A solution of compound **34***e* (0.49 g; 0.9 mmol) in ethyl acetate (75 ml) was added to a prehydrogenated sample of 20% $Pd(OH)_2$-on-carbon (0.50 g) in ethyl acetate (25 ml). It was then stirred under hydrogen at atmospheric pressure and after 15 min, gas consumption had ceased. It was filtered through a Celite pad, washed well with ethyl acetate, and the solvent was removed on the aspirator to leave 0.40 g of an amorphous solid. This was suspended in ether and extracted with 2% $NaHCO_3$. The aqueous extract was acidified with 10% HCl and the white solid collected by suction filtration, washed with water, and dried to give a white solid, mp 160–162 °C. Recrystallized from $CHCl_3$–ether, mp 162–163 °C. There was obtained 0.35 g (92%) of **35***e*.

Electrophilic additions of bromonium nitrate to unsaturated substrates

J. WILLIAM LOWN AND ALUMMOOTTIL V. JOSHUA[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 12, 1976

J. WILLIAM LOWN and ALUMMOOTTIL V. JOSHUA. Can. J. Chem. **55**, 508 (1977).

Bromonium nitrate (generated *in situ* by the reaction of bromine with silver nitrate in chloroform–pyridine) reacts *trans*-stereospecifically and regiospecifically in electrophilic additions to a series of *Z*–*E* pairs of alkenes to give bromoalkyl nitrate esters and bromoalkyl pyridinium nitrates. Addition to the less hindered (*Z*)-[β-^{2}H]-styrene is also stereospecific, eliminating the possibility of restricted rotation during addition. Reaction with conjugated dienes gives rise to bipyridinium salts from 1,4-conjugate addition and displacement. The accompanying alkyl bromonitrate esters rearrange readily to the more stable 1,4-bromonitrates in the liquid phase. In contrast to the behavior of iodonium nitrate, bromonium nitrate reacts with 3,3,3-triphenylpropene to give an allylic pyridinium nitrate, which results from phenyl migration, the structure of which was proven by synthesis. Bromonium nitrate reacts with pent-4-en-1-ol to give 2-bromomethyltetrahydrofuran. Similar reaction with cyclohex-2-en-1-ol provides products corresponding to the addition of the bromonium ion both *cis* and *trans* to the hydroxyl group, unlike iodonium nitrate where specific interaction between the hydroxyl and the pyridine group leads exclusively to *cis* addition.

J. WILLIAM LOWN et ALUMMOOTTIL V. JOSHUA. Can. J. Chem. **55**, 508 (1977).

L'addition électrophile du nitrate de bromonium (produit *in situ* par réaction du brome sur le nitrate d'argent dans le chloroforme–pyridine) sur une série de paires *Z* et *E* d'alcènes se produit régiospécifiquement et d'une façon stéréospécifique *trans* pour conduire aux esters nitrates de bromoalkyles et aux sels pyridinium de nitrates de bromoalkyles. L'addition au site le moins empêché du (*Z*)-[β-^{2}H] styrène est aussi stéréospécifique; ce résultat élimine la possibilité d'une rotation empêchée durant l'addition. La réaction avec des diènes conjugués conduit aux sels de bipyridinium par une addition conjuguée de 1,4 suivie d'un déplacement. En phase liquide, les esters bromonitrates d'alkyles qui les accompagnent se réarrangent avec facilité pour donner les bromonitrates-1,4 plus stables. Par opposition au comportement du nitrate d'iodonium, le nitrate de bromonium réagit avec le triphényl-3,3,3 propène pour donner un nitrate de pyridinium allylique qui provient d'une migration du groupe phényle; la structure de ce composé a été prouvée par synthèse. Le nitrate de bromonium réagit avec le pentène-4 ol-1 pour fournir le bromométhyl-2 tétrahydrofuranne. Une réaction semblable avec le cyclohexène-2 ol-1 conduit à des produits correspondants à l'addition de l'ion bromonium à la fois *cis* et *trans* par rapport au groupe hydroxyle; ce résultat est en opposition avec ceux observés avec le nitrate d'iodonium où une interaction spécifique entre le groupe hydroxyle et le groupe pyridine conduit exclusivement à une addition *cis*.

[Traduit par le journal]

Introduction

In previous papers we discussed the reactions of iodonium nitrate with unsaturated substrates of various types and structures and also the effect of neighboring groups in the addition reaction (1–4). The stereochemical and regiochemical outcome in these reactions was explained by assuming the formation of an intermediate iodonium ion.

Hassner and co-workers (5–7) have compared the reactivities of iodine azide and bromine azide and found that the former reacted exclusively by an ionic pathway involving a bridged iodonium ion whereas the latter can react either by an ionic or free radical pathway depending upon the nature of the solvent and the presence of oxygen.

Since the electronegativity of bromine is greater than that of iodine (6), bromonium nitrate may be expected to react by both ionic and free radical pathways. But as in the case of iodonium nitrate in chloroform–pyridine, the bromine in bromonium nitrate is also complexed to two pyridine rings. So it was anticipated that bromonium nitrate will also behave like iodonium nitrate, although the higher electrophilicity of bromonium ion may be reflected in its relative reactivity towards unsaturated substrates. Ac-

[1]NRCC scholarship holder 1974–1975.

cordingly the reactions of bromonium nitrate with a wide variety of unsaturated substrates have been examined.

Bromonium nitrate is generated *in situ* by the reaction of bromine with silver nitrate in chloroform–pyridine. The silver bromide is removed by filtration and the clear light yellow solution can be used for additions to unsaturated substrates.

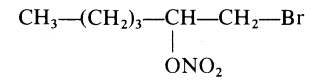
$$AgNO_3 + Br_2 \xrightarrow[\text{Pyridine}]{CHCl_3} [Br\cdot 2Py]^+NO_3^- + AgBr\downarrow$$

Results

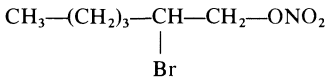
Reactions with Acyclic Alkenes

Reaction of bromonium nitrate in chloroform–pyridine with simple alkenes gives products of the type shown in [1]. In contrast to the addition

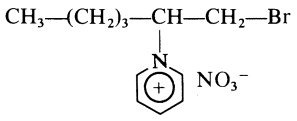
[1] 
of iodonium nitrate to hex-1-ene, which gave only Markovnikov-type addition products, bromonium nitrate gave 1-bromohex-2-yl nitrate **1** and 2-bromohex-1-yl nitrate **2** in a combined yield of 49% and in a ratio of 67:33. The bromopyridinium salt produced in this reaction in 34% yield was a mixture of two isomers, **3** and **4**, in a ratio of *ca.* 60:40. Assignments of structures to



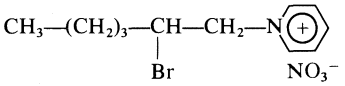
1



2



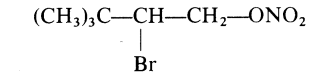
3



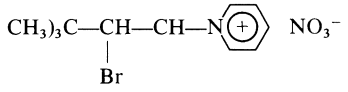
4

these and similar products and determinations of product ratios were performed by nmr spectroscopy. It was observed that methine protons α to an ONO_2 group absorb in the range 4.8–5.4 δ, whereas protons α to a bromo function absorb in the range 3.8–4.5 δ. The methylene protons α to a bromo function absorb at about 3.5 δ, whereas methylene protons α to a nitrate function absorb at 4.5–5 δ. The presence of a pyridine group in structures such as **3** deshields the methylene protons α to the bromine by about 0.7–0.9 ppm.

In the case of 3,3-dimethylbut-1-ene, the bromonitrate ester **5** and the bromopyridinium nitrate **6** with the nitrate group and pyridine respectively at the primary position are the products obtained as clearly demonstrated by the nmr spectra.

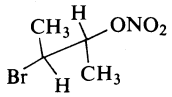


5

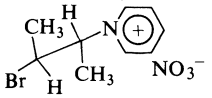


6

(*E*)-But-2-ene, on reaction with bromonium nitrate in chloroform–pyridine, afforded the *erythro*-bromonitrate ester **7** and the *erythro*-bromopyridinium nitrate **8** in 44 and 37% yields

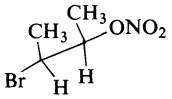


7

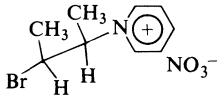


8

respectively. Similar addition to (*Z*)-but-2-ene produced the *threo*-bromonitrate ester **9** in 48% yield and the *threo*-bromopyridinium nitrate **10** in 29% yield.



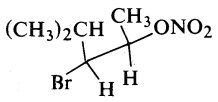
9



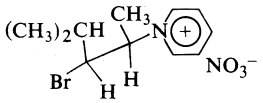
10

The addition of bromonium nitrate to (*Z*)- and (*E*)-4-methylpent-2-enes also gave stereoisomeric products as clearly shown by the nmr spectra. In the case of the (*Z*)-isomer the reaction was regiospecific and stereospecific in the forma-

tion of the *threo*-bromonitrate ester **11** and the *threo*-bromopyridinium nitrate **12**, whereas for the (*E*)-isomer, the reaction was stereospecific and regioselective. The *erythro*-bromonitrate esters **13** and **14** were produced in a ratio of

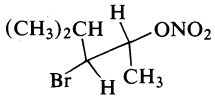


11

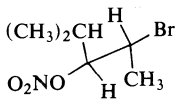


12

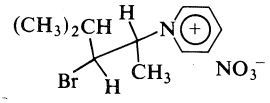
74:26. The ratio of the corresponding *erythro*-bromopyridinium salts **15** and **16** was also approximately the same as for the bromonitrate esters.



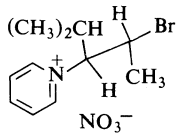
13



14

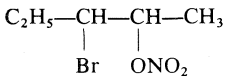


15

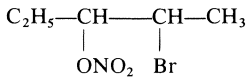


16

Reaction of bromonium nitrate in chloroform–pyridine with (*Z*)-pent-2-ene gave a mixture of *threo*-3-bromopent-2-yl and *threo*-2-bromopent-3-yl nitrates, **17** and **18**, in a ratio of 64:36, together with the isomeric *threo*-bromopyridinium nitrates, **19** and **20**, in a ratio of 70:30. For the pyridinium salts, the isomer ratio was

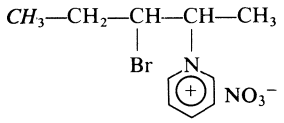


17

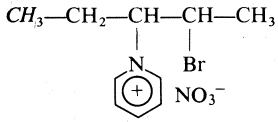


18

determined by comparing the nmr intensities of the methyl (italic portion of structures **19** and **20**) signals which appeared as triplets at δ 1.1 and 0.74 respectively.

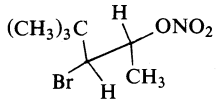


19



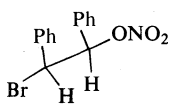
20

In the case of (*E*)-4,4-dimethylpent-2-ene, the greater bulk of the *tert*-butyl group ensures regiospecific addition of bromonium nitrate the sole product being the *erythro*-bromonitrate ester **21**, which was formed in 80% yield. No

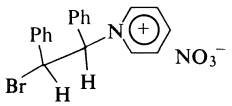


21

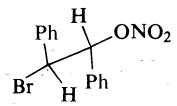
isolable yield of the corresponding bromopyridinium salt was obtained from this reaction. The reaction of bromonium nitrate with (*Z*)- and (*E*)-stilbenes was also stereospecific in the formation of the bromonitrate esters *threo* **22** and *erythro* **24** and the bromopyridinium salts *threo* **23** and *erythro* **25** respectively. **22** and **23** were produced in 52% and 32% yields respectively from the (*Z*)-isomer and **24** and **25** in 21 and 63.5% yields respectively from the (*E*)-isomer.



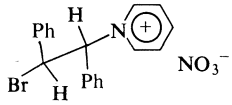
22



23

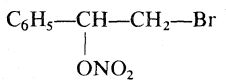


24

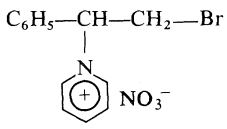


25

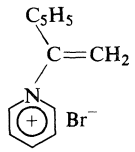
To eliminate the possibility that the observed stereospecificity in all the above reactions is due to restricted rotation in the intermediate bromocarbonium ions in the additions to (*Z*)- and (*E*)-alkenes and to establish conclusively the *trans* stereospecificity of addition, the reaction of bromonium nitrate with (*Z*)-β-deuterostyrene (>95% D) was performed. First it was shown that reaction of styrene with bromonium nitrate gave the bromonitrate ester **26** as the major product (49%). The pyridinium salt produced in this reaction was a mixture of **27** and **28** as shown by the nmr spectrum. The mixture was converted into **28** in an overall yield of 26.5% by treatment with potassium carbonate. In the analogous reaction with (*Z*)-β-deuterostyrene the bromonitrate ester **29** and the alkenyl pyridinium bromide **30** were isolated in 46% and 26.5% yields respectively. In the nmr spectrum of **29** the methine hydrogen absorbed as a doublet at $\delta_{TMS}(CDCl_3)$ 6.0 (J = 7.5 Hz) whereas for



26

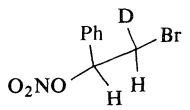


27

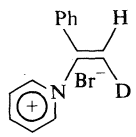


28

the protium analog **26**, it absorbed as a quartet at $\delta_{TMS}(CDCl_3)$ 6.0 (J = 6, 7.5 Hz). The methylene hydrogen in **29** appeared as a doublet further



29

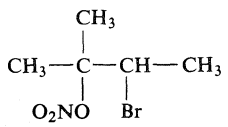


30

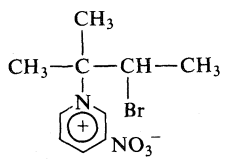
split by H–D coupling at $\delta_{TMS}(CDCl_3)$ 3.62 (J = 7.5 Hz) whereas for **26** the methylene hydrogens absorbed as a triplet at $\delta_{TMS}(CDCl_3)$ 3.62 (J = 6 and 7.5 Hz).

The nmr spectrum of **30** was identical to that of the salt formed in iodonium nitrate addition to (*Z*)-β-deuterostyrene.

2-Methylbut-2-ene with bromonium nitrate afforded the bromonitrate ester **31** as the major product together with a small yield of the corresponding bromopyridinium nitrate **32**. Ethyl

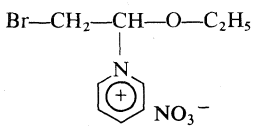


31



32

vinyl ether, an example in which the carbonium ion involved is considerably stabilized, gave only the bromopyridinium nitrate **33**.

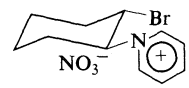


33

Reactions with Cyclic Monounsaturated Compounds

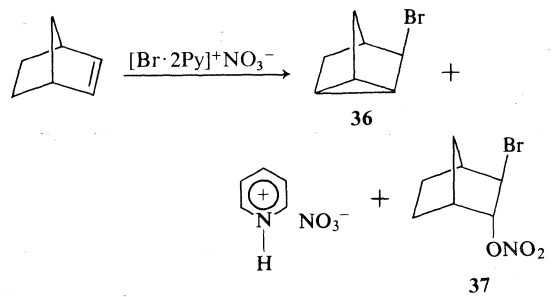
As in the case of iodonium nitrate additions, addition of bromonium nitrate to cyclic olefins allows a preliminary examination of the stereochemistry of the reaction (2). Cyclohexene gave the bromonitrate ester **34** in 52% yield which has a *trans*-diequatorial conformation as shown by the nmr spectrum. The corresponding bromopyridinium nitrate **35** was formed in 31.5% yield.

34



35

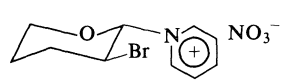
Norbornene gave nortricyclanyl bromide **36** in 50% yield and the expected bromonitrate ester **37** in 15% yield. They were readily separated by fractional distillation. No bromopyridinium nitrate was produced in this reaction, but a stoichiometric amount of pyridinium nitrate



36 37

was formed. This reaction is analogous to that undergone by INO_3 (2) and plausibly involves participation across the ring aided by removal of the proton by solvent pyridine.

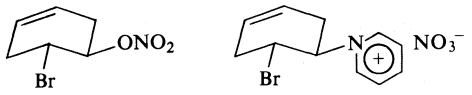
Reaction of 2,3-dihydropyran with bromonium nitrate in chloroform–pyridine afforded in 45% yield *trans*-equatorial *N*-(3-bromotetrahydropyranosyl)pyridinium nitrate **38**, the nmr spectrum of which compared well with that of the product obtained in the addition of iodonium nitrate to 2,3-dihydropyran (2). As in the case of ethyl vinyl ether no bromonitrate ester could be isolated in this reaction.



38

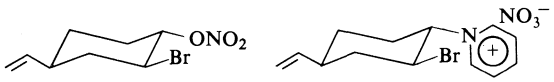
Reactions with Unconjugated Dienes

Unconjugated dienes, on reaction with 1 equiv of bromonium nitrate, gave only mono-addition products. Thus 1,4-cyclohexadiene gave 5-bromocyclohexen-4-yl nitrate **39** in 54% yield and *N*-[4-(5-bromocyclohexenyl)]pyridinium nitrate **40** in 25% yield. Reaction of bromonium nitrate



39 40

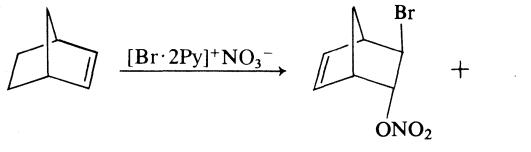
with 4-vinylcyclohexene gave the bromonitrate ester **41** in 35% yield and the bromopyridinium nitrate **42** in 40% yield corresponding exclusively to addition in the ring. The positions of bromine



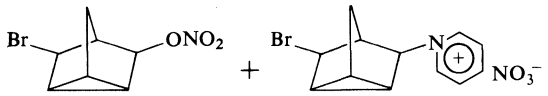
41 42

and nitrate groups in **41** and the bromine and pyridinium groups in **42** on the 1,2-cyclohexane bond could not be assigned unambiguously. As in iodonium nitrate additions the marked preference for electrophilic additions in this case to the cyclic olefinic bond may be ascribed to the greater stability of the resulting bromonium ion.

The addition of bromonium nitrate to norbornadiene shows a reduced propensity for neighboring π-bond participation than in iodonium nitrate additions. In the latter case, only products corresponding to cross-ring interactions were formed (2). On the other hand reaction of bromonium nitrate with norbornadiene produced two bromonitrate esters and one bromopyridinium nitrate. 3-Bromo-4-norbornen-2-yl nitrate **43** and tricyclo[2.2.1.$0^{2,6}$]-5-bromohept-3-yl nitrate **44** were produced in yields of 16 and 29% respectively. They were not separable by distillation. The structure of **43** was evident from the nmr spectrum of the mixture, which showed olefinic hydrogen signals at $\delta_{TMS}(CDCl_3)$ 6.3. The bromopyridinium salt formed in 12% yield



43



44 45

in this reaction was exclusively *N*-[3-(5-bromonortricyclanyl)]pyridinium nitrate **45**; corresponding to cross-ring interaction. The nmr spectrum of **45** compared well with that of the corresponding iodopyridinium nitrate.

Reactions with Conjugated Dienes

In contrast to the addition of iodonium nitrate to conjugated dienes, which gave only the iodopyridinium salts corresponding to 1,2-addition (2), the reaction of bromonium nitrate gave significant yields of bromonitrate esters (4).

Reaction of bromonium nitrate with 2,3-dimethyl-1,3-butadiene gave three products. The bromonitrate ester formed in 31% yield corresponded to the kinetically controlled 1,2-addition product **46**. This was evident from the nmr spectrum of the product soon after isolation (Fig. 1). The olefinic hydrogens absorbed as a

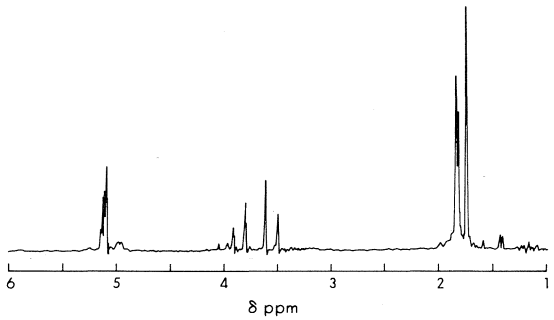


FIG. 1. Proton magnetic resonance spectrum at 100 MHz (500 Hz sweep width, 100 Hz offset) in $CDCl_3$ of 2,3-dimethyl-1,3-butadiene – bromonium nitrate adducts, **46**, 1 h after isolation. The signals at δ 3.97, 4.04, 4.95, and 4.98 correspond to the rearranged product **52**.

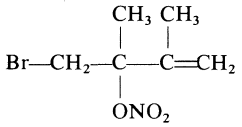
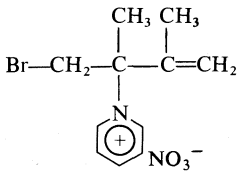


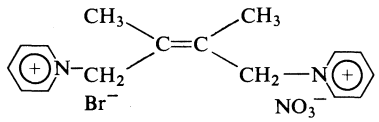
46

multiplet at $\delta_{TMS}(CDCl_3)$ 5.12, while the $-CH_2-Br$ group appeared as an AB quartet at δ 3.55 and 3.85 (J = 11 Hz). The methyl group attached to the olefinic carbon absorbed as a multiplet (allylic coupling) at δ 1.82, while the other methyl group appeared as a singlet at δ 1.73.

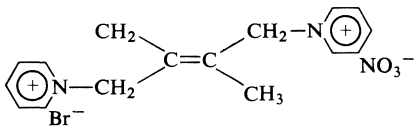
In addition, pyridinium salts were also formed which were readily separated by crystallization. The major product is assigned structure **47**, corresponding to 1,2-addition on the basis of the nmr spectrum, which was comparable with that of the product formed in iodonium nitrate addition. The other product was shown to be an approximately equimolar mixture of **48***a* and **48***b*.



47

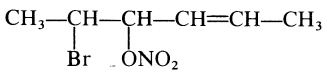


48*a*

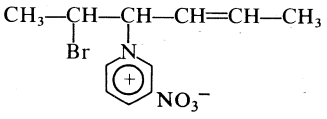


48*b*

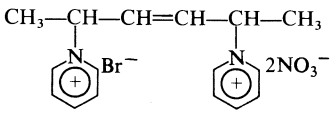
trans,trans-2,4-Hexadiene behaved similarly. The bromonitrate ester, **49** was produced in 19% yield. In this case the two pyridinium salts **50** and **51** were not separable by crystallization.



49



50



51

An interesting characteristic of these allyl nitrates is their tendency to rearrange to the thermodynamically more stable 1,4-bromonitrates. Thus both **46** and **49** rearrange either in the liquid phase or in solution to **52** and **53** respectively. The rearrangement can be followed by nmr spectroscopy. Figures 1–3 show the nmr spectra of the bromonitrate ester from 2,3-dimethyl-1,3-butadiene at different times after its isolation. In the case of **46** the rearranged product was a mixture of two isomers in approximately equal amounts as shown by high pressure

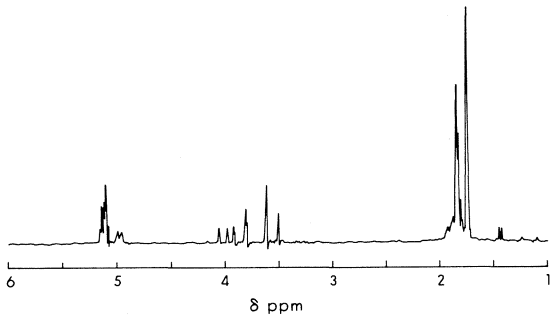


FIG. 2. Proton magnetic resonance spectrum at 100 MHz (500 Hz sweep width, 100 Hz offset) in $CDCl_3$ of 2,3-dimethyl-1,3-butadiene – bromonium nitrate adduct 3 h after isolation.

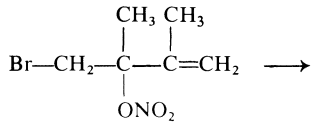
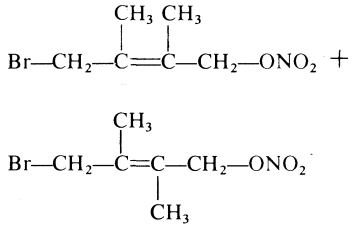
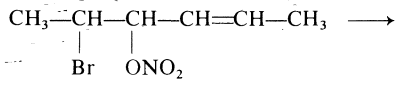


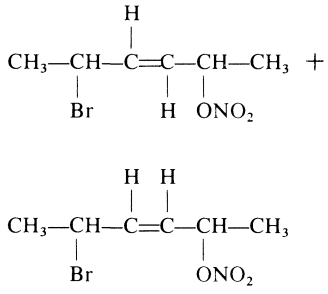
46



52*a*,*b*



49



53*a*,*b*

liquid chromatography. Figure 3 shows the nmr spectrum of the rearranged product. The $-CH_2Br$ groups appear as two singlets at $\delta_{TMS}(CDCl_3)$ 3.97 and 4.04, while the $-CH_2-ONO_2$ groups absorb as two singlets at δ 4.95 and 4.98. On this basis structures **52***a* and **52***b* are assigned to the products. Moreover, treat-

ment of the mixture with pyridine in chloroform at room temperature gave **48** in almost quantitative yield. This proves that product **48** is a mixture of two geometrical isomers **48***a* and **48***b*.

The rearranged product from **49** was predominantly the *trans*-isomer **53***a* as shown by the nmr spectrum, although high pressure liquid chromatography showed the presence of a minor product, probably the *cis*-isomer **53***b*. The nmr spectrum of **53** showed $\delta_{TMS}(CDCl_3)$ 1.43 (d, 3H, CH_3—CH—ONO_2, J = 6.5 Hz), 1.78 (d, 3H, CH_3—CH—Br, J = 7 Hz), 4.65 (quint, 1H, —CH—Br, J = 7 Hz), 5.5 (m, 1H, —CH—ONO_2). The olefinic hydrogens appeared as an octet centered at δ 5.92 with $J_{CH=CH}$ = 14.5 Hz, from which follows the *trans*-stereochemistry about the olefinic bond.

Treatment of **53** with pyridine in chloroform gave **51** in quantitative yield. The nmr spectrum of **51** showed two identical methyl groups which absorbed as a doublet at $\delta_{TMS}((CD_3)_2SO)$ 1.80. The other signals were at δ 5.8 (m, 2H, 2—CH—$\overset{+}{N}$≤), 6.15–6.5 (m, 2H, olefinic hydrogens), 8.1–9.3 (m, 10H, pyridine hydrogens).

Reactions with Acetylenic Compounds

Like iodonium nitrate, bromonium nitrate was unreactive towards non-terminal acetylenes. With terminal acetylenes, alkynyl bromides were formed together with a stoichiometric quantity of pyridinium nitrate. Thus phenylacetylene gave a 63% yield of β-bromophenylacetylene, **54**.

Ph—C≡C—Br

54

Reaction with Olefinic Alcohols

Allyl alcohol on reaction with bromonium nitrate gave two isomeric bromonitrate esters.

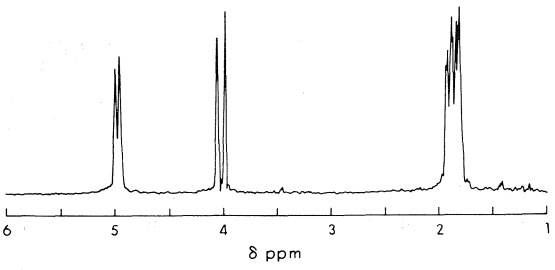


FIG. 3. Proton magnetic resonance spectrum at 100 MHz (500 Hz sweep width, 100 Hz offset) in $CDCl_3$ of 2,3-dimethyl-1,3-butadiene – bromonium nitrate adduct after complete rearrangement to **52**.

3-Hydroxyl-1-bromoprop-2-yl nitrate **55** and 3-hydroxy-2-bromoprop-1-yl nitrate **56** were formed in a combined yield of 31% and in a ratio of 69:31, as determined by nmr. The accompanying bromopyridinium salt was also a mixture of two regioisomers, **57** and **58**. The isomer

HO—CH_2—CH(—ONO_2)—CH_2—Br

57

HO—CH_2—CH(—Br)—CH_2—N$^+$ NO_3^-

58

ratio could not be determined in this case by nmr because of overlapping signals.

But-3-en-1-ol also gave a comparable result. The bromonitrate esters, **59** and **60** were formed in 33% yield (isomer ratio 57:33). The pyridinium salt consisted of two isomers, **61** and **62**, in a ratio of 85:15.

HO—CH_2—CH_2—CH(—ONO_2)—CH_2—Br

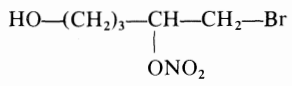
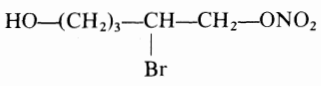
62

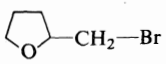
The reaction of bromonium nitrate with pent-4-en-1-ol gives an opportunity to compare the extent of neighboring hydroxy group participation in this and iodonium nitrate additions. The major product in this case was a mixture of bromonitrate esters, **63** and **64**, formed in 29% yield and in a ratio of 67:33. The cyclic ether 2-bromoethyltetrahydrofuran, **65**, was produced in only 20% yield as compared to 60% in iodonium nitrate addition. In addition the isomeric bromopyridinium nitrates **66** and **67** were



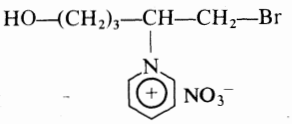
63



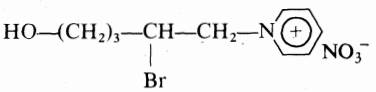
64



65



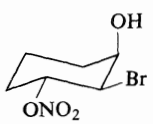
66



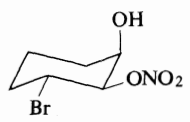
67

formed in approximately 20% yield (ratio 60:40).

Cyclohex-2-en-1-ol, on reaction with bromonium nitrate, gave a mixture of bromonitrate esters in 52% yield and bromopyridinium nitrates in 23.5% yield. Of the bromonitrates the major isomer was **68**, which is derived from a bromonium ion formed *cis* to the hydroxy group. Another isomer is assigned structure **69** which is derived from a bromonium ion formed *trans* to the hydroxy group. Compound **69** had the —CH—ONO_2 absorption in the nmr spectrum at δ 5.14 as a quartet superimposed on a multiplet.



68



69

3,3,3-Triphenylpropene is unreactive towards iodonium nitrate (1). On the other hand it does react with bromonium nitrate. The product formed in 73% yield is assigned structure **70** on the basis of the nmr spectrum, elemental analysis, and synthesis from the allyl bromide, **71**. The allylic bromide, **71** is one of the products formed in the addition of bromine to 3,3,3-triphenylpropene (8).

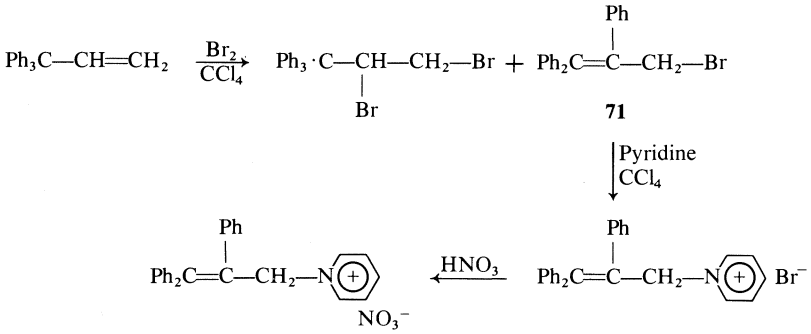
In the nmr spectrum of **70**, one of the phenyl groups was different from the other two and absorbed at about 0.4 ppm downfield. The integration showed the presence of one pyridine per molecule. In addition there was a singlet at δ 5.72 integrating for two hydrogens. This is assigned to the methylene hydrogens.

Compound **71** may be envisaged as arising as a result of a phenyl migration as shown.

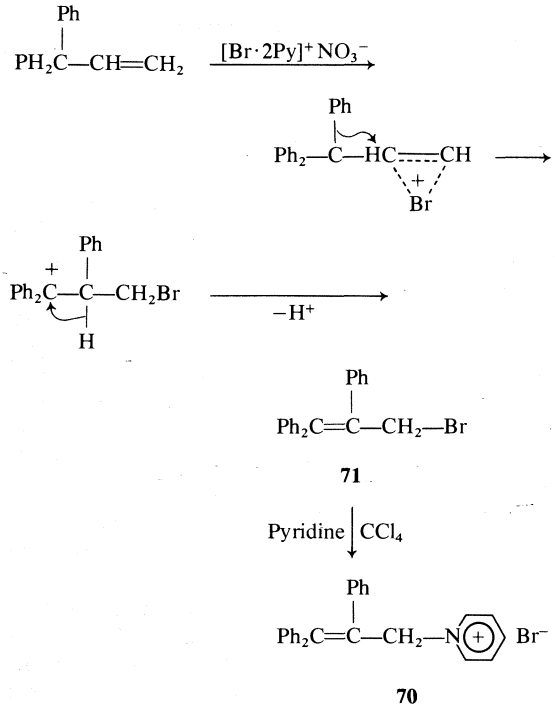
Discussion

The results show that bromonium nitrate can react with a wide variety of unsaturated substrates to form the two types of products that result from a competition of the two nucleophiles present, nitrate and pyridine, for the intermediate bromonium ion. As was found for iodonium nitrate (1), steric hindrance factors appear to play an important role directing the approach of the nucleophiles to the bromonium ion, exemplified by the regiospecific additions to 3,3-dimethylbut-1-ene to give **5** and **6** only, and similarly accounts for the formation of **7**, **8**, **9**, and **10** from the isomeric but-2-enes and of the products **11** to **21**. This steric hindrance factor resulting in regiospecificity or regioselectivity can, however, be overcome when a very stable cationic centre is generated as in the case of **31**, **32**, **33** (see below). Additions of bromonium nitrate to a series of (*Z*) and (*E*) pairs of alkenes is *trans*-stereospecific. Confirmatory evidence was obtained with (*Z*)-β-deuterostyrene that the observed stereospecificity does not arise because of restricted rotation in the intermediate bromocarbonium ions, *i.e.* that there is no equilibration of the cationic centre in the additions to olefins. In this respect $BrNO_3$ behaves like INO_3.

The stereochemical and regiochemical outcome in the additions of bromonium nitrate to unsaturated substrates can thus be explained by an ionic mechanism involving the formation of a three-membered ring bromonium ion intermediate **72**, which is opened up from the backside by nucleophilic attack by nitrate ion or pyridine.

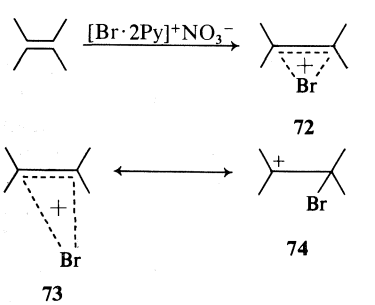


70



70

In the case of unsymmetrically substituted olefins, there can be substantial contribution from the unsymmetrically bridged form **73** and the open cationic form **74** to permit nucleophilic attack despite increased steric hindrance to permit neighboring hydroxyl group attack to form cyclic ethers. The intermediate can be sufficiently stabilized through the bridged form **73** to maintain its stereochemical integrity to lead to the observed stereospecificity in addition to alkenes. The open carbonium form **74** evidently makes a major contribution to the hybrid in those cases, *e.g.* **31**, **32**, and **33**, where a tertiary or oxonium stabilized cation is formed leading to preferential attack of the nucleophile at this centre despite the steric hindrance involved.

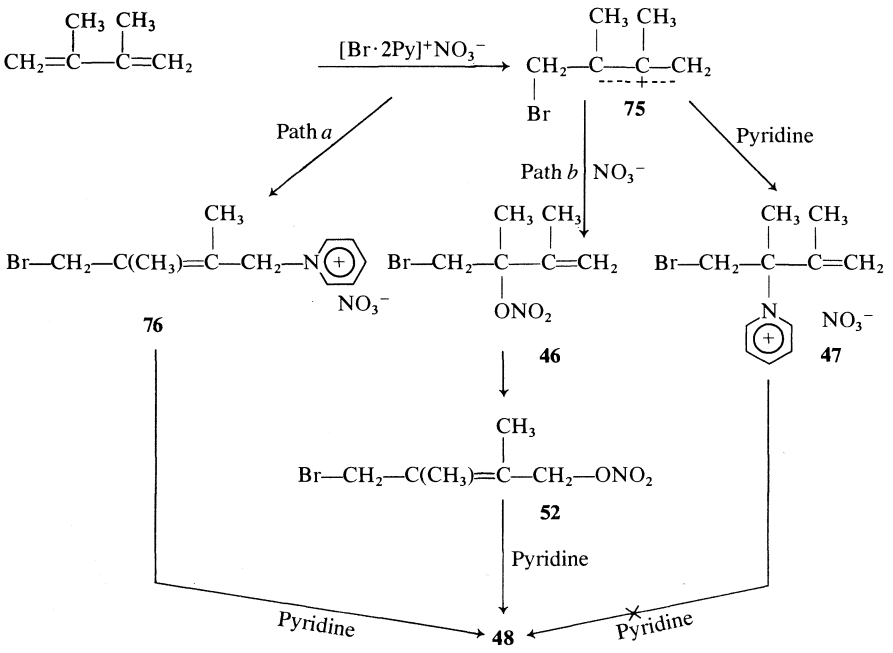


73 **74**

The observed stereospecificity in the additions to stilbenes and to (*Z*)-β-deuterostyrene and the regiospecificity in the addition to (*Z*)-β-deuterostyrene eliminate the possibility of any contribution from a free radical component under the conditions in which the above reactions were performed. Free radical contribution results in nonstereospecific addition and a reversal of the regiochemistry as is observed in bromine azide and chlorine azide additions (9). Bromonium nitrate also differs from iodonium nitrate in undergoing 1,4-conjugate additions to dienes, at least in the examples studied.

Compounds **48** and **51** corresponding to 1,4-addition may be envisaged as arising by two pathways (Scheme 1). (*a*) The initially formed bromonium ion intermediate **75** can undergo nucleophilic attack at the terminal carbon atom to give the thermodynamically more stable 1,4-addition product **76**. The allylic bromine can then be displaced by pyridine to give **48**. Alternatively, (*b*) the initially formed allyl nitrate **46** can rearrange to the thermodynamically more stable 1,4-bromonitrate **52**. Nucleophilic displacement of allylic bromine and nitrate in **52** by pyridine can lead to **48**.

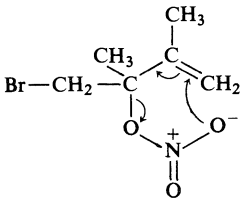
To distinguish between these two possibilities,



SCHEME 1

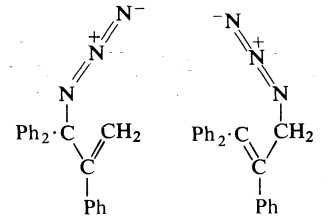
the reaction between bromonium nitrate and 2,3-dimethyl-1,3-butadiene was allowed to proceed for a longer time. The yield of 1,4-addition product was found to increase (*ca.* 8% after 3½ h, 16.5% after 12 h). Since the conversion of **46** to **48** is slow and since no equilibration of the benzylic center is observed in the addition of bromonium nitrate to (*Z*)-β-deuterostyrene it is reasonable to assume that products of the type **48** are formed by path *b*, although it is difficult to rule out path *a* entirely. A similar mechanism may be operating in the addition of iodonium nitrate to 2,3-dimethyl-1,3-butadiene (4).

As far as the mechanism of rearrangement of **46** to **52** and of **49** to **53** is concerned, one can visualize two possible pathways. First, the bromonitrate ester **46** can ionize to the allylic cation **75** and nitrate ion which can recombine to give the more stable 1,4-addition product. Alternatively, it can proceed by a concerted mechanism involving a six-membered cyclic transition state **77**.



77

Such a concerted mechanism has been postulated by Hassner for the rearrangement of the allyl azide **78** to **79** (7). Although there is insufficient



78 **79**

evidence to prove or disprove either mechanism, the concerted mechanism is more likely, since the rearrangement can proceed either in the liquid phase or in a weakly ionizing solvent like chloroform.

The reactions of iodonium nitrate and bromonium nitrate with olefins to give halonitrate esters and halopyridinium salts and with olefinic alcohols to give the corresponding addition products and/or cyclic ethers are quite general. The isolation of substantial quantities of haloalkyl nitrates in the reactions of these pseudohalogens with olefinic substrates in chloroform–pyridine is surprising in view of the reported relative nucleophilicities of pyridine and nitrate (20:1 for aqueous solutions) (10). However, since the reported heat of hydration of the nitrate ion

is -61 ± 2 kcal (g ion)$^{-1}$, (11) and therefore comparable with that of the iodide ion (12) (-68 kcal (g ion)$^{-1}$), then the nucleophilicity of this ion may be expected to be increased relative to that of the unchanged pyridine upon going to an aprotic solvent. No data are available for a more direct comparison.

In all these reactions the products isolated are formed under kinetic control. The primary products do not interconvert to any appreciable extent under the reaction conditions. This conclusion is consistent with the observed *trans* stereochemistry of addition.

Although iodonium nitrate and bromonium nitrate behave similarly towards unsaturated substrates, there is some apparent difference in reactivity between the two pseudohalogens. Thus, while iodonium nitrate is unreactive towards 3,3,3-triphenylpropene, bromonium nitrate did react with this olefin to give a pyridinium salt. While for iodonium nitrate this inertness may be attributed to steric hindrance in the olefin, the reactivity of bromonium nitrate may reflect its higher electrophilicity which is able to overcome the steric factors. For example in a competition reaction towards (*E*)-4,4-dimethylpent-2-ene the ratio of bromonitrate and iodonitrate esters was determined by nmr spectroscopy which was found to be approximately 4:1. This result suggests that bromonium nitrate is at least 4 times as reactive as iodonium nitrate.

Pent-4-en-1-ol reacts with both iodonium and bromonium nitrates to afford similar types of products. But with bromonium nitrate the proportion of the cyclized product is lower than with iodonium nitrate. This is consistent with the behaviour of pent-4-en-1-ol towards iodine and bromine, where iodine gave a much larger proportion of the cyclic ether (13).

A major difference between bromonium nitrate and iodonium nitrate is found in their reactions with phenyl, tri-alkyl, and tetra-alkyl substituted olefins. Bromonium nitrate gave substantial yields of the ester whereas iodonium nitrate gave only the pyridinium salts. With other olefinic systems too, the relative yields of pyridinium salts are in general lower in bromonium nitrate additions than in iodonium nitrate additions. If we assume that it is the thermodynamic stability of the intermediate halonium ions which allows solvent pyridine to compete successfully with the nitrate, then the above results give some indication of the relative stability of the three-membered ring iodonium ion *vs.* the three-membered ring bromonium ion. This again is consistent with the relative stabilities of iodonium and bromonium ions involved in halogen azide additions (5).

Bromonium nitrate differs from other positive bromine containing pseudohalogens, for example, bromine azide, in that with this pseudohalogen, even additions to aryl substituted olefins are stereospecifically *trans*. On the other hand addition of bromine azide to such olefinic systems under ionic conditions results in equilibration of benzylic centres suggesting involvement of an open bromocarbonium ion. This difference in behaviour may be attributed to complexation with pyridine in the case of bromonium nitrate.

Like the iodonium nitrate – pyridine complex, the bromonium nitrate – pyridine complex can also be isolated as a white solid. However, unlike the former which can be purified and shown to undergo stoichiometric addition to alkenes, attempts to purify the bromonium nitrate – pyridine complex by recrystallization were not successful. Attempted drying of the complex over anhydrous calcium sulfate in a desiccator resulted in a violent explosion.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The ir spectra were recorded on a Perkin–Elmer model 421 spectrophotometer, and only the principal, sharply defined peaks are reported. The nmr spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in appropriate deuterated solvents with tetramethylsilane as standard. Line positions are reported in ppm from the reference. Mass spectra were determined on an Associated Electrical Industries MS-9 double focussing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for thin layer chromatography.

The gc analyses were performed with an Aerograph model A-700 gas chromatograph. The lc analyses were made with a Waters Associates model ALC-100 liquid chromatograph. Microanalyses were carried out by Mrs. D. Mahlow of this department.

General Procedure for the Addition of Bromonium Nitrate to Unsaturated Substrates

Silver nitrate (6.8 g, 0.04 mol) was dissolved in a mixture of 30 ml of chloroform and 15 ml of reagent grade pyridine. The solution was cooled in an ice-water bath and bromine (6.4 g, 0.04 mol), in 15 ml of chloroform, was added dropwise to the stirred solution. The silver bromide produced was collected and washed with a

mixture of 10 ml of chloroform and 10 ml of pyridine. To the clear light yellow filtrate at 0 °C 0.04 mol of the olefin was added all at once. The mixture was stirred at 0 °C for 3–4 h and then poured into an excess of ether and chilled. The resulting oil or precipitate was collected and the ether solution concentrated *in vacuo*. The residual oil was extracted with ether, washed with 50 ml of cold 5% hydrochloric acid, and then with 50 ml of water. Concentration of the solution, after drying ($MgSO_4$), *in vacuo* gave the bromonitrate ester, which was purified by distillation under reduced pressure.

The ether insoluble residue, after washing several times with ether, was extracted with ethanol and filtered. Crystallization was effected by the addition of ether. The product thus obtained is the bromopyridinium nitrate.

In a few instances, addition of the reaction mixture to ether did not give any oil or precipitate. In those cases, the solution was concentrated *in vacuo* and the resulting oil extracted several times with ether. After that, work-up was accomplished by the procedure described before.

1-Hexene gave an isomeric mixture of (*a*) 1-bromohex-2-yl nitrate and (*b*) 2-bromohex-1-yl nitrate in 49% yield; bp 57–58 °C/0.05 torr. *Anal.* calcd. for $C_6H_{12}NO_3Br$: C 31.85, H 5.31, N 6.19, Br 35.40; found: C 31.89, H 5.30, N 6.36, Br 35.99; nmr 5.2 (0.67H, quint, J = 5.5 Hz, $—CHONO_2$), 3.55 (1.34H, d, J = 5.5 Hz, $—CH_2Br$); (*b*) 4.15 (0.33H, m, —CHBr), 4.7 (0.66H, t, $—CH_2ONO_2$). In addition were formed the corresponding pyridinium nitrates in 34% yield as an oil: nmr (*a*) *N*-[2-(1-bromohexyl)]pyridinium nitrate 4.3 (1.3H, t, J = 6.8 Hz, —CHBr), (*b*) *N*-[1-(2-bromohexyl)]pyridinium nitrate 4.8–5.55 (1H, m, $—CH\overset{+}{N}<$), 4.8 (0.7H, m, $—CH_2—\overset{+}{N}<$).

3,3-Dimethylbut-1-ene gave 2-bromo-3,3-dimethylbutyl nitrate; bp 54–55 °C/0.05 torr; 51.5% yield. *Anal.* calcd. for $C_6H_{12}NO_3Br$: C 31.85, H 5.31, N 6.19, Br 35.40; found: C 31.87, H 5.33, N 6.10, Br 35.36; nmr 4.02 (1H, m, —CHBr), 4.7 (2H, m, $—CH_2ONO_2$), 1.3 (s, 9H, $(CH_3)_3C—$). In addition was found *N*-[1-(2-bromo-3,3-dimethylbutyl)]pyridinium nitrate; mp 126–127 °C; 30% yield. *Anal.* calcd. for $C_{11}H_{17}N_2O_3Br$: C 43.28, H 5.57, N 9.18, Br 26.23; found: C 43.28, H 5.62, N 9.09, Br 26.25; nmr 4.02 (1H, m, CHBr), 4.7 (2H, m, $—CH_2ONO_2$), 1.3 (s, 9H, $(CH_3)_3C$).

(Z)-Pentene gave an isomeric mixture of (*a*) *threo*-3-bromopent-2-yl nitrate and (*b*) *threo*-2-bromopent-3-yl nitrates; bp 32–33 °C/0.06 torr; 53% yield. *Anal.* calcd. for $C_5H_{10}NO_3Br$: C 28.31, H 4.72, N 6.6, Br 37.74; found: C 28.37, H 4.75, N 6.45. Br 37.72; nmr (*a*) 4.00 (0.64H, q, J = 4.5 Hz, —CHBr), 5.31 (0.64H, octet, J = 4.5, 6.5 Hz, $—CHONO_2$); (*b*) 4.25 (0.36H, octet, J = 4.5, 7 Hz, CHBr), 5.07 (0.36H, quint, J = 4.5 Hz, $CHONO_2$). In addition were formed the corresponding (*a*) *threo-N*-[2-(3-bromopentyl)]pyridinium nitrate and (*b*) *threo-N*-[3-(2-bromopentyl)]pyridinium nitrates as an oil in 27.5% yield.

(E)-4,4-Dimethylpent-2-ene gave *erythro*-3-bromo-4,4-dimethylpent-2-yl nitrate; bp 53 °C/0.02 torr; 80% yield. *Anal.* calcd. for $C_7H_{14}NO_3Br$: C 35.00, H 5.82, N 5.82, Br 33.34; found: C 35.02, H 5.74, N 5.74, Br 33.42; nmr 4.2 (1H, d, J = 2.5 Hz, CHBr), 5.37 (1H, octet, J = 2.5, 7.5 Hz, $CHONO_2$).

2-Methylbut-2-ene gave 3-bromo-2-methylbut-2-yl nitrate; bp 30 °C/0.3 torr; 35% yield. *Anal.* calcd. for $C_5H_{10}NO_3Br$: C 28.32, H 4.72, N 6.60; found: C 28.43, H 4.93, N 6.47; nmr 4.7 (1H, q, J = 7 Hz, CHBr). In addition was formed *N*-[2-(2-methyl-3-bromobutyl)]pyridinium nitrate; mp 117–118 °C in 20% yield. *Anal.* calcd. for $C_{10}H_{15}N_2O_3Br$: C 41.25, H 5.19, N 9.62; found: C 40.83, H 5.27, N 9.20; nmr 4.9 (1H, q, J = 7 Hz, CHBr).

Cyclohexene gave 2-bromocyclohexyl nitrate; bp 67 °C/0.05 torr; 52% yield. *Anal.* calcd. for $C_6H_{10}NO_3Br$: C 32.15, H 4.47, N 6.25, Br 35.72; found: C 32.36, H 4.56, N 6.14, Br 35.65; nmr 4.03 (1H, sextet, J = 9, 4.5 Hz, —CH—Br), 5.1 (1H, m, $—CHONO_2$). In addition was formed *N*-(2-bromocyclohexyl)pyridinium nitrate; mp 135–136 °C in 31.5% yield. *Anal.* calcd. for $C_{11}H_{15}N_2O_3Br$: C 43.57, H 4.95, N 9.24, Br 26.40; found: C 43.49; H 5.00, N 9.11, Br 26.23; nmr 4.6–5.4 (2H, m, —CHBr, $—CH—\overset{+}{N}<$).

Norbornene afforded 2-bromonorborn-3-yl nitrate; bp 73 °C/0.03 torr; 15% yield. *Anal.* calcd. for $C_7H_{10}NO_3Br$: C 35.59, H 4.24; found: C 35.32, H 4.29; nmr 3.93 (1H, m, —CHBr), 4.9 (1H, m, $—CHONO_2$). Tricyclanyl bromide was also produced in 50% yield.

Norbornadiene gave (*a*) tricyclo[2.2.1.$0^{2,6}$]-5-bromohept-3-yl nitrate and (*b*) 3-bromo-5-norbornen-2-yl nitrate; bp 57 °C/0.05 torr; 45% yield. *Anal.* calcd. for $C_7H_8NO_3Br$: C 35.90, H 3.42, N 5.98, Br 34.20; found: C 35.99, H 3.50, N 5.56, Br 34.28; nmr (*a*) 4.42 (0.64H, m, —CHBr), 4.95 (1H, m, $—CHONO_2$); (*b*) 4.1 (0.36H, m, —CHBr). In addition was formed *N*-[3-(5-bromonortricyclanyl)]pyridinium nitrate; mp 174–177 °C; 12% yield. *Anal.* calcd. for $C_{12}H_{13}N_2O_3Br$: C 46.02, H 4.15, N 8.99, Br 25.57; found: C 45.85, H 4.19, N 8.87, Br 25.30; nmr 4.05 (1H, s, CHBr), 5.12 (1H, s, $—CH—\overset{+}{N}<$).

1,4-Cyclohexadiene gave 5-bromocyclohexen-4-yl nitrate; bp 56 °C/0.05 torr, 54% yield. *Anal.* calcd. for $C_8H_8NO_3Br$: C 32.43, H 3.60, N 6.30; found: C 32.06, H 3.59, N 6.22; nmr 4.30 (1H, m, —CHBr), 5.4 (1H, m, $—CHONO_2$). In addition was formed *N*-[4-(5-bromocyclohexenyl)]pyridinium nitrate; mp 132–134 °C in 25% yield. *Anal.* calcd. for $C_{11}H_{13}N_2O_3Br$: C 43.85, H 4.32, N 9.30, Br 26.58; found: C 43.66, H 4.33, N 9.07, Br 26.58; nmr 4.9–5.6 (2H, m, —CHBr and $CH—\overset{+}{N}<$).

4-Vinylcyclohex-1-ene gave 2-bromo-4(5)-vinylcyclohexyl nitrate; bp 63 °C/0.05 torr; 35% yield. *Anal.* calcd. for $C_8H_{12}NO_3Br$: C 38.41, H 4.80, N 5.60, Br 32.00; found: C 38.50, H 4.79, N 5.31, Br 32.18; nmr 4.4 (1H, m, CHBr), 5.25 (1H, m, $—CHONO_2$). *N*-[1(2)-2(1)-Bromo-4-vinylcyclohexyl)]pyridinium nitrate was also formed as an oil in 40% yield; nmr 4.7–5.6 (5H, m, —CHBr, $CH—\overset{+}{N}<$ and vinyl protons).

2,4-trans-trans-Hexadiene gave 5-bromohex-3-en-2-yl nitrate; bp 58–59 °C/0.05 torr; 19% yield. *Anal.* calcd. for $C_6H_{10}NO_3Br$: C 32.15, H 4.47, N 6.25, Br 35.72; found: C 31.95, H 4.44, N 6.07, Br 36.11; nmr 4.65 (1H, quint, J = 7 Hz, CHBr), 5.5 (1H, m, $—CHONO_2$). In addition were formed (*a*) *N*-[4-(5-bromohex-2-enyl)]pyridinium nitrate and (*b*) *N,N'*-[2,5-(hex-3-enyl)]pyridinium nitrate, bromide as an oil in 70% yield; nmr (*a*) 5.00 (0.58, m, —CHBr), and (*b*) 5.85 (1.42H, m, $—CH—\overset{+}{N}<$).

2,3-Dimethyl-1,3-butadiane gave 4-bromo-2,3-dimethylbut-2-en-1-yl nitrate; bp 57–58 °C/0.05 torr; 31% yield.

Anal. calcd. for $C_6H_{10}NO_3Br$: C 32.15, H 4.47, N 6.25, Br 35.72; found: C 31.84, H 4.43, N 6.32, Br 35.72; nmr 3.55, 3.85 (2H, 2d, J = 11 Hz, $—CH_2Br$), 5.12 (m, 2H, vinyl protons). *N*-[2-(4-Bromo-2,3-dimethylbutenyl)]pyridinium nitrate was also found as an oil in 34% yield; nmr 4.7 (2H, q, J = 12 Hz, $—CH_2Br$).

Styrene gave 2-bromo-1-phenylethyl nitrate; bp 80 °C/0.03 torr; 49% yield. *Anal.* calcd. for $C_8H_8NO_3Br$: C 39.24, H 3.24, N 5.44, Br 32.93; found: C 39.03, H 3.25, N 5.69, Br 32.53; nmr 6.00 (1H, q, J = 6, 7.5 Hz, $—CHONO_2$), 3.62 (2H, t, J = 6, 7.5 Hz, $—CH_2Br$). *N*-[1-(1-Phenylethenyl)]pyridinium bromide was also formed; bp 80 °C, 26.5% yield.

(Z)-But-2-ene gave *threo*-3-bromobut-2-yl nitrate; bp 23 °C/0.05 torr; 48% yield. *Anal.* calcd. for $C_4H_8NO_3Br$: C 24.24, H 4.04, N 7.07, Br 40.40; found: C 23.98, H 3.98, N 6.78, Br 40.79; nmr 4.26 (1H, octet, J = 4.5, 7 Hz, —CHBr), 5.12 (1H, octet, J = 4.5, 6.5 Hz, $—CHONO_2$). *threo-N*-[2-(3-Bromobutyl)]pyridinium nitrate was also formed as an oil in 29% yield.

E-But-2-ene gave *erythro*-3-bromobut-2-yl nitrate; bp 25 °C/0.03 torr; 44% yield. *Anal.* calcd. for $C_4H_8NO_3Br$: C 24.24, H 4.04, N 7.07, Br 40.40; found: C 24.24, H 4.07, N 7.01, Br 40.33; nmr 4.25 (1H, octet, J = 4.5, 7 Hz, —CHBr), 5.1 (1H, octet, J = 4.5, 6.5 Hz, $—CHONO_2$). *erythro-N*-[2-(3-Bromobutyl)]pyridinium nitrate was also formed as an oil in 37% yield.

(Z)-4-Methylpent-2-ene gave *threo*-3-bromo-4-methylpent-2-yl nitrate; bp 30 °C/0.7 torr; 58% yield. *Anal.* calcd. for $C_6H_{12}NO_3Br$: C 31.85, H 5.31, N 6.19, Br 35.40; found: C 32.02, H 5.42, N 6.26, Br 35.77; nmr 3.89 (1H, q, J = 6.5, 5 Hz, —CHBr), 5.07 (1H, quint, J = 6.5 Hz, $—CHONO_2$).

(E)-4-Methylpent-2-ene gave a mixture of (*a*) *erythro*-3-bromo-4-methylpent-2-yl nitrate and (*b*) *erythro*-2-bromo-4-methylpent-3-yl nitrate; bp 27 °C/0.17 torr; 61% yield. *Anal.* calcd. for $C_6H_{12}NO_3Br$: C 31.85, H 5.31, N 6.19, Br 35.40; found: C 32.03, H 5.41, N 6.12, Br 36.22; nmr (*a*) 4.00 (0.74H, q, J = 6.5, 5 Hz, —CHBr); (*b*) 4.24 (0.26H, quint, J = 6.5 Hz, —CHBr); (*a*, *b*) 5.24 (1H, quint, J = 6 Hz, $—CHONO_2$). In addition was formed a mixture of *erythro-N*-[3-(2-bromo-4-methylpentyl)]pyridinium nitrate; mp 108–110 °C; 21% yield. *Anal.* calcd. for $C_{11}H_{17}N_2O_3Br$: C 43.28, H 5.57, N 9.18, Br 26.53; found: C 42.48, H 5.49, N 8.73, Br 26.79; nmr 4.2–5.6 (2H, m, —CHBr, $—CH—\overset{+}{N}\lessgtr$).

(Z)-Stilbene gave *threo*-2-bromo-1,2-diphenylethyl nitrate; mp 87–88 °C; 52% yield. *Anal.* calcd. for $C_{14}H_{12}NO_3Br$: C 52.17, H 3.73, N 4.35; found: C 51.63, H 3.74, N 4.37; nmr 5.11 (1H, d, J = 9.2 Hz, —CHBr), 6.21 (1H, d, J = 9.2 Hz, $—CHONO_2$). *threo-N*-[1-(2-Bromo-1,2-diphenylethyl)]pyridinium nitrate, mp 168–171 °C, was formed in 32% yield. *Anal.* calcd. for $C_{19}H_{17}N_2O_3Br$: C 56.85, H 4.24, N 6.98, Br 19.95; found: C 55.43, H 4.29, N 6.90, Br 19.49; nmr 7.02 (1H, d, J = 12 Hz, —CHBr).

E-Stilbene gave *erythro*-2-bromo-1,3-diphenylethyl nitrate; mp 144–145 °C; 21% yield. *Anal.* calcd. for $C_{14}H_{12}NO_3Br$: C 52.17, H 3.73, N 4.35, Br 24.83; found: C 52.21, H 3.78, N 4.12, Br 24.68; nmr 5.13 (1H, d, J = 8 Hz, —CHBr), 6.28 (1H, d, J = 8 Hz, $—CHONO_2$). *erythro-N*-[1-(2-Bromo-1,2-diphenylethyl)]pyridinium nitrate; mp 174–176 °C; 63.5% yield. *Anal.* calcd. for $C_{19}H_{17}N_2O_3Br$: C 56.85, H 4.24, N 6.98, Br 19.95; found: C 56.83, H 4.28, N 6.74, Br 19.98; nmr 7.02 (1H, d, J = 12 Hz, —CHBr).

Allyl alcohol gave an isomeric mixture of (*a*) 3-hydroxy-1-bromoprop-2-yl nitrate and (*b*) 3-hydroxy-2-bromoprop-1-yl nitrate as an oil in 33% yield. *Anal.* calcd. for $C_3H_6NO_3Br$: C 18.00, H 3.00, N 7.00, Br 40.00; found: C 18.50, H 3.06, N 6.53, Br 39.95; nmr (*a*) 5.30 (0.69H, quint, J = 6 Hz, $—CHONO_2$), 3.63 (1.38H, d, J = 6 Hz, $—CH_2Br$); (*b*) 4.3 (0.31H, m, —CHBr). The corresponding *N*-[2-(3-hydroxy-1-bromopropyl)]pyridinium nitrate and *N*-[2-(4-hydroxyl-1-bromopropyl)]pyridinium nitrate were formed as an oil in 37% yield; nmr 4.5–4.4 (3H, m, $—CH—\overset{+}{N}\lessgtr$, $—CH_2—\overset{+}{N}\lessgtr$).

Cyclohex-2-en-1-ol gave a mixture of (*a*) 3-hydroxy-2-bromocyclohexyl nitrate and (*b*) 6-hydroxy-2-bromocyclohexyl nitrate; bp 81–82 °C/0.02 torr; 52% yield. *Anal.* calcd. for $C_6H_{10}NO_4Br$: C 30.00, H 4.17, N 5.82, Br 39.34; found: C 29.85, H 4.14, N 5.26, Br 33.45; nmr (*a*) 4.2 (0.625H, q, $J_{a,e}$ = 3 Hz, $J_{a,a}$ = 8.5 Hz, —CHBr), 5.41 (0.625H, sextet, $J_{a,e}$ = 4 Hz, $J_{a,a}$ = 8.5 Hz, $—CHONO_2$), (*b*) 5.14 (0.37H, q, $J_{a,e}$ = 3 Hz, $J_{a,a}$ = 8.5 Hz, $—CHONO_2$). The corresponding pyridinium salt was formed; mp 172–177 °C; 23.5% yield. *Anal.* calcd. for $C_{11}H_{15}N_2O_4Br$: C 41.38, H 4.70, N 8.78, Br 25.1; found: C 41.20, H 4.78, N 8.61, Br 24.49.

Reaction of 4-Bromo-2,3-dimethylbut-2-en-1-yl Nitrate **52** *with Pyridine in Chloroform*

A mixture of 0.224 g (1 mmol) of 4-bromo-2,3-dimethylbut-2-en-1-yl nitrate, 2 ml of pyridine, and 10 ml of chloroform was set aside overnight. Ether was added to the reaction mixture and the resulting precipitate collected. Recrystallization from methanol–ether gave the dipyridinium salt **48** in almost quantitative yield.

Reaction of 5-Bromohex-3-en-2-yl Nitrate, **53** *with Pyridine in Chloroform*

The reaction was carried out by the procedure described above for **52**. Thus reaction of 0.224 g (1 mmol) of 5-bromohex-3-en-2-yl nitrate with 2 ml pyridine in 10 ml of chloroform gave the dipyridinium salt **51** as an oil in almost quantitative yield.

Procedure for the Reaction of Bromonium Nitrate with Phenylacetylene

The procedure was the same as that used for the reaction of iodonium nitrate with terminal alkynes. β-Bromophenylacetylene **54** was obtained in 63% yield; bp 30.5 °C/0.07 torr (lit. (14) bp 84–85 °C/10 torr).

Procedure for the Reaction of Bromonium Nitrate with Pent-4-en-1-ol in Chloroform–Pyridine

The reaction was performed by the general procedure described above. Separation of the cyclic ether and hydroxy-bromo-nitrate esters was accomplished by chromatography on Florisil and elution with petroleum ether – chloroform (9:1) and then with chloroform–methanol (9:1). Evaporation of the first fraction gave 0.65 g (20%) of *2-bromomethyltetrahydrofuran*, **65**.

The nmr spectrum $\delta_{TMS}(CDCl_3)$ 1.65–2.3 (m, 4H, $2—CH_2—$), 3.4 (t, 2H, $—CH_2Br$, J = 5 Hz, 6.5 Hz), 3.5–4.3 (m, 2H, $—CH_2—O$, —CH—O).

Evaporation of the second fraction gave a mixture of hydroxy-bromo-nitrate esters, **63** and **64**; yield 29%.

From the ether insoluble residue was isolated by the

usual procedure a mixture of bromopyridinium salts, **66** and **67**; yield 20%.

3,3,3-Triphenylpropene

This compound was prepared according to reported procedures (7, 15). mp 80–81 °C (lit. mp 80–81 °C).

Reaction of Bromonium Nitrate with 3,3,3-Triphenylpropene in Chloroform–Pyridine

The reaction was carried out by the general procedure described above. No bromonitrate ester was isolated. Crystallization of the ether insoluble residue from ethanol–ether gave a mixture of compound **70** and pyridinium bromide (yield 3.75 g). Purification was effected as follows. A mixture of 1 g of the crude reaction product, 1 g of potassium carbonate, and 25 ml of water was heated on a steam bath to about 50 °C whereupon dissolution occurred. On cooling a solid separated, which was collected. Recrystallization from methanol–ether gave 0.6 g of pure *N-[1-(2,3,3-triphenyl)prop-2-enyl]pyridinium nitrate*, **70**; mp 211–212 °C. *Anal.* calcd. for $C_{26}H_{22}N_2O_3$: C 76.1, H 5.37, N 6.83; found: C 75.71, H 5.40, N 6.75. The nmr spectrum $\delta_{TMS}((CD_3)_2SO)$ 5.72 (s, 2H, $—CH_2—$), 7–7.65 (m, 15H, 3Ph), 7.9–9.17 (m, 5H, pyridine hydrogens). The melting point and nmr spectrum were identical to those of an authentic sample synthesized as follows.

Synthesis of N-[1-(2,3,3-Triphenyl)prop-2-enyl]pyridinium Nitrate, 70

To a solution of 0.64 g (2.37 mmol) of 3,3,3-triphenylpropene in 15 ml of carbon tetrachloride was added a solution of 0.397 g (2.37 mmol) of bromine in 5 ml of carbon tetrachloride and the mixture allowed to stand for 48 h. The solvent was removed *in vacuo* and the residual solid taken up in 20 ml of carbon tetrachloride. To the solution 1 ml of pyridine was added and the mixture allowed to stand for 3 h. The precipitated solid was collected and taken up in 50 ml of hot water. Addition of a few drops of concentrated nitric acid and cooling gave a precipitate, which was collected. Recrystallization from methanol–ether gave 0.7 g (72%) of *N-[1-(2,3,3-triphenyl)prop-2-enyl]pyridinium nitrate*, **70**.

Addition of Bromonium Nitrate to (Z)-β-Deuterostyrene in Chloroform–Pyridine

The reaction was carried out by the general procedure discussed before. Thus reaction of 3.78 g (0.036 mol) of (*Z*)-β-deuterostyrene with bromonium nitrate (0.04 mol) in 60 ml of chloroform and 25 ml of pyridine at 0 °C for 3 h and work-up by the usual procedure gave 4.5 g (46%) of *threo-2-deutero-2-bromo-1-phenylethyl nitrate*, **29**. The nmr spectrum $\delta_{TMS}(CDCl_3)$ 3.62 (d, further split by H–D coupling, 1H, —CHD—Br, J_{CH-CHD} = 7.5 Hz), 6.0 (d, 1H, —CH—ONO_2, $J_{CH-CH-D}$ = 7.5 Hz), 7.37 (m, 5H, Ph). The ir spectrum ν_{max} (liquid film) 1630, 1275 cm^{-1} ($—ONO_2$).

From the ether insoluble residue and by the procedure described for the addition of iodonium nitrate to (*Z*)-β-deuterostyrene was isolated 2.5 g (26.5%) of *(Z)-N-[1-(2-deutero-1-phenyl)ethyl]pyridinium bromide*, **30**. The nmr spectrum $\delta_{TMS}((CD_3)_2SO)$ 6.43 (s, 1H, $=C<^{H}_{D}$), 7.45 (m, 5H, Ph), 8.17–9.27 (m, 5H, pyridine hydrogens).

Received June 8, 1976

WILLIAM F. REYNOLDS, PAUL G. MEZEY, and GORDON K. HAMER. Can. J. Chem. **55**, 522 (1977).

Ab initio (STO-3G minimal basis set) molecular orbital calculations on 4-substituted styrenes and CH_3X–C_2H_4 pairs indicate that Δq_H (the charge density difference between β-vinyl protons) provides a direct theoretical measure of the field effect of a polar substituent. $\Sigma q_C\pi$, the total substituent-induced π electron density change in styrene provides a theoretical measure of the resonance effect of the substituent. Δq_H and $\Sigma q_C\pi$ provide the basis of a theoretical dual substituent parameter scale, T_F and T_R^0. This scale compares very closely with experimental DSP scales, indicating the latter scales are fundamentally valid. The calculations also indicate that field effects and σ inductive effects do not show parallel trends. It is concluded that field effects are more important than σ inductive effects except at very close range. Individual carbon π electron densities reflect both resonances effects and polar π inductive effects.

WILLIAM F. REYNOLDS, PAUL G. MEZEY et GORDON K. HAMER. Can. J. Chem. **55**, 522 (1977).

Des calculs *ab initio* d'orbitales moléculaires (base minimale STO/3G) sur des styrènes substitués en position 4 et sur des paires CH_3X–C_2H_4 indiquent que le Δq_H (différence dans la densité de charge entre les protons vinyliques β) fournit une mesure théorique directe de l'effet de champ d'un substituant polaire. La valeur $\Sigma q_C\pi$, qui correspond au changement total dans la densité des électrons π qui est induit par les substituants du styrène, fournit une mesure théorique de l'effet de résonance du substituant. On utilise Δq_H et $\Sigma q_C\pi$ comme base d'une échelle théorique double pour les substituants impliquant deux paramètres, T_F et T_R^0. Cette échelle se compare très bien avec les échelles expérimentales de DSP indiquant que cette dernière échelle est valide sur une base fondamentale. Les calculs indiquent aussi que les effets de champs et les effets inductifs σ ne montrent pas des tendances parallèles. On en conclut que les effets de champs sont plus importants que les effets inductifs σ, excepté à une très courte distance. Les densités d'électrons π sur chacun des carbones individuelles sont un reflet des effets combinés de résonance et d'induction polaire des électrons π.

Introduction

There are two main dual substituent parameter (DSP) scales which are claimed to divide Hammett σ constants into field/inductive and resonance substituent parameters; the σ_I–σ_R scale of Taft and co-workers (ref. 1 and references therein) and the *F*–*R* scale of Swain and Lupton (2). These DSP scales have been used to investigate substituent effects upon reaction rates, equilibrium constants, spectroscopic parameters, and calculated electron densities in aromatic molecules (3–6). While detailed statistical analyses have been presented to justify both the σ_I–σ_R scale (1) and the *F*–*R* scale (2), both DSP scales have been seriously criticized. The most important criticisms involve the criteria used for the separation of the field/inductive and resonance parameters. For example, *R* constants were evaluated assuming $R = 0$ for the $N(CH_3)_3^+$ group (2). Several groups have pointed out that this is not strictly valid (7–9). Similarly, the evaluation of σ_R values has been questioned on the grounds that it involved arbitrary (8) and possibly dubious (10) assumptions. Dewar *et al.* have particularly criticized the use of ^{19}F chemical shifts in fluorobenzenes in establishing the σ_I–σ_R scale (10). If valid, this criticism would cast particular doubt on the σ_R^0 scale which is largely based on ^{19}F chemical shifts (1). In addition, it has been claimed field parameters evaluated from aliphatic systems cannot be used in aromatic systems (11); a criticism which would cast considerable doubt on the validity of the *F* scale (2). Finally, σ_R values for individual substituents have been criticized (12).

4-Substituted styrenes have geometric charac-

[1]Present address: Department of Chemistry, McGill University, Montreal, P.Q.

teristics which allow separation of field and resonance effects (13). Consequently, we decided to carry out *ab initio* calculations on 4-substituted styrenes, using an STO/3G minimal basis set (14) and a standard geometry for the styrene system. The major purpose of this investigation was to provide a check on the validity of experimental DSP scales, based on what we hoped would prove to be an unambiguous theoretical separation of field and resonance effects. A secondary purpose was to derive a theoretical DSP scale which would apply to calculations at this level of approximation.

Since the styrene derivatives contained eight to twelve heavy atoms, the choices of minimal basis set and fixed geometries were both necessitated by cost considerations. However, we were confident that STO-3G calculations based upon fixed geometries would reproduce charge density differences with sufficient accuracy to satisfy the main purpose of the investigation. This view was supported by the fact that analogous calculations have reproduced substituent effects upon protonation energies (15) and chemical shifts (6) of aromatic derivatives with good accuracy.

Results and Discussion

Carbon and vinyl hydrogen charge densities for 4-substituted styrenes are listed in Table 1. Calculations were performed for planar and pyramidal NH_2 groups, OH, CHO, CH_3, F, CF_3, CN, and NO_2. These correspond to the minimal substituent set of Taft (1) with planar NH_2, OH, and CHO substituting for $N(CH_3)_2$, OCH_3, and $COCH_3$ for reasons of computational economy.

As a test of the accuracy of the calculated charge densities, the π charge densities for C(1) and C(β) were correlated with previously reported ^{13}C chemical shifts for these carbons (13)[2]

$$\delta_{C(1)} = 180 q_{C(1)}\pi \quad (r = 0.988)$$

$$\delta_{C(\beta)} = 193 q_{C(\beta)}\pi \quad (r = 0.987)$$

where r = correlation coefficient. Both the very good correlations and the fact that the scaling factors relating chemical shifts and charge densities are consistent with previously reported scaling factors of 160–200 ppm/π electron (17, 18) indicate that the calculations reproduce charge densities with sufficient accuracy for the purpose of the investigation as anticipated.

Since styrene is planar, electronic effects can be separated into σ and π contributions. The resonance effect of a substituent can be defined in terms of $\sum q_C\pi$, the extent of charge transfer between the substituent and the π electron system (19). Correlations of $\sum q_C\pi$ with σ_R^0 and R have been respectively reported for substituted benzenes (19, 6) and 4-substituted styrenes (13). The unique feature of the styrene system is that it also allows isolation of field effects. Through-bond effects should affect the two β vinyl hydrogen charge densities equally. However, there should be greater field-induced polarization of C(β)—H(C) than C(β)—H(B) due to the geometric arrangement of these bonds (Fig. 1). Therefore Δq_H ($\equiv q_{H(C)} - q_{H(B)}$) should in principle provide a direct measure of the electric field effect of the substituent.

There is one possible weakness in this argument. There are large π electron density changes in the phenyl group, primarily due to resonance effects. This could lead to a secondary field effect (similar to the mesomeric field effect of Dewar *et al.* (10)) which would affect $q_{H(B)}$ and $q_{H(C)}$ unequally. If so, then there would be a small resonance contribution to Δq_H and consequently an imperfect separation of field and resonance effects. To eliminate possible secondary field effects due to the phenyl group, calculations were performed for CH_3X–C_2H_4 pairs (isolated molecule or IM calculation), main-

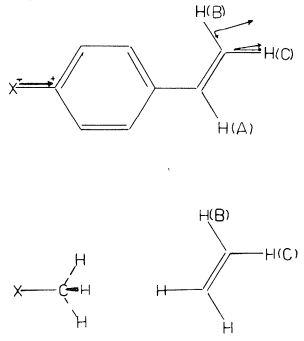

FIG. 1. 4-Substituted styrene and CH_3X–C_2H_4 pairs showing proton labelling. Arrows show electric field vectors and resolved components of field along C—H bonds.

[2] ^{13}C chemical shifts for aromatic carbons which are remote (*e.g.* 3 or more bonds removed) from a substituent are believed to accurately reflect changes in ground state carbon π electron density (see ref. 16 and references therein).

TABLE 1. Calculated charge densities ($\times 10^4$) for 4-substituted styrenes[a] relative to the unsubstituted derivative (negative sign corresponds to increased electron density)

taining the same orientation for the C—X bond and ethylene as in styrene (Fig. 1). Results are summarized in Table 2.

There is an excellent linear relationship between values of Δq_H in the two systems:

[1] $\Delta q_H(\text{styrene}) = 1.54\Delta q_H(\text{IM}) \quad (r = 0.997)$

This demonstrates that Δq_H in styrene is insensitive to secondary field effects.[3] A linear relationship was also noted between Δq_H (styrene) and μ_X(IM), the dipole moment component along the C—X bond in the IM calculation ($r = 0.988$). An even better correlation coefficient ($r = 0.996$) was obtained for a correlation of Δq_H with $\mu_X(\text{IM})/r^3$ where r is the distance from the mid-point of the polar substituent bond to the mid-point of C(β)—H(C). This is exactly what would be expected for a dipolar electric field effect since the field varies as r^{-3} (20). These results confirm that Δq_H provides a direct measure of the dipolar electric field effect of the substituent. Therefore, Δq_H and $\sum q_C\pi$ are independent parameters which can be used to separate and estimate field and resonance effects of substituents in the styrene system.

Values of these parameters are listed in Table 1. To facilitate comparison of experimental and theoretical DSP scales, Δq_H and $\sum q_C\pi$ were scaled to produce a theoretical DSP scale labelled T_F and T_R^0.[4] Δq_H for OH was scaled to +0.27 and $\sum q_C\pi$ for OH to −0.45, corresponding to σ_I and σ_R^0 for OCH_3 (1). T_F and T_R^0 values are listed in Table 3, along with σ_I and σ_R^0 values.

In general, there is very good agreement between T_F and σ_I and particularly between T_R^0 and σ_R^0 (excluding T_F values for CN and NO_2, there is a standard deviation of less than 0.05σ units between theoretical and experimental DSP scales). The use of planar NH_2, OH, and CHO in place of $N(CH_3)_2$, OCH_3, and $COCH_3$ does not appear to introduce any significant error. A similar close parallel exists if Δq_H and $\sum q_C\pi$

[3]The slope of 1.54 reflects the enhancement of the field effect when transmitted through the cavity of the polarizable phenyl group (13).

[4]It is labelled a T_R^0 scale since the vinyl group is a neutral probe which is equally capable of the accepting or donating electrons (13). The scaling is justified since the absolute value of any substituent parameter scale is arbitrarily defined. OH was chosen to define the scale since it is a group with substantial field and resonance effects (1). F could have equally well been used for this purpose.

TABLE 2. Calculated charge densities ($\times 10^4$) for CH_3X–C_2H_4 pairs, expressed relative to calculation for CH_4–C_2H_4 (negative sign indicates increased electron density)

are scaled to allow comparison with F and R. We believe that the styrene calculations provide an unambiguous theoretical separation of field and resonance effects. While the procedures used to derive the σ_I–σ_R and F–R scales have been criticized (see Introduction), *the results in Table 3 demonstrate that these scales are fundamentally valid.*

While the calculations reproduce the general pattern of substituent effects for CN and NO_2 (strong electron-withdrawing field effect and weak electron-withdrawing resonance effect), they appear to over-estimate the field effects of these substituents. By contrast the field effect of F is slightly underestimated. One possible explanation is that the deviations were due to the use of non-optimized substituent geometries. This seemed improbable since the gross change in substituent geometry from planar to pyramidal NH_2 (involving a change of 0.4 Å in hydrogen atom coordinates) changes T_F for this group by only 0.08σ units. However, to check this point, full geometry optimization was performed for CH_3F and CH_3CN. When the fully optimized geometries were used in the IM calculations, Δq_H for F changed from $+9.7 \times 10^{-4}$ to $+10.6 \times 10^{-4}$ while Δq_H for the CN derivative changed from $+21.4 \times 10^{-4}$ to $+21.8 \times 10^{-4}$. This corresponds to slightly better agreement between T_F and σ_I for F but slightly worse for CN. Thus it appears that the deviations noted in Table 3 are not due to the use of incorrect substituent geometries. Rather, we believe that these discrepancies are due to the size limitation of the basis set. In particular, there are indications from previous *ab initio* studies with STO-3G basis sets that the nitrogen atom AO basis set is not matching in quality to those for other heavy atoms.[5] This could cause a lower degree of precision in calculating molecules with one or more nitrogen-heavy atom bonds (particularly with respect to bond polarities). However, it should be stressed again that the failure of the calculations to quantitatively predict the field effects of CN and NO_2 groups does not significantly detract from the overall pattern of good agreement noted in Table 3.

TABLE 3. Derived T_F and T_R^0 substituent parameters based on STO-3G charge densities for 4-substituted styrenes and σ_I–σ_R^0 values for corresponding substituents

Substituent	T_F[a]	T_R^0[b]	σ_I[c]	σ_R^0

In addition to demonstrating the fundamental validity of experimental DSP scales, the data in Tables 1 and 2 provide further insight into the nature of polar substituent effects. First, since CH_3X is an aliphatic derivative eq. 1 suggests that the same polar substituent parameters can be used for aliphatic and aromatic compounds, contrary to the conclusions of Sjöström and Wold (11). Second, there appears to be little relation between the field effect and the σ inductive effect of the substituent. The field effect is measured by Δq_H (or T_F) while the σ inductive effect of the substituent can be estimated from $\sum q\sigma$ the substituent-induced change in σ electron density for the styrene system (Table 1). As noted previously (19, 24), the σ inductive effect primarily depends on the electronegativity of the directly bonded substituent atom, *e.g.* C < N < O < F, although other substituent atoms have some effect (particularly for CN and NO_2). By contrast, the field effect is proportional to the σ dipole moment of the substituent group as a whole (see Table 2), *e.g.* $NH_2 < OH < F \lesssim CF_3 < CN < NO_2$. As shown in Table 3, there is a close parallel between σ_I and the theoretically calculated field effect (T_F). Since polar substituent effects generally follow the σ_I order (1), this indicates that these polar effects are basically field effects rather than σ inductive effects, in agreement with previous conclusions (25). While the σ inductive effect induces large charge density changes, the calculations suggest that it

[5]According to the quality characterization of basis sets by their logarithmic energy gradients, $G_l = \partial E/\partial \log \alpha$ (where α is the orbital exponent) (21), the nitrogen STO/3G basis set appears to be off balance ($|G| = 1.52$). Convergence difficulties in the SCF procedure, that also possibly indicate lack of balance in the basis set system, have been observed with unusually high frequency for molecules containing nitrogen bonded to other heavy atoms (see *e.g.* refs. 22, 23).

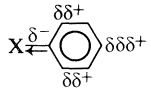
is a localized effect which attenuates very rapidly with increasing number of bonds. The main inductive charge density changes in the styrene σ system occur at the directly bonded carbon C(4). At other carbons, $q_C\sigma$ appears to primarily mirror the π charge density change (see Table 1). CNDO/2 calculations for 4-substituted 1-fluorobicyclo[2.2.2]octanes have also indicated that the σ inductive effect is a localized phenomenon with very little effect beyond three carbons removed from the substituent (19).

In addition to field and σ inductive effects, polar substituent effects can also be transmitted via perturbation of the π electron system. Substituent effects which alter the π electron system without charge transfer to or from the π electron system are labelled π inductive effects (5, 26). Two types of polar π inductive effects are believed to be important. The first is field-induced polarization of the π electron system (π_F in the terminology of Topsom (5)), an effect which was previously shown to be present in both aromatic derivatives (13, 16, 27, 28) and vinyl groups (13). The IM calculations provide further evidence for the π_F effect since electron withdrawing groups polarize the ethylene π bond towards the substituent, decreasing π electron density at C(β). Changes in ethylene π electron density correlate with Δq_H or T_F:

$$q_{C(\beta)}\pi(\text{ethylene}) = 1.50\Delta q_H(\text{styrene}) \quad (r = 0.998)$$

This demonstrates that the same field substituent parameters can be used in investigations of through-space field effects and π polarization effects, π_F.

The second type of π inductive effect is the inductoelectromeric effect (29) (π_σ in the terminology of Topsom (5)). An electronegative group can withdraw electrons from the directly bonded phenyl carbon via the C—X σ bond, *i.e.* a σ inductive effect. This may induce a redistribution of the phenyl π electron system as represented by **1** (with a possible small increase in π electron



1

density at the *meta* carbons). By contrast with π_F, the π_σ effect should not be directly proportional to polar substituent constants such as σ_I, since field and σ inductive effects are not proportional to one another.

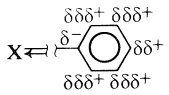
TABLE 4. Correlations of carbon charge densities for 4-substituted styrenes with T_F and T_R^0

Parameter	Value		
	ρ_F[a]	ρ_R[a]	r[b]
$q_{C(4)}\pi$	−0.089	−0.086	0.986
$q_{C(3)}\pi$	+0.023	+0.149	0.996
$q_{C(2)}\pi$	+0.002	−0.049	0.994
$q_{C(1)}\pi$	+0.033	+0.096	0.997
$q_{C(\alpha)}\pi$	−0.011	−0.017	0.998
$q_{C(\beta)}\pi$	+0.023	+0.039	0.998

[a]Weighting coefficients for equation $q_C\pi = \rho_F T_F + \rho_R T_R^0$.
[b]Correlation coefficient.

While $\sum q_C\pi$ provides a measure of the resonance effect of the substituent group, individual carbon charge densities should reflect both resonance effects and π inductive effects of the type discussed above. Correlations of individual π charge densities with T_F and T_R^0 confirm this (see Table 4).[6]

The ρ_R values for the various carbons show the expected alternation in sign and decrease in magnitude with increasing distance, *i.e.* C(4) > C(2) > C(α) and C(3) > C(1) > C(β). The pattern of ρ_F values is more complex. The expected pattern of π charge density changes associated with the π_σ effect has been illustrated schematically in **1**. When a polar substituent is separated from a phenyl group by either an aliphatic linkage (16) or a second phenyl group (29), it polarizes the entire phenyl π electron system towards the substituent (π_F effect) in a manner which can be represented schematically by **2**.



2

However, in the styrene system where the polar group is attached directly to the ring, the pattern of ρ_F values appears to be a composite of **1** and **2**. Inductive withdrawal of σ electron density from C(4) may cause a short-range perturbation of the π electron system, particularly at C(4) and C(3) (π_σ effect). This would account for the relatively poorer correlation at C(4) (since the π_σ effect is

[6]The sum of ρ_F values, $\Sigma\rho_F = 0.001$. This indicates that there is no π charge transfer component to the T_F scale (by contrast $\Sigma\rho_R = 0.232$). Therefore, the ρ_F values for individual carbons must reflect π inductive effects, *i.e.* effects which redistribute π electron density without π charge transfer to or from the substituent.

not linearly related to T_F). At longer ranges, the π_F effect seems to be dominant. It has already been shown that the vinyl ^{13}C chemical shifts in 4-substituted styrenes can be accounted for in terms of both through-space polarization of the vinyl group (as in the IM calculations, see Table 2) and polarization of the entire π electron system from phenyl to vinyl groups (13), resulting in a large field dependence for $\delta_{C(\beta)}$. This π_F effect also can account for the large ρ_F value for $q_{C(\beta)}\pi$ (Table 4).

In summary, STO-3G minimal basis set calculations for 4-substituted styrenes allow the separation and isolation of resonance effects and field effects of individual substituents. This has allowed estimation of theoretical field, T_F, and resonance, T_R^0, substituent parameters. Comparison with experimental DSP scales indicates that the latter are fundamentally valid. Individual carbon charge densities not only reflect resonance (or π charge transfer) effects but also effects by which polar substituents induce redistribution of π electron density without charge transfer to or from the substituent, *i.e.* π inductive effects. The calculations also demonstrate σ inductive effects and field effects are not parallel phenomena and that the former is important only at short range.

Details of Calculations

Throughout this study an STO–3G basis set as contracted to a minimal basis (14) was used. All *ab initio* SCF MO calculations were carried out on an IBM 370/165 computer using a version of the Gaussian 70 program (30).

Standard geometries were used for the styrene system (r_{C-H} = 1.08 Å, r_{C-C}(phenyl) = 1.40 Å, $r_{C(1)-C(\alpha)}$ = 1.46 Å, $r_{C(\alpha)-C(\beta)}$ = 1.35 Å, all angles = 120°) and for the IM calculations (r_{C-H} = 1.09 Å and tetrahedral angles for CH_3X). Substituent geometries were chosen to reproduce experimental geometries as accurately as possible. Full details of substituent geometries have been given elsewhere (31).

Substituent-induced ^{1}H chemical shifts for 4-substituted (2,2-dichlorocyclopropyl)benzenes: further evidence for intramolecular electric field effects on ^{1}H chemical shifts

ROBERT H. KOHLER AND WILLIAM F. REYNOLDS

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 8, 1976

ROBERT H. KOHLER and WILLIAM F. REYNOLDS. Can. J. Chem. **55**, 530 (1977).

Correlations of cyclopropyl proton chemical shifts for 4-substituted (2,2-dichlorocyclopropyl)-benzenes with σ_I and σ_R^0 provide evidence that these chemical shifts reflect direct field effects and weak phenyl–cyclopropyl conjugative interactions. Corrections for variable ring current effects due to substituent-induced changes in conformation improve the individual correlations but do not alter the basic pattern of results. Correlation of the β cyclopropyl ^{1}H chemical shift difference with σ_I, with calculated hydrogen electron densities, and with calculated electric field components provides further strong evidence for a field effect on ^{1}H chemical shifts.

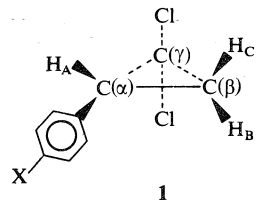
ROBERT H. KOHLER et WILLIAM F. REYNOLDS. Can. J. Chem. **55**, 530 (1977).

Des corrélations entre les déplacements chimiques des protons du cyclopropyle de (dichloro-2,2 cyclopropyl-) benzènes substitués en position 4 avec σ_I et σ_R^0 suggèrent que ces déplacements chimiques sont un reflet d'effets directs de champs et d'interactions faibles de conjugaison du phényle avec le cyclopropyle. Des corrections pour les effets de courant de cycle qui varient à cause de changements, induits par les substituants, dans la conformation améliorent les corrélations individuelles mais n'altèrent pas les tendances de base des résultats. La corrélation des différences dans les déplacements chimiques du ^{1}H en β du cyclopropyle avec le σ_I, avec les densités électroniques calculées pour l'hydrogène et avec les composantes calculées pour les champs électriques suggèrent encore plus fortement l'influence d'effet de champ sur les déplacements chimiques de ^{1}H.

[Traduit par le journal]

Introduction

Substituent-induced ^{1}H chemical shifts in 4-substituted styrenes (1) and phenylacetylenes (2) can be accounted for in terms of through-space field effects, resonance effects, and π inductive (polarization) effects. In each case, the side chain is conjugated with the phenyl group. Investigations of 4-substituted α-alkylstyrenes showed that the transmission of resonance and π inductive effects to the side chain decreased as conjugation decreased (3). Consequently, it was decided to extend these investigations to systems in which side chain conjugation was weak, in an attempt to provide further evidence for the existence of through-space electric field effects on ^{1}H chemical shifts. The compounds chosen for this purpose were 4-substituted (2,2-dichlorocyclopropyl)benzenes. These seemed particularly useful compounds for investigation since, as in the case of styrenes (1), the two β hydrogens have different geometries with respect to the 4-X phenyl group, thus potentially allowing the isolation of through-space effects from through bond effects:



1

In addition, these compounds could easily be synthesized by dichlorocarbene addition to the corresponding styrenes (4). The ABC spectrum for the dichlorocyclopropyl group is also considerably easier to analyze than the ABB′CC′ spectrum which would be given by cyclopropylbenzene derivatives. Finally, very unusual substituent-induced ^{1}H chemical shifts had been reported for **1** (5), results which suggested to us that a more thorough investigation of this system was desirable.

Results and Discussion

^{1}H chemical shifts for 4-substituted derivatives of **1** are given in Table 1. Correlations of these shifts with the dual substituent parameters σ_I and σ_R^0 are also given in Table 1, along with correla-

tions of the ^{1}H chemical shifts for 4-substituted styrenes, for comparison. σ_I should measure the polar (field/inductive) effect of the substituent while σ_R^0 measures the resonance (conjugative) effect of the substituent (6). Through-bond (resonance and inductive) effects should affect $\delta_{H(B)}$ and $\delta_{H(C)}$ equally since H(B) and H(C) are separated by the substituent by the same number of bonds. However, $\delta_{H(C)}$ should be more sensitive to through-space electric field effects since the substituent-induced electric field acts more directly along the C(β)—H(C) bond than along C(β)—H(B) (the field effect depends upon the magnitude of the electric field acting along a C—H bond (7)). This greater field effect for $\delta_{H(C)}$ should be reflected by a greater ρ_I value for $\delta_{H(C)}$ than $\delta_{H(B)}$ in the σ_I,σ_R correlations:

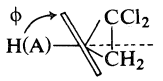
$$[1] \qquad \delta = \rho_I\sigma_I + \rho_R\sigma_R^0 + \delta_0$$

In fact ρ_I is greater for $\delta_{H(C)}$ than $\delta_{H(B)}$, indicating the presence of a significant electric field effect. By contrast ρ_R is similar for $\delta_{H(B)}$ and $\delta_{H(C)}$, as expected for a through-bond effect.

ρ_R values are slightly greater for $\delta_{H(B)}$ and $\delta_{H(C)}$ than for $\delta_{H(A)}$, as observed in a more pronounced manner for styrene. In the latter case, this reflects conjugative interactions which alter π electron density at C(β) (1). Therefore, it appears that there is weak phenyl–cyclopropyl conjugation in **1**, with the cyclopropyl C—C bonds having some π character.[1] This is consistent with previous evidence for phenyl–cyclopropyl conjugation (11–14), including the observation that the cyclopropyl group is a weaker transmitter of electronic effects than an alkene function (14).

In spite of the generally reasonable ρ_I and ρ_R values in the σ_I,σ_R^0 correlations, the correlation of $(\delta_{H(C)} - \delta_{H(B)})$ with both σ_I and σ_I,σ_R^0 is mediocre.

(2,2-Dichlorocyclopropyl)benzene is a conformationally mobile system. On the basis of Kerr constant and dipole moment measurements, Aroney *et al.* estimated that the equilibrium angle of twist, ϕ, of the phenyl group was 60° (15).



2

This represents a balance between conjugative effects which favor ϕ = 0° (as observed in electron diffraction studies of cyclopropylbenzene (11)) and steric interactions (particularly phenyl–Cl interactions). It was also concluded that *para* substituents could alter ϕ by as much as 7° (15), presumably by altering phenyl–cyclopropyl conjugation. Since variation in ϕ would significantly alter the ring current effect of the phenyl group at H(A), H(B), and H(C), it was felt that this might account for the poor correlations for $(\delta_{H(C)} - \delta_{H(B)})$. Consequently, we undertook CNDO/2 energy minimization calculations for **1**, varying ϕ from 45° to 75°. The calculations predict a shallow minimum about ϕ = 60° with the shape of the potential well being substituent-dependent. Typical results are presented in Fig. 1.[2] The apparent success of the calculation in predicting

[1]In the ^{1}H spectra of 4-substituted ethylbenzene the CH_3 protons are about 40% as sensitive to substituent effects as the CH_2 protons (8–10). This is presumably the pattern characteristic of non-conjugating alkyl groups.

[2]The complete set of calculated energy levels is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

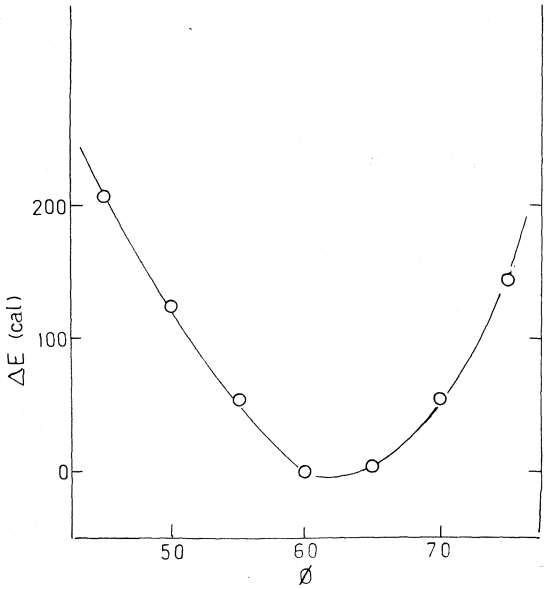


FIG. 1. Energy (cal/mol) for unsubstituted 2,2-(dichlorocyclopropyl)benzene as a function of the angle ϕ between C(α)—H and the plane of the phenyl group.

the energy minimum is in itself interesting since CNDO/2 calculations for conjugated molecules often fail to predict the most stable conformations (16). The calculations may be better in cases like this where steric interactions dominate.

A weight-averaged angle of twist, $\langle\phi\rangle$, was estimated for each derivative by first determining the relative population, N_ϕ, at each angle ϕ, using the Boltzmann expression

$$[2] \qquad N_\phi/N_0 = e^{-(E_\phi - E_0)/RT}$$

where E_0 and N_0 refer to the angle of minimum energy and T was taken as 300 K, corresponding to the probe temperature, then calculating $\langle\phi\rangle$ from

$$[3] \qquad \langle\phi\rangle = \sum^{n} N_\phi \cdot \phi \Big/ \sum^{n} N_\phi$$

Estimated values of $\langle\phi\rangle$ are given in Table 2. These are generally smaller for electron-withdrawing substituents, corresponding to increased phenyl–cyclopropyl conjugation (as expected since the cyclopropyl group is an electron donor group (14, 17)). Ring current corrections were estimated by Johnson–Bovey calculations (18), using a program written for that purpose (19). The ring current correction was estimated for the average angle $\langle\phi\rangle$. This may introduce a small error since the ring current correction varies in a non-linear fashion with angle. However, since the ring current calculations may not be quantitatively accurate (20), this approximation seemed justified. Corrected chemical shifts are given in Table 3. The correlations of $(\delta_{H(C)} - \delta_{H(B)})$ with σ_I and with $\sigma_I - \sigma_R^0$ are both improved by the ring current corrections (see Table 3). Comparison of the correlations in Tables 1 and 3 shows that substituent-induced changes in conformation introduce a spurious[3] resonance contribution to $\delta_{H(B)}$ which contributes to the poor correlation for $(\delta_{H(C)} - \delta_{H(B)})$. The corrected correlations indicate very similar field effects upon $(\delta_{H(C)} - \delta_{H(B)})$ as in the case of styrenes (Table 1). The significantly improved correlation coefficients suggests that the ring current corrections must be at least semi-quantitatively correct, in spite of the approximations noted above. This is supported by the equations given below. It is also important to note that the fundamental conclusions concerning greater field effects for $\delta_{H(C)}$ and greater resonance effects for β than α hydrogens are unaltered by corrections.

$(\delta_{H(C)} - \delta_{H(B)})$ primarily reflects field effects. The electric field effect due to a substituent can be estimated from the Buckingham equation (7):

$$[4] \qquad \Delta\delta_H = AE_z$$

where E_z is the field component acting along the C—H bond (7) and A is a constant with a value in the range $2.9–5.5 \times 10^{-12}$ (esu)$^{-1}$ (3). Conse-

[a]Correction factor to compensate for ring current change (relative to unsubstituted derivative) due to angle change in Table 2. The correction factor is opposite in sign to the ring current change to remove the effect of this change, *e.g.* the decrease in $\langle\phi\rangle$ for the NO_2 derivative leads to a positive (lowfield) shift for $\delta_{H(B)}$. Therefore the correction factor is negative.
[b]^1H chemical shift including $\Delta\delta_{RC}$.
[c]Correction factors ranged from 0.0003 ppm for $N(CH_3)_2$ to −0.0004 ppm for NO_2.
[d]Weighting factors for correlation equation $\delta = \rho_I\sigma_I + \rho_R\sigma_R^0 + \delta_0$.
[e]Correlation coefficient.
[f]Correlation with σ_I only.

quently, $(\delta_{H(C)} - \delta_{H(B)})_{corr}$ was correlated with ΔE_z(H(C)—H(B)), the difference in substituent-induced electric fields acting along the two C(β)—H bonds. Field components were estimated using aliphatic σ bond moments (21) for the substituents[4] and using previously listed parameters (19). Values of ΔE_z(H(C)—H(B)) are given in Table 4. The following correlation was obtained:

$$[5]\quad (\delta_{H(C)} - \delta_{H(B)})_{corr} = 4.31 \times 10^{-12}\Delta E_z(H(C)—H(B)) \quad (r = 0.970)$$

Both the reasonable value of A and the good correlation coefficient indicate that $\delta_{H(C)} - \delta_{H(B)}$ reflects field effects. (A much worse correlation was obtained for the uncorrected shifts (r = 0.836).)

Hydrogen charge densities were also estimated by CNDO/2 molecular orbital calculations (see Table 4). Correlation of $(\delta_{H(C)} - \delta_{H(B)})_{corr}$ *vs.* $(q_{H(C)} - q_{H(B)})$ yielded:

$$[6]\quad (\delta_{H(C)} - \delta_{H(B)})_{corr} = 26.9\Delta(q_{H(C)} - q_{H(B)}) \quad (r = 0.976)$$

The scaling factor of 27 ppm/1*s* electron is in good agreement with previously reported values which range from 18 to 30 ppm/1*s* electron (23, 24). Since through-space field effects alter hydrogen charge density by polarizing C—H bonds (1), [6] provides further evidence for the presence of these effects. Thus correlations of $\delta_{H(C)} - \delta_{H(B)}$ (corrected for changes in ring current effects) with field/inductive substituent parameters, with calculated electric field components, and with hydrogen charge densities all indicate the presence of a through-space field effect. This provides further proof for the importance of intramolecular field effects on ^1H chemical shifts.

Both the corrected correlations for **1** (Table 3) and the styrene correlations (Table 1) show a slightly greater ρ_R value for $\delta_{H(C)}$ than for $\delta_{H(B)}$. This could be taken as an indication of a secondary field effect due to the large resonance-induced π electron density changes at C(1). Due to the bond geometries, $\delta_{H(C)}$ should be slightly more sensitive than $\delta_{H(B)}$ to a secondary field effect, thus possibly accounting the slight larger

[4]*Ab initio* calculations on 4-substituted styrenes demonstrate that the field effect of the substituent is directly proportional to (aliphatic) σ bond moment of the substituent (22).

[a]Difference in electric field components (due to polar substituent) acting along C(β)—H(C) and C(β)—H(B).
[b]Charge density difference between H(C) and H(B), expressed relative to the charge density difference in the pattern compound.
[c]Charge density at C(1), relative to the parent compound (negative sign indicates increased electron density).
[d]Difference in electric field components due to both the polar substituent (dipolar field) and charge density change at C(1) (monopolar field).
[e]Charge densities scaled by ratio of experimental/calculated dipole moment in benzonitrile and nitrobenzene. Charge densities were scaled since CNDO/2 calculations respectively underestimate and overestimate electronic effects of CN and NO_2 groups (1, 2). Scaled charge densities were used in correlations.

ρ_R value for $\delta_{H(C)}$. A similar explanation has been advanced to account for the chemical shifts of $\delta_{H(A)}$ in styrene (1) and the methyl ^1H chemical shifts in trimethylanilinium ions (25, 26). On the other hand, *ab initio* calculations on styrene provide no evidence for the existence of a secondary field effect (22).

To investigate this point further, an attempt was made to calculate secondary field effects. Since field effects drop off rapidly with distance and since both resonance (1) and π polarization effects (27) cause much larger π electron density changes at C(1) than C(2,6), the secondary field effect was estimated assuming a point charge at C(1). Electron densities were estimated by CNDO/2 calculations (see Table 4). Values of $\sum \Delta E_z$(H(C)—H(B)), the sum of direct (dipolar) and secondary (monopolar) field components, are also given in Table 4. However, the correlation of this parameter with $(\delta_{H(C)} - \delta_{H(B)})_{corr}$ was worse than the correlation in [5] ($r = 0.952$ as compared to 0.970 for [5]). A similar observation was made when an attempt was made to estimate secondary field effects in styrene. This leads to the conclusion that secondary field effects are not important in these systems, in agreement with the results of *ab initio* calculations on styrene derivatives (22). However, there may be inductive transmission of the effects of electron density changes at C(1) to the side chain protons, since $q_{H(A)}$ (and $\delta_{H(A)}$) in styrene appear to reflect the electron density changes at C(1) (1). While field effects appear to dominate over inductive effects at long range (28, 29), calculations on aliphatic compounds suggest that inductive effects may be important at distances up to three bonds (29). The smaller shifts for CH_3 protons than CH_2 protons for ethylbenzenes (8–10) are consistent with inductive effects, possibly combined with weak hyperconjugative interactions of the alkyl and phenyl groups (25). The apparent resonance contribution to $\delta_{H(C)} - \delta_{H(B)}$ may be due to small substituent induced distortions of the side-chain group. The difference in ρ_R values for $\delta_{H(B)} - \delta_{H(C)}$ in each case corresponds to a resonance contribution of *ca.* 0.01 ppm. Due to the close proximity of H(B) to the phenyl group in each system, very minor substituent induced changes in bond length and/or bond angle could lead to this apparent resonance contribution.

As mentioned in the Introduction Mal'tsev *et al.* reported very unusual ^1H chemical shifts for derivatives of **1** (5). They found that $\delta_{H(A)}$, $\delta_{H(B)}$, and $\delta_{H(C)}$ for the unsubstituted derivative were to high field of the corresponding protons in both nitro and dimethylamino derivatives (5). Their data and ours are compared in Table 5. The $N(\cdot CH_3)_2$ and NO_2 derivatives show the expected low field shifts associated with the transfer of a polar solute from C_6D_{12} to CCl_4 (30) but the unsubstituted derivative shows an anomalous high field shift. However, Cox and Smith reported data for the unsubstituted derivative in CCl_4 (31) which are much more consistent with the other data. This suggests that there may be significant experimental errors in the data of Mal'tsev *et al.* (5). Certainly our ^1H chemical shift data show no similar anomalies.

Experimental

Four-substituted (2,2-dichlorocyclopropyl)benzenes were synthesized by addition of dichlorocarbene to the corresponding 4-substituted styrene, using the method of Makoszka and Wawrzyniewiecz (4). The styrenes were either obtained commercially or were available from a previous investigation (1). The (2,2-dichlorocyclopropyl)-benzene derivatives were characterized by their nmr spectra which showed characteristic ABC multiplets for the cyclopropyl protons and AA'BB' spectra for the *para*-disubstituted benzene group.

^1H spectra were obtained using procedures identical to those previously reported (1). It is estimated that individual chemical shifts are accurate to 0.001 ppm. CNDO/2 calculations were carried out on an IBM 370/165 computer using a standard program (32) and standard geometries (33). The energy minimization calculations were carried out using previously reported geometries for cyclopropylbenzenes (11, 15).

^{13}C Chemical shifts for 4-substituted phenylvinyl ethers, sulfides, and selenides: evidence concerning the relative abilities of O, S, and Se to transmit electronic effects

WILLIAM F. REYNOLDS AND ROBERT A. MCCLELLAND
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 8, 1976

WILLIAM F. REYNOLDS and ROBERT A. MCCLELLAND. Can. J. Chem. **55**, 536 (1977).

^{13}C chemical shifts for β carbons of 4-substituted phenylvinyl ethers, sulfides, and selenides plus previous data for styrenes indicate that the relative ability of link groups to transmit electronic effects between conjugative groups is S > Se ≈ — > O (where — refers to no link group, *i.e.* styrene). However, marked deviations from additivity are noted for C(1) chemical shifts which may indicate that O deactivates the ring to electronic substituent effects while S and Se activate the ring. If this explanation is valid then the actual ability of the link atom to transmit electronic effects is — > O > S > Se.

WILLIAM F. REYNOLDS et ROBERT A. MCCLELLAND. Can. J. Chem. **55**, 536 (1977).

Les déplacements chimiques du carbone-13 des carbones-β d'éthers sulfures et sélénures de vinyle et de phényles substitués en position 4, utilisés de concert avec des données antérieures pour les styrènes, indiquent que l'habilité relative des groupes liants à transmettre les effets électroniques entre les groupes conjugués est S > Se ≈ — > O (où — se réfère au cas ou il n'y a pas de groupe liant, *i.e.* le styrène). Toutefois on note des déviations importantes de l'addivité pour les déplacements chimiques du C(1); ces déviations peuvent indiquer que l'oxygène désactive le cycle par rapport aux effets électroniques des substituants alors que le S et le Se activent le cycle. Si cette explication est valide, l'habilité réelle des groupes liants à transmettre les effets électroniques serait — > O > S > Se.

[Traduit par le journal]

There has been considerable interest in the relative abilities of O, S and, to a lesser extent, Se to transmit electronic effects, particularly in the case where these atoms act as a link or bridge between two conjugative groups. The initial investigation was by Litvinenko who investigated the reactivity of the amino group to acylation in compounds of the type $X—C_6H_4—Y—C_6H_4NH_2$ where X is the variable substituent and Y = O, S, etc. (1). He concluded that the ability to transmit electronic substituent effects decreased in the order S > Se > O > —.[1] Subsequent investigations involving ^1H (2, 3), ^{19}F (4, 5), and ^{13}C (6) nmr spectroscopy supported the order S > O ≳ — in cases involving conjugative transmission of substituent effects. Perhaps the most striking feature of these investigations is the general conclusion that interposition of O or S between two conjugative groups apparently enhances the transmission of electronic effects relative to the case where the two groups are directly linked, a phenomenon which has been referred to as a positive bridge effect (1) or superconductivity (2).

The most recent investigation involved ^1H and ^{13}C chemical shifts measurements for phenylvinyl ethers and sulfides (6). However, measurements were carried out for a limited number of derivatives (including only three *para* derivatives in each case) and ^{13}C chemical shifts were measured for neat liquids. Since we had a large number of phenylvinyl ethers, sulfides, and selenides as part of another investigation (7), a further more careful ^{13}C nmr spectroscopic investigation of this system seemed desirable. It was hoped that this would provide further evidence concerning the relative position of Se on the transmission scale and possibly also help to elucidate the origin of the positive bridge effect. In fact, the investigation has shown that the previous order S > Se > O > — possibly does not reflect the ability of these linking groups to transmit substituent effects.

Results and Discussion

^{13}C chemical shifts for 4-substituted phenylvinyl ethers, sulfides, and selenides are listed

[1]Throughout this manuscript the symbol — refers to the case where the two conjugative groups are directly linked, *i.e.* biphenyl in this case.

[a]In ppm to low field for tetramethylsilane.
[b]Chemical shift relative to unsubstituted derivative.
[c]Overlapping peaks.
[d]Assignments uncertain.

in Table 1. Based on both the maximum range of substituent effects upon β carbon ^{13}C chemical shifts (from NH_2 to NO_2 derivatives) and on correlations of β carbon chemical shifts against one another, the apparent order of transmission of substituent effects is S > Se ≈ — > O (see Table 2). This parallels the order of Litvinenko (1) and subsequent workers (2–6) with respect to O, S, and Se. However, the directly bonded system (styrene) appears to be more efficient at transmitting substituent effects than previously deduced from systems of the type X—C_6H_4—Y—C_6H_4Z (1, 3–6). It could be argued that the present system supplies a more reliable order since styrene (8) (and presumably the other derivatives) are planar while the systems X—C_6H_4—Y—C_6H_4Z undergo uncertain conformational changes as Y is varied (9).

However, inspection of the phenyl carbon chemical shifts indicates an additional complexity. The effect of substituents on C(1) chemical shifts varies markedly from system to system (Table 1). Taft and co-workers have recently reported similar marked deviations from additivity of ^{13}C chemical shifts in *para*-disubstituted benzenes (10). They suggested that σ electron-withdrawing groups deactivate the ring towards both π-inductive and resonance effects of substituents (10). The obvious corollary of this is that σ-donor groups should activate the phenyl group; a trend which is apparent in ^{13}C chemical shift data for 4-substituted trimethylsilylbenzenes (11). On this basis, it would appear from our results that —SCH=CH_2 and —SeCH=CH_2 groups both activate the phenyl groups (see $\delta\Delta_{C(1)}$). While S and Se are normally considered to have electronegativities similar to carbon (12), it is possible that the polarizabilities of these atoms contribute to their apparent activating effect.[2] By contrast —OCH=CH_2 appears to be a de-

[2]Lynch has collected data for a large number of *p*-disubstituted benzenes and has concluded that the deviations from additivity for the ^{13}C chemical shifts of the carbon *para* to the variable substituent depend upon the polarizability of the fixed substituent (13). The other ^{13}C chemical shifts show little deviation from additivity.

TABLE 2. Various parameters which measure the relative abilities of O, S, and Se to transmit electronic effects, relative to the case where the two conjugative groups are directly linked

activating group (as observed for the σ-withdrawing OCH_3 group (10)) while $-CH{=}CH_2$ is essentially neutral (the total range of *para* carbon chemical shifts from NH_2 to NO_2 derivatives of benzene is 16.0 ppm (10) compared to 15.0 ppm for C(1) in styrene, see Table 2).

Taking our results in conjunction with those of Taft and co-workers (10), total range of substituent-induced *para* carbon chemical shifts (from NH_2 to NO_2) varies from 9.9 ppm in 4-substituted fluorobenzenes to 25.1 ppm in 4-substituted phenylvinyl sulfides and selenides. This raises the possibility that these deviations from non-additivity reflect variations in the sensitivity of ^{13}C chemical shifts to electron density changes rather than variations in electron density changes. Put in empirical terms, this would indicate that the scaling factor relating ^{13}C chemical shifts to π electron density changes is altered from the normal value of 160–200 ppm/π electron (14, 15) by the effect of the directly bonded atom. In support of this view, *ab initio* (STO/3G minimal basis set) calculations for 4-substituted fluorobenzenes and substituted benzenes indicate much smaller deviations from additivity than noted from the ^{13}C chemical shifts (16). However, these calculations assume a regular hexagonal structure for the benzene rings. Available structural data indicates that substituents can induce significant distortions of the benzene ring in poly-substituted benzenes (17) which might result in non-additive electronic effects not predicted by calculations based on idealized geometries. Obviously this is an area worthy of further investigation, although geometry-optimization calculations on poly-substituted benzenes would be prohibitively expensive.

If it is assumed that these non-additive effects on ^{13}C chemical shifts accurately reflect ground state electron density changes (previous investigations of ^{13}C chemical shifts in benzene derivatives support this view (18–21)), the phenyl carbon chemical shift data allow an alternative interpretation of transmission of electronic effects by O, S, and Se. The effect of the link group can be divided into two parts: (*1*) its ability to activate (or deactivate) the directly bonded carbon of phenyl group towards electronic substituent effects and (*2*) the ability to transmit these effects to the second conjugative group. On this basis, a better measure of the actual ability of the substituent group to transmit electronic effects should be the ratio of C(β) to C(1) chemical shifts. These ratios are given in Table 2. They indicate a much different order of transmission ability, *i.e.* — > O > S > Se. If this approach is correct, it indicates that the apparent 'superconducting' or 'positive bridge' effect of S and Se is not really a transmission effect but rather reflects the ability of these linking atoms to activate the phenyl group towards substituent effects. In many ways, this seems more satisfactory than an explanation involving positive bridge effects. It is also consistent with previous conclusions that O is more capable of conjugative interactions than S (22).

Assuming that the phenyl carbon shifts parallel electronic effects, a more detailed picture of these electronic effects can be obtained by correlating ^{13}C chemical shifts for C(1), C(α), and C(β) with Taft's σ_I and σ_R^0 substituent constants (23) (Table 3). These correlations indicate that C(β) and C(1) show different relative sensitivities to field/inductive and resonance effects. Considering the resonance

TABLE 3. Correlations of C(1), C(α), and C(β) chemical shifts with σ_I and σ_R^0

Y	C	ρ_I[b]	ρ_R[b]	λ[c]	r[d]
—[a]	C(1)	5.62	18.47	3.29	0.996

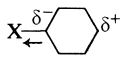
[a]Experimental data from ref. 18. Correlations were based on the same substituents as for phenylvinyl sulfide. Inclusion of other substituents gives slight different values (19).
[b]Weighting coefficients for equation $\delta = \rho_I\sigma_I + \rho_R\sigma_R^0 + \delta^0$.
[c]$\lambda \equiv \rho_R/\rho_I$.
[d]Correlation coefficient.

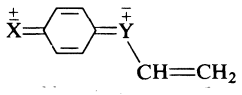
effects first, the ρ_R values indicate an enhancement of resonance effects at C(1) on going from phenylvinyl ether to the sulfide and selenide analogues. The correlations for the vinyl group indicate the alternation in sign and magnitude of ρ_R which seems typical of resonance effects. Since C(β) and C(1) have different sensitivities to field/inductive and resonance effects, $\rho_R C(\beta)/\rho_R C(1)$ should provide a better measure of the ability of the bridge group to transmit conjugative effects. These ratios are given in Table 2. While quantitatively different from $\Delta\Delta_{C(\beta)}/\Delta\Delta_{C(1)}$, they predict the same order.

There is an even greater variation of ρ_I values for C(1) since these vary by a factor of three. Taft and co-workers also noted greater variations in ρ_I than ρ_R (10). We have previously suggested that polar substituents can polarize the entire π electron system towards the substituent (20)



1

Taft *et al.* suggested that σ-withdrawing groups *para* to X would inhibit this polarization by making it more difficult to remove π electron density from the *para* carbon (while σ donor groups should enhance the polarization) (10). Our results are consistent with this explanation. In this regard, it may or may not[3] be significant that carbons *ortho* to the variable substituent show much smaller deviations from additivity (19, 20*b* and Table 1) than in the case of the *para* carbon. This is consistent with π polarization effects, **1**, as well as resonance effects, **2**, involving quininoid structures:



2

It is interesting to note that C(β) chemical shifts show a large sensitivity to field/inductive effects (in fact ρ_I is larger for C(β) than for C(1) in phenylvinyl ether). This indicates the present of polar π inductive effects, *i.e.* effects which can alter the π electron distribution without charge transfer to or from the substituent. We have previously shown that π polarization in styrene involves two components (1, 24); polarization of the entire conjugated system from vinyl to phenyl groups and through space polarization of the vinyl π bond towards the substituent. The latter effect can account for the relatively large sensitivity of C(β) to field/inductive effects. Although the vinyl group is further removed from the substituent in ethers, sulfides, and selenides than in styrene, it is aligned more directly with the C—X bond axis:

3

4

[3]It may not be significant because it could equally well be argued that this demonstrated that the deviations from additivity for the *para* carbon reflected different sensitivities of these carbons to electron density changes.

Since the field effect depends upon the field component acting along the C—C bond (25, 26), this more favorable alignment of the bond should compensate for the greater distance.

Conclusions

Results of ^{13}C chemical shift measurements for 4-substituted phenylvinyl ethers, sulfides, and selenides along with previous data for styrenes indicate that the order of transmission of substituent effects to the β carbon is S > Se ≈ — > O. However, the C(1) chemical shifts show marked deviations from additivity which can be interpreted as indicating that S and Se activate the phenyl group towards substituent effects while O deactivates this group, consistent with previous findings. If it is accepted that the phenyl carbon shifts accurately reflect ground state electron density changes (the evidence is indecisive on this point), then the actual ability of the link group to transmit conjugative effects is in the order — > O > S > Se. In any case, the very marked deviations from additivity noted in this and a previous investigation suggest that great care should be exercised in assigning ^{13}C chemical shifts in polysubstituted benzene derivatives on the basis of addivity.

Experimental

The phenylvinyl ethers, sulfides, and selenides were synthesized as part of another investigation. Details of the syntheses will be reported elsewhere (7). All compounds gave characteristic ^1H nmr spectra with an ABC vinyl spectrum and an A′A′BB′ aromatic spectrum.

^{13}C chemical shifts were measured at 25.16 MHz on a Varian XL-100 spectrometer, using 0.4 *M* solutions in CCl_4 with 8% C_6D_{12} as internal lock. All peak positions were measured relative to internal tetramethylsilane with an estimated maximum experimental error of 0.04 ppm. $\delta_{C(4)}$, $\delta_{(13)}$, and $\delta_{C(2)}$ were assigned on the basis of relative intensities, from off-resonance decoupling experiments and by assuming additivity of ^{13}C chemical shifts. These carbons show little deviation from additivity (10, 13, 19, 20*b*). The first two criteria were used to assign $\delta_{C(1)}$, $\delta_{C(\alpha)}$, and $\delta_{C(\beta)}$.

Proportionality relationships in the carbon-13 nuclear magnetic resonance spectra of *para*-disubstituted benzenes: a new interpretation of non-additive behavior

BRIAN MAURICE LYNCH

Department of Chemistry, Saint Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received September 7, 1976

BRIAN MAURICE LYNCH. Can. J. Chem. **55**, 541 (1977).

The carbon-13 chemical shifts for 214 distinct sites (the 4-carbons) in 24 sets of 1-X,4-Y-disubstituted benzenes and for 270 distinct sites (the 1- and 2-carbons) in 16 of these sets are reproduced with excellent precision (correlation coefficients 0.99 or greater) either by linear proportionality relationships with the appropriate substituent chemical shift (scs) in a monosubstituted benzene (for the 4-carbons), or by simple additivity relationships with the scs (for the 1- and 2-carbons).

Inconsistencies are pointed out in a theoretical rationalization of 4-carbon shifts used in discussing the non-additivity of these shifts in terms of a DSP approach, whereas the above one-parameter approach yields sets of proportionality constants (slopes of scs relative to Y = H) following systematic trends which are interpreted as results of changes in the excitation energy term at carbon-4 dependent upon the ionization potential of the group Y. There is no significant association between the scs slopes and sets of calculated CNDO/2 electron densities for these *para*-disubstituted benzenes.

BRIAN MAURICE LYNCH. Can. J. Chem. **55**, 541 (1977).

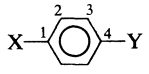
On reproduit avec une excellente précision (coefficient de corrélation de 0.99 ou plus) les déplacements chimiques de ^{13}C de 214 sites distincts (les carbones-4) dans 24 groupes de benzènes disubstitutés 1-X, 4-Y et pour 270 sites distincts (des carbones-1 et -2) dans 16 de ces groupes; ces reproductions sont effectuées soit par des relations de proportionnalité linéaire avec des déplacements chimiques du substituants appropriées (dcs) dans les benzènes monosubstitués (pour les carbones-4) ou par des règles d'additivités simples avec les dcs (pour les carbones-1 et -2).

On met en relief des inconsistances dans la rationalisation théorique des déplacements chimiques des carbone-4 utilisée dans la discussion de la non-additivité de ces déplacements en termes d'une approche DSP alors que l'approche utilisant un paramètre qui est mentionnée plus haut conduit à des groupes de constantes de proportionnalité (pentes de dcs relatives à Y = H) qui suivent des tendances systématiques que l'on interprète comme résultant de changements dans le terme d'énergie d'excitation au niveau du carbone 4 en fonction du potentiel d'ionisation du groupe Y. Il n'y a aucune association importante entre les pentes des dcs et les groupes de densités électroniques calculées par la méthode CNDO/2 pour ces benzènes *para*-disubstitués.

[Traduit par le journal]

Introduction

Additivity parameters (substituent chemical shifts, scs) derived from the carbon-13 shifts of monosubstituted benzenes have been very useful in signal assignments in polysubstituted compounds (for examples, see refs. 1–5), but a cautionary note is sounded through a recent communication of Bromilow, Brownlee, Topsom, and Taft (6), reporting marked non-additivity in *para*-substituent ^{13}C shifts for the 4-carbon in compounds of type **1**



1

with Y a fixed substituent (NO_2, F, OMe, NH_2, CN) and X a minimum basis set of substituents (7) (X = NH_2, OMe, F, Me, H, CF_3, CN, NO_2 for each Y). Taft's group analysed the influence of the Y substituent on the *para*-scs through the dual substituent parameter (DSP) approach (7), and through a suggested parallelism between the influence of Y upon the ρ_I value and upon the STO-3G *ab initio* σ-electron density at the 4-carbon of the monosubstituted benzene (*i.e.* for X = H), their results were interpreted to indicate that the σ-charge density at the 4-carbon regulates the ease of π-polarization by the distant *para*-substituent X.

Their interpretation leads to the prediction that σ-donor Y groups will show amplified *para*-

scs by comparison with Y = H, with increased ρ_I and ρ_R values. Published data for a set of phenyltrimethylsilanes (8) support this prediction, but a limited data set for bromobenzenes (measured as neat liquids) (5) also show amplified *para*-scs, and it seems inconceivable to classify a halogen as a σ-donor. Furthermore, plots of the published 4-carbon shifts for the bromobenzenes against σ_R or σ_R^0 are linear, with σ_I influences apparently absent ($\rho_I \simeq 0$). The evident failure of the Y = Br set to fit the logic of the Taft model requires a more searching examination of the reported non-additivity patterns, through examination of additional Y groups, extension of the range of X substituents, and different modelling assumptions.

In this paper, I use an alternative single-parameter approach to explore non-additivity patterns in the scs for the 1-, 2-, and 4-carbons with an extended range of substituents Y, including the following (the number of X substituents in the data set follows the Y descriptor): Br, 10; I, 8; Cl, 10; CF_3, 9; Me, 10; Et, 9; $CH{:}CH_2$, 11; $CMe{:}CH_2$, 8; $C(CMe_3){:}CH_2$, 9; $C{\equiv}CH$, 11; C_6H_5, 8; CMe_3, 8; $SiMe_3$, 7; $GeMe_3$, 6; $SnMe_3$, 7; $CO.NH_2$, 7; $O.CH{:}CH_2$, 8; $S.CH{:}CH_2$, 9; $Se.CH{:}CH_2$, 9. The single-parameter approach analyses the scs patterns in terms of δ–δ relationships (*cf.* 4, 9) as in eq. 1:

$$\delta_1 = a_0 + b\delta_0 \quad [1]$$

where δ_1 is the carbon chemical shift for a given position and substituent X, a_0 the shift calculated for the parent species with X = H, and the δ_0 are the set of carbon scs for a given position for monosubstituted benzenes with Y = H; b is the slope parameter. Such an approach is equivalent to the use of the scs in monosubstituted benzenes as *substituent constants*. Equation 1 could reproduce experimental results through additivity relationships with $b = 1$, or through *proportionality relationships*, with $b < 1$ or $b > 1$.

Results and Discussion

Table 1 assembles the results of fitting the data of Taft's group and the extended data sets of Y substituents listed above to eq. 1 to the various 4-carbon scs, using the parent δ_0 values assembled in Table 2. Proportionality relationships of excellent precision are evident for all the sets, and the data of Taft's group are reproduced almost as precisely by eq. 1 as by the DSP treatment. Two instances with evidence of saturation of substituent effects (Y = X = NO_2, scs = 2.77 ppm and Y = CF_3, X = NO_2, scs 2.74 ppm) were omitted from the analyses. Data-fitting to eq. 1 was also made for the 1- and 2-carbons for all Y substituents except those cited in ref. 6, using the appropriate scs from Table 2. For these 16 substituents and 270 sites, additivity relationships prevail ($b = 1.00 \pm 0.05$) with excellent precision (minimum correlation coefficient, 0.993). Since the goodness of fit to eq. 1 is either comparable to that for the DSP analysis (for the 4-carbons) or superior to it (*ortho*-substituents (2-carbons) are very poorly correlated by the DSP analysis (6)), one must prefer the simpler treatment unless the DSP analysis has a superior theoretical basis. The cited data for bromobenzenes (5) indicate significant deficiencies in the approach separating σ_I and σ_R as applied to carbon-13 substituent chemical shifts.

Equation 1 is remarkably successful in organizing the shift data, and the systematic trends in relative slopes, including the orders

$$F < OMe < NH_2, NO_2 < H < Me$$

$$F < H < Cl < Br < I$$

$$CMe_3 < SiMe_3 < GeMe_3 < SnMe_3$$

suggest that dependences on physical quantities attributable to the key atom of the Y substituent, such as electronegativity or ionization potential will indicate an appropriate theoretical model accounting for these trends.

The most obvious proposal is that the differing electronegativities of the key atoms of the Y groups lead to differences in their abilities to modify the charge redistribution resulting from the presence of the X substituent; for example, the smaller slope for Y = F than for Y = H would then indicate a smaller range of variation in electron density at the 4-carbon for Y = F as compared with Y = H. Note that the validity of this proposal depends upon the unproved assumption of uniform response of the 4-carbon shift (in ppm/electron) throughout the data sets, while in fact, comparisons of *ab initio* calculations of electron densities for *para*-substituted fluorobenzenes and the corresponding monosubstituted benzenes (10) indicate that variations in the electron densities approximately parallel one another. This pattern of behavior is also observed with more approximate (CNDO/2)

[a]Unless specified otherwise, shifts were determined for dilute solutions (approximately 0.4 *M*) in $CDCl_3$. The basic set of 4-carbon shifts relative to benzene is taken from ref. 6, and is reproduced in Table 2. Secondary shifts for other substituents were used in analyses if some of these substituents were missing from the available data sets; these are also listed in Table 2.

[b]Product of the standard deviation of the slope, s_b, and the t distribution for the 95% confidence level for the n data points; for a discussion of this indication of goodness of fit, see ref. 18.

[c]Standard deviation ($s_{x,y}$) from linear relationship, divided by the root-mean-square value of the n data points.

[d]Data points for X = NO_2 were omitted from the analysis.

[e]Personal communication from Professor R. W. Taft.

[f]Data in CCl_4 solvent.

[g]G. K. Hamer and W. F. Reynolds, personal communication.

[h]Data in acetone solvent.

[i]Data for 50% (w/v or v/v) solutions in CCl_4.

[j]Data for pure liquids plus 10% (v/v) benzene.

[k]Data for the benzamides are for solutions in DMSO-d_6. Concentrations of the solutions were in the range 0.1–0.4 *M*.

calculations on these two series (11), and my own CNDO/2 calculations of electron densities for a variety of *para*-disubstituted benzenes (X = H, F, NH_2, Me, NO_2, OH, CN; Y = H, NH_2, NO_2, Me, C≡CH, OH, $CO.NH_2$) yield results for the 4-carbon electron densities approximately paralleling the set Y = H (see Table 3), but displaced in direction and magnitude as a function of the Y group. Since there is no significant association ($r = -0.50$, corresponding to a vector angle of 120°) between the ratios of electron density variations and the observed scs slopes of Table 1, I conclude tentatively that the differing slopes are not a consequence of differing ranges of ground-state variations in electron density. This conclusion requires reinforcement through geometry-optimized *ab initio* calculations for full confidence in the electron densities, but the electronegativity-controlled influence of which the above model is an example would require that groups Y with key atoms of similar electronegativities should exhibit similar amplifications of scs influences. This is not so: the electronegativities of carbon and of iodine are accepted generally (12) as closely similar, yet the scs slopes are: Me, 1.103; I, 1.474.

A more successful accounting of the slope trends is obtained by postulating changes in the excitation energy term ΔE of the paramagnetic shielding expression for carbon-13 shifts[1] (Karplus and Pople (13)). Since the deviations from scs additivity do not extend beyond the 4-carbon (that bearing the substituent Y) any such changes must be highly local (Karplus and Pople (13) suggest the possibility of localized excitations). I propose that the relative energies of the ground-state and excited-state configurations of carbon-4 are modified by interaction with the key atom of the substituent Y, and that the extent of this modification will be determined largely by the ionization potential of Y.

My proposal predicts that the scs slope will be a linear function of the reciprocal of the ionization potential of the key atom of Y, and for the sets Y = F, H, Cl, Br, I and Y = CMe_3, $SiMe_3$, $GeMe_3$, $SnMe_3$, linear associations of high quality are evident between these quantities (Table 4). Further, the scs slopes for a set of groups with varying ligand nature and number (Y = F, OMe, NH_2, NO_2, C:CH_2, Me) also follow the sequence of the reciprocals of the calculated valence-state ionization potentials (*cf.* Hinze and Jaffe (14)) although the precision of the linear relationship is less. Finally, the large amplifications noted for Y = S.CH:CH_2 and Y = Se.CH:CH_2 (Table 1) by comparison with Y = O.CH:CH_2 and Y = CH:CH_2 may be interpreted (in addition to the low ionization potentials of S and Se) by a model for these groups akin to a perturbed allyl anion substituent ($\bar{C}$H.CH:CH_2), in which low-lying (albeit unoccupied) orbitals of the substituents interact strongly with carbon-4.

Conclusions

The major features of the chemical shift patterns at the 4-carbon in *para*-disubstituted benzenes, and the trends in scs effects, are well explained by the proposed modification of the excitation energy term. A test of the proposed localized nature of the modification is that scs additivity would be predicted for the 1- and for the 2-carbons in the *para*-disubstituted series (as is observed, see above) and also for the 2-, 3-, 4-, and 6-carbons in 1-Y,3-X-disubstituted benzenes. The limited available data support this latter prediction, which I hope to test in the near future with a wider data base. At present, it appears that the small scs at the 3-position in 1-X,4-Y-disubstituted benzenes exhibit an insufficient range to allow development of statistically significant correlation models.

Experimental

Materials

The substituted benzamides were prepared by ammonolysis of the commercially available benzoyl chlorides,

[1]A referee comments that correlations of appropriate inverse ionization potentials with proton and with fluorine chemical shifts have been made previously by Schaefer *et al.* (17), but these do not relate directly to my approach. My quoted data sets are concerned with the effect of ipso-substituent (Y) variation in modifying the scs influence of *para*-substituents X on the ipso-carbon (4-carbon) shifts *relative* to the species where Y = H, rather than upon the influence of variation of Y upon the ipso chemical shift where X = H. A study of this latter influence would be directly analogous to the examples studied by Schaefer *et al.*; unfortunately, our preliminary work (B. M. Lynch and J. J. MacDonald, unpublished data) indicates that the influence of Y upon the ipso shift includes (at least) contributions from steric, electron-density, and excitation-energy terms.

Vinyl sulfide hydrolysis

ROBERT A. MCCLELLAND

Department of Chemistry, University of Toronto, Scarborough College, West Hill, Ont., Canada M1C 1A4

Received July 27, 1976

ROBERT A. MCCLELLAND. Can. J. Chem. **55**, 548 (1977).

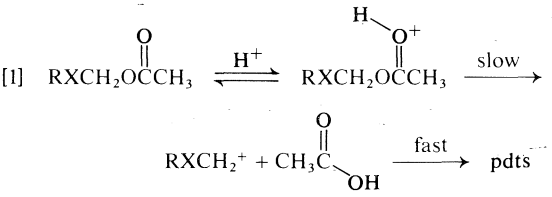
The hydrolysis of vinyl sulfides in acid solutions is shown to proceed via a mechanism analogous to that of vinyl ethers, with slow proton transfer to the carbon–carbon double bond to produce a sulfur stabilized carbonium ion. Relative rates of hydrolysis of compounds $RXCH{=}CH_2$ are CH_3S—, 41; CH_3O—, 1500; C_6H_5S—, 1; and C_6H_5O—, 10.5. This order is compared with that of other systems which produce similar stabilized carbonium ions.

ROBERT A. MCCLELLAND. Can. J. Chem. **55**, 548 (1977).

On montre que l'hydrolyse des sulfures de vinyle en solutions acides se produit par un mécanisme semblable à celui des éthers vinyliques impliquant un transfert lent de proton vers la double liaison carbone–carbone afin de produire un carbocation stabilisé par le soufre. Les vitesses relatives d'hydrolyse des composés $RXCH{=}CH_2$ sont: CH_3S—, 41; CH_3O—, 1500; C_6H_5S—, 1 et C_6H_5O—, 10.5. On compare cet ordre avec celui observé avec d'autres systèmes qui produisent des carbocations stabilisés de la même manière.

[Traduit par le journal]

A recent study (1, 2) of acylal and thioacylal hydrolysis allowed a comparison of the effects of oxygen and sulfur in a reaction generating an adjacent carbonium ion centre (reaction 1, X = O, S; R = Me, Ar),



this system showing a much closer reactivity between oxygen- and sulfur-containing compounds than that anticipated on the basis of previous results, for example, on the solvolysis of chloromethyl ethers and chloromethyl sulfides (3). For further comparison, we have turned to the acid-catalyzed hydrolysis of vinyl ethers and vinyl sulfides. Vinyl ethers are now well established (4) to undergo such hydrolyses with rate-determining proton transfer to the carbon–carbon double bond giving the intermediate oxycarbonium ion. Although no mechanistic study appears to have been carried out with vinyl sulfides, they should behave similarly, as, in fact, we will first establish. In particular, this report focuses on the hydrolysis of methyl vinyl sulfide and a series of aryl vinyl sulfides, along with their vinyl ether analogs, and a comparison of their relative reactivities in the light of the acylal–thioacylal study.

Experimental

Materials

Methyl vinyl sulfide was commercially available. Aryl vinyl ethers were prepared using a method similar to that employed previously (5). In a typical procedure, phenol (0.1 mol), ethylene bromide (0.2 mol), and sodium hydroxide (0.1 mol) were refluxed overnight with 250 ml of water. The resultant phenetoles were separated from the aqueous layer and purified by fractional distillation. These were dehydrobrominated by adding to 25 ml of dimethyl sulfoxide containing a slight excess of potassium *tert*-butoxide. Water (200 ml) was added and the vinyl ether extracted with ether and purified by vacuum distillation.

Aryl vinyl sulfides were prepared as follows. The benzenethiol (0.1 mol) and sulfuryl chloride (0.12 mol) were refluxed in 100 ml of carbon tetrachloride for 1 h, and the solvent and excess chloride removed on the rotary evaporator to yield the arylsulfenyl chloride (6). Addition of this reagent to ethylene (6) was accomplished by passing an excess of the olefin through a solution in methylene chloride. The solvent was again removed and the adduct was dehydrochlorinated with potassium hydroxide (slight excess) in refluxing 95% ethanol (*ca.* 2 h). After removal of much of the solvent and addition of water the vinyl sulfide was obtained by ether extraction and vacuum distillation.

The identity and purity of all compounds were established using ^1H and ^{13}C nmr spectroscopy; analysis of the ^{13}C nmr spectra has been reported separately (7). Boiling points of known compounds agreed with literature values (5, 8). New compounds gave satisfactory analyses.

Kinetic Measurements

All rates were obtained using uv spectroscopy at a wavelength corresponding to the greatest spectral change on hydrolysis (for methyl vinyl sulfide, λ = 225 nm; aryl vinyl ethers, 230–240, except 3-NO_2—, 280; 4-NO_2—, 330; aryl vinyl sulfides, 260–270, except 4-NO_2—, 340).

The spectrometer (Cary 16) was thermostatted at 25.0 or 50.0 °C (±0.1 °C) and the kinetic runs were initiated by addition of a solution of the substrate in methanol (0.005 ml) directly to the aqueous solution (2.5 ml) in the uv cell, final concentrations in substrate ranging from 10^{-4} to 10^{-3} *M*. First-order rate constants were evaluated as slopes of plots of ln $(A_t - A_\infty)$ or ln $(A_\infty - A_t)$ *vs.* time. Rate constants were reproducible to ±2%. Stable infinity values were obtained in all cases, and the first order plots were linear over the entire course of the reaction.

Products

The compounds studied here are expected to give acetaldehyde and the phenol or thiol on hydrolysis. In all cases quantitative conversion to the latter was verified by comparison of the uv spectrum of the products with that of an authentic sample. With methyl vinyl sulfide and phenyl vinyl sulfide conversion to both products was established by nmr spectroscopy, the solvent in this case being 0.5 *N* DCl in 80% dimethyl sulfoxide-d^6: 20% D_2O.

Results

Products

The hydrolysis of the vinyl sulfides studied here produces the expected products (9), acetaldehyde and thiol

$$CH_2{=}CHSR + H_2O \xrightarrow{H^+} CH_3\overset{O}{\overset{\|}{C}}H + RSH$$

Buffer Catalysis

Rates of hydrolysis of methyl vinyl sulfide were obtained at 50 °C in a series of buffer solutions of four different carboxylic acids. Using solutions of constant buffer ratio but differing total buffer concentration,[1] catalysis by the acid component of the buffer was found, with strict adherence to the rate law of eq. 2,

$$[2] \qquad k_{obs} = k_{H^+}[H^+] + k_{HA}[HA]$$

The catalytic coefficients are listed in Table 1, while the Bronsted plot is shown in Fig. 1. Ignoring the point for the hydronium ion (which displays a similar negative deviation in Bronsted plots involving vinyl ethers (13)) a Bronsted α value of 0.73 is obtained.

Solvent Isotope Effect

Hydrolysis of methyl vinyl sulfide in H_2O and D_2O at 25 °C using dilute HCl and DCl (0.01–0.1 *M*) as catalyst acid gave rate constants of 0.0210 M^{-1} s^{-1} for H_3O^+ and 0.00742 M^{-1} s^{-1} for D_3O^+; their ratio $k_{H_3O^+}/k_{D_3O^+}$ is 2.83.

Aryl Vinyl Ethers and Aryl Vinyl Sulfides

Rates of hydrolysis of a series of these compounds in 1 *N* HCl are reported in Table 2;

[1]Suitable corrections were made in this treatment for "buffer failure" with the stronger acids (10).

Discussion

Mechanism of Vinyl Sulfide Hydrolysis

All data are consistent with a mechanism of vinyl sulfide hydrolysis analogous to that of vinyl ethers (reaction 3)

$$[3] \quad RSCH{=}CH_2 \xrightarrow[\text{slow}]{H^+} RS\overset{+}{C}HCH_3 \xrightarrow[\text{fast}]{H_2O} \text{products}$$

Consistent with this are (*a*) the Hammett plot for the aryl vinyl sulfides (and its similarity to that of the aryl vinyl ethers (Fig. 2)), (*b*) the

solvent isotope effect, and (*c*) the general acid catalysis; (*b*) and (*c*) pointing to a process with a slow proton transfer and (*a*) consistent with the intermediacy of a thiocarbonium ion, $ArS\overset{+}{C}HCH_3$.

For comparison purposes, the Bronsted α value for ethyl vinyl ether hydrolysis (at 25 °C) is 0.70 based on carboxylic acid catalysts (13); k_{H^+}/k_{D^+} for this compound is 2.95 (14). Taking the data of a number of vinyl ethers, Kresge and co-workers have pointed out that there are rough correlations between the values of α (10) or k_{H^+}/k_{D^+} (14) and the relative reactivity. Within such a framework the two pieces of data for methyl vinyl sulfide are seen to fit quite well, although they would be more appropriate if the compound were slightly more reactive.

Oxygen vs. Sulfur

Table 3 summarizes relative rates for vinyl ethers and sulfides, along with those of the acylals and thioacylals (reaction 1). The latter data are based on the step-wise comparison previously described (1); the former data are based on direct comparison in 1 *N* HCl (Table 2), the number for methyl vinyl ether being obtained by comparing its hydrolysis rate in more dilute acid ($k_{H^+} = 0.76\ M^{-1}\ s^{-1}$ (15)) with that of methyl vinyl sulfide.

In comparing the two sets of data we note initially that the reactivity differences between the CH_3S— and C_6H_5S compounds are approximately the same, while this is not true for the oxygen analogs. More importantly in considering oxygen *vs.* sulfur there is no correlation, the oxygen-containing molecules in the $RXCH{=}CH_2$ series being substantially more reactive than their sulfur analogs, in comparison to similar cases in $RXCH_2OAc$. In explaining these behaviours a number of factors come to mind, none of which, in our opinion, satisfactorily accounts for all aspects of Table 3.

(i) Ground State Differences: One major difference in the two classes is that in the vinylic series the heteroatom is conjugatively linked with the reacting centre in the ground state; in other words there may be differences in ground state energy levels due to relative conjugative stabilizing effects in $RXCH{=}CH_2$. This explanation requires for our data that sulfur be better conjugated with the adjacent C=C than oxygen, and although there appears to be no

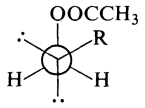
ρ(ArO)	−2.09	−3.0

[a]In 1 *N* HCl.
[b]References 1 and 2.

evidence either for or against this idea, it seems unattractive since sulfur is generally regarded as a poorer π donor. Certainly the higher nmr upfield shifts of the β-carbon and β-hydrogens in the vinyl ethers (7) is more consistent with the opposite, a greater conjugation with oxygen.

(ii) Steric Effects: A recent theoretical calculation (16) has predicted that phenyl vinyl ether is not completely planar. With longer C—S bond lengths the corresponding sulfide may be more so, giving rise again to an increased reactivity in the former due to less conjugative stabilization in the ground state. This might explain why the rate differences between MeO and C_6H_5O compounds in the two series do not correlate, while those for sulfur do.

In addition, following the reasoning of Deslongchamp (17), the conformation responsible for reaction in the acylal–thioacylal compounds must have a heteroatom lone pair aligned antiperiplanar to the leaving carboxylic acid, as below.



Front atom: O or S
R = methyl or aryl

With a *gauche* interaction between the methyl or aryl group and the carboxylate this is less stable than the conformer with these groups *anti*. The longer C—S bond lengths, however, make the *gauche* conformer more readily available in the thioacylals, and may then account for their enhanced reactivity.

(iii) Transition State Differences: Although similar cations are being formed in the two series, what is being measured here is not their stability but rather that of the transition state leading to them, so that the reactivity differences may be due to differences in detailed transition state structure. A pertinent observation here is that in general ethers are more basic than sulfides in dilute acid (18). This preference of oxygen molecules for the proton may be reflected in the vinylic rates, even though the proton is not being placed directly on the heteroatom. One can imagine perhaps that in the transition state the incoming solvated proton utilizes a heteroatom lone pair in its hydrogen bonding network, and oxygen is certainly more capable of this than sulfur (18).

In conclusion it is worth pointing out that although the differences in Table 2 appear large on a relative rate basis, on a free energy basis they are quite small, particularly when compared to the enormous rate variations observed in general for olefin hydration reactions (19) and $A_{A1}1$ acetate ester hydrolyses (1, 20).

The *para* substituent dependence of the internal rotational barrier in benzenethiol

TED SCHAEFER AND WILLIAM J. E. PARR[1]

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received August 19, 1976

TED SCHAEFER and WILLIAM J. E. PARR. Can. J. Chem. **55**, 552 (1977).

On the basis of the observed spin–spin coupling constants between the sulfhydryl and ring protons and a hindered rotor treatment of the twofold barrier to internal rotation in a series of *para* substituted benzenethiol derivatives, it is argued that V_2 is essentially zero in *p*-aminobenzenethiol and is 2.5 ± 0.2 kcal/mol in *p*-nitrobenzenethiol; having intermediate values for the methoxy, fluoro, methyl, and bromo derivatives in solution. The results are based on an assumed relationship between the four-bond and the fictitious six-bond couplings to the sulfhydryl proton. The conclusions are consistent with the observed magnitudes of the couplings over six and seven bonds, respectively, between the sulfhydryl proton and the fluorine nucleus and the methyl protons in the appropriate derivatives; as well as with the coupling between the sulfhydryl and methyl protons in 4-bromo-3-methylbenzenethiol. The experimental barriers are compared with *ab initio* molecular orbital calculations of their substituent dependence.

TED SCHAEFER et WILLIAM J. E. PARR. Can. J. Chem. **55**, 552 (1977).

En se basant sur les constantes de couplage spin–spin observées entre les protons sulfhydryles et les protons du cycle et en traitant comme un rotor empêché la barrière binaire à la rotation interne dans une série de benzènethiols substitués en *para*, on suggère que V_2 est pratiquement égal à zéro dans le *p*-aminobenzènethiol et à 2.5 ± 0.2 kcal/mol dans le *p*-nitrobenzènethiol; en solution, les valeurs sont intermédiaires pour les dérivés méthoxy-, fluoro-, méthyl- et bromo-. Ces résultats sont basés sur une relation hypothétique entre les couplages à travers quatre liaisons et sur les couplages fictifs à travers six liaisons pour le proton sulfhydryle. Les conclusions sont en accord avec les ordres de grandeur observés respectivement pour les couplages à travers six et sept liaisons entre le proton sulfhydryle et le noyau de fluor et les protons des méthyles dans des dérivés appropriés: ces conclusions sont aussi en accord avec le couplage entre les protons sulfhydryles et méthyles du bromo-4 méthyl-3 benzènethiol. On compare les barrières expérimentales avec les résultats de calculs *ab initio* d'orbitales moléculaires prédisant leur dépendance sur les substituants.

[Traduit par le journal]

Introduction

On the basis of the long-range spin–spin coupling constant over six bonds between the sulfhydryl proton and the ring proton in the *para* position, ${}^6J_p^{H,SH}$, of the analogy of its angular dependence to β-proton hyperfine interactions in radicals, and of the hyperconjugative overlap integrals involving C—H and S—H bonds, it was shown recently (1) that a maximum value of the barrier to internal rotation in benzenethiol in CCl_4 solution is 1.3 kcal/mol; although a final estimate of 1.1 ± 0.3 kcal/mol was suggested as covering most likely eventualities.

Now, in *p*-substituted phenol derivatives theory and experiment agree that substantial changes can occur in the internal rotational barrier of the phenol fragment (2), depending on the electron-withdrawing or donating characteristics of the *para* substituent. Because the internal barriers in both phenol and benzenethiol presumably arise from a partial loss of conjugation of the lone pair electrons with the π system of the ring, it is likely that *p*-substituted benzenethiol derivatives also display substituent dependent barriers to rotation of the sulfhydryl group.

Of course, ${}^6J_p^{H,SH}$ does not exist for these compounds. However, ${}^4J_o^{H,SH}$ is possibly roughly proportional to the nonexistent ${}^6J_p^{H,SH}$ so that the former may serve as an indicator of the internal barrier. Furthermore, in the *p*-fluoro and the *p*-methyl derivatives spin–spin coupling between the sulfhydryl proton, the ^{19}F nucleus, and the methyl protons constitutes a check on the deductions based on ${}^4J_o^{H,SH}$. This paper concerns itself with these questions.

Experimental

Five mole percent solutions in CCl_4 containing a little tetramethylsilane were degassed by the freeze–pump–thaw technique. For reasons of solubility or stability other

solvents were necessary for two compounds. Proton magnetic resonance spectra were calibrated in the frequency sweep mode on an HA-100 spectrometer at 305 K. Partial decoupling (3) and weak irradiation (4) experiments established the signs of coupling constants relative to $^3J_o^{H,F}$, $^3J_o^{H,H}$, and $^4J_o^{H,CH_3}$, known to be positive (5), positive (6), and negative (7), respectively. Intermolecular proton exchange was hindered by the presence of molecular sieve, although drying periods of a few weeks were sometimes necessary.

Ab initio molecular orbital calculations at the STO 3G level (8, 9) were performed on an IBM 370/158 computer system.

Results and Discussion

(1) Spectral Analyses

Spectral analyses using the program LAME (10, 11) were relatively straightforward. In Table 1 the full results of the analysis of the *p*-fluorobenzenethiol are given as an example. The standard deviations in the parameters suggest an accuracy of at least 0.02 Hz in the coupling constants of major interest in this paper. In Fig. 1 the spectrum of the sulfhydryl proton is displayed. Rather than tabulate the plethora of spectral parameters, we give in Table 2 the long-range coupling constants to sulfhydryl protons, methyl protons, and the ^{19}F nucleus for seven *p*-substituted benzenethiol derivatives. The chemical shifts of the sulfhydryl proton have been discussed for most of these compounds (12).

(2) Substituent Dependence of the Internal Barrier

(i) $^4J_o^{H,SH}$ and the Barriers

In previous work (1) it was argued that $^6J_p^{H,SH}$ in benzenethiol follows a $\sin^2\theta$ law as in [1],

$$[1] \qquad {}^6J_p^{H,SH} = {}^6J_{90}\sin^2\theta$$

where θ is the angle by which the S—H bond twists out of the aromatic plane. $^6J_{90}$ is the maxi-

mum value of $^6J_p^{H,SH}$ and the twofold potential hindering the internal barrier determines the average value of $\sin^2\theta$, which also depends on the reduced moment of inertia and the temperature. A value of $^6J_{90}$ of −1.06 Hz was preferred, a lower limit of −1.24 Hz being possible (1).

In the *para* derivatives in Table 2, $^6J_p^{H,SH}$ is not available. However, if it is assumed that $^4J_o^{H,SH}$ is dominated by a σ–π mechanism, this coupling may be used to estimate the barriers to internal rotation. In phenol (13), $|^6J_p^{H,OH}| \leq 0.03$ Hz and $|^4J_o^{H,OH}| \leq 0.07$ Hz, suggesting that $^4J_o^{H,OH}$ is nearly zero for the high barrier of 3.5 kcal/mol (14); the σ–π mechanism contributing little to the magnitude of the coupling. In toluene, for an effectively zero internal barrier (15), $^4J_o^{H,CH}/^6J_p^{H,CH} = 1.19$ (16), and if $^6J_p^{H,CH}$ is σ–π determined (17), it follows from the magnitudes of the coupling constants that the non σ–π component of $^4J_o^{H,CH}$ does not likely exceed −0.1 Hz.

In benzenethiol $^4J_o^{H,SH}$ is -0.38 ± 0.02 Hz and $^6J_p^{H,SH}$ is -0.33 ± 0.02 Hz. Therefore the ratio of the couplings lies between 1.29 and 1.03. The average is 1.16 and will be taken as holding for the compounds in Table 2. Either limit of this ratio shifts the ensuing barrier by 0.1 kcal/mol. $^6J_{90}$ is taken as −1.06 Hz and as −1.24 Hz, yielding two sets of average values of $\sin^2\theta$ in Table 3. These are related via the hindered rotor treatment (18) to the two sets of V_2, the twofold barrier to internal rotation, also given in Table 3.

(ii) Consistency of V_2 with $^7J_p^{SH,CH_3}$ and $^6J_p^{SH,CH_3}$ and $^6J_p^{F,SH}$

In toluene $^6J_p^{H,CH}$ is −0.62 Hz (16), while in *p*-xylene (19, 20) $^7J_p^{CH_3,CH_3}$ is +0.62 Hz. The sign reversal is expected for a σ–π mechanism. The magnitudes of the two numbers suggest that for the benzenethiol analogues, $^6J_p^{H,SH} = -^7J_p^{SH,CH_3}$ with the proviso, of course, that the methyl group changes the barrier. Therefore $^6J_p^{H,SH}$ here refers not to benzenethiol but to a fictitious $^6J_p^{H,SH}$ in *p*-methylbenzenethiol. In fact (Table 2), $^7J_p^{SH,CH_3}$ is 0.40 ± 0.02 Hz, whereas the assumed ratio of 1.16 for $^4J_o^{H,SH}/^6J_p^{H,SH}$ implies that the fictitious $^6J_p^{H,SH}$ is −0.38 Hz. In other words, the two V_2 values of 0.7 and 1.1 kcal/mol in Table 2 are consistent to within 0.1 kcal/mol with the magnitude of $^7J_p^{SH,CH_3}$ in *p*-methylbenzenethiol.

In *p*-fluorobenzenethiol, $^6J_p^{F,SH}$ is 1.01 ± 0.02 Hz. In *p*-fluorotoluene, $^6J_p^{F,CH_3}$ is 1.15 Hz (21). Assuming that the latter coupling determines the σ–π parameter for the C—F bond and that free methyl group rotation occurs (22), one has $\langle\sin^2\theta\rangle = 1.01/(2 \times 1.15) \times 1.06 = 0.414$; corresponding to a barrier of 0.5 kcal/mol, or a value of 0.3 kcal/mol if $^6J_{90} = -1.24$ kcal/mol. In other words, the values of 0.3 and 0.7 kcal/mol based on $^4J_o^{H,SH}$ in Table 3 are in agreement with the conclusions based on $^6J_p^{F,SH}$.

From our previous work (1) we prefer the lower values of V_2 in Table 3, although the mean values may well be as reliable. In any event, the error limits are probably near 0.2 kcal/mol.

(iii) Consistency of V_2 with $^6J_m^{SH,CH_3}$ in 4-Bromo-3-methylbenzenethiol

In *m*-xylene, $^6J_m^{CH_3,CH_3}$ is −0.21 Hz (19, 20). If this coupling is taken as the magnitude of the π electron contribution to $^5J_m^{H,CH_3}$ in toluene (19, 20), a test of the arguments concerning $^6J_{90}$

in the benzenethiol derivatives can be made as follows. In toluene and in *m*-xylene one has $\langle \sin^2 \theta \rangle$ as 0.5. In Table 3, $\langle \sin^2 \theta \rangle$ is 0.25 ± 0.02 for *p*-bromobenzenethiol, the limits being given by the extremes in $^6J_{90}$. Consequently $^6J_m^{SH,CH_3}$ in 4-bromo-3-methylbenzenethiol should be −0.21/2 or −0.11 ± 0.02 Hz. In fact, the analysis of the proton spectrum indicated a value of −0.13 ± 0.02 Hz.

Now, this compound is asymmetrical so that the internal barrier to rotation about the C—S bond may well contain a significant component which is not twofold in character. Furthermore, the presence of the methyl group may alter the magnitude of the barrier. However, if the barrier is sensitive to resonance interactions, the presence of the methyl group *meta* to the sulfhydryl group suggests a smaller perturbation than if it were placed *para* to the sulfhydryl moiety. Nevertheless the observed value of −0.13 ± 0.02 Hz for $^6J_p^{SH,CH_3}$ is consistent with the conclusions concerning the internal barrier in the *p*-substituted benzenethiol derivatives.

(iv) Comparison with p-Substituted Phenols

In Table 3, V_2 ranges from 2.5 kcal/mol for *p*-nitrobenzenethiol through 1.1 kcal/mol for benzenethiol to −0.2 kcal/mol for *p*-aminobenzenethiol, always with an accuracy of *ca.* 0.2 kcal/mol. Clearly, an electron-withdrawing group increases the barrier, presumably by increasing the conjugation[2] of the SH group with the aromatic nucleus in the planar form. Then the electron-donating groups lower the barrier by decreasing the double bond character of the C—S bond in the planar, ground state.

In the phenol analogue, the nitro group increases the internal barrier by 1 kcal/mol (2), the increase of 1.4 kcal/mol in *p*-nitrothiophenol being somewhat larger. In the phenol derivatives, the hydroxy, fluoro, and methyl groups decrease the barrier by 0.9, 0.6, and 0.3 kcal/mol, respectively, rather similar to the decreases of 1.0, 0.7, and 0.3 kcal/mol in the methoxy, fluoro, and methyl derivatives of benzenethiol. In view of the larger barrier in phenol, it appears that the sulfhydryl group is more susceptible than the hydroxyl group to substituent induced changes in conjugation with the aromatic π electrons (24).

(v) Comparison with Ab Initio MO Calculations

The STO3G calculations are rather expensive for benzenethiol derivatives, particularly when geometry optimization procedures are adopted. Optimization of the C—S—H geometry yielded C—S (S—H) bond lengths of 1.76_2 (1.34) Å and a CSH angle of 95.8° for the planar conformation of benzenethiol. These bond parameters then gave V_2 as 3.52 kcal/mol, *i.e.*, the conformation in which the S—H bond lies in a plane perpendicular to the aromatic plane had the higher energy. The apparent overestimate of about 2.4 kcal/mol is similar to the overestimate for phenol (2). When a standard geometry (25) was used, *i.e.*, C—S = 1.815 Å and ∠CSH = 109.5°, the barrier was calculated as 2.8 kcal/mol.

The optimized geometry of the CSH group above gave a barrier of 2.55 kcal/mol for *p*-aminobenzenethiol, a decrease of 0.97 kcal/mol relative to benzenethiol, close to the experimental value in Table 3. For *p*-fluorobenzenethiol the calculated decrease of 0.46 kcal/mol also compares favorably with the observed decrease of 0.6 ± 0.2 kcal/mol in Table 3. Unfortunately, no convergence in the calculations was obtained for the *p*-nitro derivative.

Apparently, the *ab initio* calculations overestimate substantially the barriers in both phenol and benzenethiol derivatives but predict substituent-induced changes in the barriers in reasonable agreement with experiment.

(vi) Correlations Involving $^4J_o^{H,SH}$ and $^5J_m^{H,SH}$

A plot of $^4J_o^{H,SH}$ against $^5J_m^{H,SH}$ is roughly linear; the former varying by 0.5 Hz, the latter by 0.1 Hz, over the range of *para* substituents in Table 2. In view of the preceding discussion, the increase in magnitude of both coupling constants reflects an increase in the σ–π contribution as the substituent varies from NO_2 to NH_2. In terms of simple MO theory, the smaller increase in $^5J_m^{H,SH}$ occurs because the two ring carbon atoms belong to the same starred (or unstarred) set and, to zero order, the mobile bond order between these carbons vanishes. Because $^5J_m^{H,SH}$ presumably contains a substantial σ component (compare corresponding couplings in phenol (13), benzaldehyde (26), aniline (23), for example), the rather small increase in $^5J_m^{H,SH}$ may reflect a compensating decrease in this component as the σ–π component grows with increasing $\langle \sin^2 \theta \rangle$.

[2]It might have been argued that an increased double bond character of the C—S bond would increase the magnitude of $^6J_p^{H,SH}$ if the coupling were transmitted via the conjugative π electrons. The opposite occurs, just as in phenol (13), and aniline (23), in agreement with the hyperconjugative ($\sin^2 \theta$) mechanism.

(vii) Intermolecular Association

The concentrations of the solutions in Table 2 are 0.5 *M* or less. At these concentrations chemical shift (27) and infrared (28) studies suggest that perhaps only about 1% of the solute molecules are associated. Of course, the solvent molecules are interacting with the solute molecules by dispersion forces, if in no other way. A gas-phase measurement of the coupling constants is desirable but their small magnitude may vitiate their determination to the needed accuracy.

Conclusions

It is very likely that *para* substituents alter the barrier to rotation about the C—S bond in benzenethiol derivatives and that the barrier ranges over as much as 2.5 kcal/mol. This conclusion, reached on the basis of long-range proton–proton spin–spin coupling constants, should be confirmed if possible by microwave or high resolution infrared or Raman measurements in the gas phase.

Acknowledgments

We are grateful to Mr. Kalvin Chum for some of the measurements and to the National Research Council of Canada for financial assistance.

A proton magnetic resonance determination of the small rotational barriers about the C—Si bond in phenyl derivatives of chloro and methyl silanes

WILLIAM J. E. PARR[1] AND TED SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received August 31, 1976

WILLIAM J. E. PARR and TED SCHAEFER. Can. J. Chem. **55**, 557 (1977).

The long-range spin–spin coupling constants between protons bonded to silicon and ring protons in $C_6H_5SiH_3$, $C_6H_5SiH_2Cl$, $C_6H_5SiH_2CH_3$, $C_6H_5SiHCl_2$, and $C_6H_5SiH(CH_3)_2$ are determined from the proton magnetic resonance spectra of benzene solutions. A hindered rotor treatment of the barrier to internal rotation about the C—Si bond, in conjunction with the coupling constants over six bonds, allows the deduction of the low-energy conformations for $C_6H_5SiH(CH_3)_2$ and for $C_6H_5SiHCl_2$, as well as of barriers of 1.0 ± 0.2 kcal/mol. The approach becomes less reliable for $C_6H_5SiH_2CH_3$ and for $C_6H_5SiH_2Cl$ and, particularly for the latter compound, the derived barrier is very likely an upper limit only. *Ab initio* molecular orbital calculations of the conformational energies are reported for $C_6H_5SiH_3$, $C_6H_5SiH_2Cl$, and for $C_6H_5SiHCl_2$.

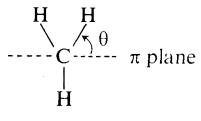
WILLIAM J. E. PARR et TED SCHAEFER. Can. J. Chem. **55**, 557 (1977).

On a déterminé les constantes de couplage spin–spin à longue distance entre les protons liés au silicium et les protons du cycle dans $C_6H_5SiH_3$, $C_6H_5SiH_2Cl$, $C_6H_5SiH_2CH_3$, $C_6H_5SiHCl_2$ et $C_6H_5SiH(CH_3)_2$; ces constantes ont été déterminées à partir des spectres de résonance magnétique nucléaire du proton en solutions benzéniques. Si l'on traite la barrière à rotation interne autour du lien C—Si sous forme de rotor empêché et que l'on utilise aussi les constantes de couplage à travers six liaisons, il est possible de déduire les conformations de basse énergie pour $C_6H_5SiH(CH_3)_2$ et pour $C_6H_5SiHCl_2$; on peut aussi en déduire que les barrières sont de l'ordre 1.0 ± 0.2 kcal/mol. Cette approche devient moins fiable pour $C_6H_5SiH_2CH_3$ et pour $C_6H_5SiH_2Cl$ et particulièrement dans le cas du dernier composé, la barrière qui est déduite est probablement uniquement une limite supérieure. On rapporte des calculs *ab initio* d'orbitales moléculaires des énergies conformationnelles pour $C_6H_5SiH_3$, $C_6H_5SiH_2Cl$ et $C_6H_5SiHCl_2$.

[Traduit par le journal]

Introduction

In toluene the coupling over six bonds between methyl protons and ring protons in the *para* position, $^6J_p^{H,CH}$ displays a $\sin^2\theta$ dependence,



1

where θ is the angle in **1** (1, 2). For free rotation about the C—CH_3 bond (3) the average value of $\sin^2\theta$ is 0.5. If it is assumed that ^6J in α and α,α derivatives is also a function of $\sin^2\theta$, reasonable twofold barriers to rotation about the C—CH_2X and C—CHX_2 bonds can be derived on the basis of hindered rotor treatments (4, 5). These yield $\langle\sin^2\theta\rangle$ as a function of the hindering potentials and of the reduced moments of inertia (4).

[1]Postdoctoral fellow, 1974–1976.

The sixfold barrier to rotation about the C—Si bond in phenylsilane is 0.018 kcal/mol (6), very similar to the 0.014 kcal/mol in toluene (3). When one or two Si—H bonds are replaced by

Si—Cl and Si—CH_3 bonds it is reasonable to discuss the predominantly twofold barriers in terms of conformations **2** to **7**. In this paper the proton magnetic resonance spectra of phenylsilane derivatives where X = Cl and CH_3 are analyzed. $^6J_p^{H,SiH}$ is discussed in terms of the ground state conformations and of the magnitudes of the internal rotational barriers. Molecular orbital calculations at the *ab initio* STO-3G level are compared with results based on $^6J_p^{H,SiH}$.

Experimental

The only compound not of commercial origin was $C_6H_5SiH_2Cl$, which was prepared from phenylsilane using anhydrous stannic chloride (7). For reasons of spectral dispersion, samples were prepared as *ca.* 10 mol% solutions in C_6D_6 containing a small amount of internal tetramethylsilane. After degassing the samples by the freeze–pump–thaw technique, the proton magnetic resonance spectra were calibrated on an HA100 spectrometer in the frequency sweep mode at a probe temperature of 305 K.

Ab initio STO-3G molecular orbital calculations (8) were performed on an IBM 370/158 system and employed a standard geometry (9) for the phenyl group, tetrahedral angles about silicon and C—Si, Si—H, Si—Cl bond lengths of 1.843, 1.48, and 2.03 Å, respectively.

Results and Discussion

Spectral Analysis

Analysis of the spectra utilized the computer program LAME (10, 11). The chemical shift and spin–spin coupling parameters are arrayed in Table 1. The analyses showed that the signs of the long-range couplings were as given in Table 1, alternative sign combinations yielding clear disagreement with spectral patterns. The $^1J(^{29}Si,H)$ values were obtained from the satellite spectra arising from the 4.7% abundant ^{29}Si.

Ring Proton Chemical Shifts

The substituent dependence of the chemical shifts of the ring protons is partially masked by the aromatic solvent induced shifts, ASIS (12–15). However, the ASIS caused by toluene are very similar to those arising from benzene (14). The parameters given for toluene itself in Table 1 originate in a neat solution of toluene, so that a comparison of these parameters with those of phenylsilane and its derivatives is approximately valid. The chemical shift of the benzene protons in benzene solution is 7.07 ppm, very close to the shift of 7.08_5 ppm of the *meta* protons of toluene in toluene solution. The shift to high field of the *ortho* and *para* ring proton is consistent with a small increased π electron density at the *ortho* and *para* carbon atoms (16) and with a negative value for the σ constant for the methyl group.

Comparison of the *para* proton shifts in Table 1 suggests that the SiH_3 group is a weak π electron acceptor (17), although for the SiH_2Cl and $SiHCl_2$ groups the conclusions are clouded by the possibility of larger ASIS values for molecules containing appreciable polar bonds (15). For the most part, the large low-field shifts of the *ortho* protons in all the phenylsilane derivatives are

hardly due to electronegativity effects. It may be noted that these shifts may be another example of the so-called heavy-atom perturbations, for which numerous and probably related explanations have been advanced (18–20).

Coupling Constants within the Phenyl Group

In benzene, to within 0.04 Hz, the couplings $^3J_o^{H,H}$, $^4J_m^{H,H}$, and $^5J_p^{H,H}$ are 7.54, 1.37, and 0.69 Hz, respectively (21). $^3J_o^{H_2,H_3}$ in the phenylsilane derivatives is less than 7.54 Hz, although only by 0.2 Hz at most. This result implies (22) that the side chains are less electronegative than the methyl group and therefore that the low-field shifts of the *ortho* protons do not have their origin in a polarization of the intervening σ electron system.

The other couplings between the ring protons in Table 1, when compared with the benzene coupling parameters and with those for toluene, are consistent with a relatively weak perturbation of the electrons in the phenyl group. For example, in phenylsilane all these coupling constants equal those in benzene to within experimental error. This fact contrasts strongly with the data for other benzene derivatives and even with the data for toluene in Table 1.

$^1J(^{29}Si,H)$

The magnitudes of these coupling constants lie within 0.5 Hz of literature values (23, 24) and the usual arguments (25–29) concerning hybridization and substituent electronegativities apply to them. Of particular interest is the iterative hybridization method of Rastelli and Pozzoli (29) which reproduces the available experimental bond angles involving silicon for phenyl- and phenylmethylsilane derivatives. Their work suggests that the bond angles do not deviate by more than 1° from a tetrahedral geometry and that therefore the tetrahedral geometry assumed in the STO-3G calculations below is reasonable.

Long-range Proton–Proton Couplings to the Side Chain

$^6J_p^{H,SiH}$ in phenylsilane has approximately half the magnitude[2] of $^6J_p^{H,CH_3}$ in toluene (see Table 1), suggesting that the σ–π parameter for the SiH_3 group is very nearly half as large as for the CH_3 group. The smaller magnitude for the SiH_3 group is at least partially attributable to the greater length (1.843 Å) of the C—Si bond, as compared to the C—C bond length (1.52 Å) in toluene.

$^4J_o^{H,SiH}$ is markedly smaller in magnitude than is $^4J_o^{H,CH_3}$ in toluene, indicating that a positive σ electron contribution partially compensates the negative π electron contribution to $^4J_o^{H,SiH}$ in phenylsilane; expected to be of nearly the same magnitude as for $^6J_p^{H,SiH}$.

In toluene, $^5J_m^{H,CH_3}$ consists of a mixture of positive σ and π electron contributions (2, 30, 31). The smaller magnitude of the corresponding coupling constant in phenylsilane can once more be partially attributed to a smaller π electron transmission of spin state information. In any event, $^6J_p^{H,SiH}$ is of primary interest and is discussed below.

$^6J_p^{H,SiH}$ and the Barriers to Internal Rotation

In a manner analogous to the work on toluene derivatives (4, 5) it is assumed that $^6J_p^{H,SiH}$ obeys [1].

$$[1] \qquad {}^6J = {}^6J_{90} \sin^2 \theta$$

For phenylsilane $\langle \sin^2 \theta \rangle$, the value of $\sin^2 \theta$ averaged over the essentially free rotation about the C—Si bond, is 0.5.

In an α,α-disubstituted phenylsilane, $\langle \sin^2 \theta \rangle$ depends on which of **5**, **6**, or **7** is the ground state conformation, on the magnitude of the internal barrier to rotation, on the temperature, and on the reduced moment of inertia; being relatively insensitive to the latter quantity. For low barriers near 305 K, the temperature of measurement, a hindered rotor treatment is essential and has been performed (4), yielding $\langle \sin^2 \theta \rangle$ as a function of the two-fold barrier to internal rotation. If **5** is the conformation of lowest energy, $\langle \sin^2 \theta \rangle$ increases from zero for a large barrier to 0.5 for free rotation; whereas if **6** is of lowest energy, $\langle \sin^2 \theta \rangle$ decreases from 0.75 to 0.5 as the barrier decreases.

(i) $C_6H_5SiH(CH_3)_2$

In toluene, α substitution by methyl groups does not change $^6J_{90}^{H,CH}$ (5, 32). A similar assumption for phenylsilane gives $^6J_{90}^{H,SiH}$ as -0.68_6 Hz. For $C_6H_5SiH(CH_3)_2$, $\langle \sin^2 \theta \rangle$ is 0.221/0.686 or 0.32. It follows that **5**, and not **6** or **7**, is the stable conformation. A reduced moment of inertia of 0.8×10^{-38} g cm^2 then implies a barrier of 1.0 ± 0.2 kcal/mol, where the error depends on possible errors in the measured coupling constant. The percentage error is larger than in the barrier of 2.0 ± 0.2 kcal/mol

[2]An analysis of a CS_2 solution gave −0.312 Hz. We are grateful to Dr. C. J. MacDonald for this information, prior to publication.

¶Upper limit.

recently derived (33) by the same method for 3,5-dibromoisopropylbenzene in solution and reflects the smaller magnitudes of $^6J_p^{H,SiH}$, the error in measurement being of the same magnitude for $^6J_p^{H,SiH}$ and $^6J_p^{H,CH}$. However, there appears to be no doubt of the ground state conformation, **5**, for the groups $HSi(CH_3)_2$ and $HC(CH_3)_2$.

(ii) $C_6H_5SiHCl_2$

Determination of the barrier in $C_6H_5SiHCl_2$ involves an estimate of the change in $^6J_p^{H,SiH}$ caused by the electronegative chlorine substituents. For the CH_2Cl moiety it has been estimated that the magnitude of $^6J_{90}^{H,CH}$ decreases by 8% from its magnitude for a CH_3 group (34). Introduction of a second chlorine substituent would presumably cause a further decrease of no more than 8%. Assuming a similar pair of numbers for $SiHCl_2$ one arrives at $^6J_{90}$ for this group of 0.58 Hz, a $\langle \sin^2 \theta \rangle$ of 0.30_5, and a barrier of 1.0 ± 0.2 kcal/mol, the error including a situation where $^6J_{90}^{H,SiH}$ is the same as in the SiH_3 group.

(iii) $C_6H_5SiH_2CH_3$

The errors in the barriers for $C_6H_5SiH(CH_3)_2$ and $C_6H_5SiHCl_2$ are somewhat mitigated by the fact that **5** is the low energy conformation and that therefore $\langle \sin^2 \theta \rangle$ varies between 0 and 0.5 as a function of the barrier. In $C_6H_5SiH_2Cl$ and $C_6H_5SiH_2CH_3$, on the other hand, $\langle \sin^2 \theta \rangle$ changes at most by 0.25 in going from free rotation to a very large barrier on the assumption that one of **2**, **3**, or **4** is the stable conformer. This insensitivity of $\langle \sin^2 \theta \rangle$, combined with the small magnitudes of the $^6J_p^{H,SiH}$ numbers and with a constant error in measurement, entails even greater uncertainties in the deductions of the barriers and ground state conformations of these compounds.

For $C_6H_5SiH_2CH_3$, $\langle \sin^2 \theta \rangle$ is 0.43, eliminating **4** as the ground state conformation because $\langle \sin^2 \theta \rangle$ must lie between 0.75 and 0.5 for **4**. A rigid **3** implies $-0.69 \times \frac{3}{8}$ or -0.26 Hz for $^6J_p^{H,SiH}$ and is perhaps compatible with the observed -0.29 Hz. However, the analogous toluene derivative has a barrier of 1.2 kcal/mol and a stable form analogous to **2**. On the assumption that the stable form of $C_6H_5SiH_2CH_3$ is **2**, the barrier becomes 0.8 kcal/mol. The relative insensitivity of $\langle \sin^2 \theta \rangle$ to the barrier leads us to suggest a barrier of 0.8 ± 0.4 kcal/mol.

(iv) $C_6H_5SiH_2Cl$

If $^6J_{90}^{H,SiH}$ in $C_6H_5SiH_2Cl$ undergoes a similar reduction in magnitude from its value in $C_6H_5SiH_3$ as that estimated in the corresponding toluenes, *i.e.*, to -0.63 Hz, $\langle \sin^2 \theta \rangle$ becomes 0.36. The assumption of **2** as stable then yields a barrier of 1.7 ± 0.5 kcal/mol. This value seems unreasonably high and could presumably only be rationalized by a strong hyperconjugative interaction of the Si—Cl bond with the π electrons system of the phenyl group in conformation **2**. The barrier in benzyl chloride is only 2.1 kcal/mol (34).

Table 2 contains the barriers to internal rotation about the bond to the aromatic carbon atom for the phenylsilane derivatives and for the available, analogous toluene derivatives. In general,

the barriers are smaller for the phenylsilane than for the corresponding toluene derivatives; as expected on the basis of steric interactions, the C—Si and Si—X bonds being longer than the C—C and C—X bonds.

Molecular Orbital Calculations

The *ab initio* STO-3G results are also given in Table 2 for $C_6H_5SiH_3$, $C_6H_5SiH_2Cl$, and $C_6H_5SiHCl_2$. The calculations agree with the coupling constant data as to the low and the high energy forms of the chlorine derivatives. However, they suggest other than a twofold form for the hindering potential and also predict rather lower barriers than those based on the coupling constant data. For $C_6H_5SiHCl_2$ a twofold barrier implies that **6** has an energy of 0.25 kcal/mol relative to **5** *if*, as calculated, **7** has an energy of 0.5 kcal/mol higher than that of **5**. The MO calculations suggest an energy of 0.44 kcal/mol for **6**. The reverse situation holds for the calculation on $C_6H_5SiH_2Cl$, where **2**, **3**, and **4** have relative energies of 0.39, 0.07, and 0.00 kcal/mol, respectively. In our opinion, however, the minimal basis set calculations are not reliable enough to vitiate the assumption of a two-fold barrier as used in the discussion of the coupling constant data.

Conclusions

The assumed twofold barriers to rotation about the C—Si bond, as derived from long-range coupling constants, are probably accurate to 20% for $C_6H_5SiH(CH_3)_2$ and $C_6H_5SiHCl_2$. Molecular orbital calculations provide support for the low-energy conformations deduced from the coupling constants. For $C_6H_5SiH_2CH_3$ and $C_6H_5SiH_2Cl$ the barriers derived from the coupling data are very likely upper limits to the true values and, for the latter compound, the method may be unreliable. It would be interesting to have microwave values for these barriers. Measurements of the spin–lattice relaxation rates of ^{29}Si and of the *ortho* ^{13}C nuclei could possibly aid in assessing the magnitudes of the internal barriers.

A stereospecific, total synthesis of thromboxane B_2

STEPHEN HANESSIAN AND PIERRE LAVALLEE[1]

Department of Chemistry, Université de Montréal, Montréal (Que.), Canada H3C 3V1

Received October 28, 1976

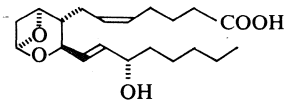
STEPHEN HANESSIAN and PIERRE LAVALLEE. Can. J. Chem. **55**, 562 (1977).

A stereospecific, total synthesis of crystalline thromboxane B_2 from D-glucose is described.

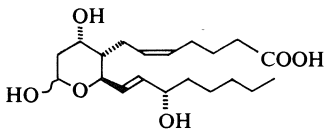
STEPHEN HANESSIAN et PIERRE LAVALLEE. Can. J. Chem. **55**, 562 (1977).

La synthèse stéréospécifique et totale de la thromboxane B_2 cristalline à partir du D-glucose est décrite.

The pioneering recent studies of Hamberg *et al.* (1) on the biosynthesis of prostaglandins has led to the discovery of a new class of compounds called the thromboxanes. It appears that in many cells, the normal transformation of endoperoxide intermediates into prostaglandins is altered in favor of the formation of thromboxane A_2, which, in turn, is rapidly transformed into thromboxane B_2 (2).



Thromboxane A_2



Thromboxane B_2

While the remarkable biological properties of the relatively unstable A_2 component (half-life in aqueous solution ~30 s) have been recognized, much less is known of the more stable B_2 component. In this paper, we describe a stereospecific total synthesis of crystalline thromboxane B_2, from D-glucose, based on the systematic and stereocontrolled introduction of functional groups.[2] Thromboxane B_2 can be considered as a 2,4,6-trideoxy-D-*ribo*-hexose, in which positions 4 and 6 are the sites of *C*-branching and chain extension, respectively. The plan for a practical synthesis of this substance was therefore based on the stereospecific introduction of the acid side chain at C-4, and appropriate chain extension at C-6 in a suitable carbohydrate derivative. Scheme 1 outlines the synthetic sequence leading to thromboxane B_2, and its C-15 epimer.[3]

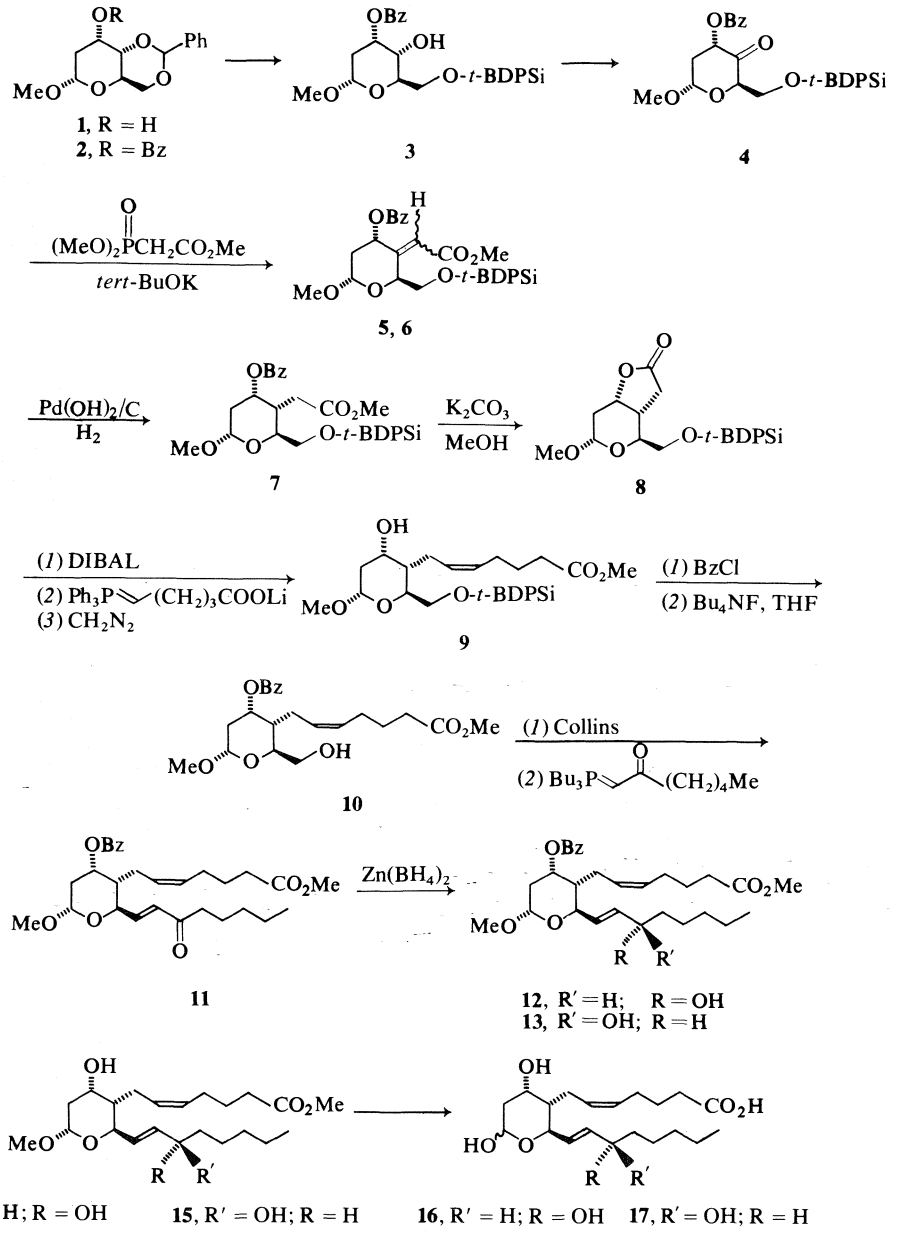
The readily available methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*ribo*-hexopyranoside **1** (4) was transformed into the corresponding 3-benzoate **2**, mp 100–101 °C, $[\alpha]_D^{25}$ +183° (*c* 1.18)[4] (89%), and the latter was sequentially hydrogenolyzed (20% $Pd(OH)_2/C$, H_2, quantitative), and silylated with *tert*-butyldiphenylsilyl chloride (5), to give the crystalline compound **3** (90%), mp 116–117 °C, $[\alpha]_D^{25}$ +90.2° (*c* 1.1). Oxidation of **3** in dimethyl sulfoxide and 1-ethyl-3-(3′-dimethylaminopropyl)carbodiimide hydrochloride (EDAC·HCl) (6) in the presence of pyridinium trifluoroacetate (25 °C, overnight), gave the highly crystalline 4-uloside derivative **4** (85%), mp 86–88 °C, $[\alpha]_D^{25}$ +148° (*c* 1.22). Lack of any detectable epimerization at C-3 was ascertained by nmr spectral data, and by subsequent transformation. Treatment of **4** with trimethylphosphonoacetate in the presence of potassium *tert*-butoxide gave a mixture of two compounds **5** and **6** that were

[1]NRCC predoctoral fellow, 1972–1976.

[2]While this manuscript was in preparation, a series of papers was published on the synthesis of thromboxane B_2 from prostaglandin $F_{2\alpha}$ and from a prostaglandin intermediate, see ref. 3).

[3]Prostaglandin numbering.

[4]Optical rotations were recorded in chloroform. Melting points are uncorrected. Crystalline compounds gave correct microanalyses. All compounds exhibited nmr spectra (60, 100 MHz) that were in accord with their structures.



SCHEME 1

separated by chromatography and isolated as syrups (95%) in a ratio of 3:2.[5] For the more polar component, $[\alpha]_D$ +162.5° (*c* 1.0); for the less polar component, $[\alpha]_D$ +199.3° (*c* 1.2). Hydrogenation (20% $Pd(OH)_2/C$, H_2, overnight) of **5** and **6** individually, or as a mixture resulting from the above reaction, gave **7**, isolated as a syrup (95%); $[\alpha]_D^{25}$ +100° (*c* 1.1). Treatment of **7** with potassium carbonate in methanol (25 °C, 60 h, N_2) gave the highly crystalline lactone **8** (85%); mp 80.5–81.5 °C; $[\alpha]_D^{25}$ +41.8° (*c* 1.05); *m/e* 409 (*M* − 31), *m/e* 383 (*M* − 57). Reduction of **8** with diisobutylaluminium hydride (DIBAL) in

[5]Ozonolysis of **5** and **6** individually gave the crystalline 4-uloside derivative **4**.

toluene (quantitative), followed by treatment with 4-carboxybutyltriphenylphosphonium bromide in HMPT, in the presence of lithium bis(trimethylsilyl)amide 7, gave, after esterification with diazomethane and chromatography, the branched-chain derivative **9** as a syrup (67–71%); $[\alpha]_D^{25}$ +62° (*c* 1); *m/e* 483 (*M* − 57), *m/e* 465 (*M* − 57 − 18). Since hydrogenation of **5** and **6** was expected to occur by *cis*-addition, it was possible that the resulting products **7** and **8** could also have alternative configurations, *i.e.* epimeric at C-4. This possibility was dismissed by detailed nmr analysis of the products **7** and **8**, and by chemical means. Thus, oxidation of **9** with EDAC·HCl in DMSO, followed by attempted equilibration with K_2CO_3–MeOH, and finally reduction with sodium borohydride gave the starting compound **9**, in which the configurations at C-3 and C-4 were preserved. It is well known from work done in this laboratory and elsewhere, that axial substituents that are vicinal to carbonyl groups are prone to epimerization, leading to the thermodynamically more stable equatorial isomer. Thus, had the catalytic reduction led to a lactone of opposite configuration at C-4 (*i.e.* D-*xylo* configuration), the axially disposed C-branched unit at C-4 would have most assuredly undergone epimerization during the treatment of the corresponding 3-uloside with base, in contrast to experimental results.

Benzoylation of **9**, followed by treatment of the product with tetra *n*-butylammonium fluoride in THF (8), gave, after chromatographic purification, compound **10** as a syrup (90%); $[\alpha]_D^{25}$ +130° (*c* 1.02); *m/e* 374 (*M* − 32). Collins oxidation (quantitative), followed by a Wittig reaction in the usual manner (9), gave the expected product **11**, isolated as a syrup in 76–80% yield; $[\alpha]_D^{25}$ +153° (*c* 1.14); M^+ 500; *m/e* 468 (*M* − 32). Reduction of **11** with zinc borohydride in a mixture of DME and ether (25 °C, 4 h) gave a mixture of the epimeric products **12** and **13** (1:1) (73%). Chromatographic separation gave the 15 *S* isomer **12**, $[\alpha]_D^{25}$ +137.8° (*c* 1.19); M^+ 502, *m/e* 484 (*M* − 18), and the 15 *R* isomer **13**, $[\alpha]_D^{25}$ +132.0° (*c* 0.91), M^+ 502, etc., as colorless syrups. Treatment of **12** and **13** individually with potassium carbonate in methanol, effected smooth debenzoylation to give the respective epimeric alcohols, **14** (15 *S* isomer), $[\alpha]_D^{25}$ +95.8° (*c* 1.09); *Exact Mass* calcd. for a fragment, *M* − H_2O: 348.2249; measured: 348.2246, and **15** (15 *R* isomer), $[\alpha]_D^{25}$ +93.2° (*c* 1.1). The chromatographic properties of **14**, and the mass spectral fragmentation of the corresponding *O*-trimethylsilyl derivative were in accord with data recorded for the natural thromboxane B_2 derivatives (1). For the bis *O*-trimethylsilyl derivative, *Exact Mass* calcd. for a fragment, *M* − 32: 510.3197; measured: 510.3214.

Finally, sequential deesterification of **14** (aqueous NaOH, 1.2 equiv.), followed by treatment with excess Dowex-50 (H^+), gave thromboxane B_2 **16**, as a chromatographically homogeneous syrup (90%), which crystallized from a mixture of ethyl acetate, ether, and petroleum ether (30–60 °C); mp and mixture mp 91–93 °C.[6] Recrystallization from the same solvent mixture gave beautiful elongated plates, mp 95–96 °C; $[\alpha]_D^{25}$ +57.4° (*c* 0.26, EtOAc); ν_{max}(film) 1705 cm^{-1} (C=O), 3380 cm^{-1} (OH); *m/e* 335 (*M* − H_2O − OH) *m/e* 317 (*M* − $2H_2O$ − OH). The epimeric derivative **17**, was similarly prepared, and isolated as a syrup.

The synthesis of thromboxane B_2 by the sequence described in this paper encompasses the elements of practicality, efficacy, and versatility, and it also provides access to intermediates that could be useful in the preparation of analogs.[7] In addition, it further illustrates the utility of carbohydrates as chiral precursors in the total synthesis of natural products (11).

[6]We thank Drs. N. A. Nelson, R. C. Kelly, and W. P. Schneider of the UpJohn Company for a sample of their synthetic material, which they reported to be identical to natural thromboxane B_2. Our preparation had chromatographic and ir spectral properties that were identical to those of the UpJohn sample.

[7]Since an optically active Wittig reagent corresponding to the C-15 side chain can be prepared from a readily available intermediate (see ref. 10), the synthesis of thromboxane B_2 can be considered as being entirely stereospecific.

Carbon monoxide activation by bromorhodate complexes; a catalyzed reduction of iron(III)[1]

BRIAN R. JAMES AND GEORGE ROSENBERG

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received July 26, 1976

BRIAN R. JAMES and GEORGE ROSENBERG. Can. J. Chem. **55**, 567 (1977).

Kinetics have been studied for the decomposition of $Rh(CO)Br_5^{2-}$ to *cis*-$Rh(CO)_2Br_2^-$ in aqueous HBr solutions at 60 °C under a carbon monoxide atmosphere. A hydrolysis step leads to formation of rhodium(I) which is stabilized as the dicarbonyl; this dicarbonyl then reacts with $Rh(CO)Br_5^{2-}$ in an autocatalytic process to give more $Rh(CO)_2Br_2^-$ via a mixed valence [$Rh^I \ldots Br \ldots Rh^{III}$] bridged intermediate. Ferric ion may be reduced according to the net reaction:

$$2Fe^{III} + CO + H_2O \rightarrow 2Fe^{II} + CO_2 + 2H^+$$

using the bromorhodate(III or I) complexes as catalyst, and the kinetics of this process are also reported.

BRIAN R. JAMES et GEORGE ROSENBERG. Can. J. Chem. **55**, 567 (1977).

On a étudié la cinétique de la décomposition du $Rh(CO)Br_5^{2-}$ en $Rh(CO)_2Br_2^-$ *cis* dans des solutions aqueuses de HBr, à 60 °C et sous une atmosphère de monoxyde de carbone. Une étape d'hydrolyse conduit à la formation de rhodium(I) qui est stabilisé sous forme de dicarbonyle; ce dicarbonyle réagit alors avec $Rh(CO)Br_5^{2-}$ dans un processus autocatalytique pour conduire à d'autre $Rh(CO)_2Br_2^-$ grâce à un intermédiaire ponté de valence mixte [$Rh^I \ldots Br \ldots Rh^{III}$]. On peut réduire l'ion ferrique suivant la réaction globale suivante

$$2Fe^{III} + CO + H_2O \rightarrow 2Fe^{II} + CO_2 + 2H^+$$

en utilisant des complexes de bromorhodates(III ou I) et on rapporte aussi la cinétique de ce processus.

[Traduit par le journal]

Introduction

We recently reported (1) on the carbonylation of bromorhodate(III) species in aqueous solutions to give the *cis*-dibromodicarbonylrhodate(I) anion, $Rh(CO)_2Br_2^-$. One path in this reductive carbonylation process was considered to involve decomposition by water of an intermediate rhodium(III) carbonyl anion which was formed in a rate-determining step and thus not detected directly. This paper considers the decomposition in aqueous hydrobromic acid solution of one such anion, the pentabromocarbonylrhodate(III) complex, $Rh(CO)Br_5^{2-}$, and investigates the use of such a system under carbon monoxide for catalytic reduction of inorganic substrates. Kinetic studies show the role of rhodium(I) intermediates. The work stems from initial observations in this laboratory that indicated that $Rh(CO)_2Cl_2^-$ could catalyze the carbon monoxide-reduction of ferric ion (2); later work has considered the catalytic reduction of molecular dioxygen (3, 4), and nitric oxide (5).

[1]Taken from the Ph.D. thesis of G. Rosenberg, University of British Columbia, Vancouver, British Columbia, 1974.

Since solutions of rhodium(III) halide complexes also activate dihydrogen (1), the potential of such systems to promote Fischer-Tropsch type reactions (the H_2-reduction of CO to hydrocarbons) seems real. Thus, the detailed understanding of the gas activation processes is important and critical.

Experimental

The cesium salts of $Rh(CO)Br_5^{2-}$ and $Rh(CO)Cl_5^{2-}$ were prepared according to the method of Cleare and Griffith (6) from the corresponding rhodium(III) trihalides; tribromide was obtained as the dihydrate from Platinum Chemicals, and the trichloride as a trihydrate from Johnson Matthey Ltd. The synthesis of the bromo complex involves boiling the tribromide in air with a mixture of conc. HBr and formic acid for 15 min; during this time the initially red solution goes yellow, and finally orange which contains the $Rh(CO)Br_5^{2-}$ anion. Addition of $(n\text{-}C_4H_9)_4NBr$ to the yellow solution (stable in the absence of air) precipitates the $Rh(CO)_2Br_2^-$ salt (7, 8).

The precipitated $Rh(CO)X_5^{2-}$ anions decomposed readily when washed with distilled water, being reduced to metal, although there was no noticeable decomposition on treatment with the hydrohalic acid at room temperature (9) (see also points in the Results and Discussion). All other materials used, and the procedure used for following CO uptake at constant pressure, have been described previously (1, 2); the CO concentration in the aqueous HBr solutions was computed from solubility data of Seidell (10), assuming the solubility to be the same as in pure water.

Results

Carbonylation of $Rh(CO)X_5^{2-}$

The solid cesium salts of $Rh(CO)X_5^{2-}$ (X = Cl, Br) are quite stable in air, and the reflectance spectra show peaks at 398 and 502 nm for the chloride, and at 440 and 550 nm for the bromide. In aqueous solutions of the corresponding hydrohalic acids, the initially measured spectra are essentially the same: λ_{max} at 393 nm (ε 450 M^{-1} cm^{-1}) and 500 nm (ε 60) for the chloride, and at 435 nm (ε 1050) and 550 nm (ε 120) for the bromide. Upon standing in an inert atmosphere (N_2 or Ar), however, the solutions decompose with evolution of CO_2 (1 mole per mole Rh) and eventual precipitation of metal; the decomposition rate increases with temperature and decreasing acidity. The decomposition reactions can be studied directly by monitoring the gas evolution rate or changes in optical density, but the methods are somewhat impractical due to the deposition of rhodium metal which ruins permanently any glassware used.

The decomposition occurs via production of Rh(I) according to reaction 1 (1, 2, 11)

$$[1] \quad Rh^{III}(CO) + H_2O \rightarrow Rh^{I} + CO_2 + 2H^+$$

Metal is likely produced via the disproportionation reaction shown in [2] (2, 12, 13):

$$[2] \quad 2Rh^{I} \rightleftharpoons Rh^{0} + Rh^{II}$$

Metal formation can be avoided by efficient removal of the Rh(I) formed in [1]. A carbon monoxide atmosphere stabilizes the Rh(I) as $Rh(CO)_2X_2^-$ (1, 2), while reagents such as ferric or dioxygen oxidize the rhodium to the trivalent state and give halorhodate(III) species (2–4); the solution products in all cases are readily confirmed by the characteristic uv/vis spectra reported previously (1, 2).

Figure 1 shows gas-uptake plots for solutions of $Rh(CO)Br_5^{2-}$ in 0.5 *M* HBr at 60 °C under a CO atmosphere. The total net measurable uptake corresponded to an apparent 1:1 mole ratio of gas:Rh; experiments in the presence of a soda-lime tube (to absorb CO_2) resulted in a 2:1 uptake. The original orange solution became yellow (λ_{max} 330 nm, ε = 3300 M^{-1} cm^{-1}) indicating reduction to $Rh(CO)_2Br_2^-$ (1). The overall reaction is

$$[3] \quad Rh^{III}(CO) + H_2O + 2CO \rightarrow Rh^{I}(CO)_2 + CO_2 + 2H^+$$

The uptake plots are sigmoid in shape suggesting autocatalytic behaviour, and maximum rates were measured over a range of rhodium concentrations (0.009–0.021 *M*) and CO pressures up to 1 atm. The maximum rates were found at about 50% reaction and were proportional to the

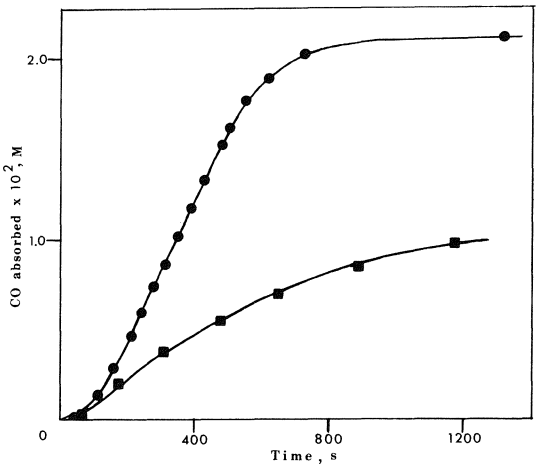

FIG. 1. Rate plot for decomposition of $Rh(CO)Br_5^{2-}$ in 0.5 *M* HBr at 60 °C under 615 mm CO; ●, 0.0207 *M* Rh; ■, 0.0086 *M* Rh.

product $[Rh^{III}][Rh^{I}]$ (Fig. 2); the same result has been found previously (1, 2) for corresponding carbonylation of $RhCl_5(H_2O)^{2-}$ and $RhBr_4(H_2O)_2^{-}$ (reaction 4):

[4] $Rh^{III} + 3CO + H_2O \rightarrow Rh^{I}(CO)_2 + CO_2 + 2H^+$

As for these systems (see ref. 2), there is a significant rate at zero $[Rh^{I}]$, as can be seen in Fig. 1 and from the non-zero intercept of Fig. 2. The rate law then for reaction 3 can be expressed as:

[5] $-d[CO]/dt = k_1'[Rh^{III}]^n + k_2'[Rh^{III}][Rh^{I}]$

where k_1' and k_2' contain all variables other than the dependence on rhodium. The slope of Fig. 2 gives a k_2' value of 0.32 M^{-1} s^{-1}. Information on the initial reaction (the k_1' term) was obtained from studies carried out in the presence of added ferric ion, which rapidly reoxidizes the Rh^{I} as it is formed and prevents the autocatalytic reaction.

In order to determine the CO dependence, maximum rate measurements were made for varying CO pressures at a constant $[Rh^{III}]$; the rate was essentially independent of CO pressure above 600 mm, but showed a first order dependence up to about 300 mm (Fig. 3). Thus at higher CO pressures k_2' is a true second order rate constant, and the second term of rate law [5] becomes $k_2[Rh^{III}][Rh^{I}]$. Integration of just this part of the rate law yields eq. 6:

[6] $\log [Rh^{I}] - \log [Rh^{III}] = k_2[Rh]_{total}\, t/2.3 + \text{constant}$

and plots of $(\log [Rh^{I}] - \log [Rh^{III}])$ *vs.* time for the data from plots such as Fig. 1 are shown in Fig. 4; as expected, the plots deviate from linearity during the first part of the reaction, but the slopes of the lines drawn give k_2 values of 0.35 and 0.39 M^{-1} s^{-1}, in reasonable agreement with the value determined from the slope of Fig. 2.

The Initial Reaction and Catalytic Reduction of Iron(III)

The initial reaction was the decomposition of $Rh(CO)Br_5^{2-}$ by water to yield a Rh^I species (*cf.* reaction 1), and thus the presence of an oxidant such as Fe^{III} should lead to an overall catalytic process in which the Rh^I is oxidized to Rh^{III}, followed by absorption of CO to give $Rh^{III}(CO)$ (see refs. 1, 2), and resumption of the catalytic cycle. Such a cycle gives the net reaction 7 with no overall gas volume change,

$$[7] \quad 2Fe^{III} + CO \xrightarrow{H_2O} 2Fe^{II} + CO_2 + 2H^+$$

and so the reaction was monitored by measuring the CO uptake in the presence of sodalime. Reaction 7 does not occur at the conditions used in the absence of rhodium.

The uptake plots for mixtures of $Rh(CO)Br_5^{2-}$ and $Fe(ClO_4)_3 \cdot 6H_2O$ in 0.5 *M* HBr at 60 °C were unusual in shape (Fig. 5), but were reproducible. There was little measurable uptake till about 500 s, after which an essentially linear CO absorption first occurred followed by an enhanced rate of absorption, which then fell away to zero. The visible spectrum of the final solution was that of $Rh(CO)_2Br_2^-$; the Fe^{III} was completely reduced to Fe^{II} which was measured spectrophotometrically as the $Fe(phen)_3^{2+}$ complex (14), after first precipitating the Rh^I carbonyl species (7, 8) as $[(n\text{-}C_4H_9)_4N][Rh(CO)_2Br_2]$. It was readily shown that the linear region of the uptake plot was associated with the ferric reduction, and for the conditions of Fig. 5 at least up to the stage of 50% Fe^{III} reduction, the solution showed a λ_{max} at 550 nm ($\varepsilon = 100\ M^{-1}\ cm^{-1}$) indicating that the rhodium is probably still present mainly as $Rh(CO)Br_5^{2-}$ (see below). The subsequent part of the absorption involves production of $Rh(CO)_2Br_2^-$ from a bromorhodate(III) species, and the stoichiometry for this stage shows about a 3:1 mole ratio of CO:Rh, consistent with reaction 4. A number of experiments using varying $[Rh^{III}]$ and $[Fe^{III}]$, like those in Fig. 5, shows that at the end of the linear region the uptake corresponds to about $(x/2 - y)$ moles of CO per x moles of Fe^{III} and y moles of Rh^{III}.

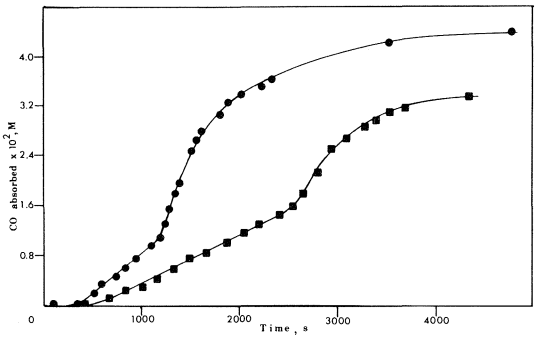

FIG. 5. Rate plot for the $Rh(CO)Br_5^{2-}$-catalyzed reduction of 0.046 *M* Fe^{III} in 0.5 *M* HBr at 60 °C under 615 mm CO, in the presence of sodalime; ●, 0.0105 *M* Rh; ■, 0.0052 *M* Rh.

Mixtures of $Rh(CO)Br_5^{2-}$ and iron(III) in 0.5 *M* HBr at 60 °C in the absence of CO (under N_2 or air) react with the stoichiometry of reaction 8

$$[8] \quad Rh^{III}(CO) + 2Fe^{III} \xrightarrow{H_2O} Rh^{III} + 2Fe^{II} + 2H^+ + CO_2$$

The final visible spectrum featured a maximum at 532 nm ($\varepsilon \approx 170$), characteristic of bromorhodate(III) species (1). More concentrated solutions of $Rh(CO)Br_5^{2-}$ (>0.02 *M*) reacted similarly, but eventually precipitated $Cs_3[Rh_2Br_9]$ as a green solid (the reflectance spectrum showed maxima at 485 and 583 nm. *Anal.* calcd: Rh 15.6, Br 54.3. Found: Rh 15.7, Br 54.2).

Reaction 8 represents the sum of reaction 1, plus the reduction of 2 equivalents of Fe^{III} by 1 equivalent of Rh^I. The coordinated CO is acting overall as a 2-equivalent reductant. The stoichiometry at the end of the linear region in uptake plots such as shown in Fig. 5 corresponds to the net reaction:

$$[9] \quad yRh^{III}(CO) + xFe^{III} + \left(\frac{x}{2} - y\right)CO \xrightarrow{\frac{x}{2}H_2O} yRh^{III} + xFe^{II} + \frac{x}{2}CO_2 + xH^+$$

The linear rates of the initial region (Fig. 5) were first-order in $[Rh^{III}]$ up to 10^{-2} *M*, and independent of the $[Fe^{III}]$. The CO dependence is first-order at lower pressures but then becomes less than one and approaches zero-order at pressures above 600 mm (Fig. 6*A*). The rate law at the higher pressure thus becomes

$$[10] \quad -d[CO]/dt = k_1[Rh^{III}]$$

with k_1 being about $0.14 \times 10^{-2}\ s^{-1}$ at 60 °C.

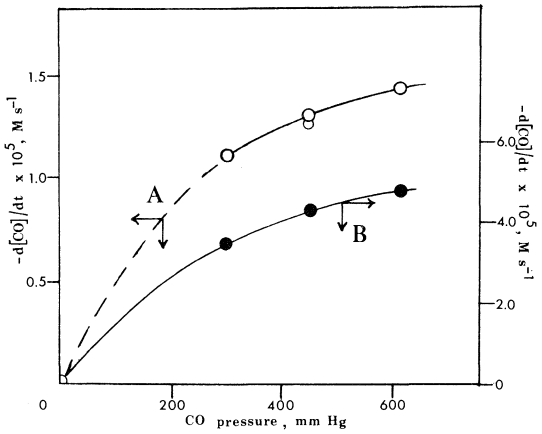

FIG. 6. (*A*) Effect of CO pressure on the reduction rate of 0.046 *M* Fe^{III} in 0.5 *M* HBr at 60 °C with 0.0105 *M* Rh. (*B*) Effect of CO pressure on the maximum rate of Rh^{III} decomposition following the catalytic Fe^{III} reduction; conditions as in *A*.

Following the linear region, the kinetics for the carbonylation of bromorhodate(III) species to give $Rh(CO)_2Br_2^-$ were determined by measuring the maximum rates after the inflexion points (Fig. 5). The rates were first-order in $[Rh^{III}]$ up to 10^{-2} *M*, and the CO dependence (Fig. 6*B*) was similar to that observed for the Fe^{III} reduction. At the higher CO pressures (>500 mm), the rate law for the second region of the uptake plots approximates to:

$$[11] \qquad -d[CO]/dt = k_3[Rh^{III}]$$

where $k_3 = (0.43 \pm 0.02) \times 10^{-2}\ s^{-1}$ at 60 °C.

Discussion

Carbon Monoxide Uptake in the Absence of Iron(III)

The autocatalytic production of $Rh(CO)_2Br_2^-$ from $Rh(CO)Br_5^{2-}$ in the absence of Fe^{III} (Fig. 1, reaction 3, rate law [5]) must proceed via a mechanism involving bridged $[Rh^{III} \ldots Br \ldots Rh^I]$ intermediates, as established previously for the reaction of CO with aquopentachloro- and bisaquotetrabromorhodate(III) complexes (1, 2).

The initial formation of $Rh(CO)_2Br_2^-$ proceeds via reactions 1 and 12

$$[1] \qquad Rh^{III}(CO) + H_2O \xrightarrow{k_1} Rh^I + CO_2 + 2H^+$$

$$[12] \qquad Rh^I + 2CO \longrightarrow Rh^I(CO)_2$$

Reaction 1 presumably gives rise to the first term in rate law [5], *i.e.* the $k_1'[Rh^{III}]^n$ term is identified as $k_1[Rh^{III}]$ and rate law [5] at higher CO pressures becomes $(k_1[Rh^{III}] + k_2[Rh^{III}][Rh^I])$. The maximum rates at approximately 50% reaction are then given by:

$$[13] \qquad -d[CO]/dt = \frac{k_1[Rh]_T}{2} + \frac{k_2[Rh]_T^2}{4}$$

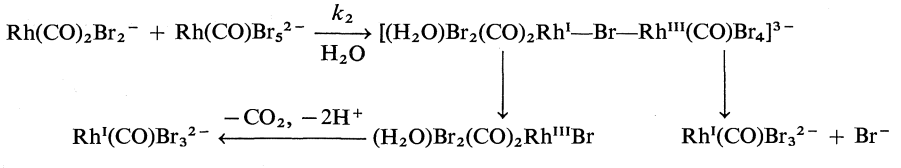
where $[Rh]_T$ = total [Rh]. Substitution of the k_2 and k_1 values, estimated by the methods described, into expression [13] gives maximum rates in good agreement with those measured from plots such as those in Fig. 1.

The reductive carbonylation process of Rh(III) to Rh(I) has been discussed in detail previously (1, 2, 15) and is thought to involve a carboxylate intermediate:

$$[14] \qquad Rh^{III}(CO) \xrightarrow{OH^-(H_2O)} [Rh(CO_2H)] \rightarrow Rh^I + CO_2 + H^+ \quad (2)$$

Some data on decomposition of a $Rh^{III}(CO)$ complex in *N*,*N*-dimethylacetamide (11) indicate that decomposition proceeds via hydroxide. Since the acid strength was not varied in the present system, it is uncertain whether attack at the carbonyl involves water or hydroxide. Furthermore it is difficult to determine whether the hydroxide or water need be coordinated to the metal before migration to the carbonyl, *i.e.* by the 'insertion mechanism'. These problems were considered in our previous paper (1), and we tend to favour attack by coordinated water or hydroxide. This implies that k_1 ($1.4 \times 10^{-3}\ s^{-1}$ at 60 °C) refers to an aquation of $Rh(CO)Br_5^{2-}$ with loss of bromide. A corresponding aquation of $RhCl_5(H_2O)^{2-}$ in acid solution has a rate constant of *ca.* $4 \times 10^{-3}\ s^{-1}$ at 60 °C and is believed to occur via a dissociative process (16), but the similarity in rate constants is probably fortuitous; the π-bonding CO ligand could possibly promote associative-type hydrolysis (17). An initially formed *trans*-$Rh(CO)(H_2O)Br_4^-$ product seems probable, with rearrangement to a *cis* geometry being required for the subsequent insertion reaction and reductive carbonylation (18). Studies on the kinetics and equilibration of various aquobromorhodate(III) species are being pursued (19). The isolation of the $Cs_3[Rh_2Br_9]$ complex from the HBr solutions of Rh(III) is of interest in this respect. The compound has been prepared earlier by the addition of CsBr to aqueous solutions of rhodium tribromide (20).

By analogy with the previous papers on the autocatalytic production of Rh^I carbonyls (1, 2), the process giving rise to the $k_2[Rh^{III}][Rh^I]$ term of rate law [5] may be written:



[15]

$$Rh(CO)_2Br_2^- + Rh(CO)Br_5^{2-} \xrightarrow[H_2O]{k_2} [(H_2O)Br_2(CO)_2Rh^{I}—Br—Rh^{III}(CO)Br_4]^{3-}$$

$$Rh^{I}(CO)Br_3^{2-} \xleftarrow{-CO_2,\ -2H^+} (H_2O)Br_2(CO)_2Rh^{III}Br \qquad Rh^{I}(CO)Br_3^{2-} + Br^-$$

[16] $$Rh^{I}(CO)Br_3^{2-} + CO \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} Rh(CO)_2Br_2^- + Br^-$$

$$K_4 = k_4/k_{-4}$$

After a two-electron transfer within the bromide-bridged intermediate, decomposition via cleavage of the newly-formed labile Rh^{I}–bromide bond will lead to $Rh(CO)Br_3^{2-}$. This species must then react with CO to form the dicarbonyl species. Above CO pressures of *ca.* 600 mm, the k_2 step is rate-determining and this implies that reaction 16 is relatively fast.

The observed CO dependence at lower CO pressures (Fig. 3) could arise from reaction 16 becoming rate-determining, or from this reaction being a pre-equilibrium for formation of $Rh(CO)_2Br_2^-$ required for the k_2 step. At lower CO pressures, if [16] is a rapid equilibrium, the maximum rate expression [13] becomes

$$-d[CO]/dt = \frac{k_1K_4[Rh]_T[CO]}{(2K_4[CO] + [Br])} + \frac{k_2K_4^2[Rh]_T^2[CO]^2}{(2K_4[CO] + [Br])^2}$$

Using the determined values of k_1 and k_2, and the measured maximum rates gives a K_4 value of $\sim 2 \times 10^3$, which would account for the data of Fig. 3. However, at lower CO pressures, this implies that the product of the carbonylation reaction would be a rhodium(I) monocarbonyl, and yet the measured stoichiometry is still 2CO:Rh, in agreement with reaction 3. Thus, the alternative explanation of [16] becoming rate-determining is favoured. Such a suggestion for the related $Rh(CO)_2Cl_2^-/RhCl_5(H_2O)^{2-}$ system was made previously (2), and evidence for a $Rh(CO)Cl_3^{2-}$ species has been obtained also (21) by studying the reaction of $Rh(CO)_2Cl_2^-$ with $Rh(CO)Cl_5^{2-}$ under N_2 atmospheres (*cf.* the reactions in [15]). There is no kinetic evidence to suggest that a $Rh(CO)Br_3^{2-}$ species will react with $Rh(CO)Br_5^{2-}$ to give a bridged species, and such a reaction involving two double-negatively charged anions is likely to be unfavourable.

The k_2 value for the reaction of $Rh(CO)_2Br_2^-$ with $Rh(CO)Br_5^{2-}$ ([15]) is about twice that for reaction of the dicarbonyl with $RhBr_4(H_2O)_2^-$ under corresponding conditions (1). Considering the less favourable electrostatic factor for $Rh(CO)Br_5^{2-}$, the π-acceptor CO ligand likely plays an important role in facilitating electron transfer to the Rh^{III} centre in the bridged complex.

Carbon Monoxide Uptake in the Presence of Iron(III); the Catalytic Reduction of Fe^{III}

The kinetics and observations for the catalytic reduction of Fe^{III} at higher CO pressures (eq. 10) are consistent with the mechanism of reaction 1 followed by:

[17] $$Rh^{I} + 2Fe^{III} \xrightarrow{fast} Rh^{III} + 2Fe^{II}$$

[18] $$Rh^{III} + CO \xrightarrow{k} Rh^{III}(CO)$$

The spectral and kinetic data show that at least up to 50% Fe^{III} reduction the catalyst is mainly regenerated as the pentabromocarbonyl species at higher CO pressures, although the nature of the coordinated ligands on the intermediates in reactions 1, 17, and 18 is not known definitely. Since $(x/2 - 1)$ moles of CO are absorbed per mole of $Rh^{III}(CO)$ during the reduction of x moles of Fe^{III}, it appears that the Rh^{I} reductant contains no coordinated CO and also implies that at the completion of ferric reduction, the Rh^{III} complex present contains no carbonyl. Step [17] then appears faster than coordination of CO to Rh^{I}, which is also known to be fast (1, 2). The stoichiometry data then tend to rule out an alternative process such as:

[19] $$Rh^{I} + CO \xrightarrow{fast} Rh^{I}(CO)$$

[20] $$Rh^{I}(CO) + 2Fe^{III} \xrightarrow{Br^-} Rh^{III}(CO)Br_5^{2-} + 2Fe^{II}$$

The mechanism of reactions 1, 17, 18 also readily accounts for the CO dependence (Fig.

6*A*). Above CO pressures of about 600 mm, reaction 18 must occur more rapidly than reaction 1, but at lower pressures reaction 18 could become rate-determining. The slope of the linear region in Fig. 6*A* at lower CO pressures would then represent an estimate for the rate of reaction between CO and a bromorhodate(III) complex; the estimated rate constant k at 60 °C is 4.5 M^{-1} s^{-1}, and this is close to a value of 2.6 M^{-1} s^{-1} extrapolated from an Arrhenius plot for the direct carbonylation of $RhBr_4(H_2O)_2^-$ in the same media (1). It should be noted that at 600 mm CO, the rate of loss of the Rh^{III} in reaction 18 (*assuming* a CO solubility of 5.2 × 10^{-4} M at this pressure) is about 2.5 × 10^{-3} $[Rh^{III}]$ s^{-1}, while the rate-loss of $Rh(CO)Br_5^{2-}$ is about 1.4 × 10^{-3} $[Rh^{III}]$ s^{-1}. The rates of reactions 1 and 18 are clearly of the same order of magnitude over the pressure range studied, and the solutions in the linear regions of uptake plots will likely contain both bromocarbonyl- and bromo-rhodate(III) species, the relative amounts depending on the CO pressure. The somewhat similar visible spectra of the species in 0.5 M HBr makes this difficult to study quantitatively. The *equilibrated* solutions of bromorhodate(III) complexes in this media (mainly $RhBr_4(H_2O)_2^-$) show a maximum at 537 nm, ε 175 M^{-1} cm^{-1} (1), and the species resulting in [17] are not necessarily equilibrated.

To account for the CO dependence via the mechanism of [1], [19], and [20] requires [19] to become rate-determining at lower CO pressure, but this would lead to metal production via reaction 2. A mechanism analogous to [1], [19], and [20] has been demonstrated by Halpern and co-workers (15) for a formally related cobalt-catalyzed CO reduction of Fe^{III} (see below).

The net reduction of Fe^{III} (reaction 7) catalyzed by the rhodium system is of interest in that the essential mechanism of reactions 1, 17, and 18 shows that any reagent capable of oxidizing aqueous bromorhodate(I) systems to the Rh^{III} state can be catalytically reduced in the presence of CO under mild conditions. Electrode potential data for the rhodium couple ($Rh^{III} + 2e \rightleftharpoons Rh^{I}$) are not yet available. Higher CO pressures will offer no advantage since reaction 1 is rate-controlling. The corresponding rhodium chloride system also effects the catalysis (2), and solutions containing halorhodate(III), carbonylhalorhodate(III), or biscarbonyldihalorhodate(I) are all equally effective since they are interconvertible in the presence of CO and an oxidant. $(Rh(CO)_2X_2^-$ acts as a six-equivalent reductant toward Fe^{III} (2).)

The non-complementary electron transfer reaction between Rh^{I} and Fe^{III} could take place by a two-step mechanism involving a transient Rh^{II} species, or possibly by a one-step termolecular reaction. The latter mechanism has rarely been postulated for reactions involving only simple metal ion species and would likely be slow (22). The electron transfer could proceed by an inner sphere mechanism involving a bromide-bridged intermediate $[Rh^{I} \ldots Br \ldots Fe^{III}]$, or by an outer sphere mechanism. Such bridged intermediates involving cyanide have been established for the related cobalt(I)–iron(III) system outlined below (15):

[21]
$$Co^{I}(CO)L_4 + 2Fe^{III}(CN)_6^{3-} \xrightarrow[\text{fast}]{OH^-} [(CN)_5Fe^{II}(CN)Co^{III}L_4(COOH)] + Fe^{II}(CN)_6^{4-}$$

$(L_4 = (CN)_2(PEt_3)_2)$

$+ CO$

$\text{slow} \downarrow -CO_2, -H^+$

$-Fe^{II}(CN)_6^{4-}$

$[(CN)_5Fe^{II}(CN)Co^{I}L_4]$

As for our $Rh^{I}/2Fe^{III}$ system, the details of the initial $Co^{I}/2Fe^{III}$ interaction remain unclear. Formally analogous $[Rh^{I} \ldots Br \ldots Rh^{III}]$ intermediates also seem well-established (1, 2), and are almost certainly involved in the autocatalytic reaction observed in the absence of Fe^{III} (Fig. 1).

Following reduction of the ferric substrate, reduction of Rh^{III} species to $Rh(CO)_2Br_2^-$ occurs (Fig. 5); subsequent to the inflexion point, the CO uptake corresponds to about 3 moles CO per Rh, indicating that the reduced Rh^{III} species contains no carbonyl and the reaction occurs according to [4]. The reductive carbonylation process now appears to show no autocatalysis, although this could be masked near the inflexion region of the curves. However, the fact that the maximum rates developed show a first-order dependence on Rh confirm no autocatalysis, or at least a relative unimportance of such a process (*cf.* reaction 5), and rate law [11]

operates at higher pressures. The measured rate constant k_3, written in terms of CO uptake, is about three times that (k_1) estimated for decomposition of $Rh(CO)Br_5^{2-}$, and since the rate constant in terms of loss of Rh^{III} will be three or two times smaller (depending whether the reduction process corresponds to reaction 4 or 3, respectively), it seems that the rate-determining step is reaction 1. Furthermore, the CO dependence (Fig. 6*B*) gives at low CO pressures a second-order rate constant of $12.6\ M^{-1}\ s^{-1}$ which corresponds to 12.6/3, *i.e.* $4.2\ M^{-1}\ s^{-1}$ for loss of Rh^{III} and again this is essentially the same as that determined for reaction 18. Thus the reduction of the Rh(III) species after catalysis almost certainly occurs at higher pressures via reaction 1 (rate-determining) and 12, and at lower pressures via reactions 18 (rate-determining), 1, and 12. The stoichiometries at the inflexion points at the higher pressures (Fig. 5) should perhaps be treated with some caution since as mentioned earlier the rates of [1] and [18] are such that the solutions at this stage could contain both carbonyl-free and carbonyl-containing rhodium(III) species.

The lack of autocatalysis, which is being studied further, could be due to the presence of excess Fe(II) species preventing formation of the required $Rh^{III} \ldots Br \ldots Rh^{I}$ bridge; evidence has been presented for the existence of bridged Co^{I}—Fe^{II} species (15).

High resolution ^1H nuclear magnetic resonance studies of a flavine and its product with $MoCl_4$ [1]

T. ROBERIE, N. S. BHACCA, AND J. SELBIN
Department of Chemistry, Louisiana State University, Baton Rouge, LA 70803

Received June 14, 1976

T. ROBERIE, N. S. BHACCA, and J. SELBIN. Can. J. Chem. **55**, 575 (1977).

The high resolution ^1H nmr spectra of the substituted flavine, 3-*N*-methyltetraacetylriboflavine (3-Me-TARF), and its non-aqueous solution complexes with $Gd(fod)_3$, $Eu(fod)_3$, $MoCl_4$, and $MoCl_4 \cdot 2CH_3(CH_2)_2CN$, were studied in order to try to discern the binding sites of the flavine as it attaches to the molybdenum. Evidence was found that all three metal atoms, Gd(III), Eu(III), and Mo(IV), are attached in solution not only by the primary binding (chelating) sites of the flavine, *viz.*, the O-4 and N-5 atoms, but also by an acetyl oxygen atom, at the C-4′ site of the ribityl side chain. 300 MHz spectra of the 3-Me-TARF have permitted the coupling constants for the side chain methine and methylene protons to be obtained.

T. ROBERIE, N. S. BHACCA et J. SELBIN. Can. J. Chem. **55**, 575 (1977).

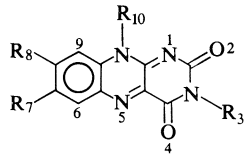
On a étudié les spectres rmn du proton à haute résolution de la flavine substituée, *N*-méthyl-3 tétraacétylriboflavine (Me-3 TARF), et de ses complexes, en solutions non-aqueuses avec $Gd(fod)_3$, $Eu(fod)_3$, $MoCl_4$ et $MoCl_4 \cdot 2CH_3(CH_2)_2CN$; ces études ont été effectuées afin d'essayer de déterminer le site de complexation de la flavine lorsqu'elle s'attache avec le molybdène. On a obtenu des résultats indiquant qu'en solution, les trois métaux Gd(III), Eu(III) et Mo(IV) ne s'attachent pas uniquement par les sites de complexation primaire (chélation) des flavines, à savoir les atomes O-4 et N-5, mais aussi par un atome d'oxygène de l'acide acétyle au niveau du site C-4′ de la chaîne latérale ribityle. Les spectres à 300 MHz du Me-3 TARF ont permis d'obtenir les constantes de couplage pour les protons du méthine et du méthylène de la chaîne latérale.

[Traduit par le journal]

Introduction

Several studies have been reported of the interactions between flavines and flavocoenzymes with metal ions, and the extensive review by Hemmerich and Lauterwein (2) is a valuable background to much of this literature. Most of the studies have been carried out in solution, mainly by Hemmerich and co-workers; but more recently there have also been X-ray structural studies of solids, primarily by Fritchie and co-workers. The solution work, mainly in aqueous but more recently in non-aqueous media, has led to the recognition of at least three types of flavine–metal complexes (2). This work, but in particular solid state structural work (3), has also established certain structural features related to metal–ligand binding at the several potential binding sites of the flavines. Whereas X-ray structures clearly establish metal–ligand binding sites, these may only be inferred from solution data. It is far from certain that solution and crystalline state structures are necessarily the same when fluxional ligands such as flavines are involved. One means for obtaining structural information on species in solution is through high resolution nuclear magnetic resonance.

We have found relatively little proton nmr (^1H nmr) data in the literature on flavoquinones (**1**).



1

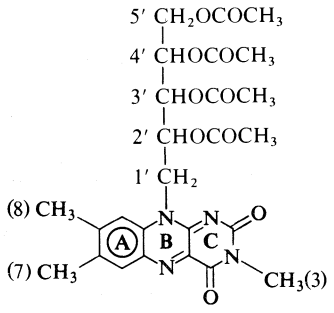
A brief report was made of the ^1H nmr spectra of FMN or riboflavin 5′-phosphate ($R_3 = H$; $R_7 = R_8 = CH_3$; $R_{10} = CH_2(CHOH)_3CH_2OPO_3H$), lumiflavin ($R_3 = H$; $R_7 = R_8 = R_{10} = CH_3$), and its 7-ethyl analogue in D_2O at pH = 6.8. The protons in positions 6 through 10 were again assigned for lumiflavin and its 9-bromo- and 9-deutero- and 6,9-dideutero-derivatives (4, 5). More thorough ^1H nmr studies of FMN and FAD (flavin adenine dinucleotide) confirmed *intra*molecular interaction between the adenine and the isoalloxazine rings in FAD and also suggested *inter*molecular interaction

[1]Presented at the First Chemical Congress of the North American Continent, Mexico City, December 4, 1975.

between isoalloxyazine rings of neighboring FAD molecules (6, 7). In 1972, a brief account of the ^1H nmr spectra was published of tetraacetylriboflavine ($R_3 = H$; $R_7 = R_8 = CH_3$; $R_{10} = CH_2(CHOCOCH_3)_3CH_2OCOCH_3$) and its complexes with Fe^{2+}, Co^{2+}, Ni^{2+}, and Cu^{2+} in acetone-d_6 (8). A full account of that work including additional information on the ^1H nmr of complexes of Cu^+, Ag^+, Zn^{2+}, Cd^{2+}, Mn^{2+}, Mg^{2+}, and Fe^{3+} has now been published (9, 10). ^1H nmr studies of hydroxyquinolinate complexes of Mo(VI, V) and V(V) have also been reported as models of molybdenum–flavine interactions (11).

Inasmuch as molybdenum and a flavine (FAD in particular) are essential co-factors in several enzyme systems (12), and since neither X-ray nor any kind of solution studies have established the ligand binding sites of flavines on molybdenum, we decided to undertake a detailed ^1H nmr study of solutions of a particular molybdenum–flavine system. From earlier studies it is not clear that biological molybdenum and FAD are even near each other (12), except possibly during a turnover of the enzyme molecule, and so we recognize that this study may or may not have any relevance to the biological systems. In any case the study has revealed some new and interesting chemistry of both molybdenum and of the derivative of riboflavin which we employed as a model of FAD.

We report here a study of the ^1H nmr spectra of 3-*N*-methyltetraacetylriboflavine (3-Me-TARF) (**2**)



2

and its non-aqueous solution complexes with $Gd(fod)_3$, $Eu(fod)_3$ (fod = 1,1,1,2,2,3,3-heptafluoro-7,7,-dimethyl-4,6-octanedione), and $MoCl_4$.

Experimental

All solutions used in this study were prepared in an efficient nitrogen-filled dry box. $CDCl_3$ was used as the solvent for the nmr work involving $Eu(fod)_3$ and $Gd(fod)_3$. On the other hand, because of the very low solubility of $MoCl_4$ in $CDCl_3$, it was dissolved in a 99:1 $CDCl_3$–ethanol mixture. These 'reagent' solutions were stored in 8.0 ml septum vials capped with teflon 'mininert' valves (obtained from Precision Sampling Corp., Baton Rouge, Louisiana 70815, Cat. No. 614250). The vials were transferred then from the dry box to N_2-filled glove bags where continuous and easy sampling could be carried out. During a typical nmr determination, the nmr sample tube containing the flavine solution was placed in the glove bag and an incremental amount of 'reagent' solution was then added with a Hamilton microliter syringe. ^1H nmr spectra were obtained at 100 and 300 MHz on Varian HA-100 and HR-300 spectrometers. A small amount of tetramethylsilane was added to the sample solution, to act both as an internal reference as well as an internal lock signal.

3-*N*-Methyl-riboflavintetraacetate (14) (3-Me-TARF) and anhydrous $Gd(fod)_3$ (15) were synthesized according to known procedures. $MoCl_4$ was supplied in vacuum sealed vials by Climax Molybdenum Company. $Eu(fod)_3$ was purchased from Kary Laboratories, Somerville, N.J.

$CDCl_3$ was dried by refluxing it under N_2 with CaH_2 before distilling it under N_2. Absolute ethanol was refluxed with magnesium acetate overnight before being distilled under N_2.

After ^1H nmr data had been obtained on the $MoCl_4$ and 3-Me-TARF, it was found from esr studies of the $MoCl_4$ dissolved in the 99:1 $CDCl_3$–ethanol mixture that there was a small quantity of Mo(V) present in the sample. Efforts to wash out the Mo(V) species from the $MoCl_4$ sample using benzene were only partially successful but in any case when the $MoCl_4$ was redissolved in the mixed solvent some Mo(IV) was oxidized to Mo(V). We believe that it may be impossible to prevent some Mo(V) from forming whenever $MoCl_4$ is put into solution. Since the observed ^1H nmr resonance broadening in the 3-Me-TARF spectra upon addition of $MoCl_4$ might be due to the impurity levels of Mo(V), we prepared the compound, $MoCl_4 \cdot 2CH_3(CH_2)_2CN$ (17), to reexamine the Mo(IV) ^1H nmr studies. This Mo(IV) compound can be made nearly Mo(V)-free. It dissolves in $CDCl_3$ without the necessity of ethanol being present (which may be the cause of the Mo(V) forming) and without any increase in Mo(V) impurity. The latter was verified by means of esr measurements. The results of the ^1H nmr study using the butyronitrile complex of $MoCl_4$ in place of $MoCl_4$ itself gave the same order of broadening effects on 3-Me-TARF. Thus the conclusion we draw is that it is indeed Mo(IV) and not Mo(V) that is responsible for the proton broadenings on the ligand and that the ligand is indeed attached to Mo(IV).

Results and Discussion

The Flavine

In the 100 MHz spectrum of 3-Me-TARF (see bottom spectrum of Fig. 1) most of the resonances corresponding to the side chain protons are indecipherable and therefore 300 MHz spectra (in $CDCl_3$ and CD_3COCD_3 solutions) of the sample were obtained (see Fig. 1). The subsequent first order, as well as calculated, spectral

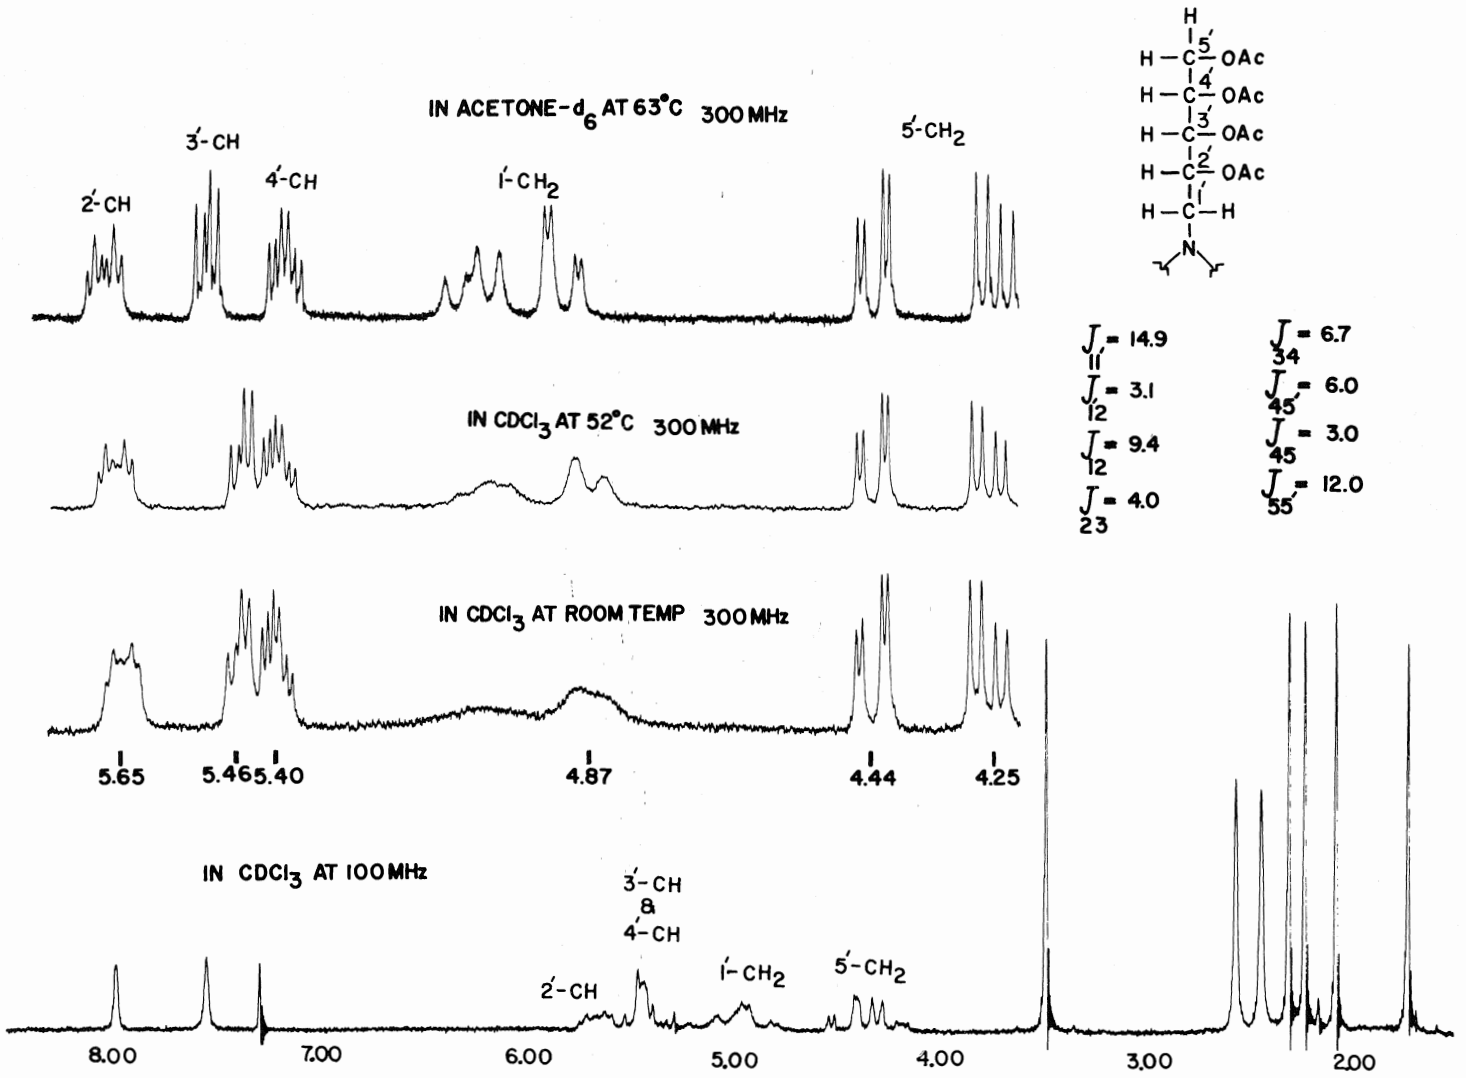


FIG. 1. 300 MHz spectra of the 4 to 6 δ region of 3-Me-TARF in acetone-d_6 at 63 °C (top spectrum) and in $CDCl_3$ at 52 °C and at ambient temperature (two middle spectra). The bottom spectrum is the complete 100 MHz spectrum run in $CDCl_3$, shown for reference. The C-2′ methylene proton resonances in $CDCl_3$ spectra are broader due to their spin–spin interaction with ^{14}N quadrupole.

analysis yields all the coupling constants related to the side chain protons. Finally from the direct comparison of these coupling constants with those of acyclic ribose and arabinose (as shown in Table 1) the ribose structure was assigned to the side chain. This conclusion is in harmony with the fact that the 3-Me-TARF had been prepared from riboflavin whose side chain possesses the *d*-ribose structure.

The Flavine and Eu(fod)$_3$

The addition of incremental amounts of Eu(fod)$_3$ to $CDCl_3$ solutions of 3-Me-TARF produced the shifts of the isoalloxazine protons as a function of concentration shown plotted in Fig. 2. The shifts fall in the order: H-6 ≫ N-3—CH_3 > H-9 ≫ C-8—CH_3 > C-7—CH_3. These data support 1:1 Eu(fod)$_3$:3-Me-TARF complexing. The H-6 proton signal is immediately severely broadened as well as shifted. The sequence of shifts confirms metal chelation at the primary binding site of the isoalloxazine, O-4 and N-5.

The shifting and broadening of methylene and methine side chain proton signals with increasing Eu(fod)$_3$ concentration were also examined and the shifts are plotted in Fig. 3. Again, 1:1 complexing is supported by the evidence shown in Fig. 3. The sequential order of shifts may be rationalized by certain side chain structural information. For example, the extreme high field position ($\delta = 1.75$) of the 2′-$OCOCH_3$ methyl peak (Fig. 1) strongly suggests that this methyl group is located in the shielding region of aromatic **A** ring and, as molecular models clearly reveal, that one of the two C-1′ methylene protons is the deshielding zone of the C-2′—carbonyl function. On the other hand, the H-2′ is

deshielded either by proximity to a carbonyl group or by proximity to the metal atom, depending upon which side of the fused ring system the ribityl side chain falls. This is the likely explanation for the large downfield shifts observed (Fig. 3) for the H-2′ resonance and for the signals of one of the two C-1′ methylene protons.

The comparatively large downfield shift of the H-4′ proton signal (Fig. 3) was not expected. We believe that this shift is caused by the proximity of the H-4′ to the Eu atom due to binding of the Eu atom by the carbonyl oxygen of C-4′—$OCOCH_3$ (*vide infra*).

The shifting of the methyl proton signals of the acetate groups with increasing $Eu(fod)_3$ concentration was examined and the results are plotted in Fig. 4. The 1:1 complexing is again evident from the latter figure as is the unexpected result that the C-4′—$OCOCH_3$ signal is shifted considerably more than the remaining three acetate signals. We interpret this result to mean that complexing of the flavine occurs not only through the primary binding site but via the 4′-acetate as well. Molecular models support this interpretation since they show that, with the 2′-acetate locked over the **A** ring (*vide infra*), only the acetate at C-5′ or C-4′ can come within reasonable bonding distance to a metal atom bound at the primary site. The choice between these two possibilities can then be made in the model by requiring the side chain configuration to conform to all other ^1H nmr shift results. From model studies and, in particular, on the basis of the ^1H nmr data for the 4′-methine and acetate protons, we propose that at least in solution there is strong evidence that the metal atom (here Eu) is bound by *three* ligand atoms, the primary binding pair, O-4 and N-5, and the carbonyl oxygen of the C-4′—acetate.

The Flavine and Gd(fod)$_3$

Gadolinium has an $^8S_{7/2}$ ground state and thus its complexes are magnetically isotropic and therefore do not exhibit dipolar shifts (13). However, the broadening of ^1H nmr lines caused by increasing concentrations of $Gd(fod)_3$ supplies very useful information since the *only* effect operating is a pseudocontact or through-space interaction. Although the signals due to the side chain methine and methylene protons are too weak and too rapidly broadened, meaningful results have been obtained for both the isoalloxazine protons and the acetate protons. The

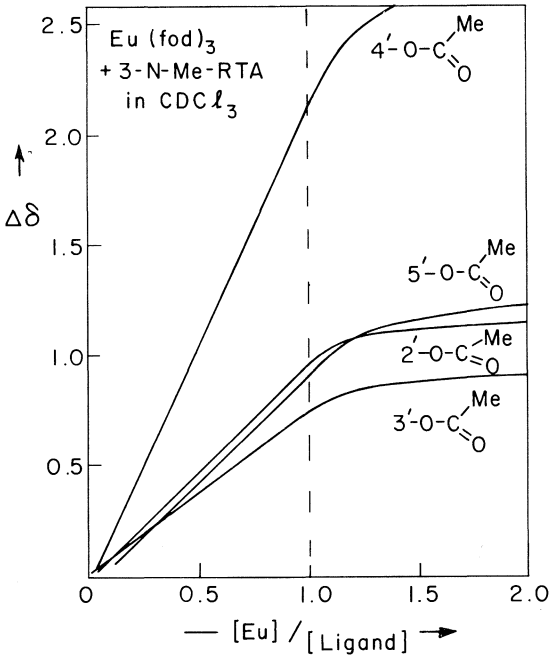

FIG. 4. Shifts in ppm of the side chain acetate methyl resonances with increasing $Eu(fod)_3$ to ligand mole ratios.

line width broadening as a function of $Gd(fod)_3$ concentration is plotted for these signals in Figs. 5 and 6, respectively. The broadening sequence (Fig. 5), H-6 ≫ N-3—CH_3 > C-7—CH_3 ≫ H-9 > C-8—CH_3, is just that expected from an isotropic magnet placed at the primary binding site between the N-5 and O-4 positions. Of much greater interest is the broadening sequence shown in Fig. 6 for the acetate methyl proton signals: C-4′ ≫ C-3′ > C-5′ > C-2′. Although these could only be followed out to a metal/ligand mole ratio of roughly 10^{-2}, it is clear that the C-4′—acetate must be much closer to the Gd atom than the other three acetate groups. Thus we again find evidence in support of attachment of the flavine to a metal atom via *three* sites.

The Flavine and $MoCl_4$

The addition of incremental amounts of $MoCl_4$ (or $MoCl_4 \cdot 2CH_3(CH_2)_2CN$, see Experimental section) to chloroform-*d* solutions of 3-Me-TARF produced the results shown in Fig. 7. The more pronounced effect is a broadening, but there is also a very slight shifting of signals. This is more evident in Fig. 8, where the broadening and slight shifting (in chloroform solutions) is shown for the several acetyl protons and the C-7 and C-8 methyl protons.

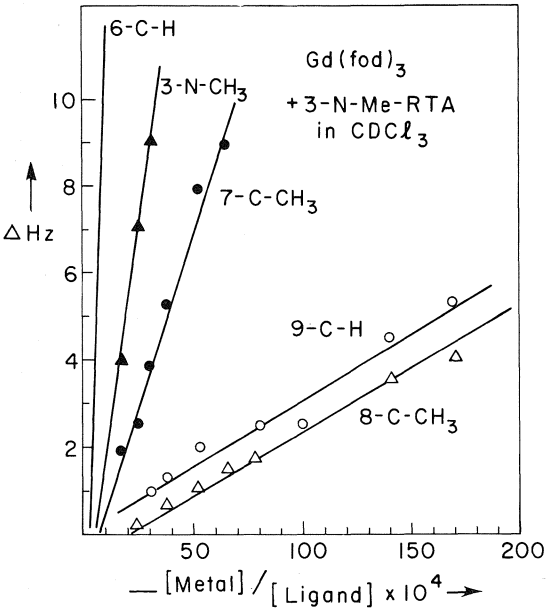

FIG. 5. Line width broadening of the isoalloxazine proton resonances plotted as a function of increasing $Gd(fod)_3$ to ligand mole ratios.

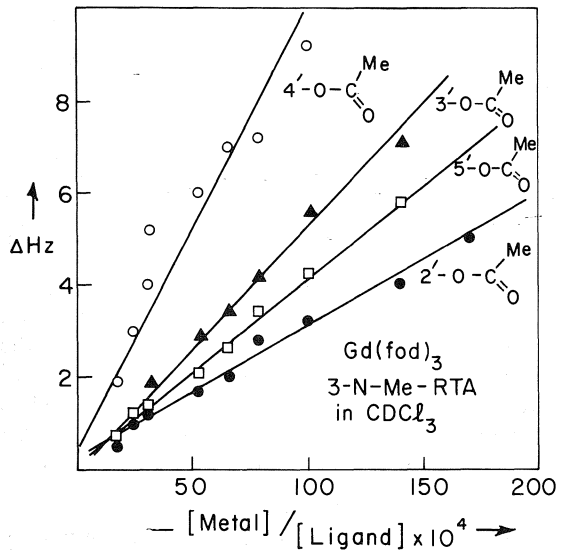

FIG. 6. Line width broadening of the side chain acetate methyl resonances plotted as a function of increasing $Gd(fod)_3$ to ligand mole ratios.

The broadening sequence in the isoalloxazine protons for the $MoCl_4$–3-Me-TARF interaction is (Fig. 9): H-9 ~ H-6 > C-8—CH_3 > *N*-3—CH_3 > C-7—CH_3. This sequence for the paramagnetic Mo(IV) species supports the binding of

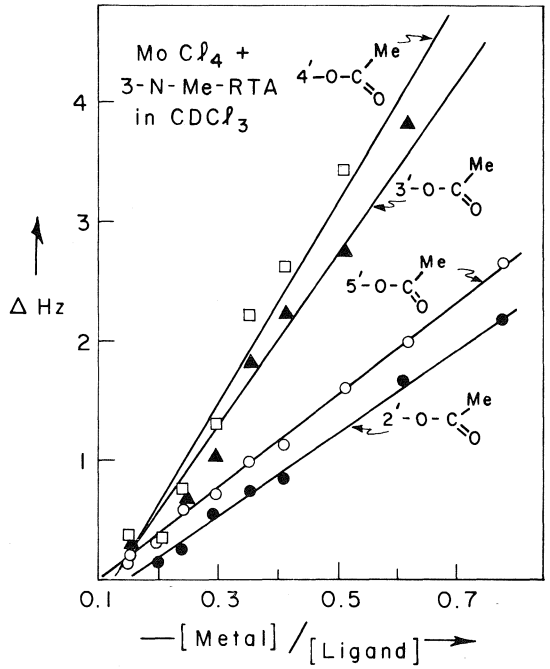

FIG. 7. Line width broadening of the side chain acetate methyl resonances plotted as a function of increasing $MoCl_4$ to ligand mole ratios.

the molybdenum atom by at least the primary binding site, O-4 and N-5. It is a sequence expected if a contact interaction is superimposed upon the pseudocontact interaction. Thus, the differences between this sequence for the gadolinium case (*vide supra*) where only pseudocontact interactions are operative, and the europium and molybdenum cases can be explained on the basis of expected increasing (Eu to Mo) contributions from contact interactions. For example, the relative positions of C-7—CH_3 and C-8—CH_3 in the Eu and Mo sequences compared to their positions in the Gd sequence bear out the increased importance of electron delocalization (*i.e.*, Fermi contact interaction) in the Mo complex. The C-7—CH_3 is spatially closer to a metal atom complexed at O-4 and N-5, but the π-electron spin density at position 7 is near 0.0 whereas it is near 0.15 at position 8 (1).

In addition to the molybdenum atom being bound by the primary site of the isoalloxazine system, it appears that it is further bound by the acetate oxygen of C-4′—$OCOCH_3$. Thus, both the broadening sequence (from Fig. 9) and the shifting sequence show the greatest effect is on the

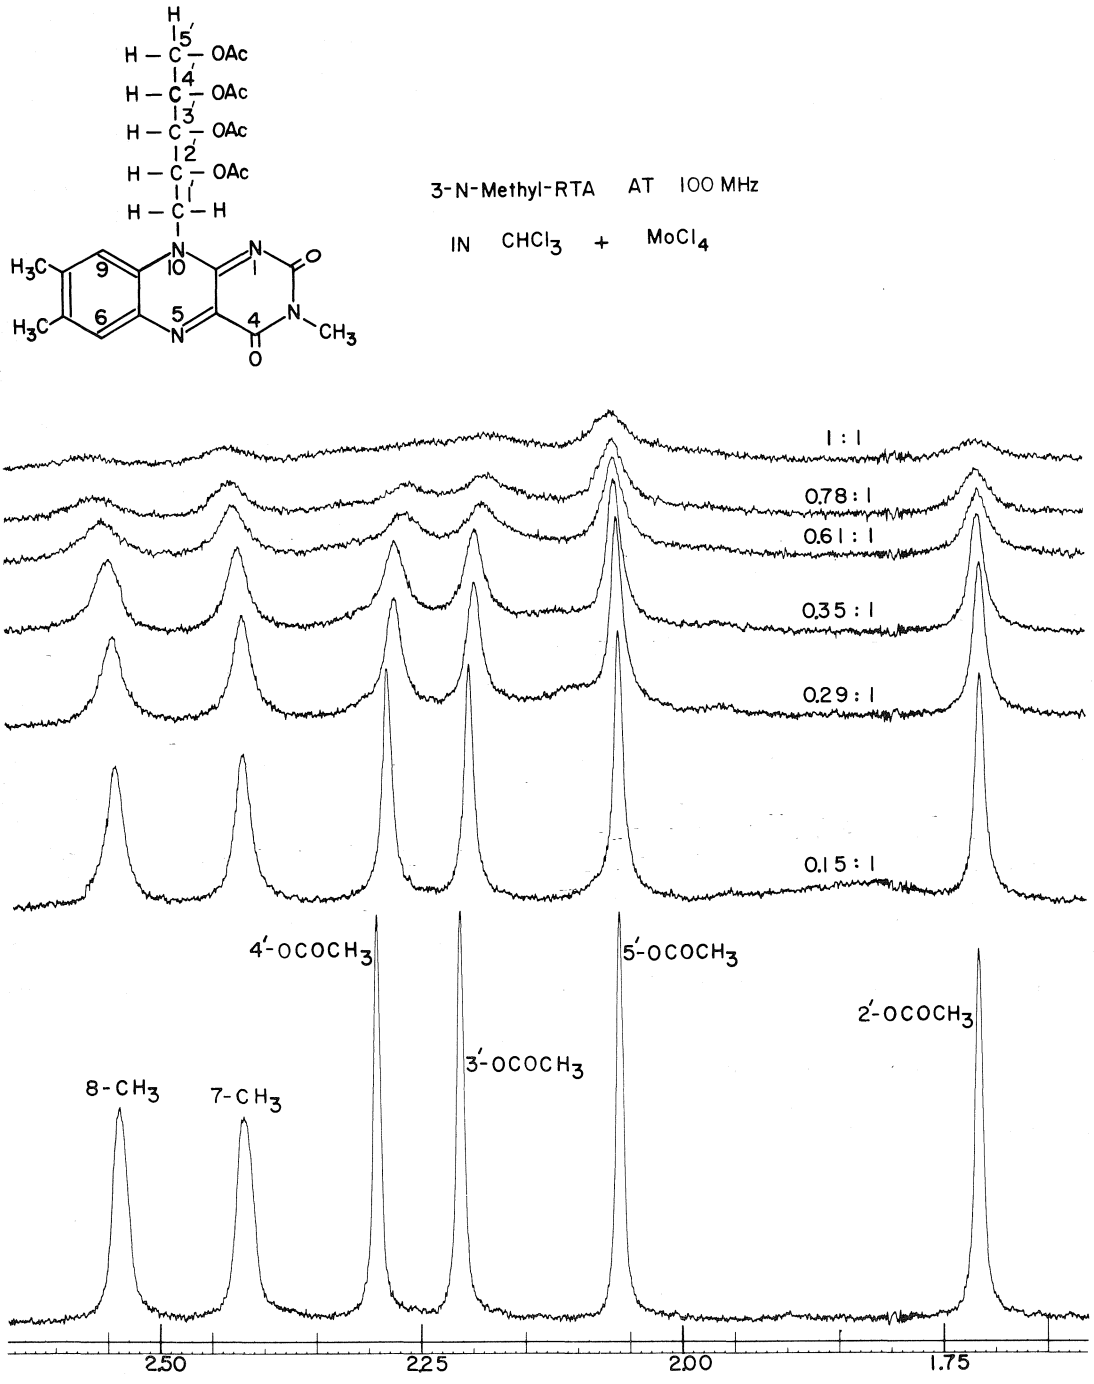

FIG. 8. 100 MHz spectrum of the 1.50 to 2.75 δ region of 3-Me-TARF at 100 sweep width and the resulting spectra obtained upon incremental additions of $MoCl_4$ solution in amounts giving mole ratios of 0:1, 0.15:1, 0.29:1, 0.35:1, 0.61:1, 0.78:1, and 1:1 as we go from bottom to top.

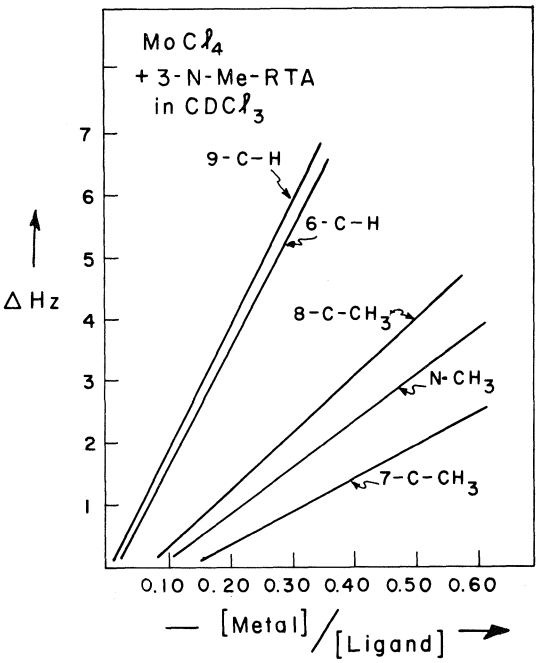

FIG. 9. Line width broadening of the isoalloxazine protons plotted as a function of increasing $MoCl_4$ to ligand mole ratios.

methyl proton of C-4′—$OCOCH_3$. This is in agreement with analogous results for both the Gd and Eu compounds.

On the basis of the foregoing results and their interpretation, it is tentatively suggested that molybdenum is bound to flavine molecules through the agency of at least two binding sites and very likely a third binding site present on the folded ribityl side chain. For the tetraacetylriboflavin compound studied here, that binding site is the C-4′—acetyl group.

Acknowledgement

The authors are grateful to the Climax Molybdenum Company for their generous donation of samples of Mo compounds. The authors are also grateful to Mr. Everett R. Santee of The University of Akron Institute of Polymer Science for his help in obtaining 300 MHz of 3-Me-TARF.

Acetyl group relaxation in four aromatic ketones

C. K. McLellan and S. Walker

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received August 5, 1976

C. K. McLellan and S. Walker. Can. J. Chem. **55,** 583 (1977).

Dielectric absorption studies have been made of group relaxation of acetophenone, 1,4-diacetylbenzene, 4-acetylbiphenyl, and 2-acetylfluorene in a polystyrene matrix, and two rigid molecules have also been examined. For acetyl group relaxation in acetophenone, $\Delta H_E = 29.6 \pm 0.6$ kJ mol^{-1} and $\Delta S_E = 26 \pm 3$ J K^{-1} mol^{-1} (95% confidence intervals). The energy barrier for acetyl group relaxation is of the same order as that obtained from nmr data. Our results for acetophenone differ appreciably from the values reported for the gaseous phase by the far-infrared approach and from those by the dielectric absorption of aromatic ketones in benzene solution. The enthalpies of activation for acetyl group relaxation in 1,4-diacetylbenzene, 4-acetylbiphenyl, and 2-acetylfluorene are 29, 30, and 32 kJ mol^{-1}, respectively, which values are identical within their experimental errors. These three substances have also been examined as pure solids, yielding enthalpies of activation for acetyl group relaxation of a similar magnitude.

C. K. McLellan et S. Walker. Can. J. Chem. **55,** 583 (1977).

On a effectué des études, dans des matrices de polystyrène, d'absorption diélectrique afin d'évaluer la relaxation du groupe de l'acétophénone, du diacétyl-1,4 benzène, de l'acétyl-4 biphényle et de l'acétyl-2 fluorène; on a aussi examiné deux molécules rigides. Pour la relaxation du groupe acétyle de l'acétophénone, $\Delta H_E = 29.6 \pm 0.6$ kJ mol^{-1} et $\Delta S_E = 26 \pm 3$ J K^{-1} mol^{-1} (avec des intervalles de confiance de 95%). La barrière d'énergie pour la relaxation du groupe acétyle est du même ordre que celle obtenue par des données de rmn. Nos résultats pour l'acétophénone diffèrent toutefois d'une façon appréciable des valeurs rapportées pour la phase gazeuse alors qu'une approche par infrarouge lointain ayant été utilisée ainsi que de celles obtenues à partir de l'absorption diélectrique de cétones aromatiques en solution dans le benzène. Les enthalpies d'activation pour la relaxation du groupe acétyle dans le diacétyl-1,4 benzène, l'acétyl-4 biphényle et l'acétyl-2 fluorène sont respectivement de 29, 30 et 32 kJ mol^{-1}; ces valeurs sont identiques à l'intérieur des erreurs expérimentales. On a aussi examiné ces trois substances à l'état de solides purs; on a pu en dériver des enthalpies d'activation pour la relaxation du groupe acétyle qui sont d'une grandeur sembable.

[Traduit par le journal]

Introduction

The energy barrier to acetyl group rotation, when the acetyl group is attached to an aromatic ring, has received some attention. A far-infrared study (1) of acetophenone in the gas phase gave a value of 13.0 kJ mol^{-1}. *Ab initio* calculations (2) yielded 18.4 kJ mol^{-1}. Fong and Smyth studied 2-acetylnaphthalene and 4-acetyl-*o*-terphenyl (3), 4-phenylacetophenone, and 1,4-diacetylbenzene (4) in benzene solution and obtained values of 4.2 to 6.3 kJ mol^{-1} for the activation enthalpy barrier (ΔH_E from Eyring theory) which the acetyl group encounters as it rotates. Grindley, Katritzky, and Topsom (5) have estimated from nmr data on *para*-substituted acetophenones that the rotation barrier for acetophenone itself is 26 kJ mol^{-1}. Thus, the energy barriers for acetyl group rotation estimated by these procedures differ considerably and merit further examination.

It seemed of interest to examine acetophenone and some related substances at low concentrations in a solid matrix where the means existed of directly separating the group relaxation contribution from the molecular relaxation. Such a procedure appeared more straightforward than studying the dielectric absorption of these solutes in an inert liquid solvent, since in this latter situation the molecular and group absorptions overlap, and the number of microwave frequencies available is usually fairly limited. In addition, in such work it is necessary to obtain the group relaxation time (τ_2), which has to be obtained at a few temperatures to estimate the enthalpy of activation for group relaxation; the deduction of τ_2 requires a Budó analysis which in a number of cases is now known to be unsatisfactory (6).

Experimental Results

The dielectric measurements have been made on a General Radio 1615A capacitance bridge in the frequency range 50 to 10^5 Hz. The mea-

suring cell was a three-terminal circular parallel plate capacitor mounted in a temperature-controlled chamber purged with dry nitrogen gas. The cell may be operated from liquid nitrogen temperature to about 400 K. For the polystyrene matrix sample of acetophenone only, additional measurements have been made using a Hewlett-Packard 4342A Q-meter with a temperature-controlled two-terminal cell in the range 2.5×10^4 to 1.5×10^7 Hz. The apparatus and measurement techniques have been described previously (7).

We have adopted the Davies and Swain (8) procedures both experimentally and in the evaluation of the relaxation time and distribution parameter by means of the Fuoss–Kirkwood equation and the enthalpy of activation from the Eyring equation. The polystyrene used here had a nominal $M_w = 230\,000$. The matrix solutions were prepared by dissolving weighed quantities of polystyrene and the desired solute in a third non-polar solvent, *trans*-1,2-dichloroethylene. This latter solvent was then removed by heating to 360 K followed by treatment in a heated vacuum oven. The resultant matrix mass was pressed (5 ton ram load) in a cylindrical die heated to 395 K to produce a sample disk 2.0 in. in diameter and approximately 0.065 in. in thickness. Prior to pressing, the matrix mass containing acetophenone was returned to the vacuum oven at 360 K for 24 h with no resultant weight loss, indicating that this preparation procedure did not produce any loss of solute from the matrix. The sample disks were allowed to relax possible strains from pressing for at least 24 h prior to measurements, and repeat measurements several months later on the same disk yielded comparable data. We have also taken the precautions which Davies and Swain (8) have pointed out are necessary for accurate measurements and have repeated their study on cyclohexyl chloride in polystyrene, obtaining an enthalpy of activation of 43 ± 7 kJ mol^{-1} for the intramolecular process, in good agreement with their value of 42 ± 2.5 kJ mol^{-1} and with the value of 43 ± 2 kJ mol^{-1} deduced from nmr studies on the pure liquid (9).

Acetophenone, 1,4-diacetylbenzene, 4-acetylbiphenyl, and 2-acetylfluorene have each been examined in a polystyrene matrix, and a sample plot of loss factor ($\varepsilon'' = \varepsilon''(\text{obs}) - \varepsilon''(\text{polystyrene})$) against log (frequency) is given in Fig. 1 for acetophenone. Similar dielectric measurements were carried out out on three of these as pure polycrystalline powders pressed into disks. The results of Eyring equation analyses of these data and of data for two other rigid molecules (4-bromotoluene and 4-nitrobiphenyl) are given in Table 1, along with relaxation times calculated from these analyses at three temperatures.

In the fitting of the data of relaxation time as a function of temperature to the Eyring equation, standard statistical techniques (10) have been employed to obtain the slope and intercept of the line and the variances of these two parameters. These data yielded values of the enthalpy (ΔH_E) and entropy (ΔS_E) of activation for the relaxation process along with confidence intervals for each of these two. The 95% confidence intervals on ΔH_E were typically $\pm 10\%$ of the nominal values, or less, in agreement with the work of Davies *et al.* (8, 11). For the ΔS_E term these confidence intervals were of the order of $\pm 50\%$ of the nominal values in some cases, since this term is often a small part of the intercept, (ln $(h/k) - \Delta S_E/R$), of the ln $(T\tau)$ *vs.* $(1/T)$ plot. For this reason an extensive study of the acetophenone/polystyrene matrix was undertaken to obtain a larger number of points on the Eyring plot extending to higher temperatures (smaller $1/T$ values). This procedure produced values of $\Delta H_E = 29.6 \pm 0.6$ kJ mol^{-1} and $\Delta S_E = 26 \pm 3$ J K^{-1} mol^{-1} (95% confidence intervals). For other samples the values have been quoted to two significant digits in line with the error estimates as outlined above.

Discussion

From good straight line plots of log $T\tau$ *vs.*

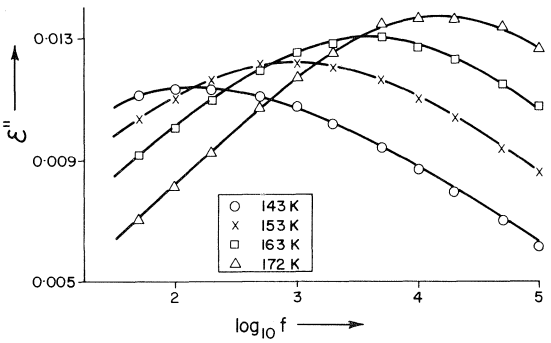

FIG. 1. Dielectric loss factor *vs.* $\log_{10} f$ for 0.265 *M* acetophenone in polystyrene at four temperatures as indicated. The solid lines result from computer analyses of the experimental points via the Fuoss–Kirkwood equation.

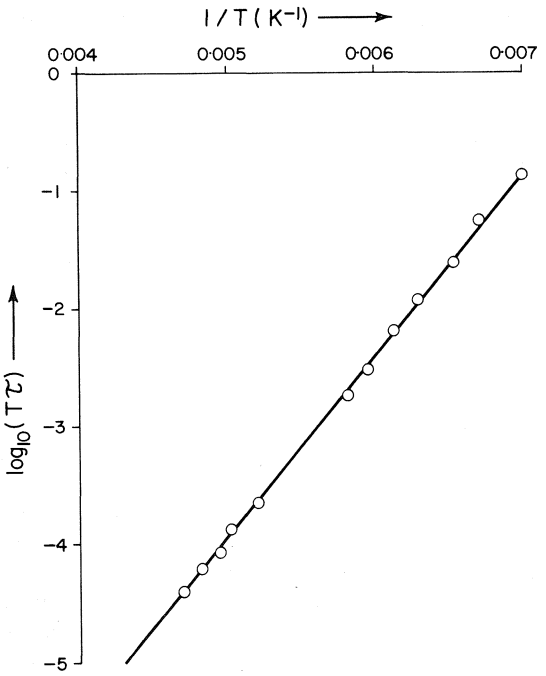

FIG. 2. Eyring plot of $\log_{10} T\tau$ *vs.* $(1/T)$ for 0.265 *M* acetophenone in polystyrene. The solid line represents the computer-generated best fit to the experimental points.

$1/T$ (for example, see Fig. 2), the corresponding enthalpies of activation were 29.6, 29, 30, and 32 kJ mol^{-1} for 3% (wt.) solutions of acetophenone, 1,4-diacetylbenzene, 4-acetylbiphenyl, and 2-acetylfluorene in polystyrene. Thus, all four ketones exhibited dielectric absorptions in similar ranges of temperature and frequency, yielding ΔH_E values in very good agreement, well within our estimate of experimental error.

If we take into account the studies of Davies and Swain (8) in polystyrene matrices at similar temperatures, the two possible sources of the dielectric absorptions in these aromatic ketones are molecular or group relaxation. For several flexible molecules examined by Davies and Swain (8), only intramolecular relaxation was observed; indeed, they noted that "molecular reorientation thus has been restricted to such low frequencies that it does not appear at all". It is to be noted that the ketones considered here differ appreciably in size, and that the enthalpy of activation for molecular relaxation tends to increase with size. For example, one may note the values in Table 1 for two rigid molecules chosen for the similarities of their sizes to those of the ketones

TABLE 1. Eyring analysis results for several molecules in polystyrene matrices (p.s.) or as compressed solids (solid)

Molecule	State	T (K)	Molarity	ΔH_E (kJ mol^{-1})	ΔS_E (J K^{-1} mol^{-1})	τ (s) 150 K	τ (s) 225 K	τ (s) 300 K

*Data provided through the courtesy of Mr. B. K. Morgan of this laboratory.

under investigation. Further, it may be seen from Table 1 that we have observed for the two larger ketones a second dielectric absorption process at higher temperatures although still below the glass transition temperatures (approximately 345 K) of the matrix samples. The ΔH_E and τ values for these absorptions are in good agreement with the corresponding values obtained from the data for the similarly-sized rigid molecule, 4-nitrobiphenyl.

Table 1 includes the results of dielectric measurements on crystalline solid samples of three of the ketones under discussion. In this state one may reasonably expect that molecular relaxation would be eliminated while group relaxation may still occur. It is apparent in this table that the ΔH_E values so obtained, being 27, 33, and 32 kJ mol^{-1} for 1,4-diacetylbenzene, 4-acetylbiphenyl, and 2-acetylfluorene, respectively, are in good agreement with the values derived from analyses of the low-temperature dielectric absorptions in the polystyrene matrix samples.

For the cases of 4-acetylbiphenyl and 2-acetylfluorene, then, we have observed two dielectric absorption processes in polystyrene matrix samples. In each case the Eyring activation parameters for the lower-temperature process is in agreement with that obtained from a crystalline sample. In addition, the parameters for the higher-temperature process are in reasonable agreement with the data for a polystyrene matrix sample of the rigid molecule 4-nitrobiphenyl. For the case of 1,4-diacetylbenzene a low-temperature absorption similarly has been observed in both the polystyrene matrix and crystalline samples. Further, for this substance the components of the substituent groups' dipole moments along the molecule's long axis cancel out one another. The possible relaxation candidates in this case then could be molecular relaxation of a rigid *cis* form of the molecule or acetyl group relaxation. A stable *cis* form would imply a high energy barrier opposing group relaxation, probably considerably higher than that obtained for acetyl group rotation by other methods. It may be noted also that the relaxation times for the slightly smaller 4-bromotoluene in polystyrene at 150, 225, and 300 K were approximately two orders of magnitude longer than those of 1,4-diacetylbenzene, which is just the opposite of what would have been expected if both molecules had exhibited molecular relaxation.

It would seem that the most likely interpretation of this information is that acetyl group relaxation has been observed in 1,4-diacetylbenzene, 4-acetylbiphenyl, and 2-acetylfluorene at temperatures near 150 K, and that molecular relaxation has also been observed in the latter two at temperatures near 320 K. One may note that in these two rod-shaped ketones the relaxation times for molecular and group processes at 300 K differed by a factor of approximately 10^6 in the polystyrene matrices, which factor is enormously larger than is usually found in liquid studies. From the existence of acetyl group relaxation in all three of these ketones one would anticipate that the same process should be found in acetophenone itself, and as Table 1 shows the ΔH_E, ΔS_E, and τ values for this molecule are entirely in accord with the values found for the lower-temperature process in the other three. The fact that the relaxation time values for acetophenone are approximately twice as long as those of the lower-temperature process in the much larger molecule 4-acetylbiphenyl is further indication that these processes could not both be molecular relaxation.

The possibility has to be considered that our matrix values do not correspond with those of an isolated molecule. Borisova and Chirkov (12) found that the energy barrier for molecular relaxation of small molecules in a polystyrene matrix was independent of concentration provided that these were below 5–7 mol%. Similarly, Davies and Swain (8) reported an anomalous dielectric absorption in one of their samples at 15% (wt.) which disappeared when solute concentration was reduced to 9%. These authors indicated that at concentrations less than 10% the solute was monomolecularly dispersed in the polystyrene matrix. Our results for each of the aromatic ketones was at a considerably lower concentration, approximately 3% (wt.). Further, it would be expected that group relaxation would be less sensitive to environment than molecular relaxation.

Conclusions

Altogether, the relaxation time and enthalpy data favour group relaxation in acetophenone, 1,4-diacetylbenzene, 4-acetylbiphenyl, and 2-acetylfluorene. Further, molecular relaxation appears to have been observed in the latter two of these completely separated from the group process.

It is interesting to compare our energy barrier

values for group relaxation in acetophenone in the polystyrene matrix with values from other procedures. A good correspondence is obtained with the estimated nmr value (5) of $\Delta G_E = 26$ kJ mol^{-1} for acetophenone in liquid solution. Our data yield $\Delta G_E = 26$ kJ mol^{-1} at 140 K, which is within the range of coalescence temperatures reported by Klinck *et al.* (13). It may be worth recollecting that the energy barrier for the intramolecular process of cyclohexyl chloride in the polystyrene matrix agreed precisely with the nmr value obtained from a study in the liquid state. The agreement with the *ab initio* calculated value of 18.4 kJ mol^{-1} is perhaps all that one can expect bearing in mind the difference in phase, the assumptions in such calculations, and the fact that they are not based on the rate theory as is the case in the Eyring treatment of both nmr and dielectric data.

Serious disagreement results between our value and that for (*a*) the one obtained from far-infrared data in the gas phase and, (*b*) the dielectric absorption of aromatic ketones in benzene solutions where in the latter case the values are about a factor of five less than our value.

It would seem that much further work is necessary in which the energy barriers are compared for group rotation in the different phases and by the different techniques. In particular, it would be interesting to compare more results from the direct techniques of dielectric absorption, ultrasonics, and nmr, and to examine further whether the energy barrier for group relaxation from dielectric absorption measurements by the matrix technique corresponds with that from nmr in the liquid phase. Certainly, significant differences have been noted for intramolecular energy barriers as determined on gases and pure liquids from far-infrared data for substituted benzaldehydes (1). It is difficult to understand why the barrier for acetyl group relaxation in benzene solution should be ~ 5 kJ mol^{-1} as determined from dielectric studies in the microwave region while the corresponding value in the matrix work is ~ 30 kJ mol^{-1}. Yet it is apparent that the matrix value is very similar to that estimated from the nmr approach in which toluene is used as the solvent. Very likely far more systems will have to be examined before an appreciation of the factors responsible is gained.

If accurate energy barrier values can be established, then these ought to be of considerable interest in relating their magnitude to conjugative, inductive, and steric effects in small aromatic molecules.

Reactions of ozonides. XII. Ozonolysis of methylenecyclohexane

DUNDAPPA R. KERUR AND DENNIS G. M. DIAPER

Department of Chemistry, Royal Military College of Canada, Kingston, Ont., Canada K7L 2W3

Received June 22, 1976

DUNDAPPA R. KERUR and DENNIS G. M. DIAPER. Can. J. Chem. **55**, 588 (1977).

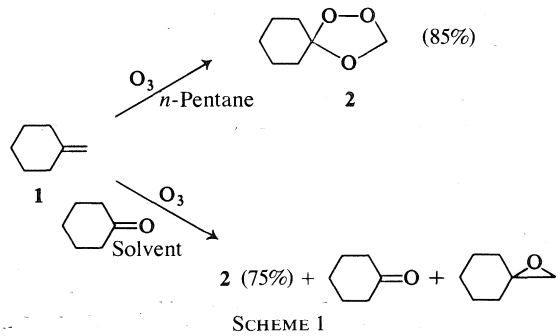
Ozonization of methylenecyclohexane in various solvents gives several peroxides and the ozonide in competing reactions. All products can be adequately explained by adaptation of the Criegee theory, without invoking a Baeyer–Villiger reaction of carbonyl solvents. Solvent effect on product proportions is not linked with dielectric constant or enol content, but appears to be a zwitterion solvation effect.

DUNDAPPA R. KERUR et DENNIS G. M. DIAPER. Can. J. Chem. **55**, 588 (1977).

L'ozonation du méthylènecyclohexane dans divers solvants conduit, par réactions concurrentes, a son ozonide ainsi qu'à plusieurs peroxydes. L'ensemble des produits peut être expliqué dans le cadre d'une modification de la théorie de Criegee, excluant l'intervention de solvants carbonyles par une réaction de Baeyer–Villiger. Cet effet est relié ni à la constante dieléctrique ni au contenu en énol du solvant, mais semble intervenir par une solvation des zwitterions.

The course of the ozonolysis of alkylidenecyclohexanes is modified by the use of very large proportions of certain carbonyl compounds as solvents (1–3). This observation led to a drastically modified general theory of ozonolysis mechanisms now largely discarded (4–7) following detailed re-investigations which showed that the products of carbonyl-modified ozonolysis were explicable by mechanism theories hitherto found adequate. There remain some unanswered questions about the observations on carbonyl-modified ozonolysis which led us to re-investigate the methylenecyclohexane reaction in detail. First it has been assumed that diminution of ozonide yields in carbonyl solvents has been due to chemical reaction of the carbonyl group. We now find that the partial suppression of ozonide formation with concomitant increase of peroxide products is not specifically a property of carbonyl solvents, but is a phenomenon shared by non-carbonyl solvents, which may even be more effective. Second, it has been assumed, but not proved, that 6-hexanolide is a secondary product from peroxides; we have now identified the peroxides and in some cases ascertained the yields.

Ozonation of methylenecyclohexane **1** in a number of solvents, carbonyl and non-carbonyl, has been found to give the products of Scheme 1 in agreement with previous reports (1–3) but we have encountered other products as well. We have also attempted to correlate the ability of a solvent to partially suppress ozonide **2** formation with its physical or chemical nature.



SCHEME 1

Experimental

The reference substances 1-hydroperoxy-1′-hydroxydicyclohexyl peroxide **3**, dicyclohexylidene diperoxide **4**, and bis(hydroxymethyl) peroxide **8** were prepared by standard procedures (8). Thin-layer chromatography was done on pre-coated silica gel on plastic (Merck) using butyl acetate solvent. For ozonides and hydroxyperoxides a 3% KI in 50% acetic acid visualizing spray was used and for the diperoxide **4**, concentrated sulphuric acid at 100 °C. R_f values were: **2**, 0.65; **3**, 0.74; **4**, 0.96; polymers, stationary. For nmr spectra, CCl_4 was used as solvent in all cases except the residue after reaction in pentane which was examined undiluted; residues from acetone, dichlorotetrafluoroacetone, and diisopropyl ketone experiments which were examined both undiluted and in CCl_4; the residue after ozonolysis in hexamethylacetone, was examined in CCl_4 and $(CMe_3)_2CO$ solvents. The nmr spectrum of bis(hydroxymethyl) peroxide **8** was obtained in D_2O with DSS marker. Infrared spectra of all liquid products were obtained from smears on NaCl plates and solids as KBr discs.

Methylenecyclohexane (Baker or Chemicals Procurement) in 0.2 *M* solution in the designated solvent (Table 1) was ozonized using an ozone–oxygen stream until absorption ceased. The residue after solvent removal was examined by thin layer chromatography, nmr and ir

spectroscopy, qualitative tests, and comparison with authentic samples. Wherever possible, crystalline products were recovered.

Thermal decomposition of 1-hydroxy-1′-hydroperoxydicyclohexyl peroxide **8** in boiling toluene gave after solvent removal cyclohexanone (25%), hexanoic acid (8%), adipic acid (4%), and dodecanedioic acid (trace). There was also an unidentified acidic brown gummy substance. This reaction will be discussed further (9).

Results

Product analyses are tabulated in Table 1.

Residues from methylenecyclohexane ozonized in most halogenated solvents showed the characteristic (10–12) ir ozonide absorption at 9.4–9.6 μm and nmr peaks at δ 5.08 ppm. Release of oxygen from lead tetraacetate in acetic acid indicated (13) hydroperoxide or oligomeric hydroperoxide (a weak result after ozonolysis in diisopropyl ketone). The presence of ketone peroxides was further demonstrated by a positive test with aqueous ferrous sulphate and ammonium thiocyanate (14). Infrared absorption at 2.9 (hydroxy) and 5.8–5.9 μm (carbonyl) was observed.

Even at slow flow rates, considerable entrainment losses of olefin and products were sustained in 1,4-dioxane which could not be cooled below its freezing point, 10 °C. Attempts to trap the mist were only partly successful. Small sample size in this solvent as in hexamethylacetone increased the seriousness of this product loss.

The nmr spectrum of the residue after ozonolysis in hexachloroacetone had no ozonide peak, but a multiplet at δ 1.62–1.80 ppm, three peaks in the 2.08–2.41 ppm region, four peaks between 3.45 and 4.20 ppm, a broad absorption centred at 5.20 ppm, and a singlet at 8.17 ppm. Extensive decomposition associated with production of hydrochloric acid from the solvent was suspected.

In trifluoroacetone, although no ozonide was produced, traces of adipic acid and cyclohexanone were detected as well as 18.5% of dicyclohexylidene peroxide **4** and 10% of bis(hydroxymethyl) peroxide **8**, mp 61–63 °C (dec.) (lit. (8) mp 62.5 °C). The latter, encountered now for the first time in methylenecyclohexane ozonolyses, was identified with an authentic sample (nmr δ 4.81 and 5.23 ppm, Na 2,2-dimethyl-2-silapentane-5-sulphonate marker). Decomposition products from authentic **8** and this sample were identical. Both **3** and **8** and oligomeric peroxides related to **8** were detected qualitatively but were not isolated in several experiments.

TABLE 1. Products from methylenecyclohexane ozonized in various solvents

Solvent	Temperature (°C)	Ozonide yield (%)	Hydroxy hydroperoxide, **3** (%)	Diperoxide, **4** (%)	Adipic acid, **5** (%)	Dodecane dioic acid, **6**	Cyclohexanone, **7**	Comments
n-Pentane	−78	89						*
Tetrahydrofuran	−45	74	11				Present	
1,4-Dioxane	10	37		2			Present	†
Cyclohexanone	−15	71		5	4		Present	
Acetone	−78	86		5	0.5		Present	
Pinacolone	−45	80			2	Present	Present	
Diisopropyl ketone	−78	77					Present	
Hexamethylacetone	−30	52					Present

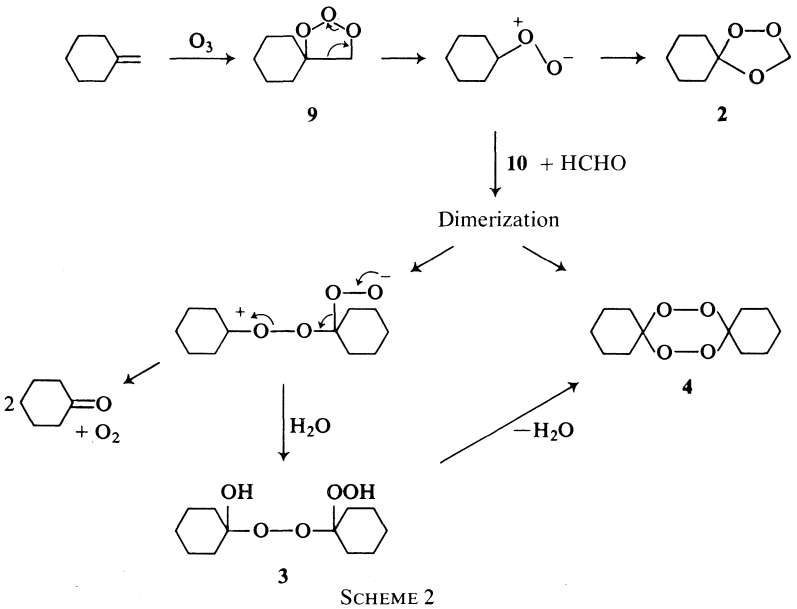
Dichlorotetrafluoroacetone	−78	Trace					Present	
Hexachloroacetone	0	0			3		Present	

*The only other product detected was a white, partially gummy material, mp 51–56 °C.
†Major losses of olefin and products by entrainment as smoke.
‡A 10% yield of $HOCH_2—O—O—CH_2OH$ (8).



SCHEME 2

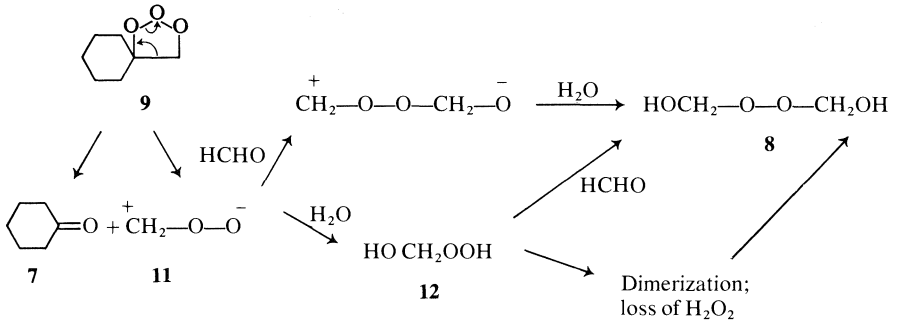
Discussion

It is remarkable that ozonide formation from alkenes is partly suppressed by carbonyl compounds but especially remarkable when that particular carbonyl compound used as solvent is one of the end products of the ozonolysis of that particular alkene and is one of the intermediates in accepted theories of the mechanism of the reaction. It is true that the initial alkene–ozone adduct here preferentially breaks up in the direction of Scheme 2 rather than Scheme 3 (15, 16), but identification of **8** shows that production of cyclohexanone is not negligible. If it is assumed that the ozonide **2** is formed solely from **10** and formaldehyde or from **11** and cyclohexanone, and that the solvent does not intervene in these or competing reactions, then ozonide yield should depend on the kinetics of these two reactions and competing zwitterion reactions. Increase of cyclohexanone concentrations should therefore increase ozonide yield, yet the result is opposite. More intermediate gives less product.

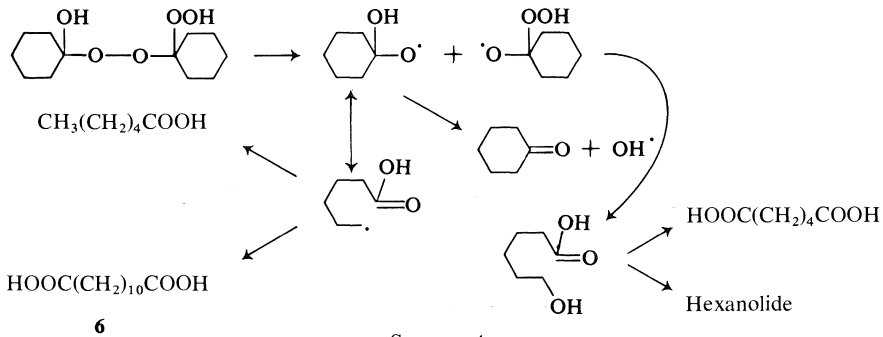
It is well known that participating solvents diminish ozonide yields in two ways at least: alcohols and acids by trapping the zwitterion giving alkoxy- or acyloxyhydroperoxides, and bases, such as pyridine, by catalysis of ozonide decomposition in a regenerative reaction. Neither appears to apply here; rather it is suggested that the role of the solvent is a complex balance of intermediate solvation effects. The most abundant polar intermediate zwitterion **10**, would seem to be the most important factor here, especially as it is the source of the relatively abundant side products **3** and **4** as well as polymers.

Story and co-workers (1–3) invoked Baeyer–Villiger oxidation of a ketone solvent as another possible mechanism for diminution of ozonide yield: we have used ^{14}C to demonstrate that cyclohexanone can function this way in ethylidenecyclohexane ozonolysis in no more than 0.02% yield (6). There is no clear relation between effectiveness of suppression of ozonide formation and dielectric constant of solvents of Table 1. The dioxane, $(Cl_3C)_2CO$, and CH_3COCH_3 results clearly show this.

Cyclohexanone and pinacolone were the ketones for which the effect was first reported, but they are in fact relatively feeble suppressants of ozonide formation. Both have a significant enol content; diisopropyl ketone, with less enol, falls between the two in suppression efficiency. Tetrahydrofuran and 1,4-dioxane, having neither enol nor ketone groups, are more powerful than either of the first two ketone solvents. The effect is not, therefore, an enol effect analogous to alcohol–zwitterion interaction. The products are completely explicable with Criegee zwitterions, provided that it is assumed that the kinetics of competing zwitterion reactions are affected by solvation. Zwitterions consumed by



SCHEME 3



SCHEME 4

peroxide production are unavailable for production of ozonide **2**. Solvation probably extends zwitterion half-life, enhancing dimerization possibilities.

The experiment with hexamethylacetone, which cannot enolize, was inconclusive. The other non-enolizable ketones employed were fluoro and/or chloro ketones. They were strong ozonide suppressants as was the enolizable CF_3COCH_3. In all cases the products were explicable through the Criegee zwitterions of Scheme 2 and Scheme 3. Cyclohexanone as a product of bimolecular loss of oxygen from zwitterions is readily explained (17). Both directions of cleavage of the primary ozonide **9** are represented in the observed products: **8** comes from **11** in several possible ways. Traces of water necessary in Schemes 2 and 3 could come from concurrent elimination reactions or from atmospheric moisture during work-up. In another solvent system, methylenecyclohexane primary ozonide cleaved (15) to give **10** rather than **11** (96.8% and 3.2%); in trifluoroacetone 90% seems to be an upper limit because 10% of **8** was isolated.

Adipic acid **5** is attributable to the decomposition of hydroxyhydroperoxide **3** which was difficult to isolate from the reaction products because of its instability. Although it was isolated from only one solvent system, qualitative tests showed it present in most, if not all, experiments. An authentic sample of **3**, heated in toluene, gave **5**, cyclohexanone, and dodecane-1,12-dioic acid **6** but not **4**. The three products detected were also formed from **3** by dry pyrolysis (18) and under acid conditions (19). In the latter case, an ionic mechanism has been invoked, but here a radical process (18, 20) is considered more likely (Scheme 4). Peroxide by-products, frequently major products, always accompany ozonides (16, 21, 22). 6-Hexanolide from alkylidenecyclohexane ozonolysis is explicable (6) as a secondary decomposition product of peroxides. No Baeyer–Villiger reaction occurred in an acetylated cyclopentene ozonolysis (23). Ozonolysis of methylenecyclohexane in the solvents presently used gave no evidence of cross ozonide formation. This is probably due in part to low concentrations of zwitterion **11** as well as the use of ketones rather than aldehydes (except the formaldehyde from primary ozonide break-up).

Ozonide **2** yield is only one part of a jig-saw puzzle of concurrent reactions in these systems; it can come from the two zwitterions **10** and **11**

which can each form a range of other condensation and decomposition products. In the solvents used, kinetics determining product ratios are not only the kinetics of zwitterion reactions, but the kinetics of solvated species. The highly polar halogenated ketones, for example, may be expected to be more efficient solvating agents than cyclohexanone for zwitterions. Zwitterion solvation, rather than enol, dielectric, or Baeyer–Villiger participation of solvent, must be the key to results hitherto described as 'carbonyl-modified' ozonolysis.

Studies on the condensation of lignins in alkaline media. Part II.[1] The formation of stilbene and arylcoumaran structures through neighbouring group participation reactions[2]

JOSEF GIERER AND INGEGERD PETTERSSON

Swedish Forest Products Research Laboratory, Chemistry Department, Box 5604, S-114 86 Stockholm, Sweden

Received September 28, 1976

JOSEF GIERER and INGEGERD PETTERSSON. Can. J. Chem. **55**, 593 (1977).

The alkaline condensation of *p*-hydroxyarylglycerol-β-aryl ether units in lignin with other phenolic structures and the subsequent reactions of the condensation products have been elucidated using appropriate model compounds. It is shown that the primary condensation of simple phenols (2,6-xylenol or resorcinol) into the α-position of phenolic compounds of the β-aryl ether type is followed by an aryl participation (A_1-3) reaction resulting in the cleavage of the β-aryl ether bond and formation of the corresponding stilbene derivative. When resorcinol is used as reaction partner, the condensation is also followed by the cleavage of the β-aryl ether linkage through another type of neighbouring group participation reaction involving the phenolate anion *ortho* to the site of condensation and giving rise to the corresponding arylcoumaran derivative.

The consequences of these findings for the course of alkaline delignification processes are briefly discussed.

JOSEF GIERER et INGEGERD PETTERSSON. Can. J. Chem. **55**, 593 (1977).

On a élucidé, utilisant des composés modèles appropriés, le mécanisme de la condensation alcaline d'unités d'éther *p*-hydroxyarylglycérol β-aryle de la lignine avec d'autres structures phénoliques et les réactions subséquentes des produits de condensation. On a montré que la condensation primaire de phénols simples (xylénol-2,6 ou résorcinol) en position α des composés phénoliques du type éther β-aryle est suivie par une réaction de participation du groupe aryle (A_1-3) qui conduit au bris du lien éther β-aryle et à la formation du dérivé stilbène correspondant. Quand on utilise le resorcinol comme partenaire de la réaction, la condensation est aussi suivie par une coupure du lien éther β-aryle par un autre type de réaction de participation de groupe voisin impliquant l'anion phénolate *ortho* par rapport au site de condensation et donnant lieu au dérivé arylcoumarane correspondant.

On discute des conséquences de ces résultats pour les processus de délignification alcaline.

[Traduit par le journal]

Numerous studies on the alkaline condensation of lignins have shown that the benzylic position in phenolic units constitutes the main site of reaction in this complex process (1–6). In most of these studies, model compounds of the *p*-hydroxybenzyl alcohol type were reacted with simple phenols and the resulting diarylmethanes were isolated. The condensation reaction was formulated as a nucleophilic addition of an *ortho*- or *para*-cyclohexadienone carbanion to the appropriate *para*-quinonemethide, followed by proton or side-chain elimination with rearomatization (7).

Results from studies using model compounds of the *p*-hydroxyaryl coumaran (8) and β-arylglycerol (9) types indicated that this conjugate addition reaction is not prevented by the presence of an aryl or an aroxy group in the adjacent β-position (*cf.* also condensations in acidic media (10)). Thus, carbanions formed from phenolic lignin structures compete, in fact, with the other nucleophiles present in the pulping liquor (SH^-, OH^- ions) for the various quinonemethide intermediates (7).

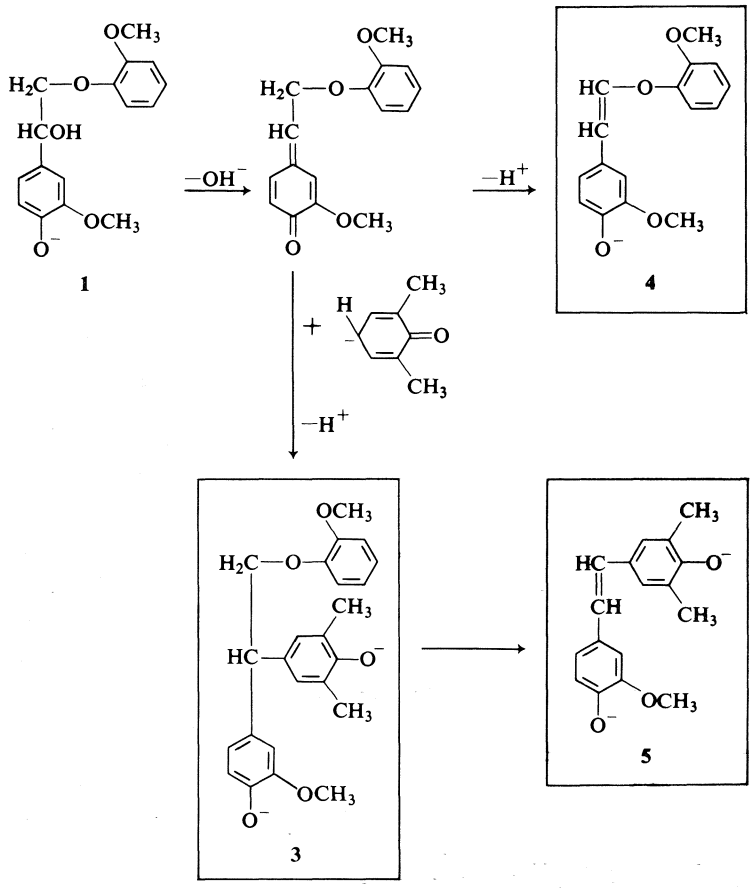
In the present work, the condensation between phenolic compounds of the β-aryl ether type and added phenols is investigated and the behaviour of the condensation products towards alkali under pulping conditions is studied.

Results and Discussion

The compounds and conditions used and the results obtained are summarized in Table 1.

[1]Part I, see ref. 18.

[2]The results of this work have been presented (by J.G.) at the Fifth Plenary Meeting of the International Academy of Wood Science, Copenhagen, Denmark, June 17–19, 1976, and at the 1976 Canadian Wood Chemistry Symposium at Mont Gabriel, Que., Canada, September 1–3, 1976.

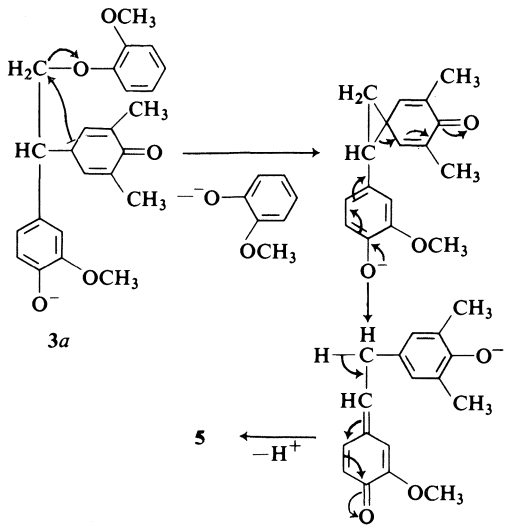


SCHEME 1

When compound **1** (Scheme 1) was reacted with 2,6-xylenol in 1 *N* sodium hydroxide at 150 °C for 1.5 h, an extensive condensation took place and the expected product **3** could be isolated in 60% yield. In a competing reaction, a proton is abstracted from the quinonemethide intermediate and the β-guaiacoxy styrene derivative **4** is formed (11). In a separate experiment it was shown that compound **4**, similarly treated with 2,6-xylenol, also gives compound **3** although in a lower yield (37%). Part of the compound **3** obtained from **1** could thus have been formed via compound **4** (*cf.* below however).

Among the remaining reaction products, the 4,4′-dihydroxystilbene **5** is of particular interest. The formation of this compound, in a small amount, is suggested to proceed via the product of condensation **3** and to involve elimination of the β-aroxy substituent through an aryl participation (A_1-3) reaction (Scheme 2). Hence, the elimination is brought about by an intramolecular nucleophilic attack of a carbanion **3***a* on the β-carbon atom resulting in the formation of a spiro cyclohexadienone intermediate. Rearrangement of this intermediate with participation of the aryloxide ion results in the opening of the three-membered ring and subsequent proton elimination yields the 4,4′-dihydroxystilbene derivative **5**.

The formation and the opening of the three-membered ring are reminiscent of the corresponding reaction steps in other eliminations of β-aroxy substituents involving neighbouring group participation such as the cleavage of β-aryl ether linkages by neighbouring mercaptide groups (12). The function of a spiro cyclohexadienone as a transient intermediate has been previously (13) proposed in order to interpret a related reaction, *i.e.* the alkaline solvolysis of 2-*p*-hydroxyphenylethyl bromide. Shortly after,



SCHEME 2

this intermediate was isolated and its behaviour under different reductive and solvolytic conditions was studied (14).

The intermediacy of the condensation product **3** in the formation of stilbene **5** was shown by treating compound **3** with 1 *N* sodium hydroxide at 170 °C for 2 h and isolating compound **5** and guaiacol in high yields (61 and 74%, respectively). Apparently, the aryl participation reaction requires a higher temperature (about 170 °C) than does the preceding condensation step.

It can be expected that the condensation of a phenol to compound **1** and the subsequent elimination of the β-guaiacoxy substituent through aryl participation will be enhanced by the presence of one or two additional phenolic hydroxyl groups in the *meta*-position(s) (resorcinol, phloroglucinol, and their derivatives). In these instances, all phenolic hydroxyl groups should contribute to the ease of formation of reactive carbanions in the *ortho*- and *para*-positions, thus facilitating both the condensation and the subsequent elimination step. In fact, treatment of compound **1** with resorcinol in 1 *N* sodium hydroxide at 150 °C for 1.5 h (Scheme 3) gave an almost quantitative yield (98%) of guaiacol, indicating an extensive condensation and elimination reaction. The reaction mixture contained, in addition to guaiacol and small amounts of unreacted resorcinol and stilbene **6** (2%), the expected stilbene **7** (11%), the bis-stilbene **8** (5%), and the arylcoumaran **9** (10.5%).

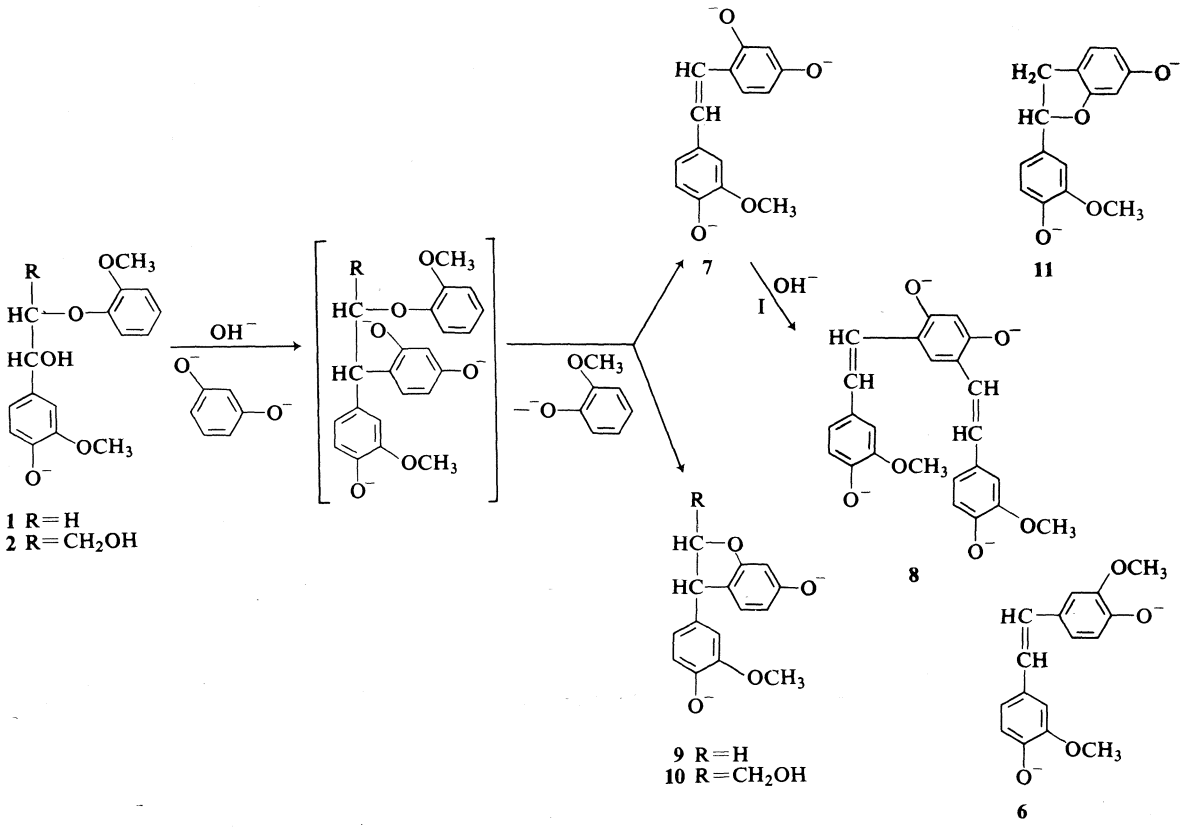

SCHEME 3

Undoubtedly, the formation of stilbene **7** follows a route analogous to that for stilbene **5** (Scheme 1). However, in the case of stilbene **7**, the precursor, *i.e.* the condensation product corresponding to compound **3** was not isolated. This is probably due to the high rate of the aryl participation reaction caused by the *ortho*- and *para*-hydroxyl groups of the resorcinol residue in the condensation product.

The high reactivity of resorcinol in this type of condensation with subsequent aryl ether cleavage through aryl participation is also reflected by the presence of the distilbene **8** in the reaction mixture. Obviously, this compound is formed by a repetition of the condensation and aryl participation reactions involving stilbene **7** and the starting compound **1** as reaction species.

Although the initial condensation product between resorcinol and compound **1** was not isolated, its intermediacy is revealed by the isolation of the 3-arylcoumaran **9**. It is obvious that this compound arises from the expected condensation product through another type of neighbouring group participation in which the *ortho*-phenolate ion nucleophilically attacks the β-carbon atom and eliminates the β-aroxy substituent. Thus, the formation of **9** competes with that of compound **7**, but both neighbouring group participation reactions result in the cleavage of the β-aryl ether linkage.

According to the nmr and mass spectroscopic data, the isolated coumaran could also be the 2-aryl-substituted isomer **11** which might be formed from stilbene **7** by a subsequent ring closure. However, this possibility was excluded by treating stilbene **7** with 1 *N* sodium hydroxide under the same conditions as were used for compound **1** and demonstrating the absence of the coumaran obtained from **1** in the resulting reaction mixture (thin-layer chromatography). This experiment also showed that a considerable part of the stilbene **7** was converted into other compounds unidentified so far. Conversely, a similar alkaline treatment of the isolated coumaran did not afford any detectable amount of the stilbene **7**. This result also supports the structure of a 3-

*s = singlet, d = doublet, m = multiplet, os = overlapping singlets.

arylcoumaran **9** since the 2-aryl isomer **11** on treatment with alkali would be expected to give an equilibrium mixture consisting of **7** and the starting compound.

Stilbene **6** is formed by a pathway analogous to the formation of **7** (and **8**), the eliminated guaiacol acting as condensation partner in competition with resorcinol.

The total yield of stilbenes **6–8** together with the arylcoumaran **9** is only about 30%. In view of the large amount of guaiacol obtained (98%), the low yields of the other reaction products may be ascribed to partial alkaline degradation of the stilbenes (see above) and/or to losses during the work-up and separation procedures (Table 1), rather than to incomplete conversion of the starting compound **1**.

The behaviour of compound **2** upon treatment with resorcinol in 1 *N* sodium hydroxide under similar conditions is analogous to that of compound **1**. Guaiacol was obtained in a large amount (51.5%) and the stilbenes **6** and **7** were isolated in 2.6 and 21.7% yields, respectively. Furthermore, the reaction mixture contained the arylcoumaran **10** (8.2%), corresponding to **9** obtained from **1**. The presence of **10** and the absence of **9** in the reaction mixture from **2** show that the initial condensation step involves the quinonemethide derived from **2**, rather than the β-guaiacoxystyrene derivative **4**. In other words, formaldehyde elimination most likely takes place after, rather than before, the condensation and aryl participation steps in the formation of **6**, **7**, and **8** (*cf.* also proton elimination from the quinonemethide in Scheme 2). The absence of **4** in the reaction mixtures obtained from the treatments of **1** or **2** with resorcinol further supports this view. Apparently, conjugate addition of the carbanion from resorcinol to the quinonemethide from **1** more effectively competes with proton

elimination than does the conjugate addition of the carbanion from 2,6-xylenol (Scheme 1). The formation of **4** during the treatment of compound **1** with 2,6-xylenol (see Scheme 1) should thus be considered as a side reaction rather than a step in the formation of stilbene **5**. Eliminated guaiacol and formaldehyde, together with the excess of resorcinol, may undergo alkaline condensation reactions yielding high molecular weight materials of the phenoplast type. Such condensations could be responsible for the lower yield of guaiacol obtained from compound **2** as compared to that obtained from **1**.

Conclusions

The results of the present work illustrate the behaviour of phenolic lignin units of the β-aryl ether type towards other phenolic structures upon heating in alkaline solution. The primary condensation, which gives the diarylmethane type of structures, is followed by the cleavage of the β-aryl ether bond through neighbouring group participation involving an aromatic nucleus (aryl participation) or, if present, a phenolate anion in the *ortho*-position to the condensation site. These reactions lead to the formation of stilbene and/or arylcoumaran types of structures. Thus, the increase in molecular size of lignin brought about by the initial condensation step involving phenolic β-aryl ether units may be counterbalanced by the subsequent fragmentation due to β-aryl ether cleavage through neighbouring group participation.

The stilbene structures found in alkali-treated lignins (15) may thus originate not only from native structures in which the carbon skeleton is preformed (aryl coumaran and 1,2-diarylpropane 1,3-diol structures) (15) (Scheme 3) but also from β-aryl ether structures which undergo condensation and subsequent aryl participation reactions.

The possible genesis of stilbene structures by this route has been recently[3] confirmed by heating wood powder (*picea abies*) with 2,6-xylenol in alkaline solution at 170 °C, demonstrating the presence of stilbene **5** as dominant component in the reaction mixture.

These findings suggest the advisability of conducting the alkaline delignification in the presence of a suitable (added) phenol. The latter, by condensing with reactive α-positions, should not only inhibit the self-condensation of lignin (16) but also facilitate its fragmentation through the neighbouring group participation reactions demonstrated in this work.

Experiments to explore this possibility are being currently carried out.

Methods

The treatments with 1 *N* sodium hydroxide were carried out in an atmosphere of nitrogen to avoid autoxidation reactions. The other reaction conditions (amount of model compound and alkali, temperature, and length of treatment) were chosen to simulate the conditions prevailing during alkaline pulping or, if necessary, to facilitate the isolation of the reaction products. These conditions and the results of the alkaline condensations are summarized in Table 1.

Work-up Procedure

After the alkaline treatment, the reaction mixture was neutralized by adding dry ice and extracted repeatedly with ethyl acetate. The combined extracts were evaporated under reduced pressure. The residue was acetylated with acetic anhydride – pyridine and the resulting mixture of acetylated reaction products was separated by column chromatography. The separation was followed by thin-layer chromatography.

Thin-layer (tlc) and Column Chromatography

The acetylated compounds were separated on an analytical scale by tlc using silica gel HF_{254} (E. Merck A. G. Darmstadt) as adsorbant and mixtures of petroleum ether – ethyl acetate in proportions between 2:1 to 4:1 as solvent systems. The spots were developed by spraying with a 1% solution of vanillin in concentrated sulphuric acid and heating at 120 °C for about 10 min. The preparative separations were carried out by column chromatography using silica gel 60 (120–230 mesh, ASTM, Merck) as adsorbant and the same mixtures of petroleum ether – ethyl acetate as those used in tlc.

The isolated compounds were identified by nmr and mass spectroscopic methods. Compound **7** was also characterized as the (acetylated) dihydro derivative.

Nuclear Magnetic Resonance Spectrometry

The nmr spectra ($CDCl_3$) were recorded with a Perkin–Elmer R-12 spectrometer. The nmr data are summarized in Table 2 which also contains the melting points of the isolated (acetylated) reaction products. Chemical shifts (τ values/ are given in ppm downfield from TMS.

Mass Spectrometry

Mass spectra were recorded on a Perkin–Elmer 270 instrument at 20 eV using the direct inlet system. Mass spectral data are summarized in Table 3.

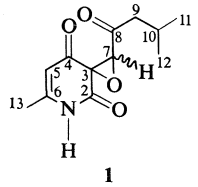
The structure of isoflavipucine **2***a*, a remarkable rearrangement product of the antibiotic flavipucine **1**, is proposed on the basis of spectral data and chemical and mechanistic considerations.

JOHN A. FINDLAY, JIRI KREPINSKY, ANITA SHUM, C. G. CASINOVI et L. RADICS. Can. J. Chem. **55**, 600 (1977).

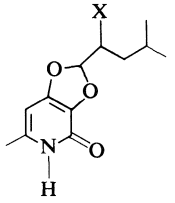
En se basant sur des données spectrales et sur des considérations chimiques et mécanistiques on propose la structure **2***a* pour l'isoflavipucine, un produit remarquable de réarrangement de l'antibiotique flavipucine **1**.

[Traduit par le journal]

Recently we reported (1) the structure **1** for flavipucine $C_{12}H_{15}NO_4$, an optically active metabolite of *Aspergillus flavipes* possessing antibiotic activity (2). In the course of isolating this substance, the co-occurrence of an isomeric compound in the culture filtrates was noted. Isoflavipucine (mp 166–171 °C) is apparently optically inactive, $[\alpha]_D^{21}$ 0° (*c* 1% 95% EtOH), and its nmr spectrum (see Table 1) is remarkably similar to that of flavipucine apart from the displacement of the signal at δ 3.80 for the C7-H to much lower field (δ 6.04) in the isomeric compound. The ultraviolet spectrum of isoflavipucine (λ_{max} (EtOH) 221 (ε 26 090), 307 (ε 10 260) nm) is substantially different from that of flavipucine indicating the presence of a new chromophore.



1



2*a* X = O=
2*b* X = O—H

We propose the structure **2***a* for isoflavipucine on the basis of spectral and chemical data. Nuclear magnetic resonance parameters (see Tables 1 and 2) and nuclear magnetic double resonance experiments are in excellent agreement with this structure. The infrared (KBr) spectrum displays a strong carbonyl absorption at 1670 cm^{-1} (conjugated amide) accompanied by a ketone band at 1730 cm^{-1} and bands assigned to conjugation at 1630 and 1610 cm^{-1}. The mass spectrum is practically indistinguishable from that of flavipucine and confirms the elemental composition while the base peak *m/e* 152 ($M - (CH_3)_2CHCH_2CO$) affirms the presence of the isobutyl ketone moiety. Microanalysis is in agreement with the elemental composition $C_{12}H_{15}NO_4$.

A useful confirmation of the isoflavipucine structure can be derived from a comparison of the ^{13}C nmr spectra of **1** and **2***a* (see Table 3). One notable difference is that isoflavipucine contains an additional sp^2 carbon (δ 143.5 ppm) at the expense of an sp^3 carbon (δ 60.0 ppm) present in flavipucine. Also, the signal at δ 68.8 ppm for C7 in flavipucine **1** is found at δ 107.6 ppm in isoflavipucine **2***a* consistent with the C7 change from mono- to dioxygen substitution. Thus the major difference between **1** and **2***a* concerning C3 and C7 is corroborated in

[1]Presented in part at the 9th International Symposium on the Chemistry of Natural Products, Ottawa, Canada (June 1974).

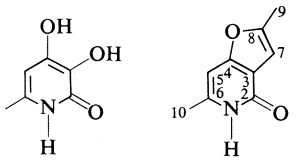
*For these parameters iterative calculations were performed using the LAOCN3 program of Bothner-By and Castellano (5). Long range couplings were assumed to be zero and the spectra were approximated by the simplified spin systems indicated in Table 2. An IBM 7040 Computer was employed for these calculations and the estimated accuracy is of the order of 0.1 Hz.

detail. Of interest in comparing the signal assignments is compound **4**, a synthetic material, which we have prepared recently.



3 **4**

Chemical corroboration of the structural assignment **2***a* comes from the ready acid hydrolysis of isoflavipucine to give 3,4-dihydroxy-6-methyl-2-pyridone **3**. This structure was confirmed by independent synthesis by the method of Lapworth and Collie (3) who converted 2,4-dihydroxy-6-methyl pyridine to the 3-nitro derivative which was reduced to 3-amino-3,4-dihydroxy-6-picoline. Treatment of the latter amino dihydroxypicoline with Na_2CO_3 gave **3**. Attempts to prepare **3** by the procedure of Hess (4) were singularly unsuccessful. We formulate **3** as a pyridone rather than a trihydroxypicoline (3) since its infrared spectrum shows bands for a conjugated amide (1650, 1610 cm^{-1}).

Reduction of the ketone in **2***a* was readily achieved by hydrogenation in glacial acetic acid with Adams' catalyst. Dihydroisoflavipucine **2***b* (mp 204–206 °C) was obtained and shows spectral characteristics consistent with its formulation. Thus, while a strong amide carbonyl band at 1670 cm^{-1} is present in the infrared (KBr) spectrum, the absence of any ketone absorption near 1730 cm^{-1} is noted. In addition, the mass spectrum displays the appropriate molecular ion at *m/e* 239 as well as prominent ions at 196 ($M - (CH_3)_2CH$) and 152 ($M - (CH_3)_2CHCH_2CHOH$) and the ultraviolet spectrum (*vide infra*) resembles that of isoflavipucine.

We have now succeeded in transforming flavipucine (mp 130–131 °C) into isoflavipucine in 30% yield by heating the crystalline solid at 138–140 °C for 15 min. Heating **1** in boiling xylene (139 °C) did not effect any transformation and this suggests an ionic rather than a radical mechanism for the interconversion **1** to **2***a*. In addition, traces of isoflavipucine can be found in the reaction mixture resulting when flavipucine is treated with cold aqueous Na_2CO_3 solution (2%).

Scheme 1 contains mechanistic proposals to account for the transformation **1** to **2***a*. In pathway '*a*' the tautomer **5** is visualized as undergoing a rearrangement via a transition state involving a four-membered ring and requiring an external proton transfer agent (*e.g.*, another molecule of **1**). Route '*b*' proposes the initial generation of a five-membered lactol ring **6** which then undergoes rearrangement via the resonance stabilized zwitterion **7** to isoflavipucine **2***a*. Both pathways require the external assistance of proton transfer agents and are consistent with the finding that the pyrolytic conversion does not occur in boiling anhydrous xylene (139 °C) but occurs readily with molten flavipucine at the same temperature. Pathway '*b*' readily accommodates the observation that isoflavipucine is optically inactive; however, route '*a*' cannot be excluded on this basis alone since racemization of **2***a* after its formation is also feasible. The pathway '*b*' is favoured by us since it would ap-

†Assignments may be interchanged. The assignments of ^{13}C resonances to the individual carbon atoms in the molecules are based on standard Fourier transform ^{13}C nmr techniques, selective ^{13}C–{^1H} decoupling experiments, spectral comparison, and known substituent effects.

pear to proceed via lower energy transition states than does route '*a*'. It, of course, requires a *cis* relationship of C4 and C8 with respect to the oxirane bridge.

Experimental

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Mass spectra were determined with a Consolidated Electrodynamics Corporation R6-1 instrument. A Varian HA-100 spectrometer was employed for recording nmr spectra. Ultraviolet spectra were obtained with a Perkin-Elmer Model 467 spectrophotometer and infrared spectra with a Perkin-Elmer Model 457 grating instrument. ^{13}C nmr spectra were obtained with a Varian XL-100-15 equipped with SL-124 Fourier transform accessory and 16K 620L computer.

Isolation of Isoflavipucine 2a

The crude chloroform extract of the acidified fermentation broth of strain F2091/7 of *Aspergillus flavipes* was chromatographed on silica gel. Initial benzene–ether (3:1) eluates yielded flavipucine (mp 130–131 °C) while later benzene ether fractions proved to be mixtures of flavipucine and isoflavipucine. Rechromatography of these fractions on silica gel columns or plates afforded pure isoflavipucine which was recrystallized from ether to give white crystals, mp 166–171 °C. *Anal.* calcd. for $C_{12}H_{15}NO_4$: C 60.75, H 6.37, N 5.90; found: C 60.41, H 6.39, N 5.75. The mass spectrum *m/e* 237 (M^+), 153, 152 (100%) (M − $(CH_3)_2CHCH_2CHO$), 126, 125, 96. The ir spectrum ν_{max} (KBr) 3440, 3110, 2960, 2870, 2800, 2750–2500, 1730, 1670 (broad v. strong), 1630, 1600, 1460, 1420, 1390, 1370, 1285, 1210, 1170, 1140, 1115, 1040, 990, 820, 740, 660, 640, 620 cm^{-1}. The uv spectrum λ_{max} (95% ethanol) 221 (ε 26 090), 307 (ε 10 260) nm. $[\alpha]_D^{21}$ 0° (*c* 1%, 95% ethanol).

Isoflavipucine 2a from Flavipucine 1

(a) By Pyrolysis

Flavipucine (200 mg) was heated in a stoppered round bottomed flask (above its melting point) at 138–140 °C for 15 min in an oil bath. Subsequent chromatography afforded isoflavipucine **2***a* (60 mg, 30% yield) identical in spectral characteristics and melting point (and mixture mp) with isoflavipucine isolated from acidified culture filtrates of *Aspergillus flavipes*.

(b) By Na_2CO_3 Treatment

Flavipucine (0.20 g) was dissolved in 2% aqueous Na_2CO_3 solution (250 ml) and the yellow solution was allowed to stand 15 min at room temperature before extraction with $CHCl_3$ which afforded after drying and evaporation an oil (0.15 g) which proved by preparative layer chromatography on silica gel to be a mixture of flavipucine and isoflavipucine (40:1). The identity of the isoflavipucine prepared in this way was confirmed by spectral data and mixture melting point with an authentic sample.

Dihydroisoflavipucine 2b

Flavipucine (0.50 g) in glacial acetic acid (20 ml) was hydrogenated over Adams' catalyst (0.10 g) for 22 h. Filtration and evaporation gave a crude product (0.49 g), essentially homogeneous on tlc, which was crystallized from ethanol yielding pure dihydroisoflavipucine (0.215 g), mp 204–206 °C. Mass spectrum *m/e* 239 (M^+), 196 (M − C_3H_7), 154, 153, 152 (100%), 141, 125, 124, 112, 109, 97, 96. The ir spectrum ν_{max} (KBr) 3300, 2960, 2900–2500, 1660 (broad, strong), 1615, 1595, 1560, 1480, 1450, 1425, 1390, 1380, 1368, 1340, 1330, 1310, 1295, 1260, 1212, 1170, 1140, 1120, 1110, 1090, 1080, 1040, 920, 858, 810, 780, 755, 740, 710, 660, 640, 590, 560, 510, 480 cm^{-1}. The uv spectrum (95% EtOH) λ_{max} 220 (ε 20 060), 308 (ε 6560) nm.

3,4-Dihydroxy-6-methyl-2-pyridone 3

(a) From Isoflavipucine

Isoflavipucine **2***a* (0.0542 g, 0.23 mmol) was added to a solution of 3.8% HCl in water–ethanol 1:1 (2 ml), and stirred at room temperature until completely dissolved. The solution was then heated at 80 °C for 14 h. The cooled aqueous solution was extracted with ether and then evaporated *in vacuo* at room temperature yielding

the white crystalline product **3** (0.0314 g, 96.5%), mp 212–226 °C. The mass spectrum *m/e* 141 (M^+). The ir spectrum ν_{max} (KBr) 3400–2300 cm^{-1} broad (NH, OH), 1650, 1600 (conjugated amide). The uv spectrum λ_{max} (H_2O) 302 (ε 3740); ($H_2O + H^+$) 300 (ε 3660); ($H_2O + OH^-$) 335 (ε 3280) nm. The nmr spectrum δ_{TMS} (D_2O), 2.3 (s, 3H, CH_3), 6.38 (s, 1H, aromatic CH).

(b) By Synthesis

3,4-Dihydroxy-6-methyl-2-pyridone prepared by the method of Lapworth and Collie (3) was identical with compound **3** obtained by hydrolysis of isoflavipucine as above.

The stereochemical dependence of ^{13}C nuclear magnetic resonance chemical shifts and ^{13}C–^{31}P couplings in some dialkylphosphonocyclohexanes

GERALD W. BUCHANAN AND JOHN H. BOWEN[1]

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received September 14, 1976

GERALD W. BUCHANAN and JOHN H. BOWEN. Can. J. Chem. **55**, 604 (1977).

^{13}C chemical shifts and ^{13}C–^{31}P couplings are reported for 15 dialkylphosphonocyclohexanes. Data are compared to those for three related hydroxyphosphonates. Both direct and vicinal ^{13}C–^{31}P couplings are useful stereochemical probes. Materials with equatorial phosphorus exhibit one bond couplings larger by *ca.* 5 Hz than their axial counterparts. Vicinal couplings follow an approximate dihedral angle dependence but are attenuated by OH substitution. In addition to the expected *gauche*-γ shielding effects, pentavalent phosphorus substituents induce minor (*ca.* 1 ppm) upfield shifts at carbons to which they bear an *anti*-periplanar relation.

GERALD W. BUCHANAN et JOHN H. BOWEN. Can. J. Chem. **55**, 604 (1977).

On rapporte les déplacements chimiques du ^{13}C et les constantes de couplage ^{13}C–^{31}P de 15 dialkylphosphonocyclohexanes. On compare ces données avec celles de trois hydroxyphosphonates voisins. Les couplages directs et vicinaux ^{13}C–^{31}P sont tous les deux des sondes stéréochimiques utiles. Les composés avec un phosphore en position équatoriale présentent des couplages à travers une liaison qui sont plus grands par environ 5 Hz que leurs contreparties axiales. Il existe une dépendance approximative entre les couplages vicinaux et l'angle dièdre; ces couplages sont toutefois atténués par l'introduction d'un OH. En plus des effets de blindage γ *gauche* attendus, les phosphores pentavalents induisent au niveau des carbones par rapport auxquels ils ont une relation *anti*-périplanaire, des déplacements chimiques mineurs (environ 1 ppm) vers les hauts champs.

[Traduit par le journal]

Introduction

It has been a decade since the first report (1) of the utility of ^{13}C nmr as a technique for the stereochemical analysis of cyclohexyl compounds and the method is now well established (2, 3). An area of recent interest has been in the application of ^{13}C nmr to conformational effects among cyclohexyl phosphorus compounds containing tri- and tetravalent phosphorus atoms (4). Herein we report our findings for a series of substituted dimethyl-, diethyl-, and diisopropylphosphonocyclohexanes in which the influence of axial and equatorial pentavalent phosphorus atoms on the carbon shifts and ^{13}C–^{31}P couplings has been examined.

Results are compared with earlier data for *cis*- and *trans*-4-*tert*-butyl-1-hydroxy-1-dimethylphosphonocyclohexanes (5) to clarify the effects of OH substitution on the nmr parameters. Employing the isomeric 4-*tert*-butyl cyclohexyl compounds as models as well as the known influence of methyl stereochemistry on carbon shifts (6), the preferred geometries of some previously unknown 2-methyldialkylphosphonocyclohexanes have been deduced.

Results and Discussion

(a) Spectral Assignments

Routinely the ^{13}C spectra were recorded using complete ^{1}H noise decoupling. Subsequently the single frequency off-resonance decoupling procedure was employed to identify CH_3, CH_2, CH, and quaternary carbons. Selective ^{1}H decoupling was used occasionally as were lanthanide shift reagent studies (0.1 *M* equivalent $Pr(FOD)_3$) to distinguish between small chemical shift differences and ^{13}C–^{31}P coupling phenomena (7). Assignments were also facilitated by the knowledge of ^{13}C–^{31}P couplings found earlier (5) in related molecules of known geometry.

(b) Chemical Shifts

The ^{13}C shieldings for compounds **1**–**18** are presented in Table 1, with the corresponding structures and numbering scheme shown in Fig. 1. Comparing the epimeric 4-*tert*-butylcyclohexyl systems **1** and **2** the most notable differences appear at C-1 and C-3,5 which are

[a]0.2–0.3 *M* solutions in $CDCl_3$.

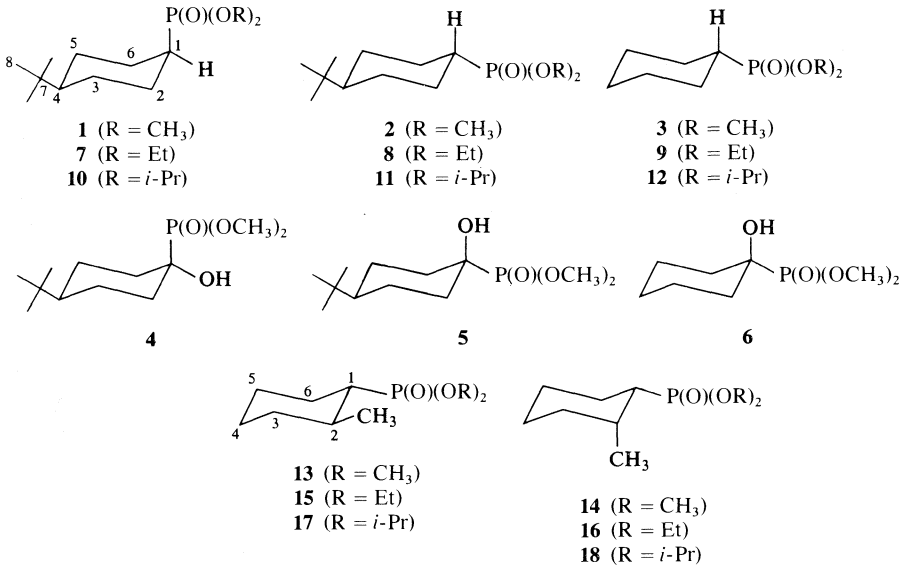

FIG. 1. Structures and numbering schemes for phosphonates.

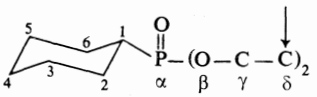
shielded by 4.4 and 3.1 ppm, respectively, in the axial isomer **1**. The observation of increased shielding for the carbon bearing the axial substituent has ample precedent (1–3) but is not always predictable (8). The upfield shift at C-3,5 of **1** exemplifies the well known '*gauche*-γ' shielding effect (2, 3). Although it is clear that these γ shifts do not correlate with the steric bulk of the axial group (8) it is interesting to note that the *gauche* γ-effect for the pentavalent $-P(O)(OCH_3)_2$ function (3.1 ppm), is nearly identical to that for the trivalent $-P(OCH_3)_2$ moiety (4).

Comparison of the C-3,5 shifts for the *trans*-isomer **2** with C-2,6 of *tert*-butylcyclohexane (δ 27.7 for a 0.3 *M* solution in $CDCl_3$) indicates the presence of a 1.2 ppm shielding effect on these resonances due to the *anti*-periplanar phosphorus substituent on C-1. Germane to this observation are the recent results of Eliel *et al.* (9) who have pointed out the operation of shielding effects at γ carbons induced by second row elements held rigidly in *trans*-coplanar orientations. For third row elements such as S or Cl, however, Eliel *et al.* found no evidence of this *trans*-γ shielding effect and suggested that none would be expected for other third row elements. Thus our findings cast doubt on the model proposed by Eliel and indicate the N, O, and F do not, as was suggested (9), play a "unique role" in the *trans*-γ shift. It is interesting to note that for a series of trivalent phosphorus substituents both shielding and deshielding *trans*-γ shifts have been obtained (4).

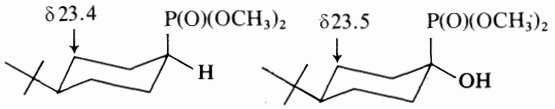
Compound **3**, which lacks the 4-*tert*-butyl substituent, exhibits C-1 and C-3,5 chemical shifts nearly identical to **2** which suggests a strong preference for an equatorial disposition of the dimethylphosphono group. In the limiting low temperature spectrum of **3** (−120 °C in CD_2Cl_2) we have not detected any resonances characteristic of the axially substituted conformer. Given the high preference for equatorial $-P(O)(OCH_3)_2$ in **3**, it is interesting to compare the C-3,5 shift for **3** (δ 26.3) with cyclohexane itself (δ 27.2 for a 0.3 *M* solution in $CDCl_3$). Again the existence of a minor (*ca.* 1 ppm) upfield *trans*-γ effect is operative for the carbons to which the pentavalent phosphorus bears an *anti*-periplanar relationship.

For the series of *cis*-4-*tert*-butylcyclohexyl isomers **1**, **7**, and **10** and the *trans*-isomers **2**, **8**, and **11**, it is evident that further branching in the O-alkyl chain of the phosphono group has only minor perturbing effects on the carbon shifts. Comparing **1**, **7**, and **10**, there is a minor deshielding (*ca.* 1 ppm) effect at C-1 as the $(OR)_2$ group changes from R = CH_3 to R = Et and R = isopropyl. Similarly in the *trans*-isomers **2**, **8**, and **11** and in the simple cyclohexyl compounds **3**, **9**, and **12** C-1 becomes deshielded as the degree of O-alkylation increases. In each case, the additional substitution is at a position



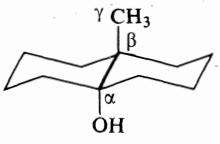
which bears a 'δ' relationship to C-1. The magnitudes of these 'δ' effects are reminiscent of those noted for linear and branched alkanes (10). Other ring carbon resonances are nearly identical in the above isomeric series. The trends for the shifts of the O-alkyl carbons are consistent with the well documented influences of alkyl substitution (2, 10).

In the context of the earlier discussion *re trans*-γ effects it is useful to compare the C-3,5 shifts for **1** and **4** shown below. Clearly the *anti*-periplanar OH in **4** has no effect on the ^{13}C shieldings of the *trans*-γ carbons. It appears therefore that even for second row elements the *trans*-γ shielding effect (9) is not completely



1 **4**

general. Recently some examples of marked *deshielding trans*-γ effects (up to 4 ppm) have been noted (11) in arrangements such as that depicted below, where both the α and the β carbons are quaternary.



When group 4B substituents are present at the *anti*-periplanar positions (*i.e.* C, Si, Ge, and Sn) one also finds substantial downfield *trans*-γ shifts (12).

For the conformationally 'mobile' hydroxyphosphonate **6** the C-3,5 shifts are similar to those of **5**, again suggesting a high preference for the equatorial dialkylphosphono functions. It is notable, however, that the C-3,5 shift for **6** does not lie between the values for the 'model' compounds **4** and **5**.

With regard to the 2-methyl compounds **13**–**18**, resonance assignments were facilitated by the previous ^{13}C–^{31}P coupling results (5) and by the known effects of methyl stereochemistry on cyclohexyl carbon resonances (6, 13). In each case the large vicinal couplings to ^{31}P indicated that the dialkylphosphono group was equatorial. For **13**, the 2-CH_3 resonance is at δ 21.8 which is 6.7 ppm deshielded relative to the case where the 2-CH_3 is axial (compound **14**). This difference in methyl shieldings is comparable to that of other epimeric methyl substituted cyclohexanes (6, 13). Further support for the designation of an axial 2-CH_3 group in **14** comes from the *gauche*-γ shielding (*ca.* 5 ppm) found at C-4 and C-6 of **14** relative to **13**. There appears to be no measurable *trans*-γ effect of the equatorial CH_3 in **13** as evidenced by the close correspondence in the C-4 and C-6 shifts for **13** and **3**. At C-1 and C-3 of **13** to **18** there are appreciable shift differences between isomers. In all instances, compounds having the axial CH_3 exhibit *ca.* 3 ppm upfield β-effects at these centres. These constitute further examples of the coexistence of shielding β and *gauche*-γ effects although the β effects are normally smaller in magnitude (2).

In **13**–**18** the O—$\overset{*}{C}$ and O—C—$\overset{*}{C}$ positions become diastereotopic (14) and therefore minor (*ca.* 0.1 ppm) shift differences are observed.

(c) Coupling Constants

(i) One Bond Couplings

The direct ^{13}C–^{31}P couplings are shown in Table 2, and from earlier work (15) the sign is assumed to be positive. Couplings for the hydroxy phosphonates **4**, **5**, and **6** are considerably larger than those for the related phosphonates **1**,

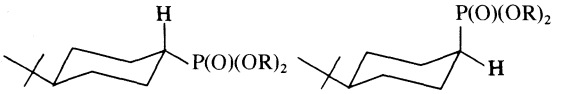
[a]Sign assumed to be positive (15).

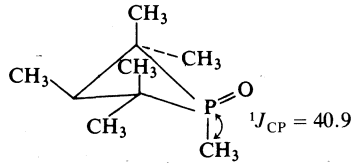
2, and **3**. These findings are in accord with those of Gray (16) who reported an increase of *ca.* 20 Hz in the ^{13}C–^{31}P coupling in phosphonates in which a hydrogen bonded to the carbon of interest is replaced by a methoxyl group.

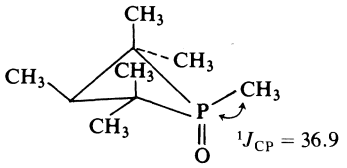
For **1–12** it is important to note the stereospecificity of the one bond ^{13}C–^{31}P J's. In the phosphonates the coupling between C-1 and an equatorial pentavalent phosphorus is 5–6 Hz larger than when the phosphorus is axial. For



$^1J_{CP} \approx 144$ Hz $^1J_{CP} \approx 139$ Hz

the hydroxyphosphonates **4** and **5** the difference is larger (7.8 Hz). The present results parallel the values for $^1J_{CH}$ at the anomeric carbons of α- and β-D-glucose (169 and 160 Hz) respectively (17), although the mechanisms of ^{13}C–^{31}P and ^{13}C–H couplings are no doubt very different. For the pentavalent phosphine oxides depicted (18) the stereochemical trend in $^1J_{CP}$ is opposite to that in the phosphonates.





A further point of interest, although we can offer no rationale at present, is the difference in $^1J_{CP}$ for the isomeric pairs **13**,**14**, **15**,**16**, and **17**,**18**. In each case where the 2-CH_3 is axial the $^1J_{CP}$ value is larger by *ca.* 2 Hz than when the 2-CH_3 is equatorial.

(ii) Geminal Couplings

In Table 3 are presented the two bond ^{13}C–^{31}P couplings found for **1–18**. For the P–O–C J's, the range of 6.4–7.4 Hz is similar to that found in cyclic phosphates (19) and in acyclic phosphonates (16). Although absolute values only are depicted in Table 3, the sign is likely negative for these couplings by analogy with the findings for $(CH_3O)_2P(O)CH_3$ (15).

TABLE 3. Geminal ^{13}C–^{31}P couplings (±0.2 Hz)[a]

	^6C—^1C—P	3.7

[a]For **13–18**, O—C carbons are diastereotopic and P—O—C J's undetermined due to spectral complexity.

With regard to the C–C–P couplings, again only absolute values are quoted since it has been noted (20) for trivalent phosphorus compounds at least, that the sign of these interactions can be positive or negative. The total range of J_{gem} values is small (1.5–4.2 Hz) and few clear trends are evident. It is notable that in the *cis*-dimethylphosphono compound **1**, J_{CCP} is 3.0 Hz whereas in the corresponding hydroxyphosphonate **4** J_{CCP} falls to 1.5 Hz. It is known for geminal

C–C–H couplings (21) that hydroxyl substituents can reduce the value of J_{gem}. In the case where the OH is axial, *i.e.* **5**, the OH group does not appreciably alter the coupling compared to **2**.

(iii) Vicinal Couplings

Data for the 3-bond couplings are collected in Table 4. For the *trans*-4-*tert*-butylcyclohexyl compounds **2**, **8**, and **11**, the couplings are nearly identical (*ca.* 16 Hz) and reflect a dihedral angle near 180° between P and C-3,5. The simple cyclohexyl systems **3**, **9**, and **12** show similar values again mirroring their high preference for equatorial phosphorus. It is instructive to recall that for the *exo*-2-norbornyl compound shown below the J_{CCCP} value is 18.4 Hz where θ again is near 180° (5). Thus these couplings tend to vary with the nature of the pathway even though the dihedral angles are essentially identical.

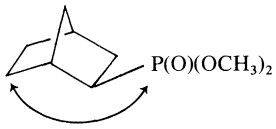
[a]Sign taken as positive (15).
[b]N.R. = non resolvable *i.e.* < 0.6 Hz.



$^{3}J_{CCCP}$ = 18.4 Hz

When an OH is inserted at C-1 as in **5** and **6** the vicinal coupling is reduced by *ca.* 5 Hz. There have been similar phenomena noted for vicinal C–H couplings (21) and for vicinal H–H interactions (22, 23) although these influences tend to be maximal when the OH is *trans*-coplanar to a terminus of the coupling path.

For the 2-methyl compounds **13–18** the vicinal couplings of the equatorial phosphorus to positions 3 and 5 of the ring tend to be slightly less than in compounds where the 2 position is not substituted. It is plausible that *gauche*-interactions between the 2-CH_3 and the equatorial P cause minor ring deformations so that the θ values deviate from 180° and result in reduced J's.

When the dihedral angle between ^{31}P and a ring carbon is near 60° (compounds **1**, **4**, **7**, and **10**) no resolvable vicinal coupling is apparent. In the 2-methyl compounds, however, resolvable J's to the methyls are obtained but they are all rather small (*ca.* 1 Hz).

Combining the present findings with those noted earlier (5) it is evident that both direct and vicinal ^{13}C–^{31}P couplings are useful stereochemical probes in pentavalent phosphorus compounds. Care must be taken however in the strict application of a Karplus type relationship for J_{CCCP}. The influence of OH groups on vicinal couplings parallels results for ^{13}C–H and H–H interactions although a sufficient number of model compounds with a wide range of dihedral angles is still lacking.

Experimental

Spectra

^{13}C spectra were measured employing a Varian XL-100-12 nmr spectrometer, equipped with a Nicolet

Materials

Compounds **4** and **5** were available from previous work (5) and **6** was synthesized from cyclohexanone and dimethyl phosphite according to the published procedure (24).

The phosphonates **3**, **13**, and **14** were synthesized via the corresponding cyclohexane-1,1-dithiols (25) which were subsequently reacted with trimethyl phosphite and Raney nickel according to recently reported methods (26, 27). Similarly **9**, **15**, and **16** were prepared using triethyl phosphite and **12**, **17**, and **18** employing triisopropyl phosphite.

For the 4-*tert*-butylcyclohexyl compounds **1**, **2**, **7**, **8**, **10**, and **11** it was necessary to proceed from 4-*tert*-butylcyclohexanone to its morpholine enamine derivative which then was converted to 4-*tert*-butylcyclohexane-1,1-dithiol using the published method (28). Conversion of the *gem*-dithiol to the phosphonates was then accomplished in a manner similar to that for the simpler cyclohexane derivatives.

Separation of epimers was accomplished in all cases by preparative glc using a 5% Ucon on Chromosorb W.H.P. column of dimensions 6 ft by 6 mm inner diameter. Typical oven temperatures were near 200 °C, with the detector near 210 °C and injector at 310 °C. The N_2 flow rate on the Perkin-Elmer 990 gas chromatograph was typically 130 ml/min. Isomer ratios obtained (%) were as follows: **1**:**2**, 58:42; **7**:**8**, 68:32; **10**:**11**, 62:38. In each case the axial epimer was eluted first (retention time near 45 min) and the equatorial isomer retention times were near 55 min. For the 2-methyl compounds **13**–**18** the isomer ratios were nearly 50:50 with the isomers having the equatorial 2-methyl group exhibiting the shorter retention times (*ca.* 40 min).

Characterization of Products

Physical properties of **7** and **8** were in agreement with those reported previously (29) as were those of **3**, **9**, and **12** (26, 27). For the remaining new materials mass spectral parent ions, refractive indices, and analytical data are collected in Table 5.

Kinetic studies on the mechanism of the decomposition of a number of β-substituted *tert*-butyl α,α-dimethylperpropionates

DENNIS D. TANNER, H. YABUUCHI,[1] AND H. LUTZER
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 14, 1976

DENNIS D. TANNER, H. YABUUCHI, and H. LUTZER. Can. J. Chem. **55**, 612 (1977).

A series of *tert*-butyl peresters having a general formula corresponding to I were synthesized.

$$Y—CH_2C(CH_3)_2CO_3C(CH_3)_3$$

I

(Y = H, C_2H_5, Cl, Br, I, C_6H_5S)

The thermally initiated rates of decomposition of these peresters were determined at several temperatures and the activation parameters for these thermolyses were calculated.

The rates of decomposition were relatively insensitive to the substituents and followed the order I > C_2H_5 > C_6H_5S > H > Br > Cl. The activation parameters and product studies were consistent with a simple two bond scission mechanism and no evidence could be found for neighboring group participation in these homolyses.

DENNIS D. TANNER, H. YABUUCHI et H. LUTZER. Can. J. Chem. **55**, 612 (1977).

On a synthétisé une série d'esters *tert*-butylés ayant une formule générale correspondant à I.

$$Y—CH_2C(CH_3)_2CO_3C(CH_3)_3$$

I

(Y = H, C_2H_5, Cl, Br, I, C_6H_5S)

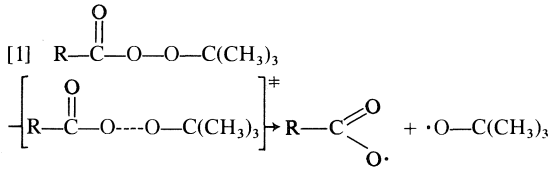
On a déterminé les vitesses de décomposition, initiées thermiquement, de ces peresters à diverses températures et on a calculé des paramètres d'activation de ces thermolyses.

Les vitesses de décomposition sont relativement insensibles à la nature des substituants et l'ordre est le suivant I > C_2H_5 > C_6H_5S > H > Br > Cl. Les paramètres d'activation et les études de produits sont en accord avec un mécanisme de scission simple de deux liens et on ne trouve aucune indication pouvant supporter la participation d'un groupe voisin dans ces réactions homolytiques.

[Traduit par le journal]

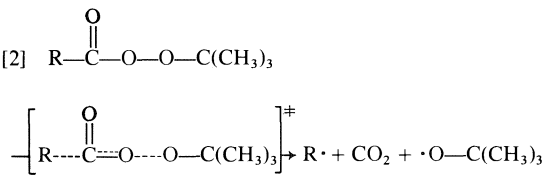
Introduction

A large number of investigations of the mechanism of *tert*-butyl perester decompositions have been concerned with the relationship between the structure of the peroxide and its mode of decomposition (1). The thermal decompositions of the simple peresters have been proposed to proceed by two mechanistically distinct pathways, one-bond scission (reaction 1) and two-bond scission (reaction 2). Kinetic criteria for



distinguishing between the two paths has been established by Bartlett and Hiatt by comparing the activation parameters of a series of peresters and by correlating these comparisons with the chemical information available for these systems (2). Although these criteria have been somewhat modified, the analysis of the problem has been well supported (1).

Another facet of the structure–reactivity relationship in perester decomposition has been the effect of neighboring groups on not only the mechanism of the decomposition, but on its

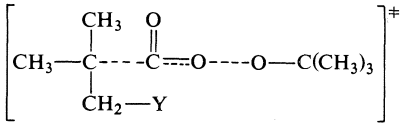


[1] Visiting scientist on leave from Sumitomo Chemical Co., Osaka, Japan.

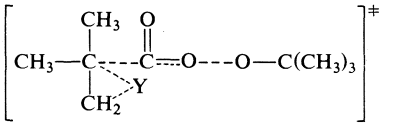
absolute rate relative to the unsubstituted perester (ref. 1, pp. 137–143).

Substituted peresters have been shown to be subject to polar effects as well as effects attributed to anchimeric assistance during homolysis (3, 4).

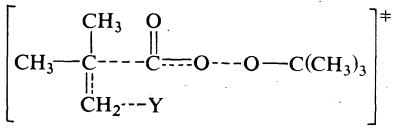
A study of the decomposition of *tert*-butyl α,α-dimethylperpropionate **1** and its β-substituted analogues affords a method for the study of the substituent effect on the decomposition of a perester which has been considered as decomposing via the two-bond scission process [2] (2,5–8). Homolytic cleavage of the β-substituted peresters can in theory proceed through a variety of possible transition states (I–IV).



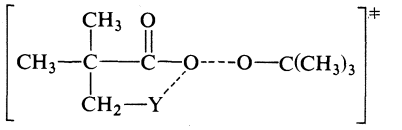
I



II



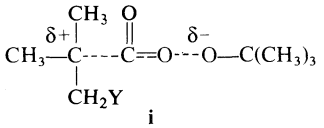
III



IV

Assisted homolysis of the (O—O) bond by the substituent Y should result in an increased rate for the decomposition of the substituted perester compared to its unsubstituted analogue (9–11). If the decomposition path proceeds via transition states II–IV one would expect the assistance to be reflected in the activation parameters, a smaller $\Delta H^{\ddagger}$ and a more negative $\Delta S^{\ddagger}$.

Polar effects on the decomposition of peresters proceeding via transition state I would predict, by inductive interaction with the polar structure **i**, that the order of the rates of decomposition of the substituted peresters would be the inductive order, $C_2H_5 > H > SCH_3 > I > Br > Cl$ (12). Unless the polar interactions were large, however, small changes in the steric requirements of the groups or upon the solvation of the transition state would easily mask the observation of a regular trend (1, 13, 14). The same polar order

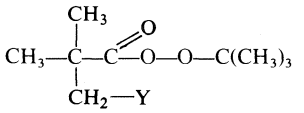


i

$SCH_3 > I > Br > Cl > F$ has been observed for the decomposition of a series of 3-substituted *tert*-butyl perpropionates. Peresters of this structure, presumably, proceed via one-bond scission, although it has been suggested that *tert*-butyl 3-methylthioperpropionate undergoes a concerted three-bond scission (15).

Results and Discussion

The rates for the thermal decomposition of the *tert*-butyl peroxides **1–6** were determined at several temperatures and the results are listed in Table 1.



1 Y = H **4** Y = Cl
2 Y = C_2H_5 **5** Y = I
3 Y = Br **6** Y = C_6H_5S

The thermolyses of cyclohexane solutions of peresters **1** and **2** (0.04 *M*) gave 98 and 99% yields of the theoretically calculated amounts of CO_2 and followed steady first-order kinetics to >80% reaction. The rate of decomposition of **1** in cyclohexane agrees extremely well with that reported by Koenig and Wolf (5)[2] for its thermolysis in isooctane, and the activation parameters are, within the limits of the experimental error (which masks any solvent effect), comparable with those reported by Bartlett and Simons (8) or by Lorand *et al.* (6) for decompositions run in chlorobenzene and cumene. The rate constant observed for **2** in cyclohexane was approximately 60% lower than that reported by Fort and Franklin (7) when its decomposition was carried out in cumene. The decreased rate of decomposition observed in the less polar

[2]The rate constant at 73.88 °C was calculated for comparison using the activation parameters reported in this manuscript.

TABLE 1. Rate constants and activation parameters for the thermal decomposition of the *tert*-butyl 3-substituted 2,2,-dimethylperpropionates (X—CH_2—$C(CH_3)_2$—CO_3—$C(CH_3)_3$) at several temperatures, in cyclohexane

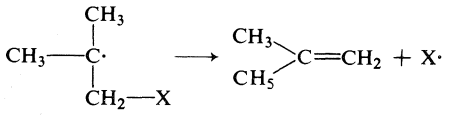
[a]Iodine was added to exclude catalyzed decomposition (0.04 *M*).

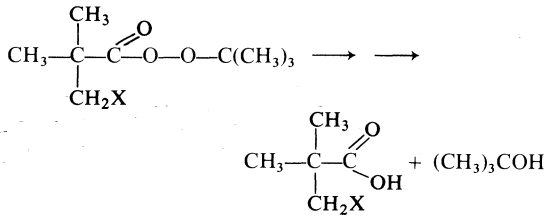
solvent, cyclohexane, would be expected for this concerted homolytic process (16).

The decompositon of **3** and **4** in various solvents (chlorobenzene, cumene, and cyclohexane) did not show simple first-order kinetics and at higher percentage decomposition the calculated instantaneous first-order rate constants increased with time. When radical scavengers such as DPPH, galvinoxyl, or molecular iodine were added steady first-order kinetics were obtained. The induced decompositions without added scavengers are presumed to be due to a β-scission process which results in a heterolytic acid catalyzed decomposition of the peroxide. Associ-



$$X\cdot + RH \longrightarrow HX + R\cdot$$

ated with the induced decompositon was a decreased yield of carbon dioxide and the accompanying production of the parent carboxylic acid. When the thermolyses were carried out in the presence of added molecular iodine first-order kinetics were obtained and quantitative



yields (100 ± 3%) of carbon dioxide were obtained. No carbonyl containing compounds could be detected by ir analyses.

Both compounds **5** and **6** (0.04 *M*) gave steady first-order kinetics in cyclohexane with added molecular iodine (0.04 *M*) and produced carbon dioxide in near quantitative yields (97 and 95%). When the thermolysis of **6** was carried out in the absence of molecular iodine the same first-order rate constant was determined (1.63×10^{-5} s^{-1}, 55 °C) and the yield of carbon dioxide (99%) was essentially the same as that obtained when the decomposition was carried out in the presence of a scavenger. It was anticipated that although the β-scission process would be quite favourable for thiyl radical elimination, the stability of the sulphur centered radical would lead almost exclusively to coupling products and

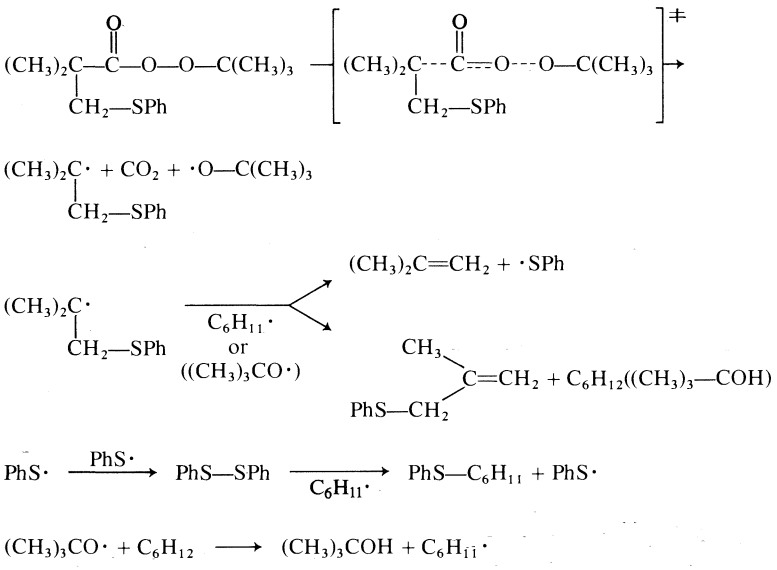
Product	Amount (mg)	Amount (mmol)	Mol/mol perester
Carbon dioxide	30.8	0.673	0.97
tert-Butyl alcohol	46.3	0.625	0.90
*Iso*butylene	33.8	0.603	0.84
β-Methylallylphenylsulphide	18.0	0.110	0.16
Cyclohexylphenylsulphide	64.1	0.334	0.47
Diphenyldisulphide	21.3	0.098	0.14



not products resulting from hydrogen abstraction. Since the acid (C_6H_5SH) catalyzed reaction would not be involved in the decomposition it was not surprising that the scavenged and unscavenged rates of decomposition were the same. A study of the decomposition products resulting from the thermolysis (75 °C) of **6**, *tert*-butyl 2,2-dimethyl-3-phenylthioperpropionate, confirmed these predictions (see Table 2), and allowed the suggestion for a decomposition mechanism which is consistent with the products of the reaction and the activation parameters that were obtained.

Mechanistic Conclusions

It has convincingly been argued that *tert*-butyl peroxypivalate decomposes by a concerted two-bond scission (1, 2, 5–7, 14). The criteria used, the magnitude of the activation parameters, and the high yields of carbon dioxide produced, have been taken with some modification (1, 4, 6) as indications of a concerted two-bond scission. The activation parameters obtained for the decomposition of peresters **1–6** vary from $\Delta H^{\ddagger}$ 30.7 ± 1.4 kcal/mol, $\Delta S^{\ddagger}$ 10.0 ± 4.3 eu (Y = Cl) to 27.9 ± 0.7 kcal/mol and 3.8 ± 0.7 eu (Y = PhS), and the interpretation of these differences must be considered mechanistically indistinguishable from *tert*-butyl peroxyperpivalate ($\Delta H^{\ddagger}$ 29.3 ± 1.4 kcal/mol and $\Delta S^{\ddagger}$ 7.8 ± 4.1 eu). The high yields of carbon dioxide obtained for all of the peresters confirm this mechanistic conclusion. The similarity in the activation parameters and the observed rate constants (a variation of less than 3 from the unsubstituted perester) are clearly indicative of the same mechanistic pathway for all of the decompositions, *i.e.* via transition state I. The minor

differences in energetics due to polar effects, steric or solvation interactions are too small to justify a detailed analysis.

Experimental

Materials

Cyclohexane and cumene (Phillips Research Grade) were purified by heating to reflux over sodium metal for several hours followed by fractional distillation. Chlorobenzene was fractionally distilled from phosphorous pentoxide. All solvents were found to be without detectable impurities by ir and glpc.

3-Bromo-2,2-dimethylpropionic acid was prepared by the reaction of fuming hydrobromic acid upon 3-hydroxy-2,2-dimethylpropionic acid. The acid was prepared by potassium permanganate oxidation of 2,2-dimethyl-1,3-propane diol according to the method of Testa *et al.* (17). The oxidation by this method netted a 36% yield of 3-hydroxy-2,2-dimethylpropionic acid, mp 122–126 °C (lit. (17) mp 123–125 °C). The hydroxycarboxylic acid was converted to 3-bromo-2,2-dimethylpropionic acid with hydrobromic acid according to a modification of a procedure described by Nerdel *et al.* (18). A mixture of 38.97 g (0.33 mol) of 3-hydroxy-2,2-dimethylpropionic acid and 218 ml (4.80 mol) of 48% hydrobromic acid was allowed to stir for 24 h at 95–100 °C while a constant flow of hydrogen bromide was bubbled through the solution. The acid was isolated by the given method (18) in a 98% yield and recrystallized from water, mp 51–52 °C (lit. (17) mp 52 °C).

3-Iodo-2,2-dimethylpropionic acid was prepared according to the method of Kohn and Schmitt (19), mp 48.5–49.5 °C (lit. (19) mp 54 °C). *Anal.* calcd. for $C_5H_9O_2I$: C 26.30, H 3.95; found: C 26.49, H 3.95.

2,2-Dimethyl-3-phenylthiopropionic acid was prepared according to the method used by Truce and Knospe (20) for the preparation of 2,2-dimethyl-3-methylthiopropionic acid. To a solution of absolute ethyl alcohol (130 ml) and sodium metal (9.7 g, 0.47 mol) was added the reaction mixture of absolute ethyl alcohol (130 ml), thiophenol (25 g, 0.52 mol), and sodium metal (11.3 g, 0.50 mol). The solution was allowed to stir for 2 h at 30 °C. The combined mixture was subsequently added dropwise into an ethyl alcohol solution of 3-chloro-2,2-dimethylpropionic acid (64 g, 0.47 mol). The reaction mixture was concentrated under vacuum and the solid residue was acidified with 10% aqueous hydrochloric acid. The aqueous solution was extracted several times with ether, and the combined ethereal extracts were dried over anhydrous magnesium sulphate. After distillation of the solvent 87 g (80%) of a white solid was isolated. The crude product was recrystallized from chloroform – carbon tetrachloride mp 115.5–116 °C (lit. (21) mp 115 °C). *Anal.* calcd. for $C_{11}H_{14}O_2S$: C 62.82, H 6.71, S 15.25; found: C 62.50, H 6.49, S 15.36.

3-Substituted 2,2-dimethylpropionyl chlorides were synthesized from their corresponding carboxylic acids (either synthesized as above or commercially available from Aldrich Chemicals Co.) by treatment with thionyl chloride (22).

2,2-Dimethyl-3-phenylthiopropionyl chloride was not prepared by the standard thionyl chloride method since reflux with thionyl chloride produced not only the desired acid chloride but also 1-thiocromanon. The acid chloride was prepared by the dropwise addition of a benzene solution of oxalyl chloride (112.5 g, 0.89 mol) to a benzene solution (100 ml) of 2,2-dimethyl-3-phenylthiopropionic acid (10.4 g, 0.05 mol). The mixture was stirred for 1 h at 30 °C. The volatile fraction of the mixture was distilled at reduced pressure (room temperature) leaving 11 g (97%) of a yellow liquid.

*tert-Butyl peresters (**1–5**)*: peresters **1–5** were prepared by the dropwise addition of (0.17 mol) of purified pyridine to a cooled, 0 °C, *n*-pentane (100 ml) solution of the acid chloride (0.15 mol) and *tert*-butyl hydroperoxide (0.25 mol). The temperature was always maintained below 5 °C. The reaction mixture was then allowed to stand at room temperature for 40 min. Subsequently the mixture was poured onto ice. The organic layer was separated and washed successively with cold 10% hydrochloric acid, 10% sodium bicarbonate solution, and distilled water, and finally dried over anhydrous sodium sulphate. After removal of the solvent, the remaining crude material (usually 80–90% yield) was purified either by recrystallization from *n*-pentane at −78 °C or by passing it through a column of Woelm neutral alumina at 0 °C, using ether as the eluant. The latter method was shown to be particularly effective to remove all traces of impurities. Peroxide contents as determined by the iodometric titration procedure developed by Silbert and Swern (23) were as previously reported (8, 24) not reliable (β-C_2H_5, 86.5%; β-H, 84.7%; β-Cl, 98.3%; β-Br, 98.2%). The purity of the peresters was therefore determined by their infrared and nmr spectra, kinetic behaviour, and elemental analysis. The refractive indices, carbonyl absorptions, microanalyses and the nmr spectra (CCl_4) of the peresters are listed in Tables 3 and 4.

*tert-Butyl 2,2-dimethyl-3-phenylthioperpropionate **6*** was synthesized in a different manner. An attempt to synthesize this perester from the corresponding acid chloride according to the procedure employed for the other peresters, led to an apparent spontaneous decomposition of the perester during the preparation. The perester **6** was consequently prepared by a simple modification of the procedure described for the other peresters. To a stirred cold (0 °C) *n*-pentane (10 ml) solution of *tert*-butyl hydroperoxide were slowly and simultaneously added two *n*-pentane solutions (10 ml each), one containing 2,2-dimethyl-3-phenylthiopropionyl chloride (3.07 g, 0.0135 mol) and the other pyridine (1.34 g, 0.0170 mol). After the addition was completed (20 min) the perester was isolated in the same manner as were the other peresters.

The nmr and ir spectra and elemental analyses of peresters **1–6** showed them to be without experimentally detectable impurities.

β-*Methylallylphenylsulphide* was prepared by the reaction of thiophenol with β-methylallyl chloride according to the procedure of Cope *et al.* (25); bp 83–84 °C/2.8 torr (lit. 89 °C/3.4 torr); the nmr spectrum (neat) was compatible with the one reported for this compound by Kwart and Evans (26). *Anal.* calcd. for $C_{10}H_{22}S$: C 73.11, H 7.36, S 19.52, found: C 73.27, H 7.46, S 19.64.

Cyclohexylphenylsulphide was prepared according to the method employed by Saville (27); bp 126–129 °C/2.8 torr (lit. 111 °C/0.1 torr); nmr (neat) 2.74–3.29 (m, 5H, aromatic), 6.80–7.51 (m, 1H, H_1 of cyclohexyl), and 8.00–9.65 (m, 10H, cyclohexyl). *Anal.* calcd for $C_{12}H_{16}S$: C 74.94, H 8.39, S 16.67; found: C 75.00, H 8.69, S 16.70.

Kinetic Studies

The rate of disappearance of the peresters was monitored by following the disappearance of the carbonyl stretching band of the peresters at 1760–1775 cm^{-1}. A Perkin-Elmer infrared spectrophotometer, Model 21 or 421, was employed throughout this study. Products from the decomposition of the peresters did not have any absorptions in this region of the infrared spectrum.

A cyclohexane solution of a perester (0.04 *M*) was initially prepared. In the case of the peresters, **4** (X = Cl), **3** (X = Br), and sometimes **5** (X = I) and **6** (X = C_6H_5S), iodine (0.04 *M*) was added in order to exclude anticipated induced decomposition of these peresters. Beer's Law was verified for this system, as evidenced by the straight lines obtained from a plot of log percentage transmittance *vs.* the known concentration of the perester, for a series of standard solutions. Aliquots (1.5 ml) of the solution were degassed by three cycles of the freeze–thaw method and sealed in Pyrex ampoules. The ampoules were then immersed in an oil bath, thermostated at the appropriate temperature within ±0.05° for 10 min, and after various subsequent reaction periods the tubes were removed from the bath, quenched in liquid nitrogen, and analyzed by ir spectroscopy. The initial and final concentrations of the peresters were obtained from the linear plots of perester concentration *vs.* ($\log T_\infty - \log T$), when T is the percentage transmittance for a known perester concentration. The errors for the rate constants reported in Table 1 are average deviations from the mean values obtained for the calculated instantaneous first-order rate constants. Duplicate experiments were carried out and the values obtained were within the experimental limits listed in Table 1.

Studies on the Perester Decomposition Products

The decompositions of 0.04 *M* solutions of peresters **1**–**6** were carried out in reaction vessels fitted with break-seals at 75 °C for 10 half-lives. The reaction vessels were opened to a vacuum line and the volatile gases were fractionated into three traps, the first two cooled to −122 °C and the third cooled to −198 °C. The content of the third trap was measured by means of a Toepler pump (see Table 5). After measurement the gas was identified by its glpc retention time (poly-pack 1, 4 ft × ¼ in. glass column, 0 °C) and was collected and submitted for mass spectral analysis. The cracking pattern, MS-9 high resolution mass spectrometer, confirmed that the gas collected was pure carbon dioxide. Infrared spectra of the residual product mixtures showed an absence of any detectable carbonyl absorption.

tert-Butyl 2,2-dimethyl-3-phenylthioperpropionate ***6*** was decomposed without added iodine and a 97% yield of carbon dioxide was collected, identified, and measured (see Table 5).

The residual reaction mixture was collected, a known amount of benzene was added as an internal standard, and the low boiling fraction of the mixture was analyzed by glpc (20 ft × ⅛ in. 4% FFAP on Chromosorb W A/W DMCS, 72 °C). Two products were detected; isobutylene (84%) and *tert*-butyl alcohol (90%). The reaction mixture was concentrated by distillation under vacuum, a known amount of dibenzyl was added as an internal standard,

TABLE 5. Measurement of carbon dioxide in the decomposition of *tert*-butyl 3-substituted 2,2-dimethylperpropionates[a,b]

Perester substrate	Perester (mmol)	Solvent	CO_2 (mmol)	Carbon dioxide (mol/mol perester)
1[c]	2.00	Cyclohexane	1.95	0.98
2[c]	2.00	Cyclohexane	1.97	0.99
4	2.00	Chlorobenzene	2.06	1.03
3	0.85	Cyclohexane	0.85	0.99
5	1.55	Cyclohexane	1.50	0.97
6	1.69	Cyclohexane	1.61	0.95
6[c]	0.72	Cyclohexane	0.71	0.97

[a]The decompositions were carried out with 0.04 *M* iodine added except where otherwise indicated.
[b]The peresters were decomposed to greater than 10 half-lives.
[c]No iodine was added.

the mixture was dissolved in ether, and analyzed by glpc (5 ft × ¼ in. 10% SE-30 on Chromosorb W A/W, 172 °C). The products found under these conditions were: β-methylallylphenylsulphide (15%), cyclohexylphenylsulphide (47%), and diphenyldisulphide (14%).

The products (see Table 2) were identified by a comparison of their glpc retention times and mass and ir spectra with those of the authentic materials.

Carbon-13, proton spin–spin coupling constants in some 4-substituted isothiazoles and related heterocyclics

RODERICK E. WASYLISHEN AND HAROLD M. HUTTON

Department of Chemistry, University of Winnipeg, Winnipeg, Man., Canada R3B 2E9

Received August 18, 1976

RODERICK E. WASYLISHEN and HAROLD M. HUTTON. Can. J. Chem. **55**, 619 (1977).

Carbon-13, proton nuclear spin–spin coupling constants have been measured for a number of 4-substituted isothiazoles. The observed values are compared with those measured in other heterocyclic systems and those calculated in the parent and related heterocyclics using finite perturbation theory and semi-empirical molecular orbital theory at the CNDO/2 and INDO levels of approximation.

RODERICK E. WASYLISHEN et HAROLD M. HUTTON. Can. J. Chem. **55**, 619 (1977).

On a mesuré les constantes de couplage spin–spin entre les noyaux de proton et de carbone-13 pour un certain nombre d'isothiazoles substitués en position 4. On a comparé les valeurs observées avec celles mesurées dans d'autres systèmes hétérocycliques et celles calculées pour le composé fondamental et pour des hétérocycles apparents; ces calculs ont été effectués, à des niveaux d'approximation CNDO/2 et INDO, à l'aide de la théorie des perturbations finies et la théorie semi-empirique des orbitales moléculaires.

[Traduit par le journal]

Introduction

Although $^{13}C,H$ coupling constants are available for a large variety of molecules (1–8), there have been few systematic studies of substituent effects on $^{n}J(^{13}C,H)$ where $n > 1$. A better understanding of substituent effects on these coupling constants should be helpful in the assignment of complex ^{13}C nmr spectra (9–11). As part of our continuing interest in the isothiazole ring system (12, 13) we report $^{n}J(^{13}C,H)$ values in a number of 4-substituted isothiazoles (**1**).

1

The observed coupling constants are compared with those observed in other heterocyclic systems. Those observed in the parent compound are also compared with coupling constants calculated using semi-empirical molecular orbital theory (4, 14–16).

Experimental

Compounds

The ester of isothiazole-4-carboxylic acid was prepared as described earlier (12). All the other isothiazoles were obtained from Raylo Chemical Company, Edmonton, Alberta. Isoxazole, and its methyl derivatives were obtained from Aldrich Chemical Company. 1-Methylpyrazole was obtained from ICN K & K Laboratories, Inc.

Carbon-13 Nuclear Magnetic Resonance Spectra

Natural abundance ^{13}C nmr spectra were measured in 10 mm sample tubes at 20 MHz using a Varian CFT-20 Fourier Transform nmr Spectrometer. Gated proton decoupling (decoupler on during the pulse delay) was used in order to retain nuclear Overhauser enhancements of the proton coupled spectra. Typically, flip angles of 30 to 40° were used with acquisition times >4 s and a pulse delay of 2–3 s. All coupling constants reported here are accurate to ±0.3 Hz or better unless otherwise indicated. All measurements were made at 33 ± 2 °C on approximately 3 *M* solutions of the 4-substituted isothiazoles in DMSO and on neat solutions of isoxazole, the methyl derivatives of isoxazole, and 1-methylpyrazole. Proton-coupled carbon-13 nmr spectra were also obtained at 55 MHz for neat solutions of isothiazole and its methyl derivatives as previously described (12).

Proton Nuclear Magnetic Resonance Spectra

^{1}H nmr spectra of the isothiazoles were obtained on a Varian A-60 nmr spectrometer. A Perkin Elmer R24 spectrometer was used to obtain approximate proton chemical shifts of neat isothiazole.

Molecular Orbital Calculations

Molecular orbital calculations at the CNDO/2 and INDO-MO-FPT levels of approximation (14, 15) were performed on an IBM 370/158 system. The following parameters were added to the MO program (14–16) so that INDO calculations on molecules containing sulfur were possible: G1(16) = 0.31302 and F2(16) = 0.21794 (17).

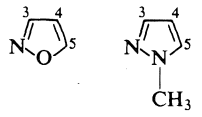
References to the geometries used for isothiazole and its derivatives are given on p. 599 of ref. 12. The structures of the isoxazole and pyrazole rings were taken from microwave studies (18, 19). Standard geometries (given on p. 110 of ref. 14) were used for the methyl substituents.

For isothiazole and its methyl derivatives the calculated coupling constants did not converge before the density

matrix rms error of 10^{-9} was reached. In these calculations this value was 0.7×10^{-5} or smaller, using a perturbation of 10^{-3}. Some of the coupling constants were still changing significantly with successive iterations when the calculations were terminated.

Results and Discussion

All $^{13}C,H$ coupling constants were extracted from the ^{13}C nmr spectra assuming that the spectra were essentially first order. This assumption was verified by simulating several of the ^{13}C nmr spectra using the computer program LAOCOON III. Proton nmr parameters were obtained for the same sample on which coupled ^{13}C nmr spectra were measured. Results for the 4-substituted isothiazoles and the neat solutions of isoxazole (**2**) and 1-methylpyrazole (**3**) are presented in Table 1.



2 **3**

The various two and three bond $^{13}C,H$ coupling constants in isothiazole and isoxazole were assigned by comparing the spectra of the parent compounds with those obtained in neat solutions of their 3-methyl- and 5-methyl- derivatives. Results for these compounds also appear in Table 1.

Calculated values of the various $^{13}C,H$ coupling constants in isothiazole, isoxazole, and 1-methylpyrazole are given in Table 2.

$^1J(^{13}C,H)$

In isothiazole, $^1J(C_5,H)$ is approximately 3.6 Hz greater than $^1J(C_3,H)$. This trend is also observed in thiazole (20), where $^1J(C,H)$ for the carbon adjacent to the sulfur is 2.6 Hz greater than that observed for the carbon adjacent to the nitrogen. Similarly in thiophene $^1J(C_2,H)$ is 184.7 Hz (21), approximately 7.1 Hz greater than the value of 177.6 Hz observed for this coupling in pyridine (22).

In all 4-substituted isothiazoles $^1J(C_5,H) > {}^1J(C_3,H)$, although the difference is only about 1 Hz in the case of X = NO_2 and CN. $^1J(C_3,H)$ and $^1J(C_5,H)$ values increase by 15.6 and 13.0 Hz respectively from X = CH_3 to X = NO_2. These values are to be compared with corresponding increases of ~10 Hz and ~16 Hz for $^1J(C_4,H)$ and $^1J(C_2,H)$ in 3-substituted thiophenes (23), and 12.3 Hz in monosubstituted benzenes (24–27) (where X varies from CH_3 to NO_2).

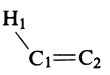
The MO calculations are not successful in predicting $^1J(C_5,H) > {}^1J(C_3,H)$. $^1J(C,H)$ values have often been related to $P^2_{C(2s)H(1s)}$, where $P_{C(2s)H(1s)}$ is the carbon $2s$ – hydrogen s bond order (4, 15). Both the CNDO/2 and INDO calculations predict $P_{C(2s)H(1s)}$ to be greater for C_3—H_3 than for C_5—H_5. It is of interest to point out that *ab initio* calculations[1] also predict such behaviour but in this case the difference in bond orders is small (29).

In isoxazole, $^1J(C_5,H)$ is 203.5 Hz, similar to the value of 201.7 Hz observed in furan (30). The value of $^1J(C_3,H)$ is approximately 10.5 Hz greater than the analogous coupling constant in pyridine (22). Also, $^1J(C_4,H)$ in isoxazole is more than 9 Hz larger than $^1J(C_3,H)$ in furan (30), pyridine (22), or benzene (31). The MO calculations on isoxazole are successful in that they predict $^1J(C_5,H) > {}^1J(C_3,H)$ or $^1J(C_4,H)$.

For 1-methylpyrazole we find that the average of $^1J(C_3,H)$ and $^1J(C_5,H)$ is approximately 5 Hz less than the value observed in pyrazole (32) where C_3 and C_5 are equivalent because of tautomerism. $^1J(C_4,H)$ in **3** is about 2 Hz less than the corresponding value in pyrazole. The INDO calculations correctly predict $^1J(C_5,H) > {}^1J(C_3,H) > {}^1J(C_4,H)$.

$^2J(C,H)$

$^2J(C_{sp^2}$–$C_{sp^2}H)$ values can be of either sign (3, 5, 33). In the fragment (**4**) $^2J(C_2,H_1)$ increases with increasing electronegativity of a substituent



4

at C_1. For example, in 1-chloroethylene (34, 35), $^2J(C_2,H_1)$ is +6.9 Hz as opposed to −2.4 Hz in ethylene (36, 37). Monosubstitution at C_2 results in opposite trends which are dependent upon the orientation of the substituent (1, 3, 34). If the substituent is *trans* to H_1, then $^2J(C_2,H_1)$ increases as the electronegativity of the substituent increases. Thus very large $^2J(C,H)$ values are observed when two electronegative substituents are *cis* to one another. For example, in 1,3-dioxide (**5**), $^2J(C,H)$ is 20.0 Hz (38).

5

[1]STO-3G level *ab initio* calculations (28) were carried out using the geometry given in reference (12).

TABLE 1. $^{13}C,H$ spin–spin coupling constants in Hz in 4-substituted isothiazoles and related compounds

Compound	C_3			C_4			C_5			$^{13}C,H$ coupling constants with substituents

*Density matrix rms error of 0.7×10^{-5}, or smaller (see text).

If the substituent at C_2 is *cis* to H_1, then $^2J(C_2,H_1)$ generally decreases as the electronegativity of the substituent increases. For example, in benzene, $^2J(C,H) = +1.0$ Hz while in chlorobenzene and nitrobenzene, $^2J(C_1,H_2) = -3.4$ and -3.5 Hz, respectively (24, 27, 31).

Some of the striking features of the data in Table 1 are the large values of $^2J(C_4,H_3)$. In contrast to monosubstituted benzenes (24–27), thiophenes (23, 32, 39, 40), and pyridines (22, 41–44) where $^3J(C,H)$ is generally larger than $^2J(C,H)$, we find several cases where the reverse is true.

For all the isothiazoles studied here, we observe that $^2J(C_4,H_3)$ is more than twice $^2J(C_4,H_5)$. This trend is in agreement with that predicted on the basis of the electronegativity arguments presented above since nitrogen is more electronegative than sulfur.

$^2J(C_4,H_5)$ becomes very small in the case of 4-bromoisothiazole.

In the case of isoxazole, $^2J(C_4,H_5) > {}^2J(C_4,H_3)$. In furan, $^2J(C_3,H_2) = 13.8$ Hz while $^2J(C_3,H_4)$ is only 4.05 Hz. Finally it is of interest to mention that in furan, $^2J(C_2,H_3) = 11.0$ Hz. In isoxazole the analogous coupling constant, $^2J(C_5,H_4)$ is 10.0 Hz.

$^2J(C_4,H_3) \simeq {}^2J(C_4,H_5) \simeq 9.8$ Hz in 1-methylpyrazole, very similar to the value of 9.5 Hz observed in pyrazole (32). One would expect $^3J(C_3,H_5)$ in 1-methylpyrazole to fall between 6.2 and 11.2 Hz, the values observed for this coupling constant in isoxazole and isothiazole (see Discussion below). Also, since $^3J(C_2,H_4) > 6.8$ Hz in both pyridine (22) and pyrole (45), we tentatively assign the splitting of 5.7 Hz in **3** to $^2J(C_3,H_4)$ instead of $^3J(C_3,H_5)$.

Previously (46), we have found that INDO calculates $^2J(C,H)$ values in unsaturated systems which are roughly 10 Hz too negative. In Table 3 we have added 10 Hz to the values calculated using INDO. For isothiazole the calculations predict $^2J(C_4,H_3)$ to be about 4.5 Hz greater than $^2J(C_4,H_5)$ in qualitative agreement with experiment. The value calculated for $^2J(C_5,H_4)$ is clearly erroneous. The experimental trends observed for $^2J(C,H)$ in isoxazole and 1-methylpyrazole seem to be reproduced reasonably well by the INDO calculations.

From plots of magnetic susceptibility anisotropy, $\Delta\chi$, *vs.* $^3J(H—C=C—H)$ Schaefer (47) has found two distinct relationships. Compounds which are generally considered aromatic including isoxazole fall on the one line, while nonaromatic compounds fall on the other line. Schaefer and co-workers (48) have also found that distinct correlations exist between $^2J(^{13}C=C—H)$ and $^3J(H—C=C—H)$ for aromatic and nonaromatic compounds. Averaging $^2J(C_4,H_5)$ and $^2J(C_5,H_4)$ and plotting this value against $^3J(C,H)$, we find that both isoxazole and isothiazole are aromatic according to the criteria discussed above.

$^3J(^{13}C,H)$

The various structural features which seem to be important in determining the magnitude of $^3J(C,H)$ in alkenes have recently been reviewed by Vögeli and von Philipsborn (49). They stated that in the $^{13}C_1—C_2=C_3—H$ fragment, an electronegative substituent at the C_1 position leads to an enhancement in $^3J(C_1,H)$, however, such a substituent at C_2 produces a decrease in $^3J(C_1,H)$. Similar observations have been made for monosubstituted benzenes (24–27). For example, in fluorobenzene, $^3J(C_1,H_3) = 11.1$ Hz and $^3J(C_2,H_6) = 5.0$ Hz (24). The value in benzene is 7.4 Hz (31).

In isothiazole and its 4-substituted derivatives, $^3J(C_3,H_5)$ is generally about twice as large as

TABLE 3. Observed and calculated $^2J(^{13}C,H)$*

Parameter	Isothiazole		Isoxazole		1-Methylpyrazole	
	Obs.	INDO	Obs.	INDO	Obs.	INDO
$^2J(C_3,H_4)$	8.2	9.1	6.2	7.6	5.7	8.1
$^2J(C_4,H_3)$	14.2	9.7	9.6	10.3	9.8	12.2
$^2J(C_4,H_5)$	5.4	5.3	14.3	13.1	9.8	10.4
$^2J(C_5,H_4)$	8.0	−3.6	10.9	10.1	—	11.2

*10 Hz has been added to all calculated values.

$^3J(C_5,H_3)$. This difference may be rationalized on the basis of electronegativity arguments since the nitrogen can be considered somewhat electronegative while the sulfur is somewhat electropositive.[2] However, it is difficult to account for the similarity of $^3J(C_2,H_4)$ and $^3J(C_4,H_2)$ in other heterocyclics. For example, in the case of thiophene, $^3J(C_2,H_4) = 10.0$ Hz, and $^3J(C_4,H_2) = 9.8$ Hz; in pyridine, $^3J(C_2,H_4) = 6.85$ Hz and $^3J(C_4,H_2) = 6.34$ Hz; in furan, $^3J(C_2,H_4) = 10.04$ Hz and $^3J(C_4,H_2) = 9.79$ Hz; in pyrrole, $^3J(C_2,H_4) = 7.46$ Hz and $^3J(C_4,H_2) = 7.31$ Hz. Notice that in every case $^3J(C_2,H_4)$ and $^3J(C_4,H_2)$ are similar.

In isoxazole we also observe $^3J(C_3,H_5) > {}^3J(C_5,H_3)$, however, in this case the difference is not as large as in the case of isothiazole.

It is interesting to note that the MO calculations correctly predict the observed trends in $^3J(^{13}C,H)$ for isothiazole and isoxazole.

In the 4-substituted isothiazoles both $^3J(C_3,H_5)$ and $^3J(C_5,H_3)$ decrease as the electronegativity of a substituent increases, however, factors other than electronegativity may be important.

Finally it is of interest to discuss the coupling constants which involve the substituent when X = CN, COOR, and CH_3. In all of the isothiazoles considered here we found that $^3J(C,H)$ coupling constants involving the carbon of the substituent were less than 2.7 Hz. These small values observed for these coupling constants are consistent with the empirical relationship, $^3J(C,H) \simeq 0.6\ ^3J(H,H)$ proposed by Vögeli and von Philipsborn (49). In isothiazole, $^3J(H_3,H_4) = 1.66$ Hz and $^3J(H_4,H_5) = 4.66$ Hz, thus one would not expect $^3J(C,H)$ to exceed 3.3 Hz.

In the methyl substituted isothiazoles we observe quite different values for $^3J(C,CH_3)$. For example, in 4-methylisothiazole $^3J(C_3,CH_3) = 4.3$ Hz while $^3J(C_5,CH_3) = 5.3$ Hz. The larger coupling constant to C_5 is probably due to the larger π-bond order for the C_4—C_5 bond as opposed to that of the C_4—C_3 bond (13, 16). Previously (13), we found $^4J(H_5,CH_3)$ much larger than $^4J(H_3,CH_3)$. As well as π-bond order, the orientation of the methyl group will also be important in determining the magnitude of $^3J(C,CH_3)$ (16). In contrast to toluene where the methyl group is essentially a free rotor (50), the barrier to methyl-group rotation in the heterocyclics studied here will probably be greater than kT (51–53).

It is interesting to notice that in the case of the 3- and 5-methyl-substituted isoxazoles, $^3J(C_4,CH_3)$ is the same within experimental error, 2.7 and 2.8 Hz, respectively.

[2]Although CNDO/2 calculations predict a slight positive charge on the sulfur (+0.0013e⁻), *ab initio* calculations (28, 29) predict a large positive charge on the sulfur (+0.443e⁻).

Acknowledgments

We would like to thank Dr. Bill Parr and Dr. Ted Schaefer for allowing us to use the MO program which has been parameterized to allow INDO calculations for 2nd row elements.

We thank the National Research Council of Canada for its support.

JOHN H. CAREY, ERNEST G. COSGROVE, and BARRY G. OLIVER. Can. J. Chem. **55**, 625 (1977).

Two types of reactions occur when hexaaquoiron(III) ion is irradiated at 254 nm in the presence of alcohols. Firstly, a charge transfer transition from a water centred orbital to an iron centred orbital produces OH· radicals which go on to abstract hydrogen from the alcohols. Secondly, the reaction with the charge transfer excited states of iron(III) species can lead to outer sphere oxidation of the alcohols. In this paper, these reactions have been studied in detail for the diol ethylene glycol in aqueous solutions. It has been found that the quantum yield of acetaldehyde, the major product of hydroxyl radical reactions with ethylene glycol, is 0.09 and the yield of formaldehyde, the major product of the direct charge transfer reaction, is 0.05 in 1 *M* ethylene glycol. The quantum yields for these major products, as well as minor products, such as glycolaldehyde and succinaldehyde, have been determined at several concentrations of ethylene glycol and iron. A detailed reaction scheme for the photolysis has been developed.

JOHN H. CAREY, ERNEST G. COSGROVE et BARRY G. OLIVER. Can. J. Chem. **55**, 625 (1977).

Il y a deux types de réaction qui se produisent lorsque l'ion hexaaquofer(III) est irradié à 254 nm en présence d'alcools. En premier lieu, il y a une transition de transfert de charge à partir d'une orbitale centrée au niveau de l'eau vers une orbitale centrée sur le fer qui produit des radicaux OH qui ensuite enlèvent de l'hydrogène des alcools. Deuxièmement il y a une réaction avec les états excités de transfert de charge des espèces du fer(III) qui peut conduire à des oxydations par les sphères extérieures de l'alcool. Dans la présente communication, on a étudié ces réactions en détail pour le diol éthylène glycol en solution aqueuse. On a trouvé que le rendement quantique d'acétaldéhyde, le produit majeur des réactions du radical hydroxyle avec l'éthylène glycol, est de 0.09 et le rendement de formaldéhyde, qui est le produit majeur de la réaction de transfert directe de charge, est de 0.05 dans l'éthylène glycol 1 *M*. On a déterminé les rendements quantiques de ces produits majeurs ainsi que des produits mineurs tel que le glycolaldéhyde et le succinaldéhyde à plusieurs concentrations d'éthylène glycol et de fer. On a développé un schéma réactionnel détaillé pour la photolyse.

[Traduit par le journal]

Introduction

Two types of reactions occur when hexaaquoiron(III) ion is irradiated at 254 nm in the presence of organic scavengers. Firstly, a charge transfer transition from a water centred orbital to an iron centred orbital produces OH· radicals which react with the organics via hydrogen abstraction (1). Secondly, the direct reaction of charge transfer excited states of iron(III) species can lead to outer sphere oxidation (2). Since either mechanism may prove to be a pathway for pollutant degradation in natural waters, particularly at sediment–water interfaces, it was decided to examine them in closer detail. The compound chosen for study was ethylene glycol which is used as a deicer and finds its way into the environment mainly in airport runoff (3).

Previous studies on the radiolysis of deaerated ethylene glycol (4) showed that high yields of acetaldehyde were produced in a chain reaction. Radiolysis of aqueous ethylene glycol in the presence of H_2O_2 (5) and far ultraviolet (185 nm) irradiation of 2 *M* aqueous ethylene glycol solutions (6) also showed acetaldehyde to be the major product. The proposed reaction mechanism was the abstraction of an α-hydrogen from ethylene glycol by OH· to produce the HO—$\dot{C}$H—CH_2OH radical which loses H_2O in an acid catalyzed reaction to produce O=CH—$\dot{C}H_2$. The O=CH—$\dot{C}H_2$ radical would then abstract hydrogen from another ethylene glycol to produce acetaldehyde. Both these radicals have been shown to be present by electron spin resonance spectroscopy (7, 8).

It was decided that a detailed look at the reactions and product yields in the aqueous iron system would shed more light on OH· radical reactions as well as reveal the extent of any direct excited state reactions in the system.

Experimental

Solutions to be irradiated were prepared from stock solutions of reagent grade chemicals to be 0.01 to 0.04 *M* ferric perchlorate, 2.0 *M* $HClO_4$, and various ethylene glycol concentrations. Irradiations were performed in a

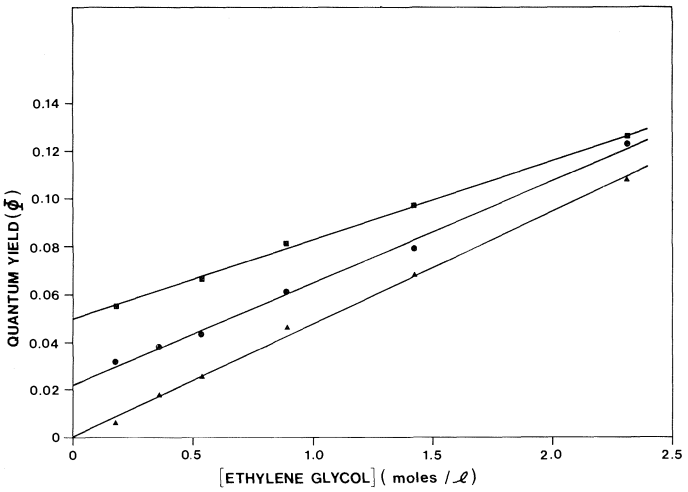

FIG. 1. The quantum yields of formaldehyde ▲, iron(II) ●, and acetaldehyde ■ as a function of ethylene glycol concentration. Concentration of ferric perchlorate: 0.02 *M*.

cylindrical quartz cell with an outer jacket through which distilled water was circulated to control the temperature to 35.0 ± 0.1 °C. Samples were deoxygenated by bubbling high purity nitrogen through them for 15 min prior to irradiation. The 254 nm light source was a photoreactor (Ultraviolet Products Inc., San Gabriel, California) containing four circular low pressure mercury lamps. A magnetic stirrer was used to agitate the solutions during photolysis. Light intensities were measured using ferrioxalate actinometry (9).

The Fe(II) yields were determined from the absorbance at 510 nm ($a = 1.09 \times 10^4$) using *o*-phenanthroline and a neutralization/dilution technique (1). All the organic analyses were performed on the supernatant after precipitation of the iron and perchlorate from the solutions by addition of known volumes of 2 *M* KOH. The presence of acetaldehyde, formaldehyde, and glycolaldehyde was demonstrated by thin layer chromatography of their 2,4-DNPH derivatives on alumina using cyclohexane–nitrobenzene (2:1) as solvent. Acetaldehyde was determined in cold H_2SO_4 with *p*-hydroxydiphenyl by measuring the absorbance at 568 nm ($a = 4.7 \times 10^4$) (10). Formaldehyde concentrations were evaluated colorimetrically ($a = 1.8 \times 10^4$ at 570 nm) using a modified chromatrophic acid technique (11). Glycolaldehyde was determined colorimetrically as the osazone (12) at 580 nm ($a = 1.76 \times 10^4$). Succinaldehyde was measured with *p*-dimethylaminobenzaldehyde (13) at 546 nm ($a = 7.1 \times 10^4$).

The solvation analysis were carried out on a Varian T-60 nuclear magnetic resonance spectrometer with probe temperature 35 °C. The treatment of the data was done using procedures described in refs. 2, 14, 15, and 16.

Results and Discussion

A preliminary study showed that the major photoproducts formed during the ultraviolet irradiation of degassed, strongly acidic, aqueous solutions of ferric perchlorate containing ethylene glycol were iron(II), acetaldehyde, and formaldehyde. Figure 1 shows that the quantum yields of these three products vary as a function of ethylene glycol concentration. In addition to these products, small yields of glycolaldehyde (0.010) and succinaldehyde (0.003) were observed. The yields of these two products were essentially independent of the ethylene glycol concentration.

Based on these results the following reaction scheme for the photolysis of aqueous iron(III) in the presence of ethylene glycol is proposed:

[1] $Fe^{3+}(aq) \underset{k_{-1}}{\overset{h\nu}{\rightleftharpoons}} Fe^{3+}(aq)^* \xrightarrow{k_1} Fe^{2+}(aq) + OH^{\cdot} + H^+$ **1**

[2] $OH^{\cdot} + HOCH_2CH_2OH \xrightarrow{k_2} HOCH_2\dot{C}HOH + H_2O$

[3] $HOCH_2\dot{C}HOH \xrightarrow[(H^+)]{k_3} \dot{C}H_2C(=O)H + H_2O$

[4] $\cdot CH_2C(=O)H + Fe^{2+}(aq) + H^+ \xrightarrow{k_4} CH_3C(=O)H + Fe^{3+}(aq)$ **2**

[5] $\cdot CH_2C(=O)H + HOCH_2CH_2OH \xrightarrow{k_5} CH_3C(=O)H + HOCH_2\dot{C}HOH$

[6] $HOCH_2\dot{C}HOH + Fe^{3+}(aq) \xrightarrow{k_6} HOCH_2\overset{O}{\overset{\|}{C}}—H + Fe^{2+}(aq) + H^+$

3 **1**

[7] $\cdot CH_2\overset{O}{\overset{\|}{C}}—H + \cdot CH_2\overset{O}{\overset{\|}{C}}—H \xrightarrow{k_7} H—\overset{O}{\overset{\|}{C}}—CH_2CH_2\overset{O}{\overset{\|}{C}}—H$

4

Reaction 1 represents the photoproduction of hydroxyl radicals by excitation of the water to iron charge transfer (CT) transition. At high scavenger concentration (>0.1 *M*) all the $OH^{\cdot}$ radicals react by abstraction of an α-hydrogen from ethylene glycol (reaction 2). The $HOCH_2\dot{C}HOH$ radical can then undergo acid catalyzed dehydration (7) to give the $\dot{C}H_2\overset{O}{\overset{\|}{C}}H$ radical via reaction 3. The major reaction of the $\dot{C}H_2\overset{O}{\overset{\|}{C}}H$ radical will be with Fe(II), which will be produced in close proximity to it, to give acetaldehyde, **2** (reaction 4). At higher ethylene glycol concentrations reaction 5, a chain propagating reaction, will begin to become important. This is evident from the positive slope, 0.033, of the acetaldehyde quantum yield as a function of glycol concentration in Fig. 1. Alternate fates of the $HOCH_2\dot{C}HOH$ and the $\dot{C}H_2\overset{O}{\overset{\|}{C}}H$ radicals are depicted in reactions 6 and 7 and result in formation of the two minor products glycolaldehyde, **3**, and succinaldehyde, **4**, respectively.

At low glycol concentration reaction 5 is unimportant and thus extrapolation of the acetaldehyde yield to zero glycol concentration will give a value for the quantum yield of acetaldehyde produced by reactions 1–4 (Φ^0 (acetaldehyde)). The primary yield of hydroxyl radicals in this system, based on the stoichiometry of reactions 1–7, is then equal to

$$\Phi(\text{hydroxyl radical}) = \Phi^0(\text{acetaldehyde}) + \Phi(\text{glycolaldehyde}) + 2\Phi(\text{succinaldehyde})$$

The limiting yields of acetaldehyde and the yields of glycolaldehyde and succinaldehyde are 0.050, 0.010, and 0.003, respectively, giving an hydroxyl radical yield of 0.066. This value is in excellent agreement with the primary hydroxyl radical yield 0.065 found by Langford and Carey (1) using *tert*-butyl alcohol as a scavenger.

Reactions 1–7 are essentially identical to those observed by Walling and Johnson (17) in the Fenton's reagent oxidation of ethylene glycol. However, several features of the present study cannot be explained by this reaction sequence. They are the appearance of formaldehyde as a photoproduct and the linear increase of quantum yields for formaldehyde and iron(II) with increasing ethylene glycol concentration. Based on reactions 1–7, the iron(II) yield should depend only on the iron(III) and the acid concentrations, and should be constant at high levels of scavenger. Some other photoprocess must be included to successfully account for all observed features.

If ethylene glycol molecules were present in the primary solvation sphere of Fe(III), a ligand-to-metal charge transfer (LMCT) transition between glycol and iron would arise. Excitation of such a transition would likely result in production of iron(II) and an electron deficient glycol. Should this glycol species react via C—C bond fission, the resulting products would be formaldehyde and a hydroxy-methyl radical. Since the latter radicals react with iron(III) to give formaldehyde and iron(II), the net products of the alcohol-to-iron CT photoreaction could be two molecules of formaldehyde and two molecules of iron(II). The C—C bond cleavage proposed is not without precedent. Cox and Kemp (18) have shown that C—C bond fission occurs upon irradiation of iron(III) species in neat alcohol glasses when tertiary alcohols are used as substrates. For primary and secondary alcohols however, the predominant process was C—H bond fission at the α-carbon.

A nuclear magnetic resonance technique for determining whether molecules are in the immediate paramagnetic environment of iron(III) has been described elsewhere (2, 14–16). Hydroxy proton linewidths measured for the ethylene glycol system were essentially identical to those obtained by Carey and Langford (2) for methyl, *tert*-butyl, and isopropyl alcohols. The linewidths are consistent with lack of entry of the scavenger into the coordination sphere and rule out the CT transition as the source of formaldehyde.

However, if ethylene glycol can react with an iron excited state prior to hydroxyl radical production, it is not necessary to propose excitation of a glycol-to-iron transition to explain reactions different from hydroxyl radical scavenging. The reactive excited state need not be long lived since

at the scavenger levels employed a significant number of glycol molecules will be present in the secondary solvation sphere of Fe(III) (*i.e.*, in encounter) at the time of excitation and thus the reaction will not be limited by diffusion of reactants. Such a reaction was recently proposed to explain scavenger dependent iron(II) yields in the photolysis of ferric perchlorate when methyl and isopropyl alcohols and formic acid were used as scavengers (2). The reaction scheme may be written as follows:

$$[8]\quad Fe(H_2O)_6^{3+} + HOCH_2CH_2OH \leftrightarrows Fe(H_2O)_6^{3+}, HOCH_2CH_2OH$$

$$[9]\quad Fe(H_2O)_6^{3+}, HOCH_2CH_2OH \xrightarrow{h\nu} Fe(H_2O)_6^{2+} + HOCH_2^{\cdot} + CH_2O + H^+$$

$$[10]\quad HOCH_2^{\cdot} + Fe(H_2O)_6^{3+} \rightarrow Fe(H_2O)_6^{2+} + CH_2O + H^+$$

The observed glycol dependence of the quantum yield is in agreement with formation of the reactive species via a reaction such as [8] while reactions 9 and 10 represent the formation of iron(II) and formaldehyde via the outer sphere oxidation and indicate that these two products should be formed in a 1:1 ratio. Thus, if the reaction via the outer sphere pathway did not affect the primary yield of hydroxyl radicals the slope of the formaldehyde and iron(II) yields (Fig. 1) should be the same. In fact, the Fe(II) slope is 0.043 l mol^{-1} while the formaldehyde slope is 0.047 l mol^{-1} and the ratio $\Phi_{Fe^{2+}}/\Phi_{CH_2O} = 0.91$. If the outer sphere reaction actually involves an excited state precursor to hydroxyl radicals, the Fe(II) slope must be corrected to account for those excited states which would have produced Fe(II) via the hydroxyl radical pathway but instead undergo prior reaction via the outer sphere pathway.

In order to calculate the magnitude of this correction, it is necessary to know the number of excited states reacting via the outer sphere pathway and the fraction of these which would have produced hydroxyl radicals. Previous studies on the outer sphere reaction suggested that it occurred with unit efficiency for those scavenger molecules in the reactive site at the time of excitation (2). Assuming this to be true for the ethylene glycol system, we find the number of excited states reacting with outer sphere scavenger at any glycol concentration would be $(\frac{1}{2})\Phi_{CH_2O}$ (recall each excited state reacting produces two formaldehyde). If we assume that the state reacting with unit efficiency is the primary excited state, then the fraction of these which would have produced hydroxyl radicals is simply the primary hydroxyl radical yield, 0.066. In this case the hydroxyl radical yield at any ethylene glycol concentration is given by the expression

$$\Phi_{OH^{\cdot}} = 0.066 - 0.066 \times \tfrac{1}{2} \times \Phi_{CH_2O}$$

and the iron(II) yield from the hydroxyl radical pathway is twice this value. Therefore in order to judge the magnitude of the outer sphere reaction from the iron(II) slope, this slope must be corrected according to corrected Fe(II) slope = observed Fe(II) slope + 2 × 0.066 × $\frac{1}{2}$ × formaldehyde slope. We calculate the corrected Fe(II) slope to be 0.046 l mol^{-1}, in good agreement with the observed formaldehyde slope.

We note that in the ethylene glycol case, the observed slope of the iron(II) yield is 0.043, somewhat higher than the 0.030 slopes previously observed for methyl and isopropyl alcohols and formic acid (2). For the latter three organics, the limiting reactivity with the excited state was thought to include a statistical factor which was related to the probability that the scavenger in encounter occupies a reactive site. A higher statistical factor might be anticipated for ethylene glycol since it has two reactive centres while methyl and isopropyl alcohols and formic acid have only one.

To provide additional support to the proposed reaction mechanisms, studies were done at three different Fe(III) concentrations. A plot of Fe(II) as a function of ethylene glycol concentration for three Fe(III) concentrations is shown in Fig. 2. It can be seen that there is very little difference between the slopes of the three lines but there is a significant change in the intercept. Even when radical–radical reaction [7] is omitted, the steady state method yields an extremely complex expression for the $\Phi_{Fe^{2+}}$. However, at zero glycol concentration, a fairly simple expression for $1/\Phi_{Fe^{2+}}{}^0$ is obtained.

$$[11]\quad \frac{1}{\Phi_{Fe^{2+}}{}^0} = \frac{V}{I}\frac{(k_1 + k_{-1})k_3}{2k_1k_6[Fe^{3+}]} + \frac{V}{I}\frac{(k_1 + k_{-1})}{2k_1}$$

where V represents volume, I light intensity in einsteins/s and $\Phi_{Fe^{2+}}{}^0$ the iron(II) yield obtained from extrapolation of the linear portion of Fig. 2 to zero glycol concentration. Since V and I are

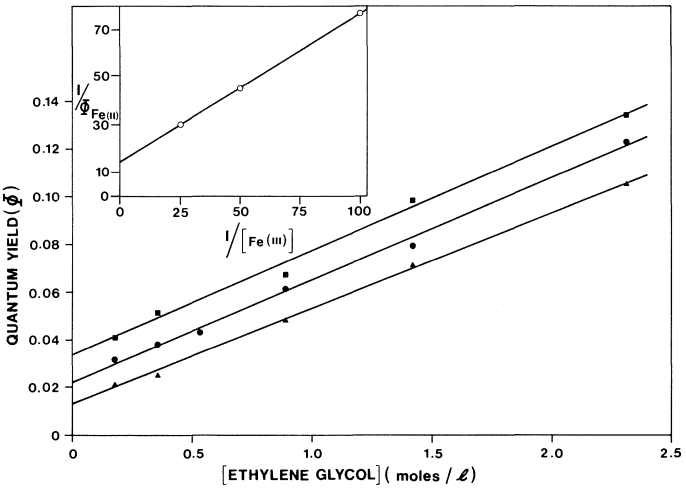

FIG. 2. The quantum yields of Fe(II) at Fe(III) concentrations of 0.01 *M*, ▲; 0.02 *M*, ●; and 0.04 *M*, ■, as a function of ethylene glycol concentration. Inset: Dependence of $1/\Phi^0$ Fe(II) on 1/Fe(III) at zero glycol concentration where Φ^0 Fe(II) is obtained by extrapolation of Fig. 2.

constant during the experiment, the expression simplifies to

$$[12] \qquad \frac{1}{\Phi_{Fe^{2+}}{}^0} = C_1 + \frac{C_2}{[Fe^{3+}]}$$

A plot of $1/\Phi_{Fe^{2+}}{}^0$ *vs.* $1/[Fe^{3+}]$ (inset Fig. 2) is seen to be linear. As the Fe(III) concentration is increased, the Fe(II) quantum yield at zero glycol (the intercept) is seen to increase as predicted by eq. 12. As the Fe(III) concentration is increased, the absolute yield of Fe(II) and glycolaldehyde increase and the yield of acetaldehyde decreases. This behaviour is consistent with the proposed reaction scheme.

The photolysis of aqueous iron solutions containing ethylene glycol proceeds by two major pathways. Reactions based on abstraction of α-hydrogens by hydroxyl radicals leads to production of acetaldehyde as the major product whereas the direct outer sphere oxidation of ethylene glycol by excited states of Fe(III) yields formaldehyde and Fe(II) as major products. The observation that different products are formed by the two different mechanisms of oxidation is of interest since it raises the possibility that scavenging with ethylene glycol/iron(III) can be used to elucidate mechanisms of photooxidation of other systems. We are presently investigating the use of this scavenger system to study reaction mechanisms during illumination of semi-conductor electrode surfaces (19) and sediment–water interfaces.

A study of 3-hydroxy-1,2,3-benzotriazin-4-one and its *O*-methyl and *O*-acyl derivatives

T. PATRICK AHERN, THOMAS NAVRATIL, AND KEITH VAUGHAN[1]

Department of Chemistry, Saint Mary's University, Halifax, N.S., Canada B3H 3C3

Received August 4, 1976

T. PATRICK AHERN, THOMAS NAVRATIL, and KEITH VAUGHAN. Can. J. Chem. **55**, 630 (1977).

3-Hydroxy-1,2,3-benzotriazin-4-one, **1**, was prepared by diazotization of *o*-aminobenzhydroxamic acid, **2**. 3-Methoxy-1,2,3-benzotriazin-4-one, **5***a*, was obtained by reaction of **1** with dimethyl sulphate and was found to be stable to thermolysis. Acetylation and benzoylation of **1** yielded the *N*-acetoxy-**5***b* and benzoyloxy-**5***c* derivatives respectively. The *N*-benzoyloxy derivative **5***c* is converted into the acetate **5***b* by a novel 'acyl-exchange' reaction in acetic anhydride. Acid hydrolysis of **1** gives anthranilic acid, and thermolyses of **1** in amyl alcohol and aniline afford amyl anthranilate and *N*-phenylanthranilamide, respectively. The ketenimine **11** is postulated as an intermediate in the thermal breakdown of **1**, and this is confirmed by the isolation of the Diels–Alder adduct **12** from reaction of **1** with phenyl isocyanate. Thermolysis of **1** in inert solvents affords a novel compound, 3-(*o*-aminobenzoyloxy)-1,2,3-benzotriazin-4-one, **6**, which polymerizes when **1** is subjected to prolonged thermolysis in diglyme. **6** resisted methylation and acid hydrolysis, but underwent acyl-oxygen cleavage when diazotization of **6** was attempted and suffered 'acyl-exchange' when acylation was attempted. The formation of **6** from **1** also involves the ketenimine **11**. The importance of these observations to an understanding of previously reported reactions of benzotriazinones is discussed. The *o*-aminobenzoyloxy derivative **6** shows potential as an *o*-aminobenzoylating agent.

T. PATRICK AHERN, THOMAS NAVRATIL et KEITH VAUGHAN. Can. J. Chem. **55**, 630 (1977).

On a préparé l'hydroxy-3 benzotriazine-1,2,3 one-4, **1**, par diazotation de l'acide *o*-aminobenzhydroxamique, **2**. On a obtenu la méthoxy-3 benzotriazine-1,2,3 one-4, **5***a*, par réaction de **1** avec le sulfate de méthyle et on a trouvé qu'il est stable vis-à-vis la thermolyse. L'acétylation et la benzoylation de **1** conduisent respectivement aux dérivés *N*-acétoxy-**5***b* et benzoyloxy-**5***c*. Le dérivé *N*-benzoyloxy **5***c* peut être transformé en acétate **5***b* par une nouvelle réaction 'd'échange acyle' dans l'anhydride acétique. L'hydrolyse acide de **1** fournit l'acide anthranilique et les thermolyses de **1** dans l'alcool amylique et l'aniline conduisent respectivement à l'anthranilate d'amyle et au *N*-phénylanthranilamide. On fait l'hypothèse que la cétimine **11** est un intermédiaire dans la décomposition thermique de **1** et cette hypothèse est confirmée par le fait que l'on peut isoler l'adduit de Diels–Alder **12** à partir de la réaction de **1** en présence d'isocyanate de phényle. La thermolyse de **1** dans des solvants inertes conduit à un nouveau composé la (*o*-aminobenzoyloxy)-3 benzotriazine-1,2,3 one-4, **6**, qui se polymérise lorsque **1** est soumis à une thermolyse prolongée dans le diglyme. On ne peut ni méthyler ni hydrolyser le composé **6** en milieu acide; toutefois si l'on essaie d'effectuer une diazotation de **6**, il subit un clivage au niveau acyl-oxygène alors qu'il subit un échange d'acyle lorsque l'on essaie l'acylation. La formation de **6** à partir de **1** implique elle aussi la cétimine **11**. On discute de l'importance de ces observations pour la compréhension des réactions rapportées antérieurement pour les benzotriazinones. Il semble que le dérivé *o*-aminobenzoyloxy **6** montre des potentialités comme agent *o*-aminobenzoylant.

[Traduit par le journal]

Introduction

3-Hydroxy-1,2,3-benzotriazin-4-one, **1**, was first reported by Harrison and Smith (1) from diazotization of *o*-aminobenzhydroxamic acid, **2**. The cyclic hydroxamic acid structure was assigned to **1** because of the observed red colouration with ferric chloride and the alkaline degradation of **1** to *o*-azidobenzoic acid. The unique nature of **1**, being a combination of hydroxamic acid and triazine moieties in a single structure, presents the possibility of some interesting chemistry. A preliminary account of the thermolysis of **1** has been reported previously (2), and this paper reports some new reactions of **1** and its derivatives.

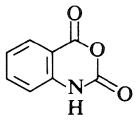
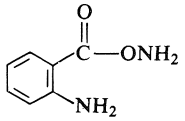
Discussion

o-Aminobenzhydroxamic acid, **2**, required for the synthesis of **1**, was prepared by the reaction of methyl anthranilate with hydroxylamine in alkaline solution as described by Scott and Wood (3). The reaction of isatoic anhydride **3** with hydroxylamine, a possible alternate route to **2**, was interpreted by Scott and Wood (3) as giving rise to the isomer of **2**, the *O*-acyl-hydroxylamine **4**.

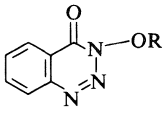
Diazotization of *o*-aminobenzhydroxamic acid, **2**, afforded the same 3-hydroxy-1,2,3-benzotriazin-4-one, **1**, described by Harrison and Smith (1); the spectral characteristics of **1**, and the structure of the derivatives described below, confirm the assignment of the cyclic hydroxamic acid structure to the diazotization product. The ir spectrum of **1** displays a broad, hydrogen-bonded hydroxyl band at 2700 cm^{-1} and carbonyl absorption at 1660 cm^{-1}. Methylation of **1** with dimethyl sulphate under basic conditions affords a single *O*-methyl derivative **5***a*, which shows an *O*-methyl proton resonance at τ 5.72 in the nmr spectrum. The structure of **5***a* was confirmed by the mass spectrum, elemental analysis, and a narrow carbonyl absorption band at 1700 cm^{-1} in the ir spectrum. The broadness of the carbonyl band in **1**, and the shift to lower frequency compared with the carbonyl absorption in **5***a*, suggest the presence of intramolecular hydrogen bonding in **1**. Strong intramolecular hydrogen bonds have also been shown to exist in other cyclic hydroxamic acids, *e.g.* *N*-hydroxy-2-pyridone (4, 5).



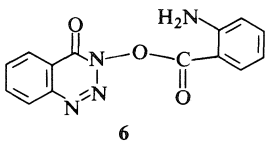
3



4



5 *a* R = CH_3
b R = $COCH_3$
c R = COPh



6

Acetylation of the *N*-hydroxytriazinone **1** with acetyl chloride or acetic anhydride afforded a single mono-acetyl derivative, characterized as the *N*-acetoxytriazinone **5***b* by the presence of a strong carbonyl band at 1805 cm^{-1} and acetyl-methyl proton resonance at τ 7.43. Reaction of the *N*-hydroxytriazinone **1** with benzoyl chloride similarly gave the *N*-benzoyloxy derivative **5***c*. The uv spectra of the *N*-hydroxytriazinone **1** and the methyl-**5***a*, acetyl-**5***b*, and benzoyl-**5***c* derivatives show distinct similarities, with common bands at 220–230 and 300–313 nm (Fig. 1). However, the band at 250–260 nm, common to **1**, **5***a*, and **5***b*, is absent in the spectrum of the benzoate **5***c*, whereas the band at 280–290 nm, common to the derivatives **5***a*, **5***b*, and **5***c*, is not observed in the spectrum of **1**. An additional band at 384 nm is observed only in the spectrum of **1**.

The mass spectral fragmentation patterns of the derivatives **5***a–c* show several common features, but also significant differences (Scheme 1). Two fragmentation pathways are evident for the *O*-methyl derivative **5***a*. The major pathway is ring cleavage (route *d*), apparently by direct loss of the fragment HNCO; *N*-alkoxy cleavage (route *a*), involving loss of CH_2O, is the lesser pathway. No fragments are observed in the mass spectrum of **5***a* corresponding to loss of N_2 (route *c*) or to *O*-alkyl cleavage (route *b*). Ring cleavage (route *d*) is also the principle fragmentation of the acetate **5***b*, but in this case *O*-acyl cleavage (route *b*) is more evident than *N*-acetoxy cleavage (route *a*); fragmentation by loss of N_2 (route *c*) is not observed. The mass spectrum of the benzoate **5***c* shows both *N*-acyloxy (route *a*) and *O*-acyl (route *b*) cleavages, but unlike the methyl and acetyl derivatives, **5***c* shows fragmentation by the loss of N_2 (route *c*) and, surprisingly, by loss of CO_2 (route *e*).

The properties and reactions of **1** described above are clearly consistent with the cyclic hydroxamic acid structure proposed previously (**1**) and no evidence has been found to suggest the existence of an *N*-oxide tautomer of **1**. In this respect, **1** is similar to many other *N*-hydroxy α-oxo compounds, which have been shown to prefer the oxo form over the *N*-oxide form (ref. 5, p. 407–408).

Thermolysis of the *N*-hydroxytriazinone **1** in anhydrous inert solvents, *e.g.* diglyme (1.3 h), *p*-xylene (2.5 h), toluene (20 h), or benzene (4–5 days), afforded in each case the same yellow solid,

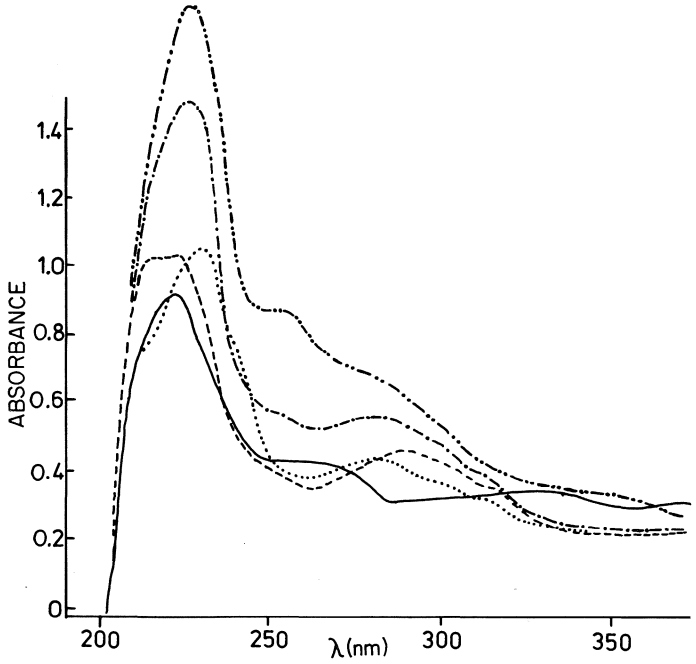


FIG. 1. Ultraviolet spectra, recorded in ethanol solution, of *I* (—) 3-hydroxy-1,2,3-benzotriazin-4-one **1**; *II* (---) 3-methoxy-1,2,3-benzotriazin-4-one **5***a*; *III* (·····) 3-acetoxy-1,2,3-benzotriazin-4-one **5***b*; *IV* (····) 3-benzoyloxy-1,2,3-benzotriazin-4-one **5***c*; and *V* (·····) 3-(*o*-aminobenzoyloxy)-1,2,3-benzotriazin-4-one **6**.

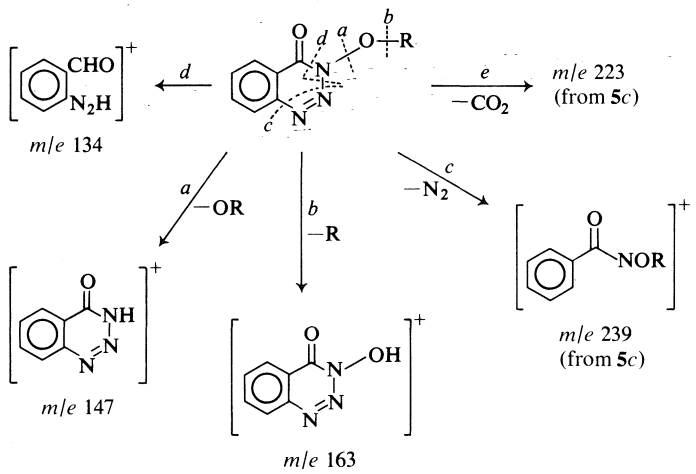


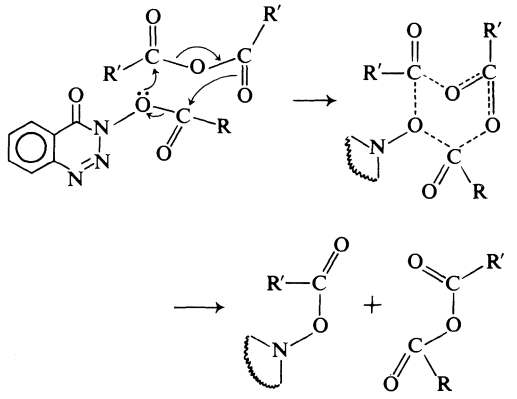
SCHEME 1

which was found by molecular ion mass measurement to have molecular formula $C_{14}H_{10}N_4O_3$. The yellow solid evidently arises from a dimerization of **1**, minus the elements of N_2O, and was identified as 3-(*o*-aminobenzoyloxy)-1,2,3-benzotriazin-4-one, **6**, on the basis of spectral data and degradation. The presence of NH_2 is indicated by bands at 3480 and 3365 cm^{-1} in the ir spectrum of **6**, which also displays bands for two carbonyl groups at 1740 and 1713 cm^{-1}. The mass spectrum of **6** exhibits fragments arising from *N*-acyloxy cleavage (route *a*), *O*-acyl cleavage (route *b*), and loss of CO_2 (route *e*), but not direct loss of N_2 (route *c*) (see Scheme 1). The uv spectrum of **6** shows close similarity to the acyl derivatives **5***b* and **5***c* (Fig. 1).

The *N*-benzoyloxy function in heterocyclic compounds is generally labile and susceptible to ready hydrolysis (6), whereas **6** was resistant to concentrated acid at room temperature and did not react with dimethyl sulphate under basic conditions. However, when diazotization of **6** was attempted in order to react the diazonium salt with hydroxylamine or azide ion, rapid cleavage of the acyloxy group resulted and the *N*-hydroxytriazinone **1** was isolated in high yield. These observations imply that the *o*-amino group in **6** renders the acyloxy group unreactive by its electron-donating resonance effect, but that this effect is reversed when the amino group is converted to a diazonium group.

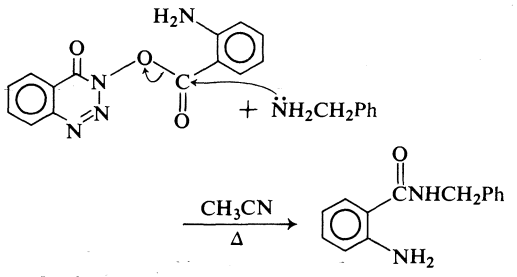
Attempted acetylation of **6** with acetyl chloride or acetic anhydride also caused acyl-oxy cleavage, affording a mixture of the *N*-acetoxy derivative **5***b* and *N*-acetylanthranilic acid. Similarly, treatment of **6** in pyridine with benzoyl chloride resulted in immediate formation of the *N*-benzoyloxy derivative **5***c*. Acylation of the amino group in **6** would certainly lessen the deactivation of the acyloxy group and this may be a factor in facilitating these apparent cleavage reactions. However, a similar 'acyl-exchange' reaction was observed when 3-benzoyloxy-1,2,3-benzotriazin-4-one, **5***c*, was treated with acetic anhydride, even though specific precautions were taken to exclude water from the reaction mixture, resulting in formation of the acetoxy derivative **5***b*. Benzoic acid, an expected product of hydrolysis of **5***c*, was not observed as a by-product in the conversion **5***c* → **5***b*. Thus, the 'acyl-exchange' reaction does not require activation by a substituent in the aryl group, and apparently is not a result of hydrolysis and re-acylation. It is therefore likely that the conversions **6** → **5***b*, **6** → **5***c* and **5***c* → **5***b* occur by a common 'acyl-exchange' mechanism involving a cyclic, six-membered transition state (*e.g.* [1]).[2] This behaviour of the *N*-aroyloxy derivatives **6** and **5***c* is analogous to the property of 1-benzoyloxy-2-pyridone, which is a good benzoylating agent

[1]



(6*a*). The *o*-aminobenzoyl derivative **6** may also have application as an *o*-aminobenzoylating (anthraniloylating) agent; indeed, benzylamine was converted into *N*-benzylanthranilamide by reaction with **6** in acetonitrile [2]. However,

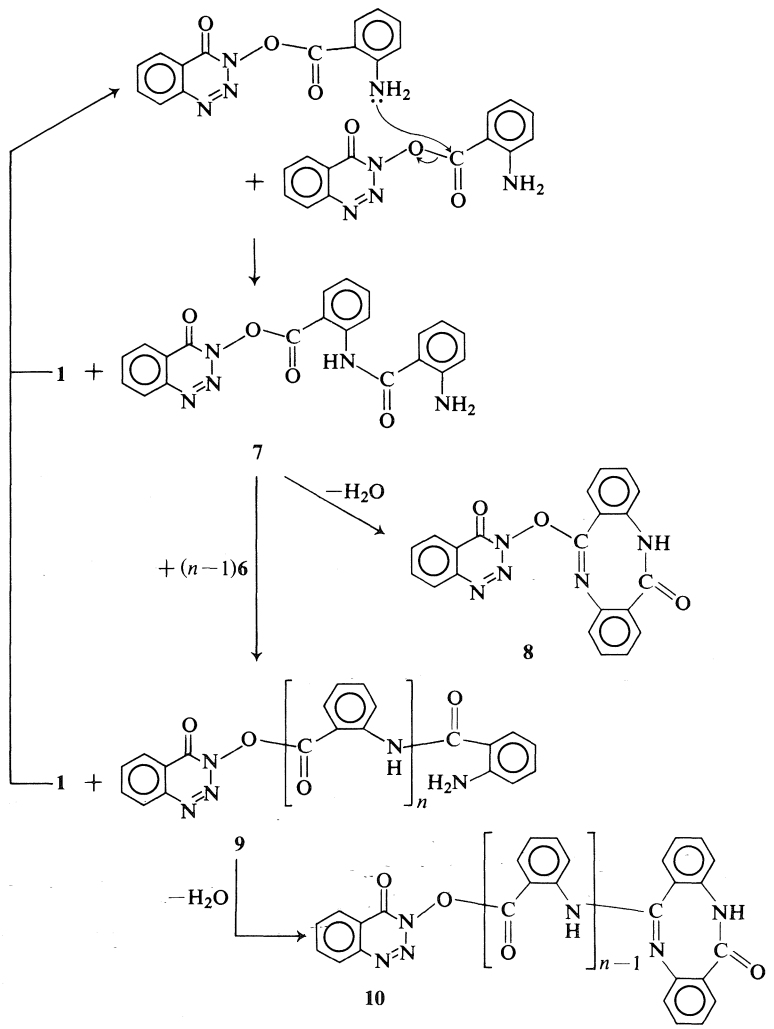
[2]



reaction of **6** with aqueous methylamine did not afford *N*-methylanthranilamide; the *N*-hydroxytriazinone **1** was recovered in the latter reaction. The synthetic potential of **6** as an *o*-aminobenzoylating agent is under further investigation.

The *N*-*o*-aminobenzoyloxy derivative **6** shows no tendency to form a diazoxepine by ring closure. Prolonged thermolysis of the *N*-hydroxytriazinone **1** in diglyme resulted in further reaction of **6**, but the preferred mode of reaction appears to be polymerization of **6**, and cyclodehydration of the polymer species. The diglyme reaction gave a low yield of a high melting solid, which exhibited mass spectral fragments as high as *m*/*e* 577. More significantly, the mass spectral fragments fall into several sequences, which are identical but for a common increment of 119 mass units (corresponding to the monomer unit —NH · C_6H_4 · CO—). This observation suggests the polymerization and cyclodehydration pathway shown in Scheme 2. Initially, the monomer **6** anthraniloylates itself by nucleo-

[2]The 'acyl-exchange' observed here is significantly different from previously observed 'acyl-transfer' reactions (20). Transacylation from benzoyl chloride has been observed in the conversion of *N*-acyl-5-aminopyrimidines to pyrimidino-isoxazoles (20*a*), whereas the transacylation of diacylanilines takes place only with carboxylic acids, or with anhydrides in the presence of a catalyst (20*b*). In the latter reactions, acylium ions are postulated as intermediates. Transacylation in anthracene di-*O*-acyl derivatives is also initiated by carboxylic acids (20*c*).



SCHEME 2

philic displacement of the *N*-oxytriazinone fragment, resulting in formation of the amide **7**, which can then readily cyclodehydrate to afford the diazocine **8**. The molecular ion of **8** (M^+ 383), and fragments at *m/e* 366, 357, 339, 322, 312, and 297 resulting from breakdown of **8**, are observed in the mass spectrum of the polymeric material from the diglyme reaction. Repeated reaction of **7** with **6** affords the polymeric amides **9** ($n = 2, 3, 4 \ldots$ etc) which can dehydrate in an analogous manner to give a series of diazocines **10**. The mass spectrum of the polymeric material shows clearly a fragment at *m/e* 502, corresponding to the molecular ion of the diazocine **10** ($n = 2$), and further fragments at *m/e* 485, 476, 458, 441, and 432. The fragments at *m/e* 577, 560, 551, and 533 correspond exactly to the breakdown predicted for the diazocine **10** ($n = 3$) on the basis of the fragmentations of **8** and **10** ($n = 2$). Thus, the mass spectrum of the polymeric material from the diglyme thermolysis of **1** is a conglomeration of the mass spectra of several diazocines of general formula **10**. Similar diazocine formation has been observed recently in the pyrolysis of an *o*-aminobenzoylimidazole (7).

The formation of **6** in the thermolysis of **1** has previously been accounted for (2) by the initial formation of the ketenimine **11**, followed by nucleophilic addition to the ketene by the hydroxylic function of a second molecule of **1** [3].

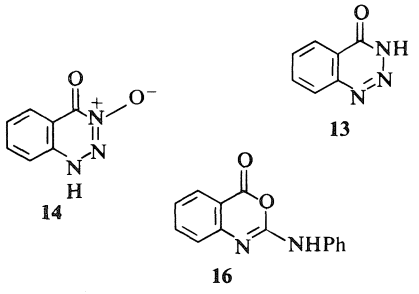
[3]  6

11

Further evidence for ketenimine formation is found in the solvolyses of **1** with nucleophilic solvents. Thermolysis of **1** in *n*-amyl alcohol affords *n*-amyl *o*-aminobenzoate and in aniline affords *N*-phenylanthranilamide, both products arising by addition of the nucleophile (ROH and $PhNH_2$ respectively) to the ketene. Addition of water to the ketene may also account for the formation of anthranilic acid in the acid hydrolysis of **1**, in contrast to the previously recorded (1) formation of *o*-azidobenzoic acid in the alkaline hydrolysis of **1**. The *N*-hydroxytriazinone **1** was recovered mainly unchanged from boiling water, but the formation of a small amount of anthranilic acid was evident. The formation of the Diels–Alder adduct, 3-phenylquinazolin-2,4(1*H*)-dione, **12**, from the reaction of **1** with phenyl isocyanate is clear evidence for the intermediate formation of **11** from **1** [4].

[4] 
12

Ketenimines, valence tautomers of benzazetidones, have been postulated as intermediates in the thermolysis of 1,2,3-benzotriazin-4(3*H*)-one **13** (8, 9), isatoic anhydride (9), saccharin (10) and 3-phenyl-1,2,3-benzotriazin-4-one (11). Several modes of formation of the ketenimine **11** in



14 13 16

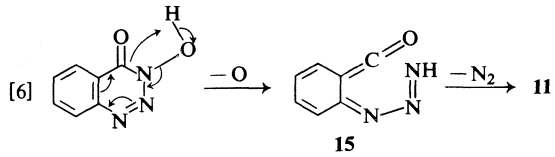
the thermolysis of **1** are possible. Direct loss of N_2O from the *N*-oxide tautomer **14** is a very attractive and simple mechanism, but the properties of **1** give no indication of the existence of an *N*-oxide tautomer and the involvement of **14** in the conversion **1** → **11** is unlikely. A further possibility is that fragmentation of **1** involves initial loss of N_2 by ring cleavage, as observed in the thermolysis of 3-phenyl-1,2,3-benzotriazin-4-one (11), in which case an analogous thermal breakdown of 3-methoxy-1,2,3-benzotriazin-4-one **5***a* would be expected. However, the *N*-methoxytriazinone was recovered quantitatively unchanged after prolonged refluxing in *p*-xylene.

Since the same ketenimine **11** has been postulated as an intermediate in the thermolysis of benzotriazinone **13** (8, 9), the possibility of an initial deoxygenation of **1** to give **13** as an intermediate was considered. Thermal deoxygenation of cyclic hydroxamic acids, although rare, has been reported previously (12). However, the conversion **1** → **6** takes place at temperatures much lower than those required to initiate reaction of benzotriazinone **13**, and benzotriazinone is not formed as a by-product of the thermolysis of **1**. Furthermore, benzotriazinone **13** was recovered almost quantitatively unchanged when an equimolar mixture of **1** and **13** was subjected to thermolysis in benzene. Only a small recovery of **13** was obtained when **1** and **13** were refluxed together in *p*-xylene and the only product in addition to **13** was the *N*-(*o*-aminobenzoyloxy)triazinone **6**, the yield of which was greater than could be accounted for on the basis of the amount of **1** used. Evidently, at least some of **6** arises by direct interaction of **1** and **13**, where the nucleophile **1** attacks the 4-oxo group in **13**, as observed previously in the reaction of benzotriazinone **13** with alcohols and other nucleophiles (13) [5].

[5] 
6

The alternative, and most likely, mechanism of formation of the ketenimine from **1** is a concerted process involving deoxygenation accom-

panied by fragmentation of the triazine ring. Such a deoxidative ring cleavage mechanism would give rise to the open-chain triazene intermediate **15**, which would be expected to undergo facile nitrogen elimination (14) directly to the ketenimine [6].



An analogous mechanism, also involving a triazene intermediate, has been postulated to account for the formation of acridone in the photolysis of 3-phenyl-1,2,3-benzotriazin-4-one (15).

The mode of thermal decomposition of the cyclic hydroxamic acid **1** is clearly different from that of benzotriazinone **13**. Thermolyses of the latter in diglyme (13), and in reactive methylene compounds (16), have been shown to be bimolecular, whereas Herlinger (8) and Crabtree *et al.* (9) have suggested that the ketenimine **11** is an intermediate in the thermolysis of benzotriazinone. Herlinger's hypothesis was based on the observation that thermolysis of **13** with phenyl isocyanate afforded the oxazinone **16**, which was explained as a Diels–Alder adduct of the ketenimine and the isocyanate. However, such a Diels–Alder reaction is contrary to the normal mode of cycloaddition of the isocyanate group (17), in which the C=N group, not C=O, is the dienophile. Crabtree *et al.* (9) also questioned the validity of the Diels–Alder mechanism for the formation of **16** from **13**, but on the basis of comparison of thermolysis temperatures; they proposed an alternative polar mechanism which was substantiated by isolation of an intermediate carbamoylbenzotriazinone. In the present work, no such intermediate was evident in the conversion **1** + PhN=C=O → **12**. The formation of **12** from the thermolysis of **1** with phenyl isocyanate is consistent with the normal mode of cycloaddition of the isocyanate, and is therefore clear evidence for the intermediate formation of the ketenimine **11** in the thermolysis of **1**.

Experimental

Melting points were recorded on a hot-stage apparatus (Reichert) and are uncorrected. Infrared spectra were recorded with Nujol suspensions on a Perkin-Elmer model 467 grating spectrophotometer; uv spectra were obtained for ethanolic solutions with a Perkin-Elmer model 402 spectrophotometer. Nuclear magnetic resonance spectra were measured on Varian A-60A or EM360 spectrometers using tetramethylsilane as internal standard. Mass spectra (medium resolution) were recorded with a Dupont/C.E.C. model 21-491 spectrometer using direct insertion, and high resolution molecular ion mass measurement was carried out by the peak-matching method, using electrical detection, with a Dupont/C.E.C. 21-110B spectrometer. Microanalyses were conducted by Chemalytics Inc., Tempe, Arizona.

o-Aminobenzhydroxamic Acid ***2***

Methyl anthranilate reacted with hydroxylamine in the presence of sodium hydroxide, according to the method of Scott and Wood (3), to yield *o*-aminobenzhydroxamic acid (43–51%); mp 144–146 °C (from ether) (lit. (3) mp 149 °C); ν_{max} 3400, 3300, 3150, 3300–2500 (broad), and 1640 cm^{-1}.

3-Hydroxy-1,2,3-benzotriazin-4-one ***1***

o-Aminobenzhydroxamic acid (32.2 g) in concentrated hydrochloric acid (56 ml), diluted with water (600 ml), was diazotized at 0–5 °C with sodium nitrite (16.0 g) in water (50 ml). The diazonium salt solution was then removed from the cold bath, stirred at room temperature for 0.75 h, and filtered to afford the *N*-hydroxytriazinone (19.2 g, 55%), mp 182–182.5 °C (dec.) (colourless needles from ethanol) (lit. (1) mp 180–181 °C), ν_{max} 2700 (broad OH), 1700 (sh), and 1660 cm^{-1}; λ_{max} 221, 260, 303, and 384 nm.

Methyl Derivative

The *N*-hydroxytriazinone **1** reacted with dimethyl sulphate in aqueous sodium hydroxide at room temperature to afford 3-methoxy-1,2,3-benzotriazin-4-one **5***a* (55% yield); mp 134–135 °C (white needles from ethanol); ν_{max} 1700 cm^{-1}; λ_{max} 220, 250(sh), 290, and 313 nm; δ($CDCl_3$) 7.3–8.5 (4H, m, aromatic), 4.28 (3H, s, —OMe); M^+ 177(22%), *m/e* 147(2%), 134(25%), 120(4%), 118(22%), 106(31%), 104(59%), 91(100%), 78(100%). *Anal.* calcd. for $C_8H_7N_3O_2$: C 54.20, H 3.98, N 23.70; found: C 53.77, H 4.03, N 23.61.

3-Acetoxy-1,2,3-benzotriazin-4-one ***5b***

(*a*) The *N*-hydroxytriazinone **1** (0.5 g) was refluxed in freshly distilled acetyl chloride (20 ml) for 1.0 h. The excess acetyl chloride was evaporated under vacuum, with care to avoid sublimation of the product, and the residue yielded the *N*-acetoxy derivative (0.26 g, 41%), mp 174–175 °C (colourless prisms from benzene), ν_{max} 1805 and 1700 cm^{-1}; λ_{max} 225, 250 (sh), 280, and 312 (w) nm; δ(DMSO-d_6) 8.5–7.9 (4H, m, aromatic) and 2.57 (3H, s, —CO·Me); M^+ 205(73%), *m/e* 163(10%), 147(5%), 135(95%), 104(50%), 91(27%) and 79(100%). *Anal.* calcd. for $C_9H_7N_3O_3$: C 52.70, H 3.41, N 20.50; found: C 52.46, H 3.54, N 20.41.

(*b*) The *N*-hydroxytriazinone **1** (0.5 g) was heated with acetic anhydride (4.0 ml) at 100 °C for 0.5 h. After standing at room temperature for 2 h, the mixture was treated with water to afford the same *N*-acetoxy derivative (0.4 g, 64%).

3-Benzoyloxy-1,2,3-benzotriazin-4-one ***5c***

The *N*-hydroxytriazinone **1** (0.5 g) was dissolved in

redistilled pyridine (3.0 ml) and freshly distilled benzoyl chloride (0.5 g) was added, whereupon a vigorous reaction ensued. The mixture was heated over a flame for 2 min and poured, with constant agitation, into cold water (15 ml). After vigorous mixing, the supernatant liquor was decanted and the residue was triturated with 1 *N* sodium carbonate (10 ml). Separation of the solid material afforded the benzoate **5***c* (0.65 g, 79%), mp 158–160 °C (pale yellow needles from ethanol), ν_{max} 1760 and 1700 cm^{-1}; λ_{max} 215 (sh), 230, 280, 300 (sh), and 313 nm; M^+ 267(53%), *m/e* 238(0.3%), 223(0.4%), 209(3%), 195(0.7%), 180(0.8%), 163(0.4%), 152(5%), 147(3%), 122(9%), 119(3%), 105(100%). *Anal.* calcd. for $C_{14}H_9N_3O_3$: C 62.90, H 3.37, N 15.70; found: C 62.68, H 3.47, N 15.68.

Reaction of the Benzoate 5c with Acetic Anhydride

3-Benzoyloxy-1,2,3-benzotriazin-4-one (0.1 g) was refluxed in anhydrous, freshly distilled acetic anhydride (0.5 ml) for 10 min and the resulting mixture was poured into cold water (10 ml). After boiling briefly to destroy acetic anhydride, the mixture was cooled and filtered to afford 3-acetoxy-1,2,3-benzotriazin-4-one **5***b* (44 mg, 62%), identical in all respects with a sample prepared above.

The aqueous mother liquor was extracted with ether, and the dried ($MgSO_4$) ether extract was evaporated to dryness. Trituration of the residue with petroleum ether afforded a small yield (less than 5%) of the *N*-hydroxytriazinone **1**. Evaporation of the petroleum ether washings gave an oily residue; tlc analysis of the residue showed that benzoic acid was not present.

3-(o-Aminobenzoyloxy)-1,2,3-benzotriazin-4-one 6

(*a*) 3-Hydroxy-1,2,3-benzotriazin-4-one (1.0 g) was refluxed in anhydrous diglyme (Na dried) (25 ml) for 1.3 h. The solution changes colour slowly from yellow to brown. Evaporation of the diglyme under vacuum left a brown oil, which solidified after 5 min. Trituration of the residue with benzene afforded 3-(*o*-aminobenzoyloxy)-1,2,3-benzotriazin-4-one **6** (0.92 g, 97%); mp 204–206 °C (dec.) (yellow prisms from toluene); ν_{max} 3480, 3365, 1740, and 1713 cm^{-1}; λ_{max} 226, 253, 276, 310, and 350 nm; M^+ found 282.0743(7%), calcd. for $C_{14}H_{10}N_4O_3$ 282.0753; *m/e* 238 (0.5%, $M - CO_2$), 163 (0.2%, $M - NHC_6H_4CO$), 147 (0.3%, $M - NHC_6H_4CO_2$), 137 (0.7%, $C_7H_7NO_2$), 120 (100%, $NH_2C_6H_4CO$).

(*b*) 3-Hydroxy-1,2,3-benzotriazin-4-one (0.5 g) was refluxed in anhydrous *p*-xylene (17.5 ml) for 2.5 h. The reaction mixture was cooled and the resulting crystalline mass was filtered to afford directly the *o*-aminobenzoyloxytriazinone **6** (0.34 g, 72%), identical with the product from (*a*) above.

(*c*) The *N*-hydroxytriazinone **1** (0.25 g) was refluxed in anhydrous toluene (20 ml) for 20 h. The yellow solution was evaporated to dryness and the residue was the *o*-aminobenzoyloxy compound **6** (quantitative yield), which was identical with the product from (*a*).

(*d*) *i*—**1** (0.25 g) was refluxed in anhydrous benzene (20 ml) for 48 h. Separation of the crystallized solid from the cooled reaction mixture afforded unchanged starting material (0.176 g, 70% recovery). Evaporation of the mother liquor under vacuum afforded the same *o*-aminobenzoyloxy compound **6** (0.065 g, 100% yield based on unrecovered starting material).

ii—**1** (0.25 g) was refluxed in anhydrous benzene (125 ml) for 112.5 h. The reaction was followed by tlc analysis until **1** did not appear on the chromatogram. Evaporation of the benzene under vacuum afforded a quantitative yield of **6**.

Prolonged Thermolysis of the N-Hydroxytriazinone 1 in Diglyme

1 (0.5 g) was refluxed in anhydrous diglyme (20 ml) for 24 h (tlc analysis of the reaction mixture showed the presence of several components after only 5 h of reflux). The reaction mixture was cooled and the precipitate was filtered to afford a solid material, yield 10.4 mg; mp > 300 °C. The mass spectrum of the high-melting solid exhibited the following fragments: *m/e* 577, 560, 551, 533, 514, 502, 485, 476, 458, 441, 432, 411, 383, 366, 357, 339, 322, 312, 297, 281, 265, 249, 238, 221, 210, 120 (base).

Evaporation of the diglyme mother liquor gave an intractable brown gum.

Thermolysis of 3-Hydroxy-1,2,3-benzotriazin-4-one 1 with 1,2,3-Benzotriazin-4-one 13

(*a*) 1,2,3-Benzotriazin-4-one (0.3 g, 0.002 mol) was dissolved in anhydrous *p*-xylene (40 ml) with 3-hydroxy-1,2,3-benzotriazin-4-one (0.66 g, 0.004 mol) and the mixture was refluxed for 2.5 h. The cooled reaction mixture produced a bright yellow precipitate; filtration afforded the *o*-aminobenzoyloxytriazinone **6** (0.55 g). Evaporation of the filtrate and trituration of the residue with benzene gave a solid which was extracted with aqueous NaOH and filtered to afford a second crop of the *o*-aminobenzoyloxytriazinone (total yield 0.58 g, 0.0021 mol). The sodium hydroxide washings were acidified with acetic acid and extracted with chloroform. Evaporation of the dried ($MgSO_4$) chloroform extract afforded unreacted benzotriazinone **13** (< 10 mg).

(*b*) **13** (0.226 g, 0.00153 mol) and **1** (0.250 g, 0.00153 mol) were mixed in anhydrous benzene (125 ml) and refluxed for 112.5 h. The solution was concentrated, under vacuum, to approximately 20 ml in volume and cooled to afford an orange precipitate, which was filtered. This solid (0.237 g) consisted almost entirely of unreacted benzotriazinone **13** (recovery > 95%), but did contain a small amount of the *o*-aminobenzoyloxytriazinone **6**.

Evaporation of the benzene filtrate afforded a pure sample of **6** (0.188 g, 87% based on **1**).

Reactions of 3-(o-Aminobenzoyloxy)-1,2,3-benzotriazin-4-one 6

(i) Acetylation

(*a*) **6** (0.2 g) was refluxed in freshly distilled acetyl chloride (10 ml) for 1 h. The solution was evaporated to dryness under vacuum and the brown, solid residue was recrystallized from benzene to afford *N*-acetylanthranilic acid (0.051 g, 40%), mp 175–176 °C, identical (mixture mp 175–176 °C and ir spectrum) with an authentic sample (Eastman). Evaporation of the benzene mother liquor gave 3-acetoxy-1,2,3-benzotriazin-4-one **5***b* (0.074 g, 51%).

(*b*) Similarly, heating **6** (0.25 g) in redistilled acetic anhydride (1.0 ml) for 10 min and treatment of the mixture with water afforded the same 3-acetoxy-1,2,3-benzotriazin-4-one (yield 70%).

(ii) Benzoylation

6 (0.25 g) was dissolved in warm, anhydrous pyridine (2 ml) and freshly distilled benzoyl chloride (0.252 g) was added in one portion. A precipitate formed quickly and was separated immediately. The solid was scrubbed with 1 *N* sodium carbonate (20 ml), filtered, and recrystallized from ethanol to afford 3-benzoyloxy-1,2,3-benzotriazin-4-one **5***c* (78% yield), identical with the product of benzoylation of **1**.

(iii) Diazotization

6 (0.25 g) was dissolved in concentrated HCl (5 ml), cooled to 0 °C and diazotized to starch–iodide end-point with sodium nitrite (0.0625 g). The diazonium salt solution was treated with hydroxylamine hydrochloride (0.1 g) in water (20 ml) and the mixture stirred for 20 min. Separation of the precipitate afforded the *N*-hydroxytriazinone **1** (0.118 g, 82%).

A similar result was observed when the diazonium salt solution was treated with sodium azide.

(iv) N-(o-Aminobenzoyl)benzylamine

3-(*o*-Aminobenzoyloxy)-1,2,3-benzotriazin-4-one **6** (0.5 g) was suspended in acetonitrile (30 ml) and benzylamine (0.2 g) was added. An immediate reaction was observed, with precipitation, and the mixture was refluxed for 0.25 h, whereupon a clear solution was obtained. The reaction mixture was cooled slowly to room temperature, and then to 0 °C, before filtration to remove a small amount of unidentified solid. Evaporation of the filtrate gave an orange residue, which was washed thoroughly with saturated $NaHCO_3$ solution and filtered to give *N*-(*o*-aminobenzoyl)-benzylamine (0.37 g, 90%), mp 120–123 °C (lit. (18) mp 123 °C), identical (ir spectrum) with an authentic sample, prepared by reaction of benzotriazinone **13** with benzylamine (13).

*(v) Reaction of **6** with Methylamine*

Aqueous methylamine (2.0 ml, 40%) was added dropwise to **6** (0.5 g), whereupon a clear solution was obtained. After standing at room temperature for 0.5 h, the solution was acidified with 2 *N* hydrochloric acid and the resulting precipitate filtered to afford the *N*-hydroxytriazinone **1** (0.2 g, 69%).

Acid Hydrolysis of 3-Hydroxy-1,2,3-benzotriazin-4-one

1 (0.7 g) was refluxed in 5 *N* hydrochloric acid (15 ml) for 0.5 h and left at room temperature for 3 h. The mixture was filtered, and the filtrate made almost neutral with solid sodium bicarbonate, which precipitated anthranilic acid (0.15 g, 25%), identical with an authentic sample.

*Thermolysis of **1** in n-Amyl Alcohol*

1 (0.5 g) was refluxed in *n*-amyl alcohol (15 ml) for 27.5 h. After cooling and standing for 2 h at room temperature, the excess alcohol was evaporated under vacuum and the oily residue was triturated with benzene. Filtration of the benzene solution and evaporation of the filtrate afforded *n*-amyl *o*-aminobenzoate (0.6 g, 94%), identical with an authentic sample (13).

*Thermolysis of **1** in Aniline*

1 (0.5 g) was refluxed in freshly distilled aniline (20 ml) for 0.5 h. The excess aniline was removed under vacuum and the brown, gummy residue was triturated with benzene – petroleum ether to give a pale yellow solid, which was recrystallized from benzene – petroleum ether to afford *N*-phenylanthranilamide (0.252 g, 35%), mp 120 °C, identical (ir spectrum) with an authentic sample (13). *Anal.* calcd. for $C_{13}H_{12}N_2O$: C 73.57, H 5.70, N 13.20; found: C 73.86, H 5.76, N 13.15.

*Reaction of **1** with Phenyl Isocyanate*

(*a*) **1** (0.25 g) and phenyl isocyanate (0.4 g) were mixed in anhydrous diglyme (10 ml) and refluxed for 1.5 h. The solution was evaporated under vacuum and the orange, gummy residue was triturated with benzene. Separation of the precipitate afforded 3-phenyl-2,4-quinazolinedione **12** (0.16 g, 45%), mp 282–284 °C (colourless needles from ethanol) (lit. (19) mp 276 °C), identical (ir spectrum) with an authentic sample prepared by base-catalyzed rearrangement of the oxazinone **16** (8). *Anal.* calcd. for $C_{14}H_{10}N_2O_2$: C 70.58, H 4.23, N 11.76; found: C 70.45, H 4.19, N 11.78.

(*b*) **1** (0.25 g) and phenyl isocyanate (0.4 g) were mixed in *p*-xylene (10 ml) and refluxed for 2.5 h. The solution was cooled in ice and the pale yellow precipitate was filtered to afford the same quinazolinedione (0.17 g, 48%). Evaporation of the *p*-xylene from the filtrate left an unidentified orange gum.

*Thermolysis of 3-Methoxy-1,2,3-benzotriazin-4-one **5***a*

5*a* (0.073 g) was refluxed in *p*-xylene (5 ml) for 22 h. Evaporation of the solution to dryness under vacuum afforded a quantitative recovery of unchanged starting material.

General base catalysis in acidic solutions. Acceleration of intramolecular phosphonate-assisted amide hydrolysis

RONALD KLUGER and C.-H. LAM

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 14, 1976

RONALD KLUGER and C.-H. LAM. Can. J. Chem. **55**, 640 (1977).

The hydrolysis of the amide linkage of 2′-phosphonobenzanilide, **1**, occurs with nucleophilic assistance from the adjacent phosphonic acid moiety. The basic component of buffers in acidic solutions provides additional rate acceleration. A Brønsted plot yields a straight line for buffers of phosphoric acid, cyanoacetic acid, chloroacetic acid, and dichloroacetic acid with $\beta \cong 1.0$. It is suggested that the second acidic group of the phosphonic acid of **1** dissociates upon formation of an addition intermediate, leading to a zwitterion ($T^{\pm}$). This zwitterionic intermediate decomposes in the rate-determining step, with added base or water removing a proton from a hydroxyl group of the intermediate. The product is a mixed phosphonic–carboxylic anhydride which hydrolyzes rapidly. It is concluded that a phosphoric acid derivative is a particularly good catalyst for this type of reaction since a stabilized intermediate can be internally generated along the reaction coordinate.

RONALD KLUGER et C.-H. LAM. Can. J. Chem. **55**, 640 (1977).

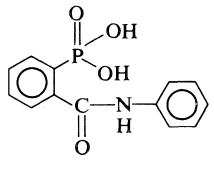
L'hydrolyse du lien amide du phosphono-2′ benzanilide **1** se produit avec l'aide de l'acide phosphonique adjacent agissant comme nucléophile. Le composant basique des tampons, en solutions acides, fournit une autre accélération de vitesse. Une courbe de Brønsted conduit à une ligne droite pour des tampons d'acide phosphorique, d'acide cyanoacétique, d'acide chloroacétique et d'acide dichloroacétique avec une valeur de $\beta \cong 1.0$. On suggère que le second groupe acide de l'acide phosphonique de **1** se dissocie lors de la formation d'un intermédiaire d'addition qui conduit à un zwitterion ($T^{\pm}$). Ce zwitterion intermédiaire se décompose dans l'étape déterminant la vitesse de la réaction alors que les bases ajoutées ou l'eau enlèvent un proton du groupe hydroxyle de l'intermédiaire. Le produit est un anhydride mixte phosphonique–carboxylique qui s'hydrolyse rapidement. On en conclut qu'un dérivé d'acide phosphorique est un catalyseur qui est particulièrement bon pour ce type de réaction puisqu'un intermédiaire stabilisé peut être généré d'une façon interne au cours de la réaction.

[Traduit par le journal]

Covalent interactions of amides and phosphates are of particular interest because of their potential significance in aggregates of proteins and nucleotides. We have been studying these interactions in model compounds containing the two functionalities in reactive proximity using hydrolysis rates as a probe (1–3). Evidence that a phosphate derivative can undergo addition to an amide includes our observation that a neighboring phosphonic acid markedly accelerates the hydrolysis of an amide (2). We have examined the mechanism of this catalytic interaction in detail in order to obtain an understanding of the stepwise processes involved. Although analogies can be drawn to situations in which carboxylic acids participate in the hydrolysis of amides, contrasts provide important information about the details of both types of interactions. In this report, we present evidence that external Brønsted bases facilitate the hydrolysis reaction promoted by a phosphonic acid in acidic solution. The function of the base can be contrasted to the requirement for Brønsted *acids* in cases involving participation by carboxylic acids (4, 5). The nature of the phosphonate–amide adduct uniquely accounts for the observed difference and suggests ways in which enzymic catalysis might be brought about.

Materials and Methods

Procedures were based on those we have used in related studies (4, 5). The substrate for these studies, 2′-phosphonobenzanilide **1**, was prepared and purified according to the procedure described by Kluger and Chan (2). Kinetic data were obtained by monitoring the decrease in absorbance at 270 nm as **1** was hydrolyzed to 2-phos-



1

phonobenzoic acid and aniline. Products were identified in a large scale reaction by spectroscopic comparison with genuine samples. Ultraviolet absorbance was followed with a Unicam SP1800A spectrophotometer and rate constants were obtained from conventional first-order plots which gave straight line fits for at least four half lives and correlation coefficients greater than 0.95 on least-squares analysis. Dissociation constants were taken from published compilations (6) and corrected for temperature (7) and proton number (8). All acid strengths were confirmed by titration. Ionic strength of the reaction medium was maintained with potassium chloride. Substrate concentration (added in ~10 μl methanol to 3 ml solution) was approximately 10^{-4} *M*.

First-order rate constants observed (k_{obsd}) for hydrolysis of **1** at varying buffer concentrations, but at constant hydrogen ion concentration, were plotted as function of buffer concentration, using the data in Table 1. From the slopes of these plots (k_{app}) the observed net buffer catalysis rate constant (k_{corr}) was obtained after correction for dissociation of the substrate:

$$k_{corr} = (\Delta k_{obsd}/\Delta[B])/f = k_{app}/f$$

$$f = [AH_2]/([AH_2] + [AH^-])$$

where AH_2 is **1** and AH^- is its conjugate base ($pK_a' = 1.6$). The dependence of k_{corr} on the separate buffer components was determined by variation of buffer ratios (changing hydrogen ion concentration) and plotting the dependence of k_{corr} on the buffer ratio. These plots indicated that k_{corr} is entirely accounted for by reaction involving the basic component of the buffer, giving k_B, the specific rate constant for general base catalysis. For Brønsted plots the rate constant, k_B, is statistically corrected for the number of basic sites on the added catalyst (8).

Results

The hydrolysis of **1**, while several orders of magnitude greater in rate than that of its unsubstituted amide analog (2), is promoted further by addition of buffers to the reaction solution in the region below p*H* 4 (see Table 1). To analyze these results we first determined that it is the undissociated form of the substrate that is reactive, based on the p*H*–rate profile for hydrolysis (2). Therefore buffer effects were necessarily corrected to account for substrate in the undissociated form, as described under Materials and Methods. Then, the effect of total buffer concentration at a particular acidity was measured. A plot of total buffer concentration *vs.* observed first-order rate constant, corrected for substrate in undissociated form, for hydrolysis of **1** (data in Table 1) gave a significant slope (k_{corr}) for all buffers we studied. The intercepts of these plots gave the values of rate constants obtained earlier for the p*H*–rate profile. It was then necessary to determine which component of the buffer is responsible for the catalysis. In order to measure this, we plotted k_{corr} as a function of the fraction of buffer present as conjugate base. The plots for all buffers (see Fig. 1) revealed that only the basic component of the buffer is involved in catalysis. Therefore, the value for the true, net rate constant, k_B, is that due to purely the basic component of the buffer, obtained from the value of the intercept of the plot of buffer, fraction *vs.* k_{corr}.

Finally, with the values of k_B obtained for the reaction of **1** with added phosphate, cyanoacetate, chloracetate, and dichloracetate buffers, a value for the Brønsted coefficient, β, was determined. Since the buffers contained different numbers of dissociable protons, conventional statistical corrections were made for each k_B (8) in the Brønsted plot. The plot (Fig. 2) utilizes the pK_a of the conjugate acid of the buffer, so that the slope is equal to $-\beta$. We find then that $\beta \cong 1.0$ (least-squares analysis gives a correlation coefficient of 0.988 for a value of $\beta = 0.98$).

Discussion

The hydrolysis of the amide functionality of **1** in acidic solutions is rapid compared to that of similar amides without adjacent acidic substituent groups (2). Kinetic studies suggested that this is due to the availability of a pathway for hydrolysis of **1** in which the phosphonic acid moiety adds to the amide center to form an internal addition intermediate. This decomposes to yield a reactive mixed anhydride along with expulsion of aniline. We now have observed that

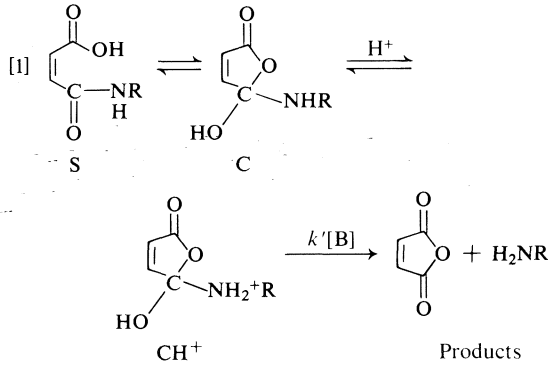
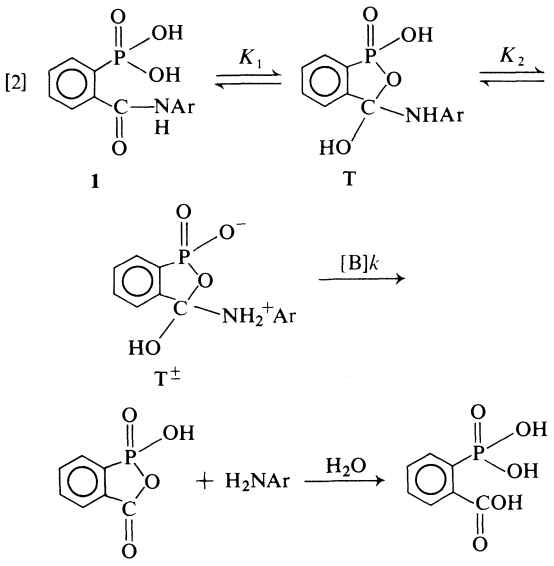
this reaction is further promoted by the conjugate base component of acidic buffers. In the case of carboxylic acid participation in the hydrolysis of amides in acidic solutions, it has been observed that the reaction is further promoted by what is described kinetically as general acid catalysis (4, 5, 9, 10). In the carboxylic acid case, recent studies have indicated that the observed general acid catalysis is probably due to a mechanism involving sequentially specific acid – general base catalysis (5, 10). This gives the same empirical rate equation for buffer catalysis as general acid catalysis (5).



For the case of phosphonic acid participation, which we observe, a parallel mechanism utilizing a similar sequence of reactions should also apply. However, the observation that the phosphonic acid reaction is subject to general base catalysis requires an important modification. In reaction 2 we have proposed a mechanism for general base-assisted hydrolysis of **1**.

The major modification of the mechanism shown in reaction 1 that appears in reaction 2, is formation of a zwitterionic intermediate $T^{\pm}$. In the case of carboxylic acid participation, intermediate C of reaction 1 cannot decompose without formation of the cationic intermediate CH^+ which decomposes in the rate-determining step. The intermediate indicated in reaction 2, T,



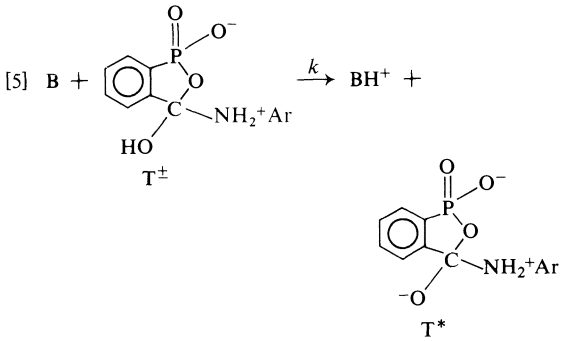
has an alternative means of arriving at a cationic nitrogen center (in order to develop a leaving group). Since the phosphonic acid moiety of **1** has two dissociable protons, formation of intermediate T only utilizes one of the acidic groups. The remaining group is a fairly strong acid (phosphonic acid monoesters typically have pK_a's near 2) and the zwitterion, $T^{\pm}$, should be present as a significant portion of the total of species T and $T^{\pm}$. The decomposition of $T^{\pm}$ requires only the Brønsted base, B, indicated in reaction 2. The rate expression for the buffer catalyzed hydrolysis of **1** according to reaction 2 is:

$$[3] \quad v = k[B][T^{\pm}] = k_B[B][\mathbf{1}] = kK_1K_2[B][\mathbf{1}]$$

$$[4] \quad k_B = K_1K_2k$$

We see from [4] that k_B depends on the stability of the intermediates relative to the starting material, the relative amount of zwitterion present, and the energy of the transition state associated with k. Since general acid catalysis was not observed, reaction proceeding via a cationic intermediate generated by protonation of T without dissociation of the phosphonic acid must not be significant. The contrast then with carboxylic acid participation [1] is that the phosphonic acid can proceed via a zwitterion, $T^{\pm}$, while the carboxylic acid cannot.

We can now analyze further the nature of the transition state associated with k by examining the results of the Brønsted plot (Fig. 2). The slope we observe of unity (or nearly that) requires that proton transfer in the rate determining step be nearly complete at the transition state (11). This suggests that transfer of the hydroxylic proton of $T^{\pm}$ to B is itself rate-determining, leading to the metastable intermediate T* which can decompose rapidly. Con-



sistent with this view, we find that the rate constant for the 'uncatalyzed' reaction of **1** (2), corresponding to water acting as a general base when plotted relative to the pK_a of its conjugate acid, hydronium ion (as in the plot of Fig. 2), falls considerably above the extrapolated line. This is consistent with arguments that suggest that water is a relatively superior catalyst for proton transfer (11) and should deviate positively from that extrapolated from Brønsted plots ($pK_a = -1.75$, $k_{H_2O} = 1.6 \times 10^{-6}\ M^{-1}\ s^{-1}$; k (extrapolated) $= 3.0 \times 10^{-7}\ M^{-1}\ s^{-1}$).[1] The decomposition of $T^{\pm}$ by a stepwise process is consistent with Jencks's expectations for many elimination reactions which produce carbonyl groups (12, 13). Since aniline is a good leaving group, the endergonic proton–transfer leading to formation of T* may become rate-determining. The observation of buffer catalysis suggests that this interpretation is applicable here. If expulsion of aniline were rate-determining, there would be no likely role for the Brønsted base catalyst. Kirby and co-workers (9, 10) have presented their findings for other amides in which structural factors determine whether buffer catalysis may be observed and for which rate-limiting proton-transfer must be invoked. Since our results are based on a limited Brønsted plot, we must regard these results as suggestive of the proposed mechanism and await further data to test these hypotheses.

[1] k_{H_2O} is obtained from the appropriate value in ref. 2 divided by the water concentration to adjust for units.

Our results suggest that one means by which enzymatic cleavage of peptides might be assisted is through electrostatic stabilization of protonated intermediates by adjacent anions. The case we have studied indicates that the zwitterion derived from a phosphonic acid addition intermediate may be a good model for this type of environment.

Rules for the quantitative prediction of stereochemistry in the reduction of cyclohexanones by sodium borohydride

DONALD C. WIGFIELD

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received July 8, 1976

DONALD C. WIGFIELD. Can. J. Chem. **55**, 646 (1977).

A procedure is outlined which allows calculation of the stereoselectivity of reduction of cyclohexanones by sodium borohydride under normal conditions (room temperature, 2-propanol as solvent). The procedure rests on incremental enthalpy values of steric hindrance, coupled with known isokinetic relationships to obtain values of $\Delta\Delta G^{\ddagger}$; thus it delineates quantitatively the steric factors governing stereoselectivity in these reductions.

DONALD C. WIGFIELD. Can. J. Chem. **55**, 646 (1977).

On décrit un procédé qui permet de calculer la stéréosélectivité de la réduction de cyclohexanones par le borohydrure de sodium dans des conditions normales (température de la pièce; propanol-2 comme solvant). Ce procédé repose sur des valeurs additives d'enthalpie due à l'empêchement stérique qui sont couplées avec des rapports isocinétiques connus afin de déterminer les valeurs $\Delta\Delta G^{\ddagger}$; ce procédé délimite donc quantitativement les facteurs stériques qui gouvernent la stéréosélectivité de ces réductions.

[Traduit par le journal]

Sodium borohydride has been known for over 30 years and has been extensively used in organic chemistry for much of this period. Yet despite its central place, the reductions of cyclohexanones by sodium borohydride are still very puzzling from the point of view of mechanism and stereochemistry. The detailed mechanism of reduction, the origin of stereoselectivity, and even a practical, if empirical, formula for quantitatively predicting stereoselectivity, are all problems that remain inadequately resolved. This communication is directed at the last of these problems.

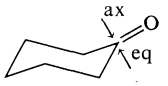
In 1953, it was recognized by Barton that "reduction (of cyclohexanones) with sodium borohydride or lithium aluminum hydride in general affords the equatorial epimer if the ketone group is not hindered, the polar (axial) epimer if it is hindered or very hindered" (1). In the 23 years that have passed since that statement was made its generality has been amply confirmed, but a *quantitative* prediction of stereochemistry has never been possible. Our recent measurements of specific activation parameters for axial and equatorial attack by sodium borohydride on a wide variety of cyclohexanones (2, 3) have indicated the reason why it is so difficult to make such predictions. The observed stereochemical product ratio must be a result of the difference in *free energy* ($\Delta\Delta G^{\ddagger}$) between the two transition states for axial and equatorial attack. Yet the reaction is *enthalpy* controlled (3), and the compensating entropy effects (isokinetic relationships) *differ* significantly depending on whether the ketone is unhindered or hindered and, to a lesser extent, whether axial or equatorial attack is being considered (3). Thus, a neat series of incremental free energy additions is not possible and efforts to find such increments must fail. Despite the fact that the origin of stereoselectivity in these reductions still remains unestablished, one line of attack worth pursuing is the reflection that, *if* changes in stereoselectivity from one ketone to another are simply the consequence of differential steric impedance between ketone and reducing agent, then it should be possible to devise a series of appropriate *enthalpy* increments for substituents in various locations around the cyclohexanone ring. By combining these increments with the appropriate isokinetic relationship, the entropy and thence the free energy increments may be obtained, leading to a calculated value of $\Delta\Delta G^{\ddagger}$, from which the derivation of stereochemical product ratio in a kinetically controlled reaction is trivial. We wish to report that this approach to predicting quantitatively the stereoselectivity successfully produces a workable tool, and details of the steps in such a calculation follow.

Step 1. Values of $\Delta H_{ax}{}^{\ddagger}$ and $\Delta H_{eq}{}^{\ddagger}$ (enthalpies of activation for axial and equatorial attack

TABLE 1. Increments in $\Delta H^{\ddagger}$ for methyl substitution on cyclohexanones

Substituent	$\Delta H^{\ddagger}$(kcal/mol) Axial attack (Base value 6.3 kcal/mol)	Equatorial attack (Base value 7.5 kcal/mol)
2-Equatorial	+1.1	+0.5
2-Axial	0.0	+2.0
3-Equatorial	+0.6	+0.7
3-Axial	+2.8	0.0
4-Equatorial	0.0	0.0
4-Axial	+0.2	+1.2

respectively) are calculated by addition of the appropriate incremental substituent effects to the base values of 6.3 kcal/mol for axial attack and 7.5 kcal/mol for equatorial attack.



These incremental substituent effects, which follow from previously published activation parameter data (2, 3), are shown in Table 1.

Step 2. The cyclohexanone under consideration is classified as unhindered, hindered, or very hindered, and values of $\delta\Delta H_{ax}^{\ddagger}$ and $\delta\Delta H_{eq}^{\ddagger}$ (difference between calculated $\Delta H^{\ddagger}$ and 'standard'[1] value for that class of ketone) calculated by [1] and [2].

$$[1] \qquad \delta\Delta H_{ax}^{\ddagger} = \Delta H_{ax}^{\ddagger} - (\Delta H_{ax}^{\ddagger})_0$$

$$[2] \qquad \delta\Delta H_{eq}^{\ddagger} = \Delta H_{eq}^{\ddagger} - (\Delta H_{eq}^{\ddagger})_0$$

For this purpose, isokinetic plots (3) make it clear that *unhindered ketones* are those which contain only 3-equatorial and/or 4-substitution (axial and/or equatorial); *very hindered ketones* are those which contain two 3-axial substituents; *hindered ketones* are those with any other substituent pattern. The values of $(\Delta H_{ax}^{\ddagger})_0$ and $(\Delta H_{eq}^{\ddagger})_0$ are indicated in Table 2 and in the isokinetic plot sketches in Fig. 1.

Step 3. The values of $\delta\Delta H_{ax}^{\ddagger}$ and $\delta\Delta H_{eq}^{\ddagger}$ are converted to $\delta\Delta G_{ax}^{\ddagger}$ and $\delta\Delta G_{eq}^{\ddagger}$ respectively using the isokinetic relationship [3]

$$[3] \qquad \delta\Delta G^{\ddagger} = \delta\Delta H^{\ddagger}(1 - T/\beta)$$

where β is the appropriate isokinetic temperature.[2] Values of $(1 - T/\beta)$, calculated from published data, (3) are given in Table 2.

TABLE 2. Conversion factors for calculation of $\Delta\Delta G_{eq}^{\ddagger}$

Factor	Type of ketone: Unhindered	Hindered	Very hindered
$(\Delta H_{ax}^{\ddagger})_0$*	6.3	8.2	10.1
$(\Delta H_{eq}^{\ddagger})_0$*	7.5	8.7	9.9
$(1 - T/\beta)_{ax}$	0.21	0.32	0.41
$(1 - T/\beta)_{eq}$	0.25	0.36	0.44
$\Delta\Delta G_0^{\ddagger}$	+1.2	+0.5	−0.2

*See footnote 1.

Step 4. $\Delta\Delta G_{ea}^{\ddagger}(= \Delta G_{eq}^{\ddagger} - \Delta G_{ax}^{\ddagger})$ is calculated from [4]

$$[4] \qquad \Delta\Delta G_{ea}^{\ddagger} = \Delta\Delta G_0^{\ddagger} + \delta\Delta G_{eq}^{\ddagger} - \delta\Delta G_{ax}^{\ddagger}$$

where the appropriate values of $\Delta\Delta G_0^{\ddagger}$ are given in Table 2.

Step 5. $\Delta\Delta G_{ea}^{\ddagger}$ is converted to stereochemical product ratio (at 25 °C) using [5]

$$[5] \qquad \%\ \text{equatorial alcohol} = \frac{100}{1 + e^{-1.69\Delta\Delta G_{ea}^{\ddagger}}}$$

Despite the rather involved above description of the calculation procedure, it is, in practice, not unduly cumbersome, and a worked example follows to illustrate this point. All data required is contained in Tables 1 and 2.

[1]The subscript 0 and the term 'standard' do not imply physical significance and simply refer to an arbitrarily chosen point on the appropriate isokinetic line.

[2]Or, more correctly, the slope of the $\Delta H^{\ddagger}$ *vs.* $\Delta S^{\ddagger}$ plot since there is no evidence that an isokinetic temperature actually exists. Insufficient information is available on the characteristics (slope, position of line) of the isokinetic relationship for very hindered ketones. However, it appears that the shift in characteristics between the line for hindered ketones and that for very hindered ketones is approximately the same as the (known) shift between the lines for unhindered ketones and hindered ketones. We have assumed here that these two shifts are, in fact, equal, and this assumption appears to work satisfactorily for product ratio prediction.

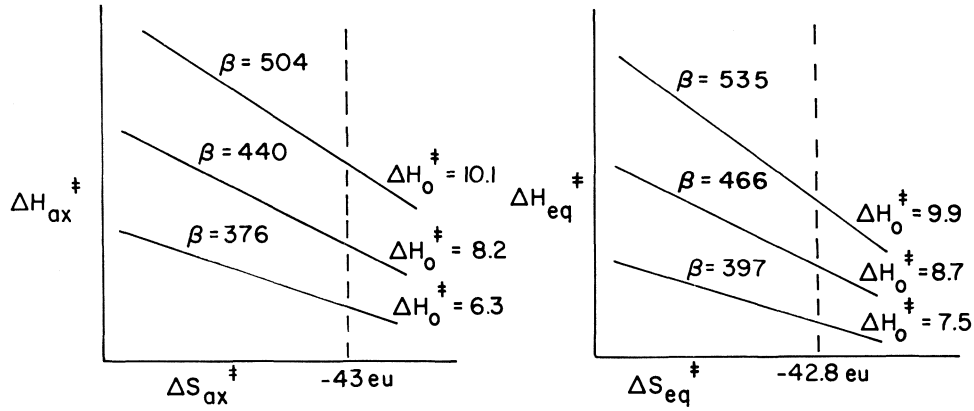


FIG. 1. Isokinetic relationships for reduction of unhindered (lower lines), hindered (centre lines), and very hindered (upper lines) ketones.

Calculation of Stereochemical Product Ratio for Reduction of 3,3,5-Trimethylcyclohexanone

Step 1. Ketone has two 3-equatorial and one 3-axial substituents.

$$\Delta H_{ax}^{\ddagger} = 6.3 + 2(0.6) + 2.8 = 10.3 \text{ kcal/mol}$$

$$\Delta H_{eq}^{\ddagger} = 7.5 + 2(0.7) + 0.0 = 8.9 \text{ kcal/mol}$$

Step 2. The ketone is classified as 'hindered'.

$$\delta\Delta H_{ax}^{\ddagger} = 10.3 - 8.2 = +2.1 \text{ kcal/mol}$$

$$\delta\Delta H_{eq}^{\ddagger} = 8.9 - 8.7 = +0.2 \text{ kcal/mol}$$

Step 3.

$$\delta\Delta G_{ax}^{\ddagger} = +2.1 \times 0.32 = +0.7 \text{ kcal/mol}$$

$$\delta\Delta G_{eq}^{\ddagger} = +0.2 \times 0.36 = +0.1 \text{ kcal/mol}$$

Step 4.

$$\Delta\Delta G_{ea}^{\ddagger} = +0.5 + 0.1 - 0.7 = -0.1 \text{ kcal/mol}$$

Step 5.

$$\% \text{ equatorial alcohol} = \frac{100}{1 + e^{-1.69(-0.1)}} = 46\% \text{ (experimental value 48\%)} \quad (3)$$

Calculated stereochemical product ratios of the reduction of a variety of cyclohexanones using this procedure, and comparisons with experimental observations are shown in Table 3.[3] Examination of Table 3 makes it clear that there is good agreement (within 4%) between calculation and experiment, which suggests that the method presented is a workable predictive tool, and also provides evidence that the original premise of differential stereoselectivity being a result of predictable incremental steric interactions may be correct. The method is clearly only valid for reductions performed under the conditions for which the activation parameters were measured (*i.e.* in 2-propanol at 25 °C), and, strictly speaking, valid only for the substituents being methyl groups. However, the calculation appears to work satisfactorily when the substituent is part of a methylene chain, either cyclic (see steroids **3**, **4**, **5**, **7**, **19** and particularly the comparison of **3** and **4**) or acyclic (entries **14**–**18**). Surprisingly, the agreement is apparently tolerable even with an isopropyl group substituent (entry **18**), but (not surprisingly) breaks down when a *tert*-butyl group is in a significantly

[3]For entries **4**, **8**, **9**, **13**, **15**, **16**, **19** of Table 3, the specific activation parameters for reduction are unknown, and thus these are pure predictions. For the other ketones (those whose specific activation parameters have been measured and from which the approach is derived) the approach is cyclic and thus deviations represent only deviations from idealized linearity. It should be emphasized, however, that because of the differing isokinetic relationships that exist, not even a cyclic prediction of stereochemistry covering a variety of ketone reductions has previously been successful. The data in Table 3 demonstrate that the approach is consistent and that it may be generally applied in a predictive way.

TABLE 3. Calculated and observed stereochemical product ratios from ketone reductions with $NaBH_4$

Ketone	% equatorial alcohol	
	Calculated	Observed*

*Product ratios are taken from ref. 3 unless otherwise noted.

hindering position (entry **16**). It is also doubtful that the relationship would be of any relevance to cyclohexanones with polar substituents. It is of interest to extend these calculations to very hindered ketones: 3,3,5,5-tetramethylcyclohexanone is a ketone for which clearly no product ratio is experimentally measurable and estimates of the ratio of axial:equatorial attack have ranged from 0.5 to 30% axial attack. (For a discussion of this point, see ref. 7.) The above calculation method gives 95.4% equatorial attack (*i.e.* 4.6% equatorial alcohol) in excellent agreement with the 95:5 product ratio recently determined on a 4-substituted derivative in our laboratory (8). Extension to the reduction of 11-ketosteroids gives an axial:equatorial product ratio of 97.2:2.8. While sodium borohydride does not reduce these highly hindered ketones, reductions of 11-ketosteroids with lithium aluminum hydride have been reported to give essentially only the axial alcohol[4] (ref. 9 and references cited therein).

In summary, the procedure outlined here appears to give a quantitative (±4%) estimate of the stereochemical product ratio in the reduction of cyclohexanones by sodium borohydride in 2-propanol. While the procedure was designed for methyl substitution, it appears to give reliable answers for cyclohexanones with a variety of nonpolar substituents, including steroids. The steric factors controlling stereoselectivity are thus delineated and the Barton generalization (1) converted to a quantitative tool.

[4]We are not aware of any efforts to detect small amounts (< 3%) of the equatorial alcohol.

Synthesis of 6-substituted 5,6,7,12-tetrahydrodibenzo[*a*,*d*]cyclooctenes[1]

ROGER N. RENAUD AND JOHN W. BOVENKAMP

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received June 4, 1976

ROGER N. RENAUD and JOHN W. BOVENKAMP. Can. J. Chem. **55,** 650 (1977).

The eight-membered ring 6,6-dicyano-5,6,7,12-tetrahydrodibenzo[*a*,*d*]cyclooctene was prepared from 2,2′-bis(bromomethyl)diphenylmethane and sodiomalononitrile. From this dicyano derivative a series of mono- and disubstituted cyclooctenes was synthesized.

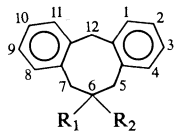
The corresponding 5,7,12-trihydro-6*H*-dibenzo[*a*,*d*]cycloocten-6-one was obtained by the ring enlargement of 5,10-dihydro-11*H*-dibenzo[*a*,*d*]cyclohepten-11-one with diazomethane. The parent compound and its dideuterio derivative were prepared from the eight-membered ring ketone. A Wittig reaction on the ketone gave the methylene derivative.

ROGER N. RENAUD et JOHN W. BOVENKAMP. Can. J. Chem. **55,** 650 (1977).

Le dicyano-6,6 tétrahydro-5,6,7,12 dibenzo[*a*,*d*]cyclooctène fut preparé à partir du bis-(bromométhyl)-2,2′ diphénylméthane en présence de sodiomalononitrile. Le groupement fonctionnel a servi à la synthèse de plusieurs composés substitués en position 6.

La trihydro-5,7,12 dibenzo-6*H*-[*a*,*d*]cyclooctènone-6 a été préparée par l'agrandissement de l'anneau cycloheptènone de la dihydro-5,10 dibenzo-11*H*-[*a*,*d*]cycloheptènone-11 en présence de diazométhane. Cette cétone fut soit réduite en cyclooctane normal et dideutérié ou transformée en dérivé méthylènique par la réaction de Wittig.

In earlier papers (1, 2), it has been shown that the eight-membered ring system, *N*-alkyl-5,6-dihydro-7*H*,12*H*-dibenzo[*c*,*f*]azocines, shows conformational behaviour in which the ring can be in a rigid and in a flexible conformation. These results were interesting enough to cause us to have a detailed look at the corresponding all-carbon ring system.[2] Thus it was necessary to have available a series of mono- and di-6-substituted 5,6,7,12-tetrahydrodibenzo[*a*,*d*]cyclooctenes **1** and this paper describes the synthesis of these compounds. The only other carbocyclic compounds reported in the literature having the skeleton of **1** are those with substitution at C-12 (3). These were prepared according to Scheme 1 where $R_1 = R_2 = H$. This approach could only have been used to synthesize some of the C-6 substituted compounds described in this paper since the first step is limited to just a few 1-substituted phenylbromoethanes. For instance, this procedure is certainly not suitable for the preparation of **1***b*, **1***d*, or **1***i*. Also, Winthrop *et al.* (3) found that the cyclization step was very sensitive to structural change in the reactants, and in some cases the desired cyclization product was not obtained.



1

	R_1	R_2

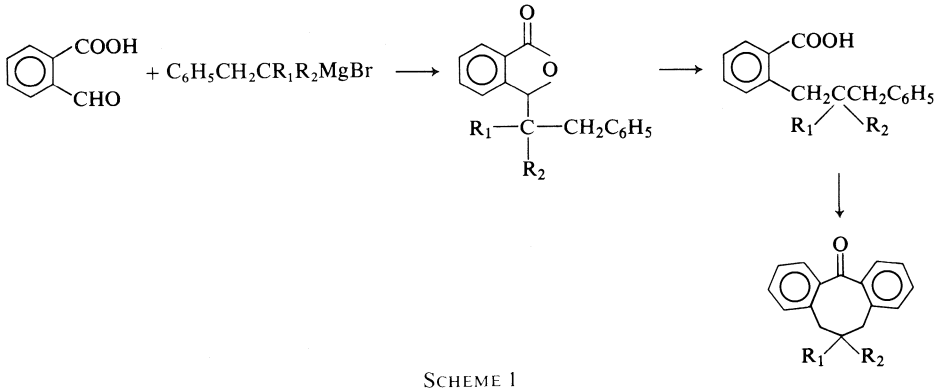
o	D	D

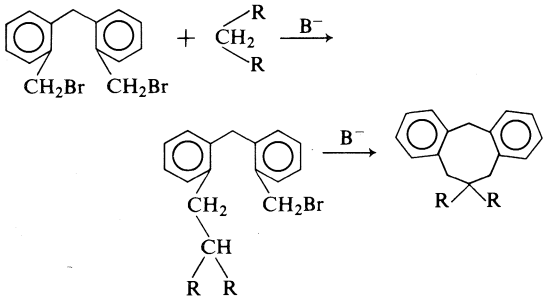
The reaction sequence chosen by us is shown in Scheme 2. The first reaction attempted was that between 2,2′-bis(bromomethyl)diphenylmethane and diethyl sodiomalonate. This reaction did not give any detectable monomeric compound **1***a* but did give a good yield of the 16-membered ring compound **3** along with some polymeric products (4). In direct contrast, the smaller sodiomalononitrile gives a good yield of eight-membered ring cyclization product. In

[1]NRCC No. 15670.

[2]A manuscript (R. R. Fraser, R. N. Renaud, and J. W. Bovenkamp) describing the conformational behaviour of this ring system is in preparation.



SCHEME 1



SCHEME 2

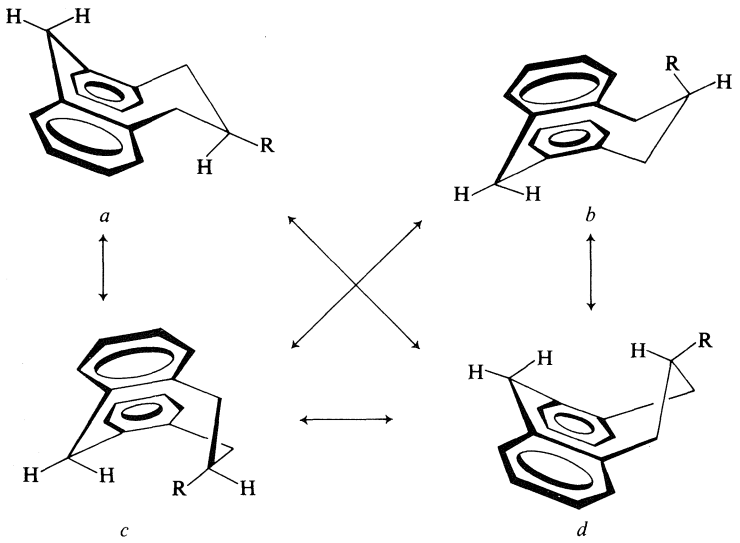
our view, the different results obtained with these disubstituted nucleophiles are due to the steric effect of the substituents during cyclization. An examination of the Dreiding models shows that the eight membered ring compound substituted at C-6 can exist in four interconvertible conformations,[3] namely two rigid boat-chair conformers (**a** and **b**) and two flexible boat-boat conformers (**c** and **d**).[4] The conformers **b** (R quasi-axial) and **c** (R inside) contain interactions which could be highly unfavourable with large groups. These are the interactions of R with the π electrons of the benzene rings in **b** or with one of the protons at C-12 in **c**. In contrast, the interactions in conformations **a** and **d** are expected to be much less severe. In the case of the *N*-alkyl-5,6-dihydro-7*H*,12*H*-dibenzo[*c*,*f*]-azocines (2), the eight-membered ring is formed readily from the dibromide and the corresponding amine even when the alkyl substituent is as large as *tert*-butyl. In these cases, cyclization to the two high energy conformations can be avoided. When two substituents are present at C-6, one of the substituents is always involved with one of the high energy interactions already mentioned. Thus, during cyclization with disubstituted nucleophiles, the development of these interactions as the transition state is approached may prevent the cyclization to the eight-membered ring. This appears to be the most plausible explanation for the bimolecular cyclization with the large diethyl sodiomalonate to give the 16-membered ring **3** (4) while with the smaller sodiomalononitrile intramolecular cyclization occurs to give the eight-membered ring **1***b*.

Starting from this dinitrile, a series of mono- and disubstituted benzocyclooctenes were synthesized (**1***c* to **1***m*). The dinitrile **1***b* could be converted to both monoacid **1***c* and diacid **1***h* under basic conditions. The hydrolysis with 5% sodium hydroxide in refluxing ethylene glycol gave only the monoacid **1***c* upon neutralization. The diacid **1***h* was obtained in good yield by refluxing the dinitrile in 25% aqueous sodium hydroxide solution for 36 h. Even after a 24 h reflux, sizeable amide peaks could be seen in the infrared spectrum.

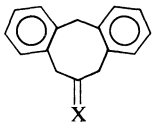
From the monoacid were obtained the methyl ester **1***d*, the alcohol **1***e*, the tosylate **1***f*, and the hydrocarbon **1***g*. Trideuterated **1***g* (at C-6, C-12, and C-12) was obtained by carrying out the hydrolysis of **1***b* in ethylene glycol-d_2. It is of interest to note that, as has been observed in the case of fluorene (7), the protons at C-12 (*i.e.* the protons of the methylene group between the two

[3]The conformational interconversion has been discussed in the case of *N*-alkyl-5,6-dihydro-7*H*,12*H*-dibenzo[*c*,*f*]azocines (2, 5).

[4]The force field calculations of Allinger *et al.* (6) indicate that in 1,4-cyclooctadiene the boat–boat conformer does not twist to relieve the severe repulsion between the hydrogens at C-3 and C-7. In the case of *N*-alkyl-5,6-dihydro-7*H*,12*H*-dibenzo[*c*,*f*]azocines (2) and of **1** (see footnote 2), the dynamic nmr is best explained by two lower energy twist–boat enantiomers.



benzene rings) are readily exchanged under relatively mild basic conditions; however, according to nmr the methylene protons at C-5

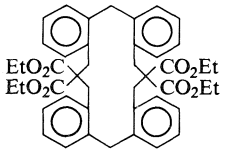


2

a X = O
b X = CH_2

and C-7, having only one adjacent benzene ring, are not exchanged. It is known that benzylic protons exchange in the presence of a very strong base (8). The diacid gave successively the diester **1***i*, the diol **1***j*, and the ditosylate **1***k*. The ditosylate upon reduction with lithium aluminum hydride gave both **1***l* and **1***m*. It was easier to obtain **1***l* pure when ether was used as the solvent while for **1***m* purification was simpler with the use of tetrahydrofuran.

The synthesis of the ketone **2***a* from 2,2′-bis(bromomethyl)diphenylmethane either by the Thorpe reaction (9) or by cyclization with ethyl ethylthiomethyl sulfoxide (10) led to very poor yields of **2***a* (2% and 6% respectively). The



3

preparation of **2***a* by the ring enlargement of 5,10-dihydro-11*H*-dibenzo[*a*,*d*]cyclohepten-5-one with diazomethane by the method described by House *et al.* (11) gave a much improved yield.

The parent hydrocarbon **1***n* was easily obtained from **2***a* by the Wolff–Kishner reaction (12). However, the synthesis of the dideuterio compound **1***o* proved to be surprisingly difficult. The tosyl derivative of the monodeuterated alcohol, obtained from the reduction of **2***a* with lithium aluminum deuteride followed by tosylation, gave back the alcohol on reduction. The bromo analogue, synthesized from the alcohol by the method of Squires *et al.* (13), gave very impure product either when reacted with lithium aluminum deuteride or with zinc dust in refluxing acetic acid-*d* (14). It is well known that the conversion of unactivated aliphatic ketones into a dideuterio methylene group is difficult to achieve without deuterium scrambling (15). Sodium cyanoborohydride, has been used to reduce ketones to methylene groups (16). It was thought worthwhile to attempt to obtain **1***o* by the use of sodium cyanoborodeuteride; however, the use of this reagent led to a hydrocarbon with excessive scrambling. A suitable sample (85% d_2, 11% d_1 and 4.5% d_3) of **1***o* was finally obtained using the improved Clemmensen reaction described by Steiner (17*a*). Thus we have further demonstrated the usefulness of Steiner's method by achieving an acceptable level of scrambling in a compound where the ketone group is next to two benzylic methylenes.

The methylene derivative **2***b* was prepared according to the method of Corey and co-workers (18) using a 1:1 ratio of Wittig reagent and ketone. When a large excess of Wittig reagent was used an impurity appeared which could not be separated by column chromatography, recrystallization, or distillation. The same impurity was also formed when the reaction was carried out using *n*-butyllithium to form the Wittig reagent and the reaction carried out in boiling ether (19). In this latter case, a large amount of the methylene **2***b* rearranged to the conjugated olefin 6-methyl-7,12-dihydrodibenzo-[*a*,*d*]cyclooctane.

Experimental

All melting points are uncorrected. Infrared spectra were observed on a Perkin-Elmer model 267 spectrophotometer and only the characteristic bands are reported. ^{1}H nuclear magnetic resonance spectra were, unless otherwise noted, taken in deuterochloroform solution on a Varian Associates spectrometer model E.M. 360 and the chemical shifts are reported on the δ scale. Molecular weight determinations were carried out on a Mechrolab vapor pressure osmometer apparatus and/or on a Hitachi–Perkin–Elmer RMU-6D mass spectrometer.

Preparation of Compound ***1b***

The method described by Bloomfield (20) for the preparation of dialkylmalononitrile was followed. Malononitrile (0.73 g, 11 mmol) freshly distilled from phosphorus pentoxide was dissolved in dry dimethyl sulfoxide (3.5 ml). This solution was added over a period of 15 min to a stirred slurry of sodium hydride (0.6 g, 25.1 mmol) in dry dimethyl sulfoxide (5 ml) in a nitrogen atmosphere and the stirring was continued for an additional 15 min with occasional cooling. Then 2,2′-bis(bromomethyl)diphenylmethane (1) (3.46 g, 9.78 mmol) in dry dimethyl sulfoxide (14 ml) was added to the above mixture over a period of 20 min with occasional cooling. The reaction mixture, after being stirred at room temperature overnight, was poured into water (250 ml). The resultant precipitate was collected by filtration and washed with water. The solid was added to benzene and after filtering off the insoluble brownish powder, the yellow solution was treated with decolourizing carbon. The benzene was removed to leave 1.92 g of a pale yellow solid melting at 174–180 °C. On recrystallization from an absolute ethanol – benzene mixture, a colourless solid melting at 183–185 °C was obtained in 50% yield (1.25 g). An analytical sample (mp 185.5–186.5 °C) was prepared; nmr 7.38 (8H, s, aromatic), 3.02–4.68 (6H, m, methylene protons at C-5, C-7, and C-12); ir ($CHCl_3$) 2256 cm^{-1} (CN). *Mol. wt.* (benzene) calcd: 258; found: 263; ms *m*/*e* 258 (M^+). *Anal.* calcd. for $C_{18}H_{14}N_2$: C 83.69, H 5.46, N 10.85; found: C 83.89, H 5.59, N 10.68.

Preparation of Compound ***1d***

The dinitrile **1***b* (1.01 g, 3.88 mmol) was added to a solution of sodium hydroxide (1.5 g) in ethylene glycol (30 ml). The mixture was refluxed for 3 h and then allowed to come to room temperature. The resulting solution was diluted with water and filtered. The precipitate which was formed on neutralization of the filtrate with concentrated hydrochloric acid was filtered off and washed with water. The resultant white solid **1***c* (0.76 g, 3.01 mmol), mp 168–170 °C, was obtained in 78% yield.

The monoacid **1***c* (0.76 g) was methylated with an excess of diazomethane in ether to give 0.76 g (95%) of a white powder, mp 98–99.5 °C. An analytical sample was prepared by recrystallization from ethanol–water to give fine white needles melting at 101–102 °C; ms *m*/*e* 266 (M^+). *Anal.* calcd. for $C_{18}H_{18}O_2$: C 81.17, H 6.81; found: C 80.63, H 6.95.

Preparation of Compound ***1e***

The methyl ester **1***d* (0.73 g, 2.74 mmol) was reduced by subjecting it to a 20 h reflux in a suspension of lithium aluminum hydride (0.27 g, 7.11 mmol) in ether. The product was worked-up in the usual manner to give 0.62 g (95%) of a white solid melting at 123.5–125 °C. An analytical sample was prepared by recrystallization from benzene – petroleum ether (bp 60–80 °C) to give a white solid with a melting point of 126.5–127 °C; nmr 6.90–7.55 (8H, m, aromatic), 2.35–4.55 (7H, m, methylenes at C-5, C-7, and C-12, and methine at C-6), 1.53 (1H, s, OH, exchanges with D_2O); ir ($CHCl_3$) 3435 cm^{-1} (OH bonded), 3609 cm^{-1} (OH free). *Anal.* calcd. for $C_{17}H_{18}O$: C 85.67, H 7.61; found: C 85.48, H 7.35.

Preparation of Compound ***1f***

The alcohol **1***e* (0.62 g, 2.60 mmol) was dissolved in pyridine and the flask was then packed in ice. After the addition of the tosyl chloride (0.60 g, 3.2 mmol) the ice was allowed to melt and the solution was stirred overnight. The reaction mixture was added to cold dilute sulfuric acid and a red gummy precipitate was obtained which was filtered and washed with water. The material was added to chloroform and filtered. On removal of the chloroform a clear orange oil was obtained (1.06 g). Attempts to crystallize the oil were unsuccessful.

Preparation of Compound ***1g***

To a stirred suspension of lithium aluminum hydride (0.23 g, 5.9 mmol) in anhydrous ether (10 ml), cooled in ice, was added 1.05 g (2.7 mmol) of the tosylate **1***f* in anhydrous ether (10 ml). The suspension was refluxed for 24 h. After destroying the excess of lithium aluminum hydride with aqueous sodium hydroxide (5%), more ether was added and the precipitate was filtered off. The ether was removed to leave a clear colourless oil (0.57 g). The oil was purified by dissolving it in chloroform and passing it through a small column of silica gel. The first 20 ml of eluent were collected. After removal of the chloroform solvent, a bulb-to-bulb distillation was carried out at 100 °C/0.01 torr to give 0.406 g (68%) of a viscous colourless oil; nmr 6.88–7.60 (8H, m, aromatic), 2.30–4.67 (6H, m, methylenes at C-5, C-7, and C-12), 1.50–2.10 (1H, br m, methine), 0.35–1.45 (3H, two broad peaks, methyl); ms *m*/*e* 222 (M^+). *Anal.* calcd. for $C_{17}H_{18}$: C 91.84, H, 8.16; found: C 91.66, H 8.13.

Preparation of the 6,12,12-Trideuterio Derivative of Compound ***1g***

The same procedure as described for the preparation of **1***g* was followed. Positions 6 and 12 were deuterated by the hydrolysis of compound **1***b* with the sodium salt of

ethylene glycol in ethylene glycol-d_2 and by neutralization of the resultant basic solution with deuterium chloride (10 *N*). The trideuterio derivative of **1***g* analyzed 91% d_3 and 9% d_2 by mass spectrometry; nmr 6.87–7.58 (8H, m, aromatic), 2.35–3.75 (4H, m, methylenes at C-5 and C-7), 0.33–1.45 (3H, two br peaks, methyl). *Anal.* calcd. for $C_{17}H_{15}D_3$: C 90.61, H and D 9.39; found: C 90.39, H and D 9.04.

Preparation of Compound **1***h*

The dinitrile **1***b* (0.60 g, 2.32 mmol) was added to a solution of sodium hydroxide (9 g) in water (27 ml) and the mixture was refluxed for 36 h.[5] The mixture was cooled and the white precipitate was filtered off and washed with water. The filtrate and the water washings were then combined and neutralized with concentrated sulfuric acid while cooling the mixture in ice. The white solid obtained upon filtration (0.42 g, 61%) melted to a clear liquid at 159–161 °C with the production of bubbles (CO_2). A recrystallization from ethanol–water did not improve the melting point. Nmr 6.94–7.61 (8H, m, aromatic), 5.1–6.9 (2H, broad peak, carboxylic hydrogens, exchanges with D_2O), 2.94–4.61 (6H, m, methylenes at C-5, C-7, C-12); in (Nujol) 1688 cm^{-1} (acid C=O). *Anal.* calcd. for $C_{18}H_{16}O_4$: C 72.96, H 5.44; found: C 73.17, H 5.63.

Preparation of Compound **1***i*

The diacid **1***h* (0.38 g) was methylated with an excess of diazomethane in ether to give a quantitative yield of a viscous clear oil. An analytical sample was obtained by a Späth distillation on a portion of the diester (125 °C/0.002 torr); nmr 6.81–7.54 (8H, m, aromatic), 3.75 (6H, s, ester methyls), 2.87–4.54 (6H, m, methylenes at C-5, C-7, and C-12); ir ($CHCl_3$) 1729 cm^{-1} (ester C=O). *Anal.* calcd. for $C_{20}H_{20}O_4$: C 74.05, H 6.22; found: C 74.20, H 6.19.

Preparation of Compound **1***j*

The diester **1***i* (1.93 g, 0.0060 mol) in ether (10 ml) was added to a suspension of 1.50 g lithium aluminum hydride in 20 ml of ether. The mixture was refluxed for 24 h. The excess hydride was destroyed by the addition of 5% aqueous sodium hydroxide, the solid was removed by filtration, the ether solution was dried, and the ether removed to leave 1.52 g (95%) of a white solid (mp 135–146 °C). An analytical sample was obtained by twice recrystallizing a portion from benzene to give a sample with mp 165–166 °C; nmr 6.87–7.56 (8H, m, aromatic), 2.63–4.53 (10H, m, methylenes at C-5, C-7, C-12, and of the CH_2OH groups), 1.77 (2H, s, OH, exchanges with D_2O); ir ($CHCl_3$) 3435 (OH bonded), 3606 cm^{-1} (OH free). *Anal.* calcd. for $C_{18}H_{20}O_2$: C 80.56, H 7.51; found: C 80.39, H 7.35.

Preparation of Compound **1***k*

When the diol **1***j* was treated with tosyl chloride at room temperature as described for the preparation of the monotosylate **1***f*, an incomplete reaction was obtained. A good yield (84%) was obtained when the reaction mixture was subjected to a 3 h reflux. An analytical sample (mp 156–158 °C) was obtained by recrystallization from methanol–water. *Anal.* calcd. for $C_{32}H_{32}O_6S_2$: C 66.65, H 5.59; found: C 66.49, H 5.66.

Preparation of Compound **1***l*

A mixture of the ditosylate **1***k* (0.20 g, 0.34 mmol) and lithium aluminum hydride in dry diethyl ether (10 ml) was heated to reflux for 2.5 days. The resultant mixture was worked-up as described for the preparation of compound **1***m*. The oily material obtained was purified by fractionation on a silica gel column using firstly chloroform (to elute impure dimethyl derivative off the column) followed by methanol (to elute the required alcohol). The viscous oil obtained was distilled in a Späth bulb at 115–130 °C/0.005 torr to give a white solid melting at 109–111 °C (41 mg, 48% yield); nmr 6.87–7.56 (8H, m, aromatic), 2.34–4.60 (8H, m, methylenes at C-5, C-7, C-12, and of the CH_2OH group), 1.78 (1H, s, OH, exchanges with D_2O), 0.38 and 1.30 (3H, two s, methyl); ir ($CHCl_3$) 3432 (OH bonded), 3610 cm^{-1} (OH free). *Anal.* calcd. for $C_{18}H_{20}O$: C 85.67, H 7.99; found: C 85.39, H 7.86.

Preparation of Compound **1***m*

A mixture of the ditosylate **1***k* (0.25 g, 0.42 mmol) and lithium aluminum hydride (0.10 g, 2.63 mmol) in dry tetrahydrofuran (10 ml) was heated to reflux for 5 days. The excess hydride was destroyed with aqueous sodium hydroxide (5%) and the precipitate filtered off. The solution was dried and the organic solvent was removed to leave an oil which contained some THF decomposition products. The mixture was chromatographed through silica gel using chloroform as the eluent. The first fraction (44 mg) contained the expected dimethyl derivative. This fraction was distilled in a Späth bulb at 75–95 °C/0.005 torr. The oil obtained was filtered through an aluminum oxide column and again distilled under reduced pressure; nmr 6.90–7.47 (8H, m, aromatic), 2.37–4.54 (6H, m, methylenes at C-5, C-7, and C-12), 0.40–1.43 (6H, two s of equal intensity and a smaller peak, methyl peaks).[6] ms *m/e* 236 (M^+). *Anal.* calcd. for $C_{18}H_{20}$: C 91.47, H 8.53; found: C 91.58, H 8.37.

Preparation of Compound **2***a*

To a solution of 5,10-dihydro-11*H*-dibenzo[*a*,*d*]cycloheptene-11-one (5.0 g, 24.3 mmol) in absolute ether (150 ml) was added boron trifluoride etherate (3.4 g, 24.0 mmol) (6). The solution was cooled to 0 °C and 480 ml of an alcohol free ether solution of diazomethane (146 mmol) were added with stirring over a period of 0.5 h. The solution was then filtered, washed with water, and then dried with $MgSO_4$. On removal of the ether, a yellowish oil was obtained. The mixture was fractionated on a column of Woelm neutral aluminum oxide (the eluent used was benzene) until all the eight-membered ring ketone had come off the column. Then the seven-membered ring ketone was eluted off the column with chloroform. The middle fractions which contained both ketones were recombined and refractionated in the same way on a new column of aluminum oxide. In this manner 1.47 g of impure compound **2***a* were obtained. It was

[5]An amide peak is present in the ir spectrum when the mixture is refluxed for 24 h, while a lower yield of diacid was obtained when refluxing for 48 h.

[6]The low temperature nmr of **1***l* has been completely interpreted (see footnote 2); however, some smaller details of the low temperature nmr of **1***m* have resisted interpretation. Thus at this time a small amount of isomerization during the reduction cannot be ruled out.

twice recrystallized from 95% ethanol to give 0.83 g of the ketone **2***a* melting at 150.5–151.0 °C. The net yield was 29%; nmr 7.00–7.42 (8H, m, aromatic), 4.00 (2H, s, methylene at C-12), 3.83 (4H, s, methylenes at C-5 and C-7); ir ($CHCl_3$) 1708 cm^{-1} (C=O). *Anal.* calcd. for $C_{16}H_{14}O$: C 86.45, H 6.35; found: C 86.35, H 6.47.

Preparation of Compound **1***n*

The ketone **2***a* (0.15 g, 0.68 mmol) was reduced using the Huang-Minlon modification of the Wolff–Kishner reaction (12). The white precipitate obtained after the work up of the reaction mixture weighed 0.13 g (88%) (mp 81.5–83.5 °C). An analytical sample (mp 86–86.5 °C) was prepared by recrystallization from 95% ethanol; nmr 6.99–7.69 (8H, m, aromatic), 3.56–4.70 (2H, broad peak, methylene at C-12), 2.68–3.50 (4H, br peak, methylenes at C-5 and C-7), 1.10–2.60 (2H, br peak, methylene at C-6); ms *m/e* 208 (M^+). *Anal.* calcd. for $C_{16}H_{16}$: C 92.26, H 7.74; found: C 92.14, H 7.90.

Preparation of Compound **1***o*

The method described by Steiner was followed (17*a*). All operations were carried out over nitrogen. Freshly distilled trimethylchlorosilane (0.50 g, 4.61 mmol) was added by syringe with gentle agitation to deuterium oxide (0.07 g, 3.80 mmol) in dry tetrahydrofuran (3 ml) in a dropping funnel. After 5 min, the resulting deuterium chloride solution was added over a period of 20 min to a stirred, ice cooled, mixture of zinc dust (0.51 g) and the ketone **2***a* (0.20 g, 0.91 mmol) in dry tetrahydrofuran (5 ml). After 1 h, a further 200 mg of zinc dust were added and the mixture was allowed to stir at room temperature overnight.

After an addition of ether (40 ml), the mixture was filtered and then washed with ice water and aqueous sodium carbonate. The ether solution was dried and the solvent removed to leave a sticky solid. This solid was subjected to an aluminum oxide column purification. The first 20 ml of benzene eluent contained 0.137 g of a white solid melting at 62–70 °C. The impure solid was recrystallized three times from 95% ethanol to give a white solid (63 mg, 33%) melting at 86–86.5 °C; nmr 7.00–7.60 (8H, m, aromatic), 3.58–4.56 (2H, br peak, methylene at C-12), 3.08 (4H, br s, methylenes at C-5 and C-7); ms 11% d_1, 85% d_2 and 4.5% d_3.

Preparation of Compound **2***b*

Compound **2***b* was prepared according to the procedure of Corey and co-workers (18). Sodium hydride (0.35 g, freed from mineral oil with *n*-pentane) and dimethyl sulfoxide (20 ml) were heated at 80 °C for 1 h under nitrogen. With a syringe, 2 ml of this solution (1.45 mmol of methylsulfinyl carbanion) was placed in a flask filled with nitrogen. The solution was cooled in an ice-water bath and methyltriphenylphosphonium bromide (0.52 g, 1.45 mmol) in warm dimethyl sulfoxide (4 ml) was added. The resulting mixture was stirred at room temperature for 1 h and then the ketone (0.303 g, 1.36 mmol) was added. After being stirred overnight at room temperature, the solution was poured into water and the aqueous solution was extracted twice with *n*-pentane. The pentane extracts were washed with water and dried over anhydrous magnesium sulfate. Upon removal of the solvent, 0.20 g of a solid was obtained which was shown by nmr to consist of 50% starting material and 50% of the desired product. The olefin (0.097 g, mp 87–88 °C, net yield 49%) was obtained free of the ketone by dissolving the mixture in benzene and filtering through a column of alumina. The retained ketone can be eluted with chloroform. The analytical sample was obtained by recrystallization from 95% ethanol to give 79 mg of white needles (mp 89–89.5 °C); nmr 6.90–7.48 (8H, m, aromatic), 4.97 (2H, s, olefinic H), 4.07 (2H, s, methylene at C-12), 3.65 (4H, s, methylenes at C-5 and C-7); ir ($CHCl_3$) 1638, 894 cm^{-1} ($CR_2{=}CH_2$); ms *m/e* 220 (M^+). *Anal.* calcd. for $C_{17}H_{16}$: C 92.58, H 7.32; found: C 92.51, H 7.42.

Received September 20, 1976

H. S. RAY, N. KH. TUMANOVA, and S. N. FLENGAS. Can. J. Chem. **55**, 656 (1977).

The oscillating planar solid microelectrode developed previously (1) has been used to investigate the reduction of the ions Co^{2+}, Ni^{2+}, Pb^{2+}, Cd^{2+}, Cu^{+}, Ag^{+}, as well as of the redox system Fe^{2+}/Fe^{3+} in solvent melts containing various amounts of CsCl and $AlCl_3$.

Similarly, the reductions of the ions Co^{2+}, Ni^{2+}, and Cd^{2+} as well as Zr^{4+} have been investigated in solvent melts containing various amounts of CsCl and $ZnCl_2$.

Well-defined limiting currents have been obtained in all systems. These were found to vary linearly with the concentration of the solute. From the slopes of E *vs.* $\log (i_L - i)$, or $\log i/(i_L - i)$, the electrode reactions were established in most cases. The analysis of the results for Zr^{4+} indicates a three step reduction process.

H. S. RAY, N. KH. TUMANOVA et S. N. FLENGAS. Can. J. Chem. **55**, 656 (1977).

On a utilisé la microélectrode solide, planaire et oscillante qui avait été développée antérieurement (1) pour étudier la réduction des ions Co^{2+}, Ni^{2+}, Pb^{2+}, Cd^{2+}, Cu^{+}, Ag^{+}, de même que le système redox Fe^{2+}/Fe^{3+}, dans des milieux fondus contenant diverses quantités de CsCl et de $AlCl_3$.

De la même manière on a étudié les réductions des ions Co^{2+}, Ni^{2+} et Cd^{2+} de même que Zr^{4+} dans des milieux fondus contenant diverses quantités de CsCl et de $ZnCl_2$.

On a pu obtenir des courants limites bien définis dans tous les systèmes. On a trouvé que ceux-ci varient d'une façon linéaire avec les concentrations du soluté. A partir des pentes de E en fonction de $\log (i_L - i)$ ou de $\log i/(i_L - i)$, on a pu établir les réactions d'électrode dans la plupart des cas. L'analyse des résultats obtenus avec Zr^{4+} indique que le processus de réduction se fait en trois étapes.

[Traduit par le journal]

Introduction

Previous work from this laboratory has resulted in the development of an oscillating planar solid microelectrode which was found to be suitable for voltammetric studies in aqueous and fused salt solutions (1).

This microelectrode consisted of a platinum or tungsten wire flame-sealed in a Pyrex capillary tube ground flat at the lower end. The electrodes were vibrated mechanically.

The limiting currents i_L obtained were well defined and reproducible and were found to be proportional to the surface area of the metal electrode disc A in cm^2, the frequency ν given as the number of oscillations per minute and the concentration of the electroreducible species i, X_i given as a mole fraction. The empirical equation relating these variables was given as

$$[1] \qquad i_L = (K_1 + K_2\nu)AX_i$$

where K_1 and K_2 are constants dependent upon temperature and the nature of the ionic species present in solution.

The electrode was used successfully at room temperature with aqueous solutions and in molten alkali nitrate electrolytes at temperatures up to 330 °C. With the molten alkali nitrate solvent, results were obtained for Ag^{+}, which is the only ion reduced at potentials below the decomposition potential of the supporting electrolyte, which is −0.5 V.

The technique was also applied to chloride melts containing AgCl dissolved in the equimolar mixture of KCl and NaCl at about 700 °C. It was found that the voltammetric curves were not well defined and exhibited unusually large residual currents. In addition, the limiting currents could not be measured with the automatically driven polarograph due to kinetic factors and had to be measured at fixed values

TABLE 1. Composition of solvent melts

CsCl (mol %)	$AlCl_3$ (mol %)	$ZnCl_2$ (mol %)	Melting point (°C)	Comments	E_{dec}* (V)
54	46	—	344	Eutectic composition in the $CsCl$–$CsAlCl_4$ subsystem	−1.55
50	50	—	377	Congruently melting compound	−1.55
41.6	58.4	—	148	Eutectic composition in the $CsAlCl_4$–$AlCl_3$ subsystem	−1.55
37.74	—	52.26	285	Compound $CsZn_2Cl_5$ and excess CsCl	−1.35
33.33	—	66.67	294	Compound $CsZn_2Cl_5$	−1.20
30.21	—	69.79	290	Compound $CsZn_2Cl_5$ and excess $ZnCl_2$	−1.30

**Versus* the Pt–foil reference electrode. Decomposition potentials versus a graphite reference electrode are of the same order of magnitude if the graphite electrode is saturated with chlorine by pre-electrolysis. Otherwise its potentials are ill-defined.

of applied potentials after allowing sufficient time for equilibrium.

In the present work the technique has been applied to dilute solutions of a large number of metal chlorides dissolved in solvent melts containing CsCl with the covalently bonded $AlCl_3$ or $ZnCl_2$.

Pure $AlCl_3$ and $ZnCl_2$ in the solid and molten states are poor electrical conductors and highly volatile. The boiling points (2) for $AlCl_3$ and $ZnCl_2$ are, respectively, 187 and 732 °C. However, solutions of these salts in molten alkali chlorides are ionic conductors and show a pronounced thermal stability which increases as the size of the alkali metal cation increases from Li^+ to Cs^+. Particularly, the solutions of $AlCl_3$ and of $ZnCl_2$ in CsCl exhibit very low vapour pressures. The increased thermodynamic stability of solutions containing CsCl is related to the presence of congruently melting compounds which appear in the phase diagrams for the systems $AlCl_3$–CsCl (3) and $ZnCl_2$–CsCl (4). Thus, in the former, the phase diagram shows the congruent compound $CsAlCl_4$ melting at 377 °C and two adjacent compositions melting at 344 and 148 °C, respectively. Similarly, the $ZnCl_2$–CsCl phase diagram indicates, among others, the compound $CsZn_2Cl_5$, which melts at 284 °C and has two adjacent eutectic compositions melting at 268 and 263 °C, respectively.

The solvent melts which have been used as supporting electrolytes for the present study involve compositions rich in CsCl, the chemical compounds $CsAlCl_4$ and $CsZn_2Cl_5$, and compositions rich in $ZnCl_2$ or $AlCl_3$. These compositions were chosen in order to observe possible solvent effects on the reduction of metal chloride cations.

The metal chloride solutes investigated include $NiCl_2$, $CoCl_2$, $CdCl_2$, $PbCl_2$, AgCl, CuCl, and the redox systems containing $FeCl_2$ and $FeCl_3$, and $ZrCl_4$.

Experimental

The anhydrous compounds $PbCl_2$, $CdCl_2$, CuCl, AgCl, $ZnCl_2$, $FeCl_3$, $NiCl_2$ as well as CsCl were all of analytical reagent grade. $AlCl_3$, $CoCl_2$, and $FeCl_2$ were Puratex reagents of 99.9% purity.

All reagents were treated at 100 °C with anhydrous gaseous HCl, degassed under vacuum and stored in desiccators. $ZrCl_4$ was added as the compound Cs_2ZrCl_6 prepared in this laboratory (5).

The $AlCl_3$–CsCl and the $ZnCl_2$–CsCl mixtures were prepared in closed Pyrex tubes by mixing together the appropriate amounts of each component and were further purified by pre-electrolysis between tungsten electrodes at 1.2 V for about 1 h and/or by bubbling chlorine gas for 1 h through the melts. The exact compositions of the various solvent melts are given in Table 1.

Solutions of the various metal chlorides in these melts were made by adding the appropriate amounts to the molten solvent through a feeding tube attached to the cell.

The voltammetric cells were made out of Pyrex glass and were operated under an inert atmosphere of argon gas. The cell design is shown in Fig. 1. The oscillating indicator electrode consisted of a tungsten wire of 0.5 mm diameter flame-sealed in a Pyrex capillary tube having an outside diameter of 0.5 cm. The tip of this electrode was ground flat until its cross-section consisted of two concentric discs, *i.e.* the tungsten wire surrounded by ground Pyrex glass.

The reference electrode was a platinum foil with surface area of about 8 cm^2. A third auxillary electrode was also present in the cell and consisted of a second platinum foil. The function of the latter was to make possible the electrochemical removal of the metallic deposits from the indicator electrode after each run. To this end the indicator electrode was made anodic and all deposits could be transferred by electrolysis to the auxillary electrode acting as a cathode. For best results, however, it was found necessary to remove the indicator electrode and polish its surface prior to each experiment.

The mechanical oscillator consisted of an electrically driven cam and piston device capable of creating a harmonic motion having an amplitude of 1 cm at various

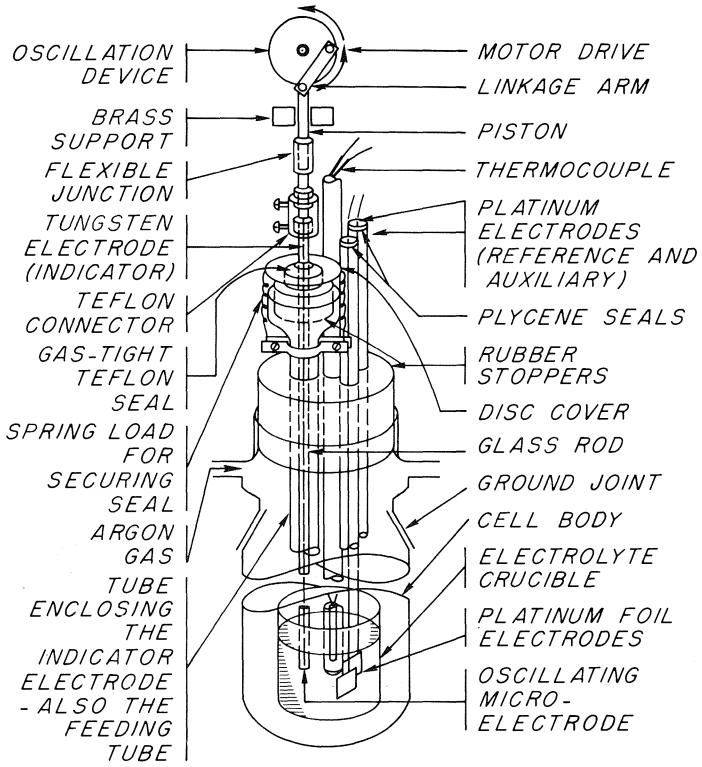

FIG. 1. Schematic diagram of the voltammetric cell.

frequencies between 30 and 200 opm. The experiments were conducted at 85 or 180 opm. As opposed to its behaviour in nitrate melts, the tungsten microelectrode did not react with chloride melts. The polarograph was a Fisher electropode, model 65, fitted with a recorder. The potential was applied at a rate of 200 mV per min.

All limiting currents were measured from the recorded voltammetric curves using the 'three tangents method'.

Results

Some typical voltammetric waves for the reduction of the cations of Ni^{2+}, Co^{2+}, Ag^{+}, Cu^{+}, and of the Fe^{2+}/Fe^{3+} redox system in the three solvent melts containing CsCl and $AlCl_3$, are given in Fig. 2.

These curves have been traced from the actual *i–v* curves recorded by the polarograph. It should be noted that for the purpose of presentation the reduction curves have been shifted arbitrarily along the current axis. The current scale indicated on the graph is common for all the metal cations and allows the exact calculation of the limiting currents for a given reduction process. However, the potential scale is exact. The order of these curves indicates the relative reducibility of the metal cations. It should also be noted that the mole fractions of the ions are all comparable and of the order of 10^{-3}, as shown.

The curves for the reduction of Ni^{2+}, Co^{2+}, Cu^{+}, Ag^{+}, and for the system Fe^{2+}/Fe^{3+} are smooth and indicate well defined limiting current plateaus. The corresponding curves for Pb^{2+} and Cd^{2+} indicate pronounced maxima. These are the only metals which at 400 °C deposit at the microelectrode in the molten state.

The concentration dependence of the limiting currents at a frequency of 85 opm is shown in Fig. 3. It is seen that all limiting currents are proportional to the mole fraction of the metal chloride in solution. For the redox system containing $FeCl_2$ and $FeCl_3$, only one reduction wave could be seen at about -1.05 V.

Figure 4 shows the shape of the reduction curves and the concentration dependence of the limiting current for Co^{2+} obtained at the much higher oscillation frequency of 180 opm. Some typical voltammetric curves obtained at the same higher frequency for the reduction of Ni^{2+}, Co^{2+}, and Cd^{2+} dissolved in the solvent melts containing CsCl and $ZnCl_2$ are given in Fig. 5.

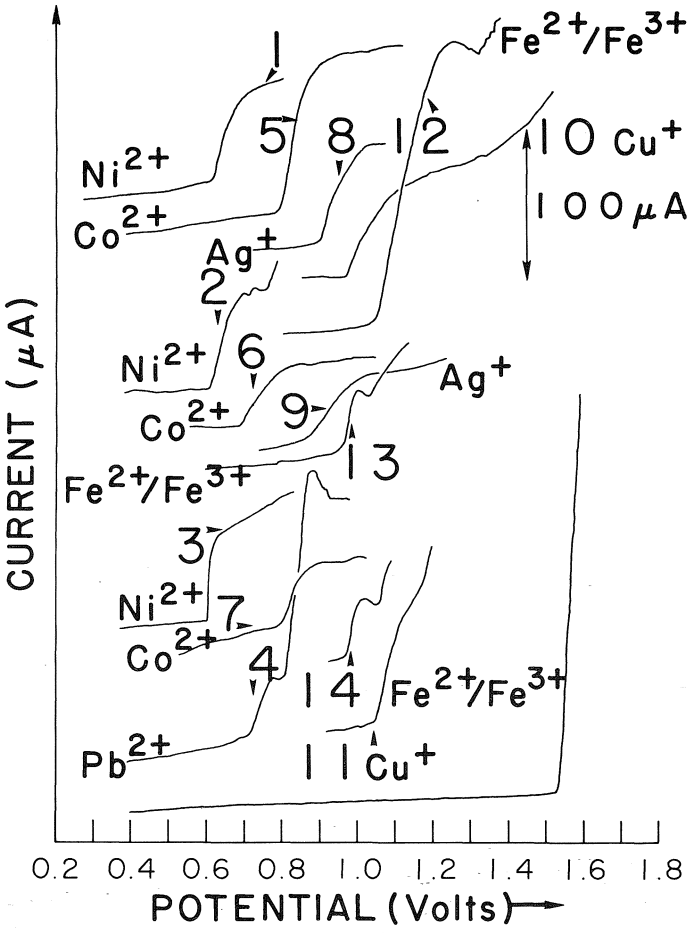

FIG. 2. Typical voltammetric waves for the reduction of metal cations dissolved in the $AlCl_3$–CsCl solvent melts. Curve (*1*) $NiCl_2$ dissolved in the CsCl–$CsAlCl_4$ melt at $X_{NiCl_2} = 5.25 \times 10^{-3}$, $t = 400$ °C. Curve (*10*) CuCl dissolved in the CsCl–$CsAlCl_4$ solvent melt at $X_{CuCl} = 8.6 \times 10^{-3}$, $t = 400$ °C. Curve (*11*) CuCl dissolved in $CsAlCl_4$–$AlCl_3$ solvent melt at $X_{CuCl} = 7.0 \times 10^{-3}$, $t = 200$ °C. Curve (*12*) $FeCl_2$ and $FeCl_3$ dissolved in the CsCl–$CsAlCl_4$ solvent melt at $X_{FeCl_2} = 5.2 \times 10^{-3}$ and $X_{FeCl_3} = 5.36 \times 10^{-3}$, $t = 400$ °C. Curve (*13*) $FeCl_2$ and $FeCl_3$ dissolved in the $CsAlCl_4$ solvent melt at $X_{FeCl_2} = 1.5 \times 10^{-3}$ and $X_{FeCl_3} = 1.5 \times 10^{-3}$, $t = 400$ °C. Curve (*14*) $FeCl_2$ and $FeCl_3$ dissolved in the $CsAlCl_4$–$AlCl_3$ solvent melt at $X_{FeCl_2} = 1.5 \times 10^{-3}$, $X_{FeCl_3} = 1.5 \times 10^{-3}$, $t = 200$ °C. Curve (*15*) Decomposition curve for the solvent melt CsCl–$CsAlCl_4$ after purification and pre-electrolysis, $t = 400$ °C. Current scale shown on diagram is common for all curves. Oscillation frequency was 85 opm. The reference electrode was a Pt foil.

These curves traced from the original automatic recordings of the polarograph also indicate well-defined limiting currents.

With regard to the behaviour of Cd^{2+} ions at low concentrations only one reduction wave could be recorded (curve *5*). However, with more concentrated solutions (curve *6*), a second reduction wave was evident. This second wave could not be seen at temperatures higher than 400 °C.

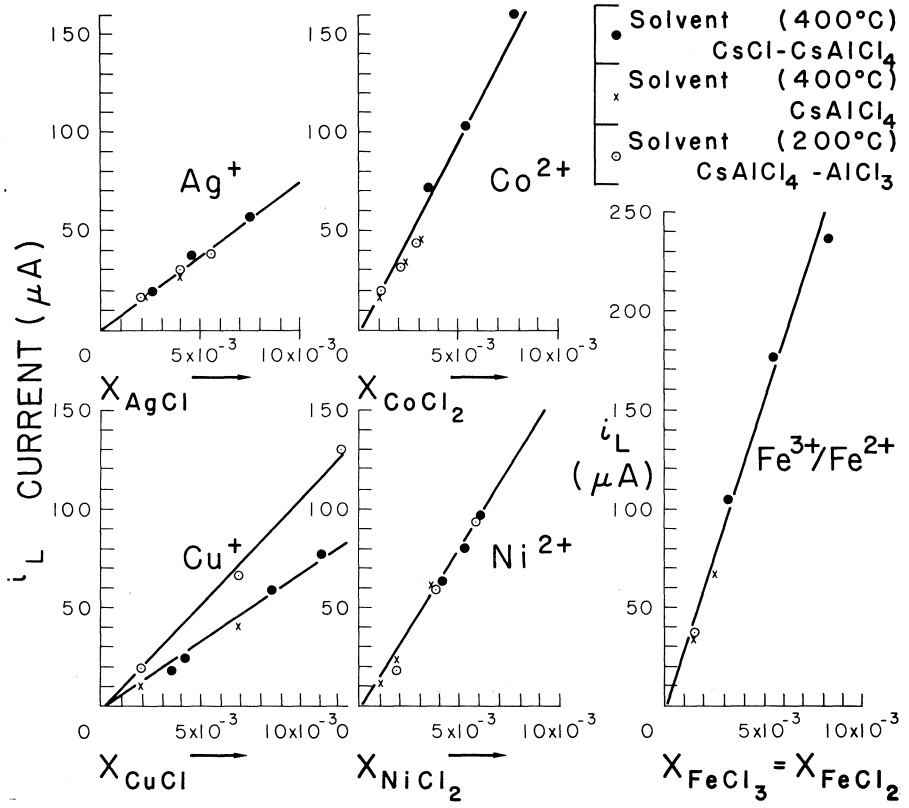

FIG. 3. Concentration dependence of the limiting currents for the reduction of various metal cations in the $AlCl_3$–CsCl solvent melts at an oscillation frequency of 85 opm.

The concentration dependence of the limiting currents at 350 °C is shown in Fig. 6.

In all cases the limiting currents are proportional to the mole fraction of the solute species. For the Cd^{2+} ions the plot is based on the limiting currents representing the first wave only.

The concentration dependence of the limiting currents, given in Fig. 3, shows that the slopes of the curves for the Ag^+ and Cu^+ ions are similar, except for Cu^+ dissolved in the $CsAlCl_4$–$AlCl_3$ solvent at 200 °C which indicates abnormally higher limiting currents. Similarly, Co^{2+} and Ni^{2+} show identical concentration dependence, the magnitude of a limiting current at a given concentration being almost double that for monovalent ions.

This relationship is to be expected since all mass transport expressions for limiting currents indicate, among others, a direct proportionality between the limiting current and the valence of the electroreducible species.

However, regarding the redox system Fe^{2+}/Fe^{3+}, the limiting current is very high, probably indicating a high diffusion rate for the small Fe^{3+} cation. It should be noted that for the redox reaction $Fe^{3+} \rightarrow Fe^{2+}$, the reaction represents a one electron electrode process and its limiting current is determined by the steady-state mass transport of Fe^{3+} from the bulk phase to the electrode-solution interface.

In Fig. 6, the slopes for the concentration dependence of the limiting currents for the reduction of divalent cations are also of similar magnitude.

The reduction of Zr^{4+} ions, added to a $ZnCl_2$–CsCl melt as the solid compound Cs_2ZrCl_6, has also been investigated. The system is of interest because zirconium has been reported to exist in four multiple oxidation states, namely, Zr^{4+}, Zr^{3+}, Zr^{2+}, and Zr^+ (6).

The reduction path of Zr^{4+} ions on a solid electrode is also related to the mechanism of electrodeposition of zirconium from fused chloride melts.

Figure 7*a* shows three voltammetric curves for the reduction of Zr^{4+} dissolved in the

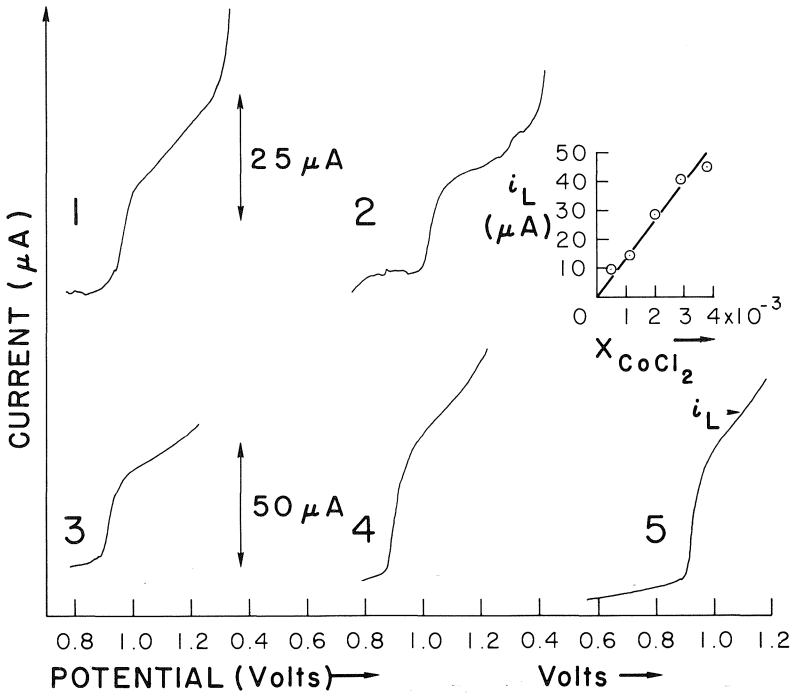

FIG. 4. Voltammetric waves for the reduction of Co^{2+}, dissolved in the CsCl–$CsAlCl_4$ solvent melt obtained at the higher oscillation frequency of 180 opm at 418 °C. Curve (*1*) Co^{2+} at $X_{CoCl_2} = 0.45 \times 10^{-3}$. Curve (*2*) Co^{2+} at $X_{CoCl_2} = 1.10 \times 10^{-3}$. Curve (*3*) Co^{2+} at $X_{CoCl_2} = 1.95 \times 10^{-3}$. Curve (*4*) Co^{2+} at $X_{CoCl_2} = 2.76 \times 10^{-3}$. Curve (*5*) Co^{2+} at $X_{CoCl_2} = 3.72 \times 10^{-3}$. Graph in upper right hand corner shows plots of i_L *vs.* X_{CoCl_2}. The reference electrode was a platinum foil.

$CsZn_2Cl_3$ melt. It should be noted that only one reduction wave appears before the breaking down of the supporting electrolyte. The reduction begins at about −1.02 V and the concentration dependence of the limiting current, shown in the upper left hand corner of the same figure, is linear.

A melt containing Zr^{4+} at a mole fraction, $X_{ZrCl_4} = 4.47 \times 10^{-3}$, after a period of about 70 h and repeated voltammetric runs began to indicate multiple reduction steps. This behaviour became more pronounced when the melt temperature was first increased to about 450 °C and then reduced to temperatures below 350 °C. The multiple reduction steps became even more evident when a run was repeated without polishing the indicator electrode surface. Figure 7*b* shows two typical voltammetric curves from among several similar recordings. They show three distinct reduction steps at about −0.85, −0.92, and −1.2 V.

The temperature dependence of the limiting current was also investigated in several cases. Figure 8 shows the temperature dependence of the limiting current obtained for a solution of $CdCl_2$ in $CsZn_2Cl_5$. The plot indicates that the dependence is exponential. The slope of the straight line represents an activation energy of about 9 kcal/mol which compares well with the activation energy for the diffusion of Cd^{2+} in some molten salts given by Delimarskii and Markov (7). It should be noted, however, that the limiting current observed in the present investigation is not necessarily controlled by diffusion alone and should also be influenced by viscosity variations with temperature.

Discussion

For metals depositing on tungsten at low temperatures, it is reasonable to assume that surface alloys do not form, and hence, the activity of the metal deposit should be unity.

For a cathodic reduction,

$$[2] \qquad M^{z+} + Ze^- \rightarrow M_{(a_M)}$$

where Z is the valence of the cation, the relationship between the applied potential and the corresponding voltammetric current on a solid

Curve *5* was obtained against a graphite rod reference electrode saturated with chlorine by pre-electrolysis.

microelectrode should be similar to that derived by Kolthoff and Lingane (8) for the reduction of metal cations at the dropping mercury electrode, when the metal deposited is insoluble in mercury. Taking into account the expected difference in the value for the constant term, this expression is:

$$[3] \quad E_{applied} = \text{Constant} + \frac{RT}{ZF}\ln (i_L - i)$$

where i_L is the limiting current and i is the current along the rising part of the wave.

The derivation of this expression was based on the assumption that the electrode reaction is totally reversible and that the magnitude of the current is defined by the cathodic process at the microelectrode which is controlled by mass transfer only.

The so-called half-wave potential $E_{1/2}$ at the mid-point of the rising voltammetric curve is given as

$$[4] \quad E_{1/2} = \text{Constant} + \frac{RT}{ZF}\ln \frac{i_L}{2}$$

Since i_L is concentration dependent, $E_{1/2}$ also changes with the concentration of the electroreducible specie in solution. Therefore, $E_{1/2}$ is not as significant a quantity in the present case as in aqueous polarography.

Similarly, considering an electrode process which involves an intermediate reduction of a cationic species from one oxidation state to another, such as

$$[5] \quad M^{Z+} + ne^- \rightarrow M^{(Z-n)+}$$

the equation of the voltammetric wave would depend on whether or not any of the reduced form is originally present in the solution.

If none of the reduced form is originally present, then the equation for the wave derived by Kolthoff and Lingane (8) should also be applicable to a solid microelectrode. The equation is given as

$$[6] \quad E = \text{Constant} - \frac{RT}{ZF}\ln \frac{i}{i_L - i}$$

When the reduced form is originally present in solution, the equation for the wave becomes

$$[7] \quad E = \text{Constant} - \frac{RT}{ZF}\ln \frac{i - (i_L)_A}{(i_L)_C - i}$$

where $(i_L)_A$ and $(i_L)_C$ are, respectively, the anodic and cathodic components of the voltammetric curve.

When the free energy for the anodic reaction is sufficiently positive then the reduction curve does not contain an anodic component even at very low concentration ratios of X(red)/X(oxid). Thus $(i_L)_A = 0$, and eq. 7 reduces to eq. 6. Similar expressions for solid microelectrodes have been given by Delimarskii and Markov (7).

Figure 9 shows plots of E *vs.* log $(i_L - i)$ for the voltammetric curves shown in Fig. 2, except

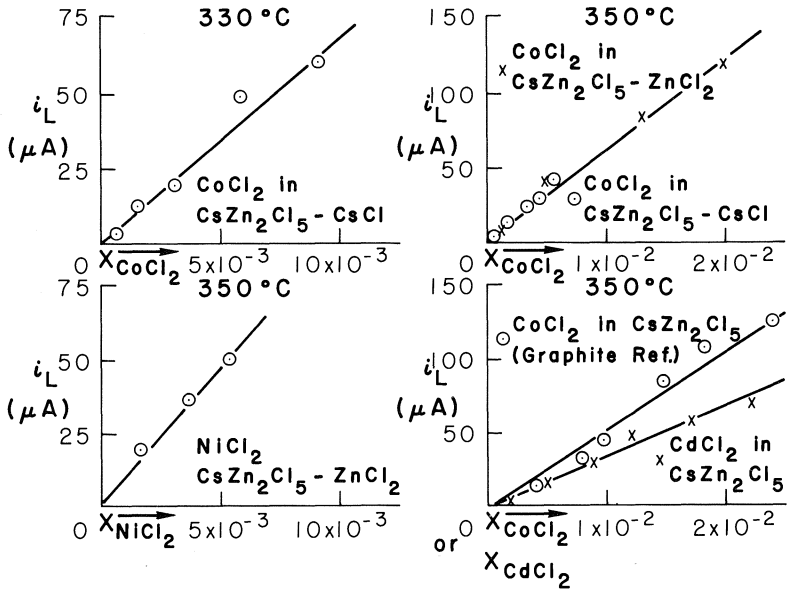

FIG. 6. Concentration dependence of limiting currents for Co^{2+}, Ni^{2+}, and Cd^{2+} ions dissolved in the CsCl–$ZnCl_2$ melts. Frequency of oscillations is common for all curves at 180 opm. Curves *1*, *2*, *3*, *4a* have been obtained against a Pt foil reference. Curve *4b* represents measurements against the graphite reference electrode.

for the reduction of Cd^{2+} and Pb^{2+} which exhibited maxima. It is evident that the linearity predicted by eq. 3 is followed in all cases. The graph also contains lines indicating theoretical slopes expected for one- and two-electron reduction processes, respectively.

It is seen that the reduction for Cu^+ and Ag^+ ions is clearly a one-electron process, while that for Co^{2+} is a two-electron process. The remaining curves indicate small deviations from the expected theoretical slopes, indicating possible irreversibility in the reduction process involved.

Similarly, Fig. 10 shows the E *vs.* log $(i_L - i)$ plots of three curves given in Fig. 5 for cations dissolved in the CsCl–$ZnCl_2$ melts.

Again, the reaction for Co^{2+} is distinctly a reversible two-electron reduction process. However, the reduction for Ni^{2+} is anomalous and shows a one-electron slope.

Figure 11 represents the analysis of multiple reduction waves obtained in the CsCl–$ZnCl_2$ solvent melt.

The corresponding voltammetric curves for the reduction of Cd^{2+} and Zr^{4+} are given in Figs. 5 and 7, and that for the redox system Fe^{3+}/Fe^{2+} is given in Fig. 2.

The graph contains plots of E *vs.* log $i/(i_L - i)$, as required by the Kolthoff–Lingane eq. 6 for reduction waves indicating multiple steps.

The redox system Fe^{3+}/Fe^{2+} showed one voltammetric curve and the plot of E *vs.* log $i/(i_L - i)$ is linear. The slope of the curve is that required for a reversible one-electron process and accordingly the reduction wave represents the reaction

$$[8] \qquad Fe^{3+} + e^- \rightarrow Fe^{2+}$$

For the first reduction wave seen in the Cd^{2+} voltammetric curve, the E *vs.* log $i/(i_L - i)$ is linear, but the slope is lower than that required for a one-electron process corresponding to a monovalent Cd^+. The second wave is not linear and cannot be defined.

For the multiple reduction steps seen in the reduction of Zr^{4+}, the first wave yields a well-defined linear plot with a two-electron slope, and the second wave indicates a one-electron slope. Accordingly, these waves represent the reduction processes

$$[9] \qquad Zr^{4+} + 2e^- \rightarrow Zr^{2+}$$

and

$$[10] \qquad Zr^{2+} + e^- \rightarrow Zr^+$$

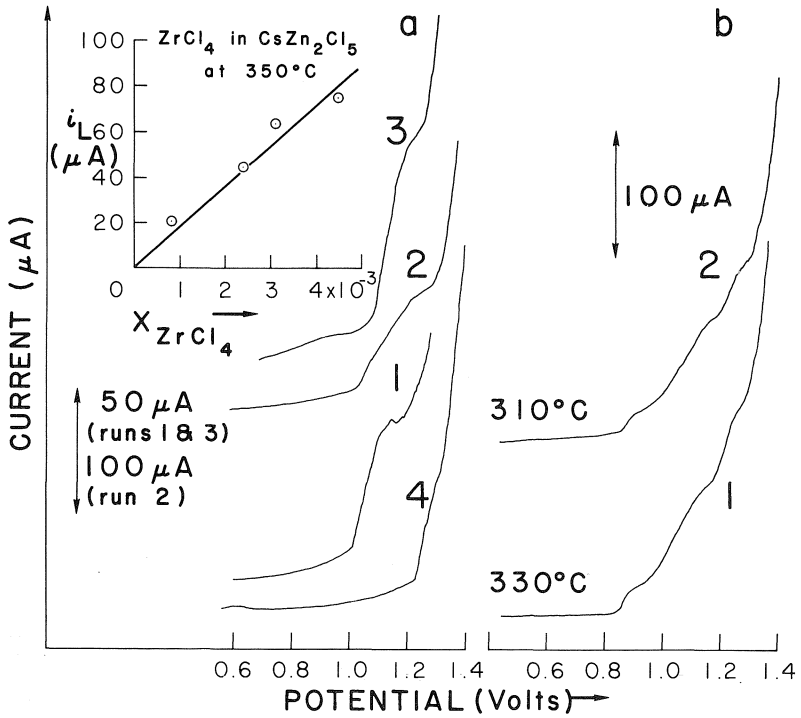

FIG. 7. Voltammetric curves for the reduction of Zr^{4+} added (as Cs_2ZrCl_6) in the $CsZn_2Cl_3$ solvent melt obtained at an oscillation frequency of 180 opm, $t = 350$ °C. Curve (*a1*) Zr^{4+} at $X_{ZrCl_4} = 2.44 \times 10^{-3}$. Curve (*a2*) Zr^{4+} at $X_{ZrCl_4} = 3.08 \times 10^{-3}$. Curve (*a3*) Zr^{4+} at $X_{ZrCl_4} = 4.47 \times 10^{-3}$. Curve (*a4*) Decomposition curve for solvent $CsZn_2Cl_3$. Plot in the upper left hand corner of Fig. 7*a* shows the concentration dependence of the limiting currents (voltammetric curve for first point not included in Fig. 7*a*). Curve (*b1*) Zr^{4+} at $X_{ZrCl_4} = 4.47 \times 10^{-3}$, $t = 330$ °C. Curve (*b2*) Zr^{4+} at $X_{ZrCl_4} = 4.47 \times 10^{-3}$, $t = 310$ °C. All measurements were against the Pt foil reference electrode at 180 opm.

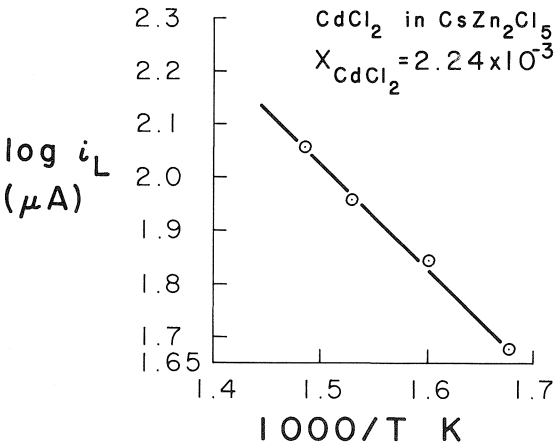

FIG. 8. Dependence of the limiting currents on temperature for a solution of $CdCl_2$ in $CsZn_2Cl_3$ melt at 180 opm. $X_{CdCl_2} = 2.24 \times 10^{-3}$.

The plot for the third wave shows slight deviations from linearity, and its average slope could be taken as representing a one-electron reduction process. Therefore, this wave could indicate the reduction to metal according to

$$[11] \qquad Zr^+ + e^- \rightarrow Zr$$

It should be noted that monovalent Zr^+ has been found in ZrCl (9) which is a chemically stable compound even at temperatures as high as 1000 °C.

These results seem to indicate that the intermediate reduction of Zr^{4+} to Zr^{3+} is not taking place in these melts. It has been shown by Copley and Shelton (10) that pure $ZrCl_3$ disproportionates to a lower valence state at temperatures above 310 °C.

It should be noted that the decomposition

voltages shown by the pure solvent electrolytes are different from those seen in voltammetric curves measured in the presence of solute metal cations. This variation may be attributed to the effect of coating the tungsten surface with minute amounts of the metal deposit during electrolysis.

The decomposition potentials for the pure solvent melts used in this study are given in Table 1.

Since half-wave potentials are not too significant in the present system and furthermore, since deposition on a solid microelectrode may proceed irreversibly, it is more meaningful to tabulate the initial deposition potentials for the electrode reactions investigated.

Table 2 shows the deposition potentials for cations in the various solvents investigated measured against the platinum reference electrode at solute mole fraction of 5×10^{-3}.

It should be noted that potential measurements taken against the graphite reference electrode saturated with chlorine did not indicate any appreciable differences from the values shown in Table 2.

Since the graphite electrode is definitely a chlorine electrode, it seems that the platinum reference electrode behaves like a chlorine electrode and that platinum dissolution does not take place. Accordingly, the possible anodic reaction at the platinum and the graphite reference electrodes should be written as

$$[12] \qquad Cl^- \rightarrow \tfrac{1}{2}Cl_2 + e^-$$

A comparison between the decomposition potentials in the various solvent melts at the common mole fraction for the solute ions of 5×10^{-3} shows that in the $AlCl_3$–CsCl solvent the lowest deposition potentials occur with the compound $CsAlCl_4$. With melts which contain $CsAlCl_4$ and an excess of either CsCl or $AlCl_3$ the potentials are slightly higher, indicating that the metal cations are at a lower activity level possibly due to complex formation. This effect, however, was not investigated in the $ZnCl_2$–CsCl melts.

Conclusions

This study has shown that the oscillating tungsten microelectrode is a very useful tool for investigating the electrochemical reduction of metal cations dissolved in chloride solvent melts in the temperature range 200 to 420 °C.

The voltammetric waves for Ag^+, Cu^+, Ni^{2+}, Co^{2+}, and for the redox system Fe^{2+}/Fe^{3+} consist of one well-defined reduction step. All the limiting currents are proportional to the mole fraction of the solute, indicating that the limiting currents are defined by steady-state mass transport.

For systems like Pb^{2+} and Cd^{2+} in solution in the CsCl–$AlCl_3$ melts, the voltammetric curves show two reduction waves with pronounced maxima. Cd^{2+} dissolved in a CsCl–$ZnCl_2$ melt also showed two waves but no maximum.

The reduction of Zr^{4+} ions at low concentrations shows one reduction wave only. However, at higher concentrations three well-defined waves are evident.

Regarding the choice of solvent melts used in this study, they are characterized mainly by CsCl as the common component and contained either $AlCl_3$ or $ZnCl_2$ in various proportions as the second component.

$AlCl_3$ and $ZnCl_2$ are useful in that they reduce the melting points of the solvent melts to temperatures as low as 200 °C. In addition they have a definite effect in reducing the residual currents which have been found to be very high in pure alkali chloride melts. The CsCl component in these melts has the additional advantage of reducing the escaping tendency of the volatile compounds $ZnCl_2$ and $AlCl_3$, due to strong chemical interactions in the liquid state. From among the various solvent melts investigated, those containing an excess of CsCl, like the CsCl–$CsAlCl_4$ and CsCl–$CsZn_2Cl_5$, appear to be the most stable supporting electrolytes.

It is of interest to note that the limiting currents in the CsCl–$AlCl_3$ and CsCl–$ZnCl_2$ solvent melts are of comparable magnitude for a given solute cation at the same concentration and temperature. A slight shift in the deposition potentials could be seen by comparing the voltammetric curves representing the various solvent melts for the reduction of a given cation, but the magnitude of the change is not sufficient to suggest the presence of different complex species in these melts. Thus, the deposition potentials of a given cation in the three melts having compositions corresponding to CsCl–$CsAlCl_4$, $CsAlCl_4$, and $CsAlCl_4$–$AlCl_3$, respectively, would be expected to be higher in the first melt containing an excess of CsCl, and hence an excess of 'free' chloride ions. Since this was not observed it should be concluded that the congruent compounds $CsAlCl_4$ and $CsZn_2Cl_5$ in the

molten state are sufficiently dissociated to provide an abundance of 'free' chloride ions in all these solvents.

Analysis of the shape of the voltammetric reduction curves following the Kolthoff and Lingane (8) relationships yielded linear plots.

The reduction of Ag^+, Cu^+, and Co^{2+} and of Fe^2/Fe^{3+} dissolved in the $CsCl$–$AlCl_3$ melts appears to be reversible, while the voltammetric curve for the reduction for Ni^{2+} indicates an abnormally high slope.

For Cd^{2+} and Pb^{2+} dissolved in the $CsCl$–$AlCl_3$ melts, the observed maxima did not allow an analysis of the shape of the voltammetric curves with any accuracy.

In the $CsCl$–$ZnCl_2$ melts the reduction of Cd^{2+} indicates the presence of an intermediated Cd^+ species.

From the analysis of the multiple reduction steps seen in the reduction of Zr^{4+}, it is concluded that the electron transfer takes place in the sequence $Zr^{4+} \rightarrow Zr^{2+} \rightarrow Zr^+$, followed by a possible final reduction step to metallic zirconium.

The electronic structure of tetraphosphorus trisulphide

JOHN D. HEAD, KEITH A. R. MITCHELL, LOUIS NOODLEMAN, AND NORMAN L. PADDOCK[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received July 27, 1976

JOHN D. HEAD, KEITH A. R. MITCHELL, LOUIS NOODLEMAN, and NORMAN L. PADDOCK. Can. J. Chem. **55**, 669 (1977).

The electronic structure of P_4S_3 has been investigated by the Xα scattered wave (XαSW) method as well as by the extended Hückel (EH) and complete neglect of differential overlap (CNDO) molecular orbital methods. The XαSW method gives a particularly good account of the ionization energies determined by HeI photoelectron spectroscopy. The valence shell levels fall into two groups. Those of lower energy are for the most part multicentre orbitals having high *s* character. The upper occupied levels are non-bonding or weakly bonding, and have a large *p* component. Contour plots of wave functions and charge distributions emphasize the importance of 'bent bonding' associated with electron density outside the framework of the cage structure, and of multicentre density inside the cage structure. These calculations provide a basis for understanding the relationship between the chemical properties of P_4S_3 and its electronic structure.

JOHN D. HEAD, KEITH A. R. MITCHELL, LOUIS NOODLEMAN et NORMAN L. PADDOCK. Can. J. Chem. **55**, 669 (1977).

On a étudié la structure électronique du P_4S_3 par la méthode des ondes diffusées de Xα (XαSW) de même que par des méthodes d'orbitales moléculaires de Hückel étendues (EH) et CNDO. La méthode XαSW fournit une bonne approximation des énergies d'ionisation qui ont été déterminées par spectroscopie photoélectronique HeI. Les niveaux des couches de valence se divisent en deux groupes. Les niveaux qui ont des énergies moins élevées sont pour la plupart des cas d'orbitales à plusieurs centres ayant un caractère *s* élevé. Les couches occupées de niveaux plus élevés ne lient pas ou ne lient que faiblement; de plus elles possèdent une composante *p* importante. Les tracés de contour des fonctions d'onde et des distributions de charge mettent en relief l'importance de la liaison déformée associée avec la densité électronique à l'extérieur du cadre de la structure en cage et de la densité à plusieurs centres à l'intérieur de la structure en cage. Ces calculs fournissent une base pour comprendre la relation entre les propriétés chimiques du P_4S_3 et sa structure électronique.

[Traduit par le journal]

Introduction

At the time of Stock's systematic investigation of the phosphorus sulphides (1), the compounds P_4S_3, P_4S_5, P_4S_7, and P_4S_{10} were known. More recently, the existence of P_4S_9 has been established (2, 3), and a new molecular form of P_4S_5 has been found (4). Although there is no detailed knowledge of the structures of the two latest additions to the series, P_4S_4 (3) and P_4S_2 (3, 5), thermochemical and spectroscopic evidence (6) suggests that these compounds, like those investigated earlier (4, 7–11), all have structures which are based on a P_4 tetrahedron. In P_4S_3, all the phosphorus atoms are tervalent, while one divalent sulphur atom is inserted in each of three coterminal edges of the phosphorus tetrahedron (Fig. 1). Similar cage structures are found for α- and β-As_4S_3 (12), P_4Se_3 (13), $As_3(CH_2)_3$-CMe (14), and the P_7^{3-} ion (15), isoelectronic with P_4S_3.

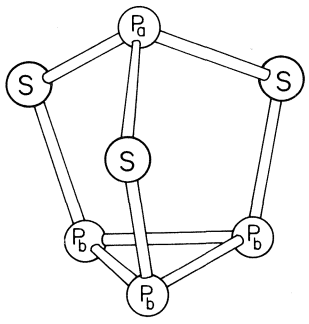

FIG. 1. The structure of P_4S_3 (7). Mean dimensions P_a—S, 2.090; P_b—S, 2.090; P_b—P_b, 2.235 Å; angles: S—P_a—S, 99.5°; P_a—S—P_b, 103.0°; S—P_b—P_b, 103.1°, P_b—P_b—P_b, 60°.

Tetraphosphorus trisulphide is the only phosphorus sulphide to retain its molecular structure in the solid, liquid, and vapour phases (16) and

[1]To whom all correspondence should be addressed.

in some chemical reactions. Although two electrons on each phosphorus atom and four on each sulphur atom are formally non-bonding, P_4S_3 is an effective donor only when the acceptor atom can release electrons to the ligand. Where structures of complexes with metal carbonyls (17, 18) are known, coordination occurs through the apical phosphorus atom, although the basal phosphorus atoms are involved in other reactions, for example with iodine (19, 20) and with elemental sulphur (21, 22). To provide a basis for assessing the chemical properties of P_4S_3 and its structural relationship to P_4 and the other molecules mentioned above, we report here a theoretical investigation of its electronic structure.

Calculational Methods

Calculations have been made with the Xα scattered wave (XαSW) (23), the extended Hückel (EH) (24), and the complete neglect of differential overlap (CNDO) (25) methods. The procedures and parameters for the EH calculations follow those used by Bartell *et al.* (26) except that *d* functions were not included. This seems reasonable since all atoms in P_4S_3 are in low oxidation states, although conventionally *d* orbitals are included in CNDO calculations for phosphorus and sulphur in all their compounds. The CNDO calculations were performed using the CNDO/2 version with the parameters specified by Pople and Beveridge (25). Convergence problems in the CNDO calculations were overcome in a way similar to those used by Bennett, McCarroll, and Messmer (27) and by Blyholder (28). This involves expressing the density matrix used as input for the *i*th iteration as

$$[1] \qquad P_i = (1 - A)P_{i-1}{}^{\text{new}} + AP_{i-1}$$

where P_{i-1} is the density matrix used as input for the $(i - 1)$th iteration and $P_{i-1}{}^{\text{new}}$ is the density matrix calculated in the $(i - 1)$th iteration. A was fixed at 0.7.

The XαSW method uses a self-consistent field approach, but does not use a basis of atomic orbital functions; the method relies instead on obtaining numerical radial functions which accurately solve a model Schrödinger equation. It is based on a statistical total energy expression in which the exchange-correlation energy $E_{XC}(\rho)$ is assumed to be a functional of the total electron density ρ (29). By using the variational principle, a set of orbitals μ_i and the corresponding one-electron eigenvalues ε_i are obtained from the one-electron Schrödinger equation

$$[2] \qquad [-\nabla^2 + V_C(r) + V_{X\alpha}(r)]\mu_i(r) = \varepsilon_i\mu_i(r)$$

This equation is given in Rydberg units (1 Ry = 13.605 eV). $V_C(r)$ is the classical Coulomb potential produced at r by the total electron density ρ and the nuclear charges, and

$$[3] \qquad X_{X\alpha}(r) = -6\alpha[(3/8\pi)\rho(r)]^{1/3}$$

is the exchange-correlation potential for the spin restricted case.

In practice, this method depends on partitioning the molecule into regions and choosing a suitable potential for each region. Each atom is surrounded by a sphere (centered at the nucleus), and the potential inside each atomic sphere is found by spherically averaging the one-electron potential $V_C(r) + V_{X\alpha}(r)$. The potential in the region between the atomic spheres (the intersphere region) is replaced by a constant volume-averaged potential, and in addition an isolated molecule is entirely surrounded by an extramolecular (outer sphere) region in which the potential is again spherically averaged. With this model potential [2] can be solved accurately by numerical methods. The wave functions are joined smoothly from one region to another, and, within the regions of spherically symmetric potentials, are expanded over spherical harmonics (the convergence in l is usually rapid). The foundations of the Xα theory and detailed descriptions of the method for solving the scattered wave equations have been discussed elsewhere (29, 30).

A recent development has been to allow the atomic spheres to overlap (31–33); the volume of the constant potential region is reduced, and the volumes over which the more accurate spherical averaging is performed are increased. Table 1 gives the atomic sphere radii and values of α (eq. 3) used here. The α values are those reported

by Schwarz (34). The ratios of the atomic sphere radii were fixed by a prescription given by Norman (32). This involved an initial calculation of a molecular charge distribution constructed from the superimposed charge densities of the free atoms, using the wave functions of Herman and Skillman (35). Preliminary sphere radii were chosen so that each sphere enclosed a total electron charge equal to the appropriate atomic number; the ratios of the atomic sphere radii for the XαSW calculations were then taken as equal to the appropriate ratios of the preliminary sphere radii. The two sets of absolute radii which have been used in this study (Table 1) are respectively 30% (Model 1) and 20% (Model 2) greater than required for contact of the spheres. For Model 1, the wave functions within the atomic spheres were expanded over a basis set involving spherical harmonics corresponding to $l = 0$ and $l = 1$; for Model 2, the basis was extended to include $l = 2$ functions.

Results

All calculations were made using the geometry of Fig. 1. Table 2 gives the one-electron eigenvalues obtained from the XαSW calculations for both the core and the valence shell levels. The one-electron ε_i are defined as

$$[4] \qquad \varepsilon_i = \frac{\partial \langle E_{X\alpha} \rangle}{\partial n_i}$$

where $\langle E_{X\alpha} \rangle$ is the expectation value of the total energy of the molecule, and n_i is the occupation number of the ith level. Ionization energies were calculated by transition state theory (27), which includes first order corrections for relaxation. For the semi-empirical methods, the ionization energies were taken to be the negatives of the calculated one-electron energies. The ionization energies calculated by all the methods are given in Table 3, together with the values measured by photoelectron spectroscopy.[2] The individual molecular orbitals from the XαSW method (Model 2) are analysed in Table 4, and the charge distributions for all the methods in Table 5. The total atomic valence-shell electron populations are given in Table 6. Table 7 gives the low lying dipole allowed excitation energies from spin restricted transition state calculations for the XαSW method (Model 1), and from differences in orbital energy for the EH and CNDO methods.

Discussion

Orbital Energies and Charge Distribution

The HeI photoelectron spectrum of P_4S_3 is shown in Fig. 2, with the ionization energies calculated by the XαSW method (Model 2) superimposed upon it. This calculation accounts particularly well for the relative positions of the energy levels (Table 3). The range covered by the first eight ionization energies is similar for Model 1 (4.45 eV) and Model 2 (4.09 eV), and close to the observed range (4.27 eV). The corresponding ranges calculated by the EH and CNDO methods, using Koopmans' theorem, are less satisfactory, being 3.38 and 6.83 eV, respectively.

The spacings in the ionization energies calculated by the XαSW method are changed slightly, but significantly, by the inclusion in Model 2 of d waves, to the extent of about 0.2–0.3 d electron

[2]The spectrum (HeI) was determined by Dr. J. N. A. Ridyard of Perkin–Elmer, using a PS-18 photoelectron spectrometer.

on each atom. Model 2 gives the slightly better description, in that the preferential stabilization of the e levels by the (small) d-wave component separates the levels clearly into the groups of 3, 3, and 2 found in the spectrum. The chief differences between the absolute values of the ionization energies calculated for Models 1 and 2 are caused by the different choices of sphere overlap.

Norman (32) has suggested that the virial theorem be used as a criterion for establishing the absolute value of the sphere overlap. For

*Model 1. Averaged over singlet–singlet and singlet–triplet transitions.

Models 1 and 2, $-2T/V = 1.000204$ and 1.000627 respectively. Although the deviation from unity is slightly greater in Model 2, this model is nevertheless preferable both because it avoids the unphysical negative intersphere charge (-4% to -13%) found for the four lowest valence orbitals in the calculations on Model 1 and because it gives the closer account of the measured ionization energies. If a constant 0.55 eV is subtracted from the ionization energies of Table 3 (Model 2), the mean deviation of the individual calculated and observed values is 0.16 eV.

The semi-empirical methods perform less well. Both follow the XαSW method in giving $17e$ as the highest occupied level, but, among the higher levels, the EH method interchanges $16e$ and $17a_1$, and CNDO interchanges $17a_1$ and $3a_2$. The ordering of levels derived from the XαSW calculations is supported by the interpretations of the photoelectron spectra of other molecules. The $3a_2$ orbital is an almost pure nonbonding combination of sulphur $3p$ (tangential) orbitals with only weak involvement of $3p$ orbitals on the basal phosphorus atoms. This is the case for all the methods (see Tables 4 and 5). The assignment of this level to the energy of the second band (9.29 eV) in Fig. 3 is consistent with the set of lone pair ionization energies of S_8, the highest being 9.23 (36) or 9.40 eV (37). The energy of the apical lone pair (defined here as the highest occupied a_1 orbital) in phosphines is lowered (relative to sulphur) by electronegative substituents, *cf.* H_2S, 10.47 (38); PH_3, 10.59 (39); $(CF_3)_2S$, 11.11 (40); $(CF_3)_3P$, 11.70 eV (41), and the corresponding assignment of the third band to $17a_1$, shown below to have this type of electron distribution, is a natural one. The equal intensities of bands 4 and 5 in the experimental spectrum suggest that this structure could correspond to a degenerate level ($16e$)

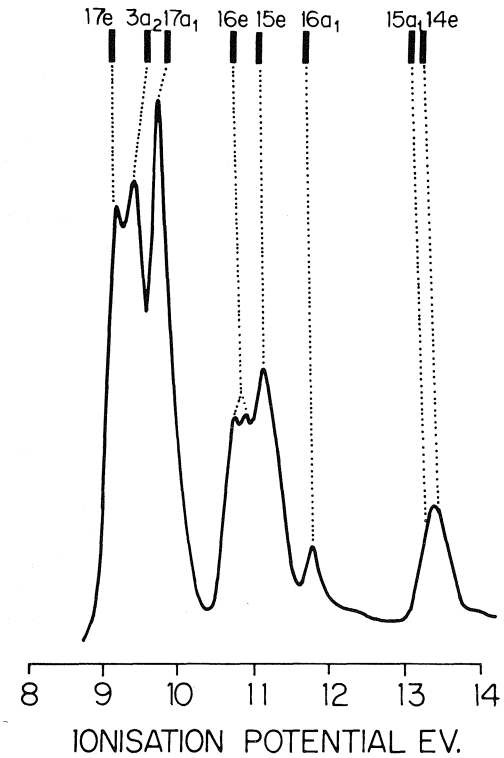

FIG. 2. The photoelectron spectrum (HeI) of P_4S_3. The ionization energies calculated by the XαSW method (Model 2), uniformly decreased by 0.55 eV from those given in Table 3 (see text) are shown at the top.

split by the Jahn–Teller effect. The eighth band seems broad enough to include both the $15a_1$ and $14e$ levels calculated to be in this region.

The ultraviolet spectrum[3] of P_4S_3 shows a single dipole-allowed band, with a transition energy of 6.0 eV ($\varepsilon = 13\,800$ l cm^{-1} mol^{-1}), near the instrumental limit of 6.2 eV. The XαSW method, through transition state theory, predicts several bands in the observable spectral region (Table 7), while the EH method predicts two bands ($17e \rightarrow 4a_2$ and $3a_2 \rightarrow 4a_2$) and the CNDO method none.

The XαSW partial wave decompositions in Table 4 show a substantial contrast between the upper occupied levels $14e$ to $17e$ and the lower valence levels $12a_1$ to $13e$. The former predominantly involve p functions (76 to 98% p), and the latter involve primarily s functions (60 to 89% s), although orbitals $13e$ and $14a_1$ have an appreciable p-content (33 and 35% respectively) which reduces their antibonding character.

[3]M. R. LeGeyt. Private communication.

The intersphere and outer sphere contributions in Table 5 also show that the upper occupied orbitals are more spatially diffuse than the lower valence orbitals. The involvement of d waves is small throughout, averaging about 5% (Table 4). From Table 2 (XαSW, Model 2) an energy gap of about 3.48 eV between the s-type and p-type states is expected. Measurements by X-ray photoelectron spectroscopy[4] show a peak, here assigned to the $13e$ state, at an energy $\sim$3.6 eV higher than the ionization energy of the deepest level ($14e$) found by HeI photoelectron spectroscopy. The separation calculated by the EH method is 3.17 eV. No direct comparison is possible with the CNDO method, because the order of the levels is different in this region, but there is no clear separation between the s- and p-type orbitals.

Orbital Compositions in the Extended Hückel and CNDO Methods

The CNDO orbitals have a larger d character (11% average) and a greater degree of s/p mixing than the XαSW orbitals. However, the components of s and p functions in the individual molecular orbitals are broadly similar to those from the XαSW method, as are the charge distributions on the various atoms (Table 5), the largest discrepancy being for the $15a_1$ state. The CNDO method indicates the states $14e$ to $17e$ to be composed primarily of p orbitals (58–86% p), while the lower states involve greater proportions of s orbitals (48–77% s).

An essentially similar situation holds in the EH calculations, although here the s/p mixing is less than from the XαSW calculations. According to the EH method, the states $14e$ to $17e$ are composed of more than 90% p functions (in an s,p basis only), and similarly $12a_1$ to $13a_1$ involve predominantly s orbitals (89 to 100% s). In common with the XαSW and CNDO methods EH indicates significant s/p mixing in the $13e$ and $14a_1$ orbitals. EH is the only method in which the amount of p character in these two orbitals (56 and 66% respectively) exceeds that of s. The EH charge distributions on the different atoms (Table 5) are similar to those from XαSW for the lower valence levels $12a_1$ to $13e$, but there are marked differences in the higher valence levels $14e$–$17e$. Figure 3 shows how the EH energy levels of the P_3 and PS_3 fragments change on

[4]M. S. Banna, D. C. Frost, C. A. McDowell, and B. Wallbank. Unpublished results.

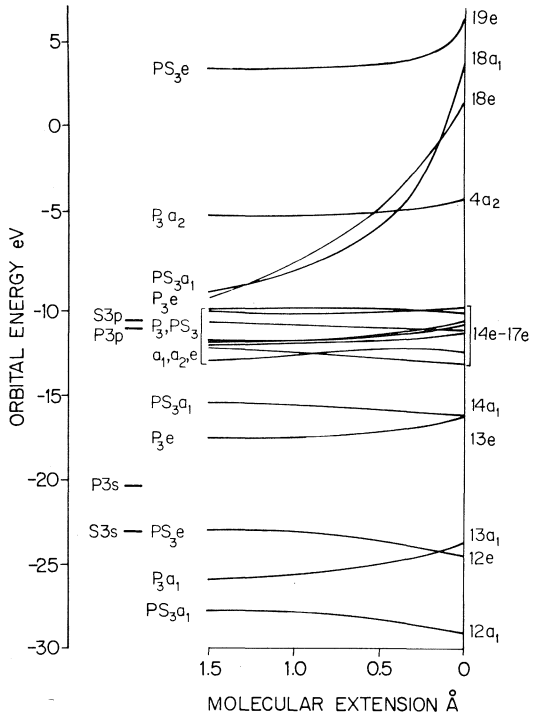

FIG. 3. Energies (EH) of the orbitals of P_3 and PS_3 approaching (C_{3v} symmetry) to form P_4S_3. The last 1.5 Å of the idealized process is shown.

bringing them together to the distance which separates them in P_4S_3. It highlights the existence of both bonding interactions between the P_3 and PS_3 fragments in the states $12a_1$, $12e$, and $14a_1$, and antibonding interactions in the states $13a_1$ and $13e$. These results are interesting in view of the similarity of the lower valence levels as determined by the EH and XαSW methods.

Contour Plots of the XαSW Orbitals and Electronic Charge Distributions

The XαSW method provides no numerical measure of bonding character corresponding to the concept of bond order in molecular orbital theory. Contour plots of wave functions and electronic charge distribution[5] are more detailed and informative, and are presented in this section for some of the more important orbitals. Wave function contour diagrams[6] for some of the higher lying levels of P_4S_3 are given in Fig. 4. Sections of a wave function belonging to $17e$ (Fig. 4 *a*, *b*) show that electron density is concentrated on the sulfur atoms in non-interacting *p* orbitals, and that there are weak interactions within the basal phosphorus ring. The apical atom barely contributes to $17e$. The $17a_1$ state, and to a lesser extent the $16a_1$ state, should be expected from consideration of symmetry, energy, and charge distribution to constitute the apical phosphorus lone pair, although the total charge on P_a from the $17a_1$ and $16a_1$ orbitals is only 1.02 electrons. Of the total electronic charge in $17a_1$, 30% is found on P_a, as compared with about 50% on P for the highest occupied a_1 orbital in PH_3 (32). The plots of $17a_1$ in Fig. 4 *c*, *d* illustrate that the electron density arises mainly from phosphorus *p* orbitals oriented towards the centre of the molecule. The $16e$, $15e$, and $15a_1$ levels are weakly bonding orbitals delocalized over both the P and S rings, but (Table 5) with little charge on P_a. Sections of a wave function belonging to $14e$, the deepest found by HeI photoelectron spectroscopy, are shown in Fig. 4*e* and *f*. Both show 'bent bonds'; in one, the bonding electrons are predominantly outside the phosphorus triangle, in the other they are concentrated somewhat outside the P_a—S internuclear axis.

Further contour plots are shown in Fig. 5 for wave functions corresponding to the lower valence levels $12a_1$ to $13e$. Figures 5*a* and *b* show that although $13e$ is antibonding with respect to atomic *s* functions for both P_b—P_b and P_b—S bonds, the appreciable mixing in of *p* waves results in net P_a—S bonding. In $14a_1$ (Fig. 5*c*) the high concentration of charge in the P_a *s*-orbital is antibonding with respect to the sulphur orbitals, and there is also appreciable bonding density in the middle of the P_3 face. The dominant feature of $13a_1$ (Fig. 5 *d*, *e*) is the multicentre nature of the bonding within the P_3 subunit; Fig. 5*d* also shows an antibonding interaction between the P_3 and PS_3 subunits. The two lowest valence orbitals, $12e$ and $12a_1$, are both strongly bonding. The former (Fig. 5*f*) corresponds to polar σ-bonding between S and P_b, and the latter (Fig. 5 *g*, *h*) has considerable multicentre character within the PS_3 subunit. The participation of *p* functions in these predominantly *s* states reduces significantly the antibonding character of the $13e$ and $14a_1$ orbitals, and slightly increases the bonding character of $13a_1$, $12e$, and $12a_1$.

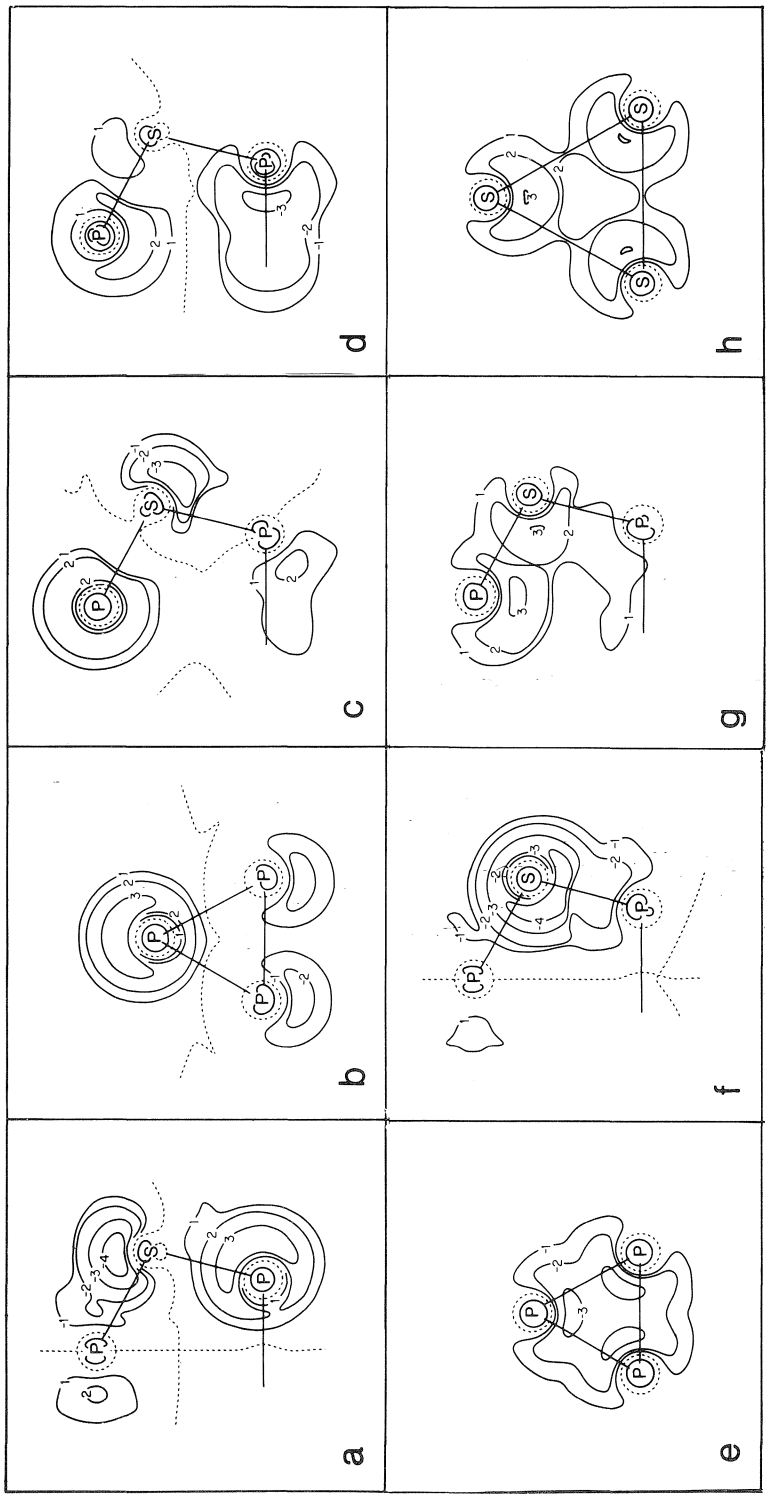

FIG. 5. Wave function contour diagrams for (*a*) and (*b*) $13e$; (*c*) $14a_1$; (*d*) and (*e*) $13a_1$; (*f*) $12e$; (*g*) and (*h*) $12a_1$. For contour specification, see Fig. 4.

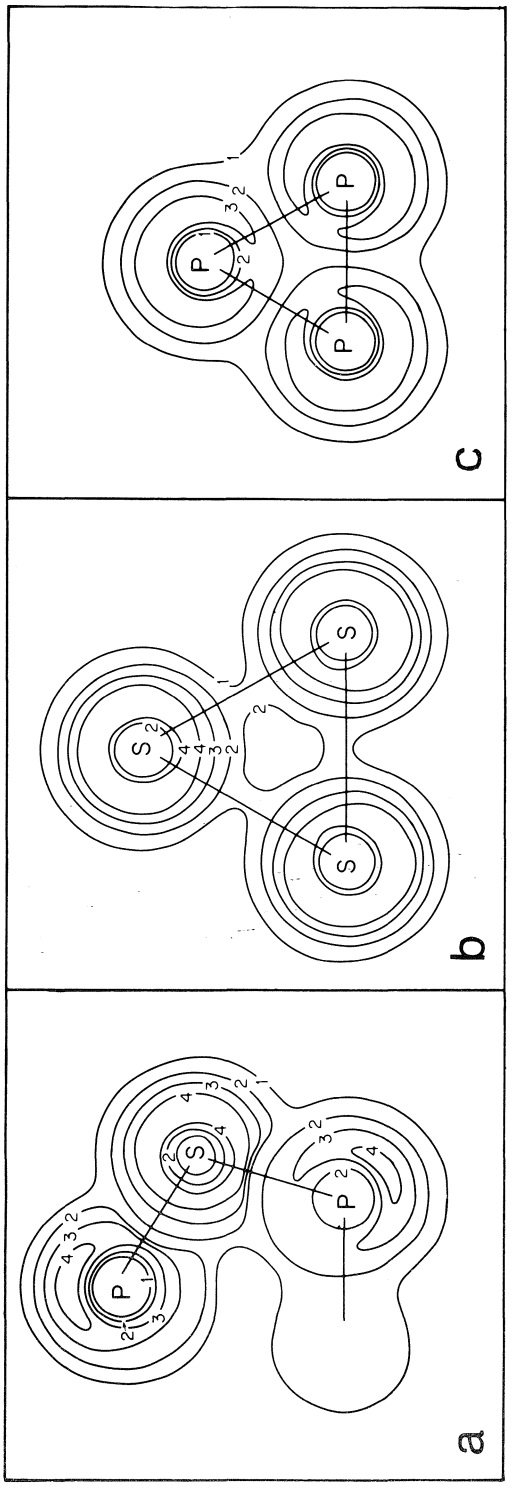

FIG. 6. Total valence charge distribution in three planes of P_4S_3. Contour specification: 1 = 0.023, 2 = 0.053, 3 = 0.084, 4 = 0.122 electrons/a_0^3.

The total electronic charge distributions (Fig. 6) show a number of features of chemical interest. Distributions characteristic of directed lone pairs at both P_a and P_b are evident in Fig. 6*a*. The symmetrical nature of the charge distribution round each sulphur atom (Fig. 6*b*) shows that direct S—S bonding is unimportant, though there is some indirect S—S bonding mediated by P_a (Fig. 6 *a*, *b*). Figure 6*c* displays both lone pair density and 'bent bonding' density in the basal phosphorus ring. The individual contour diagrams show the division into *s* type and *p* type, 13*e* and $14a_1$ being intermediate in this respect. The *s* type orbitals have appreciable electron density within the molecule, to give multicentre bonding, whereas some of the higher *p* type orbitals have electron density outside the internuclear axes, forming 'bent bonds'. Brundle and co-workers (42) have suggested that multicentre bonding density ('omnidirectional' in their terminology) may be important to the stability of P_4. According to the present analysis, such bonding may account for the frequent appearance of the P_4 structural unit in the phosphorus sulphides; it is probably significant that the ion P_3S^+, isoelectronic with P_4, is abundant in the mass spectrum of P_4S_3 (43).

Chemical Properties

Various properties of P_4S_3 depend on the fact that the higher occupied levels are essentially nonbonding, so that small perturbations can have a large effect on charge distribution. Accordingly, the ^{31}P chemical shifts of P_4 (44) and the basal phosphorus atoms of P_4S_3 (45) are both very sensitive to the solvent, the apical phosphorus atom being somewhat less so (45). The sensitivity can be attributed to the high polarizability of the occupied orbitals, especially 17*e* in P_4S_3 and 2*e* and $6t_2$ in P_4 (42, 46). It is also interesting that an investigation of the dynamic polarization of the ^{31}P nucleus (47) showed a higher scalar enhancement, and hence a greater *s* character, in the P_a than in the P_b lone pair. This result is consistent with the XαSW calculations (Table 4), which show that the *s* density in both the 'lone pair' orbitals $17a_1$, $16a_1$ is greater on P_a. Most of the chemistry of P_4S_3 involves donor–acceptor interactions. The highest occupied orbital in a symmetrical phosphine is normally of a_1 symmetry, and P_4S_3 is unusual in having its highest a_1 orbital below a degenerate orbital which has its major electron density on phosphorus spread among the basal atoms. Both types of phosphorus atom can be expected to act as donors, and we can now discuss in more detail the complexes referred to in the Introduction.

The ionization energy of $17a_1$ is 9.66 eV, comparable to that of the highest *a'* level of $MePH_2$ (9.72, 9.6 eV (48, 49)). This compound is a very weak base, and, consistently, P_4S_3 is not protonated by normally available methods. Tetraphosphorus trisulphide does, however, form the complexes *cis*-$(P_4S_3)_2M(CO)_4$ (M = Cr, Mo, W), *cis*-$(P_4S_3)_3M(CO)_3$ (M = Cr, Mo), and $Ni(P_4S_3)_4$, in which, on the basis of their ^{31}P nmr spectra, coordination takes place through P_a (17). A crystallographic analysis (18) of a further complex $P_4S_3Mo(CO)_5$ shows that a strong P_a—Mo bond is formed at the expense of all the P—S bonds in the ligand, not merely those from P_a itself. The P_a—Mo bond can be explained in terms of σ-donation from $17a_1$ (Fig. 4*c*) accompanied by π donor and acceptor interactions involving 14*e* (Fig. 4*e*), 17*e* (Fig. 4*a*), excited states of P_4S_3, and *d* and *s* orbitals of molybdenum.

In these reactions, P_4S_3 does not differ greatly from such tertiary phosphines as Ph_3P, as shown by the corresponding CO stretching frequencies in $P_4S_3Mo(CO)_5$ (18) and (in parentheses) $Ph_3PMo(CO)_5$ (50): A_1, 2075 (2075); B_1, 1985 (1989); A_1, 1965 (1945); *E*, 1940 (1950) cm^{-1}. However, P_4S_3 forms another complex[7] P_4S_3-$Mo(CO)_3$ with two strong bands (1999, 1940 cm^{-1}) in the CO stretching region, similar to the $(A + E)$ bands of $C_6H_6Mo(CO)_3$ (1991, 1919 cm^{-1}) (51) and $(PhPCl_2)_3Mo(CO)_3$ (2016, 1943 cm^{-1}) (52). The complex evidently has trigonal symmetry, and it seems most likely[7] that coordination takes place through the basal phosphorus atoms, though confirmation of coordination by a P_3 triangle by X-ray methods is not yet available, either for this compound or the rhodium complexes of P_4 (53).

An example of a different type of interaction at the basal atoms of P_4S_3 is given by its reaction with iodine. The first product that can be isolated is β-$P_4S_3I_2$ (19, 20) (Fig. 7*a*), whose formation is presumably a result of the high electron density at P_b in 17*e*. Its subsequent rearrange-

ment to give the more stable α-$P_4S_3I_2$ (54) (Fig. 7*b*) is accompanied by a reduction of the separation of the formally nonbonded P and S atoms to 3.1 Å, well below the sum of the van der Waals radii (3.5 Å). The skeletal mobility of $P_4S_3I_2$ and the occurrence of such indirect bonding are both compatible with the concept of multicentre bonding indicated by the XαSW calculations.

Concluding Remarks

Calculation of the electronic structure of P_4S_3 by the XαSW method gives a good account of the ionization energies determined by photoelectron spectroscopy. A small *d*-component is fairly evenly spread among all the orbitals, and, although it is unlikely to have a major effect on molecular geometry, it is important in determining the detailed spacing of the levels. Of the two semi-empirical methods used, EH gives a better account of the measured ionization energies, but the CNDO charge distributions are closer to those found by the XαSW method. An important feature of the XαSW calculations is that, although there are some significant effects of *s–p* mixing, there is a distinct energetic division between the lower states based mainly on 3*s* orbitals and the higher, 3*p* type. Their bonding characteristics are different, the former providing the main cohesive energy of the molecule through multicentre bonding within the P_3 and PS_3 subunits, (and perhaps accounting for the prevalence of the P_4 unit in the phosphorus sulphides) the latter being more directed, and having a high electron density both in the conventional lone pair directions, and, in some cases, outside the conventional bond axes ('bent bonds'). All these characteristics can be seen in the contour diagrams.

Chemically, P_4S_3 can be expected to act as a donor at both the apical and basal sites, as found, there being no clear theoretical preference. The donor properties of P_a are similar to those of other tertiary phosphines, and the formation of complexes with metal carbonyls can be understood in terms of the calculated molecular orbitals. The basal P_3 atoms behave like P_4, and further experimental investigations of coordination in this region would be valuable. Multicentre bonding is likely to be important here, and in such reactions as the structure transformation of β-$P_4S_3I_2$.

Use of the scaled-particle theory for the determination of single ion standard free energy of transfer between solvents

CLAUDE TREINER

Laboratoire d'Electrochimie, Université P. et M. Curie, 4, Place Jussieu—Bât. F—75230 Paris Cedex 05-ERA 310

Received September 27, 1976

CLAUDE TREINER. Can. J. Chem. **55**, 682 (1977).

The tetraphenylboron extrathermodynamic assumption is one of the methods most often used for the evaluation of single ion standard thermodynamic functions of transfer between two solvents. We show in this article that the scaled-particle theory may be useful for discriminating among those solvents for which this extrathermodynamic assumption may be questionable because of strong solute–solvent interactions. Although no general rule is proposed, the tetraphenylboron assumption seems valid in the case of the free energy of transfer between water and solvents like methanol, ethanol, acetonitrile, and formamide; it should not be used in the case of the transfer to solvents like propylene carbonate, dimethylsulfoxide or sulfolane. The scaled-particle theory may also be used to predict within 20% the standard free energy of transfer of the tetraphenylboron ion between water and aqueous mixed solvents; examples are given for water–methanol and water–ethanol mixtures.

CLAUDE TREINER. Can. J. Chem. **55**, 682 (1977).

L'hypothèse de l'équisolvatation des ions tetraphénylborure et tetraphénylarsénium est une des méthodes extrathermodynamiques les plus utilisées pour la détermination des fonctions thermodynamiques de transfert d'ions individuel entre deux solvants. Nous montrons ici que la théorie des sphères rigides peut être utilisée pour désigner les solvants pour lesquels dues à de fortes interactions soluté–solvant, cette méthode extrathermodynamique est peu sure. Aucune règle générale n'est proposée; toutefois il semble que la méthode soit valable dans le cas du transfert de l'eau à des solvants tels que le méthanol, l'éthanol, l'acétonitrile et le formamide. Elle semble devoir être rejetée dans le cas du transfert de l'eau à des solvants dont les molécules sont plus complexes tels que le carbonate de propylène, le diméthylsulfoxide et le sulfolane. La théorie des sphères rigides peut également être utilisée pour prédire à 20% près l'énergie libre standard de transfert de l'ion tétraphénylborure entre l'eau et des mélanges hydroorganiques: on donne les exemples des mélanges eau–méthanol et eau–éthanol.

Introduction

The evaluation of single ion thermodynamic properties has been the subject of many discussions. A wide variety of extrathermodynamic assumptions have been proposed (1) and have been critically reviewed in recent years (2–5); none of them has gained so much popularity as the tetraphenylboron (TϕB) assumption first proposed by Grunwald *et al.* (6) in 1960. According to this extrathermodynamic approach, the tetraphenylboron ion (ϕ_4B^-) and the tetraphenylphosphonium ion (ϕ_4P^+) are taken as identical in size and weakly solvated to the same extent. The replacement of ϕ_4P^+ with ϕ_4As^+ (7) does not change the basic assumptions of this approach. Some warnings may be found in the literature against the TϕB assumption based mostly on spectroscopic studies (8, 9); unfortunately, comparison between chemical shifts and thermodynamic quantities is not straightforward, and a theoretical approach was felt necessary.

We have shown recently (10), that the scaled-particle theory (SPT) can account for the main part of the standard free energy of transfer of a large ion like tetrabutylammonium from water to water–acetone and to water–acetonitrile mixtures. It was thus felt interesting to investigate the possibility of using the SPT to discriminate between the solvents for which the TϕB assumption could be useful for the evaluation of reliable single ion free energies of transfer between two solvents, and those for which this assumption should not be used.

Theory

According to the SPT, the standard free energy associated with the dissolution of a hard sphere in a solvent can be represented by the following relationship (11):

$$[1] \quad \Delta G^0 = \Delta G^0(\text{cav}) + \Delta G^0(\text{int}) + RT \log RT/V$$

TABLE 1. Characteristic constant* for the calculation of ΔG_t^0 for the tetraphenylarsenium ion from water to some pure organic solvents at 298.15 K using the scaled-particle theory (11)

Solvent	d	a (Å)	$10^{-3}\ \Delta G^0$† (kJ mol^{-1})	$-\Delta G_t^0$ (kJ mol^{-1}) Calcd	Expt

*ΔG_t° is expressed in the mole fraction scale.
†Equation 1, $\Delta G^\circ(\text{int}) = 0$.
‡Value at 30 °C.

where ΔG^0(cav) is the free energy for creating a cavity in the solvent and ΔG^0(int) is the free energy of interaction of the solute particle in the cavity with the solvent molecules; V is the molar volume of the solvent. In the case of the standard free energy of transfer of the solute between a reference solvent (here water) and a given solvent s, one may write:

$$[2]\quad \Delta G_t^0 = \Delta G_t^0(\text{cav}) + \Delta G_t^0(\text{int}) + RT \ln (V_w/V_s)$$

with

$$\Delta G_t^0(\text{cav}) = \Delta G_s^0(\text{cav}) - \Delta G_w^0(\text{cav})$$

and

$$\Delta G_t^0(\text{int}) = \Delta G_s^0(\text{int}) - \Delta G_w^0(\text{int})$$

ΔG_t^0(int) is not known for the chemical systems we want to study; Masterton *et al.* (12) have pointed out that when dealing with aromatic molecules, the scaled-particle theory is relatively inaccurate presumably because of uncertainties in the interaction energy term. Thus we shall assume that $\Delta G_t^0(\text{int}) \cong 0$ which corresponds to the basic hypothesis of the TϕB assumption (see Discussion section).

The only constants necessary for the calculation of ΔG_t^0(cav) are the diameter of the solute and solvent molecules considered as hard spheres and the density of the solvents. The diameter of ϕ_4As^+ was assumed equal to that of ϕ_4B^-: Grunwald's value of 8.4 Å was adopted (6). The hard sphere diameter a of the solvent molecules was calculated using the de Ligny and van der Veen (13) method based on Bondi's (14) estimates of van der Waals volumes. The a values thus obtained may be in error by some unknown amounts especially for molecules like *N*-methylpyrrolidone, but they represent a consistent set of values based on the same calculation method. The density d of the solvents were taken from the literature (15).

Results and Discussion

(*A*) *Free Energy of Transfer of* ϕ_4As^+ *from Water to Pure Solvents*

In Table 1 we present the results obtained on the mole fraction scale together with the experimental ΔG_t^0 values taken from a review article by Cox *et al.* (16) and expressed on the same concentration scale. ΔG_t^0(calcd) should of course be corrected by a coulombic term as the SPT is only concerned with uncharged particles; however, if we assume that the Born equation gives a good estimate of the electrostatic effect one can easily show that for the large ion we are dealing with ΔG_t^0(coul) is at most equal to 4.6 kJ mol^{-1} (in the case of the transfer from water to ethanol which has the lowest dielectric constant value of the solvent listed).

Most often for the solvents considered here ΔG_t^0(coul) is of the order of 2.5 kJ mol^{-1} and may therefore be neglected.

The data listed in Table 1 show that ΔG_t^0(exp) is negative from water to all the solvents studied: the comparison between calculated (eq. 2 with $\Delta G_t^0(\text{int}) = 0$) and experimental values indicates surprisingly good agreement for the transfer to methanol, ethanol, acetonitrile, and formamide. This may be taken as evidence that ΔG_t^0(int)

which has been assumed to be zero in our calculation is indeed small and may be neglected in these cases, *i.e.* the interaction between ϕ_4As^+ and the solvents is small (or similar in water and in these organic solvents).

The agreement is not good in the case of dimethylformamide and is obviously bad for sulfolane, *N*-methylpyrrolidone, dimethylsulfoxide, and propylene carbonate: even the sign of ΔG_t^0 is not predicted by the SPT. This means that in these cases we are not allowed to neglect ΔG_t^0(int) and that this term is large for some of the solvents listed (for example of the order of -67.8 kJ mol^{-1} from water to sulfolane).[1] It implies that strong solute–solvent interactions take place which are different in water and in those organic solvents. We should note however that this conclusion rests to some extent on the (reasonable) assumption that ϕ_4As^+ or ϕ_4B^- are more strongly solvated in the organic solvents than in water; it follows that ΔG_t^0(int) is negative from water to the organic solvents. This assumption is in agreement with the observations of Coetzee and Sharpe (9). It then follows that the stronger the solute–solvent interactions, the larger can be the difference between the solvation of the cation and the anion (that such a difference may exist has been indeed pointed out by Grunwald when the TϕB assumption was first proposed). The obvious conclusion is that the TϕB assumption should not be used in the cases just discussed and the following procedure can be proposed.

If ΔG_t^0(exp) $\cong \Delta G_t^0$(cav) within, say, 30% then single ion values as obtained through the TϕB assumption can be considered reliable. In other cases, the TϕB assumption should not be used.

(*B*) *Free Energy of Transfer of* ϕ_4As^+ *from Water to Mixed Solvents*

It is also interesting to compare calculated and experimental ΔG_t^0 values in the case of mixed aqueous solvents. ΔG_t^0(calcd) is obtained using equations published previously (10, 17).

ΔG_t^0(exp) from water to water–ethanol mixtures had been obtained from solubility measurements (18), and from water to water–methanol mixtures from vapor pressure measurements (19).

The density of the solvent mixtures were taken from ref. 15. Figures 1 and 2 present the results obtained with ΔG_t^0(int) = 0. The agreement between experimental and calculated ΔG_t^0 values is good, being of the order of 20%. If the Born effect is also considered the agreement is even better. It seems then, that in the cases for which ΔG_t^0 for ϕ_4As^+ may be predicted by the SPT from water to a pure solvent, the calculation may be extended to the mixture of the two solvents. However, complications may arise from strong solvent–solvent interactions as in the case of water + acetonitrile mixtures (10).

Conclusion

The tetraphenylboron assumption should be used with great care. Our study confirms previous warnings against its use, but it also shows that in the cases of the standard free energy of transfer between water and organic solvents it may be used with some confidence after comparison between experimental and calculated ΔG_t^0 data using the simple SPT equations.

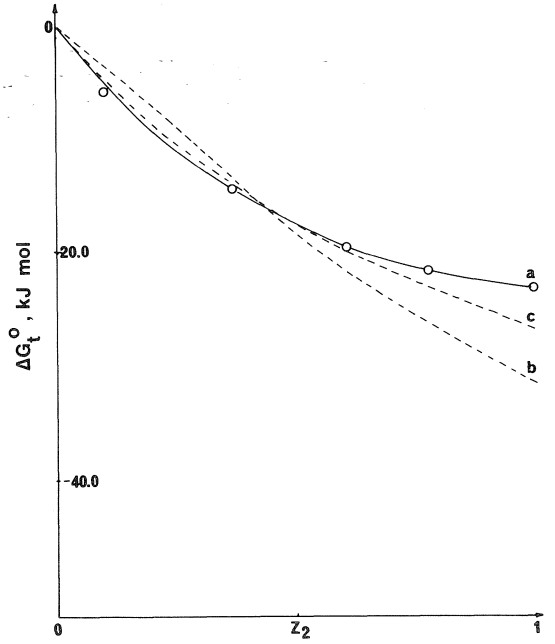

FIG. 1. ΔG_t^0 for $As\phi_4^+$ from water to water–ethanol mixtures: (*a*) "experimental", (*b*) calculated by SPT without the Born term, (*c*) calculated with the Born term ($r^+ = 4.2$ Å) (mole fraction scale).

[1]One of the referees pointed out to us the work of Neff and McQuarrie who try to introduce the influence of the solute on the solvent–solvent interactions in their solubility calculations. (Note that the discrepancies between experimental and calculated ΔG_t^0 values are usually larger when the density of the organic solvent is higher than of water.) However the system they study (neon in argon) is so different from ours that it seems difficult to apply their ideas to the present problem.

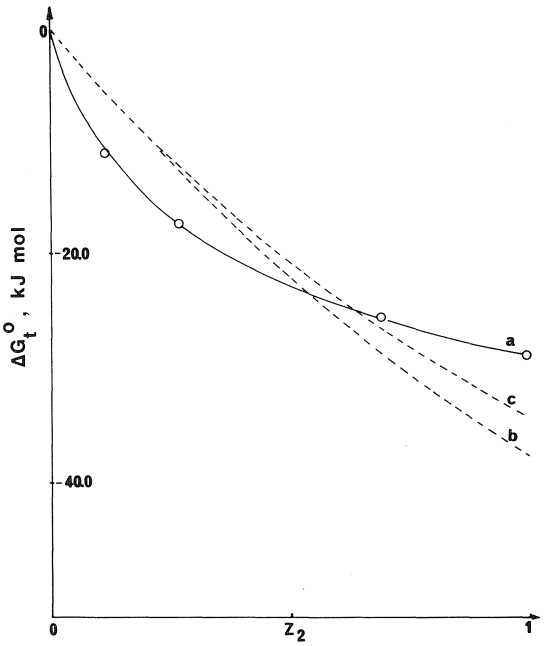

FIG. 2. ΔG_t^0 for $As\phi_4^+$ from water to water–methanol mixtures. Same notation as for Fig. 1.

It seems clear, however, that the safest way of using extrathermodynamic assumptions is to apply several different approaches to the same chemical system (23). In this respect mention should be made of the work of Parsons and Rubin (20) who have suggested that the extrathermodynamic approach of Alexander *et al.* (21), *i.e.* assuming no liquid junction potential in an emf cell, might be the "best" method available at the present time for predicting single ion standard free energy of transfer between two solvents.

Studies in solvolysis. Part VIII. An entropy correlation related to the reaction of various nucleophiles with malachite green

STEPHEN HARVEY MORRIS, JOHN MARSHALL WILLIAM SCOTT,[1] AND FREDERICK STEELE

Chemistry Department, Memorial University of Newfoundland, St. John's, Nfld., Canada A1C 5S7

Received July 5, 1976

STEPHEN HARVEY MORRIS, JOHN MARSHALL WILLIAM SCOTT, and FREDERICK STEELE. Can. J. Chem. **55**, 686 (1977).

The entropies of activation related to the reactions of aqueous malachite green with the nucleophiles water, hydroxide, hydrazine, ammonia, hypochlorite, and sulphite have been calculated from the temperature dependence of the rate constants appropriate to these reactions. The entropies of the transition states for these reactions have been characterized and the transition states shown to be 'reactant like'. A similar correlation, based on data for a series of nucleophiles attacking methyl iodide, suggests that the transition states for the S_N2 displacement reactions are also 'reactant like' with respect to the attacking nucleophile. A relationship between two distinct parameters each of which is related to the position of transition states along the reaction coordinate is considered.

STEPHEN HARVEY MORRIS, JOHN MARSHALL WILLIAM SCOTT et FREDERICK STEELE. Can. J. Chem. **55**, 686 (1977).

On a calculé les entropies d'activation reliées aux réactions du vert de malachite aqueux avec les nucléophiles eau, hydroxyde, hydrazine, ammoniac, hypochlorite et sulphite; ces calculs ont été effectués à partir de la dépendance qui existe entre la température et les constantes de vitesses appropriées de ces réactions. On a caractérisé les entropies des états de transition de ces réactions et on a démontré que les états de transitions ressemblent aux réactifs. Une corrélation semblable, basée sur des données pour une série de nucléophiles attaquant l'iodure de méthyle, suggère que, par rapport au nucléophile qui attaque, les états de transition des réactions de déplacement S_N2 ressemblent aussi au réactif. On considère une relation entre deux paramètres distincts chacun desquels est relié à la position de l'état de transition le long des coordonnées de la réaction.

[Traduit par le journal]

Introduction

The thermodynamic parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ which characterize the reactions of charged and neutral nucleophiles with triaryl carbonium ions

[1] $$Ar_3C^+ + N^{n-} \rightarrow Ar_3CN^{(n-1)-}$$

where $n = 0$, 1, and 2, have been measured frequently (1–6). The previous use of these quantities has been to extrapolate or interpolate measured rates for correlations based on relative rates (free energies of activation, $\Delta G^{\ddagger}$). Moreover, little attention has been directed to the precision with which these quantities have been measured. Reported values for the entropies of activation show considerable variation. For instance when Ar_3C^+ = malachite green and $N^{n-} = OH^-$, $\Delta S^{\ddagger}$ has been reported as -19 (4), -14 (6), -10.4 (1), and -7 (3) cal mol^{-1} K^{-1} and no systematic entropy data for these reactions exist to offer further insight into the details of the activation process.

Conclusions concerning the nature of the activated state can often be deduced from entropies of activation in conjunction with the appropriate initial state data. Correlations of this type have been used by Robertson *et al.* (7–10) for the methyl (7, 9), allyl (7), and isopropyl halides (7, 8). The correlations take the form,

[2] $$S^{\ddagger}(RX) = \alpha S(X^-) + \text{constant}$$

where R = methyl, allyl, and *s*-propyl, $S^{\ddagger}$ is the entropy of the transition state, and $S(X^-)$ is the standard entropy of the completely formed solvated aqueous anionic leaving group. The quantity α is best considered as a reaction coordinate parameter, which in this case measures the degree of resemblance of the activated state to the products, *i.e.* the fully formed ions. The quantity $S^{\ddagger}(RX)$ is calculated from the equation

[3] $$S^{\ddagger}(RX) = S_g(RX) + \delta_s S(RX) + \Delta S^{\ddagger}$$

where the symbols on the right hand side are the gas phase entropy of RX, the entropy of

[1]To whom all correspondence should be addressed.

solution of RX, and the entropy of activation respectively.

The intention of the present paper is twofold. Firstly, to provide a careful study of the temperature dependence of the rates of attack of several nucleophiles on malachite green, from which the entropies of activation can be calculated. Secondly, to combine these entropies with the appropriate initial state data so that the transition state entropies for the malachite green – nucleophile reaction series can be characterized and to use the transition state entropies as a means of investigating the details of the activation process.

Experimental

Materials

Malachite green perchlorate was prepared and purified as described elsewhere in this series. The nucleophilic reagents were the best quality grade commercially available and were used without further purification.

All solutions were prepared with freshly distilled water.

Sodium hydroxide, hypochlorite, and sulphite solutions were prepared immediately prior to use. The sulphite solutions were stabilized with quinol (*ca.* 1×10^{-5} mol dm^{-3}) which had no effect on the measured rates (18).

The ammonia solutions were buffered to $pH = 9.25$.

A stock solution of malachite green was prepared by dissolving the perchlorate in acetone (1 cm^3) and diluting to 1 dm^3 with water. The final concentration of malachite green in the reaction cells was *ca.* 5×10^{-6} mol dm^{-3}.

Kinetic Measurements

Reactions involving hydroxide and ammonia were carried out using a Unicam SP500 spectrophotometer. Solutions were contained in 10 mm stoppered silica cells and the kinetics of the pseudo first order reactions were measured by recording the decrease of the absorption at 615 nm for at least three half-lives using a Varian A25 chart recorder.

Water flowing around the cell housing was maintained at the required temperature by means of a large thermostat regulated by a Tronac PTC-1000 precision controller described in more detail in an earlier paper of the present series. Temperature control was better than ± 0.01 K.

The reactions with hypochlorite and sulphite as nucleophiles were followed by stopped-flow spectroscopy. The custom-built apparatus used for these measurements will be described elsewhere. The temperature for this system was also maintained as described above.

Analysis of Rate Constants

Kinetic data from both the above systems were analysed using a three parameter nonlinear curve fit computer program (Basic for PDP-11) based on a method given by Moore (11). Best fit values of k_0, P_0, and P_∞ related to the equation

$$[4] \quad \ln [(P_\infty - P)/(P_\infty - P_0)] = -k_0 t = -(k_1 + k_{-1})t = -(k_2[N] + k_{-1})t$$

were computed together with their respective standard deviations. The quantity k_0 is the observed pseudo first order rate constant, P_0 and P_∞ are the dye absorbances at $t = 0$ and $t = \infty$ respectively, and P is the absorbance at $t = t$. When the reaction goes to equilibrium k_0 becomes the sum of the forward (k_1) and back (k_{-1}) rate constants and k_2 the second order rate constant for the attack of the nucleophile. Using a three parameter fit in this manner P_∞ becomes a disposable parameter and correct values of k_2 may be obtained irrespective of whether the reaction goes to equilibrium or completion. Second order rate constants (k_2) were obtained subsequently from a weighted least squares slope of the linear dependence of the pseudo first order rate constant on the concentration of nucleophile. The intercept from such an analysis of the hydroxide kinetic runs also yielded the pseudo first order rate constants for the water reaction, *i.e.*

$$[5] \quad k_0 = k_2[OH^-] + k_w$$

where k_2 is the second order rate constant for the hydroxide reaction k_w the pseudo first order rate constant for the concurrent reaction with water. The k_w constants were converted to second order constants in the usual way.

Temperature Dependence of the Rate Constants

A two parameter nonlinear least squares program was used to evaluate $\Delta H^\ddagger$ and $\Delta S^\ddagger$ from the Eyring equation

$$[6] \quad \ln k_2 = \ln \left(\frac{kT}{h}\right) + \frac{\Delta S^\ddagger}{R} - \frac{\Delta H^\ddagger}{RT}$$

Values of the second order rate constants and their corresponding temperatures were introduced into the program and best fit values of $\Delta S^\ddagger$ and $\Delta H^\ddagger$ together with their respective standard deviations were calculated via an iterative procedure.

Results

Some preliminary experiments showed that the pseudo first order rate constants, measured as described above, were relatively insensitive to ionic strength effects. Ritchie *et al.* (12) observed that the addition of inert electrolytes ($< 1 \times 10^{-2}$ mol dm^{-3}), had no detectable effect on the rate of attack of hydroxide on malachite green. Consequently even though the rates are all measured at variable ionic strength in the present study, concentrations were such that ionic strength influences on the reaction rates are negligible.

The second order rate constants for the attack of each nucleophile on malachite green at various temperatures are reported in Table 1. A typical plot representing (*a*) the dependence of pseudo first order rate constants on the concentration of a particular nucleophile (ammonia) and (*b*) the influence of temperature on this correlation is shown in Fig. 1.

TABLE 1. Second order rate constants for the reaction of malachite green with a series of nucleophiles at various temperatures

[a]Number of kinetic runs.
[b]Calculated from intercept of the second order hydroxide plot.

A comparison of the new rate measurements with those reported previously is made in Table 2. The differences in both ionic strength (see above) and temperature related to the previous measurements make meaningful comparisons with the present data difficult. The rate of attack of hydroxide on malachite green reported in this communication is in good agreement with that measured by Taft (reported in ref. 12). The water rate is slighly higher than those previously reported, but since this rate is derived from the intercept of the second order plot when hydroxide ion is the nucleophile, some uncertainty in the derived water rates is inevitable. The second order rate constants associated with the reactions of sulphite and hypochlorite as nucleophiles are also in reasonable agreement with those given by Ritchie and Virtanen (17). Dixon and Bruice (15) report rate constants which are considerably smaller. Ritchie and Virtanen rationalize the difference between their measurements and those of Dixon and Bruice on the basis of ionic strength differences. For the sulphite reaction the observed rate constant is 'corrected' from 2.8×10^2 mol^{-1} dm^3 s^{-1} ($I = 1.0$) to 3×10^3 mol^{-1} dm^3 s^{-1} ($I = 0$) using the Debye–Hückel Limiting Law (DHLL). The corrected value is still low considering the temperature (303.16 K) at which the rates were measured. The use of the DHLL for large ionic strength corrections must be considered suspect.

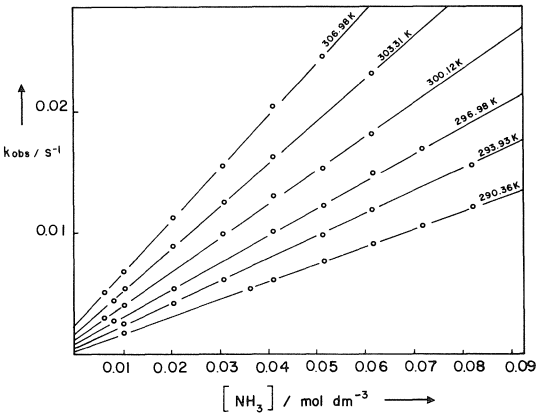

FIG. 1. The dependence of the pseudo first order rate constant on the concentration of ammonia for the reaction with malachite green at various temperatures.

The thermodynamic parameters calculated from the temperature–rate data are collected in Table 3, together with values of the standard entropies of the attacking nucleophile measured in aqueous solution at 298.16 K. These latter values collected by Latimer (13) are the most recent compilation of entropy data available, incorporating selected values by the U.S. National Bureau of Standards (14).

The entropies of activation derived from the kinetic data are negative for all the nucleophiles ranging from $-15 \rightarrow -24$ cal mol^{-1} deg^{-1}. The entropy of activation for the hydroxide ion reaction (-19.7 cal mol^{-1} K^{-1}) is in excellent agreement with that reported by Taft and coworkers (4) (-19 cal mol^{-1} K^{-1}) and is in fair agreement with the value reported by Ritchie *et al.* (6) (-14 cal mol^{-1} K^{-1}). The value of $\Delta S^{\ddagger}$ for the water reaction is more positive than previously reported values, -31.7 cal mol^{-1} K^{-1} (4) and -28.9 cal mol^{-1} K^{-1} (6), however the large differences in $\Delta S^{\ddagger}$ for this nucleophile are not surprising in view of the relatively large errors which must characterize the individual rate measurements (see above). The values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ reported here for the reactions of ammonia, hypochlorite, and sulphite with malachite green are new. The thermodynamic parameters of activation which characterize the hy-

[a]Data obtained from ref. 5.

drazine reaction, are based on the rate–temperature data reported by Dixon and Bruice (5) which were reprocessed using our computer program in order to maintain uniformity of calculation. Values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ obtained for this nucleophile are also reported in Table 3.

The entropy of activation for any given nucleophile attacking malachite green is given by

[7] $$\Delta S^{\ddagger} = S^{\ddagger}(\text{CINAC}) - S(\text{N}) - S(\text{CI})$$

where $S^{\ddagger}$(CINAC) is the entropy of the carbonium ion – nucleophile activated complex, S(N) is the entropy of the nucleophile, and S(CI) is the entropy of the carbonium ion. Hence

[8] $$S^{\ddagger}(\text{CINAC}) - S(\text{CI}) = \Delta S^{\ddagger} + S(\text{N})$$

Since S(CI) is constant for all the nucleophiles, the experimental quantities on the right hand side of [8] give a *relative* characterization of $S^{\ddagger}$(CINAC) as the structure of N is altered. Such a relative characterization of $S^{\ddagger}$(CINAC) is sufficient for the purposes of this communication. Values of $S^{\ddagger}$(CINAC) for the various nucleophiles attacking malachite green are recorded in Table 3.

Discussion

The second order rate constants related to the various nucleophiles in the present study show a wide range of reactivity (*ca.* 10^9) and these reagents may be classified tentatively in several ways. For instance water, at various times, has been postulated to react via a general-base catalysis mechanism (6), although the evidence for this is neither conclusive nor compelling. Sulphite, hypochlorite, and hydrazine are classified as α-effect nucleophiles and show enhanced reactivity when related to the pK_a of their con-

jugate acids. Hydroxide and ammonia might be described as 'normal' nucleophiles but may react as general bases (see above). The entropies of activation show no obvious correlation with the nucleophile classifications elaborated above, but tend to more negative values as the entropy of the aqueous nucleophile becomes more positive (see Table 3). The α-effect nucleophiles show no marked differences on the basis of their entropies of activation and this is unexpected, since the electronic nature of the α-effect suggests that a considerable degree of desolvation should be necessary before the effect is evident.

Whilst the entropies of activation themselves provide little indication of the details of the activation process, the entropy of the transition state is more useful. Ritchie's (18) extensive study suggests a 'reactant like' transition state, hence a correlation between $S^{\neq}$(CINAC) and the entropy of the initial state (S_i) is anticipated. The quantity S_i is given by

[9] $S_i = S(\mathrm{N}) + S(\mathrm{CI}) = S(\mathrm{N}) + \text{constant}$

hence for a 'reactant like' transition state the correlation anticipated is

[10] $S^{\neq}(\mathrm{CINAC}) = \lambda S(\mathrm{N}) + \text{constant}$

where λ is a constant. The relationship between $S^{\neq}$(CINAC) and S(N) is shown in Fig. 2, and a weighted linear least-squares treatment of the data gives $\lambda = 0.88 \pm 0.02$, *i.e.* confirming the 'reactant like' description of the transition states. This particular correlation has a further novel feature. The absolute entropies of individual ions are not known with any certainty since all entropy measurements of ions must involve two or more ions with some arbitrary division of the total entropy change between the ions involved. Although ions in chemical processes are always present in pairs, trios, quartets, etc., kinetic situations are possible where a *single ion* is the effective reagent. This is true in the present case where the hydroxide, sulphite, and hypochlorite ions are the attacking reagents. The fact that *both* the neutral and charged nucleophiles are embraced by a *single* line (Fig. 2) suggests that the approximation $S(\mathrm{H}^+) = 0$ is correct within the error of our correlation (*ca.* ±1.0 cal mol^{-1} K^{-1}). Thus the correlation between $S^{\neq}$(CINAC) and S(N) provides indirect confirmation of the scale currently used to represent single ion entropies.

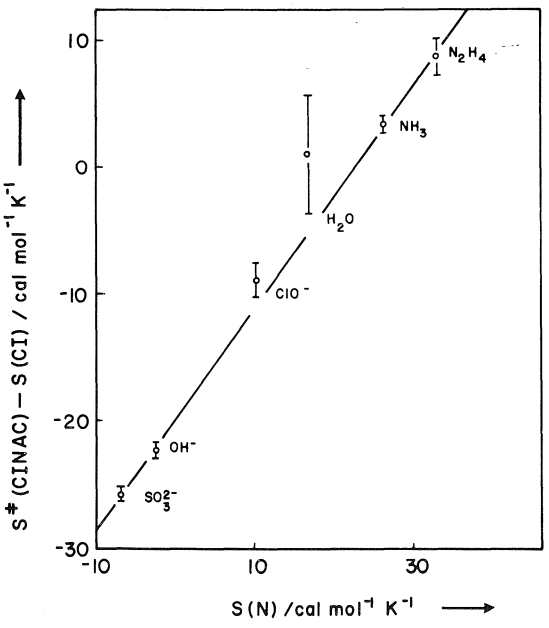

FIG. 2. An entropy correlation related to the reactions of various nucleophiles with malachite green.

Whilst there is no problem in specifying the relative values of the entropy of the initial state for the reactions representing *e.g.*, [1], the present reaction series, the possibility of specifying the entropy of the final state (S_f) as the nucleophile is varied is more problematical. However the products of the reactions for the water and hydroxide as nucleophiles differ only by a proton and hence $S_f(\mathrm{OH}^-) = S_f(\mathrm{H_2O})$, since $S(\mathrm{H}^+) = 0$. The data in Table 4 show that $\delta_N S_f \neq \delta_N S^{\neq}$ for H_2O and OH^- irrespective as to whether or not one or two water molecules are used to define the initial state for the carbonium ion reaction with water.[2] Since the quantity $S^{\neq}$(CINAC) shows no correlation with S_f for hydroxide and water we extrapolate this result to the remaining nucleophiles and retain the notion that the correlation of $S^{\neq}$(CINAC) with S(N) is the more meaningful relationship. Finally, if the appropriate kinetic data are available [10] provides a rough method of determining the standard state entropy of anions if such thermodynamic data are otherwise unavailable. The significance of the quantity λ in [10] has been discussed elsewhere by Robertson *et al.* (7–9). Constants such as λ or α (see above) are best considered as 'reaction coordinate parameters' and will be discussed more fully below.

[2] δ_N is an operator denoting changes in the structure of the nucleophile.

It is of some interest to examine the correlation between $S^{\ddagger}$ and S(N) for a system other than a triaryl carbonium ion. The reaction between methyl iodide and a similar series of nucleophiles provides a useful system for comparison. In a recent communication by Robertson, Annesa, and Scott (9), it was suggested that the mechanism for these reactions involved prior activation of the methyl halide to an intimate or tight ion pair followed by nucleophilic attack on this intermediate with *very little bond making*. This leads to the prediction that the $S^{\ddagger}(CH_3I)$ *vs.* S(N) correlation would give a slope very close to unity and this is indeed the case. The data for this correlation are displayed in Fig. 3 and tabulated in Table 4. The weighted linear least squares slope of the line is 0.94 ± 0.09 which agrees with previous proposals (9) in all respects, and perhaps represents the most important rebuttal of the usual S_N2 mechanism. The old S_N2 description of the methyl iodide displacements emphasizes the synchronous motion of the new and old bonding pairs related to the reacting carbon. The entropy correlation (Fig. 4) provides additional evidence which suggests that the old picture of these processes should be abandoned (see references given in ref. 9).

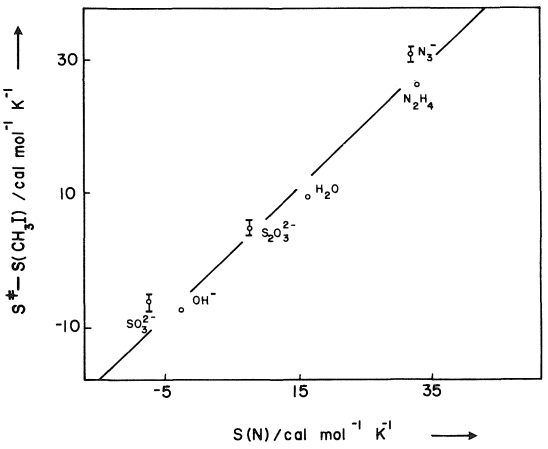

FIG. 3. An entropy correlation related to the reactions of various nucleophiles with methyl iodide.

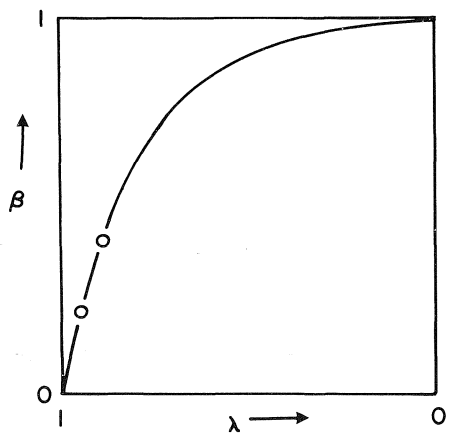

FIG. 4. The relationship between the Brønsted exponent (β) and the entropy quantity (λ).

Returning to the triaryl carbonium ion reactions we recall that Ritchie (18) has used the equation

$$[11] \qquad \log (k_n/k_0) = N_+$$

to accommodate the reaction of a range of carbonium ions and nucleophiles. The N_+ scale is defined by *p*-nitromalachite green as the standard carbonium ion and water as the standard nucleophile. Equation 11 indirectly demands that the selectivity of all nucleophiles with carbonium ions be identical. This conclusion is rather unusual and is in contradiction with data already in the literature (19). We note some thoughtful comments by Pross (20) on this matter and we hope to deal with the problem in some detail in later papers of the present series. The correlations between N_+ and the rates of attack of the nucleophiles on various carbonium ions appear adequate, but these reactions do not show any rate–equilibrium or equilibrium–equilibrium re-

lationships. This situation has prompted Ritchie (18) to postulate transition states which are somewhere between the solvent separated ($R^+//X^-$) and the intimate ion pair (R^+X^-) of the reversed Winstein scheme (21)

[12] $$R^+ + X^- \rightleftharpoons R^+//X^- \rightleftharpoons R^+X^- \rightleftharpoons RX$$

for all the nucleophiles studied. Whilst the extent of bond making does not emerge from correlations related to the N_+ scale, Dixon and Bruice (5) have shown that the Brønsted exponent (β) for a series of amines attacking malachite green is 0.4. Assuming the range of the Brønsted exponent is from zero to unity,[3] requires the conclusion that there is considerable bond making in the transition state between the amine and the carbonium ion. This conclusion is both at variance with Ritchie's views and contrasts with the entropy correlation (Fig. 2) presented here. The point is further illustrated by a comparison with the observed β values (0.22) for the reaction of similar amines with methyl iodide (22). Thus the β values and the λ parameters from the entropy correlations show a common trend for both substrates but the λ values suggest a much more 'reactant-like' transition state than the Brønsted exponents. The question then arises as to whether β or λ is the more significant measure of the position of the transition state along the reaction coordinate. Since $\beta = 0$ when $\lambda = 1$ and intuitively $\lambda = 0$ when $\beta \simeq 1$ (see footnote 3 and above) we can sketch the curve relating these two parameters, including the two experimentally observed points (Fig. 4). If Ritchie's conclusions concerning the 'reactant-like' nature of the transition state are valid then λ is the better measure of the transition state along the reaction coordinate. However the relationship between β and λ is clearly complex since the linear free energy quantity (β) may include factors to which the entropy quantity (λ) is either more or less insensitive. The correlation between β and λ does however suggest that β may be a nonlinear function of the reaction coordinate and therefore a deduction of the position of the transition state along the reaction coordinate using the Brønsted exponent is fraught with uncertainty particularly for reactions which are not proton transfers.

[3]For reactions which do not involve proton transfers as the rate determining step this proposal is arbitrary. Dixon and Bruice (5) are aware of this fact.

The rearrangement of 4-chloromethyl-1,4-dihydropyridine derivatives to pyrrolo[1,2-*c*]pyrimidines

ERIC BULLOCK, BRIAN GREGORY, AND M. THOMAS THOMAS

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1C 5S7

Received August 10, 1976

ERIC BULLOCK, BRIAN GREGORY, and M. THOMAS THOMAS. Can. J. Chem. **55**, 693 (1977).

When refluxed with urea in ethanol, certain 4-chloromethyl-1,4-dihydropyridines undergo rearrangement to give 1,2,5,9-tetrahydro-1-oxopyrrolo[1,2-*c*]pyrimidines in good yield. The structures of the products are established by spectroscopic properties and by dehydrogenation, hydrolysis, and decarboxylation to a 1,2-dihydro-1-oxopyrrolo[1,2-*c*]pyrimidine. In contrast, the reaction between thiourea and the 4-chloromethyl-1,4-dihydropyridines occurs without rearrangement and gives isothiouronium salts which were isolated as the picrates.

ERIC BULLOCK, BRIAN GREGORY et M. THOMAS THOMAS. Can. J. Chem. **55**, 693 (1977).

Lorsque l'on porte certaines chlorométhyl-4 dihydro-1,4 pyridines au reflux avec de l'urée dans l'éthanol, il se produit un réarrangement qui conduit aux tétrahydro-1,2,5,9 oxo-1 pyrrolo[1,2-*c*]pyrimidines avec de bon rendement. On a établi les structures des produits par des méthodes spectroscopiques et par déshydrogénation, hydrolyse et décarboxylation pour conduire à la dihydro-1,2 oxo-1 pyrrolo[1,2-*c*]pyrimidine. Par opposition, la réaction entre la thiourée et les chlorométhyl-4 dihydro-1,4 pyridines se produit sans réarrangement et donne des sels d'isothiouronium qui ont pu être isolés sous forme de picrates.

[Traduit par le journal]

4-Chloromethyl-1,4-dihydropyridines having electron-withdrawing substituents such as ethoxycarbonyl (1), acetyl (2), and cyano (3) groups at C_3 and C_5 were first synthesized by Benary who also reported some of their reactions with nucleophilic reagents. A reinvestigation of the action of cyanide ion on the diester **1***c* revealed that ring expansion had taken place leading to a 4,5-dihydro-1*H*-azepine (4), and this was extended to the dicyano (5) and diacetyl compounds (6). Subsequent work has shown that the chloromethyl compounds may be used in the synthesis of azepines (7), pyrroles (4–7), fulvenes (8), 2,3-dihydrofurans (6), 2-aza-8-thiabicyclo-[3.2.1]oct-3-enes (9), and furo[2,3-*b*]pyridines (10). We now report that the reaction of urea on the 4-chloromethyl compounds leads to pyrrolo[1,2-*c*]pyrimidine derivatives in adequate yield.

When the chloromethyl compound **1***c* was refluxed with urea in ethanol, the ultraviolet maxima at 231 and 349 nm (4) of the dihydropyridine chromophore were replaced, over the course of a few hours, by bands at 263 and 310 nm. Addition of water at this stage caused precipitation of a compound $C_{15}H_{20}N_2O_5$, M^+ 308 whose ultraviolet spectrum was incompatible with the presence of dihydropyridine, tetrahydropyridine, dihydroazepine, and pyrrole chromophores. The infrared spectrum revealed the presence of NH (ν_{max} 3415 cm^{-1}) and ester group(s) (ν_{max} 1707 cm^{-1}), while the mass spectrum was indicative of the presence of two ester groups (see below). The nmr spectrum showed signals due to methyl groups at δ 2.68 (t,[1] $J \sim 1$ Hz) and 2.28 (d, $J \sim 1$ Hz), which exhibit homollylic coupling to two and one protons respectively. The appearance of 1:1:1:1 quartets at δ

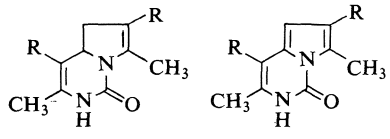
a $R_1 = COCH_3$ $R_2 = H$
b $R_1 = CO_2CH_3$ $R_2 = H$
c $R_1 = CO_2C_2H_5$ $R_2 = H$
d $R_1 = CN$ $R_2 = H$
e $R_1 = CO_2CH_3$ $R_2 = CH_3$

4.68 (H_X) and 3.22 (H_M) leaves no doubt that the protons responsible for homoallylic splitting of the methyl groups are attached to adjacent carbons (the signal due to H_A at approximately

[1]We cannot rule out the possibility that this signal consists of overlapping doublets due to the small coupling constant.

δ 2.64 is partly obscured by the methyl resonance at δ 2.68). A consideration of the origin of the compound, the above splitting pattern, and the infrared spectrum suggest the presence of the diethyl octa-2,6-diene-3,6-dicarboxylate (part structure **2**), while the low-field position of H_X suggests the attachment of a nitrogen function at this point. Since deuteration caused no change in the H_X signal the adjacent nitrogen atom is devoid of protons. In addition the nmr spectrum confirms the presence of two ethyl ester groups and a proton attached to nitrogen. These data are accommodated by the pyrrolo[1,2-*c*]pyrimidine structure **3***c*. In the presence of the paramagnetic shift reagent $Eu(fod)_3$ the H_A signal is revealed as a triplet which, like the signals due to H_M and H_X, is broadened by homoallylic coupling. The mass spectrum is in good agreement with structure **3***c*, and is dominated by fragmentation pathways involving the ethoxycarbonyl and ring methyl groups which are situated *ortho* to each other. One important pathway involves loss of ethyl group from the molecular ion to give an



3 **4**

b R = CO_2CH_3
c R = $CO_2C_2H_5$
d R = H

ion *m/e* 279 (98.5%) which subsequently loses ethanol to give an ion *m/e* 233 (81%) while sequential loss of ethoxyl and ethyl radicals from the molecular ion gives rise to the base peak at *m/e* 234. The ions at *m/e* 183, 155, and 137 are reminiscent of the 1,2,3,4-tetrahydro-2-oxopyrimidines (11) and may arise by scission between C_5 and C_9 (see Scheme 1) followed by loss of the side chain from nitrogen with concomitant hydrogen transfer to give the 2-oxopyrimidinium ion (*m/e* 183). This ion may lose ethylene from the ethyl ester by McLafferty rearrangement to give an ion at *m/e* 155 or lose ethanol to give an ion *m/e* 137.[2]

[2]In support of this interpretation, the corresponding dimethyl ester (see below) gives rise to expected ions at *m/e* 169 and 137 but no fragment analogous to the *m/e* 155 ion.

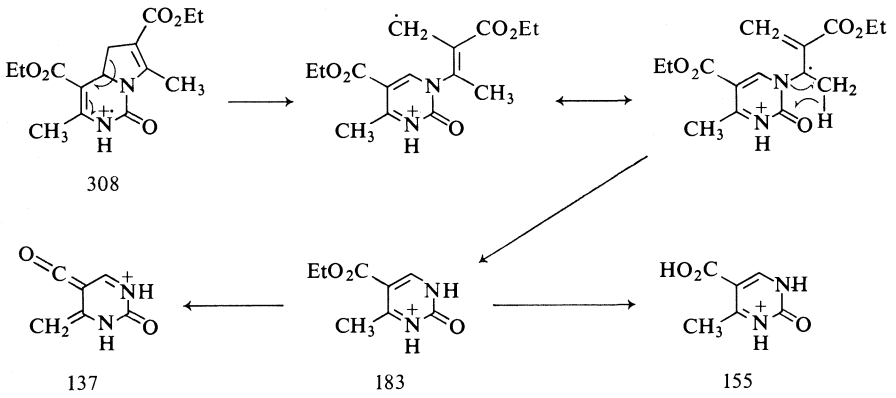
The structure **3***c* was confirmed, as outlined below, by dehydrogenation to give a compound showing an aromatic proton, and subsequent removal of ethoxycarbonyl groups to give a compound having three aromatic protons, two of which are attached to adjacent carbon atoms.

The pyrrolo[1,2-*c*]pyrimidine **3***c* was dehydrogenated by 10% palladium-on-carbon in boiling mesitylene, or, less efficiently, by heating with sulfur, to a compound $C_{15}H_{18}N_2O_5$, M^+ 306 whose nmr spectrum reveals the presence of non-equivalent ethyl esters, methyl singlets at δ 2.97 and 2.42, and a one proton singlet at δ 6.79. The low-field shift of the methyl resonances and the chemical shift of the one-proton singlet, typical of pyrrole β protons, are consistent with structure **4***c* for this product.

When **4***c* was refluxed with 50% aqueous sulfuric acid, hydrolysis and decarboxylation occurred to give **4***d*, $C_9H_{10}N_2O$, in which the functionality of the oxygen is indicated by the presence of a carbonyl stretching absorption at 1701 cm^{-1} in the infrared spectrum. The nmr of **4***d* exhibited a pair of doublets (an AB system due to adjacent aromatic protons) in addition to two methyl singlets, a broad NH singlet and a singlet due to a further uncoupled aromatic proton. The mass spectrum showed intense M and $M - 1$ ions.

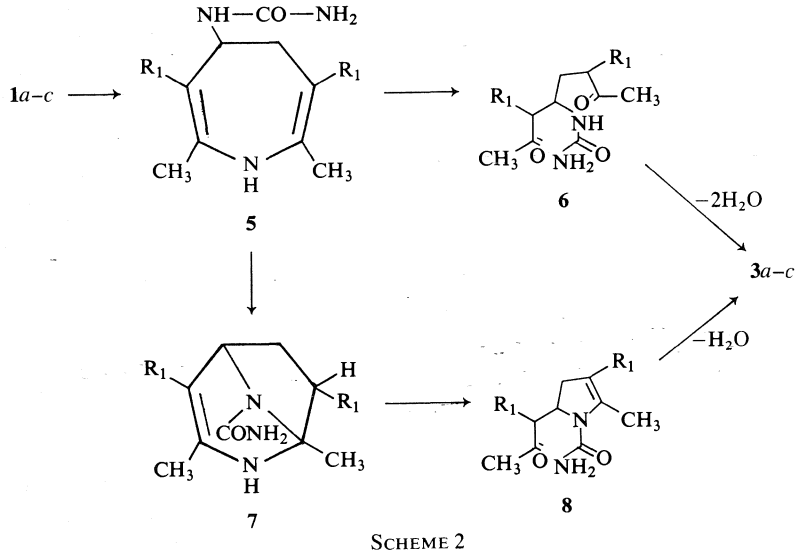
When refluxed with urea in ethanol, the dihydropyridines **1***a* and **1***b* gave the corresponding pyrrolopyrimidine derivatives **3***a* and **3***b* whose structures are supported by their spectroscopic properties. Under similar reaction conditions the dicyano compound **1***d* was unchanged.

The rearrangement of the dihydropyridines **1***a–c* to the pyrrolopyrimidines **3***a–c* is believed to proceed via alkylation of urea on nitrogen (12), with simultaneous ring expansion. to give the 4-ureido-4,5-dihydro-1*H*-azepine derivative **5** followed by hydrolytic ring-opening to give the acyclic compound **6** and subsequent cyclization. (see Scheme 2). An alternative is possible which involves intramolecular Michael addition (*cf.* ref. 13) forming **7** followed by ring-opening to give **8** and cyclization. In an attempt to isolate intermediates, several by-products including ethyl acetoacetate, ethyl 2-methylpyrrole-3-carboxylate, ethyl carbamate, and ethyl 3-ureidocrotonate were isolated from the reaction of urea with **1***c*. It is well-known that urea decomposes in boiling ethanol to give ethyl carbamate and



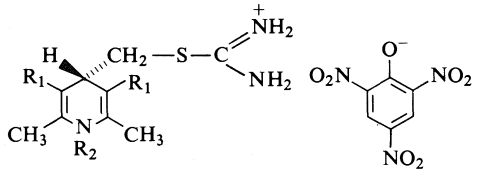
Et = C_2H_5

SCHEME 1



SCHEME 2

ammonia (14). Anderson and Johnson have shown that **1***c* reacts with ammonium hydroxide in alcohol to give ethyl 2-methylpyrrole-3-carboxylate and ethyl acetoacetate (7). In view of the suggested mechanisms (above) it is interesting that ethyl 3-ureidocrotonate may be isolated. This is formed from ethyl acetoacetate and urea (15) and demonstrates that the cyclization of a ureido function onto the carbonyl group of a β-ketoester moiety is possible under these reaction conditions. In addition, it is unlikely that dimethyl 2,7-dimethyl-4*H*-azepine-3,6-dicarboxylate, which has been shown to be an intermediate in the cyanide catalyzed ring expansion of **1***b* (16), is an intermediate in this reaction, since no pyrrolopyrimidine is formed when the azepine is refluxed in ethanol with urea alone or



a $R_1 = COCH_3$ $R_2 = H$
b $R_1 = CO_2CH_3$ $R_2 = H$
c $R_1 = CO_2CH_3$ $R_2 = CH_3$
d $R_1 = CO_2C_2H_5$ $R_2 = H$

in the presence of ammonium acetate or ammonium chloride.

The above mechanisms each suggest that the nitrogen of the dihydropyridine is eliminated during the reaction and, in support of this, it has been shown that the *N*-methyl compound **1***e* gives the pyrrolopyrimidine **3***b* when refluxed with urea.

Although the report of the degradation of the paralytic shellfish toxin saxitoxin to a pyrrolo-[1,2-*c*]pyrimidine (17) stimulated work on this ring system, there are still few synthetic routes available (18). Pyrrolo[1,2-*c*]pyrimidine derivatives have been prepared from pyrrol-2-aldehyde (19), aminoethylpyrrolidines (20), 3-(4-pyrimidyl)-1-propanol (21), and pyrimidine quaternary salts (22–24). The preparation from 4-chloromethyl-1,4-dihydropyridines represents a convenient entry into this ring system and its scope is presently under investigation.

In contrast to the rearrangement which occurs on reaction with urea, the reaction of **1***a–c,e* with thiourea has been shown to give *S*-alkylisothiouronium salts. When the 4-chloromethyl-1,4-dihydropyridines **1***a–c,e* were refluxed with thiourea in ethanol until tlc revealed absence of the chloromethyl compound, it was found that the solution still showed ultraviolet absorption typical of the 1,4-dihydropyridine (λ_{max} 231 and 350 nm) rather than the dihydroazepine (4) or pyrrolopyrimidine chromophores. Addition of picric acid to the solution allowed crystallization of the isothiouronium picrates **9***a–d*. The nmr spectra of these compounds were in agreement with the assigned structures. Again the 3,5-dicyano compound **1***d* failed to react.

The pyrrolopyrimidine **3***c* was screened for pharmacological activity, and found to have no *in vitro* antibiotic, antiparasitic, enzyme inhibitory, contraceptive, or antihypertensive activity.

Experimental

Melting points were determined using a Fisher-Johns melting point apparatus. Infrared spectra were obtained in chloroform solution using a Perkin-Elmer 237B grating infrared spectrometer. Ultraviolet spectra were measured on Unicam SP 800D or Perkin Elmer 202 spectrophotometers using solutions in 95% ethanol. Spectra were calibrated using the bands at 2850.7 and 1601.4 cm^{-1} of polystyrene (ir) or at 279.4 and 360.9 nm of a holmium oxide filter (uv). The ^1H nmr spectra were obtained on Varian HA 100 or EM 360 spectrometers using deuterochloroform as solvent unless specified otherwise. All chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. The sample of Sievers Eu(fod)$_3$ shift reagent was obtained from Norell Chemical Company, Inc., Landing, New Jersey, 07850. Mass spectra were determined at 70 eV ionizing energy using a Hitachi–Perkin-Elmer RMU 6E mass spectrometer. Only the most intense peaks are listed; normalized intensities are given in parentheses. Initial and final total ion current values differed by $< 5\%$. New compounds were homogeneous by tlc and were analyzed for C, H, N, S by Alfred Bernhardt, West Germany. The identity of known compounds was established by mp, mixture mp, and comparison of ir, nmr, and ms with those of authentic specimens.

Diethyl 1,2,5,9-Tetrahydro-3,7-dimethyl-1-oxopyrrolo[1,2-c]pyrimidine-4,6-dicarboxylate, 3c

The chloromethyl compound **1***c* (5.03 g) and urea (3.35 g) were heated under reflux in ethanol (100 ml) for 7 h and then concentrated to about 40 ml. Water (200 ml) was added and, on standing, a precipitate was formed which was filtered, washed with water, and recrystallized from cyclohexane to give the product **3***c* (4.07 g, 79%), mp 132–133 °C. *Anal.* calcd. for $C_{15}H_{20}N_2O_5$: C 58.43, H 6.54, N 9.09; found: C 58.38, H 6.61, N 9.11. Spectral data: ir 3415 (NH, free), 3217 (NH, bonded), 1707 (unsaturated ester), 1670 (amide), 1640 cm^{-1} (C=C); uv 263 (ε 26 200) 310 nm (ε 7150); ^1H nmr δ 1.29 and 1.31 (two t, J = 7.0 Hz, 6H, methyls of ethyl esters), 2.28 (d, $J_{homoallylic}$ ~1 Hz, CH_3 at C_3), 2.64 approx (m, partly obscured by methyl resonance at δ 2.68, H_A at C_5), 2.68 (t, $J_{homoallylic}$ ~ 1 Hz, 4H,[3] CH_3 at C_7), 3.22 (two q, J_{AM} 14.5 Hz, J_{MX} = 9.5 Hz, $J_{homoallylic}$ ~ 1 Hz, 1H, H_M at C_5), 4.24 and 4.20 (overlapping q, J = 7.0 Hz, 4H, CH_2 of ethyl esters), 4.68 (q broadened by homoallylic coupling, J_{AX} = 13 Hz, J_{MX} = 9.5 Hz, 1H, H_x at C_9), 9.01 (s, 1H, NH). Compound **3***c* (3.1×10^{-4} mol) and the shift reagent Eu(III)(fod)$_3$ (4.8×10^{-5} mol) in $CDCl_3$ (0.6 ml) showed δ 1.40 and 1.43 (two t, J = 7.0 Hz, 6H methyls of ethyl esters), 2.39 (s, 3H, CH_3 at C_3), 3.11 (br t, J_{AM} = 14.5 Hz, J_{AX} = 13 Hz, 1H, H_A at C_5), 3.62 (q, J_{AM} = 14.5 Hz, J_{MX} = 9.5 Hz, 1H, H_M at C_5), 4.23 (s, 3H, CH_3 at C_7), 4.40 (q, J = 7 Hz, 4H, CH_2 of ethyl esters), 5.38 (q, broadened, J_{AX} = 13 Hz, J_{MX} = 9.5 Hz, 1H, H_M at C_9), 9.95 (s, 1H, NH); ms *m/e* 308(51, M^+), 279(98), 263(40), 261(28), 235(43), 234(100), 233(81), 207(53), 206(63), 205(26), 189(69), 183(15), 163(27), 162(55), 161(33), 155(18), and 137(23).

The filtrate was concentrated to remove ethanol, acidified with hydrochloric acid, and extracted with ether. The ether was washed with water, dried ($MgSO_4$), filtered, and evaporated to give a pleasant smelling oil which contained ethyl acetoacetate. On standing, crystals were obtained, which were filtered off, recrystallized from aqueous ethanol and then sublimed to give ethyl 2-methylpyrrole-3-carboxylate mp 76–77 °C (lit. (1, 7) 78–79 °C) and had ir and ms identical with those of an authentic specimen.

In a separate experiment, after concentration and addition of water the reaction mixture was extracted using ether. Evaporation of the ether and chromatography on silica gel afforded ethyl acetoacetate, ethyl 2-methylpyrrole-3-carboxylate, diethyl 1,2,5,9-tetrahydro-3,7-dimethyl-1-oxopyrrolo[1,2-*c*]pyrimidine-4,6-dicarboxylate,

[3]The integration includes that of the signal due to H_A.

A study of the chromous chloride promoted addition of various *N*-chloro- and *N*-bromoamides (ZCONHX) to a variety of olefins shows that two types of addition products can be obtained, namely *N*-(2-haloalkyl)amides (1,2-adducts) which generally predominate and *N*-alkylamides (1,H-adducts). The total yield of addition products, the relative proportion of *N*-(2-haloalkyl)amide(s) and *N*-alkylamide, and the stereochemistry of 1,2-addition to cyclic olefins vary with the *N*-haloamide, that is with both Z and X, and also with the olefin. The best yields of 1,2-adducts were obtained with *N*-chlorocarbamates (Z = *O*-alkyl) and the proper choice of Z (*e.g.*, 2,2,2-trichloroethoxy, benzyloxy) shows the potential of this method for the synthesis of N-protected β-chloro primary amines where the amino group is attached to the less substituted carbon atom. The use of an excess of *N*-haloamide results in high yields (> 90%) of 1,2-addition based on the olefin, the excess of *N*-haloamide being simply reduced to the corresponding amide. *N*-Chloro-*N*-alkylamides (ZCONRCl) do not add to cyclohexene and are simply reduced to the corresponding amides.

HUGHES DRIGUEZ, JOHN M. PATON et JEAN LESSARD. Can. J. Chem. **55**, 700 (1977).

Une étude de l'addition, catalysée par le chlorure chromeux, de divers *N*-chloro- et *N*-bromoamides (ZCONHX) à des oléfines variées montre que deux types de produits d'addition sont possibles, soit des *N*-(halo-2 alkyl)amides (adduits-1,2) qui généralement prédominent, et des *N*-alkylamides (adduits-1,H). Le rendement total en addition, la proportion relative de *N*-(halo-2 alkyl)amide(s) et de *N*-alkylamide, et la stéréochimie d'addition-1,2 aux oléfines cycliques varient avec le N-haloamide selon la nature de Z et X, et avec l'oléfine. De façon générale, les *N*-chlorocarbamates (Z = *O*-alkyle) donnent les meilleurs rendements en addition-1,2 et avec un choix approprié de Z (par exemple un groupement trichloro-2,2,2 éthoxy ou benzyloxy), peuvent servir à la synthèse de β-chloroamines primaires N-protégées dont le groupement amino est fixé à l'atome de carbone le moins substitué. Et utilisant un excès de *N*-haloamide, il est possible d'obtenir d'excellents rendements (> 90%) en addition-1,2 par rapport à l'oléfine car le *N*-haloamide en excès est tout simplement réduit en amide correspondant. Les *N*-chloro-*N*-alkylamides (ZCONRCl) ne s'additionnent pas au cyclohexene et sont simplement réduits en amides correspondants.

Introduction

In the photochemically induced reaction of *N*-haloamides with olefins, the halogen atom can compete with the amido radical. Thus the failure of certain *N*-haloamides (*e.g.* *N*-bromo- and *N*-chloro-*N*-methylacetamide) to add to olefins (3, 4)[6] could be due to the greater reactivity of the halogen atom and not necessarily to the fact that the amido radical would abstract hydrogen in preference to adding to the double bond as proposed by Neale *et al.* (3). This hypothesis led us to study the one-electron reduction of *N*-haloamides by low-valent transition metal salts as a way of producing amido radicals without the concomitant formation of halogen atoms, and to develop a simple and efficient method for adding *N*-haloamides to olefins using chromous chloride. This paper reports a study of the scope and limitations of the method for the synthesis of *N*-(2-haloalkyl)-amides and *N*-protected β-haloamines (Scheme 1). The standard reaction conditions are very mild and the reaction procedure quite simple (see the Experimental). As will be seen, this reaction constitutes a useful alternative and complement to other methods of addition of

N-haloamides to olefins (5); namely, the thermal addition of *N*,*N*-dichlorourethane (6–8*b*, 8*c*), the photochemical addition of *N*-chlorourethane (8) and of *N*-chloro- and *N*-bromocarboxamides (4). This reaction constitutes also a novel use for the chromous ion (9, 10).

Additions

Addition of N-Chlorourethane 1a to Cyclohexene (Scheme 2: Z = CH_3CH_2O, X = Cl)

Since it is known that the photochemical addition of *N*-chlorourethane (NCU, **1***a*) to cyclohexene proceeds with a good yield (8*a*), we chose the NCU–cyclohexene system to study the possibility of using a low-valent transition metal salt to initiate the addition of *N*-haloamides to olefins. A cursory investigation of the reduction of NCU by various metal salts in aqueous methanol at *ca.* 0 °C and under an oxygen-free atmosphere (nitrogen or carbon dioxide) showed that Fe(II), Cu(I), and Ti(III)salts were ineffective whereas V(II), Cr(II), and Ti(II) chlorides did reduce NCU as evidenced by changes in color and the complete disappearance of active chlorine. The reduction of NCU by the latter three salts was then carried out under the same conditions but in the presence of cyclohexene (3 mol per mol of NCU). No β-chlorocarbamate was formed with V(II) chloride,[7] a 10% yield of β-chlorocarbamates **2***a* and **3***a* (*cis*:*trans* = 2) was obtained with Ti(II) chloride, and a 42% yield (*cis*:*trans* = 1.9) with Cr(II) chloride. This led us to investigate further the chromous chloride promoted addition of NCU **1***a* to cyclohexene.

The results of this investigation are summarized in Table 1. Besides the *cis* and *trans* β-chlorocarbamates **2***a* and **3***a* (1,2-adducts), the carbamate **4***a* (1,H-adduct)[8] was isolated in small amounts. In the presence of chloroform, which was necessary at −78 °C to maintain an homogeneous solution, higher yields of 1,2-adducts and larger *cis*–*trans* ratios were obtained (compare entries 1 and 3, 2 and 4). The yield of 1,2-adducts and, in the presence of chloroform, the proportion of the *cis* isomer **2***a*, were also increased by lowering the temperature (see entries 1 and 2, and entries 3, 4, and 5). A slow rate of addition of chromous chloride (a lower effective concentration of chromous ions) resulted in a noticeable increase in the yield of **2***a* and **3***a* (compare entries 5 and 6). A fourfold dilution of the reaction mixture and a decrease in the chloroform–methanol voluminal ratio had little effect (compare entries 6 and 7). All the NCU which did not add to cyclohexene was recovered as urethane as seen from the material balance. Bicyclohexenyl was formed in small amounts, but none of the chlorinated products (dichlorocyclohexane, 3-chlorocyclohexene, 4-chlorocyclohexene) which could be expected if chlorine atoms were involved,[9] were detected. The reaction is thus very clean and a very high yield of 1,2-adducts **2***a* and **3***a* (99% based on cyclohexene) was obtained when using an excess of NCU even though the reaction was carried out at −40 °C, in the absence of chloroform, and with a fast rate of addition of chromous chloride (entry 8).

The investigation was extended to include the addition of various *N*-haloamides **1** to cyclohexene (Tables 2 and 3) and then to a variety of olefins (Tables 4 to 8). The reaction conditions were similar to those referred to in Table 1, entry 6, except for the total amount of solvent and relative proportions of chloroform and methanol (see the Experimental).

Addition of N-Chloroamides (1, X = Cl) to Cyclohexene (Scheme 2)

The results of a comparative study of the addition of various *N*-chloroamides to cyclohexene are reported in Table 2. The total yield of addition (**2** + **3** + **4**), the ratio of 1,2-addition (**2** + **3**) to 1,H-addition (**4**), and the *cis* (**2**) – *trans* (**3**) ratio vary with the structure of **Z**: increase of the total yield of addition in the order

[7]In chloroform–methanol at −20 °C, 1.5% of β-chlorocarbamates **2***a* and **3***a* (*cis*:*trans* = 1) was formed according to vapor phase chromatographic (vpc) analysis.

[8]Throughout the paper, the addition products having a hydrogen instead of the halogen at position β will be referred to as the 1,H-adducts. They do not result from reduction of the 1,2-adducts as will be seen.

[9]Dichlorocyclohexane and, in smaller amounts, bicyclohexenyl, 3-chlorocyclohexene, and 4-chlorocyclohexene, are formed in the photochemical decomposition of *N*-chlorocarboxamides and *N*-chlorosuccinimide in the presence of cyclohexene (4*a*,*c*).

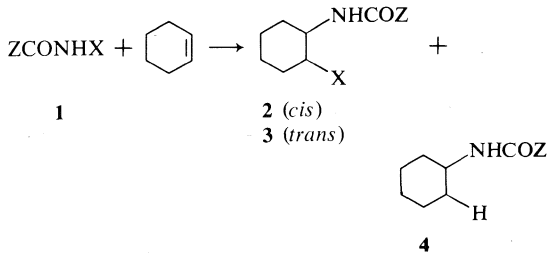
[c]By vpc.
[d]No attempt was made to detect or isolate the 1,H-adduct **4**.
[e]Cooling bath temperature of −55 °C. *N*-Chlorourea **1***i* was insoluble at −78 °C.
[f]The *cis* and *trans* isomers could not be separated completely. The *cis* adduct **2***i* was obtained pure by recrystallization.

$CCl_3 < CH_3 < CF_3 < ClCH_2 <$ *O*-alkyl; increase of the 1,2-adducts – 1,H-adduct ratio in the order $CH_3 < CH_2Cl < OC_2H_5 < CCl_3 \leq CF_3$; and variation of the *cis–trans* ratio in the order $CF_3 \simeq CCl_3 \leq CH_3 \simeq CH_2Cl <$ *O*-alkyl. Thus the best yields of 1,2-adducts **2** and **3** and the highest *cis* (**2**) – *trans* (**3**) ratios were obtained with the *N*-chlorocarbamates **1***a* to **1***d*. The addition of *N*-chloro-2,2,2-trichloroethylcarbamate **1***c* and *N*-chlorobenzylcarbamate **1***d* illustrates the potential of this reaction for the synthesis of



SCHEME 2

N-protected β-chloro primary amines. Treatment of the β-chlorocarbamates **2***c* and **3***c* with zinc dust in acetic acid at 0 °C afforded the pure β-chlorocyclohexylamines *cis* (**5**) and *trans* (**6**), respectively, which were characterized as their *N*-acetyl derivatives **2***c* (11) and **3***c* (12) (90 and 88% yield, respectively). Hydrogenolysis of the β-chlorocarbamate **2***d* followed by acetylation gave the *N*-acetyl derivative **2***c* in a 98% yield.

*Addition of N-Bromoamides (**1**, X = Br) to Cyclohexene (Scheme 2)*

The results are recorded in Table 3. The influence of the structure of Z on the yield of addition products, on the ratio of 1,2-adducts – 1,H-adduct, and on the *cis–trans* ratio is much less important than with the *N*-chloroamides. The *N*-bromoamides gave lower *cis–trans* ratios[10] and a much smaller proportion of 1,H-adduct **4** than the corresponding *N*-chloroamides. Since alkyl bromides should be reduced more easily

[10]Lower *cis–trans* ratios with the *N*-bromoamides as compared to the *N*-chloroamides have also been observed in the photochemical additions to cyclohexene (4*a*).

TABLE 3. Addition of *N*-bromoamides (**1**, X = Br) to cyclohexene (Scheme 2)

N-Bromoamide	Yield of addition products			
	2+**3** (%)	**2**/**3**	**4** (%)	Electrophilic bromination (%)[a]
$CH_3CH_2OCONHBr$ **1***j*	71	1.5	<0.5[b]	26
$ClCH_2CH_2OCONHBr$ **1***k*	77	1.3	[c]	[d]
$CCl_3CH_2OCONHBr$ **1***l*	70	1.4	[c]	20
	85[e]	1.6	[c]	12
$C_6H_5CH_2OCONHBr$ **1***m*	61	1.7	[c]	35
$CH_3CONHBr$ **1***n*	67	1.1	9	2
$ClCH_2CONHBr$ **1***o*	74	1.3	~4[f]	[d]
$CCl_3CONHBr$ **1***p*	66	1.0	[c]	[d]
$CH_3(CH_2)_3CONHBr$ **1***q*	66	1.4	[c]	2

[a]The yields of 2-bromomethoxycyclohexane and 2-bromocyclohexanol were determined by vpc: respectively, 15% and 11% for **1***j*, 2% and 8% with **1***l*, 19% and 16% with **1***m*. No 2-bromocyclohexanol was detected with **1***n* and **1***q*.
[b]By vpc.
[c]Not detected in the chromatographic fractions.
[d]Not determined.
[e]The *N*-bromocarbamate **1***l* was recrystallized from methylene chloride – pentane at *ca.* −40 °C immediately before the reaction. Five moles of cyclohexene per mol of **1***l* were used.
[f]By nmr in a mixture of **4***o* and 2-chloroacetamide.

than alkyl chlorides, the smaller amount of 1,H-adduct **4** with the *N*-bromoamides strongly suggests that this addition product does not arise from reduction of the 1,2-adducts **2** and **3**. Indeed, each of the 1,2-adducts **2***a*, **3***a*, **2***j*, and **3***j* was recovered unchanged after treatment with chromous chloride under the standard reaction conditions. These experiments also show that no *cis–trans* isomerization occurred during the addition reaction. The 1,H-adduct **4** most probably results from Cr(II) reduction of the intermediate β-amidocyclohexyl radical followed by protonolysis of the organochromium derivative. A faster halogen-atom transfer to the radical in the case of the *N*-bromoamides would then account for the smaller proportion of 1,H-addition.[11]

Due to electrophilic bromination, the *N*-bromocarbamates **1***j* to **1***m* gave lower yields of addition than the corresponding *N*-chlorocarbamates **1***a* to **1***d*. This competing ionic process limits the synthetic value of the *N*-bromocarbamates for the preparation of N-protected β-bromo primary amines. When the *N*-bromocarbamate was recrystallized at low temperature (< −40 °C) then dissolved in the cold and the solution used immediately, electrophilic bromination was less important (see **1***l*). We believe the electrophilic brominating species to be the *N*,*N*-dibromocarbamate which would then be partly removed by low temperature recrystallization. *N*-Bromocarbamates have been shown to be in equilibrium with their disproportionation products, [1], ($K \simeq 0.1$ near room temperature) (13). With the *N*-bromocarboxamides which have much less tendency to dismutate (13), electrophilic bromination was almost negligible

[1] $2ROCONHBr \rightleftarrows ROCONBr_2 + ROCONH_2$

and the yields of addition (**2** + **3** + **4**) were more or less comparable to those obtained with the corresponding *N*-chlorocarboxamides.

The addition of *N*-bromopentanoamide **1***q* was studied in order to see if intramolecular hydrogen abstraction in the amido radical could compete significantly with the intermolecular attack on the double bond.[12] It did not since the yield of addition was quite similar to that obtained with *N*-bromoacetamide **1***n*. Furthermore we could not obtain any evidence of the formation of 4-bromopentanoamide. When *N*-bromopentanoamide **1***q* was treated with chromous chloride under the same conditions but in the absence of an olefin, pentanoamide was isolated in a 95% yield. A microanalytical determination of bromine indicated that about 2% of 4-bromopentanoamide could have been formed. Thus

[11]See the accompanying paper for a discussion of the mechanistic aspects.

[12]*N*-Halocarboxamides are known to photochemically rearrange to the 4-halo isomers through a free-radical chain reaction involving an intramolecular hydrogen-atom transfer to the amido radical (3, 14). For example, *N*-bromopentanoamide was reported to yield 37% of 4-bromopentanoamide (3).

intermolecular addition of the pentanoamido radical to cyclohexene is faster than intramolecular hydrogen abstraction which appears to be slower than its chromium(II) reduction.

Additions to 1-Octene, 1-Methylcyclohexene, and Norbornene

The additions to 1-octene (Scheme 3 and Table 4) and to 1-methylcyclohexene (Scheme 4 and Table 5) illustrate the regiospecificity of the reaction. The amido group becomes attached to the less substituted carbon atom as expected if an amido radical is the attacking species. Small amounts of the 1,2-adducts **11** and **12** resulting from the attack on the more substituted carbon atom of 1-methylcyclohexene were isolated in the case of NCU **1***a* and *N*-bromoacetamide **1***n*. They were probably formed also with the other *N*-haloamides but were not isolated. The additions to norbornene (Scheme 5 and Table 6) gave exclusively products having the amido group *exo* in agreement again with the initial attack of an amido radical. Indeed, in free radical additions to norbornene, the initial addition generally occurs from the less hindered *exo* side (8*b*, 15); very few examples of a partial attack from the *endo* side have been reported (16).

With 1-octene (Table 4) and 1-methylcyclohexene (Table 5), the yields of addition products (1,2-addition plus 1,H-addition) were similar to those obtained with cyclohexene and generally somewhat lower than with norbornene (Table 6). In the case of 1-methylcyclohexene, no 1,H-adduct was isolated even with *N*-chloroacetamide **1***e* which gave the highest proportion of 1,H-addition with the other olefins whereas, with

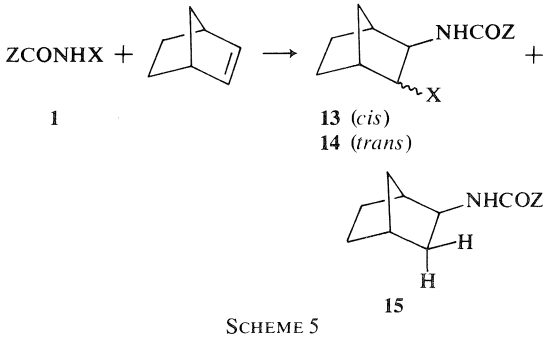
$ClCH_2CONHBr$ **1***o*	77	2.5	[b]	

[a]The ratio was determined by vpc. The *trans* isomer **12***a* was not isolated as such (see section entitled Structure of the addition products).
[b]The addition products **11** and **12** could not be isolated by preparative layer chromatography but they were probably formed according to the tlc of the crude reaction product.
[c]A chromatographic fraction contained at least one of the isomers according to the ^1H nmr and mass spectra.



SCHEME 5

1-octene and norbornene, the ratio of 1,2-addition – 1,H-addition did increase with Z in the order $CH_3 < CH_2Cl < OC_2H_5$ as found with cyclohexene. However, norbornene is unique among the mono-olefins studied in leading

TABLE 6. Addition of *N*-haloamides **1** to norbornene (Scheme 5)

[b]Only the *cis* isomer **13***e* could be isolated from the chromatographic fractions.

predominantly to 1,H-addition with *N*-chloroamides whereas with *N*-bromoamides, the amount of 1,H-addition was more or less comparable to that obtained with cyclohexene. For instance, *N*-chloroacetamide **1***e* gave 98% of 1,H-addition whereas *N*-bromoacetamide **1***n* gave 4% of 1,H-addition (Table 6). The highest yields of 1,2-addition to 1-octene and 1-methylcyclohexene were obtained with a *N*-chlorocarbamate as was the case in the additions to cyclohexene. Finally, for the 1,2-addition to 1-methylcyclohexene and to norbornene, the *cis–trans* ratios (respectively **9**:**10** and **13**:**14**) were found to vary with Z in the order $CH_3 < CH_2Cl < OC_2H_5$ and to be larger for X = Cl than for X = Br as for the 1,2-addition to cyclohexene. With a given *N*-haloamide, 1-methylcyclohexene led to a larger *cis–trans* ratio than cyclohexene whereas norbornene led to a similar *cis–trans* ratio.

Addition of NCU 1a and N-Bromo-2-chloroacetamide 1o to Conjugated Dienes

The products and yields of addition of these two *N*-haloamides to butadiene and 1,3-cyclohexadiene are given in Table 7. With NCU, no chlorinated products (1,2- or 1,4-adducts) could be detected. The adducts **16***a* and **17***a* from butadiene and **18***a* from cyclohexadiene were most probably formed *via* chromous ion trapping of the corresponding intermediate α-ethoxycarbonylamino allylic radicals. They did not arise from reduction of the allylic chlorides resulting from a 1,2- or a 1,4-addition since 3-chlorocyclohexene was not reduced to a significant extent by excess chromous chloride under similar reaction conditions. Trapping of the 4-ethoxycarbonylaminobutenyl radical occurred with equal ease at both positions 1 and 3 whereas trapping of the 4-ethoxycarbonylaminocyclohexenyl radical occurred predominantly at position 3.

The addition of *N*-bromo-2-chloroacetamide **1***o* to the above conjugated dienes did not give any brominated products. Since bromine-atom transfers are usually faster than chlorine-atom transfers, 1,2- and/or 1,4-adducts could have been expected. However, the exclusive isolation of adducts **16***o* and **17***o* from butadiene, and of adducts **18***o* and **19***o* from cyclohexadiene, does not exclude the formation first of 1,2- and/or 1,4-adducts (allylic bromides). Indeed 3-bromocyclohexene was readily reduced by chromous chloride under the reaction conditions. The formation of a relatively large proportion of **19***o* is noteworthy since the corresponding adduct **19***a* was not isolated.

Addition of N-Chlorocarbamates (1: Z = OR, X = Cl) to Various Mono-olefins

We have seen that among the *N*-haloamides studied, the *N*-chlorocarbamates were the most efficient for the 1,2-addition to simple mono-olefins like cyclohexene, 1-octene, and 1-methylcyclohexene (norbornene being an exception because of the predominant 1,H-addition of *N*-chloroamides). Furthermore, with the proper choice of the carbamate alkyl group (*e.g.* **1***c* R = CH_2CCl_3, and **1***d* R = $CH_2C_6H_5$), a method for synthesizing N-protected β-chloro primary amines, with the amino group attached to the less substituted carbon atom, becomes available. We have thus extended the chromous chloride promoted additions of *N*-chlorocarbamates to a variety of mono-olefins using NCU **1***a* as a representative *N*-chlorocarbamate. The results together with the reaction conditions are recorded in Table 8.

Cyclopentene gave a lower yield of addition (64%), a smaller *cis–trans* ratio (**20**:**21** = 1.56), and a higher proportion of 1,H-addition (**22**) than cyclohexene. Thus with NCU, the 1,2-addition – 1,H-addition ratio decreases in the order cyclohexene (14.5) > cyclopentene (2.6) > norbornene (0.76), which is also the order of increasing ring strain.

The addition to tetramethylethylene is noteworthy since upon photochemical initiation, *N*-chloroamides do not add to tetrasubstituted olefins (4*c*). Dehydrohalogenation of the 1,2-adduct **23** did occur to a small extent during the

TABLE 7. Addition of NCU **1***a* and *N*-bromo-α-chloroacetamide **1***o* to conjugated dienes

[b]Not detected in the chromatographic fractions.

work-up and/or during the chromatographic separation leading to the olefinic derivative **24**.

With styrene, no 1,2-adduct nor 1,H-adduct could be isolated. A complex mixture was obtained consisting most probably of telomers and/or polymers and was not investigated further. The addition of the intermediate β-ethoxycarbonylamino radical (C_6H_5—$\dot{C}H$—CH_2—$NHCOOC_2H_5$) to another styrene molecule was thus faster than its chromous ion reduction and/or its trapping by chlorine-atom transfer.

The additions to pregnenolone acetate illustrate the possibility of obtaining high yields of 1,2-adducts to a more complex and somewhat hindered olefin. The addition is completely regiospecific, the amido group being attached to the less substituted carbon atom (C-6) in both 1,2-adducts **25** and **26**. No 1,H-adduct was detected in the chromatographic fractions. The A and B rings' fusion is *trans* in both adducts indicating that the transfer of chlorine onto the intermediate radical at C-5 occurred from the α-side in order to give the more stable A/B *trans* junction. The predominant formation of the adduct **25** where a 1,3-diaxial interaction exists between the β-amido group at C-6 and the methyl group at C-10, shows the strong preference for the axial attack of the 5,6-double bond by the amido radical. Ponsold and Ihn (17) have studied the photochemical addition of NCU to cholesteryl acetate and to androst-5-en-3β-ol-17-one acetate and have isolated only the corresponding 5α-chloro-6β-ethoxycarbonylamino derivatives (axial attack) in 34% and 9% yield respectively.

Attempts to add NCU to 1-(*N*-piperidino)-cyclohexene were unsuccessful due to rapid electrophilic chlorination. Indeed, the active chlorine disappeared quickly (≤30 s) when NCU was mixed with this enamine in chloroform–methanol at −78 °C and 2-chlorocyclohexanone (34%) was obtained after acid hydrolysis. However, the addition of NCU to the less electron rich 1-methoxycyclohexene, followed by acid hydrolysis, led to a high yield (85%) of the α-ethoxycarbonylamino ketone **27**; no 2-chlorocyclohexanone was detected by vpc. With 1-acetoxycyclohexene, the yield of addition was much lower (43% of ketone **27**). The addition to 1-chlorocyclohexene was still less efficient (27%) giving the 1,2-adduct **28** and the 1,H-adducts **2***a* and **3***a*. The orientation of these additions is again in agreement with the attack of the olefinic system by an amido radical.

The addition of NCU to methyl acrylate and to methyl vinyl ketone gave, in low yields, respectively, the β-ethoxycarbonylamino ester **29** and the β-ethoxycarbonylamino ketone **30** via the more stable carbonyl substituted intermediate radical. No chlorinated products (1,2-adducts) were isolated. Since α-chlorocyclohexanone was not reduced to a significant extent by excess chromous chloride under similar re-

TABLE 8. Addition of *N*-chlorocarbamates (**1**, Z = OR, X = Cl) to various mono-olefins

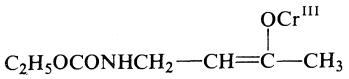
[a] By vpc.
[b] An excess of *N*-chlorocarbamate was used (2 mol per mol of olefin) and the yields are based on the olefin.
[c] After the addition of $CrCl_2$, dilute H_2SO_4 was added and the reaction mixture was stirred at room temperature for 4 h.
[d] The major product was 2-chlorocyclohexanone (34% by vpc) resulting from electrophilic chlorination.
[e] This represents a minimum yield since the compound underwent partial decomposition upon chromatography on silica gel.
[f] These yields refer to a reaction carried out with an excess of NCU **1***a* (2 mol per mol of methyl vinyl ketone) and are based on the olefin.
[g] Three moles of NCU **1***a* per mol of progesterone were used.
[h] Mixture of telomers and polymers.
[i] No addition product was isolated.

action conditions, the adducts **29** and **30** most probably result from chromous ion reduction of the intermediate carbonyl-substituted radical (1,H-addition). The addition to methyl vinyl ketone led, in addition to the 1,H-adduct **30**, to a small amount of the β-diethoxycarbonylamino ketone **31**. When the reaction was carried out with an excess of NCU, the proportion of compound **31** was increased noticeably. This compound was not formed via the adduct **30** (for

instance by addition on the enol form of **30**) since the latter did not react with an excess of NCU under the conditions used for the additions. One possible route for the formation of **31** would be the radical addition of NCU to the organochromium intermediate **32**, the assumed precursor of **31**. With a more hindered α,β



32

unsaturated ketone like progesterone, no addition product could be isolated even if an excess of NCU was used; 90% of unreacted progesterone was recovered.

The addition of NCU to 1-octyne gave a complex mixture from which the 1,2-adduct **33** and the α,α-diethoxycarbonylamino ketone **34** (resulting from the hydrolysis of a two-to-one adduct) were isolated, but in quite different proportions from two different experiments.

Miscellaneous Additions to Cyclohexene

As mentioned in the introduction, *N*-halo-*N*-alkyl amides fail to add to olefins upon photochemical decomposition (3, 4). In order to see if they could be added using the present method, we studied the addition of *N*-chloro-*N*-methyl-2,2,2-trichloroethyl carbamate and *N*-chloro-*N*-methylacetamide to cyclohexene. As indicated in Table 9, no 1,2-adduct nor 1,H-adduct was isolated or even detected; the corresponding amide was isolated in high yields and small amounts (~5%) of bicyclohexenyl were detected.

We investigated also the addition of *N*-chloro- and *N*-bromosuccinimide to cyclohexene; the corresponding *trans* 1,2-adducts **35** and **36** were isolated in low yields (Table 9). These *trans* additions to cyclohexene contrast with the predominance of *cis* addition of the *N*-haloamides **1** (ZCONHX); the bulkiness of the succinimidyl group could be responsible for this preference for *trans* addition.

Finally, the addition of *N*-fluorourethane to cyclohexene gave *N*-cyclohexylurethane (1,H-adduct **4***a*) as the sole addition product albeit in a low yield, the other reaction product being urethane according to vpc analysis (Table 9).

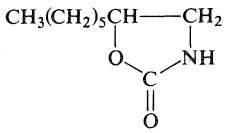
Structure and Stereochemistry of the Addition Products

All the addition products had ir and ^{1}H nmr spectra, an elemental analysis and/or a mass spectrum, consistent with their structure. The protons on the carbons bearing the amido groups are easily identified in the ^{1}H nmr spectra by the narrowing of the signal after N-deuteration; in many cases, the multiplicity of the N—H signal is resolved. The interpretation and analysis of the ^{1}H nmr and ir spectra are quite straightforward and will not be discussed further here. Chemical proofs of structure and stereochemistry are described below.

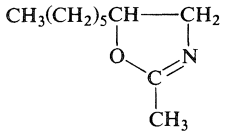
Whenever possible, known compounds were identified by comparison with samples prepared according to procedures described in the literature. For instance, the 1,H-adducts resulting from the addition to cyclohexene, 1-octene, norbornene, and cyclopentene were prepared from the corresponding amines; the *trans* 1,2-adduct **3***a* was prepared by the addition of *N*,*N*-dichlorourethane to cyclohexene (7); the *cis* and *trans* 1,2-adducts **13** and **14** were obtained from the photochemical addition of NCU **1***a* to norbornene according to the procedure published by Schrage (8*b*) who rigorously established their structure and stereochemistry.

We have already mentioned the following conversions (see section entitled Addition of *N*-chloroamides to cyclohexene): **2***c* (Z = OCH_2CCl_3) to **2***e* (Z = CH_3), **3***c* to **3***e*, **2***d* (Z = $OCH_2C_6H_5$) to **2***e*. The *cis*-β-chlorocarbamate **2***b* (Z = OCH_2CH_2Cl) and the *cis*-β-bromocarbamate **2***l* (Z = OCH_2CCl_3) were converted respectively to **2***e* (74% yield) and **2***n* (41% yield) (Z = CH_3) by zinc dust reduction followed by acetylation: **2***b*, reduction in 80% aqueous acetic acid at *ca.* 80 °C in the presence of excess potassium iodide; **2***l*, reduction in glacial acetic acid at room temperature. The compounds **2***e* (11), **3***e* (12), and **2***n* (11) have been described in the literature.

Pyrolysis of the 2-halo-*N*-ethoxycarbonyl-1-octylamines **7***a* (X = Cl) and **7***j* (X = Br) gave the oxazolidone **37**. The 1,2-adduct **7***e* (Z = CH_3, X = Cl) was converted to the oxazoline **38** by sodium methoxide. Attempts to purify the



37



38

1,2-adduct **7***n* (Z = CH_3, X = Br) by microdistillation at 140 °C yielded the hydrobromide of the oxazoline **38**.

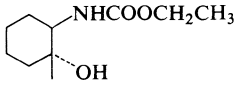
[a]Bicyclohexenyl was also detected (~2 to 5% by vpc).
[b]Bath temperature of −40 °C.
[c]The high solubility of succinimide in water prevented its complete recovery.
[d]Not determined.

The stereochemistry of the *trans* 1,2-adducts **10***a* (X = Cl) and **10***j* (X = Br) (addition to 1-methylcyclohexene) was established by their conversion to the *N*-ethoxycarbonylaziridine **39** with alcoholic potassium hydroxide. Under the same conditions, the *cis* isomers **9***a* and **9***j* were recovered unchanged. With silica gel or silicic acid, the aziridine **39** was converted to the *trans*-β-hydroxycarbamate **40**. The stereochemistry of the other 1,2-adducts **9** and **10** follows from a comparison of their ^{1}H nmr spectra with those of **9***a*, **9***j*, **10***a*, and **10***j*.

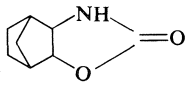
39



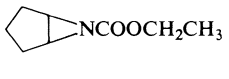
40

In the addition of NCU to 1-methylcyclohexene (Table 5), small amounts of 1,2-adducts **11***a* and **12***a* were isolated as a mixture of both isomers which were not separated as such but were treated with alcoholic potassium hydroxide to afford a mixture of **11***a* and the *N*-ethoxycarbonylaziridine **39**. On silica gel, it gave a mixture of **11***a* and the *trans*-β-hydroxycarbamate **40** which were then easily separated.

The stereochemistry of the *trans* 1,2-adduct **14***j* (Z = OCH_2CH_3, X = Br) (addition to norbornene) was confirmed by its conversion to the oxazolidone **41** (8*b*) upon pyrolysis at 180 °C. The *cis* isomer **13***j* was recovered unchanged under the same conditions.



41



42

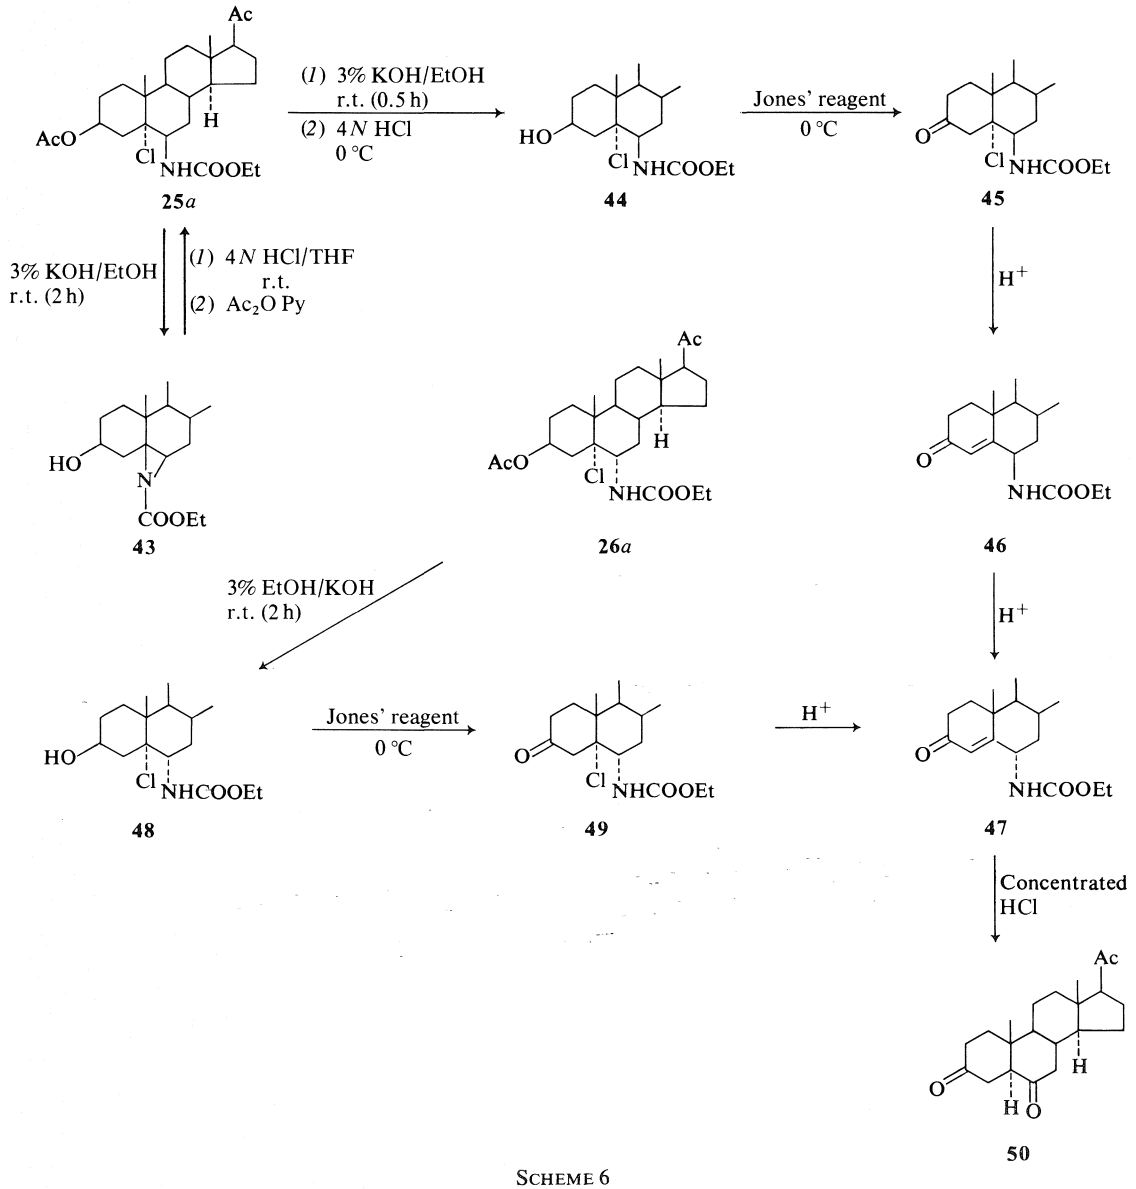
The stereochemistry of the 1,2-adducts **20** and **21** (addition to cyclopentene) was established by their treatment with alcoholic potassium hydroxide. The *trans* isomer **21** was converted to the aziridine **42** while the *cis* isomer was recovered unchanged.

The *E* configuration was tentatively assigned to the 1-amido-2-butenes **17** (addition to butadiene, Table 7) on the basis of a strong band at 960–962 cm^{-1} in the ir spectrum (18). The two olefinic protons have nearly the same chemical shifts at 60 MHz.

In the 1,2-adducts **25** and **26** obtained from the addition of *N*-chlorocarbamates to pregnenolone acetate (Table 8), the A/B ring fusion is *trans* (chlorine α at C-5) and the carbamate group at C-6 is respectively β (axial) and α (equatorial) according to ^{1}H and ^{13}C nmr spectroscopy (see the Experimental for the assignment of the ^{13}C chemical shifts). The structural conclusions derived from nmr spectroscopy are confirmed by the chemical transformations summarized in Scheme 6. The aziridine **43***a* was readily formed from **25***a* whereas, under the same reaction conditions, no aziridine was formed from **26***a*. The 3β-alcohol **44** obtained from the adduct **25***a* was oxidized by Jones' reagent under carefully controlled conditions, The 3-ketone **45** was quite labile and was characterized by its ^{1}H nmr spectrum only. Silica gel impregnated with hydrochloric acid, when added to the nmr tube, caused elimination of hydrochloric acid from **45** followed by isomerization of α,β-unsaturated ketone **46** into the more stable epimer **47**: the AB quartet centered at 3.23 ppm ($\Delta\nu_{AB}$ = 21.4 Hz, J_{AB} = 16.5 Hz) due to the protons at C-4 of ketone **45** disappeared gradually while a narrow singlet appeared at 6.10 ppm (no allylic coupling between H-4 and equatorial H-6 in **46**) which then gradually changed to a doublet (J = 1.8 Hz) at 5.99 ppm (allylic coupling between H-4 and H-6 axial in **47**). The oxidation of alcohol **48** (obtained by saponification of the 1,2-adduct **26***a*) again under carefully controlled conditions, gave the labile ketone **49** which was characterized by its ^{1}H nmr spectrum only. Elimination of HCl monitored by nmr in the same conditions as above led directly to the 6α-ethoxycarbonylamino-Δ^4-3-ketone **47**. The latter, when treated with concentrated hydrochloric acid in benzene, gave 5α-pregnane-3,5,20-trione **50** (19).

Summary and Conclusions

The present work shows that two types of adducts can be formed in the chromous chloride promoted addition of *N*-haloamides (ZCONHX) to olefins: *N*-(2-haloalkyl)amides (1,2-adducts) and *N*-alkylamides (1,H-adducts). Their relative proportion depends on the olefin, on the halogen, and on the nature of Z. For instance no 1,H-adduct was isolated from the additions to trisubstituted olefins (1-methylcyclohexene, pregnenolone acetate) whereas with conjugated olefins (methyl acrylate, conjugated dienes) it was the sole addition product(s) obtained: the conjugated dienes led to a mixture of *N*-(2-alkenyl)- and *N*-(3-alkenyl)amides. The additions of *N*-bromoamides to simple mono-olefins usually gave less than 5% of 1,H-adduct but with



SCHEME 6

certain *N*-chloroamides (*e.g.* *N*-chloroacetamide **1***c*) and olefins, it was the predominant adduct (*e.g.* 64% with 1-octene, 98% with norbornene). On the other hand, the proportion of 1,H-adduct was usually much lower with *N*-chlorocarbamates (Z = *O*-alkyl) than with *N*-chlorocarboxamides (Z = alkyl).

The best yields of 1,2-addition to a variety of olefins were obtained with *N*-chlorocarbamates. The addition of NCU **1***a* to a tetrasubstituted olefin, tetramethylethylene, is noteworthy since no addition was observed upon photochemical initiation.[6] The addition of *N*-chlorocarbamates **1***c* ($Z = OCH_2CCl_3$) and **1***d* ($Z = OCH_2C_6H_5$) shows the potential of the chromous chloride promoted additions for the preparation of N-protected β-chloro primary amines in which the amino group is attached to the less substituted carbon atom of the olefin; the regiospecificity of the additions to unsymmetrical olefins was greater than 90%. With the corresponding *N*-bromocarbamates **1***l* and **1***m*, electrophilic bromination competed with the radical addition to the extent of 20 to 35%, which severely limits

their synthetic value for the preparation of N-protected β-bromo primary amines. *N*-Bromo-2-chloroacetamide **1***o* might be useful for that purpose since the *N*-chloroacetyl group has been reported to be cleaved by thioureas in neutral medium (20). However we did not study its removal in any of the *N*-(2-bromoalkyl)-2-chloroacetamides obtained. *N*-Chlorotrifluoroacetamide could probably be used also for the synthesis of N-protected β-chloro primary amines since its yield of addition to cyclohexene was quite good and the proportion of 1,H-addition small (see Table 2).

We would like to emphasize the fact that, in these additions, all the *N*-haloamide which does not react with the olefin is simply reduced to the amide. Therefore, in the cases where electrophilic halogenation is not a competing process, high yields of addition based on the olefin can be obtained by using an excess of *N*-haloamide and the amide can be recovered (see for instance entry 7 of Table 1 and the addition to pregnenolone acetate in Table 8).

The addition of NCU to electron-poor olefins (*e.g.* 1-chlorocyclohexene, α,β-unsaturated carbonyl compounds) and to 1-octyne was inefficient. With olefins being very rich in electrons (*e.g.* enamines), electrophilic chlorination was faster than the addition. However the addition of NCU to 1-methoxycyclohexene was quite efficient (>85%) and the scope and limitations of the chromous chloride promoted addition of *N*-chloroamides to enol ethers as a method for synthesizing N-protected α-amino acetals (ketones and aldehydes) will be evaluated in a forthcoming paper.

N-Chloro-*N*-alkylamides which do not add to olefins upon photochemical initiation (3, 4) also failed to add to cyclohexene with the present method, but most probably for different reasons. In the photochemical decomposition, the halogen atom might be more reactive than the *N*-alkylamido radical, whereas, with chromous chloride, the reduction of the *N*-alkylamido radical might be faster than its addition to the olefin.

Mechanistic aspects of these chromous chloride initiated reactions are discussed in the accompanying paper in the light of the results presented in this paper, trying the rationalization of them, and in the light of additional experimental facts. We would like to point out here that the reduction of the amido radical competes with its addition to the olefin and that the reduction of the intermediate adduct-radical (leading to 1,H-addition) competes with the chain-propagation step (leading to 1,2-addition). Therefore, the slower the addition of the chromous chloride solution (the smaller the amount of chromous chloride added at a time) the better the yield of 1,2-addition as we have seen (Table 1, entries 5 and 6). However we did not try to optimize the yields of 1,2-addition by allowing the addition of very minute amounts of chromous chloride at a time.

The additions to cyclic olefins have shown that the stereochemistry of 1,2-addition does vary with the halogen, the nature of Z, and the olefin. However, discussion of the stereochemical aspects of these additions must await further investigation and we are currently studying the stereochemistry of the radical addition of *N*-haloamides to cyclic (rigid and non-rigid) as well as acyclic (*E* and *Z*) olefins, comparing chromous chloride promoted additions with photochemically initiated additions.

Experimental[13]

Melting points were determined on a Buchi apparatus and are uncorrected. Infrared spectra were taken on a Perkin-Elmer 257 spectrometer. ^{1}H nmr spectra were recorded on a Varian A-60 spectrometer using TMS as internal reference. ^{13}C nmr spectra were recorded on a Bruker HX-90 spectrometer equipped with a Nicolet 1083 computer for Fourier transform spectroscopy. Mass spectra were taken on a Hitachi RMU-6E spectrometer. Optical rotations were determined on a Perkin-Elmer 141 digital polarimeter at 589 nm. Column chromatography was done using Davison's silica gel No. 923 or 950. Merck silica gel GF_{254} was used for thin and preparative layer chromatography. Vapor phase chromatographic analyses were performed on a Hewlett Packard chromatograph model 5750 equipped with both thermal conductivity and flame ionization detectors; an OS-138 column (15% polyphenyl ether on dimethylsilylated Chromosorb W) with o.d. 0.25 in. and length 6 ft was used unless specified otherwise. Preparative separations were done on a similar column with o.d. 0.375 in. and length 6 ft. Organic phases from extractions were dried over anhydrous sodium sulfate.

N-Haloamides

With the exception of *N*-chlorourea **1***i*, *N*-bromoacetamide **1***n* (commercially available), and *N*-bromo-2,2,2-trichloroacetamide **1***p*, the *N*-haloamides were prepared by the sodium hypohalite method (13).

[13]A few addition products are fully described in the Experimental. For the others, the melting points together with the microanalytical and/or mass spectral data and the ir and ^{1}H nmr characteristic absorptions are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, K1A 0S2.

N-Chlorourea **1***i* was prepared according to the method described by Chalsty and Israelstam (21). We found that the bath temperature had to be maintained at 0 °C while evaporating the solvent (rotating evaporator) to prevent decomposition. However, when crystalline and dry, *N*-chlorourea **1***a* was stable at room temperature. The crude product (98% active chlorine, 98% yield), mp 74–76 °C (dec.), was used without purification.

N-Bromo-2,2,2-trichloroacetamide **1***p* was prepared according to the method of Park *et al.* (22) and recrystallized from methylene chloride, mp 124–125 °C (100% active bromine, 80% yield).

N-Chloro-*N*-methyl-2,2,2-trichloroethylcarbamate was prepared by treatment of the corresponding carbamate (obtained from methylamine and 2,2,2-trichloroethyl chloroformate and having mp 72–73 °C) in methylene chloride with 5% aqueous sodium hypochlorite at *ca.* 0 °C, followed by extraction with methylene chloride. The crude product contained 96% active chlorine (90% yield) and was used without purification.

N-Chloro-*N*-methylacetamide was prepared by treatment of an aqueous solution of the corresponding amide containing sodium bicarbonate with chlorine followed by extraction with methylene chloride and distillation under reduced pressure: bp 45–46 °C/16 torr (95% active chlorine, 73% yield).

Fluorination of urethane was carried out as described in the literature (23) and was followed by ^{1}H nmr spectroscopy. The reaction was stopped when the ratio of *N*-fluorourethane–urethane did not increase any more and the ratio of *N*-fluorourethane–ethanol reached a maximum. The crude product (90% active fluorine, 40% yield) was used without purification.

General Procedure for the Chromous Chloride Promoted Additions of N-Haloamides to Olefins

The additions were carried out in the apparatus illustrated in Fig. 1 under a stream of dry carbon dioxide or nitrogen. At temperatures below −70 °C, an appreciable amount of carbon dioxide dissolved in the reaction mixture which then became more viscous. A more efficient stirring could be achieved by using nitrogen but most reactions were carried out using carbon dioxide.

From 25 to 75 ml of a 1 *M* methanolic chromic chloride solution (0.2 *N* in HCl, 6.3 *M* in H_2O) (266.5 g of $CrCl_3 \cdot 6H_2O$, 16 ml of concentrated HCl, and absolute methanol[14] in a 1 ℓ volumetric flask) was reduced in flask A by stirring with freshly prepared and dry amalgamated zinc (7 g of zinc dust and 2.6 g of $HgCl_2$). The reduction took 10 to 30 min then the needed amount of the clear blue chromous chloride solution was transferred into the dropping funnel C (containing a small amount of amalgamated zinc) by closing **a** and forcing the inert gas through **b**.

The *N*-haloamide (alternatively the olefin) was dissolved in a chloroform – absolute methanol[14] mixture and the solution was cooled to the desired temperature, usually −78 °C (methanol – dry ice bath), in the reaction vessel B. The olefin (alternatively the *N*-haloamide) in solution in the same solvent was added slowly. In the case

[14]When using ordinary methanol, we could not obtain homogeneous reaction mixtures at −78 °C throughout the addition of the chromous chloride solution with olefins like cyclohexene, 1-octene, norbornene, etc.

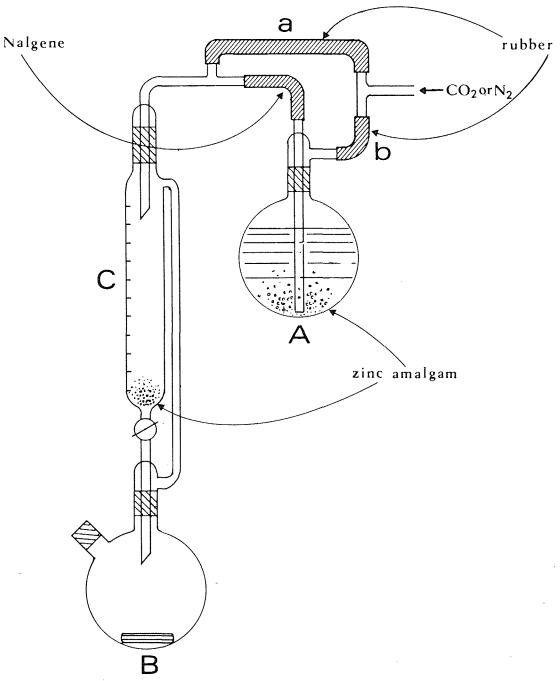


FIG. 1. Apparatus for the chromous chloride promoted addition of *N*-haloamides to olefins.

of the addition of NCU to 1-methoxycyclohexene and for the additions of *N*-bromoamides, the two solutions were cooled to −78 °C before being mixed in order to minimize the extent of electrophilic halogenation. The total amount of solvent as well as the relative proportions of chloroform and methanol had to be varied according to the solubility of the *N*-haloamide and/or the olefin in order to obtain an homogeneous solution at −78 °C; the concentration of the starting solutions varied from 0.3 to 0.9 *M* in *N*-haloamide and the chloroform–methanol voluminal ratio varied from 1.5 to 5. Such variations had little effect on the addition of NCU to cyclohexene (compare entries 6 and 7 of Table 1). The insolubility of *N*-chlorourea **1***i* precluded the use of the general conditions: the reactions were carried out at −55 °C (CCl_4–CH_2Cl_2 – dry ice bath) in chloroform–methanol 1:1.6, the starting solution being 0.1 *M* in **1***i*.

The chromous chloride solution was then added dropwise, at a slow rate (time of addition: 1.5–4 h), with vigorous stirring of the reaction mixture. The addition was stopped either immediately after no more *N*-haloamide was present in the reaction mixture (negative starch–iodide paper test) or, as in most cases, after adding an additional 10% of the chromous chloride solution. The total amount of chromous chloride added varied from 0.9–2.2 mol per mol of *N*-haloamide depending on whether the yield of 1,2-addition (based on the *N*-haloamide) was high (> 85%) or low (< 20%) respectively.

Work-up A

This work up allowed a separation of the 1,2-adduct(s) from the amide and 1,H-adduct. The reaction mixture was poured into a mixture of ice and water (five to ten

times the final volume of methanol) then extracted rapidly with ether in the presence of ice. The organic phases were washed, usually once or twice, with cold water to remove all the chromic salts then dried. The organochromium derivatives which are the precursors of the 1,H-adduct and of the amide (see the accompanying paper) were not extensively hydrolyzed and remained in the aqueous layers. The ether layer contained almost exclusively the 1,2-adduct(s). The 1,H-adduct and the amide were then obtained by continuous extraction of the combined aqueous phases for 24–48 h with methylene chloride.

Work-up B

The reaction vessel B was removed from the apparatus (to allow air to oxidize the chromous ions in excess) and the reaction mixture was allowed to warm up to room temperature after adding water, and kept at room temperature for 30–60 min. It was then thoroughly extracted with methylene chloride or chloroform. The organic layers were washed with water, combined, and dried. The organic phase contained the 1,2-adduct(s), the 1,H-adduct, and the amide. In some cases complete recovery of the amide necessitated a continuous extraction with methylene chloride.

In the case of the addition of NCU to 1-methoxycyclohexene and 1-acetoxycyclohexene (Table 8), the reaction mixture was allowed to warm up to room temperature, dilute H_2SO_4 (1 *N*) was added, and the mixture stirred for 4 h before being extracted with methylene chloride.

The addition products were isolated by preparative layer chromatography, using ether–hexane mixtures, when working on a 5–10 mmol scale as in most cases. Some reactions were carried out on a 25–50 mmol scale and column chromatography followed by preparative layer chromatography was used. The yields of addition products (Tables 1 to 9) represent yields of isolated products homogeneous by tlc. In a few cases the yields were determined by vpc using an authentic sample as standard. The chromatographic fractions were purified by recrystallization or microdistillation for complete characterization.[13] It is noteworthy that in the additions to cyclic olefins, the *cis* 1,2-adduct was always less polar than the *trans* isomer. The 1,2-adducts **11** and **12** (additions to 1-methylcyclohexene, Table 5) were slightly less polar than the *cis* 1,2-adduct **9** and, although their presence could be inferred from the tlc of the crude reaction product, they have been successfully isolated in one instance only: addition of NCU. In the case of the addition of *N*-bromoacetamide **1***n*, a chromatographic fraction less polar than the one containing the *cis* 1,2-adduct **9***n* probably contained, along with some other products, one of the isomeric 1,2-adducts **11***n* or **12***n* according to its ^{1}H nmr and mass spectrum: δ ($CDCl_3$) 1.52 (s, CH_3), 2.02 (s, $COCH_3$), 4.38 (m, CH—Br), 5.57 ppm (br s, NH); *m/e* 233, 235 (relative intensity 1:1, M^+); it was not investigated further.

The yields of amide were determined by vpc or preparative tlc. The material balance, addition products plus amide, was usually quite good (95–102%). The yields of bicyclohexenyl, of 2-halo-1-methoxycyclohexanes, of 2-halocyclohexanols, and of 2-chlorocyclohexanone were determined by vpc using authentic samples as standards. These authentic samples were either available commercially or prepared according to the literature. These compounds were isolated from the crude reaction product by preparative vpc for their complete identification (ir and ^{1}H nmr).

Typical Procedures for the Chromous Chloride Promoted Addition of N-Haloamides to Olefins

(a) Addition of NCU ***1a*** *to Cyclohexene (Excess of Olefin)*

In the reaction vessel B (Fig. 1), NCU (644 mg, 96% active chlorine, 5 mmol) was dissolved in chloroform (3 ml) and absolute methanol (1 ml) and the solution was cooled to *ca.* −78 °C. Cyclohexene (1 ml, ∼10 mmol) in chloroform (2 ml) was added slowly. The 1 *M* chromous chloride solution was then added dropwise until the starch–iodide paper test was negative: 4.5 ml (4.5 mmol) added over 70 min. The reaction mixture was poured into a mixture of ice and water (50 ml) and rapidly extracted with ether (3 × 100 ml) in the presence of ice (work-up A). The ether layer was washed once with cold water (25 ml) then dried. The solution was concentrated and analyzed by vpc: urethane, ∼0.5%; bicyclohexenyl, ∼0.8%; *N*-ethoxycarbonylcyclohexylamine **4***a* ∼0.5%; *cis* adduct **2***a*, 77%; *trans* adduct **3***a*, 11%. The solvent was removed *in vacuo* and the crude product (964 mg) separated by preparative layer chromatography (ether–hexane 1:3) to afford two main fractions. The less polar fraction consisted of *cis-2-chloro-N-ethoxycarbonylcyclohexylamine* **2***a*, mp 52–54 °C (782 mg, 76%). Two recrystallizations from pentane afforded the analytical sample, mp 57.5–58 °C (lit. (8*a*) 58 °C); ν_{max} (CCl_4) 3458 and 3350 (free and bonded NH), 1721 (C=O), 1505 (NH), 1220 and 1050 (C—O—C), 688 cm^{-1} (C—Cl axial (24)); δ ($CDCl_3$) 1.21 (t, J = 7 Hz, OCH_2CH_3), 3.81 (m, $\Delta\nu_{1/2}$ = 22 Hz, $\Delta\nu_{1/2}$ = 14 Hz after exchange with D_2O, H_1), 4.48 (q, J = 2.6 Hz, H_2), 4.11 (q, J = 7 Hz, OCH_2CH_3), 4.95 ppm (br d, J = 8 Hz, NH); *m/e* 205, 207 (3:1 ,M^+). *Anal.* calcd. for $C_9H_{16}ClNO_2$: C 52.55, H 7.84, Cl 17.24; found: C 52.35, H 7.73, Cl 17.12.

The other fraction (117 mg, 11%) consisted of *trans-2-chloro-N-ethoxycarbonylcyclohexylamine* **3***a*, mp 91–92 °C. It was recrystallized from ether–hexane for analysis, mp 93.5–94 °C (lit. (7) 96 °C); ν_{max} (CCl_4) 3460 and 3355 (free and bonded NH), 1722 (C=O), 1505 (NH), 1225, 1045, 1055 cm^{-1}; ν_{max} (CS_2) 737 cm^{-1} (C—Cl equatorial (24)); δ ($CDCl_3$) 1.25 (t, J = 7 Hz, OCH_2CH_3), 3.70 (m, $\Delta\nu_{1/2}$ ∼ 30 Hz, H_1 and H_2), 4.13 (q, J = 7 Hz, OCH_2CH_3), 4.95 (br, NH). *Anal.* calcd. for $C_9H_{16}ClNO_2$: Cl 17.24; found: Cl 17.19. It proved identical (ir, ^{1}H nmr) to an authentic sample prepared by addition of *N,N*-dichlorourethane to cyclohexene (7).

The aqueous phases from the ether extraction were combined and extracted with methylene chloride for 48 h. The organic phase was dried. The solution was concentrated and analyzed by vpc: urethane, 6%; *N-ethoxycarbonylcyclohexylamine* **4***a*, 5.5%. The products were then separated by preparative layer chromatography (ether–hexane 1:1) and proved identical (mixture mp, ir) with authentic specimens (**4***a* was prepared from cyclohexylamine and ethyl chloroformate): **4***a*, mp 53–54 °C (lit. (25) 55–56 °C); ν_{max} ($CHCl_3$) 3450 (NH), 1715 (C=O), 1515 (NH), 1230, 1060 cm^{-1} (doublet).

(b) Addition of NCU ***1a*** *to Pregnenolone Acetate (Excess of Amide)*

In the reaction vessel B (Fig. 1), a solution of pregnenolone acetate (8.96 g, 25 mmol) in chloroform

(35 ml) and absolute methanol (20 ml) was cooled to *ca.* −78 °C. A solution of NCU (8.4 g, 88% active chlorine, 60 mmol) in chloroform (15 ml) was added slowly. The 1 *M* chromous chloride solution was added dropwise until a negative starch–iodide paper test: 100 ml (100 mmol) added over 4 h (the product began to precipitate after about 60 ml of the $CrCl_2$ solution was added). The reaction mixture was allowed to warm up to room temperature while adding water (500 ml) then extracted with chloroform (5 × 100 ml) (work-up B). The organic phases were washed once with water, then collected and dried. The crude product was recrystallized from chloroform–ether to yield 8.77 g (73%) of *3β-acetoxy-5α-chloro-6β-ethoxycarbonylamino-pregnane-20-one* **25***a*, mp 200–202 °C. Recrystallization from ethanol afforded the analytical sample, mp 201–203 °C; $[\alpha]_D^{20}$ −20° (*c* 1.0, $CHCl_3$); ν_{max} ($CHCl_3$) 3455 (NH), 1726 (carbamate and ester), 1704 (ketone), 1505 (carbamate), 1250 and 1034 cm^{-1} (carbamate and ester); ^1H nmr ($CDCl_3$) 0.65 (s, 18-CH_3), 1.23 (s, 19-CH_3), 1.25 (t, J = 7 Hz, OCH_2CH_3), 2.02 (s, 20-CH_3), 2.10 (s, $OCOCH_3$), 4.13 (q, J = 7 Hz, OCH_2CH_3), 4.20 (m, $\Delta\nu_{1/2}$ < 20 Hz, H-6 equatorial), 4.90 (br d, J = 10 Hz, NH), 5.33 ppm (m, $\Delta\nu_{1/2}$ = 30 Hz, H-3 axial); ^{13}C nmr ($CDCl_3$) 13.7 (C-18) 14.6 (OCH_2CH_3), 18.9 (C-19), 21.3 (C-11 and $OCOCH_3$), 22.9 (C-15), 24.3 (C-16), 26.5 (C-2), 31.1 (C-8), 31.5 (C-21), 32.2 (C-7), 34.2 (C-1), 37.8 (C-4), 38.8 (C-12), 40.2 (C-10), 44.3 (C-13), 45.9 (C-9), 55.8 (C-6 and C-14), 61.3 (OCH_2CH_3), 63.6 (C-17), 70.6 (C-3), 83.5 (C-5), 156.1 ($-\overset{O}{\overset{\|}{C}}OCH_2CH_3$), 170.1 ppm ($O\overset{O}{\overset{\|}{C}}CH_3$) downfield TMS.[15] *Anal.* calcd. for $C_{26}H_{40}O_5NCl$: C 64.78, H 8.36, Cl 7.36; found: C 64.60, H 8.25, Cl 7.31.

The mother liquors were evaporated to dryness (4 g) and separated by column chromatography on silica gel and then preparative layer chromatography to yield, in order of decreasing polarity, 0.75 g of urethane, an additional 0.73 g (total, 9.50 g, 79%) of *1,2-adduct* **25***a*, mp 196–198 °C, and 2.55 g (21%) of *3β-acetoxy-5α-chloro-6α-ethoxycarbonylamino-pregnane-20-one* **26***a*, mp 112–115 °C. The analytical sample was obtained after two recrystallizations from ether–hexane, mp 117–119 °C; $[\alpha]_D^{20}$ + 34.6° (*c* 0.3, $CHCl_3$); ν_{max} ($CHCl_3$) 3440 (NH), 1720 (carbamate and ester), 1704 (ketone), 1250 and 1046 cm^{-1} (carbamate and ester); ^1H nmr ($CDCl_3$) 0.62 (s, 18-CH_3) 1.18 (s, 19-CH_3), 1.23 (t, J = 7 Hz, OCH_2CH_3), 2.02 (s, $COCH_3$), 2.10 (s, $OCOCH_3$), 4.05 (m, $\Delta\nu_{1/2}$ = 30 Hz, H-6 axial), 4.11 (q, J = 7 Hz, OCH_2CH_3) 4.88 (br d, J = 10 Hz, NH), 5.23 (m, $\Delta\nu_{1/2}$ = 32 Hz, H-3 axial); ^{13}C nmr ($CDCl_3$) 13.5 (C-18), 14.6 (OCH_2CH_3), 16.4 (C-19), 21.3 (C-11 and $OCOCH_3$), 22.9 (C-15), 24.1 (C-16), 26.2 (C-2), 31.6 (C-7 and C-21), 34.0 (C-1 and C-8), 36.6 (C-4), 38.7 (C-12), 41.5 (C-10), 44.1 (C-13), 45.5 (C-9), 52.4 (C-6), 55.8 (C-14), 61.0 (OCH_2CH_3), 63.4 (C-17), 70.0 (C-3), 87.8 (C-5), 156.1 ($COOCH_2CH_3$), 170.2 ppm ($OCOCH_3$) downfield from TMS.[15] *Anal.* calcd. for $C_{26}H_{40}O_5NCl$: C 64.78, H 8.36, Cl 7.36; found: C 64.67, H 8.57, Cl 7.26.

Chromous Chloride Reduction of N-Bromopentanoamide ***1q***

To a solution of *N*-bromopentanoamide (1.45 g, 90% active bromine, 7.27 mmol) in chloroform (5 ml) and absolute methanol (1 ml) cooled in a dry ice – methanol bath (*ca.* −78 °C) (see Fig. 1), the 1 *M* chromous chloride solution was added slowly: 18 mmol added over 5 h. Work-up B gave pentanoamide (862 mg, 95% by taking into account the 145 mg present in the starting material), mp 100–102 °C, identified by comparison to an authentic sample by ir and ^1H nmr spectroscopy. The crystals were ground in a mortar then dried under vacuum. A microanalytical determination of bromine gave 1.18% which could be due to the presence of some (< 2%) 4-bromopentanoamide.

Chromous Chloride Reduction of 3-Chloro- and 3-Bromocyclohexene, and 2-Chlorocyclohexanone

3-Chlorocyclohexene

A solution of 3-chlorocyclohexene (820 mg, 8.4 mmol) in chloroform (8 ml) and absolute methanol (3 ml) was cooled to *ca.* −78 °C in the reaction vessel B (Fig. 1). The 1 *M* chromous chloride solution was added slowly: 10 mmol added over 70 min. The reaction mixture remained blue during most of the addition; it turned slightly green (turquoise) towards the end of the addition indicating that no extensive reduction of 3-chlorocyclohexene had occurred. The reaction vessel was removed from the apparatus and the reaction mixture allowed to warm up to room temperature during which it became dark green. Water (50 ml) was added and the mixture was stirred at room temperature overnight. It was extracted with ether and analyzed by vpc on a SE-30 column (10% on dimethylsilylated Chromosorb W) for the dosage of cyclohexene (22%) and on the OS-138 column for the dosage of 3-methoxycyclohexene (16%), 3-chlorocyclohexene (42%), and 3-hydroxycyclohexene (25%). The products were isolated by preparative vpc for complete identification (ir and ^1H nmr).

3-Bromocyclohexene

The reaction was carried out as above except that the mixture was stirred at room temperature for 90 min after adding water. The chromous chloride solution turned green as soon as it touched the reaction mixture indicating that 3-bromocyclohexene was reduced at *ca.* −78 °C. Analysis of the crude product by vpc (SE-30 and OS-138 columns) showed that no 3-bromocyclohexene was left. However the yield of cyclohexene was 67% only, which could probably be explained by the fact that hydrolysis of the organochromium derivative was not complete after 90 min.

2-Chlorocyclohexanone

The reaction was carried out as described for 3-chlorocyclohexene except that the mixture was stirred at room temperature for 45 min after the addition of water. The reaction mixture remained blue throughout the addition indicating that no extensive reduction had occurred at *ca.* −78 °C. It turned dark green when allowed to warm up to room temperature. The product was analyzed by vpc (OS-138 column): 73% of 2-chlorocyclohexanone and 24% of cyclohexanone.

The formation of cyclohexene (22%) with 3-chlorocyclohexene and of cyclohexanone (24%) with 2-chloro-

[15]We thank Professor J. K. Saunders for the interpretation of the ^{13}C nmr spectra. The chemical shifts of ring A and B carbons, and in particular of C-3, C-5, C-6, C-8, and C-19, are in complete agreement with the structure and stereochemistry of the isomeric 1,2-adducts **25***a* and **26***a*.

cyclohexanone indicate that some reduction did occur despite the fact that the reaction mixture remained blue. The reduction probably occurred during the warming up of the reaction mixture· the diffusion of air into the reaction mixture being slow enough to allow chromous ions to be present at higher temperatures.

Removal of the Trichloroethoxycarbonyl Group

cis-β-Chlorocarbamate 2c

The adduct **2***c* (309 mg, 1 mmol) was treated with freshly activated zinc dust (300 mg) in glacial acetic acid (5 ml) at room temperature for 60 min. The reaction mixture was made strongly alkaline with an ice-cold 4 *N* NaOH solution then extracted with ether. The ether layer was dried and the solvent removed on a rotating evaporator to yield *cis-2-chlorocyclohexylamine* **5** (132 mg) as a liquid: ν_{max} ($CHCl_3$) 3400 and 3330 cm^{-1} (NH_2); δ ($CHCl_3$) 2.90 (m, $\Delta\nu_{1/2} \simeq 26$ Hz, H_1 axial) and 4.35 ppm (m, $\Delta\nu_{1/2} = 11$ Hz, H_2 equatorial). It was acetylated in the usual way, Ac_2O (0.5 ml) in pyridine (1 ml), to give *cis-2-chloro-N-acetylcyclohexylamine* **2***e* (158 mg, 90%), mp 95–96 °C (lit. (17) 88 °C). It proved identical (ir, ^1H nmr) to the *cis* 1,2-adduct **2***e* obtained from *N*-chloroacetamide **1***e* and cyclohexene.

trans-β-Chlorocarbamate 3c

The reduction (216 mg, 0.7 mmol) carried out as above gave, after acetylation of the crude β-chloroamine **6** (88 mg), *trans-2-chloro-N-acetylcyclohexylamine* **3***e* (108 mg, 88%) mp 128–130 °C (lit. (12) mp 129–130 °C) which proved identical (ir, ^1H nmr) to the *trans* 1,2-adduct **3***e* obtained from *N*-chloroacetamide **1***e* and cyclohexene.

cis-β-Bromocarbamate 2l

The reduction (291 mg, 0.8 mmol) as above gave, after acetylation of the crude amine (103 mg) followed by preparative layer chromatography (ether–hexane 4:1), *cis-2-bromo-N-acetylcyclohexylamine* **2***n* (73 mg 41%), mp 97.5–99 °C (lit. (11) 103–104 °C). It proved identical (ir, ^1H nmr) with the *cis* 1,2-adduct **2***n* obtained from *N*-bromoacetamide **1***n* and cyclohexene.

Reduction of the cis-β-Chlorocarbamate 2b (Z = OCH_2CH_2Cl)

The β-chlorocarbamate **2***b* (480 mg, 2 mmol) was treated with freshly activated zinc dust (1.2 g, added in portions of 200 mg every 2 h) and potassium iodide (1.33 g, 8 mmol) in 80% aqueous acetic acid (16 ml) at 80 °C for 16 h. The reaction mixture was cooled to 0 °C then made strongly alkaline with 4 *N* NaOH. It was extracted with methylene chloride. The organic phase was dried and the solvent removed at the rotating evaporator. The crude product was acetylated in the usual way to give, after recrystallization of the residue (345 mg), *cis-2-chloro-N-acetylcyclohexylamine* **2***e* (211 mg), mp 95–96.5 °C, which proved identical (ir, ^1H nmr) with an authentic sample.

The mother liquors (130 mg) were separated by preparative layer chromatography to yield an additional amount (63 mg) of the *cis-β-chloroamide* **2***e*, mp 96.5–97.5 °C (total amount 274 mg, 78% yield). A more polar oily fraction (15 mg) contained *cis-2-chloro-N-(2-acetoxyethoxycarbonyl)cyclohexylamine* according to the following spectral data: ν_{max} (CCl_4) 3440 and 3360 (free and bonded NH), 1735 (br and vs, ester and carbamate), 1505 (carbamate), 1240 (vs) and 1060 (ester and carbamate), 685 cm^{-1} (C-Cl ax. (24)); δ (CCl_4) 2.00 (s, $COCH_3$), 3.67 (m, $\Delta\nu_{1/2} = 18$ Hz, H_1 ax.), 4.15 (s, OCH_2CH_2O), 4.43 (q, $J = 3$ Hz, H_2 eq.), 5.07 (br d, $J = 8$ Hz, NH).

Hydrogenolysis of cis-2-Chloro-N-benzyloxycarbonylcyclohexylamine 2d

A solution of the *cis*-β-chlorocarbamate **2***d* (321 mg, 1.2 mmol) in 95% ethanol (90 ml) was hydrogenated over 30% palladium-on-charcoal at atmospheric pressure until no more carbon dioxide was produced (3 h). The catalyst was filtered and the solvent was evaporated to yield *cis-2-chlorocyclohexylamine* **5** (165 mg, quantitative) identified by ir and ^1H nmr spectroscopy. Acetylation in the usual way led to *cis-2-chloro-N-acetylcyclohexylamine* **2***e* (206 mg, 98%), mp 96–97 °C, identical (ir and ^1H nmr) to an authentic specimen.

5-(1-Hexyl)-2-oxazolidone 37

Pyrolysis of 2-Chloro-N-ethoxycarbonyl-1-octylamine 7a

The β-chlorocarbamate **7***a* (670 mg, 2.84 mmol) was heated at 185 °C under nitrogen for 3 h to give the *oxazolidone* **37**, mp 87–88 °C (486 mg, quantitative). The analytical sample (recrystallization from ether) had mp 88 °C; ν_{max} ($CHCl_3$) 3480 (NH), 1750 (C=O), 1240 and 1075 cm^{-1} (C—O—C); δ ($CDCl_3$) 3.20 and 3.70 (two t, $J = 8$ Hz, H-4), 4.58 (q, $J = 8$ Hz, H-5), 6.90 (s, NH); *m/e* 171 (M^+). *Anal.* calcd. for $C_9H_{17}NO_2$: C 63.15, H 10.01, N 8.19; found: C 62.90, H 9.98, N 8.19.

Pyrolysis of 2-Bromo-N-ethoxycarbonyl-1-octylamine 7j

The β-bromocarbamate **7***j* (400 mg, 1.43 mmol) was heated at 185 °C under nitrogen for 2 h to give, after treatment of the black residue with activated charcoal, the *oxazolidone* **37**, mp 87–88 °C (171 mg, 70%) identical (ir, ^1H nmr) with the above sample.

5-(1-Hexyl)-2-methyl-2-oxazoline 38

From 2-Chloro-N-acetyl-1-octylamine 7e

The β-chloroamide **7***e* (170 mg, 0.83 mmol) was treated with sodium methoxide in absolute methanol (18 mg of sodium and 2 ml of methanol) at 60 °C for 10 h. The reaction mixture was evaporated to dryness. The residue was dissolved in methylene chloride and washed with brine. The organic phase was dried and the solvent evaporated to give the *oxazoline* **38** as a liquid (137 mg, 97%), ν_{max} (CCl_4) 1725 (C=N), 1438 (CH_2—N), and 1230 cm^{-1} (C—O—C); δ (CCl_4) 1.81 (t, $J = 1.3$ Hz, CH_3), 3.50 (m, H-4), and 4.40 ppm (H-5); *m/e* 169 (M^+). It was further characterized as the hydrobromide derivative, mp 71–72 °C (ether); ν_{max} ($CHCl_3$) 2400–3000 cm^{-1} (very broad); δ ($CDCl_3$) 2.62 (m, CH_3), 3.95 and 4.50 (respectively d of d, $J \sim 8$ and 9 Hz, and t, $J \sim 9$ Hz, H-4), 5.40 ppm (m, H-5). *Anal.* calcd. for $C_{10}H_{20}BrNO$: C 48.00, H 8.05, Br 31.94, N 5.60; found: C 48.02, H 7.86, Br 32.70, N 5.56.

From 2-Bromo-N-acetyl-1-octylamine 7n

Attempts to purify the β-bromoamide **7***n* by microdistillation at 140 °C/0.01 torr resulted in its conversion to the *hydrobromide of the oxazoline* **38**, mp 69–70 °C, identical (ir, ^1H nmr) to the sample obtained above.

Alternatively the crude product from the addition of *N*-bromoacetamide **1***n* (8.7 mmol) to 1-octene (20 mmol), work-up A, was treated with sodium methoxide as described above to yield the *oxazoline* **38** (913 mg, 62%) identical (ir, ^1H nmr) to the sample obtained above. The

yield of **38** was taken as the yield of 1,2-adduct **7***n* assuming that its conversion to the oxazoline was quantitative.

1-Methyl-7-aza-7-ethoxycarbonylbicyclo[4.1.0]heptane ***39***

From trans-2-Chloro-2-methyl-N-ethoxycarbonylcyclohexylamine ***10a***

A solution of the *trans*-β-chlorocarbamate **10***a* (180 mg, 0.82 mmol) and potassium hydroxide (69 mg, 1.2 mmol) in 95% ethanol (10 ml) was heated to reflux for 1 h, then poured into cold water (25 ml) and extracted with ether (3 × 25 ml). After drying and evaporating the solvent, the residue was filtered on activity III neutral alumina to yield the *N-ethoxycarbonyl aziridine* **39** as a liquid (113 mg, 75%). The analytical sample was obtained by microdistillation at 64–65 °C/2.4 torr; ν_{max} (CCl_4) 1725 (C=O), 1260, 1100, 1035 cm^{-1}; δ ($CDCl_3$) 1.26 (superimposed s and t with J = 7.0 Hz, C—CH_3 and OCH_2CH_3), 2.50(t, J = 3.5 Hz, H-2), 4.20 ppm (q, J = 7.0 Hz, OCH_2CH_3). *Anal.* calcd. for $C_{10}H_{17}NO_2$: C 65.54, H 9.35, N 7.64; found: C 65.75, H 9.46, N 7.93.

The filtration on alumina removed the free aziridine (NH) resulting from partial cleavage of the *N*-ethoxycarbonyl group of **39**. The free aziridine was not recovered.

From trans-2-Bromo-2-methyl-N-ethoxycarbonylcyclohexylamine ***10j***

The *trans*-β-bromocarbamate **10***j* (150 mg, 0.56 mmol) was treated with alcoholic potassium hydroxide (1.7 mmol in 10 ml) at 50 °C for 45 min. Work-up as above gave the *aziridine* **39** (85 mg, 82%) identical (ir, ^1H nmr) to the sample obtained above. Again partial cleavage of the *N*-ethoxycarbonyl group of **39** occurred.

trans-2-Hydroxy-2-methyl-N-ethoxycarbonylcyclohexylamine ***40***

The aziridine **39** (85 mg, 0.46 mmol) in ether (10 ml) was stirred with silicic acid (1 g) for 16 h at room temperature. The mixture was filtered and the solids washed with ether–methanol 9:1. Evaporation to dryness gave the *trans-β-hydroxycarbamate* **40**, mp 109–111 °C (114 mg, quantitative). Recrystallization from methylene chloride–ether gave the analytical sample, mp 110–111 °C; ν_{max} ($CHCl_3$) 3590 (free OH), 3450 (free NH), 3430 (broad, bonded OH and NH), 1703 (bonded C=O), 1510 cm^{-1} (NH); δ ($CDCl_3$) 1.14 (s, CH_3), 1.24 (t, J = 7 Hz, OCH_2CH_3), 3.46 (br s, OH), 3.58 (m, $\Delta\nu_{1/2} \sim 25$ Hz, H-1), 4.20 (q, J = 7 Hz, OCH_2CH_3) 5.10 ppm (br d, J = 7.5 Hz, NH).

*Treatment of a Mixture of cis- and trans-2-Chloro-1-methyl-N-ethoxycarbonylcyclohexylamines (**11a** and **12a**) with Alcoholic Potassium Hydroxide*

The mixture of *cis*- and *trans*-β-chlorocarbamates **11***a* and **12***a* (386 mg, 1.75 mmol) was obtained from the chromatographic separation of the crude product from the addition of NCU (25 mmol) to 1-methylcyclohexene (50 mmol), the **11***a*–**12***a* ratio being 3.4 according to vpc analysis (see Table 5). A solution of this mixture and potassium hydroxide (202 mg, 3.6 mmol) in 95% ethanol (40 ml) was heated to reflux for 20 min. The usual work up gave a mixture of the *cis*-β-chlorocarbamate **11***a* and the aziridine **39** according to vpc analysis. It was put on a silica gel plate (1.5 mm thick) and kept at room temperature for 22 h. Elution with ether–hexane 1:2 gave two main fractions. The less polar fraction consisted of *cis-2-chloro-1-methyl-N-ethoxycarbonylcyclohexylamine* **11***a*, liquid (289 mg, 1.32 mmol). The analytical sample was obtained by microdistillation at 75 °C/0.12 torr; ν_{max} (CCl_4) 3420 (free NH), 1730 (C=O), 1505 (NH), 1230 and 1100 (C—O—C), 729 cm^{-1} (C—Cl ax. (24)); δ ($CDCl_3$) 1.28 (t, J = 7.0 Hz, OCH_2CH_3), 1.51 (s, CH_3), 4.17 (m which narrowed on D_2O exchange, H-2), 4.21 (q, J = 7.0 Hz, OCH_2CH_3), 5.03 ppm (br s, NH). *Anal.* calcd. for $C_{10}H_{18}ClNO_2$: C 54.67, H 8.26, Cl 16.14, N 6.38; found: C 54.89, H 8.09, Cl 16.32, N 6.57.

The more polar fraction was identical (mixture mp, ir, ^1H nmr) to the *trans*-β-hydroxycarbamate **40**, mp 109–110 °C (60 mg, 0.30 mmol).

The free aziridine resulting from the cleavage of the *N*-ethoxycarbonyl group was not recovered.

Oxazolidone ***41***

The *trans*-β-bromocarbamate **14***j* (70 mg, 2.3 mmol) was heated at 180 °C for 3 h under nitrogen. The brown residue was treated with activated charcoal to yield the *oxazolidone* **41** (26 mg, 63%), mp 133–134 °C (lit. (8*b*) 136–137 °C); ν_{max} ($CHCl_3$) 3470 and 3260 (free and bonded NH), 1750 (C=O), 1240 and 1050 cm^{-1} (C—O—C); δ ($CDCl_3$) 2.22 and 2.47 (m's bridgehead protons), 3.66 (d, J = 7 Hz, H-2), 4.48 (d, J = 7 Hz, H-3) 5.75 (br s, NH).

Under the same conditions, the *cis* isomer **13***j* was recovered unchanged.

N-Ethoxycarbonyl Aziridine ***42***

A solution of *trans*-2-chloro-*N*-ethoxycarbonylcyclopentylamine **21** (192 mg, 1 mmol) and potassium hydroxide (180 mg, 3 mmol) in 95% ethanol (20 ml) was heated to reflux for 10 min then poured into cold water and extracted with ether. The ether layer was dried then distilled. The residue was passed through a small column of activity III alumina with ether–hexane 1:1 to remove the free aziridine resulting from the cleavage of the *N*-ethoxycarbonyl group. The *N-ethoxycarbonyl aziridine* **42** (74 mg, 51%) was purified further by microdistillation at 83–85 °C/21 torr; ν_{max} (CCl_4) 1725 (C=O), 1275, 1190, 1105 cm^{-1}; δ ($CDCl_3$) 1.27 (t, J = 7.0 Hz, OCH_2CH_3), 2.91 (narrow m, $\Delta\nu_{1/2}$ = 3 Hz, H-1 and H-2), 4.10 (q, J = 7.0 Hz, OCH_2CH_3). *Anal.* calcd. for $C_8H_{13}NO_2$: C 61.93, H 8.38, N 9.03; found: C 61.75, H 8.38, N 9.21.

Under these conditions, the *cis* isomer **20** was recovered unchanged.

Steroidal Aziridine ***43a***

The *trans* 1,2-adduct **25***a* (1.0 g, 2.1 mmol) was suspended in a solution of potassium hydroxide (1.5 g) in ethanol (20 ml) and water (30 ml). After 2 h at room temperature, all the starting material had reacted (tlc). The reaction mixture was poured into water (200 ml) and extracted with methylene chloride. The organic layer was dried and the solvent evaporated to give the *aziridine* **43***a* (800 mg, 94%), mp 166–168 °C, homogeneous according to tlc. A recrystallization from chloroform–ether afforded the analytical sample, mp 171–172 °C, $[\alpha]_D^{20}$ +53.5° (*c* 1.0 in $CHCl_3$); ν_{max} (CS_2) 3600 and 3440 (free and bonded OH), 1715 (C=O), 1265, 1065 cm^{-1}; δ ($CDCl_3$) 0.61 (s, 18-CH_3), 1.07 (s, 19-CH_3), 1.28 (t, J = 7 Hz, OCH_2CH_3), 2.13 (s, 20-CH_3), 2.60 (m, OH), 2.83 (m, $\Delta\nu_{1/2}$ = 7 Hz, H-6), 3.80 (m, $\Delta\nu_{1/2} \sim 20$ Hz, H-3) 4.18 ppm (q, J = 7 Hz, OCH_2CH_3). *Anal.* calcd.

for $C_{24}H_{37}NO_4$: C 71.43, H 9.24, N 3.47; found: C 71.25, H 9.07, N 3.74.

5α-Chloro-6β-ethoxycarbonylamino-pregnan-3β-ol-20-one ***44***

The *trans* 1,2-adduct **25***a* (1.92 g, 4 mmol) was suspended in a solution of potassium hydroxide (3 g) in ethanol (80 ml) and water at room temperature. When all the steroid was dissolved (30 min), the solution was cooled to *ca.* 0 °C, acidified with 4 *N* HCl, then diluted with water (200 ml), and extracted with methylene chloride. The residue (1 g) after evaporation of the solvent was purified by preparative layer chromatography on silica gel (benzene–ether 1:2) to yield the pure *alcohol* **44** (0.80 g, 46%), mp 148–150 °C, which was recrystallized from ether for analysis: mp 150–151 °C; $[\alpha]_D^{20}$ −13.5° (*c* 1.0 in $CHCl_3$); ν_{max} ($CHCl_3$) 3600 (free OH), 3460 (free NH and bonded OH), 1715 (C=O), 1510 (NH), 1240 and 1040 (C—O—C), 910 cm^{-1} (str); δ ($CDCl_3$) 0.65 (s, 18-CH_3), 1.23 (s, 19-CH_3), 1.27 (t, J = 7 Hz, OCH_2CH_3), 2.15 (s, 20-CH_3), 2.48 (m, OH), 4.16 (q, J = 7 Hz, OCH_2CH_3), ~4.2 (m, H-3 and H-6), 5.00 ppm (br d, J = 10 Hz, NH). *Anal.* calcd. for $C_{24}H_{38}ClNO_4$: C 65.51, H 8.71, Cl 8.06; found: C 65.43, H 9.04, Cl 8.16.

Opening of Aziridine ***43a***

The aziridine **43***a* (200 mg, 0.5 mmol) in tetrahydrofuran (15 ml) was treated with 4 *N* HCl (5 ml) at room temperature for 16 h. The mixture was poured into water (100 ml), extracted with methylene chloride, dried, and evaporated. The residue was acetylated in the usual way and the crude product separated on a silica gel plate (benzene–ether 2:1) to yield the *trans* 1,2-adduct **25***a* (108 mg, 45%) mp 195–197 °C. It proved identical (ir, nmr) with an authentic sample.

Oxidation of Alcohol ***44***

Jones' reagent (2.7 *M* in CrO_3) was added slowly with a syringe to a cold solution (*ca.* 0 °C) of the alcohol **44** (320 mg, 0.73 mmol) in acetone (30 ml). The reaction was followed by tlc and the addition (~0.1 ml) was stopped when some starting alcohol could still be detected on the plates. The reaction mixture was poured into cold water and extracted with chloroform. The residue (284 mg) contained mainly (≥90%) the *3-ketone* **45** according to the ^1H nmr spectrum: δ ($CDCl_3$) 0.70 (s, 18-CH_3), 1.28 (t, J = 7 Hz, OCH_2CH_3), 1.42 (s, 19-CH_3), 2.20 (s, 20-CH_3), 3.23 (AB quartet: $\Delta\nu_{AB}$ = 21.3 Hz, J_{AB} = 16.5 Hz; protons at C-4), ~4.2 (m, H-6), 4.25 (q, J = 7 Hz, OCH_2CH_3), 5.28 ppm (m, NH). An attempt to purify an aliquot (80 mg) of this residue by preparative tlc on silica gel with ether resulted in partial loss of HCl and gave a mixture of ketone **45**, 6β-ethoxycarbonylamino α,β-unsaturated ketone **46**, and the 6α-isomer **47** according to the ^1H nmr spectrum.

Separation of another aliquot (120 mg) on activity III alumina with ether containing methanol (1%) gave *6α-ethoxycarbonylamino-4-pregnene-3,20-dione* **47** (104 mg, 84% from alcohol **44**) mp 162–164 °C. One recrystallization from ether gave the analytical sample, mp 164–166 °C; $[\alpha]_D^{20}$ +100° (*c* 0.43 in $CHCl_3$); λ_{max} (EtOH) 238 nm (ε 12 400); ν_{max} ($CHCl_3$) 3440 (NH), 1705 (C=O, carbamate and 20-ketone), 1670 (3-keto group), 1620 (C=C), 1230, 1110 cm^{-1}; δ ($CDCl_3$) 0.68 (s, 18-CH_3), 1.23 (t, J = 7 Hz, OCH_2CH_3), 1.28 (s, 19-CH_3), 2.15 (s, 20-CH_3), 4.15 (q, J = 7 Hz, OCH_2CH_3), 4.53 (m, $\Delta\nu_{1/2}$ = 25 Hz, H-6 axial), 5.03 (br d, J = 10 Hz, NH), 5.99 ppm (d, J = 1.8 Hz, H-4). *Anal.* calcd. for $C_{24}H_{35}NO_4$: C 71.80, H 8.79, N 3.49; found: C 71.63, H 8.62, N 3.49. Hence, on alumina, the ketone **45** lost HCl readily and the α,β-unsaturated ketone **46** was isomerized to the more stable α,β-unsaturated ketone **47**.

A third aliquot (75 mg) of the residue from oxidation of **44** was placed in an nmr tube in $CDCl_3$ with silica gel impregnated with concentrated HCl. ^1H nmr spectra were run repeatedly. First the absorptions due to ketone **45** disappeared gradually while the absorptions of *ketone* **46** appeared: δ 0.73 (s, 18-CH_3), 1.23 (t, J = 7 Hz, OCH_2CH_3), 1.33 (s, 19-CH_3), 2.16 (s, 20-CH_3), 4.18 (q, J = 7 Hz, OCH_2CH_3), 4.39 (m, H-6), 5.35 (m, NH), 6.10 ppm (narrow s, H-4). When the AB quartet at 3.23 ppm due to ketone **45** had completely disappeared, a doublet at 5.99 ppm due to α,β-unsaturated ketone **47** began to appear next to the narrow singlet at 6.10 ppm due to the 6β-isomer **46**. After 1 h, the isomerization of **46** into **47** was complete. The solution was filtered and the solvent evaporated. The residue was purified by preparative tlc on silica gel to afford pure *6α-ethoxycarbonylamino-α,β-unsaturated ketone* **47** (67 mg, 86% from **44**), mp 163–165 °C, identical (ir, nmr) to the sample obtained above.

5α-Chloro-6α-ethoxycarbonylamino-pregnan-3β-ol-20-one ***48***

The *cis* 1,2-adduct **26***a* (500 mg, 1.04 mmol) was suspended in a solution of potassium hydroxide (0.15 g) in ethanol (15 ml) and water (15 ml) and stirred at room temperature for 2 h. The mixture was poured into water (200 ml) and extracted with chloroform to yield, after evaporation of the solvent, the pure *alcohol* **48** (384 mg, 84%), mp 123–125 °C. One recrystallization from ether gave the analytical sample, mp 127–128 °C; $[\alpha]_D^{20}$ +48.3° (*c* 1.0 in $CHCl_3$); δ ($CDCl_3$) 0.62 (s, 18-CH_3), 1.20 (s, 19-CH_3), 1.28 (t, J = 7 Hz, OCH_2CH_3), 2.15 (s, 20-CH_3), ~4.2 (m, H-3 and H-6), 4.23 (q, J = 7 Hz, OCH_2CH_3), 5.08 ppm (br d, J = 10 Hz, NH). *Anal.* calcd. for $C_{24}H_{38}ClNO_4$: C 65.51, H 8.71, Cl 8.06; found: C 65.19, H 8.80, Cl 8.19.

Oxidation of Alcohol ***48***

To a cold (*ca.* 0 °C) solution of the alcohol **48** (140 mg, 0.32 mmol) in acetone (10 ml) was added slowly, with a syringe, 0.075 ml of Jones' reagent (2.7 *M* in CrO_3). Work-up as above (oxidation of **44**) gave the *3-ketone* **49** (142 mg) which was characterized by its ^1H nmr spectrum only: δ ($CDCl_3$) 0.65 (s, 18-CH_3), 1.25 (t, J = 7 Hz, OCH_2CH_3) 1.35 (s, 19-CH_3), 2.13 (s, 20-CH_3), 2.85 (s, 2H, protons at C-4), ~4.1 (m, H-6), 4.15 (q, J = 7 Hz, OCH_2CH_3), 4.95 ppm (br d, J = 10 Hz, NH).

Attempts to purify an aliquot (70 mg) by preparative tlc on silica gel gave the *6α-ethoxycarbonylamino α,β-unsaturated ketone* **47** (56 mg, 88% from **48**), mp 163–165 °C, which proved identical (ir ^1H nmr) to an authentic sample. Another aliquot (65 mg) in $CDCl_3$ was treated with silica gel impregnated with HCl in an nmr tube. ^1H nmr spectra were run repeatedly. The elimination of HCl led directly to the *6α-ethoxycarbonylamino α,β-unsaturated ketone* **47** as shown by the appearance of a doublet (J = 1.8 Hz) at 5.99 ppm while the singlet at 2.85 ppm gradually disappeared. The ketone **47** (54 mg, 92% from **48**), mp 162–164 °C, was isolated and identified by comparison with an authentic sample.

5α-Pregnane-3,6,20-trione ***50***

A mixture of α,β-unsaturated ketone **47** (100 mg, 0.2 mmol) and concentrated HCl (0.5 ml) in benzene (10 ml) was stirred at room temperature for 20 h. The crude product was separated on a thin layer silica gel plate (benzene–ether 4:1) to afford *5α-pregnane-3,6,20-trione* **50** (49 mg, 62%), mp 220–225 °C. It was recrystallized from benzene–ether to afford the analytical sample, mp 225–230 °C: $[\alpha]_D^{25}$ +63° (*c* 0.6 in $CHCl_3$) (lit. (19*a*) 232.5–233 °C, $[\alpha]_D$ +61° (*c* 1.0 in $CHCl_3$); (19*b*) 226–230 °C, $[\alpha]_D$ +59°); ν_{max} ($CHCl_3$) 1710 cm^{-1} (C=O); δ ($CDCl_3$) 0.68 (18-CH_3), 0.98 (19-CH_3) and 2.20 ppm (20-CH_3). *Anal.* calcd. for $C_{21}H_{30}O_3$: C 46.34, H 9.15; found: C 46.23, H 8.97.

The chromous chloride promoted addition of *N*-haloamides to olefins. IV.[1] Mechanistic aspects[2]

HUGHES DRIGUEZ[3] AND JEAN LESSARD

Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received July 29, 1976

HUGHES DRIGUEZ and JEAN LESSARD. Can. J. Chem. **55**, 720 (1977).

A discussion on the mechanism of the chromous chloride promoted addition of *N*-haloamides to olefins is presented on the basis of the results already reported and some additional evidence. The mechanism proposed involves a radical chain addition in which the *N*-haloamide acts as the transfer agent, the termination steps being chromium(II) reduction of the amido radical and chromium(II) reduction of the intermediate adduct radical. The addition of *N*-chloro- and *N*-bromoacetamide to norbornadiene is described. The use of chromous chloride to initiate the reaction of *N*-chloropiperidine with ethyl vinyl ether and cyclohexene led to low yields of addition.

HUGHES DRIGUEZ et JEAN LESSARD. Can. J. Chem. **55**, 720 (1977).

Le mécanisme de l'addition, catalysée par le chlorure chromeux, de *N*-haloamides aux oléfines est discuté en regard des résultats déjà rapportés et de quelques expériences additionnelles. Le mécanisme proposé fait intervenir une addition radicalaire en chaîne où l'amide *N*-halogéné agit comme agent de transfert. Les étapes de terminaison sont la réduction du radical amido et de l'adduit radicalaire intermédiaire par l'ion chromeux. On décrit l'addition du *N*-chloro- et *N*-bromoacétamide au norbornadiène. La réaction, initiée par le chlorure chromeux, de la *N*-chloropiperidine avec l'éthyl vinyl éther et avec le cyclohexène a donné de faibles rendements en addition.

In the preceding paper (1), we described the chromous chloride promoted addition of various *N*-haloamides to a variety of olefins in order to try to delineate the scope and limitations of the method for the synthesis of *N*-(2-haloalkyl)amides. We will now discuss a working hypothesis concerning the mechanism in the light of the facts reported and some additional experimental evidence described in this paper. This working hypothesis is summarized by reactions 1 to 7.[4] Some allylic hydrogen abstraction does occur as evidenced by the detection of bicyclohexenyl ($\leq 5\%$ under the usual reaction conditions) in the reaction of *N*-chlorourethane and *N*-chloro-*N*-methylacetamide with cyclohexene (1).[5]

Discussion and Results

Amido Radical Formation

Mechanistic studies on the chromium(II) reduction of alkyl halides (2–6) and of hydroxylamine and amine oxides (7–9)[6] have indicated that the first step involves the formation of a radical species. The following observations support the contention that the first step of the reaction of chromium(II) with a *N*-haloamide also involves the formation of an amido radical [1]: the orientation of the addition to unsymmetrically substituted olefins (the amide moiety is attached to the less substituted carbon atom (1))

[1]For part III of this series, see ref. 1.

[4]We have established in the preceding paper (1) that *N*-alkylamides (1,H-adducts) do not arise from chromium(II) reduction of *N*-(2-haloalkyl)amides (1,2-adducts) under the reaction conditions.

[5]The amount of bicyclohexenyl formed is probably less than the extent of allylic hydrogen abstraction since some of the cyclohexenyl radicals formed might have been converted to cyclohexene by chromium(II) reduction followed by protonolysis. 3-Chlorocyclohexene has never been detected even at *ca.* -78 °C where it was not reduced to a significant extent by excess chromous chloride (1).

[6]For reviews on the reduction of organic compounds by chromous salts, see ref. 10.

and to norbornene (the amido group is *exo*[7] (1)), the formation of nortricyclenyl derivatives in the additions to norbornadiene (see below), and the formation of formaldehyde when the reduction is carried out in methanol and in the absence of an olefin (see below). By analogy with the reduction of alkyl halides, hydroxylamine, and amine oxides, the formation of the amido radical is assumed to occur via an inner-sphere or bridged activated complex as shown in [1*a*] or in [1*b*]:[8] the *N*-haloamide could act as a bidentate ligand in the formation of the activated complex, which would lead to an amido radical bonded to the chromic ion. Even if the amido radical is not directly bonded to the chromic ion as depicted in [1*b*], it could still be associated with it since association complexes between radicals and transition metal ions have been postulated (14).

Stoichiometric Studies

If the above mechanism is correct, the generation of the amide ([1], [6], and [7]) and the formation of the 1,H-adduct ([1], [2], [4], and [5]) should require 2 mol of chromium(II) per mol of *N*-haloamide whereas the 1,2-addition process ([1], [2], and [3]) should require only a catalytic amount of chromium(II). This was confirmed by a study of the stoichiometry of these three processes.

The stoichiometry of amide formation was studied with *N*-chlorourethane and *N*-chloroacetamide, in methanol and in chloroform–methanol, and in the absence of an olefin[9]. The results are reported in Table 1. In methanol (entries 1 to 3), 1 mol of chromium(II) per mol of *N*-chloroamide was consumed and some formaldehyde was produced, which could be accounted for in the following way. The amide is formed by hydrogen abstraction from the solvent [8] and the resulting hydroxymethylene radical undergoes disproportionation to give formaldehyde [9] and most probably also coupling to give

[7]Radical attack on norbornene shows a strong preference for the less hindered *exo* face (11, 12).

[8]Since ligands on chromium(II) are readily interchanged (13) and methanol as solvent is present in large excess, the coordination sphere most probably contained methanol molecules (L = CH_3OH).

[9]*N*-Chlorourethane and *N*-chloroacetamide do not react with methanol in the absence of chromous chloride at 0 °C (no loss of active chlorine after 1 h).

ethylene glycol [10].[10] However, in chloroform–

[8] $ZCO\dot{N}H + CH_3OH \rightarrow ZCONH_2 + \cdot CH_2OH$

[9] $2 \cdot CH_2OH \rightarrow CH_2O + CH_3OH$

[10] $2 \cdot CH_2OH \rightarrow (CH_2OH)_2$

methanol (the solvent used for the additions to olefins), 2 mol of chromium(II) per mol of *N*-chloroamide were used and formaldehyde could not be detected. Thus chromium(II) reduction of the amido radical [6] appears to be faster than hydrogen abstraction from methanol, which could be due to a preferential solvation of the amido radical by chloroform;[11] protonolysis of the nitrogen–chromium bond [7] would then afford the amide.[12] If the amido radical is complexed with the halochromic ion formed in [1] (such complexation could be favored in the presence of chloroform), its reduction could occur through bridging with the halide ion of the complex (see [6*a*]) as has been suggested for the chromium(II) reduction of alkyl halides to alkanes (10).

[6*a*] $[ZCO\dot{N}H\ Cr^{III}X] + Cr^{II} \rightarrow ZCONHCr^{III} + XCr^{III}$

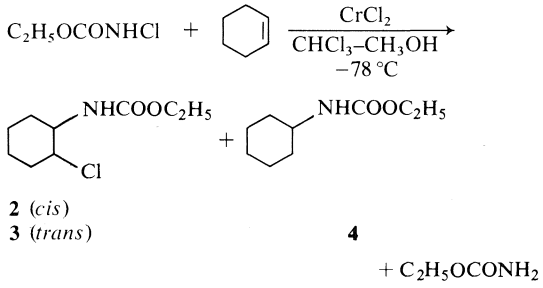
To study the stoichiometry of *N*-alkylamide formation (1,H-addition), we chose the addition of *N*-chloroacetamide to norbornene which was shown to lead almost exclusively to 1,H-addition (1). The results reported in Table 2 show that the formation of 1 mol of *N*-acetylnorbornylamine **1** requires nearly 2 mol of chromium(II) as in the postulated mechanism.

[10]The hydroxymethylene radical generated by radiolysis of methanol was reported to give ethylene glycol and formaldehyde; metal ions were found to increase the proportion of formaldehyde and an association complex $[M^{n+} \cdot CH_2OH]$ was suggested to be responsible for this (14*a*). We made no attempt to see if ethylene glycol was formed or not.

[11]The C—H bond of chloroform is less reactive than a C_α—H bond of an alcohol or an ether towards electrophilic radicals (15). Chromium(II) reduction of the amido radical could then be faster than hydrogen abstraction from chloroform.

[12]For the reduction of hydroxylamine and amine oxides in aqueous acidic medium, Taube and his co-workers (9) have suggested that the aminium radicals might react with chromium(II) by abstracting a hydrogen atom from the water molecules of the coordination sphere to explain the fact that they could not obtain evidence for the formation of a $Cr^{III}NR_3$ intermediate. The amido radical could react with chromium(II) in a similar fashion but the proposed mechanism ([6] and [7]) is similar to the accepted mechanism of chromium(II) reduction of alkyl halides (2–5, 16) and appears more probable to us.

Finally, studies on the stoichiometry of the addition of *N*-chlorourethane to cyclohexene (Table 2) have confirmed that the 1,2-addition process occurs by a chain mechanism. Indeed, the amount of urethane and *N*-cyclohexylurethane **4** formed (0.92 mmol all together) should have required about 1.8 mmol of chromous chloride; since 1.75 mmol was consumed, no chromous chloride was effectively used for the formation of the 1,2-adducts **2** and **3** (Scheme 1). Alternatively, when 1.0 mmol of chromous chloride was added to a tenfold excess of *N*-chlorourethane and a twentyfold excess of cyclohexene under the standard reaction conditions and the reaction mixture stirred at −78 °C for 24



2 (*cis*)
3 (*trans*)
4

SCHEME 1

h, 5.0 mmol of 1,2-adducts **2** and **3** were obtained together with 0.3 mmol of 1,H-adduct **4** and about 0.3 mmol of urethane; again the amount of urethane and 1,H-adduct **4** (~0.6 mmol) accounts for all the chromous chloride consumed and therefore none was used for the 1,2-addition process.

β-*Amido-alkylchromium Intermediate*

In order to obtain further evidence for the formation of a β-amido-alkylchromium intermediate, *N*-chloro-*N*-deuteroacetamide was added to norbornene, all the acidic hydrogens of the medium being replaced by deuterium (Scheme 2). In a first experiment, the reaction mixture was allowed to warm to *ca.* 0 °C then worked-up in water: no deuterium was incorporated in *N*-acetylnorbornylamine **1**. In a second experiment, heavy water was added immediately after removing the cooling bath: the isolated *N*-acetylnorbornylamine (**1**-d_2) had two deuteriums according to its nmr spectrum. The N-deuterium was exchanged readily with water, the other being at position 3 as required by the formation and protonolysis of a β-amido-alkylchromium intermediate ([4] and [5]); the

TABLE 1. Stoichiometry of the reduction of ZCONHCl in the absence of an olefin

	Reaction conditions							Yield[d] of products (%)

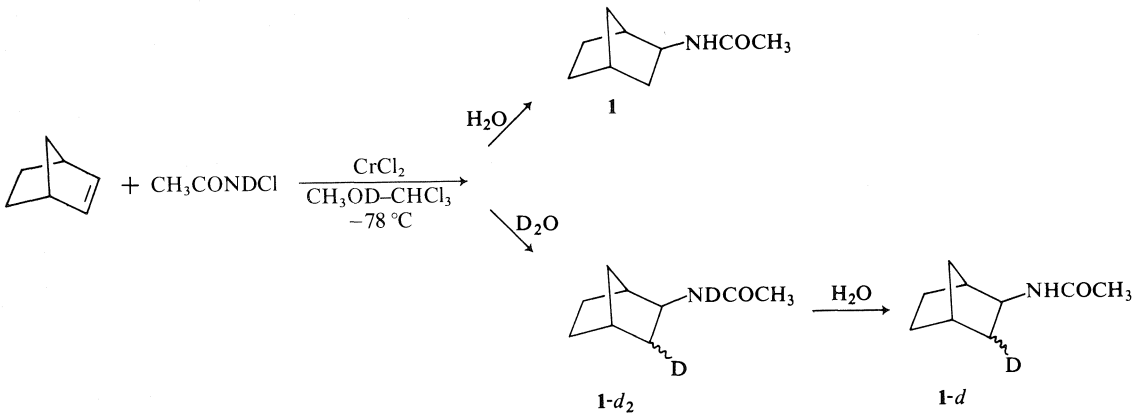
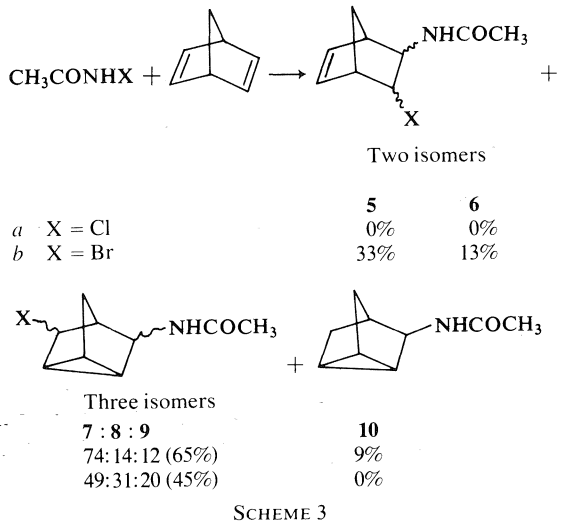
[a]The reactions were carried out in the usual conditions, that is at a bath temperature of −78 °C and in chloroform (2.5 ml) – methanol (1 ml) but the chromous chloride methanolic solution (1.0 ± 0.02 *M*) was added rapidly (5 to 10 min) which explains why the yields of addition are lower than those given in the foregoing paper (1).
[b]From tritration of unreacted chromium(II) (see Table 1, footnote *b*).
[c]By vpc.
[d]Not detected.
[e]The Cr(II)/1,H-addition and the Cr(II)/amide molar ratios were taken as 2 for the calculation of Cr(II)/1,2-addition ratio.



SCHEME 2

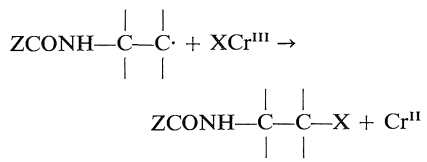
proton and carbon nmr spectra showed that the deuterium was distributed between the *exo* and *endo* positions (see the Experimental). The first experiment indicates that protonolysis of the β-amido-alkylchromium intermediate does not occur readily in the reaction medium at temperatures up to 0 °C. The proposed mechanism for the 1,H-addition process is in agreement with a number of studies on chromium(II) reduction of alkyl halides indicating that alkylchromium ions are formed when alkyl radicals are captured by chromous ions (3*a*, 5*a*, 5*c*, 9, 16) and that the corresponding alkanes result from protonolysis (3*a*, 5*c*, 16*a*, 16*d*).



SCHEME 3

Chain-transfer Step

The radical nature of the chromous chloride promoted addition of *N*-haloamides to olefins was further confirmed by the addition of *N*-chloro- and *N*-bromoacetamide to norbornadiene (Scheme 3). Indeed radical additions to norbornadiene can give 5,6-disubstituted norbornenes via 1,2-addition and/or 3,5-disubstituted nortricyclenes via 1,5-homoconjugative addition (17). *N*-Chloroacetamide led exclusively to nortricyclene products (**7***a*, **8***a*, **9***a*, and **10**) (no olefinic proton absorption could be detected in the nmr spectrum of the crude product and of the chromatographic fractions) whereas with *N*-bromoacetamide, the ratio of norbornene derivatives **5***b* and **6***b* to nortricyclene derivatives **7***b*, **8***b*, and **9***b* was approximately one-to-one.[13] The chain-transfer step is thus faster with *N*-bromoacetamide. This agrees with the proposed mechanism in which the *N*-haloamide acts as the transfer agent (see [3]), a bromine-atom transfer being faster than a chlorine-atom transfer. But it would also agree with a transfer step (see [11]) involving a ligand transfer from the halochromium(III) produced in [1] since a bromide is transferred more readily than a chloride.[14] A number of free radical 1,2-additions of organic halides to olefins have been initiated



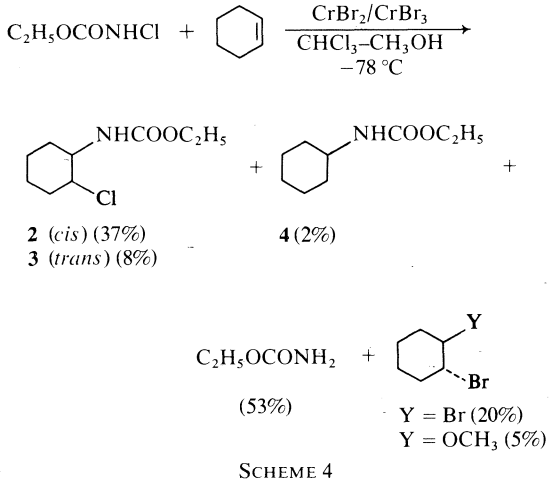
by various low-valent transition metal salts and a redox-transfer chain mechanism has been sug-

[13]The stereochemistry of the products of addition of various *N*-haloamides to norbornadiene is under study and will be reported later.

[14]The analogy between oxidation of an alkyl radical by ligand transfer and atom transfer to an alkyl radical has been discussed by Kochi (18).

gested for these reactions (19–21). However the metal salts participating in the ligand-transfer step (*e.g.* Cu(II) chloride, Fe(III) chloride) have a much higher redox potential than the chromic ion and we believe that the ligand transfer illustrated in reaction 11 is not very probable.[15,16] Nevertheless the following experiments were carried out in an attempt to distinguish between [11] and [3].

First we carried out a chromous bromide initiated addition of *N*-chlorourethane to cyclohexene in the presence of a slight excess of chromic bromide. We could not detect any β-bromocarbamate, the β-chlorocarbamates **2** and **3**, cyclohexylurethane **4**, and urethane accounting for all the starting *N*-chlorourethane (Scheme 4); this is in agreement with the chain-transfer step [3]. The yield of addition (47%) was much



SCHEME 4

lower than in the chromous chloride promoted addition (93%) (1), probably as a result of the reduction of *N*-chlorourethane by bromide ions; part of the molecular bromine thus formed was trapped by cyclohexene to give *trans*-dibromocyclohexane and *trans*-bromomethoxycyclohexane, the other part being most probably reduced by the chromous ions. We then compared the chromous chloride promoted simultaneous addition of *N*-chlorourethane and *N*-bromo-α-chloroacetamide to 1-octene with the photochemical simultaneous addition in methylene chloride at −70 °C. An excess of *N*-chlorourethane over the *N*-bromo-α-chloroacetamide was used to compensate for the fact that both the initiation step and the chain-transfer step should be faster with the *N*-bromo derivative in the chromous chloride as well as in the photochemically induced reaction. The results are summarized in Scheme 5. The proportions of crossed 1,2-adducts **12** and **14** (respectively 6–7% and 3–5%) are similar whether the addition was initiated by chromous chloride or by irradiation. The formation of crossed 1,2-adducts is therefore also in agreement with the chain-transfer step [3].[17,18]

Chain-termination Steps

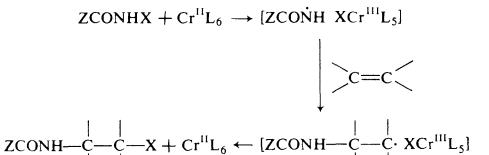
According to the proposed mechanism, the two main chain-termination steps are chromium(II) reduction of the amido radical [6] and chromium(II) reduction of the intermediate adduct radical [4]. The first one competes with the addition of the amido radical to the olefin [2] and leads to the amide through [7]; the

[15]Reaction 11 would be the microscopic reverse of the first step of the chromium(II) reduction of alkyl halides (2–6).

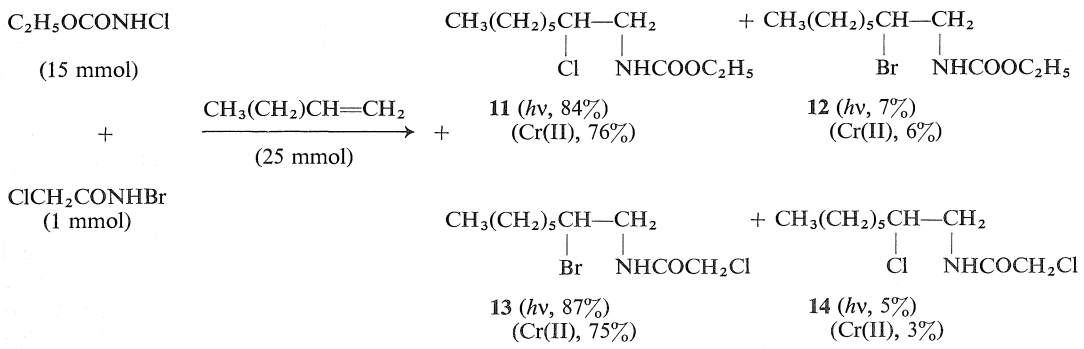
[16]Recently Surzur and Stella (22) suggested that in the radical cyclization of olefinic *N*-chloroamines catalyzed by Ti(III) chloride, oxidation of the intermediate radical does not occur by ligand transfer of chlorine from Ti(IV) chloride but rather by chlorine-atom transfer from a molecule of *N*-chloroamine. Minisci *et al.* (23) had previously shown that ligand transfer of chlorine from Ti(IV) chloride was much less efficient than from Fe(III) chloride. The redox potential of titanium(IV), although much lower than that of iron(III), is still appreciably higher than that of chromium(III).

[17]The photochemical addition of *N*-haloamides to olefins has been shown to proceed by a chain mechanism (D. Touchard, Ph.D. Thesis, Université de Sherbrooke, 1974).

[18]The two crossed experiments reported in this paragraph do not constitute fool-proof experimental evidence against the ligand-transfer step [11]. In the second experiment, some halogen exchange could have occurred between *N*-chlorourethane and *N*-bromo-α-chloroacetamide before completion of the reaction. In the first experiment, all the steps leading to a 1,2-adduct could involve radical–halochromium(III) complexes in which the halide ion would come originally from the *N*-haloamide:



Chromium(III) being substitution inert (13), the halide ion in the complex would not be exchanged readily with an halide ion in solution. Furthermore the radical–halochromium(III) complexes could react before the occurrence of any exchange between the halochromic ion in the complex and the halochromic ions in solution.



SCHEME 5

second one competes with the halogen-atom transfer [3] and leads to the 1,H-adduct through [5]. The yield of addition and the 1,2-addition – 1,H-addition ratio should then be higher when lowering the concentration of chromous chloride. Indeed in the reaction of *N*-chlorourethane with cyclohexene, the yield of addition and the 1,2-addition – 1,H-addition ratio were higher (respectively, 93% and 14.5) when the chromous chloride solution was added slowly (*e.g.* over 70 min) (lower effective concentration of chromous ions) than when it was added rapidly (*e.g.* over 10 min) (respectively, 70% and 9) (1). Similarly a very slow rate of addition of chromous chloride (3 h) led to a 94% yield of addition of *N*-chloroacetamide to norbornene (1) whereas a fast rate (5 min) led to a 43% yield of addition (Table 2); in this case the amount of 1,2-addition was too small to measure a meaningful variation of the 1,2-addition – 1,H-addition ratio.

The competition between addition of the amido radical to the olefin [2] and its chromium(II) reduction [6] should also depend on the relative reactivity of the amido radical in these two processes. The reactivity of $ZCO\dot{N}H$ towards addition to simple olefins would be expected to increase with the electrophilic character of the radical,[19] that is with the electron-withdrawing ability of the ZCO moiety. On the other hand the ease of chromium(II) reduction of $ZCO\dot{N}H$ should also increase with the ability of ZCO to accept electrons (anionic character of the organochromium derivative) but not necessarily to the same extent. The variation with Z of the ratio of addition–chromium(II) reduction of $ZCO\dot{N}H$ is indicated in Table 3 for the addition of ZCONHX to cyclohexene and indeed it shows no definite trend.[20] The ratio is the highest with the ethoxycarbonylamino radical ($Z = OC_2H_5$) which is probably more electrophilic than the acetylamino radical ($Z = CH_3$) because of the inductive effect of the ethoxy group but would be reduced less readily by chromium(II) than the latter because the carboethoxy group would be less efficient than the acetyl group to accommodate the electrons of the organochromium derivative.[21] An *N*-methylamido radical ($ZCO\dot{N}CH_3$) should be less reactive than $ZCO\dot{N}H$ towards addition to olefins because of greater spin delocalization but mainly because of a steric effect. On the other hand, the steric effect would be expected to be less important for the chromium(II) reduction. As a result, the chromium(II) reduction of $ZCO\dot{N}CH_3$ could be faster than its addition to cyclohexene which would explain that no addition products to cyclohexene were detected with *N*-chloro-*N*-methylacetamide and *N*-chloro-*N*-methyl-2,2,2-trichloroethylcarbamate (Table 3). Finally the succinimidyl radical should be more readily re-

[19]The amido radical is most probably electrophilic which implies the contribution of polar resonance forms (indicating some electron transfer from the olefin to the radical) to the stabilization of the transition state for the addition (24).

[20]It is noteworthy here that in the photochemical addition of ZCONHX (X = Cl, Br) to cyclohexene where the addition of the amido radical competes with the reactions of the halogen atom, the yield of addition increases with the electron-withdrawing power of Z (25).

[21]The acidity of the protons on nitrogen of *N*-chlorourethane ($pK_a = 8.02$) is lower than that of *N*-chloroacetamide ($pK_a = 7.22$) (F. Comtois, J. Lessard, H. Ménard, and M. Paquette, unpublished results) and the pK_a of an acetate (~25) is higher than that of acetone (~20).

TABLE 3. Ratio of addition–chromium(II) reduction of ZCONR in the addition of ZCONRX to cyclohexene

ZCONRX	Addition/chromium(II) reduction[a] (X = Cl)	(X = Br)
CCl_3CONHX	1.3	2.1
CH_3CONHX	2.3	3.5
CF_3CONHX	4.1	
$ClCH_2CONHX$	7.3	3.9
$C_2H_5OCONHX$	14.3	23
$CH_3CON(CH_3)X$	0	
$CCl_3CH_2OCON(CH_3)X$	0	
CH_2——CO | | CH_2CONX	0.22	0.18

[a]These ratios were calculated from the additions reported in ref. 1. In the cases where the yield of amide was not determined, we assumed that all the *N*-haloamide which did not add to cyclohexene and did not lead to electrophilic halogenation was converted to the amide by reduction ([4] and [5]) as in other cases: percentage of chromium(II) reduction = 100 − (yield of addition + yield of electrophilic halogenation).

duced by chromium(II) than ZCONH because of a greater stabilization of the ionic transition state (partial negative charge on the organic group). On the other hand even if it could be more electrophilic than ZCONH, it is bulkier. The low addition – chromium(II) reduction ratios in the reaction of *N*-chlorosuccinimide and *N*-bromosuccinimide with cyclohexene (Table 3) are therefore not unexpected.

For a given amido radical, the competition between addition to the olefin [2] and chromium(II) reduction [6] should depend also on the reactivity of the olefin. Indeed, in the additions of *N*-chlorourethane to 1-substituted cyclohexenes, the yield of addition increases in the order 1-chlorocyclohexene (29%) < 1-acetoxycyclohexene (47%) < 1-methylcyclohexene (87%) ≤ 1-methoxycyclohexene (90%) (1), in agreement with both the relative ability of the substituents to delocalize an unpaired electron and their relative electron-releasing power.[22] Norbornene is known to be more reactive than cyclohexene towards electrophilic radicals (27) and effectively the yields of addition of the various *N*-haloamides studied were generally higher with norbornene (1). With monosubstituted olefins the yield of addition of *N*-chlorourethane increases in the following order: methyl vinyl ketone (18%) < methyl acrylate (38%) < 1-octene (85%) (1). This is again in agreement with a competition between step [2] and step [6] and with the electrophilic character of the urethane radical.

We have seen that the competition between the halogen-atom transfer [3] and chromium(II) reduction of the intermediate adduct radical [4] does depend on the chromous ion concentration. It should also depend on other factors affecting the relative rates of [3] and [4]. One of these factors is the reactivity of the *N*-haloamide as a halogen-atom transfer agent. The additions to norbornadiene have established that an *N*-bromoamide is more reactive than an *N*-chloroamide and indeed the 1,2-addition – 1,H-addition ratio, for a given olefin, is larger with *N*-bromoamides than with the corresponding *N*-chloroamides (see Table 4). It is interesting to note in Table 4 the increase in the 1,2-addition – 1,H-addition ratio with Z in the order CH_3 < $ClCH_2$ < C_2H_5O ≤ CCl_3 < CF_3. We hypothesize that the reactivity of the *N*-haloamide in the chain-transfer step [3] increases with the electron-withdrawing power of the ZCO moiety as a result of increasing contribution of a polar resonance form to the stabilization of the transition state. Work is in progress to verify this hypothesis.

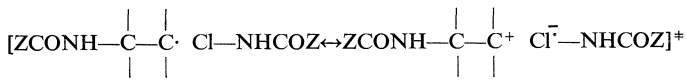
Two other factors affecting the relative rates of steps [3] and [4] and hence the 1,2-addition – 1,H-addition ratio would be, for a given *N*-haloamide, the reactivity of the intermediate adduct radical and the stability of the alkylchromium derived from it. For instance, the more stable the radical, the slower the transfer step [3]; the more stable the alkylchromium, the faster the

TABLE 4. Ratio of 1,2-addition – 1,H-addition in the addition of ZCONHX to cyclohexene

ZCONHX	1,2-addition/1,H-addition[a] (X = Cl)	(X = Br)
CH_3CONHX	0.94	7.4
$ClCH_2CONHX$	5.8	18.5
$C_2H_5OCONHX$	14.5	~140
CCl_3CONHX	≥28[b]	>33[b]
CF_3CONHX	31	

[a]Ratios calculated from the results reported in ref. 1.
[b]The 1,H-adduct was not detected in the chromatographic fractions and we assume that we would have been able to detect 2% of it.

[22]The reactivity of the olefin towards an electrophilic radical should depend not only on steric factors and on the ability of the substituents to delocalize an unpaired electron but also on their ability to donate electrons (polar effect).

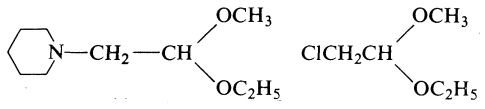


reduction of the radical [4]. We have seen that, for the additions of *N*-chloroacetamide for example, the 1,2-addition – 1,H-addition ratio is much smaller with 1-octene (0.57) and cyclohexene (0.94) than with 1-methylcyclohexene (≥ 37, no 1,H-adduct was isolated) (1). The determining factor in this case is probably the stability of the alkylchromium derivative. Indeed a secondary radical is less stable than a tertiary radical but a secondary alkylchromium should be more stable than a tertiary alkylchromium (carbanion character). In the additions to conjugated systems, both spin delocalization in the adduct radical (allylic radical, radical α to a carbonyl group) and the charge delocalization in the alkylchromium derived from it should favor the reduction step [4] over the transfer step [3] in agreement with the experimental facts reported in the preceding paper (1): the sole addition products isolated from the addition of *N*-chlorourethane to butadiene, cyclohexadiene, methyl acrylate, and methyl vinyl ketone, are derived from the reduction of the adduct radical [4]. Finally we have observed that the 1,2-addition – 1,H-addition ratio (*e.g.* addition of *N*-chlorourethane) decreases in the order cyclohexene (14.5) > cyclopentene (2.6) > norbornene (0.76), which is the order of increasing ring strain and could be the order of increasing stability of the intermediate adduct radical. But we do not know if this is due to an influence on the rate of step [3] or on the rate of step [4], or on both rates.

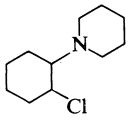
Conclusion

The discussion and experimental facts presented in this paper do not provide an answer to all the questions concerning the mechanism of the chromous chloride promoted addition of *N*-haloamides to olefins but we hope it will be useful to potential users of the reaction and might foster a more thorough mechanistic investigation. One puzzling fact is the following. Stoichiometric studies have shown that virtually no chromium(II) is used for the 1,2-addition process; however in the reactions where the yield of 1,2-addition to an excess of olefin is high (>85%), at least 0.9 mol of chromous chloride has to be added to consume all the *N*-haloamide (1).

To the best of our knowledge, no example of a radical 1,2-addition to olefins initiated by chromium(II) was known until the appearance of our preliminary reports on the chromous chloride promoted addition of *N*-chlorocarbamates to olefins (26). It would be interesting to see if chromium(II) could be used to initiate other 1,2-additions. As a first step in that direction, we studied the chromous chloride promoted addition of *N*-chloropiperidine to ethyl vinyl ether hoping that electrophilic halogenation might not compete with the radical reactions at −78 °C.[23] We did obtain the expected adduct **15** but in a very low yield (14%), the other products being the α-chloroacetal **16** (24%) resulting from electrophilic chlorination, and piperidine. The yield of 1,2-addition (**17** and **18**) to cyclohexene was also quite low (14%, **17**/**18** = 2.5), piperidine being the sole other product isolated; no chloromethoxycyclohexane (electrophilic chlorination) was detected. Thus it appears that chromium(II) reduction of the piperidino radical would be faster than its addition to either ethyl vinyl ether or cyclohexene.[24]



15 **16**



17 *cis*
18 *trans*

Experimental

The pertinent general information and a description of the apparatus used for the chromous chloride promoted reactions have been given in the preceding paper (1).

[23]According to Minisci *et al.* (21), in methanol at 0 °C and in the presence of Fe(II), Cu(I), and Ti(III) salts, electrophilic chlorination of enol ethers was faster than reduction of the *N*-chlorodialkylamine.

[24]With a milder reducing salt, the yields of 1,2-addition are much better. Minisci *et al.* (21) reported an 80% yield and a large predominance of the *cis*-adduct **17** for the addition catalyzed by the ferrous sulfate – ferric chloride couple in methanol at 0 °C; in our hands, however, the yield of 1,2-addition was 67% (**17**/**18** = 2). Using titanous chloride in methanol at −15 °C, L. Stella (Thèse de Doctorat ès-Sciences physiques, Université de Provence, 1972) obtained a 66% yield of 1,2-addition; using the same conditions, we obtained a 75% yield, (**17**/**18** = 2).

General Procedure for Stoichiometry Determinations

A known volume (5 or 10 ml) of the chromous chloride solution measured as accurately as possible in dropping funnel C was added drop-wise over 5 to 10 min into flask B containing the *N*-haloamide (and the olefin) in methanol or in chloroform–methanol and cooled in an ice bath or a dry ice – methanol bath. An excess of chromous chloride, generally 2 mol per mol of *N*-haloamide, was added rapidly (5 to 10 min). Then a standard 0.2 *N* sodium triiodide solution (10 or 25 ml) was added with a volumetric pipet. The mixture was allowed to warm to room temperature and titrated with a 0.1 *N* standard sodium thiosulfate solution using the coloration of the chloroform layer to determine the end point. The organic products were separated from the inorganic salts by continuous extraction with methylene chloride for 24–48 h. The solvent was partly removed by distillation and the resulting mixture transferred into a volumetric flask. The yields were determined by vpc using authentic samples as standards. For each of the results reported in Table 1 and Table 2, at least two determinations (sometimes three) were made. The titration values were always within 2% of one another and the yields were within 5%. The mean values are given in Tables 1 and 2.

An aliquot of the crude product was separated by preparative tlc on silica gel for complete identification of the products. Diethoxycarbonylaminomethane (Table 1, entry 1), mp 130–131 °C, proved identical (mixture mp ir, ^{1}H nmr) to an authentic sample prepared from urethane and formaldehyde (27).

The chromous chloride solution was titrated in the same apparatus, using a chloroform layer to determine the end point, and the different values were within 1% of one another.

Trapping of Formaldehyde with Dimedone in the Chromous Chloride Reduction of N-Chlorourethane and N-Chloroacetamide

The reactions were carried out under the same conditions as those used for the stoichiometry determination (see Table 1) except that no excess chromous chloride was used: the addition of the chromous chloride solution was stopped when the starch–iodide paper test was negative. The reaction flask was then heated to reflux under a stream of nitrogen and the exit gases were allowed to pass through a saturated aqueous solution of dimedone. The precipitate was collected and dried, mp 185–187 °C (lit. (28) 189 °C). In the experiments corresponding to the conditions of entries 1 and 2 of Table 1, the following quantities of precipitate were obtained: 86 mg and 115 mg respectively. In the experiment corresponding to the conditions of entry 4, no precipitate was formed.

Addition of N-Chloro-N-deuteroacetamide to Norbornene in a Deuterated Medium

Chromous Chloride Solution

To $CrCl_3 \cdot 6H_2O$ (5.3 g, 20 mmol), freshly distilled thionyl chloride was added dropwise and the mixture heated to reflux for 4 h. The excess thionyl chloride was distilled off and the violet powder was dried overnight under vacuum (29). The anhydrous $CrCl_3$ thus obtained was dissolved in CH_3OD (20 ml) containing D_2O (2 ml) and DCl (0.3 ml of a 38% solution in D_2O). The resulting green solution was reduced over zinc amalgam (prepared in D_2O acidified with DCl).

Addition

The chromous chloride solution (7 ml) was added dropwise to a solution, cooled in a dry ice – methanol bath, of *N*-chloro-*N*-deuteroacetamide (240 mg, 2.5 mmol) and norbornene (470 mg, 5 mmol) in $CHCl_3$ (2 ml) and CH_3OD (1 ml). The addition took 3 h and the reaction mixture was allowed to warm to 0 °C then poured into water (50 ml). Continuous extraction with methylene chloride for 48 h and separation of the residue by preparative layer chromatography gave *N*-acetylnorbornylamine **1**, mp 133–135 °C, (290 mg, 77%) identical (^{1}H nmr, mass spectrum) to an authentic sample.

The reaction was repeated in exactly the same conditions except for the work-up procedure. Deuterated water (20 ml) was added before the reaction mixture was allowed to warm up to room temperature. Continuous extraction followed by chromatography as above gave *N*-acetyl-*N*,3-dideutero-norbornylamine **1**-d_2, mp 132–134 °C (315 mg, 84%); δ ($CDCl_3$) 3.65 ppm (br d, $J \sim 4$ Hz, $\Delta\nu_{1/2} = 10$ Hz, H-3). Exchange with water gave *N*-acetyl-3-deutero-norbornylamine **1**-*d*; *m/e* 154 (M^+); ^{1}H nmr δ ($CDCl_3$) 3.65 ppm (br t, $J \sim 6$ Hz, $\Delta\nu_{1/2} = 14$ Hz, H-3); ^{13}C nmr δ ($CDCl_3$) 23.28 ($CO\mathit{CH}_3$), 26.47 (C-6), 28.09 (C-5), 35.44 (C-7), 35.53 (C-4), 39.80 (C-3, t, $J_{C-D} = 20.5$ Hz), 42.28 (C-1), 52.77 ppm (C-2). The signal of C-5 at 28.09 ppm is broader ($\Delta\nu_{1/2} = 2.5$ Hz) than the signal of C-6 at 26.47 ppm ($\Delta\nu_{1/2} \simeq 1$ Hz) due to coupling between C-5 and the deuterium at position 3. Since the vicinal $^3J_{C,D}$ should be about 1 Hz with the deuterium *exo* (dihedral angle of 180°) and about 0.3 Hz with the deuterium *endo* (dihedral angle of 60°), the deuterium must be distributed between the *exo* and *endo* positions.[25] The same conclusion is reached by considering the half band width of the signal of H-3 in the ^{1}H nmr spectrum of N-deuterated *N*-acetylnorbornylamine **1**-ND and of the *N*,3-dideuterated derivative **1**-d_2. The difference $\Delta(\Delta\nu_{1/2})$ between **1**-ND and **1**-d_2 is 5 Hz and should be about 7–8 Hz if the deuterium at C-3 was *exo* and about 2–3 Hz if it was *endo*.

Addition of N-Chlorourethane to Cyclohexene with a Catalytic Amount of Chromous Chloride.

Chromous chloride (10 ml of a 0.1 *M* methanolic solution, 1 mmol), was added to a solution of *N*-chlorourethane (1.29 g, 96% active chlorine, 10 mmol) and cyclohexene (2 ml, 20 mmol) in chloroform (10 ml) and absolute methanol (2 ml) cooled in a dry ice – methanol bath (−78 °C). The mixture was kept at *ca.* −78 °C under a carbon dioxide atmosphere for 24 h. A saturated sodium bisulfite aqueous solution was added to reduce the unreacted *N*-chlorourethane and the mixture was allowed to warm up to *ca.* 0 °C then extracted with ether (4 × 100 ml). The residue was separated on silica gel plates (ether–hexane 1:4) to give *cis-N-(2-chlorocyclohexyl)urethane* **2**, mp 56–58 °C (0.85 g) and *trans-N-(2-chlorocyclohexyl)urethane* **3**, mp 92–94 °C (0.18 g) (total yield of 1,2-addition: 1.03 g, 5 mmol, 50%).

The aqueous phases were combined, saturated with sodium chloride, and extracted continuously with methylene chloride for 2 days. Vapor phase chromatographic analysis of the crystalline residue, mp 46–48 °C (0.620 g), showed that it contained 0.052 g (0.3 mmol, 3%) of *N*-cyclohexylurethane **4**, the rest being urethane only.

---

[25]We thank professor J. K. Saunders for the interpretation of the ^{13}C nmr spectrum.

Additions to Norbornadiene

N-Chloroacetamide

The chromous chloride solution (20 ml, 20 mmol) was added over 5 h to a solution of *N*-chloroacetamide (940 mg, 10 mmol) and norbornadiene (1843 mg, 20 mmol) in chloroform (10 ml) – methanol (4 ml) at *ca.* −78 °C. The reaction mixture was poured into cold water and extracted rapidly with ether (4 × 200 ml), work-up A (ref. 1). The ^{1}H nmr spectrum of the residue (1310 mg) did not show any absorption in the olefinic proton region. An aliquot (570 mg) was separated on silica gel plates (ether–pentane 2:1) to give one main fraction (499 mg) showing no olefinic absorption in the nmr. The other fractions (20 mg or less) did not have any olefinic protons according to their nmr spectrum. Further separation of the main fraction (ether–pentane 1:1) followed by recrystallizations of the various fractions from ether or ether – methylene chloride allowed the complete separation of two isomeric *3-acetylamino-5-chlorononortricyclenes*, **7***a* and **8***a*. Isomer **7***a*: mp 136 °C; ν_{max} ($CHCl_3$) 3440 and 3320 (free and bonded NH), 1675 (C=O), 1520 (NH), 818 cm^{-1} (nortricyclene (30)); δ ($CDCl_3$) 2.00 (s, CH_3), 3.95 (d of t, J = 7 and 1.5 Hz, H-3), 4.05 (t, J = 1.5 Hz, H-5), 6.25 ppm (m, NH). *Anal.* calcd. for $C_9H_{12}ClNO$: C 58.22, H 6.51, N 7.54; found: C 58.42, H 6.56, N 7.32. Isomer **8***a*: mp 115 °C; ν_{max} ($CHCl_3$) 3450 and 3330 (free and bonded NH), 1675 (C=O), 1520 (NH), 815 cm^{-1} (nortricyclene (30)); δ ($CDCl_3$) 2.02 (s, CH_3), 4.05 (t, J = 1.5 Hz, H-5), 4.62 (d of t, J = 7 and 1.5 Hz, H-3), 6.32 ppm (m, NH); molecular weight by osmometry in $CHCl_3$, 187 (calcd. 185.65). *Anal.* calcd. for $C_9H_{12}ClNO$: C 58.22, H 6.51, N 7.54; found: C 58.07, H 6.56, N 7.25. A crystalline fraction containing a third isomer of *3-acetylamino-5-chlorononortricyclene*, **9***a*, was obtained but this isomer could not be isolated free from contamination by isomer **7***a*. The ir spectrum showed the characteristic absorptions of the acetylamino group and of the nortricyclene skeleton (815 cm^{-1}). In the nmr spectrum, after the exchange of NH with D_2O, H-3 appears as a triplet at 3.82 ppm with J = 1.5 Hz (beside the triplet of the H-3 proton of isomer **7***a* at 3.95 ppm) and H-5 absorbs at 4.42 ppm (m, $\Delta\nu_{1/2}$ = 4 Hz). From the nmr spectrum of the crude product, after exchange of the NH protons with D_2O, it was possible to determine the relative proportion of **7***a*, **8***a*, and **9***a* as 74:14:12.

Continuous extraction with methylene chloride of the aqueous layer from the ether extraction of the reaction mixture gave a residue (460 mg) which afforded three main fractions after chromatographic separation on silica gel plates (ether–pentane 2:1): acetamide (153 mg, 21%) identified by its mp, ir, and ^{1}H nmr spectra. A mixture of **7***a*, **8***a*, and **9***a* (60 mg, altogether 1206 mg, 65%); and *3-acetylaminonortricyclene* **10**, mp 100–102 °C (136 mg, 9%). A recrystallization from ether afforded a sample melting at 104–105 °C; ν_{max} ($CHCl_3$) 3440 (free NH), 1670 (C=O), 1510 (NH), 815 cm^{-1} (nortricyclene (30)); δ ($CDCl_3$) 2.00 (s, CH_3), 3.83 (d of t, J = 1.5 Hz), ~5.7 ppm (very broad, NH); *m/e* 151 (M^+), 91 (base peak).

N-Bromoacetamide

The reaction was carried out as above on 1.380 g (9.8 mmol) of *N*-bromoacetamide and 1.843 g (20 mmol) of norbornadiene to give, after the usual work-up, 2.134 g of crude product which was separated by preparative layer chromatography on silica gel (ether–pentane 3:1) to afford three main fractions.

(*a*) *5-Acetylamino-6-bromonorbornene* **5***b*, mp 120–123 °C (0.284 g, 13%). One recrystallization from ether gave the analytical sample, mp 126 °C; ν_{max} ($CHCl_3$) 3420 (NH), 1670 (C=O), 1505 cm^{-1} (NH); δ($CDCl_3$) 2.00 (s, CH_3), 2.80 and 3.16 (two m, H-1 and H-4), 4.00 (octet, J = 7.5, 7, and 2 Hz, H-5), 4.28 (d of d, J = 7 and 2 Hz, H-6), 6.18 and 6.38 (m, olefinic protons), 6.20 ppm (m, NH). *Anal.* calcd. for $C_9H_{12}BrNO$: C 46.97, H 5.26, Br 34.72, N 6.09; found: C 46.87, H 5.41, Br 34.70, N 5.90.

(*b*) *5-Acetylamino-6-bromonorbornene* **6***b*, mp 130–134 °C (0.734 g, 33%). One recrystallization from methylene chloride – ether gave the analytical sample, mp 134–135 °C; ν_{max} ($CHCl_3$) 3420 and 3340 (free and bonded NH), 1670 (C=O), 1500 cm^{-1} (NH); δ($CDCl_3$) 2.00 (s, CH_3), 3.16 (m, H-1 and H-4), 3.45 (t, J ~ 2.6 Hz, H-6), 4.80 (octet, J = 9, 4 and 2.6 Hz, H-5), 6.00 (m, NH), 6.38 (m, olefinic protons). *Anal.* calcd. for $C_9H_{12}BrNO$: C 46.97, H 5.26, Br 34.72, N 6.09; found: C 47.15, H 5.25, Br 34.92, N 5.87.

(*c*) A mixture of isomeric *3-acetylamino-5-bromonortricyclenes* **7***b*, **8***b*, and **9***b* in the ratio 49:31:20 by ^{1}H nmr. Chromatographic separation on silica gel plates (ether–pentane 3:1) followed by recrystallizations of the various fractions from ether gave the pure isomers **7***b* and **8***b* but the isomer **9***b* could not be isolated free from contamination by isomer **7***b*. Isomer **7***b*: mp 121–123 °C; ν_{max} ($CHCl_3$) 3440 and 3330 (free and bonded NH), 1675 (C=O), 1510 (NH), 815 cm^{-1} (nortricyclene (30)); δ ($CDCl_3$) 2.00 (s, CH_3), 3.92 (d of t, J = 7 and 1.5 Hz, H-3), 4.08 (t, J = 1.5 Hz, H-5), 6.00 ppm (m, NH). *Anal.* calcd. for $C_9H_{12}BrNO$: C 46.97, H 5.26, N 6.09; found: C 46.79, H 5.09, N 6.11. Isomer **8***b*: 125–126 °C; ν_{max} ($CHCl_3$) 3445 and 3320 (free and bonded NH), 1670 (C=O), 1515 (NH), 815 cm^{-1} (nortricyclene (30)); δ ($CDCl_3$) 2.02 (s, CH_3), 4.10 (t, J = 1.5 Hz, H-5), 4.68 (d of ill-defined t with J = 7 Hz and $\Delta\nu_{1/2}$ ~ 4 Hz, H-3), 6.45 ppm (m, NH); osmometric molecular weight determination ($CHCl_3$), 233 (calcd. 230.1). *Anal.* calcd. for $C_9H_{12}BrNO$: C 46.97, H 5.26, Br 34.72, N 6.09; found: C 46.85, H 5.51, Br 34.69, N 6.19. Mixture of **9***b* and **7***b* in a 8:21 ratio: ν_{max} ($CHCl_3$), 3440 and 3330 (free and bonded NH), 1675 (C=O), 1510 (NH), 815 cm^{-1} (nortricyclene); δ ($CDCl_3$) 2.00 (s, CH_3 of **9***b* and **7***b*), 3.92 (d of t, J = 7 and 1.5 Hz, H-3 of **7***b* masking H-3 of **9***b*), 4.08 (t, J = 1.5 Hz, H-5 of **7***b*), 4.31 (m, $\Delta\nu_{1/2}$ = 3.5 Hz, H-5 of **9***b*), 6.00 and 6.32 ppm (NH of **9***b* and **7***b*).

Chromous Bromide Promoted Addition of N-Chlorourethane to Cyclohexene.

The chromic bromide solution (5.933 g of $CrBr_3$, 3.3 ml of concentrated HCl, and absolute methanol in a 100 ml volumetric flask) was reduced over zinc amalgam as usual (1). The resulting clear blue chromous bromide solution (33 ml, 6.6 mmol) was added slowly (over 10 h) to a solution of *N*-chlorourethane (0.635 g, 97% active chlorine, 5 mmol), cyclohexene (10 ml, ~10 mmol), and chromic bromide (1.600 g, 5.5 mmol) in chloroform (6 ml) – methanol (4 ml) cooled to *ca.* −78 °C (methanol – dry ice bath). The mixture was then poured into water (100 ml) and continuously extracted with methylene chloride for 24 h. The solvent was partly removed by distillation and the resulting solution was transferred into a 25 ml volumetric flask. Analysis by vpc using authentic samples as standards gave the following results: urethane, 51%; *trans*-bromomethoxycyclohexane, 5%; bicyclo-

hexenyl, ~1%; *trans*-dibromocyclohexane, 20%; *N*-cyclohexylurethane **4**, 2%; *cis*-*N*-(2-chlorocyclohexyl)urethane **2**, 39%; *trans*-*N*-(2-chlorocyclohexyl)urethane **3**, 9%. No trace of *cis*- or *trans*-*N*-(2-bromocyclohexyl)urethane could be detected by vpc or tlc. The bromomethoxycyclohexane and dibromocyclohexane were isolated from an aliquot by preparative vpc for complete identification (ir, ^{1}H nmr). Another aliquot (12 ml) was separated by preparative tlc on silica gel (ether–hexane 1:2) to afford the *cis*-β-chlorocarbamate **2**, mp 55–57 °C (0.184 g, 37%), the *trans*-β-chlorocarbamate **3**, mp 94–96 °C (0.039 g, 8%), and urethane, mp 44–46 °C (0.113 g, 53%).

Simultaneous Addition of N-Chlorourethane and N-Bromo-α-chloroacetamide to Cyclohexene

Photochemical Addition

N-Chlorourethane (1.950 g, 95% active chlorine, 15 mmol), *N*-bromo-α-chloroacetamide (0.173 g, 1 mmol), 1-octene (2.5 ml, ~25 mmol) in methylene chloride (75 ml), and absolute methanol (2 ml) in a Vycor cell were irradiated at −70 °C at 254 nm in a Rayonnet RPR 100 reactor for 6 h. The solvent was evaporated in a rotating evaporator and the residue (3.72 g) separated by column chromatography and preparative tlc (ether–hexane 1:2) into two main fractions. The less polar fraction (3.265 g) was an oil and had ir and ^{1}H nmr practically identical to those of *N*-(2-chlorooctyl)urethane **11**. It was dried carefully and submitted to microanalysis: C 55.07%, H 9.14%, Cl 13.68%, Br 2.57%. Assuming that the fraction contained only *N*-(2-chlorooctyl)urethane **11** and *N*-(2-bromooctyl)urethane **12**, the halogen analysis would correspond to 92.3% of **11** (84% yield) and 7.7% of **12** (7% yield).

The more polar fraction, mp 43–44 °C (0.260 g), had ir and ^{1}H nmr spectra very similar to those of *N*-(2-bromooctyl)-α-chloroacetamide **13**. The crystals were ground in a mortar, dried under vacuum, and submitted to bromine and chlorine microanalysis: Br 26.78%, Cl 13.24%. Again assuming that this fraction contained only *N*-(2-bromooctyl)-α-chloroacetamide **13** and *N*-(2-chlorooctyl)-α-chloroacetamide **14**, the analysis would correspond to 94.6% of **13** (87% yield) and 5.4% of **14** (5% yield).

Chromous Chloride Promoted Addition

The reaction was carried out under the usual conditions: chromous chloride solution (18 ml, 18 mmol) added over 2 h, *N*-chlorourethane (1.954 g, 95% active chlorine, 15 mmol), *N*-bromo-α-chloroacetamide (1.175 g, 1 mmol), 1-octene (2.5 ml, ~25 mmol), chloroform (15 ml), absolute methanol (5 ml), dry ice – methanol bath. The mixture was poured into ice and water (10 ml) and rapidly extracted with ether (4 × 200 ml), work-up A (1). The residue (3.25 g) was separated into two fractions as above, each of them being submitted to bromine and chlorine analysis. The oily fraction (2.934 g) had Br 2.44% and Cl 13.75%, which would correspond to 92.7% of β-chlorocarbamate **11** (76% yield) and 7.3% of β-bromocarbamate **12** (6% yield). The crystalline fraction, mp 41–43 °C (0.222 g), had Br 27.19% and Cl 12.99%, which would correspond to 96.3% of β-bromoamide **13** (75% yield) and 3.7% of β-chloroamide **14** (3% yield).

Addition of N-Chloropiperidine to Cyclohexene

Ferrous Sulfate – Ferric Chloride Promoted Addition

The reaction was carried out at 0 °C, under nitrogen, according to the method described by Minisci *et al.* (21) with the following quantities: *N*-chloropiperidine (6.50 g, 92% active chlorine, 50 mmol), ferric chloride (7 g), ferrous sulfate (14 g), and cyclohexene (100 ml, 100 mmol). The reaction mixture was poured into cold water (500 ml), acidified with 4 *N* HCl (10 ml), and extracted with ether. The aqueous phase was made basic by adding 4 *N* NaOH (60 ml) then extracted with methylene chloride (4 × 200 ml). Molecular distillation of the residue (7.4 g) at 70 °C/0.1 torr gave a mixture (6.8 g, 67%) of *cis- and trans-N-(2-chlorocyclohexyl)piperidine* **17** and **18** in a 2:1 ratio according to the ^{1}H nmr spectrum. The two isomers were separated by preparative layer chromatography on silica gel (ethyl acetate – hexane 1:2). *cis* Isomer **17**: ν_{max} (CS_2) 680 cm^{-1} (C-Cl axial (31)); δ (CS_2) 1.0–2.1 (14H), 2.2–2.7 (5H, H-3 + 4H of the piperidine ring), 4.43 ppm (m, $\Delta\nu_{1/2}$ = 6.5 Hz, H-2 equatorial). The picrate melted at 140–141 °C (lit. (21) 146–147 °C). *trans* Isomer **18**: ν_{max} (CS_2) 730 cm^{-1} (C-Cl equatorial (31)); δ (CS_2) 1.0–2.1 (14H), 2.1–2.7 (5H, H-1 + 4H of the piperidine ring), 3.72 (m, $\Delta\nu_{1/2}$ = 25 Hz, H-2 axial). The picrate melted at 153–154 °C (lit. (21) 153–154 °C).

Titanous Chloride Promoted Addition

The addition was carried out under nitrogen as described by Stella[26] at −15 °C (CCl_4 – dry ice bath) with 60 g (100% active chlorine, 50 mmol) of *N*-chloropiperidine and 100 ml (100 mmol) of cyclohexene in 50 ml of methanol. Titanous chloride (6 ml of a 26% commercial solution, 10 mmol) was added dropwise and the mixture stirred at −15 °C for an additional 30 min. The reaction mixture was made strongly alkaline by adding 10 *N* sodium hydroxide. The precipitate was filtered on Celite and washed many times with ether. The ether layer was decanted and dried. The residue was distilled at 64 °C/0.01 torr to afford 7.4 g (75%) of a mixture of *cis- and trans-N-(2-chlorocyclohexyl)piperidine* **17** and **18** in a 2:1 ratio according to the ^{1}H nmr spectrum; ν_{max} (CS_2) 680 (C-Cl axial) and 730 cm^{-1} (C-Cl equatorial).

Chromous Chloride Promoted Addition

The reaction was carried out under the usual conditions: *N*-chloropiperidine (4.77 g, 100% active chlorine, 40 mmol), cyclohexene (8 ml, 80 mmol), chloroform (100 ml), absolute methanol (20 ml), dry ice – methanol bath (−78 °C). The chromous chloride solution (80 ml, 80 mmol) was added over 5 h. The reaction mixture was allowed to warm up to *ca.* 0 °C then acidified and extracted with ether. The aqueous phase was made strongly alkaline with a 10 *N* sodium hydroxide solution in methanol–water (1:1). The precipitate was filtered on Celite and washed many times with ether. The ether layer was washed with water then dried. The solvent was removed in the rotating evaporator. The piperidine was removed *in vacuo* to give 1.12 g (14%) of a mixture of **17** and **18** in a 2.5:1 ratio according to the ^{1}H nmr spectrum; ν_{max} (CS_2) 680 and 730 cm^{-1}; *m/e* 201, 203 (3:1, M^+).

Chromous Chloride Promoted Addition of N-Chloropiperidine to Ethyl Vinyl Ether

A solution of *N*-chloropiperidine (6.0 g, 50 mmol) in absolute methanol (50 ml) was cooled in a dry ice – methanol bath (−78 °C). Freshly distilled ethyl vinyl ether (7.2 g, 100 mmol) cooled to −78 °C was added. The chromous chloride solution (80 ml, 80 mmol) was

[26]L. Stella, Thèse de Doctorat ès-Sciences physiques, Université de Provence, 1972.

added over 30 min. Then sodium methoxide (50 ml of a ~1 *M* solution) was added. The mixture was allowed to warm up to 0 °C and made strongly alkaline with 10 *N* sodium hydroxide. The residue obtained after the usual work-up was distilled to give two compounds: (*a*) The *α-chloroacetal* **16**, bp 34 °C/15 torr (1.68 g, 24%); ν_{max} (CCl_4) 1060 and 1030 (acetal), 720 cm^{-1} (C-Cl); δ (CCl_4) 1.23 (t, J = 7 Hz, OCH_2CH_3), 3.36 (s, OCH_3), 3.45 (d, J = 5.5 Hz, $ClCH_2CH$), 3.65 and 3.68 (two q of equal intensity, J = 7 Hz, OCH_2CH_3), 4.58 ppm (t, J = 6 Hz, CH_2CH(O)(O)); *m/e* 107, 109 (5:2, $M^+ - OCH_3$). (*b*) The *adduct* **15**, bp 85–90 °C/15 torr (1.27 g, 15%); ν_{max} (CCl_4) 1060 and 1130 (acetal), 1300 cm^{-1} (C—N); δ ($CDCl_3$) 1.22 (t, J = 7 Hz, OCH_2CH_3), 1.4–1.8 (6H, piperidine ring), 2.5 (4H, piperidine ring), 2.53 (d, J = 5 Hz, NCH_2CH), 3.40 (s, OCH_3), 3.67 and 3.70 (two q, J = 7 Hz, OCH_2CH_3), 4.67 ppm (t, J = 5 Hz, CH_2CH(O)(O)); *m/e* 187 (M^+). *Anal.* calcd. for $C_{10}H_{21}O_2N$: C 64.13, H 11.30; found: C 63.74, H 11.28.

Oxidation with chromium(VI) oxide – pyridine complex. A study of reaction parameters using cholesterol as substrate[1]

EDWARD PIERS AND PAUL M. WORSTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Place, Vancouver, B.C., Canada V6T 1W5

Received September 27, 1976

EDWARD PIERS and PAUL M. WORSTER. Can. J. Chem. **55**, 733 (1977).

Oxidation of cholesterol with chromium(VI) oxide – pyridine complex under various conditions produced cholest-5-en-3-one accompanied by varying amounts of cholest-4-ene-3,6-dione. The efficiency of the oxidation and the product distribution were found to be dependent on the atmosphere, temperature, molar ratio of oxidant to substrate, molar ratio of pyridine to chromium trioxide, the heterocyclic amine used, and the proton source employed. The yield of cholest-5-en-3-one was optimized by oxidation of cholesterol with a ten-fold excess of the monopyridine – chromium(VI) oxide complex in dichloromethane under a nitrogen atmosphere at 0°C.

EDWARD PIERS et PAUL M. WORSTER. Can. J. Chem. **55**, 733 (1977).

L'oxydation du cholesterol par le complexe d'oxyde de chrome(VI) – pyridine sous diverses conditions conduit à la cholestène-5 one-3 accompagnée par des quantités variables de cholestène- 4 dione-3,6. On a trouvé que l'efficacité de l'oxydation et la distribution des produits dépendent de l'atmosphère, de la température, du rapport molaire d'oxydant–substrat, du rapport molaire de pyridine – trioxyde de chrome, de l'amine hétérocyclique et de la source de proton utilisée. On a pu optimiser le rendement de la cholestène-5 one-3 par oxydation du cholesterol avec un excès de dix fois de complexe d'oxyde de chrome(VI) – monopyridine dans le dichlorométhane, sous atmosphère d'azote, à 0°C.

The oxidation of alcohols to ketones or aldehydes with chromium(VI) reagents in non-acidic media has found extensive application in organic synthesis. However, even though a significant number of technically advantageous modifications on the original work of Sarett (1) have been reported (2–7), little detail concerning the effect of various reaction parameters on oxidations with chromium(VI) oxide – pyridine complexes has as yet become available.[2] Furthermore, it is well known that chromium(VI) oxidation of homoallylic alcohols to the corresponding β,γ-unsaturated ketones fails in acidic media (9) and is troublesome in non-acidic media (10). In order to provide fundamental information regarding both of these problems, we have studied the effect of several reaction parameters on the outcome of the chromium(VI) oxide – pyridine oxidation of cholesterol (**1**) in dichloromethane.

Oxidation of **1** under a variety of conditions afforded, in each case, the expected product cholest-5-en-3-one (**2**) accompanied by varying amounts of cholest-4-ene-3,6-dione (**3**) and trace amounts of 6β-hydroxycholest-4-en-3-one (**4**).[3] In addition, varying quantities of starting material **1** were recovered. Some of our initial results are summarized in Table 1.

As expected (3, 5), complete oxidation of cholesterol (**1**) required 6 mol equiv. of oxidant (run 3), while use of lesser quantities of oxidizing agent resulted in recovery of appreciable

[1]Support for this work from the National Research Council of Canada and an NRCC scholarship (to P.M.W.) are gratefully acknowledged.

[2]Collins (3) has shown that a six-fold molar excess of $CrO_3 \cdot 2C_5H_5N$ complex was required to oxidize primary and secondary aliphatic alcohols, while Holum (8) found that pyridine solutions of allylic or benzylic alcohols usually require only a three-fold excess of CrO_3 for complete oxidation.

[3]The allylic alcohol **4** is oxidized much faster than the homoallylic alcohol **1**. For the purpose of product analysis, compound **4** could be ignored since the ratio of **3**:**4** was >5:1. Oxalic acid catalyzed isomerization of the product mixture afforded compounds **5** and **3** along with trace amounts of **6**.

amounts of **1** (runs 1, 2). The drop in oxidation efficiency, along with an increase in the ratio of products **2**:**3**, caused by replacing the air atmosphere with nitrogen (runs 4, 5) was from a synthetic viewpoint a significant observation and was presumably due to the known (11) uptake of oxygen in chromate oxidations and the susceptibility of **2** to autoxidation. Furthermore, in contrast to Collins' (3) conclusion, a lower reaction temperature appeared to decrease oxidation efficiency (at least within a specified reaction time), but also produced a synthetically more pleasing ratio of **2**:**3** (runs 6, 7). Finally, addition of water (run 8) had the expected effect, since it is known (3) that the $CrO_3 \cdot 2C_5H_5N$ complex readily hydrates to give an insoluble, unreactive species $C_{10}H_{12}Cr_2N_2O_7$. Addition of the dehydrating agent P_2O_5 (run 9) failed to restore full oxidation efficiency.[4]

Table 2 summarizes results of experiments aimed at determining the effect of adding varying amounts of pyridine in the *in situ* oxidation of **1** with CrO_3–pyridine in dichloromethane. These results clearly show that, although pyridine is necessary for oxidation (run 5), there is no justification for the current practice (5) of employing a 2:1 molar ratio of pyridine to CrO_3 for the *in situ* generation of Sisler's complex (12). Thus, use of a 1:1 CrO_3–pyridine ratio gave oxidation results essentially identical with those obtained by employing the two substances in a 1:2 ratio (runs 2,3 and 7,8). Furthermore, filtering the solutions containing either the 2:1 or the 1:1 pyridine–CrO_3 complex before addition of the sterol left the subsequent oxidation results unchanged (footnote *e*, Table 2), even though CrO_3 itself is completely insoluble in dichloromethane. Mechanistically, therefore, our results are at least consistent with the postulate that oxidation takes place via the intermediate monopyridine complex **7**, rather than via the dipyridine complex **8** usually postulated.

Results obtained from oxidation of cholesterol (**1**) (1 mmol) with CrO_3 (6 mmol) in the presence of several different heterocyclic amines (6 mmol) in dichloromethane for 30 min are summarized in Table 3. Of those studied, pyridine appeared

[4]We feel that the most important aspect of adding P_2O_5 is the addition of a good proton source, as phosphoric acid, rather than the use of P_2O_5 as a dehydrating agent.

7 **8**

to be the most favorable amine for the purpose of minimizing the formation of enedione product **3**. Unexpectedly, it was found that virtually no oxidation occurred when aryl amines such as *N*,*N*-dimethylaniline (13) (pK_{BH^+} = 5.15) were used. Similarly, little if any cholesterol was oxidized when 2,2-dipyridyl, 4,4-dipyridyl, or picolinic acid were employed. Recently, the latter compound was shown (14) to exert a strong rate accelerating effect on chromium(VI) oxidation of alcohols in aqueous acidic media. Finally, it was found that introduction of amines such as triethylamine (pK_{BH^+} = 11.0) to a solution of the active oxidizing complex (**7** or **8**) resulted in a dramatic increase in the amount of cholesterol that was recovered.[5]

Other studies showed that enone **5** is not produced directly in the oxidizing media employed and that **5** is stable under the oxidation conditions. Therefore, it is probable that **3** is produced from **2**, probably via enolization followed by further oxidation. However, the above results demonstrate the futility of trying to avoid the formation of **3** by simply buffering the reaction media with an amine. Nevertheless, from a synthetic point of view, it is important to note that the favorable parameter changes outlined in Tables 1, 2, and 3 can be advantageously combined. That is, it was found that oxidation of cholesterol (**1**) with a ten-fold excess of the monopyridine – chromium(VI) oxide com-

[5]The proton dependence of oxidations with CrO_3–amine reagents will be the subject of a future publication.

plex in dichloromethane at 0°C under a nitrogen atmosphere produced, in very high yield, practically pure cholest-5-en-3-one (**2**).[6]

Information theory and bulk rotational or vibrational relaxation processes

ANDREW W. YAU AND HUW O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received July 14, 1976

ANDREW W. YAU and HUW O. PRITCHARD. Can. J. Chem. **55**, 737 (1977)

The possible occurrence in bulk relaxation of pure-exponential, near-exponential, and non-exponential decay of the total energy is examined in terms of the normal-mode and information-theoretic approaches. Experimental tests are suggested for the identification of pure-exponential decay caused by adherence to the 'sum rule', and of near-exponential decay. In the case of near-exponential decay (as opposed to pure-exponential decay), it is not possible to derive reliable state-to-state rate constants by invoking approximate adherence to the sum rule.

ANDREW W. YAU et HUW O. PRITCHARD. Can. J. Chem. **55**, 737 (1977).

On examine la possibilité de l'existence, dans la relaxation globale, de décompositions exponentielles pures, pratiquement exponentielle et non-exponentielle de l'énergie totale en termes des approches du mode normal et de l'information théorique. On suggère des essais expérimentaux permettant d'identifier une décomposition exponentielle pure par une adhésion à la "règle des sommes" ainsi qu'une décomposition pratiquement exponentielle. Dans le cas d'une décomposition pratiquement exponentielle (par opposition à une décomposition exponentielle pure), il n'est pas possible d'obtenir des constantes de vitesse d'état à état qui soient certaines en invoquant l'adhésion approximative à la "règle des sommes".

[Traduit par le journal]

Two recent papers from this laboratory have examined the bulk relaxation behaviour of a model diatomic molecule, infinitely diluted in an inert-gas bath, in terms of normal modes of relaxation (1, 2). An alternative treatment of simple bulk relaxation processes, in terms of an information-theoretic approach (3), has also been developed recently by Procaccia and Levine (4–6). On the surface, it appears that these two treatments are not always consistent with each other: in particular, markedly non-exponential decay of the total energy would seem to be a distinct possibility, given the right kind of experiment (2), whereas accepting pure-exponential decay as a constraint, the information-theoretic treatment provides an attractive and elegant framework within which to describe such bulk relaxation processes. Since both approaches to the problem are based on the application of the master equation, we will begin by restating the relevant useful equations.

The isothermal relaxation of a diatomic gas, with N rotation–vibration levels, diluted in a heat bath is governed by the transition matrix **A** where (1)

$$[1] \quad A_{ij} = [\mathrm{M}]Z\left\{(1-\delta_{ij})P_{ji} - \delta_{ij}\times\sum_{k=0}^{N-1}(1-\delta_{ik})P_{ki}\right\}$$

In [1], P_{ji} is the probability per collision for a transition *from* state i *to* state j, [M] is the concentration of buffer gas, and Z is the collision number. As a consequence of detailed balancing

$$[2] \quad A_{ij}\,\tilde{n}_i = A_{ji}\,\tilde{n}_j$$

where $\tilde{n}_i$ is the population of the ith level at equilibrium, **A** may be symmetrized to **B** by the

transformation

$$[3] \qquad \mathbf{B} = \mathbf{N}^{1/2}\,\mathbf{A}\,\mathbf{N}^{-1/2}$$

where

$$[3a] \qquad N_{ij} = \delta_{ij}\,\tilde{n}_i$$

The matrix **B** therefore has real eigenvalues, λ_j, which may be found using the transformation matrix **S**, *i.e.*

$$[4] \qquad \mathbf{B}\,\mathbf{S} = \mathbf{S}\,\mathbf{\Lambda}$$

The final attainment of Boltzmann equilibrium is guaranteed by the fact that one eigenvalue, λ_{N-1}, is zero, with a corresponding eigenvector

$$[4a] \qquad S_{i,N-1} = \tilde{n}_i^{1/2}$$

and all of the other eigenvalues are negative. The time evolution of the total internal energy of the system, $E(t)$, is

$$[5] \quad E(t) = \sum_{i=0}^{N-1} \varepsilon_i n_i(t) = \sum_{j=0}^{N-1} e^{\lambda_j t} \sum_{i=0}^{N-1} \tilde{n}_i^{1/2} \varepsilon_i S_{ij} \times \sum_{k=0}^{N-1} S_{kj} \tilde{n}_k^{-1/2} n_k(0)$$

where $n_i(t)$ is the population of the ith level at time t, and ε_i is the energy of that level. An alternative way of writing [5] is (1)

$$[5a] \qquad E(t) = \sum_{j=0}^{N-1} \xi_j\, e^{\lambda_j t}$$

where ξ_j, the amount of energy which decays with characteristic time constant λ_j, is given by

$$[6] \quad \xi_j = \sum_{i=0}^{N-1} \tilde{n}_i^{1/2} \varepsilon_i S_{ij} \sum_{k=0}^{N-1} S_{kj} \tilde{n}_k^{-1/2} n_k(0)$$

Inspection of [5] or [5*a*] shows that, in general, the energy must decay in a non-exponential manner: pure-exponential decay will occur under rather special circumstances. Nevertheless, these model calculations (1, 2) have shown that, often, very few of the normal modes may have associated with them a significant value of ξ_j, and in these cases the relaxation behaviour would be very difficult indeed to distinguish from a pure-exponential decay under normal experimental conditions; other examples are given by Cukier and Hynes (7).

Pure-exponential decay can occur in two ways. First, in a trivial way, when all the non-zero eigenvalues are degenerate: the necessary and sufficient condition for this to occur (8) is that the transition rate matrix should have the form

$$[7] \quad A_{ij} = \alpha \left\{ (1 - \delta_{ij})\tilde{n}_j - \delta_{ij} \times \sum_{k=0}^{N-1} (1 - \delta_{ik})\tilde{n}_k \right\}$$

where α is a constant.[1] Second, a much less restrictive and well-known condition (4–13), that the transition rates obey the 'sum rule'

$$[8] \qquad \sum_j \varepsilon_j A_{ij} = \mu(E(\infty) - \varepsilon_i)$$

for all i, where μ is a positive constant, whence

$$[8a] \qquad \frac{dE(t)}{dt} = \mu[E(\infty) - E(t)]$$

Equation 7 is, in fact, a special case of [8]. In conventional terms, we have $0 = \lambda_{N-1} > -\mu = \lambda_{N-2} \geq \lambda_{N-3} \geq \ldots \lambda_0$; adapting the formula of van Kampen (13), the vector of the symmetrized form of [8] corresponding to the eigenvalue $-\mu$ is

$$[9] \qquad S_{i,N-2} = \frac{\tilde{n}_i^{1/2}(E(\infty) - \varepsilon_i)}{\{E^2(\infty) - (E(\infty))^2\}^{1/2}}$$

Using this, together with [4*a*], it is then a simple matter (8) to show that all the other modes of relaxation are passive in the sense that all ξ_j, $j < (N-2)$ are zero: hence each of these $(N-2)$ modes only shuffles the populations without changing the total energy of the assembly of molecules.

The occurrence of pure-exponential decay requires certain relationships between the transition rates. To begin with, we may classify possible transition-probability patterns into three distinct classes.

(*i*) Those which conform to eq. 7, whence both the energy and all the individual populations decay exponentially: we do not know whether there exist any examples of such behaviour in molecular relaxation.

(*ii*) Those which conform to the sum rule, eq. 8, whence the energy will decay exponentially, but the populations will not. Several examples of such conformity are known (7), most notably the Landau–Teller transition probabilities for harmonic-oscillator transitions. It appears also

[1]Since this paper was submitted, we have learnt that this condition has been proved also by Procaccia *et al.* (9).

that certain classically computed V–T transition probabilities (14) for

$$H + HBr(v) \rightleftarrows H + HBr(v')$$

$$Cl + Cl_2(v) \rightleftarrows Cl + Cl_2(v')$$

conform approximately to the sum rule (5). On the other hand, some transition probabilities derived from quantum calculations, in the breathing-sphere approximation (15), on

$$He + CO(v) \rightleftarrows He + CO(v')$$

do not conform, in the sense that the energy evolution derived from these probabilities is not exponential for some initial population distributions.

Adherence to the sum rule is verifiable, in principle at least, by experiment since at long time, after all the initial transients have died out, the evolution of the populations depends on the initial energy but is independent of the fine structure of the initial distribution of that energy. Thus (8)

$$[10] \quad \underset{(t \gg -\lambda_{N-3}^{-1})}{n_i(t)} \rightarrow \tilde{n}_i + n_i(N-2, t)$$

$$= \tilde{n}_i + \tilde{n}_i\, e^{-\mu t} \frac{[E(\infty) - \varepsilon_i][E(\infty) - E(0)]}{\{E^2(\infty) - (E(\infty))^2\}}$$

(*iii*) Those which conform to neither [7] nor [8], in which case neither the energy nor the populations decay in a strictly exponential fashion. Again, we may subdivide into three classes: (*a*) those probabilities which conform to linear surprisal,[2] in which case, as is shown below, the range of eigenvalues can be very small; (*b*) those which conform to more complex surprisal forms (9, 16), a development which arose after we had completed this analysis, and which we will not discuss further; (*c*) arbitrary transition probabilities, such as those used in our own previous model calculations (1, 2), where the range of the eigenvalues can be very large indeed, *cf.* also ref. 17, Fig. 3.

The 'linear surprisal' form of the rate constant is

$$[11] \quad k_{i\rightarrow j} = k^0_{i\rightarrow j} \exp(-\theta|\varepsilon_j - \varepsilon_i|/kT) \equiv ZP_{ji}$$

where $k^0_{i\rightarrow j}$ is the 'prior rate constant' (the rate constant in the absence of any dynamical constraint) and θ is the 'surprisal' (a measure of the effect of the energy defect for transition from state i to state j). For a system with an array of rotation–vibration levels at temperature T (18)

$$[12] \quad k^0_{vJ\rightarrow v'J'} = \text{constant} \times T^{1/2} g_{J'} \times \exp(\Delta) \cdot \Delta \cdot K_1(\Delta)$$

where $g_{J'} = 2J' + 1$, Δ = 'reduced energy transfer' = $(\varepsilon_{vJ} - \varepsilon_{v'J'})/2kT$, and $K_1(\Delta)$ = modified Bessel function of the first order. Since $K_1(\Delta)$ is odd with respect to Δ, eq. 12 satisfies the principle of detailed balancing. This implies that the surprisal θ in eq. 11 is symmetric with respect to the initial and final states, and the rate constant then takes the form

$$[13] \quad k_{vJ\rightarrow v'J'} = \text{constant} \times (2J' + 1) \times \exp(\Delta) \cdot \Delta \cdot K_1(\Delta) \cdot \exp(-2\theta|\Delta|)$$

As examples of V–T transfer, the experimental rates of

$$Li_2^*(v) + M \rightleftarrows Li_2^*(v') + M$$

$$CO^*(v) + M \rightleftarrows CO^*(v') + M$$

have been shown to conform to a linear surprisal form (4). Among the theoretically calculated rates (14)

$$Cl + Cl_2(v) \rightleftarrows Cl + Cl_2(v')$$

$$I + I_2(v) \rightleftarrows I + I_2(v')$$

$$Br + HBr(v) \rightleftarrows Br + HBr(v')$$

have been shown to obey (approximately) the linear surprisal form, although the last reaction does not obey the sum rule (5, 6); more recently (9, 16) the $Cl + Cl_2$ case has been re-analysed, giving a functional (v, v') dependence on the surprisal. No quantal V–T data have yet, to our knowledge, been analysed in this way, but we have shown (8) that the impulsive limit of the first-order distorted-wave approximation for nearest-neighbour transitions has the same temperature dependence as the linear surprisal form. For R–T collisions, the quantal data of Green (19) on

$$He + HD(J) \rightleftarrows He + HD(J')$$

have been analysed by Procaccia and Levine (20): there is (semiquantitative) agreement in respect of the temperature coefficients, and the fit to the linear surprisal form is accurate to about $\pm 20\%$.

Given that many transition probabilities appear to obey the linear surprisal form, it is a simple matter to show that, at least for V–T and

[2]Linear surprisal forms may or may not obey the sum rule.

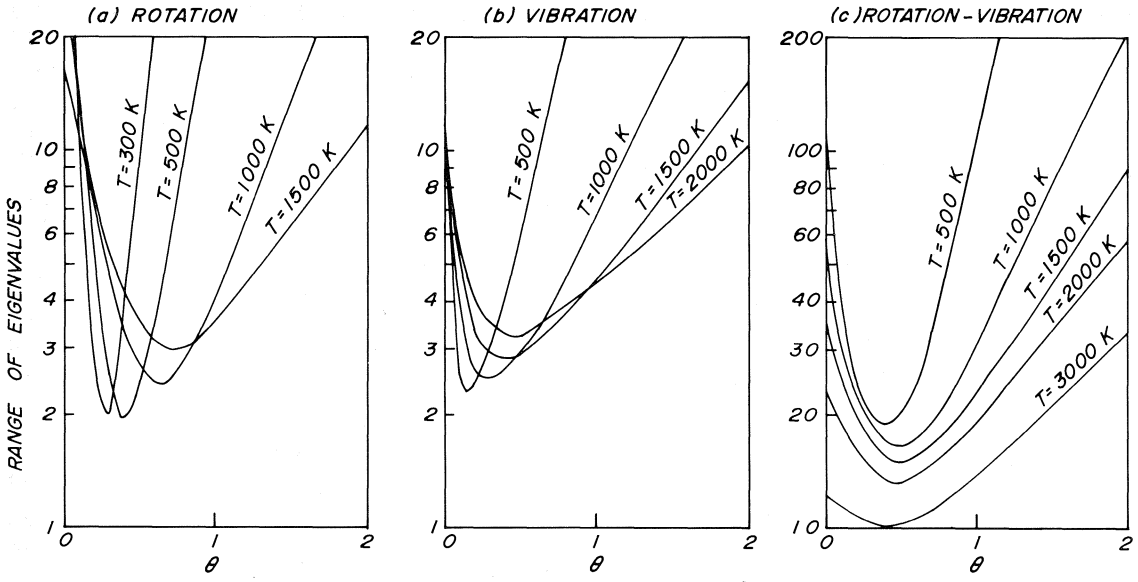

FIG. 1. Comparison of the range of eigenvalues λ_0/λ_{N-2} for the information-theoretic descriptions of three model molecules (see text) for a series of temperatures and surprisal values: (*a*) pure rotational relaxation; (*b*) pure vibrational relaxation; (*c*) mixed rotation–vibration relaxation.

R–T processes, one would expect to find *almost* pure-exponential decay of the energy, *even if* the sum rule is not obeyed. Since in eq. 13, the 'reduced energy transfer' is representative for all diatomic molecules in either pure vibrational or pure rotational relaxation if a reduced temperature scale is used, *viz.* $\beta_v = hc\omega_e/kT$ or $\beta_R = hcB_e/kT$, we can continue to use our previous model molecule, *ortho*-H_2, in this illustration. Figure 1 shows plots of the ratio λ_0/λ_{N-2} (*i.e.* the spread of the eigenvalues) for a range of values of θ, for three kinds of processes: (*a*) pure rotational relaxation involving the lowest 8 rotational states of *ortho*-H_2; (*b*) pure vibrational relaxation involving the lowest 8 vibrational states of $J=1$ H_2;[3] (*c*) mixed vibration–rotation relaxation involving the lowest 20 levels of *ortho*-H_2. Over a wide range of reduced temperature, the minimum spread in eigenvalues occurs near $\theta = 0.5$, compared with values of θ of the order of unity found in many analyses reported in the literature (20). The fact that the spread of eigenvalues is indeed modest means that these *distinct* relaxation times will be hard to resolve experimentally (1, 2) and the bulk relaxation will *appear* to be very close to a pure-exponential decay, because, in fact, we have an approximation to the $(N-1)$-fold degenerate case, eq. 7.

However, as is well known (1, 7), near-exponential decay (we may define near-exponential decay to mean that it would be difficult to detect experimentally any non-exponential behaviour) can occur when the eigenvalues are well separated, and this is shown by two pairs of calculations illustrated in Fig. 2. In these calculations, we compare the bulk relaxation behaviour for (*a*) rotation and (*b*) vibration, for a temperature change from 700 to 500 K, using transition probabilities *either* of the functional form of [13] *and* having the minimum spread of eigenvalues (see Fig. 1) *or* the empirical set of transition probabilities used previously (1, 2). The lower curve shows that the behaviour is hardly distinguishable[4] for bulk vibrational relaxation, despite the fact that in one case the spread of eigenvalues λ_0/λ_{N-2} is 2.3, whereas in the other case it is 120; in normal-mode terms, this is because the succession of normal modes of longest time constant (see *e.g.* Fig. 3 of ref. 2) are relatively close together, with the last one carrying most of the traffic (*i.e.* ξ_{N-2} dominates).

[3]In the usual formulation, each vibrational state is averaged over its rotational manifold, assuming rotational equilibrium (5). However, there is some difficulty with detailed balancing in such a formulation, and since we are interested at the present time in only a model calculation, we consider only one rotational state.

[4]Of course, drawn out on a much larger scale, both lines are slightly curved.

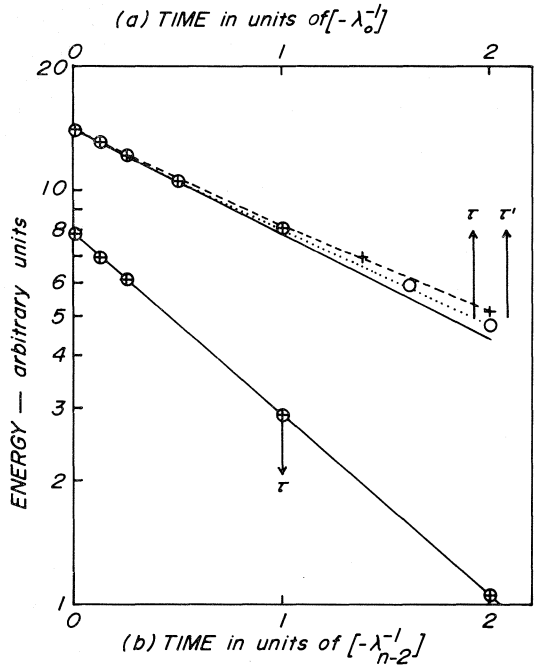

FIG. 2. Logarithmic plots of the total energy *vs.* time for (*a*) pure rotational relaxation and (*b*) pure vibrational relaxation. Open circles represent points calculated using information-theoretic rate constants of *minimum eigenvalue spread*, and crosses represent points calculated with an empirical set of transition rates (1). The solid lines represent exact exponential decay, and the vertical arrows marked τ represent the points at which $1/e$ of the total energy remains: this occurs very close to $-\lambda_{N-2}{}^{-1}$ in the vibrational cases, but near $-2\lambda_0{}^{-1}$ in the rotational cases. The eigenvalue ranges (*i.e.* λ_0/λ_{N-2}) in these calculations were (*a*) rotation 1.9 and 75, (*b*) vibration 2.3 and 120 for the information-theoretic and the empirical rates respectively.

Non-exponential decay of vibrational energy will always be difficult to detect unless the molecule is very anharmonic (which will cause a wider spacing of the eigenvalues) *and* the relative populations of high-v and low-v states change appreciably in the relaxation process.

The upper part of Fig. 2 shows the rotational relaxation behaviour using probabilities which have an eigenvalue range λ_0/λ_{N-2} of 1.9 and 75 respectively. Here the plots are just about distinguishable from each other, and they are both slightly curved. The curvature is of course more severe for the case where the range of eigenvalues is larger, and it is interesting to note that, in this case, the time it takes the energy to relax is closely related to the *fastest* time constant, not the slowest as is usually assumed: Cukier and Hynes (7) also give a numerical example of this kind, and the reasons for this behaviour are easily understood in terms of our previous discussion of rotational sound dispersion (1). For these reasons also, non-exponentiality should be much easier to detect in rotational than in vibrational relaxation, and a relatively simple experiment based on our earlier calculations (2) should suffice to settle the issue one way or the other: all that is necessary is to measure the shock-wave rotational relaxation time for hydrogen from a series of different starting temperatures to a single fixed final temperature; if a monotonically increasing progression of relaxation times is found, converging to the ultrasonic relaxation time for the final temperature in question, then the decay is non-exponential and the treatment depicted in Fig. 1 of ref. 2 would be essentially correct. In the case of T–VR processes, we can expect, as discussed previously (2), a complete spectrum of behaviour from that in which the rotational and vibrational relaxations separate completely to that where they are completely inseparable: in the former case, the considerations we have just discussed would apply, whereas in the latter case, noting (*a*) the larger spread of eigenvalues shown in Fig. 1*c* and (*b*) the apparent failure of Alexander's calculations (21) for T–VR processes in hydrogen to conform to the linear surprisal form, it would seem that non-exponential decay will be the rule rather than the exception. Thus, in fact, we see no real and irreconcilable differences between the normal-mode and the information-theoretic descriptions of bulk relaxation processes.

However, there is one aspect of the information-theoretic approach where we feel that some caution is appropriate. Procaccia and Levine (4–6) have claimed that if the observed decay is exponential, then it is possible to deduce microscopic state-to-state transition rates from the observed *bulk relaxation* time constant. If the sum rule holds, this may well be true, although some doubts have been expressed[5] about this possibility unless the relaxing system behaves in a canonically invariant manner. But it seems that adherence to the sum rule, from the evidence cited above, is unlikely to be the general behaviour, in which case the claim can have, at best, only limited validity. There are two difficulties,

[5]K. E. Shuler and R. I. Cukier, personal communications.

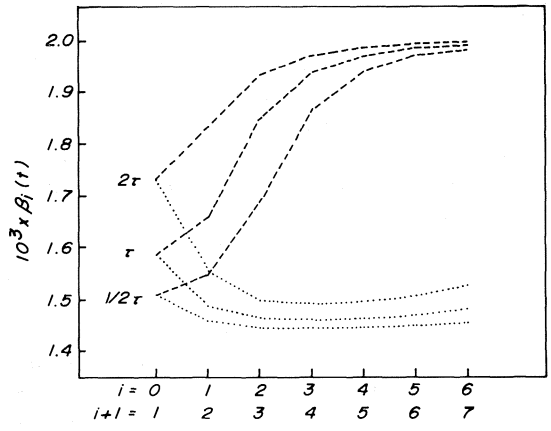

FIG. 3. Comparison of vibrational temperatures at various levels for a sudden cooling process from 700 to 500 K. The temperature is defined as $\beta_i = k \ln [n_i(t)/n_{i+1}(t)]/(\varepsilon_{i+1} - \varepsilon_i)$, and the plots are shown for $t = \frac{1}{2}\tau$, τ, and 2τ where $\tau = -\lambda_{N-2}{}^{-1}$. Dashed line = empirical probabilities (1); dotted line = information-theoretic probabilities of *minimum eigenvalue spread.*

in our view. First, a relaxation may appear to be exponential, or very nearly so, but this in no way implies that the sum rule holds, unless the long-time behaviour of the populations is shown to conform to eq. 10. Second, as can be seen from Fig. 2 (especially in the vibrational case), the bulk relaxation behaviour is extremely insensitive to the transition probabilities assumed: hence, as Carrington (22) recognized, it is a very ill-conditioned problem to work back from the observed bulk relaxation behaviour to the detailed rate constants. As an example of this, we show in Fig. 3 the behaviour of the vibrational population distributions at $\frac{1}{2}\tau$, τ, and 2τ for the two relaxations which are energetically indistinguishable in Fig. 2. Although the bulk relaxation behaviours are only imperceptibly different, the populations show diametrically different evolution behaviours, and it is evident that the ill-conditioned nature of the problem is quite severe: we can do no more than reiterate Carrington's conclusion of 15 years ago, that the present precision of relaxation experiments does not allow a meaningful deduction of transition rate constants from observed bulk relaxation rates. Nevertheless, in the absence of other sources of information, the information-theoretic approach (9) still provides the least-biased guess at a set of transition rates which will reproduce the known behaviour.

The preparation and characterisation of $Sb_3Cl_{11}F_4$

JACK G. BALLARD, THOMAS BIRCHALL,[1] AND DAVID R. SLIM
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received September 14, 1976

JACK G. BALLARD, THOMAS BIRCHALL, and DAVID R. SLIM. Can. J. Chem. **55**, 743 (1977).

The title compound has been prepared by the reaction of SbF_5 and $SbCl_5$ in liquid SO_2. Raman and Mössbauer spectra have been recorded and its crystal structure determined by three-dimensional X-ray counter measurements. Crystals are monoclinic with a = 12.359(6) Å, b = 16.480(10) Å, c = 9.387(3) Å, β = 103.96(5)°. The structure has been refined in the space group $P2_1/n$ to a final agreement index R_2 of 0.113 for 2415 independent reflections. The structure consists of a *cis* fluorine-bridged trimer with one of the chlorine atoms 25% substituted by fluorine.

JACK G. BALLARD, THOMAS BIRCHALL et DAVID R. SLIM. Can. J. Chem. **55**, 743 (1977).

On a préparé le composé mentionné dans le titre par la réaction du SbF_5 et du $SbCl_5$ dans le SO_2 liquide. On en a enregistré les spectres Raman et de Mössbauer et on a déterminé sa structure cristalline par des mesures de diffraction de rayon-X en trois dimensions. Les cristaux sont monocliniques avec a = 12.359(6) Å, b = 16.480(10) Å, c = 9.387(3) Å, β = 103.96(5)°. On a affiné la structure dans le groupe d'espace $P2_1/n$ jusqu'à un indice final de R_2 de 0.113 pour 2415 réflexions indépendantes. La structure consiste en un trimère ponté contenant un fluor *cis* avec un atome de chlore substitué à 25% par le fluor.

[Traduit par le journal]

Introduction

The $SbCl_{5-x}F_x$ system has been investigated by numerous workers since the early work of Swarts (1). All of these compounds behave as powerful Lewis acid catalysts and are excellent halogenating and oxidizing agents. From a stereochemical point of view they are of interest, since the antimony atom rarely remains five coordinate. Indeed only for $SbCl_5$ has five-coordination been established (2). However, a phase change is thought to occur at low temperatures, resulting in a different structure. Although a number of structures have been postulated (3–5), Mössbauer evidence at 4 K suggests a trigonal bipyramidal arrangement of chlorine atoms around antimony (6). SbF_5 (7), $SbCl_4F$ (8), and $SbCl_3F_2$ (9) have all been shown by X-ray crystallography to exist as *cis* fluorine-bridged tetramers. Two other chlorofluorides, $SbCl_2F_3$ (10) and $Sb_3Cl_4F_{11}$ (11) have been shown to contain the $[SbCl_4^+]$ cation and $[Sb_2Cl_2F_9^-]$ and $[Sb_2F_{11}^-]$ anions, respectively.

We now report the preparation and characterisation of $Sb_3Cl_{10.7}F_{4.3}$ which has a previously unreported trimeric structure.

Experimental

An amount of 6.73 g of doubly distilled (142–143 °C) SbF_5 was added to one side of a dry reaction vessel. Freshly distilled $SbCl_5$ (6 ml) were added to the other side of the same reaction vessel, but separated by a glass frit. All additions were made in a dry N_2 glove box. SO_2 was condensed onto the SbF_5 at −196 °C and, when allowed to warm, the SbF_5 dissolved completely. The SbF_5 in SO_2 solution was slowly added to the $SbCl_5$ and the mixture was stirred overnight. A white precipitate, partially soluble in SO_2, was produced and was washed with liquid SO_2. The SO_2 was pumped away and the dry white powder was vacuum sublimed at 20 °C. Single crystals were obtained by subliming the material in a quartz capillary tube. The sample melted at 64–69 °C.

Analysis was carried out by the Mikroanalytisches Laboratorium (Found: Sb 45.71, Cl 41.11, F 11.57. *Anal.* calcd. for $Sb_3Cl_{11}F_4$: Sb 43.91, Cl 46.95, F 9.14; $Sb_3Cl_{10}F_4$: Sb 44.80, Cl 43.55, F 11.65). The Mössbauer spectrum was recorded and analyzed by procedures already described (12, 13). Raman spectra were recorded on a Spectro Physics He/Ne (6328 Å) or an Ar ion laser (5145 Å) with a Spex 1400 Spectrophotometer system. The spectra recorded for the single crystal were the same as for the bulk material. The following crystal data were obtained.

$Sb_3Cl_{10.7}F_{4.3}$ fw = 827.5
Monoclinic, a = 12.359(6), b = 16.480(10), c = 9.387(3), β = 103.96(5), V = 1856 Å^3, Z = 4, D_c = 2.96 g cm^{-3}, F(0,0,0) = 1496, λ(Mo Kᾱ) = 0.71069 and μ(Mo Kᾱ) = 53.0 cm^{-1}.

The unit cell parameters were obtained from a least-squares refinement of 15 reflections within the range 20° < 2θ < 25°. Weissenberg and precession photographs indicated that reflections were absent for $0k0$ when $k = 2n+1$ and $h0l$ when $h+l = 2n+1$, characteristic of the non-standard space group $P2_1/n$ which is alternative setting for $P2_1/c$ (No. 14) (14). The equivalent positions of this space group are x,y,z; $-x,-y,-z$; $\frac{1}{2}-x,\frac{1}{2}+y,\frac{1}{2}-z$; $\frac{1}{2}+x,\frac{1}{2}-y,\frac{1}{2}+z$.

X-ray Intensity Measurements

The crystal, which was an irregular block of approximate dimensions 0.20 × 0.20 × 0.16 mm, was sealed in a quartz capillary and mounted on a syntex $P\bar{1}$ diffractometer with the 0.16 edge, which was perpendicular to the (0,0,1) face, almost coincident with the ϕ axis of the diffractometer. Intensities were measured with graphite monochromated radiation, using a θ–2θ scan, with a scan rate varying from 8.0 to 24.0°/min in 2θ, so that the weaker reflections were examined more slowly to minimize counting errors. Stationary background counts, with a time equal to half the scan time for each reflection, were made at each end of the scan range. One standard reflection was regularly checked to monitor the stability of the crystal and its alignment, but no significant variation was observed. A total of 3055 reflections within a unique quadrant with $2\theta < 50°$ were measured. Subsequent averaging resulted in a total of 2415 independent reflections, of which 1934 had intensities greater than three times their standard error, based on counting statistics. Lorentz, polarisation, and absorption corrections were applied to the observed intensities.

Solution and Refinement of the Structure

The positions of three independent antimony atoms were located from the three-dimensional Patterson function. The real and imaginary parts of the anomalous dispersion correction were applied to the scattering factors for neutral antimony (15). Full-matrix least-square refinement of positional and isotropic thermal parameters yielded an R_1 index of 0.32. The positions of 15 light atoms were located from a three-dimensional electron density map, 11 of which were assumed to be chlorine as they were about 2.2 Å from an antimony atom and the remaining 4 were assumed to be fluorine. Four cycles of least-squares refinement gave an R_1 index of 0.15. Anisotropic temperature factors were introduced for the antimony atoms and further refinement reduced R_1 to 0.11. Examination of the molecular geometry around Sb(2) indicated that the Sb(2)—Cl(11) bond was much shorter than the other Sb—Cl bond lengths. This suggested that Cl(11) was partially substituted by a fluorine atom. The occupation parameters of this site were varied and refinement terminated when the site contained 75% chlorine and 25% fluorine. Anisotropic temperature factors were introduced for the chlorine and fluorine atoms but the drop in R_1 index to 0.102 was insignificant based on Hamilton's significance tests (16). The final R_1 index was 0.106 and the final R_2 index with unit weight was 0.114.[2] The maximum shift was 0.1 of the estimated standard deviation in the final cycle and a difference electron density map showed no significant peaks. A list of structure factors is available on request.[3]

Discussion

The final parameters, and a list of the interatomic bond lengths and bond angles, are given in Tables 1 and 2 respectively. The trimeric unit is shown in Fig. 1 and the projection of the unit cell down the *c* axis is shown in Fig. 2.

In the atomic arrangement, each antimony atom has a distorted octahedral coordination of chlorine and fluorine. One antimony has one terminal fluorine atom and two fluorine atoms in *cis* positions, bridging to the other two antimony atoms which in turn are linked through a bridging fluorine atom. One of these antimony atoms has four terminal chlorine atoms while the other has three chlorines in a *cis* arrangement and a fourth site which consists of 75% chlorine and 25% fluorine.

In the trimer the mean Sb—Cl distance is 2.26 Å. This is comparable to the corresponding values found in $SbCl_4F$ (8), $SbCl_3F_2$ (9), $Sb_3Cl_9F_4O$ (17), and $[SbCl_4^+][Sb_2F_{11}^-]$ (11) respectively, *i.e.*, 2.29 Å, 2.25 Å, 2.26 Å, and 2.23 Å. All of these mean bond lengths are longer than that found in $[SbCl_4^+][Sb_2Cl_2F_9^-]$ (10), 2.18 Å. One might have expected that the Sb—Cl bond length in the cation would be shorter than that in the anion. Even more surprising is the 2.23 Å value found in the $[Sb_2F_{11}^-]$ salt, although it must be pointed out that this structure has never been refined satisfactorily. The *cis* Cl—Sb—Cl′ angles, which vary from 94.2° to 102.4°, are intermediate between the 90° angle expected for octahedral coordination and the tetrahedral angle achieved in the $[SbCl_4^+]$ cation. Presumably the greater repulsive effect of the chlorine atoms compared to fluorine would cause the Cl—Sb—Cl′ angles to open up from 90°.

The Sb—F (terminal) bond length, 1.87 Å, is somewhat shorter than those found in $SbCl_3F_2$ (9) and in $SbCl_9F_4O$ (17), 1.92 Å and 1.94 Å respectively. In the $[Sb_2Cl_2F_9^-]$ ion (10) the Sb—F (terminal) distances vary over rather a wide range, 1.83–1.99 Å and although the errors are rather high, this variation may be the result of cation–anion interaction which is discussed later.

The bridges between Sb(1) and Sb(2), and Sb(2) and Sb(3) are both symmetric (mean Sb—F = 2.08 Å) whereas that between Sb(1) and Sb(3) is asymmetric (Sb(1)—F = 2.04 Å, Sb(3)—F = 2.12 Å, mean = 2.08 Å). These bridging fluorine atoms complete the distorted octahedral coordination about each antimony. The mean bridge distance is comparable to the corresponding means in $Sb_3Cl_9F_4O$ (17), $SbCl_3$-

[2] R_2 is given by the expression $R_2 = [\sum w(|F_o|^2 - |F_c|^2)\sum wF_o^2]^{-1}$.

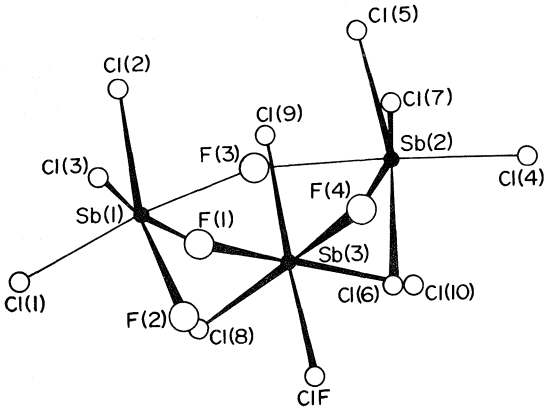

FIG. 1. View of the $Sb_3Cl_{10.7}F_{4.3}$ structure.

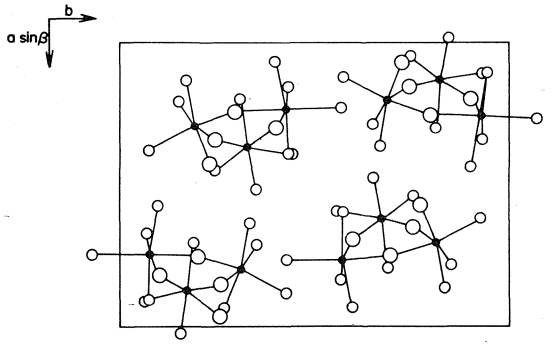

FIG. 2. Projection of the unit cell of $Sb_3Cl_{10.7}F_{4.3}$ down the *c* axis (circles of increasing size represent Sb, Cl, and F respectively).

F_2 (9), and $SbCl_4F$ (8), of 2.07 Å, 2.07(2) Å, and 2.12 Å respectively, all of which are longer than the bridging distances in $[ClO_2^+][Sb_2F_{11}^-]$ (18) and $[Sb_2Cl_2F_9^-]$, that is 2.01 Å and 2.00 Å, respectively.

The Cl—F disorder has already been discussed in the section concerning the refinement of the structure. The Sb—Cl(F) bond length, 2.12 Å, is approximately the value expected for a site consisting of 75% chlorine and 25% fluorine. We conclude that the composition of the crystal and the bulk material is a 3:1 mixture of $Sb_3Cl_{11}F_4$ and $Sb_3Cl_{10}F_5$. One site has four chlorines and two *cis* bridging fluorines as in $SbCl_4F$ (8), while the other site has three chlorines, one terminal fluorine, and two *cis* bridging fluorines, as in $SbCl_3F_2$. Two of the former and one of the latter units constitute the trimer $Sb_3Cl_{11}F_4$, while the converse is true for $Sb_3Cl_{10}F_5$. It should be noted that the relative orientation of the terminal fluorines in $Sb_3Cl_{10}F_5$ is the same as those in $SbCl_3F_2$. We have made repeated attempts to isolate pure components of the mixture by varying the sublimation conditions but with no success. However, it must be noted that the unit cell dimensions for the two compounds would be expected to be very similar.

The Sb_3F_3 unit is considerably distorted, with mean F—Sb—F′ and Sb—F—Sb′ angles of 79.4° and 158.2° respectively. These are in sharp contrast to the corresponding O—Sb—O′ and Sb—O—Sb′ angles in the trimeric anion $[Sb_3O_3F_{12}^{3-}]$ of 101° and 130° respectively (19). Presumably $Sb_3Cl_{10.7}F_{4.3}$ forms a less efficiently packed entity and the large chlorine atoms would tend to close down the F—Sb—F′ angles and hence open up the Sb—F—Sb′ angles. It is interesting to compare these angles with the corresponding angles in $SbCl_4F$ and $SbCl_3F_2$, 82.7° and 173°, and 78° and 164° respectively. Again, packing considerations are probably dominant since in these compounds there is an attempt to form an approximate cubic close packed array. However, it must be admitted that possible constraints can be expected in going from a trimer to a tetramer.

At first sight the existence of the compound as a cyclic trimer seems surprising since the only other reported antimony V chlorofluorides are cyclic tetramers, or ionic structures. An ionic structure for $Sb_3Cl_{10}F_5$ or $Sb_3Cl_{11}F_4$, similar to those already established (10, 11), that is $[SbCl_4^+]$ salts, would probably be unstable, since the basicity of the anion would be significantly reduced by the increased number of chlorines. For the compound to be a tetramer there would probably be substantial disorder as opposed to the minor disorder observed for the trimer.

Closer examination of the data for $[SbCl_4^+][Sb_2Cl_2F_9^-]$ reported by Preiss (10) reveals that there are four weak contacts from fluorine atoms of the anion to the antimony atom of the cation. These contacts, which are in the range 2.95 Å to 3.25 Å, are probably involved to some extent in the bonding. Such interaction may be the cause of the large variation in the terminal Sb—F bond lengths alluded to earlier. Each of the four weak contacts are perpendicular to a face of the $[SbCl_4^+]$ tetrahedron giving three F—Sb—Cl angles of 71° and one of 180°, as shown in Fig. 3. Mössbauer data recorded for $[SbCl_4^+][Sb_2Cl_2F_9^-]$ have been interpreted in these terms, and in addition, similar data for $[SbCl_4^+][Sb_2F_{11}^-]$ also suggest substantial cation–anion inter-

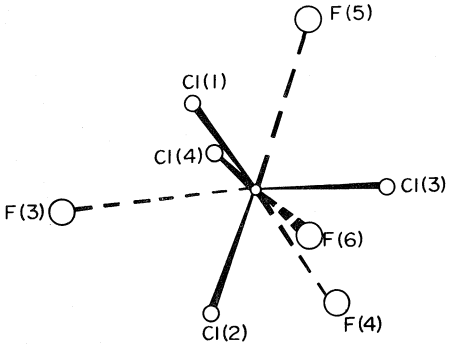

FIG. 3. A view of the antimony environment in the cation of $[SbCl_4^+][Sb_2Cl_2F_9^-]$. (The F numbering refers to the anion.)

actions (19). Furthermore the cation in $[SbCl_4^+][Sb_2Cl_2F_9^-]$ is situated in such a way, relative to the anion, so as to form the triangular arrangement of antimony atoms, which is shown in Fig. 4. The trimeric nature of the $Sb_3Cl_{10.7}F_{4.3}$ is then, perhaps, not so surprising.

Mössbauer Spectrum

The ^{121}Sb Mössbauer spectrum consisted of a resonance which could not be fitted to a single antimony site. A good fit was obtained only when two antimony sites were considered. The isomer shift and quadrupole coupling constants obtained for the two sites are, I.S. = 5.3 and 7.7 mm/s; e^2qQ_g = 8.9 and 2.7 mm/s. These values have been discussed elsewhere in more detail (20). It was concluded, on the basis of the isomer shift values, that one site would have four chlorines and two bridging fluorines while the other site would have one chlorine replaced by a terminal fluorine. Mössbauer data were unable to establish with any certainty the amounts of each site present since the recoil free fractions for the individual sites will not be the same.

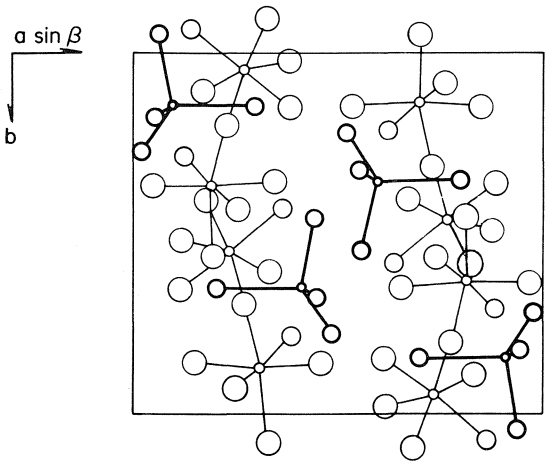

FIG. 4. Projection of the unit cell of $[SbCl_4^+][Sb_2Cl_2F_9^-]$ down the *c* axis (circles of increasing size represent Sb, Cl, and F respectively).

Raman Spectrum

The Raman spectra of the solid and liquid phases of $Sb_3Cl_{10.7}F_{4.3}$ are given in Table 3. The spectra are not easily assigned since both trimers, $Sb_3Cl_{10}F_5$ and $Sb_3Cl_{11}F_4$ have C_s symmetry. The spectra of the solid and liquid phases contain 16 and 10 bands respectively. When the solid melts some of the bands coalesce into a broad band. This is probably due to some halogen exchange occurring in the liquid form. Some of the weak bands observed for the solid were not observed for the melt. The polarization data recorded for the melt indicated that the bands at 659 cm^{-1}, 380 cm^{-1}, and 351 cm^{-1} are almost totally polarized. The band at 659 cm^{-1} can be assigned to the symmetric Sb—F stretch while those at 380 cm^{-1} and 351 cm^{-1} can be assigned to the symmetric Sb—Cl equatorial and axial stretches respectively. This agrees with the assignments made by Beattie *et al.* (21) for the *cis* fluorine-bridged tetramer $SbCl_4F$. It is reasonable to attribute the very weak band at 431 cm^{-1} to the Sb—F—Sb bridging mode,

which is consistent with the analogous assignment for that vibration (446 cm^{-1}) in $SbCl_4F$ (21). The lower frequency may be a consequence of the smaller Sb—F—Sb bridge angle, 158° as opposed to 173° for $SbCl_4F$. The bands at 121 to 175 cm^{-1} are depolarized and can be assigned to the deformation modes. The polarization data are not available for some of these bands because of their very weak intensity.

Recombination of iodine atoms by flash photolysis over a wide temperature range. VIII. I_2 in O_2[1]

R. E. ANTRIM,[2] GEORGE BURNS,[3] AND J. K. K. IP

Received May 19, 1976

R. E. ANTRIM, GEORGE BURNS, and J. K. K. IP. Can. J. Chem. **55**, 749 (1977).

Flash photolysis of I_2 in a large excess of O_2 was studied between 300 and 1173 K. Between 573 and 1173 K the rate of atomic recombination $2I(^2P_{3/2}) + O_2(^3\Sigma_g^-) \rightleftharpoons I_2(^1\Sigma_g^+) + O_2(^3\Sigma_g^-)$ was measured without interference of side reactions. Its rate constant was found to be $\log k_r^{O_2}(T) = 9.000 - 0.71 \log (T/573)$. Between 573 and 873 K there is an induction period lasting several hundred microseconds during which only a small net change in the iodine molecule concentration takes place. This induction period is consistent with the reaction $O_2(^1\Delta_g) + I_2 = O_2(^3\Sigma_g^-) + 2I$. Beow 573 K, the overall recombination rate constant has a temperature dependent negative temperature coefficient and is enhanced when the flash includes radiation in the neighborhood of 200 nm. Evidently this occurs because the flash photolysis of O_2 creates new efficient third bodies, such as O_3 and $O_2(^1\Delta_g)$, which accelerate the recombination reaction either directly or via an IO intermediate. The mechanism for the formation of IO during the flash photolysis of I_2 in an excess of O_2 was studied. It was shown that the reactions $O(^3P)$ or $O_3^* + I_2 \rightleftharpoons IO + I + (O_2)$, where O_3^* refers to an electronically or vibrationally excited state of O_3, account for the formation of IO under our experimental conditions. IO may also possibly be formed via the reaction $O_3^* + I \rightleftharpoons IO + O_2$. On the other hand, reactions between excited or ground state I atoms and O_2 suggested by earlier workers do not occur. Thus, all experimental complications observed are traceable to the presence of O_2 photolysis products and to the reaction of $I(^2P_{1/2})$ with $O_2(^3\Sigma_g^-)$.

R. E. ANTRIM, GEORGE BURNS et J. K. K. IP. Can. J. Chem. **55**, 749 (1977).

On a étudié, entre 300 et 1173 K, la photolyse éclair de I_2 dans un grand excès de O_2. Entre 573 et 1173 K, la vitesse de recombinaison atomique $2I(^2P_{3/2}) + O_2(^3\Sigma_g^-) \rightleftharpoons I_2(^1\Sigma_g^+) + O_2(^3\Sigma_g^-)$ a été mesurée sans interférence des réactions secondaires. On a trouvé que sa vitesse de réaction est égale à $\log K_r^{O_2}(T) = 9.000 - 0.71 \log (T/573)$. Entre 573 et 873 K, il y a une période d'induction qui dure plusieurs centaines de microsecondes durant laquelle il n'y a qu'un très faible changement net dans la concentration des molécules d'iode. Cette période d'induction est en accord avec la réaction $O_2(^1\Delta_g) + I_2 \rightleftharpoons O_2(^3\Sigma_g^-) + 2I$. En dessous de 573 K, la constante de vitesse globale de recombinaison possède un coefficient de température négatif qui dépend de la température et qui augmente quand l'éclair inclut des radiations aux environs de 200 nm. Evidemment ceci se produit parce que la photolyse éclair de O_2 crée de nouveaux troisième corps efficaces, tels que O_3 et $O_2(^1\Delta_g)$, qui accélèrent la réaction de combinaison soit directement ou par l'intermédiaire de IO. On a étudié le mécanisme de formation de IO durant la photolyse éclair de I_2 dans un excès de O_2. On a montré que les réactions $O(^3P)$ ou $O_3^* + I_2 = IO + I + (O_2)$, où O_3^* se réfère à un état excité électroniquement ou vibrationnellement de O_3, expliquent la formation de IO dans nos conditions expérimentales. Il est aussi possible que IO puisse se former par l'intermédiaire de la réaction $O_3^* + I \rightleftharpoons IO + O_2$. Par ailleurs, il ne semble pas que la réaction entre l'état excité ou fondamental des atomes d'iode et de O_2, qui avait été suggérée antérieurement par des chercheurs, se produit. Donc toutes les complications expérimentales qui ont été observées peuvent être attribuées à la présence de produits de photolyse de O_2 et à la réaction de $I(^2P_{1/2})$ avec $O_2(^3\Sigma_g^-)$.

[Traduit par le journal]

Introduction

One of the reactions which affects the efficiency of the iodine gas phase laser at 1315 nm is the reaction

[1] $I(^2P_{1/2}) + O_2(^3\Sigma_g^-) \rightarrow I(^2P_{3/2}) + O_2(a^1\Delta_g)$

because it is known (1) to be very fast. If laser

[3]The final portion of this work was done at the Université de Bordeaux I, Unité de Chimie, Laboratoire de Chimie Physique A, 351, cours de la Libération, 33405 Talence, France.

action is generated by flash photolysis, reaction 1 decreases the concentration of electronically excited iodine atoms, and this lowers the efficiency of the iodine laser. On the other hand, it was suggested (2) that the reverse of the reaction 1 can be used to increase the concentration of $I(^2P_{1/2})$ in an electric discharge, and thus to improve the efficiency of the iodine laser.

For these reasons, it seemed appropriate to study the iodine–oxygen reaction under the simplest possible experimental conditions. Specifically, in flash photolysis atomic recombination studies (3–13), one generates a minimum number of reactive species, making detailed elucidation of reaction mechanisms often possible.

In the present work, recombination of iodine atoms in oxygen is investigated using the flash photolysis technique over a wide temperature range, and the results are compared to earlier recombination studies.

Experimental

One spectrophotometric and one spectroscopic flash photolysis apparatus were used for the present study. The spectrophotometric apparatus, experimental and purification techniques, and methods of data analysis have been described previously (7, 8). To ensure a sufficient iodine vapour pressure in the reaction cell at high temperatures, an auxiliary oven was used (8) to prepare iodine–oxygen mixtures at elevated temperatures. Cylinder oxygen (Canox) was used without purification; in several experiments, Ultra High Purity oxygen (Matheson, minimum purity 99.95%) was used. The experiments were conducted in a double-walled quartz reaction vessel, with an outer jacket available for gas filters, which eliminate flash radiation of undesirable wavelengths. The Pyrex glass filter used in some experiments consisted of a 1.5 mm wall thickness cylindrical sleeve fitted over the quartz vessel. As in previous studies (5, 7–10), the experimental observable, from which the recombination rate constant was obtained, was the rate of change of the optical absorption at 487 nm, a wavelength close to the peak of the iodine absorption spectrum (14). The concentration of I_2 was, typically, 1 to 3×10^{-5} mol/l, while that of O_2 was 1 to 4×10^{-2} mol/l.

The kinetic spectroscopy apparatus, which was described previously (15), was equipped with a Jarrell–Ash *f*/6.3 grating spectrograph. Eastman Kodak 103F plates were used. These plates were photometered on a Joyce–Loebl microdensitometer, model Mk. IIIC.

Results

In spectrophotometric studies, the time dependent I_2 absorption was studied between 300 and 1173 K. In experiments conducted between 300 and 573 K and between 873 and 1173 K the absorption traces were similar to those observed in earlier investigations of halogen atom recombination (3). This suggests that, within the temperature specified above, the predominant reaction was the recombination of iodine atoms in the presence of chemically inert O_2:

$$[2] \qquad 2I + O_2 \rightarrow I_2 + O_2$$

In addition, I_2 should contribute to the reaction:

$$[3] \qquad 2I + I_2 \rightarrow 2I_2$$

The traces yield apparent recombination rate constants, k_r^{app}, defined by

$$[4] \quad d[I_2]/dt = k_r^{app}[I]^2[O_2] = \sum_M k_r^M[I]^2[M]$$

where M refers to O_2, I_2, and to all possible other third bodies in the reacting mixture.

Between 723 and 873 K all traces display a 'hump', *i.e.*, a slight dip and a rise before decaying smoothly with time (Fig. 1). Since the 'hump' is shallow, the optical absorption appears to be nearly in a steady state for a few hundred microseconds following initiation of the reaction. Rate constants were obtained from such anomalous traces by discarding the raw data from the first 2 ms. All apparent recombination rate constants obtained in this work are plotted in Fig. 2.

In an attempt to isolate the excitation energy from the flash lamp responsible for the anomalous 'hump', ammonia (0.5 to 1.5 atm), chlorine (1 atm), bromine (0.2 atm), and a Pyrex glass sleeve were used, in various combinations, as filters around the reaction vessel. The absorption spectra of all these filters are published elsewhere (16). No apparent change in the shape of the trace was observed in such experiments. In some runs, Ultra High Purity oxygen was used as the diluent but that did not affect the 'hump' either. When argon was substituted for oxygen as the diluent, the 'hump' disappeared, and the rate constant, k_r^{Ar}, (Fig. 2) agreed well with previous values which were determined using the same apparatus (8). The rate constants obtained from individual runs at 723 K, where the 'hump' appeared to be most noticeable, indicate that no matter what filter was used, the rate constant at this temperature did not change outside of experimental error, which is between 10 and 15%.

Between 300 and 573 K, k_r^{app}, obtained with ammonia gas or Pyrex glass filters, are in agreement with each other, within experimental error. However, they are invariably smaller than rate constants obtained without the use of filters around the reaction vessel. The apparent rate

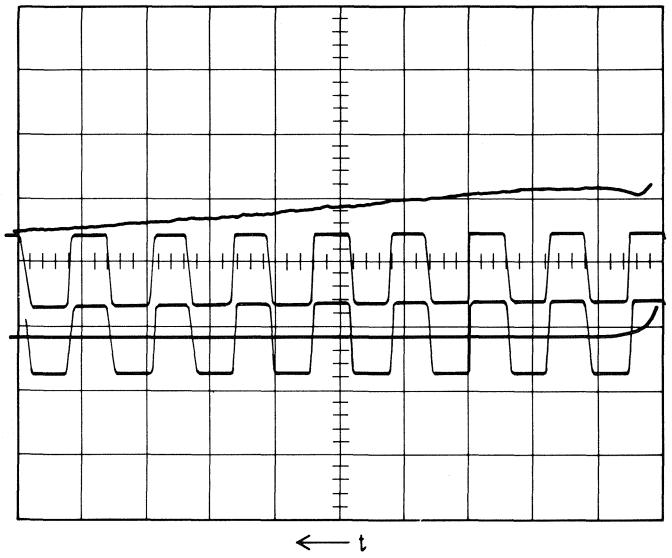

FIG. 1. Oscilloscope trace for I atom recombination in $[O_2]$ at 723 K. $[I_2] = 1.3 \times 10^{-5}$ mol/l and $[O_2] = 8.1 \times 10^{-3}$ mol l^{-1}. Flash energy 1200 J. Flash traces, ordinate 0.05 V/cm, abscissa 0.5 ms/cm. Square wave ordinate 1 V/cm.

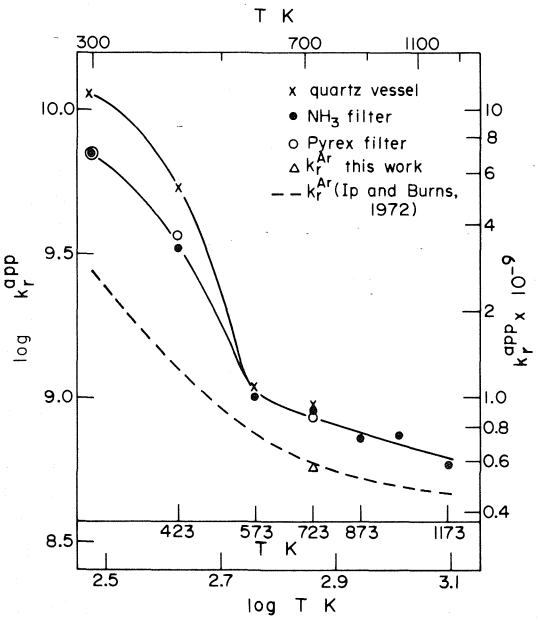

FIG. 2. Temperature dependence of k_r^{app}, the apparent iodine atom recombination rate constant in oxygen, and of k_r^{Ar} in l^2 mol^{-2} s^{-1}.

constants, determined at room temperature from mixtures with various compositions of iodine and oxygen, yield values of $k_r^{I_2}$ (reaction 3) equal to $(1.3 \pm 1.0) \times 10^{12}$ (result from experiments with quartz vessel alone) and $(1.5 \pm 0.7) \times 10^{12}$ l^2 mol^{-2} s^{-1} (combined result from experiments with ammonia and Pyrex filters), in agreement with a more accurate value of $k_r^{I_2} = 1.3 \times 10^{12}$ l^2 mol^{-2} s^{-1} reported previously (8).

In order to further study reaction generated by flash photolysis of $I_2 + O_2$ mixtures, the kinetic spectroscopy apparatus was used. In these experiments the IO spectrum was observed. The IO spectrum rose to its maximum at the time the main flash reached its peak intensity (10–15 μs). The half-life for IO decay was about 80 μs. These results are in agreement with earlier data (17). A typical IO spectrum obtained in the present work is shown in Fig. 3. This spectrum was observed previously (17) in the photolysis of iodine–oxygen mixtures in an all-quartz reaction vessel; our results confirm this finding. However, in the present work, we found that the IO spectrum was absent if a Pyrex sleeve was installed around the reaction cell (Fig. 3).

Discussion

Earlier systematic studies of halogen atom recombination reactions, over a wide temperature range, and in the presence of a large excess of various third bodies (3–13), revealed some consistent trends. In agreement with a previous investigation (11), it was invariably found (3–10) that heavier and more complex non-reacting molecules were more efficient third bodies.

The experimental recombination reaction rate

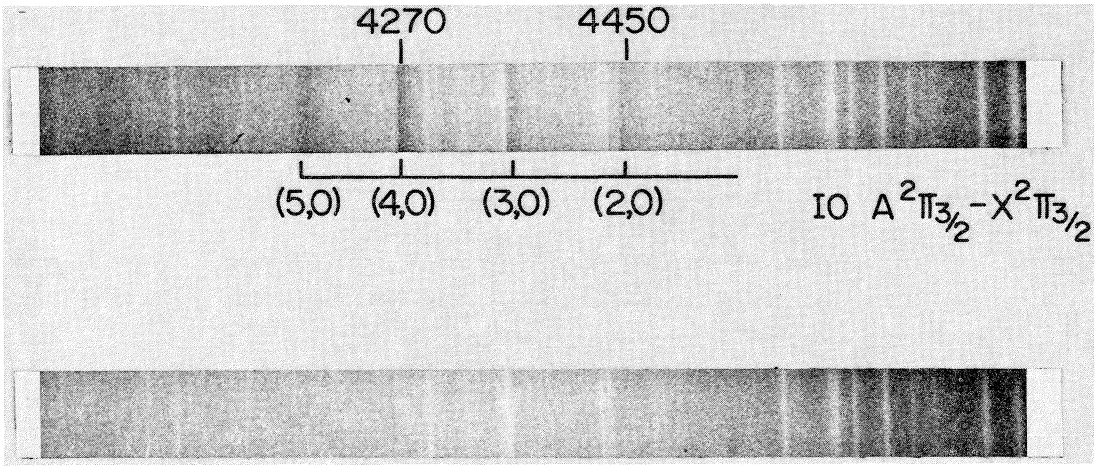

FIG. 3. Spectrum of IO produced by flash photolysis of I_2–O_2 mixtures: 2 torr I_2, 620 torr O_2, T = 350 K. Top, 25 μs delay without filter; bottom, 25 μs delay with Pyrex filter. Flash energy 1125 J.

constants could normally be expressed via the relationship

$$[5] \quad \log k_r = \log k_r^{300\,K} - n \log (T/300) + m \log (T/300)^2$$

Furthermore, the higher the efficiency of the third body, the higher was the negative temperature coefficient at room temperature, *i.e. n*. When data over a sufficiently wide temperature were accumulated (3–8), it became apparent that *m*, eq. 5, was either positive or zero, and generally increased with molecular weight and complexity of the third body as well as with chemical reactivity between the third body and recombining atom. As was shown recently (18–25), these empirical findings have a theoretical basis.

Present results on the $I_2 + O_2$ system do not fit well into these established trends (3–13). Specifically, three experimental results need to be examined: (*a*) formation of IO during flash photolysis; (*b*) the discrepancy between k_r^{app} obtained in experiments with filters around the reaction vessel and those without filters, and k_r^{app} temperature dependence; and (*c*) presence of the 'hump' between 723 and 873 K. These experimental findings are discussed below.

(a) Mechanism of the Formation of Iodine Monoxide

Under our experimental conditions, flash light may produce the following primary photolysis products: $I(^2P_{3/2})$, $I(^2P_{1/2})$, and $O(^3P)$.

Consequently, IO can be formed, in principle, via reactions 6–9:

$$[6] \quad I(^2P_{1/2}) + I(^2P_{1/2}) + O_2(^3\Sigma_g^-) \rightleftharpoons 2IO$$

$$[7] \quad I(^2P_{1/2}) + I(^2P_{3/2}) + O_2(^3\Sigma_g^-) \rightleftharpoons 2IO$$

$$[8] \quad I(^2P_{3/2}) + I(^2P_{3/2}) + O_2(^3\Sigma_g^-) \rightleftharpoons 2IO$$

$$[9] \quad I_2(^1\Sigma_g^+) + O(^3P) \rightleftharpoons IO + I(^2P_{3/2})$$

Of these reactions, the reaction 8 involves the least energetic species, is endothermic by 34 kcal/mol, and therefore should be the slowest and the least important. Furthermore, present results indicate that the mechanism involving reactions 6 and 7, proposed previously (16), plays no role in IO formation. This is because flash photolysis of $I_2 + O_2$ mixture in a reaction vessel with a Pyrex sleeve, which yields $I(^2P_{1/2})$ and $I(^2P_{3/2})$, does not produce IO. This finding is in agreement with predictions made earlier (16).

Thus, the only primary flash photolysis product, which can yield IO under our experimental conditions, is $O(^3P)$ (reaction 9). Oxygen atoms can be produced (16) by direct flash photolysis of O_2 between 180 and 200 nm. Although the absorption of short wavelengths at about 200 nm produces O_2 in a $^3\Sigma_u^+$ attractive state, these molecules should predissociate, producing $O(^3P)$ atoms. The reverse process, *i.e.* inverse predissociation leading to the formation of O_2 in $^3\Sigma_u^+$ state has been observed in shock waves (26).

Secondary photolysis products, which can yield IO, may be produced in reactions involving $O(^3P)$ atoms. Recent investigators (27) have shown that during flash photolysis of O_2 in

quartz vessels, $O(^3P)$ atoms react via:

[10] $$O(^3P) + 2O_2(^3\Sigma_g^-) \rightleftharpoons O_3^* \text{ (or } O_3) + O_2$$

where O_3^* is ozone in an electronically or vibrationally excited state. The prevailing literature (28–32) value of k_{10} is 2×10^8 l^2 mol^{-2} s^{-1} while its most recent measurement yields (27) 1×10^8 l^2 mol^{-2} s^{-1}. Therefore, the reaction half-life, τ_{10}, is of the order of 5 μs, and is about equal to τ_9, if reaction 9 were to occur on every tenth collision. Although k_9 has not been measured, the reaction

[11] $$Br_2 + O \rightarrow BrO + Br$$

occurs (33), approximately, on every ten collisions at 300 K. We conclude, therefore, that the most likely fate of the $O(^3P)$ atom in our experiments is reactions 9 and 10. Consequently, we are unable to exclude the possibility that

$$O_3^* + I_2 \rightleftharpoons IO + I + O_2$$

also contributes to the formation IO.

The formation of ozone increases the number of plausible reactions which can make interpretation of our experimental data ambiguous. This is because O_3 itself can be photolyzed (27) producing $O(^1D)$, $O_2(^1\Delta_g)$, $O_2(^1\Sigma_g^+)$, and vibrationally excited $O_2(^3\Sigma_g^-)$. Fortunately for us, this ambiguity resolved itself because in our experiment O_3 is rapidly depleted via the reaction

[12] $$I + O_3 \rightleftharpoons IO + O_2$$

The rate constant for this reaction, measured (34) by the flow discharge technique, is 5×10^{14} l mol^{-1} s^{-1}, which is about as fast as k_{11} (7×10^{14} l mol^{-1} s^{-1}). However, except in initial stages of photolysis, *i.e.* during first 30 μs or so, reaction 12 cannot be the main cause for the IO observed in our experiments. This is because IO is produced within about 15 μs after flash initiation and essentially disappears within 200 μs, while I atoms exist for milliseconds.

The mechanism of the formation of BrO in flash photolysis of Br_2 and O_2 mixtures was studied earlier (16). It was found that BrO is formed predominantly via reactions with $O(^3P)$, ozone, or excited O_2. Thus, the mechanisms of the formation of IO and BrO are essentially identical, within the limitations of the present experiments, as was suggested earlier (16).

The temperature dependence of IO formation was studied here qualitatively only up to 600 K, and it was found that the concentration of IO decreases with temperature. This is due in part to the decreased transparency of quartz at an elevated temperature, and, possibly, to the thermal decomposition of O_3^*. Similar temperature dependence for BrO formation was reported earlier (15).

(b) A Comparison of k_r^{app} Obtained with and without Filters, and its Temperature Dependence

It follows from the above discussion (*a*) that the reaction mixture in early stages of photolysis, *i.e.* first 10 to 30 μs after the flash initiation, consists of several reacting species, some of which exist in excited electronic and/or vibrational states. However, about 200–300 μs after the flash initiation, *i.e.* at the earliest time at which our spectrophotometric measurements can be made, all these species have decayed, and the reaction mixture consists of $I(^2P_{3/2})$, I_2, $O_2(^3\Sigma_g^-)$, $O_2(^1\Delta_g)$, and O_3. The $I(^2P_{1/2})$ atoms, which constitute about 20% of all iodine atoms produced by the flash, also disappear via reaction 1. The rate constant for this reaction (1) at 300 K is $1.6 \pm 0.2 \times 10^{10}$ l mol^{-1} s^{-1}, which means that, under our experimental conditions, the half-life of $I(^2P_{1/2})$ (10^{-8} to 10^{-9} s) is much shorter than the duration of the flash.

The $O_2(^1\Delta_g)$ molecules, produced via reaction 1 and by photolysis of ozone

[13] $$O_3 + h\nu \rightleftharpoons O_2(^1\Delta_g) + O$$

are quenched via

[14] $$O_2(^1\Delta_g) + O_2(^3\Sigma_g^-) \rightleftharpoons 2O_2(^3\Sigma_g^-)$$

and

[15] $$O_2(^1\Delta_g) + I(^2P_{3/2}) \rightleftharpoons O_2(^3\Sigma_g^-) + I(^2P_{3/2})$$

of which [14] should be predominant. At 300 K, k_{14} was found (35) to be equal to 1.3×10^3 l mol^{-1} s^{-1}. This means (35, 36) that under our experimental conditions, at 300 K the lifetime of $O_2(^1\Delta_g)$ is about 35 times longer than the lifetime of $I(^2P_{3/2})$, which disappears via reactions 2 and 3.

Since at 300 K the values of k_r^{app} obtained with ammonia and Pyrex glass filters are in agreement with each other, the flash photolytic reactions in these two cases appear to be indistinguishable. This conclusion is also reasonable because it was shown above that in our experiments no photochemical reactions are generated by radiation between 2000 and 2900 Å. The

difference between k_r^{app} (filter) and k_r^{app} (no filter) is due primarily to the presence of O_3, which is absent in experiments with filters, and O_3 photolysis products, of which only $O_2(^1\Delta_g)$ has a long enough lifetime to interfere with recombination reaction (27).

Therefore, in order to account for a difference in k_r^{app} (filter) and k_r^{app} (no filter) we must assume that in experiments with no filter additional recombination occurs via

[16] $$2I + O_3 \rightleftharpoons I_2 + O_3$$

[17] $$2I + O_2(^1\Delta_g) \rightleftharpoons I_2 + O_2(^1\Delta_g)$$

as well as via reaction 12 which is followed by rapid

[18] $$2IO + O_2 \rightleftharpoons I_2 + 2O_2$$

As the temperature of the reaction vessel is increased, contributions from the reactions 16, 17, 12, and 18 should decrease because the concentration of intermediate complexes, such as I—O_3, would drop with the temperature rise. Furthermore, O_3 itself is unstable with respect to O_2. For these reasons, the difference between k_r^{app} (filter) and k_r^{app} (no filter) decreases with temperature, and above 500 K, k_r^{app} (filter) = k_r^{app} (no filter) (Fig. 2). The absolute values of k_r^{app} suggest that at room temperature, the magnitude of $k_r^{O_2}$ is determined primarily by the RMC (18) mechanism. However, at highest temperatures, the ET mechanism (19) predominates. Between 573 and 1173 K the atomic recombination $2I(^2P_{3/2}) + O_2(^3\Sigma_g^-) \rightleftharpoons I_2(^1\Sigma_g^+) + O_2(^3\Sigma_g^-)$ can be measured without interference of side reactions. Its rate constant was found to be $\log k_r^{O_2} = 9.000 - 0.71 \log (T/573)$.

(c) An Induction Period in I Atom Recombination between 723 and 873 K

Production of oxygen atoms, O_3, and IO cannot explain the anomalous 'hump' in recombination traces observed between 723 and 873 K (Fig. 1). This is because the anomaly is present whether or not filters are used, even though IO, O_3, and O atoms cannot be formed in the absence of unfiltered radiation. Neither can we explain the 'hump' by impurities, because it is present even if Ultra Pure O_2 is used.

The 'hump' can be explained either by the presence of molecules, other than I_2, which absorb at 487 nm, and which are destroyed in some chemical reactions, or by a reaction which destroys stable I_2 molecules. Only the IO spectrum may, conceivably, overlap with I_2 spectrum at 487 nm; oxygen is transparent at this wavelength. However, the IO absorption could not explain the anomalous 'hump', because again it is present in experiments in which filters were used. Therefore, the only reasonable alternative is a reaction which destroys stable I_2. It is possible to calculate from the available experimental data, such as Fig. 1, that such a reaction would yield an additional decomposition of 2 to 3% of the initial iodine concentration. This can be done by extrapolating the absorption curve (Fig. 1) from $t > 2$ ms to $t = 0$ using the known k_r^{app} (Fig. 2) at 723 K.

As discussed above, the only excited species present at this temperature are $O_2(^1\Delta_g)$. It appears that at 723 K, a new reaction becomes significant.

[19] $$I_2(^1\Sigma_g^+) + O_2(^1\Delta_g) \rightarrow 2I(^2P_{3/2}) + O_2(^3\Sigma_g^-)$$

A value of k_{19} at 723 K may be estimated from the iodine molecule concentration which remains approximately constant during the induction period for about 0.5 ms after the initiation of the reaction. The steady state approximation for I_2 molecules yields

[20] $$k_{19} = \frac{(k_r^{O_2}[O_2] + k_r^{I_2}[I_2])([I(^2P_{3/2})]_{fl} + [I(^2P_{3/2})]_{eq})^2}{[I_2][O_2(a^1\Delta_g)]}$$

where $[I(^2P_{3/2})]_{eq}$ is the equilibrium concentration of iodine atoms prior to the photolysis. Typical concentrations at 723 K are $[O_2] = 1.5 \times 10^{-2}$ mol l^{-1}, and $[I_2] = 1.5 \times 10^{-5}$ mol l^{-1} and typically 20% of I_2 is decomposed by the flash. At 723 K, the concentration of iodine atoms in equilibrium with 1.5×10^{-5} mol l^{-1} iodine is 8.2×10^{-7} mol l^{-1}. From the percentage decomposition, $[I(^2P_{3/2})]_{fl} = 6 \times 10^{-6}$ mol l^{-1} and $[I_2] = 1.2 \times 10^{-5}$ mol 'immediately' after the flash. The concentration of singlet oxygen, $O_2(^1\Delta_g)$, will be $0.2[I(^2P_{3/2})]_{fl}$, because

essentially all of the excited iodine atoms form $O_2(^1\Delta_g)$ via reaction 1. Thus, $k_{19} \simeq 4 \times 10^7$ l mol^{-1} s^{-1} at 723 K.

Comparison of this value with the value obtained from the simple collision theory, using a steric factor of unity and molecular diameters of 5.0 Å for iodine and 3.4 Å for oxygen, results in an activation energy of 12 kcal/mol. This calculated activation energy is in reasonable agreement with the endothermicity of reaction 19, which is 13.1 kcal/mol.

It is possible that reaction 19 proceeds via electronically excited attractive states of iodine, which dissociate to two $I(^2P_{3/2})$ atoms. Of these states, one $(A^3\Pi_{1u})$ has dissociation energy of 1.8 kcal/mol. Two others have not been observed spectroscopically.

Because reaction 19 has an appreciable activation energy, the 'hump' can be observed only over a relatively narrow temperature range. At 573 K and below, the reaction is too slow to be observed and $O_2(^1\Delta_g)$ atoms participate in three-body recombination of iodine atoms. On the other hand, above 873 K, the reaction is essentially completed within the duration of the flash.

An alternative explanation of the 'hump' would be the reaction of two $O_2(^1\Delta_g)$ with I_2,

$$[21] \quad 2O_2(^1\Delta_g) + I_2(^1\Sigma_g^+) \rightarrow 2I(^2P_{3/2}) + 2O_2(^3\Sigma_g^-)$$

A steady state treatment similar to that involving reaction 19 predicts that $k_{21} = 3.7 \times 10^{13}$ l^2 mol^{-1} s^{-1} at 723 K. This would be an unusually fast rate constant for a termolecular reaction involving molecular species. Furthermore, it is not likely that the reaction 21 could be important because Derwent and Thrush (37) did not find the proper pressure dependence to justify the occurrence of reaction 21 in their I_2–O_2 discharge system.

These results are in essential agreement with a previous study of bromine recombination in oxygen (4), in which the recombination rate constants decrease smoothly with temperature. In contrast with excited iodine atoms, excited bromine atoms, $Br(^2P_{1/2})$ do not possess sufficient energy to excite oxygen to the $O_2(a^1\Delta_g)$ state. Therefore no 'hump' was observed in $Br_2 + O_2$ system. On the other hand, the rate constants for bromine atom recombination in a quartz cell were about 20% higher than in a Vycor reaction cell (4), which should be due to the production of O_3 in the quartz reaction vessel.

Cyclopropanediols. VI. Obtention de dérivés du cyclopropanediol

RAYMOND LE GOALLER ET JEAN-LOUIS PIERRE

Laboratoire de Chimie Organique, Université Scientifique et Médicale de Grenoble, B.P. 53, Centre de tri, 38041 Grenoble Cedex, France

Reçu le 22 juillet 1976

RAYMOND LE GOALLER et JEAN-LOUIS PIERRE. Can. J. Chem. **55**, 757 (1977).

Le texte décrit deux méthodes d'obtention de dérivés cyclopropanedioliques: la réduction des β-dicétones et le pontage des bissiloxy-1,2 alcènes dont certains sont obtenus par une nouvelle méthode.

RAYMOND LE GOALLER and JEAN-LOUIS PIERRE. Can. J. Chem. **55**, 757 (1977).

Two methods are described for the preparation of substituted cyclopropanediols: reduction of β-diketones, and bridging of 1,2-bissiloxyalkenes; a number of the latter compounds were prepared by a new method.

[Journal translation]

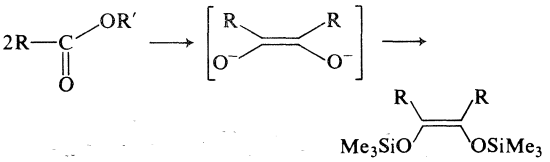
Introduction

Ce travail s'intègre à une étude générale des voies d'accès aux cyclopropanediols (réf. 1. et les références qui y sont citées). Il avait fait l'objet de deux communications préliminaires (2, 3).

Depuis que Staschewski (4) proposa pour la réduction de Clemmensen de la diméthyl-5,5 cyclohexanedione-1,3 un mécanisme faisant intervenir un cyclopropanediol, divers auteurs ont repris l'étude de cette réaction sur de nombreux substrats (réfs 5 et 6 et les références qui y sont citées), ces différents travaux vérifiant d'ailleurs l'hypothèse alors avancée.

A notre connaissance, hormis (1), aucune étude permettant de rendre accessible la structure cyclopropanediolique n'a encore été réalisée, bien qu'en fait quelques composés de ce type aient déjà été obtenus: (*i*) par réduction des β-dicétones: dès 1969, trois équipes isolent les premiers dérivés de cyclopropanediols (2, 7, 8) et plus tard, quelques diols libres ont pu être obtenus (9–11); (*ii*) par pontage des doubles liaisons: ce sont essentiellement l'action du diazométhane sur les carbonates de vinylène (12) et des dihalogénocarbènes sur les diéthers éthyléniques (13).

Pour notre part, après avoir montré que la réduction de la diméthyl-3,3 pentanedione-2,4 par le sodium dans l'éther en présence de triméthylchlorosilane (TMCS), fournissait les deux composés cyclopropaniques attendus (2), nous avons entrepris de mettre au point des méthodes d'obtention des dérivés de cyclopropanediols et nous exposons ici les résultats obtenus: (*i*) d'une part en généralisant la réduction des composés β-dicarbonylés, (*ii*) d'autre part en appliquant la réaction de Simmons et Smith aux bissiloxyalcènes, préparés pour la première fois en 1960 par Ruhlmann par une méthode qui consiste à piéger la forme ènediolique obtenue au cours de la réaction acyloïne par du TMCS (14).



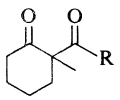
Afin d'obtenir des bis(trimethylsiloxy-1,2) alcènes dissymétriques, nous avons appliqué cette même réaction aux α-dicétones.

Résultats et discussion

A. Réduction des composés β-dicarbonylés

Afin d'éviter les complications dues à l'énolisation, nous avons utilisé des substrats non énolisés. Nous avons opéré avec du sodium dispersé et avec le mélange Na–K plus facile à mettre en œuvre et qui donne de meilleurs résultats, dans l'éther et en présence de triméthylchlorosilane (TMCS). Nous avons étudié les substrats suivants:

	R	R′		R	R′
1	Me	Me	**5**	Ph	H
2	Et	Et	**6**	Me	H
3	Et	Me	**7**	Me	OEt
4	Ph	Ph	**8**	EtO	OEt



9 R = H
10 R = Me

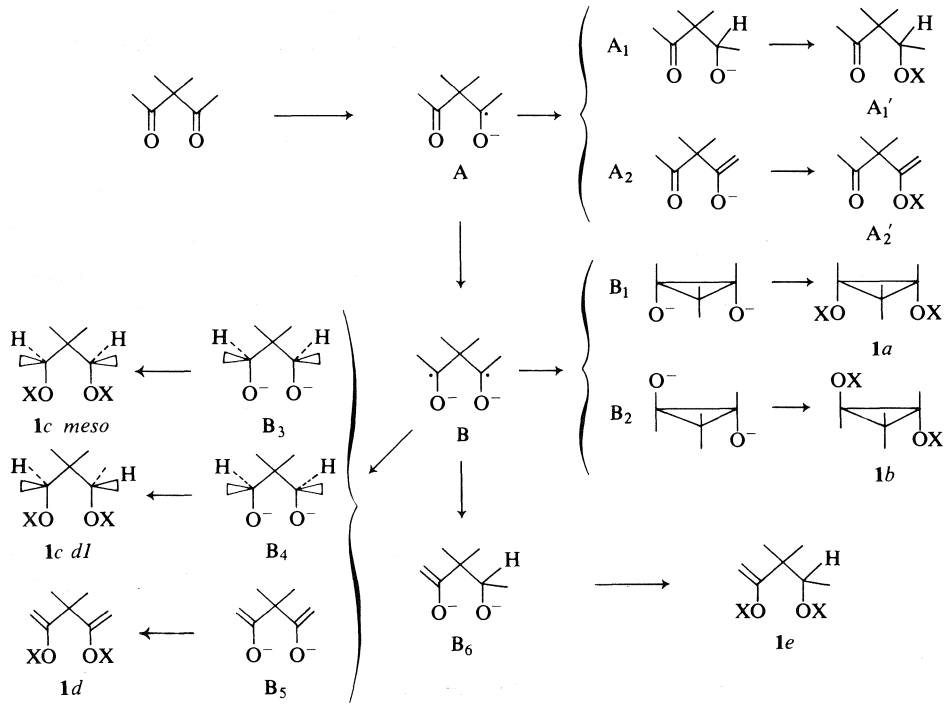


SCHÉMA 1. $X = SiMe_3$

Les résultats obtenus avec **1** ont été décrits dans notre communication préliminaire (2). Ils peuvent s'expliquer par le mécanisme généralement invoqué pour la réduction des cétones par les métaux (15) et sont résumés dans le schéma 1. Avec une quantité équivalente de sodium, on obtient deux fractions A et B. Les proportions relatives de la fraction B étant: **1***a* 20%; **1***b* 10%; **1***c meso* 15%; **1***c dl* 5%; **1***d* 20%; **1***e* 30%. Si on opère avec un excès de sodium, seule la fraction B est obtenue.

Les produits A_1' et **1***c* ont été d'autre part obtenus par action du TMCS en présence de triéthylamine sur les composés hydroxylés correspondants. Nous avons vérifié que A_2' et **1***d* donnent par hydrolyse la dicétone de départ, tandis que A_1' et **1***e* donnent le cétol attendu. L'hydrolyse de **1***a* en milieu neutre conduit à la dicétone de départ alors qu'en milieu acide concentré, nous obtenons un produit non encore identifié, mais différent du cétol obtenu par réduction de Clemmensen de la diméthyl-3,3 pentanedione-2,4 (16).

La stéréochimie de **1***a* et **1***b* a été déterminée par rmn de même que celle des isomères de **1***c* et cette étude a fait l'objet d'une communication séparée (17).

Il est à remarquer nous avons obtenu une fraction importante de transfert d'H sur les cétyles. Ce phénomène avait également été observé lors de la réduction de la cyclohexanone dans les mêmes conditions (15).

Nous avons vérifié le comportement de la dicétone initiale en milieu basique: une coupure normale est observée conduisant à l'acétate et à la méthyl-3 butanone-2. La cétone transposée de Brohmann et Pinder et de Inamoto *et al.* n'est pas observée (18). La présence de TMCS ne semble pas avoir d'effet sur la marche de la réaction puisque les résultats sont inchangés en opérant son addition avant, pendant ou après la réduction de la dicétone.

Les autres dicétones ou cétoaldéhydes étudiés ont un comportement absolument identique qui peut se résumer de la façon suivante (schéma 2).

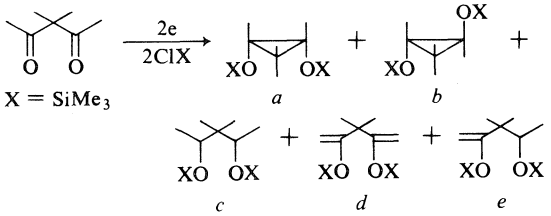

SCHÉMA 2

TABLEAU 1. Les résultats de la réduction des composés β-dicarbonylés

Produit	Rendement*(%) $a + b$	Rapport a/b	Rendement (%) $c + d + e$
1	30	2	70
2	30	2	70
3	30	2	70
4	90	*a* seul	0
5	40	3	0
6	90	1.5	0
9	30	3	60
10	50	3	50

*Il s'agit de rendements moyens établis sur plusieurs réactions, évalués par rapport au produit de départ. Dans certains cas, on obtient un peu de polymérisation.

Les résultats, obtenus en utilisant un gros excès de réducteur, ce qui permet de supprimer la fraction A et de consommer entièrement les produits de départ, sont résumés dans le tableau 1.

Pour **4** on obtient exclusivement le composé *Z*. Les produits analogues à **1***d* et **1***e* qui représentaient 50% des produits de la réaction ne peuvent intervenir. L'absence des analogues de **1***c* implique que le cétyle ne capte pas d'hydrogène ce qui semble indiquer pour **1**, les H provenaient de la dismutation du cétyle lui-même (schéma 3).

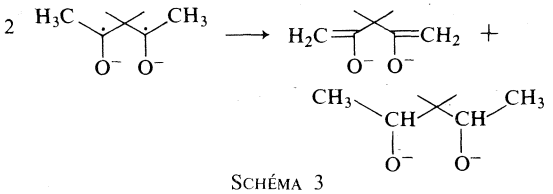

SCHÉMA 3

Le cétoaldéhyde **5** conduit aux dérivés cyclopropaniques avec un rendement de l'ordre de 40% accompagnés de nombreux sous-produits non analysables alors que **6** fournit le cyclopropane à 90%.

A titre de comparaison, nous avons effectué la réduction de **6** par le sodium dans l'ammoniac liquide, en captant ensuite les énolates formés par le TMCS. Aucun cyclopropane n'est obtenu sans doute à cause du caractère donneur de H du solvant (schéma 4).

Le β-cétoester **7** conduit également avec un excellent rendement (>80%) à un dérivé cyclopropanique **7***a* qui semble être unique mais dont nous n'avons pu préciser la structure, accompagné de 20% du composé ouvert **7***c*. (schéma 5).

La réduction de **7** dans NH_3–Et_2O–TMCS ne fournit aucun produit cyclopropanique et

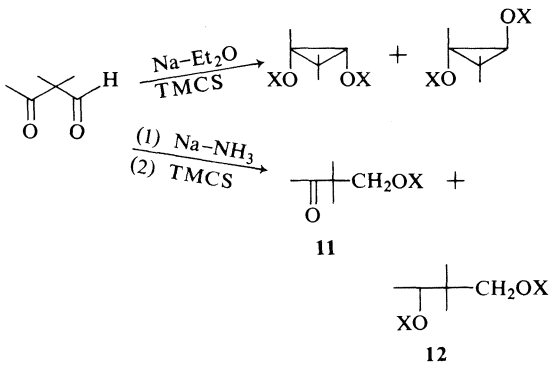

SCHÉMA 4

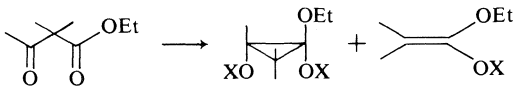

SCHÉMA 5

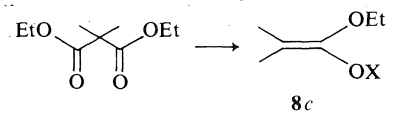
nous avons obtenu quantitativement les produits de la réduction normale **11** et **12**.

Enfin le diester **8** qui aurait pu selon le schéma de la réduction acyloïne conduire à un dérivé disiloxylé du cyclopropène, nous a en réalité fourni le composé ouvert **8***c* avec un rendement supérieur à 90%. Un résultat analogue au nôtre a été observé par réf. 19 et expliqué par réf. 20.



Les attributions de configuration ont été faites de façon certaine pour **1***a* et **1***b*, **2***a* et **2***b*, et **4***a* sur la base de l'équivalence des méthyles en 3 pour les composés *E* et de leur inéquivalence pour les composés *Z* (17). On constate que dans tous ces cas le composé *Z* est majoritaire, ce qui nous a conduit à admettre cette structure pour le composé majoritaire obtenu dans les autres cas.

Discussion

Sur le plan théorique, le résultat est clairement interprété, deux voies pouvant être envisagées (schéma 6).

L'étude électrochimique de Curphey *et al.* (7), suivie en rpe, a permis de montrer qu'il se formait un radical donnant une simple absorption large, l'absence de structure fine empêchant toute interprétation. D'autre part, Curphey

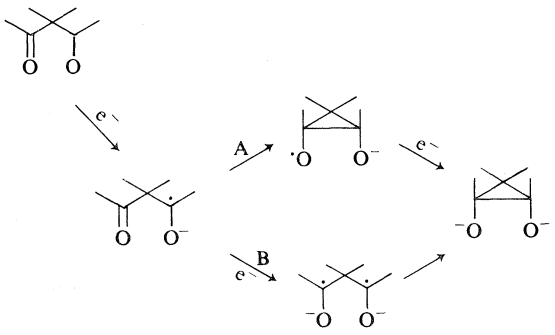


SCHÉMA 6

indique qu'il est impossible d'ajouter plus d'un électron aux dicétones, par voie électrochimique, et conclut à l'existence d'un seul radical anion. Ceci pose le problème des composés obtenus par dismutation, composés qui ne sont jamais hydroxylés ainsi que pourrait le suggérer l'intermédiaire cyclopropanique de la voie A.

B. Pontage des bis(trimethylsiloxy)-1,2 alcenes

La réaction de Ruhlmann, à laquelle nous avons apporté une petite modification en utilisant, comme agent réducteur, l'alliage sodium–potassium qui donne de meilleurs résultats que le sodium dispersé, nous a permis d'atteindre les siloxyalcènes du tableau 2. Ces produits ont été caractérisés par leurs données spectroscopiques.

La réduction des α-dicétones dissymétriques dans les mêmes conditions a conduit aux bissiloxyalcènes du tableau 3 qui ont été également caractérisés pas spectroscopie ir et rmn, à côté d'autres produits résultant de la dismutation des radicaux anions intermédiaires (21).

Pontage des bis(triméthylsiloxy)-1,2 alcènes

Nous avons examiné divers réactifs carbéniques.

(*i*) *Le diazométhane* peut donner le méthylène (CH_2:) et conduire aux cyclopropanes par addition aux oléfines (22). Ce réactif avait été utilisé avec succès par Breitbeil *et al.* (12) avec les carbonates de vinylène, mais il s'est avéré inerte sur nos composés.

(*ii*) *Le phényl carbène* (Ph—CH:) peut entre autres méthodes (22) être préparé par la décomposition catalytique de tosylhydrazones (réaction de Bamford–Stevens). *Le phényl carbène ainsi préparé, ajouté au siloxy alcènes précédents, n'a conduit à aucun phényl cyclopropane.* Les substrats sont récupérés accompagnés de goudrons.

(*iii*) L'addition thermocatalysée (Cu, 80° C) du *diazoacétate d'éthyle* (donc du carboéthoxycarbène) au bis(triméthylsiloxy)-1,2 butène-2, *Z*, a conduit, à côté du produit de duplication du carbène, à l'ester cyclopropanique correspondant avec un rendement de 60% (schéma 7).

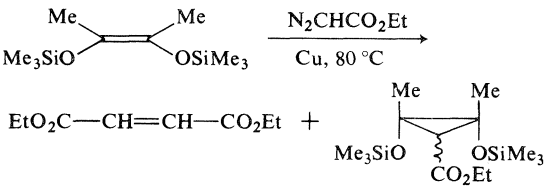

SCHÉMA 7

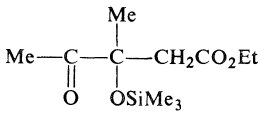
Le cyclopropane obtenu est caractérisé par spectroscopie. La relation *cis* des méthyles est démontrée par l'observation de leur équivalence magnétique (17). Par contre, nous n'avons pas de critère de la configuration relative du groupement ester. Il est important de remarquer que la réaction n'a conduit à aucun produit d'ouverture du cyclopropane, contrairement à la réaction d'addition du même réactif aux monosiloxyalcène (23).

Bien qu'elle soit positive, nous n'avons pas étendu cette réaction aux autres dissiloxyalcènes, notre but n'étant pas de préparer des cyclopropanes trifonctionnalisés. L'hydrolyse de **24** par H_2O–MeOH–C_6H_6 conduit à



(*iv*) *La réaction de Simmons et Smith.* Cette réaction, souvent apparentée aux réactions carbénoïdes (24), conduit à un cyclopropane en traitant une oléfine par de l'iodure de méthylène en présence du couple zinc/cuivre.

Nous l'avons appliquée aux siloxyalcènes des tableaux 2 et 3 et obtenu dans tous les cas les composés cyclopropaniques attendus avec de bons rendements (tableau 4).

En utilisant la technique habituelle (hydrolyse puis précipitation des sels de zinc solubles dans l'éther par du carbonate de sodium), il se forme des produits d'ouverture du cyclopropane obtenu. Le rendement est nettement amélioré si, avant hydrolyse, on remplace l'éther par du pentane dans lequel les sels de zinc sont insolubles. L'extraction est ensuite effectuée au pentane

TABLEAU 2. Les siloxyalcènes obtenus par la réaction de Ruhlmann

Produit de départ	Bis(triméthylsiloxy)-1,2 alcène		Rendement après purification (%) Na	Na–K
H—CO_2Et	Me_3SiO—CH=CH—$OSiMe_3$	**(13)***	10	12
H—CO_2-*i*-Pr			2	10

et les sels de zinc précipités sous forme d'hydroxydes par addition d'eau.

La structure des produits obtenus a été caractérisée par leurs spectres ir et rmn et leurs analyses centésimales. Les isomères *cis–trans* ont pu être séparés par cpv préparative et la stéréochimie caractérisée par rmn (17). Dans tous les cas, l'isomère *Z* est très prépondérant dans le rapport 9/1 vis-à-vis de l'isomère *E*.

Les bis(triméthylsiloxy)-1,2 cyclopropanes sont des liquides incolores stables à l'air et à la chaleur, jusqu'à 200 °C environ. Ils peuvent

TABLEAU 4. Bis(triméthylsiloxy)-1,2 cyclopropanes obtenus par réaction de Simmons et Smith

Composé		Rendement (%) Méthode classique	Méthode modifiée
	**25** *Z*	25	65

être quantitativement transformés en acétates par l'action du bromure d'acétyle. Leurs réactions avec divers autres réactifs (H_2O, ROH, HX, RLi, etc...) ont été étudiées et seront publiées prochainement (25).

Conclusions

Il est vérifié que les β-dicétones et les β-cétoesters non énolisables fournissent sous l'action du sodium dispersé ou de l'alliage Na–K dans l'éther des dérivés cyclopropanedioliques à côté d'autres produits issus des radicaux-anions intermédiaires qui limitent l'intérêt pratique de cette méthode du fait de la difficulté de séparation des produits.

Par contre, la réaction de Simmons et Smith appliquée aux bis(triméthylsiloxy)-1,2 alcènes s'est avérée être une bonne voie d'accès à ce type de composés et constitue sans doute actuellement, la méthode de choix pour préparer les dérivés de cyclopropanediols.

Partie Expérimentale

Les spectres rmn ont été enregistrés dans CCl_4 sur appareil fonctionnant à 60 MHz. Tous les déplacements chimiques sont donnés en $\delta \times 10^6$, sauf précision contraire. Les spectres ir sur Perkin-Elmer 227.

Substrats

1, **2**, **3**, **4**, **7** et **8** ont été obtenus par diméthylation des dicétones énolisables selon réf. 26; **5**, **6** et **10** à partir des èneamines selon réf. 27; **9**, selon réf. 28 suivi de méthylation.

*Réduction par $Na–Et_2O$ ou $Na–K–Et_2O$ (mode opératoire type: cas de **1**)*

Na–K est obtenu en chauffant un mélange 1:1 en poids de Na et de K. Dans un tricol équipé d'un réfrigérant, d'un agitateur et d'une ampoule à brome, maintenu sous azote sec et exempt d'oxygène, on introduit 0.5 mol de sodium dispersé dans 300 ml d'éther anhydre. A reflux d'éther on ajoute goutte à goutte un mélange de 0.5 mol de TMCS et de 0.25 mol de dicétone. On maintient ensuite l'agitation pendant 5 h à température ordinaire, on filtre rapidement et distille après évaporation de l'éther.

De nombreux essais ont été effectués. Dans tous les cas, le composé dicarbonylé est totalement consommé au bout de quelques heures.

Dans le cas **1**, la distillation conduit à deux fractions A et B (A n'est pas obtenue si on opère avec un excès de sodium).

Fraction A (54–58 °C/4 torr)

Deux produits sont séparés par cpv et identifiés.

A_1' Me—C(=O)—$C(Me)_2$—$CH(OSiMe_3)$—Me: ir 1700, 1250, 830 cm^{-1}; rmn 0.05 (s, 9H, $SiMe_3$), 0.98 (d, 3H, J = 6 Hz, CH_3—CH), 3.87 (q, 1H, J = 6 Hz, CH—CH_3), 2.00 (s, 3H, CH_3—CO), 1.00 (s, 6H, Me_2). *Anal.* calc.: C 59.40, H 10.89, Si 13.86; trouvé: C 61.60, H 10.02, Si 13.49.

A_2': Me—C(=O)—$C(Me)_2$—$C(OSiMe_3)$=CH_2: ir 3125, 1720, 1625, 1250 et 850 cm^{-1}; rmn 0.19 (s, 9H, $SiMe_3$), 1.12 (Me_2C), 2.00 (CH_3CO), 252 et 245 Hz (J = 2 Hz, CH_2=). *Anal.* calc.: C 60, H 10, Si 14; trouvé: C 60.14, H 10.34, Si 13.74.

Fraction B (65–70 °C/2 torr)

La cpv permet de distinguer six produits qui sont séparés par cpv préparative en plusieurs temps (Apiezon 20 pieds).

1*a*: 20%; ir 1250 cm^{-1}; rmn *cf* réf. 18.

1*b*: 10%; ir et nmr (voir **1***a*). *Anal.* calc.: C 56.93, H 10.94, Si 20.43; trouvé: C 57.30, H 10.90, Si 20.08.

Diacétate *E*: rmn 1.09 (s, Me_2C), 1.39 (s, *Me*-CO(CH_3)—), 1.95 (s, Me—CO—).

Spectre de masse (réalisé par M. Pechiney au laboratoire de Chimie Structurale Organique d'Orsay): faible pic à 114 (PM); pic important à *m/e* 171 (214 − 43, correspondant à la perte de CH_3CO^+); pic important à *m/e* 154 (fragmentation de MacLafferty: perte de CH_3CO_2H); pic important à *m/e* 139 (perte d'un CH_3); pics importants à *m/e* 129, 112, 97, 87 et 69 (interprétables par pertes de cétènes et de méthyle).

1*c meso*: 15%; ir 1250 cm^{-1}; rmn *cf.* réf. 18. *Anal.* calc.: C 56.52, H 11.59, Si 20.28; trouvé: C 56.77, H 11.67, Si 20.36.

1*c dl*: 5%; ir 1250 cm^{-1}; rmn *cf.* réf. 18.

1*d*: ir 1255, 1610, 3115 cm^{-1}; rmn 0.2 ($SiMe_3$), 1.15 (Me_2C), 242.5 et 237.5 (J = 1.5 Hz, H_2C). *Anal.* calc.: C 57.35, H 10.29, Si 20.58; trouvé: C 58.10, H 9.90, Si 19.87.

1*e*: ir 3100, 1610, 1250, 830 cm^{-1}; rmn 0.12 et 0.25 ($SiMe_3$), 0.91 et 1.01 (Me_2C), 1.00 (*Me*—CH, J = 6.5 Hz), 3.91 (*CH*—Me, J = 6.5 Hz), 244.5 et 235.5 Hz (=CH_2), J = 1.6 Hz. *Anal.* calc.: C 56.93, H 10.94, Si 20.43; trouvé: C 57.65, H 11.03, Si 20.18.

Nous ne détaillerons pas les résultats obtenus avec **2** et **3** qui sont en tous points identiques à ceux obtenus à partir de **1** et qui ne souffrent d'aucune ambiguïté.

Le dérivé cyclopropanique obtenu à partir de **4** est aisément identifié: **4***a*: ir 1250 cm^{-1}; rmn 0.05 ($SiMe_3$), 1.09 et 1.4 (Me, Me>C non équivalents, d'où la configuration *cis*, *cf.* réf. 18), 7.35 (massif phényl).

Réduction de **5**: Les deux isomères **5***a* et **5***b* sont séparés. Ils sont dans des proportions 75:25 et présentent les mêmes caractéristiques ir; rmn du produit majoritaire 0.05 et 0.03 ($SiMe_3$), 0.64 et 1.10 (Me_2C), 3.10 (H), 7.2 à 7.4 (Ph); rmn du produit minoritaire 0.05 et 0.30 ($SiMe_3$), 0.81 et 1.30 (Me_2C), 3.28 (H), 7.1 à 7.6 (Ph).

Là encore nous n'avons pas de critère sûr de configuration. Un raisonnement basé sur les déplacements chimiques (effet d'un Ph β-*cis* sur un proton cyclopropanique, effet d'un $OSiMe_3$) milite en faveur de la configuration *cis* pour le composé majoritaire.

Réduction de **6**: nous n'avons pas pu séparer les deux isomères **6***a* et **6***b*. Cependant la rmn du mélange permet à partir des pics du proton H d'évaluer les proportions à 60:40; rmn du mélange 0.05 ($SiMe_3$), 0.90 et 0.95 (Me_2C), 1.25 (Me), 2.45 et 2.82 (H de chaque isomère).

11: ir 1700, 1250, 1160, 830 cm^{-1}; rmn 0.05 ($SiMe_3$), 1.00 (Me_2C), 2.00 (MeCO), 3.4 (CH_2).

12: ir 1250, 1185 et 830 cm^{-1}, rmn 0.04 ($OEtMe_3$), 0.70 (Me_2C), 0.97 (*Me*—CH, d, J = 6.6 Hz), 3.65 (q, H), 3.62 (spectres AB, —CH_2—).

Réduction de **7**: nous n'avons pu séparer les deux isomères **7***a* et **7***b* dont le mélange présente en ir 1250 et 850 cm^{-1}; rmn 0.13 ($SiMe_3$), 0.85 et 0.90 (Me_2C), 1.2 (Me), 3.6 (CH_2), 1.05 (CH_3CH_2).

7*c*: ir 1700, 1250, 830 cm^{-1}; rmn 0.15 ($SiMe_3$), 1.2 (CH_3CH_2), 1.50 et 1.59 (Me, Me>=), 3.8 (CH_2).

Réduction de **9**: les deux isomères sont séparés par cpv préparative. Ils sont dans les proportions 80:20 et présentent les mêmes caractéristiques ir; rmn du produit majoritaire 0.05 ($SiMe_3$), 0.90 (Me), 1.1 à 1.9 (cycle), 2.7 (H); rmn du produit minoritaire 0.05 ($SiMe_3$), 1.00 (Me), 1.4 à 1.8 (cycle), 2.8 (H).

Réduction de **10**: la cpv sur colonne Apiezon montre quatre produits. Les produits cyclopropaniques **10***a* et **10***b* sont séparés sur DEGS 5 pied à 90 °C. *Anal.* calc.: C 60, H 10.66, Si 18.66; trouvé: C 59.63, H 11.28, Si 18.54; rmn du produit majoritaire 0.05 ($SiMe_3$), 0.82 (Me ang.), 1.16 (MeCO), 1.2 à 2 (cycle); rmn du produit minoritaire 0.05 ($SiMe_3$), 0.85 (Me ang.), 0.98 (MeCO), 1.2 à 2.2 (cycle).

Tous les produits siloxylés non cyclopropaniques obtenus ont été hydrolysés et les diols, cétones ou

dicétones obtenus comparés à des échantillons authentiques.

Les bissiloxyalcènes symétriques sont préparés par réduction des esters selon réf. 14 en utilisant comme agent réduction du sodium dispersé ou Na–K.

13: p éb 45–55 °C/12 torr; ir 3050, 1660, 1250, 840 cm^{-1}; rmn 0.05 (s, 9H), 5.5 (s, 1H).

14: p éb 65–72 °C/10 torr; ir 1660, 1250, 840 cm^{-1}; rmn 0.08 (s, 18H), 1.7 (s, 6H).

15: p éb 85–88 °C/12 torr; ir 1682, 1250, 830 cm^{-1}; rmn 0.1 (s, 18H), 0.95 (t, 6H), 1.95 (q, 4H).

16: p éb 88–89 °C/12 torr; ir 1255, 835 cm^{-1}; rmn 0.08 (s, 18H), 0.95 (d, 12H), 1.90 (H, 2H).

18: p éb 92 °C/6 torr; ir 1690, 1250, 830 cm^{-1}; rmn 0.1 (s), massifs entre 1.55 et 2.

19: p éb 90 °C/8 torr; ir 1680, 1240, 840 cm^{-1}; rmn 0.12 (s, 18H), massifs entre 1.6 et 2.2 (6H).

17: p éb 90–92 °C/9 torr; ir 1672, 1250, 830 cm^{-1}; rmn 0.1 (s, 18H), massifs à 1.5 et 2.

Les bissiloxyalcènes dissymétriques sont obtenus par la même méthode à partir des α-dicétones.

20: p éb 80–82 °C/3 torr; ir 3100, 3000, 1640, 1600, 1250, 835 cm^{-1}; rmn 0.02 (s, 9H), 0.22 (s, 9H), 6.5 (s, 1H), 7–7.4 (s, 5H).

21: p éb 80–84 °C/16 torr; ir 3090, 1670, 1250, 845 cm^{-1}; rmn 0.005 (s, 18H), 0.98 (s, 9H), 5.6 (s, 1H).

22: p éb 86–88 °C/11 torr; ir 1680, 1250–1255, 830–840 cm^{-1}; rmn 0.07 (s, 18H), 0.9 (3H), 1.6 (3H), 1.9 (2H).

23: p éb 85–89 °C/5 torr; ir 0.1 (s, 18H), 0.95, 1.5, et 1.95.

Les α-dicétones ont été obtenues par la méthode de Riley.

Carbéthoxy-1 bissiloxy-1,2 cyclopropane **24**: à 15 g de **14** (0.067 mol), additionné d'1 g de cuivre en poudre contenu dans un ballon tricol maintenu sous courant d'azote, muni d'un réfrigérant, d'une ampoule à brome et d'un agitateur magnétique, on ajoute lentement 7.6 g de diazoacétate d'éthyle dilué dans 8 g de cyclohexane. Le ballon est maintenu à 80 °C. Après filtration, la distillation permet de récupérer 11 g de produit; p éb 93–100 °C/0.7 torr (60%). La séparation en cpv (Apiezon 10 pieds) fournit 2 isomères de **24** présentant le même spectre infrarouge: 3010 (ép.) 1725, 1255, 830 cm^{-1}; rmn de **24***A* (55%) à 0.05 (s, 18H), 1.2 (t, 3H), 1.5 (s, 6H), 1.75 (s, 1H), 4.1 (q, 2H); rmn de **24***B* (45%) 0.1 (s, 18H), 1.2 (t, 3H), 1.75 (s, 6H), 2.3 (s, 1H), 4.1 (q, 2H).

L'hydrolyse de ce composé dans le mélange H_2O–MeOH–C_6H_6, fournit essentiellement (par séparation cpv Apiezon L 15%) un produit présentant en ir des bandes à 1740–1710, 1250 et 830 cm^{-1}; en rmn 0.1 (s, 9H), 1.2 (t, 3H), 1.27 (s, 3H), 2.1 (s, 3H), 2.6 (AB, J_{AB} = 16 Hz, δ_A = 90 Hz, δ_B = 114.7 Hz), 4.4 (q, 2H); en accord avec la formule proposée dans le texte.

Réaction de Simmons et Smith

A 17 g de couple Zn–Cu préparé selon Simmons–Smith (24) ou de couple Zn–Ag selon Conia et ses collegues (29) dans 80 ml d'éther anhydre, on ajoute suffisamment de CH_2I_2 pour faire démarrer le couple maintenu sous courant d'azote. On ajoute ensuite 0.1 mol de bissiloxyalcène, puis l'iodure de méthylène de façon à maintenir un bon reflux. On maintient ensuite ce reflux pendant 18 h. On élimine la majeure quantité d'éther et on ajoute 100 ml de pentane. Puis on ajoute goutte à goutte 10 ml d'eau, on filtre et on extrait au pentane. La phase organique est ensuite lavée à l'eau, jusqu'à ce que l'hydroxyde de zinc ne précipite plus. Après sèchage au sulfate de sodium, on élimine le solvant et on distille.

25: p éb 69–72 °C/5 torr; n_D^{20} 1.4182. *Anal.* calc.: C 53.66, H 10.57, Si 22.75; trouvé: C 52.89, H 10.28, Si 22.28. **25***Z*: ir 3088, 1255, 1025, 840 cm^{-1}; rmn 0.05 (s, 18H), 1.25 (6H); spectres AB δ_A = 14.7 Hz, δ_B = 45.3 Hz, J_{AB} = 6 Hz. **25***E*: ir 3075, 1255, 1025, 840 cm^{-1}; rmn 0.07 (s, 18H), 0.85 (3H), 1.15 (3H), 0.5 (2H).

Redox properties of 2,3,7,8-tetramethoxyselenanthrene: a charge-transfer donor

A. W. ADDISON, T. H. LI, AND L. WEILER

Chemistry Department, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received September 2, 1976

A. W. ADDISON, T. H. LI, and L. WEILER. Can. J. Chem. **55**, 766 (1977).

The redox properties of 2,3,7,8-tetramethoxyselenanthrene and 2,3,7,8-tetramethoxythianthrene have been studied in solution in order to compare their potential applicability as charge-transfer donors. The selenium compound is the weaker reductant, yielding a stable radical cation and a reactive dication, the former dimerizing in solution. Electron spin resonance and visible absorption spectra of the stable species were obtained. The 1:1 charge-transfer complexes of the above donors with tetracyanoquinodimethane are found to be insulators.

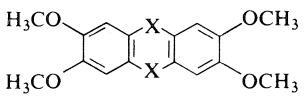
A. W. ADDISON, T. H. LI et L. WEILER. Can. J. Chem. **55**, 766 (1977).

On a étudié les propriétés rédox du tétraméthoxy-2,3,7,8 sélénanthrène et du tétraméthoxy-2,3,7,8 thianthrène; ces études ont été effectuées en solution de façon à comparer les possibilités d'application de ces composés comme donneurs de transfert de charge. Le composé contenant le sélénium est un réducteur plus faible conduisant à un cation radical stable et un dication réactif; le premier se dimérise en solution. On a obtenu les spectres rpe et d'absorption dans le visible des espèces stables. On a trouvé que les complexes de transfert de charge 1:1 des donneurs mentionnés plus haut avec le tétracyanoquinodiméthane peuvent agir comme des isolants.

[Traduit par le journal]

Introduction

Intensive current interest (1) in the field of organic conductors and in the chemistry of their component donor and acceptor species has led to the development of selenium analogs (2–4) of an as yet limited number of previously known organosulfur donors. The availability of HOMO electrons for donation is reflected by the oxidizability of a molecule, and consequently the redox properties of the sulfur and selenium-based donors (5–7), as well as of acceptors (5, 8), is receiving considerable attention, not only because of the relationships (5) between redox potentials and CT complex conductivity, but also because electrosynthesis has proved convenient in these systems (9). Our laboratories are engaged in the redox chemistry of both mononuclear and binuclear metal and pseudometal centres. We report here aspects of the redox, solution, and solid-state chemistry of 2,3,7,8-tetramethoxyselenanthrene **1**, the selenium analogue of the thianthrene **2**.



1 X = Se
2 X = S

Experimental[1]

Ultraviolet, visible, and near-ir spectra were obtained on a Cary-14 spectrophotometer, and esr spectra on a Varian E3 spectrometer, operating in the *X*-band, and calibrated with a ^{1}H nmr probe and DPPH.[1]

Electrochemistry was performed with a PAR-173 potentiostat, incorporating a PAR-176 *i*/*E* converter. A platinum sphere electrode (*ca.* 0.5 mm radius) and a Beckman rpe[1] were used as working electrodes in the three-electrode cell. The nonaqueous reference electrodes used were Ag(s)/$AgClO_4$ (0.01 *M*), TEAP[1] (0.1 *M*), CH_3CN or Ag(s)/$AgClO_4$ (0.01 *M*), TEAP (0.1 *M*), CH_3NO_2 half cells, their potentials being positive of the sce at 25 °C by 0.30 V and 0.74 V respectively.

All potentials reported herein are referred to the sce. All polarography, voltammetry, and coulometry was performed under nitrogen, in nitromethane (distilled off 4 Å molecular sieves under nitrogen), or in acetonitrile (distilled off phosphorus(V) oxide under nitrogen) and, except where noted, at 25.0 ± 0.2 °C. Supporting electrolyte was TEAP (from Eastman Kodak, recrystallized from H_2O, or from G. F. Smith) or tetraethylammonium trifluoromethanesulfonate,[1] prepared according to Rousseau *et al.* (10), both being dried *in vacuo* over phosphorus(V) oxide. Trifluoroacetic anhydride (Matheson, Coleman and Bell) was used as received.

[1]Abbreviations: DPPH, diphenylpicrylhydrazyl radical; TEAP, tetraethylammonium perchlorate; TEFS, tetraethylammonium trifluoromethanesulfonate; TFAA, trifluoroacetic anhydride; TPFS, tetra(*n*-propyl) ammonium trifluoromethanesulfonate; rpe, rotating platinum electrode; sce, saturated calomel electrode; TCNQ ,7,7,8,8-tetracyanoquinodimethane.

For simultaneous spectrophotometry and electrochemistry, a simple dual cell was constructed, incorporating a 4 cm optical path connected to an approximately 50 ml electrochemical cell by all-pyrex tubing. The solution was circulated throughout the cell by the action of a teflon-coated magnetic stirring bar.

The electrical resistivity of single crystals was measured using a two-probe technique (11). 2,3,7,8-Tetramethoxyselenanthrene **1** was prepared according to the method of Weiss *et al.* (12), and the 2,3,7,8-tetramethoxythianthrene **2** was prepared according to the method of Fries *et al.* (13). TCNQ[1] was prepared by the method of Acker and Hertler (14). All compounds were vacuum sublimed before use and gave acceptable elemental analyses. The lustrous dark blue complexes of **1** and **2** with TCNQ were prepared by adding hot concentrated solutions of the donor in acetonitrile to a hot concentrated solution of TCNQ. The complexes crystallized on cooling and they could be recrystallized from acetonitrile. The 1:1 nature of the complexes was corroborated by uv and esr spectra of acetonitrile solutions of the complexes and the chemical analyses. *Anal.* calcd. for $C_{28}H_{20}N_4O_4Se_2$ (**1**–TCNQ): C 52.99, H 3.15, N 8.83; found: C 53.12, H 3.00, N 8.60. *Anal.* calcd. for $C_{28}H_{20}N_4O_4S_4$ (**2**–TCNQ): C 62.20, H 3.73, N 10.36; found: C 62.02, H 3.46, N 10.20.

Results and Discussion

Compound **2** is known (15) to undergo two one-electron oxidation processes in solution, in a fashion similar to its unsubstituted analogue (16), and a third oxidation process has also been observed (15). Indeed, under our experimental conditions, polarography of **2** (rpe) at 1–3 $\times 10^{-4}$ *M* in acetonitrile containing *ca.* 1% TFAA (10, 17) and 0.1 *m* TEFS[1] as supporting electrolyte yielded two oxidation waves of equal height, with $E_{1/2}$-values of +0.53 and +0.88 V *vs.* sce. These two oxidation steps have been shown previously (17) in the case of **2** to be electrochemically reversible, one-electron processes, yielding the dithianthrene cation radical $\dot{\mathbf{2}}^+$ and the dication $\mathbf{2}^{2+}$, successively. Under the same conditions, polarography of the selenium compound **1** at the rpe, also yielded two well-defined oxidation waves of essentially equal height with half-height potentials of +0.90 and +1.21 V *vs.* sce.

This contrasts with a recent report (4) on the redox properties of the selenanthrene **1**, in which a single irreversible oxidation at +0.90 V was observed. No definite reason for the discrepancy can be given, as the paper by Wheland and Gillson (4) gives no details as to experimental conditions under which voltammetry was performed. However, we suspect that the species formed by the oxidation process at +0.90 V reacted rapidly with a nucleophile in their solutions, and the likelihood of the reactant's being trace water will emerge from the discussion below. It is to be noted also that a third oxidation wave was observed for neither compound **1** nor **2** in the nitromethane/TFAA solvent system below +1.2 V. A third oxidation step was observed for the selenanthrene **1** in acetonitrile/TEFS/TFAA only at a rotating gold disc electrode. Its potential (*ca.* +1.5 V) was not reproducible, although it was of the same height as the other two waves.

Diffusion control of the limiting oxidative current at the rpe for the first two oxidation steps of both the sulfur and selenium heterocycles was evidenced by excellent linearity (18) of the *i vs.* $\omega^{1/2}$ plot from 400 to 3000 rpm and leads to a value of $n = 1$ for each step, consistent with diffusion coefficients, calculated from the first wave, which are essentially the same as one another, at $D = 2.0\ (\pm 0.8) \times 10^{-5}$ cm^2 s^{-1}.

Cyclic voltammetry (platinum bead electrode) of the selenanthrene in CH_3NO_2 showed that the first two oxidation waves had peak-to-peak potential separations of 60 mV at a scan rate of 0.1 V s^{-1}, consistent with one-electron Nernstian processes (19). At scan rates of this order, the peak current ratio, i_c/i_a, was essentially unity for the first oxidation process, as expected for a chemically reversible system. However, the second oxidation process had $i_c/i_a < 0.95$ at 1.0 V s^{-1}, and the ratio decreased with decreasing scan rate, indicating decay of the expected dication product in solution. Thus, attempts to electrosynthesize this two-electron oxidation product resulted in its complete decomposition on the time scale of the electrolysis (several minutes) and bleaching of the solution.

The third oxidation process could be observed more readily in the absence of TFAA, and was irreversible at scan rates up to 4 V s^{-1} under all conditions.

In the case of the thianthrene **2**, one-electron oxidative coulometry at a platinum gauze anode (in nitromethane/TEFS) gave the green solution of the previously reported (15) radical cation $\dot{\mathbf{2}}^+$ (Table 2). Further oxidation at 150 mV positive of the second $E_{1/2}$ resulted in the consumption of another 0.93 Faraday per mol, yielding a bright blue solution of the dication $\mathbf{2}^{2+}$. The absorbance (Table 2) decreased gradually in time.

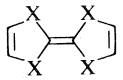
[a]Shoulder; neutral molecules in acetonitrile.
[b]Cations in nitromethane, TEFS.

Controlled potential oxidation of a 1.0 × 10^{-4} *M* solution of the selenanthrene **1** in acetonitrile/TEFS at 160 mV positive of $E_{1/2}$ for the first oxidation wave caused the solution to become bright blue. After 5 half-lives, 0.96 Faraday per mol had been consumed in production of the cation radical $\dot{\mathbf{1}}^+$ and the solution yielded an esr signal, with $g = 2.0246$ and $a_{Se} = 20.7$ G. The spectrum of the radical $\dot{\mathbf{2}}^+$ is a complex pattern at $g = 2.0073$ (20). The *g*-values are similar to those of the analogous radical cations of tetrathiofulvalene **3** (21) and its selenium counterpart **4**, the latter having $g = 2.027$ (22).



3 X = S
4 X = Se

As expected, the effect of methoxyl substituents is to delocalize the spin density on $\dot{\mathbf{1}}^+$, and lower (23) its reduction potential by *ca.* 0.24 V (16) relative to the unsubstituted radical cation ($g = 2.0315$) (24).

The solution's electronic absorption spectrum exhibited two overlapping bands of approximately equal intensity, at 690 and 820 nm (Table 2). This observation was reminiscent of the aggregation observed for the unsubstituted analog of $\dot{\mathbf{2}}^+$ in solution (25). Accordingly, simultaneous electrochemistry and spectrophotometry were carried out. The absorption spectra of increasing concentrations of $\dot{\mathbf{1}}^+$ (acetonitrile, 2% TFAA, 0.1 *M* TPFS, 27 °C), prepared by *in situ* electrooxidation of aliquots of **1** in solution at +785 mV, were obtained. The absorption band at 820 nm was dominant in the 1–20 μ*M* region, but limiting spectra (*i.e.* of the 680 nm or 820 nm species) could not be obtained directly, the former because of solubility limitations (even though the trifluoromethanesulfonate salt is appreciably more soluble than the perchlorate), the latter because of the strong association. Thus, in the above concentration range, where the absorbance of the aggregated

species may, to a first approximation, be considered negligible at 820 nm, the apparent molar absorptivity at 820 nm decreased linearly with concentration, evidencing a dimerization process. If this is written to be comparable with the case of $\dot{\mathbf{2}}^+$, then the equilibrium constant for the process

$$2\dot{\mathbf{1}}^+ + 2CF_3SO_3^- \rightleftharpoons (\mathbf{1}\cdot CF_3SO_3)_2$$

is computed to be approximately 2×10^6, for ε 11 000 at 820 nm for $\dot{\mathbf{1}}^+$. Further aggregation may also occur. This equilibrium is reflected also in a concentration dependence of the $E_{1/2}$ values (Table 1), and presumably contributes to the dependence of the $E_{1/2}$-values on solvent and supporting electrolytes.

All solutions of the radical cation $\dot{\mathbf{1}}^+$ reacted with water, being bleached immediately water was added, whereas the sulfur radical $\dot{\mathbf{2}}^+$ had a half-life of a few minutes. It is not surprising that the use of TFAA as a dehydrating agent (17) is important for preparation of $\dot{\mathbf{1}}^+$ and $\mathbf{2}^{2+}$ when they are in the 10^{-4} *M* range. It is also expected, therefore, that $\mathbf{1}^{2+}$ and $\mathbf{2}^{2+}$ will be even more susceptible to nucleophilic attack than the monocations, and thus decay more rapidly in solution. It is noteworthy that TFAA addition readily extends the potential range of reagent nitromethane/TEAP for anodic electrochemistry (to *ca.* +2.0 *vs.* sce).

The relationship between the electrochemical properties of **1** and **2** closely parallels that (6) between the fulvalenes **3** and **4**, in that selenium monocation is a stronger oxidant in solution than the sulfur analogue. The differences between the two oxidation potentials of the selenium compounds are less than for their sulfur analogues. Thus, the tendency of $\dot{\mathbf{1}}^+$ to redox disproportionate in solution is slightly greater than that of $\dot{\mathbf{2}}^+$, and a product of the process will be the relatively unstable dication.

The single crystal resistivity value (11) for the TCNQ complex of the selenanthrene **1** is $1.3 \pm 0.3 \times 10^8$ ohm cm, and for the thianthrene–TCNQ adduct, $1.1 \pm 0.3 \times 10^8$ ohm cm. Both materials are therefore insulators. It is possible that the packing geometry in the complexes is unfavourable for electron transfer. This could be contributed to by steric interactions of the methoxyl groups, if bent out of the rings' planes, or by the bent (domed) nature of the heterocyclic rings. In addition, we have been unable to detect an esr signal in either of the solid complexes of **1** or **2** with TCNQ, indicating very few unpaired spins, and hence very little net electron transfer in the ground state of the CT interactions.

The effect of methoxyl substitution appears to be greater (0.34 V) for the sulfur heterocycle than for the selenium system (0.24 V), to the extent that the relative reduction potentials of the sulfur and selenium cation radicals are reversed by methoxylation. This increased sensitivity of the sulfur compound may relate to more effective participation of the relatively lower energy orbitals of the sulfur in the ring conjugation.

Conformational and configurational analysis of hydrocarbon chains based on time-averaged carbon-13 chemical shifts

HELMUT BEIERBECK AND JOHN K. SAUNDERS
Département de Chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received August 30, 1976

HELMUT BEIERBECK and JOHN K. SAUNDERS. Can. J. Chem. **55**, 771 (1977).

The conformations of saturated hydrocarbon chains are analysed by a least-squares fit of calculated to observed time-averaged carbon-13 chemical shifts. The calculated resonances are the sums of products of conformer resonances and conformer probabilities. The conformer shieldings are derived with predictive parameters developed earlier for conformationally well defined systems. The conformer probabilities are taken to be products of rotamer probabilities. The rotamer probabilities are variables in the analysis.

HELMUT BEIERBECK et JOHN K. SAUNDERS. Can. J. Chem. **55**, 771 (1977).

On a analysé les conformations de chaînes hydrocarbonées saturées par un ajustement, par la méthode des moindres carrés, des valeurs calculées et observées pour les déplacements chimiques du carbone-13 moyennés dans le temps. Les résonances calculées sont les sommes des produits des résonances d'un conformère et des probabilités de ce conformère. On peut obtenir les blindages d'un conformère à partir des paramètres qui permettent de les prédire et qui ont été développés antérieurement pour des systèmes qui sont conformationnellement bien définis. On fait l'hypothèse que les probabilités des conformères sont les produits des probabilités des rotamères. Les probabilités des rotamères sont des variables dans cette analyse.
[Traduit par le journal]

The carbon-13 resonances of saturated hydrocarbon chains at ambient temperatures are the sums of the chemical shifts in all molecular conformations, weighted by the probability of occurrence of each conformation. If the conformer resonances may be measured, or calculated to a good approximation, the conformer populations may be derived by fitting calculated to observed time-averaged carbon-13 resonances. Since conformational analysis is a prerequisite for the determination of the configurations of mobile systems, the derivation of the conformational probabilities from time-averaged carbon-13 resonances also allows the determination of configuration in asymmetric hydrocarbon chains.

Results

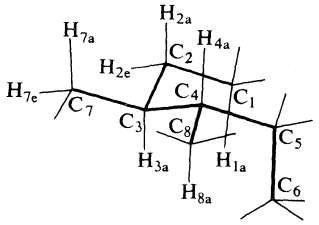
The method was developed and tested with the hydrocarbon resonances of Lindeman and Adams (1). Conformer resonances and probabilities were derived in the following way.

Conformer Chemical Shifts

The conformer resonances were derived with a set of substituent parameters described previously (2, 3). The numerical values for the parameters were treated as variables in the analysis. The derivation of the resonances for primary, secondary, tertiary, and quaternary carbons is based on four separate reference values, since α-carbon substituent effects are nonadditive. The resonances of the primary, secondary, tertiary, and quaternary carbons in ethane, propane, isobutane, and neopentane, respectively, served as starting estimates for these references. Two substituent parameters, HC and CC, account for the deshielding effect of β-carbons. A shift increment HC is associated with every 1,3-diaxial hydrogen–hydrogen interaction introduced by a β-carbon. An increment CC is associated with every carbon–carbon *gauche* interaction. Previously derived parameter values (2, 3) served as starting estimates for HC and CC. No γ-carbon parameter is required. An incoming *anti* γ-carbon does not cause any significant displacement and the upfield shift associated with the introduction of a *gauche* γ-carbon is due to the disappearance of the 1,3-diaxial hydrogen interaction, *i.e.* the elimination of an HC increment (3). The only δ-parameter which is required is a deshielding increment δ(C) associated with *syn*-axial δ-carbon interactions (4, 5). Its starting estimate was derived from methyl resonances in terpenoids. The definitions and optimized values of the structural parameters are found in Table 1.

The derivation of the carbon resonances for one of the *d,l*-3,4-dimethylhexane conforma-

tions may serve to illustrate the application of these parameters. The conformer is superimposed onto cyclohexane and the hydrogens are labelled axial and equatorial. The hydrogens and carbons are engaged in the following interactions.



HC Interactions

C(1) → H(1a)—H(3a)
C(2) → H(2a)—H(4a), H(2a)—H(7a), H(2e)—H(7e)
C(3) ← H(3a)—H(1a)
→ H(3a)—H(8a)
C(7) ← H(7a)—H(2a), H(7e)—H(2e)
→ H(7a)—H(4a)

CC Interactions

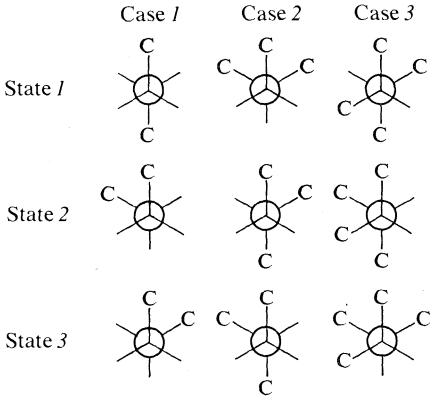
δ(C) Interactions

C(1) → C(1)—C(5)
C(2) —
C(3) —
C(7) —

Only C(1), C(2), C(3), and C(7) need to be considered for reasons of symmetry. The interactions have been divided into two groups, backward and forward along the chain, for reasons which will be explained in the section defining conformer probabilities.

Rotamer Populations

The contributions of any given conformation to the time-averaged carbon resonances are proportional to the fraction of the time that the molecule adopts that conformation. These conformer probabilities are taken to be products of rotamer probabilities. It is assumed that the energies of the rotational states about a given bond are solely a function of the atoms directly attached to the terminal carbons of that bond. If one of these carbons is primary, all three rotational states are obviously equivalent. If one of the terminal carbons of the bond is quaternary, the three rotamer populations are again assumed to be equal, whether there is a threefold axis of symmetry (*tert*-butyl group) or whether the three carbons are nonequivalent (as in 3,3-dimethylhexane). Three possibilities remain: (*1*) Both carbons are secondary. (*2*) One carbon is secondary and the other is tertiary. (*3*) Both carbons are tertiary.



The populations of the three unique rotamers (state *1*) are designated p_{11}, p_{21}, and p_{31}. Since it is assumed that only the directly bonded atoms affect the energies of the rotational states, we have

$$p_{i2} = p_{i3}$$

and

$$p_{i2} = (1 - p_{i1})/2$$

The populations of the three unique rotamers, p_{11}, p_{21}, and p_{31}, are the three remaining variables in the analysis, for which starting estimates of 1/3 were used. The optimized values are included in Table 1.

Conformer Populations

The probability of finding a molecule or molecular segment in a given conformation is taken to be the product of the probabilities of finding the individual carbon–carbon bonds in their corresponding rotational states. There are two ways to derive all conformer contributions. For short hydrocarbon chains one may simply generate all molecular conformations and derive all carbon resonances in each conformation. For longer chains one needs to deal only with the molecular segment containing the carbon in question, because only the rotational states of the closest bonds affect the carbon resonances.

TABLE 1. Definition of the structural parameters on which the present analysis is based, and their numerical values[a]

Parameter definitions	Comparison			This work

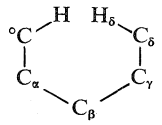
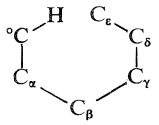
[a]The reference chemical shifts are given in ppm from TMS and the substituent parameters in ppm. The resonances in column *1* and the parameter values in columns *2* and *3*, derived from carbon resonances in rigid systems, were included for comparison. Column *1*, Observed resonances in ethane, propane, isobutane, and neopentane (9). Column *2*, Parameter values derived from resonances in decalin derivatives found in the literature (10). Column *3*, Parameter values derived from resonances in steroids and terpenoids (to be published). Column *4*, Parameter values derived from the data in Table 4, without restraints on population variables. Column *5*, Parameter values derived from the data in Table 4, and the restraint $0 \leq p_{ij} \leq 1$. Column *6*, Standard errors for the parameters in column *5*.

The conformations of the molecular segments along the four tetrahedral directions are assumed to be independent. Only unsubstituted and methylated chains are considered here. Therefore, only the conformations of molecular segments in at most two directions, backward and forward along the chain, are required.

In order to establish the presence or absence of a δ-carbon in a *syn*-axial position it is necessary to define the rotational states of at least the three closest bonds. A definition of the rotational state of the fourth bond would also be required in order to establish whether a δ-hydrogen points toward °C, *i.e.* to distinguish δ-interactions from unrealistic ε-interactions. However, the combination of rotational states leading to such an ε-arrangement is usually so improbable that the definition of the three-bond segment seemed sufficient. We will return to this point in the Discussion section.





Summation over Conformer Contributions

The summation over the conformer contributions to the carbon resonances in the 3,4-dimethylhexane isomers may serve as illustration. For these six-carbon chains it would have been simpler to generate all molecular

TABLE 2. Calculation of HC, CC, and δ(C) conformer contributions to the averaged C-13 resonances of C(1), C(2), C(3), and C(7) of *d,l*-3,4-dimethylhexane[a]

	[HC + CC + δ(C)]		×	Conformer population	=	Conformer contribution
C(1)	→	(4.57+0.00+3.55)	×	(0.500×0.581)	=	2.359
C(2)	→	(13.71+1.23+0.00)	×	(0.500×0.581×0.000)	=	0.000
C(3)	←	(4.57+1.23+0.00)	×	(0.500)	=	2.900
	→	(4.57+2.46+0.00)	×	(0.581×0.000)	=	0.000
C(7)	←	(9.14+0.00+0.00)	×	(0.500)	=	4.570
	→	(4.57+0.00+0.00)	×	(0.581×0.000)	=	0.000

[a]The conformation is defined by the figure in the text. The reference values are added after summation over HC, CC, and δ(C) contributions of all conformations. The reference values and calculated resonance averages are in ppm from TMS.

conformations and count the interactions in each conformer. However, this example will be used to demonstrate the general procedure of dealing only with three-bond segments. Only bonds C(2)—C(3), C(3)—C(4), and C(4)—C(5) give rise to nonequivalent rotational states. The conformations of the following molecular segments have to be defined.

Segment	Probability
C(1) → C(1)—C(4)	$p_{22} \times p_{31}$
C(2) → C(2)—C(5)	$p_{22} \times p_{31} \times p_{21}$
C(3) ← C(1)—C(3)	p_{22}
→ C(3)—C(6)	$p_{31} \times p_{21}$
C(7) ← C(1)—C(7)	p_{22}
→ C(7)—C(5)	$p_{31} \times p_{21}$

The resonance of C(1) receives contributions from 3 × 3 conformations, since bonds C(2)—C(3) and C(3)—C(4) occur in segment C(1)—C(4). In the conformation defined at the beginning of the Results section bond C(2)—C(3), type *2*, is in rotational state *2* and bond C(3)—C(4), type *3*, is in state *1*. This conformation of segment C(1)—C(4) therefore occurs with probability $p_{22} \times p_{31}$. The combination of the rotational states of the three bonds in segment C(2)—C(5) gives rise to 3 × 3 × 3 conformational contributions to the C(2) resonance. Bond C(4)—C(5), type *2*, is in state *1* and this conformation of segment C(2)—C(5) therefore occurs with probability $p_{22} \times p_{31} \times p_{21}$. Both C(3) and C(7) receive contributions from 3 conformations in the first part of the chain, and from 3 × 3 conformations in the second part. In the example above the probabilities of occurrence are p_{22} and $p_{31} \times p_{21}$, respectively. These products of rotamer populations are listed above with the corresponding chain segments. The derivation of the numerical values for the β- and δ-contributions to the C(1), C(2), C(3), and C(7) resonances in the same *d,l*-3,4-dimethylhexane conformation is shown in Table 2. The reference shifts are added after the derivation of the total β- and δ-shift contributions from all conformations.

Table 3 gives the substituent interactions for all carbons and segmental conformations of *meso* and *d,l*-3,4-dimethylhexane. For each segmental conformer four types of interactions are listed, namely the number of 1,3-diaxial hydrogen interactions HC, the number of carbon–carbon *gauche* interactions CC, the number of *gauche* γ-carbons γ(C), and the number of *syn*-axial δ-carbons δ(C). No substituent parameter for *gauche* γ-carbons is required. The number of γ-carbons was included simply because the sum of these four types of interactions is constant for a given chain segment, regardless of the conformation of that segment. For example, C(2) is always engaged in a total of four such interactions along C(2)—C(5). In the first conformation $n_{HC} = 1$, $n_{CC} = 2$, $n_{\gamma(C)} = 1$, and $n_{\delta(C)} = 0$, etc.

The segmental conformations are generated and listed in the tables in the following sequence. In the starting conformation all bonds are in their unique rotational state. In the direction from the lowest to the highest numbered carbon in the segment the last bond is rotated clockwise by 120° and 240°, then the second and finally the first bond. This convention is used whether the carbon under observation is at the beginning or end of the segment. For example, the conformation of segment C(2)—C(5) in the *d,l*-3,4-dimethylhexane example would be the tenth

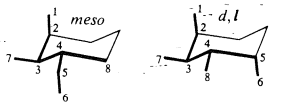
[a]For each segmental conformer four types of interactions are listed, namely the number of 1,3-diaxial hydrogen interactions HC, the number of carbon–carbon *gauche* interactions CC, the number of *gauche* γ-carbons γ(C), and the number of *syn*-axial δ-carbons δ(C). The segmental conformations are generated and listed in the following sequence. In the starting conformation all bonds are in their unique rotational states.



In the direction from the lowest to the highest numbered carbon in the segment the last bond is rotated clockwise by 120° and 240°, then the second, and finally the first bond.

[b]Interactions which lead to shift differences in *meso* and *d,l*-isomers are set in italics. For example, the set *1001* for C(7) occurs with probability $p_{31} \times p_{22}$ in the *meso* isomers (item 3 in row C(7)→) but with probability $p_{32} \times p_{22}$ in the *d,l*-isomers (item 5 in row C(7)→).

conformer generated,

$$9 \times (j - 1) + 3 \times (k - 1) + l$$
$$= 9 \times (2 - 1) + 3 \times (1 - 1) + 1 = 10$$

since the first bond C(2)—C(3) is in state $j = 2$, the second bond C(3)—C(4) in state $k = 1$, and the last bond C(4)—C(5) in state $l = 1$. Therefore the set 3100 of three HC interactions and one CC interaction of C(2) along direction C(2)→C(5) is found in position 10 in row C(2) → of Table 3.

The references, substituent parameters, and rotamer populations in Table 1 were derived with the data set in Table 4. If no constraints were placed on the rotamer parameters, p_{21} was found to be negative. The deviation of p_{21} from the smallest possible value of zero is slightly larger than the standard error for that parameter. The value of p_{21} was set equal to zero and the remaining parameters were redetermined. Both parameter sets are shown in Table 1. Table 4 also contains quaternary carbon resonances, even though the resonances of quaternary carbons are taken to be independent of conformation for reasons of symmetry and because they are only engaged in carbon–carbon *gauche* interactions. The quaternary carbon resonances were included in the analysis because substituent parameters and reference shifts were also optimized. The results of analyses of heptane and

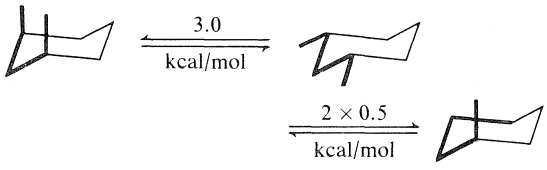
octane derivatives and of nonane are shown in Table 5.

Discussion

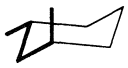
The present analysis is based on the assumption of independent rotational potentials, *i.e.* the rotational energy of any given bond is taken to be independent of the rotational states of the adjacent bonds. This model of independent rotational potentials is generally believed to be inadequate for the analysis of hydrocarbon chain conformations (6), since it does not take into account long range effects such as *syn*-axial δ-interactions. For example, the energy of the $g_{\pm}\, g_{\mp}$ combination of *gauche* rotational states is believed to be considerably higher than the sum of the energy increments associated with the two *trans*→*gauche* transitions (6).



It was decided nevertheless to test this simplest model first, and from our results it appears that the assumption of independent rotational potentials leads to a satisfactory interpretation of the conformational dependence of time-averaged C-13 chemical shifts. The parameter set in Table 1 represents a minimum set and no attempt was made to improve the fit between calculation and experiment by the addition of corrective parameters. The reference shifts are in satisfactory agreement with the corresponding resonances in ethane etc., and also with references derived with carbon resonances in conformationally well defined substrates (Table 1). The values for the structural parameters also compare favorably with parameters for rigid systems. The population parameters favor the expected rotational states. Finally, the root-mean-squares deviation between calculated and observed time-averaged carbon resonances is of the same order of magnitude as error estimates for the prediction of carbon resonances in rigid molecules. Thus there is no indication that conformations with *syn*-axial δ-interactions require special considerations, and $g_{\pm}g_{\mp}$ and $g_{\pm}g_{\pm}$ states are taken to be equally probable. For example, the following probabilities are predicted for the molecular conformations of pentane and 2-methylpentane.

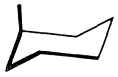
$1 \times 0.745 \times 0.745 = 0.555$

$2 \times 0.500 \times 0.745 = 0.745$



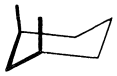
$4 \times 0.745 \times 0.128 = 0.380$

$2 \times 0.500 \times 0.128 = 0.128$

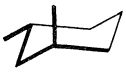


$2 \times 0.128 \times 0.128 = 0.033$

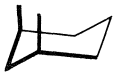
$2 \times 0.500 \times 0.128 = 0.128$



$2 \times 0.128 \times 0.128 = 0.033$



$1 \times 0.000 \times 0.745 = 0.000$



$2 \times 0.000 \times 0.128 = 0.000$

It is also quite evident that predictive schemes like Lindeman and Adam's (1) or Grant and Paul's (7), which do not explicitly take into account conformational interconversions, are successful because the average conformation of a molecular segment remains constant as additional substituents are added to the chain.

An analysis based on rotational probabilities and three-dimensional parameters automatically accounts for the effects of asymmetry, and therefore permits the assignment of resonances to nonequivalent carbons and the distinction of diastereoisomers. The assignment of the resonances for C(1) and C(6) in 2,3-dimethylpentane may serve to illustrate how molecular asymmetry leads to different resonances at nonequivalent carbons. Structural information is carried by two sets of parameters, namely the set of interactions in a given conformation and the combination of rotational states which define the probability of occurrence of that conformation. C(1) and C(6) are engaged in the same number of interactions in an equal number of conformations, since rotation about C(2)—C(3) brings C(6) into the position previously occupied by C(1). However, these same interactions occur with unequal probability. For example, the C(1) parameter set 3001 in conformation **2** occurs with probability $p_{31} \times p_{22}$, whereas C(6) experiences the same interactions with probability $p_{32} \times p_{22}$. In other words, asymmetry is not carried by the structural parameters in this

Conformation		Probability	C(1)	C(6)
1		$p_{31} \times p_{21}$	3010	3010
2		$p_{31} \times p_{22}$	3001	3010
3		$p_{31} \times p_{23}$	3010	3010
4		$p_{32} \times p_{21}$	2011	3010
5		$p_{32} \times p_{22}$	2020	3001
6		$p_{32} \times p_{23}$	2020	3010
7		$p_{33} \times p_{21}$	3010	2011
8		$p_{33} \times p_{22}$	3010	2020
9		$p_{33} \times p_{23}$	3010	2020

analysis, but rather by the population parameters. Conformers do not give rise to nonequivalent contributions if both carbons are in equivalent structural surroundings in that conformer, or if there is an equally probable conformation in which the two carbons interchange interactions. Thus, the parameter sets 3010 cancel each other in conformations **1** and **3**. The effects of the C(1) interactions 2011 in **4**, 2020 in **5** and **6**, and 3010 in **7** and **9** are offset by the corresponding C(6) interactions in **7**, **8**, and **9**, and **4** and **6**, since $p_{22} = p_{23}$ and $p_{32} = p_{33}$, and conformations **4** and **7**, as well as conformations **5**, **6**, **8**, and **9** are equally probable. This leaves the transfer of 3001 from C(1) in conformation **2** to C(6) in conformation **5**, and of 3010 from C(1) in conformation **8** to C(6) in conformation **2**. The three HC interactions cancel again and only the γ(C)—δ(C) exchange makes unequal contributions to the C(1) and C(6) resonances. The probability $p_{31} \times p_{22}$ that C(1) is engaged in a δ-interaction is higher than

TABLE 5. Observed (1) and differences ($\delta_{obs} - \delta_{calc}$) between observed and calculated time-averaged C-13 resonances for a series of heptane and octane derivatives and for nonane[c]

[a]For definition of C(1) and C(8) see footnotes, Table 4.
[b]The present method does not distinguish these *meso* and *d,l* isomers, and no assignment is implied in this case.
[c]The root-mean-squares deviation between calculated and observed resonances was 0.91 ppm.

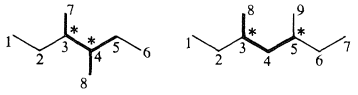
the probability $p_{32} \times p_{22}$ for C(6), and the downfield signal is therefore assigned to C(1). This assignment would appear to be quite certain, since there is little doubt that $p_{31} > p_{32}$, and that *syn*-axial δ-interactions cause rather large downfield shifts. However, the assumption that the remaining conformer resonances do not contribute to the nonequivalence of C(1) and C(6) is not rigorously true. There is no molecular symmetry operation with interchanges C(1) and C(6) and therefore $p_{31} \times p_{22}$ and $p_{31} \times p_{23}$ are not exactly equal, etc. Furthermore, deviations between calculated and actual conformer resonances will not affect C(1) and C(6) equally and may therefore also contribute to the nonequivalence of C(1) and C(6).

The 3,4-dimethylhexanes are the only examples of diastereoisomers in Table 4. Since only the spectrum of the mixture of diastereoisomers is available, they do not provide a test for the assignment of configuration. The derivation of the resonances for both isomers may nevertheless serve as an example. Table 3 lists the structural parameters in all conformations. C(1) is predicted to have the same resonances in both isomers, because the substituents on the second asymmetric carbon are beyond the three-bond segment C(1)—C(4) (v.i.). A small shift difference between *meso* and *d,l* isomers is predicted at C(2). Elimination of all interactions which occur in equally probable conformations in the *meso* and *d,l* isomers leaves two sets of parameters (set in italics in Table 3).

Conformation	*meso*		*d,l*		Probability
13	2110	↓	2101	↑	$p_{22} \times p_{32} \times p_{21}$
18	2101		2110		$p_{22} \times p_{33} \times p_{23}$
20	2110	↓	2101	↑	$p_{23} \times p_{31} \times p_{22}$
27	2101		2110		$p_{23} \times p_{33} \times p_{23}$

Since conformation **13** is less probable than **18**, the **13**/**18** interchange of the δ-interactions causes a differential downfield shift at C(2) in the *meso* isomer. This is partially offset by the **20**/**27** interchange of δ-interactions, since conformation **20** is more likely than **27**. C(3) is predicted to have the same resonance values in both isomers. The C(7) signal shows the largest observed and predicted isomeric shift. In this case the 1001 set of interactions occurs in conformation **3** in the *meso* isomer, but in conformer **5** in the *d,l* isomer. Since $p_{31} \times p_{22} > p_{32} \times p_{22}$, the low field signal is assigned to the *meso* isomer.

The further the asymmetric center is from a given carbon, the larger the number of rotational states which have to be defined in order to transmit the effect of asymmetry. The present three-bond treatment only allows the distinction of diastereoisomers with adjacent asymmetric



centers. The definition of the rotational states of the three closest bonds, together with the substituents of the δ-carbon, only specify the presence or absence of a *syn*-axial δ-interaction. It does not indicate whether a δ-hydrogen (δ-interactions) or an ε-carbon (ε-interactions) point toward the carbon in question. Thus, in the 3,4-dimethylhexanes the probabilities of δ-interactions of C(7) along the two C_β—C_γ bonds differ, since δ-interactions are only possible along C(4)—C(5), but not along C(4)—C(8). In the 3,5-dimethylheptanes, on the other hand, the δ-interactions of C(8) with C(6) and C(9) are taken to be equally probable, since the distinguishing feature, C(7), occurs beyond the three-bond segment and therefore is not recognized. In this case a definition of the rotational state of the fourth bond would be required to distinguish the two diastereoisomers.

The 2,4-dimethylhexanes may serve as examples. Table 6 lists the δ- and ε-interactions for the nonequivalent carbons C(1) and C(7) in all molecular conformations. If all rotational states in the four-bond segments C(1)—C(5), C(1)—C(8), C(7)—C(5), and C(7)—C(8) are defined, the nonequivalence of C(1) and C(7) is traced to the fact that ε-interactions with C(6) occur with probabilities $p_{21} \times p_{21} \times p_{21}$ and $p_{23} \times p_{22} \times p_{23}$ for C(1), but only with probabilities $p_{21} \times p_{22} \times p_{23}$ and $p_{22} \times p_{21} \times p_{21}$ for C(7). Since the occurrence of unrealistic ε-interactions, *i.e.* the loss of δ-interactions, is more probable for C(1), its signal is expected to be upfield from the C(7) resonance.

The asymmetry effect is still relatively large if the two asymmetric centers are only separated by a methylene group, but becomes quite small as they move apart. For example, the C(1)—C(8) differences in 2,3-, 2,4-, and 2,5-dimethylheptane are 2.2 ppm, 1.0 ppm, and 0.2 ppm, respectively (Table 5). The four-bond treatment might there-

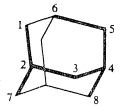
[a]Conformer probabilities: $ijk = p_{2i} \times p_{2j} \times p_{2k}$; δ8 = δ-interaction with C(8); ε6 = ε-interaction with C(6), etc.
[b]Starting conformation:



fore seem a useful general procedure. However, the need to eliminate ε-conformations, rather than introduce ε-parameters, creates complications. The elimination of such a conformation contradicts the assumption of independent rotational potentials, if that conformation would have a substantial probability of occurring. Returning to the example in Table 6, conformer **1** is taken to occur with probability $p_{21} \times p_{21} \times p_{21} = 0$ and its elimination would not pose any problem. However, conformation **24** occurs with nonzero probability $p_{23} \times p_{22} \times p_{23}$ and its elimination would contradict the assumption $p_{21} + p_{22} + p_{23} = 1$. One therefore has a choice between two approximate treatments of long range asymmetry effects. Either a four-bond treatment is adopted and conformations with ε-interactions are eliminated, even though this procedure would contradict the assumption of independent rotation potentials. Alternatively, the three-bond method is retained and long range asymmetry effects are considered separately. The assignment of the C(1) and C(7) resonances in 2,4-dimethylhexane illustrated in Table 6 was an example. Since the structural and population parameters in Table 1 seem reasonable, the three-bond treatment is retained. It would seem more appropriate to improve the prediction of conformer resonances before going to a more elaborate scheme of weighing these conformer resonances.

Finally, this method of conformational analysis is easily adopted to the description of heterosubstituted chains, since the derivation of carbon resonances in heterosubstituted substrates is entirely analogous to the predictive scheme used here (8).

Synthesis of 4,4′-bis(dicyanomethylene)bicyclohexylidine

LARRY D. PEDERSEN AND LARRY WEILER[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received August 25, 1976

LARRY D. PEDERSEN and LARRY WEILER. Can. J. Chem. **55**, 782 (1977).

4,4′-Bis(dicyanomethylene)bicyclohexylidine and its dihydro derivative, 4,4′-bis(dicyanomethylene)bicyclohexyl were prepared from the condensation of malononitrile with the corresponding diketone. Bicyclohexylidene-4,4′-dione was synthesized from the monoketal of cyclohexanedione via the symmetric azosulfide.

The uv spectra of the 4,4′-bis(dicyanomethylene)bicyclohexylidine and related model compounds indicate the presence of a long range interaction between the dicyanomethylene groups of the title compound.

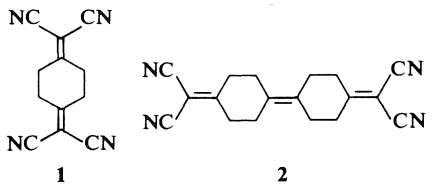
LARRY D. PEDERSEN et LARRY WEILER. Can. J. Chem. **55**, 782 (1977).

On a préparé la bis(dicyanométhylène)-4,4′ bicyclohexylidine et son dérivé dihydro bis-(dicyanométhylène)-4,4′ bicyclohexyle par condensation du malononitrile avec la dicétone correspondante. On a synthétisé la bicyclohexylidènedione-4,4′ à partir du monoacétal de la cyclohexanedione par l'intermédiaire d'un azosulfure symétrique.

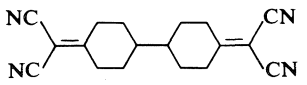
Le spectre uv du bis(dicyanométhylène)-4,4′ bicyclohexylidine et des composés modèles voisins indiquent la présence d'une interaction à longue distance entre les groupes dicyanométhylènes du composé mentionné dans le titre.

[Traduit par le journal]

Many cyano-substituted olefins form a variety of charge-transfer complexes with electron donors (1). We became interested in studying potential complexes of an acceptor in which there were two symmetrically disposed sites in the same molecule, not directly conjugated with each other. 1,4-Bis(dicyanomethylene)cyclohexane **1** (2) and 4,4′-bis(dicyanomethylene)bicyclohexylidine **2** are two examples of such molecules. We now wish to report the synthesis of **2** and its dihydro derivative **3**. Catalytic reduction



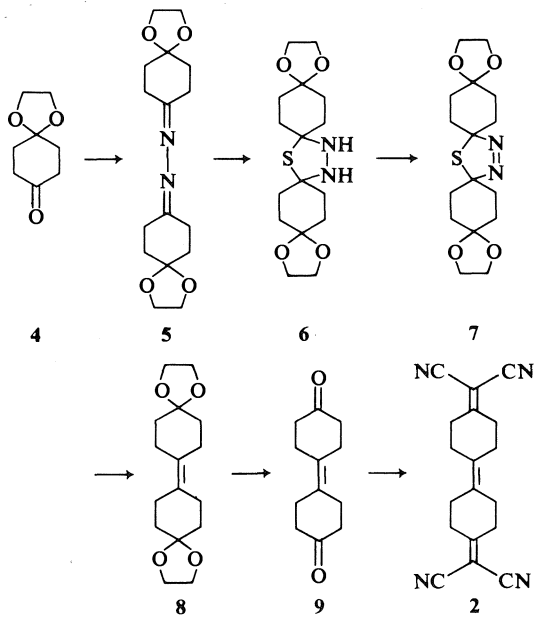
1 **2**



3

of *p,p′*-biphenol and subsequent oxidation gave bicyclohexyl-4,4′-dione (3). Condensation of this diketone with malononitrile catalyzed by β-alanine (2) gave **3** in 38% yield from the dione. All attempts to partially reduce the *p,p′*-biphenol to **9** (Scheme 1) or the corresponding diols by various catalysts and solvent systems gave either monoaromatic products or fully reduced bicyclohexyl-4,4′-diol.

Thus we turned to an investigation of the reductive dimerization of the monoketal of cyclohexane-1,4-dione **4** (4) using the azosulfide



4 **5** **6** **7** **8** **9** **2**

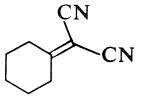
SCHEME 1

[1]Author to whom correspondence should be addressed.

method recently developed by Barton and Willis (5*a*) and by Kellogg and Wassenaar (5*b*) (Scheme 1). Treatment of **4** with hydrazine in ethanol (or methanol) gave the azine **5** which was converted into the tetrahydrothiadiazole **6** with H_2S in water. Isolation of **5** and subsequent conversion to **6** usually resulted in lower yields of **6** than the one pot reaction (5*a*). The tetrahydrothiadiazole **6** was oxidized with lead tetraacetate in methylene chloride to give the azosulfide **7** in 95% yield. Treatment of **7** with triphenylphosphine neat at 120 °C for 2 h produced a smooth elimination of nitrogen and sulfur, and the bisketal **8** was isolated in quantitative yield. Hence this symmetric reductive dimerization of a ketone is compatible with a ketal protecting group. The ketal group was removed by treating **8** with 5% aqueous hydrochloric acid in tetrahydrofuran to give bicyclohexylidene-4,4′-dione **9** in quantitative yield. Finally **9** was condensed with malononitrile with β-alanine as catalyst to give 4,4′-bis(dicyanomethylene)bicyclohexylidene **2** in 45% yield.

The infrared spectrum of the dione **9** has a strong band at 1710 cm^{-1} ($CHCl_3$) which can be compared to the reported value of 1728 cm^{-1} (CCl_4) for 1,4-cyclohexanedione (6) and 1715 cm^{-1} ($CHCl_3$) for bicyclohexyl-4,4′-dione. Also, the Raman spectrum of a powder sample of dione **9** has medium bands at 1661 cm^{-1} and 1708 cm^{-1} due to the carbon–carbon double bond and the carbon–oxygen double bond respectively. 1,4-Cyclohexanedione shows only a weak band at 1702 cm^{-1} in the Raman spectrum (7). The enhancement of the intensity of the carbonyl stretch in the Raman spectrum of **9** may be due to some coupling with the 1661 cm^{-1} band or to different solid state conformations of **9** and 1,4-cyclohexanedione.

The uv spectra of **1**–**3** and **10** are given in Table 1. The bathochromic shift from **10** to **1** is



10

consistent with a long range interaction between the dicyanomethylene groups in **1**. Similarly, a comparison of the longest wavelength absorption of **2** and **3** indicate a long range interaction through the central double bond of **2**. A similar bathochromic shift has been reported in the uv spectra of 4-methylene cyclohexanones (8). We have not been able to obtain any well defined charge transfer spectra for these dicyanomethylene derivatives in the presence of an electron donor.

TABLE 1. Ultraviolet absorption of dicyanomethylene compounds[a]

Compound	λ_{max} (nm)
Dicyanomethylenecyclohexane **10**	239 (ε 13 600)

[a]All uv spectra were obtained in methylene chloride solutions.

Experimental

All melting points are uncorrected. The ir spectra were recorded on a Perkin-Elmer Model 700 or Model 421 spectrophotometer. Raman spectra were recorded on a Cary 81 spectrometer. Nuclear magnetic resonance spectra were recorded on a Varian T60 or XL-100 spectrometer and chemical shifts are reported in δ units from internal TMS. Mass spectra were recorded on an AEI-MS9 spectrometer. Microanalyses were performed by Mr. Peter Borda, University of British Columbia.

Bicyclohexyl-4,4′-dione

Bicyclohexyl-4,4′-dione was prepared in 90% yield from *p,p′*-biphenol by catalytic reduction in ethanol ethyl acetate – acetic acid (10:10:6) using 5% Rh on alumina as catalyst at 50 psi and subsequent oxidation of the diol with Jones' reagent (9); mp 111.5–114.5 °C (lit. (3) mp 114–115 °C).

4,4′-Bis(dicyanomethylene)bicyclohexyl 3

A mixture of 5.4 g of bicyclohexyl-4,4′-dione and 3.8 g of malononitrile was melted on a steam bath. To the melt was added 1.0 ml of an aqueous β-alanine solution (0.125 g/25 ml of H_2O) and heating continued for 1 h. After cooling, the reaction mixture was washed with water and ether and the solid recrystallized from 250 ml of acetone to give 3.0 g (37.5% yield) of **3**; mp 227–228 °C; ir (CH_2Cl_2) 2250, 1600 cm^{-1}; nmr ($CDCl_3$) δ 1.45 (m, 6H), 2.25 (m, 8H), 3.04 (br d, J = 15 Hz, 4H). *Anal.* calcd. for $C_{18}H_{18}N_4$: C 74.48, H 6.21, N 19.31; found: C 74.40, H 6.06, N 19.49.

1,4-Dioxaspiro[4.5]decan-8-one Azine 5

To a stirred solution of 1.0 g of 1,4-cyclohexanedione monoketal (4) in 10 ml of methanol was added 5.8 ml of 25% hydrazine hydrate over a period of 5 min. The reaction mixture was allowed to stir for an additional 30 min. After removing the methanol by rotary evaporation, the residue was diluted with 10 ml of water and extracted with 30 ml of ether. The ether solution was dried (Na_2SO_4) and evaporated to dryness, affording 300 mg of crude product. Recrystallization from hexanes afforded 75 mg of white crystals; mp 118–120 °C; ir (CH_2Cl_2) 1645 cm^{-1}; nmr ($CDCl_3$) δ 1.68–2,0 (m, 8H), 2.44–2.66 (m, 8H), 3.96 (s, 8H); ms (70 eV) *m/e* (relative intensity):

308(81), 222(15), 207(16), 170(33), 154(100), 99(49), 86(19), 82(25), 44(47), 40(59). *Anal.* calcd. for $C_{18}H_{24}N_2O_4$: C 62.31, H 7.84, N 9.09; found: C 61.58, H 7.56, N 8.91.

Bisethylene Ketal of Cyclohexan-4-onespiro-2′-1′,3′,4′-thiadiazolidine-5′-spirocyclohexan-4-one **6**

To a stirred solution of 13.5 g of 1,4-cyclohexanedione monoketal (4) in 125 ml of ethanol was added 78 ml of 25% hydrazine hydrate over a period of 1 h. An initially formed white precipitate dissolved upon continued addition of the hydrazine hydrate. After stirring for an additional 10 min, the ethanol was removed by rotary evaporation. The residue was diluted to 150 ml with water. A stream of hydrogen sulfide was passed through this stirred aqueous solution for 2 h. The white precipitate was collected by filtration, washed with water, and air dried to give 12.8 g (86.4% yield) of crude tetrahydrothiadiazole **6**. A small amount was recrystallized from hexanes; mp 135–138 °C; ir (CH_2Cl_2) 3250, 1140 cm^{-1}; nmr ($CDCl_3$) δ 1.64–1.92 (m, 8H), 1.92–2.1 (m, 8H), 3.94 (s, 8H). *Anal.* calcd. for $C_{16}H_{26}N_2O_4S$: C 56.11, H 7.65, N 8.18, S 9.36, found: C 55.90, H 7.50, N 8.19, S 9.65.

Bisethylene Ketal of Cyclohexan-4-onespiro-2′-1′,3′,4′-thiadiazoline-5′-spirocyclohexan-4-one 7

A solution of 10.5 g of **6** in 85 ml of methylene chloride was added to a stirred solution of 15.4 g of lead tetraacetate in 50 ml of methylene chloride under nitrogen and cooled to 0 °C over a period of 45 min. The reaction mixture was allowed to warm to room temperature with stirring over a period of 1 h and was then diluted to 300 ml with methylene chloride. This mixture was washed with 200 ml of saturated sodium bicarbonate, filtered, washed with an additional 50 ml of saturated sodium bicarbonate and 50 ml of water, and dried (Na_2SO_4). Evaporation to dryness gave 9.9 g (95% yield) of thiadiazoline **7**. A small amount of **7** was recrystallized from hexanes to give clear crystals which clouded on heating at *ca.* 118 °C and decomposed with gas evolution to a white powder at 130 °C. The resulting white powder melts at 233–234 °C; ir (CH_2Cl_2) 1580 cm^{-1}; nmr ($CDCl_3$) δ 1.64–2.10 (m, 12H), 2.48–2.86 (m, 4H), 4.0 (s, 8H). *Anal.* calcd. for $C_{16}H_{24}N_2O_4S$: C 56.44, H 7.11, N 8.23; found: C 56.20, H 7.22, N 8.44.

Bisethylene Ketal of Bicyclohexylidene-4,4′-dione **8**

A mixture of 8.5 g of triphenylphosphine and 9.6 g of **7** was heated at 120 °C for 2 h. Rapid gas evolution was observed at the beginning of the reaction. After cooling, the solid reaction mixture was taken up in chloroform and chromatographed on a silica gel column (31 × 3.5 cm) eluting with chloroform. Triphenylphosphine sulfide came off first, followed by 8.0 g of the bisketal **8** (quantitative yield); mp 114–117 °C; nmr ($CDCl_3$) δ 1.50–1.84 (m, 8H), 2.20–2.50 (m, 8H), 4.00 (s, 8H). *Anal.* calcd. for $C_{16}H_{24}O_4$: C 68.54, H 8.63; found: C 68.57, H 8.46.

Bicyclohexylidene-4,4′-dione **9**

A solution of 7.9 g of bisketal **8** in 150 ml of 5% hydrochloric acid and 150 ml of tetrahydrofuran was refluxed for 1 h. After cooling, the tetrahydrofuran was removed by rotary evaporation. The resultant aqueous solution was extracted with chloroform (2 × 100 ml). The combined chloroform extracts were washed with 50 ml of saturated sodium bicarbonate and 50 ml of water, dried ($MgSO_4$), and evaporated to dryness. Thus 5.5 g (quantitative yield) of bisketone **9** was obtained. A small amount was recrystallized from hexanes; mp 117–118 °C; ir ($CHCl_3$) 1710 cm^{-1}; nmr ($CDCl_3$) δ 2.34–2.76 (m). *Anal.* calcd. for $C_{12}H_{16}O_2$: C 74.96, H 8.39; found: C 74.90, H 8.40.

4,4′-Bis(dicyanomethylene)bicyclohexylidene **2**

A mixture of 1.0 g of bisketone **9** and 1.0 g of malononitrile was melted on a steam bath. To the melt was added 5 drops of an aqueous β-alanine solution (0.125 g/25 ml of H_2O). The reaction flask was stoppered and heating continued for 30 min. The resulting light green solid reaction mixture was washed with water and ether, and recrystallized from 150 ml of ethyl acetate to give 0.685 g (45% yield) of light yellow needles; mp 223–224 °C; ir (CH_2Cl_2) 2255, 1600 cm^{-1}; nmr ($CDCl_3$) δ 2.20–3.00 (m). *Anal.* calcd. for $C_{18}H_{16}N_4$: C 74.97, H 5.59, N 19.43; found: C 74.85, H 5.73, N 19.33.

A synthetic approach to resistomycin

JOHN F. KINGSTON AND LARRY WEILER

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received September 3, 1976

JOHN F. KINGSTON and LARRY WEILER. Can. J. Chem. **55**, 785 (1977).

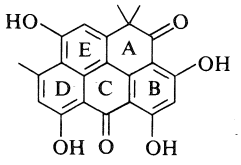
An outline of a synthetic route to the antibiotic resistomycin is presented. We report the successful construction of an intermediate containing all of the carbon atoms in resistomycin with requisite functionalities. The key steps involved an aldol type condensation of the dianion from 2,4,6-trimethoxybenzoylacetone and a suitable acetophenone. This was followed by a novel acid-catalyzed cyclization–condensation to form the naphthalene intermediate required in our scheme.

JOHN F. KINGSTON et LARRY WEILER. Can. J. Chem. **55**, 785 (1977).

On présente une ébauche d'une voie de synthèse conduisant à l'antibiotique résistomycine. On a construit avec succès un intermédiaire contenant tous les atomes de carbone de la résistomycine ainsi que les fonctions requises. Les étapes clés impliquent une condensation de type aldolique du dianion de la triméthoxy-2,4,6 benzoylacétone et d'une acétophénone appropriée. Cette réaction est suivie d'une nouvelle réaction de cyclisation–condensation catalysée par les acides conduisant au naphtalène intermédiaire requis dans notre schéma.

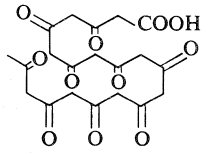
[Traduit par le journal]

Recently structure **1** was proposed for resistomycin (1, 2), an antibiotic first isolated from *Streptomyces resistomycificus* (3). The compound was resistant, hence its name, to decomposition in hot normal potassium hydroxide or hot concentrated sulfuric acid. Resistomycin is the only

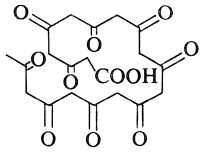


1

known example of a natural product with this pentacyclic skeleton. Its oxygenation pattern suggests that its biosynthesis involves the condensation of ten acetate units which can fold in two possible modes, **2** (1*a*) or **3** (2), to produce resistomycin. Rings B, C, D in resistomycin **1**



2



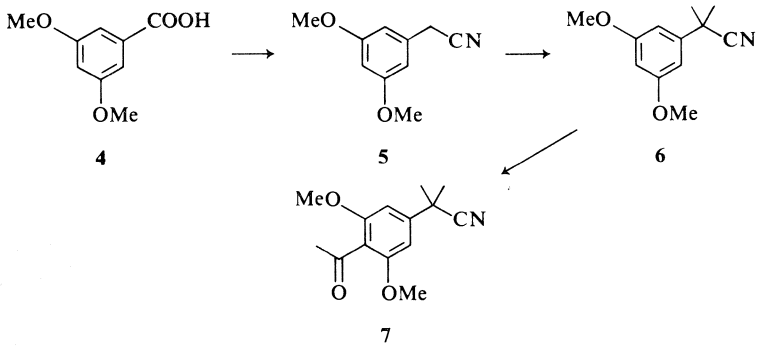
3

have distinct similarities to the tetracycline antibiotics (4) and the anthracycline family (5) of antitumor agents. In addition rings C, D, E in resistomycin **1** are quite similar to the natural phenalones and their dimers (6). This invited the hope that the methodology developed in the synthesis of resistomycin might be of widespread synthetic utility in the field of aromatic acetogenins (7).

Our general synthetic approach to resistomycin involved using a molecule containing ring E as the cornerstone on which is constructed ring D. Subsequent introduction of ring B and cyclizing to form rings C and A would generate the desired carbon skeleton as shown schematically in [1]. A suitable ring E precursor would

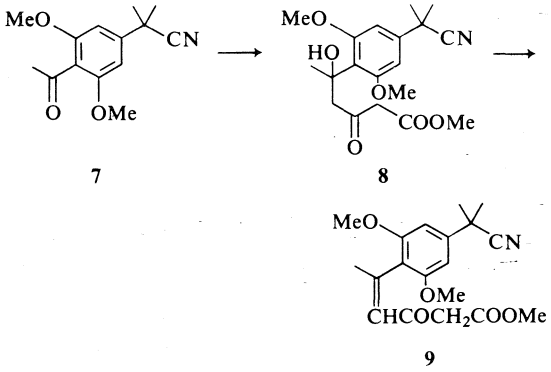
[1] 
be the keto nitrile **7**. This material was prepared from 3,5-dimethoxybenzoic acid **4** as shown in Scheme 1. The acid **4** was reduced with lithium aluminum hydride to the corresponding alcohol which was converted via the chloride to the nitrile **5** (8) in 67% yield. The nitrile **5** was alkylated in 80% yield with sodium hydride and methyl iodide in refluxing 1,2-dimethoxyethane to give **6**. Finally, acylation of **6** gave **7** in 79% yield. The symmetry of the proton and carbon nmr spectra of this product were consistent with structure **7** rather than the possible isomeric structure with the acetyl group *ortho* to the 2-methylpropionitrile group.

Reaction of acetophenone **7** with an excess of the dianion of methyl acetoacetate (9) gave the δ-hydroxy-β-keto ester **8** (10) which was charac-



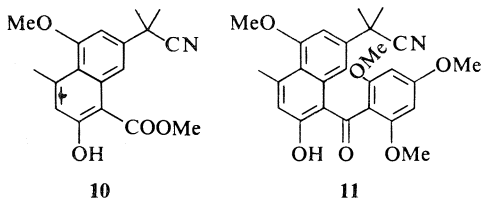
SCHEME 1. Synthesis of 2-(4-acetyl-3,5-dimethoxyphenyl)-2-methylpropionitrile **7**.

terized as its trimethylsilyl ether (11). The alcohol **8** was smoothly dehydrated to an *E,Z*-mixture of olefins **9** in greater than 85% yield from **7**. All attempts to cyclize **9** to the naphthalene **10** with acids, bases (for related base-catalyzed cyclizations, see ref. 12), or photolysis (for related photochemical cyclizations, see ref. 13) were unsuccessful. In addition attempted

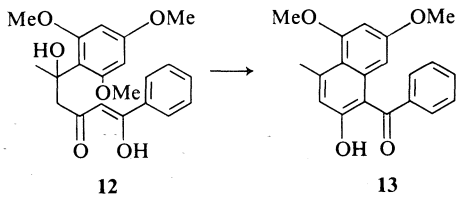


cyclizations via thermolysis or photolysis of the corresponding enol acetate of **9** were not successful.

In our proposed route to resistomycin we had intended to use **10** in an acylation reaction with 1,3,5-trimethoxybenzene to give **11**. However,

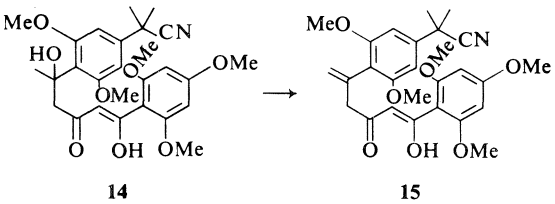


our failure to cyclize **9** to **10**, suggested that a more convergent route to **11** might fare better. In particular, we have consistently found that the α-carbon in a β-keto ester is significantly less reactive than the corresponding carbon in a β-diketone in acid- and base-catalyzed alkylation reactions. The feasibility of utilizing this fact was suggested by the following observation. An excess of the dianion of benzoylacetone (for a review of the generation and reactions of dianions from β-diketones, see ref. 14) was added to 2,4,6-trimethoxyacetophenone to produce the aldol product **12**. This material was



dehydrated with HCl in chloroform to a mixture of the corresponding *E* and *Z* alkenes. If the above dehydration reaction mixture was allowed to stand for about 5 h a new product was produced in over 50% yield from 2,4,6-trimethoxyacetophene. The structure of this new product was readily shown to be **13**.

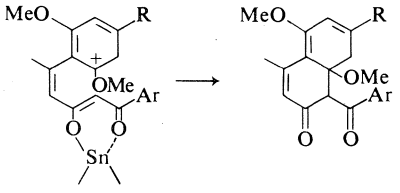
Similarly, the aldol product **14** was obtained in quantitative yield from the condensation of the dianion of 2,4,6-trimethoxybenzoylacetone with the acetophenone **7**. Attempts to dehydrate this material with HCl in chloroform gave a complex mixture of products; however, we found that boron trifluoride etherate in ether smoothly



effected the dehydration of **14**. But the major dehydration product was the unconjugated alkene **15** plus small amounts of the *E* and *Z* conjugated isomers of **15**. No attempt was made to separate the isomers at this stage. But this mixture of isomers, containing mainly **15**, was treated first with HCl in benzene to isomerize the double bond into conjugation and subsequently with stannic chloride (15) to produce the cyclized ketone **11** in *ca.* 50% yield.

At present we have very little evidence as to the mechanism of this novel cyclization to yield the naphthalenes **11** and **13**, but we suggest the following possibility. It has been shown that methoxybenzene derivatives are readily protonated on a ring carbon in strong acid (16). A similar protonation in the above cyclizations would produce **16**. Attack of the resulting elec-

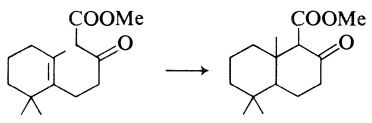
[2]



16 **17**

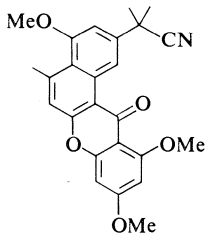
trophilic ring carbon on the tin enolate would give **17** [2] which, on loss of methanol and enolization, yields the cyclized products **11** and **13**. In this reaction the roles of electrophile and nucleophile have been reversed from those normally encountered in aromatic substitutions. The stannic chloride is essential for the cyclization and we can attribute two possible advantageous properties to this Lewis acid. First, the chelating properties of the tin may be important in holding intermediate **16** in the appropriate conformation for cyclization. In addition, the high ionic character of the tin–oxygen bond may enhance the nucleophilic character of the enol carbon and hence assist the cyclization. A similar type of mechanism may also be involved in the stannic chloride-catalyzed cyclization of the β-keto ester **18** shown in [3] (17).

[3]



18

This completes the synthesis of a resistomycin intermediate containing all of the carbon atoms of resistomycin and rings B, C, and E. The remaining steps involve a cyclization and loss of methanol to produce ring C, and an internal acylation, perhaps of the Hoesch type (18) to form ring A. In light of the above successful cyclizations [2] which we suggest are initiated by ring protonation, we undertook a study of the acid cyclizations of **11**. Indeed, treatment of **11** with a variety of strong acids gave a product in high yield which had undergone a cyclization and loss of methanol. Unfortunately this product was shown to be the xanthone **19** from its spectral properties. It would appear that protonation of



19

the ketone or trimethoxybenzene ring was occurring, as hoped, but the oxygen of the ring D hydroxyl was a more efficient nucleophile than ring E. We are currently involved in the preparation of suitable derivatives of **11** and in their subsequent cyclization.

Experimental

Infrared (ir) spectra were taken in chloroform solution (unless otherwise noted). They were recorded on a Perkin-Elmer model 700 spectrophotometer and were calibrated with the 1601 cm^{-1} band of polystyrene. Nuclear magnetic resonance (nmr) spectra were taken in deuterochloroform (unless otherwise noted) and were recorded on a Varian model T-60 spectrometer. Tetramethylsilane was used as an internal standard except where indicated. Chemical shifts are reported using the δ scale. The following abbreviations are used regarding the multiplicity of peaks: s singlet, d doublet, t triplet, q quartet, m multiplet. Coupling constants are denoted by *J* and are quoted in cycles per second (Hz). The multiplicity, coupling constants, integrated peak areas, and proton assignments are listed in parentheses after each signal. Ultraviolet–visible (uv–vis) spectra were recorded on either a Unicam model SP 800 or a Perkin-Elmer model 202 spectrophotometer. Unless otherwise noted the spectra were taken in methanol. The molar extinction coefficients of the main bands are listed in parentheses after the absorptions. The mass spectra were obtained using an Atlas CH-4b mass spectrometer. High resolution measurements were made on an AEI MS-9 mass spectrometer. Each mass (*m/e*) has its relative intensity listed in parentheses after it. Both instruments were operated at an ionizing potential of 70 V.

Melting points (mp) were determined on a Kofler hot

stage microscope and are uncorrected. Elemental microanalyses were performed by Mr. Peter Borda, University of British Columbia.

3,5-Dimethoxybenzyl Alcohol

A 1000 ml three-necked flask was fitted with a dropping funnel, a condenser with a calcium sulphate drying tube, and a magnetic stirrer. It was charged with a suspension of lithium aluminum hydride (4.80 g, 126 mmol) in THF (200 ml). A solution of 3,5-dimethoxybenzoic acid **4** (10.0 g, 55.0 mmol) in dry THF (200 ml) was added dropwise at a rate that maintained gentle reflux. After the addition was complete (1 h) the mixture was allowed to stir for an additional ½ h. This was followed by the dropwise addition of ether (250 ml) saturated with water and the dropwise addition of 6 *N* sulphuric acid (180 ml). The aqueous and organic phases were separated and the aqueous phase was extracted with ether (2 × 100 ml). The combined organic phases were washed with water (3 × 50 ml), dried over sodium sulphate, and evaporated under reduced pressure to yield 3,5-dimethoxybenzyl alcohol (9.17 g, 99%); ir 3400, 1600 cm^{-1}; nmr δ 2.16 (s, 1, hydroxyl proton, exchangeable in D_2O), 3.70 (s, 6, methoxy group protons), 4.47 (s, 2, methylene protons), 6.25 (m, 3, aromatic protons).

3,5-Dimethoxybenzyl Chloride

A 1000 ml three-necked flask was fitted with a dropping funnel, a condenser, and a magnetic stirrer. It was charged with a solution of 3,5-dimethoxybenzyl alcohol (28.4 g, 169 mmol) and pyridine (3 ml) in anhydrous ether (300 ml). A solution of thionyl chloride (50.0 g, 324 mmol) in anhydrous ether (250 ml) was added dropwise over a period of 1 h. The solution was then allowed to stir an additional 1 h before water (60 ml) was added, carefully, through the dropping funnel. The aqueous and organic phases were separated and the organic phase was washed with water (2 × 100 ml) and dried over magnesium sulphate. The solvents were removed under reduced pressure to yield 3,5-dimethoxybenzyl chloride (28.6 g, 90%) as a yellowish oil which crystallized on standing; mp 42–44 °C (lit. (8) mp 46 °C).

3,5-Dimethoxybenzyl Cyanide

A mixture of 3,5-dimethoxybenzyl chloride (33.0 g, 187 mmol), sodium cyanide (60.0 g, 1.23 mol), ethanol (600 ml), and water (150 ml) was refluxed for 4 h. The solution was poured onto 1000 g of ice. The precipitate formed was collected on a filter and dissolved in ether. This solution was dried over magnesium sulphate and the solvents were removed under reduced pressure to yield **5** (23.7 g, 75%); mp 50–51 °C (lit, (8) mp 53 °C); ir 2260 cm^{-1}; nmr δ 3.55 (s, 2, methylene protons), 3.71 (s, 6, methoxy group protons), 6.25 (m, 3, aromatic protons).

2-(3,5-Dimethoxyphenyl)-2-methylpropionitrile ***6***

A 500 ml three-necked flask was fitted with a dropping funnel, a condenser, and gas inlet and outlet tubes. It was charged with sodium hydride as a 57% dispersion in mineral oil (12.0 g, 289 mmol) and the mineral oil was removed by washing with petroleum ether (2 × 20 ml). Dry DME (150 ml) was added and the flask was flushed with nitrogen. A solution of 3,5-dimethoxybenzyl cyanide **5** (12.0 g, 67.8 mmol) in dry DME (100 ml) was added dropwise over a period of ½ h. The mixture was allowed to stir for 15 min and then methyl iodide (41.0 g, 288 mmol) was added dropwise over a period of 20 min. The mixture was refluxed for 24 h and then cooled to room temperature. Water (100 ml) and ether (150 ml) were added and the phases separated. The aqueous phase was extracted with ether (2 × 150 ml) and the combined organics were washed with water (2 × 150 ml), dried over magnesium sulphate, and the solvents were removed by evaporation under reduced pressure. The crude oil obtained was distilled *in vacuo* to afford **6** (11.1 g, 80%); bp 97 °C/2 torr (lit. (8) bp 147–150 °C/760 torr); nmr δ 1.67 (s, 6, *gem*-dimethyl group protons), 3.75 (s, 6, methoxy group protons), 6.45 (m, 3, aromatic protons).

2-(4-Acetyl-3,5-dimethoxyphenyl)-2-methylpropionitrile ***7***

A solution of **6** (511 mg, 2.50 mmol) and acetic anhydride (600 mg, 5.88 mmol) in methylene chloride (50 ml) was added to a 50 ml three-necked flask fitted with nitrogen inlet and outlet syringe needles and a magnetic stirrer. The flask was flushed with nitrogen and cooled to −10 °C in an ice–salt bath. Aluminum chloride (2.0 g, 15.0 mmol) was added, a portion at a time, with stirring, over a period of ½ h. The mixture was allowed to stir at 0 °C for an additional 1½ h after the addition of the aluminum chloride was complete. Water (15 ml) was added with vigorous shaking. The phases were separated and the aqueous phase was extracted with methylene chloride (2 × 15 ml). The combined organics were washed with water (2 × 15 ml) and dried over magnesium sulphate. The solvents were removed under reduced pressure to yield crude brown crystals which were recrystallized twice from ligroin – carbon tetrachloride to afford **22** (491 mg, 79%) as fine tan coloured crystals; mp 120–121 °C; ir 2250, 1700, 1610, 1580, 1250 cm^{-1}; nmr δ 1.78 (s, 6, *gem*-dimethyl group protons), 2.50 (s, 3, acetyl methyl group protons), 3.89 (s, 6, methoxy group protons), 6.71 (s, 2, aromatic protons); uv 262 nm (3240); ms *m/e* 247(23), 233(15), 232(100), 216(11), 175(5), 165(5), 121(3), 119(5), 116(5), 115(5), 91(8), 83(6), 57(3), 56(3), 55(5); *Anal.* calcd. for $C_{14}H_{17}O_3N$: C 68.00, H 6.93, N 5.66; found: C 67.73, H 7.05, N 5.38.

Methyl-5(4-1′-Cyano-1′-methylethyl-2,6-dimethoxyphenyl)-5-hydroxy-3-oxohexanoate ***8***

Sodium hydride as a 57% dispersion on mineral oil (175 mg, 4.17 mmol) was weighed into a 50 ml flask equipped with a magnetic stirrer. The mineral oil was removed by washing with dry THF (5 ml) and a further 10 ml of dry THF was added as solvent. The flask was stoppered with a serum cap, fitted with nitrogen inlet and outlet syringe needles, flushed with nitrogen, and cooled to 0 °C in an ice bath. Methyl acetoacetate (464 mg, 4.00 mmol) was added dropwise to the stirred mixture at a rate which maintained a vigorous but not excessive evolution of hydrogen. The reaction was allowed to stir for 10 min after the addition was complete. Next, a solution of *n*-butyllithium (165 ml, 2.50 *M*, 4.12 mmol) was added dropwise to the reaction mixture over a period of 1 min. After a further 10 min of stirring, a solution of ketone **7** (100 mg, 0.405 mmol) in dry THF (10 ml) was added to the reaction mixture, still at 0 °C. The reaction was allowed to stir at this temperature for a further 10 min and then 1 *N* hydrochloric acid (10 ml) was added in one portion. The mixture was poured into ether (100 ml) and the phases were separated. The organic phase was washed with water (5 × 15 ml) and dried over magnesium sulphate. The solvents were removed under reduced pressure and the oil obtained was separated into its components by preparative tlc on silica gel using a mixture of carbon tetrachloride and ether (2:1 v/v) as devel-

oping solvent. The band lying in the region R_f 0.1–0.2 was removed and extracted with chloroform. The solvent was removed under reduced pressure to yield **8** (129 mg, 88%); ir 3500, 2250, 1745, 1710, 1610, 1575 cm^{-1}; nmr δ 1.60 (s, 3, carbinol carbon methyl group protons), 1.70 (*gem*-dimethyl group protons), 2.95 (d, $J = 16$ Hz, 1, proton on methylene group α to carbinol carbon), 3.52 (d, $J = 16$ Hz, 1, proton on methylene group α to carbinol carbon), 3.47 (s, 2, methylene protons on carbon α to ester), 3.68 (s, 3, ester methoxy group protons), 3.90 (s, 6, ether methoxy group protons), 6.72 (s, 2, aromatic protons); uv 276 nm (1670), 283 (shoulder); ms (*a*) low resolution *m/e* 345(2), 332(8), 314(13), 249(21), 248(100), 233(11), 232(65), 230(27), 217(12), 162(25), 129(21), 101(10), 85(12), 59(14), 57(15), 55(10); (*b*) high resolution calcd. for $C_{19}H_{23}O_5N$ (P-18) (amu): 345.158; found (*m/e*): 345.162.

Methyl 5-(4-1′-Cyano-1′-methylethyl-2,6-dimethoxyphenyl)-3-oxo-5-trimethylsiloxyhexanoate

Methyl 5-(4-1′-cyano-1′-methylethyl-2,6-dimethoxyphenyl)-5-hydroxy-3-oxohexanoate **8** (95 mg, 0.26 mmol), trimethylsilylchloride (30 mg, 0.28 mmol), and hexamethyldisiliazane (24 mg, 0.15 mmol) were dissolved in dry pyridine (5 ml) and the solution was stirred at room temperature for ½ h. The fine, white precipitate formed was filtered off and washed with anhydrous ether (5 ml). The washing was combined with the filtrate and the solvents were removed under reduced pressure. The oil obtained was purified by preparative tlc on silica gel using an ether – carbon tetrachloride mixture (1:2 v/v) as developing solvent. The band at R_f 0.3–0.4 was removed and extracted with chloroform. The solvent was removed under reduced pressure to yield the TMS derivative of **8**; (52 mg, 46%); ir 2250, 1745, 1710, 1610, 1575 cm^{-1}; nmr δ −0.04 (s, 9, silyl methyl group protons), 1.66 (s, 6, *gem*-dimethyl group protons), 1.80 (s, 3, protons on methyl group α to silyl ether carbon), 2.95 (d, 1, proton on methylene group α to silyl ether carbon), 3.30 (d, 1, proton on methylene group α to silyl ether carbon), 3.55 (s, 2, methylene protons on carbon α to ester), 3.66 (s, 3, ester methoxy group protons), 3.76 (s, 6, ether methoxy group protons), 6.60 (s, 2, aromatic protons); uv 283 nm (1640); ms (*a*) low resolution *m/e* 436(3), 421(3), 406(3), 345(17), 321(10), 315(21), 314(100), 272(17), 248(28), 232(14), 230(10), 162(11), 101(10), 75(14), 59(11); (*b*) high resolution calcd. for $C_{22}H_{33}O_6NSi$ (amu): 435.207; found (*m/e*): 435.200.

Methyl 5-(4-1′-Cyano-1′-methylethyl-2,6-dimethoxyphenyl)-3-oxohex-4-enoate ***9***

Chloroform (25 ml) was saturated with hydrogen chloride by bubbling the anhydrous gas directly through the solvent for 20 min. Methyl 5-(4-1′-cyano-1′-methylethyl-2,6-dimethoxyphenyl)-5-hydroxy-3-oxohexanoate **8** (135 mg, 0.372 mmol) was added and the solution was allowed to stir at room temperature for 2 h. It was then washed with saturated aqueous sodium hydrogen carbonate solution (3 × 10 ml) and water (3 × 10 ml), and dried over magnesium sulphate. The solvent was removed under reduced pressure to afford **9** (125 mg, 98%) as an *E,Z* mixture; ir 2250, 1740, 1680, 1610, 1575 cm^{-1}; nmr δ 1.75 (s, 6, *gem*-dimethyl group protons), 2.09, 2.32 (2d, $J = 2$ Hz, 3 total, vinyl methyl groups in *E* and *Z* isomers respectively), 3.24, 3.53 (2s, 2 total, methylene protons on carbon α to ester in *E* and *Z* isomers respectively), 3.65, 3.75 (2s, 3 total, ester methoxy group protons for *E* and *Z* isomers respectively), 3.87 (s, 6, ester methoxy group protons), 6.16, 6.32 (2q, $J = 2$ Hz, 1 total, vinyl protons in *Z* and *E* isomers respectively), 6.70 (s, 2, aromatic protons); uv 285 nm (6400); ms (*a*) low resolution *m/e* 345(2), 315(11), 314(70), 272(13), 257(21), 256(100), 214(13), 176(11), 162(12), 161(10), 101(12), 59(12), 51(36); (*b*) high resolution calcd. for $C_{19}H_{23}O_5N$ (amu): 345.158; found (*m/e*): 345.158.

5-Hydroxy-1-phenyl-5-(2,4,6-trimethoxyphenyl)hexane-1,3-dione ***12***

A 50 ml flask containing isopropylcyclohexylamine (1.150 g, 8.16 mmol) and dry THF (20 ml) was equipped with a magnetic stirrer, stoppered with a serum cap, fitted with nitrogen inlet and outlet syringe needles, and flushed with nitrogen. A solution of *n*-butyllithium in hexane (3.30 ml, 2.50 *M*, 8.25 mmol) was added and the reaction was stirred at room temperature for 10 min. After this time, a solution of benzoylacetone (648 mg, 4.00 mmol) in dry THF (5 ml) was added and the reaction was stirred at room temperature for ½ h before being cooled to 0 °C. A solution of 2,4,6-trimethoxyacetophenone (168 mg, 0.800 mmol) in dry THF (2 ml) was added and the reaction mixture was stirred at 0 °C for 10 min before being quenched by the addition of 1 *N* hydrochloric acid (15 ml). The contents of the flask were poured into ether (75 ml) and the organic phase was washed with water (5 × 10 ml) and dried over magnesium sulphate. Evaporation of the solvents under reduced pressure yielded a mixture of compounds composed primarily of benzoylacetone and **12** (by tlc). Isolation of the product was accomplished by preparative tlc on silica gel using a carbon tetrachloride – ether mixture (2:1 v/v) as developing solvent. The band lying at R_f 0.3–0.4 was removed and extracted with chloroform. Evaporation of the chloroform under reduced pressure afforded **12** (303 mg, 100%) as a light yellow oil; ir 3550–3500, 1650–1550 cm^{-1}; nmr (assignment simplified by ignoring the keto tautomer present in minor amount) δ 1.75 (s, 3, carbinol carbon methyl group protons), 2.89 (d, $J = 14$ Hz, 1, proton on methylene group α to carbinol carbon), 3.24 (d, $J = 14$ Hz, 1, proton on methylene group α to carbinol carbon), 3.75 (2s, 9, methoxy group protons), 6.15 (s, 1, vinyl proton of enol), 6.18 (s, 2, protons on trimethoxyphenyl ring), 7.2–7.8 (m, 5, protons on phenyl ring); uv 338 nm (10,200); ms (*a*) low resolution *m/e* 354(50), 338(10), 324(17), 323(76), 322(17), 249(12), 221(17), 219(14), 194(14), 193(43), 177(12), 168(26), 147(45), 106(10), 105(100), 91(14), 77(48), 68(52); (*b*) high resolution calcd. for $C_{21}H_{22}O_5$ (P-18) (amu): 354.147; found (*m/e*): 354.151.

1-Phenyl-5-(2,4,6-trimethoxyphenyl)hex-4-ene-1,3-dione

Chloroform (40 ml) was saturated with hydrogen chloride by bubbling the anhydrous gas through the solvent for ¼ h. A solution of 5-hydroxy-1-phenyl-5-(2,4,6-trimethoxyphenyl)hexane-1,3-dione **12** (149 mg, 0.412 mmol) in chloroform (2 ml) was added and the solution was stirred for 1½ h before being washed with water (5 × 10 ml) and dried over magnesium sulphate. Evaporation of the solvent under reduced pressure afforded the dehydrated products (138 mg, 97%) as a crude orange oil; ir 1650–1550 cm^{-1}; nmr δ 2.15, 2.49 (2d, $J = 2$ Hz, 3 total, vinyl methyl group protons in *E* and *Z* isomers), 4.75–4.85 (several s, 9 total, methoxy group protons), 5.90–6.40 (m, vinyl proton, vinyl proton

of enol, trimethoxyphenyl ring protons), 7.30–8.20 (m, 5, phenyl ring protons).

5,7-Dimethoxy-2-hydroxy-4-methyl-1-naphthyl Phenyl Ketone ***13***

A 50 ml flask containing diisopropylamine (1.05 g, 10.4 mmol) and THF (20 ml) was equipped with a magnetic stirrer, stoppered with a serum cap, fitted with nitrogen inlet and outlet syringe needles, and flushed with nitrogen. A solution of *n*-butyllithium in hexane (4.60 ml, 2.20 *M*, 10.1 mmol) was added and the mixture was stirred for 5 min before a solution of benzoylacetone (0.810 g, 5.00 mmol) in dry THF (5 ml) was added. The reaction was refluxed under nitrogen for 2 h and then cooled to room temperature. A solution of 2,4,6-trimethoxyacetophenone (0.108 g, 0.515 mmol) in dry THF (5 ml) was added and the solution was stirred at room temperature for 2 h. After this time, the contents of the flask were transferred via a stainless steel cannula to a rapidly stirred mixture of 1 *N* hydrochloric acid (50 ml) and ether (250 ml). The organic phase was washed with water (3 × 50 ml) and dried over magnesium sulphate. The mixture of compounds obtained after evaporation of the solvents under reduced pressure was dissolved in chloroform (100 ml) saturated with anhydrous hydrogen chloride gas. This solution was stirred for 5 h and then washed with water (20 ml) and extracted with 1 *N* sodium hydroxide (5 × 20 ml). The base insoluble portion was washed with water (3 × 20 ml) and dried over magnesium sulphate. The solvents were evaporated under reduced pressure to yield a mixture of compounds which was separated into two components by preparative tlc on silica gel. A mixture of carbon tetrachloride and ether (2:1 v/v) was used to develop the plates. The band lying at R_f 0.6–0.7 was removed and extracted with chloroform. Evaporation of the chloroform under reduced pressure afforded 1-phenyl-5-(2,4,6-trimethoxyphenyl)hex-4-ene-1,3-dione (46 mg, 25%); spectral data as described under synthesis of this compound above. Extraction of the band lying at R_f 0.3–0.4 on the plates afforded **13** (88 mg, 53%). A sample of this yellow crystalline compound was sublimed for analysis; mp 135–137 °C; ir 1640, 1600, 1575 cm^{-1}; nmr δ 2.49 (s, 3, methyl group protons), 3.85 (2s, 6, methoxy group protons), 6.10–6.40 (m, 3, naphthyl ring protons), 7.30–8.40 (m, 5, phenyl ring protons); uv–vis 240 (34 300), 260 (shoulder), 285 (shoulder), 415 (shoulder), 435 nm (51 500); ms *m/e* 322(79), 305(39), 246(16), 245(100), 230(18), 188(10), 147(10), 105(12), 77(29). *Anal.* calcd. for $C_{20}H_{18}O_4$: C 74.52, H 5.63; found: C 74.40, H 5.60.

1-(2,4,6-Trimethoxyphenyl)butane-1,3-dione

A 250 ml flask containing a solution of 2,4,6-trimethoxyacetophenone (1.976 g, 9.41 mmol) in dry THF (175 ml) was equipped with a magnetic stirrer, stoppered with a serum cap, fitted with nitrogen inlet and outlet syringe needles, and flushed with nitrogen. A solution of trityl-potassium in DME (~0.5 *M*) was added dropwise until a permanent red colour appeared in the reaction mixture. During this addition a flocculent white precipitate was formed. Methyl acetate (10.0 ml, 132 mmol) was added and the reaction mixture was stirred at room temperature for 16 h, during which time the precipitate dissolved. Next, the contents of the flask were transferred via a stainless steel cannula to a rapidly stirred mixture of 1 *N* hydrochloric acid (100 ml) and ether (500 ml). The aqueous phase was extracted with ether (2 × 50 ml) and the combined organics were washed with water (100 ml) and extracted with 1 *N* sodium hydroxide (3 × 75 ml). The combined base extracts were acidified by the addition of concentrated hydrochloric acid and reextracted with ether (3 × 75 ml). The combined ether extracts were washed with water (3 × 50 ml) and dried over magnesium sulphate. The product obtained after evaporation of the solvents under reduced pressure was recrystallized from ethanol–ligroin to afford 1-(2,4,6-trimethoxyphenyl)-butane-1,3-dione (0.876 g, 37%); mp 102–104 °C; ir 1650–1560 cm^{-1}; nmr δ 2.11 (s, 2, terminal methyl group in enol tautomer), 2.26 (s, 1, terminal methyl group in keto tautomer), 3.8 (m, ~10, methoxy group protons and methylene protons of keto tautomer), 5.74 (s, 0.66, vinyl proton of enol tautomer), 6.15 (2s, 2 total, aromatic protons in keto and enol tautomers); uv 295 nm (15 200); ms *m/e* 252(15), 221(40), 196(13), 195(100), 168(19), 167(15), 165(15), 153(10), 137(10), 70(12), 61(12). *Anal.* calcd. for $C_{13}H_{16}O_5$: C 61.90, H 6.39; found: C 61.79, H 6.40.

The base insoluble portion of the product mixture from the above reaction (still in ether) was washed with water (3 × 50 ml) and dried over magnesium sulphate. The mixture obtained after the solvents were removed under reduced pressure was recycled twice following the same procedure as outlined above. This resulted in an overall yield of 55% from the original 2,4,6-trimethoxyacetophenone.

2-(3,5-Dimethoxy-4-(4,6-dioxo-2-hydroxy-6-2′,4′,6′-trimethoxyphenylhex-2-yl)phenyl)-2-methylpropionitrile ***14***

This compound was prepared following the procedure employed in the preparation of 5-hydroxyl-1-phenyl-5-(2,4,6-trimethoxyphenyl)hexane-1,3-dione **12**. The following reagents were used: isopropylcyclohexylamine (720 mg, 5.11 mmol), *n*-butyllithium in hexane (2.15 ml, 2.50 *M*, 5.36 mmol), 1-(2,4,6-trimethoxyphenyl)butane-1,3-dione (630 mg, 2.50 mmol) and 2-(4-acetyl-3,5-dimethoxyphenyl)-2-methylpropionitrile **7** (124 mg, 0.502 mmol) in dry THF (30 ml total volume). The product was separated from unreacted dione by preparative tlc on silica gel. The plates were developed with a mixture of carbon tetrachloride and ether (1:1 v/v). The band lying at R_f 0.4–0.6 was removed and extracted with chloroform. Evaporation of the solvent under reduced pressure afforded unreacted dione (395 mg, 78% of theoretical excess). No unreacted **7** was observed on the plates. Extraction of the band lying at R_f 0.1–0.2 afforded **14** (252 mg, 100%) as a clear oil; ir 3550, 2255, 1650–1560 cm^{-1}; nmr δ 1.55, 1.77, 1.70 (3s, 9 total, carbinol carbon methyl group protons in enol and keto tautomers and *gem*-dimethyl group protons respectively), 2.6–3.4 (m, 2, protons on methylene group α to carbinol carbon in enol and keto tautomers), 4.8 (several s, 15 total, methoxy group protons), 5.72 (s, <1, vinyl proton of enol tautomer), 6.15 (s, 2, protons on trimethoxyphenyl ring), 6.71 (s, 2, protons on dimethoxyphenyl ring); uv 285–310 nm (broad) (8650); ms (*a*) low resolution *m/e* 499(2), 481(4), 468(5), 252(45), 248(32), 232(32), 221(48), 197(10), 196(15), 195(100), 168(15), 161(9); (*b*) high resolution calcd. for $C_{27}H_{33}O_8N$ (amu): 499.220; found (*m/e*): 499.220.

2-(3,5-Dimethoxy-4-(4,6-dioxo-6-2′,4′,6′-trimethoxyphenylhex-1-en-2-yl)phenyl)-2-methylpropionitrile ***15***

Boron trifluoride etherate (~1 ml) was added to a stirred solution of **14** (232 mg, 0.465 mmol) in anhydrous

ether (20 ml). A precipitate which formed during the addition dissolved in 2 min. After 20 min the solution was washed with water and dried over magnesium sulphate. Evaporation of the solvents under reduced pressure afforded a crude mixture of **15** and the conjugated isomers (223 mg, 100%) as a bright orange foam; ir 2255, 1650, 1580, 1530 cm^{-1}; nmr δ 1.72 (s, 6, *gem*-dimethyl group protons), 2.23, 2.55 (2d, $J = 2$ Hz, vinyl methyl group protons in *E* and *Z* isomers), 3.3–3.9 (methylene group protons in **15** and methoxy group protons), 6.10 (s, 2, protons on trimethoxyphenyl ring), 6.66 (2s, 2, protons on dimethoxyphenyl ring), 6.0–6.7 (m, vinyl proton of **29** and vinyl proton of various enol tautomers).

2-(7-Hydroxy-5-methyl-4-methoxy-8-2′,4′,6′-trimethoxybenzoyl-2-naphthyl)-2-methylpropionitrile ***11***

A sample of the mixture of **15** and conjugated isomers (212 mg, 0.440 mmol) was dissolved in dry benzene (50 ml) and anhydrous hydrogen chloride was bubbled through the solution for 1½ h. After this time, stannic chloride (2 ml) and water (2 drops) were added and the resulting mixture was stirred at room temperature for 16 h before being poured into water (20 ml). A precipitate which had formed in the reaction flask was dissolved in chloroform (100 ml) and added to the benzene–water mixture. The organic phase was washed with water (4 × 20 ml) and dried over magnesium sulphate. Evaporation of the solvents under reduced pressure afforded 187 mg of crude product which was recrystallized from ethanol–ligroin to yield **11** (90 mg, 46%) as bright yellow crystals mp 218–220 °C. A sample was sublimed for analysis (180 °C/0.04 torr); ir 2255, 1640, 1600, 1540 cm^{-1}; nmr δ 2.70 (s, 6, *gem*-dimethyl group protons), 2.51 (s, 3, aromatic methyl group protons), 4.8 (several s, 12 total, methoxy group protons), 5.8–8.0 (several s, 5 total, aromatic protons); uv 295 (shoulder), 304 (18 000), 398 (54 400), 420 nm (shoulder); ms *m/e* 449(24), 432(28), 282(12), 267(13), 266(10), 256(23), 255(100), 242(25), 240(23), 211(12), 195(49), 180(11), 168(11), 167(10), 165(11), 152(13), 149(13), 139(16), 137(14), 115(12), 109(13), 95(13), 91(17), 85(14), 83(11), 81(17), 79(13), 77(18), 71(18), 70(11), 69(26), 67(15), 63(10), 57(52), 56(23), 55(61), 53(17), 51(16), 50(13). *Anal.* calcd. for $C_{26}H_{27}O_6N$: C 69.47, H 6.05, N 3.12; found: C 69.42, H 6.15, N 3.00.

Cyclization of ***11*** *to the Xanthone* ***19***

A 15 mg sample of **11** was dissolved in 10 ml of cold (0 °C) acetic acid containing anhydrous HCl. This reaction mixture was allowed to warm to room temperature and stirred for ½ h. The reaction mixture was poured into saturated aqueous $NaHCO_3$ and extracted with chloroform (5 × 20 ml). The extracts were combined, washed with water (2 × 10 ml), and dried over magnesium sulphate. The solvents were removed under reduced pressure to afford 13 mg of crude product which was purified by tlc on silica gel using chloroform–ether (1:1) as developing solvent. The band at R_f 0.3–0.5 was removed and extracted with chloroform to yield 8 mg of xanthone **19** as a yellow semi-solid; ir 2255, 1650, 1600 cm^{-1}; nmr δ 2.68 (s, 6, *gem*-dimethyl group protons), 2.46 (s, 3, aromatic methyl group protons), *ca.* 4.8 (three s, 9, methoxy group protons), 6–8 (several s, 5, aromatic protons); ms (*a*) low resolution *m/e* 417(65), 402(10), 349(17), 334(10), 265(27), 237(12), 180(35), 152(22), 91(20); (*b*) high resolution calcd. for $C_{25}H_{23}O_5N$ (amu): 417.1576; found (*m/e*): 417.1589.

Studies on the iodide–triiodide equilibrium

ROBERT L. BENOIT, MICHAEL F. WILSON, AND SING-YEUNG LAM
Département de chimie, Université de Montréal, C.P. 6210, Montréal (Qué.), Canada H3C 3V1

Received May 25, 1976

ROBERT L. BENOIT, MICHAEL F. WILSON, and SING-YEUNG LAM. Can. J. Chem. **55,** 792 (1977).

The solvent effect on the iodide–triiodide equilibrium has been investigated by means of calorimetric and potentiometric measurements. The aprotic solvents studied were nitromethane, nitrobenzene, sulfolane, acetonitrile, propylene carbonate, acetophenone, dimethylformamide, dimethylsulfoxide, and *o*-dichlorobenzene. The resulting enthalpy and free energy changes imply that the variations of the enthalpies and free energies of transfer of the iodide and triiodide ions probably are small and that there is an important non-coulombic contribution to these transfer parameters. Values were obtained for the enthalpy of formation of two solid triiodides, which together with values for other triiodides, cast doubt on reported calculated lattice enthalpies of triiodides and formation enthalpy of I_3^- ion in the gas phase. This latter formation enthalpy is found to be, from our solution data, more negative than -22 kcal mol^{-1}.

ROBERT L. BENOIT, MICHAEL F. WILSON et SING-YEUNG LAM. Can. J. Chem. **55,** 792 (1977).

On a étudié l'effet de solvant sur l'équilibre iodure–triiodure au moyen de déterminations calorimétriques et potentiométriques. Les solvants aprotoniques considérés incluent le nitrométhane, le nitrobenzène, le sulfolane, l'acétonitrile, le carbonate de propylène, l'acétophénone, le diméthylformamide, le diméthylsulfoxyde et l'*o*-dichlorobenzène. Les changements d'enthalpie et d'énergie libre observés impliquent des variations vraisemblablement faibles pour les enthalpies et énergies libres de transfert des ions iodures et triiodures et une composante non-coulombienne importante pour ces grandeurs de transfert. On a obtenu des valeurs de l'enthalpie de la réaction de formation de deux triiodures solides et ces valeurs jointes à celles d'autres triiodures mettent en question des valeurs publiées de l'énergie de réseau des triiodures et de l'enthalpie de formation de l'ion I_3^- en phase gazeuse. Cette dernière enthalpie de formation est, d'après nos résultats, plus négative que -22 kcal mol^{-1}.

We have recently reported thermodynamic data for an anion–molecule reaction, $Cl^-(s) + HR(s) \rightleftharpoons ClHR^-(s)$, involving hydrogen-bonding between Cl^-, a halide ion, and a series of Brønsted acids HR (1). A comparison of the enthalpy data obtained in sulfolane with gas-phase data allowed us to make a complete analysis of the solvent effect on that reaction. Another type of anion–molecule reaction of general interest is that where the molecule is an uncharged Lewis acid. We have now completed a study of such a reaction, namely

$$[1] \qquad I^-(s) + I_2(s) \rightleftharpoons I_3^-(s)$$

in a series of dipolar aprotic (dpa) solvents (s).

Association constants K for [1] have been reported for many solvents of different classes (refs. 2, 3 and references cited therein). It is generally found that K is larger for aprotic solvents than for protic solvents. These differences are qualitatively accounted for in terms of strong hydrogen-bonding interactions between I^- and the protic solvents and strong dipolar interactions between I_3^- and the dpa solvents. Values of K also vary significantly within the group of dpa solvents but apparently for another reason, *i.e.* the more basic the solvent, the stronger the interaction of the Lewis acid I_2 with the solvent and the lower the value of K.

In the present work we have tried to assess more completely the solvent effect on the iodide–triiodide equilibrium by determining first the enthalpy change $\Delta H(s, c)$[1] for

$$[2] \qquad I^-(s) + I_2(c) \rightleftharpoons I_3^-(s)$$

The solvents studied include the dpa solvents, nitromethane (NM), nitrobenzene (NB), sulfolane (TMS), acetonitrile (AN), propylene carbonate (PC), acetophenone (AP), dimethylformamide (DMF), dimethylsulfoxide (DMSO), and also *o*-dichlorobenzene (DCB). An attempt was made to estimate for some of these solvents, the free energy of transfer[1] for the single ions I^- and I_3^-, from potentiometric measurements on the redox system I^-/I_3^-, together with the

[1]The thermodynamic functions can be approximated to ΔH^0 and ΔG^0 considering the dilute solutions used and the nature of the reaction.

aid of some extrathermodynamic assumptions. Calorimetric measurements were also carried out to evaluate, through thermodynamic cycles, the enthalpy changes ΔH(c) for

[3] $$MI(c) + I_2(c) \rightleftharpoons MI_3(c)$$

(where M^+ is tetramethyl and tetrabutylammonium ions) and ΔH(g) for the gas phase reaction

[4] $$I^-(g) + I_2(g) \rightleftharpoons I_3^-(g)$$

These enthalpy changes were then compared with values calculated from emf measurements of solid-state galvanic cells (4).

Experimental

Materials

Sulfolane (Shell) was purified according to a method given earlier (1). Spectroanalytical grade DMSO (Fisher) and reagent grade DMF (Anachemia) were treated with 4A molecular sieves heated to 200 °C, decanted, and then distilled. PC (Aldrich) was doubly distilled at a temperature below 100 °C and a pressure less than 10 mm Hg; only the middle portion of the distillate was collected. AP (Matheson, Coleman, and Bell) was crystallised twice by freezing, followed by distillation under vacuum. Baker analysed NB and spectrochemical grade NM (M, C, and B) were dried with 4A molecular sieves. Reagent grade AN and DCB (Eastman) were used as received. Residual water[2] in the solvents was found to be between 0.002 and 0.02 *M* as determined by Karl Fischer titration.

Tetramethylammonium and tetrabutylammonium iodides (Me_4NI and Bu_4NI) were obtained from Eastman. The corresponding triiodide salts were synthesized by equilibrating stoichiometric amounts of the appropriate iodide and iodine under vacuum for 3 days at 70 and 40 °C for the tetramethylammonium and tetrabutylammonium salts respectively; the method was according to Topol (4). Baker analytical reagent iodine was used as purchased. Tetraethylammonium picrate (Et_4NPic) was prepared according to the method of Coetzee and Padmanabhan (5).

Calorimetry

The apparatus and calorimetric procedure used have been described in an earlier publication (6). The heats of solution of various amounts of solid iodine in 27 ml of 0.05 *M* Bu_4NI solution in the solvents (0.01 *M* Me_4NI solution in DMF) were determined at 25 °C (30 °C in the case of TMS as solvent). Molar concentration ratios of I_2 to I^- were between 0.1 and 0.9. Measurements of the heats of solution of Bu_4NI in DMF and Bu_4NI_3 in DMF and DMSO were also carried out at salt concentrations between 0.001 and 0.01 *M*. In all cases, at least three determinations were made for each reaction. Dissolving solid iodine in the solvents containing R_4NI took usually less than 10 min except in the case of TMS and NM (30 min).

Potentiometric Measurements

Electromotive force measurements were carried out using the following cell

[5]

−						+
	Bu_4NI (10^{-2} *M*)		Et_4NPic (10^{-1} *M*)	Bu_4NI (10^{-2} *M*)		
Pt	Bu_4NI_3 (10^{-2} *M*)	‖	in PC	Bu_4NI_3 (10^{-2} *M*)		Pt
	in PC			in solvent s		

The assembly was contained in a water jacketted glass vessel thermostated at 25.0 °C (30.0 °C in the case of TMS). The potentiometric measurements were made with a Tacussel-Aries 10000 potentiometer with digital readout. The Et_4NPic bridge was selected in order to eliminate the liquid junction potential (7). Measurements, made after 10 min to allow the system to equilibrate, were reproducible within 3 mV or less. Readings drifted 1–3 mV over a subsequent 15 min period. The effect of light catalyzed oxidation of I^- was assumed to be minimal in these 'redox buffered' solutions under our experimental conditions.

Results

Calorimetry

The heats of solution of solid iodine ΔH(s,c) in the dpa solvents containing 0.05 *M* Bu_4NI, as represented by [2], are listed in Table 1; the mean experimental value for each reaction is given. The completeness of [2] under our experimental conditions results from the values of $K \geq 10^5$ (3) and is evidenced for each solvent by the constancy within 0.1–0.2 kcal mol^{-1} of the heats of solution per mole of I_2 added. The results of Hepler and co-workers (8) for the same reaction in water are also included in Table 1.

The heats of solution determined for Me_4NI_3, Bu_4NI, and Bu_4NI_3 in DMF, and Bu_4NI_3 in DMSO together with literature values are given in Table 2. These heats of solution were combined with our values of ΔH(s,c) both in DMF and DMSO to yield, by means of a simple thermodynamic cycle, the ΔH(c) values for [3]

[2]On the basis of our results on the hydration of anions in dpa solvents (22) the hydration of the large ions I^- and I_3^- and hence the effect of residual water on [1] are assumed to be negligible considering the relative concentrations involved.

listed in Table 2. A ΔH(c) value obtained by Topol (4) from emf measurements on a solid-state cell is also included.

Electromotive Force Measurements

The redox system to be considered in order to calculate the emf of the cell represented by [5] is

[6] $$I_3^- + 2e \rightleftarrows 3I^-$$

Since the concentrations of iodide and triiodide are the same at both electrodes, the overall emf of the cell, ΔE, is given as

[7] $$\Delta E = E_j + 0.0296 \log {}^{PC}\gamma^s_{I_3^-} - 0.0888 \log {}^{PC}\gamma^s_{I^-}$$

where E_j is the liquid junction potential and $\log {}^{PC}\gamma_i^s$ the medium effect for the transfer of the single ionic species i from PC to solvent s. $\Delta G(i)$ and $\log \gamma_i$ are related by

[8] $$\Delta G(PC \rightarrow s)(i) = RT \ln {}^{PC}\gamma_i^s$$

Table 3 presents our observed emf values ΔE which are related to free energies of transfer of I_3^- and I^- through eqs. 7 and 8 if E_j is known.

Discussion

First we will discuss the solvent effect on the iodide–triiodide equilibrium as deduced from our calorimetric results. The data in Table 1 show that while ΔH(s,c) is endothermic in water, it is, as expected, exothermic in the aprotic solvents, but the variations between the dpa solvents are relatively small. We also note that for three out of the four solvents NB, NM, AP, and DCB where ion-pair formation is either partial or extensive, ΔH(s,c) is not very different from the values for the more dissociating aprotic solvents. The enthalpy change ΔH(s) for reaction 1 could be deduced from our ΔH(s,c) values by subtracting the generally endothermic heat of solution of solid iodine in the solvents (9). However, by comparing our values of ΔH(s,c) for reaction 2, rather than ΔH(s), we simplify the interpretation of the solvent effect on the I^-–I_3^- equilibrium by eliminating the basicity-related solvent influence on I_2 (9). This becomes apparent when we calculate $\Delta\Delta H$(s,c), the difference between the values of ΔH(s,c) for the solvent s and for PC taken as reference solvent:

[9] $$\Delta\Delta H(s,c) = \Delta H(s,c) - \Delta H(PC,c) = \Delta H(PC \rightarrow s)\,(I_3^-) - \Delta H(PC \rightarrow s)\,(I^-)$$

where $\Delta H(PC \rightarrow s)(i)$ is the enthalpy of transfer of the species i from PC to s.

Now when we compare these latter $\Delta\Delta H(s,c)$ values in Table 1 we face the difficult problem of assessing ionic solvation effects from data on a pair of ions, in our case on two anions I^-, I_3^-. The problem is not unlike that met when trying to separate heats of solution of salts M^+A^- into cationic and anionic contributions. The relatively small variations (less than 2.5 kcal mol^{-1}) of $\Delta\Delta H(s,c)$, *i.e.* the difference between the enthalpies of transfer of I_3^- and I^- is most simply accounted for by assuming that the single anions enthalpies of transfer are also small, at least for the solvents PC, DMSO, AN, DMF, and TMS. This point of view is supported by similarly small changes for the enthalpies of transfer of two more anion pairs, Cl^-,$SbCl_6^-$ (13) and Cl^-,$ClHR^-$ (7), pairs whose components are quite dissimilar. Some single anion enthalpies of transfer obtained by using the tetraphenylarsoniumtetraphenylborate (tatb) extrathermodynamic assumption (10) and given in Table 1 indicate somewhat larger variations (up to 3.3 kcal mol^{-1}). However, such single ion enthalpies of transfer carry appreciable errors coming from the many experimental steps involved in their calculation. For example from different but carefully obtained experimental data, Arnett and McKelvey (11) and Parker and co-workers (10) calculated $\Delta H(H_2O \rightarrow DMSO)$ (I^-) values to be, respectively, −2.52 and −3.23 kcal mol^{-1}. Our values for $\Delta H(PC \rightarrow s)$ (I_3^-) − $\Delta H(PC \rightarrow s)$ (I^-) are on the contrary obtained in one experimental step. We can next show that these values are not governed by coulombic interactions. An expression can be derived, from the Born equation, giving values for $\Delta H(PC \rightarrow s)$

(*i*), the enthalpy of transfer of ion *i* from PC to solvent s (12). We have given in Table 1 (line §) the ΔH(PC → s) values calculated for I^- and I_3^-. The differences deduced for ΔH(PC → s)(I_3^-) − ΔH(PC → s)(I^-) can then be shown to be at variance with our experimental values, the sign of the difference being even opposite for transfers to DMSO and DMF. A similar state of affair prevails for the enthalpies of transfer of another anion pair Cl^-,$SbCl_6^-$ (13). It would therefore seem that the non-coulombic contribution to the anionic enthalpies of transfer between dpa solvents plays an important part.

Next, we consider briefly the solvent effect on the iodide–triiodide equilibrium as deduced from our emf determinations. The interpretation of the ΔE values for cell [5], reported in Table 3, in terms of free energies of transfer by means of eqs. 7 and 8 is more difficult than in the case of the calorimetric data. First, eq. 7 shows that there are different coefficients affecting the transfer of I^- and I_3^-. Second, there is the problem of estimating E_j. Parker (*7b*) in his studies on ionic solvation in dpa solvents found good agreement between six quite different sets of extrathermodynamic assumptions and recommended the assumption that there was negligible liquid junction potential in a cell composed of silver electrodes in two dissimilar solvents linked by a 0.1 *M* Et_4NPic bridge in either solvent. With this assumption $E_j = 0$ in eq. 7, we have deduced ΔG(PC → s)(I_3^-) using eq. 7 and values of ΔG(PC → s)(I^-) calculated from the data of Parker and co-workers (10). These free energies of transfer listed in Table 3 can be compared with values calculated from an expression, derived from the Born equation, giving values for ΔG(PC → s)(*i*) (11). Just as was the case for the ionic enthalpies of transfer, the agreement is poor between the Born derived values and the experimental values. A further interpretation of transfer parameters would require the knowledge of the corresponding parameter for an uncharged analog of I^- and I_3^-, since the non-coulombic contribution to the transfer energy must be important. This latter point can be clearly seen by comparing the significant differences between ΔG or ΔE values for DMF and AN, two solvents selected for their nearly identical dielectric constant 36.7 and 38.8, respectively.

Our enthalpy data can be used to calculate enthalpy changes ΔH(c) and ΔH(g) for the formation of triiodides, respectively in the solid phase [3] and gas phase [4]. These ΔH(c) and ΔH(g) values are then compared with previously reported data. First, our calculated ΔH(c) for $M^+ = Me_4N^+$ in Table 2, is in fair agreement with a value determined from variations with temperature of emf of solid-state cells (4). Our values for $M^+ = Bu_4N^+$ calculated respectively from measurements in DMF and DMSO are reasonably close considering the many steps involved. We can then combine our values of ΔH(c) for [3] with those of Topol (4, 14) to consider the influence on ΔH(c) of the radius r_+(Å) of the cation M^+. The ΔH(c) values (kcal mol^{-1}) for MI(c) + I_2(c) ⇌ MI_3(c) are as follows: −2.1, NH_4^+ (r_+ = 1.43); −3.1, Rb^+ (r_+ = 1.48); −3.7, Cs^+ (r_+ = 1.68); −1.0, Me_4N^+ (r_+ = 3.0); and −12.0, Bu_4N^+ (r_+ = 5.0). It is clear that the exothermicity of ΔH(c) does not increase smoothly with r_+ which is contrary to what is expected from the Kapustinskii equation (15). The use of this equation by others (4, 16), in the calculation of $U(MI_3)$ (and possibly U(MI) when M is an alkylammonium ion) is then open to criticism.

We can at this point discuss the values of the enthalpy change ΔH(g) for [4] estimated (4) from values of ΔH(c) and lattice energies of MI and MI_3 calculated from a form of the Kapustinskii equation. By using his ΔH(c) values for $M^+ = Rb^+$ and Cs^+ with r_{I^-} = 2.25 Å, Topol calculated an effective radius $r_{I_3^-}$ = 2.45 Å and the lattice energies $U(RbI_3)$ and $U(CsI_3)$. From these latter values, U(RbI), U(CsI), and the experimental values of ΔH(c), Topol obtained an enthalpy change of −9.1 kcal mol^{-1} for I^-(g) + I_2(c) ⇌ I_3(g) and finally ΔH(g) = −24.0 kcal mol^{-1}. However, the lattice enthalpy $U(CsI_3)$ = 137.7 kcal mol^{-1} used by Topol differs from an older value $U(CsI_3)$ = 118 calculated by Halliwell and Nyburg (16) from the Kapustinskii equation but this time with $r_{I_3^-}$ = 3.0 Å. It is surprising that both previous authors note a good agreement between their different values for $r_{I_3^-}$ and the same set of crystallographic data (17). The latter value of $U(CsI_3)$ leads to ΔH(g) = −44 kcal mol^{-1}, *i.e.* a value 20 kcal mol^{-1} more exothermic than Topol's value. It would thus seem that such values of ΔH(g) involving the use of the Kapustinskii equation are not reliable. We have therefore calculated a limit for ΔH(g) from our enthalpies of reaction ΔH(s,c). Taking from Table 1, ΔH(s,c) = −7.5 kcal mol^{-1} for the

solvent TMS, we obtain a ΔH(s,g) value of $-7.5 - 14.9 = -22.4$ kcal mol^{-1} for the reaction $I^-(s) + I_2(g) \rightleftharpoons I_3^-(s)$. This value represents a limit for ΔH(g) since the enthalpy of solvation of I_3^- is likely to be less exothermic than that of I^-. The real value of ΔH(g) may, however, be considerably more exothermic than -22.4 kcal mol^{-1}. Such a situation has been discussed previously (6) for a similar reaction leading to the formation of hydrogen dichloride ion. Another way of estimating ΔH(g) would be to use an argument similar to that advanced by McDaniel and Vallee (18), *i.e.* that ΔH(c) for [3] should tend towards ΔH(g) in eq. 10 when r_+ is large, because $U(MI) - U(MI_3)$ then tends towards 0. Although this argument is open to criticism, since we have seen that ΔH(c) does not vary smoothly with r_+, using $\Delta H(c) = -12.0$ kcal mol^{-1} for Bu_4N^+ would lead to a limiting value for $\Delta H(g) = -12.0 - 14.9 = -26.9$ kcal mol^{-1}. Finally, a theoretical value has also been calculated for ΔH(g) using a modified Hückel procedure (19). The formation energy thus found for I_3^- with respect to the reactants in free state is 2.1 kcal mol^{-1}, a value which is at odds with the limits set above.

Comment: A problem in extracting structure information from the temperature of maximum density for aqueous solutions

JAMES R. KUPPERS

Department of Chemistry, The University of North Carolina at Charlotte, Charlotte, NC 28223

Received September 26, 1976

JAMES R. KUPPERS. Can. J. Chem. **55**, 798 (1977).

The shift in the temperature of maximum density for aqueous solutions customarily has been dissected into an *ideal* and a *structural* contribution. This analysis demonstrates that the dissection leads to the formulation of an *ideal* state which is attained by a fortuitous superposition of temperature dependent properties of pure components and, hence, cannot serve as a reliable reference state for comparing the influence of different solutes upon solution structure.

JAMES R. KUPPERS. Can. J. Chem. **55**, 798 (1977).

Le déplacement dans la température de densité maximum de solutions aqueuses est généralement disséqué en termes de contributions idéale et structurale. Cette analyse démontre que cette dissection conduit à la formulation d'un état idéal qui peut être obtenu par une superposition fortuite de propriétés des composants purs qui dépendent de la température et qu'ainsi il ne peut pas servir comme état de référence adéquat pour comparer l'influence de différents solutés sur la structure de la solution.

[Traduit par le journal]

The shift in the temperature of maximum density, TMD, of a water solution relative to that of pure water is given by the relation of Wada and Umeda (1)

$$[1] \quad \Delta\theta = -1/(1-x)2\beta V_1^*[x\alpha V_2^0 + \partial\Delta V^M/\partial T]$$

where x is the mole fraction of solute, α is the thermal coefficient of expansion of pure solute (assumed to be constant over the temperature range considered), β is the coefficient in the parabolic relation to temperature of the molar volume of water in the vicinity of 3.98 °C, V_2^0 is the molar volume of pure solute at 0 °C, V_1^* is the molar volume of water at 3.98 °C, and ΔV^M is the excess volume of mixing.

It has been assumed (1–4) that $\Delta\theta$ could be decomposed into an 'ideal' term and a 'structural' term such that $\Delta\theta = \Delta\theta_I + \Delta\theta_{st}$, where

$$[2] \quad \Delta\theta_I = -x\alpha V_2^0/(1-x)2\beta V_1^*$$

and

$$[3] \quad \Delta\theta_{st} = -(\partial\Delta V^M/\partial T)/(1-x)2\beta V_1^*$$

The 'ideal' state inferred by this decomposition is one in which ΔV^M is not necessarily zero but one in which it remains constant over some finite temperature range. In order that a solution satisfy the proposed criterion for 'ideality' it is not sufficient that $\partial\Delta V^M/\partial T$ be zero at just one specified temperature. To do so would be analogous to identifying conditions under which the compressibility factor of an imperfect gas is unity.

To further clarify this issue let us examine in detail the necessary consequences of assuming that $\Delta\theta_{st} = 0$ signifies that the solute has no influence upon the structure of water near its TMD, and then determine whether or not these consequences are consistent with our special concepts of 'ideality' of mixing. Suppose that $\Delta\theta_{st} = 0$ for a particular solute over a small finite range of concentration. This implies that $\partial\Delta V^M/\partial T$ must be zero at any concentration within this range. Now recall that

$$[4] \quad \Delta V^M = V - xV_2 - (1-x)V_1$$

where V_1, V_2, and V are the molar volumes of pure solute, pure solvent, and solution, all at some specified temperature. Furthermore

$$[5] \quad \partial\Delta V^M/\partial T = \partial V/\partial T - (1-x)(\partial V_1/\partial T) - x(\partial V_2/\partial T)$$

If we now apply eq. 5 at the TMD, then $\partial V/\partial T = 0$, and it is immediately revealed that $\partial\Delta V^M/\partial T$ at the TMD is uniquely determined by $\partial V_1/\partial T$ and $\partial V_2/\partial T$, which are properties of the pure components. However, the values to be assigned these quantities will depend upon the TMD. Note that $\partial V_1/\partial T$ and $\partial V_2/\partial T$, both functions

of temperature, were made implicit functions of concentration when $\partial V/\partial T$ was set equal to zero, *i.e.* for a given concentration of a particular solute there is a unique temperature at which the solution possesses its maximum density. Moreover, if we require that eq. 5 be set equal to zero then

$$[6] \qquad (1 - x)(\partial V_1/\partial T) = -x(\partial V_2/\partial T)$$

and if eq. 6 is required to hold over any finite range of concentration it demands a most unusual thermal expansibility for the pure solute.

This result is sufficient grounds for rejecting $\Delta\theta_{st}$ as a completely reliable indicator of solution structuring.

Having demonstrated that $\partial\Delta V^M/\partial T$ at the TMD can be calculated from the properties of the pure components, it follows immediately that, if β is sufficiently insensitive to temperature, $\Delta\theta_{st}$ can be also. Of course, this is not the method used previously for computing $\Delta\theta_{st}$. Instead, $\Delta\theta_I$ was calculated, with the assumption that α and β were constant, then subtracted from the measured $\Delta\theta$ to give $\Delta\theta_{st}$. By this artifact a $\Delta\theta_{st}$ was obtained which could be correlated with other indices to nonideality of mixing. Although $\Delta\theta_{st}$ undoubtedly contains information regarding solution structure, it cannot tell us more than $\Delta\theta$ itself.

There is still no reason to question the validity of eq. 1 provided the possible temperature dependence of α and β are recognized. Furthermore, it provides a means for calculating a fundamental thermodynamic property of the solute, $\partial\phi/\partial T$, the apparent molal expansibility of the solute at the TMD.

$$[7] \qquad \Delta\theta = -x/(1 - x)2\beta V_1^*(\partial\phi/\partial T)$$

Also, by extrapolating measured values of $\Delta\theta/x$ to infinite dilution, one may obtain a value of the partial molal expansibility of the solute at 3.98 °C, a potentially meaningful indicator of solution structural properties (5). The apparent molal expansibility of solutes in aqueous solution was used earlier as an index of the structural interaction of solutes with water (6).

Reply to comment: "A problem in extracting structure information from the temperature of maximum density for aqueous solutions"

DIGBY D. MACDONALD

Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received November 23, 1976

DIGBY D. MACDONALD. Can. J. Chem. **55**, 800 (1977).

The arguments presented by Kuppers in the preceding paper on the use of the temperature of maximum density parameters $\Delta\theta$ and $\Delta\theta_{st}$ for the analysis of the effect of solutes on the structure of water are critically examined. The validity of these arguments is challenged on both theoretical and experimental grounds. In particular, the proper choice of the standard state is stressed, and it is demonstrated that $\Delta\theta_{st}$ contains structural information which cannot be extracted from $\Delta\theta$ directly.

DIGBY D. MACDONALD. Can. J. Chem. **55**, 800 (1977).

On examine d'une façon critique les arguments présentés par Kuppers, dans la publication précédente, sur l'utilisation des paramètres de température de densité maximum $\Delta\theta$ et $\Delta\theta_{st}$ pour l'analyse de l'effet des solutés sur la structure de l'eau. Utilisant une base théorique et expérimentale on met en doute la validité de ces argumentations. En particulier, on met en relief l'importance de faire le choix approprié de l'état de référence et on démontre que $\Delta\theta_{st}$ contient une information structurale qui ne peut pas être obtenue directement à partir de $\Delta\theta$.

[Traduit par le journal]

In the preceding paper Kuppers (1) presents an analysis of the effect of solutes on the temperature of maximum density (TMD) of aqueous solutions, and claims that the structural component of the shift in the TMD of a real system, $\Delta\theta_{st}$, cannot yield more information as to the influence of solutes on the structure of water than can the observed shift, $\Delta\theta$, itself. The purpose of this communication is to present a critical examination of Kuppers' arguments, and to emphasise our previous claim (2) that the structure-selective parameter, $\Delta\theta_{st}$, *does* yield structural information which cannot be obtained directly from the undissected parameters, $\Delta\theta$.

Kuppers states that "it has been assumed that $\Delta\theta$ could be decomposed into an 'ideal' term and a 'structural' term such that $\Delta\theta = \Delta\theta_I + \Delta\theta_{st}$, . . .". Furthermore, he states that "the ideal state inferred by this decomposition is one in which ΔV^M is not necessarily zero but one in which it remains constant over some finite temperature range" (see eq. 1, preceding paper). However, by definition a thermodynamically ideal mixture is characterised by a zero ΔV^M at all temperatures, *i.e.* $(\partial\Delta V^M/\partial T) = 0$, in which case $\Delta\theta = \Delta\theta_I$. Therefore, the thermodynamically ideal system satisfies the criteria for the standard state as dictated by eq. 1 of the preceding paper. It is important to note that this definition of the standard state is independent of the composition of the system, *i.e.* both ΔV^M and its temperature dependence are *zero at all solute concentrations.* According to Kuppers, a system which is characterised by $(\partial\Delta V^M/\partial T) = 0$, but $\Delta V^M \neq 0$, is also an acceptable standard state. However, this would be analogous to stating that an acceptable standard state for aqueous HCl at 25 °C is a 1.2 *M* solution because the activity (not the activity coefficient) is equal to one at this concentration. If this were so, then each solute would be characterised by a unique standard state! Accordingly, the limited criteria suggested by Kuppers are not acceptable for defining the standard state of a liquid mixture. Interestingly enough, many structure making solutes do exhibit $\Delta\theta_{st} = 0$ at some (unique) concentration (3, 4); a behaviour which parallels that of the activity of aqueous HCl alluded to above.

The crux of Kuppers' arguments is contained in eq. 6 of the preceding paper which, he claims, "demands a most unusual thermal expansibility for the pure solute". However, this equation is better written as

$$[1] \quad (\partial V_1^0/\partial T)_{TMD} = -[x/(1-x)] \times (\partial V_2^0/\partial T)_{TMD}$$

where x is the mole fraction of solute (subscript

1) and $1 - x$ is the mole fraction of the solvent (subscript 2). The subscript TMD has been included to emphasise that the temperature to which eq. 1 above refers is the temperature of maximum density for the ideal system for a given composition (note that the TMD is a function of concentration). Work to date (3, 4) indicates that those solutes which form near ideal mixtures with water depress the temperature of maximum density (*i.e.* TMD $< 3.98\,^{\circ}C$). In this region of temperature $(\partial V_2^0/\partial T)$ is negative, and it is this unusual behaviour of the solvent (water) which is responsible for the maximum in density in the first place. Accordingly, $(\partial V_1^0/\partial T)$ is positive; a result which this author does not find "most unusual" as claimed by Kuppers.

Finally, Kuppers offers no experimental evidence to support his contention that $\Delta\theta_{st}$ cannot tell us more about the structural properties of aqueous solutions than can $\Delta\theta$ itself. On the other hand, a considerable amount of data exists which shows that those solutes which are normally regarded as water-structure makers (*e.g.* alcohols) exhibit positive $\Delta\theta_{st}$ values (as expected) even though $\Delta\theta$ may be positive or negative. Likewise, structure breakers exhibit negative $\Delta\theta_{st}$ values. This clearly demonstrates that the indexing of solutes as "structure makers" of "structure breakers" using TMD data can only be made upon the basis of $\Delta\theta_{st}$ and not upon the basis of the undissected parameter $\Delta\theta$, *i.e.* $\Delta\theta_{st}$ contains information which cannot be extracted from $\Delta\theta$ directly. The experimental evidence for the utility of $\Delta\theta_{st}$ *vs.* $\Delta\theta$ as an index of the effect of solutes on the structure of water has been examined recently by Macdonald and Hyne (2) and the reader is referred to this paper for a more detailed discussion of this subject.

The linear mixture formula in non-equilibrium chemical kinetics

ROBERT K. BOYD

Department of Chemistry, University College, Swansea, U.K.
and
Guelph-Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Guelph, Ont., Canada N1G 2W1

Received June 25, 1976

ROBERT K. BOYD. Can. J. Chem. **55**, 802 (1977).

The recent extensions of the 'eigenvalue approximation' of non-equilibrium kinetics proposed by Bartis and Widom to explain in a direct qualitative sense some general features of phenomenological chemical kinetics in ideal gas systems, have been used to investigate the problem of the 'linear mixture formula' applied to non-equilibrium kinetics of reactions proceeding in mixtures. For isomerization reactions in mixtures dilute in reactant, the model of Bartis and Widom, without further embellishment, has been shown to justify such an equation. Extrapolation of this result to account for recent empirical successes of a linear mixture formula in dissociation–recombination reactions of diatomic molecules X_2 is not straightforward; the physical implications of the mathematical approximations employed are examined, and the non-linear recombination term is accounted for in the present purely qualitative context by an appropriate linearization. However, the appreciable contributions from X_2–X_2 collisions, under the conditions of the experiments cited, introduce inescapable non-linearities if vibration–vibration exchange, for example, is important. Problems associated with the role of the free atom X as a collision partner seem likely to be less important.

ROBERT K. BOYD. Can. J. Chem. **55**, 802 (1977).

On a utilisé les extensions récentes de l'approximation des valeurs de eigen pour des cinétiques de systèmes qui ne sont pas en équilibre et qui ont été proposées par Bartis et Widom pour expliquer d'une manière qualitative directe quelques caractéristiques générales de la cinétique chimique phénoménologique dans des systèmes gazeux idéaux pour étudier le problème de la "formule de mélange linéaire" appliquée à des cinétiques qui ne sont pas en équilibre de réactions se produisant dans des mélanges. Pour des réactions d'isomérisation dans des mélanges dilués en réactif, on a montré que le modèle de Bartis et Widom sans autres embellissements justifie une telle équation. L'extrapolation de ces résultats pour tenir compte de succès empiriques récents de la "formule de mélange linéaire" dans des réactions de dissociation et de recombinaison de molécules diatomiques X_2 n'est pas directe; on a examiné les implications physiques des approximations mathématiques qui ont été utilisées et on tient compte des termes de combinaisons non-linéaires dans le contexte purement qualitatif actuel par une linéarisation appropriée. Toutefois les contributions importantes des collisions X_2–X_2 dans les conditions de réactions citées introduisent des non-linéarités qui ne peuvent être empêchées si, par exemple, l'échange vibration–vibration est important. Les problèmes associés avec le rôle de l'atome X libre agissant comme un partenaire de collision semblent vraisemblablement moins importants.

I. Introduction

The empirical relations of the phenomenological chemical kinetics of thermal systems have long been intuitively understood, in a qualitative way, on the basis of what may be conveniently termed 'local-equilibrium' theories. In general, a common basic assumption of such theories is that the internal (physical) modes of the reacting (chemical) species are equilibrated amongst themselves. This postulate greatly simplifies the theoretical treatments, as in transition state theory (1), for example; the justification for the 'local-equilibrium' assumption concerns the much shorter timescale associated with internal relaxation than with chemical reaction, under most conditions. In such cases, local-equilibrium theories offer qualitative understanding, as well as quantitative or semi-quantitative accounts, of such relations as the phenomenological rate equations, the temperature dependence of rate constants, the principle of detailed balance, etc.

However, in experiments where the rates of internal relaxation and chemical reaction are not well-separated, the local-equilibrium postulate breaks down, and in such cases it is not immediately obvious that the empirical relationships of 'normal' chemical kinetics should apply. Theoretical understanding, in a qualitative sense at least, of non-equilibrium chemical kinetics in ideal gas systems has been made possible in re-

cent years through the work of Widom and collaborators (2–4); this work represents a development of an idea first proposed by Zwolinski and Eyring (5), and subsequently extended by a number of authors (6–9). This approach will here be termed the 'eigenvalue approximation', for convenience, and is discussed at some length below. The general thrust of the present work may be divided into three main sections:

(*a*) An analysis is attempted of some of the physical implications of mathematical approximations made in the more recent developments of the eigenvalue approximation due to Widom and co-worker (3, 4).

(*b*) The simple eigenvalue theory (2–9) refers only to first-order, or pseudo-first-order, reactions. In view of the present slant towards dissociation–recombination reactions of diatomic molecules, an attempt is made to provide a justification for extending the insights and understanding offered by Widom's treatment (3, 4) to such cases.

(*c*) Recently (10–16), the laser–schlieren technique, used to follow diatomic dissociation rates in shock-tubes, has yielded rate data of high precision over a wide range of reactant composition. This development has permitted a meaningful test of the linear mixture formula for non-equilibrium chemical kinetics, *viz.*;

$$[1]\quad -\mathrm{d}[\mathrm{X}_2]/\mathrm{d}t = [\mathrm{X}_2]\sum_i k_\mathrm{d}{}^i[\mathrm{M}_i] - [\mathrm{X}]^2\sum_i k_\mathrm{r}{}^i[\mathrm{M}_i]$$

where $[\mathrm{X}_2]$ is the concentration of diatomic molecules, [X] that of the free atom, and the M_i represent the heat-bath collision partners, including both X_2 and X as well as added inert species such as argon. The first serious question as to the applicability of such a simple linear combination of separable rates, in cases where non-equilibrium effects seemed likely to be important, appears to have been raised by Byron (17). In the present work, this problem is discussed in the spirit of Widom's development (3, 4) of the eigenvalue approximation.

II. Physical Implications of Widom's Extension of Eigenvalue Approximation

In this section, the discussion will centre upon a simple isomerization reaction, proceeding via the agency of collisions with an inert heat-bath species M, assumed present in large excess:

$$[2]\quad \mathrm{A} + \mathrm{M} \underset{k_\mathrm{r}}{\overset{k_\mathrm{f}}{\rightleftharpoons}} \mathrm{B} + \mathrm{M}$$

The phenomenological rate equation for this reaction would then take the form:

$$[3]\quad -\mathrm{d}[\mathrm{A}]/\mathrm{d}t = k_\mathrm{f}[\mathrm{A}] - k_\mathrm{r}[\mathrm{B}]$$

where the concentration of M has conveniently been included in the pseudo-first-order rate constants k_f and k_r. Consideration of just *two* isomers A and B avoids the complications due to chemical mechanisms with closed loops (4, 9), and also provides a linear analogue for the dissociation–recombination reactions of homonuclear diatomic molecules.

In common with earlier work on such problems (2–9), it is assumed from the outset that the microscopic description is given by an appropriate master equation:

$$[4]\quad -(\mathrm{d}/\mathrm{d}t)|\alpha\rangle = \boldsymbol{K}^\mathrm{M}|\alpha\rangle$$

where $|\alpha\rangle$ is a column vector, whose ith component α_i ($1 \leq i \leq \mathrm{n}$) is the population per unit volume of the isomerizing molecule in state i; $\boldsymbol{K}^\mathrm{M}$ is the transport matrix for changes of state via collisions with M, such that

$$K_{ii}{}^\mathrm{M} = \sum_{i=1}^{n} k_{ij}$$

($k_{ii}{}^\mathrm{M} = 0$), and $K_{ij}{}^\mathrm{M} = -k_{ji}{}^\mathrm{M}$ for $i \neq j$. The $k_{ij}{}^\mathrm{M}$ include the concentration of M, and are thus pseudo-first-order rate constants for $i \rightarrow j$ transitions. An exact solution to this equation is known:

$$[5]\quad \alpha_i(t) = \alpha_i{}^* + \sum_{r=2}^{n} c_r{}^0\phi_r{}^\mathrm{M}(i)\exp(-\lambda_r{}^\mathrm{M}t)$$

where $\alpha_i{}^*$ is the equilibrium ($t \rightarrow \infty$) limit of α_i, the $c_r{}^0$ are constants dependent on the initial ($t = 0$) distribution function $|\alpha(0)\rangle$, $\phi_r{}^\mathrm{M}(i)$ is the ith component of the rth eigenvector of $\boldsymbol{K}^\mathrm{M}$ and $\lambda_r{}^\mathrm{M}$ is the corresponding eigenvalue. In order to contract this purely physical description to a chemical one, it is necessary to ascribe some of the states (say 1 to $m - 1$, inclusive) to isomer A, and the remainder to B, thus:

$$[6]\quad [\mathrm{A}] = \sum_{i=1}^{m-1}\alpha_i;\quad [\mathrm{B}] = \sum_{i=m}^{n}\alpha_i$$

The conditions under which the phenomenological rate equation [3] is an *exact* consequence of the microscopic description, as given

by [5] and [6], are known (9) to be impossibly stringent, and approximate solutions must be sought. The traditional 'local-equilibrium' approximation identifies the rate constants with the following theoretical constructs;

$$[7]\quad {}^{E}k_f^{M} = \sum_{i=1}^{m-1} (\alpha_i^*/[A^*]) \sum_{j=m}^{n} k_{ij}^{M}$$
$$[7]\quad {}^{E}k_r^{M} = \sum_{j=m}^{n} (\alpha_j^*/[B^*]) \sum_{i=1}^{m-1} k_{ji}^{M}$$

As discussed in the Introduction, however, this approximation is not expected to be universally valid, and in such cases a very general non-equilibrium theory may be delineated (5) by considering that the eigenvalue spectrum of $\boldsymbol{K}^{M}$ has the form:

$$[8]\quad 0 = \lambda_1^{M} \approx \lambda_2^{M} \gg \lambda_3^{M} > \ldots > \lambda_n^{M}$$

The smallest eigenvalue λ_1^{M} is identically zero for reactions in closed systems.

The exact solution [5] may, after an incubation time $\sim(1/\lambda_3^{M})$, be approximated by omitting all terms with $r \geq 3$; then by requiring that the rate constants be independent of time and of initial conditions, the following theoretical constructs are derived (2–9) as the 'eigenvalue approximations' to the rate constants:

$$[9]\quad ({}^{\lambda}k_f^{M} + {}^{\lambda}k_r^{M}) = \lambda_2^{M}$$
$$[9]\quad ({}^{\lambda}k_f^{M}/{}^{\lambda}k_r^{M}) = K^* = [B^*]/[A^*]$$

The number of almost-degenerate eigenvalues (two in the present case) must be the same as the number of chemical species. Previously, this property of the eigenvalue spectrum [8] was assumed; however, by making further assumptions whose range of validity is discussed below, Widom (3, 4) was able to derive a special case of the eigenvalue approximation for which [8] was a readily understandable result. Further, this same special case (3, 4) also led to a crucial 'orthogonality relation' for the eigenvectors of $\boldsymbol{K}^{M}$, which simultaneously guarantees detailed balance for non-trivial cases (9) (chemical mechanisms *with* closed loops), and also permits a demonstration (9) that the eigenvalue approximation is quite generally a better approximation to the 'exact' solution, as given by [5] plus [6], than is the local equilibrium approximation given by [7]. In view of these successes of the extended version (3, 4) of the eigenvalue approximation, it seemed important to investigate the special additional assumptions involved, with a view to establishing their probable range of validity with respect to the experimental systems of interest. In this model (3, 4), the discrete states labelled by the integer variables i,j are replaced by a continuum of states, labelled by x,y; the ranges of x and of y are assumed to be $-\infty \leq x(y) \leq +\infty$. Then, under various assumptions whose physical significance is discussed below, the relevant eigenvalue equation reduced (3) to:

$$[10]\quad (M_2^{M}/2)\{-[\psi_r^{M}(x)]'' + ([f(x)^{1/2}]''/[f(x)^{1/2}])\psi_r^{M}(x)\} = \lambda_r^{M}\psi_r^{M}(x)$$

where the sign of the left side of [10] has been changed from that in the original (3), in order to permit positive eigenvalues λ_r as in the discrete model. In [10], $f(x)$ is the equilibrium (Boltzmann) distribution function of the molecule (and thus independent of the nature of M), and prime denotes differentiation with respect to x; $\psi_r^{M}(x)$ is the rth eigenvector of the *symmetrized* transition kernel, and may be converted to the analogue of $|\phi_r^{M}\rangle$ in the discrete case by a simple transformation involving only $f(x)$. The quantity M_2^{M} is the second moment of the symmetrized transition probability function:

$$[11]\quad w_s^{M}(x, y) = [f(x)/f(y)]^{1/2} w^{M}(x, y) = w_s^{M}(y, x)$$

where $w^{M}(x, y)\,dy$ is the probability per unit time, in heat-bath composed of M, that a molecule in state x will undergo a transition to a state in the range y to $y + dy$, (*cf.* k_{ij} in the discrete model, Section II). Then M_2^{M} is defined by:

$$[12]\quad M_2^{M} = \int_{-\infty}^{+\infty} w_s^{M}(y, x)\cdot(y - x)^2\,dy$$

The crucial approximation in reducing the general case to the special eigenvalue equation [10] involves the assumption (3, 4) that the values of $w_s(x, y)$ be significant only for $y \approx x$; then, moments higher than the second moment M_2 may be discarded. In fact, such an assumption may be justified physically if the state label x is defined such as to be a smoothly varying function of internal energy, since energy transfers from internal modes to translational energy of a structureless atom like argon are known to be fairly small; the Landau–Teller transition probabilities for a harmonic oscillator undergoing

near-adiabatic transitions offer a possibly extreme example of this point. Thus, the above restriction (3, 4) on $w_s(x, y)$ is physically reasonable, provided the label x is a smooth function (not necessarily monotonic) of the internal energy.

Nonetheless, the state label x cannot be identified precisely with the state energy, since a specified energy may correspond to more than one state, which in turn may be ascribed to different chemical species; thus the state label x carries a more detailed description than that provided by only the state energy.

In addition, under this same assumption concerning $w_s(x, y)$, M_1 should also be small since:

$$[13]\quad \frac{w_s(x,x+\delta x)}{w_s(x,x-\delta x)} = \left[\frac{f(x-\delta x)}{f(x+\delta x)}\right]^{1/2} \times \left[\frac{w(x,\, x+\delta x)}{w(x,\, x-\delta x)}\right] \approx [e^{2\delta\varepsilon/kT}]^{1/2}[e^{-\delta\varepsilon/kT}] \approx 1.0$$

where $\delta\varepsilon$ is the internal energy difference associated with both $\pm\delta x$, (δx and $\delta\varepsilon$ small), and deexcitation processes are assumed to involve negligible activation energy. Thus, M_1 should be approximately zero, since $w_s(x,y)$ is invariant to a change of sign of y; thus, only M_2 remains in [10].

The remaining approximation concerns the functional dependence of $M_2{}^{M}$ upon the state label x, *i.e.* effectively upon the internal energy; in order for [10] to be useful, it is necessary that this functional dependence be weak, relative to that of the other factor on the left side of [10]. In turn, this implies that the functional dependence of this latter factor should be approximately that of the eigenfunction $\psi_r{}^{M}(x)$. It does not seem possible, at present, to make any useful generalization here; however, if the Landau–Teller probabilities for a harmonic oscillator are again invoked as a rather special simple case, $M_2{}^{M}$ clearly increases approximately linearly with the vibrational quantum number, since $k_{v+1,v} = (v+1)k_{10}$. The eigenvectors may be expressed (6) in terms of Gottlieb polynomials, for which the variation of the eigenvector elements is a complex function of the index μ:

$$[14]\quad l_r(\mu) = \exp(-r\theta) \times \sum_{\nu=0}^{n} [1-\exp\theta]^{\nu} \binom{r}{\nu}\binom{\mu}{\nu}$$

where θ is the vibrational spacing and n the number of levels considered. It is clear that the dependence of $l_r(\mu)$ upon μ is considerably greater than the linear dependence of $M_2{}^{M}$, discussed above, and to this extent the approximation (3, 4) of constant $M_2{}^{M}$ is reasonable in this rather special case.

It is well-known (6) that the simple harmonic oscillator model is inadequate insofar as a quantitative account of dissociation–recombination reactions of diatomic molecules is concerned. However, the results of interest here are very general conclusions regarding the transition kernel; by assuming that these results are at least approximately valid in general, Widom (3, 4) has shown that the all-important property [8] of the eigenvalue spectrum, together with the chemical principle of detailed balance, follows immediately. The present section has demonstrated that the necessary assumptions (3, 4) are consistent with the known properties of a model which is physically meaningful, even if not quantitatively valid (6).

Quite apart from these residual uncertainties just outlined, which refer to reactions proceeding via collisions with inert, structureless heat-bath molecules such as argon, additional difficulties arise when dissociation–recombination reactions of diatomic molecules are considered. These difficulties are associated with the fact that the diatomic X_2 and free atom X are usually present in significant concentration, and are clearly not inert, structureless collision partners. Discussion of these additional problems is best deferred to Section V below.

III. Dissociation–Recombination Reactions

The simple linear model used thus far is not applicable to dissociation–recombination reactions, since the recombination terms are nonlinear. The approach adopted in the present work is to devise an approximate linearization procedure, valid close to complete equilibrium, whereby the truly non-linear master equation may be re-expressed in a linear form analogous to that discussed above. The qualitative conclusions derived previously (2–9) for the linear isomerization model reaction, as well as those derived below, may then be applied to dissociation–recombination reactions. In order for this extrapolation to be valid, it is necessary that the experimental rate constants, obtained in shock-tube experiments as the ratio of a dissociation

rate to a concentration, are indeed true rate constants, independent of time and of composition; it is this crucial assumption which permits the identification of the appropriate theoretical constructs for the rate constants within the 'eigenvalue approximation', and implies that the measurements were made well after the incubation time.

While preparing this work for publication, it was realised that the results of this linearization procedure had been given previously by Nikitin (18). However, the method of derivation and limits of validity of this result are not readily available, and these are included here as an Appendix for the sake of completeness.

Then, within the limits of this approximate linearization (see Appendix), the eigenvalue approximation expressions for the rate constants are:

$$[15] \qquad \begin{aligned} (k_d^{\lambda}/k_r^{\lambda}) &= [A^*]^2/[A_2^*] = K^* \\ \lambda_2 &= (k_d^{\lambda} + 4[A^*]k_r^{\lambda}) \end{aligned}$$

This result is analogous to [9], which applies to the strictly linear isomerization model; note that, according to [15], the rate constants are true constants only if λ_2 varies with [A*] as $(1 + 4[A^*]/K^*)$. While it is true that λ_2 must increase with [A*], it does not seem possible to prove that this particular functional dependence is necessary; however, it seems likely that this apparent prediction of a composition dependence of k_d^{λ} and k_r^{λ} is an artefact of the force-fit of the true master equation into the linearized form.

In other words, in view of the somewhat artificial linearization required, it is *not* the eigenvalue which should here be regarded as the more fundamental quantity, but rather the rate constants themselves.

It is not claimed that the present linearization procedure offers a good model for quantitative treatments; rather, it was intended to provide a justification for extending to dissociation–recombination reactions the qualitative conclusions reached for isomerization reactions (2–9).

IV. Linear Mixture Formula

The experimental findings which prompted the present work involve dissociation–recombination reactions of diatomic molecules, for which [1] gives the appropriate form of the linear mixture formula. However, the discussion of the theoretical implications of such a formula is most easily given for the linear isomerization model described in Section II; extension of the qualitative conclusions thus reached to the systems of interest is then justified by the considerations of Section III.

Now, the reaction described by [2] is assumed to proceed via collisions with inert, structureless heat-bath molecules M and N, such that F_M and $F_N = (1 - F_M)$ are the mole fractions of M and N respectively in the heat-bath. Then, in view of the present restriction to ideal gas systems, the microscopic description of the rate, assumed again to be given by a master equation analogous to [4], becomes:

$$[16] \qquad -(\mathrm{d}/\mathrm{d}t)|\alpha\rangle = (F_M\boldsymbol{K}^M + F_N\boldsymbol{K}^N)|\alpha\rangle = \boldsymbol{K}|\alpha\rangle$$

This 'linear mixture formula' for the *microscopic* description is simply a consequence of the additivity and independence of collision rates in ideal gases. The present problem is to justify the contraction of [16], via the definition of chemical species [6], to the phenomenological linear mixture formula [17] relevant to our model reaction:

$$[17] \qquad \begin{aligned} -\mathrm{d}[A]/\mathrm{d}t = {} & (F_M k_f^M + F_N k_f^N)[A] \\ & - (F_M k_r^M + F_N k_r^N)[B] \end{aligned}$$

In the local equilibrium approximation, the theoretical constructs [7] for the rate constants become:

$$[18] \qquad \begin{aligned} {}^{E}k_f &= \sum_{i=1}^{m-1} \Big\{(\alpha_i^*/[A^*]) \\ &\qquad \times \sum_{j=m}^{n} (F_M k_{ij}^M + F_N k_{ij}^N) \\ &= (F_M{}^{E}k_f^M + F_N{}^{E}k_r^N) \end{aligned}$$

and similarly for ${}^{E}k_r$. Such definitions are entirely consistent with the linear mixture formula [17], as is intuitively obvious (19).

Again, however, in the non-equilibrium eigenvalue approximation (2–9), the result is non-trivial; the definitions of theoretical expressions for the rate constants analogous to [9] are derived from [16] in the usual way, and are valid whatever the composition of the heat-bath:

$$[19] \qquad {}^{\lambda}k_f + {}^{\lambda}k_r = \lambda_2; \quad {}^{\lambda}k_f/{}^{\lambda}k_r = K^*$$

In [19], λ_2 is the smallest non-zero eigenvalue of $\boldsymbol{K}$ (see [16]), and is thus a function of F_M and $F_N(= 1 - F_M)$, as well as of *all* the micro-

scopic rate constants k_{ij}^{M} and k_{ij}^{N}. If ${}^{\lambda}k_f$ and ${}^{\lambda}k_r$ are to satisfy [17], it is clearly necessary and sufficient that this functional dependence be of the following form:

$$[20] \qquad \lambda_2 = F_M\lambda_2{}^{M} + F_N\lambda_2{}^{N}$$

since K^* is not a function of the nature of M and N. ($\lambda_2{}^{M}$ is a function of the k_{ij}^{M} only, and $\lambda_2{}^{N}$ of the k_{ij}^{N}.)

A sufficient condition for [20] to be valid is that $\boldsymbol{K}^{M}$ and $\boldsymbol{K}^{N}$ shall commute; in such a case $\boldsymbol{K}^{M}$, $\boldsymbol{K}^{N}$, and $\boldsymbol{K}$ (see [16]) share common eigenvectors, so that [20] and thus [17] follow directly. This commutation condition is not necessary, since it is required only that the first two eigenvectors $|\phi_1\rangle$ and $|\phi_2\rangle$, corresponding to λ_1 and λ_2 be shared, in the present two-species model reaction; $|\phi_1\rangle = |\alpha^*\rangle$ is shared, in any event.

The question of the commutation of $\boldsymbol{K}^{M}$ and $\boldsymbol{K}^{N}$ was investigated by considering the vector $\boldsymbol{K}^{M}(\boldsymbol{K}^{N}|\alpha\rangle)$, and attempting to reduce it to a form symmetrical with respect to interchange of M and N; in the trivial two-level case ($n = 2$) it is possible to do so, using the microscopic reversibility relations $(k_{ij}^{M}/k_{ji}^{M}) = (\alpha_j{}^*/\alpha_i{}^*) = (k_{ij}^{N}/k_{ji}^{N})$. However, for $n > 2$ this is not possible, in principle, as is readily seen from writing out the matrix product explicitly; thus, $\boldsymbol{K}^{M}$ and $\boldsymbol{K}^{N}$ do not commute, in general.

However, as mentioned above, this commutation requirement is too strong; furthermore, it is not necessary that the relation [20] be obeyed *exactly*, since the experimental relation [1] may be confirmed in shock-tubes only to within an appreciable experimental scatter, even in the more recent investigations (10–16). In the spirit of the latter comment, it is instructive to consider the further approximations introduced by Bartis and Widom (4), discussed in Section II above.

The crucial eigenvalue equation [10] yields invaluable insights (3, 4) if $M_2{}^{M}$, as defined by [12], is effectively constant, *i.e.* has a much weaker dependence on the state label x than do the eigenfunctions $\psi_r{}^{M}(x)$. Under this *same* approximation (3, 4), it is clear that [10] implies that the $\psi_r{}^{M}(x)$ are independent of the nature of M, and the corresponding eigenvalues scale linearly with $M_2{}^{M}$. In fact, it is only necessary to assume that $M_2{}^{M}$ is approximately independent of x, relative to the dependence of $\psi_r{}^{M}(x)$, for $r < \hat{n}$, where $\hat{n}$ is the number of chemical species involved (9) (two in the present case).

Thus, the same approximations as used previously by Widom and co-worker (3, 4), culminating in the relation [10] plus the above assumption regarding $M_2{}^{M}$, lead immediately to [20], and thus to the linear mixture formula given by [17]. An earlier investigation (20) of this same problem concluded that the linear mixture formula was valid under local-equilibrium conditions, but was unable to justify the formula for non-equilibrium kinetics.

V. Empirical Tests of Linear Mixture Formula

A direct test of the preceding discussion, for dissociation–recombination reactions, would require data obtained using highly dilute mixtures of X_2 in mixtures of inert gases (*e.g.*, neon plus argon); no systematic investigations of this type are known to the present author. The nearest approach to this experiment was achieved by Breshears *et al.* (11) for the shock dissociation of O_2; also relevant is the elegant investigation of the relaxation of hydrogen by Dove and collaborators (21, 22). In both cases, in order to obtain good shocks into mixtures containing helium, it was necessary (11, 21, 22) to add a proportion of a diluent (Kr) heavier than He. The linear mixture formula (23, 24) appropriate to the relaxation experiment was found (21, 22) to account for the data quite satisfactorily. This observation is, at least, perfectly understandable in the context of the simple harmonic oscillator approximation; this is most readily seen in terms of the treatment due to Montroll and Shuler (25). If the factor κ (eq. (1.7) of ref. 25) is identified as $(k_{10}{}^{M}F_M + k_{10}{}^{N}F_N)$, in line with the additivity of collision rates, then it is a simple exercise to show that the original analysis (25) is not sensibly altered, and the simple Bethe–Teller expression for the energy relaxation is still obtained, modified according to the linear mixture formula (23, 24). However, in view of the finding (22) that the rotational mode is probably involved in the observed relaxation, this simple demonstration is clearly not the last word on this subject. The case of the O_2 dissociation experiments (11) is discussed more fully below.

In the case of those dissociation experiments (11–16) for which a truly meaningful test of the linear mixture rate equation [1] was possible, the heat-bath collision partners involved have been an inert gas (typically argon), the diatomic molecule X_2 itself, and the dissociated atom X.

Before discussing the added theoretical complications arising from this fact, it is appropriate to comment on the degree to which the linear mixture equation has been tested in this work (11–16), and on its success or otherwise.

It appears that the most impressive successes of [1] are in the experimental investigations with $X_2 = H_2$ (13) and $X_2 = Br_2$ (15, 16). In both cases, the experiments suggested that k_d^M, $k_d^{X_2}$, and k_d^X are all true rate constants, independent of the particular reaction mixture used. Thus, for example, the value of $k_d^{H_2}$ extracted using [1] was independent (13) of the nature of M; also, the very precise values of k_d^{Ar} obtained (13) for H_2 using the laser–schlieren technique are in excellent agreement with the equally precise results of Myerson and Watt (26), obtained in very dilute mixtures using an atomic resonance absorption technique to follow the rate of H atom production. In the case of $X_2 = Br_2$, each of k_d^{Ar}, k_d^{Kr}, $k_d^{Br_2}$, and k_r^{Br} is a true rate constant, in that values obtained from high-temperature flash photolysis (27), laser–schlieren, molecular absorption spectroscopy, or atomic two-body emission in shock waves (15, 16, 35) are all in agreement to within experimental uncertainty.

In the case of $X_2 = O_2$, the laser–schlieren results (11) are again a satisfyingly self-consistent set of data when treated in terms of the linear mixture formula [1]. However, values so obtained (11) for k_d^{Ar} are about a factor of three higher than the comparable results of Watt and Myerson (28) using atomic resonance absorption spectroscopy, which are in good agreement with direct high-temperature measurements (29) of k_r^{Ar}; this discrepancy is far outside the combined experimental scatter, and seems significant in the light of the excellent agreement, cited above, for $X_2 = H_2$. The reasons for this disagreement are not clear.

In the cases (12, 14) of $X_2 = HCl$ and $X_2 = F_2$, the linear mixture formula [1] was found to be perfectly adequate, but these experiments (12, 14) were less extensive, and do not provide as severe a test of [1] as do the first two cases discussed. Nevertheless, these findings (12, 14) provide a significant contribution to confidence in the linear mixture formula as applied to this class of reactions; on the whole, it seems to be a fair conclusion that the recent shock-tube data (11–16) are well described by the linear mixture formula [1], with only one ($X_2 = O_2$) reservation.

However, this empirical success of the linear mixture formula [1] cannot be accounted for simply and directly in terms of the considerations of Sections II, III, and IV above, since the collision partners X_2 and X are very special, not at all covered by the assumption in the theoretical treatment of inert, structureless heat-bath molecules. The case of the dissociated atom X seems marginally simpler, and will be dealt with first.

The extraordinary efficiency of free atoms X in relaxation and dissociation of X_2 is well documented, and has frequently been cited as evidence of a 'chemical' interaction. From the present point of view, this need not necessarily nullify the present theoretical treatment, provided that this extra efficiency still retains the characteristics that $M_2 \gg M_3$, M_4, etc., and that M_2 has a relatively weak functional dependence on x, (see Sections II and IV above). That is to say, relatively small energy transfers in $X–X_2$ collisions must still be appreciably more probable than larger energy transfers; as emphasized recently (30), there is a great need for further theoretical studies of this problem. The most relevant study is that due to Thompson (31), who carried out a classical dynamical study of vibrational relaxation and atom-exchange in the systems $Cl + Cl_2$ and $I + I_2$. As can be seen readily from Figs. 10 and 11 of ref. 31 the distributions over v' for the process

$$X + X_2(v) \rightarrow X_2(v') + X$$

are sharply peaked around $v = v'$, for $v = 14$ at 1100 K; this distribution is particularly narrow for $X \equiv I$, and less so for $X \equiv Cl$. Although these results (31) are invaluable, they are unfortunately inadequate to permit a quantitative evaluation of the validity of Widom's contraction of the Taylor-series expansion (3, 4), of the transition kernel, which led to [10]; this is because no information is available on the eigenvectors and their derivatives. However, the evidence available (31) is clearly consistent with the free atom X meeting the requirements of Widom's qualitative model (3, 4). In addition, of course, it must be assumed that the translational and electronic modes of the atom X are fully relaxed at all times under shock-tube conditions; then X may be regarded effectively as a structureless collision partner, and may be represented as a single state n in [A1] (see Appendix). Under these conditions, it appears that there should be no breakdown of [1] due to the special

nature of the dissociated atom X as collision partner.

No such accommodation in the present theory is possible for the case of X_2 as a collision partner, since it is the disequilibrium of the internal states of X_2 during dissociation which is the object of the present exercise. Thus, significant contributions of X_2–X_2 collisions in which *both* molecules change their internal states introduce non-linearities which are inescapable. The only escape for the present theoretical approach, in this case, would require a demonstration that in X_2–X_2 collisions, translational–vibrational exchange, for example, is much more probable than vibrational–vibrational (V–V) exchange, possibly due to non-matching of the anharmonic vibrational levels. The fitting of vibrational relaxation times of pure X_2 into semi-empirical correlation schemes (32), based upon simple theory of translational–vibrational relaxation, offers some heavily circumstantial evidence to sustain this hope, but clearly more work is necessary here also. The phenomenological success of [1] in including $k_d^{X_2}$ is thus not properly accounted for by the present approach.

An alternative theoretical approach, which has yielded useful information on this question, involves numerical (computer) experiments. In a study of a model system designed to resemble H_2 dissociation in He, McElwain and Pritchard (33) showed that the linear mixture formula would hold in mixtures containing appreciable H_2 provided that the V–V coupling was not too strong, but would break down badly if such processes were efficient, in broad agreement with present conclusions. The problem remains to ascertain the efficiency of V–V exchange for H_2 in He, under experimental shock dissociation conditions, and thus to determine into which regime (33) the real system should fall; the experimental evidence, for H_2 in Ar (13, 26), clearly indicates the linear mixture formula is valid, suggesting (33) that V–V coupling is *not* efficient in this latter system.

Similar work due to Kiefer (34), on a model system designed to simulate O_2, seems to confirm the conclusion that when V–V exchange is significant the linear mixture rate law is not valid. One explicitly stated conclusion (34), that significant deviations from the linear mixture formula seem to be largely confined to the effect of the self-atom, would appear to be an inevitable consequence of the method used (34) to reduce the 'experimental' (*i.e.* computational) data. Rate constants $k_d^{X_2}$ and k_d^{M}, where M is Ar for example, were obtained using [1] for mixtures of closely similar compositions *not* containing any X; then the rate data for a mixture of M, X_2, and X were reduced (34) through [1], using these same values of k_d^{M} and $k_d^{X_2}$. That is, *all* deviations from [1], whatever their cause, were automatically assigned (34) to the k_d^{X} so calculated. Thus, the conclusion stated elsewhere in (34) that breakdown of [1] is generally a consequence of significant V–V exchange would appear to be the appropriate one.

Such computational 'experiments' are invaluable in that they afford the opportunity of providing quantitative insights which the present analytic approach cannot provide; on the other hand, the numerical approach *alone* has not offered qualitative physical understanding. For example, the question, treated above, as to *why*, in the absence of significant V–V coupling, the linear mixture formula should be valid for non-equilibrium kinetics, was not broached in either of the studies cited (33, 34). Thus the two approaches should be considered as complementary to one another. The most pressing problem now would seem to be to account for the empirical success (11–16, 35) of the linear mixture formula in a range of systems, including *pure* diatomic X_2, for which V–V coupling and other exchanges of internal energy might be expected to be significant.

Appendix: Linearization of Dissociation–Recombination Master Equation

For convenience, in the following derivation the superscript M is dropped from the rate constants, which are again pseudo-first-order, or pseudo-second-order in the case of recombination steps. Denoting by β_n the concentration of free dissociated atoms, the relevant master equation is:

$$[A1] \quad (-d/dt)\begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \cdot \\ \cdot \\ \alpha_{n-1} \\ \beta_n \end{pmatrix} = \begin{pmatrix} \left(\sum_i k_{1i}\right) & -k_{21} & \cdots & \cdots & -k_{n,1} \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ \cdot & & & & \cdot \\ -k_{1,n-1} & -k_{2,n-1} & \cdots & \left(\sum_i k_{n-1,i}\right) & -k_{n,n-1} \\ -2k_{1,n} & -2k_{2,n} & \cdots & -2k_{n-1,n} & \left(2\sum_i k_{n,i}\right) \end{pmatrix} \begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \cdot \\ \cdot \\ \alpha_{n-1} \\ \beta_n^2 \end{pmatrix}$$

The problem with [A1] is that the two composition vectors are not identical; the aim is to approximate [A1] in such a way as to render the two vectors identical, while still retaining all the appropriate properties (2–9) of the transport matrix. This may be achieved by defining:

$$[A2] \qquad \alpha_n \equiv (\beta_n^*/2) + \Delta \quad \text{where } \Delta \equiv (\beta_n - \beta_n^*)$$

Thus, $\beta_n^2 \approx 2\beta_n^*\alpha_n$, provided $(\Delta/\beta_n^*)^2 \ll 1$; also: $(d\alpha_n/dt) = (d\beta_n/dt)$. Then, to within this approximation, [A1] may be written:

$$[A3] \qquad -(d/dt)|\alpha\rangle = \boldsymbol{L}|\alpha\rangle$$

where $L_{i,n} = -2\beta_n^* k_{n,i}$, for $1 \leq i < n$, and

$$L_{nn} = 4\beta_n^* \sum_i k_{ni}$$

all other elements of $\mathbf{L}$ are unchanged from those of the matrix in [A1]. The determinant $|\mathbf{L}|$ is zero, and thus $\mathbf{L}$ has one zero eigenvalue, λ_1 say, with the corresponding eigenvector given by $|\phi_1\rangle = |\alpha^*\rangle$, as required (2–9).

The analysis now proceeds as usual (2–9); the matrix **L** may be diagonalized by a similarity transform ($\mathbf{A}^{-1/2}\mathbf{L}\,\mathbf{A}^{+1/2}$), where **A** is a diagonal matrix with $A_{ii} = \alpha_i^*$, for $1 \leq i < n$, and $A_{nn} = 2\alpha_n^* = \beta_n^*$; the solution given as [5] then applies. The chemical classification of the states is now:

$$[A4] \qquad [A_2] = \sum_{i=1}^{n-1} \alpha_i; \quad [A] = \beta_n$$

and insertion of [5] into [A4] gives the appropriate theoretical predictions of the chemical composition as a function of time. However, the mass conservation condition upon the eigenvectors $|\phi_r\rangle$ must be reinvestigated; this is best done by deriving two expressions for β_n, one directly from α_n, and the other from the expression for $[A_2]$ plus mass balance. Thus:

$$[A5] \qquad \beta_n = \alpha_n + \tfrac{1}{2}\beta_n^* = \beta_n^* + \sum_{r=2}^{n} c_r^0 \exp(-\lambda_r t)\phi_r(n)$$

The mass balance condition is:

$$[A6] \qquad [A_2] + \tfrac{1}{2}[A] = \sum_{i=1}^{n-1} \alpha_i + \tfrac{1}{2}\beta_n = \sum_{i=1}^{n-1} \alpha_i^* + \tfrac{1}{2}\beta_n^* = \sum_{i=1}^{n} \alpha_i^*$$

From [5], we have:

$$[A7] \qquad \sum_{i=1}^{n} \alpha_i = \sum_{i=1}^{n} \alpha_i^* + \sum_{r=2}^{n} c_r^0 \exp(-\lambda_r t) \left(\sum_{i=1}^{n} \phi_r(i) \right)$$

From [A2], [A6], and [A7] is derived:

$$[A8] \qquad \beta_n = \beta_n^* + 2 \sum_{r=1}^{n} c_r^0 \exp(-\lambda_r t) \cdot \left(\sum_{i=1}^{n} \phi_r(i) \right)$$

Then, since the c_r^0 are arbitrary, it is true, for $2 \leq r \leq n$, that

$$[A9] \qquad \phi_r(n) = -2 \sum_{i=1}^{n-1} \phi_r(i) \equiv -2u_r$$

and this is the mass conservation condition upon the eigenvectors. Now, ignoring all terms with $r > 2$, yields for the eigenvalue approximation:

$$[A10] \qquad [A_2] = \sum_{i=1}^{n-1} \alpha_i = [A_2^*] + c_2^0 u_2 \exp(-\lambda_2 t)$$

$$[A11] \qquad (-\mathrm{d}/\mathrm{d}t)[A_2] = c_2^0 u_2 \lambda_2 \exp(-\lambda_2 t)$$

$$[A12] \qquad [A]^2 = \beta_n^2 \approx 2\beta_n^* \alpha_n = 2\beta_n^* \alpha_n^* + 2\beta_n^* c_2^0 \exp(-\lambda_2 t)\phi_2(n) = [A^*]^2 - 4[A^*]c_2^0 u_2 \exp(-\lambda_2 t)$$

Equations A10–A12 are consistent with the phenomenological description of the rate, provided that the rate constants correspond to the eigenvalue approximation expressions, given by [15].

An acidity function based on thiocarbonyl indicators

JOHN T. EDWARD, IVAN LANTOS, GARY D. DERDALL, AND SIN CHEONG WONG

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3C 3G1

Received July 5, 1976

JOHN T. EDWARD, IVAN LANTOS, GARY D. DERDALL, and SIN CHEONG WONG. Can. J. Chem. **55**, 812 (1977).

The ionization of 16 thiocarbonyl indicators of overlapping range has been used to establish an acidity function H_T for 10–90% sulfuric acid. Agreement with an earlier H_T scale of Tissier and Tissier using different thiocarbonyl indicators is good. Protonation constants pK_{TH^+} derived by the classic Hammett–Deyrup approach are in good agreement with those derived by the Bunnett–Olsen relations, but in less satisfactory agreement with those derived by the Marziano–Cimino–Passerini relations.

JOHN T. EDWARD, IVAN LANTOS, GARY D. DERDALL et SIN CHEONG WONG. Can. J. Chem. **55**, 812 (1977).

On a utilisé l'ionisation de 16 indicateurs thiocarbonyles ayant des écarts qui se recoupent pour établir une fonction d'acidité H_T pour l'acide sulfurique de 10–90%. L'accord avec une échelle antérieure H_T de Tissier et Tissier utilisant différents indicateurs thiocarbonyles est bon. Les constantes de protonation pK_{TH^+}, obtenues par une approche classique de Hammett–Deyrup, sont en bon accord avec celles obtenues par des relations de Bunnett–Olsen mais ne sont pas en aussi bon accord avec celles dérivées de relations Marziano–Cimino–Passerini.

[Traduit par le journal]

Introduction

The extent to which thioamides and related compounds (T) are converted into their conjugate acid forms (TH^+) in aqueous sulfuric acid is governed by an acidity function H_T (1), defined by

$$[1] \quad H_T = -\log (a_{H^+} f_T / f_{TH^+}) = pK_{TH^+} - \log ([TH^+]/[T])$$

where the symbols have their customary definitions (1, 2). This acidity function proves to be very close to H_0''' (2), which governs the protonation of tertiary anilines, in its dependence on acid concentration (3–5). Our need to interpret results on the kinetics of the acid-catalyzed hydrolysis of thioamides and thionesters (1) has led us to establish the H_T scale for 10–90% aqueous sulfuric acid, using 16 thiocarbonyl indicators of varying structures (1) and the overlap procedure of Hammett and Deyrup (6), and we report these results in this paper.

Since Hammett and Deyrup's classic paper, two new approaches for establishing an acidity function scale, and hence for obtaining thermodynamic ionization constants of weak bases, have been reported in the literature. The first approach is based on the linear free energy relationship of Bunnett and Olsen (7):

$$[2] \quad \log ([TH^+]/[T]) + H_0 = \phi(H_0 + \log [H^+]) + pK_{TH^+}$$

The ϕ parameters, which characterize the changing activity coefficient behaviour of bases with changing acidity (7–9), can be calculated from ionization ratio data for a set of indicators. The H_T scale may then be derived from the average ϕ value and the H_0 function (6, 10) by

$$[3] \quad H_T = H_0 - \phi(H_0 + \log [H^+])$$

(obtained by rearranging [2]). Tissier and Tissier (11) have applied this method and established H_T for 10–80% aqueous sulfuric acid using 11 indicators, all of them different from ours, with an average ϕ value of 0.36.

The second approach is based on another empirical linear relationship, this one discovered by Marziano, Cimino, and Passerini (M.C.P.) (12). They found that for a series of overlapping indicators A, B, C ..., at any given acid concentration the following relationship holds:

$$[4] \quad \log \frac{[H^+][B]}{[BH^+]} + pK_{BH^+} = n_B \left(\log \frac{[H^+][A]}{[AH^+]} + pK_{AH^+} \right)$$

$$\log \frac{[H^+][C]}{[CH^+]} + pK_{CH^+} = n_C \left(\log \frac{[H^+][B]}{[BH^+]} + pK_{BH^+} \right)$$

etc.

$$[4a]\quad \log\frac{[H^+][B]}{[BH^+]} = n_B \log\frac{[H^+][A]}{[AH^+]} + (n_B pK_{AH^+} - pK_{BH^+})$$

$$\log\frac{[H^+][C]}{[CH^+]} = n_C \log\frac{[H^+][B]}{[BH^+]} + (n_C pK_{BH^+} - pK_{CH^+})$$

etc. A plot of log ($[H^+][B]/[BH^+]$) for the indicator B against the corresponding function for A at the same acid concentrations should give the parameter n_B as the slope, and the protonation constant pK_{BH^+} of the second indicator can be calculated from the intercept and from n_B if pK_{AH^+} is known.

In this way, starting from an 'anchor' compound A whose protonation constant is known in dilute aqueous solution, the protonation constants of the weaker bases B, C ... may be established by a stepwise procedure which does not depend on any acidity function. Furthermore, from the same data one may derive a new activity coefficient function M_C, based on a single reference base A. Equation 4 may be rewritten as

$$[5]\quad \log\frac{f_{H^+}f_B}{f_{BH^+}} = n_B \log\frac{f_{H^+}f_A}{f_{AH^+}}$$

$$\log\frac{f_{H^+}f_C}{f_{CH^+}} = n_C \log\frac{f_{H^+}f_B}{f_{BH^+}}$$

etc. M_C is defined by

$$[6]\quad M_C = -\log\frac{f_{H^+}f_A}{f_{AH^+}} = -\frac{1}{n_B}\log\frac{f_{H^+}f_B}{f_{BH^+}} = -\frac{1}{n_C^*}\log\frac{f_{H^+}f_C}{f_{CH^+}} = -\frac{1}{n_D^*}\log\frac{f_{H^+}f_D}{f_{DH^+}} = \ldots$$

where $n_X^* = n_B n_C \ldots n_X$. This equation may be rewritten as

$$[7]\quad M_C = -\log\frac{f_{H^+}f_A}{f_{AH^+}} = \frac{1}{n_B}\left(\log\frac{[B]}{[BH^+]} + \log[H^+] + pK_{BH^+}\right)$$

$$= \frac{1}{n_C^*}\left(\log\frac{[C]}{[CH^+]} + \log[H^+] + pK_{CH^+}\right) = \ldots$$

Since thermodynamic parameters for the anchor compound A are known, M_C may be established by measurement of the ionization ratios of indicators B, C ... at higher acid concentrations, using the values of n_B, n_C ... and pK_{BH^+}, pK_{CH^+} ... already established.

The pK_{TH^+} values obtained by the M.C.P. procedure should be free from errors caused by the cumulative effects of deviations from parallelism in plots of log $[BH^+]/[B]$ against acid concentration in the classic Hammett–Deyrup procedure, and from errors inherent in the long extrapolation to dilute aqueous solution involved in the Bunnett–Olsen approach. Furthermore, the M_C function, referring to a single reference base A, should in theory eliminate the need for a multiplicity of acidity functions H_0, H_0''', H_A, H_R, etc., the differing behaviour of different types of base being reflected in different values of n.

In the present paper we apply these two new approaches also to data for the ionization of the 16 thiocarbonyl indicators, and compare the pK_{TH^+} values thus obtained with those yielded by the traditional overlap procedure of Hammett and Deyrup.

Experimental

Materials

1,3-Diethylthiourea was a gift of Professor W. Cocker, and 1,3-di-*tert*-butylthiourea was a commercial product. 4,5-dimethyl-4-imidazoline-2-thione was prepared by reaction of 3-aminobutanone hydrochloride and ammonium thiocyanate in water (13). All three compounds were purified by crystallization from ethanol and had melting points close to those reported.

Thiobenzamide (mp 117–118°C, lit. (14) mp 116°C), 4-methoxythiobenzamide (mp 151–152°C, lit. (14) mp 148.5–149.5 °C), and 4-chlorothiobenzamide (mp 131–132°C, lit. (14) mp 124°C) were prepared by reactions of the appropriate nitriles with hydrogen sulfide in the presence of triethylamine (14) and crystallized from ethanol.

Thioheptanamide was prepared by reaction of heptanamide with phosphorus pentasulfide in refluxing pyridine (*cf.* ref. 15), and melted at 63–65°C after crystallization from ethanol. *Anal.* calcd. for $C_7H_{15}NS$: C 57.9, H 10.4, N 9.6, S 22.1; found: C 58.0, H 10.2, N 9.8, S 22.0.

4-Nitrothioacetanilide was similarly prepared (mp 173.5–175°C, lit. (16) mp 175°C). The reaction mixture was quenched in water after only 10 min of reflux to prevent decomposition.

The 1,2-dithiole-3-thiones (17) were gifts of E. Klingsberg.

Ethyl thionbenzoate was prepared from benzonitrile according to the procedure of Renson and Bidaine (18), and was separated from a small amount of ethyl benzoate by chromatography of a hexane solution over alumina. The other thionesters were prepared in similar fashion. Ethyl 3-bromothionbenzoate, bp 98–99.5°C/3 torr, was a new compound: λ_{max} (EtOH) 416, 285, 251 nm (ε 119, 11500, 7350). *Anal.* calcd. for C_9H_9BrOS: C 44.1, H 3.7; found: C 44.0, H 3.9.

Thiobenzamidonium pentacyanopropenide was prepared by adding 10 mol excess of pyridinium pentacyanopropenide (19) to a solution of thiobenzamide in 70% sulfuric acid at 30–35°C (*cf.* ref. 20). Because of the hygroscopic nature of the salt it was not submitted for elemental analysis, but was analyzed by measurement of the ultraviolet absorption spectrum of a solution in sulfuric acid. The absorbances at different wavelengths were those expected for a 1:1 salt (at 275 nm, ε found 13 600; ε calcd. 13 900). 1,3-Diethylthiouronium pentacyanopropenide was prepared in similar fashion. Its spectrum established it also as a 1:1 salt (at 210 nm, ε found 23 800; ε calcd. 23 400).

Spectral Measurements

Measurements were made with a Unicam SP800 spectrophotometer having a cell compartment thermostatted at 25.0 ± 0.2°C, following general procedures already described (3–5). In general, good isosbestic points were observed for most families of spectra. When an isosbestic point was not evident (as in the case of curves for the substituted thioureas), extinction coefficients of the unprotonated (ε_T) and of the protonated bases (ε_{TH^+}) were taken as the extinction coefficients three H_0 units before and after half-ionization, determined by a preliminary plot according to Stewart and Granger (21).

Thionesters were stable in dilute or very concentrated sulfuric acid; ε_T and ε_{TH^+} could be determined with relative ease. In moderately concentrated acid, however, these compounds hydrolyzed fairly rapidly and their extinction coefficients were obtained by extrapolation to the time of preparing the solutions.

The ionization ratios I ($\equiv [TH^+]/[T]$) were then obtained from the extinction coefficients according to the equation

$$[8] \qquad \log I = \log [(\varepsilon - \varepsilon_T)/(\varepsilon_{TH^+} - \varepsilon)]$$

In an attempt to minimize errors (*cf.* Kresge and Chen (22)) most measurements were kept within the range: $\log I = \pm 0.6$.

Solubility Measurements

A suspension of an excess of solid in about 2 ml of sulfuric acid of known concentration, contained in a 10 ml flask immersed in a water-bath maintained at 25.0 ± 0.4°C, was shaken with a mechanical shaker. Saturation of neutral bases required 12–15 h; of pentacyanopropenide salts, 2–4 h. The suspension was filtered through a sintered glass funnel and the ultraviolet absorbance of the filtrate (diluted, if necessary, with acid of the same strength) was measured. Following Boyd (23), solubilities were expressed as absorbance (A) at a designated wavelength in a 1.0 cm cell without dilution.

Measurements of solubilities of thiobenzamide (Table 3) were carried out in solutions of increasing acidity, up to concentrations sufficient for 50% protonation, and corrections were made for solubility due to protonation of base by use of the equation

$$[9] \qquad A_T = A / (1 + I\varepsilon_{TH^+}/\varepsilon_T)$$

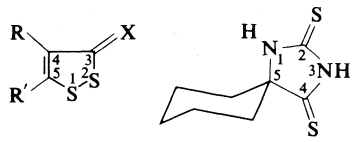
where A is the measured absorbance at 287 nm (due to T and TH^+), A_T is the absorbance due to unprotonated base, and I, ε_{TH^+} and ε_T are from results of the preceding section.

Solubilities of salts were followed by the changing absorbance of the 412 nm band of the pentacyanopropenide anion. Results are given in Table 4.

Results and Discussion

Site of Protonation of Thiocarbonyl Compounds

The 16 indicators used to establish our H_T scale are shown in Table 1 with their identifying numerals, and include several different types of thiocarbonyl compounds: thioureas (numbers 1–3), thioamides (numbers 4–8), 1,2-dithiole-3-thiones (**1**; X=S) (numbers 9, 10, and 12), a 2,4-dithiohydantoin (**2**) (number 11), and thionesters (numbers 13–16).



1 **2**

There is now general consensus that thioureas (24), thioamides (24), and thionesters (25) are protonated on the thiocarbonyl sulfur in strongly acidic solution, and ultraviolet spectral changes indicate 2,4-dithiohydantoins to be protonated on the sulfur at the 2-position (4). Protonation of the thiocarbonyl sulfur of 1,2-dithiole-3-thiones is suggested by the fact that their protonation follows the same acidity function as the other thiocarbonyl compounds, as shown by the parallelism of the curves of Fig. 1. On the other hand, the protonation of 5-phenyl-1,2-dithiole-3-one (**1**; R = H, R′ = Ph, X = O) follows H_A (26) ($pK = -3.26$), as would be expected if protonation takes place on the carbonyl oxygen.

Ionization Constant of the 'Anchor' Base

The pK_{TH^+} of the strongest base of Table 1, 1,3-di-*tert*-butylthiourea, has been determined by an extrapolation procedure due to Paul (27). Equation 1 may be rewritten as

$$[10] \qquad pK_{TH^+} = \log I - \log [H^+] + \log (f_{TH^+}/f_T f_{H^+})$$

TABLE 1. Protonation constants (pK_{TH+}) of indicators used to establish H_T scales

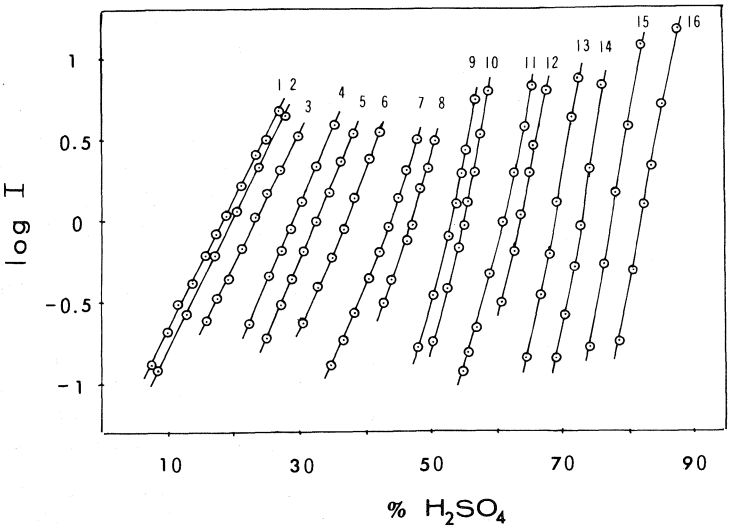

FIG. 1. Effect of acid concentration on ionization of thiocarbonyl indicators (identified by numbers in Table 1).

In dilute acid solution, as $[H^+] \rightarrow 0$, $\log (f_{TH^+}/f_T f_{H^+}) \rightarrow 0$, so that

$$[11] \quad pK_{TH^+} = \lim_{[H^+]\rightarrow 0} (\log I - \log [H^+])$$

In dilute sulfuric acid $[H^+]$ is uncertain because of the incomplete dissociation of the weak acid HSO_4^-, but perchloric acid is completely dissociated (27), so that $[H^+]$ may be determined by titration. In Fig. 2 is shown a plot of ($\log I - \log [H^+]$) against concentration of perchloric acid ($\sim$0.7–1.7 *M*). Extrapolation of the plot gives a pK_{TH^+} of -1.32 for 1,3-di-*tert*-butylthiourea.

H_T Function from the Hammett Procedure

Using the 'anchored' pK_{TH^+} value of -1.32 for 1,3-di-*tert*-butylthiourea and the experimental difference of 0.10 in the logarithm of the ionization ratio ($\Delta \log I$) between this compound and the next strongest base, 1,3-vinylenethiourea, for a given acid concentration (Fig. 1), the pK_{TH^+} of the latter in aqueous sulfuric acid was calculated to be -1.42. This is in excellent agreement with the value of -1.43 obtained from Fig. 2.

This stepwise procedure (6) was repeated for the other 14 indicators. Their pK_{TH^+} values are given in Table 1, column 3, along with the data used in calculating them (column 2). From these pK_{TH^+} values, values for H_T were calculated by application of [1] to the experimental values of I ($\equiv [TH^+]/[T]$) in different strengths of acid. Values obtained from a smoothed-out curve are given in Table 2, column 2.

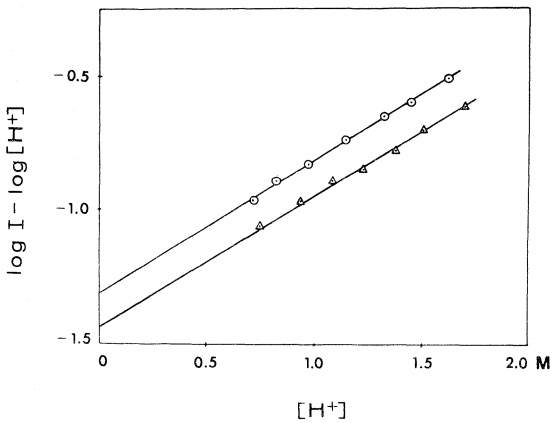

FIG. 2. Extrapolation of the ionization of 1,3-di-*tert*-butylthiourea (○) and ~~1,3-vinylenethiourea~~ (△) in perchloric acid to infinite dilution.

4,5-dimethyl-4-imidazoline-2-thione

H_T Function from the Bunnett–Olsen Approach

From [2], it is evident that a plot of ($\log I + H_0$) against ($H_0 + \log [H^+]$) for any thiocarbonyl base should give a straight line with the hydration parameter ϕ as the slope and the ionization constant pK_{TH^+} as the intercept.

This alternative to the stepwise overlap procedure of analyzing experimental ionization data has been applied to our 16 indicators, and the results are given in Table 1, columns 4–6. H_0 values were interpolated from the data of Paul and Long (28) and Jorgenson and Hartter (10) $[H^+]$ ($\equiv [H_3O^+]$) values[1] were interpolated from the data of Robertson and Dunford (29).

The pK_{TH^+} values of the 16 bases studied are mostly within 0.3 unit of those obtained by the preceding method. The ϕ values are scattered from -0.26 for 1,3-diethylthiourea and 5,5-pentamethylene-2,4-dithiohydantoin (**2**) to -0.53 for 5-phenyl (**1**; R = H, R′ = Ph, X = S) and 4-phenyl (**1**; R = Ph, R′ = H, X = S) 1,2-dithiole-3-thiones. The average ϕ value is -0.40, but only six compounds have ϕ values within the range -0.35 to -0.45. Tissier and Tissier (11) have reported less scatter in their set of ϕ values: eight of their eleven indicators had ϕ values between -0.32 and -0.38, the remaining three had values of -0.25, -0.48, and -0.52; and their average was -0.36. However, the H_T scale constructed by application of [3] shows that the average ϕ value of -0.40 gives results which are in good agreement with results of the traditional Hammett approach, especially in concentrated aqueous sulfuric acid. (Compare columns 3 and 4 with column 2 of Table 2.)

The justification for the Bunnett–Olsen approach has been empirical, and various theoretical objections to it have been raised (30–32). Accordingly, the closeness of the H_T scales established by the Bunnett–Olsen approach to that established by the traditional approach indicates the practical equivalence of the two approaches.

M_C Function for Thiocarbonyl Compounds

As another approach, the M.C.P. procedure was applied to the data of our 16 indicators, with 1,3-di-*tert*-butylthiourea again being the 'anchor'

[1]Bunnett and Olsen (7), in applying [2] to data on ionizations in sulfuric acid, took $[H^+]$ to be equal to the stoichiometric concentration of acid. Because of the small but finite dissociation of HSO_4^- in strong acid, this practice introduces a small error into the results.

TABLE 2. H_T scales derived by different methods compared with H_0''' and H_A

H_2SO_4 (%)	$-H_T$[a]	$-H_T$[b]	$-H_T$[c]	$-M_C$	$-H_T$[d]	$-H_0'''$	$-H_A$

[a]Hammett approach.
[b]Bunnett–Olsen approach.
[c]Tissier and Tissier (11).
[d]$n^*M_C - \log [H^+]$.

compound. In all cases, linear relations were found for a plot of log ($[H^+][T]/[TH^+]$) against the corresponding value of the succeeding indicator of Table 1, generally with very high correlation coefficients (>0.998 or 0.999). The results are given in Table 1, columns 7–9.

While most indicators have n values in the range of 1.0 ± 0.1, two compounds, thiocaprolactam ($n = 1.260$) and 5,5-pentamethylene-2,4-dithiohydantoin ($n = 0.814$), have n values that are appreciably different. However, this difference is no worse than many reported by Marziano *et al.* (12) for other types of bases, n values less than 0.8 or greater than 1.2 being not uncommon. Most pK_{TH^+} values differ appreciably from those calculated by the previous two methods (some by as much as one logarithmic unit). In a similar comparison, differences of these magnitudes or greater were encountered also by Marziano *et al.* (12).

From pK_{TH^+} and n values, M_C values for thiocarbonyl compounds were calculated from ionization ratios by application of [7]. They are reported in Table 2, column 5.

The M_C function for a base of type X in general is related to the appropriate acidity function H_X by:

$$[12] \qquad n^*M_C = H_X + \log [H^+]$$

n^* (1.156) being the average of n_B^*, n_C^* ... for our 16 indicators. The H_T scale thus derived from the M_C function for the thiocarbonyl compounds and from $[H^+]$ values of Robertson and Dunford (29) agrees fairly well with the H_T scales derived by the previous two methods (compare column 6 with columns 2 and 3 of Table 2), except in the most concentrated acid.

We are faced with the choice of a set of pK_{XH^+} values to accept. Marziano *et al.* (12) give various reasons for considering values derived by their approach to be more reliable: the order of pK_{XH^+} is occasionally altered to one which seems more plausible on intuitive grounds; a better linear relationship is observed between pK_{XH^+} and partial molal heats of transfer of primary nitroanilines to fluorosulfonic acid (33); etc. However, none of these arguments can be considered conclusive. It seems likely that no choice between the alternative approaches can be made without a refinement of techniques which allows measurement of very low or very high ionization ratios, $[BH^+]/[B]$, $[CH^+]/[C]$..., and hence experimental discrimination between the various extra-thermodynamic assumptions on which the different approaches are based. For the traditional Hammett–Deyrup approach, the assumption is made that for *all* acid concentrations

$$[13] \qquad \log \frac{f_B}{f_{BH^+}} = \log \frac{f_C}{f_{CH^+}} = \ldots = \log \frac{f_Z}{f_{ZH^+}}$$

For any two indicators of overlapping range, this assumption can be tested by noting whether the vertical separation between the two curves for log I (Fig. 1) at different acid concentrations remains constant (the criterion of 'parallelism' (28)). However, present experimental techniques make it possible to observe this parallelism between neighbouring curves only over a small range of acid concentrations. Arnett (34) has given reasons to believe that outside this observable range the parallelism *may* break down for certain bases, but at the moment this point cannot be established experimentally.

On the other hand, the M.C.P. approach makes the assumption that for all acid concentrations

$$[14] \quad \log \frac{f_C}{f_{CH^+}} + \log f_{H^+} = \log \left(\frac{f_B}{f_{BH^+}}\right)^{n_C} + \log (f_{H^+})^{n_C}$$

etc. This assumption is supported to the extent that plots of log ([B][H$^+$]/[BH$^+$]) against log ([C][H$^+$]/[CH$^+$]) give straight lines; again, such linear relationships can in fact be observed, because of experimental limitations, over only a limited range of acid concentrations.[2] To the extent that n_B, n_C ... approach unity, [14] reduces to [13]; however, n values frequently deviate strongly from unity.

It would seem, then, that at the moment there are no decisive grounds to preferring the M.C.P. to the Hammett–Deyrup approach, and the matter must be regarded as *sub judice*. However, the M.C.P. and Bunnett–Olsen approaches share a great practical advantage over the Hammett–Deyrup approach, in that they can be applied to compounds for which an appropriate acidity scale has not yet been, or cannot be, developed.

[2]By expressing H_T and H_0 in terms of activity coefficients, [3] becomes

$$[i] \quad \log (f_T/f_{TH^+}) + \log f_{H^+} = \log (f_B/f_{BH^+})^{1-\phi} + \log (f_{H^+})^{1-\phi}$$

(B in this case being a Hammett H_0 base.) Comparison of [i] and [14] shows that the Bunnett–Olsen and M.C.P. approaches are theoretically equivalent, and that the different results for the more concentrated acid solutions obtained by each approach come from the different ways in which extrapolation to the standard state of dilute aqueous solution is carried out.

*The Activity Coefficients f_T and f_{TH^+}**

The discussion above emphasizes the importance of direct measurements of f_X and f_{XH^+} in acidity function studies (23, 35).

The activity coefficient of a neutral Bronsted base in an acid solution is given by the ratio of its solubility in water (S_0) to its solubility in the acid under consideration (S)

$$[15] \quad f = S_0/S$$

when these solubilities are sufficiently low.

The activity coefficients of thiobenzamide in 0–40% sulfuric acid, calculated from the solubility data of Table 3, are shown in Fig. 3 along with those of 2,4-dinitrobenzamide (20) and *N*,*N*-dimethyl-3,4-dinitroaniline (36).

Following Boyd (23), activity coefficients of conjugate acids are referred to a standard ion, tetraethylammonium ion (TEA$^+$). By definition

TABLE 3. Solubilities (S) and activity coefficients (f) of thiobenzamide in various concentrations of sulfuric acid

H_2SO_4 (%)	$S \times 10^{-2}$	$S' \times 10^{-2}$[a]	log f[b]
0	1.09 (S_0)	1.09	0
8.3	0.866	0.866	0.10
16.1	0.726	0.726	0.18
24.1	0.568	0.553	0.30
33.8	0.500	0.410	0.42
39.7	0.703	0.391	0.45

[a]S' is the solubility of free base corrected for protonation.
[b]$f = S_0/S'$.

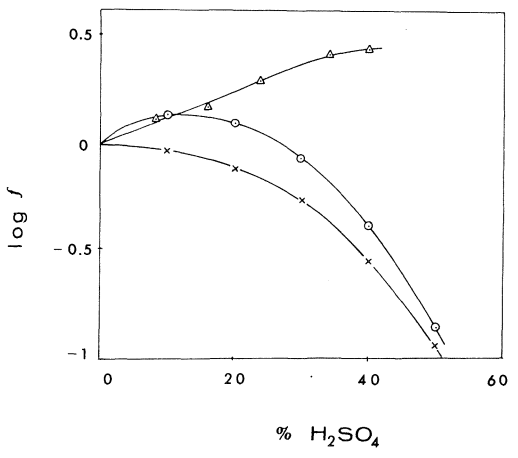

FIG. 3. Activity coefficients (f) of neutral bases: △ Thiobenzamide (T); × 2,4-Dinitrobenzamide (A); ○ *N*, *N*-Dimethyl-3,4-dinitroaniline (B$''$).

[16] $$f_{TH^+}^* = f_{TH^+}/f_{TEA^+}$$

It is impossible to measure single-ion activity coefficients, but the mean ionic activity coefficients $f_\pm$ of a sparingly soluble 1:1 salt may be determined by solubility measurements:

[17] $$f_\pm = (f_+f_-)^{1/2} = S_0/S$$

where f_+ and f_- are individual ionic activity coefficients. Boyd (23) found that the salts of many organic bases with the strong acid, pentacyanopropene (H^+PCP^-) had conveniently low solubilities. Thus, for each concentration of acid, the relative activity coefficient of the ion TH^+ is given by:

[18] $$f_{TH^+}^* = (f_{TH^+}f_{PCP^-})/(f_{TEA^+}f_{PCP^-}) = [(f_\pm(TH^+PCP^-)/f_\pm(TEA^+PCP^-)]^2$$

We have determined the solubility of the PCP salt of protonated 1,3-diethylthiourea in 37.8–69.1% sulfuric acid and of protonated thiobenzamide in 53.5–71.0% sulfuric acid (Table 3). These salts are hydrolyzed in more dilute acid solutions, and so the change in their activity coefficients in dilute acid cannot be determined directly. Yates and Sweeting (20) have described a method of anchoring these relative activity coefficients to dilute aqueous solution as standard states; the following method is simpler but basically equivalent.

Since in a given concentration of acid a_{H^+} should not be affected by the nature of base present in the vanishingly small amount necessary for spectrophotometric determination of I, the difference between H_T and any acidity function H_X is given by:

[19] $$H_T - H_X = \log(f_{TH^+}f_X/f_Tf_{XH^+})$$

so that

[20] $$\log f_{TH^+}^* = \log f_T - \log f_X + \log f_{XH^+}^* + (H_T - H_X)$$

The values of $f_{TH^+}^*$ for 1,3-diethylthiouronium ion in 0–37.8% sulfuric acid were calculated from this equation using the data of thiobenzamide for $\log f_T$; 2,4-dinitroaniline (23) for $\log f_X$, anilinium ion (23) for $\log f_{XH^+}^*$ and H_0 for H_X. (Calculations based on H_0''' (2) give essentially the same results.) The values for thiobenzamidonium ion were calculated by interpolating the first reference point (57.5% H_2SO_4) from the data of 1,3-diethylthiouronium ion. The results are shown in Fig. 4 along with those for benzamidonium ion (20) and *N,N*-dimethylanilinium ion (23).

Difference between H_T and H_A

In spite of the close similarity of amides and thioamides, there is a large difference between the protonating power of sulfuric acid when measured by thiocarbonyl indicators (T) (including thioamides) and when measured by amide indicators (A). The reasons for this difference can be understood by considering [20]. Below 40% acid, $\log f_{TH^+}^* \simeq \log f_{AH^+}^*$, and most of the difference between H_T and H_A arises from the variation in $\log f_T/f_A$. (In 30% acid, for instance, $H_A - H_T \simeq 0.8$, $\log f_T/f_A \simeq 0.7$; in 40% acid, $H_A - H_T \simeq 1.2$, $\log f_T/f_A \simeq 1.0$.) Thiobenzamide is increasingly salted-out as the concentration of acid goes up, while 2,4-dinitrobenzamide is salted-in. A part of this difference can be attributed to the specific effect of nitro groups, which cause a compound to be salted-in in sulfuric acid (35), but most of the difference comes from the different behaviour of amide and thioamide groups. Thioamides are probably more polar, and so more strongly hydrated than amides (3). Consequently, it is to be expected that they will be salted-out in acid solution as the water activity of the solution decreases.

Above 40% sulfuric acid, while $\log f_T/f_A$ still remains important, the contribution of the term

	71.0	17.40	−0.534	2.96
B	37.8	4.55 (S_0)	0	1.54
	52.1	9.12	−0.302	2.04
	60.9	16.7	−0.566	2.18
	69.1	37.4	−0.917	2.54

[a] $f_\pm = S_0/S$.
[b] f_+* $= [f_\pm/f_\pm$ (TEA$^+$PCP$^-$)]^2 and were anchored to infinite dilution.

log f_{TH^+}/f_{AH^+} to the difference between H_T and H_A becomes quite significant. (In 60% acid, for instance, $H_A - H_T \simeq 3$, log $f_{AH^+}/f_{TH^+} \simeq 1.4$.) Amidonium ions are salted-out to a much greater extent than thioamidonium ions, suggesting the latter is less hydrated than the former. This order is not unexpected since a protonated sulfur base, by virtue of its larger size and consequently lower charge density, would be expected to have lower hydration requirements.

Several classes of thio bases (thioureas, thioamides, 1,2-dithiole-3-thiones, and thionesters) have been used to construct a single H_T acidity function, indicating that structural variations have little effect on the protonation behaviour of thiocarbonyl compounds. This is probably the most striking difference between thiocarbonyl compounds and carbonyl compounds. The latter are known to exhibit a diversified acidity function behaviour, aldehydes, ketones, esters, amides, and acids following slightly different acidity functions (1, 9, 37).

Difference between H_T and H_0'''

The apparent closeness of the acidity function scales derived from thiocarbonyl (T) and tertiary aniline (B''') indicators in 10–75% aqueous sulfuric acid does not necessarily imply that the two classes of compounds have identical activity coefficient behaviour. On the contrary, available data indicate that the variation of f_T and f_{TH^+} with acid concentration is quite different from that of $f_{B'''}$ and $f_{B'''H^+}$. However, the difference $H_T - H_0'''$, which equals log $(f_{TH^+}f_{B'''}/f_Tf_{B'''H^+})$, remains small. In 30% acid, log $f_T/f_{B'''} \simeq 0.5$, log $f_{TH^+}/f_{B'''H^+} \simeq 0.6$ and in 40% acid, log $f_T/f_{B'''} \simeq 0.8$, log $f_{TH^+}/f_{B'''H^+} \simeq 0.9$, so that in both cases, log $(f_{TH^+}f_{B'''}/f_Tf_{B'''H^+}) \simeq 0.1$. Thus thioamides are hydrated to a greater extent than tertiary anilines, again probably because of the highly polar nature of the former. But this is compensated for by thioamidonium ions also being hydrated to a greater extent than tertiary anilinium ions, presumably because of the greater number of acid hydrogen atoms available for hydrogen bonding to water molecules.

Synthetic application of cyclobutanes V.[1] α-Carbalkoxymethylation of α,β-unsaturated ketones

HSING-JANG LIU AND PATRICK CHI-LIN YAO

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 23, 1976

HSING-JANG LIU and PATRICK CHI-LIN YAO. Can. J. Chem. **55**, 822 (1977).

Two general methods for α-carbalkoxymethylation of both enolizable and nonenolizable (towards the γ-position) α,β-unsaturated ketones have been developed. Method A involves three synthetic steps: photocycloaddition of the starting enone to 1,1-dimethoxyethylene, hydrolysis–oxidation of the adduct with acetic acid and 30% hydrogen peroxide, and *O*-alkylation of the resulting mixture of lactone and acid using anhydrous potassium carbonate and an alkyl iodide, *e.g.*, **13** → **17** → **21** + **22** → **23**. Method B differs from method A in the means of securing the required cyclobutanone intermediate. Thus, photocycloaddition of **13** to vinyl acetate followed by hydrolysis of the adduct gave two epimeric keto alcohols **39** whose oxidation with dimethyl sulfoxide and acetic anhydride afforded diketone **40**. Baeyer–Villiger oxidation of **40** followed by methylation of the products **21** and **22** completed the overall α-carbomethoxymethylation process to give keto ester **23**.

HSING-JANG LIU et PATRICK CHI-LIN YAO. Can. J. Chem. **55**, 822 (1977).

On a développé deux méthodes générales pour effectuer l'α-carbalkoxyméthylation de cétones α,β-nonsaturées énolisables ainsi que nonénolisables (vers la position γ). La méthode A implique trois étapes de synthèse: une photocycloaddition de l'énone de départ avec le diméthoxy-1,1 méthylène, une hydrolyse avec oxydation de l'adduit par l'acide acétique en présence de peroxyde hydrogène à 30%, et finalement une *O*-alkylation du mélange de lactone et d'acide qui en résulte faisant appel à du carbonate de potassium anhydre et un iodure d'alkyle, par exemple **13** → **17** → **21** + **22** → **23**. La méthode B diffère de la méthode A par les moyens utilisés pour obtenir la cyclobutanone requise comme intermédiaire. Ainsi la photocycloaddition de **13** sur de l'acétate de vinyle suivie par une hydrloyse de l'adduit conduit à deux cétoalcools épimères **39** qui par oxydation avec le diméthyle sulfoxyde et anhydride acétique fournissent la dicétone **40**. Une oxydation de Baeyer–Villiger de **40** suivie par une méthylation des produits **21** et **22** obtenus complète le processus global d'α-carbométhoxyméthylation conduisant au cétoester **23**.

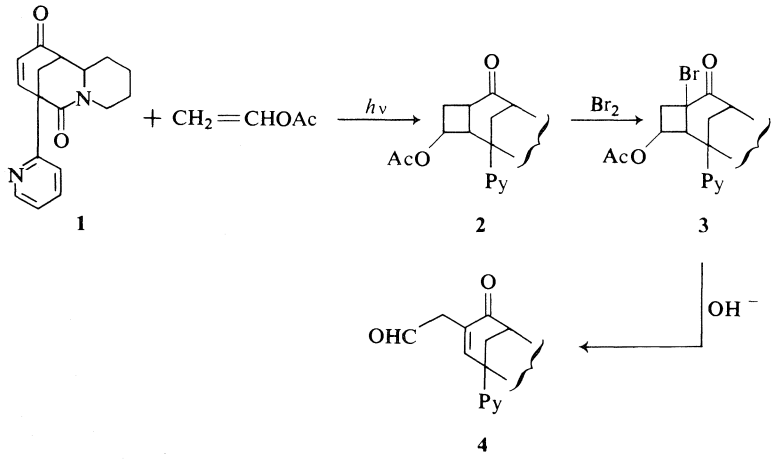
[Traduit par le journal]

Introduction

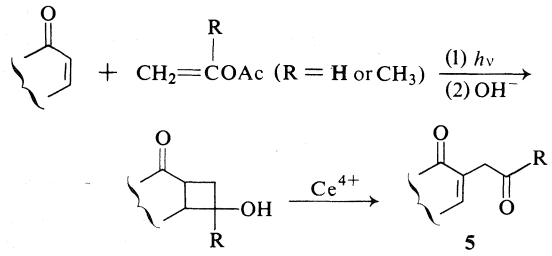
The utilization of the photocycloaddition reaction as a potential method for the introduction of a single alkyl chain specifically to the α-carbon of an α,β-unsaturated ketone was first demonstrated in the total synthesis of the *Ormosia* skeleton (5). The crucial step of alkylation of the nonenolizable enone **1** in the synthesis was achieved via a suitably substituted cyclobutane intermediate **2** using a three-step sequence (Scheme 1). This procedure was, however, later shown to be limited to α,β-unsaturated ketones in which the enolization of the ketone group towards the α′-carbon was not possible due to either substitution or strain; the preferential incorporation of a leaving group into the desirable α-position which was required for a Grob fragmentation (**3** → **4**) (6) was found difficult in cases in which the α′-carbon was also reactive (7). Using a photocycloaddition reaction as a general entry, two additional methods were subsequently developed. Valenta and coworkers (7) showed that the photoadducts of 2-cyclohexen-1-ones and enol acetates after hydrolysis underwent oxidative cleavage of the cyclobutane ring upon treatment with a variety of oxidants, in particular, ceric ammonium nitrate, to give products of type **5** (Scheme 2). More recently photoadducts of conjugated enones and vinylene carbonate were found to undergo fragmentation with alkali to yield compounds of type **6** (Scheme 3) (8). These α-monoalkylation procedures are synthetically attractive. In addition to providing useful 1,4-dicarbonyl compounds of broad synthetic interest,[2] by virtue of the mode of the initial photocycloaddition

[1]For parts I–IV of this series, see refs. 1–4 respectively.

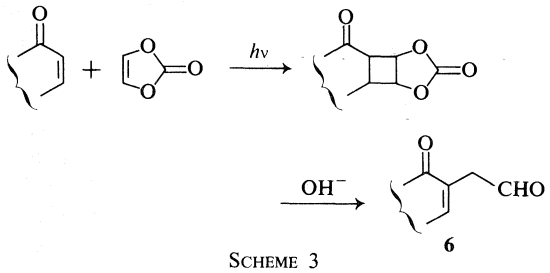
[2]For a relevant discussion see ref. 7.



SCHEME 1



SCHEME 2



SCHEME 3

reaction, they have the following outstanding features in comparison with the conventional alkylation methods (9). (*i*) An enolizable γ-hydrogen atom is not required to effect the alkylation.[3] (*ii*) The position of the double bond in the starting enone fully determines the site of the addition. (*iii*) The introduction of a single activated alkyl chain can be readily controlled.

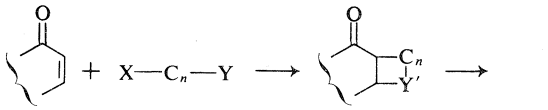
[3]Though no specific examples were given, the method cited in ref. 8 is apparently applicable to α,β-unsaturated ketones without an enolizable γ-hydrogen atom. This method has recently been extended to uracil (10) and its nucleoside (11).

Although the above procedures differ from each other in principle, they all furnish 1,4-dicarbonyl compounds of the type **5**, in which, of the three possible sites for nucleophilic attack, the side chain carbonyl has been shown to be usually more reactive (5, 12). Consequently, in cases in which the transformation of the enone system, *e.g.*, addition of Grignard reagent, is subsequently desired, it is necessary to modify the side chain in advance (12). In order to circumvent this deficiency, complementary methods allowing the direct incorporation of a less reactive functionality into the side chain are needed. We wish to report two new photochemical routes which facilitate the α-monocarbalkoxymethylation of both enolizable α,β-unsaturated ketones and those in which enolization toward the γ-position is blocked.[4]

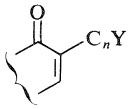
Results and Discussion

Conceptually, the α-alkylation of both enolizable and nonenolizable α,β-unsaturated ketones can be achieved by concomitant Michael type addition and cyclization, using a reagent which possesses both a nucleophilic center and a leaving group, followed by β-elimination as illustrated schematically in Scheme 4. In practice, such a scheme poses obvious problems; the reagent chosen may easily undergo polymerization or internal cyclization. It is conceivable, however, to achieve a similar transformation by the use of a cycloaddition reaction,

[4]A part of this work has been reported in preliminary form (4). A number of reactions have since been improved.

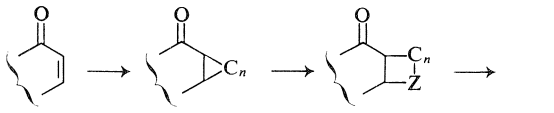


X = Leaving group
Y = Nucleophile

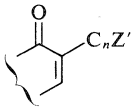


SCHEME 4

e.g., Diels–Alder reaction or photocycloaddition, to form two carbon–carbon bonds to give compounds of type **7** (as shown in Scheme 5)



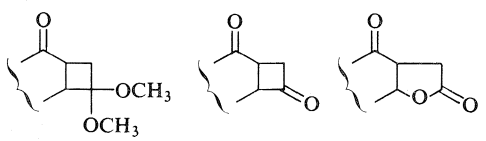
7 **8**



SCHEME 5

followed by selective introduction of a leaving group at the β-position as shown in **8**. The present studies followed this principle and the photochemical route has been used as the initial cycloaddition.

In order to facilitate the incorporation of the desired leaving group, it is necessary to activate the cyclobutane ring resulting from the photochemical process. In the first approach (method A) 1,1-dimethoxyethylene was selected for this purpose since it has been well established that its addition to conjugated enones proceeds in a head-to-tail fashion to give adducts of type **9** (13). The hydrolysis of **9** was expected to provide **10** which in principle could undergo selective Baeyer–Villiger oxidation under controlled reaction conditions to give desirable intermediates such as **11** for the regeneration of the initial double bond in the starting enone and thus completing an overall α-alkylation of a conjugated enone.



9 **10** **11**

In order to test the feasibility and generality of this alkylation procedure, four representative enones **12**–**15** were examined. The results of their photocycloaddition to 1,1-dimethoxyethylene are compiled in Table 1.

The photocycloadditions proceeded with a high degree of regioselectivity. The relative orientation of the functionalities of the photoadduct in each case follows unambiguously from further transformations. Photoadducts **16** and **17** were obtained as a mixture of *cis* and *trans* isomers. The mixture nature of these products was revealed by their nuclear magnetic resonance (nmr) spectra. Four singlets at τ 8.93, 8.89, 8.86, and 8.74 were observed for the *gem*-dimethyl group of **16** in its nmr spectrum, whereas compound **17** showed in the nmr spectrum a total of six singlets at τ 9.04, 8.98, 8.93, 8.88, 8.78, and 8.69 for the three methyl substituents. Since the two chiral centers presented in these molecules would be subsequently destroyed, no attempts were made to separate the two isomers.

Photoadduct **18** was thought to be a single stereoisomer since gas–liquid chromatography (glc) analysis showed a single peak for the distilled compound and its nmr spectrum displayed a singlet for the acetyl group at τ 8.10 and two singlets at τ 7.05 and 6.92 for the methoxy groups. The data available, however, do not permit unambiguous definition of its stereochemistry.

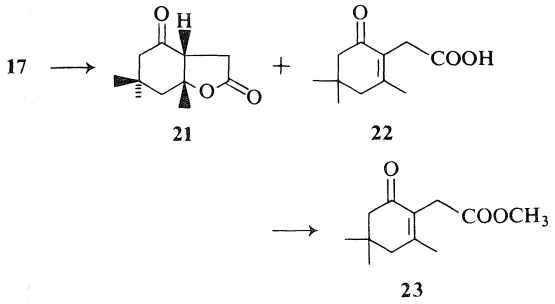
Photocycloaddition of enone **15** to 1,1-dimethoxyethlyene gave a mixture of two isomers, one of which crystallized readily from Skelly B. The mother liquor enriched in the other isomer was subsequently boiled with aqueous sodium hydroxide in methanol to epimerize it and to provide an additional crop of the first isomer. The ring junction of the crystalline compound thus obtained could readily be assigned as *cis*, since it has been established that in the bicyclo-[4.2.0]octan-2-one systems, the *trans* ring junction is readily epimerized upon treatment with base to give the thermodynamically more stable *cis* form (13). The nmr spectrum of the isolated crystalline photoadduct was in full agreement with its assigned stereochemistry. The two singlets for the methoxy groups appeared at τ 6.73 and 7.07. The appearance of one methoxy group at abnormally high field could be attributed to the shielding effect of the benzene

TABLE 1. Photocycloaddition of conjugated enones to 1,1-dimethoxyethylene

Enone	Photoadduct obtained	Isolated yield (%)
 12	 16	78
 13	 17	71
 14	 18	37
 15	 19	81

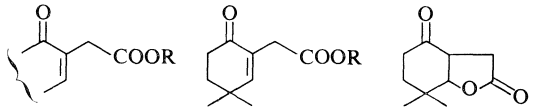
ring and suggested that the ring junction of the compound was *cis*, since inspection of Drieding models revealed that the methoxy group could be shielded by the benzene ring only when the rings were so fused.

The subsequent two-step transformation of the photoadducts **16**–**19** into compounds of type **20**, illustrated in Scheme 6 for the conversion of photoadduct **17** to keto ester **23**, completed the



SCHEME 6

overall α-carbalkoxyalkylation of a conjugated enone. Treatment of **17** with a solution of 30% hydrogen peroxide in glacial acetic acid, 1:1, furnished a mixture of keto lactone **21** and acid **22** as a result of concomitant deketalization, selective Baeyer–Villiger oxidation, and partial lactone ring cleavage. For the purpose of identification, the crystalline lactone **21**[5] could be isolated by extensive chromatography of the crude mixture. Attempts to purify the acid **22** were futile, due to its rapid conversion to the lactone **21**. For further conversion, the mixture of **21** and **22** was boiled with fivefold excess of anhydrous potassium carbonate and a large excess of methyl iodide in acetone. After 2 days, keto ester **23** was isolated in 42% yield based on **17**. Similarly, photoadduct **16** was transformed into **24** via intermediates lactone **25** and acid **26** in 41% overall yield.



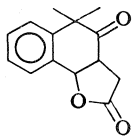
20 **24** R = CH_3 **25**
26 R = H

In the case of photoadduct **19**, the hydrolysis–oxidation proceeded abnormally. In addition to

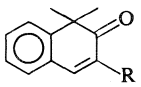
[5]Its stereochemistry follows from the fact that Baeyer–Villiger oxidation (which is known to proceed with retention of configuration (14)) of **40** with *m*-chloroperbenzoic acid gave the same lactone as the only product.

the expected products, lactone **27** and acid **28** (a total yield of 51%), a 24% yield of ester **29** was also obtained. When the mixture of **27**, **28**, and **29** was subjected to alkylation under the conditions described previously, another mixture was obtained. Though it was found to be homogeneous on thin-layer chromatography (tlc), glc analysis showed two partially overlapped peaks. Besides the expected peak at 244, the mass spectrum showed an additional peak of approximately equal intensity at 258. Exact mass measurements of these two peaks indicated a difference of a methylene unit. Although there were insufficient data to permit conclusive assignments of the identities of the two components, it was logical to deduce from the mode of the reaction that the mixture consisted of the desired ester **29** and the dialkylated compound **30**.

As a consequence of this finding, methyl iodide was replaced by a less reactive alkylating agent, namely, isopropyl iodide, in the alkylation step. As anticipated, this modification circumvented the dialkylation problem and a mixture of esters **29** and **31** was obtained. Separation of these two compounds was achieved by extensive column chromatography on silica gel. The yields of the pure substances were low, due to the loss of material incurred during the purification. It was found more convenient to separate ester **29** from lactone **27** and acid **28** prior to the alkylation reaction. Subsequent treatment of **27** and **28** with isopropyl iodide and potassium carbonate in acetone resulted in the formation of ester **31** in 71% yield. Accordingly, from photoadduct **19**, methyl ester **29** and isopropyl ester **31** were obtained in a ratio of 1:1.5 and in a total yield of 60%.

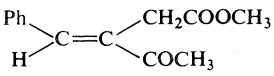


27

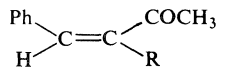


28 R = CH_2COOH
29 R = CH_2COOCH_3
30 R = $CH(CH_3)COOCH_3$
31 R = $CH_2COOCH(CH_3)_2$

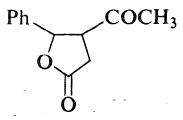
Upon hydrolysis–oxidation and subsequent alkylation under the same conditions which effected the transformation of **17** → **23**, photoadduct **18** gave rise to a 58% yield of a mixture of **32**, **33**, and **34** in the ratio of *ca.* 4:1:1 via intermediates **35** and **36**. The major product could be separated by column chromatography and its structure readily assigned as **32** on the basis of the spectral data. The minor components were obtained as a mixture of **33** and **34** as indicated by the mass spectrum showing two molecular ion peaks at 232 and 218. The two singlets at τ 8.10 and 8.07 in the nmr spectrum confirmed the presence of two acetyl groups while a high field doublet at τ 8.47 could be accounted for by the extra methyl group introduced during the alkylation. The stereochemistry of **33** and **34** was assigned as shown because of the shielding on the acetyl groups with respect to *trans*-benzalacetone as observed in the nmr spectrum. The shielding effect indicated that the acetyl group, in each case, was in the proximity of the phenyl group, which required that these two groups be *cis*. The major ester, the acetyl singlet of which appeared in the nmr spectrum at τ 7.60, was consequently assigned the *trans* structure **32**.



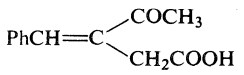
32



33 R = CH_2COOCH_3
34 R = $CH(CH_3)COOCH_3$

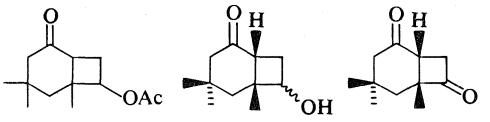


35



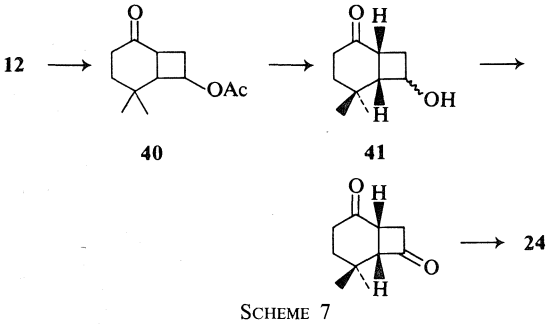
36

The second method (method B) is based on the same principle as that previously described for method A but differs from it in the means of securing the required cyclobutanone intermediate, *e.g.* **39**. Whereas in method A the cyclobutanone moiety was incorporated directly in the ketal form in the initial photochemical process and later generated *in situ*, it was produced in method B by oxidation of the corresponding alcohol which, in turn, was prepared in two steps from the starting enone and vinyl acetate. Thus, irradiation of a benzene solution of isophorone **13** and vinyl acetate afforded an 85% yield of a mixture consisting of at least two diastereomers of **37**. Hydrolysis of **37** with aqueous potassium carbonate in methanol gave a 98% yield of two epimeric alcohols **38** (1). Subsequent oxidation of **38** using dimethyl sulfoxide and acetic anhydride (15) at 5 °C resulted in the formation of diketone **39** in 91% yield. Transformation of **39** to **23** (67%) com-



37 38 39

pleted the overall α-carbomethoxymethylation process in two steps under reaction conditions similar to those used for **17** → **23**. This procedure was shown to be equally applicable to α,β-unsaturated ketones in which enolization toward the γ-position is blocked. By the same reaction sequence, the conversion of **12** into **24** was achieved in an overall yield of 45% by the route outlined in Scheme 7.



SCHEME 7

Both methods provide comparable overall yields for the conversion. Where the starting enone is easily obtainable, method B would be preferable because of the availability of the reagent required, *i.e.*, vinyl acetate. Method A however has the advantage of having relatively few steps and is more suitable in cases where the starting enone is not as easily obtained.

Experimental

General

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Mass spectra were recorded on AEI MS-50, MS-9, and MS-2 spectrometers. Infrared spectra were obtained by using Perkin-Elmer model 457 and 337 spectrophotometers. Nuclear magnetic resonance spectra were recorded on Varian A-60, 90 MHz Perkin-Elmer 32 and HR-100 spectrometers. Unless otherwise stated, carbon tetrachloride was employed as the solvent and tetramethylsilane as internal standard. The following abbreviations are used in the text: s singlet, d doublet, t triplet, q quartet, and m multiplet. Elemental analyses were performed by the microanalytical laboratory of this department. Gas chromatographic analyses were performed using an Aerograph A-90-P-3 with a column of 15% SE 30 on Chromosorb W.

Materials

The commercially available isophorone **13** and *trans*-benzalacetone **14** were freshly distilled under reduced pressure before use. 4,4-Dimethyl-2-cyclo-hexene-1-one **12** (16) and 1,1-dimethyl-2-oxo-1,2-dihydronaphthalene **15** (17) were synthesized according to the described procedures. 1,1-Dimethoxyethylene was obtained from dehydrobromination (13) of bromoacetaldehyde dimethylacetal which was prepared according to the reported procedure (18) with the modification of using methanol instead of ethanol as a solvent.

General Procedure for Photocycloaddition Reactions

The enone used was dissolved in *ca.* 15 mol excess of 1,1-dimethoxyethylene or 20 mol excess of vinyl acetate. The solution was then diluted with benzene to four or five times its original volume. A constant and moderate flow of dry and oxygen-free nitrogen was maintained to agitate the solution throughout the reaction period. The solution was irradiated using a 450 W Hanovia high-pressure quartz mercury-vapor lamp and a Pyrex filter at ~0 °C (ice bath) for 6–20 h. The progress of the reaction was monitored by checking the ir of an aliquot of the reaction mixture. Concentration of the resulting solution gave the crude adduct.

7,7-Dimethoxy-5,5-dimethylbicyclo[4.2.0]octan-2-one ***16***

4,4-Dimethyl-2-cyclohexen-1-one **12** (3.589 g, 28.94 mmol) and 1,1-dimethoxyethylene (40 g, 0.45 mol) were dissolved in benzene (~120 ml). The solution was irradiated for 15 h. The solvent and the unreacted olefin were distilled off at atmospheric pressure and the residue was subjected to bulb-to-bulb distillation at 108–112 °C/3 torr to give **16** (4.767 g, 78%): nmr τ 8.93, 8.89, 8.86, and 8.74 (all s, total 6H, *gem*-dimethyl), 6.82 (s, 6H, 2 OCH_3); ir (film) 1735 cm^{-1} (ketone); ms M^+ 212.1419 (calcd. for $C_{12}H_{20}O_3$: 212.1413).

7,7-Dimethoxy-4,4,6-trimethylbicyclo[4.2.0]octan-2-one ***17***

Irradiation (16 h) of isophorone **13** (4.272 g, 30.96 mmol) and 1,1-dimethoxyethylene furnished after distilling the crude product from bulb-to-bulb at 107–112 °C/1.7 torr, photoadduct **17** (4.969 g, 71%): nmr τ 9.04, 8.98, 8.93, 8.88, 8.78, and 8.69 (all s, total 9H, 3 CH_3), 6.88 and 6.84 (both s, 3H each, 2 OCH_3); ir (film) 1720 cm^{-1} (ketone); ms M^+ 226.1214 (calcd. for $C_{13}H_{22}O_3$: 226.1205).

3-Acetyl-1,1-dimethoxy-2-phenylcyclobutane ***18***

Irradiation (20 h) of *trans*-benzalacetone **14** (15.08 g, 0.103 mol) and 1,1-dimethoxyethylene gave rise to, after bulb-to-bulb distillation of the crude product at 82–125 °C/0.8–3.1 torr, **18** (8.850 g, 37%): nmr τ 8.10 (s, 3H, $COCH_3$), 7.05 (s, 3H, OCH_3), and 6.92 (s, 3H, OCH_3); ir (film) 1710 cm^{-1} (ketone); ms M^+ 234.1259 (calcd. for $C_{14}H_{18}O_3$: 234.1256).

cis-6,6-Dimethoxy-2,2-dimethyltricyclo[6.4.0.0^{4,7}]dodecan-1,9,11-triene-3-one ***19***

The crude product obtained from the photocycloaddition of 1,1-dimethyl-2-oxo-1,2-dihydronaphthalene **15** (8.256 g, 48 mmol) to 1,1-dimethoxyethylene (irradiated for 9 h) was dissolved in Skelly B. Upon standing at 0 °C, crystalline material **19**, mp 104.5–106 °C, was obtained. The mother liquor was concentrated and dissolved in 10 ml of methanol. One drop of 2.5 *N* aqueous sodium hydroxide was added and the resulting solution

was refluxed under nitrogen for 4 h. The reaction mixture was diluted with water and extracted with ether. The product obtained after the usual work-up of the organic solution was dissolved in Skelly B. After standing at 0 °C, it afforded an additional crop of **19**. The total amount of **19** thus obtained was 11.76 g (81%). Compound **19** exhibited the following spectral data: nmr ($CDCl_3$) τ 8.65 (s, 3H, CH_3), 8.45 (s, 3H, CH_3), 7.07 (s, 3H, OCH_3), 6.73 (s, 3H, OCH_3), and 2.60–2.82 (m, 4H, aromatic); ir ($CHCl_3$) 1710 cm^{-1} (ketone); ms M^+ 260.1408 (calcd. for $C_{16}H_{20}O_3$: 260.1413). *Anal.* calcd. for $C_{16}H_{20}O_3$: C 73.82, H 7.74; found: C 73.55; H 7.92.

7-Acetoxy-4,4,6-trimethylbicyclo[4.2.0]octan-2-one **37**

A solution of isophorone **13** (20 g, 0.145 mol) and vinyl acetate (250 g, 2.9 mol) in benzene was irradiated for 6 h. Column chromatography of the crude product on silica gel using a solution of 5% ether in benzene as eluent gave 27.6 g (85%) of **37**: ir (film) 1740 (ester) and 1705 cm^{-1} (ketone); nmr τ 4.67–5.53 (complex, total 1H, CHOAc), 7.98, 8.01 (both s, total 3H, $OCOCH_3$), and 8.81–9.08 (8 s, total 9H, 3 CH_3); ms M^+ 224.1413 (calcd. for $C_{13}H_{20}O_3$: 224.1413). *Anal.* calcd. for $C_{13}H_{20}O_3$: C 69.61, H 8.99; found: C 69.69, H 9.10.

7-Acetoxy-5,5-dimethylbicyclo[4.2.0]octan-2-one **40**

The crude product obtained after irradiating enone **12** (3.49 g, 28.15 mmol) and vinyl acetate (50 g, 0.58 mol) for 16 h was subjected to short-path distillation to give a mixture of four diastereomers of **40** (4.66 g, 79%): bp 89–94 °C/0.1 torr; nmr τ 4.67–5.38 (complex, total 1H, CHOAc), 7.96, 8.00, 8.02, 8.04 (all s, total 3H, $OCOCH_3$), and 8.81–9.09 (7 s, total 6 H, 2 CH_3); ir (film) 1730 (ester) and 1705 cm^{-1} (ketone); ms M^+ 210.12518 (calcd. for $C_{12}H_{18}O_3$: 210.12560). *Anal.* calcd. for $C_{12}H_{18}O_3$: C 68.55, H 8.63; found: C 68.17, H 8.72.

General Procedure for the Hydrolysis–Oxidation of the Photoadducts ***16–19***

The reaction was carried out in such a manner that 1 g of the photoadduct was dissolved in 10 ml of acetic acid – 30% hydrogen peroxide (1:1) solution and the resulting solution was stirred at room temperature. The progress of the reaction was monitored by tlc. At the end of the reaction (6–7 h for photoadducts **16–18** and 3 h for **19**), the solution was diluted with water and extracted with chloroform. The chloroform solution was washed with aqueous sodium bisulfite and saturated sodium chloride solutions. Drying ($MgSO_4$), filtration, and concentration gave the crude product.

cis-4,4,6-Trimethyl-7-oxabicyclo[4.3.0]nonane-2,8-dione ***21*** *and 2-Carboxymethyl-3,5,5-trimethyl-2-cyclohexene-1-one* ***22***

From photoadduct **17** (1.352 g, 6 mmol) a mixture of lactone **21** and acid **22** (700 mg, ~60%) was obtained. The crude mixture was used without purification for further transformation (see below). An analytical sample of **21** was obtained by column chromatography of the crude reaction product on silica gel with 30% benzene in Skelly B elution, followed by crystallization (petroleum ether – ether): mp 116–117 °C; nmr τ 6.45–7.40 (m, 3H, CH_2 and CH), 7.68 (s, 2H, CH_2), 8.49 (s, 3H, CH_3), 8.90 (s, 3H, CH_3), and 9.10 (s, 3H, CH_3); ir ($CHCl_3$) 1770 (lactone) and 1712 cm^{-1} (ketone); ms M^+ 196.1104 (calcd. for $C_{11}H_{16}O_3$: 196.1101). *Anal.* calcd. for $C_{11}H_{16}O_3$: C 67.32, H 8.22; found: C 67.56, H 8.26.

Acid **22** was found to undergo rapid lactonization to give **21** and was not obtained in pure form.

5,5-Dimethyl-7-oxabicyclo[4.3.0]nonane-2,8-dione ***25*** *and 2-Carboxymethyl-4,4-dimethyl-2-cyclohexene-1-one* ***26***

Photoadduct **16** (962 mg, 4.54 mmol) was treated with acetic acid – 30% hydrogen peroxide according to the general procedure to give a mixture of lactone **25** and acid **26** (668 mg, ~81%): ir (film) 2700–3450 (acid), 1768 (lactone), 1715 (ketone and acid) and 1665 cm^{-1} (ketone). Attempts made to separate these two compounds were unsuccessful due to their rapid interconversion and the mixture was used for the subsequent alkylation reaction.

2,2-Dimethyl-7-oxatricyclo[7.4.0.0^{4,8}]trideca-1,10,12-triene-3,6-dione ***27****, 3-Carboxymethyl-2,2-dimethyl-2-oxo-1,2-dihydronaphthalene* ***28****, and 3-Carbomethoxymethyl-2,2-dimethyl-2-oxo-1,2-dihydronaphthalene* ***29***

Hydrolysis–oxidation of photoadduct **19** (2.04 g, 7.85 mmol) under the described conditions gave 1.623 g of the crude product. A portion of this material (1.258 g) was purified by column chromatography on silica gel. Elution with a solution of 30% benzene in Skelly B gave 96 mg (7%) of lactone **27**. Further elution with the same solvent, gave 301 mg (24%) of ester **29**. Final elution with a solution of 10% methanol in ether afforded acid **28** (620 mg, 45%).

Compound **27** was crystallized from chloroform to give a constant mp of 109–110 °C and showed the following spectral data: nmr (CD_3OD) τ 2.55–2.82 (m, 4H, aromatic), 5.05 (t of d, J = 10 Hz, J' = 1.5 Hz, 1H, CO_2CH), 6.18–6.77 (m, 3H, CHCO, and CH_2CO_2), 8.45 (s, 3H, CH_3), and 8.55 (s, 3H, CH_3); ir ($CHCl_3$) 1785 (lactone), 1715 cm^{-1} (ketone); ms M^+ 230.

An analytical sample of **29** was obtained by bulb-to-bulb distillation at 127–131 °C (oven temperature)/0.2 torr and showed the following spectral data: nmr τ 2.66–2.88 (m, 5H, aromatic and vinylic), 6.33 (s, 3H, CO_2CH_3), 6.67 (s, 2H, $CH_2CO_2CH_3$), and 8.57 (s, 6H, *gem*-dimethyl); ir (film) 1735 (ester) and 1660 cm^{-1} (ketone); ms M^+ 244.1099 (calcd. for $C_{15}H_{16}O_3$: 244.1086). *Anal.* calcd. for $C_{15}H_{16}O_3$: C 73.75, H 6.60; found: C 73.69, H 6.59.

Acid **28** was crystallized from chloroform to a constant mp of 144–145 °C and displayed the following spectral data: nmr ($CDCl_3$) τ 2.50–2.82 (m, 5H, aromatic and vinylic), 6.55 (s, 2H, CH_2CO_2H), and 8.53 (s, 6H, *gem*-dimethyl); ir ($CHCl_3$) 2700–3500 (acid), 1720 (acid) and 1660 cm^{-1} (ketone); ms M^+ 230.0943 (calcd. for $C_{14}H_{14}O_3$: 230.0933).

3-Acetyl-5-oxo-2-phenylcycloxapentane ***35*** *and 3-Benzilidene-4-oxopentanoic Acid* ***36***

Photoadduct **18** (3.128 g, 13.4 mmol) was subjected to acetic acid – 30% hydrogen peroxide treatment to give a mixture of **35** and **36** (2.599 g, 95%) which was used without purification for the subsequent transformation.

General Procedure for Methylation of Hydrolysis–Oxidation Products of Photoadducts ***16–19***

The crude mixture obtained from the hydrolysis–oxidation of the photoadduct was dissolved in acetone (0.1 g/ml). Anhydrous potassium carbonate (~5 mol equiv.) and methyl iodide (~2 ml/1 g of reactant) were

added. The resulting mixture was refluxed under a nitrogen atmosphere for 1–4 days. After cooling to room temperature, the mixture was diluted with water and extracted with chloroform. The organic solution was washed with water, dried with $MgSO_4$, filtered, and concentrated. The crude product thus obtained was purified by column chromatography on silica gel using a solution of 10% ether in benzene as eluent.

2-Carbomethoxylmethyl-3,5,5-trimethyl-2-cyclohexene-1-one ***23***

The crude mixture of **21** and **22** (0.458 g) obtained directly from **17** was subjected to methylation conditions for 2 days according to the general procedure resulting in the formation of **23** (326 mg, 42% based on **17**): nmr τ 8.95 (s, 6H, *gem*-dimethyl group), 8.10 (s, 3H, CH_3), 7.82 (s, 2H, CH_2), 7.72 (s, 2H, CH_2), 6.73 (s, 2H, $CH_2CO_2CH_3$), and 6.38 (s, 3H, CO_2CH_3); ir (film) 1665 (ketone), and 1740 cm^{-1} (ester); ms M^+ 210.1263 (calcd. for $C_{12}H_{20}O_3$: 210.1256). *Anal.* calcd. for $C_{12}H_{20}O_3$: C 68.28, H 8.89; found: C 68.54, H 8.63.

2-Carbomethoxymethyl-4,4-dimethyl-2-cyclohexene-1-one ***24***

The crude mixture of **25** and **26** (688 mg) directly obtained from photoadduct **16**, was treated under the described reaction conditions for 2 days to give **24** (362 mg, 41% based on **16**): nmr τ 3.54 (s, 1H, vinylic), 6.34 (s, 3H, CO_2CH_3), and 6.96 (s, 2H, $CH_2CO_2CH_3$); ir (film) 1740 (ester), and 1665 cm^{-1} (ketone); ms M^+ 196.1101 (calcd. for $C_{11}H_{16}O_3$: 196.1099). *Anal.* calcd. for $C_{11}H_{16}O_3$: C 67.32, H 8.22; found: C 67.52, H 8.16.

3-(1′-Carbomethoxyethyl)-1,1-dimethyl-2-oxo-1,2-dihydronaphthalene ***30*** *and 3-Carbomethoxymethyl-1,1-dimethyl-2-oxo-1,2-dihydronaphthalene* ***29***

Attempted monomethylation of a mixture of **27**, **28**, and **29** (800 mg) in crude form with methyl iodide and potassium carbonate under the usual conditions for 3 days gave 640 mg of a mixture consisting of **30** and **29**: ir (film) 1740 (esters) and 1660 cm^{-1} (ketones); ms M^+ 258.1246 (calcd. for $C_{16}H_{18}O_3$: 258.1256) and 244.1094 (calcd. for $C_{15}H_{16}O_3$: 244.1099).

(E)-Methyl-3-benzilidene-4-oxopentanoate ***32****, (Z)-Methyl-3-benzilidene-4-oxopentanoate* ***33****, and (Z)-Methyl-3-benzilidene-2-methyl-4-oxopentanoate* ***34***

The crude mixture (279 mg) obtained from the hydrolysis–oxidation reaction of photoadduct **18** was methylated according to the general procedure for 1 day. After purification, the major product **32** (127 mg, 40% based on **18**; slower moving) was obtained in pure form and **33** and **34** as a 1:1 (nmr) mixture (58 mg, 18% based on **18**). The major product showed the following spectral data: nmr τ 2.42 (s, 1H, vinylic), 2.58–2.85 (m, 5H, aromatic), 6.65 (s, 2H, $CH_2CO_2CH_3$), 6.35 (s, 3H, CO_2CH_3), and 7.60 (s, 3H, $COCH_3$); ir (film) 1740 (ester) and 1660 cm^{-1} (ketone); ms M^+ 218.0947 (calcd. for $C_{13}H_{14}O_3$: 218.0943).

The mixture showed the two parent molecular ion peaks in the mass spectrum at 218 and 232. The nmr spectrum showed signals at τ 8.07 (s, $COCH_3$), 8.10 (s, $COCH_3$), and 8.58 (d, J = 7 Hz, CH_3) in 1:1:1 ratio.

Isopropylation of ***27*** *and* ***28***

Lactone **27** (96 mg) and acid **28** (483 mg) were dissolved in acetone (20 ml). Anhydrous potassium carbonate (1.7 g) and isopropyl iodide (1 g) were added. The resulting mixture was refluxed under nitrogen for 20 h. After the usual work-up, the oily product was purified by column chromatography on silica gel. Elution with a solution of 10% ether in benzene afforded 3-carbisopropoxymethyl-1,1-dimethyl-2-oxo-1,2-dihydronaphthalene **31** (320 mg, 71% based on consumed starting material (see below)): nmr τ 2.55–2.80 (m, 5H, aromatic and vinylic), 8.53 (s, 6H, *gem*-dimethyl), 8.78 (d, 6H, J = 6 Hz, $CO_2CH(CH_3)_2$); ir (film) 1740 (ester) and 1660 cm^{-1} (ketone); ms M^+ 272.1412 (calcd. for $C_{17}H_{20}O_3$: 272.1413). Further elution with a solution of 10% methanol in ether afforded 210 mg of the starting acid **28**.

7-Hydroxy-4,4,6-trimethylbicyclo[4.2.0]octan-2-one ***38***

To a solution of **37** (1.805 g, 8.06 mmol) in methanol (20 ml), was added saturated aqueous potassium carbonate solution (20 ml). The reaction mixture was refluxed under an atmosphere of nitrogen for 3 h. After cooling to room temperature, the reaction mixture was poured into water and extracted with chloroform. Drying ($MgSO_4$), filtration, and concentration gave an oil which was chromatographed on silica gel. Elution with a solution of 20% ether in benzene gave **38** (1.438 g, 98%): ir (film) 3400 (alcohol) and 1690 cm^{-1} (ketone); nmr τ 5.56–6.40 (complex, 2H, CHOH), 8.76, 8.79, 8.90, 8.99, 9.02, and 9.11 (all s, total 9H, 3 CH_3); ms M^+ 182.1305 (calcd. for $C_{11}H_{18}O_2$: 182.1306). *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.95; found: C 72.69, H 10.25.

4,4,6-Trimethylbicyclo[4.2.0]octane-2,7-dione ***39***

A solution of **38** (1.438 g, 7.9 mmol) in dimethyl sulfoxide (15 ml) and acetic anhydride (10 ml) was kept at 5 °C for 4 days. Water (30 ml) was added and the resulting solution, after stirring at room temperature for 2 h, was extracted with chloroform. The chloroform solution was washed with saturated aqueous sodium carbonate and water, dried ($MgSO_4$), filtered, and concentrated. The crude product was chromatographed on silica gel with a solution of 5% ether in benzene as eluent to give **39** (1.294 g, 91%): ir (film) 1778 (ketone) and 1700 cm^{-1} (ketone); nmr τ 6.53 (dd, 1H, J = 18, J' = 10 Hz, $COCH_2CH$), 6.93 (dd, 1H, J = 18, J' = 5 Hz, $COCH_2CH$), 7.42 (dd, 1H, J = 10, J' = 5 Hz, COCH), 8.68 (s, 3H, CH_3), 8.98 (s, 3H, CH_3), and 9.17 (s, 3H, CH_3); ms M^+ 180.1148 (calcd. for $C_{11}H_{16}O_2$: 180.1150).

Keto Ester ***23*** *from* ***39***

Diketone **39** (1.156 g, 6.42 mmol) was dissolved in glacial acetic acid (15 ml) and 30% hydrogen peroxide (15 ml) was slowly added. The reaction mixture was stirred at room temperature for 16 h. Water (50 ml) was added and the resulting solution extracted with chloroform. The extracts were washed with aqueous sodium bisulfite solution and water. Drying ($MgSO_4$), filtration, and concentration gave a mixture of **21** and **22** (1.07 g, ~85%) which, without purification, was dissolved in acetone (15 ml) and anhydrous potassium carbonate (3.8 g) and methyl iodide (2 ml) were added. The reaction mixture was refluxed under a nitrogen atmosphere for 2 days. After cooling to room temperature, the mixture was poured into water and extracted with chloroform. The organic solution, after the usual work-up gave an oily product which was purified by column

chromatography on silica gel. Elution with a solution of 10% ether in benzene afforded **23** (903 mg, 67% from **39**).

7-Hydroxy-5,5-dimethylbicyclo[4.2.0]octan-2-one ***41***

Saturated aqueous sodium carbonate solution (10 ml) was added to a solution of **40** (449 mg, 2.14 mmol) in methanol (10 ml). The reaction mixture was stirred at room temperature under a nitrogen atmosphere for 16 h. Work-up in the usual manner followed by column chromatography of the oily product on silica gel using a solution of 20% ether in benzene as eluent gave **41** (348 mg, 97%): ir (film) 3420 (alcohol) and 1700 cm^{-1} (ketone); nmr τ 5.42–6.44 (complex, 2H, CHOH), 8.90, 8.92, 8.98, and 9.02 (all s, total 6H, *gem*-dimethyl); ms M^+ 168.1154 (calcd. for $C_{10}H_{16}O_2$: 168.1150). *Anal.* calcd. for $C_{10}H_{16}O_2$: C 71.39, H 9.59; found: C 71.64, H 9.44.

5,5-Dimethylbicyclo[4.2.0]octane-2,7-dione ***42***

Under the same conditions described previously for the oxidation of **38** to **39**, keto alcohol **41** (252 mg, 1.5 mmol) was treated with dimethyl sulfoxide (3 ml) and acetic anhydride (2 ml). Chromatography of the crude product on silica gel with benzene elution gave **42** (214 mg, 86%): ir (film) 1780 (ketone) and 1705 cm^{-1} (ketone); nmr τ 8.87 and 8.98 (both s, 3H each, *gem*-dimethyl); ms M^+ 166.0998 (calcd. for $C_{10}H_{14}O_2$: 166.0993).

Keto Ester ***24*** *from* ***42***

The transformation was carried out by the use of the same reaction sequence and conditions described for **39** → **23**. Oxidation of **42** (1.351 g, 8.14 mmol) with 30% hydrogen peroxide (20 ml) and acetic acid (20 ml) gave a mixture of **25** and **26** (1.362 g, ~92%) which was methylated with potassium carbonate (5 g) and methyl iodide (3 ml) in acetone (15 ml) to give, after bulb-to-bulb distillation of the crude product at 110 °C (oven temperature)/0.2 torr, **24** (1.082 g, 68% from **42**).

Received September 13, 1976

BRIAN MAURICE LYNCH and SURESH CHANDRA SHARMA. Can. J. Chem. **55**, 831 (1977).

3-Oxo-*s*-triazolo[4,3-*a*]pyridine and various *C*-methyl derivatives (general structure **1**) have been converted into the 2-β-D-ribofuranosyl species **2** and thence **4** via Friedel–Crafts catalyzed reaction with tetra-*O*-acetyl-β-D-ribofuranose, followed by deblocking. During the course of these reactions, rearrangements into the isomeric 3-β-D-ribofuranosyl-2-oxo-*s*-triazolo[1,5-*a*]-pyridines occur through ring-opening of the pyridine rings yielding species **3** and **5**. The proportion of rearrangement products is dependent upon the position and number of the *C*-methyl substituents.

Structural assignments for these compounds are based upon comparisons of spectroscopic properties (^{1}H nmr, ^{13}C nmr, uv) with model compounds from each isomeric series; structural assignments for these models are based on unequivocal mass-spectral fragmentation patterns. Unlike related triazolopyridine nucleosides with the ribose moiety attached to a pyridine nitrogen (Lynch and Sharma (1976)), there are no unusual aspects in the conformations of the nucleosides of types **4** and **5**.

BRIAN MAURICE LYNCH et SURESH CHANDRA SHARMA. Can. J. Chem. **55**, 831 (1977).

On a transformé l'oxo-3 *s*-triazolo[4,3-*a*]pyridine et ses divers dérivés *C*-méthylés (structure générale **1**) en espèces β-D-ribofurannosyl-2 **2** et de là en composés du type **4** par l'intermédiaire d'une réaction catalysée de Friedel–Crafts avec le tétra-*O*-acétyl-β-D-ribofurannose suivie d'un déblocage du produit. Au cours de ces réactions, il se produit des réarrangements, par une ouverture du cycle de la pyridine, qui conduisent aux β-D-ribofurannosyl-3 oxo-2 *s*-triazolo-[1,5-*a*]pyridines isomères **3** et **5**. La proportion de produits de réarrangement dépend de la position et du nombre de substituants *C*-méthyle.

Les attributions de structure de ces composés sont, dans chaque série, basées sur des comparaisons de propriétés spectroscopiques (rmn ^{1}H, rmn ^{13}C, uv) avec des composés modèles; les attributions de structures pour ces modèles sont basées sur des types non-équivoques de fragmentations de spectres de masse. Par opposition avec les triazolopyridines nucléosides voisins ayant une portion ribose attachée à l'azote de la pyridine (Lynch et Sharma (1976)) il n'y a pas d'aspects inusités dans les conformations des nucléosides des types **4** et **5**.

[Traduit par le journal]

Introduction

In this paper, we report further exploration of synthetic routes to nucleosides of triazolopyridines (for the initial paper, see ref. 1), focussing attention on representatives of two isomeric ring systems possessing bridgehead nitrogen atoms. As noted previously (1), the objective of this synthetic program is to obtain positionally isomeric nucleosides expected to possess differing constraints on preferred sugar–base torsional angles.

As starting heterocyclic components, we used a series of 3-oxo-*s*-triazolo[4,3-*a*]pyridines of general structure **1**. These compounds were prepared by reactions of the appropriately substituted 2-hydrazinopyridines with urea or ethyl chloroformate (2, 3) and were converted into the trimethylsilyl derivatives, and then subjected to Lewis-acid catalyzed glycosylation using 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose and tin(IV) chloride. This method provides triacetylribofuranosides of β-configuration (4, *cf.* 5), readily deblocked to the corresponding nucleosides, and avoids the epimerizations sometimes observed (6, 7) using the fusion method.

Results and Discussion

The glycosylations of compounds of general structure **1** would be expected to give 2-substituted derivatives, but reactions with the

methyl-substituted species **1***d*, **1***e*, and **1***f* provided *mixtures of comparable amounts of two isomeric triacetylnucleosides* from each starting material. These were separable into the individual species by preparative thin-layer chromatography. Each triacetylnucleoside species was deblocked readily to the corresponding nucleoside (or mixture of nucleosides in some cases) by methanolic sodium methoxide. The compounds **1***a* and **1***c* yielded single triacetylnucleosides,[4] and the dimethyl compound **1***g* provided one major product and a trace of a second triacetylnucleoside; again, deblocking was effected readily.

Accompanying *O*- and *N*-glycosylation might explain the formation of two products from a single starting heterocycle, but the conditions used for glycosylation are those standard for *O*- to *N*-rearrangement (8) of glycosides. We suggest that the isolations of two isomeric species from a single starting material result from rearrangement of the 3-oxo-*s*-triazolo[4,3-*a*]-pyridine nuclei to 2-oxo-*s*-triazolo[1,5-*a*]pyridine nuclei during the reaction sequence. There is equivocal support in the literature for this suggestion. Potts *et al.* (9) have observed rearrangements of certain 3-substituted-*s*-triazolo-[4,3-*a*]pyridines into 2-substituted-*s*-triazolo[1,5-*a*]pyridines, but they specifically exclude the 3-oxo species, noting that it is degraded into 'pyridine derivatives', without rearrangement. However, closer examination of some of their reported experimental results shows that they are consistent with our proposed rearrangement. Thus, methylation of the parent oxo compound **1***a* by dimethyl sulfate in alkali was reported to yield two products: one assigned as 2-methyl-3-oxo-*s*-triazolo[4,3-*a*]pyridine **1***b*, mp 112–113 °C, and a second minor species of 'unknown constitution' (9), mp 217–219 °C with decomposition, assigned the formula $C_{14}H_{16}N_6O_3$. We noted that the reported analytical data are consistent with a hemihydrate species ($(C_7H_7N_3O)_2 \cdot H_2O$), and repetition of the methylation experiments in our laboratory provided the two products with the physical properties cited by

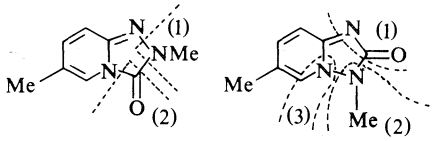
[4]A referee has pointed out that the assignment of anomeric configuration is readily verifiable by preparation of the 2′,3′-*O*-isopropylidene derivative, and use of the differences in proton chemical shifts of the methyl groups to diagnose configuration (a difference greater than 0.18 ppm characterizing a β configuration (14)); indeed, this approach was employed in Part I (1). Preparation of this derivative from the parent **1***a* using the standard procedure furnished an oil after preparative thin-layer chromatography, which showed *C*-methyl proton signals at δ 1.36 and 1.60, thus confirming the β assignment.

Potts' group (separations were effected by preparative thin-layer chromatography), and the ^{1}H nmr spectra of thoroughly dried samples showed *N*-methyl and aromatic ring proton signals in the ratio 3:4. We therefore assign the second product as 3-methyl-2-oxo-*s*-triazolo-[1,5-*a*]pyridine, **3***b*. The unrearranged 2-methyl-3-oxo compound **1***b* shows a pattern of aromatic ring proton shifts closely similar to one set of the triacetylribosylation and ribosylation products (see Table 1*a*), *i.e.* a one-proton signal in the range δ 5.9–6.6, assigned as proton 6 of species **1**, **2**, and **4**; two protons of closely similar chemical shifts between δ 6.7–7.4, assigned to protons 7 and 8, and a low-field one-proton signal showing a well-resolved *ortho*-coupling of *ca.* 7 Hz and falling in the range δ 7.4–7.8, assigned to the 5-proton. These shifts, and the *C*-methyl proton shifts, closely resemble those reported for correspondingly substituted simple *s*-triazolo[4,3-*a*]pyridines by Potts *et al.* (10).

In contrast, the ^{1}H nmr spectrum of the minor methylation product, assigned above as the 3-methyl-2-oxo species **3***b*, shows aromatic ring proton shifts fitting the pattern of the second set of triacetylribosylation and ribosylation products (Table 1*b*), *i.e.* a one-proton signal between δ 6.6–7.1, assigned to the 6-proton in type **3** or **5** species; two one-proton signals between δ 7.47–7.87, assigned to the 8- and the 7-protons, and a low-field one-proton signal at δ 7.9–8.25 from the 5-proton.

The matching of patterns to those of **1***b* and **3***b* is strongly suggestive of rearrangements from the [4,3-*a*] to the [1,5-*a*] series in the glycosylation processes, but since the glycosylation of the [4,3-*a*] compound **1***a* yields a single triacetylnucleoside, and deblocking yields a single nucleoside, each one of which shows ^{1}H nmr patterns (Table 1) indicative of retention of the *s*-triazolo[4,3-*a*]pyridine structure; more decisive evidence would be marshalled through comparison of species where rearrangements occurred in both the methylation and the glycosylation processes, together with unequivocal structure proofs of the methylation products.

This evidence was provided by a methylation study of 6-methyl-3-oxo-*s*-triazolo[4,3-*a*]pyridine **1***d*, which on glycosylation yields a mixture of two products. The major methylation product (mp 135 °C, 71% yield) gave a ^{13}C nmr spectrum closely similar to that of the parent compound **1***d*, and also to one of the triacetylnucleosides obtained from **1***d* (see Table 2), and is therefore assigned as the 2,6-dimethyl-3-oxo-*s*-triazolo-[4,3-*a*]pyridine **6**. The ^{1}H nmr spectrum of this product closely resembled that of the compound assigned as **1***b*. The second methylation product (mp 234 °C, 10% yield) is expected to have structure **7** (3,6-dimethyl-2-oxo-*s*-triazolo[1,5-*a*]-pyridine), and the isomeric nature and the structures of the two methylation products were proved by their mass spectra and fragmentation patterns. Each compound gave a molecular ion peak at *m/e* 163, and the species of mp 135 °C showed successive losses of N—CH_3 ($M^+ - 29$) and CO (($M^+ - 29$) − 28) moieties, while the compound of mp 234 °C fragmented successively with the loss of N—C—O ($M^+ - 42$), N—CH_3 (($M^+ - 42$) − 29), and HCN (($M^+ - 71$) − 27). The fragmentation sequences are indicated on the proposed structures **6** and **7**, and these sequences are in full agreement with expectation.



6 **7**

We therefore conclude that the two sets of triacetylribosylation products, and the corresponding sets of deblocked nucleosides, represent 2-glycosylated *s*-triazolo[4,3-*a*]pyridines and 3-glycosylated *s*-triazolo[1,5-*a*]pyridines respectively. The electronic absorption spectra of the two series of compounds (Table 3) (general structures **1**, **2**, **4**, and **6** for one series, and general structures **3**, **5**, and **7** for the other) show significant differences: five distinct absorption maxima for the [4,3-*a*] series, and three for the [1,5-*a*] series. These differences are useful in monitoring the separations of isomer mixtures by thin-layer chromatography.

Rearrangements in basic media analogous to those occurring during the methylations of compounds **1***a* and **1***d* are well documented (9, 11, 12), and acid-catalyzed reactions have been reported for *s*-triazolo[4,3-*a*]pyrimidine/*s*-triazolo[1,5-*a*]pyrimidine and *s*-triazolo[4,3-*c*]-quinazoline/*s*-triazolo[1,5-*c*]quinazoline conversions (11, 12). These reactions may be generalized as variations of a Dimroth rearrangement, as illustrated in Scheme 1.

Under basic conditions, following Novinson

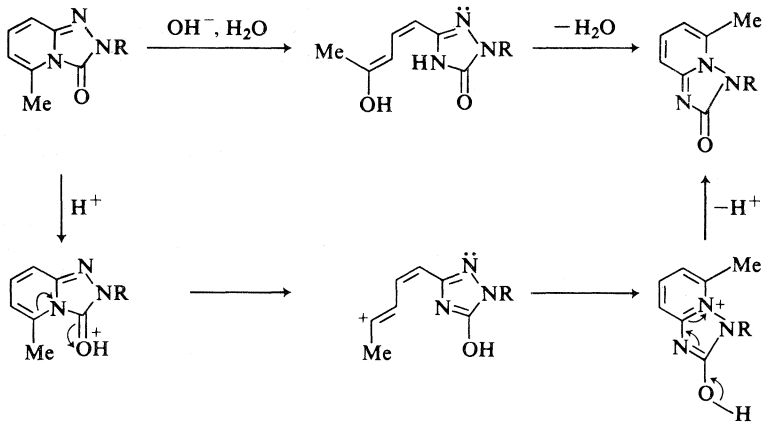


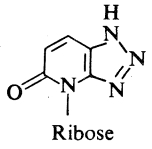
SCHEME 1. Proposed rearrangement pathways for conversions of *s*-triazolo[4,3-*a*]pyridines into *s*-triazolo[1,5-*a*]pyridines.

and co-workers (11) we postulate nucleophilic attack at the carbon adjacent to the bridgehead nitrogen to yield a triazole intermediate, then recyclizing to the isomeric species. The acid-catalyzed process is suggested to involve initial protonation (or Lewis acid conjugation) followed by ring-opening to generate a carbonium-ion intermediate, again recyclizing as indicated. The extent of rearrangement during triacetylribosylation appears to be determined by the extent of stabilization of the proposed carbonium ion; thus, complete rearrangement occurs on triacetylribosylation of 5-methyl-3-oxo-*s*-triazolo-[4,3-*a*]pyridine **1***c* to yield **3***c* (in **1***c*, the methyl group would stabilize the carbonium ion most effectively), and virtually complete rearrangement with 5,7-dimethyl-3-oxo-*s*-triazolo[4,3-*a*]-pyridine **1***g*; the other methyl-substituted species give mixtures of both isomeric triacetylnucleosides in comparable amounts, and with the parent species **1***a*, no rearrangement occurs.

Rearrangements were also found to accompany attempted syntheses and substitution reactions of derivatives of the parent compound **1***a*. Thus, nitration of **1***a* using nitric acid – acetic anhydride reagent afforded a product $C_8H_6N_4O_4$, mp 218–220 °C, assigned as 2-acetyl-6-nitro-3-oxo-*s*-triazolo[4,3-*a*] pyridine **9**. Sublimation of a crude sample of **9** yielded a deacetylated product $C_6H_4N_4O_3$, mp 299–301 °C, with a ^{1}H nmr spectrum differing significantly from that of **9** in the aromatic region. Since the remote 2-acetyl substituent would be expected to have little effect on the aromatic ring shifts, we suggest that the product of mp 299–301 °C is 6-nitro-2-oxo-*s*-triazolo[1,5-*a*]pyridine **10**; the differences in the ^{1}H nmr spectra of the two products (see Experimental) resemble those for the isomeric series assembled in Table 1. An attempted synthesis of the 6-nitro-3-oxo-*s*-triazolo[4,3-*a*]pyridine by ring closure of 2-ethoxycarbonylhydrazino-5-nitropyridine with *N*-sodium hydroxide at 80 °C failed, since the product of mp 299–301 °C was obtained, probably through base-catalyzed rearrangements of the [4,3-*a*] compound.

The Conformations of Triazolopyridine Nucleosides

In marked contrast to the related compound 4-β-D-ribofuranosyl-*vic*-triazolo[4,5-*b*]pyrid-5-one, **8**, which shows marked deshielding of H-1′ by comparison with monocyclic precursors, and a large 1′–2′ proton coupling (6.50 Hz) (*cf.* ref. 1), the nucleosides of series **4** and **5**



8

exhibit normal H-1′ shielding (δ 5.8–6.0) and 1′–2′ couplings (series **4**, 3.8–4.5 Hz, series **5**, 3.4–3.8 Hz). The severe conformational constraints proposed to account for the ^{1}H nmr patterns of **8** are thus absent in the series **5**, although in each type of compound the sugar–base link is positioned between an amide carbonyl and a conjoined ring.

The differing behavior is interpreted in terms of the greater separation between the amide oxygen (at C-2) and the ribose carbon C-1′ in

type **5** compounds in contrast to **8**, allowing the type **5** compounds greater rotational freedom and conformational flexibility; thus models using 120° bond angles for the six-membered ring moiety of **8**, and 108° internal angles for **5**, together with standard bond lengths (13), indicate that the O—C-1′ separation in **8** is 0.27 nm, and in **5** is 0.30 nm.

Experimental

General

Melting points were determined using a Fisher-Johns apparatus and are uncorrected. The ^1H nmr spectra were recorded with a Varian A-60D instrument, and the ^{13}C nmr spectra using a Varian CFT-20. All chemical shifts are expressed in parts per million from tetramethylsilane, present as internal reference. Electronic absorption (uv) spectra were measured for solutions in methanol, with a Beckman Acta III spectrophotometer. Specimens for elemental analyses were dried at 65 °C/0.2 torr for at least 6 h and were analyzed using a Hewlett-Packard model 185 analyser. Mass spectra were obtained using a DuPont CEC 21-491 instrument. Thin-layer chromatography was performed using Fluka Kieselgel GF 254. All extracts were dried over anhydrous sodium sulfate and evaporations were effected below 35 °C under reduced pressure. Known compounds referred to in details of experiments had physical properties according with literature values.

Standard Procedure for Reactions of 3-Oxo-s-triazolo-[4,3-a]pyridines with Tetra-O-acetylribofuranose

For details of scale and duration of reactions, see Table 4. The appropriate 3-oxo-*s*-triazolo[4,3-*a*]pyridine was heated under reflux in excess of hexamethyldisilazane in the presence of a catalytic amount of ammonium sulfate for 6 h, with precautions for exclusion of moisture. Hexamethyldisilazane was removed under reduced pressure, and the crude trimethylsilyl derivative of the triazolopyridine was dissolved in 1,2-dichloroethane. A

solution of tetra-*O*-acetyl-β-D-ribofuranose in dichloroethane was added, followed by tin(IV) chloride. The mixture was heated under reflux for the indicated time, washed with saturated aqueous sodium hydrogen carbonate, and the organic layer was separated and dried. Concentration of the reaction mixture yielded the crude triacetylnucleosides. For the examples where single products were obtained (species **2***a*, **3***c*), the crude materials were purified by crystallization from the indicated solvent. The mixtures containing both *s*-triazolo[4,3-*a*]pyridine and *s*-triazolo[1,5-*a*]pyridine triacetylnucleosides (**2***d*, **3***d*; **2***e*, **3***e*; **2***f*, **3***f*; **2***g*, **3***g*) were separated by preparative thin-layer chromatography on silica gel, using a benzene:ethyl acetate:methanol (30:75:5 v/v) solvent system in development. The separated species were purified by crystallization as indicated.

Deblocking of the Triacetylnucleosides

The triacetylnucleoside was treated with an excess of freshly prepared 1% (w/v) sodium methoxide in methanol at room temperature for 18 h. The reaction mixture was passed through an Amberlite IRC-50(H) column and eluted with methanol. Concentration under reduced pressure, followed by crystallization from methanol, provided the deblocked nucleosides listed in Table 5. Deblocking of the triacetylnucleosides in the *s*-triazolo-[4,3-*a*]pyridine series led to some isomerization, as the mother liquors contained proportions of the *s*-triazolo-[1,5-*a*]pyridine nucleosides detectable by ^{1}H nmr spectroscopy.

Methylation of 3-Oxo-6-methyl-s-triazolo[4,3-a]pyridine, 1d

3-Oxo-6-methyl-*S*-triazolo[4,3-*a*]pyridine **1***d* (1.50 g) was dissolved in methanol (60 ml) and treated with methyl iodide (1.0 ml) and anhydrous potassium carbonate (1.40 g). The reaction mixture was stirred at room temperature for 18 h and concentrated under reduced pressure. Preparative thin-layer chromatography on silica gel with development in an ethyl acetate:methanol (93:7 v/v) solvent system provided 2,6-dimethyl-3-oxo-*s*-triazolo[4,3-*a*]pyridine **6** (1.16 g, 71%), mp 135 °C; *m/e* 163 (100%, M^+), 134 (20%, $M^+ - NCH_3$), 106 (30%, $M^+ - NCH_3 - CO$), after evaporation and crystallization from methanol, together with 3,6-dimethyl-2-oxo-*s*-triazolo[1,5-*a*]pyridine **7** (0.17 g, 10%), mp 234 °C; *m/e* 163 (100%, M^+), 121 (100%, $M^+ - CNO$); 92 (60%, $M^+ - CNO - NCH_3$), 65 (100%, $M^+ - CNO - NCH_3 - HCN$) after similar recrystallization.

Methylation of 3-Oxo-s-triazolo[4,3-a]pyridine, 1a

This was effected according to Potts *et al.* (9), providing a 3:1 mixture ^{1}H nmr spectroscopic examination from *N*-methyl signal intensities) of the 2-methyl species **1***b* and the 1-methyl species **3***b*, with melting points coincident with those reported (9).

Nitro Compounds and Rearrangements

(a) Nitration of 3-Oxo-s-triazolo[4,3-a]pyridine, 1a

To **1***a* (2.00 g) in acetic anhydride (40 ml) was added (dropwise) a solution of nitric acid (90%, 4 ml) in acetic anhydride (6.0 ml) at 5 °C. After completion of addition the reaction mixture was kept below 10 °C for 30 min and poured onto ice (200 g). Filtration afforded a

product (0.63 g), mp 218–220 °C. *Anal.* calcd. for $C_8H_6N_4O_4$: C 43.25, H 2.72, N 25.22; found: C 43.16, H 3.10, N 25.12; *m/e* 222 (3.7%, M^+), 180 (100%, $M^+ -$ NCO); ^{1}H nmr spectrum (DMSO-d_6) δ 2.68 (s, 3H, N—$COCH_3$), 7.50 (d, 1H, J = 10.0 Hz, H-8), 8.07 (dd, 1H, J = 1.50 and 10.0 Hz, H-7), 8.95 (d, 1H, J = 1.50 Hz, H-5), assigned as 2-acetyl-6-nitro-3-oxo-*s*-triazolo[4,3-*a*]-pyridine, **9**. Sublimation of the crude material provided 0.40 g, mp 299–301 °C. *Anal.* calcd. for $C_6H_4N_4O_3$: C 40.00, H 2.24, N 31.11; found: C 39.61, H 2.35, N 31.44; *m/e* 180 (100%, M^+); ^{1}H nmr spectrum (DMSO-d_6) δ 7.72 (d, 1H, J = 9.5 Hz, H-4), 8.42 (dd, 1H, J = 2.50 and 9.5 Hz, H-5), 9.88 (d, 1H, J = 2.50 Hz, H-7), assigned as 6-nitro-2-oxo-*s*-triazolo[1,5-*a*]pyridine, **10**.

(b) Synthesis and Ring Closure of 2-Ethoxycarbonylhydrazino-5-nitropyridine

Synthesis—2-Hydrazino-5-nitropyridine (2.20 g) was heated at 100 °C with ethyl chloroformate (20 ml) for 1 h; excess ethyl chloroformate was removed under reduced pressure, and the residue was washed with saturated aqueous sodium hydrogen carbonate, dried, evaporated, and crystallized from aqueous ethanol, providing 2-ethoxycarbonylhydrazino-5-nitropyridine (2.86 g), mp 161–162 °C.

Ring Closure—The above compound (2.50 g) was heated at 80 °C in 1 *N* aqueous sodium hydroxide for 15 min; after cooling to room temperature, the reaction mixture was neutralized with dilute sulfuric acid and the precipitated solid was collected. Crystallization from ethanol gave 6-nitro-2-oxo-*s*-triazolo[1,5-*a*]pyridine **10**, (1.43 g), mp and mixture mp 299–301 °C, identical to the material obtained in (*a*) above.

^{13}C nuclear magnetic resonance studies. 64.[1] The ^{13}C spectra of a variety of bicyclo[3.2.1]octanols

J. B. STOTHERS AND C. T. TAN[2]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received September 10, 1976

J. B. STOTHERS and C. T. TAN. Can. J. Chem. **55**, 841 (1977).

The ^{13}C nmr spectra of a series of 20 bicyclo[3.2.1]octanols and -octenols have been determined to examine the shielding effects of the hydroxyl group on the skeletal carbons in this ring system. For comparison, the previously unreported data for a few closely related alcohols in the [2.1.1], [2.2.1], and [3.2.2] systems were also collected. The utility of these substituent effects for configurational and conformational assignments is discussed.

J. B. STOTHERS et C. T. TAN. Can. J. Chem. **55**, 841 (1977).

On a déterminé les spectres rmn du ^{13}C d'une série de 20 bicyclo[3.2.1]octanols et -octénols afin d'examiner les effets de blindage du groupe hydroxyle sur le squelette carboné de ce système cyclique. Pour fins de comparaisons, on a aussi rassemblé des valeurs, qui n'avaient pas été rapportées antérieurement, pour quelques alcools voisins dans les systèmes [2.1.1], [2.2.1] et [3.2.2]. On discute de l'utilité de ces effets de substituants pour des attributions de configuration et de conformation.

[Traduit par le journal]

As part of our continuing examination of the effects of molecular geometry on ^{13}C shieldings we have obtained the spectra of a series of bicyclo[3.2.1]octanols and -octenols to compare the effects of the hydroxyl group on the skeletal shieldings in this ring system with the results for other bicyclic systems (1). The prime reason for investigating these series is that the well-defined carbon skeleton allows one to study the shielding variations as a function of molecular geometry. The [3.2.1] saturated examples have the additional feature of a flexible six-membered ring permitting an examination of this factor on the shielding trends. In general, the shifts produced by the substituent at carbons within four bonds are of particular interest as potential probes for stereochemical analysis. A possible deficiency in the use of bicyclic systems as models for these perturbations is the contribution of 'strain' to the observed shieldings, a factor which is difficult to assess. However, the influence of strain could be revealed in a comparison of the corresponding interactions in a variety of systems differing in strain energy. For this reason, the bicyclo[3.2.1]octane skeleton was selected as a model system for comparison with the results for the bicyclo[2.2.1]heptane and bicyclo[2.2.2]octane skeletons which are more highly strained and of similar strain, respectively. According to molecular mechanics the calculated strain energies for the parent hydrocarbons are 17.1, 13.0, and 12.1 kcal/mol for the [2.2.1], [2.2.2], and [3.2.1] systems, respectively (2). Another reference point is, of course, provided by the cyclohexanol system for which the data for a variety of derivatives are available (3) as are the results for several decalols (4) and sterols (5). While it is well established that ^{13}C shieldings for compounds in closely related series are correlated very well by additivity of substituent effects, the origins of these effects are not well understood (6) but empirical analysis of the data on carefully selected systems, in combination with the continuing development of shielding theory, may gain the ultimate goal of understanding. In any event, the results may be applied directly to problems involving the skeletons for which data are available. A few of the compounds included in this study have been reported previously (7); these have been reexamined, however, to obtain data for the entire series under closely similar conditions, 5–15% solutions in deuteriochloroform, for internal consistency and for meaningful comparison with previous results.

Experimental

Materials

The compounds examined in this study have been

[a]In ppm from internal TMS for $CDCl_3$ solutions; values in square brackets may be interchanged. Values in parentheses are the shifts produced upon acetylation, *i.e.*, for a given carbon $\delta_C^{ROAC} - \delta_C^{ROH}$. For the acetates the carbonyl signals appeared in the range 170.1 ± 0.2 ppm and the methyl carbons absorbed at δ_C 21.2 ± 0.1.
[b]Substituent orientations (*exo*/*endo*) are given with respect to the larger of the two unsubstituted bridges.
[c]Data taken from ref. 8.
[d]For ease of comparisons within this table, **15**, **20**, and **21** are numbered in an unconventional manner and the substitutions are listed in quotation marks.

described in the literature and samples with the appropriate physical data were prepared from the published procedures. Infrared and proton spectra of each alcohol were recorded to ensure their identities. The parent ketone of each alcohol was available from earlier studies in this laboratory (8, 9) and **2**, **6**, **16**, and **18** had been prepared as intermediates in these ketone syntheses. The remaining examples were, with two exceptions, obtained by reduction of the appropriate ketone; **3**, **7**, **9**, **17**, **19**, **21**, **23**, **25**, **28**, and **30** were isolated as the sole products of metal hydride reduction using $LiAlH_4$, $NaBH_4$, or $LiAlH(OMe)_3$. Mixtures of **4**/**5**, **11**/**12**, **13**/**14**, and **20**/**21** were obtained in approximately 1:3 ratios by reduction and the relative intensities of the two sets of signals in their ^{13}C spectra readily permitted assignments to the individual isomers. A sample of **12** was also available from Li–NH_3 reduction of bicyclo[3.2.1]octa-3,6-dien-2-one. Ketone reduction failed to provide samples of **8** and **26** thereby requiring a different approach. Thus **8** was prepared from **9** via the tosylate, acetolysis, and hydrolysis (**10**) while **26** was generated from norbornene as described by Baird (11).

^{13}C Spectra

A Varian XL-100-15 system operating in the Fourier transform mode at 25.2 MHz was employed for the ^{13}C spectra. Carbon types were distinguished by off-resonance decoupling. All compounds were examined as $CDCl_3$ solutions (5–15%, w/v) containing TMS as an internal standard.

Results

The ^{13}C shieldings for the series of bicyclo-[3.2.1]octanols, their unsaturated analogs, and the corresponding hydrocarbons are listed in Table 1; our data for these hydrocarbons were reported previously (8). For each alcohol, the carbinyl signal was readily assigned from its characteristic position, δ_C 66–82. The bridgehead carbon signals were distinguished by off-resonance decoupling and, thus, directly assigned for the 3- and 8-alcohols with the exception of **20** and **21** for which the allylic centres were taken to be at lower field as in the olefin. For the 2- and 6-alcohols, that at lower field was assigned to the bridgehead carbon α to the carbinyl centre. The olefinic signal assignments were made by comparison of the observed shieldings with those for the corresponding olefin. Reversal of the present assignments for **16**–**21** would require that the hydroxyl group exerts markedly

larger substituent effects in this ring system than in bicyclo[2.2.2]octenols (1*a*) and bicyclo[2.2.1]-heptenols (1*b*) and that these effects are directionally opposite in **18**–**21** from those found for the corresponding analogs in these other bicyclic systems. Such drastic alterations in substituent effects are unprecedented. For **11** and **12**, the assignments listed in Table 1 seem the more consistent with the findings for the norborn-5-en-2-ols (1*b*) and the bicyclo[2.2.2]oct-5-en-2-ols, particularly the upfield shift for C-7 in **12** and the small downfield shift for C-7 in **11**. For **13** and **14**, there is no difficulty completing the assignments because of their symmetry.

The methylene assignments for the remaining unsaturated alcohols were made on the basis of the appearance of the pattern in the off-resonance decoupled spectrum and by consideration of the shifts caused by the hydroxyl substitution relative to those found for analogous substitutions in other bicyclic systems. For example, the off-resonance pattern for C-2 in **20** and **21** was a clean triplet while C-6 and C-7 gave rise to more complex multiplets owing to the fact that the protons bonded thereto form a closely coupled system. Grutzner (12) has discussed the basis for such assignments. The C-6 and C-7 signals in **20** and **21** were assigned as listed since it was expected that the 8-hydroxyl group shields both carbons; reversal of the assignments would mean that C-6 is shielded by ~7 ppm while C-7 is deshielded by 1–2 ppm, a very strange pattern. Both were expected to be shielded since the methylene carbons in 7-norbornanol (**23**) are shielded relative to those in norbornane (see Table 2). Although a recent paper (7) reports that the methylene carbons in **23** are equivalent, in an unspecified medium, we find C-2,C-3 (*syn* to the hydroxyl) 0.2 ppm upfield from C-5,C-6. Reduction of **25** with deuterium over PtO_2 furnished **23**-*5,6-d*$_2$ whose spectrum permitted unequivocal methylene assignments. The off-resonance decoupled spectra of **11**, **12**, **16**, and **17** readily identified the C-8 methylene signal and C-3 and C-4 were distinguished for **11** and **12** by the expected 8–10 ppm downfield shift (the β effect) exhibited by C-3. For **16** and **17**, the C-6 and C-7 signals were distinguished from the expected upfield shift for C-7 arising from the γ effect of the hydroxyl group. Finally, the three methylene signals for **18** and **19** were assigned by comparison with the shifts produced by the hydroxyl group in the 2-norbornanols (1*b*). It could be anticipated that the hydroxyl substituent effects at C-7 and C-8 in **18** and **19** should be closely similar to those for C-3 and C-7 in the corresponding norbornanols while the shift for C-2 (**18**, **19**) may resemble those for C-5 in the norbornanols. In fact with the present assignments the shifts at these centres in **18** are 12.1, −4.1, and −1.1 ppm, respectively, while the corresponding shifts for *exo*-2-norbornanol are 12.6, −3.9, and −1.5 ppm.

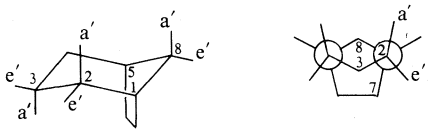
The methylene signals in the spectra of bicyclooctanols **2**–**9** were assigned in a similar fashion; those for **4** and **5** were particularly straightforward. The less intense methylene signals arose from C-8 while C-6,C-7 were distinguished from C-2,C-4 by their patterns in the off-resonance decoupled spectra. For **6** and **7**, the C-7 and C-8 signals were identified by the off-resonance spectra and, as in the case of **18** and **19**, these were distinguished in **6** by the marked downfield shift, 12.3 ppm, expected for C-7. The highest field signal, ~19 ppm, was ascribed to C-3 for **6** and **7** while C-4 was identified by the

upfield shifts arising from the γ effect of the hydroxyl group. For **8** and **9**, the C-3 signal was readily identified by its upfield position and lower relative intensity. The absorption positions appear to distinguish C-2,C-4 from C-6,C-7 for **8** but the relatively small difference of 0.8 ppm for these shieldings in **9** renders our assignment equivocal. The off-resonance spectra served to identify the C-8 signal for **2** and **3** showing that the hydroxyl shields this centre in **2** by −7.6 ppm; this tends to support our assignment for **9** in which C-2,C-4 are shielded by −7.5 ppm. In **2**, C-6 can be expected to be least affected by the hydroxyl group leading to its assignment as 28.4 ppm, while the remaining methylene signals cannot be definitively assigned since all are very similar, 26.5–26.9 ppm. Similarly, the assignments for C-3 and C-6 in **3** may be interchanged but those for C-4 and C-7 seem most appropriate. The present assignments for **2**–**5** agree with those reported recently by Lippmaa *et al.* (7) although the individual shieldings in the two sets of data differ by 0–0.9 ppm presumably because of the difference in solvent but the medium is unspecified for the earlier data (7). The shifts produced upon acetylation of **2**–**5** and **8** are included in Table 1 and these are unexceptional (1*b*, 7).

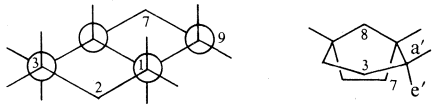
The data for a few previously unreported model compounds are collected in Table 2. The assignments for **23** were discussed above and those for **25** and **26** presented no problems. For **28**, the assignments are by no means established but seem the most reasonable; a similar situation obtains for **30**.

Discussion

The bicyclo[3.2.1]octane skeleton (**31**) contains a cyclohexane ring with two axial substituents, the 6,7-ethano bridge, which form a unit analogous to the norbornane skeleton. Comparisons can be made to both parent systems to gain a better understanding of hydroxyl substituent effects. The six-membered ring of **1** exists predominantly in the chair conformation **31***a* with the *endo*-2 and *exo*-3 C—H bonds essentially equatorial. The 6,7 bridge tends to pinch together the axial bonds at C-1,5 (**31***b*) such that the axial bonds at C-2,4 are splayed relative to their arrangement in a 'strainless' cyclohexane or decalin (**32**). Thus, this ring is flattened at C-2,3,4 and this should be accentuated in the Δ^6 derivatives because of the shorter



a **31** *b*



32 **33**

6,7 bond (**33**). Introduction of a 3,4 double bond renders this portion of the molecule planar. In the saturated skeleton, *endo*-3 and *endo*-6 substitution could introduce nonbonded interactions of sufficient magnitude to alter the conformation of the six-membered ring. It is of interest, therefore, to examine the shielding changes produced by hydroxyl substitution to check for shifts which differ appreciably from those expected from the data for cyclohexanols and norbornanols. For this purpose, the differences $\delta_C^{ROH} - \delta_C^{RH}$, from Tables 1 and 2 are collected in Table 3. Some caution is necessary since some assignments were based in part on the anticipated hydroxyl effects but, in most cases, there was other evidence to support the assignments, as discussed above, and often the alternative assignments would require remarkable variations in the substituent effects. Table 3 includes data for some model cyclohexanols, decalols, and norbornanols. Considerable effort has been directed toward the study of substituted cyclohexanols (3–5) and a recent discussion of hydroxyl substituent effects in cyclohexanols, decalols, and sterols (5) can serve as a basis for examination of the present data.

A priori it is reasonable to expect the effects of *exo*-3-hydroxyl substitution to resemble those for an unhindered equatorial hydroxyl group in the cyclohexanol and decalol systems (items 1, 2: Table 3) but items 3 and 4 show marked differences with all carbons less shielded by the OH group. It is particularly interesting that the bridgehead carbons fail to exhibit appreciable γ *anti* shifts although in sterols analogous methine carbons tend to show larger upfield shifts than methylene carbons (5). The enhanced α effect (~4 ppm) may be a result of the smaller dihedral angle between the hydroxyl and the *exo*-2 and -4 protons caused by ring flattening. Some support for this notion is given by the

[a] $\Delta\delta^{OH} = \delta_c^{ROH} - \delta_c^{RH}$ where RH = hydrocarbon (in ppm); positive values indicate downfield shifts.
[b] These substituent effects were obtained by comparison of the shieldings for the 3- and 4-*tert*-butylcyclohexanols with those for *tert*-butylcyclohexane in $CDCl_3$ (C. T. Tan, Ph.D. thesis, University of Western Ontario, 1976).
[c] Data from ref. 4.
[d] Data from ref. 1*b*.

50 ppm α effect observed for 16α-hydroxyl substitution in androstane (5) relative to the ~45 ppm shift found for 2α and 3β substitution. An equatorial hydroxyl group at C-2 in the [3.2.1] system, however, exerts effects which are very similar to those in the corresponding decalol (*cf.* items 5 and 6). The smaller α effect can be ascribed to a γ interaction with a neighboring methylene proton on C-7 (C-9 in the decalol). Although suggestions to the contrary have been made (14), it seems generally true that γ *gauche* carbons must bear a hydrogen atom closely neighboring the hydroxyl group to produce an upfield γ *gauche* effect. Introduction of the Δ^6 double bond produces a larger α effect (item 7), as expected, since the olefinic proton at C-7 is well separated from the hydroxyl group, whereas the Δ^3 double bond decreases the α effect (item 8) by enhancing the γ interaction with C-7 through ring flattening at C-2. In accord with this interpretation, a larger upfield shift is found for C-7. However, a puzzling feature emerges from the shifts for items 6–8. While the γ *anti* effects at C-4 and C-8 are similar for **3** and **12** (−2 ppm) there is a downfield shift of 2 ppm for C-8 in **17**. The C-8 assignment for **17** was confirmed by the off-resonance spectrum and the lowest field methylene carbon in olefin **15** was proved to be C-2 by deuteration (15). A larger downfield shift (4 ppm) occurs for the corresponding interaction in *exo*-2-bicyclo[3.2.1]-octa-3,6-dienol (8). Upfield γ *anti* effects are common (16) but with fully substituted intervening carbons these are downfield (1*c*).

Items 9–18 include compounds bearing axial hydroxyl groups and the 3-hydroxy [3.2.1] derivatives exhibit marked differences from axial alicyclic alcohols having two β methylene groups (items 9, 10). In the former, pronounced ring-flattening at C-3 can be anticipated through the *syn*-axial δ interaction of the hydroxyl group with C-6 and C-7, an arrangement known to cause deshielding (1*a*, 1*b*, 17). The shifts for the *endo*- and *exo*-3 derivatives (items 3, 4, 11, and 12) are remarkably similar indicating ^{13}C spectra could not be used for stereochemical assignments in closely related cases. In contrast, the *exo*-2-hydroxyl derivatives seem well behaved with the somewhat flattened ring of **2** leading to slightly stronger α and β effects and reduced γ effects relative to those found for the decalol (items 13 and 14), trends which are accentuated upon introduction of the 6,7- double bond

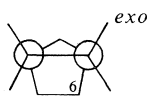
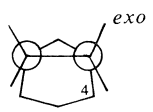
[a] $\Delta\delta_C = \delta_C^{ROH} - \delta_C^{RH}$ (in ppm) where RH is the appropriate olefin. Negative values are upfield shifts.
[b] Data taken from ref. 1*b*.
[c] Data taken from ref. 1*c*.

(item 15). As above, the allylic alcohol **16** exhibits an attenuated α effect and a smaller upfield shift for C-8. In **16**, C-7 is strikingly shielded, a γ *anti* effect in the expected direction but more than twice as large as that found for the saturated analog **2**. This would suggest that the dihedral angle relating the hydroxyl group and the *anti* γ carbon is a critical factor governing these effects.

An *endo*-8 hydroxyl group is axial with respect to the six-membered ring (see **31***a*) and the substituent effects for **9** are similar for the model decalol (item 13). The Δ^3 function produces the trends expected from ring flattening and the removal of one γ *gauche* interaction. Similar upfield γ *anti* effects occur in the [3.2.1] and [2.2.1] systems (items, 17–19 and 21) for which the geometries must be similar. The smaller γ *gauche* effects in the [2.2.1] cases (items 19 and 20) are ascribed to the increased separation of the hydroxyl group from the *exo*-protons. An *exo*-8-hydroxyl group exerts comparable γ *gauche* shifts (items 22 and 23) while its effects at the carbons of the six-membered ring are similar to those for the equatorial models (items 1, 2, and 5).



34

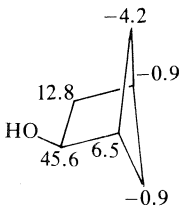


35

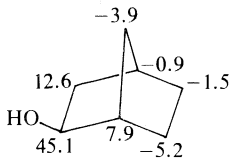
The effects of an *exo*-6-hydroxyl group in the [3.2.1] skeleton resemble those for an *exo*-2-OH group in the norbornane system (items 24–26) with curious differences in the α effects and the β effects at the bridgehead carbons. The attenuation of the γ *anti* effect in the [3.2.1] case relative to that in the [2.2.1] system may reflect the change in dihedral angle. Representations **34** and **35** illustrate the relative orientations of the bonds in this portion of the two bicyclic systems. Differences for an *endo*-6-hydroxyl group are also apparent from **34** and **35** and there is a significant difference in the γ *gauche* effects at C-6 and C-4, respectively (items 27 and 28).

An *endo* γ C—H bond is more nearly aligned with the C—O bond in the [2.2.1] skeleton indicating that the transmission of the γ *gauche* effect is more effective when the hydroxyl and a hydrogen are closer. It is also interesting that the γ *anti* effects at C-7 (C-8) (items 28–30) are more shielding in the [3.2.1] examples. Any interchanges of the methylene assignments for **19** lead to an even stronger set of shifts. As noted above, the angular dependence of the γ *anti* effects seems quite striking.

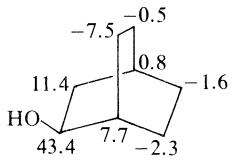
To compare the hydroxyl substituent effects in a variety of bicyclic systems the results for the [2.1.1], [2.2.1], [2.2.2], and [3.2.2] skeletons are shown in **36**–**39**; those for the [2.2.1] and [2.2.2] were reported earlier (1*a*, 1*b*). The effects are very similar indicating the absence of significant perturbations due to strain.



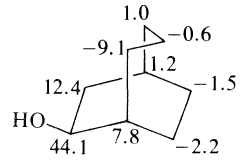
36



37



38



39

The hydroxyl substituents effects on the sp^2 carbons of the unsaturated alcohols are listed in Table 4. The general trends are similar to those discussed above with γ *gauche* interactions producing larger upfield shifts than γ *anti* effects. The δ effects are larger than those in Table 3 with maximum deshielding effects occurring in the compounds in which the hydroxyl group closely approaches the double bond. These resemble *syn*-axial perturbations in saturated systems (1*a*, 1*b*, 17). In the two allylic alcohols, both olefinic carbons appear to be deshielded by the hydroxyl group, behavior which is analogous to acyclic allylic alcohols.

In summary, the most puzzling trends are associated with γ *anti* effects for which the angular dependence may be a critical factor. It has been established that the degree of substitution of the intervening carbons in the γ fragment also has a major influence on the magnitude and direction of these shifts (1*c*). Thus their use for diagnostic purposes must be approached cautiously. Interestingly, there seems to be no obvious trend associated with the different strain energies of these various bicyclic systems. In general the relative orientations of the hydroxyl and a γ C—H bond tend to govern the magnitude of the upfield shift. The present data confirm earlier conclusions on this point (5) although contrary proposals have appeared (14).

Acknowledgements

We are grateful for the financial support of the National Research Council of Canada for this study and we thank Ms. Lucille Gough, Cornelia Ferriera, and Inara Grikis for technical assistance. We thank Dr. A. K. Cheng who kindly provided us with a sample of bicyclo[2.1.1]-hexane by Wolff–Kishner reduction of the ketone which was generously given to us by Prof. J. L. Charlton.

ANTHONY D. BARANYI, MARIO ONYSZCHUK, YVON LE PAGE, and GABRIELLE DONNAY. Can. J. Chem. **55**, 849 (1977).

The title compound has two $PbBr_2 \cdot 2[(CH_3)_2SO]$ units, $Z = 2$, in a cell with $a = 11.093(2)$, $b = 12.382(3)$, $c = 4.540(1)$ Å, belonging to space group *Pmmn*. The structure was solved by Patterson functions and was refined by full-matrix least-squares calculations to a final R of 0.054 for 348 observed diffractometer intensities. Passing through the unit cell are two antiparallel, infinite polar chains, each with symmetry *mm*2, extending along z and interacting with each other by weak van der Waals forces. Lead(II) is six-coordinate with a close, covalent hemisphere consisting of two bromine atoms [Pb—Br^{I},Br^{II} 2.93(1) Å], and two oxygen atoms [Pb—O,O′ 2.50(3) Å] which subtend an angle of 157.9(9)° at lead, located at the intersection of the O—Pb—O′ and Br^{I}—Pb—Br^{II} perpendicular mirror planes. The other hemisphere consists of bridging bromine atoms from the neighboring $PbBr_2 \cdot 2$dmso unit [Pb—Br^{III},Br^{IV} 3.24(1) Å], resulting in a rectangle of bromine atoms around lead [Br^{I}—Pb—Br^{II} 90.5(1)°, Br^{III}—Pb—Br^{IV} 80.2(1)°]. The distortion of the octahedral coordination sphere around lead is discussed in terms of (*a*) a repulsive effect of the Pb(II) valence lone electron-pair, (*b*) weak Br—S bonding, and (*c*) crystal packing forces.

ANTHONY D. BARANYI, MARIO ONYSZCHUK, YVON LE PAGE et GABRIELLE DONNAY. Can. J. Chem. **55**, 849 (1977).

Le composé mentionné dans le titre a deux unités de $PbBr_2 \cdot 2[(CH_3)_2SO]$ et $Z = 2$ par maille de dimensions $a = 11.093(2)$, $b = 12.382(3)$, $c = 4.540(1)$ Å et appartenant au groupe d'espace *Pmmn*. On a résolu la structure par les fonctions de Patterson et on l'a affinée par méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.054 pour 348 intensités observées par diffractométrie. Passant par la maille, il y a deux chaînes polaires infinies et antiparallèles qui possèdent chacune une symétrie *mm*2 s'étendant le long de l'axe z et qui interagissent l'une avec l'autre par des forces de Van der Waals faibles. Le plomb(II) est hexacoordonné avec un hémisphère covalent fermé consistant de deux atomes de brome [Pb—Br^{I},Br^{II} 2.93(1) Å] et deux atomes d'oxygène [Pb—O,O′ 2.50(3) Å] qui soutendent un angle de 157.9(9)° au niveau du plomb, situé à l'intersection des plans miroirs perpendiculaires de O—Pb—O′ et Br^{I}—Pb—Br^{II}. L'autre hémisphère consiste d'atomes de brome qui forment un pont et qui proviennent de l'unité $PbBr_2 \cdot 2$dmso voisine [Pb—Br^{III},Br^{IV} 3.24(1) Å]; ces arrangements conduisent à l'existence d'un rectangle d'atomes de brome autour de l'atome de plomb [Br^{I}—Pb—Br^{II} 90.5(1)°, Br^{III}—Pb—Br^{IV} 80.2(1)°] .On discute de la distorsion de la coordination octaédrique de la sphère autour du plomb en termes: (*a*) d'un effet répulsif de la paire d'électrons libres de valence du Pb(II), (*b*) de liaisons Br—S faibles et (*c*) de forces d'entassement du cristal.

[Traduit par le journal]

Introduction

Crystal and molecular structures of coordination compounds of lead(II) halides and pseudohalides are known only for lead(II) chloride-bis-thiourea (1), $PbCl_2 \cdot 2$tu, and di-isothiocyanato lead(II)-bis-dimethylsulphoxide (2), $Pb(NCS)_2 \cdot 2$dmso. In the first structure, lead is seven coordinate due to bonding with four sulphur and two chlorine atoms, all at the corners of a distorted trigonal prism, and a third chlorine atom near the center of a prism face. Sulphur atoms and apical chlorine atoms bridge to neighbouring lead atoms forming a polymeric chain. Polymeric chains are also present in crystalline $Pb(NCS)_2 \cdot 2$dmso, the lead atom of which is six-coordinate in a distorted octahedral arrangement of two nitrogen atoms and two bridging sulphur atoms approximately coplanar, with one oxygen atom above and another below the plane (2).

Adducts of lead(II) bromide with a variety of O-, S-, and N-donor ligands have been prepared and characterized (3), but few conclusions were made about structure on the basis of the measured vibrational spectra. Of the available complexes, $PbBr_2 \cdot 2dmso$ was chosen for an X-ray diffraction study because it offered the possibility of a direct comparison with the structure of $Pb(NCS)_2 \cdot 2dmso$ (2). Structures of dimethylsulphoxide complexes are also of particular interest because of the ambidentate coordinating ability of this ligand. Dimethylsulphoxide is sulphur-bonded in $Ir(C_{15}H_{13}O)Cl_2 \cdot 2dmso$ (4), $PdCl_2 \cdot 2dmso$ (5), $Pd(NO_3)_2 \cdot 2dmso$ (6), and $[Ru(dmso)(NH_3)_5][PF_6]_2$ (7); oxygen-bonded in $[FeCl_2(dmso)_4][FeCl_4]$ (8), $CuCl_2 \cdot 2dmso$ (9), $(CH_3)_2SnCl_2 \cdot 2dmso$ (10), $SnCl_4 \cdot 2dmso$ (11), $Pb(NCS)_2 \cdot 2dmso$ (2), and $La(NO_3)_3 \cdot 4dmso$ (12); and oxygen-bridge-bonded in $3HgCl_2 \cdot 2dmso$ (13).

Experimental

Lead(II) bromide-bis-dimethylsulphoxide, $PbBr_2 \cdot 2dmso$ (3)

Small white needles were obtained after $PbBr_2$ (3.7 g, 10 mmol) was dissolved in dimethylsulphoxide (50 ml) at 40 °C, and the solution was allowed to stand for several days until crystallization took place. Crystals were separated by filtration and dried with suction in a nitrogen-filled dry-box. The complex decomposed rapidly to a white powder on exposure to moist air, and at approximately 100 °C in a capillary tube filled and sealed under nitrogen. *Anal.* calcd. for $PbBr_2 \cdot 2[(CH_3)_2SO]$: C 9.2, H 2.3, Pb 39.6; found: C 9.3, H 2.3, Pb 38.5.

Data Collection

The crystal selected for study was held in a Lindeman glass capillary tube by a thin film of silicone grease, sealed under nitrogen, and mounted with the longest dimension of the crystal, *c*, approximately parallel with the rotation axis of the Eulerian cradle to minimize absorption. The dimensions of the crystal were *ca.* 0.01 × 0.01 × 0.30 mm.

The diffraction aspect *P**n* was determined from rotation, Weissenberg, and precession films using Ni-filtered CuK_α radiation, and two possible space-groups were indicated: *Pmmn* and $P2_1mn$. Measurements of the independent reflections with the diffractometer confirmed the systematic extinction *hk*0 for $h + k = 2n + 1$. The unit-cell parameters were refined by least-squares fit of χ,ϕ,ω and 2θ values for 12 general reflections with $2\theta > 35°$ measured on a diffractometer with MoKα radiation. Crystal data are:

$PbBr_2 \cdot 2[(CH_3)_2SO]$ fw = 523.3
Orthorhombic, $a = 11.093(2)$, $b = 12.382(3)$, $c = 4.540(1)$ Å, $u = 623.6$ Å^3, $Z = 2$, $\rho_c = 2.79$, Space group *Pmmn*, (D_{2h}^{13}), MoKα, $\lambda = 0.70926$ Å, μ(MoKα) = 202.6 cm^{-1}, $T = 20$ °C.

Intensities were measured on a Picker four-circle automated diffractometer using graphite monochromated MoKα radiation. Reflections were collected using the θ–2θ scan method, scanning from 0.6° below α_1 to 0.6° above α_2 at $\frac{1}{2}°$ 2θ min^{-1}, with 20 s background counts being measured at each end of the scan. The intensities of three standard reflections, measured after every 10 reflections, showed only the deviations from the mean predicted from counting statistics. A total of 883 symmetry independent reflections were measured in the range $5° \leq 2\theta \leq 60°$, 348 of which had $I > 2\sigma(I)$ and were classed observed. Intensities were corrected for Lorentz and polarization factors by means of the DATRDN program of X-Ray 70 (14). No absorption corrections were made because the width of the crystal is only 0.01 mm, which is considerably smaller than the calculated optimum size, $t_{opt} = 0.33$ mm (15). The transmission factor was in the range 0.82 to 0.87, and the error due to absorption was estimated to be ±5% on intensities. Atomic scattering factors were taken from Hanson *et al.* (16) and corrections were made for anomalous dispersion of lead, bromine, and sulfur (17).

Structure Determination and Refinement

A study of the Patterson function provided a unique spatial distribution of the heaviest atoms, Pb, Br, and S, giving a pseudo-body-centered Bravais lattice which had not been noticed from photographic measurements. The mean of $h + k + l$ odd intensities was only 14% of the mean of $h + k + l$ even intensities. A partial Patterson synthesis of $h + k + l$ odd terms indicated that the difference between the true structure and the body-centered pseudo-structure was not due to the light atoms, but mainly to a displacement of the lead atom from the center of the rectangle of bromine atoms (18). A model of two parallel chains along [001], probably in space group *Pmm*2, pseudo-*Imm*2, was indicated. The systematic extinctions in this space group become structural absences. The difference from a model of antiparallel chains, rejected by the partial Patterson synthesis, lay only in the *z* coordinate of one oxygen atom. Since *Pmm*2 is a subgroup of *Pmmn*, both models were first refined and compared in that space group.

The *n* glide-plane systematic extinctions were included in the observed data. The model of parallel chains refined to a residual *R* of 0.090 using isotropic temperature factors for the five atoms Pb, Br, S, O, and C. In the least-squares calculation all atoms were accepted except one oxygen atom whose temperature factor became unacceptably large during refinement.

The difference Fourier synthesis showed a wide peak at the position where an oxygen atom was expected in the model of antiparallel chains. By introducing the oxygen atom in this position, the residual *R* decreased to 0.055, using anisotropic thermal parameters for Pb, Br, and S.

An analysis of this model showed that it was compatible with space group *Pmmn*, the largest difference being 4σ in the *z* position of bromine. After removing the systematic extinctions of the *n* glide-plane from the data, the structure was further refined in the *Pmmn* space group by full-matrix least-squares methods using anisotropic temperature factors for all atoms. Three cycles were required for final convergence. The function minimized was $\Sigma\omega(|F_o| - |F_c|)^2$ where $\omega = 1$. The refinement terminated with an unweighted residual *R* of 0.054 for all atoms except hydrogen which could not be located from

TABLE 2. Final anisotropic thermal parameters ($U_{ij} \times 100$ Å^2) and their estimated standard deviations*

Atom	U_{11}	U_{22}	U_{33}	U_{12}	U_{13}	U_{23}
Pb	4.86(13)	4.84(11)	2.67(8)	0.0	0.0	0.0
Br	3.95(22)	5.85(23)	5.03(24)	0.0	0.21(16)	0.0
O	13.9(26)	6.9(20)	5.1(15)	0.0	0.0	3.1(15)
S	6.9(66)	4.95(51)	4.00(46)	0.0	0.0	0.36(43)
C	7.8(21)	10.1(22)	6.4(17)	−4.8(19)	−0.1(16)	−1.2(17)

*The form of the thermal ellipsoid is: $\exp(-2\pi^2 \sum_{i=1}^{3}\sum_{j=1}^{3} h_i h_j a_i^* a_j^* U_{ij})$.

the final difference-Fourier map. When the refinement was repeated with a statistical weighting of the data, $\omega = 1/\sigma^2$, an R value of 0.055 was obtained: the refined parameters and estimated standard deviations were unchanged within the error limits. The refinement displayed a large U_{11} thermal parameter for the oxygen atoms. This thermal motion had smeared out the Pb—O peak in the partial Patterson synthesis to such an extent that this peak was absent and led to the initial assumption of space group *Pmm*2. The final residual R of 0.054 corresponds to a partial residual of 0.044 on 214 observed $h + k + l = 2n$ structure factors and 0.086 on 134 odd ones. The larger residual for the odd terms indicates that they contribute less to the sum of the structure factors than even terms rather than forming a large contribution to the sum of the errors.

Results and Discussion

Atomic co-ordinates are listed in Table 1, anisotropic temperature factors in Table 2, and bond distances and angles in Table 3. Observed and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The crystal structure consists of two antiparallel chains of symmetry *mm*2 extending along the z direction, corresponding to one another by an n glide-plane perpendicular to c. The chains consist of $PbBr_2 \cdot 2dmso$ units bridged through bromine atoms (Fig. 1). Lead has a coordination number of six and sits at the intersection of the two mirror planes. Four bromine atoms form a rectangle in a mirror plane with two short Pb—Br bonds (2.93(1) Å) and two longer bridging Pb—Br interactions (3.24(1) Å). The Br—Pb—Br angles range from 80 to 95°. The two oxygen atoms of the dimethylsulphoxide groups complete the coordination sphere of lead and subtend an angle of 157.9(9)° at lead. The dmso units point toward the region of short Pb—Br distances (Fig. 2).

The directions of the largest thermal motions of Br and O are perpendicular to the plane of their bonds. The maximum vibration of sulfur is in the same direction as oxygen, while the carbon atoms vibrate in the xy plane, indicating a probable oscillation of the dmso group around the S—O bond. The lead atom has an oblate thermal motion ellipsoid along the z axis, corresponding to transverse vibrations of chains rather than to independent movements of individual lead atoms.

The coordination sphere of lead has changed drastically from the parent $PbBr_2$ in which lead is bound to nine bromine atoms, six at the apices of a trigonal prism and three beyond the centers of the three prism faces (19). The lead–bromine distances in $PbBr_2$ range from 3.0 to 3.88 Å. In $PbBr_2 \cdot 2dmso$ lead is six-coordinate and there are two distinct coordination hemispheres (Fig. 2). There is a close-packed, covalently bound region consisting of two oxygen atoms, O and O′, and two bromine atoms, Br^I and Br^{II}. The Pb—Br^I and Pb—Br^{II} distances,

[1]The structure factor table is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

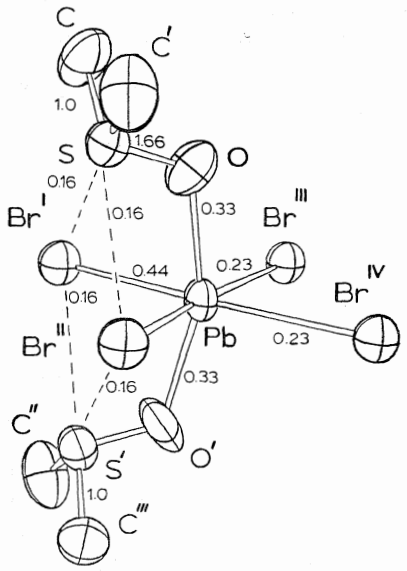

FIG. 2. ORTEP plot (26) of the molecular structure (including Br^{III} and Br^{IV} from the next unit) showing equatorial plane, atomic labelling, and bond valences in valence units (vu).

2.93(1) Å, are only slightly longer than the sums of corresponding covalent radii (2.7 Å) and appreciably shorter than the sums of corresponding van der Waals radii (3.9 Å), indicating that Pb—Br^{I} and Pb—Br^{II} bonds are predominantly covalent. Lead–oxygen distances, 2.50(3) Å, also show appreciable covalent character, being much closer to the covalent radii sum, 2.31 Å, than to the van der Waals radii sum, 3.5 Å. In the same region $Br^{I,II}$—O, $Br^{I,II}$—O′, and Br^{I}—Br^{II} interatomic approaches are equal to or greater than the sums of their respective van der Waals radii (Table 3). On the opposite side of the lead atom, *i.e.*, in the second hemisphere, there are two bridging bromine atoms from the neighboring $PbBr_2$·2dmso unit (Fig. 2). The Pb—Br^{III} and Pb—Br^{IV} distances, 3.24 Å, are greater than the sums of their ionic radii, 3.13 Å (25) but less than the sums of their van der Waals radii, 3.9 Å. The other interatomic approaches, O. . .$Br^{III,IV}$ and Pb. . .S, are equal to, or greater than the sums of the respective van der Waals radii (Table 3).

Three possibilities are suggested for the distortions of the octahedral configuration around Pb(II): (*a*) a repulsive effect of the Pb(II) valence lone electron-pair, (*b*) weak Br. . .S bonding, and (*c*) crystal packing forces.[2] Each of these possibilities will now be discussed in detail.

(*a*) The two dmso molecules of each octahedral cluster are bent away from 180°, O—Pb—O′ 157.9(9)°, toward the nearest bromine atoms, Br^{I} and Br^{II}, rather than towards the more distant bromine atoms, Br^{III} and Br^{IV}, a region one might have expected more sterically able to accommodate dmso molecules. A similar distortion of the O—Pb—O angle (160.1(8)°) in crystalline $Pb(NCS)_2$·2dmso was attributed to the repulsive effect of the unshared electron-pair of Pb(II) occupying a coordination site between two bridging thiocyanate groups (2). In $PbBr_2$·2dmso, none of the angles in the $PbBr_4$ rectangle is large enough to suggest the presence of a directed lone electron-pair. However, the unsymmetrical arrangement of bromine atoms and the 22° departure of the O—Pb—O′ angle from linearity suggest the existence of a repulsive effect which might be due to the distribution of the unshared electron-pair of Pb(II) being asymmetric rather than spherically symmetric. Similar examples of coordination spheres containing short and long bonds as well as angular distortions have been reported for As(III), Sb(III), and Bi(III) compounds and attributed to asymmetric lone electron-pairs (20).

(*b*) Thc fact that Br. . .S and S. . .O nonbonding distances are slightly less than the corresponding van der Waals radii sums (Table 3) prompts us to suggest that the observed distortions of the Pb(II) octahedral coordination sphere might be due to weak Br. . .S and S. . .O bonding within chains. When this possibility is examined in terms of the bond valence analysis of Donnay and Allman (21), or Brown (22), Pb(II) emerges with two strong, two medium, and two weak bonds, corresponding to Brown's configuration A. Bond valence units (vu) around Pb(II) were calculated from bond distances in the usual way (21, 22) and are given in Fig. 2. Lead(II) is assigned a bond valence sum of 2.0 and the proportions among the six bonds are similar to those of SnO in which Sn(II) is six-coordinate in a distorted octahedral geometry (22). Although the long Pb—Br bonds have only half the bond valence of the short Pb—Br

[2]These were suggested and preferred by one of the referees.

TABLE 4. Data for dimethylsulphoxide compounds

	Compound	M—S distance (Å)	M—O distance (Å)	M—O—S angle (deg)	S—O distance (Å)	Reference
S-bonded:	$Ir(C_{15}H_{13}O)Cl_2 \cdot 2dmso$	2.24			1.44, 1.46	4
	$PdCl_2 \cdot 2dmso$	2.29			1.47	5

bonds, their bond valence is large enough to indicate that Br^{III} and Br^{IV} are within the primary coordination sphere of Pb(II). The fact that the bond valence sum at each Br atom is 0.67 rather than 1.0 vu suggests that Br atoms are involved in additional bonding interactions, most likely with nearby S atoms of coordinated dmso molecules. Unfortunately, bond valences around sulfur cannot be calculated directly because the required sulfur radii are not yet available; however, bond valences surrounding sulfur can be obtained indirectly as follows. Since the total bond valence of oxygen is 2.0 vu and 0.33 vu of this is attributed to the Pb—O bond, 1.66 vu remain for the S—O bond. Sulfur is also covalently bound to two methyl groups, each bond accounting for 1.0 vu. Therefore, the bond valence sum at sulfur is 3.66 vu instead of 4.0 vu required by its oxidation number. If the difference of 0.34 vu is attributed to a weak interaction of the sulfur atom with two neighbouring Br atoms, *i.e.*, 0.17 vu per bond, the total bond valence of each Br atom becomes 1.0 as shown in Fig. 2. This proposal is supported by the good agreement between the observed Br. . .S distance of 3.53(1) Å and the calculated distance of 3.2 to 3.6 Å obtained from the bond valence equation (22). Additional evidence of a Br. . .S interaction is provided by the Pb—O—S angle of 115.6(15)° being the smallest reported in crystal structures of dmso complexes (Table 4). Since the S. . .O distance between neighbouring $PbBr_2 \cdot 2dmso$ units in the same chain is about 10% less than the van der Waals radii sums, the possibility of weak S. . .O bonding cannot be excluded. The S=O bond length (1.59(3) Å) in $PbBr_2 \cdot 2dmso$ is one of the longest found in dmso complexes (Table 4). The S—C bond length is unchanged from that in solid dmso (1.80 Å) (23).

(*c*) Crystal packing forces are usually proposed to account for differences in structure observed between the gaseous and crystalline phases of a substance. Unfortunately, such a comparison is not possible with $PbBr_2 \cdot 2dmso$ because it does not exist in the gaseous phase. Nevertheless, the fact that so many non-bonding approaches (Table 3) are approximately equal to van der Waals radii sums might suggest that deviations from a Pb(II) octahedral configuration are due primarily to inter- and intra-chain van der Waals forces arising from dipole–dipole, dipole – induced dipole, and London dispersion forces among neighbouring molecules and atoms (24). Thus the small interatomic Br. . .S and S. . .O distances with the consequent deviation of the O—Pb—O′ angle from 180° may not be due to weak bonding interactions, as previously suggested, but merely the result of the need for the crystal to achieve the most efficient packing arrangement possible both within each chain and between the chains.

The heat capacities, volumes, and expansibilities of *tert*-butyl alcohol – water mixtures from 6 to 65 °C

CEES DE VISSER,[1] GERALD PERRON, AND JACQUES E. DESNOYERS[2]

Department of Chemistry, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received September 9, 1976

CEES DE VISSER, GERALD PERRON, and JACQUES E. DESNOYERS. Can. J. Chem. **55**, 856 (1977).

The densities and specific heat capacities of mixtures of *tert*-butyl alcohol (TBA) and water (W) have been measured at 6, 10, 25, 40, 55, and 65 °C. From these data the apparent molal volumes (ϕ_V), heat capacities (ϕ_C), and expansibilities (ϕ_E) were evaluated. Generally, the temperature dependence of these quantities is rather characteristic of hydrophobic solutes in water. At high concentrations ϕ_C and ϕ_V resemble those of surfactants, suggesting the existence of some microphase separation. At low temperatures ϕ_C show a significant hump as a function of concentration, which is probably not due to the presence of the —OH group on the TBA molecule. A similar behaviour is observed for ϕ_E. The ϕ_V and ϕ_C of water in TBA have also been calculated; $\phi_{V,W}$ is in the TBA-rich region 2 to 2.5 $cm^3\ mol^{-1}$ smaller than the molar volume of water, but $\phi_{C,W}$ is of the same order of magnitude as the molar heat capacity of water.

CEES DE VISSER, GERALD PERRON et JACQUES E. DESNOYERS. Can. J. Chem. **55**, 856 (1977).

Les masses volumiques et capacités calorifiques des mélanges du *tert*-butanol (TBA) et de l'eau (W) ont été mesurées à 6, 10, 25, 40, 55 et 65 °C. Les volumes (ϕ_V), capacités calorifiques (ϕ_C) et expansibilités (ϕ_E) molaires apparents ont été calculés sûr tout le domaine de concentration. En général la dépendance sur la température de ces quantités est assez typique du comportement des solutés hydrophobes dans l'eau. Aux fortes concentration ϕ_C et ϕ_V ressemblent à ceux des détergents suggérant l'existence d'une fonction de microphases. Aux basses températures ϕ_C augmente d'une façon non-linéaire avec la concentration avant de diminuer rapidement vers sa valeur molaire aux plus fortes concentrations. L'existence de cette bosse en fonction de la concentration ne semble pas reliée à la présence du groupement OH. Un comportement similaire est observé pour ϕ_E. Les volumes et capacités calorifiques molaires apparents de W dans le TBA ont aussi été calculés; $\phi_{V,W}$ dans la région riche en TBA est de 2 à 2.5 $cm^3\ mol^{-1}$ plus petit que le volume molaire de W mais $\phi_{C,W}$ est du même ordre de grandeur que la capacité calorifique molaire de W.

Introduction

The numerous studies on mixtures of alcohols and water have been very well reviewed by Franks and co-workers (1–3). Most of the alcoholic systems fall in a class of solutions which are generally classified as typically aqueous (3–5); the excess free energy G^E is positive, $|TS^E| > |H^E|$ (entropy-controlled mixing), the solution tends to unmix at high temperatures and the concentration dependence of the thermodynamic properties show characteristic trends. The hydrophobic character of the cosolvent seems to be responsible for the general behaviour of these solutions.

tert-Butyl alcohol (TBA) is of particular interest since, although it is quite hydrophobic, it is still miscible in all proportions with water. Most properties of this binary system, especially in the water-rich region, have been well investigated (1–14). However, precise heat capacity data over the whole concentration range and at many temperatures are still scarce: previous studies were often limited to the water-rich region and to 25 °C (14, 15). Only Kenttamaa *et al.* (6) reported mean molar heat capacities over the whole mole fraction range. Unfortunately, they reported their data "at about 30–33 and 50–53 °C". Moreover, as will be shown in this paper, mean molar heat capacities do not give much information on specific (structural) effects on dissolution. Also the heat capacities of pure TBA are not known accurately enough above 25 °C (16).

Heat capacity data are of interest since they are known to be very sensitive to structural changes in solutions. We therefore felt it would be useful to measure this property for mixtures of TBA and water over a wide temperature range

[1]On leave of absence from Department of Chemistry, the Free University of Amsterdam, Amsterdam, The Netherlands.

[2]To whom correspondence should be addressed.

and whenever possible over the complete mole fraction range. Under similar conditions the volumes were also evaluated because the flow microcalorimetric technique used for the measurements of the differences in heat capacities requires the knowledge of precise densities. In addition, the apparent molal expansibilities can then be calculated from the temperature dependence of the apparent molal volumes.

Finally, it should be mentioned that precise data of the binary TBA–W system are required for a systematic study of ternary systems involving the TBA–W mixtures, which we have investigated (17).

Experimental

All solutions were prepared by weight with deionized (Continental Deionised Water System) distilled water, and TBA (Baker Analyzed Reagent) was used as such (14).

The solution densities (d) and heat capacities per unit volume (σ) were measured with a flow densimeter (18) and a Picker flow microcalorimeter (19, 20). At 25 °C, the detection limits, in differential measurements, were respectively $\pm 3 \times 10^{-6}$ g cm^{-3} and $\pm 7 \times 10^{-5}$ J K^{-1} cm^{-3}. The experimental techniques, the uncertainties at other temperatures, and the general procedures have been described elsewhere (18–21). In the present study, using a flow rate of 0.6 cm^{-3} min^{-1} and a heating power of 21 mW, the temperature increment during the heat capacity measurements was ~0.5 °C. All data are expressed relative to NaCl solutions (20). The absolute temperature of the measurements was measured to 0.01 K with a Hewlett-Packard Quartz Thermometer.

Results

The apparent molal volume, ϕ_V, and heat capacity, ϕ_C, of TBA in the mixtures were calculated from the data using the following equations:

$$[1] \qquad \phi_V = \frac{M}{d} - \frac{1000(d - d_0)}{mdd_0}$$

and

$$[2] \qquad \phi_C = Mc_p + \frac{1000(c_p - c_{p0})}{m}$$

where M is the solute molecular weight, m the molality, and c_p the specific heat capacity. The density d_0 and specific heat capacity c_{p0} of pure water are taken respectively from Kell (22) and Stimson (23). The difference in specific heat capacity can be derived from the measured difference in heat capacity per unit volume by the relation:

$$[3] \qquad c_p - c_{p0} = c_{p0}\left\{\frac{\sigma - \sigma_0}{\sigma_0} + 1\right\} d_0/d - c_{p0}$$

where σ_0 is given by $c_{p0}d_0$. By reversing TBA and W, it is of course also possible using eqs. 1 to 3 to calculate the corresponding functions for water.

The original data and derived ϕ_V and ϕ_C values at 6, 10, 25, 40, 55, and 65 °C are given elsewhere.[3] Except for ϕ_C at 65 °C, at least 10 measurements were made below $m_{TBA} = 1$ at each temperature and both ϕ_V and ϕ_C were fitted by least-squares methods to equations of the form:

$$[4] \qquad \phi = \phi^\theta + Am$$

The resulting coefficients at different temperatures are collected in Table 1. At 10 °C two different sets of measurements yielded slightly different ϕ_C^θ (486.3 and 482.9 J K^{-1} mol^{-1}) values. Since we do not know which one is the best, we used them both in order to calculate $\phi_C - \phi_C^\theta$. In Table 1 the mean value for ϕ_C^θ has been reported. The value of ϕ_V^θ at 25 °C is in good agreement with that (87.95 cm^3 mol^{-1}) reported by Franks and Smith (7) obtained from precise density measurements at very low concentrations. The agreement with the data of Avédikian *et al.* (14) is also within the experimental error. The value of 87.73 cm^3 mol^{-1} reported by Jolicoeur and Lacroix (24) is slightly lower but they obtained ϕ_V^θ by extrapolating against molarity with a lowest concentration of 0.27 mol l^{-1}. Kenttamaa *et al.* (6) reported partial molal volumes at 15, 25, 40, and 50 °C covering the complete mole fraction range. Their infinite dilution data ($\bar{V}^\theta = \phi_V^\theta$) deviate generally by about 2 cm^3 mol^{-1} from the present results. However, calculation of ϕ_V for the complete mole fraction range using their density data shows that only below $X_{TBA} = 0.05$ do important differences exist; above $X_{TBA} = 0.05$ the agreement with the present data is generally within 0.1 cm^3 mol^{-1}, both at 25 and 40 °C. Their values for the molar volume of pure TBA at 25 °C (supercooled liquid) of 94.96 cm^3 mol^{-1} and at 40 °C of 96.88 cm^3 mol^{-1} are in excellent agreement with the present results of 94.97 and 96.86 cm^3 mol^{-1}, respectively, given in Table 1. Finally, Nakanishi *et al.* (25) reported on excess and partial molal volumes of TBA–W systems at 25 °C. Calcula-

tions of the ϕ_V from their densities yield very close results to the present ones below $X_{TBA} = 0.3$ while at higher X_{TBA} their values are slightly lower, the difference increasing to 0.2 cm³ mol⁻¹ for the molar volume of pure TBA.

Our ϕ_C^θ at 25 °C is in excellent agreement with that, 464.0 J K⁻¹ mol⁻¹, reported by Jolicoeur and Lacroix (24) and with the corrected value (20) of 462.8 J K⁻¹ mol⁻¹ given by Avédikian *et al.* (14). It is also possible to obtain ϕ_C^θ ($= \bar{C}_p^\theta$) from the integral heat of solution method as carried out by Alexander and Hill (12). At 25 °C, a value for $\bar{C}_p^\theta$ of 475 ± 20 J K⁻¹ mol⁻¹ can be derived from their data, which is, although less accurate, in agreement with the present results.

The molar heat capacities of pure TBA C_p^0 above room temperature are, as mentioned before, rather scarce. Only Oetting (26) seems to have reported heat capacities and entropies of TBA from 15 to 330 K. His (interpolated) heat capacities at 25, 40, and 55 °C are 220, 233, and 244 J K⁻¹ mol⁻¹ respectively. These data are, especially at higher temperatures, in very good agreement with our results given in Table 1. Precise data for ϕ_C in the TBA–W mixture are also scarce in the literature. Kenttamaa *et al.* (6) reported mean molar heat capacities C_p at temperatures around 31.5 and 51.5 °C. From the present results it is also possible to calculate mean molar heat capacities using the following equation:

$$[5] \qquad C_p = \sigma(X_W M_W + X_{TBA} M_{TBA})/d$$

Values obtained using eq. 5 at 25, 40, and 55 °C show the same trends as those given by Kenttamaa *et al.* (6). Arnaud *et al.* (15) reported also mean molar heat capacities up to $X_{TBA} = 0.27$. The difference from the present results is within 1 J K⁻¹ mol⁻¹ in most cases. We can therefore say that the present data are in good agreement with existing literature values where available and give us confidence that they are close to the true values.

Discussion

Thermodynamic properties of binary solvent mixtures are often discussed in terms of excess molar thermodynamic functions. With the exception of free energies and entropies these are defined by

$$[6] \qquad Y^E = Y - X_1 Y_1^0 - X_2 Y_2^0$$

where Y is the mean molar quantity and Y_1^0 and Y_2^0 are the standard molar quantities of the two pure components. The excess volumes and heat capacities of the TBA–W mixtures at 25, 40, and 55 °C are shown in Fig. 1. On this kind of graph the TBA–W mixtures do not seem too anomalous. With the exception of the pronounced asymmetry with C_p^E, this system does not appear too different from other liquid mixtures, and shows little dependence on temperature. On the other hand, if the apparent molal volumes and heat capacities are plotted against the mole fraction of TBA, then the particularities of this hydrophobic solute are more evident as seen from Figs. 2 and 3. The ϕ_V goes through a characteristic minimum in the water-rich region and this minimum is more pronounced and shifted to higher concentrations the lower the temperature. In the TBA-rich region ϕ_V tends to the molar volume of TBA as expected. The general trends of ϕ_C are again typical of hydrophobic solutes; ϕ_C first increases with concentration and then rapidly falls to its molar value. These transitions are even sharper if partial molal quantities are plotted instead of apparent molal ones. For example $\bar{C}_p$ nearly reaches its molar value at concentrations as low as 0.1 mole fraction. Qualitatively speaking, ϕ_V and ϕ_C of TBA in W are quite similar to those of surfactants (27, 28) which also show characteristic maxima and minima but of course at much lower concentration (10^{-3} to 10^{-1} mol kg^{-1}). Still, the similarity between the present system and surfactants suggests that the relatively sharp increase in volume and decrease in heat capacity corresponds to some kind of microphase transition as in the case of micellization. Above 0.1 to 0.2 mole fraction, the hydrophobic part of TBA is seeing only other TBA molecules. The system can probably be considered to be a micro emulsion although the present data do not give us information on the size and structure of the aggregates.

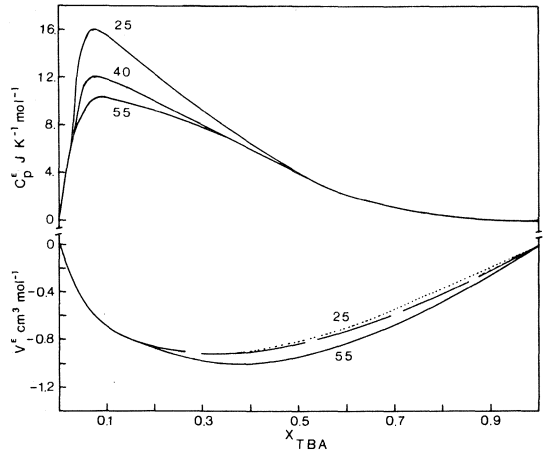

FIG. 1. Excess molar volumes and heat capacities of *tert*-butyl alcohol and water at 25, 40, and 55 °C.

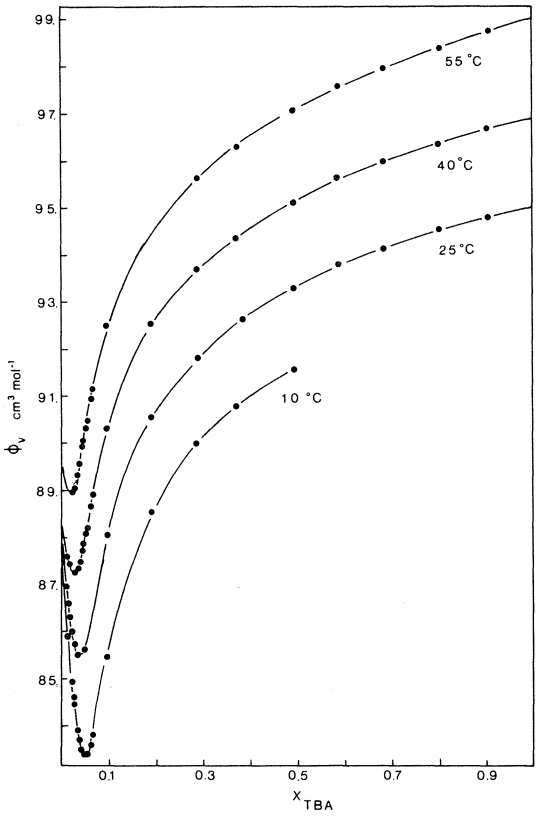

FIG. 2. Apparent molal volumes of *tert*-butyl alcohol in water at different temperatures.

The concentration dependence of the apparent molal quantities, $\phi_Y - \phi_Y^\theta$, are plotted for the water-rich region in Figs. 4 and 5. Here the volumes are showing the normal trends of hydrophobic solutes: the negative slopes, increasing in magnitude as the temperature is lowered, are also observed with hydrophobic electrolytes (21). On the other hand, the concentration and temperature dependences of $\phi_C - \phi_C^\theta$ show significant differences with normal hydrophobic electrolytes. For example, tetrapentylammonium bromide (21) and nonyltrimethylammonium bromide (28) have negative

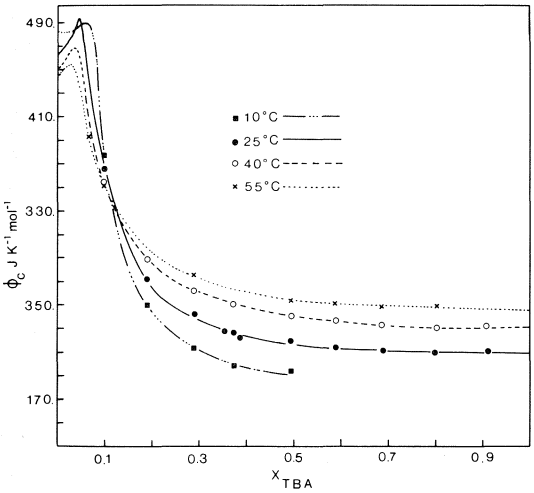

FIG. 3. Apparent molal heat capacities of *tert*-butyl alcohol in water at different temperatures.

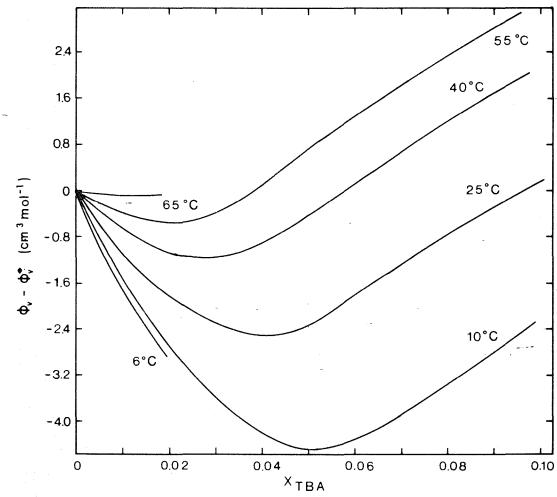

FIG. 4. Excess apparent molal volumes of *tert*-butyl alcohol in the water-rich region at different temperatures.

initial slopes at high temperatures and positive ones at low temperatures. With TBA, the initial slope changes little with temperature from 25 °C upwards while $\phi_C - \phi_C^0$ is nearly independent of concentration at low temperatures in the water-rich region. There is also a significant hump in $\phi_C - \phi_C^0$ at 25 and 10 °C at higher concentrations. A somewhat similar observation was made with tetrabutyloctanoate in water (29).

Recently Savage and Wood (30) have suggested that the interaction of the polar group (*e.g.* the —OH group) of one molecule with the alkyl chain of another may be just as important

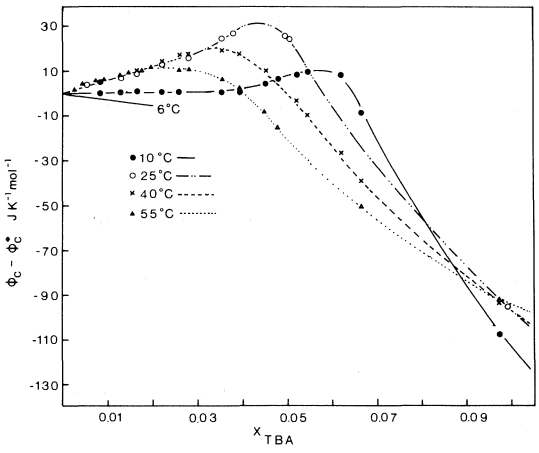

FIG. 5. Excess apparent molal heat capacities of *tert*-butyl alcohol in the water-rich region at different temperatures.

as the hydrophobic–hydrophobic interactions in predicting the signs and magnitudes of pair interaction functions. As a check that the peculiar behaviour of $\phi_C - \phi_C^0$ of TBA was not due to the presence of the —OH group we have also begun a study of ϕ_C of triethylamine in water (31). At 15 °C this liquid is completely miscible with water. As with TBA, $\phi_C - \phi_C^0$ changes little with concentration at rather low concentrations, rises to over 150 J K^{-1} mol^{-1} at about 1 mol kg^{-1}, and then decreases sharply to about -400 J K^{-1} mol^{-1}. The hump in $\phi_C - \phi_C^0$ is therefore related to hydrophobic interactions and suggests that there are structural changes which occur in these solutions at certain concentrations which resemble a microphase separation or higher order transition in the liquid phase. The sharp decrease in $\phi_C - \phi_C^0$ can well be accounted for in terms of contact pairing: the hydrophobic solutes lose part of their cospheres on contact association. The hump in $\phi_C - \phi_C^0$ probably corresponds to a much weaker transition since it is not seen with excess volumes and enthalpies. One such possibility would be a solvent-shared association complex which could occur in a cooperative way (32).

At present we cannot offer any reasonable explanation for the peculiar temperature dependence of $\phi_C - \phi_C^0$ at low concentration. Studies are under way now with other non-electrolyte–water systems to clarify this behaviour.

The apparent molal expansibilities ϕ_E can be calculated from the temperature dependence of

ϕ_V. At low concentration ϕ_E can be shown to be in excellent agreement witn the direct measurements of Desrosiers and Desnoyers (33). The concentration dependence of ϕ_E is shown for three temperatures on Fig. 6; ϕ_E initially increases sharply, goes through a maximum and finally tends to the molar expansibility E^0 of pure TBA, the maximum being more pronounced at low temperatures. The negative sign of $\phi_E^\theta - E^0$ is consistent with the models of hydrophobic hydration (34, 35); since there is less free space in the cosphere of an hydrophobic solute ($\phi_V^\theta - V^0 < 0$) there will be less expansion during a rise in temperature. The maximum in ϕ_E is obviously related to the minimum in ϕ_V. It is also related to the maximum in ϕ_C. This follows from Eley's theory (36) and from the scaled-particle theory (37) which both show that there is a relation between the heat capacity of cavity formation and the change in expansibility of the medium with temperature. It is therefore not surprising that interactions giving rise to an extremum with ϕ_C should also influence ϕ_E.

The temperature dependences of ϕ_C^θ, ϕ_V^θ, and ϕ_E^θ are compared with the corresponding molar values of pure TBA in Fig. 7. These data are all fairly typical of hydrophobic solutes and are consistent with the models that suggest that these solutes promote water structure at low concentrations; the positive value of $\phi_C^\theta - C_p^0$ and negative values of $\phi_V^\theta - V^0$ and $\phi_E^\theta - E^0$ all decrease in magnitude as the temperature increases. The positive sign of $T\,\partial\phi_E^\theta/\partial T$ ($= -\partial\phi_C/\partial P$) also seems characteristic of hydrophobic solutes (38).

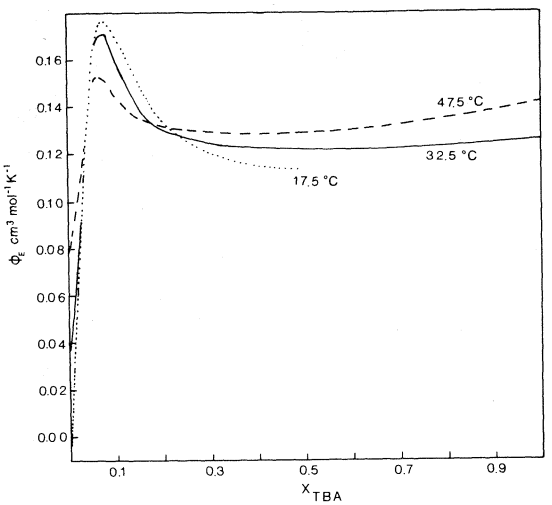

FIG. 6. Apparent molal expansibilities of *tert*-butyl alcohol in water.

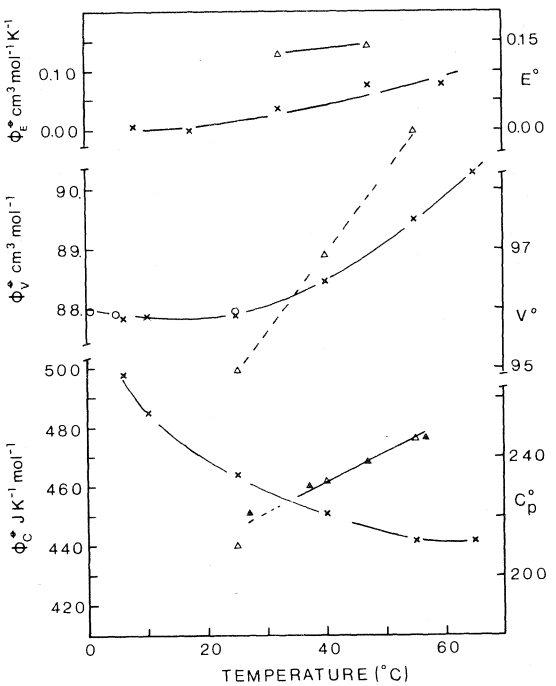

FIG. 7. Standard apparent molal volumes, heat capacities, and expansibilities and the corresponding molar quantities as a function of temperature. Standard apparent molal quantities: ×: present results; ○: ref. 7. Molar quantities: △: present results; ▲: ref. 26.

Finally, since we have volume and heat capacity data over the whole concentration range, except at low temperatures, it is also possible to calculate the apparent molal volumes

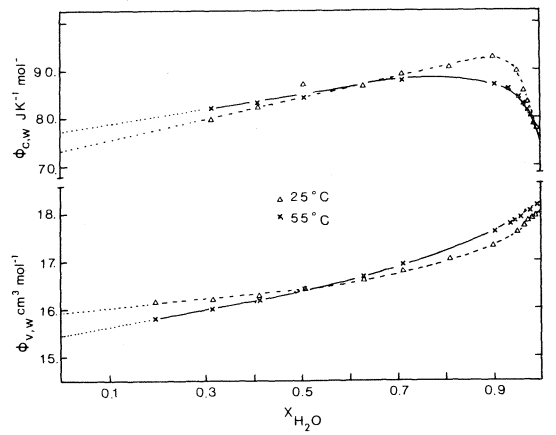

FIG. 8. Apparent molal volumes and heat capacities of water in *tert*-butyl alcohol at 25 and 55 °C.

and heat capacities of W in TBA–W mixtures. These are shown in Fig. 8. The $\phi_{V,W}^0$ in TBA is lower than its molar volume V_W^0 by about 2 to 2.5 $cm^3\ mol^{-1}$ as we would expect from a closer packing of the TBA molecules around the water molecule compared with the more open structure of pure water. On the other hand, as with water in dimethylformamide (39), $\phi_{C,W}^0$ remains comparable with $C_{p,W}^0$ and the difference hardly changes with temperature. Further work is under way to find the origin of this apparently anomalous value of $\phi_{C,W}^0$.

NOTE ADDED IN PROOF: Work presently under way in this laboratory indicates that ϕ_C of many apparently hydrophobic nonelectrolytes (ethers, esters, ketones, and amides) in water show a large initial decrease with concentration at 25 °C in contrast to alcohols, carboxylic acids, and amines. Alcohols may therefore not be typical of hydrophobic solutes as far as heat capacities are concerned.

The structure and energetics of low-lying states of RCO and RNN free radicals[1]

N. Colin Baird and Harish B. Kathpal

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received September 15, 1976

N. Colin Baird and Harish B. Kathpal. Can. J. Chem. **55**, 863 (1977).

The important geometrical variables in the structures of the lowest $^2A'$ and $^2A''$ states of the free radicals HCO, CH_3CO, NH_2CO, HNN, and CH_3NN have been determined by *ab initio* MO calculations using the STO-3G basis set. The energy differences between the states, and the energies of the radicals relative to their decomposition products and relative to their hydrogen atom addition products, are reported using both STO-3G and 4-31G basis sets in the restricted open-shell calculations. The trends in these results and their relation to available experimental data are discussed.

N. Colin Baird et Harish B. Kathpal. Can. J. Chem. **55**, 863 (1977).

Utilisant des calculs d'orbitales moléculaires *ab initio* faisant appel à une base STO-3G, on a déterminé des variables géométriques importantes dans les structures des états $^2A'$ et $^2A''$ les plus bas des radicaux libres HCO, CH_3CO, NH_2CO, HNN et CH_3NN. On rapporte les différences d'énergie entre ces états et les énergies des radicaux, relatives à leurs produits de décomposition et relatives à leurs produits d'addition d'atome d'hydrogène, en faisant appel à des bases STO-3G et 4-31G dans des calculs restreints de couches ouvertes. On discute des tendances dans ces résultats et de leur relation avec des données expérimentales disponibles.

[Traduit par le journal]

Introduction

Free radicals of the type R—Ċ=O and R—N=N· are often encountered as transient intermediates in photochemical reactions. Although the parent system HCO has been the subject of both spectral studies (1, 2) and sophisticated *ab initio* calculations (3, 4), rather little information is available for its derivatives (*e.g.*, CH_3CO, NH_2CO, PhCO). For the dinitrogen radicals, the parent HNN has received some theoretical attention (4–6) although neither it nor its simple derivatives (*e.g.*, CH_3NN) have been characterized experimentally as yet.

We wish to report here the results of our *ab initio* molecular orbital calculations for the ground and lowest-lying excited state of the parent and methyl derivative of both the RCO and RNN series, and also for NH_2CO, a radical which is isomeric with the *N*-formamido radical NHCHO which we discussed previously (7).

Method of Calculation

All results reported herein are based upon Roothaan restricted open-shell SCFMO calculations (8); to improve convergence, half-electron method wavefunctions were used as initial guesses to the open-shell eigenvectors (9). The basis sets used were the minimal STO-3G and the extended 4-31G sets, with the usual molecular scale factors, of Pople and co-workers (10, 11). All geometry optimizations are believed accurate to 0.01 Å and to 1°. The calculations were performed on the CDC Cyber 73 computer at the University of Western Ontario, using programs described previously (9).

In CH_3CO and CH_3NN, carbon–hydrogen bond lengths of 1.090 Å and tetrahedral H—C—H bond angles were assumed. For NH_2CO, nitrogen–hydrogen distances of 1.013 Å and H—N—H and H—N—C bond angles of 120°, and a completely coplanar arrangement of atoms, were assumed.

Results and Discussion

Geometric Structure of the Radicals

Optimum geometries calculated using the STO-3G basis set for the lowest pair of electronic states of each of the five radicals are given in Table 1. For HNN and HCO, the results of optimizations using the 4-31G basis are also given (in parentheses).

The restricted open-shell results for both the ground $^2A'$ state and the low-lying $^2A''$ state of HCO agree very well with the latest experimental values (2) given in square brackets in Table 1.

[1]Research supported by the National Research Council of Canada.

TABLE 1. Geometries of XCO and XNN radicals[a]

Radical	State	R_{CO} or R_{NN} (Å)	R_{CX} or R_{NX} (Å)	∠OCX or ∠NNX
HCO	$^2A'$	1.19	1.11	126°
		(1.18)	(1.09)	(129°)
		[1.175]	[1.125]	[125.0°]
	$^2A''(C_{\infty v})$	1.20	1.07	180° ass.
		(1.19)	(1.05)	(180° ass.)
		[1.186]	[1.064]	180°
CH_3CO	$^2A'$	1.19	1.54	128°
	$^2A''(C_{3v})$	1.20	1.48	180° ass.
NH_2CO	$^2A'$	1.21	1.38	128°
	$^2A''(C_{2v})$	1.22	1.41	180° ass.
HNN	$^2A'$	1.23	1.06	111°
		(1.18)	(1.02)	(118°)
	$^2A''(C_{\infty v})$	1.20	1.01	180° ass.
		(1.17)	(0.98)	(180° ass.)
CH_3NN	$^2A'$	1.23	1.52	116°
	$^2A''(C_{3v})$	1.20	1.44	180° ass.

[a]Values in parentheses refer to the 4-31G basis; those in square brackets are experimental values from ref. 2. See also the values quoted in ref. 20.

Both basis sets reproduce the small increase in the carbon–oxygen length, and the larger decrease in the carbon–hydrogen length, which occur upon excitation and linearization. The agreement between the STO-3G and the experimental H—C—O angle in the ground state is particularly good. Similar restricted and unrestricted SCF results using larger basis sets have been reported by Bruna, Buenker, and Peyerimhoff (*3a*) and by Botschwina (*3b*) respectively. Unrestricted STO-3G open-shell results give too long a carbon–oxygen distance in the $^2A'$ state due to contamination of the wavefunction by quartet character (4).

In fact the structure for the $^2A'$ state of the formyl radical HCO is quite similar to that of formaldehyde H_2CO. Removal of one hydrogen atom from the latter yields a radical with an HCO angle increased by 3° and a CO bond length decreased by 0.03 Å according both to experiment and to STO-3G calculations. Similar trends are evident when one compares the structure of the HNN radical to that of *trans*-diimide HNNH.[2] Upon hydrogen abstraction from the latter,[2] the HNN bond angle is calculated to increase by 6° and the NN distance to decrease by 0.04 Å. Thus the rather different HXY bond angles in the ground states of the isoelectronic radicals HNN and HCO are inherited from the HNNH and H_2CO systems.

As in HCO, excitation and linearization in the HNN system leads to a significant shortening of the bond to hydrogen (see Table 1). However the NN bond length decreases upon excitation of HNN compared to the slight increase which occurs in HCO.

The structures calculated for the methyl derivatives are very similar to those found for the parent radicals. Thus the CO length in CH_3CO and the NN lengths in CH_3NN are equal to those for HCO and HNN respectively in both ground and excited states, and the bond angles in the ground states are only a few degrees larger for the methyl systems (see Table 1). The C—C and C—N length in the linear excited state are significantly shorter than in the bent ground state, in analogy with the H—C and H—N contraction mentioned above for the parent systems.

The carbon–oxygen bond lengths calculated for the $^2A'$ and $^2A''$ states of the carbamyl free radical, NH_2CO, are slightly longer than those in HCO and CH_3CO, although the bond angles about the central heavy atom are identical to those in CH_3CO. The carbon–nitrogen distance in the $^2A'$ state of 1.38 Å is shorter than that *calculated* by the same method for any of the low-lying states of either formamide, NH_2CHO, or the *N*-formamido radical, NHCHO (7, 12). The CN length in the excited A'' state is larger,

[2]See ref. 4 for the calculated STO-3G structures of H_2CO and HNNH, and the experimental structure of the former.

TABLE 2. Ground state energetics for RCO and RNN radicals

Radical	Total energies (au)		Energies[a] of H atom addition (kcal mol^{-1})		C—X or N—X bond dissociation energies[b] (kcal mol^{-1})	
	STO-3G	4-31G	STO-3G	4-31G	STO-3G	4-31G
HCO	−111.7301	−113.0666	80.0	79.1	+6.1	+9.9
CH_3CO	−150.3242	−152.0612	78.2	78.0	+17.0	+5.5
NH_2CO	−166.0690	−168.0193	70.3	99.8	+6.6	−2.1
HNN	−107.9894	−109.2320	38.1	50.0	−3.9	−8.9
CH_3NN	−146.5749	−148.2086	41.8	50.5	+1.6	−24.5

[a]Energies for H addition products refer to standard geometries and are from ref. 13. The energies for atomic hydrogen use optimum atomic exponents (13). Use of optimum STO-3G geometries for the product decreases the 4-31G energy of addition by 3.6 kcal mol^{-1} for HNN and by 0.2 kcal mol^{-1} for HCO.

[b]Negative dissociation energies indicate that the products are more stable than is the reactant radical. The HNH angle in NH_2 was taken to be the STO-3G optimum value of 101° (7). The CH_3 radical was assumed to be planar with 120° bond angles.

and is close to that established for these other systems (7, 12).

Ground-state Energies

The total energies, calculated both by the STO-3G and by the 4-31G bases, for the ground states of the five radicals are listed in Table 2, along with the calculated energies of hydrogen atom addition to yield formaldehyde, acetaldehyde, formamide, *trans*-diimide, and *trans*-methyldiimide. (Total energies for these products and for atomic hydrogen were taken from the compilations by Pople and co-workers (13), and refer to 'standard' rather than optimized geometries.) Also given in Table 2 are the energy differences between the radicals and the ground states of the dissociation products formed by X—C or X—N fission.

The hydrogen addition energies of 78 kcal mol^{-1} for the acetyl radical, CH_3CO, agree fairly well with the value of 88 which is obtained using the most recent experimental heats of formation for CH_3CO (14) and acetaldehyde and hydrogen (15). Closer agreement is not expected, given the significant change in correlation energy that probably accompanies such reactions. For the same reason, too much faith should not be placed in the calculated values for diimide and methyldiimide (Table 2).

Although the hydrogen addition energies calculated for the methyl derivatives are almost identical to those of HCO and HNN, the values for NH_2CO are quite different than those for HCO (see Table 2). In particular the STO-3G basis set predicts the hydrogen atom affinity of NH_2CO to be 9.3 kcal mol^{-1} *less* than that for HCO whereas the more reliable 4-31G basis predicts the result for NH_2CO is 20.7 kcal mol^{-1} *greater* than for HCO. Much of this discrepancy is due probably to a significant underestimation by the STO-3G method of the substantial stabilizing interaction between the $—NH_2$ group and the carbonyl double bond in the formamide molecule itself (13*c*). Apparently this stabilizing interaction is much less important in the radical, with the result (by 4-31G) that the C—H bond dissociation energy in formamide is significantly greater than those in formaldehyde and acetaldehyde. Interestingly, the effect of conjugation between a p_π lone pair on nitrogen with the carbonyl group was also found to be smaller in the Σ_N state of the *N*-formamido radical, $\cdot NH—C(H)=O$, than in formamide (7).

The carbon–carbon bond dissociation energies calculated for the CH_3CO free radical bracket the latest experimental value of +11 kcal mol^{-1} for this process (14). According to both basis sets, the dissociation energy for NH_2CO to give CO and the ground π state of NH_2 is somewhat less than that for CH_3CO. At first glance this prediction would appear to be in conflict with the fact that NH_2CO is stable to decomposition at much higher temperatures than is CH_3CO (16*a*). However, resistance to decomposition refers to the *kinetic* stability of the radicals whereas the dissociation energies relate to *thermodynamic* stability. The NH_2CO radical appears more stable since its activation energy for decomposition is larger than is that for CH_3CO (14, 16*b*). This is so presumably because of the presence of two avoided crossings in the decomposition of the former as compared to only one for CH_3CO and HCO. (Decomposition of *linear* HCO to ground state H and CO

TABLE 3. $^2A' \rightarrow {}^2A''$ excitation energies (in kcal mol^{-1})

	Geometry used		ΔE	
Radical	$^2A'$ state	$^2A''$ state	STO-3G[a]	4-31G[b]
HCO	$^2A'$	$^2A'$	58.2	52.5
	$^2A'$	$^2A''$	29.1	23.9
				(23.9)
CH_3CO	$^2A'$	$^2A'$	58.3	54.2
	$^2A'$	$^2A''$	29.0	
NH_2CO	$^2A'$	$^2A'$	92.8	
	$^2A'$	$^2A''$	62.3	67.0
	$^2A''$	$^2A''$	25.1	28.3
HNN	$^2A'$	$^2A'$	51.4	44.5
	$^2A'$	$^2A''$	36.5	20.0
				(22.4)
CH_3NN	$^2A'$	$^2A'$	50.2	
	$^2A'$	$^2A''$	33.0	

[a]See Table 1 for numerical values used (STO-3G results).
[b]Values in parentheses are 4-31G energies using optimum 4-31G geometries (see Table 1).

requires excitation of one π electron to the σ system, whereas dissociation of planar NH_2CO with a linear N—C—O arrangement to ground state NH_2 and CO requires the excitation of both a b_1 and a b_2 electron into an a_1 orbital. In the *bent* geometries of the radicals the crossings are avoided and no actual excitations need occur; however, their 'memory' gives rise to activation barriers for decomposition in excess of the bond energy, and to activation energies for recombination of the reaction products (17).) Similarly, the activation energy for recombination of the NH_2 and CO radicals should be greater than that of 6.0 kcal mol^{-1} found for CH_3 + CO (14). For this reason we feel that the value of 89 kcal mol^{-1} given by Back and Boden for the C—H bond dissociation energy of formamide must be too low since it is based upon the assumption that the activation energies for recombination in the two reactions are identical (16*b*). We are currently engaged in a study of the potential surfaces for RCO decomposition reactions to clarify further this point.

The *total* energy calculated by the 4-31G basis for the ground state of the carbon-centered radical NH_2—$\dot{C}$=O is virtually identical to that computed for the (planar) π_N ground state of the isomeric nitrogen-centered radical $\dot{N}$H—C(H)=O by the same method (see Table 2 and ref. 7). Since the 4-31G basis underestimates the N—H bond energy in methylamine by about 7 kcal mol^{-1} more than it does the C—H bond in acetaldehyde, it is probable that in reality the N—H and C—H bond energies in formamide are not equal but rather that the value for C—H is 5–10 kcal mol^{-1} less than for N—H. Experimentally, free radical abstraction of hydrogen from formamide occurs preferentially, if not exclusively, at the carbon atom (16), suggesting that the carbon-centered radical is indeed the more stable species (assuming that no activation energy in addition to the reaction enthalpy is required for abstraction from the closed-shell species).

The A'' Excited States of the Radicals

It is well-known that, in its linear geometry, the $^2A'$ ground state and the lowest-lying $^2A''$ state of HCO become the two degenerate components of the $^2\pi$ state (18, 19). The same situation should arise also for HNN, CH_3CO, and CH_3NN although the designation of linear geometries (of the heavy atoms) for the latter two is ^2E rather than $^2\pi$. The $^2A'$ and $^2A''$ states of NH_2CO are *not* degenerate for a linear N—C—O geometry, however, as discussed below.

The *relative* energies of the $^2A'$ and $^2A''$ states of the five radicals are given in Table 3. In each case we report both the *vertical* excitation energy (*i.e.*, that computed using the optimum $^2A'$ geometry for both states) and the *adiabatic* energy (*i.e.* that computed using optimum geometries appropriate to each state). The working hypothesis is that the vertical energy can be

associated with highest-intensity band in the electronic spectrum, and the adiabatic energy with the O—O band.

The only experimental spectral data available for these systems are those for HCO (18, 19). The adiabatic energy difference of 23.9 kcal mol^{-1} calculated by 4-31G is in excellent agreement[3] with the difference in electronic energies of 24.8 observed by Johns, Priddle, and Ramsay (18). The strongest sharp bands in the absorption spectrum occur in the 46–51 kcal mol^{-1} region, in very good agreement with the 4-31G vertical excitation energy of 52.5 kcal mol^{-1}. The corresponding STO-3G energies are about 5 kcal mol^{-1} higher than are the 4-31G results (see Table 3). The calculated excitation energies for CH_3CO are virtually identical to those for HCO (Table 3), and thus the positions of the intensity maximum band and the O—O band in the spectra should be very similar.

Both the STO-3G and 4-31G calculations predict that vertical excitation from the $^2A'$ ground state to the $^2A''$ excited state of both HNN and CH_3NN should require less energy than for the RCO free radicals (see Table 3). The 4-31G basis set results predict the maximum intensity bands in HNN should occur about 1000 Å to the red of those for HCO. The two basis set predictions disagree as to the relative adiabatic excitation energies of HCO and HNN. (The STO-3G basis predicts larger adiabatic energy gaps for HNN and CH_3NN than for HCO and CH_3CO, whereas the 4-31G basis predicts a slightly smaller gap for HNN than for HCO (see Table 3).) Recalculation of the latter results using optimum 4-31G geometries (see results in parentheses in Table 3) does not alter these conclusions.

The excitation energies for the NH_2CO free radical given in Table 3 are much greater than those for the related HCO and CH_3CO radicals. In addition, the NH_2CO radical is unusual in that the $^2A'$ and $^2A''$ states are still widely split in energy even for a linear N—C—O geometry. The difference in electronic structure of the linear states is illustrated in Fig. 1. In the $^2A'$ state, the π electron system (perpendicular to the five-atom plane) contains four electrons and corresponds essentially to a p_π lone pair on nitrogen

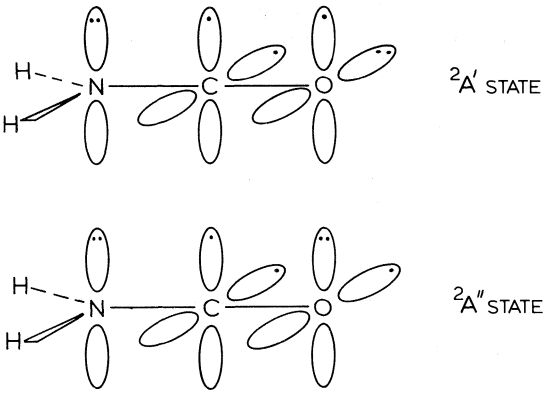

FIG. 1. Electron configurations in the $^2A'$ and $^2A''$ states of NH_2CO.

conjugated to a two-electron carbonyl π bond. The in-plane p orbitals perpendicular to the N—C—O line contain three electrons essentially localized as shown in Fig. 1 with one at carbon and two at oxygen. In the $^2A''$ state, however, the π system contains five electrons and corresponds essentially to lone p_π pairs on nitrogen and oxygen and a single p_π electron on carbon (see Fig. 1). The in-plane p orbitals, however, now form a strong two-electron carbon–oxygen 'π' bond. The five-electron N—C—O π network is very similar to that in the lowest $^3n\pi^*$ state of formamide (12). In both cases there appears to be no stabilization associated with conjugation of the nitrogen lone pair with the three-electron π network of the CO unit. In fact the optimum geometry about the nitrogen in the $^2A''$ state of NH_2CO is probably pyramidal as it is in the $^3n\pi^*$ state (12) and the ground state of formamide; however, we have not investigated this point in these calculations.

As a consequence of the conjugative stabilization of the $^2A'$ state but not the $^2A''$ state, the energy gap between the states amounts to 28.3 kcal mol^{-1} (by 4-31G) at the optimum linear geometry for the $^2A''$ state (see Table 3). The predicted O—O band energy (by 4-31G) is 67.0 kcal mol^{-1}, some 43.1 kcal mol^{-1} greater than that predicted for HCO. Similarly the vertical excitation energy calculated for NH_2CO is much greater than that for HCO.

[3]Since both states involved originate from the same degenerate state in the linear geometry, there should be no large difference in correlation energy between the two states; thus calculations even without CI should give good excitation energy predictions.

WCl_6 reacts with tetrahydrothiophene (tht) to yield initially $[C_4H_8SC_4H_8Cl]_2$ $[W_2S_2Cl_6(tht)_2]$. The sulfonium ion is slowly degraded at 120 °C in tht and a green, neutral complex $[W_2S_2Cl_4(tht)_4]$ is produced. The formation of $[C_4H_8SC_4H_8Cl]^+$ occurs through the desulfurization of tht by WCl_6 to form $Cl(CH_2)_4Cl$, which in turn alkylates a tht molecule. The identity of most of the organic by-products of these reactions has been determined, and on this basis it is suggested that *S*-chlorination of tht occurs to give $[C_4H_8SCl]$ Cl. The degradation of this species by various possible pathways may account for the formation of some of the diverse products.

P. MICHAEL BOORMAN, TRISTRAM CHIVERS et KALABEERAPPA N. MAHADEV. Can. J. Chem. **55**, 869 (1977).

WCl_6 réagit avec le tétrahydrothiophène (tht) pour conduire initialement au $[C_4H_8SC_4H_8Cl]_2$ $[W_2S_2Cl_6(tht)_2]$. L'ion sulfonium se dégrade lentement à 120 °C dans le tht et un complexe vert, neutre $[W_2S_2Cl_4(tht)_4]$ se produit. Il y a formation du $[C_4H_8SC_4H_8Cl]^+$ par une désulfurisation du tht par WCl_6 conduisant au $Cl(CH_2)_4Cl$ qui, à son tour, vient alkylé une molécule de tht. On a déterminé l'identité de la plupart des sous-produits de ces réactions et sur cette base on suggère qu'une *S*-chloration du tht se produit pour donner le $[C_4H_8SCl]Cl$. La dégradation de cette espèce par divers mécanismes possibles permet d'expliquer la formation de quelques-uns des divers produits finals.

[Traduit par le journal]

Introduction

In an earlier publication (1) we showed that tungsten hexachloride reacts with alkyl sulfides to give $(R_3S)_2[WCl_6]$. The reactions involve *S*-dealkylation followed by reductive elimination of R_2S_2. Alkylation of R_2S by RCl probably occurs at the tungsten site through the intermediacy of $WCl_4(R_2S)_2$. Clearly there could not be a completely analogous reaction between WCl_6 and a cyclic sulfide and it was therefore of interest to study such a case.

Frequent references have been made recently to the incorporation of WCl_6 into organometallic catalytic systems, such as for olefin metathesis (2), and yet few comprehensive studies of systems involving WCl_6 and relatively simple organic molecules have been reported. The ability of WCl_6 to react with Lewis bases to form adducts, with or without reduction of tungsten, has been well documented (3). Fowles and co-workers have also reported on the reactivity of various tungsten halides with potential donors in which organic molecules underwent an unexpected reaction, rather than forming the predicted adduct (4, 5). Reactivity of this kind with potential sulfur donors is of particular interest in that it may possibly be relevant to proposed mechanisms for hydrodesulfurization processes on molybdenum or tungsten-containing heterogeneous catalysts (6).

In this paper we discuss the direct reaction of WCl_6 (and WCl_5) with tetrahydrothiophene (tht) from which we have obtained two new dimeric tungsten species. Of particular interest was the ability of the tungsten halide to desulfurize the cyclic sulfide and the nature of the organic by-products which arise.

Experimental

General Procedures

All handling procedures were carried out in a dry nitrogen atmosphere. Tetrahydrothiophene (Aldrich 93% Technical Grade) was dried by refluxing over CaH_2, triple-distilled under nitrogen, and degassed before use. The purity was checked by gas chromatography. Tungsten hexachloride was obtained from Alfa Inorganics and was resublimed *in vacuo* before use; WCl_5 was obtained as previously described (1). Tungsten was analyzed by ignition to the oxide and other elements were determined by Alfred Bernhardt Laboratories. Infrared spectra were recorded as Nujol mulls between CsI plates using a

Beckman IR 20-A spectrometer; far infrared spectra were recorded as Nujol mulls between polyethylene plates using a Digilab FTS-16 spectrometer. Magnetic data were obtained using a standard Gouy technique at 22 °C. The susceptibilities were corrected for the diamagnetism of the ligands using Pascal's constants. The nmr spectra were recorded using a Varian HA-100 spectrometer and mass spectra using a Varian MAT CH5 Series 1 Mass Spectrometer. Conductivity data were obtained in dry $PhNO_2$ solutions by standard methods. Molecular weight determinations were made by cryoscopy in $PhNO_2$.

Volatile by-products from the various reactions were separated on Reoplex 400 columns, and fed directly into the mass spectrometer from the Varian Aerograph Series 1200 gas chromatograph.

Reactions of WCl_6 and WCl_5 with tht

The reactions were carried out in evacuated sealed Pyrex tubes at 120 °C for 72 h. In a typical experiment 4–5 g of WCl_6 were loaded into a tube in the glovebox, and tht (*ca.* 10 ml) was added, whereupon a vigorous exothermic reaction occurred. Attempts to isolate solid products at this stage resulted in the formation of oils. After 72 h of refluxing at 120 °C, a brown solid product was produced, with a green supernatant liquid. Upon addition of hexane to the filtered green solution a green precipitate was formed, which was washed with hexane and dried *in vacuo*. The brown compound which was earlier removed by filtration from the mother liquor was washed with CH_2Cl_2 and hexane and dried. Yields were typically:

Green compound, **1**, $W_2Cl_4S_6C_{16}H_{32}$, 16%.
Brown compound, **2**, $W_2Cl_8S_6C_{24}H_{48}$, 73%.

Some green product was lost during the CH_2Cl_2 washing of the brown product. Identification of the products as $\left[\text{C}_4\text{H}_8\text{S}\text{—}(CH_2)_4Cl\right]_2[W_2S_2Cl_6(tht)_2]$ brown and $[W_2S_2Cl_4(tht)_4]$ (green) is discussed later. Analytical data are presented in Table 1.

The reaction system was modified for the purpose of collecting and identifying volatile by-products, so that an H-shaped tube was used which was loaded with reactants in one vertical arm. After reaction under sealed evacuated conditions the volatiles were cold distilled into the second arm and sealed off.

The mixture was fractionated, and from ^1H nmr spectra it was found to contain large quantities of HCl in the first two of five fractions. The large amount of tht in the heavier fractions precluded identification of all of the compounds, but in the fifth (heaviest) fraction 2-chlorotetrahydrothiophene was suggested on the basis of a characteristic multiplet centered at δ 5.68. Subsequently this was confirmed by running each fraction through a gas chromatographic column (Reoplex 400) directly into the mass spectrometer. Complete separation was achieved, and the components identified are shown in Table 2. Apart from confirming the presence of 2-chlorotetrahydrothiophene in fraction 5, the other components of interest were ethylene and a dihydrothiophene. This was identified as 2,3-dihydrothiophene by addition of a *bona fide* sample of this species to a gas chromatographic sample.

*Reaction of **1** with Pyridine*

Approximately 0.5 g of **1** was dissolved in *ca.* 5 ml of pyridine (py) and after stirring for 3 h at room temperature, hexane was added. The green precipitate so formed was filtered, washed with hexane, and dried in vacuum. The product **3** was identified as $[W_2Cl_4S_2(py)_4]$ (calcd.: W 41.8, Cl 15.9, C 27.0, H 2.26; found: W 41.9, Cl 16.9, C 28.2, H 2.62).

*Reaction of **1** with Et_4NCl*

0.5 g of **1** was reacted in CH_2Cl_2 (~20 ml) with an approximately 5 *M* excess of Et_4NCl, also dissolved in CH_2Cl_2 (~15 ml). A tarry green precipitate was formed which was converted to a dark green powder by stirring with fresh CH_2Cl_2. After washing with hexane and drying, the compound was found by infrared spectroscopy to contain Et_4N^+ cations and no coordinated tht. Analysis indicated that this product was $(Et_4N)_2$ $[W_2S_2Cl_6]$, **4**, which requires: W 40.6, Cl 23.5, S 7.09, N 3.10, C 21.3, H 4.45; found: W 40.7, Cl 23.2, S 7.30, N 2.86, C 21.1, H 4.35.

Preparation of $\left[\text{C}_4\text{H}_8\text{S}\text{—}(CH_2)_4Cl\right]^+Cl^-$ *(**5**)*

This compound was prepared by reaction of tht with 1,4-dichlorobutane in a 1:1 ratio in a sealed tube containing a catalytic quantity of HCl. Both **5** and

were formed but after repeated recrystallization **5** could be isolated in a pure state. The spectral properties of **5** are shown in Table 3 and in the Fig. 1*c* (nmr).

Preparation of  *(6)*

The bis(sulfonium) ion was most readily prepared as compound **6** by refluxing an excess of tht with 1,4-diiodobutane. After 2–3 h a cream colored precipitate formed which was filtered, washed with hexane, and dried at 80 °C under vacuum. Spectral data are given in Table 2 and in Fig. 1*b*. (Calcd. for  C 29.6, H 4.98, S 13.2, I 52.2; found: C 29.8, H 4.84, S 13.3, I 52.5%.)

Reaction of 1 with **5**

$[W_2S_2Cl_4(tht)_4]$ (0.5 g) was dissolved in CH_2Cl_2 and a 3*M* quantity of  was added also in CH_2Cl_2 solution. Immediate formation of a brown precipitate occurred which was filtered, washed with CH_2Cl_2, hexane, and dried in vacuum. Analysis and infrared spectra showed that this product was identical with **2**. (Calcd. for  $[W_2S_2Cl_6(tht)_2]$: W 31.2, Cl 24.0, C 24.4, H 4.1; found: W 31.1, Cl 23.9, C 24.3, H 4.29.)

Results and Discussion

Characterization of the Green Compound 1 as $[W_2S_2Cl_4(tht)_4]$

The soluble green compound obtained from the direct reaction of WCl_6 or WCl_5 with tht was shown by analysis to have the empirical formula $[WSCl_2(tht)_2]_n$ (Table 1). The compound hydrolyzes rapidly in moist air with liberation of both HCl and H_2S, suggesting the presence of both coordinated chloride and sulfide ions. The solubility of **1** in polar organic solvents enabled solution data to be obtained. Solutions in nitrobenzene were non-conducting and the cryoscopically determined molecular weight in this solvent was 870 ± 50, consistent with the formulation of **1** as the dimer $[WSCl_2(tht)_2]_2$ (calculated molecular weight 926). The magnetic susceptibility of **1**, χ_m, calculated for a formula $WSCl_2(tht)_2$ was $+41 \times 10^{-6}$ cgs units, giving a relatively low magnetic moment of 0.32 BM per tungsten atom, at 21 °C. This formally tungsten (IV) (d^2) compound might have been expected to possess a larger degree of paramagnetism, if it were not a bridged binuclear species, since even relatively low symmetry mononuclear tungsten (IV) species tend to have μ values in the range 1.5–2.0 BM (7). Nevertheless the paramagnetism was found to be sufficiently large to prevent the observation of an nmr spectrum of **1** in the non-coordinating solvent CH_2Cl_2.

In dmso (d_6) the spectrum of free tht was observed, presumably due to displacement of this weak sulfur donor by the strongly donating solvent. The infrared spectrum of **1** is typical of coordinated tht. The free ligand possesses a band at 685 cm^{-1} which has been assigned to C—S stretching (8), which usually is lowered upon coordination. Such is the case in the spectrum of **1** where the ν(C—S) band occurs at 665 cm^{-1}. No band is observed in the 500 cm^{-1} region of the spectrum which could be assigned to a terminal W=S group, suggesting that the compound therefore contains bridging sulfide groups. Two strong bands at 312 cm^{-1} and 275 cm^{-1} (shoulder) can probably be assigned to W—Cl stretching vibrations.

These observations are consistent with a

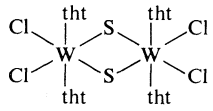
*Based on ^{35}Cl, ^{127}I.

structure of **1** which involves a sulfur-bridged dimer as shown below, or one of its geometric isomers:



Further evidence in favor of such a structure was obtained by reaction of **1** with pyridine, which enabled the compound **3**, $W_2S_2Cl_4(py)_4$, to be isolated as a green solid. The infrared spectrum of **3** showed the presence of coordinated pyridine, the absence of terminal W=S groups, and bands at 312 cm^{-1} (vs) and ~275 cm^{-1} (shoulder) which we assign to W—Cl stretching. The latter region of the spectrum is very similar to that of the spectrum of **1**, as expected if pyridine has displaced tht from a common $W_2S_2Cl_4$ structural unit. The solution properties of **3** support this conclusion, since in nitrobenzene as solvent it is an essentially non-conducting dimeric species, although some slight dissociation probably occurs (observed molecular weight 740 ± 50; calculated for $W_2S_2Cl_4(py)_4$, 890).

Characterization of the Brown Compound, **2**, *as* 
The insoluble brown compound, **2**, was the major product from the reaction of WCl_6 (or WCl_5) with tht. Its characterization presented some problems due to its insolubility. Analysis (Table 1) was consistent with a simple formulation as $WCl_4(tht)_3$ but such a formulation was inconsistent with the following facts. Firstly, $WCl_4(tht)_2$ is a known compound (7) which exhibits no tendency to take up further tht. Secondly, upon hydrolysis of **2**, H_2S is liberated (in addition to HCl) suggesting the presence of inorganic sulfide. Furthermore, the infrared and nmr spectral properties were not consistent with this suggestion.

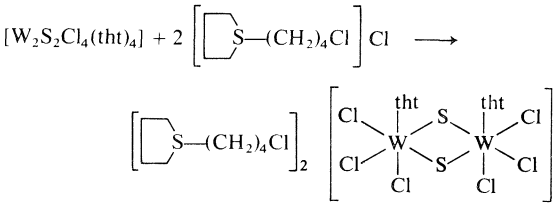
Thermal decomposition of **2** in a sealed, evacuated tube gave rise to two volatile products. One of these was readily identified as tht, while the other was a red oil with a mass spectrum suggesting the formulation  , **5**. However, the presence of a C—Cl bond in the structure of **2** could not be unequivocally identified from the infrared spectrum, and so both **5** and the corresponding disulfonium cation derived from tht and $Cl(CH_2)_4Cl$ were synthesized. The mass spectrum of

6 showed no parent ion peak (Table 3) and thus this technique was unable to prove conclusively which cation occurs in the compound **2**.

The two plausible structures of **2** involving such sulfonium ions derived from tht and $Cl(CH_2)_4Cl$ are:

(*A*) 
(*B*) 
Analysis cannot distinguish between (*A*), (*B*), and $WCl_4(tht)_3$, but strong support for (*A*) was derived from the ^1H nmr spectrum of **2** in dmso (d_6). (This was the only solvent in which **2** showed appreciable solubility.) The spectra of **2**, **5**, and **6** are shown in Fig. 1, and it can readily be seen that the δ 2.0–4.0 region of the spectrum suggests that structure (*A*) involving a monosulfonium cation is correct. The displacement of tht by dmso (d_6) is also implied by the spectrum of **2**.

Confirmation of structure (*A*) was obtained by synthesis of **2** from the green compound **1**, and the sulfonium chloride **5**, in CH_2Cl_2 solution:



The corresponding compound $(Et_4N)_2[W_2S_2Cl_6(tht)_2]$ was not obtained from the reaction of Et_4NCl with **1**, but instead the compound **4**, $(Et_4N)_2[W_2S_2Cl_6]$ was obtained, from which the sixth ligand, neutral tht, had been lost. **4** showed no tendency to take up further chloride ion to yield the anion of structure (*B*).

The other properties of **2** are consistent with

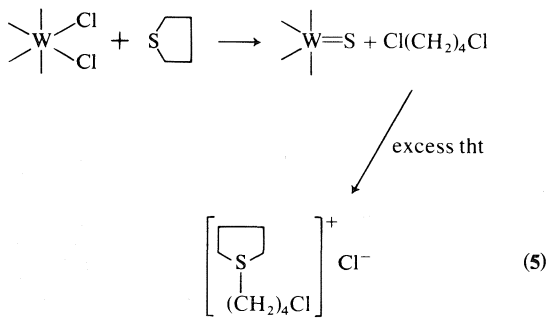
formulation as (*A*). Its infrared spectrum shows bands typical of coordinated tht, in addition to bands found for compound **5**, although the C—Cl stretching vibration found as a strong band at 644 cm^{-1} in the spectrum of **5** is relatively weak in the spectrum of **2**. The presence of both the sulfonium cation and coordinated tht makes a complete assignment of the spectrum of **2** impossible. The magnetic moment of **2** was found to be 1.05 BM per tungsten atom, rather higher than that of **1**. Nevertheless the relationship between **1** and **2** is proven by the synthesis of **2** from **1** and **5**. The reverse reaction, conversion of **2** into **1** is readily achieved by heating **2** in a sealed tube with tht and HCl (catalytic quantity). After 72 h at 120 °C a good yield of **1** can be obtained, together with products of decomposition of the sulfonium cation which are discussed later.

These reactions all confirm the relationship between **1** and **2** in which a common binuclear tungsten species $[W_2S_2Cl_4]$ is involved. It seems likely that more examples of such sulfur-bridged species will be discovered in the chemistry of tungsten with sulfur donors, since we have already found other examples of this phenomenon (9, 10) and Fowles and co-workers have suggested polymeric sulfur-bridged structures for $WSCl_2$ and $WSCl_3$ (11).

Mechanism of Reaction Between WCl_6 and tht

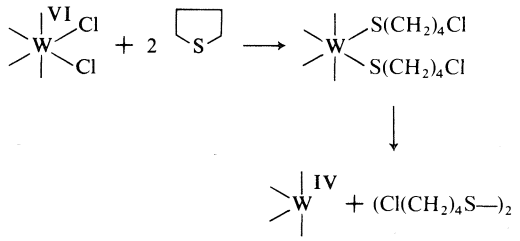
The predominant product from the reaction between WCl_6 and tht has been shown to be **2**, and the origin of this product is a matter of some interest, since the WCl_6 has abstracted sulfur from the ring system and has been reduced to W(IV). The secondary product, **1**, has been shown to arise from the degradation of **2** in the presence of excess tht, and HCl.

The postulated pathway for desulfurization of tht by WCl_6 is shown in Scheme 1. Such a pathway is consistent with the presence of the sulfonium cation, and inorganic sulfide in the product.



SCHEME 1

The reaction is very similar to that between $MoCl_5$ and tetrahydrofuran (thf) reported by Kepert and Mandyczewsky (12) which yields $MoOCl_3(thf)_2$ with 1,4-dichlorobutane as the by-product. The present reaction is more complex, however, due to the concomitant reduction of tungsten (VI) to tungsten (IV). This leaves more room for conjecture and it was at first expected that a reductive elimination of organic disulfide would be involved as in the case of simple alkyl sulfides (1). This is shown in Scheme 2.



SCHEME 2

However an analysis of the volatile by-products from the reaction failed to show any sign of disulfides (Table 2). Instead, a major product, which begins to be formed very early in the reaction, is HCl. A more likely mechanism therefore would seem to be an *S*-chlorination reaction with subsequent reactions of the chlorosulfonium ion, as studied extensively by Wilson and co-workers (13, 14). Such a reaction can follow two pathways, involving either the elimination of HCl (Pummerer Reaction) or C—S bond cleavage to yield a sulfenyl chloride (13). For the present system these alternatives are shown in Scheme 3.

The superposition of Schemes 1 and 3 would account for the desulfurization of tht to yield the cation in **2**, the presence of inorganic sulfide in **2**, the reduction of W(VI) to W(IV), and the nature of several of the by-products. The sequence of the reduction and desulfurization reactions is uncertain, and indeed they may well occur simultaneously. The immediate formation of large quantities of HCl upon reaction of WCl_6 with tht suggests that the reduction reaction begins at an early stage.

Scheme 3 is able to account for the formation of at least two of the important by-products. Both 2-chlorotetrahydrothiophene and 2,3-dihydrothiophene were confirmed as being prod-

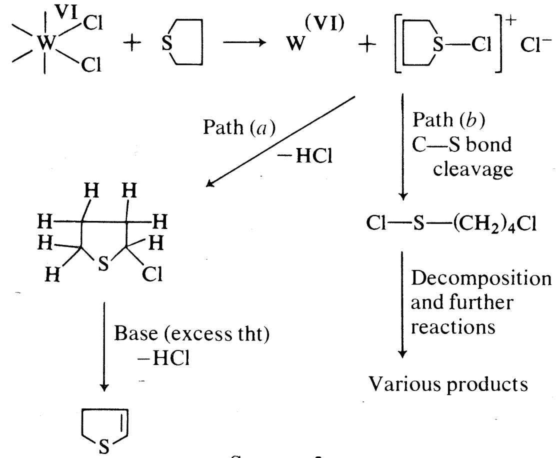
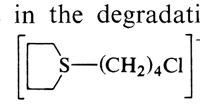


SCHEME 3

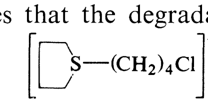
ucts. This is consistent with the *S*-chlorination of tht and subsequent reactions described by Wilson and co-worker (14), who showed that direct reaction of Cl_2 with tht in various solvents yields 2-chlorotetrahydrothiophene and under some circumstances 2,3-dichlorotetrahydrothiophene. However, we found no evidence for the presence of the latter compound. Loss of HCl from 2-chlorotetrahydrothiophene is presumably responsible for formation of  .

The alternative pathway for the degradation of  Cl, which has been previously established for chlorination reactions of thioethers is via C—S bond cleavage to produce a sulfenyl chloride. In the case of tht this would imply the formation of $Cl(CH_2)_4SCl$. It is well known that sulfenyl halides are highly reactive species and even the simplest of such compounds, CH_3SCl, has been shown to decompose spontaneously to yield at least seven different products (15). It is therefore conceivable that some of the products listed in Table 3 arise in this way, but in view of the lack of information in the literature on the reactivity of this particular sulfenyl chloride, we can only speculate upon the mechanisms involved.

A second source of volatile organic by-products lies in the degradation of



ions, in the conversion of **2** to **1**. To identify those species which might arise in this way, compound **2** was subjected to controlled thermal decomposition. The volatiles from the direct dry decomposition were only tht and **5**, which were readily identified by mass spectroscopy, and the residue was $WSCl_2$. However, upon heating **2** to 120 °C in excess tht and in the presence of HCl, decomposition of the cation occurred with the production of **1**. The volatiles were collected and analyzed by gc/ms as shown in Table 4. In the case of chlorobutene there is some uncertainty as to the isomer produced, and thus the description given is a general one. It may be noted that thiophene is produced and thus may arise via this route to produce the small amounts found in the products from the WCl_6/tht reaction. The presence of acetylenic thiols implies that the degradation of



involves rupture of the tht ring, as well as of the side chain. Clearly this is a complex reaction and there is little point in speculating about the pathways involved. It is of interest, however, that the reaction of WCl_6 with tht is capable of desulfurization of the ring, and yields a number of alkenic by-products, including

ethylene. Apart from the information that may be useful in studies of heterogeneous catalytic hydrodesulfurization, it is possible that direct desulfurization of organosulfur constituents of hydrocarbon fuels may be a viable proposition, particularly in view of the alkenic by-products formed.

Received August 10, 1976

LAURENCE K. THOMPSON, BARATHAM S. RAMASWAMY, and ELIZABETH A. SEYMOUR. Can. J. Chem. **55,** 878 (1977).

A series of cobalt(II) and zinc(II) complexes of the title ligand are reported which contain mixed stereochemistries, *e.g.*, five-coordinate trigonal bipyramidal cations $[M(ligand)X]^+$, and four-coordinate anions, $[MX_4]^{2-}$ (M = Co, Zn; X = Cl, Br, NCS). The blue cobalt complexes, $[Co(ligand)X]_2[CoX_4]$, are readily converted to purple five-coordinate complexes, [Co(ligand)X]X, by recrystallisation from a solvent containing water, *e.g.* acetone. Other five-coordinate cobalt and zinc derivatives were also prepared, [Co(ligand)X]X (X = NO_3, ClO_4), $[Co(ligand)X]BPh_4$ (X = Cl, Br, NCS, NO_3, ClO_4), $[Zn(ligand)X]BPh_4$ (X = Cl, Br, I, NCS). Nuclear magnetic resonance data for all the zinc complexes indicate a significant deshielding of one benzene ring proton on each coordinated benzimidazole group. Conductance data suggest the possibility of cationic association through pseudo-hydrogen bonding in both the cobalt and zinc derivatives involving Cl, Br, NCS anions.

LAURENCE K. THOMPSON, BARATHAM S. RAMASWAMY et ELIZABETH A. SEYMOUR. Can. J. Chem. **55,** 878 (1977).

On rapporte la préparation d'une série de complexes du cobalt(II) et du zinc(II) contenant le ligand mentionné dans le titre et qui contiennent des stéréochimies mixtes; par exemple des cations bipyramidaux trigonaux pentacoordonnés $[M(ligand)X]^+$ et des anions tétracoordonnés $[MX_4]^{2-}$ (M = Co, Zn; X = Cl, Br, NCS). Les complexes bleus du cobalt, $[Co(ligand)X]_2[CoX_4]$, se transforment facilement en complexes pentacoordonnés violets [Co(ligand)X]X, par recristallisation à partir d'un solvant contenant de l'eau, par exemple l'acétone. D'autres dérivés pentacoordonnés du cobalt et du cuivre ont aussi été préparés: [Co(ligand)X]X (X = NO_3, ClO_4), $[Co(ligand)X]BPh_4$ (X = Cl, Br, NCS, NO_3, ClO_4) et $[Zn(ligand)X]BPh_4$ (X = Cl, Br, I, NCS). Les données de rmn pour tous les complexes du zinc indiquent qu'il y a un déblindage important d'un proton du noyau benzénique de chacun des groupes benzimidazole qui a été coordonné. Les données de conductivité suggèrent la possibilité d'une association cationique, par l'intermédiaire d'un pseudo pont hydrogène dans les dérivés du cobalt ainsi que du zinc, qui impliquerait les anions Cl, Br, NCS.

[Traduit par le journal]

Introduction

The coordinating ability of a number of monodentate benzimidazole derivatives has been reported in the literature (1–6). However, examples of polyfunctional benzimidazole derivatives and their complexes appear to be lacking. We report here the synthesis and characterization of a trisbenzimidazole derivative, tris(2-benzimidazylmethyl)amine, which contains four potential donor sites (Fig. 1, ligand abbreviated NTB) and a number of its cobalt and zinc complexes. The ligand has been synthesized by two independent routes, one involving condensation of *o*-phenylenediamine with nitrilotriacetonitrile and the other by condensation of the diamine with nitrilotriacetic acid (Fig. 1).

Reaction of the ligand with cobalt and zinc salts, MX_2 (M = Co, Zn; X = Cl, Br, NCS) in ethyl alcohol led to the formation of ionic derivatives, $[M(NTB)X]_2[MX_4]$, containing five-coordinate pseudo-trigonal bipyramidal cations and a four-coordinate tetrahedral anion. The blue cobalt complexes appear to be stable in fairly dry non-aqueous solvents but on recrystallization from aqueous acetone a series of purple five-coordinate derivatives, [Co(NTB)X]X (X = Cl, Br, NCS) were formed. These trigonal bipyramidal cations could also be stabilized as their tetraphenylborate salts by direct synthesis from alcoholic solution. Other

five-coordinate derivatives include pink cobalt nitrate and perchlorate derivatives, [Co(NTB)X]X, [Co(NTB)X]BPh_4 (X = NO_3, ClO_4) and a series of white zinc complexes, [Zn(NTB)X]BPh_4 (X = Cl, Br, I, NCS). Structural assignments have been justified by electronic, vibrational, and nmr spectra and by conductance and magnetic data.

Experimental

Nuclear magnetic resonance data were obtained in deuterated DMSO with Varian Associates A60 and EM360 Spectrometers using $SiMe_4$ as internal calibrant. Electronic spectra were recorded using Beckman DK2A and Cary 17 Spectrometers and infrared data using Perkin-Elmer models 457 and 283. Magnetic susceptibilities were obtained by the Faraday method at room temperature using a Cahn model #7600 coupled to a Cahn gram electrobalance and conductivity data were obtained using a General Radio Company bridge with impedance comparator and a constant temperature bath adjusted to 25 °C. Microanalyses were carried out by the Beller laboratories, Göttingen, W. Germany and by Chemalytics, Tempe, Arizona. Metal analyses were determined by Atomic Absorption using a Varian Techtron AA-5, after prior digestion of the samples in concentrated HCl or ternary solution (HNO_3, H_2SO_4, $HClO_4$ in a ratio of 10:1:4 respectively).

Tris(2-benzimidazylmethyl)amine (NTB)

Method A

Nitrilotriacetonitrile (5.0 g, 0.037 mol) and *o*-phenylenediamine (12.0 g, 0.11 mol) were finely ground, mixed, and heated together using an oil bath at 200–210 °C. When evolution of ammonia was essentially complete (approx. 24 h) the cooled solid was crushed to a fine powder, washed with ether, and extracted into methanol and refluxed with decolourizing charcoal. After filtration the methanol solution was reduced in volume to give a creamy crystalline product (10.0 g, 66% yield) which was recrystallized from methanol and dried thoroughly under vacuum (mp 271 °C). Vacuum drying of the product appears to be essential since nmr data indicate the presence of solvate molecules (*e.g.*, methanol, ethanol) in the undried product, in a ratio of 1:3, (ligand(solvent)$_3$). These solvate molecules are probably hydrogen bonded, one to each imidazole ring.

Method B

Nitrilotriacetic acid (15.3 g, 0.0800 mol) and *o*-phenylenediamine (27.0 g, 0.250 mol) were finely ground and heated together at 190–200 °C for 1 h using an oil bath. The reaction mixture was cooled and crushed, and refluxed in methanol containing decolourizing charcoal. The solution was filtered hot and its volume reduced until on cooling pinkish white crystals were obtained (17.5 g, 54% yield). Recrystallization was effected using methanol and the product dried under vacuum (mp 270 °C). *Anal.* calcd. for $C_{24}H_{21}N_7$: C 70.8, H 5.16, N 24.1; found: C 70.5, H 5.21, N 23.5. Infrared spectrum (Nujol mull) 3140 (νNH), 1622, 1588 (νCN) cm^{-1}; nmr (DMSO-d_6) (σ(relative intensity)) 12.1(8.5) (broad singlet, NH), 7.60(17), 7.19(17) (*AA'BB'* multiplet, aromatic CH), 4.12(17) (CH_2); mass spectrum, major mass peaks (*m/e*(relative intensities)) 407(3) P, 277(15), 276(80), 248(8), 146(57), 133(10), 132(96), 131(100), 119(24), 104(22), 92(9), 77(24).

Metal Complexes of NTB

Complexes of Mixed Stereochemistry [M(NTB)X]$_2$-[MX_4]

Stoichiometric amounts of the metal salt, MX_2 (hydrated or anhydrous) (M = Co, Zn; X = Cl, Br, NCS) and NTB were dissolved separately in hot absolute ethanol and the hot solutions mixed with stirring for about 1/2 h. In some cases the products crystallized from the hot solution while in others reduction in volume followed by cooling was necessary to induce crystallization. The products were recrystallized from absolute ethanol and dried under vacuum at 90 °C.

Five-coordinate Complexes

[Co(NTB)X]X (X = Cl, Br, NCS)

The blue cobalt complexes of mixed stereochemistry were found to be hydrolytically unstable in aqueous solvents and on recrystallization from aqueous acetone (approx. 10% H_2O) purple complexes of formula [Co(NTB)X]X were produced. The compounds were dried under vacuum at 90 °C.

[Co(NTB)X]BPh_4 (X = Cl, Br, NCS, NO_3, ClO_4)

A hot ethanolic solution of the ligand and a slight

excess of sodium tetraphenylborate was added with stirring to a hot ethanolic solution of a stoichiometric amount of the cobalt salt. On cooling purple (X = Cl, Br, NCS) and pink (X = NO_3, ClO_4) products were obtained which were recrystallized from ethanol and dried under vacuum at 90 °C.

The chloro-, bromo-, and isothiocyanato compounds were also synthesized by adding ethanolic $NaBPh_4$ to an ethanolic solution of [Co(NTB)X]X.

[Zn(NTB)X]BPh₄ (X = Cl, Br, I, NCS)

These complexes were prepared in a similar fashion to the analogous cobalt derivatives.

[Co(NTB)X]X (X = NO_3, ClO_4)

Stoichiometric amounts of the cobalt salt and NTB were mixed in hot ethanol to give pink solutions from which pink crystalline solids were obtained. The products were recrystallized from acetone and dried under vacuum at 90 °C.

Analytical and other data for these systems are given in Table 1.

Results and Discussion

Characterization of the Ligand

Our interest in this ligand, which to our knowledge has not been previously reported in the literature, stemmed in part from our earlier involvement with ligands containing imidazoline rings (7) which were obtained by simple condensation of dinitriles with diamines, *e.g.*, ethylenediamine. A simple extension of this reaction to the trinitrile, nitrilotriacetonitrile, led to the title ligand which appeared to have the right geometrical features to be a stereochemically selective 'tripod' ligand capable of forcing metal ions to adopt predominantly one stereochemistry, *i.e.*, a distorted trigonal bipyramid.

2-Substituted benzimidazoles have been prepared in good yield by the reaction of *o*-phenylenediamine with monobasic acids (*e.g.* formic, propionic, acetic, etc.) under reflux in dilute hydrochloric acid. Extension of this reaction to dibasic acids, *e.g.* oxalic and malonic, did not lead to 2-substituted benzimidazoles, but with succinic acid both mono and bis-2-benzimidazole derivatives were produced (8, 9). Hein and co-workers (10) prepared 2-alkyl and -aryl benzimidazole derivatives by the high temperature (250 °C) condensation of acids, esters, amides, or nitriles with an appropriate diamine in the presence of polyphosphoric acid which acts both as a catalyst and a solvent. Both of these methods were tried for the preparation of NTB but with little success. A much better method proved to be the direct fusion of nitrilotriacetonitrile or nitrilotriacetic acid with *o*-phenylenediamine at high temperatures, followed by recrystallization from methanol (Fig. 1). The products obtained by both synthetic routes were identical in all respects as indicated by analysis, melting point, infrared, nmr, and mass spectros-

copy. An attempted degradation of NTB using conc. HCl was carried out under reflux. NTB did not degrade but simply formed its hydrochloride salt from which NTB was regenerated on treatment with base.

In the nmr spectrum of the ligand the methylene protons are all equivalent, appearing as a singlet shifted downfield slightly in comparison with nitrilotriacetonitrile, while the aromatic protons appear as a symmetrical set of peaks typical of the *AA'BB'* spectrum observed for symmetrically *ortho*-disubstituted benzene rings, *e.g.*, *o*-phenylenediamine, naphthalene, benzimidazole, etc. (Table 5). The symmetrical nature of this set of peaks indicates a plane of symmetry bisecting each benzimidazole unit and passing through the 2-carbon atom. This suggests that the imidazole ring proton is delocalized equally along the N—C—N framework. This proton appears as a very broad resonance at 12.1 σ. As will be shown later, the symmetry or lack of symmetry associated with this set of nmr peaks indicates whether or not the benzimidazole rings are coordinated.

The infrared spectrum of NTB is similar to that of benzimidazole itself.

Characterization of the Complexes

Complexes of the general formula $[M(NTB)X]_2[MX_4]$ (M = Co, Zn; X = Cl, Br, NCS), $[M(NTB)X]X$ (M = Co; X = Cl, Br, NCS, NO_3, ClO_4), and $[M(NTB)X]BPh_4$ (M = Co; X = Cl, Br, NCS, NO_3, ClO_4; M = Zn; X = Cl, Br, I, NCS) were obtained. These complexes bear some resemblance to previously reported systems involving tetradentate tripod ligands. Sacconi and co-workers (11–13) have recently reported five-coordinate cobalt and nickel complexes of potentially tetradentate tripod ligands based on triethylamine with a β position on each ethyl group replaced by a donor group, *e.g.*, N, O, P, As. The bulkiness of the coordinating groups appeared to be a factor in directing the stereochemistry of the resulting complexes, *e.g.*, with decreasing bulkiness of the donor groups a trend towards six-coordination was observed. In addition complexes were cited where the ligand behaved as a bidentate or terdentate. In terms of the chromophoric environment of the ligand, NTB, it bears more resemblance to trenMe (tris(2-dimethylaminoethyl)amine) which acts as a tetradentate tripod ligand, forming pseudo-trigonal bipyramidal systems (14). NTB appears to be the first example of a tetradentate tripod ligand involving three coordinating benzimidazole groups.

Cobalt Complexes

The tetraphenylborate ion is a good noncoordinating anion which has been used effectively to stabilize five-coordinate cations. Reaction of NTB with cobalt salts in ethanol, in the presence of one equivalent of sodium tetraphenylborate, produces a series of complexes $[Co(NTB)X]BPh_4$ (X = Cl, Br, NCS, NO_3, ClO_4) (Table 1). Electronic spectral data for these salts are given in Table 2. The solid mull transmittance and acetone solution spectra are very similar indicating a similar metal ion stereochemistry both in the solid state and in solution. The spectral band positions and their intensities are not typical of either octahedral or tetrahedral cobalt(II) but they bear a close resemblance to previously reported spectra for pseudo-trigonal bipyramidal cobalt derivatives containing tetradentate tripod ligands (Figs. 2, 3) (11–14).

Recent studies by Bertini and co-workers (15) have attempted to simulate observed spectra of some pseudo-trigonal bipyramidal cobalt(II) complexes using both the crystal field and angular overlap approach. Using a C_{3v} field good agreement was obtained between calculated and observed transition energies for the chromophores $CoNN_3Br$ (NN_3 = trenMe), $CoNS_3Br$ (NS_3 = tris(2-*tert*-butylthioethyl)amine) and $CoNP_3Br$ (NP_3 = tris(2-diphenylphosphinoethyl)amine). Four major transitions are observed in these systems assigned from the $^4A_2$ ground state in C_{3v} symmetry. A low energy band around 5–6 kK, assigned to $^4E \leftarrow {}^4A_2$, appears to be largely unaffected by structural variations whereas tetrahedral distortion tends to shift the other $^4E \leftarrow {}^4A_2$ and the P ← F transitions to lower energy. The main features of the spectra include four bands: $^4E \leftarrow {}^4A_2$ (5–6 kK), $^4E \leftarrow {}^4A_2$ (10–12 kK), $^4A_2(P) \leftarrow {}^4A_2$ (14–16 kK), $^4E(P) \leftarrow {}^4A_2$ (17.5–19.5 kK).

The spectra of the tetraphenylborate NTB derivatives exhibit absorptions in three main areas; 5.2–6.8 kK, 10.5–13.3 kK, 16.7–20.5 kK. The lower energy band shows little fine structure in solution but in the solid state splitting of the band is observed in some cases, which is en-

*Labels mean the following: *a*, solution in acetone; *b*, mull transmittance spectrum (room temperature); *c*, solution in nitromethane. [ ] shoulder, ( ) molar extinction coefficient. Some bands have been assigned twice, *i.e.* to both five-coordinate and tetrahedral cobalt(II). These bands probably contain overlapping components associated with both stereochemistries.

†The $^4A_2(P) \leftarrow {}^4A_2$ transition appears to be missing in almost all the spectra with the exception of [Co(NTB)Cl]Cl and $[Co(NTB)Cl]BPh_4$ where a weak shoulder at 16000 cm^{-1} can possibly be assigned to this transition.

hanced at low temperature (77 K). The high energy band is split into two components in most cases, especially in solution. The splitting of this band has been observed in some other trigonal bipyramidal systems and can possibly be associated with spin–orbit effects or deviations from C_{3v} symmetry. In the NTB complex ions the ligand is assumed to be acting as a tetradentate in an approximately C_{3v} symmetry environment (Fig. 4) and the observed spectral bands are tentatively assigned as follows: $^4E \leftarrow {}^4A_2$ (5.2–6.8 kK), $^4E \leftarrow {}^4A_2$ (10.5–13.3 kK), and $^4E(P) \leftarrow {}^4A_2$ (two components 16.7–20.5 kK) (Table 2). (The $^4A_2(P) \leftarrow {}^4A_2$ transition is probably hidden beneath the band envelope associated with $^4E(P) \leftarrow {}^4A_2$; see footnote †, Table 2.)

Magnetic data (Table 3) indicate that these complexes are high spin, typical of systems of this type with hard donor atoms (16). The

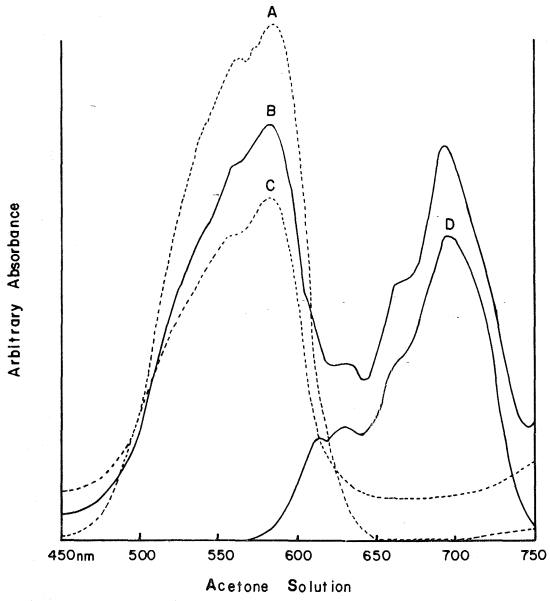

FIG. 3. Acetone solution spectra to illustrate the presence of $[CoBr_4]^{2-}$ and $[Co(NTB)Br]^+$ in the cobalt bromide complex of mixed stereochemistry. The chloro- and isothiocyanato analogues exhibit similar spectra which indicate the presence of four-coordinate anions and five-coordinate cations. *A*, [Co(NTB)Br]Br; *B*, $[Co(NTB)Br]_2[CoBr_4]$; *C*, [Co(NTB)Br]BPh_4; *D*, $[nBu_4N]_2[CoBr_4]$.

'nucleophilic reactivity constant' established by Sacconi (16) for the donor set N_4X (X = Cl, Br, NCS) lies in the range 15.4–19.1, typical of high spin systems. The magnetic moments for

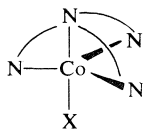

FIG. 4. Stereochemistry of NTB complex.

the five-coordinate tetraphenylborate derivatives fall in the range 4.3–4.7 BM. Moments for typical trigonal bipyramidal systems with tripod ligands containing N, O, S, P donor atoms fall in the range 4.4–4.7 BM (11, 13, 14).

The tetraphenylborate complexes (X = Cl, Br, NCS) exhibit conductances (Table 3) which are somewhat lower than would be expected for 1:1 electrolyte species (17). These data are rather difficult to rationalize in the light of the proposed nature of these species, which are assumed to exist as five-coordinate cations stabilized by the tetraphenylborate anion. However cationic association leading to large bulky ions with low ion mobility and the low ion mobility associated with BPh_4^- itself could lead to significantly lower molar conductances than would be expected. Cobalt complexes of tren-(2,2′,2′′-triaminotriethylamine) of formula $[Co_2(tren)_2X_2](BPh_4)_2$ (X = OCN^-, SCN^-, Cl^-, N_3^-) have recently been shown to contain five-coordinate, outer sphere bridged cations, in which the bridging association is thought to occur via a hydrogen bond, Co—X----HN—Co (18). This association leads to weak antiferromagnetic exchange between the cobalt centres. Outer sphere association of this type could possibly exist in the NTB complexes via the imidazole ring hydrogen, which is likely to reside on the non-coordinating ring nitrogen atom.

A concentration dependence of the molar conductance of [Co(NTB)Br]BPh_4 in nitromethane was studied in the range 10^{-3}–10^{-5} *M* at 25 °C (Table 3). Λ_0 was found to be 75.9 and the slope of the Kohlrausch plot ($\Lambda_0 - \Lambda_e$ *vs.* $\sqrt{c}$) was found to be 960. A typical slope for a 1:1 electrolyte is around 200 (slope for $NaBPh_4$ in $MeNO_2$ = 216 (19)) and it is evident that cationic association is occurring in solution. One possible associative mechanism could involve pseudo-hydrogen bonding, as suggested previously, of an axial halogen (or pseudo-halogen) on one ion with one of the three imidazole hydrogen atoms on another to form a species of the type $\{[Co(NTB)Br]_n\}^{n+}$. It

seems likely that the other cobalt halide and thiocyanate derivatives would behave similarly in nitromethane. Further studies on the concentration dependence of the conductivity of these systems are being carried out. However, additional support for an associative interaction of this type is apparent when one considers the molar conductance values which follow the order NCS > Br > Cl, in keeping with the electronegativities associated with these coordinated anions. Also the strong association that exists between NTB and alcohols (a 1:3 solvate is formed on recrystallization from, *e.g.*, methanol or ethanol which required prolonged drying under vacuum to desolvate) lends support to an associative effect of a hydrogen bonding type in the NTB complexes.

The purple complexes [Co(NTB)X]X (X = Cl, Br, NCS) have magnetic moments (Table 3) typical of high spin systems and electronic spectra which are identical to their tetraphenylborate analogues both in solution and in the solid state (Fig. 2). This indicates that these species contain pseudo-trigonal bipyramidal cations, apparently stabilized by a negative ion capable of coordination. Spectral assignments for these five-coordinate cations are assumed to be the same as those for the tetraphenylborate analogues (Table 2).

Conductivity data in nitromethane (Table 3) indicate species with some ionic character and low values again suggest the possibility of cationic association involving N—H---X bridges. This is supported by the conductance values which follow the order NCS > Br > Cl. An alternative explanation for the low conductance values for these systems results from a consideration of solution equilibria involving the formation of *e.g.* neutral four- or six-coordinate species:

$$[Co[NTB]X]X \rightleftharpoons [Co(NTB)X_2] \ (T_d \text{ or } O_h)$$

In the octahedral case NTB would act as a tetradentate, while in the tetrahedral case it would presumably act as a bidentate ligand. Electronic spectra of nitromethane solutions of these complexes do not show the presence of bands attributable to tetrahedral or octahedral species but are the same as the spectra obtained in acetone.

The pink nitrate and perchlorate complexes, [Co(NTB)X]X (X = NO_3, ClO_4), have electronic spectra (Table 2) which are almost identical to their tetraphenylborate analogues,

their three main absorption bands occurring at slightly higher energies than the corresponding chloro, bromo, and isothiocyanato derivatives. It seems reasonable to suppose that these compounds contain trigonal bipyramidal cations each with one coordinated nitrate and perchlorate group. Magnetic data for these systems also appear to be consistent with five-coordinate, trigonal bipyramidal cobalt(II).

Conductivity data for the nitrato derivatives in nitromethane (Table 3) suggest the presence of 1:1 electrolytes. The bisperchlorato derivative appears to be a 1:2 electrolyte, which is rather surprising since it implies displacement of a coordinated perchlorate group by a nitromethane molecule. The tetraphenylborate analogue exhibits a lower molar conductance which could possibly be associated with a 1:2 electrolyte in the presence of a large bulky ion like BPh_4^-. The electronic spectra of nitromethane solutions of $[Co(NTB)(ClO_4)]ClO_4$ and $[Co(NTB)(ClO_4)]BPh_4$ are almost identical, but differ somewhat in terms of transition energies (Table 2) from their corresponding acetone spectra, suggesting possible axial involvement of a solvent molecule.

The deep blue complexes $[Co(NTB)X]_2[CoX_4]$ (X = Cl, Br, NCS) exhibit electronic spectra (Fig. 3) (Table 2) which show unequivocally the presence of tetrahedral $[CoX_4]^{2-}$ anions and five-coordinate cations identical to those present in the purple complexes [Co(NTB)X]X and $[Co(NTB)X]BPh_4$. In each case a 1:1 correspondence is observed between the peaks associated with the $[CoX_4]^{2-}$ anions in the blue complexes and the salts $[n\text{-}Bu_4N][CoX_4]$ run in the same solvent. Magnetic data (Table 3) indicate high spin systems but the moments are slightly lower than would be expected. The observed moment should represent an average for the three metal centres in the complex and an average moment based on two five-coordinate cations (Table 3) and *e.g.* $CoCl_4^{2-}$, should be around 4.4 BM. The low observed moments could indicate the presence of cationic association in the solid state, *e.g.* of the hydrogen bonding type (18), leading to weak antiferromagnetic exchange.

The thiocyanate complex exhibits a molar conductance close to the range expected for a 1:2 electrolyte, while the lower values of the chloride and bromide complexes are perhaps more typical of 1:1 electrolytes. Again the conductance order follows the sequence NCS > Br > Cl suggesting a hydrogen bonding association between cations. These conductivity data are paralleled by the analogous zinc complexes $[Zn(NTB)X]_2[ZnX_4]$. A comparison of the solution (CH_3NO_2, $(CH_3)_2CO$) and solid electronic spectra of these mixed stereochemistry systems suggests that the same species exist both in the solid state and in solution.

Zinc Complexes

Two series of zinc complexes were obtained: $[Zn(NTB)X]_2[ZnX_4]$ (X = Cl, Br, NCS) and $[Zn(NTB)X]BPh_4$ (X = Cl, Br, I, NCS). The former are thought to be analogous to the cobalt complexes of mixed stereochemistry, containing two five-coordinate cations and a four-coordinate, tetrahedral anion. The tetraphenylborate salts are assumed to contain trigonal bipyramidal cations. Conductivity data in nitromethane (Table 3) indicate ionic species, but again low values suggest the possible existence of associative effects.

Nuclear magnetic resonance data obtained in DMSO-d_6 (Table 5) indicate that the ligand is acting as a quadridentate and lies on a threefold axis of symmetry within each complex cation. The methylene proton resonance occurs as a singlet in each case, indicating equivalent methylene protons, which are shifted downfield slightly (12–18 Hz) with respect to the free ligand. NTB exhibits a very symmetrical set of aromatic proton resonances (*AA'BB'*) indicative of a plane of symmetry within each benzimidazole group. In all the complexes the aromatic proton resonances are observed in two groups of lines (Fig. 5). Three protons remain at essentially the same chemical shift observed for the free ligand, while one proton of the lower field pair is shifted downfield considerably. It is assumed that the benzene ring protons nearest to the imidazole ring are the more deshielded and would be observed at lower field, corresponding to the lower field half of the aromatic proton resonances observed for NTB. On coordination one of these protons, which is still coupled to the other ring protons, is shifted downfield by some 70–80 Hz. This significant downfield shift corresponds to a marked deshielding of one ring proton with respect to the others.

One obvious conclusion to draw from the lack of symmetry of the benzene ring proton reson-

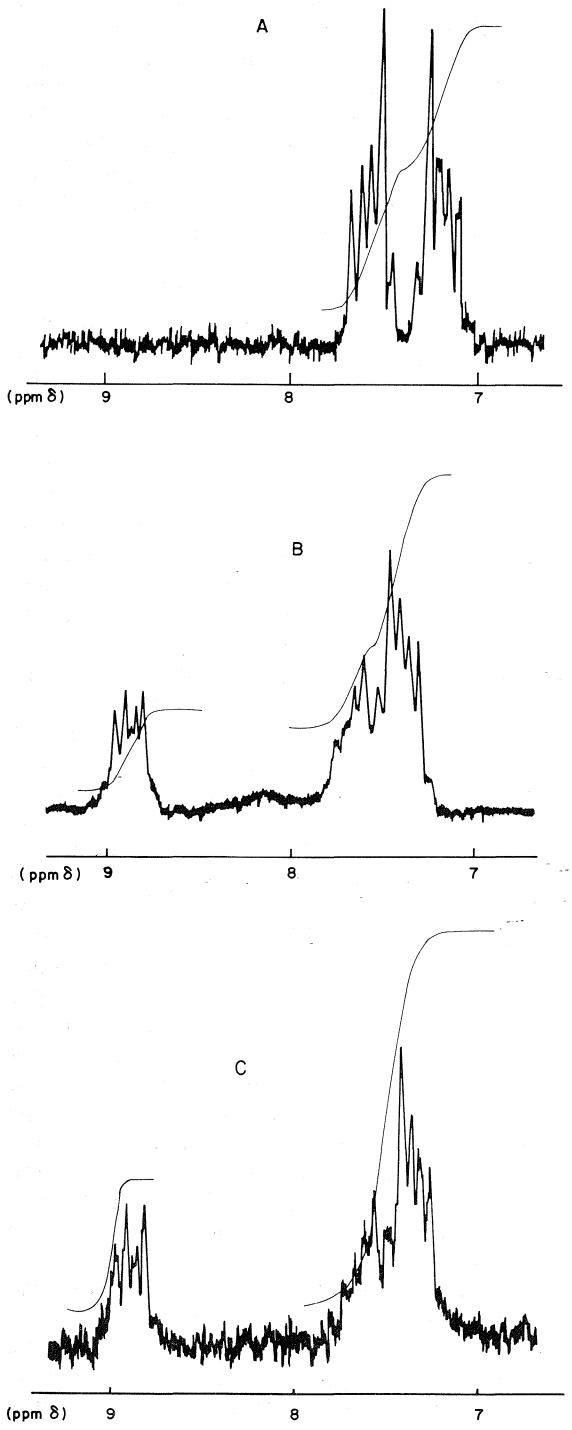

FIG. 5. Nuclear magnetic resonance spectra in DMSO-d_6. *A*, NTB; *B*, [Zn(NTB)Br]BF_4 (the tetrafluoroborate complex was used because of interfering peaks associated with the corresponding tetraphenylborate complex); *C*, [Zn(NTB)Br]$_2$[$ZnBr_4$].

ances would be the coordination of one imidazole nitrogen to a zinc ion. In addition, since only one set of benzimidazole proton resonances appear in the spectrum, it is assumed that all three benzimidazole groups are involved in coordination to the same metal. The slight downfield shift associated with the methylene protons suggests coordination of the apical nitrogen also.

Models suggest that an essentially strain free way for the ligand to coordinate to a metal ion would be as a tripod ligand, with the apical nitrogen occupying an axial site and a nitrogen atom from each benzimidazole group occupying a trigonal equatorial site in a pseudo-trigonal bipyramidal structure. In this configuration one α proton in each benzene ring lies close to the other axial site which contains an electronegative group, *e.g.* Cl, Br, NCS. The close proximity of this electronegative group to the α ring proton could be responsible for a through space electronic interaction leading to a deshielding effect and a downfield shift of the α proton. Alternative, but perhaps less likely, explanations would be an electron withdrawing effect, transmitted from the axial anionic group via the metal through five bonds or from a neighbouring hydrogen bonded ion in an associated structure, if such association exists in highly polar dimethylsulfoxide.

Infrared Data

The infrared spectra of the NTB complexes studied were in general fairly complex and did not provide very much structurally useful information. This was especially true in the far infrared where interfering bands associated with the ligand itself prevented any definitive structural assignments.

Infrared spectra of the nitrate derivatives contain bands that can be assigned to ionic and monodentate nitrate groups. The bisnitrato derivative exhibits bands at 846, 1390, and 700 cm^{-1} (Table 4) which can be associated with an ionic nitrate, and are absent in the tetraphenylborate analogue. Both compounds exhibit bands around 980 and 1310 cm^{-1} assigned to A_1 modes associated with a monodentate nitrate group (20). In the case of the perchlorate derivatives it is possible to pick out a strong doublet (1050, 1130 cm^{-1} for [Co(NTB)(ClO_4)]ClO_4; 1050, 1140 cm^{-1} for [Co(NTB)(ClO_4)]BPh_4) due to the $\nu_3(T_2)$ vibration in a tetrahedral species like ClO_4^- which is split into $A_1 + E$ on lowering the symmetry from T_d to C_{3v}. This suggests the

*m = multiplet, s = singlet, bs = broad singlet, nd = not detected. The H_a and H_b protons appear as asymmetric complex multiplets which appear to contain five major components, one of which has relatively low intensity. In estimating the chemical shifts associated with these protons the centre of gravity of the four higher intensity components was determined in each case.

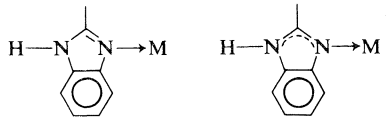

FIG. 6. *a*, Localized ring structure; *b*, delocalized ring structure.

presence of a coordinated perchlorate group in both cases. The bisperchlorato derivative exhibits a strong singlet at 1110 cm^{-1}, which is assigned to the $\nu_3(T_2)$ stretching vibration in an ionic perchlorate group (20).

The thiocyanate complexes exhibit bands associated with CN stretch in the range 2039–2097 cm^{-1} (Table 4). For the complexes $[M(NTB)(NCS)]_2[M(NCS)_4]$ (M = Co, Zn) the higher energy band is assigned to N-bonded thiocyanate in the complex cation, while the lower energy band is associated with N-bonded thiocyanate in the anion $[M(NCS)_4]^{2-}$ (M = Co, Zn). The tetraphenylborate complexes exhibit a single CN stretch which is associated with N-bonded thiocyanate, while for the complex $[Co(NTB)(NCS)]NCS\cdot H_2O$ the higher energy band is assigned to N-bonded thiocyanate and the lower energy band to ionic thiocyanate (21).

NTB exhibits two absorptions at 1622 and 1588 cm^{-1} which are assumed to be due to CN stretch in the imidazole ring. The complexes all exhibit the same two bands; the lower energy band falling in the range 1590–1607 cm^{-1}, while the higher energy band falls in the range 1610–1632 cm^{-1}. In most cases, with the exception of the nitrate and perchlorate complexes, the higher energy band lies below its counterpart in the free ligand, while the lower energy band occurs above 1588 cm^{-1} in all cases. The close similarity of all the complexes in this spectral region suggests a similar coordination environment around the metal in all cases and the behaviour of the ligand as a tetradentate.

A previous study on the cobalt and nickel complexes of some bidentate imidazoline ligands (7) related the CN stretching frequency in the imidazoline rings to the state of localization along the NCN ring framework. As expected, X-ray data confirmed the coordination of the imidazoline ring via the tertiary nitrogen, but also suggested two possible structural types based on CN bond lengths. A CN frequency below that of the free ligand indicated a delocalized imidazoline ring, with essentially equal CN bond lengths while frequencies higher than the free ligand suggested a more localized ring structure in which the CN bond lengths were different. By analogy with the imidazoline complexes the nitrato and perchlorato derivatives possibly have more localized ring structures (Fig. 6*a*) while the other complexes possibly have more delocalized ring structures (Fig. 6*b*). Also it is assumed that in the NTB complexes the imidazole ring is coordinated to the metal via the tertiary ring nitrogen atom (Fig. 6).

The kinetics of the solid state transformation of racemic to optically active 1,1′-binaphthyl

KEITH R. WILSON AND RICHARD E. PINCOCK

The Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received August 24, 1976

KEITH R. WILSON and RICHARD E. PINCOCK. Can. J. Chem. **55**, 889 (1977).

Rates of the solid state reaction which thermally converts racemic to optically active 1,1′-binaphthyl (mp 158 °C) have been determined at temperatures between 105 and 135 °C using polycrystalline samples. The presence of a sufficiently uniform distribution of enantiomorphic seed crystals results in a smooth conversion of the racemate to the eutectic crystal forms of binaphthyl. Although it is possible to force the resolution reaction almost to completion at higher temperatures (150 °C) where the melt phase is an intermediate, lower final specific rotations are obtained when only solid phases are involved (below 145 °C) because of the independent nucleation of racemic material from the reacting crystals. Both spontaneous nucleation and reaction rates in the solid state were increased by grinding the initially prepared samples and were decreased by the storage of samples. The Arrhenius activation energy of this phase transformation giving optically active product is *ca.* 60 kcal/mol in a variety of different samples. This is consistent with a mechanism in which a molecule of 1,1′-binaphthyl attains considerable freedom from the racemic solid in order to interconvert to its enantiomer and add to the growing optically active phase.

KEITH R. WILSON et RICHARD E. PINCOCK. Can. J. Chem. **55**, 889 (1977).

On a déterminé, à des températures allant de 105 à 135 °C et faisant appel à des échantillons polycristallins, les vitesses de réactions à l'état solide, qui permettent de transformer d'une façon thermique du binaphthyl-1,1′ (pf 158 °C) racémique en produit optiquement actif. La présence d'une distribution suffisamment uniforme de cristaux permettant d'ensemencer un énantiomorphe conduit à la conversion facile du racémique en une forme cristalline eutectique du binaphtyl. Il est possible de forcer la réaction de façon à obtenir une résolution pratiquement complète à des températures plus élevées (150 °C) alors que la phase fondue est un intermédiaire; toutefois on obtient des rotations spécifiques finales qui sont plus basses quand il n'y a que des phases solides d'impliquées (en dessus de 145 °C) et ce résultat est dû à la nucléation indépendante du composé racémique à partir des cristaux qui réagissent. La nucléation spontanée et les vitesses de réaction à l'état solide sont toutes les deux augmentées lorsque l'on broie les échantillons préparés initialement; toutefois elles sont diminuées lorsque l'on garde les échantillons d'une façon prolongée. L'énergie d'activation d'Arrhénius de cette transformation de phase conduisant à un produit optiquement actif est d'environ 60 kcal/mol dans une grande quantité d'échantillons différents. Cette valeur est en accord avec un mécanisme dans lequel une molécule de binaphtyl-1,1′ devient très libre du solide racémique de façon à se convertir dans son énantiomère et à s'additionner à la phase optiquement active qui est en croissance.

[Traduit par le journal]

The transformation of optically inactive into optically active 1,1′-binaphthyl may occur simply by heating a sample below its melting point (1). This is possible because the racemate form (mp 145 °C) of this compound is unstable relative to a mixture of separate *R*(−) and *S*(+) enantiomeric crystals (mp 158 °C). At temperatures of *ca.* 76 to 145 °C a solid state reaction of racemate occurs and optically active product (*i.e.* an unequal mixture of *R* and *S* crystals) may result. This reaction shows the typically complex aspects of solid state transformations (2–4); it appears to be sensitive to any previous treatment which influences the size of crystals and the presence of lattice imperfections. It is well known in general that these factors greatly determine the ability to nucleate and grow new interfaces between the reactant and product. In the case of the solid state resolution of binaphthyl such factors may determine the extent of optical resolution as well as the rate of development of optical activity. When ordinarily recrystallized racemic binaphthyl is used these complex and variable factors result in widely scattered and erratic values for the final optical activity even in polycrystalline samples taken from a single preparation (see Fig. 2 of ref. 1).

However, the recrystallization of binaphthyl

which is slightly optically active gives samples which show a smooth and consistent development of optical activity and allows a more thorough investigation of this solid state reaction. We report here our observations on the kinetic aspects of the transformation of several of these samples of 1,1′-binaphthyl into optically active product. Relatively few solid → solid reactions, especially organic reactions, have been kinetically studied (2). In this case the reacting system is very simple in that the product is at least molecularly the same as the reactant. The availability of smoothly resolving samples presents an opportunity to study the rate of production of enantiomorphic crystals and obtain information on the specific mechanism of the solid state resolution of 1,1′-binaphthyl. Also, as discussed below, the system lends itself in a unique way to the study of factors affecting the spontaneous nucleation of a new phase in an organic crystal.

Experimental

Samples of 1,1′-binaphthyl used in these kinetic studies were prepared from racemic binaphthyl by admixture of small amounts of optically active binaphthyl according to procedure B of ref. 1. The designation of the individual batch, the total weight, and the specific rotation in benzene are, respectively; *S*-1, 3.0 g, +1.4°; *S*-2, 4.0 g, +11.8°; *S*-3, 5.7 g, +1.8°; and *R*-1, 3.8 g, −11.0°. As indicated by the notations *R* and *S*, three samples gave predominately *S*(+) and one gave *R*(−) binaphthyl when heated at temperatures of 105 to 150 °C.

The resolution reaction of each batch was followed by heating individually sealed ampules containing a carefully weighed amount (15–20 mg) of the polycrystalline binaphthyl at a given temperature for various lengths of time. Samples were dissolved in benzene and optical rotations measured as previously described on a Bendix type 143A automatic polarimeter at the sodium D line (5890 Å). Since the kinetic characteristics of individual batches changed after storage (*e.g.*, see Fig. 1 for a comparison of samples before and after storage at 25°C for 6 weeks) all samples were stored at 0 °C and runs reported here were performed within 5 weeks.

All batches resolved to final rotations greater than $[\alpha]_D \pm 200°$ when heated at 150 °C, but with a half-life too short at this temperature for an accurate kinetic description. (Optically pure 1,1′-binaphthyl has $[\alpha]_D \pm 245°$ (1).) The final rotation in several runs at temperatures in the range 105 to 135 °C was considerably less than ±200° (see Table 1 of ref. 1).

An assessment of how closely the relatively easily measured optical rotations of a sample reflected the actual extent of phase transformation of racemate to eutectic forms of binaphthyl was carried out using quantitative X-ray powder diffraction (5) (with a Debye–Scherrer powder camera, Philips PW 1024/10). By choosing one line in the diffraction pattern of the racemate

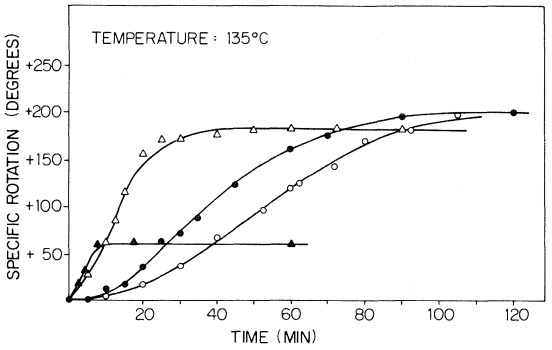

FIG. 1. Kinetic data for the solid state resolution of neat, polycrystalline 1,1′-binaphthyl, *S*-1 kinetic batch at 135 °C. (d = 10.1 Å) and one in the pattern of the eutectic form (d = 6.4 Å) which is distinct in a mixture of the two forms, the disappearance of racemate and the appearance of eutectic could be quantitatively followed. A standard procedure for exposure and development of powder photographs, followed by analysis on a microdensitometer (Joyce double beam recording instrument MKIIIc) and calibration with known mixtures of eutectic and racemate forms resulted in reproducible analyses which agreed within 2% (6). Application of this method to the analysis of the phase transformation of the *S*-2 kinetic batch at 125 °C, and comparison to the independently obtained optical rotations, showed that the ratio $[\alpha]_t/[\alpha]_{final}$ was closely equivalent to the extent of phase transformation, *i.e.* to the mole fraction of the eutectic form present. As this is the case even in this batch of binaphthyl which resolved only to a relatively low rotation ($[\alpha]_{final}$ 136° at 125 °C) then the fraction of final rotation achieved at any time is a good measure of the actual fraction of eutectic form present at that time, *i.e.* $y = [\alpha]_t/[\alpha]_{final}$, where y is the mole fraction of eutectic form. The mole fraction of product phase, y, is thereby made accessible from readily measured optical activity data alone; it is a direct measure of the fraction of reaction and therefore suitable for further kinetic analysis.

Results and Discussion

The thermal production of optical activity in specially seeded samples of 1,1′-binaphthyl shows a very prominent difference from that in ordinary racemic samples; the resolution reaction in any small portion of the sample is remarkably smooth and consistent. This is shown, for example, in some representative specific rotation *vs.* time plots for the various kinetic batches in Figs. 1, 2, and 3. The specially prepared batches apparently have a highly refined and uniform dispersion of seed crystals which enable a smooth development of optical activity even in small polycrystalline samples.

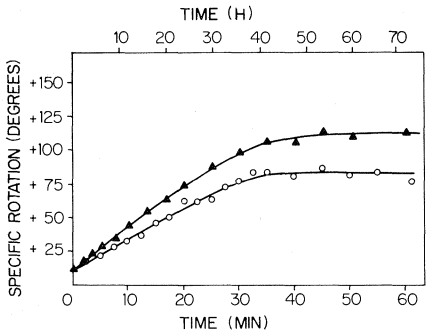

FIG. 2. Kinetic data for the solid state resolution of neat, polycrystalline 1,1′-binaphthyl, *S*-2 kinetic batch, at 115 °C (upper time scale ▲) and at 135 °C (lower time scale ●).

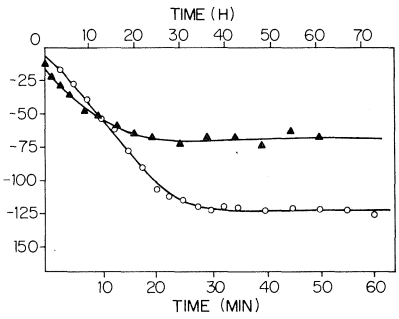

FIG. 3. Kinetic data for the solid state resolution of neat, polycrystalline 1,1′-binaphthyl, *R*-1 kinetic batch, at 115 °C (upper time scale ▲) and at 135 °C (lower time scale ●).

Although the activity of samples develops smoothly, there appears to be no characteristic shape to the curves. Some are sigmoid (although none have prolonged induction periods), while others appear to increase linearly with time or even show an initial rate maximum. The extent of resolution also varies in different batches and in the same batch at different temperatures. Generally lower resolutions were obtained at lower temperatures. As discussed below a low final rotation indicates nucleation and growth during a run of the enantiomer opposite from that seeded into the sample.

As shown in Fig. 1 the results of kinetic runs were sensitive to grinding of the crystals and such disruption of the initial crystals always caused a faster resolution to a lower specific rotation. Storage of samples resulted in the opposite results; a higher final rotation was obtained from samples stored at 0 °C for 4 months (see Fig. 3 of ref. 1) and a somewhat slower rate of resolution occurred in a sample stored at 25 °C for 6 weeks (see Fig. 1). These effects of storage and of grinding, as well as the relationship of temperature to extent of resolution may all be explained in a qualitative manner after consideration of the mechanism of the resolution reaction.

An ideal seeded sample, *i.e.* suitable for the production of optically pure binaphthyl, consists of a slight excess of one enantiomer (*e.g.*, the *R* enantiomer in its 'eutectic' crystal form) and *all* the rest of the sample would be in the *R,S*-racemate form (1). When such a sample is heated, and provided that no nucleation of the other enantiomer (*e.g.*, the *S* eutectic form) occurs, the growth of only *R* enantiomeric crystals proceeds at the expense of *R,S*-racemate and the entire sample is converted to optically pure *R* crystals. In practice such an ideal sample is probably impossible to obtain and, in addition, nucleation during a run can be an important factor in obtaining a high optical resolution.

When nucleation occurs in a racemic 1,1′-binaphthyl reactant phase, which could be a racemic crystal below 145 °C or a melt below 158 °C, it is just as likely to involve *R* molecules as *S* molecules (7). In other words, nucleation (which is independent of crystal growth) is expected to create *R* and *S* crystallites with equal probability. The growth of these new nucleites produces separate *R* and *S* eutectic crystals and leads to low overall resolutions. Low values of the final rotation therefore may result from the presence of initial seed crystallites of undesired enantiomer in the material before heating and/or from the nucleation of racemic material during the reaction.

All of the specially seeded samples appear to be sufficiently free from unwanted enantiomeric 'seeds' so that high rotations (greater than 200° or 82% optically pure) resulted when samples were heated at 150 °C. At this temperature, the reaction involves a conversion of racemate through the melt to optically active solid (1). Since a binaphthyl melt will remain supercooled indefinitely at 150 °C, nucleation in a melted phase does not occur at this temperature. The situation in the seeded samples at 150 °C therefore approaches the ideal for production of optically pure product as mentioned above. In this way, advantage can be taken of the phase relationships in the 1,1′-binaphthyl system in order to obtain, reproducibly, excellent resolutions in either direction in a single heating step (1).

In the solid → solid conversion (not involving

melt), which occurs below 145 °C, nucleation in some samples definitely occurs as is shown by the lower final specific rotations. The inability to control or even reproduce the nucleation of new product sites (and the resulting autocatalytic growth of product) is the major reason why solid state reactions are so dependent on the past history of samples. Mild disruption of the binaphthyl crystals by grinding produces a greater reactant–product interface and causes a more rapid reaction. In addition there are stresses, dislocations, and other imperfections produced by grinding and these act as sites for the nucleation of racemic material. The result is the observation of higher rates of reaction but to a lower degree of resolution (shown in Fig. 1). On the other hand, storage of samples apparently allows for slow annealing out of such nucleation sites and gives material that resolves slower but to a greater extent. In samples prone to nucleation (*e.g.*, *R*-1 as in Fig. 3), lower temperatures and therefore longer reaction times gave lower final rotations possibly because the nucleation of racemic material has a greater dependency on time and temperature than does the rate of phase transfer.

Although some features of this solid state reaction may therefore be qualitatively understood, the above examples of the variations present in different batches and the effects of grinding and storage all provide a good illustration of the complex sensitivity of a solid state reaction to the previous treatment of a sample. Samples of binaphthyl that resolve to high optical purity are available (1) but our results here show that reproducible preparations of samples which give essentially the same extent and rate of resolution below 140 °C would be very difficult.

Kinetic Analysis

As already indicated by the varied qualitative results discussed above, the solid state resolution of various samples of 1,1′-binaphthyl is too complex to fit any single general kinetic scheme. Nevertheless there are few kinetic studies of simple solid → solid organic transformations and the ease of measurement of optical rotations with binaphthyl presents an opportunity to obtain data which might fit (at least in an individual preparation) some empirical kinetic equation for solid state reactions. However, the relationship of measured specific rotations to the actual extent of phase transformation must first be considered.

In an ideal solid state resolution, *i.e.* one giving a completely resolved product (a situation approached by batches *S*-1 and *S*-3), the extent of phase transformation (y) at any time must equal the ratio of measured specific rotation to the final specific rotation ($y = [\alpha]_t/[\alpha]_{final}$). For a batch of binaphthyl that finally resolves only to a restricted extent (batches *S*-2 and *R*-1) the phase transformation may not necessarily run parallel to the specific rotation. However, the relationship of measured rotations to extent of phase transformation given above was experimentally established by quantitative X-ray analysis of partially reacted samples (6). Therefore for a comparison of various rate equations, the use of measured rotations as an expression of the fraction of phase transformation is justified.

Of the rate equations for solid state reactions that have been developed two seem most widely used (2, 3). The first of these, the Avrami–Erofeev equation may be expressed by the relationship $-\log(1 - y) = (kt)^n$ and a plot of log [log (1/(1-y))] against log (t) results in a line with the slope equal to n. Such a plot was made for all four kinetic batches, two of which are illustrated in Figs. 4 and 5. With the *S*-1 batch the results fit a straight line (with n near two) rather well (Fig. 4). Less perfect fits are found with the other batches where the plots are better described at a given temperature as two straight lines. The most obvious bend occurs with the *S*-2 kinetic batch (Fig. 5) which gives limiting slopes of 0.65 and 1.9 at all four temperatures.

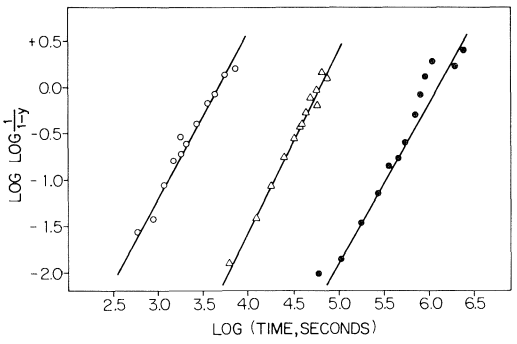

FIG. 4. Avrami–Erofeev plots for the solid state resolution of neat, polycrystalline 1,1′-binaphthyl, *S*-1 kinetic batch at 135 °C ○, and 105 °C ●. The results from the sample stored 6 weeks at 25 °C are plotted against [log (time) + 1] and given by ▲ from a run at 135 °C.

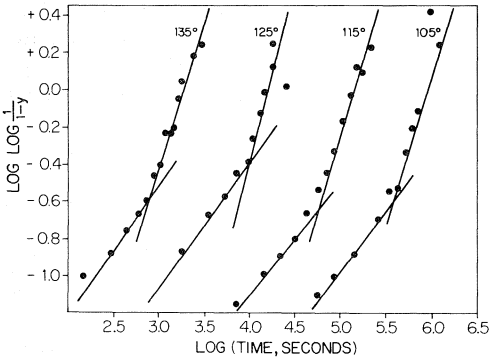

FIG. 5. Avrami–Erofeev plots for the solid state resolution of neat, polycrystalline 1,1′-binaphthyl, *S*-2 kinetic batch at 135, 125, 115, and 105 °C.

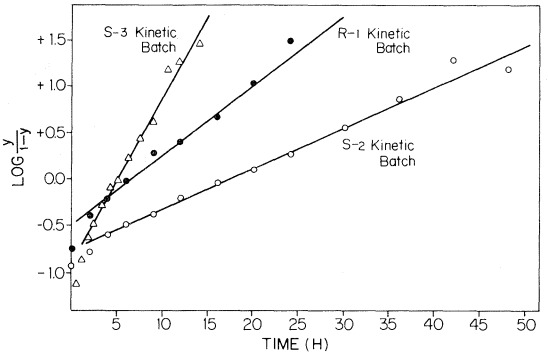

FIG. 6. Prout–Tompkins plots for the solid state resolution of neat polycrystalline 1,1′-binaphthyl, *S*-2, *S*-3, and *R*-1 kinetic batches at 115 °C.

Any mechanistic implications from the fit of data from the *S*-1 batch to the Avrami–Erofeev equation are not altogether certain. One common interpretation of the exponent n is that it is composed of two quantities, namely $n = \beta + \gamma$ (2, 8). The β component refers to the number of steps required to form a nucleus and is revealed in a power law of the type $N = kt^{\beta}$ where N is the number of nuclei formed in time t. In the case of the *S*-1 and *S*-3 kinetic batches the high resolutions finally attained indicate that nucleation (which gives racemic product) is not important, *i.e.* $\beta = 0$. The observed value of $n = 2$ is then equivalent to γ, the number of dimensions in which growth of existing crystallites occur. At least in the case of the *S*-1 batch of Fig. 4 the implication is that the growing product crystallites spread in two dimensions along, for example preferred lattice planes or boundaries between racemate crystallites.

The other commonly used rate law is the Prout–Tompkins equation: $\log (y/(1-y)) = kt$ + constant. Plots of $\log (y/(1-y))$ against time often show two straight lines (2); in the case of 1,1′-binaphthyl the plots show linearity beyond $y \simeq 0.3$ for all the kinetic batches (see representative runs in Fig. 6). Since a rate constant k is derived from the slopes of such plots the Prout–Tompkins treatment leads to a determination of an activation energy for the reaction, at least in this part of its overall reaction progress. This is shown in Fig. 7, where Arrhenius activation energies, calculated from $2.30R$ (slope of line) are 57.7, 62.4, 59.4, and 67.0 kcal mol^{-1} for the *S*-1, *S*-2, *S*-3, and *R*-1 batches, respectively. This large activation energy for a conversion of racemate to eutectic crystals may be contrasted with

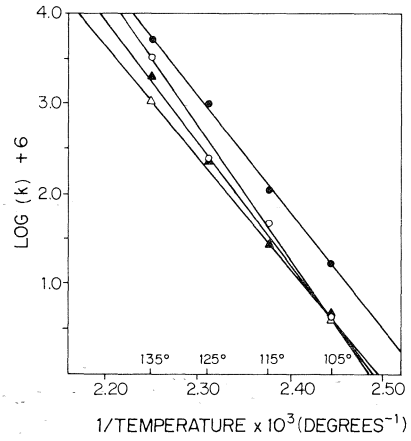

FIG. 7. Relation of log k (from Prout–Tompkins plots) to reciprocal temperature for the solid state resolution of neat, polycrystalline 1,1′-binaphthyl, kinetic batches *S*-3 ●, *R*-1 ○, *S*-2 ▲, and *S*-1 △.

the relatively small enthalpy value of approximately 7 kcal mol^{-1} required to melt the racemate (6). This contrast shows that the resolution is certainly not analogous simply to the release of molecules from the racemate to an interface resembling the melt. Even if an activation energy expected for interconversion of enantiomers in solution (*ca.* 22 kcal/mol in *n*-heptane) (9) is added to the energy required to melt the racemate the figure obtained is still far from the observed *ca.* 60 kcal/mol activation energy.

The observed energy may be more closely related to the energy increment associated with the removal of a single molecule from inside a crystal to the vapour state. This is twice the energy needed to vaporize the complete crystal (*i.e.* the heat of sublimation which is about 22

kcal/mol^{-1}). The energy required for this process of breaking the van der Waals forces in the racemate crystal is then approximately 44 kcal mol^{-1} and if the molecule interconverts to its enantiomer in addition to effectively vaporizing, an activation energy estimate could be as high as 44 + 22 = 66 kcal mol^{-1}.

The fact that 1,1′-binaphthyl has an activation energy of the order of 60 kcal mol^{-1} means that for the resolution reaction to be observable at all at the moderate temperatures used, the high activation energy must be compensated by a high entropy of activation. The high activation energy and entropy are consistent with a picture in which a molecule of 1,1′-binaphthyl attains a great deal of freedom from the solid, similar to that obtained by transfer to a gas phase, in order to interconvert to enantiomer and grow the optically active solid phase.

Alkyl 4-chloromethyl-1,2,3,4-tetrahydro-6-methyl-2-oxopyrimidine-5-carboxylates are obtained from the reaction of 1,2-dichloroethyl ethyl ether with alkyl 3-ureidocrotonates. Reaction of the chloromethyl compounds with basic nucleophilic reagents causes ring expansion and leads, in high yield, to 7-substituted 2,3,6,7-tetrahydro-2-oxo-1*H*-1,3-diazepine derivatives. In the case of sulfhydryl ion, intramolecular Michael addition follows ring expansion and gives derivatives of 3-oxo-8-thia-2,4-diazabicyclo[3.2.1]octane, whose structures are established by spectroscopic examination and chemical degradation. The alkyl 7-alkoxy-2,3,6,7-tetrahydro-2-oxo-1*H*-1,3-diazepine-5-carboxylates react rapidly with acid to give alkyl 1-carbamoyl-2-methylpyrrole-3-carboxylates. Mechanisms are suggested for these rearrangement reactions.

ERIC BULLOCK, ROGER A. CARTER, REGINA M. COCHRANE, BRIAN GREGORY et DOUGLAS C. SHIELDS. Can. J. Chem. **55**, 895 (1977).

On obtient les chlorométhyl-4 tétrahydro-1,2,3,4 méthyl-6 oxo-2 pyrimidinecarboxylates-5 d'alkyle par réaction du dichloro-1,2 éthoxyéthane avec des uréidocrotonates-3 d'alkyle. La réaction des composés chlorométhylés avec des réactifs nucléophiles basiques produit une extension de cycle et conduit, avec de bons rendements, aux dérivés tétrahydro-2,3,6,7 oxo-2 1*H* diazépines-1,3 substitués en position 7. Dans le cas de l'ion sulfhydryle, l'addition intramoléculaire de Michael suit l'extension de cycle et conduit aux dérivés oxo-3 thia-8 diaza-2,4 bicyclo-[3.2.1]octanes dont les structures ont pu être déterminées par des méthodes spectroscopiques et une dégradation chimique. Les alkoxy-7 tétrahydro-2,3,6,7 oxo-2 1*H* diazépine-1,3 carboxylates-5 d'alkyle réagissent rapidement avec les acides pour conduire au carbamoyl-1 méthyl-2 pyrrolecarboxylates-3 d'alkyle. On suggère des mécanismes pour ces réactions de réarrangement.

Lack of suitable synthetic methods has limited studies of monocyclic 1,3-diazepines to derivatives of tetramethylene urea, 4,5,6,7-tetrahydro-1*H*-1,3-diazepine, and hexahydro-1,3-diazepine (1, 2). 1,3-Diazepines of higher oxidation level have recently been prepared from 2-amino-1-methylimidazole (3), 3,5,6-triphenyltriazine,[1] and 1,3-disubstituted uracil-carbene adducts (5) while the dihydro-1,3-diazepine-2,4-dione squamolone has been isolated from *Anona squamosa* (6). We have recently (7) reported the ring expansion of 4-chloromethyl-1,2,3,4-tetrahydro-2-oxopyrimidine derivatives to derivatives of 1*H*-1,3-diazepine and now present an account of this work in full.

Earlier, we have shown (8) that dialkyl 4-chloromethyl-1,4-dihydrolutidine-3,5-dicarboxylates (9) will undergo ring expansion reactions when treated with basic nucleophilic reagents. In the case of cyanide ion, evidence has been presented which supports a mechanism involving loss of proton from the ring nitrogen, followed by rapid elimination of halide ion with concomitant ring expansion and conjugate addition of hydrogen cyanide (10). Other evidence has been obtained, however, which suggests that under certain conditions, such chloromethyl compounds behave as typically homoallylic systems and reactions may proceed via an homoallyl carbonium ion which is stabilized by electron release from the ring nitrogen,[2] reminiscent of the behaviour of 3,5-dimethoxy-1,4-dihydrobenzyl tosylate (11).

By analogy with these results, it was antici-

pated that 4-chloromethyl-1,2,3,4-tetrahydro-2-oxopyrimidines (*e.g.*, **1***a*) would undergo ring expansion. 1,2,3,4-Tetrahydro-2-oxopyrimidines are readily available by the Biginelli reaction (12, 13) between urea, a β-ketoester, and an aldehyde, or by the Folkers and Johnson modification using ethyl 3-ureidocrotonate and an aldehyde in the presence of acid (14). The nmr spectrum of ethyl and methyl 3-ureidocrotonate, prepared by the method of Donleavy and Kise (15), showed the presence of only one tautomer and one geometrical isomer. The appearance of the NH resonance at low field (δ ~ 10–15 ppm) (16–18) and its relative insensitivity to changes in solvent polarity and concentration (19) are characteristic of chelation in vinylogous amides, imides, and urethanes. Accordingly the chelated *Z*-configuration **2** is assigned to these 3-ureidocrotonates. Since the condensation of 1,2-dichloroethyl ethyl ether

afforded in good yield, a compound $C_9H_{13}ClN_2O_3$ (7), the spectroscopic properties of which were in full accord with the assigned structure **1***c*. Thus the mass spectrum was dominated by peaks at *m/e* 183, 155, and 137, which arise through loss of a chloromethyl radical to give the resonance stabilized ion **4***b*, followed by loss of ethylene[4] by a McLafferty rearrangement to give ion **5**, or loss of ethanol to give ion **6** (see Scheme 1). A number of ethyl 4-alkyl-1,2,3,4-tetrahydro-2-oxopyrimidine-5-carboxylates have been prepared and undergo similar fragmentations[5] (see Experimental). At high inlet temperatures, thermal elimination of HCl from **1***c* takes place. The nmr spectrum showed two broad NH absorptions, one of which is a doublet and is coupled to a proton attached to an adjacent carbon which appeared as a multiplet at δ 4.45. Deuteration resulted in the disappearance of both NH signals, while the CH signal at δ 4.45 collapsed to a triplet thus demonstrating the presence of the NH—CH—CH_2 moiety and eliminating the 2-imino-1,3-oxazine structure **7***a*. The methylene group appeared as a doublet, showing that, although the CH—CH_2 should, in principle, be an ABX system (C_4 is asym-

[3]It is well-known that 1,2-dichloroethyl ethyl ether reacts with ethyl acetoacetate in the presence of ammonium hydroxide to give a furan (21) and a pyrrole (21) and with urea to give 2-aminooxazole (22), while dialkylureas react with ethyl acetoacetate to give 1,3-oxazines (23). To reduce the number of possible products we decided to use the Folkers–Johnson approach. Subsequently, Ashby and Griffiths (24) have shown that a product identical with ours is formed from 1,2-dichloroethyl ethyl ether, ethyl acetoacetate, and urea, although in considerably lower yield.

[4]In the case of the methyl ester **1***a*, which has been prepared in a similar manner, and other 4,6-dialkyl-1,2,3,4-tetrahydropyrimidines, the loss of the 4-alkyl substituent gives an ion *m/e* 169 which loses methanol to give ion **6**. As expected, no ion corresponding to **5** is observed.

[5]The fragmentation of various aryl 1,2,3,4-tetrahydro-2-oxo-pyrimidines lacking electron-withdrawing substituents at C-5 is dominated by loss of aryl radicals (25).

metric), the methylene hydrogens are equivalent and free rotation is permitted about C_4—C_4'. The chemical shift values were in good agreement with those of authentic 1,2,3,4-tetrahydro-2-oxopyrimidines. The 2-oxo tautomeric structure was supported by the similarity between the ultraviolet spectra of **1***c*, ethyl 3-aminocrotonate, and ethyl 3-ureidocrotonate. In order to unequivocally eliminate[6] the 2-imino-1,3-oxazine structure **7***b*, compound **1***c* was reduced to the known ethyl 4,6-dimethyl-1,2,3,4-tetrahydro-2-oxopyrimidine-5-carboxylate using tri-*n*-butyltin hydride (cf. ref. 26) in the presence of azobisisobutyronitrile, thus confirming the structure **1***c*. Reduction of **1***b* using sodium borohydride in acetonitrile gave an isomeric product whose spectroscopic properties were in agreement with the 1,3-diazepine structure **8***e* resulting from ring expansion. None of this product was detected in the tributyltin hydride reduction.

The action of bromine (2 mol) in chloroform on the methyl ester **1***a* gave the 6-dibromomethyl compound **1***b*, whose nmr spectrum showed a 1H singlet at δ 8.03 and lacked the 3H singlet due to the C_6 methyl group. A similar compound was obtained by bromination of methyl 1,2,3,4-tetrahydro-4,6-dimethyl-2-oxopyrimidine-5-carboxylate (cf. ref. 27). We have been unable to effect hydrolysis of the 6-dibromomethyl compounds to the 6-aldehydes.

Treatment of the chloromethyl compound **1***a* in methanol with dilute aqueous potassium hydroxide, followed by acidification, resulted in formation of a small amount of methyl 2-methylpyrrole-3-carboxylate **9***a* and a major product $C_8H_{10}N_2O_3$ whose mass spectrum showed a molecular ion at *m/e* 182 and fragments at *m/e* 139, 124, 108, and 107 due to loss of HNCO followed by loss of methyl or methoxyl radicals and methanol respectively (cf. ref. 28). The nmr spectrum showed signals due to an NH_2 group, a pair of adjacent aromatic protons, a methyl group attached to an aromatic ring, and a methyl of methoxycarbonyl group. The nmr and ms are consistent with the *N*-carbamoylpyrrole structure **9***c*. The structure was confirmed when **9***c* was shown to give the pyrrole **9***a* when treated with base. Potassium fluoride in acetonitrile converted **1***a* directly to **9***a* in good yield. The ethyl ester **1***c* yielded a similar

N-carbamoylpyrrole **9***d* with potassium hydroxide in ethanol. Several unsuccessful attempts were made to synthesize **9***d* by a rational route. For example, ethyl 2-methylpyrrole-3-carboxylate **9***b* was converted to the corresponding pyrrolylmagnesium bromide which reacted with methyl chloroformate[7] to yield ethyl 1-methoxycarbonyl-2-methylpyrrole-3-carboxylate, **9***e*. However, reaction of **9***e* with ammonia gas in methanol resulted only in removal of the methoxycarbonyl group to regenerate **9***b*. Con-

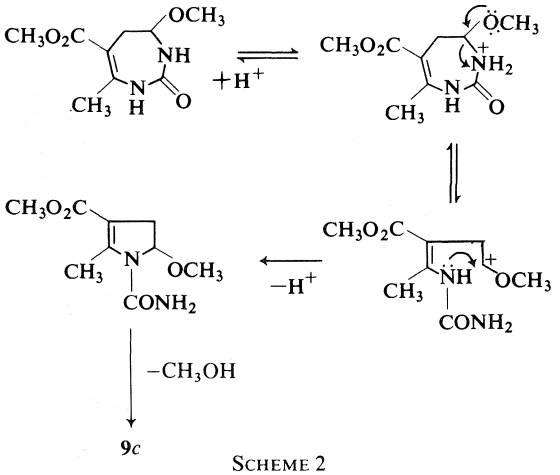
[6]Additional support was obtained when compound **1***c* was converted to ethyl 1-carbamoyl-2-methylpyrrole-3-carboxylate.

[7]The methyl ester was used in order to facilitate the interpretation of the reaction of the product, a 1-methoxycarbonyl-3-ethoxycarbonylpyrrole, with ammonia.

densation of α-chloroacrylonitrile (cf. ref. 29) with ethyl 3-ureidocrotonate did not yield **9***d*.

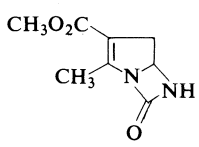
When the chloromethyl compound **1***a* was reacted with sodium methoxide in methanol, a major product $C_9H_{14}N_2O_4$ was obtained and was assigned the 7-methoxy-1,3-diazepine structure **8***b*. The nmr spectrum showed singlets due to methoxyl and methoxycarbonyl groups and a doublet which was due to a C-methyl group which exhibited homoallylic coupling. In addition, the spectrum showed two NH absorptions, one of which was coupled to H_X of an AMX system. The H_X proton appeared at δ 4.76 as a multiplet which was changed to a 1:1:1:1 quartet on exchange of the labile NH protons for deuterium. A consideration of this and the chemical shift of proton H_X suggests the presence of the —CH_2—CH(OCH_3)—NH— moiety. In spin decoupling experiments, irradiation on the proton H_X at δ 4.76 caused the quartet at δ 3.70 due to H_M to collapse to a doublet (J = 14.5 Hz) but no change in the H_A signal (broadened d at δ 2.67) while irradiation at δ 2.67 caused the quartet of H_M at δ 3.70 to collapse to a doublet (J = 6.5 Hz). The homoallylic coupling of the proton H_A to the C-methyl group and the above nmr data provide strong support for the structure **8***b*.

When treated with methanolic hydrogen chloride or other acidic reagents at room temperature the methoxy-1,3-diazepine **8***b* was very rapidly and quantitatively converted to the 1-carbamoylpyrrole **9***c*. In the absence of water, we believe this reaction occurs via protonation at N-1 followed by methoxyl-assisted cleavage, in a manner reminiscent of acetal hydrolysis, to give a carbonium ion (see Scheme 2). Cyclization

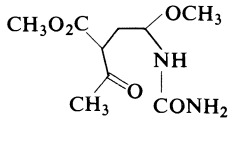


SCHEME 2

by nucleophilic attack of N-3, and acid-catalyzed loss of methanol would then yield **9***c*. An alternative mechanism, which cannot be excluded, involves protonation of the methoxyl group, transannular displacement to give the 1,6-diazabicyclo[3.2.0]heptanone **10**, and subsequent acid-catalyzed ring opening to **9***c*. In the presence of water, a third mechanism is possible which involves hydrolytic ring-opening of the vinylogous urethane to give the ketoester **11**. Subsequent cyclization and loss of methanol would

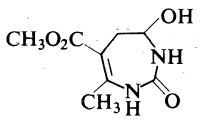


10

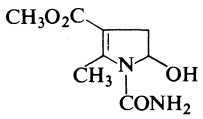


11

yield **9***c*. In the formation of **9***c* or **9***d* directly[8] from the chloromethyl compounds **1***a* and **1***c* respectively, the pathway appears to depend on the solvent used. The reaction proceeds via the 7-alkoxy-1,3-diazepine in high alcohol:water ratios and requires acid to complete the transformation to the pyrrole. Carbinolamines *e.g.* **12**, **13** appear to be formed competitively in aqueous ethanol or aqueous tetrahydrofuran.



12

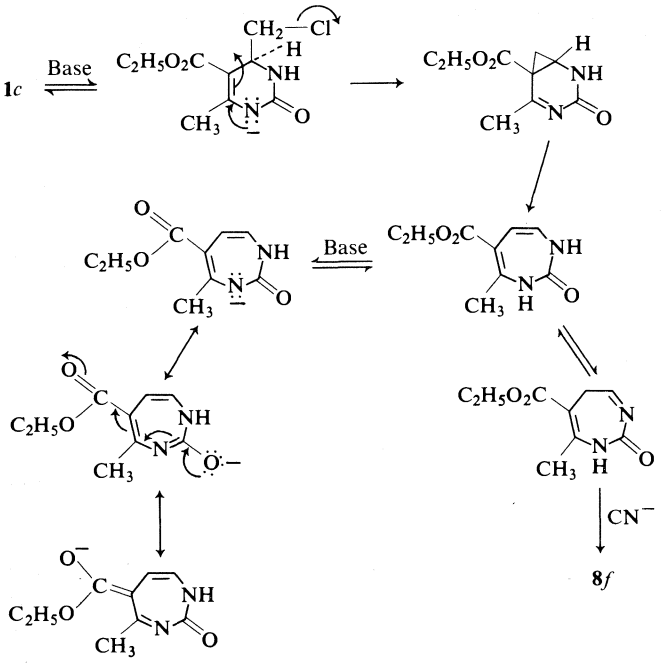


13

Other 7-substituted 1,3-diazepines have been prepared from **1***a* and **1***c* using nucleophilic reagents. Thus the 7-ethoxy compound **8***h* was prepared by the action of potassium cyanate in dry ethanol on **1***c*, while tetramethylammonium hydroxide and **1***c* in methanol gave the 7-methoxy compound **8***g* without ester exchange. The reaction of the chloromethyl compounds **1***a* and **1***c* with potassium cyanide, potassium succinimide, or diethyl sodiomalonate gave the 7-cyano-1,3-diazepines **8***a* and **8***f* (7),[9] 7-succinimino-1,3-diazepines **8***c* and **8***i*, and 7-diethoxycarbonylmethyl-1,3-diazepines **8***d* and **8***j* respectively. The spectroscopic properties of the compounds **8***a*–**8***j* were in good agreement

[8]For the ring contraction of a pyrimidine to a pyrrole under reductive/acidic conditions see ref. 30.

[9]Some of our results reported earlier (7) have recently been confirmed by Ashby and Griffiths (24).



SCHEME 3

with the proposed structures. Thus, the ultraviolet absorption maxima which invariably appeared about 265 nm (ε 13 000 approximately) are about 15 nm to shorter wavelength than those of typical 4,6-dialkyl-1,2,3,4-tetrahydro-2-oxopyrimidine-5-carboxylates and may reflect a decrease in planarity of the cyclic ureidocrotonate chromophore. In the case of the 7-succinimino- and 7-(diethoxycarbonylmethyl)-1,3-diazepines, the base peaks in the mass spectrum were formed by a McLafferty rearrangement which resulted in loss of succinimide or diethyl malonate respectively.

Although, in principle, ring expansion of **1***a* and **1***c* may take place by participation of either N-3 or the aminocrotonate system, the former would result in attachment of the nucleophile at C-6 rather than C-7 as found. It has been observed that the reaction of **1***a* and **1***c* in dipolar aprotic solvents, *e.g.* dimethyl sulfoxide or dimethylformamide, with bases such as cyanide, *tert*-butoxide, methoxide, or succinimide anions or 1,5-diazabicyclo[4.3.0]non-5-ene causes the production of an intensely violet-colored solution. This violet color gradually fades over 30–60 min to give a yellow-brown solution and work-up by addition of water at this point results in isolation of ring-expanded product in high yield. The violet-colored species is formed by reaction of **1***c* with cyanide anion in aprotic solvents such as pyridine, tetrahydrofuran, or acetonitrile only on addition of a crown ether such as dicyclohexyl-18-crown-6 and is not observed at all in hydroxylic solvents. Alkyl 4,6-dimethyl-1,2,3,4-tetrahydro-2-oxopyrimidine-5-carboxylates and the 1,3-diazepines **8***a*–**8***j* do not give violet-colored solutions with bases in dimethyl sulfoxide and dimethylformamide. These results are accommodated by a mechanism shown in Scheme 3. In the absence of kinetic measurements we are not able to eliminate the possibility that ring expansion takes place by a mechanism involving a homoallylic carbonium ion.

Recently, Ashby and Griffiths have reported (24) the reaction of potassium hydrosulfide in ethanol with **1***c* to give the 8-thia-2,4-diazabicyclo[3.2.1]octane derivatives **14***a* and **14***c*. We have studied[10] the reaction of compounds **1***a* and **1***c* with sulfhydryl ion and have similarly observed the formation of compounds **14***a*–**14***c*, whose structures follow from the lack of ultraviolet maxima above 210 nm, the presence of saturated acid or ester and unsaturated ester carbonyl frequencies in the infrared spectra, and

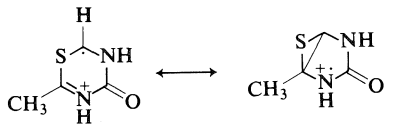
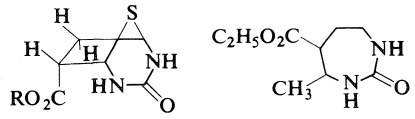
the formation of the ion **15** at *m/e* 130 by loss of acrylic acid or its esters in the mass spectra. The nmr spectra are in agreement with those reported (24). In addition, we have obtained chemical confirmation for this structure. Thus carboxylic acid **14***a* eliminated urea on treatment with acid to yield the known 2-methyl-3-thenoic acid and desulfurization of **14***c* with Raney nickel gave the hexahydro-2-oxo-1,3-diazepine **16**.



15



14

16

a R = H
b R = CH_3
c R = C_2H_5

Compounds **1***c*, **8***f*, and **9***d* were screened for pharmacological activity, and found to have no *in vitro* antibiotic, antiparasitic, enzyme inhibitory, contraceptive, and antihypertensive activity.

Experimental

Melting points were determined using a Fisher–Johns melting point apparatus. Infrared spectra were obtained in chloroform solution using a Perkin-Elmer 237B grating infrared spectrometer. Ultraviolet spectra were measured on Unicam SP 800D or Perkin-Elmer 202 spectrophotometers using solutions in 95% ethanol. Spectra were calibrated using the bands at 2850.7 and 1601.4 cm^{-1} of polystyrene (ir) or at 279.4 and 360.9 nm of a holmium oxide filter (uv). The pmr spectra were obtained on Varian HA 100 or EM 360 spectrometers using deuterochloroform as solvent unless specified otherwise. All chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. Mass spectra were determined at 70 eV ionizing energy using a Hitachi–Perkin-Elmer RMU 6E mass spectrometer. Only the most intense peaks are listed; normalized intensities are given in parentheses. Initial and final total ion current values differed by $< 5\%$. New compounds were homogeneous by tlc and elemental analyses were performed by Alfred Bernhardt, West Germany. The identity of known compounds was established by mp, mixture mp, and comparison of ir, pmr, and ms with those of authentic specimens.

Ethyl 3-ureidocrotonate was prepared by the method of Donleavy and Kise (15). The product, after two recrystallizations had mp 169.5–170.5 °C (lit. (15) mp 170 °C). Methyl 3-ureidocrotonate was prepared in a similar manner and had mp 186–186.5 °C (lit. (31) mp 180–181 °C); pmr (DMSO-d_6) δ 2.28 (s, CH_3 at C_3), 3.63 (s, methyl ester), 4.82 (d, $J \sim 1$ Hz, olefinic H), 6.83 (br s, NH_2), 10.2 (br s, NH).

Methyl 4-Chloromethyl-1,2,3,4-tetrahydro-6-methyl-2-oxopyrimidine-5-carboxylate, ***1a***

Methyl 3-ureidocrotonate **2***a* (15.8 g) was stirred to a stiff paste with 1,2-dichloroethyl ethyl ether (15.7 g) and heated slowly to 95 °C. At this temperature the reaction mixture existed as two liquid phases and on mixing, a vigorous reaction occurred in which hydrogen chloride and ethanol vapour were evolved. After a few minutes the melt solidified and was then cooled, triturated with absolute methanol (15 ml), and filtered. The solid was suspended in absolute methanol and heated under reflux for 6 h, during which time a slow stream of dry hydrogen chloride was passed through the solution.[11] The resulting solution was then concentrated, cooled, and the crude product obtained by filtration. Recrystallization once from methanol and twice from dry acetone yielded the pure product (11.2 g, 51%), mp 196 °C. *Anal.* calcd. for $C_8H_{11}ClN_2O_3$: C 43.92, H 5.07, Cl 16.20, N 12.80; found: C 44.09, H 4.91, Cl 16.15, N 12.67.

[11]Elimination of ethanol in the presence of hydrogen chloride in the early stages of the reaction caused some ester exchange.

The ir 3420, 1705, 1685, 1640 cm^{-1}; pmr δ (DMSO-d_6) 2.22 (s, 3H, CH_3 at C_6), 3.59 (d, J = 3.8 Hz, 2H, —CH_2-Cl), 3.66 (s, 3H, —CO_2CH_3), 4.43 (doublet t approximating to a q, J = 3.8 Hz and 7.5 Hz, 1H, H at C_4), 7.49 (br d, $J \sim 3$ Hz, 1H, N_1-H), 9.25 (br s, N_3-H): on addition of D_2O, the NH absorptions at δ 7.49 and 9.25 disappeared and the signal at δ 4.43 simplified to a triplet, J = 3.8 Hz; mass spectrum *m/e* 218(0.5, M^+, ^{35}Cl), 169(100) 137(53), 42(15).

Ethyl 4-Chloromethyl-1,2,3,4-tetrahydro-6-methyl-2-oxopyrimidine-5-carboxylate, **1***c*

The crude material obtained from the reaction of ethyl 3-ureidocrotonate (**2***b*, 8.6 g) with 1,2-dichloroethyl ethyl ether (7.9 g) was recrystallized twice from acetone to give the pure product **1***c* (7.56 g, 65%) as colorless needles, mp 176.5–177 °C. *Anal.* calcd. for $C_9H_{13}ClN_2O_3$: C 46.42, H 5.59, Cl 15.27, N 12.03; found: C 46.28, H 5.74, Cl 15.13, N 11.94. The ir 3420, 1705, 1682, 1645 cm^{-1}; pmr δ (DMSO-d_6) 1.27 (t, J = 7 Hz, 3H, CH_3 of ethyl), 2.22 (s, 3H, CH_3 at C_6), 3.62 (d, J = 4.5 Hz, 2H, CH_2Cl), 4.12 (q, J = 7 Hz, 2H, CH_2 of ethyl), 4.45 (m, 1H, H at C_4) 7.5 (br d, 1H, N_1-H) 9.2 (br s, 1H, N_3-H): on addition of D_2O the NH absorptions at δ 7.5 and 9.2 disappeared and the multiplet at δ 4.45 collapsed to a triplet (J = 4.5 Hz); ms, *m/e* 232(1, M^+, ^{35}Cl), 189(3), 187(9), 183(100), 155(34), 137(35), 110(5), 86(5), 84(4), 42(14).

The chloromethyl compound **1***c* (20 mg), tri-*n*-butyltin hydride (213 mg), and azobisisobutyronitrile (2 mg) in dry xylene (1.5 ml) were heated at 90 °C for 24 h. After evaporation of the xylene at reduced pressure, the crude material was separated by preparative tlc using silica gel GF_{254} and 4:1 benzene–acetone as eluting solvent. Further purification by sublimation at 80 °C/0.01 torr, gave the product, ethyl 1,2,3,4-tetrahydro-4,6-dimethyl-2-oxopyrimidine-5-carboxylate (8 mg, 47%); mp 193–194 °C (lit. (32) mp 192.5–193.5 °C), mixture mp 193.5–194 °C, which had identical ms to that of authentic material and in particular had major ions at *m/e* 198, 183, 155, 137.

Ethyl 2,3,6,7-Tetrahydro-4-methyl-2-oxo-1H-1,3-diazepine-5-carboxylate, **8***e*

Sodium borohydride (0.25 g) was added over 10 min to a stirred solution of the chloromethyl compound **1***c* (0.50 g) at 75 °C. After stirring for a further 1½ h, the acetonitrile was evaporated and water (10 ml) added to the residue. Extraction with chloroform (4 × 10 ml) gave the almost pure product (0.40 g). Purification by sublimation at 80 °C/0.01 torr or recrystallization from ethanol gave pure ethyl 2,3,6,7-tetrahydro-4-methyl-2-oxo-1*H*-1,3-diazepine-5-carboxylate (0.37 g, 87%); mp 194–195 °C (lit. (24) mp 192–193 °C). *Anal.* calcd. for $C_9H_{14}N_2O_3$: C 54.53, H 7.12, N 14.13; found: C 54.58, H 7.06, N 14.04. The ir 3425, 3396, 3216, 1692, 1645; the pmr (pyridine-d_5) δ 1.08 (t, J = 7.0 Hz, CH_3 of ethyl ester), 2.42 (s, CH_3 at C_4), 2.68 (m, 6-CH_2), 3.27 (m, 7-CH_2), 4.07 (q, J = 7.0 Hz, CH_2 of ethyl ester), 8.27 (br s, N_1-H) 9.08 (N_3-H).

Methyl 6-Dibromomethyl-1,2,3,4-tetrahydro-4-methyl-2-oxopyrimidine-5-carboxylate

A solution of bromine (17.6 g) in chloroform (100 ml) was added, over a period of 15 min to a suspension of methyl 1,2,3,4-tetrahydro-4,6-dimethyl-2-oxopyrimidine-5-carboxylate (9.2 g) in chloroform (100 ml). The solid rapidly dissolved after approximately 10 ml of the bromine solution had reacted. Considerable heat was evolved as the reaction proceeded, accompanied by brisk evolution of hydrogen bromide. After briefly refluxing on a stream bath, the chloroform solution was cooled, washed with saturated sodium bicarbonate solution (3 × 5 ml) and water (2 × 50 ml), and dried ($MgSO_4$). Removal of the solvent on the rotary evaporator yielded an orange gum which crystallized on treatment with methanol. The crude material (16.2 g) was recrystallized twice from methanol–benzene (1:5, v/v) to give the pure product (14.1 g, 82%) as colorless needles mp 162–162.5 °C. *Anal.* calcd. for $C_8H_{10}Br_2N_2O_3$: C 28.07, H 2.92, Br 46.75, N 8.18; found: C 28.11, H 3.05, Br 46.94, N 8.32. The ir 3422, 1720, 1705, 1645 cm^{-1}; pmr (DMSO-d_6) 1.16 (d, J = 6.5 Hz, CH_3 at C_4), 3.77 (s, CH_3 of ester), 4.23 (m, a double q, approximating to a 1:1:1:1 q, J = 6.5 Hz and 3 Hz H at C_4), 7.5 (br s, N_3-H), 8.0 (s, $CHBr_2$), 9.47 (br s, 1H, N_1-H); exchange of the NH protons using D_2O simplified the signal at δ 4.23 to a quartet (J = 6.5 Hz); ms 340(2, M^+, ^{79}Br isotopes), 329(47), 327(91), 325(47), 167(100).

Methyl 6-Dibromomethyl-4-chloromethyl-1,2,3,4-tetrahydro-2-oxopyrimidine-5-carboxylate, **1***b*

Following the procedure used in the previous preparation, bromine (8.8 g) in chloroform (75 ml) was reacted with the chloromethyl compound **1***a* (5.4 g) in chloroform (75 ml). The reaction mixture was washed with 5% sodium acetate solution (3 × 50 ml), water (2 × 50 ml), and worked-up in the manner indicated. The crude product was recrystallized from methanol to give colorless crystals of **1***b* (8.1 g, 87%); mp 186–187 °C. *Anal.* calcd. for $C_8H_9Br_2ClN_2O_3$: C 25.47, H 2.39, Br 42.50, Cl 9.41, N 7.43; found: C 25.56, H 2.52, Br 42.37, Cl 9.49, N 7.61. The ir 3405, 1720, 1710, 1640 cm^{-1}; the pmr (DMSO-d_6): δ 3.7 (d, $J \sim 4$ Hz, 2H, CH_2Cl), 3.77 (s, 3H, CH_3O_2C), 4.53 (double t approximating to q, $J \sim 4$ Hz and 3 Hz, 1H, H at C_4), 7.6 (br, 1H, N_3-H), 8.03 (s, 1H, $CHBr_2$), 9.65 (br s, 1H, N_1-H). Deuterium exchange simplified the signal at δ 4.53 to a t $J \sim 4$ Hz.

Methyl 1-Carbamoyl-2-methylpyrrole-3-carboxylate, **9***c*

(*a*) To a solution of the chloromethyl compound **1***a* (2.2 g) in methanol (100 ml) was added potassium hydroxide (0.84 g) in water (15 ml). After stirring overnight at room temperature, water (50 ml) was added and the solution was concentrated to approximately 70 ml on a rotary evaporator. The aqueous solution was extracted with ether (3 × 50 ml) and then acidified with hydrochloric acid (3 ml, 6 *N*). The aqueous solution was cooled in ice for 3 h and then filtered to yield the 1-carbamoylpyrrole **9***c* as almost colorless needles. Recrystallization from aqueous methanol and sublimation at 125 °C/0.05 torr yielded the pure product (1.32 g, 72%); mp 210–211 °C. *Anal.* calcd. for $C_8H_{10}N_2O_3$: C 52.74, H 5.53, N 15.38, found: C 52.66, H 5.36, N 15.26. The ir 3512, 3405, 1738, 1707, 1588, 1570, 1440, 1375, 1320 cm^{-1}; the pmr (DMSO-d_6): δ 2.73 (s, CH_3 at C-2), 3.78 (s, CH_3 of methyl ester), 6.53 (d, J = 3.5 Hz,

4-H), 7.25 (d, J = 3.5 Hz, 5-H), 7.79 (br s, 2H, NH_2); the ms m/e 182(51, M^+), 139(76), 124(32), 108(100), 107(42), 106(20).

Evaporation of the dried ($MgSO_4$) ether extract yielded a low-melting solid identified, after sublimation at 55 °C/0.1 torr, as methyl 2-methylpyrrole-3-carboxylate **9***a*; mp 64 °C (lit. (33) mp 63–64 °C, (34) mp 67–68 °C) and whose spectral properties were consistent with those reported for this compound.

The 1-carbamoyl pyrrole **9***c* was also formed from the chloromethyl compound by the action of sodium bicarbonate in dimethyl sulfoxide.

(*b*) A solution of the methoxydiazepine **8***b* (1.05 g) in absolute methanol (50 ml) was treated with a slow stream of dry hydrogen chloride. The solution became very warm and after a few minutes developed a bright green color which almost immediately faded. At this point, the gas flow was halted and the solution allowed to cool. The solvent was removed under reduced pressure and the residue purified by recrystallization from aqueous methanol and sublimation at 125 °C/0.05 torr to give the product **9***c* (0.85 g, 95%); mp 210–211 °C undepressed on admixture with the product from (*a*) and having identical spectral properties.

*Ethyl 1-Carbamoyl-2-methylpyrrole-3-carboxylate, **9d***

Finely ground chloromethyl compound **1***c* (2.3 g) was added, in portions of approximately 0.25 g, to a stirred mixture of aqueous potassium hydroxide (15 ml, 1 *M*) and ethanol (10 ml). Stirring was continued for 12 h at room temperature, when hydrochloric acid was added (3 ml, 6 *M*). After cooling in ice, the crude product was filtered off and recrystallized from aqueous ethanol. Sublimation at 110–115 °C/0.05 torr yielded the pure product **9***d* (1.4 g, 71%); mp 186–187 °C. *Anal.* calcd. for $C_9H_{12}N_2O_3$: C 55.09, H 6.17, N 14.28; found: C 55.01, H 6.04, N 14.12. The ir 3510, 3400, 1740, 1702, 1585, 1570 cm^{-1}; pmr (DMSO-d_6) δ 1.27 (t, J = 7 Hz, CH_3 of ethyl), 2.7 (s, CH_3 at C-2), 4.23 (q, J = 7 Hz, 2H, CH_2 of ethyl), 6.49 (d, J = 3.5 Hz, H at C-4), 7.2 (d, J = 3.5 Hz, H at C-5), 7.75 (br s, 2H, NH_2); the broad singlet at δ 7.75 disappeared in the presence of D_2O; ms m/e 196(38, M^+), 153(54), 124(93), 108(100), 107(28), 106(21), 80(24), 53(29).

*The Reaction of the Chloromethylpyrimidine **1a** with Anhydrous Potassium Fluoride*

The chloromethyl compound **1***a*, (218 mg) and anhydrous potassium fluoride (580 mg) in dried acetonitrile (30 ml) were heated under reflux for 4 days and then evaporated to dryness. The solid residue was washed with water (2 × 5 ml), and the residue extracted with benzene (3 × 10 ml). The benzene solution was dried ($MgSO_4$), filtered, and evaporated to give a colorless solid (119 mg) which afforded, after sublimation at 40–50 °C/0.01 torr, colorless crystals (84 mg, 60%), identified as methyl 2-methylpyrrole-3-carboxylate; mp 64 °C (lit. (33) mp 63–64 °C, (34) 67–68 °C) having spectral properties identical with an authentic specimen.

*3-Ethoxycarbonyl-1-methoxycarbonyl-2-methylpyrrole **9e** and Reaction with Ammonia*

A solution of ethyl 2-methylpyrrole-3-carboxylate (1.5 g) in dry ether (25 ml) was added to the Grignard solution prepared from the reaction of ethyl iodide (1.5 g) and magnesium (0.25 g) in dry ether (25 ml). To the well-stirred solution, under nitrogen, dimethyl carbonate (1.9 g) in ether (10 ml) was added. The resulting mixture was stirred at room temperature for 2 h and then refluxed for 12 h. The reaction mixture was treated with 10% ammonium chloride and then extracted with ether (3 × 20 ml). Evaporation of the ether extract yielded an orange oil which was chromatographed on neutral alumina (Fluka type 507C neutral) using benzene as eluant. The first fractions were evaporated and purified by sublimation at 35 °C/0.01 torr to give the product as colorless crystals; mp 40 °C (lit. (35) mp 39.5–41 °C) ms, m/e 211(82, M^+), 182(100), 166(70), 165(30), 138(31), 122(25), 106(26), 59(45), 42(26); the ir, uv, and pmr were identical with those reported by Biellmann and Goeldner (35).

The above pyrrole diester (50 mg) was dissolved in anhydrous methanol (5 ml) and the solution saturated with dry ammonia gas. After standing overnight at room temperature, the solution was evaporated and the residue purified by sublimation at 40 °C/0.01 torr when crystals (31 mg, 85%) of ethyl 2-methylpyrrole-3-carboxylate **9***b* were obtained. No traces of ethyl 1-carbamoyl-2-methylpyrrole-3-carboxylate **9***d* were found on examination of the crude product by both tlc and mass spectrometry.

*Methyl 7-Methoxy-2,3,6,7-tetrahydro-4-methyl-2-oxo-1H-1,3-diazepine-5-carboxylate, **8b***

(*a*) A solution of the chloromethyl compound **1***a* (4.4 g) and sodium methoxide (6.1 g) in absolute methanol (250 ml) was stirred at room temperature for 24 h, then distilled until 120 ml of methanol had been collected. To the concentrate, water was added and after cooling in ice for 2 h the crude product was obtained by filtration. Recrystallization from absolute methanol yielded the pure product **8***b* (3.1 g, 70%); mp 199–200 °C. *Anal.* calcd. for $C_9H_{14}N_2O_4$: C 50.46, H 6.59, N 13.08; found: C 50.33, H 6.44, N 12.98. The ir 3415, 3395, 1700, 1685, 1680, 1640 cm^{-1}; pmr (pyridine-d_5, HA 100) δ 2.51 (d, $J_{homoallylic}$ = 1 Hz, CH_3 at C_4), 2.67 (br d, J_{AM} = 14.5 Hz, H_A at C_6), 3.35 (s, CH_3O—), 3.70 (q, J_{AM} = 14.5 Hz, J_{MX} = 6.5 Hz, H_M at C_6), 3.67 (s, CH_3 of ester) 4.76 (m, J_{MX} = 6.5 Hz, J_{AX} = 2 Hz, H_X at C_7), 9.13 (br d, H at N_1), 9.66 (br s, H at N_3). Irradiation at δ 4.76 caused the q at δ 3.70 to collapse to a d, J = 14.5 Hz but no change in the d at δ 2.67; irradiation at δ 2.67 caused the q at δ 3.70 to change to a d, J = 6.5 Hz; addition of D_2O to the solution resulted in disappearance of the signals δ 9.13 and 9.66 while the resonance at δ 4.76 changed to a q; ms m/e 214(5, M^+), 182(54), 151(22), 140(43), 123(21), 108(49), 96(17), 60(100), 42(41).

(*b*) The chloromethyl compound (4.4 g) was reacted with a solution of potassium hydroxide (1.2 g) in methanol (170 ml) by the above procedure and yielded the product (2.7 g, 61%) identical in all respects with that obtained in (*a*) above.

*Ethyl 7-Methoxy-2,3,6,7-tetrahydro-4-methyl-2-oxo-1H-1,3-diazepine-5-carboxylate, **8e***

A solution of the chloromethyl compound **1***c* (2.3 g) and tetramethylammonium hydroxide (2 ml, 0.2 *M* aqueous) in methanol (100 ml) was stirred at room temperature for 24 h and then concentrated by distilla-

tion to about 30 ml. Addition of water (30 ml) afforded a crystalline material which recrystallized from methanol to give the pure methoxydiazepine **8***e* (1.8 g, 78%) as small, colorless prisms; mp 195–196 °C. *Anal.* calcd. for $C_{10}H_{16}N_2O_4$: C 52.60, H 7.02, N 12.28; found: C 52.42, H 7.04, N 12.19. The ir 3412, 3395, 1698, 1685, 1675, 1640 cm^{-1}; pmr (DMSO-d_6) δ 1.2 (t, J = 7 Hz, CH_3 of ethyl), 2.17 (s, CH_3 at C_4), 2.5 approximately (d of H_A, partly obscured by DMSO), 2.97 (one half of the H_B quartet, J_{BX} = 5 Hz approximately), 3.18 (s, CH_3O at C_7, conceals one half of H_B quartet), 4.07 (q, J = 7 Hz, CH_2 of ethyl ester) 4.43 (m, overlaps with q at δ 4.07, H_X at C_7), 7.95 (br, N_1-H), 8.5 (br, N_3-H), ms *m/e* 228(4, M^+), 196(33), 151(21), 60(100), 42(24).

Methyl 7-Cyano-2,3,6,7-tetrahydro-4-methyl-2-oxo-1H-1,3-diazepine-5-carboxylate, 8a

When sodium cyanide (2.5 g) was added to a stirred solution of the chloromethyl compound **1***a* (4.4 g) in dimethyl sulfoxide (35 ml), an intense violet color was immediately developed, which faded over 0.5 h to give a yellow solution. Stirring was continued for 12 h at room temperature, when sodium chloride was precipitated. Ice water (500 ml) was then added and the precipitated product was collected and washed with water, methanol (25 ml), and ether (25 ml). Recrystallization from aqueous methanol yielded the colorless crystalline product (3.3 g, 78%); mp 238–239 °C (dec.). *Anal.* calcd. for $C_9H_{11}N_3O_3$: C 51.67, H 5.30, N 20.09; found: C 51.87, H 5.30, N 20.02. The ir (KBr) 3320, 3225, 3100, 2240, 1695–1670 (broad), 1620 cm^{-1}; pmr (DMSO-d_6) δ 2.27 (s, 3H, CH_3 at C_4), 2.63 (br d partially obscured by DMSO signal, J_{AM} ~ 16 Hz, H_M at C_6), 3.28 (q, 1H, J_{AM} = 15.5 Hz, J_{AX} = 6 Hz, H_A at C_6), 3.68 (s, 3H, CH_3O_2C), 4.73 (m, 1H, H_X of AMX coupled to N_1-H), 7.95 (br d, 1H, J ~ 6.5 Hz N_1-H), 8.77 (br s, 1H, N_3-H); the CH_XCN multiplet, which is symmetrical since the coupling constants to H_A and N_1-H are almost the same, is simplified to a double doublet J_{AX} = 6 Hz, J_{MX} ~ 2.5 Hz on addition of D_2O; ms *m/e* 209(69, M^+) 182(57), 178(29), 177(14), 150(27), 128(41), 123(24), 122(23), 108(24), 96(100), 68(22), 55(53), 53(25), 42(67).

Ethyl 7-Cyano-2,3,6,7-tetrahydro-4-methyl-2-oxo-1H-1,3-diazepine-5-carboxylate, 8f

Reaction of the chloromethyl compound **1***c* (5.0 g) and sodium cyanide (2.5 g) in dimethyl sulfoxide (30 ml) in a similar manner to the above yielded, after recrystallization from aqueous ethanol, the pure product (4.1 g, 84%); mp 236–237 °C (dec.). *Anal.* calcd. for $C_{10}H_{13}N_3O_3$: C 53.80, H 5.87, N 18.83; found: C 53.62, H 5.69, N 18.95. The ir (KBr) 3322, 3225, 2243, 1695–1670 (broad) 1622 cm^{-1}; the pmr (DMSO-d_6) δ 1.22 (t, J = 7 Hz, 3H, CH_3 of ethyl), 2.25 (s, 3H, CH_3 at C_4), 2.62 (d, partially obscured by DMSO signal, J_{AM} ~ 15.5 Hz, H_M), 3.23 (q, 1H, J_{AM} = 16 Hz, J_{AX} ~ 5.5 Hz, H_A), 4.13 (q, J = 7 Hz, 2H, CH_2 of ethyl), 4.72 (m, 1H, CH_XCN coupled to N_1-H), 7.9 (br m, 1H, N_1-H), 8.73 (br s, 1H, N_3-H); deuteration caused the H_X signal to collapse to a double doublet, J_{AX} = 5 Hz, J_{MX} ~ 2 Hz; ms *m/e* 223(36, M^+), 196(34), 178(30), 150(23), 142(26), 123(23), 122(20), 96(100), 42(61).

Ethyl 7-Ethoxy-2,3,6,7-tetrahydro-4-methyl-2-oxo-1H-1,3-diazepine-5-carboxylate, 8h

The chloromethyl compound **1***c* (4 g) and potassium cyanate (4 g) were refluxed in dry ethanol (300 ml) for 15 h. The ethanol solution was then decanted from inorganic material, evaporated, water (20 ml) added, and the resulting suspension extracted with chloroform (4 × 25 ml). The chloroform extract was washed with water (2 × 10 ml), dried ($MgSO_4$), filtered, and evaporated. Crystallization of the residue from aqueous ethanol yield the product as pale yellow crystals (3.47 g, 83%); mp 171–172 °C (lit. (24) mp 164–166 °C).

Methyl 2,3,6,7-Tetrahydro-4-methyl-2-oxo-7-(1-succinimino)-1H-1,3-diazepine-5-carboxylate, 8c

The chloromethyl compound **1***a* (1 g) and potassium succinimide (0.756 g) in dimethylformamide (10 ml) were stirred for 24 h at room temperature. Water (80 ml) was added and after cooling for 4 h at 0 °C, the precipitated solid was obtained by filtration and recrystallized from methanol to give the succiniminodiazepine **8***c* (0.637 g, 53%) mp 216–217.5 °C (dec). *Anal.* calcd. for $C_{12}H_{15}N_3O_5$: C 51.24, H 5.38, N 14.94; found: C 51.36, H 5.32, N 14.96. The ir (KCl) 3336, 3196, 1711, 1681, 1636 cm^{-1}; pmr (DMSO-d_6) δ 2.14 (s, CH_3 at C_4), 2.53 (s, CH_2—CH_2 of succinimino group), 2.60–3.40 (m, H's at C_6), 3.60 (s, CH_3 of ester), 5.09 (dd, H at C_7), 7.10 (br s, N_1-H), 8.52 (br s, N_3-H); ms *m/e* 281(2, M^+), 182(100), 151(27), 140(69), 123(31), 108(63), 99(82), 96(30), 56(78), 55(31), 42(60).

Ethyl 2,3,6,7-Tetrahydro-4-methyl-2-oxo-7-(1-succinimino)-1H-1,3-diazepine-5-carboxylate, 8i

The chloromethyl compound **1***c* (4.31 g) and potassium succinimide (3.738 g) in dry dimethylformamide (20 ml) were stirred at room temperature for 20 h. The dimethylformamide was removed at 50 °C/0.01 torr and the residue triturated with water (30 ml) and cooled in the refrigerator to give, after filtration, the almost pure product **8***i* (4.295 g, 78%). The pure succinimino compound, mp 202–205 °C, was obtained by recrystallization from ethanol. *Anal.* calcd. for $C_{13}H_{17}N_3O_5$: C 52.88, H 5.80, N 14.23; found: C 52.84, H 5.74, N 14.23. The ir 3490, 3233, 1718 (sh), 1710, 1641 cm^{-1}; pmr (pyridine-d_5) δ 1.02 (t, J = 7.0 Hz, CH_3 of ethyl ester), 2.39 (s, CH_3 at C_4 and —CH_2CH_2— of succinimino group), 3.03 (dd, J_{AM} = 14 Hz, J_{AX} = 2.5 Hz, H_A at C_6), 3.72 (br t, overlaps with signal at δ 4.02, J_{AM} = 14 Hz, J_{MX} = 10 Hz, H_M at C_6), 4.02 (q, J = 7.0 Hz, CH_2 of ethyl ester), 5.76 (dd, J_{AX} = 2.5 Hz, J_{MX} = 10 Hz, H_X at C_7), 8.38 (br s, N_1-H), 9.68 (br s, N_3-H); ms *m/e* 295(0.7, M^+), 250(1.5), 196(100), 155(20), 151(39), 150(45), 124(32), 123(27), 108(27), 99(77), 56(47), 42(21).

Ethyl 7-Diethoxycarbonylmethyl-2,3,6,7-tetrahydro-4-methyl-2-oxo-1H-1,3-diazepine-5-carboxylate, 8j

Sodium hydride in paraffin (1.5 g, approximately 1:1) was washed with dry petroleum ether (4 ml) and anhydrous tetrahydrofuran (2 × 4 ml). The remaining solid was suspended in anhydrous tetrahydrofuran (4 ml) and diethyl malonate (1.93 g) was added. After stirring for 0.5 h, the chloromethyl compound **1***c* (2.32 g) was added and stirring continued for 3 days. After addition of water (25 ml) the crystals (2.53 g, 71%) thus obtained were filtered off and shown to be homogeneous by tlc. Recrystallization from 95% ethanol gave the product as colorless needles; mp 157–159 °C. *Anal.* calcd. for $C_{16}H_{24}N_2O_7$: C 53.93, H 6.79, N 7.86; found: C 53.74, H 6.71, N 8.02. The ir (KCl) 3321 and 3206 (NH str.),

1749 (malonate ester), 1693 (unsaturated ester), 1676 (urea C=O), and 1614 (C=C) cm^{-1}; pmr δ 1.25 (t, J = 7.0 Hz, 9H, CH_3's of ethyl esters), 2.25 (s, CH_3 at C_4), 2.4–3.4 (m, 2H, 6-CH_2), 3.49 (d, J = 9.0 Hz, CH of malonate), 4.19 (m, CH_2's of ethyl esters and H at C_7), 6.15 (s, N_1-H), 7.95 (s, N_3-H); ms *m/e* 356(1, M^+), 311(9), 196(100), 151(17), 142(59), 133(25), 115(36), 96(31), 43(34), 42(22).

Methyl 7-Diethoxycarbonylmethyl-2,3,6,7-tetrahydro-4-methyl-2-oxo-1H-1,3-diazepine-5-carboxylate, ***8d***

Reaction of the chloromethyl compound **1***a* (0.438 g) with sodiodiethylmalonate in an analogous manner yielded the product **8***d* (0.336 g, 49%) as colorless needles, mp 161–162 °C. *Anal.* calcd. for $C_{15}H_{22}N_2O_7$: C 52.63, H 6.48, N 8.18; found: C 52.95, H 6.41, N 8.27. The ir (KCl) 3329 and 3209 (N—H str.), 1741 (ester of malonate), 1698 (unsaturated ester), 1676 (urea C=O), and 1616 (C=C) cm^{-1}; pmr δ 1.25 (t, 6H, CH_3 of ethyl esters), 2.86 (m, 2H, 6-CH_2), 3.47 (d, J = 9.0 Hz, 1H, CH of malonate), 3.67 (s, 3H, methyl ester), 4.19 (overlapping q and unresolved m, 5H, CH_2's of ethyl ester and H at C_7), 6.05 (br d, N_1-H), 7.73 (br s, N_3-H); ms *m/e* 342(3, M^+), 182(100), 151(13), 140(18), 133(24), 128(60), 115(31), 96(29), 43(28), 42(22).

Methyl 1-Methyl-3-oxo-8-thia-2,4-diazabicyclo[3.2.1]-octane-7-carboxylate, ***14b***

To a solution of the chloromethylpyrimidine **1***a* (4.38 g) in anhydrous methanol (150 ml) was added potassium hydrosulfide solution (8 ml of 6.3 × 10^{-3} M), and the mixture stirred at 50–60 °C for 2 h. After concentrating to approximately 30 ml, the mixture was cooled, diluted with ether (100 ml), and allowed to stand at 0 °C overnight. The solid (3.42 g) which deposited was crystallized twice from aqueous methanol to yield the product (2.09 g, 48%) as colorless cubic crystals which decomposed at 200 °C. *Anal.* calcd. for $C_8H_{12}N_2O_3S$: C 44.44, H 5.56, N 12.95, S 14.80; found: C 44.32, H 5.51, N 12.79, S 14.70. The ir (KBr) 3575, 3515, 3315, 3205, 1745, 1730, 1677, 1643 cm^{-1}; pmr (DMSO-d_6) δ 1.83 (s, 3H, CH_3 at C-1), 2.1–3.45 (complex signals partly obscured by DMSO signal, approximately 3H), 3.68 (s, 3H, methyl of ester), 5.03 (m, approximately t, 1H, H at C-5), 7.35–7.75 (two overlapping resonances, total 2H, N_2-H and N_4-H). Deuteration caused disappearance of signals at δ 7.35–7.75 and conversion of the δ 5.03 signal to a double d (J = 3.5, 1 Hz approximately); ms *m/e* 216(22, M^+) 183(21), 130(100), 84(22), 59(21), 42(37).

Ethyl 1-Methyl-3-oxo-8-thia-2,4-diazabicyclo[3.2.1]-octane-7-carboxylate, ***14c***

Reaction of the chloromethyl compound **1***c* with sodium hydrosulfide in a manner similar to that of Ashby and Griffiths yielded, after recrystallization three times from ethanol and once from water, the product; mp 203–205 °C (lit. (24) mp 200–202 °C).

Acid-catalyzed Hydrolysis of 1-Methyl-3-oxo-8-thia-2,4-diazabicyclo[3.2.1]octane-7-carboxylic Acid ***14a*** *to 2-Methyl-3-thenoic acid*

The sulfur compound **14***a* (24) (0.200 g) was refluxed with concentrated hydrochloric acid (30 ml) for 4.5 h, cooled, and extracted with chloroform (3 × 30 ml). The bulked chloroform extract was evaporated and the brown tarry residue extracted with water (8 ml) over a steam bath for 0.5 h. The aqueous solution was then decanted and cooled when 2-methyl-3-thenoic acid (0.01 g, 7%) was obtained as brownish yellow crystals; mp 114–116 °C (lit. (36) mp 115–117 °C). The product has identical ir, uv, nmr, and ms to material prepared by the method of Gaertner (36).

Ethyl 2,3,4,5,6,7-Hexahydro-4-methyl-2-oxo-1H-1,3-diazepine-5-carboxylate, ***16***

The sulfur compound **14***c* (0.245 g) and Raney nickel W2 (approximately 3 g) in 90% ethanol (100 ml) were refluxed with stirring for 4 h. The reaction mixture was then cooled, filtered through a pad of Celite, and evaporated to give a colorless residue (202 mg, 95%); mp 140.5–142 °C. *Anal.* calcd. for $C_9H_{16}N_2O_3$: C 53.99, H 8.05, N 13.99; found: C 54.01, H 8.09, N 13.99. The ir 3420, 1727, 1666 cm^{-1}; the nmr δ 1.24 (t, J = 7.0 Hz, CH_3 of ethyl ester), 1.25 (d, J = 7.0 Hz, CH_3 at C_4), 2.0 (m, 2H, 6-CH_2), 2.69 (m, 1H, H at C_5), 3.17 (m, 2H, 7-CH_2), 3.80 (m, 1H, H at C_4), 4.13 (q, 2H, J = 7.0 Hz, CH_2 of ethyl ester), 5.60 (br s, NH), 5.98 (br s, NH); after exchange with D_2O, the m at δ 3.80 changed to two q, J = 7.0 Hz and 3.2 Hz; ms *m/e* 200(6, M^+), 101(8), 86(8), 73(10), 55(8), 44(100).

N-Methylamino acids in peptide synthesis. V. The synthesis of *N*-*tert*-butyloxycarbonyl,*N*-methylamino acids by *N*-methylation[1]

S. T. CHEUNG AND N. LEO BENOITON

Department of Biochemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9A9

Received August 23, 1976

S. T. CHEUNG and N. LEO BENOITON. Can. J. Chem. **55**, 906 (1977).

The preparation of enantiomerically pure *N*-*tert*-butyloxycarbonyl,*N*-methylamino acids by *N*-methylation of the parent amino acid derivatives using sodium hydride and methyl iodide in tetrahydrofuran at room temperature is described for neutral amino acids including *O*-benzyl-protected threonine and tyrosine. Methylation of the *O*-benzylserine derivative under these conditions gives the *N*-methyldehydroalanine derivative. The β-elimination is completely suppressed, giving the corresponding *N*-methylserine derivative when the reaction is carried out at 5 °C. Other related data on *N*-methylation and *N*-methylamino acid derivatives are presented.

S. T. CHEUNG et N. LEO BENOITON. Can. J. Chem. **55**, 906 (1977).

On décrit la préparation des *N*-méthylamino-acides *N*-*tert*-butyloxycarbonylés optiquement purs par la *N*-méthylation, à l'aide d'hydrure de sodium et d'iodure de méthyle dans le tétrahydrofuranne à la température de la pièce, de dérivés des acides aminés correspondants; cette méthode a été appliquée aux acides aminés neutres, y compris la thréonine et la tyrosine protégées par un groupe *O*-benzyle. La méthylation du dérivé de la *O*-benzylsérine, dans de telles conditions, conduit au dérivé de la *N*-méthyldéhydroalanine. Lorsque l'on effectue la réaction à 5 °C, l'élimination β est complètement supprimée et l'on obtient le dérivé *N*-méthylsérine correspondant. On présente d'autres données sur la *N*-méthylation et les dérivés d'acides *N*-méthylaminés.

[Traduit par le journal]

Easy access to derivatives of *N*-methylamino acids which can be used in peptide synthesis is desirable for anyone wishing to incorporate an *N*-methylamino acid into peptides. We have previously described a method of preparing *N*-benzyloxycarbonyl derivatives of *N*-methylamino acids by *N*-methylation of the *N*-benzyloxycarbonylamino acid using sodium hydride – methyl iodide in THF containing DMF at 80 °C (2),[2] and subsequently in neat THF at room temperature (4).[3] The latter method is preferable since the former also esterifies the carboxyl group, and removal of the ester group by saponification is accompanied by some racemization (6). We now report the preparation of enantiomerically pure *N*-*tert*-butyloxycarbonyl,*N*-methylamino acids by this simple procedure, a small modification which allows the preparation of derivatives of serine as well, and other data related to *N*-alkylations. In the accompanying papers, we describe a general method for determining the enantiomeric purity of *N*-methylamino acids and their derivatives (7), and report that all of the other methods except one[4] which have been used to prepare optically active *N*-methylamino acids and their derivatives do not give optically pure products (8), a fact which adds considerably to the value of our method of synthesis.

The *N*-*tert*-butyloxycarbonyl,*N*-methylamino acids which we have prepared by reaction of the parent amino acid derivative with sodium hydride (3 mol) and methyl iodide (8 mol) in THF at room temperature are described in Table 1. All

[1]Supported by a grant from the Medical Research Council of Canada. N.L.B. is an Associate of the MRCC. Presented in part at the First Chemical Congress of the North American Continent, Mexico City, Mexico, Dec. 1975. For part IV of this series, see ref. 1.

[2]The abbreviations for the amino-acid derivatives are those recommended by the IUPAC–IUB Commission on Biochemical Nomenclature (3). The amino-acid symbols represent the L-isomer. Other abbreviations used: Boc, *tert*-butyloxycarbonyl; Bz, benzoyl; Bzl, benzyl; Z, benzyloxycarbonyl; THF, tetrahydrofuran; DMF, *N*,*N*-dimethylformamide; ΔAla, didehydroalanine.

[3]Pioneering work on urethane methylation using sodium hydride – methyl iodide was done by Dannley and Lukin (5).

[4]Only the synthesis of an *N*-*p*-toluenesulfonyl,*N*-methylamino acid followed by cleavage with sodium in liquid ammonia gives an optically pure product (8).

$$(CH_3)_3COCO—NHCHR—COOH \xrightarrow[THF,\ 23\ °C]{NaH,\ CH_3I} (CH_3)_3COCO—\underset{\displaystyle CH_3}{\underset{|}{N}}CHR—COOH$$

compounds were shown to contain <0.1% of unmethylated derivative, and <0.1% of contaminating enantiomer (8), except for the *O*-benzyl derivatives whose optical purities were not established. Boc-MeVal-OH has been crystallized for the first time, albeit with difficulty. The melting points for Boc-MeAla-OH and the dicyclohexylammonium salt of Boc-MeVal-OH are higher than those recorded in the literature (see below). Higher melting points for the *N*-benzyloxycarbonyl derivatives of these two *N*-methylamino acids are also reported. These data are in line with our findings (8) that these derivatives are not optically pure when prepared by most of the other methods.[4]

The *O*-benzyl groups of Boc-Thr(Bzl)-OH and Boc-Tyr(Bzl)-OH were found to be stable to the reaction conditions, allowing preparation of the appropriate *N*-methyl derivatives. These are oils which do not precipitate out in the presence of dicyclohexylamine in light petroleum. In contrast, Boc-Ser(Bzl)-OH underwent β-elimination simultaneously with the *N*-methylation to give an excellent yield of Boc-MeΔAla-OH.[5] Similar β-eliminations have been reported for analogous reactions (11, 14). Since we had not in our previous work (4) attempted the methylation of Z-Ser(Bu^t)-OH, which should be less susceptible to β-elimination, we did the experiment and obtained a mixture containing about 75% of the desired Z-MeSer(Bu^t)-OH and 25% of Z-MeΔAla-OH.[6] The latter could be removed easily by crystallizing it out as the dicyclohexylammonium salt thus allowing a practical synthesis (60% yield) of the pure desired compound.[7] At this stage, the temperature of the reaction was lowered to see if β-elimination might be suppressed completely. At 5 °C it was,

[l]Dehydroalanine, from the methylation of Boc-Ser(Bzl)-OH. $\delta_{\beta\text{-}H}$, 5.42; $\delta_{\alpha\text{-}H}$, 6.00 ppm. [m]Methylation at 5 °C for 72 h.

[5]This derivative would be accessible also by methylation of Boc-ΔAla-OMe using methyl iodide and potassium carbonate in DMF (21).

[6]It follows that this compound could best be prepared from Z-Ser(Bzl)-OH.

[7]The rule seems to be that the Boc- and Z-methylamino acids protected on the side chain by a benzyl or *tert*-butyl group (*i.e.* for Ser, Thr, Tyr, Asp, Glu) do not form insoluble dicyclohexylammonium salts, while other derivatives exemplified by Boc-MeSer(Me)-OH, Z-MeVal-OH, Z-Ser(Bu^t)-OH, and Z-MeΔAla-OH do.

and the *N*-methylation still occurred, albeit more slowly. In fact, this allowed the preparation of not only Z-MeSer(Bu^t)-OH, but Boc-MeSer-(Bzl)-OH in 80% yield as well! It should be noted that this also provides two routes to optically pure *N*-methylserine which is not readily accessible.[8]

Several of the compounds described in Table 1 were obtained from the Boc-amino acids prepared in our own laboratory. Considerable difficulty was encountered when the Boc-amino acids (Boc-Val-OH and Boc-Phe-OH in particular) were purchased from commercial suppliers. The reactions did not go to completion, or else they went to completion only when carried out on a small scale (see below). Fortunately, we were able to resolve this dilemma, after most of this work had been carried out. It was found that there were no difficulties with the methylations when starting materials (Boc-Val-OH and Boc-Phe-OH) were left overnight *in vacuo* at 56 °C before they were used.[9]

In view of the more sluggish reaction at 5 °C, we compared the extents of *N*-methylation for the two types of derivatives and found that Z-Ala-OH had undergone 91% methylation, and Boc-Ala-OH 56% methylation, after 15 h. Hence the methylation of a Z-derivative proceeds more quickly.

In the previous paper (4), we had reported that methylations of Z-Glu-OH and Z-Asp-OH did not go to completion, probably due to precipitation during the reaction. Since other methylations have been carried out in acetonitrile (22), we investigated this solvent as an alternative to THF in case it might prove advantageous.[10] Excellent yields of Z-MeAla-OH and Z-MeLeu-OH were obtained, but no success was achieved with the dicarboxylic amino acids. Methylation of Z-Phe-OH was incomplete, but Z-MePhe-ONa precipitated from the aqueous solution during work-up, and regeneration of this gave pure Z-MePhe-OH (32%), mp 68–69 °C (lit. (11) mp 65–70 °C; (23) mp 69–71 °C). Acetonitrile, therefore, can be used as solvent for the methylations, but it does not offer any obvious advantage.

In order to see if *N*-acyl,*N*-methylamino acids could also be prepared by our method, a few *N*-acylamino acids were methylated. The results, as well as others obtained using the methylation procedure of Olsen (silver oxide and methyl iodide in DMF) (11), are given in Table 2. All these methylations were incomplete, except that of Bz-Leu-OH using our procedure. Moreover, the Bz-MeIle-OH obtained was shown to be partially epimerized. The reaction can be made to go to completion if carried out at 80 °C in the presence of DMF (2), however, these conditions also esterify the carboxyl group. Z-Ala-OH also was nearly completely esterified when a reaction was carried out at 80 °C in the absence of DMF. Since the ester group would normally be removed by saponification, and basic conditions are known to partially racemize fully protected *N*-methylamino acids (6), it would seem that this approach for the preparation of optically active *N*-acyl,*N*-methylamino acids is likely not to give products which are enantiomerically pure.

N-tert-Butyloxycarbonylamino acids are useful in peptide synthesis because the Boc-group satisfies the requirements of a selectively removable protecting group. Since *N*-methylamino acids and their derivatives often behave differently than the corresponding unmethylated compounds under various reaction conditions, it was thought useful to compare the rates of cleavage of the Boc-group from an *N*-methylamino and an amino acid under the same conditions. The amounts of amino acid and *N*-methylamino acid released during specified time periods from four derivatives left in a solution of trifluoroacetic acid (2%) in dichloromethane were determined with an amino-acid analyzer. This dilution was

TABLE 2. Extent of *N*-methylation[a]

Substrate	Percentage methylated[b]
For-Leu-OH	33

[a]Using sodium hydride/methyl iodide in THF at 23 °C.
[b]Assuming methylated + unmethylated derivative = 100%.
[c]22% using methylation procedure of Olsen (11).
[d]Gave 60% yield of Bz-MeLeu-OH.
[e]54% using procedure of Olsen (11).
[f]Partial epimerization occurred.

[8]The methylation of serine derivatives will form the subject of a subsequent communication.

[9]We thank Dr. N. Chaturvedi, of Chemical Dynamics, for the gifts of Boc-Val-OH and Boc-Phe-OH, and for the valuable suggestion that our difficulties might be due to the presence of hydrazoic acid, which could be removed by using reduced pressure.

[10]These experiments were carried out by Mr. K. Kuroda.

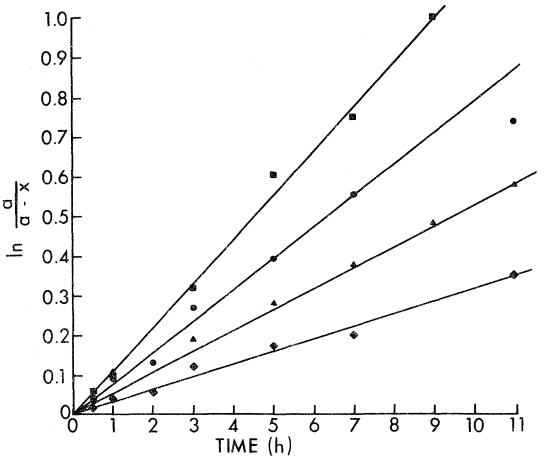

FIG. 1. Calculated least-squares lines of best fit for the apparent first-order cleavage of Boc-derivatives by 2% trifluoroacetic acid in dichloromethane at 23 °C. k = apparent first-order rate constant determined from the slope of the line: (■) Boc-MeAla-OH, $k = 30.9 \times 10^{-6}$; (●) Boc-MeLeu-OH, $k = 22.1 \times 10^{-6}$; (▲) Boc-Ala-OH, $k = 14.7 \times 10^{-6}$; (◆) Boc-Leu-OH, $k = 8.9 \times 10^{-6}$.

used because it was found to give rates slow enough to measure. The results are given in Fig. 1 in the form of a first-order reaction plot. It is seen that for both amino acids tested (alanine and leucine), the Boc-group was cleaved from the *N*-methylamino acid at least twice as fast (2.5 and 2.1 ×) as from the corresponding amino acid. This result is in agreement with the theory that acidolytic cleavage of urethane protecting groups is initiated by protonation of the oxygen atom of the urethane carbonyl group (see ref. 24 for a discussion) which would be favored by the positive inductive effect of the *N*-methyl group, but it is also compatible with protonation being at the nitrogen atom.

Experimental

Materials and Methods

Sodium hydride was obtained from Ventron Corporation, Berverly, Massachusetts, and J. T. Baker Chemical Company, Phillipsburg, New Jersey as a 57–60% dispersion in oil, which contained 1.6–3.7% by weight of NaOH (25). Methyl iodide, silver oxide, acetonitrile, THF, and DMF were products from Fisher Scientific Company, Fair Lawn, New Jersey. THF was refluxed over $LiAlH_4$ for 24 h, and distilled directly into the reaction vessel. This is a change from our previous method of purifying THF which we recommend. Acetonitrile was distilled from P_2O_5. DMF was distilled from CaO immediately before use. Light petroleum refers to the 30–60 °C fraction, from Fisher.

Boc-Ala-OH and Boc-Leu-OH·H_2O were purchased from Beckman Instruments, Palo Alto, California; Boc-Ser(Bzl)-OH, Boc-Thr(Bzl)-OH and Boc-Tyr(Bzl)-OH from Bachem Feinchemickalien, Marine Del Ray, Calif.; and Z-Ser(Bu^t)-OH dicyclohexylammonium salt from Fluka AG, Buchs, Switzerland. The latter was converted to the free acid using aqueous citric acid. Other *N-tert*-butyloxycarbonylamino acids were synthesized by the method of Schwyzer *et al.* (26). Water of hydration was removed by drying a solution of the compound in chloroform (10 ml/mmol) over $MgSO_4$ for ½ h, and evaporating. Final traces of chloroform were removed by reevaporating after having added THF, twice.

Proton nmr (Varian T-60) and amino-acid analyses after deprotection (70% aqueous trifluoroacetic acid for the Boc group, hydrogenation for the benzyl group, and acid hydrolysis for acyl groups) were used routinely for monitoring reactions and characterizing products. Amino-acid analyses were carried out with a Beckman model 120B amino-acid analyzer with the eluting buffer at half-normal flow rate to allow determination of the *N*-methylamino acids (27). Proton chemical shifts are for solutions in deuterochloroform and are given in ppm relative to tetramethylsilane as internal standard. Optical rotations were measured with a Perkin-Elmer model 141 polarimeter using a 1-dm tube. Melting points were taken by the capillary method, and are uncorrected. Elemental analyses were done by Organic Microanalyses, Montreal, on the compounds dried *in vacuo* over P_2O_5.

N-tert-Butyloxycarbonyl,N-methylamino Acids

N-tert-Butyloxycarbonylamino acid (10 mmol) and methyl iodide (5 ml, 80 mmol) were dissolved in purified THF (30 ml), and sodium hydride dispersion (1.32 g, 30 mmol) was added cautiously with gentle stirring to the solution at 0 °C. The suspension, protected from the atmosphere by a drying tube, was stirred at room temperature for 24 h, and the *N-tert*-butyloxycarbonyl,*N*-methylamino acid was isolated and purified as previously described for the *N*-benzyloxycarbonyl derivatives (4), using 5% aqueous citric acid for acidification. For methylations at lower temperature, the reaction vessel was kept in an ice-bath for 15 min after addition of sodium hydride, and then left at 5 °C.[11] Dicyclohexylammonium salts were prepared by adding excess amine to the product dissolved in ether, followed by the addition of light petroleum and storage at 4 °C. Recrystallization from the same solvent mixture gave yields of 65–75%.

The methylation of Boc-Val-OH is extremely sensitive to the quality of the THF used. The methylation of Boc-Ala-OH requires twice the volume of THF, otherwise the reaction is incomplete due to precipitation during the reaction, but it proceeds even if undistilled THF is used. Methylations of Boc-Thr(Bzl)-OH and Boc-Tyr(Bzl)-OH were incomplete when carried out on a 2 mmol scale, but complete on a 1 mmol scale. We were unable to achieve complete methylation (30–50% unmethylated) of samples of Boc-Val-OH (Chemical Dynamics, South Plainfield, N.J.; and Beckman, recrystallized), Boc-Ile-OH·½H_2O (Beckman, dehydrated) and Boc-Phe-OH (Chemical Dynamics; Peninsula, San Carlos, Calif.; Beckman, recrystallized). A 50:50 mixture of the latter and Boc-Phe-OH synthesized by us gave the same in-

[11]It is imperative that the temperature not be allowed to exceed 5 °C. Erratic results were obtained when a cold-room constantly used by others was used.

complete reaction despite the fact that an experiment with the synthetic Boc-Phe-OH alone run in parallel was successful. Methylations of Boc-Ser(Bzl)-OH and Z-Ser (Bu^t)-OH at 5 °C were complete when carried out on a 5 mmol scale but incomplete on a 10 mmol scale. It was then found that the problem could be eliminated by subjecting the starting materials to reduced pressure.[9]

N-Benzyloxycarbonyl,N-methylamino Acids[10]

Methylation conditions and work-up were as described above, with compounds being crystallized from ethyl acetate – light petroleum. Z-Ala-OH (10 mmol) in acetonitrile gave Z-MeAla-OH (84%); mp 67–68 °C; $[\alpha]_D^{26}$ −25.8° (*c* 1 in ethanol), −31.0° (*c* 2 in acetic acid) (lit. mp 58–59 °C, $[\alpha]_D^{20}$ −39.2° (*c* 1 in ethanol) (28); mp 64.5–66 °C, $[\alpha]_D^{28}$ −33.1° (*c* 2 in acetic acid) (29); mp 65–66 °C, $[\alpha]_D^{25}$ −29.2° (*c* 2 in DMF) (2); mp 62–64 °C, $[\alpha]_D^{28}$ −31.0° (*c* 2 in acetic acid) (11); mp 61–62 °C, $[\alpha]_D$ −31 °C (*c* 2 in acetic acid) (30)). Z-Leu-OH (5 mmol) in acetonitrile gave Z-MeLeu-OH (72%), mp 74–75 °C (lit. mp 73–74 °C (2, 4)). Z-Val-OH (10 mmol) in THF gave Z-MeVal-OH (87%), mp 70–71 °C, $[\alpha]_D^{26}$ −86.3° (*c* 2 in ethanol) (lit. mp 69–70 °C, $[\alpha]_D^{24}$ −85.8 °C (*c* 1 in ethanol) (31); mp 68–69 °C, $[\alpha]_D^{27}$ −84.8 °C (*c* 1 in ethanol) (4); mp 70 °C, $[\alpha]_D^{20}$ −82.6° (*c* 1 in ethanol) (14); mp 68.5–69 °C $[\alpha]_D^{20}$ +90 (*c* 0.5 in ethanol) for the D-isomer (32).

Kinetic Cleavage Experiments

A solution of Boc-derivative (0.5–2.0 mmol) in 2% trifluoroacetic acid in dichloromethane (5 ml) was divided into 0.5 ml portions which were kept at 23 ± 1 °C in screw-capped vials. At selected time periods, a tube was freed of solvent by passing a stream of nitrogen into the open vial. The residue was dissolved in citrate buffer, p*H* 7.0, and the mixture was kept frozen until analyzed. Liberated amino acids were determined with the amino-acid analyzer using a 1 × 15 cm column of Aminex A-5 resin eluted with 0.2 *N* sodium citrate buffer at 23 °C at half-normal flow rate (34 ml/h). Ninhydrin color constants were determined for each compound. The data are as follows: p*H* 4.25 buffer: MeLeu, elution time 78.5 min, constant 7.5; Leu, 87.5 and 42.7. p*H* 3.28 buffer: MeAla, 28 and 2.65; Ala, 40 and 38.3. Boc-derivatives are partially cleaved by these buffers if elution is carried out at 57 °C.

Received August 23, 1976

S. T. CHEUNG and N. LEO BENOITON. Can. J. Chem. **55**, 911 (1977).

A method capable of detecting one part in one thousand of the other isomer is described for determining the enantiomeric purity of *N*-methylamino acids and their cleavable derivatives. The method consists in converting the *N*-methylamino acid to its *N*-benzyloxycarbonyl derivative, and/or coupling the derivative with benzyl N^{ε}-benzyloxycarbonyl-L-lysinate using *N,N'*-dicyclohexylcarbodiimide, followed by removal of protecting groups by catalytic hydrogenation or other cleavage methods not affecting the chirality of the product. The resulting diastereomeric lysyl peptides are analyzed by ion-exchange chromatography on a 15 cm column of Aminex A-5 resin using an amino-acid analyzer. The method is applicable to samples contaminated by the corresponding unmethylated amino acid or derivative, and in effect, provides a new method for determining the enantiomeric purity of amino acids and their derivatives as well.

Examples are given where, in some cases, optical purity verification or configurational assignment for *N*-methylamino acids can be achieved by inspection of the nmr spectra of related lysyl dipeptide derivatives.

S. T. CHEUNG et N. LEO BENOITON. Can. J. Chem. **55**, 911 (1977).

On décrit une méthode de détermination de la pureté énantiomérique d'acides *N*-méthylaminés et de leurs dérivés pouvant être clivés qui permet de détecter une partie dans mille de l'autre isomère. Cette méthode est basée sur la conversion de l'acide *N*-méthylaminé en dérivé *N*-benzyloxycarbonylé et/ou le couplage, à l'aide de la *N,N'*-dicyclohexylcarbodiimide, du dérivé avec le N^{ε}-benzyloxycarbonyl L-lysinate de benzyle; on enlève ensuite les groupements protecteurs par une hydrogénation catalytique ou par d'autres méthodes de clivage n'affectant pas la chiralité du produit. On analyse les peptides diastéréoisomères contenant de la lysine qui en résultent par chromatographie d'échange ionique sur une colonne de 15 cm de résine Aminex A-5 utilisant un analyseur d'acide aminé. La méthode peut être appliquée à des échantillons contaminées par les acides aminés non-méthylés correspondants ou leurs dérivés et fournit en effet une nouvelle méthode pour déterminer la pureté énantiomérique d'acides aminés ainsi que celle de leurs dérivés.

On donne quelques exemples où la vérification de la pureté optique ou l'attribution de configuration des acides *N*-méthylaminés a pu être effectuer par un examen des spectres rmn des dérivés de dipeptides connexes contenant de la lysine.

[Traduit par le journal]

Despite the many methods available for determining the optical purity of amino acids (see ref. 2) there is no general method available for determining the optical purity of *N*-methylamino acids or their derivatives. N-Protected *N*-methylamino acids are used in peptide synthesis, and these are accessible by methylation of the corresponding N-protected amino acids, so a method applicable to the derivatives as well as the free *N*-methylamino acids, would be valuable. This paper describes such a method. The method consists in coupling the N-protected *N*-methylamino acid, or an *N*-methylamino acid which has been converted to its *N*-benzyloxycarbonyl derivative, with an N^{ε}-protected L-lysine ester, followed by deprotection and analysis for the diastereomeric lysyl dipeptides with an amino-acid analyzer. There are conflicting reports in the literature on the application to *N*-methylamino acids of the method of Manning and Moore (2) for determining amino-acid enantiomers. We have reexamined this question. Some data on the analysis of related protected diastereomeric peptides by nmr spectroscopy are also given. Results on the application of the chromatographic method to *N*-methylamino acids and their derivatives pre-

[1]Supported by a grant from the Medical Research Council of Canada. N.L.B. is an Associate of the MRCC. Presented in part at the First Chemical Congress of the North American Continent, Mexico City, Mexico, Dec. 1975. For part V of this series, see ref. 1.

pared by various methods appear in the accompanying paper (3).

In 1968, Manning and Moore described a simple and elegant chromatographic method for the determination of amino acid enantiomers (2). The method consists of reacting the amino acid with, in most cases, L-leucine *N*-carboxyanhydride, followed by analysis for the leucyl-amino acid dipeptide with an amino-acid analyzer. Choice of the appropriate chromatographic system allows complete separation of the diastereomeric L-L- and L-D-dipeptides. We attempted to apply this method to *N*-methylamino acids, using L-alanine *N*-carboxyanhydride instead of L-leucine *N*-carboxyanhydride because our *N*-methylation experiments had been carried out with leucine derivatives. We reported that the reaction was sluggish, that more by-products were formed, but that it worked (4). Reexamination of this, however, led us to retract this conclusion (5). It was found that the peptide H-Ala-MeLeu-OH[2] had an unusually low ninhydrin color-yield, and that the peaks had been misassigned. Since then, three reports on the use of this method for configurational assignments for MeAla and MePhe (7) and optical purity determinations for MeLeu (8) and MeAla[3] have come to our attention. We have therefore again reexamined this question. The reaction was carried out as described (4), and the peptides were analyzed as previously described (5) but also by pumping the eluting buffer at half-normal flow-rate, which allows definite distinction between *N*-methylamino acids and amino acids or peptides.[4] D,L-Alanine and D,L-leucine were used as controls. We found that L-alanine *N*-carboxyanhydride did not couple with D,L-MeAla, D,L-MeLeu, and D,L-MeVal; and that D,L-leucine *N*-carboxyanhydride did not couple with D,L-MeVal and D,L-MeLeu; but that D,L-leucine *N*-carboxyanhydride did couple with D,L-MeAla. These results are in agreement with the two reports for MeAla (7),[3] and also our previous conclusion for MeLeu (5). There is no obvious explanation for the different behavior of MeAla towards leucine *N*-carboxyanhydride and alanine *N*-carboxyanhydride. We suggest extreme caution in interpreting results if this method is used.

Having resigned ourselves several years ago to the impossibility of using the method of Manning and Moore, we were nevertheless able to establish the optical purity of one of our synthetic derivatives, Z-MeLeu-OH. This was accomplished by incorporating the *N*-methylamino acid, through the intermediate benzyl ester, into the dipeptide H-Ala-MeLeu-OH, whose diastereomers could be separated with the amino-acid analyzer (10). In the process, we established that this peptide had an unusually low ninhydrin color-yield (6% of that for H-Ala-Leu-OH) (10), and that the color-yield of its retro-isomer H-MeLeu-Ala-OH was negligible (10). It occurred to us that a lysyl residue should impart a normal color-yield to a dipeptide containing an *N*-methylamino acid regardless of its position in the peptide, and that the diastereomeric peptides might be separable on a short column of the analyzer which is used to separate basic amino acids. This proved to be the case, and we were able to couple our synthetic Boc- and Z-methylamino acids directly with a lysine derivative to achieve our objective.

The reactions are described in [1]. For the lysine derivative, we chose the H-Lys(Z)-OBzl whose protecting groups are then removed by catalytic hydrogenation, which also deprotects the Z-methylamino acid.[5] Boc-derivatives are deprotected by an additional treatment, with trifluoroacetic acid.[6] For determination of the optical purity of a free *N*-methylamino acid, it is converted to its Z-derivative which is obtained as an oil and used as such. The coupling is carried out on a 0.2 mmol scale. For the coupling reagent, we examined the use of *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (13), and *N,N'*-dicyclohexylcarbodiimide

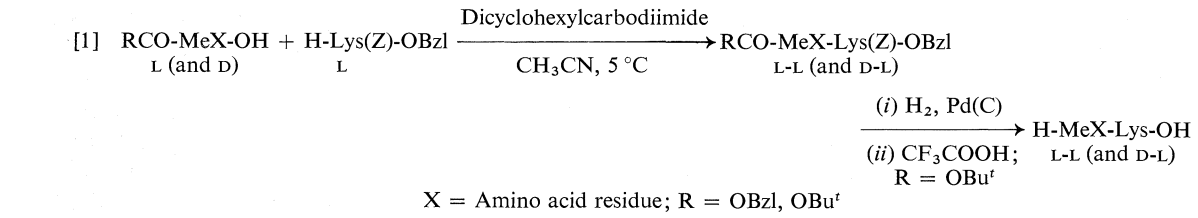
[2]The abbreviations for the amino-acid and peptide derivatives are those recommended by the IUPAC–IUB Commission on Biochemical Nomenclature (6). When not indicated, the amino-acid symbols represent the L-isomer. Other abbreviations used: Boc, *tert*-butyloxycarbonyl; Bzl, benzyl; Tos, *p*-toluenesulfonyl; Z, benzyloxycarbonyl.

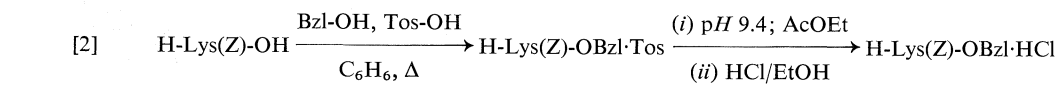
[3]D. H. Rich, personal communication.

[4]The color-yield increases by more than twice if the compound is not an ordinary amino acid or peptide (4).

[5]H-Lys(Z)-OMe, with saponification of the dipeptide before hydrogenation, can be used to prepare the diastereomeric mixture for reference, but not for the analysis of optical purity because saponification would partially racemize the peptide (11).

[6]The purity of a Tos-methylamino acid prepared by the method of Fischer and Lipschitz (12) can be established similarly, if sodium in liquid ammonia is used for deprotection (3).





with *N*-hydroxysuccinimide as additive (14), which seemingly might have offered advantages (10), but we obtained the cleanest products using *N*,*N*′-dicyclohexylcarbodiimide alone (15). Acetonitrile was chosen as solvent to minimize acyl-urea formation (16). The yields obtained are not high (30–40% ?), but adequate for the purpose. The H-Lys(Z)-OBzl was prepared as the hydrochloride by the azeotropic method as shown in [2] followed by purification by extraction from a solution at p*H* 9.4 as had been done for the methyl ester (17), followed by crystallization. Without the purification (18), the *p*-toluenesulfonyl salt always contained some H-Lys(Z)-OH and/or H-Lys-OBzl. We found that the same compound prepared from Z-Lys(Z)-OH using phosphorus pentachloride and benzyl alcohol had a wide melting range several degrees lower than that reported (19).

The analysis of amino acids with a Beckman analyzer according to Spackman *et al.* (20) is based on the separation of the acidic and neutral amino acids on a long (62 cm) column of AA-15 resin, eluted with p*H* 3.25 and 4.25 buffers, and the basic amino acids on a short (7 cm) column of PA-35 resin, eluted with p*H* 5.28 buffer. Chromatography of the diastereomeric peptide pairs for H-MeAla-Lys-OH and H-MeVal-Lys-OH on the short column using p*H* 5.28 buffer as eluent gave single broad peaks at 55–60 min, and buffers of higher p*H* gave peaks emerging sooner which were sharper. However, good separation was achieved on the intermediate length (15 cm) column of Aminex A-5 resin, using p*H* 6.50 as eluting buffer. This additional column has been part of our instrument for nearly a decade, and has proven useful on several other occasions (10, 21). The chromatographic data for these and other dipeptides appear in Table 1. The data were obtained by chromatography of the products obtained by coupling the *N*-protected amino acids with H-D,L-Lys(Z)-OBzl.[7] The identities of the peaks were established by synthesis and chromatography of the L-L-peptides. Integration of the peaks gave the relative ninhydrin color-yields for each pair of diastereomers. Higher color-yields were observed for an L-D-peptide than for its L-L-isomer. This contrasts with the lower color yields for L-D-peptides not containing *N*-methylamino acids (2). These color-yield ratios are correct provided the mixtures from which they were obtained were 50:50 mixtures. Evidence for this is presented below. All the diastereomers are completely separated by the systems described, allowing detection of as little as one part in one thousand of one isomer in a diastereomeric mixture. This was confirmed by analyzing mixtures containing decreasing amounts of an L-D-peptide, prepared by the

TABLE 1. Chromatographic data for analysis of H-MeX-Lys-OH diastereomers[a]

X	Elution time (min)[b] L-L	Elution time (min)[b] D-L	Ninhydrin color-yield ratio D-L/L-L

[b]Other elution times: lysine, 38; ammonia, 50; *N*,*N*′-dicyclohexylurea, 53.
[c]p*H* 7.50 eluting buffer.

[7]An alternative would be to couple the racemic *N*-methylamino-acid derivative with the optically active ester. The D-L-peptide obtained would then be the enantiomorph of the L-D-peptide obtained above.

addition of a 50:50 diastereomeric mixture to a solution of the L-L-peptide. The feasibility of this experiment implies that L-L-peptide gave a single peak with the analyzer. All our synthetic L-L-peptides did so (3). This proves that none of the reactions ([1] and [2]) involved in the method cause racemization, and establishes the validity of its use for demonstrating that an *N*-methylamino acid or its derivative is enantiomerically pure. The accuracy of the method was verified by analyzing samples of Z-MeAla-OH containing 2.5 and 10% of D-isomer, prepared by adding racemate to the enantiomer. The results were within 12% of the theoretical values.[8]

A noteworthy and valuable feature of the method is that it can be applied to a compound in the presence of some of the corresponding unmethylated compound. This is because the unmethylated peptide emerges from the column shortly before the corresponding methylated peptide for the eight peptides listed in Table 1. Moreover, each unmethylated diastereomeric peptide pair emerges separated, which provides, in effect, a new, general method for the determination of the enantiomeric purity of amino acids and their derivatives, which we are using routinely in preference to the method of Manning and Moore (2).

Recent additions to the methods allowing distinction between dipeptide diastereomers include nmr spectroscopy. Weinstein and Pritchard have reported different chemical shifts for the alanine methyl group in some *N*-protected alanyl dipeptide methyl esters (22), and Davies *et al.* have reported different chemical shifts for the methoxy methyl group in the *N*-benzoyl dipeptide methyl esters containing alanine and valine (23). Examination of the nmr spectra (100 MHz) of a few protected lysyl dipeptides containing an *N*-methylamino acid revealed that the diastereomers of Z-MeLeu-Lys(Z)-OMe and Z-MeVal-Lys(Z)-OMe could be readily distinguished by virtue of the different chemical shifts of the methoxy methyl singlets. These are at 371 (L-L) and 368 (D-L) Hz for the leucyl derivative (*N*-methyl, 283), and 371.5 (L-L) and 366.5 (D-L) Hz for the valyl derivative (*N*-methyl, 287). Integration of the pertinent peaks allowed the demonstration that the products formed by coupling equimolar amounts of Z-D,L-MeVal-OH or Z-D,L-MeLeu-OH with H-Lys(Z)-OMe were 50:50 mixtures of L-L- and D-L-isomers. When these protected racemic *N*-methylamino acids were coupled with 0.1 mol. equiv. of ester, the products contained the peptides in the L-L:D-L ratios of 57:43 and 58:42, respectively. It thus transpires that some kinetic resolution obtains, the L-L-isomer being favored, but not when there is enough ester present to react with all of the *N*-methylamino acid derivative. We therefore consider the color-yield ratios described above (Table 1) as true values.

Use of nmr as described above, in effect, provides a second method, albeit a less sensitive one, for determining the enantiomeric purity of MeLeu and MeVal, and their derivatives, or for establishing the configuration of samples of these *N*-methylamino acids. The method cannot be used for MeAla, since the methoxy methyl singlets of Z-D,L-MeAla-Lys(Z)-OMe coincide. Boc-D,L-MeLeu-Lys(Z)-OMe also did not give separated methoxy methyl peaks. However, another derivative of this same peptide, namely Z-D,L-MeLeu-Lys(Z)-OH, gave separated *N*-methyl singlets, at 282 and 278 Hz.

Experimental

Materials and Methods

The Boc- and Z-methylamino acids were prepared as described in (1). L-Alanine *N*-carboxyanhydride, mp 92 °C, and D,L-leucine *N*-carboxyanhydride mp 49–50 °C, were prepared from the Z-amino acid using thionyl chloride by standard procedures (24). Acetonitrile was distilled from P_2O_5. The amino-acid analyzer was a standard model 120B Beckman instrument. Aminex A-5 resin was purchased from Bio-Rad Laboratories, Richmond, California. The resin compresses more during an analysis than do the AA-15 and PA-35 resins, and give more variable elution times. The eluting buffers were prepared by adding 50% NaOH to the standard p*H* 5.28 buffer.

Synthesis of H-Lys(Z)-OBzl·HCl

A mixture of H-Lys(Z)-OH (5.60 g, 20 mmol), *p*-toluenesulfonic acid·H_2O (4.56 g, 25 mmol), benzyl alcohol (25 ml), and benzene (35 ml) was heated (oil bath) under reflux for 7 h, the water formed being collected in a Dean–Stark receiver. Ether (100 ml) and light petroleum (100 ml) were added with shaking to the cooled mixture. The precipitate was collected and washed well with light petroleum. Four grams of the air-dried product (10.4 g) were suspended in water (100 ml), the p*H* of the solution was adjusted to 9.0,[9] and the ester was extracted into ethyl acetate (50 ml). The aqueous layer was washed with ethyl acetate (25 ml), the combined extracts were dried ($MgSO_4$), and the solvent was

[8]Higher accuracy could likely be obtained, but we did not explore this further.

[9]A few drops of ethyl acetate solubilize the ester.

evaporated off. Evaporation was repeated after the addition of ethanol (10 ml), and ethanolic HCl (20 ml) was added. After cooling overnight, the crystals were collected and washed by trituration in ether. Yield: 1.5–1.6 g (45–50%), mp 140–141 °C, $[\alpha]_D^{27}$ − 12.4° (*c* 0.5 in 0.1 *N* HCl) (lit. mp 139 °C, $[\alpha]_D$ − 9.9° (19) and mp 138–140 °C, $[\alpha]_D$ − 7.0° (9)). Thin-layer chromatography on silica gel GF_{254} in 1-butanol – acetic acid – water (4:1:1) gave R_f 0.80; H-Lys(Z)-OH, 0.60; H-Lys-OBzl, 0.23. Melting point for H-D,L-Lys(Z)-OBzl·HCl, 135–135.5 °C. Substantial amounts of H-Lys-OBzl were formed when the reaction was carried out for a longer period of time.

Derivatization of the N-Methylamino Acid

The *N*-methylamino acid is converted to its *N*-benzyloxycarbonyl derivative by the usual procedure. The crystals or residue (≃1 mmol; we have occasionally used 0.5 mmol) remaining after evaporation of a solution are dissolved in 3 ml of 4 *N* NaOH, 0.2 ml of benzyl chloroformate is added, and the mixture is stirred vigorously at 5 °C for 4 h. The solution is extracted with ether (5 ml), acidified to Congo Red with 5 *N* HCl while still cold, and the product is extracted into ethyl acetate (10 ml × 2). The combined extracts are washed with water (× 2), dried ($MgSO_4$), and evaporated to give an oil, which is used as such to avoid fractionation. The yield for MeVal is lower than for MeAla or MeLeu.

Dipeptide Synthesis

To the Boc- or Z-methylamino acid (0.2 mmol) in 2 ml of acetonitrile at 5 °C are added H-Lys(Z)-OBzl·HCl (81.4 mg, 0.2 mmol) and triethylamine (20.3 mg, 0.2 mmol). The mixture is stirred for 15 min, *N,N'*-dicyclohexylcarbodiimide (41.2 mg, 0.2 mmol) is added, and the mixture is stirred at 5 °C for 18 h. One drop of acetic acid is added, followed by acetone (5 ml), and the mixture is filtered after cooling for 1 h. The solvents are evaporated off, the residue is taken up in chloroform (35 ml), and the solution is washed successively with 10% aqueous citric acid (× 2), water, aqueous $NaHCO_3$ (× 2), and water, dried, and the solvent is evaporated off. The protected peptides which were analyzed by nmr were prepared in the same manner using H-Lys(Z)-OMe·HCl (17). One of these was then saponified.[5]

The residue is taken up in 80% aqueous acetic acid and the solution is hydrogenated over 10% palladium-on-charcoal catalyst (100 mg) for 18 h after filtration through Celite. The catalyst is removed by filtration, the solution is evaporated to dryness, and the residue is left for 1 h in 70% aqueous trifluoroacetic acid if a Boc-group is present. After evaporation, 10 ml of water are added, and the last traces of *N,N'*-dicyclohexylurea are allowed to crystallize by leaving the solution at 5 °C for several hours.

Analysis of Diastereoisomers

A 1-ml aliquot of the above solution which has been filtered through Celite is diluted to 5 ml with 0.2 *N* sodium citrate, p*H* 2.2, and 0.5 ml of this is analyzed using the conditions described in Table 1. The relative amounts of the two isomers in the sample are obtained by comparison of the surface areas of the two peaks after having divided the surface area of the D,L-peak by the color-yield ratio given in Table 1. These ratios can be obtained by couplings in which either one or both of the components are racemic.

NOTE ADDED IN PROOF

We have found in studies on couplings that if 1-hydroxybenzotriazole (W. König and R. Geiger. *Chem. Ber.* **103**, 788 (1970)) is added to the *N,N*-dicyclohexylcarbodiimide-mediated coupling of a Z-methylamino acid, the acylurea normally formed does not appear, and the yields are very good (F.M.F. Chen and N.L.B.).

N-Methylamino acids in peptide synthesis. VII. Studies on the enantiomeric purity of *N*-methylamino acids prepared by various procedures[1]

S. T. CHEUNG AND N. LEO BENOITON

Department of Biochemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9A9

Received August 23, 1976

S. T. CHEUNG and N. LEO BENOITON. Can. J. Chem. **55**, 916 (1977).

The enantiomeric purity of *N*-methylamino acids and their derivatives obtained by various procedures has been examined by analysis with an amino-acid analyzer of the diastereomeric lysyl dipeptides formed by coupling them with a lysyl derivative. *N*-Benzyloxycarbonyl, and *N*-*tert*-butyloxycarbonyl,*N*-methylamino acids obtained by methylation of the parent derivative using sodium hydride and methyl iodide, and *N*-methylamino acids obtained by methylation of the *p*-toluenesulfonylamino acid followed by treatment with sodium in liquid ammonia, are optically pure. Compounds obtained by other procedures which include reductive alkylations or the use of silver oxide – methyl iodide are generally not optically pure.

S. T. CHEUNG et N. LEO BENOITON. Can. J. Chem. **55**, 916 (1977).

On a examiné la pureté énantiomérique d'acides *N*-méthylaminés et de leurs dérivés qui avaient été obtenus par divers procédés; ces études ont été effectuées en examinant à l'aide d'un analyseur d'acide aminé des dipeptides diastéréoisomères contenant de la lysine et qui ont été formés par couplage de ces acides aminés avec un dérivé contenant de la lysine. Les acides *N*-méthylaminés portant aussi des groupes *N*-benzyloxycarbonyle ou *N*-*tert*-butyloxycarbonyle, obtenus par méthylation du composé de base à l'aide d'hydrure de sodium et d'iodure de méthyle, ainsi que les acides *N*-méthylaminés obtenus par une méthylation de l'acide *p*-toluènesulfonylaminé correspondant suivie par un traitement avec le sodium dans l'ammoniac liquide, sont optiquement purs. Les composés obtenus par d'autres méthodes, y compris les alkylations réductives et l'utilisation de l'oxyde d'argent et l'iodure de méthyle, ne sont généralement pas optiquement purs.

[Traduit par le journal]

N-Methylamino acids are frequently encountered, or incorporated into peptides for various studies of a biological or physical nature. A method for their preparation has been available since the time of Fischer [1],[2] and a second, more commonly used one [2] was introduced by Quitt *et al.* (4) in 1963. Others [3]–[5] have made their appearance more recently. It has generally been accepted that these methods give optically pure products, however, the only criterion of purity available has been specific rotation measurements. No unequivocal method of establishing the enantiomeric purity of *N*-methylamino acids has been available. In the accompanying paper (1), we describe a method for doing this. In this paper, we report the results of enantiomeric purity determinations on *N*-methylamino acid products prepared by most of the general methods available for their synthesis. Also included are results on the optical purity of *N*-benzylamino acids prepared by reductive alkylation using various reducing agents.

Methylation of p-Toluenesulfonyl Derivatives

This method involves methylation of the Tos-amino acid in basic solution with methyl iodide at 65 °C (2), followed by cleavage of the Tos-amido group by one of various procedures [1].[4] The results appear in Table 1. All cleavage methods using acid led to significant racemization. Only sodium in liquid ammonia (3) gave pure products. The original acid hydrolysis method of Fischer and Lipschitz (2) gave less racemization than did acidolytic cleavage by hydrogen bromide in acetic acid (11), which gave about the same results whether carried out at room temperature or at 70 °C. The fact that at least one of these methods gave optically pure products proves that the inversion occurs

during cleavage, and not during the methylation.[5] The inversion observed for acidolytic cleavage agrees with our previous demonstration that hydrogen bromide in acetic acid racemizes N-substituted *N*-methylamino acids (12). The inversion observed for cleavage by acid hydrolysis is probably higher than that which would occur for the corresponding unmethylated derivative, but this was not verified.

Methylation of Urethane Derivatives using Silver Oxide

This method involves methylation of the Boc- or Z-derivative in DMF using silver oxide and methyl iodide, sometimes aided by heating, followed by saponification of the methyl ester which is formed [3] (5, 6). The results appear in Table 2. It is seen that all products contained either about 1% or else substantially more of the D-isomer. Generally, except for *N*-methylalanine which was higher, all Boc-derivatives were about 2% racemized. Boc-MeLeu-OH

[3]Similar work, presented at a meeting in 1970, was published by Okamoto *et al.* in 1974 (6).

[4]Fischer and Lipschitz also used phosphonium iodide in hydriodic acid for Tos-amido cleavage (2).

[5]The methylation of Tos-Phe-OH may be an exception to this because in their work, Fischer and Lipschitz isolated two fractions of Tos-MePhe-OH, one with a specific rotation 15% lower than that of the other (2).

[e]55% of the ester remained.

might be purer, but it was not examined. Except for *N*-methylleucine, the Z-derivatives were 8–28% racemized, the higher figures being for those which had been more difficult to saponify. These results confirm our previous demonstration that fully protected *N*-methylamino acids are racemized by base (12). The Boc-derivatives were more easy to saponify than the Z-derivatives, and we attribute the higher degree of optical purity of products to this fact. The amino-acid side chain also had no effect on the results for the Boc-derivatives, which contrasts with the pronounced effect it had on the results for the Z-derivatives. It would seem that the method of methylating itself does not cause racemization. The results for *N*-methylalanine derivatives seem anomalous in several respects.

Methylation of Urethane Derivatives using Sodium Hydride

The more recent version of this method involves the methylation of the Boc- or Z-derivative in THF using sodium hydride and methyl iodide at room temperature to give directly the N-protected *N*-methylamino acid [5] (8–10). The results appear in Table 2. All the derivatives tested were optically pure, except for Z-MeIle-OH, which contained 0.9% of diastereomer. Since procedures are available for deprotecting these derivatives without affecting their chirality, this method provides a source for optically pure *N*-methylamino acids.

The earlier version of this method included some DMF as well as THF as solvent, with heating [4] (7). The product is the corresponding methyl ester. The protected *N*-methylamino acid is then obtained by saponification. But we have also shown that fully protected *N*-methylamino acids can undergo some inversion in aqueous base (12). Therefore, products obtained in this manner are suspect, and in view of our success with the recent version of this method, none were examined. It should be noted, nevertheless, that *N*-methylamino acid derivatives with a free methylamino group are not racemized by base, therefore optically pure *N*-methylamino acids are still accessible through this procedure as well as via [3] if the saponification is carried out after removal of the N-protecting group. Removal of N-protecting groups occurs without change in chirality, unless hydrogen bromide in anhydrous acetic acid is used on a

derivative containing a free carboxyl group (12). Finally, we have not shown definitely that methylation according to this earlier version gives optically pure products, but we have no reason to believe otherwise.

Methylation by Successive Reductive Alkylations

This method involves reductive alkylation of the amino acid using benzaldehyde and either of two reducing agents, sodium borohydride, or hydrogen and palladium-on-charcoal catalyst, to give the *N*-benzylamino acid, followed by methylation by the procedure of Clarke–Eschweiler (13, 14) using aqueous formaldehyde in hot formic acid [2] (4). The first alkylation is carried out on the sodium salt of the amino acid. This promotes Schiff base formation by deprotonating the amino group, and also solubilizes the amino acid. The benzyl group is finally removed by catalytic hydrogenation. The results are given in Table 3. The products prepared using sodium borohydride all contained between 2.7–13.9% of D-isomer, except for *N*-methylleucine which contained 0.3% of D-isomer. Particularly striking are the results for the two 'hindered' compounds, *N*-methylvaline and *N*-methylisoleucine, which had undergone ~25% inversion.

In order to identify the origin of the racemization, *N*-benzylamino acids were prepared by both procedures, and examined for optical purity. All of the products, except Bzl-Leu-OH, were found to be racemized, but generally to an extent less than had been found for the corresponding *N*-methylamino acids. This suggested that racemization might also be occuring during the second step of the synthesis, namely, the methylation. This was proven definitely, at least for alanine, after an optically pure sample of Bzl-Ala-OH was synthesized by another procedure. Methylation of this by the Clarke–Eschweiler method gave a product containing 5.5% of the D-isomer.

The reductive alkylation of an amino acid to the benzylamino acid involves the reduction of the Schiff base in the presence of base. It is known that tautomerism of a Schiff base can occur under these conditions, (see ref. 15 for references and a discussion), and this would be promoted by the adjacent carboxylate anion. The partial racemization observed for the *N*-benzylamino acids[6] (Table 3) can therefore be accounted for on this basis, as in [6].

[6] $PhCH{=}N{-}CHR{-}COO^- \rightleftarrows PhCH_2{-}N{=}CR{-}COO^-$

The mechanism of the Clarke–Eschweiler reaction has been investigated in several laboratories (17, 18). A common by-product of the reaction is the carbonyl compound, attributed to hydrolysis of the isomerized Schiff base, exemplified as in [7] for a primary amine. The methylation of a few chiral primary amines

[7] $RCH_2{-}N{=}CH_2 \rightarrow RCH{=}N{-}CH_3 \xrightarrow{H_2O} RCHO + CH_3NH_2$

including a benzylamine has been examined (18, 19) and despite formation of some carbonyl product, no evidence for epimerization was obtained, leading to the conclusion that

[6]These results should be taken into account if *N*-benzylamino-acid derivatives are used for purposes, for example, such as the synthesis of optically active α-hydrazino acids (16).

the Clarke–Eschweiler reaction proceeds without epimerization (18, 19), and to the postulate that any isomerized Schiff base is neither further methylated nor reisomerized, but converted completely to the carbonyl compound (18). However, benzylamino acids incorporate an additional factor besides the benzyl group, the carboxyl group, which would also favor migration of unsaturation. The latter is substantiated by the nature (methylamine and carbon dioxide) and extent of by-product formation during the methylation of amino acids (14). The combination of these two groups must be sufficient to cause a small but significant reversal of the isomerization, as in [8]. This seems to be the first report of an epimerization occuring during methylation by the Clarke–Eschweiler procedure.

[8] $PhCH_2—\overset{+}{N}(=CH_2)—CHR—COOH \rightleftarrows PhCH_2—\overset{+}{N}(CH_3)=CR—COOH$

Reductive Alkylations at Acidic pH

Having demonstrated that reductive alkylations carried out at alkaline p*H* give partially racemized Bzl-amino acids (Table 3), the use of cyanoborohydrides as reducing agent was examined. These reagents of Borcht and Hassid (20) are stable down to p*H* 3, and effective at acidic p*H*. Indeed, it was found that by carrying out the reduction of L-alanine at p*H* 6.5, optically pure Bzl-Ala-OH was obtained in good yield (Table 3). However, success was not achieved until a p*H*-stat was used. Addition of sodium cyanoborohydride to an aqueous amino acid solution causes an immediate rise in p*H* of about 3–4 units, and a sample of Bzl-Ala-OH containing as much as 20% D-isomer was once obtained. This served to demonstrate dramatically the effect of p*H* on the optical integrity of an amino acid which is undergoing reductive alkylation, and confirmed our suspicions that benzylamino acids prepared by the methods of Quitt *et al.* (4) are not optically pure because base is added to the reaction mixture. However, it is sometimes necessary for practical reasons, to keep the amino acid in solution. We were unable to prepare Bzl-Val-OH using sodium cyanoborohydride at p*H* 6.5 because valine is not soluble enough at this p*H*.

In view of the demonstration that racemization had also occurred during the methylation of Bzl-Ala-OH by the Clarke–Eschweiler procedure, attempts were made to use sodium cyanoborohydride instead of formic acid as reducing agent for the reductive methylation of Bzl-Ala-OH. The same, but even worse, solubility problem arose. A few mixed solvents were examined, but without success. The question was abandoned, without exhaustive consideration.

General

The results, obtained with difunctional amino acids, can be summarized as follows: optically pure *N*-methylamino acids can be obtained using methods [1](b) and [5]. For the latter, Z-groups can be cleaved off by catalytic hydrogenation or hydrogen bromide in aqueous acetic acid (12), and Boc-groups, by any acidolytic reagent other than hydrogen bromide in anhydrous acetic acid (12). Though it has not been proven definitely, methods [3] and [4] probably give optically pure *N*-methylamino acids provided that saponification is not used before N-deprotection to obtain the final product. The two alternatives are saponification subsequent to N-deprotection, or O-deprotection by acid hydrolysis. Optically pure N-protected *N*-methylamino acids can be obtained by methylation of the corresponding amino acid derivative using method [5] for Boc- and Z-derivatives, and [1] for Tos-derivatives. *N*-Methylleucine is exceptional in that, in addition to the above, essentially optically pure products are obtainable also using methods [2] and [3] (the Boc-derivative).

With respect to the relative sensitivities to inversion of the different amino acids under synthetic conditions, the side-chain of leucine consistently allowed the least amount of inversion. The side-chains of valine and isoleucine allowed surprizingly high amounts of inversion during reductive alkylations (Table 3), and caused more racemization than others during saponifications (Table 2) because their derivatives are more difficult to saponify. When all methods are taken into consideration, alanine is the most sensitive to inversion, since even both products obtained by method [3] (Table 2) were substantially racemized. *N*-Methylalanine also racemized more than did *N*-methylvaline during tosyl removal by acid (Table 1). The demonstration that inversion occurred in many of the cases examined provides an explanation for the discrepancies in physical data (melting

points and specific rotations) which are recorded in the literature, particularly for *N*-methylalanine and *N*-methylvaline and their derivatives, for the same compounds prepared by various methods (see ref. 10 for examples). *N*-Methylamino acids other than those considered here have been prepared over the years by the methods described. The results presented in this paper as well as recognition of the individuality of the amino acids should be borne in mind when attempting to assess the likelihood that these were optically pure.

It is interesting to note that the classical synthetic method of Fischer–du Vigneaud [1](b) gives optically pure products, while variations of this and some other methods do not, and that the introduction of this method (3), a synthesis of N^{α}-methylhistidine by methylation of Tos-His(Bzl)-OH and subsequent deprotection, represented the introduction of the use of sodium in liquid ammonia for the removal of these *N*-protecting groups in amino acid and peptide chemistry.

Experimental

The Z- and Boc-methylamino acids prepared using sodium hydride [5] (Table 2) were those described in (10). The same derivatives obtained using silver oxide [3] (Table 2) were prepared as described by Olsen (5). The *N*-alkylamino acids recorded in Table 3 were prepared as described by Quitt *et al.* [2] (4), except for the Bzl-Ala-OH obtained using $NaCNBH_3$. The *N*-benzylamino acids were cleaved by catalytic hydrogenation in 80% aqueous acetic acid. Silver oxide and sodium borohydride were products from Fisher Scientific Company, Fair Lawn, New Jersey; sodium cyanoborohydride, from Sigma Chemical Company, St. Louis, Missouri.

For synthesis from the Tos-derivatives [1], synthetic Tos-Ala-OH and Tos-Val-OH (2) were methylated with heating for 1 h according to Fischer and Lipschitz (2) to give Tos-MeAla-OH, mp 128–130 °C, and Tos-MeVal-OH, mp 87 °C, upon acidification of the solutions. Half-gram quantities were treated with the reagents described in Table 1. The acid hydrolysis was carried out in a sealed tube. Samples treated with HBr/AcOH were evaporated to an oil, and the *N*-methylamino acid was isolated by adsorption onto Dowex 50 (H^+) followed by elution with aqueous ammonia.

Solutions containing *N*-methylamino acid or amino acid were evaporated to dryness. Residual compounds and Boc- and Z-derivatives were examined for enantiomeric purity as described in the accompanying paper (1). The values recorded in the tables are considered to be accurate to within about ±10%.

Optically Pure Bzl-Ala-OH

A mixture containing L-alanine (8.9 g, 0.1 mol), 10 ml of benzaldehyde and 50 ml of water was stirred until it became homogeneous (30 min). A p*H*-stat charged with *N* HCl was connected to the solution and the p*H* was adjusted to 6.5 and kept at that p*H*. Sodium cyanoborohydride (1.89 g, 0.03 mol) was added, and after stirring for 2 h, the additions of aldehyde and reducing agent were repeated. Stirring was continued until HCl consumption had ceased (24 h). The copious precipitate was brought into solution by adjusting the p*H* to 8.5, excess benzaldehyde was removed by extraction with ether, and the product was crystallized by bringing the p*H* back to 6.5. The air-dried product, after washing with ether (yield, 90%), was recrystallized from water–ethanol. The compound had the expected nmr spectrum, and was shown to contain <0.1% of the D-isomer.

BALA C. NALLIAH, DAVID B. MACLEAN, RUSSELL G. A. RODRIGO, and RICHARD H. F. MANSKE. Can. J. Chem. **55**, 922 (1977).

3,4-Methylenedioxyphthalide-α-carboxylic acid has been synthesized in four steps from piperonal. From it and phenylethylamines ten phthalideisoquinoline and spirobenzylisoquinoline alkaloids have been synthesized.

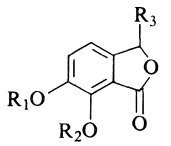
BALA C. NALLIAH, DAVID B. MACLEAN, RUSSELL G. A. RODRIGO et RICHARD H. F. MANSKE. Can. J. Chem. **55**, 922 (1977).

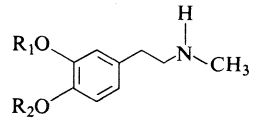
Utilisant le pipéronal comme produit de départ, on a synthétisé, en quatre étapes, l'acide méthylènedioxy-3,4 phtalide α carboxylique. Utilisant cet acide ainsi que des phényléthylamines, on a synthétisé dix alcaloïdes des séries phtalideisoquinoléine et spirobenzylisoquinoléine.

[Traduit par le journal]

We report a simple and efficient synthesis of 3,4-methylenedioxyphthalide-α-carboxylic acid **1** and illustrate its use in the total synthesis of six spirobenzylisoquinoline (1) and four phthalideisoquinoline (1) alkaloids.

Piperonal was carboxylated (2) to provide piperonal-2-carboxylic acid (63%) which was treated successively with aqueous potassium cyanide and 15% hydrochloric acid to yield 3,4-methylenedioxyphthalide-α-carboxamide **2** (71%) (mp 239–240°C; ν_{max}(Nujol) 3460, 3220, 1770, and 1650 cm^{-1}).[1] The amide was hydrolyzed by brief treatment with hot concentrated hydrochloric acid to the acid **1** (70%) (mp 210°C; ν_{max}(Nujol) 1790 and 1733 cm^{-1}). The acid **1** now obtained in 31% overall yield from piperonal (four steps) is the methylenedioxy analogue of meconine-α-carboxylic acid **3** employed by Haworth and Pinder (3) in their synthesis of the phthalideisoquinoline alkaloid, hydrastine. This route to the phthalideisoquinolines has since been virtually ignored presumably because of the inaccessibility of the hitherto unknown **1** and of **3**.



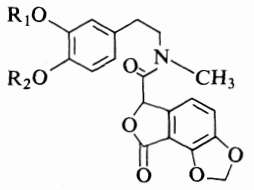


1 $R_1 + R_2 = CH_2$, $R_3 = CO_2H$
2 $R_1 + R_2 = CH_2$, $R_3 = CONH_2$
3 $R_1 = R_2 = Me$, $R_3 = CO_2H$
4 $R_1 + R_2 = CH_2$
5 $R_1 = R_2 = CH_3$

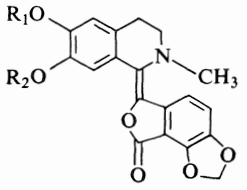
When **1** was converted to its acid chloride (oxalyl chloride, tetrahydrofuran, reflux) and condensed with *N*-methylhomopiperonylamine **4** it provided the amide **6** (61%) (mp 155°C, $\nu_{max}(CHCl_3)$ 1665 and 1780 cm^{-1}). This amide underwent Bischler–Napieralski cyclization with phosphorus oxychloride in acetonitrile to yield the dehydrophthalideisoquinoline **8** (72%) (mp 259°C; $\nu_{max}(CHCl_3)$ 1760 cm^{-1}). Contrary to an earlier suggestion (4) this compound has been shown to have the *E* configuration because of a strong nuclear Overhauser enhancement at the

[1]The full range of spectral data (consistent with the assigned structures) will be reported in detail in the full communication.

proton at C-10 when the N-Me group is irradiated. The dehydrophthalide **9** (**9**, mp 218°C; $\nu_{max}(CHCl_3)$ 1765 cm^{-1}) was similarly obtained from **5** through the amide **7** (**7**, mp 145–146°C; $\nu_{max}(CHCl_3)$ 1660, 1780 cm^{-1}).



6 $R_1 + R_2 = CH_2$
7 $R_1 = R_2 = CH_3$



8 $R_1 + R_2 = CH_2$
9 $R_1 = R_2 = CH_3$

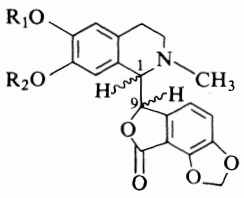
Catalytic hydrogenation of **8** (H_2/Pt/acetic acid) provided (±)-adlumidine **10** (mp 199°C) (31%) ((−)-adlumidine is also known as capnoidine) and (±)-bicuculline **11** (mp 216°C) (34%) separable by chromatography (tlc) on silica gel. Similarly, (±)-adlumine **12** (mp 191°C) (32%) and (±)-corlumine **13** (mp 174°C) (35%) were obtained by the hydrogenation of **9**.[2]

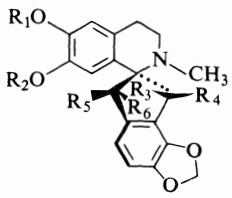
All the known spirobenzylisoquinoline alkaloids (1) possess methylenedioxy substitution in ring D and several carry two different oxygen substituents in ring C (*e.g.*, **14**–**17**). The latter type is not easily obtainable by the usual indanetrione approach and to date only one synthesis, that of yenhusomidine **16** has been reported (5).

The synthetic value of **1** is enhanced by an earlier observation (6) that a dehydrophthalide-isoquinoline similar to **8** (and **9**) was smoothly rearranged to products like **14**–**17**. In the present instance **8** upon treatment with diisobutylaluminum hydride in dry tetrahydrofuran at 0°C under nitrogen for 1 h provided (±)-corydaine (7) **14** (26%) and (±)-sibiricine (8) **15** (41%) while similar treatment of **9** yielded (±)-yenhusomidine (9) **16** (42%) and (±)-raddeanone (10) **17** (27%).

We have observed that in these reactions the sibiricine/corydaine (or raddeanone/yenhusomidine) ratio in the product is highest when the reaction mixture is worked-up immediately. Conversely, when the hydride is decomposed by methanol at completion of the reaction as

[2]All synthetic alkaloids reported here were chromatographically pure (tlc on at least two solvent systems) and were found to be identical with natural samples (where available) in their chromatographic and spectroscopic properties.





10 $R_1 + R_2 = CH_2$ (1*S*,9*S* and 1*R*,9*R*)
11 $R_1 + R_2 = CH_2$ (1*S*,9*R* and 1*R*,9*S*)
12 $R_1 = R_2 = CH_3$ (1*S*,9*S* and 1*R*,9*R*)
13 $R_1 = R_2 = CH_3$ (1*S*,9*R* and 1*R*,9*S*)
14 $R_1 + R_2 = CH_2$, $R_3 = H$, $R_4 = OH$, $R_5 + R_6 = O$
15 $R_1 + R_2 = CH_2$, $R_3 = OH$, $R_4 = H$, $R_5 + R_6 = O$
16 $R_1 = R_2 = CH_3$, $R_3 = H$, $R_4 = OH$, $R_5 + R_6 = O$
17 $R_1 = R_2 = CH_3$, $R_3 = OH$, $R_4 = H$, $R_5 + R_6 = O$
18 $R_1 + R_2 = CH_2$, $R_3 = H$, $R_4 = OH$, $R_5 = OH$, $R_6 = H$
19 $R_1 = R_2 = CH_3$, $R_3 = H$, $R_4 = OH$, $R_5 = OH$, $R_6 = H$

before but the mixture is then left stirring overnight at room temperature, the corydaine (or yenhusomidine) content now predominates. Furthermore, sibiricine may be transformed to corydaine (potassium hydroxide, methanol, reflux) although we have not yet been successful in effecting 100% conversions. These observations imply that aldol (6) and retro-aldol reactions occurring at the β-hydroxyketone system in ring C transform the sibiricine (raddeanone) configurations, initially produced, into the more stable corydaine (yenhusomidine) arrangements where intramolecular hydrogen bonding of the hydroxyl group to the nitrogen atom has been shown to prevail (7, 9). This process racemizes two chiral centres; its operation is probably responsible for the fact that those alkaloids for which rotations are reported have been found in an optically inactive form and it also raises the possibility that corydaine and yenhusomidine may be artefacts produced from sibiricine and raddeanone respectively by exposure to base during isolation. Further investigations in this area are in progress.

The preferential formation of sibiricine or raddeanone may be accounted for if one assumes that, after reduction, both oxygens of the original lactone remain coordinated with aluminum until ring closure occurs.

Sodium borohydride reduction (methanol, 24 h, room temperature) of (±)-corydaine **14** and (±)-yenhusomidine **16** yielded (±)-ochrobirine (11) **18** (80%) and (±)-yenhusomine (9) **19** (78%), respectively. The diastereomic *cis*-

diols were not formed in detectable amounts (tlc).[3]

Further applications of **1** in isoquinoline alkaloid synthesis are under investigation.

Our original synthesis (1) of ochotensimine, using a Pictet–Spengler reaction of an indanedione to construct the spirobenzylisoquinoline skeleton, was subsequently modified (2) by using a bromoindanedione to afford eventual access to those alkaloids having two oxygen functions on the five-membered ring. In principle, this strategy provides for control of both functionality and stereochemistry, permitting the synthesis of any of the alkaloids of this class. In practice, although the intermediate **1***a* was synthesized, apparently with complete stereoselectivity, and required only *N*-methylation to be converted to the alkaloid **2***a* having different oxidation levels at C-9 and C-14, the Eschweiler–Clarke reaction failed, and an alternative pro-

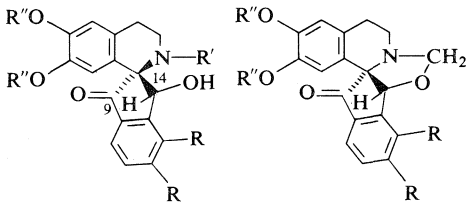
cedure led to ochrobirine, in which the C-9 carbonyl is also reduced.

The hydroxyl groups at C-14 appeared to be implicated in the failure of the Eschweiler–Clarke reaction, and a modified reductive methylation sequence has now been developed that takes this feature into account. The procedure was first investigated in a model series with an analog lacking the ring D methylenedioxy group. A solution of **3***a* (16 mg) and



1 R + R = —OCH_2O—, R′ = H
a R″ + R″ = —CH_2—
b R″ = CH_3
2 R + R = —OCH_2O—, R′ = CH_3
a R″ + R″ = —CH_2—
b R″ = CH_3
3 R = H, R″ = CH_3
a R′ = H
b R′ = CH_3
4 R = H, R″ = CH_3

formaldehyde (37% aqueous, 0.1 ml) in 5 ml of acetonitrile was stirred at room temperature under nitrogen for 2 h. Evaporation under reduced pressure afforded a residue which was dissolved in methylene chloride and washed with water; the material obtained from the organic layer was recrystallized and the product, mp 160–163°C, had the spectroscopic characteristics (ir, nmr, ms) expected for the oxazolidine **4**. A solution of **4** (20 mg) and sodium cyanoborohydride (3.3 mg) in 3 ml of methanol containing sufficient dilute hydrochloric acid to bring it to p*H* 3 was stirred at room temperature under nitrogen for 1 h. Dilution with water and extraction into methylene chloride afforded a product (12 mg) which showed the spectroscopic characteristics (ir, nmr, ms) expected for **3***b*.

The intermediate **1***a* (2) was then converted by the same reaction sequence to **2***a*, mp 127–128°C, the structure assigned to the alkaloid corydaine (3). Despite the difference in melting points, the spectroscopic and tlc characteristics of the synthetic product were identical in all significant respects with those of the optically active natural material.

The corresponding sequence of reactions converted the intermediate **1***b* to its *N*-methyl derivative **2***b*, mp 239–241°C, the structure assigned to the alkaloid yenhusomidine (4). The spectroscopic data for natural and synthetic samples confirm their identity. The synthesis of racemic yenhusomidine by a different route was announced recently (5).

Our reductive methylation sequence appeared to lead unequivocally to the configuration at C-14 shown in the products and to provide chemical proof for this assignment in the alkaloids. However, we have now become aware of the work of Nalliah *et al.* (6) who have synthesized these alkaloids by a different route; comparison of samples and spectra confirms the identities of their products with ours. One outcome of their work has been the demonstration of the facile isomerization of these alkaloids, and that **2***a* and **2***b* are thermodynamically the more stable epimers. Our route remains stereoselective, but since we have not proven that equilibration could not have taken place during the isolation of the products, it falls short of providing the intended *proof* of configuration.

High resolution ^{119}Sn nuclear magnetic resonance studies by pulse Fourier transform

C. R. Lassigne and E. J. Wells

Department of Chemistry, Simon Fraser University, Burnaby 2, B.C., Canada V5A 1S6

Received November 8, 1976

C. R. Lassigne and E. J. Wells. Can. J. Chem. **55**, 927 (1977).

The T_1's, linewidths (T_2's), and chemical shifts of ^{119}Sn nuclei in a variety of tin compounds have been surveyed using pulse Fourier transform techniques. The results span the very large chemical shift range for tin-119 (~2000 ppm), and indicate rather short T_1 values with widely varied T_2 relaxation times. Possible mechanisms are discussed for both T_1 and T_2 relaxation times. Our results show an approximate correlation between T_1 (^{119}Sn) and the paramagnetic contribution to the observed shielding of the ^{119}Sn nucleus, indicating that apart from a large scalar contribution in Sn(IV) iodides and bromides, the dominant ^{119}Sn T_1 mechanism is spin rotation interaction.

C. R. Lassigne et E. J. Wells. Can. J. Chem. **55**, 927 (1977).

On a examiné les T_1, les largeurs des lignes (T_2) et les déplacements chimiques du noyau ^{119}Sn dans une grande variété de composé de l'étain; ces études ont été effectuées en utilisant les techniques de transformation de Fourier pulsées. Les résultats recouvrent une très grande variété de déplacements chimiques pour l'étain-119 (~2000 ppm) et indiquent que les valeurs de T_1 sont relativement courtes même avec des temps de relaxation T_2 qui varient beaucoup. On discute des mécanismes possibles pour les temps de relaxation T_1 ainsi que T_2. Nos résultats montrent qu'il existe une corrélation approximative entre les T_1 de ^{119}Sn et la contribution paramagnétique au blindage observé au niveau du noyau de ^{119}Sn; cette corrélation indiquerait, en plus d'une grande contribution scalaire dans les bromures et les iodures du Sn(IV), que le mécanisme prédominant dans le T_1 du ^{119}Sn est une interaction spin rotation.

[Traduit par le journal]

I. Introduction

The ^{119}Sn isotope ($I = 1/2$) is the most abundant isotope of tin and the one most frequently studied in nmr investigations. Previous measurements of ^{119}Sn chemical shifts have been done under rapid passage dispersion mode (1) and also absorption mode signals involving proton decoupling (2). However now that Fourier transform is readily available a number of heavy nuclei may be studied with greater ease. We report the results of some signal-averaged pulse Fourier transform experiments on ^{119}Sn in a variety of tin compounds.

II. Experimental

All spectra were obtained on natural abundance (8.68%) ^{119}Sn samples in 12 mm tubes at 15.05 MHz, using a modified NMR-Specialties spectrometer with a home built crossed-coil, external water-lock probe.[1] The sample was not spun. Fourier transformation of the free induction decay (FID) was accomplished using a Nicolet 1082 FT system. Spin–lattice relaxation times were obtained by the usual 180°–τ–90° pulse sequence. All chemical shifts are given relative to the reference $Sn(CH_3)_4$.

All tin compounds were obtained commercially except for $SnCl_2$, $SnBr_2$, $SnCl_4 \cdot 2CH_3OH$, and $SnCl_4 \cdot 2CH_3CN$. Both stannous chloride and bromide were prepared by

[1] T. P. Higgs, A. Brooke, and E. J. Wells. Unpublished results.

reacting stannous oxide with concentrated HCl and HBr respectively. Both stannic chloride adducts were prepared by reacting methanol and acetonitrile with cold $SnCl_4$ (anhydrous) producing immediately a white precipitate of $SnCl_4 \cdot 2CH_3OH$ and $SnCl_4 \cdot 2CH_3CN$. The melting points of these adducts are in agreement with those reported in the literature (3).

III. Results and Discussion

1. Chemical Shifts

The large range of chemical shifts observed (Table 1) shows that the major contributory term to the shielding of the tin-119 nucleus is the paramagnetic term. This has been shown to be the case for ^{13}C chemical shifts (4) and also ^{119}Sn (5)[2]. The diamagnetic contribution to the total shielding constant remains essentially constant and it is the changes in the paramagnetic term which cause the changes in observed chemical shift for a particular nucleus. The chemical shift data are tabulated in Table 1.

The variation in chemical shift for the series $(CH_3)_nSnCl_{4-n}$ is the same as that observed for $(n\text{-butyl})_n$ $SnCl_{4-n}$ (1, 2) and similarly suggests that there are two important factors opposing each other in the shielding of the tin nuclei of this series: (*a*) an inductive effect resulting in the increased shielding by the addition of alkyl groups and (*b*) an opposite effect due to $(p \rightarrow d)\pi$ bonding between Sn and Cl. The tin chemical shifts and coupling constants J_{Sn-C-H} are very dependent on the concentration and type of solvent used, in agreement with the results of Hunter and Reeves (2), and suggesting specific solvation effects. A typical high resolution ^{119}Sn spectrum is shown in Fig. 1.

In Me_4Sn we have measured $J_{^{119}Sn-^{13}C}$ to be 338 Hz while in Me_3SnCl the coupling constant is measured to be 387 Hz (Fig. 1). The increase in $J_{^{119}Sn-^{13}C}$ in going from Me_4Sn to Me_3SnCl is due to the slight increase in '*s*' character at the

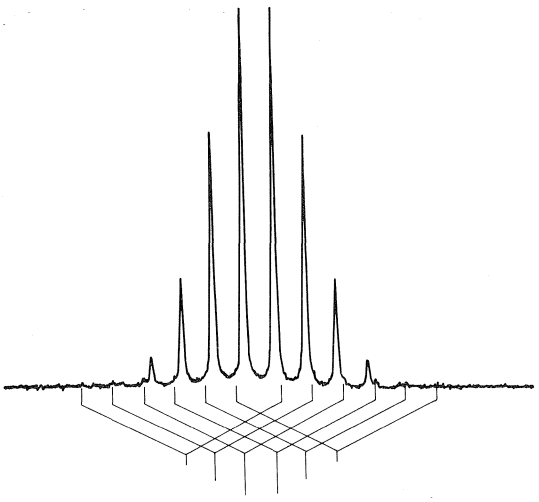

FIG. 1. Natural abundance ^{119}Sn FT spectrum of $Sn(CH_3)_3Cl$, 5 *M* in CCl_4 solvent. The eight inner members of the expected proton coupled decet are clearly visible with separation 59.9 Hz. Additional splitting due to ^{13}C (in natural abundance) is visible (387 Hz) and indicated below (8000 scans, 1.1 s delay).

[2]C. R. Lassigne and E. J. Wells. Unpublished results.

tin atom by the substitution of a Cl for a Me group.

2. Linewidths and T_2 Relaxation

The linewidth is indicative of the various possible spin–spin relaxation mechanisms contributing to the transverse relaxation time T_2. The possible mechanisms are: (*a*) experimental, *i.e.* magnet inhomogeneity, (*b*) scalar relaxation, and (*c*) exchange, which can be determined from the temperature dependence. The T_2 values measured for the various ^{119}Sn compounds are listed in Table 1.

$SnCl_4$, $SnBr_4$, and SnI_4 (5, 6) all have a T_2 dominated by scalar relaxation of the second kind (7) to the geminal halogen nuclei assumed to be relaxing independently,

$$[1]\quad R_2^{SC} = \frac{1}{T_2} = \frac{4\pi^2 J^2 S(S+1)}{3} \times \left\{ T_{1Q} + \frac{T_{2Q}}{1 + (\omega_I - \omega_S)^2 T_{2Q}^2} \right\} N_s$$

where J is the scalar coupling constant between nuclei I and S; S is the spin of the quadrupolar nucleus, usually $T_{1Q} = T_{2Q}$ for liquids and N_s is the number of quadrupolar nuclei involved. The large scalar coupling constants (5, 6) in all three compounds along with the fairly short T_{1Q} of the quadrupolar halogens produce a relatively efficient transverse relaxation in ^{119}Sn.

The series of methyltin chlorides shows decreasing linewidths as the number N_s of chlorines is decreased. Again this is consistent with the scalar contribution to T_2 by the rapidly relaxing chlorines according to [1].

The two adducts of stannic chloride ($SnCl_4 \cdot 2CH_3OH$ and $SnCl_4 \cdot 2CH_3CN$) have a smaller linewidth than the anhydrous $SnCl_4$. This may be a reflection of the decrease in *s* character of the tin nucleus in going from a tetrahedral (sp^3) geometry to a *cis*-octahedral (sp^3d^2) geometry (8, 9). This decrease in *s* character of the nucleus would cause the $J_{^{119}Sn-Cl}$ to be smaller than the 470 Hz reported by Sharp, and therefore would make a smaller contribution to T_2^{SC} (see eq. 1) making the tin-119 linewidth smaller. Also the change to the octahedral species increases the moment of inertia, lowering the angular velocity correlation time τ_ω and raising the angular orientation correlation time τ_θ, assuming rotational equipartition of energy and rotational diffusion. This effect shortens T_{1Q} and thus decreases the scalar T_2 at the Sn in the fast relaxation limit of quadrupolar spin *S*.

3. Spin–Lattice Relaxation Times (T_1)

The wide range of T_1's shows that a number of spin–lattice mechanisms may be operative. The possible mechanisms are: (*a*) dipole–dipole, (*b*) scalar relaxation, (*c*) spin–rotation, and in some cases (*d*) chemical shift anisotropy. The last case would only be found in the compounds which do not have T_d or O_h symmetry and thus may contain an anisotropic shielding for the central tin-119 nucleus. However, for the near-symmetrical structures studied here, this contribution is expected to be very small and is neglected hereafter. In principle, this contribution can be isolated by variable temperature, variable field T_1 studies.

For tetramethyl tin, we have shown[2] that T_1 is strictly dominated by the spin–rotation interaction. The T_1 of $SnCl_4$ is also dominated by spin–rotation as has been demonstrated by Sharp (5). However in $SnBr_4$ (6) and SnI_4 (5) the spin–lattice relaxation rate is a mixture of both spin–rotation and scalar relaxation. For neat $SnBr_4$, Sharp (5) has decomposed the T_1 mechanisms, obtaining $T_1^{SR} \simeq 7$ s, $T_1^{SC} \simeq 1.8$ s at 300 K. For the neat SnI_4 case, Sharp (5) obtained data at 477 K and extrapolation of his data back to 300 K yields $T_1^{SR} \simeq 10$ s and $T_1^{SC} \simeq 0.38$ s. Our T_1 solution data for the various Sn(IV) halides are in agreement with Sharp's (5, 6) reported values on the neat liquids. We were only able to measure the T_1 of one $SnCl_4$ adduct ($SnCl_4 \cdot 2CH_3OH$) because the signal of the acetonitrile adduct was very weak. The $SnCl_4 \cdot 2CH_3OH$ adduct most probably relaxes by spin–rotation; its T_1 (7.3 s) is much longer than $SnCl_4$ (T_1 = 1.6 s). We interpret this as due to a smaller angular correlation time (τ_ω) due to increased moment of inertia, along with a smaller spin–rotation constant (C_0) related to the smaller paramagnetic shielding (10). All of the T_1's of methyl tin chlorides here most probably are also dominated by the spin–rotation interaction, with the dipole–dipole relaxation being negligible because of the r^{-6} dependence. Both Sn(II) dihalides in their respective acids have similar T_1 values (4 s). Aqueous solutions of Sn(II) halides exhibit concentration dependent ^{119}Sn spectra which resolve at low temperature (11). ^{119}Sn spectra of Sn(II) halides are concentration dependent, but to date we have been unable to

resolve individual species resonances. Sn(II) halide solutions thus cannot be identified from Sn(IV) halide solutions by either ^{119}Sn shifts or T_1 values.

From the data in Table 1 there is a trend showing that with increasing paramagnetic chemical shift there is also an increase in the T_1^{SR}. The reason for this is that the trace of the paramagnetic term of the shielding tensor becomes smaller with the upfield shift in going from $Sn(CH_3)_4$ to SnI_4 and thus the spin–rotation constant becomes smaller (10); also the value of τ_ω decreases with increasing moment of inertia causing overall a less effective spin–rotation interaction and therefore the T_1^{SR} values become longer.

The total nuclear shielding constant has been related to the spin–rotation constant (12, 13);

$$\sigma_{av} = \frac{e^2}{3mc^2}\left\{\left\langle 0\left|\sum_k \frac{1}{r_k}\right|0\right\rangle - \sum_j \frac{Z_j}{R_{ij}}\right\} + \left\{\frac{2\pi}{\hbar g_I}\cdot\frac{M_p}{m_e}\cdot IC_0\right\} = \sigma_d' + \sigma_p' \quad [2]$$

Deverell (10) has argued that the first term σ_d' associated with a given nucleus i is constant from molecule to molecule, and that the paramagnetic shielding σ_p' given by the second bracketed term is responsible for the shift differences observed. Thus, σ_p' is directly related to the spin–rotation constant C_0 (Hz) and the molecular moment of inertia I. The spin–rotation relaxation rate R_1^{SR} for the central nucleus of a spherical top molecule is given by Hubbard (14) and McClung (15) as:

$$R_1^{SR} = T_{1,SR}^{-1} = \frac{2IkT}{\hbar^2}(2\pi C_0)^2\tau_\omega \quad [3]$$

where τ_ω is the correlation time for reorientation of the angular momentum vector. In the rotational diffusion limit τ_ω is related to the reorientational correlation time $\tau_{\theta,2}$.

$$\tau_{\theta,2}^*\tau_\omega^* = \tfrac{1}{6} \quad [4]$$

where the reduced correlation times τ_ω^*, $\tau_{\theta,2}^*$ are

$$\tau_\omega^* = \left(\frac{kT}{I}\right)^{1/2}\tau_\omega$$

$$\tau_{\theta,2}^* = \left(\frac{kT}{I}\right)^{1/2}\tau_{\theta,2} \quad [5]$$

Combination of [3] with σ_p' of [2] and τ_ω of [5] yields

$$R_1^{SR} = 2g_I^2\left(\frac{m_e}{M_p}\right)^2(kT)^{1/2}\tau_\omega^*\frac{(\sigma_p')^2}{I^{1/2}} \propto \tau_\omega^*\frac{(\sigma_p')^2}{I^{1/2}} \quad [6]$$

In general τ_ω^* can only be obtained from detailed relaxation studies. τ_ω^* values for those compounds that have been investigated are remarkably constant, at the same temperature in different media. Thus we have found $\tau_\omega^* = 0.054$ for neat $Sn(CH_3)_4$ at 300 K;[2] Sharp (5) finds $\tau_\omega^* = 0.048$ for neat $SnCl_4$ at 298 K, and 0.108 and 0.134 at 423 K for neat $SnCl_4$ and neat SnI_4 respectively. This suggests that τ_ω^* can be approximated as a constant in [6].

The validity of [6] across the present data may then be tested quantitatively from an absolute chemical shift scale which evaluated the σ_p'. We have determined such a scale for ^{119}Sn by temperature dependent relaxation studies of neat liquid $Sn(CH_3)_4$ and its isotopic modifications (16), which yielded a value of (17.7 ± 2) kHz for the spin–rotation interaction constant C_0 of ^{119}Sn. Use of this value in [2] sets σ_p' ($Sn(CH_3)_4$) as −3200 ppm. The measured ^{119}Sn shifts, spin–rotation relaxation rates, and calculated molecular constants for some of the other molecular species are displayed in Table 2, and these data are plotted according to [6] in Fig. 2.

Although the dependence is not exact, and is not expected to be because of the approximations made (isotropic motion, rotational diffusion limit, τ_ω independent of medium) we see that [6] does indeed correlate the measured relaxation behaviour with the measured shifts to first order. This verifies our interpretation of the relaxation as due predominantly to the spin–rotation mechanism, and also validates Deverell's relation between the spin–rotation constant and the paramagnetic shielding term for ^{119}Sn in a variety of compounds.

Comparison of the measured slope of Fig. 2 with the numerical coefficient of [6] yields an average value of τ_ω^* for these molecules in the liquid phase at 304 K of 0.055. The smallness of this value compared to unity confirms that molecules on or near the best fit line are in the rotational diffusion limit. $SnBr_4$ and $Sn(CH_3)Cl_3$ are apparently anomalous in this series. The anomaly of $SnBr_4$ has been noticed previously (6), and this molecule alone of the tin tetrahalides is thought to be in intermediate motion between rotational diffusion and inertial rotation.

TABLE 2. ^{119}Sn values for σ_p'; I and R_1^{SR}

	σ_p' (ppm)	I ($\times 10^{40}$) (g cm^2)	$(\sigma_p'^2\sqrt{I})$ ($g^{-1/2}cm^{-1} \times 10^{-12}$)	T_1^{SR}(obs) (s)	R_1^{SR}(obs) (s^{-1})

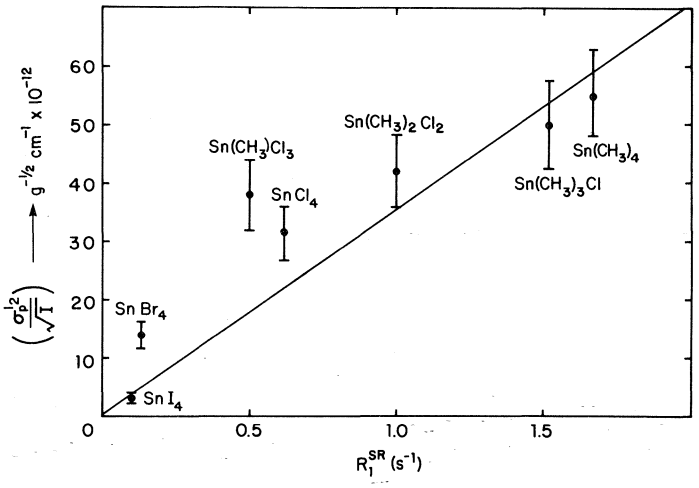

FIG. 2. ^{119}Sn relaxation and shift data from Table 2 plotted according to [6].

Generally, we conclude that the rather short spin–lattice relaxation times of ^{119}Sn make it a useful nucleus for further high resolution FT nmr studies.

Effect of nitric oxide on hydrogen formation in irradiated HCl[1]

NEIL M. BALLASH, SURJIT S. NAGRA, AND DAVID A. ARMSTRONG
Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received June 28, 1976

NEIL M. BALLASH, SURJIT S. NAGRA, and DAVID A. ARMSTRONG. Can. J. Chem. **55**, 932 (1977).

Nitric oxide reduces the production of hydrogen in irradiated HCl and leads to ClNO formation. The results can be interpreted on the basis of a competition between HCl and NO for H atoms and $(HCl)_x^-$ negative ion intermediates. The yield of $(HCl)_x^- = 2.4 \pm 0.3$ per 100 eV is similar to that found from experiments with chlorine, as was the total yield of scavengable H atoms plus electrons, $g_e + g_H$. From analyses of the competition kinetics for experiments both with and without added SF_6, the ratio of the termolecular rate constant for reaction of H with NO in the presence of HCl as third body to that for reaction of H with HCl was estimated to be $6.3 \pm 0.8 \times 10^{-19}$ cm^3 molecule^{-1} at 298 K.

NEIL M. BALLASH, SURJIT S. NAGRA et DAVID A. ARMSTRONG. Can. J. Chem. **55**, 932 (1977).

L'oxyde nitrique réduit la production d'hydrogène dans du HCl irradié et conduit à la formation de ClNO. On peut interpréter les résultats en se basant sur une compétition entre HCl et NO pour les atomes d'hydrogène et les intermédiaires ioniques négatifs $(HCl)_x^-$. Le rendement de $(HCl)_x^- = 2.4 \pm 0.3$ par 100 eV est semblable à celui trouver pour des expériences avec le chlore; il en avait été aussi de même pour le rendement total: atomes d'hydrogène piégeables plus électrons, $g_e + g_H$. A partir de l'analyse de la cinétique de compétition pour des expériences effectuées avec et sans SF_6 ajouté, le rapport de la constante de vitesse termoléculaire de la réaction de H avec NO en présence de HCl comme troisième corps et de celle de la réaction de H avec HCl peut être estimé à $6.3 \pm 0.8 \times 10^{-19}$ cm^3 molecule^{-1} à 298 K.
[Traduit par le journal]

Introduction

The mechanism of hydrogen formation in irradiated HCl has previously been investigated with the electron scavengers SF_6, CCl_4, and C_7F_{14} (1, 2), and with chlorine and bromine, which consume hydrogen atoms as well as negative ion species (1, 3). In the work reported here nitric oxide was used as a scavenger of intermediates. Like chlorine and bromine this molecule reacts with hydrogen atoms (4–6) as well as electrons (7). However, reaction 1 differs from

[1] $$H + NO + M \rightarrow HNO + M$$

the hydrogen atom reactions of the halogens (reaction 2) in that it requires the presence of a

[2] $$H + X_2 \rightarrow HX + X \quad (X = Cl \text{ or } Br)$$

third body for stabilization of the HNO molecule. Since the stabilization probability should decrease with increased translational energy of H, [1] is likely to be more specific for thermal H atoms than [2]. Thus, the use of nitric oxide provides a further and more definitive means of confirming the presence of this species. In addition the results discussed here support earlier evidence for the formation of an $(HCl)_x^-$ negative ion intermediate.

Experimental

Materials

Matheson 'electronic grade' HCl was purified by preirradiation and sublimation as already described (8). The nitric oxide and sulfur hexafluoride were also from the Matheson Company and of research grade. The sulfur hexafluoride was degassed before storage. The nitric oxide was separated from NO_2 and other trace impurities by sublimation. All gases were stored in liquid nitrogen traps attached to the mercury free vacuum line used for filling the radiation cells.

Apparatus and Procedure

Irradiations were performed at 298 K with an AECL ^{60}Co gamma cell 220 which accommodated the 350 cm^3 cylindrical pyrex cells. After irradiation these were reattached to the preparation line and the HCl and NO were condensed in a small side arm immersed in liquid nitrogen. For samples with large NO concentrations the side arm was immersed in a solid nitrogen slurry. The hydrogen was pumped through a trap to remove nitric oxide and into another vacuum line for analysis as already described (8).

The dose rate was determined regularly wth HCl, for which $G(H_2)$ in the absence of scavengers is 8.0 ± 0.2

[b]Yield per 100 eV of electrons forming H atoms (see text).

molecules per 100 eV (3). The average dose rate over the duration of the study was 5×10^{16} eV g^{-1} min^{-1}. Other details of technique and procedure may be found in earlier references (8, 9).

Results

From other work (see, for example, ref. 10) it can be shown that reaction 3 will compete with reaction 4 under the conditions employed here.

[3] $$Cl + NO + HCl \rightarrow ClNO + HCl$$

[4] $$Cl + Cl + HCl \rightarrow Cl_2 + HCl$$

By transferring a small aliquot of the irradiated mixture to a 1 cm path length spectroscopic cell and scanning the absorption in the 180 to 260 nm range the production of ClNO was confirmed from its strong absorption at 197 nm (11). However, the yields of this product were not examined in detail.

Hydrogen yields were normally measured in the dose range 0 to 4.6×10^{18} eV g^{-1} and hydrogen concentration *vs.* dose plots were linear to much larger doses, which showed that reactions of H atoms or other intermediates with products were unimportant. Table 1 summarizes the 100 eV yields obtained with various amounts of nitric oxide added to HCl at three different concentrations. Average deviations of replicate experiments were normally ≤ 0.15 molecules per 100 eV.

Previous studies (1–3, 12) have led to the conclusion that primary processes in HCl produce HCl^+, electrons, thermal hydrogen atoms (H), and hot hydrogen atoms (H) with the following yields per 100 eV: $g_{HCl^+} = g_e = 4.0$, $g_H = 1.8$, and $g_H = 2.2$. Electrons are captured in reactions 5 through 7 and hydrogen formation occurs through reactions 9 and 10.

[5] $$e + 2HCl \rightleftarrows (HCl)_2^{-*}$$

[6] $$(HCl)_2^{-*} + HCl \rightarrow H + Cl^-.2HCl$$

[7] $$(HCl)_2^{-*} + HCl \rightarrow (HCl)_2^- + HCl$$

[8] $$(HCl)_x^- + HCl \rightarrow H + Cl^-.xHCl$$

[9] $$H + HCl \rightarrow H_2 + Cl$$

[10] $$H + HCl \rightarrow H_2 + Cl$$

As stated earlier chlorine formation in [4] will be suppressed by [3] but this would not influence hydrogen production. Also, reaction 10 is rapid (13) and [1] cannot compete with it. However, interpretation of the hydrogen yields is complicated by the possibility that nitric oxide may compete for electrons and/or $(HCl)_x^-$, as well as for H atoms. For that reason the effect of nitric oxide on hydrogen yields from HCl containing 1 to 1.25 mol% SF_6 was also investigated. This scavenger suppresses all reactions of electrons (*i.e.* [5] through [8]) and should make it possible to study the competition between NO and HCl

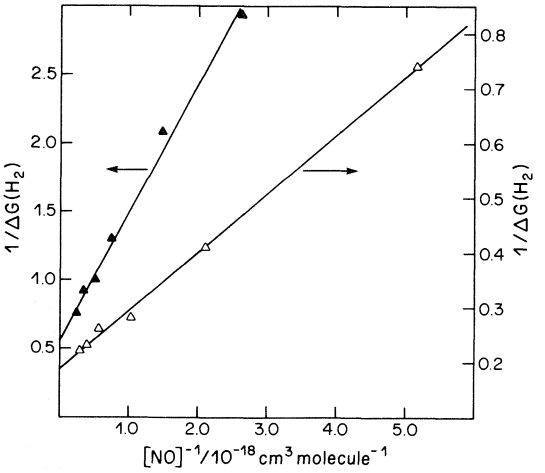

FIG. 1. Reciprocal plots of the change in $G(H_2)$ against $[NO]^{-1}$. Filled points, 1 to 1.25 mol% SF_6 present; open points, no SF_6 present; [HCl] = 19.4×10^{18} molecules cm^{-3}.

for thermal hydrogen atoms alone (*cf.* ref. 14). Under these circumstances the competition between reactions 1 and 9 should be described by expression 11, where y_H is equal to g_H.

$$[11] \quad \{\Delta G(H_2)\}^{-1} = y_H^{-1}\{1 + k_9/k_1[NO]\}$$

The solid points in Fig. 1 are values of $\{\Delta G(H_2)\}^{-1}$ from experiments with varying [NO] in $19.4_4 \times 10^{18}$ molecules cm^{-3} of HCl containing 1 mol% SF_6. The intercept of the linear plot gives $y_H = 1.8 \pm 0.1$ molecules per 100 eV. The slope divided by intercept leads to $k_9k_1^{-1} = 1.7 \pm 0.2 \times 10^{18}$ molecules cm^{-3}. The results of similar experiments with $38.8_8 \times 10^{18}$ molecules cm^{-3} of HCl are reported in Fig. 3 and discussed later.

Discussion

The magnitude of y_H from the experiments described in the preceding paragraph is in excellent agreement with g_H from other experiments (see above). Also, taking k_9 at 298 K = $1.1 \pm 0.1 \times 10^{-13}$ cm^3 $molecule^{-1}$ s^{-1} from a number of experimental studies (15, 16) one finds from $k_9k_1^{-1} = 1.7 \pm 0.2 \times 10^{18}$ molecule cm^{-3}, $k_1 = 6.6 \pm 1.0 \times 10^{-32}$ cm^6 $molecule^{-2}$ s^{-1} for HCl as third body. This is somewhat larger than $\sim 3 \times 10^{-32}$ cm^6 $molecule^{-2}$ s^{-1} for argon as third body (4–6), which seems entirely reasonable, and closer to $6.0 \pm 0.2 \times 10^{-32}$ cm^6 $molecule^{-1}$ s^{-1} for hydrogen as third body. Further justification for the magnitude of $k_9k_1^{-1}$ and for the termolecular character of reaction 1 in HCl is given later. However, the values of y_H and $k_9k_1^{-1}$ from the system with SF_6 present are seen to be in reasonable accord with expectations for the scavenging of thermal H atoms, and we turn now to the interpretation of experiments with NO alone as scavenger.

Reactions 6 and 7 are fast and NO should not compete with them. This is also true for the clustering of $(HCl)_2^-$ to form $(HCl)_x^-$, which is not explicitly shown. To allow for the possible scavenging of e and/or $(HCl)_x^-$ one can use the term B to represent the fraction of electrons proceeding through reactions 5 to 8 to form H atoms. The total hydrogen yield is then given by

$$[12] \quad G(H_2) = g_H + A\{g_H + Bg_e\}$$

where A, the fraction of H atoms undergoing [9], is equal to $\{1 + k_1[NO]/k_9\}^{-1}$. Both A and B must go to unity as $[NO] \rightarrow 0$, and the decrease in $G(H_2)$ for $[NO] \neq 0$ is given by [13].

$$[13] \quad \Delta G(H_2) = g_H + g_e - A\{g_H + Bg_e\}$$

In the event that NO did not react with e or $(HCl)_x^-$ B would always be unity and [13] could be reduced to the same reciprocal form as [11] with y_H now equal to $(g_e + g_H)$. This expression was tested for the results in Table 1 by making plots of $\{\Delta G(H_2)\}^{-1}$ *vs.* $[NO]^{-1}$. The open points in Fig. 1 illustrate this for the $19.4_4 \times 10^{18}$ molecule cm^{-3} HCl concentration. From the magnitudes of the slope/(intercept) apparent values of $k_9 \times k_1^{-1}$ equal to 0.8×10^{18}, 0.5×10^{18}, and 0.2×10^{18} molecules cm^{-3} were found for [HCl] = 38.9×10^{18}, 19.4×10^{18}, and 9.7×10^{18} molecules cm^{-3}, respectively. The fact that these decrease progressively with [HCl] and are all smaller than the value of $k_9k_1^{-1}$ from the experiments with SF_6 present demonstrates that a simple competition for H atoms alone does not hold. This was also shown by the fact that $(g_e + g_H)$ from the intercepts $(= y_H^{-1})$ varied from 5.9 to 5.2 to 4.3 respectively for the three HCl concentrations.

For the purpose of investigating the scavenging of e and $(HCl)_x^-$ by NO, expression 13 was rearranged to [14].

$$[14] \quad \{g_H + g_e - \Delta G(H_2) - Ag_H\}A^{-1} = g_eB$$

Assuming $k_9k_1^{-1} = 1.7 \times 10^{18}$ molecules cm^{-3} from above, we calculated the values of A in column four of Table 1 for the experimental conditions listed in columns one and two, and used

them to evaluate the quantity on the left-hand side of expression 14. This was used as a measure of g_eB and is given in column five of Table 1. Also the dependence of g_eB on [NO]/[HCl] is shown in Fig. 2*a*, where it is interesting to note that: (*a*) the points for the three HCl concentrations fall on a single curve; and (*b*) this is flat at ~2 molecules/100 eV for [NO]/[HCl] $\geq$ 0.04. Since $g_e = 4.0$ the latter feature suggests that NO cannot compete with reaction 5, but does scavenge $(HCl)_x^-$ in reaction 15 (also see below).

[15] $(HCl)_x^- + NO \rightarrow$ *No* H *or* H_2

Likely products for this reaction are HNO and $Cl^-.(x - 1)HCl$.

Figure 2*b* presents a plot of $\{g_e(1 - B)\}^{-1}$ *vs.* [HCl]/[NO], which conforms to expression 16.

[16] $$\{g_e(1 - B)\}^{-1} = (g_{(HCl)_x^-})^{-1}\left\{1 + \frac{k_8[HCl]}{k_{15}[NO]}\right\}$$

The intercept leads to $g_{(HCl)_x^-} = 2.4 \pm 0.3$ molecules per 100 eV and the (slope/intercept) to $k_8/k_{15} = 1.4 \pm 0.3 \times 10^{-2}$. Thus, the quantity B can now be set equal to $[(1 - \alpha) + \alpha\{1 + k_{15}[NO]/k_8[HCl]\}^{-1}]$, where $\alpha = k_7/(k_6 + k_7) = (g_{(HCl)_x^-}/g_e) = 0.60$. This formula has the correct form to explain Fig. 2*a* and leads also to expression 16.

To determine whether the values of the parameters above are consistent with the best value of $k_9k_1^{-1}$ the following approach was employed.

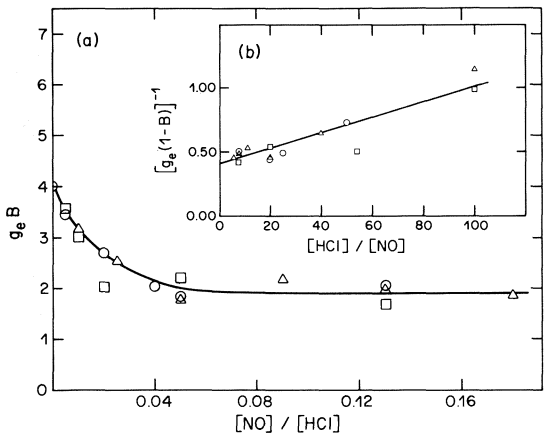

FIG. 2. Effect of NO on hydrogen atom formation by electrons. (*a*) Plot of number of electrons forming H atoms per 100 eV, g_eB, *vs.* [NO]/[HCl]. (*b*) Plot of $\{g_e(1 - B)\}^{-1}$ *vs.* [HCl]/[NO]. ○, [HCl] = 9.7 × 10^{18}; △, 19.4 × 10^{18}; □, 38.9 × 10^{18} molecules cm^{-3}.

Substituting the explicit formula for B into expression 13 and rearranging it, one obtains

[17] $$A = \frac{[g_H + g_e - \Delta G(H_2)]}{g_H + g_e\left[(1 - \alpha) + \alpha\left\{1 + \frac{k_{15}[NO]}{k_8[HCl]}\right\}^{-1}\right]}$$

Using the magnitudes of α and $k_{15}k_8^{-1}$ determined above the fraction A of H atoms undergoing [9] was recalculated. It is plotted as a function of the nitric oxide pressure in Fig. 3. The scatter of points is greater for experiments with SF_6 present because the fractional change in $G(H_2)$ for a given [NO] is much smaller. However, the results for the different HCl concentrations both with and without SF_6 fall on a single line. The slope of this gave $k_9k_1^{-1} = 1.6 \pm 0.2 \times 10^{18}$, whence using k_9 from above we find $k_1 = 6.9 \pm 1.0 \times 10^{-32}$ cm^6 $molecule^{-2}$ s^{-1}. These values are within experimental error the same as those found from the experiments with SF_6 present in the Results section, and a more elaborate determination of α, $k_{15}k_8^{-1}$, and $k_9k_1^{-1}$ by successive approximation is not required.

The observed value of $g_{(HCl)_x^-} = 2.4 \pm 0.3$ is very similar to $g_{(HCl)_x^-} = 2.4 \pm 0.3$ at 274 K and 2.5 ± 0.1 molecules per 100 eV at 196 K estimated by Davidow and Armstrong (1) using chlorine as a scavenger. Also the magnitude of $k_8/k_{15} = 1.2 \times 10^{-2}$ is to be compared with $k_8/k_{18} = 3.3 \times 10^{-3}$ calculated for 298 K from the earlier results.

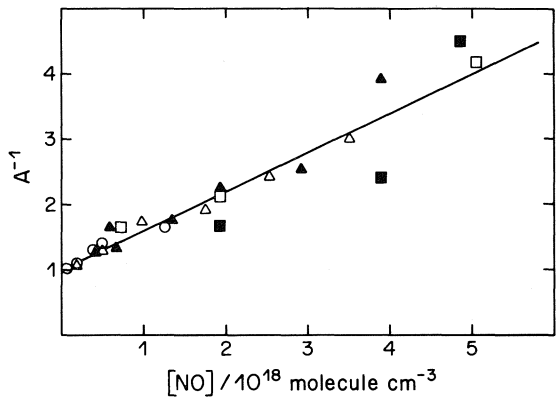

FIG. 3. Reciprocal of the fraction A of H atoms reacting with HCl. Plotted as a function of NO concentration. HCl concentrations shown by points as in Fig. 2; filled points, 1 to 1.25 mol% SF_6 present; open points, without SF_6.

[18] $(HCl)_x^- + Cl_2 \rightarrow$ *No* H *or* H_2

Although the interpretation of the present results is relatively complex these comparisons strongly support the view that NO is scavenging the same species $(HCl)_x^-$ as was previously postulated to explain the chlorine results. The absence of a competition for free electrons is not entirely unexpected, since electron capture by nitric oxide is much slower than by the common electron scavengers SF_6 and CCl_4. The electron capture mechanism in pure NO is considered to involve reactions 19, 20, and 21 (7).

[19]/[20] $e + NO + NO \rightleftharpoons NO^- + NO$

[21] $NO^- + 2NO \rightarrow$ Stable ions

The magnitude of k_{19}, which determines the rate when every NO^- undergoes [21],[2] is $8 \pm 4 \times 10^{-31}$ cm^6 $molecule^{-2}$ s^{-1}. Assuming reaction 22 occurs with a rate constant similar to reaction 19

[22] $e + NO + HCl \rightarrow NO^- + HCl$

the maximum rate of capture in HCl for a given set of [HCl] and [NO] would be 8×10^{-31} [NO][HCl]. With this and a rate of electron capture by HCl $= 10.4 \pm 0.7 \times 10^{-50}$ $[HCl]^3$ from (12) we find that 13% nitric oxide in HCl will capture electrons at one tenth, one twentieth, and one fortieth the rate by HCl at concentrations of 9.7×10^{18}, 19.4×10^{18}, and 38.9×10^{18} molecules cm^{-3} respectively.

The fate of HNO in the HCl system is obviously of particular interest. In contrast to the analogous process in HI (17), reaction 23

[23] $HNO + HCl \rightarrow H_2 + ClNO$

is found from data in ref. 18 to be endothermic by 10 kcal per mole and can be excluded. Some HNO may disappear in reaction 24 (19–21) and by reaction with NO (19).

[24] $HNO + HNO \rightarrow H_2O + N_2O$

However, an important factor here is the presence of Cl_2 and ClNO, which may remove NO through reactions 25 and 26.

[25] $Cl_2 + HNO \rightarrow HCl + ClNO$

[26] $ClNO + HNO \rightarrow HCl + 2NO$

These reactions are exothermic and seem likely in the present circumstances.

[2]In HCl NO^- should undergo the reaction $NO^- + HCl \rightarrow Cl^- + HNO$ which has a second order rate constant of 1.6×10^{-9} cm^3 s^{-1} (22).

Received September 7, 1976

B. MARIO PINTO, DOLATRAI M. VYAS, and WALTER A. SZAREK. Can. J. Chem. **55**, 937 (1977).

Nucleoside analogs, namely 6-chloro-9-(4-benzoyl-1-oxa-4-azacyclohexan-2-yl)-9*H*-purine **6** and 6-chloro-9-(4-benzoyl-1-thia-4-azacyclohexan-2-yl)-9*H*-purine **7**, were obtained by treatment of 4-benzoyl-2-hydroxy-1-oxa-4-azacyclohexane **13** and 4-benzoyl-2-hydroxy-1-thia-4-azacyclohexane **18**, respectively, with 6-chloropurine, methyldiphenylphosphine, and diethyl azodicarboxylate in refluxing tetrahydrofuran. Compounds **13** and **18** were obtained by *O*-deacetylation of the corresponding 2-acetoxy derivatives **11** and **16** with a catalytic amount of sodium methoxide in chloroform. 2-Acetoxy-4-benzoyl-1-oxa-4-azacyclohexane **11** was obtained from 4-benzoyl-1-oxa-4-azacyclohexane **10** by treatment with *tert*-butyl peracetate, cuprous chloride, and benzene, whereas 2-acetoxy-4-benzoyl-1-thia-4-azacyclohexane **16** was prepared by a Pummerer reaction with 4-benzoyl-1-thia-4-azacyclohexane 1-oxide **15**. The ^{13}C nmr spectra of all the compounds are reported; the spectra provided unambiguous proof of structure.

B. MARIO PINTO, DOLATRIA M. VYAS et WALTER A. SZAREK. Can. J. Chem. **55**, 937 (1977).

On a obtenu des analogues nucléosides à savoir la chloro-6 (benzoyl-4 oxa-1 aza-4 cyclohexanyl-2)-9 9*H*-purine **6** et chloro-6 (benzoyl-4 thia-1 aza-4 cyclohexanyl-2)-9 9*H*-purine **7** par les réactions respectives du benzoyl-4 hydroxy-2 oxa-1 aza-4 cyclohexane **13** et du benzoyl-4 hydroxy-2 thia-1 aza-4 cyclohexane **18** avec la chloro-6 purine, la méthyldiphénylphosphine et l'azodicarboxylate de diéthyle dans le tétrahydrofuranne au reflux. On a obtenu les composés **13** et **18** par une *O*-déacylation des dérivés acétoxy-2 correspondants (**11** et **16**) avec des quantités catalytiques de méthylate de sodium dans le chloroforme. On a obtenu l'acétoxy-2 benzoyl-4 oxa-1 aza-4 cyclohexane **11** à partir du benzoyl-4 oxa-1 aza-4 cyclohexane **10** par réaction avec le peracétate de *tert*-butyle, le chlorure cuivreux et le benzène alors qu'on a préparé l'acétoxy-2 benzoyl-4 thia-1 aza-4 cyclohexane **16** par une réaction de Pummerer avec le benzoyl-4 thia-1 aza-4 cyclohexane oxyde-1 **15**. On rapporte les spectres rmn du ^{13}C de tous les composés; les spectres fournissent une preuve non-ambigue des structures.

Introduction

In the quest for potent anticancer agents for chemotherapeutic use, an active area of research in this laboratory is the synthesis of novel nucleoside analogs containing more than one hetero-atom in the carbohydrate ring. A stimulus for this aspect of nucleoside chemistry was provided by the fact that *N*-[2-(9-adenyl)-3,5-dihydroxy-6-(hydroxymethyl)morpholino]iso-nicotinamide **1**, obtained by condensation of periodate-oxidized adenosine with isonicotinic acid hydrazide, is a substituted morpholine structure and possesses both antitumor and immunosuppressive properties (1). The reduction of the adduct of periodate-oxidized adenosine 5′-phosphate and methylamine has also afforded a nucleotide analog of an *N*-methylmorpholine derivative (2*a*), and a uridine-base derivative of a morpholine derivative has been synthesized by Jones and Walker (2*b*) by reacting "uridine-dialdehyde" with benzoylhydrazine. As part of this program, the synthesis (3) and conformational analysis (4) of nucleoside-base derivatives of 1,4-oxathiane (**2** and **3**), 1,4-dithiane **4**, and 1,4-dioxane **5** have been reported; some of these compounds have exhibited anticancer activity.[2]

As a further extension, in this paper we report the synthesis of 6-chloro-9-(4-benzoyl-1-oxa-4-azacyclohexan-2-yl)-9*H*-purine **6** and 6-chloro-9-(4-benzoyl-1-thia-4-azacyclohexan-2-yl)-9*H*-purine **7** from the readily available, non-carbohydrate precursors, 1-oxa-4-azacyclohexane **8** and 1-thia-4-azacyclohexane **9**, respectively. In earlier studies (6, 7), suitably protected

[1]Author to whom inquiries should be addressed.

[2]W. A. Szarek, D. M. Vyas, and A. Bloch, unpublished results.

carbohydrates have been converted into derivatives of 1-oxa-4-azacyclohexanes. Interestingly, several guanidine derivatives of 1-thia-4-azacyclohexane and 1-thia-4-azacycloheptane have also been studied (8) for their potential antihypertensive properties. ^{13}C magnetic resonance (^{13}Cmr) and proton magnetic resonance (^{1}Hmr) spectroscopic data of all intermediates, side-products, and product nucleosides are also reported in this paper; these data have been employed for proof of structure and examination of conformational behaviour.

In contrast to our earlier study (4) on ^{13}Cmr spectra of 1,4-oxathiane derivatives in which the assignment of chemical shifts was straightforward, in the case of the present series of

5 X = Y = O

6 7

compounds, namely the *N*-acylated nitrogen heterocycles, the assignment of signals in their ^{13}Cmr spectra obtained at ambient temperature was complicated because of broadening of certain signals owing to restricted rotation about the amide bond (9). Hirsch *et al.* (10) have recently reported barriers to amide rotation in a series of substituted, six-membered nitrogen heterocycles, including 4-benzoyl-1-oxa-4-azacyclohexane **10**, as studied by ^{13}C dnmr. In the present study, spectra obtained at various temperatures were employed to distinctly assign the signals of all of the carbons in the six-membered rings. Details of a ^{1}H dnmr study of the effects of substitution on nitrogen on barriers to rotation of cyclic amides have been published (11).

Results and Discussion

Commercially available 1-oxa-4-azacyclohexane **8** was readily converted into 4-benzoyl-1-oxa-4-azacyclohexane **10** (see Scheme 1) by treatment with benzoyl chloride and pyridine in chloroform. Treatment of **10** with *tert*-butyl peracetate in refluxing benzene in the presence of cuprous chloride for 5.5 h by the procedure of Sosnovsky and Lawesson (12) afforded chromatographically separable 2-acetoxy-4-benzoyl-1-oxa-4-azacyclohexane **11** and *trans*-2,3-diacetoxy-4-benzoyl-1-oxa-4-azacyclohexane **12** in a ratio of approximately 4:1, respectively; prolonged heating resulted in the formation of a greater proportion of **12**.

The regioselectivity of the acetoxylation reaction to give the 2-acetoxy derivative **11** was readily confirmed by ^{13}Cmr spectroscopy. The ^{13}C chemical shifts for the 1-oxa-4-azacyclohexane derivatives **8** and **10**–**13** are given in Table 1. In the case of compounds **11** and **13**, the spectral data are reported at temperatures at which the rates of rotation about the amide bond are slow, intermediate, and fast on the nmr time-scale; in the case of 4-benzoyl-1-oxa-4-azacyclohexane **10**, the two temperatures given are those representing slow and intermediate rates. The data given for the diacetate **12** are those for the slow-exchange rate. The

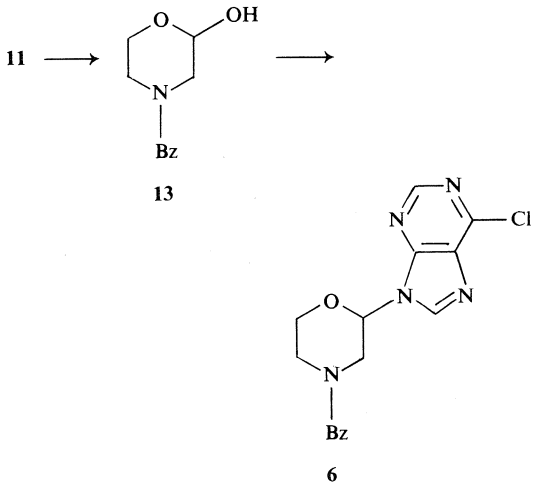
[d]Signal not observed.

presence of the acetoxy group at C-2 in 2-acetoxy-4-benzoyl-1-oxa-4-azacyclohexane **11** causes a large downfield shift (~22 ppm) of the C-2 signal relative to that in the spectrum of 4-benzoyl-1-oxa-4-azacyclohexane **10** and only slight changes in the chemical shifts of the C-3 and C-5 signals. It is noteworthy that the C-6 signal in the spectrum of **11** (recorded at the slow-exchange limit) is shifted upfield by 6.0 ppm relative to the corresponding signal in the spectrum of **10**. This result is consistent with the preponderant conformation of compound **11** having the acetoxy group in the axial orientation, since there then would be a γ steric interaction (4, 13) between this group and the axial hydrogen at C-6. The assignment of the axial orientation for the acetoxy group is in accordance with the anomeric effect (14), and was corroborated by the observation, in the ^{1}Hmr spectrum of **11**, of the H-2 signal as a broad singlet at τ 3.82 ($J_{2,3} + J_{2,3'} \simeq 5$ Hz); the value of 5 Hz includes the long-range coupling across oxygen.

The constitution and stereochemistry of the diacetoxy derivative, *trans*-2,3-diacetoxy-4-benzoyl-1-oxa-4-azacyclohexane **12**, were also established by nmr spectroscopy. The observation that the C-6 signal in the ^{13}Cmr spectrum of the diacetate **12** is shifted upfield by 1.3 ppm relative to that in the spectrum of the monoacetate **11** (recorded at 305 K) is only consistent with the second acetoxy group being at C-3 in compound **12**; the presence of this group at C-6 or C-5 would be expected to cause a downfield shift of the C-6 signal in **12** (relative to **11**) as a consequence of the α or β effect (4, 15), respectively. In the ^{1}Hmr spectrum of **12** the H-2 and H-3 signals appeared as broad singlets having half-height widths of 3 and 4 Hz,[3] respectively, an observation which suggests that the acetoxy groups at C-2 and C-3 in the preferred conformation of **12** are *trans*-diaxially disposed. This stereochemistry is also manifested by the upfield shifts (4.3 and 6.9 ppm) of the C-5 and C-6 signals, respectively, in the ^{13}Cmr spectrum of **12** relative to the corresponding signals in the spectrum of 4-benzoyl-1-oxa-4-azacyclohexane **10** (recorded at 270 K) attributable to the γ steric interactions between the axial acetoxy groups and the axial hydrogens at C-5 and C-6.

Another interesting aspect of the ^{13}Cmr-spectral study of compounds **10** and **11** is the effect of restricted rotation about the amide bond on ^{13}C chemical shifts. In the spectrum of **10** at 295 K the C-3 and C-5 resonances appear as a broad band; however, at 270 K distinct signals are observed at 48.2 and 42.5 ppm indicating a slow rate of rotation about the amide bond on the nmr time-scale. Previous workers have shown (17) that the carbon *syn* to the carbonyl oxygen of an amide is shielded relative to the corresponding carbon in the *anti* conformer. Thus, the signals at 48.2 and 42.5 ppm are assigned to the carbons which are *anti* and *syn*, respectively, to the carbonyl oxygen. In the case of the 2-acetoxy derivative **11**, the C-3 and C-5 resonances, which appear as a broad band at 305 K (see Fig. 1*b*), are resolved into two sharp peaks at 48.2 and 43.8 ppm at the fast-exchange limit (see Fig. 1*a*); the signal at 48.2 ppm is assigned to C-3 on the basis of an expected β effect of a neighboring acetoxy group. At the slow-exchange limit, signals for the two ring carbons α to the nitrogen for the two rotational isomers are clearly revealed (see Fig. 1*c*); the signals for the *syn* and *anti* isomers were assigned on the basis of the approach outlined above.

Treatment of compound **11** with a catalytic amount of sodium methoxide afforded 4-benzoyl-2-hydroxy-1-oxa-4-azacyclohexane **13** (see Scheme 2) as a colorless syrup. The ^{13}C



SCHEME 2

[3]These values presumably include long-range couplings across the two heteroatoms in the ring (compare refs. 4 and 16).

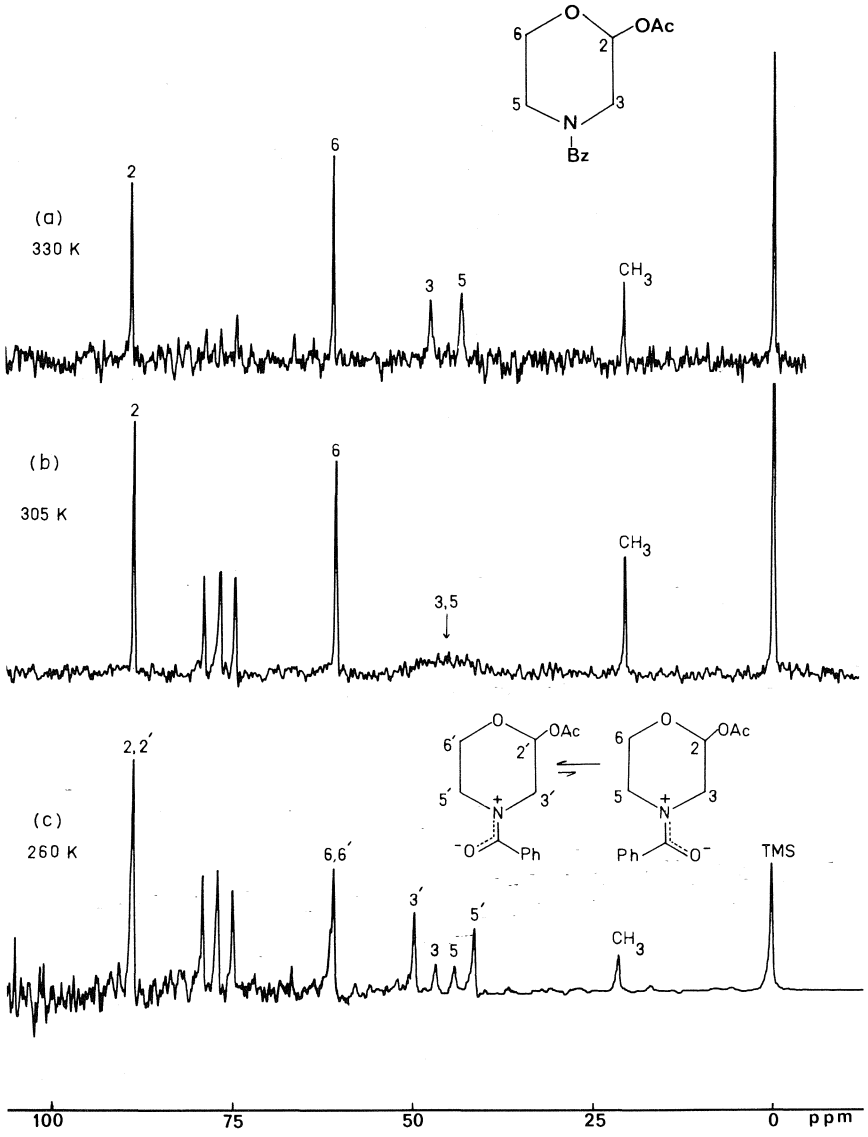


FIG. 1. ^{13}Cmr spectra of 2-acetoxy-4-benzoyl-1-oxa-4-azacyclohexane **11** at (*a*) 330 K, (*b*) 305 K, and (*c*) 260 K.

chemical shift assignments for the 2-hydroxy derivative **13** were relatively straightforward and are documented in Table 1. Compound **13** was converted into the nucleoside analog **6** in 50% yield by treatment (18) with 6-chloropurine, methyldiphenylphosphine, and diethyl azodicarboxylate in refluxing tetrahydrofuran. The maximal uv absorption for **6** at 264 nm in neutral, acid, or basic solution is in agreement (19) with a 9-substituted purine. The value (12 Hz) obtained for $J_{2',3'} + J_{2',3''}$ from the ^{1}Hmr spectrum of **6** is indicative of a preponderance in chloroform-*d* of the conformer having the purine moiety in an equatorial orientation. This conformational preference is further indicated by the observation that the C-6′ signal in the ^{13}Cmr spectrum of nucleoside **6** (recorded at 330 K) is shifted upfield by only 0.8 ppm (see Table 2) with respect to the C-6 signal in the spectrum of **10**; a preference for the conformer having the purine moiety in an axial orientation would have been expected to be

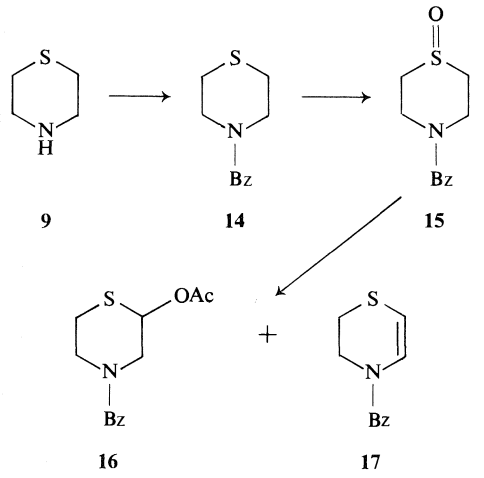
manifested by a significantly larger upfield shift of the C-6′ signal owing to a γ steric interaction between the purine ring and the axial hydrogen at C-6′.

1-Thia-4-azacyclohexane **9**, prepared from diethanolamine by the method of Cymerman-Craig *et al.* (20), was converted into 4-benzoyl-1-thia-4-azacyclohexane **14** (see Scheme 3) by treatment with benzoyl chloride and pyridine in chloroform. The sulfoxide **15** was obtained from **14** by oxidation with sodium metaperiodate by the method of Leonard and Johnson (21). Treatment of **15** with 2.4 equiv. of acetic anhydride in benzene containing a trace of *p*-toluenesulfonic acid monohydrate at 60 °C for 3.5 h afforded the chromatographically separable Pummerer-reaction product **16**, as a colorless syrup, and a small proportion of 4-benzoyl-1-thia-4-azacyclohex-2-ene **17**; treatment of **15** with these reagents at 80 °C for 1 h afforded a 1:1 mixture of the Pummerer-reaction product **16** and the elimination product **17**.

The ^{13}C chemical shift assignments in the spectrum of 4-benzoyl-1-thia-4-azacyclohexane **14** (see Table 3) were made in analogy to those made in the spectrum of 4-benzoyl-1-oxa-4-azacyclohexane **10**; however, in the case of **14**, the C-2 and C-6 signals were observed to have slightly different chemical shifts. The assignment of the C-2 and C-6 signals was made by an extension of the approach employed for the C-3 and C-5 signals.

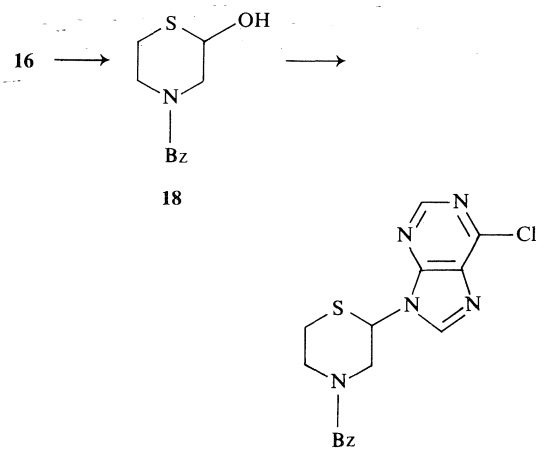


9 **14** **15** **16** **17**

SCHEME 3

In Fig. 2 are shown the ^{13}Cmr spectra of the sulfide **14** and the sulfoxide **15**. The relative shifts observed for corresponding signals parallel the trends described previously (4) for 1,4-oxathiane and 1,4-oxathiane 1-oxide.

The ^{13}Cmr spectrum of the Pummerer product **16** was analyzed in a manner analogous to that employed in the case of 2-acetoxy-4-benzoyl-1-oxa-4-azacyclohexane **11**. A salient feature again is the 4.1 ppm upfield shift of the C-6 signal in the spectrum of **16** (recorded at the slow-exchange limit) relative to the corresponding signal in the spectrum of 4-benzoyl-1-thia-4-azacyclohexane **14** indicating that the preponderant conformation of compound **16** has the acetoxy group at C-2 in the axial orientation; the value (~8 Hz) obtained for $J_{2,3} + J_{2,3'}$ from the ^{1}Hmr spectrum of **16** could also be considered to be in agreement with this assignment, provided that it is noted that the value presumably includes the long-range coupling across sulfur. Moreover, the assignment is in accordance with previous examples (22) of the anomeric effect in sulfur heterocycles. Finally, the ^{13}Cmr spectra of **16** recorded at both fast- and slow-exchange limits exhibit nearly identical features to those described above for the spectra of 2-acetoxy-4-benzoyl-1-oxa-4-azacyclohexane **11**.



SCHEME 4

Treatment of compound **16** with a catalytic amount of sodium methoxide afforded 4-benzoyl-2-hydroxy-1-thia-4-azacyclohexane **18** (see Scheme 4) as a colorless syrup. Compound

[a]In ppm downfield from internal TMS in chloroform-*d*. [b]Values represent extremities of a broad band. [c]Values in parentheses are peak heights standardized on the basis of each carbon of the minor isomer having a peak height of 1.0. [d]Signal not observed. [e]Slightly broadened peak.

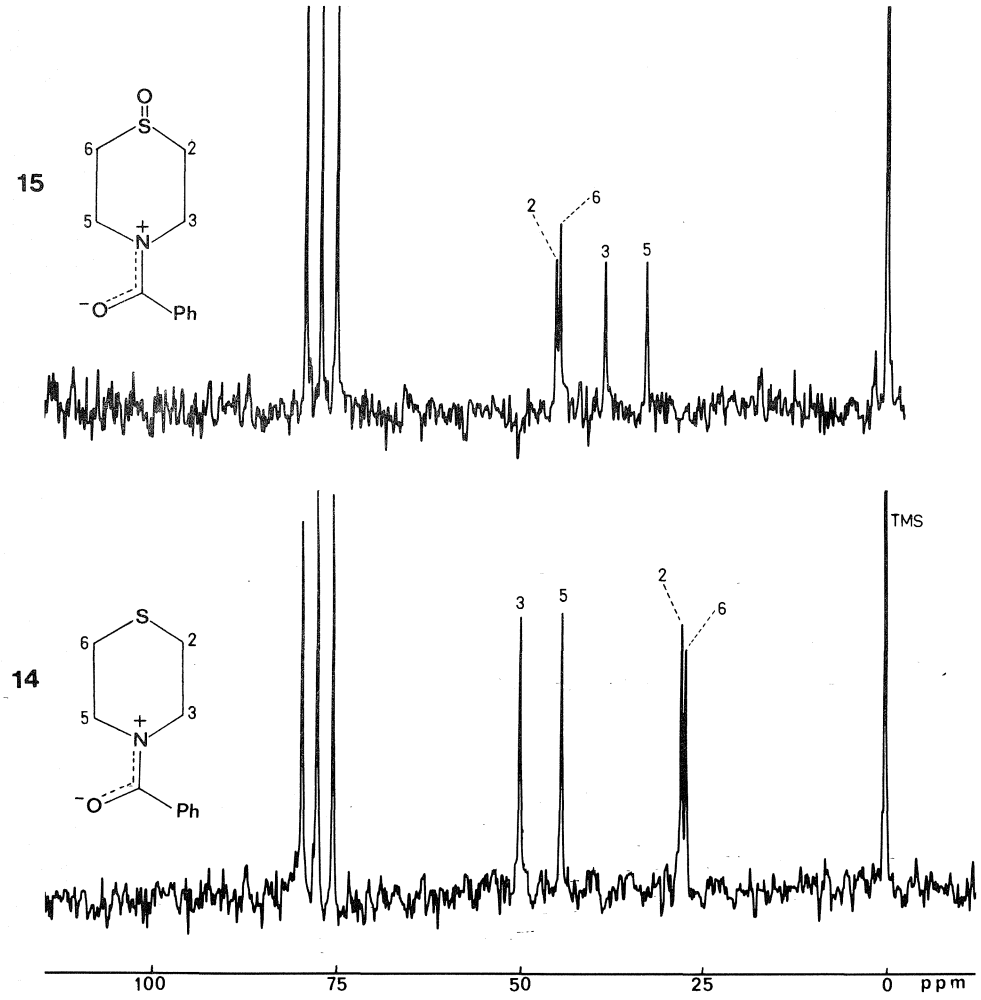

FIG. 2. ^{13}Cmr spectra of 4-benzoyl-1-thia-4-azacyclohexane **14** and 4-benzoyl-1-thia-4-azacyclohexane 1-oxide **15** recorded at 250 K.

18 was then converted into the nucleoside analog **7** in 35% yield by the same coupling procedure as described for **6**. The maximal uv absorption for **7** at 264–266 nm in neutral, acid, or basic solution is in agreement with a 9-substituted purine. The ^{13}C chemical-shift data for **7** are given in Table 2. As in the case of 2-acetoxy-4-benzoyl-1-thia-4-azacyclohexane **16**, the ^{13}Cmr and ^{1}Hmr data suggested that the preponderant conformation of the nucleoside analog **7** has the substituent at C-2 in the axial orientation; however, the C-6 signal in the spectrum of **7** (recorded at 330 K) is shifted upfield by only 1.4 ppm relative to the C-6 signal in the spectrum of **14**.

Experimental

Melting points were determined with a Fisher-Johns melting point apparatus and are uncorrected. The ir spectra were recorded on a Perkin-Elmer 180 spectrophotometer. Ultraviolet (uv) spectra were recorded on a Beckman ACTA MIV spectrophotometer. Proton magnetic resonance (^{1}Hmr) spectra were recorded at 60 MHz on a Varian EM-360 or Bruker HX-60 spectrometer in chloroform-*d* with tetramethylsilane (TMS, $\tau = 10.00$) as the internal standard. ^{13}Cmr spectra were recorded in chloroform-*d* solution on a Bruker HX-60 spectrometer equipped with a FT60M Fourier transform accessory at 15.09 MHz; chemical shifts are given in ppm downfield from TMS. Thin-layer chromatography was performed with silica gel G as the adsorbent in the following solvent systems (v/v): (*A*) benzene – ethyl acetate, 1:1; (*B*) 4:1; (*C*) 1:2; (*D*) petroleum ether (bp 60–80 °C) – ethyl acetate – methanol, 3:3:1. The

developed plates were air dried, and exposed to uv light and/or sprayed with a solution of cerium sulfate (1.0%) and molybdic acid (1.5%) in 10% aqueous sulfuric acid, and heated at ~150 °C. Column chromatography was performed on Brinkmann silica gel (70–325 mesh). Solvents were evaporated under reduced pressure below 50 °C.

4-Benzoyl-1-oxa-4-azacyclohexane ***10***

To a solution of 1-oxa-4-azacyclohexane **8** (10 g, 0.115 mol) in chloroform (100 ml) containing pyridine (18.9 g) at 0 °C was added benzoyl chloride (16.3 g, 0.116 mol) in chloroform (20 ml) over a period of 1.5 h. The mixture was stirred at room temperature for 8 h and then poured onto ice. The layers were separated, and the organic layer was washed successively with 6 *N* hydrochloric acid, aqueous sodium hydrogen carbonate solution (3 × 30 ml), aqueous copper sulfate solution (30 ml), and water (30 ml). The organic layer was dried over anhydrous magnesium sulfate, and the solvent evaporated to afford a syrup (20 g) which crystallized upon cooling *in vacuo*. The sample was recrystallized from ether–hexane to give **10** as white crystals (16.8 g, 76%); mp 69–70 °C; ^{1}Hmr data: τ 2.62 (s, 5H, Ph), 6.38 (br s, 8H, 2H-2′s, 2H-3′s, 2H-5′s, 2H-6′s).

2-Acetoxy-4-benzoyl-1-oxa-4-azacyclohexane ***11***

To a stirred solution of 4-benzoyl-1-oxa-4-azacyclohexane **10** (0.75 g, 3.9 mmol) in benzene (50 ml) containing cuprous chloride (40 mg), under an atmosphere of nitrogen at 81 °C, was added *tert*-butyl peracetate (0.56 g of a 75% solution in Mineral Spirits, 3.2 mmol) in benzene (15 ml) over a period of 2 h. The mixture was stirred at 81 °C for 3.5 h. Thin-layer chromatography indicated the presence of three new components having R_F values of 0.5, 0.4, and 0.3 together with unreacted starting material **10** (R_F 0.2). The mixture was cooled, diluted with benzene (50 ml), washed successively with aqueous sodium hydrogen carbonate solution (2 × 25 ml) and water (25 ml), and dried over anhydrous sodium sulfate. Evaporation of the solvent afforded a syrup which was chromatographed on silica gel, with solvent *A* as eluant, to give components having R_F values of 0.5, 0.4, 0.3, and 0.2. The component having an R_F value of 0.5 was obtained from ethanol as white crystals (28 mg), mp 146–147 °C, and was identified as being *trans*-2,3-diacetoxy-4-benzoyl-1-oxa-4-azacyclohexane **12**; ^{1}Hmr data: τ 2.5 (s, 5H, Ph), 3.82, 4.02 (two-1H br s, $W_{1/2}$ = 3 and 4 Hz, respectively, H-2 or H-3), 5.50–7.00 (m, 4H, 2H-5′s, 2H-6′s), 7.82 (s, 3H, OAc), 7.90 (s, 3H, OAc). *Anal.* calcd. for $C_{15}H_{17}NO_6$: C 58.62, H 5.58, N 4.56; found: C 58.61, H 5.66, N 4.48.

The component having an R_F value of 0.4 was isolated as a syrup (12 mg) and was not identified. The component having an R_F value of 0.3 was isolated as a syrup and was identified as being 2-acetoxy-4-benzoyl-1-oxa-4-azacyclohexane **11** (82 mg, 44%); ^{1}Hmr data: τ 2.5 (s, 5H, Ph), 4.0 (br s, 1H, H-2), 5.6–7.1 (6H, 2H-3′s, $|J_{2,3} + J_{2,3'}| \simeq 5$ Hz, 2H-5′s, 2H-6′s), 7.9 (s, 3H, OAc). The component having R_F value of 0.2 was isolated as a white solid and was identified as being unreacted starting material **9** (0.60 g).

4-Benzoyl-2-hydroxy-1-oxa-4-azacyclohexane ***13***

To a stirred solution of 2-acetoxy-4-benzoyl-1-oxa-4-azacyclohexane **11** (0.29 g, 1.16 mmol) in chloroform (20 ml) at 0 °C was added sodium methoxide (~0.1 *M*) in methanol (1 ml); stirring was continued at 0 °C for 5 h. Thin-layer chromatography (solvent *A*) indicated the presence of a new component having an R_F value of 0.1. The solution was washed with an aqueous sodium hydrogen carbonate solution (2 × 7 ml) and then with water (7 ml), and dried over anhydrous magnesium sulfate. Evaporation of the solvent afforded a syrup which was identified as being 4-benzoyl-2-hydroxy-1-oxa-4-azacyclohexane **13** (0.24 g, 98%); ^{1}Hmr data: τ 2.58 (s, 5H, Ph), 5.17 (br s, 1H, after deuteriation of OH, H-2) 5.67–6.92 (br signals, 6H, 2H-3′s, 2H-5′s, 2H-6′s).

6-Chloro-9-(4-benzoyl-1-oxa-4-azacyclohexan-2-yl)-9H-purine ***6***

A mixture of 6-chloropurine (0.179 g, 1.16 mmol), methyldiphenylphosphine (0.232 g, 1.16 mmol), and diethyl azodicarboxylate (0.202 g, 1.16 mmol) in dry tetrahydrofuran (20 ml) was added to 4-benzoyl-2-hydroxy-1-oxa-4-azacyclohexane **13** (0.235 g, 1.14 mmol) in dry tetrahydrofuran (20 ml) with stirring; stirring was continued for 20 h at room temperature. The reaction mixture was brought to reflux, and each of the reagents (0.5 equiv.) was added; refluxing was continued for 12 h. The reaction mixture was concentrated, and the residue was chromatographed on silica gel, with solvent *C* as eluant, to give a component having an R_F value of 0.1 in solvent *A* and 0.2 in solvent *C*. The sample was obtained as a white foam and was identified as being 6-chloro-9-(4-benzoyl-1-oxa-4-azacyclohexan-2-yl)-9*H*-purine **6** (0.20 g, 50%); mp 61 °C (sintered at 55 °C); ir (chloroform): 1578, 1550, and 1480 (purine ring), 1625 (C=O) cm^{-1}; uv λ_{max} (ethanol): 264 (ε 3492) (purine ring), 248 (ε 3257) (benzamide), 210 nm (ε 7039) (purine ring); λ_{max} (ethanol containing a trace of hydrochloric acid): 264 (ε 3603), 248 (ε 3408), 209 nm (ε 6536); λ_{max} (ethanol containing a trace of sodium hydroxide): 264 (ε 3743) shoulder, 246 (ε 5251), 217 nm (ε 16 480); ^{1}Hmr data: τ 1.28, 1.63 (2s, 1H each, H-2, H-8), 2.55 (s, 5H, Ph), 4.05 (d of d, 1H, $|J_{2',3'} + J_{2',3''}| = 12$ Hz, H-2′), 5.1–6.9 (6H, H-3′, H-3″, H-5′, H-5″, H-6′, H-6″). *Anal.* calcd. for $C_{16}H_{14}N_5O_2Cl$: C 55.90, H 4.10, N 20.37, Cl 10.32; found: C 55.87, H 4.23, N 20.21, Cl 10.52.

4-Benzoyl-1-thia-4-azacyclohexane ***14***

Crude 1-thia-4-azacyclohexane **9**, prepared from diethanolamine (16.8 g, 0.16 mol) by the method of Cymerman-Craig *et al.* (20), was dissolved in chloroform (250 ml) and pyridine (16 g) was added to the solution. The mixture was cooled to 0 °C, and benzoyl chloride (27.3 g, 0.19 mol) was then added dropwise with stirring over a period of 1 h; stirring was continued at room temperature for 12 h. The mixture was stirred vigorously with 2 *N* hydrochloric acid, and the layers were separated. The organic layer was washed successively with aqueous sodium hydrogen carbonate solution (4 × 150 ml), aqueous copper sulfate solution (100 ml), and water (2 × 100 ml), and dried over anhydrous magnesium sulfate. Evaporation of the solvent afforded a brown syrup which was chromatographed on silica gel, with solvent *A* as eluant, to yield a syrup (15 g) having an R_F value of 0.5. Compound **14** was obtained from ether

as a white, crystalline solid (45% based on diethanolamine); mp 68 °C; ^{1}Hmr data: τ 2.65 (s, 5H, Ph), 6.23 (m, 4H, 2H-3′s, 2H-5′s), 7.41 (m, 4H, 2H-2′s, 2H-6′s). For compound **14**, mp 63 °C has been reported (5). *Anal.* calcd. for $C_{11}H_{13}NOS$: C 63.80, H 6.28, N 6.76, S 15.48; found: C 63.90, H 6.53, N 6.61, S 15.38.

4-Benzoyl-1-thia-4-azacyclohexane 1-Oxide ***15***

To a solution of 4-benzoyl-1-thia-4-azacyclohexane **14** (3.63 g, 17.5 mmol) in methanol (25 ml) at 5 °C was added sodium metaperiodate (3.74 g, 17.5 mmol) in 1:1 (v/v) methanol–water (50 ml) with stirring; stirring was continued at 5 °C for 24 h. The mixture was evaporated to dryness, and the residue was extracted with chloroform (150 ml). The extracts were washed with aqueous sodium thiosulfate solution (25 ml) and then with water (25 ml), and dried over anhydrous magnesium sulfate. Evaporation of the solvent afforded a yellow solid (3.44 g) which was revealed by tlc (solvent *D*) to consist of two components having R_F values of 0.6 and 0.2; fractionation on silica gel, with solvent *D* as eluant, yielded the two components. The faster-moving component (0.94 g) was identified as being unreacted starting material **14**. The slower-moving component was recrystallized from ethyl acetate to give **15** as white crystals (2.50 g, 86%); mp 113–114 °C; ir (KBr): 1048 (S=O) cm^{-1}; ^{1}Hmr data: τ 2.57 (s, 5H, Ph), 5.90 (m, 4H, 2H-3′s, 2H-5′s), 7.20 (m, 4H, 2H-2′s, 2H-6′s). *Anal.* calcd. for $C_{11}H_{13}NO_2S$: C 59.22, H 5.83, N 6.28, S 14.37; found: C 59.14, H 5.91, N 6.21, S 14.21.

Pummerer Reaction with 4-Benzoyl-1-thia-4-azacyclohexane 1-Oxide ***15***

A solution of the sulfoxide **15** (0.85 g, 3.8 mmol) in benzene (40 ml) containing acetic anhydride (1 ml) and *p*-toluenesulfonic acid monohydrate (~10 mg) was heated at 60 °C for 3.5 h. Thin-layer chromatography (solvent *B*) showed the presence of two new components having R_F values of 0.6 and 0.3 together with unreacted sulfoxide **15** (R_F 0.05). The reaction mixture was stirred vigorously with aqueous sodium hydrogen carbonate solution (50 ml) for 2 h, and the layers were separated; the organic layer was washed with aqueous sodium hydrogen carbonate (2 × 15 ml) and then with water (20 ml), and dried over anhydrous magnesium sulfate. Evaporation of the solvent afforded a partially crystalline syrup which was chromatographed on silica gel, with, initially, solvent *B* and, finally, ethanol as eluants. The faster-moving component (R_F 0.6) was recrystallized from ether to give **17** (66 mg, 20%); mp 89–90 °C; ^{1}Hmr data: τ 2.57 (s, 5H, Ph), 3.34 (br d, 1H, H-3), 4.70 (br d, 1H, H-2) 5.86 (m, 2H, 2H-5′s), 6.89 (m, 2H, 2H-6′s). *Anal.* calcd. for $C_{11}H_{11}NOS$: C 64.42, H 5.36, N 6.83, S 15.64; found: C 64.64, H 5.32, N 6.64, S 15.41.

The slower-moving component (R_F 0.3) was isolated as a syrup (0.33 g, 80%) and was identified as being 2-acetoxy-4-benzoyl-1-thia-4-azacyclohexane **16**; ^{1}Hmr data: τ 2.59 (s, 5H, Ph), 4.32 (br s, 1H, $|J_{2,3} + J_{2,3'}| \simeq$ 8 Hz, H-2), 5.67–7.67 (br signals, 6H, 2H-3′s, 2H-5′s, 2H-6′s), 7.93 (s, 3H, OAc). *Anal.* calcd. for $C_{13}H_{15}NO_3S$: C 58.90, H 5.66, N 5.28, S 12.10; found: C 59.01, H 5.63, N 5.14, S 11.94.

The unreacted sulfoxide **15** (0.49 g, 2.2 mmol) was isolated as a white, crystalline solid.

When the reaction was performed at 80 °C, most of the starting sulfoxide **15** was consumed in 1 h, and compounds **16** and **17** were produced in a ratio of ~1:1.

4-Benzoyl-2-hydroxy-1-thia-4-azacyclohexane ***18***

To a stirred solution of 2-acetoxy-4-benzoyl-1-thia-4-azacyclohexane **16** (0.30 g, 1.15 mmol) in chloroform (20 ml) at 0 °C was added sodium methoxide (0.1 *M*) in methanol (1 ml); stirring was continued at 0 °C for 2 h. The solution was washed with aqueous sodium hydrogen carbonate solution (2 × 7 ml) and then with water (10 ml), and dried over anhydrous magnesium sulfate. Evaporation of the solvent afforded a syrup (0.25 g, 98%) which was homogeneous in tlc (solvent *A*, R_F = 0.4) and was identified as being 4-benzoyl-2-hydroxy-1-thia-4-azacyclohexane **18**; ^{1}Hmr data: τ 2.58 (s, 5H, Ph), 5.17 (br signal, 1H, H-2), 5.50–7.83 (br signals, 7H, 2H-3′s, 2H-5′s, 2H-6′s, OH).

6-Chloro-9-(4-benzoyl-1-thia-4-azacyclohexan-2-yl)-9H-purine 7

A mixture of 6-chloropurine (0.172 g, 1.11 mmol), methyldiphenylphosphine (0.223 g, 1.11 mmol), and diethyl azodicarboxylate (0.194 g, 1.11 mmol) in dry tetrahydrofuran (20 ml) was added to a solution of 4-benzoyl-2-hydroxy-1-thia-4-azacyclohexane **18** (0.249 g, 1.11 mmol) in tetrahydrofuran (20 ml) with stirring; stirring was continued for 12 h at room temperature. Thin-layer chromatography (solvent *A*) indicated the presence of starting material **18**. The mixture was heated at reflux temperature for 2 h, and each of the reagents (1 equiv.) was added. Thin-layer chromatography (solvent *A*) indicated that most of **18** (R_F 0.4) had been consumed, and revealed the presence of a new component having an R_F value of 0.2. The reaction mixture was evaporated to dryness, and the orange residue was chromatographed on silica gel, with solvent *A* as eluant, to yield the 2 compounds **18** and **7**. Compound **7** was obtained from ethyl acetate as a white, crystalline solid (121 mg, 35%); mp 174–175 °C; ir (KBr): 1588, 1565 and 1478 (purine ring), 1625 (C=O) cm^{-1}; uv λ_{max} (ethanol): 265 (ε 7475), 215 nm (ε 10 918) (purine ring); λ_{max} (ethanol containing a trace of hydrochloric acid): 265 (ε 7628), 215 nm (ε 10 204); λ_{max} (ethanol containing a trace of sodium hydroxide): 261 (ε 7653) shoulder (purine ring), 245 (ε 9260) (benzamide), 217 nm (ε 11 531) (purine ring); ^{1}Hmr data: τ 1.53, 1.60 (2s, 1H each, H-2, H-8), 2.33–2.67 (m, 5H, Ph), 4.33–4.67 (br signal, 1H, $|J_{2',3'} + J_{2',3''}| = 8$ Hz, H-2′), 4.92–6.13 (2H, H-3′, H-3′′), 6.30–8.17 (4H, H-5′, H-5′′, H-6′, H-6′′). *Anal.* calcd. for $C_{16}H_{14}N_5OSCl$: C 53.44, H 3.89, N 19.47, S 8.92, Cl 9.86; found: C 53.39, H 4.04, N 19.31, S 8.78, Cl 9.92.

The unreacted starting material **18** was obtained as a syrup (24 mg).

T. Bruce Grindley, B. Mario Pinto, and Walter A. Szarek. Can. J. Chem. **55**, 949 (1977).

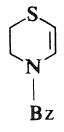
The rotational barrier in 4-benzoyl-1-thia-4-azacyclohex-2-ene has been investigated by total line-shape analysis of variable temperature ^{1}H nmr spectra in acetonitrile-d_3. Separate treatment of the vinyl and methylene signals yielded sets of values for activation parameters which were in excellent agreement. Assignment of the major and minor rotational isomers was made from chemical-shift data derived from the ^{13}C nmr spectrum at 243 K in acetonitrile-d_3.

T. Bruce Grindley, B. Mario Pinto et Walter A. Szarek. Can. J. Chem. **55**, 949 (1977).

On a étudié la barrière à la rotation dans le benzoyl-4 thia-1 aza-4 cyclohexène-2 par une analyse globale de la forme des raies des spectres rmn du proton, à température variable, dans l'acétonitrile-d_3. Des traitements séparés des signaux des groupes vinyles et méthylènes ont conduit à des ensembles de valeurs pour les paramètres d'activation qui sont en très bon accord. L'attribution des isomères majeurs et mineurs de rotation a été effectuée à partir de données de déplacements chimiques dérivées de spectres rmn ^{13}C à 243 K dans l'acétonitrile-d_3.
[Traduit par le journal]

Introduction

A large number of studies of rotational barriers in amides has been performed (1, 2). Nevertheless, there have been few systematic studies (3, 4) of the effects of substitution on nitrogen on these rotational barriers and no study in which it is possible to clearly separate resonance, steric, and bond angle effects. A useful technique for investigating such intramolecular rate processes is the total line-shape analysis of variable temperature, nuclear magnetic resonance (nmr) spectra. The validity and reliability of the careful application of this technique to appropriate systems has been confirmed by comparison of the results obtained by the line-shape method with those obtained by direct thermal equilibration (for example, see refs. 5 and 6). However, to obtain accurate values of the enthalpies and entropies of activation, it is necessary to perform the line-shape analysis over as large a temperature range as possible, and to have systems of sufficient complexity (7) to facilitate band-shape matching over this range. In the present article the rotational barrier in 4-benzoyl-1-thia-4-azacyclohex-2-ene **1** has been investigated by total line-shape analysis of variable temperature ^{1}H nmr spectra in acetonitrile-d_3. Compound **1**,



1

an interesting candidate for heterocyclic conformational analysis, was obtained during the course of a synthesis of some novel nucleoside analogs (8).

Experimental

Acetonitrile-d_3 was obtained from Stohler Isotope Chemicals. ^{1}H nmr spectra at 220 MHz were measured on a Varian HR-220 spectrometer at the Canadian 220 MHz NMR Centre; the solution was 0.8 *M* in acetonitrile-d_3. Spectra required for simulation were recorded using a 500-Hz sweep width. Temperatures were obtained by measuring peak separations in standard Varian samples of methanol and ethylene glycol and converting these into temperature values using the quadratic equation (9) of Van Geet for methanol and the linear equation (10) for ethylene glycol. Temperature gradients within the sample region of the HR-220 spectrometer

are considered to be negligible because of the large distance between the heating unit and the probe; temperatures are believed to be accurate to ±1 °C. Coupling constants and chemical shifts were obtained by analysis of the spectra (500-Hz sweep width) recorded at 245.9, 255.0, and 267.0 K using a modified version of the iterative program NMR-LAOCN-4A (11); coupling constants were assumed to be temperature invariant. Chemical shifts in the exchange-broadened region were derived by a linear extrapolation of the values obtained at the three lowest temperatures; this procedure resulted in excellent matching of the experimental and calculated chemical shifts of the vinyl signals, but the chemical shifts of the methylene signals required adjustment. Similarly, linear extrapolation of the population values obtained at the three lowest temperatures afforded values for the exchange-broadened region. Line widths were found to be unchanged at the slow and fast exchange limits and were assumed to be temperature invariant. Calculation of simulated line shapes was performed by use of a slightly modified version of the DNMR3 program (12) on a CDC-6400 computer equipped with a CALCOMP plotter. Rate constants were obtained by visual comparison of the experimental spectra with those calculated for various rates; the errors were considered to be the ranges in rates over which it was impossible to distinguish between the experimental and calculated spectra.

Activation parameters and errors were calculated by the use of a weighted, linear least-squares program (RATES)[1] which employed equations described by Wolberg (13); this program weights the data in accordance with their estimated errors and specifically treats errors in both temperatures and rate constants.

^{13}C nmr spectra were recorded in a 0.4 *M* acetonitrile-d_3 solution on a Bruker HX-60 spectrometer equipped with a FT60M Fourier transform accessory at 15.1 MHz, with tetramethylsilane (TMS) as the internal standard; chemical shifts are given in parts per million downfield from TMS. A 90° pulse was employed. The probe thermocouple was used for temperature calibration (error ±1 °C).

Results and Discussion

The conformational analysis of 4-benzoyl-1-thia-4-azacyclohex-2-ene **1** is potentially complex because of the occurrence of two dynamic processes, namely, ring inversion and restricted rotation about the amide bond, as illustrated in Fig. 1. In the present work it has been found to be possible to study the latter process without interference from the former; this situation is not surprising, since the magnitude of the inversion barrier would be expected to be significantly lower than that for amide rotation. Thus, for example, in the case of 4-benzoyl-1-oxa-4-azacyclohexane the free energies of activation for the inversion (14) and rotation (3) processes have been determined to be 7.4 and 14.4 kcal/mol, respectively. The remainder of this section, therefore, will be concerned with the conformational equilibrium of the two amide isomers **1***a* and **1***b*.

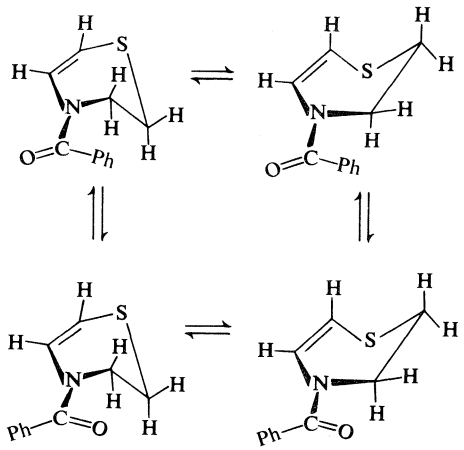


FIG. 1. Conformational processes in 4-benzoyl-1-thia-4-azacyclohex-2-ene **1**.

The determination of the conformational preference in the case of several tertiary amides has frequently been a difficult task by ^1H nmr spectroscopy (15). In the present work the assignment of the major and minor rotational isomers was readily made from chemical-shift data derived from the ^{13}C nmr spectrum at 243 K in acetonitrile-d_3. Previous workers have shown (16) that the carbon *syn* to the carbonyl oxygen of an amide is shielded relative to the corresponding carbon in the *anti* conformer. In Table 1 are documented ^{13}C chemical-shift data for the rotational isomers **1***a* and **1***b*. On the basis of this data, isomer **1***b* was deemed to be the major contributor to the rotational equilibrium. Thus, in the case of isomer **1***b*, the C-5 signal is shifted upfield by 6.7 ppm relative to the corresponding signal in the spectrum of **1***a*, whereas the C-3

TABLE 1. ^{13}C chemical-shift data[a] of rotational isomers

Isomer	Temperature (K)	Carbon 2	3	5	6
1*a*	243	104.5 (1.0)	121.5 (1.0)	47.5 (1.0)	25.9
1*b*	243	101.2 (2.2)	124.5 (2.8)	40.8 (2.3)	25.9

[a]In ppm downfield from internal tetramethylsilane (TMS) in acetonitrile-d_3. Values in parentheses are peak heights standardized on the basis of each carbon of the minor isomer **1***a* having a peak height of 1.0.

[1]Copies of the RATES program may be obtained from T.B.G.

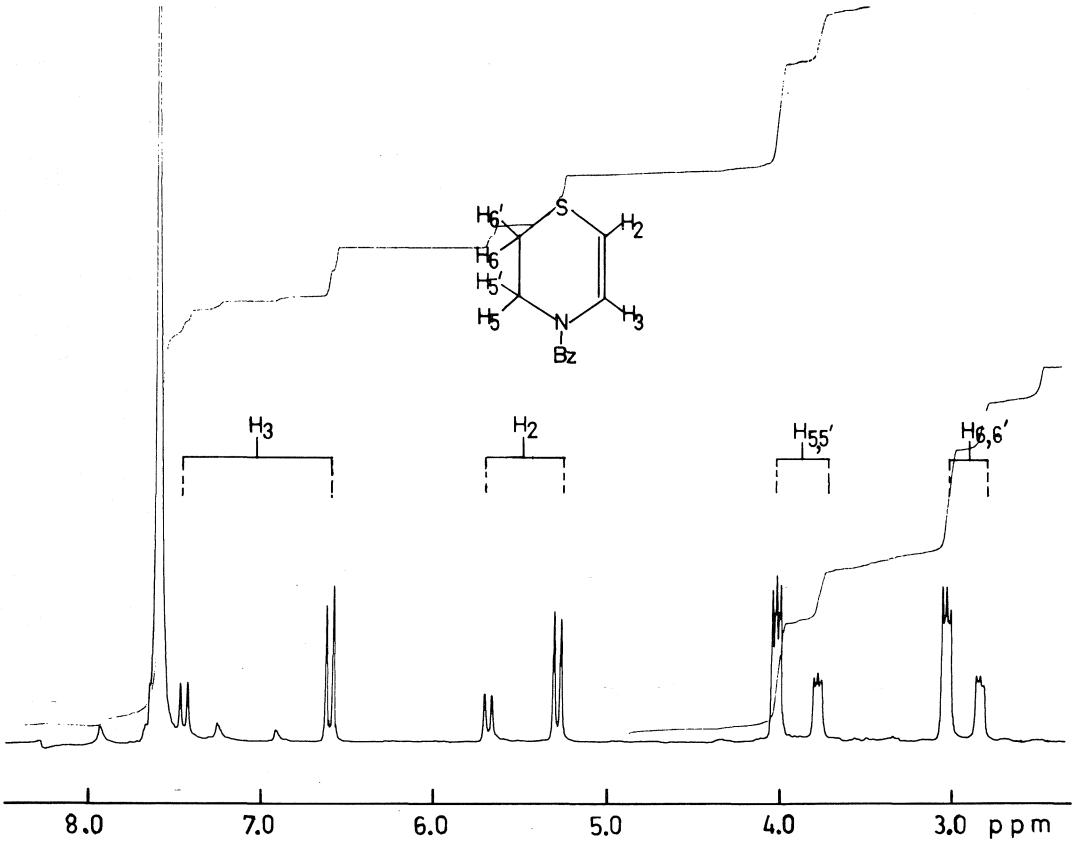

FIG. 2. ^{1}H nmr spectrum at 220 MHz of 4-benzoyl-1-thia-4-azacyclohex-2-ene **1** (0.8 *M* in acetonitrile-d_3) at 255.0 K.

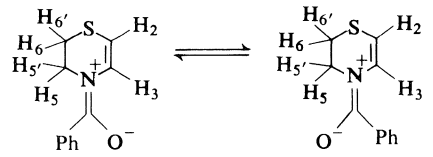
signal is shifted downfield by 3.0 ppm. It is interesting to note that the signals for the C-2 carbons in the two isomers are also distinct, whereas those for the C-6 carbons are not. Moreover, C-2 in the major isomer **1***b* is shielded relative to the corresponding carbon in the minor isomer **1***a*.

The ^{1}H nmr spectrum at 220 MHz of 4-benzoyl-1-thia-4-azacyclohex-2-ene **1** (0.8 *M* in acetonitrile-d_3) at 255.0 K is shown in Fig. 2. The signal assignments were readily made on the basis of published (17) chemical-shift data. Integration of the spectrum showed that isomers **1***a* and **1***b* were present in the ratio 1:2.1, respectively. An interesting feature of the spectrum is the observation that the sequence of signals for the individual isomers **1***a* and **1***b* in the case of each of the vinyl protons is the reverse of that in the case of the protons of each of the methylene groups. Moreover, the sequence of signals for H-3 and H-5,5′ in the



1*a* **1***b*

^{1}H nmr spectrum is the reverse of that for C-3 and C-5 in the ^{13}C nmr spectrum.

The static parameters obtained from the LAOCN-4A analysis of the two ABCC′DD′ systems, corresponding to the vinyl and methylene protons in **1***a* and **1***b*, in the 220 MHz spectrum recorded at 255.0 K are given in Tables 2 and 3. The values of the long-range coupling constants were estimated from line widths, and are in agreement with those reported for ^4J across sulfur (18) and amide nitrogen (19).

TABLE 3. Calculated coupling constants (Hz) for vinyl and methylene protons in **1**

Parameter	Value	Parameter	Value
$J_{2,3}$	8.4	$J_{5,5'} = J_{6,6'}$	−11.0
$J_{2,6} = J_{2,6'}$	~0.6	$J_{5,6} = J_{5',6'}$	7.8
$J_{3,5} = J_{3,5'}$	~1.1	$J_{5,6'} = J_{5',6}$	2.8

1 are illustrated in Figs. 3–5. The total line-shape analysis was performed by independently treating the exchange processes for the vinyl and methylene protons as AB ⇌ CD and AA′BB′ ⇌ CC′DD′, respectively. The effects of the long-range couplings were incorporated by adjusting the appropriate line-width parameter. The two-spin system was simulated by analysis of the process going from the more populated conformer to the less populated conformer (**1***b* → **1***a*), whereas the four-spin system was simulated by analysis of the process going from the less populated conformer to the more populated conformer (**1***a* → **1***b*); this approach was adopted in order to eliminate any possible bias in the analysis, since the rate constants for the processes in the two directions were expected to be significantly different. The rate constants derived from this treatment are documented in Table 4.

Activation parameters for the restricted rotation about the amide bond in 4-benzoyl-1-thia-4-azacyclohex-2-ene **1** were calculated as described in the Experimental section. The results are presented in Table 5. In addition to the careful execution of the present analysis, the reliability of the values of the derived parameters may be attributed to the fact that, in the case of compound **1**, each spin system is comprised of two components each of which has a significantly different chemical-shift difference between the corresponding signals of the two isomers, a situation which permits the observation of maximum broadening of the individual segments at different temperatures. A further outstanding feature of the data is the very close agreement between the sets of parameters obtained by independent analysis of the two-spin system and the four-spin system.

The magnitude of the barrier to rotation determined for amide **1** ($\Delta G^{\ddagger}$ 14.79 or 14.37 kcal/mol at 300 K) is essentially the same as those of the barriers in some related amides, for example, 1-benzoylpiperidine (14.82 kcal/mol at 292 K) and 1-benzoyl-4-piperidone (14.32 kcal/mol at 303 K). However, in the case of acyclic amides, the magnitude of the rotational barrier is decreased by the introduction of unsaturation into one of the substituents attached to nitrogen (see Table 6); Jackman (2)

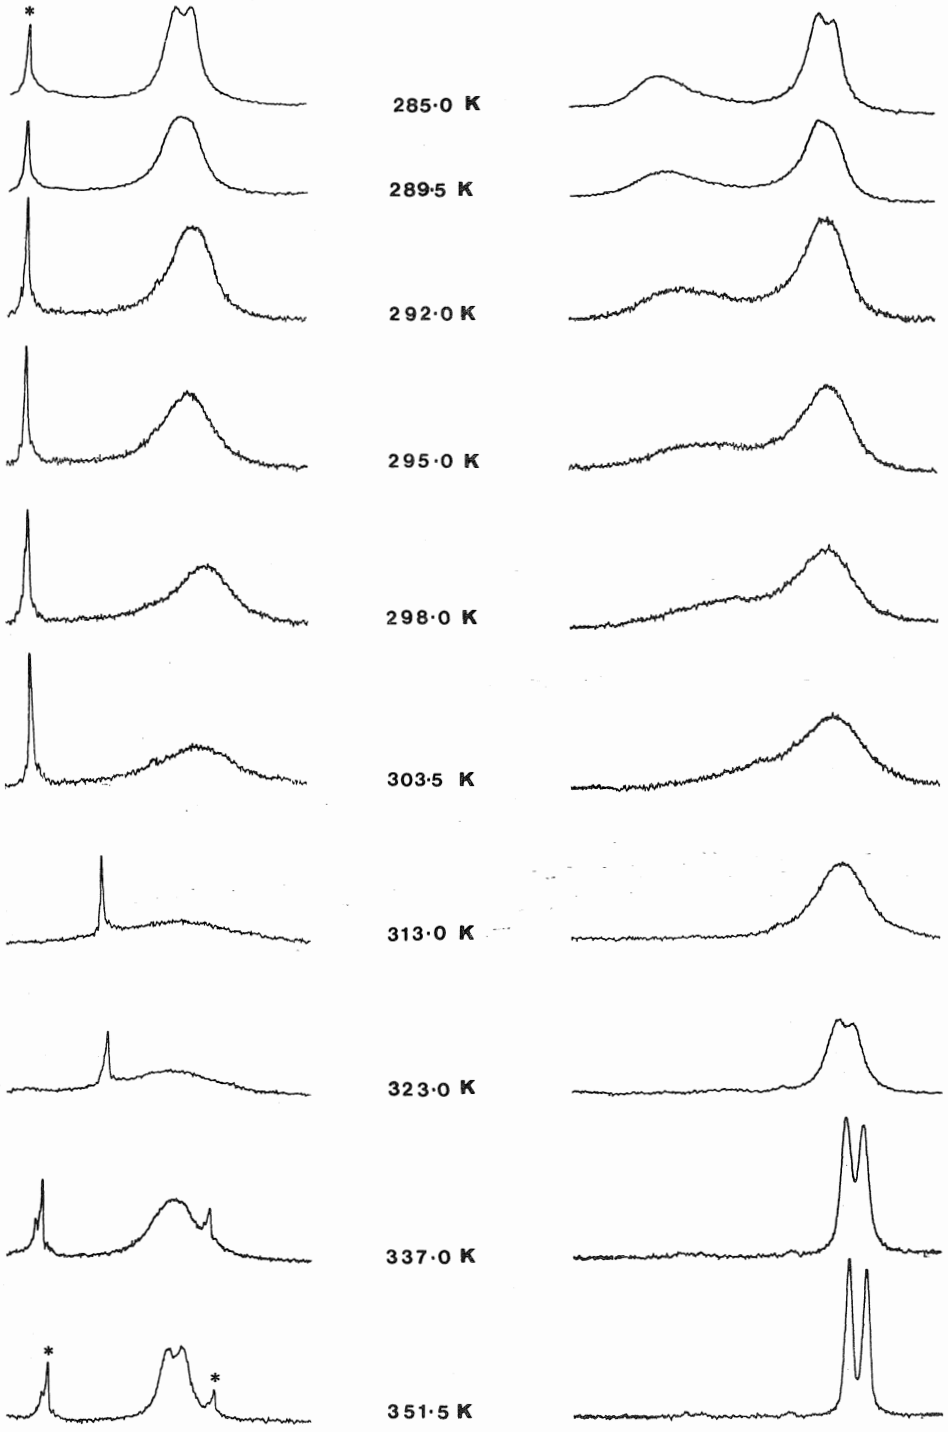

FIG. 3. Experimental dnmr spectra of vinyl protons in **1**. Peaks marked with * are spinning sidebands. The H-3 signal for isomer **1***a* was obscured by the phenyl resonances.

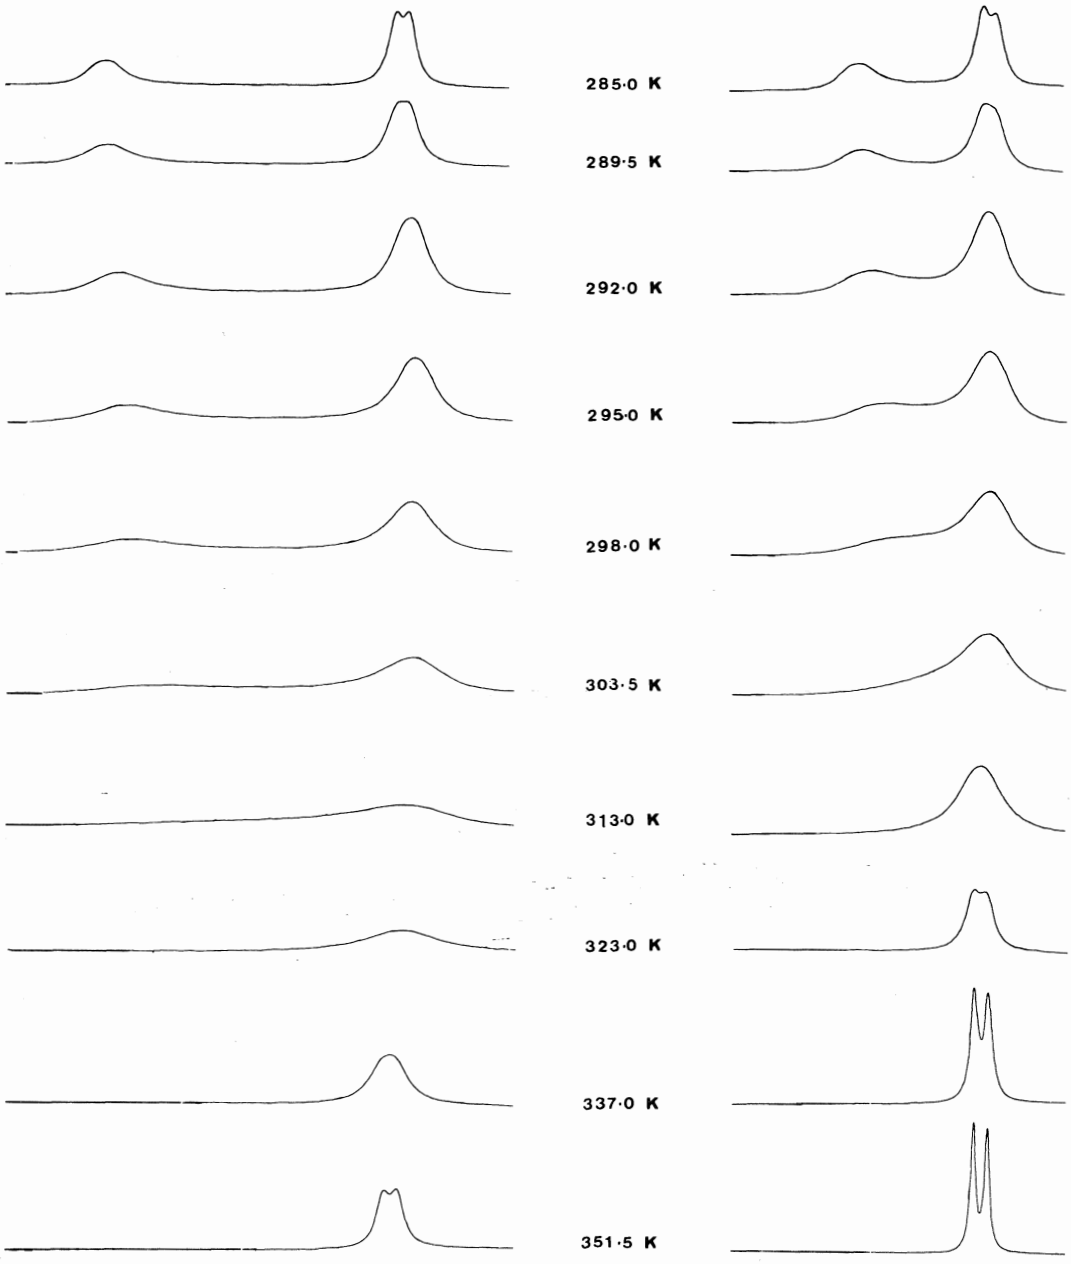

FIG. 4. Calculated dnmr spectra of vinyl protons in **1**.

has suggested that resonance stabilization of the transition state is a key factor in causing this decrease in the free energy of activation. On the basis of the results obtained in the present work, namely that the magnitude of the rotational barrier in amide **1** does not differ substantially from those in corresponding saturated amides, it would appear that other factors may also be of significance. A detailed investigation of the barriers in appropriate cyclic amides is

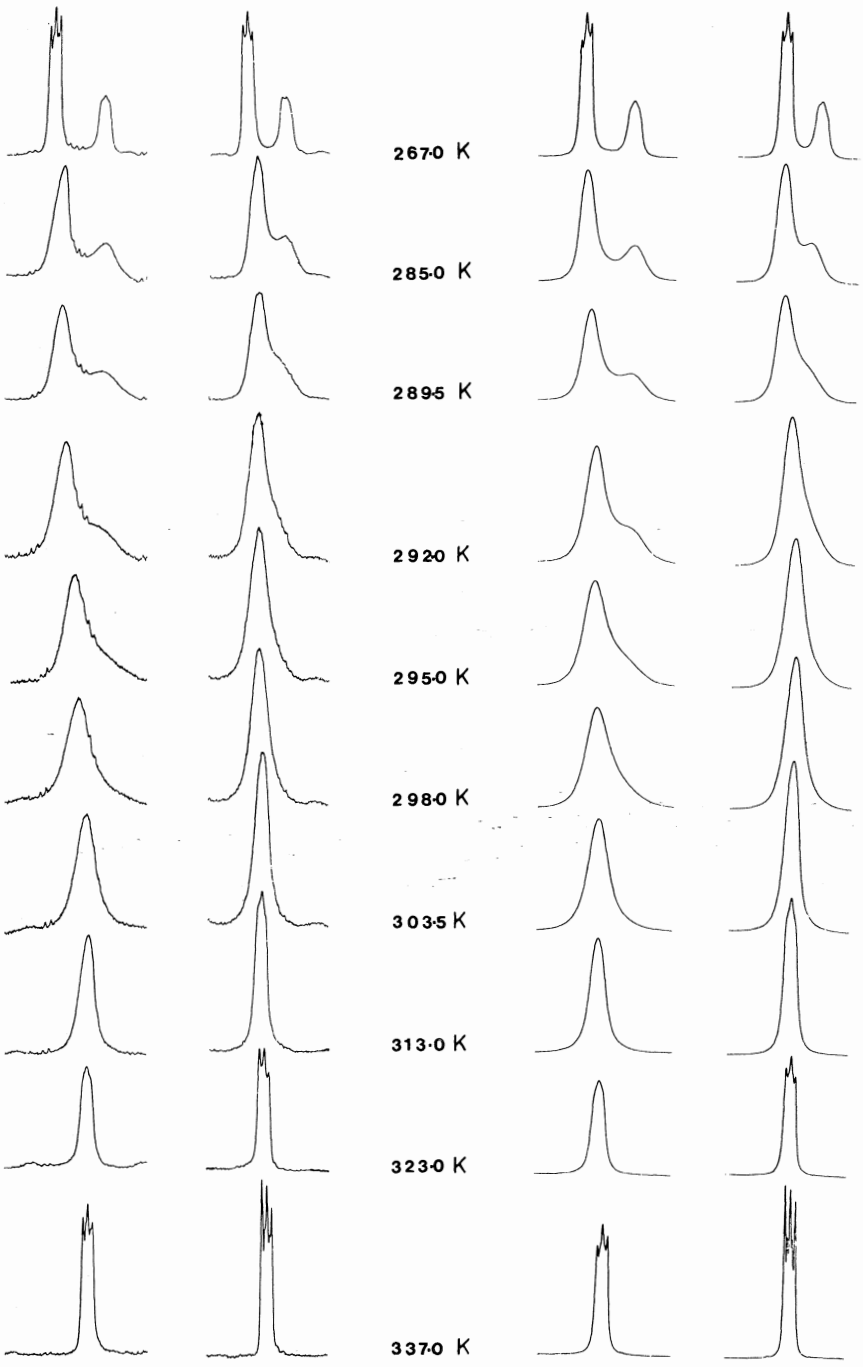

FIG. 5. Experimental (left) and calculated (right) dnmr spectra of methylene protons in **1**.

TABLE 5. Activation parameters for the restricted rotation about the amide bond in **1**

Parameter	AB ⇌ CD	AA'BB' ⇌ CC'DD'	Mean value
	(*a*) Data for process **1***a* → **1***b*		
E_a (kcal/mol)	14.9 ±0.2	14.6 ±0.2	14.8 ±0.2
Log A	12.9 ±0.2	12.7 ±0.2	12.8 ±0.2
$\Delta H^{\ddagger}$ (kcal/mol)	14.1 ±0.2	14.0 ±0.2	14.1 ±0.2
$\Delta S^{\ddagger}$ (eu)	−1.7 ±0.8	−2.6 ±0.8	−2.2 ±0.8
$\Delta G^{\ddagger}$ (kcal/mol)[a]	14.8_2 ±0.1	14.7_6 ±0.1	14.7_9 ±0.1
	(*b*) Data for process **1***b* → **1***a*		
E_a (kcal/mol)	14.8 ±0.3	14.4 ±0.2	14.6 ±0.3
Log A	13.1 ±0.2	12.9 ±0.2	13.0 ±0.2
$\Delta H^{\ddagger}$ (kcal/mol)	14.2 ±0.3	13.8 ±0.2	14.0 ±0.3
$\Delta S^{\ddagger}$ (eu)	−0.8 ±0.9	−1.6 ±0.8	−1.2 ±0.9
$\Delta G^{\ddagger}$ (kcal/mol)[a]	14.3_9 ±0.1	14.3_4 ±0.1	14.3_7 ±0.1

[a]Values for $\Delta G^{\ddagger}$ were calculated at 300 K; the errors in these values were obtained by the use of the following formula (20) for the linearized relative statistical error in $\Delta G^{\ddagger}$:

$$(\sigma_{\Delta G^{\ddagger}}/\Delta G^{\ddagger})^2 = [\ln (k_B T/hk)]^{-2}(\sigma_k/k)^2 + [1 + \{\ln (k_B T/hk)\}^{-1}]^2(\sigma_T/T)^2$$

TABLE 6. Barriers to rotation in some acyclic amides[a]

Compound	$\Delta G^{\ddagger}$ (kcal/mol)	Temperature (K)	Reference

Crystal and molecular structure of L-prolinatodiphenylboron

STEVEN J. RETTIG AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Place, Vancouver, B.C., Canada V6T 1W5

Received September 13, 1976

STEVEN J. RETTIG and JAMES TROTTER. Can. J. Chem. **55**, 958 (1977).

Crystals of L-prolinatodiphenylboron are monoclinic, $a = 5.9427(5)$, $b = 14.4633(7)$, $c = 8.9654(4)$ Å, $\beta = 98.423(8)°$, $Z = 2$, space group $P2_1$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to a final R of 0.037 and R_w of 0.053 for 1477 reflections with $I \geq 3\sigma(I)$. The proline ring exhibits conformational disorder. The crystal structure consists of discrete molecules linked by N—H...O hydrogen bonds (N...O = 2.893(3) Å) along the short a axis. Intramolecular N—B coordination occurs to form a system of two fused five-membered rings. Bond lengths (corrected for libration) are: N—B, 1.630(3), O—B, 1.529(3), O—C, 1.219(3) and 1.300(3), N—C, 1.506(3) and 1.507(3), C(sp^3)—C(sp^3), 1.525(4), C(sp^2)—C(sp^3), 1.517(3), and mean C—C(phenyl), 1.394 Å.

STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **55**, 958 (1977).

Les cristaux du L-prolinatodiphénylbore sont monocliniques, $a = 5.9427(5)$, $b = 14.4633(7)$, $c = 8.9654(4)$ Å, $\beta = 98.423(8)°$, $Z = 2$, groupe d'espace $P2_1$. On a résolu la structure par les méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.037 et de R_w de 0.053 pour 1477 réflexions avec $I \geq 3\sigma(I)$. Le cycle de proline présente du désordre conformationnel. La structure cristalline consiste de molécules individuelles liées par les ponts hydrogène N—H...O (N...O = 2.893(3) Å) le long de l'axe a qui est court. La coordination N—B intramoléculaire se produit de façon à former un système de deux cycles à cinq chaînons qui sont reliés. Les longueurs des liaisons (corrigées pour les librations) sont: N—B, 1.630(3), O—B, 1.529(3), O—C, 1.219(3) et 1.300(3), N—C, 1.506(3) et 1.507(3), C(sp^3)—C(sp^3), 1.525(4), C(sp^2)—C(sp^3), 1.517(3) et la valeur moyenne de C—C(phényle) 1.394 Å.

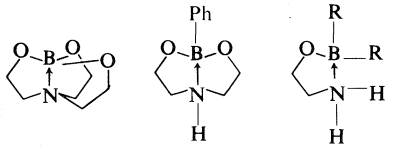
Introduction

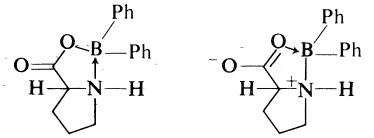
The crystal structures of a number of ethanolamine esters of the boron acids (**1–3**) have



1 **2** **3**

a, R = C_6H_5
b, R = *p*-FC_6H_4
c, R = *p*-$CH_3C_6H_4$

recently been determined (1–6). The unusual hydrolytic and oxidative stability (7) of these compounds is attributed to intramolecular N—B coordination. The mixed anhydrides of diphenylborinic acid and amino acids form a closely related class of compounds which exhibit similar hydrolytic stability (8–10) and are also believed to feature intramolecular N—B coordination. We now report the crystal structure of a member of this class of compounds, namely L-prolinatodiphenylboron **4**.



4*a* **4***b*

Experimental

A solution of L-proline (0.67 g, 5.8 mmol) in 75 ml of 1:1 ethanol/water was added to a solution of diphenyl borinic acid (from acid hydrolysis of 1.30 g, 5.8 mmol of 2-aminoethyldiphenylborinate) in 75 ml of ethanol/diethylether. Precipitation of a fine white powder commenced almost immediately. The reaction mixture was refluxed for 1 h, allowed to cool, and filtered. The precipitate was washed with water, then with ethanol, and dried to yield 1.40 g (5.0 mmol, 87% yield) of L-prolinatodiphenylboron. *Anal.* calcd. for $C_{17}H_{18}BNO_2$: C 73.16, H 6.50, N 5.02; found: C 73.13, H 6.41, N 5.11. Melting point (decomp) 263–265 °C.

Crystals suitable for X-ray analysis were obtained by recrystallization from 2-butanone. The crystal chosen for study was mounted with a^* parallel to the goniostat axis and had dimensions of *ca.* 0.40 × 0.25 × 0.40 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least-squares treatment of $\sin^2\theta$ values for 20 reflections measured on a diffractometer with Cu K_α

radiation (λ = 1.5418 Å). Crystal data (at 22 °C) are:

$C_{17}H_{18}BNO_2$ fw = 279.1

Monoclinic, a = 5.9427(5), b = 14.4633(7), c = 8.9654(4) Å, β = 98.423(8)°, V = 762.26(9) Å^3, ρ_m = 1.20 (flotation in aqueous KI), Z = 2, ρ_c = 1.2161(1) g cm^{-3}, $F(000)$ = 296, $\mu(CuK_\alpha)$ = 6.3 cm^{-1}. Absent reflections: $0k0$, $k \neq 2n$, space group $P2_1$ (C_2^2, No. 4).

Intensities were measured with nickel-filtered Cu K_α radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 2° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed. Background counts (10 s) were measured at each end of the scan. Data were measured to 2θ = 146° (minimum interplanar spacing 0.81 Å). The intensity of the check reflection, measured every 40 reflections throughout the data collection, remained constant to within ±3%. Lorentz and polarization corrections and check reflection scaling were applied, and the structure amplitudes were derived. No absorption correction was made in view of the low value of μ. Of the 1590 independent reflections measured, 1482 had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time averaged background count. These reflections were used in the solution and refinement of the structure.

The systematic absences allow space groups $P2_1$ or $P2_1/m$, the centrosymmetric space group $P2_1/m$ being ruled out by the presence of the chiral L-proline moiety. The structure was solved by direct methods, 210 reflections with $|E| \geq 1.40$ being used in the symbolic addition procedure for noncentrosymmetric crystals (11). Four sets of phases were generated by a computer program which determines phases using the tangent formula (12).[1] There were two nearly identical sets of phases with R_k of 0.16 and all 210 phases determined. The highest 20 peaks on E-maps calculated from both sets of phases accounted for all of the nonhydrogen atoms except C(4). The difference between the two E-maps was in the location of the C(4) peak, which had an electron density which was about 50% of that observed for the other carbon atoms. One of the two possible C(4) locations was chosen on the basis of slightly higher electron density and more reasonable geometry.

Two cycles of isotropic, followed by two cycles of anisotropic full-matrix least-squares refinement of the nonhydrogen atoms, gave R = 0.073. Examination of the thermal parameters of C(3), C(4), and C(5) (especially C(4)) indicated conformational disordering of the proline ring where C(4) is either folded away from or toward O(1). A difference map calculated at this point gave positions for 14 of the 18 hydrogen atoms; of those associated with C(3)—C(5) only two were found. C(4) was then refined as a split atom, initially with site occupancies fixed at 0.5 and later allowed to vary, reducing R to 0.045. A difference map then gave positions for the remaining hydrogen atoms associated with C(3), C(4), and C(5). The atom H(4a) is shared by both C(4) and C(4′) and thus has a site occupancy of 1.0. The second hydrogen atom associated with C(4′) was not located and has been left out of the refinement. The site occupancy of H(4b) was not refined but was kept equal to that of C(4). The atoms C(3), C(5), and their respective hydrogen atoms could not be successfully refined as split atoms and the disorder manifests itself as relatively large thermal parameters for these atoms. The entire structure was refined for three more cycles giving a final R of 0.037 and R_w of 0.053 for 1477 reflections with $I \geq 3\sigma(I)$ (5 reflections which had $|F_o| - |F_c| > 3\sigma(F)$ were removed from the data set in the final stages of refinement).

The least-squares refinement was based on the minimization of $\Sigma w[|F_o| - |F_c|/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was 5.3 × 10^{-8}. The scattering factors of ref. 14 were used for the non-hydrogen atoms and those of ref. 15 for the hydrogen atoms. Anomalous scattering factors from ref. 16 were used for the nonhydrogen atoms. The anisotropic thermal parameters employed in the refinement are U_{ij} in the expression:

$$f = f^0 \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c^*)]$$

where f^0 is the tabulated scattering factor and f is that corrected for thermal motion. The weighting scheme: $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

The absolute configuration of the molecule was determined from that known for the L-proline moiety. On the final cycle of refinement the mean parameter shift was 0.05σ and no parameter shift was greater than 0.55σ. The mean error in an observation of unit weight was 1.448. A final electron density difference map showed maximum fluctuations of ± 0.20 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 2 respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

[2]The structure factor table is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation (T), libration (L), and screw (S) motion (17) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is (excluding the C(4) atoms) 0.0018 Å^2. Analyses were successful for the two phenyl groups C(6)—C(11), B and C(12)—C(17), B (rms $\Delta U_{ij} = 0.0017$ and 0.0028 Å^2 respectively), and for the eight atom group O(1), O(2), N, C(1), C(2), B, C(6), and C(12) (rms $\Delta U_{ij} = 0.0023$ Å^2).

The appropriate bond distances have been corrected for libration (18, 19), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values.

Results and Discussion

Figure 1 shows a general view of the molecule and the crystallographic numbering scheme and Fig. 2 shows a general view of the packing arrangement. Bond angles are given in Table 4 and intra-annular torsion angles in Table 5.

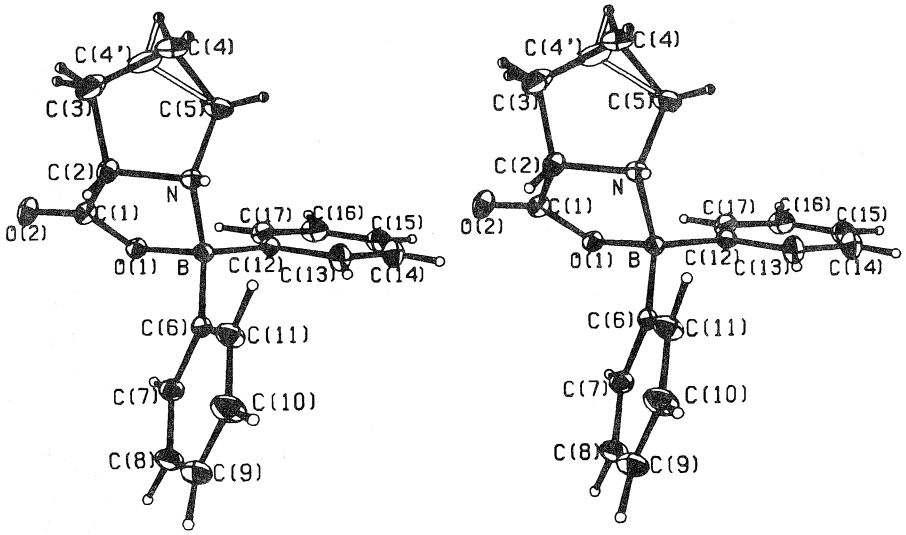

FIG. 1. A stereo view of the L-prolinatodiphenylboron molecule. 50% ellipsoids are shown for the nonhydrogen atoms. Hydrogen atoms have been given artificially small temperature factors for clarity.

Table 6 lists nonbonded distances and details of the hydrogen-bonding scheme.

The expected intramolecular N—B coordination occurs to form a system of two fused five-membered rings, both of which are puckered (see Table 5). The coordination of the boron atom is tetrahedral, slightly distorted by the 98.5(2)° O(1)—B—N angle. The disordering of C(4) results in two conformations for the proline ring, that containing C(4) being folded away from O(1) while that containing C(4′) is folded toward O(1) (see Fig. 1).

The C(6)—C(11) phenyl ring is rigorously planar within experimental error while the

*Superscripts refer to atoms at positions noted below.
[1] $1 + x, y, z$.
[2] $-x, \frac{1}{2} + y, -z$.
[3] $x - 1, y, z$.

C(12)—C(17) ring is not, although all atoms of the ring lie within ±0.01 Å of the mean plane. The boron atom is significantly displaced from both phenyl mean planes, by −0.023 Å from the C(6)—C(11) plane and by 0.045 Å from the C(12)—C(17) plane. The dihedral angles defining the orientation of the phenyl rings are: O(1)[B—C(6)]C(7), 38.5(2), N[B—C(6)]C(11), −35.7(3), O(1)[B—C(12)]C(17), 6.4(3), and N[B—C(12)]C(13), 78.9(3)°. The dihedral angle between normals to the mean planes is 104.1°.

The BOCCN ring in **4** may be regarded as a keto derivative of those in **1**–**3** and **5** (20). The C(1) carbonyl group in **4** significantly alters the electron distribution around the BOCCN ring when compared to **1**–**3**, an effect also noted for the substituted ring in **5**. The O—B, O—C, C—C, C—N, and N—B bond lengths are 1.529(3),

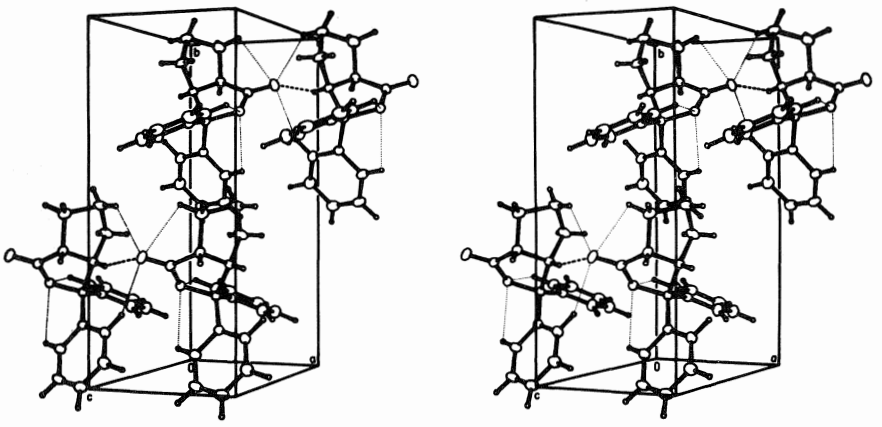

FIG. 2. A stereo view of the packing arrangement. Broken lines represent hydrogen bonds and dotted lines C—H...O interactions.

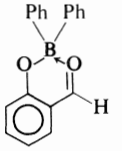
6



7

1.300(3), 1.517(3), 1.507(3), and 1.630(3) Å in the present structure compared to values[3] of 1.43(1), 1.43(1), 1.52(1), 1.49(1), and 1.647(9) Å for **1** (1, 2); 1.467(7), 1.415(4), 1.519(5), 1.486(1), and 1.666(3) Å for **2** (3); 1.477(5), 1.412(4), 1.503(5), 1.488(2), and 1.654(2) Å for **3** (4–6); and 1.452(2), 1.426(2), 1.530(2), 1.513(2), and 1.692(2) Å for **5** (20). The most important influence of the carbonyl group on the electron distribution in the BOCCN ring is contribution to the overall structure by resonance forms such as **4***b*. This is evidenced by increases in the B—O and C—N bond lengths and decreases in the B—N and C—O bond lengths in **4** when compared to those in **2** and **3**. The C—C bond in **4** at 1.517(3) Å corresponds to a normal C(sp^2)—C(sp^3) single bond whereas the ring C—C bonds in **2** and **3** are significantly shorter than normal C(sp^3)—C(sp^3) single bonds.

The B—C distances of 1.612(3) and 1.614(3) Å are near the weighted mean B—C distance of 1.615(9) Å for compounds **2**, **3**, **5**, and related diphenylboron chelates **6** (21) and **7** (22). The individual B—C distances in these compounds range from 1.599(2) Å in **5** to 1.639(8) Å in **6**. The mean phenyl C—C distance is 1.394(10) Å and as in other B-substituted phenyl rings (6, 23) the C—C distances decrease with greater distance from the boron substituent, the mean values being 1.401(2), 1.391(2), and 1.384(12) Å. The substituent-induced angular variations are also as expected (6, 23); the mean angles in the phenyl rings at carbon atoms bonded to boron and at the *ortho*, *meta*, and *para* positions relative to the boron substituent are 116.2(5), 122.0(6), 120.2(4), and 119.4(1)°.

The mean C(sp^3)—H and C(ar)—H distances of 0.94(5) and 0.96(5) Å are as expected for X-ray data. Both of the N—C bonds are significantly longer than the usual distance of 1.485 Å. All other bonds not involving the disordered C(4) atom are normal.

The crystal structure consists of discrete molecules of L-prolinatodiphenylboron linked together by N—H...O hydrogen bonds (N...O = 2.893(3) Å) along the short *a* axis. There are a number of weak C—H...O interactions which may have some influence on the structure, both in the orientation of the phenyl rings and also the greater occupation of the C(4) site since the partially occupied site H(4b) is involved in one of these interactions.

[3]Weighted mean values are given where appropriate. Here and elsewhere in this paper when mean values are quoted, numbers in parentheses refer to rms deviations from the mean.

Flash thermolysis of formal oxirene–arene adducts. Rearrangement to cycloheptatriene carboxaldehydes and the question of the formation of oxirene[1]

E. G. LEWARS AND G. MORRISON

Department of Chemistry, Trent University, Peterborough, Ont., Canada K9J 7B8

Received September 16, 1976

E. G. LEWARS and G. MORRISON. Can. J. Chem. **55**, 966 (1977).

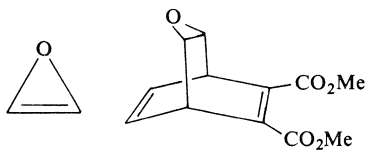
Flash thermolysis of 11,12-epoxy-9,10-dihydro-9,10-ethanoanthracene (dibenzobarrellene oxide) (**2**) gave 5*H*-dibenzo[*a*,*d*]cycloheptene-5-carboxaldehyde (**3**). At higher temperatures the products included 5*H*-dibenzo[*a*,*d*]cycloheptene-10-carboxaldehyde (**4**), 5*H*-dibenzo[*a*,*d*]cycloheptene (**5**), and fluorene (**6**). Flash thermolysis of dimethyl 3-oxatricyclo[3.2.2.0^{2,4}]nona-6,8-diene-6,7-dicarboxylate (the oxide of barrellene-2,3-dicarboxylic acid dimethyl ester) (**16**) gave a compound considered to be either dimethyl 3-methanoyl-1,3,5-cycloheptatriene-1,2-dicarboxylate (**17**) or dimethyl 1-methanoyl-1,3,5-cycloheptatriene-2,3-dicarboxylate (**18**), while at higher temperatures dimethyl 1-methanoyl-1,3,5-cycloheptatriene-6,7-dicarboxylate (**19**) was obtained. **16** also yielded small amounts of ketene, which was detected by low-temperature infrared spectroscopy. The mechanistic significance of these results is discussed.

E. G. LEWARS et G. MORRISON. Can. J. Chem. **55**, 966 (1977).

La thermolyse éclair de l'époxy-11,12 dihydro-9,10 éthano-9,10 anthracène (oxyde du dibenzobarrèllène) (**2**) conduit au 5*H*-dibenzo[*a*,*d*]cycloheptènecarboxaldéhyde-5 (**3**). A des températures plus élevées, les produits obtenus comprennent le 5*H*-dibenzo[*a*,*d*]cycloheptènecarboxaldéhyde-10 (**4**), le 5*H*-dibenzo[*a*,*d*]cycloheptène (**5**) et le fluorène (**6**). La thermolyse éclair de l'oxa-3 tricyclo[3.2.2.0^{2,4}]nonadiène-6,8 dicarboxylate-6,7 de diméthyle (l'ester diméthylique de l'oxyde de l'acide barrèllènedicarboxylique-2,3) (**16**) conduit à un composé que l'on considère être soit le méthanoyl-3 cycloheptatriène-1,3,5 dicarboxylate-1,2 de diméthyle (**17**) ou le méthanoyl-1 cycloheptatriène-1,3,5 dicarboxylate-2,3 de diméthyle (**18**) alors qu'à des températures plus élevées, on obtient le méthanoyl-1 cycloheptatriène-1,3,5 dicarboxylate-6,7 de diméthyle (**19**). **16** conduit aussi à des petites quantités de cétène qui peut être détecté par spectroscopie infrarouge à basse température. On discute des implications mécanistiques de ces résultats.

[Traduit par le journal]

Oxirene (**1**) is a molecule of considerable interest (2) which has, however, never been isolated. The molecule represents both an experimental and a theoretical challenge: there is evidence that oxirene, if formed, rapidly rearranges to ketene (2*a*), and while the involvement in the photochemical Wolff rearrangement of a species with the symmetry of oxirene has been elegantly demonstrated (2*b*), it is by no means clear if this species is a true intermediate or merely a transition state (2*c*). The reverse Diels–Alder reaction has been widely used for generating highly reactive alkenes (3), and its application to the synthesis of oxirene appeared to us a possibility worthy of investigation. To this end, a promising precursor would appear to be a (formal!) adduct of oxirene and an arene, since the activation energy of the reaction will be lowered insofar as the transition state resembles the products, owing to the thermodynamic stability of the incipient arene. Indeed, an apprehension of the putative utility of such oxirene–arene adducts for the generation of the elusive heterocycle is implicit in a paper by Vogel and coworkers (4) where passing reference is made to the possibility of effecting cleavage of adduct **16** to "acetylene oxide" and dimethyl phthalate. We were intrigued by this possibility, as well as the question of the pathway that would be followed should **16** decline to be so obliging.

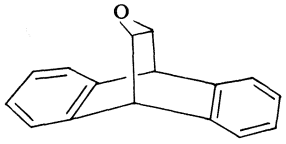


1 **16**

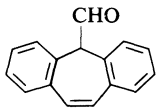
For our purpose, the ideal technique for effecting the reverse Diels–Alder reaction ap-

[1]A preliminary communication of some of this work has been published (1).

peared to be flash thermolysis (flash vacuum thermolysis/pyrolysis). In this technique (5), the compound in the vapor phase at low pressure contacts a hot surface for a duration of the order of a few ms; the resulting thermolysate is then deposited on a cold surface for chemical or spectroscopic investigation. With these facts in mind, we subjected to flash thermolysis with observation of the low-temperature infrared spectrum (*5a*) compound **2** (6), a formal oxirene–anthracene adduct, and the above-mentioned compound **16** (a formal oxirene – dimethyl phthalate adduct). Although thermolysis of **16** gave some evidence for the formation of **1**, the main pathways taken by **2** and **16** were more complex.



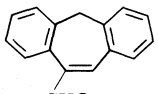
2



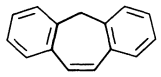
3

Thermolysis of **2** gave a mixture, the composition of which varied considerably with the thermolysis temperature. The identity of the components was established by chromatographic isolation and direct comparison with authentic samples, and the composition was calculated from the integrated ^{1}H nmr spectra. The results are summarized in Table 1.

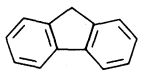
The formation of **3** may be rationalized by epoxide cleavage to **7** and a Wagner–Meerwein shift to give **8**, followed by carbon–carbon bond cleavage (**8**, arrow *1*),[2] while the alternative cleavage (**8**, arrows *2*) would give the *o*-xylylene



4



5



6

9 which could be converted to **4** by a 1,5-sigmatropic suprafacial shift of a hydrogen atom (7). Thermolysis of **3** at 500 °C gives only a small (*ca.* 5%) yield of **4**, showing that most of the aldehyde **4** formed under these conditions arises from **2** without the intermediacy of **3**. Intermediate **8** may also be involved in the transformation of **3** to **4**, since electrophilic attack of the aldehyde group of **3** on the transannular

[2]*Cf.* ref. 6.

TABLE 1. The products of the thermolysis of **2**

Temperature (°C)	Thermolysate composition (mol%)					
	2	**3**	**4**	**5**	**6**	Others*
400	20	75	5	0	0	0
500	0	10	90	0	0	0

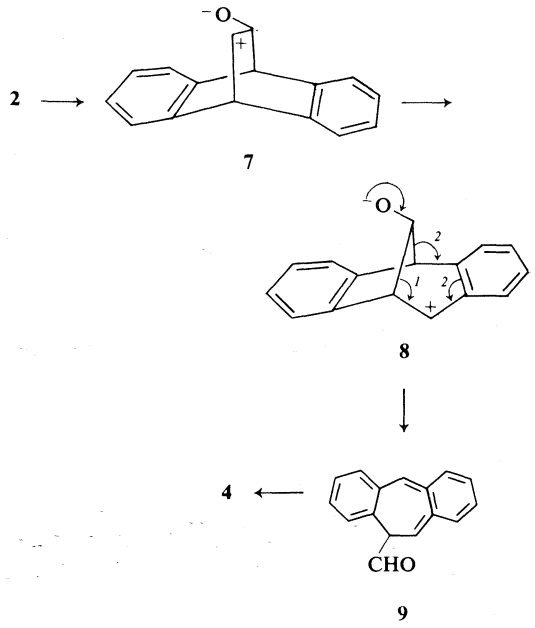
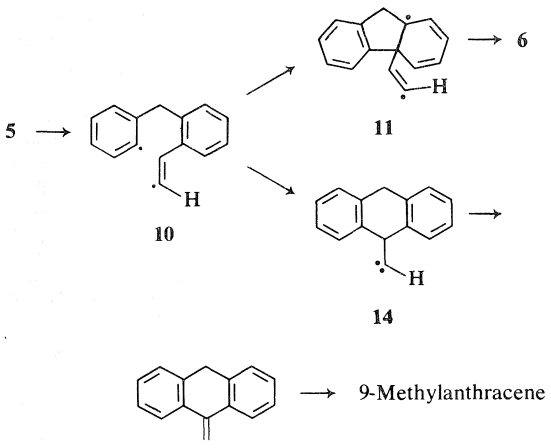
800	0	0	0	0	25	75

*Compounds showing mainly only aromatic H's in the ^{1}H nmr spectrum; the presence of 8 aromatic H's was assumed.



double bond would generate **8**. Transannular reactions are not prominent in seven-membered rings, but one need rationalize only a low yield of **4**. We wish to point out that the invoking of an ionic mechanism here does not necessarily imply that we regard it as being more likely than a free radical one. Since explicit mechanistic studies were not conducted, a detailed discussion of reaction mechanisms seems pointless here. The dibenzocycloheptatriene **5** is presumably a decarbonylation product of **4**, and fluorene (**6**) probably results from loss of ethyne from **5** (**5** → **10** → **11** → **6**), which seems more likely (8) than concerted extrusion, which would require an antiaromatic transition state (9).

That these thermolysis products had the structures which have been assigned them was suggested by their infrared and ^{1}H nmr spectra and their molecular weights (mass spectra)

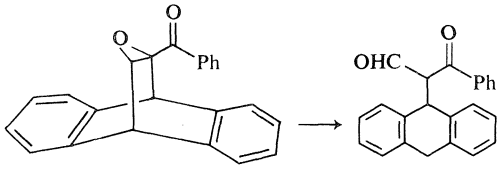


15

and confirmed by direct comparison with authentic samples. An authentic sample of **3** was made by isomerizing **2** with acidic alumina, as described by Cristol and Bly (6). A surprising feature of the nmr spectrum of **3** is that the aldehyde proton and the proton on the adjacent carbon give sharp singlets, rather than the expected doublets. Space-filling molecular models suggest that the proximal *ortho* hydrogens of the lateral benzene rings constrain the CHO group to take up a conformation such that the dihedral angle between the C—H bonds of the CHO group and the hydrogen on the adjacent carbon is *ca.* 90°, making any coupling small (<1 Hz) (10).

Authentic samples of **4** and **5** were synthesized from the commercially available (Aldrich 10-bromo-5*H*-dibenzo[*a*,*d*]-5-cycloheptenone by reduction and metallation followed by carbonylation with dimethylformamide, giving **4**, or protonation with water, giving **5**.[3]

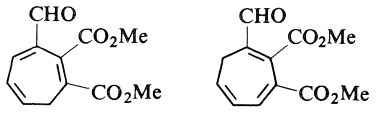
Besides fluorene, 9-methylanthracene seems to be a major component (*ca.* 20%) of the 800 °C thermolysate. The presence of this was not rigorously demonstrated, but is rendered likely by two facts: the ^{1}H nmr spectrum of the thermolysate mixture showed, besides a singlet at δ 3.77 for fluorene, a sharp singlet at δ 3.00, the position of the methyl group of 9-methylanthracene (these were the only peaks in the nonaromatic region of the spectrum). Furthermore, the mass spectrum of an impure sample of the non-fluorene material, collected from a partially resolved vpc peak, gave a molecular ion of *m*/*e* 192, consistent with a methylanthracene. This probable component could arise by the kind of mechanism suggested by Srinivasan and co-workers for the photorearrangement of **12** to **13** (12). However, the fact that thermolysis of the aldehyde **4** at 700 °C gave **5** and the putative 9-methylanthracene (molar ratio 1.5;1 by ^{1}H nmr) suggests the pathway **5** → **10** → **14** → **15** → 9-methylanthracene.



12 13

When the thermolysate was trapped at −140 °C on the sodium chloride disc of an infrared cryostat, at none of the thermolysis temperatures tried (see Table 1) was there any indication of ketene[4] or of a species which gave ketene or was otherwise unstable, and vpc examination of the 650 and 800 °C thermolysates (the only ones containing unidentified components) showed that anthracene, if present, was only a minor (not more than *ca.* 5%) component. Clearly, if reverse Diels–Alder cleavage of **2** to **1** and anthracene occurred under our conditions, it represented only a minor pathway.

The flash thermolytic behavior of **16** was somewhat analogous to that of **2**. At 300 °C there was obtained a 62% yield of an aldehyde, mp 105–106 °C, as well as 4% yield of another aldehyde, mp 108–110 °C, and 24% of recovered **16**. The aldehyde of mp 105–106 °C was assigned structure **17** or **18** on the basis of its



17 18

formula, $C_{12}H_{12}O_5$, spectra, and transformation to the other aldehyde (see below). The ^{1}H nmr spectrum showed an AMX pattern (δ_A 7.50, δ_M 6.52, δ_X 5.97, J_{AM} = 5.5 Hz, J_{MX} =

[3] **5** has been made by other methods, see *e.g.* ref. 6; a patent describes the preparation of **4** from the corresponding methyl compound (11).

[4] *Cf.* ref. 2*a*.

9 Hz) with H_X also coupled to a CH_2 group at δ 2.67 (J = 7 Hz), revealing a $C{=}CH_A{-}CH_M{=}CH_X{-}CH_2$ grouping with H_A strongly deshielded. In addition, the spectrum displayed a CHO peak (δ 9.48, s) and two CO_2Me methyls (δ 3.77, 6H, giving way to two 3H singlets on addition of Eu(fod)$_3$-d_{27} shift reagent). This spectrum is very similar to that of a compound reported by King *et al.* (13) which differs from **17**/**18** only in having a phenyl group in place of a CHO, and is almost uniquely compatible with structure **17**/**18**. Consonant with this structure, the ultraviolet spectrum revealed extensive unsaturation, λ_{max}(MeOH) 242 (ε 15 600), 285 nm (ε 5000), and the infrared spectrum showed λ_{max}(KBr) 5.80 (conjugated ester) and 5.93 μm (conjugated aldehyde). We believe a choice between **17** and **18** cannot be made with the information at hand.

Thermolysis of **17**/**18** or of **16** at 400 °C gave, in addition to a 23% yield of the aldehyde discussed above, a 58% yield of the aldehyde of mp 108–110 °C. This compound was assigned structure **19** on the basis of its formula, $C_{12}H_{12}O_5$, spectra, and formation from **16** by treatment with acidic alumina. The ^{1}H nmr spectrum displayed, besides a CHO peak (δ 9.43, s) and two CO_2Me methyls (δ 3.77, s and 3.45, s), an olefinic ABCD system (δ 7.50–7.27, m, 1H; 7.13–6.93, m, 1H; 6.93–6.67, m, 2H) and a peak at 5.63 (s, 1H). Structure **19** is strongly supported by the infrared spectrum, λ_{max}(KBr) 5.76 (saturated ester), 5.86 (conjugated ester), 5.94 μm (conjugated aldehyde), and the ultraviolet spectrum λ_{max}(MeOH) 228 (ε 34 000), 313 nm (ε 6500), which is quite similar to the uv spectra reported by Eschenmoser and co-workers (14) and Vogel *et al.* (15) for **20** and **21** respectively. Aside from its electronically isolated central carbomethoxy group, our aldehyde is a half-way house between **20** and **21**. The significantly shorter wavelength absorption of the conjugated ester groups in the infrared spectrum of **17**/**18** (5.80 μm) as compared to that of the conjugated ester group of **19** (5.86 μm) probably reflects close juxtaposition of the central carbomethoxy group to its neighbours.[5] In **19**, on the other hand, the central carbomethoxy group is attached to an sp^3-hybridized carbon and can lie out of the planes defined by the carbon–carbon double bonds bearing the other carbonyl groups. The fact that the carbomethoxy groups of **20** absorb at 5.85 μm is consistent with this suggestion. Further support for a bis(carbomethoxy)cycloheptatriene carboxaldehyde structure for this aldehyde was provided by the fact that treatment of **16** with acidic alumina gave the aldehyde in 50% yield; this rearrangement finds precedence in the alumina-promoted isomerization of **2** to **3** (6).

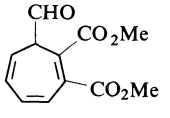
21



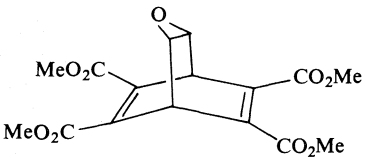
22

The formation of the aldehydes **17** or **18**, and **19**, can be rationalized by C—O bond cleavage (*cf.* **7**; heterolytic, as shown here, when promoted by alumina, possibly homolytic under flash thermolysis conditions) and Wagner–Meerwein-type rearrangement to give a bicyclo[3.2.1] system, analogous to **8**, which undergoes another Wagner–Meerwein-type shift, yielding **22**; this could be transformed into **17** or **18**, or into **19**, by sequential 1,5-sigmatropic hydrogen atom shifts (on thermolysis) (17) or by alumina-catalyzed double bond isomerization.

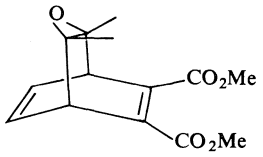
When the thermolysate from runs in the temperature range 600–800 °C was trapped at −140 °C on the sodium chloride disc of an infrared cryostat, a band at 4.63 μm, growing weaker as the cryostat was allowed to warm up, and attributable to ketene, was seen. The simplest interpretation of this is that oxirene was extruded from **16** and isomerized to ketene, but isomerization of **16** to the bicyclo[2.2.2]-octadienone followed by extrusion of ketene cannot be ruled out. Based on the strength of the ketene band from a known amount of **16** we estimate the yield of ketene to be roughly

[5]Propinquity of a polar group to a carbonyl group can shift the infrared absorption of the carbonyl to shorter wavelength (see, *e.g.* ref. 16).

5% at the optimum temperature of 700 °C, and vpc examination of the crude thermolysate showed a peak with the same retention time as dimethyl phthalate, again roughly 5% of the mixture. The ^{1}H nmr spectrum of the crude 700 °C thermolysate showed three carbomethoxy methyls, but could not be used to estimate the yield of dimethyl phthalate since the signals of one of the products of this high-temperature thermolysis, 7-carbomethoxyisocoumarin (22), obscure those of dimethyl phthalate.



23



24

A few flash thermolysis experiments were also conducted with the barrellene oxides **23** (18) and **24** (19) using the infrared cryostat. Compound **23** gave a band at 4.63 μm (optimum temperature 600 °C) suggesting that ketene was formed to the extent of roughly 10%, and the vpc trace showed that material of the same retention time as tetramethyl benzene-1,2,4,5-tetracarboxylate constituted about 10–20% of the crude thermolysate. Compound **24**, too, gave a band at 4.63 μm, ascribed to dimethylketene (optimum temperature 500 °C), indicating that the ketene was formed in a yield of roughly 5%, and vpc examination of the crude thermolysate showed a peak with the same retention time as dimethyl phthalate, representing *ca.* 2–5% of the mixture. These results, which, we are fully aware, are only suggestive, lend credence to the hypothesis that some barrellene oxides thermolytically extrude an oxirene, which quickly rearranges to a ketene. We are investigating the possibility that appropriate substitution of the barrellene oxide system might make extrusion of oxirene the main reaction.[6]

[6]See ref. 13 for a discussion of a case where small substituent changes showed a large effect on the propensity toward reverse Diels–Alder fragmentation of a thiabarrellene derivative.

Summary

The question as to whether **16** (4) or **2** undergo thermal reverse Diels–Alder cleavage to oxirene (**1**) and the corresponding arene has been essentially answered. The main reaction pathway is isomerization to cycloheptatriene carboxaldehydes, although **16** (as well as **23** and **24**) do give small amounts of ketene (or dimethylketene, from **24**), which could be interpreted as evidence for the extrusion of oxirene.

Experimental

All melting points were determined on a Fisher-Johns melting point hot stage and are uncorrected.

Unless stated otherwise, all infrared spectra (ir) were recorded as carbon tetrachloride solutions on a Unicam SP-200 spectrophotometer. The spectra were calibrated with the 6.24 μm band of polystyrene film.

Ultraviolet spectra (uv) were recorded in methanol solutions, unless stated otherwise, with a Unicam SP-800A spectrophotometer using 1 cm pathlength cells.

^{1}H nuclear magnetic resonance spectra (nmr) were recorded in deuteriochloroform solution unless stated otherwise, with a Jeol C-60 HL spectrometer. Chemical shifts are reported in parts per million downfield from tetramethylsilane as internal references (δ scale). The following abbreviations apply: s = singlet, d = doublet, t = triplet, dd = doublet of doublets, m = an unresolved multiplet.

Mass spectra were obtained with an A.E.I. MS 12 spectrometer at an electron beam energy of 70 eV. High resolution mass spectra were taken on a Varian MAT 311A mass spectrometer.

Gas chromatography was carried out with a Pye series 104 gas chromatograph equipped with a flame ionization detector. The instrument was fitted with both a $\frac{3}{8}$ in. × 7 ft, 10% silicon grease on Chromosorb W glass preparative column, and a $\frac{1}{4}$ in. × 5 ft, 5% SE-30 on Chromosorb W glass analytical column. Helium was employed as the carrier gas.

Unless otherwise stated, all R_f values refer to analytical thin layer chromatography (tlc) using commercially available aluminum sheets precoated with silica gel 60F-254, layer thickness 0.2 mm (Brinkmann Instruments, Rexdale, Ontario). Preparative tlc was performed on 20 × 20 cm glass plates coated with Fluka silica gel HF-254. Each plate contained approximately 20 g of silica gel to which a maximum of 200 mg of material was applied. The bands were visualized with a Mineralight UVS-12 ultraviolet lamp and extracted with a methanol–dichloromethane (1:10) solution.

Unless otherwise stated, anhydrous magnesium sulphate was used for drying of solutions. Solvents were removed with a Büchi Rotovapor in conjunction with a water aspirator.

The gas phase thermolyses were carried out by subliming a known amount of material, typically 50 mg, under high vacuum (10^{-4}–10^{-3} torr) through a hot quartz tube. The product mixture was then frozen out on either a liquid-nitrogen-cooled cold finger or the sodium chloride disc of the cryostat (Fig. 1). Sublimation of

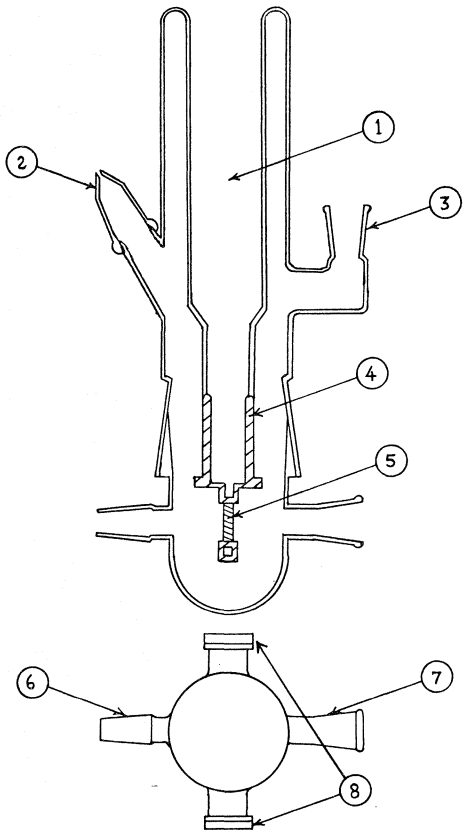


FIG. 1. Infrared cryostat (*ca.* one-quarter actual size): *1.* liquid nitrogen reservoir, *2.* head carrying thermocouple wires (wires sealed at orifice with epoxy resin), *3.* joint for receiving Pirani gauge, *4.* metal collar (attached to reservoir through glass-to-metal seal), *5.* NaCl disc, *6.* to vacuum system, *7.* to thermolysis tube (51 × 1 cm), *8.* optical windows. Silicone grease was used on all ground-glass joints.

the substrate was facilitated by the use of a preheater set at 100 °C. A post-heater, situated immediately after the oven, was utilized at a temperature of 175 °C to eliminate any condensation of the thermolysate prior to its impingement onto the liquid-nitrogen-cooled surface. When all the material had been thermolyzed and the products frozen out, the infrared spectrum could be taken, or, alternatively, the vacuum broken and the products rinsed off for analysis.

The quartz tube inserted through the oven was capped at one end by a B14 ground glass socket and joined to the cryostat via another B14 ground glass joint. The furnace unit enveloping the quartz tube was a Lindberg Type 550 35A oven, capable of maintaining temperature (±5 °C) up to 1000 °C. The preheater and post-heater were 2.5 × 10 cm pieces of Pyrex tubing wrapped with asbestos strips, 30-gauge Nichrome wire, and glass wool, and connected to variable transformers.

The cryostat consisted of two sections. The upper section contained a 270 ml liquid nitrogen reservoir. The sodium chloride disc was held in a hollow brass frame which formed part of the reservoir enabling liquid nitrogen to circulate within the frame. The temperature of the disc was measured with a chromel–alumel thermocouple inserted into a small hole in the disc. The lower section of the cryostat was fitted with two B14 ground glass joints connecting the cryostat to the vacuum system and to the quartz tube, and also contained two sodium chloride windows directly opposite one another and at right angles to the other joints. The upper and lower sections were joined by a B60 ground glass joint which enabled the sodium chloride plate to be turned 90° while still under vacuum to a position in line with the two optical windows for the recording of spectra. The vacuum system utilized a Speedivac E.D. 35 mechanical pump and a two-stage oil diffusion pump, and was connected to the thermolysis unit through a liquid-nitrogen-cooled trap. The pressure at the cryostat and at the trap were monitored with an Edwards Pirani G9 gauge and an Edwards No. 6 Penning gauge, respectively. Contact times are thought to have been a few ms (*5c*).

Thermolysis of **2**

400 °C

Thermolysis of **2** (40 mg) gave 36 mg of thermolysate (yellow oil). The nmr spectrum of the crude thermolysate showed it to be a mixture of unchanged **2**, as well as **3** and **4** in the molar ratio 4:15:1. The material was subjected to preparative tlc (methanol – light petroleum, 1:20) to give **2** (8 mg), **3** (25 mg), and **4** (2.5 mg). The aldehyde **3**, R_f = 0.25, was crystallized from ether; mp 110–112 °C (lit. (6) mp 112–114 °C) and readily formed a yellow 2,4-dinitrophenylhydrazone derivative (2,4-DNP), mp 215–217 °C (lit. (6) mp 221–223 °C). The aldehyde showed ir λ_{max} 5.77 μm; uv λ_{max} (hexane) 224, 290 nm; nmr (CCl_4) δ 4.33 (1H, s), 6.70 (2H, s), 7.15 (8H, m), 9.40 (1H, s); *m/e* 220(M^+).

500 °C

Compound **2** (47 mg) gave 42 mg of an oily thermolysate which was shown by nmr to contain **3** and **4** in the molar ratio 1:9. Preparative tlc (methanol – light petroleum, 1:20) gave a band (R_f = 0.56) which gave 34 mg of **4**. The product crystallized from ether to give a colourless solid mp 133–134 °C (lit. (11) mp 133–135 °C); 2,4-DNP (red) mp 235–237 °C; ir λ_{max} 5.88 μm, uv λ_{max} (hexane) 228, 303 nm; nmr δ 3.58 (2H, s), 7.20 (8H, m), 7.62 (1H, s), 9.68 (1H, s); *m/e* 220 (M^+). *Exact Mass* calcd. for $C_{16}H_{12}O$: 220.08826; found: 220.08835.

650 °C

Compound **2** (54 mg) afforded on thermolysis an oil (49 mg) which was shown by nmr to contain **4** and **5** in a molar ratio 5:13. Preparative tlc gave **4** (13 mg) and **5** (25 mg). Compound **5** (R_f = 0.74) was recrystallized from methanol to give a white solid, mp 123–126 °C (lit. (6) mp 132–134 °C); ir λ_{max} 6.65, 6.88 μm; uv λ_{max} (hexane) 223, 289 nm; nmr δ 3.66 (2H, s), 6.90 (2H, s) 7.15 (8H, m); *m/e* 192 (M^+).

800 °C

The 800 °C thermolysate of **2** was shown by nmr to contain **6** (25 mol %). Preparative gas chromatography of the thermolysate (column temperature = 190 °C) gave a 3 mg sample of **6**, mp 109–112 °C. Mixture melting

point was 109–113 °C with an authentic sample of mp 109–111 °C. The two samples were indistinguishable by their ultraviolet, infrared, and mass spectra as well as their retention times on gas chromatography.

Thermolysis of ***16***

300 °C

Compound **16** (40 mg) gave 34 mg of an oil which was shown by nmr to contain unchanged **16**, **17** (or **18**), and **19** in the molar ratio 4:15:1. The thermolysates from three runs were combined (190 mg) and subjected to preparative tlc (ether–hexane, 1:1). Extraction of the bands gave **16** (47 mg), **17**/**18** (118 mg), and **19** (8 mg). Compound **17**/**18** (R_f = 0.20) crystallized from ether, mp 105–106 °C, and formed a red 2,4-DNP, mp 208–210 °C. The aldehyde possessed the following characteristics: ir λ_{max} (KBr) 5.80, 5.93 μm; uv λ_{max} 242 (ε 15 600), 285 nm (ε 5000); nmr δ 2.67 (2H, d, J = 7 Hz), 3.77 (6H, s), 5.97 (1H, m, J = 9, 7 Hz), 6.52 (1H, dd, J = 9, 5.5 Hz), 7.50 (1H, d, J = 5.5 Hz), 9.48 (1H, s) *m*/*e* 236 (M^+). *Exact Mass* calcd. for $C_{12}H_{12}O_5$: 236.06792; found: 236.06791.

400 °C

Compound **16** (56 mg) on thermolysis at 400 °C gave 49 mg of a yellow oil. Analysis by nmr showed **17** (or **18**) and **19** in a molar ratio of *ca.* 1:3. Preparative tlc (ether–hexane 1:1) of two thermolysates combined (119 mg) gave **17**/**18** (28 mg) and **19** (70 mg). Compound **19** (R_f = 0.55) was crystallized from ether to give a solid, mp 108–110 °C 2,4-DNP (red) mp 227–228 °C; ir λ_{max} (KBr) 5.76, 5.86, 5.94 μm; uv λ_{max} 228 (ε 34 000), 313 nm (ε 65 000); nmr δ 3.45 (3H, s), 3.77 (3H, s), 5.63 (1H, s), 6.67–6.93 (2H, m), 6.93–7.13 (1H, m), 7.27–7.50 (1H, m); *m*/*e* 236 (M^+). *Exact Mass* calcd. for $C_{12}H_{12}O_5$: 236.06792; found: 236.06860.

Infrared Cryostat Experiments with ***2***, ***16***, ***23***, *and* ***24***

All analytical thermolyses for the low temperature infrared studies were conducted with *ca.* 7 mg of substrate. The thermolysate was condensed on the liquid-nitrogen-cooled sodium chloride disc of the cryostat and the spectrum recorded. Gas chromatographic analysis of the thermolysates was done by rinsing the product mixture from the sodium chloride disc with hot carbon tetrachloride.

Thermolyses of **2** at temperatures from 300 to 900 °C resulted in infrared spectra with no absorption due to ketene, although at 700, 800, and 900 °C the gas chromatograph trace (analytical column, temperature = 180 °C) showed five main peaks, one of these (not more than *ca.* 5% of the mixture) possessing the same retention time as anthracene.

Thermolysis of **16** at 600, 700, and 800 °C resulted in infrared spectra having a weak to medium absorption at 4.63 μm due to ketene. Gas chromatography (analytical column, temperature = 183 °C) revealed a complex mixture with five main products. A minor product (*ca.* 5% of the mixture) had a retention time identical to that of dimethyl phthalate.

The 600 °C thermolysate of **23** had an infrared spectrum with a weak to medium absorption band at 4.63 μm, ascribed to ketene. Gas chromatography (analytical column, temperature = 200 °C) showed three main products, one of which constituted *ca.* 20% of the mixture and had the same retention time as tetramethyl benzene-1,2,4,5-tetracarboxylate.

The infrared spectra of the 400, 500, 600, and 800 °C thermolysates of **24** all showed absorption at 4.65 μm attributable to dimethyl ketene. The optimum temperature for dimethyl ketene formation was 500 °C. Gas chromatography (analytical column temperature = 150 °C) showed that a product with the same retention time as dimethyl phthalate was obtained in all these thermolyses as a minor product (*ca.* 3% of the mixture). An authentic infrared spectrum of dimethyl ketene was obtained by flash thermolysis of dimethyl ketene dimer (2,2,3,3-tetramethylcyclobutane-1,3-dione)[7] at 700 °C and 0.10 torr.

Except for the disappearance of a ketene band with compounds **16**, **23**, and **24**, no change occurred in any of the infrared spectra when the product mixtures were allowed to warm to room temperature.

*11,12-Epoxy-9,10-dihydro-9,10-ethanoanthracene (****2****)*

The following modifications of the literature (6) procedure were made.

11,12-Dichloro-9,10-dihydro-9,10-ethanoanthracene (6.0 g, 22 mmol) and Zn–Cu couple (20) (6.0 g 92 mmol) were refluxed under a $CaCl_2$ drying tube with anhydrous ethanol (800 ml) for 1 week. Filtration and evaporation gave a solid which was taken up in dichloromethane and washed with 3 × 50 ml of water, dried, and evaporated to give 9,10-dihydro-9,10-ethenoanthracene (4.42 g, 95%), mp 106–112 °C (lit. (6) mp 118–119 °C).

Epoxidation of the ethenoanthracene to afford **2** was effected with *m*-chloroperbenzoic acid, essentially as described (6) for reaction with perbenzoic acid. Recrystallization from ether gave a 75% yield of **2**, mp 158–160 °C (lit. (6) mp 154–165 °C).

*Authentic 5H-Dibenzo[a,d]cycloheptene-5-carboxaldehyde (****3****)*

An authentic sample of **3** was prepared according to the procedure outlined by Cristol and Bly (6). The epoxide **2** was eluted through a column of acidic alumina (previously washed with 5% trifluoroacetic acid in CCl_4, then with CCl_4) with carbon tetrachloride as reported. The sample obtained gave a melting point of 111–113 °C (lit. (6) mp 112–114 °C) and formed a 2,4-DNP derivative, mp 214–217 °C (lit. (6) mp 221–223 °C). The mixture melting point of the authentic and thermolytic samples of **3** (mp 110–112 °C) was 110–113 °C. The two samples were indistinguishable by ir, uv, and nmr spectrometry.

*Authentic 5H-Dibenzo[a,d]cycloheptene-3-carboxaldehyde (****4****)*

Reduction of the ketone function of the commercially available (Aldrich) 10-bromo-5*H*-dibenzo[*a*,*d*]cycloheptene-5-one was accomplished by the method of Toda *et al.* (21). The bromo ketone (1.00 g) afforded the bromo compound (0.950 g, 91%) as a solid foam which decomposes slowly on standing, mp (crude solid) 67–78 °C; ir λ_{max} 6.69 μm; uv λ_{max} (hexane) 288 nm; nmr δ 3.58 (2H, s), 7.00 (8H, m), 7.43 (1H, s); *m*/*e* 270 (M^+). *Exact Mass* calcd. for $C_{15}H_{11}{}^{79}Br$: 270.00446; found: 270.00311.

[7]Kindly donated by Professor A. H. Rees of this department.

This bromide (50 mg, 0.18 mmol) was placed in a round bottom flask flushed with nitrogen gas, and sealed with a wired-on septum. Anhydrous ether (1 ml) was syringed in and swirled to dissolve the bromide. Over 10 s, 2 *M* *n*-butyllithium (0.10 ml, 0.20 mmol) was injected with slight agitation of the flask; the brown lithium salt sometimes precipitated. After 4 min, dimethylformamide (5 ml, distilled from calcium hydride) was added and the mixture magnetically stirred 1 h. The mixture was then diluted with 10 ml of ether and washed successively with 10 ml of 1 *M* hydrochloric acid, 10 ml of water, and 5 ml of a saturated sodium bicarbonate solution. The ether solution was dried, concentrated, and the residue subjected to preparative tlc (dichloromethane, run 2×). A band of $R_f = 0.51$ on extraction gave **4** (13 mg, 32%), mp 132–134 °C (lit. (11) mp 133–135 °C); mixture melting point with the thermolytic sample (mp 133–134 °C), 133–134 °C; 2,4-DNP mp 236–237 °C. The authentic and thermolytic samples gave very similar infrared spectra; their nmr and uv spectra were indistinguishable, and the infrared spectra of their 2,4-DNP derivatives were identical.

*Authentic 5H-Dibenzo[a,d]cycloheptene (**5**)*

Treatment of the lithium derivative of the bromo compound (see above) with water instead of dimethylformamide, followed by the work-up described for the synthesis of **3**, gave **5** (98%) as a cream-colored solid, mp 124–127 °C (lit. (6) mp 132–134 °C). The mixture melting point with thermolytic **5** of mp 123–126 °C was 123–126 °C, and the authentic and thermolytic samples were indistinguishable by ir, uv, and nmr spectrometry.

*Dimethyl 3-Oxatricyclo[3.2.2.0^{2,4}]nona-6,8-diene-6,7-dicarboxylate (**16**)*

Compound **16** was prepared essentially as described by Vogel and coworkers (4) but with the following modifications.

Pyridinium tribromide ("pyridinium hydrobromide perbromide") (0.85 g, 2.6 mmol), 1,4-cyclohexadiene (0.213 g, 2.6 mmol), and hexane (10 ml) in a stoppered round bottom flask were magnetically stirred for 4 h (until the orange pyridinium tribromide had been converted to the white pyridinium bromide). Filtration and concentration gave dibromocyclohexene (0.556 g, 90%).

This material (556 mg, 2.30 mmol) and *m*-chloroperbenzoic acid (575 mg of 85% peracid, 2.84 mmol) in chloroform (10 ml) were allowed to stand in a stoppered flask at room temperature for 4 days. The precipitated *m*-chlorobenzoic acid was filtered off and the filtrate washed successively with 4 ml of a saturated sodium bisulfite solution (2×), 4 ml of a saturated sodium bicarbonate solution (2×), and 4 ml of a brine solution (1×). The organic layer was dried and concentrated to afford 1,2-epoxy-4,5-dibromocyclohexane (412 mg, 70%). Sodium metal (0.16 g, 6.9 mmol) was added in small pieces to dry methanol (4 ml). When all the sodium had dissolved, the excess methanol was distilled off to give a thick slurry of methanol – sodium methoxide. Anhydrous ether (4 ml) was added, then a solution of the 1,2-epoxy-4,5-dibromocyclohexane (0.36 g, 1.4 mmol) in anhydrous ether (2 ml). The bright yellow solution was then refluxed 1 h. Work-up of the reaction mixture as outlined in the literature (4) gave oxepin (0.134 g, 70%).

Dimethyl acetylene dicarboxylate (0.96 g, 6.7 mmol) and oxepin (0.63 g, 6.7 mmol) were dissolved in ether (2 ml) and allowed to stand in a stoppered flask at room temperature for 1 week. Concentration and crystallization from ether gave **16** (1.48 g, 93%), mp 55.5–56 °C (lit. (4) mp 56 °C). The nmr spectrum was identical to that previously reported (4).

*Dimethyl 1-Methanoyl-1,3,5-cycloheptatriene-6,7-dicarboxylate (**19**)*

Isomerization of **16** to **19** was effected by column chromatography. A 2.0 cm × 10 cm column containing 20 g of Fisher alumina (neutral, activity I) was washed with 20 ml of trifluoroacetic acid – carbon tetrachloride (1:20), and then with 100 ml of carbon tetrachloride. Compound **16** (50 mg) in carbon tetrachloride was passed through the column, eluting with carbon tetrachloride. After 1 h a faint brown band was observed moving down the column. Preceding this band was another product, $R_f = 0.22$ (tlc with dichloromethane) which was collected. Evaporation of the eluate gave a colourless oil (30 mg, 60%) which was shown by ir, uv, and nmr spectrometry to be identical with the thermolytic sample **19**.

Rearrangement of a barrellene oxide to an isocoumarin under flash thermolysis conditions. An apparent series of sigmatropic shifts

E. G. LEWARS AND G. MORRISON

Department of Chemistry, Trent University, Peterborough, Ont., Canada K9J 7B8

Received September 16, 1976

E. G. LEWARS and G. MORRISON. Can. J. Chem. **55**, 975 (1977).

Flash thermolysis of dimethyl 3-oxatricyclo[3.2.2.0^{2,4}]nona-6,8-diene-6,7-dicarboxylate (the oxide of barrellene-2,3-dicarboxylic acid dimethyl ester) (**2**) at 700 °C gave methyl isocoumarin-7-carboxylate (**3**) as a major component of the thermolysate. The rearrangement is discussed in terms of sigmatropic shifts in cycloheptatrienes and their norcaradiene tautomers.

E. G. LEWARS et G. MORRISON. Can. J. Chem. **55**, 975 (1977).

La thermolyse éclair de l'oxa-3 tricyclo[3.2.2.0^{2,4}]nonadiène-6,8 dicarboxylate-6,7 de diméthyle (l'oxyde du barrèllènedicarboxylate-2,3 de diméthyle) (**2**) à 700 °C conduit à l'isocoumarinecarboxylate-7 de méthyle (**3**) comme produit majeur de la thermolyse. On discute du réarrangement en termes d'un déplacement sigmatropique dans les cycloheptatriènes et leurs tautomères norcaradiènes.

[Traduit par le journal]

Our interest in oxirene (**1**) led us to study the flash thermolysis of the barrellene oxide **2** in the hope of effecting reverse Diels–Alder cleavage to **1** and dimethyl phthalate (1). At temperatures in the range 300–600 °C, the main reaction was rearrangement to cycloheptatriene

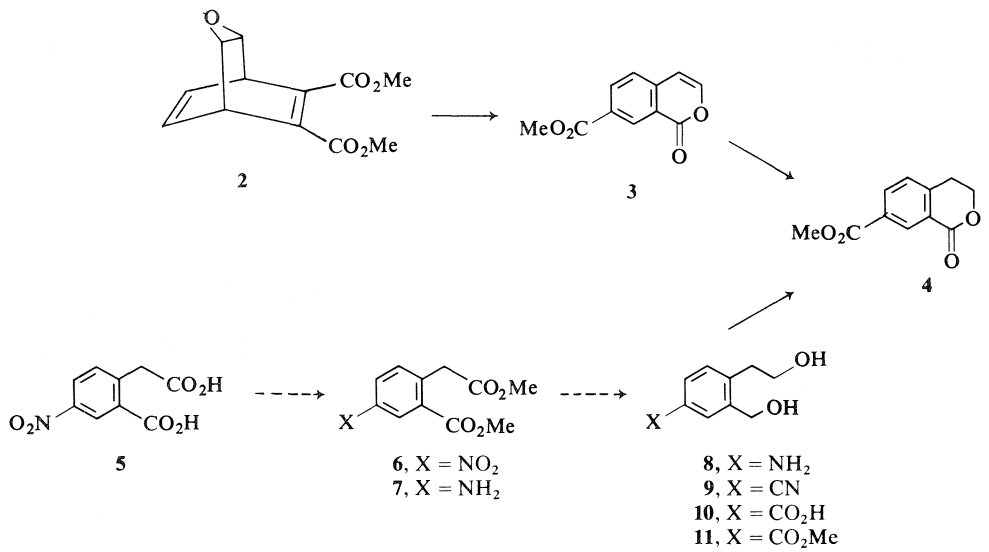
1

carboxaldehydes, although the formation of a small amount of ketene, detected by low-temperature infrared spectrometry, could be interpreted as indicating that the desired fragmentation had occurred to a minor extent. Here, we wish to report that flash thermolysis of **2** at 700 °C gave methyl isocoumarin-7-carboxylate (**3**).

When **2** was subjected to flash thermolysis (1) at 700 °C, a complex thermolysate (10 spots on thin layer chromatography) was obtained from which only one pure compound was isolated. This compound, a colorless, microcrystalline solid, was shown by mass spectrometry to have the formula $C_{11}H_8O_4$, corresponding to the loss of methanol from **2**. Its origin and ^{1}H nmr spectrum [δ ($CDCl_3$) 3.90 (s, 3H), 6.40 (d, J = 6 Hz, 1H), 7.20 (d, J = 6 Hz, 1H), 7.32 (d, J = 8 Hz, 1H), 8.15 (d of d, J = 8 and 2 Hz, 1H), 8.72 (d, J = 2 Hz, 1H)] suggested that it might be a benzene-ring-substituted isocoumarin, and its infrared [λ_{max} (KBr) 5.81 μm] and ultraviolet [λ_{max} (MeOH) 225 (ε 24 000), 242 (ε 17 000), 250 (ε 16 000), 285 nm (ε 16 000)] spectra were consistent with this view. The isocoumarin structure received strong support when the compound absorbed one and only one molar equivalent of hydrogen at atmospheric pressure in the presence of palladium–charcoal, giving a dihydro derivative, δ ($CDCl_3$) 3.05 (t, J = 6 Hz, 2H), 3.88 (s, 3H), 4.47 (t, J = 6 Hz, 2H), 7.23 (d, J = 8 Hz, 1H), 8.05 (d of d, J = 8 and 2 Hz, 1H), 8.58 (d, J = 2 Hz, 1H), λ_{max} (KBr) 5.82 μm, λ_{max} (MeOH) 214 (ε 38 000), 236 nm (sh, ε 11 400). The nmr spectra pointed strongly to a 1,2,4-substituted benzene ring, and the low-field position of the isolated (weakly coupled, J = 2 Hz) proton in both compounds indicated that it was located between the carbons bearing carbonyl groups,[1] thus suggesting structure **3** for the thermolysis product, and structure **4** for its dihydro derivative.

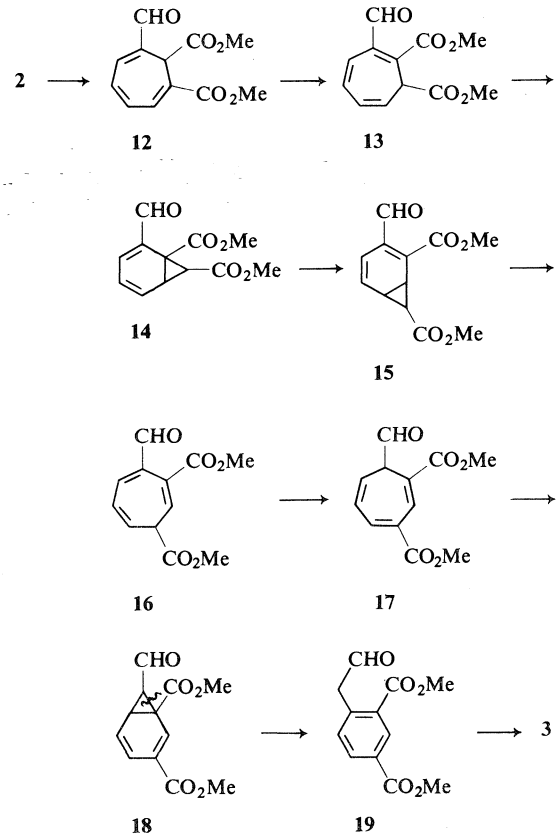
That structures **3** and **4** were correct was shown by an unambiguous synthesis of **4** starting with 4-nitrohomophthalic acid **5** (3), the structure of which has been rigorously established (4). Compound **5**, made by treating homophthalic acid with fuming nitric acid, was converted into the carbomethoxy diol **11** by standard

[1] *Cf.* the analogous proton in 3-toluic acid (δ 7.4 or 7.8) and in benzene-1,3-dicarboxylic acid (δ 8.7) (2).



procedures. The oxidation of **11** to the dihydroisocoumarin **4**, effected by activated manganese dioxide (5) in good yield (73%), is noteworthy; although the oxidation of 2-(2-hydroxymethylphenyl)ethanols to dihydroisocoumarins by chromium trioxide has been reported (6), the yield was very low (*ca.* 10%). We believe that this oxidation, as effected by activated manganese dioxide, proceeds by oxidation of the benzylic hydroxyl (7) to an aldehyde group which is attacked by the remaining hydroxyl group; the resulting hemiketal is again a benzylic alcohol, and is oxidized to **4**.

The barrellene oxide **2** has been shown (1) to rearrange at 400 °C to the cycloheptatriene carboxyaldehyde **12**. The observation that **12** gave the isocoumarin **3** under the same conditions as those under which **2** rearranged to **3** enables us to propose a likely mechanism for the genesis of **3**. Two consecutive sigmatropic shifts of hydrogen could convert **12** into **13**, the norcaradiene tautomer of which, **14**, could undergo a 1,5-sigmatropic shift of carbon giving **15**, the norcaradiene tautomer of **16**; another 1,5-hydrogen shift (to give **17**) followed by tautomerization leads to **18**, which could reasonably be expected to isomerize to **19**. The isomerization of cycloheptatrienes by sigmatropic shifts of hydrogen and of carbon is well known (8), and the conversion of cycloheptatriene and its derivatives to toluene or substituted toluenes (**19** is a toluene substituted in the benzene nucleus and on the side chain) is well established (ref. 9, and especially refs. 11–16 therein). The cyclization of **19** to the isocoumarin **3**, possibly by way of the enol form of **19**, appears reasonable.



The mechanism of the rearrangement of **2** to **12** can thus be plausibly rationalized (1), and the subsequent transformation[2] of **12** into **3** is interpretable in terms of amply documented processes.

Experimental

General experimental techniques, including a description of thermolysis procedures and the apparatus used, are given in our earlier paper (1). Homophthalic acid, for the preparation of **5**, was purchased from the Aldrich Chemical Company.

Thermolysis of 2 at 700 °C; Methyl Isocoumarin-7-carboxylate (3)

Compound **2** (203 mg) gave 150 mg of thermolysate as a sticky solid. The ^{1}H nmr spectrum of the crude mixture showed it to be composed of *ca.* 25 mol % isocoumarin **3**. Preparative tlc (chloroform, run 3×) gave a band of $R_f = 0.36$ which on extraction gave a white powder, 23 mg. Recrystallization from carbon tetrachloride gave colorless microneedles, 17 mg, mp 178–179 °C; *m/e* 204 (M^+). *Exact Mass* calcd. for $C_{11}H_8O_4$: 204.04170; found: 204.04320.

Methyl Dihydroisocoumarin-7-carboxylate (4)

A thermolytic sample of **3** (12.1 mg, 0.059 mmol) in ethyl acetate (2 ml) was hydrogenated at 1 atm with 5% Pd/charcoal (*ca.* 50 mg). Approximately 1 mol. equiv. of hydrogen was absorbed over 30 min. Filtration and concentration gave 11.9 mg of the dihydro derivative **4** (97%). Recrystallization from carbon tetrachloride gave microcrystals, mp 108–109 °C; *m/e* 206 (M^+). *Exact Mass* calcd. for $C_{11}H_{10}O_4$: 206.05735; found: 206.05774.

Thermolysis of 12

Aldehyde **12** (80 mg) was thermolyzed at 700 °C and the crude thermolyzate was subjected to preparative tlc (chloroform, run 3×). The band of $R_f = 0.36$ was extracted and the material was crystallized from carbon tetrachloride to give 7 mg of a white powder, mp 177–178 °C; the mixture mp with isocoumarin **3**, from epoxide thermolysis, of mp 178–179 °C was 177–179 °C, and the two materials had identical ir, uv, and mass spectra.

Authentic Methyl Isocoumarin-7-carboxylate (4)

Diester 6

4-Nitrohomophthalic acid (**5**) (3) (400 mg, 1.7 mmol) was dissolved in methanol (20 ml) and a slight excess of standardized diazomethane solution was added. Evaporation gave 386 mg (87%) of 4-nitrohomophthalic acid dimethyl ester. Recrystallization from methanol gave white plates, mp 87–88 °C; ir λ_{max} 5.75, 7.39 μm; uv λ_{max} 219, 262 nm; nmr δ 3.67 (3H, s), 388 (3H, s), 4.08 (2H, s), 4.40 (1H, d, $J = 8$ Hz), 4.90 (1H, dd, $J = 8$, 2 Hz), 8.68 (1H, d, $J = 2$ Hz); *m/e* 253 (M^+).

Amino Diester 7

Compound **6** (420 mg, 1.6 mmol) in ethyl acetate (15 ml) was hydrogenated at 1 atm with 5% Pd–charcoal (100 mg). Over 2 h, *ca.* 3 mol. equiv. of hydrogen were absorbed. Filtration and concentration gave 333 mg (90%) of 4-aminohomophthalic acid dimethyl ester, mp 93–98 °C; ir λ_{max} 5.79 μm; uv λ_{max} 221, 248, 320 nm; nmr δ 3.62 (3H, s), 3.75 (3H, s), 3.78 (2H, s), 6.59 (1H, dd, $J = 8$, 2 Hz), 688 (1H, d, $J = 8$ Hz), 7.15 (1H, d, $J = 2$ Hz); *m/e* 223 (M^+). *Exact Mass* calcd. for $C_{11}H_{11}NO_4$: 223.08445; found: 223.08429.

Amino Diol 8

Vitride reducing agent (sodium bis(2-methoxyethoxy)-aluminum hydride in benzene) (6.0 ml of a 70% solution, 22 mmol) in tetrahydrofuran (130 ml, distilled from calcium hydride) was brought to reflux under a nitrogen atmosphere. 4-Aminohomophthalic acid dimethyl ester (1.30 g, 5.0 mmol) was added over 1.5 h. After refluxing an additional 6 h, the mixture was carefully poured into ice water (100 ml) and continuously extracted with dichloromethane overnight. Drying and concentration of the organic layer gave 0.91 g (93%) of an oil which showed mainly one spot on analytical thin layer chromatography (methanol–dichloromethane, 1:20); $R_f = 0.20$, ir λ_{max} (CH_2Cl_2) 6.15 μm; uv λ_{max} 240, 290 nm, shifting to shorter wavelength on addition of acid; nmr (DMSO-d_6) δ 2.63 (2H, t, $J = 6$ Hz), 3.50 (2H, m), 4.40 (2H, s), 6.37 (1H, dd, $J = 8$, 2 Hz), 6.56 (1H, d, $J = 2$ Hz), 6.77 (1H, d, $J = 8$ Hz); *m/e* 167 (M^+). *Exact Mass* calcd. for $C_9H_{13}NO_2$: 167.09407; found: 167.09473.

Cyano Diol 9

Amino diol **8** (826 mg, 4.9 mmol) was dissolved in a solution of concentrated sulfuric acid (5 ml) and water (7 ml). When solution was complete, another 20 ml of water was added and the solution was cooled to 0 °C. To the cooled solution was added sodium nitrite (355 mg, 5.1 mmol), at such a rate as to keep the temperature of the solution below 5 °C. After addition, the solution was stirred at 0 °C for 30 min, and carefully neutralized with sodium carbonate. A solution of cuprous cyanide (0.50 g, 5.6 mmol) and sodium cyanide (0.60 g, 12.2 mmol) in water (20 ml) was added, and stirred at room temperature for 1 h. The solution was then continuously extracted with dichloromethane overnight and the organic layer dried and concentrated to afford 353 mg (40%) of **9** as an oil. Analytical tlc (methanol–dichloromethane, 1:20) showed one spot, $R_f = 0.26$; uv λ_{max} 235 nm, no change on addition of acid, showing no amine was present; *m/e* 177 (M^+).

Carboxy Diol 10

The crude cyano diol (**9**) (353 mg, 2.0 mmol) was refluxed with 10% sodium hydroxide (20 ml) for 2 h. The solution was extracted with ether to remove non-basic impurities and the aqueous layer was acidified with concentrated hydrochloric acid. The acidified solution was continuously extracted with ether overnight and the ether layer dried and evaporated to give 193 mg (49%) of **10**, mp 153–157 °C; ir λ_{max} (KBr) 5.90 μm; uv λ_{max} 238 nm; nmr (DMSO-d_6/$CDCl_3$) δ 2.83 (2H, t, $J = 6$ Hz), 3.65 (2H, t, $J = 6$ Hz), 4.55 (2H, s), 7.15 (1H, d, $J = 8$ Hz), 7.70 (1H, d, $J = 8$ Hz), 7.87 (1H, s); *m/e* 196 (M^+). *Exact Mass* calcd. for $C_{10}H_{12}O_4$: 196.07300; found: 196.07270.

Carbomethoxy Diol 11

An ethereal solution of diazomethane was added to a solution of the acid-diol **10** (90 mg, 0.46 mmol) in

[2]It is of course possible that a pathway exists for the transformation of **2** into **3** without the intermediacy of **12**; we choose, however, to invoke Occam's razor.

methanol (3 ml) until a yellow color persisted. The solution was then evaporated to give 81 mg (84%) of the ester **11** as an oil; ir λ_{max} 5.80 μm; uv λ_{max} 239 nm, nmr δ 2.86 (2H, t, J = 6 Hz), 3.73 (2H, t, J = 6 Hz), 3.80 (3H, s), 4.50 (2H, s), 7.10 (1H, d, J = 6 Hz), 7.70 (1H, dd, J = 6, 2 Hz), 7.77 (1H, d, J = 2 Hz); m/e 210 (M^+).

*Methyl Dihydroisocoumarin-7-carboxylate (**4**)*

The diol **11** (81 mg, 0.39 mmol) was refluxed with activated manganese dioxide (5) (0.80 g) in ether (15 ml) for 12 h. The mixture was filtered, dried, and concentrated to give 58 mg (73%) of a solid that showed one spot (R_f = 0.30) on tlc (dichloromethane). The compound was crystallized from carbon tetrachloride to give microcrystals, mp 106–107 °C. The mixture melting point with the compound (mp 108–109 °C) obtained from hydrogenation of thermolytic methyl isocoumarin-7-carboxylate was 106–108 °C. The two samples were indistinguishable by ir, uv, and nmr spectrometry, and by tlc.

An optically active cyclopropene as a mechanistic probe in cyclopropene photochemistry

JAMES A. PINCOCK AND ALEXIOS A. MOUTSOKAPAS
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received September 27, 1976

JAMES A. PINCOCK and ALEXIOS A. MOUTSOKAPAS. Can. J. Chem. **55**, 979 (1977).

The photochemistry of methyl 1-methyl-2-phenylcyclopropene-3-carboxylate has been examined in both the racemic and optically active forms. In the excited singlet the cyclopropene is converted to 2-methoxy-5-methyl-4-phenylfuran whereas the triplet state dimerizes to a tricyclohexane derivative. Experiments with optically active cyclopropene ester demonstrate that photochemical racemization occurs about 2.5 times as fast as conversion to the furan product indicating that there is an intermediate vinyl carbene on the singlet surface. No racemization is observed in the triplet state.

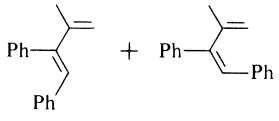
JAMES A. PINCOCK et ALEXIOS A. MOUTSOKAPAS. Can. J. Chem. **55**, 979 (1977).

On a examiné la photochimie du méthyl-1 phényl-2 cyclopropènecarboxylate-3 de méthyle dans ses formes racémique et optiquement active. Dans l'état singulet excité, le cyclopropène est transformé en méthoxy-2 méthyl-5 phényl-4 furanne alors que l'état triplet se dimérise en un dérivé tricyclohexane. Des expériences avec l'ester de cyclopropène optiquement actif permettent de démontrer que la racémisation photochimique se produit environ 2.5 fois plus rapidement que sa conversion en dérivé de furanne; ces résultats indiquent qu'il y a un intermédiaire vinyle carbène à la surface du singulet. Il n'y a aucune racémisation d'observé à l'état triplet.
[Traduit par le journal]

Introduction

The photochemistry of cyclopropene derivatives has been shown to be remarkably dependent on the multiplicity of the excited state involved. Singlet states react by σ-bond cleavage to give products which are explained in terms of the chemistry of vinyl carbenes; an example is shown in reaction 1 for the direct irradiation of 3,3-dimethyl-1,2-diphenylcyclopropene, **1**, to a mixture of *cis*- and *trans*-1,2-diphenyl-3-methylbutadiene, **3** and **4**, with a quantum yield for the conversion of 0.045 (1). In contrast, triplet states generated by

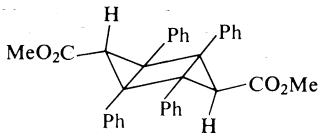
[1] 
1 **2**



3 **4**

sensitization techniques give high yields of cyclopropene dimers; for example, [2], photolysis of methyl 1,2-diphenylcyclopropene-3-carboxylate, **5**, in the presence of a variety of sensitizers gives the tricyclic dimer **6** with quantum yields as high as 0.8 (2).

[2] 
5

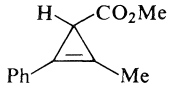


6

The surprising feature of these results is that, despite the extra energy introduced by electronic excitation, in neither case is there efficient ring cleavage to relieve the strain energy (~54 kcal/mol (3) in the ground state) of the cyclopropene ring. The triplet reacts with high quantum yield but retains the three-membered ring; the singlet reacts by ring cleavage but with very low efficiency. This low efficiency for singlet state reactivity has been explained by thermal return of the carbene intermediate (*i.e.* **2** in [1]) to the cyclopropene (1). Such thermal behaviour of vinyl carbenes is well known and is in fact the basis of a synthetic procedure for the preparation of cyclopropenes (1, 4). More quantitative information is available from a study (5) of the thermal racemization of 1,3-diethylcyclopropene where return of the carbene intermediate to starting

material is favoured over rearrangement to products by a factor of 9. Thus the possibility exists that the low efficiency of cyclopropene excited singlet reactions is a result of favourable return and not of inherent unreactivity of the cyclopropene ring.

In order to test this possibility and also to gain a better understanding of vinyl carbene intermediates generated from excited states we have examined the photochemistry of both racemic and optically active methyl 1-methyl-2-phenylcyclopropene-3-carboxylate, **7**, by direct and sensitized irradiations.



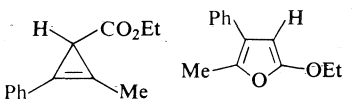
7

Results and Discussion

(1) Synthesis of Methyl 1-Methyl-2-phenylcyclopropene-3-carboxylate

In a series of papers D'yakonov and coworkers (6, 7) have reported that the reaction of ethyl diazoacetate with 1-phenylpropyne gives two products, the cyclopropene ester **8**, and the 2-ethoxyfuran **9**, as in [3]. This carbenoid reaction was said to be catalyzed by copper sulfate with the ratio of **9**/**8** increasing with increased amounts of catalyst and temperature and is quoted in standard texts (8) as an example of copper catalysis affecting the ratio of carbene to 1,3-dipolar addition in ketocarbenes. As an obvious precursor to the methyl ester **7**[1] we have examined this procedure for the preparation of **8** in some detail. By ^{1}H nmr analysis of the crude reaction mixtures immediately after these rapid (~10 min) reactions were completed the ratio of **9**/**8** could be easily determined. Under a variety of conditions no **9** could be detected. However, on distillation of the reaction mixtures (P = 0.3 torr, T = 125 °C)[2] when copper sulfate was present, considerable amounts of an ethoxyfuran presumed to be **9** were observed. The amount was dependent on the temperature and duration of the distillation and in fact heating the reaction for 3 h at 120 °C and then distilling gave only the furan. In contrast the ester **8** could be cleanly distilled when copper sulfate was absent. The conversion of **8** to **9** is therefore not a simple thermal reaction but is metal catalyzed. Since the presence of copper sulfate as a catalyst improved the yield of the addition reaction and only interfered with the isolation procedure, this difficulty is best avoided by saponification of the crude reaction mixture and purification of the cyclopropene as the free acid. The acid was then cleanly converted to **7** by 3-methyl-1-*p*-tolyltriazene (9).

[3] $N_2CH—CO_2Et + PhC{\equiv}CMe \xrightarrow[90\text{–}120\ ^\circ C]{CuSO_4}$

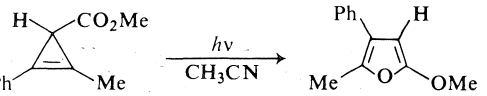


8 **9**

(2) Direct Photolysis of Methyl 1-Methyl-2-phenylcyclopropene-3-carboxylate

The cyclopropene ester **7** was irradiated in acetonitrile solution using a 200 W medium pressure Hanovia lamp and a Vycor filter. Analysis by ^{1}H nmr of the crude photolysate indicated one major component (estimated at ~75% yield based on reacted cyclopropene), 2-methoxy-5-methyl-4-phenylfuran, **10** [4]. Isolation of this furan proved to be extremely difficult since it was sensitive to air oxidation. Pure samples could be obtained by column chromatography but the recoveries were always low. The gross structure of **10** was suggested by several key spectral features; lack of a carbonyl band in the infrared and a vinyl singlet in the ^{1}H nmr at 5.25 δ. This high field signal is characteristic of the 3H in 2-alkoxyfuran derivatives; compare, for example, 5.10 δ for 2-methoxyfuran (10). The remaining question then was the substitution pattern of the phenyl and methyl groups. Advantage was taken of the ready oxidation of alkoxy furans to derivatives of esters of 4-keto-2-butenoic acids (6, 7, 11). There are two possibilities as shown in [5] and [6]. Compound **13** is known (12) and its ^{1}H nmr gives the expected allylic coupling (J = 2 Hz) of a

[4]



7

[1]The methyl ester was preferred for the photochemical study because the methoxy singlet makes monitoring by nmr easier, particularly when using chiral shift reagents.

[2]Temperatures of the flask in a bulb-to-bulb distillation.

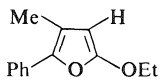
12 13

methyl doublet and a vinyl quartet. As well, the ir bands in the carbonyl region are at 1680 and 1731 cm^{-1}. Oxidation of **10**, however, did not give **13** but rather, as the only product, **11**; ^1H nmr δ: 2.40 (s, 3H), 3.73 (s, 3H), 6.28 (s, 1H) and 7.35–7.40 (s, 5H). Moreover the carbonyl bands in the infrared are at 1728 and 1760 cm^{-1}. The observation of the sharp singlets for the methyl and vinyl protons and the different ir bands rule out **13** as an oxidation product. Therefore the furan from the photolysis of the cyclopropene ester **7** must be the 5-methyl-4-phenyl derivative **10**.

D'yakonov (6, 7) has reported that this is the same furan substitution pattern obtained by addition of ethyl diazoacetate to 1-phenylpropyne; note **9** in [3]. As shown above this furan is actually formed in a catalyzed thermal process by rearrangement of the cyclopropene ester **8**. The ^1H nmr spectrum of **9** showed methyl (2.20 δ) and vinyl (5.10 δ) singlets which seemed sufficiently different from those of **10**, methyl (2.36 δ) and vinyl (5.25 δ), to be surprising when the only change should be from a 2-ethoxy group in **9** to a 2-methoxy group in **10**. Similar differences also occurred in the carbon spectra: for **9**, 86.1 (C-2 of ring) and 14.5 δ (CH_3); for **10**, 90.9 and 12.6 δ. This discrepancy was easily clarified by air oxidation of **9**. Although the ethyl ester corresponding to **11** should have been formed, the product actually obtained was the ethyl ester of **13**; by ^1H nmr the allylic coupling was obvious and the ir bands were at 1728 and 1687 cm^{-1}.[3] Therefore D'yakonov's **9** is actually **14**.



14

[3]D'yakonov does not report an nmr spectrum but does give ir bands of 5.78 (1718 cm^{-1}) and 5.96 μm (1678 cm^{-1}).

Two factors concerning the direct photolysis of **7** are noteworthy. First of all the product obtained, 2-methoxy-5-methyl-4-phenylfuran **10**, is a result of σ-bond cleavage of the cyclopropene ring as expected. This must reflect the reactivity of the excited singlet state since intersystem crossing efficiencies for phenyl substituted cyclopropenes are known to be low (2). Moreover generation of the triplet state by sensitization (see below) does not give the furan product. The second feature of this photolysis is that the product obtained results from cleavage of the cyclopropene single bond which is methyl rather than phenyl substituted. This seems surprising since one might have expected the alternate cleavage to be preferred. At the moment we have no explanation for this behaviour except to note that similar effects seem to be present in the ground state thermal chemistry of cyclopropenes, *i.e.* substitution that should normally stabilize radical centers and make bond cleavage easier raises the activation barrier (5).

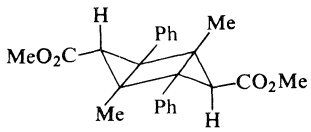
(3) Sensitized Photolysis of Methyl 1-Methyl-2-phenylcyclopropene-3-carboxylate, 7

Photolysis of **7** in either acetone as solvent or in acetonitrile with benzophenone gave very clean conversions to a dimeric product **15**, mp 33–34 °C, mass spectrum parent ion, 376. (Note [7].)

[7] 
7 15

This conversion could be nicely followed by ^1H nmr spectra taken during photolysis in deuterated acetone. Although there are six possible *anti*-structures for a tricyclic hexane formed from dimerization of **7** the simplicity of the ^1H nmr spectrum (δ 1.63 (s, 3H), 2.85 (s, 1H), 3.41 (s, 3H), 7.20 (m, 5H)) requires that the structure have either both carbomethoxy groups *endo* or both *exo*. The structure of an analogous dimer (**6** in [2]) has been confirmed by X-ray crystallography (13) and both groups are *exo*. Therefore the photoproduct from **7** is either **15** or the isomeric **16**. Evidence for the proposed

structure **15** is available from photolysis of optically active **7** as described below.



16

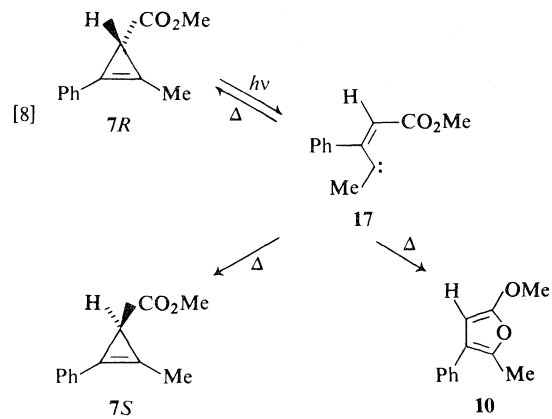
(4) Optically Active Methyl 1-Methyl-2-phenylcyclopropene-3-carboxylate; Determination of Optical Purity

The resolution of 1-methyl-2-phenylcyclopropene-3-carboxylic acid by formation of the diastereomeric salts with *l*-ephedrene has been reported previously (14) although without experimental details. The resolved acid was then converted to the methyl ester with 1-methyl-3-*p*-tolyltriazine (9) as for the racemic acid.

Rather than use optical rotation measurements to determine optical purity of the cyclopropene ester **7** we have found that the chiral lanthanide shift reagent, tris(3-heptafluorobutyryl-*d*-camphorato)europium III, [Eu(hfbc)$_3$], is preferable (15). This ^{1}H nmr method has the obvious advantage that, provided resolution of the enantiomeric signals can be attained, the percentage composition can be determined even in the presence of other compounds which would interfere with rotation measurements. Shown in Fig. 1 is a spectrum of optically active **7**, $[\alpha]_D^{25}$ 76.1° (*c* 1.34, CH_3CN) with added Eu(hfbc)$_3$. The enantiomeric signals are obviously well resolved. No detailed studies were made to attempt to maximize the chemical shift differences; rather the shift reagent was added until reliable resolution was obtained (molar ratio of Eu(hfbc)$_3$:**7** of about 0.1). Peak areas were measured by at least five integrator scans and then the values averaged. From the spectrum in Fig. 1 the following values are obtained; —OMe signal, ratio high field/low field 1:3.12; methine H, 1:3.13; —CMe, 3.19:1. Therefore the sample contains 76 ± 1% (+) enantiomer.

(5) Direct Photolysis of Optically Active Methyl 1-Methyl-2-phenylcyclopropene-3-carboxylate, 7

With a convenient method available for monitoring racemization of **7** during photolysis a study for the intervention of vinyl carbene intermediates in the conversion of cyclopropene **7** to the furan **10** is now possible. This is outlined in [8]. If **17** is an intermediate in the photolysis, *i.e.*



the end point of the excited state chemistry, and if thermal return of **17** to **7***R* (or **7***S*)[4] competes with conversion to the furan **10** then photochemical racemization of the cyclopropene should occur faster than its rate of disappearance. This results because **17** as drawn is flat and return to either of the two enantiomers is equally probable.

The results for the photolysis of optically active **7** are shown in Table 1. The cyclopropene

TABLE 1. Photoracemization of **7** as a function of conversion to **10**

Conversion (%)	Racemization of **7** (%)
10	29 ± 2
16	39 ± 4
25	56 ± 8

was photolyzed and its disappearance monitored by gas chromatography. At the conversions given the cyclopropene was reisolated by thin layer chromatography and the enantiomeric composition determined. Clearly from the results photochemical racemization is occurring about 2.5 times as fast as conversion.

(6) Sensitized Photolysis of Optically Active Methyl 1-Methyl-2-phenylcyclopropene-3-carboxylate, 7

Photolysis of optically active **7** in acetone gave no indication of photochemical racemization. For example, a sample of 65 ± 2% (+)-enriched **7** was photolyzed until 50% conversion to the dimer **15**. Reisolation of **7** and measurement of the enantiomeric composition indicated 67 ± 3%

[4]Note that the absolute configurations of the cyclopropenes are unknown but are unnecessary for this study.

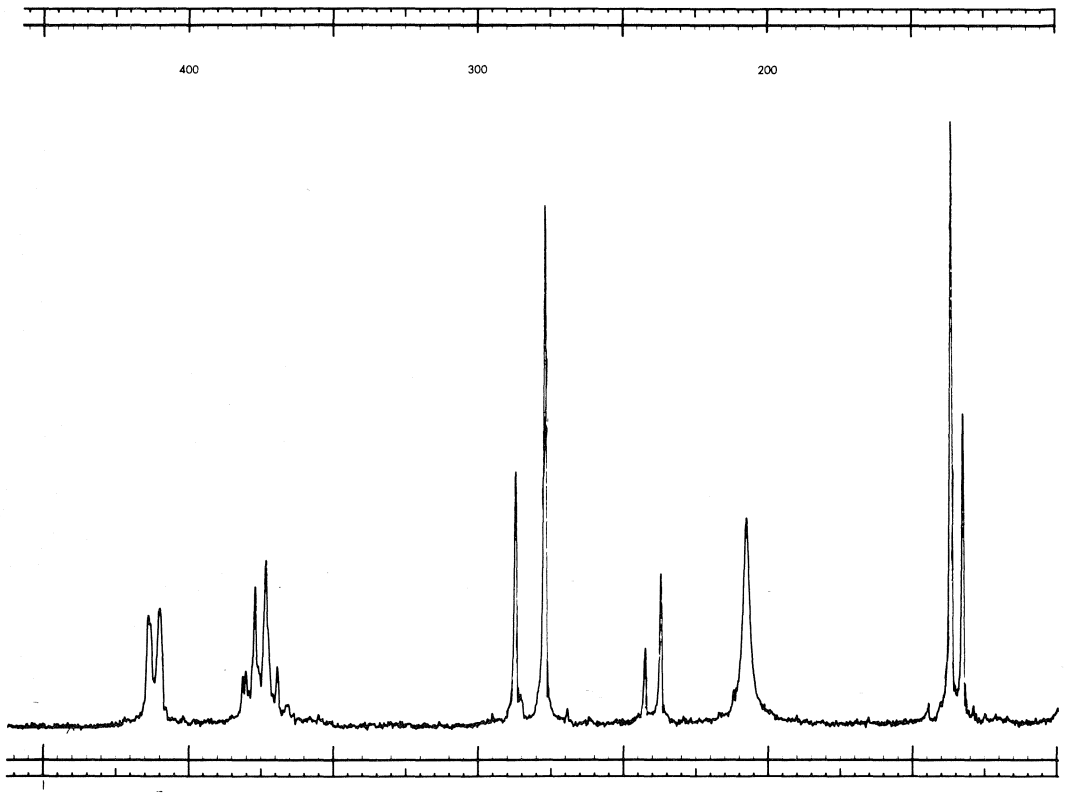


FIG. 1. Nuclear magnetic resonance spectrum of (+)-enriched **7** with $Eu(hfbc)_3$.

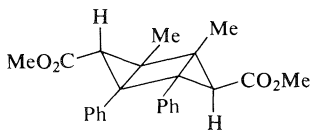
(+)-enriched. Similar results were observed at lower conversions. These observations demonstrate that the triplet state does exhibit only π-bond reactivity to form the dimer with no indication of σ-bond cleavage.

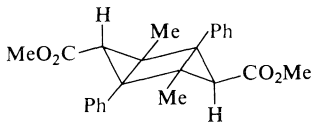
Moreover, this result is only consistent with structure **15** as the correct one for this dimeric product. As shown in [9] and [10] the two possible dimers **15** and **16** would be formed by two possible orientations of cyclopropene rings. However dimer **16** can only be formed by reaction of two cyclopropenes of opposite configuration, **7***R* + **7***S*. Therefore each time a dimer of structure **16** was formed a *d*/*l* pair of **7** would have reacted and the residual cyclopropene would have increased in optical purity. On the other hand, formation of **15** only occurs by reaction of cyclopropenes of the same configuration, **7***R* + **7***R* as shown or **7***S* + **7***S*. Since the rate constants for the *R* + *R* and the *S* + *S* reactions will be the same, the rates will only be dependent on the concentrations of *R* and *S*.

[9] 
7*R* **7***R*



15

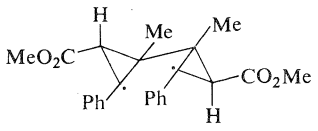
[10] 
7*R* **7***S*



16

Therefore the rates of disappearance of *R* and *S* will be the same as the ratio of their concentrations and the *R*/*S* ratio in the unreacted cyclopropene will remain constant. Since this is the observed behaviour for the photolysis of optically active **7**, the structure of the dimeric product must be **15**.

The triplet state photochemistry of cyclopropene ester **7** is then as shown in [7]. Interestingly enough the dimer obtained probably has worse steric interactions than the alternate possibility assuming that a phenyl–phenyl interaction is worse than a phenyl–methyl one. However, this observation is nicely explained by the suggestion (2) that the primary photochemical product of these triplet state reactions is actually a diradical, *i.e.*, **17**. The formation of **15** then results because **17** allows maximum delocalization of the radical centers in the intermediate.



17

(7) General Conclusions on Cyclopropene Photochemistry

The results of this study confirm previous observations on cyclopropene excited state reactivity; singlet states react only by σ-bond cleavage and triplet states by dimerization. The low quantum yield for singlet reactivity (1) is at least in part explained by photochemical racemization of the cyclopropene. At the moment there is not an example where both quantum yield of racemization and reactivity have been measured so the overall efficiency of ring opening is unknown. It would not be surprising if this efficiency were high considering the highly exothermic nature of this process.

The reactivity of triplet cyclopropenes is more puzzling. In a recent publication of *ab initio* calculations of the cyclopropene – vinyl carbene surface (16) the exothermic nature of the triplet cyclopropene to triplet vinyl carbene conversion is clearly shown. Why then does the cyclopropene remain intact long enough to react with another molecule in the ground state? The answer must be that there is a barrier on the cyclopropene – vinyl carbene triplet surface which does not exist on the singlet surface. Preliminary results by MINDO-3 calculations[5] suggest that this indeed may be the correct explanation.

Experimental

1-Methyl-2-phenylcyclopropene-3-carboxylic Acid

A variation of the reported procedure was followed (6, 7). To 23.7 g (0.204 mol) of 1-phenylpropyne and 20 mg (0.126 mmol) of copper sulfate heated to 120 °C in an oil bath was added 13.5 g (0.118 mol) of ethyl diazoacetate (16) over a 15 min period. The reaction mixture was then cooled and added to a solution of 20 g KOH in 360 ml of 95% ethanol. After stirring at room temperature for 48 h 800 ml of water was added and the mixture extracted with 2 × 200 ml ether to recover the unreacted acetylene. The aqueous phase was then acidified with 10% HCl and extracted with 2 × 200 ml ether. The extract was washed with 2 × 200 ml saturated NaCl, dried over $MgSO_4$, and concentrated to give 7.27 g of dark brown solid. This solid was chromatographed on 110 g of silica gel using $CHCl_3$ as eluant. The volume from 200–800 ml contained 6.03 g of crude acid which could be recrystallized to give 4.05 g (0.0232 mol, 20% yield) of pure 1-methyl-2-phenylcyclopropene-3-carboxylic acid; mp 139–140 °C (lit. (6) 137.2–137.9); ^{1}H nmr ($CDCl_3$) δ 2.37 (s, 3H), 2.48 (s, 1H), 7.4–7.6 (m, 5H), 9.8 (br s, 1H).

Methyl 2-Methyl-2-phenylcyclopropene-3-carboxylate

To 0.250 g (1.44 mmol) of the acid in 10 ml of ether was added 0.500 g (3.3 mmol) of 1-methyl-3-(*p*-tolyl)triazene (9) dissolved in 10 ml of ether. The reaction mixture was stirred for 20 h at room temperature. The solution was then washed with 4 × 10 ml of 10% HCl, 15 ml of 10% $NaHCO_3$, and finally with 2 × 15 ml water. The ether solution was dried over $MgSO_4$ and concentrated to give 0.244 g (1.31 mmol, 91%) of the known (17) ester: ^{1}H nmr ($CDCl_3$) δ 2.33 (s, 3H), 2.45 (s, 1H), 4.18 (s, 3H), 7.2–7.3 (s, 5H); ir (film) 1730, 1895 cm^{-1}; uv (CH_3CN) 257 nm (ε 17 700).

Photolysis of Methyl 1-Methyl-2-phenylcyclopropene-3-carboxylate

In a typical experiment 1.00 g of the ester was dissolved in 300 ml of CH_3CN (distilled from P_2O_5) and irradiated for 2.5 h in a nitrogen atmosphere with a 250 W Hanovia medium pressure lamp and a Vycor filter. Evaporation of the solvent gave 1.14 g of material which by nmr analysis contained ~75% of 2-methoxy-5-methyl-4-phenylfuran. This furan could be purified in low yield by column chromatography; 240 mg of the crude photolysate on 13 g of basic alumina eluted with 25% ether in petroleum ether gave 38.1 mg (16% yield based on initial cyclopropene) of pure furan: ^{1}H nmr ($CDCl_3$), δ 2.36 (s, 3H), 3.87 (s, 3H), 5.25 (s, H), 7.3–7.5 (s, 5H); ^{13}C nmr ($CDCl_3$) δ 12.57 (q), 57.82 (q), 80.89 (d); ir (film) 1612 cm^{-1}; ms 188(100), 173(100), 145(26), 131(22), 102(40). Elemental analysis on this compound was not attempted because of its ready oxidation by air.

Air Oxidation of 2-Methoxy-5-methyl-4-phenylfuran

A solution of 30 mg (0.16 mmol) of the furan in 2 ml of $CHCl_3$ was saturated with air for 1 h. Evaporation of the

[5]R. J. Boyd and J. A. Pincock, to be published.

solvent gave a quantitative yield of methyl 4-keto-3-phenyl-2-butenoic acid as a pale yellow oil; ^{1}H nmr ($CDCl_3$) δ 2.43 (s, 3H), 3.78 (s, 3H), 6.17 (s, H), 7.4–7.5 (m, 5H); ir (film) 1728, 1760 cm^{-1}. *Anal.* calcd. for $C_{12}H_{12}O_3$: C 70.57, H 5.92; found: C 70.82, H 5.68.

2-Ethoxy-4-methyl-5-phenylfuran

According to the procedure of D'yakonov (6, 7) 5.8 g (0.050 mol) of 1-phenylpropyne and 29 mg of $CuSO_4$ at 120 °C were reacted with 2.85 g (0.025 mol) of ethyldiazoacetate over 15 min. The ^{1}H nmr of the crude reaction mixture indicated no furan but only ethyl 1-methyl-2-phenylcyclopropene-3-carboxylate, diethyl fumarate, and 1-phenylpropyne. The reaction mixture was then maintained at 120 °C under nitrogen for 3 h, at which point ^{1}H nmr analysis indicated the cyclopropene ester had completely disappeared. Bulb-to-bulb distillation then gave two fractions: fraction 1, 70–90 °C/10 torr, consisting of 1-phenylpropyne and diethyl fumarate; fraction 2, 125–130 °C/0.2 torr, 2-ethoxy-4-methyl-5-phenylfuran, 620 mg (3.2×10^{-3} mol, 13%); ^{1}H nmr ($CDCl_3$) δ 1.38 (t, 3H), 2.20 (s, 3H), 4.05 (q, 2H), 5.10 (s, 1H), 7.0–7.5 (m, 5H); ^{13}C nmr ($CDCl_3$) δ 12.2 (q), 14.5 (q), 66.58 (t), 86.19 (d).

Air Oxidation of 2-Ethoxy-4-methyl-5-phenylfuran (6)

A solution of 60 mg (0.29 mmol) of the furan in 2 ml of $CHCl_3$ was saturated with oxygen for 1 h. Removal of the solvent gave a quantitative yield of ethyl 3-benzoyl-2-butenoate: ^{1}H nmr δ 1.02 (t, J = 7 Hz, 3H), 2.10 (d, J = 2 Hz, 3H), 3.95 (q, J = 7 Hz, 2H), 5.98 (q, J = 2 Hz, 1H), 7.0–7.3 (m, 3H), 7.7–8.0 (m, 2H); ir (film) 1685, 1728 cm^{-1}.

Sensitized Photolysis of Methyl 1-Methyl-2-phenylcyclopropene-3-carboxylate

A solution of 200 mg (1.06 mmol) of the ester in 5 ml of acetone was irradiated for 22 h in a Pyrex container using a 200 W Hanovia medium pressure lamp. After evaporation of the acetone and recrystallization of the residue from benzene there was obtained 102 mg (51%) of the bicyclic dimer: mp 32–34 °C; ^{1}H nmr ($CDCl_3$) δ 1.63 (s, 3H), 2.85 (s, 1H), 3.41 (s, 3H), 7.20 (m, 5H); ir (film) 1745 cm^{-1}; ms 376(3), 344(7), 316(22), 284(100), 258(25), 256(22), 129(20), 115(20), 105(26), 91(25). *Anal.* calcd. for $C_{24}H_{24}O_4$: C 76.56, H 6.43; found: C 76.43, H 6.49.

Resolution of 1-Methyl-2-phenylcyclopropene-3-carboxylic Acid

The resolution of this acid has been described (14) but no experimental details were given. In a typical resolution experiment a mixture of 0.765 g (4.42 mmol) of the acid and 0.730 g (4.42 mmol) of *l*-ephedrene was dissolved in 20 ml of benzene and heated to 50 °C for 10 min. The salt solution was cooled and 70–90 °C petroleum ether was added until a slight cloudiness appeared. The mixture was then left to crystallize. The precipitated salt was crystallized four times in this way to give 0.420 g (28.1% yield). The salt was then dissolved in 30 ml of 2% KOH in 30% methanol–water solution and stirred for 24 h at room temperature. The ephedrene was extracted with ether and then the aqueous layer was acidified to pH 2 with 10% H_2SO_4. The acid was extracted with ether and the ether layer dried over $MgSO_4$ and concentrated *in vacuo* to give 0.168 g (78% based on the salt) of the acid. The acid was transformed to the ester as described above. Measurement of the optical rotation gave $[\alpha]_D^{25}$ +76.1° (c 1.340, CH_3CN). The enantiomeric purity of this sample was measured at 76 ± 1% (+) as shown by the ^{1}H nmr spectrum, Fig. 1, in the presence of Eu(hfbc)$_3$ (15).

The relative contributions of nuclear repulsion and electronic attraction to conformational rotational potentials have been analysed for several types of systems. It is shown that decomposition of a computed total energy into these two components provides a diagnostic tool for the evaluation of the reliability of such computations. It is also pointed out that Hartree–Fock theory is sufficient to reproduce experimental stereochemical observations, provided that one is aware of the accuracy needed to compute the molecular electronic wavefunction. This accuracy is predetermined by the nuclear or electronic dominance of the process.

IMRE G. CSIZMADIA, GIANNOULA THEODORAKOPOULOS, H. BERNHARD SCHLEGEL, MYUNG-HWAN WHANGBO et SAUL WOLFE. Can. J. Chem. **55**, 986 (1977).

On a analysé les contributions relatives de la répulsion nucléaire et de l'attraction électronique par rapport au potentiel rotationnel conformationnel de plusieurs types de systèmes. On a montré que la décomposition, dans ces deux composantes, de l'énergie totale calculée fournit un outil diagnostique pour l'évaluation de la certitude de tels calculs. On met aussi en relief que la théorie de Hartree–Fock est suffisante pour reproduire des observations stéréochimiques expérimentales à condition que l'on soit conscient de la précision nécessaire pour calculer les fonctions d'onde électroniques moléculaires. Cette précision est prédéterminée par la dominance nucléaire ou électronique du processus.

[Traduit par le journal]

Introduction

With the advent and availability of computer programmes for the computation of the total energies and stable geometries of molecules, theoretical stereochemistry has entered an extremely productive era (1). Accumulated experience in this field seems to indicate that there are two classes of problems. In the first, it is found that SCF-MO computations performed at almost any level of accuracy afford fairly good agreement with experiment; but in the second, very extensive computations combined with careful geometry optimization are required to yield such agreement.

The classical example of the first type is rotation in ethane (2), and for the second type, the classical examples are rotation in hydrogen peroxide (3) and pyramidal inversion in ammonia (4). Thus, even the simplest semi-empirical computations are able to reproduce the *ca.* 3 kcal/mol barrier of ethane, but to reproduce the *trans* barrier to rotation in hydrogen peroxide (*ca.* 1 kcal/mol), it has been necessary to go almost to the Hartree–Fock limit using *d*-orbitals on oxygen and *p*-orbitals on hydrogen, in conjunction with geometry optimization at each torsional angle (3*a*).

It might be tempting to suggest that the difficulty lies in the relatively low barrier that is being computed. However, the rotational barrier in methanol is also about 1 kcal/mol, and it can be reproduced without great difficulty (5) (*i.e.*, methanol is a member of the first class of molecules). Consequently, it is clear that, for the class of compounds exemplified by H_2O_2, one has to use a much more accurate wavefunction than for the class of compounds exemplified by ethane.

Why it is necessary to approach the Hartree–Fock limit more closely in one case than in another does not appear to have been discussed previously, and the purpose of the present work is to attempt an analysis of this problem. In terms of this analysis it becomes possible, in

principle, to estimate the quality of computation that will be necessary to reproduce a particular observation.

Theory

In the Born–Oppenheimer approximation, the total energy (E_{tot}) of a molecular system is the sum of electronic attraction ($E_{elec} = T + V_{ne} + V_{ee}$, where T, V_{ne}, and V_{ee} are the kinetic energy, electron–nuclear attraction, and electron–electron repulsion terms, respectively), a negative quantity and nuclear repulsion (E_{nucl}), a positive quantity (eq. 1).

$$[1] \qquad E_{tot} = E_{elec} + E_{nucl}$$

The nuclear repulsion component can be computed without difficulty, according to classical electrostatics, from the nuclear charges (Z_I, Z_J, etc.) and their interatomic distances (R_{IJ}) (eq. 2)

$$[2] \qquad E_{nucl} = \sum_{I=1} \sum_{J>I} \frac{Z_I Z_J}{R_{IJ}}$$

In contrast, computation of the electronic component requires solution of the Schröedinger equation through the variation theorem (eq. 3).

$$[3] \qquad E_{elec} = \frac{\langle \psi_{elec} | H_{elec} | \psi_{elec} \rangle}{\langle \psi_{elec} | \psi_{elec} \rangle}$$

Clearly, the effort required to evaluate eq. 2 is insignificant in comparison to what is needed for eq. 3.

It is therefore useful to be aware of the equality shown in eq. 1, because it means (1*a*) that a semi-quantitative understanding of E_{tot} based on experimental observations (*e.g.*, observations of conformational equilibria) can be combined with a computation of E_{nucl} to provide a semi-quantitative understanding of E_{elec} and, in particular, its phase.[1]

Our chemical experience is that molecules have stability with respect to separated atoms. This requires that E_{nucl} and E_{elec} always have opposite phase (see Fig. 1*b*). Were this not the case, our chemical experience would consist either of a collapsing universe (Fig. 1*a*) in which only a single giant atom exists, or a dissociating universe (Fig. 1*c*), in which only separated atoms exist. These alternatives are illustrated schematically for the general case of a diatomic molecule in Fig. 1, and they allow the formulation of a rule:

"*The nuclear and electronic components of a molecular conformational potential curve always have opposite phase*".

We may now note that, in any region of a potential curve corresponding to that cross-section of a conformational hypersurface which describes the conformational change, the total energy is in phase either with the electronic component or with the nuclear component. Employing the example of the stretching potential shown in Fig. 1*b*, it can be seen that at a large internuclear separation ($r_e < r < \infty$) the total energy is in phase with the electronic component (and may be said to be electronic dominant) and, at a shorter bond length ($0 < r < r_e$), the total energy is in phase with the nuclear component (and may be said to be nuclear dominant). This observation permits the formulation of a second rule:

"*In any region of a potential curve, the variation of the total energy of a molecular system during conformational change is in phase either with the nuclear repulsion (nuclear dominant) or with the electronic attraction (electronic dominant)*".

As a consequence of this second rule, we should recognize that the total energy may be in phase with one of these components *throughout* the conformational charge, as in the case of rigid rotation in ethane in which the total

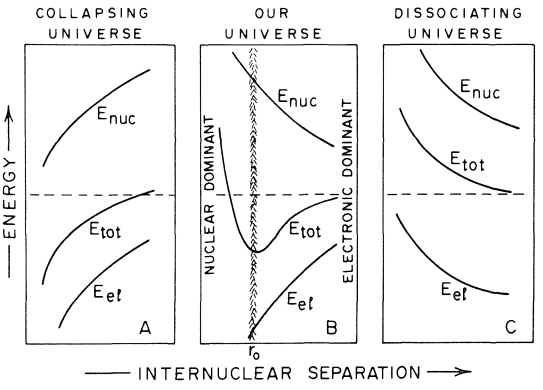

FIG. 1. Alternatives of nuclear and electronic components of the total energy. (*A*) Collapsing universe, where E_{nucl} and E_{elec} are in phase. (*B*) Our universe, where E_{nucl} and E_{elec} are in opposite phase. (*C*) Dissociating universe, where E_{nucl} and E_{elec} are in phase.

[1]By phase we mean the direction of change, *i.e.* the sign of the derivative with respect to a geometrical parameter of the molecule.

energy is in phase with the nuclear repulsion (see below), or there may be a cross-over from electronic dominance to nuclear dominance at some point. This cross-over represents a balance between the attractive electronic forces and the repulsive nuclear forces. These considerations permit the formulation of a third rule:

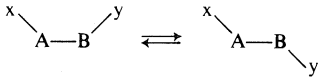
"*Whenever there is a change from nuclear dominance to electronic dominance in a conformational process, this change will be found at an energy extremum*".

Discussion

The preceding considerations have been derived by inductive reasoning, and we may now consider their application to the problems of torsion and pyramidal inversion.

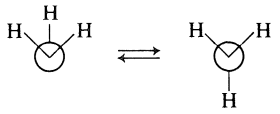
(a) Rotation (Torsion)

In the general molecule **1**, nuclear repulsion is a maximum and electronic attraction is a minimum in the most crowded conformation **1***a* if we allow rigid rotation only. The opposite is true for the less crowded conformation **1***b*.



1*a* **1***b*

Whether the actual structure adopted by **1** is closer to **1***a* or to **1***b* will then depend on the relative importance of nuclear repulsion and electronic attraction. For example, $^{-}CH_2OH$ (6) displays two energy minima corresponding to the W and Y conformations **2***a* and **2***b*.



2*a* **2***b*

As shown in Fig. 2, (*i*) the nuclear and electronic components have opposite phase; (*ii*) the total energy is in phase either with the nuclear repulsion or the electronic attraction; (*iii*) the more stable Y conformation is dominated by nuclear repulsion, and the less stable W conformation is dominated by electronic attraction; a balance between the two components is achieved at the transition state which connects the two minima. Thus, the rotational behaviour of $^{-}CH_2OH$ illustrates the operation of all three rules.

A second example is given in Fig. 3 for

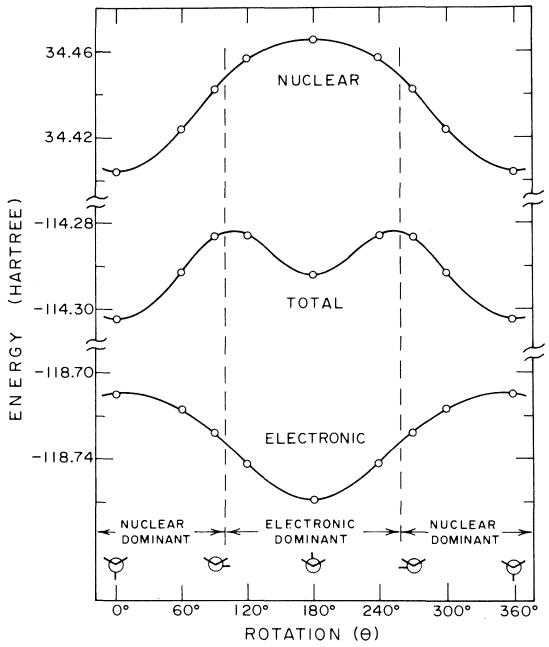


FIG. 2. The variation of total energy as well as its nuclear and electronic components of $^{-}:CH_2—OH$ with the rotational (dihedral) angle along the C—O bond.

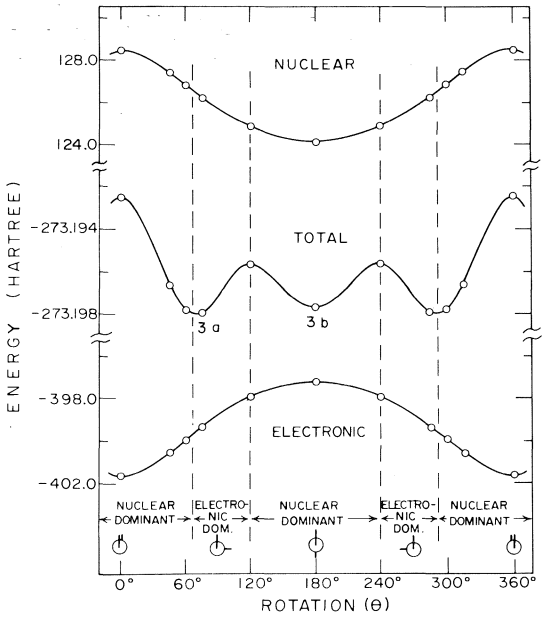

FIG. 3. The variation of total energy as well as its nuclear and electronic components of $FCH_2—CH_2F$ with the rotational (dihedral) angle along the C—C bond.

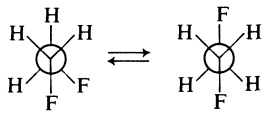
1,2-difluoroethane as obtained by a minimal (STO-3G (7)) basis set calculation. In this case, the higher minimum (**3***b*) is fully dominated by nuclear repulsion, and the change in dominance between the opposing nuclear and electronic components occurs in the *gauche* conformation (**3***a*).



3*a* **3***b*

Consequently, both the position and the energy of the lower minimum (**3***a*) depend upon the accuracy of the computation of the electronic component. The situation is analogous to that of hydrogen peroxide (*cf.* Fig. 4*B*) but different from that of ethane (*cf.* Fig. 5). In the latter case, the total energy is in phase with only one of the components. However, it should be noted that the behavior changes from nuclear dominance to electronic dominance as one changes from rigid rotation (*cf.* Fig. 5*A*) to relaxed rotation (*cf.* Fig. 5*B*) on the conformational hypersurface (8, 9). Because one of the components is always dominant the total barrier is always relatively easy to obtain even though the component barrier heights differ significantly in the two modes shown in Fig. 5 *A* and *B*.

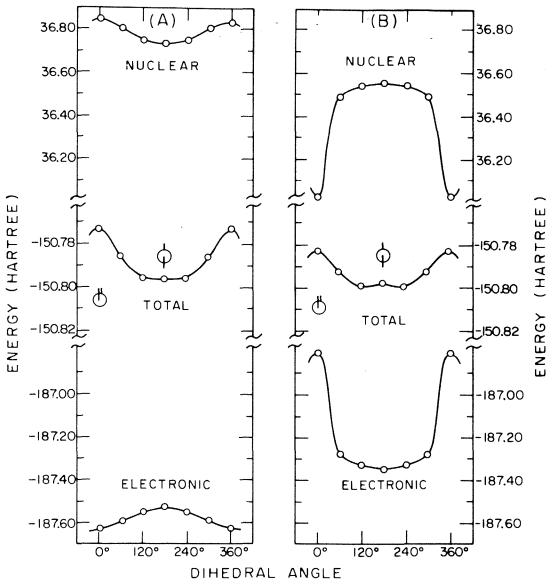


FIG. 4. The variation of nuclear repulsion, total and electronic energy of HOOH with angle of (*A*) rigid rotation and (*B*) relaxed rotation about the O—O bond.

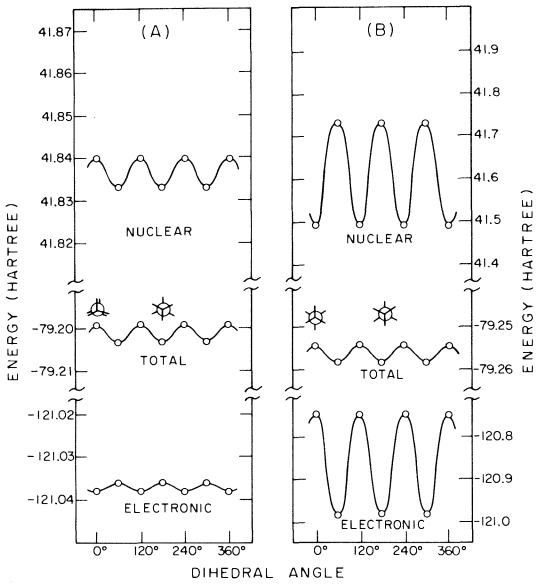

FIG. 5. The variation of nuclear repulsion, total and electronic energy of CH_3CH_3 with angle of (*A*) rigid rotation and (*B*) relaxed rotation about the C—C bond.

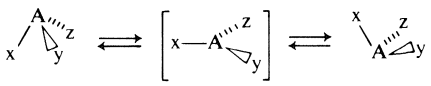
The situation is much more complicated in the case of H_2O_2 because there is a change from exclusive nuclear dominance to balanced dominance as one goes from Fig. 4*A* to Fig. 4*B*. Consequently, both geometry optimization (*i.e.*, relaxation) and the inclusion of polarization functions in the basis set are required to obtain the small *trans* barrier (Fig. 4*B*) (10).

(b) Inversion

In a pyramidal molecule **4**,



4*a* **4***b* **4***c*

nuclear repulsion is greater in the pyramidal conformations **4***a* and **4***c* than in the planar conformation **4***b* when rigid inversion (*i.e.*, inversion with fixed bond lengths) is considered. For relaxed inversion (*i.e.*, inversion with variable bond lengths) the opposite may be true. However, the barrier to pyramidal inversion is always dominated by one of the components and the minimum is always characterized by a change in dominance. Therefore, the computation of the barrier to inversion will depend upon the accuracy of the electronic component. The pyramidal inversion of NH_3 exemplifies this mode of motion (11).

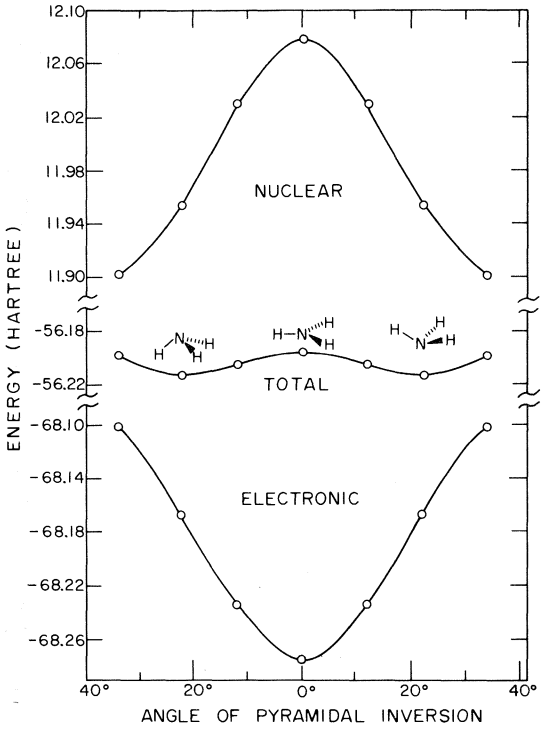


FIG. 6. The variation of nuclear repulsion, total and electronic energy of NH_3 with angle of relaxed pyramidal inversion.

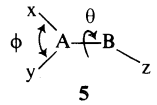
Figure 6 shows relaxed pyramidal inversion of NH_3. The total energy is nuclear dominant between the two minima, including the planar transition state. The minima are characterized by a change from nuclear to electronic dominance. The calculated barrier is thus very sensitive to the accuracy of the calculation.

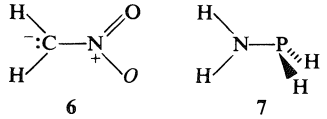
(c) Rotation–Inversion

The conformational surface $E = E(\theta,\phi)$ associated with two independent modes of motion such as pyramidal inversion (ϕ) and rotation (θ) may be calculated for any molecule (*e.g.*, **5**) that has these internal modes of motion available by virtue of its molecular structure



5

Two systems of interest are $^{-}CH_2NO_2$ (**6**) and NH_2PH_2 (**7**)



6 **7**

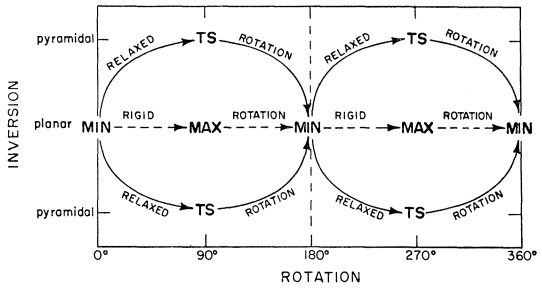


FIG. 7. The topological features of a general rotation–inversion surface.

The rotation–inversion surfaces of **6** (12) and **7** (13) are to be published elsewhere. However, Fig. 7 summarizes the topological features of both surfaces.

Rigid and relaxed rotational cross-sections of the surfaces of **6** and **7** are shown in Figs. 8 and 9 respectively. In the case of **6** the components are well behaved, and there is no change in dominance on going from rigid rotation to relaxed rotation. However, the situation with H_2NPH_2 is different. For the rigid rotation, the nuclear and electronic components are in phase *with each other and with the total energy*! This represents an exception to the three rules proposed above. However, when the geometry is relaxed to permit rotation and nitrogen inversion to occur simultaneously, the apparent

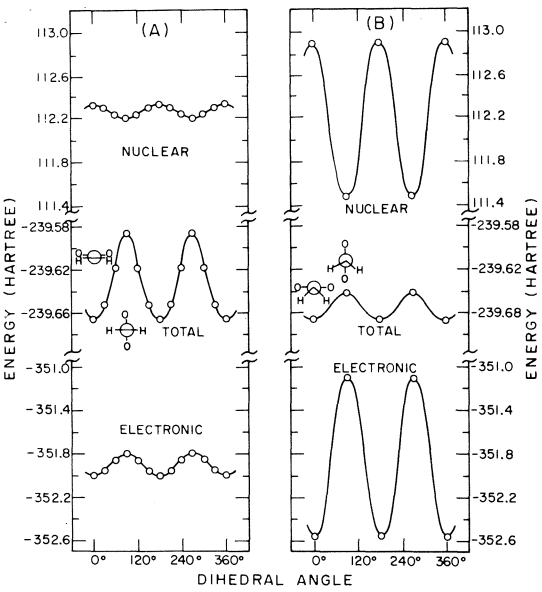

FIG. 8. The variation of nuclear repulsion, total and electronic energy of $^{-}CH_2NO_2$ with angle of (*A*) rigid rotation and (*B*) relaxed rotation about the C—N bond.

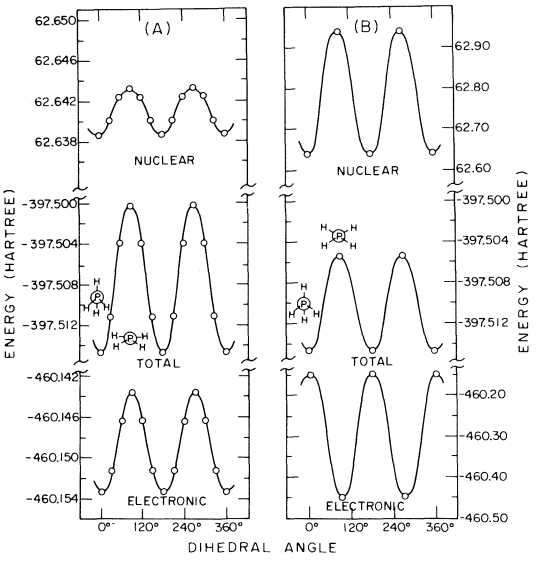

FIG. 9. The variation of nuclear repulsion, total and electronic energy of H_2PNH_2 with angle of (*A*) rigid rotation and (*B*) relaxed rotation about the P—N bond.

discrepancy disappears. This leads to the conclusion that the three rules are strictly valid along the "reaction coordinates". The rules may not be operative along an unstable cross-section, because the system will "roll down" from the side of the surface to the nearest minimum path.

Conclusion

In conclusion, it appears that when there is exclusive dominance of one component (either electronic or nuclear) it is relatively easy to reproduce the experimental stabilities (thermodynamic or kinetic) by theoretical calculations. However, when there is a change in dominance along a given mode of motion the accuracy of the calculations required to reproduce the corresponding experimental stabilities is very high.

Finally, it appears that the anti-parallelism of the phases of the nuclear and electronic components may be valid throughout the hypersurface or for only certain regions of it: the latter type of surface is the more intriguing. In this case, one of the two components may be in phase with the total energy in one region of the hypersurface, and the other component may be in phase with the total energy in another region of the hypersurface, as in the case of rigid and relaxed rotation. On going from one region of the hypersurface to the other, both the nuclear and the electronic components must change phase.

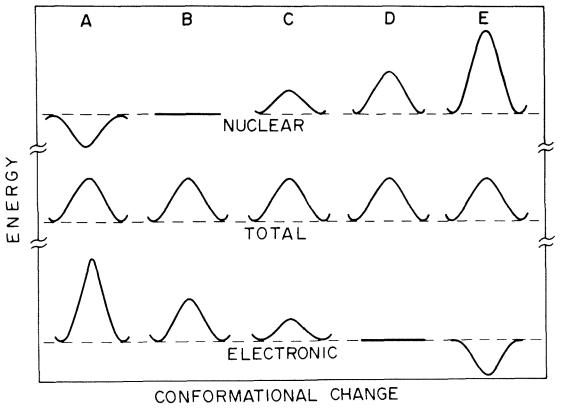

FIG. 10. The variation of the nuclear repulsion, total and electronic energy of a molecule with conformational change showing in five stages (*A* to *E*) the change in the phase of the two components but no change in the phase of the total energy.

Such a simultaneous change would require the existence of an intermediate region in which both components are in phase with the total energy. This is illustrated schematically in Fig. 10. Clearly, the situation is more complicated when there is a change of dominance during the conformational change, as in HO—OH, $^-CH_2$-OH, FCH_2—CH_2F, and NH_3.

Density of states and the steepest descent method: a non-iterative procedure

ANDREW W. YAU AND HUW O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received September 13, 1976

ANDREW W. YAU and HUW O. PRITCHARD. Can. J. Chem. **55**, 992 (1977).

A non-iterative approximation to the method of steepest descent is given for the evaluation of state density in a molecular system. Test calculations on 'large' and 'small' model molecules consisting of harmonic oscillators and rigid rotors show excellent agreement with the 'exact' first-order steepest-descent solutions, but are almost an order of magnitude faster in computing times.

ANDREW W. YAU et HUW O. PRITCHARD. Can. J. Chem. **55**, 992 (1977).

On présente une approximation non-itérative pour la méthode de descente la plus rapide pour l'évaluation de la densité d'états d'un système moléculaire. Des essais de calcul sur des molécules modèles "grande" et "petite" consistant d'oscillateurs harmoniques et de rotors rigides montrent un accord excellent avec les solutions "exactes" de descente la plus rapide du premier ordre, mais sont presque un ordre de grandeur plus rapide en temps de calcul.

[Traduit par le journal]

The density of states $N(E)$ of a model molecule at energy E is an important quantity in statistical rate theories (1, 2). Several approximate methods of calculation have been proposed in recent years, and extensive comparisons between them have been made by Forst and Prášil (3). Among various 'quantal' methods, the method of steepest descent (3–5) proves most attractive since it yields excellent approximations to the exact count, whilst requiring less computation than the method using Cauchy's residue theorem (6, 7).

The method of solution of the (first-order) steepest-descent approximation (4) has been derived independently by Forst and Prášil (3) and by Hoare and Ruijgrok (5): $N(E)$, formally the inverse Laplace Transform of the partition function, is related analytically to the saddle point of the integrand of the inversion integral; in this procedure, several iterations (10 to 15 for the first energy and typically 5 thereafter) are required to determine the saddle point. In the present paper, we report an alternative procedure which does not require such an accurate determination of the saddle point: a sufficiently accurate value for the saddle point can be constructed without iteration, with a consequent saving in computing time of a factor of between 5 and 10 in the calculation of $N(E)$. Since in unimolecular rate calculations $N(E)$ is required at some hundreds of values of the energy, the time saving can become appreciable.

The density of states $N_{vr}(E)$ for a system with v independent vibrators and r free rotors[1] is formally the inverse Laplace Transform of the partition function $Z(\beta)$ (3–5), *i.e.*

$$[1] \quad N_{vr}(E) = \mathscr{L}^{-1}\{Z(\beta)\} = (2\pi i)^{-1} \times \int_{c-i\infty}^{c+i\infty} Z(\beta) \exp(\beta E)\, d\beta \equiv I$$

where $\beta = 1/kT$ is the transform parameter; the sum of states $G_{vr}(E)$ is readily related to $N_{v,r+2}(E)$ (1).

To evaluate I, one defines

$$[2] \quad \phi(\beta) = \ln [Z(\beta)] + \beta E$$

and the first-order steepest-descent method gives (3)

$$[3] \quad I \simeq \exp [\phi(\beta^*)][2\pi\phi''(\beta^*)]^{-1/2}$$

where β^* is the *saddle point*. Since

$$[4] \quad \phi'(\beta^*) = 0$$

$$[4a] \quad \left.\frac{-\partial \ln Z(\beta)}{\partial \beta}\right|_{\beta^*} = E$$

identifying β^* as the (inverse) temperature at which the average energy of the system is E (8). In the Forst–Prášil formulation (3), eq. 4 is transformed to an algebraic equation via $\theta = \exp(-\beta)$. The transformation, although mathematically convenient, makes subsequent

[1]We follow the definition of Forst and Prášil (1, 3): a two-dimensional rotor is counted as two one-dimensional rotors.

computations more difficult. This is because, whereas β^* is between 0 and 10^{-3}, θ^* is between 0.999 and unity; thus, whilst a precision of 10^{-4} suffices for β^*, a precision of 10^{-10} is needed for θ^* (3). And it is precisely this less stringent requirement on the precision in β^*, together with the thermodynamic relation [4*a*], that permits a 'one-shot' approximation which yields accurate $N_{vr}(E)$. Note that using eq. 4*a*, one obtains

$$[5]\quad I \simeq Z(\beta^*)\exp(\beta^* E)\left[-2\pi\left.\frac{\partial E(\beta)}{\partial\beta}\right|_{\beta^*}\right]^{-1/2}$$

The 'one-shot' approximation is achieved by relating β^* explicitly to β_0, a first approximation, via the Taylor expansion of E, using [4*a*], *viz.*

$$[6a]\quad E(\beta^*) = E(\beta_0) + \Delta\beta\frac{\partial E}{\partial\beta} + \tfrac{1}{2}(\Delta\beta)^2\frac{\partial^2 E}{\partial\beta^2} + O[(\Delta\beta)^3]$$

$$[6b]\quad = \frac{-\partial \ln Z}{\partial\beta} - \Delta\beta\frac{\partial^2 \ln Z}{\partial\beta^2} - \tfrac{1}{2}(\Delta\beta)^2\frac{\partial^3 \ln Z}{\partial\beta^3} - O[(\Delta\beta)^3]$$

where $\Delta\beta = \beta^* - \beta_0$ and all derivatives are evaluated at β_0. Now substituting the first-order approximation

$$[7]\quad \Delta\beta \simeq \Delta E\left(\frac{\partial E}{\partial\beta}\right)^{-1}$$

where $\Delta E = E(\beta^*) - E(\beta_0)$, back into the $(\Delta\beta)^2$ term of eq. 6*a*, one obtains

$$[8]\quad \beta^* \simeq \beta_0 + \Delta E\left(\frac{\partial E}{\partial\beta}\right)^{-1} \times\left[1 - \tfrac{1}{2}\Delta E\left(\frac{\partial E}{\partial\beta}\right)^{-2}\left(\frac{\partial^2 E}{\partial\beta^2}\right)\right]$$

$$[8a]\quad \equiv \beta_0 - \Delta E\left(\frac{\partial^2 \ln Z}{\partial\beta^2}\right)^{-1} \times\left[1 + \tfrac{1}{2}\Delta E\left(\frac{\partial^2 \ln Z}{\partial\beta^2}\right)^{-2}\left(\frac{\partial^3 \ln Z}{\partial\beta^3}\right)\right]$$

It might be thought that values of I thus computed might be grossly in error since [8] is only a second-order approximation to β^*, and the truncation error in β^* would be magnified by the exponential in eq. 5. However, since $\phi'(\beta^*) = 0$, a simple error analysis gives

$$[9]\quad \delta[\exp(\phi)] \simeq \exp(\phi)\phi'\delta\beta + O(\delta\beta)^2 \simeq O(\delta\beta)^2$$

which is necessarily small *near* β^*. This insensitivity arises because $\exp(\beta E)$ increases with β whereas $Z(\beta)$ decreases. In test calculations, I computed using [5] and [8] agrees with the exact steepest-descent solution to better than 1% even when β_0 differs from β^* by as much as 20%, except for very large r at low E (since then $Z(\beta) \propto \beta^{-r/2}$). Thus, the ultimate performance of this approximation hinges upon the initial choice of β_0. In practice, however, where $N_{vr}(E)$ is computed at hundreds of energies, typically only 50–100 cm^{-1} apart, β^* for two neighbouring energies are not very different. Thus, except for the first cycle, we may take β_0 to be the β^* value corresponding to the preceding energy, *fully exploiting the fact that in* [8], β_0, ΔE *and* $(\partial E/\partial\beta)|_{\beta_0}$ *are all known quantities*: β^* is readily determined by explicit evaluation of $(\partial^2 E/\partial\beta^2)|_{\beta_0}$; no iteration is needed. This leaves only the choice of the initial value of β_0 at the starting energy, and for r rigid rotors and n groups of harmonic oscillators of degeneracies g_i and frequencies ν_i ($\nu_1 < \nu_2 < \ldots < \nu_n$ and $\sum_i^n g_i = v$), the following empirical relation is convenient[2]

$$[10]\quad \beta_0 = \frac{r}{2E} + \frac{m}{S_m}\ln\left(1 + \frac{S_m}{E}\right)$$

where

$$S_m = \sum_{i=1}^{m} g_i\nu_i$$

with

$$m = 1 \quad \text{if} \quad g_1\nu_1 \geqslant E$$

or

$$m = n \quad \text{if} \quad S_n \leqslant E$$

and

$$S_m \leqslant E < S_{m+1}$$

otherwise.

To test the performance of the method, we have computed $N_{vr}(E)$ for two model molecules for which both exact direct counts and exact steepest-descent solutions are available (3): they are model *A*, representing a typical 'small' molecule and model *B* representing a typical 'large' molecule, both with varying numbers of rotors. Tables 1 and 2 compare these previous calculations with those using eqs. 10, 8, and 5;

[2]Because of the insensitivity of I to β_0 (see text above), any empirical relation which gives a good approximation to β^* will suffice: the choice of [10] is based on the realisation that β_0 is exactly β^* for a system of r rotors or v degenerate oscillators.

following Forst and Prášil (3), the tabulated quantities are *reduced* state densities, *i.e.*

$$[11] \qquad N_{vr}'(E) = N_{vr}(E)/Q_r'$$

where Q_r' is the classical partition function for r rotors with the factor $(kT)^{r/2}$ deleted. Note that in practice, one would not use eq. 10 to estimate β_0 at each value of the energy, as we have done in this test, but one would use the value of β^* calculated at the preceding value of the energy; this will be a better approximation than [10], so that the method will actually perform better than is shown in Tables 1 and 2 in any practical application.

We conclude by noting that since the desired accuracy of $N_{vr}(E)$ in unimolecular rate calculations is of the order of a few percent, this method should prove efficient and useful in the entire range where the standard steepest-descent method is applicable: at low energy, direct counts, for which efficient algorithms exist (9, 10), may be used. We note also that the accuracy of the approximation improves as E increases, making it attractive for calculations in the very high energy range, such as are needed in mass-spectral applications.[3] Finally, generalisation to more

Ring formation via β-keto ester dianions

PHAIK-ENG SUM AND LARRY WEILER[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received October 4, 1976

PHAIK-ENG SUM and LARRY WEILER. Can. J. Chem. **55**, 996 (1977).

The reaction of α,ω-dihalides with the dianion of methyl acetoacetate gives a mixture of mono- and bisalkylated products. The monoalkylated products can be cyclized via the monoanion to cyclic β-keto esters with a seven- or eight-membered ring. Alternatively these monoalkylated products can be cyclized via the dianion to γ-cyclopentyl- or γ-cyclohexyl-β-keto esters.

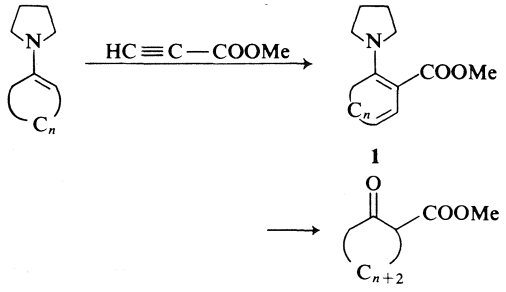
PHAIK-ENG SUM et LARRY WEILER. Can. J. Chem. **55**, 996 (1977).

La réaction de dérivés dihalogénés α,ω avec le dianion de l'acétoacétate de méthyle conduit à un mélange de produits mono- et bisalkylés. Les produits monoalkylés peuvent être cyclisés, par l'intermédiaire du monoanion, en esters β cétoniques cycliques possédant un cycle à sept ou huit membres. D'une manière alternative, ces produits monoalkylés peuvent être cyclisés, par l'intermédiaire du dianion, en esters β-céto γ-cyclopentyl ou γ-cyclohexyl.

[Traduit par le journal]

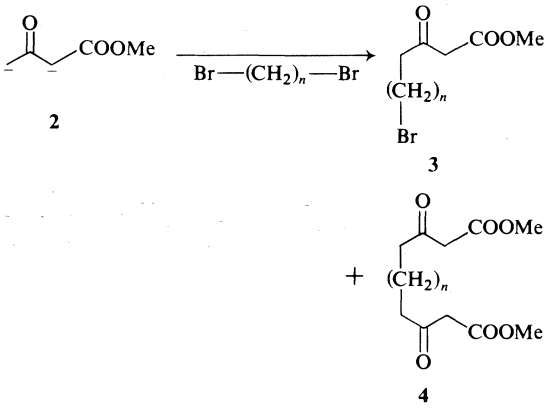
Previously, cyclic β-keto esters were prepared by two different routes. The first route involves carboxylation of the corresponding cyclic ketone with diethyl carbonate and base (1). Alternatively, they have been prepared by the route shown in reaction 1 (2–4). In this case, the ketone is first converted into the corresponding enamine and this is treated with methyl propiolate to yield the enamine **1** in which two carbons have been inserted into the original ring. Hydrolysis of **1** and reduction yields the cyclic β-keto ester with two more carbons than the starting

[1]



cyclic ketone. Neither of these routes offers any regioselective control over the position of carboxylation, except in the case of an α-alkylated starting ketone. We would like to report a new synthesis of cyclic β-keto esters.

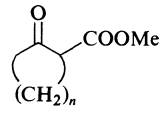
On treating the dianion of methyl acetoacetate (**2**) (5) with 1 equiv. of an α,ω-dihaloalkane, a mixture of products containing approximately equal amounts of the monohalo β-keto ester **3** and the bis β-keto ester **4** is



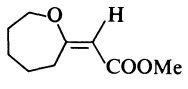
obtained (see ref. 5 also). Except in the case of $n = 3$ (5), no cyclic β-keto ester could be detected in these reactions. Even if the purified monohalo compound **3** ($n = 4$, 5, or 10) was allowed to reflux with 1 equiv. of sodium hydride in tetrahydrofuran (THF) for several hours, no sign of C-alkylation at the α-carbon was observed. This correlates with the previously observed lack of reactivity of the α-carbanion of β-keto esters in THF (refs. 5–7 and references therein) and the fact that no dialkylation was observed in this alkylation or in the original dianion alkylations (5). However, treating the monohalo compounds **3** ($n = 4$ or 5) with 1 equiv. of sodium methoxide in refluxing methanol lead to cyclization at the α-carbon to

[1]Author to whom correspondence may be addressed.

yield the corresponding cyclic β-keto esters in good yield. In addition, we have found that the crude mixture of **3** and **4** could also be subjected to these cyclization conditions to produce the cyclic β-keto esters **5** (n = 4 or 5) in reasonable yield. These cyclic β-keto esters could be



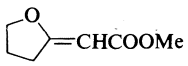
5



6

readily separated from the bisalkylated product **4** and hence this provides a simple two-step synthesis of **5** from acyclic precursors.

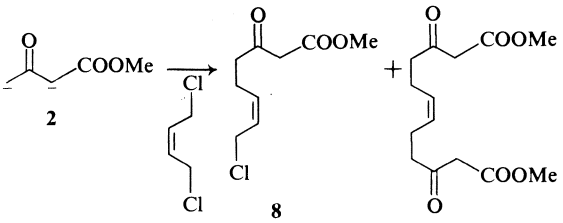
We were intrigued by the lack of cyclization of the monoanion of **3** in THF and investigated this further for n = 4. Cyclization of **3** (n = 4) in THF could eventually be induced by treating the bromo compound **3** with sodium hydride in a mixture of THF and hexamethylphosphoramide (HMP). But the cyclization proceeded exclusively via O-alkylation to yield **6**. This is consistent with the observed intermolecular O-alkylation of β-keto esters in dipolar aprotic solvents (8). The O-alkylation product appeared to be exclusively the *E* isomer shown. This was determined by comparing the nmr spectra of **6** with the corresponding *E,Z* isomers of the cyclic furylidene **7** (9).[2] The formation of **6** probably



7

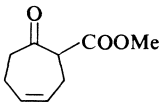
involves cyclization of the ω-shaped conformation (10) of the monoanion from **3**. This is expected to be the most stable conformation, in which dipole–dipole repulsions are minimized, of the *free* monoanion formed in HMP (11).

We have also found that the dianion **2** from methyl acetoacetate reacts with *cis*-1,4-dichloro-2-butene to yield the mono-alkylated product **8** and the bis β-keto ester **9** in approximately equal amounts. The geometry about the double bond of both products is thought to remain *cis*. In the case of **8**, the nmr spectrum of the olefinic protons shows a 12 Hz coupling which is consistent with a *cis* geometry. The ir spectra of **8** and **9** are consistent with the proposed *cis* geometry. Cyclization of the monochloro product **8** with sodium methoxide in methanol gave the seven-membered ring compound **10** as the

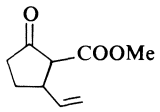


2 **8** **9**

only detectable product in mediocre yield. The fact that only **10** was observed was interesting because one might expect formation of the five-membered ring product **11** as well.[3] An



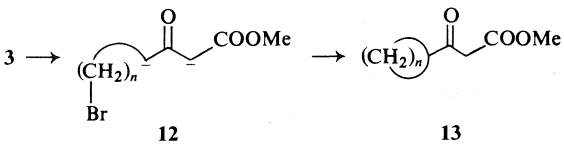
10



11

examination of molecular models of the carbanion from **8** indicates that the transition state to the seven-membered ring is quite favourable. The presence of the four sp^2-hybridized ring carbons in the transition state leading to **10** no doubt reflects the ease of the formation of the seven-membered ring in this case. If the geometry of the double bond in **8** were *trans*, then direct cyclization to **10** would be impossible and one would probably observe production of the five-membered ring product **11**.[3]

The stability of the monoanions of the halides **3** in THF has led to another useful facet in the chemistry of β-keto ester dianions. Treatment of the monoanions of **3** in THF with 1 equiv. of lithium diisopropyl amide generated the dianion **12** which, in the case of n = 4 and 5, underwent an internal cyclization to provide the β-keto esters **13** along with some bisalkylated product **4** which could be readily separated by



12 **13**

thin layer chromatography. This route to **13** is quite convenient when compared to the previously reported multistep route to these compounds (12).

[2]P.E. Sum and L. Weiler, unpublished results.

[3]Professor Borch (University of Minnesota) has informed us that reaction of dianion **2** with 1,4-dichloro-2-butene of unknown stereochemistry followed by cyclization does lead to a mixture of **10** and **11**.

Experimental

Melting points, which were determined on a Kofler hot stage microscope, and boiling points are uncorrected. All ir spectra were recorded in $CHCl_3$ solution using a Perkin-Elmer Model 700 spectrophotometer, and were calibrated with the 1601 cm^{-1} band of polystyrene. The ^1H-nmr spectra were recorded in $CDCl_3$ solution on either a Varian model T-60 or HA-100 spectrometer. The signal positions are reported using the δ scale with tetramethylsilane as internal standard. The multiplicity, coupling constants, and integrated peak areas are indicated in parentheses after each signal. The mass spectra were obtained using an Atlas CH-4B mass spectrometer, and high resolution determinations were obtained using an AEI MS-9 or MS-50 mass spectrometer. Both instruments were operated at an ionizing potential of 70 eV. Elemental microanalyses were performed by Mr. Peter Borda, University of British Columbia. The silica gel used was obtained from E. Merck and that used for thin layer chromatography (tlc) was the grade PF_{254}, whilst that used for column chromatography was the grade finer than 200 mesh ASTM.

Alkylation of the Dianion of β-Keto Esters with Dihaloalkanes

Reactions of 1,4-Dibromobutane with Dianion 2

Sodium hydride, as a 57% mineral oil dispersion (1.0896 g, 0.02 mol) was weighed into an oven-dried 100 ml flask, and tetrahydrofuran (50 ml) was distilled from lithium aluminum hydride, directly into this flask. The flask was fitted with a magnetic stirrer and septum cap, cooled in ice to 0 °C, and flushed with nitrogen. Methyl acetoacetate (2.32 g, 0.02 mol) was added dropwise, and the reaction mixture was stirred for 10 min after the addition was complete. *n*-Butyllithium, as a 2.2 *M* solution in hexane, (9 ml, 0.02 mol) was added dropwise to the reaction which was allowed to stir for a further 10 min before the addition of 1,4-dibromobutane (4.3186 g, 0.02 mol) in one portion. The reaction mixture was allowed to stir for an additional 1 h at 0 °C. It was then quenched with dilute hydrochloric acid, extracted with ethyl ether (2 × 50 ml), washed with saturated sodium bicarbonate (2 × 50 ml) and saturated sodium chloride solution (50 ml), dried over magnesium sulfate, and filtered. The solvents were removed by evaporation under reduced pressure to give 3.2729 g of crude products. Purification of these products was achieved by tlc using silica plates and a mixture of carbon tetrachloride and ethyl ether (7:3 v/v) as eluent. Two components were isolated from this chromatography, and these were, in order of elution, methyl 8-bromo-3-oxooctanoate (**3**, $n = 4$) (26%) and dimethyl 3,10-dioxododecanedioate (**4**, $n = 4$) (15%).

Methyl 8-bromo-3-oxooctanoate (**3**, $n = 4$) was characterized by: ir 1745 and 1720 cm^{-1}; nmr δ 1.25–2.0 (m, 6H), 2.56 (t, $J = 7.0$ Hz, 2H), 3.5 (s, 2H), 3.42 (t, $J = 6.2$ Hz, 2H), and 3.75 ppm (s, 3H); ms *m/e* (relative intensity) 40(44), 41(16), 43(57), 44(100), 55(9), 59(6), 69(16), 73(1), 101(8), 113(11), 116(20), 129(2), 171(11), 177(5), 179(4), 250(1), and 252(1). *Anal.* calcd. for $C_9H_{15}BrO_3$: C 43.05, H 6.02, Br 31.82; found: C 42.96, H 5.93, Br 31.98.

Dimethyl 3,10-dioxododecanedioate (**4**, $n = 4$) was characterized by: ir 1745, 1720 cm^{-1}; nmr δ 1.1–1.8 (m, 8H), 2.52 (t, $J = 6.20$ Hz, 4H), 3.42 (s, 4H), and 3.75 ppm (s, 6H); ms *m/e* (relative intensity) 41(20), 43(20), 55(29), 58(20), 59(33), 69(22), 74(13), 83(17), 97(45), 101(37), 111(22), 116(68), 129(24), 139(27), 153(12), 171(100), 172(10), 181(13), 213(8), 255(8), 268(11), and 286(1). *Anal.* calcd. for $C_{14}H_{22}O_6$: C 58.73, H 7.74; found: C 58.67, H 7.66.

Reaction of 1,5-Dibromopentane with Dianion 2

The procedure used in this reaction was the same as that employed in the reaction of 1,4-dibromobutane with dianion **2**. The reagents used were: sodium hydride, as a 57% mineral oil dispersion (1.0896 g, 0.02 mol), methyl acetoacetate (2.32 g, 0.02 mol), *n*-butyllithium, as a 2.2 *M* solution in hexane (9 ml, 0.02 mol), and 1,5-dibromopentane (4.6 g, 0.02 mol) which gave 4.16 g of a mixture of crude products. Purification of these products was achieved by tlc using a mixture of carbon tetrachloride and ethyl ether (7:3 v/v) as eluent. Two components were isolated from this chromatography, and these were, in order of elution, methyl 9-bromo-3-oxononaoate (**3**, $n = 5$) (25%) and dimethyl 3,11-dioxotridecanedioate (**4**, $n = 5$) (16%).

Methyl 9-bromo-3-oxononaoate (**3**, $n = 5$) was characterized by: ir 1745 and 1720 cm^{-1}, nmr δ 1.2–2.0 (m, 8H), 2.55 (t, $J = 7.0$ Hz, 2H), 3.42 (t, $J = 6.5$ Hz, 2H), 3.45 (s, 2H), and 3.72 ppm (s, 3H); ms *m/e* (relative intensity) 43(72), 44(75), 55(36), 58(40), 59(21), 69(12), 74(17), 83(25), 84(16), 101(25), 111(11), 116(100), 117(15), 127(9), 129(8), 185(25), 191(15), 193(13), 264(0.1), and 266(0.1). *Anal.* calcd. for $C_{10}H_{17}BrO_3$: C 45.30, H 6.46, Br 30.14; found: C 45.47, H 6.27, Br 29.90.

Dimethyl 3,11-dioxotridecanedioate (**4**, $n = 5$) was characterized by: ir 1745 and 1720 cm^{-1}; nmr δ 1.2–1.8 (m, 10H), 2.5 (t, $J = 7.0$ Hz, 4H), 3.45 (s, 4H), and 3.75 ppm (s, 6H); ms *m/e* (relative intensity) 43(35), 55(58), 59(48), 69(28), 81(10), 84(22), 97(20), 101(47), 111(43), 116(79), 125(23), 129(29), 153(25), 167(76), 185(100), 195(20), 227(18), 267(16), 268(16) and 300(7). *Anal.* calcd. for $C_{15}H_{14}O_6$: C 59.98, H 8.05; found: C 59.87, H 8.05.

Reaction of 1,10-Dibromodecane with Dianion 2

The procedure used in this reaction was the same as that employed in the reaction of 1,4-dibromobutane with dianion **2**. The reagents used were: sodium hydride, as a 57% mineral oil dispersion (1.0896 g, 0.02 mol), methyl acetoacetate (2.32 g, 0.02 mol), *n*-butyllithium as a 2.2 *M* solution in hexane (9 ml, 0.02 mol), and 1,10-dibromodecane (5.996 g, 0.02 mol), which gave 7.03 g of a mixture of crude products. Purification of the products was achieved by tlc using a mixture of carbon tetrachloride and ethyl ether (7:3 v/v) as eluent. Two components were isolated from this chromatography, and these were, in order of elution, methyl 14-bromo-3-oxotetradecanoate (**3**, $n = 10$) (39%) and dimethyl 3,16-dioxooctadecanedioate (**4**, $n = 10$) (22%) which was identified by comparison of its ir and nmr spectra with those of the authentic compound.

Methyl 14-bromo-3-oxotetradecanoate (**3**, $n = 10$) was characterized by: ir 1745 and 1720 cm^{-1}; nmr δ 1.0–1.6 (m, 18H), 2.5 (t, $J = 7.0$ Hz, 2H), 3.42 (s, 2H), 3.42 (t, $J = 6.5$ Hz, 2H), and 3.7 ppm (s, 3H); ms (*a*) high resolution calculated for $C_{15}H_{27}BrO_3$: 334.1144 amu;

found (*m/e*): 334.1120; (*b*) low resolution *m/e* (relative intensity) 55(82), 58(89), 59(45), 69(45), 71(40), 74(33), 81(29), 83(31), 85(33), 97(23), 101(26), 116(100), 129(41), 130(16), 138(14), 149(11), 159(9), 162(16), 163(9), 179(10), 181(11), 183(11), 193(6), 195(8), 236(5), 252(3), and 254(6).

*Methyl 2-Cycloheptanone Carboxylate (**5**, n = 4)*

An oven-dried 100 ml 3-neck flask was fitted with a condenser and calcium chloride tube, and a 10 ml dropping funnel. Fifty millilitres of dry methanol was added gradually to the flask containing sodium (0.23 g, 0.01 mol). When the sodium had dissolved, a crude mixture of compound **4** ($n = 4$) and 3.5 g of methyl 8-bromo-3-oxooctanoate (**3**, $n = 4$) in 2 ml of methanol was added dropwise to the sodium methoxide solution. The reaction mixture was then heated to gentle boiling and refluxed for 13 h. It was then allowed to cool and the methanol was removed under reduced pressure. Water (25 ml) was added to dissolve the solid, and the product was extracted with ethyl ether (2 × 25 ml). The organic layer was then washed with water until it was neutral to litmus, dried over magnesium sulfate, and the solvent removed under reduced pressure to give 1.9254 g of crude product which was chromatographed on silica plates using a mixture of carbon tetrachloride and ethyl ether (7:3 v/v) as eluent. The top fraction isolated from this chromatography was methyl 2-cycloheptanone carboxylate (**5**, $n = 4$) (73% based on bromo-compound **3**, $n = 4$) which was characterized by: ir 1735 and 1700 cm^{-1}; nmr δ 1.2–2.0 (m, 8H), 2.5 (m, 2H), 3.5 (m, 1H), and 3.7 ppm (s, 3H); ms (*a*) high resolution calculated for $C_9H_{14}O_3$: 170.0943 amu; found (*m/e*): 170.0944; (*b*) low resolution *m/e* (relative intensity) 41(33), 55(73), 68(23), 69(20), 74(31), 82(31), 87(25), 110(37), 111(6), 113(27), 128(15), 138(100), 139(45), 142(43), and 170(60).

*Methyl 2-Cyclooctanone Carboxylate (**5**, n = 5)*

This compound was prepared by the same procedure as that employed in the preparation of compound **5** ($n = 4$). The reagents used were: sodium (0.23 g, 0.01 mol), dry methanol (50 ml), and 4.2 g of a crude mixture of compound **4** ($n = 5$) and methyl 9-bromo-3-oxononaoate (**3**, $n = 5$). The crude product was chromatographed as above to give 73% (based on compound **3**) of methyl 2-cyclooctanone carboxylate (**5**, $n = 5$) which was characterized by: ir 1735 and 1700 cm^{-1}; nmr δ 1.0–2.0 (m, 1.0H), 2.4 (m, 2H), 3.38 (m, 1H), and 3.65 ppm (s, 3H); ms (*a*) high resolution calculated for $C_{14}H_{16}O_3$: 184.1099 amu; found (*m/e*): 184.1098; (*b*) low resolution *m/e* (relative intensity) 41(52), 43(32), 45(27), 55(92), 59(19), 68(36), 68(36), 69(44), 74(100), 83(23), 84(34), 86(18), 87(31), 96(27), 98(23), 109(23), 124(27), 125(4), 152(63), 153(31), 156(36), and 184(67).

*Methyl 2-Oxacycloheptaethylidene Carboxylate (**6**)*

Hexamethylphosphoramide (15 ml) was added to an oven-dried 25 ml flask containing 0.027 g of sodium hydride (as a 57% mineral oil dispersion). The flask was fitted with a magnetic stirrer and a septum cap and was flushed with nitrogen. Methyl 8-bromo-3-oxooctanoate (**3**, $n = 4$) (0.125 g, 0.0005 mol) in 1 ml of tetrahydrofuran was added dropwise to the solution. The reaction mixture was allowed to stir for 1½ h. It was then diluted with pentane, washed with water, and dried over magnesium sulfate. The solvents were removed by evaporation under reduced pressure. Purification was achieved by tlc to give 0.0502 g (59%) of compound **6** which was characterized by: ir 1700, 1630, and 840 cm^{-1}; nmr δ 1.2–1.9 (m, 6H), 3.2 (m, 2H), 3.7 (s, 3H), 4.2 (m, 2H), and 5.25 ppm (s, 1H); ms: (*a*) high resolution calculated for $C_9H_{14}O_3$: 170.0943 amu; found (*m/e*): 170.0944; (*b*) low resolution *m/e* (relative intensity) 41(73), 43(36), 44(82), 56(100), 60(28), 69(30), 70(86), 75(34), 83(32), 85(86), 87(51), 98(32), 102(28), 111(41), 129(30), 134(45), 139(77), 140(61), 143(42), and 170(66).

*Reaction of Sodio Lithio Methyl Acetoacetate (**2**) with Dihaloalkene*

Preparation of cis-1,4-Dichloro-2-butene

N-Chlorosuccinimide (11.74 g, 0.088 mol) was dissolved in 400 ml of anhydrous methylene chloride. The flask was fitted with a septum cap and magnetic stirrer, cooled in ice, and flushed with nitrogen. Methyl sulfide (5.456 g, 0.088 mol) was added dropwise over a few minutes. A heavy white precipitate was observed. The reaction mixture was then cooled to −20 °C (carbon tetrachloride, plus dry ice) and *cis*-2-butene-1,4-diol (3.520 g, 0.040 mol) in 5 ml of methylene chloride was added over 10 min. The resulting solution was then warmed to 0 °C and stirred for 50 min. The white precipitate disappeared, leaving a clear colorless solution. The mixture was stirred for an additional 70 min, diluted with pentane, and poured into 400 ml of ice-cold brine. The aqueous phase was extracted with pentane (2 × 200 ml) and the organic layers were combined. It was then washed with cold brine (2 × 400 ml) and dried over magnesium sulfate. The solvents were removed under reduced pressure and the resulting crude product was then distilled to give 3.6104 g (72%) of *cis*-1,4-dichloro-2-butene, bp 128 °C/760 torr (lit. (13) bp 83–85 °C/80 torr).

*Alkylation of Sodio Lithio Methyl Acetoacetate (**2**) with cis-1,4-Dichloro-2-butene*

The procedure used in this reaction was the same as that employed in the reaction of 1,4-dibromobutane with dianion **2**. The reagents in this preparation were: sodium hydride, as a 57% mineral oil dispersion (1.0896 g, 0.02 mol), methyl acetoacetate (2.32 g, 0.02 mol), *n*-butyllithium, as a 2.2 *M* solution in hexane (9 ml, 0.02 mol) and *cis*-1,4-dichloro-2-butene (2.5 g, 0.02 mol) which gave 3.00 g of crude product. Purification of the products was achieved by tlc on silica using a mixture of carbon tetrachloride and ethyl ether (7:3 v/v) as eluent. Two components were isolated from this chromatography, and these were, in order of elution, methyl 3-oxo-8-chloro-6-octenoate (**8**) (18%) and dimethyl 3,10-dioxo-6-dodecenedioate (**9**) (18%). Methyl 3-oxo-8-chloro-6-octenoate (**8**) was characterized by: ir 1745, 1720, and 1660 cm^{-1}; nmr δ 2.2–2.8 (m, 4H), 3.45 (s, 2H), 3.75 (s, 3H), 4.08 (d, $J = 6.5$ Hz, 2H), and 5.5–5.8 ppm (m, 2H); ms: (*a*) high resolution calculated for $C_9H_{13}ClO_3$: 204.0553 amu; found (*m/e*): 204.0540; (*b*) low resolution *m/e* (relative intensity) 53(20), 55(16), 59(20), 67(42), 69(100), 81(14), 94(13), 95(13), 101(79), 109(13), 127(13), 136(25), 137(34), 168(37), 169(10), and 204(1).

Dimethyl 3,10-dioxo-6-dodecenedioate (**9**) was characterized by: ir 1740, 1718, and 1660 cm^{-1}; nmr δ 2.18–2.8 (m, 8H), 3.45 (s, 4H), 3.75 (s, 3H), and 5.4 ppm (t, $J = 4.0$ Hz, 2H); ms (*a*) high resolution calculated for $C_{14}H_{20}O_6$: 284.1259 amu; found (*m/e*): 284.1305; (*b*)

low resolution *m/e* (relative intensity) 43(33), 57(10), 59(12), 71(25), 85(19), 91(16), 94(29), 95(33), 101(61), 109(13), 113(12), 116(20), 127(19), 129(13), 136(12), 137(45), 150(12), 155(18), 159(12), 168(48), 169(100), 179(11), 221(16), 252(11), and 284(4).

*Methyl 2-Oxo-5-cycloheptene Carboxylate (**10**)*

This compound was prepared by the same procedure as that employed in the preparation of compound **5**. The reagents used were: sodium (0.1570 g, 0.0068 mol), dry methanol (10 ml), and pure methyl 3-oxo-8-chloro-6-octenoate (**8**) (0.1383 g, 0.0068 mol) which gave 0.0460 g (40%) of methyl 2-oxo-5-cycloheptene carboxylate (**10**) characterized by: ir 1735, 1700, and 1660 cm^{-1}; nmr δ 2.0–2.8 (m, 4H), 3.65 (m, 1H), 3.72 (s, 3H), and 5.78 ppm (t, J = 4.0 Hz, 2H); ms (*a*) high resolution calculated for $C_9H_{12}O_3$: 168.0787 amu; found (*m/e*): 168.0779; (*b*) low resolution *m/e* (relative intensity) 32(100), 39(38), 42(47), 44(28), 53(22), 55(20), 59(23), 66(22), 67(68), 68(38), 79(24), 80(31), 81(46), 84(34), 101(21), 108(23), 109(21), 110(21), 136(95), 137(43), and 168(60).

Internal Dialkylation at the γ-Carbon of the Dianion of Methyl Acetoacetate

*Methyl 3-Oxo-3-cyclopentyl Propanoate (**13**, n = 4)*

Sodium hydride, as a 57% mineral oil dispersion, (1.0896 g, 0.02 mol) was weighed into an oven-dried 100 ml flask, and tetrahydrofuran (50 ml) was distilled, from lithium aluminum hydride, directly into the flask. The flask was fitted with a magnetic stirrer and a septum cap, cooled in ice to 0 °C, and flushed with nitrogen. Methyl acetoacetate (2.32 g, 0.02 mol) was added dropwise, and the reaction mixture was stirred for 10 min after the addition was complete. *n*-Butyllithium as a 2.2 *M* solution in hexane (9.6 ml, 0.021 mol) was added dropwise to the reaction which was allowed to stir for a further 10 min before the addition of 1,4-dibromobutane (4.3186 g, 0.02 mol). The reaction was then stirred for 1 h and lithium diisopropylamide (made by stirring 3.08 ml of diisopropylamine with 9.9 ml of *n*-butyllithium at 0 °C for ½ h) was added dropwise. The reaction mixture was stirred for an additional 30 min. It was then quenched with dilute hydrochloric acid, extracted with ethyl ether (2 × 50 ml), washed with saturated sodium bicarbonate and water, and dried over magnesium sulfate. The solvents were removed under reduced pressure to give 3.29 g of crude products. Purification was achieved by tlc on silica using a mixture of carbon tetrachloride and ethyl ether (7:3 v/v) as eluent to give methyl 3-oxo-3-cyclopentyl propanoate (**13**, n = 4) in 26% yield based on methyl acetoacetate or in approximately quantitative yield based on the amount of monohalide intermediate produced. Compound **13** (n = 4) was characterized by: ir 1740 and 1710 cm^{-1}; nmr δ 1.05–2.0 (m, 8H), 3.0 (m, 1H), 3.5 (s, 2H), and 3.75 ppm (s, 3H); ms *m/e* (relative intensity) 41(64), 43(50), 44(19), 57(7), 59(60), 69(62), 74(19), 96(40), 97(100), 101(73), 129(86), 139(7), and 170(51). *Anal.* calcd. for $C_9H_{14}O_3$: C 63.51, H 8.29; found: C 63.68, H 8.16.

*Methyl 3-Oxo-3-cyclohexylpropanoate (**13**, n = 5)*

This compound was prepared by the same procedure as that employed in the preparation of methyl 3-oxo-3-cyclopentylpropanoate (**13**, n = 4). The reagents used were: sodium hydride, as a 57% mineral oil dispersion (0.545 g, 0.01 mol), methyl acetoacetate (1.16 g, 0.01 mol), *n*-butyllithium (4.8 ml, 0.01 mol), 1,5-dibromopentane (2.30 g, 0.01 mol), and lithium diisopropylamide (made by stirring 1.67 g, 0.016 mol of diisopropylamine with 7.5 ml of *n*-butyllithium at 0 °C for ½ h), which gave 1.79 g of crude products. This crude material was chromatographed to give methyl 3-oxo-3-cyclohexylpropanoate (**13**, n = 5) in 32% yield based on methyl acetoacetate. This compound was characterized by: ir 1740 and 1710 cm^{-1}; nmr δ 1.8–2.0 (m, 10H), 2.3–2.6 (m, 1H), 3.45 (s, 2H), and 3.72 ppm (s, 3H); ms *m/e* (relative intensity) 41(64), 43(29), 44(50), 55(76), 59(26), 69(48), 74(22), 83(100), 100(25), 101(35), 106(20), 129(33), 143(8), and 184(29). *Anal.* calcd. for $C_{10}H_{16}O_3$: C 65.19, H 8.75; found: C 65.19, H 8.70.

Thermolysis of (−)-(*R*)-1-benzyl-2-(2-phenyl-2-butyl)diazene, (−)-*R*-**4**, produces (+)-(*S*)-2-methyl-1,2-diphenylbutane with 12% net retention of configuration at 110 °C in benzene or pentane containing 1 *M* butanethiol. The ratio of the rate constant for coupling of the initial radical pair to that of rotation of the 2-phenyl-2-butyl radical, k_c/k_r, is calculated to be ~0.04–0.08. Thermolysis of (+)-(*S*)-1-(2-phenyl-2-butyl)-2-(2-propyl)diazene at 100 °C in benzene containing 1 *M* butanethiol produces 2,3-dimethyl-3-phenylpentane with no observable rotation. The product must be less than 15% optically pure. The reaction produces (−)-(*R*)-2-phenylbutane, (−)-(*R*)-**16**, with 0.6–1.3% retention of configuration. The ratio of the rate constant for disproportionation to (−)-(*R*)-**16** to k_r is calculated to be 0.02–0.04. Thermolysis of (−)-(*R*)-1-(4-nitrophenyl)-2-(2-phenyl-2-butyl-diazene, (−)-(*R*)-**12**, at 175 °C in diphenylether produced no 2-(4-nitrophenyl)-2-phenylbutane. This product was produced on photolysis of (+)-(*S*)-**12** in hexadecane at 15 °C but had no rotation. Neither (+)-(*S*)-**7** nor (−)-(*R*)-**12** was racemized during thermolysis and (+)-(*S*)-**12** was not racemized during photolysis. Activation parameters for thermolysis of (±)-**4** are $\Delta H^{\ddagger}$ = 33 kcal/mol, $\Delta S^{\ddagger}$ = 15 eu and for (±)-**12**, $\Delta H^{\ddagger}$ = 37.3 kcal/mol, $\Delta S^{\ddagger}$ = 5.5 eu.

La thermolyse du (−)-(*R*) benzyl-1 (phényl-2 butyl-2)-2 diazène, (−)-*R*-**4**, conduit au (+)-(*S*) méthyl-2 diphényl-1,2 butane avec une rétention nette de 12% de la configuration à 110 °C dans du benzène ou dans du pentane contenant 1 *M* de butanethiol. Le rapport des constantes de vitesse du couplage de la paire de radicaux initiaux et de la rotation du radical phényl-2 butyle-2, k_c/k_r, est d'environ 0.04–0.08. La thermolyse du (±)-(*S*) (phényl-2 butyl-2)-1 (propyl-2)-2 diazène à 100 °C dans du benzène contenant 1 *M* de butanethiol conduit au diméthyl-2,3 phényl-3 pentane pratiquement sans rotation. Le produit doit être moins que 15% optiquement pur. La réaction fournit du (−)-(*R*) phényl-2 butane, (−)-(*R*)-**16**, avec une rétention de configuration de 0.6–1.3%. On a calculé que le rapport de la constante de vitesse de disproportionation en (−)-(*R*)-**16** sur k_r est de 0.02–0.04. La thermolyse du (−)-(*R*) (nitro-4 phényl)-1 (phényl-2 butyl-2)-2 diazène, (−)-(*R*)-**12**, à 175 °C dans l'éther diphénylé ne conduit pas au (nitro-4 phényl)-2 phényl-2 butane. Ce composé est obtenu par photolyse du (+)-(*S*)-**12** dans l'hexadécane à 15 °C mais il n'y a pas de rotation. Il n'y a pas de racémisation lors de la thermolyse du (+)-(*S*)-**7** ou du (−)-(*R*)-**12** et le (+)-(*S*)-**12** n'est pas racémisé durant sa photolyse. Les paramètres d'activation pour la thermolyse de (±)-**4** sont $\Delta H^{\ddagger}$ = 33 kcal/mol, $\Delta S^{\ddagger}$ = 15 ue et pour (±)-**12** $\Delta H^{\ddagger}$ = 37.3 kcal/mol, $\Delta S^{\ddagger}$ = 5.5 ue.

[Traduit par le journal]

The results of the earlier studies of the thermolysis of the chiral diazenes **1** (1) and **2** (2) are consistent with the assumption that in these compounds both C—N bonds are breaking simultaneously in the rate determining step, [1].

[1] $\mathrm{R{-}N{=}N{-}R' \longrightarrow R\cdot N_2\cdot R'}$

2

There has already been evidence, which is still accumulating, that such a concerted cleavage occurs on thermolysis of a number of acyclic (3) and cyclic (4) diazenes. In most of these compounds R· and R′· are radicals of similar stability.

[1]This research was supported by the National Research Council of Canada.

[2]Holder of a National Research Council of Canada Studentship 1966–1968, a Province of Alberta Scholarship, 1966–1967, and a University of Alberta Dissertation Fellowship 1968–1969.

At the time that we initiated studies in this area we began also to examine diazenes that might provide stereochemical evidence for one-bond cleavage (5) as indicated by racemization of optically active starting material, [2], in which R·

[2] (+)-R—N=N—R′ ⇄ R· ·N=N—R′ ⇄ (−)-R—N=N—R′

is a much more stable radical than is R′·.

Since our work began, stereochemical evidence for one-bond cleavage during thermolysis of several optically active diazenes has appeared (6). Other evidence for one-bond cleavage has been obtained from kinetic (7), pressure (8), and nmr (9) studies of, and the observation of isomerization (10) in, the thermolysis of diazenes.

In this paper the thermolyses of (−)-(*R*)-1-benzyl-2-(2-phenyl-2-butyl)diazene (−)-(*R*)-**4**, (+)-(*S*)-1-(-2-phenyl-2-butyl)-2-(2-propyl)diazene (+)-(*S*)-**7**, and (−)-(*R*)-1-(4-nitrophenyl)-2-(2-phenyl-2-butyl)diazene (−)-(*R*)-**12** are described. The diazenes each contain a 2-phenyl-2-butyl group, chosen because it cannot undergo racemization by reversible hydrogen atom abstraction, and constitute a series in which the other substituent is varied from benzyl to 2-propyl to 4-nitrophenyl. This is in order of decreasing radical stability. It was expected that (−)-(*R*)-**4** would undergo concerted two-bond cleavage and produce a coupling product with retention of configuration (1, 2), whereas (−)-(*R*)-**12** would decompose by a one-bond cleavage reaction [2] and thus might racemize during thermolysis. The mechanism of thermolysis of (+)-(*S*)-**7** is not so easy to predict and a comparison of the stereochemistry of the product of coupling with that from (−)-(*R*)-**4** might be informative. In fact, indirect evidence indicates that the coupling product from (+)-(*S*)-**7** was formed with a somewhat smaller amount of retention of configuration than that from (−)-(*R*)-**4**, that (+)-(*S*)-**7** was not racemized during thermolysis, and that (−)-(*R*)-**12** was not racemized during either thermolysis or photolysis.

Syntheses of Optically Active Diazenes and Coupling Products

The syntheses of the optically active diazenes and of the coupling products expected from (−)-(*R*)-**4** and (+)-(*S*)-**7** are outlined in Schemes 1 to 3. Rotations given are those calculated for optically pure compounds. The maximum rotations and absolute configurations of (+)-(*R*)-(2-phenyl-2-butyl)diazane (+)-(*R*)-**3** (11),[3] (−)-(*R*)-1,2-diphenyl-2-methyl-2-butanone (−)-(*R*)-**5** (12), and (−)-(*R*)-2-methyl-2-phenylbutanoic acid (−)-(*R*)-**9** (13) have been determined. Thus, the absolute configurations and maximum rotations of (−)-(*R*)-**4**, (+)-(*S*)-1,2-diphenyl-2-methylbutane (+)-(*S*)-**6**, (+)-(*S*)-2,3-dimethyl-3-phenyl-1-pentene (+)-(*S*)-**10**, (−)-(*S*)-2,3-dimethyl-3-phenylpentane (−)-(*S*)-**11**, and (−)-(*R*)-**12** are established. The absolute configuration and maximum rotation of (+)-(*S*)-**7** were determined by hydrogenolysis to (−)-(*S*)-2-phenyl-2-butylamine (−)-(*S*)-**8**, of known configuration (11). This amine was also prepared again in this work from (+)-(*S*)-2-methyl-2-phenylbutanoic acid (+)-(*S*)-**9** to check the magnitude of its rotation.

The magnitude of the rotation of the optically pure coupling product (−)-(*S*)-**11** expected from thermolysis of optically active **7** is smaller than expected. It was prepared from (−)-(*R*)-**9** by reactions that do not affect the chiral center and the immediate precursor (+)-(*S*)-**10** has a significant rotation. Values of $[M]_D$ −19.2 or −4.4° for the rotation of (−)-(*S*)-**11** were calculated using Brewster's empirical rules (14). By estimating the density of (−)-(*S*)-**11** to be 0.87 values of α_D −9.5 or −2.2° (neat, *l* 1 dm) were obtained. The larger values were obtained using the higher polarizability of the phenyl group which has been found to give the more accurate estimate of rotation for many compounds. However, it is known that empirical rules for calculating optical rotation give erroneous results for compounds with 2-propyl groups attached to the chiral center (15), presumably because of steric crowding. The rotation of (−)-(*S*)-**11** did not vary greatly with wavelength down to 300 nm, the shortest wavelength utilizable. The maximum rotation at the position of a low intensity peak was $[\alpha]_{310}^{23}$ = −33° (*c* 1.05, CH_3OH).

Results

Rates and Products of Thermolysis

The rates of thermolysis of (±)-**4**, (±)-**7**, and (±)-**12** are presented in Table 1. The rate of thermolysis of (±)-**4** is about 17 times that of **1** (1). This is about the effect to be expected on replacing a hydrogen atom of **1** by an alkyl group (16). The rate of thermolysis of (±)-**7** is nearly

[3]A much more convenient method of resolution of (±)-**3** has been found, see Experimental.

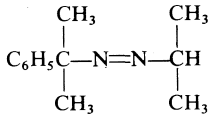
TABLE 1. Rates of thermolysis of diazenes (±)-**4**, (±)-**7**, and (±)-**12**

Diazene	Solvent	Concentration (M)	Temperature (°C)	Moles N_2[a]	$k \times 10^4$ (s^{-1})
(±)-**4**	Cumene	0.16	86.6	0.85	0.131[b]
(±)-**4**	Cumene	0.16	103.7	0.89±0.04[c]	1.18±0.05[c]
(±)-**7**	Cumene	0.25	122.5	0.85±0.01[c,d]	1.46±0.02[c]
(±)-**12**	Diphenyl ether	0.35	160.5	0.88±0.01[c]	0.213±0.007[c,e]
(±)-**12**	Diphenyl ether	0.35	187.0	0.90±0.02[c]	2.77±0.03[c]

[a]Mol N_2 per mol of diazene.
[b]At 103.7 °C $\Delta H^{\ddagger}$ = 33 kcal/mol, $\Delta S^{\ddagger}$ = 15 eu.
[c]Average of two runs.
[d]Based on 2 mol of gas (N_2 + propane or propene) per mol of 7.
[e]At 160.5 °C $\Delta H^{\ddagger}$ = 37.3 ± 0.6 kcal/mol, $\Delta S^{\ddagger}$ = 5.5 ± 1.5 eu.

identical to that of 1-(2-phenyl-2-propyl)-2-(2-propyl)diazene **13** (17). Thus, replacement of a methyl group in **13** by an ethyl group has little effect on the rate of thermolysis.



13

The rate of thermolysis of (±)-**12** is very much slower than that of either (±)-**4** or (±)-**7**. This might suggest that (±)-**12** thermolyzes by a mechanism different from that of the other two compounds, but the main factor contributing to the rate difference between (±)-**7** and (±)-**12** is the difference in the entropies of activation, about 8 eu (reported for **13** (17) $\Delta H^{\ddagger}$ = 36.0 kcal/mol, $\Delta S^{\ddagger}$ = 14 eu), assuming that the activation parameters of (±)-**7** and **13** are nearly the same. A larger difference in the enthalpies of activation than the observed 1.7 kcal/mol might have been expected if **13** were decomposing according to [1] and (±)-**12** according to [2].

Thermolysis of a 10^{-2} M solution of (±)-**4** in benzene at 110 °C produced toluene, (±)-**6**, 3,4-dimethyl-3,4-diphenylhexane **14**, and 1,2-diphenylethane **15** in a 12:53:22:13 molar ratio in 50% total yield [3]. About a 10% yield of a mixture, only partially resolved under the gc conditions used, of 2-phenylbutane (±)-**16**, 2-phenyl-1-butene **17**, Z- and possibly E-2-phenyl-2-butene Z- and E-**18** was also formed, as was about a 20% yield of several unidentified compounds. Very similar results were obtained when pentane was used as solvent.

Thermolysis of (±)-**4** in the presence of 1 M butanethiol or benzenethiol resulted in greatly increased yields, relative to those of (±)-**6**, toluene, and (±)-**16**, Table **2**. No symmetrical

[3] (±)-**4** $\xrightarrow{\Delta}$ $C_6H_5CH_3$ + (±)-**6** +  **14**

+ $C_6H_5CH_2CH_2C_6H_5$ +  + 
15 (±)-**16** **17**

+  + 
Z-**18** *E*-**18**

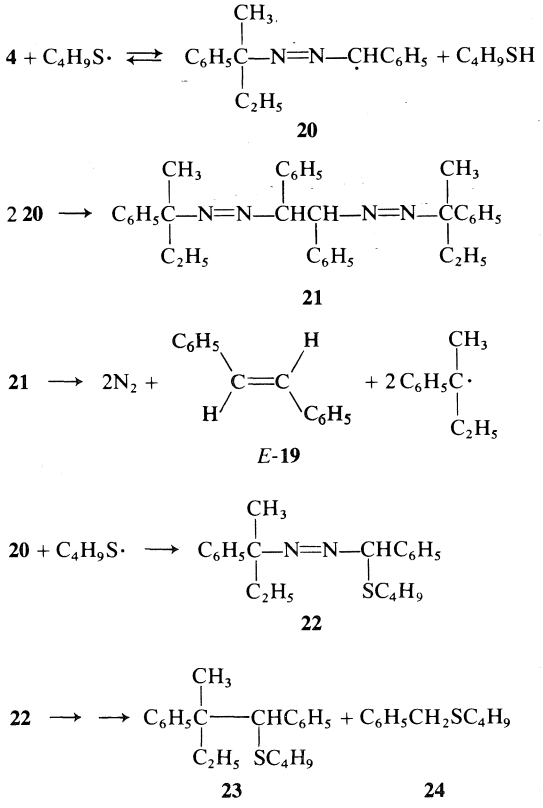
coupling products were formed. Toluene and (±)-**16** are formed outside the initial solvent cage from benzyl and 2-phenyl-2-butyl radicals by abstraction of hydrogen atoms from the thiols. An additional source of toluene could be from disproportionation of the two radicals in the initial solvent cage. Since the yield of toluene is only slightly higher than that of (±)-**16** only ~2% of the radicals undergo disproportionation in the cage. Such a high ratio of coupling to disproportionation is common to benzylic radical pairs (1, 18).

TABLE 2. Relative yields (%) of products from thermolysis of (±)-**4** at 110 °C in the presence of scavengers

Solvent	[Thiol] M	Toluene	(±)-**16**	(±)-**6**
Pentane–benzenethiol	1.2	46	46	8
Benzene–benzenethiol	0.97		77	23
Benzene–butanethiol	0.84		28[a]	15[a]
Butanethiol	9.7		74	26

[a]Absolute % yields.

Numerous other products, most of which were eluted between (±)-**16** and (±)-**6** under the gc conditions used, were also formed in the presence of the thiols. About half the amount of these products, relative to (±)-**6**, was formed in the presence of benzenethiol as was formed in the presence of butanethiol. Only one of these compounds was identified and it was shown to be *E*-1,2-diphenylethene *E*-**19**, formed in ~5% yield in the presence of butanethiol. No *E*-**19** was formed in the absence of thiol. The formation of *E*-**19** in low yield has been observed on thermolysis of 1,2-dibenzyldiazene in the absence of scavenger (19). Its origin in these reactions is not clear. It cannot be formed under the present conditions by dehydrogenation of **15** because none of the latter compound is formed. A possible route to the formation of *E*-**19** is shown in Scheme 4. Thermolysis of diazenes in the presence of thiols produces appreciable amounts of bis(methylene)diazanes (azines) (20). Presumably this occurs by successive hydrogen atom abstractions from the diazene by thiyl



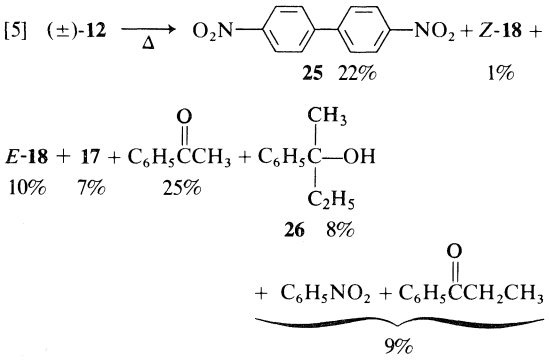
SCHEME 4

[4] 
radicals [4] (20). This would mean that the radical generated upon abstraction of the first hydrogen atom must have enough stability so that it can survive sufficiently long in the presence of thiol to undergo a second hydrogen atom abstraction. The radical **20** generated in this way from **4** cannot undergo a second hydrogen atom abstraction.

Dimerization of two such radicals would give the bis-diazene **21** and subsequent thermolysis of this compound could produce *E*-**19**. The radical **21** also could couple with a thiyl radical to form the diazene **22** which would give rise to at least two other products **23** and **24** on thermolysis. A search for these compounds was not made.

Thermolysis of 0.5 *M* (±)-**7** in benzene at 100 °C produced (±)-**16**, **17**, *Z*-**18**, (±)-**11**, and **14** in a 23:2:2:59:14 molar ratio in 51% total yield. Very similar results were obtained at 125 °C. No *E*-**18** was detected. No attempt was made to detect other products of the 2-propyl radical. In the presence of 1 *M* butanethiol a 64:36 molar ratio of (±)-**16**:(±)-**11** was formed in 57% total yield. No symmetrical coupling product **14** was detected. A number of unidentified other products that eluted near (±)-**11** under the gc conditions used were formed in both the presence and absence of thiol. Under both conditions considerable amounts of hydrazone were formed. A significantly larger yield, 30%, of (±)-**11** was formed in the absence of butanethiol than in its presence, 21%. This indicates that a considerable amount of coupling between 2-phenyl-2-butyl and 2-propyl radicals must occur outside the initial solvent cage in benzene. Similar behavior was observed recently for 2-butyl and diphenylmethyl radicals (21).

Products of thermolysis of 0.3 *M* (±)-**12** under nitrogen in diphenyl ether at 175 °C that were identified are shown in [5]. Nitrobenzene and 1-phenyl-1-propanone were eluted together under the gc conditions used. The identified products accounted for ~50% of the 2-phenyl-2-butyl radicals. Unexpectedly, neither (±)-**16** nor the coupling product **14** could be detected. The coupling product **14** was shown to survive heat-



ing at 175 °C in diphenyl ether for a time equal to several half-lives of decomposition of (±)-**12**. None of the unsymmetrical coupling product 2-(4-nitrophenyl)-2-phenylbutane **27** was detected either. As in the thermolysis of (±)-**7**, *E*-**18** predominates greatly over *Z*-**18**.
