniques. [Traduit par le journal]

Introduction

The techniques to determine relative nuclear positions in relatively small molecules by studying their nuclear magnetic resonance spectra in nematic solutions (1–3) have recently been extended to include structure determinations of complex ions (4, 5). This has been a valuable addition to existing techniques since otherwise only X-ray and neutron diffraction are available for the study of ions. The orientation of complex ions is achieved in lyotropic nematic phases based on detergent/water/alcohol/electrolyte systems. In the original communications a complex ion detergent, anionic or cationic whichever is appropriate for the sign of the charge on the complex ion to be determined, is synthesized and nematic phases prepared. The preparation of the complex ion detergents by several generalized methods have been described and structure studies of methylammonium, dimethylammonium, acetate, and dimethyltin have already been reported (6–9).

The present study is an extension of these methods to include orientation of complex ions without preparation of the complex ion detergent. In this study we shall show that nematic phases can be prepared by using simple monatomic ion salts of detergent acids but substituting a complex ion electrolyte for a simple electrolyte in the phase. Some sacrifice of signal is inevitable but we shall show that a complex cation can be oriented in both anionic and cationic detergent nematic phases. The present study of the structure of the dimethylthallium ion illustrates a departure in technique and reveals some new aspects of electrical double layer phenomena.

Experimental Section

The proton n.m.r. spectra of the oriented dimethylthallium ion in the lyotropic nematic phases were recorded on a HA-100 spectrometer at 30.6 °C. The HA-100 was operated in the locked mode. The position of the individual peak was obtained by bracketing with frequency difference markers from the lock signal.

Cesium decyl sulfate was prepared by neutralizing cesium carbonate with decyl sulfuric acid, which was prepared by passing sodium decyl sulfate through an acidified chromatographic column containing Dowex 50-H^+. Decylammonium tetrafluoroborate was prepared from the reaction of decylamine and fluoboric acid. Dimethylthallium nitrate was prepared by shaking an equivalent amount of silver nitrate in an aqueous suspension of dimethylthallium bromide. The insoluble silver bromide precipitate was filtered and the solution was concentrated and allowed to stand. Dimethylthallium nitrate was recrystallized from the ethanol–water solvent system and then dried in a desiccator under reduced pressure.

Several lyotropic nematic phases were prepared which were typically birefringent and oriented by the magnetic field used in the n.m.r. experiment. The compositions of typical phases are listed in Table 1.

Results and Discussion

The proton n.m.r. spectra of the dimethylthallium ion oriented in the anionic nematic phases of cesium decyl sulfate, *n*-decanol, and deuterium oxide were recorded. Figure 1 illustrates the typical spectrum of oriented dimethylthallium ion in the lyotropic anionic nematic phases. The spectrum consists of a 1:2:1 triplet and each of which has several components. The central peaks (*a*) of total relative intensity 2 are symmetrically arranged, while at +2058 Hz the upper resonance (*b*) of relative intensity 1 is not a symmetrical arrangement of transitions. The high field signals are always somewhat broader because they are more affected by an heterogeneity in the nematic order of the phase. The two abundant isotopes of thallium are ^{203}Tl (29.52%) and ^{205}Tl (70.48%), both with spin $\frac{1}{2}$. The gyromagnetic ratios of ^{203}Tl and ^{205}Tl differ by only 1% and the differences in dipolar and scalar couplings are too small to resolve peaks associated with each isotopic species. Only one set of triplets was observed and this infers that the value of $|D_{Tl-H} + J_{Tl-H}|$ is very small, *i.e.*, that D and J have opposite signs.

The scalar coupling J_{Tl-H} in isotropic solutions was reported to be −403 Hz and independent of concentration by Maher and Evans (10). Another Tl—H scalar coupling

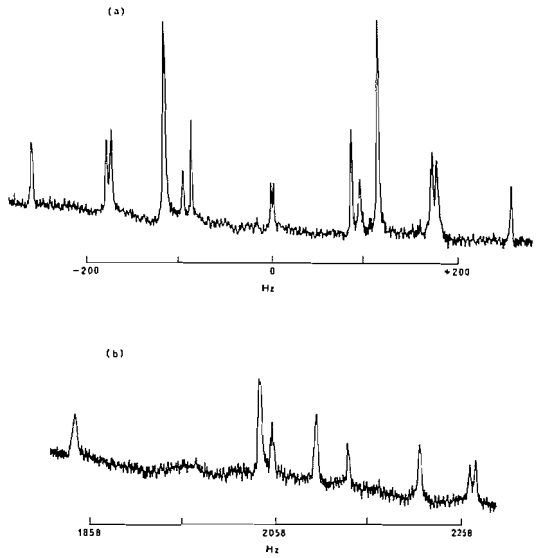

FIG. 1. Proton magnetic resonance spectrum of dimethylthallium ion oriented in a lyotropic phase of cesium decyl sulfate, *n*-decanol, and D_2O. (*a*) Central components of the triplet. (*b*) The high field component which is centered at about 2058 Hz with respect to the symmetric spectrum of the components.

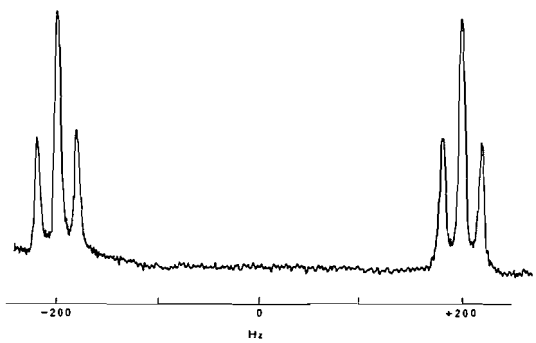

FIG. 2. Proton magnetic resonance spectrum of dimethylthallium ion oriented in a lyotropic nematic phase of decylammonium tetrafluoroborate and D_2O.

constant of 408 Hz was reported by Chan and Reeves from the ^{205}Tl magnetic resonance (11). The environment of an isotropic aqueous solution is sufficiently different from the aqueous part of the nematic phase to warrant investigation of medium effects on J (6). Isotropic concentrated micellar solutions were prepared by adding minimum amounts of deuterium oxide to the nematic phases. The mean value of J_{Tl-H} in the isotropic micellar solutions was found to be 403.4 ± 0.4 Hz.

The proton n.m.r. spectrum of the oriented dimethylthallium ion is determined by three parameters: The inter- and intramethyl proton–proton dipolar couplings, D_{12} and D_{11}, and the intermethyl scalar coupling J_{12}. These parameters were obtained from the analysis of the spectrum by using a modified UEA computer program (12) with iterative fitting to minimum error in the peak positions. The derived values and the compositions of the nematic phases are tabulated in Table 1.

Several cationic lyotropic nematic phases with about 3 to 4.5% by weight dissolved dimethylthallium nitrate were made from decylammonium tetrafluoroborate and deuterium oxide. The proton n.m.r. spectra of the oriented dimethylthallium ion were taken and Fig. 2 shows a typical spectrum obtained in the cationic nematic phase. In contrast to those obtained in an anionic phase, the proton spectrum of the dimethylthallium ion oriented in the cationic phase shows two sets of well separated triplets. However no fine structure could be resolved for the individual components of the triplet. This is due to the very small intermethyl proton dipolar coupling and the slight difference in ^{203}Tl and ^{205}Tl proton coupling. It is assumed that the dimethylthallium ion has the same structure and geometric parameters in both the anionic and cationic phases. The intermethyl proton–proton dipolar coupling constant D_{12} of the dimethylthallium ion was calculated and kept invariant in the spectrum analysis. Only these transitions near the center of the peaks were selected in the iterative fitting process. The dipolar and scalar coupling constants were also listed in Table 1. The spectral analysis indicates that the enhanced line width obtained derives from the number of closely spaced transitions arising from intermethyl proton–proton dipole–dipole couplings.

The dimethylthallium ion is known to be linear (13) and Fig. 3 depicts the geometric parameters necessary for discussion. Assuming that the methyl groups rotate freely and independently, the ratio of D_{12} to D_{11} is given as (14)

$$[1]\quad \frac{D_{12}}{D_{11}} = \frac{-3\sqrt{3}}{\pi} \times \int_0^{2\pi} \frac{[(\beta - 1) + \cos\phi]}{[(\beta + 2) - 2\cos\phi]^{5/2}}\, d\phi$$

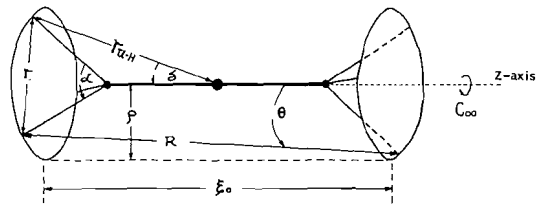

FIG. 3. Geometric parameters appropriate for a discussion of the structure of the dimethylthallium ion. On the n.m.r. time scale the C—Tl—C bond direction is a C_∞ axis, denoted as the z axis. The methyl protons rotate freely on two circles displaced a distance ξ_0. The intramethyl proton–proton distance is r. The instantaneous value of the intermethyl proton–proton distance is designated as R; this axis makes an angle θ with the z axis. ρ is the radius of the two circles swept out by the rotating methyl protons. r_{Tl-H} is the thallium–proton distance and this vector makes an angle δ with the z axis. The C—H—C angles are given the symbol α.

where φ is the relative rotational angle between the two methyl groups and $\beta = (3\xi_0^2/r^2) = (\xi_0^2/\rho^2)$ such that ρ is the distance from the methyl proton to the C_∞ axis of symmetry and ξ_0 is the separation between the two parallel planes containing the three protons of the same methyl groups. The value of β was obtained by numerical computation of the integral in eq. 1. For free rotation the value $\beta = 21.28 \pm 0.05$ was obtained from the experimental values of D_{12} and D_{11}. If we now assume that $\rho = 1.034$ Å (from a tetrahedral carbon and a C—H bond distance of 1.097 Å) the values of other geometric parameters can be evaluated and are listed in Table 2.

The structure of dimethylmercury in a thermotropic solution (15) and that of dimethyltin in a lyotropic nematic phase (6) have been studied. With the same reasonable assumptions

TABLE 2. The structural parameters of the dimethylthallium ion with freely rotating methyl group

Parameter	Value
D_{12}/D_{11}	-0.0822 ± 0.0002
β	21.28 ± 0.05
ρ	1.034 ± 0.005 Å
ξ_0	4.77 ± 0.03 Å
$\sqrt{\langle R^2 \rangle}$	4.88 ± 0.03 Å
θ	$12.23 \pm 0.2°$
δ	$23.44 \pm 0.2°$
r_{Tl-H}	2.019 ± 0.010 Å

TABLE 3. The proton dipolar coupling and degree of orientation of methanol molecule in the nematic phases

Composition, wt. %								
Decylammonium tetrafluoroborate	Cesium decyl sulfate	D_2O	*n*-Decanol	NH_4BF_4	CH_3OH	D_{HH} (Hz)	S_{C_3}	$\Delta\nu_D$ of D_2 (Hz)
48.05		47.54	3.04	0	1.38	177.1	8.53×10^{-3}	307
47.41		41.58	4.59	3.63	2.79	180.3	8.68×10^{-3}	286
45.56		48.85	2.19	1.36	2.02	148.0	7.13×10^{-3}	235
	46.38	47.91	4.42		1.29	150.3	7.24×10^{-3}	341

of linear species and free rotation of the methyl groups, the metal–carbon distances were calculated to be 2.052 Å for r_{Hg-C} and 2.015 Å for r_{Sn-C}. The present calculated value of 2.019 Å for the thallium–carbon distance falls within the same range.

In the linear skeleton of the dimethylthallium ion, the thallium atom is a center of symmetry. The average thallium–proton dipolar coupling constant D_{Tl-H} can be related to the intramethyl proton dipolar coupling constant D_{11} as (15)

$$[2] \quad D_{Tl-H} = \frac{-3\sqrt{3}\gamma_{Tl}}{\gamma_H} \sin^3\delta(2 - 3\sin^2\delta)$$

where γ_{Tl} is the average gyromagnetic ratio of ^{203}Tl and ^{205}Tl. The values of D_{Tl-H} were obtained from the experimental values of D_{11} and were tabulated also in Table 1. With the values of D_{Tl-H} being known, the scalar coupling constant J_{Tl-H} was evaluated from the separation of the triplets. The average value of J_{Tl-H} obtained over the five cationic nematic phases is 403.3 ± 0.4 Hz, which is in good agreement with the value obtained from the isotropic micellar solutions.

The dimethylthallium ion in the nematic phase may be characterized by the degree of orientation of the C_∞ axis. The C_∞ axis is perpendicular to the proton–proton vector in the same methyl group so that (16)

$$[3] \quad D_{11} = -\frac{h\gamma_H^2}{4\pi^2 r^3} S_{C\infty}$$

where γ_H is the proton gyromagnetic ratio and r is the intramethyl proton–proton distance. The values of degree of orientation of the C_∞ axis of the dimethylthallium ion were calculated from the experimental D_{11} values. Table 1 also gives the S_{C_∞} values.

The present results show that the degree of orientation of the dimethylthallium ion is about 60 to 90 times higher in the anionic nematic phase than in the cationic phase. A tentative explanation would be that electrostatic interactions between the positive dimethylthallium ion and the electrical double layer interface play an important role on the orientation of the complex ion. It is proposed that the dimethylthallium ion which achieves orientation in the nematic phase does so in an exchange process in the interface region of the oriented electrical double layer. The proposed exchange process in the interstitial water of the nematic phase and with the electrical double layer interface can be considered somewhat analogous to ion-pair formation at the interface and a free ion environment in water. In the anionic nematic phase the ionic head groups at the electrical double layer interface are negatively charged. The attractive forces between these negatively charged ionic head groups and the positively charged dimethylthallium ions contribute to the latter spending more time in the electrical double layer interface during the exchange process. Therefore a high degree of orientation of the dimethylthallium ion results. On the other hand, in a cationic nematic phase the repulsive forces between the ionic head groups and the dimethylthallium ions (both positively charged) cause the dimethylthallium ions to spend a relatively longer lifetime in less ordered regions of the interstitial water; and hence a smaller degree of orientation of the complex ions is observed.

In order to support the proposal that electrostatic interactions are significant in the orientation of ions in a nematic phase, we have also studied the orientation of the neutral methanol and D_2O molecules in both the anionic and cationic phases. The proton magnetic resonance spectra of the methanol molecules oriented in a lyotropic nematic phase show clearly a triplet expected for the intramethyl proton dipolar

For personal use only.

coupling. The compositions of the nematic phases studied here and the intramethyl dipolar coupling constants of the methanol molecule are given in Table 3. The degree of orientation of the C_3 axis (S_{C_3}) was evaluated by using eq. 3 with the assumption that the interproton distance of the methyl group is 1.795 Å (17). The present results show that the degree of orientation of the neutral methanol molecule has similar values in both cationic and anionic phases. This is the first firm evidence that ionic distribution in the electrical double layer can greatly affect the degree of orientation of counter ions while leaving a neutral molecule such as methanol and D_2O relatively unperturbed. Further studies are continuing in this area.

We thank the National Research Council of Canada and the Defense Research Board of Canada for their financial support of this research.

Received August 2, 1974

ROBERT R. FRASER, MOHAMMAD A. RAZA, ROGER N. RENAUD, and ROBERT B. LAYTON. Can. J. Chem. **53**, 167 (1975).

The influence of substituents on the conformational properties of *N*-substituted 5,6-dihydro-7*H*,12*H*-dibenz[*c*,*f*]azocines and their conjugate acids was studied by n.m.r. spectroscopy. The position of the equilibrium between a rigid boat-chair and a flexible twist-boat conformation has been measured. The twist-boat conformation in deuterochloroform increased as the size of the substituent increased. However, the effect was opposite for the series of conjugate acids in trifluoroacetic acid.

A number of inversion barriers for the boat-chair ⇌ twist-boat and the twist-boat ⇌ twist-boat equilibria in $CDCl_3$ and TFA were determined. It was found that all barriers to interconversion were raised on protonation. The barrier to racemization for the twist-boat form of the quaternary methiodide of **1** was found to be > 18 kcal/mol.

ROBERT R. FRASER, MOHAMMAD A. RAZA, ROGER N. RENAUD et ROBERT B. LAYTON. Can. J. Chem. **53**, 167 (1975).

On a étudié, par spectroscopie r.m.n., l'influence des substituants sur les propriétés conformationnelles de dihydro-5,6 7*H*,12*H*-dibenz[*c*,*f*]azocines *N*-substitués et de leurs acides conjugués. On a mesuré la position de l'équilibre entre une conformation rigide bateau-chaise et une conformation flexible bateau-croisé. La conformation bateau-croisé dans le chloroforme deutéré augmente à mesure que la grosseur du substituant augmente. Toutefois l'effet est opposé pour la série des acides conjugués dans l'acide trifluoroacétique.

On a déterminé, dans $CDCl_3$ et dans TFA, un certain nombre de barrières d'inversion pour les équilibres bateau-chaise *vs.* bateau-croisé et bateau-croisé *vs.* bateau-croisé. On a trouvé que toutes les barrières aux interconversions sont augmentées par protonation. La barrière à la racémisation, dans la forme bateau-croisé du sel d'ammonium quaternaire de **1**, est plus grande que 18 kcal/mol. [Traduit par le journal]

We have recently described a study of the conformational properties of *N*-methyl-5,6-dihydro-7*H*,12*H*-dibenz[*c*,*f*]azocine, **1**, by means of proton n.m.r. spectroscopy (1). This compound is of inherent interest as an unexplored medium sized heterocycle, as well as serving as a model for 1,4-cyclooctadiene, for which no experimental evidence has been reported.[3] The azocine was found to possess two stable conformations, the boat-chair (BC) and twist-boat (TB) forms, whose barrier for the TB → BC transformation amounted to 15.3 kcal/mol (1). We wish to report an extension of these studies to include azocines **2**–**6** in which the bulk of substituents at the nitrogen atom varies considerably. In this manner, the influence of the substituent on the conformational properties of the free base and its conjugate acid (in trifluoroacetic acid) can be examined.

[1]NRCC No. 14326.
[2]NRCC Postdoctoral Fellow 1972–1973.
[3]In a recent paper Dunitz and Waser (2*a*) proposed two conformers, the rigid and flexible forms, for 1,4-cyclooctadiene. Subsequently Turner *et al.* (2*b*) suggested the rigid form as being energetically favored. This nomenclature, as pointed out to us by one of the referees, is based upon dynamic rather than static characteristics of each conformer. In spite of our use of the terms "rigid crown" and "flexible" conformers in our previous paper (1) we wish now to change nomenclature. There are two conformers of cyclooctane (3) which closely resemble the two allowed conformations of the azocine ring. These are the boat-chair (BC) and twist-boat (TB) conformers whose names will now be used to designate the rigid crown and flexible forms respectively.

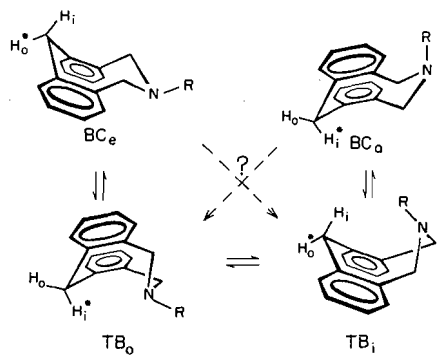
Conformational Equilibria

For any *N*-substituted azocine, four stable conformations are capable of being populated. These are the BC_a and BC_e forms and the TB_i and TB_o forms where the orientation of the substituent on nitrogen can be described as axial-like or equatorial-like in the BC forms (subscript a or e) and inside or outside in the TB forms (subscript i or o). Scheme 1 depicts the most probable interconversion pathway for these conformations. The BC_e form converts to the TB_o form via rotation about the Ar—CH_2—Ar bonds. Inversion of the ring of TB_o produces TB_i which can invert at the Ar—CH_2—Ar end to produce BC_a. Models suggest that either a $BC_e \rightarrow TB_i$ or $BC_a \rightarrow TB_o$ conversion would have a much greater energy barrier and seem less probable as an alternate pathway. It should be noted that the complete pathway $BC_e \rightarrow TB_o \rightarrow TB_i \rightarrow BC_a$ must be followed to interchange the environment of the ring protons of the BC conformer while $TB_o \rightarrow TB_i$ will result in exchange of the environments of the methylene protons of the TB form (provided *N*-inversion is rapid).



SCHEME 1. The most probable pathway for interconversion of the boat-chair and twist-boat conformations.

Criteria for Conformational Assignments

The elucidation of the conformational properties of **1** was possible as a result of distinctive differences in the n.m.r. spectral properties of the BC and TB species. The following criteria were employed.

(*a*) Temperature dependence of *K* for the BC ⇌ TB equilibrium. By integration of identifiable signals for the two isomers as a function of temperature, values for ΔS were obtainable. Since the TB form could be expected to have the greater entropy, assignment of conformation could be made.

(*b*) ^2J for $(Ar)_2CH_2$ protons. The BC conformation shows a more positive ^2J (−12 to −14 Hz) than does the TB form (−19 Hz). This is in accord with the stereochemical dependence of ^2J on hyperconjugative withdrawal (4).

(*c*) $J_{H-\overset{+}{N}-CH}$ in TFA. In TFA, the conjugate acids of the azocines exhibit vicinal H—$\overset{+}{N}$—C—H coupling constants, which obey a Karplus relation (5). The BC conformer is characterized by a value of zero to one Hz for the H—$\overset{+}{N}$—C—H coupling constant between protons having a 90° dihedral angle between them.

(*d*) Shift equivalence. A further criterion is used in this study. It is seen that, in $CDCl_3$, one of the conformers shows nonequivalent methylenes, while the other has singlet methylene peaks. The only assignment consistent with Scheme 1 is for the TB form to be responsible for the singlet absorptions.

The BC ⇌ TB Equilibrium in $CDCl_3$

Use of the above methods of configurational assignment has allowed determination of the position of the BC to TB equilibrium for azocines **2–6** in $CDCl_3$. Although inversion at nitrogen is rapid in this solvent (6), the ring inversion barrier varies from 15 to 16.5 kcal/mol and results in broadening of all lines at 27 °C. For this reason, integration measurements were made at 0 °C or below, where kinetic broadening is no longer present. The results which are summarized in Table 1 will be briefly described for each derivative.

2 (R = H)

The unsubstituted amine in deuterochloroform gives rise to one extensive broad n.m.r signal in the methylene region (δ 2–5) at ambient temperature, as seen in Fig. 1. As the tempera-

†In 93% $CDCl_3$, 7% TFA as solvent.
‡75% $CDCl_3$, 25% DMSO-d_6 as solvent.

ture is lowered to −30 °C, (see insert *A*) this absorption sharpens to reveal two AB quartets in a ratio of 2:1. The lack of any other peaks indicates the presence of a single conformer. This must be the BC form, since (*a*) the methylene protons are nonequivalent and (*b*) a ^2J of −12.7 Hz is found for the CH_2Ar_2 group. Raising the temperature causes coalescence of the central peaks of the N—CH_2 protons at 50 °C (see insert *B*). From this coalescence temperature the barrier to the BC ⇌ BC interconversion is 16.1 kcal/mol.[4]

[4]All barriers quoted in this paper have been derived from measurement of the coalescence temperature or assigning an upper or lower limit to the coalescence temperature. The equations which we used to calculate ΔG^* are those for a two-site exchange and for an AB system, as given by Binsch (7). Normally, determinations of ΔG^* by this method are accurate to ±0.2 kcal/mol. In the values we have measured, there is additional uncertainty in ΔG^* for several reasons: (*a*) in $CDCl_3$, the barrier represents a weighted average of two BC ⇌ two TB conformers, (*b*) in TFA, small quantities of unidentified conformers may be involved in the interconversion pathway, (*c*) overlap of peaks impairs accuracy, and (*d*) line-broadening as a result of a changing rate of relaxation of ^{14}N and concomitant partial decoupling of the ^{14}N—C—H splittings may distort line shapes.

In view of these complications, we have not undertaken accurate determinations of barriers by the more sophisticated complete line shape method. We are restricted by these complexities to obtaining approximate values for the barriers which may be in error by up to 1 kcal/mol.

3 (R = $CD_2\phi$)

The n.m.r. spectrum of this derivative also showed only two AB quartets ascribable to a BC conformation.

4 (R = $CH(CH_3)_2$)

At 0 °C, the spectrum showed two AB quartets characteristic of the BC form and two singlets representing the TB conformer. Integration of the methylene region gave a value of 1.44 for K_{eq} (TB dominant). At −51 °C, this equilibrium constant decreased to 0.61. These data reveal a ΔS of +8 e.u., which confirms the assignment. Retention of the singlet character for the two methylene group absorptions down to −51 °C is a strong indication that ring inversion for the TB conformer of **4** has a barrier of less than 11 kcal/mol. This conclusion is valid, provided that the methylene protons of a slowly inverting TB form are magnetically nonequivalent. Such nonequivalence is extremely probable for **4** in view of its presence for **6** in $CDCl_3$ and **1**, **3**, and **4** in TFA (*vide infra*).

5 (R = $C(CH_3)_3$)

The spectrum of the *N*-*t*-butyl derivative at 0 °C shows the presence of TB and BC forms in a ratio of 8:1 (from integration of the two separated *t*-butyl singlets). Assignments are again based on the appearance of two singlets for the major and two AB quartets for the minor component. In addition, a change in the medium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

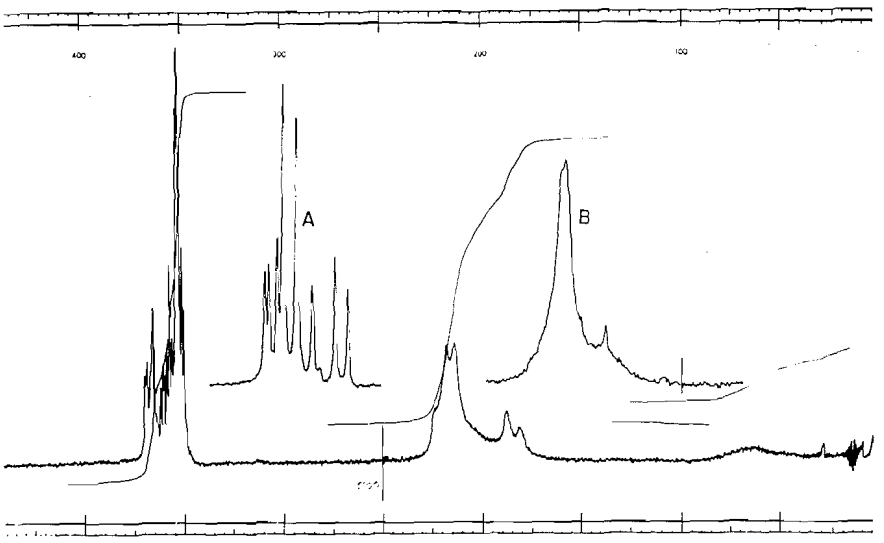

FIG. 1. The 100 MHz p.m.r. spectrum of **2** in $CDCl_3$ at 27 °C. Insert *A* shows the methylene absorption at −30 °C; insert *B* at 48 °C, just below the temperature at which the AB quartet for the NCH_2 protons coalesce.

to a 13:1 mixture of $CDCl_3$:TFA gave approximately equal amounts of the two conformers. It was found that the change in equilibrium distribution from +10° to −10° indicated a ΔS of 8 e.u. consistent with the above assignment. Heating the same solution to 40 °C caused coalescence of the two signals, indicative of a barrier to interconversion of 16.5 kcal/mol.

A final point regarding the spectrum of **5** in $CDCl_3$ was the maintenance of the two singlet absorptions at −60 °C, again indicative of a barrier to inversion of <11 kcal/mol for the TB form.

Studies in TFA Solvent

As reported in our study of **1**, the use of trifluoroacetic acid as solvent gives spectra of the conjugate acids. Perhaps the most important property of this solvent is its ability to completely protonate all basic nitrogen atoms and thereby prevent any nitrogen inversion processes. Previously work by Booth and Little (8) has established the deprotonation of substituted piperidines to be very slow ($t_{1/2}$ > 200 d) in this solvent. We have found that deprotonation is also slow for the azocines used in this study. For example, adding TFA to a solution of **1** in TFA-*d* showed only a gradual change in the singlet character of the $\overset{+}{N}(D)—CH_3$ absorption over a period of a day. The half-life for dedeuteration

$\overset{+}{N}(H)—CH_3$

(producing a $\overset{+}{N}(H)—CH_3$ doublet) was approximately 1.5 days. Similarly, for **5**, the half-life for exchange was found to be >1.5 d. Thus, any kinetic processes leading to line-broadening or coalescences ($\Delta G^{\ddagger} \leq 20$ kcal) cannot involve the intermediacy of free amine and consequent nitrogen inversion processes. In effect, the four diastereomers depicted in Scheme 1 (H or D in place of lone pair) can only interconvert via conformational processes on the n.m.r. time scale.

1 (R = CH_3)

We have now carried out a more detailed examination of the temperature dependence of the equilibrium for **1** in TFA. In this solvent at 27 °C, the spectrum actually shows three $N—CH_3$ group absorptions at δ 2.39, 2.98, and 3.45. The weakest peak at δ 3.45 was not noted in our initial study (1). But as the temperature is lowered, this peak sharpens to a clear doublet (TFA) or singlet (TFA-*d*). This isomer amounts to 4.6% of total mixture at 20 °C. Raising the temperature causes further broadening until, at 45°, it is no longer discernible. At 70°, all peaks in the spectrum have become broadened, indicating the onset of interconversion of all diastereoisomers. In view of the complexity of this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

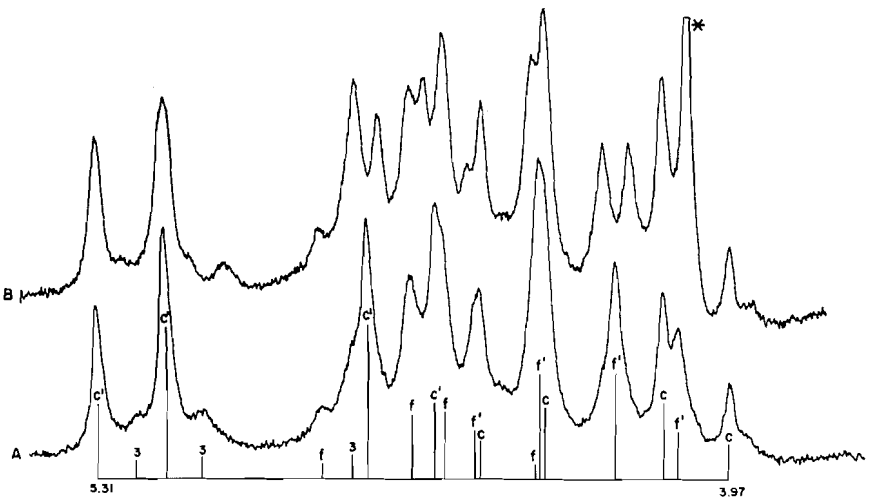

FIG. 2. The complete absorption of all methylene protons in the 100 MHz spectrum of **3**. *A* shows the spectrum in TFA-*d*, *B*, in TFA. The individual assignments are given on the stick spectrum at the bottom where the primed letter is used to denote the N—CH_2 absorption. The two peaks near the extreme left hand side bearing the label 3 likely represent a third conformer. The peak marked with an asterisk in *B* is due to a small amount of water in the solvent.

system, we are limited to the following qualitative conclusion: in order for coalescence of all peaks to occur in the range of 70 to 90 °C, the BC $\rightleftharpoons$ TB and TB $\rightleftharpoons$ TB equilibria must have barriers of 17 to 18 kcal/mol in TFA.

In our initial study, the most abundant isomer was assigned a BC conformation and the next most abundant isomer, a TB conformer, on the basis of geminal and vicinal coupling constants. We have now measured the equilibrium between these isomers by integration of the methyl absorptions at +20 and −20 °C.

From the data shown in Table 1, the less abundant isomer is found to possess the greater entropy, in accord with the previous assignment.

A detailed assignment of all of the peaks in the spectrum of **1** in TFA can be made by comparison with its spectrum in TFA-*d*. The same is true for the spectrum of **3** which shows even fewer overlapping peaks. For this reason, we have chosen **3** to illustrate their spectral characteristics in both solvents.

3 (R = $CD_2\phi$)

Figure 2 shows the absorptions in the methylene region, (*A*) in TFA-*d* and (*B*) in TFA. The proton assignments are indicated by the stick spectra using the nomenclature explained in the legend. In (*B*), three of the four pairs of *N*-methylene protons show vicinal coupling to the proton on nitrogen, while in (*A*), the smaller H—D splitting is not detectable. The lowest field doublet for the *N*-methylene protons of the BC form does not show this splitting, as the dihedral angle is near 90° in this case. Since evidence to be presented later will show that the proton on nitrogen is equatorial in the BC forms of **1** and **3**, these *N*-methylene protons must be pseudo-axial. Previously, several examples of downfield shifts for structurally similar axial-like protons have been described (9–11). It is, therefore, likely that the lower field half of the $ArCH_2Ar$ absorption for BC **1** and **3** also represents pseudo-axial protons. It is not possible to assign configuration to any of the protons of the TB conformers.

A study of the spectrum of **3** in TFA-*d* as a function of temperature, revealed a broadening and coalescence of the α-methylene peaks (δ 4.28) at 60° which indicates a TB $\rightleftharpoons$ TB barrier of 16.5 kcal/mol. The fact that the lines due to the BC conformer remain sharp at this temperature shows that the BC $\rightleftharpoons$ TB barrier is much higher (>17 kcal/mol). It is also clear that the barrier to racemization (see section on **6** for explanation of this process) in the TB conformer must be low. Otherwise, the protons α to nitrogen would appear as two AB quartets.

2 (R = H)

For the azocine **2** in TFA at −17°, the BC form dominates over the TB by a 4:1 ratio. The two sharp singlets representing the TB form show

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

that both the TB ⇌ TB inversion and the racemization processes are rapid ($\Delta G^{\ddagger} < 13$ kcal/mol). As the temperature is raised to 45°, all methylene absorptions coalesce. However, insufficient resolution of the peaks prevents an accurate determination of the BC ⇌ TB barrier.

4 ($R = CH(CH_3)_2$)

The only reliable data obtainable from the spectrum of **4** in TFA is the ratio of BC to TB conformers. As Table 1 shows, the BC form dominates at both 27 and −3° and the entropy difference between the two forms is 4 e.u.

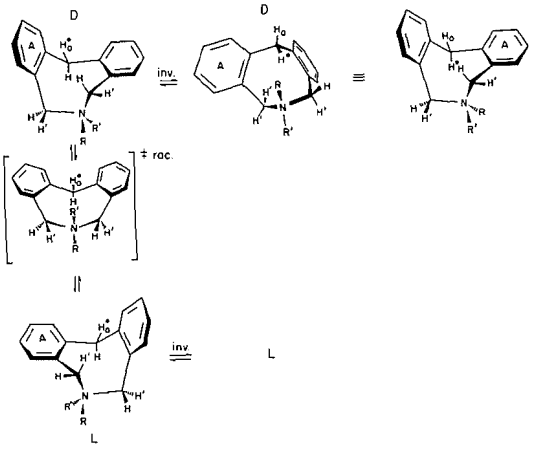
5 ($R = C(CH_3)_3$)

Solvent has a marked effect on the BC ⇌ TB equilibrium of **5**. Integration of the signals for the two *t*-butyl groups in TFA gave a BC to TB ratio of 91:9 in contrast to the ratio of 11:89 in $CDCl_3$. As mentioned previously, equal amounts of the two conformers occur when a 13:1 proportion of $CDCl_3$ to TFA is used as solvent. In addition, a third isomer's presence is indicated by a third singlet in the *t*-butyl region. Heating to 50° caused coalescence of the two large peaks ($\Delta G^{\ddagger}_{BC \rightarrow TB} = 16.5$ kcal/mol) but the minor peak only begins to broaden at this temperature. It seems likely that the minor peak is due to a second BC form whose interconversion barrier is >17 kcal/mol, since a TB form with the *t*-butyl group inside would possess considerably more strain energy.

Conformational Properties of the Quaternary Methiodide, 6

The quaternary salt, **6**, provides interesting spectra for comparison with those exhibited by the conjugate acids in TFA. Spectra of **6** were measured using a 3:1 mixture of $CDCl_3$:DMSO-d_6 solvent. Peaks due to both BC (80%) and TB forms (20%) were observed and these remained unchanged over the temperature range of −20 to +60°.[5] Two features of the absorption due to the TB conformer are particularly noteworthy. Both the CH_2Ar_2 and N—CH_3 peaks are sharp singlets, while the α-methylene absorptions give rise to an AB quartet. Assuming the singlets are not the result of fortuitous shift equivalence, these observations show that the TB ⇌ TB ring inversion barrier is low (<14 kcal/mol) but nonequivalence of the

[5]Accurate integration measurements as a function of temperature could not be obtained, due to overlap of peaks.



SCHEME 2. Allowed conformational interconversions between twist-boat forms. It is notable that ring inversion (inv.) causes interchange of the environments of the $ArCH_2Ar$ protons since one enantiomer (arbitrarily labelled D in the figure) upon inversion reforms the same enantiomer. Only interconversion of enantiomers (rac.) which can only occur via the symmetrical boat-like form will cause equivalent environments for the N—CH_2 protons.

α-methylenes reveals that an additional conformational barrier exists for **6**. This is the barrier to racemization for the TB conformers. As shown in Scheme 2, the symmetrical boat conformation represents a transition state for this process (severe nonbonded interactions between the inside N—CH_3 and the inside C—H bonds of the CH_2Ar group occur). Only a combination of ring inversion and this racemization process can render the α-methylenes equivalent.

Configuration at Nitrogen in TFA

We have seen that the $BC_e \rightleftharpoons TB_o \rightleftharpoons TB_i \rightleftharpoons BC_a$ equilibria have barriers in the range of 15 to 18 kcal/mol. This means that rapid equilibration of all isomers is occurring at room temperature. It is of interest to assign the con-

figuration at the protonated nitrogen atom for as many of the species as possible, to ascertain their thermodynamic stabilities.

One reliable criterion for this purpose is the value for the chemical shift of the proton on the nitrogen. In **2**, the two protons of the $\overset{+}{N}H_2$ group differ in chemical shift by 1.5 p.p.m. Such a shift in a BC conformation is readily ascribed to the ring current effects of the two aromatic rings (12) which cause shielding of the quasi-axial proton and deshielding of the quasi-equatorial one. It follows that in alkylated azocines a high-field N—H shift indicates an equatorial alkyl group on nitrogen and *vice versa*.[6] On this basis, the BC forms of the four azocine derivatives are assigned the configurations shown in Table 2. Additional n.m.r. features allow at least a tentative assignment to be made to the TB forms of **1** and **3**. Their TB forms show AB patterns for both types of methylenes consistent with slow inversion and rapid racemization on the n.m.r. time scale. Since slow racemization in **6** most likely results from the presence of an inside $N—CH_3$ group, it is unlikely that either **1** or **3** have the alkyl group inside.

Nuclear Magnetic Resonance Parameters

The chemical shifts and coupling constants for all identified isomers of the series of azocines are summarized in Tables 3 and 4. Assignments have been made on the basis of the many criteria already outlined. As in the case of **3**, corroboration of all shift assignments has been made by studies in TFA-*d* solvent in comparison with TFA as solvent. Additional aid for the identification of the α-methylene absorptions is available from the well-documented downfield shift on protonation (13).

Discussion

The results of this study of compounds **1–6** provide clear evidence that these azocines are capable of existing in two ring conformations as suggested by Dunitz and Waser (2). The stabilities of the BC and TB conformations are basically similar, so that substitutions at nitrogen involving alkyl group size and protonation can significantly alter the position of the conformational equilibrium. In particular, examination of Table 1 shows that an increase in the size of the group on nitrogen increases the proportion of TB conformation in the free base, but has the opposite effect in the series of conjugate acids in TFA. The complete explanation for this contrasting behavior would require knowledge of the configuration at nitrogen in all members of both series of conformations in $CDCl_3$ and TFA.

The configuration at nitrogen is known for the BC forms of the conjugate acids in TFA as indicated in Table 2. However, the only information regarding the BC forms of the free bases comes from an X-ray study of **2**. In the solid state, the methyl group was found to occupy the

[6]Confirmatory evidence for these assignments is found in the data in Table 3. Compounds **1** and **3** show vicinal coupling between the high-field methylene and NH protons, whereas **4** and **5** show coupling between the low-field methylene and N—H protons.

pseudo-axial position (14). Information regarding TB forms is even more scarce. It would, therefore, be overly speculative to rationalize the effect of substituents on the BC ⇌ TB equilibrium at this time.

Three conformational interconversion processes have been identified from a study of temperature effects on suitable spectra. These are the BC ⇌ TB (A) TB ⇌ TB (B) interconversions and the racemization process for **6** (C). Table 5 summarizes these results. Process A varies from 15 to 16.5 kcal/mol in $CDCl_3$ and is raised to >17 kcal/mol in TFA. Process B shows a marked change from <11 kcal/mol in $CDCl_3$ to up to 17.5 kcal/mol in TFA. A minimum of 18 kcal/mol is found for process C in **6** in contrast to its very low value (undetectable by n.m.r.) for other TB forms. There appears to be a very marked influence of protonation in raising all barriers to interconversion. Since this increase is also produced by quaternization (*e.g.*, **6**), the effects are most logically attributed to bond length changes and increased steric interactions when the nitrogen becomes tetrasubstituted and positively charged. The presence of the racemization barrier in **6** undoubtedly arises from the severe passing interaction between the inside *N*-methyl group and the inside hydrogen of the CH_2Ar_2 methylene group.

These findings constitute the first data on the conformational properties of the dibenzazocine ring and to some extent, it may be anticipated that the results provide an indication of the conformational properties of 1,4-cyclooctadiene.

Experimental

The melting points are all uncorrected. All n.m.r. spectra were recorded on a Varian HA-100 spectrometer. All coupling constants were determined with an accuracy of ±0.1 Hz and chemical shifts are reported on the δ scale. Measurement of the probe temperature was carried out using a methanol thermometer. Such measurements should be accurate to ±2.0 °C.

α-Dideuteriobenzylamine

To a solution of benzonitrile (4.2 g) in 50 ml of dry THF, was added slowly 1.64 g of $LiAlD_4$ and the solution was refluxed for 14 h. Then, the reaction mixture was cooled in ice, and the excess hydride was decomposed with water. After filtration, the solvent was removed *in vacuo* and the residue was dissolved in ether. The ethereal solution was dried with $MgSO_4$, filtered, and distilled. A clear oil (2.0 g, 44%) was obtained. Examination of the product by g.l.c. and n.m.r. showed that the benzylamine has a deuterium content of 98% in the α-position. This amine was converted to **3** (15) whose deuterium content was found to be 97.8% by low voltage mass spectrometry.

*N-Substituted-5,6-dihydro-7H,12H-dibenz[c,f]azocines (**1**, **2**, and **4**)*

The azocines **1**, **2**, and **4** were synthesized as reported in the literature (1, 15).

*N-t-butyl-5,6-dihydro-7H,12H-dibenz[c,f]azocine, **5***

The azocine **5** was synthesized using the general method described by Casadio *et al.* (15, method E).

The crude solid residue obtained from the reaction was purified by sublimation *in vacuo* to give 65% of the azocine melting at 61–62 °C.

Anal. Calcd. for $C_{19}H_{23}N$: C, 85.98; H, 8.74; N, 5.28. Found: C, 85.79; H, 8.84; N, 5.19.

*N-Methyl-5,6-dihydro-7H,12H-dibenz[c,f]azocine Methiodide, **6***

To a solution of the azocine **1** (80 mg) in 8 ml of ethanol was added 80 mg of methyl iodide. The solution was refluxed for 30 min. On cooling to room temperature, the methiodide crystallized into colorless crystals. Most of the solvent was siphoned out. The solid was washed twice with ether and dried in an atmosphere of dry nitrogen.

Anal. Calcd. for $C_{17}H_{20}NI$: C, 55.89; H, 5.48; N, 3.83; I, 34.79. Found: C, 55.90; H, 5.56; N, 3.85; I, 34.58.

Complexes of Cobalt(II), Nickel(II), and Copper Acetates, Perchlorates, and Tetrafluoroborates with Heterocyclic Ligands Containing VA and VIA Group Donor Atoms

C. PRETI AND G. TOSI

Istituto di Chimica Generale ed Inorganica, University of Modena, 41100 Modena, Italy

Received July 10, 1974

C. PRETI and G. TOSI. Can. J. Chem. **53**, 177 (1975).

Cobalt(II), nickel(II), copper(II), and copper(I) acetate, perchlorate, and tetrafluoroborate complexes with thiazolidine-2-thione, thiomorpholin-3-one, and thiomorpholin-3-thione have been prepared. On the basis of infrared and far infrared spectra, electronic spectroscopy, magnetism, and molecular conductance, the stereochemistries of these complexes were identified. Assignments for the metal–ligand modes have also been made. By the use of infrared spectroscopy it has been possible to distinguish whether or not the polyanions present in the complexes are coordinated to the transition metal ion or are present as free ions. Spectroscopic parameters for the complexes have been calculated and compared with similar chromophores containing sulfur, oxygen, and nitrogen donor atoms.

C. PRETI et G. TOSI. Can. J. Chem. **53**, 177 (1975).

On a préparé les complexes des acétates, perchlorates, et tétrafluoroborates de cobalt(II), nickel(II), cuivre(II), et cuivre(I) avec la thiazolidinethione-2, la thiomorpholinone-3, et la thiomorpholinethione-3. En se basant sur les spectres infrarouge et infrarouge lointain, sur la spectrocopie électronique, sur le magnétisme et la conductance moléculaire, on a identifié les stéréochimies des ces complexes. On a aussi fait des attributions pour les mode metal–ligand. En faisant appel à la spectroscopie infrarouge, on a pu déterminer si les polyanions présents dans les complexes sont ou ne sont pas coordonnées à l'ion de métal de transition ou s'ils sont présents sous forme d'ions libres. On a calculé les paramètres spectroscopiques de ces complexes et on les a comparés avec des chromophores similaires contenant des atomes de soufre, d'oxygène et d'azote comme donneur. [Traduit par le journal]

We have reported in previous papers the study of coordination compounds with heterocyclic ligands and transition metal halides (1–3) in order to study the competition between VA and VIA donor atoms in heterocyclic ligands in the coordination to the metals. We now describe the preparation of some new complexes of cobalt(II), nickel(II), copper(II), and copper(I) acetates, perchlorates and tetrafluoroborates with thiazolidine-2-thione

(ttz = S=C—NH—CH_2—CH_2—S),

thiomorpholin-3-one

(tm = O=C—NH—CH_2—CH_2—S—CH_2),

and thiomorpholin-3-thione

(ts = S=C—NH—CH_2—CH_2—S—CH_2)

for comparison purposes in order to check the influence of the anion both on the coordination number of the metal (hence on the stereochemistry of the complex), and on the different behavior in the coordination of the donor atoms of the ligands.

According to the methods reported in the Experimental section we have obtained microcrystalline compounds, soluble in methanol, ethanol, *N*,*N*′-dimethylformamide, and nitromethane.

The metal complexes obtained, analytical data, room temperature magnetic moments, conductivity measurement values, and other physical properties are reported in Table 1. The most important i.r. data are shown in Tables 2, 3, and 4, solid state electronic spectra are reported in Tables 5, 6, and 7.

The cobalt(II) complexes have tetrahedral or octahedral stereochemistries, the nickel(II)-derivatives are tetrahedral, octahedral, or square planar while the copper(II) complexes of tm are hexacoordinated. In the derivatives of ttz and ts the copper is present as copper(I) as demonstrated by magnetic susceptibility measurements. The complex [$Cuttz_3ClO_4$] has been previously reported (4) and we have included it in this paper for comparison purposes only.

As for the infrared spectra, we observe that in the ttz-derivatives (Table 2), ν(NH) appears as a

sharp band and shows a negative shift of *ca.* 250 cm^{-1}, having as reference ν(NH) value for the free ligand in chloroform solution. The thioamide I band, the band at 1288 cm^{-1}, attributed to ν(C═S) + δ(NCS), and those due to symmetric and asymmetric ν(CS) show positive shifts suggesting that the sulfur atoms are not involved in the coordination to the metals.

Passing on thiomorpholin-3-one derivatives (Table 3), we observe that ν(NH) falls at 3260–3330 cm^{-1} compared to the value of 3400 cm^{-1} for ν(NH) for the free ligand in chloroform solution. The vibration of the C═O group is shifted towards lower frequencies in the spectra of cobalt(II) and nickel(II) derivatives, while it is the same as in the free ligand in the spectra of copper(II) complexes. The stretching vibrations due to the prevailing contribution of ν(CS) symmetric and asymmetric occur at the same wave numbers or show small positive shifts in the cobalt and nickel derivatives and are shifted towards lower energies in the spectra of the copper complexes.

In the derivatives of thiomorpholin-3-thione (Table 4), we observe that the bands I, II, and III of the —N—C═S group (5) are at about the same wave numbers as in the free ligand spectrum. The ν(NH) in the ts-complexes is shifted towards lower energies of about 200 cm^{-1} using as reference the value of 3380 cm^{-1} for ν(NH) for the free ligand in chloroform solution. The bands due to the prevailing contribution of ν(CS) are at the same wave numbers or show very small negative shifts.

From these facts we can suppose that in tm-complexes the coordination center is the oxygen atom in the derivatives of cobalt and nickel and the sulfur atom in the complexes of copper. In fact the carbonyl stretching frequency is lowered by *ca.* 40 cm^{-1} whenever the oxygen atom is bonded to a metal (6). The small negative shift of ν(NH) in the tm-derivatives spectra could arise from intermolecular hydrogen bonding.

The nitrogen atom clearly is the donor atom in the ttz- and ts-complexes; in fact, when a ligand is *N*-bonded, the ν(NH) occurs as a sharp band near 3100–3200 cm^{-1} (2, 3, 7–12). According to Singh and Rivest (13) a sharp NH band in the metal derivatives is indicative of absence of hydrogen bonding and a comparison of these values with the ν(NH) solution frequency of the ligand could be used to suggest a coordination through the nitrogen atom.

The above conclusions are in accord with most of the observations on the previously reported complexes, furthermore the electronic spectra provide some further evidence to this point.

As for the polyanions present in the complexes, by means of infrared spectroscopy, it is possible to determine whether or not they are coordinated to the transition metals. Coordination lowers the original symmetry of the free ion and results in the splitting of the originally degenerate modes, and in the previously forbidden i.r. modes becoming allowed.

The acetate ion is able to coordinate as a simple unidentate ligand, as a chelate (symmetrical or asymmetrical), and as a bridging group in polymeric complexes. All the acetate derivatives of cobalt, nickel, and copper with the different ligands are nonelectrolytes in nitromethane, Λ lying in the range 6.6–5.7 ohm^{-1} cm^2 mol^{-1} (14). By comparing the infrared spectra of our complexes with those of the acetate ion in compounds of known structure, it has been possible to distinguish between the various types of coordination (15).

In the complexes $[Nittz_2Ac_2]\cdot 2H_2O$, $[Nits_2Ac_2]$, $[Cots_2Ac_2]$, and $[Cutm_4Ac_2]$ the observed carboxy-group frequencies and their separation (150–170 cm^{-1}) are as expected for unidentate coordination.

The position of the carboxy-bands and their separation, 80 cm^{-1}, indicate a symmetric bidentate coordination of the acetate in the complexes $[Cotm_2Ac_2]\cdot H_2O$ and $[Nitm_2Ac_2]\cdot H_2O$.

As for the perchlorate derivatives, monodentate coordination results in a lowering of symmetry, $T_d \rightarrow C_{3v}$. The originally triply-degenerate modes, ν_3 and ν_4 of the free ion, are both split into two bands and the previously forbidden i.r. modes ν_1 and ν_2 of the free ion become i.r. active. In the complexes $[Cuttz_3ClO_4]$, $[Nits_2(ClO_4)_2]$, and $[Cuts_3ClO_4]$ the ν_3 mode is split in two bands in the range 1110–1085 cm^{-1}, while ν_4 is split into two bands between 640–620 cm^{-1}. The ν_1 mode appears at some 950 cm^{-1} while ν_2 lies at 460 cm^{-1} (Tables 2 and 4). The ν_1 mode in $[Cuttz_3ClO_4]$ is combined with a ligand band which is reinforced; in the two remaining complexes one of the two bands of split ν_4 overlaps the —N—C═S first band.

The i.r. values of all the remaining perchlorate derivatives are typical for a nonbonded perchlorate group (16).

In the tetrafluoborato derivatives, when the

anion is bonded to a transition metal, we observe a similar behavior as in perchlorate group, *i.e.* ν_3 and ν_4 split, ν_1 and ν_2 i.r. active.

The complexes $[Cuttz_3BF_4]$, $[Nits_2(BF_4)_2]$, and $[Cuts_3BF_4]$ have i.r. spectra which suggest an anion coordinated to the metal (17). ν_1 and ν_2 lie in the ranges 760–750 cm^{-1} and 354–350 cm^{-1}; ν_4 and ν_3 split in the ranges 540–525 cm^{-1} and 1160–1020 cm^{-1}, respectively (Tables 2 and 4).

It is further observed that in the other fluoborato derivatives this anion is not bonded to the metal ions.

The conductivity values agree very well with these i.r. results.

The medium absorption bands present in the range 3480–3450 cm^{-1}, ν(OH), in $[Nittz_2Ac_2]\cdot 2H_2O$, $[CuttzAc]\cdot 2H_2O$, $[Cotm_2Ac_2]\cdot H_2O$, $[Nitm_2Ac_2]\cdot H_2O$, $[Cutm_6](BF_4)_2\cdot 2H_2O$, and $[Cots_4](BF_4)_2\cdot 4H_2O$ confirm the presence of water of crystallization. This water is purely lattice water since it is lost near 100 °C. In addition the wagging, the twisting, and the rocking vibrational modes of coordinated water are not present in the expected ranges (18).

Analysis of the electronic spectra of the complexes allows us to determine the mode of bonding.

With cobalt(II), complexes of tetrahedral and octahedral geometries are formed. Their magnetic moments and solid state electronic spectra (Tables 1 and 5) are in accord with those expected for these stereochemistries. As for the tetrahedral derivatives the magnetic moments at room temperature (4.1–4.9 B.M.) and the electronic spectra are consistent with a tetrahedral configuration for high spin cobalt(II) derivatives (Tables 1 and 5). Using the frequencies of ν_3 and ν_2 we have calculated the values of Dq, B', and β (19). The B' values suggest that there is a considerable orbital overlap.

As for the octahedral derivatives of cobalt(II) (μ 4.9–5.5 B.M.), the Dq, B', and β parameters were evaluated using ν_2 and ν_3 (19). Unfortunately, the ν_1 wave number was not identified from the experiments because in the tm free ligand spectrum a medium-strong absorption is present at 8300 cm^{-1}. The calculated ν_1 wave numbers are reported in Table 5.

Passing on to nickel(II) derivatives (Table 6) we have obtained tetrahedral, octahedral, and square planar complexes; the magnetic moments measurements and solid state electronic spectra are in very good agreement with these results.

The complex $[Nittz_4](ClO_4)_2$ (μ 3.5 B.M.) has a spectrum typical of tetrahedral Ni(II) (Table 6) (20, 21); Dq and B' were calculated using only ν_2 and ν_3 values, because of the ambiguous assignment of ν_1.

The reflectance spectra of the nickel complexes of ttz with BF_4 and of tm with Ac, ClO_4, and BF_4 are typical of octahedral nickel(II) (Table 6). A band at 8500 cm^{-1} was identified as a d–d transition only in the ttz-derivative, a medium-strong absorption due to the tm ligand being present at some 8300 cm^{-1}. Dq, B', and β parameters have been calculated from ν_2 and ν_3 only.

The B' values of the tetrahedral complex and of the octahedral derivatives suggest that there is a considerable orbital overlap with a strong covalency in the metal–ligand σ bonds.

The magnetic moments at room temperature lie within the range usually observed for octahedral high spin nickel(II) compounds. The μ value of $[Nittz_6](BF_4)_2$ is lower than expected, probably because of the hygroscopicity of the compound that could strongly interfere.

All the remaining nickel(II) diamagnetic derivatives have a square planar geometry except $[Nits_2(BF_4)_2]$ (μ = 2.1 B.M.).

The assignment of the d–d bands (Table 6) is made by assuming the convention that the metal x and y axes lie between the metal–ligand bonds (22). In the complex $[Nits_2(BF_4)_2]$ shoulders are present in addition to the reported bands, and the $^1A_{1g} \rightarrow {}^1B_{1g}$ transition appears only as a shoulder; we can therefore assign to this compound a distorted structure with a predominantly planar environment.

The above suggested stereochemistries are supported by the absence of electronic transitions below 10 000 cm^{-1}.

By assuming a value of $F_2 = 10F_4 = 800$ cm^{-1} for the Slater–Condon interelectronic repulsion parameters (23), a correction factor of 2800 cm^{-1} gives Δ_1 values, Table 6.

According to the conductivity values (Table 1) and to the solid state electronic spectra (Table 7), the copper(II) derivatives of tm have an octahedral stereochemistry.

The spectral data of cupric acetate – tm complex indicate the presence of octahedrally coordinated copper(II), in spite of the low magnetic

moment, 1.7 B.M. and of the presence of a band at 27 400 cm^{-1}.

By comparison of *Dq* values reported for CoL_4^{2+} cations (24) we can see that for CoS_4 chromophores *Dq* lies in the range 316–425 cm^{-1}; the corresponding range for CoN_4 chromophores is 467–538 cm^{-1}. Table 5 shows that *Dq* values of the complexes of the type CoL_4^{2+} are in very good agreement with the literature data for CoN_4 chromophores. The complex $[Cots_2Ac_2]$ shows a *Dq* value that is, using the "law of the average environment", typical of CoN_2O_2 chromophore. This value is obviously lower than those of CoN_4^{2+} complexes.

As for CoL_6^{2+} cations, the *Dq* values for CoS_6 chromophores are in the range 770–860 cm^{-1}, for CoO_6 chromophores in the range 920–980 cm^{-1}, while the values corresponding to CoN_6 chromophores are higher than 1000 cm^{-1} (21, 25). The *Dq* values of our CoL_6^{2+} complexes agree very well with the data for CoL_6^{2+} derivatives containing cobalt–oxygen bonds.

These results strongly support the i.r. conclusions that the cobalt(II) derivatives of ttz and ts are *N*-bonded while the tm-derivatives are *O*-bonded.

Comparison of the electronic spectrum of the complex $[Nittz_4](ClO_4)_2$ with those of derivatives involving Ni—S bonds and Ni—N bonds confirms that this compound is *N*-bonded, since the band energies are at higher values than in *S*-bonded derivatives (2, 21).

As for the octahedral nickel(II) derivatives, the *Dq* values for NiS_6 chromophores and NiO_6 chromophores lie between 770–810 cm^{-1} and 850–930 cm^{-1}, respectively, higher values being expected for NiN_6 groups (21, 25). The derivatives of thiomorpholin-3-one (Table 6), have *Dq* values in accord with the reported data for NiO_6^{2+} cations. The *Dq* value for the ttz-derivative is in the range typical for NiO_6 chromophores, but this ligand contains sulfur and nitrogen donor atoms only.

Taking into account the relative order of the lowest energy band in the square planar nickel complexes increasing in the approximate sequence $NiS_4 < NiN_2O_2 \sim NiN_2X_2 \sim NiO_4 < NiN_4$, we can place ttz and ts in the spectrochemical series of nitrogen donors.

We can conclude that the nickel(II) ion is oxygen-bonded in the tm-derivatives and nitrogen-bonded in the derivatives of ttz and ts.

From these results the bands which appear in the i.r. spectra of the complexes and which are absent in the free ligands spectra, in the range 250–252 cm^{-1} and 215–228 cm^{-1} in both ttz- and ts-complexes of cobalt(II) and nickel(II), can be attributed to ν(Co—N) and ν(Ni—N), respectively (2, 26–28). New medium strong bands appear at 431–440 cm^{-1} in the complexes of tm with cobalt(II) and nickel(II), which could be attributed to a metal–oxygen interaction (29, 30).

In the copper derivatives the coordination center is the sulfur atom in the complexes of tm and the nitrogen atom in the complexes of ttz and ts. The strong band present in the i.r. spectra of the copper–tm derivatives in the range 358–371 cm^{-1} could be attributed to ν(Cu—S), according to literature data (31). This assignment is supported by the noticeable shift of the bands due to the prevailing contribution of C—S bond stretching towards lower wave numbers and by the absence of absorption bands in the range 290–330 cm^{-1} where ν(Cu—N) generally lies. In the copper derivatives of ttz and ts the bands present in the range 310–330 cm^{-1} could be attributed to a ν(Cu—N) stretch (4, 9, 32).

Experimental

Preparation of the Ligands

Thiomorpholin-3-one

tm supplied by Aldrich was purified by extraction with ethyl ether in soxlet apparatus (m.p. 93 °C, lit. 93 °C) (33).

Thiomorpholin-3-thione

ts was prepared by treating thiomorpholin-3-one with an excess of P_4S_{10} slurry in refluxing benzene as previously described (7) (m.p. 141–141.5 °C).

Thiazolidine-2-thione

ttz supplied by Fluka, was twice recrystallized from hot water (m.p. 106–107 °C, lit. 106–107 °C) (34).

Preparation of Complexes

The complexes $[Cotm_2Ac_2] \cdot H_2O$, $[Cots_2Ac_2]$, and $[Nitm_2Ac_2] \cdot H_2O$ have been obtained by reaction of the corresponding metal acetate in a little excess of molten ligands. The compound $[Nittz_2Ac_2] \cdot 2H_2O$ has been obtained by reaction of nickel acetate in refluxing stirred chlorobenzene solution of the ligand. The complexes $[Nits_2Ac_2]$ and $[Cutm_4Ac_2]$ have been prepared by reaction of the corresponding acetate in refluxing stirred chloroform solution of the ligands, while [CuttzAc] has been prepared in a similar way in ethanol solution.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

All the perchlorate derivatives have been prepared by reaction of the corresponding metal perchlorate in ethanol in refluxing stirred chloroform solution of the ligands. When the complexes did not separate out during the reactions, the compounds were obtained by adding petroleum ether.

The tetrafluoborato complexes have been obtained by reaction of the metal tetrafluoborate in molten ligands in the required stoichiometrical ratio.

The complexes have been purified by means of repeated washing with chloroform in the case of ttz-derivatives, with ethyl ether and toluene for tm- and ts-derivatives, respectively.

Infrared Measurements

The i.r. spectra have been recorded in the range 4000–200 cm^{-1} with Perkin–Elmer 457 and 225 spectrophotometers as KBr discs. The far i.r. spectra (400–200 cm^{-1}) were recorded as Nujol mulls between polyethylene sheets.

Ultraviolet–Visible Spectra

Solid state electronic spectra have been recorded with a Shimadzu MPS-50L spectrophotometer by the method of Venanzi and co-workers (35).

Magnetic Susceptibility Measurements

These were carried out by Gouy's method. Molecular susceptibilities were corrected for diamagnetism of the component atoms by use of the Pascal's constants.

Conductivity Measurements

These measurements were carried out with a WTW LBR type conductivity bridge for 10^{-3} M solutions in nitromethane at 25 ± 0.1 °C.

We thank Dr. M. Menozzi for his experimental work and the National Research Council (C.N.R.) of Italy for financial support.

^{13}C Nuclear Magnetic Resonance Studies of Organometallic Compounds. IX. Phenylaminocarbene Derivatives[1]

HOWARD C. CLARK, JOHN E. H. WARD,[2] AND KATSUTOSHI YASUFUKU
Department of Chemistry, The University of Western Ontario, London, Ontario N6A 3K7

Received July 31, 1974

HOWARD C. CLARK, JOHN E. H. WARD, and KATSUTOSHI YASUFUKU. Can. J. Chem. **53**, 186 (1975).

The ^{13}C nuclear magnetic resonance parameters for a series of transition metal carbene complexes of the type *trans*-$[(CH_3)Pt(As(CH_3)_3)_2(p\text{-}XC_6H_4NH(CH_3)C)]^+PF_6^-$ are presented. Comparisons of the σ^+ substituent constants for —X with the carbene carbon shieldings reveal that both σ and π interactions are occurring between the aromatic rings and the carbene carbons. A quantitative inverse relationship between these carbene carbon shieldings and those of analogous phenylthiocarbene complexes is discussed. The phenyl rings are shown to adopt *cis* orientations with respect to the carbene methyl groups.

HOWARD C. CLARK, JOHN E. H. WARD et KATSUTOSHI YASUFUKU. Can. J. Chem. **53**, 186 (1975).

On présente les paramètres de résonance magnétique nucléaire du carbone 13 d'une série de complexes entre des métaux de transitions et des carbènes du type *trans*-$[(CH_3)Pt(As(CH_3)_3)_2(p\text{-}XC_6H_4NH(CH_3)C]^+PF_6^-$. La comparaison des constantes σ^+ des substituants X avec les valeurs de blindage des carbones du carbènes montre que des interactions σ et π se produisent entre le noyau aromatique et les carbones du carbène. On discute d'une relation quantitative inverse entre ces blindages des carbones des carbènes et ceux de complexes analogues contenant des phénylthiocarbènes. On montre que les noyaux phényles adoptent des orientations *cis* par rapport aux groupes méthyles des carbènes. [Traduit par le journal]

Introduction

In a previous ^{13}C nuclear magnetic resonance spectroscopic study (2), we examined a series of transition metal carbene complexes of the sort $p\text{-}XC_6H_4S(CH_3)CW(CO)_5$, **A**, where X = —OH, —OCH_3, —CH_3, —F, —H, or —Br. Unexpectedly, the ^{13}C n.m.r. data revealed that the carbene carbons were *shielded* as the overall electron withdrawing properties of the *para* substituents *increased*; as expressed in terms of their substituent constants. Thus, a plot of $\sigma_{para}{}^n$ (3) for —X *vs.* the appropriate carbene carbon shielding gave a linear relationship with negative slope. In contrast, a similar plot for σ^+ *vs.* the carbene carbon shieldings of a series of complexes with *para*-substituted phenyl groups directly attached to the carbene carbon, $(R(R')CW(CO)_5$, **B**, where R = $p\text{-}C_6H_4X$, and R′ = —OCH_3) gave a trend with positive slope (2, 4). Thus, for series **B**, a more typical trend is followed where the carbene carbons are *deshielded* as the overall electron withdrawing properties of the *para* substituents increase.

It would appear then, that the presence of the intervening sulfur atom between the carbene carbon and *para*-substituted phenyl group markedly affects the transmission of electron density from the phenyl ring to the carbene carbon. Since nitrogen, which is also a common hetero atom in carbene ligands, may also exhibit unusual electron transmitting or insulating properties, we have synthesized and obtained the ^{13}C and ^1H n.m.r. parameters of a series of platinum(II) phenylamino carbene complexes of the type *trans*-$[(CH_3)Pt(As(CH_3)_3)_2(p\text{-}XC_6H_4NH(CH_3)C]^+PF_6^-$, where —X = —Br, —Cl, —H, —CH_3, and —OCH_3. Here, the effects of varying —X can be studied not only via ^{13}C shieldings, but also by ^{13}C—^{195}Pt coupling constants.

Experimental

The following chemicals were obtained commercially and used without further purification: aniline, *p*-chloroaniline, *p*-bromoaniline, *p*-toluamine, and *p*-anisamine. *trans*-$[(CH_3)Pt(As(CH_3)_3)_2(C(OCH_3)CH_3)]^+PF_6^-$, **1** was prepared by the method of Chisholm and Clark (5).

All reactions and recrystallizations were carried out using spectroscopic grade solvents. Microanalyses were performed by Chemalytics Inc., Tempe, Ariz. Uncorrected

4	—H	3	25.2	4.23	25.1	4.15	†
5	$-CH_3$	1	26.4	4.43	26.4	4.48	153–154
6	$-OCH_3$	1	25.8	4.33	25.9	4.46	150–152

*Complex melts with decomposition.
†Complex is an oil.

melting points were determined on a Thomas Hoover unimelt capillary melting point apparatus.

The ^{13}C n.m.r. spectra were measured on a Varian XL-100-15 spectrometer operating in the pulsed Fourier transform mode at 25.2 MHz. All spectra were determined with noise-modulated proton decoupling using 3 s delays between pulses. The spectra were taken on methylene chloride-d_2 solutions in 5 mm sample tubes and were calibrated using the solvent resonances as secondary calibration standards (6).

The ^1H n.m.r. spectra were recorded on a Varian HA-100 spectrometer; the ^1H chemical shifts are reported with TMS as the internal standard.

Preparation of trans-$[(CH_3)Pt(As(CH_3)_3)_2(p\text{-}XC_6H_4NH(CH_3)C)]^+PF_6^-$ *(Compounds 2–6, see Table 1)*

To a solution of *trans*-$[(CH_3)PtAs(CH_3)_3)_2(C(OCH_3)CH_3)]^+PF_6^-$, **1**, (0.15 g, 0.23 mmol) in *ca.* 0.5 ml chloroform was added excess *para*-substituted aniline (*ca.* 1.3 mmol). The reaction was considered to be complete when the methoxyl resonance of **1** in the ^1H n.m.r. spectra of the reaction mixture had disappeared. Next, the reaction mixture was evaporated and the dark brown residue was extracted several times with *ca.* 10 ml 1:1 ether–pentane. The residue was chromatographed through a short Florisil column with methylene chloride. Concentration of the eluted solution, followed by the addition of ether, gave pale brown crystals. These were repurified by crystallization from ether–chloroform.

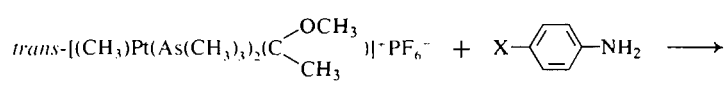
The aniline carbene complex could not be obtained in the crystalline state. The crude mixture obtained by chromatography with methylene chloride was rechromatographed on a short Florisil column eluting with benzene, 1:1 pentane–chloroform, and chloroform. The colorless oil recovered from the chloroform solution proved to be the desired product.

Analytical data are summarized in Table 1.

Results

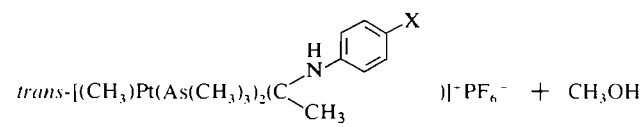
Preparation of the Complexes

All the new *para*-substituted phenylaminocarbene complexes **2–6** were prepared by the aminolysis reaction shown in reaction 1 (7, 8).



1

[1]



2–6

It is evident from the reaction times in Table 1 that the reaction rates depend markedly on the nature of the *para*-substituent —X, being most rapid for anilines with electron-releasing substituents. This is reminiscent of the observations of Connor and Fischer (8), who prepared complexes of the type $(p\text{-}XC_6H_4NH(CH_3)C)Cr(CO)_5$ by the general method shown in reaction 1.

Our attempts to prepare analogs of **2–6** where —X = —F, $-CF_3$, and $-NO_2$ were unsuccessful. When —X = —F, formation of the phenylaminocarbene complex was observed in solution by ^1H n.m.r. spectroscopy; however, the complex could not be isolated. On the other hand, when —X = $-CF_3$ or $-NO_2$, the phenylaminocarbene complexes were apparently not formed. This is presumably due to the rather

slow reaction rates for anilines with electron withdrawing *para*-substituents. In such cases, reduction to platinum(0) was observed, as we have noticed in the preparation of related platinum(II) carbene complexes. Finally, we should note that our attempts to prepare bis-(dimethylphenylphosphine) analogs of **2–6** were also unsuccessful; it would appear that the transition states for the aminolysis reaction are sufficiently sterically hindered to preclude phenylaminocarbene formation (7).

Nuclear Magnetic Resonance Results

The ^{13}C n.m.r. shieldings and coupling constants obtained from the spectra of **2–6** are summarized in Tables 2 and 3, respectively. The assignments of the carbon resonances of the platinum-methyl, arsenic-methyl, carbene-methyl and carbene carbons were carried out by comparisons with related derivatives (1, 9). However, the assignments of all the aromatic carbons were not so straightforward. The signals arising from the *quaternary* carbons C_1 and from the *para* carbons C_4 could be distinguished from the *ortho* and *meta* carbons on the basis of their relative intensities. The *quaternary* carbons C_1 were distinguished from the *para* carbons C_4 by their characteristic $^3J_{PtCNC}$ value (*ca.* 20 Hz). (We would not anticipate that $^6J_{PtCNCCCC}$ values would be large, since we have observed that $^nJ_{PtC}$ values generally decrease in magnitude as the number of intervening atoms between the coupling nuclei increases (10, 11).) Each complex gave a signal at *ca.* 121.5 (±1) p.p.m., which was assigned to the 2,6 carbons on the basis of the well-known insensitivity of ^{13}C shieldings of aromatic carbons *meta* to a varied substituent (12). All these assignments were checked by assuming additivity of the individual *para*-substituent effects (12*b*) on the aryl carbon shieldings of **2**, **3**, **5**, and **6**. The average deviation between the observed and predicted shieldings of all the aromatic carbons of those complexes is 0.6 p.p.m.

We have not determined the relative signs of the $^{13}C—^{195}Pt$ coupling constants; thus, the absolute values of those parameters are provided in Table 3. Needless to say, the use of absolute values of the coupling constants is adequate for the arguments we will present later.

The ^1H n.m.r. data for the new phenylaminocarbene complexes **2–6** are summarized in Table 4. The assignments of the ^1H chemical shifts and J_{PtH} values were based on arguments similar to those used to assign the ^1H n.m.r. parameters of related carbene complexes.

Discussion

The ^{13}C n.m.r. data reveal that with variations in the *para*-substituent —X, characteristic variations in the ^{13}C shieldings and $^{13}C—^{195}Pt$ coupling constants may occur. For example, those parameters for the platinum-methyl (*ca.* −19.1 (±0.2) p.p.m. and *ca.* 318 (±4) Hz), arsenic-methyl (*ca.* 9.3 (±0.1) p.p.m. and *ca.* 50 (±1) Hz, and carbene-methyl (*ca.* 38.2 (0.2) p.p.m. and 46 (2) Hz) carbons are almost invariant. The carbene carbon shieldings are more sensitive and vary from 246.2 to 252.0 p.p.m., over a range of *ca.* 6 p.p.m. In comparison, the carbene carbon shieldings for the related phenylthiocarbene complexes **A** were found to span a range of *ca.* 2.2 p.p.m. (2). The $^1J_{PtC}$ values for the carbene carbons of **2–6**, as well as the $^3J_{PtCNC}$ values for the C_1 aromatic carbons are essentially invariant at *ca.* 686 (±2) and 21 (±1) Hz, respectively. Finally, the shieldings of the aromatic carbons of **2–6** are sensitive to variations in —X, as would be anticipated (12).

Carbene Carbon Shieldings

Our results (2) for the phenylthiocarbenes **A** revealed regular relationships between the σ^+ and σ^n_{para} substituent constants (3) and δ_C (carbene). Accordingly, we have plotted σ^+ *vs.* δ_C (carbene) for the phenylaminocarbene complexes **2–6**, as shown in Fig. 1, and by linear

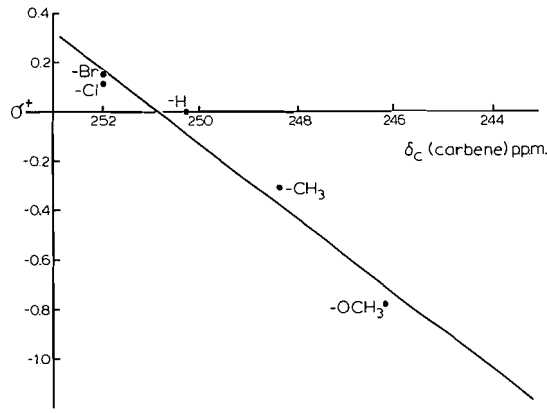

FIG. 1. Plot of σ^+ *vs.* δ_C (carbene) for the phenylaminocarbene complexes **2–6**.

regression analysis obtain eq. 2[3]

$$[2]\quad \sigma^+ = 0.15(\pm 0.01)\delta_C\ (\text{carbene}) - 38.3(\pm 1.5)$$
$$r = 0.983$$

The excellent linear fit indicates that the changes in carbene carbon shieldings are sensitive to the changes in overall ($\sigma + \pi$) electron density induced by variations in the *para*-substituent —X. When the ^{13}C shielding data for the carbene carbons are compared wtih the σ_{para}^n substituent constants, a very similar plot results, except for the point for the methoxyl derivative **6**. For that

[3]The average deviations of the slopes and intercepts for all the linear equations presented here are calculated on the basis of the maximum possible error due to the inherent uncertainty of the experimental measurements. These errors have already been cited in Tables 2 and 3. It is worthwhile noting that these variations represent the maximum error in *precision* and that as such they may be generous estimates.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

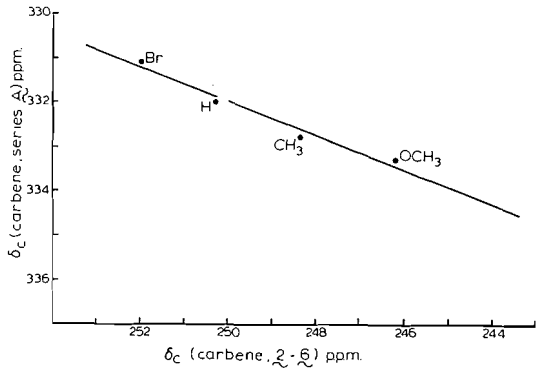

FIG. 2. Plot δ_C (carbene, **A**) *vs.* δ_C (carbene; **2**, **4–6**) for complexes sharing common *para*-substituents —X.

relationship, a poorer linear correlation coefficient ($r = 0.901$) was obtained. Thus, it would appear that the σ^+ parameters provide a better model than the $\sigma_{para}{}^n$ constants for these complexes.

It is particularly interesting to compare the carbene carbon shieldings of analogs of the phenylthio and phenylamino series of complexes. A plot of these data is given in Fig. 2, and eq. 3 provides the linear regression analysis parameters.

$$[3]\quad \delta_C\text{ (carbene, A)} = -0.38(\pm 0.03)\delta_C\text{ (carbene, 2, 4–6)} + 427(\pm 7)$$
$$r = 0.984$$

To our surprise, the carbene carbon shieldings of these series of complexes appear to be *inversely* related. Whereas an increase in the overall electron withdrawing properties of —X causes *shielding* of the carbene carbons in series **A**, it causes a *deshielding* of the carbene carbons in **2–6**. Thus, it would appear that the transmission of electron density through sulfur markedly differs from that through nitrogen, assuming that the change in transition metal and its substituents is of minor importance. We assume that only the degree and not mode of metal–carbene bonding differs between the two series. Since nitrogen can transmit changes in electron density via s and p-orbitals, while sulfur has s, p, and d orbitals available, such a result is not entirely unreasonable. In any event, eq. 3 indicates that both series of complexes regularly reflect changes in electron density at the carbene carbon induced by variations in —X.

In addition, the phenylaminocarbenes carbene carbons follow shielding trends similar, but not identical to the phenylmethoxylcarbenes carbons in **B**. While the slopes of plots of σ^+ *vs.* the shieldings for those carbons of both series are positive, there does not appear to be a relationship between these carbene carbon shieldings for analogous compounds. Thus, the three series of carbene complexes, **A**, **B**, and **2–6**, exhibit markedly different shielding variations at the carbene carbons.

Aryl Carbon Shieldings

Next, we considered the aryl carbon shieldings in order to determine whether any interactions of the carbene carbon with the p-XC_6H_4NH— group were revealed. Thus differences in the bonding of a carbene carbon, which can employ both σ and π bonding, and a proton, which employs only σ bonding, would be reflected in comparisons between the individual aryl carbons of **2–6** and the parent *para*-substituted anilines. The ^{13}C shieldings of those derivatives may be predicted with considerable precision as described in ref. 12*b*. A consideration of the individual substituent effects in the anilines p-$XC_6H_4NH_2$ yields the following shielding data, where C_1 is bound to the NH_2 moiety: —X = —Br, δC_1 145.1, $\delta C_{2,6}$ 117.1, $\delta C_{3,5}$ 133.0, and δC_4 113.4 p.p.m.; —X = —Cl, δC_1 144.8, $\delta C_{2,6}$ 116.7, $\delta C_{3,5}$ 130.0, and δC_4 125.1 p.p.m.; —X, = —H, δC_1 146.7, $\delta C_{2,6}$ 115.4, $\delta C_{3,5}$ 129.6, and δC_4 118.9 p.p.m.; —X = —CH_3, δC_1 143.8, $\delta C_{2,6}$ 115.3, $\delta C_{3,5}$ 130.3, δC_4 127.8 p.p.m.; and —X = —OCH_3, δC_1 139.0, $\delta C_{2,6}$ 116.4, $\delta C_{3,5}$ 115.2, and δC_4 150.3 p.p.m.

First, we note that carbons C_1 of the carbene complexes **2–6** are shielded by an average of *ca.* 5 p.p.m. with respect to the corresponding carbons in the parent *para*-substituted anilines. (Summaries of the qualitative origins of ^{13}C shieldings of aromatic carbons appear in refs. 2 and 10.) Assuming that the neighborhood anisotropies of the nitrogen atoms are similar in both series of compounds, it would appear that there is an appreciable shift of electron density into the aromatic ring from the nitrogen atoms and probably carbene carbon atoms. This may be substantiated by reviewing the shieldings of C_4 in the parent anilines and carbene derivatives.

In contrast, those carbons for **2–6** are *deshielded* by *ca.* 9.5 p.p.m. with respect to the *para*-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

substituted anilines. Thus, it would appear that the assumption that the neighborhood anisotropies of the nitrogen atoms in **2–6** and the *para*-anilines are similar may not be reasonable. In any event, since *para*-carbon shieldings are believed to be mainly governed by resonance effects, it follows that a substantial π-delocalization from the aromatic ring may be occurring. These considerations as well as the correlation described by eq. 2 support the notion that σ and π electron density variations are transmitted from the aromatic ring to the nitrogen and carbene carbon atoms of **2–6**.

Interestingly, the C_1 carbons of the phenylthiocarbene derivatives A are *deshielded* by *ca.* 8 p.p.m. with respect to the parent thiols, in contrast to the C_1 carbons in **2–6** which are *shielded* by *ca.* 5 p.p.m., with respect to the parent anilines. Thus, the two series of complexes again exhibit opposite trends (see eq. 3), presumably arising from the differing electron transmitting properties of the sulfur and nitrogen hetero atoms.

^{13}C—^{195}Pt Coupling Constants

The insensitivity of the ^{13}C—^{195}Pt coupling constants obtained for **2–6**, with regard to variations in the *para*-substituent —X, is quite reasonable when it is noted that the changes in electron density at C_1 and the carbene carbon should arise mainly via changes in π-electron density. Moreover, we have previously shown that many ^{13}C—^{195}Pt coupling constants do not appear to be sensitive to π-bonding in bonds between the coupling nuclei (10, 13), but only to changes in σ-hybridization. Since the changes in σ-electron density at C_1 and the carbene carbon are likely very small, we would anticipate that both $^1J_{PtC}$ (carbene) and $^3J_{PtCNC}$ would be almost invariant, as we observe.

We have previously shown that there exists a marked stereochemical dependence of the $^3J_{PtCNC}$ values in alkylamino carbenes (1). While it is difficult to predict the stereochemical disposition of the *para*-substituted phenyl groups in **2–6** without recourse to further data, the constancy of the $^3J_{PtCNC}$ values at *ca.* 21 (±1) Hz at least indicates that these complexes probably have similar geometries in solution. Fortunately, the ^1H n.m.r. data allows us to determine which isomer about the carbene carbon – nitrogen bond predominates.

^1H Nuclear Magnetic Resonance Parameters

Like their ^{13}C counterparts, the ^1H n.m.r. parameters for the platinum-methyl, arsenic-methyl, and carbene-methyl groups apparently vary randomly within narrow ranges. However, the magnitudes of the $^3J_{HCNH}$ values merit comment. By ^1H n.m.r. studies, Moser and Fischer (14) have shown that analogous complexes of the sort p-$XC_6H_4NH(CH_3)CCr(CO)_5$, **C**, favor the isomer in which the *para*-substituted phenyl ring is *cis* to the carbene methyl group. Those complexes exhibit a $^3J_{HCNH}$ value of 1.0 (±0.1) Hz, identical to those ^1H—^1H coupling constants we have observed for **2–6**. Since the complexes of series **C** provide good n.m.r. models for **2–6** (1), it would appear that the substituted phenyl groups in the latter complexes also adopt *cis* orientations with respect to the carbene-methyl groups.

We thank the National Research Council of Canada for financial support of this project and for an award of an NRCC postdoctoral fellowship to J.E.H.W.

An X-Ray Study of the Synthetic Intermediate 9-Cyano-1,10-dimethyl-6-ethylenedioxy-1-octalin

HARRY LYNTON AND PIK-YUEN SIEW

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received March 19, 1974

HARRY LYNTON and PIK-YUEN SIEW. Can. J. Chem. **53**, 192 (1975).

The crystal structure of the synthetic intermediate, 9-cyano-1,10-dimethyl-6-ethylenedioxy-1-octalin, $C_{15}H_{21}O_2N$, was solved by direct methods. The compound crystallizes in the space group $P2_1/c$ with cell dimensions $a = 12.282(4)$, $b = 7.144(3)$, $c = 15.619(5)$ Å, $\beta = 104.04(1)°$. Refinement was carried out isotropically for hydrogen and anisotropically for non-hydrogen atoms using full matrix least squares to an R-value of 0.043 for 1669 observed reflections.

This compound, which has a *cis* configuration at the octalin ring junction, is a precursor to a moiety of the alkaloid thelepogine. The *cis* conformation is essential for total synthesis of thelopogine by this route.

HARRY LYNTON et PIK-YUEN SIEW. Can. J. Chem. **53**, 192 (1975).

On a résolu par des méthodes directes la structure cristalline de l'intermédiaire de synthèse, cyano-9 diméthyl-1,10 éthylènedioxy-6 octaline-1, $C_{15}H_{21}N_2O$. Le composé cristallise dans le groupe d'espace $P2_1/c$ avec des dimensions de mailles $a = 12.282(4)$, $b = 7.144(3)$, $c = 15.619(5)$ Å, $\beta = 104.04(1)°$. On a fait un affinement isotropique pour les atomes d'hydrogène et anisotropique pour les autres atomes; on a utilisé la méthode des moindres carrés (matrice complète) jusqu'à une valeur R de 0.043 pour les 1669 réflections observées.

Ce composé qui possède une configuration *cis* à la jonction des cycles de l'octaline, est un précurseur pour une portion de l'alcaloide thélépogine. Cette conformation *cis* est essentielle pour la synthèse de la thélépogine par ce schéma. [Traduit par le journal]

Introduction

Thelepogine, a diterpenoid alkaloid extracted from the grass species *thelepogon elegam* (1, 2), has been identified together with other alkaloids in investigations primarily concerned with the use of a variety of grasses as pasture materials.

Compound **2** represents a moiety of the novel structure found for thelepogine (**1**). It is therefore of interest as a possible intermediate in a total synthesis of the alkaloid. Recently, a total synthesis of compound **2** was completed (3) through the precursor 9-cyano-1,10-dimethyl-6-ethylenedioxy-1-octalin (**3**). Before utilizing compound **2** for further work, it was essential to ensure that the stereochemistry at the octalin ring junction was the same as in the alkaloid (4). Unfortunately, neither the stereochemistry of compound **2** nor any of its precursors could be ascertained with confidence by spectroscopic means. As compound **2** does not itself form crystals suitable for X-ray structure analysis, the precursor compound **3** was chosen. Compound **3** is convertible into compound **2** in four steps by a method which does not affect the stereochemistry at the ring junction.

Experimental

The crystal data are as follows:

$C_{15}H_{21}O_2N$ m.w. = 237.34

Monoclinic, $a = 12.282(4)$, $b = 7.144(3)$, $c = 15.619(5)$ Å, $\beta = 104.04(1)°$, $V = 1329.45$ Å^3, $Z = 4$, $p_c = 1.34$ g cm^{-3} (22 °C, MoKα_1, $\lambda = 0.7093$ Å).

The unit cell dimensions and their estimated standard deviations (in parentheses) were obtained from a least squares evaluation of the angular settings of 12 independent reflections. The space group is $P2_1/c$ (C_{2h}^5) No. 14 in ref. 5.

The crystals are translucent, stable at room temperature and with respect to prolonged humidity and X-rays.

A crystal of size 0.44 × 0.44 × 0.32 mm^3 was mounted with the a axis along the ϕ direction of the Picker, computer-controlled, four-angle diffractometer. Intensity data were collected with graphite monochromated MoKα_1 radiation and a scintillation detector using a $\theta/2\theta$ scan. Four octants hkl, $h\bar{k}l$, $\bar{h}kl$, and $\bar{h}\bar{k}l$, were explored to a 2θ maximum of 50°. In this region there were 2364 independent reflections of which 1669 were con-

sidered observed. The threshold was taken as 10% of the background or 20 counts, whichever was the higher; a scan speed of 1°/min was used with a scan range of 2.2°. The background was measured for 20 s at each end of the range. Data were also corrected against two standard reflections taken at intervals of 25 readings. The linear absorption coefficient for MoKα radiation is 0.872 cm^{-1}. No corrections were made for absorption or extinction.

Structure Analysis

From an E-map computed with phases established by the method of symbolic addition (6), coordinates were obtained for the twelve best defined peaks, all in general positions (4e). Based on the phases using these positions, a Fourier synthesis was computed from which coordinates for the remaining non-hydrogen atoms were established in general positions.

Refinement was carried out isotropically, then anisotropically by full matrix least squares for each of the atoms. The R-value for observed reflections was then 0.103. Scattering factor curves used were those given in ref. 7. The weighting scheme used was $1/w = 1 + [(|F_o| - P_2)/P_1]^2$ with $P_1 = 9.7$ and $P_2 = 19.7$.

From a difference synthesis, coordinates were established for the 21 hydrogen atoms in general positions. Each of these hydrogen atoms was first assigned the isotropic temperature factors of the carbon atoms to which it is attached. Full matrix least squares refinement was then carried out isotropically for hydrogen and anisotropically for non-hydrogen atoms to a final R-value of 0.043. In the final refinement cycle, no parameter shift/estimated standard deviation ratio exceeded 0.44 for hydrogen and 0.27 for other atoms. A final difference synthesis showed no residual peaks greater than 0.1 e Å^{-3}.

A list of the observed and calculated structure factors for the parameters as listed in Tables 1 and 2 has been placed in the Depository of Unpublished Data.[1] Bond distances and angles are given in Fig. 1. The stereochemistry of the molecule is shown in Fig. 2.

Discussion

The decrease in the residual R, obtained by inclusion of the refined hydrogen parameters, is significant by Hamilton's test (8) at the 0.005 (0.5%) level.

The C—H bond lengths range from 0.96–1.02 Å, e.s.d. 0.02 Å, and are comparable with many other values reported in the literature. C(14)—H(18) 1.04(4) Å and C(14)—H(19) 0.92(3) Å are outside this range, but are calculated for atoms with large thermal parameters and are consequently less reliable. H—C—C bond angles range 115–120° for carbon atoms

H(18)	−8(3)	643(5)	252(2)	110(11)
H(19)	112(2)	672(5)	314(2)	74(9)
H(20)	176(2)	839(3)	216(1)	33(6)
H(21)	45(2)	849(4)	158(1)	42(7)

with sp^2 hybridization and 105–114° for sp^3 carbons. Estimated standard deviations are 1–2°. The H(14)—C(11)—C(1) bond angle is exceptionally large, 117°.

All the C—C single bond distances are in the range 1.504–1.563 Å, except for the short C(9)—C(12) 1.483 Å adjacent to the C(12)—N triple bond 1.138 Å, C(2)—C(3) 1.493 Å adjacent to the C(1)—C(2) double bond 1.322 Å and C(14)—C(15) 1.495 Å in the five membered ring. These short bonds probably result from partial transfer of electrons from adjacent multiple bonds, and in the case of C(14)—C(15) distortion in the five membered ring. The C—O bond lengths range from 1.402–1.429 Å. All bond lengths are within the limits reported for other compounds with similar molecular moieties. All non-hydrogen bonds have e.s.d. of 0.003 Å. Bond angles for non-hydrogen atoms range 117.0–125.5° for trigonal situations, 104.4–108.5° for tetrahedral in the five membered ring and 104.7–117.0° elsewhere, e.s.d. being 0.2°. Except where ring strain is present these correspond with expected values of 120° and 109.5°. The C(9)—C(12)—N bond angle is 178.2(4)°, very close to linear.

The three ring system of this structure consists of an octalin fused ring system with an ethylenedioxy moiety at C(6). The cyanide group at C(9) and the methyl group at C(10) are *cis* to each other. This configuration is the same as in the alkaloid thelepogine, and allows the possibility of a total synthesis of the alkaloid by this route.

We wish to thank Dr. R. B. Kelly for the crystals and for suggesting the problem, the National Research Council of Canada for financial support. We also thank Dr. J. M. Stewart of the University of Maryland for use of his computer programs.

Reactions of Ketene Acetals. III.[1] A New Synthesis of α-Pyrones. II[2]

ALAIN BÉLANGER AND PAUL BRASSARD
Département de Chimie, Université Laval, Québec, Québec G1K 7P4

Received November 27, 1973[3]

ALAIN BÉLANGER and PAUL BRASSARD. Can. J. Chem. **53**, 195 (1975).

The cycloaddition of chloroketene acetals to α,β-unsaturated aldehydes and ketones gives the corresponding 2,2-dialkoxy-3-chloro-3,4-dihydro-1,2-pyrans. Treatment of these compounds with alkoxides in dimethylsulfoxide or dimethylformamide yields α-pyrones directly. Some intermediates and by-products have been identified and the reaction conditions have been studied.

ALAIN BÉLANGER et PAUL BRASSARD. Can. J. Chem. **53**, 195 (1975).

La cycloaddition des acétals du chlorocétène aux aldéhydes et cétones α,β-insaturés donne les dialcoyloxy-2,2 chloro-3 dihydro-3,4 pyrannes-1,2 correspondants. En présence d'alcoolates dans le diméthylsulfoxyde ou le diméthylformamide, ces substances se transforment directement en α-pyrones. Quelques intermédiaires et sous-produits de la réaction sont identifiés et les conditions expérimentales étudiées.

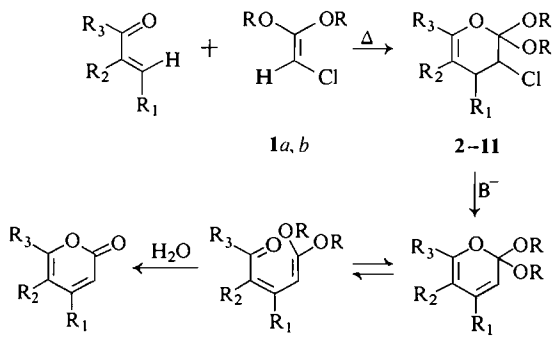
The convenient synthesis of dihydropyrans from enals or enones and ketene acetals devised by McElvain *et al.* (1) seemed, with some modification, to provide an interesting basis for a new and simple synthesis of α-pyrones (Scheme 1). 3-Chloro-3,4-dihydro-1,2-pyrans have now been prepared (by the cycloaddition of chloroketen acetals to α,β-unsaturated carbonyl compounds) and are easily converted to the corresponding aldehydo or keto esters. However all attempts to eliminate hydrogen chloride from the latter by various means yielded only starting material, cyclopropanes or complex mixtures of unidentified products. Eventually it was found that the dehydrohalogenation of the chlorodihydropyrans by sodium methoxide in dimethylsulfoxide gave the α-pyrones directly. This paper describes the preparation of a number of alkyl and aryl α-pyrones; the use of β-functionalized enones and a discussion of the mecanism are reported in the companion article.



SCHEME 1

The Preparation of 2,2-Dialkoxy-3-chloro-3,4-dihydro-1,2-pyrans

These dihydropyrans were prepared in moderate yields (27–66%) by heating the α,β-unsaturated aldehyde or ketone and an excess of chloroketene dialkyl acetal (1.5 equiv.) at 82–155° for 0.5–105 h, generally in a sealed tube. With the exception of the 4-phenyl and 4,6-diphenyl derivatives, the chlorodihydropyrans are viscous substances; all are relatively unstable, become rapidly discolored, and most do not give satisfactory analyses. The liquid compounds show a slight absorption at about 1740 cm^{-1} in their i.r. spectra, probably due to decomposition products (not detected by n.m.r. spectroscopy) which could not be eliminated by the usual means. After distillation, these were converted directly to the α-pyrones without further purification.

The chlorodihydropyrans can be conveniently characterized by spectroscopic means; they all show an intense band between 1655 and 1700 cm^{-1} due to the enol ether double bond and generally four typical peaks between 1145 and 980 cm^{-1} for the orthoester group. Nuclear magnetic resonance gives characteristic spectra

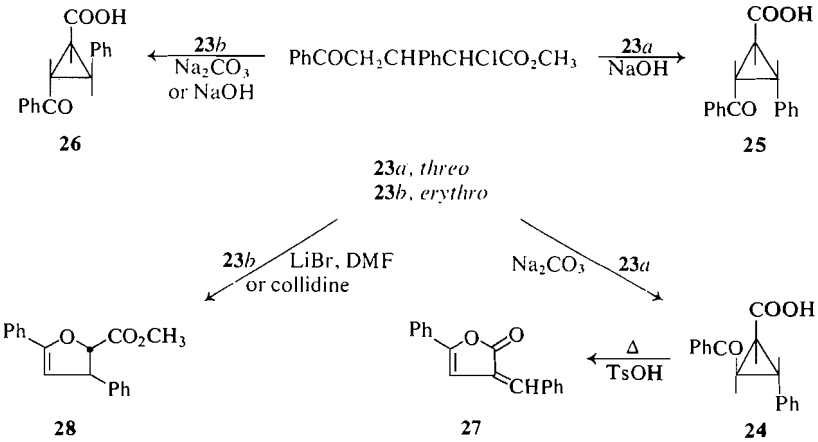

SCHEME 2

for these compounds with signals at δ 4.10–4.55 (3-CH), 2.45–2.70 (4-CH_2), 4.50–5.60 (5-CH), and 6.10–6.45 (6-CH) with the appropriate coupling constants. The compounds substituted in the 4 position can give diastereoisomeric mixtures and these are present for the 4-propyl (**3**, **4**) and 4,6-diphenyl (**7**) derivatives. Only one isomer is observed, however, in the reaction mixtures of products **5** and **6**. In each case, the configurations are assigned on the basis of the expected coupling constants for the most stable conformation. The magnitude of the coupling constants for the protons in positions 3 and 4 (J = 4.5 and 10.5 Hz) seems to indicate, in spite of the limited number of observations, that these substances assume essentially rigid conformations (equatorial 3-CH and pseudo-axial 4-CH for the *cis*-isomers; axial 3-CH and pseudo-axial 4-CH for the *trans*); this also seems confirmed in one case (**7***b*) by the existence of long-range coupling between the protons in the 3 and 5 positions).

The Hydrolysis of Chlorodihydropyrans and the Attempted Dehydrohalogenation of the Corresponding Esters

The acid hydrolysis of 2,2-diethoxy-3,4-dihydro-1,2-pyrans under mild conditions is known to yield the corresponding δ-oxo esters (1). The 3-chloro derivatives have now been found to behave in an analogous way; in particular *cis*- and *trans*-3-chloro-4,6-diphenyl-3,4-dihydro-1,2-pyran give the *erytho*- and *threo*-4-benzoyl-2-chloro-3-phenylbutanoates, respectively. This conclusion is confirmed by n.m.r. data, the relative magnitude of the constants for the coupling between the protons in 3 and 4 ($J_{erythro} > J_{threo}$) being such as predicted (2).

Dehydrohalogenations at this stage were attempted by various means using the *erythro*-ester **23***b*. Silver nitrate in boiling methanol gives several products, none of which seems to be the expected substance. Lithium bromide in dimethylformamide and *s*-collidine at 140° both give a principal product tentatively identified as *trans*-2-carbomethoxy-3,5-diphenyl-3,4-dihydrofuran (ν_{max} 1750 cm^{-1}; δ ($CDCl_3$) 3.79 s (CO_2CH_3), 4.48 dd (J = 3.0, 6.0 Hz) (3-CH), 4.99 d (J = 6.0 Hz) (2-CH), 5.5 d (J = 3.0 Hz) (4-CH) 7.10–7.90 m (aromatic CH)) (3).

Bases such as sodium carbonate and hydroxide produced only cyclopropanecarboxylic acids, the configurations of which are well known (4). Some of these reactions are highly stereospecific; thus the *threo*-ester **23***a* in the presence of carbonate gives *cis*-3-benzoyl-*trans*-2-phenylcyclopropanecarboxylic acid (**24**) while hydroxide yields the epimerized *trans*,*trans*-isomer **25**. As expected, the *erythro*-ester **23***b*, with both reagents forms the same product, the *trans*,*cis*-acid **26** (Scheme 2).

An attempt to rearrange the cyclopropanecarboxylic acid **24** by heating it in the presence of *p*-toluenesulfonic acid gave a product which on spectroscopic and analytical grounds is thought to be α-benzal-γ-phenylcrotonolactone (**27**).

The Preparation of α-Pyrones (Scheme 1)
4-Aryl; 4,6-Diaryl; and 4,5,6-Trialkyl-α-pyrones

The compounds are formed quite straight forwardly from the corresponding chlorodihydro-

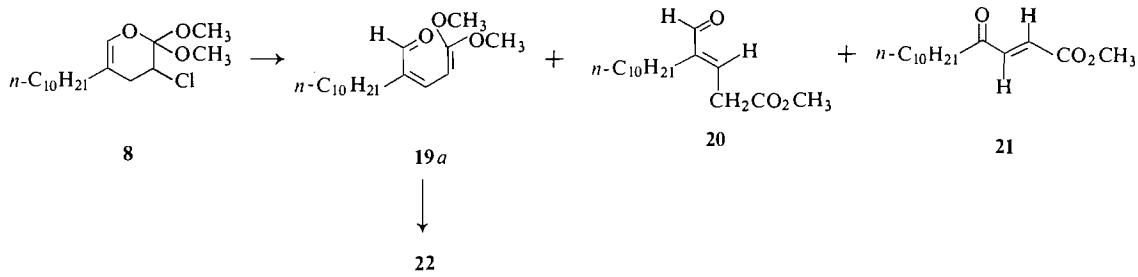

SCHEME 3

pyrans using 4.5 equiv. of sodium methoxide in dimethylsulfoxide. The yields are excellent (72–85%) and no by-products are detected (method A).

4- and 6-Alkyl-α-pyrones

α-Pyrone and the 6-methyl derivative could not be prepared by the foregoing procedure and their intermediates are thought to be unstable under these conditions. The 4-propyldihydropyran **3** was inert to methoxide but potassium *t*-butoxide gave a low yield of the α-pyrone **15** along with a very small quantity of a by-product which probably is one of the corresponding 4-formylbutenoic esters (method B).

6-Aryl-α-pyrones

Under the usual conditions, 6-phenyl-α-pyrone (**11**) is obtained in low yield (15%) and numerous variations of the method were devised in order to improve the efficiency of the reaction and to gain some insight into the nature of the process. Sodium hydroxide was found to be inactive and potassium *t*-butoxide did not raise the yield. By replacing the usual solvent by the lower-melting dimethylformamide and carrying out the reaction at −10°, a good yield of the naturally occurring 6-phenyl-α-pyrone (**18**) was obtained along with appreciable amounts of two esters. The pyrone can be isolated by chromatography on Florisil which retains the by-products. The mixture of esters can be isolated by the use of silica gel activity I with the concomitant decomposition of the pyrone. The by-products appear to be the methyl *trans*-4-benzoylbut-2- and 3-enoates and could not be separated by chromatography (method C).

5-Alkyl-α-pyrones (Scheme 3)

Compounds of this type were considered of particular interest since they have the substitution characteristics of steroidal dienolides. 3-Chloro-5-*n*-decyl-3,4-dihydro-1,2-pyran (**8**), under the usual conditions (4.5 equiv. of methoxide in DMSO at 25°) gave as principal product methyl *trans*-4-formyltetradeca-3-en-1-oate (**20**) and a low yield of the α-pyrone **22**. No reaction is observed when either potassium *t*-butoxide at −5° or sodium methoxide in dimethylformamide at 25° are used.

A slight modification of the work-up process produced an unexpected result. By adding ice to the reaction mixture instead of pouring it into water, the oxidation product **21** is obtained besides the usual aldehydo ester **20**. The use of larger amounts of base (8 equiv.) gives a new type of product in a moderate yield (55%); this was eventually identified as 2-*n*-decyl-5,5-dimethoxypenta-2,4-dien-1-al (**19***a*), an unstable substance which undergoes spontaneous and almost quantitative rearrangement to the α-pyrone (probably in the presence of moisture) (method D).

α-Pyrones from Chlorodiethoxydihydropyrans

The dimethyl acetal of chloroketene was used throughout this investigation in order to simplify the n.m.r. spectra of the reaction mixture which are often complex. Since the diethyl derivative is more readily accessible, an attempt was made to compare the efficiency of both acetals. The analogous chlorodihydropyrans are obtained in comparable yields but seem to be less stable than the dimethoxy derivatives. In the case of the 5-*n*-decyl compound **9**, a similar amount of the pentadienal **19***b* is produced but the rearrangement to the α-pyrone is much less efficient (17%). The same results are observed in the case of the 4-propyl derivatives **4***a*,*b*.

Experimental

The melting points were taken in capillary tubes using a calibrated thermometer (Thomas-Hoover Apparatus). The i.r. spectra were recorded on a Beckman IR-12 instrument, u.v. spectra on a Beckman DK-1A spectropho-

tometer and the n.m.r. on a Varian A60 spectrometer with tetramethylsilane as internal standard.

3-Chloro-2,2-dialkoxy-3,4-dihydro-1,2-pyrans

General Method

The α,β-unsaturated aldehyde or ketone, the chloroketen dialkyl acetal **1***a,b* (1.5 equiv.) (5,6), and hydroquinone (1–5 mg) are placed in a glass tube which is flushed with nitrogen, sealed, and heated. The excess acetal and the volatile by-products are then evaporated under vacuum and the dihydropyran is distilled or crystallized from the appropriate solvent. The distilled products contain small amounts of impurities and must be converted immediately to the α-pyrones:

3-Chloro-2,2-dimethoxy-3,4-dihydro-1,2-pyran (**2**) from acrolein (4.0 g) and **1***a* (125°, 3 h), b.p. 90–92°/12 mm (56%); ν_{max} (film) 1665, 1130, 1090, 1050, 1030 cm^{-1}; δ (neat) 2.50 m (4-CH_2), 3.30 and 3.32 2s (2,2-OCH_3) 4.32 t (J = 6.0 Hz) (3-CH), 4.75 dt (J = 3.5, 6.0 Hz) (5-CH), 6.25 dt (J = 2.0, 6.0 Hz) (6-CH).

cis- and *trans*-3-Chloro-2,2-dimethoxy-4-propyl-3,4-dihydro-1,2-pyran (**3***a,b*) from *trans*-hex-2-enal (3.0 g) and **1***a* (145°, 72 h), b.p. 110–130°/7 mm (39%); ν_{max} (film) 1660, 1140, 1090, 1060 cm^{-1}; δ ($CDCl_3$) 0.85–1.10 m (4-$(CH_2)_2CH_3$), 1.30–1.60 m (4-$(CH_2)_2CH_3$), 3.31, 3.32, 3.40, and 3.42 4s (2,2-OCH_3), 4.00–4.25 m (3-CH), 4.50–4.75 m (5-CH), 6.22 dd (J = 3.0, 6.5 Hz) (6-CH).

cis- and *trans*-3-Chloro-2,2-diethoxy-4-propyl-3,4-dihydro-1,2 pyran (**4***a,b*) from *trans*-hex-2-enal (3.0 g) and **1***b* (150°, 72 h), b.p. 105–116°/7 mm (39%); ν_{max} (film) 1660, 1110, 1090, 1050 cm^{-1}; δ ($CDCl_3$) 0.90–1.15 m (2,2-OCH_2CH_3 and 4-$(CH_2)_2CH_3$), 1.15–1.60 m (4-$(CH_2)_2CH_3$), 3.71 q (J = 7.0 Hz) (2,2-OCH_2CH_3), 4.00–4.25 m (3-CH), 4.50–4.80 m (5-CH), 6.24 dd (J = 3.0, 6.0 Hz) (6-CH).

cis-3-Chloro-4-ethyl-2,2-dimethoxy-3,4,5,6,7,8-hexahydro-1,2-benzopyran (**5**) from 2-propylidenecyclohexanone (5.0 g) (b.p. 89–90°/8 mm) (7) and **1***a* (150°, 105 h), b.p. 80–90°/0.01 mm (27%); ν_{max} (film) 1698, 1150, 1120, 1065, 1000 cm^{-1}; δ ($CDCl_3$) 0.95 t (J = 7.0 Hz) (4-CH_2CH_3), 1.50–2.50 m (4-CH_2CH_3 and 5,6-$(CH_2)_4$-, 3.40 and 3.42 2s (2,2-OCH_3), 4.28 d (J = 4.5 Hz) (3-CH). (This product contains a small amount of the *trans*-isomer, δ 4.18 d (J = 9.0 Hz) (3-CH).)

trans-3-Chloro-2,2-dimethoxy-4-phenyl-3,4-dihydro-1,2-pyran (**6**) from cinnamaldehyde (6.0 g) and **1***a* (150°, 72 h), b.p. 95–96°/1.0 mm (43%), m.p. 106–107° (ether); ν_{max} (KBr) 1662, 1610, 1120, 1070, 1040, 1020 cm^{-1}; δ ($CDCl_3$) 3.46 and 3.49 2s (2,2-OCH_3), 3.85 m (4-CH), 4.22 d (J = 10.0 Hz) (3-CH), 4.89 dd (J = 2.5, 6.0 Hz) (5-CH), 6.42 dd (J = 2.5, 6.0 Hz) (6-CH), 7.38 s (4-C_6H_5).

Anal. Calcd. for $C_{13}H_{15}ClO_3$: C, 61.41; H, 5.90. Found: C, 61.31; H, 5.93.

trans-3-Chloro-2,2-dimethoxy-4,6-diphenyl-3,4-dihydro-1,2-pyran (**7***a*) from benzalacetophenone (6.0 g) and **1***a* (150°, 72 h), m.p. 125–126° (ether – petroleum ether, b.p. 30–60°) (36%); ν_{max} (KBr) 1655, 1600, 1580, 1145, 1110, 1005, 980 cm^{-1}; δ ($(CD_3)_2CO$) 3.48 and 3.53 2s (2,2-OCH_3), 3.95 dd (J = 2.5, 10.5 Hz) (4-CH), 4.52 d (J = 10.5 Hz) (3-CH), 5.51 d (J = 2.5 Hz) (5-CH), 7.25–7.85 m and 7.40 s (4,6-C_6H_5).

Anal. Calcd. for $C_{19}H_{19}ClO_3$: C, 69.00; H, 5.74. Found: C, 69.08; H, 5.71.

cis-3-Chloro-2,2-dimethoxy-4,6-diphenyl-3,4-dihydro-1,2-pyran (**7***b*), m.p. 79–80° (ether – petroleum ether, b.p. 30–60°) (21%); ν_{max} (KBr) 1655, 1605, 1115, 1072, 1060, 1025 cm^{-1}; δ ($CDCl_3$) 3.45 and 3.51 2s (2,2-OCH_3), 4.31–4.53 (AB part of an ABX system; J = 1.5, 2.0, 4.5 Hz) (3,4-CH), 5.59 dd (J = 1.5, 2.0 Hz) (5-CH), 7.25–7.90 m and 7.42 s (4,6-C_6H_5).

Anal. found: C, 68.94; H, 5.59.

2-*n*-Decylacrolein. A mixture of lauraldehyde (20.0 g), dimethylamine hydrochloride (14.0 g), and formaldehyde (30 ml of a 37% aqueous solution) is stirred at 75° for 24 h and then steam-distilled. After extraction of the distillate with ether and evaporation of the solvent, the residue is fractionated under vacuum and gives 2-*n*-decylacrolein, b.p. 70–75°/0.1 mm (79%); λ_{max} (ethanol) 218 nm (log ε 4.10); ν_{max} (film) 3090, 2700, 1700, 1630 cm^{-1}; δ ($CDCl_3$) 0.98 (CH_3), 1.32 bs ($(CH_2)_9$), 6.01 s (*trans*-C=CH) 6.28 s (*cis*-C=CH), 9.63 s (CHO). Semicarbazone, m.p. 145–146° (ethanol).

Anal. Calcd. for $C_{14}H_{27}ON_3$: C, 66.36; H, 10.74; N, 16.58. Found: C, 66.25; H, 10.97; N, 16.35.

3-Chloro-5-*n*-decyl-2,2-dimethoxy-3,4-dihydro-1,2-pyran (**8**) from 2-*n*-decylacrolein (10.0 g) and **1***a* (150°, 24 h), b.p. 100–120°/0.01 mm (48%) ν_{max} (film) 1680, 1125, 1070 cm^{-1}; δ ($CDCl_3$) 0.91 ~ t (J = 6.0 Hz) (5-$(CH_2)_9CH_3$), 1.30 s (5-$CH_2(CH_2)_8CH_3$), ~1.90 m (5-$CH_2(CH_2)_8CH_3$), 2.51 m (4-CH_2), 3.38 and 3.43 2s (2,2-OCH_3), 4.32 t (J = 5.5 Hz) (3-CH), 6.13 bs (6-CH).

3-Chloro-5-*n*-decyl-2,2-diethoxy-3,4-dihydro-1,2-pyran (**9**) from 2-*n*-decylacrolein (3.0 g) and **1***b* (155°, 24 h), b.p. 127–137°/0.08 mm (49%); ν_{max} (film) 1670, 1120, 1100, 1050 cm^{-1}; δ ($CDCl_3$) 0.80–1.00 m (2,2-OCH_2CH_3 and 5-$(CH_2)_9CH_3$), 1.27 s (5-$CH_2(CH_2)_8CH_3$), ~ 1.90 m (5-$CH_2(CH_2)_8CH_3$), 2.49 m (4-CH_2), 3.67 and 3.72 2 q (J = 7.0 Hz) (2,2-OCH_2CH_3), 4.27 t (J = 5.5 Hz) (3-CH), 6.10 bs (6-CH).

3-Chloro-2,2-dimethoxy-6-methyl-3,4-dihydro-1,2-pyran (**10**) from methyl vinyl ketone (5.7 g) and **1***a* (82°, 1.5 h), b.p. 72–74°/12 mm (60%); ν_{max} (film) 1670, 1120, 1100, 1040, 1020 cm^{-1}; δ (CCl_4) 1.79 m (6-CH_3), 2.45 m (4-CH_2), 3.32 and 3.37 2s (2,2-OCH_3), 4.22 t (J = 5.5 Hz) (3-CH), 4.52 m (5-CH).

3-Chloro-2,2-dimethoxy-6-phenyl-3,4-dihydro-1,2-pyran (**11**) from acrylophenone (4.8 g) (b.p. 100–105°/10 mm) (8) and **1***a* (150°, 24 h; 100°, 0.5 h), b.p. 122–128°/1.2 mm (66, 58%); ν_{max} (film) 1665, 1600, 1580, 1125, 1095, 1050, 1020 cm^{-1}; δ ($CDCl_3$) 2.69 dt (J = 4.0, 5.5 Hz) (4-CH_2), 3.40 and 3.45 2s (2,2-OCH_3), 4.32 t (J = 5.5 Hz) (3-CH), 5.37 t (J = 4.0 Hz) (5-CH), 7.25–7.75 m (6-C_6H_5).

Hydrolysis of 3-Chloro-2,2-dimethoxy-3,4-dihydro-1,2-pyrans and Attempted Dehydrohalogenation of the Corresponding Esters

Hydrolysis

Methyl threo-4-benzoyl-2-chloro-3-phenylbutanoate (**23***a*). *trans*-3-Chloro-2,2-dimethoxy-4,6-diphenyl-3,4-dihydro-1,2-pyran (**7***a*) (700 mg) in aqueous HCl (20 ml; 1.0 *N*) was heated on a water bath for 2 h. Extraction of the solution with ether gave the *threo*-ester **23***a* (510 mg), m.p. 45–46° (ether – petroleum ether, (b.p. 30–60°); ν_{max} (KBr) 1748, 1685, 1600, 1585 cm^{-1}; δ ($CDCl_3$) 3.58 d (J = 2.5 Hz) (4-CH_2), 3.68 s (CO_2CH_3), 4.20 dd (J = 2.5, 6.0 Hz)

(3-CH), 4.90 d (J = 6.0 Hz) (2-CH), 7.32 s, ~ 7.55 and ~ 8.00 2 m (aromatic CH).

Anal. Calcd. for $C_{18}H_{17}ClO_3$: C, 68.25; H, 5.37. Found: C, 68.22; H, 5.45.

Methyl erythro-4-benzoyl-2-chloro-3-phenylbutanoate (*23b*). A mixture of the *cis*-isomer 7*b* (300 mg), methanol (5 ml), water (10 ml) and concentrated HCl (1.0 ml) was refluxed for 30 min. On cooling, the *erythro*-acid **23***b* crystallized (215 mg), m.p. 99–100°; ν_{max} (KBr) 1735, 1682, 1600 cm^{-1}; δ ($CDCl_3$) 3.58 s (CO_2CH_3), 3.70 d (J = 3.5 Hz) (4-CH_2), 4.15 dd (J = 3.5, 7.5 Hz) (3-CH), 4.62 d (J = 7.5 Hz) (2-CH), 7.30 s, ~ 7.50 and ~ 7.95 2 m (aromatic CH).

Anal. found: C, 68.17; H, 5.53.

Formation of Cyclopropanecarboxylic Acids

The methyl ester **23***a* or *b* (200 mg) was stirred for 1 h in an aqueous solution (5 ml) of the appropriate base, which was then further diluted with water, extracted with ether, acidified, and again extracted with ether:

cis-3-Benzoyl-*trans*-2-phenylcyclopropanecarboxylic acid (**24**) from **23***a* and Na_2CO_3 (600 mg), m.p. 173–174° (ether – petroleum ether, b.p. 30–60°) (148 mg) (lit. (4) m.p. 174–175°); ν_{max} (KBr) 1695, 1678, 1600, 960 cm^{-1}; δ ($CDCl_3$) 2.58–3.54 (ABC system) (1,2,3-CH), 7.48 s, ~7.60 and ~8.15 2 m (aromatic CH), 10.80 s (COOH).

trans-3-Benzoyl-*trans*-2-phenylcyclopropanecarboxylic acid (**25**) from **23***a* and NaOH (50 mg), m.p. 151–152° (ether – petroleum ether) (77 mg) (lit. (4) m.p. 152–153°); ν_{max} (KBr) 1695, 1670, 1600, 1010 cm^{-1}; δ ($CDCl_3$) 3.08–3.82 (ABC system) (1,2,3-CH), 7.25 s, ~7.45 and ~8.00 2 m (aromatic CH), 11.50 s (COOH).

trans-3-Benzoyl-*cis*-2-phenylcyclopropanecarboxylic acid (**26**) from **23***b* and Na_2CO_3 (600 mg) or NaOH (50 mg), m.p. 134–135° (ether – petroleum ether) (30 and 74 mg) (lit. (4) m.p. 136–137°); ν_{max} (KBr) 1708, 1680, 1600, 1015 cm^{-1}; δ ($CDCl_3$) 2.78 dd (J = 5.0, 10.0 Hz), 3.28 dd (J = 7.0, 10.0 Hz) and 3.80 dd (J = 5.0, 7.0 Hz) (1,2,3-CH), 7.58 s, ~7.60 and ~8.15 2 m (aromatic CH), 10.60 s (COOH).

α-Benzal-γ-phenylcrotonolactone (**27**). A mixture of *cis*-3-benzoyl-*trans*-2-phenylcyclopropanecarboxylic acid (**24**) (190 mg), *p*-toluenesulfonic acid (2 mg) and benzene (40 ml) was refluxed for 3 h, poured in water and extracted with ether. The ethereal phase after extraction with an aqueous solution of $NaHCO_3$ gave **16**, m.p. 149–150° (preparative t.l.c.; benzene) (ether – petroleum ether, b.p. 30–60°) (lit. (9) m.p. 155°); λ_{max} (ethanol) 250, 384 nm (log ε 4.31, 4.37); ν_{max} (KBr) 1790–1785, 1630, 1600, 1590 cm^{-1}; δ ($CDCl_3$) 7.00 s (4-CH), ~ 7.70 m (3-CHC_6H_5 and 5-C_6H_5).

Anal. Calcd. for $C_{17}H_{12}O_2$: C, 82.25; H, 4.85. Found: C, 82.18; H, 4.95.

α-Pyrones

Method A

A solution of the chlorodihydropyran **5**, **6**, or 7*a* and sodium methoxide (4.5 equiv.) in anhydrous dimethylsulfoxide was stirred at room temperature for 24 h under nitrogen, then poured into a mixture of ice and water and extracted with ether.

4-Ethyl-5,6,7,8-tetrahydrocoumarin (**12**) from **5** (1.3 g) (50 ml of DMSO), m.p. 80–81° (ether – petroleum ether, b.p. 30–60°) (the mother liquor from this crystallization was chromatographed on silica gel (30 g) using a mixture of benzene and ether (4:1) as eluant) (78%); λ_{max} (ethanol) 245, 265 (sh) nm (log ε 4.18, 4.12); ν_{max} (KBr) 1705, 1640, 1560 cm^{-1}; δ ($CDCl_3$) 1.21 t (J = 7.5 Hz) (4-CH_2CH_3), 1.70–1.95 m (6,7-CH_2), 2.25–2.70 m (4,5,8-CH_2), 6.05 s (3-CH).

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.15; H, 7.92. Found: C, 74.19; H, 7.89.

4-Phenyl-α-pyrone (**13**) from **6** (570 mg), (50 ml of DMSO), m.p. 75–76° (ether – petroleum ether, b.p 30–60°) (85%); λ_{max} (ethanol) 228, 272, 298 (sh) (log ε 4.20, 4.17, 4.07); ν_{max} (KBr) 1705, 1640, 1540, cm^{-1}; δ ($(CD_3)_2CO$) 6.63 m (3-CH), 6.75 dd (J = 2.0, 5.5 Hz) (5-CH), 7.55–8.00 m (4-C_6H_5 and 6-CH).

Anal. Calcd. for $C_{11}H_8O_2$: C, 76.73; H, 4.66. Found: C, 77.03; H, 4.47.

4,6-Diphenyl-α-pyrone (**14**) from 7*a* (430 mg) (60 ml of DMSO), m.p. and mixture m.p. 136–137° (ether – petroleum ether, b.p. 30–60°) (72%) (lit. (10) m.p. 137–138°); λ_{max} (ethanol) 263, 345 nm (log ε 4.35, 4.15); ν_{max} (KBr) 1700, 1630, 1540 cm^{-1}; δ ($CDCl_3$) 6.54 d (J = 1.5 Hz) (3-CH), 7.34 d (J = 1.5 Hz) (5-CH), 7.50–8.10 2 m (4,6-C_6H_5).

Method B

A solution of the chlorodihydropyran **3** or **4** and potassium *t*-butoxide (8 equiv.) in anhydrous dimethylsulfoxide was stirred at room temperature under nitrogen, diluted by addition of ice and extracted with ether.

4-Propyl-α-pyrone (**15**) from **3** (500 mg) (50 ml of DMSO; 6 h), b.p. 100–110°/11 mm (preparative t.l.c.; ether-hexane, 1:1), (43%) and from **4** (600 mg) (40 ml of DMSO; 2 h) (10%); λ_{max} (ethanol) 285 nm (log ε 4.00); ν_{max} (film) 1730, 1645, 1555 cm^{-1}; δ ($CDCl_3$) 0.98 t (J = 7.5 Hz) (4-$CH_2CH_2CH_3$), 1.62 m (4-$CH_2CH_2CH_3$), 2.42 t (J = 7.0 Hz) (4-$CH_2CH_2CH_3$), 6.08–6.22 m (3,5-CH), 7.49 d (J = 6.0 Hz) (6-CH).

Anal. Calcd. for $C_8H_{10}O_2$: C, 69.54; H, 7.30. Found: C, 69.47; H, 7.33.

Method C

A solution of the chlorodihydropyran **11** and sodium methoxide (4.5 equiv.) in anhydrous dimethylformamide is stirred at −10°, then poured in ice water and extracted with ether.

6-Phenyl-α-pyrone (**18**) from **11** (783 mg) (50 ml of DMF; 20 h) (chromatographed on Florisil (50 g); benzene–ether, 97:3), m.p. 64–65° (ether – petroleum ether, b.p. 30–60°) (53%) (lit. (11) m.p. 64–65°); λ_{max} (ethanol) 332 nm (log ε 4.23); ν_{max} (KBr) 1720, 1632, 1549 cm^{-1}; δ ($CDCl_3$) 6.33 d (J = 9.0 Hz) (3-CH), 6.72 d (J = 7.0 Hz) (5-CH), 7.40–8.00 m (4-CH, 6-C_6H_5). When the crude product of a similar reaction is chromatographed on silica gel activity I (benzene–ether, 49:1) an oil is obtained, tentatively identified as a mixture of methyl *trans*-4-benzoyl-2-buten-1-oate (**16**) and methyl *trans*-4-benzoyl-3-buten-1-oate (**17**) (23%); ν_{max} (film) 1750–1710, 1695–1665 cm^{-1}; δ ($CDCl_3$) ~3.40 (AB part of an ABX system) (2-CH_2 of **17**), 3.75 s (CO_2CH_3), ~3.89 (AB part of an ABX system) (4-CH_2 of **16**), 6.00 dt (J = 1.0, 16.0 Hz) (2-CH of **16**), 7.00–8.15 (olefinic and aromatic CH). The α-pyrone **18** and the mixture of esters **17** and **18** can be obtained from the same reaction mixture by chromatography on silica gel activity III.

Method D

A solution of the chlorodihydropyran **8** or **9** and sodium methoxide (8.0 equiv.) in anhydrous dimethylsulfoxide was stirred at room temperature under nitrogen, diluted by addition of ice and extracted with ether.

5-*n*-Decyl-α-pyrone (**22**). 3-Chloro-5-*n*-decyl-3,4-dihydro-1,2-pyran (**8**) (500 mg; 25 ml of DMSO) gives a crude product, the major component of which is 2-*n*-decyl-5,5-dimethoxypenta-2,4-dien-1-al (**19***a*); ν_{max} (film) 1599 cm^{-1}; δ ($CDCl_3$) 3.82 and 3.88 2 s (OCH_3), 4.88 d (J = 11.0 Hz) (4-CH), 7.29 d (J = 11.0 Hz) (3-CH), 9.57 s (CHO). This compound is unstable and is converted within a few hours into the α-pyrone **22**. By the use of preparative t.l.c. (chloroform), the reaction mixture yielded the following substances: methyl trans-4-formyltetradeca-3-en-1-oate (**20**) (10%); λ_{max} (ethanol) 226 nm (log ε 4.41); ν_{max} (film) 2710, 1750, 1700, 1650, 1200, 1180 cm^{-1}; δ ($CDCl_3$) 0.95 (CH_3), 1.30 bs ($(CH_2)_8$), 3.45 d (J = 7.0 Hz) (2-CH_2), 6.78 t (J = 7.0 Hz) (3-CH), 9.60 s (CHO); 5-*n*-decyl-α-pyrone (**22**), m.p. 9.5–11.5° (distilled at 0.1 mm) (52%); λ_{max} (ethanol) 300 nm (log ε 3.77); ν_{max} (film) 1750, 1725, 1648, 1549 cm^{-1}; δ ($CDCl_3$) 0.95 ~ t (5-$(CH_2)_9CH_3$), 1.29 bs (5-$CH_2(CH_2)_8CH_3$), 2.30 ~ t (5-$CH_2(CH_2)_8CH_3$), 6.37 d (J = 10.5 Hz) (3-CH), 7.20–7.45 m (4,6-CH).

Anal. Calcd. for $C_{15}H_{24}O_2$: C, 76.22; H, 10.23. Found: C, 76.30; H, 10.39.

When the reaction was carried out with 5.5 equiv. of the base the following products were isolated:

Compounds **20** (11%) and **22** (31%) and methyl *trans*-tetradec-2-en-4-on-1-oate (**21**), m.p. 61.5–62° (ether–petroleum ether, b.p. 30–60°), (17%); λ_{max} (ethanol) 221 nm (log ε 4.29); ν_{max} (KBr) 3070, 1730, 1670, 1640 cm^{-1}; δ ($CDCl_3$) 0.95 (CH_3), 1.30 bs ($(CH_2)_8$), 2.62 t (J = 7.0 Hz) (5-CH_2), 3.80 s (CO_2CH_3), 6.96 dd (J = 16.0 Hz; Δν = 20.4 Hz) (2,3-CH).

Anal. Calcd. for $C_{15}H_{26}O_3$: C, 70.83; H, 10.30. Found: C, 71.09; H, 10.38.

From the chlorodihydropyran **9** (500 mg; 25 ml of DMSO, 8.0 equiv. of methoxide), the crude product contained 2-*n*-decyl-5,5-diethoxypenta-2,4-dien-1-al (**19***b*); δ ($CDCl_3$) 4.85 d (J = 12.0 Hz) (4-CH), 7.30 d (J = 12.0 Hz) (3-CH), 9.50 s (CHO); and **20**. This mixture was allowed to stand for 24 h, chromatographed as described above and gave the methyl ester **20** (15%) and the α-pyrone **22** (17%).

Reactions of Ketene Acetals. IV. A New Synthesis of α-Pyrones. III

ALAIN BÉLANGER AND PAUL BRASSARD
Département de Chimie, Université Laval, Québec, Québec G1K 7P4
Received November 27, 1973[1]

ALAIN BÉLANGER and PAUL BRASSARD. Can. J. Chem. **53**, 201 (1975).

A simple one-step synthesis of α-pyrones and 3-chloro-α-pyrones from β-functionalized α,β-enones and ketene acetals has been devised. The method has also been adapted to the preparation of some 4-methoxy-α-pyrones. Finally the mechanism of the reaction has been investigated.

ALAIN BÉLANGER et PAUL BRASSARD. Can. J. Chem. **53**, 201 (1975).

Une synthèse simple d'α-pyrones et de chloro-3 α-pyrones en une étape à partir d'α,β-énones β-fonctionnalisées a été réalisée. La méthode s'adapte aussi à la préparation de quelques méthoxy-4 α-pyrones. Enfin le mécanisme de la réaction a été étudié.

In a companion paper (1) we described a new synthesis of α-pyrones. This method involved the cycloaddition of chloroketene acetals to α,β-unsaturated carbonyl compounds followed by a dehydrohalogenation which yields α-pyrones. It was then assumed that placing the leaving-group on the enone should facilitate the elimination step, prevent the formation of by-products, and simplify the overall process. This modification uses the more readily accessible ketene dialkyl acetals and produces the α-pyrones directly in moderate to good yields (30–77%) (Scheme 1; R_1 = OAc, OBz, or Cl; R_2 and R_3 = H, alkyl, or aryl). β-Functionalized enals and β-alkylenones are either unreactive or give only exchange reactions.

The great stability of a 2,2,4-trimethoxy-3,4-dihydro-1,2-pyran suggested that the cycloaddition of chloroketene acetals to β-methoxy enones and a subsequent dehydrohalogenation would provide a new synthesis of 4-methoxy-α-pyrones. The 3-chloro-4-methoxy-3,4-dihydro-1,2-pyrans are formed by heating the substrates at about 150° (35–80%) and converted to the expected α-pyrones with yields of 32–90%. (Scheme 2; R_1 = OMe; R_2 = H, R_3 = aryl or styryl; and R_2 = alkyl, R_3 = aryl).

The Reaction of β-Functionalized Enones with Ketene Acetals (Scheme 1)

With β-Acetoxy and β-Benzoyloxy Enones

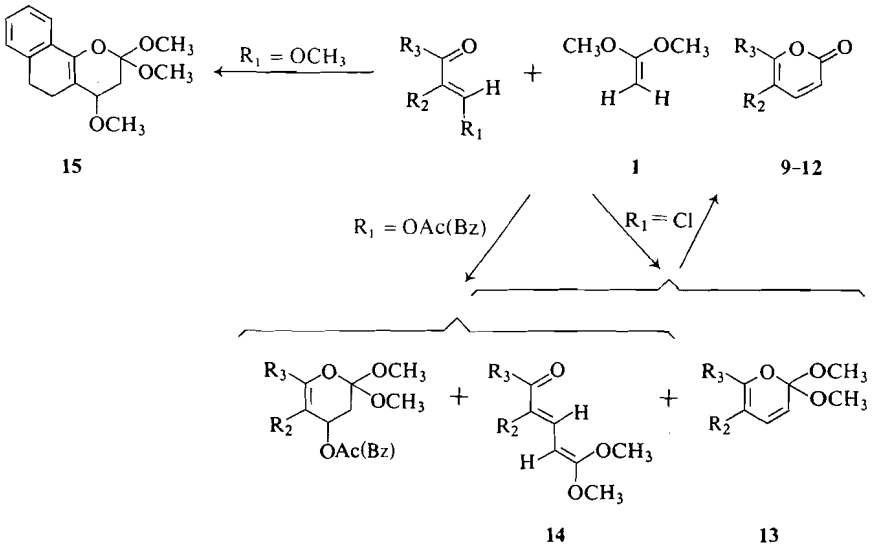
The β-acetoxy enones **3***a*, **4***a*, **5***a*, and **7***a* react readily with ketene dimethyl acetal (**1**) when heated at about 95° for 3–8 h. Examination of the n.m.r. spectra of the crude product usually reveals the presence of a mixture of the expected 4-acetoxy-2,2-dimethoxy-3,4-dihydro-1,2-pyran and elimination product, the 5,5-dimethoxypentadienone. The magnitude of the coupling constant between the protons in the 2 and 3 positions of the latter (~15 Hz) indicates that the tautomer has the *trans*-configuration (β-acetoxyacrylophenone reacts in 48 h at room temperature and gives only the relatively unstable dihydropyran).

Since all attempts to separate the dihydropyran from the dienone were unsuccessful, the mixture was then heated to 120–130° when a vigorous reaction ensued. The α-pyrone could then be isolated directly by chromatography on Florisil. Most variations of the experimental procedure such as the use of an inert solvent (xylene) or the addition of acetic acid to the reaction mixture produced no appreciable effect; no α-pyrone is obtained when the heating is carried out under vacuum. The use of a benzoyloxy derivative in one case gave analogous results but a somewhat lower yield.

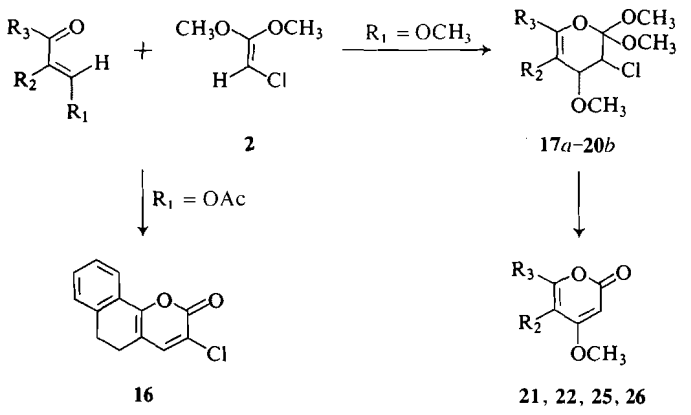
With β-Chloro Enones

The reaction was next attempted with 3-chloroacrylophenone (**5***c*) and produced quite different results. At 95° hydrogen chloride was completely eliminated and the mixture after evaporation consisted essentially of the *trans*-pentadienone and the 1,2-pyran. These isomers could not be separated and their nature was deduced solely from spectral data. By subtracting in the n.m.r. spectrum the signals due to the now familiar pentadienone, the structure of the other

[1]Revision received August 2, 1974.



SCHEME 1



SCHEME 2

isomer, 6-phenyl-1,2-pyran, is readily arrived at (a methoxyl peak at δ 3.40 seems characteristic of cyclic structures (1) and the presence of doublets at 5.45 (J = 9.5 Hz) and 6.00 (J = 6.5 Hz) and of a doublet of doublets at 6.50 confirms the proposed structure, *i.e.* the coupling constants are the same as in the corresponding α-pyrone but the chemical shifts are quite different).

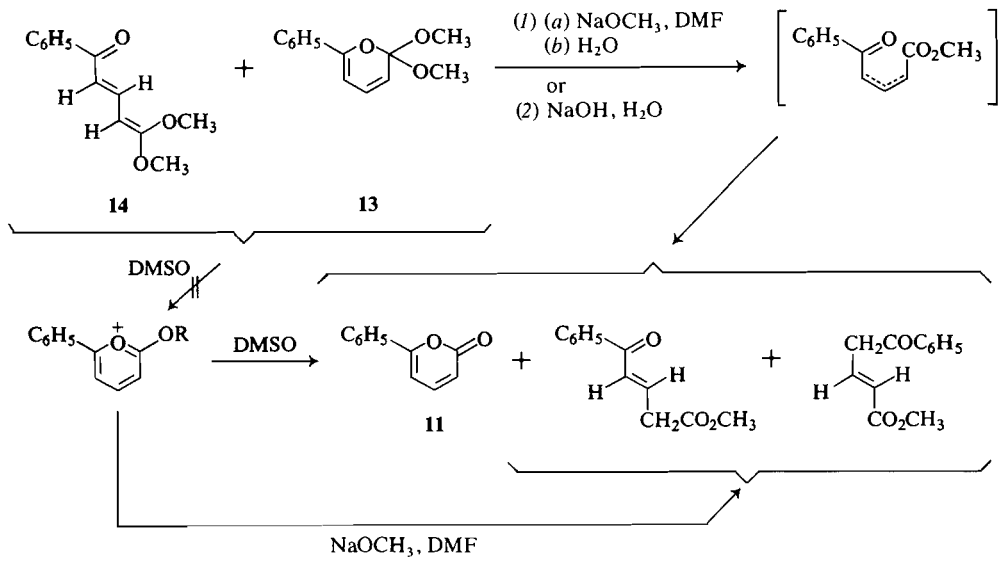
A subsequent heating of the mixture of isomers at 120° resulted in extensive decomposition and in the formation of only a trace of the α-pyrone. Chromatography on silica gel also decomposed these products but the addition of benzoic acid followed by heating at the same temperature gave good yields of 6-phenyl-α-pyrone and methyl benzoate.

With β-Methoxy Enones

These enones were significantly less reactive than the foregoing and the cycloaddition had to be carried out at 135° in a sealed tube. Only the 4-methoxydihydropyran was obtained and heating it progressively to 200° only caused decomposition; moreover it was quite inert to alkoxides under the usual conditions. This negative result suggested that analogous 4-methoxydihydropyrans could be used in the synthesis of 4-methoxy-α-pyrones, many derivatives of which are naturally occurring compounds.

With Chloroketene Dimethyl Acetal (Scheme 2)

When 2-acetoxymethylene-α-tetralone (**4***b*) was heated to 130° for 24 h with chloroketene dimethyl acetal (**2**) an 82% yield of the correspond-



SCHEME 3

ing 3-chloro-α-pyrone **16** was obtained. Although the procedure was not further explored it undoubtedly constitutes an excellent method of preparing certain compounds of this type.

The Reaction of β-Methoxy Enones with Chloroketene Acetals (Scheme 2)

In this procedure 2-methoxymethylene-α-tetralone (**4***b*), 3-methoxyacrylophenone (**5***b*), 2-methoxyvinyl styryl ketone (**7***b*), and 3′,4′-methylenedioxystyryl 2-methoxyvinyl ketone (**8**) were successfully added to chloroketene dimethyl acetal (**2**) at the boiling point of the latter; 2-methoxymethylenecyclohexanone (**3***b*) and 3-methoxy-2-isopropylacrolein were found to be unreactive whereas 2-methoxyvinyl 3′-pyridyl ketone (**6**) gave a variety of products, none of which seemed to be the expected dihydropyran. In most cases, both diastereoisomers were obtained and the *cis*-compounds are thought to be usually predominant; however only the *cis*-isomer **20***a* was observed but the yield was low in this instance and the *trans*-isomer could have remained undetected. These isomers can be partially separated by chromatography on Florisil but, with the exception of those of **17***a* and *b*, the configurations cannot be assigned with certainty since the signals for the protons in positions 3,4 of the dihydropyran system are usually superimposed. The 6-phenyl isomers **18***a* and *b* show very different reaction rates in the presence of sodium methoxide and the more reactive one is assumed to be the *cis*-compound. Other mixtures do not show this characteristic and structures have been tentatively assigned on the basis of small differences in chemical shifts and coupling constants, and of chromatographic behavior.

The dehydrohalogenation of the 3-chloro-2,2,4-trimethoxydihydropyrans was attempted under the usual conditions (4.5 equiv. of methoxide in DMSO). The mixture of isomers **17***a* and *b* gave a 90% yield of the corresponding α-pyrone but a similar reaction with the 6-phenyl compounds **18***a* and *b* showed the rapid disappearance of the *cis*-isomer while a large amount of the *trans*-isomer remained unaffected (a prolonged reaction increases the proportion of by-products) The pure *trans*-compound **18***b* gave a very low yield (14%) which could not be improved but the *cis*-isomer **18***a* at $-10°$ could be converted more efficiently to the α-pyrone (40%). Finally the 6-styryl derivatives **19***a* and *b* and **20***a* reacted readily at low temperatures but provided only moderate yields of the expected products (37–43%).

The Mechanism of the Reaction (Scheme 3)

The conversion of 3- or 4-functionalized dihydropyrans to α-pyrones in the presence of alkoxide or by heating raises a number of mechanistic problems. There seems to be little doubt that an elimination occurs in the first step of the process, that the 1,2-pyran is the initial intermediate, and that an equilibrium then exists between the latter and the oxodienes since all of these are occasionally observed (the fact that

the 1,2-pyran appears only when hydrogen chloride is eliminated by a thermal reaction remains unexplained). We have elucidated two main problems: (*a*) whether the α-pyrones are produced by a nucleophilic attack on the 1,2-pyran-oxodiene mixture or by the formation and subsequent conversion of the corresponding pyrilium salt and (*b*) whether the ketoester by-products are formed during the reaction or by subsequent hydrolysis (these compounds are not observed in the thermal procedure).

It has been shown that 1,2-pyrans exist mainly in the oxodiene form and that substituents capable of enhancing the resonance in this isomer also displace the equilibrium in its favor (2–5). The formation of α-pyrones was thought at first to proceed through the pyrilium salt because of the ease with which 5,5-dimethoxy-2-*n*-decyl-penta-2,4-dienal (1) was converted to such a compound and since the intermediate 1,2-pyrans (orthoesters) were expected to be stable in basic media. The postulate which assumed that pyrilium salts were formed from the 1,2-pyrans and that a lowering of the reaction temperature would increase the concentration of the latter and thence facilitate the formation of the specific intermediate presented certain difficulties at the outset. Indeed there seemed to be no valid reason why the 4-phenyl-, 4-alkyl-, and 4,6-diphenyldihydropyrans should yield α-pyrones quite readily whereas the 6-phenyl and 5-alkyl derivatives having comparable electronic effects behaved abnormally (1). The difficulty in effecting the conversion and the occurrence of appreciable amounts of ketoester by-products in the last instances seemed related rather to steric factors and a greater ease of isomerization (in the case of the 4-methoxy dihydropyrans the ease of isomerization could be due to an electronic effect). It should be noted here that 2-*n*-decyl-pentadienal is only encountered when a large excess of methoxide is used and it is possible that this structure is stabilized by a Michael-type addition and is regenerated during hydrolysis.

The initial assumption that 1,2-pyrans are the first intermediates even in the base-induced reaction was tested by treating the mixtures of isomers **13** and **14** with sodium methoxide in dimethylformamide at $-10°$. Hydrolysis and chromatography of the reaction mixture gave 6-phenyl-α-pyrone (**11**) and a small amount of the usual ketoesters. The next step in the elucidation of the mechanism consisted in determining whether preformed pyrilium salts were capable of undergoing the conversion to α-pyrones under similar conditions. Pirkle and Dines (6) had previously proposed the intermediacy of pyrilium salts in the nitration of α-pyrones and confirmed this possibility by thermally converting the former to dienolides (4-methoxy pyrilium salts are known to be stable under analogous conditions) (7). We prepared 2-ethoxy-6-phenyl-pyrilium fluoroborate (**27**) and dissolved it in dimethylsulfoxide. Examination of the reaction mixture both before hydrolysis (DMSO-d_6) and after revealed efficient conversion to the α-pyrone; when a similar reaction was carried out with the usual amount of methoxide (DMF, $-10°$) only a trace of compound **11** was obtained (the reaction mixture consisted mainly of the ketoester by-products). However, by dissolving the mixture of isomers **13** and **14** in deuterated dimethylsulfoxide, a progressive decomposition of the substrates was observed but neither the pyrilium salt nor the α-pyrone could be detected.

It now seems quite obvious that pyrilium salts must be discounted as intermediates in the new synthesis of α-pyrones that we describe. The latter compounds can only result from the hydrolysis of or the nucleophilic attack on the oxodiene. This was confirmed when hydrolysis of the mixture of isomers **13** and **14** with aqueous sodium hydroxide was found to yield the α-pyrone and the usual ketoesters. The configuration of the oxodiene also seems to enter into consideration. Although it could not be established which isomer was present in the case of the 2-*n*-decylpenta-2,4-dienals, the ease with which they are converted to the α-pyrone seems to indicate a *cis*-configuration; on the other hand some dienones produced at higher temperatures are undoubtedly *trans*. The *cis*-oxodienes are therefore hydrolyzed to a mixture of *cis*- and *trans*-oxopentenoates and the *cis*-esters then cyclize spontaneously to the α-pyrones. The improved yields we have observed at low temperature undoubtedly result from slower rates of isomerization. As to the thermal formation of α-pyrones, McElvain (8) has proposed a mechanism for the conversion of ketene acetals to esters and this seems a plausible process for the transformation we have observed. Indeed the elimination of hydrogen chloride from chlorodihydropyran at 95° prevents the formation of the α-pyrone since the reagent would be

volatilized under these conditions and a similar situation is observed when the corresponding acetoxy compounds are heated under vacuum.

Experimental

The melting points were taken in capillary tubes using a calibrated thermometer (Thomas-Hoover Apparatus). The i.r. spectra were recorded on a Beckman IR-12 instrument, u.v. spectra on a Beckman DK-1A spectrophotometer, and the n.m.r. on a Varian A60 spectrometer with tetramethylsilane as internal standard.

The Preparation of β-Functionalized α,β-Enones

No attempt has been made to determine the configuration of these compounds since (*a*) in most cases only one isomer is obtained, (*b*) the β-hydrogen is not always discernible in the n.m.r. spectrum, and (*c*) compounds of this type are known to isomerize readily under the reaction conditions used. However the chemical shifts, when visible, and the coupling constants of the olefinic protons suggest that the configurations are *cis*.

2-Methoxymethylenecyclohexanone (3b)

A mixture of the sodium salt of 2-hydroxymethylenecyclohexanone (10.0 g) (9), dimethylsulfate (7.0 ml), anhydrous potassium carbonate (10.0 g), and acetone (100 ml) was refluxed for 24 h. The methyl ester **3***b* was isolated in the usual way, b.p. 110–115°/10 mm (34%) (lit. (10) b.p. 85°/3.2 mm); ν_{max} (film) 1685, 1600 cm^{-1}; δ ($CDCl_3$) 1.50–2.50 m ($(CH_2)_4$), 3.90 s (OCH_3), 7.18 t (J = 2.0 Hz) (C=CH).

2-Chloromethylene-α-tetralone (4c)

A solution of 2-hydroxymethylene-α-tetralone (2.6 g) (11), thionyl chloride (1.2 ml), and benzene (10 ml) was refluxed for 4 h. Evaporation of the mixture under vacuum gave the chloro compound **4***c*, m.p. 61–62° (ether – petroleum ether) (90%); λ_{max} (ethanol) 272 nm (log ε 4.29); ν_{max} (KBr) 1670 cm^{-1}; δ ($CDCl_3$) 3.03 s ($(CH_2)_2$), 7.20–7.50 and 7.80–8.40 2 m (aromatic and vinyl CH).

Anal. Calcd. for $C_{11}H_9OCl$: C, 68.57; H, 4.71. Found: C, 68.70; H, 4.81.

3-Methoxyacrylophenone (5b)

A mixture of the sodium salt of 3-hydroxyacrylophenone (15.0 g) (12), dimethylsulfate (8 ml), anhydrous potassium carbonate (10.0 g), and acetone (50 ml) was refluxed for 3 h. The methyl ether **5***b* was isolated in the usual way, b.p. 100–105°/0.1 mm (88%) (lit. (10) b.p. 112°/1.8 mm); λ_{max} (ethanol) 274 nm (log ε 4.12); ν_{max} (film) 1670 cm^{-1}; δ ($CDCl_3$) 3.80 s (OCH_3), 6.43 d (J = 12.5 Hz) (2-CH), 7.40–7.70 and 7.85–8.15 2 m (aromatic CH), 7.90 d (J = 12.5 Hz) (3-CH).

2-Methoxyvinyl 3′-Pyridyl Ketone (6)

A solution of hydrogen chloride (7.8 g) in anhydrous methanol (10 ml) was added dropwise at 0° to a suspension of the sodium salt of 3′-pyridyl 2-hydroxyvinyl ketone (10.0 g) (13) in methanol (10 ml). After allowing the reaction to rest for 1/2 h at the same temperature and evaporating it under vacuum, the methyl ether **6** was obtained by pouring the residue into a 5% solution of sodium carbonate, extracting the latter with ether and distilling the residue over sodium carbonate (50 mg), b.p. 170–175°/0.9 mm, m.p. 74–75° (47%); λ_{max} (ethanol) 240, 278 nm (log ε 4.00, 4.08); ν_{max} (KBr) 1670, 1640 cm^{-1}; δ ($CDCl_3$) 3.89 s (OCH_3) 6.38 d (J = 12.0 Hz) (1-CH), 7.45 dd (J = 4.5, 8.5 Hz) (5′-CH), 7.92 d (J = 12.0 Hz) (2-CH), 8.25 dt (J = 2.0, 8.5 Hz) (4′-CH), 8.82 dd (J = 2.0, 4.5 Hz) (6′-CH), 9.20 d (J = 2.0 Hz) (2′-CH).

Anal. Calcd. for $C_9H_9O_2N$: C, 66.25; H, 5.56; N, 8.58. Found: C, 66.32; H, 5.84; N, 8.32.

2-Methoxyvinyl Styryl Ketone (7b)

A mixture of the sodium salt of 2-hydroxyvinyl styryl ketone (10.0 g) (14), dimethylsulfate (5.5 ml), anhydrous potassium carbonate (6.0 g), and acetone (50 ml) was refluxed for 5 h. The methyl ether 7*b* was isolated in the usual way, b.p. 140–145°/0.2 mm, m.p. 89–90° (ether – petroleum ether) (57%); λ_{max} (ethanol) 226, 309 nm (log ε 4.13, 4.32); ν_{max} (KBr) 1650 cm^{-1}; δ ($CDCl_3$) 3.70 s (OCH_3), 5.95 d (J = 12.5 Hz) (1-CH), 6.92 d (J = 16.0 Hz) (α-styryl CH), 7.25–7.65 m (aromatic CH), 7.74 d (J = 16.0 Hz) (β-styryl CH), 7.86 d (J = 12.5 Hz) (2-CH).

Anal. Calcd. for $C_{12}H_{12}O_2$: C, 76.59; H, 6.43. Found: C, 76.85; H, 6.60.

3′,4′-Methylenedioxystyryl 2-Methoxyvinyl Ketone (8)

A suspension of the sodium salt of 3′,4′-methylenedioxystyryl 2-hydroxyvinyl ketone (4.0 g), dimethylsulfate (2.0 ml), potassium carbonate (2.18 g), and acetone (20 ml) was refluxed for 3 h. The methyl ether **8** was obtained in the usual way, m.p. 90–91° (carbon tetrachloride) (50%); λ_{max} (ethanol) 259, 304, 348 nm (log ε 4.12, 4.20, 4.37); ν_{max} (KBr) 1650 cm^{-1}; δ ($CDCl_3$) 3.82 s (OCH_3), 5.95 d (J = 12.5 Hz) (1-CH), 6.08 s (—OCH_2O—), 6.75 d (J = 16.0 Hz) (α-styryl CH), 6.80–7.35 m) (aromatic CH), 7.65 d (J = 16.0 Hz) (β-styryl CH), 7.86 d (J = 12.5 Hz) (2-CH).

Anal. Calcd. for $C_{13}H_{12}O_4$: C, 67.23; H, 5.21. Found: C, 67.50; H, 5.08.

The Synthesis of α-Pyrones from β-Functionalized α,β-Enones

From β-Acetoxy or β-Benzoyloxy Enones

A mixture of the β-acetoxy or β-benzoyloxy enone and ketene dimethyl acetal (**1**) (3–5 equiv.) (in this procedure (15) benzene was replaced by xylene) was heated under nitrogen. The excess of the acetal and the volatile by-products were evaporated under vacuum and the residue heated at 120–130° for 10–15 min. The following products were obtained.

5,6,7,8-Tetrahydrocoumarin (**9**) from 2-acetoxymethylenecyclohexanone (**3***a*) (3.09 g) (16) (110°; 15 h) was chromatographed on Florisil (107 g) (benzene–ether, 23:2), m.p. 64–65° (ether – petroleum ether) (30%) (lit. (17) m.p. 64.5–65°); λ_{max} (ethanol) 304 nm (log ε 3.88); ν_{max} ($CHCl_3$) 1740, 1720, 1649, 1560 cm^{-1}; δ ($CDCl_3$) 1.50–1.90 m (6,7-CH_2), 2.20–2.60 m (5,8-CH_2) 6.12 d (J = 9.5 Hz) (3-CH), 7.10 d (J = 9.5 Hz) (4-CH).

Anal. Calcd. for $C_9H_{10}O_2$: C, 71.98; H, 6.71. Found: C, 72.36; H, 6.69.

5,6-Dihydro-2-naphtho[1,2-*b*]pyrone (**10**) from 2-acetoxymethylene-α-tetralone (**4***a*) (200 mg) (18) (95°; 8 h) (preparative t.l.c.; benzene – ethyl acetate, 7:3), m.p. 102–103° (ether) (76%) (lit. (19) m.p. 96–97°); λ_{max} (ethanol) 237, 354 nm (log ε 4.15, 4.27); ν_{max} (KBr) 1720, 1630, 1540 cm^{-1}; δ ($CDCl_3$) 2.60–3.10 m (5,6-CH_2), 6.28 d (J = 9.5 Hz) (3-CH), 7.10–7.60 and 7.70–8.20 2 m (3- and aromatic CH).

Anal. Calcd. $C_{13}H_{10}O_2$: C, 78.77; H, 5.09. Found: C, 78.78; H, 5.13.

6-Phenyl-α-pyrone (**11**) from 3-acetoxyacrylophenone (**5***a*) (300 mg) (11) (95°; 2 h) (preparative t.l.c.; benzene – ethyl acetate, 7:3; and filtration on Florisil), m.p. 64–65° (77%) (lit. (20) m.p. 63–64°) and from 3-benzoyloxyacrylophenone (200 mg) (24) (95°; 2 h) (61%).

6-Styryl-α-pyrone (**12**) from 2-acetoxyvinyl styryl ketone (7*a*) (200 mg) (21) (95°; 2 h) (preparative t.l.c.; dichloromethane–benzene, 1:1), m.p. 112.5–113° (ether – petroleum ether) (67%) (lit. (22) m.p. 115–116°); λ_{max} (ethanol) 262, 270, 370 (log ε 4.21, 4.22, 4.29); ν_{max} (KBr) 1730, 1630, 1530 cm^{-1}; δ ($CDCl_3$) 6.19 d (J = 7.0 Hz) (5-CH), 6.23 d (J = 9.0 Hz) (3-CH), 6.68 d (J = 16.0 Hz) (α-styryl CH), 7.20–7.70 m (4-, β-styryl and aromatic CH).

Anal. Calcd. for $C_{13}H_{10}O_2$: C, 78.77; H, 5.09. Found: C, 78.79; H, 5.12.

From β-Chloro Enones

*6-Phenyl-α-pyrone (**11**).* The condensation of 3-chloroacrylophenone (**5***c*) (200 mg) (23) with ketene dimethyl acetal (1.00 g) under nitrogen at 95° for 5 h gave, after evaporation, a mixture of 2,2-dimethoxy-6-phenyl-1,2-pyran (**13**); δ ($CDCl_3$) 3.40 s (OCH_3), 5.45 d (J = 9.5 Hz) (3-CH), 6.00 d (J = 6.5 Hz) (5-CH), 6.52 dd (J = 6.5, 9.5 Hz) (4-CH)) and *trans*-5,5-dimethoxy-1-phenylpenta-2,4-dien-1-one (**14**); δ 3.71 s (OCH_3), 4.80 d (J = 11.5 Hz) (4-CH), 6.79 d (J = 15.0 Hz) (5-CH). After heating this mixture with benzoic acid (180 mg) for 10 min at 120°, 6-phenyl-α-pyrone, m.p. 64–65° (80%) and methyl benzoate (125 mg) were isolated in the usual way.

*5,6-Dihydro-2-naphtho[1,2-b]pyrone (**10**).* This pyrone is obtained as in the preceding paragraph from 2-chloromethylene-α-tetralone (**4***c*) (200 mg), **1** (1.00 g) (95°; 10 h) and benzoic acid (180 mg), m.p. 102–103° (preparative t.l.c.; benzene – ethyl acetate, 7:3) (79%).

From β-Methoxy Enones

*2,2,4-Trimethoxy-3,4,5,6-tetrahydro-2-naphtho[1,2-b]-pyran (**15**).* This pyran **15** was obtained by heating a mixture of 2-methoxymethylene-α-tetralone (**4***b*) (1.0 g) (24) and **1** (1.40 g) for 30 h at 135°, m.p. 68–69° (ether – petroleum ether) (92%); ν_{max} (KBr) 1665, 1120, 1095, 1050 cm^{-1}; δ ($CDCl_3$) 1.80–2.90 m (3,5,6-CH_2) 3.38, 3.43 and 3.48 3s (OCH_3), 4.11 bt (J = ~7.5 Hz) (4-CH), 7.10–7.80 m (aromatic CH).

Anal. Calcd. for $C_{16}H_{20}O_4$: C, 69.54; H, 7.30. Found: C, 69.65; H, 7.52.

From β-Acetoxy Enones and Chloroketene Dimethyl Acetal

A mixture of 2-acetoxymethylene-α-tetralone (**4***a*) (3.6 g) and chloroketen dimethyl acetal (**2**) (7.3 g) (25) was heated at 130° for 24 h, and evaporated under vacuum. The residue gave 3-chloro-5,6-dihydro-2-naphtho[1,2-*b*]-pyrone (**16**), m.p. 142–143° (ether) (82%); λ_{max} (ethanol) 245, 252, 370 (log ε 4.11, 4.17, 4.16); ν_{max} (KBr) 1740, 1720, 1640, 1535 cm^{-1}.

Anal. Calcd. $C_{13}H_9O_2Cl$: C, 67.10; H, 3.89; Cl, 15.22. Found: C, 67.31; H, 3.93; Cl, 15.34.

The Preparation of 3-chloro-2,2,4-trimethoxy-3,4-dihydro-1,2-pyrans

A mixture of the β-methoxy enone and chloroketene dimethyl acetal (**2**) (25) (2–4 equiv.) was heated at 150° under nitrogen. After evaporation of the volatile products under vacuum, the residue was chromatographed on Florisil.

cis- and *trans*-3-Chloro-2,2,4-trimethoxy-3,4,5,6-tetrahydro-2-naphtho[1,2-*b*]pyrans (**17***a* and *b*) were obtained from 2-methoxymethylene-2-tetralone (**4***b*) (900 mg) and **2** (48 h). Chromatography (benzene then benzene–ether 19:1) gave the *trans*-isomer **17***b*, m.p. 107–109° (ether – petroleum ether) (19%); ν_{max} (KBr) 1661, 1130, 1108, 1070, 990 cm^{-1}; δ ($CDCl_3$) 2.30–3.10 2m (5,6-CH_2), 3.49, 3.58 and 3.65 3s (2,2,4-OCH_3), 4.24 bd (J = 8.0 Hz) (4-CH), 4.49 d (J = 8.0 Hz) (3-CH), 7.20–7.70 2m (aromatic CH).

Anal. Calcd. for $C_{16}H_{19}O_4Cl$: C, 61.83; H, 6.16. Found: C, 62.14; H, 6.10.

Later fractions gave a mixture of the *cis-* and *trans*-isomers (8%) and the *cis*-isomer **17***a* (an oil) (53%); ν_{max} (film) 1660, 1135, 1100, 1065, 1055 cm^{-1}; δ ($CDCl_3$) 2.30–3.20 2m (5,6-CH_2), 3.38, 3.55 and 3.59 3s (2,2,4-OCH_3), 4.39 bd (J = 5.0 Hz) (4-CH), 4.62 d (J = 5.0 Hz) (3-CH), 7.20–7.80 2m (aromatic CH).

cis- and *trans*-3-Chloro-2,2,4-trimethoxy 6-phenyl-3,4-dihydro-1,2-pyrans (**18***a* and *b*) were prepared from 3-methoxyacrylophenone (**5***b*) (2.0 g) and **2** (36 h). Chromatography (benzene) gave successively: the *trans*-isomer **18***b* (an oil) (20%); ν_{max} (film) 1665, 1100, 1052, 1025 cm^{-1}; δ ($CDCl_3$) 3.50, 3.56 and 3.58 3s (2,2,4-OCH_3), 4.36 d (J = 1.5 Hz) (3,4-CH), 5.63 t (J = 1.5 Hz) (5-CH), 7.40–7.90 2m (aromatic CH); a mixture of the *cis-* and *trans*-isomers (16%); the *cis*-isomer **18***a* (an oil) (53%); δ ($CDCl_3$) 3.41, 3.52, and 3.58 3s (2,2,4-OCH_3), 4.56 d (J = 2.0 Hz) (3,4-CH), 5.50 t (J = 2.0 Hz) (5-CH), 7.30–7.90 2m (6-C_6H_5).

cis- and *trans*-3-Chloro-2,2,4-trimethoxy-6-styryl-3,4-dihydro-1,2-pyrans (**19***a* and *b*) were obtained from 2-methoxyvinyl styryl ketone (7*b*) (1.0 g) and **2** (48 h). Chromatography (benzene) gave successively: a mixture of the *cis-* and *trans*-isomers (38%); the *cis*-isomer **19***a*, m.p. 109–110° (ether – petroleum ether) (24%); ν_{max} (KBr) 1650, 1130, 1091, 1071, 1050 cm^{-1}; δ ($CDCl_3$) 3.39, 3.49, and 3.54 3s (2,2,4-OCH_3), 4.49 d (J = 2.0 Hz) (3,4-CH), 5.03 t (J = 2.0 Hz) (5-CH), 6.47 d (J = 16.0 Hz) (α-styryl CH), 7.00–7.80 m (β-styryl and aromatic CH).

Anal. Calcd. for $C_{16}H_{19}O_4Cl$: C, 61.83; H, 6.16. Found: C, 62.12; H, 6.28.

cis-3-Chloro-2,2,4-trimethoxy-3′,4′-methylenedioxystyryl-3,4-dihydro-1,2-pyran (**20***a*) was prepared from 2-methoxyvinyl 3′,4′-methylenedioxystyryl ketone (**8**) (1.0 g) and **2** (32 h). Chromatography (benzene) gave only the *cis*-isomer **20***a*, m.p. 124–125° (ether) (35%); ν_{max} 1655, 1120, 1091, 1071, 1050 cm^{-1}; δ ($CDCl_3$) 3.35, 3.46, and 3.52 3s (2,2,4-OCH_3), 4.48 d (J = 2.0 Hz) (3,4-CH), 4.98 t (J = 2.0 Hz) (5-CH), 5.97 s (—OCH_2O—), 6.31 d (J = 16.0 Hz) (α-styryl CH), 6.80–7.40 m (β-styryl and aromatic CH).

The Synthesis of 4-Methoxy-α-pyrones

A solution of the chlorodihydropyran and sodium methoxide (4.5 equiv.) in the appropriate solvent was stirred under nitrogen, diluted by addition of ice and extracted with ether.

4-Methoxy-5,6-dihydro-2-naphtho[1,2-*b*]pyrone (**21**) was obtained from the mixture of *cis-* and *trans*-pyrans **17***a* and *b* (420 mg) (25 ml of DMSO; 25°; 15 h), m.p. 173–174° (ether) (90%); λ_{max} (ethanol) 222, 228, 260, 270, 330, 340 nm (log ε 4.27, 4.29, 3.81, 3.81, 4.23, 4.23); ν_{max} (KBr) 1705, 1640, 1555 cm^{-1}; δ ($CDCl_3$) 2.40–3.10 m

(5,6-CH_2), 3.86 s (4-OCH_3), 5.58 s (3-CH), 7.10–8.10 2m (5- and aromatic CH).

Anal. Calcd. for $C_{14}H_{12}O_3$: C, 73.66; H, 5.31. Found: C, 73.78; H, 5.21.

4-Methoxy-6-phenyl-α-pyrone (**22**) from the *trans*-pyran **18***b* (640 mg) (50 ml of DMSO; 25°; 24 h) (preparative t.l.c.; chloroform), m.p. 125–126° (ether) (14%) (lit. (26) m.p. 129.5–131.5°); λ_{max} (ethanol) 220, 233, 315 nm (log ε 4.23, 4.21, 4.19); ν_{max} (KBr) 1708, 1645, 1569 cm^{-1}; δ ($CDCl_3$) 3.90 s (4-OCH_3), 5.62 d (J = 2.0 Hz) (3-CH), 6.51 d (J = 2.0 Hz) (5-CH), 7.40–8.10 2m (6-C_6H_5).

Anal. Calcd. for $C_{12}H_{10}O_2$: C, 71.28; H, 4.98. Found: C, 71.08, H, 4.92.

Compound **22** was also obtained from the *cis*-isomer **18***a* (500 mg) (40 ml of DMF; −10°; 12 h), m.p. 125–126° (40%) along with a mixture of the methyl *trans*-4-benzoyl-3-methoxybut-2- and 3-en-1-oates (**23** and **24**) (23%); ν_{max} (film) 1740, 1700, 1665, 1640 cm^{-1}; δ ($CDCl_3$) 3.62, 3.68, 3.75, and 3.83 4s (OCH_3 and CO_2CH_3), 3.95 s (4-CH_2), 4.50 s (2-CH_2), 5.30 s (2-CH), 6.38 s (4-CH), 7.40–7.70 and 7.85–8.20 2m (aromatic CH).

4-Methoxy-6-styryl-α-pyrone (**25**) from the mixture of *cis*- and *trans*-pyrans **18***a* and *b* (207 mg) (30 ml of DMF; −20°; 20 h) (preparative t.l.c.; chloroform), m.p. 136–137° (ether) (43%) (lit. (27) m.p. 138–140°); λ_{max} (ethanol) 226, 233, 255, 343 nm (log ε 4.32, 4.33, 4.28, 4.42); ν_{max} ($CHCl_3$) 1710, 1641, 1560 cm^{-1}; δ ($CDCl_3$) 3.87 s (4-OCH_3), 5.60 d (J = 2.0 Hz) (3-CH), 6.05 d (J = 2.0 Hz) (5-CH), 6.70 d (J = 16.0 Hz) (α-styryl CH), 7.30–7.70 m (β-styryl and aromatic CH).

Anal. Calcd. for $C_{14}H_{12}O_3$: C, 73.66; H, 5.30. Found: C, 73.90; H, 5.35.

6-(3′,4′-Methylenedioxystyryl)-4-methoxy-α-pyrone (**26**) from the *cis*-pyran **20***a* (280 mg) (30 ml of DMF; −20°; 5 h), m.p. 233–234° (ether) (37%) (lit. (28) m.p. 233°); λ_{max} (ethanol) 221, 248, 370 nm (log ε 4.24, 3.91, 4.37); ν_{max} (KBr) 1720, 1640, 1555 cm^{-1}; δ ($(CD_3)_2SO$) 3.88 (4-OCH_3), 5.68 d (J = 2.0 Hz) (3-CH), 6.13 s (—OCH_2O—), 6.32 d (J = 2.0 Hz) (5-CH), 6.63 d (J = 16.0 Hz), 6.90–7.50 m (β-styryl and aromatic CH).

Anal. Calcd. for $C_{15}H_{12}O_5$: C, 66.17; H, 4.44. Found: C, 66.10; H, 4.26.

Miscellaneous Reactions

2-Ethoxy-6-phenylpyrilium Fluoroborate (27)

A mixture of 6-phenyl-α-pyrone (**11**) (240 mg) and of a solution of triethyloxonium fluoroborate (methylene chloride, 0.01 *M*) (1.4 ml) was stirred at room temperature for 48 h, filtered and evaporated. The residue upon crystallization from acrylonitrile – methylene chloride gave 2-ethoxy-6-phenylpyrilium fluoroborate, m.p. 147.5–148° (86%); λ_{max} (ethanol) 238, 332 nm (log ε 4.23, 4.14); ν_{max} (KBr) 1641, 1519 cm^{-1}.

Anal. Calcd. for $C_{13}H_{13}O_2BF_4$: C, 54.20; H, 4.54. Found: C, 54.07; H, 4.41.

Reactions of 2-Ethoxy-6-phenylpyrilium Fluoroborate

With Sodium Methoxide. A solution of 2-ethoxy-6-phenylpyrilium fluoroborate (200 mg) and sodium methoxide (167 mg) in dimethylformamide (20 ml) was stirred for 15 min at −15°. The n.m.r. spectrum of the crude product showed the presence of the corresponding methyl ketoesters. Thin-layer chromatography revealed only a trace of the α-pyrone **11**.

With Dimethylsulfoxide. 2-Ethoxy-6-phenylpyrilium fluoroborate (50 mg) was dissolved in deuterated dimethylsulfoxide (0.8 ml). After 10 min, the n.m.r. spectrum of the reaction mixture revealed mainly 6-phenyl-α-pyrone and the usual working up gave a 90% yield of the pyrone **11**.

With Acetic Acid. A mixture of 2-ethoxy-6-phenylpyrilium fluoroborate (200 mg) and acetic acid (1 ml) was heated at 120° for 10 min, dissolved in ether and washed with water. Evaporation of the solvent gave 6-phenyl-α-pyrone (**11**) (83%).

Reactions of the Mixture of Isomers 13 and 14

With Sodium Methoxide. The mixture of isomers **13** and **14** prepared as before from 3-chloroacrylophenone (**5***c*) (1.0 g) and **1** (1.7 g) was treated with sodium methoxide (280 mg) in dimethylformamide (20 ml) at −10° for 10 min. The reaction medium after dilution by addition of ice gave 6-phenyl-α-pyrone (**11**) (34%) and a mixture of the corresponding ketoesters (7%) (1), (preparative t.l.c.; benzene – methylene chloride – ethyl acetate, 5:4:1). The n.m.r. spectrum of a similar reaction on a small scale in deuterated dimethylsulfoxide shows the presence of the 1,2-pyran **13** and another substance which is probably one of the open-chain dienones.

With Aqueous Base. The mixture of the isomers **13** and **14** obtained as above was dissolved in ether (40 ml) and extracted several times with a 2% aqueous solution of sodium hydroxide. Evaporation of the ethereal layer gave a mixture of the pyrone **11** (78%) and of the corresponding ketoesters (15%).

A New Thiophene Synthesis

JOHN M. MCINTOSH AND HAMDY KHALIL

Department of Chemistry, University of Windsor, Windsor, Ontario N9B 3P4

Received August 30, 1974

JOHN M. MCINTOSH and HAMDY KHALIL. Can. J. Chem. **53**, 209 (1975).

2,5-Dihydrothiophenes are dehydrogenated to thiophenes in high yield using chloranil in *tert*-butanol or pyridine. The presence of a fully substituted carbon atom blocks the reaction. The method allows a flexible regiospecific synthesis of thiophenes in high yield from readily available starting materials.

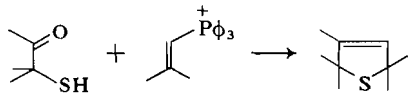
JOHN M. MCINTOSH et HAMDY KHALIL. Can. J. Chem. **53**, 209 (1975).

Le chloranil, dans le *tert*-butanol ou la pyridine, permet de déshydrogéner les dihydro-2,5 thiophènes en thiophènes avec de bons rendements. La présence d'un carbone complètement substitué arrête complètement la réaction. La méthode fournit une synthèse flexible et régiospécifique de thiophènes qui s'effectue avec de bons rendements à partir de composés de départ facilement accessibles. [Traduit par le journal]

Because of the importance of their role in biological systems, much attention has been focussed on the synthesis of pyrroles. Consequently, a variety of methods is available for their construction from a number of different types of starting materials (1). However, the methods available for the preparation of the related thiophenes are generally much more classical and not nearly so varied. Several methods are available for formation of the ring (2), perhaps the best known of these being the Hinsberg (3) synthesis utilizing thiodiacetic ester and the sulfide-induced cyclization of 1,4-difunctional compounds (4). Each of the methods suffers from a lack of generality, especially when applied to the synthesis of polyalkylated materials. Furthermore, while direct substitution of the thiophene nucleus occurs very easily at the positions adjacent to sulfur (5), preparation of β-substituted or unsymmetrical trisubstituted compounds can present a complex problem.

We recently published a new synthesis of 2,5-dihydrothiophenes **1** (6, 7) which provides an extremely facile and general route to this type of compound. Unlike most other methods for this synthesis, the method does not require the corresponding thiophene as a starting material (8), but rather involves the condensation of mercaptoaldehydes and ketones with vinylphosphonium salts. The method allows the formation of alkylated products in a completely regiospecific manner.

We have already shown the utility of **1** in the preparation of conjugated dienes (6) and as part



1

of a program to expand the utility of **1** in synthesis, we considered their dehydrogenation to thiophenes. Of the many reagents available for dehydrogenation, we chose to investigate the use of chloranil and we present here the results of that investigation.

2 **3**

Prior to the start of our work, there were some indications of its potential success. Wynberg *et al.* (9) reported the chloranil-induced dehydrogenation of several 2,3-dihydrothiophenes in excellent yields and the stability of the thiophene ring to the reaction conditions has been noted (9, 10).

The use of quinones for dehydrogenation reactions has been reviewed (11). Although chloranil is the least reactive of these materials, we have used it routinely as a matter of economy and convenience. The use of *o*-chloranil does not seem to afford any advantage in the examples cited here.

Results and Discussion

The traditional solvents used for quinone dehydrogenation have been benzene and its chlorinated derivatives. However, we chose to

use *tert*-butanol or pyridine in order to facilitate the work-up procedure as the separation of the thiophenes from the aromatic solvents caused problems in trial experiments. The quinones are only modestly soluble in *tert*-butanol and since an excess is required for acceptable rates of reaction, the mixture is heterogeneous at all times. However, as can be seen by the yields of products (Table 1) this does not seem to affect the reaction adversely. The unreacted reagent can easily be recovered from the medium.

The ease with which pyridine can be removed by acid extraction prompted an investigation of its use. When chloranil is added to pyridine it dissolves but almost immediately an exothermic reaction occurs with the precipitation of a brown solid. The nature of this has not been determined but it appears to function in the same manner as the quinone. However, the unreacted quinone cannot be recovered from this medium.

As can be seen from inspection of Table 1, the yields from representative 2,5-dihydrothiophenes[1] are generally excellent. However, under our conditions, migration or elimination of alkyl groups from fully substituted centers does not occur and the starting material is recovered in nearly quantitative yields in these cases.

The overall yield of alkylated thiophenes from mercaptocarbonyl compounds is also recorded in Table 1. As can be seen, this route allows a simple regiospecific two-step procedure for the formation of thiophenes under very mild conditions from a set of starting materials which is different from that normally used.

[1]Prepared as outlined in ref. 6. Yields and spectral data on compounds 2*a*, *c*–*e* are incorporated in a manuscript now in preparation.

Experimental

Unless otherwise noted, n.m.r. spectra were obtained on a JEOLCO C60HL spectrometer in deuteriochloroform and are reported in p.p.m. from TMS as internal standard. Gas–liquid chromatography analyses were carried out on an F and M Model 720 gas chromatograph utilizing an 8 ft × 0.375 in. 20% SE30 on Chromosorb W column. The flow rate of the helium carrier gas was 1 ml/s. Chloranil was recrystallized from benzene prior to use. Unless otherwise noted, the drying agent used was anhydrous sodium sulfate and solvents were removed on a rotary evaporator at reduced pressure. Chromatography was performed using Fisher neutral alumina, 80–200 mesh, Brockman activity grade 1. Microanalyses were performed by A. B. Gygli, Microanalysis Laboratory, Toronto, Ontario.

General Procedure

A. Using tert-Butanol as Solvent

A stirred mixture of dihydrothiophene (8 mmol) and chloranil (39 mmol) in *tert*-butanol (60 ml) was heated at reflux for 6 h. Excess chloranil was filtered, the filtrate was added to 600 ml of water and this was extracted with pentane or ether (3 × 150 ml). The organic layer was washed with water (6 × 150 ml), 5% sodium hydroxide (2 × 100 ml) and finally with water until the washings were neutral. The dried solution was evaporated and the residue was chromatographed using pentane as eluant. The thiophene was obtained essentially pure by evaporation of the pentane. Reduction of the reaction time to 3 h afforded incomplete reaction.

B. Using Pyridine as Solvent

Chloranil (39 mmol) was added with stirring to dry pyridine (100 ml). An exothermic reaction occurred immediately and a deep red color developed. After 5 min a deep brown precipitate formed. This mixture was stirred for 15 min and the dihydrothiophene (8 mmol) was added all at once. The mixture was refluxed 6 h, cooled, poured into 600 ml of water, and extracted with ether (4 × 150 ml). The extracts were washed with 10% hydrochloric acid (2 × 100 ml), dried and concentrated. Chromatography as previously outlined gave the thiophene.

Analytical samples were collected from g.l.c. Indices of refraction and n.m.r. spectra are shown in Table 2. Infrared spectra were generally uninformative.

Nuclear Magnetic Resonance Studies. XXVII.[1] Homoenolization of Fenchone. A Mechanistic Study Utilizing ^{13}C and ^{2}H Nuclear Magnetic Resonance

A. L. JOHNSON,[2] J. B. STOTHERS, AND C. T. TAN
Department of Chemistry, University of Western Ontario, London, Ontario
Received August 29, 1974

A. L. JOHNSON, J. B. STOTHERS and C. T. TAN. Can. J. Chem. **53**, 212 (1975).

Deuterium exchange occurs at five β positions in fenchone under homoenolization conditions (t-BuO$^-$–t-BuOD, 185°), C-6 (*exo* and *endo*), C-8, C-9, and C-10. Both ^{13}C and ^{2}H n.m.r. methods were employed to monitor deuterium incorporation and the particular advantages of the latter are illustrated. The relative rates of the five exchange processes were determined directly by ^{2}H n.m.r. in contrast to the earlier homoenolization studies for which the stereoselectivity of exchange was established indirectly. The intermediate homoenolate ion can lead to rearrangement and the rearrangement products have been characterized by ^{13}C n.m.r. as the 3,3,6-trimethylnorcamphors. Homoenolization of this mixture gave further evidence on the stereochemistry of homoenolate formation.

A. L. JOHNSON, J. B. STOTHERS et C. T. TAN. Can. J. Chem. **53**, 212 (1975).

Dans des conditions d'homoénolisation (t-BuO$^-$–t-BuOD, 185°) l'échange de deutérium se produit dans cinq positions β de la fenchone; ces cinq positions sont les positions C-6 (*exo* et *endo*), C-8, C-9 et C-10. Des méthodes impliquant la r.m.n. du ^{13}C et du ^{2}H ont été utilisées pour suivre l'incorporation du deutérium; les avantages particuliers de la dernière méthode sont démontrés. On a déterminé directement par r.m.n. du ^{2}H les vitesses relatives des cinq processus d'échange; ces résultats sont en contraste avec les études antérieures d'homoénolisation pour lesquelles la stéréosélectivité de l'échange n'avait été établit qu'indirectement. L'ion homoélonate intermédiaire peut conduire à des réarrangements; les produits de réarrangements ont été caractérisés par r.m.n. du ^{13}C comme étant les triméthyl-3,3,6 norcamphres. L'homoénolisation de ce mélange peut donner d'autres preuves sur la stéréochimie de la formation de l'homoénolate.

[Traduit par le journal]

Several years ago, Nickon and Lambert (1) presented the first example of base-catalyzed hydrogen abstraction from the β-position of a bicyclic ketone, a process they termed homoenolization. Their initial example was camphenilone (**1**) and through an elegant series of experiments it was unequivocally established that hydrogen–deuterium exchange only occurred at the C-1, C-6, and methyl positions (2). Reaction through the symmetric homoenolate anion **2** leads to deuterium incorporation at C-1 and C-6, equivalent in **2**, and serves to racemize **1** thereby rendering the methyl groups equivalent and thus masking any stereoselectivity which may be involved in the exchange at the *exo* and *endo* methyl positions. To examine the stereochemistry of exchange at C-6 the reverse reaction, homoketonization of 1-acetoxynortricyclene (**3**), was studied (3) and it was found that in alkaline media protonation occurred with high stereoselectivity favoring inversion of configuration, *i.e.* *exo*-protonation.

The synthetic potential of skeletal rearrangement via homoenolate anions to generate systems otherwise difficult to obtain was also demonstrated in the initial investigations of homoenolization by Nickon *et al.* (4). Treatment of brexan-2-one (**4**) with t-BuO$^-$–t-BuOH at 185° gave a 60% yield of brendan-2-one (**5**). A similar rearrangement of longicamphenilone (**6**) was employed by Coates and Chen (5) to generate the *endo*-bridged system **7** as a structural proof for one of the solvolysis products of longicamphenilyl tosylate. Further information on homoenolization in polycyclic systems was provided by Arigoni and co-workers (6) who examined deuterium exchange in longicamphor (**8**) and copacamphor (**9**) under homoenolization conditions. While **8** was found to incorporate up to 3 equiv. of deuterium, only monodeuteration was observed for **9** exclusively at the α-position. Clearly, the additional deuterium incorporation in **8** shows that homoenolization occurred. The lack of more remote exchange in

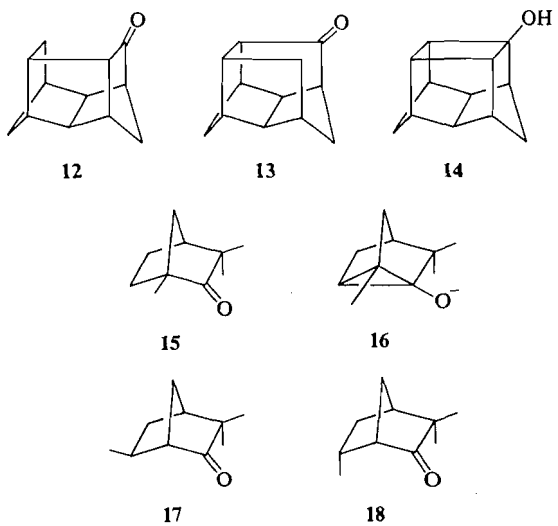
a R = H; R′ = Me
b R = Me; R′ = H

9 was attributed to "the additional strain imposed by the three-membered bridge on the [2.2.1]bicycloheptane system" but it seems somewhat surprising that **9** failed to homoenolize in view of the **4** → **5** conversion; perhaps more vigorous conditions and/or a longer reaction time would cause more extensive deuterium exchange. In addition to these polycyclic examples, homoenolization has been invoked to account for the results in two acyclic examples (7, 8), in one of which ^{13}C labelling experiments afforded evidence for a pathway involving two homoenolate ions (8).

Evidence that homoenolization can occur concurrently with enolization in bridged ketones containing an α-methylene group was recently presented (9). The *endo*- and *exo*-isocamphanones (**10***a* and *b*, respectively) are interconvertible via a common homoenolate ion **11** which could also lead to camphor. The interconversion of **10***a* ⇌ **10***b* gave further evidence for preferential *exo*-protonation of **11** since **10***a* gave only 1.5% of **10***b* whereas, under comparable conditions, **10***b* gave 42% of **10***a*; in these experiments the relative yields of camphor were 58 and 22%, respectively.

Each of the foregoing examples involves proton abstraction from a β-position of the ketone but more remote abstraction should also be possible and has in fact been observed at the *syn*-methyl of camphor (10) and for the half-cage ketone **12** rearranging to **13**. Homoketonization of the bird cage alcohol **14**, expected to be the intermediate alkoxide species, gave the same mixture of **12** and **13** heavily favoring the latter (11).

In the earlier work, a variety of techniques was employed to establish the course of deuterium exchange by homoenolate ions. For example, the details of camphenilone homoenolization were elucidated through a combination of ^{1}H n.m.r., i.r., and mass spectra together with separate synthesis of deuterated analogs (1–3). More recently, we have demonstrated that the same information is more readily available by ^{13}C n.m.r. (9). The characteristic effects produced by ^{2}H-labelled centers in ^{13}C spectra afford a straightforward monitor for deuterium exchange studies in a variety of systems (1, 12). Comparison of the ^{13}C spectrum of the labelled material with that of the unlabelled compound immediately reveals the site(s) of deuterium incorporation and integrated intensity data provide a measure of the ^{2}H content at the individual carbons. In practice, however, meaningful intensity data from ^{13}C spectra require careful selection of the optimum operating conditions, because of variations in relaxation times and nuclear Overhauser enhancements of nonequivalent



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

carbons, and calibration data from spectra of the natural abundance material. In our experience, the precision of quantitative assessments of the ^2H content at individual centers is 3–5% and, thus, lightly labelled centers can be missed. A second deficiency of the ^{13}C method concerns exchange at methylene carbons bearing nonequivalent hydrogens. In general, the ^{13}C absorption pattern will be the same regardless of which hydrogen undergoes exchange. Hence, information on the stereochemistry of exchange at such methylene carbons is unavailable from the ^{13}C spectrum.

The striking advantages of ^2H n.m.r. for mechanism studies have been clearly illustrated (13) and, in the present case, the use of ^2H spectra of the labelled species neatly overcomes the major deficiencies of the ^{13}C method. Since magnetic relaxation of deuterium nuclei is induced entirely by an intramolecular quadrupole mechanism (14) there is no Overhauser enhancement accompanying proton decoupling. In addition, ^2H relaxation times are relatively short (15) which minimizes the possibility of partial saturation. These two features circumvent the major pitfalls associated with ^{13}C spectra and render integrations of ^2H spectra more favorable. Another advantage of ^2H spectroscopy accrues from the low natural abundance of deuterium, 0.015%. Thus, even at low incorporation levels of *ca.* 1%, the n.m.r. signals of ^2H labels will be about two orders of magnitude more intense than the natural abundance signals and one can readily monitor lightly deuterated centers. With proton decoupling and the absence of other magnetic nuclei, deuterium spectra consist of relatively narrow singlets having half-widths of *ca.* 1 Hz for each nonequivalent site. Although the shieldings for ^1H and ^2H in identical environments are the same, on a p.p.m. scale, for observations at the same magnetic field (16), the shift range for ^2H nuclei is reduced by a factor of 6.5 because of the lower magnetogyric ratio and the spectra of compounds containing similar but nonequivalent ^2H nuclei may have heavily overlapping signals. In many cases, this inconvenience may be reduced through the use of lanthanide shift reagents to obtain greater shift dispersion (17). Even with overlapping signals, however, precise integrated intensities may be obtained by computer line-shape fitting rather than the usual electronic integration. Our experience indicates that the line-shape fitting technique permits precisions of the order of 1–2%.

The results of a detailed examination of the behavior of fenchone (**15**) under homoenolization conditions, namely at 185° in *t*-BuO^-–*t*-BuOD are presented in this paper; a preliminary account of part of this work has appeared (9).

Deuterium incorporation was monitored by both ^{13}C and ^2H n.m.r., and from the latter data, the relative rates of exchange were estimated for the *exo*- and *endo*-6-protons and at the three methyl groups. This direct measure of the stereoselectivity is the key advantage of the ^2H n.m.r. method for this study. The intermediate homoenolate ion **16** can lead to rearranged ketones; these have been characterized by ^{13}C n.m.r. and their homoenolization behavior was examined.

Experimental

Materials

Commercial fenchone was employed for these studies. Initially, the camphor present (~5%) was not removed before use but in the later stages this impurity was removed by reaction with 2,4-dinitrophenylhydrazine or by preparative gas chromatography (g.c.) on a 20% SE-30 column. *t*-Butyl alcohol-*O*-d_1 was prepared according to the procedure of Young and Guthrie (18). For the second set of homoenolization runs, the preparation of the alcohol-*O*-d_1 was modified. After the initial hydrolysis of the borate ester, a small amount of potassium metal was added to the wet alcohol and the alcohol was distilled. This was repeated and a third distillation from molecular sieves gave *t*-butyl alcohol-*O*-d_1 which was $<0.005\ M$ in water by Karl Fischer titration.

Homoenolization Experiments

The general procedure followed was essentially as described by Nickon *et al.* (2). Typically, fenchone was added to the base, prepared by dissolving potassium metal in *t*-butyl alcohol, to give a solution containing ketone–*t*-BuO^-–*t*-BuOH(D) in the mole ratio 1:4:60. Aliquots were placed in glass tubes which were sealed after degassing. After heating at 185 ± 3° for varying periods of time, the tubes were opened and the ketonic products isolated by pentane extraction in average yields of 80%. The total product composition was analyzed by g.c. on 20% SE-30 or 10% FFAP columns. In each case a small peak appeared at a slightly longer retention time than fenchone. In the longer runs, this second peak made up 6–7% of the total product. After column chromatography on alumina, the second peak was reduced to *ca.* 5% of the total product, and could be easily separated from fenchone by preparative g.c. on SE-30 columns.

Characterization of the Minor Products

Some larger scale runs were conducted to obtain samples of the second fraction by g.c. on SE-30 columns.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Infrared spectra of these samples indicated the presence of an alcohol which was readily removed by chromatography on alumina. Its chromatographic (g.c., t.l.c.) behavior was identical to that of fenchol. Gas chromatographic analysis of alcohol-free material on a 15% DEGS column showed this second fraction to contain two partially separated components in a ratio of *ca.* 1:3. The i.r. spectrum exhibited strong carbonyl absorption and its ^{13}C spectrum consisted of 18 signals in the higher field region with 2 additional peaks at low field, 220.0 and 219.3 p.p.m.; the latter, in the ratio of *ca.* 1:3, are typical carbonyl carbon signals. The high field signals formed two sets of nine, having an intensity ratio of *ca.* 1:3. Off-resonance decoupling established that each set contained three methyl, two methylene, three methine, and one quaternary carbon signals. The signal at lowest field in each of these groups, 57.0 and 56.3 p.p.m., arose from a methine carbon, whereas the three at highest field in each group were methyl signals, 21.0, 21.3, and 23.2; 18.1, 20.0, and 23.9 p.p.m., respectively. The remaining signals appeared at: 31.5, 31.7, 30.6, 36.3 (CH_2's); 33.5, 46.6, 33.4, 46.9 (CH's), and 46.0 and 47.7 p.p.m. (quaternary C's); the less intense peaks of the two sets of signals are listed first.

Model experiments showed that the reduction of fenchone with $LiAlH(OMe)_3$ gave fenchol which was >96% *endo*. A sample of the mixture of rearranged ketones was reduced to provide a mixture of the corresponding alcohols which by g.c. on a 10% SE-30 column were present in the ratio of 3:1 but not well resolved. Column chromatography on silica gel gave upon elution with ether–pentane (3:97) a fraction which was essentially a single component and a second fraction enriched in the less abundant isomer; these fractions were examined by ^{13}C n.m.r. The spectrum of the single component contained 10 signals which were shown by off-resonance decoupling to arise from methyl (18.9, 20.1, and 31.2 p.p.m.), methylene (31.8 and 35.5 p.p.m.), methine (33.2, 48.6, 49.5, and 83.9 p.p.m.), and one quaternary carbon at 37.4 p.p.m. The spectrum of the second fraction contained in addition to these signals a set of nine more intense peaks at 19.7, 21.7, and 30.6 (CH_3's); 29.7 and 34.8 (CH_2's); 24.1, 49.3, 51.1, and 80.6 p.p.m. (CH's). From its intensity it was apparent that the 37.4 p.p.m. signal is common to both isomers.

A 400 mg sample of the ketone mixture was subjected to the homoenolization conditions for 200 h and the product was analyzed by g.c. using the 15% DEGS column. This mixture was found to contain 75% of fenchone and 25% of the two ketones in a ratio of 4:1, *i.e.* the relative amount of the more abundant isomer originally present was much reduced.

Spectra

^{13}C spectra were obtained with a Varian XL-100-15 system operating in the Fourier transform mode. To optimize operating conditions for measuring the integrated intensities in the ^{13}C spectra, samples of fenchone in $CDCl_3$ were run under a variety of conditions varying the pulse width and repetition rate using sweep "windows" of 1 kHz or less. Under conditions which gave essentially equal integrals for each nonequivalent protonated carbon in fenchone, the deuterated samples of fenchone-d_x at similar concentrations were examined and the relative intensities of the absorption for each carbon were measured. As a check on these results, mass spectral data were obtained using a Varian M-66 instrument to determine the relative concentrations of the various deuterated species in each sample. The estimates of deuterium content at the individual carbons by ^{13}C n.m.r. were judged to be within $\pm 5\%$ and comparison of the total ^2H content with that from the mass spectra supports this.

Deuterium spectra were obtained at 15.4 MHz with a Varian XL-100-15 system in the Fourier transform mode. A solvent mixture of C_6F_6 and $CHCl_3$ (1:4 v/v) was used and the instrument locked to the ^{19}F signal with noise modulated proton decoupling. Because of the relatively small ^2H shift range, on a frequency scale, and the fact that the signals are ~1 Hz wide, the individual signals of similar deuterium nuclei are heavily overlapped. Greater shift dispersion was obtained through the use of the $Pr(fod)_3$ shift reagent but line broadening accompanies the increased dispersion. Consequently, line-shape fitting by computer, assuming Lorentzian line shapes, was employed to obtain the relative areas of the individual absorption signals. For this purpose a modified version of the BMDX85 program (19) was used. With the total deuterium content, as measured by mass spectrometry, the relative concentrations of deuterium at individual centers was readily calculated and these data are judged to have precisions of 1%. Shift reagent studies of the proton spectra of fenchone, using a Varian HA-100 instrument, were also carried out to confirm the assignments in the ^2H spectra.

Results

^{13}C Nuclear Magnetic Resonance Assessment of Deuterium Incorporation

Initially, the prime reason for examining the behavior of **15** under homoenolization conditions was the need for unequivocal ^{13}C n.m.r. assignments in this bicyclic system. Analogous behavior to that of **1**, which had been studied in detail (1, 2), was expected but the unsymmetrical homoenolate ion **16**, in contrast to **2**, could lead to rearranged product and could reveal stereoselectivity of exchange at the *exo*- and *endo*-methyl carbons, C-8, and C-9. In the first set of experiments, the progress of deuterium incorporation in **15** was monitored with ^{13}C n.m.r. and mass spectrometry. From the ^{13}C spectra, the specific carbons undergoing exchange were readily revealed because of the distinctive spectral changes produced by deuterium incorporation (9, 12); spectra of two samples are shown in Fig. 1. The triplets characteristic of —CHD— and —CH_2D groups were apparent only for the C-6 and *exo*-methyl (C-8) absorptions while isotope shifts for C-1, C-3, and C-5 were also observed. Careful integration of the ^{13}C absorptions for all protonated and partially protonated carbons

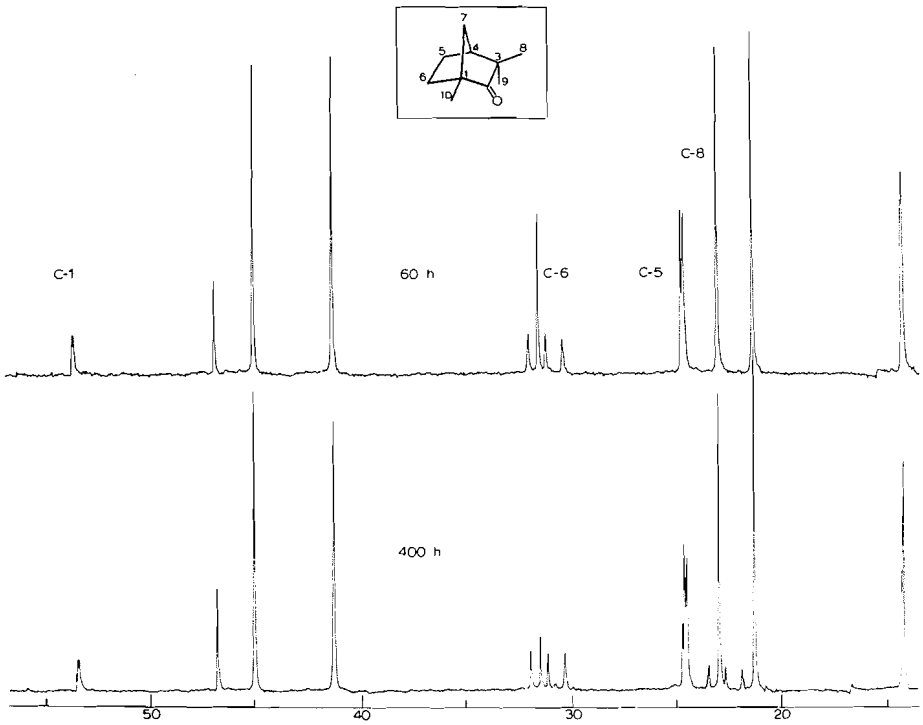


FIG. 1. ^{13}C spectra of **15** after treatment with *t*-BuO$^-$–*t*-BuOD at 185° for the times indicated. The scale is in p.p.m. from TMS.

gave a measure of the ^2H content at C-6 and the *exo*-methyl group. For example, the C-6 absorption consisted of a singlet identical to that in normal fenchone and a CHD triplet, the relative intensity of the latter provides a measure of the extent of monodeuteration at this center. From the intensities of the non-deuterated carbons, a "standard" intensity for a single carbon for each sample was obtained as the average. The difference between this "standard" value and the sum of the —CH_2— and —CHD— intensities gave the relative concentration of the —CD_2— species. As a check on the ^2H assay by ^{13}C n.m.r., each sample was analyzed by mass spectrometry to obtain precise data on the ^2H content. These data for samples which were allowed to react for various times are listed in Table 1. The agreement between the total atoms ^2H/molecule obtained by mass spectrometry and ^{13}C n.m.r.

is gratifyingly good, even though the estimated error for the measurement of ^2H content at individual carbons by ^{13}C n.m.r. is *ca.* 5%.

To try to maximize the deuterium content in **15**, one sample recovered after 140 h was treated again with a fresh deuterium pool for 260 h and a sample from a 400 h run was reacted with fresh base for an additional 400 h. From the latter experiment it was apparent that up to 6 deuterium atoms can be incorporated into **15** under homoenolization conditions; this result is in complete accord with some preliminary data obtained by Lambert (10) several years ago. The ^{13}C spectrum of this sample very clearly served to point up some of the deficiencies in the ^{13}C n.m.r. method for deuterium analysis. The presence of species containing more than five ^2H nuclei demands that exchange has occurred at centers in addition to C-6 and C-8, but the ^2H content at the lightly deuterated centers was not observable from the ^{13}C spectrum. In addition the exchange was so extensive at C-6 that the intensity of the "quintet", probably a triplet of triplets, for the $—CD_2—$ containing molecules precluded precise integrations of the $—CH_2—$ and —CHD— absorptions. The intensity of the "quintet" is not meaningful for comparison with the intensities of the signals from protonated carbons, since the former absorption lacks the significant Overhauser enhancement produced by proton decoupling. Another weakness of the ^{13}C analysis is the fact that it is not possible to distinguish between *exo* and *endo* deuteration at C-6, only the total ^2H incorporation at this carbon can be assayed.

Notwithstanding these deficiencies, however, ^{13}C spectra can be valuable for quantitative analysis of deuterium incorporation in a host of systems. In the present case, the major result of the exchange was clearly apparent from the ^{13}C spectra and the total deuterium content was readily assayed for C-6 and C-8.

Identification of the Rearrangement Products

Examination of the recovered material from each run by g.c. on SE-30 columns showed an additional peak, comprising 6–7% of the total product, having a longer retention time than that of fenchone (93–94% of the isolated product). Column chromatography on alumina of the total product decreased the second fraction to *ca.* 5% for products obtained from the longer runs. Since the g.c. retention time corresponded to that of fenchol, there was apparently some reduction (~1%) of the fenchone, presumably by undissolved potassium metal. Some larger scale runs provided larger samples of the second fraction and, after removal of the alcohol, g.c. analysis of these on a DEGS column showed the minor fraction to contain two components in a ratio of *ca.* 1:3, although the peaks were not separately resolved. Infrared spectra and ^{13}C n.m.r. spectra confirmed that these were ketonic and isomeric with fenchone since each contained three methyl, two methylene, three methine and one quaternary carbon signal in the higher field region of the ^{13}C spectrum, besides a typical carbonyl carbon signal near 220 p.p.m. (20). The positions (see Experimental) of the individual resonances corresponded well with those expected for ketones **17** and **18**, the 3,3,6-trimethyl norcamphors, which could arise from homoenolate **16** by cleavage of the bond formed between the original carbonyl carbon and C-1 in **15**. The assignments have been discussed in conjunction with a ^{13}C study of several methyl substituted norcamphors (21).[3] For additional confirmation of the structure of these rearranged ketones, the mixture was reduced to the corresponding *endo*-alcohols with $LiAlH(OMe)_3$. This reagent was chosen since a variety of methyl norcamphors give alcohols which are 96–98% *endo* upon reaction with it; for example, the alcohol formed from fenchone is >96%-*endo*. The product was found to contain two major components in a ratio of *ca.* 1:3 by g.c. analysis on SE-30 columns, but, again, separate bands were not resolved. Column chromatography on silica gel, however, afforded two fractions, one of which was essentially a single alcohol corresponding to the more abundant component of the original mixture, while the second fraction was enriched in the less abundant component (70%) together with the more abundant alcohol (30%). The ^{13}C shielding of these two alcohols (see Experimental) accorded well with those expected for the *endo*-alcohols, corresponding to **17** and **18**; the ^{13}C data for several methyl norbornanols were available (22) since the

[3]In the paper describing the ^{13}C spectra of these norcamphors, there is a typographical error and the shielding of C-3 in fenchone should read 47.1 p.p.m.

norcamphors cited above had been reduced to the alcohols. Thus it can be concluded that the homoenolate ion **16** opened in the two possible modes to produce **15** or a mixture of **17** and **18**. Since the concentration of the minor products never exceeded 5% even in the longest runs, this appears to be the equilibrium amount.

A sample of the mixture of rearranged ketones (**17** and **18** in a ratio of 1:3) was treated with *t*-BuO$^-$–*t*-BuOH at 185° for 200 h and the isolated product was examined by g.c. It was found that the ratio of ketones was 20:5:75 for **17**, **18**, and **15**, respectively, thus **18** is the more reactive of the rearranged ketones.

^2H *Nuclear Magnetic Resonance Assessment of Deuterium Incorporation in* **15**

A number of developments suggested that a second examination of **15** might be valuable. After obtaining the results discussed above, we extended our study of homoenolization to other bicyclic systems and had some difficulty with reproducibility of the rates of deuterium incorporation. We found that a modified drying procedure of the *t*-butyl alcohol-*O*-d_1 eliminated this problem and all subsequent work was done with *t*-butyl alcohol which tested $<0.005\ M$ in water by Karl Fischer titration. The rate-depressing effect of water on *t*-BuO$^-$–*t*-BuOH has been discussed by Cram *et al.* (23). It may be noted that the general precautions regarding the use of *t*-BuO$^-$ have been discussed recently (24); these problems have been circumvented in the present work by generation of the base *in situ*. Recently, the n.m.r. spectrometer was modified to perform ^2H experiments in the Fourier transform mode. The direct examination of deuterated samples by ^2H n.m.r. offered distinct advantages over the ^{13}C approach as noted in the introduction. Consequently, a second set of experiments was carried out for **15** under homoenolization conditions.

A prime reason for this re-examination was to follow the rate of deuterium incorporation at the *exo*- and *endo*-6 protons separately and to check for small extents of incorporation in the remaining two methyl groups (C-9 and C-10): features which could not be discerned by ^{13}C n.m.r. The ^2H spectra of samples of **15**-d_x recovered after treatment with *t*-BuO$^-$–*t*-BuOD consisted of three distinct absorptions at 5.79, 5.98 and 6.32 p.p.m. upfield from the

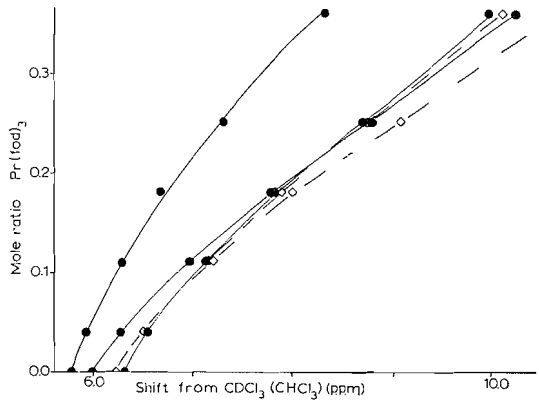

FIG. 2. Effects of Pr(fod)$_3$ on the relative shifts of **15**; ^2H shifts (●) are indicated with full lines, ^1H shifts (○) with dashed lines. Spectra were obtained for $CHCl_3$–C_6F_6 (4:1 v/v) solutions.

absorption of $CDCl_3$. These signals were tentatively assigned to the 6-*exo*-, 6-*endo*-, and C-8-methyl deuterons, respectively. In the ^1H spectrum of **15**, the C-10 methyl group absorbs at 6.22 while the C-8 and C-9 protons are equivalent at 6.32 p.p.m., upfield from $CHCl_3$ in $CHCl_3$–C_6F_6 (4:1) solution. Thus, this medium is inappropriate for the desired measurements, since the ^2H signals had line widths of 1.0–1.2 Hz (0.06–0.08 p.p.m.). To increase the separation of the deuterium resonances as well as to obtain unequivocal proof for the assignments of the C-6 signals, spectra were obtained using Eu(fod)$_3$ and Pr(fod)$_3$ as shift reagents. The results with the latter reagent seemed better for our purposes and the shifts produced in its presence were examined in detail.

Upon addition of Pr(fod)$_3$ to solutions of **15**-d_x in $CHCl_3$–C_6F_6 (4:1 v/v), each of the three signals noted above shifted to higher field with the central peak exhibiting the greatest relative shift. These shifts over the range of 0–0.36 equiv. of Pr(fod)$_3$ are plotted in Fig. 2, together with the corresponding shifts for the remaining methyl protons as observed in ^1H spectra. Decoupling experiments in the ^1H spectra confirmed the tentative assignments noted above for the 6-deuterons. In the more dispersed spectra the methylene proton absorption at highest field was essentially a six-line pattern with repeated spacings of 13, 7 and 2 Hz corresponding in a first-order analysis to the couplings with the *exo*-6, *endo*-5 and *exo*-5

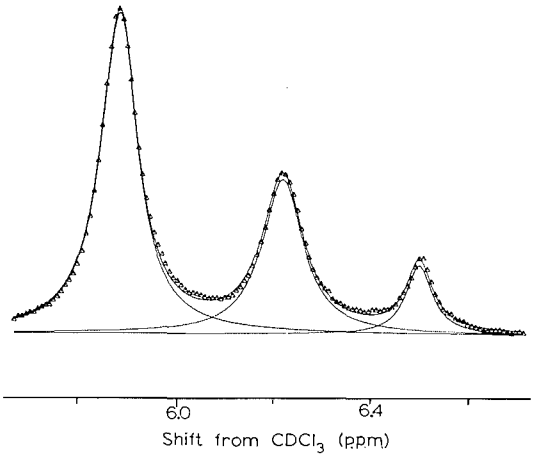

FIG. 3. Observed (△) and computer-fitted (full line) ^2H spectra of **15**-$d_{1,18}$ after treatment for 40 h with *t*-BuO^-–*t*-BuOD at 185°. The spectrum was obtained in $CHCl_3$–C_6F_6 (4:1) containing 0.03 equiv. of $Pr(fod)_3$. The line-shape fitting utilized 130 data points; the individual Lorentzian curves for each absorption are also shown.

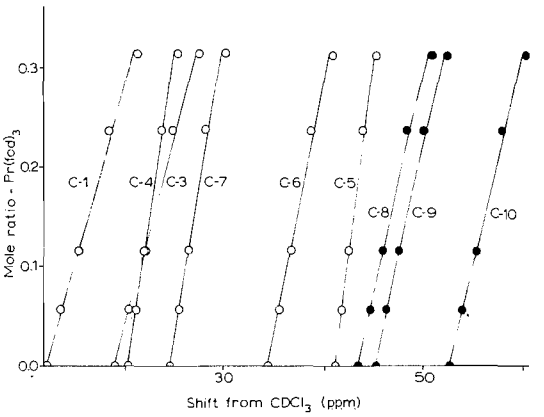

FIG. 4. Effects of $Pr(fod)_3$ on the ^{13}C shieldings of **15**. Spectra were obtained for $CDCl_3$–C_6F_6 (1:4 v/v) solutions.

protons, respectively. Double irradiation at the position of the *exo*-6 proton, as found from the ^2H spectrum, eliminated the larger of these splittings in the high field methylene proton pattern, confirming the assignments for the *exo*- and *endo*-6-deuterium nuclei. For the **15**-d_x samples isolated after reaction with the base for relatively short times, ^2H spectra for solutions containing about 0.05 equiv. of $Pr(fod)_3$ were recorded and the relative intensities of the three absorption signals measured by line-shape fitting by computer. An example is shown in Fig. 3. These data, together with the total ^2H content determined for each sample by mass spectrometry, provided a measure of the relative extent of deuteration at the three positions.

From Fig. 2, it is apparent that the three types of methyl protons show different shifts with added $Pr(fod)_3$ reagent so that, in principle, the ^2H spectra of heavily doped samples should permit the detection of deuterium at C-9 and C-10. In practice, however, the increased line broadening which accompanied the increased shifts produced by the lanthanide reagent gave spectra with insufficient resolution of the closely-lying absorptions for good integrations, although it was apparent for 40, 100, and 300 h samples that some deuteration had occurred at C-9 and C-10. At somewhat lower concentrations of **15** in $CHCl_3$–C_6F_6 (1:4 v/v), the relative shifts are larger for comparable amounts of added $Pr(fod)_3$; this solvent change was serendipitous. With 0.25 equiv. of $Pr(fod)_3$ five resonances were apparent in the ^2H spectrum of the 300 h sample at 8.76, 10.66, 10.82, 11.04, and 11.50 p.p.m. upfield from $CDCl_3$. From the relative intensities and the known effects of added $Pr(fod)_3$ these signals could be assigned to the *exo*-6, C-8, C-9 (or 10), *endo*-6, and C-10 (or 9) deuterons. It remained to distinguish unequivocally between the C-9 and C-10 signals. Since the assignments for the ^{13}C signals for each of the methyl carbons were known (21), ^{13}C spectra of **15** were recorded with added $Pr(fod)_3$ to determine the relative shifts for each. These results are shown in Fig. 4 from which it is apparent that the order of the methyl shieldings is unchanged with added shift reagent. In the ^1H spectrum of solutions containing 0.313 equiv. of $Pr(fod)_3$, the methyl protons absorbed at 10.95, 11.08, and 11.93 p.p.m., upfield from $CHCl_3$. Selective proton decoupling at the highest field methyl protons gave a ^{13}C spectrum in which only the highest field carbon signal was decoupled; selective irradiation at the lowest field methyl protons decoupled only the third highest field ^{13}C signal. Thus, the shieldings of the methyl signals are in the same order in both ^1H and ^{13}C spectra, namely, C-8 < C-9 < C-10, and the assignments were completed for the ^2H spectra.

With the greater relative shift dispersion obtained in $CHCl_3$–C_6F_6 (1:4) solutions, ^2H

spectra for 40, 100, and 300 h samples were recorded and the extent of deuteration at C-6, C-8, C-9, and C-10 determined by line-shape fitting. To illustrate the line-shape fitting, the spectrum of a 300 h sample is reproduced in Fig. 5. The deuterium incorporation data for several samples from this second set of homoenolization experiments are listed in Table 2.

Discussion

A comparison of the results in Tables 1 and 2 readily reveals the significantly faster rates of deuterium incorporation found for the second set of experiments. We attribute the difference to the use of a drier medium for the second set. These results are the more informative with regard to the details of homoenolization of **15** because the stereoselectivity of the exchange could be determined. From the results for the samples from the shorter reaction times in Table 2, one can estimate the first-order rate constants for deuteration at the *exo*-6, *endo*-6, and *exo*-methyl positions as $\sim 7 \times 10^{-6}$, $\sim 2 \times 10^{-6}$, and $\sim 2 \times 10^{-7}\ s^{-1}$, respectively. The pathways available for these processes can be set out as in Scheme 1 and as a test of the relative magnitudes of these estimated rate constants for C-6 and *exo*-methyl exchange, the rate equations for Scheme 1 were numerically integrated using the MIMIC simulation language of the CDC computer, neglecting secondary kinetic isotope effects. The observed and computed ^2H concentrations at the three sites for the 10, 20, and 40 h runs are listed in Table 3, as obtained using $k_X:k_N:k_M$ of 3.5:1.0:0.085. Inclusion of a primary isotope effect of 4–5

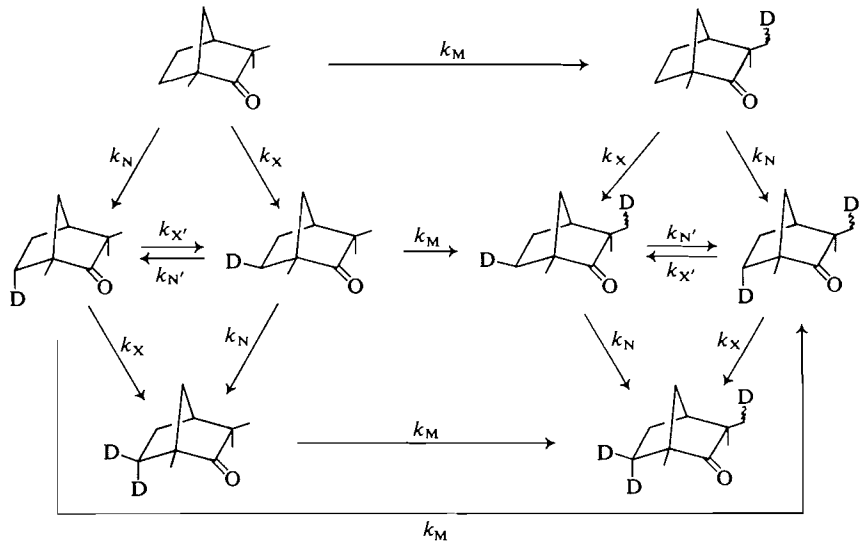

SCHEME I

for the inversion reactions, $k_{N'}$ and $k_{X'}$, led to consistently poorer agreement with experiment indicating that the isotope effect is <2. These inversion reactions represent the formation of the homoenolate ion **16** by abstraction of an *endo*-deuterium and ring opening by *exo*-deuteration, or the reverse. Effectively this partitions the homoenolate ion according to the relative rates k_X and k_N, modified by the isotope effect of deuterium abstraction. Since the standard free energies of formation of *endo*- and *exo*-6-deuteriofenchone are nearly equal, $k_{X'} = k_{N'}$ and assuming the isotope effects for *exo*- and *endo*-deuterium abstraction to be equal it follows that $k_{X'} = k_X k_N/(k_X + k_N) \times k_D/k_H = k_{N'}$.

From the homoenolate ion **16**, formed by abstraction of a C-6 proton in **15**, there are four ways in which the ring opening can occur to give ketones. Cleavage of bond *a* with retention or inversion at C-6 produces *endo*-6-deuterio-**15** or *exo*-6-deuterio-**15**, respectively (arrows N and X indicate *endo*- and *exo*-deuteration). Similarly, cleavage of bond *b* leads to the *exo*-6-methyl derivative **18** (arrow N) or its *endo* isomer **17** (arrow X). From the results cited earlier it is apparent that the bond *a* cleavage is favored by *ca.* 20:1, with *exo*-deuterium attack, *i.e.* inversion at C-6, favored over *endo*-deuteration by a factor of *ca.* 3.5. Since **18** is the more abundant of the two rearrangement products, inversion at the methyl bearing center with cleavage of bond *b* is also the favored pathway. Apparently, the relative rates of *endo* and *exo* attack are similar for both modes of cleavage, *a* or *b*, since **18** and **17** were formed in a ratio of *ca.* 3:1. Since *exo*-deuteration is favored in the ring opening of **16** it follows, by the principle of microscopic reversibility, that *exo*-proton abstraction from

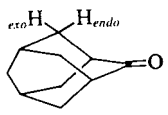
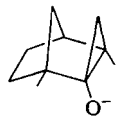
19



20



21

C-6 in **15** is the lower energy process. The experiment in which the mixture of **17** and **18** was subjected to homoenolization conditions shows this to be the case since **18** was converted to **15** significantly faster than **17**. Homoenolization of **18** to **16** must involve *exo*-proton abstraction while *endo* abstraction is required for **17** → **16**. Thus, the stereochemistry of homoenolization of **15** is analogous to that of **2** as deduced by Nickon *et al.* (3) from the homoketonization of **3**. The latter in a variety of alkaline media gave *exo*-6-deuterionorcamphor with high stereoselectivity (95–98%). These reactions, however, proceed under much milder conditions and a quantitative comparison of the ΔΔG values for *exo* and *endo* deuteration of the two homoenolate ions is precluded. It may be noted that a recent examination of the homoenolization of adamantanone (**20**) showed that *exo*-deuteration occurred at the β-positions about 15 times faster than *endo*, under conditions comparable to those of the present study (25).

For the samples from the longer reaction times in Table 2 it is apparent that the ^2H content at C-6 passes through a maximum and approaches an equilibrium value because of dilution of the deuterium pool by exchanged protons. The progressive increases in ^2H concentration at C-9 and C-10, therefore, can only provide lower limits for the estimated rates of exchange at these centers. It appears, however, that *endo*-methyl exchange (C-9) is *ca.* twice as fast as bridgehead methyl exchange (C-10) and approximately 25% as fast as exchange at the *exo*-methyl carbon. In any event, the stereoselectivity of methyl exchange is a new observation for homoenolization reactions. From the relative rates, $k^{C\text{-}8} \approx 4k^{C\text{-}9} \approx 10k^{C\text{-}10}$, the activation energies differ by *ca.* 1 kcal/mol. The fact that the rates are different for the three methyl carbons provides evidence for the intermediacy of homoenolate ions such as **21** since the inductive effect of the carbonyl group, as an activating influence for proton abstraction, would be comparable at each methyl carbon. In principle, species such as **21** could lead to ring expanded products but none was isolated or detected. This was not unexpected since cyclopropanols open in base to give the product derived from the more stable carbanion (26) hence **21** → **15** is the favored path. The alternative ring opening of **21** would lead to an enolizable ketone which could undergo condensation reactions. The stereoselectivity of methyl exchange as observed for **15** could be useful for preparing selectively deuterated derivatives for other tracer studies.

We wish to thank the National Research Council of Canada for financial support of this study. We are grateful to Charles S. Peters for his modification of the Varian FT program to generate the experimental line shape data, to Dr. L. L. Coatsworth for his modification of the BMDX85 program for Lorentzian line-shape fitting and to Prof. N. C. Baird for his assistance with several aspects of the data processing. We thank Prof. D. H. Hunter for valuable discussions, Prof. A. Nickon for helpful comments on the manuscript and Inára Grikis for technical assistance.

The Catalysis of Proton Exchange in Creatinine by General Acids and General Bases

R. SRINIVASAN AND ROSS STEWART

Department of Chemistry, University of British Columbia, Vancouver, British Columbia V6T 1W5

Received July 9, 1974

R. SRINIVASAN and ROSS STEWART. Can. J. Chem. **53**, 224 (1975).

The rate of exchange of methylene protons in creatinine has been followed in D_2O by means of proton magnetic resonance spectroscopy over a range of acidity from p*D* 12.22 to $D_A - 4.24$. A plot of the logarithm of the rate against acidity function is in the form of a "W", one wing of which involves reaction of neutral creatinine with hydroxide ion, and the other diprotonated creatinine with water. The central peak represents reaction of protonated creatinine with a molecule of creatinine acting as base. The reaction is subject to catalysis by buffers.

The activation of exchange produced by protonating the substrate is designated *proton activating factor*, p.a.f., and factors affecting its size are discussed in terms of structure.

R. SRINIVASAN et ROSS STEWART. Can. J. Chem. **53**, 224 (1975).

Faisant appel à la résonance magnétique du proton, on a pu suivre la vitesse d'échange des protons méthyléniques de la créatinine dans D_2O, à des acidités allant de p*D* 12.22 à D_A −4.24. Une courbe du logarithme de la vitesse en fonction de l'acidité à la forme d'un "W"; une portion implique la réaction de la créatinine neutre avec l'ion hydroxyde et l'autre celle de la créatinine diprotonée avec l'eau. Le pic central représente la réaction de la créatinine protonée avec une molécule de créatinine agissant comme base. La réaction est sujette à une catalyse par les tampons.

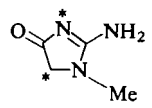
On appelle *facteur d'activation du proton* (p.a.f.) l'activation de l'échange produite par la protonation du substrat; on discute des facteurs influençant sa grosseur en terme de structure.

[Traduit par le journal]

Introduction

Carbon–hydrogen bonds in compounds containing electronegative groups often exhibit measurable rates of ionization in basic media, and, as a consequence, the literature contains many reports of studies of base-catalyzed exchange in such compounds (1). However, there are few examples of general-acid catalyzed exchange in which the base abstracts a proton from the conjugate acid of the substrate. The difficulty in studying general-acid catalyzed exchange is one of finding conditions where the exchange rate and the concentrations of the base and protonated substrate can all be determined. Nitrogen heterocyclic compounds such as creatinine are attractive systems for study in this regard, since their nitrogen atoms are both basic and electronegative.

Though creatinine, which is an end product of nitrogen metabolism in vertebrates, can exist in different tautomeric forms (2) the most stable tautomer has been shown to be 1-methyl-2-amino-2-imidazolin-4-one, **1** (3). The methylene protons are reported to undergo exchange in basic media at rates greater than those for hydrolysis (4). We report herein studies of acid and base catalysis of proton exchange at the 5-position in this compound over a wide range of acidity.



1

Experimental

Measurements of acidity in the aqueous region were made on a Radiometer Model 26 p*H* instrument with an aqueous glass–calomel assembly. The electrode system was calibrated using standard aqueous buffers. The p*D* values were obtained from the relationship p*D* = p*H* reading + 0.40 (5).

Solvents and Reagents

The deuterated solvents D_2O (99.7 atom% D), D_2SO_4, CH_3OD, and aqueous solutions of DCl and NaOD were obtained from Merck, Sharp and Dohme of Canada Limited. Prior to use D_2O was heated to boiling and allowed to cool with a slow stream of nitrogen bubbling through it. The remaining deuterated solvents were used as supplied.

Creatinine was purified by crystallization from aqueous ethanol. *N,N*-Dideuteriocreatinine was obtained by dissolving crystallized creatinine in a consider-

able excess of CH_3OD–D_2O and removing the solvent *in vacuo*. Commercial samples of sodium acetate and sodium formate (AR grade) were dried at 140° before use. Sodium pivalate was prepared from pivalic acid and sodium bicarbonate by standard techniques, crystallized from aqueous ethanol, and dried at 140°. The Hammett indicators were purified by crystallization to constant melting point.

1,3-Dimethyl-2-iminoimidazolidin-4-one Hydrochloride (4, X = Cl)

1,3-Dimethyl-2-iminoimidazolidin-4-one hydroiodide (**4**, X = I) was synthesized by the method of Kenyon and Rowley (4), m.p. 212–214° dec; lit. (4) m.p. 213–215.5° dec. The corresponding hydrochloride was prepared by treating a well-stirred hot suspension of lead chloride in water (3.27 g, 11.77 mmol in 50 ml water) with an aqueous solution of the hydriodide (3.0 g, 11.77 mmol in 10 ml water). The mixture was heated and stirred for an hour, cooled, and the lead iodide removed by filtration. The filtrate was concentrated to about 20 ml, cooled, filtered again, and the filtrate evaporated to dryness to give a colorless solid (95% yield), m.p. 232–235° dec. (from ethanol).

Anal. Calcd. for $C_5H_{10}N_3OCl$: C, 36.70; H, 6.11; N, 25.70. Found: C, 36.55; H, 6.10; N, 25.85.

Determination of the Basicity of Creatinine in D_2O (pK')[1]

The acid dissociation constant of creatininium ion, pK', was determined by a standard spectrophotometric procedure (6) in D_2O, at 34.5°, ionic strength 1.2, the conditions under which most of the kinetic experiments were done.

A solution of boric acid in D_2O was prepared, the ionic strength adjusted to 1.2 with sodium chloride, and the pD brought to 9.84 with NaOD. A portion of this solution (3 ml) was transferred to a cuvette and thermostated at 34.5°. A creatinine solution (10 μl, 3.0×10^{-2} M) was injected into this solution and the absorbance at 234 nm (λ_{max} for creatinine) immediately recorded. A buffer solution without creatinine was used as blank. Similar measurements were made in acetic acid – sodium acetate buffer (3.40×10^{-2} M) at pD 4.23, 4.63, 5.01, 5.42, and 5.78. The absorbance of creatininium ion at 234 nm was determined in 0.01 M DCl. In all measurements the ionic strength was held at 1.2 by the addition of sodium chloride. The pK' value determined under these conditions is 5.40 ± 0.05, compared to the thermodynamic pK of 4.72, determined in H_2O at 34.5° (7).

Acidity Measurements

All acidity measurements on solutions employed in kinetic studies were made after the creatinine was dissolved. This is necessary in view of the concentration of creatinine used (0.18 to 1.20 M) and its basicity. The pD values of creatinine solutions were adjusted with DCl or NaOD, both those with, and those without, added buffer. In the sulfuric acid region the acidities of creatinine solutions are determined by standard indicator procedures (8). Since no precise acidity function

[1]The prime indicates the nonthermodynamic character of the pK, caused by the high ionic strength of the medium (1.2).

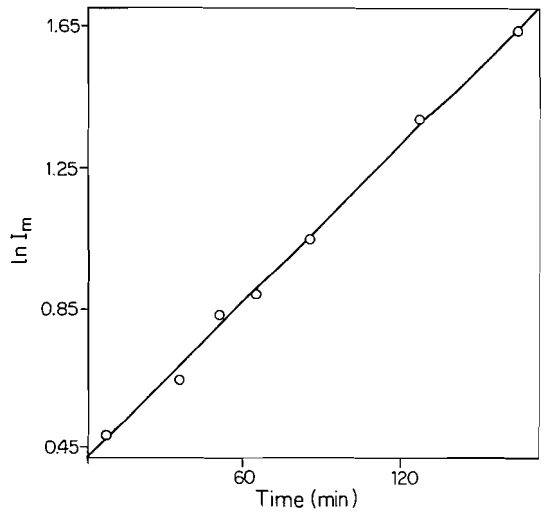

FIG. 1. Exchange kinetics for creatinine in sodium acetate buffer, [NaOAc] = 0.9 M, $[Cr]_a$ = 0.18 M, μ = 1.2, pD = 5.84, T = 34.5°.

governing the process believed to be taking place with creatinine in this region (protonation[2] of creatininium ion in D_2O) is available we have used derived D_A values as an approximation. The D_A function being unknown we have employed standard Hammett indicators (4-chloro-2-nitroaniline, 2,6-dichloro-4-nitroaniline, 2,4-dinitroaniline, 4-chloro-2,6-dinitroaniline, and 2-bromo-4,6-dinitroaniline) to determine the apparent D_0 values for the solution mixtures (8*b*, 8*c*) and have converted these directly to apparent D_A values. It is assumed that the relationship between D_0 and D_A is the same as that between H_0 and H_A.

Kinetic Measurements

The exchange of methylene protons was followed using a Varian T-60 MHz spectrometer at a sweep width of 100 Hz using the general procedure outlined previously (9). The solvent peak (HOD) was used as lock signal. The n.m.r. tube containing the sample was thermostated at 34.5° and periodically introduced into the n.m.r. probe (probe temperature 34.5°). The reaction was usually followed up to 75% completion.

Since the *N*-methyl protons of creatinine did not exchange under the reaction conditions the peak corresponding to these protons was used as reference. The extent of exchange was determined from the ratios of the areas due to methylene and *N*-methyl peaks. The acidity of the medium did not change during the reaction.

The exchange reaction followed first-order kinetics. The observed first-order exchange constant k_{obs} was obtained by plotting the data according to eq. 1.

$$\ln I_m = k_{obs}t \qquad [1]$$

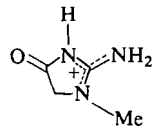
where $I_m = R_t/S_t$, R_t = average area of the *N*-methyl peak, and S_t = average area of the methylene peak,

[2]For the sake of simplicity the term protonation is used for either the addition of a proton or a deuteron.

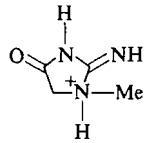
both at time t. A typical rate plot for the exchange of creatinine is shown in Fig. 1. The reproducibility was within ±10%.

Results

Matsumoto and Rapoport (3) have shown the most stable form of creatinine to be **1**, but some uncertainty exists regarding the structure of creatininium ion. Grzybowski and Datta (7) envisaged two possibilities (**2** and **3**).

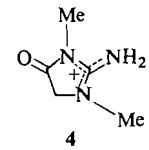


2



3

Structure **2** would be expected to be more stable than **3** in view of its ability to delocalize the positive charge. Verification of this structure was achieved by comparing the ultraviolet absorption spectrum of creatininium chloride with that of 1,3-dimethyl-2-iminoimidazolidin-4-one hydrochloride, the structure of the corresponding iodide having been established as **4** (X = I) (4). Creatininium chloride and **4** (X = Cl) have very similar absorption spectra (λ_{max}(pH3) = 215 nm, ε = 4940; λ_{max}(0.01 M HCl, EtOH) = 215 nm, ε = 5130 for creatininium



4

chloride (3) and λ_{max}(pH2) = 220 nm, ε = 4880; λ_{max}(0.01 M HCl, EtOH) = 218 nm, ε = 6390 for **4** (X = I)) and we conclude that **2** is the favored structure for the cation.

The exchange of methylene protons of creatinine was investigated over the entire range of acidity accessible to experiment (76% sulfuric acid to pD 12.22). Rate measurements in more acidic solutions were precluded for solubility reasons, while in more basic solutions the exchange was too fast to permit meaningful measurements. The acidity was varied by addition of DCl or NaOD; the results are summarized in Table 1. When log k_{obs} was plotted against the most appropriate acidity functions obtainable (see Experimental section) a "W" shaped curve resulted (Fig. 2). The shape of the curve suggests that the substrate undergoes exchange by both general-acid and general-base catalyzed routes.

The rate of the reaction at a given acidity in the absence of added buffer may be represented by eq. 2.

TABLE 1. Exchange rates for creatinine in aqueous solution (1.2 M) in absence of added buffer

pD	k_{obs} (min^{-1})	pD	k_{obs} (min^{-1})

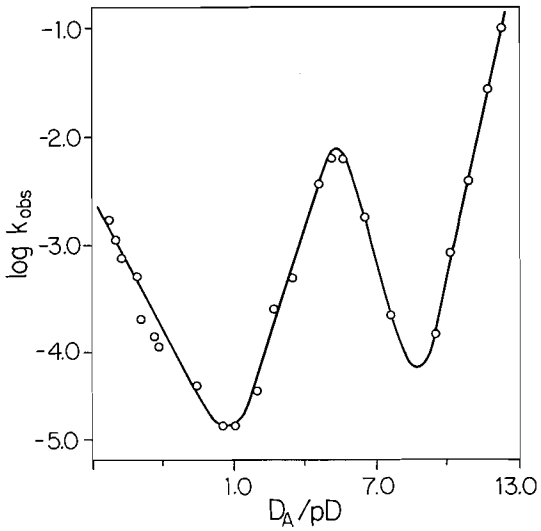

FIG. 2. Effect of acidity on the exchange rate of creatinine at 34.5°, in absence of added buffer; creatinine concentration 0.18 *M* to 1.2 *M*.

$$[2]\quad \frac{-d[Cr]_T}{dt} = k_1[Cr][OD^-] + k_2[CrD^+][OD^-] + k_3[Cr][D_2O] + k_4[CrD^+][D_2O] + k_5[CrD^+][Cr'] + k_6[Cr][Cr']$$

$[Cr]_T$ = total concentration of neutral creatinine and creatininium ion containing methylene proton(s) at time t; $[CrD^+]$ = concentration of creatininium ion containing methylene proton(s) at time t; $[Cr]$ = concentration of neutral creatinine containing methylene proton(s) at time t; $[Cr']$ = total concentration of neutral creatinine. The k's refer to second-order exchange rate constants corresponding to the elementary steps represented by the terms associated with them. The contribution made by each term depends upon the acidity of the medium, the magnitude of k, and the concentration of creatinine. (To simplify the kinetic treatment no distinction has been made between molecules containing two protons and those containing one proton and one deuteron. The conclusions are unaffected by this simplification.)

pD Region 9.55 to 12.22

A satisfactory straight line can be drawn through the points in the log k_{obs} *vs.* p*D* plot (Fig. 2) giving a slope of 1.05. This means that the exchange in this region can be completely accounted for in terms of proton loss by creatinine to OD^-, and eq. 2 reduces to eq. 3

$$[3]\quad \frac{-d[Cr]_T}{dt} = k_1[Cr][OD^-]$$

Since $[Cr] = [Cr]_T$ in this region k_{obs} would be governed by eq. 4

$$[4]\quad k_{obs} = k_1[OD^-]$$

An average value of 36.3 M^{-1} min^{-1} is obtained for k_1, using the first five rate constants shown in Table 1 and using the corresponding p*D* values to calculate $[OD^-]$ ($pK_{D_2O} = 14.8$ (10)).

pD Region 7.60 to 3.50

Creatinine exists mostly as a free base at p$D > 5.4$ and as the conjugate acid at p$D < 5.4$. The shape of the plot suggests that most of the exchange results from abstraction of a methylene proton from creatininium ion by neutral creatinine. If this is so, eq. 2 reduces to eq. 5.

$$[5]\quad \frac{-d[Cr]_T}{dt} = k_5[CrD^+][Cr']$$

Equation 5 can be written in an integratable form as shown by the following sequence of equations

$$[6]\quad [Cr'] = [Cr]_a\frac{K'}{K' + [D^+]}$$

where $[Cr]_a$ is the analytical concentration of added creatinine (usually 1.2 *M*), and $[D^+]$ is calculated from the glass electrode measurements.

$$[7]\quad [CrD^+] = \frac{[D^+]}{K' + [D^+]}[Cr]_T$$

Therefore

$$[8]\quad \frac{-d[Cr]_T}{dt} = k_5\frac{K'[D^+]}{(K' + [D^+])^2}[Cr]_a[Cr]_T$$

Equation 9 gives the value of k_{obs}

$$[9]\quad k_{obs} = \frac{k_5K'[D^+]}{(K' + [D^+])^2}[Cr]_a$$

When k_{obs} was plotted against $K'[D^+]/(K' + [D^+])^2$ a reasonably satisfactory linear relationship was observed (Fig. 3), indicating that indeed, almost all the exchange in this region arises by abstraction of proton from creatininium ion by creatinine. A value of 2.38 ×

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

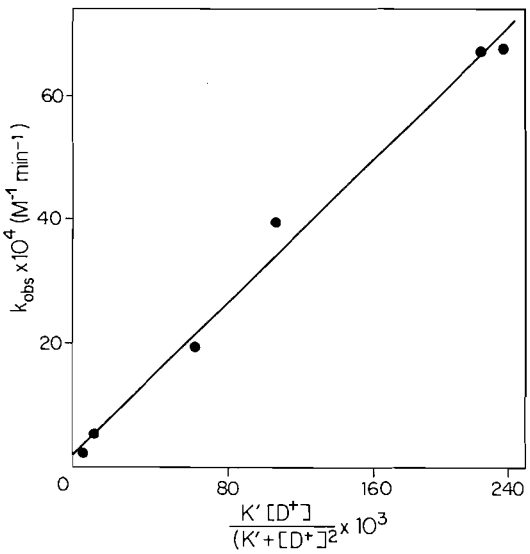

FIG. 3. Plot of k_{obs} *vs.* $K'[D^+]/(K' + [D^+])^2$.

$10^{-2}\ M^{-1}$ min^{-1} is calculated for k_5 from the slope of this plot. Further, the observation that the exchange rate could be adequately represented by eq. 5 at pD 7.60 suggests that the ratio k_5/k_6 must be large, a surprising result in light of the results obtained with carboxylate buffers.

Since the exchange rate constants k_5 and k_6 refer to exchanges by creatininium ion and creatinine respectively (where the substrates differ by a proton) we term the activation due to protonation, p.a.f. (proton activating factor). The blander terms reactivity ratio and discrimination factor were used previously for this quantity (9).

The significance of the maximum in the log k_{obs} *vs.* pD plot (Fig. 2) can be seen by imposing on eq. 9 the following condition, one that must be satisfied by a continuous differentiable function at the maximum.

$$\frac{\mathrm{d} \log k_{obs}}{\mathrm{d}\ \mathrm{p}D} = 0$$

This leads to the conclusion that the pD value at the maximum rate is equal to pK'. The theoretical curve (pD region 7.60 to 3.50 in Fig. 2) in the log k_{obs} *vs.* pD plot was constructed by nonlinear least square fitting of the data according to eq. 9, the pK' and k_5 values being treated as arbitrary parameters. This procedure gives a value of $2.77 \times 10^{-2}\ M^{-1}$ min^{-1} for k_5 and a value of 5.36 for pK', in excellent agreement with the values referred to above ($k_5 = 2.38 \times 10^{-2}\ M^{-1}$ min^{-1} and p$K' = 5.40$).

Sulfuric Acid Region

The exchange in this region follows the D_A acidity function reasonably well, but with a slope much less than unity (0.55) in keeping with a reaction involving attack by water on the conjugate acid of an amide (11–14). Although D_A is probably a satisfactory function to use, it is not the actual function governing the protonation (see Experimental section). Accordingly, we have not attempted a detailed analysis of the sort that leads to information about the role of water in the reaction (11, 12).

Exchange in Presence of Buffers

The rate of exchange in presence of buffer (DA/A^-) may be represented by eq. 11

$$[11] \quad \frac{-\mathrm{d}[Cr]_T}{\mathrm{d}t} = k_{DA}[DA][Cr] + k_{A^-}[A^-][Cr] + v_0$$

where v_0 is the exchange rate in the absence of buffers, the rate of proton abstraction by creatinine from creatininium ion being the major component. The other coefficients are exchange rate constants referring to the species indicated by the subscripts. The magnitudes of k_{DA} and k_{A^-} may be calculated by standard procedures (15). Since rate measurements were made at pD values close to the pK' value, eq. 12 must be inserted into eq. 11 to permit integration.

$$[12] \quad \frac{[Cr]}{[Cr]_T} = \frac{K'}{K' + [D^+]} = \gamma$$

The exchange rates were studied at constant pD but different total buffer concentration $[Buf]_T$, the creatinine concentration being kept as low as possible, in order to minimize v_0. A plot of k_{obs} *vs.* $[Buf]_T$ produces a straight line of slope k_2', defined by eq. 13 (Fig. 4).

$$[13] \quad k_2' = k_{DA}\gamma\{1 - [A^-]/[Buf]_T\} + k_{A^-}\gamma[A^-]/[Buf]_T$$

The magnitudes of k_{A^-} and k_{DA} can be obtained from eq. 13 if k_2' is determined at different pD values. The second-order rate constant for the abstraction of a methylene proton by A^- from creatininium ion, $k_{CrD^+ + A^-}$ is calculated (9) from k_{DA} and pK_{DA}. The second order rate

[d]Reference 19.
[e]Calculated from the general relation $pK_{DA} = 0.41 + 1.02\ pK_{HA}$ (20).
[f]An error of ±25% in the specific catalytic constants would introduce an error of ±35% in this ratio (21).

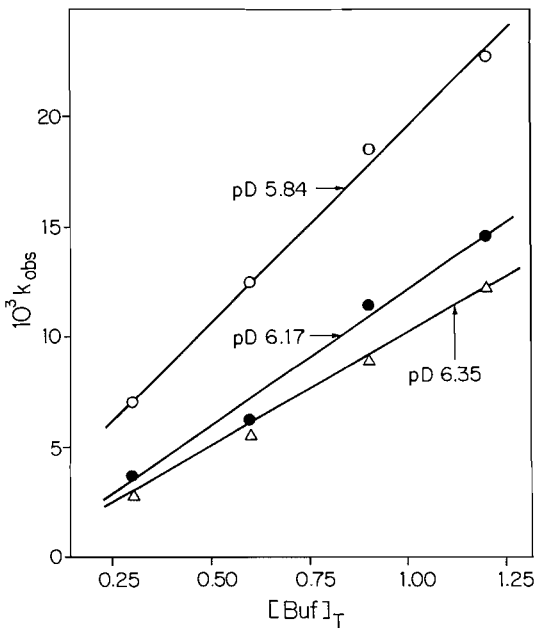

FIG. 4. Plot of k_{obs} *vs.* buffer molarity in acetate buffer solution, $\mu = 1.2$, $T = 34.5°$, $[Cr]_a = 0.18\ M$.

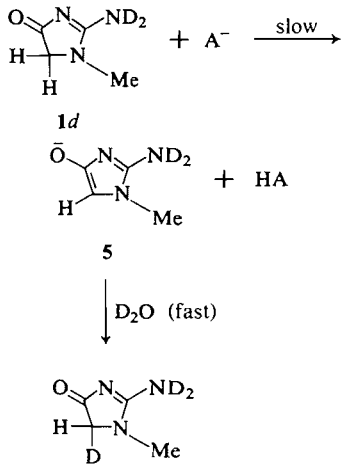
constant k_{Cr+A^-} for proton abstraction from creatinine by A^- is equal to k_{A^-}. The exchange rate constants for the acid- and base-catalyzed reactions were estimated by this procedure in acetate and pivalate buffers.

The kinetics of exchange was investigated in formate buffer at p*D* 4.27 and 4.80. Under these experimental conditions formate-catalyzed exchange of creatinine was not observable. Furthermore, the uncatalyzed exchange rate (v_0) is competitive with the formic acid catalyzed rate to such an extent that the rate constants for formic acid catalysis are, at best, estimates. Similar but less serious difficulties were encountered using acetate and pivalate buffers. The results obtained in buffer solutions are presented in Table 2.

Discussion

The general base- and general acid-catalyzed exchange of creatinine is understandable in terms of the mechanisms shown in Schemes 1 and 2, which are analogous to those generally accepted for other prototropic reactions (1, 9, 16).



SCHEME 1. General base catalysis.

The acidity of the methylene protons arises chiefly from the presence of electronegative nitrogen atoms in the ring (1*d*, *e*) and from the neighboring carbonyl group. Further, the intermediate **5** resulting from the loss of a methylene proton by creatinine is a substituted imidazole which is aromatic in the sense that imidazole is aromatic. The resulting stabilization of the intermediate undoubtedly provides a considerable driving force towards exchange.

The calculated p.a.f. values for creatinine in acetate and pivalate buffers ($k_{CrD^+ + A^-}/k_{Cr+A^-}$)

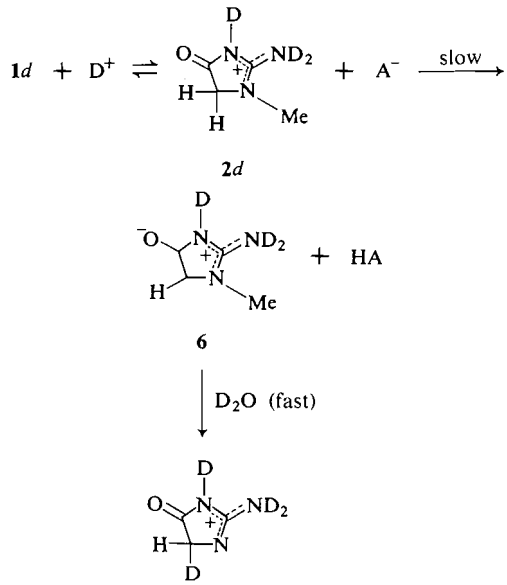


SCHEME 2. General acid catalysis.

are 17 and 36 (Table 2), very low values that seem to have no precedents in the literature. Because of the problem of creatinine self-catalysis these numbers can be considered only as approximate. However, in view of the enormous variation in p.a.f. that results from changes in the structure of the substrate the errors in these quantities are relatively small.

The largest p.a.f., 10^{12}, is observed with acetone (9, 17) while the lowest reported to date, 10^2, is for the exchange of the 7-methyl protons of 6,7,8-trimethyllumazine (9). Stewart and McAndless (9) suggested that large values of p.a.f. might be associated with substrates whose acidity and basicity are very far apart, *e.g.* acetone. Unfortunately, we are not able to determine directly the equilibrium carbon acidity of creatinine. There are, however, some structural features of creatinine that distinguish it sharply from acetone, and hence may account for the very low p.a.f. value that is observed. First, protonation occurs not at the carbonyl group, as in the case of acetone, but at nitrogen.[3] This difference would not be critical *if* the activating positive charge were destroyed in both cases by the subsequent proton loss from carbon. It is destroyed in the case of acetone, but not in the case of creatinine, which goes through the mesoionic intermediate **6**, a much less stable structure.

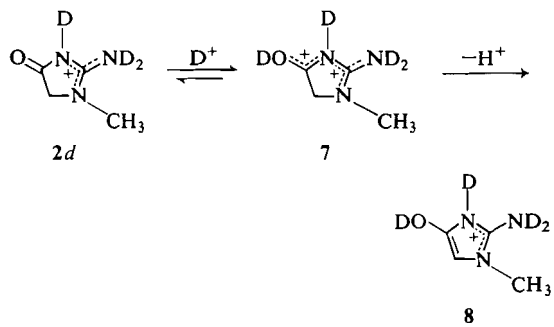
A second factor that doubtless contributes to the low p.a.f. is the fact that intermediate **5**, being a substituted imidazole, has aromatic character.

An examination of Table 3 shows that the rate of exchange in creatininium ion is quite sensitive to the strength of the attacking base. Unfortunately, a variety of carboxylate buffers could not be used to obtain a Brönsted value because of experimental difficulties associated with the need to use large amounts of substrate in the measurements and the consequent difficulty in detecting catalysis by bases that are much weaker than creatinine itself.

Though the thermodynamic base strength of creatinine is slightly more than that of acetate anion creatinine is much less effective a base in abstracting a proton from creatininium ion than acetate is. We ascribe this effect for the most part to increased steric crowding in the transition state of the creatininium ion – creatinine reaction, a consequence that thermodynamic basicity constants would fail to reflect.

In the sulfuric acid region the results are consistent with doubly charged cation **7** being the intermediate. It is interesting that in this case deprotonation at carbon (presumably by a water molecule acting as base) reduces the charge by a full unit, unlike the case with the monocation **2**. This is consistent with the curve shown in Fig. 1 since it is clear that a high p.a.f. is associated with the path from **2***d* to **7** to **8**.

The degree of activation caused by protonation is clearly related to the sites of protonation and deprotonation within the molecule. It is



[3]The low p.a.f. values could be accounted for by exchange occurring through the minor component, the O-protonated form. The observation that **2***d* and **4** undergo exchange at comparable rates rules out this possibility. A detailed analysis of this problem will be presented in a subsequent publication.

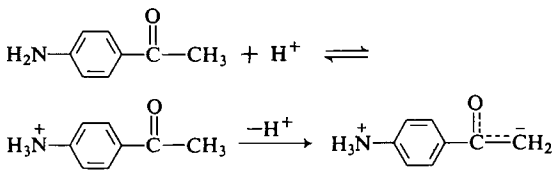
obvious that a remote, nonconjugated site will cause only a small degree of activation. Thus, protonation of the amino group will be expected to catalyze the enolization of *p*-aminoacetophenone to only a small degree, there being full charge separation in the intermediate.



Proximity of the protonation and deprotonation sites does not appear to be the most important factor, however, in determining catalytic effectiveness. These two sites are as close in creatinine as they are in acetone, much closer, indeed, than in 6,7,8-trimethyllumazine (Scheme 3, protonation and deprotonation sites marked by asterisks). However, as we have seen, these two sites are not in conjugation in creatinine, unlike the situation with the other two compounds.

Isotopic Scrambling and Mass Spectral Fragmentation Studies with 2-Ferrocenylethyl and 2-Ferrocenylethyl-1,1-d_2 Systems

CHOI CHUCK LEE, SHI-CHOW CHEN, AND RONALD G. SUTHERLAND

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0

Received July 8, 1974

CHOI CHUCK LEE, SHI-CHOW CHEN, and RONALD G. SUTHERLAND. Can. J. Chem. **53**, 232 (1975).

In a number of reactions including the solvolysis of 2-ferrocenylethyl-1,1-d_2 tosylate (**1**—OTs-1-d_2) in 60% EtOH, HCOOH, or CF_3CH_2OH, the reaction of **1**—OH-1-d_2 with $SOCl_2$ in tetrahydrofuran or toluene, and the treatment of **1**—Cl-1-d_2 with $AlCl_3$ in CH_2Cl_2, no scrambling of the D-label from C-1 to C-2 was observed, indicating the absence of any 1,2-ferrocenyl shifts in any of these S_N1 type of reactions. In the mass spectral fragmentation of **1**—X and **1**—X-1-d_2, where X = OTs, OH, OCHO, OCH_2CF_3 and Cl, a number of common features were observed, including $M^+ \xrightarrow[\text{or } -CD_2X]{-CH_2X} C_5H_5FeC_6H_6^+ \rightarrow C_5H_5Fe^+ \rightarrow Fe^+$ and $M^+ \xrightarrow{-HX} C_5H_5FeC_7H_7^+$ ($C_5H_5FeC_7H_5D_2^+$) $\rightarrow C_7H_7^+$ ($D_7H_5D_2^+$) $\rightarrow C_5H_5^+$ ($C_5H_5^+$, $C_5H_4D^+$, $D_5H_3D_2^+$).

CHOI CHUCK LEE, SHI-CHOW CHEN et RONALD G. SUTHERLAND. Can. J. Chem. **53**, 232 (1975).

On n'observe aucune compétition du deutérium sur le C-1 vers le C-2 pour un grand nombre de réactions de solvolyse du tosylate du ferrocenyl-2 éthyl-1,1-d_2 (**1**—OTs-1-d_2) dans l'éthanol à 60%, l'acide formique ou le trifluoroéthanol ou pour la réaction de **1**—OH-1-d_2 avec $SOCl_2$ dans le tétrahydrofuranne ou le chloroforme et pour le traitement de **1**—Cl-1-d_2 avec $AlCl_3$ dans CH_2Cl_2; ces résultats indiquent qu'il n'y a pas du tout de déplacements 1,2 du groupe ferrocényle dans ces réactions du type S_N1. Lors de la fragmentation en spectrométrie de masse de **1**—X et de **1**—X-1-d_2 où X = OTs, OH, OCHO, OCH_2CF_3 et Cl, on a observé un certain nombre de processus qui sont communs à tous les composés incluants $M^+ \xrightarrow[\text{ou } -CD_2X]{-CH_2X} C_5H_5FeC_6H_6^+ \rightarrow C_5H_5Fe^+ \rightarrow Fe^+$ et $M^+ \xrightarrow{-HX} C_5H_5FeC_7H_7^+$ ($C_5H_5FeC_7H_5D_2^+$) $\rightarrow C_7H_7^+$ ($D_7H_5D_2^+$) $\rightarrow C_5H_5^+$ ($C_5H_5^+$, $C_5H_4D^+$, $D_5H_3D_2^+$).

[Traduit par le journal]

Richards and co-workers (1) have reported that the solvolysis of 2-ferrocenylethyl-1,1-d_2 tosylate (**1**—OTs-1-d_2) in HOAc or 80% acetone resulted in no detectable scrambling of the D-label from C-1 to C-2. Consideration of the kinetic and stereochemical data from **1**—OTs and related systems has led these workers to conclude that solvolyses of β-ferrocenylalkyl tosylates may involve participation of the interannular electrons of the ferrocenyl group (1, 2). Since solvolyses in more ionizing and/or less nucleophilic solvents than HOAc or 80% acetone might give rise to more extensive isotopic scrambling, in the present work, solvolytic reactions with **1**—OTs-1-d_2 were carried out in 60% EtOH, HCOOH, or CF_3CH_2OH. In all of these cases, no scrambling of the label from C-1 to C-2 was detectable by n.m.r. in the reaction products, **1**—OH-1-d_2, **1**—OCHO-1-d_2, and **1**—OCH_2CF_3-1-d_2 (details given in the Experimental section), indicating the absence of any 1,2-ferrocenyl shift. In the trifluoroethanolysis, the yield of **1**—OCH_2CF_3 was low; but when this reaction was effected in the presence of CF_3CH_2ONa, a high yield of product was obtained, presumably via the S_N2 process. An attempt was also made in solvolyzing **1**—OTs in CF_3COOH, but only decomposition resulted. This observation is similar to the finding that the attempted trifluoroacetolysis of 2-(*p*-ferrocenylphenyl)ethyl tosylate resulted only in extensive decomposition (3).

Schlögl and co-workers (4, 5) have reported that the reduction of the oxime of acetylferrocene with $LiAlH_4$ or preferably with $LiAlH_4$—$AlCl_3$ gave *N*-ethylaminoferrocene as one of the products. It was suggested that the formation of this secondary amine resulted from a 1,2-migra-

[d]Metastable peaks observed for 1—OH, 1—OH-1-d_2, 1—OCH_2CF_3, 1—OCH_2CF_3-1-d_2, 1—Cl, and 1—Cl-1-d_2.
[e]Metastable peaks observed for 1—OH, 1—OH-1-d_2, 1—OCHO, 1—OCHO-1-d_2, 1—OCH_2CF_3, 1—OCH_2CF_3-1-d_2, 1—Cl, and 1—Cl-1-d_2.

tion of the ferrocenyl group to nitrogen. Since $AlCl_3$ is known to have a great propensity for inducing rearrangements, it is of interest to include in the present work a study on the effect of $AlCl_3$ on 2-ferrocenylethyl-1,1-d_2 chloride (**1**—Cl-1-d_2). While the treatment of **1**—OH-1-d_2 with excess $SOCl_2$ resulted in extensive decomposition, **1**—Cl-1-d_2 was prepared without rearrangement from the reaction of **1**—OH-1-d_2 with $SOCl_2$ in tetrahydrofuran or toluene as solvent. The observation that **1**—Cl-1-d_2 was formed without any isotopic scrambling is also of interest since, for example, the reaction of 2-phenylethanol-1-^{14}C with $SOCl_2$ without a solvent gave essentially a complete scrambling of the label between C-1 and C-2 (6), while degenerate rearrangements arising from 1,2-hydride shifts were observed even in a nonpolar solvent such as toluene when 2-butyl chloride was formed from the decomposition of 2-butyl-1-^{14}C chlorosulfite derived from the alcohol and $SOCl_2$ (7). When **1**—Cl-1-d_2 was treated with $AlCl_3$ in CH_2Cl_2, the recovered **1**—Cl-1-d_2 was again isotopically nonrearranged. Thus all the present results show that 1,2-ferrocenyl shifts do not take place in any of the reactions studied, and these findings would tend to suggest the absence of any neighboring carbon group participation in S_N1 type of reactions with the 2-ferrocenylethyl derivatives.

Available from the present work are a number of 2-ferrocenylethyl derivatives including **1**—OTs, **1**—OH, **1**—OCHO, **1**—OCH_2CF_3, **1**—Cl, and the corresponding 1,1-dideuterio analogs. In using mass spectrometry as a means of identifying these compounds, it was noted that their mass spectra show certain fragmentation patterns common to all of these 2-ferrocenylethyl systems as given in Scheme 1. In addition, individual behaviors not common to all of the 5 compounds are given in Scheme 2. The relative abundance of these fragmentation ions are summarized in Table 1.

The mass spectrum of **1**—OH has been reported by Egger (8) and the presently observed mass spectrum of **1**—OH is essentially the same except that the relatively weak peaks for *m/e* 91 and 65 were not reported in the earlier work. The presence of ions at *m/e* 199 and 121 ($C_5H_5FeC_6H_6^+$ and $C_5H_5Fe^+$) as major peaks are well known for monosubstituted ferrocenes (8, 9), and the fragmentation sequence of molecular ion → 199 → 121 → 56 has been noted for a number of methyl or ethyl esters of ω-ferrocenylalkanoic acids (10). From the present work with **1**—X and **1**—X-1-d_2 (X = OTs, OH, OCHO, OCH_2CF_3, or Cl), it is clear that in the frag-

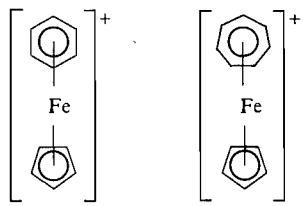
mentation of $C_5H_5FeC_5H_4CH_2CH_2X^+ \rightarrow C_5H_5FeC_6H_6^+$, the C-1 methylene group is lost as CH_2X in the process since **1**—X-1-d_2 also gave rise to the ion with *m/e* 199.

In the formation of $C_5H_5FeC_7H_7^+$ (*m/e* 212) from $C_5H_5FeC_5H_4CH_2CH_2X^+$, HX is lost with the H likely coming from C-2, since in the work with **1**—X-1-d_2, the D-label at C-1 remains intact in the process. The present results as summarized in Schemes 1 and 2 and Table 1 suggest that C_6H_6 and C_7H_7 are energetically favorable structures as ligands in the mass spectral fragmentations of 2-ferrocenylethyl systems. A similar observation has also been made by Roberts *et al.* (10) in their studies with ω-ferrocenylalkanoates. Egger (8) has suggested that the structure of $C_5H_5FeC_6H_6^+$ may be **2**. Analogously, $C_5H_5FeC_7H_7^+$ may be **3**, which could give rise to the tropylium ion, *m/e* 91. Roberts *et al.* (11) have demonstrated with D-labeling that the C_7H_7 ligand bonded to iron in the mass spectra of substituted ferrocences is the symmetrical tropylium species.



2 **3**

The presence of the tropylium ion is also confirmed by the present work since the decomposition of $C_7H_5D_2^+$ gave rise to $C_5H_5^+$, $C_5H_4D^+$, and $C_5H_3D_2^+$, indicating D-scrambling in $C_7H_5D_2^+$ (Table 1).

Experimental

The n.m.r. spectra of various compounds were recorded on a Varian T-60 or HA-100 spectrometer. The mass spectral studies were carried out using an AEI MS-12 spectrometer at 140° and 70 eV.

2-Ferrocenylethyl and 2-Ferrocenylethyl-1,1-d_2 Tosylates (1—OTs and 1—OTs-1-d_2)

1—OTs and **1**—OTs-1-d_2 were prepared from the reaction of the corresponding alcohol with *p*-toluenesulfonyl chloride in pyridine as reported by Richards and co-workers (1). The yields obtained were considerably better than the reported 24% (1), the difference being probably due to the use of a simpler work-up procedure in the present study. A typical preparation is given below.

To a solution of 1.0 g (4.4 mmol) of 2-ferrocenylethanol (12) in 4.0 ml of dried pyridine, cooled in an ice-bath, was added portionwise, with stirring, 1.0 g (5.2 mmol) of *p*-toluenesulfonyl chloride. The mixture was allowed to stand in the ice-bath for 3 h and the resulting brown solution was poured into 50 g of cracked ice. The material was extracted three times with 50 ml portions of $CHCl_3$. The combined extract was washed successively with a 5% HCl solution, a saturated $NaHCO_3$ solution, and H_2O. After drying over Na_2SO_4, the $CHCl_3$ was removed under reduced pressure. The viscous residue was dissolved in hot *n*-hexane and filtered. On cooling in the refrigerator, 1.31 g (78%) of **1**—OTs was recovered as orange needles, m.p. 77–79° (lit. (1) m.p. 78–79°), n.m.r. ($CDCl_3$) δ 2.43 (s, 3H, $PhCH_3$), 2.70 (t, J = 7 Hz, 2H, $FcCH_2$), 4.07, 410 (overlapping singlets, $C_5H_4FeC_5H_5$), 4.20 (t, J = 7 Hz, partially overlapping with the Fc H's, CH_2OTs), 7.3–7.9 (m, 4H, arom.). For the 1,1-dideuterio analog, **1**—OTs-1-d_2, the n.m.r. spectrum showed that the triplet at 4.20 p.p.m. has disappeared and the triplet at 2.70 p.p.m. has become a broad singlet.

Solvolysis of 1—OTs and 1—OTs-1-d_2 in 60% Ethanol

A solution of 200 mg (0.52 mmol) of **1**—OTs in 10 ml of 60% ethanol – 40% H_2O (v/v) was heated under reflux for 1.5 h. The resultant material was cooled to room temperature, poured into 40 ml of CH_2Cl_2, and washed with a saturated $NaHCO_3$ solution and with H_2O. After drying over Na_2SO_4 and removal of the solvent, the residue was recrystallized from petroleum ether (b.p. 60–70°) to give 105 mg (88%) of 2-ferrocenylethanol (**1**—OH) as orange needles, m.p. 34–35° (lit. (12) m.p. 32.5–33.5°), n.m.r. ($CDCl_3$) δ 1.81 (s, 1H, OH), 2.60 (t, J = 7 Hz, 2H, $FcCH_2$), 3.74 (t, J = 7 Hz, 2H, CH_2OH), 4.10, 4.13 (overlapping singlets, 9H, $C_5H_5FeC_5H_4$). In a similar reaction using **1**—OTs-1-d_2, the product obtained was **1**—OH-1-d_2, the n.m.r. spectrum of which showed that the triplet at 2.60 p.p.m. for the C-2 protons has become a broad singlet, and that there was no detectable absorption at the 3.7 p.p.m. region for the C-1 protons, indicating the absence of any D-scrambling from C-1 to C-2.

Formolysis of 1—OTs and 1—OTs-1-d_2

A solution of 830 mg (2.16 mmol) of **1**—OTs in 6.0 ml of 98–100% HCOOH (BDH analytical reagent) was stirred at room temperature (22°) for 2.5 h. The resultant material was poured into 50 g of cracked ice and then was extracted three times with 50 ml portions of CH_2Cl_2. The combined extract was washed with saturated $NaHCO_3$ solution and with H_2O and then dried over Na_2SO_4. After removal of the solvent, the residue was chromatographed through a silicic acid column, eluting with a 1:1 mixture of hexane–chloroform, to give 500 mg (90%) of 2-ferrocenylethyl formate (**1**—OCHO) which showed only one component on t.l.c. analysis; n.m.r. ($CDCl_3$) δ 2.70 (t, J = 7 Hz, 2H, $FcCH_2$) 4.03, 4.10 (overlapping singlets, $C_5H_4FeC_5H_5$), 4.28 (t, J = 7 Hz, partially overlapping with the Fc H's, CH_2O), 8.00 (s, 1H, CHO). In the presence of a shift reagent (about 0.1 mg $Eu(fod)_3$ and 90 mg sample) the 2-proton triplet at 4.28 p.p.m. for the C-1 protons was shifted downfield to 4.50 p.p.m., clearly separated from the Fc protons at about 4.1 p.p.m. From the analogous reaction with **1**—OTs-1-d_2, the product obtained was **1**—OCHO-1-d_2, the n.m.r. spectrum of which, in the presence of $Eu(fod)_3$, showed a singlet for the C-2 protons at 2.80 p.p.m. and the absence of any absorption at the 4.5 p.p.m. region, indicating no detectable D-scrambling from C-1 to C-2.

Trifluoroethanolysis of 1—OTs and 1—OTs-1-d_2

A solution of 300 mg (0.78 mmol) of **1**—OTs in 10 ml of CF_3CH_2OH was stirred at room temperature under N_2 for 6 h. At the end of this period, a stream of N_2 was bubbled through the reaction mixture to remove the solvent. Flaked ice was added and the mixture worked up as in the formolysis. Removal of the solvent from the dried CH_2Cl_2 extract gave 160 mg of an oily residue which was found to be a complex mixture by t.l.c. analysis. Chromatographic purification through a silicic acid column, eluting with 10% $CHCl_3$ in *n*-hexane, gave a fraction containing a single component according to t.l.c. and identified as the desired product, 2-ferrocenylethyl trifluoroethyl ether (**1**—OCH_2CF_3), n.m.r. ($CDCl_3$) δ 2.65 (t, J = 7 Hz, 2H, $FcCH_2$), 3.6–4.1 (overlapping t and q, J = 7 and 8.5 Hz, respectively, for the C-1 CH_2 and CH_2CF_3), 4.16 (s, Fc H's). The n.m.r. spectrum of the analogous product from **1**—OTs-1-d_2 showed that the triplet for the C-2 protons at 2.65 p.p.m. has become a singlet and there was a clear quartet of relative intensities of 1:3:3:1 centered at 3.8 p.p.m. for the methylene protons of the trifluoroethyl group. There was no evidence of overlapping of the quartet with any absorption by the C-1 methylene protons indicating no detectable H at C-1 and no scrambling of the D-label.

Since the yield of **1**—OCH_2CF_3 from the above experiment was poor, a much better yield was obtained when the reaction was carried out in the presence of CF_3CH_2ONa. To a solution of 30 mg (1.3 mmol) of Na in 10 ml of CF_3CH_2OH was added 400 mg (1.04 mmol) of **1**—OTs. The mixture was then stirred at room temperature under N_2 for 3 h. The resultant material was poured into ice and worked up the usual way except that the CH_2Cl_2 extract was washed with 5% HCl instead of $NaHCO_3$. Removal of the solvent from the dried extract gave 300 mg (92%) of a residual oil consisting of a single component according to t.l.c. and identified as **1**—OCH_2CF_3 by n.m.r.

Reaction of 1—OH or 1—OH-1-d_2 with $SOCl_2$

To a stirred and cooled (ice-bath) solution of 400 mg (1.74 mmol) of **1**—OH in 25 ml of dried tetrahydrofuran (THF) was added 0.20 ml (2.8 mmol) of $SOCl_2$. Stirring was continued at ice-bath temperature for 1 h and then at room temperature for an additional h. The resultant material was poured into ice and worked up as in the formolysis. Removal of the solvent from the dried CH_2Cl_2 extract gave a residue which on crystallization from *n*-hexane followed by sublimation yielded 180 mg (42%) of orange crystalline 2-ferrocenylethyl chloride, (**1**—Cl), m.p. 52–53° (lit. (13) m.p. 52–54°), n.m.r. (CCl_4) δ 2.80 (t, J = 8 Hz, 2H, $FcCH_2$), 3.55 (t, J = 8 Hz, 2H, CH_2Cl), 4.10 (s, 9H, Fc H's). A similar reaction carried out in toluene instead of THF gave **1**—Cl in 30% yield. When the reaction was carried out with **1**—OH-1-d_2 in either THF or toluene, the product obtained was **1**—Cl-1-d_2, the n.m.r. spectrum of which showed that the triplet at 2.80 p.p.m. has become a singlet and that there was no observable absorption at the 3.5 p.p.m. region, indicating no detectable scrambling of the D-label.

Treatment of 1—Cl or 1—Cl-1-d_2 with $AlCl_3$

In a 100-ml 3-necked round bottom flask equipped with a N_2 inlet, a reflux condenser fitted with a $CaCl_2$ tube and a dropping funnel was placed 110 mg (0.82 mmol) of $AlCl_3$ in 20 ml of CH_2Cl_2. Stirring of the mixture at ice-bath temperature under N_2 for 5 min gave a brownish red solution to which a solution of 100 mg (0.40 mmol) of **1**—Cl in 20 ml of CH_2Cl_2 was added. The reaction mixture was stirred at room temperature under N_2 for 1 h and then poured into ice. More CH_2Cl_2 was added and the mixture was made basic with saturated $NaHCO_3$. The organic layer was separated and the aqueous layer further extracted with CH_2Cl_2. After washing with H_2O, drying over $MgSO_4$, and removal of the CH_2Cl_2, chromatographing the residue through a silicic acid column, eluting with *n*-hexane, gave as a first fraction 15 mg of an unknown yellow liquid and then 40 mg (40%) of recovered **1**—Cl which showed the same n.m.r. spectrum as the starting material.

The unknown fraction, after chromatographing once more through the silicic acid column, still appeared to be impure. Its n.m.r. and mass spectra, however, suggested the probable presence of ethylferrocene as a major component. The n.m.r. spectrum of this unknown showed ferrocenyl absorptions at the 4.10 p.p.m. region and a triplet and quartet, respectively, at 1.16 and 2.30 p.p.m., suggesting an ethyl group, with other absorptions, presumably from impurities, overlapping the triplet and at the 4.0–4.1 region. The mass spectrum of this unknown fraction has as its base peak *m/e* 214 which would fit the molecular ion for ethylferrocene. Other major fragmentation ions were observed at *m/e* 199, 121, and 56, with a metastable peak for 214 → 199 at 185.1.

When **1**—Cl-1-d_2 was treated with $AlCl_3$ in a similar way, 40% **1**—Cl-1-d_2 was recovered which showed the same n.m.r. spectrum as the starting material, indicating the absence of any detectable scrambling of the D-label from C-1 to C-2.

On décrit la synthèse d'aminoalkyl-1 hydroxy-1 tétraméthylène-2,2 tétrahydro-1,2,3,4 naphtalènes ainsi que leur réarrangement de Wagner–Meerwein en aminoalkyl-4a hexahydro-1,2,3,4,4a,9 phénanthrènes. [Traduit par le journal]

Introduction

A general, versatile strategy for the synthesis of morphine related compounds was described by one of us several years ago (1). The key intermediates are 1,2,3,4,4a,9-hexahydrophenanthrenes angularly substituted as in **1** thus providing for chemical developments unattainable by the classical Grewe synthesis of morphinans or Gates synthetic approach to morphine (2). The purpose of this communication is to illustrate the applicability of Belleau's approach to morphinan precursors and related structures.

Generally speaking, 2,2-tetramethylene-1-tetralone **2** (R^1 = H or OCH_3) can react with Reformatsky (1), Grignard (1), Wittig or Corey's reagents to give adducts that are especially prone to suffer Wagner–Meerwein arrangements so as to yield 4a-substituted-1,2,3,4,4a,9-hexahydrophenanthrenes (**4**) and/or the isomeric 2,3,4,4a,-9,10-hexahydrophenanthrenes (**6**). The utility of this general strategy as applied to the syntheses of lactone **7** from **3** (R^1 = H, n = 1, Z = CO_2-Et) and of imino ether **8** from **5** (R^1 = H) was reported earlier (1, 3).

The presence of a functional group Z on the substituent at the 4a position in **4** and its (Z's) juxtaposition relative to the Δ10-double bond suggests that cyclization, through a variety of reaction types, to 4a,10-bridged-1,2,3,4,4a,9,10,10a-octahydrophenanthrene systems (**9**) might be achievable. The well known analgesic agent, *N*-methyl-3-hydroxymorphinan (**10**) is one example of a **9**-type system.

It was this possibility, coupled with the anticipated versatility of the approach and the high probability of interesting biological activity in some of the potentially preparable **9**-type systems, that led us into this work.

In this paper we will describe the synthesis of 4a-aminoalkyl-1,2,3,4,4a,9-hexahydrophenanthrenes (**4**) and the methods that have been developed for the synthesis of **3** where Z equals an amino group and n varies from 1 to 3. Later papers will describe the cyclization and related chemistry of some of these **4**-type systems (10). A communication concerning the application of the above described approach has been published recently (9).

Results and Discussion

The syntheses of the 1-aminoalkyl-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalenes were carried out as summarized in Scheme 2. The 2,2-tetramethylene-1-tetralones **2** (R^1 = H, OCH_3) were prepared according to the method of Mousseron *et al.* (4). Treatment of ketones **2** (R^1 = H, OCH_3) with excess dimethylsulfonium methylide (*in situ*) in cold DMSO solution produced the epoxides **11** (R^1 = H, OCH_3) in excellent yield. We have found that precautions for excluding moisture and air from this epoxide synthesis are unnecessary in this instance (5). These reactions were commonly run in an open Erlenmeyer flask using commercial reagent grade DMSO.

Epoxides **11** (R^1 = H, OCH_3) were converted into the desired amino alcohols **12** (R^1 = H, OCH_3) by heating with an excess of the amine NHR^2R^3 either with or without a solvent. Except in the case of benzylamine, all of these reactions were carried out in a steel pressure bomb at steam bath temperature. The progress of the reactions was followed in some cases by removing aliquots, evaporating off the solvent, and taking the n.m.r. spectrum of the residue. It was usually possible to distinguish clearly the AB pattern of the methylene hydrogens α to

oxygen in any unreacted epoxide. If such was the case, the reaction was heated for additional time until it was complete.

The preparation of the primary amine **12** ($R^1 = R^2 = R^3 = H$) gave us some difficulty. Heating mixtures of epoxide with either ammonium hydroxide or liquid ammonia led to a mixture of **12** ($R^1 = R^2 = R^3 = H$) and its dimer **13**. This problem was circumvented by preparing the *N*-benzylamino alcohol **12** ($R^1 = R^2 = H$; $R^3 = CH_2\phi$) and then hydrogenolyzing to the primary amine.

Cyanomethylation (6) of ketone **2** ($R^1 = H$) provided the β-cyanoalcohol in good yield. This was then reduced with lithium aluminum hydride to give compound **14**.

Ketones **2** ($R^1 = H$, OCH_3) were refluxed in ether with the Grignard reagent prepared from magnesium and 3-chloro-*N*,*N*-dimethylpropylamine to provide the desired amino alcohols **15** ($R^1 = H$, OCH_3) in excellent yields.

The physical properties, yields, and analytical data for the 1-aminoalkyl-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalenes are summarized in Table 1.

Synthesis of 4a-(Aminoalkyl)-1,2,3,4,4a,9-hexahydrophenanthrenes. The Wagner–Meerwein Rearrangement of 1-(Aminoalkyl)-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalenes

Wagner–Meerwein rearrangements of 2,2-tetramethylene-1-cyclohexanol and closely related benzo-fused systems have been the subject of extensive studies by a number of workers (7). The nature of the products produced in such reactions and their rates of formation are determined by a number of factors including the size of each ring in the spiro system, the dehydrating agent, the nature of the carbonium ion generated, the conformation of the leaving group, and the relative thermodynamic stabilities of the products. On the basis of the earlier work one would predict that acid catalyzed dehydration of

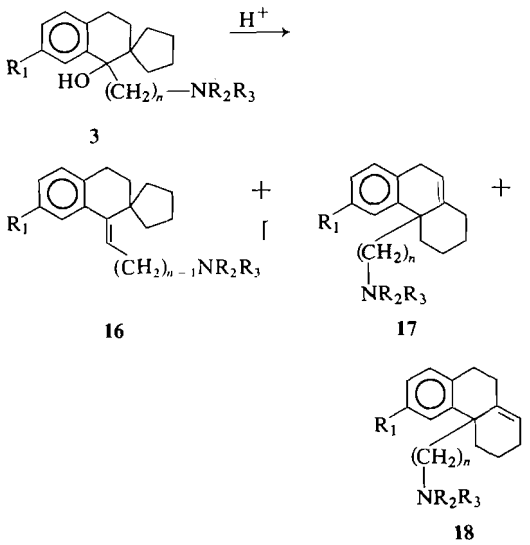


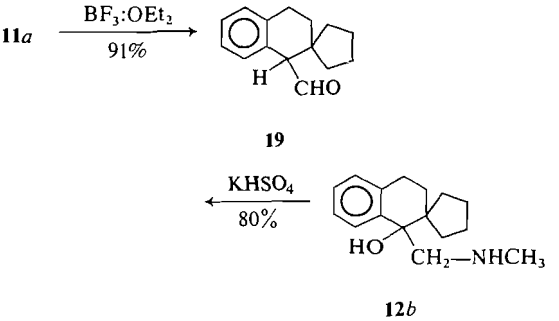
SCHEME 3

systems such as **3** (Scheme 3) would lead to either **16**, **17**, or **18** or mixtures of these three structural types.

When the amino alcohols **12**, **14**, and **15** were treated with concentrated hydrochloric acid we observed the formation of two types of products, **16** and **17** (Scheme 3). We have not observed the formation of the isomeric amine **18**. The relative amounts of these products were found to be related to the concentration and the type of acid used to carry out the rearrangement. Not unexpectedly the reaction temperature and the reaction time are also important determinants in the ratio of **16** to **17**.

A priori one would expect the acid concentration to have an effect on the relative amounts of *exo*-methylene product **16** (proton loss) and the 1–2 alkyl shift product **17**. When the aminomethyl alcohol **12** ($R^1 = R^2 = H$; $R^3 = CH_3$) is heated with $KHSO_4$ at 160° for 1 h, aldehyde **19** is obtained in 80% yield, whereas treatment with concentrated HCl yields solely the 1,2,3,4,-4a,9-hexahydrophenanthrene amine **17**. The n.m.r. spectrum of **19** shows a downfield formyl proton as a doublet ($J = 4.5$ Hz) clearly indicating that the formyl group is attached to a secondary carbon center. We feel that the likeliest origin of aldehyde **19** is from enamine **16** ($n = 1$; $R^1 = R^2 = H$; $R^3 = CH_3$) which is formed by proton loss rather than 1–2 alkyl shift.

Similarly, when the aminoethyl compound **14** is stirred with concentrated hydrochloric acid, a



SCHEME 4

smooth rearrangement to the 1–2 alkyl shift product **17** ($R^1 = R^2 = R^3 = H$) occurs in 92.5% yield. If, however, a more dilute ethanolic hydrochloric acid solution is used, a mixture of the **16** and **17** type products is produced.

It was necessary to use formic acid at 98° as the rearrangement condition to obtain the Δ10-amine **17** ($n = 3$; $R^1 = OCH_3$; $R^2 = R^3 = CH_3$) from the *N*,*N*-dimethyl-3-aminopropyl alcohol **6** ($R^1 = OCH_3$). Rearrangement conditions which had been successful in the aminomethyl and aminoethyl cases, namely concentrated hydrochloric acid at reflux and at 25° respectively, failed to yield the Δ10-system for the aminopropyl analog.

The n.m.r. evidence for the production of the 1,2,3,4,4a,9-hexahydrophenanthrene type system **17** is based upon three main points: (*a*) The observed paramagnetic shift of the benzylic methylene signal of the starting materials **3** and the 1,2,3,4,4a,9-hexahydrophenanthrene system **17** (Table 3). (*b*) The presence in **17** of an olefinic signal at *ca.* δ 5.65. (*c*) The obvious coupling of the olefinic hydrogen and the benzylic methylene hydrogens ($J = 4.0$ Hz).

Biological Activity

All the compounds described in this paper were subjected to a routine pharmacological screening procedure which has been described (8). With the exception of amines **14**, **15***a*, and **17***h*, none of these compounds was found to exhibit any significant CNS effects in oral doses of up to 300 mg.

Amino alcohol **14** exhibited "antidepressant" activity in mice at 40 mg/kg. Its related aminoolefin **17***h* produced signs of CNS stimulation at 40 mg/kg. All of these activities were judged to be nontherapeutic and no further work was undertaken.

Experimental

The i.r. spectra were recorded on a Unicam SP-200G grating i.r. spectrometer. The n.m.r. spectra were determined on a Varian A60-A spectrometer using tetramethyl silane as an internal standard. Melting points are uncorrected and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories Inc., Skokie, Illinois.

*1-Oxomethylene-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene (**11**; R^1 = H)*

Sodium hydride (5.1 g of a 56% mineral oil dispersion; 0.119 mol) was washed twice with dry petroleum ether (30–60°) to remove the mineral oil. Dry DMSO (30 ml) was then added, followed by a solution of trimethylsulfonium iodide (22.4 g; 0.109 mol) in DMSO (120 ml). The solution was magnetically stirred and a mixture of 2,2-tetramethylene-1-tetralone **2** (R^1 = H) (18.4 g; 0.091

mol) in DMSO (30 ml) was added slowly over 1 h. The reaction mixture became purple colored after *ca.* 30 min. After stirring at room temperature overnight (19 h) the reaction mixture was poured into cold water (700 ml) and extracted three times with ether. The combined extracts were washed three times with water, dried (Na_2SO_4), and evaporated to dryness *in vacuo*. A residue of 18.1 g (93%) of a yellow oil was obtained, b.p. 123–124°/0.05 mm.

Anal. Calcd. for $C_{15}H_{18}O$: C, 84.07; H, 8.47. Found: C, 83.99; H, 8.51.

*7-Methoxy-1-oxomethylene-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene (**11**; $R^1 = OCH_3$)*

This was prepared as described above in 90% yield; white needles (95% ethanol) m.p. 96–98°.

Anal. Calcd. for $C_{16}H_{20}O_2$: C, 78.65; H, 8.25. Found: C, 78.58; H, 8.30.

*1-Formyl-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene (**19**)*

Boron trifluoride etherate (4 ml; 0.032 mol) was added to a solution of epoxide (1.07 g; 5 mmol) in benzene (20 ml). After 12 min at 25° with occasional shaking, the reaction was worked up to give 0.97 g of a brown liquid. Nuclear magnetic resonance indicated that this liquid contained 91% aldehyde **19**. The 2,4-DNP derivative was prepared and recrystallized from acetone–methanol, bright yellow-orange crystals, m.p. 231–232° dec.

Anal. Calcd. for $C_{21}H_{22}N_4O_4$: C, 63.94; H, 5.62; N, 14.21. Found: C, 64.13; H, 5.62; N, 14.48.

*Syntheses of 1-Aminomethyl-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalenes (**12***a–h)*

Compounds **12***b*, *d*, *e* and *g* were prepared as in the procedure given for **12***b*. The *N*-benzylamines **12***c* and *h* were prepared as indicated below for **12***h*. The primary amines **12***a* and *f* were prepared as indicated for **12***a*. See Table 1 for the yields, melting points, and analyses of **12***a–h*.

*1-N-methylaminomethyl-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene (**12***b)*

A mixture of **11** (R^1 = H) (1.07 g; 5 mmol), 30–35% aqueous methylamine (5 ml), and dioxane (5 ml) was heated at 98° in a Parr pressure bomb for 20 h. The mixture was then evaporated to dryness *in vacuo*, the residue was dissolved in ether and the HCl salt prepared by bubbling in HCl gas until no further precipitation occurred. The precipitate was filtered off and recrystallized from *n*-propanol–ether to afford 911 mg (65%) of light beige crystals, m.p. 216–217° dec.

*7-Methoxy-1-N-benzylaminomethyl-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene (**12***h)*

A mixture of **11** ($R^1 = OCH_3$) (7.5 g; 30.6 mol) and benzylamine (20 ml) was refluxed under N_2 for 18 h. The excess benzylamine was distilled off at reduced pressure. The distillation residue was dissolved in ether and washed three times with water. Addition of 10% HCl precipitated the hydrochloride salt. This was filtered off, washed with ether, and recrystallized from methanol–ether, m.p. 202–202.5°, 8.80 g (75%).

*1-Aminomethyl-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene (**12***a)*

A mixture of **12***c* (2.0 g; 5.6 mmol), 10% Pd/C (200 mg), and 95% ethanol was hydrogenolyzed in a Parr hydrogenator at room temperature. Hydrogen uptake was complete after 3 h. The catalyst was filtered off and the filtrate was evaporated to dryness *in vacuo* leaving 1.47 g (98%) of a white solid. An analytical sample melted at 230–231.5° (ethanol–ether).

1-Cyanomethyl-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene

To a stirred solution of 23.4 ml (0.055 mol) of 2.35 *M* butyl lithium in hexane at −80° under nitrogen was added 23.4 ml of dry THF and then 2.6 ml (0.05 mol) of acetonitrile dissolved in 10 ml of THF. After stirring for 0.75 h, a solution of ketone **2** (R^1 = H) (10 g; 0.05 mol) in 25 ml of dry THF was added all at once. After stirring for 10 min the cold bath was removed and the reaction stirred for 10 min before it was poured into ice water acidified with hydrochloric acid. The layers were separated and the aqueous phase was extracted three times with ether. The combined organic phases were washed once with brine, dried (Na_2SO_4), and evaporated to dryness *in vacuo* to give 10.25 g (85%) of a light beige colored solid, m.p. 59–62.5°. The analytical sample was recrystallized from benzene – petroleum ether (30–60°), m.p. 60–62.5°, white needles.

Anal. Calcd. for $C_{16}H_{19}NO$: C, 79.63; H, 7.94; N, 5.80. Found: C, 79.45; H, 8.10; N, 6.20.

1-(2-Aminoethyl)-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene

A solution of nitrile (above) (11.24 g, 0.0476 mol) in ether (60 ml) was added as rapidly as possible to a refluxing suspension of LAH (2.6 g; 0.685 mol) in ether (50 ml). The suspension was refluxed with stirring for 24 h. The reaction was worked up in the usual manner to give 9.59 g of a yellow viscous oil. This was dissolved in ether and the hydrochloride salt was prepared by adding ether saturated with HCl gas. This provided 6.1 g (45.5%) of a white solid, m.p. 164–164.5°. An analytical sample was recrystallized from ethanol–ether, m.p. 166–166.5°.

*1-(N,N-Dimethyl-3-aminopropyl)-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene (**15**; R^1 = H)*

To a refluxing mixture of magnesium turnings (3.6 g; 0.15 mol), dry ether (50 ml) and *ca.* 0.02 ml of methyl iodide was added a solution of freshly distilled 3-chloro-*N*,*N*-dimethylpropylamine (18.15 g; 0.15 mol) in 50 ml of dry ether. After refluxing with stirring for 1.5 h a solution of ketone **9** (R^1 = H) (20 g; 0.1 mol) in 50 ml of ether was added. The reaction was refluxed an additional 18 h and then worked up in the usual way to yield 27.0 g of a heavy brown oil (94%) The hydrochloride salt was prepared with ether–HCl and recrystallized from methanol–ether; white solid, m.p. 156.5–157°.

*7-Methoxy-1-(N,N-dimethyl-3-aminopropyl)-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene (**15**; $R^1 = OCH_3$)*

This was prepared as described above in 75% yield. The free base was a crystalline white solid, m.p. 85–86°. An analytical sample of the hydrochloride salt was recrystallized from 2-propanol-ether, m.p. 174.5–175.5°.

Syntheses of 4a-Aminomethyl-1,2,3,4,4a,9-hexahydrophenanthrenes (17a–i)

Compounds **17***a*, *b*, *e*, *f* and *g* were prepared as in the procedure given for **17***c*. See Table 2 for the yields, melting points, and analyses of **17***a–i*.

N-Benzyl-4a-aminomethyl-1,2,3,4,4a,9-hexahydrophenanthrene (17c; $R^1 = R^2 = H$; $R^3 = CH_2\phi$)

N-Benzyl-1-aminomethyl-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene hydrochloride **12***c* (40.0 g; 0.112 mol) was dissolved in 200 ml of hot methanol. This solution was added over 10 min to 800 ml of boiling concentrated hydrochloric acid in a 3-l flask with vigorous stirring (CAUTION! foaming may occur). The solution was refluxed for 10 min then allowed to cool and poured into 600 ml 50% aqueous sodium hydroxide and 1 l of ice. The solution was extracted with five 200-ml portions of ether, the extracts were washed once with brine, dried (Na_2SO_4) and evaporated to dryness *in vacuo*. The resultant oil was taken up in 400 ml of ether and 150 ml of 10% aqueous hydrochloric acid was added with vigorous stirring. A solid separated which was filtered off and recrystallized from 2-propanol–ether to yield 20.0 g (53%) of pure **17***c* as its hydrochloride, m.p. 193–195°.

Wagner–Meerwein Rearrangement of 12b using $KHSO_4$

An intimate mixture of ground, freshly fused $KHSO_4$ (1.09 g; 8 mmol) and 1-*N*-methylaminomethyl-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene hydrochloride (**12***b*) (564 mg; 2 mmol) was put under nitrogen and then immersed in a 200° oil bath for 70 min. Water was added, then 10% aqueous NaOH, and then it was extracted with ether. The ether extract was washed with water, dried (Na_2SO_4), and evaporated *in vacuo* to leave 358 mg of a brown oil. Nuclear magnetic resonance examination of this oil showed >95% aldehyde **19**. A 2,4-DNP derivative was prepared and recrystallized from acetone–methanol, m.p. 225–227° dec. Mixture m.p. with the 2,4-DNP prepared from the BF_3 derived aldehyde was 225–227° (dec.).

4a-N,N-Dimethylaminomethyl-1,2,3,4,4a,9-hexahydrophenanthrene (17d)

A solution of 4a-*N*-methylaminomethyl-1,2,3,4,4a,9-hexahydrophenanthrene **17***b* (2.175 g; 9.5 mmol), methyl iodide (15 ml; excess), and *ca.* 100 ml AR.Et_2O was heated at reflux for 1 h. The reaction mixture was evaporated to dryness *in vacuo* leaving 2.97 g of a cream-colored solid. This was recrystallized from MeOH to yield 1.82 g of white crystals, m.p. 191.5–195° (dec.) (57% yield).

4a-(2-Aminoethyl)-1,2,3,4,4a,9-hexahydrophenanthrene (17h)

Concentrated hydrochloric acid (30 ml) was added slowly and with stirring to 1-(2-aminoethyl)-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene (**14**), (7.84 g; 32 mmol). After stirring at 25° for 0.5 h the reaction mixture had nearly solidified. It was alkalized with 10% sodium hydroxide solution and extracted twice with ether. The ether extract was washed twice with water, dried (Na_2SO_4), and evaporated *in vacuo* to give 6.73 g (92.5%) of **17** ($n = 2$; $R^1 = R^2 = R^3 = H$) as a thick oil which crystallized on standing. Its hydrochloride recrystallized from ethanol–ether as a white solid, m.p. 202–205.5° dec.

6-Methoxy-4a-N,N-dimethyl-3-aminopropyl-1,2,3,4,4a,9-hexahydrophenanthrene (17i)

A solution of 7-methoxy-1-(3-*N*,*N*-dimethylaminopropyl)-1-hydroxy-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalene (**15**) ($R^1 = OCH_3$) (8.85 g; 27.9 mmol) in glacial formic acid (200 ml) was heated on a steam bath at 98° for 19 h. After the solution was cooled to 25° it was alkalized by the careful addition of concentrated NH_4OH and extracted twice with ether. After washing (H_2O) and drying (Na_2SO_4) the ether was removed *in vacuo* leaving 6.48 g of a red-brown oil whose n.m.r. spectrum indicated 90% content of **17***i* (70%). The hydrochloride salt was prepared in the usual manner and recrystallized from isopropanol, white crystals, m.p. 205–208° (dec).

Base-catalyzed Rearrangement Reactions of 4a-Aminomethyl-1,2,3,4,4a,9-Hexahydrophenanthrenes. Synthesis of D-Normorphinans

TERRY T. CONWAY,[1] TERRENCE W. DOYLE,[1] YVON G. PERRON, JACQUES CHAPUIS, AND BERNARD BELLEAU

Bristol Laboratories of Canada, Candiac, Quebec J5R 1J1

Received July 12, 1974

TERRY T. CONWAY, TERRENCE W. DOYLE, YVON G. PERRON, JACQUES CHAPUIS, and BERNARD BELLEAU. Can. J. Chem. **53**, 245 (1975).

The syntheses of members of the D-normorphinan system, which is unreported prior to this work, are described. Two methods employing 4a-aminomethyl-1,2,3,4,4a,9-hexahydrophenanthrenes (**1***a–d*) as starting materials were developed. These were the base-catalyzed rearrangement of **1** to the 4a-aminomethyl-4a,10a-*cis*-1,2,3,4,4a,10a-hexahydrophenanthrenes **2** followed by base-catalyzed ring closure of one of these (**2***b*) to *N*-methyl-D-normorphinan (**3**) and the intramolecular cyclization of the chloramine derived from **2***c* to give 10-substituted-*N*-benzyl-D-normorphinans which were transformed into a number of derivatives.

The $Eu(fod)_3$ induced shifts in the n.m.r. spectra of certain of these D-normorphinans are reported and form the basis of a configurational assignment to one of the products obtained on chloramine solvolysis.

TERRY T. CONWAY, TERRENCE W. DOYLE, YVON G. PERRON, JACQUES CHAPUIS et BERNARD BELLEAU. Can. J. Chem. **53**, 245 (1975).

On décrit la synthèse d'un certain nombre de composés contenant le système D-normorphinane; aucune synthèse de ce système n'avait été rapportée avant le présent travail. On a développé deux méthodes faisant appel aux aminométhyl-4a hexahydro-1,2,3,4,4a,9 phénanthrène (**1***a–d*) comme produits de départ. Ces deux méthodes font appel à des réarrangements, catalysés par les bases, des produits **1** en aminométhyl-4 hexahydro-1,2,3,4,4a,10a phénanthrènes **2** de stéréochimie 4a,10a *cis*; la cyclisation catalysée par les bases de **2***b* fournit le *N*-méthyl D-normorphinane **3** et la cyclisation intramoléculaire de la chloramine dérivée de **2***c* fournit les *N*-benzyl D-normorphinanes substitués en position 10 qui sont transformés en un grand nombre de dérivés.

On rapporte les spectres r.m.n. de certain de ces D-normorphinanes lorsqu'ils sont mis en présence du réactif $Eu(fod)_3$; ces spectres forment la base de l'attribution configurationnelle d'un des produits obtenus par la solvolyse de la chloramine. [Traduit par le journal]

In the preceding communication, the synthesis of 4a-alkylamino-1,2,3,4,4a,9-hexahydrophenanthrenes via acid-catalyzed rearrangements of 1-hydroxy-1-aminoalkyl-2,2-tetramethylene-1,2,3,4-tetrahydronaphthalenes was described (1). In this paper we should like to report our results on the base-catalyzed rearrangements of the 4a-aminomethyl-1,2,3,4a,9-hexahydrophenanthrenes to 4a,10a-*cis*-4a-aminomethyl-1,2,3,4,4a,10a-hexahydrophenanthrenes and on the subsequent base-catalyzed ring closure of 4a,10a-*cis*-4a-*N*-methylaminomethyl-1,2,3,4,-4a,10a-hexahydrophenanthrene (**2***b*) to *N*-methyl D-normorphinan (**3**). The results of ring closures of the chloramine derived from 4a,10a-*cis*-4a-*N*-benzylaminomethyl-1,2,3,4,4a,10a-hexahydrophenanthrene (**2***c*) are also discussed.

Results and Discussion

The synthesis of *N*-substituted β-phenethylamines via base-catalyzed addition of amines to styrene has been demonstrated by Wegler and Pieper (2*a*) and Falk and co-workers (2*b*). More recently Freter and co-workers have utilized a variation of this method in the synthesis of tetrahydroquinolines (3). The addition of amines to α- and γ-vinylpyridines has been demonstrated by Doering and Weil (4). Recently Gates *et al.* have applied this reaction to the syntheses of cinchona alkaloids (5). These results suggested to us that base catalyzed rearrangement of the readily available 4a-aminomethyl-1,2,3,4,4a,9-hexahydrophenanthrenes to the 4a-aminomethyl-

SCHEME 1

1,2,3,4,4a,10a-hexahydrophenanthrenes followed by intramolecular base-catalyzed addition to the styrenoid double bond might provide an entry into the previously unreported D-normorphinan or D-norisomorphinan series (depending on the stereochemistry of the 4a-aminomethyl-1,2,3,4a,-10a-hexahydrophenanthrene produced in the first instance). Consequently the isomerization of 4a-aminomethyl-1,2,3,4,4a,9-hexahydrophenanthrenes (**1***a–d*) has been examined.

The base-catalyzed isomerization of these systems is an allylic proton transfer reaction (6). In recent years it has been found that the use of solvents of high polarity such as dimethylsulfoxide (DMSO) permits rapid isomerizations at low temperatures (6*a*).

Treatment of 4a-aminomethyl-1,2,3,4,4a,9-hexahydrophenanthrene (**1***a*) with potassium *tert*-butoxide in DMSO for 30 min at 25 °C gave 4a-aminomethyl-4a,10a-*cis*-1,2,3,4,4a,10a-hexahydrophenanthrene (**2***a*) in 73% yield (see Scheme 1).[2] The stereochemistry of the product was shown by the n.m.r. spectrum (see Table 1). An examination of Drieding models permits an estimation of the dihedral angles of the 4a,10a-*cis*-1,2,3,4,4a,10a-hexahydrophenanthrene and 4a,10a-*trans*-1,2,3,4,4a,10a-hexahydrophenanthrene systems between H_{10} and H_{10a} (H_B and H_C, respectively, in Table 1). For the 4a,10a-*cis* system $\phi H_B H_C \cong 20°$ and for the 4a,10a-*trans* system $\phi H_B H_C \cong 100°$. The Karplus equation predicts a value of $J_{H_BH_C} \cong 7.0$ Hz for the 4a,10a-*cis* system and $J_{H_BH_C} \cong 0.1$ Hz for the 4a,10a-*trans* system (7). In compounds **2***a–d* and compound **5** $J_{H_BH_C} = 5.9$ Hz thus indicating the *cis* stereochemistry of these compounds. Recently Nelson and co-workers have reported $J_{H_BH_C} = 0$–1 Hz for the parent 4a,10a-*trans*-1,2,3,4,4a,10a-hexahydrophenanthrene (8).

Similarly, treatment of compounds **1***b–d* with potassium *tert*-butoxide in DMSO (either for 30 min or 24 h, see Experimental) produced compounds **2***b–d* (in 52, 89, 65% yields, respectively) of 4a,10a-*cis* stereochemistry. These results are not too surprising in view of the greater thermodynamic stability of the 4a,10a-*cis*-1,2,3,4,4a,10a-hexahydrophenanthrenes relative to the *trans* isomer. An examination of models indicates that in going from 4a,10a-*trans* to 4a,10a-*cis* the molecule is relieved of two *syn* triaxial interactions (4a-aminomethyl substituent and axial hydrogens at C_1 and C_3, see Scheme 1[3]) as well as a *gauche* interaction of H_B and the C_{10a}—C_1 bond. As the reactions are carried our under what might be expected to be equilibrating conditions the exclusive formation of the 4a,10a-*cis*

[2]In addition to the amine approximately 25% of neutral material was isolated which consisted of at least three components which were not identified.

[3]Only one of two possible conformers of the 4a,10a-*cis* systems is illustrated in Scheme 1. The second conformer is expected to be considerably less stable (see Scheme 2).

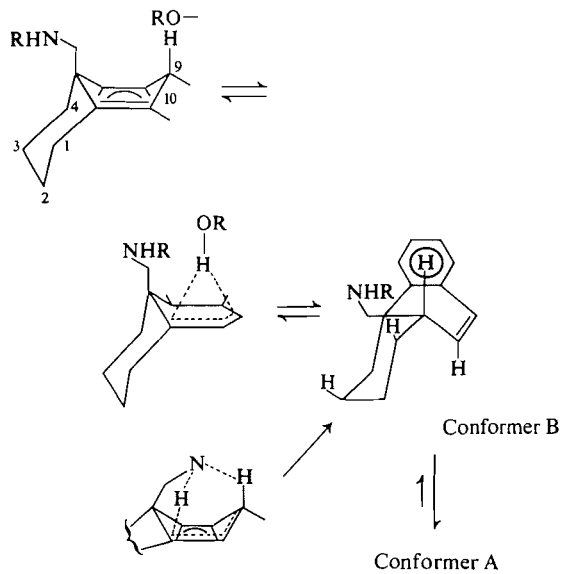
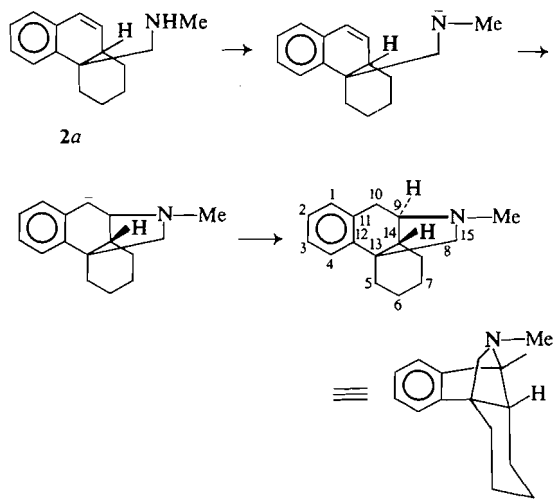
systems is to be expected. The possibility that stereospecific allylic proton transfer is occurring must also be considered. Cram and co-workers have shown that in solvents of high polarity such as DMSO allylic proton transfer may proceed with a high degree of intramolecularity (6*c* and references therein). An examination of a model of **1***a–d* shows that these systems are ideally disposed for such a process (Scheme 2). Stereospecific proton transfer of the axial 9-β-hydrogen in **1***a–d* would lead to the less stable conformer of the 4a,10a-*cis*-1,2,3,4,4a,10a-hexahydrophenanthrene systems which may undergo ring inversion to the more stable conformer. Similarly Nieuwstad and Van Bekkum have postulated that proton transfer in the isomerization of 1,4-dihydronaphthalene to 1,2-dihydronaphthalene occurs in a one-step manner via a transition state involving proton transfer on one face of the molecule (see Scheme 2) (9).



SCHEME 2

With the desired 4a-aminomethyl-4a,10a-*cis*-1,2,3,4,4a,10a-hexahydrophenanthrene systems at hand the conversion of these to the D-normorphinans was studied next. Treatment of *N*-methyl-4a-aminomethyl-4a,10a-*cis*-1,2,3,4,4a,-10a-hexahydrophenanthrene (**2***b*) with lithium diisopropylamide in benzene or of *N*-methyl-4a-aminomethyl - 1,2,3,4,4a,9 - hexahydrophenan - threne (**1***b*) with potassium *tert*-butoxide in DMSO gave *N*-methyl-D-normorphinan (**3**) (in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



SCHEME 3

71 and 31% yields, respectively). For the purposes of large scale preparations of **3** it was found to be more convenient to use the latter procedure, thus eliminating the necessity of isolating **2***b* in the direct conversion of **1***b* to **3** (see Experimental).

Treatment of compounds **2***a*, *c*, and *d* under the conditions described for the conversion of **2***b* to **3** failed to give any D-normorphinans. The failure of the 6-methoxy derivative **2***d* may be ascribed to destabilization of the presumed intermediate benzyl carbanion (see Scheme 3) by the *p*-methoxyl function. The failure of the primary amine **2***a* to add to the styrenoid double bond might have been expected on the basis of the results of Wegler and Pieper (2*a*), Falk and co-workers (2*b*), and Freter *et al.* (3). The first authors (2*a*) report only moderate yields for the addition of primary amines (methylamine 10%, propylamine 18%, cyclohexyl amine 30%) and ammonia (8%) to styrene. Similarly, Freter *et al.* (3) report only a 10% yield of tetrahydroquinoline from primary amine. The failure of compound **2***c* to cyclize may be due to steric factors, since the transition state leading to addition of the *N*-anion to the double bond would require eclipsing of the C_{15}—N bond thus bringing the bulky benzyl group into proximity with either the fused benzene ring or the protons at C_{14} and C_5.

Attempts to demethylate *N*-methyl-D-normorphinan (**3**) by the usual methods failed to give, for example, the desired parent D-normorphinan **8**. Treatment of **3** with phenyl chloroformate gave the eliminated product **i**.[4] The n.m.r. spectrum of **i** indicated the B/C-*cis* ring juncture shown. The n.m.r. spectrum of **3** (the n.m.r. spectra of all D-normorphinans prepared in this study are recorded in Table 2) confirmed the assigned structure. The proton at C_9 exhibits a doublet of broadened triplets at 3.06 δ $J_{H_9H_{10}}$ = 3 Hz and $J_{H_9H_{14}}$ = 5 Hz. An examination of molecular models permits one to estimate the dihedral angle ϕ $H_9H_{14} \cong 37°$ on the basis of which one may predict a value of $J_{H_9H_{14}} \cong 5$ Hz which corresponds to one of the observed coupling constants. One would predict a coupling constant $J_{H_9H_{14}} < 0.3$ Hz for the corresponding D-norisomorphinan. The predicted values for $J_{H_9H_{10cis}} \cong 0.6$ Hz and $J_{H_9H_{10trans}} \cong 3.1$ Hz which would account for the broadened nature of the observed coupling constant of 3 Hz.

Chloramine Solvolysis

In view of the failure to demethylate *N*-methyl-D-normorphinan (**3**), an alternative approach was explored.

The use of *N*-chloramines in the syntheses of bicyclic amines via intramolecular addition to olefins has received much attention in recent years (10–15). The *N*-chloramine **4** was prepared from *N*-benzyl-4a-aminomethyl-4a,10a-*cis*-1,2,3,4,4a,10a-hexahydrophenanthrene (**2***c*) according to the method of Nakano and Votický (16). Refluxing a solution of **4** in methanol produced 20% of **2***c* and 50% of 10-*trans*-methoxy-*N*-benzyl-D-normorphinan.[5] Compound **5** was the only cyclized product which could be recovered from the reaction. Similarly treatment of **4** in aqueous tetrahydrofuran resulted in **2***c* in 26% yield and the formation of 10-*trans*-hydroxy-*N*-benzyl-D-normorphinan (**9**) in 34% yield.

Two mechanistic possibilities have been proposed to account for the products obtained in unassisted 'solvolyses'. Gassman has proposed the intermediacy of nitrenium ions to account for both the unassisted and silver ion assisted

[4]T. T. Conway, unpublished results. The results of this and related experiments will be published elsewhere.

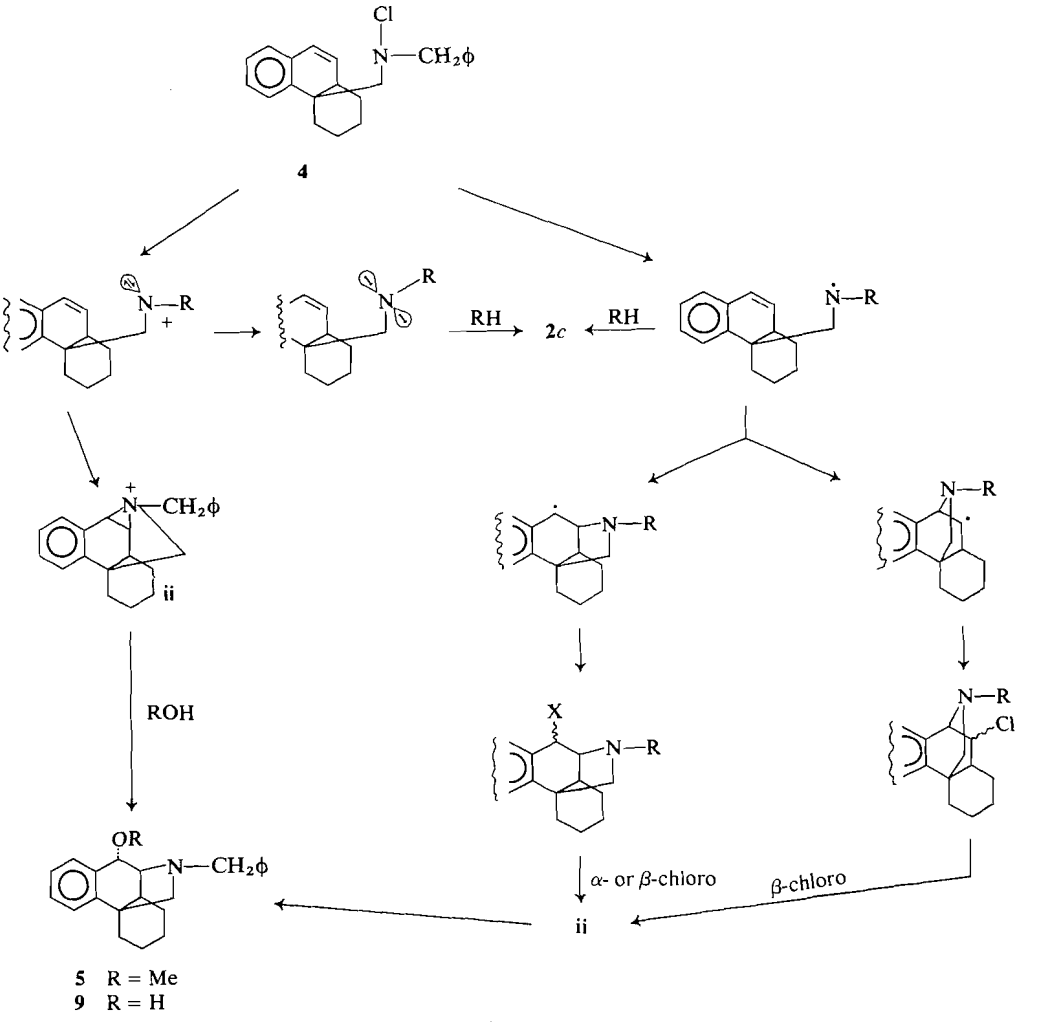
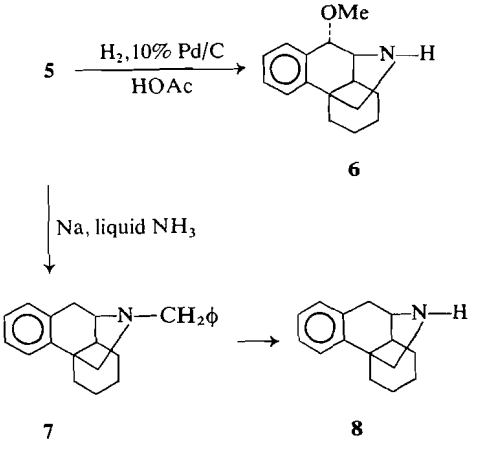


SCHEME 4

solvolyses (10*a*). On the other hand Edwards *et al.* (14*a*) and Hobson and co-workers (14*b*) have presented convincing evidence for a radical chain mechanism in these reactions (see Scheme 4). Either of these mechanisms may account for the products observed in our system.

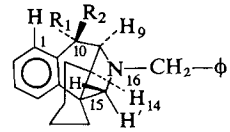
Hydrogenolysis of compund **5** with Pd/C in acetic acid did not give the desired D-normorphinan **8**, rather, 10-*trans*-methoxy-D-normorphinan (**6**) was isolated in 70% yield. Treatment of **5** with sodium in liquid ammonia gave *N*-benzyl-D-normorphinan (**7**) which on hydrogenolysis with Pd/C in acetic acid gave the desired D-normorphinan (**8**) in 75% yield (Scheme 5). Similarly hydrogenolysis of compound **9** gave 10-*trans*-hydroxy-D-normorphinan (**10**) in 89% yield.



SCHEME 5

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The n.m.r. spectra of *N*-benzyl-D-normorphinan (**7**) and D-normorphinan (**8**) were compatible with the assigned structures showing the same splitting pattern for H_9 as in *N*-methyl-D-normorphinan (**3**) (see Table 2). The hydrogenolysis of the methoxy function in **5** with sodium in liquid ammonia established the position of substitution as C_{10}. The n.m.r. spectra of compounds **5** and **9** were ambiguous with respect to the assignment of the configuration of the methoxy and hydroxy functions relative to the alkylamino bridge. In order to resolve this problem compound **9** was oxidized with chromic acid (17) to 10-keto-*N*-benzyl-D-normorphinan (**11**) in 53% yield (69.5% based on alcohol consumed). The i.r. spectrum of **11** ($CHCl_3$ solution) showed a carbonyl absorption at 1682 cm^{-1} as expected for carbonyl adjacent to an aromatic ring. The n.m.r. spectrum of **11** shows deshielding of H_1 *ortho* to the carbonyl. The coupling constant for $H_9, J_{H_9H_{14}} = 5.0$ Hz, confirming the assignment of B/C-*cis* stereochemistry. Reduction of **11** with lithium aluminum hydride in ether gave a mixture of the 10-*trans*-hydroxy **9** and 10-*cis*-hydroxy-*N*-benzyl-D-normorphinan (**12**) in a ratio of 2:3 (99% yield). The epimeric alcohols were separated by chromatography. Compound **12** was hydrogenolyzed to 10-*cis*-hydroxy-D-normorphinan (**13**) in 82% yield.



9 $R_1 = OH; R_2 = H$
12 $R_1 = H; R_2 = OH$

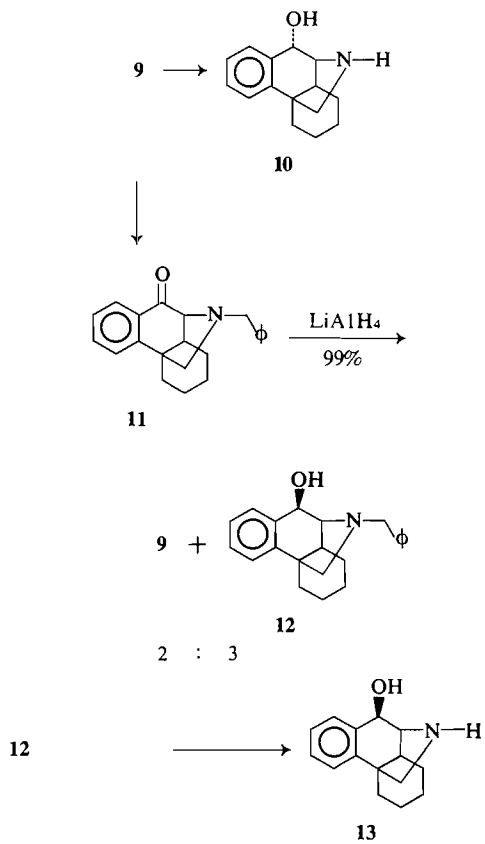
FIG. 1

Examination of a model of ketone **11** shows that the approach of hydride from the side opposite the alkylamino bridge might be expected to be slightly less hindered than from the same side leading one to predict that the formation of **12** over **9** should be favored as is the case. The configurational assignments to **9** and **12** have been made on the basis of their 100 MHz n.m.r. spectra and the magnitude of the $Eu(fod)_3$ induced shifts (18).

The 60 MHz n.m.r. spectra of the 10-substituted D-normorphinans are recorded in Table 2. In the spectra of the secondary amines, compounds **6**, **10**, and **13**, the protons on C_{15} appear as broadened singlets. On the other hand in the n.m.r. spectra of the *N*-benzyl substituted compounds **5**, **9**, **11**, and **12** the protons on C_{15} appear as pairs of doublets. An examination of molecular models indicates that in these compounds the benzyl group most likely adopts (for steric reasons) the configuration in which the benzyl group is on the side of the methyl amino bridge opposite the aromatic ring of the D-normorphinans. Consequently, we have assigned the upfield doublet (shielded) to H_{15}' and the downfield doublet to H_{15} (see Fig. 1).

The use of lanthanide shift reagents in the configurational assignment of pairs of isomers has been demonstrated for a number of systems (19) including alcohols (19*a*, *b*, *e*, *f*, and *g*), ethers (19 *g* and *i*), esters (19*h*), sulfoxides (19*c*), and phosphetan oxides (19*d*). A number of authors have shown the utility of lanthanide shift reagents in the analysis of the n.m.r. spectra of bifunctional compounds (20).

On addition of $Eu(fod)_3$ to compounds **9**, **11**, and **12** lanthanide induced shifts (l.i.s.) are



SCHEME 6

[d]Product concentration = 4.7×10^{-5} mol in 0.4 ml $CDCl_3$.

observed (recorded in Table 3). Presumably in the alcohols **9** and **12** the primary sites of coordination of the europium complex are the hydroxyl functions in competition with the tertiary amine. *A priori* one would predict a greater shift for protons on C_{15} in the isomer having the hydroxyl group oriented *cis* to the aminomethyl bridge. The observed l.i.s. for compounds **9** and **12** bear out this prediction. In the *cis* isomer **12** H_{15} and H_{15}' as well as H_9 and 2 H_{16} show considerably greater l.i.s. thus confirming the configurational assignments of compound **9** as the *trans* alcohol and compound **12** as the *cis* alcohol. The greater l.i.s. of H_1 in compound **12** is also to be expected in as much as the hydroxyl group in **12** is oriented in a pseudo equatorial position while that of compound **9** is pseudo axial. This relationship may also be deduced from the 100 MHz n.m.r. spectra of **9** and **12** before the addition of $Eu(fod)_3$. In compound **12** H_1 is more shielded than in compound **9** (7.44 *vs.* 7.30 δ). The possibility that the tertiary amine is the primary site of coordination of the $Eu(fod)_3$ in compounds **9** and **12** may be ruled out since if this were the case one would expect l.i.s. of greater magnitude for H_{15}, H_{15}' and the two H_{16} protons. The same argument would apply if the $Eu(fod)_3$ were to form a complex with the bidentate ligand in compound **12**.[6]

In the ketone **11** the results would seem to indicate a competition of the tertiary amine and keto functions for the $Eu(fod)_3$. While the magnitude of the l.i.s. for the protons at C_{15} and C_{16} is greater than in the alcohols **9** and **12** the relatively greater shifts for H_1 and H_9 indicate that some complex formation with the keto function must be occurring in competition with the amine.

[6]A similar argument has been used by Okutani and co-workers (20*b*) in their configurational assignment to the diastereoisomeric 1-cyclohexyl-2-phenylazetidin-3-ols. They have observed coordination of $Eu(DPM)_3$ to occur exclusively at the hydroxyl function in their compounds.

Experimental

The i.r. spectra were recorded on a Unicam Sp-200G grating i.r. spectrometer. The n.m.r. spectra were determined on a Varian A60-A spectrometer using tetramethyl silane as an internal standard, with the exception of compounds **9**, **11**, and **12** which were recorded at 100 Mc (see below). Melting points are uncorrected and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, Illinois. The 100 Mc spectra and $Eu(fod)_3$ experiments were carried out by Mr. R. Vulcano of Bristol Laboratories (Syracuse) whose assistance in this matter is gratefully acknowledged. The i.r. spectra of all compounds were compatible with the assigned structures.

Base-catalyzed Rearrangements of 4a-Aminomethyl-1,2,3,4,4a,9-hexahydrophenanthrenes

4a,10a-cis-4a-Aminomethyl-1,2,3,4a,10a-hexahydrophenanthrene (2a)

To a solution of 400 mg (1.88 mmol) of 4a-aminomethyl-1,2,3,4,4a,9-hexahydrophenanthrene **1***a* in 7 ml dry DMSO was added 400 mg (3.58 mmol) potassium *tert*-butoxide at ambient temperature ($\sim$23 °C). The solution initially turned green, then to deep red-brown and warmed slightly. The solution was stirred 30 min, poured into 50 ml water and extracted into methylene chloride (3 × 25 ml). The aqueous layer was saturated with NaCl and extracted with ether (1 × 25 ml). The organic extracts were washed with water (1 × 25 ml), dried over Na_2SO_4, filtered, and concentrated. The residue was taken up in 50 ml of ether and extracted into 10% HCl (3 × 10 ml). The aqueous phase was neutralized with Na_2CO_3 and extracted with methylene chloride (3 × 25 ml). The extracts were dried over Na_2SO_4, filtered, and evaporated to yield 288.3 mg (73%) of pure (as determined by n.m.r.) 4a,10a-*cis*-4a-aminomethyl-1,2,3,4,4a,10a-hexahydrophenanthrene, b.p. 122–125°/0.01 mm. The amine formed a hygroscopic hydrochloride, m.p. 205–210 °C (dec.) (recrystallized from methanol–ether).

Anal. Calcd. for $C_{15}H_{19}N{\cdot}HCl{\cdot}3/8H_2O$: C, 70.22; H, 8.15; N, 5.46. Found: C, 70.40; H, 8.05; N, 5.59.

N-Methyl-4a,10a-cis-4a-aminomethyl-1,2,3,4,4a,10a-hexahydrophenanthrene (2b)

Treatment of 2.41 g (10.20 mmol) of *N*-methyl-4a-aminomethyl-1,2,3,4,4a,9-hexahydrophenanthrene with 620 mg (5.5 mmol) of potassium *tert*-butoxide in 90 ml dry DMSO for 72 h at ambient temperature gave 1.26

g (52%) of *N*-methyl-4a,10a-*cis*-aminomethyl-1,2,3,4,4a,-10a-hexahydrophenanthrene after the usual work-up (see above). The amine formed a crystalline oxalate, m.p. 203–203.5 °C (recrystallized from methanol).

Anal. Calcd. for $C_{16}H_{21}N{\cdot}C_2H_2O_4$: C, 68.12; H, 7.30; N, 4.41. Found: C, 68.31; H, 7.35; N, 4.56.

N-Benzyl-4a-aminomethyl-4a,10a-cis,1,2,3,4,4a,10a-hexahydrophenanthrene (2c)

Method A. To 1.30 g (6.1 mmol) of 4a,10a-*cis*-4a-aminomethyl-1,2,3,4,4a,10a-hexahydrophenanthrene **2a** in 10 ml ethanol was added 0.645 g (6.1 mmol) benzaldehyde. The solution was let stand 1 h at room temperature, 0.29 g (6.1 mmol) sodium borohydride was added, and the solution stirred 1 h at room temperature. The solution was poured into 50 ml water and extracted into methylene chloride (3 × 25 ml), the extracts were dried over Na_2SO_4 and evaporated to yield 1.95 g (quantitative) of *N*-benzyl-4a-aminomethyl-4a,10a-*cis*-1,2,3,4,-4a,10a-hexahydrophenanthrene. The amine formed a hygroscopic hydrochloride, m.p. 243–245 °C (decomposition) (recrystallized from methanol – ethyl acetate).

Anal. Calcd. for $C_{22}H_{25}N{\cdot}HCl{\cdot}1/2H_2O$: C, 75.73; H, 7.79; N, 4.01. Found: C, 75.81; H, 7.75; N, 3.99.

Method B. Treatment of *N*-benzyl-4a-aminomethyl-1,2,3,4,4a,9-hexahydrophenanthrene hydrochloride (16.57 g, 0.049 mol) with 16.0 g (0.141 mol) of potassium *tert*-butoxide in 100 ml dry DMSO at ambient temperature for 30 min gave, after the usual work-up, 15.1 g of an oil. The oil was taken up in 150 ml of ether and the amine hydrochloride was precipitated to yield 14.77 g (89%) of the salt, m.p. 243–245 °C (dec.).

6-Methoxy-N-methyl-4a,10a-cis-4a-aminomethyl-1,2,3,4,4a,10a-hexahydrophenanthrene (2d)

Treatment of 3.40 g (11.5 mmol) of 6-methoxy-*N*-methyl-4*a*-aminomethyl-1,2,3,4,4*a*,9-hexahydrophenanthrene with 3.40 g (30 mmol) of potassium *tert*-butoxide in 25 ml dry DMSO for 24 h at ambient temperature followed by the usual work-up gave 2.05 g of a pale brown oil. The hydrochloride salt was prepared and recrystallized from isopropanol–ether, m.p. 208–209 °C. The salt was treated with 20% Na_2CO_3 and re-extracted into ether. The extract was dried over Na_2SO_4 and evaporated to give 1.80 g (65%) of pure 6-methoxy-*N*-methyl-4a-aminomethyl-4a,10a-*cis*-1,2,3,4,4a,10a-hexahydrophenanthrene b.p. 139–141 °C/0.25 mm. Pure hydrochloride salt was prepared for analysis, m.p. 209–209.5 °C.

Anal. Calcd. for $C_{17}H_{23}NO{\cdot}HCl{\cdot}1/5H_2O$: C, 68.65; H, 8.27; N, 4.71. Found: C, 68.69; H, 8.38; N, 4.55.

N-Methyl-D-normorphinan (3)

Method A

From N-Methyl-4a-aminomethyl-1,2,3,4,4a,10a-hexahydrophenanthrene (2b). A solution of 900 mg (4.0 mmol) of *N*-methyl-4a-aminomethyl-1,2,3,4,4a,10a-hexahydrophenanthrene **2b** in 5 ml of dry benzene was added (under nitrogen and with magnetic stirring) to a solution of lithium diisopropylamide (prepared by adding 0.80 ml of a 5.07 *N* solution of methyl lithium in ether to a mixture of 0.56 ml (4 mmol) diisopropylamine in 15 ml dry benzene at 25 °C). The reaction mixture was refluxed for 4 h, cooled to 25 °C, and an equal volume of water added. The organic phase was separated, washed twice with water (20 ml), dried over Na_2SO_4, filtered, and evaporated at reduced pressure to yield 640 mg (71%) of *N*-methyl-D-normorphinan (**3**). The cyclohexylsulfamate salt of this material was prepared, m.p. 117–118.5 °C (recrystallized from ethanol–ether).

Anal. Calcd. for $C_{16}H_{21}N{\cdot}C_6H_{13}NO_2S$: C, 64.99; H, 8.43; N, 6.89; S, 7.89. Found: C, 64.81; H, 8.54; N, 6.79; S, 7.82.

Method B

From N-Methyl-4a-aminomethyl-1,2,3,4,4a,9-hexahydrophenanthrene (1b)

To a solution of 100.6 g (0.543 mol of *N*-methyl-4a-aminomethyl-1,2,3,4,4a,9-hexahydrophenanthrene in 730 ml of dry DMSO was added 32.0 g (0.286 mol) potassium *tert*-butoxide. The solution was stirred at room temperature for 140 h at which time an additional 13.5 g (0.120 mol) of potassium *tert*-butoxide was added. The solution was heated to 35–38 °C for 20 h, poured into 4 l of ice water, and extracted with ether (3 × 500 ml). The organic phase was extracted with 3 *N* HCl (3 × 100 ml), the aqueous layer made alkaline with 30% NaOH and extracted into ether (3 × 100 ml). The extracts were dried over Na_2SO_4 and concentrated to yield 51.5 g of crude *N*-methyl-D-normorphinan (**3**). The compound was distilled to yield 31.26 g (31%) of pure *N*-methyl-D-normorphinan, b.p. 108–114 °C/0.005 mm. An additional 4.4 g, b.p. 114–125 °C/0.005 mm was also obtained. A small sample was redistilled, b.p. 98–101 °C/0.05 mm (bath 150 °C).

N-Benzyl-N-chloro-4a,10a-cis-4a-aminomethyl-1,2,3,4,4a,10a-hexahydrophenanthrene (4)

To a solution of 9.09 g (30 mmol) of *N*-benzyl-4a,10a-*cis*-4a-aminomethyl-1,2,3,4,4a,10,10a-hexahydrophenanthrene **2c** in 100 ml of dry methylene chloride was added 4.0 g (30 mmol) *N*-chlorosuccinimide (16). The solution was stirred 30 min, washed with water (4 × 25 ml), dried over Na_2SO_4, and concentrated to yield 10.2 g of an oily *N*-chloro derivative. The n.m.r. spectrum of **4** was compatible with the assigned structure.

10-trans-Methoxy-N-benzyl-D-normorphinan (5)

Chloramine **4** (10.11 g, 30 mmol prepared from 9.09 g amine) was placed in 250 ml of dry methanol and boiled at reflux for 18 h. The solvent was removed at reduced pressure, the residue taken up in 50 ml of water, neutralized with Na_2CO_3, and extracted into ether (4 × 25 ml). The extracts were shaken with 25 ml of 10% HCl. A solid separated which was removed by filtration to give 2.0 g of the hydrochloride salt of the starting amine **2c**. The aqueous layer was neutralized with solid Na_2CO_3 and extracted into ether. The extracts were dried over Na_2SO_4 and concentrated to yield 5.12 g of 10-*trans*-methoxy-*N*-benzyl-D-normorphinan (**5**) contaminated with ~5% starting amine. A small sample was chromatographed on Florisil with ϕH–Et_2O (19:1) to give pure **5** as an oil. The amine was converted to its hydrochloride salt which was amorphous.

Anal. Calcd. for $C_{23}H_{27}NO{\cdot}HCl$: C, 74.67; H, 7.62; N, 3.79. Found: C, 74.39; H, 7.83; N, 3.85.

10-trans-Methoxy-D-normorphinan (6)

A mixture of 2.59 g (7.8 mmol) 10-*trans*-methoxy-*N*-benzyl-D-normorphinan and 100 mg 10% Pd/C in 50 ml acetic acid was hydrogenated at atmospheric pressure at 22 °C. When 1 equiv. H_2 had been absorbed, the solution was filtered and evaporated. The residue was taken up in 50 ml of water, neutralized with Na_2CO_3, saturated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

with NaCl, and extracted into methylene chloride (3 × 50 ml). The extracts were dried over Na_2SO_4, filtered, and evaporated to yield 1.68 g of an oil. Trituration with 5 ml ether and filtration gave 1.35 g of pure 10-*trans*-methoxy-D-normorphinan (**6**) as a solid, m.p. 105–107 °C.

Anal. Calcd. for $C_{16}H_{21}NO$: C, 78.97; H, 8.70; N, 5.76. Found: C, 78.67; H, 8.83; N, 5.77.

N-Benzyl-D-normorphinan (7)

To a solution of 0.05 g sodium in 30 ml of liquid ammonia was added 462.3 mg (1.39 mmol) of 10-*trans*-methoxy-*N*-benzyl-D-normorphinan **5** in 20 ml ether over 5 min. The solution was stirred 10 min and 3 ml ethanol added over 1 min to quench the excess sodium. The ammonia was allowed to evaporate and the residue partitioned between water and ether. The ethereal extracts were dried over Na_2SO_4, filtered, and evaporated to yield 274.4 mg crude *N*-benzyl-D-normorphinan (65%). The oil was chromatographed on Florisil (20 g) with benzene–ether (9:1) to give 200 mg (47.5%) pure compound 7 as an oil.[7] Compound 7 formed an amorphous hydrochloride salt.

Anal. Calcd. for $C_{22}H_{25}N{\cdot}HCl{\cdot}3/4H_2O$: C, 74.76; H, 7.84; N, 3.96. Found: C, 74.70; H, 7.95; N, 4.01.

D-*Normorphinan (8)*

Hydrogenation of 464.6 mg (1.53 mmol) of *N*-benzyl-D-normorphinan (7) over 50 mg 10% Pd/C in acetic acid (50 ml) gave after work-up (see preparation of **6**) 243.5 mg (75%) of D-normorphinan (**8**), b.p. 118–120 °C/0.06 mm. On standing in carbon tetrachloride a crystalline carbonate formed, m.p. 98 °C (with gas evolution), which contained carbon tetrachloride.

Anal. Calcd. for $C_{15}H_{19}N{\cdot}H_2CO_3{\cdot}1.25\ CCl_4$: C, 44.30; H, 4.52; N, 2.99. Found: C, 44.47; H, 4.68; N, 3.15.

Careful drying of the sample (below 50 °C) gave the carbonate.

Anal. Calcd. for $C_{15}H_{19}N{\cdot}H_2CO_3$: C, 69.79; H, 7.68; N, 5.08. Found: C, 69.87; H, 8.08; N, 5.46.

10-trans-Hydroxy-N-benzyl-D-normorphinan (9)

A solution of 10.11 g (30 mmol) chloramine **4** in 150 ml THF–H_2O (4:1) was refluxed 18 h. The solution was evaporated and the residue partitioned between ether-saturated $NaHCO_3$ (200–50 ml). The ethereal extract was dried over Na_2SO_4. Evaporation gave 8.63 g of an oil. Thin-layer chromatography (10% EtOAc-ϕH) on alumina indicated the presence of 2 major components one of which was the starting amine. The oil was chromatographed on 650 g of alumina (Act II) via dry-column technique (21) using 20% EtOAc–ϕH as eluting solvent. In this manner 2.33 g pure starting amine (25.6%) was recovered (elutes 1st from the column) and 3.25 g of the desired 10-*trans*-hydroxy-*N*-benzyl-D-normorphinan (34%; 45% conversion) was obtained as a crystalline solid, m.p. 124–125 °C. A small sample was converted to its hydrochloride salt. This salt did not give a sharp m.p. (dec.), 140–160 °C.

Anal. Calcd. for $C_{22}H_{25}NO{\cdot}HCl$: C, 74.24; H, 7.36; N, 3.93. Found: C, 74.52; H, 7.44; N, 3.89.

[7]In larger scale experiments yields as high as 90% of **7** could be obtained. The average yield for four experiments was 71%.

10-trans-Hydroxy-D-normorphinan (10)

Hydrogenation of 2.233 g (7 mmol) of 10-*trans*-hydroxy-*N*-benzyl-D-normorphinan (**9**) over 100 mg 10% Pd/C in 50 ml acetic acid in the usual manner yielded 1.43 g of a gum. On trituration with benzene the gum crystallized. Filtration gave 1.05 g (66%) pure 10-*trans*-hydroxy-D-normorphinan, m.p. 142–143 °C (recrystallized from benzene). The amino alcohol gave an amorphous hydrochloride salt.

Anal. Calcd. for $C_{15}H_{19}NO{\cdot}HCl$: C, 67.78; H, 7.58; N, 5.27. Found: C, 67.62; H, 7.42; N, 5.12.

10-Keto-N-benzyl-D-normorphinan (11)

A solution of chromic acid was prepared according to the method of Brown *et al.* (17). To 10 g (0.033 mol) sodium dichromate dihydrate in 30 ml of water was added 13.6 g sulfuric acid (0.134 mol). The solution was then diluted to 50 ml with water.

To 1.75 g (5.5 mmol) 10-*trans*-hydroxy-*N*-benzyl-D-normorphinan **10** in 20 ml acetone – 10 ml water was added 4 ml of the CrO_3 solution. The resultant solution was stirred 18 h at room temperature (~22 °C). The solution was diluted to 100 ml with water, neutralized with solid sodium carbonate and extracted into ether (5 × 20 ml). The extracts were dried over Na_2SO_4, filtered, and evaporated to yield 1.65 g of an oil. The oil was chromatographed on Alumina (Act III) with benzene: 0.41 g (23%) starting material and 0.94 g (53.5%, 69.5% conversion) of 10-keto-*N*-benzyl-D-normorphinan (**11**) were obtained. Recrystallization of the ketone from benzene gave white needles, m.p. 106–106.5 °C.

Anal. Calcd. for $C_{22}H_{23}NO$: C, 83.24; H, 7.30; N, 4.41. Found: C, 83.34; H, 7.28; N, 4.29.

10-cis-Hydroxy-N-benzyl-D-normorphinan (12)

To a solution of 800 mg (2.52 mmol) 10-keto-*N*-benzyl-D-normorphinan **11** in 25 ml dry ether at 25 °C was added 0.3 ml of a 4 *M* lithium aluminum hydride solution. The solution was stirred 5 min at 25 °C and cooled to 0–5 °C in an ice bath. To this was added 0.05 ml water. The suspension was stirred 5 min at 20 °C and filtered. Evaporation of the filtrate gave 800 mg of a mixture of the 10-*trans*- and 10-*cis*-hydroxy-*N*-benzyl-D-normorphinans **9** and **12**. Trituration of the gum with 25 ml of petroleum ether (30–60°) caused partial crystallization of the 10-*trans* isomer. The mother liquors (enriched in 10-*cis* isomer) were evaporated and chromatographed on 70 g of alumina (Activity III) via dry-column technique using benzene – ethyl acetate (9 l) as the eluting solvent. 10-*cis*-Hydroxy-*N*-benzyl-D-normorphinan **13** was obtained as an oil; 470 mg (59.5%). The 10-*trans*-hydroxy isomer totaled 320 mg (40.5%) (total yield (99%).

The 10-*cis*-hydroxy isomer formed a crystalline hydrochloride, m.p. 276–278 °C (dec.) (recrystallized from methanol – ethyl acetate).

Anal. Calcd. for $C_{22}H_{25}NO{\cdot}HCl$: C, 74.24; H, 7.36; N, 3.94. Found: C, 74.27; H, 7.39; N, 3.83.

10-cis-Hydroxy-D-normorphinan (13)

Hydrogenation of 319 mg (1 mmol) of 10-*cis*-hydroxy-*N*-benzyl-D-normorphinan **12** in 20 ml acetic acid over 100 mg 10% Pd/C in the usual manner gave 251 mg of an oil. Trituration of the oil with 5 ml of ether induced crystallization. Filtration gave 190 mg (82%) of the

desired 10-*cis*-hydroxy-D-normorphinan **13**. The sample was recrystallized from benzene, m.p. 165–166 °C.

Anal. Calcd. for $C_{15}H_{19}NO$: C, 78.57; H, 8.35; N, 6.10. Found: C, 78.72; H, 8.48; N, 5.99.

Chemistry of Proximal π-Bond Systems. Part III.[1] Synthesis of Substituted Benzopolycyclic Hydrocarbons

D. N. BUTLER AND R. A. SNOW

Chemistry Department, York University, Toronto, Ontario M3J 1P3

Received August 7, 1974

D. N. BUTLER and R. A. SNOW. Can. J. Chem. **53**, 256 (1975).

A series of 21 bridged, vicinal, exocyclic dimethylene hydrocarbons (**1–21**) have been converted to the related benzopolycyclic dimethyl esters (**C1–C21**) by oxidation of their respective dimethyl acetylenedicarboxylate Diels–Alder adducts (**B1–B21**).

This synthetic sequence represents an excellent, general route to aromatic ring-substituted benzopolycyclic hydrocarbons.

D. N. BUTLER et R. A. SNOW. Can. J. Chem. **53**, 256 (1975).

On a transformé une série de 21 hydrocarbures (**1–21**) pontés comportant des diméthylènes exocycliques vicinaux en esters diméthyliques des dérivés benzopolycycliques correspondants (**C1–C21**); cette conversion s'est effectuée par oxydation des adduits de Diels–Alder (**B1–B21**) provenant de la réaction entre les hydrocarbures **1–21** avec l'acétylènedicarboxylate de méthyle.

Cette séquence synthétique représente une excellente route générale pour conduire à des hydrocarbures benzopolycycliques substitués sur le noyau aromatique.

[Traduit par le journal]

Introduction

The incorporation of benzo anellation into bi- and polycyclic hydrocarbons has been used in recent literature (1) to compare the mechanisms of the thermal, photochemical, or solvolytic rearrangements or isomerisms in these systems with those in the corresponding parents by locating one (or more) of the π-bonds in a benzene ring (or rings). The most general preparative route to these compounds involves benzyne cycloadditions (π^2s and π^4s) to suitable conjugated cyclic dienes (2). However, such syntheses do not easily lend themselves to benzene-ring substituted derivatives and indeed, in most of the examples described herein, only the parent hydrocarbons have been synthesized.

The possibility of exploitation of the well known effects of aromatic substituents (perhaps best illustrated in the work of Tanida *et al.* (3*a*) and Brown and Tritle (3*b*) relating to the benzonorbornane system) in unravelling mechanistic details, as well as the positional labels such substitution affords, make a general synthesis of ring-substituted benzo bi- and polycyclic hydrocarbons desirable. The availability of a series of related vicinal exocyclic dimethylene hydrocarbons (4) has allowed the realization of this synthetic goal.

[1]For Part II see ref. 14.

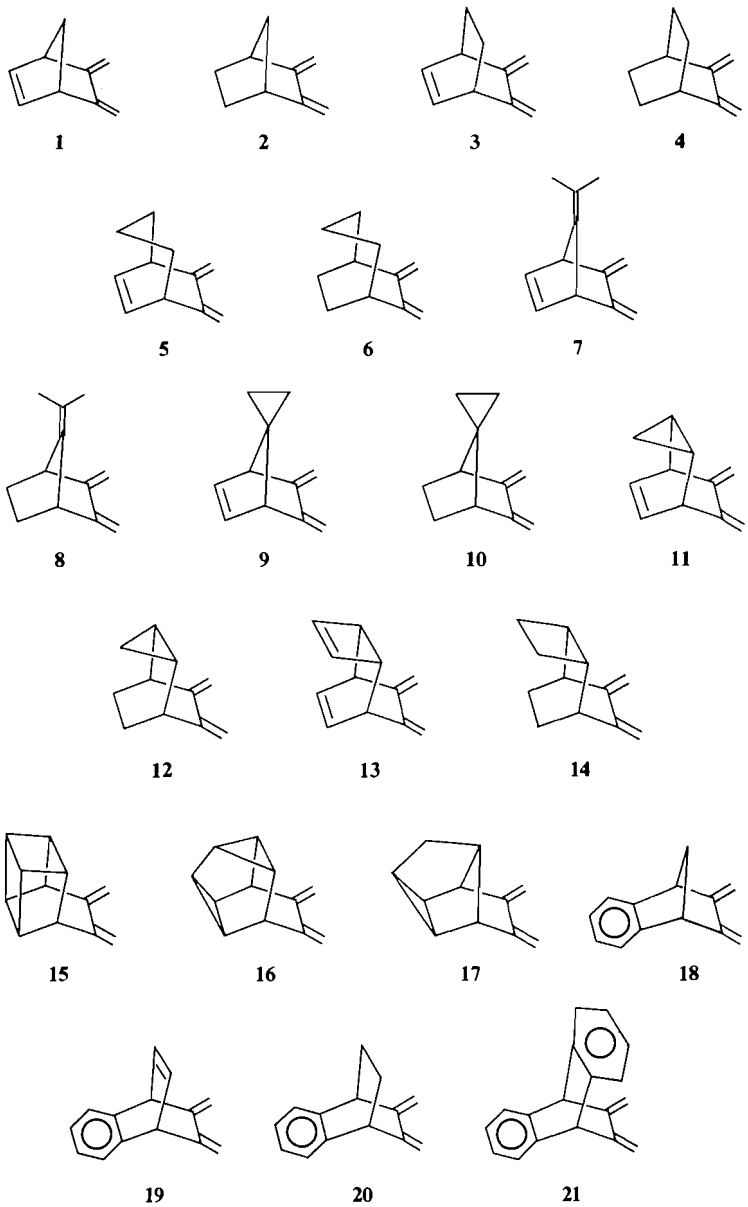
Results and Discussion

The three dienes **16**, **17**, and **18** have not been described prior to this work. They were respectively prepared via the tosylation – base-catalyzed double elimination route (4) from the corresponding *trans*-bis primary alcohols **22***a*, **23***a*, and **24***a*.

The silver-catalyzed rearrangement (5) of dimethyl pentacyclo[4.2.2.$0^{2,5}$.$0^{3,8}$.$0^{4,7}$]decane-(*trans*)-9,10-dicarboxylate (6) to the dimethyl snoutane dicarboxylate **22***b* provided, after reduction, the intermediate diol **22***a* necessary for diene **16**. For hydrocarbon **17**, dimethyl tetracyclo[4.3.0.$0^{2,4}$.$0^{3,7}$]nonane-(*endo,cis*)-8,9-dicarboxylate (7) was epimerized ($NaOCH_3$–CH_3OH) to the *trans*-diester **23***b*, before reduction ($LiAlH_4$) to the corresponding diol **23***a*. For **18**, the known adduct of indene and maleic anhydride (8) was hydrolyzed and esterified (diazomethane) to the *cis*-dimethyl ester before epimerization to **24***b* and reduction to the *trans*-diol, **24***a*, as above.

The dienes 1–21 were readily characterized as their respective tetracyanoethylene (TCNE) adducts, **A1–A21** (where X and Y represent the corresponding bridge moieties of the hydrocarbon structures **1–21**). In every case these compounds corresponded to the expected 1:1 Diels–Alder adducts as indicated by their respective, predicted parent ions in the mass

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



spectra and their consentaneous p.m.r. spectra.[2] The melting points of these adducts are recorded in the Experimental section.

Whereas the TCNE additions to the dienes were very rapid (typically less than 5 min for completion in tetrahydrofuran solvent), the reactions with dimethyl acetylenedicarboxylate (DMAD) in CCl_4 solvent showed considerable rate differences ranging from less than 5 min for **4** (fastest) to 2 days at reflux temperature (75°) for **9** (slowest) for complete reaction. In general, those of the hydrocarbons **1**–**21** containing the diene fragment on a five-membered ring were the slowest to react in spite of the locked *cisoid* conformation of the diene. At present, a quantitative study of the Diels–Alder reaction rates of

[2]Spectroscopic and analytical data have been placed in the Depository of Unpublished Data. Copies of the material in the Depository may be obtained at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

TABLE 1. DMAD Adducts **B1**–**B21**; physical and spectroscopic data[a]

Adduct	Melting point (°C)	Molecular formula	Observed parent ion *m/e*	Proton magnetic resonance assignments[b]: Vicinal vinyl —C(H)=C(H)—	Bridgehead —C(H)—	Ester —CH_3	Dihydro aromatic —CH_2—	Other proton assignments
B1	57	$C_{15}H_{16}O_4$	260	6.72 (2H)	3.33 (2H)	3.68 (6H)	3.09 (4H)	1.99 (2H)[e]
B2	73.5–74.5[c]	$C_{15}H_{18}O_4$	262	—	2.70 (2H)	3.68 (6H)	3.01 (4H)	0.91–1.80 (6H)[e]
B3	60.5–61.5	$C_{16}H_{18}O_4$	274	6.23 (2H)	3.31 (2H)	3.67 (6H)	3.05 (4H)	1.29 (4H)[e]
B4	60.5–61.5[d]	$C_{16}H_{20}O_4$	276	—	2.29 (2H)	3.70 (6H)	3.04 (4H)	1.15–1.65 (8H)[e]
B5	45 – 46	$C_{17}H_{20}O_4$	288	6.17 (2H)	2.61 (2H)	3.70 (6H)	3.03 (4H)	1.15–1.83 (6H)[e]
B6	26	$C_{17}H_{22}O_4$	290	—	2.13 (2H)	3.69 (6H)	2.96 (4H)	1.31–1.91 (10H)[e]
B7	99.5–101	$C_{18}H_{20}O_4$	300	6.87 (2H)	3.85 (2H)	3.75 (6H)	3.17 (4H)	1.45 (6H) *gem* dimethyl
B8	63 – 64	$C_{18}H_{22}O_4$	300[f]	—	3.04–3.17 (2H)	3.76 (6H)	3.04–3.17 (4H)	0.96–1.73 (4H)[e]; 1.55 (6H) *gem* dimethyl
B9	61.5–62	$C_{17}H_{18}O_4$	286	6.75 (2H)	2.76 (2H)	3.68 (6H)	3.10 (4H)	0.45 (4H) cyclopropyl
B10	87.5–88	$C_{17}H_{20}O_4$	288	—	1.98 (2H)	3.69 (6H)	3.03 (4H)	1.04–1.95 (4H)[e]; 0.20–0.54 (4H) cyclopropyl
B11	80.5–81.5	$C_{17}H_{18}O_4$	286	5.92 (2H)	3.32 (2H)	3.68 (6H)	3.13 (4H)	0.35–1.22 (4H) cyclopropyl
B12	100 –101	$C_{17}H_{20}O_4$	288	—	2.44 (2H)	3.70 (6H)	3.12 (4H)	0.51–1.56 (8H)[e] and cyclopropyl
B13	95 – 96	$C_{18}H_{18}O_4$	298	6.00–6.11 (4H)	3.10–3.24 (2H)	3.76 (6H)	3.10–3.24 (4H)	2.49–2.61 (2H) cyclobutenyl
B14	87.5–88.5	$C_{18}H_{22}O_4$	302	—	→	3.78 (6H)	3.09 (4H)	0.98–1.28 (2H) and 1.80–2.29 (10H)[e] cyclobutyl and bridgehead
B15	89 – 90	$C_{18}H_{18}O_4$	298	—	→	3.78 (6H)	3.19 (4H)	2.79–3.56 (8H) cyclobutyl and bridgehead
B16	138 –139	$C_{18}H_{18}O_4$	298	—	2.96 (2H)	3.73 (6H)	3.20 (4H)	2.09–2.23 (2H) and 1.52–1.68 (4H) cyclopropyl
B17	95 – 96	$C_{17}H_{18}O_4$	286	—	2.43 (2H)	3.67 (6H)	3.06 (4H)	1.28–1.93 (6H)[e]; cyclopropyl and bridgehead
B18	71 – 71.5	$C_{19}H_{18}O_4$	310	—	3.58 (2H)	3.63 (6H)	3.05 (4H)	6.74–7.14 (4H) aromatic; 2.22 (2H)[e]
B19	73.5–74.5	$C_{20}H_{18}O_4$	322	6.74 (2H)	4.48 (2H)	3.67 (6H)	3.18 (4H)	6.66–7.14 (4H) aromatic
B20	104.5–105.5	$C_{20}H_{20}O_4$	324	—	3.65 (2H)	3.75 (6H)	3.17 (4H)	6.86–7.39 (4H) aromatic; 1.23–1.73 (4H)[e]
B21	177 –178	$C_{24}H_{20}O_4$	372	—	4.70 (2H)	3.63 (6H)	3.23 (4H)	6.80–7.24 (8H) aromatic

24

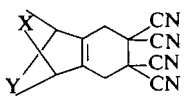
a R = —CH_2OH
b R = —$COOCH_3$

certain of these dienes is underway to try to correlate the spectroscopic data with geometric and reactivity parameters. Only two of these DMAD adducts have been described previously (**B2** (9) and **B4** (10)). The Diels–Alder reaction yields were all quantitative as indicated by p.m.r. spectroscopy, although isolation of the crystalline adducts was difficult in many cases and is not necessary if the benzopolycyclics, **C1–C21**, are the synthetic goal.

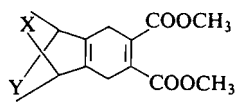
The spectral evidence supporting the expected adduct structures **B1–B21** is collected in Table 1. No 2:1 or other unexpected products were observed under the equimolar conditions used for these reactions.

Oxidation of these 21 DMAD adducts **B1–B21** in benzene at room temperature with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) afforded the benzopolycyclic dimethyl esters **C1–C21**, in quantitative yield. Isolation as crystals was again very difficult in many cases and several of these compounds failed to crystallize. These were hydrolyzed to the corresponding phthalic acids to obtain analytical samples.

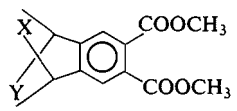
The spectroscopic data compiled in Table 2 leave no doubt as to the structures **C1–C21** as shown. One of these bridged benzene diesters, **C2**, is known (11).



A1–A21

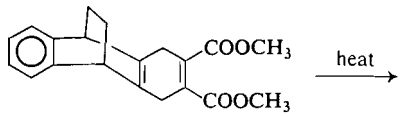


B1–B21

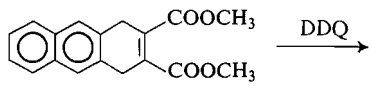


C1–C21

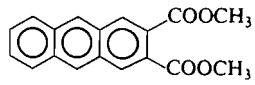
Adduct **B20** lost ethylene on heating at 230° in an oil bath to furnish **25** which was readily oxidized by DDQ to **26**, shown to be identical to the known dimethyl anthracene-2,3-dicarboxylate (12).



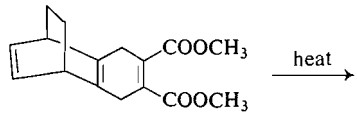
B20



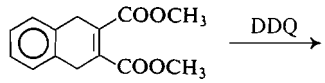
25



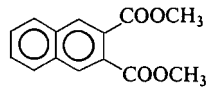
26



B3



27



28

Entirely similar chemistry was observed for **B3** with respect to dimethyl 1,4-dihydronaphthalene-2,3-dicarboxylate (**27**) and dimethyl naphthalene-2,3-dicarboxylate (**28**) (13).

In conclusion, these syntheses obviously provide an efficient route into aromatic ring-substituted benzopolycyclic hydrocarbon systems. Other dienophiles such as propiolic esters, mono- and dicyanoacetylene, phenylacetylene, quinones, etc. would obviously extend the utility of the method. One limitation is the unreactivity of certain of the dienes. For example, reaction of **21** with tolan was unsuccessful even at elevated temperatures. DMAD was chosen to

illustrate the generality of the synthetic sequence and because we have used this dienophile in our rate studies and thus needed to characterize the products.

Many of these adducts and the bridged phthalic esters contain proximal π- or other thermally reactive and/or photoreactive bonding systems and a study of their thermal chemistry and photochemistry is underway.

Taken collectively, the proton chemical shift data for the dienes **1–21** (4), the TCNE adducts **A1–A21**, the DMAD adducts **B1–B21** and the benzopolycyclic dimethylesters **C1–C21** together with the equivalent data for 2,3-dimethylenebicyclo[2.2.2]octa-5,7-diene (14), provide an extensive field for the critical assessment of anisotropic and geometric effects on chemical shifts in these related, rigid molecules. We are currently analyzing the proton and ^{13}C magnetic resonance data in these terms.

Experimental

All melting points are uncorrected. The i.r. spectra were determined on a Unicam SP1000 spectrophotometer as liquid films or KBr discs. The p.m.r. spectra were recorded on a Varian HA100 instrument in carbon tetrachloride or deuteriochloroform using tetramethylsilane as the internal standard. Mass spectra were taken at 70 eV using a Hitachi-Perkin Elmer RMU-6E instrument. The u.v. spectra were run on a Unicam SP800A spectrophotometer. Microanalyses were obtained from A. B. Gygli, Toronto.

9,10-Dimethylenepentacyclo[4.4.0.0^{2,4}.0^{3,8}.0^{5,7}]decane (16)

Anhydrous silver fluoroborate (0.5 g) was added to a stirred solution of dimethyl pentacyclo[4.2.2.0^{2,5}.0^{3,8}.0^{4,7}]-decane-(*trans*)-9,10-dicarboxylate (8.3 g) (6) in ethanol-free chloroform (50 ml) at room temperature and the stirring continued for 12 h. The dark reaction mixture was passed through a column of alumina (Woelm; activity grade 1; 3 × 15 cm) followed by a chloroform wash (50 ml). The total red eluate was evaporated and vacuum distilled to give a white solid b.p. 140°/0.9 mm, (5.9 g), which was recrystallized from methanol to give pure **22***b* (5.0 g), m.p. 75.5–76°; p.m.r. δ ($CDCl_3$) 1.23–1.91 (m, 6H), 2.83 (m, 2H), 3.24 (m, 2H), 3.73 (s, 6H) p.p.m.; i.r. (CCl_4) $\nu_{C=O}$ 1740 cm^{-1}; *m/e* M$^+$ 248, calcd. 248.

Anal. Calcd. for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50. Found: C, 67.77; H, 6.82.

This material was subjected to the general reduction–tosylation–elimination procedure (4) to secure diene **16**. All the intermediates showed consistent i.r. and p.m.r. spectra for the structures indicated.

9,10-*trans*-Bis(hydroxymethyl)pentacyclo[4.4.0.0^{2,4}.0^{3,8}.0^{5,7}]decane (**22***a*), m.p. 77.5–78° (methanol).

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39. Found: C, 74.79; H, 8.54.

Di-*p*-toluenesulfonate, m.p. 152–153° (methanol).

Anal. Calcd. for $C_{26}H_{28}O_6S_2$: C, 62.38; H, 5.64. Found: C, 62.38; H, 5.31.

9,10-Dimethylenepentacyclo[4.4.0.0^{2,4}.0^{3,8}.0^{5,7}]decane **16**, m.p. 77° (preheated block: this diene readily polymerized); p.m.r. δ (CCl_4) 1.50 (m, 4H), 1.90 (m, 2H), 2.94 (m, 2H), 4.74 (s, 2H), 5.28 (d, J = 0.9 Hz, 2H) p.p.m.; i.r. (CCl_4) 890, 1315, 1620, 2940, 3050 cm^{-1}; u.v. (cyclohexane) λ_{max} 246 (7490), 254 (7970), and 263 sh (4760) nm; *m/e* M$^+$ 156, calcd. 156.

Anal. Calcd. for $C_{12}H_{12}$: C, 92.26; H, 7.74. Found: C, 91.88; H, 8.01.

8,9-Dimethylenetetracyclo[4.3.0.0^{2,4}.0^{3,7}]nonane (17)

Dimethyl tetracyclo[4.3.0.0^{2,4}.0^{3,7}]nonane-(*endo,cis*)-8,9-dicarboxylate (38 g) (7) was held under reflux for 6 h in methanol (150 ml) containing sodium methoxide (0.3 g). The methanol was evaporated under vacuum and the remaining oil partitioned between solvent ether (200 ml) and 0.1 *N* hydrochloric acid (250 ml). After separation, the aqueous phase was extracted with ether (2 × 75 ml) and the combined ether phases were dried ($MgSO_4$) and evaporated to the colorless oily *trans*-dimethyl ester **23***b* (36.6 g) showing two methoxyl (—OCH_3) absorptions (δ = 4.00 and 4.02 p.p.m.) in the p.m.r. spectrum (CCl_4). This material was subjected directly to the general reduction–tosylation–elimination procedure (4) to secure diene **17**. All the intermediates showed consistent i.r. and p.m.r. spectra for the structures indicated.

8,9-*trans*-Bis(hydroxymethyl)tetracyclo[4.3.0.0^{2,4}.0^{3,7}]-nonane (**23***a*) failed to crystallize.

Di-*p*-toluenesulfonate, m.p. 143–144° (methanol–chloroform).

Anal. Calcd. for $C_{25}H_{28}O_6S_2$: C, 61.50; H, 5.78. Found: C, 61.81; H, 5.61.

8,9-Dimethylenetetracyclo[4.3.0.0^{2,4}.0^{3,7}]nonane (**17**), liquid (vacuum transferred at 120°/0.01 mm); p.m.r. δ (CCl_4) 1.05 (m, 2H), 1.29 (m, 1H), 1.53 (m, 2H), 1.77 (m, 1H), 2.48 (m, 2H), 4.75 (s, 2H), and 5.12 (s, 2H) p.p.m.; i.r. (film) 801, 816, 882, 1078, 1198, 1361, 1657, 2858, 2965 and 3062 cm^{-1}; u.v. (cyclohexane) λ_{max} 204 (2590), 234 (6590), 250 (7315), 265 sh (4700) nm; *m/e* M$^+$ 144, calcd. 144.

Anal. Calcd. for $C_{11}H_{12}$: C, 91.61; H, 8.39. Found: C, 91.58; H, 8.26.

2,3-Dimethylene-1,4-methano-1,2,3,4-tetrahydronaphthalene (18)

Dimethyl 1,4-methano-1,2,3,4-tetrahydronaphthalene-(*trans*)-2,3-dicarboxylate (**24***b*) (8) was subjected to the general reduction–tosylation–elimination procedure (4) to secure diene **18**. All the intermediates showed consistent i.r. and p.m.r. spectra for the structures indicated.

2,3-*trans*-Bis(hydroxymethyl)-1,4-methano-1,2,3,4-tetrahydronaphthalene (**24***a*), m.p. 102–102.5° (benzene).

Anal. Calcd. for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90. Found: C, 76.66; H, 7.78.

Di-*p*-toluenesulfonate, m.p. 159–160° (methanol–chloroform).

Anal. Calcd. for $C_{27}H_{28}O_6S_2$: C, 63.30; H, 5.52. Found: C, 63.34; H, 5.58.

2,3-Dimethylene-1,4-methano-1,2,3,4-tetrahydronaphthalene (**18**), m.p. 83° (sublimed 60°/0.01 mm); p.m.r. δ (CCl_4) 2.00 (q, 2H), 3.75 (m, 2H), 4.98 (s, 2H), 5.10 (s, 2H), and 7.02 (m, 4H) p.p.m.; i.r. (KBr disc) 736,

781, 894, 1461, 1630, 2981, 3070 cm^{-1}; u.v. (cyclohexane) λ_{max} 213 (6845), 232 sh (5780), 239 sh (4895), 246 sh (4365), 273 (1276), and 279 (1235) nm; *m/e* M^+ 168, calcd. 168.

Anal. Calcd. for $C_{13}H_{12}$: C, 92.81; H, 7.19. Found: C, 92.78; H, 7.04.

TCNE Adducts A1–A21

The hydrocarbons **1–21** (0.05 g) were separately mixed with TCNE (1.1 equiv. wt.) dissolved in dry tetrahydrofuran (5 ml) and stirred at room temperature for 1 h. The solvent was evaporated under vacuum, the residue rubbed with a small quantity of dry ether, and the crystalline adducts collected by filtration. These products were either recrystallized from ether or sublimed under vacuum (0.01 mm) to afford the pure adducts.[2] Melting points from hydrocarbon: **1**, 193–194°; **2**, 187–188°; **3**, 163–164°; **4**, 207–208°; **5**, 265°; **6**, 236.5–237°; **7**, 196–197°; **8**, 230–231°; **9**, 153–154°; **10**, 178°; **11**, 217.5–218°; **12**, 205–206°; **13**, 198–199°; **14**, 215.5–216.5°; **15**, 216–217°; **16**, 138–139°; **17**, 173.5–174.5°; **18**, 174.5–175°; **19**, 232–232.5°; **20**, 248–249°; **21**, > 300°.

DMAD Adducts B1–B21

The freshly recrystallized or vacuum transferred dienes **1–21** (1 mmol) were individually mixed with exactly 1 equiv. of freshly vacuum-transferred dimethyl acetylenedicarboxylate in CCl_4 (15 ml) and this mixture was held under reflux until the diene *exo*-methylene proton signals were seen to disappear as indicated by p.m.r. spectroscopy. The times varied from 5 min to 2 days. The reaction mixtures were evaporated under vacuum to quantitatively afford the crude adducts **B1–B21**. Crystallization was wasteful and difficult to effect for some of these adducts; petroleum ether (30–60°) or methanol were the preferred solvents for these recrystallizations. The melting points and some spectroscopic data of these adducts appear in Table 1.

Benzopolycyclic Dimethyl Esters C1–C21

The crude adducts **B1–B21** (1 mmol) were separately dissolved in benzene (5 ml) and DDQ (1.2 mmol) added. The resulting mixtures were stirred magnetically for 24 h, then filtered and eluted with benzene through short beds of neutral alumina (Woelm; activity grade 1; 8 × 1 cm). The colorless eluates were evaporated under vacuum to afford the benzopolycyclic dimethyl esters **C1–C21** (melting points and pertinent spectral data are collected in Table 2). Crystallization was again difficult for many of these adducts, though petroleum ether (30–60°) and methanol were the most useful solvents. Those diesters which failed to crystallize and which were previously unknown compounds (*viz.* **C1**, **C8** and **C10**) were hydrolyzed overnight in aqueous methanolic KOH and the corresponding phthalic acids isolated in the usual way.[2]

C1 diacid, m.p. 178°, preheated block (aqueous methanol); **C8** diacid, m.p. 177–178°, preheated block (aqueous methanol); **C10** diacid, m.p. 118°, preheated block (aqueous methanol).

Dimethyl Anthracene-2,3-dicarboxylate (26)

The adduct **B20** (30 mg) was heated in an oil bath at 230° until gas evolution ceased (15 min) and the residue was recrystallized from methanol to give dimethyl 1,4-dihydroanthracene-2,3-dicarboxylate (**25**), m.p. 120–121°; p.m.r. δ (CCl_4) 3.93 (s, 10H), 7.30–7.77 (m, 6H); *m/e* M^+ 296, calcd. 296.

A Primary Hydrogen–Deuterium Isotope Effect Study on the Carbonyl Elimination Reaction of 9-Fluorenyl Nitrate with Various Bases[1]

PETER JAMES SMITH AND LORRAINE MARION NOBLE

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0

Received July 22, 1974

PETER JAMES SMITH and LORRAINE MARION NOBLE. Can. J. Chem. **53**, 263 (1975).

The carbonyl elimination reaction of 9-fluorenyl nitrate with various nitrogen bases in anhydrous ethanol at 0 °C was examined. In all cases fluorenone was formed in 100% yield indicating that there was not any substitution. A reasonable Brønsted plot was obtained for reaction promoted by structurally similar bases with $\beta = 0.84$ which suggests a product-like transition state. As well, deviations from the Brønsted plot are discussed. Primary hydrogen–deuterium isotope effects were measured for reaction promoted by 11 different amine bases. A reasonable correlation was obtained for structurally similar bases when a plot of k^H/k^D *vs.* pK_a was made. The conclusion is reached that when k^H/k^D reaches a maximum, ~9.2 at 0 °C, it remains unchanged and hence is a poor measure of transition state geometry. As well, very poor correlations are found when the abstracting base is tertiary which leads to the conclusion that a comparison of k^H/k^D values is not warranted for structurally different bases.

PETER JAMES SMITH et LORRAINE MARION NOBLE. Can. J. Chem. **53**, 263 (1975).

On examine la réaction d'élimination du carbonyle du nitrate de fluorényl-9 à 0 °C dans l'étanol anhydre en présence de diverses bases azotées. Dans tous les cas, la fluorénone se forme avec un rendement de 100% montrant qu'il n'y a pas de substitution. Une courbe de Brønsted raisonnable a été obtenue pour la réaction catalysée par des bases de structure similaire et la valeur $\beta = 0.84$ suggère un état de transition qui ressemble aux produits. On discute aussi des déviations de la droite de Brønsted. On a mesuré les effets isotopiques primaires de l'hydrogène et du deutérium pour la réaction catalysée par 11 bases azotées différentes. On a obtenu une corrélation raisonnable pour des bases similaires lorsque une courbe de k^H/k^D en fonction du pK_a a été faite. On arrive à la conclusion que lorsque k^H/k^D atteint un maximum, ~9.2 à 0 °C, cette mesure demeure inchangée et devient une mesure imprécise pour la géométrie de l'état de transition. De plus on trouve de mauvaises corrélations quand la base enlevant le proton est tertiaire; ceci conduit à conclure qu'une comparaison des valeurs k^H/k^D ne peut se faire pour des bases qui ont des structures différentes. [Traduit par le journal]

Introduction

The carbonyl elimination reaction ($E_{CO}2$) of 9-fluorenyl nitrate with acetate ion in anhydrous ethanol has been investigated (1). The absence of deuterium exchange between the nitrate ester and ethanol-*O-d* as well as primary nitrogen and hydrogen–deuterium isotope effects of 1.0091 ± 0.0007 and 4.3 ± 0.2, respectively, led the authors to conclude that the reaction was a one-step concerted process.

The degree of carbon–hydrogen bond rupture at the transition state can be determined by measuring the primary hydrogen–deuterium isotope effect. It is now generally assumed that this effect is at a maximum when the proton is one-half transferred to base at the transition state, C—H—B, and that smaller values for the isotope effect are obtained when the proton is more than or less than half transferred (2). Consequently, a systematic increase in the strength of the abstracting base should lead to a more reactant-like transition state (3) and a decrease

Concerted mechanism:

(increase) in the magnitude of k^H/k^D if the proton is less (more) than half transferred.

It is reasonable to expect that the transition state for the reaction of 9-fluorenyl nitrate with base is reactant-like since a nitrogen effect, $k^{14}/k^{15} = 1.0091$, was obtained (1) which indicates a small degree of O—N bond rupture at the transition state for the reaction with acetate ion. Consequently, a small degree of carbon–hydrogen bond rupture is predicted since it has been shown that the degree of carbon–hydrogen and carbon–nitrogen bond rupture is complementary for the E2 reaction of quaternary ammonium ions (4). Accordingly, in the present study, β-deuterium isotope effects have been measured for the $E_{CO}2$ reaction of 9-fluorenyl nitrate with 11 different nitrogen bases in ethanol at 0 °C.

Results

Hydrogen–Deuterium Isotope Effects

The rate constants for the reaction of 9-fluorenyl nitrate and 9-fluorenyl-9-*d* nitrate with the various bases in ethanol are shown in Table 1. The primary hydrogen–deuterium effects calculated from the rate data are also given in this table along with the pK_a of the conjugate acid of the abstracting base in water.

Discussion

Rate Measurements

The second-order rate constants for the reaction of 9-fluorenyl nitrate with various amine bases (**1**–**11**) in ethanol at 0 °C, Table 1, are plotted against the pK_a of the conjugate acid of the abstracting base, Fig. 1. It is seen that a straight line is obtained for the structurally similar bases, the primary amines, and the two heterocycles, amines **1**–**6**, with a slope $\beta = 0.84$. The rate constants covered a range of about 1.8 log units, while pK_a's covered a range of 2 units. One can conclude that the large value for β suggests that the transition state for the proton transfer is product-like; *i.e.*, the proton is more than one-half transferred from carbon to the amine. It is noteworthy, however, that Bordwell and Boyle (10) have shown for the deprotonation of nitroalkanes and ketones that β changed very

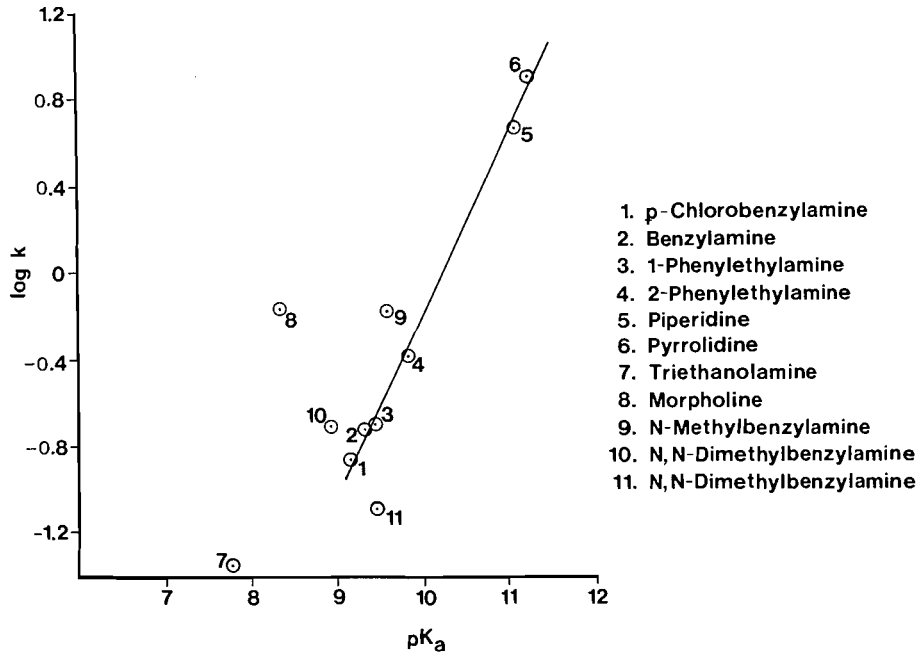

FIG. 1. Plot of log k *vs.* pK_a for the $E_{co}2$ reaction of 9-fluorenyl nitrate with various amine bases in ethanol at 0 °C.

little over a pK_a range of almost 20 units. He concluded that either β is a very poor guide to the extent of proton transfer in the transition state or that transition-state structures for the reactions studied vary to a small extent over wide ΔpK_a ranges.

It is reasonable that points 7 and 8, reaction promoted by triethanolamine and morpholine, fall off the Brønsted plot since such correlations between log k and pK_a are observed only for structurally similar bases. Triethanolamine and morpholine will be solvated to a much greater extent than amines **1–6** due to the oxygen atoms and hence will be less available as bases for steric reasons. As well, points 9–11 also fall off the line, and here reaction is promoted by *N*-methylbenzylamine, *N*,*N*-dimethylbenzylamine, and *N*,*N*-diethylbenzylamine where there is presumably a steric factor associated with the attack of the secondary and two tertiary amines at the 9-hydrogen; the rate constants for reaction promoted by benzylamine and *N*,*N*-diethylbenzylamine are 0.192 and 0.0834 l mol^{-1} min^{-1}, respectively.

Hydrogen–Deuterium Isotope Effects

The rate constant for reaction of 9-fluorenyl nitrate and 9-fluorenyl-9-*d* nitrate with the various amine bases was determined under pseudo first-order conditions with excess base. The second-order rate constants, as shown in Table 1, were obtained from the pseudo first-order by dividing by the concentration of base. In all cases the same base solution was used to measure the rate constants for reaction of the undeuterated and deuterated substrates. As well, for every base used, the optical density at infinity was the same for reaction of the undeuterated and deuterated compounds indicating that the reaction was solely elimination.

The primary hydrogen–deuterium isotope effects obtained for reaction with amines **1–8**; the primary amines as well as piperidine, pyrrolidine, morpholine, and triethanolamine, appear to vary with pK_a. A plot of k^H/k^D versus pK_a for all of the bases studied is shown in Fig. 2. From the plot of the data for amines **1–8**, it can be seen that the smaller the pK_a (the weaker the abstracting base) the smaller is the primary hydrogen–deuterium isotope effect; *i.e.* for triethanolamine pK_a and k^H/k^D are 7.76 and 7.61 while for pyrrolidine they are 11.27 and 9.26, respectively.

Since Thornton[2] has predicted (3) and it has been shown experimentally (4) that for E2 reac-

[2]The Thornton prediction is a particular application of the well-established general principle that the proton in the transition state is nearer the weaker base (11).

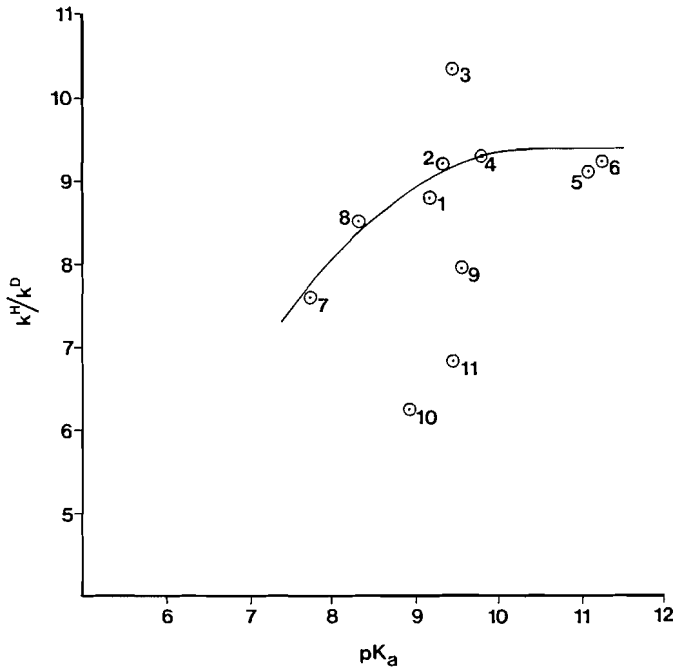

FIG. 2. Plot of k^H/k^D *vs.* pK_a for the $E_{CO}2$ reaction of 9-fluorenyl nitrate with various amine bases in ethanol at 0 °C.

tions the transition state has greater carbon–hydrogen bond rupture when reaction is promoted by weaker bases, then it can be concluded that for the $E_{CO}2$ reaction of 9-fluorenyl nitrate with the amine bases a *decrease* in the magnitude of k^H/k^D indicates *increased* C—H bond weakening with the proton more than one-half transferred to base at the transition state (on the right hand side of Westheimer's curve). Further evidence that the transition state is product-like is given by the large Brønsted β of 0.84.

Furthermore, it appears that the value for the primary hydrogen–deuterium isotope effect levels off at a value of approximately 9.2 for all bases, excluding 1-phenylethylamine, in the series **1–8** with pK_a greater than 9. In other words, it appears that there is a broad maximum in Westheimer's curve with $k^H/k^D \simeq 9.2$ (this value corresponds to the theoretical maximum of $\simeq$ 7.4 at 30° calculated for the loss of a stretching vibration). Consequently, for bases of the series with $pK_a > 9$ one cannot determine the change in transition state geometry since the value of k^H/k^D remains essentially constant. It may be concluded that k^H/k^D is either insensitive to the structure of the transition state or that the activated complex does not change for reaction with bases with pK_a greater than 9.

It appears that the data for triethanolamine and morpholine lie on the plot shown in Fig. 2, whereas the rate constants obtained for reaction with these two bases did not satisfy the Brønsted relationship shown in Fig. 1. It is not unexpected that triethanolamine and morpholine would effect the rate of reaction differently than amines **1–6** due to the presence of the oxygen atoms which would lead to quite different solvation effects. However, when they act as abstracting bases at the transition state, the degree of C—H bond rupture as measured by k^H/k^D should be dependent only on their pK_a and hence the observed correlation.

It should be noted that whereas the rate constant for 1-phenylethylamine falls on the Brønsted plot the value of $k^H/k^D = 10.36$, determined for reaction promoted by this primary amine, is significantly higher than for all other amines. Indeed, the value of 10.36 is greater than expected for the loss of a stretching vibration and may suggest that tunneling is operative in this particular instance. In any event, it appears that it is not reasonable to interpret the value of k^H/k^D obtained for reaction promoted by 1-phenylethylamine and, for example, 2-phenylethylamine in terms of the degree of C—H bond weakening at the transition state.

It is of particular interest that the values for the hydrogen–deuterium isotope effect determined for reaction of 9-fluorenyl nitrate with *N*-methylbenzylamine, *N*,*N*-dimethylbenzylamine, and *N*,*N*-diethylbenzylamine, amines **9–11**, do not fall on the plot of k^H/k^D *vs.* pK_a, Fig. 2. In all three cases, the magnitude of k^H/k^D is less than expected for an amine base with their respective pK_a values. This is not unreasonable as it is expected that the ability of the two tertiary amines and the secondary to protonate and to abstract the 9-hydrogen to be quite different whereas the abilities of a primary amine might be similar. Consequently, it is proposed that amines **9–11**, due to steric effects, act as weaker abstracting bases for the $E_{CO}2$ reaction than indicated by their pK_a values. This would lead to the situation where there is a greater extent of C—H bond weakening than expected from the pK_a value with a corresponding decrease in the magnitude of the primary isotope effect as observed.

In conclusion, it must be pointed out that for the reaction investigated great care must be taken in interpreting the magnitude of k^H/k^D in terms of the degree of carbon–hydrogen bond weakening at the transition state because of the great scatter of points on the plot of k^H/k^D *vs.* pK_a. It may be reasonable to compare values obtained for structurally similar bases but even for this situation it appears that, for several bases with different pK_a values, experimentally identical values of k^H/k^D are obtained.

Experimental

Materials

9-Fluorenyl Nitrate

This compound was prepared by the action of silver nitrate on 9-bromofluorene in acetonitrile (12) and was recrystallized from petroleum ether (b.p. 30–60°), m.p. 88–89° (lit. (13) m.p. 88–89°).

9-Fluorenyl-9-d Nitrate

The deuterated compound was prepared by the following reaction sequence: (*a*) reduction of 9-fluorenone to 9-fluorenol-9-*d* with lithium aluminum deuteride; (*b*) conversion of the alcohol into 9-bromofluorene-9-*d* by means of acetyl bromide; and (*c*) reaction of the bromo compound with silver nitrate. The overall yield of 9-fluorenyl-9-*d* nitrate was 70%. The product, recrystallized from petroleum ether, had a melting point of 88.0–89.0° and was at least 99% deuterated in the 9-position, as shown by n.m.r. analysis.

9-Fluorenol-9-d

9-Fluorenone (24.0 g, 0.133 mol) was treated for 8 h with lithium aluminum deuteride (3.0 g, 0.07 mol) in 300 ml of diethyl ether which had been dried by distillation from lithium aluminum hydride. The complex was decomposed by addition of water, the precipitated salts were removed by filtration, and the product was isolated from the ether solution. Recrystallization from benzene gave 22.7 g of 9-fluorenol-9-*d* (93% yield), m.p. 153.5–154.0° (lit. (14) m.p. 156°).

9-Bromofluorene-9-d

Acetyl bromide (16.6 g, 0.135 mol) was added all at once to 9-fluorenol-9-*d* (12.5 g, 0.068 mol) and the flask stoppered. A vigorous reaction set in, and in a short time the mixture solidified. The reaction was completed by warming the mixture on a steam bath, and acetic acid and excess reagents were removed under reduced pressure. The residue was recrystallized from petroleum ether (b.p. 30–60°), giving 12.9 g (77% yield) of 9-bromofluorene-9-*d*, m.p. 98.5–100.0 (lit. (15) m.p. 102–103°).

Amines

All the amines were obtained from commercial sources. Each amine, immediately before use, was fractionally distilled under reduced pressure.

Kinetic Measurements

The reaction rate was followed spectrophotometrically by measuring the optical density of the reaction solutions at 380 nm, the λ_{max} of the elimination product fluorenone. The reaction solution was analyzed for nitrite and nitrate ions by the method of differential reduction to ammonia (16) and no nitrate ion was found. Nitrite ion, from the $E_{CO}2$ reaction, was found in theoretical quantities. Consequently, since a large excess of base was used in the kinetic study, the pseudo first-order rate constant obtained is for the carbonyl elimination reaction as S_N2 displacement and solvolysis are not observed.

A solution of 9-fluorenyl nitrate (0.003–0.009 *M*) and the appropriate amine base (0.04–0.57) in anhydrous ethanol, prepared by mixing temperature-equilibrated solutions of each reactant, was maintained in a constant-temperature bath at ±0.02°. At suitable time intervals 5-ml samples were removed and added to approximately 15 ml of quenching solution. The resulting solution was diluted to 25 ml with ethanol and the optical density of this solution was measured on a Perkin-Elmer Hitachi spectrophotometer. The quenching solution was prepared by mixing 5 ml of an acid solution of 2 ml of concentrated H_2SO_4 in 100 ml of water with 10 ml of 95% ethanol.

The pseudo first-order rate constants for the disappearance of fluorenyl nitrate was determined by plotting log $(OD_\infty - OD_t)$ against time for the equation $kt = 2.303 \log (OD_\infty - OD_0/(OD_\infty - OD_t)$, where OD_0, OD_∞ and OD_t are the optical densities at time zero, infinity, and t, respectively. The best fit of the data was obtained by the method of least squares using a computer program. These constants were converted into second-order constants by dividing by the concentration of the base.

Photo-oxidation of Iodomethane in Solid Argon[1]

J. F. OGILVIE,[2] VIRGINIA R. SALARES, AND MICHAEL J. NEWLANDS

Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland A1C 5S7

Received June 14, 1973[3]

J. F. OGILVIE, VIRGINIA R. SALARES, and MICHAEL J. NEWLANDS. Can. J. Chem. **53**, 269 (1975).

Photolysis of iodomethane in the presence of oxygen in solid argon near 10 K has yielded several products detected by their vibrational absorption spectra. Isotopic labeling of reactants has proved methanal, water, hydrogen iodide, carbon monoxide, carbon dioxide, and hydroperoxyl radicals to be significant products, and a further set of major absorptions is attributed to hydrogen hypoiodite HOI, hydrogen-bonded to methanal. Other minor vibrational features are discussed, and a possible reaction scheme is briefly outlined.

J. F. OGILVIE, VIRGINIA R. SALARES et MICHAEL J. NEWLANDS. Can. J. Chem. **53**, 269 (1975).

La photolyse de l'iodométhane, en présence d'oxygène dans l'argon solide près de 10 K, conduit à plusieurs produits détectés par leur spectre d'absorption vibrationnelle. Le marquage isotopique des réactifs a prouvé que le méthanal, l'eau, l'iodure d'hydrogène, le monoxyde de carbone, le dioxyde de carbone et des radicaux hypropéroxyles sont des produits importants; on a attribué un autre groupe majeur d'absorptions à de l'hypoiodite d'hydrogène (HOI) lié par pont hydrogène au méthanal. On discute d'autres vibrations mineures et on décrit un schéma réactionnel possible. [Traduit par le journal]

Introduction

In his investigation of photolysis of iodomethane in solid oxygen Roebber (1) postulated that several trapped radicals may have been produced, but lack of isotopically substituted reactants and problems of spectral range and resolution hampered positive identification. Also only a few trapped radicals were at that time characterized by vibrational spectra; even for many pertinent stable substances, reliable absorption spectra were available for neither gas phase nor argon matrix. Now that these conditions no longer prevail, we are able, in performing similar experiments, to identify several products unambiguously, and we have also obtained evidence for a previously undetected molecule which seems to be a major product.

Experimental

The apparatus consisted essentially of a refrigerator (Air Products Displex CS-202) mounted in an infrared spectrophotometer (Perkin–Elmer 225) and connected to both a metal high-vacuum pumping system and a glass manifold for sample preparation. In the conduct of each experiment, after deposition of gases during 5–10 h, frozen samples were irradiated for 10–30 h (low pressure Hg lamp) and 1–2 h (HPK 125 lamp); the extent of photodecomposition of reactants and formation of products was measured by analysis of vibrational absorption spectra recorded before and after each irradiation operation. Flow of gases to the refrigerator was controlled by needle valves in the range 0.1–0.7 μmol s^{-1}, monitored by Penning and Pirani pressure gauges. The gases were frozen on a CsI window in the refrigerator, held at 8–10 K (measured by a Chromel *vs.* 0.07% Fe/Au thermocouple). The irradiation sources were mercury arcs: Philips HPK 125, 125 W operating at a pressure $\sim 8 \times 10^5$ N m^{-2}, or a specially constructed lamp, 8 W operating at a pressure of 1.3×10^3 N m^{-2} so as to emit principally at 39 412 and 54 069 cm^{-1}. A filter transmitting 8 000–14 000 and 24 000–47 000 cm^{-1} was occasionally used with the HPK 125 lamp. Spectral slit widths of the spectrometer varied from 0.3–1.5 cm^{-1} in the range 200–4000 cm^{-1}; wavenumber accuracy and reproducibility were 0.5 cm^{-1} for sharp lines.

Iodomethane ($H_3{}^{12}CI$ from Fisher, $D_3{}^{12}CI$ from Merck, Sharp and Dohme, and $H_3{}^{13}CI$ (86.3% enrichment) from Prochem) was distilled and degassed before use. $^{16}O_2$ was generated from $KMnO_4$; $^{18}O_2$ (94 atomic% enrichment) was obtained from Yeda. Mixtures of $^{16}O_2$, $^{18}O_2$, and $^{16}O^{18}O$ (~40 atomic% ^{18}O randomly distributed, as deduced from ozone byproduct composition) were prepared by electric discharge of $^{16}O_2$ and $^{18}O_2$. Argon (Matheson, 99.998% nominal purity) was used directly from the cylinder. $D_2{}^{12}CO$ was generated from polyoxymethylene-d_2 (Merck, Sharp and Dohme). Mixtures of iodomethane vapor (or $D_2{}^{12}CO$) and argon, or oxygen and argon, were prepared and stored several hours before use.

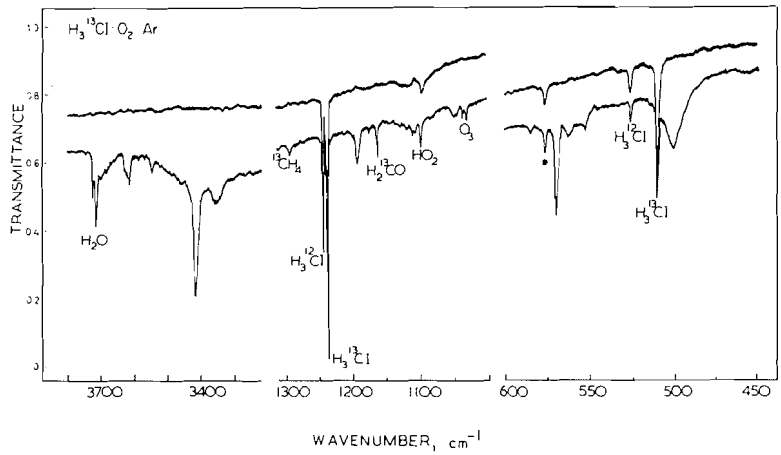

FIG. 1. Selected portions of spectra of $H_3{}^{13}Cl{:}{}^{16}O_2{:}Ar = 1{:}25{:}200$. Upper spectrum, before photolysis; lower trace, sample had been irradiated for 27 h with the low-pressure Hg lamp. * represents background feature.

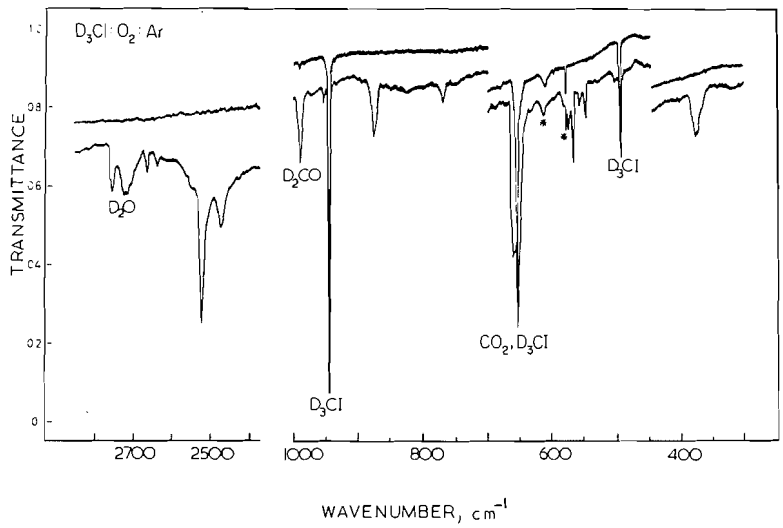

FIG. 2. Selected portions of the spectrum of $D_3{}^{12}Cl{:}{}^{16}O_2{:}Ar = 1{:}20{:}100$. Upper spectrum, before photolysis; lower spectrum, sample had been irradiated for 30 h with the low-pressure Hg lamp and 2 h with the HPK 125 lamp.

Results

Representative spectra recorded before and after irradiation of iodomethane–oxygen–argon mixtures are shown in Fig. 1 and 2. That a reaction had occurred after irradiation was clearly evident from the reduction in intensity of iodomethane lines and appearance of many new absorptions. (In contrast, when only iodomethane–argon mixtures were irradiated, no spectral changes were detected.) Characteristic growth patterns with the two radiation sources were observed for the new absorptions. By comparison of relative intensities during various photolytic operations within particular and between different experiments, lines exhibiting similar intensity patterns were grouped and are now presented in text and tables. Isotopic labeling of reactants permitted identification of produced substances; mixtures of both ^{12}C- and ^{13}C-containing iodomethane or all of $^{16}O_2$, $^{18}O_2$, and $^{16}O^{18}O$ were particularly useful in indicating the number of either carbon or oxygen atoms in carriers of major absorption features. By this method, it was ascertained

that no carrier of other than weak absorptions contained two or more carbon or oxygen atoms. Varying mole fractions of iodomethane and oxygen by dilution with argon was also helpful, a technique which Roebber (1) did not exploit.

Water, characterized by absorptions listed in Table 1, had both sharp lines at wavenumbers attributed to isolated molecules (2–4), and broad lines attributed to water hydrogen-bonded to other polar molecules within the same cavity bounded by argon and oxygen molecules. During an annealing operation, in which the sample temperature was allowed to rise to 20–30 K before recooling, sharp lines at 3712.7 and 3723.5 cm^{-1} decreased in intensity, lines at 3678 and 3614 cm^{-1} increased, and that at 3700 cm^{-1} was little affected.

Methanal is also readily identified by its characteristic fundamentals, for which wavenumbers are listed in Table 2 and compared with published values (5, 6). Intensity measurements indicated dissimilar rates of iodomethane decomposition and methanal formation during irradiation. Simultaneous destruction of methanal by radiation from the HPK 125 lamp was confirmed in separate experiments with $D_2CO:O_2:Ar$ samples.

Carbon monoxide and dioxide were both easily detected; wavenumbers are listed in Table 3. Atmospheric carbon dioxide hampered quantitative absorbance measurements in the 2350 and 667 cm^{-1} regions, but there is no doubt that rates of carbon dioxide formation and of iodomethane decomposition were dissimilar. In fact, use of the HPK 125 lamp after the low-pressure lamp resulted in a relatively rapid increase of CO_2. This behavior is consistent with its production via a secondary process.

Carbon monoxide lines are generally as previously reported (7–10), with slight variation attributed to matrix environment effects. An

intense line at 2149 cm^{-1} has been previously assigned to $^{12}C^{16}O$ adjacent to $H_2{}^{16}O$ (10), although a shoulder at 2152 cm^{-1} has not previously been cited.

Underneath the fairly sharp lines assigned to $^{12}C^{16}O$ was a broad line about 2138 cm^{-1} with an apparent shoulder at 2125 cm^{-1}. As shown in Fig. 3, ^{18}O- or ^{13}C- labeled reactants produced a shift of the CO lines leaving the broad line distinct. On the other hand, when $D_3{}^{12}CI$ was used, this broad line disappeared, but another appeared about 1525 cm^{-1}, also unaffected by ^{18}O-labeled reactant. These observations lead to assignment of the absorbing species as hydrogen iodide (11). The breadth of the lines and shift from the gas-phase band center both indicate extensive hydrogen bonding.

Weak absorptions at wavenumbers noted in Table 4 indicate by their behavior on isotopic labeling that the carrier is the hydroperoxyl radical, consistent with similar wavenumbers measured in different experiments on this apparatus (12). Although lines were also found near the wavenumbers appropriate to OH and OD valence-stretching fundamentals of these radicals, that the peak intensities were anomalously large and that these lines were present when the lines listed in Table 4 were, in some experiments, absent strongly indicate that they belong to a different molecular carrier (*vide infra*).

Some weak lines listed in Table 5 appear to be due to the s-transoid rotamer of methanoic acid (HCOOH and DCOOD), by comparison with results obtained for a carbon monoxide matrix (13) and the vapor phase (14).

A weak line at 1304 cm^{-1} in $H_3{}^{12}CI$ experiments which was insensitive to ^{18}O presence but which shifted to 1296 cm^{-1} when $H_3{}^{13}CI$ was used is attributed to methane (15). The lines were relatively most intense when the mole fraction of oxygen in the argon matrix was smallest. Other fundamentals of CH_4 or CD_4 would have been masked by absorptions of H_3CI, D_3CI, or D_2CO present in greater abundance.

Weak lines at 1032 and 1038 cm^{-1}, unaffected by ^{13}C- or D-labeled reactants were observed after irradiation with the low-pressure Hg lamp when oxygen mole fractions were relatively large, and even when iodomethane was absent. Assignment to ozone is consistent with known argon matrix wavenumbers (16).

The remaining lines detected after irradiation are not easily assigned to specific known molecules. One group of these, listed in Table 6, was fairly intense and had similar intensity behavior during various operations and under varied experimental conditions. Selected regions of spectra illustrated in Figs. 1 and 2 show these lines obtained from two sets of isotopically labeled reactants.

Other lines, listed in Table 7, are difficult to assign to particular molecules, but the wavenumber values and isotope shift do provide some clues to the nature of the chromophores.

Discussion

Tentative Identification of Hydrogen Hypoiodite

The lines in Table 6 may be analyzed according to the wavenumber positions and isotope effects as follows. The lines near 3400 and 2500 cm^{-1} are obviously O—H and O—D stretching modes. The lines between 540 and 575 cm^{-1} are suitable for O—I valence-stretching modes; these values are similar both to the mean, 504 cm^{-1}, of wavenumbers of symmetric and antisymmetric stretching modes of IO_2-containing molecules (17), and to the single fundamental of the IO free radical, 673 and 504 cm^{-1}, in its two characterized electronic states (18). The lines near 1190 and 870 cm^{-1} are appropriate to a deformation mode in which most of the amplitude (and kinetic energy) of vibration belongs to the H and D atoms. All lines are insensitive to ^{13}C-labeling, indicative of absence of carbon in the carrier. When ^{16}O- and ^{18}O-reactants, including $^{16}O_2$, $^{18}O_2$, and $^{16}O^{18}O$, were used, no further lines were produced; thus the carrier contains a single oxygen atom. The best estimate of the carrier consistent with these observations is hydrogen hypoiodite HOI. Two further broad lines, near 502 cm^{-1} in H_3CI and 377 cm^{-1} in D_3CI experiments, seem to have similar intensity behavior to the

553.5		553.8	548	522.3

lines in Table 6, but show no ^{18}O shift, perhaps because of their breadth. The large deuterium isotope shift is appropriate to a H- or D-stretching or, more likely in this wavenumber region, deformation mode. The breadth of these two lines suggests strongly hydrogen-bonded interactions. Because of the line breadth and insensitivity to ^{18}O-labeling, these lines will be assumed not to belong to the same carrier, in the same environment, as the lines in Table 6.

On the basis of assignment of these twelve lines to four isotopic varieties of hydrogen hypoiodite with a common vibrational force field, a complete normal coordinate analysis has been conducted. The results (19) include a fit of these wavenumbers to 0.2% accuracy and a potential energy distribution entirely consistent with the above deductions. Comparison of the force field parameters obtained thus for HOI with those for the other hydrogen hypohalites HOF, HOCl, and HOBr, all with ~0.2% fitting accuracy, shows gradual periodic trends expected for such a family of simple molecules. These results are taken as strong support for the identification of the new carrier as stated.

Other Unidentified Products

Sharp but weak lines between 760 and 840 cm^{-1} (*cf.* Table 7) appeared during irradiation with the low-pressure Hg lamp but disappeared rapidly when the HPK 125 lamp was used. Isotopic shifts are appropriate to either O—O or I=O vibrations. We expect the O—O bond to be much more susceptible to rupture by near ultraviolet radiation, copiously emitted by the HPK 125 lamp, than the I=O bond. $H_3{}^{12}COOH$ and $D_3{}^{12}COOD$ absorb at 820 and 794 cm^{-1} respectively (20); the measured deuterium shifts are much smaller. Other peroxides expected to absorb in this region are the radical H_3COO and its iodide H_3COOI.

Lines near 3350 or 2475 cm^{-1} were relatively broad, presumably indicative of OH or OD groups involved in hydrogen bonding. Two weak lines at 1754 and 1054 cm^{-1} (and their isotopic counterparts) gave measurable absorbances in experiments only with larger oxygen mole fractions (~0.25) but they do not necessarily belong to the same carrier. The former line exhibited shifts appropriate to a carbonyl stretching mode, whereas the broader line at 1050 cm^{-1} seemed to be unaffected by ^{13}C-labeling.

Groups of lines between 500 and 600 cm^{-1} are much more sensitive to ^{18}O-presence than to ^{13}C-labeling, indicative of O—I vibrations for instance, but not C—I. Their carriers may be further iodine oxides or oxyacids, but absorbance effects on annealing do indicate that a few different species are involved.

Mechanism of Photolytic and Oxidation Processes

A full treatment of the reactions must explain the production of the following species definitely detected: H_2O, H_2CO, CO, CO_2, HI, HO_2, O_3; and the probable detection of HOI, HCOOH, CH_4, some peroxide; but the absence of CH_3, OI, HCO, OH, H_2O_2, H_2O_3, H_2O_4, HIO_2, HIO_3, HIO_4. The following set of reactions briefly summarizes a reasonable, but not unique, explanation of the product distribution under the conditions of these experiments:

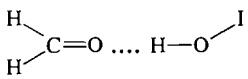
$$[9]\quad H_3CI \xrightarrow{h\nu} H_3C + I \rightarrow H_3CI \text{ (recombination)}$$

Separate experiments with one of H_3CI, O_2, or D_2CO in argon justify inclusion of reactions 2, 7, and 9, and experiments on D_2CO and O_2 in Ar for [3]. This reaction scheme may be compared with those proposed for the gas phase photo-oxidation of iodomethane (21–23). Whether ozone was produced only directly from oxygen in experiments with iodomethane could not be ascertained.

Evidence exists for the production of both H_2CO and HOI in the same matrix cage in that widths of HOI lines were greater than those of, for instance, ozone, and the shifts of some methanal vibrations from wavenumbers associated with isolated molecules in solid argon (5, 6). These effects suggest a hydrogen-bonded interaction of form



The resulting perturbation of HOI wavenumbers probably does not appreciably affect the force field parameters calculated from these measurements (19).

The Behavior of Thiochromanone and Isothiochromanone Sulfoxides in the Schmidt Reaction: Isolation of a Novel Azide Product from Thiochromone Sulfone[1]

IAN W. J. STILL, M. THOMAS THOMAS, AND ALAN M. CLISH[2]
Department of Chemistry, University of Toronto, Toronto, Ontario L5L 1C6

Received September 23, 1974

IAN W. J. STILL, M. THOMAS THOMAS, and ALAN M. CLISH. Can. J. Chem. **53**, 276 (1975).

The Schmidt reaction has been carried out on thiochroman-4-one 1-oxide and a number of related sulfoxides. In all cases lactam formation by attack of HN_3 on the carbonyl group of the keto sulfoxide appears to predominate, with no evidence for sulfoximine formation. The question of aryl *vs.* alkyl migration, as in other systems, is dependent on the degree of substitution of the alkyl group. When the Schmidt reaction was carried out upon thiochromone 1,1-dioxide two products, the lactam resulting from preferential vinyl migration and a novel α-azido sulfone resulting from 1,4-addition, were obtained.

IAN W. J. STILL, M. THOMAS THOMAS et ALAN M. CLISH. Can. J. Chem. **53**, 276 (1975).

On a effectué la réaction de Schmidt sur la thiochromanone-4 oxyde-1 et un certain nombre de sulfoxydes qui lui sont apparentés. Dans tous les cas, il y a formation de lactame par attaque de HN_3 sur le groupement carbonyle du céto-sulfoxyde et cette réaction semble prédominante; on n'a trouvé aucune preuve expérimentale pour la formation d'une sulfoxymine. La question de la migration des groupes aryles par opposition à la migration à des groupes alkyles dépend du degré de substitution en accord avec ce qui a été observé dans d'autres systèmes. Lorsque l'on effectue la réaction de Schmidt sur la thiochromonedioxyde-1,1, on obtient deux produits: la lactame résultant de la migration préférentielle du groupe vinyle et une nouvelle α-azido sulfone qui résulte d'une addition-1,4. [Traduit par le journal]

Introduction

The Schmidt reaction of ketones was first reported over fifty years ago and the scope and mechanism of this rearrangement reaction have been extensively reviewed by Smith (1) and, more recently, by Koldobskii *et al.* (2) Interest in this reaction, and the mechanistically related Beckmann rearrangement, remains high, however, as indicated by a number of recent publications (3–6). Some years ago, Evans and Lockhart (7) had studied a series of tetralones **1***a* and contrasted their behavior in the Schmidt reaction with that of the analogous chromanones **1***b*. They concluded that the preference for the formation of cyclic benzamide derivatives (by alkyl rather than aryl migration) in the heterocyclic series could be attributed to the electron-releasing effect of oxygen. It occurred to us that the thiochromanone **1***c* series of compounds would be interesting to study from this point of view as the hetero atom in this series might be expected to show quite different behavior according to whether it was present as the sulfide, sulfoxide, or sulfone functionality. Indeed, Wünsch and co-workers (8) had earlier examined a limited number of thiochromanones and thiochromanone 1,1-dioxides with variable substituents in the aromatic ring only. In addition to completing the series by including the corresponding sulfoxide **2***a* and its derivatives in the present work, we have also attempted to study the effect of variation in the substitution pattern of the heterocyclic ring on the course of the Schmidt rearrangement.

The interesting results obtained recently by Williams and Cram (9) from the reaction of certain keto-sulfoxides with hydrazoic acid, in which attack at both functional groups was observed, and the work already referred to by Hill and Cullison (5) on the fragmentation of isothiochromanone oxime under the conditions of the Beckmann rearrangement provided a further impetus for our study.[3] Our findings in relation to these aspects will also be discussed.

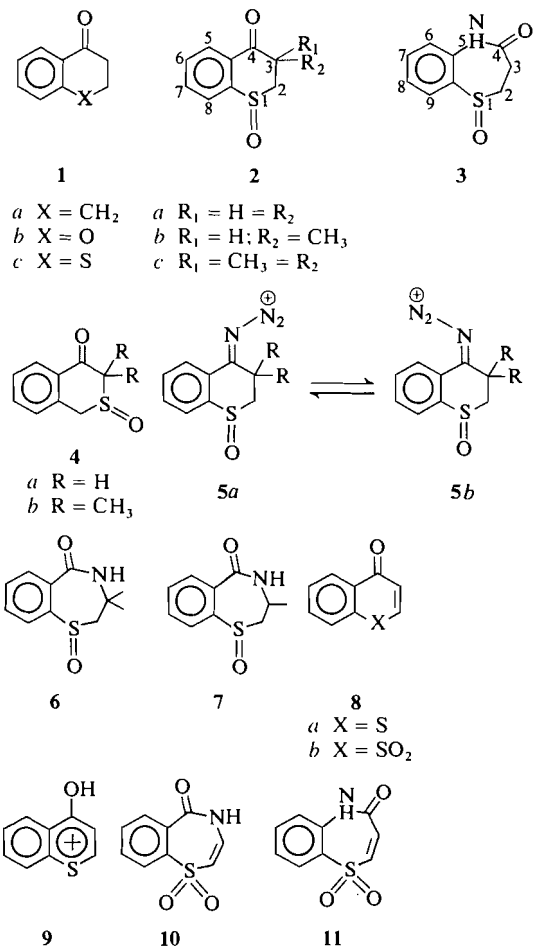
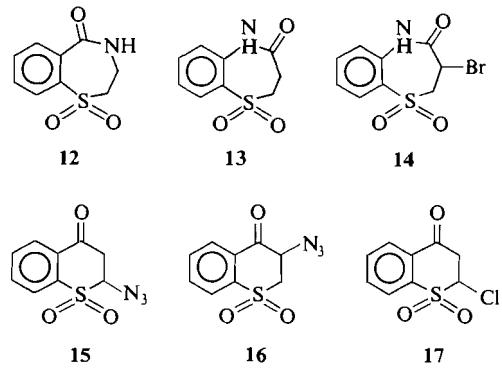
Results and Discussion

The product expected from the Schmidt reaction of thiochromanone 1-oxide **2***a* was the lactam 2,3-dihydro-1,5-benzothiazepin-4(5*H*)-one 1-oxide **3**, resulting from preferred aryl migration in the (presumed) intermediate iminodiazonium ion **5***a*. The sole product isolated from the reaction did indeed possess this structure, the proof of which rests mainly on analytical and mass spectral (molecular ion) data, as well as analogy with the earlier work of Wünsch *et al.* (8). Because of the relative insolubility of this compound and the related sulfoxide lactams it was not possible to use n.m.r. data in assigning structure in the manner reported in earlier studies of the Schmidt reaction of some chromanone derivatives (10, 11).

It was found in the mass spectrum of the lactam **3**, for example, that there were no significant amounts of the fragment ions at *m/e* 105 or 153 due to C_7H_5O(benzoyl) and $C_7H_5SO_2$-(benzoyl + SO), whereas in the lactam **6**, resulting from the Schmidt reaction of 3,3-dimethylthiochroman-4-one 1-oxide **2***c*, fragment ions are observed at *m/e* 105 and 153 with intensities of 71 and 75%, respectively. Thus it can be argued from this and several similar considerations of the mass spectra that in the case of lactam **6** both the S=O and the C=O units are directly bonded to the aromatic ring and thus this lactam is a substituted 2,3-dihydro-1,4-benzothiazepin-5-(4*H*)-one 1-oxide. Conversely, the lactam **3** and related lactams (see Table 1) which lack such fragment ions are members of the isomeric 2,3-dihydro-1,5-benzothiazepin-4(5*H*)-one 1-oxide series.





The results of the Schmidt reaction on some simple thiochromanone sulfoxides are summarized in Table 1. In the parent case and in the 8-methyl and 2,2-dimethyl substituted analogs aryl migration is strongly preferred over the alternative primary alkyl migration. In the case of **2***c*, as has been mentioned above, the preference is for tertiary alkyl over aryl migration, leading to the alternative lactam insertion product. Whether this result, however, is a reflection of migratory aptitude or simply involves equilibration of the two possible iminodiazonium ions **5***a* and *b* followed by concerted (*anti*) migration in the sterically more favorable ion **5***b*, is a dilemma posed in a recent review of the Schmidt reaction (12), but unfortunately one not resolved by the present study. Interestingly, in the intermediate case of 3-methylthiochroman-4-one 1-oxide, **2***b*, two isomeric lactams are obtained, in a roughly 3:5 ratio, indicating that both possible modes of migration occur. The major product has been assigned the structure of the 3-methyl derivative of **3**, corresponding to aryl migration,

TABLE 1. Products of Schmidt rearrangement of thiochromanone sulfoxides

Starting sulfoxide	Lactam	Melting point[a] (°C)	Isolated yield (%)
Thiochroman-4-one 1-oxide, **2***a*	**3**	184–185[b]	30
8-Methyl-**2***a*	9-Methyl-**3**	210–211[b]	52
2,2-Dimethyl-**2***a*	2,2-Dimethyl-**3**	201–202[c]	77
3-Methylthiochroman-4-one 1-oxide, **2***b*	3-Methyl-**3**	195–196[c]	45
	7	292–294[b]	27
3,3-Dimethylthiochroman-4-one 1-oxide, **2***c*	**6**	235–236[c]	82
Isothiochromanone 2-oxide, **4***a*	—	—	—
3,3-Dimethylisothiochromanone 2-oxide, **4***b*	—	—	—[d]

and the minor product is assigned structure **7** arising from *sec*-alkyl migration.

It is interesting to note in passing that Wünsch and his collaborators (8) had attempted to carry out the Schmidt reaction on 3,3-dimethylthiochroman-4-one but obtained only small amounts of uncharacterizable oils, a not uncommon result with *tert*-alkyl ketones. The reason for the quite different result we have obtained with the analogous sulfoxide is not clear. The rather low isolated yield of the lactam **3** from the parent thiochroman-4-one 1-oxide is probably attributable to the greater solubility of the unsubstituted lactam in water or to formation of water-soluble cleavage products. In the case of 3-methylthiochroman-4-one 1-oxide, where both isomeric lactams are obtained, they were found to have rather similar solubility characteristics in hydroxylic solvents and so we do not feel that there is likely to be any significant amount of the alternative lactam product in the thiochroman-4-one 1-oxide reaction.

Attempts to carry out the Schmidt reaction on isothiochromanone sulfoxide **4***a* (see Table 1) met with no success, due presumably to the much greater likelihood of ring cleavage occurring via carbonium ion intermediates arising from protonation in the strongly acidic media employed. Indeed, charring and decomposition of both **4***a* and of isothiochromanone itself, as indicated by immediate formation of a deep brown color in concentrated sulfuric acid, was evident even before addition of the sodium azide. In contrast, members of the thiochromanone sulfoxide series (and the related sulfides) dissolve in concentrated sulfuric acid with the formation of a very deep red color, which is discharged on dilution with water. The only other sulfide examined, 3,3-dimethylisothiochromanone was likewise decomposed by exposure to concentrated sulfuric acid, although rather surprisingly the corresponding sulfoxide **4***b* was recovered unchanged in the Schmidt reaction.

We have also attempted to carry out the reaction of thiochroman-4-one 1-oxide **2***a* with hydrazoic acid in the presence of chloroform at 45°, conditions used by Whitehead and Bentley (13) for the formation of sulfoximines from simple sulfides, as well as by Williams and Cram (9) for the formation of Schmidt rearranged sulfoximines from acyclic keto sulfoxides structurally rather similar to ours. Although the latter authors found that attack at sulfur was apparently faster than attack on the carbonyl group, our attempts to isolate sulfoximines according to the procedures detailed in the excellent review by Oae *et al.* (14) have been without success. Only lactam formation was observed, but in somewhat lower yield than in the procedure carried out at 25° in the absence of chloroform. Even in the case of the sterically unfavorable 3,3-dimethylthiochroman-4-one 1-oxide, only attack at carbonyl (lactam formation) could be observed under these conditions.

To complete our investigation we attempted to carry out the Schmidt reaction on the unsaturated analogs of thiochromanone, namely thiochromone **8***a* and its 1,1-dioxide **8***b*.[4] Treatment of the former under the conditions of the Schmidt reaction led, not surprisingly, to an almost quantitative recovery of unreacted ketone, presumably because of the initial formation and relative stab-

[4]The third member of this series, the analogous sulfoxide, is at present unknown. Attempts to synthesize this potentially interesting molecule are currently under investigation in our laboratory.

ility of the thiapyrylium cation **9**. In the case of the sulfone, however, a more interesting result was the formation of two products, one of which is a lactam arising from 1,2-addition of HN_3 to the carbonyl group, followed by Schmidt rearrangement, and the other is an α-azido sulfone resulting from 1,4-addition of HN_3.

The lactam formed has been assigned structure **10**, *i.e.* the product of vinyl migration, rather than the isomeric lactam structure arising from aryl migration. Some evidence in support of the gross structure of the lactam came from its mass spectrum which had a base peak at *m/e* 209 (molecular ion) and showed evidence of rearrangement to a cyclic sulfinate, followed by consecutive loss of SO, O, and CO leading (presumably) to an indole fragment at *m/e* 117 (< 10%). A second major fragmentation led, by loss of CHO + HCN (or some alternative combination of the same composition), to an ion at *m/e* 153 (11%) and by subsequent loss of O to an ion at *m/e* 137 (6%). Confirmation of the assignment as structure **10**, rather than the isomer **11**, was sought by reducing the unsaturated lactam to the known 2,3-dihydro-1,4-benzothiazepin-5(4*H*)-one 1,1-dioxide, **12**, synthesized by the method of Wünsch *et al.* (15) from 2-mercaptobenzoic acid. Several attempts to reduce the double bond by palladium or platinum catalyzed hydrogenation, at pressures up to 5 atm, were totally unsuccessful, perhaps because of catalyst poisoning by the sulfur and/or nitrogen atom in the substrate. An alternative approach was to synthesize 2,3-dihydro-1,5-benzothiazepin-4(5*H*)-one 1,1-dioxide, **13**, by Schmidt rearrangement of thiochroman-4-one 1,1-dioxide as described in the earlier paper by Wünsch *et al.* (8) and dehydrogenate this to the unsaturated lactam isomer **11** which, of course, should *not* have been identical with our lactam product. Such attempts, using chloranil and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone in refluxing dioxan or xylene were also quite ineffectual. Finally, however, we were able to convert 3-bromothiochroman-4-one 1,1-dioxide by the Schmidt reaction under Wünsch's conditions (8) into the 3-bromo-2,3-dihydro-1,5-benzothiazepin-4(5*H*)-one 1,1-dioxide, **14**, in good yield. Simple dehydrobromination of this compound by heating with pyridine afforded, again in good yield, the unsaturated lactam **11**. This compound was clearly different from, although isomeric with, our original unsaturated lactam.Compound **11**, for example, shows a carbonyl band in the infrared at 1665 cm^{-1} as compared to 1650 cm^{-1} shown by the (benzoyl) carbonyl of **10**. Compound **11** is considerably more soluble in organic solvents than **10** and the n.m.r. spectrum confirmed the presence of both the NH group and the double bond. Finally, the mass spectrum of **11** is exceedingly simple compared to that of **10**. It reveals a molecular ion at *m/e* 209 (14%) but, unlike the isomeric lactam, fragments by a simple mechanism involving loss of first SO_2 to give a peak at *m/e* 145 (36%), followed by loss of CO leading to the indole fragment ion at *m/e* 117 (100%) which, as expected, further fragments almost exclusively by loss of HCN (16).

Although the final confirmation of structure thus did not include the direct comparison with a known compound which we would have liked, we feel that the evidence described establishes the structure of **10** beyond reasonable doubt. It is inconceivable, for example, that in the rearrangement of 3-bromothiochroman-4-one 1,1-dioxide, using the conditions described by Wünsch *et al.* (8) for the rearrangement of the parent thiochromanone sulfone, the lactam formed could be other than that expected from preferred aryl migration *i.e.* **14**.

The second product from the Schmidt reaction of **8***b* could be isolated only by reducing the reaction time and by carefully controlling the p*H* during the work-up procedure. That this product is the simple adduct of thiochromone 1,1-dioxide and HN_3 **15** was shown by analytical, i.r., and n.m.r. data. It is well known from the work of Moore *et al.* (17) that addition of HN_3 to quinones occurs readily, although the initial hydroquinone adducts often undergo disproportionation to aminoquinones accompanied by loss of nitrogen. The Schmidt rearrangement of simple quinones to azepine-2,5-dione derivatives has also been reported by Rickards and Smith (18). In our case, nucleophilic addition of azide ion could, in principle, occur at either the C-2 or C-3 position in **8***b* (or its conjugate acid) leading to either **15** or **16**. Attempts to add azide ion and other nucleophiles to **8***b* under neutral or basic conditions were unsuccessful, and led only to water-soluble cleavage products (presumably sulfinates) by nucleophilic addition at C-2 followed by elimination. This proposition has some support from the work of Nesmeyanov and Rybinskaya (19) on the addition of azide to acyclic β-sulfonyl α,β-unsaturated ketone sys-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

tems and that of Elkaschef *et al.* (20) on the ring opening of thiochromones by the attack of even relatively weak nucleophiles such as amines. This ease of ring opening may be taken as somewhat indirect evidence that C-2 is the preferred site for nucleophilic attack, given the relative leaving group capabilities of $ArC{=}O$ and $ArSO_2^-$.

By the addition of HCl in acetic acid to thiochromone 1,1-dioxide (21) we obtained an excellent yield of 2-chlorothiochroman-4-one 1,1-dioxide, **17**. This compound was clearly distinct from the known 3-chloro isomer and showed a remarkable similarity in the n.m.r. to our HN_3 adduct **15**. Finally, by extending this method to the addition of HN_3 in chloroform to **8***b* we were able to prepare the expected adduct **15** identical in all respects with the product of the Schmidt reaction.

We believe that the α-azido sulfone **15** may be the first representative of this class of compound.[5] A study of its chemical behavior is under way in our laboratory and will be the subject of a separate publication.

Experimental

General

The i.r. spectra (cm^{-1}) were recorded (Nujol mulls unless otherwise stated) on a Perkin-Elmer 337 grating spectrophotometer and the low resolution mass spectra were obtained on a Bell and Howell 21-490 spectrometer. Accurate mass measurements were carried out on the AEI MS-902 instrument. Nuclear magnetic resonance spectra were recorded on a Varian T-60 spectrometer in $CDCl_3$ with TMS as internal standard. Elemental analyses were performed by the Scandinavian Microanalytical Laboratory, Box 25, DK2730 Herlev, Denmark. Column chromatography and thin-layer chromatography (analytical and preparative) were run on silica gel using Fisher A.C.S. grade solvents. All melting points and boiling points are uncorrected.

Thiochromanones

Thiochroman-4-one, 8-methylthiochroman-4-one, 3-methylthiochroman-4-one, and isothiochromanone were prepared as described previously (22). The synthesis of 2,2-dimethylthiochroman-4-one was also reported earlier by us (23). The synthesis of 3,3-dimethylisothiochroman-4-one from isothiochromanone by reaction with methyl iodide and sodium hydride used essentially the method we described recently to prepare 3,3-dimethylthiochroman-4-one from its unsubstituted counterpart (24).

Sulfoxides

The general method, using H_2O_2 – acetic acid, for the conversion of thiochromanones into their corresponding sulfoxides has been described (23). In the case of the isothiochromanone sulfoxides a much shorter reaction time (1–2 h) sufficed. 3,3-Dimethylisothiochromanone 2-oxide could not be obtained crystalline and the liquid, as is usual with such sulfoxides, decomposed on attempted distillation, but n.m.r. and i.r. data for this compound were in accord with the expected structure.

Schmidt Reaction on Thiochroman-4-one 1-Oxide (2a)

The ketone (634 mg) was dissolved in concentrated H_2SO_4 (4 ml). To the stirred solution at 0–5° was added sodium azide (488 mg) in portions over 15 min. After 2 h at 0–5°, the deep red mixture was stirred at 25° for 16 h before pouring rapidly over crushed ice with stirring. The pale brown solid (210 mg) which formed was filtered off from the ice-cold solution and recrystallized from methanol, m.p. 184–185° (dec.) The 2,3-dihydro-1,5-benzothiazepin-4(5*H*)-one 1-oxide **3** so obtained had i.r. bands at 3110, 3180(NH); 1665(C=O); and 1040(S=O) cm^{-1} and the mass spectrum showed a molecular ion peak at *m/e* 195(25%) and major fragment ions at *m/e* 167(10), 149(20), and 147(18).

Anal. Calcd. for $C_9H_9NO_2S$: C, 55.38; H, 4.61; N, 7.18; S, 16.41. Found: C, 55.36; H, 4.75; N, 7.13; S, 16.48.

Schmidt Reaction on 8-Methylthiochroman-4-one 1-Oxide

Using the above procedure the lactam 9-methyl-**3** was obtained as a white solid, m.p. 210–211° (MeOH). Infrared bands were observed at 3100, 3180(NH); 1640, 1690(C=O); and 1035(S=O) cm^{-1}. The mass spectrum showed a molecular ion peak at *m/e* 209(9) and major fragment ions at *m/e* 193(35), 160(18), 150(19), 143(35), and 107(12).

Anal. Calcd. for $C_{10}H_{11}NO_2S$: C, 57.41; H, 5.30; N, 6.70; S, 15.30. Found: C, 57.27; H, 5.30; N, 6.66; S, 15.35.

Schmidt Reaction on 2,2-Dimethylthiochroman-4-one 1-Oxide

The above procedure afforded the lactam 2,2-dimethyl-**3** as a white solid, m.p. 201–202° (95% EtOH). Infrared bands were observed at 3100, 3160(NH); 1640, 1680 (C=O); and 1040(S=O)cm^{-1}. The mass spectrum showed a molecular ion peak at *m/e* 223(11) and major fragment ions at *m/e* 152(14), 141(32), 125(27), and 123(17).

Anal. Calcd. for $C_{11}H_{13}NO_2S$: C, 59.18; H, 5.87; N, 6.28; S, 14.34. Found: C, 59.07; H, 5.84; N, 6.21; S, 14.31.

Schmidt Reaction on 3,3-Dimethylthiochroman-4-one 1-Oxide (2c)

The above procedure afforded 3,3-dimethyl-2,3-dihydro-1,4-benzothiazepin-5(4*H*)-one 1-oxide, **6**, as a white solid, m.p. 235–236° (95% EtOH). Infrared bands appeared at 3180(NH); 1640(C=O); and 1035(S=O) cm^{-1}. The mass spectrum showed a molecular ion peak at *m/e* 223(20) and major fragment ions at *m/e* 166(41), 161(21), 152(75), 146(16), 136(23), 121(21), 118(31), and 105(71).

Anal. Calcd. for $C_{11}H_{13}NO_2S$: C, 59.18; H, 5.87; N, 6.28; S, 14.34. Found: C, 59.11; H, 5.96; N, 6.16; S, 14.44.

Schmidt Reaction on 3-Methylthiochroman-4-one 1-Oxide (2b)

The reaction of **2***b* (582 mg) with sodium azide – concentrated H_2SO_4, conducted under the usual conditions,

[5]NOTE ADDED IN PROOF: Since this work was submitted for publication the preparation of a similar compound has been reported (26).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

was stopped after 3 h at 25°. Only a small amount of precipitate (32 mg) formed on pouring the concentrated H_2SO_4 solution over crushed ice. The cold aqueous filtrate was neutralized with solid sodium hydrogen carbonate and extracted thoroughly with methylene chloride. Evaporation afforded a crude solid product (438 mg). Treatment of the solid with a small quantity of chloroform and filtration of the residual solid gave a white solid (151 mg), identical with the original solid obtained on pouring the reaction mixture over ice. The combined product was recrystallized from methanol, m.p. 292–294° (dec.). This compound had infrared bands at 3150, 3075(NH); 1660(C=O); and 1035(S=O)cm^{-1}. Mass spectral analysis showed the expected molecular ion in accord with structure **7** at *m/e* 209(1) and major fragment ions at *m/e* 153(18), 152(100), 150(17), 136(10), 121(18), and 104(11).

Anal. Calcd. for $C_{10}H_{11}NO_2S$: C, 57.41; H, 5.30; N, 6.70; S, 15.30. Found: C, 57.30; H, 5.43; N, 6.57; S, 15.41.

The chloroform-soluble filtrate obtained by the above procedure was evaporated, affording a white solid (251 mg) further purified by column chromatography and elution with 5% methanol in chloroform. Recrystallization from methanol afforded white prisms of the lactam 3-methyl-**3**, m.p. 195–196°. Infrared $\nu_{max}(CHCl_3)$ 3150, 3100(NH); 1660(C=O); and 1020(S=O)cm^{-1}. Mass spectrum *m/e* 209(100), 193(37), 167(22), 152(28), 150(15), 146(15), 136(45), 123(44), and 106(26). Nuclear magnetic resonance δ 1.2(3H, d, J = 6 Hz); 3.4(3H, m); 7.2–8.0(4H, m); 8.8(1H, br s) p.p.m.

Anal. Calcd. for $C_{10}H_{11}NO_2S$: C, 57.41; H, 5.30; N, 6.70; S, 15.30. Found: C, 57.01; H, 5.25; N, 6.48; S, 15.23.

*Attempted Schmidt Reaction on 3,3-Dimethylisothiochromanone 2-Oxide (**4b**)*

A solution of the keto sulfoxide (416 mg) in concentrated H_2SO_4 (5 ml) was treated in the usual manner at 0–5° with sodium azide (405 mg) and the solution finally maintained at 25° for 18 h. The usual work-up procedure afforded only starting material (315 mg, 75%).

*Schmidt Reaction on Thiochromone 1,1-Dioxide (**8b**)*

Thiochromone sulfone (21, 23) (0.97 g) was dissolved in concentrated H_2SO_4 (10 ml) and cooled to 0–5°. Careful addition of sodium azide (0.39 g) over 1 h was followed by stirring at 0° for 30 min and then at 25° for a further 30 min. The reaction mixture was poured on to ice and the yellow precipitate formed removed at once by filtration. The acidity of the aqueous solution was adjusted to around p*H* 7 by the addition of sodium acetate and the solution then extracted thoroughly with chloroform. Partial evaporation of the chloroform extracts afforded a yellow solid identical with that obtained from the original aqueous solution by filtration and the two fractions were combined (56 mg, 6%) and recrystallized from methanol as yellow needles, m.p. 295–296°. The infrared spectrum showed bands at 3350, 3220(NH); 1650(C=O); 1320 and 1145(SO_2) cm^{-1}. Mass spectral analysis showed the expected molecular ion at *m/e* 209(100) in accord with the lactam structure **10**, and major fragment ions at *m/e* 161(24), 153(11), 152(7), 145(8), 137(6), 121(8), and 104(9).

Anal. Calcd. for $C_9H_7NO_3S$: C, 51.68; H, 3.37; N, 6.70; S, 15.30. Found: C, 51.60; H, 3.43; N, 6.61; S, 15.35.

The chloroform filtrate obtained by isolation of the yellow solid (lactam) described above was evaporated and a pale yellow solid (103 mg, 10%) obtained by crystallization from aqueous alcohol, m.p. 110–111°. That this compound possessed the structure **15** was shown by the following spectral and analytical data. (Mass spectral analysis was unsatisfactory, presumably due to the thermal instability of the azide.) Infrared $\nu_{max}(CHCl_3)$ 2125 (N_3); 1697 (C=O); 1325 and 1140, 1120(SO_2) cm^{-1}; δ 3.5 (2H, doublet of quartets); 5.1 (1H, dd) (J_{AB} = 18 Hz, J_{AX} = 4 Hz, J_{BX} = 5 Hz); 7.7–8.3 (4H, m) p.p.m.

Anal. Calcd. for $C_9H_7N_3O_3S$: C, 45.57; H, 2.98; N, 17.72; S, 13.48. Found: C, 45.62; H, 2.99; N, 17.64; S, 13.65.

*3-Bromo-2,3-dihydro-1,5-benzothiazepin-4(5H)-one 1,1-dioxide (**14**)*

This compound, m.p. 235–237° (dec.) on recrystallization from ethanol–DMF, was prepared by the reaction of HN_3 with 3-bromothiochroman-4-one 1,1-dioxide according to the general procedure described by Wünsch *et al.* (8).

Anal. Calcd. for $C_9H_8BrNO_3S$: C, 37.24; H, 2.76; S, 11.03; Br, 27.58. Found: C, 37.45; H, 2.80; S, 11.51; Br, 27.41.

*1,5-Benzothiazepin-4(5H)-one 1,1-dioxide (**11**)*

The above lactam (200 mg) was heated with dry pyridine (3 ml) until all the solid had dissolved, and then for a further 1–2 min. The unsaturated lactam (128 mg, 89%), had m.p. 214–215° on recrystallization from 95% ethanol. Infrared ν_{max} 3115, 3170(NH); 1665(CO): 1315 and 1140(SO_2)cm^{-1}. Nuclear magnetic resonance δ (acetone-d_6) 5.33 (1H, part of AB quartet); 6.01–6.73 (5H, multiplet); 8.97 (1H, br s) p.p.m. *m/e* 209(14), 145(36), 117(100), 90(43).

Anal. Calcd. for $C_9H_7NO_3S$: C, 51.68; H, 3.37. Found: C, 51.72; H, 3.48.

Addition of HCl to Thiochromone 1,1-Dioxide

Thiochromone 1,1-dioxide (395 mg) was suspended in glacial acetic acid and the mixture saturated with dry HCl gas (21). After 30 min, the reaction mixture was poured into ice water and 2-chlorothiochroman-4-one 1,1-dioxide, **17** (371 mg, 80%) was collected by filtration as a white solid, m.p. 98–100° (hexane–benzene). Infrared $\nu_{max}(CHCl_3)$ 1700(C=O); 1320 and 1140(SO_2) cm^{-1}; δ 3.75 (2H, doublet of quartets); 5.3 (1H, dd) (J_{AB} = 18 Hz, J_{AX} = 4 Hz, J_{BX} = 6 Hz); 7.7–8.3 (4H, m) p.p.m.

Anal. Calcd. for $C_9H_7ClO_3S$: C, 46.85; H, 3.03; Cl, 15.40; S, 13.88. Found: C, 46.96; H, 3.12; Cl, 15.29; S, 13.85.

Addition of HN_3 to Thiochromone 1,1-Dioxide

Thiochromone 1,1-dioxide (388 mg), in chloroform (5 ml) was treated with a solution of hydrazoic acid in chloroform (6 ml; approximately 0.4 M), prepared according to the method of Fieser and Fieser (25). After 15 min at 25°, the solution was evaporated and the product **15** obtained as a pale yellow solid (449 mg, 95%) recrystallized from aqueous alcohol, m.p. 110–112°. This compound was identical (m.p., mixture m.p., i.r., n.m.r.) with the azide obtained in the Schmidt reaction of thiochromone 1,1-dioxide.

We wish to thank Erindale College, Univerity of Toronto, for financial support of this work.

Substrate Inhibition in the Hydrolysis of Hippuric Acid Esters by Carboxypeptidase A[1]

JOE MURPHY AND JOHN W. BUNTING

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received July 29, 1974

JOE MURPHY and JOHN W. BUNTING. Can. J. Chem. **53**, 283 (1975).

The dependence of initial velocity upon substrate concentration has been examined in the carboxypeptidase A catalyzed hydrolysis of the following hippuric acid esters (at p*H* 7.5, 25°, ionic strength 0.5): $C_6H_5CONHCH_2CO_2CHRCO_2H$: R = CH_3; CH_2CH_3; $(CH_2)_2CH_3$; $(CH_2)_3CH_3$; $(CH_2)_5CH_3$; $CH(CH_3)_2$; $CH_2CH(CH_3)_2$; C_6H_5; $CH_2C_6H_5$. All of these esters display marked substrate inhibition of their enzymic hydrolyses. With the exception of R = CH_3, the velocity-substrate concentration profiles for each of these esters can be rationalized by the formation of an E.S_2 complex which, independent of the alcohol moiety of the ester, reacts approximately 25 times more slowly than the E.S complex. For most of these esters, the formation of E.S_2 approximates ordered binding of the substrate molecules at the catalytic and inhibitory sites. While binding at the catalytic site is markedly dependent on the nature of the R group, binding of a second substrate molecule to E.S is not significantly affected by the nature of the R side chain. For R = C_6H_5, the D ester is neither a substrate nor a competitive inhibitor of the hydrolysis of the L-ester but can replace the L-ester at the binding site which is responsible for substrate inhibition. The kinetic analysis suggests that this behavior of D- and L-enantiomers is also typical of the other esters examined (except possibly R = CH_3). For R = CH_3 only, substrate activation also seems to occur prior to the onset of substrate inhibition at higher substrate concentrations.

JOE MURPHY et JOHN W. BUNTING. Can. J. Chem. **53**, 283 (1975).

On a examiné la dépendance, sur la concentration du substrat, de la vitesse initiale de l'hydrolyse, catalisée par la carboxypeptidase A, des esters suivants de l'acide hippuriques (à p*H* 7.5, 25°, force ionique de 0.5): $C_6H_5CONHCH_2CO_2CHRCO_2H$: R = CH_3; CH_2CH_3; $(CH_2)_2CH_3$; $(CH_2)_3CH_3$; $(CH_2)_5CH_3$; $CH(CH_3)_2$; $CH_2CH(CH_3)_2$; C_6H_5; $CH_2C_6H_5$. L'hydrolyse enzymatique de tous ces esters montrent une inhibition importante par le substrat. En faisant exception du cas où R = CH_3, tous les profils de la vitesse par rapport à la concentration de substrat, pour chacun de ces esters, peuvent être rationalisés par la formation d'un complexe E.S_2 qui, indépendant de la portion alcoolique de l'ester, réagit environ 25 fois moins rapidement que le complexe E.S. Pour la plupart de ces esters, la formation des complexes E.S_2 est approximativement parallèle avec la liaison ordonnée des molécules de substrat aux sites catalytique et inhibiteur. Alors que la liaison au site catalytique dépend d'une façon importante sur la nature du groupe R, la liaison d'une deuxième molécule de substrat au complexe E.S n'est pas effectée d'une manière importante par la nature de la chaîne latérale R. Pour R = C_6H_5, l'ester D n'est ni un substrat ni un inhibiteur compétitif de l'hydrolyse de l'ester L mais peut remplacer l'ester L au site de liaison qui est responsable pour l'inhibition du substrat. L'analyse de la cinétique suggère que la façon de réagir des énantiomères D et L est aussi typique des autres esters examinés (à l'exception possiblement de R = CH_3). Dans le cas particulier où R = CH_3, l'activation du substrat semble aussi se produire avant l'apparition de l'inhibition du substrat à des concentrations de substrat plus élevées.

[Traduit par le journal]

The hydrolysis of many ester and peptide substrates by bovine carboxypeptidase A is complicated by complex substrate activation and inhibition effects (1–9). Thus, the enzymic hydrolyses of *O*-hippuryl-L-3-phenyllactic acid (**1**: R = $CH_2C_6H_5$) and *O*-hippuryl-L-mandelic acid (**1**: R = C_6H_5) exhibit substrate inhibition at substrate concentrations greater than approximately 10^{-3} *M* (3, 5, 7, 8), whereas for *O*-hippurylglycolic acid (**1**: R = H) substrate activation is observed (4, 9). Complex substrate activation and inhibition effects have also been observed with *N*-hippuryl and *N*-carbobenzoxy-

glycyl amino acid substrates (1, 2, 6, 8). On the other hand, a few ester substrates are known for which the enzymic hydrolysis seems to be free of activation and inhibition effects over the experimentally attainable substrate concentration ranges (7, 10–14). Substrate activation and inhibition are also much less pronounced with tripeptide substrates than with their smaller dipeptide analogs (15, 16).

A schematic model has been presented (17) to account qualitatively for substrate activation and inhibition in these reactions. This model assumes multiple sites for the binding of substrate molecules to carboxypeptidase A and also requires that alternative binding modes are possible within one or more of these sites. The model is supported by the X-ray crystallographic study of carboxypeptidase A crystals, which has revealed a relatively "open" active-site region (18–20). Model-building studies indicate (19, 20) that at least two substrate molecules of the size of an *N*-acyl dipeptide can be contained in this active-site region in various orientations which allow reasonable noncovalent bonds (hydrogen bonds, electrostatic interactions, hydrophobic interactions, etc.) between the substrate and enzyme.

A comprehensive quantitative description of the kinetics of hydrolysis in the presence of substrate activation and inhibition has been lacking, and this has hampered the study of the substrate specificity and mechanism of action of this enzyme. Individual attempts have been made to explain the dependence of initial velocity on substrate concentration for **1**: R = C_6H_5 and **1**: R = $CH_2C_6H_5$. Thus, Awazu *et al.* (7) fitted the substrate inhibition of the hydrolysis of **1**: R = C_6H_5 to a relatively simple kinetic scheme which suggested that inhibition arises from the formation of a nonproductive 1:2 enzyme–substrate complex ($E.S_2$). However, McClure *et al.* (3) postulated a much more complex scheme for **1**: R = $CH_2C_6H_5$ that requires either inactive enzyme–substrate complexes containing up to five substrate molecules per enzyme molecule, or alternatively, the existence of four enzyme species having different activities toward this substrate. It seems unlikely that two substrates which are structurally as closely related as **1**: R = C_6H_5 and **1**: R = $CH_2C_6H_5$ would be involved in such kinetically different mechanisms. Substrate inhibition has also been interpreted in terms of an $E.S_4$ complex for the peptide substrate, carbobenzoxyglycylphenylalanine (2), although later studies have suggested (5, 8) that substrate activation, related to the formation of an $E.S_2$ species (6), is also important at lower concentrations of this substrate. These diverse results with a few substrates clearly indicate that a comprehensive systematic study under constant experimental conditions is essential if these phenomena are to be quantitatively understood.

We have recently reported (9) an analysis of substrate activation for three hippuric acid esters (**1**: R = H, **1**: R = *p*-ClC_6H_4 and *O*-hippuryl-2-methyllactic acid) and have shown that in each of these cases substrate activation is consistent with the formation of $E.S_2$ complexes. In a companion investigation, we have now studied the dependence of initial velocity on substrate concentration for the enzymic hydrolysis (p*H* 7.5, 25°, ionic strength 0.5) of a series of nine hippuric acid ester substrates (**1**) for carboxypeptidase A. The purpose of this study was two-fold. Firstly, we felt that it should be possible to quantitatively interpret substrate inhibition for the previously studied **1**: R = C_6H_5 and **1**: R = $CH_2C_6H_5$ and other hippuric acid esters by a common mechanism. Secondly, we hoped to define the specificity of carboxypeptidase A with respect to the alcohol moiety of ester substrates, and compare this specificity with recent studies in our laboratory (21, 22) on the reversible binding of carboxylate anion inhibitors to this enzyme, and with the limited available data on the specificity of this enzyme for peptide substrates.

Experimental

Synthesis of Substrates

All esters, except where indicated below, were prepared as the racemates. The synthesis of *O*-hippuryl-DL-2-hydroxybutanoic acid (**1**: R = C_2H_5) from hippuric acid and benzyl 2-bromobutanoate has been previously described (14).

*O-Hippuryl-*DL*-lactic acid (1: R = CH_3)*: this was similarly prepared; yield 30% from 2-chloropropionic acid, m.p. 169–170°; p.m.r. (CF_3CO_2H): δ 1.71 (3H, d, J = 7 Hz), 4.57 (2H, d, J_{CHNH} = 4 Hz), 5.43 (1H, q, J = 7 Hz), 7.67 (6H, m).

Anal. Calcd. for $C_{12}H_{13}NO_5$: C 57.4; H 5.21; N 5.58. Found: C 57.4; H 5.27; N 5.72.

The remaining esters were synthesized by the following general route: a stirred mixture of hippuryl chloride (23) (4.7 g, 0.024 mol), the 2-hydroxy-acid[2] (RCH(OH)CO_2H,

[2]Usually prepared from the commercially available 2-bromo acids by refluxing in 1 *M* aqueous KOH solution for 18–20 h.

0.029 mol) and tetrahydrofuran (60 ml) was treated dropwise with pyridine (5 ml, 0.060 mol). The resultant mixture was stirred at room temperature for 15–20 h. Pyridine hydrochloride was filtered off and the solvent removed under vacuum. The viscous yellow residue was redissolved in dichloromethane or chloroform (200 ml) and extracted with 3 *M* hydrochloric acid (35 ml). After drying over anhydrous magnesium sulfate, the organic solvent was removed under vacuum to give the crude ester as a solid or an oil which solidified upon standing. These crude products were recrystallized from acetonitrile–1,2-dichloroethane mixtures.

O-Hippuryl-DL-*2-hydroxyisovaleric acid (1: R = $CH(CH_3)_2$)*: yield 54% from 2-bromoisovaleric acid; m.p. 162–163°; p.m.r. (CF_3CO_2H): δ 1.14 (6H, m), 2.37 (1H, m), 4.60 (2H, d, J_{CHNH} = 4 Hz), 5.23 (1H, d, J = 4 Hz), 7.73 (6H, m).

Anal. Calcd. for $C_{14}H_{17}NO_5$: C 60.2; H 6.14; N. 5.02. Found: C 60.4; H 6.19; N 5.15.

O-Hippuryl-DL-*2-hydroxyvaleric acid (1: R = $(CH_2)_2CH_3$)*: yield 42% from 2-bromovaleric acid; m.p. 137–139°; p.m.r. (CF_3CO_2H): δ 1.07 (3H, t, J = 7 Hz), 1.83 (4H, m), 4.63 (2H, d, J = 4 Hz), 5.40 (1H, t, J = 6 Hz), 7.80 (6H, m).

Anal. Calcd. for $C_{14}H_{17}NO_5$: C 60.2; H 6.14; N 5.02. Found: C 60.35; H 6.29; N 4.94.

O-Hippuryl-DL-*2-hydroxyisocaproic acid (1: R = $CH_2CH(CH_3)_2$)*: yield 49% from 2-bromoisocaproic acid; m.p. 128–129°; p.m.r. (CF_3CO_2H): δ 1.12 (6H, d, J = 6 Hz), 2.00 (3H, m), 4.65 (2H, d, J = 4 Hz), 5.47 (1H, distorted triplet), 7.77 (6H, m).

Anal. Calcd. for $C_{15}H_{19}NO_5$: C 61.4; H 6.54; N 4.77. Found: C 61.3; H 6.79; N 4.89.

O-Hippuryl-DL-*2-hydroxycaproic acid (1: R = $(CH_2)_3CH_3$)*: yield 35% from 2-bromocaproic acid; m.p. 158–159°; p.m.r. (CF_3CO_2H): δ 0.95 (3H, t, J = 6 Hz), 1.48 (4H, m), 2.07 (2H, m), 4.58 (2H, d, J = 4 Hz) 5.32 (1H, t, J = 6 Hz), 7.73 (6H, m).

Anal. Calcd. for $C_{15}H_{19}NO_5$: C 61.4; H 6.54; N 4.77. Found: C 61.2; H 6.47; N 4.76.

O-Hippuryl-DL-*2-hydroxyoctanoic acid (1: R = $(CH_2)_5CH_3$)*: yield 80% from 2-bromooctanoic acid; m.p. 142–143°; p.m.r. (CF_3CO_2H): δ 0.95 (3H, t, J = 6 Hz), 1.42 (8H, m), 2.05 (2H, m), 4.63 (2H, d, J = 4 Hz), 5.38 (1H, t, J = 6 Hz), 7.77 (6H, m).

Anal. Calcd. for $C_{17}H_{23}NO_5$: C 63.5; H 7.21; N 4.36. Found: C 63.0; H 7.34; N 4.30.

O-Hippuryl-DL-*mandelic acid (1: R = C_6H_5)*: yield 77% from hippuryl chloride and DL-mandelic acid; m.p. 151–152°; p.m.r. (CF_3CO_2H): δ 4.68 (2H, d, J_{CHNH} = 4 Hz), 6.32 (1H, s), 7.55–7.73 (11H, m).

Anal. Calcd. for $C_{17}H_{15}NO_5$: C 65.2; H 4.83; N 4.47. Found: C 65.1; H 5.18; N 4.53.

O-Hippuryl-L-*mandelic acid*: yield 63% from hippuryl chloride and L-mandelic acid; m.p. 166–167° (lit. (24) 167–168°); $[\alpha]_D^{24}$ +102° (*c* 3.04, dimethyl formamide) (lit. (24) +104° (*c* 3.14, dimethyl formamide).

O-Hippuryl-D-*mandelic acid*: yield 56% from hippuryl chloride and D-mandelic acid; m.p. 165–166° $[\alpha]_D^{24}$ −102° (*c* 2.94, dimethyl formamide).

O-Hippuryl-DL-*3-phenyllactic Acid (1; R = $CH_2C_6H_5$)*: prepared as the sodium salt as described by McClure (23); m.p. 191–194° after recrystallization from acetone (lit. (23) 125–126°). This product has a satisfactory p.m.r. spectrum and is 50% hydrolyzed by carboxypeptidase A. The difference between the m.p. of this product and the literature value may be due to water of crystallization in the literature product. Commercial samples of this salt frequently contain one (or more) mole of water per mole of sodium salt.

Kinetics

Carboxypeptidase A was obtained as a toluene-preserved suspension from Worthington Biochemical Corporation (Code COA). Stock solutions of this enzyme and of the substrates were prepared as described previously (14).

All hydrolyses (enzymic and nonenzymic) were followed on a Radiometer p*H*-Stat in aqueous solution at 25°, ionic strength 0.5 (substrate + NaCl). The general experimental technique and estimation of the velocities for the enzymic hydrolyses (performed at p*H* 7.5) have been described elsewhere (14). Calculations for the racemic esters are based on the assumption that only the L-ester is hydrolyzed. This has been established for several carboxypeptidase A substrates (3, 5, 11, 25) and was supported by the observation that only 50 ± 2% of each racemic ester had been hydrolyzed by carboxypeptidase A at equilibrium. We also confirmed that *O*-hippuryl-L-mandelic acid is 100% hydrolyzed by carboxypeptidase A, and that the D-enantiomer is not a substrate for this enzyme.

All esters were completely hydrolyzed in aqueous base (p*H* 10–11). Pseudo first-order rate constants for the non-enzymic reactions were obtained from the slopes of linear first-order plots, and in each case the values of k_{OH} were obtained by averaging four runs in the region p*H* 10–11.

Results

The dependence of initial velocity of enzymic hydrolysis on substrate concentration at p*H* 7.5 is shown in Fig. 1 for nine hippuric acid esters: **1**: R = CH_3; CH_2CH_3; $(CH_2)_2CH_3$; $(CH_2)_3CH_3$; $(CH_2)_5CH_3$; $CH(CH_3)_2$; $CH_2CH(CH_3)_2$; C_6H_5; $CH_2C_6H_5$. In each case, substrate inhibition is clearly important at high substrate concentrations. For each ester, Lineweaver–Burk plots at substrate concentrations less than that at which the maximum velocity occurs are linear, and so suggest that in these low substrate concentration ranges the reactions proceed through the formation of an E.S complex. The intercepts of such plots afford estimates of k_{cat} and K_m for each ester (although these parameters are better evaluated as described later), except for the lactic acid derivative, **1**: R = CH_3, for which both intercepts are indistinguishable from zero (Fig. 2) and thus suggest that K_m is relatively large for this ester.

Inspection of Fig. 1 at high substrate concentrations suggests that the velocity does not decrease to zero at very large substrate concentrations, but rather approaches a nonzero limiting

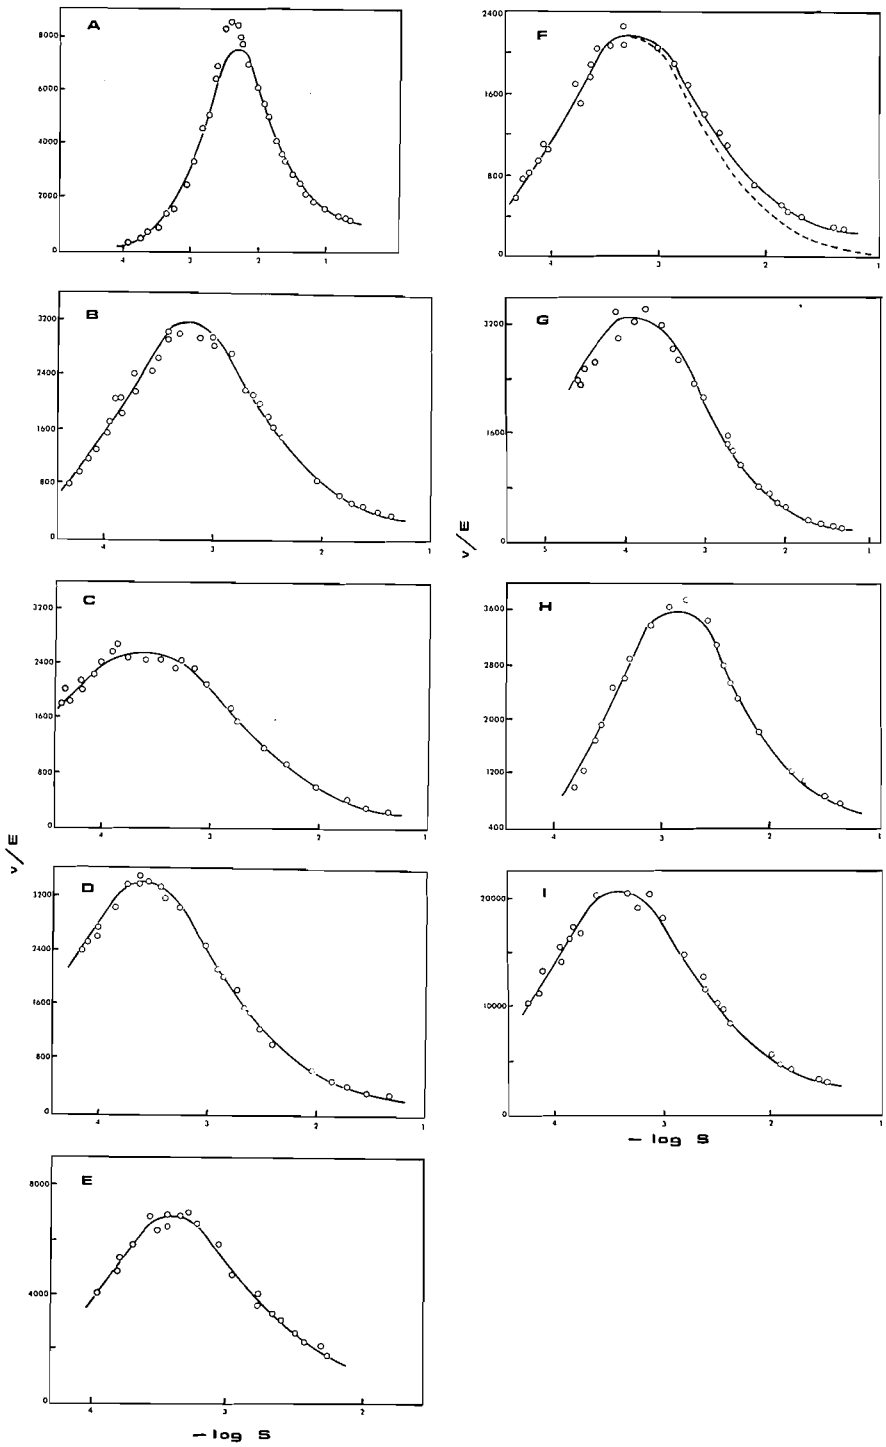

FIG. 1. Dependence of initial velocity (v/E, min^{-1}) on substrate concentration for the hydrolysis of the L-enantiomer (S, mol/l) of racemic esters $C_6H_5CONHCH_2CO_2CHRCO_2H$ by carboxypeptidase A (pH 7.5, 25°, ionic strength 0.5): (*A*) R = CH_3; (*B*) R = CH_2CH_3; (*C*) R = $(CH_2)_2CH_3$; (*D*) R = $(CH_2)_3CH_3$; (*E*) R = $(CH_2)_5CH_3$; (*F*) R = $CH(CH_3)_2$; (*G*) R = $CH_2CH(CH_3)_2$; (*H*) R = C_6H_5; (*I*) R = $CH_2C_6H_5$. Lines indicate the calculated velocities according to eq. 2 and the parameters in Table 1. The broken line is the best fit for $k_3 = 0$.

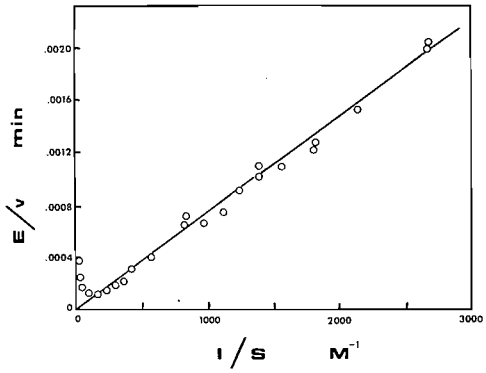

FIG. 2. Lineweaver–Burk plot for the hydrolysis of the L-isomer of the racemate of $C_6H_5CONHCH_2CO_2$-$CH(CH_3)CO_2H$ by carboxypeptidase A (p*H* 7.5, 25°, ionic strength 0.5).

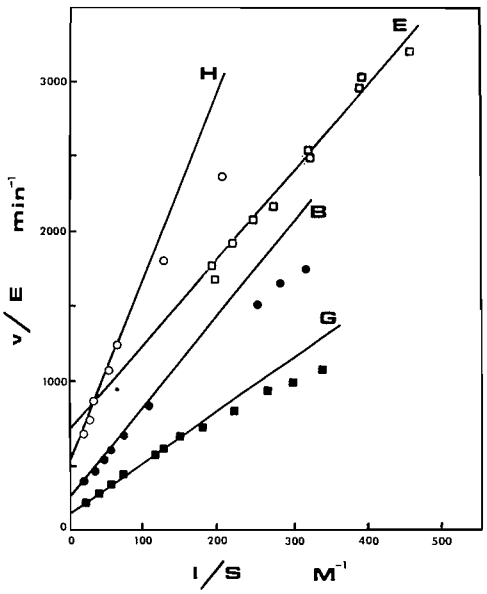

FIG. 3. Dependence of v/E on $1/S$ for some esters in Fig. 1.

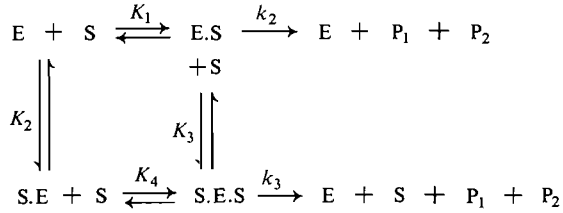
value. Support for a nonzero limiting velocity is also provided by plots of v/E *vs.* $1/S$ shown in Fig. 3. For each ester, such plots approach linearity at the highest substrate concentrations and upon extrapolation to $1/S = 0$ it is clear that the limiting velocity (*i.e.* ordinate intercept) is nonzero.

The simplest kinetic scheme that is capable of fitting the observed overall dependence of initial velocity on substrate concentration seems to be that shown in Scheme 1. If it is assumed that the equilibria are established rapidly relative to k_2 and k_3, then Scheme 1 predicts the



SCHEME 1

velocity dependence in eq. 1, which has the form of eq. 2. Equation 2 has been fitted to the experi-

$$[1]\quad \frac{v}{E} = \frac{\dfrac{k_2 S}{(1 + K_1/K_2)} + \dfrac{k_3 S^2}{K_3(1 + K_1/K_2)}}{\dfrac{K_1}{1 + K_1/K_2} + S + \dfrac{S^2}{K_3(1 + K_1/K_2)}}$$

$$[2]\quad \frac{v}{E} = \frac{k_2^{app} S + k_3 S^2/K_{SS}^{app}}{K_S^{app} + S + S^2/K_{SS}^{app}}$$

mental data for each of the nine esters in Fig. 1 by the iteration technique that we have previously described (26) for second-degree equations of this form. For all esters except **1**: R = CH_3 and **1**: R = $(CH_2)_5CH_3$, unique sets of parameters k_2^{app}, k_3, K_S^{app}, and K_{SS}^{app} were obtained from the iteration and are collected in Table 1; the curves in Fig. 1 are calculated using eq. 2 and these determined parameters, and give an acceptable fit to the experimental data. In agreement with the extrapolations in Fig. 3, the iteration procedure also suggests a nonzero limiting velocity. Modified iterations, in which k_3 was fixed at zero, gave considerably poorer fits to the experimental data in all cases than the fits obtained from the free iterations. An example of the type of velocity–concentration profile obtained for $k_3 = 0$ is shown for **1**: R = $CH(CH_3)_2$ in Fig. 1 (broken line), and it is clear that this assumption forces the velocity to fall off more rapidly at higher substrate concentrations than is actually observed experimentally.

Unlike the cases discussed above, the data for **1**: R = $(CH_2)_5CH_3$ could not be fitted to eq. 2 by a unique set of kinetic parameters. Multiple solutions to eq. 2 were obtained from the iteration technique, each having less than 5% average error between calculated and experimental velocities. In fact, any value for K_{SS}^{app} less than $5 \times 10^{-4}\,M$ (with suitable modification of the other parameters) leads to an acceptable fit to the data for this ester. In an effort to select the physically meaningful solution to eq. 2 for this ester, a combination of graphical and iter-

ative analyses was attempted. Thus, when k_3 was fixed at the limiting value indicated for this ester in Fig. 3 (700 min^{-1}), and the other three parameters were allowed to vary during the iteration to give the best fit to the experimental data, a unique solution was obtained. The parameter values for this solution are included in Table 1. The multiple solutions obtained in the free iteration for this ester seem to be related to the limited substrate concentration range that could be covered ($<5\times10^{-3}$ M) owing to solubility limitations. Unlike the other esters, in this case the approach to the limiting velocity at high substrate concentrations does not seem to be sufficiently well defined to allow a unique fit in the free iteration.

A different problem was encountered in attempting to fit the data for **1**: R = CH_3 to eq. 2. The best fit obtained is shown in Fig. 1 using the parameters in Table 1, and gives an average error of 10.1%. This relatively large error in the difference between calculated and experimental velocities is mainly due to the inability of the calculated curve to afford a satisfactory fit to the data points in the vicinity of the maximum velocity. This negative deviation of eq. 2 in this region was encountered for all sets of parameters which give reasonable fits to the data at both low and high substrate concentrations, and seems to suggest that eq. 2 is not sufficient to represent the experimental data in this case.

The influence of the presence of the D-ester in these racemic substrates has been investigated in the case of *O*-hippurylmandelic acid (**1**: R = C_6H_5). The dependence of the initial velocity of enzymic hydrolysis upon the concentration of the L-isomer is indicated in Fig. 4 for

FIG. 4. the pure L-ester, the racemic ester, and a mixture of the D and L esters in the ratio D/L = 9.2 at all substrate concentrations. The data obtained for the pure L-isomer are in close agreement with those reported previously for this ester by Kaiser and co-workers (7). The data in Fig. 4 clearly indicate that the D-ester is an inhibitor of the hydrolysis of its enantiomer at high substrate concentrations. Each of these three sets of experimental data can be fitted to eq. 2 to give the kinetic parameters in Table 2. The only param-

eter that is significantly affected by the increasing proportions of D-isomer is K_{SS}^{app}, with K_S^{app}, k_2^{app}, and k_3 all being effectively constant within experimental error. The ability of the D-ester to change K_{SS}^{app}, but not k_3, suggests that the nature of the inhibition by the D-isomer is essentially similar to that caused by the L-ester when the latter acts as an inhibitor of its own hydrolysis. Thus the enzyme, L-ester substrate (S) and D-ester inhibitor (I), may combine to form an I.E.S. complex which must then react at about the same rate as for the S.E.S species in Scheme 1, if k_3 is to be independent of inhibitor concentration as is observed.

The rates of the nonenzymic base-catalyzed hydrolysis of some of these hippurate esters have also been measured. Second-order rate constants, k_{OH}, are collected in Table 3, and are compared with k_2^{app} for the enzymic hydrolyses.

Discussion

With the exception of **1**: R = CH_3, the substrate inhibition observed in the enzymic hydrolysis of the eight other hippuric acid esters in the present study appears to be assignable to the binding of two molecules of substrate to the enzyme. Substrate inhibition occurs because the rate of hydrolysis of the $E.S_2$ complex (k_3) is significantly smaller than that of the E.S complex (k_2). As the results of the experiments with *O*-hippuryl-D-mandelic acid show, the role of an L-ester substrate as an inhibitor can also be assumed by the D-ester. The action of carboxypeptidase A on the racemic hippuric acid esters is thus best described in terms of the three complexes E.S, $E.S_2$, and E.S.I, all of which can hydrolyze to form products. The substrate inhibition of the carboxypeptidase A catalyzed hydrolysis of **1**: R = $CH_2C_6H_5$ was ascribed previously by McClure *et al.* (3) to a complex reaction sequence involving two enzyme species and $E.S_5$ complexes. In contrast, the data obtained here for this same ester can be explained by a much simpler scheme, which invokes no more than two molecules of substrate, binding to a single enzyme species.

[a]At 25°, ionic strength 0.5.

The scheme proposed previously by Kaiser and co-workers (7) to account for substrate inhibition in the hydrolysis of *O*-hippuryl-L-mandelic acid by carboxypeptidase A is essentially Scheme 1, but with the additional assumption that $E.S_2$ is nonproductive, *i.e.* $k_3 = 0$. As discussed above, this assumption leads, in general, to a significantly poorer fit between the calculated and experimental velocities for the hippuric acid ester substrates than when k_3 is allowed to assume positive values.

The conclusion that substrate inhibition can be attributed, in general, to the binding of two molecules of substrate to the enzyme is in good agreement with theoretical models proposed previously to account for the phenomenon. Based mainly on kinetic studies, Vallee and co-workers (17, 27) postulated that the hydrolysis of ester and peptide substrates by carboxypeptidase A occurs at two different catalytic sites, each of which can bind but not hydrolyze, *both* types of substrate. They suggested that substrate inhibition (or activation) could arise from the binding of a second molecule of substrate to the "wrong" site. For example, substrate inhibition of ester hydrolysis would result, on the basis of this model, from binding of a second molecule of ester to the peptide catalytic

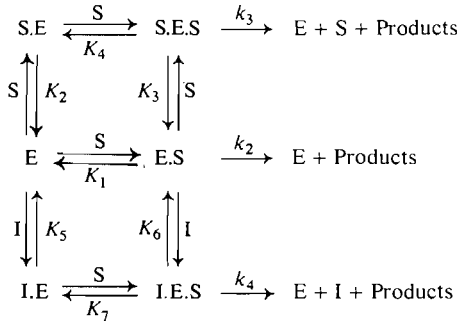
For personal use only.



SCHEME 2

site. Subsequently, Lipscomb and co-workers deduced from their X-ray diffraction work (18–20) that the active site of carboxypeptidase A is located at the bottom of a deep cleft in the enzyme. Model building studies indicated that this cleft could accommodate two, but no more than two, *N*-acyl dipeptide (or depsipeptide) molecules. Lipscomb has suggested that binding of two substrate molecules in this manner might account for the observed substrate inhibition and activation phenomena.

In the light of the current observation that the presence of the D-ester can influence the rate of hydrolysis of the L-ester, Scheme 1 must be modified as in Scheme 2 (where I represents the D-ester) which generates the rate eq. 3.

$$[3] \qquad \frac{v}{E} = \frac{k_2 S + (k_3/K_3)S^2 + (k_4/K_6)I.S}{K_1 + (1 + K_1/K_2)S + (K_1/K_5)I + (1/K_3)S^2 + (1/K_6)I.S}$$

For a constant ratio n of the D- to L-isomer, eq. 3 may be transformed to eq. 4

$$[4] \qquad \frac{v}{E} = \frac{k_2 S + [(k_3/K_3) + (nk_4/K_6)]S^2}{K_1 + [1 + (K_1/K_2) + (nK_1/K_5)]S + [(1/K_3) + (n/K_6)]S^2}$$

which may be rearranged to have the same form as eq. 2, but with

$$[5] \qquad K_S^{app} = \frac{K_1}{1 + (K_1/K_2) + (nK_1/K_5)}$$

$$[6] \qquad k_2^{app} = \frac{k_2}{1 + (K_1/K_2) + (nK_1/K_5)}$$

$$[7] \qquad K_{SS}^{app} = \frac{1 + (K_1/K_2) + (nK_1/K_5)}{(1/K_3) + (n/K_6)}$$

$$[8] \qquad k_3^{app} = \frac{(k_3/K_3) + (nk_4/K_6)}{(1/K_3) + (n/K_6)}$$

If the random binding of the substrate and its D-isomer to the enzyme is operative, as in Scheme 2, an increase in the D- to L-isomer ratio, n, should effect a reduction in k_2^{app} and K_S^{app}, little or no change in k_3^{app}, and an unpredictable change in K_{SS}^{app}. The data obtained for the enzymic hydrolysis of mixtures of D- and L-*O*-hippurylmandelic acid demonstrate (Table 2) that increasing the value of n from 0 to 9.2 in this system causes a marked decrease in K_{SS}^{app}, but no significant changes in K_S^{app}, k_2^{app}, and k_3^{app}. These results are inconsistent, apparently, with the behavior predicted for Scheme 2, although the apparent independence of k_3^{app} of n suggests that $k_3 \approx k_4$ for this system. However, if the inequality [9] were to hold, then

$$[9] \qquad nK_1/K_5 < 1 + (K_1/K_2)$$

eqs. 5–8 would reduce to eqs. 10–13

$$[10] \qquad K_S^{app} = \frac{K_1}{1 + (K_1/K_2)}$$

$$[11] \qquad k_2^{app} = \frac{k_2}{1 + (K_1/K_2)}$$

$$[12] \qquad K_{SS}^{app} = \frac{1 + (K_1/K_2)}{(1/K_3) + (n/K_6)}$$

$$[13] \qquad k_3^{app} = \frac{(k_3/K_3) + (nk_4/K_6)}{(1/K_3) + (n/K_6)} = K_3 \text{ (for } k_3 = k_4)$$

which indicate that only K_{SS}^{app} should be dependent on n, which is consistent with the data of Table 2. Equation 12 may be combined with the values of K_{SS}^{app} and n listed in Table 2 to afford $K_3(1 + K_1/K_2) = K_6(1 + K_1/K_2) = 2.6$ mM, *i.e.* $K_3 = K_6$. Thus, the two enantiomers of the ester have equal affinity for the inhibitory site in the E.S complex.

For the enzymic hydrolysis of mixtures of the enantiomers of *O*-hippurylmandelic acid, K_6 cannot be greater than 2.6 mM, while K_1 cannot be less than 1.0 mM (since $K_1 > K_S^{app}$). Thus, when $n = 9.2$, nK_1/K_6 must be greater than 3.3. Clearly, K_5 must be appreciably greater than K_6

if the inequality [9] is to remain valid at all values of n investigated.[3] Binding of the D-ester inhibitor to the regulatory site is thus facilitated if an L-ester substrate molecule is already bound to the active site. This type of behavior, involving cooperative interaction between two binding sites, is commonly observed in allosteric enzymes (28).

The inequality [9] also indicates that K_5 must be considerably greater than K_1; *i.e.* the affinity of E for binding of L-ester at the catalytic site, *i.e.* formation of E.S, is much greater than for binding of D-ester at the inhibitory regulatory site (I.E). A special case of $K_5 > K_1$ is obligatory ordered binding of substrate to the catalytic site before inhibitor may bind to the regulatory site (*i.e.* $K_5 = \infty$). Thus, this special case of Scheme 2 cannot be distinguished for this ester from genuine random binding for which the inequality [9] is obeyed. It should also be noted that if K_5 is infinite, then K_2 is also likely to be infinite (since $K_3 = K_6$ is indicated above), and so the data of Table 2 are also consistent with ordered binding of the L-ester to catalytic and inhibitory sites. In fact, the restriction inherent in inequality [9] implies that substrate inhibition via formation of an $E.S_2$ complex approximates ordered binding of the two substrate molecules to the enzyme for this ester.

In a recent report, Lang and co-workers (29) have shown that *O*-hippuryl-D-3-phenyllactic acid inhibits the hydrolysis of its L-enantiomer. Although these workers have not attempted a detailed kinetic analysis of the nature of this inhibition, inspection of their data suggests that the influence of the D-isomer in the racemate on the hydrolysis of the L-isomer of this ester is exactly analogous to our observations on the lower homolog *O*-hippurylmandelic acid (Fig. 4). The actual form of inhibition which is observed for these D-esters with their L-enantiomers as substrates must be construed as mixed inhibition, since from the above discussion it is clear that $K_5 \neq K_6$ and $k_4 \neq k_2$.

All other hippuric acid esters studied in this work are racemic mixtures. If the random binding mechanism of Scheme 2 is applicable to the carboxypeptidase A catalyzed hydrolysis of these esters, the dependence of initial velocity on L-ester substrate concentration should be described by eq. (4) (where $n = 1$) and the apparent kinetic parameters by eqs. 5–8 (with $n = 1$). Inspection of the experimental values for the parameters in Table 1 indicates that K_{SS}^{app} is essentially constant for all seven esters listed, while K_S^{app} depends strongly on the nature of the R side chain. These two observations can be satisfied simultaneously by the eqs. 5–8 ($n = 1$) only if one of the following conditions is valid: (*a*) K_1/K_2 and K_1/K_5 are variable, but K_3 and K_6 vary in such a way that K_{SS}^{app} is always approximately constant; (*b*) K_1/K_2, K_1/K_5, K_3, and K_6 are all constant, but K_1 varies from one ester to another; (*c*) K_3 and K_6 are constant, and for all esters studied, the inequality (14) is valid.

$$[14] \qquad K_1/K_2 + K_1/K_5 \ll 1$$

It seems extremely unlikely that five different equilibrium constants can all vary in such a manner that their combination in K_{SS}^{app} remains unchanged. Thus, condition *a* can probably be ruled out. Condition *b* implies that binding of the ester (D or L) to the regulatory site of the free enzyme should be dependent on the R side chain, whereas binding of the ester to the regulatory site of the E.S complex should be independent of the side-chain. Although not impossible, this does not seem too probable. Condition *c* seems to be the only one capable of explaining the variation of K_S^{app} and constancy of K_{SS}^{app} in a satisfactory manner. The inequality [14] in condition *c* asserts that the L-ester is bound much more strongly to the active site of the free enzyme than either enantiomer is to the regulatory site. This restriction is essentially similar to that required (inequality [9]) in the interpretation of *O*-hippuryl-mandelic acid hydrolysis by a random binding scheme, and so suggests that for each of the esters in Table 1, formation of $E.S_2$ approximates ordered binding. Thus, using condition *c* and $K_3 = K_6$ and $k_3 \approx k_4$ as were established above for the mandelic acid derivative, the eqs. 5–8 (with $n = 1$) simplify to:

$$K_S^{app} = K_1$$
$$k_2^{app} = k_2$$
$$K_{SS}^{app} = K_3/2$$
$$k_3^{app} = k_3$$

Thus, K_S^{app} represents the dissociation constant of the catalytically active E.S complex; k_2^{app} is

[3]This argument assumes that K_2 cannot be considerably smaller than K_1, so that $K_1/K_2 \gg 1$ is not possible. This assumption is supported by the constancy of K_{SS}^{app} for the various hippuric acid esters, as discussed later.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

the specific rate of hydrolysis of E.S; K_{SS}^{app} for racemic esters is half of the dissociation constant for $E.S_2$ to E.S and S; and k_3^{app} is the specific rate of hydrolysis of $E.S_2$.

The effect of the R side chain of the alcohol moiety of the hippuric acid esters **1** on the rate of hydrolysis of the E.S complex may be compared with the effect of R on the alkaline hydrolysis of these esters by consideration of the k_2^{app}/k_{OH} ratios in Table 3. These results suggest that, to a first approximation, the influence of R on the enzymic hydrolysis is not seriously different from the effect of R on the alkaline hydrolysis. Possible exceptions to this behavior are manifested by the enhanced k_2/k_{OH} values for the esters **1**: R = $CH_2C_6H_5$ and **1**: R = $(CH_2)_5CH_3$. The k_2^{app} values for these two esters are clearly larger than one would predict from a comparison of the enzymic and alkaline hydrolysis rates of the other substrates. In these two cases, the labile ester group may possibly be closer to (or better oriented with respect to) the catalytic groups of the enzyme, perhaps because of increased steric interaction between the larger R groups of these substrates and the enzyme.

The values of k_2 and K_1 from Table 1 are both dependent on the nature of the R side chain of the ester; however, there is no apparent relationship between these two parameters. Independent behavior of k_2 and K_1 has also been observed by Auld and Vallee (15, 16) in the hydrolysis of *N*-acyl tripeptides by several metallocarboxypeptidases at various p*H* values. This result is compatible with the assumption that the binding of substrate to the active site is fast relative to the rate of hydrolysis of the E.S complex, since if the rates of equilibration of E and E.S were comparable with k_2, then one would expect an influence of k_2 on K_S^{app}.

Inspection of the values of K_{SS}^{app} ($= K_3/2$) in Table 1 indicates that, with the exception of **1**: R = $(CH_2)_5CH_3$ and **1**: R = CH_3, K_3 is approximately constant for the other esters listed. Thus, the binding of most substrates to the regulatory site of E.S is independent of the size, nature, or hydrophobicity of the R side chain. The constancy of K_{SS}^{app} for the racemic esters also implies that the R group has no significant influence on the binding of D enantiomers of these substrates to the regulatory site. The binding of either enantiomer to the E.S complex must, therefore, involve only the 2-hippuroxyacetate moiety of the ester. These results suggest that the ester molecule is bound to the regulatory site of E.S such that the R side chain does not contact the enzyme molecule. The smaller K_{SS}^{app} and K_3 values for **1**: R = $(CH_2)_5CH_3$ may reflect the onset of an increased interaction between the regulatory site and the side chain when R becomes large, or may be due to the increased relief of solvent entropy when this large hydrophobic moiety is removed from a strictly aqueous environment.

With the possible exception[4] of **1**: R = $(CH_2)_5CH_3$, values of the ratio k_2/k_3 listed in Table 1 appear to be constant within experimental error. Thus, the second ester molecule appears to bind so as to decrease the rate of enzymatic hydrolysis by a constant factor, independent of the nature of R. This could be accomplished if the binding of the ester molecule to the regulatory site were to cause a small but constant conformational change at the active site, such that the distance between (or orientation of) the catalytic groups of the enzyme and the ester bond of the substrate becomes altered. Conformational mobility of the active site region of carboxypeptidase A has been clearly indicated by X-ray diffraction, chemical modification, and spectroscopic studies (19, 20, 30–33). The independence of the proposed conformational change on the R side chain is not too surprising if, as discussed above, the R group of the ester molecule bound to the regulatory site is not in contact with the enzyme.

Unlike K_3, K_{SS}, and k_2/k_3, the parameter K_1 displays a marked dependence on the nature of the R moiety of the hippuric acid esters. Variation of the hydrophobic R group exerts a strong influence, therefore, on the binding of these substrates to the active site of the enzyme. The X-ray crystallographic studies of carboxypeptidase A suggest that the side chain of the substrate *C*-terminal residue is accommodated at the active site by insertion into a hydrophobic pocket of the enzyme (18–20). The influence of R on substrate binding might be ascribed, therefore, to varying degrees of hydrophobic interac-

[4]As discussed in the Results section, the parameters for this ester were obtained by a less satisfactory method than for the other esters listed in Table 1. Consequently, values of k_2/k_{OH} and k_2/k_3 for this ester may be erroneously high. There is no doubt, however, that K_{SS}^{app} for this ester is significantly smaller than the approximately constant value of 1.0 m*M* obtained for the other substrates.

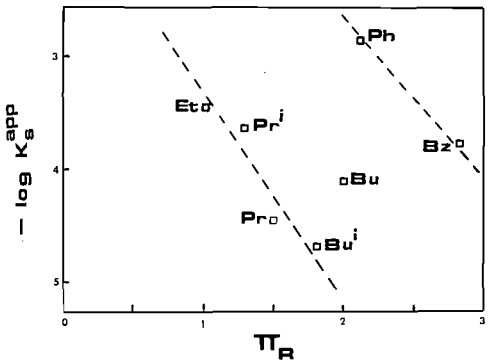

FIG. 5. Dependence of log K_S^{app} on π_R in the hydrolysis of $C_6H_5CONHCH_2CO_2CHRCO_2H$ by carboxypeptidase A. Linear correlations (broken lines) are suggested by inhibition studies (21, 22).

tion between the substrate and the enzyme. The importance of hydrophobic interaction between the enzyme and inhibitor anions has been demonstrated in our laboratory (21, 22) by showing that inhibition constants for the binding of RCO_2^- and $RCH(CO_2^-)_2$ which are competitive inhibitors of the hydrolysis of **1**: R = $CH_2C_6H_5$ by carboxypeptidase A are linearly correlated with Hansch's π parameter (34, 35), provided the hydrophobic moiety of the inhibitor does not become too large.

The dependence of K_1 for the present hippuric acid esters on π is shown in Fig. 5. Although data over only a relatively narrow range of π values is available, two points are clear from this plot. Firstly, increasing the hydrophobic character of R strengthens the binding of substrate to the enzyme only if R is relatively small. Beyond a certain optimum hydrophobicity (π value), binding of substrate is weakened, presumably because the R group is now too large to fit into the hydrophobic pocket in its energetically most favorable conformation. Secondly, substrates with aromatic side chains are bound less strongly to the active site than those with aliphatic side chains of comparable hydrophobicity. Both of these features are also observed in the binding of the above competitive inhibitor carboxylate anions to this enzyme (21, 22) and so there can be little doubt that the hydrophobic side chains of the ester substrates **1** and the carboxylate anion inhibitors previously studied are accommodated by the same hydrophobic region of the enzyme.

The apparent discrimination of aliphatic and aromatic hydrophobic groups by the enzyme is not readily interpreted. Such discrimination does not appear to be present in the binding of peptide substrates for which carbobenzoxyglycylglycyl-L-phenylalanine ($K_m = 2.5 \times 10^{-4}$ *M*) apparently binds about tenfold more strongly to carboxypeptidase A than does carbobenzoxyglycylglycyl-L-leucine ($K_m = 3 \times 10^{-3}$ *M*) (15) in accord with the greater hydrophobicity of the benzyl side chain (π = 2.63) of phenylalanine than of the isobutyl side chain (π = 1.80) of leucine. The data for the analogous hippurate esters, **1**: R = $CH_2C_6H_5$ and **1**: R = $CH_2CH(CH_3)_3$, in Table 1 indicate that the isobutyl side chain appears to be bound approximately eight times more strongly than the benzyl group. This points out a further way in which carboxypeptidase A discriminates between ester and peptide substrates, and is in accord with the now generally accepted view of different productive binding modes to this enzyme for ester and peptide substrates (17, 29, 36, 38).

The inability to fit the maximum velocity observed for the lactic acid derivative (**1**: R = CH_3) with eq. 2 suggests that both substrate activation and substrate inhibition may be occurring to some extent with this ester. In view of our recent observations (9) of substrate activation with the related *O*-hippuryl-2-methyllactic acid and the known substrate activation for *O*-hippurylglycolic acid, the occurrence of substrate activation for **1**: R = CH_3 is not really unexpected. Even in the absence of any interference from substrate activation, one might have predicted that **1**: R = CH_3 could show a different overall set of kinetic parameters for eq. 2 than the other esters investigated here. Thus, the expected large value of K_1 for this ester may lead to the inequalities [9] and [14] not being applicable in this case and so the simplified forms of K_S^{app}, k_2^{app}, and K_{SS}^{app} discussed above may not hold for this ester.

We appreciate the continued support of this work by the National Research Council of Canada and the award of an Ontario Graduate Fellowship to J.M.

An Epitetrathiodioxopiperazine with 3*S*,6*S* Configuration from *Hyalodendron* sp.

GEORGE M. STRUNZ, MASATOSHI KAKUSHIMA, AND MERLYN A. STILLWELL

Canadian Forestry Service, P.O. Box 4000, Fredericton, New Brunswick E3B 5G4

Received July 24, 1974

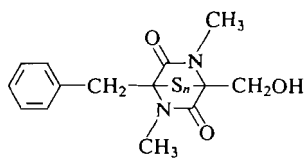
GEORGE M. STRUNZ, MASATOSHI KAKUSHIMA, and MERLYN A. STILLWELL. Can. J. Chem. **53**, 295 (1975).

(3*S*,6*S*)3-Benzyl-6-hydroxymethyl-1,4-dimethyl-3,6-epitetrathiopiperazine-2,5-dione has been isolated from cultures of *Hyalodendron* sp. The same compound is produced when hyalodendrin is heated with methanol – hydrochloric acid.

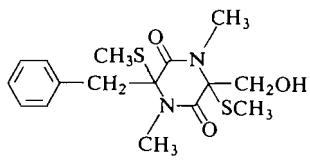
GEORGE M. STRUNZ, MASATOSHI KAKUSHIMA et MERLYN A. STILLWELL. Can. J. Chem. **53**, 295 (1975).

La (3*S*,6*S*) 3-Benzyl-6-hydroxyméthyl-1,4-diméthyl-3,6-epitetrathiopiperazine-2,5-dione a été isolé de cultures d'une espèce *d'Hyalodendron*. Le même composé est produit en chauffant l'hyalodendrine avec une solution de méthanol et d'acide chlorhydrique.

The fungitoxic epidithiodioxopiperazine hyalodendrin, **1**, and the corresponding di(methylthio) ether, **2**, both with 3*S*,6*S* configuration have recently been isolated from culture filtrates of *Hyalodendron* sp. (1–3). Metabolites **1** and **2**, and the trisulfide **3**, of undetermined absolute configuration, were obtained from cultures of an unidentified fungus (NRRL 3888) (4). The metabolite **1**, with *R* configuration at positions 3 and 6, and compounds **2** and **4**, evidently belonging to the same stereochemical series, are produced by *Penicillium turbatum* (5). Gliovictin, a metabolite of *Helminthosporium victoriae* also has structure **2** (6) and is likewise enantiomeric (3*R*,6*R*) with the corresponding *Hyalodendron* product.



1 $n = 2$
3 $n = 3$
4 $n = 4$



2

We record here some observations made during a study of the 3*S*,6*S* tetrasulfide **4**, isolated from fermentations of *Hyalodendron* sp. This compound, $C_{14}H_{16}N_2O_3S_4$, was present in chloroform extracts of the filtered culture medium in amounts which ranged up to 3% of the yield of pure hyalodendrin. It was slightly more polar than the latter, and could be separated and purified by preparative-layer chromatography, followed by crystallization. Comparison of the spectral characteristics of **4** (see Experimental section) with those of its co-metabolites **1** and **2** leave no doubt as to its constitution. Comparison of the circular dichroism curve of the *Hyalodendron* tetrasulfide (see Experimental section) with that published for the *Penicillium* metabolite (5) establishes that these compounds are enantiomeric at positions 3 and 6. A detailed discussion of the geometry of the tetrasulfide system of **4** is deferred at this stage, although it is noted that the synthetic compound *N*,*N'*-dimethyl-3,6-epitetrathiopiperazine-2,5-dione and sporidesmin G have been shown by X-ray analysis to be structurally similar with respect to the epitetrathiodioxopiperazine moiety (7, 8).

A tetrasulfide, identical in all respects (including c.d. spectrum) with the *Hyalodendron* tetrasulfide, was obtained in modest yield when hyalodendrin was refluxed in methanolic hydrochloric acid until no starting material remained (t.l.c.). By-products from this transformation, depleted in sulfur, resisted preliminary purifica-

tion attempts and have not been investigated further at this stage. Tetrasulfide formation was also effected in low yield by shaking a solution of hyalodendrin in the culture medium (3) (initial p*H* 3.5, methanol co-solvent) for a period comparable with the fermentation time. This result raises the possibility that the tetrasulfide isolated could be an artifact, formed from hyalodendrin by a similar acid-catalyzed mechanism. Although such a possibility cannot be excluded at present, the fact that the *P. turbatum* tetrasulfide is produced in a substantially different medium (5), and that sporidesmin G appears to be a true metabolite[1] seems to attest the 'natural' origin of at least part of the *Hyalodendron* tetrasulfide.

Refluxing hyalodendrin in aqueous methanol solution without addition of hydrochloric acid also led to the formation of a tetrasulfide. This transformation occurred more slowly than that in acid solution and the yield of tetrasulfide obtained was substantially higher. The product formed under these conditions was *racemic*.

Conversion of epidithiodioxopiperazines to the corresponding tetrasulfides (with retention of configuration) has previously been effected by the action of dihydrogen disulfide (9, 10). In bioassays, the 3*S*,6*S* tetrasulfide **4** was in general comparable with hyalodendrin (in some cases slightly less effective) in its ability to inhibit the growth of selected test fungi.[2]

Experimental

See refs. 1 and 2 for description of instrumentation, etc.

Isolation of 'Natural' Tetrasulfide 4

The production and isolation of hyalodendrin and bisdethiodi(methylthio) hyalodendrin have been detailed elsewhere (1–3). In a typical isolation sequence, material extracted with chloroform from 37 l of filtered culture medium which had supported growth of *Hyalodendron* sp. for 12 days was chromatographed on a column of silica gel (500 g Kieselgel, 100–200 mesh, Gebr. Herrmann, Köln). The eluates were monitored by t.l.c. Elution with benzene–chloroform (65:35) afforded initially 2 g of hyalodendrin. In the later fractions, the emergence of a second compound, with slightly lower R_f became evident (t.l.c.). Fractions containing the new compound were combined and rechromatographed on a preparative-layer plate of silica gel (benzene–acetone, 9:1, $R_f \sim 0.5$). This separation provided 78 mg of crude tetrasulfide, which gave 60 mg of crystalline material from benzene–cyclohexane. Recrystallization from benzene–cyclohexane afforded colorless crystals, m.p. 133–139° (pulverized crystals, 125–132°); c.d. (*c* 2.81 × 10^{-3} *M* in MeOH, 1 mm cell) λ nm (Δε): 370(0), 328(+0.9), 316(0), 297(−4.4), 287(0), 263(+13.6), 225(inflection +12.1), 230(0), and <220 (−*ve* max); ν_{max}(KBr) *inter alia* 3400, 1666, 1648, 1375, 1060, 742, 735, 701, and 657 cm^{-1}; n.m.r. ($CDCl_3$, 220 MHz) δ 3.03 (3H, s), 3.07 (3H, s) 3.25 (2H, d, $J \sim 15$ Hz), broadened base), 3.83 (1H, d, $J \sim 12$ Hz), 4.02 (1H, d, $J \sim 15$ Hz), 4.20 (1H, d, $J \sim 12$ Hz), 7.09–7.27 (5H, m). The signal for the hydroxyl proton (broad absorption around δ 3.25) disappeared on deuterium exchange. Mass spectrum *inter alia*, *m/e* 260 (base peak) $(M - S_4)^+$, 242 $(M - S_4 - H_2O)^+$, 169 $(M - S_4 - C_7H_7)^+$, and 64.

Anal. Calcd. for $C_{14}H_{16}N_2S_4O_3$: C, 43.27; H, 4.15; N, 7.21; S, 33.01. Found: C, 43.42; H, 4.11; N, 7.20; S, 33.02.

Acid Treatment of Hyalodendrin

Methanol – Hydrochloric Acid

A solution of hyalodendrin (582 mg, 1.79 mmol) in methanol (30 ml) containing 1 *N* aqueous hydrochloric acid (3.0 ml) was heated under reflux for 24 h, when no starting material remained. (Longer reaction times, up to 16 days, did not appear to have much effect on either the yield or c.d. properties of the tetrasulfide product.) After addition of saturated sodium chloride solution, the mixture was extracted thoroughly with chloroform. The extracts were washed with saturated sodium bicarbonate solution, dried ($MgSO_4$), and evaporated *in vacuo*. The tetrasulfide **4** was separated and purified by repeated chromatography on preparative-layer plates of silica gel (benzene–acetone, 94:6). Crystallization from benzene–cyclohexane gave 100 mg (0.257 mmol) of colorless crystals of **4**, m.p. 132–136° (pulverized crystals, 125–132°); mixture melting point with 'natural' **4**: 125–132°; c.d., i.r. (KBr), n.m.r. ($CDCl_3$, 220 MHz), and mass spectra identical with 'natural' **4** (*vide supra*). An analytical sample was prepared by recrystallizations from benzene: colorless prisms, m.p. 135–138°.

Anal. Calcd. for $C_{14}H_{16}N_2S_4O_3$: C, 43.27; H, 4.15; N, 7.21; S, 33.01. Found: C, 43.30; H, 4.16; N, 7.28; S, 32.99.

Culture Medium, pH 3.5 (3)

Because of the low solubility of hyalodendrin in water, methanol was used as co-solvent. An aliquot (1 ml) of a solution of hyalodendrin (2 g) in methanol (40 ml) was added to each of 40 1-l Erlenmeyer flasks, each containing 500 ml of synthetic culture medium at p*H* 3.5 (3). The flasks were stoppered with foam-plastic plugs (as used in fermentation) and shaken on a gyratory shaker at 22° for 14 days (final p*H* ~ 4). Unchanged hyalodendrin and tetrasulfide **4** were recovered from the chloroform extracts by chromatography as described above (isolation of 'natural' tetrasulfide **4**). Recrystallization from benzene–cyclohexane afforded 37 mg of **4** as almost colorless crystals, m.p. 133–142°; c.d. (*c* 2.75 × 10^{-3} *M* in MeOH, 1 mm cell) λ nm (Δε): 370 (0), 330 (+0.9), 318 (0), 298 (−4.2), 288 (0), 264 (+12.8), 254 (inflection + 10.4), 231 (0), and <220 (−*ve* max); i.r. (KBr), and mass spectra identical with those of 'natural' **4**.

Formation of Racemic Tetrasulfide 4

A solution of hyalodendrin (1.0 g, 3.08 mmol) in methanol (40 ml) and water (4 ml) was heated under reflux for 18 days, when no unchanged starting material remained (t.l.c.). A saturated aqueous solution of sodium

[1]Dr. A. Taylor. Personal communication.
[2]M. A. Stillwell. Unpublished data.

chloride was added and the mixture was extracted with chloroform. Material from the chloroform extracts was chromatographed on preparative layer plates of silica gel (benzene–acetone, 9:1), and the product corresponding in R_f with the tetrasulfide **4** was collected. Recrystallization from benzene afforded 410 mg (1.05 mmol, 68% theoretical) of tetrasulfide as almost colorless crystals, m.p. 155–166°; c.d. (c 2.92 × 10^{-3} M in MeOH, 1 mm cell) 600–250 nm, $\Delta\varepsilon = 0$; n.m.r. ($CDCl_3$, 220 MHz) and mass spectra identical with those of 'natural' tetrasulfide **4**. The main peaks in the i.r. (KBr) spectrum were essentially as quoted for 'natural' **4**: minor differences were detectable in the fingerprint region. An analytical sample was prepared by recrystallizations from benzene–chloroform, m.p. 159–166°.

Anal. Calcd. for $C_{14}H_{16}N_2S_4O_3$: C, 43.27; H, 4.15; N, 7.21; S, 33.01; 0, 12.35. Found: C, 43.26; H, 4.20; N, 7.22; S, 32.97; 0, 12.28.

Mol. Wt. Calcd. for $C_{14}H_{16}N_2S_4O_3$: 388.6. Found (osmometer, $CHCl_3$ solvent): 399.

NOTE ADDED IN PROOF: An additional correlation of the *Hyalodendron* tetra- and disulfide has been effected by sodium borohydride reduction of the former, followed by oxidation with iodine–iodide solution (*cf.* ref. 11). This treatment yielded a product, identical in all respects, including c.d. spectrum, with hyalodendrin.

The enantiometric relationship of bisdethiodi(methylthio)hyalodendrin and gliovictin was confirmed by direct comparison of the former with a sample of the latter, kindly provided by Professor Arigoni.

We thank Mr. J. Hoyle, University of Alberta for the circular dichroism measurements and Mrs. M. Austria, University of New Brunswick for the mass spectra.

The Adsorption, Desorption, and Exchange Reactions of Oxygen, Hydrogen, and Water on Platinum Surfaces. II. Hydrogen Adsorption, Exchange, and Equilibration

Y. K. PENG AND P. T. DAWSON[1]

Chemistry Department and Institute for Materials Research, McMaster University, Hamilton, Ontario L8S 4M1

Received August 13, 1974

Y. K. PENG and P. T. DAWSON. Can. J. Chem. **53**, 298 (1975).

The adsorption, desorption, exchange, and equilibration reactions of hydrogen and deuterium on a platinum filament have been investigated by thermal desorption mass spectrometry. A surface saturated with hydrogen at 120 °K has a coverage 4.2×10^{14} molecules cm^{-2} and gives desorption spectra with four distinct peaks: β_1(165 °K), β_2(220 °K), β_3(280 °K), and β_4(350 °K). Apparent activation energies and pre-exponential factors were determined for the β_2-, β_3-, and β_4-peaks. For both co-adsorption and sequential adsorption of H_2 and D_2 the mass 2, 3, and 4 desorption spectra have identical shapes and the gas desorbs at equilibrium throughout. It is concluded that hydrogen adsorbs dissociatively. Exchange and equilibration were studied at 120, 210, and 285 °K by determining the surface composition and isotope distribution after varying fractions of preadsorbed H had been replaced. Following exchange at 120 °K the desorption spectra show a higher D content and a lack of equilibrium in the desorbing gas at low temperature. In most other experiments the mass 2, 3, and 4 desorption spectra had identical shapes and the gas desorbed at equilibrium. The results are interpreted by a model which requires that the polycrystalline platinum surface is intrinsically heterogeneous. It appears that different mechanisms are unnecessary to interpret the differences in kinetics observed for exchange and equilibration at low temperatures.

Y. K. PENG et P. T. DAWSON. Can. J. Chem. **53**, 298 (1975).

On a étudié, par spectrométrie de masse impliquant la désorption, les réactions d'équilibre et d'échange de l'hydrogène et du deutérium sur un filament de platine. Une surface saturée avec de l'hydrogène à 120 °K supporte 4.2×10^4 molécules cm^{-2} et conduit à des spectres de désorption contenant 4 pics distincts: β_1(165 °K), β_2(220 °K), β_3(280 °K) et β_4(350 °K). On a déterminé les énergies d'activation apparente et les facteurs pre-exponentiels pour les pics β_2, β_3, et β_4. Pour la co-adsorption et l'adsorption en séquence de H_2 et D_2, les spectres de désorption des masses 2, 3 et 4 ont des formes identiques et le gaz se désorbe à l'équilibre à tout moment. On en conclut que l'hydrogène s'absorbe d'une façon dissociative. On a étudié l'échange et l'équilibre à 120, 210 et 285 °K en déterminant la composition à la surface et la distribution isotopique après que diverses fractions d'hydrogène préadsorbé avaient été remplacées. Après échange à 120 °K, le spectre de désorption montre un contenu en deutérium qui est plus élevé et un manque d'équilibration dans les gaz désorbants à base température. Dans la plupart des expériences, les spectres de désorption des masses 2, 3 et 4 ont des formes identiques et les gaz se désorbent à l'équilibre. On interprète les résultats à l'aide d'un modèle qui demande que la surface polycristalline du platine soit intrinsèquement hétérogène. Il semble qu'il ne soit pas nécessaire de faire appel à différents mécanismes pour interpréter les différences dans les cinétiques observées pour l'échange et l'équilibration à base température. [Traduit par le journal]

Introduction

The adsorption and isotope interchange reactions of hydrogen and deuterium have been studied on many transition metal surfaces (1, 2). The isotope interchange reactions have been classified as either exchange, in which one isotope is preadsorbed

[1] $$D_2(g) + H(a) \rightarrow HD(g) + D(a)$$

or equilibration, for which both isotopes are initially present in the gas phase

[2] $$H_2(g) + D_2(g) \rightleftarrows 2HD(g)$$

Many basic types of mechanism have been proposed for the exchange and equilibration reactions, together with some subtle variants, but the experimental evidence for any mechanism is limited and our understanding of these reactions is still very poor. Of particular interest is the observation that under the same experimental conditions the kinetics of the exchange and equilibration reactions on platinum differ, from

which it is inferred that these reactions proceed via different mechanisms (3, 4).

In an attempt to gain more information on these reactions, the adsorption, exchange, and equilibration processes have been investigated by thermal desorption mass spectrometry using a platinum filament which has been characterized in earlier studies of oxygen adsorption (5). In the experiments described in this paper the isotopic composition of the surface has been determined at various stages during exchange with and equilibration of the gas phase. This is in contrast with previous studies in which these reactions have been followed by gas phase composition measurement alone.

Experimental Methods

The ultra-high vacuum system used in this work is the same as that described previously (5, 6). The sample filament, a 12 cm length of 0.01 in. diameter platinum (Johnson, Matthey and Mallory, Grade I), equipped with 0.003 in. diameter sensing leads for temperature measurement and control, was spot welded to heavy tungsten leads. This sample was from the same spool and processed in the same way as that described in the first paper of this series (5). In low temperature experiments a filament temperature of 120 °K was obtained by immersing the heavy tungsten leads of the press seal in liquid nitrogen.

Hydrogen and deuterium were purified by diffusion through palladium. Hydrogen and deuterium pressures were monitored with a quadrupole mass spectrometer which was calibrated against an ion gauge attached directly to the reaction vessel. This ion gauge was removed from the system after calibration. The relative sensitivity for H_2 and D_2 was found to be 1.5. However, in contrast with flash experiments in a closed system, the areas under the mass 2 and mass 4 desorption spectra differed by only $\sim 5\%$ since the measured pumping speed for H_2 was greater than that for D_2 by a factor of ~ 1.4. The desorption spectra were obtained with a slow linear heating rate of 5.6 deg s^{-1} using an automated Kelvin double bridge.

Results

Adsorption of Hydrogen on Platinum

Thermal Desorption Spectra

The thermal desorption spectra obtained after exposure of the clean platinum filament to various doses of hydrogen are shown in Fig. 1. The adsorbed phase obtained by saturating the surface at 120 °K with hydrogen at 10^{-4} Torr is unstable at temperatures higher than 140 °K and produces a desorption spectrum, spectrum *e*, with four distinct peaks with peak maxima at 165, 220, 280, and 350 °K, designated the β_1-, β_2-, β_3-, and β_4-peaks, respectively. The saturation coverage obtained under these conditions is 4.2×10^{14} molecules cm^{-2}; this coverage is

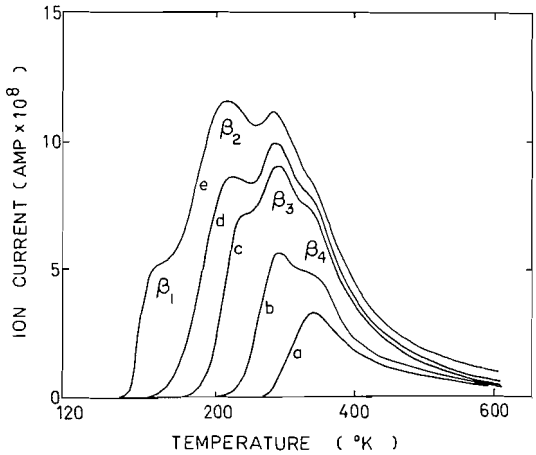

FIG. 1. Thermal desorption spectra obtained after hydrogen adsorption on platinum at 120 °K for (*a*) 2×10^{-7}, (*b*) 6×10^{-7}, (*c*) 3×10^{-6}, (*d*) 2×10^{-5}, and (*e*) 6×10^{-4} Torr s.

unaffected by prolonged pumping at the adsorption temperature. Desorption spectra obtained with increasing exposure, spectra *a–e* reveal that the β-peaks develop successively as the coverage increases. This is most simply interpreted as the population of binding states of steadily decreasing binding energy with increasing coverage; however, account may have to be taken of possible induced heterogeneity in addition to the intrinsic heterogeneity expected for a polycrystalline surface.

At 210 and 285 °K the adsorbed phases produced spectra similar to spectra *c* and *a* respectively of Fig. 1. At 10^{-6} Torr the saturation coverages were 2×10^{14} molecules cm^{-2} at 210 °K and 8×10^{13} molecules cm^{-2} at 285 °K.

Tsuchiya *et al.* (7) also observed four peaks (α, β, γ, and δ) in hydrogen desorption spectra from platinum black. The α and γ peak maximum temperatures correspond closely to those observed in the present work for the β_1- and β_4-peaks respectively and their β falls exactly between the β_2- and β_3-peaks, however, no features analogous to their δ were observed.

Desorption Kinetics

Extensive overlap between the peaks makes it difficult to determine the order for the desorption kinetics. The kinetic parameters for the desorption process have been determined from the variation of the peak maximum temperature, T_m, with heating rate, b, assuming first order kinetics. Plots of $\log (T_m^2/b)$ vs. $1/T_m$ for values

TABLE 1. Activation energies, $E^{\ddagger}$, and pre-exponential factors, ν, for hydrogen desorption from platinum

Desorption peaks	$E^{\ddagger}$(kcal mol^{-1})	ν (s^{-1})
β_2	7.0	1.3×10^6
β_3	9.0	1.6×10^6
β_4	12.4	1×10^7

of b varying from 1.2 to 28 deg s^{-1} were linear. From the slopes of these lines (5, 8) the kinetic parameters for desorption shown in Table 1 were calculated.

Tsuchiya *et al.* only report kinetic parameters for their γ hydrogen for which $E^{\ddagger} = 12$ kcal mol^{-1} and $\nu = 3.8 \times 10^5$ (7); these values compare well with those shown in Table 1 for the β_4-peak which occurs at the same temperature.

Sticking Probability

The initial sticking probability, determined by the flash desorption method, was 0.29 at 120 °K and 0.15 at 285 °K. This temperature dependence suggests a weakly-bound precursor to adsorption in the β-state (9–11) and is in good agreement with that reported by Norton and Richards (4) although the magnitudes they report are slightly smaller. Procop and Völter report a much lower initial sticking probability of $\sim 4 \times 10^{-3}$ (12) and Tsuchiya *et al.* (7) observed the opposite temperature dependence, indicating an activation energy to adsorption.

Adsorption of Hydrogen and Deuterium

Co-adsorption

At 120 °K, the sample was exposed for 10 min to a flowing mixture of H_2 and D_2 in approximately equal amounts at a total pressure of 10^{-8} Torr. The mass 2, 3, and 4 desorption spectra obtained after this co-adsorption are shown in Fig. 2. It should be noted that all the spectra have identical shapes. Furthermore, if f_{H_2}, f_{D_2}, and f_{HD} are the fractions of H_2, D_2, and HD in the desorbing gas, we can define the reaction quotient, Q, for the desorbing gas as

$$[3] \qquad Q = (f_{HD})^2/(f_{H_2})(f_{D_2})$$

It can be seen that the reaction quotient has a magnitude identical with the equilibrium constant, K, for the entire desorption spectrum.

Sequential Adsorption

At 120 °K, the surface was first subjected to a limited 2 min exposure to H_2 gas at 2×10^{-8} Torr and then after pumping the H_2 gas from the system the surface was saturated using D_2 gas at 10^{-5} Torr for a further 3 min. In the time required to saturate the surface very little exchange would occur at 120 °K. The mass 2, 3, and 4 desorption spectra obtained after this sequential adsorption are shown in Fig. 3. As was the case following co-adsorption, the spectra have identical shapes and the values determined for Q are fairly close to the equilibrium values.

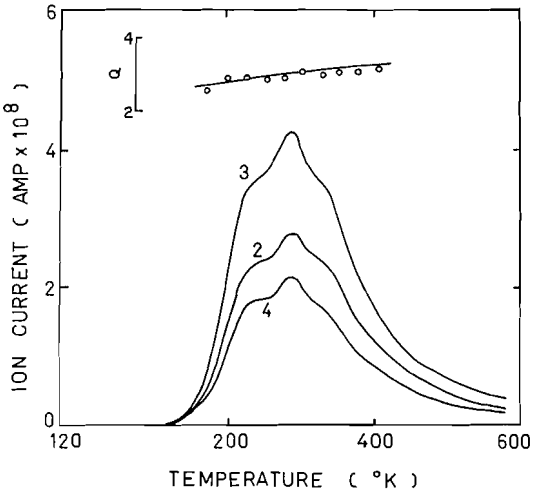

FIG. 2. Mass 2, 3, and 4 desorption spectra obtained after the platinum filament had been exposed at 120 °K to a flowing equimolar mixture of H_2 and D_2 for a total exposure of 5×10^{-6} Torr s. The inset shows the reaction quotient for the desorbing gas, $Q = (f_{HD})^2/(f_{H_2})(f_{D_2})$, as data points compared with its values at equilibrium (curve); $K = 4.24 \exp(-157/RT)$ (25).

These results show that the adsorbed isotopes desorb at equilibrium, *i.e.* no steps leading to equilibrium, such as adatom migration, are slow. Furthermore, they strongly suggest that hydrogen is dissociatively adsorbed in the β-state on platinum. The argument is somewhat tautological in that we are defining adsorption in the atomic state to be adsorption for which complete isotope mixing occurs on desorption. It is perhaps more correct to conclude that hydrogen adsorbs in the β-state in a manner such that the residual interaction between the hydrogen atoms is small and the interaction with the original partner is not appreciably different from that with other hydrogen atoms.

Exchange and Equilibration Reactions

These reactions have been studied at three different temperatures by determining the surface composition and isotope distribution in the

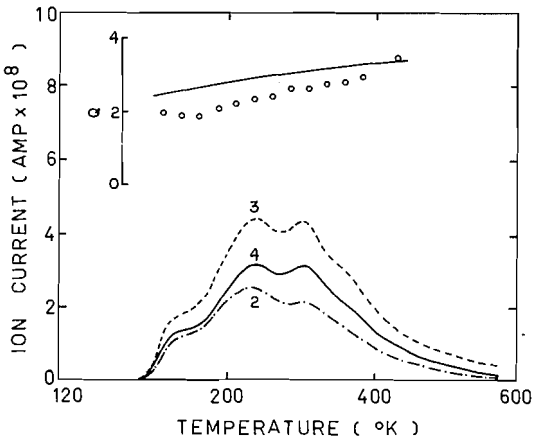

FIG. 3. Mass 2, 3, and 4 desorption spectra obtained after the platinum filament had been exposed at 120 °K, first to H_2 gas up to approximately one-half monolayer coverage and subsequently to D_2 gas up to saturation coverage. The reaction quotient is shown as an inset.

desorption spectra after varying fractions of preadsorbed hydrogen had been replaced.

Exchange at 120 °K

The hydrogen saturated surface (Fig. 1*e*) was exposed to D_2 gas at 10^{-4} Torr in a closed system. After a fraction of the preadsorbed hydrogen had been replaced the isotopic composition of the adlayer was determined from the mass 2, 3, and 4 desorption spectra. Spectra obtained after 28, 48, and 64% of the preadsorbed hydrogen had been replaced are shown in Figs. 4, 5, and 6 respectively; the reaction quotient, Q,

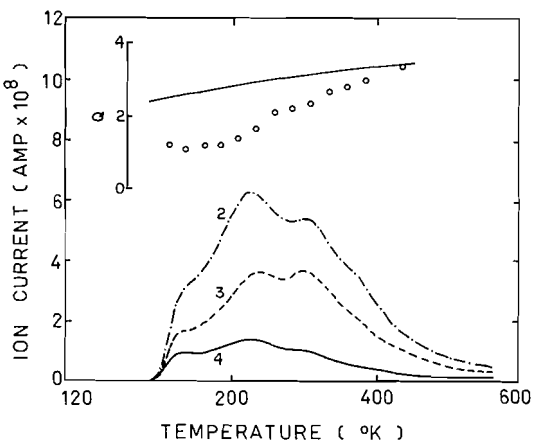

FIG. 4. Mass 2, 3, and 4 desorption spectra obtained after exposing a saturated hydrogen adlayer (Fig. 1*e*) at 120 °K to gas phase deuterium at 10^{-4} Torr for 10 min. At this stage, 28% of the preadsorbed hydrogen has been exchanged.

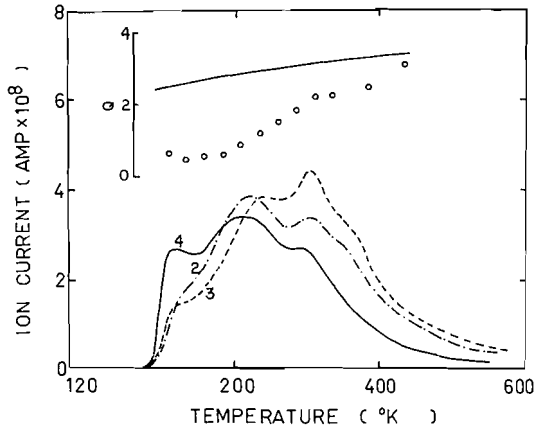

FIG. 5. Mass 2, 3, and 4 desorption spectra obtained after exposing a saturated hydrogen adlayer at 120 °K to gas phase deuterium at 10^{-4} Torr for 50 min. 48% of the preadsorbed hydrogen has been exchanged.

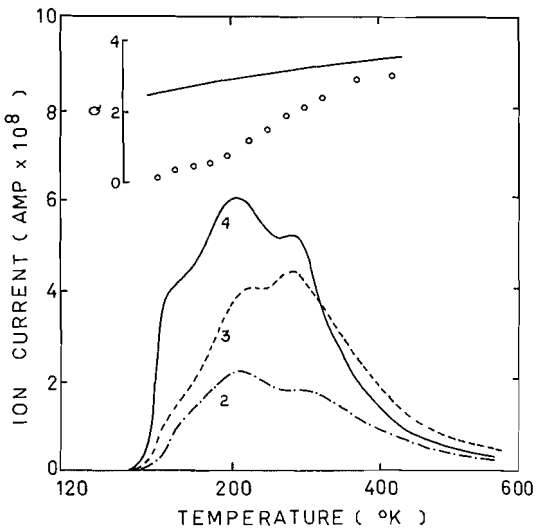

FIG. 6. Mass 2, 3, and 4 desorption spectra obtained after exposing a saturated hydrogen adlayer at 120 °K to gas phase deuterium at 10^{-4} Torr for 120 min. 64% of the preadsorbed hydrogen has been exchanged.

is also recorded. Note that, especially in Figs. 5 and 6, the desorption spectra obtained for the three isotopic species are quite different and the reaction quotient does not correspond to its equilibrium value, particularly below 250 °K where the β_1- and β_2-peaks occur. The exchange reaction is a slow process at 120 °K but 80% of the preadsorbed hydrogen was replaced after a five-hour exposure. This contrasts with the much more limited exchange observed by Tsuchiya *et al.* (3).

Equilibration at 120 °K

Similar experiments have been carried out to see how the isotopic composition of the surface varies during equilibration of an equimolar gas phase mixture of H_2 and D_2 at 2×10^{-4} Torr on a platinum surface which had been saturated with hydrogen. After only a few minutes the gas phase had equilibrated whereas only a small fraction (~20%) of the preadsorbed hydrogen had been replaced. In a blank experiment, with the platinum filament removed, the equilibration was very slow confirming that the rapid equilibration in the gas phase was taking place on the platinum surface. The observation that exchange is slower than equilibration at low temperatures has been reported previously (3, 4).

The desorption spectra obtained after 20 min, when 28% of the preadsorbed hydrogen had been replaced, are shown in Fig. 7. These spectra are very similar to those shown in Fig. 4 after 28% replacement by exchange. However, after 50 min, when 48% of the hydrogen had been replaced the spectra (Fig. 8) differ from those obtained during exchange (Fig. 5) in that the shapes are identical and $Q \simeq K$ throughout the desorption process. This is to be expected if the whole surface is in equilibrium with an equilibrated gas mixture.

Exchange and Equilibration at 210 and 285 °K

The exchange reaction proceeds rapidly at these temperatures and preadsorbed hydrogen can be completely replaced. Similar desorption spectra were obtained when the hydrogen saturated surface was exposed either to D_2 gas or a mixture of H_2 and D_2; mass 2, 3, and 4 spectra have identical shapes with Q equal to K throughout.

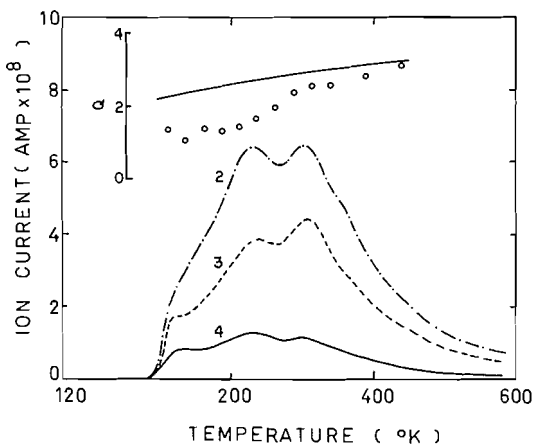

FIG. 7. Mass 2, 3, and 4 desorption spectra obtained after exposing a saturated hydrogen adlayer at 120 °K to an equimolar gas phase mixture of H_2 and D_2 at 2×10^{-4} Torr for 20 min. At this stage 28% of the hydrogen has been replaced.

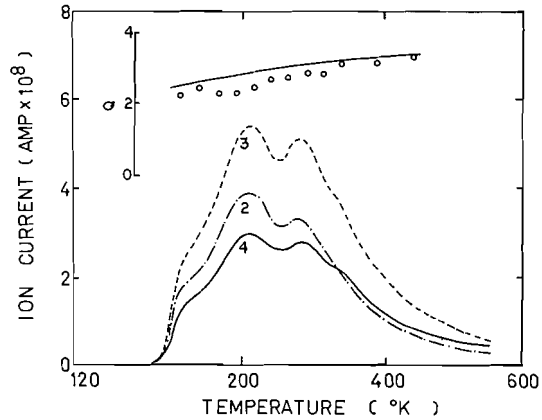

FIG. 8. Mass 2, 3, and 4 desorption spectra obtained after exposing a hydrogen saturated adlayer at 120 °K to an equimolar gas phase mixture of H_2 and D_2 at 2×10^{-4} Torr for 50 min. 48% of the preadsorbed hydrogen has been replaced.

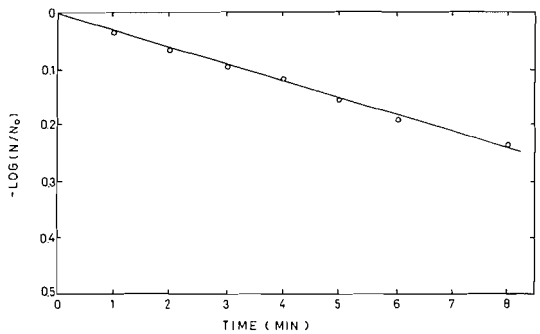

FIG. 9. Variation of the fraction of preadsorbed hydrogen remaining on the surface with time of exposure to gas phase D_2 at 3×10^{-8} Torr. The filament temperature was 210 °K throughout.

Figure 9 shows the variation in the fraction of hydrogen remaining on the surface after it had been saturated at 210 °K and then exposed at 210 °K to D_2 gas at 3×10^{-8} Torr for varying times. The straight line obtained in this semilog plot shows that the rate of exchange is first order with respect to the coverage of adsorbed hydrogen, *i.e.* $\ln (n/n_0) = kt$. This has been reported in studies where the variation in gas phase composition was measured (4) rather than the surface composition. The rate constant, k, determined from the slope of this plot is 5×10^{11}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

molecules cm^{-2} s^{-1} which is about 20 times smaller than the value reported by Norton and Richards (4). However, the gas pressure used in the present work was 400 times smaller, so the difference between the values for k could be attributed to a gas pressure dependence for a pseudo rate constant. The results would agree if the reaction order in D_2 was 0.50 which is the upper limit for the order determined during equilibration at 208 °K (4). Considering the different methods used to follow the reaction, the agreement is satisfactory.

Discussion

The Adsorbed States of Hydrogen on Platinum

The adsorption of hydrogen on platinum surfaces has been studied extensively but the nature of the adsorbed states is not well understood. It is generally accepted that hydrogen is adsorbed in at least two states (13–16). Strongly-bound hydrogen is associated with a negative surface potential whereas weakly-bound hydrogen, present on the surface at higher coverage, has a positive surface potential (13, 15, 16). Strongly and weakly adsorbed hydrogen have infrared absorption bands at 4.86 μ and 4.74 μ respectively (14). Hydrogen in the strongly-bound state is believed to be atomic but there is little agreement concerning the nature of the weakly-bound state, whether it is atomic (14, 17, 18) or molecular (13, 16).

Any reversibly adsorbed species, *i.e.* any species which can be removed by pumping at the adsorption temperature, could not be detected in the present thermal desorption experiments. However, the weakly adsorbed, electropositive, species desorbs into vacuum between 200 and 250 °K (15, 16) and must therefore have been detected in the present work. The complete isotope mixing observed in both co-adsorption and sequential adsorption supports the view that this species is adsorbed atomically, in the sense discussed earlier. The reversibly adsorbed species, probably the precursor to adsorption in the β-state, present when the surface is in equilibrium with gas phase hydrogen is probably molecular. While this even more weakly bound hydrogen undoubtedly plays an important role in the equilibration and exchange reactions, it seems unlikely that these molecules are sufficiently perturbed to effect isotope exchange between molecules within this adlayer.

Desorption Kinetics

The kinetic parameters for desorption of β-hydrogen (Table 1) are characterized by low pre-exponential factors when compared with the value expected for simple first order processes of $\sim 10^{13}$ s^{-1}. This implies a statistically improbable transition state in the desorption mechanism. The calorimetric heat of adsorption of hydrogen extrapolated to zero coverage has been reported as 28 kcal mol^{-1} on supported platinum (19) and 25 kcal mol^{-1} on a platinum filament (20). Thus the measured activation energies (Table 1) are much lower than the heats of adsorption and must be apparent activation energies for desorption, again suggesting that the mechanism is complex. One possibility is a two-step process in which formation of an adsorbed molecular complex represents the first, rate-limiting, step. However, one should not ignore the possibility that the observed kinetic parameters are an artefact of the experimental method. Thus if we assume a value of $\nu = 10^{13}$ s^{-1}, then the calculated $E^{\ddagger}$ for the β_4 desorption would be 21 kcal mol^{-1} in better agreement with the heats of adsorption. The nature and origin of such "slow" desorption processes (21) is worth further investigation.

Heterogeneity of the Surface

The role of intrinsic, as opposed to induced, heterogeneity of platinum surfaces in the binding of hydrogen is uncertain. It has been argued that the surface is homogeneous in one case because the various forms of adsorbed hydrogen seem to be interrelated (7) and in another, the argument is based on the linearity of the first order exchange plots and the completeness of exchange (4). On the other hand the small amount of hydrogen which is exchangeable at low temperature has been taken to indicate a heterogeneous surface (22). However, contamination could reduce the extent of exchange (23).

In sequential adsorption experiments the observation of a memory effect is a strong indication that the surface is heterogeneous. In the sequential adsorption experiment shown in Fig. 3 there is no evidence of such a memory effect but this does not necessarily indicate that the surface is homogeneous as will be discussed later. The desorption spectra observed after exchange of 48 and 64% of the preadsorbed hydrogen, Figs. 5 and 6, have widely differing shapes for the desorbing isotopes. This is very

difficult to understand if the surface were homogeneous. In these experiments the center of the filament was at a higher temperature than the ends which were in good thermal contact with the coolant. Thus it could be claimed that the exchange is faster in the center of the filament and that during desorption the gas desorbs first from this same portion of the filament. The experiments were therefore repeated with the whole reaction vessel and sample filament press seal completely immersed in an isopentane slush at 113 °K. The results were unchanged and therefore the differences in the shapes of the mass 2, 3, and 4 desorption spectra cannot arise from a nonuniform temperature of the sample during exchange. The surface must be heterogeneous.

Model for the Exchange and Equilibration Results

Assuming that β-hydrogen is adsorbed dissociatively on a heterogeneous platinum surface we can interpret the present observations with the following model. For simplicity, consider that only two types of crystal plane, A and B, are present on the surface. The binding energy of hydrogen adatoms on plane A is assumed to be slightly lower than that on plane B.

In the exchange reaction, prior to the introduction of D_2 gas both plane A and B are saturated with β-hydrogen adatoms and every adatom on a given plane is assumed to have the same binding energy. In the presence of D_2 gas exchange will occur more rapidly on plane A where the hydrogen is more weakly bound. After 50% of the preadsorbed hydrogen has been replaced the surface isotope composition will be predominantly D on plane A but still mainly H on plane B, represented schematically in Fig. 10*a*. Isotope mixing on each plane can be expected below 140 °K (16), the temperature where desorption starts, and therefore the isotope composition of the gas desorbing from each plane should be determined by the equilibrium constant for the isotope exchange reaction, *K*. However, desorption from a surface containing planes of type A and B in macroscopic patches and with a surface isotope distribution as shown in Fig. 10*a* would give rise to a desorbing gas with a higher deuterium content at low temperature compared with that desorbing at higher temperatures (Figs. 5 and 6). We assume that the β_1-, β_2-, β_3-, and β_4-peaks arise, at least in part, from the intrinsic heterogeneity of the polycrystalline surface. These desorption features overlap considerably so if, for example, the β_1- and β_3-peaks were attributed to type A planes (two peaks could arise from adatom interactions, *i.e.* induced heterogeneity) whereas the β_2- and β_4-peaks were from type B planes then we would expect an apparent reaction quotient, *Q*, deviating considerably from its equilibrium value, as observed at lower desorption temperatures. At higher temperatures adatom mobility will increase and mixing between different macroscopic planes will produce a statistical distribution of adatoms accounting for the observation that *Q* approaches its equilibrium value at higher desorption temperatures (Figs. 5 and 6). In this way the model successfully interprets the two salient features of the exchange results, the higher mass 4 component at low desorption temperatures and the deviation of *Q* from *K*.

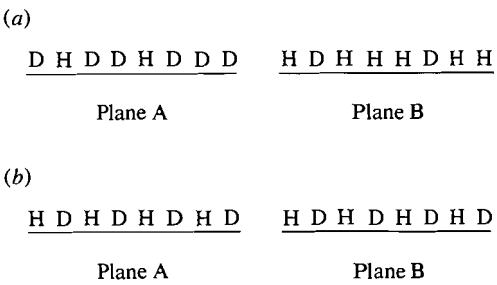

FIG. 10. Schematic diagram showing the distribution of isotopes between type A and B planes after 50% of the preadsorbed hydrogen had been replaced by exposure to (*a*) D_2 gas and (*b*) an equimolar mixture of H_2 and D_2.

In contrast, during equilibration of an equimolar gas phase mixture of H_2 and D_2 the isotope composition of each plane will successively reach the equilibrium value. Figure 10*b* schematically represents the isotope distribution on the surface after 50% of the preadsorbed hydrogen has been replaced. The mass 2, 3, and 4 desorption spectra obtained from the surface represented in Fig. 10*b* should have identical shapes and a reaction quotient, *Q*, close to the equilibrium value, *K*, as observed in Fig. 8.

This model for the exchange and equilibration results makes it unnecessary to invoke different mechanisms to explain the difference in kinetics of exchange and equilibration (3, 4). The equilibration reaction will occur predominantly on plane A, where hydrogen is more weakly bound, until the gas phase is equilibrated whereas in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

exchange reaction, after hydrogen on plane A has been replaced further exchange occurs on plane B with a slower rate. Thus the model would predict that both reactions would occur rapidly in the initial stages but the exchange reaction will slow down as the preadsorbed hydrogen concentration decreases. Actually during the initial stage of exchange some of the preadsorbed isotope appears rapidly in the gas phase and this is subtracted before constructing the kinetic plots (4). Though the origin of this desorbing gas is unspecified, it could represent the initial fast exchange reaction on type A planes. However the reason why this appears initially as homonuclear molecules is not clear.

At low temperature a difference in the activation energy for reaction on type A and B planes of as little as 1 kcal mol^{-1} would result in rates differing by a considerable factor, *i.e.* $\sim 10^2$ at 100 °K. At higher temperatures the difference becomes less significant, accounting for the observation that the rates of equilibration and exchange become comparable at higher temperatures (3, 4).

Sequential Adsorption

In the sequential adsorption experiment, Fig. 3, there is no evidence of a memory effect, complete isotope mixing occurs on desorption. Complete mixing does not necessarily indicate that the surface is homogeneous since mixing can occur during desorption or at the adsorption temperature if the adatoms are sufficiently mobile. However since after the exchange reaction (Figs. 5 and 6) the mass 2, 3, and 4 desorption spectra are quite different in shape, the adlayer cannot have sufficient mobility to produce the complete mixing observed following sequential adsorption (Fig. 3). Interpretation of the exchange results requires that the surface be heterogeneous and so some alternative explanation for the complete mixing observed after sequential adsorption must be found. The total sticking probability for hydrogen on polycrystalline platinum is initially high and remains more or less unchanged up to half-coverage and then drops very rapidly (4). Adsorption of gases on single crystal planes shows a similar variation of sticking probability with coverage and, moreover, there is no simple correlation between initial sticking probability and binding energy (24). Thus a similar variation of sticking probability for hydrogen adsorption on type A and B planes of polycrystalline platinum seems likely. In this case, preadsorption of hydrogen up to half-coverage would populate both type A and type B planes and in the subsequent adsorption of deuterium the remaining empty sites on both planes will be occupied. On completion of the sequential adsorption the isotope distribution on the surface would resemble that shown in Fig. 10*b*. Isotope mixing on each plane prior to desorption would result in complete mixing. Since Q does not exactly equal K following sequential adsorption (Fig. 3) we conclude that the distribution of isotopes on different planes is not identical as is suggested in the simple model of Fig. 10*b*.

Exchange and Equilibration Mechanisms

The exchange and equilibration reactions occur rapidly at temperatures below those required for desorption of the binding state investigated in this work, the β-state. Clearly additional adsorbed states which are unstable in the absence of gaseous hydrogen are important in achieving exchange and equilibration. An increase in surface coverage on introducing gas phase hydrogen presumably either reduces the binding energy of the whole adlayer, through adsorbate–adsorbate interactions, permitting exchange with the gas phase, or provides a distinct binding state of intermediate energy between the β-state and the gas phase and therefore a pathway to exchange. The nature of these additional states has not been examined in this work and therefore we can provide no direct evidence for any of the detailed mechanisms proposed for the exchange and equilibration reactions.

Conclusions

The results described in the present paper show that, for polycrystalline platinum surfaces, heterogeneity plays an important role in the exchange and equilibration reactions of hydrogen. It is shown that different mechanisms are not required to interpret differences in the kinetics observed for these reactions. However it is not established that different mechanisms do not exist. Particularly we would stress that different mechanisms may exist at different temperatures; thus, at low temperature exchange may occur between the atomically adsorbed β-state and a (molecularly) adsorbed precursor state whereas at high temperature and low pres-

sure the reactions may occur entirely within an atomically adsorbed β adlayer.

^{119}Sn Mössbauer Spectra of Sn–Ni Compounds

G. MICHAEL BANCROFT[1] AND K. DAVID BUTLER[2]

Department of Chemistry, University of Western Ontario, London, Ontario N6A 3K7

Received September 5, 1974

G. MICHAEL BANCROFT and K. DAVID BUTLER. Can. J. Chem. **53**, 307 (1975).

^{119}Sn Mössbauer spectra have been recorded for eleven tin–nickel compounds of the type $Cl_xSn[NiLCp]_{4-x}$ (L = CO, PPh_3; x = 2, 3) and $Cl_3SnNiL_2Cp.S$ (S = solvent molecule). The center shifts are used to distinguish coordinated $SnCl_3$ and uncoordinated ionic $SnCl_3^-$, respectively. In the $SnCl_3^-$ compounds, the Mössbauer parameters indicate that the solvent molecules are not bonded to the Sn atom. In compounds containing Sn—Ni bonds, the center shifts and quadropole splittings show that $Ni(PPh_3)Cp$ is the best donor of the first row transition metal moieties, and that the Sn—Ni bond has the highest Sn s character. Ni(CO)Cp is a slightly poorer donor than $Ni(PPh_3)Cp$, and the Sn—Ni bond has a smaller s character.

G. MICHAEL BANCROFT et K. DAVID BUTLER. Can. J. Chem. **53**, 307 (1975).

On a enregistré les spectres Mössbauer de ^{119}Sn de onze composés étain–nickel du type $Cl_xSn[NiLCp]_{4-x}$ (L = CO, PPh_3; x = 2, 3) et $Cl_3SnNiL_2Cp.S$ (S = une molécule de solvant). Les déplacements de centre ont été utilisés pour distinguer les $SnCl_3$ coordonnés et des espèces des $SnCl_4$ ioniques non coordonnées. Dans les composés $SnCl_3^-$, les paramètres du spectre Mössbauer indiquent que les molécules de solvant ne sont pas liées à l'atome d'étain. Dans les composés contenant des liens Sn—Ni, les c.s. et q.s. montrent que, parmi les groupes contenant des métaux de transition de la première rangée, le $Ni(PPh_3)Cp$ est le meilleur donneur; ces données permettent aussi de conclure que le lien Sn—Ni a le plus grand caractère s pour l'atome Sn. Le complexe Ni(CO)Cp est un plus mauvais donneur que $Ni(PPh_3)Cp$ et le lien Sn—Ni a un caractère s plus petit. [Traduit par le journal]

Introduction

^{119}Sn Mössbauer spectra of compounds containing a Sn—M (M = transition metal) bond have been the subject of a number of recent studies (1–6). The great majority of such compounds have contained $Mn(CO)_5$, $Fe(CO)_2Cp$, or $Co(CO)_4$ moieties or phosphine substituted derivatives. Center shifts and quadrupole splittings have been very useful in distinguishing and explaining differences in the Sn—M bonds, and partial quadrupole splittings (7) have been successfully applied in correlating and predicting quadrupole splittings (1, 2). In addition, ^{119}Sn Mössbauer center shifts have been used to distinguish between coordinated and uncoordinated $SnCl_3$ groups (8–11). Thus, coordinated $SnCl_3$ containing tetravalent Sn normally has center shifts under 2 mm s^{-1}, while uncoordinated $SnCl_3^-$ containing divalent Sn has a center shift of over 3 mm s^{-1}.

A number of Sn compounds containing nickel of the type $Cl_xSn[NiLCp]_{4-x}$ (L = CO, PR_3; x = 2, 3) and $Cl_3SnNiL_2Cp.S$ (S = solvent molecule) have recently been prepared (12–17). Conductivity and mass spectrometric studies in these papers indicated that a Sn—Ni bond was present in the $Cl_xSn[NiLCp]_{4-x}$ compounds. This evidence is substantiated by the covalent Ge—Ni bond shown by X-ray diffraction studies of the Ge analogue $Cl_3GeNi(PPh_3)Cp$ (15). In contrast, the above studies indicated that the $Cl_3SnNiL_2Cp.S$ compounds are ionic and can be formulated as $[CpNiL_2]^+[S.SnCl_3]^-$ although the role of the solvent molecule is unclear. In the original report of the compounds with L = PPh_3 and S = CH_2Cl_2 or $(CH_3)_2CO$ (13), the authors suggested that the solvent molecules were bonded to the Sn on the basis of infrared data and the difficulty with which the solvent molecules are removed. The ν(CO) band of acetone in the acetone complex was at 1705 cm^{-1} compared with 1740 cm^{-1} in gaseous acetone. A similar reduction of 23 cm^{-1} in the (C—Cl) stretching frequency for CH_2Cl_2 was noted (13) in the CH_2Cl_2 compound. The ^{1}H n.m.r. signals due to the solvent molecules were not shifted detectably from those of the free solvent, but this is possibly due to dissociation in solution.

As part of our continuing ^{119}Sn Mössbauer

studies on Sn metal bonds, we report the ^{119}Sn Mössbauer spectra of a number of Sn—Ni compounds. The Mössbauer spectra are very useful in distinguishing between coordinated and uncoordinated $SnCl_3$, and the role of the solvent molecule is clarified in the $SnCl_3^-$ compounds. The bonding of the NiLCp moiety is compared with the $Mn(CO)_5$, $Fe(CO)_2Cp$, and $Co(CO)_4$ moieties studied earlier.

Experimental

The compounds were synthesized using methods outlined previously (12–17). The identity and purity of all compounds was checked from melting points, infrared, and n.m.r. spectra. Microanalyses were performed by Chemalytics Inc. (Arizona, U.S.A.). All compounds were made and stored under a nitrogen atmosphere and carefully recrystallized from deoxygenated solvents immediately before Mössbauer spectra were run.

The two new solvent analogues $[Cl_3Sn][Ni(PPh_3)_2Cp].S$ (S = CH_3OH, THF) were prepared by recrystallization from the appropriate solvent.

Anal. Calcd. for $[Cl_3Sn][Ni(PPh_3)_2Cp].CH_3OH$: C, 55.7; H, 4.34; Cl, 11.8. Found: C, 55.3; H, 4.09; Cl, 11.2.

Anal. Calcd. for $[Cl_3Sn][Ni(PPh_3)_2Cp].THF$: C, 57.2; H, 4.58; Cl, 11.3. Found: C, 57.2; H, 4.19; Cl, 11.9.

The THF, acetone, and methanol adducts dissociated extensively to $CpNi(PPh_3)Cl$ and $SnCl_2$ in solution (13–15), but the required product recrystallized on cooling overnight at −20 °C.

$[Cl_3Sn][Ni(dppe)Cp]$ was prepared in 60% yield by mixing one mole equivalent each of 1,2-bis(diphenylphosphino)ethane and $[Cl_3Sn][Ni(PPh_3)_2Cp]$ in acetone.

Anal. Calcd. for $[Cl_3Sn][Ni(dppe)Cp]$: C, 49.8; H, 3.91; Cl, 14.2. Found: C, 50.1; H, 3.79; Cl. 15.3.

$[Ni(PPh_3)_2Cp]PF_6$.acetone was synthesized by mixing mole equivalents of $CpNi(PPh_3)Cl$, PPh_3, and $AgPF_6$ in acetone. AgCl was removed by centrifugation and decantation, and the yellow product crystallized when the volume of the acetone was reduced under vacuum (yield 85%).

Infrared spectra were recorded on a Perkin-Elmer 621 spectrometer calibrated with polystyrene. ^1H n.m.r. spectra were measured using a Varian T-60 spectrometer, and the spectra were calibrated with TMS and chloroform. Mössbauer spectra were obtained on an Austin Science Associates spectrometer using a Ba $^{119m}SnO_3$ source at room temperature. Calibration and computation were obtained using methods previously described (18, 19).

Results and Discussion

The Mössbauer parameters for the tin–nickel compounds are given in Table 1. The compounds can immediately be divided into two groups on the basis of their center shifts: compounds **1–7** having center shifts larger than 3 mm s^{-1}, and compounds **8–11** having center shifts less than 2 mm s^{-1}. These results strongly indicate that the first seven compounds contain an anionic $SnCl_3^-$ (divalent tin) species which is not coordinated to the nickel atom. The low center shifts for compounds **8–11** show that a Sn—Ni bond exists in these compounds. These conclusions are entirely consistent with previous assertions (12–17).

The center shifts and quadrupole splittings for the anionic $SnCl_3$ compounds are very similar despite the variation in solvent molecule. This evidence suggests that the solvent molecules are not coordinated to the Sn to give $S.SnCl_3^-$ species as previously suggested (13). Confirmation of this assertion comes from the compound $[CpNi(PPh_3)_2^+][PF_6^-]$.acetone, whose infrared ν(CO) band is a narrow doublet at 1709/1713 cm^{-1}, little different from the position of the band for the corresponding tin-containing compound. In addition, it has been shown (20) from an X-ray diffraction study that the acetone molecule in the metal–metal bonded compound $(Cl_3Sn)Pd(PPh_3)(h^3\text{-}C_3H_5)$ (0.4 acetone) is not bound to any other atom in the molecule. The ν(CO) band for acetone in this compound occurs at 1710 cm^{-1}, close to the values observed here for the acetone-containing compounds. Similarly, the structure of the compound $[Co(dppe)_2Cl^+][SnCl_3^-]$ in solvated form (with C_6H_5Cl) is known from a diffraction study (10). It contains a discrete $SnCl_3^-$ ion, and the C_6H_5Cl molecule is not bonded to either the anion or cation, both of which have very similar geometries to the same ions in the unsolvated form of the compound.

The solvent molecules are surprisingly difficult to remove from the ionic compounds if they are not bonded, acetone and dichloromethane only being removed from compounds **2** and **3** (Table 1) at 85° and 115° respectively under vacuum (13). On the other hand, it is difficult to prevent the spontaneous loss of dichloromethane from the neutral compound **10** at room temperature. The ν(C—Cl) infrared band for the neutral and ionic compounds containing CH_2Cl_2 differ by only 6 cm^{-1}.

Using center shifts and quadrupole splittings, it is interesting to compare the character of the Sn—Ni bond with other Sn transition metal bonds previously studied. It is apparent from Table 2 that $Cl_3SnNi(PPh_3)Cp$ has the largest center shift and quadrupole splitting of the four first row transition metal $SnCl_3$ derivatives. The large center shift indicates that the Sn—Ni bond has the highest s character in the series and the large quadrupole splitting shows that the

8, $Cl_2Sn[Ni(CO)Cp]_2$	1.87	2.15	This work

$Ni(PPh_3)Cp$ moiety is the best donor of the four transition metal moieties (1, 2). This large donor ability of the $Ni(PPh_3)Cp$ group should be reflected in a very large negative partial quadrupole splitting value (> -1.1 mm s^{-1}), but as in previous studies we do not want to assign *pqs* values from distorted $SnCl_3$ derivatives.

In contrast, both the center shift and quadrupole splitting for $Cl_2Sn[Ni(CO)Cp]_2$ are proportionately smaller than their analogues (Table 2, compounds **5**–**8**), indicating that the Ni(CO)Cp group is not as good a donor as $Ni(PPh_3)Cp$, and that the Sn—Ni bond contains less Sn s character for the carbonyl derivative. As predicted by the point charge model, one would expect that the Cl_2SnM_2 compounds should have quadrupole splittings about 15% larger than their Cl_3SnM analogues. An increase of at least this amount is found for M = $Mn(CO)_5$, $Fe(CO)_2Cp$, and $Co(CO)_4$, but an increase in the quadrupole splitting of only 7% is found on going from $Cl_3SnNi(PPh_3)Cp$ to $Cl_2Sn[Ni(CO)Cp]_2$. The weaker donor properties of the carbonyl species are not unexpected because of the excellent acceptor ability of CO relative to PPh_3. Similar effects in the ^{119}Sn Mössbauer parameters are found in the phosphine and phosphite substituted $Cl_xSn[Fe(CO)_2Cp]_{3-x}$ compounds (23, 24).

The Determination of Traces of Nickel(II) by Solid State Spectroscopy

DOUGLAS EARL RYAN AND JIRI HOLZBECHER

Trace Analysis Research Centre, Dalhousie University, Halifax, Nova Scotia B3H 4J1

Received August 28, 1974

DOUGLAS EARL RYAN and JIRI HOLZBECHER. Can. J. Chem. **53**, 311 (1975).

Traces of nickel(II) are determined by measurement of light absorption in the solid state after co-precipitation with a large excess of α-benzildioxime. The detection limit is 0.2 μg Ni and nickel can be recovered even from 1000 ml sample volumes (*i.e.* <1 ng/ml can be determined). Only a few foreign ions interfere.

DOUGLAS EARL RYAN et JIRI HOLZBECHER. Can. J. Chem. **53**, 311 (1975).

On détermine des traces de nickel(II) par mesure d'absorption de la lumière à l'état solide après co-précipitation avec un grand excès d'α-benzildioxime. La limite de la détection est de 0.2 μg de nickel et on peut même récupérer le métal à partir d'échantillons ayant des volumes de 1000 ml (*i.e.* on peut déterminer des quantités <1 ng/ml). Seulement quelques ions étrangers interfèrent dans cette analyse. [Traduit par le journal]

Introduction

In recent communications, methods have been described for the determination of trace metal ions by solid state fluorescence after preconcentration by co-precipitation. Two major principles were used: (*1*) co-precipitation with an inorganic carrier and subsequent activation by ignition to produce a phosphor (1–3); (*2*) co-precipitation of a fluorescent chelate with a large excess of a non-fluorescent, water insoluble chelating agent (4, 5).

While these methods exhibit a high sensitivity, because of the preconcentration effect, they often suffer from interferences. Since color-forming methods in solution are not usually subject to interferences to such a degree as fluorimetric methods, the potential of spectrophotometry in the solid state, based on chelate formation, was studied.

The basic requirements for a suitable chelating agent can be summarized as follows: (*a*) react to form a color with the metal ion of interest, (*b*) be selective, (*c*) have a low solubility in water so that the method would be essentially independent of the sample volume, (*d*) have appreciable solubility in some organic, water miscible solvent.

One of the very selective color and, at the same time, precipitation reactions is that of α-dioximes with nickel(II). Among various dioximes α-benzildioxime shows a very low water solubility, dissolves readily in dimethylsulfoxide, and can be easily synthesized. The present paper describes the determination of nickel(II) at ng/ml levels using co-precipitation of the nickel chelate with α-benzildioxime and subsequent measurement of the light absorption of the precipitate.

Experimental

Apparatus and Reagents

All spectrophotometric measurements were made with a Farrand VIS-UV Chromatogram Analyzer or with a Zeiss Chromatogram Spectrophotometer. The sample cell was an aluminum sheet painted white with drilled holes (diameter 5 mm) and covered with a glass plate. It was packed with a sample powder which was held in place by masking tape; the glass was removed prior to measurement.

A stock solution containing 1000 μg/ml of nickel(II) was prepared from nickel(II) chloride hexahydrate (BDH) and was standardized by EDTA titration using xylenol orange (6). The α-benzildioxime was synthesized according to the procedure given in the monograph by Diehl (7). Benzil (BDH) (40 g) was dissolved in 200 ml of hot methanol; 32 g of hydroxylamine hydrochloride (Baker) were added and the reaction mixture was boiled and stirred for 3 h. After cooling, the precipitate of dioxime was filtered off with suction, washed with hot water and then with 50% ethanol; 12 g of white, crystalline product were obtained after drying. It was used without further purification. The reagent solution was 1% (w/v) in dimethylsulfoxide (Fisher, Certified A.C.S.).

The buffer solution (pH ~ 10) was prepared by mixing 70 g of ammonium chloride with 570 ml of concentrated ammonia and diluting to 1 l with water.

The ammonium tartrate (Baker & Adamson) solution was 1 M.

Procedure

To 100 ml of solution containing 0.2–10.0 μg of nickel add 3 ml of ammonia buffer (pH ~ 10)[1], 1 ml of 1 M ammonium tartrate and, finally, 3 ml of the reagent solution with rapid stirring. Filter the precipitate through a filter crucible, wash with distilled water and dry in a vacuum desiccator for 1 h. Pack the cell (grinding of the powder causes electrostatic charge and thus packing difficulties) and measure the light absorption. Settings of the Farrand instrument: function SIG (single beam), λ, 435 nm (on both monochromators), excitation filter removed, filter 3–73, screen mesh reducer 0.625 and aperture 0.021 in the analyzer leg, range 1.0 (if measurement at 570 nm is desired use aperture 0.062).

Results and Discussion

The reflectance spectrum of the nickel chelate in the solid state (obtained with the Zeiss instrument) exhibits two absorption maxima at 435 and 570 nm, absorption at 435 nm being stronger and thus recommended for measurement. This is in agreement with the spectrum obtained in solution of the nickel chelate in amyl-alcohol.

Typical calibration curves are shown in Fig. 1 (two different runs); A, 0.2–2 μg, B, 1–10 μg Ni. They do not pass through the origin because the plate background was selected as the base line (zero absorption). The relative standard deviation of six determinations of 2 μg Ni/100 ml (20 ng/ml) is ~7%.

Factors Affecting the Method

It is necessary to have the reagent solution as concentrated as possible so that the minimum amount of solvent is introduced, together with the reagent, into the sample solution. The solubility of the resulting precipitate is thus kept low and dependence on the sample volume is minimized. Dimethylsulfoxide has been selected as a solvent since at least a 1% solution of the reagent could be prepared. Three ml of this solution added to 100 ml of water are sufficient to produce enough precipitate (~ 30 mg) to fill a hole in the measuring cell.

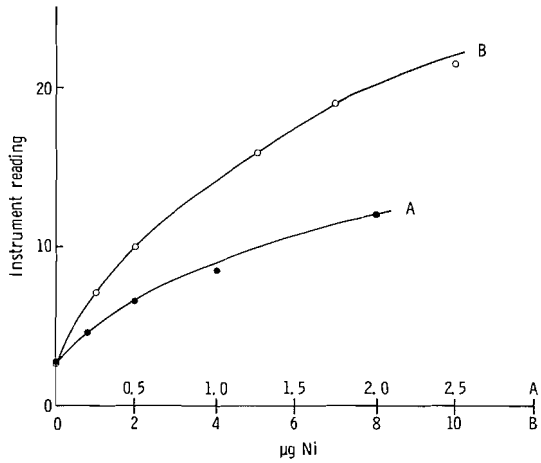

FIG. 1. Calibration curves for nickel. A, 0.2–2.0 μg; B, 1.0–10.0 μg.

While at pH ~ 5 there is virtually no difference in absorption between the precipitates separated from solution containing nickel- and respective blank, the absorption of the precipitates from nickel containing solutions increases sharply with increasing pH up to ~8, and then remains essentially unchanged up to pH ~10. For better masking, pH ~ 10 was selected for further work.

There is no appreciable dependence of light absorption or quality of the precipitate upon the rate of addition of the reagent solution. Essentially the same readings are obtained for precipitates filtered immediately after their precipitation and those allowed to stand for various periods of time (up to 1 h) before filtration.

The light absorption of the powder increases with increasing sample volume (containing 2 μg Ni) from 10 to 100 ml and remains virtually constant with further increase of volume up to 1 l. This fact makes it possible to increase the sensitivity of the method by an order of magnitude if a large volume of sample is available. Lower readings for sample volumes under 100 ml can be attributed to the increased solubility of the precipitate (due to the higher concentration

[1]If the buffer is insufficient, due to the original acidity of the sample solution, adjust pH to ~10 by addition of 1:1 ammonia.

of organic solvent) and thus lower effectiveness of co-precipitation of the nickel chelate.

When the precipitation is performed at elevated temperatures progressively lower readings are obtained. Precipitation at the room temperature is, therefore, recommended.

The presence of 1 mmol of ammonium tartrate in the solution does not have an appreciable effect on the calibration curve. Tartrate is, therefore, included in the procedure to mask some metal ions which would otherwise precipitate in basic medium, particularly iron(III).

The method is independent of many variables: p*H* (within 8–10), volume (100–1000 ml), rate of reagent addition, time of standing before filtration (up to 1 h at least), presence of a large amount of tartrate.

It has been observed that the precipitates become paler in color upon drying. If the light absorption is measured while still wet a stronger signal is obtained making possible the determination of even 0.1 μg Ni/100 ml; however the uncertainty in water content, especially during the measurement in the instrument, results in poorer reproducibility.

At least a 1000-fold weight excess of the following ions is without interference in the determination of 2 μg Ni in 100 ml of water: aluminum(III), bismuth(III), cadmium(II), calcium(II), iron(III), lead(II), magnesium(II), manganese(II), mercury(II), palladium(II), potassium(I), silver(I), sodium(I), tin(IV), zinc(II), acetate, borate, bromide, citrate, fluoride, iodide, nitrate, perchlorate, phosphate, sulfate, sulfide, and thiocyanate. A 50-fold excess of cobalt(II) and a 10-fold excess of chromium(III), copper(II), iron(II), and EDTA are also without interference. Cyanide can be tolerated only at a 1:1 ratio.

Iron(III) does not interfere even at 10 000-fold excess (20 mg Fe) provided 2 mmol of tartrate are present and the p*H* is adjusted to ~ 10 with ammonia. For still higher amounts of iron(III), the higher concentration of tartrate necessary to keep iron in solution results in a decrease of the signal.

Since the detection limit of the method is 0.2 μg Ni, it should be possible to determine 0.2 μg Ni in 20 mg iron. For example, the method was applied to the determination of nickel in a sample of mild steel (British Chemical Standards, #324). After dissolution of the sample in diluted hydrochloric and nitric acids, tartrate was added and the solution was neutralized with concentrated ammonia. Aliquots were taken and, after dilution, the regular precipitation procedure was performed. The average nickel content given was 0.050%, found 0.049%; the results demonstrate the potential of the method in a relatively complex matrix.

The simplicity, sensitivity, and reproducibility of the method should lead to many applications for the determination of very small amounts of nickel.

This work was supported by a grant from the National Research Council of Canada.

FRANZ H. A. RUMMENS, ROBERT D. GREEN, ALLAN J. CESSNA, MITSUO OKA, and CHOI CHUCK LEE. Can. J. Chem. **53**, 314 (1975).

Reaction of triphenylvinyl bromide, labeled at C-2 with ^{14}C or ^{13}C (**1**—Br-2-^{14}C or **1**—Br-2-^{13}C), with HOAc–AgOAc gave an isotopically rearranged product, **1**—OAc-*x*-^{14}C or **1**—OAc-*x*-^{13}C. After conversion of the product to 1,2,2-triphenylethanol (**2**—*x*-^{14}C or **2**—*x*-^{13}C), ^{14}C assays after degradation to benzophenone, or analyses by FT c.m.r. and by ^{13}C satellites of p.m.r. in the FT or CW mode all gave results that were in reasonable agreement, indicating 6.8 ± 0.9% scrambling of the label from C-2 to C-1. The work shows that while the c.m.r. technique eliminates the need for degradation, the tracer method, with appropriately high specific activities, is capable of giving higher precision.

FRANZ H. A. RUMMENS, ROBERT D. GREEN, ALLAN J. CESSNA, MITSUO OKA et CHOI CHUCK LEE. Can. J. Chem. **53**, 314 (1975).

Le bromure de triphénylvinyle portant un ^{13}C ou un ^{14}C en position 2 (**1**—Br-2-^{13}C ou **1**—Br-2-^{14}C) réagit avec le couple AcOH-AcOAg pour donner un produit qui est isotopiquement réarrangé, **1**—OAc-*x*-^{13}C ou **1**—OAc-*x*-^{14}C. Après conversion du produit un triphényl-1,2,2 éthanol (**2**—*x*-^{13}C ou **2**—*x*-^{14}C), les déterminations de ^{14}C sur le produit dégradé en benzophénone ou une analyse par transformation de Fourier du spectre r.m.c. du ^{13}C et l'analyse des bandes satellites du ^{13}C dans le spectre r.m.c. du proton ont tous donné des résultats qui sont généralement en accord et qui indiquent qu'environ 6.8 ± 0.9% d'isotope migre de la position 2 vers la position 1. Ce travail montre que quoique la technique de la r.m.c. du carbone élimine la nécessité de dégradation, la méthode des marqueurs avec des activités spécifiques elevées est capable de donner une plus grande précision. [Traduit par le journal]

As facilities for ^{13}C n.m.r. become more commonly available, it is of interest to extend the utilization of the c.m.r. technique to quantitative isotopic scrambling studies which have generally been investigated using ^{14}C as tracer. A recent example of such a quantitative application is the work of Vaughan and co-workers (1) who studied the mechanism of the acid-catalyzed racemization of (−)-camphene-8-^{13}C. These workers pointed out the advantage of ^{13}C n.m.r. over the previously employed ^{14}C-labeling since the amount of the ^{13}C-label at the C-8, C-9, and C-10 positions could be measured simultaneously without the necessity of degradation. The data obtained suggested a number of racemization processes including a small, but not quite negligible *endo*-methyl 3,2-migration (1), although this conclusion has recently been questioned (2). Recently, ^{14}C-labeling has been utilized in this laboratory to study the extent of degenerate rearrangement arising from 1,2-phenyl shifts in solvolyses of triphenylvinyl-2-^{14}C triflate (3). In the present work, the extent of isotopic scrambling arising from a similar degenerate 1,2-phenyl shift in the reaction of triphenylvinyl bromide (**1**—Br) with HOAc–AgOAc is investigated. The reactant, **1**—Br, is labeled at the C-2 position with ^{13}C or ^{14}C. Quantitative measurements using ^{13}C n.m.r. are explored and the results are compared with those obtained from the ^{14}C tracer studies.

Treatment of $PhCH_2MgCl$ with $^{14}CO_2$ or $^{13}CO_2$ gave the corresponding labeled phenylacetic acid which was converted to **1**—Br-2-^{14}C or **1**—Br-2-^{13}C by procedures previously described for the preparation of **1**—Br-2-^{14}C (3). Acetolysis of either of these labeled bromides in the presence of AgOAc gave **1**—OAc-*x*-^{14}C or

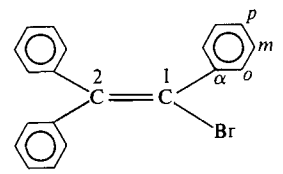
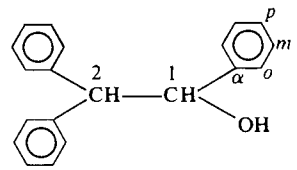
1—OAc-*x*-^{13}C, which was reduced with $LiAlH_4$, again as previously described (3), to give 1,2,2-triphenylethanol-*x*-^{14}C or 1,2,2-triphenylethanol-*x*-^{13}C (**2**—*x*-^{14}C or **2**—*x*-^{13}C). In the ^{14}C tracer work, the scrambling of the label from C-2 to C-1 was determined by oxidation of **2**—*x*-^{14}C to benzophenone (3) and the results are given in Table 1.

In the quantitative measurements using ^{13}C n.m.r., the total amount of ^{13}C enrichment and the distribution of the ^{13}C-label at the C-1 and C-2 positions of the reactant and product molecules, **1**—Br-2-^{13}C and **2**—*x*-^{13}C, have to be



1—Br



2

ascertained. The product is analyzed as the alcohol, **2**—*x*-^{13}C, rather than as triphenylvinyl acetate (**1**—OAc-*x*-^{13}C) since in **2**, the C-1 and C-2 ^{13}C signals are clearly separated from the aromatic absorptions and these signals are enhanced by the nuclear Overhauser effect (N.O.E.). The unlabeled reactant and product molecules, containing ^{13}C in its natural abundance, are used to establish the effect of relaxation time, T_1, on spectral intensities as well as to determine the relative N.O.E. enhancement factors for the carbon nuclei of interest. The labeled molecules were then used for the remaining measurements.

The ^{1}H-decoupled ^{13}C n.m.r. spectrum of **1**—Br is given in Fig. 1. The C-2 signal appears at 144.2 p.p.m. since in the spectrum of **1**—Br-2-^{13}C this is the strongest peak. From considerations based on the additivity of chemical shifts of related compounds, peaks *b*, *c*, and *d* at 144.2, 141.7, and 122.7 p.p.m. (Fig. 1) are tentatively assigned, respectively, to C-2 and C-α of the ring geminal to Br, the other two C-α, and C-1.[1] The remaining signals are due to the other aromatic carbons, C-*o*, C-*m*, and C-*p* of the three rings. If these assignments are correct, and if the N.O.E. enhancement for the quaternary carbons, peaks *b*, *c*, and *d*, is negligibly small, the ratio of intensities of *b*:*c*:*d* should be 2:2:1. Using the computer integration of these spectral regions and normalizing peak *c* to an intensity of 2.00, from three separate spectra, the average ratio of the intensities of C-2:C-1 was found to be 0.97 ± 0.19. This ratio is certainly unity within the limits of the experimental uncertainty.

The ^{1}H-decoupled ^{13}C n.m.r. spectrum of **2** is shown in Fig. 2. The absorptions at 76.0 and 59.8 p.p.m. are assigned to C-1 and C-2, respectively, since in the product molecule, **2**—*x*-^{13}C, the 59.8 p.p.m. peak is much stronger and this should correspond to C-2 as the ^{14}C tracer work indicated only 6–7% scrambling of the label from C-2 to C-1. The peaks at 140.9, 141.8, and 142.7 p.p.m. may be assigned to the three C-α while the remaining absorptions are due to the other aromatic carbons.

If T_1 for the nuclei of interest were different, the recovery of magnetization of each nucleus between pulses would be different and hence their ratio of intensities might be dependent on the pulse repetition rate. It is, therefore, desirable to test, under the present experimental conditions (HX 90 spectrometer, spectral width 5000 Hz, 4K memory, 4K pulses, pulse repetition rate

[1]In one spectrum only (shown in Fig. 1), peak *b* was found to be resolved into two components separated by approximately 4.5 Hz or 0.2 p.p.m.

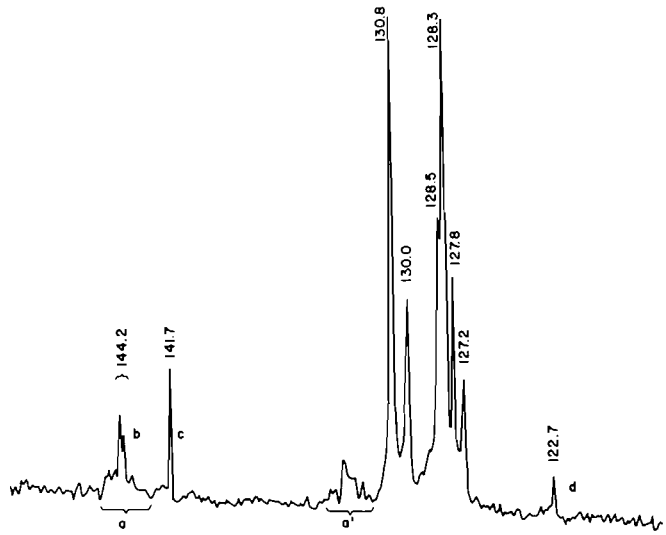

FIG. 1. ^{1}H-decoupled ^{13}C n.m.r. spectrum of triphenylvinyl bromide (**1**—Br). Peak positions are in p.p.m. from tetramethylsilane. C_6F_6, used as the locking compound, gave absorptions in the 144 and 132 p.p.m. regions (*a* and *a'*).

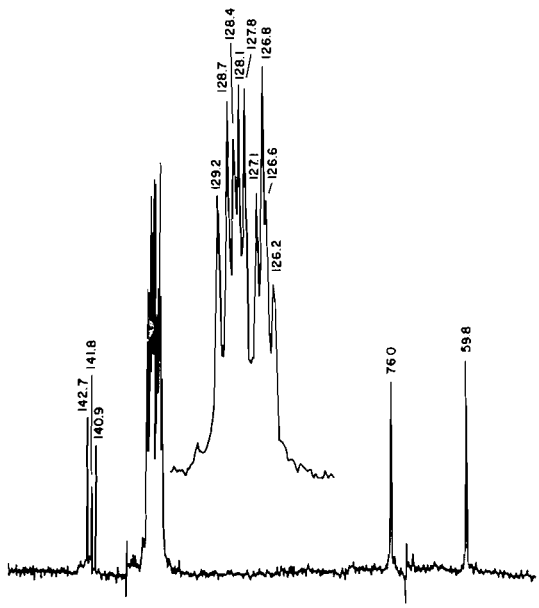

FIG. 2. ^{1}H-decoupled ^{13}C n.m.r. spectrum of 1,2,2-triphenylethanol (**2**). Peak positions are in p.p.m. from tetramethylsilane.

1.0 s), whether the relative intensities of C-1 and C-2 of **2** would vary with different pulse repetition rates. From triplicate spectra obtained with acquisition times of 0.5, 1.0, 2.0, and 4.0 s, the average value of the intensity ratio, I_2/I_1, was found to be 0.99 $\pm$ 0.05 and this ratio did not show any perceptible change with pulse repetition rate.

Using the ratio of intensities of (C-1 + C-2) to (C-*o* + C-*m* + C-*p*) of the unlabeled **2**, to be designated as $(I_1^0 + I_2^0)/I_{arom}$, as a reference standard, the extent of ^{13}C scrambling from C-2 to C-1 in the product molecule, **2**—*x*-^{13}C, derived from the original reactant, **1**—Br-2-^{13}C, can be calculated as illustrated in Appendix 1. The results are summarized in Table 2.

The extents of ^{13}C scrambling obtained from the ^{13}C n.m.r. spectra of **2** and **2**—*x*-^{13}C could be checked by measurements using the ^{13}C satellites of the ^{1}H signals of C-1 and C-2. The ^{1}H n.m.r. spectra of **2** and **2**—*x*-^{13}C, obtained by the FT mode with the HX 90 spectrometer, are shown in Fig. 3. The well separated signals due to the C-1 and C-2 protons (doublets *a* and *b*, respectively, in Fig. 3), and their respective ^{13}C satellites, are readily observable. From the spectrum of **2**—*x*-^{13}C (Fig. 3*B*), using the treatment derived in Appendix 2 and the appropriate integrated intensities, the ^{13}C enrichment and the

TABLE 2. Total ^{13}C enrichment and % ^{13}C scrambling from C-2 to C-1 in 1,2,2-triphenylethanol-*x*-^{13}C (**2**—*x*-^{13}C) calculated from ^{13}C n.m.r.

I_2/I_1	$(I_2 + I_1)I_{arom}$	^{13}C enrichment (%)	^{13}C scrambling from C-2 to C-1 (%)

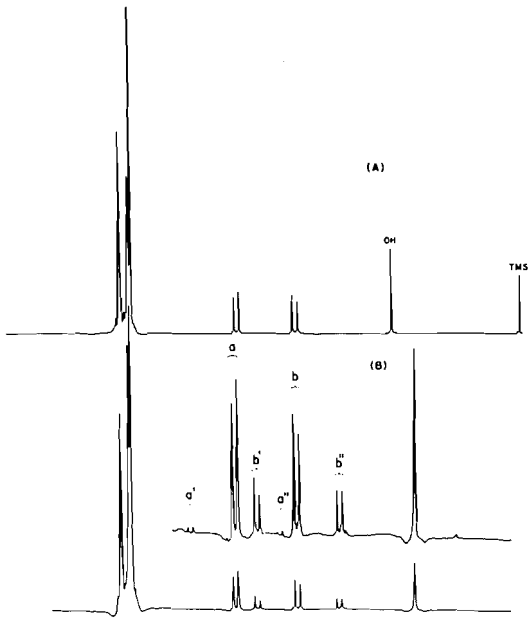

FIG. 3. ^{1}H n.m.r. spectra of 1,2,2-triphenylethanol (**2**) (*A*) and 1,2,2-triphenylethanol-*x*-^{13}C (**2**—*x*-^{13}C) (*B*).

^{13}C scrambling from C-2 and C-1 were calculated. The results are given in Table 3.

Another independent analysis of the extent of ^{13}C scrambling in **2**—*x*-^{13}C was carried out using the intensities of the C-1 and C-2 proton signals and their respective ^{13}C satellites (4). From a set of three spectra obtained with the HA100 spectrometer, the average intensity values were found to be 92, 4.0, 53, and 43, respectively, for the C-1 proton, C-1 satellites, C-2 proton, and C-2 satellites. Calculation from these data as described in the following paper (5) gave a total ^{13}C enrichment of 47% and a scrambling of the label from C-2 to C-1 of 6.6%. This result is in good agreement with those given in Table 3.

It is seen that the results from the n.m.r. work, including c.m.r. (Table 2), ^{13}C satellites of FT p.m.r. (Table 3) and ^{13}C satellites of CW p.m.r. (with HA100 spectrometer) all showed reasonable agreement, the average extent of 1,2-phenyl shift ± standard deviation in the reaction of **1**—Br-2-^{13}C with HOAc–AgOAc being 6.8 ± 0.9%. This value is also in agreement with the results from the ^{14}C tracer studies (Table 1). The present studies thus demonstrate that ^{13}C n.m.r. can be utilized quantitatively in appropriate isotopic scrambling investigations. However, the ^{14}C tracer method, although requiring additional steps involved in the degradation of the reaction product, is not obsolete. An important advantage in the radioactive tracer method that is made apparent from the present work in that the use of reactants of high specific activity is capable of giving results of higher precision and also allows for the use of liberal amounts of inactive carriers in aiding the isolation and purification of the desired products.

TABLE 3. Total ^{13}C enrichment and % ^{13}C scrambling from C-2 to C-1 in 1,2,2-triphenylethanol-*x*-^{13}C (**2**—*x*-^{13}C) calculated from ^{13}C satellites

p	*q*	^{13}C enrichment (%)	^{13}C scrambling from C-2 to C-1 (%)
46.2	11.9	50	6.0
45.9	12.7	50	5.4
44.5	10.2	48	7.0

It is of interest to point out that the 6.8 ± 0.9% 1,2-phenyl shift observed in the present work is, coincidentally, essentially the same as the extent of the analogous isotopic scrambling in the acetolysis of triphenylvinyl-2-^{14}C triflate (**1**—OTf-2-^{14}C) (3). In the solvolyses of **1**—OTf-2-^{14}C (3), it was suggested that the isotopic scrambling arises from a 1,2-phenyl shift across the double bond in the triphenylvinyl cation or ion-pair, the longer the lifetime of the cation or ion-pair, the greater the extent of isotopic rearrangement. Apparently, a similar mechanism operates in the reaction of C-2 labeled **1**—Br with HOAc–AgOAc.

Experimental

*Triphenylvinyl-2-^{14}C Bromide (**1**—Br-2-^{14}C) and Triphenylvinyl-2-^{13}C Bromide (**1**—Br-2-^{13}C)*

1—Br-2-^{14}C was prepared as described previously (3). Carboxyl-labeled phenylacetic acid was prepared by carbonation of $PhCH_2MgCl$ with $^{13}CO_2$ (from $BaCO_3$-^{13}C, 91 atom % ^{13}C, obtained from Merck, Sharp and Dohme of Canada, Ltd. and diluted with about an equal amount of ordinary $BaCO_3$), and then converted to **1**—Br-2-^{13}C by the same series of reactions as used in the preparation of **1**—Br-2-^{14}C (3).

*Reaction of **1**—Br-2-^{14}C or **1**—Br-2-^{13}C with HOAc–AgOAc*

A solution of 2.5 g (7.5 mmol) of **1**—Br-2-^{14}C or **1**—Br-2-^{13}C and 1.4 g (8.3 mmol) of AgOAc in 60 ml of glacial HOAc was refluxed with stirring for 24 h. The reaction mixture was cooled and the HOAc was removed in a rotary evaporator. The residue was dissolved in 100 ml of ether and washed with 10% K_2CO_3 solution and with H_2O. After drying over $MgSO_4$, the ether solution was treated with $LiAlH_4$ as described previously (3) to give 1,2,2-triphenylethanol-*x*-^{14}C or *x*-^{13}C (**2**—*x*-^{14}C or **2**—*x*-^{13}C). In a preparative run using non-labeled material,

20 g of **1**—Br was treated with HOAc–AgOAc in an analogous manner and the product, triphenylvinyl acetate (**1**—OAc), was isolated by the removal of the ether after drying and crystallization of the residue from 95% ethanol to give 16 g (90%) of **1**—OAc, m.p. 103–105° (lit. (6) m.p. 104–105°).

In the ^{14}C work, the alcohol, **2**—x-^{14}C, with added carrier if necessary, was degraded by oxidation to benzophenone (3). In the ^{13}C studies, except for one set of ^{1}H spectra obtained by the HA100 spectrometer for ^{13}C satellite analysis, all other n.m.r. spectra were obtained in CS_2 solution using a Bruker HX 90 spectrometer operating in the FT mode at 90.0 MHz for ^{1}H and at 22.63 MHz for ^{13}C, using a Nicolet 1080 series computer with 12K memory to collect and transform the free induction decays. In most cases, 4K memory was used for data collection.

The financial support given by the National Research Council of Canada and the technical assistance of B. A Davis are gratefully acknowledged.

Appendix 1

^{13}C Scrambling in **2**—x-^{13}C from ^{13}C Nuclear Magnetic Resonance Spectral Intensities

Since **2**—x-^{13}C consists of a mixture of **2**—2-^{13}C and **2**—1-^{13}C, let the integrated intensities of the ^{13}C signals at the C-2 and C-1 positions be I_2 and I_1. As part of the total intensity is due to naturally occurring ^{13}C (1.11%), let this part be designated I_2^0 and I_1^0, and let the part of the intensity due to ^{13}C enrichment be designated I_2^* and I_1^*.

From a typical measurement

$$I_2/I_1 = (I_2^* + I_2^0)/(I_1^* + I_1^0) = 9.81$$

and

$$(I_2 + I_1)/I_{arom} = (I_2^* + I_2^0 + I_1^* + I_1^0)/I_{arom} = 2.68$$

Since for the unenriched **2**,

$$(I_2^0 + I_1^0)/I_{arom} = 0.120$$

$$\frac{I_2^* + I_1^* + I_2^0 + I_1^0}{I_2^0 + I_1^0} = \frac{I_2^* + I_1^*}{I_2^0 + I_1^0} + 1 = \frac{2.68}{0.120} = 23.3$$

Converting the intensities to percentage ^{13}C

$$\frac{I_2^* + I_1^*}{1.11 + 1.11} + 1 = 23.3$$

Therefore $I_2^* + I_1^* = 47.3\%$, and this is the ^{13}C enrichment of the **2**—x-^{13}C.

Since

$$\frac{I_2^* + I_2^0}{I_1^* + I_1^0} = \frac{I_2^* + 1.11}{I_1^* + 1.11} = 9.81$$

and $$I_2^* = 47.3 - I_1^*$$

Hence $$I_1^* = 3.5\%$$

and ^{13}C scrambling from C-2 to C-1

$$(3.5/47.3) \times 100 = 7.4\%$$

Appendix 2

^{13}C Scrambling in **2**—x-^{13}C from ^{13}C Satellite Intensities

Firstly, for the reactant molecule, **1**—Br-2-^{13}C, let I_2 and I_1 be the ^{13}C intensities at C-2 and C-1, and let $I_2/I_1 = p$.

Since ^{13}C is present in natural abundance at C-1

$$I_1 = 1.11\%$$

Therefore

$$I_2 = I_1 p = 1.11p\%$$

The total ^{13}C content would be

$$I_2 + I_1 = 1.11(p + 1)\%$$

and the total ^{13}C enrichment would be

[1] $$I_2 - I_1 = 1.11(p - 1)\%$$

Now consider the product molecule, **2**—x-^{13}C, consisting of **2**—2-^{13}C and **2**—1-^{13}C.

Let I_2 and I_1 be the ^{13}C intensities at C-2 and C-1, and let

$$I_2/I_1 = q$$

it can be shown that the % of ^{13}C

$$\text{at C-1} = I_1/(I_2 + I_1) \times \text{total } ^{13}\text{C content} = 1.11(p + 1)/(q + 1)$$

$$\text{and at C-2} = \%\text{ total } ^{13}\text{C} - \%\ ^{13}\text{C at C-1} = 1.11q(p + 1)/(q + 1)$$

Subtracting the natural ^{13}C abundance of 1.11% would give the % ^{13}C enrichments at C-1 and C-2 (% $^{13}C_1$* and % $^{13}C_2$*) as follows

$$\%\ ^{13}C_1^* = [1.11(p + 1)/(q + 1)] - 1.11 = 1.11(p - q)/(q + 1)$$

$$\%\ ^{13}C_2^* = [1.11q(p + 1)/(q + 1)] - 1.11 = 1.11(pq - 1)/(q + 1)$$

Hence the % ^{13}C scrambling from C-2 to C-1 would be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$[2]\quad \frac{\%^{13}C_1^*}{\%^{13}C_1^* + \%^{13}C_2^*} \times 100 = \frac{(p-q)100}{p-q+pq-1}$$

Referring to the peaks of Fig. 3*B*:

$$q = I_2/I_1 = (b' + b'')/(a' + a'')$$

Since

$$\text{The } \%\ ^{13}\text{C at C-2} = [(b' + b'')/(b + b' + b'')] \times 100 = 1.11q(p+1)/(q+1)$$

it can be shown that

$$p = \frac{100\left(\frac{b' + b''}{a' + a''} + 1\right)}{1.11\left(\frac{b' + b''}{a' + a''}\right)\left(1 + \frac{b}{b' + b''}\right)}$$

Thus p and q can be calculated from the integrated intensities of the C-2 proton (doublet b), the C-2 satellites ($b' + b''$), and the C-1 satellites ($a' + a''$). The treatment also eliminates the need for the use of the ratio of the very large doublet a to the very small satellites $a' + a''$. Knowing p and q, the total ^{13}C enrichment and the $\%\ ^{13}C$ scrambling from C-2 to C-1 can be calculated from eqs. 1 and 2.

Nuclear Magnetic Resonance Studies on the Acetolysis and Trifluoroacetolysis of Trianisylvinyl-2-^{13}C Bromide

MITSUO OKA AND CHOI CHUCK LEE

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0

Received June 24, 1974

MITSUO OKA and CHOI CHUCK LEE. Can. J. Chem. **53**, 320 (1975).

The product from the reaction of trianisylvinyl-2-^{13}C bromide (**3**—Br-2-^{13}C) with HOAc–AgOAc or with CF_3COOH–CF_3COOAg was converted to 1,2,2-trianisylethanol-x-^{13}C (**4**—x-^{13}C) and examined for isotopic scrambling by the use of relative intensity ratios in the c.m.r. spectra with the CH_3O absorption as the internal standard, or by the intensities of the ^{13}C satellites in the p.m.r. spectra. About 20 and 50% rearrangements of the ^{13}C-label from C-2 to C-1 were found, respectively, for the acetolysis and trifluoroacetolysis. The results are in accord with the suggestion that there may be a competition between 1,2-aryl shifts in the triarylvinyl cation or ion-pair and the reaction of the ion with solvent to give product.

MITSUO OKA et CHOI CHUCK LEE. Can. J. Chem. **53**, 320 (1975).

Le produit de la réaction du bromure de trianisylvinyl-2-^{13}C (**3**—Br-2-^{13}C) avec AcOH–AcOAg ou avec CF_3COOH–CF_3COOAg a été transformé en trianisyl-1,2,2 éthanol-x-^{13}C (**4**—x-^{13}C). Faisant appel à la résonance magnétique nucléaire du carbone et utilisant l'absorption du OCH_3 comme référence interne, on a pu déterminer la compétition isotopique dans ces produits; une autre méthode d'arriver au même résultat est d'examiner l'intensité des bandes satellites ^{13}C dans le spectre r.m.n. du proton. On a trouvé environ respectivement 20 et 50% de réarrangement du ^{13}C de la position C-2 vers la position C-1 dans les réactions d'acétolyse et de trifluoroacétolyse. Ces résultats concordent avec l'hypothèse qu'il peut y avoir une compétition entre les déplacements 1,2 des groupes aryles dans le cation triarylvinyle ou une paire d'ion et la réaction de l'ion avec le solvant pour donner le produit. [Traduit par le journal]

In the preceding paper (1), the extent of isotopic scrambling in the reaction of triphenylvinyl-2-^{13}C bromide (**1**—Br-2-^{13}C) with HOAc–AgOAc was measured using ^{13}C n.m.r. and the ^{13}C satellites of ^{1}H n.m.r. The results, indicating $6.8 \pm 0.9\%$ rearrangement arising from 1,2-phenyl shifts across the double bond in the triphenylvinyl cation, were found to be in agreement with analogous scrambling data obtained from the same reaction with **1**—Br-2-^{14}C (1). In this work, the reaction product, **1**—OAc-x-^{13}C, was converted to 1,2,2-triphenylethanol-x-^{13}C (**2**—x-^{13}C) and the ^{13}C enrichments in the C-1 and C-2 positions of this product molecule were measured from c.m.r. intensity ratios utilizing the total intensities of the *o*, *m*, and *p*-carbons of the aromatic rings as a reference standard. The present work extends the study on the use of n.m.r. to measure isotopic scrambling in ^{13}C labeled systems. The reactions investigated are those of tri-*p*-methoxyphenylvinyl-2-^{13}C bromide (trianisylvinyl-2-^{13}C bromide, **3**—Br-2-^{13}C) with HOAc–AgOAc and with CF_3COOH–CF_3COOAg. The method (2) is based on measurements of relative intensities in the c.m.r. spectrum with respect to a suitable internal standard, and in the present work, the CH_3O absorption containing ^{13}C in its natural abundance is utilized as such an internal standard.

3—Br-2-^{13}C was prepared in a manner similar to the preparation of **1**—Br-2-^{13}C (1). Reaction of *p*-$CH_3OPhCH_2{}^{13}COOEt$ with *p*-CH_3OPh-MgBr gave 1,1,2-trianisylethanol-1-^{13}C which on treatment with Br_2 in HOAc yielded the desired trianisylvinyl-2-^{13}C bromide (**3**—Br-2-^{13}C). The acetolysis of **3**—Br-2-^{13}C in the presence of AgOAc was carried out at reflux temperature for 2 h as described by Rappoport and Gal (3), while the trifluoroacetolysis in the presence of CF_3COOAg was effected at room temperature for 10 min. The reaction product, **3**—OAc-x-^{13}C or **3**—$OOCCF_3$-x-^{13}C, was reduced twice successively with $LiAlH_4$ (4) to give 1,2,2-trianisylethanol-x-^{13}C (**4**—x-^{13}C) for n.m.r. examination.

The ^{1}H-decoupled ^{13}C n.m.r. spectrum of ordinary **4** with ^{13}C in its natural abundance, in $CDCl_3$ as solvent and as the locking compound, is shown in Fig. 1*A*. The chemical shifts from the c.m.r. spectra as well as data from the p.m.r. spectra of **4** are given in Table 1. From Fig. 1*A*, the intensity ratios for the unenriched **4**, I_1/I_s, I_2/I_s, and I_2/I_1, where I_1, I_2, and I_s are the

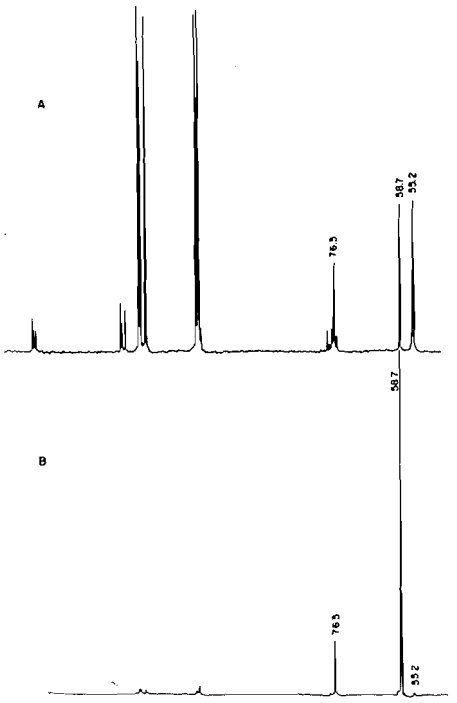

FIG. 1. ^{1}H-decoupled ^{13}C n.m.r. spectra of unenriched 1,2,2-trianisylethanol (**4**) (*A*) and of 1,2,2-trianisylethanol—*x*-^{13}C (**4**—*x*-^{13}C) (*B*) derived from acetolysis of 90% enriched trianisylvinyl-2-^{13}C bromide (**3**—Br-2-^{13}C).

integrated intensities of C-1, C-2, and the $\bar{C}H_3O$ standard, respectively, were measured, and the results are given in Table 2.

Figure 1*B* shows the ^{1}H-decoupled ^{13}C n.m.r. spectrum of **4**—*x*-^{13}C derived from the acetolysis, in the presence of AgOAc, of **3**—Br-2-^{13}C prepared from $BaCO_3$-^{13}C that was commercially designated as 90% enriched. While I_2/I_1 could be measured from Fig. 1*B*, the CH_3O absorption, I_s, was too weak; but with an amplified spectrum, I_1/I_s was obtained (Table 2). A duplicate experiment was carried out using 45% enriched **3**—Br-2-^{13}C, while a third measurement was made by diluting the 90% enriched **4**—*x*-^{13}C with carrier to give 9% enrichment. Using the appropriate intensity ratios and calculations as illustrated in the Experimental section, the scrambling of the label from C-2 to C-1 for the various experiments were obtained. The results, showing about 20 ± 1% rearrangement, are summarized in Table 2. Also included in Table 2 is the result, indicating about 50% rearrangement, calculated from the c.m.r. intensity ratios for the **4**—*x*-^{13}C derived from trifluoroacetolysis, in the presence of CF_3-COOAg, of 45% enriched **3**—Br-2-^{13}C.

The ^{13}C scrambling from C-2 to C-1 was also measured by the ^{13}C satellite intensities in the ^{1}H n.m.r. spectra of **4**—*x*-^{13}C obtained from acetolysis or trifluoroacetolysis of 90% enriched **3**—Br-2-^{13}C. Figure 2 shows a p.m.r. spectrum of **4**—*x*-^{13}C derived from the trifluoroacetolysis. Data on chemical shifts and coupling constants are summarized in Table 1. From the amplified portion of the spectrum, it is seen that the upfield portions of the satellites for the C-1 and C-2 protons, H_a and H_b, are complicated by overlaps. The total satellite intensity is, therefore, taken as twice the integrated area of the downfield half of the H_a and H_b satellites. It may be also noted that the H_b absorption is clearly split by long range coupling with the ^{13}C at C-1 as indicated in Fig. 2. From the intensity values for the C-1 proton, C-1 satellites, C-2 proton, and C-2 satellites, calculations as shown in the Experimental section gave the extents of ^{13}C scrambling from C-2 to C-1 as 21 and 50%, respectively, for the acetolysis and trifluoroacetolysis (Table 2).

1,2-Anisyl shifts across the double bond in the triarylvinyl cation have been observed in the solvolysis of 2,2-dianisyl-1-phenylvinyl bromide (**5**) in HOAc–AgOAc (5) and in CF_3CH_2OH or 60% EtOH (6).[1] Considerations of the kinetics, stereochemistry, and nature of products in reactions of **5** and related triarylvinyl systems (5, 6) have led to the conclusion that such solvolyses proceed via the S_N1 mechanism without β-aryl participation. The rearrangement of the 2,2-dianisyl-1-phenylvinyl cation to the 1,2-dianisyl-2-phenylvinyl cation took place readily since the latter ion, with the anisyl substituent at C-1, is more stable. The present results demonstrate the occurrence of degenerate 1,2-anisyl shifts in the trianisylvinyl cation. As suggested earlier in accounting for the different extents of degenerate 1,2-phenyl shifts in the triphenylvinyl system (4), there may be a competition between 1,2-aryl shift in the triarylvinyl cation or ion-pair and the reaction of the ion with solvent to give product. Thus, a greater extent of rearrangement may be related to a longer lifetime of the cation or ion-pair. In the present work, about 20% 1,2-anisyl shift is

[1]For references to other 1,2-aryl shifts and general reviews on reactions of vinyl cations, see literature cited in ref. 4.

*Based on the commercial designation of 90% enrichment without dilution or diluted with carrier by factors of 2 and 10.
†I_1, I_2, and I_s are, respectively, the integrated c.m.r. intensities for C-1, C-2, and the CH_3O internal standard.

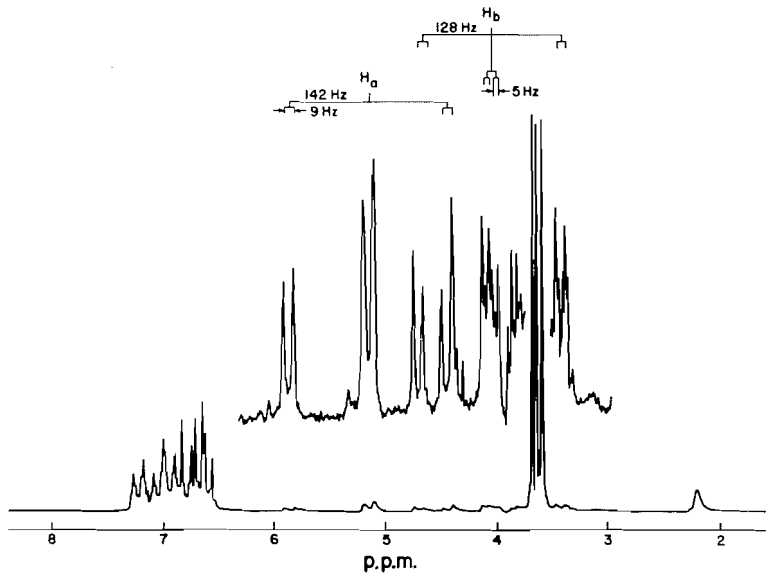

FIG. 2. ^{1}H n.m.r. spectrum of 1,2,2-trianisylethanol—*x*-^{13}C (**4**—*x*-^{13}C) derived from trifluoroacetolysis of 90% enriched trianisylvinyl-2-^{13}C bromide (**3**—Br-2-^{13}C).

found in the reaction of **3**—Br-2-^{13}C with HOAc–AgOAc, and this compares with about 7% rearrangement arising from 1,2-phenyl shifts in the analogous reaction with **1**—Br-2-^{13}C (1). The difference reflects the greater migratory aptitude of the anisyl group and probably also suggests a longer lifetime for the more stable trianisylvinyl cation as compared to the triphenylvinyl cation. For the trifluoroacetolysis, the extremely low nucleophilicity of the solvent (7, 8) allows the 1,2-anisyl shift to compete favorably to give the completely scrambled trianisylvinyl cation with 50% rearrangement, and this is in accord with the previous finding (4) that in solvolytic studies with triphenylvinyl-2-^{14}C triflate, the highest rearrangement was observed in the solvent of lowest nucleophilicity.

Experimental

1,1,2-Trianisylethanol-1-^{13}C

p-Methoxyphenylacetic acid-1-^{13}C was prepared from reaction of *p*-CH_3OPhCH_2MgCl with $^{13}CO_2$ from 90% enriched $Ba^{13}CO_3$ (Merck, Sharp and Dohme of Canada Ltd.) as previously described for the analogous preparation of *p*-$CH_3OPhCH_2{}^{14}COOH$ (9). Esterification of the labeled acid in absolute EtOH in the presence of a catalytic amount of H_2SO_4 gave a 97% yield of the ester, *p*-$CH_3OPhCH_2{}^{13}COOCH_2CH_3$, p.m.r. ($CCl_4$) δ 1.20 ($CH_3$ of Et, t, J = 7 Hz), 3.42 (CH_2, J^{13}_{CCH} = 8 Hz), 3.70 (CH_3O, s), 4.07 (CH_2 of Et, q of d, J^{13}_{CCH} = 4 Hz), 6.67–7.20 (aromatic, m).

To the Grignard reagent prepared from 11.2 g (0.060 mol) of *p*-CH_3OPhBr and 2.0 g (0.082 mol) of Mg in 80 ml of tetrahydrofuran (THF) was added over a period of 1 h a solution of 3.7 g (0.019 mol) of *p*-CH_3OPhCH_2-$^{13}COOC_2H_5$ in 35 ml of THF. The reaction mixture was refluxed for 2 h and then poured into a solution of 20 g NH_4Cl and 4 ml NH_4OH in 200 ml H_2O. The THF layer was separated and the aqueous layer was extracted twice with ether. The combined THF solution and ether extract was washed with H_2O and dried over $MgSO_4$. After removal of the solvent, the residual product was washed with CCl_4 and then recrystallized from EtOH to give 4.4 g (63%) of 1,1,2-trianisylethanol-1-^{13}C, m.p. 129° (lit. (10) m.p. 130–131°), p.m.r. ($CDCl_3$) δ 2.23 (OH, broad s), 3.52 (CH_2, J^{13}_{CCH} = 4 Hz), 3.73, 3.77 (three CH_3O two singlets), 6.60–7.43 (aromatic, m).

Trianisylvinyl-2-^{13}C Bromide (3—Br-2-^{13}C) (4)

A solution of 2.1 g (0.013 mol) of Br_2 in 10 ml of HOAc was added dropwise with stirring to a solution of 4.2 g (0.012 mol) of 1,1,2-trianisylethanol-1-^{13}C in 200 ml of HOAc. The reaction mixture was stirred at room temperature for 7 h and then poured into 250 ml of H_2O containing 1.0 g of $Na_2S_2O_3$. The product was collected by filtration, washed with H_2O, and recrystallized from CH_3OH to give 3.2 g (65%) of **3**—Br-2-^{13}C, m.p. 120–122° (lit. (10) m.p. 119–121°), p.m.r. ($CDCl_3$) δ 3.70, 3.77, 3.80 (three CH_3O, three singlets), 6.53–7.07 (aromatic, m). Comparison of the c.m.r. spectra of the labeled **3**—Br-2-^{13}C and the unlabeled **3**—Br indicated that the ^{13}C enrichment was located only at one quaternary carbon at 141.7 p.p.m. and this absorption was assigned to C-2 of the **3**—Br-2-^{13}C.

Acetolysis of Trianisylvinyl-2-^{13}C Bromide (3—Br-2-^{13}C) (3)

In a typical run, a mixture of 0.90 g (2.1 mmol) of 90% enriched **3**—Br-2-^{13}C, 0.38 g (2.3 mmol) of AgOAc, 13 ml of HOAc, and 1.0 ml of acetic anhydride was heated under reflux for 2 h. The hot solution was filtered,

most of the solvent evaporated off, the residue redissolved in cyclohexane, and the solution was again filtered. After removal of the solvent from the cyclohexane solution, the residual trianisylvinyl-*x*-^{13}C acetate (**3**—OAc-*x*-^{13}C), recovered as an oil, p.m.r. ($CDCl_3$) δ 2.00 (AcO, s), 3.77, 3.82 (three CH_3O, two singlets), 6.67–7.33 (aromatic, m), and was utilized directly for reduction to 1,2,2-trianisylethanol-*x*-^{13}C (**4**—*x*-^{13}C). In preliminary larger scale runs with unlabeled material, **3**—OAc, recrystallized from EtOH, m.p. 97–98° (lit. (3) m.p. 97–98°), was obtained in yields of more than 90% as reported by Rappoport and Gal (3).

Trifluoroacetolysis of Trianisylvinyl-2-^{13}C Bromide (3—Br-2-^{13}C)

When 0.90 g (2.1 mmol) of **3**—Br-2-^{13}C and 0.50 g (2.3 mmol) of CF_3COOAg were added to 13 ml of CF_3COOH, a purple color developed and the mixture was stirred at room temperature for 10 min. The solution was filtered, the solvent removed at room temperature under reduced pressure, the residue redissolved in cyclohexane, and the solution was again filtered. After removal of the solvent from the cyclohexane solution, the residual **3**—$OOCCF_3$-*x*-^{13}C was recovered as an oil, p.m.r. ($CDCl_3$) δ 3.75, 3.78 (three CH_3O, two singlets), 6.67–7.30 (aromatic, m), and was utilized directly for reduction to **4**—*x*-^{13}C. In preliminary runs with unlabeled material, the oily **3**—$OOCCF_3$ was obtained in about 50% yield, the mass spectrum of which show *m/e* 458 as the molecular ion and the base peak.

1,2,2-Trianisylethanol-x-^{13}C (4—x-^{13}C)

The **3**—OAc-*x*-^{13}C and **3**—$OOCCF_3$-*x*-^{13}C, obtained from acetolysis and trifluoroacetolysis, respectively, were reduced successively twice with $LiAlH_4$ to give **4**—*x*-^{13}C (4). The following is a typical experiment.

The **3**—OAc-*x*-^{13}C obtained from the acetolysis of 0.90 g of 90% enriched **3**—Br-2-^{13}C was dissolved in 35 ml of THF and 1.0 g of $LiAlH_4$ was added portionwise. After the reaction mixture was refluxed for 5 h, H_2O was added and the resulting material was extracted 4 times with ether. The combined extract was washed with H_2O, dried over Na_2SO_4, and the ether was removed to give a product, the p.m.r. analysis of which indicated that it was a 30:70 mixture of the ketone, $AnCOCHAn_2$-*x*-^{13}C, and the alcohol, **4**—*x*-^{13}C. The product mixture was redissolved in 40 ml of THF and treated once more with 1.0 g of $LiAlH_4$ as described above. The recovered colorless product was recrystallized from EtOH, giving 0.50 g of pure **4**—*x*-^{13}C, m.p. 113–114°.

Anal. Calcd. for $C_{23}H_{24}O_4$ (90% ^{13}C enriched for one C atom): C, 75.86; H, 6.62. Found: C, 76.09; H, 6.70.

Nuclear Magnetic Resonance Studies

The ^{1}H-decoupled ^{13}C n.m.r. spectra were obtained at 25.2 MHz on a Varian XL-100-15 spectrometer operating in the FT mode. The spectra were collected with 0.4 s acquisition time, a pulse width of 50 μs, for a 5000 Hz spectral width or with 2.0 s acqusition time, a pulse width of 90 μs, for a 1000 Hz spectral width, by a 6201/i computer with 8K memory. The data length for all spectra were 4960 points. The accumulation time was 0.5–2.0 h depending on amounts of sample (0.1–0.5 g) which were examined in 12 mm sample tubes in either $CDCl_3$ or acetone-d_6. The assignments for C-1 and C-2 of 1,2,2-trianisylethanol-*x*-^{13}C (**4**—*x*-^{13}C) (Table 1 and Fig. 1) were confirmed by mass spectrometry in that the fragmentation of **4**—*x*-^{13}C showed that the An_2CH^+ fragment was much more enriched in ^{13}C than the $AnCHOH^+$ fragment. These assignments are also consistent with the corresponding chemical shifts for C-1 and C-2 of 1,2,2-triphenylethanol-*x*-^{13}C (**2**—*x*-^{13}C) which were assigned unambiguously by ^{14}C data (1).

As an illustration of the calculation of the ^{13}C scrambling from C-2 to C-1 in the **4**—*x*-^{13}C using the intensity ratios I_1/I_s, I_2/I_s, and I_2/I_1 (Table 2), take as an example the data from the acetolysis of 90% enriched **3**—Br-2-^{13}C. If we designate I_1^0 and I_1^* as the ^{13}C absorption due to the naturally abundant ^{13}C at C-1 and to the ^{13}C enrichment at C-1, from Table 2, it is seen that

$$I_1^0/I_s = 0.586,$$

and

$$I_1/I_s = (I_1^0 + I_1^*)/I_s = 10.4$$

Hence

$$(I_1^0 + I_1^*)/I_1^0 = 10.4/0.586 = 17.7$$

Converting the intensities to % ^{13}C

$$(1.1 + I_1^*)/1.1 = 17.7$$

Therefore, the ^{13}C enrichment at C-1 = I_1^* = 18%.

Where I_2/I_s is also measured from the c.m.r. spectrum, I_2^* can be calculated in the same way.

In the **4**—*x*-^{13}C from the experiment with 90% enrichment, I_s was too weak in comparison to I_2 for an accurate measurement of I_2/I_s, hence I_2/I_1 was utilized. Since

$$I_2/I_1 = (I_2^0 + I_2^*)/(I_1^0 + I_1^*) = 6.54,$$

and

$$I_2^0/I_1^0 = 1.68$$

$$\frac{(I_2^0 + I_2^*)I_1^0}{(I_1^0 + I_1^*)I_2^0} = 6.54/1.68 = 3.89$$

Converting the intensities to % ^{13}C

$$\frac{(1.1 + I_2^*)1.1}{(1.1 + 18)1.1} = 3.89$$

Therefore,

The ^{13}C enrichment at C-2 = I_2^* = 73%

Hence, the calculated ^{13}C enrichment = 18 + 73 = 91% and the ^{13}C rearrangment from C-2 to C-1 = (18/91) × 100 = 20%.

The p.m.r. spectra were obtained using a Varian HA-100 spectrometer. Determinations of ^{13}C scrambling by satellite intensities were carried out using products derived from acetolysis or trifluoroacetolysis of 90% enriched **3**—Br-2-^{13}C. For the trifluoroacetolysis, from a set of three spectra (an example is given in Fig. 2), the average intensity values for the C-1 proton, C-1 satellites, C-2 proton, and C-2 satellites, respectively, were found to be 49, (2 × 22), 47, and (2 × 21). Hence, the ^{13}C contents at C-1 and C-2, respectively, were [44/(49 + 44)] × 100 = 47% and [42/(47 + 42)] × 100 = 47%. Thus ^{13}C enrichments at each of C-1 and C-2, would be 47 − 1.1 = 46%, giving a total enrichment of 92% and a scrambling of the label from C-2 to C-1 of (46/92) × 100 = 50%. In a similar way, the p.m.r. spectra of the **4**—*x*-^{13}C derived

from the acetolysis of 90% enriched **3**—Br-2-^{13}C gave average intensity values for the C-1 proton, C-1 satellites, C-2 proton, and C-2 satellites of 50, 12, 21, and 48, respectively, and these intensities corresponded to a 21% ^{13}C scrambling from C-2 to C-1.

The financial support given by the National Research Council of Canada and the technical assistance in obtaining the c.m.r. and p.m.r. spectra given by Mr. Mytosk Mazurek of the Prairie Regional Laboratory of the National Research Council are sincerely acknowledged.

Received September 3, 1974

MICHAEL J. BULA, J. STEPHEN HARTMAN and CHIRAKAL V. RAMAN. Can. J. Chem. **53**, 326 (1975).

Halogen redistribution in the sparingly soluble boron trihalide adducts of Me_3P, Me_3PO, and Me_3PS gives mixed boron trihalide adducts of these bases. Only small proportions of the fluorine-containing mixed boron trihalide adducts are present at equilibrium in the Me_3PS adduct system, in accord with previous studies of adducts of other sulfur donors. The effects of the donor on F,Cl and F,Br halogen redistribution are discussed.

MICHAEL J. BULA, J. STEPHEN HARTMAN et CHIRAKAL V. RAMAN. Can. J. Chem. **53**, 326 (1975).

La redistribution des halogènes, dans les adduits peu solubles des halogénures de bore avec Me_3P, Me_3PO et Me_3PS, conduit à des adduits de ces bases avec des trihalogénures mixtes de bore. Seulement une faible portion d'adduit de trihalogénure mixte de bore contenant du fluor est présent à l'équilibre dans le système d'adduits avec Me_3PS; ce résultat concorde avec des études antérieures sur des adduits d'autres dérivés du soufre agissant comme donneurs. On discute des effets du donneur sur la redistribution des halogènes F,Cl et F,Br. [Traduit par le journal]

Introduction

Recent studies have demonstrated that oxygen-donor and sulfur-donor adducts of the boron trihalides show characteristic differences in halogen redistribution equilibria (1–3). Striking deviations from the statistical distribution of halogens among mixed and unmixed boron trihalide adducts were observed when sulfur was the donor and fluorine was one of the halogens (1, 2). We now report a study of adducts of a further series of related Lewis bases, Me_3P, Me_3PO, and Me_3PS, to provide further information about the effects of the donor atom on halogen redistribution in adducts.

Some n.m.r. parameters for boron trihalide adducts of Me_3P have been reported previously (4–6), and the BCl_2Br and $BClBr_2$ adducts of Et_3P and Me_3P have been identified by n.m.r. (7). In the course of the present work, Drake and Rapp reported n.m.r. studies of mixed boron trihalide adducts of PH_3 and CD_3PH_2 (8), as well as n.m.r. parameters of unmixed boron trihalide adducts of related phosphines (9). Also Sisler and co-workers have shown that certain methyldichlorophosphine – boron trihalide adducts undergo halogen redistribution between the phosphorus and boron halogens (10). Nuclear magnetic resonance parameters of the BCl_3, BBr_3, and BI_3 adducts of Me_3PS have recently been reported (11, 12).

[1]To whom all correspondence should be addressed.

Experimental

Trimethylphosphine was prepared from methyl magnesium iodide and phosphorus trichloride in ether, and purified via the silver iodide complex (13). Trimethylphosphine oxide was prepared from phosphorus oxychloride by the method of Burg and McKee (14). Trimethylphosphine sulfide (Maybridge Research Chemicals) was dried under vacuum overnight and used without further purification. ^1H spectra revealed no impurities in any of the bases. The purification of the boron trihalides and methylene chloride has been described previously (3), as has the n.m.r. instrumentation (1, 3).

Nuclear magnetic resonance samples containing Me_3P were prepared entirely on a high-vacuum system. The less volatile compounds Me_3PO and Me_3PS were added to n.m.r. tubes in a dry box. After weighing, solvent, Lewis acids, and n.m.r. reference compounds were condensed in at $-196°$, and the samples were sealed off. The BF_3 adducts of all of the bases were very soluble in methylene chloride but the BCl_3 and especially the BBr_3 adducts were much less soluble, and the low solubility restricted the study. Solubility problems were serious in the mixed-adduct systems as well; insoluble material, which was not further investigated, was present in many samples.

Results

Nuclear magnetic resonance parameters are given in Table 1. All of the adduct and free-base ^1H signals were split into 1:1 doublets by

*^{1}H, −90°, p.p.m. to low field of internal tetramethylsilane; ^{19}F, −50°, p.p.m. to high field of internal $CFCl_3$; methylene chloride solution.

†Literature values of ^{1}H chemical shift and $J_{^{1}H-^{31}P}$: Me_3P, 0.97 δ and 2.0 Hz in methylene chloride (23); 0.81 δ and 2.5 Hz in benzene (5). $Me_3P.BF_3$, 0.63 δ and −11.3 Hz in benzene (5); 1.38 δ and 10.6 Hz in acetonitrile (6). ^{19}F chemical shift and ^{11}B—^{19}F coupling constant in acetonitrile: $Me_3P.BF_3$, 139.0 p.p.m. and 51 Hz (6).

‡Literature values of ^{1}H chemical shift and $J_{^{1}H-^{31}P}$: Me_3PS, 1.73 δ, 13.0 Hz; $Me_3PS.BCl_3$, 2.07 δ, 13.5 Hz; $Me_3PS.BBr_3$, 2.14 δ, 13.7 Hz in methylene chloride (11).

§Obtained by plotting the ^{1}H n.m.r. parameter obtained from the averaged (Me_3PS + $Me_3PS.BF_3$) resonance *vs.* BF_3/Me_3PS ratio; the constant value obtained at high ratios was taken to be the BF_3 adduct value.

coupling to ^{31}P. In the Me_3P adduct resonances there was also a pronounced broadening of the doublet components due to unresolved coupling with ^{11}B, so that the closely-spaced mixed-adduct resonances could not be resolved. This problem was overcome by the use of ^{11}B decoupling. Typical ^{1}H spectra with well-resolved mixed-adduct resonances are shown in Fig. 1. It was not possible, except in the Me_3PO system, to resolve the more closely spaced BCl_nBr_{3-n} adduct ^{1}H peaks. In the Me_3PO and Me_3PS mixed-adduct systems the proton chemical shifts showed a dependence of up to 0.15 p.p.m. on sample composition. However relative chemical shifts between successive mixed-halogen adducts in the series (donor).BF_nX_{3-n} (n = 0–3, X = Cl, Br) were constant to within 0.02 p.p.m. in different samples.

In Fig. 1 the contrast is evident between the large proportions of mixed-adduct species present at equilibrium in the Me_3PO adduct sample and the small proportions in the Me_3PS adduct sample. In the Me_3P system there are large proportions of the BF_2Cl adduct but only very small proportions of the $BFCl_2$ adduct.

Pronounced differences in the appearance of the ^{19}F resonances of fluorine-containing adducts of each of the three bases, described below, arise because of different degrees of resolution of ^{11}B–^{19}F and ^{19}F–^{31}P coupling in the different adduct series.

Me_3P Adducts

Separate doublets for $Me_3P.BF_3$ and Me_3P could be observed at −40° in the ^{1}H spectrum, but only averaged signals were observed at room temperature due to rapid chemical exchange (5, 15). Since the BF_2Cl, $BFCl_2$, and BCl_3 adducts under ^{11}B decoupling gave separate sharp doublets at room temperature in

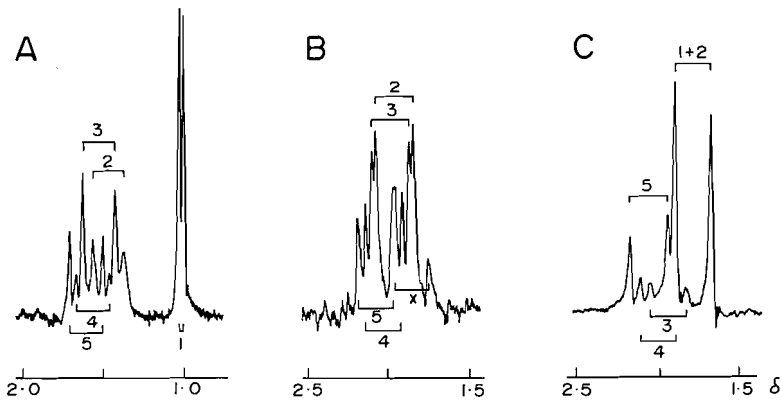

FIG. 1. ^1H n.m.r. spectra of methylene chloride solutions of Lewis base, BF_3, and BCl_3. (*A*) Me_3P, −40°, ^{11}B decoupled; (*B*) Me_3PO, 35°; (*C*) Me_3PS, −90°, 3:1:1 molar ratio. Identification of doublets: *1*, free base; *2*, BF_3 adduct; *3*, BF_2Cl adduct; *4*, $BFCl_2$ adduct; *5*, BCl_3 adduct. An exchange-averaged doublet arising from free Me_3PO and an unknown species is marked X.

the presence of excess Me_3P, exchange of free base with these adducts is much slower than with the BF_3 adduct.

^{19}F spectra of the Me_3P adducts were eight-line multiplets due to coupling to both ^{11}B and ^{31}P. There is an approximate inverse relationship between ^{11}B–^{19}F and ^{19}F–^{31}P coupling constants. The eight-line multiplets of the BF_3 and BF_2Cl adducts overlapped and it was not possible to resolve the low-intensity multiplet arising from the $BFCl_2$ adduct.

Me_3PO Adducts

Separate 1:1 doublets were observed for Me_3PO and its BF_3 adduct at 35° in the ^1H spectrum, showing that chemical exchange is slower than in the Me_3P–BF_3 adduct system. A small doublet arising from an impurity, and appearing at about 0.09 p.p.m. to low field of the BF_3 adduct doublet, was present as well and apparently corresponds to a small second ^{19}F peak observed at 150.3 p.p.m. Me_3PO–BCl_3 samples also gave, in addition to the 1:1 doublets of free base and adduct, a small doublet at lower field.

In the Me_3PO–BF_3–BCl_3 system additional large doublets corresponding to the BF_2Cl and $BFCl_2$ adducts were observed in the ^1H spectrum, indicating that large amounts of the mixed-halogen adducts are present at equilibrium. However, a precipitate formed, and in several samples that should have contained an excess of uncomplexed Me_3PO if only 1:1 adduct were formed, no free-base doublet could be detected. Titration of further Me_3PO into one such solution gave a "free-base" doublet but this had variable chemical shift; as more Me_3PO was added the doublet moved to higher field toward the normal position of the Me_3PO resonance. This is indicative of a very rapid chemical exchange between Me_3PO and a complex. Since no additional doublets could be "frozen out" even at −90°, the exchange would have to be a very rapid process. Protonation of Me_3PO due to the presence of impurity H_2O or HF does not seem likely as a similar effect was not observed in unmixed-halogen samples, and a more plausible explanation is the formation of ionic mixed boron trihalide adducts (16), which exchange rapidly with free base. Low solubilities and an appreciable variation of adduct chemical shifts with solution composition made this system especially difficult to study.

Similar effects were encountered in the Me_3PO–BF_3–BBr_3 system, but not in the Me_3PO–BCl_3–BBr_3 system where the formation of BCl_2Br and $BClBr_2$ adducts was demonstrated by the appearance of large new closely-spaced adduct resonances without any extraneous peaks. The extra complexity when both fluorine and a heavier halogen are present is reminiscent of the tetramethylurea–BF_3–BCl_3 system in which ionic adducts could be formed in large amounts (16), and it seems likely that ionic adducts of low solubility are formed in the present system. If these have structures such as $(Me_3PO)_2BF_2^+$. Cl^-, the anomalies in the spectra could be explained. Slow formation of such species would be consistent with the observation that initially-soluble n.m.r. samples eventually become insoluble after storage and crystallization at −78°.

^{19}F spectra of Me_3PO–BF_3–BCl_3 solutions

contained peaks which could be assigned to the BF_3, BF_2Cl, and $BFCl_2$ adducts, and a large additional peak at 138.8 p.p.m. which also appeared in spectra of Me_3PO–BF_3–BBr_3 solutions. The BF_3, BF_2Cl, and $BFCl_2$ adduct peaks were successively more broadened, but no splittings due to spin–spin coupling were resolved. The presence of the additional peak confirms that these systems are complex. The very weak and broad BF_2Br and $BFBr_2$ adduct resonances could not be adequately resolved.

Me_3PS Adducts

The presence of BF_3 causes a pronounced shift of the Me_3PS proton resonance to low field, demonstrating that an adduct is formed. However, separate 1:1 doublets could not be observed for Me_3PS and its BF_3 adduct even at $-100°$, showing that chemical exchange with excess base occurs much more rapidly than in the BF_3 adducts of Me_3P and Me_3PO. Separate doublets due to free and complexed Me_3PS could however be resolved in the Me_3PS–BCl_3 system below $-5°$, and in the Me_3PS–BBr_3 system at room temperature.

In the Me_3PS–BF_3–BCl_3 system separate low-temperature doublets could be observed for all of the BF_nCl_{3-n} adducts except the BF_3 adduct. All of these doublets coalesced with the free-Me_3PS doublet below room temperature to give a single averaged 1:1 doublet due to rapid chemical exchange. Approximate coalescence temperatures are: BF_2Cl adduct, $-70°$; $BFCl_2$ adduct, $-30°$; BCl_3 adduct, $-5°$. The BF_nBr_{3-n} adducts could be formed in the same way and behaved similarly. All of these mixed boron trihalide adducts were present in only small concentrations at equilibrium, compared to the unmixed-halogen adducts. In the Me_3PS–BCl_3–BBr_3 system a single broadened doublet, of chemical shift intermediate between the chemical shifts of the BCl_3 and BBr_3 adducts, indicated but did not prove the presence of the BCl_2Br and $BClBr_2$ adducts.

The ^{19}F spectrum of $Me_3PS.BF_3$ was a broad single peak whereas the BF_2Cl and $BFCl_2$ adducts gave broad 1:1:1:1 quartets due to coupling with ^{11}B; coupling with ^{31}P could not be detected.

Discussion

Effects of the Donor Atom

The Me_3PO and Me_3PS adduct results are in accord with the previously noted pattern of differences between oxygen-donor and sulfur-donor boron trihalide adducts (2), although here the oxygen-donor results are complex as with tetramethylurea (16) rather than simple as with Me_2O (3). Thus at equilibrium only small proportions of mixed F,Cl and F,Br adducts of Me_3PS are present, in contrast to the much larger proportions of these adducts of Me_3PO. Also the BF_3 adduct of Me_3PS, unlike that of Me_3PO, undergoes such rapid exchange with free base that separate free-base and BF_3 adduct peaks cannot be resolved at $-100°$. This very rapid exchange is in accord with a very weak donor–acceptor bond in $Me_3PS.BF_3$, and hence with the inability of Boorman and Potts to isolate this adduct at 0 °C (11). The similarity to the Me_2S system is striking. The $Me_3PS.BF_nCl_{3-n}$ adduct peaks coalesce with the free Me_3PS peak at temperatures that are within 10° of those observed in the coalescence of the corresponding adduct peaks in the $Me_2S.BF_nCl_{3-n}$ adduct system (1), further demonstrating the great similarity between the sulfur-donor systems. The principal difference between them is that the Me_3PS system gives detectable amounts of *both* the BF_nCl_{3-n} and BF_nBr_{3-n} series of mixed adducts; it is the first sulfur donor reported to do so.

In the Me_3P adducts the phosphorus donor does not appear to give rise to unique effects. The rates of donor–acceptor bond breaking are within the range observed for oxygen-donor adducts, slower than with Me_2O and faster than with tetramethylurea as donor. The halogen redistribution equilibrium gives large amounts of $Me_3P.BF_2Cl$ but surprisingly only small amounts of $Me_3P.BFCl_2$. These studies were hampered by low solubilities. It is interesting that when Me_3N is present as well in the system the $Me_3P.BFCl_2$ adduct is present in larger relative proportions (22).

The occurrence of very small or zero amounts of fluorine-containing mixed adducts at equilibrium has also been noted in adducts of certain of the Me_nPH_{3-n} series of bases. Successive methylation of PH_3 gives successively more stable BF_3 adducts (17). PH_3 does not form a BF_3 adduct, whereas the BCl_3 and BBr_3 adducts are quite stable; in this situation no BF_2Cl or $BFCl_2$ adducts could be detected, although the probable presence of BF_2Br and $BFBr_2$ adducts was reported (8). $MePH_2$ forms a weak BF_3 adduct (8, 17) and in this system both the BF_nCl_{3-n} and BF_nBr_{3-n} series of mixed adducts

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

were present in sufficient amounts to be detected. The $Me_3P.BF_3$ adduct, which is more stable, gives larger proportions of fluorine-containing mixed boron trihalide adducts. Thus the very nonstatistical redistribution equilibria between fluorine and heavier halogens is neither a specific sulfur-donor effect nor an effect of "soft bases" in general, but seems to occur in systems where there is an anomalously large difference between BF_3 and BCl_3 acceptor strengths. The *cause* of such large differences in basicity towards these superficially similar Lewis acids has not yet been satisfactorily explained.

Nuclear Magnetic Resonance Parameters

^1H complexation shifts of the adducts are as expected from previous work, those of Me_3PS being smaller than those of the corresponding Me_3PO adducts. For each donor, complexation shifts are smallest for the BF_3 adduct and largest for the BBr_3 adduct. The ^1H n.m.r. parameters are consistent with literature values where these are available. It is of interest that Grobe and Möller report a ^1H complexation shift to *high* field in $Me_3P.BF_3$ (5), apparently as a result of a specific solvent–solute interaction. They used benzene as a solvent. To obtain meaningful complexation shifts, anisotropic solvents such as benzene which are capable of strong specific interactions with solute species (18) should be avoided.

Table 1 gives magnitudes and not signs of the coupling constants. Grobe and Möller assign the ^1H–^{31}P coupling constant as positive in free Me_3P and negative in the BF_3 adduct (5). Since the magnitude of this coupling constant varies only slightly among all of the adducts the sign is probably negative in all of these species as well.

^{19}F chemical shifts of BF_nX_{3-n} (n = 1–3, X = Cl, Br) adducts normally move to lower field with increasing substitution of fluorine by a heavier halogen (1–3, 16, 19). This trend is reversed in the Me_3P adducts, where the $BFBr_2$ adduct has a chemical shift intermediate between those of the BF_3 and BF_2Br adducts. This apparent anomaly can be accounted for in terms of "pairwise interaction" parameters, as we have discussed elsewhere (20). ^{19}F pairwise interaction parameters derived from Table 1 can be used to calculate a chemical shift of 134.2 p.p.m. for $Me_3P.BFCl_2$. Thus the low-intensity eight-line ^{19}F multiplet of this adduct occurs approximately midway between the overlapping $Me_3P.BF_3$ and $Me_3P.BF_2Cl$ multiplets and is obscured by them.

Adduct Solubility and Further Reactions

Low solubilities and further reactions of the adducts have prevented studies as detailed as those that we have carried out on boron trihalide adducts of other donors (1–3, 16). Other workers have experienced similar difficulties with these adduct systems (8, 12, 15). Cowley and Mills attributed their phosphine adduct solubility difficulties to reaction with the methylene chloride solvent to give quaternary phosphonium salts (15). BCl_3, PCl_3, and *t*-butyl chloride have been shown to give an ionic product (21). Formation of ionic boron trihalide adducts seems especially likely in the Me_3PO system which may be as complex as the tetramethylurea adduct system (16), and in which the solubility problems are much worse.

We wish to thank the National Research Council of Canada for financial support of this work, Dr. J. M. Miller for help with the ^{11}B decoupling experiments, and the Department of Chemistry, McMaster University, for the use of ^{19}F n.m.r. facilities.

The Thermal Rearrangement of α-Substituted Silanes

ALAN R. BASSINDALE, A. G. BROOK, PETER F. JONES, AND JOHN M. LENNON
Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received July 15, 1974

ALAN R. BASSINDALE, A. G. BROOK, PETER F. JONES, and JOHN M. LENNON. Can. J. Chem. **53**, 332 (1975).

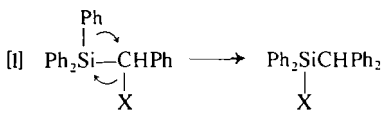
The thermal rearrangement of α-substituted silanes ($R_3SiCHXR'$), in which there is exchange of X and R between the silicon atom and the adjacent carbon atom, has been studied. Kinetic parameters for two compounds ($Me_3SiCBrPh_2$ and $Ph_3SiCHOAcPh$) have been measured. Migratory aptitudes of both X and R have been examined. A mechanism involving initial migration of X to silicon, to form an "inverse ylid" ($R_3\bar{S}iX—\overset{+}{C}HR'$) is proposed.

ALAN R. BASSINDALE, A. G. BROOK, PETER F. JONES et JOHN M. LENNON. Can. J. Chem. **53**, 332 (1975).

On a étudié le réarrangement thermique de silanes α-substitués ($R_3SiCHXR'$) dans lesquels il y a un échange de X et de R entre l'atome de silicium et l'atome de carbone adjacent. On a mesuré les paramètres cinétiques pour la réaction de deux composés le ($Me_3SiCBrPh_2$ et $Ph_3SiCHOAcPh$). On a examiné les aptitudes migratrices des groupes X et R. On propose un mécanisme impliquant une migration initiale du X vers le silicium formant un "ylide inverse" du type ($R_3\bar{S}iX—\overset{+}{C}HR'$). [Traduit par le journal]

Introduction

We have previously reported, in a brief communication, that certain α-substituted benzyltriphenylsilanes undergo the following thermal rearrangement (1)

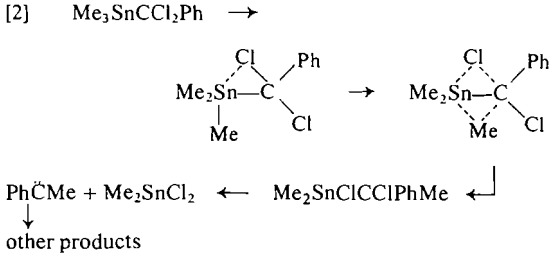


[1] $Ph_2Si(Ph)—CHPh(X) \longrightarrow Ph_2SiCHPh_2(X)$

(X = F, Cl, OAc, OTos)

The present study represents a more detailed examination of this rearrangement together with some extension in its scope.

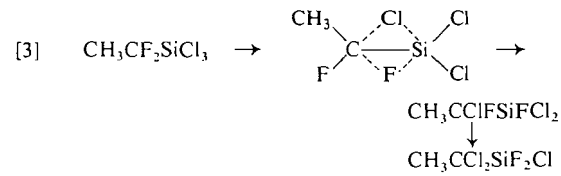
Other examples of this kind of thermal rearrangement are known. Seyferth and co-worker (2) reported that dimethyldichlorostannane was one of the products of the thermolysis of trimethyl(α,α-dichlorobenzyl)tin at 150° in cyclohexene. The reaction course proposed was



[2] $Me_3SnCCl_2Ph \rightarrow Me_2Sn(Cl)(Ph)—C(Me)(Cl) \rightarrow Me_2Sn(Cl)—C(Ph)(Me)(Cl)$

$Me_2SnClCClPhMe \rightarrow PhCMe + Me_2SnCl_2$ (other products)

Haszeldine and co-workers (3, 4) have described a similar rearrangement involving halogen exchange between the adjacent carbon and silicon atoms



[3] $CH_3CF_2SiCl_3 \rightarrow CH_3(Cl)(Cl)C(F)(F)—Si(Cl)(Cl) \rightarrow CH_3CClFSiFCl_2 \rightarrow CH_3CCl_2SiF_2Cl$

which they considered to involve a cyclic transition state of the type shown. Such a doubly-bridged transition state is of the type encountered in a symmetry-allowed, type-I dyotropic rearrangement (5); however, at present there is no unambiguous mechanistic evidence for a simultaneous double σ-shift. It was, therefore, of considerable importance to determine the activation parameters E_a, $\Delta S^{\ddagger}$, and A for the thermal rearrangement of these α-substituted silanes and we have measured these for two representative examples. As an additional aid to the interpretation of the mechanism the relative migratory aptitudes of a variety of groups on both silicon and the α-carbon have been studied.

Results and Discussion

A series of α-substituted silanes, $R_3SiCHXR'$ (R = Ph, Me; X = F, Cl, Br, OTos, OAc;

R′ = Ph, Me, H), $R_3SiCBrPh_2$ (R = Ph, Me, Et) and chlorobenzyltriphenylgermane were heated in sealed, flame dried Pyrex ampoules under a variety of conditions. The products obtained, the conditions, and the extent of reaction are given in Table 1. The reactions observed are summarized below

[4] $R_3SiCHXR' \rightarrow R_2SiXCHRR'$

[5] $R_3SiCBrPh_2 \rightarrow R_2SiBrCPh_2R$

[6] $Ph_3GeCHClPh \rightarrow Ph_2GeClCHPh_2$

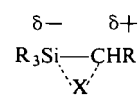
The kinetics of the rearrangement of bromobenzyhydryltrimethylsilane (**1**) and acetoxybenzyltriphenylsilane (**2**) were studied. Both reactions were first-order in reactant to at least 90% completion.

The results, as shown in Table 2, are inconsistent with a highly-ordered doubly-bridged transition state which would be expected to have a very large, negative $\Delta S^{\ddagger}$. The near-zero value of $\Delta S^{\ddagger}$ (−1.3 e.u.) for **1** is indicative of a relatively open transition state. Thus, the results in Table 1 are consistent with and strongly support the following mechanism

[7] $R_3SiCHXR' \rightarrow R_3\bar{S}i\text{—}\overset{+}{C}HR' \rightarrow R_2SiXCHR'R$
(X)

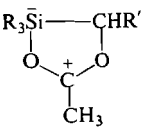
3

The "inverse ylid", **3**, may be either a transition state or a discrete intermediate but our results do not allow a distinction to be made. However, the first, and rate-determining, step indicated by the study of relative migratory aptitudes appears to be the formation of the "inverse ylid" by migration of X from carbon to silicon. The transition state for this step should resemble a singly-bridged species, **4**,



4

with a considerably less negative value of $\Delta S^{\ddagger}$ than expected for a doubly-bridged transition state. An acetoxy group, unlike a bromine atom, should migrate through a five-centered species, **5**,



5

and the value of −20 e.u. for $\Delta S^{\ddagger}$ for **2** is consistent with this interpretation. With this alternative mode of migration the rearrangement of **2** relative to **1** should have a lower activation

energy, a more negative $\Delta S^{\ddagger}$ and a smaller A value. These trends are clearly illustrated by the data in Table 2, where comparison shows lowering of the activation energy from 37 to 30 kcal mol^{-1}, change of $\Delta S^{\ddagger}$ from −1.3 to −20 e.u., and lowering $\log_{10} A$ from 13.9 to 9.1, for **2** relative to **1**. The comparison must be qualitative rather than quantitative since R and R′ differ in the two compounds but the kinetic parameters indicate that a dyotropic mechanism is most unlikely, and the transition state is not significantly bridged but resembles the "inverse ylid" **3**.

Recently O'Brien and co-worker (6) have obtained good kinetic evidence for the intermediacy of an "inverse ylid" in the SbF_5-catalyzed rearrangement of 2-chloro-2-trimethylsilylpropane

[8] 
Products (Nu = nucleophile)

This is, of course, the catalyzed equivalent of the present rearrangement and is well known in organosilicon chemistry. The aluminum chloride catalyzed isomerization of (chloromethyl)trimethylsilane to chlorodimethylethylsilane was reported by Sommer and co-workers in 1947 (7).

Based on the results given in Table 1 the relative ease of migration of X from carbon to silicon appears to decrease in the following order: F > OTos > OAc > Cl > Br ≫ OMe. This coincides with the expected order of stabilization of a penta-coordinated silicon atom, based on bond energies, and the electronegativities of X, with the exception that since alkoxy compounds do not thermally rearrange, other factors not yet fully understood must be involved at least in these cases.

The ease of migration of R from silicon to carbon decreased in the order Ph > Me, Et. Thus bromobenzhydryldiphenylmethylsilane on heating rearranged to triphenylmethylphenylmethylbromosilane as a result of exclusive phenyl migration

[9] $Ph_2MeSiCBrPh_2 \rightarrow PhMeSiBrCPh_3$

After 1 h at 253° a sample of bromobenzyltrimethylsilane contained no 1-phenylethyldimethylbromosilane (although the n.m.r. spectrum did show a substantial amount of benzyltrimethylsilane, presumably due to redistribution[1]). Under the same conditions bromobenzyltriphenylsilane rearranged to benzhydryldiphenylbromosilane to the extent of 30%. (Redistribution products were also present.) The migration of a phenyl group to a carbonium ion center is generally faster than alkyl migration (8). If the inverse ylid was a true intermediate formed in the rate determining step then the rate of

[1]The rate of rearrangement of α-bromo compounds was difficult to duplicate. In addition they sometimes underwent redistribution reactions concurrently with rearrangement, according to the reaction

$$R_3SiCHBrR' \rightarrow R_2SiBrCHRR' + R_3SiCH_2R' + R_3SiCBr_2R'$$

The extent of redistribution was variable and may have been catalyzed by traces of unknown impurities. However, a sample of bromobenzyltriphenylsilane containing 5% by weight of dibenzoyl peroxide rearranged at the same rate to give the same product mixture as a sample without added peroxide. Therefore, free radical intermediates in either rearrangement or redistribution reactions appear unlikely.

migration of R from silicon to carbon would be relatively fast and should not affect the overall reaction rate. Therefore the reactivity series observed does not necessarily reflect migratory aptitudes of aliphatic and aromatic moieties, but rather the ability of R to stabilize the ylid through delocalization of the positive charge on the carbon atom.

With changes in R′ the ease of rearrangement decreases in the order Ph > Me > H. This order is consistent with a build up of positive charge on the α-carbon and reflects the ability of the groups to stabilize a carbonium ion.

Finally it was observed that α-chlorobenzyltriphenylsilane rearranged faster than the analogous germanium compound. This probably reflects the greater bond energy of Si—X compounds and the lower energy of the silicon d orbitals.

As a further test of the proposed mechanism equimolar solutions of α-fluorobenzyltriphenysilane (**6**) in $CDCl_3$ and DMSO-d_6 were heated to 140° for 4½ h. The solution in DMSO-d_6 was 32% rearranged to benzhydryldiphenylfluorosilane (**7**), the remaining material being unreacted **6**. The solution in $CDCl_3$ contained only unreacted **6**. The faster reaction in polar solvents is evidence of substantial charge separation in the transition state.

In summary, the available evidence strongly supports the open-chain mechanism for rearrangement of α-substituted silanes, where Si—X bond formation is significantly developed in the transition state. The transition state thus resembles an inverse ylid.

Experimental

Experiments involving reactive organometallic reagents were carried out under nitrogen using dried, purified solvents. Infrared spectra were recorded on a Perkin–Elmer 237B instrument. Nuclear magnetic resonance spectra were determined using Varian T-60 or A-60 spectrometers. Melting points were measured on a Fisher–Johns apparatus and are recorded uncorrected. Analyses were carried out by A. B. Gygli, Toronto.

Preparation of Starting Materials

Known compounds were prepared by the standard literature preparations. All benzyltriphenylsilyl derivatives were prepared by the action of HX on phenyltriphenylsilydiazomethane (1). The general method is given below and the results of individual preparations are given in Table 3.

The experimental procedure was as follows. A solution of diazoalkane and excess acid in an organic solvent was allowed to stand at ambient temperature, in the dark, until the color of the diazoalkane was completely discharged. With HCl the gas was bubbled through the reaction mixture until decolorization occurred. The workup procedure involved washing the reaction mixture several times with water, drying the organic layer over $MgSO_4$, removing the solvent on a rotary evaporator, and then recrystallizing the product. Reaction conditions and other information are given in Table 3. The n.m.r. spectra of starting materials and products are shown in Table 4.

Rearrangement Studies

Samples of the α-substituted silanes were sealed in carefully flame-dried Pyrex ampoules which were then immersed in an oil bath. After a given time, the sample was removed and the contents analyzed. The results are given in Table 1.

Synthesis of Previously Unknown Rearrangement Products

Acetoxybenzhydryltriphenylsilane

A mixture of benzhydryldiphenylchlorosilane (5 g, 13 mmol) and silver acetate (2.16 g, 13 mmol) in benzene (50 ml) was stirred for 16 h at ambient temperature, filtered, and the filtrate was evaporated to dryness. The residue was recrystallized from pentane to yield acetoxybenzhydryldiphenylchlorosilane 2.55 g (48%), m.p. 113–115°.

Anal. Calcd. for $C_{27}H_{24}O_2Si$: C, 79.37; H, 5.92. Found: C, 79.70; H, 6.03.

Tosyloxybenzhydryldiphenylsilane

A mixture of benzhydryldiphenylchlorosilane (5 g, 13 mmol) and silver tosylate (3.62 g, 13 mmol) in benzene (50 ml) was stirred for 16 h at ambient temperature, filtered, and the filtrate was evaporated to dryness. The residue was recrystallized from pentane to afford tosyloxybenzhydryldiphenylsilane 2.65 g (40%), m.p. 162–163°.

Anal. Calcd. for $C_{33}H_{28}O_3SSi$: C, 74.40; H, 5.30. Found: C, 74.27; H, 5.49.

(Triphenylmethyl)diphenylbromosilane

Bromobenzhydryltriphenylsilane (4 g, 7.9 mmol) was sealed in a glass ampoule and heated at 240° for 1 h. A black solid was obtained which was dissolved in benzene, clarified with activated charcoal, and recrystallized from hexane to yield pure (triphenylmethyl)diphenylbromosilane, m.p. 214–215°.

Anal. Calcd. for $C_{31}H_{25}BrSi$: C, 73.64; H, 5.05; Br, 15.81. Found: C, 73.51; H, 4.98; Br, 15.83.

(Triphenylmethyl)phenylmethylbromosilane

Bromobenzhydryldiphenylmethylsilane (4 g, 9 mmol) was sealed in a glass ampoule and heated at 240° for 1 h. The brown solid obtained was dissolved in benzene, clarified with activated charcoal, and recrystallized from hexane to afford (triphenylmethyl)phenylmethylbromosilane, m.p. 133–135°.

Anal. Calcd. for $C_{26}H_{33}BrSi$: C, 70.42; H, 5.24; Br, 18.01. Found: C, 70.51; H, 5.12; Br, 17.82.

Methylbenzhydryldimethylbromosilane

Bromobenzhydryltrimethylsilane (2 g) was heated at 240° for 22 h. After this time, the brown liquid was flash-distilled under aspirator pressure in a Kugelröhr apparatus. The resulting clear liquid, methylbenzhydryldimethylbromosilane was analyzed immediately.

Kinetic Studies

In a typical run, ten or more aliquots of the α-substituted silane in sealed tubes were simultaneously immersed in an oil bath whose temperature was constant to within ±1°. The ampoules were removed periodically and the extent of reaction was measured by integration of suitable signals in the n.m.r. spectrum. A plot of log [reagent] *vs.* time gave a good straight line and first order rate constants were obtained with an accuracy of better than ±10%. Several runs were carried out at each temperature. The results are given in Table 2.

Carbon-13 Spin–Lattice Relaxation Times for Selected Steroids

JOHN W. APSIMON
Chemistry Department, Carleton University, Ottawa, Canada K1S 5B6
AND
HELMUT BEIERBECK AND JOHN K. SAUNDERS
Département de Chimie, Université de Sherbrooke, Sherbrooke, Québec J1K 2R1

Received July 10, 1974

JOHN W. APSIMON, HELMUT BEIERBECK, and JOHN K. SAUNDERS. Can. J. Chem. **53**, 338 (1975).

The spin–lattice relaxation time (T_1) data for a number of androstane and cholestane derivatives is presented. The NT_1 value of carbon-3 in several of the compounds is found to be shorter than the average NT_1 value for the other ring carbons which is interpreted in terms of anisotropic motion with the long steroid axis being the preferred axis of rotation. As this effect is only observed for carbon-3, an effective molecular correlation time can be calculated from the average NT_1 value for all other CH and CH_2 carbons. The correlation time (τ_i) for internal rotation of a methyl group is shown to depend on the number of 1,3 diaxial methyl group – hydrogen interactions. Thus τ_i(C-19) is shorter than τ_i(C-18) for androstane, τ_i(C-19) is shorter for *trans*-cholestanol than for either *cis*-cholestanol or cholesterol. The effects of substituents and conformational changes on τ_i as well as the effect of solvent on T_1 are discussed.

JOHN W. APSIMON, HELMUT BEIERBECK et JOHN K. SAUNDERS. Can. J. Chem. **53**, 338 (1975).

Nous avons mesuré les temps de relaxation spin–milieu (T_1) pour un nombre des dérivés de l'androstane et du cholestane. Dans plusieurs de ces composés, on trouve que la valeur de NT_1 pour le carbone-3 est plus court que la moyenne obtenue pour les autres carbones CH et CH_2 cycliques; ce résultat est interprété en termes de mouvements anisotropiques dont l'axe préféré de rotation est l'axe le plus long du stéroide. Comme on observe cet effet seulement pour le carbone-3, on peut utiliser la moyenne des autres carbones CH et CH_2 rigide pour calculer la valeur du temps de correlation effectif de la molécule. Il est démontré que le temps de correlation (τ_i) pour la rotation interne d'un groupement méthyle dépend du nombre des interactions 1,3 diaxiales méthyle – hydrogène. Ainsi, τ_i(C-19) est moins long que τ_i(C-18) pour l'androstane, τ_i(C-19) est plus court dans *trans*-cholestanol que dans le *cis*-cholestanol ou le cholestérol. L'effet des substituents et le changement de conformation sur τ_i, ainsi que l'effet du solvant sur T_1, sont discutés. [Traduit par le journal]

The advent of the Fourier transform technique has not only made the recording of natural abundance C-13 spectra routine but has also made feasible the recording of spin–lattice relaxation time (T_1) data. A number of reports (1, 2) have appeared in which the strategies employed are presented and possible application quoted. However, to date, little evidence has been given to the possibility of using T_1 data for structural conformational analysis. In order to explore this possibility we have recorded the C-13 T_1 values for a number of monosubstituted androstanes as well as for several cholestane derivatives. The results are given in Tables 1 and 2 together with the values recorded by Allerhand *et al.* (2) for cholesteryl chloride. Rather than give the T_1 values for each carbon of each compound, we have shown in Fig. 1 the complete set of values recorded for cholesterol and androstan-4β-ol and then in the tables quoted the average NT_1 values of all rigid CH and CH_2 carbons, with the exception of C-3, as these were always within experimental error of the average.

In the limit of extreme narrowing ($\omega^2\tau_c^2 \ll 1$), the T_1 value for a protonated carbon is given by eq. 1 (1) provided the molecule is undergoing isotropic motion. The symbol N represents the

$$\frac{1}{T_1} = \frac{N\hbar^2\gamma_C^2\gamma_H^2}{(r_{C-H})^6}\tau_c \qquad [1]$$

number of protons attached to the observed carbon, r_{C-H} is the C—H bond length, and τ_c is the rotational correlation time which can be expressed as in eq. 2 with η being the viscosity and $4\pi a^3/3$ the effective molecular volume. From eq. 1, it is evident that for isotropic motion T_1

$$\tau_c = \frac{4\pi\eta a^3}{3\hbar T} \qquad [2]$$

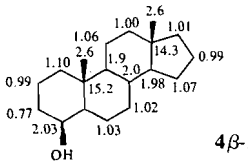
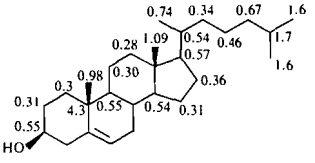
(CH) = $2T_1$ (CH_2) ≪ T_1 (C) and this can be used to assign the various carbons as either C, CH, or CH_2 (4, 5). In Fig. 1, the T_1 values for the carbons of the ring system of cholesterol can be seen to follow this type of behavior. The CH_3 groups and side chain carbons have at least one extra degree of freedom and thus their T_1 values cannot be expressed in terms of eq. 1. The correlation time of these carbons is a combination of two correlation times, namely τ_c and the time for internal reorientation τ_i. Its cross-correlational effects are negligible and provided the motion is isotropic, T_1 is expressed by eq. 3 (2) where the constants *A*, *B*, and *C* depend on the angle between the axis of rotation and the C—H bond vector. If σ is the angle between the C—H bond

$$[3]\quad \frac{1}{T_1} = \frac{N\hbar^2\gamma_H{}^2\gamma_C{}^2}{r_{C-H}{}^6}\tau_c \times \left[A + B\frac{6\tau_i}{6\tau_i + \tau_c} + C\frac{3\tau_i}{3\tau_i + 2\tau_c}\right]$$



4β-Androstanol



Cholesterol

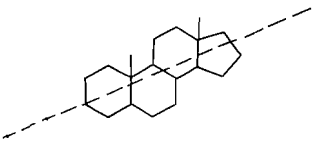
FIG. 1. Carbon-13 spin–lattice relaxation times for 4-β-androstanol and cholesterol.

vector and the axis of internal rotation, then $A = \frac{1}{3}(\cos^2\sigma - 1)$; $B = 3\sin^2\sigma\cos^2\sigma$, and $C = \frac{3}{4}\sin^4\sigma$ which gives for a tetrahedral carbon $A = 1/9$, $B = 8/27$, and $C = 16/27$ (5). The value of T_1 for a CH_3 group or a side chain with one degree of freedom, relative to a rigid CH carbon, is given by eq. 4 where α is for the rigid CH carbon, β refers to carbons with internal motion, and $\rho = \tau_{c/\tau_i}$.[1] In the limit of very slow internal

$$[4]\quad \frac{T_1^{\alpha}}{N^{\beta}T_1^{\beta}} = \frac{1}{9}\left[1 + \frac{16}{6+\rho} + \frac{16}{3+2\rho}\right]$$

reorientation, $\rho \to 0$ and $N^{\beta}T_1^{\beta} = T_1^{\alpha}$ whereas in the limit of very rapid rotation, $\rho \to \infty$ and $9\,T_1^{\alpha} = N^{\beta}T_1^{\beta}$. Thus, for example, T_1 for a CH_3 group can vary from $\frac{1}{3}T_1$ (CH) to $3T_1$ (CH). In the case of cholesterol in CCl_4 as was the case of cholesteryl chloride, $3T_1$ (CH) = T_1 (CH_3) *i.e.* the limit of rapid rotation. As can be observed, $2T_1$ (CH_2) = T_1 (CH) for all ring carbons in the cholestane derivatives. From this Allerhand *et al.* (2) concluded that cholesteryl chloride is undergoing isotropic motion. However, in the androstane examples, NT_1 (C-3) is, in many compounds, less than that observed for other ring carbons. In steroids the long steroidal axis passes through or very close to C-3 as shown below and intuitively we expect rotation about this axis to be more rapid than about any other axis. In T_1 determinations, we are measuring the

[1]Strictly speaking $\rho = D_2/D_1$ *i.e.* the ratio of the diffusion rates.



motion of the C—H bond vector of the proton causing relaxation. If this vector resides on a preferred axis of rotation, then obviously its molecular motion will be less than that for C—H bonds that are not on the axis. Levy *et al.* (1) have shown for monosubstituted aromatic compounds that T_1 (*para*) < T_1 (*ortho*) = T_1 (*meta*) as the preferred axis of rotation is coincident with the *para* C—H bond. Examination of Table 1 shows that for androstan-3β-ol, T_1 (C-3) is within experimental error of other NT_1 values whereas for androstan-3α-ol, T_1 (C-3) is significantly less than the average NT_1 value. For the 3β-OH compound, H-3 is axial and thus rotation about the long axis will cause motion of the C—H bond whereas for the 3α-OH, H-3 is equatorial and the C—H bond will approach coincidence with the long steroid axis thus significantly reducing the motion of this bond. This effect of anisotropic motion in the androstan-3α-ol as well as several other derivatives is observed only for C-3 as all other ring CH and CH_2 carbons exhibit values with experimental error of the average value. This apparent anomaly from comparison with much simpler molecules (6) is a result of complex molecular motion as well as the experimental error.

This explanation has, of necessity, been qualitative as the theory of anisotropic motion developed to date requires high symmetry restriction (6) and is thus inapplicable in the steroids. Thus, observation of identical NT_1 values for rigid carbons does not necessarily indicate that the molecule is undergoing isotropic motion. However, eq. 1 can be used at least to a first approximation in order to obtain correlation time data although the correlation time so obtained is not the isotropic correlation time but an effective correlation time (7). From this, the internal reorientation time can be calculated as has been performed in the tables.

Inspection of the τ_G data for the androstane derivative leads to a number of interesting substituent effects. The value of τ_i for C-18 is $1.7 \pm 0.2 \times 10^{-12}$ s for all ring A or B substituted compounds and for the 17 ketone. For C-19, τ_i for the 3α, 3β, and 4α alcohols as well as the 11, 16, and 17 ketones is $0.6 \pm 0.1 \times 10^{-12}$

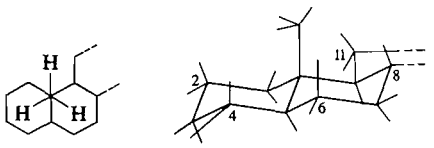
s. The other values vary significantly (greater than 25%) from these. The rotation rate, $1/\tau_i$, is a measure of the energy difference between the energy of the preferred conformation of the CH_3 group and the transition state to rotation. In ethane, the barrier to rotation is 3.6 kcal/mol which corresponds to a correlation time of 8×10^{-11} s. The τ_i value in these compounds is of the order of 10^{-12} s and consequently the barrier to rotation is significantly less than that of ethane. It is instructive in order to explain the effect of substituents on T_1 to compare the value of C-19 in the 17-keto and the Δ^5 compounds. The preferred conformation for the 17 ketone will be as shown in **a** below in which the CH_3 group has 1,3 diaxial interactions with the axial protons of carbons 2, 4, 6, 8, and 11. For the Δ^5 compound, one of these interactions has been removed and the interaction with two others has become less severe. The energy of the preferred



a

conformation of the CH_3 group is thus less in the 5-ene than in the 17 ketone. For both compounds, the transition state for rotation is when the C—H bonds of the CH_3 eclipse the C—C bonds and hence the energy difference of this state between the two compounds will be less. The barrier to rotation for the 5-ene will thus be higher resulting in a slower rotation rate and a shorter T_1. The same argument is true for the replacement of a β axial proton by a keto group although the effect is somewhat smaller. It is of interest to note that for C-18 an 11 or 16-keto group causes a significant change in T_1 whereas the 17 ketone shows values in line with the ring A substituted compounds.

The compounds with a β axial hydroxyl group would be, at first sight, expected to cause an increase in the rotation rate of the C-19 methyl group. However, ring A is quite flexible and studies on 2β and 4β alkyl substituted steroids (8) have shown that ring A in the compounds is distorted. A reasonable twist-boat conformation can be obtained[2] in which the internuclear distance between the CH_3 and the OH is at or greater than the sum of their respective van der Waal's radii. The net effect of such a distortion is to remove one 1,3 CH_3 – hydrogen interaction and to slightly alleviate another. Thus the rotation rate of the CH_3 group in these compounds would be less than that of the 17 ketone as the energy of the preferred conformation has been decreased whereas the energy of the transition state is only slightly affected. Evidence for this distortion is also observed in the chemical shift of C-6 for the 4α and 4β compounds. In the former, δ for C-6 is 20.4 p.p.m. whereas in the latter it is 25.4 p.p.m., both of which are shielded relative to the unsubstituted value of 28.4 p.p.m. Thus a significant variation of T_1 as a result of conformational change has been observed.

The various cholestane derivatives exhibit similar behavior to that of the androstane derivative. For *cis*-cholestanol, τ_G for C-19 is longer than in the *trans*-compound as the CH_3 group is now axial to one ring and equatorial to the other thus decreasing the number of 1,3 diaxial interactions. As expected, the values of τ_G calculated for cholesterol and androst-5-ene agree within experimental error even though the effective correlation times of the ring carbons are significantly different and one compound exhibits evidence for anisotropic motion whereas the other does not.

The effect of solvent can be seen from the values quoted for cholesterol and androstan-4-one in CCl_4 and $CDCl_3$. For the former a large difference is observed whereas for the latter, T_1 is independent of solvent within experimental error. In both cases the difference in viscosity is similar to the viscosity difference between the two pure solvents. Combining eq. 1 and 2 for a specific carbon gives T_1 in terms of the macroviscosity η as shown in eq. 5 and thus, provided *a*

$$[5] \qquad \frac{1}{T_1} = \frac{K\eta a^3}{T}$$

is constant, $1/T_1$ at constant temperature should be proportional to the viscosity. That this is not the case is evident as cholesterol exhibits a difference in T_1 which is larger than the difference in viscosities whereas for 4-androstanone the difference is negligible. Also the values for cholesterol are approximately half of that recorded for cholesteryl chloride (2) in the same solvent. A portion but not all of this difference

[2]We wish to thank Professor Hart for helpful discussion in this area.

is due to a difference in temperature, 30 °C compared to 42 °C. It has been shown (9) for 1-decanol that the motion of the CH_2 attached to the OH is restricted relative to the CH_2 attached to the CH_3 group because of the interaction between the OH group and CCl_4. In the steroid, a similar effect is present and the variation is explicable qualitatively by consideration of solvation of the functional group as CCl_4 can form H bonds with the OH group but not with a keto nor a chloro group whereas $CDCl_3$ can form hydrogen bonds with both hydroxyl and carbonyl groups. This demonstrates that for n.m.r. relaxation data we are concerned with microviscosity rather than macroviscosity as determined by normal viscosity measurements.

It is apparent from this work that T_1 data can be a useful aid in structural and conformational analysis. Evidence for anisotropic motion has been presented but, provided the preferred axis of rotation is not close to coincidence with the C—H bond vector of the proton causing relaxation, values of an effective molecular correlation time and hence the internal reorientation time for the CH_3 groups can be calculated. The value of τ_i depends on the number of 1,3 diaxial CH_3 group – H interactions. Thus τ_i will depend on the configuration of the CH_3 group as seen from the difference for C-19 between *trans*- and *cis*-cholestanol with the τ_i value for an equatorial CH_3 being longer than that in *cis*-cholestanol. The CH_3 group C-19 has more 1,3 diaxial interactions than C-18 and thus its τ_i is shorter than τ_i (C-18) in androstane. A ketone group in the molecule will affect the T_1 value observed if it removes one β axial proton and thus we can distinguish, for example, between the 2-keto and 3-keto compound but not between the 2- and 4-ketones from τ_i for C-19. From a conformational standpoint, the effect on C-19 of β hydroxyls at C-2 and C-4 illustrates the possibility of use of T_1 data for conformational analysis as in these compounds where ring A is distorted, a significant effect on T_1 was observed.

Experimental

All steroids used in this study were available in the laboratory. The T_1 values were recorded on 0.8–1.0 *M* solutions, generally at 35 °C. In all cases 1 ml of solution in 10 mm tubes was used. Approximate viscosities were measured using standard techniques.

The equipment consisted of a Bruker HX-90 spectrometer operating in the single coil mode and a Nicolet 1083 computer. A 90° pulse corresponded to a pulse width of 20 μs and thus sweep widths up to 4000 Hz could be used. In order to check the values obtained when using a 4 kHz sweep width, the T_1 values were determined with the pulse at both the high and low frequency ends of the spectrum. The values for all carbons were independent of which end of the spectrum the pulse was placed. Normally, spectral widths of 2000 or 2500 Hz were used. The T_1 values were obtained from the standard (180–τ–90–$5T_1$) pulse sequence (1) using at least 10 τ values for the CH_2 carbons and 14–20 τ values for CH and CH_3 carbons. A least-squares plot of ln $(M_\infty - M_z)$ *vs.* τ was used to obtain the values of T_1. The values in the tables are quoted to ±10% even though the standard deviation from the least squares plot is of the order of 2%. This difference is added in order to account for errors in M_∞ (generally three to six values recorded), long term drift and errors that result when two peaks of unequal T_1 are close together.

We gratefully acknowledge generous financial assistance from the National Research Council of Canada.

6*H*-Dibenzo[*b*,*d*]pyrans. I. Synthesis

JOHN P. DEVLIN
Pharma Research Canada Ltd., Pointe Claire, Quebec H9R 1G8
Received August 28. 1974

JOHN P. DEVLIN. Can. J. Chem. **53**, 343 (1975).

The preparation of 2′,4′-dihydroxy- and 2′,6′-dihydroxybiphenyl-2-carboxylic acid lactones (**3** and **4**) is described. Grignard addition to or direct boron trifluoride etherate – sodium borohydride reduction of these lactones yields respectively these 6,6-substituted (*e.g.* **6**) or the 6,6-unsubstituted (**13***a*) 6*H*-dibenzo[*b*,*d*]pyrans. Evidence that the reductive route proceeds without ring cleavage is presented.

JOHN P. DEVLIN. Can. J. Chem. **53**, 343 (1975).

On décrit la synthèse des lactones des acides dihydroxy-2′,4′ et dihydroxy-2′,6′ biphenylcarboxylique-2. Par addition de Grignard ces lactones donnent des 6*H*-dibenzo[*b*,*d*]pyrans substitués en 6,6 (*e.g.* **6**). Par réduction avec le borohydrure de sodium – éthérate de fluorure de bore elles fournissent des 6*H*-dibenzo[*b*,*d*]pyrans non substitués en 6,6 (**13***a*). On présente la preuve que cette réduction procède sans ouverture du cycle.

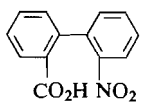
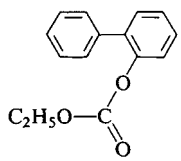
We have investigated the effects of the inclusion of the 6*H*-dibenzo[*b*,*d*]pyran ring system in a variety of pharmacologically active molecules (1). The synthesis of the basic nucleus is herein reviewed and a novel preparation of the 6,6-unsubstituted members is described.

2′-Hydroxybiphenyl-2-carboxylic acid lactones were invariably the synthetic precursors to the compounds prepared in this study. In the earlier literature the copper-catalyzed condensation of the diazonium salt of an anthranilic acid and the appropriate phenol (2, 3) or of the corresponding phenyl anthranilate (4, 5) was frequently employed although the yields were generally very low. More recently the oxidative cyclization (6–10) of biphenyl-2-carboxylic acids and the decomposition of the corresponding peroxides (5, 8, 11–14) have been investigated. The intramolecular condensation of 2′-nitrobiphenyl-2-carboxylic acid **1** (15), the photoacylation of ethyl 2-biphenylyl carbonate **2** (16), and the Baeyer–Villiger oxidation of 9-fluorenones (17, 18) offer interesting and novel approaches.

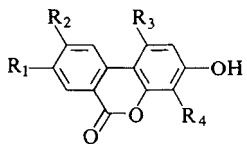


1

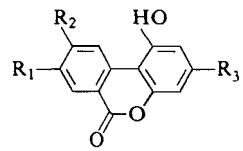


2

2′,4′Dihydroxybiphenyl-2-carboxylic acid lactones of the general formula **3** (R_3 = H) are most conveniently prepared by the condensation of the appropriate 2-bromobenzoic acid with resorcinol or a 2-substituted resorcinol in the manner described by Hurtley (19). Under these conditions no trace of the alternate condensation product **4** (R_3 = H) was found; however, when



3



4

the condensation of 2-bromobenzoic acid was effected with 5-methyl- and with 5-methoxyresorcinol the isomers **4** (R_3 = CH_3 and R_3 = OCH_3) were also formed in yields of 0.4 and 12%, respectively, of the total crude products. The separation of these isomers was more conveniently accomplished by chromatography of the dimethyl derivatives, the preparation of which are described below. The lactones which have been prepared in this study are described in Table 1.

The reaction of 2′-hydroxybiphenyl-2-carboxylic acid lactones with excess methyl magnesium iodide and the thermal dehydration of the intermediary dimethyl carbinols (*e.g.* **5**) to 6,6-dimethyl-6*H*-dibenzo[*b*,*d*]pyrans (*e.g.* **6**) has been described (3, 20). We have applied this procedure to the preparation of the dimethyl derivatives which are described in Table 2, with the modification that the dimethyl carbinols (**5**) were

dehydrated by brief treatment at room temperature with boron trifluoride in benzene.

The separation of the dimethyl derivatives (**7** and **8**) of the two isomers obtained from the condensation of 2-bromobenzoic acid and orcinol, as indicated above, was effected by chromatography of the crude reaction product. The constitution of **7** is well established (20) and therefore the identity of **8** was obvious. The n.m.r. spectra ($CDCl_3$) of these two isomers (Table 3) were distinct. The anisotropic effect of the hydroxyl at C-1 in compound **8** produced a downfield shift ($\Delta\delta$ 0.77) of the C-10 proton over that observed for compound **7**. Similarly, the methyl protons at C-1 in compound **7** were deshielded by the neighboring aromatic ring and were found at δ 2.57 whereas the methyl protons in compound **8** occurred at δ 2.25. These n.m.r. variations were particularly useful for the identification of compounds **9** and **10** as described below.

The isomers **9** and **10** obtained by the methylation of the lactone mixture from the condensation of 2-bromobenzoic acid and 5-methoxyresorcinol, were separated by chromatography and identified by a comparison of their n.m.r. spectra ($CDCl_3$). As would be anticipated, the difference between the chemical shifts of the C-10

proton of **9** and that of **10** was not as pronounced as in the foregoing examples. Nevertheless, a slight difference (Δδ 0.06) did occur (see Table 3) and the assignments which were made received support from the downfield shift (Δδ 0.15) of the methoxyl protons at C-1 (**9**) over that at C-3 (**10**). The latter effect parallels that observed for the dimethyl ether of *N*-acetylapocrotonosine (21). Further evidence for these assignments was provided by a comparison of the n.m.r. spectra (CD_3SOCD_3) of compound **9** with that of the precursor, **11***a* (see Table 4). Molecular models demonstrate that in this substance the bulky dimethylcarbinol (at C-2), the methoxy (at C-6′), and the hydroxy (at C-2′) groupings maintain rings A and B almost perpendicular to each other and permit shielding of the methoxy- and the dimethylcarbinol protons by rings A and B, respectively. If the structural assignments of compounds **9** and **10** were reversed then the precursor to **9** would have the constitution **11***b* and the shielding effect on the methoxyl would not be observed. The n.m.r. spectrum of the dimethyl ether (**11***c*) supported this observation in that the protons of both shielded methoxyls resonated at δ 3.61 (compare **11***a*) while the protons of the methoxyl at C-4′ were found at δ 3.83.

hydrogen bromide, followed by dehydrohalogenation yielded 6*H*-dibenzo[*b*,*d*]pyran (**13***a*). For our purposes a direct reductive route (**12** → **13**) was certainly more attractive, and to this end we investigated the utilization of the sodium borohydride – boron trifluoride combination which had been developed by Petitt and co-workers (23–26). This reagent has been shown (23, 24) to effectively reduce aliphatic esters and lactones to the corresponding ethers; however, when either the alcohol or acid moiety was aromatic, ethers were not formed and only the corresponding alcohols were obtained (25, 26). Nevertheless, we have applied this technique to the reduction of the 2′-hydroxybiphenyl-2-carboxylic acid lactones (**12***a–d*) and have obtained only the corresponding 6*H*-dibenzo[*b*,*d*]pyrans (**13***a–d*) in high yield. It may be considered that reduction initially occurs to the phenolic alcohol **14** with subsequent dehydration to the ether by boron trifluoride; a dehydration possibly encouraged by the close proximity of the interacting groups. In order to determine whether this 'two step' mechanism was involved, compound **14***b* was prepared by lithium aluminum hydride reduction of **12***b* and treated with boron trifluoride etherate in tetrahydrofuran under the same reaction conditions employed in the reduction procedure. No significant amount of compound **13***b* was detected. When **14***b* was heated at 250°, however, dehydration did occur and **13***b* was obtained in a moderate yield.

The foregoing evidence supports a reductive mechanism not involving ring cleavage. The sequence (12 → 15 → 16 → 17 → 13) may be considered as a likely pathway and is analogous to that which has been suggested (24) for the mechanism involved in the boron trifluoride – sodium borohydride reduction of aliphatic esters. The inherent stability of the oxonium ions **15** and **17** provides a logical explanation for the absence of ring cleavage products.

Experimental

Melting points were determined on a Reichert Kofler Micro Heating Stage and are uncorrected. Ultraviolet spectra were recorded in ethanol solution on a Bausch and Lomb Spectronic 505 and i.r. spectra on a Perkin Elmer 237B spectrophotometer. Nuclear magnetic resonance spectra were taken on a Varian T-60 spectrometer. Tetramethylsilane was used as an internal standard. Elemental analyses were determined at Microanalysis Laboratories Limited, Toronto.

2′4′-Dihydroxy-biphenyl-2-carboxylic Acid Lactones (3a–f)

The following procedure (19) was used in the preparation of compounds **3***a–f*, the physical properties of which are described in Table 1.

A solution of the appropriate 2-bromobenzoic acid (0.05 mol), resorcinol (0.1 mol), and sodium hydroxide (0.1 mol) in water (30 ml) was heated under reflux for 30 min. A 10% aqueous solution of copper sulfate (5 ml) was then added whereupon a slightly exothermic reaction ensued. The resulting mixture was heated under reflux for an additional 10 min and then cooled to 20°. The insoluble product was collected, washed well with water and dried. This material was of sufficient purity to be used as such for the preparations of the 6*H*-dibenzo[*b*,*d*]pyrans which are described below. Analytical samples were recrystallized to constant melting point (Table 1).

2′,4′-Dihydroxy-6′methylbiphenyl-2-carboxylic Acid Lactone (3g)

This compound was prepared by the copper-catalyzed condensation of 2-bromobenzoic acid (44.3 g, 0.22 mol) and orcinol (50.2 g, 0.40 mol) in aqueous 1.5 *N* sodium hydroxide solution (270 ml) in the general manner described above, with the exception that the reaction mixture was heated under reflux for 1 h following the addition of the copper sulfate solution. The crude product (16.7 g, 34%) was recrystallized from glacial acetic acid to provide **3***g* (14.7 g, 30%; see Table 1).

2′,4′-Dihydroxy-6-methoxybiphenyl-2-carboxylic Acid Lactone (3h)

This compound was prepared by the copper-catalyzed condensation of 2-bromobenzoic acid (22.1 g, 0.11 mol) and 5-methoxyresorcinol (25 g, 0.21 mol) in aqueous 1 *N*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

sodium hydroxide solution (220 ml) in the general manner described above, with the exception that the reaction mixture was heated under reflux for 30 min following the addition of the copper sulfate solution. The crude product (15 g, 56%) was crystallized from methanol and from acetonitrile to provide **3*h*** (7.7 g, 29%; see Table 1).

3-Hydroxy-6,6-dimethyl-6H-dibenzo[b,d]pyrans

The following procedure was used in the preparation of all compounds listed in Table 2.

A suspension of the appropriate 2′,4′-dihydroxybiphenyl-2-carboxylic acid lactone (0.15 mol) in benzene (750 ml) was added over 15 min to a solution of methyl magnesium iodide prepared from magnesium turnings (24.3 g, 1 mol) and methyl iodide (130 g, 0.9 mol) in ether (400 ml). The ether was removed by distillation and the resulting mixture was heated under reflux for 3 h. The reaction mixture was cooled and poured into a mixture of concentrated sulfuric acid (40 ml) and ice (600 g) with vigorous stirring. The insoluble solid was collected and dried. The benzene phase was removed, dried over sodium sulfate, and evaporated. The residue was combined with the foregoing insoluble solid and the resulting mixture was suspended in benzene (300 ml). Boron trifluoride was bubbled in at a moderate rate at room temperature until a uniform solution was formed (15 min to 1 h). The reaction mixture was then poured into 2 *N* sodium hydroxide solution (300 ml) with vigorous stirring. The benzene was removed, and the aqueous phase was neutralized with 2 *N* hydrochloric acid and extracted with ether (3 × 100 ml). The ether extracts were combined with the benzene phase, dried over sodium sulfate, and evaporated. The crude product so obtained was crystallized to constant melting point (see Table 2).

*1-Hydroxy-3,6,6-trimethyl-6H-dibenzo[b,d]pyran (**8**) and 3-Hydroxy-1,6,6-trimethyl-6H-dibenzo[b,d]pyran (7)*

2-Bromobenzoic acid (88.4 g, 0.44 mol) was condensed with orcinol (99.2 g, 0.80 mol) in the manner described above for **3*g***. The crude product (29.5 g) was not purified further but was reacted in the general manner, described above, with excess methyl magnesium iodide, prepared from magnesium (24.3 g) and methyl iodide (130 g) in ether (220 ml). The crude product was similarly dehydrated with boron trifluoride and then twice chromatographed on silica (chloroform). Compound **8** (70 mg, 0.07% overall) was thereby obtained as a beige solid (m.p. 160–163°) which on sublimation (120°/0.05 mm) yielded colorless prisms, m.p. 162–165°; λ_{max} 275 (sh, log ε 4.19), 282 nm (log ε 4.21); n.m.r.: see text.

Anal. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71. Found: C, 79.64; H, 6.82.

Later column fractions provided compound 7 (15.9 g, 15.1% overall; see also Table 2) m.p. 143–144° (lit. (22) m.p. 144°); λ_{max} 272 nm (sh log ε 4.10), 276 (log ε 4.13), 305 nm (log ε 3.98); n.m.r.: see text.

*1-Hydroxy-3-methoxy-6,6-dimethyl-6H-dibenzo[b,d]-pyran (**10**) and 3-Hydroxy-1-methoxy-6,6-dimethyl-6H-di-benzo[b,d]pyran (**9**)*

2-Bromobenzoic acid (8.4 g, 0.042 mol) was condensed with 5-methoxyresorcinol (9.5 g, 0.08 mol) in the manner described above for **3*h***. The crude product (5.8 g, 60%) was not purified further but was reacted, in the general manner described above, with excess methyl magnesium iodide prepared from magnesium (3.5 g) and methyl iodide (18 g) in ether (30 ml). The crude intermediate was similarly dehydrated with boron trifluoride and then chromatographed on silica (chloroform). Compound **10** (410 mg, 3.8% overall) was thereby obtained as a pale yellow oil which on further purification by short path distillation (200°/0.3 mm) and crystallization from toluene–hexane provided colorless prisms, m.p. 124–125°; λ_{max} 287 (log ε 4.21), 302 nm (sh, log ε 4.08); n.m.r.: see text.

Anal. Calcd. for $C_{16}H_{16}O_3$: C, 74.98; H, 6.29. Found: C, 75.00; H, 6.42.

Later column fractions provided compound **9** (3.1 g, 29% overall; see also Table 2), which on recrystallization from toluene yielded colorless prisms, m.p. 146–148°; λ_{max} 288 (log ε 4.21), 303 nm (sh, log ε 4.07); n.m.r.: see text.

*2-(1-Hydroxyisopropyl)-2′,4′-dihydroxy-6′methoxybi-phenyl (**11*a*)***

A suspension of **3*h*** (35 g, 0.145 mol) in benzene (400 ml) was added over 15 min to a solution of methyl magnesium iodide prepared from magnesium (18 g, 0.74 mol) and methyl iodide (100 g, 0.7 mol) in ether (100 ml) and heated under reflux for 4 h. The reaction mixture was cooled then poured into 1 *M* KH_2PO_4 (1000 ml) containing ice (500 g). The benzene–ether layer was removed, dried over sodium sulfate, and applied directly to a short column (15 cm × 15 cm) of silica gel (1 kg) and eluted with ether. Earlier fractions provided **9** (12.8 g, 35%) followed by the title compound (**11*a***, 5.8 g, 15%). Recrystallization from ether–hexane provided colorless needles, m.p. 99–110° (dec.); n.m.r.: see text.

Anal. Calcd.[1] for $C_{16}H_{18}O_4 \cdot \frac{1}{2}(C_2H_5)_2O$: C, 69.43; H, 7.45. Found: C, 69.92; H, 7.38.

*2-(1-Hydroxyisopropyl)-2′,4′,6′-trimethoxybiphenyl (**11*c*)***

A solution of **11*a*** (1.8 g, 0.0066 mol) in dimethyl sulfoxide (35 ml) was treated with methyl iodide (12 g, 0.084 mol) and powdered anhydrous potassium carbonate (12 g, 0.087 mol). The mixture was stirred at room temperature for 24 h and then diluted with water (100 ml). The crude product was extracted with ether (2 × 50 ml) and the combined extracts washed with water (3 × 20 ml), dried over sodium sulfate and evaporated. The residue upon chromatography (chloroform–silica) provided the title compound (**11*c***, 0.51 g, 26%) as a white solid. Recrystallization from hexane – carbon tetrachloride yielded colorless prisms, m.p. 119–121°; n.m.r.: see text.

Anal. Calcd. for $C_{18}H_{22}O_4$: C, 71.50; H, 7.53. Found: C, 71.82; H, 7.40.

*6H-Dibenzo[b,d]pyran (**13*a*)***

A cooled solution of 2′-hydroxybiphenyl-2-carboxylic acid lactone (37.3 g, 0.19 mol) in a mixture of boron trifluoride etherate (500 ml) and tetrahydrofuran (1 l) was added over 15 min to a suspension of sodium borohydride (25 g, 0.66 mol) in tetrahydrofuran (500 ml) under dry nitrogen while maintaining the reaction temperature below 10°. The reaction mixture was then raised within 30 min to the reflux temperature, kept under reflux for 1 h, and then cooled to −3°. Ice cold aqueous 2 *N* hydro-

[1]The presence of ½ mol of ether was confirmed in the n.m.r. spectrum of this substance. It was not expelled by drying at room temperature for 48 h; higher temperatures dehydrated **11*a*** to **9**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

chloric acid (800 ml) was then cautiously added and the temperature was allowed to increase to 25°. Water (4000 ml) was added and the reaction mixture was extracted with chloroform (3 × 500 ml). The combined extracts were evaporated and the oily residue was heated at 80° with aqueous 2 *N* sodium hydroxide solution (800 ml) for 20 min. The resulting mixture was cooled and extracted with ether (4 × 100 ml). The ether extracts were combined, dried over sodium sulfate, and evaporated. The resulting violet oil (33.6 g) was distilled to provide the title compound (29.1 g, 84%) as a clear colorless oil, b.p. 122–123°/0.2 mm (lit. (21) b.p. 108–110°/0.2 mm); λ_{max} 263 (log ε 4.12), 270 (log ε 4.13), 291 (sh, log ε 3.66), and 310 nm (log ε 3.85); n.m.r. ($CDCl_3$): δ 5.07 (s, 2H, $-CH_2O-$).

Anal. Calcd. for $C_{13}H_{10}O$: C, 85.69; H, 5.53. Found: C, 85.54; H, 5.32.

*3-Hydroxy-6H-dibenzo[b,d]pyran (**13b**)*

This substance was prepared in a manner analogous to that described above for compound **13***a* with the following modification. The crude product dissolved on treatment with hot aqueous 2 *N* sodium hydroxide solution. The ether extracts were discarded and the free phenol was precipitated with 4 *N* hydrochloric acid, dried, and recrystallized from carbon tetrachloride to provide the title compound as colorless needles (88%), m.p. 108–110°; λ_{max} 280 (log ε 4.08), 297 (sh, log ε 3.98), and 319 nm (log ε 4.01); n.m.r. ($CDCl_3$): δ 5.02 (s, 2H, $-CH_2O-$).

Anal. Calcd. for $C_{13}H_{10}O_2$: C, 78.77; H, 5.09. Found: C, 79.15; H, 5.17.

*3-Hydroxy-4-methoxy-6H-dibenzo[b,d]pyran (**13c**)*

This substance was prepared in a manner analogous to that described for compound **13***b*. The crude product was recrystallized from ethanol and provided the title compound as colorless plates (70%), m.p. 143–145°; λ_{max} 282 (log ε 4.17), 308 nm (sh, log ε 3.85); n.m.r. (CD_3SOCD_3): δ 3.77 (s, 3H, $-OCH_3$), 5.13 (s, 2H, $-CH_2O-$).

Anal. Calcd. for $C_{14}H_{12}O_3$: C, 73.67; H, 5.30. Found: C, 73.48; H, 5.44.

*3-Nitro-6H-dibenzo[b,d]pyran (**13d**)*

This substance was prepared in a manner analogous to that described for compound **13***a*. The crude product was recrystallized from ethanol and provided the title compound as yellow needles (67%), m.p. 118–119°, λ_{max} 252 (log ε 3.82), 308 (log ε 3.91), and 354 nm (log ε 3.94); n.m.r.: (CD_3SOCD_3): δ 5.35 (s, 2H, $-CH_2O-$).

Anal. Calcd. for $C_{13}H_9NO_3$: C, 68.72; H, 3.99; N, 6.17. Found: C, 68.55; H, 3.95; N, 6.25.

*2-Hydroxymethyl-2′,4′-dihydroxybiphenyl (**14a**)*

A suspension of **5***a* (2.1 g, 0.01 mol) in tetrahydrofuran (500 ml) was added over 5 min to a stirred solution of lithium aluminum hydride (1 g, 0.026 mol) in tetrahydrofuran (50 ml) at room temperature. The reaction mixture was heated under reflux for 1 h and then cooled to 10°. Ethyl acetate (50 ml) was cautiously added over 10 min followed by aqueous 6 *N* sodium hydroxide solution (75 ml). The tetrahydrofuran – ethyl acetate phase was removed and discarded. The aqueous alkaline solution was cooled by the addition of ice (100 g), acidified with 4 *N* hydrochloric acid, and extracted with ether (2 × 100 ml). The ether extracts were combined and evaporated. The residual oil upon crystallization from water provided **14***a* (1.4 g, 65%) as a beige solid, m.p. 136°. One recrystallization from benzene yielded colorless needles, m.p. 138–139°; n.m.r. (CD_3SOCD_3): δ 4.37 (s, 2H, $-CH_2OH$).

Anal. Calcd. for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59. Found: C, 72.46; H, 5.50.

*Attempted BF_3 Dehydration of **14b***

A solution of **14***b* (800 mg) in a mixture of boron trifluoride etherate (15 ml) and tetrahydrofuran (60 ml) was heated under reflux for 90 min. The reaction mixture was cooled and aqueous 2 *N* hydrochloric acid (15 ml) was added followed by water (80 ml). The resulting mixture was extracted with chloroform (3 × 50 ml). The extracts were combined and evaporated and the residue was heated at 80° with aqueous 2 *N* sodium hydroxide solution (15 ml) for 20 min. The red solution was extracted with ether (2 × 20 ml). The ether extracts were discarded and the aqueous phase was acidified with 4 *N* hydrochloric acid and extracted with ether (3 × 50 ml). This extract was dried over sodium sulfate and evaporated. The residue was crystallized from water to provide **14***b* (450 mg, 56% recovery) as a beige crystalline solid, m.p. 136°, identical in all respects with the starting material. The mother liquor was examined by t.l.c. (silica gel, 10% methanol–chloroform) but failed to indicate any trace of compound **13***b*.

*Thermal Dehydration of **14b***

A test tube containing compound **14***b* (400 mg) was immersed in an oil bath preheated to 250° and maintained at this temperature for 30 min. The melt, so obtained, was cooled, dissolved in ether (10 ml), filtered, and evaporated. The residue was dissolved in methanol (2 ml) and water (8 ml) and extracted with hot carbon tetrachloride (4 × 5 ml). The extracts were combined, dried over magnesium sulfate, and evaporated. The residue was triturated with cold carbon tetrachloride and the insoluble solid (180 mg, 49%) was collected, dried, and identified as compound **13***b*, m.p. 102–106°, by t.l.c. and spectral comparisons.

6*H*-Dibenzo[*b*,*d*]pyrans. II. Boron Trifluoride Catalyzed Acylation of Hydroxy-6*H*-dibenzo[*b*,*d*]pyrans

JOHN P. DEVLIN
Pharma Research Canada Ltd., Pointe Claire, Quebec H9R 1G8

Received August 28, 1974

JOHN P. DEVLIN. Can. J. Chem. **53**, 350 (1975).

The Friedel–Crafts acetylation of 3-hydroxy-6*H*-dibenzo[*b*,*d*]pyrans (**1**) with acetic acid in the presence of boron trifluoride is described. Representatives unsubstituted at C-1 acylate exclusively at C-2. A methyl or methoxyl substituent at C-1 directs acylation to the C-4 position. The identities of the individual isomers are established primarily on the basis of n.m.r. spectral interpretations.

JOHN P. DEVLIN. Can. J. Chem. **53**, 350 (1975).

On décrit l'acylation selon Friedel–Crafts des hydroxy-3 6*H*-dibenzo[*b*,*d*]pyrans par l'acide acétique en présence de trifluorure de bore. Pour les composés non substitués en C-1, l'acylation se fait exclusivement en C-2. Un substituant méthyle ou méthoxy en C-1 dirige l'acylation en C-4. Il est possible d'identifier les différents isomères principalement au moyen de leur spectre r.m.n.

We have investigated the pharmacological effects of the inclusion of the 6*H*-dibenzo[*b*,*d*]-pyran ring system in a variety of biologically active molecules.

The *o*-acetyl derivatives of hydroxy-6*H*-dibenzo[*b*,*d*]pyrans were of particular interest in relation to our investigations of the anti-allergic activities of benzopyranobenzopyran carboxylic acids (*e.g.* PR-D-92, **2**) (2). Unfortunately, the reactions of dibenzo[*b*,*d*]pyrans have received scant attention in the literature and no reports were available in relation to the introduction and orientation of acyl groups in the monohydroxy representatives (*e.g.* **1** and **7**). We have investigated the Friedel–Crafts acylation of these compounds and have found the method of choice to be that of direct condensation with the appropriate acid in the presence of boron trifluoride (3–5). This preparative route was preferred on the basis of the convenience of the reaction, the ease of work-up and the high yields obtained. The use of aluminum trichloride was discouraged by the facile rearrangement of C-1 unsubstituted 6,6-dimethyldibenzo[*b*,*d*]pyrans in the presence of this Lewis acid to the corresponding 4-hydroxy-9,9-dimethylfluorene. This rearrangement, which is herein represented by the conversion of **3** to **4**, will be described in greater detail in a forthcoming paper.

3-Hydroxy-6*H*-dibenzo[*b*,*d*]pyrans without substitution at C-1 (**1**) rapidly condensed at room temperature with acetic acid in benzene solution in the presence of boron trifluoride and provided exclusively the 2-acetyl derivatives (**5**) in high yields (Table 1). In one instance (**1***c*) an increase in the reaction temperature resulted in the formation of a small amount of the 4-acetyl derivative (**6**) although the overall yield of monoacetylated product was reduced. The individual identities of these isomers were established by n.m.r. spectroscopy. In **5***c* the C-1 and C-4 protons, in $CDCl_3$ solution, occur as sharp singlets at δ 8.01 and 6.47, respectively, whereas in **6** the C-1 and C-2 protons are observed as **a** pair of doublets (J = 9 Hz) centered at δ 7.76 and 6.64, respectively.

3-Hydroxy-6*H*-benzo[*b*,*d*]pyrans with substitution at C-1 (**7**) behave somewhat differently than the unsubstituted series. The 1-methyl representative (**7**, R = CH_3) under the acetylation conditions described above yielded both isomers **8** and **9** in yields of 34 and 17%, respectively. The individual structural assignments in this instance are based primarily upon the deshielding effect of the acetyl carbonyl on the chemical shift of the C-1 methyl protons in isomer **8** (δ 2.82) relative to that in **9** (δ 2.56). This shift (Δδ 0.26) parallels that observed (Δδ 0.24) for the methyl protons in the n.m.r. spectra (6) of *o*-tolualdehyde (δ 2.65) and *p*-tolualdehyde (δ 2.41).

The main product from the boron trifluoride catalyzed acetylation of 1-methoxy-3-hydroxy-6,6-dimethyl-6*H*-dibenzo[*b*,*d*]pyran (**7**, R = OCH_3) was identified by n.m.r. spectroscopy as a monoacetyl derivative having the constitu-

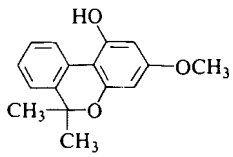
11 $R_1 = H; R_2 = COCH_3$



12

[*b*,*d*]pyran (**12**) (1) provided the 2-acetyl derivative (**13**). The identity of this product was established by the dark blue coloration with ferric chloride solution, the sharp low-field n.m.r. signal for the bound hydroxyl proton (δ 15.33) and finally by the facile conversion with diethyl oxalate to the tetracyclic carboxylic acid (**14**).

Methylation of **13** provided **15**. If the acetyl derivative of **7** (R = OCH_3) had the constitution **10**, methylation in the same manner should also provide **15**. This was not the case and the methylation product was, by elimination, assigned the constitution **16**. The monoacetyl derivative of **7** (R = OCH_3) were thereby identified as **11**. An attempt to demethylate **15** and **16** with hydriodic acid – acetic acid resulted in cleavage of the acetyl group as well, so that in both instances only the phenol, **17**, was obtained.

The specific orientation of the acetyl group to the C-2 position of the phenols (**1**) in the boron trifluoride catalyzed acylation herein described, parallels that observed for the Friedel–Crafts acylation of 3-alkoxyphenols (3). That the introduction of a substituent at C-1 results in partial (**7**, R = CH_3) or predominant (**7**, R = OCH_3) acylation at C-4, may be accounted for on the basis of steric crowding at C-2 and in the case of **7** (R = OCH_3), additional electronic direction to this position.

Experimental

Melting points were determined on a Reichert Kofler Micro Heating Stage and are uncorrected. Ultraviolet spectra were recorded in ethanol solution on a Bausch and Lomb Spectronic 505 and i.r. spectra (KBr pellet) on a Perkin Elmer 237B spectrophotometer. Nuclear magnetic resonance spectra were taken on a Varian T-60 spectrometer. Tetramethysilane was used as an internal standard. Elemental analyses were determined at Microanalysis Laboratories Limited, Toronto.

*The Rearrangement of 6,6-Dimethyl-6H-dibenzo[b,d]-pyran (**3**) to 4-Hydroxy-9,9-dimethylfluorene (**4**)*

Aluminum trichloride (1.4 g, 0.011 mol) was added at once to a solution of 6,6-dimethyl-6*H*-dibenzo[*b*,*d*]pyran (2.1 g, 0.01 mol) in ethylene dichloride (100 ml). The reaction mixture was stirred at room temperature for 15 min and then poured into 2 *N* hydrochloric acid (100 ml). The organic phase was removed, washed with water (50 ml), dried over sodium sulfate, and evaporated. The residue was crystallized from hexane and provided **4** (1.85 g, 88%) as colorless prisms m.p. 91–94° (lit. (7) m.p. 90–91°); λ_{max} 262 (log ε 4.11), 270 (log ε 4.13), 286 (log ε 3.92), 294 (log ε 3.92), 305 nm (log ε 3.67); n.m.r. ($CDCl_3$): δ 1.47 (s, 6H, $(CH_3)_2C$), 5.15 (broad s, 1H, —OH).

*2-Acetyl-3-hydroxy-6H-dibenzo[b,d]pyrans (**5a–g**)*

Boron trifluoride was bubbled, at a moderate rate (*ca.* 100 ml/min) for 1 h, into a solution of the 3-hydroxy-6*H*-dibenzo[*b*,*d*]pyran (**1**, 0.05 mol) in benzene (200 ml) containing acetic acid (0.06 mol) at room temperature. The reaction mixture was stirred at room temperature for 16 h and then poured into 2 *N* sodium hydroxide solution (500 ml) with vigorous stirring. After 5 min the mixture was acidified with 4 *N* hydrochloric acid and the benzene layer was removed. The aqueous phase was extracted with ether (2 × 200 ml). The ether extracts were combined with the benzene portion, dried over sodium sulfate, and evaporated. The 2-acetyl derivatives so obtained were recrystallized to constant melting point. These derivatives are described in Table 1.

*4-Acetyl-3-hydroxy-6,6-dimethyl-6H-dibenzo[b,d]pyran (**6**)*

Boron trifluoride was bubbled, at a moderate rate (*ca.* 100 ml/min), into a solution of **1***c* (19 g, 0.085 mol) and acetic acid (8.4 g, 0.14 mol) in benzene (260 ml) under reflux. After 3 h the reaction mixture was cooled and poured into aqueous 2 *N* sodium hydroxide solution (230 ml) with vigorous stirring. The mixture was acidified with 4 *N* hydrochloric acid and the benzene layer was removed. The aqueous phase was extracted with benzene (3 × 100 ml). The extracts were combined with the former benzene portion, dried over sodium sulfate, and evaporated. The residue was recrystallized from hexane and provided **5***c* (7.8 g). The mother liquor was evaporated and upon chromatography on silica ($CHCl_3$–hexane) provided the title compound (0.27 g, 1.2%) as yellow prisms m.p. 139–141°; λ_{max} 2.72 (log ε 4.31), 298 (sh log ε 4.06), 364 nm (log ε 3.33); ν_{max} 1627, 1605, 1593, 1570 cm^{-1}; n.m.r. ($CDCl_3$): δ 1.70 (s, 6H, —$(CH_3)_2$-CO—), 2.77 (s, 3H, —$COCH_3$), 6.64 (d, J = 9 Hz, 1H, C-2-H), δ 7.76 (d, J = 9 Hz, 1H, C-1-H).

Anal. Calcd. for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01. Found: C, 76.30; H, 6.03.

Later fractions yielded a further amount (1.2 g) of **5***c* (total yield 9 g, 40%; compare Table 1). Recrystallization from hexane yielded colorless plates m.p. 108–109°; λ_{max} 260 (log ε 4.33), 289 (sh, log ε 4.02), 299 (sh log ε 3.83), 347 nm (log ε 3.67); ν_{max} 1642, 1610, 1574 cm^{-1}; n.m.r.: see Table 1.

*2-Acetyl-3-hydroxy-1,6,6-trimethyl-6H-dibenzo[b,d]pyran (**8**) and 4-Acetyl-3-hydroxy-1,6,6-trimethyl-6H-dibenzo[b,d]pyran (**9**)*

A solution of **7** (R = CH_3) (6.8 g, 0.028 mol) and acetic acid (1.9 g, 0.031 mol) in benzene (100 ml) was treated with boron trifluoride for 30 min in the manner described above for the preparation of compounds (**5***a–g*). After 72 h at room temperature the reaction mixture was similarly worked up and the crude product was chromatographed on silica ($CHCl_3$). The first fraction yielded **8** (1.36 g, 11%) as a pale yellow oil. Distillation (110°/0.1 mm) and recrystallization from hexane provided yellow prisms m.p. 74–75°; λ_{max} 274 (log ε 4.34), 298 (sh log ε 3.88), 362 nm (log ε 3.19); ν_{max} 1612, 1590, 1560 cm^{-1}; n.m.r. ($CDCl_3$): δ 1.63 (s, 6H, —$(CH_3)_2CO$—), 2.56 (s, 3H, CH_3-Ar), 2.68 (s, 3H, $COCH_3$), 6.65 (s, 1H, C-2-H), 14.5 (s, 1H, —OH).

Anal. Calcd. for $C_{18}H_{18}O_3$: C, 76.57; H, 6.43. Found: C, 76.59; H, 6.49.

Later column fractions yielded **8** (2.67 g, 34%) which on recrystallization from heptane provided pale yellow prisms, m.p. 110–111°; λ_{max} 263 (log ε 4.25), 285 (sh, log ε 3.98), 313 nm (log ε 3.65); ν_{max} 1642, 1610, 1574 cm^{-1}; n.m.r. ($CDCl_3$): δ 1.60 (s, 6H, —$(CH_3)_2CO$—), 2.68 (s, 3H, $COCH_3$), 2.82 (s, 3H, $ArCH_3$), 6.50 (s, 1H, C-4-H), 14.1 (s, 1H, OH).

Anal. Calcd. for $C_{18}H_{18}O_3$: C, 76.57; H, 6.43. Found: C, 76.75, H, 6.49.

*4-Acetyl-1-methoxy-3-hydroxy-6,6-dimethyl-6H-dibenzo[b,d]pyran (**11**)*

A solution of **7** (R = OCH_3) (8.3 g, 0.032 mol) and acetic acid (2.93 g, 0.049 mol) in benzene (250 ml) was treated with boron trifluoride in the manner described above for the preparation of compound (**5***a–g*). After 2 days at room temperature the reaction mixture was similarly worked up and the crude product was chromatographed on silica ($CHCl_3$). The title compound was obtained as a colorless oil which crystallized from benzene–hexane and provided pale yellow crystals (5.7 g, 59%), m.p. 89–90°; λ_{max} 275 (log ε 4.33), 286 (sh log ε 4.29), 345 nm (log ε 3.11); ν_{max} 1630, 1590, 1573 cm^{-1};

n.m.r. (CCl_4): δ 1.65 (s, 6H, —$(CH_3)_2CO$—), 2.62 (s, 3H, CH_3CO), 3.92 (s, 3H, OCH_3), 6.05 (s, 1H, C-2-H), 8.10 (m, 1H, C-10-H), 13.67 (s, 1H, OH).

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.46; H, 6.08. Found: C, 72.69; H, 6.21.

*2-Acetyl-1-hydroxy-3-methoxy-6,6-dimethyl-6H-dibenzo[b,d]pyran (**13**)*

A solution of **12** (21 g, 0.082 mol) and acetic acid (7.2 g, 0.12 mol) in benzene (250 ml) was treated with boron trifluoride in the manner described above. After 10 days at room temperature, although the reaction was still incomplete, the mixture was worked up in the usual way. The crude product was chromatographed on silica and provided the title compound (9.1 g, 37%) which on recrystallization from hexane yielded pale yellow needles, m.p. 172–174°; λ_{max} 277 (log ε 4.44), 292 (log ε 4.43), 348 nm (log ε 3.31); ν_{max} 1615, 1585, 1565 cm^{-1}; n.m.r. (CCl_4): δ 1.63 (s, 6H, —$(CH_3)_2CO$—), 2.64 (s, 3H, —$COCH_3$), 3.86 (s, 3H, —OCH_3), 5.93 (s, 1H, C-4-H), 8.60 (m, 1H, C-10-H).

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.46; H, 6.08. Found: C, 72.45; H, 5.91.

*4-Oxo-5-methoxy-8,8-dimethyl-4H,8H-(2)benzopyrano(3,4-h)-(1)-benzopyran-2-carboxylic Acid (**14**)*

A suspension of **13** (1.0 g, 0.0034 mol) in ethanol (15 ml) containing diethyl oxalate (0.9 g, 0.0062 mol) was added at once to a solution of sodium (0.69 g, 0.03 mol) in ethanol (15 ml) at the reflux temperature. The reaction mixture was heated under reflux for 45 min, cooled to 10°, and acidified with 4 *N* hydrochloric acid. Water (50 ml) was then added and the resulting mixture was extracted with ether (3 × 50 ml). The combined extracts were dried over sodium sulfate and evaporated. The residue was treated with a mixture of acetic acid (10 ml) and concentrated hydrochloric acid (5 ml) under reflux for 2 h. The reaction mixture was then diluted with water (100 ml) and extracted with chloroform (5 × 80 ml). The combined chloroform extracts were dried over sodium sulfate and evaporated. The residue was crystallized from ethyl acetate and provided the title compound (0.35 g, 30%). Recrystallization from acetonitrile yielded pale yellow prisms, m.p. 242–248° (dec.); λ_{max} 276 (log ε 4.42), 304 (sh, log ε 3.57), 334 nm (log ε 3.32); ν_{max} 1718, 1660, 1620, 1608, 1598, 1585, 1562 cm^{-1}; n.m.r. (CD_3SOCD_3): δ 1.63 (s, 6H, —$(CH_3)_2CO$—), 3.88 (s, 3H, OCH_3), 6.65 (s, 1H, C-6-H), 6.72 (s, 1H, C-3-H), 8.65 (m, 1H, C-12-H).

Anal. Calcd. for $C_{20}H_{16}O_6$: C, 68.17; H, 4.57. Found: C, 68.14; H, 4.57.

*2-Acetyl-1,3-dimethoxy-6,6-dimethyl-6H-dibenzo[b,d]pyran (**15**)*

A solution of compound **13** (1 g, 0.0034 mol) and methyl iodide (2.3 g, 0.016 mol) in acetone (50 ml) was heated under reflux in the presence of powdered anhydrous potassium carbonate (2.3 g, 0.015 mol) for 15 h. The reaction mixture was cooled, filtered, and evaporated. The residue was dissolved in toluene (30 ml), filtered and evaporated. The residue was crystallized from toluene–hexane to provide compound **15** (0.9 g, 85%) as colorless prisms, m.p. 121–122°; λ_{max} 259 (log ε 4.19), 281 (log ε 4.08), 301 (log ε 3.91), 310 nm (log ε 3.84); ν_{max} 1695, 1605, 1585, 1565 cm^{-1}; n.m.r. (CD_3SOCD_3): δ 1.58 (s, 6H, —$(CH_3)_2CO$—), 2.45 (s, 3H, —$COCH_3$), 3.64 (s, 3H, —OCH_3), 3.82 (s, 3H, —OCH_3), 6.55 (s, 1H, C-4-H), 8.17 (m, 1H, C-10-H).

Anal. Calcd. for $C_{19}H_{20}O_4$: C, 73.06, H; 6.45. Found: C, 73.09; H, 6.38.

*4-Acetyl-1,3-dimethoxy-6,6-dimethyl-6H-dibenzo-[b,d]pyran (**16**)*

Compound **11** (1 g, 0.0034 mol) was methylated in the manner described above for the preparation of compound **15**. The crude product was similarly crystallized from toluene–hexane and provided compound **16** (0.85 g, 81%) as colorless needles, m.p. 152–153°; λ_{max} 276 (log ε 4.24), 287 (log ε 4.25) 301 nm (sh, log ε 3.84); ν_{max} 1700, 1613, 1600, 1590, 1580 cm^{-1}; n.m.r. (CD_3SOCD_3): δ 1.57 (s, 6H, —$(CH_3)_2CO$—), 2.42 (s, 3H, —$COCH_3$), 3.90 (s, 3H, —OCH_3) 4.03 (s, 3H, —OCH_3), 6.55 (s, 1H, C-2-H), 8.34 (m, 1H, C-10-H).

Anal. Calcd. for $C_{19}H_{20}O_4$: C, 73.06; H, 6.45. Found: C, 73.47; H, 6.72.

*1,3-Dihydroxy-6,6-dimethyl-6H-dibenzo[b,d]pyran (**17**)*

(*a*) Compound **15** (300 mg, 1.2 mmol) was heated under reflux in a mixture of acetic acid (2.5 ml) and hydriodic acid (57%, 2.5 ml) for 45 min. The reaction mixture was cooled, diluted with water (50 ml), and extracted with chloroform (2 × 50 ml). The extracts were combined, dried over sodium sulfate, and evaporated. The residue was purified by thick-layer chromatography (2-mm 20 × 20 cm silica gel plate, 7% methanol – 93% chloroform) and on recrystallization from toluene provided compound **17** (180 mg, 77%) as colorless needles m.p. 147–148°; λ_{max} 288 (log ε 4.21), 300 nm (log ε 4.08); n.m.r. (CD_3SOCD_3): δ 1.53 (s, 6H, —$(CH_3)_2CO$—), 5.88 (d, J = 2.5 Hz, 1H, C-2- or C-4-H), 6.12 (d, J = 2.5 Hz, 1H, C-4- or C-2-H), 8.40 (m, 1H, C-10-H), 9.47 (broad s, 1H, C-3-OH), δ 9.90 (s, 1H, C-1-OH).

Anal. Calcd. for $C_{15}H_{14}O_3$: C, 74.36; H, 5.82. Found: C, 74.54; H, 5.68.

(*b*) Compound **16** (300 mg, 1.2 mmol) was also treated with acetic acid – hydriodic acid and in a similar manner the crude product provided compound **17** (170 mg, 73%) m.p. 147–148°, identical with that obtained in (*a*).

A 2-Azapentadienyl Carbanion: a Nonstereospecific Electrocyclization

D. H. HUNTER AND R. P. STEINER
Department of Chemistry, University of Western Ontario, London, Ontario N6A 3K7

Received August 21, 1974

D. H. HUNTER and R. P. STEINER. Can. J. Chem. **53**: 355 (1975).

Treatment of 1,3,5-triphenyl-4-aza-1,3-pentadiene under selected basic conditions leads to either isomerization among the azapentadienes or to cyclization. Analysis of the products from reaction under aprotic conditions (LiTMP in THF) suggested that the open-chain delocalized carbanion exists in both the W and sickle forms. The open-chain anions were observed to electrocyclize in a nonstereospecific manner to produce a 1:1 mixture of *cis*- and *trans*-2,4,5-triphenyl-1-pyrrolines. Reaction in protic media (methanol and *tert*-butyl alcohol) produced a 1,5-proton transfer as well as cyclization. The details of the 1,5-proton transfer reaction were elucidated using methanol-*O-d* and the collapse preferences and intramolecularity in this medium were determined.

D. H. HUNTER et R. P. STEINER. Can. J. Chem. **53**, 355 (1975).

Le traitement du triphényl-1,3,5 aza-4 pentadiène-1,3, dans des conditions basiques choisies, conduit soit à une isomérisation entre les azapentadiènes soit à une cyclisation. L'analyse des produits formés par la réaction dans des conditions aprotiques (LiTMP dans THF) suggère qu'un carbanion délocalisé sur une chaîne ouverte existe dans la forme W et dans la falsiforme. On a observé que les anions en chaîne ouverte s'électrolisent d'une façon non-stéréospécifique pour conduire à un mélange 50:50 des triphényl-2,4,5 pyrrolines-1 *cis* et *trans*. La réaction dans des milieux protiques (méthanol ou *tert*-butanol) conduit à un transfert-1,5 de proton de même qu'à une cyclisation. On a élucidé les détails de la réaction de transfert-1,5 de proton en faisant appel à du méthanol-*O-d*; on a déterminé la nature des effondrements préférentiels et la nature intramoléculaire de la réaction dans ce milieu. [Traduit par le journal]

Introduction

We have previously reported (1) the remarkably rapid and stereoselective electrocyclization of a 2,4-diazapentadienyl anion. This stands in contrast to the lack of reactivity of the pentadienyl anion (2). We have now studied a 2-azapentadienyl anion since its propensity for cyclization might be expected to lie between the other two systems. This in fact was the case and as a consequence information has been obtained about open-chain anion stabilities and geometries. A striking effect of aza-substitution on the electrocyclization rate and stereochemistry has been observed.

In order to make a direct comparison with our earlier work on the 1,3,5-triphenyl-2,4-diazapentadienyl anion **5**, the particular system chosen for study was the 1,3,5-triphenyl-2-azapentadienyl anion **4**.

Preparation and Characterization of Substrates

1,3,5-Triphenyl-4-aza-1,3-pentadiene

From a synthetic viewpoint, of the three carbon acid precursors to the 1,3,5-triphenyl-2-azapentadienyl anions, 1,3,5-triphenyl-4-aza-1,3-pentadiene **1** appeared to be the most attractive substrate. Synthesis of **1** was accomplished by condensation of chalcone and benzylamine yielding a 3:1 mixture of geometrical isomers of **1**. On the basis of the magnitude of the proton–proton coupling constant between the vinyl protons ($J \approx 17$ Hz), the carbon–carbon double bond in **1** was assigned the *trans*-geometry in both isomers. Thus apparently the two isomers of **1** differ by being *syn* or *anti* at the carbon–nitrogen double bond. The major equilibrium isomer was obtained in a pure state by recrystallization. However, it is not known whether this isolated isomer of **1** corresponds to the *syn* or *anti* possibility. The *syn–anti* interconversion rates of **1** are sufficiently slow to permit characterization but are accelerated by base.

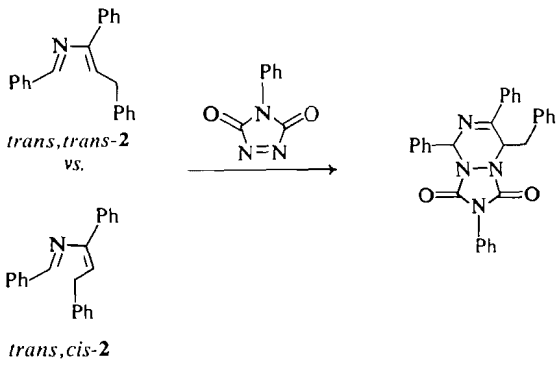
1,3,5-Triphenyl-2-aza-1,3-pentadiene

The 1,3,5-triphenyl-2-aza-1,3-pentadienes **2** were prepared by base-catalyzed isomerization of **1** and the appropriate data are gathered in Table 1. As indicated in runs 4 and 5, when **1** was reacted in 0.22 *M* potassium methoxide – methanol at 60° the fastest reaction was equilibration of the *syn* and *anti* forms of **1** to provide a 3.2:1 mixture of unassigned geometry. More slowly a mixture of geometrical isomers of **2** was produced in a time-dependent ratio. At low percentages of conversion (run 4) *trans,cis*-**2** was preferred by about 3:1, whereas at apparent equilibrium (run 5) *trans,trans*-**2** was favored by 2:1 and no **1** was observed.

The major isomer from run 5 (assigned the *trans,trans* geometry as described below) was isolated by t.l.c., purified, and characterized by n.m.r., i.r., and mass spectrometry. The minor isomer could not be isolated due to hydrolysis on silica gel.[1] Instead, its structure was assigned on the basis of its n.m.r. spectrum in the mixture of the two isomers of **2**.

The geometries of the isomers of **2** were assigned on two counts. First, the geometry of the carbon–nitrogen double bond was assumed to be *trans*(*syn*) since geometrical isomerization around this bond ought to be rapid at ambient temperature (3) and thermodynamics should certainly favor the *syn*-isomer. Second, the geometry at the carbon–carbon double bond was assigned on the basis of relative reactivity of the two isomers of **2** with 4-phenyl-1,2,4-triazoline-3,5-dione to form a Diels–Alder type product. The relative reactivity was assessed by n.m.r. monitoring of the changes in the ratio of the two isomers of **2** in a mixture upon successive addition of aliquots of the triazolinedione. The major isomer of run 5 reacted at least five times faster than the minor isomer. This reactivity ratio is a minimum because the increasing signals of the product partially overlapped those of **2**.

The more reactive isomer (the major isomer of run 5) was assigned the *trans,trans*-**2** structure since it is anticipated that it will more readily adopt the *S-cis* conformation necessary for Diels–Alder reactivity. The product of the reaction of *trans,trans*-**2** with the triazolinedione was isolated by t.l.c. and characterized by n.m.r., i.r., and mass spectrometry. These data were consistent with the product of a Diels–Alder reaction.



[1]The major isomer also underwent some hydrolysis during t.l.c. yielding β-phenylpropiophenone.

trans-2,4,5-Triphenyl-1-pyrroline (trans-3)

Treatment of **1** under more basic conditions, *tert*-butyl alcohol – potassium *tert*-butoxide, first at 25° led to isomerization to **2** (runs 1 and 2 of Table 1) and then at 120° to *trans*-**3** (run 11 of Table 2) as the only observed product in good yield. This product was shown to be isomeric with **1** and **2** by mass spectrometry but unlike **1** and *trans,trans*-**2**, *trans*-**3** yielded the five-membered ring oxidation product, 2,3,5-triphenylpyrrole, upon oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ).

The presence of a carbon–nitrogen double bond in *trans*-**3** was verified by i.r. with observation of a band due to C=N and absence of an N—H bond. The analysis of the 100 MHz proton n.m.r. spectrum as an ABCM pattern, with assistance of the LAOCOON III program, was consistent with placement of the carbon–nitrogen double bond as in *trans*-**3** and is inconsistent with the other possibility. The proton–proton coupling constant for the 4 and 5 hydrogens, $J = 6.7$ Hz, was consistent with but did not require a *trans* configuration.

The *trans* configuration was assigned by establishing that this material had the thermodynamically preferred configuration at positions 4 and 5. This was done in two ways. First, treatment of *trans*-**3** with potassium *tert*-butyl alcohol-*O*-*d* at 120° (run 13) which is the condition required for its formation from **1** (run 11) yielded *trans*-**3** back again but having incorporated **4** atoms D/molecule in the pyrroline ring. This indicates that the conditions of run 11 are more than sufficient to ensure formation of the thermodynamically more stable isomer or *trans* phenyl groups. More convincingly when *cis*-**3**, whose preparation is discussed below, was treated un-

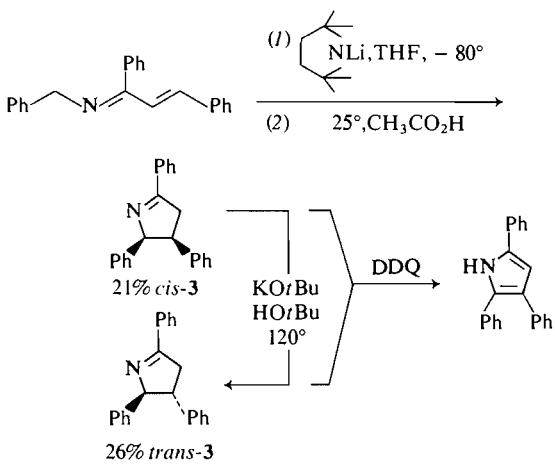
For personal use only.

der the same conditions (run 12), *trans*-**3** was observed as the only reaction product and in good yield.

cis-2,4,5-Triphenyl-1-pyrroline (cis-3)

When **1** was treated with lithium 2,2,6,6-tetramethylpiperidide (LiTMP) in tetrahydrofuran (THF) and the resultant blue solutions were quenched with acetic acid, a new product distribution was observed. As indicated in runs 9 and 10 of Table 1, if the temperature was kept below $-10°$ only **1** and **2** were obtained. However upon warming the solutions to 0° and above (runs 14 and 15) cyclized materials became the major products. In contrast to *tert*-butoxide in *tert*-butyl alcohol (run 11), both *cis*-**3** and *trans*-**3** were produced and in similar amounts. The two cyclized products could be separated by t.l.c. The structure assignment for *cis*-**3** was analogous to that for *trans*-**3**.



Mass spectrometry confirmed its isomeric nature to **1**, **2**, and *trans*-**3**, and oxidation with DDQ yielded 2,3,5-triphenylpyrrole. The presence of C=N was shown by i.r., and n.m.r. was consistent with the structure indicated. As mentioned above, evidence for the *cis* assignment lies in its conversion to *trans*-**3** upon treatment with potassium *tert*-butoxide in *tert*-butyl alcohol at 120° (run 12).

Discussion

As described in the Results section, the reaction of **1** under selected basic conditions can lead to specific types of isomerization. Under mildly basic conditions interconversion between open-chain isomers can be observed both in protic media (potassium methoxide in methanol or lithium *tert*-butoxide in *tert*-butyl alcohol at 60° and potassium *tert*-butoxide in *tert*-butyl alcohol at 25°) and aprotic media (LiTMP in THF below $-10°$). Under more vigorous basic conditions conversion to cyclic isomers occurs also in protic media (potassium *tert*-butoxide in *tert*-butyl alcohol at 120°) and aprotic media (LiTMP in THF above 0°). This differing reactivity between open-chain isomerization and cyclization has made it possible to obtain information on the role of the 1,3,5-triphenyl-2-aza-pentadienyl anion **4** in both processes.

The discussion of the properties of the 1,3,5-triphenyl-2-azapentadienyl anion **4** will first center on the geometries of the open-chain anion, then its electrocyclization reaction, both rate and stereochemistry, and then on its behavior as a short-lived species in protic solvent with emphasis on stability, collapse ratio, and intramolecularity.

Anion Geometries

In an attempt to ascertain the geometry that anion **4** prefers to adopt, quenching of the lithium salt of **4** in THF with acetic acid was investigated. When pure **1** was treated with a slight excess of LiTMP in THF at $-78°$, a deep blue color resulted. As indicated in runs 9 and 10 of Table 1, addition to this of an equivalent of acetic acid at either $-78°$ or $-15°$ led to the same mixture of four open-chain isomers. That these isomers had arisen from quenching of **4** was established using CH_3CO_2D. The n.m.r. spectrum of the reaction mixture was qualitatively consistent with incorporation of 1 atom D/molecule. In spite of the sensitivity of **1** to geometrical isomerization a control experiment verified that the isolated isomer of **1** survived the work-up conditions unchanged. The 3:1 geometrical isomer ratio for **1** is then both the kinetic and thermodynamic mixture.

The observation of four geometrical isomers of **1** and **2** requires that anion **4** exist in more than one geometry. The interconversion between anion geometries must be reasonably facile since equilibration occurs within 300 min at $-78°$ (run 9). Rapid interconversion rates are not unexpected since allyl and pentadienyllithiums show coalescence phenomena in their proton n.m.r. spectra consistent with fairly rapid geometrical interconversions (4).

The 2-azapentadienyl anion can, in principle, adopt four different geometries; a W shape, two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

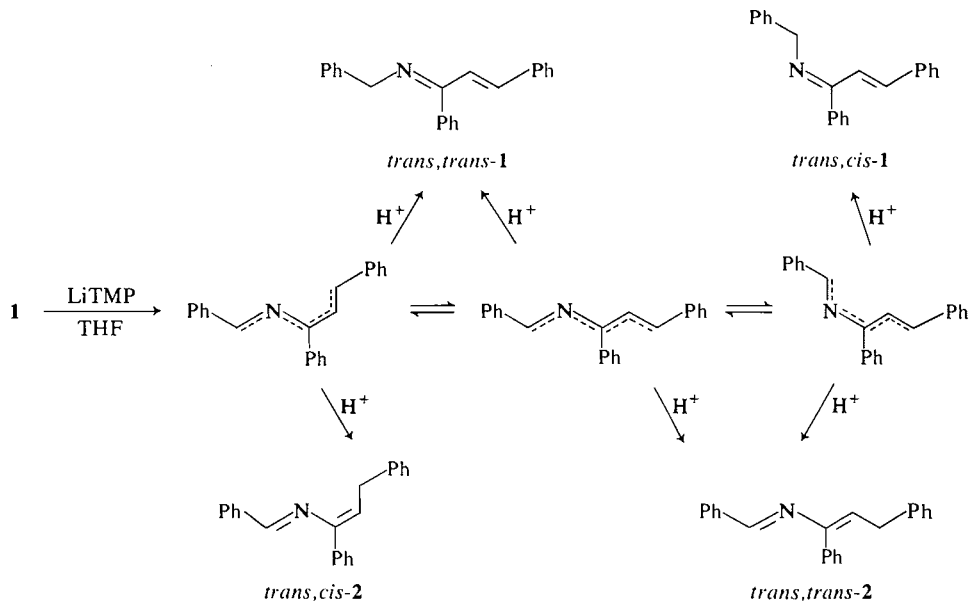


FIG. 1. Geometries anticipated for **4** and products of quenching.

sickle shapes, and a U shape. Of these, the U shape should be the least favored and n.m.r. results for pentadienyllithiums (2) support this contention. If phenyl rings are placed at the 1,3, and 5 positions of the W and two sickle shapes so as to minimize nonbonded interactions (5), the anions shown in Fig. 1 are obtained. Figure 1 also indicates the four products that could arise upon quenching of these anions. Since all four products are observed and occur in similar amounts, it would appear that the three geometries of anions do exist and in similar amounts. A direct calculation of anion populations from product distribution was not achieved since all three anions can form two products.

However, it can be concluded that anion **4** exists in a W shape and in two sickle shapes. These shapes can interconvert fairly rapidly and at equilibrium they exist in similar amounts.

The Electrocyclization Reaction

As mentioned above, under more vigorous conditions cyclization was observed in both protic and aprotic media and information was gathered on both the rates and stereochemistry of the cyclization reaction.

Rate of Cyclization

Information on the propensity of anion **4** for electrocyclization has been obtained in both protic and aprotic media and can be compared with the earlier results (1) for the 1,3,5-triphenyl-2,4-diazapentadienyl anion **5**. As is indicated in runs 9, 10 and 14, 15, while anion **4** may be generated at $-78°$ in THF, electrocyclization is not observed until above 0°. This is in contrast with **5** which electrocyclizes competitively with its formation at $-78°$ in THF.

This same phenomenon is illustrated for protic solvents in runs 1–5 and 11. Both potassium methoxide in methanol and lithium *tert*-butoxide in *tert*-butyl alcohol at 60° are sufficiently basic to convert **1** to **2**, presumably through the short-lived anion **4**. However, potassium *tert*-butoxide in *tert*-butyl alcohol, a kinetically much stronger base, at 120° must be used to produce electrocyclization. A rate ratio of at least 10^6 between the rate of anion formation and the rate of electrocyclization can be deduced.[2]

The results in both protic and aprotic media correspond to a reaction profile where a more rapidly formed open-chain anion **4** slowly electrocyclizes in the rate-determining step. This should be contrasted with the results obtained

[2]Potassium *tert*-butoxide in *tert*-butyl alcohol is a kinetically stronger (6) base than potassium methoxide in methanol by about 10^6. The 60° temperature difference (120° *vs.* 60°) should correspond to an additional rate ratio depending upon the activation energy (an unknown).

For personal use only.

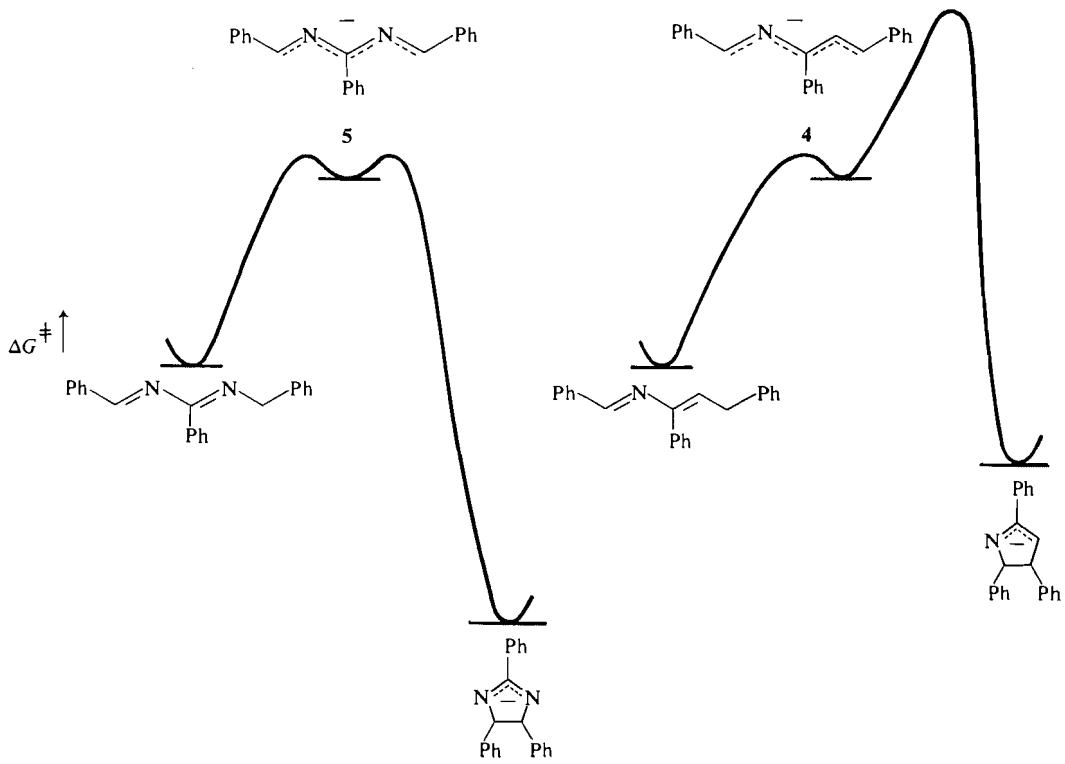

FIG. 2. Free energy profiles for formation and electrocyclization of anions **4** and **5**.

for the 2,4-diazapentadienyl anion **5**. In this earlier study (1) it was found that while formation of **5** seemed to occur at a rate comparable to **4** in both protic and aprotic media, the rate of electrocyclization of **5** was significantly faster. Electrocyclization and anion formation occurred at competitive rates with **5**. The difference in behavior in the two systems is summarized in the energy profiles of Fig. 2. The difference in ease of electrocyclization is presumably a reflection of the difference in the stability of the cyclized forms of the anions. The negative charge should reside primarily on the termini of the three atom system coincident with the position of the nitrogen.

Stereochemistry of Electrocyclization

When a solution of the lithium salt of **4** in THF was allowed to warm to 0–5° for 30 min and then quenched with acetic acid (run 14) significant amounts of cyclization were observed and cyclization was complete at 180 min and 25° (run 15). Under these conditions both *cis*-**3** and *trans*-**3** were isolated as the major products and in similar amounts (a *cis–trans* ratio of 1.2 in run 14 and 0.8 in run 15) along with minor amounts of the oxidation product, 2,3,5-triphenyl-pyrrole. It is likely that the observed *cis*-**3**:*trans*-**3** of *ca.* 1 is close to the actual kinetic product distribution on two counts. First, base-catalyzed equilibration of *cis*-**3** (run 12) and *trans*-**3** (run 13) yields just *trans*-**3** in analogy to the diaza-system (1). Second, if there is *cis–trans* equilibrium in THF, it must be slow as shown by the slight, if real, change in the *cis*-**3**:*trans*-**3** ratio with a significant change in reaction conditions (runs 14 and 15).

In contrast to the kinetic distribution in the aprotic medium, the conditions necessary to produce electrocyclization in protic media are also sufficient to equilibrate any cyclized products. As shown in run 11, reaction of **1** in a potassium *tert*-butoxide – *tert*-butyl alcohol solution at 120° for 30 min is necessary to produce significant cyclization and only *trans*-**3** is observed. As mentioned earlier, reaction of *cis*-**3** under the same conditions (run 12) results in complete conversion to *trans*-**3**. That *trans*-**3** is probably

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

the thermodynamically most stable of the possible, 2,3,5-triphenylpyrrolines is shown by the base-catalyzed exchange results of run 13 with *trans*-**3**; *trans*-**3** was recovered as the only product of run 13 and had completely exchanged the pyrroline ring (4 atoms D/molecule). Thus apparently all centers within the pyrroline ring had an opportunity to epimerize and *trans*-**3** remained the sole product. Thus the results in *tert*-butyl alcohol do not also allow determination of the kinetic ratio of *cis*-**3** and *trans*-**3** from electrocyclization of **4** but provide the equilibrium product.

A comparison (Fig. 3) with the stereochemical behavior of the 2,4-diazapentadienyl anion **5** is revealing since **5** produced exclusively the cyclized material with *cis*-phenyl groups ($\geq$ 99.7%). This change in stereoselectivity corresponds to a change in the *cis–trans* product ratio of $\geq$300 on aza-substitution. This marked sensitivity of stereochemistry to aza-substitution deserves some mechanistic comment, as does the observation of a nonstereospecific electrocyclization.

One mechanistic scheme invokes the same U-shaped geometry of anion (as in Fig. 3) for electrocyclization of both the diazapentadienyl anion **5** and the monoazapentadienyl anion **4**. In this scheme the change in product distribution would reflect a change in the relative rates of the conrotatory and disrotatory modes of electrocyclization. In the symmetrical anion **5** the expected disrotatory mode (7) is exclusively involved. However, in the unsymmetrical anion **4** the conrotatory and disrotatory modes are competitive. This change in stereoselectivity could be a result of changes in orbital symmetry demands accompanying loss of molecular symmetry (8).

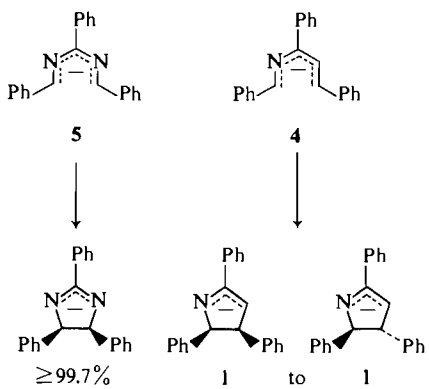

FIG. 3. Comparison of the stereochemistry of electrocyclization of anions **4** and **5**.

A second and similarly unprecedented scheme assumes the same disrotatory mode of electrocyclization for both **4** and **5**. The different product stereochemistries are then a consequence of reaction from different anion geometries. Both U and W shaped anions would lead to cyclized material with *cis*-phenyl rings and the 'sickle' shaped anion would produce *trans*-product. Such differing stereochemistries could then arise if the highly reactive diazapentadienyl anion **5** were produced initially in the W shape and electrocyclized before or while geometrical interconversions occurred.

The much less reactive azapentadienyl anion **4**, in contrast, is observed to undergo geometrical interconversions much faster than electrocyclization. Analogous mechanistic schemes in which both **4** and **5** undergo equilibration of geometries before electrocyclization suffer from the disadvantage of having to postulate either different distributions of geometries or differing geometry reactivities as a result of aza-substitution. While these remain as possibilities, they prove difficult to rationalize convincingly.

These two contrasting mechanisms correspond to cases where the changes in product stereochemistry are attributed to changes, first, in reaction pathway or second, in reactant structure (geometry). The data gathered in this study are insufficient to distinguish between these mechanistic possibilities but a more complete analysis will be reported in a subsequent paper on the all-carbon system.

Relative Stability of the Azapentadienes

The relative thermodynamic stabilities of some of the isomers of **1** and **2** can be deduced from the isomerization results of runs 1–6 of Table 1. Analysis of the reaction mixture of runs 3, 4, 6, 7, and 8 in which unreacted **1** was present revealed a facile base-catalyzed *syn–anti* isomerization which provided a 3:1 mixture of **1**. The results of equilibration of **1** (runs 1, 2, and 5) showed that only **2** is present at equilibrium between **1** and **2** and *trans,trans*-**2** predominates over *trans,cis*-**2** by a factor of 2. Although there is no direct evidence bearing on the point, by analogy with **2**, it is likely that the isolated and major equilibrium isomer of **1** also has the *trans,trans* structure. While *trans,trans*-**2** is predominant at equilibrium, it is *trans,cis*-**2** that is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the kinetically preferred product (runs 3, 4, 6, 7, and 8). This occurs whether the reaction involves ion-pairs ($LiOC(CH_3)_3$ in $HOC(CH_3)_3$; run 3) or dissociated ions ($KOCH_3$ in $HOCH_3$; run 4). If the initial product distribution reflects the intermediate anion stability, the sickle shaped anion would appear to be the most stable.

While it is not surprising that none of the 2-aza-1,4-pentadienes were present upon equilibration of **1** and **2**, the exclusive formation of **2** was unexpected. Simple Hückel molecular orbital calculations predict the reverse. Although the generality of this observation has not been demonstrated, base-catalyzed isomerization of 2-aza-2,4-pentadienes to 2-aza-1,3-pentadienes may be a satisfactory synthetic route to some examples of this unique functionality, *i.e.* vinylimines.

Intramolecularity

Since examples of base-catalyzed 1,5-proton transfer reactions are few, an attempt was made to further characterize the intermediate anion by comparing isomerization and hydrogen–deuterium exchange (runs 6, 7, and 8). The extent of involvement of an intramolecular component in the 1,5-proton shift was estimated from the percentage of d_0 material found in *trans,trans*-**2** and *trans,cis*-**2** produced from **1** after short reaction times in CH_3OD (runs 6 and 7). The geometrical isomers of **2** were not analyzed directly but the combined hydrolysis product, β-phenylpropiophenone, was analyzed by mass spectrometry and showed 0.9 atoms D/molecule. Although this 10% intramolecular component should be a lower limit, due to concurrent exchange of both **1** and **2**, model calculations indicate corrections should be minor.

Although the observed 1,5-proton shift could actually be the result of two consecutive 1,3 shifts, this is unlikely. The anion **5** produced by proton abstraction from the central carbon of the analogous 2,4-diazapentadienyl system, hydrobenzamide, was found to protonate exclusively at the terminal position. The 1,3-proton shift via **5** occurred with 14% intramolecularity in CH_3OD. The only other examples of base-catalyzed 1,5-proton shifts involves tautomers of triphenylmethane (9) (Fig. 4). Only one of these systems has been studied in methanol-*O*-*d* but comparable results are available for *tert*-butyl alcohol-O-*d* and these systems show consistently higher intramolecular components (~50%) than the open-chain systems (~10%). While the geometries differ between these two types of substrates, the difference in pK_a between substrate and solvent has also changed. The pK_a's of the aza-substituted pentadienes are estimated from kinetic acidity to be ~24 and triphenylmethane has been assigned a pK_a of 32.5 on the MSAD scale (6). It is surprising that in comparison to the large change in substrate pK_a's, the change in intramolecularity is quite small. However, the actual intramolecularity will be less than 10% if significant amounts of protium are introduced from the protons in solvent reinforced by an isotope effect on protonation.

Collapse Ratios

The exchange data of runs 6, 7, and 8 also can be used to determine the preferred positions of protonation of the intermediate anions **4**. The percentage of isotopic exchange in recovered **1** gives a measure of the acts of carbanion formation that have occurred but with deuteration at the 1-position. The percentage of **2** observed gives a measure of carbanion formation from **1** but with collapse at the 5-position. The extent of isotopic exchange in **1** does not give a true measure of collapse at the 1-position since there is a small intramolecular component (see above) but the correction is small.

The results of runs 6, 7, and 8 were simulated by numerical integration of the corresponding reaction scheme using the MIMIC language of the CDC computer. As is qualitatively evident from the isotopic exchange results and as borne out more quantitatively ($k_{-1}/k_{-5} = 1.6$), there is only a slight preference for deuteration of anion **4** at the 1-position. A comparison of these results with the quenching results of runs 9 and 10 shows that again there is a close competition between reaction at each end of anion **4** but under quenching conditions, reaction at the 5-position predominates ($k_{-1}/k_{-5} = 0.3$). Although several factors could be involved, the products do indicate that different ratios of anion geometries are present and different geometries may show different collapse ratios.

The overall picture from both these studies indicates that in spite of apparently large differences in the thermodynamic stability of the two products of anion collapse (**1** and **2**), there is only slight selectivity in the collapse ratio. The observed collapse ratio is consistent with an anion whose positional reactivity is little affected

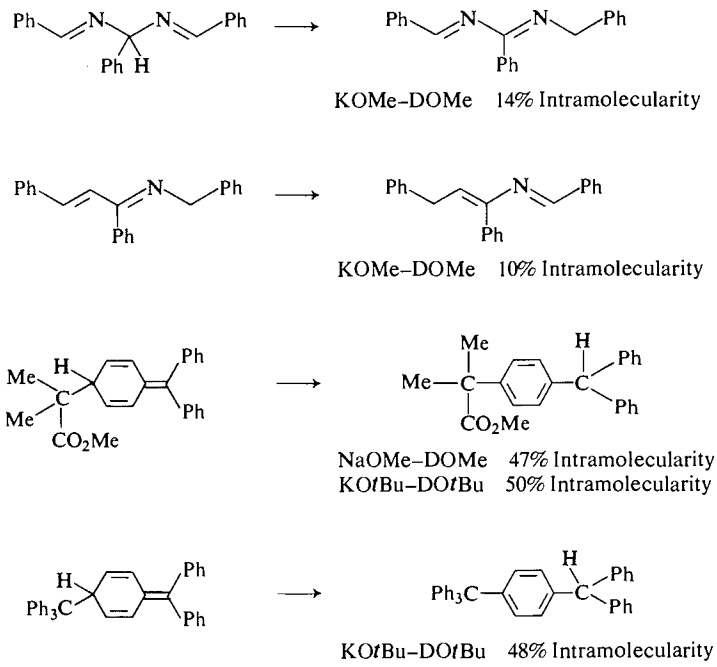

FIG. 4. Examples of reactions involving 1,5-proton shifts of pentadienyl anions and the observed intramolecularity.

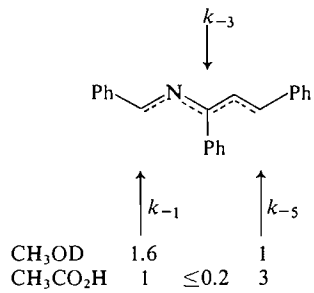
by product stability but may reflect similar steric demands. The absence of quenching products due to reaction in the middle (the 3-position) would also seem to support this hypothesis. The charge distribution in **4** may also be important (10) but its contribution is not readily evaluated in the present system.



Experimental

Solvent and Bases

The methanol was distilled from magnesium and the *tert*-butyl alcohol was distilled from calcium hydride. The potassium *tert*-butoxide in *tert*-butyl alcohol (0.53, 0.03 *M* in H_2O) and the potassium methoxide in methanol (0.22, 0.05 *M* in H_2O) were prepared by the reaction of the alcohol with freshly cleaned potassium and were stored under argon. The methanol-*O-d* was prepared from dimethyl carbonate (11) and the base solution was prepared as above (0.59, 0.08 *M* in D_2O). The *tert*-butyl alcohol-*O-d* (12) was similarly reacted with potassium to produce a base solution (0.53 *M*).

Tetrahydrofuran (THF) was freshly distilled from lithium aluminum hydride before use. Solutions of lithium 2,2,6,6-tetramethylpiperidide in THF (1.0–2.0 *M*) were prepared by adding an equivalent of *n*-butyllithium (Alfa Inorganics) to a cooled solution (~−20°) of 2,2,6,6-tetramethylpiperidine in THF followed by stirring for 1 h from cold up to ambient temperature.

1,3,5-Triphenyl-1-4-azapenta-1,3-diene (1)

A mixture of chalcone (5.0 g, 23.3 mmol) and benzylamine (2.5 g, 23.3 mmol) in 150 ml of hexane (freshly distilled from calcium hydride) was refluxed 8 h over 50 g of 5A molecular sieves using a Barrett water trap. After filtration and solvent removal, the crude oil crystallized upon refrigeration. Recrystallization from hexane yielded 2.6 g (30%) of product, m.p. 83–85°. It is imperative that the crystals be grown slowly.

Mass spectrum: *m/e* 297, molecular ion. The n.m.r. spectrum (CCl_4) showed a 2 hydrogen singlet at δ = 4.40, and one hydrogen doublet at δ = 6.35 (*J* = 17 Hz), and a 16 hydrogen multiplet in the region δ = 6.96–7.53. The i.r. spectrum ($CHCl_3$) showed C=N at 1598 cm^{-1}.

A second geometrical isomer was present in the crude oil but was not isolated. The n.m.r. (CCl_4) of the second component in the mixture showed a 2 hydrogen singlet at δ = 4.80, a 1 hydrogen doublet at δ = 6.67 (*J* = 17 Hz), and an apparent 16 hydrogen multiplet at δ = 6.96–7.53 as obtained by difference.

1,3,5-Triphenyl-2-azapenta-1,3-diene (2)

A degassed solution of **1** (0.1 g, 0.34 mmol) in 0.64 ml of 0.53 *M* potassium *tert*-butoxide in *tert*-butoxide in

tert-butyl alcohol was stirred at ambient temperature for 0.5 h. The reaction mixture was extracted using ether and water. After the ether layer was washed once with water, once with saturated sodium chloride, and dried with magnesium sulfate, the solvent was removed under reduced pressure. An n.m.r. of the residual oil indicated a 3:1 ratio of *trans,trans*-**2** to *trans,cis*-**2**.

Thin-layer chromatography (silica gel, 10% ether-in-hexane) resulted in isolation of β-phenylpropiophenone (66% yield, m.p. 68–69°) and *trans,trans*-**2** (28%, m.p. 44–46°). Mass spectrum: *m/e* 297 for molecular ion. The n.m.r. spectrum (CCl_4) showed a 2 hydrogen doublet at $\delta = 3.72$ ($J = 7.5$ Hz), a 1 hydrogen triplet at $\delta = 5.60$ ($J = 7.5$ Hz), a 15 hydrogen multiplet in the region $\delta =$ 6.82–7.78, and a 1 hydrogen singlet at $\delta = 8.09$.

The i.r. spectrum ($CHCl_3$) showed C=N at 1630 cm^{-1}.

The geometrical isomer, *trans,cis*-**2** was not isolated but was characterized from its n.m.r. spectrum (CCl_4) in the mixture before t.l.c.; a 2 hydrogen doublet at $\delta =$ 3.36 ($J = 8$ Hz), a 1 hydrogen triplet at $\delta = 6.01$ ($J =$ 8 Hz), a 1 hydrogen singlet at $\delta = 7.86$, and a 15 hydrogen multiplet at the region $\delta =$ 6.82–7.78 as obtained by difference.

Diels–Alder Reaction of trans,trans-2 and trans,cis-2 with 4-Phenyl-1,2,4-triazoline-3,5-dione

The relative rates of reaction of a 2:1 mixture of *trans,cis*-**2** and *trans,trans*-**2** (0.1 g, 0.34 mmol in 0.5 ml CCl_4) were followed by n.m.r. monitoring of the doublets at $\delta = 3.36$ and 3.72 as aliquots (3 mg, 0.017 mmol) of 4-phenyl-1,2,4-triazoline-3,5-dione were added. The final ratio of doublets was 8:1 before the upfield doublet disappeared into the other increasing signals. After solvent removal, the crude oil was separated by t.l.c. (silica gel, chloroform) yielding the Diels–Alder adduct (45 mg, 33%) as the major product (m.p. 105–107° from hexane–benzene). Mass spectrum: $m/e = 472.7$ for molecular ion. The n.m.r. spectrum ($CDCl_3$) showed a 2 hydrogen AB part of an ABX at $\delta = 3.05$–3.65 ($\nu_a = 3.16$, $\nu_b = 3.50$ and $J_{ab} = 14$ Hz, $J_{ax} = 5$ Hz, and $J_{bx} = 6$ Hz), the 1 hydrogen X part at $\delta = 5.72$, a 1 hydrogen singlet at $\delta =$ 6.46, and a 20 hydrogen multiplet at $\delta = 6.86$–8.06. The i.r. spectrum ($CHCl_3$) showed carbonyl bands at 1780 and 1720 cm^{-1}.

trans-2,4,5-Triphenyl-1-pyrroline (trans-3)

A degassed solution of **1** (0.1 g, 0.34 mmol) in 0.68 ml of 0.53 *M* potassium *tert*-butoxide in *tert*-butyl alcohol in a sealed evacuated tube was heated for 30 min at 120°. The reaction mixture was extracted using ether, and washed with water, with saturated sodium chloride and dried with magnesium sulfate. After ether removal, the residue was separated by t.l.c. (10% ether in hexane) and the main band yielded 68 mg (68%) of material (m.p. 89.5–91, from hexane). Mass spectrum: $m/e = 297$ for molecular ion.

The n.m.r. spectrum ($CDCl_3$) showed a 2 hydrogen multiplet $\delta = 7.61$–8.02 and a 13 hydrogen multiplet $\delta = 6.94$–7.50. The remaining 4 hydrogen pattern was analyzed as an ABCM with the assistance of the LAOCOON III program: $\nu_a = 3.16$, $\nu_c = 3.40$, $\nu_b = 3.58$, $\nu_m = 5.30$ and $J_{ab} = -16.8$ Hz, $J_{ac} = 7.6$ Hz, $J_{bc} = 9.3$, $J_{am} = 2.0$ Hz, $J_{bm} = 2.2$ Hz, and $J_{cm} = 6.7$ Hz. The i.r. spectrum ($CHCl_3$) showed no N—H absorption and C=N at 1602 cm^{-1}.

cis-2,4,5-Triphenyl-1-Pyrroline (cis-3)

A solution of **1** (0.1 g, 0.34 mmol) in a minimum of THF was added by syringe to a solution of 0.5 mmol lithium 2,2,6,6-tetramethylpiperidide in 5 ml of THF held at −78° under an argon atmosphere. After stirring for 30 min at 0–6°, the dark blue solution was treated with an excess of acetic acid. The reaction mixture was treated with water and ether and the ether layer was washed twice with water, once with saturated sodium chloride solution, dried, filtered, and solvent removed. Nuclear magnetic resonance of the residual oil indicated 85% conversion to cyclic materials. Silica gel t.l.c. (10% ether in hexane) yielded 29% *trans*-**3** and 35% *cis*-**3** plus 5% of 2,3,5-triphenylpyrrole. Compound *cis*-**3** (m.p. 88–90°) depressed the m.p. of *trans*-**3** and was recovered unchanged after melting. Mass spectrum: *m/e*-297 for molecular ion. The n.m.r. spectrum (CCl_4) showed a 2 hydrogen multiplet $\delta = 7.82$–8.15, a 13 hydrogen multiplet $\delta = 6.60$–7.58, 1 hydrogen multiplet 5.43–5.64, 1 hydrogen multiplet 3.79–4.21, 2 hydrogen multiplet 3.18–3.48. The i.r. spectrum ($CHCl_3$) showed no N—H absorption and C=N at 1611 cm^{-1}.

2,3,5-Triphenylpyrrole

Both *cis*-**3** and *trans*-**3** (94 mg, 0.32 mmol) were oxidized separately in 5 ml of benzene at reflux under an argon atmosphere using 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (72 mg, 0.32 mmol). After 1 h at reflux, the solution was concentrated and the product purified by t.l.c. (silica gel, 10% ether in benzene) yielded 63 mg (67%) of material (m.p. 138–140°, undepressed by admixture with an authentic sample) (13).

Isotopic Exchange of trans-3

A degassed solution of *trans*-**3** (75 mg, 0.25 mmol) in 1 ml of 0.24 *N* potassium *tert*-butoxide in *tert*-butyl alchol-*O-d* in a sealed evacuated tube was heated at 120° for 30 min. After cooling, the reaction mixture was extracted using ether and water. After drying and solvent removal, the residue was purified by t.l.c. (silica gel, 10% ether–hexane). After recrystallization from hexane, mixture m.p. with *trans*-**3** showed no depression and both the n.m.r. and mass spectra showed incorporation of 4 atoms D/molecule into the pyrroline ring.

Isomerization of cis-3

A degassed solution of *cis*-**3** (100 mg, 0.34 mmol) in 0.68 ml of 0.54 *M* potassium *tert*-butoxide in *tert*-butyl alcohol in a sealed evacuated tube was heated at 120° for 30 min. After the usual work-up, the residue recrystallized from hexane yielded 88% of material of m.p. 89–91° (undepressed by admixture with an authentic sample of *trans*-**3**).

Isomerization and Exchange of 1

To the stirred degassed potassium methoxide in methanol (methanol-*O-d*) solution held at constant temperature and under an argon atmosphere was added solid **1**. At the reported time the reaction was poured into water and ether. The ether layer was washed twice with water, once with saturated sodium chloride solution, dried over magnesium sulfate and solvent removed on a rotary evaporator. The residual oils were analyzed by n.m.r. and separated by t.l.c. (silica gel, 10% ether in hexane).

The deuterium content of **1** was determined by analyzing (mass spectroscopy) the β-phenylpropiophenone obtained by hydrolysis on silica gel.

Isomerization of 1 with Lithium 2,2,6,6-Tetramethylpiperidide

To a stirred degassed solution of LiTMP in THF under argon at the reported temperature, was added solid **1**. After stirring for the reported time, the reaction was quenched with water and extracted with ether *vs.* water. The ether layer was further extracted twice with water, once with saturated sodium chloride solution, dried over magnesium sulfate, filtered, and the solvent removed with a rotary evaporator. The residual oils were separated by silica gel t.l.c. (10% ether in hexane) and analyzed by n.m.r.

The authors wish to thank the National Research Council of Canada for financial support.

A Nuclear Magnetic Resonance Study of the Conformation of Six-membered Chelate Rings in Four-coordinate Complexes

WILLIAM R. CULLEN, LAURANCE D. HALL, JOHN T. PRICE, AND GREGORY SPENDJIAN

Chemistry Department, University of British Columbia, Vancouver, British Columbia V6T 1W5

Received July 15, 1974

WILLIAM R. CULLEN, LAURANCE D. HALL, JOHN T. PRICE, and GREGORY SPENDJIAN. Can. J. Chem. **53**, 366 (1975).

The ditertiary arsine $(CH_3)_2AsCH_2CH(C(CH_3)_3)CD_2As(CH_3)_2$ (L–L) forms 'tetrahedral' (L–L)Ni(CO)$_2$ and square planar (L–L)NiOC(CF$_3$)$_2$C(CF$_3$)$_2$O. In both complexes the conformations of the chelate rings are locked with the *t*-butyl groups equatorial. The dihedral angles are very similar in spite of the anticipated differences in angles at the central atom. The square planar complexes (L–L)′PtbipyCl$_2$ and (L–L)$_2$′PtCl$_2$ and their palladium analogs ((L–L)′ = $H_2NCH_2CH(C(CH_3)_3)CD_2NH_2$) also have their chelate rings in locked chair conformations. This results in the identification of isomers in the case of (L–L)$_2$′M^{2+}. The $^3J_{H-H}$ couplings indicate that the dihedral angles are similar in the group VIII complexes with a degree of puckering which could be less than in related complexes of L–L. The $^3J_{Pt-H}$ couplings indicate changes in the puckering about the N...N axis.

WILLIAM R. CULLEN, LAURANCE D. HALL, JOHN T. PRICE et GREGORY SPENDJIAN. Can. J. Chem. **53**, 366 (1975).

L'arsine ditertiaire $(CH_3)_2AsCH_2CH(C(CH_3)_3)CD_2As(CH_3)_2$(L–L) forme des complexes (L–L)Ni(CO)$_2$ tétraédrique et (L–L)NiOC(CF$_3$)$_2$C(CF$_3$)$_2$O plan carré. Dans chacun de ces complexes, les conformations des cycles des ligands sont bloquées avec les groupements *t*-butyles en positions équatoriales. Les angles dièdres sont très semblables malgré les différences que l'on aurait pu anticiper pour les angles vers l'atome central. Dans les complexes plan carré (L–L)′PtbipyCl$_2$ et (L–L)$_2$′PtCl$_2$ de même que dans leurs analogues avec du palladium ((L–L)′ = $H_2NCH_2CH(C(CH_3)_3)CD_2NH_2$), les cycles des ligands sont aussi bloqués dans des conformations chaises. Ceci conduit à l'identification d'isomères dans le cas des complexes (L–L)$_2$′M^{2+}. Les constantes de couplage $^3J_{H-H}$ indiquent que les angles dièdres sont similaires dans les complexes du groupe VIII avec un degré de plissement qui pourrait être plus faible que dans les complexes apparentés contenant les groupes (L–L). Les constantes de couplage $^3J_{Pt-H}$ montrent qu'il y a un changement dans le degré de plissement autour de l'axe N...N.

[Traduit par le journal]

Introduction

In earlier publications (1–5) we have discussed the conformation of five- and six-membered chelate rings in the octahedral metal carbonyl complexes (L–L)M(CO)$_4$ and (L–L)M′(CO)$_3$X, (M = Cr, Mo, W; M′ = Mn, X = Cl, Br, I). The ligands, L–L, were specially prepared to allow studies by high resolution n.m.r. techniques and in particular were of the type $(CH_3)_2AsCH_2$-$CHRCH_2As(CH_3)_2$ (R = H, **1**; R = CH_3, **2**; R = $C(CH_3)_3$, **3**) for the studies on the six-membered chelate rings (4, 5). We were able to show that complexes of **1** with the group VI carbonyls undergo fast conformational chair $\rightleftharpoons$ chair interconversion while the similar complexes of **3** have locked chair configurations with the *t*-butyl group in an equatorial position. Similarly the Mn(CO)$_3$X complexes of **3** were locked allowing the characterization of two isomers **A** and **B**, X = halogen. R = *t*-butyl. The preferred isomers have the same chair configuration as the

analogous complexes of **1** (**A**, R = H) which, surprisingly, are also locked (5). This preferred configuration is the one that minimizes the interaction between the arsenic methyl groups and the axial halogen atom (6). Conformational calculations (7, 8) predict that the six-membered rings would be puckered chairs as we have found in solution (4, 5) and as others have found in the solid state (*e.g.* 6, 9–11).

The present work extends our n.m.r. and conformational study of six-membered chelate ring systems to four-coordinate complexes of Ni, Pd, and Pt. Ligand **3** and the analogous diamine ligand ($NH_2CH_2CH(C(CH_3)_3)CH_2NH_2$, **4**) were used as chelating agents. Selectively deuterated ligands, **3**-d_2 and **4**-d_2 $(CH_3)_2AsCH_2CH(C(CH_3)_3$-$CD_2As(CH_3)_2$ and $NH_2CH_2CH(C(CH_3)_3)$-CD_2NH_2, were prepared in order to simplify the n.m.r. spectra of the chelate complexes.

Experimental

Infrared spectra were recorded on a Perkin-Elmer 457 instrument. The n.m.r. spectra were run on an extensively modified Varian HA-100 instrument (12). The final refined n.m.r. parameters were obtained using the LAOCOON III program modified for use on the U.B.C. IBM 300-67 computer. Microanalyses were done by Mr. Peter Borda of this department.

Preparation of Ligands

The preparation of ligands **3** and **3**-d_2 has been described previously (4). The preparation of 1,3-diamino-2-*t*-butylpropane, ligand **4**, is described below. This and the analogous deuterated compound **4**-d_2 were prepared in a similar manner starting with the appropriate diol, $HOCH_2CH(C(CH_3)_3)CH_2OH$ or $HOCD_2CH(C(CH_3)_3)CH_2OH$, which were prepared as previously reported (4). Perfluoropinacol (PFP) was prepared according to published procedures (13).

The Preparation of 2-t-Butyl-1,3-propanediol Ditosylate

2-*t*-Butyl-1,3-propanediol (15 g) was added slowly to tosyl chloride (50 g) in pyridine (200 ml) and the resulting solution stirred for 16 h at 5°. Water (100 ml) was added and the mixture maintained at a temperature of 5° for an additional hour before additional water (1 l) was added. The resulting precipitate was filtered to give a crude yield of 40 g (82%). The compound was recrystallized from ethanol and its n.m.r. spectrum measured on a sample dissolved in $CDCl_3$. Resonance signals centered at 7.6 (area 8), 4.2 (area 4), 2.5 (area 6), 1.8 (area 1), and 0.96 (area 9) p.p.m. correspond to the aryl, methylene, methyl, methyne, and *t*-butyl protons, respectively.

The Preparation of 1,3-Diamino-2-t-butylpropane

Sodium azide (35 g) was added to a solution of 2-*t*-butyl-1,3-propanediol ditosylate (35 g) in dimethylformamide (300 ml). The temperature of the suspension was raised to 130–140° and stirred continuously for 4 h. The cooled mixture was diluted with ether (300 ml) and then extracted with eight (100 ml) portions of water. The remaining ether layer was dried over anhydrous sodium sulfate for 2 h, filtered, and reduced in volume (to 50 ml). The resulting azide solution was diluted with anhydrous THF (50 ml) and added slowly to a suspension of excess $LiAlH_4$ (15 g) in anhydrous THF (50 ml) and stirred at room temperature for 2 h and at 50° for an additional 8 h. The THF suspension was cooled and treated with water (15 ml), 15% sodium hydroxide solution (15 ml), and again with water (45 ml). The resulting suspension was filtered and the filtrate dried over anhydrous sodium sulfate, filtered, then evaporated to leave a pale yellow liquid (6.3 g) (yield 60%).

The 1,1-dideutero-2-*t*-butyl-1,3-diaminopropane was prepared in a similar manner. This ligand's n.m.r. spectrum ($CDCl_3$ solution) shows resonance multiplets centered at 2.9 (area 2), 2.1 (area 4), 1.3 (area 1), and 1.0 (area 9) p.p.m. from TMS and represent the methylene, amine, methyne, and *t*-butyl protons, respectively. Upon the addition of D_2O, the signal at 2.1 p.p.m. disappeared while a new signal appeared at 4.7 p.p.m. attributable to the formation of HOD. The i.r. spectrum (liquid film) had adsorptions at 3370 (s), 3280 (s), 2960 (s), 2860 (s), 2200 (w), 2090 (w), 1595 (s), 1475 (s), 1395 (m), 1365 (m), and 900 (m) cm^{-1}. The bands at 2200 and 2090 cm^{-1} are attributed to the C—D stretching absorptions and are not the result of an azide impurity. The diamine was used directly for complex formation without further purification.

Preparation of Complexes

The Preparation of $(CO)_2NiAs(CH_3)_2CH_2CH$-$((CH_3)_3)CH_2As(CH_3)_2$

1,3-Bis(dimethylarsino)-2-*t*-butylpropane (0.5 g) was added to a stirred solution of nickel carbonyl in benzene and was maintained under a nitrogen atmosphere. After heating the mixture to 40° for 30 min, the resulting yellow solution was filtered and evaporated to dryness. The residue was sublimed (80° at 0.01 mm) to yield a cream-colored solid (0.55 g, 81%) m.p. 135°. The i.r. spectrum of a sample dissolved in cyclohexane had two carbonyl stretching vibrations at 2005 (s) and 1944 (vs) cm^{-1}.

Anal. Calcd. for $C_{13}H_{26}As_2NiO_2$: C, 36.7; H, 6.12. Found: C, 36.6; H, 6.29.

The Preparation of $O(CF_3)_2CC(CF_3)_2ONiAs(CH_3)_2$-$CH_2CH(C(CH_3)_3)CH_2As(CH_3)_2$

Upon the addition of ligand **3** to a solution of potassium bis(perfluoropinacolato)nickel(II) in benzene (30 ml) at 40° under a nitrogen atmosphere a change in color from violet to orange was observed. The orange solution was extracted with two portions of water (10 ml), dried over anhydrous sodium sulfate, filtered, and evaporated to dryness. The orange residue was recrystallized from CH_2Cl_2 – petroleum ether to give orange crystals, m.p. 245° (yield 80%). The ^{19}F n.m.r. spectrum of the complex measured in $CHCl_2$ solution showed a sharp resonance at 73.0 p.p.m. upfield from $CFCl_3$.

Anal. Calcd. for $C_{17}H_{26}As_2F_{12}NiO_2$: C, 29.1; H, 3.70. Found: C, 29.0; H, 3.70.

The Preparation of $NH_2CH_2CH(C(CH_3)_3)CH_2NH_2$-$MCl_2$ (M = Pd or Pt)

An equimolar quantity of the diamine ligand (0.2 g) was added to an aqueous solution of K_2MCl_4 and stirred at 50° for 2–3 min. The precipitate of complex chloride was filtered and washed with water until no chloride ion could be detected by silver nitrate solution. This almost colorless material was used directly for further syntheses.

The Preparation of $(NH_2CH_2CH(C(CH_3)_3)CH_2NH_2)_2MCl_2$

The diamine ligand was added to an equimolar quantity of $(NH_2CH_2CH(C(CH_3)_3)CH_2NH_2)MCl_2$ in water (15 ml), then stirred and heated (80°) until most of the insoluble material had dissolved. The solution was filtered and the filtrate reduced in volume (1 ml). The white product was precipitated by the addition of acetone, then recrystallized from concentrated solutions of water (5°) (yield ~85%).

Anal. Calcd. for $C_{14}H_{36}Cl_2N_4Pt$: C, 31.9; H, 6.8; N, 10.6. Found: C, 31.8; H, 7.0; N, 10.9.

Anal. Calcd. for $C_{14}H_{36}Cl_2N_4Pd$: C, 38.4; H, 8.3; N, 12.8. Found: C, 38.4; H, 9.0; N, 12.9.

The deuterated analogs were prepared similarly.

The Preparation of $[(bipy)MNH_2CH_2CH(C(CH_3)_3)CH_2NH_2]Cl_2$

α,α′-Dipyridyl (0.2 g) was added to an equimolar quantity of $NH_2CH_2CH(C(CH_3)_3)CH_2NH_2MCl_2$ in water (20 ml) then stirred and heated (90°) for 1 h under an atmosphere of nitrogen. The resulting solution was filtered, then reduced in volume (1 ml) before acetone was added to precipitate the product. The pure (yellow) products were obtained by recrystallizing twice from concentrated solutions of acetone–water at 5° (yield 80%).

Anal. Calcd. for $C_{17}H_{26}Cl_2N_4Pd.2H_2O$: C, 40.9; H, 6.0; N, 11.2. Found: C, 40.5; H, 6.2; N, 11.0.

Anal. Calcd. for $C_{17}H_{26}Cl_2N_4Pt.2H_2O$: C, 34.6; H, 5.1; N, 9.5. Found: C, 34.2; H, 5.6; N, 9.4.

The n.m.r. spectra of the Pd and Pt complexes have signals attributed to the dipyridyl group at 8.21 and 8.75 p.p.m. and 8.14 and 8.75 p.p.m., respectively, from external TMS. The signals attributed to the six-membered ring protons are summarized in Table 1.

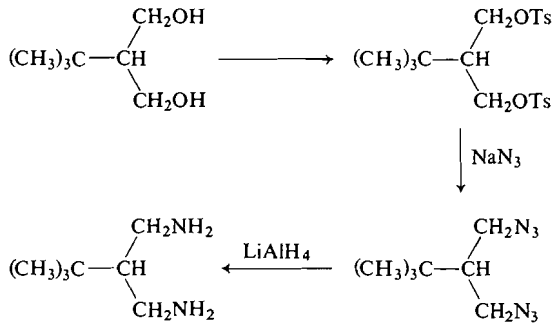
Results and Discussion

The new ligand 1,3-diamino-2-*t*-butylpropane, **4**, was prepared from the appropriate diol via the azide (Scheme 1). Althought the method is not original (14, 15) it is given in detail since deviations result in diminished yields.

The n.m.r. spectrum of the amine was as expected and, although it was not subjected to microanalysis, the complete characterization of its complexes leaves no doubt that it is formulated correctly.

The bis dimethylarsino analog **3** reacts with nickel tetracarbonyl to afford the expected chelate complex $(L\text{–}L)Ni(CO)_2$ (L–L = **3**). This complex which contains nickel in the zero oxidation state is probably pseudo tetrahedral. The diamagnetic square planar complex (L–L)Ni(PFP) (L–L = **3**, PFP = $^-O—C(CF_3)_2—C(CF_3)_2—O^-$) which contains nickel(II) was also prepared.

In order to simplify the n.m.r. spectra the complex $(L\text{–}L)Ni(CO)_2$ (L–L = **3**-d_2) was measured in a saturated benzene solution (the complex decomposes in $CHCl_3$). The spectrum of the ring protons is of the ABX type. The downfield



SCHEME 1

portion of the spectrum is deceptively simple and is seen as a doublet which is sharpened only slightly when the sample is deuterium decoupled. The AB portion of the spectrum is partly hidden by the arsenic methyl signal but it is considerably sharpened when the sample is deuterium decoupled. The AB portion of the spectrum is, therefore, associated with the axial proton on the ring carbon adjacent to the arsenic atom and the axial proton on the central carbon atom. Similarly the n.m.r. spectrum of $PFPNiAs(CH_3)_2\text{-}CH_2CH(C(CH_3)_3)CD_2As(CH_3)_2$ (measured in CH_2Cl_2) is also of the deceptively simple ABX type and is similar in appearance to the spectra of the analogous group VIB complexes $(L\text{–}L)M(CO)_4$ (4). The downfield X portion of the spectrum sharpened only slightly upon deuterium decoupling when compared with the upfield AB portion which indicates the two protons on the carbon adjacent to the arsenic atoms have quite different chemical shifts; the upfield one is near the chemical shift of the proton on the central carbon atom. All the derived n.m.r. parameters are listed in Table 1.

Both nickel complexes have vicinal coupling constants for the protons on the ring carbons with values of approximately 12 and 1 Hz (Table 1). The former value is representative of an axial–axial interaction between the two vicinal protons and indicates that the *t*-butyl group occupies an equatorial position with respect to the 'locked' ring. The values are comparable to those found in the analogous group VIB complexes which are thought to have puckered chair configurations (4). The $^3J_{H_{ax}-H_{eq}}$ coupling (~1 Hz) for these nickel complexes are slightly smaller than they are for the analogous manganese tricarbonyl halides (~2 Hz) (5) and may indicate that the nickel compounds are slightly

[a]Chemical shifts are given downfield from external TMS in p.p.m. The couplings involving platinum were measured from spectra obtained from a Varian XL-100 spectrometer using Fourier transform techniques. Couplings are given in Hz.

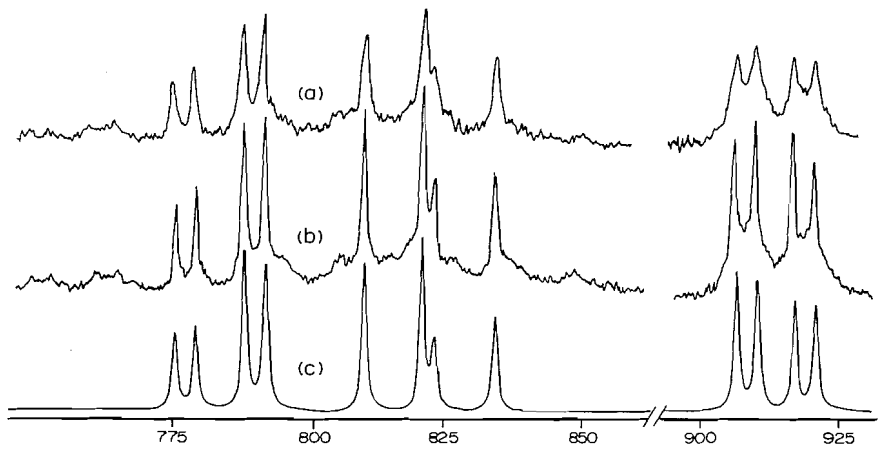

FIG. 1. The bridge proton region of the n.m.r. spectrum of $[bipyPtNH_2CH_2CH(C(CH_3)_3)CD_2NH_2]Cl_2$ in D_2O: (*a*) is the normal spectrum, (*b*) is the same region run with deuterium decoupling, (*c*) is the computer simulated spectrum using the parameters listed in Table 1.

more puckered. The small differences, however, may be caused by inductive effects and not by conformational distortions. It is not surprising to find that the conformation of the chelate ring in the octahedral and square planar complexes is very similar since the As—M—As angle is expected to be ~90° and this, together with the As—M distance is expected to have the greatest effect on ring conformations (2, 7). The 'tetrahedral' nickel complex $(L–L)Ni(CO)_2$ could be expected to have a different degree of puckering because the As—Ni—As could be greater than 90° but it seems that the angle subtended by a ligand at a metal is more a function of of the ligand than the metal. For example the P—Fe—P angle in the isoelectronic complex $(C_6H_5)_2PC{=}CP(C_6H_5)_2CF_2CF_2CF_2Fe(NO)_2$ is 87° (16).

The n.m.r. spectra of the nickel complexes were not measured in the same solvents as the analogous $M(CO)_4$ and $M(CO)_3X$ complexes because of solubility and stability problems. This makes it difficult to make a detailed comparison of the chemical shifts of the ring protons. It is probably significant that H_{ax} is considerably upfield of H_{eq} in the $—CH_2—$ group as is the case for the $(L–L)M(CO)_4$ complexes of ligands **1** and **3** (4). However in the 'locked' $(L–L)M'(CO)_3X$ complexes of ligand **1**, H_{ax} (2.24 p.p.m.) is downfield of H_{eq} (1.77 p.p.m.) (values are for X = Br) and the same trend is seen in the isomer of the $(L–L)M'(CO)_3X$ complex of ligand **3** which has the same conformation (**A**, R = H or *t*-butyl). In the case where X = Br, H_{ax} is at 1.86 p.p.m. and H_{eq} at 1.91 p.p.m. This downfield shift for H_{ax} when it is adjacent to an axial halogen on the metal may indicate some interaction between the two.

The diamine **4** reacts with MCl_4^- (M = Pt, Pd) to afford the insoluble MCl_2 derivatives which were not suitable for n.m.r. studies. Fortunately further reaction of **4** afforded the ionic $(L–L)_2M^{2+}2Cl^-$ which could be investigated in aqueous solution. In order to obtain a complex with only one ligand **4** chelated to the group VIII metal, the insoluble MCl_2 derivatives were treated with α,α′-dipyridyl to afford the water soluble $(L–L)M(bipy)^{2+}$ $2Cl^-$ complexes.

Figure 1 shows the n.m.r. spectrum of the ring protons of the platinum–bipy complex dissolved in D_2O. The upfield (X) portion of this ABX spectrum is considerably sharpened when the sample is deuterium decoupled and is associated with the proton on the central ring carbon. The AB portion of the spectrum is assigned to the protons on the ring carbon atom that is adjacent to a nitrogen atom. The equatorial proton has a chemical shift at lower field than the axial proton on the same carbon. The magnitudes of the coupling constants (Table 1) indicates an axial–axial interaction between protons 2 and 3, **A** which requires the *t*-butyl group to have taken an equatorial position and effectively locked the six membered ring. The n.m.r. spectrum of the diamine metal complexes definitely eliminates the possibility of any existence of skew-boat con-

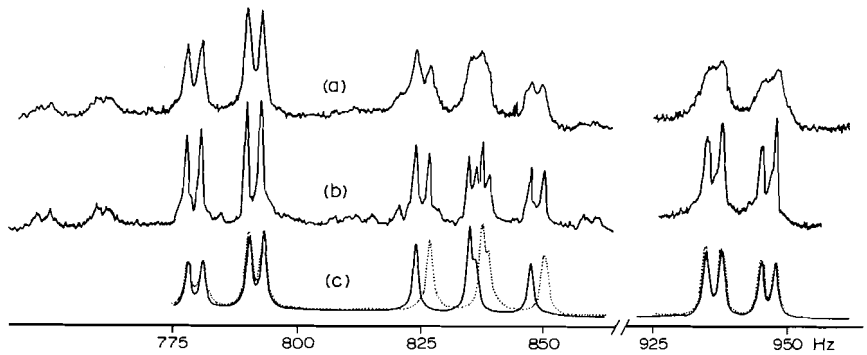

FIG. 2. The bridge proton region of the n.m.r. spectrum of $[Pt(NH_2CH_2CH(C(CH_3)_3)CD_2NH_2)_2]Cl_2$ in D_2O: (*a*) is the normal spectrum, (*b*) is the same region run with deuterium decoupling, (*c*) is the computer simulated spectrum using the parameters listed in Table 1, both isomers are included — and ... lines, but Pt–H couplings are not.

formers because a locked configuration of this type would lead to two conformers (depending upon the positions of the $-CD_2-$ and $-CH_2-$ groups relative to the ring). The $^3J_{Pt-H}$ couplings also provide evidence for a locked chair configuration as will be described below.

The parameters from the analogous palladium complex indicate a very similar structure in solution.

The n.m.r. spectrum of the ion $(L-L)_2Pt^{2+}$ (L–L = **4**) is shown in Fig. 2. Analysis of the spectrum shows that two isomers are present in solution in equal amounts. The derived parameters for the two isomers are nearly identical indicating both isomers have their six-membered rings locked in chair configurations with the *t*-butyl group equatorial (for the same reasons as those given for the dipyridyl complexes). The two isomers undoubtedly have the structures shown in Fig. 3 where both rings are locked with the *t*-butyl groups equatorial. The chemical shifts of the axial protons on the $N-CH_2-$ group differ slightly for each isomer and examination of Fig. 3 shows that these are the protons whose magnetic environment changes most in the two isomers. The palladium analog shows the same isomer distribution and the n.m.r. parameters indicate identical structures in solution. In a similar study of $(L-L)_2M^{2+}$ complexes Appleton and Hall (17, 18) isolated isomeric compounds for L–L = *meso*-$H_2NCH(CH_3)CH_2CH(CH_3)NH_2$. These are probably related as in Fig. 3 with the equatorial methyl groups providing the locking force. However the 60 MHz n.m.r. spectra did not reveal the difference. Their vicinal $^3J_{H-H}$ couplings of 2.5 Hz (ax–eq) and 11.0 Hz (ax–ax)

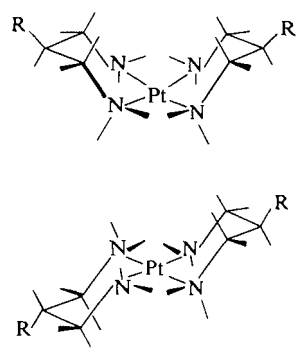

FIG. 3. Structures of the two isomers of $[Pt(NH_2CH_2CHRCH_2NH_2)_2]^{2+}$.

are similar to those obtained in the present investigation. In another paper (19) n.m.r. evidence for geometric isomerism was obtained by these workers when L–L is $H_2NCH_2CHOHCH_2NH_2$.

It seems that $^3J_{Pt-H}$ couplings follow a Karplus type relationship where the *trans* coupling is expected to be ~90 Hz and the *gauche*, ~31 Hz from amino acid derivatives (20) or ~65 and ~15 Hz, respectively, from diamine complexes (19, 21). In the platinum complexes of **4** both isomers of $(L-L)_2Pt^{2+}$ have the same values indicating that there is little steric interaction between the two halves of the ion. Furthermore the ratio $^3J_{Pt-H_{eq}}/^3J_{Pt-H_{ax}}$ is ~3. This indicates that the very similar values obtained by Appleton and Hall do indicate locked six-membered rings in the complexes of $H_2NCH_2CHXCH_2NH_2$ (X = Cl, OH) (19). In the dipyridyl complex of **4** the $^3J_{Pt-H}$ couplings are considerably changed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

although their sum (54.5 + 30.5) Hz is much the same as in the $(L\text{–}L)_2Pt^{2+}$ complexes of the same ligand. This suggests that a conformational change involving the N—Pt—N and CNNC planes, has taken place since the $^3J_{H-H}$ are invarient.

Although it is difficult to compare coupling constants obtained from different compounds in different solvents, it seems that the ditertiary arsine complexes have slightly larger $^3J_{H_{ax}-H_{ax}}$ and smaller $^3J_{H_{ax}-H_{eq}}$ values than the diamine complexes. This could indicate that the diamine complexes are less puckered.

Our study indicates that the chemical shift of protons attached to ring carbons bonded to nitrogen are at lower field than those bonded to the central ring carbon and agreee with the results of Appleton and Hall (17, 19, 21). For a pair of geminal protons, the axial proton is as usual (22, 23) at higher field than the equatorial proton. In the arsenic complexes investigated the protons on the carbon bonded to arsenic are at much higher field than in the nitrogen complexes. This is presumably caused by the more electropositive nature of the arsenic atom relative to nitrogen.

The authors wish to thank the National Research Council of Canada for financial support of this work in the form of operating grants (to W.R.C. and L.D.H.) and Postdoctorate Fellowships (to J.T.P. and G.S.). We also thank Mr. R. B. Malcolm for helpful discussions.

Investigations of Substituent Effects by Nuclear Magnetic Resonance Spectroscopy and All-valence Electron Molecular Orbital Calculations. IV. 4-Substituted Phenylacetylenes[1]

DANIEL A. DAWSON[2] AND WILLIAM F. REYNOLDS
Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received July 15, 1974

DANIEL A. DAWSON and WILLIAM F. REYNOLDS. Can. J. Chem. **53**, 373 (1975).

^{13}C and ^{1}H spectra have been determined for 18 4-substituted phenylacetylenes and carbon charge densities have been estimated by CNDO/2 molecular orbital calculations. Correlations of these parameters with σ_I and σ_R^0 indicate that the important mechanisms of transmission of substituent effects are field, resonance, and π polarization effects, as previously noted for 4-substituted styrenes. Evidence is presented that demonstrates that both ^{1}H and ^{13}C chemical shifts for these compounds reflect ground state charge densities. CNDO/2 calculations on a variety of aromatic derivatives suggest that the σ_I dependence of ^{19}F chemical shifts in these derivatives may primarily be due to π polarization.

DANIEL A. DAWSON et WILLIAM F. REYNOLDS. Can. J. Chem. **53**, 373 (1975).

On a déterminé les spectres r.m.n. du ^{1}H et du ^{13}C de 18 phénylacétylènes substitués en position 4 et on a estimé les densités de charge au carbone par des calculs d'orbitales moléculaires CNDO/2. Les corrélations de ces paramètres avec σ_I et σ_R° montrent que les mécanismes important de transmission des effets des substituants sont des effets de champ de résonance et de polarisation π tel que noté antérieurement pour des styrènes substitués en position 4. Les données sont présentées pour démontrer que les déplacements chimiques du proton et du carbone 13 pour ces composés réflètent les densités de charges à l'état fondamental. Les calculs CNDO/2 sur un grand nombre de dérivés aromatiques suggèrent que la dépendance des déplacements chimiques du ^{19}F sur σ_I dans ces dérivés peut être due principalement à une polarisation π.
[Traduit par le journal]

Introduction

We recently utilized n.m.r. spectral parameters (measured under inert conditions) and all-valence electron molecular orbital calculations to determine mechanisms of transmission of substituent effects in a series of 4-substituted styrenes and α-alkylstyrenes (1, 2). It was concluded that field effects, resonance effects, and π inductive (polarization) effects are all important in determining electronic distributions in these molecules.

Classical electric field calculations (3), CNDO/2 molecular orbital calculations (4), and correlations of ^{1}H and ^{13}C chemical shifts with field (F) and resonance (R) divided substituent parameters (DSP) (5) were used to determine mechanisms of transmission of substituent effects in styrenes. If chemical shift – DSP correlations are valid (see refs. 6 and 7 for objections to the approach), then the weighting factors for closely related systems should vary in a manner which is consistent with the proposed mechanisms of transmission of substituent effects (1). This has been partially tested by comparing results for nonplanar α-alkylstyrenes with those for planar styrenes (2).

As a further test, it was decided to carry out a similar investigation of 4-substituted phenylacetylenes. The only previous systematic investigation of this system was by Cook and Danyluk who measured ^{1}H chemical shifts of eight 4-substituted phenylacetylenes at infinite dilution in CCl_4 (8). Since CCl_4 is not an inert solvent for ^{1}H chemical shifts (9), this prevented a meaningful comparison with the styrene data which were determined in C_6H_{12} (1). In addition, it has been suggested that a minimum of 10 substituents should be included in an investigation of this type (6, 10). Consequently, a more detailed investigation seemed necessary. ^{13}C and ^{1}H chemical shifts have been measured (under inert conditions) for 18 4-substituted phenylacetylenes. Results are reported below.

Results and Discussion

^{1}H and ^{13}C chemical shifts and ^{13}C–^{1}H coupling constants are given in Table 1. In most

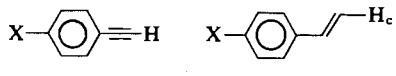
[a]Chemical shifts not assigned due to complexity of the spectrum.

cases, infinite dilution ^1H chemical shifts in C_6D_{12} were estimated from least-squares plots of ^1H chemical shift *vs.* concentration in the range 0.5–3 mol%. In those cases where solubility precluded dilution studies (see Experimental), infinite dilution shifts were taken as the chemical shift of a single solution of <0.25 mol%. It is estimated that infinite dilution chemical shifts are accurate to ±0.002 p.p.m. Repeated experimental measurements with different concentrations, spectral widths, etc. suggested that ^{13}C chemical shifts were accurate to ± 0.04 p.p.m. and ^{13}C–^1H coupling constants to ±0.2 Hz.

Hydrogen and carbon charge densities estimated by CNDO/2 molecular orbital calculations are summarized in Table 2.

(a) ^1H and ^{13}C Chemical Shifts and Mechanisms of Transmission of Substituent Effects

In order to compare mechanisms of substituent effects in 4-substituted styrenes and phenylacetylenes, it is particularly instructive to compare substituent-induced ^1H chemical shifts for the *trans* vinyl proton, H_c, in styrene and the ethynyl proton in phenylacetylene. For example, the $N(CH_3)_2$ group induces smaller chemical shifts in phenylacetylene than in styrene (−0.147 p.p.m. compared to −0.250 p.p.m.) whereas the NO_2 group induces larger shifts (+0.302 p.p.m. compared to +0.249 p.p.m.). One possible explanation for these observations is that field–inductive effects are enhanced in phenylacetylene relative to styrene while resonance effects are reduced (since NO_2 and $N(CH_3)_2$ groups respectively have dominant field and resonance effects (5, 11)).



1 2

To test this explanation, it was originally intended to correlate ethynyl ^1H and ^{13}C chemical shifts with F and R (5), just as in the case of styrene (1). However, it was noted that many substituents whose F and R values seemed doubtful to us (*e.g.* $Si(CH_3)_3$, CF_3, NH_2, CH_3CO, C_6H_5O (1)), appeared to have more reasonable σ_I and σ_R values (11). Consequently, ^{13}C and ^1H chemical shifts for both 4-substituted phenylacetylenes and styrenes were correlated with σ_I and σ_R^0.[3] Twelve substituents

$$[1] \qquad \delta = \delta^0 + \rho_I\sigma_I + \rho_R\sigma_R^0$$

were chosen for the correlations which were common to both families and for which σ_I and σ_R^0 values were available (see Table 3). Halogens were omitted for reasons previously discussed (1), while a correction was applied for the magnetic

[3]σ_R^0 gave more precise correlations than the other σ_R scales of Taft and co-workers (11).

[d]Charge densities for $C{\equiv}N$ and NO_2 derivatives scaled by ratios of experimental and calculated dipole moments for benzonitrile and nitrobenzene. Charge densities were scaled because CNDO/2 calculations respectively underestimate and overestimate electronic effects of $C{\equiv}N$ and NO_2 groups in aromatic derivatives (1, 37). Scaled charge densities were used for correlations in Table 3 and eqs. 2 and 3.
[e]Negative sign represents increased electron density.

anisotropy effect of the phenyl substituent. Correlations of both chemical shifts and carbon charge densities with σ_I and σ_R^0 are given in Table 3.

λ values ($\lambda = \rho_R/\rho_I$) for δ_H, $\delta_{C(\beta)}$, and $q_{C(\beta)}$ correlations all indicate decreased resonance/field effects for phenylacetylenes relative to styrenes. The δ_H and $q_{C(\beta)}$ correlations both support the postulate of increased field effects and decreased resonance effects. By contrast, ρ_I for the $\delta_{C(\beta)}$ correlation shows only a slight increase while ρ_R shows a marked decrease from styrene to phenylacetylene. However, correlations of $\delta_{C(\beta)}$ *vs.* $q_{C(\beta)}$ provide an explanation for this apparent anomaly since they indicate that ethynyl ^{13}C chemical shifts are less sensitive than vinyl ^{13}C chemical shifts to carbon charge density changes. Thus the nearly equal field

[2] $\delta_{C(\beta)}$ (styrene) $= \delta^0 + 3.6 \times 10^2 q_{C(\beta)}$ ($r = 0.967$)

[3] $\delta_{C(\beta)}$ (phenylacetylene $= \delta^0 + 2.7 \times 10^2 q_{C(\beta)}$ ($r = 0.974$)

dependence for $\delta_{C(\beta)}$ in styrene and phenylacetylene can be attributed to a trade-off between larger field-induced charge density changes for ethynyl carbons and lower sensitivity of the chemical shifts of these carbons to charge density changes.[4] Similarly, the large decrease in ρ_R can be attributed to a combination of the latter factor plus smaller resonance-induced changes in carbon charge density for phenylacetylenes.

δ_H in phenylacetylene should be slightly less sensitive to through-space field effects than

[4]This explanation has been advanced by Cushley and co-workers (12) to account for their observation that ^{13}C chemical shifts in alkynes and alkenes show similar sensitivities to field effects. Further evidence is provided in section *b*.

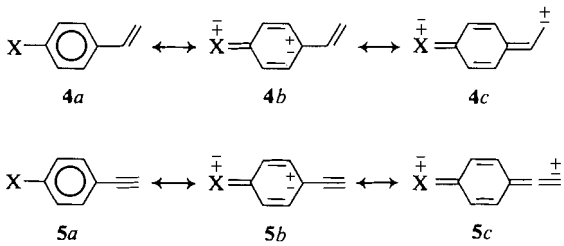
δ_H (phenylacetylene)	6.14×10^3	0.021
$\delta_{H(C)}$ (Styrene), $\alpha^c = 120°$	7.01×10^3	0.025
$\delta_{H(C)}$ (Styrene), $\alpha = 130°$	6.37×10^3	0.023

[a]Electric field component acting along C—H bond. The field component is evaluated half way along the C—H bond (13). The electric field is that due to an axially symmetric substituent dipole of dipole moment 1 Debye, located 0.9 Å from C(4), along the C(4)—X bond.
[b]Electric field estimated by the Buckingham equation (3), $\delta = \delta^0 + A.E_z$, assuming an average value for A of 3.5×10^{-12} (1).
[c]α = C(1)—C(α)—C(β) valence angle (1).

[5]This assumes that the A constant in the Buckingham eq. 3 is identical for C(sp^2)—H and C(sp)—H bonds. The evidence on this point is contradictory (13, 14).



4a 4b 4c

5a 5b 5c

the phenyl group was noted for α-*t*-butylstyrenes where steric hindrance minimizes phenyl–vinyl conjugation (2). On the basis of i.r. spectroscopic evidence, Katritzky and co-workers have recently concluded that the ethynyl group in substituted phenylacetylenes can be an electron donor or acceptor by resonance, depending on the nature of the substituent (16). This also holds for the vinyl group in styrene (1, 17). Katritzky and co-workers have also summarized evidence that the ethynyl group is less susceptible to resonance interactions than the vinyl group (16), in agreement with our results. Thus the increased field dependence and the decreased resonance dependence for $\delta_{C(\beta)}$ and δ_H in 4-substituted phenylacetylenes can be reasonably accounted for in terms of increased π polarization effects and increased localization of resonance interactions in the phenyl group. Correlations of phenylacetylene chemical shifts with F and R reproduce the trends from the σ_I, σ_R^0 correlations. Therefore, we conclude that δ–DSP correlations for styrenes and phenylacetylenes show trends which are consistent with the proposed mechanisms of transmission of substituent effects.

(b) Evidence that ^1H and ^{13}C Chemical Shifts Reflect Intramolecular Electronic Effects

Implicit in the above discussion is the assumption that substituent-induced changes in δ_H and $\delta_{C(\beta)}$ in phenylacetylene reflect intramolecular electronic effects with insignificant contributions from solvent and magnetic anisotropy effects. This investigation has provided evidence that this is a valid assumption. λ is nearly equal for δ_H (λ = 1.19) and $\delta_{C(\beta)}$ (λ = 1.26). In a specific case like this, a cross correlation of the two chemical shifts should be linear, provided that intramolecular electronic effects are dominant. On the other hand, if there are significant contributions from magnetic anisotropy effects and solvent–solute interactions (6) or if λ is not equal for the two nuclei (10), then a δ–δ plot should be

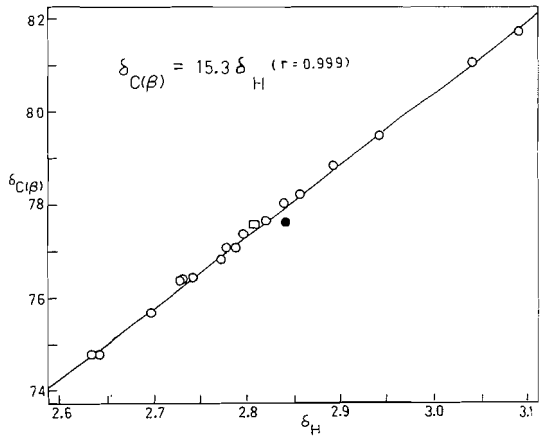


FIG. 1. Plot of β ^{13}C chemical shifts *vs.* ^1H chemical shifts for 4-substituted phenylacetylenes. Filled circle is point for 4-ethylbiphenyl while square is point for the same derivative corrected for the anisotropic magnetic susceptibility of the phenyl substituent.

nonlinear. In fact the δ_H–$\delta_{C(\beta)}$ plot for phenylacetylene is linear (Fig. 1). Only the phenyl derivative shows a significant deviation, due to the ring current effect of the phenyl substituent. The $\delta_{H(C)}$–$\delta_{C(\beta)}$ correlation for styrene is also linear:

$$[4] \qquad \delta_{C(\beta)} = 18.2\delta_{H(\beta)} \quad (r = 0.996)$$

By constrast, $\delta_{H(B)}$ for styrene gives a poorer correlation with $\delta_{C(\beta)}$ (r = 0.957), as expected since $\delta_{H(B)}$ is relatively less sensitive to field effects (λ = 3.1) than $\delta_{C(\beta)}$ (λ = 1.9) and $\delta_{H(C)}$ (λ = 1.8).

The δ–δ correlations and the $\delta_{C(\beta)}$–$q_{C(\beta)}$ correlations (eqs. 2 and 3) illustrate that both β ^{13}C and ^1H chemical shifts in styrenes and phenylacetylenes are dominated by changes in C(β) charge density. Changes in carbon π charge density alter ^1H chemical shifts by polarizing the C—H bond (13, 18). Unit change in π charge density for an sp^2 carbon should respectively induce ^{13}C and ^1H chemical shifts of 160–200 p.p.m. (19, 20) and 10 p.p.m. (13, 21). Thus the expected slope for eq. 4 is 16–20, in quantitative agreement with the observed value. The smaller slope for the phenylacetylene δ–δ plot indicates that ^{13}C chemical shifts for sp carbons are less sensitive to charge density changes than ^{13}C chemical shifts for sp^2 carbons (see part *a*).

We have concluded that ^1H chemical shifts in styrenes and phenylacetylenes are sensitive to resonance, π polarization, and field effects. The

For personal use only.

first two mechanisms alter ^1H chemical shifts as a result of changes in carbon π charge density while the third mechanism acts by through-space polarization of the C—H bond. Therefore, one might expect that δ_H for phenylacetylene would show a proportionately larger σ_I dependence than $\delta_{C(\beta)}$, due to through-space field effects. However, field induced C—C σ bond polarization leads to a field effect upon ^{13}C chemical shifts which is an order of magnitude greater than field effects on ^1H chemical shifts (22). This is further enhanced by the closer proximity of $C_{(\beta)}$ (since field effects vary as $1/r^3$ (4)). Thus the relative sensitivity of $\delta_{C(\beta)}$ and δ_H to through-space field effects should be similar to their relative sensitivity to all electronic effects (*ca.* 15, see Fig. 1), leaving λ almost unaltered. Similarly, $\delta_{H(C)}$ for styrene shows a similar field dependence ($\lambda = 1.8$) as $\delta_{C(\beta)}$ ($\lambda = 1.9$). By contrast, $\delta_{H(\beta)}$ (where through-space field effects are negligibly small (1)) shows a smaller field dependence ($\lambda = 3.1$).

(c) The Validity of δ–DSP Correlations and the Evidence for π Polarization Effects

There have been two recent criticisms of δ–DSP correlations for aromatic derivatives from quite different viewpoints (6, 7). These criticisms will be considered in turn.

Wiley and Miller have argued that these correlations are theoretically unsound and that ^1H chemical shifts in particular are sensitive to many factors other than intramolecular electronic effects (6). We have already discussed this criticism in some detail (10). The results presented above support our previous conclusions that these correlations are meaningful when chemical shifts are measured for a large number of substituents under inert conditions (1, 2, 10). They also confirm that these chemical shifts reflect intramolecular electronic effects.

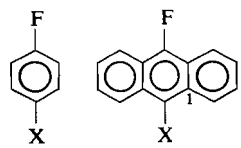
While Wiley and Miller reject δ–σ correlations, Mitchell and Phillips claim that substituent-induced chemical shifts in a large variety of systems (including 4-substituted styrenes) are linearly related to σ_p (7). They conclude that 'the statistical superiority of DSP correlations should not be used as a reason for proposing unusual mechanisms of transmission of substituent effects' and suggest that these apparent mechanisms may simply be artifacts of the correlation (7).

While a limited number of families may correlate with σ_p, this approach should not be of general validity since different systems will often have different resonance–field ratios (10). Even for compounds of type **6**, where Mitchell and Phillips claim that ^{19}F chemical shifts adequately correlate with σ_p (7), recent results on further families of this type show that λ varies by more than 2 as G is changed (23). Perhaps the most compelling evidence for the necessity of DSP treatment of chemical shifts is provided by our results for 4-substituted styrenes (1). Correlations of $\delta_{H(B)}$ and $\delta_{H(C)}$ with σ_p give different slopes but do not identify the origin of the difference (7). However, correlations with F and R demonstrated that the difference is due to through-space field effects (1). The evidence is not based on statistical arguments but rather on the observation that DSP correlations, classical electric field calculations, and molecular orbital calculations of charge density provide a consistent picture of field effects (1). Similarly, the conclusions concerning resonance and π polarization effects in styrenes and phenylacetylenes are based on the pattern of weighting factors (f and r or ρ_I and ρ_R) and the fact that these factors vary in a reasonable manner on going from styrene to α-*t*-butylstyrene or phenylacetylene.

6

Since Mitchell and Phillips specifically cast doubt on the existence of π effects which depend on σ_I (or F) (7), the evidence for these effects will be considered in greater detail. In addition to our DSP correlations, ^{13}C chemical shifts and calculated charge densities for both trimethylammonio styrene derivatives (2) and α-, β-, and γ-substituted phenylalkanes (24) provide evidence for phenyl π polarization. In the latter compounds, the degree of polarization depends upon both the polarizing ability of the substituent and its distance from the phenyl group (23).

Stock and co-workers noted an increased σ_I dependence of ^{19}F chemical shifts on going from



7 **8**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

7 to **8** (25). This was attributed to an increased π inductive effect in **7**. Taft and co-workers have also noted a σ_I dependence of ^{19}F chemical shifts in compounds of type **6** which they attributed to π inductive effects (23, 26).

9

Both sets of results could be due to π polarization effects. Alternatively they could be due to a π inductive effect in which the polar C—X bond induces a π charge density change at the bonded carbon, with this perturbation inducing π charge density changes at other carbons similar to that due to a resonance effect (27, 28). The basic difference between the two mechanisms is the magnitude of charge density change at the *ortho* carbons.

In an attempt to distinguish between the two possible mechanisms, CNDO/2 calculations were performed for ammonio derivatives of benzene, anthracene, diphenylmethane, and stilbene. Ammonio derivatives were chosen because this group has a large positive field–inductive effect and a zero (5) or small negative (29) resonance effect. The calculated π charge densities (see Fig. 2) indicate a substantial π inductive effect in each case and correctly reproduce the experimental observations of enhanced

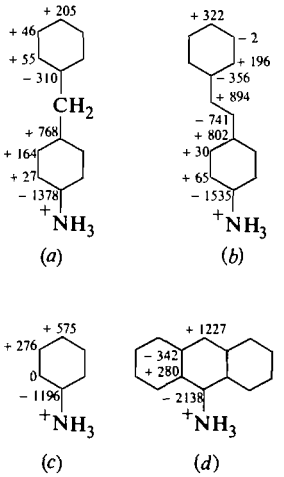


FIG. 2. Changes in π charge densities for aromatic derivatives induced by an ammonio group (positive charge density corresponds to decreased electron density): (*a*) diphenylmethane, (*b*) *trans*-stilbene, (*c*) benzene, (*d*) anthracene. Charge densities × 10^4.

π inductive effects for anthracene relative to benzene (25) and stilbene relative to diphenylmethane (23, 26). The patterns of π charge density generally resemble **3** more than **9**, *i.e.* basically a π polarization effect. Just as in the case of styrene (2), calculations for diphenylmethane and stilbene indicate that π polarization can be transmitted through space but is enhanced in a planar conjugated system.

Calculations were also performed for the corresponding fluoro derivatives (**6**, **7**, and **8**) with X = H, NH_3^+. Calculated changes in F $2p_z$ (π) charge density due to the ammonio group (respectively +0.0029, +0.0042, +0.0097, and +0.0154 for diphenylmethane, stilbene, benzene, and anthracene derivatives) parallel the σ_I values for ^{19}F chemical shifts for the same families of compounds (respectively −1.95, −2.84, −8.13, and −13.08 in CCl_4 (23)).[6]

In summary, there is a considerable body of evidence indicating the presence of a π inductive effect in aromatic derivatives which follows the σ_I or F order. The evidence is based not only on weighting factors in chemical shift – DSP correlations but also on chemical shifts and charge densities for individual compounds where resonance effects are minimized. The evidence is not based on statistical arguments but rather on the consistent pattern of results for a large variety of compounds. In addition, δ–δ plots for styrenes and phenylacetylenes provide further evidence that ^{13}C and ^1H chemical shifts (measured under inert conditions) can be used to probe electronic effects of remote substituents.

(d) Substituent Effects on Ethynyl ^{13}C–^1H Coupling Constants

The directly bonded ethynyl ^{13}C–^1H coupling constant has a similar relative sensitivity to reasonance-field effects ($\lambda = 1.09$) as $\delta_H(\lambda = 1.19)$. In fact, the two parameters are linearly related:

[6]The experimental σ_I value for diphenylmethane is taken from the correlation for triphenylmethane derivatives (23). There should be little difference between the two series. The calculations predict a smaller relative change from stilbene to benzene than noted experimentally. This is presumably due to solvent effects on the experimental chemical shifts since Dayal and Taft (23) have noted that solvent effects decrease σ_I dependence of ^{19}F chemical shifts for triphenylmethane and stilbene derivatives while increasing the σ_I dependence for benzene and anthracene derivatives.

TABLE 5. Methods of synthesis and physical properties of 4-substituted phenylacetylenes which were synthesized for this investigation

Substituent	Synthetic method	Melting or boiling point	
		This work	Literature
CH_3	[a]	59.5–60°/15mm	52–53°/11mm (40)

$$[5] \qquad \Delta J_{C-H} = 10.0\Delta\delta_H \quad (r = 0.991))$$

The fact that this relationship exists suggests that the substituent dependence of J_{CH} is also due to polarization of the C—H bond, either by field effects or π charge density changes at C(β). Since J_{CH} is insensitive to magnetic anisotropy effects, eq. 5 also provides further evidence that δ_H reflects intramolecular electronic effects.

To summarize, correlations of ethynyl ^1H and ^{13}C chemical shifts and carbon charge densities for 4-substituted phenylacetylenes with σ_I and σ_R^0 indicate that field – inductive substituent effects are enhanced and resonance effects are inhibited, relative to 4-substituted styrenes. This is attributed to increased π polarization of the ethynyl group and increased localization of resonance effects within the phenyl group. Both styrene and phenylacetylene chemical shifts can be interpreted in terms of field, resonance, and π polarization effects. There is a linear relationship between the ^1H chemical shifts and ^{13}C–^1H coupling constants, suggesting that the substituent dependence of the coupling constant arises from C—H bond polarization.

Linear cross correlations of β ^{13}C and ^1H chemical shifts for both phenylacetylenes and styrenes confirm that these substituent-induced chemical shifts are reflecting ground state electron density changes. The dominant factor appears to be carbon π electron density changes. Both the phenylacetylene results and comparisons of calculated electron distributions for benzene, anthracene, stilbene, and diphenylmethanes with previously reported ^{19}F chemical shifts indicate that π polarization effects are important in these derivatives.

The above results support our previous conclusions that: (*i*) ^1H and ^{13}C chemical shifts measured at infinite dilution in a noninteracting solvent can be used to monitor changes in ground state electron distributions in aromatic derivatives and (*ii*) correlations of substituent-induced chemical shifts with divided substituent parameters (F and R or σ_I and σ_R) can be used to deduce mechanisms of transmission of electronic effects.

Experimental

Synthesis of Compounds

The parent phenylacetylene was obtained commercially, 4-phenoxyphenylacetylene was supplied by Professor G. H. Schmid, University of Toronto and 4-vinylphenylacetylene was supplied by Dr. G. K. Hamer, University of Toronto. All of the other phenylacetylenes except 4-methylmercaptophenylacetylene were known compounds and were synthesized by previously reported methods. Details of synthesis and physical properties are

summarized in Table 5. Purities of compounds were checked by their n.m.r. spectra.

4-Methylmercaptophenylacetylene

4-Methylmercaptoacetophenone (m.p. 81–82°), prepared by Friedel–Crafts acylation of thioanisole with acetyl chloride and aluminum chloride in chloroform (30), was stirred with semicarbazide hydrochloride and sodium acetate in 50:50 ethanol–water. The resulting semicarbazone (m.p. 216–217°) was filtered off, washed with water, ethanol, and ether, and dried. The semicarbazone was suspended in 10 times its weight of glacial acetic acid and powdered selenium dioxide was added slowly (31). The solution was heated on a water bath (70°) and stirred overnight. After cooling, the precipitate was collected, washed with water, and dried. The crude selenadiazole was a reddish brown solid (m.p. 124–126° dec.). It was pyrolyzed over sand to give 4-methylmercaptophenylacetylene (b.p. 83°/0.6 mm).

Anal. Calcd. for C_9H_8S: C, 72.93; H, 5.44; S, 21.63. Found: C, 72.90; H, 5.35; S, 21.57.

Recording of Spectra

^1H spectra were recorded on a Varian HA-100 spectrometer operating in frequency sweep mode at 27 °C. Spectra were recorded in forward and reverse directions (6–8 spectra per solution) at a sweep rate of 0.05 Hz/s. Internal tetramethylsilane (3 mol%) was used as a lock and reference signal. In most cases, spectra were measured for three phenylacetylene solutions with concentrations (in C_6D_{12}) between 0.5 and 3.0 mol%. For NH_2, NO_2, C≡C—H, and C≡N derivatives, limited solubility made this procedure impossible and spectra were recorded for single solutions of <0.25 mol%.

^{13}C spectra were recorded on a Varian XL-100-15 (with 16K 620i computer) operating in pulsed Fourier transform mode at a probe temperature of 32 °C. Proton-decoupled spectra were recorded for 0.4 *M* solutions of phenylacetylene in CCl_4 with 8 mol% C_6D_{12} as a lock signal. Spectra were recorded with a spectral width of 5000 Hz and acquisition time of 0.8 s.

^{13}C–^1H couplings were determined from proton-coupled ^{13}C spectra with a spectral width of 500 Hz and acqusition time of 8 s. ^{13}C–^1H couplings are estimated to be accurate to within ±0.2 Hz.

Molecular Orbital Calculations

CNDO/2 molecular orbital calculations were carried out on an IBM 370 computer, using a standard CNINDO program (32). Standard bond lengths and angles were used for phenylacetylene (33). Substituent bond lengths and angles are tabulated elsewhere (34).

The Reactivity of Tungsten Halides with Organic Sulfides: S-Dealkylation and Reductive Elimination Reactions[1]

P. MICHAEL BOORMAN,[2] TRISTRAM CHIVERS, AND KALABEERAPPA N. MAHADEV

Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received September 9, 1974

P. MICHAEL BOORMAN, TRISTRAM CHIVERS, and KALABEERAPPA N. MAHADEV. Can. J. Chem. **53**, 383 (1975).

Tungsten hexa- or pentachloride reacts with alkyl sulfides to give $(R_3S)_2[WCl_6]$. The reactions involve S-dealkylation followed by reductive elimination of R_2S_2. Alkylation of R_2S by RCl probably occurs at the tungsten site through the intermediacy of $WCl_4(R_2S)_2$. The latter compounds have been shown to be unstable with respect to displacement of the sulfide ligands by halide ions or neutral donors and therefore form excellent intermediates for W(IV) synthetic chemistry.

P. MICHAEL BOORMAN, TRISTRAM CHIVERS et KALABEERAPPA N. MAHADEV. Can. J. Chem. **53**, 383 (1975).

Les penta- et hexa-chlorures de tungstène réagissent avec les sulfures d'alkyle pour donner des $(R_3S)_2[WCl_6]$. Les réactions impliquent une S-déalkylation suivie par une élimination réductrice de R_2S_2. L'alkylation de R_2S par RCl se produit principalement sur le tungstène par l'intermédiaire de $WCl_4(R_2S)_2$. On a démontré que les ligands sulfures de ces derniers composés peuvent être facilement déplacés par les ions halogénures ou par des donneurs neutres et qu'ils forment par conséquent d'excellents intermédiaires pour la chimie de synthèse impliquant le W(IV). [Traduit par le journal]

Introduction

The coordination chemistry of heavy metals with sulfur donor ligands is of potential importance in the context of metalloenzyme chemistry and industrial catalysis. The reactivity of tungsten-halides towards alkyl sulfides has been discussed in two previous reports (2, 3). Simple adducts of WCl_6 and WCl_5 with alkyl sulfides result from the reaction of the component species in dilute carbon tetrachloride solution (2). Schaeffer-King and McCarley (3) reported that $WCl_4(tht)_2$ and $WCl_4(Et_2S)_2$ (tht = tetrahydrothiophene) may be prepared from the normally unreactive WCl_4 by refluxing with the neat ligands.

In this paper we discuss the direct reactions of organic sulfides with tungsten(VI) and tungsten(V) chlorides which yielded the unexpected products, $(R_3S)_2[WCl_6]$. Evidence will be presented concerning the mechanism of reaction which must involve both dealkylation and alkylation of sulfur as well as a metal–sulfur redox reaction. The identity of the products has been confirmed by spectroscopic studies, alternative syntheses, and by a full X-ray crystallographic study of the compound $(Et_3S)_2[WCl_6]$.

[1]A preliminary account of this work has appeared previously (1).

Experimental

General Procedures

All handling procedures were carried out in a dry nitrogen-filled glove box. Alkyl sulfides were obtained from Aldrich Chemicals, dried with calcium hydride, and redistilled under nitrogen before use. Alkylthiotrimethylsilanes were prepared by published methods (4). Tungsten hexachloride was obtained from Alfa Inorganics and resublimed *in vacuo* before use. Conversion of WCl_6 to WCl_5 was effected by red phosphorus reduction (5), followed by resublimation. Tungsten was analyzed by ignition to the oxide, and chloride potentiometrically. Other analyses were carried out by Chemalytics and Alfred Bernhardt Laboratories. Infrared spectra were recorded as Nujol mulls between CsI plates using a Beckman IR 20-A spectrometer. Visible spectra were recorded in the solid state as Nujol mulls with a Cary 16 spectrophotometer and magnetic data were obtained using a standard Gouy technique, at 22°. The susceptibilities were corrected for the diamagnetism of the ligands using Pascal's constants. Nuclear magnetic resonance spectra were recorded with a Varian A-60 spectrometer.

Syntheses of $(R_3S)_2WCl_6$

The reactions of WCl_5 and WCl_6 with sulfides were carried out in evacuated sealed Pyrex glass tubes. The halides were loaded in the glove box, and the alkyl sulfides were condensed on *in vacuo*, at liquid nitrogen temperature. The sealed tubes were allowed to warm up to room temperature, but exothermic reactions occurred

immediately upon melting of the R_2S. Orange-brown crystalline products were slowly deposited. Characterization of these products as the $(R_3S)_2WCl_6$ complexes is discussed in the Results section.

Synthesis of $WCl_4(Me_2S)_2$

The complex was prepared from WCl_4 and Me_2S in a similar way to the ethyl sulfide adduct previously reported (3).

Anal. Calcd. for $WCl_4(Me_2S)_2$: W, 40.9; Cl, 31.5; C, 10.6; H, 2.7. Found: W, 41.0; Cl, 31.9; C, 10.1; H, 2.7.

Molecular weight determinations, carried out cryoscopically in nitrobenzene, gave values of 120 ± 15 for $WCl_4(Me_2S)_2$, 150 ± 20 for $WCl_4(Et_2S)_2$; ($WCl_4(Me_2S)_2$ = 450; $WCl_4(Et_2S)_2$ = 506). In each case the solutions showed electrical conductance behavior well below that expected for 1:1 electrolytes, inferring that the low molecular weight values were due primarily to loss of coordinated sulfide ligand in the $PhNO_2$ solvent. Subsequent reactions were carried out to check the reactivity towards ligand displacement.

Reaction of $WCl_4(Me_2S)_2$

With Neutral Ligands

Dissolution of $WCl_4(Me_2S)_2$ in dioxane, followed by pumping off volatiles, yielded $WCl_4(Me_2S)$ (dioxane).

Anal. Calcd. for $WCl_4(Me_2S)$: W, 38.6; Cl, 29.8. Found: W, 39.0; Cl, 29.1.

The addition of 2 mol of stronger donors such as Ph_3P and Me_2PhP to the dioxane solutions of $WCl_4(Me_2S)_2$, followed by removal of volatiles, yielded the known adducts $WCl_4(Ph_3P)_2$ (3, 6) and $WCl_4(PMe_2Ph)_2$ (7). With an excess of $PhMe_2P$ the seven coordinate adduct $WCl_4(PPhMe_2)_3$ was readily formed, as reported previously (7). These compounds were identified on the basis of i.r. spectra and physical appearance.

With Chloride Ion

Two molar quantities of tetraethylammonium chloride displaced the alkyl sulfide to form $(Et_4N)_2WCl_6$, when solid Et_4NCl was shaken with a CCl_4 solution of $WCl_4(Me_2S)_2$.

Anal. Calcd. for $(Et_4N)_2WCl_6$: W, 28.0. Found: W, 27.6.

The i.r. spectrum showed the presence of Et_4N^+ ions and the absence of Me_2S. The same product could also be precipitated from CH_2Cl_2 solution of the two reagents.

Reaction of Me_3SCl (solid) with a CCl_4 solution of $WCl_4(Me_2S)_2$ yielded $(Me_3S)_2WCl_6$, identified by its i.r. spectrum which was identical to that of the product obtained from the $WCl_{5/6}/Me_2S$ reactions.

Anal. Calcd. for $(Me_3S)_2WCl_6$: W, 33.4. Found: W, 33.2.

With Alkyl Chlorides

Direct reaction of $WCl_4(Me_2S)_2$ with methyl chloride was accomplished by cold distilling MeCl onto the complex contained in a thick-walled glass tube. On warming, reaction ensued to yield $(Me_3S)_2WCl_6$ (identified by i.r. spectrum and solubility properties), but there was a severe explosion hazard. Reaction of $WCl_4(Me_2S)_2$ with ethyl chloride would only occur in the presence of ethyl sulfide, at 50°, whereupon $(Et_3S)_2WCl_6$ was produced.

Results and Discussion

Characterization of the Compounds $(R_3S)_2WCl_6$

Analytical data (Table 1) show that major products from the reaction of WCl_5 or WCl_6 with R_2S are identical. Physical and spectroscopic properties of the respective products were also invariant with respect to sample origin. Infrared spectra are consistent with the presence of both R_3S^+ cations and WCl_6^{2-} anions. The essential features with suitable reference spectra are presented in Table 2. The compounds were so insoluble that no solution spectra could be obtained. However, the solid state electronic spectra of the $(R_3S)_2WCl_6$ complexes were recorded as mulls in the transmission mode. Since the electronic spectrum of the WCl_6^{2-} ion appears to be cation dependent (10, 11), it does not provide a good diagnosis of the presence of the ion. Not surprisingly therefore, as shown in Table 3, although the charge-transfer bands for our compounds are similar to those previously reported, there is some variation in the ligand-field regions of the spectra.

The magnetic moments for $(R_3S)_2WCl_6$ were 1.45 B.M., well within the range of 1.43–1.47 B.M. reported by Peacock and co-worker (10) for alkali metal hexachlorotungstates (IV).

The ultimate proof of the identity of our compounds has been obtained through a full crystal structure of $(Et_3S)_2WCl_6$.[3] This compound crystallizes in the space group $C\bar{1}$ with two WCl_6^{2-} ions located on nonequivalent centers of symmetry. A pair of $(C_2H_5)_3S^+$ ions is centrosymmetrically associated with each WCl_6^{2-} ion.

Discussion of Reaction Mechanism

Reduction of transition metal halides by sulfur compounds has been reported previously (12), but the oxidation products of the sulfides have not been identified. In addition, the formation of hexachlorotungstate(IV) ions by reaction of amines with WCl_6 has been described (13), but again, no experimental evidence for the mechanism was reported.

In the present work the reactions are of potentially broad interest, since they involve S-dealkylation, S-alkylation, and a redox reaction, under relatively mild conditions. We have therefore obtained a considerable body of experimental evidence to support the mechanisms described in Schemes 1 and 2 for the reactions between R_2S and WCl_6 and WCl_5 respectively. Schemes 1 and 2 can be broken down into four

[3]We thank Kerr and Durley for a preliminary communication of their results (17).

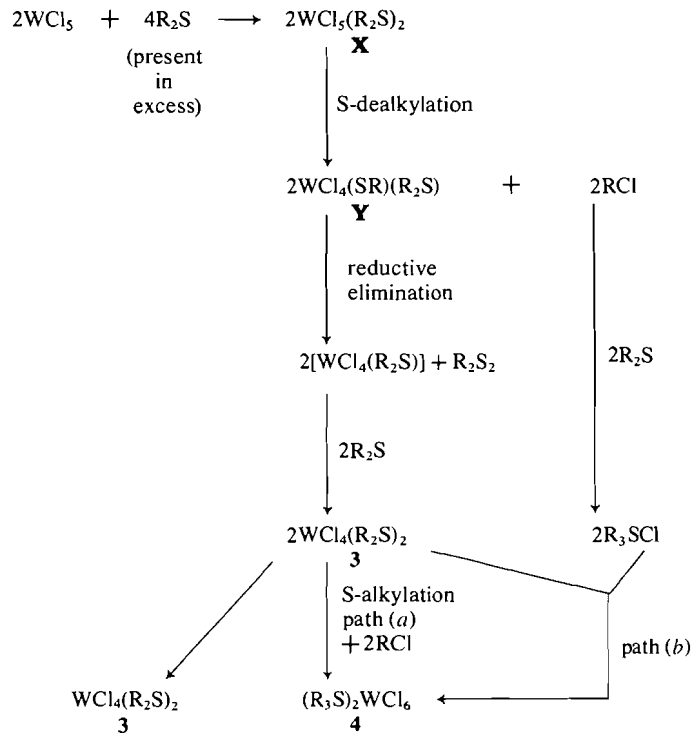


SCHEME 2

steps, and experimental evidence will be presented to support the plausibility of each.

(1) Uptake of R_2S by WCl_x ($x = 5, 6$)

Previous work (2) has shown that adducts such as WCl_6L_2, WCl_6L, and WCl_5L_2 can readily be formed with sulfur donors. In dilute solution in CCl_4 the reaction terminates at this stage, since no other products could be isolated, and no evidence was obtained for reduction occurring.

(2) Dealkylation of Sulfur

Dealkylation of sulfides has been reported in several instances, although relatively high boiling solvents have usually been involved. Such dealkylation reactions may be temperature sensitive (14). In the specific case of tungsten halides, Fowles and co-workers (15) showed that $WSeCl_4$ will dealkylate dimethoxyethane to yield $WSeCl_3$ (OCH_2CH_2OMe), but no instance of S-dealkylation by tungsten has been reported. In the case of direct reaction with the higher tungsten halides, the exothermicity of the coordination reaction is probably responsible for the difference in behavior between the "neat" ligand reactions and those done in dilute solution.

(3) Reductive Elimination of R_2S_2

The key reaction is the reduction of W(VI) and W(V) to W(IV) which would result in the formation of dialkyldisulfides.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$W(VI) + 2S^{2-} \rightarrow W(IV) + S_2^{2-}$$

$$2W(V) + 2S^{2-} \rightarrow 2W(IV) + S_2^{2-}$$

It has been confirmed that in both the WCl_5 and WCl_6 reactions, R_2S_2 is formed. For example in the case of $WCl_6 + Me_2S$ the distilled solvent shows n.m.r. signals due to Me_2S ($\tau = 7.92$) which is present in excess, and Me_2S_2 ($\tau = 7.61$). Although this result confirms the oxidation product is R_2S_2, it does not conclusively prove that W—SR moieties were involved. Evidence in favor of the latter was obtained by reaction of tungsten chlorides with the thioalkylation reagents Me_3SiSR (16). In CS_2 solvent the tungsten products are complex, and depend upon the stoichiometry of the reaction, but simple replacement of Cl by —SR was invariably followed by reduction of W(VI) and W(V) and production of R_2S_2 identified by the n.m.r. spectrum of the distillate. These reactions in fact lead to some interesting low-valent polynuclear tungsten compounds which will be described in a later paper, but the reaction can be simplified by carrying it out in the presence of R_2S. The following reaction was shown to occur, which verifies the possible steps from **2** to **3** in Scheme 1.

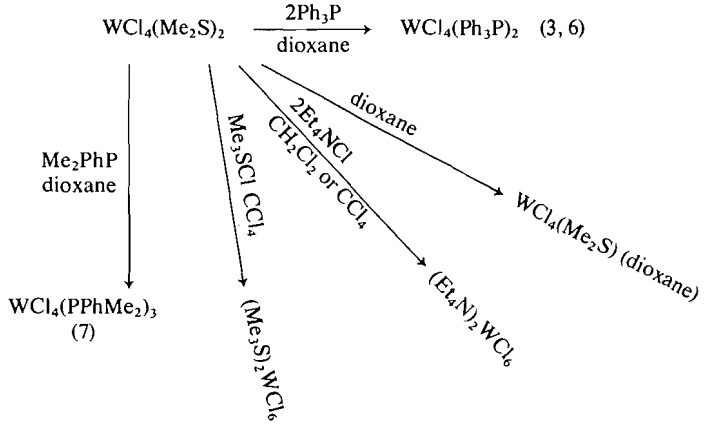
$$WCl_6 + 2Me_3SiSEt + Et_2S \xrightarrow{CS_2} WCl_4(Et_2S)_2 + Et_2S_2 + 2Me_3SiCl \text{ (excess } Et_2S, \sim 5 \text{ mol)}$$

The presence of excess Et_2S thus prevents the complication of polymerization reactions occurring. Alkylthiolato-groups are clearly unstable with respect to oxidation by W(V) and W(VI).

(4) Reactivity of $WCl_4(R_2S)_2$ as an Intermediate

The above reaction with Me_3SiSEt and Et_2S gives support to the possible synthesis of $WCl_4(R_2S)_2$ (**3**) complexes as intermediates. Further studies were undertaken to investigate whether in the presence of RCl, RCl and R_2S, or R_3SCl, **3** could be converted to the eventual product **4**.

Although the synthesis, vibrational spectra, and magnetic properties of the complexes $WCl_4(Et_2S)_2$ and $WCl_4(tht)_2$ were reported by McCarley and co-worker (3), relatively little has been done to investigate their reactivity. We have found that these complexes, and in particular the new compound $WCl_4(Me_2S)_2$, are extremely reactive. Molecular weight measurements in nitrobenzene show that loss of ligand is a facile reaction even in this relatively poor donor solvent. Displacement of sulfide by other donors is such that this type of compound is potentially of even more value than $WCl_4(RCN)_2$ (6) as an intermediate in tungsten(IV) synthetic chemistry. The low boiling point Me_2S is particularly easy to remove from the system. The following reactions are typical examples[4]



Thus reaction of $WCl_4(Me_2S)_2$ with Me_3SCl can definitely yield **4** in Schemes 1 or 2, making path (*b*) viable, if Me_3SCl could be formed from Me_2S and MeCl in the reaction mixture. Separate experiments showed that direct reaction of R_2S and RCl required relatively vigorous conditions, which would suggest that path (*a*) may be a more likely alternative. Accordingly it was found that sealed tube reactions of MeCl with $WCl_4(Me_2S)_2$

[4]References indicate previous reports of these complexes.

For personal use only.

readily yielded $(Me_3S)_2[WCl_6]$ at room temperature, and although EtCl would not easily react alone it did so readily in the presence of Et_2S at $\sim 50°$, yielding $(Et_3S)_2[WCl_6]$. Since RCl cannot be identified in the reaction mixture it is probably rapidly converted into product **4** at the tungsten site.

As final evidence, it will be observed that in Scheme 2, for every mole of **4** formed an equimolar quantity of **3** would also result, since there is inadequate RCl or R_3SCl for complete conversion to **4**. As shown in Table 1 only 50% of the WCl_5 could be converted into **4**. An equimolar amount of **3** was also produced, as expected. In the WCl_6 reactions yields of at least 75% of the $(R_3S)_2WCl_6$ products could be obtained, and no $WCl_4(R_2S)_2$ was identified as a product.

In summary, therefore, there is a large body of evidence which supports Schemes 1 and 2. To our knowledge this is the first example of the reductive elimination of R_2S_2 from a metal center, and is the first fully documented report of the mechanism of reduction of higher halides of tungsten by neutral ligands.

We thank the National Research Council of Canada for financial support.

Electrochemical Behavior of the Lead Electrode in HCl and NaCl Aqueous Electrolytes

REMIGIO GERMANO BARRADAS, KEITH BELINKO, AND JOHN AMBROSE[1]

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received June 14, 1974

REMIGIO GERMANO BARRADAS, KEITH BELINKO, and JOHN AMBROSE. Can. J. Chem. **53**, 389 (1975).

The electrochemical properties of lead electrodes in aqueous chloride solutions were experimentally investigated over a range of 0.1 to 6.0 *M* HCl with the aim of extending previous work carried out only at 1.0 *M* HCl concentration. Experimental results using the rotating disc electrode technique, cyclic voltammetry, galvanostatic and potentiostatic charging conditions were employed in conjunction with spectroscopic studies of the electrolyte and X-ray powder diffraction analyses of electrode surface products. Experiments were also carried out in simulated sea water (3% NaCl) at different p*H* and compared with results obtained using HCl at the same molar concentration. At all chloride concentrations the overall reaction led to the formation of $PbCl_2$ on the electrode surface, with the exception that in NaCl solutions where p*H* $\geq$ 6.5, Pb(OH)Cl was found to be one of the products. For concentrations of less than 0.4 *M* HCl, our results indicated that the diffusion of chloride ions to the electrode surface was the limiting factor in the formation of a passivating $PbCl_2$ layer. At concentrations of about 0.7 *M* HCl, the electrochemical behavior showed a pattern of results which were interpreted in terms of a "passivation–dissolution" competitive mechanism consistent with the solubility minimum of $PbCl_2$ in aqueous chloride solutions.

REMIGIO GERMANO BARRADAS, KEITH BELINKO et JOHN AMBROSE. Can. J. Chem. **53**, 389 (1975).

On a étudié expérimentalement les propriétés électrochimiques d'électrodes de plomb dans des solutions aqueuses de chlorure entre 0.1 et 6.0 *M* en HCl; le but en était d'étendre un travail précédent qui n'avait été effectué que jusqu'à 1.0 *M* en HCl. Les résultats expérimentaux obtenus (en utilisant la technique de l'électrode à disque tournant, de la voltamétrie cyclique et de la charge galvanostatique et potentiostatique) ont été utilisés en conjonction avec des données spectroscopiques de l'électrolyte et des diagrammes de rayons-X des poudres des produits de surface des électrodes. On a aussi effectué des expériences dans de l'eau de mer artificielle (3% de NaCl) à différents p*H* et on a comparé les résultats avec ceux obtenus en utilisant du HCl à la même concentration molaire. A toutes les concentrations de chlorure, la réaction globale conduit à la formation de $PbCl_2$ à la surface de l'électrode. Il y a toutefois une exception pour les cas de solutions de NaCl à p*H* $\geq$ 6.5 où Pb(OH)Cl est l'un des produits formés. A des concentrations plus basses que 0.4 *M* en HCl, nos résultats indiquent que la diffusion des ions chlorures vers la surface de l'électrode est le facteur contrôlant la formation d'une couche passivante de $PbCl_2$. A des concentrations de l'ordre de 0.7 *M* en HCl, le comportement électrochimique montre un ensemble de résultats qui a été interprété comme résultant d'un mécanisme compétitif "passivation–dissolution" en accord avec les minima de solubilité de $PbCl_2$ dans des solutions aqueuses de chlorure. [Traduit par le journal]

Introduction

Recent interest (1–5) has been focused on the possibility of the $Pb/PbCl_2$ electrode as an economical substitute for the Ag/AgCl electrode in sea water activated batteries which employ a Mg alloy anode. The $Pb/PbCl_2$ electrodes have been made by a number of procedures of which the hot-pressing method has been found to be convenient and satisfactory (3). The discharge characteristics of these electrodes have been studied (1–5), but there has been relatively little fundamental electrochemistry of Pb in aqueous chloride solutions reported in the literature (5–8).

Our studies in 1 *M* HCl have already been reported (9) and in the present paper further experimental studies are extended to other HCl concentrations ranging from 0.1 to 6 *M*. In addition results for simulated sea water (3% NaCl) at various p*H* will be presented and correlated with data for HCl at the same concentration (0.5 *M*).

Experimental

The apparatus for electrochemical measurements, cells and rotating disc assembly were as described before (9). In addition a PAR model 170 electrochemistry system was used for some of the measurements. p*H* changes during the electrolysis of simulated sea water (3% NaCl) were monitored by a glass electrode contained in a side tube in the working compartment of the three compartment cell. The reference electrode was saturated calomel and all potentials unless stated otherwise refer to this electrode.

Pb of 99.999% purity (Alfa Inorganics Inc.) was made into discs and embedded in Teflon. The surface was cleaned with hydrogen peroxide – acetic acid mixture and finally rubbed with microcloth (Buehler Ltd.).

AnalaR chemicals were employed and solutions made up with triply distilled water. NaCl solutions of various p*H* were prepared by the addition of the requisite amount of HCl. Galvanostatic formation of $PbCl_2$ on Pb in aqueous 0.1 *M* HCl, its discharge characteristics, the effects of temperature, and presaturation of the electrolyte with $PbCl_2$ were carried out with rectangular shaped electrodes with an apparent surface area of 2 cm^2 prepared from Pb foil (99.99% purity supplied by A.D. MacKay Inc.). In these studies the reference electrode used was Ag/AgCl and the potentials in Figs. 1 and 2 refer to this electrode.

Results and Discussion

(a) Galvanostatic Work

Galvanostatic charging curves of Pb in 0.1 *M* HCl as shown in Fig. 1*a* and *b* consisted of two parts designated as regions I and II. The potential in region I was always found to be steady whereas the potential in region II was found to be time dependent.

The potential in region II was found to rise with time (as Fig. 1*a*) for $PbCl_2$ presaturated electrolytes, and also in 0.1 *M* HCl for current densities greater than 5 mA/cm^2 at temperatures $\leqslant$15 °C. In 0.1 *M* HCl at 25 °C the potential in region II fell at first as a function of time (Fig. 1*b*) for current densities in excess of 3 mA/cm^2 for the rectangular shaped electrode. However, for disc electrodes the same effect did not occur until about 5 mA/cm^2. It is difficult to establish an exact current density for the change in behavior due to uncertainties of surface roughness. When the electrolyte was stirred by bubbling with N_2 gas over the rectangular electrode, or by rotating the disc electrode, falling potentials in region II were observed at $\leqslant$15 °C. In $PbCl_2$ presaturated solutions, stirring had no effect on the potential behavior in region II.

Products taken from the electrode surface in the course of both potential regions I and II were found by X-ray powder diffraction analysis to be $PbCl_2$; no other species were detected. This is suggestive that there is only one distinct electrochemical step occurring during the galvanostatic electrolyses, which may be represented by the overall reaction

[1] $$Pb + 2Cl^- \rightarrow PbCl_2 + 2e$$

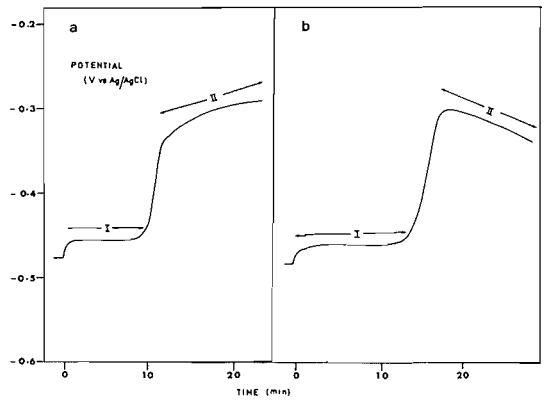

FIG. 1. Polarization curves of Pb at 25 °C and 4 mA/cm^2. (*a*) 0.1 *M* HCl solution presaturated with $PbCl_2$; (*b*) 0.1 *M* HCl.

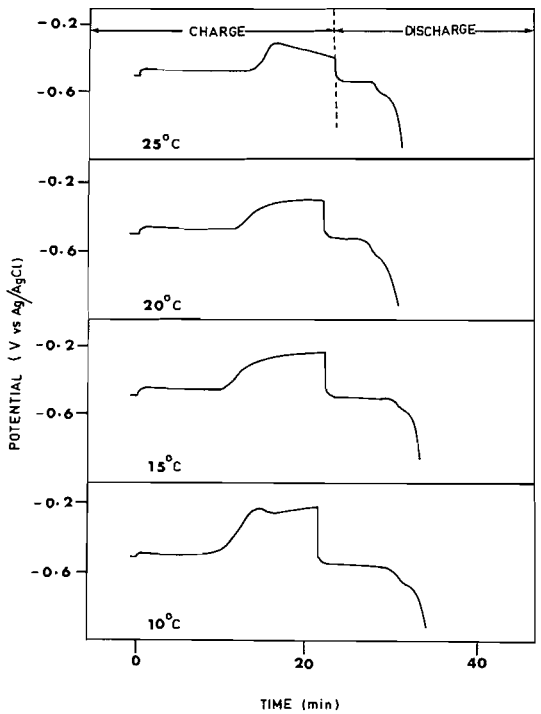

FIG. 2. Polarization curves of Pb in 0.1 *M* HCl at 4 mA/cm^2 for different temperatures.

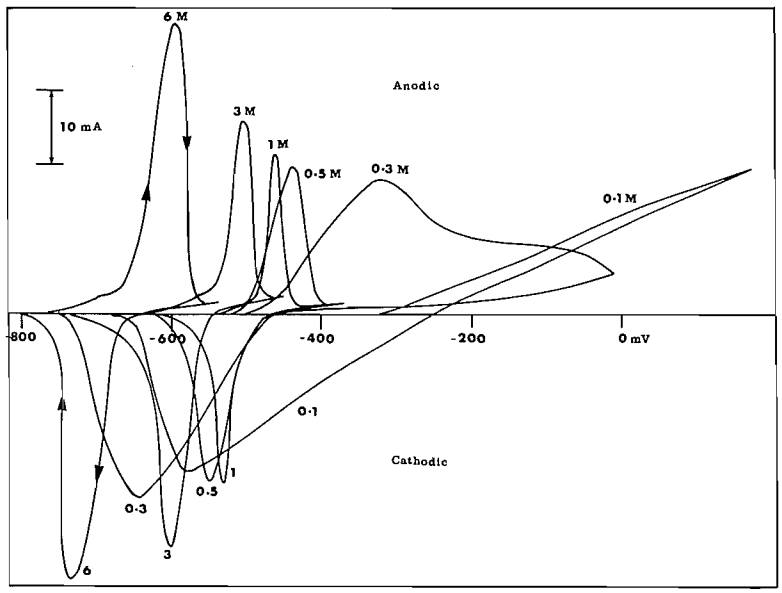

FIG. 3. Cyclic voltammograms recorded with a sweep rate of 10 mV/s in various HCl concentrations.

Complementary evidence concerning the formation of $PbCl_2$ was obtained from open circuit potential measurements. In all instances the potential of the electrode fell to a value of approximately -484 mV at 25 °C in 0.1 *M* HCl, Fig. 1, which agrees rather well with the value calculated from E^0 given by Parsons for $Pb/PbCl_2$ (10).

The rise in potential between regions I and II (Fig. 1) can therefore be due to the formation of a passivating layer of $PbCl_2$. The subsequent behavior in region II can be explained in the following way. In presaturated $PbCl_2$ solutions and at temperatures $\leqslant 15$ °C the dissolution of the passivating layer of $PbCl_2$ is inhibited, and therefore, increases in thickness with time at sufficiently high c.d., thereby causing the potential in region II to increase. At 25 °C the dissolution of the $PbCl_2$ layer is enhanced and the converse effect in thickness and potential behavior are apparent, except at low current densities. The behavior of the electrode on stirring the electrolyte is consistent with the above interpretations.

Charge and discharge curves are depicted in Fig. 2 for different temperatures. It is noteworthy to mention that two potential arrests were observed on discharge, as has been observed in previous work (2) on hot pressed $PbCl_2$ plates. During the course of the second potential arrest the formation of dendritic lead, confirmed by X-ray powder diffraction analysis, was observed on the electrode, especially in $PbCl_2$ presaturated solutions where the second arrest was considerably larger. It may be concluded that the Pb is formed by reduction of soluble Pb(II) species.

Further insight into the nature of the first cathodic arrest may be gained by considering the ratio of the charge represented by this arrest, Q_c (*i.e.*, the first plateau on the cathodic side of Fig. 2), to the charge represented by the first anodic plateau, Q_a, from Fig. 2. The ratio Q_c/Q_a varies from 0.3 at 25 °C to 0.9 at 10 °C at a current density of 4 mA/cm^2. Q_c/Q_a was also sensitive to changes in applied current density, *e.g.* changing from 0.08 at 3 mA/cm^2 to 0.5 at 5 mA/cm^2 at 25 °C. In $PbCl_2$ saturated HCl the cathodic arrests are poorly separated and an accurate estimation of Q_c is difficult. However, Q_c/Q_a approximates to unity and is temperature independent under these conditions. From the variable nature of Q_c/Q_a in 0.1 *M* HCl without presaturation of $PbCl_2$, it could be inferred that the first cathodic arrest is in all likelihood due to the reduction of surface $PbCl_2$ as represented by the reverse of reaction 1.

(b) Cyclic Voltammetry

Voltammograms for Pb in various concentra-

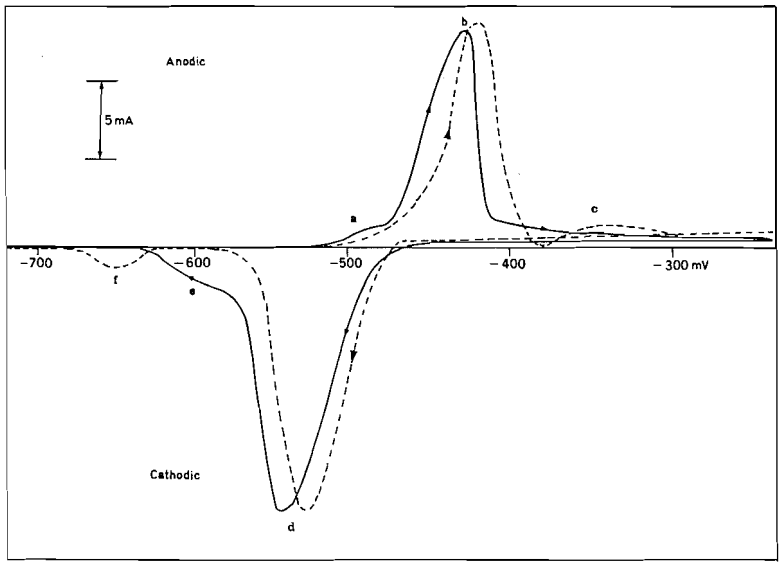

FIG. 4. (—) Cyclic voltammogram in 0.5 M HCl at v = 10 mV/s. (---) Cyclic voltammogram recorded in 3% NaCl at v = 10 mV/s.

tions of HCl and also 3% NaCl (simulated sea water) at a sweep rate of 10 mV/s are shown in Figs. 3 and 4, respectively. For concentrations above 0.5 M HCl they are divided into five regions, Fig. 4: (*a*) a pre-peak region, (*b*) an anodic passivation peak, (*c*) a reactivation region, (*d*) a cathodic peak, and (*e*) a shoulder at more negative potentials which appears only in HCl solutions.

The two cathodic processes (*d*) and (*e*) seen in HCl can be correlated with the two plateaux seen in the galvanostatic reduction of $PbCl_2$ plates (2). The shoulder is increased in size with the addition of $PbCl_2$ to the electrolyte. Since Pb dendrites, identified by X-ray powder diffraction, only begin to appear in this voltage region this shoulder may be correlated with the second cathodic arrest reported in part (*a*), and is probably therefore due to the reduction of soluble Pb(II) species.

The voltammogram changes considerably with Cl^- ion concentration Fig. 3, but very little with pH, Fig. 4. For all concentrations of Cl^- ion, i_p (current at the peak on a voltammogram) was found to be linear with $v^{1/2}$ (v = sweep rate). For a solution diffusion controlled process (22),

$$[2] \qquad i_p = 3.67 \times 10^5 n^{3/2} A c_0^{\,b} D^{1/2} v^{1/2}$$

where n = number of electrons, A = electrode surface area, $c_0^{\,b}$ = bulk concentration of Cl^- ion, D = diffusion coefficient. From [2] it is possible to calculate diffusion coefficients, D. Data for the various HCl concentrations using the values taken from peak (*b*) are shown in Table 1.

The total charge under the anodic passivation

*ω = 25 Hz.

peak (*b*), Q_A, was obtained by integrating the curve to the point of passivation. Q_A for different sweep rates and HCl concentrations is given in Table 2. The variation of Q_A with sweep rate suggests some degree of dependence on the extent of oxidation with time spent in the anodic region. The value of Q_A was also found to be dependent on HCl concentration displaying a minimum at 0.7 *M*. The implications of this trend in behavior will be discussed under section (*c*) on a comparative basis with the results of rotating disc experiments.

As in 1.0 *M* HCl (9), i_p was found to be proportional to E_p, the potential at the peak on a voltammogram. The slopes of i_p *vs.* E_p plots, which represent a resistance, possibly that of a surface layer, were approximately 1 $\pm$ 0.5 ohm cm^2 for all concentrations studied except 0.1 *M* HCl, where the "resistance" appears unexpectedly to be approximately ten times higher; an observation which is not easy to interpret.

For low Cl^- ion concentrations (0.1 to 0.3 *M*) voltammograms of stationary discs were somewhat irreproducible and cannot be divided into three anodic regions. At sweep rates of the order of 10 mV/s the first anodic peak is poorly defined, and extends over a wide potential region. This is especially noticeable in the case of 0.1 *M* HCl where a very broad peak was observed over a potential region of at least 1 V, but at no point were currents small enough to indicate passivation. On repeated cycling, *i.e.* forming and reducing the surface layer several times, current oscillations were observed. A plot of the peak current i_p *vs.* $v^{1/2}$ for the sweep rate range 1 to 20 mV/s was found to be linear, and the diffusion coefficient calculated from eq. 2 and given in Table 1 is of the same order of magnitude as the diffusion coefficient of HCl (3×10^{-5} cm^2/s) (11), which suggests that Cl^- ion diffusion is the limiting process.

In 0.3 *M* HCl the broad anodic peak is followed by a flat portion with the electrode finally passivating at about 0 mV, Fig. 3. Again reproducibility is irregular and electrodes which have been previously cycled show rising currents after the anodic peak instead of a flat portion, and larger cathodic peaks were observed. Plots of i_p *vs.* $v^{1/2}$ were also linear, and the diffusion coefficient calculated (see Table 1) is now much lower than that for 0.1 *M* HCl, so that solution diffusion of Cl^- is no longer limiting. It seems clear that surface growth on the electrode is becoming an important process as the HCl concentration is increased from 0.1 to 0.3 *M* as evidenced by progressive cycling in 0.3 *M*. Although cathodic peaks are observed when the anodic scan extends only as far as the rising portion of the curve in both concentrations under quiescent conditions, the hysteresis on the return sweep is higher in 0.3 than 0.1 *M*. In addition the cathodic peaks persist in 0.3 *M* even upon rotating the electrode.

When a concentration of 0.5 *M* HCl is reached, surface growth is the predominant part of the anodic process. Previous work in 1.0 *M* HCl (9) has shown that a reversible dissolution

step is taking place in region (*a*) and the main peak (*b*) is due to surface formation of $PbCl_2$. At 0.5 M HCl and higher concentrations, values of D are down to 10^{-7} cm^2/s (Table 1), so that solute diffusion of Cl^- is again not a limiting factor. Such values of calculated diffusion coefficient from eq. 2 are meaningless in 0.5 M Cl^-, because eq. 2 applies only for a solution diffusion limiting process. They only serve to show that there is a trend in changing values of D as calculated from eq. 2 with pH as shown in Table 3. The role of pH changes is also reflected by the slopes of E_p *vs.* i_p plots which were found to increase as the pH decreased, Fig. 5. Such changes in electrochemical behavior with pH are possibly associated with changes in surface structure, as might be expected, for example, from the observed formation of species such as Pb(OH)Cl at higher pH. This speculation is supported by X-ray powder diffraction evidence of precipitate of Pb(OH)Cl from $PbCl_2$ solutions at high pH (7.0). In the voltammogram at pH 6.5, Fig. 4, two new peaks marked (*c*) and (*f*) were observed. Peak (*c*) shifts to more negative potentials with decreasing pH values and eventually disappears in 0.5 M HCl. It is noteworthy to mention that peak (*c*) is very reproducible, but that peak (*f*) is far less reproducible by comparison, thereby making it difficult to correlate these two peaks. Despite the identification of Pb(OH)Cl, and the probability that it may be one of the species which is changing the surface structure of the electrode, the experimental evidence about the behavior of peak (*c*) shifting to more cathodic potentials with decreasing pH values cannot be used as evidence that only Pb(OH)Cl forms at the electrode. One would expect that the reverse behavior of peak (*c*) as a function of pH and potential must occur if only Pb(OH)Cl was the new surface product. Peak (*c*) must therefore represent some undeterminable species occurring through localized hydrolysis other than just Pb(OH)Cl. In essence, it is impossible to characterize the nature of peak (*c*) on the basis of the experimental results obtained.

For HCl concentrations greater than 0.5 M, the current falls rapidly after the main anodic peak to a very small value, and thereafter, rises linearly but very slowly with increasing potential. The rate of rise also increases with sweep rate. A voltammogram (extended to more positive potentials) in 0.7 M HCl showed that the small current was maintained as far as +2.4 V when irregular oscillation in currents occurred due to O_2 evolution. On reverse of the sweep, the linear dependence of current upon potential was maintained until reduction of the surface layer took place.

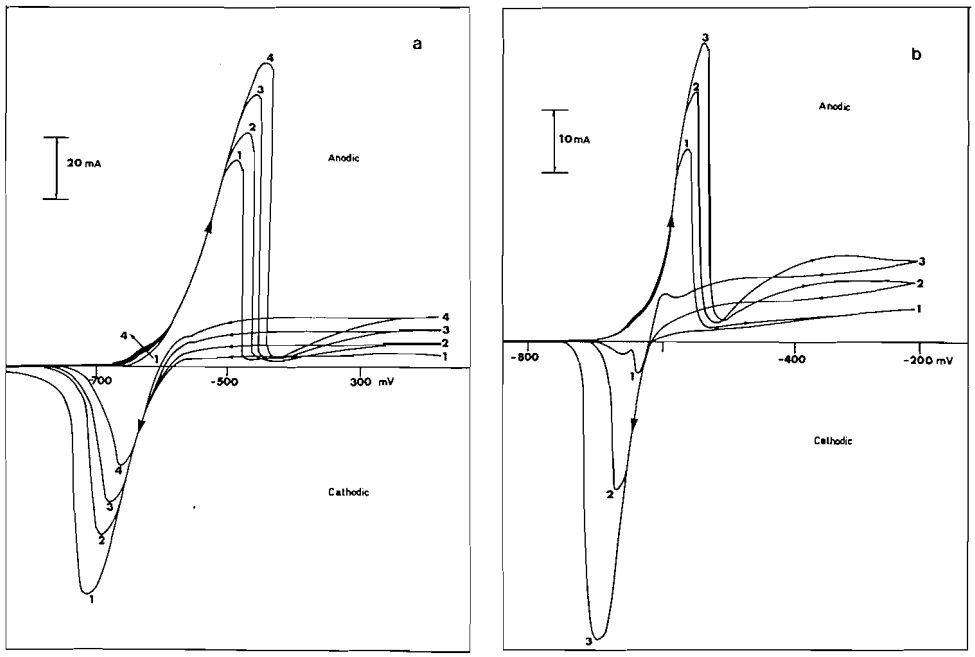

FIG. 6. Cyclic voltammograms recorded in 6 *M* HCl. (*a*) v = 50 mV/s; (*1*) 0, (*2*) 9, (*3*) 25, and (*4*) 49 Hz. (*b*) v = 10 mV/s; (*1*) 0, (*2*) 9, (*3*) 16 Hz.

Voltammograms in 3.0 and 6.0 *M* HCl were morphologically the same as in 0.5 *M*. The fall in current after the first anodic peak was much faster than in 0.5 *M* HCl, and for slow sweep rates it was almost vertical in 6.0 *M*. As in 1.0 *M* HCl (9), the observed currents were dependent upon sweep rate in the pre-peak region, but during the rest of the rising portion the current became sweep rate independent. The potential at which the current becomes sweep rate independent determines the beginning of the formation of the surface layer. In section (*d*) it will be shown that this observation correlates well with the rotating disc progressive cycling experiments, which do not show appreciable cathodic peaks when the anodic sweep extends only as far as the pre-peak region.

The behavior on the cathodic side of the voltammograms can be correlated to the anodic behavior. In 3.0 and 6.0 *M* HCl, the main cathodic peak has a linear section which has a slope equal to the slope of the rising section of the anodic side. The shoulder on the cathodic side of the peak appears only in $\leqslant 1$ *M* HCl, and then only at the lower sweep rates. Two cathodic peaks appear on some of the runs, and a consistent pattern in their behavior is seen only on the rotating electrode. These results are discussed below where further details on the nature of the surface growth are investigated.

(c) Cyclic Voltammetry using the Rotating Disc Electrode Technique

Behavior in Concentrations Greater than 0.4 M HCl

The rotating Pb disc was used in all concentrations, and except for the two lowest concentrations (0.1 and 0.3 *M*), an increase in currents compared with the stationary disc was observed. Although peak currents were generally proportional to $\omega^{1/2}$ (ω is the electrode angular velocity), the behavior in the reactivation region was more complicated, and depended simultaneously on HCl concentration and sweep rate. This made it difficult to analyze the data quantitatively.

In 6.0 *M* HCl currents in the reactivation region rose to steady value at 50 mV/s which increased with increasing rotation speed. On reversing the sweep in the reactivation region the current fell slowly, so that over a limited range of potentials, currents were higher on the reverse than on the forward sweep, Fig. 6*a*. At 10 mV/s there was evidence of a broad peak in the reacti-

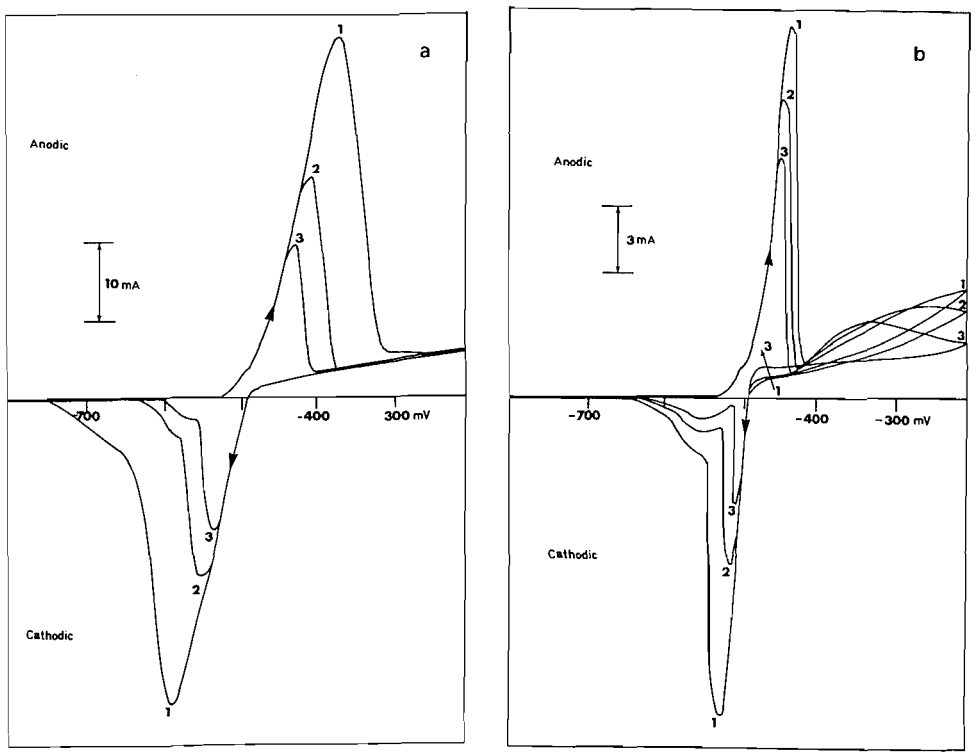

FIG. 7. Cyclic voltammograms for Pb is 0.7 *M* HCl; ω = 25 Hz. (*a*) (*1*) *v* = 200 mV/s, (*2*) 60 mV/s, (*3*) 20 mV/s. (*b*) (*1*) *v* = 10 mV/s, (*2*) 6 mV/s, (*3*) 3 mV/s.

vation region, Fig. 6*b*. In all cases, the current observed at the point of sweep reversal was maintained on the reverse sweep with only a slight fall which occurred about 100 mV prior to the reduction of the surface layer, irrespective of whether the current at the point of sweep reversal was rising or falling.

In other concentrations the behavior in the reactivation region is similar to that shown in Fig. 6*a* and *b*. At sweep rates below about 10 mV/s, the current passes through a maximum just after passivation and then attains a potential independent value, although sometimes oscillations in current are observed before the steady value is reached, Fig. 7*a* and *b*. An extended voltammogram in 0.7 *M* HCl showed that this steady value was maintained until oxygen evolution occurred at about +2 V, and was indicated by a gradual rise in current and the appearance of small bubbles on the electrode. This behavior is contrasted with that under quiescent conditions where a very gradual rise in current with increasing potential occurred. The current can be attributed to a thickening of the surface layer, because on the cathodic sweep, the cathodic peak was very much greater than for smaller anodic excursions. At sweep rates above 10 mV/s the behavior was similar to the stationary case, *i.e.*, a linear rise to a potential independent value, except that the rate of rise was greater. On the reverse sweep linearity was maintained until reduction of the surface layer took place, and as under quiescent conditions the current–potential slope during reduction was similar to that on oxidation. In the case where the current passed through a maximum in the reactivation region, the current on the reverse part of the cycle depended on the point of reversal. If the point of reversal occurred during the rising part of the peak, then currents on the reverse were the same or higher than that on the forward sweep. If reversal happened after the maximum, then reverse currents were lower. This is illustrated in Fig. 8 where a sweep rate of 8.3 mV/s was used in 0.7 *M* HCl. It was found that *i vs.* $\omega^{1/2}$ was linear for all points within the reactivation region.

The use of HCl solutions saturated with $PbCl_2$

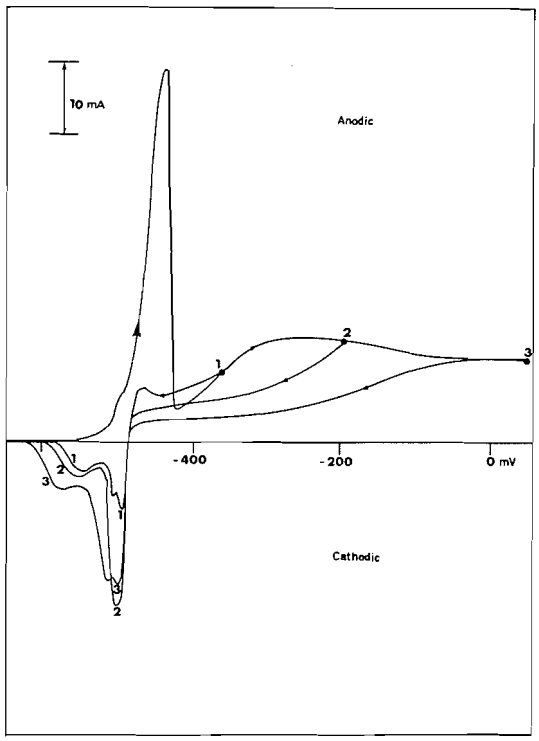

FIG. 8. Progressive cycling experiments in 0.7 *M* HCl; v = 8.3 mV/s; ω = 49 Hz; 1–3 are points of sweep reversal.

removed the reactivation effect, but changes in i_p with ω were unaffected. This shows that the reactivation process is dependent on the concentration of $PbCl_2$ in solution. However, the observation that i_p remains unaffected suggests that the main anodic peak is caused by a different reaction mechanism in the process of passivating the lead electrode, and this need not necessarily depend on any specific concentration of lead chloride in solution. Therefore, one surmises that the reactivation region is associated with the formation of soluble lead species subsequent to the passivating step.

Small changes in E_p with rotation speed, ω, were observed as might be expected from a dissolution–precipitation mechanism (9), but the behavior of the electrode depended greatly on its previous history, such as whether the electrode surface was freshly prepared or had undergone one or more oxidation–reduction cycles. The peak height increases and appears at more positive potentials with successive cycles until generally about the fifth cycle after which the peaks are reproducible. Therefore, in all these experiments the electrode was precycled about 5 times while being rotated at different speeds before actual measurements were made. In carrying out a series of runs starting at ω = 25 Hz and increasing in steps of $\omega^{1/2} = 1$ up to ω = 100 Hz, and then decreasing again in steps of $\omega^{1/2} = 1$, appreciable hysteresis in E_p were observed, but there were no significant perturbations in the values of i_p. The cycles were extended just past the point of passivation. It was found that the width of the hysteresis in E_p depended on the rotation speed used during the precycling.

The hysteresis effect is summarized in Table 4 where ΔE_p is the peak potential difference between the run where ω is increasing, and where it is decreasing. It is not possible at present to give a very satisfactory explanation of the results, but the cause may in part be due to the effects of changes in surface roughness which occur during an experiment. It had been formerly stated (9) that formation and reduction of a surface layer of $PbCl_2$ would cause roughening of the Pb surface, and dissolution would tend to smooth the surface. The discs have been observed to appear brighter after a voltammogram on a rotating electrode than on a stationary electrode, although etch pits appear when appreciable dissolution takes place. The occurrence of surface roughening or smoothing is probably very sensitive to hydrodynamic conditions, and quantitative treatments are not possible with

*10 mV/s.

the available data. If the major reaction is dissolution, then currents would be expected to be higher where the Pb surface is initially rough. Consideration of a surface growth mechanism is much more complicated, because a nucleation and growth process would be very sensitive to surface asperities; alternatively a dissolution–precipitation mechanism would be equally sensitive to the hydrodynamic conditions near the electrode.

The cathodic side of the voltammograms in all concentrations shows the large amount of electrode dissolution that occurs. Data for voltammograms which extend only a short way into the reactivation region are given in Table 5. The ratio of cathodic charge to anodic charge, Q_C/Q_A is dependent upon rotation speed and HCl concentration (Q_A and Q_C are charges consumed in the anodic and cathodic reactions, respectively). The ratio approaches values closest to 1 at zero rotational speed, in all concentrations (with the exception of 0.2 *M* HCl) and at all sweep rates. Because the values are so close to unity, distinction between different sweep rates and concentrations is not possible until the electrode is rotated. The ratio reaches a maximum value at the highest sweep rate studied, and at 0.7 *M* HCl. In addition the ratio is larger at $\omega = 25$ than at $\omega = 64$ Hz. These results are consistent with the trend in the shape of voltammograms recorded in different HCl concentrations (Fig. 3) and the data of Q_A shown in Table 2. With respect to Fig. 3, since these voltammograms were all recorded with the same sweep rate, the half-width of the main anodic peak is indicative of the time required for the electrode to passivate. A minimum in the half-width occurs at about 0.7 *M* HCl. A similar result is shown in Table 2, where a minimum in Q_A, the charge under the main anodic peak (*cf.* Fig. 4, peak (*b*)), is observed at 0.7 *M* HCl. A minimum in Q_A was again found at approximately 0.7 *M* HCl under rotating conditions.

This trend in behavior is apparently consistent with solubility considerations which predict least dissolution when mass transport of products away from the electrode surface is minimal (at zero or low rotation speeds), when the Cl^- concentration is near the minimum in the solubility curve for lead chloride, and when surface/solution contact time is shortest (highest sweep rate).

Behavior at Concentrations Less than 0.4 M HCl

In 0.4 *M* HCl and lower concentrations, the stationary and rotating electrodes show different behavior. The difference is most pronounced in 0.1 *M* HCl (*cf.* Fig. 3 and Fig. 9). The stationary electrode gives increasing currents with potential over a very wide potential range and this is accompanied by appreciable loss of Pb. On

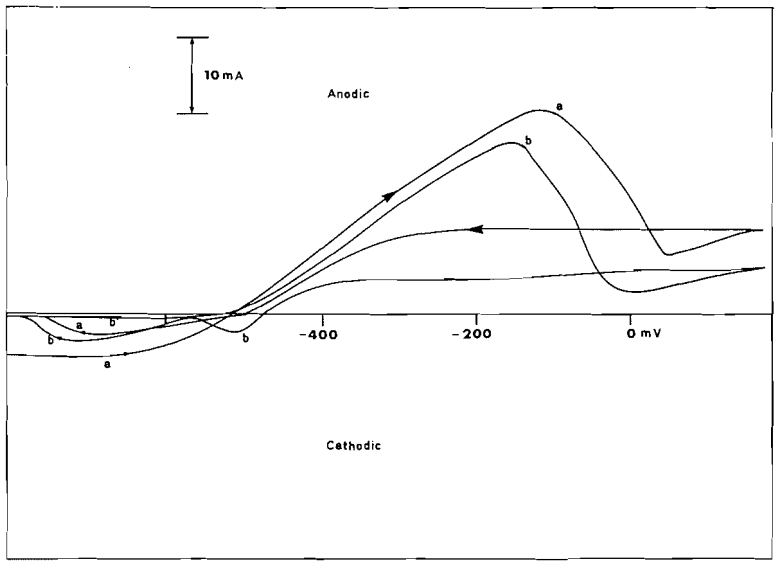

FIG. 9. Cycling voltammogram recorded in 0.1 *M* HCl at 8 mV/s. (*a*) $\omega = 64$ Hz, (*b*) $\omega = 16$ Hz.

rotation, the voltammogram is similar to the voltammograms of the stationary Pb electrode in concentrations above 0.4 *M*. The transition from one type of behavior to the other could be clearly seen under certain conditions. For example, in 0.4 *M* for varying sweep rates two anodic peaks were observed, the more positive of which increased with decreasing sweep rate and the other decreased (see Fig. 10). The second peak disappears upon rotation. In 0.3 *M* HCl cycling with changing rotation speed showed that the anodic peak has approximately the same type of shape (Fig. 11, curve 1), except for small changes in peak potential and peak height similar to those discussed earlier for higher HCl concentrations. If the rotation is stopped, but the cycling continued, the peak changes as depicted by curves 2 to 5, Fig. 11. This change in profile which indicates a delay in attaining passivation must be attributed to surface growth becoming increasingly difficult. It therefore follows that because of its dependence upon Cl^- ion concentration and hydrodynamic conditions, surface growth is dependent upon a solution diffusion of Cl^- ions.

The cathodic peaks were found to increase in size when the rotation of the electrode was stopped, Fig. 11. It is, however, not possible to determine whether the process is a reduction of a surface layer only. Reduction of soluble species may likely be a concurrent reaction.

It is of interest to note that the reactivation of the electrode on rotation in these low concentrations is similar to those in higher concentrations.

(d) Progressive Cycling Experiments

Progressive cycling of the electrode with and without rotation were carried out. Results in 0.5 *M* HCl, at a sweep rate of 5 mV/s at $\omega = 0$ and $\omega = 36$ are shown in Fig. 12*a* and *b*, respectively. Results at higher rotation speed are substantially the same as those for $\omega = 36$.

In the stationary case the cathodic peak grows steadily as the anodic scan extends along the rising portion of the anodic peak. There is an appearance of a small shoulder on the forward side of the cathodic peak. The size of the cathodic peak continues to grow until passivation is reached on the anodic side.

In the experiments carried out with a rotating electrode (Fig. 12*b*) the same qualitative trend of results was observed on the early rising portion of the main peak where forward and backward sweeps have the same current. This may be ascribed to a dissolution process unhindered by surface growth as had been shown previously (9), (*cf.* section (*e*)). By the time curve 2 is reached a cathodic peak appears which increases in size up to curve 4. In run 6 where the electrode on the anodic side is being swept as far as the reactivation region, the cathodic peak shifts about 10 mV to a more positive value. The shoulder increases

commensurately in size. Experiments in 0.7 *M* HCl where the anodic excursion was extended to higher overpotentials the cathodic peak was found to increase, while the shoulder remained practically unchanged. It appears that a large proportion of the residual current observed in the reactivation region is used in building up the surface layer. For a particular anodic excursion the cathodic peak current, but not the shoulder current depends on ω.

In some situations, *e.g.*, 1.0 *M* HCl, the cathodic peak is split in two with the more negative peak decreasing, and the positive peak increasing as the anodic sweep extends through the point of passivation (9). In order to establish the sequence of cathodic peak formation, an extended series of new experiments in 1.0 *M* HCl was carried out in which anodic sweeps to a particular potential were made with the electrode being either held at the selected potential, or placed on open circuit for varying lengths of time before the reverse sweep was performed. In all cases a sweep rate of 5 mV/s, and a rotation speed of 25 Hz was employed. The holding potentials were (*i*) −460 mV which is at the peak maximum, (*ii*) −450 mV which is at the peak maximum, (*iii*) −440 mV which is the point of passivation, and (*iv*) −390 mV which is well into the reactivation region. At all these potentials passivation was reached on holding the potential.

In the experiments where the current was not interrupted, three peaks were observed (I) −510 to −515 mV, (II) −525 to −530 mV, and a third broad peak (III) from −545 mV to more cathodic values. The latter was about twice as broad as peaks (I) and (II), Fig. 13. Data for peak heights with different hold times are given in Table 6, and from inspection peak (I) is seen to increase in height with increasing potential of hold.

When the electrode was allowed to remain on open circuit, different results were obtained. Over the whole range of hold times peak (I) was practically constant in size, while peak (II) decreased with length of holding time. Peak (I) was larger when the sweep extended to a less anodic potential. Although the maximum currents of peak (III) did not change, the peak increased in

width with increasing time of hold during passage of current. When the current was switched off during the hold period, this third peak was unaffected by length of holding time.

The above data is complicated by the fact that the cathodic peaks arise not only from the forward sweep in which surface growth and accompanying dissolution take place, but also

from the reverse part of the sweep where enhanced surface growth can take place.

By comparison of anodic and cathodic charges, it was apparent that dissolution of the surface layer was very great with Q_C/Q_A usually less than 0.5. Furthermore the anodic charge consumed during the sweep reversal after holding was similar to the cathodic charge of peaks (I) and (II). This implies that the cathodic peaks could both have been formed entirely during the sweep reversal. These suppositions were confirmed by starting the reversal sweep at −510 mV instead of any of the selected holding potentials shown in Table 6. The combined cathodic charges were reduced to a very small value, and both peaks (I) and (II) disappeared when the electrode was allowed to stand for any length of time on open circuit. If the sweep reversal was performed immediately then only peak (II) remained. It is plausible that the species being reduced in the potential region represented by peak (I) is formed during the sweep reversal and its formation may be related to the small anodic peak observed just before reduction.

Peak (II) disappears on holding the potential either with the current being on or off. The species undergoing reduction at the originally formed peak (II) potential is not formed in the reverse sweep. Although the peak (II) height decreases in the reactivation region, it is not certain whether the species are removed electrochemically in the reactivation reaction or just dissolved away from the electrode.

The shape of peak (III) suggests a reduction of a soluble species of Pb(II). It occurs at the same potential as the shoulder (*e*) discussed in section (*b*) of this paper.

Progressive cycling experiments in 1.0 *M* HCl show peak (III) to appear when the potential of the electrode is swept into the rising portion of the main oxidation peak, but the charge under the peak only begins to increase after passivation has occurred. This is true where passivation is reached either by holding the potential, or by extending the anodic scan to some appropriate anodic value. Thus in cases where the electrode is still active at the point of sweep reversal, *e.g.*, holding at −470 mV, peak (III) is small. Where the anodic scan extended far into the reactivation region, peak (III) was eventually obscured by peak (II).

It seems likely that peak (II) is representative of a surface layer produced by dissolution–precipitation (9, 23), since the charge shown by peak (II) passes through a maximum when anodic sweeps are extended just to the point of passivation, and that it is not formed on the reverse sweep. This proposed surface layer may be sufficiently soluble to render the Pb surface liable to further oxidation. This would then give rise to the reactivation behavior and the formation of another surface layer whose reduction is observed as peak (I). The reduction of this secondary layer can be expected to occur at a somewhat different potential from the dissolution–precipitation product, since the modes of formation of the two layers are different. Formation of the layer represented by peak (I) can only occur on the reverse part of the sweep if the reaction causing dissolution of the surface layer

is somewhat lessened. This may explain the anodic currents observed under the main peak region in the reverse part of the sweep.

Anodic sweeps, under quiescent conditions, which were completed by holding the electrode for various times at different potentials in the reactivation region, were followed by sweeps which began at a potential just positive to peak (I) (about −510 mV). The cathodic sweeps showed only peak (II), which decreased sharply with increasing hold times in the reactivation region. When the hold times were long the

cathodic charge became small and, it is consistent with the longer periods that the electrode surface film could dissolve accordingly. If a normal voltammogram had been conducted, this effect would have been obscured because surface growth occurs during the reverse part of the sweep.

(e) Rotating Disc at Constant Potential

At low overpotentials it was found that constant anodic currents were dependent on ω. As in the case of 1.0 *M* HCl (9) an analysis of the dissolution reaction mechanism was carried out on the basis of the current being limited by diffusion away from the electrode of a soluble Pb species. Plots of i^{-1} *vs.* $\omega^{-1/2}$ were made, and it was found that straight lines were obtained for all the HCl concentrations studied. Figure 14 exemplifies this general observation. The data obtained for dependence of log slope and log i_∞ upon potential are given in Table 7, and illustrated in Figs. 15 and 16 for 0.5 *M* HCl (i_∞ = current minus contribution from diffusion).

It should be noted that except for 0.1 and 0.5 *M* HCl intercepts were near zero indicative of i_∞ to be large. This corresponds to a large exchange current. The Nernstian slope of about 30 mV for all the concentrations except for the case of 0.1 *M* HCl supports the conclusion that the overall reaction involves a two electron step.

The change in slope in 0.1 *M* HCl is possibly due to the relatively dilute concentration of the electrolyte which could cause a change in the nature of the dissolution mechanism. This hypothesis is supported by the finding that in 0.1 *M* HCl a much wider range of potentials could be studied before the slopes of i^{-1} *vs.* $\omega^{-1/2}$ became independent of potential, contrary to the other HCl concentrations.

(f) Potentiostatic Transients

In view of the complexity of the surface growth process, as evidenced by our earlier experimental results, interpretation of the *i–t* transients was found to be just as difficult. A series of transients at different potentials in 6.0 *M*, Fig. 17, and previously published results in 1.0 *M* HCl under stationary and rotating conditions (9), show that the current in all cases passes through a maximum. At lower overpotentials where passivation does not occur the currents were found to attain a steady value. At larger times (*i.e.*, after passivation), under rotating conditions, the currents began to rise again towards a steady value, and these steady values had a linear dependence upon $\omega^{1/2}$. In $PbCl_2$ saturated solution no final rise in currents were observed.

It is not possible to reconcile the appearance of a current maximum with a previously proposed dissolution–precipitation process (9, 23). Our present results could not be adequately used to fit any surface nucleation models proposed by other workers (12–15). For example, a comparison of the data for 1.0 and 6.0 *M* HCl with the theoretical reduced variable plot for instantaneous nucleation (12, 13) is shown in Fig. 18. The fit is extremely poor, but seems to be slightly improved for the higher HCl concentration, and also by rotating the electrode. In 6.0 *M* HCl there was no significant change in the reduced variable plot upon rotation of the electrode.

Preliminary work based on very different experimental conditions where surface roughness is minimized gave results which seem to indicate that some pattern of surface nucleation may possibly be operative. However, considerable amount of additional work appears to be necessary, before any firm conclusion can be made in terms of models and quantitative theory.

(g) Spectral Studies

The solubility curve for $PbCl_2$ in aqueous chloride solutions exhibits a minimum (16–18) suggestive of complexation of the Pb^{2+} ion by chloride. The ligand-to-metal charge-transfer bands for $PbCl_n^{2-n}$ complexes have been studied by u.v.-absorption (16–18). Since charge-transfer bands generally shift to longer wavelength with greater complexation, it is possible to establish spectroscopically which species predominate in solution for different Cl^- ion concentrations.

Spectral studies were carried out for Pb^{2+} (formed electrochemically under potentiostatic conditions) in various HCl concentrations and in 3% NaCl at different p*H*. For the complex $PbCl_n^{2-n}$, the value of n increases correspondingly with the increase of chloride ion concentration. For example in 0.1 *M* HCl, $PbCl^+$ is the predominant species and only traces of $PbCl_2$ are detected. At 0.5 *M* HCl concentration, the amount of $PbCl_2$ present in solution far exceeds those of $PbCl^+$ and $PbCl_3^-$. When more HCl is present (*e.g.*, between 0.5 to 3.0 *M*) the main complex is $PbCl_3^-$, whereas at concentrations in excess of 3.0 *M*, the predominant species is $PbCl_4^{2-}$. The results reported in the literature (16–18) were obtained under a constant ionic strength of 4.0 *M*. Under conditions of higher ionic strength the tendency is obviously towards the formation of higher charged complex species. It should be emphasized that our spectral data of solutions obtained after electrolytic conditions at varying concentrations are not unexpectedly somewhat different from those published by other workers (16–18). Nonetheless the general trends of complex species formation in our experiments are in reasonable agreement with those reported in the literature.

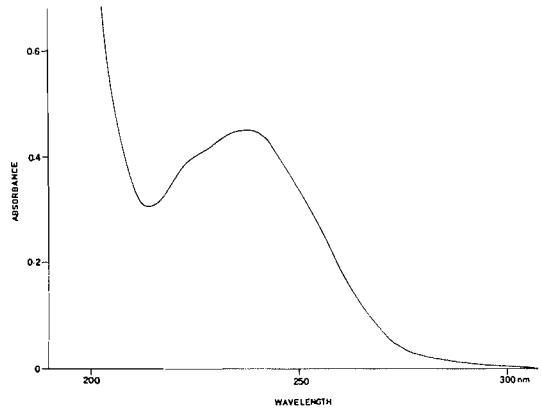

FIG. 19. Ultraviolet-absorption spectrum of 10^{-4} *M* $PbCl_2$ in 0.5 *M* HCl. Absorption band for $PbCl^+$ occurs at 225 nm. Absorption band for $PbCl_2$ occurs at 242 nm.

The spectrum for $PbCl_2$ in 3% NaCl is identical to that obtained for $PbCl_2$ in 0.5 *M* HCl under normal chemical conditions, Fig. 19. The spectrum changes little with p*H* up to p*H* 7 above which precipitation of Pb(OH)Cl, identified by X-ray diffraction, occurs. The formation of Pb(OH)Cl leads to a decrease in the intensities of the $PbCl^+$ and $PbCl_2$ spectral bands proportionally. Although the formation of Pb(OH)Cl at high p*H* as a surface layer is likely, there is no spectral evidence for the presence of such a species in solution. Perhaps it absorbs at too short a wavelength, or is only so very slightly soluble to the extent that no significant spectral band arises.

Conclusions

There was a noticeable transition in the electrochemical behavior of Pb in aqueous chloride solutions occurring at approximately 0.4 *M* HCl. At concentrations lower than 0.4 *M* HCl, where the solubility of $PbCl_2$ is relatively high (16), and where surface growth is limited by diffusion of Cl^- ion, passivation of the electrode was somewhat inhibited. This implied that the rate of surface growth was low compared to the

rate of dissolution. Although rotation of the electrode increased the amount of dissolution, transport of Cl^- ion to the electrode surface was found to be enhanced, and hence passivation occurred more readily. At Cl^- ion concentrations greater than 1.0 *M*, the solubility of $PbCl_2$ is again relatively high (16), but since there is now no limitation by diffusion of Cl^- to the surface of the electrode, passivation of the electrode was easily attained.

The competition between surface growth and dissolution as demonstrated by our experimental data gave rise to another noticeable transition in the trend of the electrochemical behavior at about 0.7 *M* HCl, which approximately coincides with the minimum in the solubility curve for $PbCl_2$ in chloride solutions. This led us to conclude that chemical dissolution of the surface $PbCl_2$ played an important role in the passivation mechanism.

Dissolution of the $PbCl_2$ layer after passivation also appeared to be a significant factor. This was indicated by the large reactivation currents observed in the voltammograms and potentiostatic transients under rotating conditions. This reactivation behavior had been postulated previously to be caused by the rupture of the surface layer of $PbCl_2$ by Cl^- ion (7), and in other electrochemical systems not involving Pb electrodes (19–21). The dissolution reaction of the passivated layer may be expressed as follows

$$PbCl_{2(surf.)} + nCl^- \rightarrow PbCl_{n+2}^{n-}$$

Rotating Ring-disc Electrode Studies of Lead in HCl and NaCl Solutions

REMIGIO GERMANO BARRADAS, KEITH BELINKO, AND ELENA GHIBAUDI
Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received July 22, 1974

REMIGIO GERMANO BARRADAS, KEITH BELINKO, and ELENA GHIBAUDI. Can. J. Chem. **53**, 407 (1975).

The rotating ring-disc electrode technique was used to investigate the nature of the dissolution reactions that take place during the anodic charging of a Pb electrode in aqueous chloride electrolytes. Chemical dissolution of the $PbCl_2$ film formed on the disc was found to be an important process which occurred prior to and after passivation of the disc electrode. A ring current due to the electrochemical dissolution of the Pb disc was only observed at low disc currents during galvanostatic charging experiments, or at low disc overpotentials in potentiostatic and voltammetric studies. Observations of anodic ring current excursions under potentiostatically cathodic conditions hitherto not reported in the literature are described.

REMIGIO GERMANO BARRADAS, KEITH BELINKO et ELENA GHIBAUDI. Can. J. Chem. **53**, 407 (1975).

On a utilisé la technique de l'électrode à disque tournant annulaire pour étudier la nature des réactions de dissolution qui ont lieu durant la charge anodique d'une électrode de Pb dans des électrolytes de chlorures aqueux. On a trouvé que la dissolution chimique, du film de $PbCl_2$ formé sur le disque, est un processus important qui a lieu avant et après la passivation de l'électrode. On a observé un courant d'anneau dû à la dissolution électrochimique du disque de Pb uniquement à des bas courants de disque durant les experiences de charges galvanostatiques ou à des bas niveaux de surtension du disque dans des études potentiostatique et voltamétrique. On décrit l'observation de courant d'anneau anodique sous des conditions potentiostatiquement cathodiques; aucune observation de ce genre n'avait été rapportée dans la littérature jusqu'à maintenant.
[Traduit par le journal]

Introduction

Recent investigations on the electrochemical nature of lead in aqueous chloride solutions have been reported elsewhere (1, 2). The purpose of the present work is to characterize the dissolution reactions that occur prior to and after passivation of the lead electrode. This may be accomplished by using a rotating ring-disc electrode (3, 4), since a potentiostatically controlled ring acts as a probe for the detection of soluble species discharged by the disc. If the collection efficiency (5) of the ring-disc system is known it is possible to establish what fraction of the anodic disc current is due to the dissolution reaction.

Experimental

Lead of 99.999% purity was obtained from Alfa Inorganics, Inc. Ring-disc measurements were made on both a rotating Pb ring – Pb disc electrode (RPbR–PbDE), and a rotating Pt ring – Pb disc electrode (RPtR–PbDE). The disc and ring were embedded in Teflon. When a Teflon separator alone was used to separate the disc and ring, a 20 kohm resistance was observed between the two electrodes. Electrical contact was presumably occurring as a result of fine lead particles depositing within the pores of the Teflon separator. This problem was eliminated by using a 0.07 mm PVC sleeve (Ideal-Hellerman (Canada) Ltd.) around the disc for additional insulation. This arrangement gave a resistance better than 10^3 Mohms between the ring and disc electrodes.

The disc, internal ring, and external ring radii of the RPbR–PbDE were 0.302, 0.354, and 0.416 cm, respectively. The corresponding dimensions for the RPtR–PbDE were 0.296, 0.347, and 0.407 cm, respectively. The calculated collection efficiency, N, was 0.29 for the RPbR–PbDE and 0.28 for the RPtR–PbDE. Smaller ring-disc gap separation resulted with shorting between the ring and disc due to plating out of lead. Experimentally, the collection efficiency was generally found to be 0.28 ± 0.04. A higher value of N than that predicted by theory is explained by a change in ring-disc geometry resulting as a consequence of the large amounts of lead depositing on the ring. Since the lead preferentially deposited on the innermost part of the ring, the gap separation between the ring and disc was constantly changing, and unless the electrode was cleaned periodically, collection efficiencies of the order of 0.45 were obtained. An added complication was encountered when using the RPtR–PbDE. Since the hydrogen overpotential is different on Pt and Pb, it was hard to obtain reproducible results once Pb started depositing on the Pt ring. Hence, unless otherwise stated, most experiments described in this paper involved the use of the RPbR–PbDE. The RPtR–PbDE was only used in order to verify certain experimental findings obtained with the RPbR–PbDE.

The mounted ring-disc electrode was rotated with a

Beckman variable drive assembly Model No. 188501. The lead surface was cleaned with a hydrogen peroxide–acetic acid mixture (6), and finally rubbed with microcloth (Buehler Limited). Electropolishing resulted with preferential dissolution around the edges of the disc giving rise to a hemispherical surface, and was consequently not used.

AnalaR reagent grade chemicals were employed and solutions made up with triply distilled water. NaCl solutions of various p*H* were prepared by addition of the requisite amount of HCl in some experiments. Nitrogen gas was passed through the solution prior to electrolysis and maintained with a slight pressure over the solution during an experiment. All experiments were conducted at room temperature.

A PAR model 170 Electrochemistry System was used for most disc electrode measurements. The potential at the ring was maintained by a second floating-ground potentiostat (Wenking type 70 HP10) using another counter electrode, as described elsewhere (7). A Shielded Line Isolator (Berkleonics, Inc.) was also employed to ensure isolation of the two instruments; however, this gave the same results obtained by simply floating one of the instruments. In order to verify that no coupling was occurring between the ring and disc electrodes, a Wenking Potentiometer (type PPT69) was used to test the constancy of the ring potential during an experiment. At no time did the ring potential change by more than ± 0.1 mV from its potentiostatted value. Ring currents were monitored on a Honeywell type 530 XY recorder. A Wenking Model 61RH Potentiostat was also used for some measurements.

The reference electrode was saturated calomel, and all potentials mentioned in this paper refer to this electrode. The thin Luggin capillary was mounted at 1–2 mm below the center of the disc electrode throughout all the experiments.

Results and Discussion

(a) Ring Polarograms and Titration Curves (11)

A ring polarogram for the RPbR–PbDE in 3% NaCl[1] is shown in Fig. 1. Curve (*a*) represents the residual ring current, while curve (*b*) is the ring polarogram obtained by holding the disc potential at -480 mV. The disc current was constant at 0.95 mA. A collection efficiency of about 0.29 was observed for the entire potential range shown. This suggests that the ring current was limited by diffusion of soluble Pb^{2+} species to the surface of the ring within this range of potentials.

Ring-disc titration curves for the RPbR–PbDE in 3% NaCl and 0.5 *M* HCl, at electrode rotation speed $\omega = 25$ Hz, were attempted. The disc current was galvanostatically controlled and the ring currents were corrected for the residual current. In 0.5 *M* HCl, the collection efficiency was found to be about 0.28 for the whole range of disc currents shown (Fig. 2). However, in 3% NaCl, the collection efficiencies were significantly lower than 0.28 for low disc currents (<5 mA), but they eventually approached the theoretical value at higher disc currents. Therefore the data for NaCl were not plotted in Fig. 2, because such a graphical representation does not depict what is commonly known as a ring-disc titration curve (11). The observations in 3% NaCl can be explained by the removal of a small concentration of soluble Pb^{2+} species. Since the p*H* of a 3% NaCl solution is about 6.5, the formation of PbOHCl in the vicinity of the disc is not unlikely (2). The inability to detect PbOHCl at the ring may be due to the insolubility of lead hydroxychloride.

[1]3% NaCl in normal scientific units corresponds to approximately 0.5 mol dm^{-3}.

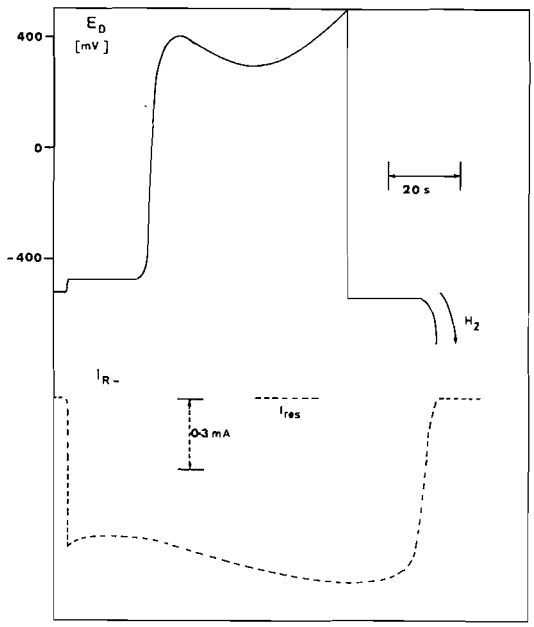

FIG. 3. Galvanostatic charging curve for the Pb disc electrode in 0.5 *M* HCl at 13 mA/cm^2; ω = 25 Hz (—). Corresponding ring current – time profile; E_R = −700 mV (---).

(b) Galvanostatic Studies

Constant current charging curves for Pb in aqueous chloride solutions were characterized by two anodic potential regions (2). X-Ray powder diffraction analysis of the products taken from the electrode surface in the course of both oxidation stages indicated the presence of $PbCl_2$ only. Figure 3 shows a galvanostatic transient for Pb in 0.5 *M* HCl at 13 mA/cm^2, and at ω = 25 Hz. The corresponding ring current – time profile is also shown; the ring was held at a cathodic potential of −700 mV. The ring current remained essentially constant for the duration of the first anodic plateau at the disc. The value of the ring current during this first disc potential region was about 0.57 mA. From the collection efficiency of the ring-disc electrode (0.29), one can calculate that only 50% of the total disc current was utilized in building up a passivating layer of $PbCl_2$. It is difficult to postulate whether the Pb^{2+} species reduced at the ring originated from a simple electrochemical dissolution step

[1] $$Pb \rightarrow Pb^{2+} + 2e^-$$

or from a chemical dissolution of the $PbCl_2$ layer being formed.

TABLE 1. Q_D and Q_R *vs.* ω data for galvanostatic studies

ω (Hz)	Q_D (mC)	Q_R (mC)	% of total charge due to dissolution
4	52	43	17
9	56	44	21
16	76	61	20
25	110	63	43
36	168	67	60
49	216	68	69

During the second disc potential region (*i.e.*, after passivation of the disc), the ring current increased slightly and finally levelled off to a steady value, despite the fact that the disc potential continued to increase. The ring current was observed to remain constant regardless of whether the disc was subsequently reduced or placed on open circuit. The constancy in ring current is highly indicative of chemical dissolution at the disc, possibly caused by a chemical breakdown of the passivating $PbCl_2$ layer. This reaction may be represented by

[2] $$PbCl_{2(surf)} + nCl^- \rightarrow PbCl_{2+n}^{n-}$$

Chemical breakdown of this nature has been previously postulated (1, 2, 8).

From experimental knowledge of the chemical dissolution of the passivating $PbCl_2$ layer, it was possible to estimate the charge associated with passivating the Pb disc electrode. This was accomplished by first allowing the disc to passivate at a current density of 13 mA/cm^2, and followed immediately by switching the disc current off. The ring current was then recorded as a function of time until all the $PbCl_2$ present on the surface of the disc had dissolved. Table 1 gives the total charge required to passivate the disc for different rotation speeds:

[3] $$Q_D = \tau i_D$$

where τ = time required to passivate the disc electrode under galvanostatic charging conditions, i_D = disc current. The charge accumulated by the ring after the disc current was turned off is given by

[4] $$Q_R = \int_{t=0}^{t=t_f} i_R' \, dt$$

where Q_R = charge corresponding to the passivating layer on the disc, and t_f is the time required to completely dissolve the passivating layer and

[5] $$i_R' = (i_R - i_{res})/N$$

where i_R = ring current, i_{res} = residual current at the ring, and N = collection efficiency.

Table 1 shows that the amount of charge lost due to dissolution during surface formation of $PbCl_2$ is large and increases with increasing rotation speed. It has been previously mentioned that the collection efficiency changes during the course of such an experiment owing to changes in geometric configuration brought about by the plating of Pb on the ring. The large variations indicated by the data regarding Q_R as a function of rotation speed may possibly be associated with the changes in collection efficiency.

By assuming the total charge required to passivate the disc to be about 45 mC, and taking the density of $PbCl_2$ as 5.9 g/cm^3, the thickness of the passivating layer was estimated to be about 4000 Å.

(c) Potentiostatic Experiments

Disc current – time measurements at low overpotentials (less than 70 mV) showed typical steady currents under controlled rotation conditions. The ring held at a reducing potential of −700 mV maintained a steady cathodic current. Ring to disc current ratios were generally within 0.02 of the theoretical collection efficiency.

A potentiostatic transient for a Pb disc in 3% NaCl, under rotating conditions, and at an oxidizing potential of −380 mV is shown in Fig. 4. A growth transient is displayed and a reactivation of the electrode occurs subsequent to passivation. The cathodic transient was recorded at a disc potential of −550 mV. The corresponding ring current – time profile is also shown for a ring potential of −700 mV. Except for the small initial dissolution part of the anodic disc transient, the ring current was found to be constant and independent of disc passivation or reactivation. Also, at any chosen rotation speed, the value of the ring current was independent of the potential applied to the disc, when the potential was sufficiently anodic to give rise to a growth transient. As with the galvanostatic studies, the same ring current was observed if the disc current was suddenly switched off. This suggests that the reduction step at the ring is diffusion control due to the release of soluble Pb^{2+} species by a chemical dissolution reaction at the surface of the disc. Under these conditions the limiting ring current is given by

$$[6] \qquad i_R = (nNFAc_0D)/\delta$$

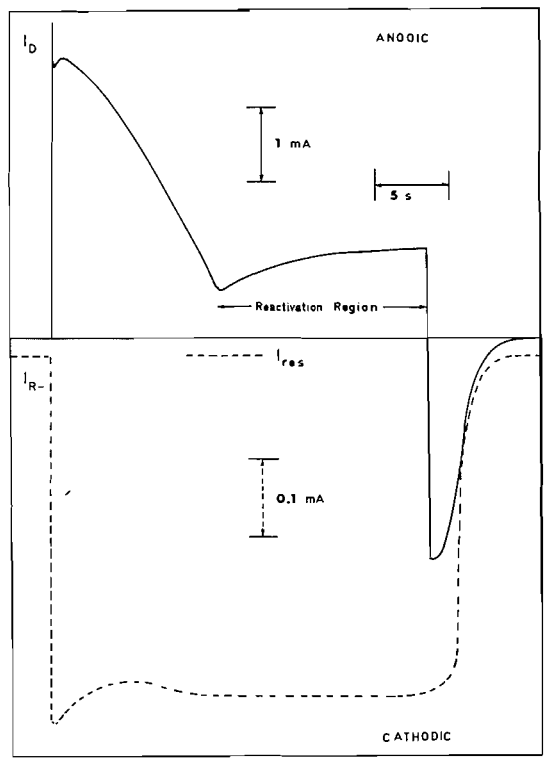

FIG. 4. Current – time transients for the Pb disc recorded potentiostatically in 3% NaCl. Potential stepped to −380 mV; reducing potential, −550 mV (—). Current *vs.* time curve for the Pb ring; E_R = −700 mV (---).

where n = number of electrons, F = Faraday constant, A = disc electrode surface area, c_0 = the concentration of soluble Pb^{2+} species in equilibrium with the disc, D = diffusion coefficient, and δ = diffusion layer thickness. The collection efficiency N, in eq. 6 corrects for the actual amount of current measured at the ring (i_R). From Levich (9), the thickness of the diffusion layer is

$$[7] \qquad \delta = 1.62\, D^{1/3}\nu^{1/6}\omega^{-1/2}$$

where ν = kinematic viscosity. Combining eqs. 6 and 7 gives

$$[8] \qquad i_R = (nFNAc_0D^{2/3}\omega^{1/2})/1.62\nu^{1/6}$$

A plot of i_R *vs.* $\omega^{1/2}$ for Pb in 3% NaCl is shown in Fig. 5. As stated *vide supra* the value of the oxidizing potential at the disc is immaterial. The data presented in Fig. 5 was taken after $PbCl_2$ had been formed and the disc placed on open circuit (see Fig. 6). If the diffusion coeffi-

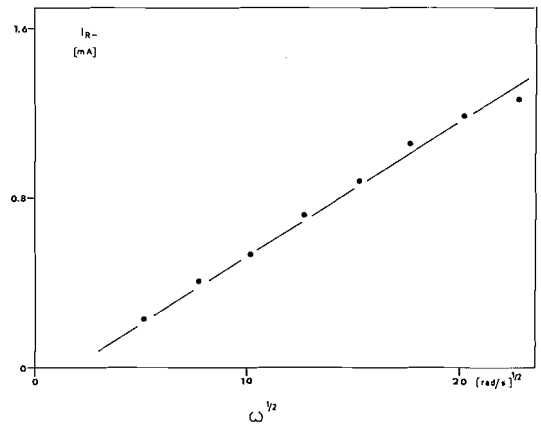

FIG. 5. Plot of i_R *vs.* $\omega^{1/2}$ for the Pb ring electrode in 3% NaCl showing chemical dissolution at the disc.

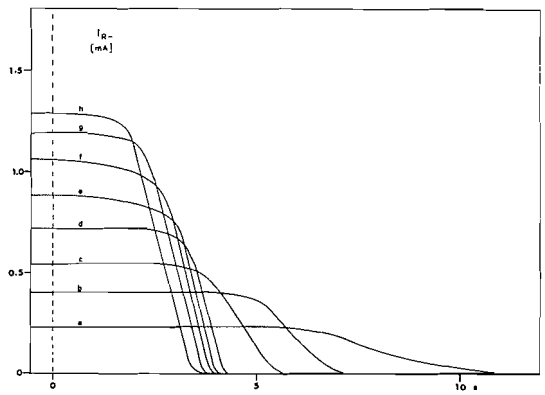

FIG. 6. Ring current – time transients recorded subsequent to passivation at the disc; $E_R = -700$ mV. The dotted line refers to the point at which the disc was switched off. (*a*) $\omega = 4$ Hz, (*b*) 9 Hz, (*c*) 16 Hz, (*d*) 25 Hz, (*e*) 36 Hz, (*f*) 49 Hz, (*g*) 64 Hz, (*h*) 81 Hz.

cient for the soluble Pb^{2+} species is assumed to be 10^{-5} cm^2/s in eq. 8, the concentration of soluble Pb^{2+} in equilibrium with the disc can be estimated to be 5×10^{-3} *M*, which compares reasonably well with the calculated value of 6.73×10^{-3} *M* using the solubility data of Table I in a paper published by Lewin (10).

Similar to the galvanostatic studies, it was possible to estimate an approximate thickness of the passivating layer. A series of ring current – time transients at different ω is shown in Fig. 6. The point at which the disc was switched off is indicated. These experiments were conducted with a RPbD–PbRE in 3% NaCl; the disc was stepped to -350 mV and allowed to passivate while the ring current was monitored with a reducing potential of -700 mV. Q_R as defined by eq. 4 for different ω is presented in Table 2. The charges were generally found to be significantly smaller than those associated with passivating the disc under galvanostatic conditions. Table 2 also gives the percent of the total charge lost due to dissolution during the formation of the passivating $PbCl_2$ layer. These values show fair agreement with the corresponding results obtained under constant current conditions. Based on an average value of Q_R in Table 2, the thickness of the passivating layer under potentiostatic conditions was estimated to be about 700 Å. A slight change in Q_R (about 3 mC) was observed when the disc was stepped to another anodic potential (-300 mV); such a small change in Q_R is not sufficiently reliable to draw any significant conclusion about the system under investigation.

TABLE 2. Q_R from potentiostatic studies as a function of ω

ω (Hz)	Q_R (mC)	% of total charge due to dissolution
4	7.2	19

36	8.2	49
49	8.8	53
64	9.4	54
81	10.2	60

(d) Cyclic Voltammetry

Figure 7 shows a rotating ring disc experiment conducted in 3% NaCl at p*H* 2.2. The ring electrode was held constant at -700 mV, while the disc was subjected to a linear potential sweep. Only at the very beginning of the rise of the disc current did the reduction current at the ring show corresponding changes due to an electrochemical dissolution of the Pb disc. Once the electrochemical dissolution step was replaced by the formation of a surface film, the ring currents were found to be steady, and independent of disc potential, with the exception of a slight change in ring current at about the point of disc passivation.

Chemical dissolution of the electrode surface layer of $PbCl_2$ was experimentally verified by switching off the disc current after passivation. The ring current fell steadily, eventually reaching the residual current value, demonstrating that

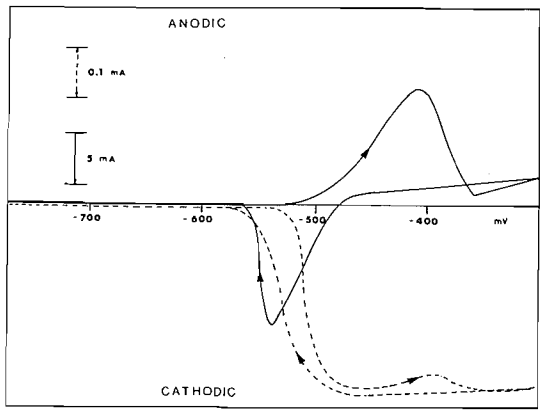

FIG. 7. Ring-disc experiment in 3% NaCl at pH 2.2; ω = 25 Hz. Disc potential swept at v = 20 mV/s; E_R = −700 mV. (---) i_R, (—) i_D.

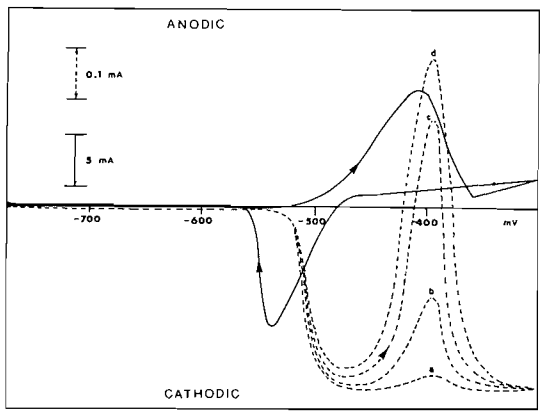

FIG. 8. Ring-disc experiment in 3% NaCl at pH 2.2; ω = 25 Hz. Disc potential swept at v = 20 mV/s. E_R held constant at (*a*) −700 mV, (*b*) −650 mV, (*c*) −600 mV, (*d*) −550 mV. (---) i_R, (—) i_D.

the surface layer on the disc had completely dissolved.

(e) Some Apparently Unusual Observations

The ring-disc results presented so far have involved monitoring the ring current at a ring potential of −700 mV. When a lower cathodic overpotential was applied to the ring an unexpected behavior in i_R was observed. Figure 8 shows a series of ring-disc experiments conducted in 3% NaCl at pH 2.2. As in Fig. 7, the Pb disc electrode was subjected to a voltammetric sweep while the ring current was monitored. However, a number of different ring potentials were used. Curve (*a*) corresponds to a reducing potential of −700 mV, curve (*b*) −650 mV, curve (*c*) −600 mV, and curve (*d*) −550 mV. When the disc began to passivate the ring current showed a sudden excursion in the anodic direction, and if the ring potential was less cathodic (curves (*c*) and (*d*)), the ring current actually became anodic. This result was found to be independent of pH (values $\leqslant$6.5) of the solution. It was quite sensitive to rotation speed by displaying increasing positive ring currents with faster rotation speeds. These investigations have also shown a dependence on Cl^- ion concentration. The effect appears to decrease somewhat with increasing Cl^- ion concentration (from 0.5 to 3.0 M), but the anodic ring current excursion persists. Potentiostatic transient studies showed similar effects. The results obtained under galvanostatic studies, on the other hand, were not well defined. Although there was a tendency for ring currents to show a slightly smaller cathodic value at the point of passivation, with corresponding decreasing cathodic overpotentials; no anodic currents were ever observed.

As mentioned in the Experimental section, the ring potential was monitored with a potentiometer, and at no time was coupling observed between the two potentiostats. The result observed is not an experimental artifact (12) because it has been checked often under varying conditions by three independent workers. The behavior may possibly be due to a concurrent anodic process occurring together with the reduction of soluble Pb^{2+} species. The formation of an unstable species such as Pb^+ at the disc seems unlikely in view of the magnitudes of currents and times involved. A plausible explanation could involve oxidation of the Pb at the ring. This speculation is possible only if the value of the reversible potential for the Pb/Pb^{2+} couple changes so as to make what was initially a cathodic overpotential to an anodic overpotential at the point of passivation.

Open circuit measurements of the Pb electrode as a function of $PbCl_2$ concentration have confirmed that a Nernstian behavior is followed according to the relation

$$[9] \qquad E_{Pb/Pb^{2+}} = E^0 + \frac{RT}{2F} \ln a_{Pb^{2+}}$$

where $E_{Pb/Pb^{2+}}$ is the reversible potential for the Pb/Pb^{2+} couple. If at the point of passivation the concentration of soluble Pb^{2+} species arriving at the ring is considerably lessened, the

For personal use only.

reversible potential of the ring should shift to a more negative value according to eq. 9. When this happens the overpotential at the ring (defined as $E_{\text{Potentiostatted}} - E_{Pb/Pb^{2+}}$) will decrease accordingly. In view of the reversible nature of this system (1), even a small change in $E_{Pb/Pb^{2+}}$ at the point of disc passivation may be sufficient to give rise to an anodic ring overpotential, which can qualitatively account for the observed anodic excursions in ring current.

Some indirect corroborative experiments to support the above-mentioned tentative explanation may be offered. If a $PbCl_2$ layer was allowed to form on the disc, and subsequently the disc current was switched off while the open circuit potential at the ring was monitored, the ring potential then remained steady for a short period of time and later slowly decreased to a more negative value before finally levelling off. This experiment was essentially the same as those previously described except that now the ring open circuit potential was monitored instead of the ring current. The change in rest potential at the ring from the time the disc current was switched off to the time when all the $PbCl_2$ on the disc had dissolved was about 60 mV. Although it is not possible to measure directly the rest potential at the ring during an experiment when the disc was under an applied potential, changes in the reversible potential of the Pb ring cannot be discounted.

It would indeed be highly desirable to offer at least an empirical semiquantitative treatment to fit the given explanation of the anodic excursion, say for example, to predict some shape of a curve or model in order to calculate the concentration of Pb^{2+} which corresponds to the observed anodic currents. However, it does not seem possible at present to make any quantitative estimates of the reversible potential at the ring at any time during the experiment, because the entire process is a dynamic one. Experimentally we could not conceive any viable way to measure the reversible potential at the ring during a potentiodynamic sweep at the disc electrode used in this work.

Nuclear Magnetic Resonance Evidence for High Barrier of Conformational Inversion in Hexahydro-3,3,7,7-tetramethyl-1,2-oxazepine-5-one

RODERICK E. WASYLISHEN,[1] KENNER C. RICE, AND ULRICH WEISS

Laboratory of Chemical Physics, National Institute of Arthritis, Metabolism, and Digestive Diseases, National Institutes of Health, Bethesda, Maryland 20014

Received July 8, 1974

RODERICK E. WASYLISHEN, KENNER C. RICE, and ULRICH WEISS. Can. J. Chem. **53**, 414 (1975).

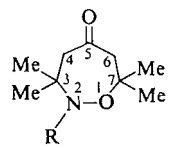
Variable temperature proton n.m.r. spectra indicate an activation energy of 19.0 ± 0.5 kcal/mol for conformational equilibration in hexahydro-3,3,7,7-tetramethyl-1,2-oxazepine-5-one. It is suggested that the rate process involves slow conformational interconversion of the seven-membered ring and not slow inversion at the nitrogen atom. The synthesis of several related 1,2-oxazepines is described.

RODERICK E. WASYLISHEN, KENNER C. RICE et ULRICH WEISS. Can. J. Chem. **53**, 414 (1975).

Les spectres r.m.n. du proton, à température variable, indiquent que l'énergie d'activation pour l'équilibre conformationnel de l'hexahydrotétraméthyl-3,3,7,7 oxazépinone-1,2,5 est de 19.0 ± 0.5 kcal/mol. On suggère que le processus dynamique implique une interconversion conformationnelle lente du cycle à sept membres qu'une inversion lente autour de l'atome d'azote. On décrit la synthèse de plusieurs oxazépines-1,2 reliées au produit principal.

[Traduit par le journal]

In an earlier publication (1) the synthesis of hexahydro-3,3,7,7-tetramethyl-1,2-oxazepine-5-one (**1***a*) and two of its derivatives (**1***b* and *c*) was described.



1

a R = H
b R = COC_6H_5
c R = Me

Here we wish to discuss the observed (1) magnetic nonequivalence of the four methylene hydrogens and the four methyl groups in the 60 MHz proton n.m.r. spectra of **1***a*, *b*, and *c* at room temperature. Above room temperature, the proton n.m.r. spectra of the methylene and methyl groups of **1** first show broadening characteristic of intermediate exchange rates (2, 3). Finally, at temperatures above 150 °C, the resonances of the four methylene hydrogens simplify to two relatively sharp resonances (one each for the two hydrogen atoms on C_4 and C_6, respectively), while the four resonances observed for the four nonequivalent methyl groups at room temperature collapse into two resonances (one for the two methyl groups at C_3 and one for the two at C_7).

By a careful study of the methyl resonances at several temperatures it has now been possible to obtain an estimate of T_c, the coalescence temperature, and thus an estimate of the free energy of activation at this temperature, using the expression (4):

$$\Delta G_c^{\ddagger} = 4.57\, T_c(9.97 + \log_{10} T_c/\Delta\nu)$$

The observed chemical shift differences, $\Delta\nu$, when the rate of exchange is slow, the observed coalescence temperature, and the calculated $\Delta G_c^{\ddagger}$ values are listed in Table 1, which also gives the experimental details. It will be seen that all three compounds show exceptionally high coalescence temperatures and energy barriers.

Several influences could be responsible, singly or in combination, for the large energy barriers; the most obvious of these are steric interactions between the two pairs of *gem*-methyl groups leading to slow conformational inversion of the seven-membered ring, and pyramidal inversion of the nitrogen which would also be slow on the n.m.r. time scale. Of these, the possibility of slow nitrogen inversion can be eliminated. Barriers to

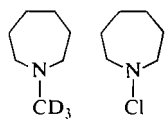
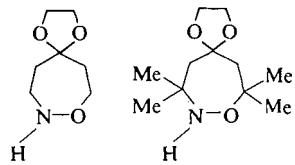
TABLE 1. Spectral data and activation parameters for compounds **1***a*, *b* and *c*

Compound	Solvent[a]	Δν (Hz)[b]	T_c (°K)[c]	$\Delta G_c^{\ddagger}$ (kcal/mol)[d]
1*a*	DMF-d_7	8.5	359	19.0
		4.1	350	19.0
	Toluene-d_8	19.5	374	19.2
1*b*	DMF-d_7	22.5	388	19.9
		10.5	377	19.9
	Toluene-d_8	21.4	395	20.3
		17.6	391	20.2
1*c*	DMF	9.1	407	21.6

[a]The concentration of all samples was approximately 5 mol% in dimethylformamide-d_7 (DMF) or toluene-d_8. A small amount of tetramethylsilane (TMS) was added and each sample was thoroughly degassed by the freeze–thaw technique and sealed under vacuum.
[b]All n.m.r. spectra were measured at a sweep width of 1 or 2 Hz/cm as a function of temperature on a Varian A-60 spectrometer. All Δν values refer to methyl resonances and were obtained at approximately 308 °K.
[c]Temperatures were measured using the standard ethylene glycol samples.
[d]Errors in $\Delta G^{\ddagger}$ are probably less than 0.2 kcal/mol.
[e]The coalescence temperature was not reached at the b.p. of toluene-d_8.



2*a* **2***b*

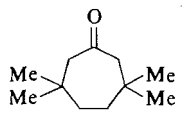


3*a* **3***b*

nitrogen inversion in saturated compounds with seven-membered rings seldom exceed 10 kcal/mol (5); *cf.* the value of 6.4 kcal/mol found for **2***a* (6). It is well known (5) that direct bonding of the nitrogen to an electronegative group increases the barrier to inversion but the observed energies (*e.g.*, 8.4 kcal/mol for **2***b* (6)) fall far short of those needed to explain our findings on **1***a–c*. Furthermore, the presence of bulky substituents on or close to a pyramidal nitrogen generally results in lowering of barriers to nitrogen inversion (5), while we found the barrier in **1***c* even higher than that in **1***a* or *b*.

To examine the influence of the *gem*-methyl groups on the energy barriers we have observed for **1***a*, *b*, and *c*, we have prepared and investigated compounds **3***a* and **3***b*.[2] For a 10 mol% solution of **3***b* in DMF-d_7 the coalescence temperature for one set of methyl groups (Δν = 18.5 Hz) was 88 °C and $\Delta G^{\ddagger}$ = 18.6 kcal/mol, not very different from the value obtained for **1***a*. On the other hand, room-temperature spectra of a 5 mol% solution of **3***a* in toluene-d_8, taken at 60, 100, and 220 MHz, show that the pairs of protons at C-3, C-4, C-6, and C-7 each have equivalent chemical shifts. At temperatures below −60°, these signals begin to show broadening but it has so far not been possible to obtain analyzable spectra in the region of slow exchange. However, because T_c is less than −60 °C, it is unlikely that $\Delta G^{\ddagger}$ should be greater than 12 kcal/mol.

Since the activation energy for site exchange in **3***b* seems at least 6 kcal/mol larger than that in **3***a*, our results suggest that the large barrier in **1***a–c* is due to slow conformational inversion of the seven-membered ring and that the methyl groups play a role. However, they cannot be the only influence responsible. The $\Delta G^{\ddagger}$ values for **1***a–c* listed in Table 1 are more than 10 kcal/mol larger than the ones reported recently by Borgen (7) for the geometrically similar compound, 3,3,6,6-tetramethylcycloheptanone (**4**). In contrast to the results for **1***a–c*, magnetic nonequivalence of the methyl and methylene protons



4

[2]Initial attempts to prepare hexahydro-1,2-oxazepine-5-one, the parent ketone of **3***a*, have been unsuccessful so far.

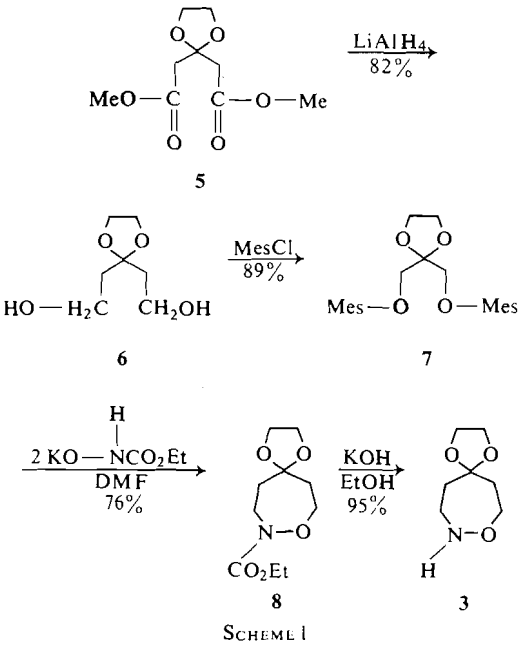

SCHEME 1

of **4** is only observed at temperatures below −80 °C. From the coalescence temperature, an activation energy of 8.5 kcal/mol was calculated for site exchange in **4**. The nature of this inversion barrier has been discussed in detail by Borgen and Dale (8).

The large barriers for **1** compared with those observed for **4** may involve a partial rotation of the N—O bond which entails eclipsing of the lone pairs on nitrogen and oxygen. There is now considerable experimental evidence that lone-pair electrons on adjacent atoms in a ring increase the barrier to rotation about the bond joining them, and thus increase the barrier to ring inversion. (See ref. 9 and references therein.) Also, recent *ab initio* calculations by Radom *et al.* (10) predict a barrier to rotation of approximately 11.7 kcal/mol in hydroxylamine. The corresponding barrier in ethane is only 2.928 ± 0.025 kcal/mol (11). In the case of **3***a*, eclipsing of lone pairs on nitrogen and oxygen may not be necessary for conformational inversion of the seven-membered ring. Thus our results indicate that motion about the various ring skeleton bonds in **1***a–c* and about **3***b* is strongly influenced by the presence of the methyl groups at C_3 and C_7.

Synthesis of 3a and 3b

The synthetic sequence shown in Scheme 1 was used to prepare **3***a*; it is similar to one employed by Pifferi and Consonni (12) for the preparation of hexahydro-1,2-oxazepine. Reduction of **5** to **6** was improved over that given in the literature (13) by using tetrahydrofuran as the solvent and alkali (14) for working up the reaction mixture. The remaining steps in the sequence proceeded smoothly and require no comment.

Attempted ketalization of 3,3,7,7-tetramethyl-1,2-oxazepine-5-one (**1***a*) to **3***b* by standard ketalization procedures with ethylene glycol and an acid catalyst under azeotropic removal of water was unsuccessful, as was transketalization (15) using dimethylformamide ethylene ketal and acetic or methanesulfonic acid as catalysts. Transketalization of **1** to **3***b* was accomplished, however, using 2-ethyl-2-methyl-1,3-dioxolane and a catalytic amount of *p*-toluenesulfonic acid according to the method of Dauben (16).

Experimental

Boiling points and *melting points* (hot stage) are uncorrected. The i.r. spectra were recorded on a Perkin-Elmer model 257 instrument; for proton n.m.r. spectra either a Varian A-60, HA-100, or HR-220 spectrometer was used. Line positions are given using the δ scale, with tetramethylsilane as internal standard. The multiplicity, integrated peak areas, and coupling constants are indicated in parentheses. The mass spectra were obtained using a Hitachi-Perkin-Elmer RMU 6E instrument. Microanalyses were performed by the Analytical Section, National Institutes of Health.

2,2-Bis(2-hydroxyethyl)-1,3-dioxolane (6)

This material was prepared using a modification of the method previously described (13). 2,2-Biscarbomethoxymethyl-1,3-dioxolane (17) (**5**) (91.5 g, 0.42 m) in dry tetrahydrofuran (300 ml) was added dropwise to a slurry of lithium aluminum hydride (26.6 g, 0.7 m) in dry tetrahydrofuran (1500 ml). After the addition was complete, the reaction mixture was refluxed for 45 min, cooled, and water (27.0 ml) in dry tetrahydrofuran was added dropwise, followed by the dropwise addition of 15% aqueous sodium hydroxide (27.0 ml). After stirring for 15 min,

water (81 ml) in tetrahydrofuran (150 ml) was added dropwise, and stirring was continued for 30 min. The solids were then filtered, and washed well with tetrahydrofuran. The filtrate and washings were combined and evaporated *in vacuo*. Distillation of the residue in high vacuum gave 56.1 g (82%) of 2,2-bis(2-hydroxyethyl)-1,3-dioxolane (**6**); b.p. 126–128°/0.12 mm (lit. (13) b.p. 105–110°/0.01 mm., 53% yield); n.m.r. (60 MHz, $DCCl_3$) δ 1.92 (triplet, 4H, J = 6.0), 3.46 (singlet, 2H, exchanges with D_2O), 3.56 (triplet, 4H, J = 6.0), and 4.01 (singlet, 4H).

2,2-Bis(2-mesyloxyethyl)-1,3-dioxolane (7)

To a stirred solution of 2,2-bis(2-hydroxyethyl)-1,3-dioxolane (**6**) (25.0 g, 0.154 m) dissolved in dry pyridine (200 ml), mesyl chloride (45.0 g, 0.394 m) was added dropwise, keeping the temperature between 20 and 25° (ice bath). After the addition was complete, stirring was continued for 1 h. The reaction mixture was next poured onto ice, stirred for 15 min, and extracted with chloroform (3 × 150 ml). The combined chloroform extracts were backwashed with sufficient ice-cold 10% hydrochloric acid to remove the pyridine, dried with anhydrous magnesium sulfate, filtered, and the chloroform was evaporated under reduced pressure (bath temperature < 30°). The crystalline residue was recrystallized from 95% ethanol to give 43.6 g (89%) of slightly colored 2,2-bis-(2-mesyloxyethyl)-1,3-dioxolane (**7**), m.p. 85–88° (dec.). Recrystallization from methanol (charcoal) gave white material, m.p. 89–91° (dec.). The compound slowly decomposed on standing at room temperature but could be kept for several weeks at −5°; n.m.r. (60 MHz, $DCCl_3$) δ 2.17 (triplet, 4H, J = 7.0 Hz), 3.05 (singlet, 6H), 4.0 (singlet, 4H), and 4.36 (triplet, 4H, J = 7.0 Hz); i.r. (chloroform) 1340 and 1358 cm^{-1} among others.

Anal. Calcd. for $C_9H_{18}S_2O_8$: S, 20.14. Found: S, 19.93.

Potassium N-Hydroxyurethane

Potassium metal (9.15 g, 0.228 m) was dissolved in a mixture of absolute ethanol (200 ml) and dry ether (300 ml). *N*-Hydroxyurethane (24.0 g, 0.228 m) in dry ether (100 ml) was added dropwise with stirring. Absolute ether (400 ml) was next added during 15 min. After stirring for 15 min, the solid was filtered, washed with ether, and dried *in vacuo* to give 30.6 g (93%) of light yellow potassium *N*-hydroxyurethane.

Hexahydro-2-carbethoxy-1,2-oxazepine-5-one Ethylene Ketal (8)

To dry dimethylformamide (1.0 l) which had been preheated to 85°, were added in one portion the bismesylate (**7**) (10.3 g, 0.033 m) and potassium hydroxyurethane (10.0 g, 0.0694 m) while stirring. After 10 min, another addition of **7** (10.3 g, 0.033 m) and potassium hydroxyurethane (10.0 g, 0.0694 m) was carried out. Fifteen minutes later final portions of **7** (10.3 g, 0.033 m) and potassium hydroxyurethane (17.4 g, 0.121 m) were added. The reaction mixture was then heated with stirring at 90–100° for 1 h. At the end of this time the batch was cooled, filtered, and the solids were washed with chloroform (50 ml). The combined filtrate and washings were evaporated *in vacuo*; the residue was taken up in chloroform (350 ml) and washed with water (4 × 50 ml). The chloroform solution was dried (anhydrous magnesium sulfate), filtered, and the chloroform evaporated *in vacuo*. The distillation of the residue *in vacuo* gave hexahydro-2-carbethoxy-1,2-oxazepine-5-one ethylene ketal (**8**) (17.17 g, 76%), b.p. 125–127°/0.45 mm; n.m.r. (60 MHz, $DCCl_3$) δ 1.28 (triplet, 3H, J = 7.0 Hz), 1.98 (2 triplets, 4H, $J \sim 6.5$ Hz), 3.67 (triplet, 2H, $J \sim 6.5$ Hz), 3.96 (singlet, 4H), 4.03 (triplet, 2H, $J \sim 6.5$ Hz) and 4.20 (quartet, 2H, J = 7.0 Hz). Mass spectrum, M^+ 231; i.r. (liquid film) 1700 cm^{-1} (C=O).

Anal. Calcd. for $C_{10}H_{17}NO_5$: N, 6.05. Found: N, 6.24.

Hexahydro-1,2-oxazepine-5-one Ethylene Ketal (3a)

Hexahydro-2-carbethoxy-1,2-oxazepine-5-one ethylene ketal (9.25 g, 0.04 m) was added to a solution of potassium hydroxide (6.6 g of 85%, 0.1 m) in 125 ml of absolute ethanol and the reaction mixture was refluxed for 1.5 h. It was then cooled, and the potassium carbonate that had precipitated during the reflux period was filtered and washed with ethanol (25 ml). The combined ethanol filtrate and washings were evaporated *in vacuo* to a syrup, water (35 ml) was added, and the p*H* of the mixture adjusted to 10 with acetic acid. After saturating with salt, the aqueous solution was extracted with chloroform (4 × 50 ml). The combined chloroform extracts were dried (anhydrous magnesium sulfate), filtered, and evaporated *in vacuo*. The residual oil was distilled in high vacuum to yield 6.02 g (95%) of hexahydro-1,2-oxazepine-5-one ethylene ketal (**8**), b.p. 53–55°/0.06 mm; n.m.r. (60 MHz, $DCCl_3$) δ 1.78 (broad triplet, 2H, $J \sim 6$ Hz), 2.00 (triplet, 2H, J = 6.5 Hz), 3.70 (triplet, 2H, J = 6.5 Hz), 3.88 (singlet, 4H), and 5.55 (broad singlet, 1H). Mass spectrum M^+ 159, i.r. (liquid film) 3280, 1290, 1150 and 1075 cm^{-1} among others.

Anal. Calcd. for $C_7H_{13}NO_3$: N, 8.80. Found: N, 8.86.

3,3,7,7-Tetramethyl-1,2-oxazepine-5-one Ethylene Ketal (3b)

3,3,7,7-Tetramethyl-1,2-oxazepine-5-one (5.0 g) (**1a**) and *p*-toluenesulfonic acid monohydrate (500 mg) were added to 2-ethyl-2-methyl-1,3-dioxolane (44 g). The solution was refluxed while the 2-butanone formed was removed by slow distillation through a packed column. After 8 h, t.l.c. (silica gel 60 F 254, 30% ethyl acetate in hexane, 2,4-dinitrophenylhydrazine spray) showed essentially complete conversion to the ketal. The dark reaction mixture was evaporated to a syrup, taken up in hexane (200 ml), treated with Norite, and filtered. The hexane was evaporated *in vacuo* and the residue distilled in high vacuum. This gave 3.52 g (56%) of compound (**3b**), b.p. 53–57°/0.07 mm. For analysis the material was crystallized from hexane at −70° (m.p. ~ 29–31°) and redistilled *in vacuo*, b.p. 100–101°/5.0 mm; n.m.r. (220 MHz, $DCCl_3$) δ 0.95 (3H, singlet), 1.22 (6H, singlet), 1.32 (3H, singlet), 1.62–1.76 (3H, multiplet), 2.22 (1H, doublet, J = 14.0 Hz), 4.06–4.16 (2H, multiplet), 4.18–4.28 (2H, multiplet), and 4.65 (1H, broad, exchanges with D_2O). Mass spectrum, M^+ 215; i.r. (liquid film) 3260, 1359, 1208, 1088, 1030, and 970 cm^{-1} among others.

Anal. Calcd. for $C_{11}H_{21}NO_3$: N, 6.51. Found: N, 6.51.

The photochemistry of the $[Cr(RNH_2)_5Cl]^{2+}$ ions where R = H, CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9 has been investigated in water and in acetone/water solutions at p*H* 3. In water and in 33 w/w% acetone/water, the predominant reaction for each ion was found to be amine aquation to give predominantly *cis*-$[Cr(RNH_2)_4(H_2O)Cl]^{2+}$. Photolysis of $[Cr(CH_3NH_2)_5Cl]^{2+}$ in acidified acetone yielded a solvent substituted product $[Cr(CH_3NH_2)_4(S)Cl]^{2+}$ which has predominantly the *cis*-configuration but the extents of water and acetone substitution were not established. The amine quantum yields are almost solvent independent, only slightly wavelength dependent, and they decrease significantly in going from R = H to R = *n*-C_4H_9. The chloride quantum yields, which are of the order of 10^{-4} at 565 nm, are about an order of magnitude smaller than had been previously reported for $[Cr(NH_3)_5Cl]^{2+}$; they are several times larger at 401 nm. The chloride quantum yields show a significant decrease upon changing the solvent from water to 33% acetone/water.

The solvent independence of the main photochemical reaction suggests that the reaction is determined primarily by the photophysical properties of the reacting excited state. The different wavelength and solvent dependences of the amine and chloride quantum yields suggest that the two reactions do not originate from the same excited state. In addition the relative constancy of chloride yields as the ligand field strength of the ligands varies supports the idea that the reponsible state is not a ligand field state. Together with the increase in chloride quantum yield at shorter wavelengths, it suggests that the chloride originates from an excited state partaking of ligand to metal charge transfer character.

C. F. C. WONG et A. D. KIRK. Can. J. Chem. **53**, 419 (1975).

On a examiné, dans l'eau et dans des solutions aqueuses d'acétone à p*H* 3, la photochimie des ions $[Cr(RNH_2)_5Cl]^{2+}$ dans lesquels R = H, CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9. Dans l'eau et dans l'acétone aqueuse à 33% p/p, on a trouvé que la réaction principale pour chaque ion est l'hydratation de l'amine pour donner principalement le *cis*-$[Cr(RHN_2)_4(H_2O)Cl]^{2+}$. La photolyse de $[Cr(CH_3NH_2)_5Cl]^{2+}$, dans de l'acétone acidifiée conduit à un produit où il y a eu substitution par le solvant, $[Cr(CH_3NH_2)_4(S)Cl]^{2+}$ et ce complexe a principalement la configuration *cis*; on n'a toutefois pas établi les pourcentages de substitution par l'eau ou l'acétone. Les rendements quantiques de l'amine sont pratiquement indépendants du solvant, dépendent légèrement de la longueur d'onde et diminuent d'une façon importante lorsque l'on passe de R = H à R = *n*-C_4H_9. Les rendements quantiques en chlorure, qui sont de l'ordre de 10^{-4} à 565 nm, sont pratiquement 10 fois plus petits que ceux rapportés précédemment pour le $[Cr(NH_3)_5Cl]^{2+}$; ils sont beaucoup plus grands à 401 nm. Le rendement en chlorure diminue d'une façon importante lorsque le solvant passe de l'eau pure à de l'acétone à 33% dans l'eau.

Le fait que la réaction photochimique principale soit indépendante du solvant suggère que le cours de la réaction est déterminé principalement par les propriétés photophysiques des états excités réactionnels. La variation des rendements quantiques en amine et en chlorure suivant la longueur d'onde et le solvant indique que les deux réactions ne procèdent pas par le même état excité. De plus, le fait que les rendements quantiques du chlorure sont relativement constants lorsque le champ de force du ligand varie supporte l'idée que l'état excité responsable pour la réaction n'est pas un état rattaché au champ du ligand. Ces résultats, couplés avec le fait que le rendement quantique en chlorure augmente à basse longueur d'onde, suggèrent que le chlorure provient d'un état excité qui est attaché au transfert de charge entre le métal et le ligand.

Introduction

The proposal by Adamson (1) seven years ago that the mode of photoaquation of mixed ligand "non-octahedral" chromium(III) complexes could be predicted as preferential loss of the strong field ligand on the weak field axis served to stimulate a large number of studies. As a consequence the photochemical behavior of such compounds

For personal use only.

when irradiated in acidic aqueous solution is now much better characterized (2). It has emerged that the situation is more complicated than suggested by the above proposal. Many complexes do not follow the simple rule (3) and in addition the stereochemistry of the photoaquation process may be complex (2, 4). It now appears, however, that if the relative σ and π donating capabilities of the particular ligands in the complex are known (5), and if the relative extents of axial (d_{z^2}) and equatorial ($d_{x^2-y^2}$) labelization can be estimated (6), a reasonable prediction may be made of the mode of reaction (2) and perhaps even of the quantum yields (7). However, some aspects of the stereochemistry (4, 8), and the question of whether the reactions are essentially dissociative or associative in nature, remain unclear. All of the above refers to what is known about photolysis in aqueous solution.

This study of $[Cr(RNH_2)_5Cl]^{2+}$ complexes was undertaken to explore the effects of change of solvent on the photolysis modes and quantum yields, and in addition to explore for these compounds any trends in quantum yield with wavelength, temperature, and the nature of the group R. Underlying this was the question of whether the reaction modes would alter dramatically or not, whether this would lead to useful conclusions about the nature of the excited states involved, and whether the solvent played a role in determining the solution quantum yields.

A survey of the literature shows that very few studies of the photolysis of chromium(III) complexes have been undertaken in solvents other than water (1, 9). In addition most of the existing work has been concerned with quenching and energy transfer effects and has not brought to bear on the questions posed at the outset of this study. Two exceptions are a study by Wasgestian (10) which showed that hexacyanochromate exhibits essentially the same quantum yield for photosolvation in water and DMF, and the work of Langford and Tipping (11) which had similar objectives to those outlined here. The latter authors investigated the photolysis of $[Cr(NH_3)_6]^{2+}$, $[Cr(NH_3)_5Cl]^{2+}$, $[Cr(CH_3NH_2)_5Cl]^{2+}$, and $[Cr(CH_3CH_2NH_2)Cl]^{2+}$ in water and dimethyl sulfoxide. They did not investigate the nature of the products however and in some aspects their numerical data and trends were in disagreement with ours, as are some of the conclusions drawn.

The choice of the solvent system to be compared with water was one important consideration. It would be of great interest to compare photolysis of complexes in water and in a strong ligand solvent such as ammonia or an alkyl amine. We were inhibited from so choosing, however, by the rapidity of the competing thermal reactions in such solvents together with the difficulties of purification, handling, p*H* control, and analysis. We therefore chose to begin with the simpler acetone/water system because of its good solubility properties, the poor coordinating ability of acetone which might be expected to amplify any solvent effects, the ease of its purification, and the stability of its perchloric acid solutions. The work has led to some useful conclusions about the role of the solvent in chromium(III) photochemistry.

Experimental

Preparation of Complexes

$[Cr(NH_3)_5Cl]Cl_2$ was obtained as a by-product from the preparation of μ-hydroxo-bis{pentamminechromium(III)} chloride as described by Linhard and Weigel (12).

$[Cr(NH_3)_5Cl](ClO_4)_2$ was obtained from the chloride by reprecipitation with sodium perchlorate and twice recrystallized. The purity of the product was confirmed spectrophotometrically and by ion exchange chromatography.

$[Cr(RNH_2)_5Cl](ClO_4)_2$, R = CH_3, C_2H_5, n-C_3H_7, and n-C_4H_9 were prepared as described by Parris and Wallace (13).

Photolysis Apparatus and Actinometry

Monochromatic light at 401, 479, and 565 nm was obtained by means of Balzers' interference filters (Rolyn Corp., Filtraflex B20) with half widths of 7, 8, and 6 nm respectively. Actinometry was based on 8×10^{-3} *M* solutions of $KCr(NH_3)_2(NCS)_4$ (potassium reineckate) (14). Two procedures were used. In the first an actinometer cell placed directly behind the photolysis cell was used to integrate the total transmitted light flux, F_A. The effective transmittance T_u of the front solution over the transmission band of the interference filter was then calculated (this was made easier by the fact that the transmittance spectrum of the complexes was close to linear over the narrow band of the filter) and the integrated flux absorbed in the photolysis solution calculated as

$$F_u = F_A(1 - T_u)$$

The technique required that the light beam be parallel, a continuous water film be between the two cells, the cell edges be masked, and that the front solution have a transmittance in the range of 30 → 70% for good precision. The advantage of the technique lay in its precision. Several runs with $KCr(NH_3)_2(NCS)_4$ in both cells gave light fluxes calculated from the two cells agreeing to better than 2%.

The second actinometric technique, of advantage at low temperature where the reineckate quantum yield was not known, was to calibrate a photocell which observed the reflected light from a beam-splitter (8%), using reineckate at room temperature, and then continuously monitor, and integrate, the photocell output during a run. This technique had a precision better than 5%.

Difference Spectrophotometry and Product Spectra[1]

The difference spectra used to calculate the product spectral data in Table 1 were obtained by photolyzing to about 10% conversion, stirred 2×10^{-2} *M* solutions of complex in the appropriate acidified solvent system. The difference spectrum was then obtained by running the spectrum of the photolyzed solution *vs.* the same path length of the unphotolyzed solution as reference (Cary 17 spectrophotometer, 0 → 0.2 expanded adsorbance scale).

The extent of conversion was measured precisely by means of the p*H* change in the solution, and the resultant solution composition, together with the starting spectrum and the difference spectrum after photolysis, was used to calculate point by point the spectrum of the total photolysis product.

pH and Chloride Determinations

Solutions, about 10^{-2} *M* in complex, were made up with one of three solutions listed in the second footnote of Table 2. Each photolysis sample was accompanied by a sample kept in the dark.

All p*H* measurements were made at 20 °C with a combination micro glass electrode (Metrohm AG 1900 Herisau) coupled to a Metrohm Compensator E388 potentiometer/p*H* meter. For the quantitative work in aqueous solutions, the proton uptake was determined by measuring the p*H* of the photolyzed and dark solutions

[1]Copies of the spectra of the complexes and of their photoproducts have been lodged with the Depository of Unpublished Data. Photocopies may be obtained, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

and using the ΔpH method (15). With 33 w/w% acetone/water solutions, the proton uptake was also determined by back titration with standard base until the starting p*H* was reached. The titrimetric and ΔpH methods were found to be equivalent and so the latter, being quicker and simpler, was used almost exclusively. For work with pure acetone solutions, the final exposed and dark solutions were diluted with water to give solutions which were approximately 33 w/w% acetone and the ΔpH method was used.

Free chloride was determined using a concentration cell without transference (16), the silver/silver chloride electrodes used being masked to avoid photovoltaic effects. The photolysis cell used was a modified 1.0 cm quartz spectrophotometer cell. With an internal reference containing an aqueous solution 4.0×10^{-4} *M* in KCl and 0.050 *M* in $KClO_4$, the apparatus was calibrated over the range of chloride concentrations 1.25×10^{-5} to 4.0×10^{-4} *M* in water (all solutions supported by 0.050 *M* $KClO_4$) and 5.0×10^{-6} to 4.0×10^{-4} *M* in 33 w/w% acetone/water solutions supported by 0.020 *M* $KClO_4$. During photolysis runs, the solution was continuously mixed with a magnetic stirrer and the chloride concentration was continuously measured.

Results and Discussion

Studies of the thermal reaction (13) of the chloropentakis(alkylamine)chromium(III) complexes have shown that they exclusively lose chloride, with rate constants that increase as the size of the alkyl group increases. Thus their thermal reaction mode is a close parallel to the behavior of chloropentammine chromium(III) ion. One would expect a similar parallel in the photochemical reaction modes. Three photoinduced processes are conceivable, photoreduction, solvent substitution of amine and of chloride. Studies of chloropentammine have shown the main photoreaction to be "antithermal" (17), that is, loss of ammonia with chloride loss being

minor, while photoreduction appears not to occur at wavelengths of irradiation down to 250 nm (15). The product of amine photoaquation has been shown (17*b*, 18) to be predominantly *cis*-$[Cr(NH_3)_4H_2OCl]^{2+}$.

Our preliminary investigations of these systems therefore occasioned no surprise in that the main photoreaction mode observed in all cases at our irradiation wavelengths both in water and acetone/water mixtures was loss of amine with only minor contributions from chloride loss. We did find, however that the actual chloride quantum yields were significantly lower than reported earlier (16). The quantum yield data are presented and discussed later.

One of the questions of interest in this work was whether the stereochemistry of the photoreaction would alter throughout the series of complexes or with change of solvent. Investigation of this question requires isomeric analysis of the chloroaquotetrakisalkylamino product, which in this work presented difficulties. Ion-exchange chromatography fails to separate *cis* and *trans* chloroaquotetrammine isomers and little better success can be expected with the alkyl–amine analogs. One is therefore forced to use u.v./visible spectroscopic methods and this is made uncertain by the fact that the spectral information for the product isomers is not available as they have not been prepared. Such preparations can be quite difficult and time consuming and were not attempted. Fortunately the spectral differences between *cis* and *trans* isomers of this type are quite large (18) (Table 1) so it was our view that quite a reasonable assessment of the isomeric nature of the product could be made in the absence of the exact spectral data.

Table 1 lists three sets of spectral data for *cis*-$[Cr(NH_3)_4(H_2O)Cl]^{2+}$ together with the spectrum of the photolysis product of $[Cr(NH_3)_5Cl]^{2+}$, derived by the procedure described in the experimental section. Table 1 also presents spectra of the starting complexes and photolysis products of $[Cr(n\text{-}C_4H_9NH_2)_5Cl]^{2+}$, $[Cr(C_2H_5NH_2)_5Cl]^{2+}$, $[Cr(n\text{-}C_3H_7NH_2)_5Cl]^{2+}$, and $[Cr(n\text{-}C_4H_9NH_2)_5Cl]^{2+}$, derived by the same procedure. The data for chloropentammine chromium(III) photolysis in water, where the product is already known to be almost pure *cis*-chloroaquotetrammine, is presented to inspire some confidence that product spectra can be obtained reasonably precisely by this procedure. It can be seen that the spectrum obtained matches well in λ_{max} values although the ε_{max} of the bands are somewhat larger than our directly measured values. It will be noted that there is some disagreement in the literature data for *cis*-$(Cr(NH_3)_4H_2OCl]^{2+}$ and it may be that the photochemically derived molar absorptivities of Table 1 are more precise than those in the literature as impurities likely to occur in the complex will lead to lowered molar absorptivities. The chloride quantum yields, discussed later, are sufficiently small that aquopentammine does not interfere.

Comparison of the spectra of the photolysis products of the chloropentakis(alkylamino)-chromium(III) complexes with their starting complexes, and with *cis*- and *trans*-$[Cr(NH_3)_4(H_2O)Cl]^{2+}$, indicates that in each case the product appears to be predominantly *cis*. Close examination reveals some anomalies; for each product/reactant pair the red shift of λ_{max} and decrease in ε_{max} of the second ligand field band parallels the ammine case, but in contrast λ_{max} of the first ligand field band seems slightly blue shifted, and ε_{max} for the *cis*(*?*)-$[Cr(n\text{-}C_3H_7NH_2)_4H_2OCl]^{2+}$ and *cis*(*?*)-$[Cr(n\text{-}C_4H_9NH_2)H_2OCl]^{2+}$ are lower than the corresponding reactants. We believe these differences are real, and are not due to admixture of *trans* material, but are due to influences of steric hindrance on ligand field strengths of the ligands. Table 3 shows some relevant spectral data for Cr(III) complexes. Whereas CH_3NH_2 is a better base, and presumably a better σ donor than NH_3, nevertheless $\Delta[Cr(NH_3)_5Cl]^{2+} > \Delta[Cr(CH_3NH_2)_5Cl]^{2+}$. That this is due to steric crowding in the pentakis(alkylamino) complex is supported by the other data in Table 3, which show that $[Cr(ibn)_3]^{3+}$ (ibn = isobutylenediamine) where steric hindrance can be seen from models to occur, has Δ smaller than $[Cr(en)_3]^{3+}$ and $[Cr(pn)_3]^{3+}$, and $[Cr(CH_3NH_2)_6]^{2+}$ has Δ smaller than $[Cr(NH_3)_6]^{3+}$ by the same extent. Thus we believe that the blue shift of the first ligand field band upon water substitution to go from $[Cr(RNH_2)_5Cl]^{2+}$ to *cis*(*?*)-$[Cr(RNH_2)_4H_2OCl]^{2+}$ can be explained in terms of relief of steric strain, allowing shorter Cr—N bonds and larger Δ for the remaining alkylamine ligands, in the aquoproduct, with this factor overwhelming the influence of substitution of one amine by water.

Table 1 also gives the product spectrum for

TABLE 3. Spectral data for some chromium(III) complexes

Complex	$\lambda_{max}(4T_{1g})$ (nm)	$\lambda_{max}(4T_{2g})$ (nm)	$\Delta = \bar{\nu}_{max}(4T_{2g})$ cm^{-1} × 10^{-3}
$[Cr(NH_3)_6]^{3+}$	350	464	21.55

$[Cr(n\text{-}C_4H_9NH_2)_5Cl]^{2+}$	390	531	18.83*

*No attempt has been made to allow for splitting to yield $^4E_2$ and $^4B_2$ bands in these C_{4v} complexes. The value given merely indicates the approximate overall ligand field strength.

photolysis of $[Cr(CH_3NH_2)_5Cl]^{2+}$ in pure acetone. In this solvent, although up to three water molecules are present in the solvation sphere (due to the water added in making up the perchloric acid solutions) it may be that some acetone substitution occurs. Again, however, the product spectrum is typical of that expected for a *cis* product.

In the absence of accurate spectral data for the product complexes it would be foolish to try to make quantitative estimations of the proportion of *cis* isomer in the product. However it is reasonable to conclude that all the complexes studied photolyze to give mainly the *cis* solvated product, whether in acetone or water or acetone/water mixtures. Thus any rules for the stereochemistry of photoreactions may be more solvent independent than for the thermal reactions, where it is found that the stereoretentivity observed in water does not necessarily apply in dimethylformamide, dimethylsulfoxide (19), or in liquid ammonia (7, 8).

The quantum yield data obtained in this work is summarized in Table 2, where in the case of the amine yields the results quoted are generally the mean of at least two determinations agreeing to better than 3%. The quantum yields for chloride are significantly less precise, as discussed elsewhere (16), and are probably subject to some systematic errors.

The quantum yield for amine release shows a general decrease in going through the series from chloropentammine to the butylamine homolog. The question of whether there is a general relationship between overall photolysis quantum yields and the average ligand field strength (or the roughly equivalent quantity ΔE, the spacing of the maxima of the lowest quartet and lowest doublet absorption bands) has often been addressed. The relationship applies roughly for a number of octahedral complexes (20), and has been shown to apply equally roughly in series of mixed ligand complexes (3*c*). The present investigation reveals another series of closely related complexes which show such a crude relationship between quantum yield and ligand field strength. There is not a good quantitative relationship, however, as the large drop in Δ lies between ammine and methylamino, while the largest drop in quantum yield of amine release lies between methylamino and ethylamino.

It now appears fairly certain that the main photoreaction of complexes of this type arises from the quartet state (9, 10, 21) and in the following attempt to rationalize the ligand field strength/quantum yield relationship this will be assumed. It also has been shown that the complex trisethylenediaminechromium(III) has a return intersystem crossing efficiency close to one at room temperature in aqueous solution (21). Since complexes of the type studied here do not phosphoresce in aqueous solution at room temperature, and since their lowest quartet/doublet spacing is less than for $[Cr(en)_3]^{3+}$ it can be reasonably expected that return intersystem crossing is also efficient under the photolysis conditions. The quantum yield for reaction would then be given simply by

$$[1] \qquad \phi_{reaction} = \frac{k_R}{k_2 + k_3 + k_R}$$

where k_2, k_3, and k_R are respectively the first order rate constants for fluorescence, internal

conversion to the ground state, and reaction. Since these complexes do not fluoresce in solution and since the quantum yield of reaction is less than one, $k_2 \ll k_3 + k_R$ so that

$$[2] \qquad \phi_R \approx \frac{k_R}{k_3 + k_R}$$

If this analysis is correct it becomes clear that the decrease in amine quantum yield in the series might reside either in an increase in k_3 with alkylamine bulk or a decrease in k_R, or both. The internal conversion rate constant can be expected to depend on the energy above the ground state of the thermally equilibrated quartet excited state, the degree of distortion, and the density of states available for crossover. Moving to the bulkier, weaker field amine certainly decreases the energy spacing, might lead to less distortion, and would increase the density of states, so it is quite reasonable to expect k_3 to increase in the series $[Cr(NH_3)_5Cl]^{2+}$ to $[Cr(n\text{-}C_4H_9NH_2)_5Cl]^{2+}$.

If the explanation of the trend is not photophysical due to changes in internal conversion rate constant in the series, it could reside in a decrease in k_R in the series. If so it would be supportive of an associative mechanism of photosubstitution. Thus, for an associative mechanism, the bulkier amine complexes would be expected to react more slowly due to steric hindrance of the entering solvent molecules. In contrast a dissociative reaction would be expected to show the reverse trend, due to the strain present in the reactant molecule, and its consequent relief upon dissociation of an amine ligand. It is clear that not enough information is yet available to decide which of these explanations is correct or even valid, but it does point out the need for further photophysical studies of the effect of structure on the rate constants for intersystem crossing, and if possible, internal conversion.

The solvent dependence data, which is most complete for $[Cr(CH_3NH_2)_5Cl]^{2+}$ shows that the amine quantum yield increases only by about 10% in going from water to pure acetone. In contrast the quantum yields for chloride seem to decrease by a factor of about two in going from water to 33% acetone (Table 2 lists one reversal of this trend, but this probably reflects varying systematic errors in the chloride yields). The two reaction modes therefore show different solvent effects. The constancy of the amine quantum yield with solvent composition is again suggestive that it is determined largely by purely photophysical factors. The result further implies that the mechanism is either dissociative, or, if associative must involve a water molecule already in the coordination sphere, even in the "100%" acetone solution, as the writers would not expect substitution of acetone in an associative process to occur as fast as water substitution.

Table 2 also shows different wavelength dependencies for the amine and chloride yields, chloride increasing at the shorter wavelength, amine decreasing slightly. Together with the facts that the amine quantum yield is sensitive to the overall ligand field strength of the ligands, while chloride is not, and that amine release increases only slightly in acetone, while chloride decreases significantly, the data overall is suggestive that the two modes of reaction arise from different excited states. Whereas analogy to earlier studies suggests the lowest quartet excited state is responsible for the amine photolysis, the observations on chloride release support reaction through a solvated state having charge transfer character of the type represented by $Cr(II)(RNH_2)_5 \cdot Cl$, as has been earlier suggested (15). Thus at shorter wavelength of irradiation the participation of such a state would be favored, it would show a yield of successful chloride release that was sensitive to the preference of chloride for the solvent, and the tendency to form such a state would be relatively independent of the amine ligand field strength, depending mainly on the redox properties of Cr(III) and Cl^-.

Based on sensitization experiments other workers (22) have suggested that production of chloride arises from the doublet state; this is not necessarily in conflict with our proposal, as both types of excited state could exist and would be expected to release chloride. However it seems to us unlikely that the chloride yields formed here, increasing to shorter wavelength, arise from the doublet state. Langford and Tipping (11) have suggested that chloride arises from the same quartet state as releases amine; this however would fail to explain the different wavelength dependencies of the two processes.

Table 4 shows apparent activation energies for amine loss; no large temperature dependence exists. Following the analysis of Chen (23), based on eq. 2 and its underlying assumptions, one can easily derive the equation

TABLE 4. Activation energies for amine release in $[Cr(RNH_2)_5Cl]^{2+}$ photolyses at 565 nm

Complex	E_{app}(kcal mol^{-1})	$E_3 - E_R$(kcal mol^{-1})	Solvent
$[Cr(NH_3)_5Cl]^{2+}$	2.1 ± 0.4	3.5 ± 0.6	Water
$[Cr(CH_3NH_2)Cl]^{2+}$	1.2 ± 0.3	1.9 ± 0.5	Water
	0.8 ± 0.4	1.2 ± 0.6	33% acetone
$[Cr(C_2H_5NH_2)Cl]^{2+}$	1.5 ± 0.3	2.0 ± 0.4	Water
	1.8 ± 0.4	2.4 ± 0.5	33% acetone
$[Cr(n\text{-}C_3H_7NH_2)Cl]^{2+}$	1.9 ± 0.4	2.4 ± 0.4	33% acetone

[3] $$\log\left(\frac{1}{\phi} - 1\right) = \frac{E_R - E_3}{RT}$$

Plots of log $(1/\phi - 1)$ *vs.* $1/T$ are linear and lead to the values for $E_R - E_3$ shown also in Table 4. Since E_3 is certain to be positive, one may conclude that the reaction of the excited state has a small but appreciable activation energy. However, there appears to be no significant influence of solvent or amine bulk on these values within the precision limits of this data.

A Raman Spectral Study of the Kinetics of Hydrolysis of Acetonitrile Catalyzed by Hg(II)[1]

YU-KEUNG SZE[2] AND DONALD E. IRISH[3]

Department of Chemistry, University of Waterloo, Waterloo, Ontario N2L 3G1

Received August 7, 1974

YU-KEUNG SZE and DONALD E. IRISH. Can. J. Chem. **53**, 427 (1975).

Raman spectroscopy has been employed to follow the relatively slow rate of hydrolysis of acetonitrile, catalyzed by mercury(II). Raman lines at 2275 and 2305 cm^{-1} are characteristic of CH_3CN bound to Hg^{2+}, and are distinct from lines of bulk solvent. The intensities of these new lines decrease with time. From the intensities, concentrations of bound acetonitrile, $[CH_3CN]_B$ were calculated for a time span of 400 min. The data fit a second order rate law: Rate = $k[CH_3CN]_B[H_2O]$. The specific rate constant, k, obtained from four sets of data for the system $Hg(ClO_4)_2$–CH_3CN–H_2O equals $1.05 \pm 0.06 \times 10^{-4}$ mol^{-1} l min^{-1} at 25 °C. The energy of activation is 18.9 kcal mol^{-1}. In the proposed mechanism water molecules attack acetonitrile molecules which are bound to Hg^{2+} and form a mercury(II)–acetamide complex. Raman lines characteristic of this species are observed. This species slowly converts to mercury(II) ammine complexes and acetic acid. Anions which coordinate with Hg^{2+} more strongly than CH_3CN, such as nitrate or acetate, slow or prevent the hydrolysis reaction.

YU-KEUNG SZE et DONALD E. IRISH. Can. J. Chem. **53**, 427 (1975).

On a utilisé la spectroscopie Raman pour suivre l'hydrolyse, relativement lente de l'acétonitrile, catalysée par le mercure(II). Les lignes Raman à 2275 et 2305 cm^{-1} sont caractéristiques du CH_3CN lié au Hg^{2+} et se distinguent facilement des lignes du solvant. Les intensités de ces lignes diminuent avec le temps. A partir des intensités, les concentrations d'acétonitrile lié, $[CH_3CN]_B$ ont pu être déterminées pour une période de 400 min. Les données suivent une équation de vitesse du deuxième ordre; la vitesse est égale $k[CH_3CN]_B[H_2O]$. La constante de vitesse spécifique, k, est obtenue à partir de quatre séries de données pour le système $Hg(ClO_4)_2$–CH_3CN–H_2O et cette valeur est égale à $1.05 \pm 0.06 \times 10^{-4}$ mol^{-1} l min^{-1} à 25 °C. L'énergie d'activation est de 18.9 kcal mol^{-1}. Dans le mécanisme proposé, des molécules d'eau attaquent des molécules d'acétonitriles qui sont complexés au Hg^{2+} et forment des complexes mercure (II)-acétamide. On observe les lignes Raman caractéristiques de ces espèces. Cette espèce se transforme lentement en complexe amino mercurique et en acide acétique. Les anions qui se coordonnent avec le Hg^{2+} d'une façon plus forte que le CH_3CN, tels que les nitrates et les acétates, ralentissent ou empêchent la réaction d'hydrolyse. [Traduit par le journal]

Introduction

Mixtures of water and acetonitrile are stable at room temperature and are frequently used as mixed solvents for electrolyte studies. Under strongly acidic or basic conditions and at higher temperatures acetonitrile hydrolyses to give acetamide and subsequently acetic acid (1). Several substances, namely boron halides (2), 100% sulfuric acid (3), manganese dioxide (4), and alkaline hydrogen peroxide (5), accelerate the hydrolysis of acetonitrile at room temperature. The catalytic action of nickel (6), $ZnCl_2$ (7), and cation exchange resins containing Cu^+, Zn^{2+}, Ag^+, and Cd^{2+} (8) have been reported at higher temperatures. The effect of mercuric salts on the rate of hydrolysis of acetonitrile in 3 *N* acid media in the temperature range from 70–95 °C was studied by Travagli (9–13). He reported that HgO in acidic media accelerates the action of acids. The reaction was followed by analysis for NH_3, evolved from aliquots removed periodically and cooled, and was found to be first order with respect to CH_3CN both in the presence and absence of HgO. The rate of the mercury-catalyzed reaction was found to be dependent on the acids used and decreased in the order $H_2SO_4 > HClO_4 > HNO_3 > HCl$.

The hydrolysis of acetamide in acid media is much faster than that of acetonitrile (by approxi-

mately 350 times in 4 *M* acid) unless the concentration of the acid is very high (14). Under the conditions used by Travagli the formation of acetamide was not revealed but its existence was not excluded. The hydrolysis of acetamide is also faster than acetonitrile in aqueous NaOH solution (15).

The rate of hydrolysis, catalyzed by Hg^{2+} at room temperature, is sufficiently slow that it has been possible to follow the reaction with Raman spectroscopy using a conventional system. The observation of Raman lines from the reacting species and their products provides unique information about the intermediates and their role in the mechanism. Anion effects have also been investigated.

Experimental

Solutions of $Hg(ClO_4)_2$ were prepared from HgO (Fisher Certified Reagent) and $HClO_4$ (~70%, Baker Analyzed Reagent). Appropriate amounts of the $Hg(ClO_4)_2$ solution and water were mixed and kept at 25 ± 0.05 °C in a water bath together with a bottle of CH_3CN (Matheson, Coleman, and Bell, Spectroquality). After thermal equilibrium was achieved, CH_3CN was added to the $Hg(ClO_4)_2$ solution to the 25 ml mark. Since CH_3CN has a lower density, two liquid layers occur with very little mixing. Immediately after a timer was started, the solution was shaken well. The solution showed a small volume contraction. A few drops of CH_3CN were added to bring the volume to the mark. The solution was mixed well and the total amount of CH_3CN determined by weighing.

Raman spectra were obtained as previously described (16). A portion of the solution was poured into the sample cell thermostatted at 25 ± 0.05 °C. The spectrum from 2150 to 2400 cm^{-1} was scanned. Readings of the timer were marked on the spectrum. The time of scanning 2290 cm^{-1} (a point midway between the two bands at 2275 and 2305 cm^{-1} used for analysis) was interpolated and was taken as the reaction time. The scanning of this region required 4 min. The time lapse is negligible since the reaction is slow. The reaction causes a decrease in the volume of the solution by a few percent. To correct for this change, the remaining portion of the solution (also thermostatted at 25 °C) was used for density measurements. A correction curve, density–time, was obtained.

Other solutions for the kinetic measurements were prepared by the same procedures. Most of the kinetic measurements were carried out in duplicate.

Results and Discussion

Spectral Changes of $HgA_2/H_2O/CH_3CN$ Systems with Time, where $A = ClO_4^-$, NO_3^-, OAc^-

Raman and infrared spectra of solutions $Hg(ClO_4)_2/CH_3CN/H_2O$ (or $Hg(NO_3)_2/CH_3CN/H_2O$) show features which are very different from those reported in studies of other electrolytes dissolved in CH_3CN–H_2O (17–20). A number of new lines were observed, the positions of which do not depend on time or the ratios of the three components: $Hg(ClO_4)_2$ (or $Hg(NO_3)_2$), CH_3CN, and H_2O. The intensities of these new lines increase with time. The intensities of a set of lines which can be assigned to acetonitrile decrease with time.

For solutions containing acid and the mixed solvent of acetonitrile and water, reaction is very slow at room temperature. For example, after a period of two weeks, for the solution with composition 4.7 mol $HClO_4$, 21.8 mol H_2O, and 7.7 mol CH_3CN per l, at room temperature CH_3CN is only diminished by approximately 4% as measured from decrease in the intensity of the bands of acetonitrile. Solutions containing nitric acid and acetic acid behave similarly. It is reasonable to assume that under the reaction conditions (25 °C; acid concentration usually equal to 0.15 *M*, and at most 0.5 *M*) for the solutions containing mercury salts, catalysis of the reaction by acid is negligible.

Figures 1 and 2 show spectra recorded at different times for the solution with composition 1.7 mol $Hg(ClO_4)_2$, 19.7 mol H_2O, 9.8 mol CH_3CN, and 0.15 mol $HClO_4$ per l. Positions of bands of acetonitrile are listed in Table 1. The bands at 2275 and 2305 cm^{-1} were not observed in pure acetonitrile or its aqueous solutions. The intensities of these bands decrease with time. It is reasonable to assign these bands to acetonitrile bound to mercury. The 2275 cm^{-1} band was also observed by Addison *et al.* (21) for $Hg(NO_3)_2$ in pure acetontrile. A band at 2270 cm^{-1} is characteristic of CH_3CN bound to Ag^+ (17, 22, 23).

In systems containing $Hg(ClO_4)_2$, the anion gives four bands at 460, 625, 930, and 1110 cm^{-1}. The first two bands are symmetrical (Fig. 1). The band at 930 cm^{-1} overlaps seriously with the 931 cm^{-1} line of acetonitrile. The band at 1110 cm^{-1} appears to be asymmetric. The asymmetry is partly due to overlapping with the 1040 cm^{-1} band of acetonitrile. The contour of this band appears to be practically independent of the concentration of the salt. Raman studies of a large number of perchlorate solutions indicate that in the near-saturated solutions (24) and concentrated solutions (25) of $Hg(ClO_4)_2$ association between the cation and ClO_4^- does not occur, at least to a significant extent.

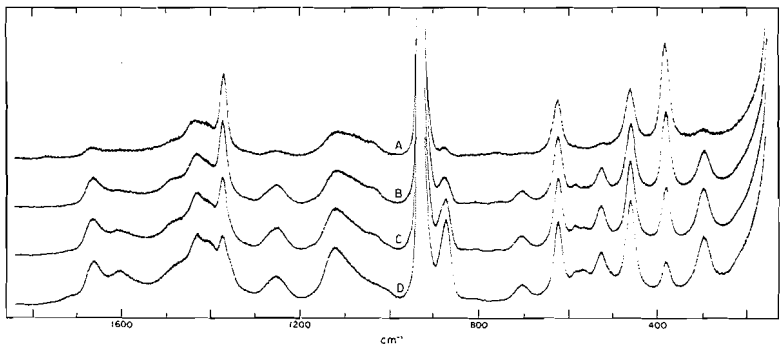

FIG. 1. Raman spectra in the 160–1840 cm^{-1} region for the 2/1 solution (1.70 mol $Hg(ClO_4)_2$, 19.7 mol H_2O, 9.8 mol CH_3CN, 0.15 mol $HClO_4$ per l) as a function of time. (*A*) 164.4–215.8 min; (*B*) 518.7–658.7 min; (*C*) 1191.7–1331.7 min; (*D*) 2989.2–3129.2 min.

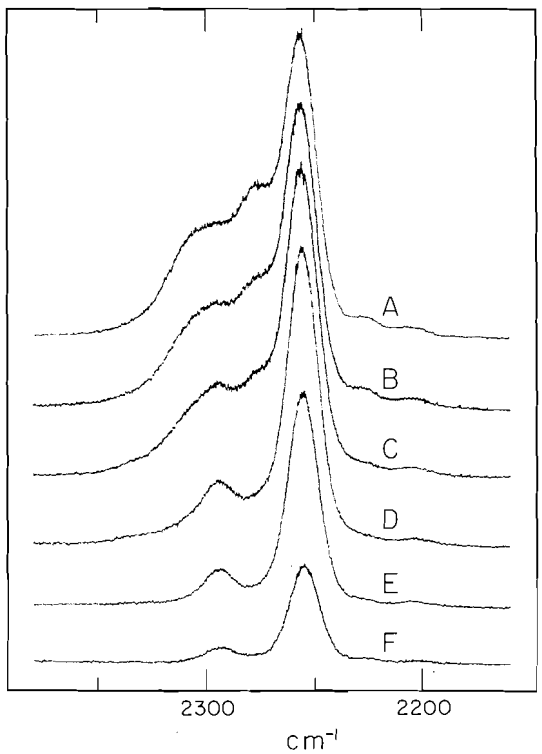

FIG. 2. Raman spectra in the 2160–2380 cm^{-1} region for the 2/1 solution as a function of time. (*A*) 46.7 min; (*B*) 146.5 min; (*C*) 256.7 min; (*D*) 504.8 min; (*E*) 1107.1 min; (*F*) 3187.6 min.

Solutions containing $Hg(NO_3)_2$ in the mixed solvents of acetonitrile and water give bands at 716, 740, 1030, and 1045 cm^{-1} (Fig. 3); bands in the 1200–1600 cm^{-1} region overlap with the acetonitrile bands. These bands compare reasonably well in position with results for aqueous solutions and can be assigned to solvated nitrate (716 and 1045 cm^{-1}) and nitrate bound to mercuric ion (740 and 1030 cm^{-1}). Intensity analysis of the spectra recorded a few hours after preparation indicated that the degree of association of mercuric nitrate is larger in the mixed solvent system of CH_3CN/H_2O than in its aqueous solution. The degree of association of $Hg(NO_3)_2$, however is a function of time (Fig. 3). It decreases as more acetonitrile is hydrolyzed.

Systems of $Hg(OAc)_2/H_2O/CH_3CN$ give no indication of reaction. No new bands were observed in spectra recorded approximately 24 h after the preparation of the solutions. Mercuric acetate gives rise to the following bands in the mixed solvents: 275, 498, 691, 890, 939, 1017, and 2943 cm^{-1}; the bands in the 1400 cm^{-1} region are weak and obscured by the bands due to acetonitrile. For aqueous solutions of $Hg(OAc)_2$, the band positions are identical (± 1 to 2 cm^{-1}) to those observed for $Hg(OAc)_2$ in the mixed solvents. A sodium acetate solution (2 *M*), on the other hand, gives the following bands: 476, 618, 653, 927, 1348, 1414, 1760, 2935, 2985 cm^{-1}. The 275 cm^{-1} band of mercuric acetate is fairly strong and polarized. This band can reasonably be assigned to the mercury–acetate stretching vibration. The appearance of this band together with the difference in band positions between the $Hg(OAc)_2$ and NaOAc solutions strongly suggests that $Hg(OAc)_2$ is highly associated. This is in agreement with the very large value of the association constant, β_2 ($\sim 10^9$) for $Hg(OAc)_2$ obtained by two different methods (26, 27). The absence of the bands at 2275 and 2305 cm^{-1} in the $Hg(OAc)_2/H_2O/CH_3CN$ solutions which can be ascribed to bound acetonitrile indicates that there is no

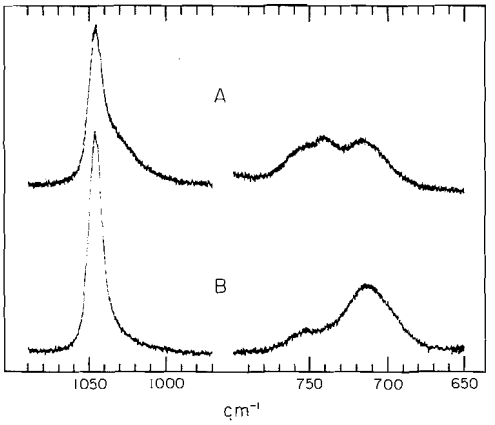

FIG. 3. Raman spectra in the 650–800 cm^{-1} and 960–1090 cm^{-1} regions for the solution with composition: 1 mol $Hg(NO_3)_2$, 21 mol H_2O, 12 mol CH_3CN, and 0.2 mol HNO_3 per litre. (*A*) ≈12 h; (*B*) ≈36 h after the solution was prepared. Spectral slit widths for the 650–800 cm^{-1} region: 10 cm^{-1} and 960–1090 cm^{-1} region: 5 cm^{-1}.

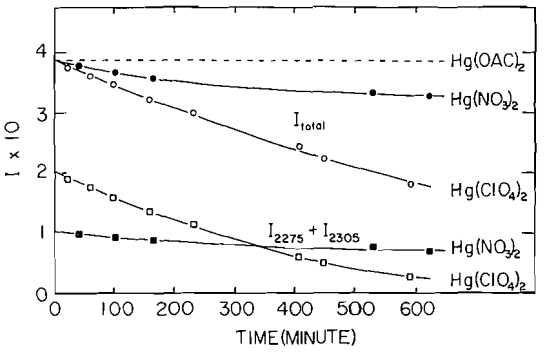

FIG. 4. Intensity in the 2150–2400 cm^{-1} region as a function of time for solutions containing different mercuric salts.

complex formation between Hg^{2+} and CH_3CN and further supports the fact that $Hg(OAc)_2$ exists in its molecular form in solutions.

A comparison of the effect of the three salts on the rate of the hydrolysis of acetonitrile is shown in Fig. 4. The intensities of the total C≡N stretching region, as well as the intensities of lines ascribed to CH_3CN bound to Hg^{2+} (*i.e.*, 2275 + 2305 cm^{-1}) are plotted against time. Since in solutions of $Hg(OAc)_2/H_2O/CH_3CN$, no evidence of hydrolysis was observed, a dashed horizontal line is shown. The compositions of the $Hg(ClO_4)_2$ and $Hg(NO_3)_2$ solutions are similar: 1.69 mol $Hg(ClO_4)_2$, 25.2 mol H_2O, 7.78 mol CH_3CN, 0.15 mol $HClO_4$, and 1.70 mol $Hg(NO_3)_2$, 26.3 mol H_2O, 8.22 mol CH_3CN, 0.48 mol HNO_3 per l. It is apparent that $Hg(ClO_4)_2$ affects a faster reaction than $Hg(NO_3)_2$. This is attributed to a higher concentration of solvated Hg^{2+} in the $Hg(ClO_4)_2$ system which in turn results in a larger intensity ($I_{2275} + I_{2305}$).

Interaction Between Hg(II) and CH_3CN

The intense bands at 2275 and 2305 cm^{-1} (Fig. 2) indicate that the affinity of mercury for acetonitrile is large, in the absence of competition from stronger ligands like halides or acetate. As will be seen later, the $\bar{n}$ value, defined as the average number of acetonitrile molecules bound

to one mercuric ion, can exceed 3.5, which indicates that $HgCH_3CN^{2+}$, $Hg(CH_3CN)_2^{2+}$, $Hg(CH_3CN)_3^{2+}$, $Hg(CH_3CN)_4^{2+}$ or even higher complexes can exist. Based on Raman spectral results, the following order is inferred for the degree of formation of mercury complexes: $ClO_4^- < H_2O < CH_3CN < NO_3^- \ll (Cl^-, Br^-, OAc^-)$. This observation, together with the fact that the rate of the hydrolysis reaction is closely related to the concentration of the bound acetonitrile concentration, accounts for the results of Travagli: *viz.* that the catalytic effect of a mercury salt decreased in the order $ClO_4^- > NO_3^- \gg Cl^-$ (12).

Spectral Data for Possible Products of the Reaction

The frequencies of the new lines with intensities which increase with time were compared with those of a large number of compounds (28).[4] Acetic acid is one of the products. Its bands are, however, not evident until the reaction time exceeds 1800 min. Band positions characteristic of mercuric acetate and sodium acetate are not observable in spectra of the reaction mixture when products predominate.

The final product containing the nitrogen atom can probably be NH_4^+ or $Hg(NH_3)_x^{2+}$. The species $Hg(NH_2)_x^{-(x-2)}$ is excluded at once by comparison with the known infrared spectra (29, 30), The NH_4^+ ion is not easily distinguished from other products. The lines of mercury-ammine complexes, on the other hand, are clearly observed in the spectra. Their existence is consistent with the very high values of their stability constants in aqueous solutions (31).

Complexes of the formula $[HgCH_3CONH]^+$ and $Hg(CH_3CONH)_2$ exist in dilute aqueous solutions of mercuric chloride and CH_3CONH_2 (32). Their stability constants have been measured by p*H* titration methods. Although these stability constants are very high ($\log K_1 = 8.15$ and $\log K_2 = 7.54$) the concentrations of the complexes are limited by the very low dissociation constant of acetamide, $\log K_a = -15.1$, where $K_a = [CH_3CONH^-][H_3O^+]/[CH_3CONH_2]$(33). A comparison between the infrared results of the compound $Hg(CH_3CONH)_2$ and the spectra for the hydrolysis products indicates that the concentration of $Hg(CH_3CONH)_2$, if it is present, must be very low.

Acetamide and its complex with mercury are difficult to distinguish spectroscopically. It is probable that they both exist in the solutions. $AcNH_2$ reacts with $Hg(NO_3)_2$ (34) and $HgCl_2$ (35), in aqueous solution to form adducts of the formulae $Hg(NO_3)_2 \cdot 2AcNH_2$ and $HgCl_2 \cdot AcNH_2$. No water of crystallization is bound in these compounds. The existence of the acetamide–mercury complex in aqueous solution is indicated by the presence of a strong and polarized band at 300 cm^{-1} which can reasonably be assigned to a Hg–ligand stretching vibration of $Hg(AcNH_2)_x^{2+}$. Indirect evidence supports this association. For solutions containing $Hg(NO_3)_2/CH_3CN/H_2O$, the concentration of nitrate bound to Hg^{2+} decreases as inferred by the decrease in intensity of the bands at 740 and 1030 cm^{-1} (Fig. 3), which indicates that NO_3^- is displaced by a ligand with greater affinity for Hg^{2+}.

The above discussion suggests that the products of the hydrolysis are acetamide and/or its complexes with mercury, mercury ammine complexes, and acetic acid. In general, coordination of the oxygen atom of an amide to a metal ion results in a shift of the C=O stretching mode to a lower frequency and the C—N stretching mode to a higher frequency (36–39). This we did not observe. Acetamide is probably bound to Hg via the N atom as in crystalline mercury(II) acetamide (40, 41). This feature is peculiar as compared with other acetamide complexes such as Ni (42, 43), Cu (44, 45), and H^+ (46), in which the oxygen atom is bound to the cation. The Hg—N bond in the Hg–acetamide complex is a reflection of the great affinity of mercury for nitrogen ligands. Positions of all the bands observed for the products, the polarization data, and the assignments are listed in Table 2.

Quantitative Measurements

In this section, results of experiments designed to obtain the rate law for the reaction are presented. Four solutions with different H_2O/CH_3CN molar ratios were prepared. These solutions will be identified by their molar ratios hereafter. The concentration of $Hg(ClO_4)_2$ was fixed at 1.7 *M* in all four runs to maintain essentially constant the influence of the salt. The intensities of bands in the 2150–2400 cm^{-1}

[4]Tables of data not included in this paper can be found in this source.

*Assignments are consistent with results of polarization studies and intensity changes with time. Assignments are inferred from the literature but there is considerable disagreement concerning assignments of the skeletal deformation modes.
†Observed for the solution with the composition = 1.7 mol $Hg(NO_3)_2$, 26.3 mol H_2O, 8.2 mol CH_3CN, 0.48 mol HNO_3 per l, 12 h after preparation.
‡Not investigated.

region have been measured at appropriate time intervals. Typical spectra in this region were shown in Fig. 2.

Spectral data in the 2150–2400 cm^{-1} region were obtained for the 1.3/1 solution, recorded at intervals of time up to 4414.9 min (28). The *ca.* 2275 and 2305 cm^{-1} bands have been assigned to acetonitrile bound to mercury(II) ion; the intensity ratio of these two bands appears to be a constant (1.23 ± 0.20) independent of time until the intensities are very low and thus of lower accuracy. This constancy suggests that Fermi resonance occurs between these two bands as discussed elsewhere for the $Zn(NO_3)_2/CH_3CN/H_2O$ system (28). For other $Hg(ClO_4)_2$ or $Hg(NO_3)_2/H_2O/CH_3CN$ solutions similar results were obtained. Small differences exist between the zinc and mercury systems. For acetonitrile bound to Hg^{2+} the combination occurs at (923 + 1370) or 2293 cm^{-1}. On Fermi resonance with the fundamental the two lines 2275 and 2305 cm^{-1} are observed; the 2305 cm^{-1} line has a lower peak height but greater integrated intensity because of its width. For the zinc case, the combination occurs at (937 + 1370) or 2307 cm^{-1}, the observed pair of lines occur at 2290 and 2315 cm^{-1} and the intensity at 2315 cm^{-1} is less than the intensity at 2290 cm^{-1}. This comparison (both position and intensity) suggests that (ν_f^b − 2293) for the mercury–acetonitrile complex is smaller than the (ν_f^b − 2307) for the zinc–acetonitrile complex, where ν_f^b is the fundamental ascribed to the bound form of CH_3CN, in the absence of Fermi resonance.

The intensity–time data were interpreted as follows. The intensities at $t = 0$ were obtained by extrapolation. The molar intensity of acetonitrile, J, defined as the total intensity at $t = 0$ divided by the stoichiometric concentration of acetonitrile, does not change appreciably as the solution compositions change. At 25 °C, the J values for the 1.3/1, 2/1, 3.2/1, and 5.2/1 solutions are 48.5, 51.1, 49.2, and 51.6 mol^{-1} l

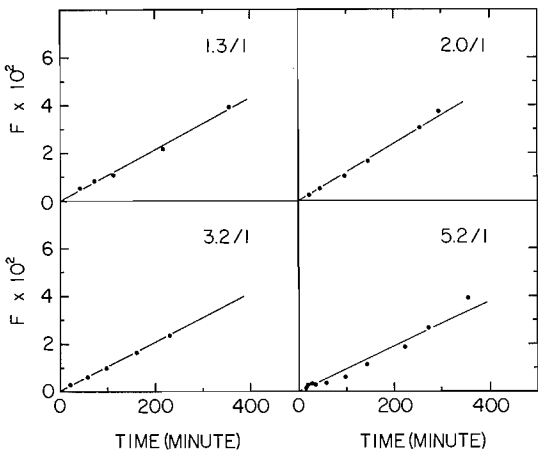

FIG. 5. F against time for the four solutions of $Hg(ClO_4)_2$–H_2O–CH_3CN.

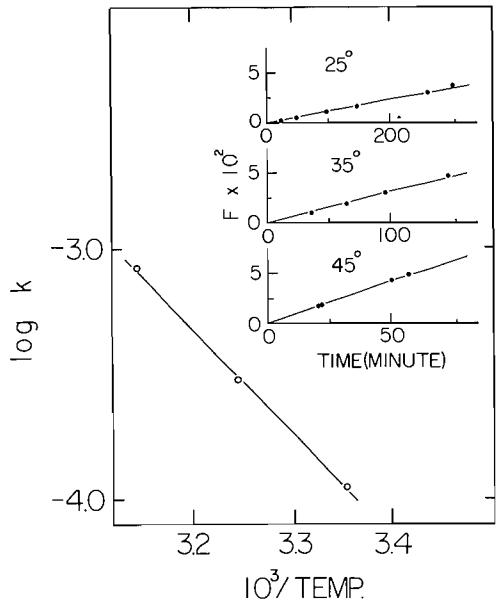

FIG. 6. F against time for the 2/1 solutions at different temperatures, and the logarithm of the rate constant, log k, against the reciprocal of temperature (K).

respectively. For the solution 1.7 mol $Hg(NO_3)_2$, 26.25 mol H_2O, 8.22 mol CH_3CN, 0.48 mol HNO_3 per l, the composition of which is similar to the 3.2/1 solution, the J value is 47.2 mol^{-1} l. Thus it is reasonable to assume that the molar intensities of both the bound and bulk acetonitrile are equal within experimental error. Similar results have been observed in our previous study (28) of $Zn(NO_3)_2/H_2O/CH_3CN$ and have been reported by others (17).

The concentrations of acetonitrile bound to mercury at time t, $[CH_3CN]_B$, were calculated by dividing $(I_{2275} + I_{2305})$ by the molar intensity, J. By dividing $[CH_3CN]_B$ at $t = 0$ by the stoichiometric concentrations of mercury in the solutions, the average numbers of acetonitrile molecules bound to one mercuric ion, $\bar{n}$, can be calculated. They are 3.58, 3.05, 2.44, and 1.84 for the 1.3/1, 2/1, 3.2/1, and 5.2/1 solutions respectively. Presumably all the mercuric ions are bound to at least one acetonitrile molecule in these solutions.

The $[CH_3CN]_B$–time data are consistent with a second order rate expression. For 1.7 M $Hg(ClO_4)_2$ solutions

$$\text{Rate} = k[CH_3CN]_{B,t}[H_2O]_t$$

Plots of $\{[H_2O]_0 - [CH_3CN]_{B,0}\}^{-1} \cdot \ln\{[CH_3CN]_{B,0}[H_2O]_t/[H_2O]_0[CH_3CN]_{B,t}\}$, called F, against time (Fig. 5) are linear with slopes k of 1.08, 1.12, 1.03, and 0.95 $\times$ 10^{-4} mol^{-1} l min^{-1} for the 1.3/1, 2/1, 3.2/1, and 5.2/1 solutions respectively. An average value of 1.05 $\pm$ 0.06 $\times$ 10^{-4} mol^{-1} l min^{-1} is obtained for k. The value of $[H_2O]_t$ is given by $[H_2O]_0 - \{[CH_3CN]_{B,0} - [CH_3CN]_{B,t}\}$. It was found that the data are not consistent with a first order rate law in $[CH_3CN]_B$ nor with a reaction first order in $[CH_3CN]_B$ and second order in $[H_2O]$. To avoid complications from subsequent reactions only the data obtained in the first 400 min have been tested. Note that the concentrations have been corrected for volume changes which occur during the course of reaction.

Although $(I_{2275} + I_{2305})$ decreases monotonically with time, $(I_{2255} + I_{2295})$, assigned to bulk or unbound acetonitrile, increases or remains almost constant over the first 400 min. This observation will be explained later.

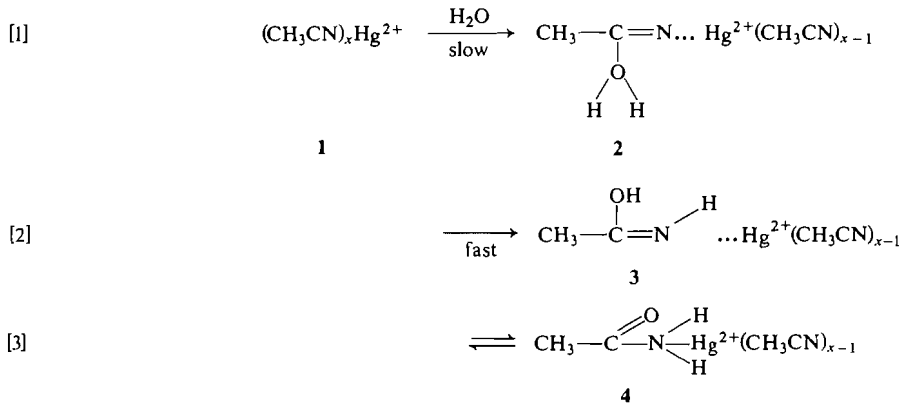
Data for the 2/1 solution have also been obtained at 35 and 45 °C. The energy of activation, E_a, for the reaction was found from the log k against $1/T$ plot (Fig. 6) to be 18.9 kcal mol^{-1}. Travagli reported a value of 21.8 kcal mol^{-1} for the reaction catalyzed by Hg(II) in 3 N $HClO_4$ solution (12). Because he worked at high temperatures with a high concentration of acid and low concentrations of mercury salt, the catalytic effect of the acid is significant. As he noted, the activation energy for the Hg(II) catalyzed reaction alone is obtainable by reducing k by the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

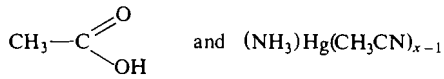
amount contributed by the acid (11). This yields a value of 19.3 kcal which is in good agreement with the results obtained from Raman data, considering different experimental conditions.

Mechanism for the Hydrolysis Reaction

It is assumed that virtually all of the Hg^{2+} is initially solvated by acetonitrile; this species $(CH_3CN)_xHg^{2+}$ undergoes reaction as follows



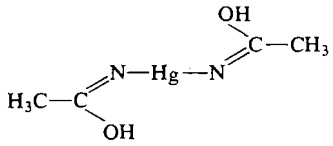
Subsequent slow reaction gives



Water attacks species **1** slowly giving intermediate **2**, which is transformed by proton transfer to species **3** and **4**. Species **5** and **6** are significant only after the reaction has progressed for a very long time. A final mercury(II) species is believed to be $Hg(NH_3)_n^{2+}$. However, prior to its formation a species such as **6** which could recycle through steps 1 to 4 is possible. Species **1**, **4**, **5**, and a form of **6** are spectroscopically observable. Species **1** is presumably an ion–dipole complex which is very stable. No Raman frequency attributable to the metal–nitrogen stretch has been observed and thus substantial covalence is excluded. However, the shift in the position of the C≡N stretch is clear indication of the solvation of the cation by acetonitrile and parallels the observations for Zn^{2+} (28) and Ag^+ (23). Observation of lines identical to those of pure acetamide provides support for species **4**; in addition an intense line at 300 cm^{-1} ascribed to the Hg^{2+}—N stretch suggests that the acetamide is associated with the mercury ion. In species **1** to **4** it is not clear what value should be assigned to x. Because more than one molecule of acetonitrile in the solvation sphere of Hg^{2+} is hydrolyzable, the constancy of the line intensity of bulk acetonitrile (2255 + 2295 cm^{-1}) over the first 400 min of reaction is rationalized. The apparent increase in intensity of the 2255 + 2295 cm^{-1} lines over this time span, even after correction for volume changes, may suggest some displacement of CH_3CN from the first coordination sphere of Hg^{2+} in steps such as 1–3.

In the four solutions the mercury(II) concentrations were identical but different amounts of CH_3CN were bound to Hg^{2+}. Presumably remaining sites in the primary coordination sphere are occupied by water molecules; the amount of bound water increases as the H_2O/CH_3CN ratio increases, judging from the $\bar{n}$ data quoted earlier. But the reactivity of all acetonitrile molecules in the primary coordination spheres must be the same and independent of the number or nature of other ligands bound to Hg^{2+} for the rate law to be as observed. The fact that rate depends on total water concentration, despite the wide variation in the amount of bound water over the four solutions, suggests that both unbound and possibly bound water are reactive species. The reaction thus involves acetonitrile in the primary solvation sphere of Hg^{2+} reacting with water while in a medium of acetonitrile (bulk) and water. Apparently the differences in the solvent compositions of the four solutions also do not affect the reactivity of the bound acetonitrile. This behavior does not appear to be widespread although it is difficult to find comparable studies in the literature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



A structure similar to **2** has been proposed for mercury(II) acetamide from X-ray studies (40). According to n.m.r. data, however, the proton is probably bonded to the nitrogen atom (41). These results support the conclusion that the acetamide anion acts as a monodentate N-bonded ligand and that the CN bond is of extensive double bond character. The ability of mercury to form stable bonds with nitrogen accounts for a relatively low activation energy (18.9 kcal compared with 24–26 kcal for acids (14)) and the failure of most other metals to catalyze the reaction at room temperature.

Mercury acetamide complexes appear to be much more stable than mercury acetonitrile towards hydrolysis reactions. The fact mentioned earlier that $Hg(AcNH_2)_2(NO_3)_2$ and $HgAcNH_2Cl_2$ can be prepared from aqueous solutions supports this conclusion. For the 2/1 solution in this study the time for half of the acetonitrile to be hydrolyzed is 650 min (for solutions with higher H_2O/CH_3CN ratios, this period is shorter) as estimated from the intensity variation in the 2150–2400 cm^{-1} region. It is apparent from spectra of this solution that the principal species after this time interval is acetamide. Even when 75% of the acetonitrile is converted (at approximately 1800 min) only a very small amount of acetamide is converted to acetic acid as judged from the bands characteristic of acetic acid and the ammine complexes.

The merit of using mercury(II) to catalyze the reaction is that it is one of very few substances which cause conversion of acetonitrile to acetamide, only mild conditions are required, and the product forms with high yield and purity according to the spectra. Reaction is slower with MnO_2 (4) and side reactions are more numerous with nickel catalysts (6). In suitable cases the use of a mercury(II) catalyst may be advantageous.

Determination of 3 × 3 Harmonic Force Field of Planar X_2YZ Molecules[1]

J. C. D. Brand and Ch. V. S. Ramachandra Rao
Department of Chemistry, University of Western Ontario, London, Ontario N6A 3K7

Received July 12, 1974

J. C. D. Brand and Ch. V. S. Ramachandra Rao. Can. J. Chem. **53**, 437 (1975).
The problem of multiple solutions encountered during the determination of a 3 × 3 General Harmonic Force Field is analyzed. The A_1 force fields of the planar molecules $COCl_2$, NO_2F, and H_2CO, are considered and formaldehyde is treated in some detail as illustration.

J. C. D. Brand et Ch. V. S. Ramachandra Rao. Can. J. Chem. **53**, 437 (1975).
On analyse le problème des solutions multiples rencontrées durant la détermination d'un champ de force harmonique général de 3 × 3. Le champ de force A_1 des molécules planaires $COCl_2$, NO_2F et H_2CO sont considérées et on traite, en détail à titre exemple, la molécule de formaldéhyde. [Traduit par le journal]

Introduction

During the least-squares refinement of the force constants of a polyatomic molecule, it is quite common to encounter a situation where several distinct solutions to the force field fit the available data equally well even when the data are in excess. Multiple solutions to the force field result from the fact that force constants are essentially determined from the data as the solutions of a set of polynomial equations of varying degrees. An illuminating discussion of this problem in the case of the 2 × 2 E species force field of XY_3 molecules was given by Hoy, Stone, and Watson (1). McKean and Duncan (2) have given an extensive survey of the problem of multiple solutions for several 2 × 2 and 3 × 3 cases. By analyzing the equations to be solved, Moule and Rao (3) have discussed the uniqueness of the force field of the CH_3F molecule whose vibrations are divided into $3A_1 + 3E$ and found that it is easier to treat the problem in the compliance scheme rather than the force constant scheme.

It is one thing to determine a set of force constants from given data by a least-squares technique and another to establish the uniqueness or otherwise of such a set. In fact, the latter problem has been considered in only a few cases. It is not uncommon either to ignore the existence of alternative physically-reasonable sets of solutions or to discriminate between them on empirical grounds. In this note, we shall discuss a method of establishing the uniqueness of a 3 × 3 force field of A_1 species determined using a variety of data taking $COCl_2$, NO_2F, and H_2CO as illustrations. Force fields of these molecules have of course been determined but an analysis of their uniqueness problem is lacking. We assume that the following data are given for the three molecules: (*i*) $COCl_2$ (frequencies and centrifugal distortion constants) (4); (*ii*) NO_2F (frequencies and centrifugal distortion constants) and $^{15}NO_2F$ (frequencies) (5); (*iii*) H_2CO, D_2CO, HDCO, and $H_2{}^{13}CO$ (frequencies) (2, 6). It is shown that the combination of data represented by (*i*) does not yield a unique solution to the force field whereas the data in (*ii*) and (*iii*) are capable of doing so. In each case we are concerned with the uniqueness, not the actual calculation, of the force field.

[1]Contribution No. 117 of the Photochemistry Unit.

The Method

With the standard notation, the symmetry coordinates for the five in-plane vibrations are taken as (6)

$$\left.\begin{aligned} S_1 &= \frac{1}{\sqrt{2}}(\Delta r_1 + \Delta r_2) \\ S_2 &= \Delta R \\ S_3 &= \frac{1}{\sqrt{6}}(2\Delta\alpha - \Delta\beta_1 - \Delta\beta_2) \end{aligned}\right\} A_1 \text{ species}$$

and

$$\left.\begin{aligned} S_5 &= \frac{1}{\sqrt{2}}(\Delta r_1 - \Delta r_2) \\ S_6 &= \frac{1}{\sqrt{2}}(\Delta\beta_1 - \Delta\beta_2) \end{aligned}\right\} B_2 \text{ species}$$

The secular equation in the compliance scheme, in terms of "symmetry forces", is given by (7)

$$[1] \qquad (\mathbf{G}^{-1}\mathbf{C})\mathbf{N} = \mathbf{N}\mathbf{\Lambda}^{-1}$$

Using $\mathbf{K} = \mathbf{G}^{-1}$ and $\mathbf{\Phi} = \mathbf{\Lambda}^{-1}$, the above equation is written as

$$[2] \qquad (\mathbf{KC})\mathbf{N} = \mathbf{N}\mathbf{\Phi}$$

This can be expanded as an algebraic equation for the three vibrations of the A_1 species into linear (L), quadratic (Q), and cubic ($\mathscr{C}$) parts, (3):

$$[3] \qquad L(C_{ij}) = \phi_1 + \phi_2 + \phi_3$$

$$[4] \qquad Q(C_{ij}) = 0$$

and

$$[5] \qquad \mathscr{C}(C_{ij}) = 0$$

For the B_2 species, the corresponding equations are

$$[6] \qquad K_{55}C_{55} + K_{66}C_{66} + 2K_{56}C_{56} = \phi_5 + \phi_6$$

and

$$[7] \qquad (K_{55}K_{66} - K_{56}^2)(C_{55}C_{66} - C_{56}^2) = \phi_5\phi_6$$

The centrifugal distortion constants $\tau_{\alpha\beta\gamma\delta}$ are related to the compliance constants C_{ij} linearly (7, 8)

$$[8] \qquad \frac{-112.9615 \times 10^{-4}}{I_\alpha^e I_\beta^e I_\gamma^e I_\delta^e} \sum_{i,j} J_{\alpha\beta}{}^i J_{\gamma\delta}{}^j C_{ij} = \tau_{\alpha\beta\gamma\delta}$$

$J_{\alpha\beta}{}^i = (\partial I_{\alpha\beta}/\partial S_i)_e$. The τ values are in cm^{-1}, when masses are expressed in a.m.u., internuclear distances in Å, and the stretching, stretch–bend, and bending compliance constants in Å $mdyn^{-1}$, $mdyn^{-1}$, and $(mdyn\ Å)^{-1}$ respectively. Of the four independent τ values, τ_{aaaa}, τ_{bbbb} and τ_{aabb} depend only on the force constants of the A_1 species while τ_{abab} depends only on those of the B_2 species. The set of eqs. 3–8 can now be seen to determine in a simple way the uniqueness or otherwise of the force field.

$COCl_2$ (ν and τ)

Mirri *et al.* (4) have tried to determine the nine force constants of $COCl_2$ for the A_1 and B_2 species using five frequencies and four τ values. As can be seen from the linear nature of eq. 8 connecting τ_{abab} and C_{ij}, one finds from eqs. 6–8, that *two and only two* discrete sets of compliance constants (hence force constants) can be obtained for the B_2 species.[2] This fact does not appear to have been realized (4).

For the A_1 species, Mirri *et al.* (4) noted that it was not possible to determine a unique set of force constants. They obtained several sets corresponding to the range of variation of two chosen force constants F_{12} and F_{23}. We note initially that for the given data, eqs. 3–5 and 8 give rise to four independent linear equations, a quadratic, and a cubic equation in terms of the six compliance constants. From Bézout's theorem (9), the number of mathematically possible solutions is given by the product of the degrees of all the equations. Thus in the present case, we have $2 \times 3 = 6$ sets of solutions for the A_1 species force field. In principle, Bézout's or Sylvester's eliminant may be used to reduce the system of equations to a polynomial equation of degree six in each one of the unknowns, in turn, after which the equation is solved numerically for each of the six values of that unknown. Since the physical solution should correspond to real values of C_{ij} and complex roots occur in pairs, we should obtain a minimum of two and a maximum of six real solutions. Thus with the given data, the force field is *not* unique.

$^{14}NO_2F$ (ν and τ) and $^{15}NO_2F$ (ν)

Mirri *et al.* (5) have obtained the force constants of NO_2F for the A_1 and B_2 species using the ten frequencies of $^{14}NO_2F$ and $^{15}NO_2F$ as well as the four τ values of $^{14}NO_2F$. This essentially means supplementing the type of data of the previous problem with the isotopic shifts.

For the B_2 species, it is now obvious that the solution is unique since the two B_2 frequencies of $^{15}NO_2F$ provide one more independent linear equation from eq. 6 in terms of the three compliance constants C_{55}, C_{66}, and C_{56}. This eliminates one of the two possible sets making the solution to the B_2 force field unique.

For the A_1 species we have five independent linear equations, in terms of the six compliance constants, coming from [3] and [8], and two quadratic equations coming from [4] for the two molecules. These are easily seen to be adequate

[2]For a 2×2 case, even in the force constant scheme, the equation analogous to [8] is linear. Since $|\mathbf{F}| = \lambda_5\lambda_6/|\mathbf{G}|$, we have

$$\tau_{abab} = -2(I_a^e I_b^e I_c^e I_d^e)\tau_{abab}$$
$$= |\mathbf{G}|/\lambda_5\lambda_6[(J_{ab}{}^5)^2 F_{66} + (J_{ab}{}^6)^2 F_{55} - 2(J_{ab}{}^5 \cdot J_{ab}{}^6)F_{56}]$$

to establish the uniqueness of the A_1 species force field.

H_2CO, D_2CO, HDCO, and $H_2{}^{13}CO$ (Frequencies)

Formaldehyde provides one of the most illuminating examples illustrating the occurrence of two indistinguishable sets of force constants (2). We shall therefore treat this case in a little more detail.

Duncan and Mallinson (6) have obtained the best set of force constants for formaldehyde using all the available data. They have noted that the physically-reasonable alternative set of A_1 species force constants determined from the frequency data of H_2CO, D_2CO, and HDCO (2) is incompatible with the ^{13}C frequency shifts. We now show that these frequency shifts provide the *minimum* extra data necessary to make the force field unique. We assume that the given data consist of the frequencies of all the four molecules[3] and note that the B_2 species force field is uniquely determined. The nine data of H_2CO, D_2CO, and $H_2{}^{13}CO$ give rise to nine equations in terms of the six compliance constants C_{ij}: three linear, three quadratic, and three cubic coming from eqs. 3, 4, and 5 respectively.

For HDCO, the secular equation being of order five ($5A' \leftarrow 3A_1 + 2B_2$) gives rise to five polynomial equations of degrees 1 to 5. Since the B_2 force field is known, the fifth degree equation reduces to a cubic equation $\mathscr{C}_3 = 0$ in terms of the six compliance constants of the A_1 species. As a result, the cubic and quartic equations reduce to quadratic equations in six variables. These equations are somewhat tedious to form and since it is not necessary to consider them in the present context we shall ignore them.

The four linear equations are given by

$$[9]\quad L_i \equiv K_{11}{}^iC_{11} + K_{22}{}^iC_{22} + 2K_{33}{}^iC_{33} + 2K_{12}{}^iC_{12} + 2K_{13}{}^iC_{13} + 2K_{23}{}^iC_{23} = \mu_i$$

where $i = 1, 2, 3$, and 4 indexes the isotopes H_2CO, D_2CO, HDCO, and $H_2{}^{13}CO$ respectively. μ_i consists of given data and for HDCO includes additional terms involving C_{55}, C_{66}, and C_{56} which are known. The advantage of analyzing the uniqueness problem in the compliance scheme lies in the fact that the above four equations are completely independent unlike in the force constant scheme (10). Solving them for C_{11}, C_{22}, C_{33}, and C_{12} in terms of $x = C_{13}$ and $y = C_{23}$ and substituting in [4] and [5], we have

$$[10]\quad Q_i(x, y) \equiv A_ix^2 + 2H_ixy + B_iy^2 + 2U_ix + 2V_iy + W_i = 0$$

for $i = 1, 2, 3, 4$ and

$$[11a]\quad \mathscr{C}_1(x, y) \equiv C_{22}x^2 - 2C_{12}xy + C_{11}y^2 + [\lambda_1\lambda_2\lambda_3/|\mathbf{G}^{-1}| - C_{33}(C_{11}C_{22} - C_{12}{}^2)] = 0$$

$$[11b]\quad \equiv a_{30}x^3 + a_{21}x^2y + a_{12}xy^2 + a_{03}y^3 + a_{20}x^2 + a_{11}xy + a_{02}y^2 + a_{10}x + a_{01}y + a_0$$

The remaining three cubic equations are not independent of $\mathscr{C}_1 = 0$ and lead to three product rule relations. The coefficients in eqs. 10 and 11*b* are functions of K_{ij} and ϕ_i. For given values of C_{11}, C_{22}, C_{33}, and C_{12}, eq. 11*a* becomes a quadratic equation in x and y.

The force constants of formaldehyde for the A_1 and B_2 species obtained by Duncan and Mallinson (6), along with the corresponding compliance constants, are given in Table 1. When the minimum number of algebraic equations is used, as in the above, the calculated compliance (force) constants are extremely sensitive to the data used. Thus for the sake of consistency, we take as data the calculated values obtained by using the best and unique set of force constants (6).

It is instructive to solve the above equations in a graphical form. Equation 10 in general represents an ellipse, a parabola, or a hyperbola depending upon whether $H_i^2 - A_iB_i$ is negative, zero, or positive, respectively. In the present case, all the four eqs. 10 are found to represent ellipses, the values of $H_i^2 - A_iB_i$ ($i = 1, 2, 3, 4$) being -14.36, -105.34, -42.19, and -15.11. These were drawn to scale using a CalComp plotter under the control of a PDP-11 computing system. Figure 1 shows the two ellipses $Q_1 = 0$ and $Q_2 = 0$ representing H_2CO and D_2CO molecules. $Q_1(x, y) = 0$ and $Q_2(x, y) = 0$ which in general have four common points of intersection can be seen to be intersecting at two real points ($x_1 = -0.037$, $y_1 = 0.059$) and ($x_2 = -0.047$, $y_2 = 0.044$) which are close to each other. The remaining two points correspond to complex roots. The two sets of compliance con-

[3]Even though only one of the isotopic shifts, $\Delta\nu_2(^{12}C—^{13}C)$, is known experimentally at present, it does not in any way vitiate the method of analysis presented here.

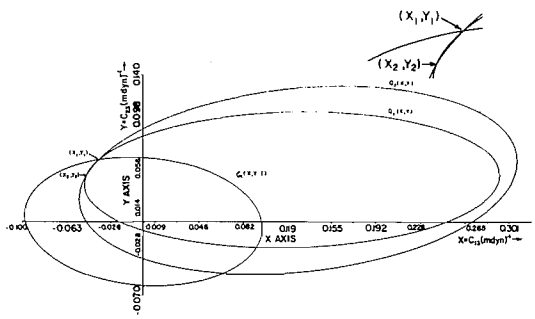

FIG. 1. Ellipses $Q_1 = 0$, $Q_2 = 0$, and $\mathscr{C}_1(I) = 0$ (see eqs. 10 and 11*a*) representing H_2CO, D_2CO, and H_2CO, respectively. Their common point of intersection corresponding to the unique solution to the force field gives the compliance constants $C_{13} = -0.037$ and $C_{23} = 0.059$ in units of mdyn^{-1}. The inset shows the points of intersection.

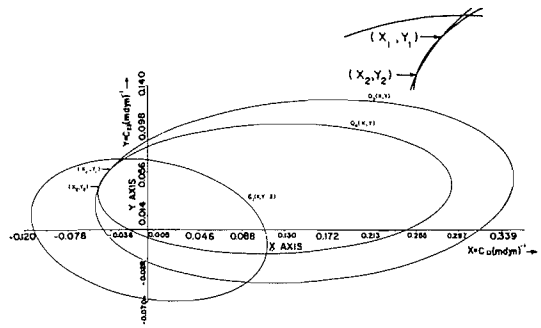

FIG. 2. Ellipses $Q_3 = 0$ and $Q_4 = 0$ (see eq. 10) representing HDCO and $H_2{}^{13}CO$ respectively. They intersect in the same two points (x_1,y_1) and (x_2,y_2) as do $Q_1 = 0$ and $Q_2 = 0$ (see Fig. 1). $\mathscr{C}_1(II) = 0$ representing H_2CO (see eq. 11*a*) can be seen to be incompatible with both the points. The inset shows the points of intersection.

stants C_{11}, C_{22}, C_{33}, and C_{12} corresponding to (x_1,y_1) and (x_2,y_2) are now obtained using the four linear eqs. 9. These values are also given in Table 1 as Sets I and II.

Ellipses $Q_3 = 0$ and $Q_4 = 0$, shown in Fig. 2, representing HDCO and $H_2{}^{13}CO$ are found to intersect at exactly the same two points (x_1,y_1) and (x_2,y_2). Thus these two equations are of no help in determining a unique solution.

Now a simple way to demonstrate that the cubic equation $\mathscr{C}_1 = 0$ weeds out Set II is by considering eq. 11*a* instead of [11*b*]. For the two sets of C_{11}, C_{22}, C_{33}, and C_{12} values corresponding to the two points of intersection (x_1,y_1) and (x_2,y_2), we have two quadratic equations $\mathscr{C}_1(x,y:I) = 0$ and $\mathscr{C}_1(x,y:II) = 0$ in x and y which are again found to represent ellipses. These were drawn in Figs. 1 and 2. While $\mathscr{C}_1(I) = 0$ in Fig. 1 is found to eliminate (x_2,y_2), retaining Set I as the unique solution to the force field, $\mathscr{C}_1(II) = 0$ in Fig. 2 can be seen to be incompatible with both the sets. Incidentally the method also suggests that we have effectively used seven data in obtaining a unique set of six compliance constants. The best set of potential constants is of course obtained by the least-squares refinement procedure employing all the data (6).

Conclusions

In this paper it is shown that the uniqueness of a 3 × 3 harmonic force field can be established more easily than has been thought possible hitherto. A similar analysis wherever possible

TABLE 1. The A_1 and B_2 species force field of formaldehyde (6)

Species	Force constant*	Value	Compliance constant*	Value	Compliance constants Set I	Compliance constants Set II
A_1	F_{11}	4.963	C_{11}	0.2040	0.2039	0.2171
	F_{22}	12.903	C_{22}	0.0801	0.0801	0.0801
	F_{33}	0.570	C_{33}	1.8016	1.8019	1.7698

can be carried out for several molecules, with a variety of data, involving 3 × 3 force fields. It may be noted that the simplified nature of the analysis is a consequence of choosing the compliance scheme.

We thank Dr. G. D. Zeiss for his help in plotting the curves shown in Figs. 1 and 2. This work was supported by the National Research Council of Canada.

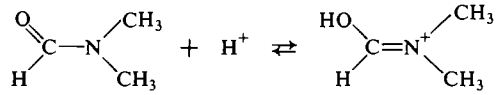
Protonation du *N,N*-diméthylformamide: étude par spectrométries vibrationnelle et électronique

P. COMBELAS, M. COSTES ET C. GARRIGOU-LAGRANGE
Centre de Recherches Paul Pascal, Domaine Universitaire, 33405 – Talence, France

Reçu le 27 juin 1974

P. COMBELAS, M. COSTES et C. GARRIGOU-LAGRANGE. Can. J. Chem. **53**, 442 (1975).

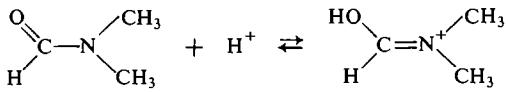
Les spectres infrarouges et Raman du diméthylformamide en solution aqueuse acide (chlorhydrique ou sulfurique) montrent l'existence d'un seul équilibre de protonation



Le pK correspondant, déterminé par spectroscopie ultraviolette, est égal à -1.35 ± 0.05; par spectroscopie Raman, une valeur moins précise (-1.1 ± 0.5) a été obtenue. Ces résultats infirment certaines conclusions précédentes tendant à mettre en évidence l'existence de deux équilibres d'ionisation du diméthylformamide.

P. COMBELAS, M. COSTES, and C. GARRIGOU-LAGRANGE. Can. J. Chem. **53**, 442 (1975).

Infrared and Raman spectra of acidic (hydrochloric or sulfuric) aqueous solutions of dimethylformamide indicate the existence of a single protonation equilibrium.



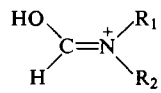
The pK for this reaction was evaluated as -1.35 ± 0.05 from u.v. spectra; a less precise value (-1.1 ± 0.5) was obtained from Raman spectra. This result disagrees with earlier conclusions which favored the existence of two ionization equilibria for dimethylformamide.

[Journal translation]

Parmi les composés organiques, les amides possèdent des propriétés basiques relativement importantes. Leur protonation par les acides minéraux ou organiques a fait l'objet d'un très grand nombre de travaux à la fois qualitatifs (localisation du site de protonation) et quantitatifs (détermination des pK).

Il résulte de ces études que le proton se fixe préférentiellement sur l'oxygène (1), et que les pK sont proches de zéro (2). Toutefois certains travaux récents effectués par r.m.n. montrent qu'on ne peut pas éliminer une faible protonation sur l'azote (3). Certains auteurs interprètent d'ailleurs leurs résultats obtenus par spectrométrie ultraviolette par l'existence de deux valeurs de pK (4), interprétation contestée par d'autres auteurs (5).

La spectrométrie de vibration doit permettre de montrer s'il existe une ou deux espèces protonées. Jusqu'à présent, à notre connaissance, peu d'études de ce type ont été faites. Spinner (6) analysant les spectres infrarouges et Raman du *N,N*-dimethylformamide (DMF) en solution aqueuse chlorhydrique ou sulfurique et à l'état de chlorhydrate solide, conclut à la présence de la forme ionique classique



1

et, en outre, d'une forme pouvant avoir l'une des structures (**2**) ou (**3**) selon le milieu considéré

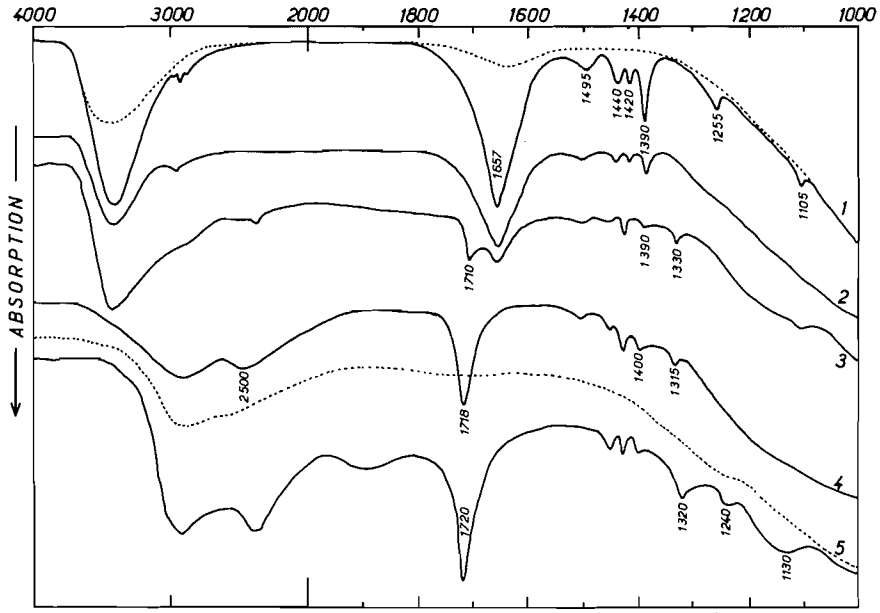

FIG. 1. Spectres infrarouges entre 4000 et 1000 cm^{-1} du DMF (5 *M*) dans des solutions aqueuses sulfuriques à différentes concentrations (*X M*) en acide sulfurique. *1*, $X = 0$; *2*, $X = 4$; *3*, $X = 8$; *4*, $X = 18.5$, DMF = 7.5 *M*. Courbes en pointillés: spectre du solvant en l'absence d'amide. Conditions experimentales: spectromètre Perkin–Elmer 225, cellule CaF_2 de quelques microns d'épaisseur.

Une étude de l'hydratation et de la protonation du *N,N*-diméthylacétamide (DMA) (7) nous avait permis de conclure à l'existence des équilibres suivants

[1] $$B + H_2O \rightleftarrows B \ldots H_2O$$

[2] $$B \ldots H_2O + H^+ \rightleftarrows BH^+ \ldots H_2O$$

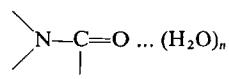
excluant toute autre forme d'interaction amide–acide. Il nous a semblé intéressant de reprendre ce type de travail dans le cas du DMF et d'y adjoindre la mesure du (ou des) p*K* en utilisant plusieurs techniques complémentaires: les spectrométries ultraviolette, infrarouge et Raman.

Dans une première partie, nous analyserons les spectres de vibration du DMF en solution aqueuse chlorhydrique ou sulfurique, tandis que, dans la seconde partie, nous déterminerons le p*K* du DMF dans ces solutions.

Analyse des spectres de vibration du DMF en solution aqueuse acide

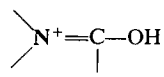
Sur les figs. 1, 2 et 3 sont représentés les spectres infrarouges et Raman du DMF en solution aqueuse à diverses concentrations d'acide sulfurique (figs. 1, 3) ou chlorhydrique (fig. 2).

Les variations spectrales les plus nettes que l'on peut observer se situent dans le domaine 1600–1800 cm^{-1} où se trouve la bande de vibration de valence νC=O de l'amide. En l'absence d'acide, la fréquence de cette bande est de 1657 cm^{-1} environ. Elle correspond à l'amide neutre dont les groupements carbonyle sont liés à l'eau



4

une ou deux liaisons hydrogène pouvant s'établir sur l'atome d'oxygène de ce groupe amide (7). Par additions d'acide chlorhydrique ou sulfurique, cette bande tend à disparaître progressivement au profit d'une bande de plus haute fréquence entre 1700 et 1720 cm^{-1} qui subsiste seule dans les spectres des solutions les plus acides. Ceci semble correspondre à un équilibre entre deux formes amide, l'une neutre (**4**), l'autre (**1**) résultant de l'interaction avec l'acide. Par analogie avec nos précédents résultats (7, 8), cette deuxième forme est attribuée aux espèces protonées



1

probablement liées à l'eau.

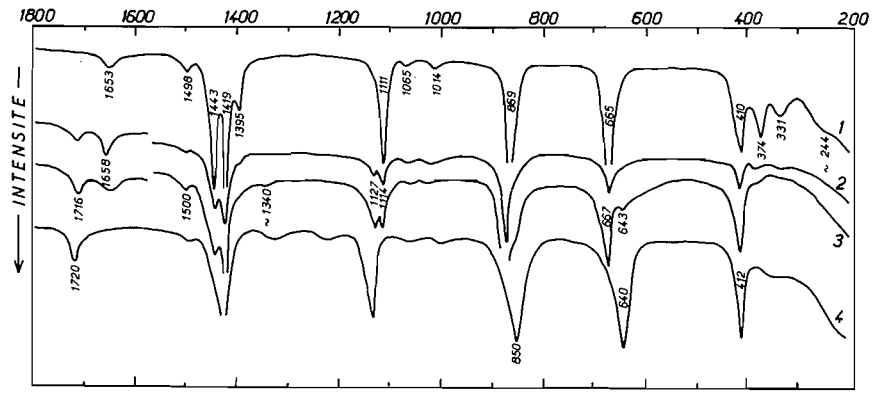

FIG. 2. Spectres Raman entre 1800 et 200 cm^{-1} du DMF (2.5 *M*) dans des solutions aqueuses chlorhydriques à différentes concentrations (*X M*) en acide chlorhydrique. Spectromètre Coderg PHl. Laser He–Ne. *1*, $X = 0$; *2*, $X = 4.2$; *3*, $X = 6.3$; *4*, $X = 12.6$.

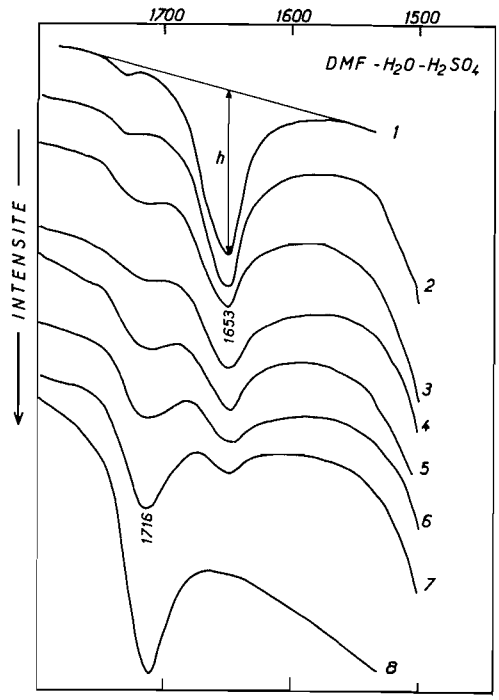

FIG. 3. Spectres Raman entre 1800 et 1500 cm^{-1} du DMF dans des solutions aqueuses sulfuriques à différents pourcentages *P* en acide sulfurique. Concentrations en DMF: *cf.* tableau 1. Spectromètre Coderg PHl. Laser He–Ne Spectra Physics modèle 125(63 mW). Température voisine de 22 °C. *1*, $P = 1.5$; *2*, $P = 6$; *3*, $P = 12$; *4*, $P = 18$; *5*, $P = 24$; *6*, $P = 27$; *7*, $P = 35$; *8*, $P = 46.5$.

La bande intense à $\simeq 1700\,cm^{-1}$ caractéristique de la protonation n'a pas encore été attribuée de manière indiscutable dans les sels d'amide. Nous la faisons correspondre comme dans le cas du DMA (7) à la vibration $\nu C{=}N^+$. Sa fréquence varie quelque peu avec l'acidité (figs. 1–3) ce qui peut être relié à une influence du milieu sur les ions.

On note par ailleurs, d'une part, l'apparition d'une absorption large vers 2500 cm^{-1} (fig. 1) qui peut correspondre à la vibration νOH des cations amidium (**1**) (7) et d'autre part une faible bande à environ 1340 cm^{-1} (figs. 1 et 2) qui peut résulter du couplage entre les vibrations νCO et δOH du DMF protoné (7).

Cette interprétation qualitative des spectres ne conduit donc à envisager, contrairement à Spinner (6), qu'un seul type d'équilibre entre deux formes: amide neutre et amide protoné, cette dernière ayant la structure classique (**1**). Il apparaît difficile d'introduire une autre espèce de type ionique (**2**) ou non-ionique (**3**) caractérisée par une bande $\nu C{=}O$ de fréquence identique à celle de l'amide neutre associé à l'eau (**4**) et qui n'existerait que dans le cas de l'acide chlorhydrique ou du chlorhydrate solide. En effet nos résultats sont très comparables d'un acide à l'autre, en infrarouge et en Raman, seules les concentrations d'acide et d'amide utilisées pouvant perturber l'allure des spectres en modifiant le nombre de chaque espèce.

Spinner (6) appuyait son raisonnement sur une valeur du p*K* du DMF proche de 0 à −0.5 par comparaison avec le résultat trouvé par Huisgen *et coll.* (9) dans un mélange acide perchlorique – acide acétique glacial, aucune mesure n'ayant été faite en milieu aqueux.

Nous avons donc déterminé le p*K* du DMF dans les solutions d'acide chlorhydrique et sulfurique.

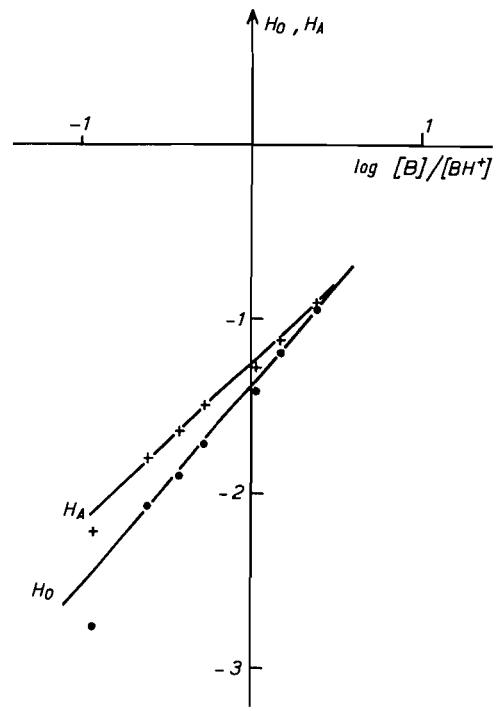

FIG. 5. Evolution du rapport log |B|/|BH^+| du DMF mesuré par spectrométrie ultraviolette en fonction de H_0 et H_A pour H_2SO_4.

Détermination du p*K* du DMF en solution aqueuse acide

Dans le cas de la protonation d'une base faible par un acide fort, il n'est pas possible d'utiliser l'échelle habituelle des p*H*. La concentration en acide demandée pour les réactions étant souvent très importante, il est impossible de faire l'approximation de la solution idéale et il faut tenir compte des coefficients d'activité. La détermination de ces coefficients étant longue et difficile, Hammett (10*a*) a établi empiriquement une fonction d'acidité H_0 définie par la relation 3

$$[3] \qquad H_0 = \mathrm{p}K_{\mathrm{BH}^+} + \log \frac{|\mathrm{B}|}{|\mathrm{BH}^+|}$$

|B| et |BH^+| étant les molarités des formes libres et protonées et il a dressé des tables de valeurs H_0 pour un certain nombre d'acides forts.

Pour déterminer les molarités |B| et |BH^+|, deux techniques ont été utilisées: la spectrométrie ultraviolette, méthode classique de mesure (10*b*), et la spectrométrie Raman, technique plus délicate en raison des sources d'erreurs expérimentales.

Mesures effectuées par spectroscopie ultraviolette

Nous avons étudié la région 180–230 mμ caractéristique de l'absorption du DMF. La fig. 4 montre la variation de l'absorbance à 205 mμ avec les fonctions H_0 et H_A, cette dernière étant plus spécialement adaptée aux amides (11). Ces deux courbes présentent un point d'inflexion qui donne la valeur du p*K* au point de demi-neutralisation, soit: p$K \simeq -1.4$.

L'application de la relation (3) aux résultats obtenus pour chaque fonction d'acidité est représentée sur la fig. 5. Les droites ainsi tracées ont des pentes voisines de 1 (0.95 et 1.20) et leur ordonnée à l'origine conduit à une valeur moyenne du p*K* de -1.35 ± 0.05. Elle est en accord avec un résultat r.m.n. (12) (p$K = -1.34$) publié au cours de ce travail, mais non pas avec les mesures cryoscopiques (13) et potentio-

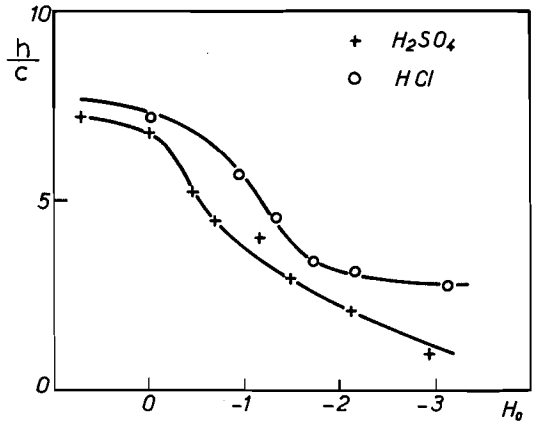

FIG. 6. Variation de l'intensité diffusée à 1650 cm^{-1} du DMF en solution aqueuse sulfurique ou chlorhydrique en fonction de H_0.

métriques (9) ($pK \simeq 0$), relatives à d'autres milieux.

Mesures effectuées par spectrométrie Raman

Peu de travaux de ce type ont été réalisés jusqu'à maintenant. On note les résultats de Deno et Wisotsky (14) sur différentes molécules: acétamide, méthanol, dioxane, acétone et acétonitrile. De nombreux paramètres plus ou moins contrôlables affectent la précision de telles mesures (diffusion parasite, dépoussiérage des

TABLEAU 1. Protonation du DMF par l'acide sulfurique

3.76	28.1	−3.1	2.8

solutions, stabilité de la source laser, fluorescence éventuelle, etc.). Par ailleurs, la faible intensité des bandes intéressantes conduit à étudier des solutions nettement plus concentrées en amide que lors des expériences précédentes ($\simeq 3$ M au lieu de 10^{-3} M). Ces concentrations étant très élevées, il faudrait pour être exact utiliser les coefficients d'activité.

Une étude préalable de mélanges binaires DMF–eau de diverses concentrations en amide permet de vérifier la loi de diffusion $h = \alpha_v C$ avec h = hauteur de la bande déterminée comme l'indique la fig. 3; C = molarité du DMF; α_v = coefficient de diffusion englobant tous les autres paramètres.

Cette loi testée sur les bandes ν(C=O) à 1650 cm^{-1} et ν(CH) à 2950 cm^{-1} donne,[1] dans le domaine des concentrations utilisées, de très bonnes relations linéaires $h = \alpha_v C$. Celle qui est obtenue pour la vibration de valence carbonyle peut en outre servir de courbe étalon pour les mélanges ternaires acides et donner ainsi les quantités $|B|$ et $|BH^+|$ à l'équilibre.

[1]L'intensité de cette dernière bande a été utilisée par la suite comme référence.

Dans le cas des solutions acides, toutes précautions ont été prises afin de limiter au maximum les risques d'hydrolyse du DMF (solutions refroidies lors de leur préparation, enregistrement immédiat des spectres). On ne constate ainsi aucune modification sensible des spectres dans un délai de 30 min.

Les résultats obtenus pour H_2SO_4 et HCl sont rassemblés dans les tableaux 1 et 2 et sur les figs. 6 et 7. Les valeurs des pK obtenues en utilisant la fonction H_0 (figs. 6, 7) sont p$K \simeq -0.9$ pour H_2SO_4 et p$K \simeq -1.3$ pour HCl.

On est conduit à prendre une valeur moyenne de l'ordre de -1.1 ± 0.5 qui, compte tenu du manque de précision de cette technique, semble en assez bon accord avec les mesures u.v. et r.m.n. Ceci est intéressant à noter étant donné la grande différence de concentration en amide qui existe entre ces diverses mesures.

Ces études quantitatives u.v. et Raman mettent ainsi en évidence une valeur unique du pK d'ionisation contrairement aux conclusions de divers auteurs (4, 6). Elles sont cohérentes avec l'interprétation qualitative des spectres de vibration que nous avons proposée dans la première partie. Nous pensons que les phénomènes secondaires pouvant parfois être observés sur les spectres (déplacement de fréquences des bandes, apparente variation du pK) doivent s'interpréter, comme l'ont suggéré certains auteurs (5, 11) par des effets du milieu sur les ions.

Nous remercions Mademoiselle H. Richard de l'aide qu'elle nous a apportée pour l'enregistrement et l'étude des spectres ultraviolets.

Kinetics of Environmental Averaging, and the Stereochemistry of $(CH_3)ClGe(C_5H_7O_2)_2$. A Case of a Second Order Kinetic Process

KEN A. HERSH AND NICK SERPONE[1]

Department of Chemistry, Sir George Williams Campus, Concordia University, Montreal, Quebec H3G 1M8

Received September 3, 1974

KEN A. HERSH, and NICK SERPONE. Can. J. Chem. **53**, 448 (1975).

Dynamic n.m.r. studies on the stereochemistry of $(CH_3)ClGe(C_5H_7O_2)_2$ (acac = $C_5H_7O_2^-$), indicate that the complex adopts the *cis* configuration in $CDCl_3$–CCl_4 solutions. Kinetics of environmental averaging of the acac ring proton (—CH=) and acac methyl groups between the respective nonequivalent sites in the C_1 isomer have been investigated in the temperature range −31.0 to 23.1° by line-broadening techniques. Kinetics of the averaging process are second order in complex concentration. Activation parameters are: $E_a = 6.0 \pm 0.3$ kcal/mol, $\Delta S^* = -30 \pm 1$ e.u., and $k_{25} = 1.6 \times 10^2\ M^{-1}\ s^{-1}$. Rearrangements are viewed as occurring via a germanium–oxygen bond rupture as a first step to yield a five-coordinate intermediate. The rate-determining sequence is thought to involve proper orientation of two five-coordinate species prior to formation of a bis-acac bridged dimer.

KEN A. HERSH et NICK SERPONE. Can. J. Chem. **53**, 448 (1975).

Des études de r.m.n. dynamique sur la stéréochimie du $(CH_3)ClGe(C_5H_7O_2)_2$ (acac = $C_5H_7O_2^-$), indiquent que le complexe adopte une configuration *cis* en solution dans $CDCl_3$–CCl_4. On a étudié, à des températures allant de −31.0° à 23.1° et en faisant appel aux techniques des élargissements de bandes, la cinétique de la répartition moyenne de l'environnement des protons du noyau acac (—CH=) et des groupes méthyles acac le tout entre les différents sites non équivalent dans l'isomère C_1. La cinétique de ces processus est du second ordre en concentration du complexe. Les paramètres d'activation sont $E_a = 6.0 \pm 0.3$ kcal/mol, $\Delta S^* = 30 \pm 1$ e.u., et $k_{25} = 1.6 \times 10^2\ M^{-1}\ s^{-1}$. On imagine que les réarrangements se produisent par l'intermédiaire de la rupture d'un lien germanium–oxygène dans une première étape ce qui conduirait à un intermédiaire penta-coordonné. On croit que l'étape déterminante de la réaction implique l'orientation correcte des deux espèces penta-coordonnées avant la formation d'un dimère ponté impliquant un bis-acac. [Traduit par le journal]

Introduction

Recent publications (1–3) from this laboratory have reported on dynamic n.m.r. studies on the stereochemistry of, and on the kinetics and mechanism(s) of environmental averaging processes in the six-coordinate complexes $R_2Sn(acac)_2$ (1, 2), $RClSn(acac)_2$ (1, 2) (R = C_6H_5, CH_3; acac = $C_5H_7O_2^-$, anion of acetylacetone), and $(C_6H_5)ClM(acac)_2$ (3) (M = Ge, Si). It was established that these complexes adopt predominantly the *cis* structure in solution with $\lesssim 5\%$ of the *trans* form present in the $RClM(acac)_2$ chelates. Intramolecular, first-order environmental averaging of methyl groups in the C_2 diphenyltin compound, and of acac ring protons and acac methyl groups in the C_1 monochloro complexes was identified as occurring via a twist mechanism (see, for example, ref. 4 and references therein) if rearrangements proceed by a sole reaction pathway. We now wish to report our findings on the stereochemical nature, and on the configurational rearrangement processes in the six-coordinate $(CH_3)ClGe(acac)_2$ complex in chloroform-*d* – carbon tetrachloride solutions.

Similar studies (5, 6) on several dihalobis(β-ketoenolato)germanium(IV) complexes (halogen = chlorine, bromine, iodine; β-ketoenol = acetylacetone, pivaloylacetone, dipivaloylmethane (dpm)) have also been carried out. It was shown (5, 6) that the dichloro chelates are mainly *cis* in solution with about 15–20% of the *trans* isomer present (5). Aging a mixture of crystals of the two geometrical isomers of $Cl_2Ge(dpm)_2$, yielded the *trans* isomer (6). Also, on the basis of the kinetic data, a one Ge—O bond rupture was favored over a twisting, nonbond-rupture mechanism for the first order exchange of methyl groups between the two nonequivalent sites of the *cis* C_2 complexes (6).

Experimental

Methyltrichlorogermane was purchased from Alfa Inorganics and used as received. Acetylacetone (2,4-pentanedione) was Fisher Certified Reagent. Reagent grade carbon tetrachloride (Anachemia) and dichloromethane (Fisher) were dried by refluxing over calcium hydride chips (Fisher) and distilled therefrom prior to use. Chloroform-*d* was prepared as reported elsewhere (6, 7). Thallium(I) acetylacetonate was prepared by allowing excess acetylacetone to react with a suspension of thallous carbonate in 95% alcohol.

Melting points were determined with a Gallenkamp melting point apparatus (Model MF-370), and are uncorrected. Capillaries were sealed with modelling clay under dry nitrogen in a glove bag. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn.

Methylchlorobis(2,4-pentanedionato)germanium(IV)

The synthesis of this product is similar to that of the phenylchloro analogue (3). Thus reaction of thallous acetylacetonate (6.15 g, 21.3 mmol) with a 75-ml dry dichloromethane solution of methyltrichlorogermane (2.29 g, 11.8 mmol) gave a yield of 32% (1.20 g) of the desired white compound which was recrystallized from dichloromethane–hexane solution. M.p. 128–132° (dec.), lit. 128–132°.[2]

Anal. Calcd. for $C_{11}H_{17}O_4ClGe$: C, 41.12; H, 5.33. Analyses on two separate samples gave: C, 25.98, 15.98; H, 3.98, 3.13.

A gravimetric determination of chlorine on a freshly prepared sample in this laboratory gave 11.0% (calcd. 11.04).

This compound decomposes within 2–3 days. Purity of freshly prepared products was checked by infrared and n.m.r. spectra. Neither O—H stretching bands nor C—O stretching bands above 1600 cm^{-1} were observed. N.m.r. chemical shifts in $CDCl_3$–CCl_4/TMS (17.6 g/100 ml; ~31°), −1.11 p.p.m. (Ge—CH_3), −2.07 p.p.m. (acac—CH_3), and −5.57 p.p.m. (acac—CH=).

Nuclear Magnetic Resonance Spectra

Owing to the rapid decomposition of this complex, solutions were prepared under rigorous anhydrous conditions in a dry nitrogen atmosphere in a glove bag just prior to recording n.m.r. spectra. N.m.r. samples were flamesealed *in vacuo* after degassing. Solvent used consisted of a mixture (54.5/45.6 w/w) of chloroform-*d* and carbon tetrachloride to which was added TMS as an internal standard. Such mixture permitted spectra to be recorded down to temperatures of *ca.* −80° (8).

Proton chemical shifts (±0.02 p.p.m.) and variable temperature spectra were recorded in the frequency-sweep mode on a Varian HA-100 high-resolution n.m.r. spectrometer operating at 100.00 MHz and equipped with a V-6040 variable temperature controller and a V-4343 variable temperature probe accessories.

Probe temperatures were calculated with the Van Geet equations (9) and were measured as described earlier (1). Possible experimental errors, consequential in the accuracy of the results, have also been described elsewhere (1).

Determination of Residence Times

Residence times of a —CH= proton in a particular site were obtained from n.m.r. spectra recorded in the temperature range −31.0 to 23.1°. Selected n.m.r. lineshape parameters were: $W_{1/4}$, $W_{1/2}$, and $W_{3/4}$, the full linewidths at one-quarter, one-half, and three-quarters of maximum amplitude; $\delta\nu_e$, the chemical shift separation during exchange; and R, the ratio of maximum intensity to minimum central intensity at $(\nu_a + \nu_b)/2$. Average values of these parameters for five spectral scans are tabulated in Table 1. Mean residence times, $\tau = \tau_a\tau_b/(\tau_a + \tau_b)$, for exchange of ring protons were estimated by comparing experimental lineshape parameters with those from calculated spectra using the Gutowsky-Holm (10) total lineshape equation for two-site exchange. Procedures of the calculation have been detailed earlier (1, 11). The chemical shift separation, $\delta\nu$, is temperature dependent (see Fig. 1 of ref. 3);[3] transverse relaxation times, T_2, are also temperature dependent as evidenced from differences in $W_{1/2}$ of the —CH= proton resonances in the slow and fast exchange regions; *e.g.* $W_{1/2}$ at 55.6° is 0.74 Hz, while at −70.2° $W_{1/2}$ is 2.32 Hz (low field line) and 2.54 Hz (high field line), and at −80.7° the corresponding values are 8.58 and 9.33 Hz. Values in Hz for $\delta\nu_e$ at slow exchange are: 16.02 (−80.7°), 15.76 (−78.4°), 15.62 (−76.1°), 15.39 (−73.0°), 15.29 (−70.2°), 14.70 (−61.7°), 14.18 (−53.5°), 13.75 (−46.2°), and 12.98 (−36.8°); others are collected in Table 1. Values of the transverse relaxation times, $T_{2a} = T_{2b}$, were estimated from line-widths of the acetylacetonate —CH= proton signal of $(CH_3)_2Sn(acac)_2$ in $CDCl_3$–CCl_4/TMS (12).

Below coalescence (−13.3°), mean lifetimes were extracted from a comparison of R, $\delta\nu_e$, $W_{1/4}$, $W_{1/2}$, and $W_{3/4}$. At and above coalescence, τ values were determined by comparing experimental and calculated values of $W_{1/4}$, $W_{1/2}$, and $W_{3/4}$. Mean residence times (Table 1) are average values in which $\delta\nu_e$ was given a weighting factor of two.

The order of the kinetics of environmental averaging of —CH= protons was ascertained by determining mean lifetimes at four different concentrations in the range 0.27–0.52 M at −31.5° and −2.2°. These lifetimes were obtained by digitizing n.m.r. spectra point by point as intensity *vs.* frequency in Hz. Digitization and computer fitting of the spectra were accomplished as described elsewhere (14).

Results and Discussion

Stereochemistry

The stereochemistry of methylchlorobis(2,4-pentanedionato)germanium(IV), $(CH_3)ClGe$-

[2]While our studies were underway we learned that the stereochemistry of this complex and others was being investigated. We thank Professor D. W. Thompson for communicating his unpublished results to us.

[3]The parameter $\delta\nu$ was obtained at each temperature (below coalescence) from differences in chemical shifts (in Hz; 50 Hz spectra) of the resonances corresponding to the *a* and *b* sites of an AB uncoupled system for the acac—CH= proton. Values so obtained were plotted against temperature, and the linear portion of the plot extrapolated to get $\delta\nu$ values above coalescence.

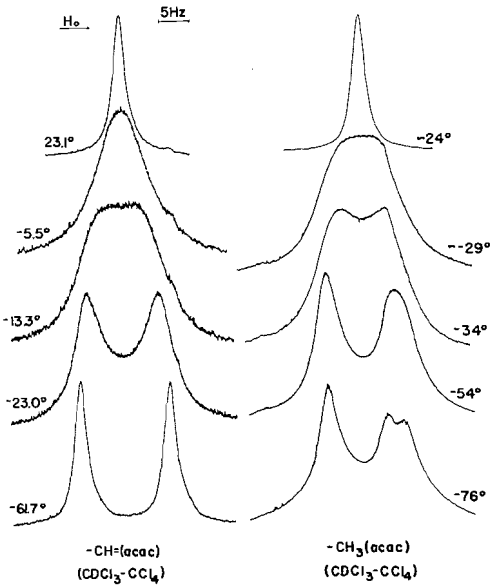

FIG. 1. Acetylacetonate ring proton and methyl proton n.m.r. spectra as a function of temperature for $(CH_3)ClGe(acac)_2$ in $CDCl_3$–CCl_4/TMS solutions.

$(acac)_2$, in solution may be inferred from proton n.m.r. spectra. Two diastereomeric forms are possible for this six-coordinate chelate: one with methyl and chloro groups in *cis* positions, and the other with the monodentate ligands *trans* to each other. The *cis* diastereomer (point group C_1) has no symmetry and, therefore, may give rise to four acetylacetonate methyl and two ring proton resonances. The *trans* form (C_{2v}) should reveal one acetylacetonate methyl and one —CH= proton resonance signal. Proton n.m.r. spectra at several selected temperatures between 23 and −76° are reproduced in Fig. 1. At ambient temperatures the proton spectrum consists of single, sharp ring proton ($W_{1/2}$ = 0.74 Hz) and methyl proton resonances. Below room temperature, line broadening is observed. The methyl resonance begins to split into two lines at *ca.* −29°, and at *ca.* −54° the upfield line splits again to give a total of four lines in the low temperature region (the downfield doublet is unresolved probably owing to chemical shift degeneracy of the two components). The ring proton spectrum reveals a doublet at −61.7°; with increasing temperature the two components broaden and collapse at −13.3°. Line broadening is ascribed to an environmental averaging process which exchanges ring protons and methyl groups between the respective two and four nonequivalent sites of the *cis* diastereomer. An additional observation in the —CH= proton spectrum is a slightly perceptible resonance on the high field side of the upfield component. This resonance is attributed (1, 3) to a small amount (probably not more than 5%) of the *trans* isomer; the corresponding methyl signal is apparently masked by the more intense signals of the *cis* diastereomer.

Kinetics of Environmental Averaging

In the present case, Fig. 1 shows that resonance lines due to nonequivalent nuclei (two —CH= protons and four CH_3 groups) simultaneously broaden and then merge into a single ring proton and a single methyl resonance. These spectra imply simultaneous time-averaging of the four methyl group environments and of the two ring proton environments. Six, independent, first-order rate constants are needed to describe the four-site exchange process. Such an analysis is complicated even with the availability of fast digital computers, and to make matters worse, relaxation times T_2 appear to be temperature dependent (see Experimental section). We have chosen, instead, to study the environmental averaging process by means of the two-site exchange of ring protons owing to its greater simplicity; only one first-order rate constant is required. Mean lifetimes (Table 1) for a —CH= proton in a particular site were obtained from comparisons of experimental spectra with those computed by the Gutowsky–Holm (10) method. In Fig. 2a are illustrated experimental spectra at −2.2° for several concentrations; Fig. 2b shows the comparison between the experimental spectra (solid circles) and the computer-fitted spectra (solid triangles; open circles represent good fit).

Concentration dependence of the mean residence times, summarized in Table 2, indicates that environmental averaging of proton resonances in $(CH_3)ClGe(acac)_2$ is concentration dependent and is second order. This dependence is also pictured in Fig. 3 which shows linear plots of τ_A *vs.* $[(CH_3)ClGe(acac)_2]^{-1}$ at −31.5° and −2.2°. Thus, the rate of environmental averaging may be written as Rate = $k[(CH_3)ClGe(acac)_2]^2$ since

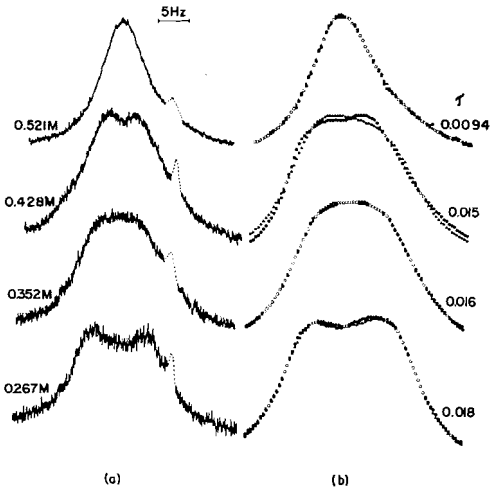

FIG. 2. Acetylacetonate ring proton n.m.r. spectra as a function of concentration of $(CH_3)ClGe(acac)_2$ in $CDCl_3$–CCl_3/TMS solutions at −2.2°: (*a*) experimental spectra; (*b*) comparison of experimental and calculated n.m.r. spectra; solid circles represent experimental points, solid triangles represent calculated points, and open circles denote perfect fit of experimental and calculated points.

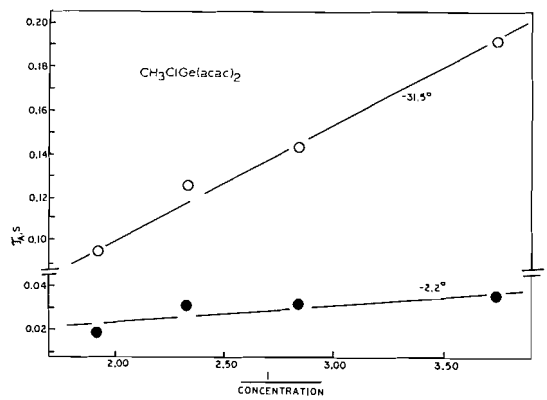

FIG. 3. Plots of the mean lifetime τ_A as a function of $[(CH_3)ClGe(acac)_2]^{-1}$ at the indicated temperatures.

TABLE 2. Concentration dependence of mean residence times for —CH= protons of $(CH_3)ClGe(acac)_2$ in $CDCl_3$–CCl_4/TMS solutions

Concentration (*M*)	$\tau_{(-31.5)} \times 10^2$ (s)	$\tau_{(-2.2)} \times 10^3$ (s)
0.521	4.8	9.4
0.428	6.3	15
0.352	7.2	16
0.267	9.7	18

$$\tau_A^{-1} = [(CH_3)ClGe(acac)]^{-1}\text{Rate}$$
$$= k[(CH_3)ClGe(acac)_2]$$

From the slope of the linear plot at −31.5° of Fig. 3, $k = 19\ M^{-1}\ s^{-1}$ in good agreement with $k = 16\ M^{-1}\ s^{-1}$ obtained from the log k *vs.* $1/T$ plot (Fig. 4 of ref. 3).

Arrhenius activation energy, E_a, and frequency factors, A, were computed from the slope and intercept, respectively, of the least-squares straight line plot of log k *vs.* $1/T$ (see Fig. 4 of ref. 3), where k is the second-order rate constant for the exchange process. The entropy of activation was determined from the relation

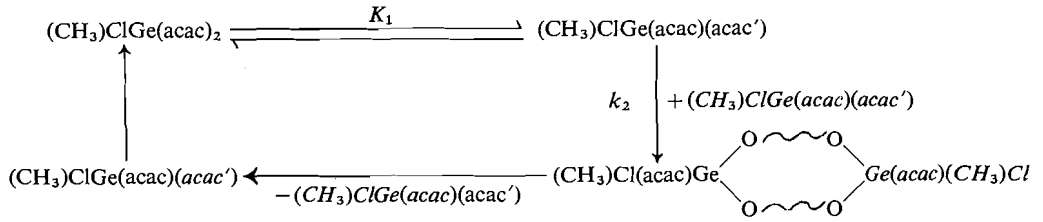
$$\Delta S^{\ddagger} = R[\ln A - \ln RT/Nh] - R$$

Arrhenius and Eyring activation parameters for intermolecular exchange of —CH= protons in $(CH_3)ClGe(acac)_2$ are

$$E_a = 6.0 \pm 0.3 \text{ kcal/mol}$$
$$\log A = 6.65 \pm 0.28$$
$$\Delta H_{25}^{\ddagger} = 5.5 \pm 0.3 \text{ kcal/mol}$$
$$\Delta S_{25}^{\ddagger} = -30 \pm 1 \text{ e.u.}$$
$$\Delta G_{25}^{\ddagger} = 14.43 \pm 0.05 \text{ kcal/mol}$$
$$k_{25} = 1.6 \times 10^2\ M^{-1}\ s^{-1}$$

(concentration = 0.548 *M*). The reported random errors were estimated at the 95% confidence level. These errors represent scatter in the data and not systematic errors which may be larger (1) owing to the temperature dependence of the transverse relaxation time, T_2.

It is instructive to compare the above activation parameters with those from exchange processes in analogous phenylchlorotin, -germanium, and methylchlorotin acetylacetonate complexes. It was shown earlier (3) that rearrangements in $(C_6H_5)ClM(acac)_2$ complexes, where M is Sn(IV) and Ge(IV), have nearly identical activation parameters; *e.g.* E_a = 12.8 kcal/mol (M = Ge) and 12.7 kcal/mol (M = Sn). Therefore it does not seem unreasonable to expect both $(CH_3)ClSn(acac)_2$ and $(CH_3)ClGe(acac)_2$ to have similar activation parameters. In the case of the former complex, the activation energy is 8.6 kcal/mol greater (1). This difference cannot be attributed to differences in electronic effects of the metal in view of similarities in the data (3) on phenyl-



chloro complexes; however it is not unexpected since rearrangements in the tin complexes are intramolecular but intermolecular in the methylchloro germanium chelate.

Mechanisms for the Exchange Process

Stereochemical rearrangements for a complex of the type *cis*-M(chel)$_2$XY via a dissociative S_N1 process have been discussed in some detail before (4). We immediately discount dissociation of the methyl group in $(CH_3)ClGe(acac)_2$ in a medium such as chloroform-*d* – carbon tetrachloride. Although a chloride dissociative process through a square pyramidal intermediate (methyl group basal, and attack by Cl^- at the methyl group) would explain the observed simultaneous time-averaging of acetylacetonate methyl and ring proton environments, it is not considered as a likely path in the present case for the following reasons. First, analogous studies in $M(acac)_2X_2$ complexes (6, 11, 14) (M = Ti, Sn, and Ge; X = F, Cl, or Br) have demonstrated that rearrangements are independent of the nature of the halogen. Second, chloride (^{36}Cl) exchange between tetraethylammonium chloride and $Sn(acac)_2Cl_2$ is slow ($k_2 = 0.0018$ M^{-1} s^{-1} at 15° in $CHCl_3$) (15). Finally, we note that the rate of environmental averaging is second order in the concentration of $(CH_3)ClGe(acac)_2$; a halide dissociative path would be expected to be first order in the concentration of the complex.[4] In addition, the entropy of activation, -30 ± 1 e.u., discourages a dissociative process. Brown (16) has pointed out that $\Delta S^{\ddagger}$ should be positive for a dissociative mechanism and negative for an associative one, in the absence of strong solvent effects. The latter effects probably amount to no more than about 10 e.u. for halogenated organic solvents (13). For the above reasons, complete dissociation of an $acac^-$ ligand is also not considered likely.

A tentative pathway[5] involves the intermolecular exchange of an acetylacetonate ligand. The process is viewed in the scheme below where the primed ligand, acac', represents a dangling unidentate ligand.

The equilibrium defined by K_1 must be shifted largely toward the six-coordinate species as we observed no n.m.r. resonances attributable to the five-coordinate germanium species. The rate-determining sequence, k_2, is thought to involve formation of the bis-acac bridged dimeric species, but prior to this, the five-coordinate species would have to be in the correct orientation (the slow step) for attack by the dangling acetylacetonate ligand end onto the "vacant" coordination site (the "vacant" site may be occupied by a solvent molecule). The rate expression from the proposed mechanism is $R = k_2K_1[(CH_3)ClGe(acac)_2]^2$ consistent with our observations.

Partial support from the National Research Council of Canada is gratefully appreciated.

[4]Consideration of several pathways involving a metal–chlorine bond breaking as a first step reveals no rate expression that contains second order dependence on the concentration of the complex. In all the cases we have looked at the rate law was always first order with respect to [complex].

[5]A referee has suggested that the proposed mechanism would predict that configurational rearrangements in a mixture of $(CH_3)ClGe(dik)_2$ and $(CH_3)ClGe(dik')_2$ (where dik and dik' denote two different β-diketonate ligands) should be accompanied by intermolecular exchange of dik and dik'. Although this possibility is not unexpected, it has not been tested for the present system; but we note however that mixtures of $Ti(dik)_2X_2$ and $Ti(dik')_2X_2$ do yield a mixed complex $Ti(dik)(dik')X_2$ (see *e.g.* ref. 17 and references therein). Also, the mechanism would predict that intermolecular exchange between $(CH_3)ClGe(acac)_2$ and free Hacac may be accompanied by configurational rearrangements, but not necessarily at the same rate. These possibilities are presently being investigated for the corresponding organotin chelates for which a mechanism for ligand exchange has been proposed (see ref. 13). The case for $(CH_3)ClGe(acac)_2$ will be the subject of a further study.

$\Delta G^\theta, \Delta H^\theta, \Delta S^\theta$ de transfert de H_2O et du couple H^+, OH^- de l'eau à ses mélanges contenant jusqu'à 40% de EtOH, *tert*-BuOH, DMSO, acétone et urée à 25°C

HENRI GILLET, LÉVON AVÉDIKIAN ET JEAN-PIERRE MOREL

Laboratoire d'Etude des Interactions Solutés–Solvants, Groupe de Chimie Physique, Université de Clermont, Les Cézeaux, B.P. 45, 63170 Aubière, France

Reçu le 30 juillet 1974

HENRI GILLET, LÉVON AVÉDIKIAN et JEAN-PIERRE MOREL. Can. J. Chem. **53**, 455 (1975).

Nous avons mesuré les enthalpies de neutralisation de HCl en solution diluée dans les mélanges hydroorganiques contenant jusqu'à 40% en poids de *t*-BuOH, DMSO, acétone et urée d'une part, et les constantes d'autoprotolyse de mélanges eau–DMSO et eau–urée d'autre part. Nous avons ainsi pu obtenir les grandeurs thermodynamiques normales ΔG^θ, ΔH^θ et ΔS^θ de la réaction de dissociation de l'eau dans ces milieux. Les résultats relatifs aux mélanges eau–urée doivent être interprétés avec prudence compte-tenu du fait que la dissociation propre de l'urée n'est pas négligeable devant celle de l'eau. A partir de différentes données de la littérature nous avons calculé les valeurs de l'enthalpie libre et de l'enthalpie de transfert de la molécule H_2O du liquide pur aux mélanges ci-dessus. (Nous avons également calculé pour ces mélanges, les coefficients de dilatation isobare et les coefficients de variation de la constante diélectrique avec la température.) Par suite, les grandeurs relatives au tranfert du couple d'ions H^+, OH^- ont été évaluées (ainsi que celles de l'eau aux mélanges eau–EtOH); elles sont comparées à celles déjà connues pour HCl et les halogénures alcalins; leurs différentes variations ne permettent pas d'établir de corrélation simple avec les propriétés structurales habituellement admises pour les milieux considérés.

HENRI GILLET, LÉVON AVÉDIKIAN, and JEAN-PIERRE MOREL. Can. J. Chem. **53**, 455 (1975).

We have measured the heat of neutralization of dilute solutions of HCl in aqueous–organic mixtures containing up to 40% by weight of *t*-BuOH, DMSO, acetone, and urea; autoprotolysis constants of the mixtures H_2O–DMSO and H_2O–urea also were determined. Thus the usual thermodynamic quantities ΔG^θ, ΔH^θ, and ΔS^θ could be determined for the dissociation of water in these mixtures. The results for the H_2O–urea mixtures must be accepted with caution because the dissociation of urea itself is not negligible compared to that of water. Using various literature data we have calculated values of the Gibbs free energy and the enthalpy for the transfer of a molecule of water from the pure liquid to the mixtures noted above. (We also have calculated for these mixtures the coefficients of isobaric expansion and those for the variation with temperature of the dielectric constant.) In addition, the values for the transfer of the ion pair H^+,OH^- have been determined as well as those for the transfer from water to H_2O–EtOH mixtures. These are compared to those already known for HCl and the alkali halides. It is not possible to establish a simple correlation between the differing variations of these quantities with the structural properties usually considered to exist in the media studied. [Journal translation]

Introduction

Pour calculer l'enthalpie de la réaction de dissociation d'un acide faible en milieu hydro-organique, il est nécessaire de connaître l'enthalpie de neutralisation d'une acide fort par une base forte dans ces solvants. Nous avons déjà effectué de telles déterminations expérimentales (1, 2).

L'étude de nouveaux mélanges à l'aide d'un appareillage plus précis nous conduit à proposer aujourd'hui la grandeur ΔH_n, enthalpie de neutralisation de l'acide chlorhydrique par la soude dans les mélanges riches en eau contenant jusqu'à 40% en poids d'alcool *t*-butylique, d'acétone, de diméthylsulfoxyde et d'urée. Les produits d'autoprotolyse de ces milieux, nécessaires au calcul des entropies de réaction, ont été déterminés ou pris dans la littérature.

Nous donnons les valeurs du coefficient de dilatation isobare et du coefficient de variation avec la température de la constante diélectrique des mélanges, calculées à partir des données de la littérature; elles nous permettent de corriger les enthalpies expérimentales au moyen d'une relation dérivant de la théorie de Debye–Hückel–Bjerrum, et d'accéder aux grandeurs normales de la réaction de dissociation de l'eau.

De même, à l'aide des données de la littérature, nous pouvons calculer les variations de l'enthalpie libre et de l'enthalpie molaire partielle de l'eau lors du transfert du liquide pur aux

mélanges. Il est alors possible de séparer les grandeurs de transfert relatives au couple d'ions H^+,OH^-; celles-ci pourront être comparées aux grandeurs de transfert des halogénures alcalins et de HCl lorsqu'elles sont connues. Il sera intéressant d'examiner la modification de solvatation, causée par l'addition d'un cosolvant, des ions provenant de la dissociation propre de l'eau.

Partie theorique

Produit d'autoprotolyse. Enthalpie libre

L'expérience donne $K_i^c = \underset{c \to 0}{\text{limite}} ([H^+][S^-])$

où $[H^+]$ est la concentration en protons, mesurée à l'électrode de verre, et $[S^-]$ celle des ions lyates de toute nature (OH^-, RO^-, ...), concentration déterminée par la quantité d'une base forte (NaOH) ajoutée dans le milieu. Cette définition de la constante thermodynamique d'équilibre dans l'échelle molaire (désignée par l'exposant c) implique le choix d'une activité égale à l'unité pour le solvant qui est donc pris comme état de référence.

Dans l'eau

$$\Delta G_d^{0c}(H_2O) = -RT \ln K_i^c$$

est l'enthalpie libre normale de la réaction de dissociation de l'eau

$$H_2O = {}^wH^+ + {}^wOH^-$$

(où l'exposant w indique la phase solvant, ici l'eau).

Les états de référence sont l'eau pure à gauche, et les solutions idéales de molarité unité des ions dans l'eau à droite. Si, dans un mélange hydroorganique, on néglige les ions lyates autres que OH^- (en particulier les ions RO^- provenant des alcools ROH), la valeur de K_i permet de calculer l'enthalpie libre normale de la réaction de dissociation dans le solvant hydroorganique s

$${}^sH_2O = {}^sH^+ + {}^sOH^-$$

Cette approximation est justifiée pour les mélanges contenant de l'alcool *t*-butylique de faible produit d'autoprotolyse et, *a fortiori*, pour ceux d'eau et de solvant aprotique (acétone, DMSO). Elle est naturellement plus discutable pour l'urée dont la dissociation propre entre en concurrence avec celle de l'eau (3, 4).

Remarquons que dans le cas d'un mélange, l'état de référence d'activité unité est l'eau dans ce mélange s à gauche; l'enthalpie libre normale de transfert de la réaction de dissociation de l'eau, de l'eau au mélange hydroorganique, est alors

$$\begin{aligned} {}^s\delta\Delta G_d^{0c}(H_2O) &= RT \ln 10^{s\delta}pK_i^c \\ &= {}^s\delta\mu^{0c}(H^+) + {}^s\delta\mu^{0c}(OH^-) \\ &\quad - {}^s\delta\mu(H_2O) \end{aligned}$$

où les opérateurs ${}^s\delta$ symbolisent les différences des grandeurs concernées entre le solvant s et l'eau, c'est-à-dire les grandeurs de transfert.

La variation du potentiel chimique de l'eau peut se calculer à l'aide des pressions de vapeur de l'eau dans les mélanges

$${}^s\delta\mu(H_2O) = RT \ln \frac{{}^sp(H_2O)}{{}^wp(H_2O)}$$

On peut ainsi accéder à la somme des grandeurs de transfert des ions H^+ et OH^-.

Enthalpies de neutralisation

L'expérience donne la chaleur mise en jeu lors de la neutralisation d'une solution diluée d'acide fort ($c = 5 \times 10^{-3}$ *M*) par la soude.

$$Cl^-,H^+(c) + OH^-,Na^+(c) = H_2O + Na^+,Cl^-(c)$$

L'enthalpie normale de la réaction de dissociation peut être obtenue si l'on connait l'enthalpie de dilution des ions. Nous avons proposé une relation (5) permettant d'évaluer celle-ci dans le domaine d'application de la deuxième loi de Debye–Hückel–Bjerrum pour des électrolytes dont l'association est négligeable

$$\log f_\pm = \frac{-A\sqrt{c}}{1 + A \ln 10 \sqrt{c}}$$

soit

$$\begin{aligned} \Phi_L = -\Delta H_{\text{dilution}} &= \frac{A_H B_H + C_H}{B_H^2} \\ &- 2\frac{A_H B_H + 2C_H}{B_H^3}\frac{1}{\sqrt{m}} + \frac{2C_H}{B_H^4}\frac{1}{m(1 + B_H\sqrt{m})} \\ &+ 2\frac{A_H B_H + 3C_H}{B_H^4 m}\ln(1 + B_H\sqrt{m}) - \frac{2C_H}{B_H^4}\frac{1}{m} \end{aligned}$$

où m est la molalité et

$$A_H = -uv$$

$$B_H = v$$

$$C_H = uv^2$$

avec

$$u = 3RT^2\left(\frac{1}{T} + \frac{\partial \ln D}{\partial T} + \frac{\alpha}{3}\right)$$

$$v = A \ln 10 \sqrt{\rho_0}$$

D, α, ρ_0 étant respectivement, la constante diélectrique, le coefficient de dilatation isobare et la masse volumique du solvant pur.

Dans le cadre de la théorie de Bjerrum, qui se révèle plus satisfaisante que celle classique où intervient le paramètre d'approche $\hat{a}$ des ions pour claculer Φ_L (5), cette grandeur ne dépend pas de la nature de l'électrolyte si l'on peut négliger son association. Les mesures d'enthalpie de neutralisation étant effectuées en solution diluée ($c = 5 \times 10^{-3}$ M) nous utiliserons donc ces valeurs calculées de Φ_L pour accéder à la grandeur normale

$$\Delta H_d^0(H_2O) = -\Delta H_n^0 = -\Delta H_n - \Phi_L$$

En milieu hydroorganique, cette grandeur s'écrit:

$$\Delta H_d^0(H_2O) = {}^s\overline{H}^0(H^+) + {}^s\overline{H}^0(OH^-) - {}^s\overline{H}(H_2O)$$

On voit que l'enthalpie de transfert du couple H^+,OH^- de l'eau au solvant s peut être calculée si l'on connait l'enthalpie molaire partielle de l'eau dans ce solvant.

Partie expérimentale

Solvants

L'eau, tridistillée dans un appareil en quartz, a été dégazée sous vide juste avant la préparation des mélanges.

L'alcool *t*-butylique a été purifié suivant la technique décrite dans un précédent mémoire (6).

Le DMSO provenant de la S.N.P.A. a été purifié par une double distillation sous pression réduite en présence de charbon activé après avoir séjourné pendant plusieurs jours sur chaux vive (E.b.$_{2mm}$ = 46–47 °C).

L'acétone, un produit Prolabo pur, a été distillée deux fois après avoir séjourné plusieurs jours sur Sikkon Fluka.

L'urée, un produit Prolabo R.P.p.a., a été utilisé sans autre purification.

Détermination des enthalpies de neutralisation

Les mesures ont été réalisées à l'aide d'un calorimètre L.K.B. à titration type 8700, à 25 °C. Nous avons utilisé une cellule contenant 100 cm^3 d'acide chlorhydrique. Les solutions acides, environ 5×10^{-3} M, dans chaque milieu étudié, ont été préparées à partir de solutions aqueuses, environ 0.1 M, titrées à l'aide de carbonate de sodium et de borax.

Nous avons neutralisé l'acide par une solution aqueuse de soude de concentration 2.5 M ajoutée à l'aide d'une burette à piston Tacussel, type électroburap, à la vitesse de 0.2 cm^3 min^{-1}. Des précautions ont été prises pour éviter au maximum la carbonatation de la soude.

Dans un premier temps, nous avons procédé à un étalonnage électrique sur la solution d'acide, puis dans un deuxième à la réaction de neutralisation. Les effets thermiques correspondants, ont été enregistrés. Les longueurs l, proportionnelles aux énergies mises en jeu, ont été mesurées au temps $t/2$, t désignant la durée de l'effet thermique. Cette détermination graphique permet d'éliminer l'influence des phénomènes thermiques secondaires: agitation, fuites thermiques, dilution de la soude, etc. (7).

Les mesures ont été faites à des pourcentages en solvant organique déterminés par l'évolution des ΔH_n. Nous avons fait de trois à six essais pour chaque mélange.

Dans le cas des mélanges eau–acétone, l'excès de soude ajouté après neutralisation totale provoque une réaction parasite exothermique mettant en jeu le solvant, sans doute une cétolisation, qui perturbe la partie finale des courbes (absence de linéarité) et conduit à une précision plus faible des déterminations. L'importance de la perturbation croît avec la teneur en acétone.

L'urée, en solution dans l'eau, se décompose suivant la réaction

$$CO(NH_2)_2 \rightarrow CNO^- + NH_4^+$$

A 25 °C, cette réaction est peu rapide (8) mais les mélanges ne doivent quand même pas être conservés longtemps.

En milieu basique, la réaction de décomposition est catalysée par les ions OH^- (9) et les ions ammonium sont transformés en ammoniac

$$NH_4^+ + OH^- \rightarrow NH_3 + H_2O$$

En milieu acide, les ions cyanate sont quantitativement détruits par la réaction (8)

$$CNO^- + 2H^+ + 2H_2O \rightarrow NH_4^+ + H_2CO_3$$

Il y a donc consommation d'ions H^+ et le titre des solutions acides diminue au cours du temps, ce qui conduit à des résultats erronés pour les ΔH_n. A faible concentration en acide, la réaction est relativement lente et l'on obtient des résultats reproductibles si l'acide est ajouté au mélange juste avant la mesure.

Détermination des pK_i

Nous avons étudié les cellules galvaniques suivantes:

(I) électrode de verre/HCl(m_1), solvant (s)/AgCl, Ag

(II) électrode de verre/NaOH(m_2), KCl(m_3), solvant (s)/AgCl, Ag

m représente la molalité.

Dans le solvant s les tensions réversibles peuvent s'écrire

$${}^sU(I) = {}^sU^0(I) + k \text{ og } \{{}^sa_1(H^+) \cdot {}^sa_1(Cl^-)\}$$

$${}^sU(II) = {}^sU^0(II) + k \log \{{}^sa_2(H^+) \cdot {}^sa_2(Cl^-)\}$$

Les relations équivalentes dans l'eau sont obtenues, en remplaçant les indices supérieurs s par w. a représente l'activité.

Sachant que $K_i = a(H^+) \cdot a(OH^-)$ on peut écrire

$${}^s\delta U^\theta = {}^s\delta U(I) - 2k\left(\log \frac{{}^sm_1}{{}^wm_1} + \frac{{}^wA\sqrt{{}^w\rho\,{}^wm_1}}{1 + {}^wB\,{}^wq\sqrt{{}^w\rho\,{}^wm_1}} - \frac{{}^sA\sqrt{{}^s\rho\,{}^sm_1}}{1 + {}^sB\,{}^sq\sqrt{{}^s\rho\,{}^sm_1}}\right)$$

et

$${}^s\delta U^\theta - k\,{}^s\delta pK_i = {}^s\delta U(II) - k \log \frac{{}^sm_3\,{}^wm_2}{{}^wm_3\,{}^sm_2}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Pour l'étude des mélanges eau–urée, nous avons placé dans la cellule une masse connue de solution aqueuse de HCl, puis ajouté les masses d'urée nécessaires pour obtenir des mélanges à 10, 20, 30 et 40% en poids de substance organique. Une lecture de U(I) a été faite dans chaque milieu. Nous avons exploré une gamme de six concentrations comprises entre 3×10^{-3} et 10^{-2} M. Les valeurs de ${}^{s}\delta U^{0}$ obtenues concordent parfaitement.

Nous avons opéré de la même façon pour la cellule II mais avec des concentrations plus élevées en soude (10^{-1} à 2.5×10^{-2} M) et en KCl (10^{-1} à 5×10^{-2} M). Si la diminution de la concentration en soude n'a pas d'influence sur le résultat, il n'en est pas de même de la diminution de la concentration en KCl. En effet les valeurs de pK_i, qui demeurent constantes dans la gamme de concentrations indiquée ci-dessus, décroissent lorsque la concentration en KCl devient inférieure à 5×10^{-2} M. Ceci a été attribué à la présence, en milieu alcalin, d'ions cyanate qui perturbent le fonctionnement de l'électrode AgCl, Ag lorsque la concentration en ions chlorure est faible.

Pour chaque teneur en urée, nous avons calculé, à partir des mesures de tensions réversibles, les termes ${}^{s}\delta U^{0}$ et ${}^{s}\delta U^{0} - k{}^{s}\delta \mathrm{p}K_i$, et nous en avons déduit pK_i.

Pour l'étude des mélanges eau–DMSO, nous avons employé la même méthode de mesure; mais nous avons pu utiliser, dans la cellule II, des concentrations en soude et en KCl comprises entre 3×10^{-3} et 10^{-2} M. En effet, dans ce cas, la valeur de la concentration en KCl n'a pas d'influence sur le pK_i.

Les mesures potentiométriques ont été effectuées, soit avec un potentiomètre Radiometer 4, soit avec un millivoltmètre Tacussel Aries 10000. Les électrodes AgCl, Ag étaient des électrodes Tacussel Ag/AgCl 1 et l'électrode de verre de la même marque, type TB/HA. La cellule de mesure était maintenue à température constante (25.0 ± 0.1 °C) par une circulation d'eau thermorégulée.

Résultats

Produits d'autoprotolyse

On trouve dans la littérature les valeurs de pK_i des mélanges aqueux de EtOH, *t*-BuOH, acétone (10) que nous utilisons pour les calculs. Dans le cas des mélanges eau–DMSO, les valeurs que nous avons obtenues, à 25 °C, sont en accord avec celles données par différents auteurs (11, 4, 12) et conformes à celles déterminées à 20 °C (13). Par contre, pour les mélanges eau–urée, on observe un écart croissant avec le pourcentage en urée entre nos valeurs et celles données par Woolley et Hepler (4); les remarques formulées dans la partie expérimentale peuvent expliquer cet écart.

Nous avons rassemblé dans le tableau 1 les valeurs de pK_i ramenées à l'échelle molaire en retranchant le terme $2 \log {}^{s}\rho$ et déduites, pour les compositions particulières indiquées, de la courbe de variation $\mathrm{p}K_i = f(X)$.

Enthalpies de neutralisation. Grandeurs de transfert

Les valeurs des enthalpies de neutralisation regroupées dans le tableau 2 correspondent aux résultats expérimentaux. Elles sont déterminées à 200 J mol^{-1} près.

Certaines des mesures dont nous présentons ici les résultats (systèmes H_2O–*t*-BuOH et H_2O–acétone) avaient été précédemment réalisées par l'un d'entre nous à l'aide d'un autre appareillage (1 et 2): si l'allure des variations et les écarts relatifs restent identiques pour les deux séries de résultats, il est à noter que les valeurs obtenues présentent parfois des écarts sensibles. Les déterminations déjà effectuées dans les mélanges eau–DMSO (14) ne permettent pas une définition précise des variations dans la zone riche en eau.

Nous avons déduit des résultats précédents les grandeurs de transfert dont les valeurs sont rassemblées dans le tableau 3. Pour effectuer les calculs, nous avons utilisé les valeurs des enthalpies de neutralisation lissées et corrigées du terme de dilution pour obtenir les grandeurs normales. Dans le domaine de concentrations étudié, ce terme est en général faible (123 J mol^{-1} dans l'eau); il permet cependant de mieux préciser l'allure des courbes de variation et peut atteindre 530 J mol^{-1} dans le mélange contenant 40% de *t*-BuOH. Dans le cas du système H_2O–EtOH, les valeurs de $\Delta H_d^0(H_2O)$ utilisées sont celles obtenues en prenant la moyenne des valeurs proposées par Hepler *et coll.* (15) et par l'un de nous (16).

Propriétés des solvants

Nous avons consigné dans le tableau 4 les valeurs des enthalpies libres et des enthalpies

molaires partielles de l'eau dans les différents mélanges. Le tableau 5 contient, pour ces mêmes mélanges, les valeurs des coefficients de dilatation isobare et des variations de la constante diélectrique avec la température. Toutes ces grandeurs ont été soit trouvées dans la littérature, soit calculées à partir de données de la littérature.

Discussion

Nous avons d'abord tracé, fig. 1, les variations de l'entropie molaire partielle de l'eau dans les différents mélanges étudiés ici; notons que celles de la grandeur d'excès ($\bar{S}^E = \bar{S} + R \ln x$) sont semblables quoique déplacées vers les valeurs négatives. Il n'est naturellement pas possible de déduire de cette quantité molaire partielle, l'évolution de la structure de la phase aqueuse lors de l'addition de cosolvant. Notons cependant que pour l'urée, composé réputé briseur, on observe une augmentation de $\bar{S}(H_2O)$; au contraire, pour les alcools que l'on admet être des promoteurs de la structure de l'eau, c'est une diminution de $\bar{S}(H_2O)$ qui apparaît. Dans le cas de l'alcool *t*-butylique, on observe sur la courbe un point d'inflexion pour un pourcentage en poids de l'ordre de 17% (fraction molaire égale à environ 0.05); on retrouve ici une composition caractéristique de ce mélange qui pourrait correspondre à un maximum de structure (39).

Examinons maintenant, fig. 2, les variations du potentiel chimique du couple d'ions H^+,OH^-, et comparons les en particulier à celles de H^+,Cl^-: dans les deux cas, on observe une diminution en milieu eau–urée (40) et des augmentations pour les quatre autres mélanges (41, 42); l'augmentation est toujours plus rapide (en fonction de l'addition de cosolvant) pour le couple H^+,OH^- que pour H^+,Cl^-

(par exemple, à 40% en poids de *t*-BuOH, on atteind ~6.6 kJ pour le premier contre ~3.8 kJ pour le second). L'addition de cosolvant à l'eau diminue donc beaucoup plus fortement la solvatation de l'ion OH^- que celle de l'ion Cl^-. L'effet est particulièrement spectaculaire dans les mélanges eau–DMSO où, à 40%, l'enthalpie libre de transfert de H^+,Cl^- est sensiblement nulle alors que celle de H^+,OH^- atteind ~5.5 kJ. Dans les mélanges eau–*t*-BuOH, où nous avons mesuré ces grandeurs pour les chlorures alcalins (43), on peut voir que le comportement

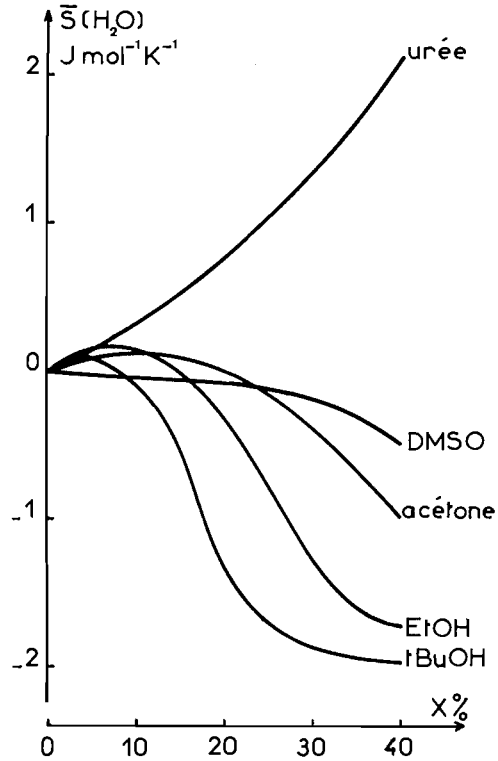

FIG. 1. Entropie molaire partielle de l'eau dans les mélanges hydroorganiques à 25 °C (état de référence: eau liquide à 25 °C).

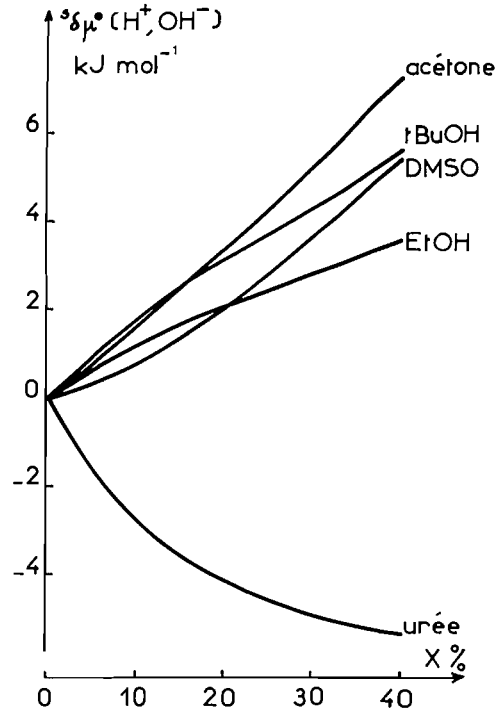

FIG. 2. Potentiel chimique normal (échelle molaire) de transfert du couple H^+,OH^- de l'eau aux mélanges hydroorganiques à 25 °C.

de H^+,OH^- est intermédiaire entre celui de H^+,Cl^- (variations les moins importantes) et celui des chlorures alcalins.

Pour les enthalpies de transfert, fig. 3, on observe un maximum endothermique bien marqué dans les mélanges eau–*t*-BuOH, comme nous en avions observé un pour les chlorures alcalins (6): celui-ci, situé dans les deux cas vers 25% en poids d'alcool, est moins important dans le cas du couple H^+,OH^- (~6.5 kJ) que pour les chlorures alcalins (~10 kJ pour NaCl). Dans les mélanges eau–urée, on observe un transfert exothermique régulièrement croissant attribuable à la basicité de l'urée vis-à-vis du proton. Par contre, dans eau–DMSO, malgré le caractère basique également marqué de la molécule de cosolvant, c'est un effet endothermique qui est observé: ceci laisse supposer que le transfert de l'ion OH^- est très fortement endothermique. Si l'on regarde maintenant les entropies de transfert (fig. 4) deux constatations s'imposent: les deux alcools, EtOH et *t*-BuOH, donnent lieu à des variations opposées dans la zone riche en eau; d'autre

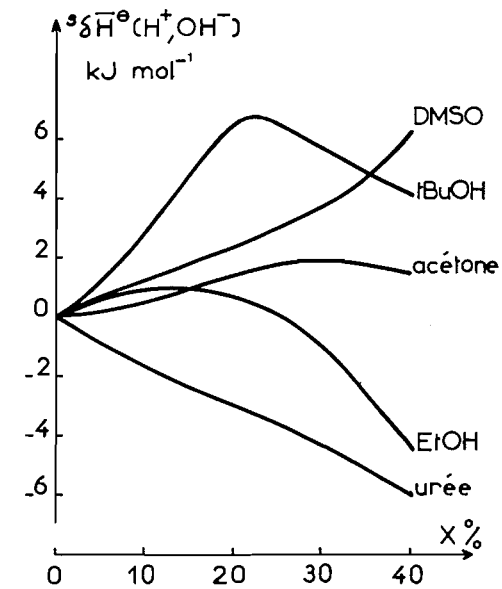

FIG. 3. Enthalpie normale de transfert du couple H^+,OH^- de l'eau aux mélanges hydroorganiques à 25 °C.

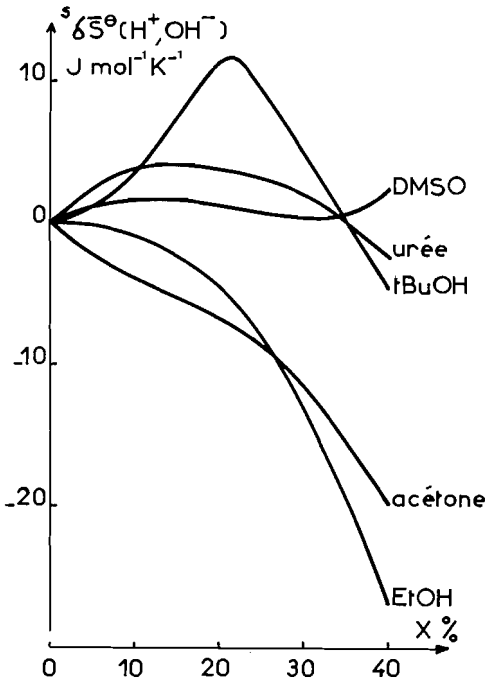

FIG. 4. Entropie normale de transfert (échelle molaire) du couple H^+,OH^- de l'eau aux mélanges hydroorganiques à 25 °C.

part, les entropies de transfert sont positives aussi bien dans eau–*t*-BuOH, milieu réputé plus structuré que l'eau pure jusqu'à environ 15% en poids, que dans le mélange eau–urée réputé moins structuré. En résumé, le potentiel chimique de transfert du couple H^+,OH^- entre l'eau et les mélanges à 20% en poids de cosolvant est contrôlé par l'enthalpie de transfert pour le DMSO et aussi bien pour l'alcool *t*-butylique que pour l'urée; c'est au contraire la contribution entropique qui prévaut pour l'éthanol et l'acétone. Par suite, il n'apparaît pas clairement au vu des grandeurs thermodynamiques que les caractéristiques structurales du milieu soient déterminantes pour expliquer le transfert de ces ions.

A Photochemical Route to *N*-Acyl Imines[1,2]

WILLIAM A. COURT,[3] OLIVER E. EDWARDS,[4] CIRO GRIECO,[5] WERNER RANK,[3] AND TAKEHIRO SANO[3]

Division of Biological Sciences, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received October 24, 1974

WILLIAM A. COURT, OLIVER E. EDWARDS, CIRO GRIECO, WERNER RANK, and TAKEHINO SANO. Can. J. Chem. **53**, 463 (1975).

Irradiation of two steroidal α-azido ketones gave *N*-acyl imines by formal acyl migration onto nitrogen. Spectroscopic characteristics (u.v., i.r., ^{1}H n.m.r., and ^{13}C n.m.r.) and chemistry of these is described. Similarly an α-azido γ-lactone gave a 5,6-dihydro-1,3-oxazin-2-one which added methanol readily to give a 4-methoxytetrahydro-1,3-oxazine-2-one. Possible mechanisms are considered for the observed rearrangements.

WILLIAM A. COURT, OLIVER E. EDWARDS, CIRO GRIECO, WERNER RANK et TAKEHIRO SANO. Can. J. Chem. **53**, 463 (1975).

L'irradiation de deux cétones stéoridales portant chacun un groupe azido en α conduit aux *N*-acylimines provenant d'une façon formelle d'une migration acyle vers l'azote. On décrit les caractéristiques spectroscopiques (u.v., i.r., ^{1}H r.m.n. et ^{13}C r.m.n.) et la chimie de ces composés. De la même manière une α-azido γ-lactone conduit à une dihydro-5,6 oxazinone-1,3,2 qui peut additionner facilement du méthanol pour donner une méthoxy-4 tétrahydro-oxazinone-1,3,2. On considère divers mécanismes possibles pour les réarrangements observés.
[Traduit par le journal]

We wish to record what we believe to be the first examples of photochemical generation of *N*-acyl imines.

Irradiation[6] of methylene chloride solutions of 3β,20β-diacetoxy-12α-azido-5β-pregnan-11-one **1** (1) containing *ca.* 0.1 molar-equiv. of dry pyridine or triethylamine, at 5° or lower, gave as major product (60% isolated) the acyl imine **2**. This had m.p. 192°; $[\alpha]_D$ +184° (*c* 0.13, 95% ethanol); λ_{max} (ethanol) 288 nm (ε 1080); ν_{max} (CCl_4) 1742, 1715, and 1662 cm^{-1}. Its ^{1}H n.m.r. spectrum had a one-proton signal at δ 7.95 (N=CH—) and its ^{13}C n.m.r. spectrum in C_6D_6 had signals at 189.1 (CO—N) and 169.2 p.p.m. (N=CH—). On alumina compound **2** was partially hydrated to **3** (R = H). The hydration was more efficient if a solution of **2** in aqueous dioxane was stirred in the presence of a sulfonic acid ion-exchange resin. The hydroxy lactam **3** (R = H) had ν_{max} ($CHCl_3$) 3520, 3405, 1730, and 1680 cm^{-1}. Treatment of **2** or **3** with anhydrous *p*-toluene sulfonic acid or acidic ion-exchange resin in methanol gave **3** (R = CH_3). This had m.p. 209°; $[\alpha]_D$ +144° (95% ethanol); ν_{max} (CCl_4) 3230, 1740, and 1670 cm^{-1}. In addition to a 1H doublet at δ 6.0 (NH) its ^{1}H n.m.r. spectrum contained a doublet (^{1}H) at δ 4.23. The NH doublet disappeared on shaking with D_2O while the doublet at δ 4.23 collapsed to a singlet. Irradiation of **1** in methanol gave **3** (R = CH_3) directly. That this was probably a two-step process was shown by irradiation of **2** in methanol. The resulting solvation of the imino double bond in **2**, giving rise to **3**, was of comparable speed to the direct photoconversion of **1** to **3**.

Catalytic reduction of **2** gave the saturated lactam **4** as a glass which distilled at 180°, 1×10^{-4} Torr. This had $[\alpha]_D$ +49° (95% ethanol); ν_{max} (CCl_4) 3230, 1740, and 1670 cm^{-1}. In its ^{1}H n.m.r. spectrum, a 2H multiplet at δ 3.3

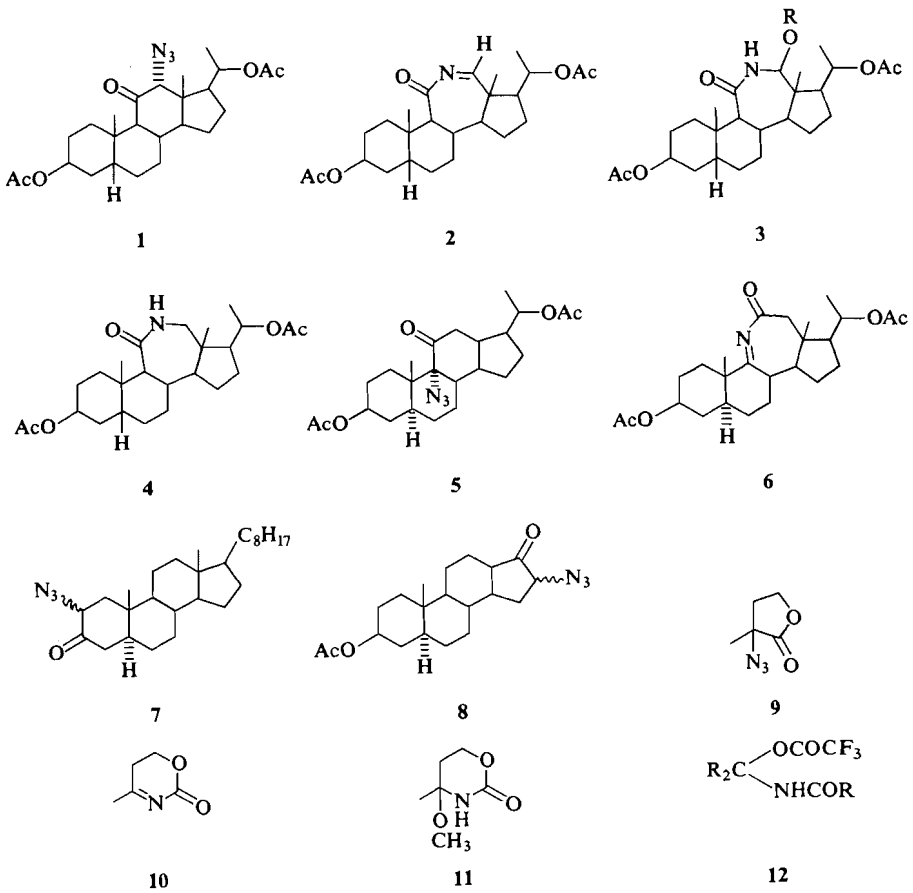
[6]A high-pressure Hanovia 100 W mercury lamp was used, with a Pyrex filter. The photolysis of **1** was slower using a Rayonet reactor with lamps with peak emission at 350 nm.



became a quartet when acidified D_2O was added, consistent with its assignment to the system —$CONHCH_2C$—. In refluxing dry dimethylaniline **1** was converted slowly (14 h) into a mixture rich in **2** (50% isolated).

When a methanol solution of 3β,20β-diacetoxy-9α-azido-5α-pregnane-11-one (**5**) (1) was irradiated[6] with wavelengths greater than 300 nm at 5° it gave a 38% yield of the *N*-acyl imine **6**, m.p. 223°; $[\alpha]_D$ +31°; λ_{max} (ethanol) 278 nm (ε 500); ν_{max} (CCl_4) 1737, 1698, and 1668 cm^{-1}. A 2H quartet in its ^1H n.m.r. spectrum centered at δ 2.8 could be attributed to the hydrogens on C-12. Its ^{13}C n.m.r. spectrum in C_6D_6 had signals at 174 (N=C) and 180 p.p.m. (11-carbonyl). Other products[7] from the photolysis of **5** will be described in the full paper. In contrast to the behavior of **1** and **5**, irradiation of methanol solutions of 2α- or 2β-azidocholestan-3-one (**7**) and 16α- and 16β-azido-3-acetoxyandrostan-17-one (**8**) gave complex mixtures containing little, if any, of the desired methoxylactams. On the basis of these observations we suggest that for conformationally rigid α-azido ketones an axial orientation of the azide group (as in **1** and **5**) is necessary for efficient formation of *N*-acyl imine.

Interest in generation of the nitrogen heterocycle present in the ansa macrolide maytansine (2) prompted us to photolyse the α-azido lactone **9** (3). Irradiation of **9** in methanol using a Hanovia 100 W lamp and Vycor filter for 7 h at *ca.* −25° gave a mixture of *N*-acyl imine **10** (4-methyl-5,6-dihydro-1,3-oxazin-2-one) and methoxy urethane **11** (4-methoxy-4-methyltetrahydro-1,3-oxazine-2-one) in the ratio 2.5:1. Further irradiation of this mixture for 3 h at 5° converted it into a 1.5:1 mixture of the two products. The solvation of **10** could also be induced by acid catalysis.

Irradiation of **9** in methylene chloride at −25°

[1]

[2] 
gave a product which from its n.m.r. spectrum and reactions was nearly pure acylimine **10** which had ν_{max} (CH_2Cl_2) 1735 and 1645 cm^{-1} and λ_{max} (dioxane) 262 nm (ε 1060). Its n.m.r. spectrum had signals at δ 2.27 (t, J = 1.8 Hz, 3H), 3.77 (m, 2H), and 4.40 (t, J = 5.5 Hz, 2H). The methoxy urethane **11** had m.p. 89°; ν_{max} ($CHCl_3$) 3430, 3250, 3130, and 1710 cm^{-1}. It gave ^1H n.m.r. signals at δ 1.50 (3H), 1.99 (m, 2H), 3.30 (s, 3H) 4.38 (m, 2H), and 7.88 (broad, NH).

In contrast to the results with **1**, **5**, and **9**, both Millership and Suschitzky (4) and Margaretha and Steffen (5) were unable to detect acyl migration onto nitrogen during photolysis of α-azido lactam and an α-azido ketone, respectively.

The above formal 1,3-acyl migrations onto nitrogen are probably initiated by nitrene formation (Eq. 1). However the long wavelengths that are effective in producing the acyl imines leaves open a second alternative for the photochemical reaction involving Norrish type 1 cleavage of the cyclic ketone (Eq. 2).

N-acyl imines are probable transient intermediates in numerous reactions (6–15). Their possible importance in biosynthesis has been recognized (16). Meyers and Shaw (17) have recently described the synthesis of an analog of **11** in which an acyl imine may be an intermediate. Two acyl imines which have been isolated arose from thermal analogs of the above 1,3-acyl migration (4, 18). Tsuda and Hayatsu described the preparation in low yield of a steroidal *N*-acyl imine produced by rearrangement of an enamide (19) and recently *N*-acyl imines have been produced by elimination of trifluoroacetic acid from compounds of type **12** (20).

Preparation of the other steroid analogs of **3** and **6**, and of compounds related to **10** and **11** which may be useful in synthesis of maytansine, are being explored.

Silyl-, Germyl-, and Stannyl-pentacarbonylmetalates of Chromium, Molybdenum, and Tungsten[1]

E. E. ISAACS AND W. A. G. GRAHAM

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2E1

Received September 3, 1974

E. E. ISAACS and W. A. G. GRAHAM. Can. J. Chem. **53**, 467 (1975).

The new anions $[R_3M'M(CO)_5]^-$ (R_3M' = Ph_3Si, $MePh_2Si$, Ph_3Ge, Ph_3Sn, Me_3Sn, and Ph_3Pb; M = Cr, Mo, W) have been prepared as tetraethylammonium salts by reaction of $R_3M'Li$ with $[Et_4N(ClM(CO)_5]$. The redistribution reaction between $[Ph_3SnW(CO)_5]^-$ and $[Cl_3SnW(CO)_5]^-$ affords $[PhCl_2SnW(CO)_5]^-$ or $[Ph_2ClSnW(CO)_5]^-$. Anhydrous HCl reacts with $[Ph_3SiW(CO)_5]^-$ and $[Ph_3GeW(CO)_5]^-$ to form $[ClW(CO)_5]^-$ but with $[Ph_3SnW(CO)_5]^-$ to form $[Cl_3SnW(CO)_5]^-$. An insertion reaction of $SnBr_2$ with $[BrW(CO)_5]^-$ forms the new anion $[Br_3SnW(CO)_5]^-$ while $SnCl_2$ and $GeCl_2$ (from $HGeCl_3$) react with $[ClM(CO)_5]^-$ to produce the known species $[Cl_3M'M(CO)_5]^-$ (M' = Ge, Sn; M = Cr, Mo, W). Infrared spectra in the carbonyl stretching region are reported for all anions.

E. E. ISAACS et W. A. G. GRAHAM. Can. J. Chem. **53**, 467 (1975).

On a préparé, par réaction de $R_3M'Li$ avec $Et_4N[ClM(CO)_5]$, les nouveaux anions $[R_3M'M(CO)_5]^-$ (R_3M' = Ph_3Si, $MePh_2Si$, Ph_3Ge, Ph_3Sn, Me_3Sn et Ph_3Pb; M = Cr, Mo, W) sous forme de sels de tétraéthylammonium. La réaction de redistribution entre $[Ph_3SnW(CO)_5]^-$ et $[Cl_3SnW(CO)_5]^-$ conduit à $[PhCl_2SnW(CO)_5]^-$ ou $[Ph_2ClSnW(CO)_5]^-$. Le HCl anhydre réagit avec $[Ph_3SiW(CO)_5]^-$ et $[Ph_3GeW(CO)_5]^-$ pour conduire à $[ClW(CO)_5]^-$ mais HCl anhydre réagit avec $[Ph_3SnW(CO)_5]^-$ pour former $[Cl_3SnW(CO)_5]^-$. Une réaction d'insertion du $SnBr_2$ avec du $[BrW(CO)_5]^-$ conduit au nouvel anion $[Br_3SnW(CO)_5]^-$ alors que $SnCl_2$ et $GeCl_2$ (obtenu à partir de $HGeCl_3$) réagissent avec $[ClM(CO)_5]^-$ pour conduire aux espèceş connues $[Cl_3M'M(CO)_5]^-$ (M' = Ge, Sn; M = Cr, Mo, W). On rapporte les spectres infrarouges, dans la région de l'élongation du carbonyle, de tous les anions

[Traduit par le journal]

Introduction

The synthesis and study of bonds between transition metals and the elements below carbon in the fourth main group has attracted wide interest (1–3). Most of the reported compounds are neutral molecules, and the chemistry of anionic complexes containing these bonds is much less well developed. The inherent interest of such complex ions, as well as their probable synthetic value, prompted the present work.

The first anionic, mononuclear derivatives of the hexacarbonyls of chromium, molybdenum, and tungsten to contain ligands of the fourth main group other than carbon were the six compounds $[Ph_4As]^+[Cl_3M'M(CO)_5]^-$ (M' = Ge, Sn; M = Cr, Mo, W) (4). They were prepared by the displacement of carbon monoxide from $M(CO)_6$, under ultraviolet irradiation, by the anions $[Cl_3Ge]^-$ and $[Cl_3Sn]^-$ as the tetraphenylarsonium salts. More recently, the anions $[X_3M'M(CO)_5]^-$ (X = Cl, Br, I) have been prepared by reaction of halide ion with the claimed neutral complexes $[X_2M'M(CO)_5]$ (5).

[a]Infrared spectra in tetrahydrofuran except as noted. Bands in parentheses were too broad for accurate measurement.
[b]The τ value quoted in footnotes refers to the methyl group of the compound in question.
[c]τ 9.25 in acetone-d_6.
[d]τ 9.96; $^2J(Sn—CH_3)$ = 37 Hz (^{117}Sn and ^{119}Sn coupling not resolved); acetone-d_6.
[e]τ 9.28; $^2J(^{29}Si—CH_3)$ = 5.2 Hz; CD_3CN.
[f]Infrared in CH_2Cl_2; unstable in tetrahydrofuran.
[g]τ 10.0; $^2J(Sn—CH_3)$ = 33 Hz (^{117}Sn and ^{119}Sn coupling not resolved); acetone-d_6.
[h]τ 9.12; $^2J(^{29}Si—CH_3)$ = 5.4 Hz; CD_3CN.
[i]τ 9.90; $^2J(^{117}Sn—CH_3)$ = 35.5 Hz; $^2J(^{119}Sn—CH_3)$ = 37.0 Hz; CD_3CN.

Although the present work is restricted to anions in which a single carbonyl ligand is replaced by an X_3M' or R_3M' group, it is of interest to note that more than one such replacement is possible. Thus, Ruff (4) in his original report isolated $[Ph_4As]_2^+[(Cl_3Ge)_2Mo(CO)_4]^{2-}$, and obtained spectroscopic evidence for several other disubstituted products. More recently, displacement of benzene from π-$C_6H_6M(CO)_3$ and $(\pi$-$C_6H_6)_2M$ by $[SnCl_3]^-$ has been reported to form the ions $[(Cl_3Sn)_3M(CO)_3]^{3-}$ and $[(Cl_3Sn)_6M]^{6-}$ respectively (6).

Experimental

Melting points were determined using a Kofler hot-stage microscope. Analytical results (Table 1) were obtained by the Microanalytical Laboratory of this department. Infrared spectra of the carbonyl stretching region were measured by means of a Perkin–Elmer Model 337 spectrometer at a scanning rate of 39 cm^{-1} min^{-1}, and recorded in expanded form (1 cm of chart ≈ 10 cm^{-1}) on an external recorder. Spectra were calibrated with bands of gaseous CO and DBr, and are considered accurate to ±1 cm^{-1}. Band positions quoted in Table 2 refer to the midpoint at half-height.

Table 2 lists as footnotes selected n.m.r. data for the $MePh_2Si$ and Me_3Sn derivatives. The phenyl substituents appeared as a complex multiplet at τ 2.2–2.8, and the characteristic τ 8.6 triplet – 6.4 quartet due to $[Et_4N]^+$ was observed in all spectra.

Solvents and Reagents

Tetrahydrofuran for use in reactions was dried over calcium hydride; that used as infrared solvent was also distilled from potassium benzophenone under nitrogen. Dichloromethane was dried over phosphorus pentoxide, and *n*-pentane over calcium hydride. All solvents were purged with nitrogen before use.

Chromium, molybdenum, and tungsten hexacarbonyls

were purchased from Strem Chemicals, Inc. Triphenyltin chloride and Sn_2Me_6 were obtained from M & T Chemicals Inc. Triphenylchlorosilane and $MePh_2SiCl$ were obtained from Pierce Chemical Company, Ph_3PbCl from PCR Inc., and $HGeCl_3$ from Alfa Products Division of Ventron Corp. The literature method (7) was used to prepare $[Et_4N][XM(CO)_5]$ (M = Cr, Mo, W; X = Cl, Br). Lithium metal was obtained from Alfa Products as 3.2 mm wire; high-sodium (1.0% Na) and low-sodium (0.01%) grades were equally satisfactory.

All reactions and crystallizations were carried out under a nitrogen atmosphere, and details of representative preparations are given below.

Preparation of $[Et_4N][Ph_3SiCr(CO)_5]$

Lithium wire (*ca.* 6 cm, excess) was wrapped in a piece of polyethylene, pounded with a hammer, cut into small pieces, and dropped into a solution of Ph_3SiCl (3.5 g, 11.9 mmol) in 25 ml tetrahydrofuran. The solution was magnetically stirred for 3–4 h, by which time it had become deep red. It was then transferred by means of a 50 ml syringe, taking care to leave any excess lithium behind, and added slowly to a solution of $[Et_4N][Cr(CO)_5Cl]$ (3.3 g, 9.2 mmol) in 50 ml tetrahydrofuran. The reaction mixture was stirred at room temperature for 1 h and then the solvent was removed under reduced pressure. The sticky solid residue was extracted with *ca.* 120 ml dichloromethane, the extract was filtered through Celite, and ether was added to the filtrate to precipitate a white solid. The analytical sample was recrystallized twice from dichloromethane–ether to afford 4.4 g (82% yield) of flaky white crystals.

Preparation of $[Et_4N][Cl_3GeCr(CO)_5]$

Trichlorogermane (1.5 ml, 2.7 g, 15.0 mmol) was added to a magnetically stirred solution of $[Et_4N][Cr(CO)_5Cl]$ (3.0 g, 8.4 mmol) in 80 ml dichloromethane. The solution was heated to reflux for 15 min and then filtered through Celite. Addition of ether precipitated a pale yellow compound which was collected and shaken with a methanol–water (1:1) solution to remove yellow adsorbed impurities. The solid was filtered, dried, and recrystallized from dichloromethane–ether to give 3.3 g (78% yield) of white crystals.

Preparation of $[Et_4N][Cl_3SnMo(CO)_5]$

Tin(II) chloride (2.0 g, 10.6 mmol) and $[Et_4N][ClMo(CO)_5]$ (3.0 g, 7.5 mmol) were refluxed in 80 ml dichloromethane for 1 h. The yellow solution became pale orange and was filtered through Celite. Addition of ether to the filtrate precipitated an oil; the solvents were decanted and the oil washed with ether and with *n*-pentane. The remaining oil was then extracted with 60 ml dichloromethane, 40 ml ether was added, and the solution was filtered leaving behind an orange solid residue. An additional 20 ml of ether was added to the colorless filtrate, which upon cooling at 0° overnight afforded the white crystalline product (1.7 g, 38% yield).

Preparation of $[Et_4N][Me_3SnMo(CO)_5]$

To a solution of hexamethylditin (1.8 g, 8.6 mmol) in 25 ml tetrahydrofuran, lithium clippings (excess) were added and the solution stirred for 1 h. The deep red solution was added to a solution of $[Et_4N][Mo(CO)_5Cl]$ (3.1 g, 7.7 mmol) in tetrahydrofuran (100 ml) and the reaction mixture stirred for 1 h. The solvent was removed and the solid residue extracted with dichloromethane and filtered through a 10 cm column packed with aluminum oxide. Addition of ether precipitated an oil which gave a pale yellow solid after pumping overnight in high vacuum. Two careful recrystallizations from dichloromethane–ether–pentane afforded the analytical sample (2.4 g, 58% yield).

Preparation of $[Et_4N][Ph_3PbMo(CO)_5]$

Lithium clippings (excess, from 6 cm wire) were added to a solution of Ph_3PbCl in tetrahydrofuran (25 ml). The reaction was slightly exothermic, and the mixture turned black after *ca.* 3 h stirring. The organolithium solution was then added to a solution of $[Et_4N][Mo(CO)_5Cl]$ (3.6 g, 9.0 mmol) in 100 ml tetrahydrofuran and the reaction mixture was stirred for an additional 0.5 h. After removal of solvent under reduced pressure, the solid residue was extracted with dichloromethane and filtered through Celite. The filtrate was concentrated and ether was added in 5 ml portions until the solution became cloudy. During cooling overnight, white crystals formed which were collected (3.1 g, 43% yield). The sample was sufficiently pure for further reaction. The analytical sample was obtained by two further recrystallizations from dichloromethane–ether.

Preparation of $[Et_4N][Ph_3GeW(CO)_5]$

Hexaphenyldigermane (3.5 g, 6.5 mmol) or alternatively Ph_3GeCl (3.2 g, 10.6 mmol) in 20 ml tetrahydrofuran was stirred with excess lithium wire. The reaction was slightly exothermic and a milky precipitate appeared. The disappearance of the white precipitate was followed by color changes from deep yellow through dark green to a deep red color over a period of 4 to 6 h (3 h for Ph_3GeCl). This reaction mixture was added slowly to a solution of $[Et_4N][W(CO)_5Cl]$ (4.5 g, 9.3 mmol) in 100 ml tetrahydrofuran and stirred for 0.5 h. Solvent was then removed under reduced pressure. The residue was extracted with dichloromethane, filtered through Celite, and the filtrate concentrated under a stream of nitrogen. On cooling at 0° overnight, fluffy white crystals formed (4.5 g, 55% yield).

Preparation of $[Et_4N][Ph_2ClSnW(CO)_5]$

A mixture of $[Et_4N][Ph_3SnW(CO)_5]$ (2.38 g, 2.96 mmol) and $[Et_4N][Cl_3SnW(CO)_5]$ (1.00 g, 1.47 mmol) was heated at 150° in the absence of solvent. The progress of the reaction was followed by the removal of samples at short intervals and recording their spectra in dichloromethane. After 1 h the mixture was cooled to room temperature and the crude product extracted with dichloromethane. Solvent was removed from the extract, leaving an oil which solidified on pumping overnight at 60°. Three recrystallizations from dichloromethane–ether afforded the analytical sample (2.0 g, 88% yield). Trace amounts of starting materials were difficult to eliminate.

Under similar conditions using $[Et_4N][Ph_3SnW(CO)_5]$ and $[Et_4N][Cl_3SnW(CO)_5]$ in 1:2 molar ratio, $[Et_4N][PhCl_2SnW(CO)_5]$ was obtained.

Reactions of Anions with Hydrogen Chloride

An ethereal HCl solution was prepared by bubbling gaseous HCl (Matheson of Canada Ltd.) through 200–250 ml of diethyl ether for 30 min. The flask was capped by means of a rubber septum and the molarity of the solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

determined by titrating 10 ml aliquots, placed in water, against a standard NaOH solution.

An aliquot of ethereal HCl (0.4 ml, 1.3 mmol HCl) was added to a solution of $[Et_4N][Ph_3GeW(CO)_5]$ (0.6 g, 0.8 mmol) in tetrahydrofuran (15 ml). The initially colorless solution turned yellow at once. The infrared spectrum showed the disappearance of starting material and new bands at 2065 (w), 1916(s), and 1857(m), which were identical with those of an authentic sample of $[Et_4N][ClW(CO)_5]$. Reaction of $[Et_4N][Ph_3SiW(CO)_5]$ under the same conditions afforded the same product in an equally rapid reaction. When gaseous HCl was passed over a stirred dichloromethane solution of $[Et_4N][Ph_3SiW(CO)_5]$, the same product was formed.

A sample of $[Et_4N][Ph_3SnW(CO)_5]$ in tetrahydrofuran reacted rapidly and completely with ethereal HCl under the above conditions forming $[Et_4N][Cl_3SnW(CO)_5]$, recognized by its infrared spectrum (Table 2). The product was stable to further treatment with excess ethereal HCl. In dichloromethane, gaseous HCl formed the same product.

Results and Discussion

Synthesis

As noted above, the previously reported group IV ligands in the pentacarbonylmetalates of chromium, molybdenum, and tungsten have been restricted to X_3Ge and X_3Sn (X = Cl, Br, I). We have prepared and characterized a number of new complexes of this type in which the group IV ligand is Ph_3Si, $MePh_2Si$, Ph_3Ge, Ph_3Sn, Me_3Sn, and Ph_3Pb. The reaction is a displacement using the well-known lithio derivatives $R_3M'Li$, in which the preferred starting material is the chloropentacarbonyl anion (7).

$$[ClM(CO)_5]^- + R_3M'Li \xrightarrow{\text{tetrahydrofuran}} [R_3M'M(CO)_5]^- + LiCl$$

Use of the tetraethylammonium salt of $[ClM(CO)_5]^-$ affords the product as the tetraethylammonium salt as well. The progress of the reaction could be monitored, and excess $R_3M'Li$ avoided, by following the disappearance of the highest carbonyl stretching band of $[ClM(CO)_5]^-$. Reactions took place smoothly at room temperature in about 1 h, affording the product in yields ranging from 40 to 90%.

Tetraethylammonium salts of the new anions reported here form colorless crystals,[2] soluble in polar solvents such as dichloromethane, acetone, and tetrahydrofuran, but not in ether or in hydrocarbon solvents. The compounds are stable in the solid state in air for long periods. Most are stable for periods of days in solution under a nitrogen atmosphere, but $[Et_4N][Cl_3SnW(CO)_5]$ decomposed in tetrahydrofuran solution in a few minutes.

An interesting and perhaps advantageous alternative route to certain of the trihalogeno derivatives was discovered involving insertion of $SnCl_2$, $SnBr_2$, and $GeCl_2$ into the metal–halogen bond of $[XM(CO)_5]^-$ anions.[3]

$$[ClM(CO)_5] \xrightarrow{SnCl_2,\ 40°,\ CH_2Cl_2} [Cl_3SnM(CO)_5]^-$$

$$[ClM(CO)_5] \xrightarrow{HGeCl_3,^{(3)}\ 40°,\ CH_2Cl_2} [Cl_3GeM(CO)_5]^-$$

$$[BrM(CO)_5] \xrightarrow{SnBr_2,\ 40°,\ CH_2Cl_2} [Br_3SnM(CO)_5]^- \quad (M = Cr, Mo, W)$$

The insertion reactions were complete within a few minutes and yields were high. Subsequent to our work, we learned that $[Cl_3SnM(CO)_5]^-$ (M = Cr, Mo, W) had been prepared independently by this route.[4]

Chemical Reactions

A reaction of some interest and considerable synthetic value is that of redistribution. Thus, mixed organohalogenotin complexes were obtained by the following reactions at 150° without solvent.

$$2[Et_4N][Ph_3SnW(CO)_5] + [Et_4N][Cl_3SnW(CO)_5] \rightarrow 3[Et_4N][Ph_2ClSnW(CO)_5]$$

Use of 1:2 molar ratio afforded $[Et_4N][PhSnCl_2W(CO)_5]$. Such a redistribution is familiar in organotin chemistry, and was first applied by Gorsich to tin transition metal derivatives (8). In the present work, only the reaction between $[Ph_3SnW(CO)_5]^-$ and $[Cl_3SnW(CO)_5]^-$ was investigated, so its generality has not been established.

Reactions of $[Ph_3M'W(CO)_5]^-$ (M' = Si, Ge, Sn) with hydrogen chloride in ether–tetrahydrofuran were investigated. For the triphenylsilyl and triphenylgermyl derivatives, very rapid cleavage of the metal–metalloid bond occurred.

$$[Et_4N][Ph_3M'W(CO)_5] + HCl \xrightarrow[\text{tetrahydrofuran}]{\text{ether}} [Et_4N][ClW(CO)_5] + (HM'Ph_3)$$

[2]In a few cases the crystals were pale yellow in appearance, presumably due to adsorbed impurities. The yellow color was removed by shaking the crystals with water–methanol (1:1).

[3]Trichlorogermane is presumed to serve as a source of $GeCl_2$ in this reaction.

[4]Unpublished results of H. Behrens and H. P. Burkon, quoted in footnote 11 of ref. 5.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Formation of $[ClW(CO)_5]^-$ was indicated by infrared spectroscopy. The hydride $HM'Ph_3$ is written in parentheses since it is the other presumed product of the reaction.

On the other hand, the tin-tungsten anion reacted under similar conditions to cleave the phenyl-tin bond.

$$[Et_4N][Ph_3SnW(CO)_5] + 3HCl \xrightarrow[\text{tetrahydrofuran}]{\text{ether}} [Et_4N][Cl_3SnW(CO)_5] + 3PhH$$

In this reaction, the behavior of $[Ph_3SnW(CO)_5]^-$ parallels that of the neutral, isoelectronic $Ph_3SnRe(CO)_5$, where the reaction product is $Cl_3SnRe(CO)_5$ (9, 10).[5] The different character of the cleavage reaction with silicon and germanium on the one hand, and tin on the other is not understood, but may be the consequence of the relative rate of Ph—M′ cleavage, which would be greater for tin.

Protonation of $[Et_4N][Ph_3SnW(CO)_5]$ and $[Et_4N][Cl_3GeMo(CO)_5]$ using a pentane – 85% H_3PO_4 mixture[6] afforded only the corresponding hexacarbonyl. The intent in this reaction was to prepare the hypothetical neutral seven-coordinate hydrides, *e.g.*, $Ph_3SnW(H)(CO)_5$, but no direct evidence for their formation was obtained. The products of the phosphoric acid reactions can readily be interpreted in terms of initial formation of the hydrido species, which would rapidly undergo reductive elimination of Ph_3SnH to form coordinatively unsaturated $M(CO)_5$; partial decomposition of the latter would provide carbon monoxide for conversion of the balance to $M(CO)_6$.[7] This process would be analogous to the elimination of Ph_3SiH from π-$C_5H_5Mn(CO)_2HSiPh_3$ (12).

In a further attempt to prepare a seven-coordinate neutral derivative, $[Ph_3GeW(CO)_5]^-$ was reacted in tetrahydrofuran with Ph_3PAuCl; the Ph_3PAu ligand is considered to have a small steric requirement. However, the reaction product (established by infrared spectroscopy) was $[ClW(CO)_5]^-$. Again, one could speculate that $[Ph_3GeW(CO)_5AuPPh_3]$ was formed as an intermediate, followed by elimination of $Ph_3GeAuPPh_3$ and attack of chloride ion on the $W(CO)_5$ moiety.

A further comparison of the reactivity of these anions with that of neutral trihalogeno derivatives is provided by their reaction with $AgBF_4$. Reaction of $[Et_4N][Cl_3SnW(CO)_5]$ with $AgBF_4$ in acetonitrile solvent afforded $[CH_3CNW(CO)_5]$, recognized by infrared and mass spectroscopy. Neutral trichlorotin compounds are normally converted to the trifluoro analogs (13).

Reactions of several anions $[Ph_3M'M(CO)_5]^-$ with triphenylphosphine were attempted, but the carbonyl groups were inert to substitution; for example, there was no reaction when $[Et_4N][Ph_3SnMo(CO)_5]$ was stirred overnight in dichloromethane solution with excess triphenylphosphine. Under similar conditions $[Cl_3SnMo(CO)_5]^-$ reacted to form *cis*-$Mo(CO)_4(PPh_3)_2$ in almost quantitative yield (4); this trend is consistent with the expected stronger σ-donor ability of the organotin ligands (14). Under ultraviolet irradiation, $[Et_4N][Ph_3SnMo(CO)_5]$ and PPh_3 in dichloromethane reacted to form a product with carbonyl stretching bands at 2021(ms), 1920(sh), 1902(vs), and 1887(m) cm^{-1}, although a satisfactory analysis could not be obtained to confirm that the product was the anticipated $[Ph_3SnMo(CO)_4PPh_3]^-$.

Infrared Spectra

Free anions of the type $[R_3M'M(CO)_5]^-$ are expected to have idealized C_{4v} symmetry, under which three infrared-active carbonyl stretching fundamentals are expected ($2A_1 + E$). In addition, the B_1 mode is often observed as a weak band in the infrared, since the symmetry is not strictly C_{4v} (15). All of these bands are observed in the typical spectrum shown in Fig. 1*a*, which is that of $[Et_4N][Ph_3SiMo(CO)_5]^-$ in tetrahydrofuran. In addition all of these ions show a weak shoulder on the low frequency side of the higher A_1 band, which is an A' vibration of the radially mono-^{13}CO substituted species present in natural abundance (16). Since this latter weak band invariably falls 6–9 cm^{-1} below the $A_1^{(2)}$ band, it is not listed in Table 2.

[5]Reactions with $Ph_3SnRe(CO)_5$ were carried out in CCl_4 (9) or CH_2Cl_2 (10) rather than ether–tetrahydrofuran, but we have shown that for the Si—W and Sn—W anions, the product is the same in CH_2Cl_2, without ether.

[6]These conditions are well-suited to the preparation of neutral hydrides of low stability (11).

[7]A similar scheme would account for the cleavage of Si—W and Ge—W bonds by hydrogen chloride, in which case chloride ion would attack the coordinatively unsaturated intermediate forming $[ClW(CO)_5]^-$.

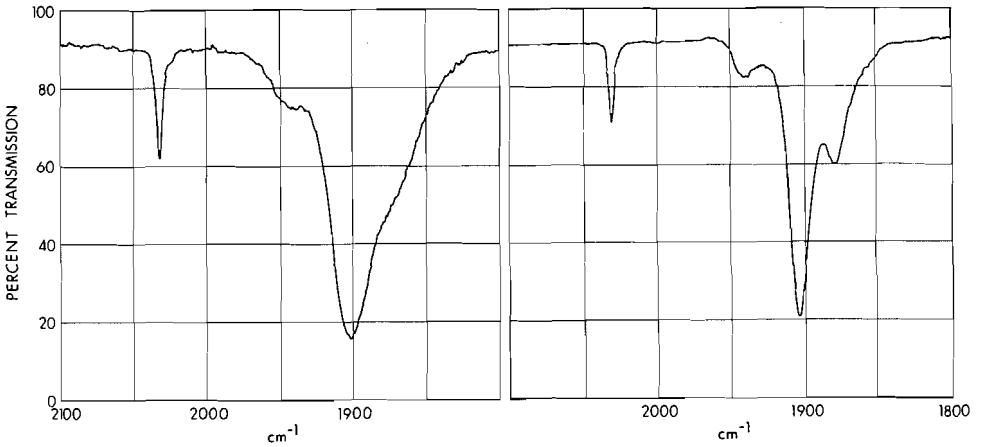

FIG. 1. Infrared spectra of $[Et_4N][Ph_3SiMo(CO)_5]$ in dichloromethane (left) and tetrahydrofuran (right) illustrating superior band sharpness in the latter. Band positions and assignments in the right hand spectrum are 2031 cm^{-1} ($A_1^{(2)}$), 1943 cm^{-1} (B_1), 1905 cm^{-1} (E), and 1880 cm^{-1} ($A_1^{(1)}$).

Carbonyl bands have previously been reported in dichloromethane solution for the trichlorogermanium and trichlorotin derivatives (4). We have observed that the bands are less broad in tetrahydrofuran, so that, for example, the E and $A_1^{(1)}$ bands are clearly resolved. This solvent effect is illustrated in Fig. 1. There is no significant frequency shift between the two solvents.

In general, the band positions are shifted to lower frequency by 40–70 cm^{-1} as compared to the corresponding neutral, isolectronic complexes $R_3PM(CO)_5$, (M = Cr, Mo, W) (17), and by 80–130 cm^{-1} compared to $R_3M'M''(CO)_5$ (M′ = Si, Ge, Sn; M″ = Mn, Re) complexes (18). This shift is consistent with the higher electron density on the metal in the anionic compound which leads to increased back donation. Carbonyl stretching force constants using the Cotton–Kraihanzel (15) approximation have been evaluated and discussed for all the compounds of Table 2 (19). Since these derived parameters are available in a rather straightforward way from the given frequencies, they will not be reported here. The force constants range from 14.24 to 15.38 mdyn $Å^{-1}$ for k_1 and 14.90 to 15.91 for k_2, lower by 1–1.5 mdyn $Å^{-1}$ than in the neutral, isoelectronic derivatives.

We thank the National Research Council of Canada for financial support and for a postgraduate scholarship to E.E.I.

Déroulement anormal d'une réaction de Michaelis–Becker: caractère ambident de l'anion diéthylphosphonate $(C_2H_5O)_2PO^-$; stéréochimie de la réaction de Michaelis–Becker

CLAUDE BENEZRA ET JEAN-LOUIS BRAVET
Département de Chimie, Université d'Ottawa, Ottawa, Canada K1N 6N5

Reçu le 28 juin 1974

CLAUDE BENEZRA et JEAN-LOUIS BRAVET. Can. J. Chem. **53**, 474 (1975).

La réaction du phosphonate diéthylique monosodique $NaOP(OC_2H_5)_2$ avec les mésylates des *cis* et *trans*-*t*-butyl-4 cyclohexanols a été étudiée dans le toluène, le dioxanne et la diméthylformamide (DMF). A côté des produits attendus de la réaction (élimination et P-alcoylation), se forment des produits provenant de l'attaque par l'oxygène du groupe phosphonate. Cette attaque est en compétition avec la P-alcoylation (réaction de Michaelis–Becker normale) et correspond à la seule réaction de substitution dans la DMF. Une interprétation des résultats est proposée qui fait intervenir la théorie des acides et bases durs et mous et également la solvatation préferentielle. Le caractère S_N2 de la réaction de Michaelis–Becker est confirmé.

CLAUDE BENEZRA and JEAN-LOUIS BRAVET. Can. J. Chem. **53**, 474 (1975).

The reaction of sodium diethylphosphonate $NaOP(OC_2H_5)_2$ with the mesylates of *cis* and *trans*-4-*t*-butyl cyclohexanols has been studied in toluene, dioxane, and dimethylformamide (DMF). Beside the products expected from the reaction (elimination and P-alkylation products originating from initial O-attack have been isolated. This latter reaction competes with P-alkylation (normal Michaelis–Becker reaction) and is the only substitution reaction in DMF. Results are interpreted in terms of the HSAB (Hard and Soft Acids and Bases) theory and by preferential solvation. Since the substitution products are of inverted configuration, the S_N2 mechanism seems to be well substantiated.

Parmi les méthodes de synthèse de liaison carbone–phosphore les plus utilisées, la réaction de Michaelis–Becker (1) est une des plus anciennes. Dans cette réaction, un sel alcalin d'un phosphonate dialcoylique, $HP(O)(OR)_2$, réagit avec un halogénure (1) ou un pseudo-halogénure ($X = OSO_2R'$) (2) pour donner un phosphonate

$$(RO)_2P{-}O^-M^+ + R'X \rightarrow R'P(O)(OR)_2 + MX$$

Cette réaction comporte deux aspects encore mal connus: d'une part, bien qu'il soit généralement admis (3), le caractère S_N2 du mécanisme n'a pas été démontré; d'autre part, l'anion phosphonate est *ambident*

$$(RO)_2P{-}O^- \leftrightarrow (RO)_2\bar{P}{=}O$$

et peut théoriquement attaquer soit par l'oxygène, soit par le phosphore. Il n'y a, à notre connaissance aucun exemple, dans la littérature, de phosphonate alcalin réagissant par l'oxygène (O-alcoylation). Le seul exemple qui se rapproche d'une réaction de Michaelis–Becker avec O-alcoylation est celui du sel d'*argent* du phosphonate diéthylique qui réagit avec les chlorures de triarylméthyle pour donner des produits d'O- et de P-alcoylation (4).

En étudiant la réaction de phosphonate diéthylique monosodique avec les méthanesulfonates (mésylates, Ms) des *cis* et *trans*-*t*-butyl-4 cyclohexanols, nous avons découvert que, d'une part, l'anion phosphonate $(EtO)_2PO^-$ pouvait réagir par l'oxygène et que, d'autre part, les réactions de substitution se déroulaient avec *inversion* de configuration, apportant ainsi une confirmation du mécanisme S_N2 postulé. Les résultats de cette étude conduite avec trois solvants (dioxanne, toluène, diméthylformamide) sont décrits dans cet article.

Résultats

Les réactions ont été réalisées sur chacun des deux épimères purs **1***b* et **2***b* dans trois solvants différents dans des conditions identiques de concentration. L'anion du phosphonate diéthylique a été préparé *in situ* par réaction du sodium métallique sur $HP(O)(OC_2H_5)_2$, sous azote. Après obtention d'une solution claire du sel de sodium, le mésylate dissous dans un solvant approprié a été rajouté sous azote et le mélange réactionnel chauffé à la température indiquée dans les tableaux 1 et 2, suivant un temps variable. Le tableau 3 résume les résultats.

TABLEAU 1. Résultats obtenus à partir du mésylate *axial* **1***b*

Poids (g) de mésylate (mmol)	Solvant	Durée (h) de réaction température	Produits de réaction: g (mmol)*					
			5	**1***b*	**2***a*	**2***d*	**1***e*	**4**
5.00(21)	Dioxanne	168 h (reflux)	0.94 (6.8)	0.74 (3.3)	0.12 (0.74)	0.42 (1.4)	0.10 (0.4)	0.79 (2.9)
5.00(21)	Toluène	168 h (reflux)	1.39 (10.1)	0.37 (1.6)	0	0.28 (0.97)	0.18 (0.69)	0.77 (2.8)
4.03(17)	DMF	40 h (140 °C)	1.81 (13.1)	0.03 (0.1)	0.09 (0.6)	0.12 (0.4)	0.02 (0.06)	0

*Les produits sont indiqués par ordre d'élution (**5** élué en premier, **4** en dernier).

TABLEAU 2. Résultats obtenus à partir du mésylate *équatorial* **2***b*

Poids en g du mésylate de départ (mmol)	Solvant	Durée (h) de réaction et température	Produits de réactions: g (mmol)*				
			5	**2***b*	**1***a*	**1***d*	**3**
5.00(21)	Dioxanne	168 h (reflux)	0.28 (2.0)	2.63 (11.3)	0.15 (0.96)	0.34 (1.2)	0.87 (3.1)
3.00(13)	Toluène	168 h (reflux)	0.40 (2.9)	0.74 (3.2)	0	0.39 (1.3)	0.75 (2.7)
5.00(21)	DMF	24 h (140°)	1.63 (11.8)	0	0.30 (1.9)	0.54 (1.9)	0

*Classés par ordre d'élution (**5** est élué en premier, **3** en dernier).

TABLEAU 3. Résultats d'ensemble

Produit de départ	Solvant	Nature de la réaction			Attaque‡	Par
		Elimination*	Substitution*	Autres*†	P	O
 **1** (R = SO_2CH_3)	Dioxanne	56	42	2	57	43
	Toluène	70	26	4	73	27
	DMF	91	9	0	0	100
 **2** (R = SO_2CH_3)	Dioxanne	27	73	0	59	41
	Toluène	42	58	0	67	33
	DMF	75	25	0	0	100

*% Elimination + % substitution + % "autres" = 100%.
†Produits avec rétention de la configuration: **1***e*.
‡% attaque par P + % attaque par O = 100%.

Tout d'abord quelques remarques générales s'imposent; la réaction est la plus rapide dans la diméthylformamide (DMF); 24 à 48 h sont suffisantes pour que tout le mésylate de départ soit consommé. Dans les autres solvants étudiés, le temps de réaction est beaucoup plus long (1 semaine) et le mésylate de départ n'a pas entièrement réagi. Après réaction et isolement du mélange réactionnel (voir Partie expérimentale), les produits ont été séparés sur colonne de silice.

Structure et configuration des composés obtenus

Le *t*-butyl-4 cyclohexène **5** a été identifié par spectroscopie (i.r. et r.m.n.) et par chromatographie sur couche mince (c.c.m.) à un échantillon authentique. On récupère dans la plupart des cas (sauf pour les réactions dans le toluène) l'alcool de configuration *inverse* de celle du mésylate de départ. Les alcools *axial* **1***a* et *équatorial* **2***a* ainsi obtenus, ont été identifiés (i.r., r.m.n., c.c.m.) à des échantillons authentiques.

On isole également des *phosphates* **1***d* et **2***d* à

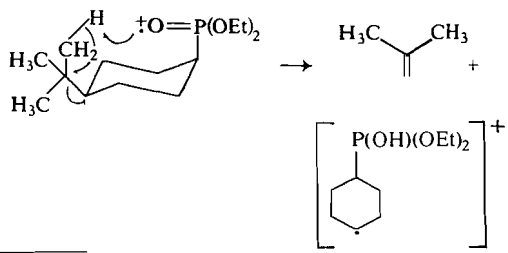
la place des phosphites **1***c* et **2***c*, produits d'une O-alcoylation. Ces phosphates sont très vraisemblablement des artefacts provenant de l'oxydation lors de l'isolement des phosphites correspondants. Nous reviendrons sur ce point important lors de la discussion. Les phosphates ainsi obtenus ont été identifiés (i.r., r.m.n., c.c.m.) à des échantillons authentiques préparés par phosphorylation des alcools correspondants (5). L'aspect en r.m.n. du signal du proton H-1 permet d'ailleurs l'attribution non équivoque de la configuration *axiale* ou *équatoriale*. Il est bien connu, en effet, que dans le cyclohexane, un hydrogène *axial* donne un signal en r.m.n. considérablement plus étendu qu'un hydrogène équatorial (6).

La réaction avec le mésylate *axial* offre une particularité par rapport à celle avec le mésylate *équatorial*. Dans le premier cas, en effet, on obtient toujours, un hydrogène phosphonate éthylique **1***e* de configuration *identique* (axiale) à celle du mésylate de départ. Cette *rétention* de configuration ne peut s'expliquer que par une attaque directe de l'anion phosphonate sur le soufre du groupement mésylate et transestérification. Ce point sera traité plus en détail dans la discussion. La détermination de la structure de l'hydrogène phosphonate mono-éthylique découle de l'analyse centésimale et des propriétés spectroscopiques: la liaison P—H est visible en infrarouge (2420 cm^{-1}) et l'hydrogène attaché au phosphore apparaît en r.m.n. sous forme d'un doublet avec une forte constante de couplage J_{P-H} = 721 Hz. La configuration *axiale* du groupe $PH(O)(OC_2H_5)$ est prouvée par l'aspect en r.m.n. de l'hydrogène H-1 (multiplet étroit, compatible avec un hydrogène équatorial). D'autre part, les deux hydrogènes phosphonates **1***e* et **2***e* ont été préparés[1] à partir du mélange commercial (Aldrich) des *t*-butyl-4 cyclohexanols et de PCl_3 et d'EtOH (7). Ils ont été séparés par chromatographie sur colonne de silice.

La configurations des *t*-butyl-4 cyclohexylphosphonates diéthyliques **3** et **4** a été plus difficile à établir. Les analyses centésimales et les propriétés spectrales (i.r. et r.m.n.) sont compatibles avec les structures attribuées. D'autre part, nous leur attribuons une configuration *inverse* de celle du mésylate de départ, ce qui est compatible avec un mécanisme S_N2 pour la réaction de Michaelis–Becker.

Les structures sont essentiellement fondées sur la spectrométrie de masse. Comme c'est généralement le cas pour des épimères (8), notamment des dérivés organophosphorés (9), les spectres des deux épimères **3** et **4** sont très semblables, notamment, ils montrent tous les deux un pic de masse à *m/e* 276 et un pic de base à *m/e* 219, correspondant à la perte du radical $[(CH_3)_3C\cdot]$. La différence essentielle entre les deux spectres est l'intensité du pic à *m/e* 220, correspondant à la perte d'isobutylène. Par rapport au pic de base, ce pic représente 27% dans l'isomère auquel nous attribuons la configuration équatoriale **4** alors qu'il représente 98% du pic de base dans l'isomère *axial* **3**. Ceci peut s'expliquer par une élimination plus facile lorsque les groupes *t*-butyle et $P(O)(OC_2H_5)_2$ sont *cis* [1].

[1]



[1]Cette synthèse aurait dû normalement donner les phosphites mixtes (*t*-butyl-4 cyclohexyl-1) $P(OC_2H_5)_2$. L'obtention des hydrogènes phosphonates **1***e* et **2***e*, peut s'expliquer par l'hydrolyse d'un intermédiaire tel que (*t*-butyl-4 cyclohexyl-1) $P(OC_2H_5)$ (Cl) → (*t*-butyl-4 cyclohexyl-1) $P(OC_2H_5)(OH)$ qui est sous forme hydrogène phosphonate.

Ces attributions sont confirmées par l'utilisation des complexes de terres rares [Eu(dpm)$_3$] en r.m.n.: l'effet de l'addition d'Eu(dpm)$_2$ sur le déplacement chimique du *t*-butyle est considérable pour l'isomère *cis* ou *axial* **3** (l'addition de 0.50 équivalent d'Eu^{III} fait passer le déplacement chimique du *t*-Bu de 0.88[2] à 1.2. p.p.m. soit ($\Delta\delta$ = 0.33 p.p.m.) alors que l'effet de l'Eu^{III} sur l'isomère *trans* (où les groupes *t*-Bu et P(O)(OC$_2$H$_5$)$_2$, *trans*, sont plus éloignés) est faible ($\Delta\delta$ = 0.09 p.p.m.). Bien que l'effet des complexes de terres rares dépende non seulement de la distance au centre considéré, mais aussi de l'angle de contact Φ (10), l'effet le plus important est celui qu'on attendrait avec la configuration attribuée: l'Eu^{III} complexe l'oxygène du groupe P=O (11).

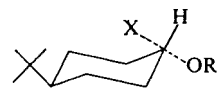
La réaction de Michaelis–Becker étudiée ici est stéréospécifique: avec le mésylate *axial* **1***b*, aucune trace du phosphonate *axial* **3** ou du phosphate *axial* **1***d* n'a pu être décelée, avec le mésylate *équatorial* **2***b*, ni **4** ni **2***d* n'étaient présents.[3]

Discussion

Des résultats résumés dans les tableaux 1, 2 et 3, deux constatations intéressantes sont à faire: (*a*) La réaction de Michaelis–Becker est stéréosélective et donne des produits avec *inversion complète* de configuration (avec l'exception des produits secondaires **1***e*, obtenus avec l'isomère *axial*); le caractère S_N2 (tout au moins en ce qui concerne le cours stéréochimique de la réaction) semble donc bien établi. (*b*) Le caractère *ambident* de l'anion phosphonate (EtO)$_2$P$^{\cdots}$O$^-$ a été démontré par l'isolement de phosphites (oxydés en phosphates) et d'alcools de configuration inverse du mésylate de départ (et provenant donc de l'attaque par l'oxygène).

Si l'on fait le bilan des produits obtenus, on s'aperçoit qu'il faut considérer trois types de réaction: (1) élimination (obtention de *t*-butyl-4 cyclohexène); (2) substitution par le phosphore (produits normaux de Michaelis–Becker) et (3) substitution par l'oxygène (produits anormaux). Considérons successivement ces trois points.

Il faut tout d'abord noter le fort pourcentage d'élimination (obtention du *t*-butyl-4 cyclohexène **5**): celle-ci varie de 56 à 91% du total de la réaction[4] pour le mésylate axial **1***b* et de 27 à 75% pour l'équatorial **2***b*. Si l'élimination de type E_2 est attendue avec l'isomère **1***b* à cause de l'orientation favorable (*trans*-diaxiale) des groupes H et MsO, elle est plus difficile à expliquer dans le cas de l'isomère équatorial. Ce résultat est cependant loin d'être unique puisque Winstein *et al.* (12) ont déjà décrit 10 à 40% d'élimination dans le cas de la réaction de BrLi et ClLi avec les tosylates **1** et **2** (R = SO$_2$C$_6$H$_4$-CH$_3$). Pour expliquer l'élimination dans le cas de l'isomère équatorial **2**, malgré un arrangement stéréoélectronique défavorable, ils ont proposé un mécanisme baptisé "merged bimolecular substitution and elimination" (12) dans lequel l'état de transition classique pour une S_N2 est remplacé par un intermédiaire **6**



6

qui peut évoluer soit vers une élimination, soit vers une substitution. Le fort pourcentage d'élimination qui a été observé avec les mésylates est à rapprocher de l'étude par Roudier (13) de la réaction de Michaelis–Becker de NaOP(OC$_4$H$_9$)$_2$ avec l'iodure de cyclohexyle; le seul produit obtenu est le cyclohexène. Comme on pouvait s'y attendre (14), le pourcentage d'élimination augmente avec la température de la réaction (c'est avec la DMF qu'il est le plus élevé).

En ce qui concerne les produits de substitution, les produits normaux de Michaelis–Becker (les phosphonates **3** et **4**, produits de P-alcoylation), le tableau 3 montre que la meilleure façon de les obtenir consiste à faire la réaction dans le toluène. En termes de théorie des acides et bases "durs" et "mous" de Pearson *et coll.* (15), les composés de P-alcoylation correspondent à l'attaque d'une base "molle" (P) sur un centre "mou" (*C*—OMs). Néanmoins ce centre C est beaucoup plus "dur" que lors de la réaction de

[2]En unités δ, par rapport au TMS, référence interne.

[3]Les isomères **3** et **4** ont, en c.c.m., le même R_f (éluant: acétate d'éthyl – hexane 1:1) après une élution; ils ont cependant des R_f nettement différents, et il devient facile de les distinguer, après 3 élutions successives dans le même mélange de solvants. En solution dans CDCl$_3$, le signal du groupe *t*-butyle se trouve au même endroit (0.87 p.p.m.) dans les deux épimères; en solution benzènique, cependant, le déplacement chimique du *t*-butyle est de 0.86 p.p.m. pour **3** et de 0.75 p.p.m. pour **4**.

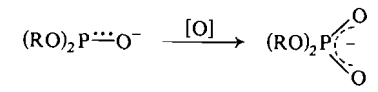
Michaelis–Becker ordinaire avec des halogénures comme groupes partants, ce qui explique l'obtention de produits correspondant à une O-alcoylation: phosphites (puis phosphates) et alcools.

L'O-alcoylation est importante; elle représente, pour le composé *axial* **1***b*, 27% (toluène), 43% (dioxanne) et 100% (DMF), pour le composé *équatorial*, **2***b*, 33% (toluène), 41% (dioxanne) et 100% (DMF). Il y a deux sortes de produits provenant d'une attaque par l'oxygène, les phosphates **1***d* et **2***d* et les alcools **1***a* et **2***a*. Ces derniers proviennent très certainement de l'hydrolyse *in situ* des phosphites correspondants. En effet à partir du mésylate *axial* **1***b* on obtient l'alcool *équatorial* **2***a* et à partir de **2***b*, on obtient l'alcool **1***a*; il y a donc *inversion* de configuration.

L'obtention des phosphates **1***d* et **2***d* au lieu des phosphites attendus **1***c* et **2***c* s'explique sans doute par une oxydation lors de l'isolement de ces phosphites. En effet, bien que la réaction ait été effectuée sous azote, on aurait pu concevoir une oxydation préalable de l'anion phosphonate en anion phosphate et attaque nucléophile de l'anion phosphate sur le carbone porteur du groupe OMs.



Cette hypothèse a été écartée de la façon suivante: le mésylate équatorial **2***b* en solution dans la DMF a été traité par une quantité stoéchiométrique du sel de sodium du phosphate diéthylique $(NaO)P(O)(OC_2H_5)_2$ et chauffé pendant 24 h. Le seul produit formé a été le *t*-butylcyclohexène. D'ailleurs il est connu (16) que l'anion phosphate $(C_2H_5O)_2PO_2^-$ n'est que faiblement nucléophile.

Un résultat du tableau 3 est frappant, si le % d'O-alcoylation est comparable dans le toluène et le dioxanne en revanche, il y a 100% d'attaque par l'oxygène dans la DMF. Si, avec Hudson (17), on admet que dans un ion ambident on peut traiter les deux centres nucléophiles indépendamment, on peut concevoir que la DMF, qui solvate préferentiellement les "gros" anions (18) (ici le P), rendrait ainsi l'oxygène plus disponible pour une attaque nucléophile. D'ailleurs le fait d'obtenir 91 et 75% d'élimination à partir des isomères *axial* **1***b* et *équatorial* **2***b*, respectivement, dans la DMF pourrait être interprété non seulement comme résultant d'une température plus élevée (favorisant donc l'élimination au détriment de la substitution (14), mais aussi comme étant le résultat de l'attaque d'une base "dure" (1′O^- de P—O^-) sur un acide "dur" (1′H en β du groupe MsO: [2]).

[2] 
Les résultats décrits ici suggèrent que le diéthylphosphonate de sodium se retrouve sous forme de paire d'ions intimes: $(C_2H_5O)_2P—O^- \ldots Na^+$, dans le dioxanne et la toluène (favorisant l'attaque par le phosphore) et sous forme d'ions séparés (et solvatés) dans le DMF.[5] Dans ce dernier cas, la charge négative serait, probablement, plutôt sur l'oxygène, rendant compte ainsi du pourcentage élevé d'O-alcoylation.

La rareté des O-alcoylations dans les conditions de Michaelis–Becker s'explique bien par la théorie des acides et bases "durs" et "mous" (15); le centre d'attaque (le carbone C—X) est "mou" quand X est un halogène (et donc est attaqué préférentiellement par la base "molle", le P de P⋯O^-) et "dur" quand X = OTs ou OMs (et donc l'attaque par l'oxygène de P⋯O^-, base dure, devient compétitive). En répétant l'expérience de Myers *et al.* (2) sur le tosylate de cyclohexyle, nous avons pu mettre en évidence la formation, à côté du phosphonate de cyclohexyle attendu, de composés à liaison O—P (phosphites ou phosphates).

La réactivité des centres dans un ion ambident dépend du substrat, du solvant et du cation (19). Lorsque le milieu est homogène c'est l'atome nucléophile de plus forte densité électronique qui réagit sur le centre positif (C—X). Ainsi peut-on expliquer l'exemple d'Arbuzov et Kaziljnikova (4) dans lequel le sel d'argent du phosphonate diisopropylique donne des *phosphites* avec des chlorures de triarylméthyle.

$$Ar_3CCl + AgOP(O—iso\text{-}Pr)_2 \rightarrow Ar_3COP(O—iso\text{-}Pr)_2$$

Cet exemple diffère cependant des conditions de Michaelis–Becker; en effet en raison de la catalyse électrophile de l'ion Ag^+ la réaction a un caractère S_N1 plus prononcé et on observe

[5]Nous remercions un rapporteur d'avoir suggéré cette interprétation complémentaire.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

une attaque par l'atome de plus forte électronégativité (19).

La nature homogène ou hétérogène du milieu réactionnel, dans les réactions avec les ions ambident a également son importance (20); avec les ions phénolates, par exemple, on observe plus de C-alcoylation en milieu hétérogène, plus d'O-alcoylation en milieu homogène. Dans le cas des réactions étudiées ici, la réaction, homogène pendant un certain temps, devient hétérogène à cause de la précipitation de NaOMs.

Enfin, il est intéressant de constater la formation (bien qu'en faible quantité) dans le cas du mésylate *axial* **1***b*, d'hydrogène phosphonate *axial* **1***e* donc, avec rétention de configuration. On ne peut expliquer l'obtention de ces produits que par une attaque directe sur le soufre du groupe mésylate (laissant donc intacte la liaison C—O *axiale*) et transestérification de l'anion phosphonate sur l'alcool axial ainsi obtenu. Nous n'avons pas, pour l'instant, d'explication pour le fait que le composé equivalent (**2***e*) ne se forme pas dans le cas du mésylate équatorial.

En conclusion, cette étude a montré d'une part le caractère S_N2 de la réaction de Michaelis–Becker (obtention des produits avec *inversion* de configuration) d'autre part, un des rares exemples de réactivité à l'oxygène de l'anion phosphonate $Na^{+-}OP(OC_2H_5)_2$. En contrôlant le groupe portant et le solvant, il devient donc possible d'orienter la réaction de Michaelis–Becker vers une O- ou vers une P-alcoylation.

Partie expérimentale

Indications générales

Le dioxanne a été purifié de la façon suivante: après une nuit sur du CaH_2, il a été reflué 2 h puis distillé. La diméthylformamide (DMF) a été distillé puis passé sur une colonne d'alumine basique Woelm cation–otropique, activité I, de Waters Associates Inc. pour le débarrasser de l'eau résiduelle. Le toluène a été distillé et conservé sur sodium. Le phosphonate diéthylique, d'Aldrich, a été distillé avant réaction.

Séparation des isomères axial et équatorial du t-butyl-4 cyclohexanol

Le produit commercial, d'Aldrich, contient un mélange 2:1 des isomères équatorial et axial (on peut évaluer les proportions par r.m.n. en intégrant l'hydrogène-C*H*OH). Le mélange d'épimère (35.0 g) est chromatographié sur 1000 g d'oxyde d'aluminium Shawinigan de McArthur Chemical (Montréal). Au mélange éther de pétrole – éther (1:1) on élue 10.46 g d'isomère *axial* pur **1***a*, puis 6.07 g d'un mélange des deux alcools et enfin à l'éther pur sont élués 16.04 g d'isomère *équatorial* pur **2***a*.

Préparation des mésylates **1***b et* **2***b*

(*a*) A une solution refroidie dans la glace d'alcool axial **1***a* (5.00 g, 320 mmol) dans du chlorure de méthylène (60 ml) contenant du CH_3SO_2Cl (4.22 g, 36.8 mmol), on ajoute goutte à goutte une solution de triéthylamine (3.72 g, 36.8 mmol) dans du chlorure de méthylène (6.0 ml). Après addition, on laisse réagir à température ambiante pendant 10 min et on ajoute 60 ml d'eau. La phase organique est séparée, puis la phase aqueuse est extraite du chlorure de méthylène. Les phases organiques réunies sont réunies, lavées à l'eau, séchées sur Na_2SO_4 et évaporées à sec; on obtient ainsi 7.59 g de mésylate *axial* **1***b* pur. On purifie en recristallisant dans l'éther de pétrole (30–60°).

(*b*) Le même mode opératoire est suivi pour l'alcool équatorial on utilise 6.70 g (4.30 mmol) d'alcool + 80 ml CH_2Cl_2 + 5.16 g (45.0 mmol) de CH_3SO_2Cl + 4.56 g (45 mmol) de triéthylamine + 7.0 ml CH_2Cl_2. On obtient 10.0 g d'un *mélange* d'alcool de départ et de mésylate équatorial **2***b* (1:4) que l'on sépare sur colonne de silice. On obtient ainsi 7.77 g de mésylate équatorial **2***b* pur. (Rendement 75%.)

Procédé général (réaction de Michaelis–Becker)

A l'aide d'une ampoule à addition munie d'un égalisateur de pression, on ajoute pendant environ vingt minutes, sous azote, goutte à goutte une solution de 1.25 n millimoles (mmol) de $HP(O)(OEt)_2$ dans 0.33 n ml de solvant, à une suspension de 1.15 n atome-g de sodium dans 0.75 n ml de solvant. A la fin de l'addition, on chauffe le mélange à 100° jusqu'à disparition complète du sodium (environ 1 à 2 h). On ajoute ensuite, toujours sous azote, n mmoles de mésylate dissoutes dans n ml de solvant, goutte à goutte, pendant 30 min. Le mélange est alors chauffé à reflux pendant le temps indiqué sur les tableaux 1 et 2.

Isolement et séparation du mélange

(*a*) *Toluène*: On filtre le précipité de $NaOSO_2CH_3$ et on évapore à sec le toluène. Le mélange est alors mis sur une colonne de silice (40 fois le poids du brut).

(*b*) *DMF et dioxanne*: On ajoute 3 n ml d'éther au mélange réactionnel et on ajoute n ml d'eau. On extrait 3 fois à l'éther de la manière habituelle, puis les fractions éthérées sont lavées à l'eau jusqu'à neutralité, séchées sur sulfate de sodium et évaporées à sec.

Les produits sont élués à l'éther pur puis avec des mélanges éther–méthanol contenant des quantités croissantes de méthanol. Les résultats sont consignés dans les tableaux 1 et 2.

Synthèse des phosphates de t-butylcyclohexyle et de diéthyle **1***d et* **2***d*.

A un mélange de *trans-t*-butyl-4 cyclohexanol **1***a* (0.50 g, 3.2 mmol), d'$HP(O)(OC_2H_5)_2$ (0.43 g, 3.0 mmol) et de (CCl_4 0.94 g, 6.1 mmol), on ajoute goutte à goutte 0.34 g (3.4 mmol) de triéthylamine. On chauffe a reflux 4 h puis le mélange refroidi est filtré et le précipité lavé à l'éther. Les filtrats mis ensemble sont séchés sur Na_2SO_4, évaporés à sec et chromatographiés sur silice. On recueille l'alcool qui n'a pas réagi et le phosphate de *t*-butyle et de diethyle **1***d* (0.15 g, 0.51 mmol) que l'on identifie (i.r., r.m.n., c.c.m.) au produit **1***d* obtenu directement dans la réaction de Michaelis–Becker.

Le même mode opératoire (5) est suivi pour préparé le phosphate équatorial **2***d*; à partir de 0.84 g de $HP(O)(OC_2H_5)_2$, on obtient ainsi 0.51 g (1.8 mmol) de composé

2*d* identifié au produit de la réaction de Michaelis–Becker (i.r., r.m.n., c.c.m.).

Synthèse des hydrogènes phosphonates ***1e*** *et* ***2e*** *selon (7)*

A un mélange refroidi à 0 °C de PCl_3 (6.85 g, 50 mmol) et d'éther anhydre (10 ml), on ajoute goutte à goutte pendant 1 h un mélange des *t*-butyl-4 cyclohexanols d'Aldrich (7.80 g, 50 mmol) et de *N,N*-diméthylaniline (6.05 g, 50 mmol) dans 10 ml d'éther anhydre. On rajoute ensuite, pendant 2 h, un mélange d'éthanol anhydre (4.6 g, 100 mmol) et de *N,N*-diméthylaniline (12.1 g, 100 mmol). A la fin de la réaction, on rajoute 25 ml d'éther anhydre, on filtre lave le précipité à l'éther anhydre et évapore à sec; 11.56 g de résidu sont chromatographiés sur colonne de silice; on recueille les alcools qui n'ont pas réagi, puis les hydrogènes phosphonates; **2***e* (2.51 g, 10.1 mmol), un mélange de **2***e* + **1***e* (1.00 g, 4.0 mmol) puis **1***e* pur (1.00 g, 4.3 mmol).

Nous remercions Madame Danielle Landry pour son aide technique très appréciable et le Conseil national de la recherche du Canada pour son aide financière (octroi A-5496).

La photolyse du sulfure de méthyle et de vinyle

GILLES LEDUC ET YVES ROUSSEAU

Département de Chimie, Université de Montréal, C.P. 6210, Montréal, Québec H3C 3V1

Reçu le 3 juin 1974

GILLES LEDUC et YVES ROUSSEAU. Can. J. Chem. **53**, 483 (1975).

La photolyse du sulfure de méthyle et de vinyle dans la région 230–270 nm donne des produits dont la formation s'explique par les deux scissions primaires suivantes.

$$CH_3—S—CH=CH_2 + h\nu \rightarrow CH_3^{\cdot} + {}^{\cdot}S—CH=CH_2$$

$$CH_3—S—CH=CH_2 + h\nu \rightarrow CH_3S^{\cdot} + {}^{\cdot}CH=CH_2$$

L'addition de méthanethiol (10 à 15%) permet de doser les radicaux méthyles et vinyles formés.

$$R^{\cdot} + CH_3SH \rightarrow RH + CH_3S^{\cdot}$$

La somme des rendements quantiques en méthane et en éthylène tend alors vers l'unité pour des temps d'irradiation courts.

GILLES LEDUC and YVES ROUSSEAU. Can. J. Chem. **53**, 483 (1975).

The photolysis of methylvinylsulfide in the 230–270 nm region yields products which can be explained by the following primary reactions.

$$CH_3—S—CH=CH_2 + h\nu \rightarrow CH_3^{\cdot} + {}^{\cdot}S—CH=CH_2$$

$$CH_3—S—CH=CH_2 + h\nu \rightarrow CH_3S^{\cdot} + {}^{\cdot}CH=CH_2$$

The methyl and vinyl radicals are titrated by the addition of methyl mercaptan to the system.

$$R^{\cdot} + CH_3SH \rightarrow RH + CH_3S^{\cdot}$$

At short photolysis time, the sum of the methane and ethylene quantum yields is near unity.

Introduction

L'étude de la photolyse du sulfure de méthyle et de vinyle (SMV) a été entreprise pour déterminer les processus primaires et les produits qui en résultent. Castonguay et Rousseau (1) ont démontré que la décomposition photosensibilisé au mercure (Hg 6^3P_1) du méthylvinyléther (MVE), homologue oxygéné du SMV, s'explique principalement par une scission du lien CH_3—O [1].

[1] $CH_3OCHCH_2 + Hg\,(^3P_1) \rightarrow CH_3^{\cdot} + {}^{\cdot}O—CH=CH_2 + Hg\,(^1S_0)$

Il a été également souligné que l'éthylène formé provient d'un processus intramoléculaire et il semble que le taux de réaction des radicaux primaires avec la molécule de départ est faible.

L'étude de la photolyse de sulfures d'alkyle par Knight et coll. (2–4) a démontré que le processus primaire de décomposition est une scission du lien C—S,

[2] $R—S—R + h\nu \rightarrow R^{\cdot} + {}^{\cdot}S—R$

De plus, les radicaux méthyles formés lors de la photolyse du sulfure de méthyle semblent posséder un surplus d'énergie.

La présente étude permet d'établir certains mécanismes de réaction et de comparer le comportement du SMV avec celui des molécules ci-haut mentionnées.

Partie expérimentale

Le SMV est obtenu de la Compagnie K & K et purifié par chromatographie en phase gazeuse (colonne 10 pd × 1/4 po remplie avec 30% d'huile DC-200 sur chromosorb W). Le produit est ensuite introduit dans une rampe à vide, distillé pour éliminer l'eau et le CO_2, et, gardé dans un ballon fermé par une valve au mercure. Le méthanethiol (CH_3SD) obtenu de la Compagnie Merck Sharp et Dohme et le perfluoropropane obtenu de la Compagnie Matheson sont utilisés tels quels.

La décomposition photolytique du produit se fait dans une cellule cylindrique en quartz (5 cm de diamètre × 9.4 cm de longueur) irradiée par une lampe de pression moyenne au mercure (Hanovia "Utility Lamp"). Un filtre de Vycor est placé entre la lampe et la cellule.

Le spectre u.v. du produit est pris sur un spectromètre Cary 17 (fig. 1). La photolyse du SMV se fait donc entre 230 et 270 nm (limites imposées par le filtre de Vycor et la capacité d'absorption du produit).

L'actinométrie est faite dans la même cellule (remplie

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

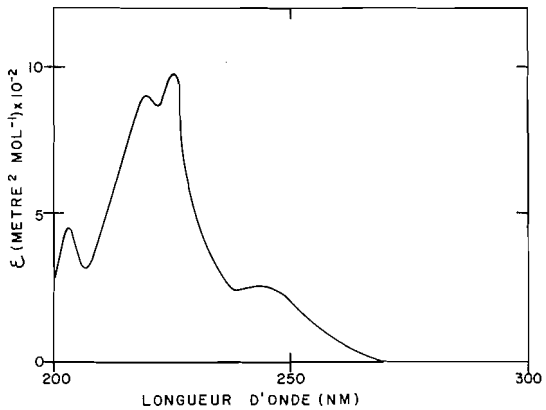

FIG. 1. Spectre u.v. du sulfure de méthyle et de vinyle.

grâce à un systême sans mercure) en utilisant une lampe de basse pression au mercure (Hanovia "Flat Spiral" Z1500-203) et l'actinomètre utilisé est un mélange N_2O–butane (5).

Les produits les plus volatils sont analysés après distillations à différentes températures grâce à une burette à gaz et un chromatographe en phase gazeuse (colonne 10 pd × 1/4 po remplie de "Porapak Q") couplé au système à vide pour permettre une injection directe des produits à analyser. Les composés lourds sont injectés à la seringue sur la même colonne utilisée pour purifier le SMV. L'analyse qualitative des produits de réaction est effectuée à l'aide des temps de rétention sur les colonnes lors des chromatographies et d'un spectromètre de masse (CEC 21-104) après avoir recueilli ces derniers à la sortie de la colonne.

Résultats et discussions

L'analyse des produits plus volatils que le SMV permet d'identifier les composés suivant, CH_4, C_2H_4, C_2H_6, $CH_3CH{=}CH_2$, $C_2H_3{-}C_2H_3$, CH_3SH et CH_3SCH_3. Le taux de formation des principaux produits en fonction du temps d'irradiation est donné à la fig. 2 pour une pression de SMV de 6.7 kPa.

Ces résultats démontrent qu'il y a formation, lors de la photolyse du SMV, de radicaux $CH_3{\cdot}$ (CH_4 et C_2H_6) et de radicaux $C_2H_3{\cdot}$ (C_2H_4 et butadiène-1,3). L'absorption d'un photon par le SMV produit une molécule excitée SMV* qui, ensuite, subit une scission homolytique. Les processus primaires peuvent se décrire ainsi,

[3] $SMV + h\nu \rightarrow SMV^*$

[4] $SMV^* \rightarrow CH_2{\cdot} + {\cdot}SCH{=}CH_2$

[5] $SMV^* \rightarrow CH_3S{\cdot} + {\cdot}CH{=}CH_2$

Le comportement du radical $C_2H_3S{\cdot}$ ne peut être établi à partir des produits identifiés mais il

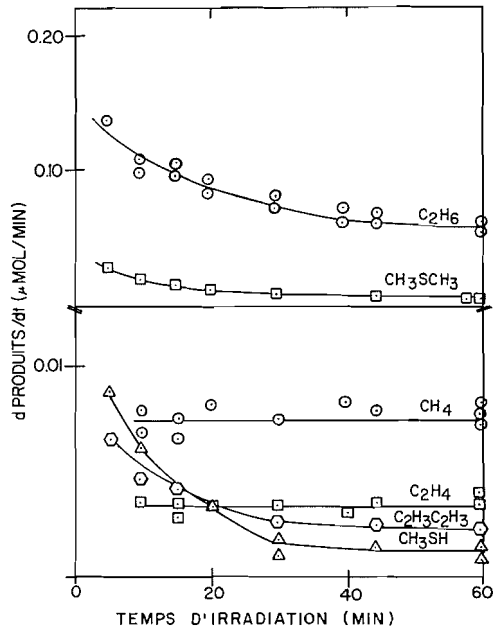

FIG. 2. Taux de formation des principaux produits en fonction du temps d'irradiation.

pourrait être responsable de la formation du dépôt blanchâtre présent sur les parois à la fin d'une photolyse. Les autres radicaux primaires formés lors des scissions [4] et [5] peuvent réagir entre eux pour former les composés analysés.

[6] $CH_3{\cdot} + CH_3{\cdot} + M \rightarrow C_2H_6 + M$

[7] $CH_3{\cdot} + C_2H_3{\cdot} \rightarrow CH_3CHCH_2$

[8] $CH_3{\cdot} + CH_3S{\cdot} \rightarrow CH_3SCH_3$

[9] $C_2H_3{\cdot} + C_2H_3{\cdot} \rightarrow C_2H_3{-}C_2H_3$

[10] $CH_3S{\cdot} + CH_3S{\cdot} \rightarrow CH_3SSCH_3$

Addition de NO

L'addition de 0.5 kPa de NO dans une cellule contenant 6.7 kPa de SMV inhibe la production de C_2H_6, diminue le taux de formation d'éthylène ($T_{C_2H_4}$) et la quantité de méthane obtenue est alors très faible (tableau 1).

La formation d'éthylène, malgré la présence de NO dans le système, peut s'expliquer par un processus intramoléculaire.

[11] $SMV^* \rightarrow C_2H_4 + CH_2S$

La réaction 8, impliquant deux radicaux ne peut être responsable de la formation de sulfure de méthyle en présence de NO. Par contre le sulfure de méthyle pourrait être formé directe-

ment par réaction de radicaux méthyles sur le substrat.

[12] $CH_3^{\cdot} + CH_3{-}SCH{=}CH_2 \rightarrow CH_3SCH_3 + C_2H_3^{\cdot}$

Addition de CH_3SD. Effet de l'energie des photons incidents

Pour doser les radicaux primaires ($CH_3^{\cdot}$ et $C_2H_3^{\cdot}$), l'addition de CH_3SD à 6.7 kPa de SMV s'avère efficace. Les taux de formation de méthane, d'éthylène et d'éthane en fonction du CH_3SD ajouté (fig. 3) démontrent cette efficacité. Il faut remarquer que lors des expériences effectuées avec le CH_3SD, CH_4 signifie en réalité CH_4 et CH_3D et de même C_2H_4 signifie C_2H_4 et C_2H_3D. La capacité d'absorption du CH_3SD est telle que même dans les conditions expérimentales les plus défavorables utilisées ici (15% CH_3SD – 85% SMV) le méthanethiol absorbe

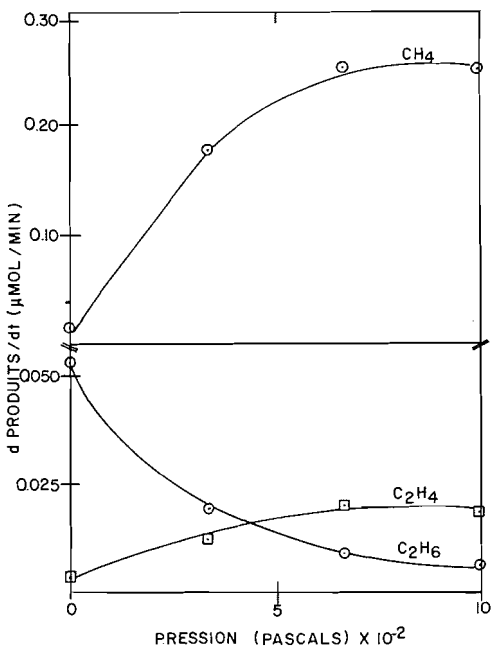

FIG. 3. Taux de formation de CH_4 (CH_4 + CH_3D), C_2H_4 (C_2H_4 + C_2H_3D) et C_2H_6 en fonction de la pression de CH_3SD ajouté.

moins de 1% de la lumière incidente totale. Les réactions 13 et 14 permettent le dosage de ces radicaux.

[13] $CH_3^{\cdot} + CH_3SD \rightarrow CH_3D + CH_3S^{\cdot}$

[14] $C_2H_3^{\cdot} + CH_3SD \rightarrow C_2H_3D + CH_3S^{\cdot}$

L'enrichissement isotopique du méthane et de l'éthylène analysés au spectromètre de masse confirme ces réactions. En calculant le taux total (T_T) de formation de ces radicaux comme étant

[15] $$T_T = T_{CH_4} + T_{C_2H_4} + 2T_{C_2H_6}$$

on trouve un rendement quantique total ($\phi_T = T_T/I_a$) s'approchant de l'unité pour les temps de réaction courts. Les processus primaires semblent bien décrits par les réactions 3, 4, 5 et 11.

L'analyse qualitative des produits lourds apporte d'autres précisions. Ainsi en absence de CH_3SD la formation de ces produits s'explique par la réaction de radicaux méthyles avec la molécule de départ:

[16] $CH_3^{\cdot} + SMV \rightarrow CH_3{-}S{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}{}^{\cdot}CH_2$

[17] $CH_3^{\cdot} + SMV \rightarrow CH_3{-}S{-}\dot{C}H{-}C_2H_5$

[18] $CH_3{-}S{-}(C_3H_6)^{\cdot} + C_2H_3S^{\cdot} \rightarrow CH_3{-}S{-}(C_3H_7) + C_2H_2S$

[19] $CH_3{-}S{-}(C_3H_6)^{\cdot} + C_2H_3S^{\cdot} \rightarrow CH_3{-}S{-}(C_3H_5) + C_2H_4S$

Aucun produit ne permet d'affirmer la contribution des radicaux $C_2H_3S^{\cdot}$ aux réactions 18 et 19. Cependant le taux de formation du radical thiovinyl étant le même que celui des radicaux méthyles (réaction 4) cette hypothèse est fort plausible.

Les produits lourds identifiés sont les suivants, $CH_3{-}S{-}CH_2CH_2CH_3$, $CH_3{-}S{-}CH{=}CHCH_3$, $CH_3{-}S{-}\underset{\displaystyle CH_3}{\underset{|}{C}}{=}CH$, $CH_3{-}S{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}C_2H_5$, $CH_3{-}S{-}\underset{\displaystyle CH_3}{\underset{|}{C}}{=}C{-}CH_3$ et $CH_3{-}S{-}S{-}CH_3$ [10].

Le sulfure d'isopropyle et de méthyle n'a pas été identifié mais il est probable que sa présence est voilée par le SMV lors de l'analyse au chromatographe. La formation des autres produits lourds peut s'expliquer ainsi:

13.3	0.0064	0.0064	0.042	0.0053	0.0012	0.0012
16.7	0.0052	0.0065	0.054	0.0058	0.0013	0.0012

[20] $CH_3^{\cdot} + CH_3—S—(C_3H_6)^{\cdot} \rightarrow CH_3—S—\underset{\displaystyle CH_3}{\underset{|}{CH}}—CH_2—CH_3$

[21] $CH_3^{\cdot} + CH_3—S—(C_3H_5) \rightarrow CH_3—S—(C_4H_8)^{\cdot}$

[22] $CH_3—S—(C_4H_8)^{\cdot} + C_2H_3S^{\cdot} \rightarrow CH_3S—\underset{\displaystyle CH_3}{\underset{|}{C}}=CHCH_3 + C_2H_4S$

En présence de CH_3SD seul le sulfure de méthyle et de propyle (en plus du disulfure de méthyle) est détecté.

[23] $CH_3—S—\dot{C}H—C_2H_5 + CH_3SD \rightarrow CH_3—S—CHD—C_2H_5 + CH_3S^{\cdot}$

L'analyse au spectromètre de masse montre un enrichissement en deutérium pour ce produit. La réaction 17 est donc suffisamment rapide pour permettre la formation de $CH_3—S—\dot{C}HC_2H_5$ même en présence de CH_3SD.

L'addition de 1.0 kPa de CH_3SD à 6.7 kPa de SMV permet également de remarquer la variation du rapport 24 en fonction de la source lumineuse utilisée:

$$[24] \qquad \frac{k_5}{k_4} = \frac{T_{C_2H_4}}{T_{CH_4} + 2T_{C_2H_6}}$$

Ce rapport tient compte uniquement des réactions 4, 5, 6, 13 et 14 mais dans les conditions expérimentales précitées ce sont les plus importantes.

La variation de ce rapport (tableau 2) démontre que plus l'énergie moyenne des photons incidents augmente, plus ce rapport augmente.

Variation de la pression du substrat

Une étude du taux de formation de différents composés en fonction de la pression de SMV (tableau 3) montre une augmentation de ce taux pour l'éthylène, et le sulfure de méthyle, et, une diminution pour les produits de réactions interradicalaires. Un accroissement du taux de formation des produits résultant de réactions entre les radicaux méthyles et le SMV est également remarquée.

La réaction 12 explique l'augmentation de $T_{C_2H_4}$ et de $T_{CH_3SCH_3}$. Les radicaux $C_2H_3^{\cdot}$ formés réagissent ensuite pour donner de l'éthylène.

[25] $C_2H_3^{\cdot} + SMV \rightarrow C_2H_4 + R^{\cdot}$

[26] $C_2H_3^{\cdot} + C_2H_3S^{\cdot} \rightarrow C_2H_4 + C_2H_2S$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Une réaction semblable entre radicaux méthyles et thiovinyles explique la formation du méthane et la diminution de T_{CH_4} en fonction de la pression du substrat.

[27] $CH_3^{\cdot} + C_2H_3S^{\cdot} \rightarrow CH_4 + C_2H_2S$

Une pression plus élevée de SMV favorise les réactions radicaux–molécules au détriment des réactions inter-radicalaires. L'augmentation du taux de formation de C_2H_4 nous porte à croire que la réaction d'abstraction du radical $C_2H_3^{\cdot}$ [25] sur le SMV est plus importante qu'une réaction de dismutation avec un autre radical alors que pour le méthane c'est le cas contraire qui se produit.

On remarque pour le $T_{C_2H_6}$ une remontée pour une pression de 16.6 kPa et la même tendance semble s'amorcer pour le butadiène-1,3. L'augmentation locale de la concentration des radicaux à plus haute pression (*i.e.* l'absorption de la lumière se fait dans un espace plus restreint) explique ce phénomène. Egalement, pour l'éthane, une pression totale plus élevée signifie une plus grande facilité de désactivation (réaction 6).

Addition de C_3F_8

L'addition de C_3F_8 au milieu réactionnel permet de mettre en évidence un intermédiare excité qui peut être désactivé par collision.

[28] $SMV^* + C_3F_8 \rightarrow SMV + C_3F_8$

Deux séries d'expériences (tableau 4) indiquent la présence d'un tel intermédiaire. Dans une première série la cellule est remplie de 6.7 kPa de SMV et de diverses pressions de C_3F_8. Dans la deuxième série on ajoute également 1.0 kPa de CH_3SD.

Aux basses pressions (<40.0 kPa) il y a augmentation du taux de formation de l'éthane (première série) et du méthane (deuxième série) en fonction de la pression. La désactivation de radicaux méthyles chauds par le C_3F_8 peut expliquer un tel comportement.

[29] $CH_3^{\cdot *} + C_3F_8 \rightarrow CH_3^{\cdot} + C_3F_8$

Un calcul de l'enthalpie de la réaction 4 (tableau 5) donne un ΔH de -238 kJ/mol. Lors de l'irradiation environ 460 kJ/mol sont transferrés au SMV. Il est donc fort probable que les radicaux méthyles soient formés avec un surplus d'énergie. Cependant la désactivation de ces radicaux $CH_3^{\cdot *}$ par le C_3F_8 rend ces derniers moins réactifs avec le SMV et ainsi il y a un plus grand nombre de radicaux disponibles pour former du méthane ou de l'éthane.

TABLEAU 4. Taux de formation de produits (μmol/min) en fonction de la pression de C_3F_8 (kPa)

	Expérience 1*	Expérience 2*	
$P_{C_3F_8}$	dC_2H_6/dt	dCH_4/dt	dC_2H_4/dt
0	0.0670	0.225	0.020
20.0	0.0692	0.248	
40.0	0.0720	0.257	0.021
80.0	0.0669	0.252	0.024
113.3	0.0633	0.248	0.027
153.2	0.0588	0.240	0.25

*Expérience 1: sans CH_3SD; expérience 2: avec 1.0 kPa.

TABLEAU 5. Calcul des enthalpies de réactions (6, 7)

Réaction	ΔH (kJ/mol)
$CH_3SCH{=}CH_2 \rightarrow CH_3^{\cdot} + {}^{\cdot}SCH{=}CH_2$	238
$CH_3SCH{=}CH_2 \rightarrow CH_3S^{\cdot} + CH_2CH^{\cdot}$	347
$CH_3OCH{=}CH_2 \rightarrow CH_3^{\cdot} + {}^{\cdot}OCH{=}CH_2$	268
$CH_3OCH{=}CH_2 \rightarrow CH_3O^{\cdot} + CH_2CH^{\cdot}$	381

La présence d'un troisième corps (réaction 6) pour désactiver la molécule nouvellement formée contribue également à l'augmentation de la quantité de C_2H_6 mesurée à pression plus élevée.

Aux plus hautes pression de C_3F_8 (>40.0 kPa) la diminution de T_{CH_4} et $T_{C_2H_6}$ est due à la désactivation subie par l'intermédiaire excité SMV*.

En portant sur un graphique $(dCH_4/dt)^{-1}$ *vs.* $P_{C_3F_8}$ (fig. 4) les résultats obtenus à 80.0,113 et

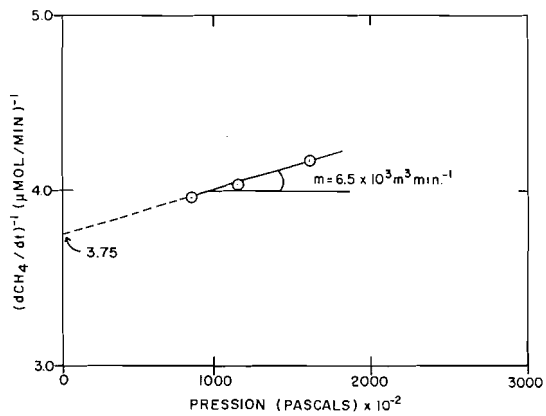

FIG. 4. Inverse du taux de formation du méthane en fonction de la pression de C_3F_8.

153 kPa de C_3F_8 on obtient une droite. Considérant les réactions 3, 4, 5, 13 et 28 comme les seules importantes, on trouve l'équation:

$$[30] \quad \frac{dCH_4}{dt} = \frac{1}{I_a}\left(1 + \frac{k_5}{k_4}\right) + \frac{1}{I_a}\frac{k_{28}[PFP]}{k_4}$$

où [PFP] est la concentration de C_3F_8 ajouté dans la cellule.

En prenant comme valeur de $k_5/k_4 = 7.3/92.7$ pour la lampe utilisée on trouve alors que $k_{28}/k_4 = 1.9 \times 10^3$ m^3 mol^{-1}. En estimant le diamètre de collision entre le C_3F_8 et le SMV à 0.5 nm et en supposant que chaque collision dissipe suffisamment d'énergie pour empêcher toute scission subséquente, on évalue alors k_{28} à 1.63×10^8 m^3 mol^{-1} s^{-1} et de là $k_4 = 8.6 \times 10^{10}$ s^{-1}. Le temps de vie τ du SMV* est donc de 1.2×10^{-11} s. La constante k_5 est alors calculée comme étant 6.8×10^9 s^{-1}.

L'augmentation du taux de formation de l'éthylène (pour des pressions de C_3F_8 allant de 0 à 113.3 kPa) pourrait s'expliquer par la réaction 17 suivie des réactions 31 et 32.

$$[31] \quad CH_3S\dot{C}HCH_2CH_3 + M \rightarrow (CH_3SMV)^{\cdot *} + M$$

$$[32] \quad (CH_3SMV)^{\cdot *} \rightarrow C_2H_4 + \dot{C}H_2SCH_3$$

Ces réactions peuvent expliquer également la hausse du taux de formation de l'éthylène lorsqu'on augmente la pression de SMV et contribuer à la formation de l'éthylène malgré l'addition de NO au mélange réactionnel.

En conclusion, la photolyse du SMV permet donc de mettre en évidence un intermédiaire excité dont le temps de vie est 1.2×10^{-11} s. Castonguay (8) a trouvé un temps de vie de 1.4×10^{-10} s pour le MVE.

L'énergie fournie à la molécule de SMV est inférieure à 471 kJ/mol (lampe de pression moyenne avec filtre Vycor) alors que celle fournie au MVE est de 471 kJ/mol (lampe de basse pression, 1). Malgré cela le temps de vie du SMV est plus court. De même le SMV est promu à un singulet lors de l'excitation (photolyse directe) alors que le MVE est promu à un triplet (réaction photosensibilisée, 1). Cette différence dans le mode d'excitation peut se traduire par une différence dans la réactivité. Cependant l'équation bien connue (9)

$$[33] \quad k_i = v_i\left(\frac{E - E_a}{E}\right)^N$$

qui peut s'appliquer pour une scission homolytique comme celles considérées ci-haut permet d'expliquer cette différence dans les temps de vie. En effet on remarque que l'énergie nécessaire pour briser le lien CH_3—S dans le SMV est plus faible que celle pour briser le lien CH_3—O dans le MVE (tableau 4). Donc E_a est plus élevée pour le MVE que pour le SMV d'où une constante k_i plus grande pour le SMV. De même la liaison vinyl – S est suffisamment faible pour en permettre la scission (compétition entre les réactions 4 et 5) alors que la liaison vinyl – O est plus forte et aucun clivage de celle-ci n'a été mis en évidence. Considérant l'équation 33, il est normal qu'un accroissement de l'énergie E augmente la probabilité de la scission du lien le plus fort relativement au bris de la liaison plus faible et c'est ce qui se produit lorsqu'on accroit l'énergie des photons incidents (tableau 1).

Une autre explication nous vient à l'esprit lorsqu'on considère le spectre électronique du SMV. Il y a chevauchement de deux transitions électroniques dans la région où s'effectue la photolyse. La première bande plus faible correspond à une transition $4S \leftarrow \Pi$ et la seconde à une transition $\Pi^* \leftarrow \Pi$ (10). Une augmentation de l'énergie des photons se traduirait par une importance accrue de l'absorption dans la bande $\Pi\Pi^*$

$$[34] \quad (\Pi,\Pi^*) \rightarrow \dot{C}_2H_3 + CH_3S^{\cdot}$$

$$[35] \quad (\Pi,4S) \rightarrow CH_3^{\cdot} + C_2H_3S^{\cdot}$$

Donc un déplacement hypsochrome de la région d'irradiation augmenterait la possibilité de formation du radical vinyl.

La mise en évidence d'un intermédiaire excité nous porte à croire cependant que la molécule a le temps de redistribuer son énergie électronique en énergie vibrationnelle et ainsi l'énergie totale fournie à la molécule lors de l'absorption d'un photon est plus importante que le type de transition électronique subie par cette même molécule.

L'utilisation de mélanges approximativement équimolaires d'hydroxypyridines et de DO-pyridines permet la mise en évidence sur la perte de CO, d'un effet isotopique, identique en ce qui concerne les isomères 3 et 4. Ce résultat suggère que les tautomères énoliques constituent essentiellement la phase gazeuse, comme le confirme d'ailleurs une étude des rapports d'abondance métastable au niveau d'ions fragments hydroxypyridine et sur les mêmes ions créés par ionisation directe. La 2-hydroxypyridine exhibe également un effet isotopique quoique plus faible ainsi que le confirme l'étude de mélanges équimolaires 2-éthoxy et 2-éthoxy-d_5-pyridines. La mise en évidence du tautomère énolique est également invoquée pour cet isomère.

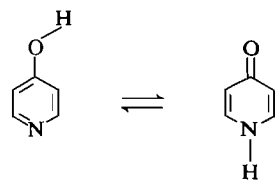
3- and 4-Hydroxypyridines exist in their enolic form, in the gas phase, as evidenced by the similarity of the deuterium isotope effects on the loss of CO, calculated on nearly equimolar mixtures of HO- and DO-pyridines. This is confirmed by analysis of metastable ratios evaluated on hydroxypyridine fragment ions and on the same ions produced by direct ionization. 2-Hydroxypyridine shows a weaker isotope effect for the same reaction and this is confirmed by the study of an equimolar mixture of 2-ethoxy- and 2-ethoxy-d_5-pyridines. It is shown that 2-hydroxypyridine also exists as its enolic form, in the gas phase.

Introduction

Les 2-, 3- et 4-hydroxypyridines (**1**, **2** et **3**) étant des composés susceptibles de participer à un équilibre protomère du type énol–cétone ont fait l'objet de nombreuses recherches tant à l'état solide qu'en solution. Les résultats des études spectroscopiques et physico-chimiques établissent que les 2- et 4-hydroxypyridines existent presque exclusivement sous forme pyridone à l'état cristallin et en solution; par contre, l'isomère 3-hydroxy se présente comme tel à l'état condensé et dans les solvants de faible constante diélectrique (1) (schéma 1). En phase gazeuse, au contraire, quelques données récentes de la littérature indiquent une plus grande stabilité des tautomères énoliques. Ainsi, Grønneberg et Undheim (2), par des mesures de potentiels d'ionisation, concluent à la présence unique des molécules 2-, 3- et 4-hydroxypyridines. La prépondérance de l'isomère énolique a encore été confirmée par spectroscopie u.v.: à 120–140 °C en phase vapeur, le dérivé 2-hydroxylé existe en tant que tel à raison de 65 ± 15% (3).



4-Hydroxypyridine Forme énolique-(OH) — 4-Pyridone Forme pyridone-(NH)

SCHÉMA 1

Nous nous proposons dans le présent travail, de confirmer l'existence prépondérante des formes énoliques des hydroxypyridines dans la source du spectromètre de masse par la mise en évidence d'effets isotopiques primaires mesurés au niveau des ions de fragmentation directe et métastables. La manifestation de tels effets a d'ailleurs déjà permis d'apporter de précieux renseignements mécanistiques (4–6).

SCHÉMA 2

Résultats expérimentaux et discussion

Les spectres de masse des 3- et 4-hydroxypyridines mentionnés dans la littérature (7, 8) révèlent une élimination compétitive de HCN et de CO au départ des ions moléculaires; par contre, le dérivé 2-hydroxy perd quasi spécifiquement une molécule de CO. Pour **2** et **3**, dont on a remplacé l'hydrogène tautomérisable par du deutérium, nous observons l'expulsion de cyanure d'hydrogène quasi spécifiquement sous forme DCN. Ce phénomène n'a trouvé, jusqu'à présent, aucune explication pleinement satisfaisante.

Toutes ces éliminations sont appuyées par des transitions métastables, qui dans le cas de l'expulsion de CO présentent un sommet concave, traduisant une libération d'énergie cinétique.

La perte de HNC ne se conçoit pas aisément au départ d'une forme NH (2-pyridone ou 4-pyridone). Il faut d'ailleurs remarquer que l'élimination de HCN, observée au départ de l'isomère 3-hydroxypyridine, incapable de présenter une forme pyridone, accrédite cette suggestion. Par contre, l'élimination de CO peut être envisagée aussi bien à partir d'une forme lactame qu'au départ d'un ion de type CH obtenu par migration de l'hydrogène hydroxylique de l'énol (schéma 2).

De telles migrations d'hydrogène ont déjà été invoquées pour expliquer, notamment, la dégradation du phénol et de l'aniline (réf. 8, p. 116 et réf. 9). Si un tel réarrangement, uniquement concevable au départ d'une forme énolique, constitue l'étape déterminante, le marquage au deutérium de l'hydrogène hydroxylique modifie les probabilités de rupture des liaisons O—H et O—D. Il en résulte une diminution de l'intensité de l'ion fille ou métastable associé à l'élimination de CO. La manifestation de tels effets isotopiques correspondrait donc à la mise en évidence de tautomères énoliques.

La mesure de ces effets n'est toutefois pas simple, car les dérivés monodeutériés des 3- et 4-hydroxypyridines éliminent une molécule de DCN. Les pics correspondants se confondent avec ceux provenant de la perte de CO et il est nécessaire pour les distinguer de travailler à haute résolution. Dans ces conditions, afin d'augmenter la précision de la mesure, seules les valeurs relatives i du rapport des intensités $([M - CO]^{\cdot+})/(M^{\cdot+})$ sont déterminées et ce sur des mélanges approximativement équimoléculaires en produits mono- et non deutériés.

$$i = \frac{\left|\frac{[M - CO]^{\cdot+}}{M^{\cdot+}}\right|_{HO-Py}}{\left|\frac{[M - CO]^{\cdot+}}{M^{\cdot+}}\right|_{DO-Py}}$$

Les résultats expérimentaux sont repris au tableau 1.

Les valeurs pour les pics métastables ne peuvent bien entendu pas être déterminées à cause de la superposition mentionnée ci-dessus. Pour des raisons identiques, il n'est pas possible

d'évaluer l'effet isotopique éventuel sur la perte de H(D)CN et ce aussi bien au niveau des ions de fragmentation directe et métastables comme illustré ci-après (schéma 3). Les valeurs mesurées des effets isotopiques primaires (i) rapportées au tableau 1 sont de l'ordre de grandeur de celles auxquelles on pouvait s'attendre au vu des données de la littérature (10, 11), du moins pour les dérivés 3- and 4-hydroxylés.[1]

Comme, d'une part la 3-hydroxypyridine existe entièrement sous forme OH, et comme d'autre part, on peut *a priori* admettre un même effet isotopique pour une rupture O—H d'un hydroxyle fixé en position 3 ou 4, la quasi égalité de i pour **2** et **3** laisse présumer que la 4-hydroxypyridine se trouve au moins de façon largement prédominante, sous forme OH en phase gazeuse. Ces résultats sont en parfait accord avec les conclusions du travail de Grønneberg et Undheim (2). La valeur de i de 1.04 pour la 2-hydroxypyridine ne permet par contre pas, à ce stade, de tirer de conclusions. Cependant, comme cette substance n'élimine pas de HCN, il n'y a pas superposition des pics relatifs à la perte de CO et DCN dans la molécule deutériée. Il est donc possible ici, de mesurer l'effet isotopique i^* au niveau des transitions métastables (première région libre de champ).

$$i^* = \frac{[m^*(M - CO)]_{2HO-Py}}{[m^*(M - CO)]_{2DO-Py}}$$

Les valeurs de i et i^* mesurées à basse résolution sur un mélange équimoléculaire de 2-hydroxypyridine non et monodeutériés sont reprises au tableau 2. Comme on peut le remarquer, le faible effet isotopique (i) mesuré à basse résolution (1.07, tableau 2)[2] est quasi identique à celui obtenu à haute résolution (1.04, tableau 1). Ce résultat confirme la précision des valeurs renseignées au tableau 1. La faible valeur de i mesurée au niveau d'ions de fragmentation directe, pour la 2-hydroxypyridine, permet de douter de l'existence d'un effet isotopique réel et partant exclut à ce stade toute conclusion quant à la composition de la phase gazeuse. Il est dès lors apparu plus intéressant de confirmer la manifestation de l'effet isotopique au niveau de transition métastable de première région libre de champ. Il est en effet bien établi que l'effet isotopique augmente avec la diminution de l'énergie moyenne interne de l'ion précurseur (10), et ce pour un même mécanisme de réarrangement. L'observation de la valeur de i^* de 1.8, au niveau métastable, (tableau 2), permet de conclure à la présence, au moins partielle, du tautomère énolique de la 2-hydroxypyridine en phase gazeuse. En effet, la diminution de l'intensité du métastable correspondant à l'élimination de CO suite à la substitution isotopique implique une migration préalable de l'hydrogène

[1]Bien que des effets isotopiques secondaires de l'ordre de deux aient été rapportés par Neeter et Nibbering (11), il faut remarquer qu'il est difficile de chiffrer indépendemment un effet isotopique primaire et secondaire pour de tels processus de réarrangement prototropique; en général, la seule considération des effets isotopiques primaires est appliquée (4, 5, 6, 10).

SCHÉMA 4

hydroxylique au cours d'une étape déterminante. Une forme 2-pyridone pouvant éliminer directement CO, n'aurait conduit par conséquent à aucune modification d'intensité suite au marquage au deutérium, aussi bien au niveau d'ions de fragmentation directe que métastable, tout au moins si l'on exclut l'effet isotopique secondaire. Le bien-fondé d'une telle hypothèse de travail sera d'ailleurs confirmé plus loin par l'étude d'un mélange 2-éthoxy et 2-éthoxy-d_5-pyridines.

TABLEAU 2. Valeurs de i et i^* d'un mélange equimoléculaire de 2-hydroxypyridine non- et monodeutériées

	i^*	i

$-CO$ / $-CO$		

Créations d'ions "in situ"

Les substituants éthyle ou acétyle fixés sur un hétéroélément tel l'azote ou l'oxygène éliminent par un mécanisme unique à quatre centres, respectivement de l'éthylène et du cétène (4, 5, 12, 13). A partir des 3- et 4-éthoxy ou acétoxypyridines, il est donc, en principe, possible de créer un ion fragment identique en structure à celui d'un ion moléculaire de type OH (schéma 4).

Les rapports d'abondance métastables pour la perte de HCN et de CO, mesurés au départ des ions fragments $M - \overline{CH_2CO}^{\cdot +}$ et $M - \overline{C_2H_4}^{\cdot +}$ issus respectivement des substrats acétoxy et éthoxypyridines, et ceux mesurés sur les ions moléculaires hydroxypyridines correspondants sont renseignés au tableau 3. La similitude dans les rapports d'abondance pour les dérivés substitués en 3 (Tableau 3) implique l'identité de structure des ions fragments $M - \overline{CH_2CO}^{\cdot +}$ et $M - \overline{C_2H_4}^{\cdot +}$ et de l'ion moléculaire de la 3-hydroxypyridine (14, 15, 16). Comme on sait de manière non ambiguë que cette substance existe sous forme OH, ce résultat confirme l'élimination de cétène ou d'éthylène par un mécanisme à quatre centres. Un même schéma de fragmentation s'appliquant en toute logique aux dérivés 4 substitués, la quasi égalité des valeurs renseignées pour **3**, **6** et **7** (tableau 3) démontre à nouveau l'existence de la 4-hydroxypyridine, en phase vapeur dans le spectromètre de masse, sous forme énolique.

La création "*in situ*" de la 4-pyridone, espérée au départ de la *N*-éthyl-4-pyridone n'a

SCHÉMA 5

pu malheureusement être réalisée, celle-ci se dégradant presque exclusivement par une perte de monoxyde de carbone au départ de l'ion moléculaire, excluant ainsi une confirmation supplémentaire de nos résultats.

L'absence d'élimination compétitive de HCN et de CO dans le cas de la 2-hydroxypyridine ne permet pas une analyse semblable à celle mentionnée au tableau 3. Néanmoins, les 2-éthoxypyridines donnent naissance sous l'impact électronique, du moins partiellement, à des ions fragments de type 2-hydroxy (*vide infra*).

Il est donc possible d'évaluer des effets isotopiques pour **1** ou pour des ions correspondants formés *in situ* au départ de spectres relevés sur des mélanges 50:50 en produits deutérié et non deutérié (tableau 2). La quasi égalité des valeurs de i, d'une part, et de i^*, d'autre part, confirme l'existence en phase gazeuse du tautomère énolique pour **1**; une telle égalité observée à la fois sur les transitions métastables et ordinaires, correspondant à l'élimination de CO (tableau 2), pourrait même suggérer l'existence unique de la forme 2-hydroxypyridine, résultat déjà avancé par Grønneberg et Undheim (2). En effet, un mélange, à l'état gazeux, de 2-pyridone/2-hydroxypyridine aurait conduit à des effets isotopiques plus petits que 1.09[3] et 1.7 obtenus au départ d'éthoxypyridine à moins que cette dernière ne se dégrade aussi via un mécanisme à six centres pour donner le même mélange, ce qui paraît totalement improbable (schéma 5). Il peut toutefois sembler surprenant que la 2-hydroxypyridine, contrairement aux deux autres isomères, ne perde pas de molécule de HCN. Ceci pourrait toutefois s'expliquer par

l'intervention d'un effet *ortho*, exercé par l'azote pyridinique qui faciliterait le transfert de l'hydrogène hydroxylique et accréditerait d'ailleurs par la même occasion notre hypothèse selon laquelle une forme 2-pyridone élimine difficilement HNC. L'abaissement notable de l'énergie d'activation correspondant à l'élimination de CO, éclipserait par voie de conséquence toute possibilité de perte de HCN. L'intervention de cet effet *ortho* pourrait expliquer la petite valeur de l'effet isotopique observé sur la 2-hydroxypyridine et d'autre part certaines fragmentations propres aux pyridines substituées en position 2, comme la perte intense d'un radical hydrogène et méthyle au départ des substrats 2-méthoxy- et 2-éthoxypyridines, conduisant probablement à la quaternisation de l'azote. De tels effets *ortho* exercés par l'azote pyridinique ont été mentionnés dans la littérature (réf. 7, pp. 427, 465 et 471; 17).

Conclusions

L'étude de mélanges OH- et OD-pyridines révèle une diminution de l'intensité de l'ion fille et de l'ion métastable correspondant à l'élimination de CO, suite au marquage isotopique. Cette observation suggère que les tautomères énoliques constituent principalement la phase gazeuse. En effet, dans ce cas, l'expulsion de CO ne peut se concevoir que suite à la migration de l'hydrogène hydroxylique et ceci dans une étape déterminante. Par contre, les formes lactames, pouvant éliminer directement CO sans réarrangement, ne présenteront pas un tel effet isotopique primaire.

L'égalité dans les effets isotopiques primaires et secondaires, relatifs à la perte de CO, au départ des substrats 3- et 4-hydroxypyridines, vérifie le bien-fondé de nos hypothèses. L'analogie dans les rapports d'abondances métastables, calculés d'une part au niveau d'ions fragments hydroxypyridines, et d'autre part au niveau des mêmes ions, résultant d'une ionisation directe, confirme également nos résultats. L'isomère 2-hydroxypyridine présente aussi un effet isotopique, beaucoup plus faible certes mais réel, sur la perte de CO. Celui-ci se retrouve exactement sur les ions fragments 2-hydroxypyridines, créés via une élimination d'éthylène au départ de 2-éthoxypyridine. Si cette élimination procède suivant le mécanisme conventionnel à quatre centres, cette égalité dans les effets isotopiques suggère que le tautomère énolique constitue quasi uniquement la phase gazeuse.

Partie expérimentale

Tous les spectres ont été relevés sur un spectromètre A.E.I. MS 902, soit par introduction dans la source (Intr. dir.), soit via le système en verre (Intr. liq.), travaillant à 70 eV (100 μA, 8 kV).

Les valeurs d'effet isotopique ainsi que les rapports d'abondance mentionnés constituent la moyenne de plusieurs balayages, effectués dans les mêmes conditions expérimentales. La comparaison des transitions métastables de première région libre de champ est réalisée par la technique de refocalisation d'ions (18, 19) (4 kV) en maintenant constante la tension du multiplicateur d'électrons.

La réalisation de mélanges équimolaires en produits hydrogéné et monodeutérié est réalisée par échange direct dans la source du spectromètre grâce à l'admission contrôlée de D_2O via le système d'introduction des gaz. L'évolution du taux de deutériation est suivie au moyen de l'oscilloscope de l'appareil et l'admission de D_2O est coupée dès que l'on obtient un mélange équimolaire. Les expériences en haute résolution (environ 10.000) ont été réalisées avec la perfluorotributylamine, comme substance de référence. Les intensités relatives rapportées ci-après sont résumées par rapport au pic de base. Seuls sont mentionnés les fragments dont l'intensité est supérieure à 3%.

Chlorinolysis of an anhydropenicillin affords a 2-(2′-chloro-3′*S*-amino, -acylamino or -phthalimido-4′-oxo)azetidinyl-3-methyl-2-butenoyl chloride, as a mixture of 2′*R* (*cis*) and 2′*S* (*trans*) epimers in which the 2′*R* epimer usually predominates. Hydrolysis of the acid chloride and treatment of the carboxylic acid with aqueous bicarbonate causes cyclization, in the case of a 3′-acylamino substituent, to a 2*R*-6-(1′-carboxy-2′-methyl-prop-1′-enyl)-1-oxa-3,6-diaza-4*S*,5*R*-bicyclo[3,2,0]hept-2-ene-7-one. The mechanisms of these transformations are discussed, and alternative routes to such fused oxazoline–azetidinones are also presented.

The oxazolines undergo ready hydrolysis to sulfonic acid salts of 2-(2′*R*-acyloxy-3′*S*-amino-4′-oxo)azetidinyl-3-methyl-2-butenoates upon treatment with the hydrate of a sulfonic acid in acetone solvent. Neutralization of these salts proceeds without O → N acyl transfer, because acylation yields a diacylated azetidinone in which the new acyl substituent is attached to nitrogen. Monobromination of the allylic methyl groups of these salts, followed by treatment with 2 molar-equiv. of triethylamine, leads to a deep-seated rearrangement, in high yield, to an oxazinone. The mechanism of this rearrangement and, in particular, the role of acylimines in this and related reactions, including the biosynthesis of penicillin, are discussed.

SAUL WOLFE, SHUI LUNG LEE, JEAN-BERNARD DUCEP, GÉRARD KANNENGIESSER et WHA SUK LEE, Can. J. Chem. **53**, 497 (1975).

La chlorolyse d'un anhydropénicilline conduit au chlorure de (chloro-2′ *S*-amino, acylamino ou phtalimido-3′ oxo-4′)-2 azétidinyl méthyl-3 butène-2 oyle sous forme de mélange d'épimères 2′*R* (*cis*) et 2′*S* (*trans*) dans lequel l'épimère 2′*R* prédomine d'une façon générale. Lorsque le substituant en 3′ est un groupe acylamino, l'hydrolyse du chlorure d'acide et le traitement de l'acide carboxylique avec une solution aqueuse de bicarbonate amènent une cyclisation conduisant à la 2*R* (carboxy-1′ méthyl-2′ propène-1′ yl)-6 oxa-1 diaza-3,6 4*S*,5*R*-bicyclo[3,2,0] heptène-2 one-7. On discute des mécanismes de ces transformation et on présente aussi des méthodes alternatives pouvant conduire à de telles oxazoline–azétidinones condensées.

Les oxazolines, traitées par l'hydrate de l'acide sulfonique dans de l'acétone, s'hydrolisent facilement et conduisent aux sels sulfoniques des (*R*-acyloxy-2′ *S*-amino-3′ oxo-4′)-2 azétidinyl méthyl-3 butene-2 oates. La neutralisation de ces sels se fait sans transfert des groupes acyles de O → N; ce résultat est dû au fait que l'acylation conduit à une azétidinone diacylée dans laquelle le nouveau groupement acyle est attaché à l'azote. La monobromuration des groupes méthyles allyliques de ces sels, suivi par le traitement avec deux moles de triéthylamine, conduit, avec un bon rendement et par l'intermédiaire d'un réarrangement important, à une oxazinone. On discute du mécanisme de ce réarrangement et en particulier du rôle des acylimines dans cette réaction et dans d'autres réactions qui lui sont reliées incluant la biosynthèse de la pénicilline.

Introduction

Penicillins are *N*-acylated derivatives of 6-aminopenicillanic acid (**1**, 6-APA) (1). Their chemical and biological properties were elucidated following intensive effort by British and American chemists during the Second World War. As a result of this (2) and later (3) work, it was believed for some time that antibacterial activity was associated uniquely with compounds containing the fused β-lactam thiazolidine ring system found in 6-APA. The investigations of Abraham and Newton and their collaborators into the structure and biological properties of Cephalosporin C (**2**) and its derivatives (4) therefore constituted not only a major therapeutic advance but also a psychological breakthrough

[1]Portions of this work were presented at the Canadian Chemical Conference of the Chemical Institute of Canada, Quebec City, June, 1972, and at the 9th IUPAC Symposium on the Chemistry of Natural Products, Ottawa, June, 1974.

because, through this work, it was demonstrated that the five-membered thiazolidine ring is not essential for activity. The later discovery of the cephamycin antibiotics (**3**) revealed (5) that structural modification in the azetidinone ring is also possible. In recent years, the fused thiazolidine β-lactam **4**, known as Woodward's intermediate (6), and its functional equivalents (7) have been employed as starting materials for the synthesis of unnatural bicyclic azetidinones possessing antibacterial activity. In addition, a number of elegant and efficient total syntheses of penicillin and cephalosporin derivatives have appeared (6, 8). The effect of all of this work is that Alexander Fleming's forecast[2] of the future of β-lactam antibiotics research (9*a*) continues to be correct; and it does not seem unduly optimistic to predict that clinically useful azetidinones with structures quite different from those of the natural products will eventually become available (9*b–d*).

In a series of communications (10) we have described the transformation of anhydropenicillins **5** (11) into a variety of sulfur-free monocyclic and bicyclic azetidinones. The purpose of the present paper is to present details of the preparation of the fused oxazoline azetidinones **6**. Some novel reactions of the compound **6** (R_1 = $PhCH_2$; R_2 = CH_3, $PhCH_2$) are also discussed.

Results and Discussion

The Anhydropenicillin Route to Oxazolines

The conversion of a penicillin into an oxazoline of type **6** involves the elimination of H_2S from the nucleus and, is, formally, an oxidative rearrangement. Sheehan (12), Barton *et al.* (13), and Stoodley and Whitehouse (14) have reported on the synthesis of such oxazolines employing *t*-BuOCl (12), $PhICl_2$ (13), and $Hg(OAc)_2$ (14) as the oxidizing agents.

The key step in the present work is the chlorinolysis of an anhydropenicillin. Treatment of **5** (R = *p*-TsOH·H_2N) with excess chlorine in methylene chloride solvent at 0 °C, followed by evaporation of the solvent, afforded a quantitative yield of **7** as a 4:1 mixture of 2*R*(*cis*):2*S*(*trans*) epimers. The mechanism of this reaction has not been investigated but is believed to proceed via attack at sulfur, with subsequent rupture of the C5—S bond of the chlorosulfonium intermediate, as depicted in **8** (R = *p*-TsOH·H_2N). In agreement with this view is the spectroscopic characterization of the compound **9** (R = phthalimido) following the reaction of **5** (R = phthalimido) with a limited amount of chlorine, and the conversion of this compound, on standing, to **10** (R = phthalimido) (15). An analogous mechanism has been suggested by Kukolja (16) for the chlorine-promoted fission of the C5—S bond of penicillin itself.

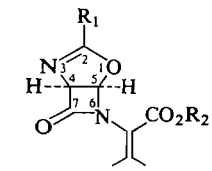
5



6

At 0 °C, hydrolysis of **7** to the carboxylic acid **11** was complete in 3 h in aqueous tetrahydrofuran or aqueous acetone. Neutralization of these reaction mixtures with a slight excess of sodium bicarbonate yielded the amino acid salt **12**, which could be converted into acylaminoazetidinones **13**. Alternatively, the same compounds could be obtained from anhydropenicillins **5** (R = RCONH) by a chlorination–hydrolysis sequence.

Dissolution of the azetidinone **13** (R = $PhCH_2$) in 5% bicarbonate, followed by acidification of the solution, afforded the oxazoline **6** (R_1 = $PhCH_2$; R_2 = H) in 53% overall yield from anhydrobenzylpenicillin. The methyl and benzyl

[2]And we are not at the end of the penicillin story. Perhaps we are only just at the beginning.

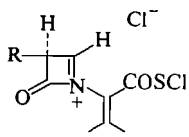
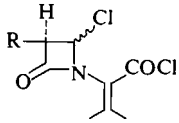
8

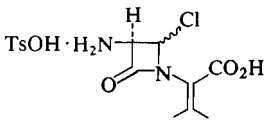


9

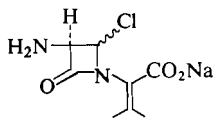


10

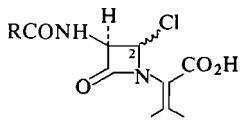
esters of this compound (**6**, $R_2 = CH_3$ or CH_2Ph) were prepared without difficulty using diazomethane and phenyldiazomethane, respectively. Since **13** is a mixture of epimers at C2, in which the compound having the *R* configuration (*cis*) predominates, and cyclization to an oxazoline affords a compound which also has the *R* configuration at the same asymmetric center, it is evident that the new C—O bond is formed with net retention of configuration.



11

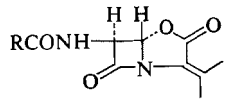


12

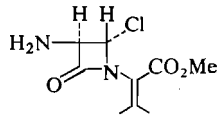


13

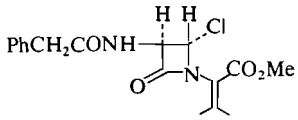
Two mechanistic paths can be considered to account for this result. In the first, cyclization may generate the *oxa*anhydropenicillin **14** (R = $PhCH_2$), with inversion of configuration at C2. Then the new C—O bond may undergo a displacement, also with inversion, by the acylamino oxygen. Two kinds of observations lend credence to this proposal: (*i*) the oxaanhydropenicillin **14** (R = $PhCH_2O$) could be isolated in 48% yield following bicarbonate treatment of the azetidinone **13** (R = $PhCH_2O$), which has a less nucleophilic carbonyl group in the side chain; (*ii*) the *trans*-disubstituted azetidinone **16** could be characterized spectroscopically following phenylacetylation of **15**, but it underwent rapid and spontaneous cyclization to the oxazoline **6** ($R_1 = PhCH_2$; $R_2 = CH_3$). In contrast, **17**, the



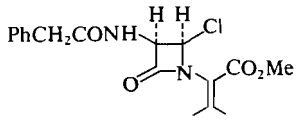
14



15



16



17

C2 epimer of **16**, could be isolated and characterized fully. This latter compound, however, also cyclized to **6** ($R_1 = PhCH_2$; $R_2 = CH_3$) during chromatography on silica gel or alumina.
