The synthesis and thermal decomposition of bis(phenylthio)methyl derivatives of mercury

TRISTRAM CHIVERS AND RITCHWICK RAM

Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received February 7, 1977

TRISTRAM CHIVERS and RITCHWICK RAM. Can. J. Chem. **55**, 2554 (1977).

The mercurials, $[(PhS)_2CH]_2Hg$ and $PhHgCH(SPh)_2$, have been prepared from $(PhS)_2CHLi$ and $HgBr_2$ or PhHgCl, respectively. The unsymmetrical compound decomposes readily both in the solid state and in various solvents. The symmetrical compound is more stable but also undergoes decomposition in certain refluxing solvents. The identity of the products suggests that the major decomposition route involves homolytic fission of the Hg—$CH(SPh)_2$ bond and that PhS migration to mercury plays only a minor role.

TRISTRAM CHIVERS et RITCHWICK RAM. Can. J. Chem. **55**, 2554 (1977).

On a préparé les dérivés organomercuriques $[(PhS)_2CH]_2Hg$ et $PhHgCH(SPh)_2$ respectivement à partir de $(PhS)_2CHLi$ et $HgBr_2$ ou PhHgCl. Le composé non-symétrique se décompose facilement aussi bien à l'état solide que dans divers solvants. Le composé symétrique est plus stable mais il subit aussi une décomposition dans certains solvants à reflux. La nature des produits formés suggère que la principale route de décomposition implique une fission homolytique du lien Hg—$CH(SPh)_2$ et que la migration du PhS vers le mercure ne joue qu'un rôle mineur dans le mécanisme.

[Traduit par le journal]

Introduction

A number of investigations of organometallic derivatives containing β-sulfur substituents indicate that decomposition via the formation of M—SR bonds is a general feature of these compounds (1–4). By analogy with polyhalomethylmercurials (5), RS migration to mercury in derivatives of the type $PhHgCH_n(RS)_{3-n}$ (n = 1, 2) could provide a source of thio(alk)aryloxy carbenes. To test this idea we have prepared the mercurials $PhHgCH(SPh)_2$ and $Hg[CH(SPh)_2]_2$ and investigated their decomposition in various solvents. The synthesis of $Hg(CH_2SPh)_2$ and reactions with lithium and zinc to give $LiCH_2SPh$ and $Zn(CH_2SPh)_2$, respectively, have been briefly reported (3).

Experimental

General

All solvents were distilled from CaH_2 prior to use. Reactions involving lithium reagents were carried out under an atmosphere of dry, oxygen-free nitrogen.

The following instruments were used to obtain spectroscopic data: Infrared Spectra (Perkin Elmer Models 337 and 467), ^1H NMR Spectra (Varian HA 100), Mass Spectra (Varian CH5 operating at an ionising potential of 70 eV).

Microanalyses were performed by Alfred Bernhardt Mikroanalytisches Lab., W. Germany.

Synthesis of $[(PhS)_2CH]_2Hg$

$(PhS)_2CHLi$ (20 mmol) (6) in THF (20 ml) was added over 5 min to mercury(II) bromide (3.6 g; 10 mmol) in THF (15 ml) at 0°C. The turbidity of the initial suspension rapidly gave way to the final greenish mixture. Addition of ice-cold water (~200 ml) precipitated the product as white lumps which were collected, washed with water, and air dried. Analytically pure $Hg[CH(SPh)_2]_2$ was obtained as a white powder (mp 92–94°C) by slow precipitation from a solution in THF upon addition of pentane. (Yield = 4.97 g; 75%.) *Anal.* Calcd. for $C_{26}H_{22}HgS_4$: C 47.13, H 3.32, Hg 30.21, S 19.34. Found: C 46.99, H 3.33, Hg 30.21, S 19.17. The ^1H nmr spectrum (CS_2) exhibited signals at τ 2.58–3.03 (m, C_6H_5S) and τ 5.72 (s, $\diagdown CH—Hg\diagup$), $^2J_{^{199}Hg-^1H}$ = 129 Hz, with the appropriate intensity ratios.

The infrared spectrum showed a band at 462 cm^{-1} assigned to ν_{as} HgC_2. The mass spectral data are given in Table 1.

Synthesis of $PhHgCH(SPh)_2$

$(PhS)_2CHLi$ (15 mmol) in THF (25 ml) was added over 10 min to PhHgCl (4.7 g; 15 mmol) in THF (75 ml) at 0°C. The turbidity of the suspension rapidly gave way to a pale yellow-green mixture. The crude product was precipitated from this mixture by the addition of ice-cold water (200 ml). Slow addition of *n*-pentane to a toluene solution of the crude product (dried over $MgSO_4$) gave white crystals of analytically pure $PhHgCH(SPh)_2$; mp 107–108°C. Yield = 2.64 g; 43%. *Anal.* Calcd. for $C_{19}H_{16}HgS_2$: C 44.90, H 3.15, Hg 39.40, S 12.60. Found: C 44.93, H 3.08, Hg 39.30, S 12.54.

The ^1H nmr spectrum ($CDCl_3$) exhibited signals at τ 2.27–2.49 (m, Hg—C_6H_5, *m*- and *p*-), τ 2.49–2.97 (m, SC_6H_5), τ 2.97–3.14 ("d of d", Hg—C_6H_5, *o*-) and τ 5.30 (s, Hg—$CH\diagup\diagdown$), $^2J_{^{199}Hg-^1H}$ = 113 Hz, with the appro-

priate intensity ratios. In the infrared spectrum bands at 450 and 580 cm^{-1} are assigned to Hg—aryl and Hg—alkyl stretching frequencies, respectively. The mass spectral data are given in Table 1.

Decomposition of the Mercurials

The experimental results for the decomposition of $Hg[CH(SPh)_2]_2$ and $PhHgCH(SPh)_2$ in various solvents are summarized in Tables 2 and 3, respectively. A description of the general procedure for the work-up of reaction mixtures and the identification of products follows. After the decomposition, mercury metal was filtered off and weighed. Solvents were removed *in vacuo* and the decomposition products were isolated, where possible, and identified by comparison of their infrared spectra and mp with those of authentic samples. For comparison purposes, Ph_2Hg and PhHgCl were commercial samples (Alfa Inorganics). PhHgSPh and $Hg(SPh)_2$ (mp 150°C, *cf.* lit. 151–152°C) (7) were prepared by the reactions of benzenethiol with PhHgCl and HgO, respectively. $(PhS)_2CH_2$ was prepared from CH_2I_2 and PhSNa using the literature procedure (6). $(PhS)_3CH$, $[(PhS)_2CH]_2$, and $(PhS)_2C{=}C(SPh)_2$ were characterized by complete microanalytical data in addition to mp, infrared, ^1H nmr, and mass spectra (Table 4).

In cases where it was not possible to isolate pure organosulfur products, the molar composition of mixtures of $(PhS)_2CH_2$, $(PhS)_3CH$, and $[(PhS)_2CH]_2$ could be estimated from the integrated intensities of the aliphatic ≡CH signals in their ^1H nmr spectra. The progress of the decomposition was conveniently monitored by ^1H nmr spectroscopy.

Results and Discussion

The mercurials $Hg[CH(SPh)_2]_2$ and $PhHgCH(SPh)_2$ were obtained in fairly good yields from the readily available lithium reagent, $(PhS)_2CHLi$ (6), and $HgBr_2$ or PhHgCl, respectively. Two observations for the unsymmetrical mercurial prompted us to undertake a detailed investigation of the decomposition of these two compounds. First, solid samples darkened during several days at room temperature. Secondly, solutions in various solvents slowly deposited mercury. The results for the symmetrical mercurial are presented first.

Decomposition Pathways of $Hg[CH(SPh)_2]_2$

Table 2 summarizes the experimental results for the decomposition of $Hg[CH(SPh)_2]_2$ in various solvents and *in vacuo*. While the decomposition of the mercurial in low boiling-point solvents (*e.g.* $CHCl_3$, THF) is very slow, the mercurial is quantitatively converted to mercury metal in refluxing toluene or *in vacuo* at 150°C. By analogy with the extensive literature (10, ref. 11, pp. 403–421) on the thermal decomposition of R_2Hg compounds, the decomposition of $Hg[CH(SPh)_2]_2$ can be rationalised by postulating homolytic fission of the Hg—C bond in the initial rate-determining step.

$$[1]\quad Hg[CH(SPh)]_2 \xrightarrow{\text{slow}} (PhS)_2CH\cdot + \cdot HgCH(SPh)_2$$

$$[2]\quad \cdot HgCH(SPh)_2 \xrightarrow{\text{fast}} (PhS)_2CH\cdot + Hg$$

The decomposition products $(PhS)_2CH_2$ and $[(PhS)_2CH]_2$ can then be formed from the radicals produced in [1] and [2] by (*a*) abstraction of hydrogen from solvent or starting mercurial, or (*b*) dimerization, respectively. The detection of bibenzyl as a product in the decomposition in toluene solution provides support for the proposed radical mechanism (12).

$$[3]\quad (PhS)_2CH\cdot + C_6H_5CH_3 \rightarrow (PhS)_2CH_2 + C_6H_5CH_2\cdot \rightarrow (C_6H_5CH_2)_2$$

The formation of $[(PhS)_2CH]_2$ by a radical–molecule encounter, as in [4],

$$[4]\quad (PhS)_2CH\cdot + Hg[CH(SPh)_2]_2 \rightarrow [(PhS)_2CH]_2 + \cdot HgCH(SPh)_2$$

cannot, however, be ruled out on the basis of the available evidence.

The purple radical $(PhS)_2N\cdot$, isoelectronic with $(PhS)_2CH\cdot$, has recently been characterized by Barton and co-workers and shown to have unusual stability (13). In this work, no direct evidence, *e.g.* by esr, could be obtained for radical formation possibly because the steady state concentration of $(PhS)_2CH\cdot$ radicals was too low.

The origin of the predominant organosulfur product in the thermal decomposition of $Hg[CH(SPh)_2]_2$, *i.e.* $(PhS)_3CH$ is less certain. Seebach and co-workers have proposed the following sequence of reactions to explain the

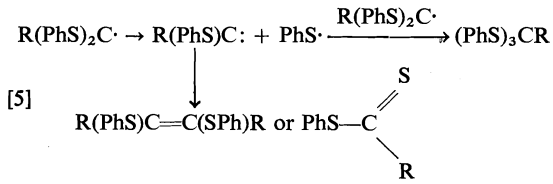
products of thermolysis of $(PhS)_3C—C(SPh)_3$ (14) (R = SPh).



[5]

In the present work, reaction 5 (R = H) does not explain the formation of $(PhS)_3CH$ since no carbene ($PhS\ddot{C}H$) derived products have been detected. Direct abstraction of PhS from the starting mercurial by $(PhS)_2CH\cdot$ appears to be the most likely explanation for the formation of $(PhS)_3CH$.

[6] $(PhS)_2CH\cdot + Hg[CH(SPh)_2]_2 \rightarrow (PhS)_3CH + (PhS)_2CHHg\dot{C}H(SPh)$

Unexpectedly the decomposition of $Hg[CH(SPh)_2]_2$ in acetone produced the olefin $(PhS)_2C{=}C(SPh)_2$ in *ca.* 15% yield, in addition to $(PhS)_3CH$. Radical disproportionation followed by dimerization of the carbene formed would be a possible explanation, but the absence of $(PhS)_2CH_2$ among the products rules out this alternative.

[7] $2(PhS)_2CH\cdot \rightarrow (PhS)_2C: + (PhS)_2CH_2$

$\downarrow$

$\frac{1}{2}(PhS)_2C{=}C(SPh)_2$

A second possibility involves transfer of H atoms from $(PhS)_2CH\cdot$ *to the solvent* followed by dimerization of the carbene, $(PhS)_2C$:, but it was not possible to detect 2-propanol by nmr in the solvent after decomposition. Thus we do not have a satisfactory explanation for the formation of the olefin in acetone but not in other solvents.

Decomposition Pathways of $PhHgCH(SPh)_2$

Table 3 summarizes the experimental results for the decomposition of $PhHgCH(SPh)_2$ in various solvents. The decomposition of the unsymmetrical mercurial occurred more readily than the symmetrical mercurial and in most solvents took place at room temperature. The identification of the reaction products was considerably more difficult than in the case of the symmetrical mercurial due to the formation of PhHg— and PhSHg— derivatives, in addition to organosulfur compounds. In an attempt to rationalise the formation of the various products a number of competing decomposition pathways have been considered.

(a) Homolytic Fission

By analogy with previously reported studies of the thermal decomposition of $PhHgCH_2Ph$ (15) and related molecules, homolytic fission of the $Hg—CH(SPh)_2$ bond to give $(PhS)_2CH\cdot$ would explain the formation of $(PhS)_2CH_2$, $[(PhS)_2CH]_2$, and $(PhS)_3CH$ in the same way as for the symmetrical mercurial.

[8] $PhHgCH(SPh)_2 \xrightarrow{slow} PhHg\cdot + (PhS)_2CH\cdot$

The fate of the phenylmercury radical can be either as shown in [9] or [10].

[9] $2PhHg\cdot \rightarrow Ph_2Hg + Hg$

[10] $PhHg\cdot \rightarrow Ph\cdot + Hg$

Reaction 9 implies that equimolar amounts of diphenylmercury and mercury are formed and that the quotient mol Hg/mol $PhHgCH(SPh)_2$ = 0.5. This is true for PhHg radicals produced by the electrochemical reduction of dilute solutions of phenylmercury halides in ethereal solvents (16). In this work, the quotient was often >0.5 (see Table 3) and mol Ph_2Hg < mol Hg suggesting that reaction 10 is also an important route to metallic mercury.

A third possible reaction pathway for the phenylmercury radical is reaction with solvent, which would explain the formation of PhHgCl in methylene chloride. Similarly, PhHgSPh could result from abstraction of a PhS· radical from the starting mercurial by PhHg·.

[11] $PhHg\cdot + PhHgCH(SPh)_2 \rightarrow PhHgSPh + PhHg\dot{C}H(SPh)$

An alternative route to PhHgSPh *viz.* intramolecular PhS migration to mercury is discussed below.

(b) PhS Migration to Mercury

The migration of an RS substituent from α-carbon to a transition metal has been observed to occur readily (1–4) and, in the case of mercury derivatives, is a possible route to PhHgSPh.

[12] $PhHgCH(SPh)_2 \rightarrow PhHgSPh + PhS\ddot{C}H$

This intramolecular rearrangement invokes the formation of the carbene, $PhS\ddot{C}H$, previously trapped as an adduct with cyclohexene (17). When the decomposition of $PhHgCH(SPh)_2$ was carried out in refluxing cyclohexene or in benzene/cyclohexene none of the expected adduct, 7-phenylmercaptonorcarane, could be detected. It therefore appears that PhS migration to mercury plays an unimportant role in the de-

composition of $PhHgCH(SPh)_2$ and the formation of PhHgSPh is best explained by direct attack of PhHg· on the mercurial.

(c) Symmetrization of $PhHgCH(SPh)_2$

The formation of $(PhS)_2Hg$ is more difficult to rationalise. It is well known that unsymmetrical mercurials, RHgR′, have a strong tendency to symmetrize to give R_2Hg and $R_2'Hg$ (ref. 11, pp. 364–402). In the case of $PhHgCH(SPh)_2$, symmetrization followed by PhS migration to mercury is a possible source of $(PhS)_2Hg$.

[13] $2PhHgCH(SPh)_2 \rightarrow Ph_2Hg + Hg[CH(SPh)_2]_2$

[14] $Hg[CH(SPh)_2]_2 \rightarrow (PhS)_2Hg + 2PhS\ddot{C}H$

The unsymmetrical mercurial does not, however, form $(PhS)_2Hg$ even in refluxing solvents (Table 2) and thus this route to $(PhS)_2Hg$ can be discounted. Finally, it was shown in independent experiments that $(PhS)_2Hg$ is not formed by the disproportionation of PhHgSPh either in toluene or methylene chloride.

Conclusion

The products of the decomposition of the mercurials, $Hg[CH(SPh)_2]_2$ and $PhHgCH(SPh)_2$, in various solvents are best rationalised by postulating initial homolytic fission of a Hg—$CH(SPh)_2$ bond. In the case of the unsymmetrical derivative, the well-known affinity of mercury for sulphur is demonstrated, but the formation of Hg—S products apparently does not occur via intramolecular migration. Thus these mercurials, unlike the analogous haloalkyl compounds, are not useful as carbene transfer reagents.

Vibrational spectra and normal coordinate analysis of crystalline lithium metasilicate

V. DEVARAJAN AND H. F. SHURVELL[1]

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received January 12, 1977

V. DEVARAJAN and H. F. SHURVELL. Can. J. Chem. **55**, 2559 (1977).

Infrared and Raman spectra of polycrystalline lithium metasilicate have been recorded. A vibrational assignment in terms of the various symmetry species of the unit cell group, C_{2v}, has been made. A normal coordinate analysis of the unit cell vibrations at the centre of the Brillouin zone ($k = 0$) was carried out to support the assignment and provide descriptions of the vibrational modes. The results are discussed in the light of previous normal coordinate calculations on the isolated metasilicate chain.

V. DEVARAJAN et H. F. SHURVELL. Can. J. Chem. **55**, 2559 (1977).

On a enregistré les spectres infrarouges et Raman du métasilicate de lithium en phase polycristalline. Une analyse des coordonnées normales de vibration du cristal, dans l'approximation de $k = 0$, a permis de relier les bandes observées dans les spectres aux diverses espèces de symétrie du groupe de la maille élémentaire, tout en fournissant une description détaillée des modes normaux. Les résultats des calculs sont comparés à ceux obtenus précédemment pour une chaîne métasilicate isolée.

Introduction

The vibrational spectra of metasilicate (SiO_3) chains are of interest since they form the structural unit of many glasses, and studies of these chains give an indication of structural disorders in the glasses. Recently, Brawer and White (1, 2) recorded the Raman spectra of a number of meta and disilicates in both crystalline and glassy states. By comparing the spectra obtained from these two states and carrying out simple force field calculations on isolated silicate chains and sheets, they were able to study the structural disorders in several alkali silicate glasses. Although the conclusions reached by Brawer and White are qualitatively correct, there is a need for a more complete investigation of the vibrational spectra and force fields of crystalline meta and disilicates. We are not aware of any previous detailed study on lithium metasilicate.

In the present work, we have recorded the ir and Raman spectra of crystalline lithium metasilicate (Li_2SiO_3) and have carried out a normal coordinate analysis of the vibrations at the centre of the Brillouin zone ($k = 0$) in order to support the vibrational assignments, and give qualitative descriptions of the normal modes.

Crystal Structure and Vibrations

Lithium metasilicate, Li_2SiO_3, belongs to the orthorhombic system with four molecules per crystallographic unit cell. The space group is C_{2v}^{12} ($Cmc2_1$) (3–5). However, the primitive (Bravais) cell contains only two molecules. The structure contains double $(SiO_3)_n$ chains running parallel to the c_0 axis. The projection of the orthorhombic unit cell along its c_0 axis is shown in ref. 3. Figure 1 illustrates an $(SiO_3)_n$ chain.

There are twelve atoms per primitive unit cell giving rise to thirty-six vibrations including three acoustic modes. The factor group is C_{2v} and the distribution of the thirty-six vibrations into the various symmetry species can be made using the procedures of Adams and Newton (6) and Fateley *et al.* (7). The result of this analysis is

$$\Gamma_{vib}^{C_{2v}} = 10A_1 + 8A_2 + 8B_1 + 10B_2$$

Further division of the vibrations into internal and external vibrations of the SiO_3 double chain and the identification of their symmetry species can be made using the method due to Adams and Newton (6). The results are given below:

Motion	Species
Internal vibrations (chain)	$6A_1 + 4A_2 + 4B_1 + 6B_2$
Librations (chain)	$1A_2$
Translations (Li and chain)	$3A_1 + 3A_2 + 3B_1 + 3B_2$
Acoustic modes	$1A_1 + 1B_1 + 1B_2$
Total	$10A_1 + 8A_2 + 8B_1 + 10B_2$

[1]To whom all correspondence should be addressed.

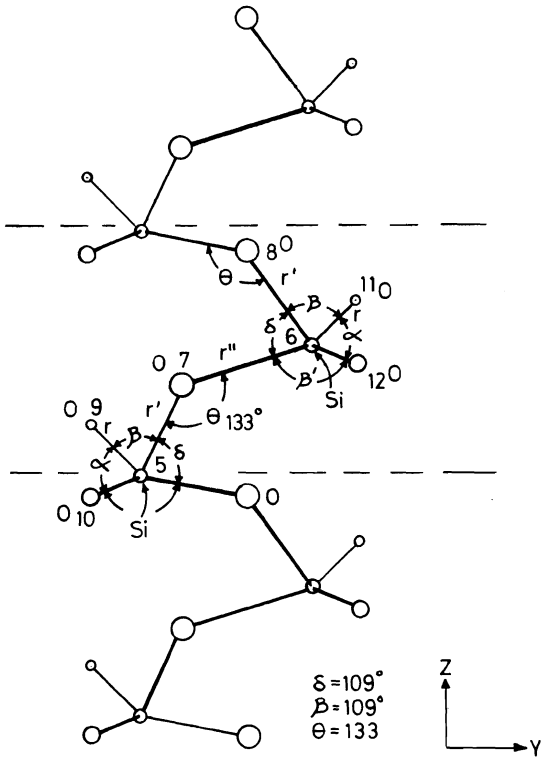

FIG. 1. An $(SiO_3)_n$ chain in the Li_2SiO_3 crystal.

Excluding the acoustic modes we should be able to observe $9A_1 + 8A_2 + 7B_1 + 9B_2$ vibrations in the spectra. All modes are Raman active, while the A_2 species modes are inactive in the infrared. Although longitudinal optical modes are allowed in the Raman spectrum of noncentrosymmetric crystals, it was not possible to identify any of these modes in the present work.

Experimental

Lithium metasilicate (Li_2SiO_3) was obtained in powder form from Alfa Products and used without further purification. The infrared spectra of the compound in Nujol mulls and KBr or CsI pellets were recorded using a Perkin-Elmer model 180 spectrometer. No important differences were observed between these spectra. The infrared spectrum is shown in Fig. 2.

Raman spectra were recorded in the polycrystalline form as a powder and as a solid formed from slowly cooling a melt. The Raman instrument consists of a Jarrell-Ash 25-100 monochromator, a cooled RCA C3103-02 photomultiplier, and photon counting electronics. The 514.5 nm line of an argon ion laser was used as the excitation line, at a power of 500 mW. A filter was not used, since plasma lines were not observed in the spectra. Although it was not possible to grow a single crystal of Li_2SiO_3, a Wollaston prism was mounted in front of the entrance slit of the monochromator to detect any polarization effects. In fact, some of the weaker bands did show some enhancement for certain orientations of the prism, or the solid sample formed from the melt. These intensity effects can be seen in Fig. 3. However, these partial depolarization measurements did not enable us to identify the A_1 modes. Table 1 contains a listing of the observed infrared and Raman wavenumbers. The selection of several very weak features for inclusion in Table 1 was based on their consistent appearance in a number of spectra obtained from different samples.

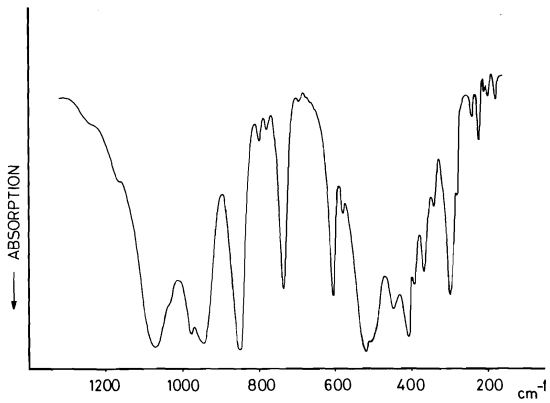

FIG. 2. The infrared spectrum of a CsI pellet of Li_2SiO_3.

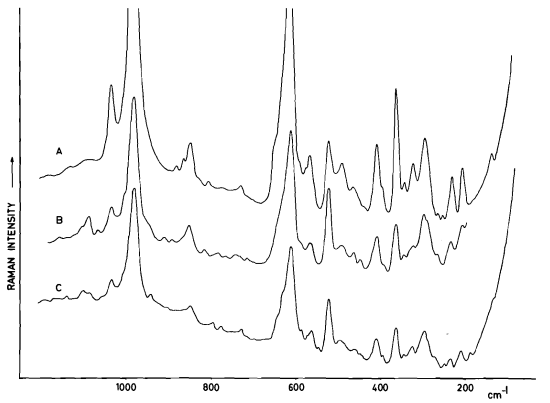

FIG. 3. Raman spectra of solid Li_2SiO_3 obtained by cooling a melt. Traces A and B were obtained by using parallel and perpendicular orientations, respectively, of a Wollaston prism analyser. Trace C was obtained using a different orientation of the sample with perpendicular orientation of the prism.

Vibrational Assignment

Lack of polarization measurements makes it difficult to assign the vibrational frequencies to specific symmetry species of the C_{2v} factor group. However, it is possible to identify the A_2 species as they are present in the Raman spectra, but absent in the infrared. A possible assignment can be made in terms of group frequencies of the

[b]The numbering of force constants is given in Table 2.

metasilicate chain and the Li—O polyhedra. By using the concept of internal coordinates and the symmetry of the chain in the crystal, we can predict the distribution of stretching, bending, and torsional modes into various symmetry species of the factor group C_{2v}. It is more difficult to identify the frequencies and symmetry species corresponding to the external modes involving the motion of lithium atoms. However, some characteristic frequencies and force constants of the Li—O polyhedra are available in the literature (8, 9) and these may be used for assignment purposes.

General valence force constants for the SiO_4 tetrahedra and Li—O polyhedra were taken from the literature (9, 10) and a preliminary normal coordinate analysis (see next section) was carried out on the unit cell. It was then possible to associate the observed frequencies with the corresponding calculated frequencies. The calculated frequencies were evaluated according to the symmetry species and this enabled us to assign the observed frequencies. Although the above-mentioned process appears crude, it is unlikely to produce any large error in the internal vibration region for the following reasons: (*1*) Although the force constants were transferred from similar molecules they are unlikely to be changed in any drastic way in the new environment. (*2*) The change in geometry, which is included in the kinetic energy term, can account for the observed splitting and shifts in

the frequencies. (*3*) Because there is only one chain per primitive unit cell there are no complications of correlation splitting. The tentative assignments thus made are given in Table 1.

Normal Coordinate Analysis

The normal coordinate analysis of the crystal vibrations at the centre of the Brillouin zone ($k = 0$) was carried out following the Wilson **FG** matrix procedure adapted to crystals by Shimanouchi *et al.* (11). The internal coordinates used are based on the SiO_3 chain and the Li—O polyhedra. The SiO_3 chain coordinates are shown in Fig. 1. In the Li—O polyhedra, only Li—O stretching coordinates were used. The cartesian symmetry coordinates corresponding to the C_{2v} factor group, which help in reducing the dimensions of the secular equation to be solved, were constructed using the usual projection operator techniques (11).

The force constants used to set up the potential energy matrix were of the general valence type. As the SiO_3 chain is made up of SiO_4 tetrahedra, force constants for the SiO_4 group were taken from the work of Devarajan and Funck (10). The lithium atom is surrounded by five oxygen atoms. Of these, four lie at distances of approximately 2.0 Å from the lithium atom, whereas the fifth is at a distance of 2.6 Å. In the work of Jungerman (9), the value of the Li—O stretching force constant for a distance of 2.0 Å is given as 0.3 mdyn $Å^{-1}$. For 2.6 Å, the value is practically zero. A total of thirty-six force constants were used for the preliminary calculations which were used for the assignment of the observed frequencies. In the next step, the force constants were adjusted on a trial and error basis, allowing for the different Si—O bond lengths in the chain and the different Li—O distances. The Jacobian elements $\partial\nu/\partial f$ further aided the adjustment procedure by indicating the value and direction (positive or negative) by which the force constants should be changed. After several calculations, the agreement between the observed and calculated frequencies improved to a satisfactory level, without introducing unrealistic values for any force constants. Considering the approximations and uncertainties involved, it was felt that it would not be worthwhile attempting any further refinement of the force constants.

Potential energy distributions in terms of force constants were also calculated. All the above-mentioned calculations were carried out using the modified versions of computer programs AXSMZ and LSMX of Shimanouchi (12). The final set of force constants and their values are given in Table 2. The observed frequencies, calculated frequencies with descriptions of the normal modes and important contributing force constants are given in Table 1.

TABLE 2. General valence force constants for lithium metasilicate

Number	Description of force constant	Vaue[a]
1	f_{D1}(Li—O str, 2.02 Å)	0.35

[a]Stretching and stretch–stretch interaction constants are in mdyn/Å; bending and bend–bend interaction constants are in mdyn-Å; stretch–bend interaction constants are in mdyn.

Discussion

In a recent paper, Brawer (1) calculated the frequencies and intensities in the Raman spectrum of the metasilicate chain in some alkali metasilicate glasses and crystals. He used a central Si—O stretching force constant $k =$ 5.0 mdyn $Å^{-1}$ and a non-central Si—O force

constant of $0.17k$. The Si—O—Si bending force constant was neglected. Bilton *et al.* (13) used $f_{Si-O} = 4.0$ mdyn Å^{-1}, $f_{O-Si-O} = 0.3$ mdyn Å^{-1}, and $f_{Si-O-Si} = 0.03$ mdyn Å^{-1} in a simplified calculation on the silicate chains in the pyroxene minerals enstatite and augite. Another normal coordinate calculation on silicate chains was carried out by Etchepare (14) using force constants taken from the earlier work of Siebert (15).

It is difficult to compare the results of the present complete unit cell calculation with the previous calculations on isolated chain models. However, it appears that our results do not agree at all well with this earlier work. There may be several reasons for this. The vibrational frequencies and assignments on which the previous workers based their calculations may not have been reliable. The simple force fields used are probably inadequate and the isolated metasilicate chain model may not be applicable to lithium metasilicate.

It can be seen in Table 1 that the frequencies assigned to Si—O stretching modes have contributions from bending force constants. This is expected in view of the chain structure. The Li—O stretching modes all lie below 500 cm^{-1} and couple with chain bending modes.

Conclusions

A fairly complete assignment of the unit cell vibrations of crystalline lithium metasilicate has been made. The observed coincidences between Raman and infrared wavenumbers for the normal modes is in agreement with the reported C_{2v} factor group. Although the results of the normal coordinate calculations reported here do not agree with previous calculations on isolated metasilicate chains, it is felt that the present results are more reliable, since they correlate well with experimentally observed frequencies and are based on a complete unit cell model.

The simple short range general valence force field used in this work appears to be adequate. However, the inclusion of additional long range forces would no doubt further improve the calculation. It is hoped that the more complete force field reported here for the metasilicate chain structure might be useful for further studies of glasses containing this structural unit.

RODERICK E. WASYLISHEN and BRIAN A. PETTITT. Can. J. Chem. **55**, 2564 (1977).

Deuterium nmr spin–lattice relaxation times have been measured for dilute solutions of adamantane-d_{16} in CH_2I_2, $CHBr_3$, CCl_4, $CHCl_3$, and CH_2Cl_2. The reorientation correlation times, τ_2, calculated from the experimental data are used to calculate τ_J, the angular momentum correlation times, assuming both the *J*-diffusion and Hubbard relations. The derived τ_J values suggest that adamantane executes small step diffusion in CH_2I_2 and $CHBr_3$, and large step diffusion in CCl_4, $CHCl_3$, and CH_2Cl_2. The calculated τ_J values do not appear to be related to the mean times between collisions calculated using a hard sphere model. Both variable solvent and variable temperature experiments indicate 1 ps/cP for the viscosity dependence of the adamantane reorientation time, about 1/36th the value predicted using the familiar Stokes–Einstein equation.

Carbon-13 and ^1H nmr T_1 data indicate that reorientation of hexamethylenetetramine in H_2O (28 ps/cP), $CHCl_3$ (27 ps/cP), and $CHBr_3$ (18 ps/cP) is severely hindered because of intermolecular hydrogen bonding.

RODERICK E. WASYLISHEN et BRIAN A. PETTITT. Can. J. Chem. **55**, 2564 (1977).

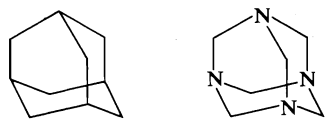
On a mesuré des temps de relaxation spin–réseau par rmn du deutérium pour des solutions diluées d'adamantane-d_{16} dans CH_2I_2, $CHBr_3$, CCl_4, $CHCl_3$ et CH_2Cl_2. On a utilisé les temps de corrélation de réorientation, τ_2, calculés à partir des données expérimentales, pour calculer, τ_J, les temps de corrélation de moment angulaire en utilisant à la fois les relations de diffusion *J* et de Hubbard. Les valeurs τ_J suggèrent que l'adamantane exécute de petits pas de diffusion dans le CH_2I_2 et le $CHBr_3$ et de grands pas de diffusion dans le CCl_4, le $CHCl_3$ et le CH_2Cl_2. Il ne semble pas qu'il y ait de relation entre les valeurs de τ_J calculées et les temps moyens entre les collisions calculés en utilisant un modèle de sphère dure. Des expériences où l'on a fait varier soit le solvant soit la température indiquent que la dépendance qui existe entre la viscosité et le temps de réorientation de l'adamantane est de 1 ps/cP soit environ 1/36ème de la valeur prédite utilisant l'équation bien connue de Stokes–Einstein.

Des données de T_1 obtenues par rmn du ^{13}C et du ^1H indiquent que la réorientation de l'hexaméthylènetétramine dans H_2O (28 ps/cP), $CHCl_3$ (27 ps/cP) et $CHBr_3$ (18 ps/cP) est très empêchée à cause de liaison hydrogène intramoléculaire.

[Traduit par le journal]

Introduction

Adamantane (Fig. 1*a*) and hexamethylenetetramine, HMTA, (Fig. 1*b*) belong to the molecular point group T_d, but their approximate sphericity makes them especially suitable for studies on molecular rotation. Rotational and translational motions in the solids have been studied (1, 2) and ^{13}C relaxation work on adamantane (3) in CS_2 at one temperature has been interpreted in terms of rotational diffusion. Results are presented here from experiments on the viscosity and temperature dependence of the spin–lattice relaxation times of these molecules, and interpreted in terms of some current theoretical ideas on molecular rotations in liquids.



a *b*

FIG. 1. Structure of (*a*) adamantane, (*b*) hexamethylenetetramine.

Theory

The simplest model for the rotation of spherical molecules, beginning with the original work of Bloembergen, Purcell, and Pound (4),

assumes that the sphere is embedded in a continuous fluid medium and reorients in small, random jumps. A critical feature of the model is the boundary condition requiring that the fluid velocity at the surface of the sphere is equal to the velocity of the surface. The calculation can be repeated with the more general boundary condition requiring the fluid velocity at the surface to be some fraction, κ, of the surface velocity.

$$[1] \qquad \boldsymbol{v}(\boldsymbol{r}) = \kappa\boldsymbol{\omega} \times \boldsymbol{r}$$

where $\boldsymbol{r}$ is a vector from the centre of the sphere to an arbitrary point on its surface, $\boldsymbol{\omega}$ is the angular velocity of the sphere, $\boldsymbol{v}$ is the velocity of the fluid, and $\kappa \in [0,1]$. The rotational friction coefficient is then calculated by pretending that the angular velocity is $\kappa\boldsymbol{\omega}$, and the usual expression for the reorientation correlation time becomes

$$[2] \qquad \tau_2 = \frac{4}{3}\frac{\pi r^3 \kappa \eta}{kT}$$

where η is the shear viscosity.

The factor κ has been introduced in other ways. Gierer and Wirtz (5) argued that the molecule changes the viscosity of the fluid in its neighbourhood to $\eta' = \kappa\eta$ and give a procedure for calculating the 'microviscosity factor', κ, which is not very successful in practice (6). Kivelson *et al.* (7) have given the expression

$$[3] \qquad \kappa = \frac{3}{4}\frac{1}{r^2}\frac{\langle T^2\rangle}{\langle F^2\rangle}$$

relating κ to the mean-square torque, $\langle T^2\rangle$, and mean-square force, $\langle F^2\rangle$, on the molecule; which is as yet untested due to the difficulties in determining the latter two quantities from realistic potentials. It seems best at this stage to regard κ as an empirical parameter, with $\kappa = 1$ representing the usual 'stick' condition and $\kappa = 0$ the 'slip', or inertial, condition.

To determine whether or not a small step diffusion model is appropriate, Wallach and Huntress (8) examined the ratio of the observed to the inertial reorientation times. A variant of this idea is given here. The average (in a Maxwellian distribution of energies) of the time required for a spherical molecule to rotate through angle θ is

$$[4] \qquad \tau_{FR} = \theta\left(\frac{2I}{\pi kT}\right)^{1/2}$$

where I is the moment of inertia. In an unambiguous case of small step diffusion, $\tau_2 = 1/6R$, $R = \langle\Delta\theta^2\rangle/2\tau_2$, and $\langle\Delta\theta^2\rangle^{1/2} = \theta = \sqrt{3}/3$ radians is the root-mean-square angle diffused through in time τ_2. According to this argument, $\chi = \tau_2/\tau_{FR}$ must be substantially greater than unity for rotations slow enough to be small step diffusion; *i.e.*

$$[5] \qquad \chi = \left(\frac{3\pi}{2}\right)^{1/2}\tau_2^* \gg 1$$

where $\tau^* = \tau(kT/I)^{1/2}$ is a reduced time.

The work of Gordon (9) and McClung (10) extending the diffusion model to steps of arbitrary size appears to be quite successful for small molecules (11). In this theory, the molecule is assumed to rotate inertially in steps that are interrupted by instantaneous collisions that randomize the magnitude and direction of the angular momentum (J-diffusion), the time of a collision after the previous one being assumed to follow a Poisson distribution. The central feature of the J-diffusion model is a relationship between τ_2 and the angular momentum correlation time, τ_J, which for spheres is (10, 12)

$$[6] \qquad \tau_2^* = \tau_J^* X/(1 - X)$$

where

$$[7] \qquad X = \frac{1}{5}\left\{1 + 4\sum_{a=1}^{2} b^2[1 - F(b)]\right\}$$

$$[8] \qquad F(b) = \pi^{1/2} b \exp(b^2)\,\mathrm{erfc}\,(b)$$

$$[9] \qquad b = (2)^{-1/2}\tau_J^* a$$

and erfc (Z) is the complementary error function (13).

One clear virtue of this theory is that it includes the small step diffusion limit for $\tau_2^* \gg \tau_J^*$, in which case eq. 6 reduces to the Hubbard relation (14)

$$[10] \qquad \tau_2^*\,\tau_J^* = 1/6$$

In fact, it suggests placing the boundary between 'small' and 'large' step angular diffusion in the neighbourhood of $\tau_2^* = 2.5$ where the Hubbard and J-diffusion relations begin to diverge significantly (ref. 12, Fig. 1). Equation 5 shows that this is a stronger statement than the χ-test.

A model due to Ivanov (15, see also 16) allows for stochastic rotation in jumps of arbitrary size, but assumes that the time required to make a jump is small compared to the time between jumps; *i.e.* the rotation is severely hindered. The

TABLE 1. Characteristic times in the rotation of CCl_4 (ps)

Temperature (°C)	τ_2 (exp)	τ_J Exp.	τ_J *J*-diffusion	τ_J Hubbard	β^{-1}
−11	2.76	0.0857	0.085	0.0818	0.098
30	1.72	0.133	0.131	0.113	0.108
46	1.48	0.151	0.151	0.125	0.110

important relationship here is

$$[11] \qquad \tau_2 = \frac{\beta^{-1}}{1 - A_2}$$

where β is the jump rate and

$$[12] \qquad A_2 = \frac{1}{5}\left\langle \frac{\sin 5\theta/2}{\sin \theta/2} \right\rangle$$

an average over a distribution of jump angle θ. Steele (16) calculated

$$[13] \quad A_2 = \frac{1}{5}\{1 + 2[e^{-\langle\theta^2\rangle/2} + e^{-2\langle\theta^2\rangle}]\}$$

for a gaussian distribution of jump angle with rms value $\langle\theta^2\rangle^{1/2}$. This is a two parameter theory and thus a measured value of τ_2 must be accompanied by an assumed value of β or $\langle\theta^2\rangle^{1/2}$. β can be identified with the collision frequency, but this is a doubtful concept for hindered rotation.

The independent binary collision approximation for a rough sphere fluid (17) provides a theoretical means for determining β. Within the terms of the *J*-diffusion model, the identification $\tau_J = \beta^{-1}$, the mean time between collisions, can be made because collisions are responsible for changes in angular momentum. For collisions of molecules of type *b* on a molecule of type *a*, this theory gives

$$[14] \qquad \beta_{ab} = \left(\frac{8\pi kT}{\mu_{ab}}\right)^{1/2} n_b \sigma_{ab}^2 g(\sigma_{ab})$$

where μ_{ab} is the reduced mass of the (*a*,*b*) pair, n_b is the number density of *b*, $\sigma_{ab} = \frac{1}{2}(\sigma_a + \sigma_b)$ is the collision diameter, and $g(\sigma_{ab})$ is the radial distribution function for *b* on *a* at the point of contact.

Table 1 summarizes the work of Gillen *et al.* (11) on CCl_4 and includes values of β^{-1} for which $g(\sigma)$ was calculated in the Percus–Yevick approximation for the hard sphere model (18) with $\sigma = 5.46$ Å calculated from atomic volume increments (19). The agreement with the *J*-diffusion predictions of τ_J is excellent, and the comparison between τ_J and β^{-1} is quite reasonable considering the simplicity of the rough hard sphere model. For the continuous potentials of real fluids, a collision is not an instantaneous event and the correlated binary collisions are important (17).

Experimental

Adamantane (99+%, Gold Label) and HMTA (99+%) were obtained from Aldrich Chemical Company.

Adamantane-d_{16} was purchased from Merck, Sharp and Dohme.

All solvents were available commercially, and when available spectro-quality solvents were used.

All spin–lattice relaxation rates were measured using the inversion–recovery pulse sequence ($d - 180° - t - 90°$), where d is a delay time ($d > 5T_1$) and t is a variable time. T_1 values were calculated from the slope of a plot of $\ln(\langle M_z\rangle_0 - \langle M_z\rangle)$ *vs.* t (20). Deuterium relaxation rates of adamantane-d_{16} were measured at 10 MHz on a Bruker B-KR322 variable frequency spectrometer. Proton-decoupled ^{13}C nmr spectra were obtained on a Varian CFT-20 spectrometer (8 mm variable temperature probe). Full *n*0*e* factors were measured for the methylene carbons of adamantane and HMTA in all solutions using the gated proton decoupler on the CFT-20 with $d \simeq 10T_1$ (21).

Viscosities were measured using an Ostwald viscometer and density bottles.

Results and Discussion

In Table 2, the ^2H spin–lattice relaxation times of perdeuteroadamantane in five halomethanes at 23°C are listed. τ_2's were calculated from the usual expression (20, 22)

$$[15] \qquad \frac{1}{T_1} = \frac{3\pi^2}{2}\left(\frac{e^2qQ}{h}\right)^2 \tau_2$$

with $e^2qQ/h = 174$ kHz, the value for cyclohexane (23); and τ_J's were calculated from these according to the *J*-diffusion and Hubbard relations with $I = 373.7$ amu Å^2. These are accompanied by mean times between collisions, β^{-1}, calculated from eq. 14 using Lebowitz's solution of the Perkus–Yevick equation for mixtures of hard spheres (24). For comparison,

the corresponding quantities for the pure solvents are included. A plot of the adamantane τ_2's *vs.* viscosity gives a straight line with a slope of approximately 1 ps/cP, whereas eq. 2 with $\kappa = 1$ and $V = (4/3)\pi r^3 = 147.2$ Å^3 (19) gives 36 ps/cP.[1] This indicates that the reorientation of adamantane in these solvents is in a near 'slip' condition, *i.e.* essentially inertial. In general, the τ_2's of adamantane-d_{16} are similar to those of the solvents. It is a little slower than CH_2Cl_2, $CHCl_3$, and CCl_4, where it is only 1 to 1.5 Å larger in diameter and has a larger moment of inertia; whereas it is a little faster than $CHBr_3$ and CH_2I_2, which have larger moments of inertia.

The τ_J data and the success of the J-diffusion model with CCl_4 (11) suggest that adamantane executes large angle inertial steps in CH_2Cl_2, $CHCl_3$, and CCl_4; but crosses the boundary into small step diffusion in the much more viscous $CHBr_3$ and CH_2I_2. The β^{-1}'s, which are strongly affected by the number densities, do not follow the trend expected from the J-diffusion model for adamantane. The hard sphere and J-diffusion models have numerous assumptions that could produce this discrepancy, and it would be foolhardy to attach significance to it. If experimental τ_J's become more available in the literature, the general order of magnitude accuracy of β^{-1} should be encouragement to pursue better values of this quantity.

In Table 3 deuterium T_1 values for 0.2 M adamantane-d_{16} in CCl_4 are given at several different temperatures. Plotting τ_2 *vs.* η/T gives a slope of approximately 1 ps/cP when applied to a temperature of 23°C, in agreement with the result obtained by varying the viscosity at constant temperature (Fig. 2).

TABLE 3. Deuterium T_1 values for 0.2 M adamantane-d_{16} in CCl_4

Temperature (°C)	T_1[a] (s)	τ_2 (ps)
71.6	1.38	1.62
70.4	1.39	1.60
59.2	1.34	1.66
49.4	1.16	1.92

23.9	1.05	2.12

[a]Error in T_1 is less than 10%.

^{13}C spin–lattice relaxation times for ≤ 0.5 M solutions of adamantane and HMTA at 24.5 ± 2°C are given in Table 4. The τ_2's obtained for adamantane in $CDCl_3$ and $CHBr_3$ are slightly less than those obtained from the deuterium data (Table 2). Although there are several sources of error in the τ_2's (the experimental error in the T_1's, the assumed quadrupole coupling constant, and r_{CH}), the lower values for adamantane relative to adamantane-d_{16} are qualitatively consistent with the lower moment of inertia.

The temperature dependence of ^{13}C T_1's for 0.5 M solutions of HMTA in D_2O and 0.4 M solutions of HMTA in $CHBr_3$ were measured. From plots of τ_2 *vs.* η/T, straight lines were obtained and the slopes, when applied to 25°C, gave viscosity dependences of 27.8 ± 3 ps/cP and 18.3 ± 2 ps/cP, respectively. Atomic volume increments (19) gave $V = 130.8$ Å^3 for HMTA, which implies a viscosity dependence of 32

[1]In the disordered α-phase each adamantane molecule is in a cubic lattice (2, 25). If one assumes 74% of the available space in the cubic lattice is occupied by spheres, then $V = 150.5$ Å^3 from the measured density of α-adamantane (25).

ps/cP.[2] A value of 27 ps/cP was calculated from the work of O'Reilly and Petersen (27) on HMTA in $CDCl_3$.

Thus, the observed τ_2's for HMTA in D_2O and $CDCl_3$ suggest that the rotation obeys a near stick condition; that is, it is consistent with the small step diffusion model. However, the well known complexities of hydrogen bonding (28) are not adequately represented by such a simplistic model of the boundary. The rotation may be within the scope of the Ivanov jump model, but no reasonable argument was found for choosing jump rates or rms jump angles.

The steeper slope observed for HMTA in chloroform compared to HMTA in bromoform suggests chloroform is a better proton donor than bromoform and hence forms stronger hydrogen bonds with HMTA. This suggestion is consistent with conclusions reached by Paterson and Cameron (29).

[2]HMTA crystallizes in the body centered cubic space group (2, 26); assuming 68% of the available space is occupied by spheres gives $V = 118.9$ Å^3, significantly smaller than the value calculated using the parameters of Edward (19). Using the above value of V, and eq. 2 with $\kappa = 1$ gives a viscosity dependence of 28.9 ps/cP.

Acknowledgements

We wish to thank Dr. Ronald Dong for carrying out the deuterium nmr measurements, Mr. Werner Danchura for the moment of inertia calculations, and Mr. Doug Durnin for the viscosity measurements.

Motion of the SO_3^-NH radical trapped in potassium sulfamate. Electron spin resonance dipolar coupling tensors for the motionless radical

L. BONAZZOLA, J. P. MICHAUT, AND J. RONCIN

Laboratoire de Résonance Electronique et Ionique (Associé au CNRS), Université de Paris-Sud, 91405 Orsay, France

Received January 12, 1977

L. BONAZZOLA, J. P. MICHAUT, and J. RONCIN. Can. J. Chem. **55**, 2570 (1977).

The temperature dependence of the esr couplings in SO_3^-NH radical trapped in potassium sulfamate single crystals allows the study of the motion of this radical in the matrix and the determination of N and H dipolar tensors corresponding to the motionless radical. These values are compared with different theoretical calculations.

L. BONAZZOLA, J. P. MICHAUT et J. RONCIN. Can. J. Chem. **55**, 2570 (1977).

Les mouvements du radical SO_3^-NH piégé dans une matrice monocristalline de sulfamate de potassium sont étudiés à partir de la variation du couplage rpe avec la température. On détermine les tenseurs dipolaires des H et N relatifs au radical immobile et on les compare aux valeurs obtenues par différentes méthodes théoriques.

Introduction

It has been shown in a recent paper (1) on the study by epr of $SO_3^-NH_2^+$ radicals trapped in a single crystal of sulfamic acid, that the motion undergone by the radicals may be determined from the variations of the coupling tensors of H and N atoms as a function of temperature. The H and N tensors of the radical at rest may also be determined. A similar study on SO_3^-NH radicals trapped in a single crystal of potassium sulfamate is presented in this paper. The aim of this work was first to give another example of a coupling tensor for a radical at rest, for which the unpaired electron is borrowed by N atom. Secondly the knowledge of such coupling tensors from which contributions due to the motion of the radicals have been eliminated, making comparison between experimental and calculated hyperfine anisotropic coupling tensors possible.

Experimental

Potassium sulfamate was obtained from the neutralization of sulfamic acid by potassium hydroxide. Single crystals were grown from aqueous solutions by slow cooling. SO_3^-NH radicals are formed by irradiating potassium sulfamate crystals with a ^{60}CO source. The spectra were recorded on a JEOL ME IX spectrometer at five temperatures (4, 87, 156, 223, 293 K). Since the variations of the couplings as a function of temperature are weak, and since the accuracy in the determination of the coupling tensors depends strongly on the degree of orthogonality of the reference frame axes, the orientation of the crystal has to be exactly the same at all temperatures. Therefore, we first recorded the spectra at all temperatures for a rotation around one particular axis, then the spectra at all temperatures around a second axis, and so on. At 4 K, for technical reasons, the experiments were performed on a different single crystal, which was rotated about its crystallographic axes.

Results

Our results are reported in Tables 1 and 2. The signs of the principal values of the total hyperfine tensors have been assigned in the following way:

All H couplings have been taken to be negative as usual in the case of protons of π radicals.

It is generally assumed that the largest principal value (X) of the N tensor is positive. It is less obvious how to attribute the signs of the two other principal values Y and Z of the N tensor. It can be seen from Table 2 that the principal value Y does not vary significantly with temperature, within experimental errors. As shown previously (5), this indicates that torsional oscillations of the N—H group occur around an axis which is the principal direction corresponding to Y. This principal direction (0.900,0,0.435, Table 2) is parallel within 3° to the S—N bond of the undamaged molecule in the crystal (0.9202,0,0.3915, ref. 4). Let X_0 and Z_0 be the values of X and Z for a rotation angle $\theta = 0$ around the S—N bond. For a rotation angle θ, $Z = Z_0 \cos^2\theta + X_0 \sin^2\theta$, *i.e.* $Z = Z_0 + (X_0 - Z_0)\sin^2\theta$; $X_0 - Z_0$ is positive because $|Z_0| < |X_0|$ and $X_0 > 0$; when the temperature increases the experimental results show that $|Z|$ increases (Table 2). Consequently, Z has to be positive.

Let us now assume that the N tensor has a nearly cylindrical symmetry when the radical is at rest. Then, Z_0 and Y_0 (*i.e.* the values of Z and

Y for the motionless radical) are equal. Since Y does not vary with temperature, $Y = Y_0$. It is seen from Table 2 that $|Z| < |Y|$; as Z is positive and decreases when the temperature decreases, Z_0 and consequently Y_0 have to be negative. With the present choice of the signs of X, Y, and Z, the N isotropic coupling (11.9 ± 0.15 G, Table 2) is smaller than the coupling found by Rowland (13.5 G, ref. 2) and Morton *et al.* (13.1 G, ref. 3) who postulated that the three principal values of the N tensor were positive.

Discussion

Structure and Position of the Radical SO_3^-NH in the Crystal

It is easy to determine the angle SNH in the SO_3^-NH radical from the directions of the S—N bond (*i.e.* the direction of the principal value Y of the N tensor), and the N—H bond

(*i.e.* the direction of the principal value C of the H tensor). The angle SNH is found to be 117°. As shown previously (6), the angle HNH of $\dot{N}H_2$ radical is 110° and the N isotropic coupling is 11.3 G. The spin density in the $2p_z$ orbital of SO_3^-NH is only about 0.9 and N isotropic coupling of SO_3^-NH (to be compared to NH_2) is 11.9/0.9 = 13.2 G. This result confirms that the N isotropic coupling increases with the angle XNY as predicted previously on the basis of an INDO calculation (6).

From crystallographic data (4) and esr results at 4 K, it can be shown that the H atom in the SO_3^-NH radical is in the plane determined by the S, N, and one O (say O_I) atoms of the parent molecule (Fig. 1). The S—N bond is a ternary symmetry axis for the SO_3 group in the molecule and hence, making the assumption that the skeleton of the molecule is not affected by the radiation process, there should be two other equivalent positions for the H atoms in the plane SNO_{II} or in the plane SNO_{III} (see Fig. 1) The esr spectra show that these two positions are not occupied. The reason for this is the existence of steric hindrance in the crystal as shown by Fig. 2, on which we have plotted the distance between H and its two closest neighbours in the crystal, an O atom of an adjacent molecule (O_{II}') and a K ion (K_I), as a function of the angle θ representing the rotation of the NH group around the S—N bond (θ = 0 being the equilibrium position found experimentally). Because of the symmetry in the crystal, only the region $0 < \theta < 180°$ is illustrated. The sum of van der Waals radii is 2.6 Å for the atoms O and H and 2.53 Å for the atom H and the K cation. From Fig. 2, it can be seen that both the conditions OH ≥ 2.6 Å and KH ≥ 2.53 Å are satisfied only when $-30° < \theta < 30°$. It is clear that the radical cannot have more than one equilibrium position in the crystal but that torsional oscillations around S—N are allowed.

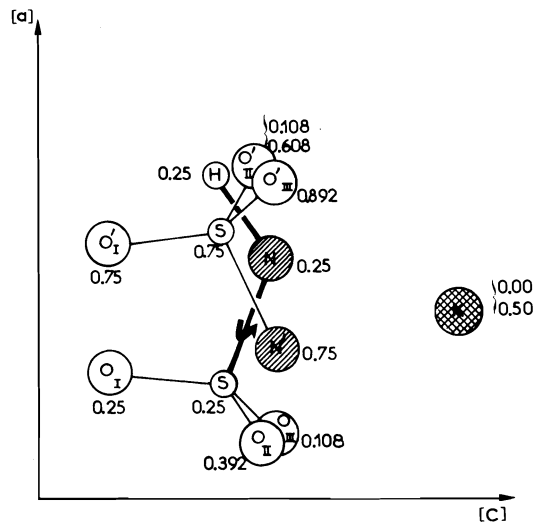

FIG. 1. Projection on the (010) plane of the SO_3^-NH free radical and its nearest neighbours in the *a*, *b*, *c* reference frame. The numbers correspond to the *b* coordinates of atoms. Steric hindrance occurs with O_{II}' and K.

Motions of SO_3^-NH in the Crystal

We have already remarked that esr results show that a torsional oscillation of N—H group occurs around the S—N bond, and that this N—H group has only one equilibrium position in the crystal. Therefore, the potential governing the oscillations of N—H around S—N may be represented by $V(\theta) = (V_0/2)(1 - \cos\theta)$, where V_0 is the maximum barrier height. Using the method already described (5), V_0 and the coupling tensor of the motionless radical may be determined. Very good agreement between experimental and calculated anisotropic tensor principal values is achieved (see Table 2) using the following parameters: V_0 = 6.5 kcal/mol; X_0 = 30.1 G (principal direction parallel to the orbital); Y_0 = 14.9 G (principal direction parallel to the S—N bond). In the same way, the proton dipolar coupling is influenced by the torsional oscillations of the N—H group (5). Thus, V_0 and the H dipolar tensor for the motionless radical may also be obtained from the data relative to the H tensor (Table 1): A_0 = −15.5 G (principal direction along the N—H bond); B_0 = 0.3 G (principal direction parallel to the π orbital). The maximum barrier height V_0 found from the data for the H tensor is slightly lower than from the N data. The first determination is very probably the more accurate because the variations of couplings with temperature are larger for N than for H.

The physical meaning of the barrier V_0 in the formula $V(\theta) = (V_0/2)(1 - \cos\theta)$ is questionable. As shown on Fig. 2, the torsional oscillations are not forbidden by steric hindrance for $-30° < \theta < 30°$. For small oscillations, the potential well has certainly an intramolecular origin. Because of the three possible equilibrium positions due to the symmetry of the radical, a better representation of the potential might be $V(\theta) = (V_0/2)(1 - 3\cos\theta)$. For small values of

θ, the relation:

$$(V_0/2)(1 - \cos\theta) \simeq (V_0/2)(1/9)(1 - \cos 3\theta)$$

is approximately valid, and the physically meaningful barrier would be in fact 6.5/9 = 0.75 kcal/mol. This value is the height of the barrier which would hinder the free rotation of N—H bond if there were no steric hindrance in the trapping matrix.

Dipolar Coupling Tensors for the Radical at Rest

The N and H dipolar coupling tensors corresponding to motionless radicals have been derived from the temperature dependence of the couplings. They are respectively 30.1, −14.9, −15.2 G for N and −15.5, 0.3, 15.2 G for H. These tensors are given in Table 3 for $SO_3^-NH_2^+$ and SO_3^-NH radicals for a unit spin density. They may be compared to the calculated tensors.

(a) Nitrogen Coupling Tensor

Let us neglect the small π density in the bonds and consider the nitrogen tensor to be cylindrical. The theoretical principal values of N and H tensors given in Table 3 have been calculated by different methods: using Roothan and Clementi waves functions (7) (column 4, Table 3); the Mc Connel and Strathdee formula (8) using a Slater orbital (column 5, Table 3); by the same formula using a linear combination of Slater type orbitals (column 6, Table 3); in a spin unrestricted LCAO-MO-SCF approach using contracted gaussian-type functions for the expansion of molecular orbitals (10) (column 7, Table 3).

Good agreement between experiment and calculations is found only in the first and third cases. In the last calculation (column 7), the authors of ref. 10 claim to have found good agreement between experimental and theoretical tensors but, in fact, it is because the motion of the radical has not been accounted for.

(b) Proton Coupling Tensor

In the same way, the calculated H tensors are given in Table 3. Columns 5 and 6 concern $\dot{N}H_2$ radical, and column 7 concerns NH_3^+. Poor agreement is found between calculated and experimental tensors. This may be due to the poor accuracy of the wave function as soon as the distance from the N nucleus increases.

Conclusion

Measurements of the temperature dependence of the H and N couplings in SO_3^-NH radicals

trapped in a single crystal of potassium sulfamate allow the determination of the relative signs of the principal values of the N coupling tensor; the study of the torsional oscillations of the NH group around the S—N bond; the determination of the N and H dipolar coupling tensors corresponding to the radical at rest. These are the tensors that are to be compared to the theoretical calculations of the couplings. Let us note that these tensors, from which the contributions due to the motion of the radicals have been eliminated, may only be obtained in cases when there is a measurable temperature dependence of the couplings. As seen from Tables 1, 2 even measurements at 4 K do not give directly the tensor of the motionless radical because the zero point residual motions may give contributions of a few gauss (for N, $X_0 = 30.1$ G, $Y_0 = -14.9$ G, $Z_0 = -15.2$ G to be compared to the experimental values at 4 K, $X_0 = 26.7$ G, $Y_0 = -14.9$ G, $Z_0 = -11.8$ G).

The ^{1}H nmr spectrum of [10]-paracyclophane has been recorded at 220 MHz and the methylene protons assigned on the basis of homonuclear decoupled spectra. Local anisotropic contributions to chemical shifts for protons sited above or near the aromatic ring of [10]-paracyclophane have been calculated using a classical model previously proposed by Grant. The residual incremental shift was shown to follow the Waugh–Fessenden–Johnson–Bovey classical ring current model, but the loop separation originally invoked was shown to be unnecessary. These corrected ring current contributions also correlate very well with the quantum-mechanical approach of Haigh and Mallion.

ARVIND AGARWAL, JOHN A. BARNES, JOHN L. FLETCHER, MICHAEL J. MCGLINCHEY et BRIAN G. SAYER. Can. J. Chem. **55**, 2575 (1977).

On a enregistré le spectre rmn du proton du [10]paracyclophane à 220 MHz et on a attribué les protons méthylènes en se basant sur le spectre découplé d'une façon homonucléaire. Des contributions anisotropes locales aux déplacements chimiques des protons situés au-dessus ou près du cycle aromatique du [10]paracyclophane ont été calculées en faisant appel à un modèle classique proposé antérieurement par Grant. On a montré que l'augmentation résiduelle du déplacement suit le modèle classique de courant de cycle de Waugh–Fessenden–Johnson–Bovey mais on a trouvé qu'il n'est pas nécessaire de faire appel à la séparation de boucle qui avait été invoquée originalement. Ces contributions de courant de cycle corrigées offrent aussi une très bonne corrélation avec l'approche de mécanique quantique de Haigh et Mallion.

[Traduit par le journal]

Introduction

The deshielding of aromatic protons relative to olefinic protons has occupied the attention of nmr spectroscopists and theoreticians for almost 20 years, and the collective wisdom of these deliberations has been the subject of a number of reviews (1–3). Following the ideas of Pauling (4), the ring current concept was applied to benzene by Pople (5) who treated the system as possessing a point dipole located at the centre of the ring and showed that this would account for the downfield shift of benzene relative to ethylene. In a now classic paper, Waugh and Fessenden (6) developed their "Free Electron Model" in which the π-electrons were regarded as being analogous to a simple current loop and, using the well-established methods of classical electrodynamics (7), they were able to evaluate the induced field at any point whether in or out of the plane of the ring. The downfield shift of the benzene protons predicted by an in-plane current loop was 2.79 ppm and, in order to correlate with the then accepted shift of ~1.5 ppm (*i.e.*, the difference between benzene and the vinylic protons of 1,3-cyclohexadiene), Waugh and Fessenden separated the π current into two loops, one above and one below the ring plane; the separation between the loops was *empirically* adjusted to be 1.28 Å, and a very convenient tabulation of chemical shift increments calculated on this basis has been provided by Johnson and Bovey (8). Following the quantum mechanical treatment of McWeeny (9), Haigh and Mallion (10, 11) have presented a similar tabulation; both Johnson and Bovey (8) and Haigh and Mallion (11) approaches allow the evaluation of chemical shifts for out-of-plane protons.

In their original paper, Waugh and Fessenden (6) applied their theory to out-of-plane protons and they presented experimental and calculated nmr shift data on [10]-paracyclophane. Although

[1]To whom all correspondence should be addressed.
[2]Revision received March 23, 1977.

their 40 MHz spectrum clearly showed the presence of high field protons in the methylene chain, the resolution was insufficient to allow any definitive assignments to be made. We now present the 220 MHz spectrum of [10]-paracyclophane (Fig. 1) in which the five aliphatic resonances are clearly resolved. These data allow a critical and comparative evaluation of both Johnson–Bovey (8) and Haigh–Mallion (11) ring current theories.

Experimental

Proton spectra were obtained on a Varian HR 220 spectrometer operating at 220 MHz and 18°C. Proton homonuclear decoupled spectra were obtained on a Varian HA 100 spectrometer operating at 100 MHz at 35°C using standard techniques.

Concentrations of 0.1–0.2 *M* were used in $CDCl_3$ as solvent, and the peak positions were extrapolated to infinite dilution; TMS was used as an internal standard.

A section of the 220 MHz spectrum is shown in Fig. 1, and the data are listed in Tables 1 and 2.

Results and Discussion

1. The ^1H Nuclear Magnetic Resonance Spectrum of [10]-Paracyclophane

As previously mentioned, a number of models have been proposed to account for the shifts of aromatic protons. The now widely accepted free electron model was used in an attempt to rationalize the shifts of the out-of-plane protons in [10]-paracyclophane; however, the lack of resolution in the 40 MHz spectrum made quantitative verification of the theory somewhat hazardous. Nevertheless, constant application to a variety of aromatic systems has almost bestowed an imprimatur upon the theory. However, with the technological advances of two decades, a number of discrepancies are now apparent. Thus, in 1957 there was no method of reliably determining the structure of [10]-paracyclophane (or at least the most populated conformation in solution) and the authors had to estimate the proton positions relative to the aromatic ring by using Fisher–Hirschfelder models and trying to allow for the twisting motions of the decamethylene bridge. It is perhaps not surprising that the original assignment of the methylene protons as following the sequence: α, β, δ, γ, ε is incorrect. The 220 MHz spectrum, together with the homonuclear decoupling data, unequivocably established the order of the proton resonances as: α, β, γ, δ, ε with the ε protons at highest field.

δ	0.73	0.82	1.13
ε	0.51	0.59	1.10

TABLE 2. Experimental vicinal coupling constants and calculated dihedral angles

Positions	*J* (Hz)	φ (Calculated, deg): Karplus	φ (Calculated, deg): Refined
Ring–α			155.5
α–β	6.2±0.1	62±3 or 112±3	62
β–γ	6.0±0.1	68±4 or 106±4	106
γ–δ	7.1±0.1	38±2 or 133±2	133
δ–ε	7.6±0.1	24±3 or 144±3	141.3

2. The Structure of [10]-Paracyclophane

The apparent inconsistency discussed above prompted us to direct our investigations toward a quantitative appraisal of the ring current tabulations (8, 11). Consequently, it was essential to know the structure of the molecule. In the absence of crystallographic data, it is necessary to calculate the molecular conformation of lowest energy, and for such systems a high degree of success has been achieved using Allinger's molecular mechanics calculations (12, 13). Thus, the correlation between the predicted and ob-

served structures of [8]-paracyclophane is very good and so one can confidently use this approach as the best available at present. Since the ^1H nmr spectrum shows only five methylene environments, the molecule is conformationally mobile on the nmr time scale; indeed Allinger calculated that the molecule would have a rather flat potential energy minimum allowing considerable amplitude of ring oscillation. The preferred conformation for [10]-paracyclophane was calculated to have a non-planar aromatic ring in which the *para*-carbons were displaced upwards through 8.4°, while the α-carbons were displaced downwards through 4.4° (13). The molecular mechanics method also predicted the conformation of the decamethylene chain, and an attempt to verify these predictions was undertaken using the Karplus theory (14, 15) relating vicinal coupling constants ($^3J_{HH}$) and dihedral angles which has been extensively used in structure determinations (16).

The dihedral angles of the most populated conformation were determined from the coupling constants obtained from the homonuclear decoupled spectra using the following relationship:

$$[1] \qquad J = A + B\cos\phi + C\cos 2\phi$$

where $A = 7$ Hz, $B = -1$ Hz, $C = 5$ Hz, a set of empirically derived parameters which refer to an H—C—C—H fragment in a carbon chain (17). The observed coupling constant is in fact an average of four coupling constants whose dihedral angles of interaction are ϕ, $120 + \phi$, ϕ, and $|120 - \phi|$. Then,

$$[2] \quad J_{obs} = 0.25(2J_{\phi} + J_{\phi+120} + J_{120-\phi})$$

with this consideration, eq. 1 becomes:

$$[3] \quad J_{obs} = 2.5\cos^2\phi - 0.25\cos\phi + 5.75$$

The calculated dihedral angles are listed in Table 2. In this analysis it was assumed that each $-CH_2-CH_2-$ unit could be regarded as an $[AX]_2$ system, since the chemical shifts of the protons in a given methylene group are dynamically averaged to give only one value and the chemical shift differences between adjacent methylene groups are relatively large. While this simplification is justifiable for the $J_{\alpha\beta}$, $J_{\beta\gamma}$, and $J_{\gamma\delta}$ couplings such is not the case for the $J_{\delta\varepsilon}$ case which is more correctly regarded as $[[AB]_2]_2$; consequently the dihedral angle predictions from $^3J_{H_\delta H_\varepsilon}$ are distinctly less reliable than are the others. Of course, the dihedral angle between the aromatic ring and the α-carbon—β-carbon bond is not evaluable directly as there is no appropriate coupling constant. This angle was approximated from a Fieser model and refined as outlined below. Now, accepting the values for the non-planarity of the ring and C_α atoms as calculated by Allinger (13), use of molecular models made it relatively easy to decide the unique combination of dihedral angles which allowed the construction of the decamethylene bridge. Finally, a molecular geometry programme (18) was used empirically to adjust not only the dihedral angles (within the calculated error limits) but also the aliphatic C—C—C bond angles (to parallel the behaviour of the corresponding angles in [8]-paracyclophane) such that the ε-carbon coordinates (x,y,z) corresponded to the ε′-carbon coordinates $(\bar{x},\bar{y},z)$ as required by C_2 symmetry. Throughout these calculations, the aromatic ring carbon–carbon bond lengths were taken as 1.39 Å, the exocyclic sp^2–sp^3 bond as 1.50 Å and the C—C and C—H bonds in the polymethylene chain as 1.54 and 1.08 Å respectively. Each H—C—H plane was positioned orthogonally to the appropriate C—C—C plane. It is gratifying that these experimental data, *viz.*, coupling constants, reinforce Allinger's theoretically predicted molecular geometry as shown by comparing Fig. 2 with Fig. 2 in ref. 13.

3. *Comparison of Ring Current Theories*

These structural data allow the evaluation of incremental shifts for the methylene protons lying out of the aromatic ring plane using both the semiclassical (8) and quantum mechanical (11) approaches. In order to predict chemical shifts relative to TMS it is necessary to select the "standard methylene shift" appropriate to the system. Typical values for large cycloalkanes average to 1.30 ppm (19), and this is the standard we have used. The chemical shifts thus predicted by the Johnson–Bovey (8) and Haigh–Mallion (11) tabulations for the α, β, γ, δ, and ε protons are presented in Table 1, and may be compared with the experimental values in the same table. It is apparent that, while both methods are qualitatively very useful, the quantitative agreement with the experimental shifts is not uniform throughout all positions which experience the effect of the ring current. The semi-classical method shows good agreement for protons held

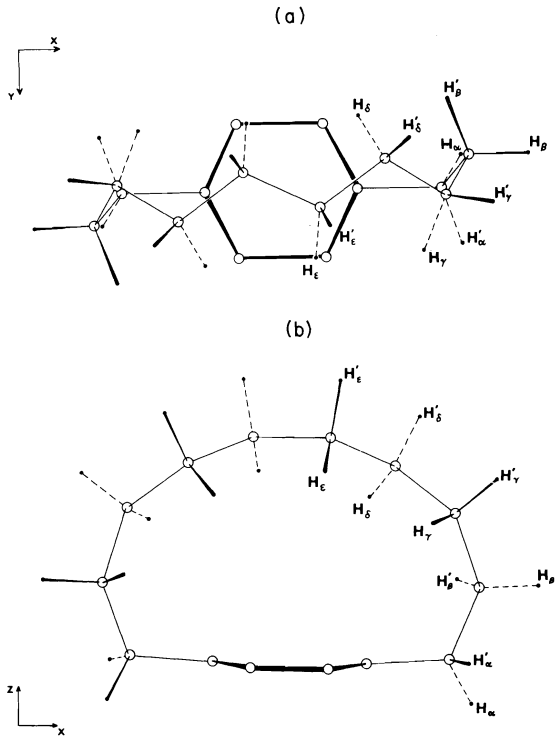

FIG. 2. Preferred conformations of [10]-paracyclophane: (*a*) plan, (*b*) elevation, the hydrogen atom positions are shown in perspective relative to the carbon atom to which they are attached.

over the centre of the ring, but becomes less reliable as the value of ρ increases and *z* decreases. However, the quantum mechanical approach gives adequate agreement in these latter regions but seriously underestimates the upfield shifts of the protons directly above the ring, as was originally inferred (10, 20). The work of Rose (21) on pyridylphenanthrenes also supports this generalization.

4. Local Anisotropic Contributions

It was apparent that the present ring current theories did not provide a complete rationale for the experimentally observed shifts and that some other important contribution had been overlooked. It had earlier been suggested by Pople (22, 23) that local anisotropic effects were a large contributing factor to the deshielding of the protons in benzene. Furthermore Barfield, Grant, and Ikenberry (24) have now successfully demonstrated that local anisotropic contributions to chemical shifts may be evaluated using the ^{13}C chemical shielding tensors so painstakingly obtained by Waugh and co-workers (25, 26) using proton-enhanced nuclear induction spectroscopy (27). Grant's data (24) clearly show that local anisotropic contributions cannot be ignored for in-plane protons in condensed aromatic systems,[3] and we now extend these calculations to out-of-plane protons.

Using the analogy of a current circulating in a loop of wire (24), the proton shielding component, σ_{ii}^{H}, is given by

$$[4]\quad \sigma_{ii}^{H} = \frac{a}{\pi}\frac{1}{[(a+\rho)^2 + z^2]^{1/2}} \times \left[K + \frac{a^2 - \rho^2 - z^2}{(a-\rho)^2 + z^2}\cdot E\right]\cdot \sigma_{ii}^{C}$$

where a is the radius of circulation about each carbon atom, taken as 0.47 Å (24), ρ and z are the usual cylindrical coordinates, and K and E are complete elliptical integrals of the first and second type with the argument

$$k^2 = \frac{4a\rho}{(a+\rho)^2 + z^2}$$

More simply, $\sigma_{ii}^{H} = G\sigma_{ii}^{C}$ where σ_{ii}^{H} and σ_{ii}^{C} are the proton and carbon shielding components and G is a geometric factor. The isotropic shielding, as measured in solution, is given by averaging the components

$$\langle\sigma^{H}\rangle = \tfrac{1}{3}[\sigma_{11}^{H} + \sigma_{22}^{H} + \sigma_{33}^{H}]$$

The ^{13}C shielding tensors used in this study are taken from refs. 25 and 26; values used for aromatic carbons bearing alkyl chains are those listed by Waugh for hexaethylbenzene, while those for aromatic carbons with hydrogen substituents are the average of the appropriate values from pentamethylbenzene and durene. To convert the values from shifts relative to benzene into absolute shifts, it is necessary to add 71 ppm to each ^{13}C shielding tensor (24). The local anisotropic contributions for each methylene proton brought about by circulations about each ring carbon in [10]-paracyclophane are presented in Table 3.

[3]A dipolar approximation presented in ref. 24 contains an algebraic error due to mis-evaluation of the elliptical integral power series. However, this does not materially affect the conclusions drawn previously, *i.e.*, it is unsafe to calculate chemical shifts for proximate protons using only a dipolar formula. For the situation in ref. 24, the correct dipolar formula is

$$\langle\sigma^{H}\rangle = \frac{a^2}{3r_{CH}^{\,2}}\left(\sigma_{11}^{C} + \frac{a}{r_{CH}}\cdot\sigma_{22}^{C} + \sigma_{33}^{C}\right)$$

5. Experimentally Determined Ring Currents

We can now define the ring current contribution (ΔRC) to the chemical shift as the difference between the experimental shift (δ) and that calculated by adding the local anisotropic contribution to the standard, *i.e.*,

$$[5] \quad (-\delta)_{\text{expt}} = -1.30 + \text{LA term} + \Delta\text{RC}_{\text{expt}}$$

These "experimentally determined ring current shifts" are listed in Table 3 together with ring current shifts calculated using the equation

$$[6] \quad \Delta = \frac{C}{[(a+\rho)^2 + z^2]^{1/2}} \times \left[K + \frac{a^2 - \rho^2 - z^2}{(a-\rho)^2 + z^2} \cdot E\right]$$

where $C = ne^2/6\pi M_e c^2 = 8.970$, where n is the number of circulating electrons of charge e and mass M_e, c is the velocity of light, ρ and z are the usual cylindrical coordinates, and a is the radius of circulation about the ring taken as 1.39 Å. In this case ρ and z are measured in Å rather than ring radii.

The quoted shifts are the average of two shifts Δ_1 and Δ_2 obtained by taking $z_1 = z + S/2$ and $z_2 = z - S/2$, where S is the separation of the current loops. It is necessary to accept that any ring current contribution calculated semi-classically must follow an equation of the type [6] where the only adjustable parameters are C and S. Waugh and Fessenden chose to adjust the separation of the loops, while Barfield, Grant, and Ikenberry adjusted both C and S. Our approach was to adjust the separation between the loops to get the best correlation between the "experimental ring current shifts" and the calculated shifts, and then to evaluate C empirically.

It is now apparent from our data that the arbitrary separation into two loops is not only unnecessary but is actually detrimental to the optimum fit. Now a plot (Fig. 3) of the $\Delta\text{RC}_{\text{expt}}$ values *vs.* calculated ring current by the Johnson–Bovey (8) method ($\Delta\text{RC}_{\text{J–B},S=0}$) provides a value for C, and follows the equation

$$[7] \quad \Delta\text{RC}_{\text{expt}} = 1.04\,\Delta\text{RC}_{\text{J–B},S=0} - 0.06$$

The correlation coefficient, $\bar{r}$, was found to be a maximum (0.9928) at $S = 0$; the correlation worsened very rapidly on invoking loop separation. Typically, $S = 1.0$ Å, $\bar{r} = 0.9461$; $S = 1.28$ Å (ref. 6), $\bar{r} = 0.8883$; $S = 1.63$ Å (ref. 24),

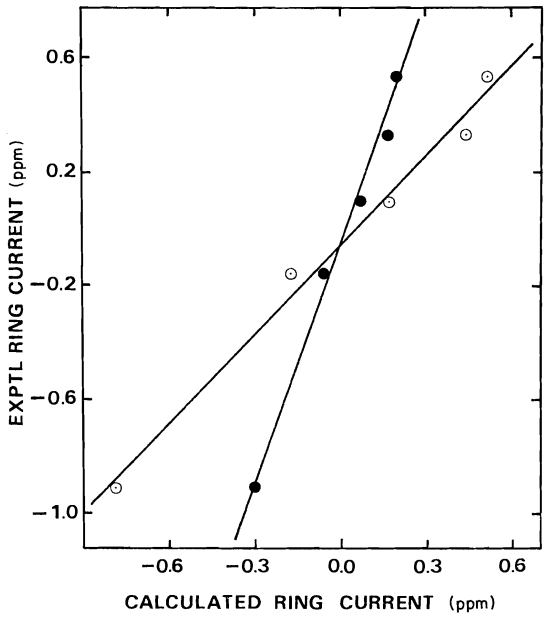

FIG. 3. Plot of experimental ring current (ΔRC_{expt}) *vs.* calculated ring current ($\Delta RC_{J-B,S=0}$, ○; and ΔRC_{H-M}, ●).

$\bar{r} = 0.7634$; $S = 2.0$ Å, $\bar{r} = 0.6161$. Therefore, the data force upon us the conclusion that the arbitary separation of the ring current into two loops is unnecessary; furthermore, the ring current increments derived by a semi-classical approach and those determined experimentally show good agreement.

A plot of measured chemical shift ($-\delta$) *vs.* calculated ring current ($\Delta RC_{J-B,S=0}$) also shows an interesting correlation, *viz.*,

$$[8] \quad (-\delta) = 1.57\,\Delta RC_{J-B,S=0} - 1.36 \qquad (\bar{r} = 0.9974)$$

Combining eqs. 5, 7, and 8, we see that

$$[9] \quad LA = 0.53\,\Delta RC_{J-B,S=0}$$

indicating that the ring current contribution to the incremental shift is of the order of 65%.

This whole postulate receives strong support from Dailey's work on magnetic anisotropy which showed that the ring current only contributes to the extent of ~60% to the chemical shifts of aromatic hydrocarbons (28).

Having shown that the experimental ring current shifts are readily rationalizable from the semi-classical viewpoint, it is of interest to determine whether any analogous correlation exists for the quantum mechanical theory. This latter theory has only one variable parameter which was obtained from a linear regression analysis of data for planar polycyclic aromatics.

A plot of our experimental ring current shifts against those predicted from the quantum mechanical approach shows excellent agreement ($\bar{r} = 0.9932$) and follows the equation

$$[10] \quad \Delta RC_{expt} = 2.73\,\Delta RC_{H-M} - 0.06$$

It will be noted that the predictions of the Johnson–Bovey (8) and Haigh–Mallion (11) tabulations differ by a factor of ~2.6 in the limit (11). Using our data (see Table 3) the following relationships were found

$$[11] \quad \Delta RC_{J-B,S=0} = 2.60\,\Delta RC_{H-M}$$

$$[12] \quad \Delta RC_{J-B,S=1.28} = 2.02\,\Delta RC_{H-M}$$

where $\bar{r} = 0.9998$ and 0.8938 respectively, thus reinforcing our earlier arguments dispelling the necessity for loop separation.

It is especially gratifying to see that the two entirely different models are compatible with the experimental data. Previous statements (11, 21) that the two theories are only applicable to specific spatial regions of the aromatic molecule are nullified when the correct ring current increments are evaluated. Thus previously published experimental ring currents which did not allow for the local anisotropic corrections would not be expected to fit either ring current model, except fortuitously.

One would have anticipated that eqs. 7 and 10 should have zero intercept since the overall chemical shift of any given methylenic proton is assumed to be a composite of only three terms *viz.*, LA and RC terms, which are of course position dependent, and the standard shift, which is the same for all protons in the chain. Since one obtains the identical non-zero intercept from both the semi-classical and quantum mechanical approaches, we propose that the standard methylene shift in chloroform be taken as 1.36 ppm rather than the initially chosen value of 1.30 ppm.

In the previous treatment of [10]-paracyclophane (6), the predicted shifts of the protons α to the ring gave such poor agreement that they were ignored, and these shifts were merely compared to the corresponding protons in ethylbenzene. However, the present approach adequately accounts for the α-CH_2 shift *without* invoking an inductive effect of the phenyl ring; that is, the inherent standard shift for the α-proton can still

be taken as 1.36 ppm. Thus, it would seem that the so-called inductive effect of the phenyl ring can be wholely attributed as being a manifestation of the anisotropic nature of the electron distribution within the ring.

In calculating incremental methylene proton shifts using a combination of local anisotropic and ring current contributions *from the aromatic ring*, we have assumed that local anisotropic contributions from atomic neighbours in the polymethylene chain are allowed for by suitable choice of a standard. One should point out[4] that whilst our determination of the local currents involves the use of the total carbon shielding tensor (the effect of the delocalised current being ignored), comparison of the isotropic ^{13}C shifts in benzene and for the C-2, C-3 resonances in cycloheptatriene shows that the delocalised effect must be relatively small.

We feel that this approach to the problem of the ring currents is valuable in that the investigation of the methylene protons is less hazardous than investigating the aromatic protons for which the choice of a standard shift is more difficult and controversial. An extension of the concepts developed here allows a study of ring currents in arene-metal π-complexes and this will be dealt with in a subsequent publication.

Conclusions

Present ring current tabulations do not allow for the local anisotropic contributions to the chemical shifts of protons in aromatic environments; independent calculation of these local anisotropic contributions allows the evaluation of corrected (experimental) ring current shifts. These corrected shifts were found to show simple relationships to both the quantum mechanical and semi-classical approaches; in each case, the correlation coefficients were excellent. However, the separation of the current loops in the semi-classical approach while aesthetically satisfying was shown to be unnecessary.

Acknowledgements

We wish to express our sincere gratitude to Professor Norman L. Allinger (University of Georgia) for his most generous gift of the sample of [10]-paracyclophane and for discussions on molecular geometry. We also wish to thank Dr. A. A. Grey for use of the 220 MHz spectrometer facilities (Ontario Research Foundation, Sheridan Park Research Centre, Mississauga, Ontario), Dr. F. G. Riddell (University of Stirling, Scotland) for helpful discussions, and our colleague Professor D. P. Santry for computational advice.

Financial assistance from the National Research Council of Canada is gratefully acknowledged.

[4]We thank a particularly diligent referee for this and other valuable comments on the manuscript.

The hydrolysis of substituted cyclopropyl bromides in water. IV. The effect of vinyl and methyl substitution on $\Delta C_p^{\ddagger}$[1]

SURENDRA SINGH[2] AND ROSS ELMORE ROBERTSON[3]

Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received August 27, 1976[4]

SURENDRA SINGH and ROSS ELMORE ROBERTSON. Can. J. Chem. **55**, 2582 (1977).

In this study of the effect of vinyl and methyl substitution on the rates of hydrolysis of cyclopropyl bromides in water, we examine the changes in $\Delta C_p^{\ddagger}$ with substitution and configuration. The unusual values of $\Delta C_p^{\ddagger}$ found by Ong and Robertson (Can. J. Chem. **52**, 2660 (1974)) for the hydrolysis of 2-*cis*- and *trans*-vinylcyclopropyl bromide are shown to be characteristic of the vinyl substituent and reflect either a transition state which corresponds to a low degree of charge separation or to internal cancellation due to the formation of an extended dienylic cation. The 2,3-*cis*,*cis*-dimethylcyclopropyl bromide gave a value of $\Delta C_p^{\ddagger} = -145$ cal mol^{-1} deg^{-1}, comparable to limiting values obtained for hydrolysis of 1- and 2-adamantyl nitrate. The corresponding value of $\Delta C_p^{\ddagger}$ for 2,3-*cis*,*trans*-dimethylcyclopropyl bromide (-56 cal mol^{-1} deg^{-1}) was less negative than for the 2,3-*trans*,*trans* isomer (-75 cal mol^{-1} deg^{-1}). The mechanistic implications are discussed.

SURENDRA SINGH et ROSS ELMORE ROBERTSON. Can. J. Chem. **55**, 2582 (1977).

Dans cette étude sur l'effet des substituants vinyle et méthyle sur les vitesses d'hydrolyse de bromures de cyclopropane dans l'eau, on examine les changements dans les $\Delta C_p^{\ddagger}$ en fonction de la substitution et de la configuration. On a montré que les valeurs inusitées de $\Delta C_p^{\ddagger}$ trouvées par Ong et Robertson (Can. J. Chem. **52**, 2660 (1974)) pour l'hydrolyse des bromures de vinyl-2 cyclopropane *cis* et *trans* sont caractéristiques du substituant vinyle et sont un reflet soit d'un état de transition qui correspond à un très bas degré de séparation de charge ou à une annulation interne due à la formation d'un cation diènyle étendu. Le bromure de diméthyl-2,3 cyclopropane *cis-cis* a une valeur de $\Delta C_p^{\ddagger} = -145$ cal mol^{-1} deg^{-1} qui peut se comparer avec les valeurs limites obtenues pour l'hydrolyse des nitrates d'adamantyle-1 ou -2. La valeur correspondante du $\Delta C_p^{\ddagger}$ pour le bromure de diméthyl-2,3 cyclopropane *cis-trans* (-56 cal mol^{-1} deg^{-1}) est moins négative que pour l'isomère 2,3 *trans-trans* (-75 cal mol^{-1} deg^{-1}). On discute des implications mécanistiques de ces résultats.

[Traduit par le journal]

This report on the hydrolysis of substituted cyclopropyl bromides is an outgrowth of an earlier study of the hydrolysis of 2-vinylcyclopropyl bromides (1). In that study, the values of $\Delta C_p^{\ddagger}$ for the hydrolysis of the *cis* and *trans* isomers were found to be -27 and -35 cal mol^{-1} deg^{-1}, respectively. Values of $\Delta C_p^{\ddagger}$ in this range for displacement of a bromide ion (as opposed to displacement of tosylate or methanesulfonate (2)) have been associated with a minimal charge development at the transition state for hydrolysis in water and in the absence of other evidence this was the interpretation proposed by Ong and Robertson. Certain theoretical calculations were seen to lend support to this hypothesis (3, 4), even though results obtained in different solvents suggested that under other conditions a greater degree of charge development might be expected (5, 6). Thus in a previous study on the solvolysis of substituted cyclopropyl bromides in acetic acid, Schleyer *et al.* had concluded that there was "considerable" charge development at the transition state (7). That different degrees of charge development at the transition state will be found with different solvents is altogether reasonable unless the transition state corresponds to a limiting case (8). However, the unusually "low" value of $\Delta C_p^{\ddagger}$ for hydrolysis of the 2-vinylcyclopropyl bromides in water was unexpected, hence this earlier work was extended to include a study of the hydrolysis of other substituted cyclopropyl bromides. Some of these results have been published (9, 10) and these together with the results from the present study are collected in Table 1.

As in the past, rate data were determined by a conductance method (2). The limiting factor in such a study is frequently the limited solubility

of the substituted compound. Our attempt to extend the study to *trans*-2,2,3-trimethylcyclopropyl bromide and *cis*-2,2,3-trimethylcyclopropyl bromide was thwarted by low solubility while the dimethyl substituted cyclopropyl bromides were found sufficiently soluble for our purpose.

The range of the temperature–rate study was about 30°C and the resulting data were fitted to the equation $\log k = A_1 + A_2/T + A_3 \log T$. The constants are collected in Table 2 and provide a means of interpolating rate constants and quasi-thermodynamic parameters.[5] Relative rates for hydrolysis in water are given in Table 3. We accept the hypothesis (5, 6, 11–14) that the activation process for the solvolysis of cyclopropyl halides in water as in other solvents involves anchimeric assistance from σ-bond interaction and electrocyclic ring opening (15, 16).

Substitution of carbonium ion stabilizing groups on the α-carbon of cyclopropyl bromide was known to have a relatively small effect on the rate of solvolysis (17, 18) and so was not investigated. In water, the relative effect of β-Me substitution on the rate of hydrolysis varied widely (Table 3). Such differences can be attributed to a combination of non-bonded interaction, facilitation of σ-bond participation, and variation in the probability of nucleophilic interaction (k_{2n}, ref. 8) as a consequence of the special configurational considerations imposed by the cyclopropyl structure and the requirement for opening of the ring. Dispersal of electron deficiency by substituents will have two effects on the observed rate: (*1*) to delay nucleophilic interaction and (*2*) to enhance the external effects of the charge of Br^-; the latter will result in more negative values of $\Delta C_p^{\ddagger}$, in water. Rate enhancement due to the vinyl group (280/3000)

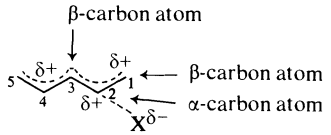
†Comparable value for 7 is 2.79×10^{-4} s^{-1}.

may be attributed to stabilization of the activated state by conjugation, but if the transition state resembled the extended ion:



the substitution of a methyl would be expected to cause a much larger increase in the rate, whereas dispersal of electron deficiency would result in large negative values of $\Delta C_p^{\ddagger}$ (10). Neither expectation is found (Fig. 1 *A*–1*F* and Table 2). The simpler explanation is that the presence of a β-vinyl substituent facilitates nucleophilic attack by water. The relative rate ratios are higher in *C* and *D* where methyl substitution is on the other β-C but the difference is hardly remarkable. Methyl-substitution on the vinyl group (*E*, *F*) results in reduced ratios both here and by comparison with the allylic system.[6] Even in the latter where there is minimal steric hindrance to nucleophilic attack, substitution of Me in the α or γ position results in a rate enhancement of only 720 (*cis*) and 620 (*trans*), respectively (Table 4). We note also that the presence of a vinyl group *per se* does not result in abnormally 'low' $\Delta C_p^{\ddagger}$ values here as is the case for the cyclopropyl system, although the value for **16** is somewhat less than that for **11**. From Table 5, it is obvious that the relative effect of methyl substitution is virtually independent of the ionizing properties of the solvolyzing medium. This fact is consistent with a small degree of charge development at the transition state.

The kinetic α-deuterium isotope effects found (Table 6) appear to support the same conclusion. In general such isotope effects reflect changes in hybridization and to a lesser degree the nature of incoming and leaving groups (20). The k_H/k_D values for this series are small, but due to the fact that the exocyclic bond in the cyclopropyl system is already close to being sp^2 hybridized, no large effect is likely to accompany activation. Our limited results confirm this expectation and no attempt was made to determine this effect in every case, since it follows that in this series the α-deuterium isotope effect is unlikely to be a useful mechanistic indicator.

Attempts to attach physical significance to the negative temperature coefficient of $\Delta H^{\ddagger}$ for ionogenic reactions in water began with a recognition of the unique nature of solvation of weakly polar solutes in water and the effect of charge development and temperature on what has been termed the hydrophobic solvation shell (2). Initially it was assumed that charge development in the activation process modified the complete solvent shell to a greater or lesser degree, depending on the degree of charge separation at the transition state. Such an interpretation is deficient in several respects. We have noted that a value of $\Delta C_p^{\ddagger}$ of about -30 cal mol^{-1} deg^{-1} does not depend on water structure. Further, there is evidence that the major component of $\Delta C_p^{\ddagger}$ associated with modification of water structure is caused by charge development on the anion (9). There is the possibility, suggested by

[6]E. C. F. Ko, unpublished work (University of Calgary).

TABLE 4. Relative rates of solvolysis of substituted allylchlorides and the heat capacities of activation (19)

Albery and Robinson (21), that ion-pair return could contribute a negative component to $\Delta C_p^{\ddagger}$, while partitioning between two possible mechanisms will make a positive contribution (22, 23). In spite of these possible complications this empirical coefficient is a useful indicator of mechanistic differences, particularly within a given series of related compounds (Table 2). While a value of $\Delta C_p^{\ddagger} \approx -80$ cal mol^{-1} deg^{-1} was considered limiting for displacement of a halide (2), and it was known that on destruction of the apparent water structure by the addition of >0.2 mole fraction of acetonitrile or ethanol, the corresponding $\Delta C_p^{\ddagger}$ now approached the 'base value' of −30 cal mol^{-1} deg^{-1}, large negative contributions to $\Delta C_p^{\ddagger}$ from ion-pair return, as postulated by Albery and Robinson, did not seem important. However with the discovery that 1- and 2-adamantyl nitrate gave a value of $\Delta C_p^{\ddagger}$ more negative than −130 cal mol^{-1} deg^{-1} (24) and 2,6-dimethylbenzyl nitrate gave a value of this coefficient in the same range compared to −101 cal mol^{-1} deg^{-1} found for 4-methylbenzyl nitrate (which we had previously regarded as reacting by an S_N1 mechanism (25)), the limiting value of $\Delta C_p^{\ddagger}$ for displacement in water was seen to be much more negative than previously suspected. Even making allowance for the unexplained −30 cal mol^{-1} deg^{-1} unrelated to water structure, these new large values of $\Delta C_p^{\ddagger}$ seemed far too large to be related to charge development on the anion, alone. While some contribution from ion-pair return could not be excluded and seemed plausible, this explanation is not without objection (24). If values of $\Delta C_p^{\ddagger}$ more negative than −130 cal mol^{-1} deg^{-1} be taken to signal front-side (*i.e.* limiting) displacement in water, then less negative values

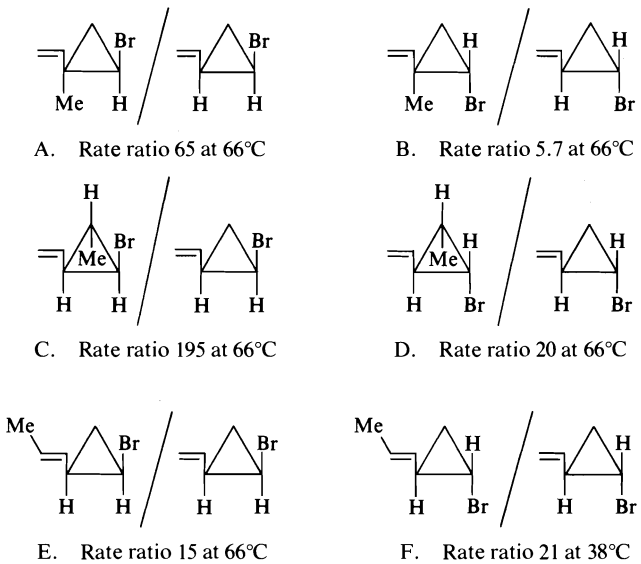

FIG. 1. Relative rates of hydrolysis for methyl substitution in a series of cyclopropyl bromides.

TABLE 5. Relative rates of solvolysis of the dimethylcyclopropyl derivatives in water and acetic acid with different leaving groups at 100°C

found in Table 2 for all save **3** are to be associated with a transition state where bond making has been initiated. In such cases there seems no reason to reject the hypothesis that the values of $\Delta C_p^{\ddagger}$ reflect the relative degree of charge development on the anion at the transition state. Thus **1** and **2** (Table 2) have values of $\Delta C_p^{\ddagger}$ about the same as found for MeBr (26) and hence reach the transition state at about the same degree of charge development while those reactants having a β-vinyl substituent (**5–10**) reach the transition state with a minimal charge separation. The 2,3-*trans,trans*-homologue with a value of $\Delta C_p^{\ddagger} = -75$ cal mol^{-1} deg^{-1} will have a charge development midway between **1**, **2**, and the 4-methylbenzyl nitrate which previously had been considered to react by an S_N1 mechanism.

As an alternative to this simple interpretation of the low $\Delta C_p^{\ddagger}$ values which characterize vinyl substitution, Singh has suggested (27) that the presence of a 2-vinyl substituent provides the possibility of approach to a dienylic cation of several forms depending on the stereochemistry at the 3–4 and 4–5 bonds. If there is 'considerable' charge development on Br^- at the transition state, it is conceivable that such an extended ion could shield or, through internal electrostatic interaction, largely reduce external effects. This balance between internal and external electrostatic effects contains a possible explanation for the difference in $\Delta C_p^{\ddagger}$ between *cis* and *trans* configurations for hydrolysis of crotyl (19) and cyclopropyl halides.

Experimental

In this work the monobromides were prepared by reduction of dibromo derivatives with tri-*n*-butyltin hydride (28, 29). The dibromides were prepared by addition of dibromo carbene to the appropriate olefin (30).

1,1-Dibromo-trans-2,3-dimethylcyclopropane

trans-2-Butene (100 g, 1.78 mol, K & K) and potassium *tert*-butoxide (76 g, 0.68 mol, Ventron Alfa Products) were placed in a 2 ℓ three-necked flask. Distilled bromoform (130 g, 0.52 mol, Fisher Scientific Co.) was added dropwise at about −30°C under a nitrogen atmosphere.

The mixture was stirred for 2 h after addition was complete. The temperature was raised slowly overnight and then the addition complex was hydrolyzed with 250 ml of water. The organic layer was separated and the aqueous layer was extracted with two 50 ml portions of pentane. The combined organic extracts were dried over anhydrous Na_2SO_4. The solvent was removed with a rotary suction evaporator and then distilled to give the product: bp 55°C /9 Torr.

2,3-cis,trans-Dimethylcyclopropyl Bromide

1,1-Dibromo-*trans*-2,3-dimethylcyclopropane (17.1 g, 0.075 mol) was reduced with tri-*n*-butyltin hydride (21.6 g, 0.075 mol) to give 2,3-*cis*,*trans*-dimethylcyclopropyl bromide: bp 40°C/20 Torr. It was further purified by preparative glc using a 30% FFAP column (20 ft, $\frac{3}{8}$ in. on 60–80 Chromosorb W). For preparative glc work, in general, the following conditions were used: flow rates, carrier gas $N_2 \simeq 25$ ml/min, $H_2 \simeq 20$ ml/min; temperatures inlet ≃ 150°C, oven ≃ 90°C, collector ≃ 120°C, detector ≃ 250°C.

Spectral data: $nmr_{TMS}(CCl_4)$ δ 2.55–2.70 (m, 1H, CHBr), 1.04–1.22 (m, 6H, $2CH_3$), 0.55–0.85 (m, 2H, ring protons); ms parent peak at *m/e* 148, 150 (1:1), base peak at *m/e* 69 and significant peaks at *m/e* 133, 135 (1:1), 82, 81, 80, 79, 68, 67, 53, 41, 39.

1-Deuterium-2,3-cis,trans-dimethylcyclopropyl Bromide

Spectral data: $nmr_{TMS}(CCl_4)$ δ 1.05–1.22 (m, 6H, $2CH_3$), 0.55–0.85 (m, 2H, ring protons); ms parent peak at *m/e* 149, 151 (1:1), base peak at *m/e* 70 and significant fragments at *m/e* 134, 136 (1:1), 82, 81, 80, 79, 69, 68, 54.

1,1-Dibromo-cis-2,3-dimethylcyclopropane

cis-2-Butene (100 g, 1.78 mol, K & K) and potassium *tert*-butoxide (76 g, 0.68 mol, Ventron Alfa Products) were placed in a 2 ℓ three-necked flask. Distilled bromoform (130 g, 0.52 mol, Fisher Scientific Co.) was added dropwise at about −25°C under a nitrogen atmosphere. The mixture was stirred for 2 h after addition was complete. The temperature was raised slowly overnight and then hydrolyzed with 250 ml of water. The organic layer was separated and the aqueous layer was extracted with two 50 ml portions of pentane. The combined organic solution was then dried over anhydrous Na_2SO_4. The low boiling fraction was removed with a rotary suction evaporator and then the residual was distilled to give the product: bp 50–56°C/10 Torr.

2,3-trans,trans-Dimethylcyclopropyl Bromide

1,1-Dibromo-*cis*-2,3-dimethylcyclopropane (40 g, 0.17 mol) was reduced with tri-*n*-butyltin hydride (50.6 g, 0.17 mol) to give the isomeric monobromides. The *cis*:*trans* ratio was 5:1 (by glc) bp 34–36°C/30 Torr. These two isomeric monobromides were then purified and separated through preparative glc using a 30% FFAP column (20 ft × $\frac{3}{8}$ in. on Chromosorb 60–80).

2,3-trans,trans-Dimethylcyclopropyl Bromide

Spectral data: $nmr_{TMS}(CCl_4)$ δ 2.13 (m, 1H, CHBr), 1.05–1.21 (m, 2H, ring protons), 1.09 (s, 6H, $2CH_3$); ms parent peak at *m/e* 148, 150 (1:1), base peak at *m/e* 69 and significant fragments at *m/e* 133, 135 (1:1), 82, 81, 79, 68, 67, 53, 41.

1,1-Dibromo-trans-2,3-methylvinylcyclopropane and 1,1-Dibromo-2-(1-propenyl)cyclopropane

trans-Piperylene (93 g, 1.37 mol, Aldrich) and potassium *tert*-butoxide (100 g, 0.98 mol, Ventron Alfa Products) were placed in a 2 ℓ three-necked flask. Freshly distilled bromoform (170 g, 0.67 mol, Fisher Scientific Co.) was added dropwise at about −20 to −30°C under N_2 atmosphere. After complete addition of the bromoform, the reaction mixture was stirred for 2 h at about −25°C. The temperature was then raised slowly overnight and the addition product was hydrolyzed with water. The organic layer was separated and the aqueous layer extracted with two 50 ml portions of pentane. The combined organic layer was dried over anhydrous Na_2SO_4 and the solvent was then removed by a rotary suction evaporator and the residual distilled to give the product: bp 60°C/7 Torr. This distillate on reduction gave four isomeric monobromides: *(1) 2,3-cis-vinyl,trans-methylcyclopropyl bromide, (2) 2,3-cis-methyl,trans-vinylcyclopropyl bromide, (3) 2-cis-(1-propenyl)cyclopropyl bromide, (4) 2-trans-(1-propenyl)cyclopropyl bromide.*

1,1-Dibromo-*trans*-2,3-methylvinylcyclopropane and 1,1-dibromo-2-(1-propenyl)cyclopropane (23 g, 0.09 mol) were reduced with tri-*n*-butyltin hydride (27.0 g, 0.09 mol) to give the four isomeric monobromides: bp 40°C/8 Torr, which were then separated and purified through preparative glc using a QF_1 column (20 ft × $\frac{3}{8}$ in. on 45–60 Chromosorb W).

2,3-cis-Vinyl,trans-methylcyclopropyl Bromide

Spectral data: $nmr_{TMS}(CCl_4)$ δ 5.22–5.60 (m, 1H, —CH═), 4.79–5.08 (m, 2H, ═CH_2), 2.80–2.94 (m, 1H, CHBr), 1.24 (d, 3H, CH_3), 0.84–1.44 (m, 2H, ring protons); ms parent peak at *m/e* 160, 162 (1:1), base peak at *m/e* 79, 81 (1:1) significant fragments at *m/e* 80, 77, 66, 65, 53, 51, 41, 39.

2,3-cis-Methyl,trans-vinylcyclopropyl Bromide

Spectral data: $nmr_{TMS}(CCl_4)$ δ 5.30–5.68 (m, 1H, —CH═), 4.92–5.16 (m, 2H, ═CH_2), 2.66–2.82 (m, 1H, CHBr), 1.16 (s, 3H, CH_3), 1.00–1.46 (m, 2H, ring protons). The mass spectrum was almost identical to that of 2,3-*cis*-vinyl,*trans*-methylcyclopropyl bromide.

2-cis-(1-Propenyl)cyclopropyl Bromide

Spectral data: $nmr_{TMS}(CCl_4)$ δ 5.36–5.72 (m, 1H, ═CH—), 5.00–5.28 (m, 1H, ═CH—), 2.86–3.08 (m, 1H, CHBr), 1.56–1.82 (d, 3H, CH_3), 1.16–1.82 (d, 3H, ring protons). The mass spectra were almost identical to that of 2,3-*cis*-vinyl,*trans*-methylcyclopropyl bromide.

2-trans-(1-Propenyl)cyclopropyl Bromide

Spectral data: $nmr_{TMS}(CCl_4)$ δ 5.26–5.66 (m, 1H, ═CH—), 4.82–5.12 (m, 1H, ═CH—), 2.50–2.68 (m, 1H, CHBr), 1.56–1.82 (m, 4H, CH_3 and one ring proton), 0.92–1.24 (m, 2H, CH_2).

The mass spectrum was almost identical to that of 2,3-*cis*-vinyl,*trans*-methylcyclopropyl bromide.

Product Analysis

Approximately 0.05 g $CaCO_3$, 1 ml water, and a glass bead together with 5–6 μl of the pure substrate were added to a small test tube and stirred. About 1 μl of the aqueous solution was injected onto a glc (on FFAP column 6 ft × $\frac{3}{16}$ in.). The test tube was sealed and placed in a bath at the appropriate temperature. After 1–2 half-lives, 1 μl of the solution was again injected on the glc under the same conditions. The solution was allowed to react for a further time corresponding to several half-lives and a further chromatogram obtained. The reference allylic alcohols were synthesized by standard reactions of alkyllithium on the appropriate aldehyde or ketone, and the resulting alcohols checked by mass spectrometry.

2,3-Dimethylcyclopropyl Bromides

The only product from the solvolysis of three isomeric monobromides (*cis-cis*, *trans-trans*, *cis-trans*) was found to be *trans*-α,γ-dimethylallyl alcohol. *cis*-α,γ-Dimethylallyl alcohol was not detected.

The *trans* and *cis*-α,γ-dimethylallyl alcohols were prepared by adding methyllithium to a mixture of *cis*- and *trans*-crotonaldehyde. The commercially available α,γ-dimethylallyl alcohol had similar retention time to those prepared in the laboratory.

2,2-Methylvinylcyclopropyl Bromides

The only product from both of these 2,2-methylvinylcyclopropyl bromides was found to be 3-methyl-1,4-pentadien-3-ol. The corresponding primary alcohol was not detected.

3-Methyl-1,4-dipenten-3-ol was prepared by the reaction of vinyllithium on methylvinylketone.

2,3-cis-Vinyl,trans-methylcyclopropyl Bromide

The only product of solvolysis of 2,3-*cis*-vinyl,*trans*-methylcyclopropyl bromide was probably 3,5-hexadiene-2-ol.

cis-2-(1-Propenyl)cyclopropyl Bromide

The products of solvolysis of 2-*cis*-(1-propenyl)cyclopropyl bromide were 1,4-hexadiene-3-ol and probably 3,5-hexadiene-2-ol.

Before ending this section, it must be emphasized that in almost all the cases, only the corresponding allylic alcohols were observed.

Studies of the rearrangements of aminoalkylsilanes to alkylaminosilanes

JAMES M. DUFF[1] AND ADRIAN G. BROOK[2]

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received January 10, 1977

JAMES M. DUFF and ADRIAN G. BROOK. Can. J. Chem. **55**, 2589 (1977).

A wide variety of aminoalkylsilanes (R_3SiCR_2NHR') are rearranged to the isomeric alkylaminosilanes ($R_3SiNR'CHR_2$) by traces of *n*-butyllithium. It is shown that an equilibrium exists between the isomeric amide ions (N^-) and carbanions (C^-) which are involved as intermediates in the rearrangement. The values of the equilibrium constants were determined for several systems and in one case the rates and activation parameters were obtained for both the forward and reverse directions. The overall kinetics were also investigated for several systems and kinetic parameters were obtained. In some cases anion isomerization was the rate-controlling step; in other cases the rate-controlling step was the proton transfer between the starting amine and the carbanion which leads to product.

JAMES M. DUFF et ADRIAN G. BROOK. Can. J. Chem. **55**, 2589 (1977).

On a montré qu'une grande variété d'aminoalkylsilanes (R_3SiCR_2NHR') se réarrangent en alkylaminosilanes isomères ($R_3SiNR'CHR_2$) sous l'influence de traces de *n*-butyllithium. On a montré qu'il existe un équilibre entre les ions amides isomères (N^-) et les carbanions (C^-) qui sont impliqués comme intermédiaires dans le réarrangement. On a déterminé les valeurs des constantes d'équilibre pour plusieurs systèmes et dans un cas on a pu obtenir les vitesses et les paramètres d'activation pour les deux directions de l'équilibre. On a aussi étudié les cinétiques globales de plusieurs systèmes et on a pu obtenir les paramètres cinétiques. Dans quelques cas, l'isomérisation de l'anion est l'étape déterminant la vitesse; dans d'autres cas, l'étape déterminante est le transfert du proton entre l'amine de départ et le carbanion qui conduit au produit.

[Traduit par le journal]

The rearrangement of silyl groups from carbon to more electronegative elements (O, S) is now well known, having been observed under thermal or photochemical conditions or where radical or anionic intermediates are involved (for general accounts of many of these reactions, see ref. 1). Following our investigations of the rearrangements of silylcarbinols to alkoxysilanes (2, 3) where isomeric oxyanions and carbanions have been shown to be intermediates, we turned

$$R_3SiCR_2(OH) \xrightarrow{:B} R_3SiCR_2(O^-) \rightleftarrows R_3SiO\bar{C}R_2 \xrightarrow{BH^+} R_3SiOCHR_2$$

our attention to the related nitrogen system and now wish to report on the rearrangement of aminomethylsilanes (silylmethylamines) to methylaminosilanes (for a preliminary report, see ref. 4).

Whereas traces of di- or trialkylamines were sufficient to effect the rearrangement of many silylcarbinols to their related alkoxysilanes (3), the very fact that aminomethylsilanes are isolable and survive distillation at elevated temperatures indicates that the Si—C—NH → Si—N—CH rearrangement occurs much less

$$R_3Si{-}CR_2(NHR') \longrightarrow R_3SiNCHR_2(R')$$

readily and is not effected by organic amines. However, it was found that 0.05 to 0.2 mol equiv. of *n*-butyllithium, added to a solution of the aminomethylsilane at 10–100°C led to a clean rearrangement at a convenient rate for many but not all of the compounds studied.

The catalyzed rearrangement can be described in terms of the sequence of steps shown in Scheme 1. Butyllithium reacts rapidly and completely with the parent amine, NH, to form a small amount of amide ion, N^-, which may isomerize (step *2*) to the isomeric carbanion, C^-, by migration of the silyl group from carbon to nitrogen. Finally, the carbanion, C^-, reacts with starting amine, NH, (step *3*) to yield product, CH, and regenerate amide ion which subsequently isomerizes, an overall chain process converting starting amine, NH, to product, CH (for studies of the migration of silicon from

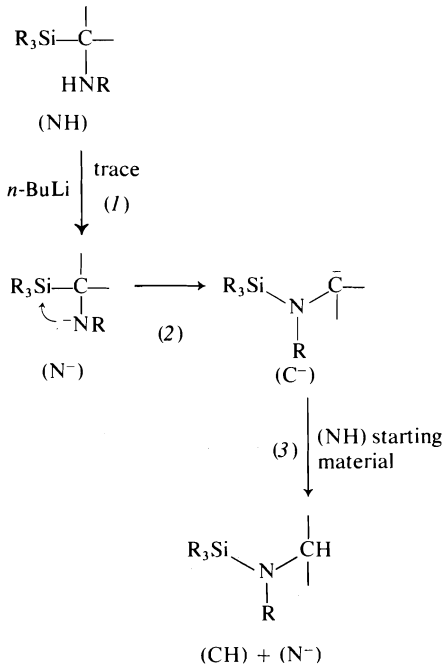
11 $Me_3SiCPh_2NHCH_2Ph$	0.10	25	8	No rearrangement[e]

[a]Rearrangements carried out in benzene solution in nmr tubes sealed under nitrogen. If THF used as solvent, rearrangements were much faster.
[b]Method of alternative synthesis: *A*, $R_3SiCl + R'R''NH + Et_3N$; *B*, $R'R''NLi + R_3SiCl$.
[c]Very slow at room temperature.
[d]Rearrangement required many hours at 25°C.
[e]Hydrolysis gave 0.9 equiv. of starting material and 0.1 equiv. of rearrangement product.

nitrogen to nitrogen, see ref 5*a*; from oxygen to nitrogen, see ref. 5*b*).

As might be expected, the ease of this catalyzed rearrangement was found to be very dependent on structural features, as reference to Table 1, which lists the compounds studied, will show. *N*-Alkylaminomethyltrimethyl- (or triphenyl-) silanes such as **1**, **2**, **3** rearranged



SCHEME 1

either at room temperature or at somewhat elevated temperatures on treatment with butyllithium in hexane or benzene. This infers that the nucleophilicity of N^- for silicon, the relative stabilities of N^- and C^-, and the basicity of C^- relative to N^- in the final proton abstraction step *3* were collectively compatible with the overall rearrangement process. When a phenyl group (which should effectively stabilize C^-) was attached to carbon as in the aminobenzyl compounds **4**, **5**, **6**, **7**, the rearrangement occurred more readily, in general. However, if the *N*-alkyl group was replaced by *N*-phenyl as in **8** and **9**, no rearrangement was observed, possibly because the N^- was now too weak a nucleophile toward silicon. However, if two phenyls were attached to carbon (thereby greatly stabilizing the C^- by delocalization as well as reducing its basicity) the *N*-phenyl compound **10** rearranged. In contrast, the *N*-alkylbenzhydryl compound **11** did not rearrange, probably because C^- was now too weak a base to be able to abstract a proton from NH, since it was subsequently shown that the anionic rearrangement $N^- \rightleftarrows C^-$ (step *2*) had occurred (*vide infra*) under the reaction conditions.

Fortunately, it was possible to cast further light on this behavior both by examining separately the anion equilibrium $N^- \rightleftarrows C^-$ (step *2*), including its kinetics in one case, and also by studying in detail the kinetics of the

catalyzed rearrangements of several of the *N*-alkylaminoalkyltrimethylsilanes.

These more detailed kinetic studies were interpreted on the basis of Scheme 2, with which all data acquired were consistent for the compounds studied. In all cases studied, step *3* appeared to be irreversible, a conclusion supported by the failure of either *N*-methyl or *N*-benzyl silylamines to undergo metallation.

$$NH \xrightarrow[\text{Fast}]{n\text{-BuLi, trace}} N^- \qquad \text{(step 1)}$$

$$N^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C^- \qquad \text{(step 2)}$$

$$C^- + NH \xrightarrow{k_2} CH + N^- \qquad \text{(step 3)}$$

SCHEME 2

The reaction of amine with butyllithium appears to be fast and complete. The $N^- \rightleftarrows C^-$ isomerization has been found to be a reversible equilibrium whose position varies markedly with the structure of the compound involved, and which is the rate-controlling step in some catalyzed rearrangements.

In other cases, step *3*, the protonation step has been found to be rate-controlling. Thus it is clear that quite different kinetic behavior can be anticipated from different aminoalkylsilanes. It is useful to describe the studies of the anionic equilibrium before discussing the kinetics of the catalyzed rearrangements.

The Anionic Equilibrium

The anionic equilibrium, step *2*, was studied for several compounds by treating them with a full equivalent (or excess) of *n*-butyllithium, and then observing the nmr spectrum of the system. Table 2 reports the data obtained.

TABLE 2. Equilibrium proportions of anions[a]

Compound	%N^-	%C^-
$Me_3SiCH_2NHC_6H_{11}$	>99	
$Me_3SiCH_2NHCH_2Ph$	>99	
$Me_3SiCHPhNHMe$	68	32[b]
	71.5	28.5[c]
$Me_3SiCHPhNHC_6H_{11}$	53	47
$Me_3SiCHPhNH$-*i*-Pr	50	50
$Me_3SiCPh_2NHCH_2Ph$	0	100

[a]General conditions involved addition of 1.0 to 1.2 equiv. of *n*-BuLi in hexane to 1 equiv. of amine in hexane and then determining anion proportions by nmr.
[b]25°C.
[c]19°C.

Under such conditions the nmr spectrum characteristic of $Me_3SiCH_2NHC_6H_{11}$, for example, immediately disappeared and was replaced by a similar spectrum attributable to the corresponding amide ion. No change in the latter spectrum occurred over 13 h at room temperature indicating that under these conditions the amide ion did not isomerize. Derivatization of the reaction mixture with methyl iodide gave essentially pure *N*-methyl derivative consistent with the exclusive presence of the amide ion. On the other hand the benzhydryl compound $Me_3SiCPh_2NHCH_2Ph$ when metallated existed completely as the carbanion $Me_3SiN(CH_2Ph)$-$\bar{C}Ph_2$ as judged by the change in the nmr spectrum with time and from derivatization studies with MeOD.

In contrast, aminobenzyl compounds Me_3-SiCHPhNHR′ (R′ = alkyl) when metallated formed equilibrium mixtures containing significant amounts of both N^- and C^-, whose proportions could be measured. Thus, when *N*-methylaminobenzyltrimethylsilane (Me_3Si-CHPhNHMe) was treated with an equimolar amount of *n*-butyllithium, a rapid reaction occurred to give an equilibrium mixture of amide ion and carbanion. The proportions of the

$$Me_3SiCHPhNHMe \xrightarrow{n\text{-BuLi}} PhCH(SiMe_3)\text{—}\bar{N}Me \rightleftarrows PhC^-(SiMe_3)\text{—}NMe$$

two anions could be measured by nmr techniques and were about 70% N^- to 30% C^- in hexane at room temperature. The proportions were approximately 50:50 for the *N*-cyclohexyl and *N*-isopropyl derivatives. Attempts to measure the rates of interconversion of the ions by variable temperature nmr techniques were unsuccessful since line broadening was observed up to 90°C by which temperature serious decomposition occurred. Attempts to study the equilibrium by C-metallation of *N*-methyl-*N*-benzylaminotrimethylsilane were inconclusive since reagents such as *tert*-butyllithium did not react at an appreciable rate.

However, it was found that if the *N*-methylaminobenzylsilane in hexane at −78°C was treated with 1 equiv. of *n*-butyllithium a nearly colourless solution was obtained whose nmr spectrum indicated that only the amide anion was present. On warming, the spectrum started to change, with absorption due to the isomeric

carbanion appearing. Concomitant with the appearance of the carbanion, the solution changed colour, becoming deep red-orange. The rearrangement continued until equilibrium was reached. The rate of attainment of equilibrium could be conveniently studied in the temperature range 10–40°C where $K_e = C^-/N^-$ was found to lie between 0.44 and 0.52. Analysis of the data from this study permitted the determination of the rate constants for both the forward and reverse reactions at various temperatures, and the activation parameters E_{act} and $\Delta S^{\neq}$. The value for E_{act} of 17.0 kcal/mol for the isomerization of the amide ion to carbanion, was slightly smaller than the E_{act} for conversion of carbanion to amide ion (17.4 kcal/mol) and the greater thermodynamic stability observed for the amide ion actually arose from small differences in $\Delta S^{\neq}$.

It was found that the $N^- \rightleftarrows C^-$ equilibrium was very sensitive to small amounts of reagents such as THF and TMEDA, and Table 6 shows how the percentage of C^- at 36°C changed from 23.5% C^- with no TMEDA present to 100% C^- with 1.12 mol equiv. of added TMEDA for the *N*-methylaminobenzylsilane. Similarly, in a different experiment at 18°C, the percentage of C^- changed irregularly with added THF, decreasing from 26.6% C^- (no THF) to about 18.7% C^- (with 1.23 mol equiv. of added THF) and then increasing to about 70% C^- with 2.45 mol equiv. added THF. It was also found that if excess THF was added to the equilibrium mixture of carbanion and amide anion in hexane at 0°C, and then after 30 min the reaction mixture was drowned in MeOD prior to aqueous work-up, the *N*-methylbenzylamine isolated was monodeuterated on the benzylic carbon. The almost 100% monodeuteration must have arisen from ionic precursors which were essentially 100% carbanion in composition.

It is clear that the $N^- \rightleftarrows C^-$ equilibrium is very sensitive to added basic reagents. Both THF and TMEDA are known to coordinate with lithium cations and such solvation evidently favours the Li^+C^- ion pair relative to the Li^+N^- pair. It follows that traces of amine (either starting material or product) are liable to play a similar role in affecting the position of the ionic equilibrium, which may account for the small erratic variations in the value of the equilibrium constant observed in otherwise identical runs. In this connection it was demonstrated that addition of 1 or 2 mol equiv. of triethylamine to the system accelerated the rate of anion isomerization, and altered somewhat the position of the equilibrium.

Kinetics of the Catalyzed Rearrangements of Aminoalkylsilanes to Alkylaminosilanes

It was found possible to observe the overall kinetics of rearrangement of several alkylaminoalkylsilanes ($R_3SiCHRNHR'$) to the isomeric dialkylaminosilanes ($R_3SiNR'CH_2R$) when catalyzed by small amounts of *n*-butyllithium. The kinetic scheme is not a simple one and interpretable results from a situation such as is given in Scheme 2 are only obtained if certain conditions concerning the relative magnitudes of the rate constants are fulfilled. In general, depending on the relative magnitudes of k_1, k_{-1}, and k_2 it is possible for the overall rearrangement to be either complex, *pseudo* first-order, or *pseudo* zero-order in starting amine. In the latter two categories at least four possible cases can be recognized and these are described in the Appendix, where the relevant rate equations are derived. Examples of rearrangements which appear to fit three of these situations have been observed, and will be described.

A. The Catalyzed Rearrangement of $Me_3SiCH_2NHC_6H_{11}$ in THF. Case 1

The rate of rearrangement of $Me_3SiCH_2NHC_6H_{11}$ could be followed by nmr spectroscopy using THF as solvent in the temperature range 30–50°C, but benzene or hexane could not be employed since unduly high temperatures (60–80°C) were required to obtain convenient rates. The concentrations of starting material and product were followed with time, and a plot of ln percentage amine with time was a good straight line for at least 3 half-lives indicative of a *pseudo* first-order reaction. Typical data are given in the Experimental section and in Table 10.

Since it was known from the anionic equilibrium studies that the $N^- \rightleftarrows C^-$ equilibrium lay strongly to the left (*vide supra*), then $k_{-1} \gg k_1$, and reference to the Appendix suggests that case *1* is applicable, with $k_{-1} \gg k_2[NH]$. Under these conditions proton transfer is the rate-determining step. A plot of $\ln k_2K_e$ *vs.* $1/T$ gave a good Arrhenius plot from which $E_{act} =$ 12.5 kcal/mol was obtained. $\Delta S^{\neq}$ cannot be obtained directly since it depends on K_e whose value is not known. If K_e is assumed to be

$< 10^{-2}$, which is consistent with the failure of the system to show any evidence in the nmr for the presence of C^- when the equilibrium was studied, then $\Delta S^{\ddagger} > -24$ eu.

B. The Catalyzed Rearrangement of Me_3SiCH_2NHMe. Case 2

With *N*-methylaminomethyltrimethylsilane difficulty was encountered in finding a solvent system that would give rearrangement at a reasonable rate and also yield reasonably separated nmr signals for the starting amine and rearrangement product. Thus rearrangement was virtually instantaneous in THF (<1 min at 20°C), and while THF–hexane (1:1) gave reasonable rates, the nmr signals (either Me_3Si or NMe) of both reagent and product were superimposed. In 1:3 THF–benzene rearrangement occurred at a reasonable rate at 30°C, and while the Me_3Si signals were superimposed, the N–Me signals of reagent and product were separated by about 6 Hz. This latter system was investigated.

The kinetics were in accord with a zero-order reaction since a plot of percentage amine *vs.* time gave a straight line. The data for various temperatures are given in the Experimental section where the slopes were determined using the least-squares method. The data fit case *2* (Appendix) where the anionic rearrangement of N^- to C^- is the rate determining step (*i.e.* $k_{-1} \gg k_1$, $k_2[NH] \gg k_{-1}$). Thus k_1 listed in Table 9 could be calculated directly from k_{obs}, and the Arrhenius plot of ln k_1 *vs.* $1/T$ gave a straight line yielding the parameters $E_{act} =$ 14.4 kcal/mol and $\Delta S^{\ddagger} = -26$ eu. The large negative $\Delta S^{\ddagger}$ is consistent with the proposed cyclic transition state arising from intramolecular nucleophilic attack of N^- on silicon.

C. The Catalyzed Rearrangement of $Me_3SiCHPhNHMe$. Case 4

When samples of *N*-methylaminobenzyltrimethylsilane in hexane were heated to 35–55°C with 0.05–0.15 mol equiv. of *n*-butyllithium the rearrangement could be conveniently followed by observing the trimethylsilyl peaks in the nmr spectrum of both the starting amine and the rearrangement product. The disappearance of starting material was first-order for up to about 2 half-lives, after which time the reaction speeded up. This effect may be due to changes in solvation effects with the changing medium or to the assumptions made in the solution of the kinetic equations not holding rather than to a change in mechanism. Similar linear plots of ln [amine] with time were obtained at other temperatures.

Since the study of the anionic equilibrium for this amine showed $k_1 \approx k_{-1}$ and since the observed kinetics are first order in amine, case *4* appears to apply where $k_2[NH] \ll k_1 \simeq k_{-1}$. Thus there is relatively fast equilibration of ions, followed by a rate-controlling proton transfer.

As appropriate to case *4*, a plot of ln $k_2/(1 + 1/K_e)$ derived from the k_{obs} at various temperatures *vs.* $1/T$ gave a reasonably straight line which yielded an E_{act} of 22.5 kcal/mol for the overall rearrangement. In the absence of knowledge about the actual values of K_e under the conditions of the catalyzed rearrangement it is not possible to calculate $\Delta S^{\ddagger}$. If K_e is assumed to be 0.5, then $\Delta S^{\ddagger} \simeq 1$ eu.

Summary

The above material has clearly demonstrated that the rearrangement of secondary alkylaminoalkylsilanes to dialkylaminosilanes is a complex reaction, sensitive to the medium and to the structure of the reagents. While all aspects of the reactions have not been investigated in depth, the data obtained are clearly consistent with the mechanism proposed by steps 1–3 depending on the structure of the reagents and the nature of the medium either the anionic rearrangement (eq. 2) or the protonation step (eq. 3) may be rate-controlling.

Because of the demonstrated sensitivity of the reaction and particularly the ionic equilibrium to solvent effects, it is probably not meaningful to compare the activation parameters obtained for the systems studied in detail, since each was done in a different solvent system; however, the data are summarized in Table 3. What is clear is that the expected electronic effects are observed as far as general ease of rearrangement of various amines is concerned. Thus *N*-phenyl compounds, which might be expected to be weak nucleophiles due to electron delocalization, generally fail to rearrange, whereas *N*-alkyl compounds generally do rearrange. Similarly, *C*-phenyl compounds, where stabilization of the intermediate carbanion can be expected, generally rearrange readily at room temperature, with protonation of the carbanion (step *3*) being the rate-determining step.

The results obtained clearly reveal that the

TABLE 3. Kinetic data for alkylaminoalkylsilane rearrangements

[b]In THF–benzene (1:3) from 20–50°C.
[c]In hexane from 25–55°C.

rearrangements of the aminomethylsilanes mechanistically generally follow the behavior previously described for the α-silylcarbinols. Major differences, resulting in the more complex mechanism are (*a*) the decreased nucleophilicity towards silicon of the amide ion *vs.* an oxyanion and (*b*) the decreased reactivity of the carbanion toward NH as compared to the more acidic OH of a silylcarbinol.

Experimental

Reactions involving organometallic reagents were carried out under nitrogen, using solvents dried over sodium. The *n*-butyllithium was a commercial product (Ventron). Nuclear magnetic resonance studies normally employed a Varian T-60 or A-60 instrument equipped with a variable temperature probe.

Synthesis of Silylmethylamines

Most compounds were prepared by the method of Speier and co-workers (6). The data for the compounds prepared are summarized in Table 4 which lists conditions, yields, and analysis for new compounds, and Table 5, which lists the nmr spectral details of new compounds. Two typical procedures are described below.

N-Methyl-N-cyclohexylaminomethyltrimethylsilane

A stirred solution of 16.7 g (0.10 mol) of bromomethyltrimethylsilane and 22.6 g (0.20 mol) of *N*-methylcyclohexylamine was heated in an oil bath at 140–150°C for 30 min. The resultant two-phase liquid was worked up with ether and 5% sodium hydroxide and the organic layer was dried and distilled to give 13.1 g (64%) of *N*-methyl-*N*-cyclohexylaminomethyltrimethylsilane, bp 216–218°C/760 Torr.

N-Methylaminobenzyltrimethylsilane

A. Anhydrous methylamine was bubbled through a sample of α-bromobenzyltrimethylsilane (12.15 g, 0.05 mol) stirred in an oil bath at 130°C. The entire system was maintained under a pressure of 100 Torr by bubbling the effluent gas through a mercury column. After 8 h a thick slurry was obtained. Work-up with ether and 5% sodium hydroxide gave a mixture (*ca.* 4:1, respectively) of the desired amine and starting bromobenzylsilane. The amine was separated by precipitation of its hydrochloride salt from ether. The salt was treated with base and the amine was distilled to give 4.8 g (42%) of *N*-methylaminobenzyltrimethylsilane, bp 44–45°C/0.1 Torr.

B. A solution of α-bromobenzyltrimethylsilane (12.15 g, 0.05 mol) in methylamine (15 ml, collected in a liquid nitrogen bath) in a sealed, thick-walled Pyrex tube was heated at 120°C for 1 h. The tube was cooled in liquid nitrogen before opening and the product was worked-up as above and distilled to give 7.55 g (79%) of product.

When a solution of bromomethyltrimethylsilane and methylamine was prepared in a sealed tube, the tube exploded violently before the sample had warmed to room temperature. A safety shield was damaged in the process. Although the possibility of a badly prepared tube cannot be ruled out (a thick-walled, annealed, Pyrex Carius tube was used) the low temperature at which the explosion occurred and the violence of the explosion implies that a rather vigorous exothermic reaction may have occurred.

Proportions of Equilibrated Anions

Solutions in hexane of various *N*-alkylaminoalkyltrimethylsilanes in an nmr tube were treated with a slight molar excess of *n*-butyllithium. After about 15 min, the proportions of species present, as observed by the intensity of the trimethylsilyl signal in the nmr spectra, were constant. Typical results are listed in Table 2.

Thus, a solution of 0.13 g (0.5 mmol) of *N*-methylaminobenzyltrimethylsilane in 0.25 ml dry hexane under N_2 in an nmr tube stoppered with a serum cap was treated with 0.25 ml (0.55 mmol) of *n*-butyllithium. The tube was shaken, and after the peak heights had ceased to change, the trimethylsilyl signals were recorded. A correction for the variation in peak widths was made since the signal from the nitrogen anion was broader than that of the carbanion signal ($W_{\frac{1}{2}}(N^-)/W_{\frac{1}{2}}(C^-) = 1.46$ in the above case). It was found that the proportions of anions at 19°C were $N^-:C^- = 71.5:28.5$.

Derivatization of the Equilibrating Anions

When solutions of lithiated $Me_3SiCHPhNHR$ (R = Me, C_6H_{11}) were treated with methyl iodide or trimethylchlorosilane only a slow reaction occurred as judged by the rate of disappearance of the deep red colour of the anion. Because of this slow reaction it was considered that the trapping of anions by these reagents would not provide a reliable measure of the equilibrium mixture. Addition of deuterated methanol (MeOD) to the anion solutions resulted in instantaneous

decolourization. The resulting deuterated product could be analyzed by nmr spectroscopy.

A. Lithiated $Me_3SiCHPhNHC_6H_{11}$ in Hexane

A solution of 0.52 g (2.0 mmol) of *N*-cyclohexylaminobenzyltrimethylsilane in 5 ml of hexane was allowed to react with 1.0 ml (2.2 mmol) of *n*-butyllithium in hexane (M = 2.2). After 30 min at room temperature the deep red solution was treated with 2 ml of MeOD. The solution was evaporated to dryness and the residue was extracted with water (1 ml) and deuterochloroform (1 ml). An nmr spectrum of the deuterochloroform solution indicated that three products, $Me_3SiCHPhNHC_6H_{11}$, $Me_3SiNC_6H_{11}$(CHDPh), and C_6H_{11}NHCHDPh in the ratio 3:2:1, respectively, were present. The mixture was stirred with methanol for 30 min to fully desilylate the aminosilane. Examination of the resultant product by nmr indicated that a 55:45 mixture, respectively, of the starting aminobenzylsilane, $Me_3SiCHPhNHC_6H_{11}$, and *N*-cyclohexyl-α-D-benzylamine, $PhCHDNHC_6H_{11}$, was present. The latter product showed a slightly distorted 1:1:1 triplet (J = 1.9 Hz) as expected for the benzyl proton split by the α-deuteron. Both products were also identified by comparison of their gc retention times with authentic samples. The result is in close agreement with the nmr study of the hexane solution of the anions which indicated a 53:47 ratio, respectively, of nitrogen anion and carbanion.

B. Lithiated $Me_3SiCHPhNHC_6H_{11}$ in Hexane–THF

In a similar experiment to the above, the red solution of anions prepared in hexane was cooled to 0°C and was diluted with an equal volume of dry THF. Addition of MeOD and work-up as above gave, as the only significant product (>90%), the deuterated amine, C_6H_{11}NHCHDPh.

C. Lithiated $Me_3SiCHPhNHMe$ in Hexane–THF

A solution of *N*-methylaminobenzyltrimethylsilane was metallated in hexane as above and the resultant deep red solution was cooled to 0°C and was treated with an equal volume of THF. After 30 min MeOD was added and the product was worked-up with ether and water. Removal of solvent at reduced pressure, with mild warming, gave a liquid which was shown by nmr and gc to contain only hexamethyldisiloxane and *N*-methyl-α-D-benzylamine.

D. Lithiated $Me_3SiCHPhNHMe$ in Hexane–THF; Isolation of the p-Toluenesulfonamide

In a similar procedure to the above the anionic solution from 0.97 g (5.0 mmol) of *N*-methylaminobenzyltrimethylsilane and 1 equiv. of *n*-butyllithium in hexane–THF was deuterated. Solvent was removed and the residue was treated with 10 ml of 5% sodium hydroxide solution and 1.90 g (10 mmol) of *p*-toluenesulfonyl chloride. An insoluble oil was obtained when the suspension was warmed to *ca.* 60°C and shaken. This oil was separated by decantation. Treatment with 10 ml of ethanol gave 0.52 g (38%) of fine white crystals of *N*-methyl-*N*-(α-D-benzyl)-*p*-toluenesulfonamide, mp 87–91°C. Recrystallization from ethanol gave mp 92–93°C (lit. (8) mp 95°C); nmr ($CDCl_3$) δ 7.7–8.2 (m, 9H, aryl), 4.88 (br t, $J \simeq$ 1.8 Hz, 1H, PhCHD) 2.55 (s, 3H, N–CH_3), 2.40 ppm (s, 3H, $ArCH_3$).

E. Lithiated N-Benzylaminobenzhydryltrimethylsilane

The title amine, in ether or benzene was treated with an equimolar (or excess) amount of *n*-butyllithium in hexane and a single, deeply coloured lithiated species was formed, as indicated by the nmr spectrum of the system. Hydrolysis followed by rapid work-up (to avoid cleavage of the Si—N bond) gave an almost quantitative yield of the rearrangement product *N*-benzyl-*N*-benzhydryltrimethylsilylamine.

Effects of TMEDA and THF on the Anionic Equilibrium

To a solution of $Me_3SiCHPhNHMe$ (96.5 mg, 105.5 μl, 0.50 mmol) in hexane (165 μl) at −78°C under nitrogen in an nmr tube fitted with a serum cap, was added 229 μl (0.55 mmol; M = 2.4) of a solution of *n*-butyllithium in hexane. The solution was mixed in the cold and then was allowed to warm to room temperature. After about 15 min, when the equilibrium composition had been reached, the relative amounts of carbanion and nitrogen anion were measured by scanning the two Me_3Si peaks at a sweep width of 100 Hz and a sweep time of 100 s.

(These conditions gave a reliable measurement of the peak widths which varied considerably with added THF or TMEDA and for which corrections were made.) The equilibrium mixture was similarly measured following the addition of small amounts of TMEDA (at 36°C) or THF at 18°C (the low temperature was necessary to minimize decomposition in the presence of THF). The results are summarized in Table 6. The measurements in THF were not highly reliable above 2 equiv. because the nitrogen anion peak became very broad and decomposition products had appeared at this stage.

Effect of Added Triethylamine on Rates of Anion Isomerization

Three nmr tubes were prepared as follows: tube *A*, 0.13 g (145 μl, 0.50 mmol) $Me_3SiCHPhNHMe$ and 0.25 ml hexane; tube *B*, 0.13 g of amine, 0.18 ml hexane, and 0.051 g (70 μl, 0.5 mmol) Et_3N; tube *C*, 0.13 g of amine, 0.11 ml hexane, and 0.102 g (141 μl, 1.0 mmol) of Et_3N. Each tube was cooled in liquid N_2, 0.30 ml (0.66 mmol) of *n*-butyllithium in hexane was added, and the kinetics were then determined at 15.6–18.5°C. Plots of ln ($\%N^- - \%N^-_\infty$) *vs.* time (9) gave linear plots from which the following data were obtained. *A*. (no Et_3N) $k_{obs} = 0.054\ min^{-1}$, $K_e = k_1/k_{-1} = 0.45$. *B*. (1 equiv. Et_3N) $k_{obs} = 0.088\ min^{-1}$, $K_e = 0.39$, *C*. (2 equiv. Et_3N) $k_{obs} = 0.153\ min^{-1}$, $K_e = 0.48$.

Studies of Catalyzed Systems

Catalyzed Rearrangement of $Me_3SiCHPhNH$-i-Pr.

A solution of 0.22 g (1.0 mmol) of the title amine in 0.5 ml of dry benzene was treated with 0.10 mmol (50 μl, $M = 2.0$) of *n*-butyllithium in hexane and tightly sealed in a vial. The colour rapidly turned red-orange. After 2 weeks the vial was opened and the solvent was removed under reduced pressure. The nmr spectrum of the residue was identical to that of a pure sample of $Me_3SiN(i\text{-}Pr)CH_2Ph$, bp 56–57°C/0.1 Torr, prepared from $PhCH_2NH$-*i*-Pr, PhLi, and Me_3SiCl in 60% yield. The glc retention times of the residue and of the authentic rearrangement product on a 20% SE 30 on Chromosorb G column were identical.

Similarly a solution of 0.166 g (0.50 mmol) of *N*-phenylaminobenzhydryltrimethylsilane in dry benzene (0.50 ml) in an nmr tube under nitrogen at room temperature was treated with 21 μl (0.05 mmol) of *n*-butyllithium in hexane. The rearrangement at room temperature was followed by nmr spectroscopy. A new peak at 10 Hz to low-field of the trimethylsilyl peak of the starting amine, attributed to rearranged product was observed to grow steadily. The rearrangement was 30% complete in 2 h and was 100% complete after 20 h at room temperature.

When *N*-benzylaminobenzhydryltrimethylsilane was treated with a catalytic amount (0.1 equiv.) of *n*-butyllithium in benzene or ether solvent a deep, dark-red solution was obtained. No evidence for extensive rearrangement could be obtained from spectroscopic studies of the solutions. Hydrolysis after several hours at room temperature gave mainly starting material along with approximately 0.1 equiv. of the rearrangement product, *N* - benzyl - *N* - benzhydryltrimethylsilylamine which likely arose from protonation of the intermediate benzhydryl anion.

Kinetics of the Anionic Equilibrium

A solution of 96.5 mg (105.5 μl, 0.050 mmol) of $Me_3SiCHPhNHMe$ in hexane (166 μl) under nitrogen in a serum capped nmr tube was cooled to −78°C and was treated with 229 μl (0.55 mmol; $M = 2.4$) of *n*-butyllithium in hexane. The solution was mixed and the tube was quickly inserted into the pretuned nmr probe set at a selected temperature. The trimethylsilyl peaks of the nitrogen anion and carbanion were scanned at ½ or 1 min intervals using a sweep width of 500 Hz and a sweep time of 500 s. Following completion of a run the sample was left in the probe for a sufficient time to ensure that equilibrium $[N^-_\infty]$ had been reached.

The final peak width ratio was determined using a sweep width of 100 Hz and a sweep time of 100 s. The relative peak heights of nitrogen anion and carbanion were corrected for peak width differences and the results were tabulated as relative percentage of each anion. For the system

$$N^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C^-$$

it is readily shown (9) that for a first order reaction the integrated rate expression has the form

$$\ln \frac{[N^-] - [N^-_\infty]}{[N^-_0] - [N^-_\infty]} = (k_1 + k_{-1})t = k_{obs}t$$

where $[N^-_\infty]$ is the concentration of the nitrogen anion at equilibrium. For the present case where identical initial concentrations were used, the denominator of the log term may be neglected. The plot of ln ($[N^-] - [N^-_\infty]$) *vs.* time was a good straight line and analysis by the least-squares method for the typical example shown in Fig. 1 at 9.4°C, gave $k_{obs} = (0.432 \pm 0.003) \times 10^{-3}\ s^{-1}$ with a correlation coefficient of 0.999.

Table 7 lists the results of similar runs at different temperatures. The values of k_1 and k_{-1} were obtained from the relationships $k_1/k_{-1} = C^-_\infty/N^-_\infty = K_e$ and $k_{obs} = k_1 + k_{-1}$.

The Arrhenius plots of ln k_1 and ln k_{-1} *vs.* $1/T$, were

[a]Standard solution: 105.5 µl (96.5 mg, 0.50 mmol) amine; 166 µl hexane; 229 µl (0.55 mmol; $M = 2.4$) *n*-butyllithium in hexane.
[b]Correlation coefficient for least-squares analysis of data.
[c]From the relations, $k_{obs} = k_1 + k_{-1}$ and $K_e = k_1/k_{-1}$.

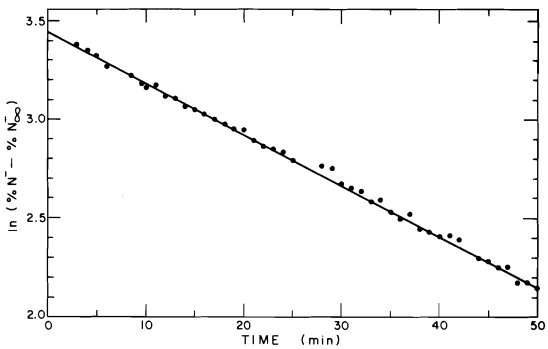

FIG. 1. Equilibration of metallated $Me_3SiCHPhNHMe$ in hexane at 9.4°C.

good straight lines (correlation coefficients 0.994 and 0.993, respectively). Analysis of the results yielded the following data (10)

$$N^- \xrightarrow{k_1} C^- \quad E_{act} - 17.0 \text{ kcal/mol}, \quad \Delta S^{\ddagger} = -17.8 \text{ eu}$$

$$C^- \xrightarrow{k_{-1}} N^- \quad E_{act} = 17.4 \text{ kcal/mol}, \quad \Delta S^{\ddagger} = -15.1 \text{ eu}$$

It was noted in this experiment (and similar experiments) that there were random variations in the values of K_e, from about 0.44–0.52, a range greater than that expected as a result of variations in temperature (if $\Delta G = 0.4$ kcal/mol, then K_e would range from 0.48 to 0.52). The variation is attributed to inaccuracies in the measurements and to the pronounced effects (*vide supra*) of traces of amines and other basic species on the position of the equilibrium.

Kinetics of the Rearrangement of $Me_3SiCHPhNHMe$

A solution of 145 µl (131 mg, 0.678 mmol) of $Me_3SiCHPhNHMe$ in hexane (419 µl) under nitrogen in an nmr tube stoppered with a serum cap was inserted in the nmr probe at a desired temperature. When the instrument had been tuned the sample was treated with 45.5 µl (0.10 mmol; $M = 2.2$) of a solution of *n*-butyllithium in hexane. The sample was quickly mixed and reinserted in the probe. The trimethylsilyl peaks of the starting amine and rearranged product, $Me_3SiNMe(CH_2Ph)$ were scanned at ½ or 1 min intervals.

TABLE 8. Kinetic data for the catalyzed rearrangement of $Me_3SiCHPhNHMe$ in hexane[a]

Temp. (K)	$k_{obs} \times 10^3$ (s^{-1})[b]	$\ln\left(\frac{k_2}{1 + 1/K_e}\right)$[c]
308.7	0.230 ± 0.001	−6.57
313.4	0.316 ± 0.002	−6.25

328.5	1.96 ± 0.03	−4.43
328.9	1.99 ± 0.03	−4.41

[a]Standard solution: 145 µl (131 mg, 0.678 mmol) amine; 419 µl hexane; 45.5 µl (0.10 mmol; $M = 2.2$) *n*-butyllithium in hexane. Molarity in amine (100%) = 0.949. Molarity in base [cat] = 0.164.
[b]Least-squares correlation coefficient 0.999 or better in all runs.
[c]From $k_{obs} = k_2[cat]/(1 + 1/K_e)$.

The results were tabulated as peak height *vs.* time; since both peaks were sharp and of equal width there was no need to apply a peak width correction. The data for several temperatures are given in Table 8. A plot of $\ln k_2/(1 + 1/K_e)$ *vs.* $1/T$ gave a straight line with a slope corresponding to $E_{act} = 22.5$ kcal/mol, as shown in Fig. 2.

Kinetics of the Rearrangement of Me_3SiCH_2NHMe

A solution of 78.2 µl (58.5 mg, 0.50 mmol) of Me_3SiCH_2NHMe in benzene (300 µl) – THF (100 µl) under nitrogen in a serum-capped nmr tube was treated with 20.9 µl (0.05 mmol; $M = 2.4$) of *n*-butyllithium solution in hexane. The kinetics were followed by measuring the heights of the *N*-methyl peaks of the starting amine and rearranged product (6 Hz separation) at ½ or 1 min intervals. A sweep width of 500 Hz and sweep time of 100 s were employed. A peak width correction factor was applied to correct for the wider peak of the rearranged product and the height of the product peak was divided by two to account for the mass balance (N—Me → NMe_2).

A plot of percentage amine *vs.* time was a good straight line over more than 90% of the reaction (zero-order kinetics), and the slope, k_{obs}, was obtained by the least-squares method. Data for various temperatures are given in Table 9, and an Arrhenius plot for this data gave $E_{act} = 14.4$ kcal/mol and $\Delta S^{\ddagger} = -26$ eu.

Kinetics of Rearrangement of $Me_3SiCH_2NHC_6H_{11}$

TABLE 10. Kinetic data for the catalyzed rearrangement of $Me_3SiCH_2NHC_6H_{11}$ in THF[a]

Temp. (K)	$k_{obs} \times 10^4$ (s^{-1})	c.c[b]	k_2K_e (s^{-1})[c]
305.4	1.12 ± 0.005	0.999	0.00112
311.8	1.59 ± 0.006	0.999	0.00159
316.9	2.02 ± 0.013	0.999	0.00202
323.2	2.96 ± 0.01	0.999	0.00296
331.6	5.71 ± 0.018	0.999	0.00571
337.9	7.65 ± 0.09	0.997	0.00765

[a]Standard solution: 109 μl (92.5 mg, 0.50 mmol) amine, 370 μl (0.050 mmol) *n*-butyllithium in hexane (M = 2.4). Concentration of catalyst, [cat] = 0.10 M.
[b]Correlation coefficient from least-squares analysis of data.
[c]From $k_{obs} = k_2K_e$ [cat].

$SiCH_2NHC_6H_{11}$ in dry THF (370 μl) under nitrogen in a stoppered, serum-capped nmr tube was used to pretune the nmr probe at a given temperature. The solution was then treated with *n*-butyllithium solution (20.9 μl, 0.050 mmol; M = 2.4). The reaction was followed kinetically by measuring the Me_3Si peaks using a sweep width of 250 Hz and a sweep time of 500 s. Although these peaks were very close together (1 Hz separation) they were well resolved. It was necessary, however, to use filtering (filter bandwidth 0.2–0.4) to suppress ringing of the product peak, which tended to perturb the starting material peak. A peak width correction factor was applied, the signal of the starting amine being slightly broader than that of the product. A plot of log percentage amine *vs.* time was a good straight line from which k_{obs} was derived. The data are given in Table 10. An Arrhenius plot of $\ln k_2K_e$ *vs.* $1/T$ gave a good straight line (c.c. 0.995) and the data gave E_{act} = 12.5 kcal/mol, and $\Delta S^{\ddagger} = -33.5 - 1.987 \ln K_e$. On the assumption that $K_e < 10^{-2}$, $\Delta S^{\ddagger} > -24$ eu.

Appendix

The following outlines the mathematical derivations of the equations used in the kinetic studies: NH = amine, N^- = amide ion, C^- = carbanion, CH = rearrangement product.

Solution of the Kinetic Scheme for the Catalyzed Rearrangement

For the system:

A $$NH + n\text{-BuLi} \xrightarrow[\text{fast}]{\text{very}} N^- + \text{butane}$$

B $$N^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C^-$$

C $\quad C^- + NH \xrightarrow{k_2} CH + N^-$

$$\text{Rate} = -d[NH]/dt = k_2[NH][C^-]$$

Neglecting reaction A, and using no assumptions, the scheme reduces to two differential equations.

$$[1] \qquad -\frac{d[NH]}{dt} = k_2[NH][C^-]$$

$$[2] \qquad -\frac{d[C^-]}{dt} = -k_1[N^-] + k_{-1}[C^-] + k_2[NH][C^-]$$

Substitute $[N^-] = [cat] - [C^-]$ in [2] ([cat] = [*n*-BuLi] added)

$$[3] \qquad -\frac{d[C^-]}{dt} = -k_1[cat] + k_1[C^-] - k_{-1}[C^-] + k_2[NH][C^-]$$

$$= k_2[NH][C^-] + (k_1 - k_{-1})[C^-] - k_1[cat]$$

Approximation I

If $k_{-1} \gg k_1$, the steady state approximation will hold. (This situation is known to apply for Me_3SiCH_2NHMe and $Me_3SiCH_2NHC_6H_{11}$.) Then,

$$-\frac{d[C^-]}{dt} = -k_1[N^-] + k_{-1}[C^-] + k_2[NH][C^-] = 0$$

Using $[N^-] = [cat] - [C^-]$ gives

$$k_1[C^-] - k_{-1}[cat] + k_{-1}[C^-] + k_2[NH][C^-] = 0$$

or

$$(k_1 + k_{-1} + k_2[NH])[C^-] = k_1[cat]$$

$$[4] \qquad [C^-] = \frac{k_1[cat]}{k_1 + k_{-1} + k_2[NH]}$$

or when $k_{-1} \gg k_1$, this reduces to

$$\frac{k_1[cat]}{k_{-1} + k_2[NH]}$$

Substituting for $[C^-]$ in the rate expression [1] gives

$$-\frac{d[NH]}{dt} = \frac{k_2[NH] \times k_1[cat]}{k_{-1} + k_2[NH]}$$

(*a*) Now, if $k_{-1} \gg k_2[NH]$, and since $K_e = k_1/k_{-1}$ then

$$-\frac{d[NH]}{dt} = k_2K_e[NH][cat] \qquad \text{Case } 1$$

i.e. pseudo first-order with $k_{obs} = k_2K_e[cat]$. This case involves proton transfer as the rate-determining step, and appears to apply to $Me_3SiCH_2NHC_6H_{11}$.

(*b*) If, however, $k_2[NH] \gg k_{-1}$ then

$$-\frac{d[NH]}{dt} = k_1[cat] \qquad \text{Case } 2$$

i.e. pseudo zero-order with $k_{obs} = k_1[cat]$, the kinetics tending to first order as [NH] becomes small. Case *2* is a situation where the rearrangement of the anion is the rate controlling step, and appears to apply to Me_3SiCH_2NHMe.

Approximation II

Instead of approximation I ($k_{-1} > k_1$), suppose $k_1 \approx k_{-1}$ as is known to be true for $Me_3SiCHPhNHMe$.

(*a*) Now, if $k_2[NH] \gg k_1, k_{-1}$ the steady state approximation will hold and the rate of the ionic equilibrium determines the overall rate and

$$\text{Rate} = -\frac{d[NH]}{dt} = \frac{k_2[NH]k_1[cat]}{k_1 + k_{-1} + k_2[NH]}$$

and substituting for $[C^-]$ from [4] above into [1]

$$-\frac{d[NH]}{dt} = k_1[cat] \qquad \text{Case } 3$$

i.e. pseudo zero-order with $k_{obs} = k_1[cat]$.

(*b*) Alternatively if $k_2[NH] \ll k_1, k_{-1}$, the pre-equilibrium assumption will be applicable (a case where protonation is the rate controlling step). Now

$$[C^-]/[N^-] = k_1/k_{-1} = K_e$$

Using $[N^-] = [cat] - [C^-]$ gives

$$[C^-] = K_e[cat] - K_e[C^-]$$

$$[C^-] = \frac{K_e[cat]}{1 + K_e} = \frac{[cat]}{1 + 1/K_e}$$

Substituting in the rate expression [1] gives

$$-\frac{d[NH]}{dt} = \frac{k_2[NH][cat]}{1 + 1/K_e} \qquad \text{Case } 4$$

i.e. pseudo first-order with $k_{obs} = k_2[cat]/(1 + 1/K_e)$. This case appears to apply to $Me_3SiCHPhNHMe$.

Reactions of the dipyrido[1,2-*a*:2′,1′-*c*]pyrazinium dication in basic solution

DONALD J. NORRIS,[1] JOHN W. BUNTING, AND WILLIAM G. MEATHREL[2]

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received January 24, 1977

DONALD J. NORRIS, JOHN W. BUNTING, and WILLIAM G. MEATHREL. Can. J. Chem. **55**, 2601 (1977).

The reactions of the dipyrido[1,2-*a*:2′,1′-*c*]pyrazinium dication (**1**) in basic solutions have been investigated. In aqueous base, this cation is involved in two rapid p*H*-dependent equilibration reactions associated with pK_a values of 9.9 ± 0.2 and 10.4 ± 0.2. Spectral studies indicate that pK_a 9.9 is associated with pseudobase formation by the addition of hydroxide ion at C-2 or C-4 of one of the pyridinium rings. The pK_a 10.4 is most probably attributable to the formation of a dipseudobase by addition of two hydroxide ions in the pyrazinium ring of **1**. The kinetics of these pseudobase formation reactions have been investigated by stopped-flow spectrophotometry over the range p*H* 9–13. Similar methoxide addition reactions occur in basic methanolic solutions.

The dication **1** also undergoes a slow decomposition reaction in aqueous base to initially form the 1-(formylmethyl)-2,2′-dipyridyl cation (**2**). The rate of this reaction, which has been measured as a function of p*H* at 25°C for p*H* 8–12, passes through a maximum in the vicinity of p*H* 10.2. The cation **2** undergoes a further decomposition reaction in these solutions to give an unidentified product.

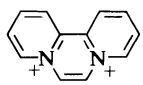
DONALD J. NORRIS, JOHN W. BUNTING et WILLIAM G. MEATHREL. Can. J. Chem. **55**, 2601 (1977).

On a étudié les réactions du dication dipyrido[1,2-*a*:2′,1′-*c*]pyrazinium (**1**) en solutions basiques. Dans la base aqueuse, ce cation est impliqué dans deux réactions d'équilibration rapide qui dépendent du p*H* et qui sont associées avec des valeurs de pK_a de 9.9 ± 0.2 et de 10.4 ± 0.2. Des données spectrales indiquent que le pK_a de 9.9 est associé avec la formation de la pseudobase par addition de l'ion hydroxyde au niveau des atomes C-2 ou C-4 de l'un des cycles pyridinium. On doit probablement attribuer le pK_a de 10.4 à la formation de la dipseudobase par addition de deux ions hydroxydes au niveau du cycle pyrazinium de **1**. On a étudié la cinétique des réactions de formation de ces pseudobases par spectrophotométrie à flux stoppé à des p*H* allant de 9 à 13. Des réactions d'addition semblables impliquant le méthylate se produisent dans des solutions méthanoliques basiques.

Le dication **1** subit aussi une réaction de décomposition lente en solution aqueuse basique pour conduire au départ au cation (formylméthyl)-1 dipyridyl-2,2′ (**2**). La vitesse de cette réaction, que l'on a mesurée à 25°C à des p*H* allant de 8 jusqu'à 12, passe par un maximum autour de p*H* 10.2. Le cation **2** subit une réaction de décomposition subséquente dans ces solutions pour conduire à un produit non-identifié.

[Traduit par le journal]

In continuing our studies (1) of the reactions of heteroaromatic cations in basic solution, we have now investigated the dipyrido[1,2-*a*:2′,1′-*c*]-pyrazinium dication **1** (2, 3). This dication proved



1

to be involved in two rapid p*H*-dependent equilibria in both aqueous and methanolic basic solutions, and also to slowly undergo decomposition reactions[3] in such solutions. We are not able at present to definitely identify all intermediates involved in these reactions from their spectral properties. However, we have established that in dilute aqueous base the dication **1** initially decomposes to **2** which in turn undergoes slow decomposition reactions in these solutions. We

[2]Present address: Thomson Research Associates Ltd., Toronto, Ont.

[3]The term 'decomposition' is used in this work to conveniently distinguish slow irreversible reactions from rapid equilibration reactions.

have also determined the pH-dependence of the rates of conversion of **1** into **2**, and have measured rate and equilibrium constants for the pH-dependent equilibria in which **1** is involved.

Results

Rapid Equilibration Reactions

The uv spectra of fresh aqueous solutions of the dication **1** are pH-dependent above pH 8 (Fig. 1). Acidification of fresh solutions of pH < 12 readily regenerates the spectrum of **1** indicating that these pH-dependent equilibria are readily reversible. Further spectral changes occur at pH > 12. These changes appear to be the result of irreversible reactions since clean spectra of **1** are no longer obtained upon acidification of such solutions. The spectral changes in Fig. 1 are consistent with **1** being involved in acid–base equilibria having pK_a values of 9.9 ± 0.2 and 10.4 ± 0.2, respectively, for the interconversion of **1** and A and of A and B as indicated in Scheme 1. These pK_a values are

$$\mathbf{1} \underset{}{\overset{pK_a = 9.9}{\rightleftharpoons}} \mathrm{A} \overset{pK_a = 10.4}{\rightleftharpoons} \mathrm{B}$$

SCHEME 1

sufficiently close together that the spectrum of pure A, uncomplicated by the presence of significant amounts of either **1** or B, is not observable directly. We have therefore calculated the spectrum of pure A from the spectra of pH 9.34, 9.88, and 10.74 solutions by making use of the spectra of **1** (pH 7) and B (pH 11.76) and the pK_a values. This calculated spectrum is presented

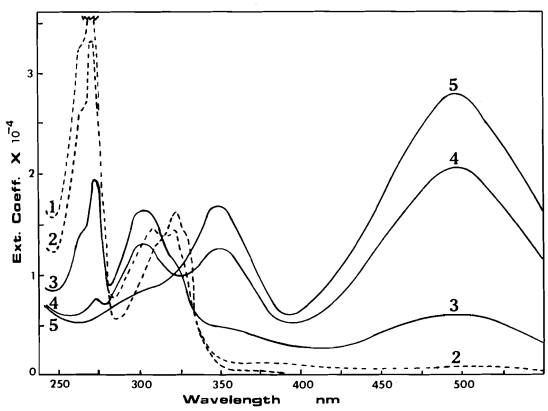

FIG. 1. The pH-dependence of the uv–visible spectra of fresh aqueous solutions of the dication **1**: Curve *1* pH 7.0; *2* pH 9.34; *3* pH 9.88; *4* pH 10.74; *5* pH 11.76.

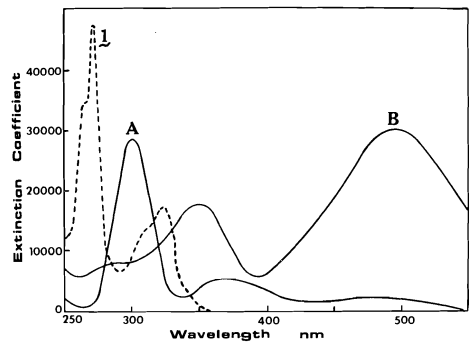

FIG. 2. Ultraviolet–visible spectra of **1** (pH 7), A calculated as described in text; and B pH 11.76.

in Fig. 2 along with the spectra of **1** and B for comparison.

Similar spectral changes were observed when **1** was dissolved in basic methanolic solutions. Thus, in neutral methanol the spectrum of **1**, essentially identical to that in water at pH 7, is observed; addition of 1 equiv. of $NaOCH_3$ gives a spectrum similar to that calculated for A; in more concentrated $NaOCH_3$ solutions (up to 1 M $NaOCH_3$) a spectrum is obtained which is similar to that observed for B at pH 11.7. The similarities of the spectra in aqueous and methanolic solutions indicate that very similar species are present in both basic media, and we designate the species in methanolic solutions as A′ and B′ to correspond to A and B, respectively, in aqueous solutions. Upon acidification of these fresh basic methanolic solutions, the spectrum of **1** is again regenerated, and so these reactions in basic methanol are also readily reversible.

The species A and B are not soluble in aqueous solutions at ^{1}Hmr spectral concentrations. However, ^{1}Hmr spectra are obtainable in basic methanol. The ^{1}Hmr spectra of **1** (*a*) in neutral CD_3OD, (*b*) in the presence of 1 equiv. of $NaOCD_3$, and (*c*) in the presence of 1 M $NaOCD_3$ are shown in Fig. 3. Acidification of solution *b* with DCl in D_2O regenerates the spectrum of **1**. In this initially acidified solution, the spectrum of **1** is superimposed on a broad envelope signal which slowly disappears over about 10 h to regenerate a clean spectrum of **1**. This two-phase regeneration of **1** upon acidification suggests that the basic ^{1}Hmr solution *b* actually contains a mixture of at least two species. One of these is presumably A′ which has been shown above at uv spectral concentrations to immedi-

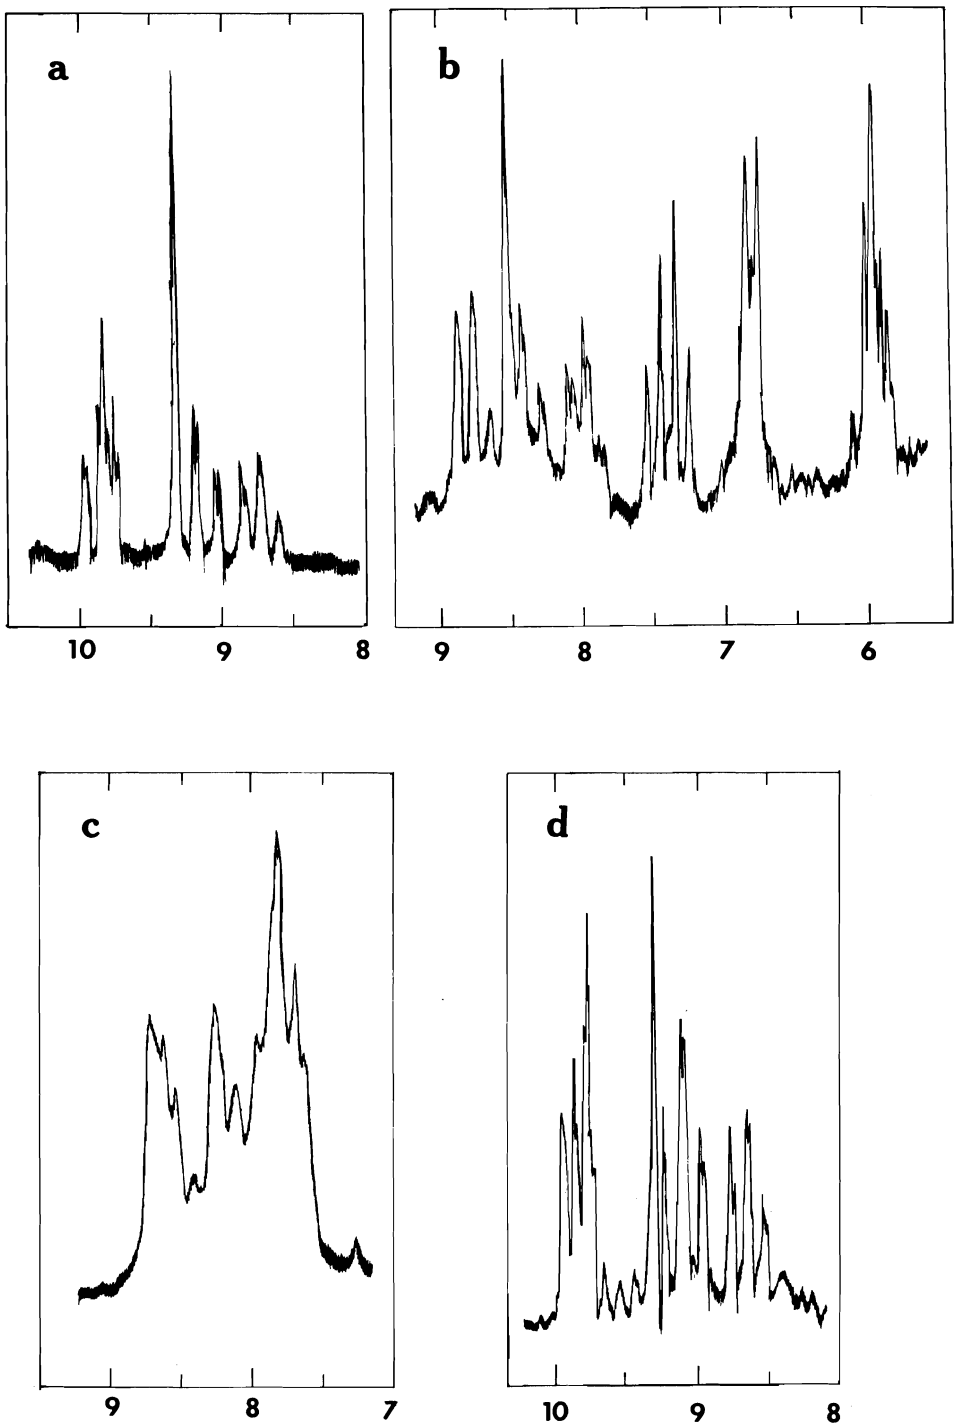

FIG. 3. ^{1}Hmr spectra of **1**: (*a*) in neutral CD_3OD; (*b*) in CD_3OD containing $NaOCD_3$ (1 equiv.); (*c*) in CD_3OD containing 1 *M* $NaOCD_3$; (*d*) solution *b* at 10 h after acidification with DCl in D_2O (all chemical shifts are δ ppm).

ately revert to **1** upon acidification. The other species is only slowly reconverted to **1** on acidification, and the fact that it is only apparently produced in the more concentrated ^{1}Hmr spectral solutions suggests the possibility that this latter species is a product of reaction between two or more heterocyclic molecules related to **1**. The broad, poorly defined, peaks in the spectrum of solution *c* (Fig. 3) also tend to suggest the presence of a mixture of two or more species.

Significantly, the complete ^{1}Hmr spectrum of **1** is regenerated upon acidification. This indicates that the acid–base equilibria involving A′ do not involve anion formation by removal of a ring hydrogen atom from **1**. If such were the case, this hydrogen atom would be replaced by deuterium upon acidification and would result in a modified spectrum for **1**.

The rate of equilibration of **1** with A and B was found to be amenable to investigation by stopped-flow spectrophotometry. When solutions of **1** are mixed with buffers in the range p*H* 9.0–9.8 a single reaction, which is first-order in heterocycle, is observable at 305 nm. However, at p*H* > 9.8 two absorbance changes are observed at 305 nm. These changes are consistent with the occurrence of two consecutive reactions (Fig. 4*a*). When this experiment is repeated at 500 nm, initially there is no change in absorbance but eventually a reaction, which is first-order in heterocycle, is observed (Fig. 4*b*). These observations are consistent with the rapid formation of A at all p*H* values, and then a subsequent slower equilibration to B at p*H* > 9.8 Pseudo first-order rate constants for the equilibration of **1** with A (k^{A}_{obs}) and of **1** and A with B (k^{B}_{obs}) are plotted as a function of p*H* in Fig. 5.

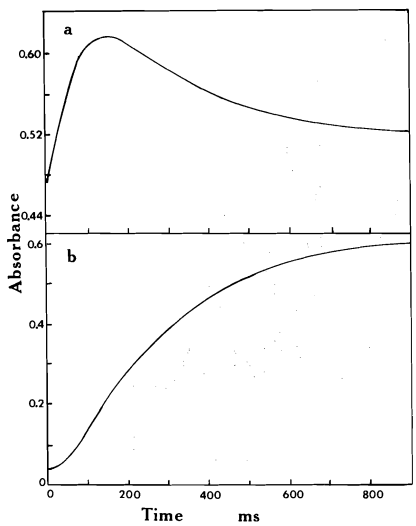

FIG. 4. Time-dependence of the absorbance of **1** (2.0×10^{-5} *M*) at p*H* 10.66 at 305 nm (*a*) and 500 nm (*b*). (Solutions of **1** in water were mixed on the stopped-flow apparatus with buffer p*H* 10.66.)

Slow Decomposition Reactions

Upon prolonged treatment of the dication **1** with aqueous base, the p*H*-dependent uv spectra discussed above undergo further changes. Examples of such time-dependent spectral changes are illustrated in Fig. 6 at p*H* 8.1 and 11.76. At both these p*H* values the final uv spectrum has a single maximum in the vicinity of 280 nm. A similar final spectrum is observed over the entire p*H* 7–13 range, although there appears to be a slight shift in the position of this peak from 281 nm in neutral solution to 277 nm in the most basic solutions. These spectral changes proved to be first-order in heterocycle, and the p*H*-dependence of the pseudo first-order rate constant (k^{1}_{dec}) for this reaction is indicated in Fig. 7. This p*H*-profile passes through a maximum in the vicinity of p*H* 10, and at lower and higher p*H* values k^{1}_{dec} appears to become linearly dependent on $[H^+]$ and $[OH^-]$, respectively (lines of slope +1 and −1 in Fig. 7). The line in Fig. 7 is of the form

$$k^{1}_{dec} = \frac{k}{1 + [H^+]/K_1 + K_2/[H^+]}$$

with $k = 1.04 \times 10^{-3}$ s^{-1}, pK_1 = 9.9 and pK_2 = 10.4, and appears to give a reasonable fit to the experimental data.

The uv spectrum of the decomposition product having λ_{max} in the vicinity of 280 nm is quite similar to the basic aqueous spectra of both

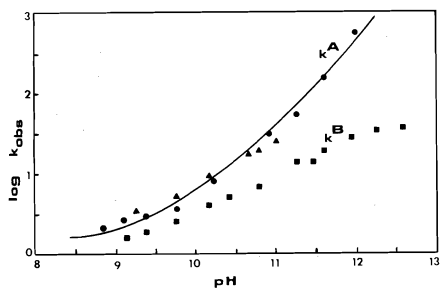

FIG. 5. p*H*-dependence of log k^{A}_{obs} (s^{-1}) for equilibration of **1** with A (● 272 nm; ▲ 305 nm) and of log k^{B}_{obs} (s^{-1}) for equilibration of A with B (■). All data at 25°C, ionic strength 0.1. Curve is calculated from: $k^{A}_{obs} = 1.3 \times 10^{4}[OH^-] + 1.4$.

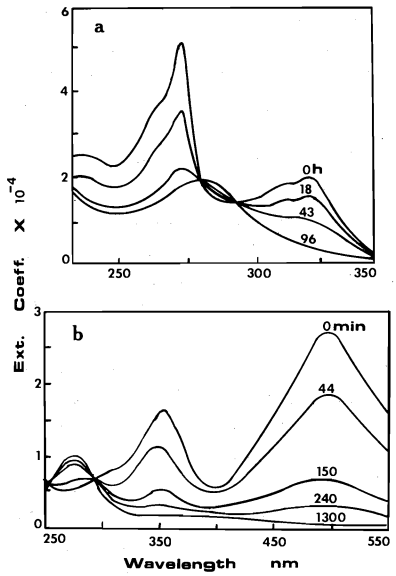

FIG. 6. Time-dependence of the uv–visible spectrum of solutions of **1** at p*H* 8.1 (*a*) and p*H* 11.76 (*b*). (25°C, ionic strength 0.1.)

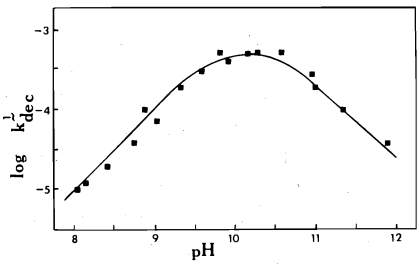

FIG. 7. p*H*-dependence of the rate of decomposition of **1** (k^1_{dec} s^{-1}) at 25°C, ionic strength 0.1. Curve is calculated from the equation given in the text.

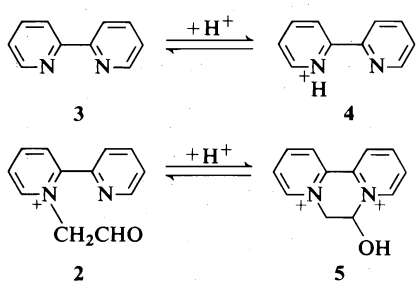
2,2′-dipyridyl **3** (λ_{max} = 278 nm) and the cation **2** (λ_{max} = 277 nm), which is an intermediate in the synthesis of **1**. Both these species would seem to be reasonable products to which **1** might decompose in basic solution. Although **2** and **3** have quite similar spectra in basic solution, they are readily distinguishable on the basis of their uv spectra in acidic solution. Thus in aqueous acid **3** gives the protonated species **4** (λ_{max} = 302 nm; pK_a = 4.3 (4)) while **2** undergoes a rapid p*H*-dependent ring-closure (5) to give **5** (λ_{max} = 321 nm; pK_a = 4.35 ± 0.04) which is actually a covalent hydrate of **1**. Acidification to p*H* 0.5 of p*H* 9.3 solutions containing the decomposition product of **1** gave a spectrum that was almost completely superimposable on the spectrum of **2** in acidic solutions (*i.e.* **5**), and which was quite different from the spectrum of the 2,2′-dipyridyl cation **3**. However, similar acidification of p*H* 11.8 solutions containing the decomposition product of **1** gave only a slight shift to λ_{max} = 276 nm with no overall change in the shape of the spectrum.



3 **4**

2 **5**

This apparent difference in the decomposition products of **1** at p*H* 9.3 and 11.8 was enlightened, when it was observed that the cation **2** also undergoes a slow decomposition in basic aqueous solutions. Thus when solutions of **2** were kept at p*H* 11.76 for about 30 min and then acidified, the spectrum of **5** was not regenerated; rather, the spectrum of a species of λ_{max} = 276 nm was obtained and this spectrum is similar to that observed upon acidification of a solution of **1** which had decomposed at p*H* 11.76. Similar acidification of a p*H* 9.3 solution of **2** after 30 min regenerated the spectrum of **5**, however after prolonged exposure (several days) of **2** to p*H* 9.3 the uv spectrum of acidified solutions tended towards that observed at p*H* 11.76. These observations suggest a p*H*-dependent decomposition of **2**, with the rate of decomposition increasing as the p*H* is increased. The rate of this decomposition was followed at 25°C at several p*H* values, and was found to be first-order in heterocycle. Pseudo first-order rate constants (k^2_{dec}) for this process are given in Table 1 at several p*H* values, and a comparison with k^1_{dec} for the rate of decomposition of the dication **1** at the same p*H* values is given. The rate of decom-

10.74	3.1	0.95
10.27	4.9	(0.47)[b]

[a]At 25°C, ionic strength 0.1.
[b]By extrapolation, assuming reaction is first-order in [OH^-].

position of **2** appears to be approximately first-order in hydroxide ion.

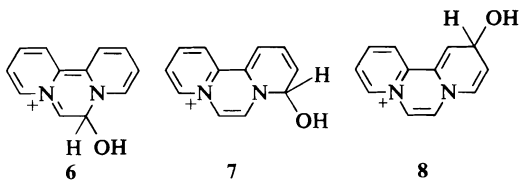
Although the above uv spectral studies rule out 2,2′-dipyridyl as a major product of the decomposition reaction of either **1** or **2**, it was found that small amounts of 2,2′-dipyridyl (~5% yields) could be obtained from the decomposed solutions of these two species. Thus chloroform extraction of a solution of **1** which had been kept at p*H* 10.95 for 2 days gave a small amount of a species that had uv and ^{1}Hmr spectral properties that were identical to those of an authentic sample of 2,2′-dipyridyl.

The dication **1** was also observed by uv spectrophotometry to undergo decomposition upon standing in basic methanolic solutions. This reaction has not been studied in detail, but it is clear from the uv spectral data that the decomposition product in methanol is not the same as the product in basic aqueous solution.

Discussion

Rapid Equilibration Reactions

Since the dication **1** has no readily ionizable hydrogen atoms, the pK_a = 9.9 associated with the conversion of **1** to A must presumably represent hydroxide ion addition to **1** to form a pseudobase species. Three such pseudobase species appear to be possible; these are **6**, **7**, and **8** which would be formed by hydroxide ion addition to **1** at a carbon atom in either the pyrazinium ring or at C-2 or C-4 of one of the pyridinium rings, respectively. By virtue of the



6 **7** **8**

proximity of the two positively charged nitrogen atoms, the carbon atoms of the pyrazinium ring would be expected to be more electron-deficient than the carbon atoms in the pyridinium rings. However, the formation of **6** by hydroxide ion addition in the pyrazinium ring results in disruption of the Kekulé resonance structures of all three rings of **1**, whereas in the formation of each of **7** and **8** one aromatic pyridinium ring is conserved. Consequently **7** and **8** would each be expected to be thermodynamically more stable than **6**.

The observed uv spectrum of A (λ_{max} = 302 nm) also tends to eliminate **6** as the structure of A. Thus, to a first approximation, one might consider a useful model for **6** to be six conjugated C=C double bonds with a terminal amino group (*i.e.* (—CH=CH)$_6$—NH$_2$). The spectrum of such a system would be expected to show absorption at much longer wavelengths than is observed for the major peaks of A (6). The intense peak in the vicinity of 302 nm for A is consistent with the presence of a substituted pyridinium cation as in **7** or **8**. It is difficult to predict the complete uv spectra of **7** and **8** since there seem to be no useful models to indicate the spectral consequences of the interaction of the pyridinium and dihydropyridine ring systems both via the 2,2′-bond of the dipyridyl moiety and the C=C bridging the two ring nitrogen atoms. The absorption peak in the vicinity of 370 nm may be indicative of the presence of a 1,2-dihydropyridine ring system since even simple 1,2-dihydropyridines lacking other chromophoric substituents have λ_{max} in the vicinity of 325 nm (7).

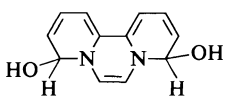
The ^{1}Hmr spectrum of A′ in Fig. 3*b* is also indicative of methoxide adducts analogous to **7** or **8** rather than the methoxide adduct related to **6**. Thus the signals in the region δ 8–9 in Fig. 3*b* are typical of protons on a pyridinium ring; *e.g.* for the *N*-methylpyridinium cation in D_2O: δ 8.93 H(2, 6); 8.61 H(4); 8.17 H(3, 5). In particular, the doublet in the vicinity of δ 8.9 in Fig. 3*b* is quite characteristic of the proton on the carbon atom adjacent to the pyridinium nitrogen atom. There does appear, however, to be an additional signal in this δ 8–9 region. This region integrates somewhat high for four protons relative to the rest of the spectrum. Possibly also located in this region is the signal from the proton on the bridge carbon atom adjacent to the positively charged nitrogen atom of the methoxide adducts related to **7** and/or **8**. The presence of this characteristic pyridinium spectrum also tends to rule out the methoxide adduct corresponding to **6**, since aromatic character is lacking in this latter structure. The signals in the region δ 6–8 are consistent with the presence of a dihydropyridine ring such as is present in **7** or **8**. A simple analysis of this region does not seem to be possible, however, and so suggests the possibility that a mixture of the methoxide adducts corresponding to **7** and **8** is actually present.

We therefore tentatively conclude that A is either **7** or **8** or a mixture of these two species.

The A′ species in methanol solution would then consist of the corresponding methoxide adduct(s).

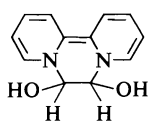
The pH-dependence of k^{A}_{obs} in Fig. 5 is typical of that usually observed for cation–pseudobase equilibration reactions (11, 12). Separation of the pseudo first-order rate constants for formation (k_f) of A from **1** and decomposition (k_d) of A to **1** indicates that over the pH range investigated these rate constants can be represented by $k_f = 1.3 \times 10^4[OH^-]\ s^{-1}$ and $k_d = 1.4\ s^{-1}$. The line in Fig. 5 for k^{A}_{obs} is calculated from $k_f + k_d$ using these relationships and gives an acceptable fit to the experimental data. The terms in k_{H_2O} for k_f and in $k_1[H^+]$ for k_d, which are usually required (11, 12) for a complete description of the pH-dependence of the rates of cation–pseudobase equilibration, are not observable over the pH range that is amenable to investigation for **1** $\rightleftharpoons$ A.

The fact that the rate of formation of species B is readily observable on the stopped-flow spectrophotometer clearly indicates that B is not simply an alkoxide ion derived from A. Alkoxide ion formation is also not consistent with the occurrence of a similar reaction to generate B′ in methanolic solution, nor with the drastic spectral change associated with the conversion of A to B. The intense long-wavelength band of $\lambda_{max} = 498$ nm in the spectrum of B is suggestive of the presence of an extensively conjugated nonaromatic species. A number of such species can be generated by the addition of a second hydroxide ion to **7** or **8** (*e.g.* **9**). We feel that such



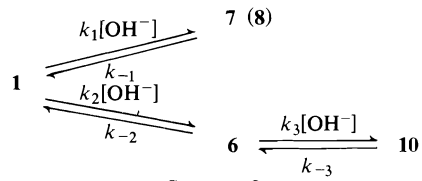
9

species can be ruled out since simple pyridinium ions do not generate significant amounts of pseudobase species even in quite strongly basic aqueous solutions (*e.g.* in aqueous 1 *M* KOH) (8–10). A more likely structure for B is **10** in which two hydroxide ions have added to the carbon atoms of the pyrazinium ring of **1**.



10

The pH-dependence of k^{B}_{obs} for the formation of B is also not consistent with simple hydroxide ion addition to A. Such a reaction would be expected to be first-order in $[OH^-]$, whereas in fact k^{B}_{obs} seems to depend on less than the first power of $[OH^-]$ even at p$H > 11.5$ where k^{B}_{obs} is not complicated by the rate constant for the reverse reaction. From Fig. 5 we estimate that k^{B}_{obs} is approximately linear in $[OH^-]^{0.5}$. Such a fractional order suggests that no single step in the reaction under observation is entirely rate-controlling. Presumably **10** would be formed by hydroxide ion addition to a small amount of **6** present in the equilibrium mixture A that is believed to be predominantly **7** and/or **8**. Such a situation is described in Scheme 2.



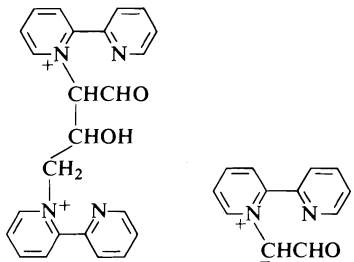
SCHEME 2

Slow Decomposition Reactions

The above data clearly indicate that the cations **1** and **2** both decompose to the same product in aqueous base. The formation of **2** as an intermediate in the decomposition of **1** is established at pH 9.3 from the uv spectra of acidified solutions of the initial decomposition product. At p$H > 11$ it is not possible to unequivocally establish the presence of **2** from spectral data because **2** decomposes faster than **1** in this region (Table 1). It seems likely, however, that **2** is an intermediate in the decomposition of **1** at all pH values since these two cations give identical decomposition products at all pH values as judged by the uv spectra of decomposed solutions. The nature of this final decomposition product has not been unequivocally established.[4] Although the uv spectrum of this product in basic solution ($\lambda_{max} = 276$ nm) is very similar to the spectrum of 2,2′-dipyridyl ($\lambda_{max} = 278$ nm), it does not undergo a bathochromic shift to $\lambda_{max} = 302$ nm upon acidification. Such a shift is typical of the monocation of 2,2′-dipyridyl. In fact the apparent pH-independence of the uv spectrum of the decomposition product suggests that it undergoes no protonation of a pyridine nitrogen atom in the range pH = 0–12. Since the spectrum seems to suggest that the dipyridyl

[4]Attempts to isolate this product at higher concentrations of **1**, produced brown oils which seemed to be complex mixtures.

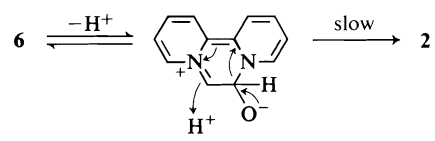
unit is still intact in the decomposition product, the lack of a protonation in this region suggests that this dipyridyl unit already contains a pyridinium ring. In fact the similarity in the uv spectra of **2** and the decomposition product suggest that the decomposition of **2** in no way disrupts the electronic structure of the pyridylpyridinium moiety of **2**. The simplest structure for the decomposition product that is consistent with the above consideration is that of the dimeric aldol condensation product **11**.



11 **12**

Since the conversion of **2** to **11** is kinetically first-order in **2** and also approximately first-order in hydroxide ion, the deprotonation of **2** to generate the carbanionic zwitterion **12** must be considered to be the rate-determining step in the formation of **11**.

The observed p*H*-dependence for the decomposition of **1** (Fig. 7) suggests that the conversion of **1** to **2** actually occurs via either A or else another species which is present in a rapid p*H*-independent equilibrium with A. As discussed above, the most likely structures for A are **7** and **8**. It is difficult to conceive of **7** or **8** as being intermediate in the formation of **2**, however, the structure **6** which has been ruled out for A clearly is a likely candidate for an intermediate between **1** or **2**. We therefore suggest that a small amount of **6** is present in solution in equilibrium with **7** and/or **8** and that decomposition of **1** to **2** proceeds through **6**. The presence of a small amount of **6** was also inferred above from the p*H*-dependence of the equilibration of **7** (or **8**) and **10**. The observed p*H*-dependence in Fig. 7 then requires a transition state in the same protonation state as **6** (*e.g.* **13** $\xrightarrow{k[H^+]}$ **2**). Of course, a kinetically equivalent mechanism would be rate-determining protonation prior to C—N bond-breaking, rather than the concerted reaction shown in **13**. In this case, the alkoxide ion derived from **5** would be a reaction intermediate.



13

Experimental

The bromide salts of the cations **1** and **2** were synthesized as described by Calder and Sasse (2).

Determination of pK_a Values and Spectrum of A

Inspection of the p*H*-dependence of the spectra of fresh aqueous solutions of the dication **1** (25°C, ionic strength 0.1) indicates that the peak at 271 nm decreases in intensity with increasing p*H* whereas a new peak at 494 nm appears and increases in intensity with increasing p*H* (Fig. 1). This latter long wavelength absorption maximum results in high p*H* solutions being red in colour. Consideration of the differences between the spectra at p*H* 7 and p*H* 11.76 allows estimates that 50% of the change in intensity at 271 nm is complete at p*H* ~9.7 whereas 50% of the total increase in intensity at 494 nm is not complete until p*H* ~10.5. This suggests that these p*H*-dependent spectra do not merely reflect the equilibration between two species, but rather two successive p*H*-dependent equilibria are involved. The fact that unique isosbestic points are not observed over the entire p*H* range further confirms that complex equilibria are involved.

Assuming that the spectrum at p*H* 7.0 represented pure **1** and that the spectrum at p*H* 11.76 represented pure B, the above estimates of the two pK_a values were used to calculate an approximate spectrum for A from the observed spectra of each of p*H* 9.34, 9.88, and 10.74 solutions. These estimated spectra were averaged to give an approximate spectrum of A. These spectra were then used to calculate the concentrations of each of **1**, A, and B at each p*H*, and new pK_a values were thus estimated. These new estimates for the pK_a values were used to re-evaluate the spectra of A and B and the above procedure was repeated to give new pK_a values. After several cycles, the spectra calculated for A and B from the observed spectra at each of p*H* 9.34, 9.88, 10.74, and 11.76 were consistent to within 0.1 mM^{-1} cm^{-1} at all wavelengths. This self-consistency was attained with pK_a values of 9.9 and 10.4, respectively, for the equilibria in Scheme 1.

Equilibration Kinetics

The rates of equilibration of **1** with A and B were observed by mixing aqueous solutions of **1** (p*H* ~7) with buffers of ionic strength 0.2 at 25°C in a Durrum–Gibson stopped-flow spectrophotometer. The equilibration of **1** with A was followed at 272 and 305 nm. At 272 nm, the absorbances of A and B are approximately equal and are also approximately 10% of the absorbance of **1** at this wavelength. Plots of log $(A - A_\infty)$ against time were linear over more than three half-times at p*H* < 9.5 and were linear for 2–3 half-times at p*H* > 9.5. The deviations from strict first-order kinetics after 3 half-times at p*H* > 9.5 is presumably due to the equilibration of A with B. Pseudo first-order rate constants (k^A_{obs}) were calculated from the linear region of the log $(A - A_\infty)$ *vs.* time plot. At 305 nm, A_∞ could not be obtained directly at p*H* > 9.5 because of the large difference in absorbance

intensities of A and B at this wavelength. In this case, A_∞ was calculated from the estimated extinction coefficient of A at 305 nm based on the calculated spectrum in Fig. 2. Values of k^{A}_{obs} estimated in this way at 272 nm and 305 nm are in close agreement (Fig. 5).

Rates of equilibration of **1** and A with B were followed at 500 nm where neither **1** nor A has any significant absorbance. Values of the pseudo first-order rate constant k^{B}_{obs} were estimated from the slopes of log $(A_\infty - A)$ *vs.* time plots.

Decomposition Kinetics

Rates of decomposition of both **1** and **2** were determined spectrophotometrically at 25°C in buffer solutions of ionic strength 0.1. For **1**, the reaction was followed at 304 or 310 nm for pH < 11, and at 500 nm for pH > 11. Rates of decomposition of **2** were obtained at 390 nm, which is a peak in the pH-dependent spectrum of **2**. This decrease in absorbance at 390 nm in basic solution, closely parallels the spectral change of acidified solutions of partially decomposed **2**. Pseudo first-order rate constants (k_{dec}) were calculated for both **1** and **2** from the slopes of linear plots of log $(A - A_\infty)$ *vs.* time.

Received March 7, 1977

GEORGE M. STRUNZ, WU-YUN REN, MERLYN A. STILLWELL, and ZDENEK VALENTA. Can. J. Chem. **55**, 1610 (1977).

A dextrorotatory product isolated from cultures of *Trichoderma album* has been identified as 5-hydroxy-3-methoxy-5-vinyl-2-cyclopenten-1-one, and a synthesis of the latter in racemic form is described. The possibility that this compound might be an artifact produced during the isolation procedure, rather than a true metabolite, is not excluded.

GEORGE M. STRUNZ, WU-YUN REN, MERLYN A. STILLWELL et ZDENEK VALENTA. Can. J. Chem. **55**, 1610 (1977).

Un produit dextrogyre isolé des cultures du *Trichoderma album* s'avère etre l'hydroxy-5 méthoxy-3 vinyl-5 cyclopent-2 èn-1 one et on décrit la synthèse de celui-ci sous forme racémique. On n'a pas éliminé la possibilité que ce composé soit un artefact produit au cours d'isolement au lieu d'un vrai métabolite.

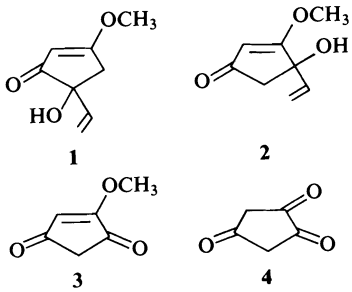
Trichoderma album, in plate culture, exhibits antagonism to a variety of microorganisms.[2] This prompted us to examine products extracted from the filtrates after growth of *T. album* in liquid-shake culture. From chromatography of extracted material, we have obtained, in low yield, a new optically active cyclopentenone derivative, $C_8H_{10}O_3$, the structure determination and synthesis of which are described herein.

The compound displays ir absorption ($CHCl_3$) at 1700 and 1592 cm^{-1} (strong), and a uv chromophore $\lambda_{max}(CH_3OH)$ at 243 nm (ε 15 600). These features, together with nmr signals corresponding to an olefinic hydrogen at δ 5.36 (poorly resolved doublet, $J \sim 1.5$ Hz), and methyl ether protons at δ 3.95 (3H, s) are readily interpreted in terms of a 3-methoxy-2-cyclopenten-1-one system (1–3). Infrared absorption at 3555 cm^{-1} indicates the presence of hydroxyl functionality: the latter is further manifested as an exchangeable one-proton signal at δ 3.19 in the nmr spectrum. A three-proton multiplet at δ 5.14–6.20 resembles closely the 11-peak pattern displayed by the vinyl hydrogens of 3-methyl-1-buten-3-ol (4), and the presence of a (tertiary) vinyl carbinol system can accordingly be inferred. The base peak in the mass spectrum, at *m/e* 55, corresponding to the ion $(C_3H_3O)^+$ provides support for this structural feature.

The combined spectral data can be accommodated by either of the isomeric structures **1** or **2**. (The geminal protons on the ring appear in the nmr spectrum as a two-proton doublet at δ 2.83 ($J \sim 1.5$ Hz).)

The remaining structural ambiguity was resolved by synthesis. Structure **2** was selected as the initial synthetic target since it appeared that it should be accessible by reaction of the known compound **3** with a vinyl Grignard reagent. Accordingly, **3** was prepared (5, 6), via 1,2,4-cyclopentane trione **4** (7), from diethyl acetonedicarboxylate and diethyl oxalate. Reaction of **3** with vinyl magnesium bromide in tetrahydrofuran (8) afforded a complex mixture of products, possibly as a result of anion formation at C-5 (5). The desired product **2** was, however, obtained in 32% yield (not optimized) on changing the solvent to ether, in which both reactants were but sparingly soluble.[3] That the compound obtained from the *T. album* fermentation was not **2** was immediately obvious on

[1]Author to whom correspondence should be addressed.
[2]J. L. Ricard: personal communication. We thank Dr. Ricard for providing a culture of *T. album*.
[3]The Grignard reagent was prepared in tetrahydrofuran in the normal manner (8): it was suspended in anhydrous ether after removal of the former solvent (nitrogen stream).



1 2

3 4

comparison of their spectra (see Experimental). Thus, for example, though the nmr spectra showed some similarities, significant differences were evident in the signals corresponding to the C-2 vinyl proton, and the methylene protons (for **2**, *singlets* at δ 5.33 and 2.68 ppm, respectively).

While **3**, derived from the more favorable enolic form of **4**, is the sole product (80%) reported from acid-catalyzed reaction of the latter with methanol (6), it appeared that similar treatment of **2** might give rise to an equilibrium mixture containing both **1** and **2**. In the event, when **2** was set aside at ambient temperature in methanol solution containing a catalytic quantity of sulfuric acid, tlc analysis revealed the gradual formation of a second, more polar product. After 4 h, 69 mg of **2** and 45 mg of **1** were recovered, starting from 150 mg of the former.

Comparison of solution spectra and tlc behavior of synthetic **1** thus prepared, with those of the *T. album* product established their identity. A biosynthetic pathway to **1** might comprise cyclization of a tetraketide precursor to a six-membered (orsellinic acid-type) intermediate, with subsequent loss of carboxyl, oxidation, and ring contraction.

The possibility that **1** could be an artifact produced from a metabolite during the isolation procedure was considered, on comparing its chromatographic characteristics with those of the crude extracts from which it was obtained. Since production of **1** has not been observed in subsequent fermentations, we have, as yet, no further evidence relating to the question of its authenticity as a 'true natural product'.

Bioassays, using the disc method, showed that **1** was devoid of antifungal activity against test organisms sensitive to the crude *T. album* extracts.

Experimental

Melting points were determined on a hot-stage apparatus and are uncorrected. Infrared and ultraviolet spectra were recorded on a Beckman Acculab 2 and a Perkin-Elmer 402 spectrophotometer, respectively. Nuclear magnetic resonance spectra were obtained for solutions in deuterochloroform using a Varian T-60 intrument, with tetramethylsilane as internal standard. Preparative thin layer chromatography was carried out on 0.5 mm layers of silica gel GF-254 (E. Merck); bands were detected by viewing under uv light (254 nm).

*Isolation of 5-Hydroxy-3-methoxy-5-vinyl-2-cyclopenten-1-one, **1***

Material extracted with chloroform from filtered culture medium[4] that had supported growth of *T. album* (liquid shake culture, temperature *ca.* 15°C) for 3 weeks, was passed through a short column of silica gel using chloroform as eluent. After removal of solvent *in vacuo*, the residue was chromatographed on preparative layer plates of silica gel (benzene–acetone, 4:1). A distinct band at R_F *ca.* 0.5 was isolated by extraction with methanol. On rechromatography using the same system, the principal band appeared to have shifted to lower R_F (artifact?). The yield of crystalline product, **1**, obtained from this band was less than 1 mg per litre culture medium. After crystallization from ether–*n*-hexane, **1** was sublimed at 0.1 Torr to give colorless crystals, mp 75–77°C; $[\alpha]_D$ +63° (*c* 0.741 g/100 ml methanol); cd (7.433 × 10^{-4} *M* in methanol, 1 mm cell) λ nm (Δε): 335(0), 281 (+2.36), 263 (0), 238 (+4.32), 219 (0), <219 (negative); ir (KBr) *inter alia* 3400 (br), 3080, 2990, 2940, 2850, 1695, 1575, 1355, 1250, 1190, 1110, and 975 cm^{-1}; ir ($CHCl_3$) 3555, 1700, 1592 (s), and 1362 cm^{-1}; uv λ_{max}(CH_3OH) 243 nm (ε 15 600); nmr spectrum described in text; ms (peaks of relative abundance greater than 20%) *m/e* 154.0631 (73) (calcd. for $C_8H_{10}O_3$: 154.0630), 125(48), 98(34), 97(26), and 55(100).

*Preparation of 4-Hydroxy-3-methoxy-4-vinyl-2-cyclopenten-1-one, **2***

Vinylmagnesium bromide was prepared in anhydrous tetrahydrofuran from magnesium turnings (300 mg; 12.3 × 10^{-3} g-atom) in the usual manner (8). The solvent was then removed with the aid of a stream of dry nitrogen, and the solid residue was suspended in anhydrous ether (50 ml). To the stirred suspension of vinyl Grignard reagent (ambient temperature, nitrogen atmosphere) was added in several portions from a dropping funnel, 2-methoxy-2-cyclopentene-1,4-dione, **3**, (1 g, 7.93 mmol) (5–7) suspended in ether (20 ml). The mixture was stirred under the same conditions for 4 h, after which saturated ammonium chloride solution was added. The material obtained on work-up (extraction with ethyl acetate etc.) was subjected to chromatography on preparative layer plates of silica gel (benzene–acetone 7:3), affording 98 mg of the cyclopentenedione starting material and 387 mg (32%) of **2**.

The product, **2**, was a colorless gum, ir (neat film) *inter alia* 3380 (br), 3100, 3020, 2990, 2950, 2850, 1690, 1600, 1332, 1252, 1206, and 1171 cm^{-1}; uv λ_{max}(CH_3OH) 238 nm; nmr δ 2.68 (2H, s), 3.73 (1H, br, exchangeable) 3.90 (3H, s), 5.33 (1H, s), and 5.14–6.23 (3H, m, *cf.* ref. 4); ms (peaks of relative abundance greater than 20%) *m/e*

[4]The culture medium was the basal synthetic medium of Jennison *et al.* (9), but with sucrose as carbon source. Nitrogen was provided by L-glutamic acid.

154.0626(79) (calcd. for $C_8H_{10}O_3$: 154.0630), 127(28), 125(24), 109(57), 108(25), 97(23), 96(87), 95(29), 57(25), and 55(100).

5-Hydroxy-3-methoxy-5-vinyl-2-cyclopenten-1-one, ***1***, *Synthetic*

The cyclopentenone vinyl carbinol, **2**, (150 mg, 0.97 mmol) was dissolved in anhydrous methanol (30 ml), and concentrated sulfuric acid (2 drops) was added. The pale yellow solution was stirred at 21°C for 4 h. It was then poured into dilute sodium carbonate solution, and extracted thoroughly with ethyl acetate. The extracts were washed with brine, dried over magnesium sulfate, and evaporated. Preparative layer chromatography of the residue on silica gel plates (benzene–acetone, 7:3) afforded starting material, **2**, (69 mg) and the isomer **1** (45 mg). After recrystallization from ether–*n*-hexane, **1** was obtained as colorless crystals, mp 65–67°C; ir ($CHCl_3$), uv (CH_3OH), and nmr ($CDCl_3$) spectra, as well as tlc behavior identical with those of the *Trichoderma* product; ir (KBr) *inter alia*, 3360 (br), 3100, 3025, 3005, 2980, 2950, 2850, 1680, 1575, 1355, 1250, 1195, 1150, 975, and 815 cm^{-1}; ms, *m/e* 154.0622; calcd. for $C_8H_{10}O_3$, 154.0630.

Acknowledgments

We thank Messrs A. I. Budd and J. Hoyle, University of Alberta, Edmonton, for the accurate mass measurements and circular dichroism measurements, respectively. Mrs. M. Austria, University of New Brunswick, kindly recorded other mass spectra.

The affinity of aldehydic compounds to complex formation. Nickel(II) and cobalt(II) complexes with 2-pyridinecarboxaldehyde

M. S. El-Ezaby,[1] M. A. El-Dessouky, and N. M. Shuaib

Department of Chemistry, Kuwait University, Kuwait

Received August 10, 1976[2]

M. S. El-Ezaby, M. A. El-Dessouky, and N. M. Shuaib. Can. J. Chem. **55**, 2613 (1977).

The interactions of Ni(II) and Co(II) with 2-pyridinecarboxaldehyde have been investigated in aqueous solutions at $\mu = 0.10\ M\ (KNO_3)$ at 30°C. The stability constants of different complex equilibria have been determined using potentiometric methods. Spectrophotometric methods were also used in the case of the nickel(II) – 2-pyridinecarboxaldehyde system. It was concluded that nickel(II) and cobalt(II), analogous to copper(II), enhance hyrdation of 2-pyridinecarboxaldehyde prior to deprotonation of one of the geminal hydroxy groups. Complex species of 1:1 as well as 1:2 metal ion to ligand composition exist under the experimental conditions used.

M. S. El-Ezaby, M. A. El-Dessouky et N. M. Shuaib. Can. J. Chem. **55**, 2613 (1977).

On a étudié, en solutions aqueuses, à une valeur de $\mu = 0.10\ M$ de (KNO_3) et à 30°C, les interactions du nickel(II) et du cobalt(II) avec le pyridinecarboxaldéhyde-2. On a déterminé, faisant appel à des méthodes potentiométriques, les constantes de stabilité des équilibres des différents complexes. On a aussi utilisé des méthodes spectrophotométriques dans le cas du système nickel(II) pyridinecarboxaldéhyde-2. On en conclut que le nickel(II) et le cobalt(II), comme le cuivre(II), augmentent l'hydratation du pyridine – carboxaldéhyde-2 avant la déprotonation de l'un des groupes hydroxy géminés. Des espèces complexes de composition ion métallique/ligand de 1:1 de même que 1:2 existent dans les conditions expérimentales utilisées.

Introduction

Although few reports discuss the complex formation of aldehydic compounds with metal ions, they are involved in Schiff bases metal complexes (1). Their importance cannot be overshadowed in many biological processes. Pyridoxal and pyridoxal phosphate, a well known 4-pyridinecarboxaldehyde derivative, in the presence of metal ions was shown to catalyze model reactions in vitro alone by enzymes in vivo (2).

In spite of the fact that some metal ions form quite stable complexes with some pyridinealdoximes (3), reports on the interaction of pyridinecarboxaldehydes with metal ions are scarce. The hydration of 2-pyridinecarboxaldehyde is facilitated in aqueous solutions by metal ions and, furthermore, one of the geminal hydroxy groups is easily deprotonated by forming a 5-membered chelate (4–6). In this work, we report the interaction of nickel(II) and cobalt(II) ions with 2-pyridinecarboxaldehyde.

Experimental

Materials

2-Pyridinecarboxaldehyde (2PA) was obtained from Fluka, and was redistilled under a reduced pressure of nitrogen and stored in dark at 0°C. Stock solutions of 1.0 *M* of the compound in 1.0 *M* HCl or 1.0 *M* HNO_3 were stored at 0°C in dark and were stable by uv spectral criteria (λ_{max} 235 nm ($\varepsilon_{max} = 6.1 \times 10^3$) for equilibrated aldehyde + hydrate, p*H* 6–10, $\mu = 0.5\ M$ KCl) over a

period of a month. The concentration of the stock solutions of $NiCl_2$ or $Ni(NO_3)_2$ and $Co(NO_3)_2$ were checked complexometrically by EDTA titrations.

Radiometer pH meter model 63 (accurate to ±0.01 pH units) provided with combined glass electrode type GK (301 c) was used to record the hydrogen-ion concentration. The titrations were carried out in 25 ml thermostated cell. Sodium hydroxide carbonate-free titrant (0.102 M) was added in small increments through Metrohm Herisau Multi-Dosimat E 415 microburette accurate to ±0.005 ml. The pH meter was calibrated as previously reported (7).

Spectrophotometric measurements in the visible region (wavelength range 450–700 nm) were recorded on a Unicam SP 8000 double-beam spectrophotometer. The instrument was calibrated as described previously (7).

All pH metric and spectrophotometric measurements were taken at 30°C. The ionic strength was 0.10 M KNO_3 in potentiometric work and 0.5 M KCl in the case of spectrophotometric study. In potentiometric study, solutions of different metal ions and ligand concentrations were used in the pH range 2.75–11.00. The metal ions concentrations were in the range (1.0–4.0) × 10^{-3} M and that of the ligand in the range of (1.0–6.0) × 10^{-3} M. In spectrophotometric work, the range of concentrations of nickel(II) ions was (0.006–0.015 M) and that of ligand was (0.1–0.5 M).

Results

Pyridinecarboxaldehydes may exist in different forms in aqueous solutions at various pH values. The equilibrium reactions which involve these species and their corresponding protonation constants are represented as follows:

$$[1] \qquad POH^- + H^+ \rightleftharpoons P.H_2O \qquad K_P \left\uparrow \right. + H^+$$

$$[2] \qquad POH^- + 2H^+ \rightleftharpoons HP.H_2O^+$$

$$[1a] \qquad \beta_{101}' = \frac{[P{\cdot}H_2O]}{[POH^-][H^+]}$$

$$[2a] \qquad \beta_{102}' = \frac{[HP{\cdot}H_2O^+]}{[POH^-][H^+]^2}$$

where $HP.H_2O^+$, $P.H_2O$, and POH^- are the hydrated species of the protonated and deprotonated species and the deprotonated form of the hydrated species, respectively. The protonation constants β_{101}' and β_{102}' can be determined by spectrophotometric methods (4). The protonation constant K_p can also be determined by potentiometric methods (4). The values of the constants are listed in Table 1.

The titration curves of the 1:1 ligand to metal ion ratio show sharp inflection at $a = 1$ (pH range 5.0–7.0), Fig. 1, coinciding with that of ligand indicating that complex formation did not occur at pH values lower than ~7.0. An inflection point, however, occurs at $a \simeq 3.0$ in Ni system and 2.5 in Co system which may indicate that a 1:1 complex in addition to a hydrolysable complex species may exist. Titration curves of other mole ratios indicated that 1:2

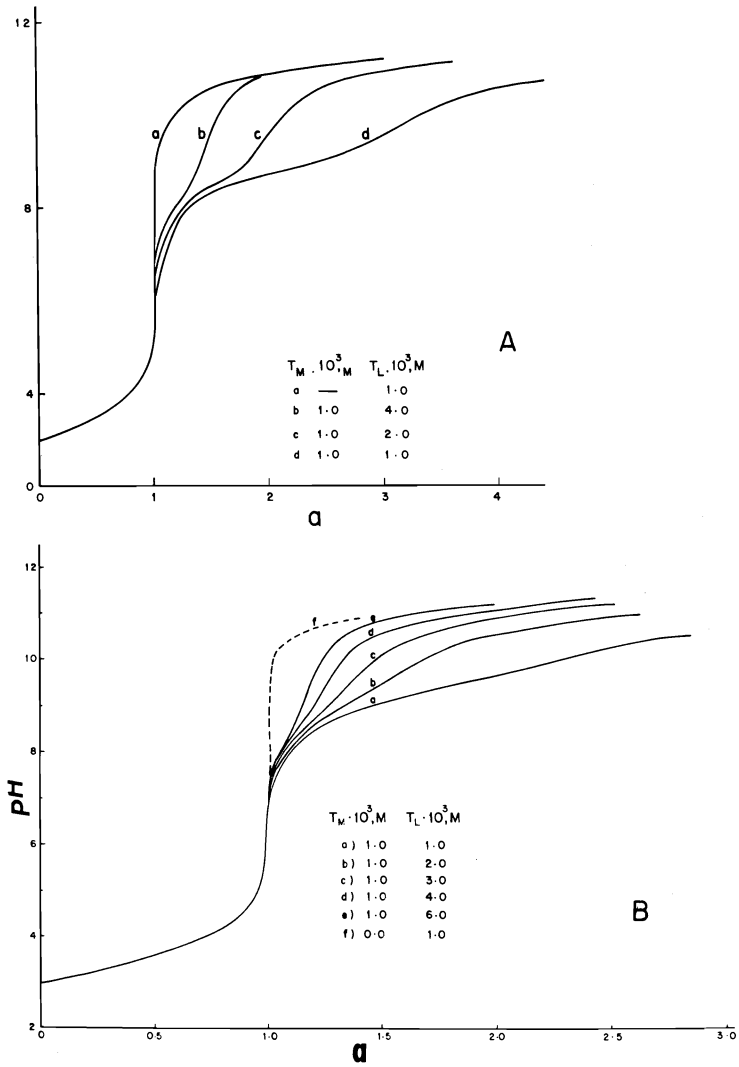

FIG. 1. The dependence of a (the ratio of moles of base to moles of ligand) on pH. (A) Ni(II)–2PA system; (B) Co(II)–2PA system.

complexes may occur with little possibilities of forming other higher complexes or even hydrolysable species, Fig. 1.

The color of the solutions of Ni(II)–2PA and Co(II)–2PA changed during titration from light green to light blue in the case of the former and purple to orange in the case of the latter. Slight precipitation occurs at pH values greater than 10.5, particularly in solutions of low ligand to metal ions ratios.

Titration data of the 1:1 ligand to metal ions ratio have been treated alone to describe different equilibria in solutions. Programme MINIQUAD and its modified versions MINIQUAD 75 have been used to test different models. Initially guessed values of stability constants β_{qjk} for the following generalized reaction are subjected to refinement

[3] $q\mathrm{P.H_2O} + j\mathrm{M^{2+}} + k\mathrm{H^+} \rightleftharpoons (\mathrm{P.H_2O})_q\,\mathrm{M}_j(\mathrm{H})_k^{2j+k}$

The model which gave the best fit is

[4] $\mathrm{P.H_2O} + \mathrm{M^{2+}} \rightleftharpoons (\mathrm{POH})\mathrm{M^+} + \mathrm{H^+}$

[5] $\mathrm{P.H_2O} + \mathrm{M^{2+}} + \mathrm{H_2O} \rightleftharpoons (\mathrm{POH})\mathrm{MOH} + 2\mathrm{H^+}$

[6] $\mathrm{P.H_2O} + \mathrm{M^{2+}} + 2\mathrm{H_2O} \rightleftharpoons (\mathrm{POH})\mathrm{M(OH)_2^-} + 3\mathrm{H^+}$

The MINIQUAD log β_{qjk}'s for the above model reactions are listed in Table 1. The

addition of one extra species or different model other than those shown above leads to an increase in the crystallographic R factor, greater X^2 value, or both. Equilibrium reactions 4, 5, and 6 have shown to occur only in Ni–2PA system while 4 and 5 only occur in Co–2PA system.

Titration data for other greater ligand to metal ions mole ratios indicated that only 2:1 complex species is further formed in solution. The equilibrium reaction which describes the experimental data is

$$[7] \quad 2P.H_2O + M^{2+} \rightleftharpoons (P.OH)_2M^0 + 2H^+$$

The MINIQUAD log β_{qjk}'s for Ni(II) and Co(II) systems are depicted in Table 1. The distribution diagram of the systems Ni(II)–2PA and Co(II)–2PA are shown in Fig. 2.

Ni(II)–2PA has been studied also by spectrophotometric methods. Figure 3 shows the spectra of Ni(II)–2PA system at different pH values in the wavelength range 450–700 nm. The band maxima shifted gradually to lower wavelengths as the pH increases. Isosbestic point is observed at λ 660 in the pH range 6.0–8.0. By using graphical methods (9), it was found that two absorbing species are present in the pH range 2.0–5.0 and 7.1–9.5. The pH dependence of absorbance (at a particular wavelength) on the initial concentrations of both metal ions and ligand is shown in Fig. 4. A unique formation curve was obtained when the average molar absorptivity ($= A_s/l\,T_M$) (where A_s, T_M, and l are the absorbance, total metal concentration, and light path length, respectively) was plotted against $-\log [P.H_2O]$ in the pH range 1.5–3.5, Fig. 5. The concentration of the free ligand, $P.H_2O$, was calculated by making use of the following equation

$$[8] \quad [P{\cdot}H_2O] = \frac{T_L[H^+]^{J-i}\prod_{l=0}^{i} k_l}{\sum_{j=0}^{J}[H^+]^{J-j}\prod_{l=0}^{j} k_l} \qquad T_L \gg T_M$$

Where k_l is the stepwise dissociation constant of the protonated ligand and T_L is the total ligand concentration. The absorbance data were analysed by the least-squares procedures. The sum of the squared deviations, s,

$$[9] \quad s = \sum_{1}^{N_p}(\bar{\varepsilon}_{obs} - \varepsilon_{calcd})^2 = \sum_{1}^{N_p}\left(\bar{\varepsilon}_{obs} - \frac{\sum_{0}^{N}\varepsilon_n\beta_n\,P{\cdot}H_2O}{\sum_{0}^{N}\beta_n\,P{\cdot}H_2O}\right)^2$$

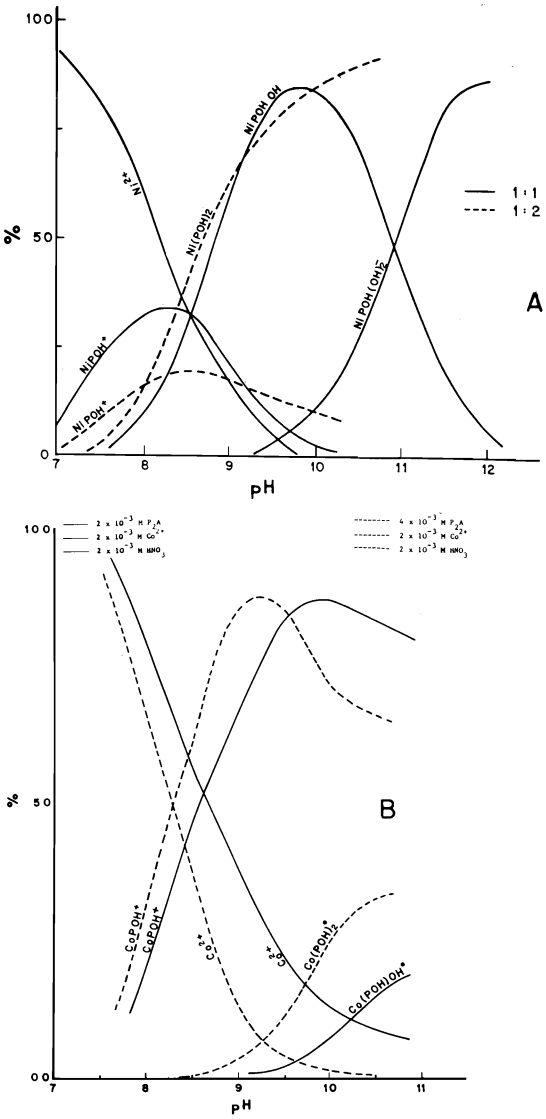

FIG. 2. Distribution of complex species. (*A*) Ni(II)–2PA system; (*B*) Co(II)–2PA system.

(where ε_n, β_n, N_p are the molar absorptivity of the nth species, the overall stability constant, and number of experimental points) is minimized with respect to the average molar absorptivity. Initially guessed values for the stability constants are usually made to solve for the $n + 1$ unknown by Gauss–Jordan elimination method. The method of steepest descents (10) is used to optimise the values of the stability constants to reduce s. The molar absorptivities and the sum of the squared residuals are then recalculated. The whole process may be repeated till refined β's could be obtained from the initial guesses. The plot of s *vs.* β_n or $\log \beta_n$ gives the optimum

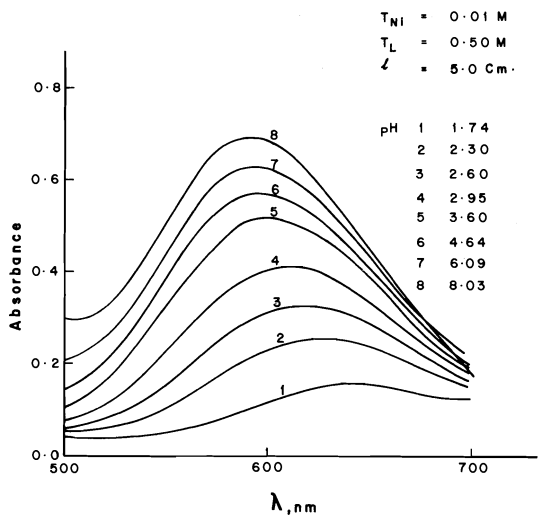

FIG. 3. The spectra of Ni(II)–2-pyridinecarboxaldehyde system at different pH values.

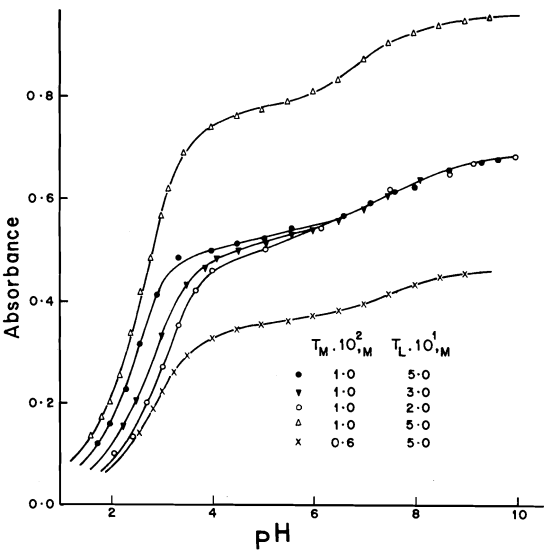

FIG. 4. The absorbance of Ni(II)–pyridinecarboxaldehyde system as functions of pH at λ 600 nm.

value of β_n which can be used to get β_m (7). Initial guesses for the stability constants of the following reactions

[10] $$Ni^{2+} + P.H_2O \rightleftharpoons NiP.H_2O^{2+}$$

$$\beta_{110} = \frac{[Ni\ P{\cdot}H_2O]}{[Ni^{2+}][P{\cdot}H_2O]}$$

[11] $$Ni^{2+} + 2P.H_2O \rightleftharpoons Ni(P.H_2O)_2{}^{2+}$$

$$\beta_{210} = \frac{[Ni(P{\cdot}H_2O)_2]}{[Ni^{2+}][P{\cdot}H_2O]^2}$$

have been subjected to refinement according to

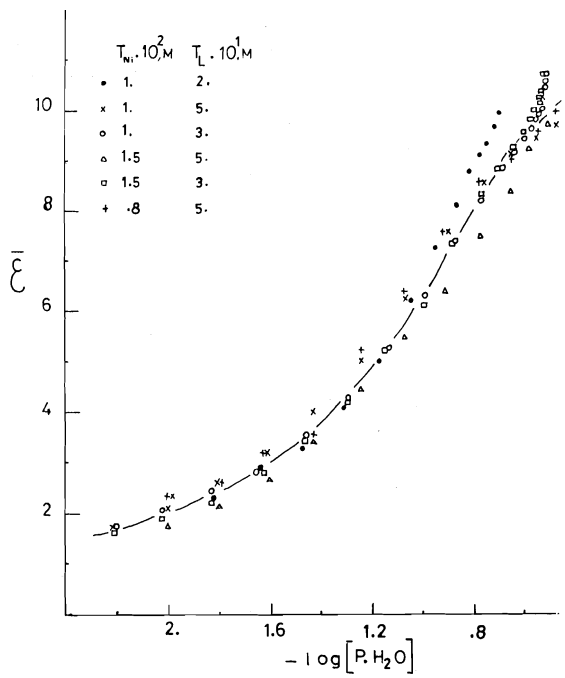

FIG. 5. The formations curve of Ni(II)–pyridinecarboxaldehyde system as functions of $P.H_2O$ species.

the above procedure using programme MONONUC (11). Table 2 shows the values of the refined β's. Back calculations of the $\bar{\varepsilon}$ from the obtained β's were in good agreement with the observed values within the allowed limits of experimental errors. At pH higher than 6 the absorbance is dependent upon pH when the metal concentration was kept constant while varying the initial concentration of the ligand, Fig. 4. This behaviour may be attributed to the deprotonation of the complex species $Ni(P.H_2O)_2{}^{2+}$ as the pH increases, *i.e.*,

[12] $$Ni(P.H_2O)_2{}^{2+} \rightleftharpoons Ni(P.H_2O)POH^+ + H^+$$

$$\beta_1 = \frac{[Ni(P{\cdot}H_2O)^{2+}]}{[Ni(P{\cdot}H_2O)POH^+][H^+]}$$

[13] $$Ni(P.H_2O)_2{}^{2+} \rightleftharpoons Ni(POH)_2 + 2H^+$$

$$\beta_2 = \frac{[Ni(P{\cdot}H_2O)_2{}^{2+}]}{[Ni(POH)_2][H^+]^2}$$

The protonation constants of the complex species $Ni(P.OH)_2$ can be calculated if first estimates of the β_1' and ε_0 can be determined at a given wavelength using eq. 14 (7).

[14] $$\bar{\varepsilon} = \frac{A_s}{lT_M} = \frac{\varepsilon_0 + \varepsilon_1\beta_1[H^+]}{1 + \beta_1[H^+]}$$

TABLE 2. Summary of the values of log β′ obtained from spectrophotometric methods for Ni(II)–2PA system at λ 600 nm

$T_M \times 10^2$	$T_L \times 10$	$\log \beta_{110}$	$\log \beta_{210}$	ε_1	ε_2
1.0	1.0	1.18	1.70	4.5	—
1.5	5.0	1.18	1.95	5.4	12.2
1.5	3.0	1.18	1.70	6.1	16.9
0.6	3.0	1.52	1.60	6.6	—
0.8	5.0	1.01	1.77	—	—
0.8	3.0	1.22	1.78	8.1	14.7
1.0	2.0	1.20	1.70	5.6	—
1.0	3.0	1.39	1.62	9.0	15.6
1.0	5.0	1.17	1.71	8.2	13.7

where ε_0 and ε_1 are the molar absorptivities of $Ni(POH)_2$ (they may be determined from the saturation value of absorbance in the pH range 9–10) and $Ni(P.H_2O)(POH)^+$ species. First approximations to ε_2 and β_2 at the same wavelength were evaluated using eq. 15.

$$[15] \quad \frac{\bar{\varepsilon} - \varepsilon_0}{[H^+]^2} + \beta_1 \frac{\bar{\varepsilon} - \varepsilon_1}{[H^+]} = \varepsilon_2\beta_2 - \bar{\varepsilon}\beta_2$$

where ε_2 is the molar absorptivity of $Ni(P.H_2O)_2$ which was employed to refine β_1 and ε_1 employing eq. 16.

$$[16] \quad \frac{\bar{\varepsilon} - \varepsilon_0}{[H^+]} + \beta_2[H^+](\bar{\varepsilon} - \varepsilon_2) = \varepsilon_1\beta_1 - \bar{\varepsilon}\beta_1$$

The results were found to converge by the third cycle of iteration. The values of log β_1' and log β_2' are 9.52 and 16.95, respectively.

Discussion

Complexes of Ni(II) and Co(II) with 2-pyridinecarboxaldehyde seem to be facilitated by the formation of the stable five-membered ring chelates through N and O atoms of the ligand. The chelates formation enhances deprotonation of the hydrated species of 2-pyridinecarboxaldehyde. The complex formation equilibria discussed in the forementioned results can be written in another form

$$[17a] \quad M^{2+} + POH^- \rightleftharpoons M(POH)^+$$

$$[17b] \quad M^{2+} + POH^- + OH^- \rightleftharpoons M(POH)(OH)$$

$$[17c] \quad M^{2+} + POH + 2OH^- \rightleftharpoons M(POH)(OH)_2$$

$$[17d] \quad M^{2+} + 2POH^- \rightleftharpoons M(POH)_2$$

Table 3 lists the calculated values of the stability constants of these equilibria including those reported for copper(II)–2PA system. It is clear that the order of complexing obeys the Irving–Williams series which, in turn, suggests high spin complexes in octahedral crystal field. However, the data cannot be interpreted in terms of the formation of more than bis complexes with 2PA. This conclusion strongly indicates that positive charge is essential for the complex species to attract another ligand species. In other words, neutral bis complex is incapable to deprotonate further a ligand species, $P.H_2O$, to form a tris chelated complex. However, the 5th and 6th coordination sites may be coordinated to the neutral ligand species, $P.H_2O$, or most probably to water molecules.

TABLE 3. Equilibrium constants for the equilibria 17

Parameter	Value		
	Co^{2+}	Ni^{2+}	Cu^{2+}
$\log \beta_{110}$	6.52	7.26	10.67
$\log \beta_{210}$	10.94	14.23	20.50
$\log \beta_{11-1}$	8.94	12.51	17.80
$\log \beta_{111}$	—	1.23	2.72
$\log \beta_{212}$	—	1.73	4.75

The enhanced deprotonation of hydrated species of 2-pyridinecarboxaldehyde may give the notion that metal complexes with pyridinic nitrogen can also facilitate deprotonation of one of the geminal diol of aldehyde group in either the meta or para position of pyridine. In current studies on the interaction of 4-pyridinecarboxaldehyde with amphetamine, it was found that metal ions, specially Cu(II), facilitate rapid condensation reactions at the ketone moiety at pH 5.0, a process which cannot be rapidly formed at pH's lower than 8 in the absence of metal ions (12). This kind of complex formation may raise the question of the possibility of other aldehydic compounds containing groups of complexing properties such as NH_2, OH . . . etc., to behave more or less in a similar manner.

Ammonium fluorolanthanates: solid state synthesis, infrared spectral and X-ray diffraction data

KRISHNAN RAJESHWAR AND ETALO A. SECCO[1]

Department of Chemistry, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received March 4, 1977

KRISHNAN RAJESHWAR and ETALO A. SECCO. Can. J. Chem. **55**, 2620 (1977).

Solid state synthesis of thirteen ammonium fluorolanthanates is reported. Two main types of fluorolanthanates appeared in the primary synthesis reaction, *viz.* NH_4LnF_4 and $(NH_4)_3Ln_2F_9$.

The final decomposition product of the fluorolanthanates is LnF_3 with $NH_4Ln_2F_7$ appearing as an intermediate in $(NH_4)_3Ln_2F_9$ decomposition.

Infrared absorption spectra and X-ray diffraction data for the stable fluorolanthanates are presented.

KRISHNAN RAJESHWAR et ETALO A. SECCO. Can. J. Chem. **55**, 2620 (1977).

On rapporte la synthèse à l'état solide de 13 fluorolanthanates d'ammonium. Il semble qu'il y a deux types principaux de fluorolanthanates qui apparaissent dans la réaction primaire de synthèse soit NH_4LnF_4 et $(NH_4)_3Ln_2F_9$.

Le produit de décomposition final des fluorolanthanates est LnF_3 alors que $NH_4Ln_2F_7$ apparait comme un intermédiaire dans la décomposition de $(NH_4)_3Ln_2F_9$.

On présente des spectres d'absorption infrarouge et des données de diffraction de rayons-X pour les fluorolanthanates stables.

[Traduit par le journal]

Introduction

Ammonium fluorolanthanate is a stable source of anhydrous lanthanide fluoride (1); also it is a member of a family of compounds exhibiting the novel property of an "up-converter" phosphor (2).

The synthesis of ammonium fluorolanthanate in liquid medium has been reported (1, 3): aqueous solution precipitation yields the hydrate while attempts to obtain the anhydrous compounds in non-aqueous media have not been successful. Recently the feasibility of "dry method" synthesis of anhydrous fluorolanthanate, *viz.* solid state reaction of La_2O_3 and NH_4F had been shown (4). This paper is a more comprehensive report on the "dry method" synthesis of a new series of ammonium fluorolanthanates along with their physico-chemical and structural properties. An attempt is made to correlate the observed trends in behavior with lanthanide ion size.

Experimental

La_2O_3, Pr_2O_3, Sm_2O_3, Gd_2O_3, Dy_2O_3, and Yb_2O_3 were supplied by Alfa Inorganics Inc., MA, U.S.A. while Nd_2O_3, Eu_2O_3, Tb_2O_3, Ho_2O_3, Tm_2O_3, Lu_2O_3, and Y_2O_3 were obtained from American Potash and Chemical Corp., IL, U.S.A.; the stated purities ranged from 99.9% to 99.999%. Each oxide was ignited to 800°C before using; no thermal effect was observed up to 850°C in the DTA heating trace after ignition. NH_4F was Fisher Certified grade.

Each Ln_2O_3–NH_4F reaction mixture was thoroughly mixed and ground in a mortar. An excess of NH_4F, 15:1, was used to ensure the fluorolanthanate with the highest NH_4F:LnF_3 ratio expected. The mixture contained in a covered Pt crucible was heated in a sealed oven, whose temperature was controlled within ± 1°C, in the range 130–150°C for a period 1–3 days. The progress of the reaction was noted by monitoring the weight loss as a function of anneal time. Completion of reaction was indicated by a gravimetric arrest and the absence of any property (X ray, DTA, etc.) characteristic of the reactants. This gravimetric value was compared with the theoretical value from the expected reaction scheme. The validity of the reaction scheme was confirmed by the decomposition behavior of the isolated intermediate compounds and the internal consistency of the experimental results.

Thermal analyses (DTA, TG, DTG) were done with the instrumentation and platinum-ware already described (5, 6). X-Ray powder diffraction patterns were obtained according to the procedure reported (7). Infrared spectra of the samples were recorded on Perkin-Elmer Model-180 instrument using Nujol and fluorocarbons as mulling agents (8).

Results

The observed and theoretical quantitative results for the various fluorolanthanates are tabulated in Table 1.[2] From these results the

[1]To whom correspondence should be addressed.

reactions may be classified into two groups:

Group A

[1] $Ln_2O_{3(s)} + nNH_4F_{(s)} \rightarrow 2NH_4LnF_{4(s)} + (n-2)NH_{3(g)} + (n-8)HF_{(g)} + 3H_2O_{(g)}$

where Ln = Pr, Nd, Sm, Eu, Gd, and Tb for $n \geq 8$;

Group B

[2] $Ln_2O_{3(s)} + nNH_4F_{(s)} \rightarrow (NH_4)_3Ln_2F_{9(s)} + (n-3)NH_{3(g)} + (n-9)HF_{(g)} + 3H_2O_{(g)}$

where Ln = Dy, Ho, Er, Tm, Yb, Lu, and Y for $n \geq 9$.

In addition to the above reaction equations, the unusual behavior of the La_2O_3–NH_4F reaction is to be noted where the stable solid product is a 1:1 mixture of NH_4LaF_4 and LaF_3 which results from the disproportionation of the unstable intermediate $NH_4La_2F_7$, *viz.*

[3*a*] $La_2O_{3(s)} + nNH_4F_{(s)} \rightarrow NH_4La_2F_{7(s)} + (n-1)NH_{3(g)} + (n-7)HF_{(g)} + 3H_2O_{(g)}$

for $n \geq 7$, and

[3*b*] $NH_4La_2F_{7(s)} \rightarrow NH_4LaF_{4(s)} + LaF_{3(s)}$

Thermal Analyses

Group A

The results on NH_4LnF_4 compounds, Table 2, are placed with the Depository of Unpublished Data.[2] NH_4PrF_4 is described below as a typical member.

DTA, TG, and DTG curves for NH_4PrF_4 are given in Fig. 1*A*, traces *a*, *b*, and *c*, respectively. A single step endothermic decomposition is observed, *i.e.*

[4] $NH_4PrF_{4(s)} \rightarrow PrF_{3(s)} + NH_{3(g)} + HF_{(g)}$

The calculated weight loss of 15.8% agrees with the observed 16.0%. The solid product PrF_3 was confirmed by its characteristic X-ray diffraction (9*a*).

DTA, TG, and DTG traces for the La compound are given in Fig. 1*B*. The DTA trace reveals two endothermic effects assigned to [3*b*] and [3*c*],

[3*c*] $NH_4LaF_{4(s)} \rightarrow LaF_{3(s)} + NH_{3(g)} + HF_{(g)}$

The TG heating curve of the unstable intermediate showed a single step [3*c*] since [3*b*] does not involve a weight change. The arrest in the isothermal–time gravimetric experiments corresponded to 38.7% weight loss which is consistent with the loss of 38.4% calculated for $n = 10$ according to [3*a*]. The observed weight loss of 8.2% agrees with the calculated loss of 8.6% from [3*c*].

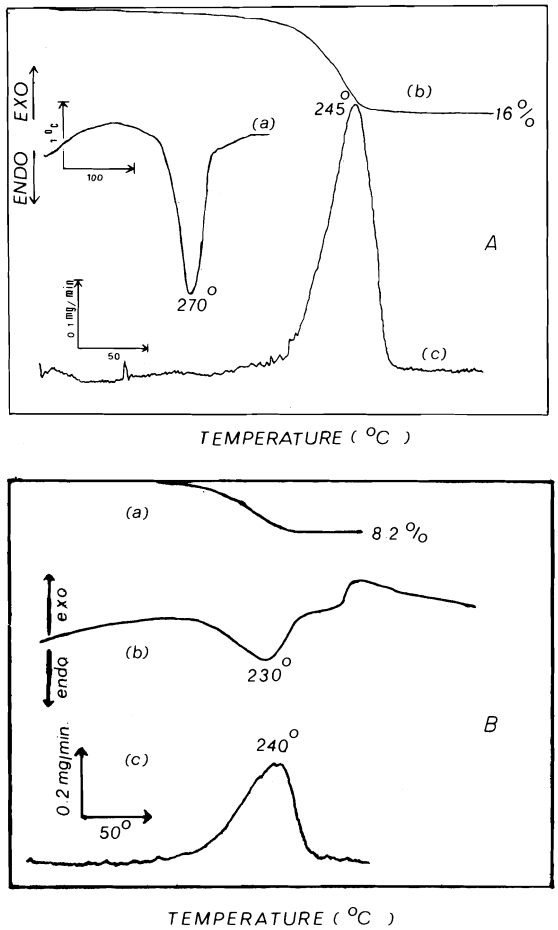

FIG. 1. (*A*) Thermal analyses traces for NH_4PrF_4; (*B*) thermal analyses traces for $NH_4LaF_4 \cdot LaF_3$.

Group B

The experimental data on $(NH_4)_3Ln_2F_9$ and $NH_4Ln_2F_7$ compounds, Table 3, are placed with the Depository of Unpublished Data.[2] The dysprosium compound is described below as representative of this group.

Figure 2*A* includes the DTA, trace *a*, TG, trace *b*, and DTG, trace *c* for $(NH_4)_3Dy_2F_9$. Two step decomposition is observed in accordance with [5*a*] and [5*b*],

[5*a*] $(NH_4)_3Dy_2F_{9(s)} \rightarrow NH_4Dy_2F_{7(s)} + 2NH_{3(g)} + 2HF_{(g)}$

[5*b*] $NH_4Dy_2F_{7(s)} \rightarrow 2DyF_{3(s)} + NH_{3(g)} + HF_{(g)}$

Heating $(NH_4)_3Dy_2F_9$ at 230°C permitted the

isolation of $NH_4Dy_2F_7$. Thermal analyses traces on $NH_4Dy_2F_7$, Fig. 2*B*, confirm reaction [5*b*]. DyF_3 was confirmed by X-ray powder diffraction (9*b*).

There was no evidence for the postulated ammine intermediates (1), *viz.* $YF_3 \cdot \frac{1}{2}NH_3$ and $ErF_3 \cdot \frac{1}{2}NH_3$, during the thermal decomposition of $(NH_4)_3Y_2F_9$ and $(NH_4)_3Er_2F_9$, respectively.

Infrared Spectral Data

The infrared spectral results for NH_4LnF_4, $(NH_4)_3Ln_2F_9$, and $NH_4Ln_2F_7$ are presented in Tables 4, 5, and 6, respectively. The number of active modes and their absorption frequencies display an internal consistency within each series. The assignments are based on the data of known ammonium fluorometallates.

The sequence of spectra for each fluorolanthanate, on stepwise heating to its decomposition temperature, reveals the progressive disappearance of bands characteristic of NH_4^+ leading to the final spectrum of Ln—F band characteristic of LnF_3.

X-Ray Diffraction Data

The X-ray powder diffraction data for NH_4LnF_4, $(NH_4)_3Ln_2F_9$, and $NH_4Ln_2F_7$ are tabulated in Tables 7, 8, and 9, respectively. The

[a]CuKα radiation.

number of active planes and their distances exhibit internal consistency within each series. However, the NH_4LnF_4 series reveals a distinction between Ln = Pr, Nd and Ln = Sm, Eu, Gd, Tb. Indexing the X-ray diffraction data by the Hesse–Lipson method (17, 18) shows a hexagonal system fit for NH_4NdF_4 and NH_4PrF_4 with unit cell dimensions a = 9.56 Å and c = 12.37 Å and a = 9.61 Å and 12.45 Å, respectively. On the other hand, NH_4SmF_4 and NH_4GdF_4 were indexed to the cubic system with a = 11.80 Å and 11.76 Å, respectively.

The close similarity of the diffraction data for the $(NH_4)_3Ln_2F_9$ series suggests these compounds to be isostructural. $(NH_4)_3Yb_2F_9$, selected as a representative member of this series, was indexed to the monoclinic system with unit cell dimensions a = 7.11 Å; b = 7.31 Å; and c = 12.54 Å.

The diffraction patterns for the $NH_4Ln_2F_7$ group of compounds also reveal an internal consistency associated with structural isotypes. The indexing of the diffraction data for $NH_4Dy_2F_7$, selected as representative of this group, showed the best fit for a cubic system with a = 13.40 Å.

Discussion

The members in the ionic radius range 1.35–1.55 Å, La—Tb, formed only NH_4LnF_4 compounds; the members from Dy to Y, ionic radius 1.58–1.69 Å, yielded $(NH_4)_3Ln_2F_9$ which in turn disproportionated to the corresponding $NH_4Ln_2F_7$. Our failure to detect certain $(NH_4)_3Ln_2F_9$ members, $(NH_4)_2Ln_2F_{11}$ and $NH_4Ln_3F_{10}$ series reported elsewhere (1, 10) may be explained in terms of (*i*) the higher solid synthesis temperature exceeded the compound stability temperature and (*ii*) the stabilizing effect of the solvent on specific compound formation in wet synthesis.

The known ammonium fluorolanthanates along with the ionic radius parameter ρ are listed in Table 10; ρ is defined as $r_{NH_4^+}/r_{M^{3+}}$, where $r_{NH_4^+}$ is the constant NH_4^+ radius and M^{3+} is the variable tervalent metal radius. The table reveals that lanthanides with ρ < 1.55 can form

$NH_4F:LnF_3$ compounds in ratios of 1:1, 1:2, and 3:2. For lanthanides with $1.55 < \rho < 1.69$, a wider range of compounds, excluding 1:1 ratio, is in evidence. Table 11 lists other ammonium fluorometallates for comparison purposes. In^{3+} with $\rho = 1.77$ exhibits the widest range of compounds including 1:1 type. Bi^{3+} and B^{3+} with ρ values of 1.49 and 6.22, respectively, form only 1:1 fluorometallate whereas the remaining M^{3+} elements with $1.96 < \rho < 2.81$ form 1:1 and 3:1 compounds. Two regions of stability for the 1:1 compound in NH_4F–MF_3 systems are noted, *viz.* $1.35 < \rho < 1.55$ and $\rho > 1.77$; the 3:1 compound is observed only for $\rho > 1.77$.

Thoma (11) predicted $ALnF_4$ formation for $1.40 > \rho > 0.77$ and A_3LnF_6 formation for $\rho > 1.43$ in AF_3–LnF_3 systems (A = alkali element). Obviously, the ammonium fluorometallates do not fit the simplified prediction by Thoma: hydrogen bonding from NH_4^+ could be the critical factor responsible for the extensive range of stable composition in ammonium fluorometallates.

The peak decomposition temperatures of the fluorolanthanates observed in this study along with NH_4ScF_4 and NH_4FeF_4 are plotted against corresponding ρ values in Fig. 3. The thermal stabilities of NH_4LnF_4 and $NH_4Ln_2F_7$ rise with increasing ρ value whereas $(NH_4)_3Ln_2F_9$ becomes less stable at higher ρ values. The higher stability of $NH_4Ln_2F_7$ relative to its parent $(NH_4)_3Ln_2F_9$ is evident. The results also support the failure to observe NH_4LnF_4 as a stable intermediate in the decomposition of its parent $NH_4Ln_2F_7$. However, extrapolation of the linear dependence of the $NH_4Ln_2F_7$ series to $NH_4La_2F_7$ suggests that NH_4LaF_4 can be a stable product of $NH_4La_2F_7$ decomposition as observed.

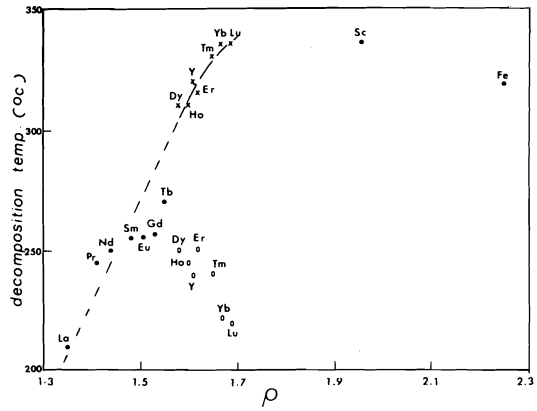

FIG. 3. Plot of peak decomposition temperatures of fluorolanthanates versus ρ, ionic radius parameter.

Hydrogen bonding in the ammonium fluorolanthanates is indicated in the infrared spectra by the splitting of the triply degenerate ν_4 of NH_4^+, the multiplicity of absorption peaks in 2900–3300 cm^{-1} regions and the appearance of the $(\nu_4 + \nu_6)$ combination band (12). By analogy with Fe and Al analogs (13, 14), the ammonium fluorolanthanate structure may be visualized as layers of LnF_6 octahedra (built up by mutual sharing of corners and edges) with interleaving layers of NH_4 groups. The splitting of ν_3 and ν_4 modes in the octahedral LnF_6^{3-} suggests a distorted configuration. It is to be noted that the triply degenerate ν_4 does not split in $NH_4Ln_2F_7$. A detailed discussion of these structures must await single-crystal structural data.

NOTE ADDED IN PROOF: The assignment of 2300 cm^{-1} frequency to the combination $\nu_4 + \nu_6$ was questioned by one referee. We suggest therefore the combination band is more likely $\nu_2 + \nu_6$, consistent with ref. 15.

Study of NH_4EuF_4 in solid state reaction Eu_2O_3–NH_4F. Thermal analyses, calorimetry, and decomposition kinetics

KRISHNAN RAJESHWAR AND ETALO A. SECCO[1]

Department of Chemistry, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received March 4, 1977

KRISHNAN RAJESHWAR and ETALO A. SECCO. Can. J. Chem. **55**, 2628 (1977).

The solid state reaction Eu_2O_3–NH_4F leading to the formation of NH_4EuF_4 was studied by thermal analyses and X-ray diffraction.

The heat of decomposition of NH_4EuF_4 and the kinetics of thermal decomposition of NH_4EuF_4 are reported.

KRISHNAN RAJESHWAR et ETALO A. SECCO. Can. J. Chem. **55**, 2628 (1977).

On a étudié, à l'aide d'analyses thermiques et de diffraction de rayons-X, la réaction à l'état solide de Eu_2O_3–NH_4F conduisant à la formation de NH_4EuF_4.

On rapporte l'enthalpie de décomposition de NH_4EuF_4 et sa cinétique de décomposition thermique.

[Traduit par le journal]

Introduction

The formation of ammonium fluorolanthanate as a stable intermediate was reported in the solid state reaction of Ln_2O_3–NH_4F which yields LnF_3 as the final product (1, 2). No study has yet been reported on the steps leading to the fluorolanthanate formation and its subsequent mode of decomposition.

This paper contains the results of thermal analyses, calorimetry, and thermal decomposition kinetics on NH_4EuF_4, selected as a typical member of the NH_4LnF_4 series.

Experimental

The Eu_2O_3 used had a stated purity of 99.999% supplied by American Potash and Chemical Corp., West Chicago, IL, U.S.A. and the NH_4F was Fisher Certified grade.

The procedure followed for the synthesis of ammonium tetrafluoreuropiate(III) is described elsewhere (2).

Thermal analyses (DTA, TG, DTG) were done with the instrumentation and Pt-ware already described (2).

The heat of decomposition was determined using the DSC accessory to the duPont 990 Thermoanalyzer module; zinc fusion was used as standard. The specific heats of NH_4EuF_4 and EuF_3, at constant pressure, were determined as a function of temperature using a sapphire disc as standard. Gold sample pans were used in DSC measurements.

X-Ray powder diffraction patterns were obtained according to the procedure reported (3). Infrared spectra of the samples were recorded on Perkin-Elmer Model-180 instrument using Nujol and fluorocarbons as mulling agents (4).

Results and Discussion

The DTA heating trace for 1:10 molar ratio Eu_2O_3:NH_4F, Fig. 1, reveals three endothermic effects. The first endotherm is attributed to overlapping reactions, disproportionation of NH_4F as reported (1, 5), and fluorination of Eu_2O_3, *viz.*

[1*a*] $$n NH_4F_{(s)} \rightleftarrows (n/2)NH_4HF_{2(l)} + (n/2)NH_{3(g)}$$

and

[1*b*] $$Eu_2O_{3(s)} + nNH_4HF_{2(l)} \rightarrow 2NH_4EuF_{4(s)} + (n-2)NH_3 + (n-8)HF_{(g)} + 3H_2O_{(g)}$$

where the symbols *n*, s, l, and g assume their normal usage. The second thermal effect is due to volatilization of unreacted bifluoride, *i.e.*

[2] $$NH_4HF_{2(l)} \leftrightarrows NH_{3(g)} + 2HF_{(g)}$$

which is confirmed by its peak intensity depen-

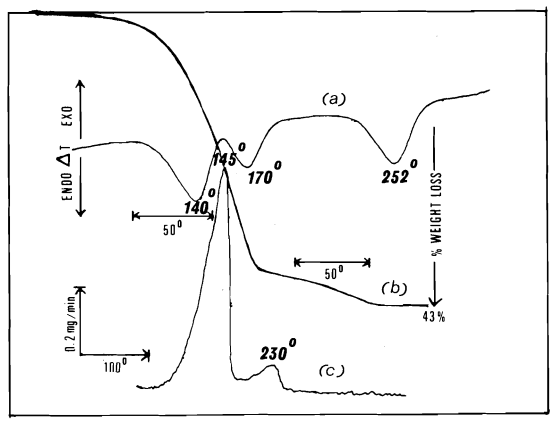

FIG. 1. Thermal analyses traces for 1:10 molar ratio Eu_2O_3:NH_4F mixture.

[1]To whom correspondence should be addressed.

dence on NH_4F excess in the mixture. TG and DTG traces, Fig. 1, exhibit the expected weight losses consistent with the assignments.

The X-ray powder diffraction pattern of the residue after the second endothermic peak, 180°C, is identified with the NH_4EuF_4 pattern (2). The diffraction pattern of the residue after the third endotherm is identified with EuF_3 in the orthorhombic modification (6). Infrared spectra of the residues are also consistent with the identification of NH_4EuF_4 and anhydrous EuF_3 (2) at the appropriate stages in heating. Accordingly, the third endotherm in DTA and the second peak in DTG traces are due to decomposition, *viz.*

[3] $$NH_4EuF_{4(s)} \rightarrow EuF_{3(s)} + NH_{3(g)} + HF_{(g)}$$

Figure 2 presents TG, DTA, and DTG heating traces a, b, and c, respectively, for NH_4EuF_4 prepared under isothermal conditions (2).

The ΔH of decomposition of NH_4EuF_4, reaction 3 in the range 235–265°C, is determined to be 21.82 ± 0.10 kcal/mol. Heat capacity measurements as a function of temperature indicate a heat capacity change of −0.004 kcal/mol deg associated with the decomposition, negligible within limits of the ΔH measurement. Using the literature values (7, 8) for ΔH_f^0 of $NH_{3(g)}$, $HF_{(g)}$, and $EuF_{3(s)}$, that is, −11.04 kcal/mol, −64.80 kcal/mol, and −429 kcal/mol, respectively, the ΔH_f^0 of $NH_4EuF_{4(s)}$ is computed as −526.6 kcal/mol.

The standard ΔH of reaction 1*c* is calculated,

[1*c*] $$Eu_2O_{3(s)} + 8\,NH_4F_{(s)} \rightarrow 2\,NH_4EuF_{4(s)} + 6\,NH_{3(g)} + 3\,H_2O_{(g)}$$

using literature data (9, 10) to be −12.44 kcal. The absence of any exothermic effect in the DTA trace is due to the greater endothermic effect generated by reaction 1*a* with $\Delta H = \sim +16$ kcal. The first endotherm represents, therefore, a net thermal effect. Previous studies on ammonium fluoride – metal fluoride complexes (11) have shown that thermal effects originating with NH_4HF_2 formation frequently overshadow the effect arising from the actual complex formation.

The standard enthalpy change for direct fluorination, reaction 1*d*, *viz.*

[1*d*] $$Eu_2O_{3(s)} + 8\,NH_4F_{(s)} \rightarrow 2\,EuF_{3(s)} + 8\,NH_{3(g)} + 2\,HF_{(g)} + 3\,H_2O_{(g)}$$

shows a large positive value. The standard entropy changes for both [1*c*] and [1*d*] are assumed to be sufficiently positive at the reaction temperature to yield a negative free energy term to favor reaction 1*c*, that is, formation of NH_4EuF_4 intermediate. This interpretation suggests that NH_4EuF_4 resulting from the secondary reaction between EuF_3 and excess NH_4F, *i.e.*

[4] $$EuF_{3(s)} + NH_4F_{(s)} \rightarrow NH_4EuF_{4(s)}$$

is energetically unfavorable.

Thermal Decomposition Kinetics

The isothermal decomposition of ammonium tetrafluoroeuropiate(III) was studied in the range 160–225°C. The experimental fractional decomposition *vs.* time ($\alpha - t$) data were processed through all the known kinetic rate expressions. The $\alpha - t$ data, $\alpha \geq 0.9$ and over the temperature range studied, show the best linear relationship with the contracting-sphere equation, Fig. 3.

[5] $$1 - (1 - \alpha)^{1/3} = kt$$

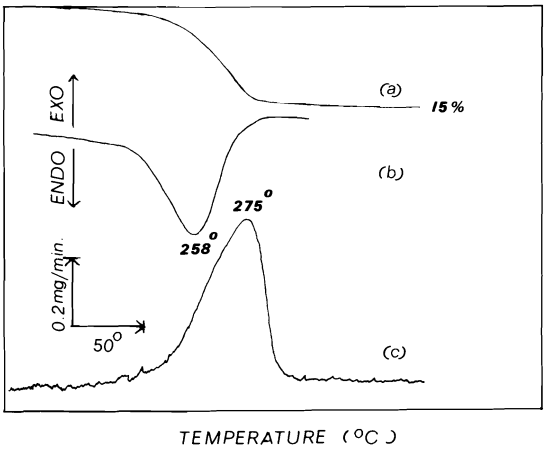

FIG. 2. Thermal analyses traces for NH_4EuF_4.

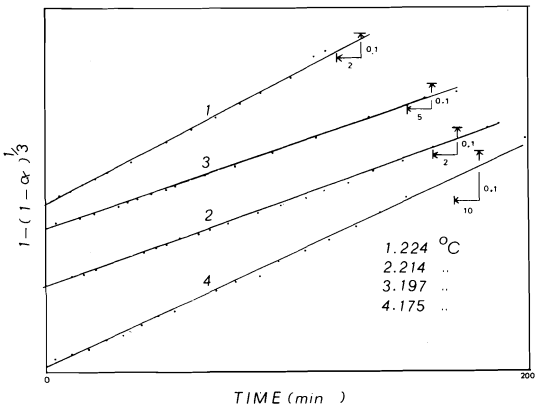

FIG. 3. Plot of $1 - (1 - \alpha)^{1/3}$ *vs.* time.

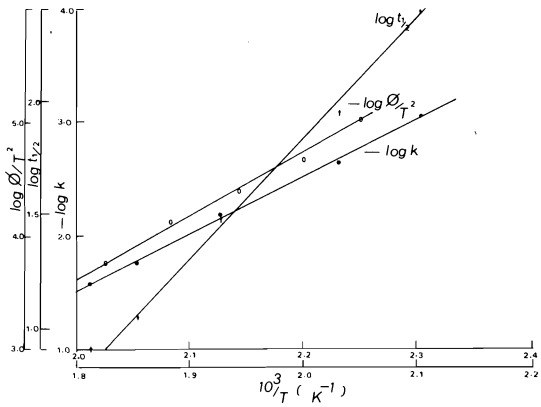

FIG. 4. Plots of log rate parameter *vs.* $10^3/T$ (K).

The activation energy, E_a, of 23 $\pm$ 1 kcal/mol is obtained from the slope of the Arrhenius plot, Fig. 4.

Two additional independent evaluations of E_a, Fig. 4, yield values of 24 $\pm$ 1 kcal/mol, from log $t_{1/2}$ ($t_{1/2}$ is half-life) *vs.* $10^3/T$(K) plot under isothermal conditions, and 26 $\pm$ 2 kcal/mol, from log ϕ/T^2 *vs.* $10^3/T$(K) plot under continuous, non-isothermal heating conditions where T is the peak temperature for the specific heating rate ϕ, 2–50°C/min. The reproducible value for E_a, within experimental limits, obtained by three independent analytical methods establishes a high confidence index for E_a.

The cubic crystal structure of NH_4EuF_4 may be compared with its analogues NH_4FeF_4 and NH_4AlF_4 (12, 13) where layers of EuF_6^- octahedra are interspersed with layers of NH_4^+ groups. The decomposition mode is postulated to proceed via proton-transfer from NH_4^+ to neighboring EuF_6^- resulting in the formation of NH_3 and HF, *i.e.*

[6] $NH_4EuF_{4(1/2\ c)} \rightarrow (NH_3 \ldots HF \ldots EuF_3)_{ad}$

where "1/2 c" refers to a "half-crystal" site on the surface and "ad" refers to surface adsorbed state. The subsequent growth of the product layer of EuF_3 in a three dimensional manner follows. Support for eq. 6 and the proton-transfer step is based on the close correspondence of E_a for NH_4EuF_4 and ammonium perchlorate (14) where it is accepted that a proton-transfer step is operative in the perchlorate.

Simple electrochemical synthesis of vanadium(II) halides

JACOB J. HABEEB, LYNN NEILSON, AND DENNIS G. TUCK
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received February 28, 1977

JACOB J. HABEEB, LYNN NEILSON, and DENNIS G. TUCK. Can. J. Chem. **55**, 2631 (1977).

Vanadium metal dissolves rapidly in a cell Pt/X_2 in CH_3CN/V (anode) (X = Cl, Br, I) under applied voltages of 5–50 V. The solution phase yields crystalline $VCl_2.2CH_3CN$, $VBr_2.CH_3CN$, or VI_2; the acetonitrile adducts decompose to VX_2 on heating in vacuo. Overall yields of VX_2, based on weight of metal dissolved, are 80–90%.

JACOB J. HABEEB, LYNN NEILSON et DENNIS G. TUCK. Can. J. Chem. **55**, 2631 (1977).

Le vanadium métallique se dissout rapidement dans une cellule Pt/X_2 dans CH_3CN/V (anode) (X = Cl, Br, I) lorsque l'on applique des voltages de 5 à 50 V. De la phase liquide se forment le $VCl_2.2CH_3CN$, $VBr_2.CH_3CN$ ou VI_2 à l'état cristallin; les adduits avec l'acétonitrile se décomposent en VX_2 par chauffage sous vide. Dans chaque cas le rendement global de VX_2, basé sur le poids de métal dissous, est d'environ 80 à 90%.

Introduction

Reviews of the chemistry of vanadium show that the lower oxidation states are the least accessible, and the chemistry of vanadium(II) in particular is relatively unexplored (1). Routes to this oxidation state is aqueous solution (2, 3) require the electrolytic or chemical reduction of V^V, V^{IV}, or V^{III}. A number of preparations of anhydrous VCl_2, VBr_2, and VI_2 have been reported (ref. 4, pp. 134–137); these have generally involved reduction of VX_3 with hydrogen at 500°C, the reaction of VX_3 and HX (X = Cl only) at 950°C, or the disproportionation of VX_3 at temperatures above 400°C. We now report that the acetonitrile adducts of VCl_2 and VBr_2 can be prepared in good yield at room temperature by the electrochemical oxidation of vanadium metal in the presence of halogen in acetonitrile solution. The adducts are easily decomposed *in vacuo* to yield the parent dihalides. In the case of iodine, the method yields VI_2 directly. The preparative method is similar to that reported previously for complexes of indium (5), for anionic halogeno complexes of transition metals (6), and for organo-cadmium compounds (7).

Experimental

Materials

Vanadium metal (99.7%) was supplied by Alfa Inorganics in the form of a rod, 5 mm diameter. Acetonitrile (reagent grade) was dried and redistilled before use. Halogens (reagent grade) were used as supplied.

Voltages between 5 and 50 V (dc) were supplied from a Coutant 50/50 power pack, delivering up to 50 V and 0.5 A; any dc unit satisfying these conditions can be used.

Electrochemical Procedure

In a typical experiment, 50 cm^3 acetonitrile containing 10 mg of tetraethylammonium perchlorate and 2–3 g bromine (or iodine) formed the solution phase, which was deoxygenated by bubbling with nitrogen before electrolysis. In the case of chlorine, a stream of gas (~25 cm^3 per min) was bubbled through the solution together with diluent nitrogen. The vanadium anode had a surface area (in contact with the solution) of 1.5 cm^2; the cathode was a coil of platinum wire (1 mm in diameter, 10 cm long). The electrodes were 1–2 cm apart. The voltage and current set out below are those actually observed in our experiments, and would no doubt be affected by changes in solution composition, etc. We have made no attempt to study the effect of such variables on the yield.

Analytical Procedures

Vanadium was determined by measuring the absorption at 450 nm following the addition of hydrogen peroxide (8). A standard solution was prepared by dissolving vanadium metal in acid.

Halogen was determined titrimetrically with potassium thiocyanate/silver nitrate, and by the Oakdale–Thompson method (9).

Results and Discussion

Vanadium(II) Chloride

Vanadium dissolved readily at a voltage of 28 V; the current was maintained at approximately 150 mA for 1 h. The green solution formed in the first 10 min gave way to a dark brown mixture. After expulsion of excess chlorine with nitrogen at the end of the electrolysis, dry ether was added to bring down a dark green precipitate which was dried *in vacuo* for 30 min at 230°C. This compound, $VCl_2.2CH_3CN$ (see Table 1), on further heating (15 min at 350°C) formed the dark brown – black VCl_2. The yield of $VCl_2.2CH_3CN$ (1.8 g) was 90%, based on

TABLE 1. Analytical results for vanadium(II) halides

Compound	Vanadium Found (%)	Vanadium Calcd. (%)	Halogen Found (%)	Halogen Calcd. (%)
$VCl_2.2CH_3CN$*	25.3	25.0	34.8	34.8
VCl_2	41.8	41.8	58.2	58.2
$VBr_2.CH_3CN$†	20.3	20.2	63.9	63.5
VBr_2	24.3	24.2	75.1	75.8
VI_2	16.5	16.7	82.7	83.3

*The presence of CH_3CN was confirmed by infrared absorptions (Nujol mull) at 2310 ($\nu(C\equiv N)$) 998, 903, and 725 cm^{-1}.
†CH_3CN vibrations (Nujol mull) at 2320, 980, and 730 cm^{-1}. Both acetonitrile adducts appear to react on grinding with alkali metal halides.

vanadium dissolved (0.51 g). The current efficiency is surprisingly high; a total of 700 coulomb (7.2×10^{-3} Faraday) caused 0.01 mol of vanadium to dissolve, to be compared with a quantity of 3.6×10^{-3} mol calculated on the assumption that the primary electrode process is $V_{(m)} \rightarrow V^{2+}{}_{(sol)} + 2e^-$. This efficiency ($\sim$275%) implies that substantial chemical reaction is occurring between vanadium and chlorine under the reaction conditions. Vanadium metal does not react with chlorine below 200–250°C, and in any case in such reactions the product (ref. 4, p. 120) is VCl_4 rather than VCl_2. Hathaway and Holah (10) have reported that vanadium reacts with elemental chlorine, bromine, and iodine in acetonitrile (= L), but in each the product is a vanadium(III) species, which in the case of chlorine is formulated by these authors as $[VCl_3L_3]L$. In the present case, the precipitation of $VCl_2.2CH_3CN$ from the reaction mixture establishes that the final product VCl_2 is not formed by thermal decomposition of some higher halide.

One obvious explanation of the present results would involve the chemical and electrolytic oxidation $V_{(m)} \rightarrow V^{3+}{}_{(sol)}$, followed by cathodic reduction to $V^{2+}{}_{(sol)}$. Against this, however, must be set the work of Suzuki (11), who showed that anodic dissolution of vanadium metal into a LiCl/KCl eutectic gave rise to $V^{2+}{}_{(sol)}$, both immediately after dissolution and in equilibrated melts. We tentatively conclude that the direct electrolytic production of vanadium(II) accounts for a fraction of the VCl_2 produced; the remainder, perhaps a substantial fraction, may result from electrolytic and/or chemical reduction in situ. Whatever the detailed mechanism, the method is a rapid and simple route to VCl_2 and $VCl_2.2CH_3CN$. The structure of these compounds is by no means established, and either one or both may involve metal cluster units. Little is known about the adducts of VCl_2, other than the hydrates (3, 12); the compounds $VCl_2.2EtOAc$ (13), $VCl_2.4py$ (13), and a series of ammines (14) and methylammines (15) have been reported, but no structural information is available. Further work on this topic is planned.

Vanadium(II) Bromide

A voltage of 5 V gave a current of 45 mA, which was maintained for 8 h, by which time 0.115 g of vanadium had dissolved. The black crystals which had deposited in the vessel were collected, crushed, and dried *in vacuo* at 120°C for 30 min. Analysis showed that this material was the adduct $VBr_2.CH_3CN$ which on further heating (230°C, 10 min) lost acetonitrile to give the black VBr_2. The yield of $VBr_2.CH_3CN$ (0.47 g) is 84%, based on the vanadium dissolved. The current efficiency, calculated as for the chloride, is 33%, suggesting that in this case there is no significant chemical process over and above the electrochemical reaction.

As in the chlorine system, there are previous reports in the literature on the direct reaction of vanadium metal and bromine. At high temperatures (ref. 4, p. 132) (400–550°C), the product is VBr_3, whereas the reaction in hot acetonitrile (10) produces $[VBr_2L_4](Br_3)$. The electrochemical process therefore is unique in stabilising the vanadium(II) state.

Vanadium(II) Iodide

Electrolysis for 2 h at 50 V and 40 mA caused 0.063 g of vanadium to dissolve (current efficiency 83%). Black crystals were deposited in the cell; these were collected, washed with petroleum ether, and dried *in vacuo* (25–80°C). This solid is vanadium(II) iodide (yield 100 mg; 26% based on vanadium consumption). We were not able to recover any further material from the reaction mixture.

Again we may note the sharp difference between the electrochemical product and that from direct reaction between vanadium and iodine in a sealed tube at 120–300°C (VI_3) (ref. 4, p. 133), or in hot acetonitrile (10) ($[VL_6](I_3)_3$).

General

The preparations described lead to vanadium(II) halides and their acetonitrile derivatives in good yield. The method is quick and simple, although the mechanism and processes involved

are not yet clear. The adducts of VCl_2 and VBr_2 present interesting problems which we plan to investigate further.

The enthalpy of isomerisation of methyl isocyanide

MOHAMMAD H. BAGHAL-VAYJOOEE, JOHN L. COLLISTER, AND HUW O. PRITCHARD
Chemistry Department, York University, Downsview, Ont., Canada M3J 1P3

Received March 2, 1977

MOHAMMAD H. BAGHAL-VAYJOOEE, JOHN L. COLLISTER, and HUW O. PRITCHARD. Can. J. Chem. **55**, 2634 (1977).

A controlled thermal explosion in which methyl isocyanide isomerises quantitatively to methyl cyanide has been studied in a calorimeter at 300 K. The enthalpy of isomerisation $\Delta H = -23.70 \pm 0.14$ (2 sdm) kcal mol^{-1}, from which values of the enthalpies of formation of both gaseous and liquid methyl isocyanide are calculated.

Similar measurements for ethyl isocyanide yield $\Delta H = -21.5 \pm 1.0$ kcal mol^{-1}.

MOHAMMAD H. BAGHAL-VAYJOOEE, JOHN L. COLLISTER et HUW O. PRITCHARD. Can. J. Chem. **55**, 2634 (1977).

On a étudié une explosion thermique contrôlée dans laquelle l'isocyanure de méthyle s'isomérise quantitativement au cyanure de méthyle; cette étude a été effectuée dans un calorimètre à 300 K. L'enthalpie d'isomérisation $\Delta H = -23.70 \pm 0.14$ (2 sdm) kcal mol^{-1}; à partir de cette donnée, on a pu calculer les valeurs des enthalpies de formation de l'isocyanure de méthyle à l'état gazeux et à l'état liquide.

Des mesures semblables avec l'isocyanure d'éthyle conduisent à un $\Delta H = 21.5 \pm 1.0$ kcal mol^{-1}.

[Traduit par le journal]

Introduction

The currently accepted value for the enthalpy of isomerisation of methyl isocyanide to methyl cyanide is of the order of (minus) 15–16 kcal mol^{-1}, this being the difference between the heat of combustion for methyl isocyanide measured by Guillemard (1) and by Lemoult (2), and the heat of combustion for methyl cyanide measured by Lemoult (2). It has now become important to know this quantity with greater precision, particularly in the analysis of thermal explosion-limit data for methyl isocyanide (3), but also in an analysis of the unimolecular fall-off data for this isomerisation (4).

After some reflection, it will become clear to the reader that in this particular case, measurements of the high-temperature equilibrium for this isomerisation would be, to say the least, very difficult, and therefore a calorimetric technique would seem to be more tractable. Consequently, we undertook a study of the thermal isomerisation of gaseous methyl isocyanide induced by an electrically heated filament, on a scale consistent with an accurate calorimetric determination of the energy released: our principal constraint was the nature of the calorimeter available, a diphenyl-ether isothermal calorimeter (5) operating at 27°C, and the most severe limitation was the size of the reaction-vessel cavity, which was much too small for us to have exploited the full accuracy of this calorimeter in these measurements.

The Controlled Thermal Explosion of Methyl Isocyanide

The basic design constraints are as follows: the maximum reaction vessel size is 200 ml and the vapour pressure of the product at 27°C is 100 Torr; this corresponds to approximately 10^{-3} mol of the reactant, and an expected energy release of about 15 cal. The accuracy of the calorimeter is of the order of 0.01% for energy releases of the order of 350 cal.

Our initial experiments showed that if a platinum wire suspended on the axis of the vessel was heated to a temperature of about 375°C in the presence of about 100 Torr of methyl isocyanide, liquid condensed on the walls immediately, and a brown residue was produced. However, if the initial pressure of isocyanide was reduced to about 50 Torr, the pressure rise due to heating in the centre of the vessel was insufficient to cause condensation at the walls, and the isocyanide was converted cleanly and completely to the cyanide in about 4 min: using a 0.003 in. diameter platinum wire, the electrical energy release was of the order of 250 cal, compared with the chemical energy release of now, about 7

or 8 cal. On the other hand, if the wire was heated to 450°C, an explosion occurred after about 1 s: the isocyanide was completely consumed, the major product was methyl cyanide in about 98% yield, together with a small amount of non-condensable gas (about 0.2 Torr) and some slight discoloration of the vessel walls. Moderation of this explosion with about 50 Torr of carbon dioxide reduced the severity of the explosion somewhat, with the result that the conversion of isocyanide to cyanide was between 99.97 and 99.99% complete, and no non-condensable products were formed.

Experimental Details

As a result of this experimentation, the final experimental arrangement was as follows. A 35 cm length of 0.001 in. diameter platinum wire was suspended in the form of a V (using a small glass bead as a weight to keep it taut) down the centre of the cylindrical reaction vessel, 19 cm long and 4 cm in diameter. The reaction vessel was completed with a small-bore Teflon stopcock with FETFE sealing rings (Ace Glass 8195-03), appropriate current and potential leads for the platinum heating wire, and a pair of heat shields to prevent convection of heat up the main calorimeter tube (*cf.* Fig. 1 of ref. 5).

The vessel was pumped out on a vacuum line and filled with about 50 Torr of pure methyl isocyanide, the pressure being measured with a Texas Instrument quartz spiral gauge (calibrated by cathetometer against a wide-bore mercury manometer) and a Hewlett-Packard 2802A thermometer (calibrated at 0°C and 327°C): these observations were required to define the number of moles of reactant. Then about 50 Torr of inert gas, either carbon dioxide or argon, was added and the reaction vessel was isolated and placed in the calorimeter; great care was taken to ensure the rigorous exclusion of oxygen, since the heat of combustion of methyl isocyanide is of the order of 20 times the expected heat of isomerisation (1, 2).

The calorimeter was allowed to stand overnight and after a satisfactory fore-period had been established, the reaction was initiated using a 2 s dc pulse at about 37–38 V, supplied from a Hewlett-Packard 6289A power supply operating in constant voltage mode. The voltage across the heater and the current through the heater (measured as the voltage across a standard 10 ohm resistor in series) were displayed on a Hewlett-Packard 7100B two-channel recorder: the electrical energy input was calculated from these two traces by graphical integration; the time for which the heater was switched on was derived from the movement of the chart paper (calibrated by supplying 0.5 s pulses to an event marker on the recorder). Figure 1 shows a typical recorder trace for the current and voltage, from which it can be deduced that the temperature at the wire at the peak of the explosion was about 700°C. Following the recording of a satisfactory after-period, the reaction vessel was removed from the calorimeter and its contents analysed by gas chromatography to confirm the completeness of the reaction.

The sample of methyl isocyanide was one used previously (3) and was purified by preparative gas-phase chromatography: no impurities could be detected either using gas-phase chromatography or mass spectrometry.

Results

The results of four experiments, two using argon and two using carbon dioxide as the diluent, are shown in Table 1: the agreement between the results of the four experiments, calculated assuming that methyl isocyanide at 50 Torr is a perfect gas, is excellent. We may combine the final result for the enthalpy of isomerisation with (preliminary) results from a new heat of combustion study of methyl cyanide by Barnes and Pilcher (6) to give the following enthalpy of formation values for methyl isocyanide (where the errors quoted are now ±2 sdm).

Compound	ΔH_f (liquid) (kcal mol^{-1})	ΔH_{vap} (kcal mol^{-1})	ΔH_f (gas) (kcal mol^{-1})	Reference
CH_3CN	9.70 ± 0.18	7.92 ± 0.03	17.62 ± 0.19	6
CH_3NC	$33.9_5 \pm 0.3_5$	$7.3_7 \pm 0.2_5$*	41.32 ± 0.24	This work

*The value of the enthalpy of vaporisation of methyl isocyanide quoted here is derived from two measurements of the vapour pressure (66.59 Torr at 0°C and 207.10 Torr at 24.9°C).

These tentative results depend, of course, on our assumption that methyl isocyanide at 50 Torr and 35°C is a perfect gas. It is known that methyl cyanide is partly dimerised in the gas phase, and using the equilibrium constant of Rowlinson (7), we calculate that under these conditions, the compressibility factor (PV/nRT) for methyl cyanide would be between 0.993 and 0.995. We may surmise that methyl isocyanide is not so strongly dimerised from the observation that it has a much smaller pressure coefficient of thermal conductivity (8), by about a factor of 4. We attempted to measure the vapour density of methyl isocyanide, but at these low densities, with the equipment available to us, we were unable to do better than to show that the compressibility factor was within 0.5% of unity. A slightly more reliable indication comes from

TABLE 1. Calorimetric determination of the energy released in the explosive isomerisation of methyl isocyanide at 300.05 K

Number of moles of reactant*			Diluent	Energy released

						Mean‡	23.70±0.07

*Volume of vessel = 197.93±0.01 cm^3; ideal-gas molar volume at STP = 22.4174 ℓ (9).
†Calibration constant of calorimeter (5): number of calories = (7.9425±0.0006)Δl; 1 cal = 4.184 J.
‡The errors quoted in this table are calculated as follows: columns 1, 2, 5, 6: an estimate of the *maximum* possible uncertainty in each individual determination; columns 3, 7, 8: errors calculated by the normal rules for combining standard deviations; final mean value: mean calculated as a weighted mean of the four results listed in the final column.

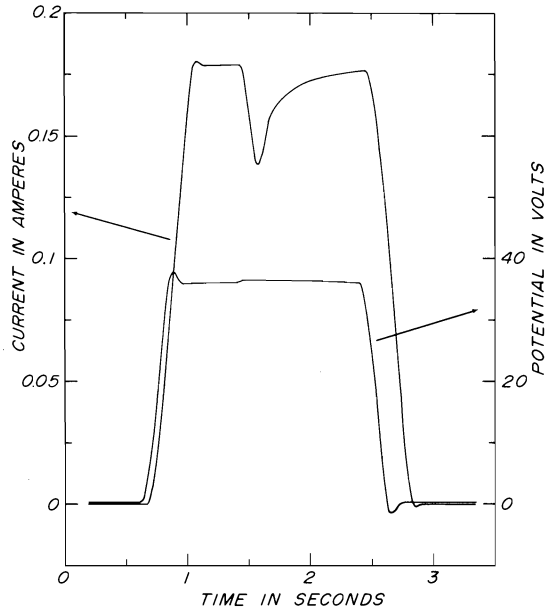

FIG. 1. Recorder traces of the current and voltage used to initiate the explosion, which occurs at about the 1.5 s marker. The attendant rise in the mean temperature of the wire to 691°C is shown by the marked drop in current (since the voltage is held constant). Apart from the slight voltage ripple when the explosion occurs, the applied voltage is a square-wave pulse; however the distortion of the traces due to pen lag and overshoot were so reproducible that no difficulty was encountered in performing the desired integration.

some auxiliary experiments in which we found that the reduction in pressure in the reaction vessel after isomerisation was usually of the order of 0.5 to 1% of the total initial isocyanide pressure.

We attempted to repeat these experiments for ethyl isocyanide, but because the vapour pressure of ethyl cyanide at 27°C is only 50 Torr, we chose to work with an initial isocyanide pressure of about 45 Torr. Under these conditions the explosive isomerisation was clean, but conversion was incomplete. The results of four experiments with carbon dioxide as diluent were −21.1, −21.6, −22.2, and −21.7 kcal mol^{-1} (where correction had been made for 1.5, 22, 6, and 2% of incomplete reaction respectively). It would seem reasonable to accept a tentative value of $\Delta H = -21.5 \pm 1.0$ kcal mol^{-1} for this isomerisation, and we also report an approximate enthalpy of vaporisation of about 7.9 kcal mol^{-1} (based on two vapour pressure measurements, 30.76 Torr at 0°C and 104.66 Torr at 25.2°C) for ethyl isocyanide.

Linear free energy relationships. VIII.[1] Ionization potentials of aliphatic compounds

HARRY W. GIBSON

Webster Research Center, Xerox Corporation, Webster, NY, U.S.A. 14580

Received January 28, 1977

HARRY W. GIBSON. Can J. Chem. **55**, 2637 (1977).

Ionization potentials (IP) of HX, CH_3X, C_2H_5X, and i-C_3H_7X, where X is a substituent with non-bonded electrons, are directly proportional to ionization potentials of 4-substituted quinuclidines. This is taken as evidence that in general the energy required to remove an electron from a substituent X, as is the case in HX, CH_3X, C_2H_5X, and i-C_3H_7X, is directly proportional to the energy required to remove an electron from a site remote from the substituent, as in the quinuclidines in which an electron is lost from the ring nitrogen. Furthermore, the IP's of the HX–i-C_3H_7X series are directly proportional to inductive substituent constants, σ_I, providing a valuable correlation between gas and solution phase behavior.

HARRY W. GIBSON. Can. J. Chem. **55**, 2637 (1977).

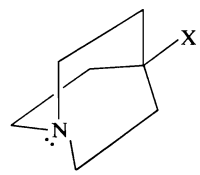
Les potentiels d'ionisation (IP) de HX, CH_3X, C_2H_5X et i-C_3H_7X, où X est un substituant comportant des électrons non-liés, sont directement proportionnels aux potentiels d'ionisation des quinuclidines substitués en position 4. On considère cette corrélation comme une indication que, d'une façon générale, l'énergie requise pour enlever un électron d'un substituant X, comme dans le cas de HX, CH_3X, C_2H_5X et i-C_3H_7X, est directement proportionnelle à l'énergie requise pour enlever un électron d'un site éloigné du substituant comme dans les quinuclidines dans lesquelles un électron est perdu par l'azote du cycle. De plus, les potentiels d'ionisation de la série HX à i-C_3H_7X sont directement proportionnels aux constantes inductives des substituants, σ_I, fournissant une corrélation très utile entre le comportement en phase gazeuse et en solution.

[Traduit par le journal]

Molecular orbital energy levels are determining factors both for chemical reactivity and many physical properties, especially spectral and electrical properties. Our previous work using linear free energy relationships (1–7), including the Hammett equation (8), was aimed at quantitatively relating these energy levels to molecular structure (1–4, 6, 7) and in turn to electrical properties (5) of aromatic compounds. In the first paper of this series it was shown that the ionization potentials (IP) of substituted benzenes are linearly related to the sums of the Hammett substituent constants. To understand and predict the properties of aliphatic series a similar linear free energy relationship would be most helpful.

A. Linear Free Energy Relationships

A number of correlations of ionization potentials of aliphatic compounds with Taft or inductive substituent constants have appeared (9). However, the substituents were restricted to hydrogen or alkyl groups. The only exception is the study of some quinuclidines (**1**) (10), in which substituents with non-bonded electrons were examined. It was our objective to determine if the ionization potentials of simple alkanes substituted with groups bearing non-bonded electrons could be correlated with the ionization potentials of series **1** and more generally with substituent constants.



1

Table 1 contains the ionization potentials of such series of HX, CH_3X, C_2H_5X, and i-C_3H_7X compounds; most are adiabatic, derived by photoelectron spectroscopy. Figure 1 is a plot of the IP of CH_3X *vs.* the vertical IP of **1** for seven different X groups. As can be seen, with the exception of the point for X = NO_2 (see below), an excellent linear correlation exists.[2] Similar

[1]References 1–7 comprise parts I–VII of this series.

[2]The inadequacy of the correlation coefficient r for goodness of fit has been pointed out (11). In this case the conclusion is based on comparison of the average deviation of points from the line with the precision of the data (estimated to be 0.2–0.3 eV for the data of Table 1).

TABLE 1. Ionization potentials (eV)[a] of aliphatic compounds RX

Point No.	X	$\sigma_{I,X}$	Ionization potential HX	CH_3X	C_2H_5X	i-C_3H_7X
1	$N(CH_3)_2$	0.11	8.36	8.12	—	—
2	$NHCH_3$	0.11	9.18	8.36	—	—

[g]IP value given for these compounds is the average of the first two IP's which are due to spin-orbit coupling ($^2E_{3/2}$, $^2E_{1/2}$) of the non-bonding p-orbitals. The resultant splitting increases in the order Cl < Br < I and is not usually observed for F (see ref. 17).
[h]From ref. 17.

correlations exist for the data of HX, C_2H_5X, and i-C_3H_7X *vs.* those of **1**.

In series **1** the ionization process corresponds to loss of a non-bonded electron from the nitrogen atom; the energetics of the process are modified by the substituents X either through space or through bonds or both. In contrast, in the HX, CH_3X, C_2H_5X, i-C_3H_7X compounds it is generally loss of a non-bonded electron from the substituent itself that comprises the ionization process. This can be seen by reference to Fig. 2 in which the direct relationship[2] between IP's of CH_3X and HX is shown; the IP of HX is taken to be essentially that of X. (See below for discussion of point 18.) Thus variation of X involves a change in the site and nature of the ionization and not merely a substituent effect. The correlation of Fig. 1 therefore indicates that the energy required to remove an electron directly from a substituent is proportional to the energy required to remove an electron from a site remote from the substituent.

To substantiate this conclusion the dependence of IP for these series on the inductive substituent constant, $\sigma_{I,X}$, was determined. In Fig. 3

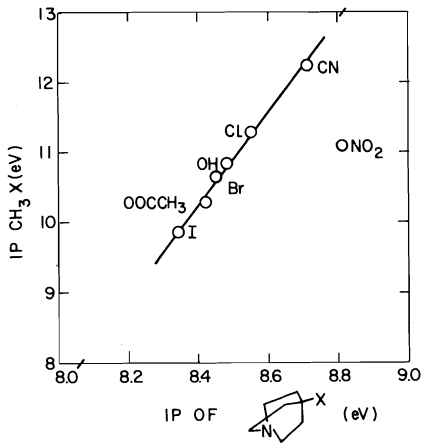

FIG. 1. Ionization potentials of substituted methanes (CH_3X) *vs.* ionization potentials of 4-substituted quinuclidines (**1**, QX). Linear least-squares line without X = NO_2: $IP_{CH_3X} = 6.61IP_{QX} - 45.30$; correlation coefficient, $r = 0.994$; average deviation of IP_{CH_3X} from the line = 0.08 eV.

the IP of CH_3X is plotted *vs.* $\sigma_{I,X}$ (8*a*). As can be seen, with the exception of points for X = NO_2, F, I, and OH (see below), a good linear relationship exists.[2] Similar relationships exist for the

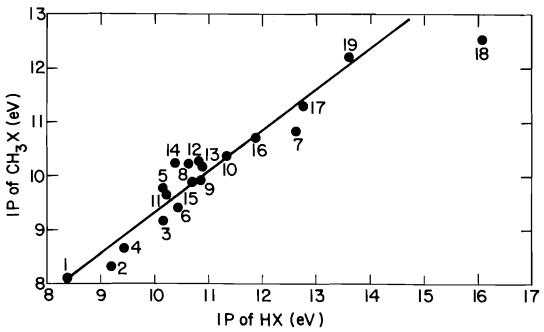

FIG. 2. Ionization potentials of substituted methanes (CH_3X) *vs.* ionization potentials of HX. Least-squares fit without X = F: $IP_{CH_3X} = 0.746\ IP_{HX} + 1.92$; correlation coefficient, $r = 0.957$; average deviation of IP_{CH_3X} from the line, 0.24 eV. For point code see Table 1.

HX, C_2H_5X, and *i*-C_3H_7X series. The fit parameters are given in Table 2. The linear relationships demonstrate that in general the energy required to remove an electron from non-bonding orbitals of a substituent X in the gas phase (IP) is directly proportional to the ability of the substituent to stabilize a charge in a remote part of a molecule in solution ($\sigma_{I,X}$).

B. Deviations

As we have seen in Figs. 1 and 3, the points for X = NO_2 are anomalous. In fact, the deviations in CH_3X, C_2H_5X, and *i*-C_3H_7X are systematic; NO_2 has an effective $\sigma_I = 0.50 \pm 0.01$. In other words, for these compounds the nitro group is not as electron poor as it normally appears to be. In correlations of IP with Hammett substituent constants, however, nitro compounds do not deviate (2). Nor does X = NO_2 ($\sigma_1 = 0.70$) deviate from the line (IP = $0.952\sigma_{I,X} + 8.07$; correlation coefficient, $r = 0.968$; standard deviation of points from the line 0.07 eV) for series **1** (X = C_6H_5, OH, $OOCCH_3$, Cl, Br, I, CN, NO_2, C≡CH, H, CH_3, C_2H_5, *i*-C_3H_7, and *tert*-C_4H_9) (10). Therefore, the deviation is not inherent to the gas phase. A possible explanation is that remote substituents, as involved in the IP of **1** and ArX and $\sigma_{I,X}$ in solution, are influenced predominantly by the positively charged nitrogen atom of the nitro group, whereas electrons within the NO_2 group which are involved in the IP of CH_3X, C_2H_5X, and *i*-C_3H_7X reside in a net neutral environment. This would lead to non-proportionalities between the energetics of the two situations, making X = NO_2 deviate below the line in correlations such as those of Figs. 1 and 3.

TABLE 2. Least-squares fits of ionization potential *vs.* inductive substituent constant[a]

$IP = m\sigma_{I,X} + b$

Series	*m*	*b* (eV)	*n*[b]	*r*[c]	AD[d] (eV)
HX	8.43	7.99	16	0.920	0.40
CH_3X	7.05	7.67	16	0.948	0.27
C_2H_5X	5.99	7.89	13	0.909	0.27
i-C_3H_7X	5.95	7.67	11	0.938	0.26

[b]Number of points.
[c]Correlation coefficient (see footnote 2).
[d]Average deviation of points from the line.

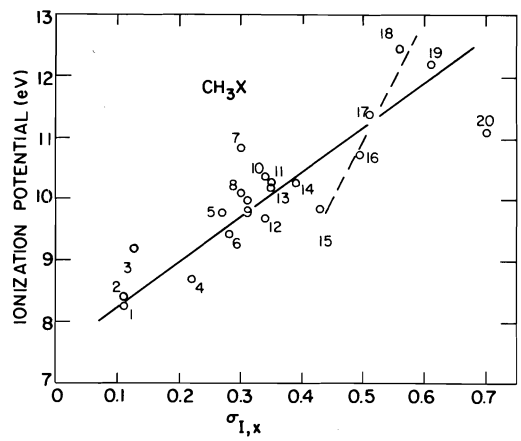

FIG. 3. Ionization potential *vs.* inductive substituent constant for CH_3X. Solid line, points 1–6, 8–14, 16, 17, 19. Dashed line, points 15–18. For point code see Table 1. For fit parameters see Table 2.

While the point for X = OH does not deviate significantly (less than the standard deviation) from the line of Fig. 1, X = OH is deviant in plots of IP *vs.* σ_I for HX, CH_3X (Fig. 3), C_2H_5X, *i*-C_3H_7X, and **1** by 2–4 standard deviations, the IP's being higher than expected. For series **1** the effective $\sigma_I = 0.43$; for the other four series the effective $\sigma_I = 0.46 \pm 0.05$. OH is thus effectively more electron withdrawing or less electron rich in the gas phase than in solution. This is also corroborated by the IP data for phenols which are up to 3.5 standard deviations higher than expected (2). Using the equation (8*b*) $\sigma^+ = 1.14\sigma_I + \sigma_R$, $\sigma_R{}^+ = -1.24$ (8*a*), and the effective σ_I value (0.46), for OH we calculate $\sigma^+ = -0.72$. This can be compared to the solution value of -0.92 (8*a*) and the value of -0.59 assigned on the basis of IP's of phenols (12). In fact, as has been pointed out (10), the solution-derived σ_I for OH is less than that of OCH_3 (8*a*); this seems incorrect in view of the relative gas phase values. There is apparently a solvent effect operative which reduces the solution σ_I of OH relative to the gas phase and to other substit-

TABLE 3. Assignment of inductive substituent constants on the basis of ionization potentials of aliphatic compounds RX

X	Ionization potential[a] (eV) HX	CH_3X	C_2H_5X	i-C_3H_7X	σ_I

uents; hydrogen bonding of the hydroxyl hydrogen with solvent would have this effect.

In the case of the halogens, a separate straight line may be drawn (see dashed line, Fig. 3). This indicates an internal consistency in the halogen family. Interestingly, in substituted benzenes the fluoro substituent with consistency leads to higher ionization potentials than expected on the basis of its substituent constant (2). The fewer examples of substituted iodobenzenes have lower ionization potentials than expected (2). This has led to assignment of a new σ^+ value for I (12). Also, **1**, X = I deviates below the correlation line for **1** by two standard deviations (10). Thus the deviations of F and I are systematic in the gas phase. For series **1** the effective σ_I of I is 0.29; for the other four series the effective $\sigma_I = 0.31 \pm 0.01$ for I. Thus I is more electron rich in the gas phase than in solution. This may be the consequence of its polarizability, which in solution would tend to lead to a more positive character by interaction with solvent. For F the effective $\sigma_I = 0.69 \pm 0.01$ from data for CH_3X and C_2H_5X. From Fig. 2 it is apparent that there is a difference between the effect of F on HX and CH_3X (point 18). From the data for HX the effective $\sigma_I = 0.96$ for F. This difference may be attributed to the inability of H to π-bond via hyperconjugation with F, in contrast to CH_3, C_2H_5, and i-C_3H_7 which can. It may be that π-bonding of F is more important in the gas phase than in solution, where it can hydrogen bond, leading to a difference in the effect of F in the two states. The different slope of the halogen line may then reflect a regular change in these two properties (polarizability and π-bonding) peculiar to the halogens.

Alternative rationalization of the deviations involves the size or 'hardness' of the X group. In small groups (OH, F) electron–electron repulsion is relaxed during ionization, allowing the relatively high nuclear charge to cling more tenaciously to the leaving electron than would be expected. Another way of stating this is that the small groups appear more electronegative (higher IP) than they should relative to large groups because they have no space to put the charge. The reverse is true for large soft groups (I, NO_2). In this vein in the gas phase ^-OH has been shown to be more basic (more electron releasing) than $^-OCH_3$ (13).

C. Assignment of Substituent Constants

Using the linear correlation equations it is also possible to assign new inductive substituent constants. A cogent argument can be made that the determination of all substituent constants, both aromatic and aliphatic, should be made from gas phase ionization potentials and that solvent effects then be treated as perturbations associated with either the main group or the substituent. Table 3 summarizes a number of inductive substituent constants estimated in this manner but not previously reported by other methods (8).

NOTE ADDED IN PROOF: A report which appeared after acceptance of this paper describes the relationship between IP's of HX and CH_3X in terms of orbital symmetry [$n(\pi)$, π, $n(\sigma)$] and hyperconjugative effects.

Conclusions

There is a general correlation of gas phase ionization potentials of substituted alkanes containing non-bonded electrons with ionization potentials of quinuclidines bearing these substituent and also with substituent constants derived from solution phase reactions. These relationships are of value both for estimation of such gas phase energy levels from substituent constants and vice versa.

Received February 8, 1977

ROGER N. RENAUD, JOHN W. BOVENKAMP, ROBERT R. FRASER, and RAJ CAPOOR. Can. J. Chem. **55**, 2642 (1977).

The effect of substituents at the 3-position in a series of *N*-methyl 5,6-dihydro-7*H*,12*H*-dibenzo[*c*,*f*]azocines on the geminal coupling constants of the C-12 methylene protons has been determined. The slope of the Hammett plot of ^2J *vs.* σ has been found to be $+0.20$. The orientation of the methylene protons with respect to the π orbitals of the benzene ring bearing the substituent is such that no hyperconjugative effect should be present. The value of $+0.20$ is in contrast to a previously measured slope of -1.9 for compounds having a geometry ideal for hyperconjugative effects and substantiates the predictions of theoretical MO calculations. As a result, the reliability of this conformational dependence of ρ for use in conformational analysis has been strengthened.

A comparison of the data for the azocines with those in the literature indicates the difference between the minimum and maximum effects of a phenyl substituent on a geminal coupling constant of an attached methylene group is 5.5 Hz.

ROGER N. RENAUD, JOHN W. BOVENKAMP, ROBERT R. FRASER et RAJ CAPOOR. Can. J. Chem. **55**, 2642 (1977).

On a déterminé l'effet des substituants en position 3 d'une série de *N*-méthyle dihydro-5,6 7*H*,12*H*-dibenzo[*c*,*f*]azocines sur les constantes de couplage géminales des protons méthyléniques en position C-12. La pente de la courbe de Hammett de ^2J en fonction de σ est de $+0.20$. L'orientation des protons méthyléniques par rapport aux orbitales π du noyau benzénique portant le substituant est telle qu'il ne devrait pas y avoir d'effet d'hyperconjugaison dans ce système. La valeur de $+0.20$ est en opposition avec la pente mesurée antérieurement de -1.9 pour des composés ayant une géométrie idéale pour des effets d'hyperconjugaison et apporte un support aux prédictions des calculs théoriques d'orbitales moléculaires. Ces résultats renforcent la crédibilité de la dépendance conformationnelle de ρ pour son utilisation en analyse conformationnelle.

Une comparaison des données pour les azocines avec celles rapportées dans la littérature indique que la différence entre les effets minimum et maximum d'un groupement phényle sur une constante de couplage géminale d'un groupe méthylène qui y est attaché est de 5.5 Hz.
[Traduit par le journal]

We have previously shown (1, 2) that the effect of *para* substituents on the geminal coupling constants of the methylene protons in several series of benzylic systems was proportional to the Hammett substituent constants and that the magnitude of change in ^2J, represented by ρ, the slope of the Hammett plot, depended upon the conformation of the methylene protons with respect to the adjacent aromatic ring. This angular dependence was attributed to the fact that hyperconjugation of a benzene ring with the adjacent methylene group causes a negative shift[3] in J which is itself angularly dependent. Both valence bond (VB) calculations (6) and molecular orbital (MO) calculations (7) predicted a maximum effect on ^2J when $\phi = 0°$ and no effect when $\phi = 90°$, where ϕ is defined using the conformers shown in Fig. 1. However, in the calculations, there was a discrepancy between the predictions of the VB and MO methods in the region of $\phi = 90°$. The former predicted a

[1]NRCC No. 15949.

[2]Present address: Defence Research Establishment Ottawa, Ottawa, Canada.

[3]Since the geminal coupling constants in benzylic systems have been shown to be negative (3), it is most convenient to describe the effect of, for example, the phenyl group in toluene ($^2J = -14.8$ Hz (4)) *vs.* methane ($^2J = -12.4$ (5)) as causing a negative shift in ^2J.

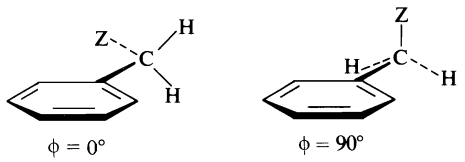

FIG. 1. The dihedral angle ϕ is the angle between the π orbital and an imaginary line passing through both protons of the methylene group (7). In refs. 6 and 8 the geometry is described by a different angle θ, where θ is the angle between the π orbital and a C—H bond.

small negative influence on ^2J, the latter predicted no effect. Since the previous studies on substituent effects were limited to several series of compounds having $\phi = 0°$ and one in which $\phi = 72°$ (2), it seemed desirable to examine an additional series of compounds having ϕ fixed in the region of 90°. The substituent effects on ^2J in such a series should provide a test of the contrasting theoretical predictions and thereby substantiate the explanation for the conformational dependence of ρ.[4]

Recently the conformational properties of several *N*-alkyl 5,6-dihydro-7*H*,12*H*-dibenzo[*c*,*f*]azocines (11, 12) were elucidated using proton nmr spectroscopy. The predominant conformation of the eight-membered ring was shown to be a rigid boat-chair form. Models indicated that the orientation of the methylene protons at C-12 with respect to each adjacent benzene ring was equivalent to $\phi \approx 90°$. An X-ray diffraction study on **1***a* where X = H and **1***d* where X = Br revealed that, in the solid, both molecules exist in a boat-chair conformation with the *N*-methyl group in a pseudo-axial position (13). The angles ϕ for **1***a* and **1***d* were found to be 87.5 ± 0.3° and 86.9 ± 1.2° (14), respectively. ^{1}H nmr spectroscopy has established for **1***a* the presence, in solution, of a rapidly interconverting equilibrium between a boat-chair (BC) and a flexible twist-boat (TB) conformation. In $CDCl_3$ at 10°C, at which temperature interconversion of conformers is slow in the nmr time scale, the ratio of BC to TB conformers was found to be 92:8 (11). The ^{1}H nmr spectrum of **1***d* also shows the molecule to prefer the rigid conformation with the *N*-methyl group in the same orientation.[5]

[4]This conformational dependence of ρ has already given information regarding the conformational properties of benzylic systems (9, 10).

[5]The chemical shifts of the methyl protons were shown to differ by 1.2 ppm with the axial methyl signal being to high field (11). Since the chemical shifts of the methyl groups remained constant (±0.02 ppm) throughout the series, its orientation is therefore constant.

Thus, in both the solid state and in solution, changing the substituent at C-3 does not affect the ring conformation nor the methyl groups orientation. Therefore, a series of 3-substituted *N*-methyl 5,6-dihydro-7*H*,12*H*-dibenzo[*c*,*f*]azocines **1** comprise an ideal system for the study of the π effect on the geminal coupling constant in the untested area of $\phi = 90°$.

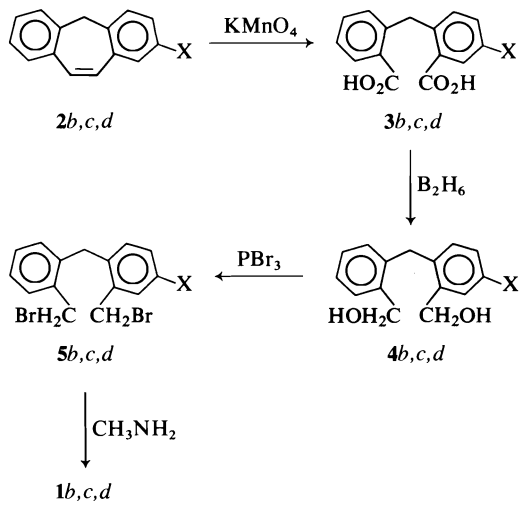
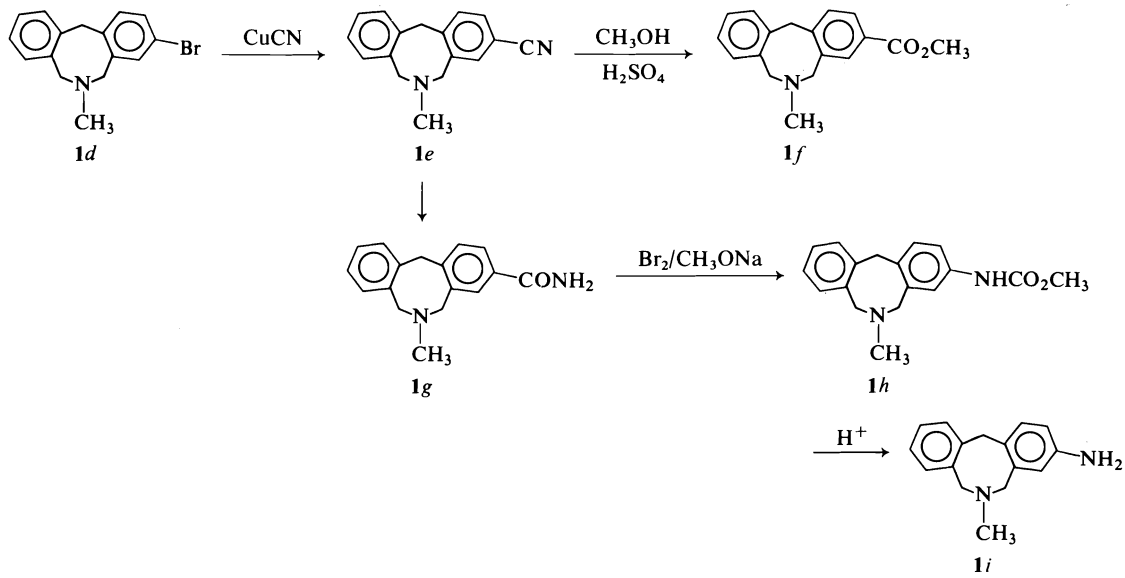
i X = NH_2

The synthesis of the requisite compounds (**1***a* to **1***i*) was accomplished using the methods shown in Schemes 1 and 2. One specific aspect of interest is the synthesis of **1***i* from the amide **1***g*. The normal Hofmann rearrangement on the amide **1***g* was not successful (15). However, the method of Radlich and Brown (16) gave the desired amine in good yield. In this method the Hofmann rearrangement is carried out on the amide using a solution of bromine and sodium methoxide in methanol producing the carbamate **1***h*. Hydrolysis of **1***h* with refluxing hydrochloric acid gave the required amine **1***i*.



SCHEME 1



SCHEME 2

A typical ^{1}H nmr spectrum of the compounds studied is presented in Fig. 2 showing the methylene region of the spectrum of **1***i*. The spectrum is simplified by the fact that the signals of the strongly dominant BC conformation are well separated. In deuterochloroform at 10°C, the spectrum of **1***i* shows three well-defined AB quartets in the ratio of 1:1:1. They are centered at δ 3.92 ($^2J = -12.9$ Hz), 4.05 ($^2J = -14.8$ Hz), and 4.08 ($^2J = -14.8$ Hz). The quartet having a ^2J of -12.9 Hz corresponds to the protons on C-12 while the two quartets with a ^2J of -14.8 Hz are attributed to the protons on C-5 and C-7 (12). In two instances (**1***c* and **1***f*) problems occurred with the overlapping of peaks. The high field doublet due to the protons on C-12 was not resolved adequately from the peaks due to the protons on C-5 and C-7 in order for accurate geminal coupling constants to be measured. Fortunately, a complete set of geminal coupling constants could be obtained from the low field doublets of the C-12 protons for each of the azocines in Table 1.

The correlation between these geminal coupling constants and the Hammett σ values for the substituents (17) is graphically shown in Fig. 3. The slope of the best fitted line, calculated from a least-squares program (18), was +0.20 with a standard deviation of 0.085. From this slope, along with the values obtained before for the rigid systems 3-phenylphthalans ($\phi = 0°$; $\rho = -1.9$), 2-methyl-1-phenylisoindolines ($\phi = 0°$; $\rho = -1.7$) and 5*H*-dibenzo[*a*,*d*]cycloheptene-10,11-oxides ($\phi = 72°$; $\rho = +0.19$) (2), it can be concluded that the effect of the substituents on the geminal coupling constants at C-12 varies with the angle ϕ in accordance with the predictions of MO theory (7). As Fig. 4 shows the perturbation of the negative increment to ^2J follows a $\cos^2\phi$ relation (7) not the irregular double minimum curve predicted by VB calculations (6).

Another result of considerable significance is the value for ^2J in the unsubstituted azocine. The geminal coupling constant between the protons at C-12 (-12.7 Hz) is the least negative yet reported for a derivative of diphenylmethane. This is, of course, consistent with the fact that in this molecule ϕ is estimated to be 86° in which case there is essentially no hyperconjugative effect of either benzene ring on the geminal coupling constant.

It is now possible to reexamine the magnitude of the increment to ^2J due to the hyperconjugative interaction of a benzene ring. Previously Cookson *et al.* (19), from a variety of compounds having an unsaturated function (carbonyl, double bond or phenyl) adjacent to a CH_2, estimated the hyperconjugative effect to be about 6 Hz per adjacent unsaturated function group when $\phi = 0°$. The increment to ^2J for a CH_2 group α to a carbonyl has recently been estimated on the basis of further data (8), to be between +3 and -6 Hz depending on ϕ. Data

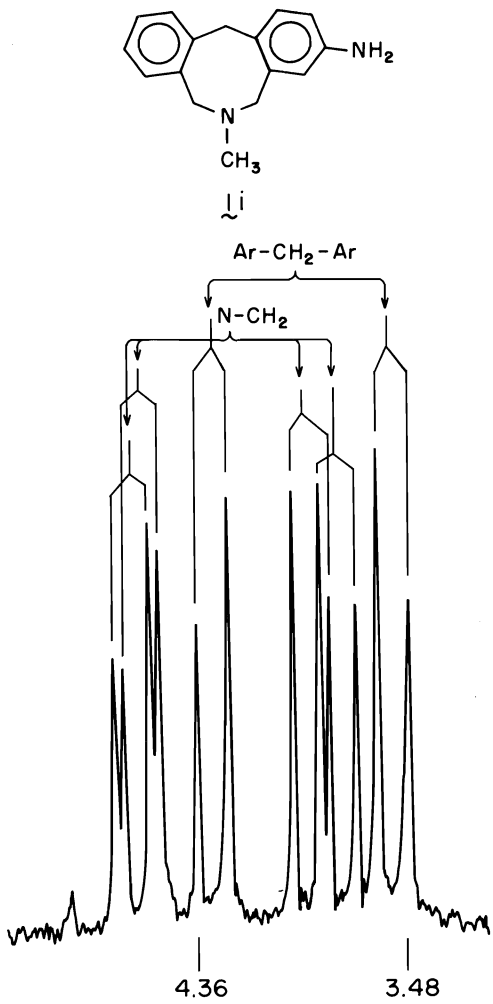


FIG. 2. The absorption of all methylene protons in the 100 MHz nmr spectrum of **1***i* in $CDCl_3$ at 10°C.

for estimating the effect of a phenyl group above was previously limited by (*a*) lack of a value for ^2J in the region of 90° and (*b*) inaccuracy in the measurement of ^2J (for $\phi = 0°$) at the 9-position of fluorene. The very careful study of Lehn and co-workers (4) showed that $^2J_{H-D}$ in fluorene, measured under conditions where quadrupolar relaxation effects were absent, was 3.5 Hz. Using the correction factor $^2J_{H-H} = 6.75$, $^2J_{H-D}$ as established earlier by one of us (9) and subsequently adopted by Bothner-By (20), the value for $^2J_{H-H}$ in fluorene is -23.6 Hz. Thus a comparison of this value ($\phi = 0°$) with that of the azocine and the carbocycle given in Table 2 for $\phi = 87°$, shows the difference between the minimum and maximum effects of the two aryl substituents on ^2J is 11 Hz. Two additional ^2J's measured in diaryl methanes whose conformations are known are also given in Table 2. All these data are consistent with the assignment of an angularly dependent increment to J. The value of this increment (per phenyl substituent) can be expressed as $\Delta J = -5.5 \cos^2 \phi$.

TABLE 1. The ^2J-values* for the benzylic methylene protons at C-12

	In $CDCl_3$ at 10°C

*Although the angle may change with the nature of R (21), it has been determined for R = H by Ferrier and Iball (22).
†From a manuscript in preparation by R. R. Fraser, R. N. Renaud, and J. W. Bovenkamp.

Experimental

All melting points are uncorrected. Infrared spectra were observed on a Perkin-Elmer model 267 spectrophotometer and only characteristic bands are reported. Unless specified routine nmr spectra were taken in deuterochloroform solution on a Varian Associates spectrometer model E.M. 360 and the chemical shifts are reported on the δ scale. Precise coupling constant determinations were carried out using a Varian HA-100 spectrometer. All coupling constants were determined with 0.2 *M* solutions in deuterochloroform at 10°C. The spectral line positions were always determined from an average of at least ten measurements.

Preparation of ***1a***

This compound has been synthesized previously (11) starting from the commercially available dibenzsuberone.

Preparation of ***2b***, ***2c***, *and* ***2d***

The synthesis of **2***b*, **2***c*, and **2***d* has been described in ref. 23.

Preparation of ***3b***

Oxidation of **2***b* with potassium permanganate as described for the synthesis of **3***a* (11) gave a white solid (mp 213–217°C) in a yield of 58%. Upon recrystallization from methanol–water, a solid mp 224.5–225.5°C, was obtained; ^{1}H nmr (DMSO-d_6) 8.08–6.79 (9H, m, aromatic and carboxyl hydrogens), 4.65 (2H, s, methylene), 2.32 (3H, s, methyl).

The dimethyl ester derivative of **3***b* was prepared by methylating the diacid with an excess of diazomethane in ether. The viscous oil obtained was purified by a bulb to bulb distillation under reduced pressure. *Anal.* calcd. for $C_{18}H_{18}O_4$: C 72.46, H 6.08; found: C 72.64, H 6.17.

Preparation of ***3c***

The olefin **2***c* was oxidized in the same manner as **2***b*; however, a low overall yield of **3***c* was obtained because about one third of the crude oxidation product was the diacid with the bridgehead methylene group further oxidized to the ketone. After a careful fractional recrystallization from methanol–water, a 29% yield of the required white solid was obtained (mp 227–228°C); ^{1}H nmr (DMSO-d_6) 7.95–6.78 (9H, m, aromatic and carboxyl hydrogens), 4.60 (2H, s, methylene), 3.75 (3H, s, methoxyl).

Preparation of ***3d***

Oxidation of **2***d* (as described for **2***b*) gave a white solid which after recrystallization from methanol–water had an mp of 240.5–242°C (63%); ^{1}H nmr (DMSO-d_6) 8.11–6.74 (9H, m, aromatic and carboxyl hydrogens), 4.63 (2H, s, methylene).

The dimethyl ester derivative of **3***d*, obtained by methylation with diazomethane, had an mp of 40–42°C after a bulb to bulb distillation under reduced pressure. *Anal.* calcd. for $C_{17}H_{15}O_4Br$: C 56.22, H 4.16, Br 22.00; found: C 56.26, H 4.07, Br 22.07.

Preparation of ***4b***, ***4c***, *and* ***4d***

The diacids **3***b*, **3***c*, and **3***d* were reduced in near quantitative yields with diborane using the procedure of Schmitt *et al.* (24). A diagram of the apparatus used is given in ref. 25. Physical properties of: (*i*) **4***b*: mp 134–136°C; ^{1}H nmr: 7.59–6.63 (7H, m, aromatic), 5.09 and 5.05 (2H, two equal t (J = 5 Hz), two OH, exchange with D_2O), 4.48–4.43 (4H, two equal d (J = 5 Hz) two methylenes from the CH_2OH groups, two s in D_2O), 3.94 (2H, s, methylene), 2.30 (3H, s, methyl). (*ii*) **4***c*: mp 140.0–140.5°C; nmr: 7.51–6.01 (7H, m, aromatic), 5.10 and 5.07 (2H, two equal t (J = 5 Hz), two OH, exchange with D_2O), 4.46 and 4.41 (4H, two equal d, (J = 5 Hz), two methylenes of the CH_2OH groups, two s in D_2O), 3.86 (2H, s, methylene), 3.70 (3H, s, methoxyl). (*iii*) **4***d*: mp 142–144°C; ^{1}H nmr: 7.68–6.57 (7H, m, aromatic), 5.14 and 4.97 (2H, two equal t (J = 5 Hz), two OH, exchange with D_2O), 4.41 (4H, d (J = 5 Hz), two methylenes of the CH_2OH groups, two s in D_2O), 3.87 (2H, s, methylene).

Preparation of ***5b***, ***5c***, *and* ***5d***

The diols **4***b*, **4***c*, and **4***d* were converted to the corresponding dibromides with phosphorus tribromide using the same procedure used to obtain **5***a* (11). The yields of the crude products were nearly quantitative and analytical samples were obtained by recrystallization from a mixture of benzene and ethanol. Physical properties of: (*i*) **5***b*: mp 92–93°C; ^{1}H nmr: 7.52–6.76 (7H, m, aromatic), 4.50 and 4.48 (4H, two equal s, methylenes of the CH_2Br groups), 4.24 (2H, s, methylene), 2.34 (3H, s, methyl). *Anal.* calcd. for $C_{16}H_{16}Br_2$: C 52.20, H 4.38, Br 43.41; found: C 52.40, H 4.46, Br 43.27. (*ii*) **5***c*: mp 77.5–78.5°C; ^{1}H nmr: 7.37–6.71 (7H, m, aromatic), 4.47 and 4.40 (4H, two equal s, methylenes of the CH_2Br groups), 4.17 (2H, s, methylene), 3.77 (3H, s, methoxyl). *Anal.* calcd. for $C_{16}H_{16}Br_2O$: C 50.03, H 4.20, Br 41.61; found: C 50.20, H 4.23, Br 41.44. (*iii*) **5***d*: mp 118.5–119.5°C; ^{1}H nmr:

7.60–6.69 (7H, m, aromatic), 4.45 and 4.38 (4H, two equal s, methylenes of the CH_2Br groups), 4.20 (2H, s, methylene). *Anal.* calcd. for $C_{15}H_{13}Br_3$: C 41.61, H 3.03, Br 55.36; found: C 41.48, H 3.04, Br 55.21.

Preparation of 1b, 1c, and 1d

The ring closure reactions of the compounds **5***b*, **5***c*, and **5***d* were carried out with a 33% ethanolic solution of monomethylamine in 1-hexanol according to the procedure of Casadio *et al.* (26) (method *B*). Somewhat better yields were obtained if, during the work-up, the residue obtained on removal of the solvent is made strongly acidic with hydrobromic acid and heated for a short time at 60°C to make sure that all of the azocine has been taken up. The crude products were purified either by sublimation (**1***b* and **1***c*) or by recrystallization from 95% ethanol (**1***d*). Physical properties of: (*i*) **1***b*: mp 86–87.5°C; ^{1}H nmr: 7.42–6.82 (7H, m, aromatic), 4.89–3.48 (6H, m, methylenes at C-5, C-7, and C-12), 2.25 (3H, s, methyl at C-3), 1.95 (3H, s, *N*-methyl). *Anal.* calcd. for $C_{17}H_{19}N$: C 86.03, H 8.07, N 5.90; found: C 85.81, H 7.96, N 5.73. (*ii*) **1***c*: mp 101.5–102.5°C; ^{1}H nmr (CCl_4): 7.21–6.41 (7H, m, aromatic), 4.63–3.39 (6H, m, methylenes at C-5, C-7, and C-12), 3.63 (3H, s, methoxyl), 1.81 (3H, s, *N*-methyl). *Anal.* calcd. for $C_{17}H_{19}NO$: C 80.60, H 7.56, N 5.53; found: C 80.54, H 7.68, N 5.64. (*iii*) **1***d*: mp 142.5–143.5°C; ^{1}H nmr: 7.39–6.86 (7H, m, aromatic) 4.79–3.35 (6H, m, methylenes at C-5, C-7, and C-12), 1.92 (3H, s, *N*-methyl). *Anal.* calcd. for $C_{16}H_{16}NBr$: C 63.59, H 5.34, N 4.63, Br 26.44; found: C 63.44, H 5.22, N 4.65, Br 26.25.

Preparation of 1e

The compound **1***e* was prepared from **1***d* according to the method described by Newman and Boden (27) with some modification. A stirred mixture of **1***d* (1.00 g, 3.33 mmol), cuprous cyanide (0.685 g, 7.65 mmol), and freshly distilled *N*-methylpyrrolidone (35 ml) was refluxed for 3 h. The reaction mixture was cooled and then poured into a solution of ethylenediamine (20 ml) and water (60 ml). The complex was broken up by heating the mixture at 80°C for 1.5 h. The mixture was then twice extracted with benzene. The combined extracts were washed with 10% aqueous sodium cyanide and then water. The benzene solution was shaken twice with 24% aqueous hydrobromic acid. Upon neutralization with aqueous sodium hydroxide 0.700 g (mp 172–175°C) of white solid was obtained. This solid was sublimed to give 0.643 g (78%) of a white solid (mp 174.5–176°C); ^{1}H nmr: 7.47–6.87 (7H, m, aromatic), 4.85–3.50 (6H, m, methylenes at C-5, C-7, and C-12), 1.92 (3H, s, *N*-methyl). *Anal.* calcd. for $C_{17}H_{16}N_2$: C 82.22, H 6.49, N 11.28; found: C 82.23, H 6.54, N 11.33.

Preparation of 1f

The nitrile **1***e* (0.204 g, 0.823 mmol) and 5 ml of a mixture of concentrated sulfuric acid and methanol (33 wt.% concentrated sulfuric acid) were refluxed overnight. Water was added (20 ml) and the solution was neutralized with aqueous sodium hydroxide. The resultant white precipitate was collected (0.209 g, 91%) (mp 151–154°C). Recrystallization from a methanol–benzene mixture gave small white needles melting at 159–159.5°C; ^{1}H nmr: 8.03–7.02 (7H, m, aromatic), 4.89–3.59 (6H, m, methylenes at C-5, C-7, and C-12), 3.86 (3H, s, carbomethoxy), 1.95 (3H, s, *N*-methyl). *Anal.* calcd. for $C_{18}H_{19}NO_2$: C 76.84, H 6.81, N 4.98; found: C 77.01, H 6.81, N 5.10.

Preparation of 1g

The nitrile **1***e* (0.333 g, 1.34 mmol) was slowly added to 3.5 ml of a mixture of concentrated sulfuric acid and water (85 vol.% sulfuric acid) at 75°C. The solution was heated at 85–90°C for 1.5 h. After being cooled, the reaction solution was added to a mixture of concentrated ammonium hydroxide (16 ml), ice, and water (30 ml). The solid that precipitated out was collected and extracted with hot acetone several times. On removal of the acetone, 0.294 g (82%) of the amide **1***g* (mp 235.5–238°C) was obtained; ^{1}H nmr (DMSO-d_6) 8.04–6.96 (9H, m, aromatic and amide hydrogens), 4.90–3.53 (6H, m, methylenes at C-5, C-7, and C-12), 1.88 (3H, s, *N*-methyl).

Preparation of 1h

The compound **1***h* was prepared according to a modified procedure described by Radlich and Brown (16). A solution of sodium methoxide in methanol (8.5 ml) was prepared from sodium (0.38 g) in a three-necked flask equipped with a reflux condenser (protected by a drying tube) and a separatory funnel. The solution was cooled to −45°C with a dry ice – acetone bath and then bromine (0.93 g) was added dropwise with vigorous stirring. When the colour had discharged, the amide **1***g* (0.294 g, 1.11 mmol), dissolved in 3.5 ml of dioxane and 2.5 ml of methanol, was added slowly while maintaining the temperature at −40°C. After the addition, a further 2.5 ml of methanol was added. The temperature was then raised to 62°C for 1.25 h. The solution was cooled to 25°C. Water (30 ml) was added and the mixture was extracted twice with chloroform. The combined chloroform layers were washed with sodium chloride solution and then dried with anhydrous $MgSO_4$. On removal of the solvent 0.286 g (87%) of a white solid (mp 144–146°C) was obtained; ^{1}H nmr: 7.51–6.64 (8H, m, aromatic and NH hydrogens), 4.87–3.47 (6H, m, methylenes at C-5, C-7, and C-12), 3.75 (3H, s, carbamate methyl), 1.95 (3H, s, *N*-methyl).

Preparation of 1i

The carbamate **1***h* (0.286 g, 0.96 mmol) was added to 20 ml of 37% aqueous hydrochloric acid and the solution was refluxed for 17 h. At the end of the reflux period, the solution had become dark in colour. On neutralization with aqueous sodium hydroxide, a green precipitate was obtained which was collected by filtration and washed with water to leave 0.140 g (61%) of a solid melting at 144–146.5°C. An analytical sample was obtained by recrystallization from benzene and then sublimed to give a white solid melting at 151.5–152°C; ^{1}H nmr: 7.51–6.32 (7H, m, aromatic), 4.86–3.10 (8H, m, methylenes at C-5, C-7, and C-12 and amine hydrogens), 1.96 (3H, s, *N*-methyl). *Anal.* calcd. for $C_{16}H_{18}N_2$: C 80.63, H 7.61, N 11.76; found: C 80.51, H 7.49, N 11.59.

Received December 14, 1976

CARLA PICCINNI-LEOPARDI, OMER FABRE, DANIEL ZIMMERMANN, JACQUES REISSE, F. CORNEA, and C. FULEA. Can. J. Chem. **55**, 2649 (1977).

The free energies of activation for hindered rotation around the C—N bond have been determined for a series of *N*,*N*-disubstituted thioamides by means of ^{13}C and ^1H dynamic nmr. A comparison between barriers for 20 amides and the corresponding thioamides, studied under similar conditions, has been drawn up using both our results and data obtained from the literature. An excellent linear correlation has been obtained. The same correlation also holds for primary (thio)amides and seems to be of general significance. Substituent effects on the barrier heights of thioamides and amides are discussed in connection with some particular cases.

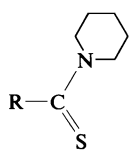
CARLA PICCINNI-LEOPARDI, OMER FABRE, DANIEL ZIMMERMANN, JACQUES REISSE, F. CORNEA et C. FULEA. Can. J. Chem. **55**, 2649 (1977).

L'energie libre d'activation associée à la rotation empechée autour du lien C—N a été déterminée pour une série de thioamides en utilisant la rmn dynamique de ^{13}C et ^1H. Une comparaison entre les barrières de 20 amides et des thioamides correspondants a été effectuée en se basant non seulement sur nos données mais aussi sur des valeurs fournies par la littérature. Une excellente corrélation linéaire a été obtenue. Cette corrélation est valable également pour des (thio)amides primaires et semble donc de portée générale. Les effets de substituants sur les hauteurs de barrière de quelques thioamides et amides sont discutés.

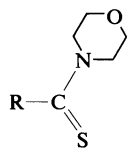
Introduction

Our study of the physical properties of thioamides and amides has led us to determine the barriers to rotation around the carbon–nitrogen bond of the thiobenzamides **1***a*–**1***f* and **2***b*, **2***d*, and **2***f*.

As usual, we had a choice of three possibilities



1



2

a R = C_6H_5—CH_2
b R = *p*-NO_2—C_6H_4
c R = *m*-NO_2—C_6H_4
d R = C_6H_5
e R = *p*-Cl—C_6H_4
f R = *p*-OCH_3—C_6H_4

b R = *p*-NO_2—C_6H_4
d R = C_6H_5
f R = *p*-OCH_3—C_6H_4

for obtaining the chemical exchange rates from the shape of nmr signals: the use of approximate equations (*i.e.* the single parameter methods), the total line shape (TLS) method, and the observation of coalescence phenomenon. The use of approximate equations, relating some features in the experimental nmr spectrum (such as line separation, linewidth, peak-to-valley ratio, or peak-to-peak ratio) to the exchange rate, may be the cause of appreciable errors at the level of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, as has already been demonstrated (1, 2). It may thus appear desirable to determine exchange parameters using information taken from the complete spectral lineshape. It has been demonstrated by Drakenberg *et al.* (2) and Shoup *et al.* (3), however, that the use of the complete lineshape is, *per se*, not necessarily a guarantee of accurate activation parameters. $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values can, in fact, be inaccurate because of unavoidable systematic errors due to $|\delta\nu|$ and T_2 temperature dependence ($|\delta\nu|$ is the chemical shift difference, in the

[1]Author to whom correspondence should be addressed.

absence of exchange, between the two exchanging sites and T_2 the transverse relaxation time, assumed to be the same for nuclei at either site). On the other hand, when evaluated near coalescence, the free energy of activation ($\Delta G^{\ddagger}$) is found to be quite insensitive to systematic errors on these two parameters, and, consequently, the error for $\Delta G^{\ddagger}$ may be assumed to be determined essentially by statistical random errors (if the accuracy of temperature measurement is optimized (4)). Accordingly, we preferred to determine the free energies of activation at the coalescence temperature ($\Delta G_c^{\ddagger}$). It may be objected that the determination of $\Delta G_c^{\ddagger}$ could preclude comparison between different thioamides and amides, because of the temperature dependence of this parameter. From this point of view $\Delta H^{\ddagger}$ would appear at first sight to be a better kinetical parameter. Nevertheless, as will be discussed later, $\Delta G_c^{\ddagger}$ may be considered to be a good measure of the intramolecular enthalpy contribution to the barrier.

Experimental

^{13}C chemical shifts have been reported previously for all the thiobenzamides studied (5), in $CDCl_3$ solutions, the only exception being derivative **1***a*. The ^{13}C chemical shifts for this compound are the following (in ppm, downfield from TMS as internal standard): (*i*) thiocarbonyl carbon 198.5; (*ii*) aromatic carbons: C-1 136.3, *ortho*, *meta*, and *para* carbons 126.9, 127.9, and 128.8; (*iii*) heterocyclic carbons: α-*N*-methylene carbons 51.1 and 51.6, β-*N*-methylene carbons 25.3 and 26.2, γ-*N*-methylene carbon 23.9.

The ^{13}C dnmr measurements were carried out on a Bruker HX-90 spectrometer equipped with a B-ST 100/700 variable temperature system and operating at 22.63 MHz in the Ft mode. The spectrometer was internally locked on a C_6F_6 sample contained in a coaxial capillary. The precision in $|\delta\nu|$ values is ± 1.5 Hz.

The ^1H dnmr spectra were recorded with a Varian A-60 spectrometer equipped with a variable temperature probe and a V-6040 variable temperature controller. Accurate frequency measurements of the ^1H nmr signals were performed by the audio sideband technique. Precision in $|\delta\nu|$ values can be estimated to ± 1 Hz, due to the shape of the signals.

Solutions were 1 *M* in *o*-dichlorobenzene, unless otherwise stated.

Temperatures, measured both before and after each spectrum, were determined from the temperature dependent chemical shift of ethylene glycol in the Varian A-60 probe and by mercury or alcohol thermometers in the Bruker HX-90 probe. All temperature sensors were calibrated independently by a melting point method (see ref. 4). The error for temperature measurements was estimated to be ± 0.5°C, including statistical and systematic errors such as those due to temperature gradients. The error in $\Delta G_c^{\ddagger}$ due to an error of 1°C in T_c is 50 cal mol^{-1}.

Results

By means of ^1H and ^{13}C dynamic nuclear magnetic resonance (dnmr) we have studied the hindered rotation around the C(S)—N bond in the molecules **1***a*–**1***f* and **2***b*, **2***d*, and **2***f*. The free energies of activation (which are listed in Table 1) have been calculated at coalescence from [1]:

$$[1] \quad \Delta G_c^{\ddagger} = 4.576T_c(10.32 + \log(T_c/k_c))$$

where k_c, the rate constant for rotation at the coalescence temperature (T_c), is given by [2]:

$$[2] \quad k_c = \pi|\delta\nu|/\sqrt{2}$$

$|\delta\nu|$ is the chemical shift difference in Hz between the two exchanging sites (in our case, the α-*N*-methylene protons or the α-*N*-methylene carbons) in the condition of infinitely slow exchange rate. Attention must be drawn to the fact that the $|\delta\nu|$ value which should be used in [2] is the $|\delta\nu|$ value at T_c. The $|\delta\nu|$ value we used in our calculations was the low temperature value measured for $T < T_c$. However, it must be noted that $|\delta\nu|$ is relatively temperature independent in the slow exchange region. Since $\Delta G_c^{\ddagger}$ is quasi-insensitive to small errors in $|\delta\nu|$, when the $|\delta\nu|$ value is high (which is the case), this approximation is therefore perfectly admissible. In fact, $\Delta G_c^{\ddagger}$ values are essentially affected by errors in T_c and we took care to minimize this kind of error by using a method already described (4).

Equation 2 is derived from the Gutowsky–Holm equation (6) describing exchange between two equally populated sites which are not coupled with each other or with other nuclei in the molecule. It holds for cases where, in the absence of exchange, lineshapes are Lorentzian and linewidths are smaller than the non-exchanging chemical shift. Gutowsky and Holm (6) have shown that the overlap of the components of the doublet is negligible when the linewidth is smaller than about $\frac{2}{3}$ of the true (*i.e.* assuming no exchange and no overlap) separation between the components. In cases where the linewidth is greater than $\frac{2}{3}|\delta\nu|$, the rate constant cannot be calculated from the simplified [2] and the observed coalescence temperature is not equal to the coalescence temperature which would have been observed in the absence of overlap.

α-*N*-Methylene carbons give well separated narrow signals with Lorentzian lineshapes in

TABLE 1. $|\delta\nu|$ (Hz), T_c (K) and $\Delta G_c^{\ddagger}$ (kcal mol^{-1}) for the restricted rotation around the C—N bond in some thiobenzamides (1 mol ℓ^{-1} in *o*-dichlorobenzene, unless otherwise stated)

the ^{13}C noise-decoupled spectrum. Therefore, all the conditions are fulfilled to use [1]–[2]. On the other hand, α-*N*-methylene protons give broadened triplets (because of the coupling with β-*N*-methylene groups). The lineshapes are not Lorentzian, but the linewidths remain smaller than $\frac{2}{3}|\delta\nu|$ and signals do not overlap. We were able to test the applicability of [2] in this particular case because, in the experimental conditions we used, and by chance, the $|\delta\nu|$ values observed in ^{1}H and in ^{13}C nmr were the same for unsubstituted thiobenzoylpiperidine, *i.e.* compound **1***d*. We were then able to compare the coalescence temperatures determined by ^{1}H and ^{13}C nmr. As is shown in Table 1, the two coalescence temperatures compare very well within the limits of experimental errors. We were then justified in making use of [2] when we evaluated by ^{1}H dnmr the rotational barriers of derivatives similar to **1***d*, which we did for compounds **1***a*–**1***f*.

We determined the $\Delta G_c^{\ddagger}$ of thiobenzoylmorpholines by ^{13}C dnmr. For these molecules, coalescence could not be accurately obtained by ^{1}H dnmr because of interference from other spectral lines.

Discussion

Before starting a discussion concerning the structural effect on $\Delta G^{\ddagger}$ values, it is necessary to consider the $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$ problem. As has been stated previously, it may be argued that $\Delta H^{\ddagger}$ (or E_a) is a better kinetic parameter than $\Delta G^{\ddagger}$, since $\Delta G^{\ddagger}$ is the sum of an enthalpy and an entropy factor. Nevertheless, it is well known that, because of the mutual compensating effect of the correlated errors on $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ (7), $\Delta G^{\ddagger}$ can be obtained with much greater accuracy than $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ (2, and see, for example, ref. 8). Moreover, $\Delta H^{\ddagger}$, like $\Delta S^{\ddagger}$ and $\Delta G^{\ddagger}$, can be described as the sum of an intermolecular contribution and an intramolecular contribution ($\Delta Y^{\ddagger} = \Delta Y^{\ddagger}_{\text{inter}} + \Delta Y^{\ddagger}_{\text{intra}}$, where $Y = G, H, S$). In some particular cases, it has been proved that the intermolecular contributions to $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, or ΔH^0 and ΔS^0, have a mutual compensating effect in a series of homologous systems (9). As Sandström noted (10), it is very difficult to prove that such a situation exists for the activation parameters of (thio)amides but this possibility cannot be ruled out. We can also say that the intermolecular contributions to $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, whatever they may be, must be similar for similar systems. We may finally observe that the intramolecular contribution to $\Delta S^{\ddagger}$ must be very small as is the case for all equilibria, or pseudo-equilibria, between two stereoisomers. This affirmation is based on an estimate of the difference between the partition functions of stereoisomers in the gas phase (11). The translational contribution to the entropy difference must be the same for two stereoisomers for obvious reasons, so the only possible differences arise from vibrational and rotational contributions. In our case, the symmetry number of the two molecular species (fundamental state and activated state) is equal to one, so the only difference between the two rotational partition functions is originated by the difference between the products of principal inertia moments. This contribution is known to be very small (<1 eu) in such systems (11).

Without any precise knowledge of the vibrational modes in the low frequency region, it is difficult to make an estimate of the vibrational contribution to the partition functions. Nevertheless, it seems safe to assume that the low frequency regions are similar for the two molecular species if we consider the thioamides and the corresponding amides as being roughly constituted of two independent moieties linked by the four-atom system C—C(X)—N which is the only system strongly modified by the $2\pi/4$ rotation around the C—N bond. It is clear that this group itself is characterized by some low frequency absorptions (torsional oscillation around the C—N bond in the fundamental state, out-of-plane and in-plane bending of the C(X) bond), but it is difficult to imagine that these contributions to the entropy of activation are larger than 2 or 3 eu and very different from compound to compound. This last point is the most important for a comparison of barriers obtained for various amides and thioamides.

Therefore, for the reasons previously discussed, we consider that $\Delta G^{\ddagger}$ is a good measure of the intramolecular contribution to the enthalpy of activation or, at least, that the variation of $\Delta G^{\ddagger}$ from one compound to another in a series of homologous molecules reflects the variation of the intramolecular contribution to $\Delta H^{\ddagger}$. We can then compare the $\Delta G^{\ddagger}$ values obtained for these two kinds of molecules in order to see if the intramolecular structural features have similar consequences on the barrier in the two series. This kind of approach has already been used by measuring the increments (in terms of $\delta\Delta G^{\ddagger}$) associated with the formal transformation *amide* → *thioamide* (12–14). We have preferred to use a slightly different approach based on a careful selection of many pairs of symmetrically disubstituted amides and thioamides recently studied in the literature. For each amide–thioamide pair we have selected barrier values determined in conditions which are as similar as possible (solvents, concentrations and temperatures). Our approach simply consists of the establishment of a linear correlation of the form

$$\Delta G^{\ddagger}(\text{thioamide}) = a + b\Delta G^{\ddagger}(\text{amide})$$

A least-squares linear regression analysis gives the following equation:

$$[3]\quad \Delta G^{\ddagger}(\text{thioamide}) = 1.13 + 1.11\Delta G^{\ddagger}(\text{amide})$$

Correlation coefficient, $r = 0.97$

Number of points: 20

represented in Fig. 1. The amide barriers chosen for this calculation are given in Table 2 and the corresponding values for thioamides are given in Table 3.

The average difference between values of the experimental barriers for thioamides (given in Table 3) and values of the barriers calculated by means of [3] is 0.54 kcal mol^{-1}, while the maximum and the minimum deviations are, respectively, equal to 1.73 and 0.09 kcal mol^{-1}. In 15 of the 20 cases, the difference in absolute value is smaller than 0.6 kcal mol^{-1}.

All the (thio)amides, except three, are formamides, alkyl-, or arylamides. The three exceptions in each series (entries 1, 4, 7 in Tables 2 and 3) correspond to derivatives with halogen or cyano substituents fixed on the (thio)carbonyl group. This small number of examples was selected in order to prove that even with such substituents the linear correlation holds very well. Moreover, and to test the generality of our relation, we added to the 20 points of the graph represented in Fig. 1 five further points corresponding to the barrier values of primary amides and thioamides studied by Walter *et al.* (24). Then the intercept and the slope become equal to 1.47 kcal mol^{-1} and 1.10, respectively, the correlation coefficient remaining equal to 0.97. It seems therefore that the same linear correlation holds for a great variety of primary and tertiary amides and thioamides.

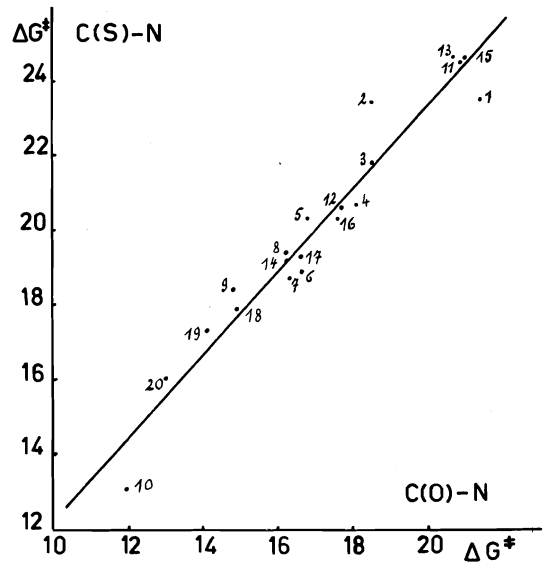

FIG. 1. The linear correlation between barriers of thioamides and amides ($\Delta G^{\ddagger}$, in kcal mol^{-1}; numbers refer to Tables 2 and 3).

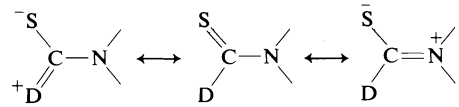
§C. Piccinni-Leopardi *et al.*, unpublished results.

It is difficult to decide whether the experimental value for the slope *b* is significantly different from unity or not. By the usual methods of correlation analysis, it is possible to calculate that the exact slope value is included, with a probability equal to 0.9, between the limits 1.0 and 1.2. The same treatment applied to the intercept proves without any doubt that this term is significantly different from zero. This conclusion reflects the fact that higher barrier values are generally observed for thioamides as opposed to amides. Both this problem and other problems like those concerning the substituent effects on the barriers of amides and thioamides have already been extensively discussed in the literature (see for example refs. 10, 12–14, 22 and the references cited therein). Electron donors have a lowering effect on the barrier when attached to the thiocarbonyl (or carbonyl) carbon. Such an effect can be observed both with alkyl and phenyl substituents, and with chlorine and fluorine atoms acting as π donors. On the other hand, electron acceptors like CN have virtually no effect on the barrier which remains similar to that for the unsubstituted system, *i.e. N,N*-dimethylthioformamide (12). Qualitatively, the electron donor effect can be justified in terms of the relative weight of the canonical structure I in the following scheme:



I II III

Any factor which increases the relative weight of I lowers the barrier. When D is a phenyl group, the donating effect can be increased or reduced by the substitution on the aromatic system. In the series of thiopiperidides and thiomorpholides studied during this work, we observed a decrease of the barrier for **1***f* (or **2***f*) but an increase for **1***b* (or **2***b*) relative to the unsubstituted derivative **1***d* (or **2***d*). We made

For the thioamides of entries 6 and 9 only the $\Delta G^{\ddagger}$ values obtained by approximate methods were available. In these cases we preferred to calculate the barriers to rotation at coalescence by [1] from the $|\delta\nu|$ and T_c data furnished in the original papers.
‡See the footnote ‡, Table 2.

the same observation in the case of the corresponding amides (C. Piccinni-Leopardi *et al.*, unpublished results). In the thiobenzoylpiperidines or -morpholines and in the corresponding amides, the phenyl ring in the preferred conformation is not in the plane of the thioamide group. An X-ray diffraction study (25) on thiocarbamoyl-4-pyridine has shown that the dihedral angle between the two planar moieties is 38°. Nevertheless, such an angle is not sufficient to completely suppress the conjugation between the two π systems (26) and the influence of the *para* substituents on the barrier is proof of the existence of an interaction between the two systems.

We will now point out the difference which exists between barriers of one thiopiperidide and the corresponding thiomorpholide (**1***b* compared to **2***b*, **1***d* to **2***d*, and **1***f* to **2***f*). Hirsch *et al.* (27), who observed the phenomenon in the case of benzoylpiperidine and benzoylmorpholine, considered the difference to be of no significance. We disagree with this conclusion since we have observed the same behaviour for three couples of thioamides and the analogous couples of amides. In all cases, the barrier in the (thio)morpholide is lower than the barrier in the corresponding (thio)piperidide. Considering the similarities between piperidine and morpholine it seems difficult to invoke a steric effect. It is therefore tempting to correlate the lower barrier in the (thio)morpholide series with a lower availability of the nitrogen lone pair electrons in morpholine compared to piperidine. A measure of this lower availability is given by the first ionization potentials of these two molecules, *i.e.* 8.91 eV for morpholine and 8.66 eV for piperidine (values obtained by photoelectron spectroscopy), since the first ionization potential may be safely assigned to the lone pair orbital on nitrogen (28).

Work is now in progress in order to see if the

barrier heights of amides and thioamides can be interpreted in terms of the electron-donating properties of the amine moiety and the electron-withdrawing properties of the acyl moiety as can be described in a HOMO–LUMO scheme (29).[2]

Aromatic substitutions with carbanion nucleophiles. III. The kinetics of the reaction of picryl chloride with diethylmalonate anion[1]

KENNETH T. LEFFEK AND ANNA E. MATINOPOULOS-SCORDOU
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received August 3, 1976[2]

KENNETH T. LEFFEK and ANNA E. MATINOPOULOS-SCORDOU. Can. J. Chem. **55**, 2656 (1977).

The reaction between 1-chloro-2,4,6-trinitrobenzene (picryl chloride) and diethylmalonate anion in benzene–DMSO 7:1 v/v solvent has been investigated by means of stopped-flow and uv–visible spectrophotometers. The results support a simple bimolecular aromatic substitution with a fast formation of a Meisenheimer-like coloured intermediate, followed by a slower decomposition to the picryl ester. The latter is rapidly deprotonated by the excess base. The steps of the reaction were followed separately and the rate constants and activation parameters have been measured.

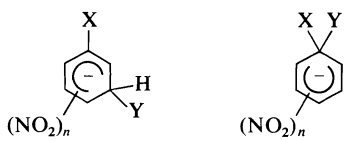
KENNETH T. LEFFEK et ANNA E. MATINOPOULOS-SCORDOU. Can. J. Chem. **55**, 2656 (1977).

Travaillant dans un mélange de solvant formé de benzène et de DMSO 7:1 v/v et faisant appel à des spectrophotomètres à flux stoppé et uv–visible, on a étudié la réaction entre le chloro-1 trinitro-2,4,6 benzène (chlorure de picryle) et l'anion du malonate d'éthyle. Les résultats supportent un mécanisme de substitution aromatique bimoléculaire simple avec la formation rapide d'un intermédiaire coloré ressemblant à ceux de Meisenheimer qui est suivie par une décomposition plus lente conduisant à un ester de picryle. Ce dernier est rapidement déprotoné par un excès de base. On a suivi séparément les diverses étapes de la réaction et on en a mesuré les constantes de vitesse et les paramètres d'activation.

[Traduit par le journal]

Introduction

Except for the attack of bases derived from ketones on nitroaromatics, yielding mainly stable Janovsky or Zimmermann complexes (1–7), few reactions between carbanions and aromatic molecules have been reported (3–11). They all involve active methylene groups and, in contrast to ketones, usually lead to aromatic nucleophilic substitution products. Also, contrary to the case of oxygen nucleophiles where the kinetically controlled intermediate **1** is initially formed and is followed by the thermodynamically controlled **2**, with carbanion nucleophiles only one coloured intermediate has been observed in each reaction, which has been assumed to have the structure **2**. Direct observation by nmr has been reported only for the case of 2,4,6-trinitrocyclohexadienate with X = OCH_3 and Y = $CH(COCH_3)COOC_2H_5$ (12).



1 **2**

In the present study, a development of previous work on 1-fluoro-2,4-dinitrobenzene (13–14), the reaction between picryl chloride and diethylmalonate anion has been investigated using stopped-flow and uv–visible spectrophotometers. The results support the mechanism shown in reaction 1, with k_1, $k_3 \gg k_2$ and $k_{-1} \ll k_1$, $k_{-3} \ll k_3$.

Results and Discussion

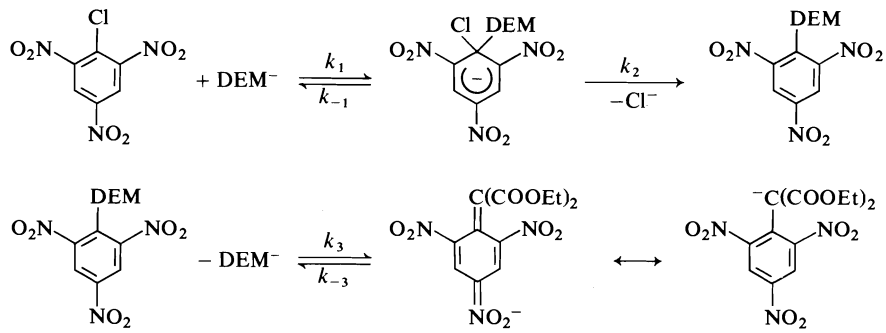
Absorption Spectra

When solutions of picryl chloride and diethylmalonate sodium salt in DMSO are mixed, a red colour appears immediately which slowly changes to violet after about 4 h. This reaction cannot be studied kinetically because the formation of the red colour is too fast to be followed with a stopped-flow spectrophotometer. An additional inconvenience is that picryl chloride reacts slowly with DMSO to yield picric acid (15), so that stock solutions may not be used. The addition of benzene to the DMSO solvent decreases the rate of formation of the intermediate and increases its rate of decomposition. A mixture of benzene–DMSO of 7:1 v/v was found to be suitable for measurement of both the formation

[1]Presented at the 59th Annual Chemical Conference of the Chemical Institute of Canada, London, Ont., June 6–9, 1976.

[2]Revision received March 28, 1977.

[1]



and decomposition rates. The spectra observed at various times after mixing are shown in Fig. 1. The decomposition of the initial intermediate to the final stable anion (λ_{max} 523 nm) goes through an isosbestic point, but is quite fast so that only part of the initial form can be scanned (curve 1).

With the excess of base, necessary to simplify the kinetic measurements, the reaction goes through to the final violet anion and if the conversion is assumed to be complete, the molar extinction coefficient of the peak at 523 nm is 9700 M^{-1} cm^{-1}. A sample of 2,4,6-trinitrophenyldiethylmalonate was isolated from the reaction carried out under preparative conditions and reacted with excess diethylmalonate anion in the same solvent. This gave a product peak at 523 nm, ε = 9600 M^{-1} cm^{-1}. The anion of the ester, which was isolated in reasonable purity and a solution made up by weight, gave λ_{max} 522 nm, ε = 9500 M^{-1} cm^{-1}. Thus, the reaction under study goes essentially to completion and is free from side reactions.

To obtain a spectrum of the initial intermediate a series of scans at fixed wavelengths and variable time were made on the stopped-flow spectrophotometer. From these, a series of spectra at definite times after mixing was obtained as shown in Fig. 2. It can be seen that there is an initial formation of an intermediate, essentially complete after about 20 ms, the spectrum of which closely resembles that of a Meisenheimer complex. A steady state exists from about 20 ms to about 2 s, after which decomposition of the intermediate takes place. Thus, by choosing the appropriate time base the rate constants for the formation and the decomposition of the intermediate of the reaction can be measured independently.

The final deprotonation step can be studied separately, using 2,4,6-trinitrophenyldiethylmalonate as substrate.

Kinetic Measurements

For an equilibrium in which the forward reaction is second order and the reverse reaction is first order, the integrated kinetic equation is

$$[2] \qquad \ln \frac{x_e}{x_e - x} = (k_1 b + k_{-1})t$$

where x_e and x are the product concentrations at equilibrium and at time t, respectively, k_1 is the second-order rate constant for the forward reaction and k_{-1} is the first-order rate constant for the reverse reaction and b is the reagent concentration, diethylmalonate anion in this case. If the concentration b is in excess of that of the substrate to the extent that it undergoes no significant change during the reaction, [2] yields a pseudo first-order rate constant k_{obs} equal to $(k_1 b + k_{-1})$. Thus, k_1 and k_{-1} can be obtained from the slope and intercept of a plot of k_{obs} *vs.* b.

The results for the formation of the intermediate are given in Table 1, for seven different temperatures. At two temperatures the rate constants were measured at the two wavelengths of 445 and 495 nm to check that the two peaks observed in Fig. 2 were, in fact, due to the same species. The second-order rate constants are the same within experimental error, showing that this is the case.

The half-lives for these runs ranged from 1 to 5 ms, *i.e.* at the limit of the capability of the stopped-flow spectrophotometer, and although satisfactory correlation coefficients of 0.995 to 0.999 were obtained for individual runs, the uncertainties in the observed rate constants were frequently large and the scatter in the second-order rate constants considerable. At all temperatures k_{-1} was approximately zero within experimental error.

Table 2 shows the rate constants for the decomposition of the intermediate at five tempera-

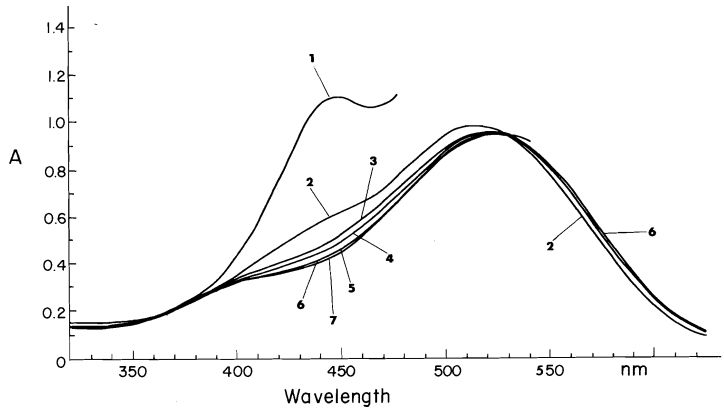


FIG. 1. Absorption spectra of the reaction mixture of picryl chloride and diethylmalonate anion in benzene–DMSO 7:1 v/v at times after mixing of *1*, 0.45 min; *2*, 1.8 min; *3*, 4.9 min; *4*, 6.2 min; *5*, 15 min; *6* and *7*, 29, 51, and 81 min.

tures, which were measured on a standard uv–visible spectrophotometer. The first-order rate constant is independent of base concentration, indicating that this step is first-order as written in the reaction scheme, with no base catalysis. The half-lives for these reactions varied between $\frac{1}{2}$ and 3 min.

The kinetics of the deprotonation step are shown in Table 3. This reaction was again very rapid, with half-lives of 1 to 5 ms and the plots of k_{obs} *vs.* b had intercepts of zero within experimental error.

The activation parameters for all three steps of the reaction are given in Table 4. These results indicate an almost irreversible formation of one coloured intermediate which decomposes to the substitution product and is finally converted to the anion of the product. The rate determining step is the decomposition of the intermediate to the product. The presence of an isosbestic point supports the absence of competing or sequential equilibria (16). The identity of the intermediate may be the C-1 complex **2** as shown in the reaction scheme [1], or it may be the C-3 complex **1**. If the latter is the case, then the C-1 complex is not observed at all, since we see only one coloured intermediate. The reaction would then follow the scheme in [3], where $k_0 \gg k_1$. Since C-1 complexes are generally thermodynamically more stable than C-3 complexes, k_{-1} must be small and k_2 large if the C-1 complex is not observed. Therefore, reaction schemes [1] and [3] are indistinguishable kinetically. However, the rate constant for the back reaction, which on the basis of [3] would be equal to $k_{-0}k_1/k_0$, is close to zero and if an upper limit of 1 s^{-1} is assumed, $K_0 = k_0^2/(k_{-0}k_1) = 5.8 \times 10^{-5}\ M^{-1}$ at 25°C for the C-3 complex. This represents the lower limit for K_0. Since C-1 complexes are generally much more stable, K_1 should be at least of the order of $10^7\ M^{-1}$ and a second coloured intermediate should be observed. This suggests that the coloured intermediate which we observe is not the C-3 complex.

Additional evidence may be obtained by examination of the reaction with trinitrobenzene. Under the conditions used in the reaction, diethylmalonate anion attacks trinitrobenzene to form a coloured complex at a rate which was too fast to measure with the stopped-flow spectrophotometer. Therefore, the attack on trinitrobenzene is considerably faster than that on picryl chloride. Since picryl chloride is activated

towards nucleophilic attack relative to trinitrobenzene, and since the steric effect of the Cl on the NO_2 groups is not expected to be large, this is evidence supporting the formation of the C-1 rather than the C-3 complex.

The activation parameters of Table 4 are quite reasonable. The large activating power of the three nitro groups together with the strong nucleophilicity of the carbanion are expected to lead to a small enthalpy of activation for the formation of the intermediate. Its decomposition, involving the breaking of a carbon–chlorine bond, has a much greater enthalpy of activation. That both the formation and decomposition reactions should have negative entropies of activation would not have been predicted, since the latter would be expected to be much more positive, within the experimental error. However, negative entropies have been observed for other reactions (14, 18). The previously proposed explanations,

that the incipient chloride ion enhances the solvation of the transition state of the decomposition reaction, fits, in a qualitative sense, the present results.

The activation parameters for the proton transfer step are quite reasonable for this carbon acid, the negative entropies are again consistent with many reports in the literature (19–24).

Experimental

Materials

Sodium diethylmalonate was prepared from sodium ethoxide and diethylmalonic ester. Sodium was dissolved

in absolute ethanol and then freshly redistilled diethylmalonic ester was added in a 1:1 molar ratio. After shaking the mixture overnight at room temperature, the alcohol was removed under vacuum and the white salt dried at room temperature (yield 87% on a 0.05 mol scale).

Picryl chloride (Matheson, Coleman & Bell) was recrystallized from chloroform (mp 82.5–83.5°C).

The sodium salt of picryldiethylmalonate (2,4,6-trinitrophenyldiethylmalonate) was prepared from sodium diethylmalonate and picryl chloride. Picryl chloride (0.02 mol) in DMSO was added slowly to the diethylmalonate salt (0.04 mol) in DMSO. The mixture was stirred overnight at room temperature, then poured into ice water and the dark purple precipitate was filtered, washed with cold water and petroleum ether, and then dried at room temperature (yield 72%).

For preparation of the ester, the salt was suspended in absolute ethanol, acidified with dilute sulfuric acid, heated to boiling, and filtered. The filtrate was allowed to cool slowly and colourless needle crystals were obtained (yield 50% on a 0.01 mol scale). The crystals were recrystallized from absolute alcohol, mp 57–58°C (lit. (25) mp 58°C).

Dimethyl sulfoxide was dried over 4A molecular sieve and then distilled over CaH_2 under nitrogen at reduced pressure. The middle fraction was collected (bp 48°C/3.0 Torr) and stored in a dark bottle under nitrogen.

Thiophene-free benzene was dried over $CaCl_2$ and then distilled over sodium (bp 80.5°C). For the kinetic runs, both solvents were used within 1 week after purification.

Kinetic Procedure

The absorption spectra were recorded on a SP800B spectrophotometer in cells of 1.0 cm path length. The same instrument, connected to an external recorder

TABLE 5

allowing for expansion of the signal and choice of any region of absorbance between 0–2, was used for the slow kinetic runs. The temperature was controlled within 0.05°C.

The fast reactions were followed on a Durrum–Gibson stopped-flow spectrophotometer fitted with a 2 mm light-path optical cell. The drive syringes, the mixing-jet, and the cell were kept within 0.05°C of the quoted temperature by means of an RTE-8 Neslab circulating bath. The dead time of the instrument was 1 ms checked by the standard reaction between $Fe(NO_3)_3$ and KCNS. In all the cases the solutions were prepared on the same day of measurement, the base in 3:1 v/v benzene–DMSO, the substrate in benzene. The solutions of the base were prepared and handled in a glove bag, under nitrogen. The weighed amount of base was dissolved in DMSO corresponding to $\frac{1}{4}$ of the volume required. Then, benzene was added to the mark in the volumetric flask. Dilutions were made by 3:1 v/v benzene–DMSO prepared in the same way.

For the stopped-flow, all the results reported correspond to at least three consecutive superimposed runs. The traces of percentage transmittance *vs.* time, stored on a Tektronix 564 oscilloscope were photographed, the transmittance converted to absorbance, and the pseudo first-order rate constants calculated by the Guggenheim method (26). A least-squares calculation provided the best line. Standard errors and correlation coefficients were calculated at the same time. Whenever possible scans were made at two or three time bases in which case the arithmetic mean of the rate constants was used. The errors reported refer to the standard error of the least-squares method. However, an error of 10%, estimated by duplicate runs, should be taken into account due to the fact that the instrument was being used at the limit of its capability with respect to the speed of the reaction.

For the slow kinetic runs, absorbance readings *vs.* time were obtained directly on the Unicam. The Guggenheim method was used again for the first order rates. Three runs were obtained for each base concentration and the arithmetic mean rate was calculated. This was repeated for various base concentrations and the average value obtained. Sample runs are given in Table 5.

Aromatic substitutions with carbanion nucleophiles. IV. The kinetics and mechanism of the reaction of picryl bromide with diethylmalonate anion

KENNETH T. LEFFEK AND ANNA E. MATINOPOULOS-SCORDOU

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received December 20, 1976

KENNETH T. LEFFEK and ANNA E. MATINOPOULOS-SCORDOU. Can. J. Chem. **55**, 2664 (1977).

The reaction of picryl bromide with sodium diethylmalonate has been studied in benzene–DMSO 7:1 v/v by means of stopped-flow and uv–visible spectrophotometers. A Meisenheimer-like intermediate was detected, decomposing to yield the stable violet anion of the substitution product. The rate constants of the individual steps have been measured and the activation parameters calculated. Comparison with those obtained for picryl chloride support a bimolecular substitution via the 1,1-complex. The reaction with 1,3,5-trinitrobenzene is too fast to be measured in the same solvent system. The equilibrium constant is estimated to be of the order of 10^4–10^5.

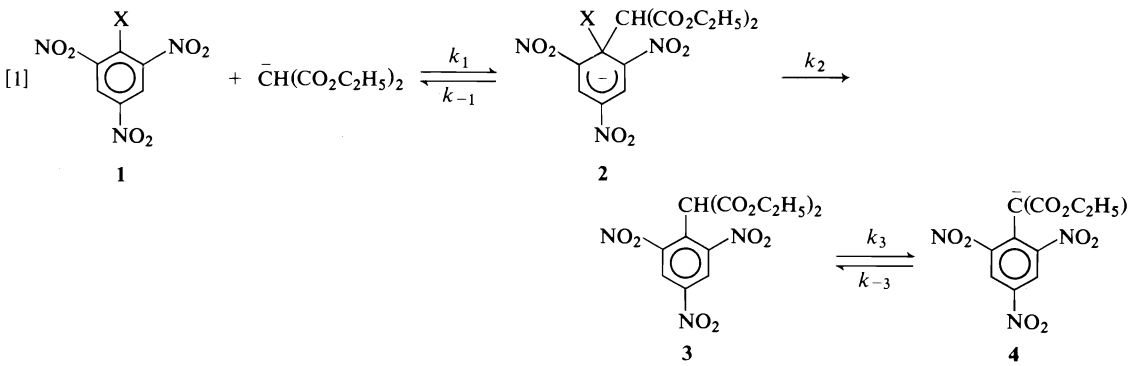
KENNETH T. LEFFEK et ANNA E. MATINOPOULOS-SCORDOU. Can. J. Chem. **55**, 2664 (1977).

Travaillant dans des solutions de benzène–DMSO 7:1 v/v et faisant appel à des spectrophotomètres à flux stoppé et uv–visible, on a étudié la réaction du bromure de picryle avec le sel de sodium du malonate d'éthyle. On a détecté un intermédiaire ressemblant à ceux de Meisenheimer qui se décompose pour conduire à l'anion violet stable du produit de substitution. On a mesuré les constantes de vitesse pour chacune des étapes et on en a calculé les paramètres d'activation. Une comparaison de ces données avec celles obtenues pour le chlorure de picryle supporte un mécanisme de substitution bimoléculaire par l'intermédiaire d'un complexe 1:1. La réaction avec le trinitro-1,3,5 benzène est tellement rapide que sa vitesse ne peut être mesurée dans le même système de solvant. On estime que la constante d'équilibre est de l'ordre de 10^4 jusqu'à 10^5.

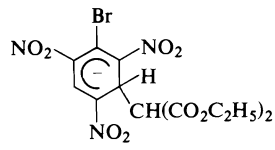
[Traduit par le journal]

Introduction

The study of the reaction between picryl chloride and sodium diethylmalonate in benzene–DMSO 7:1 v/v (1) led to mechanism [1] for X = Cl with $k_1, k_3 \gg k_2$ and $k_{-1} \ll k_1$, $k_{-3} \ll k_3$.



In the present study the similar reaction of picryl bromide is examined and the rate constants and activation parameters compared with those of the chloro-compound. The work of Gan and Norris (2) predicts that if the above mechanism is correct, the value of k_1 for picryl bromide will be clearly less than that of picryl chloride, whereas if we are actually observing the formation of the 1,3-complex **5**, the rate constant should be almost identical to that observed for picryl chloride.



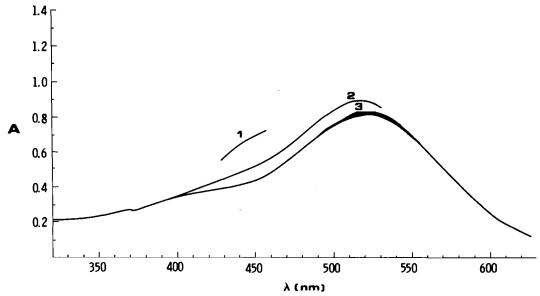


FIG. 1. Absorption spectra of the interaction of picryl bromide (0.75×10^{-4} *M*) and diethylmalonate anion (2.1×10^{-3} *M*) in benzene–DMSO 7:1 v/v at times after mixing of *1*, 0.43 min; *2*, 0.70 min; *3*, 1.37 min.

Results and Discussion

Picryl bromide in benzene, mixed in 1:1 v/v ratio with an excess of sodium diethylmalonate in benzene–DMSO 3:1 v/v gives rise to a red colour which changes very quickly to a violet stable product. The behaviour is similar to that of picryl chloride (1) with the difference that the decomposition is faster, so that observation of the visible spectrum on the conventional spectrophotometer shows only a shift towards higher wavelength, Fig. 1. The slow reaction of picryl bromide with DMSO does not interfere with the reaction under these conditions.

A check in either DMSO or DMSO–benzene 1:1 v/v, where the intermediate is more stable, shows the transition through an isosbestic point more clearly, as can be seen in Fig. 2, for the latter case.

The change of the spectrum at short times could be followed only by means of a stopped-flow spectrophotometer. Measurement at various wavelengths for different time bases showed that the two peaks initially formed at 447 and 492 nm increase up to a steady-state equilibrium after which the decomposition becomes dominant and the peak at the shorter wavelength gradually disappears whereas the other is shifted to higher wavelength due to the formation of the product as shown in Fig. 3. The product is similar in all respects with the one obtained from picryl chloride (1) and was thus identified as **4**. Because of the fast decomposition of the intermediate, the true extinction coefficients could not be measured. The assumption that the absorbance at equilibrium corresponds to the complete conversion of all the substrate gave good straight lines for $A = f(c)$ from which the approximate figures of $\varepsilon_{447} = 16\,700$ and $\varepsilon_{492} = 14\,800$ $cm^{-1}\,M^{-1}$ were calculated.

The formation of the intermediate was followed on a stopped-flow spectrophotometer at 447 nm for six temperatures. A check of the rate at 492 nm at 15.2°C gave the same rate constants as those obtained at 447 nm indicating that both peaks belong to a single intermediate. The second-order reaction was reduced by use of an excess of base, to pseudo first-order, the rate constant of which, k_{obs}, plotted against the base, [2], gave as slope k_1, the second-order rate constant for complex formation.

$$[2] \qquad k_{obs} = k_1 b + k_{-1}$$

The results are given in Table 1 and all the kinetic runs correspond to correlation coefficients of 0.995–0.999. The rate constant for the decomposition to reactants (k_{-1}) could not be obtained from the intercept but was very small and assumed to be approximately zero.

The decomposition of the same complex, followed on a conventional spectrophotometer at

447 nm, was independent of the base concentration. The results given in Table 2 are in accord with [3] in which K_1 is the equilibrium constant for the formation of the intermediate. This step

$$[3] \quad k_{dec} = k_2\left(\frac{K_1 b}{1 + K_1 b}\right) \simeq k_2 \text{ if } K_1 b \gg 1$$

is much slower than the formation of the intermediate and since the last deprotonation step has a second-order rate constant of $k_3 = (64 \pm 8) \times 10^4\ s^{-1}\ M^{-1}$ at 25°C (1), the decomposition is the rate-determining step of the overall reaction. The activation parameters for both the formation and decomposition of the intermediate are given in Table 3. These parameters are quite similar to those obtained for picryl chloride and may be rationalized in the same manner (1).

An attempt was made to study the reaction of trinitrobenzene with the same carbanion under identical conditions. A complex with λ_{max} at 460 (ε 29 400) and 564 (ε 14 100) was observed. However, the rate of formation was too fast for the stopped-flow method. For [TNB] = 0.2×10^{-5} M and [DEM] = 0.11×10^{-3} M, the reaction is over at approximately 4 ms. An attempt to

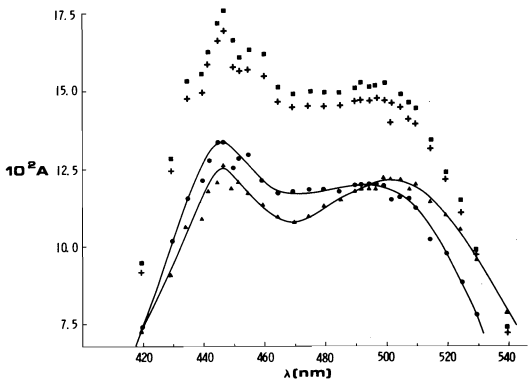

FIG. 3. Change of absorption spectrum during the reaction of picryl bromide and diethylmalonate anion in benzene–DMSO 7:1 v/v at times after mixing of ● 9.2 ms, + 23.1 ms, ■ 69.4 ms, ▲ 18.5 s.

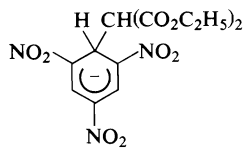
calculate the equilibrium constant (K_{eq}) using the Benesi–Hildebrand method (3) was equally unsuccessful because the ratio $[TNB]_0/A_{eq}$ where $[TNB]_0$ = initial concentration of substrate, A_{eq} = absorbance at equilibrium, was essentially constant. The slope of $[TNB]_0/A_{eq} = f(1/b)$, where b = base concentration, was estimated to be of the order of 10^{-8}–10^{-9} which gives a K_{eq} of the order of 10^4–10^5 M^{-1}. The only conclusion which could be drawn from this reaction was the useful observation that the unsubstituted substrate reacts faster than the chloro- or bromo-substituted ones. The only visible spectrum of a diethylmalonate anion addition product reported is that of **6** which in DMF shows λ_{max} at 460 and 568 nm (4).



6

In the present work, the trinitrobenzene reaction shows λ_{max} at 459, 562 nm in pure DMSO;

TABLE 3. Activation parameters for the reaction of picryl bromide with diethylmalonate anion

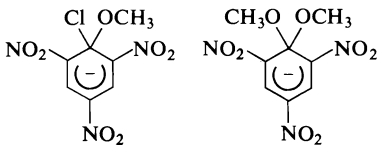
X	λ_{max} (nm)	($s^{-1} M^{-1}$)	(kcal/mol)	(cal mol^{-1} deg^{-1})	($s^{-1} M^{-1}$)	(kcal/mol)	(cal mol^{-1} deg^{-1})
H	460 564						
Cl	445 495	58±2	2.2±1.3	−24.4±4.1	17.3±0.2	14.5±0.7	−18.0±2.3
Br	447 492	25±0.5	1.9±0.6	−27.5±1.8	24.1±0.3	12.0±0.5	−25.6±1.8

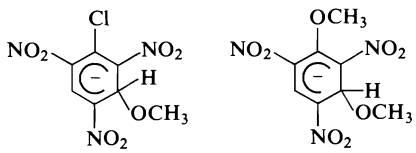
458, 562 nm in benzene–DMSO 1:1 v/v; and 460, 564 nm in benzene–DMSO 7:1 v/v. This suggests strongly that the product is actually the anionic complex **6**. The ratio of the extinction coefficients at the two wavelengths is approximately 2:1 as expected from such complexes.

A summary of the results in Table 4 shows that between the two halo-substrates picryl chloride forms the intermediate 2.3 times faster than the picryl bromide at 25°C, whereas the rate of decomposition of the same intermediate is slower by a factor of 1.4 than that of the bromo-complex. Gan and Norris (2) found that the rate constants for the formation of **7** and **8** in methanol differed by a factor of about 2 at 25°C, with that for **7** being the greater. In contrast they observed identical rate constants, within experimental error, for the formation of **9** and **10**.



7 **8**

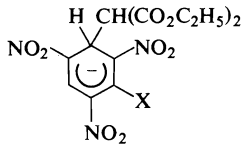
Thus, for both picryl chloride and bromide, the assignment of the observed attack of the carbanion to the halo-substituted position of the substrate, yielding **2**, gives the most satisfactory rationalization of the results, since it presents an interpretation of these reactions and those of Gan and Norris (2) on a common set of criteria even though these criteria indicate a C-1 attack in the present case, whereas they fit a C-3 attack for the reaction of picryl chloride with methoxide (2). If the observed colour is accepted as the C-1 complex, the main factor on which the reactivity



9 **10**

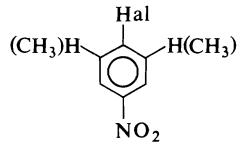
depends would be the electronegativity of the substituent present (5), the difference in the steric requirements of the chlorine and bromine not being large enough to account for such a difference in rate (6). Chlorine being more electronegative, facilitates the attack and leads to faster formation of the intermediate. The decomposition depends mainly on the ease with which the bond between carbon and the substituent is broken, and since bromine is the better leaving group, the faster decomposition of the bromo-complex is expected, as observed. Another factor supporting the mechanism shown in [1] is the fast reaction of trinitrobenzene. Since so far in aromatic nucleophilic substitutions, attack at unsubstituted positions has always been faster mainly because of steric reasons (7), the formation of **11** would be expected to be faster than that of **6**.

Finally, for the overall rate represented by k_2, the ratio $k_{Cl}/k_{Br} = 0.7$ is obtained. The result agrees with the previous range of $k_{Cl}/k_{Br} = 0.5$–



11

0.8 obtained for the reaction between sodium phenoxide and **12** (6).



12

Experimental

Picryl bromide was prepared according to the method of Sygden and Willis (8) using 1-bromo-2,4-dinitrobenzene as starting material. The yield of crude material was only 29%. The product was recrystallized from absolute ethanol (mp 123–124°C).

Purification of the other chemicals used, as well as the procedure followed during the experiments, were described previously (1).

Reactions of some 2,5-dialkylpyridines with aldehydes and phenyllithium

JOHN A. FINDLAY AND GREG C. LONERGAN

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3

Received June 21, 1976[1]

JOHN A. FINDLAY and GREG C. LONERGAN. Can. J. Chem. **55**, 2670 (1977).

The structure chemistry and stereochemistry of novel and complex adducts of type **3** obtained by reactions of 2,5-dialkylpyridines with aliphatic aldehydes and phenyllithium is discussed. A mechanism of formation is proposed.

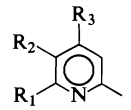
JOHN A. FINDLAY et GREG C. LONERGAN. Can. J. Chem. **55**, 2670 (1977).

On discute de la chimie et de la stéréochimie de la structure de nouveaux adduits complexes de type **3** obtenus par des réactions de dialkyl-2,5 pyridines avec des aldéhydes aliphatiques et du phényllithium. Un mécanisme pour la formation de ces composés est proposé.

[Traduit par le journal]

In the course of preparing 4-methyl-1-(5-methyl-2-pyridyl)pentan-2-ol, **2***a* (1) by phenyllithium catalyzed condensation of 2,5-dimethylpyridine **1***a* with isopentanal an unanticipated and remarkable by-product was recovered in 18% yield. The structure **3***a*, 2,5-dimethyl-2-(5′-methyl-2′-picolyl)-3-(1′′-hydroxy-4′′-methylbutyl)-6-phenyl-4,5-didehydropiperidine dihydrochloride, is assigned to it on the basis of chemical and spectroscopic evidence.

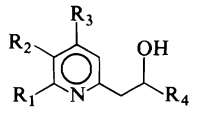
Treatment of bromobenzene in ether with 2 equiv. of lithium gave a solution containing phenyllithium which turned red-brown upon addition of 1 equiv. of 2,5-dimethylpyridine **1***a*. Subsequent addition of isopentanal followed by acidic (HCl) work-up afforded an organic layer from which the white crystalline adduct separated. The elemental composition, $C_{25}H_{34}ON_2 \cdot 2HCl$, ascertained by microanalysis and supported by mass spectral data, is consistent with a dihydrochloride adduct derived from two molecules of 2,5-dimethylpyridine, one of benzene, and one isopentanal and possessing a total of ten sites of unsaturation. The presence of phenyl and 5-methyl-2-picolyl features was learned from the nmr ($CDCl_3$) spectrum which shows a total of eight protons in the aromatic region, two of which display chemical shifts and couplings appropriate for a 2,5-dialkyl substituted pyridinium moiety (2), δ 7.99 (s, 1H, $W_{1/2}$ = 4 Hz, C6H) and 7.12 (d, J = 8 Hz, C3H), while signals corresponding to five phenyl hydrogens plus a C4 pyridinium proton are accommodated in a complex multiplet centred near δ 7.5. Furthermore,



1

a $R_1,R_3 = H; R_2 = CH_3$
b $R_1,R_2,R_3 = H$
c $R_1,R_2 = H; R_3 = CH_3$
d $R_1,R_3 = CH_3; R_2 = H$
e $R_1,R_3 = H; R_2 = C_2H_5$

$C_6H_5Li \mid R_4CHO$



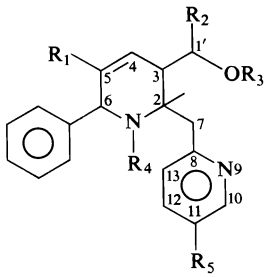
2

a $R_1,R_3 = H; R_2 = CH_3; R_4 = (CH_3)_2CHCH_2$
b $R_1,R_2,R_3 = H; R_4 = (CH_3)_2CHCH_2$
c $R_1,R_3 = H; R_2 = CH_3; R_4 = C_6H_5$
d $R_1,R_2 = H; R_3 = CH_3; R_4 = (CH_3)_2CHCH_2$
e $R_1,R_3 = CH_3; R_2 = H; R_4 = (CH_3)_2CHCH_2$

the mass spectrum corroborates the 5-methyl-2-picolyl feature in displaying a strong ion *m/e* 272 ($M - 2HCl - C_7H_8N$). In addition, nmr signals at δ 2.32 (3H, s) and an AB quartet at δ 3.63, 3.48 (J = 18 Hz) are consistent with the 5-methyl-2-methylene pyridinium substituent attached via the 2-methylene group to a fully substituted carbon. The presence of a secondary hydroxyl is confirmed by the broad singlet at δ 4.00 (1H) transformed to a doublet of doublets after addition of D_2O. This signal is displaced to δ 5.15 in a monoacetate derivative **3***b* (*vide infra*). Additional methyl singlets are located at δ 1.81

[1]Publication was delayed 6 months at the authors' request.

and 1.55 while a pair of doublets at δ 0.80 (3H, J = 6 Hz) and 0.76 (3H, J = 6 Hz) are ascribed to an isopropyl feature. Furthermore, double irradiation near δ 1.5 ppm causes collapse of the δ 4.00 signal to a broad singlet ($W_{1/2}$ = 10 Hz) and the isopropyl methyl doublets to singlets thus confirming the sequence $(CH_3)_2$-$CHCH_2CHOH$-.



3

a ·2HCl $R_1,R_5 = CH_3$; $R_2 = (CH_3)_2CHCH_2$; R_3,R_4 = H

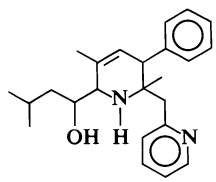
Thus the adduct comprises four structural units; namely, phenyl, 5-methyl-2-picolyl, and 1-isopentanol groups attached to a nitrogen containing framework originating from a second 2,5-dimethylpyridine molecule. Assuming that this latter is an intact six-membered nitrogen containing ring, it remains to place the above identified appendages on a didehydro-2,5-dimethylpiperidinium nucleus. Initial difficulty in arriving at a unique structural conclusion based on spectral data was due to the fact that the nmr signals for the hydrogens attached to the presumed didehydropiperidinium system could not be assigned unambiguously. Thus, the relevant signals are displayed as broad singlets at δ 2.45 (1H, $W_{1/2}$ = 8 Hz), 4.82 (1H, $W_{1/2}$ = 8 Hz), and 5.91 (1H, $W_{1/2}$ = 6 Hz). Decoupling experiments did not provide any useful information. Hence, apart from structure **3***a*, alternates such as **4**, **5***a*, and **5***b* could not readily be excluded.

The nmr ($CDCl_3$) spectrum of the monoacetate **3***b* of the dihydrochloride **3***a* shows new features consistent with a secondary acetoxyl function at δ 5.15 (1H, apparent triplet, $J \simeq 6$ Hz, -C*H*OCOCH$_3$) and δ 2.06 (3H, s, CH_3COO-) while other non aromatic downfield hydrogens again appear as broad singlets and are located at δ 2.93 ($W_{1/2}$ = 7 Hz), 4.89 ($W_{1/2}$ = 7 Hz), and 5.88 ($W_{1/2}$ = 6 Hz) and defy unique assignments.

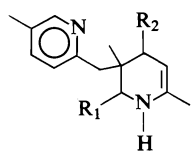
Dehydration of the adduct **3***a* was readily accomplished using thionyl chloride and gave an anhydrodihydrochloride. Its nmr ($CDCl_3$) spectrum shows a δ 5.25 triplet (1H, J = 6.5 Hz) ascribed to the A part of a new AX_2 system while other downfield signal patterns remain essentially unchanged. The ultraviolet spectrum (EtOH) λ_{max} 250 (ε 15 000) is reasonably consistent with a tetrasubstituted conjugated diene possessing an exocyclic double bond (calculated λ_{max} 242).

The only structure for the adduct in agreement with the foregoing is **3***a* in which the double bond is located between carbons 4 and 5 of the piperidinium moiety, thus allowing for the generation of the tetraalkyl substituted diene **6**[2] upon dehydration. Alternative structures, for example **4**, **5***a*, or **5***b* capable of featuring a new chromophore after dehydration would necessarily give rise to dienamine systems with quite different uv chromophores. Furthermore, structure **3***a* is fully supported by a detailed analysis of nmr spectral data.

The free base **3***c* is readily obtained from **3***a* by



4·2HCl



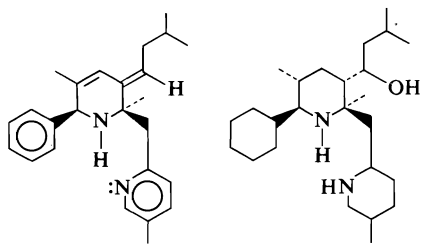
5

a ·2HCl $R_1 = C_6H_5$; $R_2 = (CH_3)_2CHCH_2CHOH$
b ·2HCl $R_1 = (CH_3)_2CHCH_2CHOH$; $R_2 = C_6H_5$

[2]For stereochemical assignments, *vide infra*.

treatment with dilute sodium hydroxide solution at room temperature and can be converted back to the dihydrochloride by hydrochloric acid. Thionyl chloride converts the free base **3***c* directly to the anhydrodihydrochloride **6**. Acetylation of the free base **3***c* with acetic anhydride – pyridine affords the monoacetate **3***d* and the *O*,*N*-diacetate **3***e* both of which can be hydrolyzed back to **3***c*. The monoacetate dihydrochloride obtainable by treatment of **3***a* with acetic anhydride – pyridine is now formulated as **3***b*. The structures of these transformation products are fully supported in detail by spectroscopic and analytical data.

Attempts at selective hydrogenation of **3***a* and **3***c* under a variety of catalytic conditions were unsuccessful and it was apparent from incomplete reductions that the isolated double bond and the phenyl group are reduced simultaneously. Catalytic hydrogenation of **3***a* at room temperature under pressure (40 psi) using Adam's catalyst gave in 75% yield a crystalline (mp 138–141°C) product devoid of ultraviolet absorption and displaying a molecular ion *m*/*e* 392 (*M* − 2HCl) in its mass spectrum, corresponding to a tetradecahydro derivative formulated as **7**.[2]



6·2HCl **7**·2HCl

Consistent with our structural assignment, **3***a* is the preparation of the homolog **3***f*, $C_{27}H_{38}ON_2 \cdot 2HCl$ by parallel reaction of 5-ethyl-2-methylpyridine with phenyllithium and isopentanal. As anticipated, this adduct shows nmr ($CDCl_3$) signals for two additional vinylic methylene groups, one at δ 1.85 (2H, q, J = 8 Hz) and 2.59 (2H, q, J = 8 Hz). The corresponding acetate **3***g* and free base **3***h* of this homolog were prepared and characterized and displayed the expected spectral features.

When isobutanal was treated with a benzene solution of 2,5-dimethylpyridine in the presence of phenyllithium, the crystalline adduct **3***j* was obtained, isolated as the dihydrochloride **3***i*.

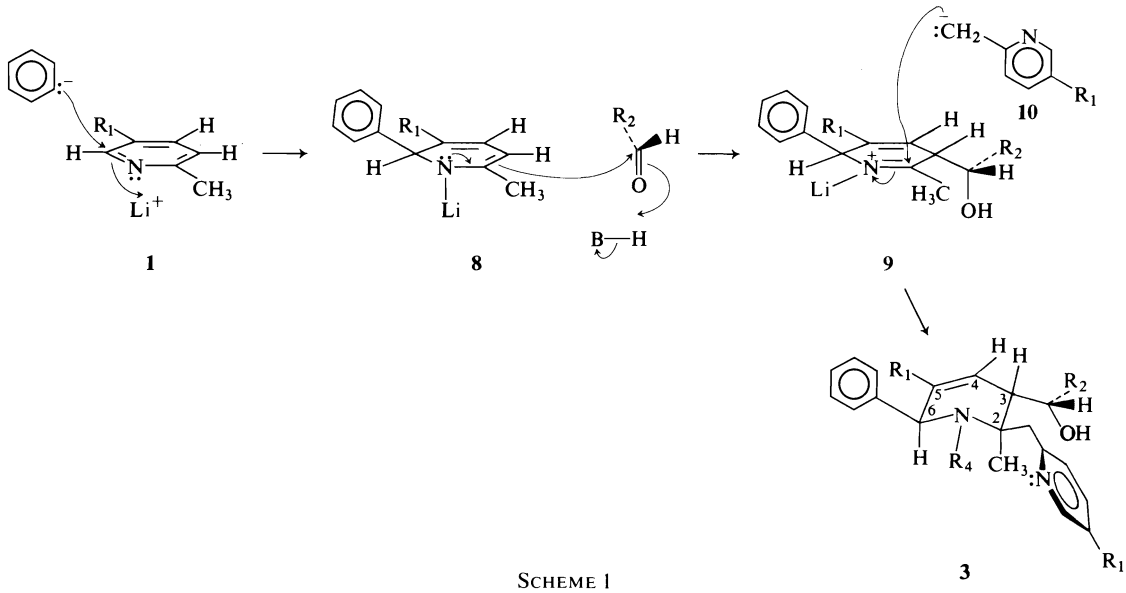
No adduct of the type **3** could be isolated following parallel reaction involving 2-picoline **1***b* or 2,4-dimethylpyridine **1***c* and the alcohols **2***b* (60%) and **2***d* (25%), respectively, were recovered. Similarly, the reaction of 2,5-dimethylpyridine **1***a* with benzaldehyde in the presence of phenyllithium gave the expected compound **2***c* in 25% yield and no novel adduct was detected. Product **2***e* was obtained in 75% yield in the same reaction system, employing 2,4,6-trimethylpyridine **1***d* and isopentanal. Thus the ready formation of novel adducts of type **3** occurs with 2,5-dialkylpyridines and aliphatic aldehydes.

While no firm conclusion can yet be reached concerning the complete stereochemistry of the system **3**, the configuration contained in structure **3** is suggested by the following considerations. Throughout the series **3***a*–**3***h*, the C3H appears as a broad singlet indicating a dihedral angle near to 80° with its neighbours at C4 and C1′. Thus the hydrogen at C3 is probably quasiaxial allowing the bulky alkanol side chain to be quasi equatorial. To best accommodate the sterically encumbered C2 the larger methylpicolyl substituent is placed equatorial and *trans* to the large C3 substituent while the smaller methyl group occupies the axial site. To avoid serious steric crowding from the C2 axial substituent the C6 phenyl group should be disposed in the quasi equatorial position.

The low nmr field position of the C2 methyl throughout the series **3***a*–**3***h* is explained by its position β to the amine (or ammonium) nitrogen and its possible orientation with respect to the deshielding zone of the pyridine (or pyridinium) nucleus. Thus in the three ammonium salts (**3***a*, **3***i*, **3***f*) this methyl's signal is found near δ 1.8 while in the corresponding free bases it is located near δ 1.25 ± 0.1. In all cases the chemical shifts are lower than anticipated (3) for the effect of a β-nitrogen alone, no doubt due to the deshielding by the appropriately oriented heteroaromatic nucleus.

Support for the assignment of configuration at C1′ comes from the ready dehydration of **3***a* to **6** allowed by the easy attainment of a *trans* antiparallel relationship of the C3 hydrogen and the C1′ hydroxyl, together with the observation that such a configuration will lead, on dehydration, to the sterically feasible geometry at C1′ in which the vinylic hydrogen is *cis* to the bulky C2 substituents as in structure **6**.

Additional support for the stereochemical assignment **3** can be derived from mechanistic



SCHEME 1

considerations (see Scheme 1). The generation of the 1-lithio-2-phenyl-1,2-dihydropyridine system **8** is well precedented (4). The dienamine **8** is visualized as attacking an aldehyde molecule via a transition state which for steric reasons requires orientation of the aldehyde alkyl group away from the C2 methyl and the formation of the intermediate quaternary lithioimmonium ion **9** in which the substituents at C3 and C6 have the preferred *trans* relationship. Discharge of the cation **9** via least hindered approach of the anion **10** at C2 would result in the unique stereochemistry **3** for the adducts. Thus mechanistic considerations indicate why a single stereoisomer results in a process in which four chiral centres are developed.

Some support for the initial phase of this mechanism is found in the observations of Giam *et al.* (4) who obtained the unexpected product **13** in 33% yield when a solution of 2-phenylpyridine **11** was treated with 1-lithio-2-phenyl-1,2-dihydropyridine **8**. These authors suggest the intermediacy of **12** which undergoes further transformation to **13** (Scheme 2). Thus the nucleophilicity of **8** at position 5 is precedented. In addition it is also known that 1-lithio-2-substituted-1,2-dihydropyridines react with alkyl halides to produce 2,5-disubstituted pyridines (5, 6).

A variation of the mechanism proposed in Scheme 1 in which the anion **10** makes initial attack at the 2 position of the pyridine **1** can also be considered and could be expected to lead to product and stereochemistry **3**; however, it seems to be less likely in view of the above precedents.

The reluctance of **3***a* to undergo selective reduction at the 4,5-double bond can be explained on the basis of the stereochemistry **3**. Steric impedance on the one side from the axial methyl and quasi equatorial isopentanol side chain and on the other from the presence and orientation of the phenyl ring. Once the phenyl ring is reduced, the isolated double bond becomes more accessible to the catalyst from the β side (to give stereochemistry **6**) which accords with the experience that the double bond is apparently reduced at approximately the same rate as the phenyl ring.

*Abbreviations: s singlet, t triplet, q quartet, m(s) multiplet(s), dt doublet of triplets, dd doublet of doublets, dq doublet of quartets.

Experimental

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. High resolution mass spectra were obtained from the Mass Spectrometry Laboratory, University of Alberta. Other mass spectra were obtained with an Hitachi–Perkin-Elmer RMU-6D spectrometer. The 60 MHz spectra were recorded with a Varian T-60 instrument and 220 MHz spectra were recorded with a Varian HR 220 instrument. Line positions are reported in ppm from tetramethylsilane which was used as internal standard. The ir spectra were recorded with a Perkin-Elmer 457 grating infrared spectrophotometer. The uv spectra were obtained with a Perkin-Elmer model 467 spectrophotometer.

Adduct 3a

Under nitrogen atmosphere, bromobenzene (39.5 g, 0.25 mol) in absolute ether (50 ml) was added to a stirred suspension of lithium (3.45 g, 0.5 mol) in ether (200 ml) at a rate to maintain steady refluxing. After 4 h the metal had all dissolved and 2,5-dimethylpyridine (27 g, 0.25 mol) was added over 2 h. The flask was then cooled to 0°C and isopentanal (23 g, 0.25 mol) in ether (25 ml) was added over 1½ h at 0–+5°C. Then water (50 ml) was added followed by 12 *N* HCl (50 ml). The aqueous layer was separated and treated with anhydrous sodium carbonate (55 g in H_2O, 100 ml). Chloroform extraction gave a crude brown oil (45 g) which yielded crystals upon heating. Filtration and recrystallization from CCl_4–CH_2Cl_2 (4:1) gave adduct **3***a* (9.9 g, 18.3%) as white needles, homogeneous on tlc, mp 178–190°C. *Anal.* calcd. for $C_{25}H_{36}ON_2Cl_2$: C 66.52, H 7.98, O 3.55, N 6.21; found: C 66.04, H 7.71, O 4.10, N 6.17. Mass spectrum: *m/e* 378.26737(4) (*M* − 2HCl, calcd. 378.26711), 291(7), 272(17), 230(26), 194(6), 186(33), 185(6), 184(13), 173(9), 170(5), 150(7), 149(68), 145(8), 144(6), 139(6), 131(8), 129(11), 128(8), 117(5), 115(5), 108(26), 107(27), 106(11), 105(6), 91(23), 86(6), 85(100), 79(5), 77(5), 57(31), 43(12), 42(5), 41(9). Zerevitinov active hydrogen determination: calcd. for 4 active H: 0.88%; found: 0.81%. The ir spectrum ν_{max} ($CHCl_3$) 3400 cm^{-1} (hydroxyl). The uv spectrum ν_{max} (EtOH) 218, 279, 277 nm (ε 14 000, 3500, 3100).

From the mother liquors of **3***a* the expected amino alcohol **2***a* was recovered in 16% yield by preparative plate silica gel chromatography ($CHCl_3$–MeOH, 9:1) as a yellow solid, mp 53–54°C, identical with an authentic sample of **2***a* characterized earlier (1).

Monoacetate Dihydrochloride 3b

A solution of **3***a* (0.2 g), pyridine (5 ml), and acetic anhydride (8 ml) was stirred at room temperature for 22 h. Excess reagent and solvent were evaporated yielding a crude solid (0.18 g). Recrystallization from CCl_4–CH_2Cl_2 (4:1) gave product **3***b* (0.15 g, 77%), homogeneous on tlc, mp 175–183°C. Mass spectrum: *m/e* 420.27739(18) (M^+ − 2HCl, calcd. 420.27768), 361(6) (420 − C_4H_9), 272(33), 254(72), 230(31), 229(19), 212(41), 184(19), 173(18), 170(21), 169(72), 157(29), 156(57), 155(56), 149(64), 143(27), 129(25), 108(35), 107(34), 106(20), 91(39), 85(100), 57(41), 43(89). The ir spectrum ν_{max} ($CHCl_3$) 1740 cm^{-1} (ester). The uv spectrum λ_{max} (EtOH) 214, 270, 277 nm (ε 11 000, 3200, 2700).

Free Base 3c

A solution of **3***a* (1.1 g) in ethanol (60 ml) and 2 *N* NaOH (10 ml) was stirred at room temperature for 22 h. Solvent evaporation, water (20 ml) addition, and extraction with chloroform afforded a crude product (1.1 g), which on recrystallization from CCl_4–hexane (2:1) gave product **3***c* (1.0 g), homogeneous on tlc, mp 143–143.5°C. *Anal.* calcd. for $C_{25}H_{34}ON_2$: C 79.36, H 9.00, O 4.31, N 7.41; found: C 78.80, H 9.12, O 4.51, N 7.28. Zerevitinov active hydrogen determination calcd. for 2 active H: 0.53%; found: 0.45%. The ir spectrum ν_{max}(CCl_4) 3300 cm^{-1} (hydroxy/NH). The uv spectrum λ_{max} (EtOH) 217, 270, 277 nm (ε 11 500, 3500, 3100). Mass spectrum: *m/e* 378(52) (M^+), 320(9) (M^+ − C_5H_{11}), 307(32), 291(33), 272(93) (378 − C_7H_9N), 253(57), 252(58), 230(78), 212(76), 210(32), 186(91), 184(67), 183(40), 180(100), 108(41), 107(85) ($C_7H_9N^+$), 106(42), 91(21).

Monoacetate 3d and O,N-Diacetate 3e

A solution of the free base **3***c* (0.14 g) in pyridine (5 ml) and acetic anhydride (8 ml) was stirred at room temperature for 40 h. Evaporation of solvent gave a crude mixture (0.13 g) which was separated by preparative tlc on silica gel ($CHCl_3$–CH_3OH, 20:1) and afforded two major compounds; namely, monoacetate **3***d* (0.028 g) an oil, homogeneous on tlc and diacetate **3***e*, homogeneous on tlc, mp 128–130°C.

Compound **3***e*: *Anal.* calcd. for $C_{29}H_{38}O_3N_2$: C 75.29, H 8.28, O 10.38, N 6.06; found: C 75.24, H 8.08, O 10.72, N 5.71. Mass spectrum: *m/e* 462.28809(1) (M^+, calcd. 462.28824), 345(10), 296(16), 255(7), 254(31), 184(5), 108(19), 107(100), 106(7), 91(5), 43(32). The ir spectrum ν_{max} ($CHCl_3$) 1735 cm^{-1} (ester), 1635 cm^{-1} (amide). The uv spectrum λ_{max} (EtOH) 218, 270, 276 nm (ε 13 600, 3000, 2800). No active H (Zerevitinov).

Compound **3***d*: Mass spectrum *m/e* 420(49) (M^+), 361(21), 360(22), 343(23), 314(25), 272(78), 254(98), 253(48), 252(49), 250(32), 230(52), 212(78), 210(49), 196(63), 184(40), 182(41), 169(95), 157(39), 156(44), 155(61), 143(42), 129(46), 108(50), 107(100), 106(50), 91(57), 85(40). The ir spectrum ν_{max} ($CHCl_3$) 1730 (ester), 1640 cm^{-1} (aromatic). The uv spectrum λ_{max} (EtOH) 218, 279, 275 nm (ε 13 000, 3100, 2800).

Adducts 3f and 3i

The adducts **3***f* and **3***i* were prepared in 6.4 and 4% yield from **1***e* and **1***a*, respectively, via the same procedure employed for preparation of **3***a* and replacing isopentanal for isobutanal for **3***i*.

Compound **3***f*: mp 177–186°C. *Anal.* calcd. for $C_{27}H_{40}ON_2Cl_2$: C 67.64, H 8.35, O 3.34, N 5.84; found: C 67.53, H 8.30, O 3.65, N 5.93. Mass spectrum *m/e* 406(24) (M^+ − 2HCl), 319(21), 286(35), 245(20), 244(50), 200(60), 199(27), 198(30), 197(27), 196(75), 182(51), 170(40), 163(95), 158(25), 153(46), 130(30), 129(60), 128(30), 123(29), 122(91), 121(91), 120(22), 117(21), 115(20), 107(31), 106(100), 105(20), 93(25), 91(71), 85(79), 84(70), 79(40), 77(43). The ir spectrum ν_{max} ($CHCl_3$) 3370 cm^{-1} (OH/NH). The uv spectrum λ_{max} (EtOH) 215, 270, 276 nm (ε 11 600, 3700, 3070).

Free Bases 3h and 3j

The free bases **3***h* and **3***j* were prepared from **3***f* and **3***i* in 95% and 93% yield, respectively, via the same procedure used to prepare free base **3***c* from the dihydrochloride adduct **3***a*.

Compound **3***h*: mp 141–142°C. Mass spectrum *m/e* 406(29) (M^+), 320(27), 319(60), 287(21), 286(100), 285(22), 284(22), 268(20), 267(43), 266(44), 265(18), 251(35), 245(45), 244(72), 238(35), 227(34), 226(60), 224(43), 215(20), 213(21), 210(28), 208(65), 201(20), 200(75), 199(46), 198(65), 197(58), 196(70), 194(30), 187(42), 183(42), 182(75), 181(41), 172(34), 171(35), 170(38), 169(68), 164(31), 163(85), 162(29), 161(26), 159(26), 158(28), 157(26), 154(20), 153(75), 144(22), 143(22), 141(25), 131(32), 130(33), 129(68), 128(32), 123(40), 122(40), 121(76), 120(65), 117(60), 115(62), 107(64), 106(90), 105(60), 104(47), 84(72). The ir spectrum ν_{max} ($CHCl_3$) 3300 cm^{-1} (OH/NH). The uv spectrum λ_{max} (EtOH) 218, 270, 276 nm (ε 14 000, 4900, 4000)

Compound **3***j*: mp 144–145°C. Mass spectrum *m/e* 364(26) (M^+), 331(29), 321(30), 291(41), 264(51), 259(44), 258(76), 253(36), 225(60), 224(33), 216(22), 215(29), 214(35), 187(55), 186(57), 185(40), 184(75), 182(100), 181(41), 174(28), 173(86), 170(46), 158(21), 153(63), 130(71), 129(30), 128(50), 108(60), 107(86), 106(41), 91(36). The ir spectrum ν_{max} ($CHCl_3$) 3300 cm^{-1} (OH/NH). The uv spectrum λ_{max} (EtOH) 217, 270, 277 nm (ε 11 300, 4900, 3300).

Monoacetate 3g

The monoacetate **3***g* was prepared from the dihydrochloride adduct **3***f* in 63% yield via the same procedure used to prepare **3***b* from **3***a* and showed mp 175–185°C. Mass spectrum *m/e* 448(40) (M^+ − 2HCl), 370(25), 269(26), 268(80), 267(27), 266(32), 250(23), 226(43) 224(41), 198(23), 183(64), 182(90), 170(49), 169(48), 163(48), 157(22), 156(21), 155(22), 141(30), 129(36), 128(35), 122(85), 121(85), 120(39), 112(23), 106(88). The ir spectrum ν_{max} ($CHCl_3$) 1730 cm^{-1} (ester). The uv spectrum λ_{max} (EtOH) 215, 270, 276 nm (ε 13 800, 4420, 3650).

Hydrolysis of O,N-Diacetate 3e

A solution of *O,N*-diacetate **3***e* (0.06 g) in ethanol (20 ml) and 20% NaOH (2 ml) was refluxed gently for 24 h. After solvent evaporation, addition of water (10 ml), and chloroform extraction, a crystalline product (0.055 g) was obtained on evaporation, homogeneous on tlc, mp 142–143.5°C, identical in all respects (including mixture mp) with free base **3***c*.

Catalytic Hydrogenation of Adduct 3a to 7

A solution of **3***a* (0.1 g) in ethanol (25 ml) containing PtO_2 (0.018 g) was shaken in a Parr apparatus under H_2 at 40 psi at room temperature for 30 h. Filtration and evaporation gave 0.08 g of crystalline product, homogeneous on tlc, mp 138–141°C. The mass spectrum *m/e* 392(10) (M^+ − 2HCl), 310(30), 309(100), 305(36), 280(91), 218(22), 212(23), 198(80), 194(68), 192(22), 179(21), 160(20), 152(42), 113(45), 112(21), 111(40), 110(38), 98(51). The ir spectrum ν_{max} ($CHCl_3$) 3400 cm^{-1} (OH/NH). No uv chromophore.

Compounds 2b, 2c, 2d, and 2e

The compounds **2***b*, **2***c*, **2***d*, and **2***e* were obtained from experiments performed as for the preparation of **3***a* in which the substituted pyridines employed were **1***b*, **1***a*, **1***c*, and **1***d*, respectively, and in the case of **2***c* benzaldehyde was used instead of isopentanal. All were isolated by preparative layer chromatography on silica gel ($CHCl_3$–CH_3OH, 20:1). All except **2***c* (mp 76–83°C) were obtained as oils and all showed the expected (1) M^+ and ir, uv, and nmr characteristics.

Anhydro Adduct 6a

A solution of **3***a* (0.2 g), pyridine (3 ml), and thionyl chloride (1 ml) was stirred at 0–5°C for 4 h. Careful evaporation of volatile materials gave a crude product (0.18 g). Purification by preparative tlc and subsequent recrystallization (CCl_4–CH_2Cl_2, 1:1) gave compound **6***a* (0.06 g, 33%), homogeneous on tlc, mp 142–144°C. *Anal.* calcd. for $C_{25}H_{34}N_2Cl_2$: C 69.27, H 7.91, N 6.46; found: C 68.94, H 7.95, N 6.60. Mass spectrum *m/e* 360(8) (M − 2HCl), 254(43), 253(60), 252(100), 251(46), 250(65), 238(53), 236(43), 210(89), 197(48), 196(87), 182(79), 155(71), 154(23), 153(22), 152(24), 141(20), 107(50), 106(33). The nmr (60 MHz) spectrum ($CDCl_3$ δ_{TMS}: 0.60 (d, J = 7 Hz, 3H, C3′Me_a), 0.70 (d, J = 7 Hz, 3H, C3′Me_b), 1.30 (m, 1H, C3H), 1.54 (bs, $W_{1/2}$ = 4 Hz, C5Me), 1.63 (s, 3H, C2Me), 1.9 (m, 2H, 2′HaHb), 2.23 (s, 3H, C11Me), 3.27 (d, J = 18 Hz, 1H, C7Ha), 3.60 (d, J = 18 Hz, 1H, C7Hb), 4.74 (bs, $W_{1/2}$ = 6 Hz, 1H, C6H), 5.26 (t, J = 7 Hz, 1H, C1′H), 7.015 (d, J = 7 Hz, 1H, C13H), 7.4 (m, 6H, phenyl H's plus C12H), 8.10 (bs, $W_{1/2}$ = 5 Hz, 1H, C10H), 7.8 (bs, deuterium exchangeable 2H, $—\overset{+}{N}H_2—$), 3.4 (bs, deuterium exchangeable pyridinium $—\overset{+}{N}H—$). The uv spectrum λ_{max} (EtOH) 220 (s), 250 nm (ε 10 000, 15 000).

Acknowledgments

This work was supported in part by financial assistance from the National Research Council of Canada. The 220 MHz spectra were obtained by courtesy of Canadian 220 MHz NMR Centre, University of Toronto. Thanks are due to Z. Valenta (Chemistry Department, University of New Brunswick) for helpful discussion on the stereochemistry.

I. P. HAJDU, I. NEMES, D. GÁL, V. L. RUBAYLO, and N. M. EMANUEL. Can. J. Chem. **55**, 2677 (1977).

The induced decomposition of α-phenylethylhydroperoxide (HROOH) has been investigated in three different systems: hydroperoxide + cyclohexene + AIBN + O_2 (I); cyclohexene substituted by isooctane (II), and cyclohexene substituted by chlorobenzene (III). The decomposition products of the HROOH were in all cases acetophenone (RO) and methylphenylcarbinol (HROH).

It was established that peroxy radicals induced the decomposition. The considerable material balance deficit in I is due to the addition of the peroxy radicals to cyclohexene the rate constant of which was estimated from the experimental data. No material balance deficit was observed with II. Experiments supported the assumption that both RO and HROH were formed simultaneously in the interaction between peroxy radicals and HROOH.

The rate constant of the reaction $HRO_2^{\cdot} + HROOH \rightarrow HROH + O_2 + HRO^{\cdot}$ was measured as $k = 1.03 \times 10^9 \exp(-13\,100/RT)$. It is suggested that in the autoxidation of ethylbenzene the induced decomposition of HROOH is fast enough to be the main source of RO and HROH.

I. P. HAJDU, I. NEMES, D. GÁL, V. L. RUBAYLO et N. M. EMANUEL. Can. J. Chem. **55**, 2677 (1977).

On a étudié la décomposition induite de l'hydroperoxyde d'α-phényléthyle (HROOH) dans trois systèmes différents: l'hydroperoxyde + le cyclohexène + AIBN + O_2 (I); on substitue le cyclohexène par de l'iso-octane (II) et le cyclohexène par du chlorobenzène (III). On a trouvé que les produits de décomposition de HROOH sont, dans tous les cas, l'acétophénone (RO) et le méthylphénylcarbinol (HROH).

On a établi que la décomposition est induite par les radicaux peroxy. Le fait que la balance des matériaux est considérablement déficitaire dans I est dû á l'addition de radicaux peroxy au cyclohexène, réaction pour laquelle on a mesuré la constante de vitesse. On n'a observé aucun déficit dans la balance des matériaux avec le système II. Les expériences supportent l'hypothèse que les produits RO et HROH se forment simultanément lors de l'interaction entre les radicaux peroxy et HROOH.

La constante de vitesse de la réaction $HRO_2^{\cdot} + HROOH \rightarrow HROH + O_2 + HRO^{\cdot}$ est $k = 1.03 \times 10^9 \exp(-13\,100/RT)$. On suggère que lors de l'autooxydation de l'éthylbenzène, la décomposition induite de HROOH est suffisamment rapide pour être la source principale de RO et de HROH.

[Traduit par le journal]

Hydroperoxides are primary products of hydrocarbon oxidation processes. The kinetics and routes by which they are decomposed to other products are of general interest. As indicated by Hiatt *et al.* (1), the difficulty of measuring true rates for the decomposition can be attested by several attempts referred to in the literature.

Recently, we have shown by direct tracer experiments (2) that in the oxidation of ethylbenzene the thermal homolysis of α-phenylethylhydroperoxide, though very important as the degenerate branching process, cannot provide the amounts of products formed from the hydroperoxide and observed experimentally. Since hydroperoxides are very labile toward attack by free radicals, we assumed that their decomposition, induced by peroxy radicals, was the main route for the formation of secondary products.

In the case of secondary hydroperoxides, reaction 1 was suggested as an interaction between peroxy radicals and hydroperoxides (3):

[1] $HRO_2^{\cdot} + HROOH \rightarrow HROOH + {}^{\cdot}ROOH$

(where $HRO_2^{\cdot}$, HROOH, and ·ROOH mean

peroxy radical, hydroperoxide molecule, and hydroperoxide radical, respectively) followed by the instantaneous decomposition of ROOH into ketone and an ·OH radical. Similar reactions were suggested by Robertson and Waters (4), Benson (5), and Martan *et al.* (6) for alkoxy and hydroxyl radicals. However, it is known that the alcohol is formed also.

According to Dean and Skirrow (7), the induced decomposition might proceed by the following route:

[2] $HRO_2\cdot + HROOH \rightarrow HRO\cdot + O_2 + HROH$

(HRO· and HROH are alkoxy radicals and alcohol, respectively). Skibida *et al.* (8) and Ingold (9) suggest different possibilities for the detailed mechanism of reaction 2.[1] The importance of processes [1] and [2] becomes especially striking if we take into account that the oxidation intermediates possess higher reactivity toward peroxy radicals than the parent hydrocarbon (10, 11).

The possibility of an O—H bond rupture also cannot be excluded. This type of reaction was studied thoroughly by Howard, Schwalm, and Ingold (3) as well as by Niki *et al.* (12) who determined the rate constants of the following hydrogen transfer reaction:

[3] $R'O_2\cdot + ROOH \rightarrow R'OOH + RO_2\cdot$

Naturally, parallel to the induced decomposition, the termination reaction of the peroxy radicals yields alcohol and ketone molecules according to a Russell-type combination (13):

[4] $HRO_2\cdot + HRO_2\cdot \rightarrow RO + O_2 + HROH$

where RO means ketone. This latter process, however, becomes decisive *as a source of products* only at high initiation rates.

Consequently we studied the reactions between α-phenylethylhydroperoxide and different peroxy radicals, generated *in situ* by the initiated oxidation of two hydrocarbons. The choice of cyclohexene and isooctane as hydrocarbons was motivated by two reasons: (*i*) both can be oxidized at temperatures where the thermal decomposition of the α-phenylethylhydroperoxide can be neglected, and (*ii*) by their comparison we can obtain information with respect to the interaction of the peroxy radicals with double bonds. In addition, peroxy radicals were generated also by the hydrogen transfer between radicals from the decomposition of an initiator and α-phenylethylhydroperoxide.

[1]One of the referees suggested a third possibility via a four centered transition state which seems acceptable to the authors.

Experimental

Materials

Commercial cyclohexene (purity higher than 99%) was distilled twice from metallic sodium, bp, 82.5°C. α-Phenylethylhydroperoxide (HROOH) was prepared in our laboratory as described elsewhere (14). 2,2,4-Trimethylpentane (purity 99.2%) was used without further purification. Azobisizobutyronitrile (AIBN) was "Fluka" product and has been recrystallized four times from chloroform, mp, 101–101.5°C. Acetophenone (RO) and phenylmethylcarbinol (HROH) ("Fluka") were used without further purification. Cyanopropylhydroperoxide (CPH) was prepared by the AIBN-initiated oxidation of ethylbenzene according to Buligin *et al.* (15).

2,6-Di-*tert*-butyl-4-methylphenol (ionol) and 2,4,6-tri-*tert*-butylphenol were used as commercial products ("Fluka").

Analysis

Molecular products were analyzed by glc as described earlier (16).

Procedure

Experiments have been carried out at atmospheric pressure in a glass reactor using an oxygen stream of 1.8–3.0 $dm^3\ h^{-1}$ between 70–90°C. Neat cyclohexene was used while chlorobenzene was the solvent for studies with isooctane.

Experimental Results

Thermal Decomposition of HROOH

A chlorobenzene solution of HROOH (0.2 mol dm^{-3}) was kept at 110°C for 7 h. Measurable quantities of products were not detected during this time and thus the thermal decomposition of the HROOH in the temperature range of 70–90°C can be neglected. Neither HROH nor RO added in amounts 0.1 mol dm^{-3} at 90°C affected these results. A chlorobenzene solution of HROOH (0.2 mol dm^{-3}) and AIBN (0.03 mol dm^{-3}) was kept at 70–90°C in argon atmosphere; no decomposition of the HROOH was detected.

Study of the System HROOH + Cyclohexene + AIBN + O_2

The accumulated amounts of phenylmethylcarbinol and acetophenone formed from the induced decomposition of α-phenylethylhydroperoxide in the course of the initiated oxidation of cyclohexene *vs.* time are shown in Figs. 1 and 2. Separate experiments done with up to 0.5 mol dm^{-3} HROOH content have shown that the addition of the hydroperoxide to the system

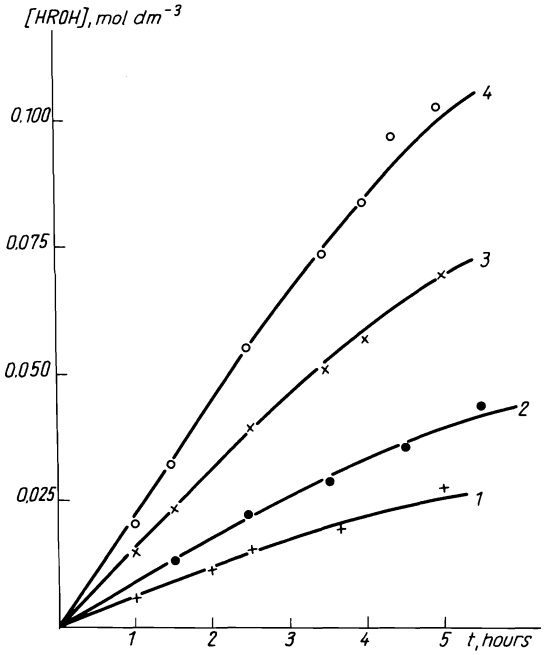

FIG. 1. Accumulation of HROH during the decomposition of α-phenylethylhydroperoxide induced by cyclohexenylperoxy radicals at 70°C. Initial HROOH concentrations were *1*, 0.25; *2*, 0.50; *3*, 0.75; and *4*, 1.00 mol dm^{-3}.

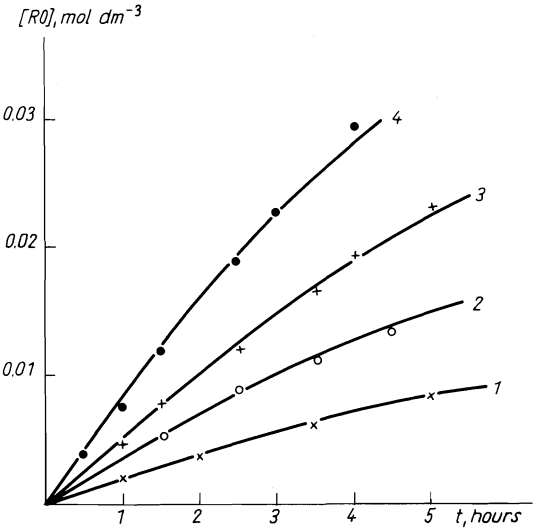

FIG. 2. The same as Fig. 1 for the accumulation of acetophenone.

cyclohexene + oxygen does not affect the kinetics of the accumulation of cyclohexenylhydroperoxide and the kinetic parameters of the oxidation. Thus, *e.g.*, at an initiation rate of 1.6×10^{-6} mol dm^{-3} s^{-1} the kinetic chain length of the cyclohexene oxidation is about 70 which remains unchanged in the presence of α-phenylethylhydroperoxide.

Figure 3 shows the consumption of the HROOH (its initial concentrations were 0.75 and 0.50 mol dm^{-3}, respectively). The dashed lines refer to the consumed amounts of [HROOH] calculated from the product accumulation [HROH] + [RO]. It is evident that, in the system AIBN + cyclohexene + HROOH + O_2, a material balance deficit exceeding 60% was observed.

Study of the System HROOH + Isooctane + AIBN + O_2

Figure 4 shows the accumulation of both RO and HROH for an initial concentration of HROOH of 0.50 mol dm^{-3}, as well as the consumption of the HROOH obtained in two different ways: (*i*) by measuring it directly, and (*ii*) calculated from the product accumula-

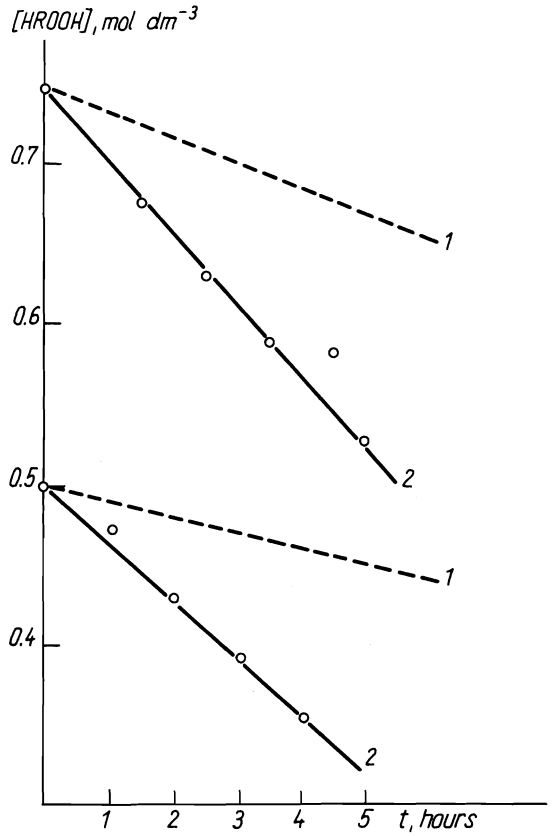

FIG. 3. Consumption of HROOH at its two different initial concentrations at 70°C. *1*, calculated from the accumulation of products; *2*, experimental data.

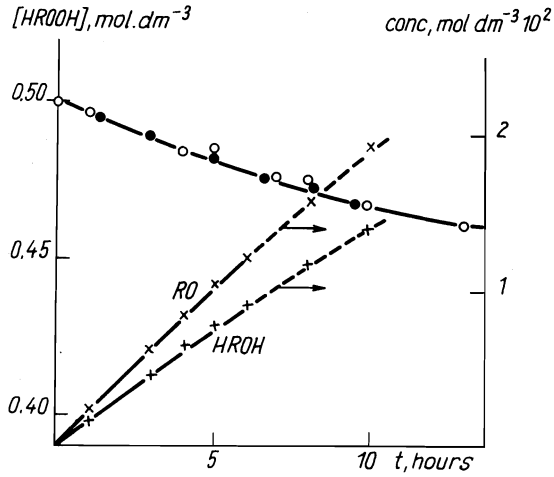

FIG. 4. Accumulation of RO and HROH during the decomposition of HROOH induced by isooctylperoxy radicals at 70°C. Consumption of HROOH in the same system. Full circles, experimental data; open circles, calculated from the accumulation of products.

tion. It can be seen that the material balance is satisfactory, that is, amounts of HROOH decomposed are recovered exclusively in the form of RO and HROH. In this case the amount of RO accumulated exceeds that of the HROH while with cyclohexene as substrate the reverse was found.

Decomposition of HROOH in the Presence of AIBN and Oxygen

Three main products have been found: RO, HROH, and CPH. In order to determine the reaction order with respect to both HROOH and AIBN two series of runs were performed at 80°C: (*i*) at constant $[HROOH]_0 = 0.2$ mol dm^{-3}, $[AIBN]_0$ has been varied between 0.015–0.060 mol dm^{-3}, and (*ii*) at constant $[AIBN]_0 = 0.060$ mol dm^{-3}, $[HROOH]_0$ has been varied between 0.020 and 0.35 mol dm^{-3}. The partial reaction order was 1 with respect to AIBN and zero with respect to HROOH.

The temperature-dependence of the decomposition was studied between 70 and 90°C at $[HROOH]_0 = 0.20$ mol dm^{-3} and $[AIBN]_0 = 0.030$ mol dm^{-3}. Experimental data for the accumulation of HROH are given in Fig. 5.

The separate determination of the accumulation of CPH was vital. Corresponding experimental data are plotted in Fig. 6. Unfortunately, curves in Fig. 6 should be regarded only as approximate, because of impurities in the CPH-standard.

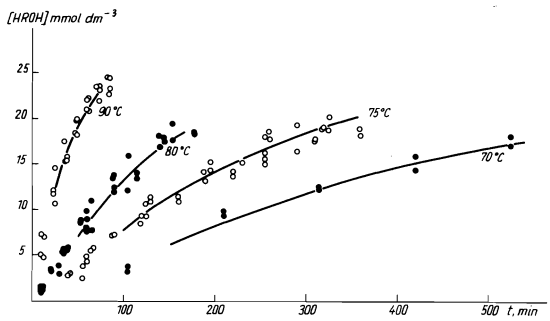

FIG. 5. Accumulation of HROH *vs.* time at different temperatures, $[AIBN]_0 = 0.030$; $[HROOH]_0 = 0.20$ mol dm^{-3}. Points correspond to experimental values; curves are calculated.

Using the decomposition rate constant and radical yield of the AIBN we have calculated the amounts of CPH expected theoretically assuming that all the 'escaped radicals' lead to CPH, and compared them to the experimental values. The agreement was satisfactory.

Determination of the Radical Yield (f) of the Decomposition of AIBN

There are several data in the literature for chlorobenzene solvent, but they are contradictory and we could not exclude *a priori* that the addition of HROOH affecting the viscosity and the dielectric constant of the solution might affect the value of *f*. Therefore, the value of *f* has been determined at 80°C in an oxygen atmosphere in the presence of 0.20 mol dm^{-3} HROOH, and using 2,6-di-*tert*-butyl-4-methylphenol as inhibitor.[2] We obtained $f = 0.6$, in good agreement with some literature values and this indicated that neither oxygen nor HROOH affected *f*.

Discussion

The material balance deficit observed during the decomposition of HROOH 'induced' by the oxidation of cyclohexene, and its absence if isooctane was used, can be easily explained by taking into account the addition of peroxy radicals to double bonds observed in the course of olefin oxidations (17).

The existence of the balance deficit may be regarded as an indirect proof of the occurrence

[2]In this case the conditions for the gas chromatography were changed. Carrier: Chromosorb W; stationary phase, 10% Apiezon L; length of column, 80 cm; temperature, 150°C; internal standard, 2,4,6-tri-*tert*-butylphenol.

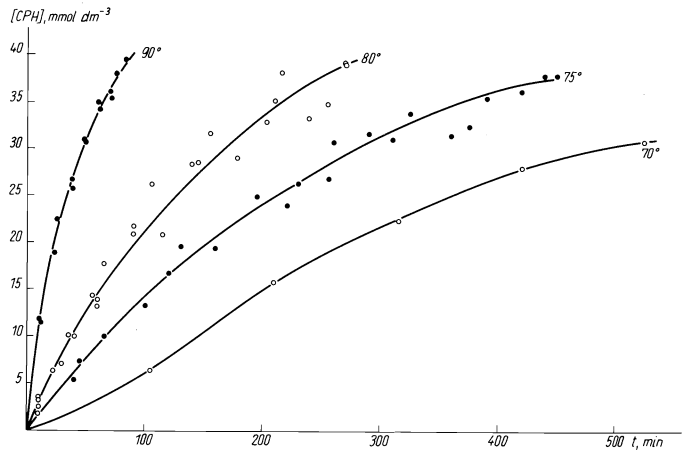

FIG. 6. Accumulation of CPH *vs.* time at different temperatures; $[AIBN]_0 = 0.030$; $[HROOH]_0 = 0.20$ mol dm^{-3}.

of transfer process [3]. Namely, it must be assumed that the cyclohexenylperoxy radicals react with α-phenylethylhydroperoxide:

[5] $HR'O_2\cdot + HROOH \rightarrow HR'OOH + HRO_2\cdot$

that is, the chain carrier radicals of the oxidation are exchanged for α-phenylethyl peroxy radicals and consequently:

[6] $HRO_2\cdot + R'H_2 \xrightarrow{O_2} DO_2\cdot$

where D is a radical formed by the addition of $HRO_2\cdot$ to cyclohexene. The consumption of cyclohexene in process [6] is:

$$[7] \quad -\left(\frac{d[R'H_2]}{dt}\right)_6 = k_6[HRO_2\cdot][R'H_2]$$

The left side of [7] can be easily obtained from Fig. 3, since

$$[8] \quad -\left(\frac{d[R'H_2]}{dt}\right)_6 = w_1 - w_2 \equiv \Delta W$$

where

$$[9] \quad w_1 = -\left(\frac{d[HROOH]}{dt}\right)$$

and

$$[10] \quad w_2 = \frac{d([RO] + [HROH])}{dt}$$

From [7] and [8]

$$[11] \quad k_6 = \frac{\Delta W}{[HRO_2\cdot][R'H_2]}$$

In eq. 11 $[HRO_2\cdot]$ is not known. However, it can be assumed that the rate determining termination occurs between α-phenylethylperoxy radicals. This assumption yields the maximal steady state concentration of $[HRO_2\cdot]_{st}^{max}$ from $w_i = k_t([HRO_2\cdot]_{st}^{max})^2$. Thus the minimal value of k_6 can be computed:

$$[12] \quad k_6^{min} = 2.8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

in good agreement with literature data (18), giving 2.5 dm^3 mol^{-1} s^{-1}.

Figure 7 shows the initial accumulation rates of acetophenone and phenylmethylcarbinol *vs.* the initial concentration of the α-phenylethylhydroperoxide. Two important conclusions can be drawn: (*i*) the initial rates of the product accumulations exceed essentially the rates of initiation for both products, and (*ii*) the initial rates of the accumulation depend linearly on $[HROOH]_0$. These experimental facts indicate that both products are formed primarily in the induced decomposition. The ratio of the slopes of the two straight lines shows that the rate of the accumulation of alcohol exceeds by approximately 2.5 times that of the ketone formation.

Since with isooctane as substrate the accumulation rates of both acetophenone and phenylmethylcarbinol are considerably lower than the rate of initiation, it is obvious that in this case the $HRO_2\cdot$ radicals cannot be considered the main chain carriers *and* that they react faster with HROOH than do the isooctylperoxy radicals.

The calculations of the rate constants of reactions 1 and 2 were carried out from the experimental results obtained for the system HROOH + AIBN + O_2. Since the kinetic chain length, expressed as the ratio of the accumulation rates

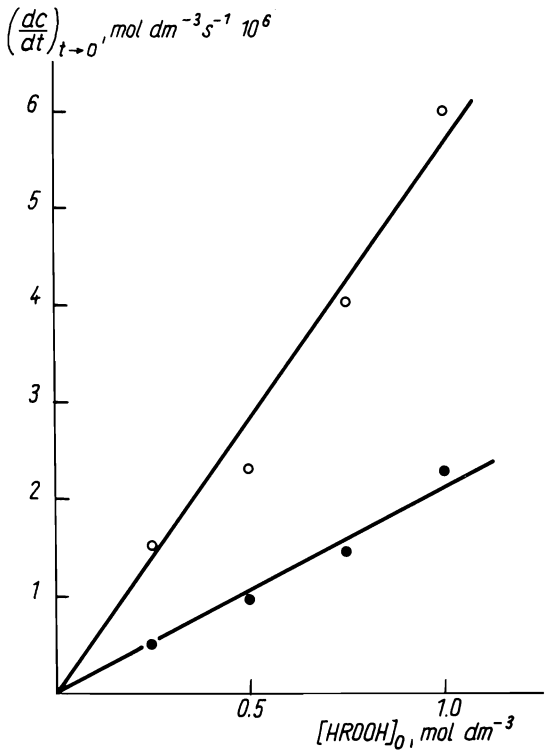

FIG. 7. The initial rates of accumulation of the HROH (open circles) and RO (full circles) *vs.* initial concentration of HROOH at 70°C during the oxidation of cyclohexene.

of the products to the initiation rate (w_i), is larger than unity:

$$[13] \quad \nu = \frac{d([RO] + [HROH])}{dt} \cdot \frac{1}{w_i} > 1$$

ketone and alcohol are formed also in reactions 1 and 2. The values of ν found in the range under investigation are: 70°C, ν = 1.57; 75°C, ν = 1.54; 80°C, ν = 1.59; 90°C, ν = 1.59. By knowing the rate of initiation, we can distinguish the two pathways of product formation (radical combination and induced decomposition). This is shown for one run in Fig. 8.

$HRO_2\cdot$ radicals are generated in the interaction between cyanopropylperoxy radical ($rO_2\cdot$) and HROOH in a hydrogen transfer process:

$$[14] \quad rO_2\cdot + HROOH \rightarrow rOOH + HRO_2\cdot$$

According to literature data, HROH molecules yield ketone in the presence of oxygen (19, 20). Therefore, in order to obtain the actual formation rates of ketone and alcohol, the experimental rate values must be corrected by the

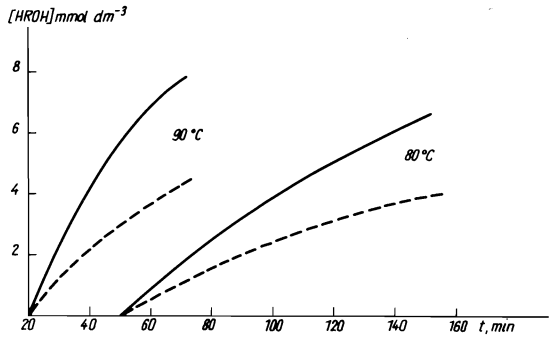

FIG. 8. Formation of HROH in radical combination and in induced decomposition (dotted line) at different temperatures.

consumption rate of the HROH. (Calculations of these corrections are deposited as supplementary material.[3])

The requirements to be fulfilled by the mechanism are as follows. Both RO and HROH should be formed by two different pathways, partly from the combination of $HRO_2\cdot$ (the validity of the Russell mechanism for the radical combination process (13) has been accepted) and partly in decomposition induced by $HRO_2\cdot$. New radicals formed in the induced decomposition are consumed by their reactions with HROOH.

Consequently the mechanism suggested for the induced decomposition of HROOH besides reactions 1, 2, 4, and 14 includes the following processes:

$$[15] \quad AIBN \xrightarrow{O_2} 2frO_2\cdot$$

$$[16] \quad HRO\cdot + HROOH \rightarrow HROH + HRO_2\cdot$$

$$[17] \quad \cdot OH + HROOH \rightarrow H_2O + HRO_2\cdot$$

$$[18] \quad \cdot OH + HROOH \rightarrow H_2O + RO + \cdot OH$$

$$[19] \quad HRO\cdot + HROOH \rightarrow HROH + RO + \cdot OH$$

Cross combination reactions between $rO_2\cdot$ and $HRO_2\cdot$ have been neglected because the CPH concentrations found experimentally were in good agreement with their expected values.

With respect to the H-transfer reaction [16] Benson estimated $k_{16} = 10^{8.0} \exp(-7\,500/RT)$ for *tert*-butylhydroperoxide and the corresponding alkoxy radicals (5). Since the reactivities of alkoxy radicals and ·OH do not differ greatly,

[3]Photocopies of Table 1 may be obtained upon request, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

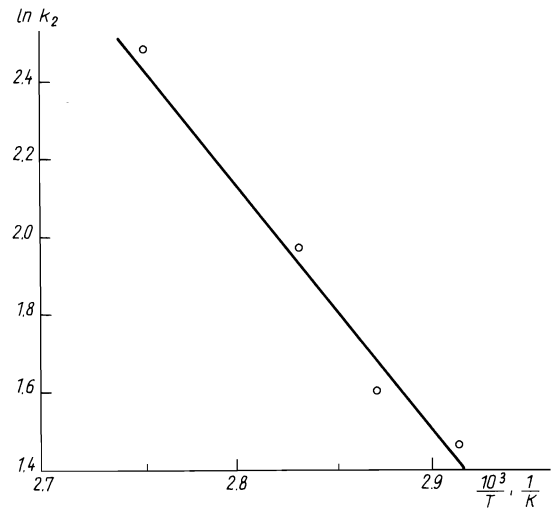

FIG. 9. The Arrhenius plot of the rate constant k_2.

it can be assumed that reaction 17 is also fast. Since peroxy radicals are capable of abstracting tertiary hydrogen from the hydroperoxide molecules (reaction 1), it was assumed that hydroxyl and alkoxy radicals (reactions 18 and 19) reacted in a similar way.

Assuming steady state concentrations for the radicals we obtain the following rates of formation of the products:

$$[20]\quad w_{\mathrm{HROH}} \equiv \frac{\mathrm{d[HROH]}}{\mathrm{d}t} = 2k_2[\mathrm{HROOH}](w_i/k_4)^{1/2} + \tfrac{1}{2}w_i$$

and

$$[21]\quad w_{\mathrm{RO}} \equiv \frac{\mathrm{d[RO]}}{\mathrm{d}t} = K[\mathrm{HROOH}](w_i/k_4)^{1/2} + \tfrac{1}{2}w_i$$

where

$$[22]\quad K = \left(1 + \frac{k_{18}}{k_{17}}\right)\left(k_1 + \frac{k_2k_{19}}{k_{16} + k_{19}}\right)$$

and

$$[23]\quad w_i = 2fk_{15}[\mathrm{AIBN}]$$

Using our experimental data we have determined w_{HROH} and w_{RO} by the parabolic method and the corresponding constants:

$$[24]\quad k_2 = \frac{w_{\mathrm{HROH}} - \frac{1}{2}w_i}{2[\mathrm{HROOH}](w_i/k_4)^{1/2}}$$

and

$$[25]\quad K = \frac{w_{\mathrm{RO}} - \frac{1}{2}w_i}{[\mathrm{HROOH}](w_i/k_4)^{1/2}}$$

Calculations have been carried out for runs performed at $[\mathrm{HROOH}]_0 = 0.20$ mol dm^{-3}; results are given in Table 1.[3]

Corrections for the radical-initiated oxidative transformation of the alcohol to ketone were calculated in the following way.

The rate of the transformation can be expressed as

$$-\frac{\mathrm{d[HROH]}}{\mathrm{d}t} = k^{\mathrm{HROH}}[\mathrm{HROH}][\mathrm{HRO_2}\cdot] = k^{\mathrm{HROH}}[\mathrm{HROH}](w_i/k_4)^{1/2}$$

Earlier we have reported (21) the value of the ratio $k^{\mathrm{HROH}}/k^{\mathrm{RH_2}}$ where k^{HROH} and $k^{\mathrm{RH_2}}$ are the rate constants of the hydrogen abstraction from alcohol and ethylbenzene molecules by α-phenylethylperoxy radicals, respectively. According to literature data (22) $k^{\mathrm{RH_2}} = 9.6 \times 10^5 \exp(-8\,500/RT)$ dm^3 mol^{-1} s^{-1} and consequently the values of k^{HROH} are: 70°C, 32.2; 75°C, 36.3; 80°C, 39.6; 90°C, 47.4 dm^3 mol^{-1} s^{-1}. The calculations are correct only if the ratio of the formation rates of alcohol and ketone remains constant during one run (assuming that the mechanism remains unchanged). The ratios of the formation rates are given separately in Table 1.

After taking into account these corrections for the alcohol–ketone transformation, we obtain the Arrhenius plot of k_2 given in Fig. 9.

$$[26]\quad k_2 = 1.03 \times 10^9\, \mathrm{e}^{-13100/RT}\ \mathrm{dm^3\ mol^{-1}\ s^{-1}}$$

The following rate constants were used: $k_{15} = 1.737 \times 10^{15} \exp(-30\,800/\mathrm{RT})$ s^{-1} and $k_4 = 1.9 \times 10^7$ dm^3 mol^{-1} s^{-1} (23).

Knowing k_2, w_i, [HROOH], and the corrections to w_{HROH} we can calculate $[\mathrm{HROH}] = f(t)$ by graphical integration. The comparison with the experimental values gives satisfactory agreement as shown in Fig. 5.

Regiospecific horse liver alcohol dehydrogenase-catalyzed oxidations of some bishydroxycyclohexanes

J. Bryan Jones and H. Bruce Goodbrand

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received February 7, 1977

J. Bryan Jones and H. Bruce Goodbrand. Can. J. Chem. **55**, 2685 (1977).

Horse liver alcohol dehydrogenase has been shown to be effective in catalyzing regiospecific oxidations of only the primary alcohol functions of several cyclohexane substrates possessing both primary and secondary alcohol substituents. The reactions, which were all performed on a preparative scale, were also enantioselective in some cases.

J. Bryan Jones et H. Bruce Goodbrand. Can. J. Chem. **55**, 2685 (1977).

On a montré que la déhydrogénase d'alcool provenant du foie de cheval est efficace pour catalyser les oxydations régiospécifiques des fonctions alcool primaire uniquement dans plusieurs substrats de cyclohexane possédant à la fois des substituants alcool primaire et secondaire. Les réactions qui ont toutes été effectuées sur une base préparative sont aussi quelquefois énantiosélectives.

[Traduit par le journal]

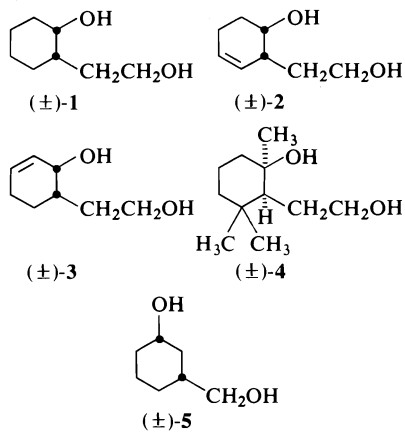
One of the consequences of the current high level of sophistication in organic synthesis has been an increased demand for reagents capable of effecting a transformation in a rigidly controlled manner. As a result of their individual specificities, many enzymes are uniquely suited to meeting the most exacting requirements in this regard, including catalysis of highly regiospecific and selective reactions which would otherwise involve several operations with traditional reagents (1).

Selective oxidation of one specified hydroxyl group only in a polyhydroxylated molecule is an example of the control that can be achieved. Oxidations of this type, whose synthetic value is self-evident, are catalyzed by the nicotinamide coenzyme-dependent alcohol dehydrogenases (1). The commercially available NAD^+/NADH-dependent enzyme from horse liver, HLADH, is currently the alcohol dehydrogenase of the most general preparative utility (1, 2).[1] Recently, it was demonstrated that HLADH possessed the ability to mediate regiospecific, and often highly enantioselective, oxidation of only one alcohol function of chiral bishydroxycyclopentanes (2*b*).

We have now extended our investigation of this aspect of HLADH catalysis to some cyclohexyldiol substrates. Synthetically viable regiospecific oxidations were observed with each substrate evaluated and, as in the cyclopentyl series (2*b*), the results were in accord with diamond lattice analysis predictions.

Results

The substituted cyclohexanes **1**–**5** were examined. They, or their immediate precursors, were synthesized in good yields largely by



application of literature procedures. The racemates **1**–**5** were all found to be substrates of HLADH; the results are summarized in Table 1. In each case, the rate of oxidation was sufficiently rapid for preparative-scale reactions to be carried out. Accordingly, (±)-**1**–**5** were subjected to HLADH-catalyzed oxidations with

[1]Abbreviations used: NAD^+ and NADH, oxidized and reduced forms, respectively, of nicotinamide adenine dinucleotide; HLADH, horse liver alcohol dehydrogenase; FMN, flavin mononucleotide (riboflavin phosphate).

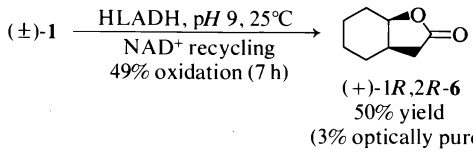
TABLE 1. Relative rates of HLADH - catalyzed oxidation of (±)-**1–5***

Substrate	V_{rel}
Cyclohexanol	1.0
(±)-**1**	0.39
(±)-**2**	0.43
(±)-**3**	0.30
(±)-**4**	0.09
(±)-**5**	~0.05

*Relative velocities were measured at 25°C in 0.05 *M* glycine–NaOH buffer, p*H* 9.0.

FMN being employed to effect *in situ* recycling (3) of catalytic amounts of the expensive NAD^+ coenzyme required.

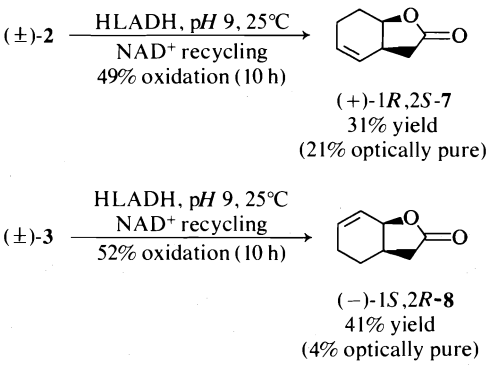
HLADH-mediated oxidation of (±)-**1** proceeded as shown in Scheme 1. Oxidation was



SCHEME 1

totally regiospecific for the primary hydroxyl group, with the aldehyde initially formed undergoing subsequent enzyme catalyzed oxidation (2*b*,*c*) to give the observed product **6** directly. Some enantioselectivity was also manifest during the reaction but the preference for the previously characterized (4) 1*R*,2*R*-enantiomer of **6** was marginal only.

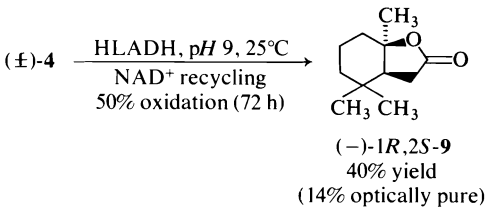
Complete regiospecificity for primary hydroxyl oxidation was also observed with the unsaturated diols (±)-**2** and -**3** as substrates (Scheme 2). An encouraging degree of enantioselectivity occurred during the oxidation of (±)-**2**, whereas for the isomeric substrate **3**, the product lactone **8** was almost racemic.



SCHEME 2

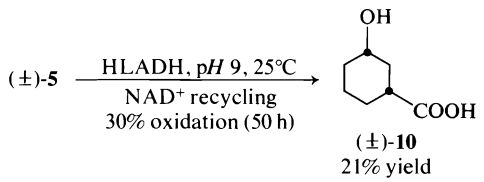
The absolute configurations and optical purities of the Scheme 2 lactones were assigned using the literature data available (4*a*).

Although the more highly substituted cyclohexyldiol (±)-**4** underwent HLADH-catalyzed transformation rather slowly, relatively efficient oxidation of the hydroxyethyl function was again observed.[2] The lactone **9**, enriched in the 1*R*,2*S*-enantiomer (5), was formed as shown in Scheme 3.



SCHEME 3

Attention was then directed towards the 1,3-disubstituted diol (±)-**5**. HLADH-catalyzed oxidation was very slow for this substrate but once more was completely specific for the primary alcohol, with *cis*-3-hydroxycyclohexane carboxylic acid (**10**) being the only product. As Scheme 4 indicates, the acid **10** was devoid of optical activity.



SCHEME 4

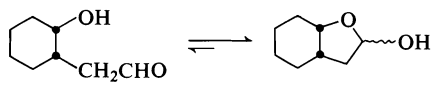
Discussion

The selection of structures **1–5** for evaluating the ability of HLADH to discriminate between unhindered primary and secondary alcohol groups attached to cyclohexane moieties was governed by several factors. A major consideration was our desire to choose compounds which were clearly of organic chemical interest. For example, the diols **1–3** lead to lactones **6–8**, which are of prostaglandin synthon value (4), while **4** is a precursor of *cis*-tetrahydroactinodiolide **9**, a member of a group of potent cat and beetle attractants (5, 6). In addition, structures **1–3** and **5** are cyclohexyl analogues of the cyclopentyldiols studied previously (2*b*).

[2]In this case it cannot be claimed that the process is a truly selective one in the chemical sense, since the hydroxyethyl group is the only oxidizable function present.

Each of **1–5** was a substrate of HLADH (Table 1). While the rates of oxidation of **4** and **5** were low, they were still marginally above the level (1% of V_{rel} of cyclohexanol (1)) required for synthetic-scale reactions to remain viable. Each practical-mode enzymic oxidation was performed on preparatively-significant (0.6–0.8 g) amounts of **1–5**. All reactions were terminated as close to the 50% oxidation stage as was practical since, for enzyme-mediated transformations of racemates, this is the point at which pure enantiomers will be obtained if the stereospecificity is absolute. The course of each oxidation was monitored by glc and the reactions were conveniently worked-up using simple continuous solvent extraction procedures. The percentage yields cited in the schemes are of the purified isolated products and were calculated taking the extent of oxidation into account. No attempt was made to optimize the yields in this initial survey. As the experimental details indicate, much higher yields should be obtainable using modified work-up procedures. Recrystallization of optically-active products was avoided in order to preclude the possibility of optical fractionation and all optical purities were determined from the specific rotations reported for the pure enantiomers.[3]

From analyses of the structures of **1–4** using the diamond lattice section (see below for details) it was predicted that HLADH would catalyze oxidation of the primary alcohol function exclusively. The results obtained (Schemes 1–3) are in complete accord with this projection. The hydroxyaldehydes, such as **11**, formed in the initial step were not detected



11 **12**

in the final reaction mixtures owing to the facility with which their hemiacetals, *e.g.*, **12**, undergo HLADH-catalyzed oxidation (2*b*,*c*) to the lactones **6–9**. The regiospecificities of these reactions parallel those observed for HLADH-mediated oxidation of the related *cis*-2-hydroxyethylcyclopentyl alcohols (2*b*).

[3]Attempts to measure enantiomeric excesses directly using glc or hplc analyses of diastereomeric derivatives or by nmr in the presence of shift reagents were unsuccessful.

In principle, selective enzymic oxidations of the above type could be accompanied by high enantioselectivity. However, the diamond lattice analyses of (+)- and (−)-**1–4** gave no indication that any significant enantiomeric preferences should manifest themselves. The very low to modest levels of enantiomeric enrichments observed in the Scheme 1–3 reactions were therefore not unexpected.[4] As with the analogous cyclopentyl substrates (2*b*), the degree of enantiomeric enrichment is influenced by the presence and/or position of a double bond in the ring. Although no dramatic stereospecificity was evident with (±)-**1–4** as substrates, it is interesting to note that in each case, the lactone products **6–9** are of the same absolute configuration type. Furthermore, in keeping with the apparent proclivity of HLADH to favour 'unnatural' configurations (1, 2), the enzymically-preferred configurations of the prostaglandin synthons **6–8** and the actinolide **9** are opposite to those of the 'natural' series.

HLADH-catalyzed oxidation of the 1,3-diol **5** was also completely regiospecific for the primary alcohol function, with the aldehyde product produced first being further transformed into the corresponding acid **10**. The latter reaction is presumably due to the aldehyde dehydrogenase content of HLADH (1). The hydroxymethyl specificity of the HLADH-catalyzed transformation of (±)-**5**, the sluggish nature of the reaction, and the racemic nature of the product are in accord with the diamond lattice analysis detailed below. The course of the enzymic oxidation of **5** contrasts sharply with that of the related *cis*-3-hydroxyethylcyclopentanol substrate. In the latter case, the process was highly enantioselective, with oxidation of the secondary hydroxyl group predominating (2*b*).

Diamond Lattice Section Analyses

The diamond lattice (7) section used is an updated model (1, 2*a*) based on those formulated previously (7, 8).

The behaviours of **1–4** are interpretable in terms of one basic lattice analysis. This is depicted in Fig. 1 using the enantiomers of

[4]No literature data on the individual enantiomers of **1–4** are available. Accordingly, since the optical purities of the lactone products **6–9** were so low, no attempt was made to establish the absolute configurations and optical purities of the diols **1–4** recovered from the Scheme 1–3 reactions.

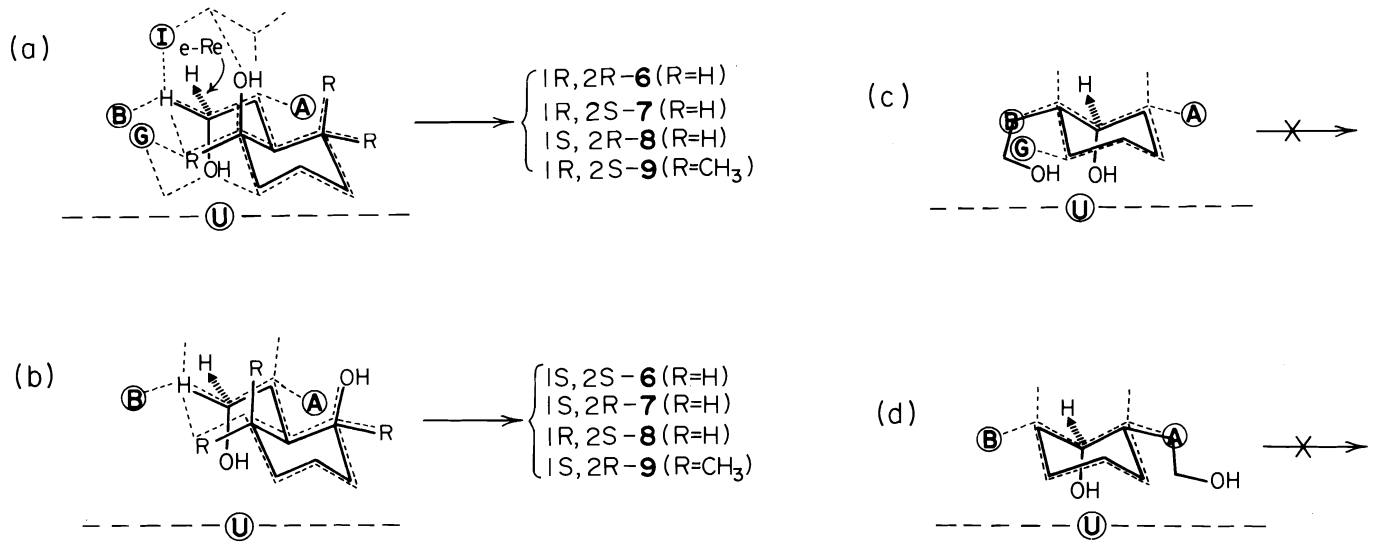


FIG. 1. Diamond lattice analysis of the regiospecificity of HLADH with respect to diols **1**–**4**. The relevant portions of the lattice (described in detail in refs. 1 and 2*a*), including the forbidden or unfavourable positions **A**, **B**, **G**, **I**, and **U**, are indicated by the dashed lines. The enantiomers of **1** (R = H) and **4** (R = Me) are used as the representative structures in the diagrams. When, as in (*a*) and (*b*), the hydroxyethyl groups of either enantiomer of **1** or **4** are oriented such that removal of the *pro-R*-hydrogen from the *e-Re* direction can occur as required by the model (1), there are no unfavourable lattice interactions. Oxidation of the primary alcohol group is thus an allowed process. Neither of the orientations in (*a*) and (*b*) appears more favoured than the other. There is thus no reason to expect any significant enantiomeric discrimination. On the other hand, oxidation of the secondary alcohol moiety is not allowed. Positioning of either enantiomer to permit hydride removal at C-1 in the required *e-Re* direction, as in (*c*) and (*d*), results in violation of forbidden position **A** (and possibly **G**), or **B**, by the respective hydroxyethyl groups. The introduction of double bonds into the cyclohexane ring, as for **2** and **3**, does not alter the analysis in any significant manner.

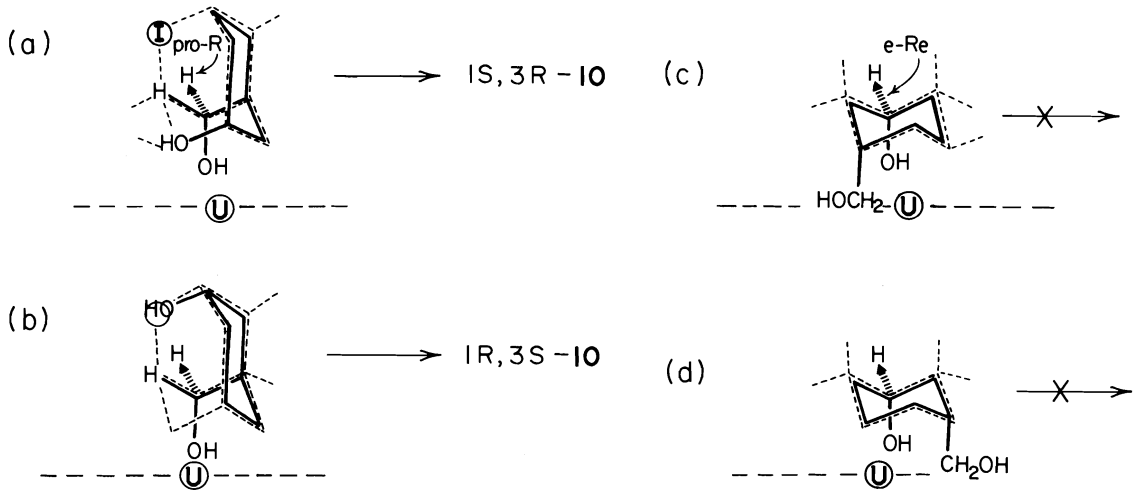

FIG. 2. Diamond lattice analysis of the regiospecificity of HLADH towards (±)-**5**. Oxidation of the primary alcohol function via removal of the *pro-R* hydrogen from the *e-Re* direction as shown in (*a*) and (*b*) are allowed processes since no forbidden positions are violated (position **I** is merely somewhat unfavoured relative to the other allowed lattice locations (1)). In contrast, oxidations of the secondary alcohol functions of either (+) or (−)-**5** are not preferred processes. These would require axial orientation of the C-1 hydroxyl group in order to permit hydride removal from the required (1) *e-Re* direction. Such orientations of the substrate are disfavoured since they force the hydroxymethyl substituents into the highly forbidden **U** region of the lattice as shown in (*c*) and (*d*).

1 and **4** for illustrative purposes. As Fig. 1 indicates, HLADH-catalyzed oxidation is a permitted process when the hydroxyethyl group of each enantiomer of **1**–**4** is positioned in the lattice in accordance with the known stereochemical requirements of the hydride removal step (1). Comparisons of the Fig. 1*a* and *b* orientations of each pair of enantiomers do not provide any reason to expect significant enantioselectivity during the hydroxyethyl group oxidation process. In contrast, when the secondary alcohol functions of (+)- and (−)-**1**–**4** are in the transition state-like orientation required for oxidation, the hydroxyethyl substituents interact adversely with at least one forbidden lattice position, as shown in Fig. 1*c* and *d*. Accordingly, oxidation at C-1 is precluded. The experimental results of Schemes 1–3 are in total accord with this analysis.

For the 1,3-diol **5**, the lattice analysis also unambiguously predicts preferred oxidation of the hydroxymethyl groups (Fig. 2). The oxidation is, however, a slow process because both enantiomers of **5** are required to be in their thermodynamically disfavoured diaxial conformations in order for *pro-R*, *e-Re*-hydride removal (1) to take place. Position **I** is only a moderately unfavourable lattice location (1) and its violation as indicated in Fig. 2*b* is evidently not serious enough to result in the Fig. 2*a* orientation being preferred to a sufficient degree for enantiomeric distinctions to be manifest.

Oxidation of the secondary alcohol function of **5** would require the C-1 hydroxyl group to be axially oriented (1). As shown in Fig. 2*c* and *d*, oxidation in such orientations is precluded for both enantiomers since, in each case, the hydroxymethyl group is required to project into the highly forbidden **U** region of the lattice.[5]

Conclusions

From the current and previous (2*b*) results, it is now clear that HLADH can be used with confidence to effect regiospecific and selective oxidation of one only of two or more hydroxyl groups within the same substrate molecule. Such selectivity in a single step reaction can very rarely be achieved using chemical oxidizing agents (9, 11). Furthermore, the course of the enzymic oxidation is predictable and may also be enantioselective to a greater or lesser degree. However, it is clear that small structural changes in the substrate can have large influences on both regiospecificity and enantio-

[5]The reader is urged to use molecular models to confirm the analyses of both Figs. 1 and 2.

selectivity which cannot yet be explained. Further work on this aspect is in progress.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Nuclear magnetic resonance spectra were recorded in C^2HCl_3 on a Varian T-60 instrument and ir data were obtained on liquid films (unless specified otherwise) using a Perkin-Elmer 237 spectrometer. Gas–liquid chromatographic analyses were made on 3% QF-1 on Chromosorb G columns with an F & M 400 unit. NAD^+ and FMN were purchased from Sigma and HLADH (EC 1.1.1.1, 3× crystallized) from Worthington.

*cis-2-Hydroxyethylcyclohexanol ((±)-**1**)*

cis-2-Hydroxycyclohexylacetic acid lactone ((±)-**6**) bp 130°C/15 Torr (lit. (12*a*) bp 140–145°C/25 Torr); ir, 1775 cm^{-1}; nmr δ 1.0–2.8 (11H, m) and 4.55 (1H, m) ppm was prepared in three steps from cyclohexanone by the method of Klein (12). The lactone (±)-**6** (10 g, 0.071 mol) was added to a cooled (0°C), stirred, suspension of lithium aluminum hydride (2.71 g, 0.77 mol) in dry ether (200 ml). The mixture was then kept at 20°C for 2 days. Water (10 ml), followed by an excess of 15% aqueous sodium hydroxide, was then added cautiously. The dried ($MgSO_4$) ether solution was evaporated and the residual oil distilled to give the diol (±)-**1** (13) (7.5 g) bp 108°C/0.2 Torr; ir 3600 cm^{-1}; nmr δ 1.6 (11H, m) and 3.75 (5H, m) ppm.

*cis-2-Hydroxyethylcyclohex-3-enol ((±)-**2**)*

cis-6-Hydroxycyclohex-2-enylacetic acid lactone ((±)-**7**) was prepared (three steps) from cyclohexa-1,3-diene by the procedure of Corey and Ravindranathan (4*c*). It had bp 105°C/0.15 Torr; ir 1775 cm^{-1}; nmr δ 1.6–3.3 (7H, m), 4.95 (1H, m), and 5.8 (2H, m) ppm. Lactone (±)-**7** (5.0 g, 3.6 mmol) was added with stirring to lithium aluminum hydride (1.37 g, 3.6 mmol) in dry ether (50 ml). The mixture was refluxed for 1 h and then worked-up with saturated aqueous ammonium chloride. The dried ($MgSO_4$) solution was evaporated and distilled to yield the diol (±)-**2** (1.4 g) bp 105°C/0.15 Torr; ir 3600, 3000, and 1645 cm^{-1}; nmr δ 1.4–2.5 (7H, m), 3.7 (2H, s, OH), 3.8 (3H, m), and 5.5 (2H, m) ppm. *Anal.* calcd. for $C_8H_{14}O_2$: C 67.63, H 9.85, O 22.52; found: C 67.80, H 9.83, O 22.37.

*cis-6-Hydroxyethylcyclohex-2-enol ((±)-**3**)*

Cyclohexene was converted in four steps to cyclohex-2-enylacetic acid bp 116°C/1 Torr (lit. (14) bp 109–112°C/4 Torr); nmr δ 1.2–2.9 (9H, m) and 5.7 (2H, m) ppm as described by Youssef and Sharaf (14). This material was then converted via iodolactonization (12*b*) to *cis*-2-hydroxycyclohex-3-enylacetic acid lactone ((±)-**8**) bp 87–89°C/0.4 Torr (lit. (12*b*) bp 140–145°C/20 Torr); ir 1770, 1660, and 1620 cm^{-1}; nmr δ 1.2–3.0 (7H, m), 4.85 (1H, m), and 6.0 (2H, m) ppm. The lactone (±)-**8** (4.03 g, 0.029 mol) was added with stirring to lithium aluminum hydride (1.11 g, 0.029 mol) in dry ether (50 ml). After being stirred at 20°C for 14 h, the mixture was worked-up by the cautious addition of water and the ether layer dried ($MgSO_4$) and evaporated. Distillation yielded the diol (±)-**3** (4.0 g) bp 101°C/0.4 Torr; ir 3600 cm^{-1}; nmr δ 1.3–1.9 (5H, m), 1.9–2.2 (2H, m), 2.85 (2H, s, OH), 3.8 (2H, t), 4.15 (1H, m), and 5.85 (2H, m) ppm. *Anal.* calcd. for $C_8H_{14}O_2$: C 67.63, H 9.85, O 22.52; found: C 67.81, H 9.86, O 22.33.

*cis-2-Hydroxyethyl-1,3,3-trimethylcyclohexanol ((±)-**4**)*

cis-Tetrahydroactinodiolide ((±)-**9**) was prepared from cyclohexanone in eight steps according to the procedure of Sakan *et al.* (5*b*); it had ir ($CHCl_3$) 1770 cm^{-1}; nmr δ 0.9 (3H, s), 1.05 (3H, s), 1.53 (3H, s), and 1.0–2.5 (9H, m) ppm.

The lactone (±)-**9** (5.0 g, 27.4 mmol) was added to lithium aluminum hydride (1.04 g, 27.4 mmol) in dry ether (200 ml) and the mixture refluxed for 1 day. The reaction mixture was then quenched cautiously with a little water and anhydrous Na_2SO_4 added. The filtered, dried ($MgSO_4$), ether solution was evaporated and the resulting solid recrystallized from ether to give the diol (±)-**4** (3.0 g) mp 96–97°C; ir ($CHCl_3$) 3600 cm^{-1}; nmr δ 0.8–2.2 (9H, m), 0.9 (3H, s), 1.0 (3H, s), 1.2 (3H, s), and 3.7 (2H, t) ppm. *Anal.* calcd. for $C_{11}H_{22}O_2$: C 70.94, H 12.09, O 16.97; found: C 70.90, H 11.93, O 17.17.

*cis-3-Hydroxymethylcyclohexanol ((±)-**5**)*

Cyclohex-3-ene carboxylic acid was converted by the method of Grave and Heinke (14) into *cis*-3-hydroxy-*trans*-4-iodocyclohexane carboxylic acid lactone mp 134°C (lit. (15) mp 134°C). This iodolactone (15.2 g, 0.06 mol) was then added slowly over 30 min at 0°C to a solution of tri-*n*-butyltin hydride (20.34 g, 0.07 mol) in dry benzene. The reaction mixture was stirred at 20°C overnight, and was then evaporated and distilled *in vacuo*. The crude lactone obtained was saponified directly with aqueous sodium hydroxide (7 g, 0.15 mol NaOH) at 20°C for 4 h followed by 2 h under reflux. The cooled solution was washed with ether, then acidified with concentrated hydrochloric acid and extracted with ethyl acetate. Evaporation of the dried ($MgSO_4$) extract gave the hydroxy acid (±)-**10** (2.5 g) mp 131–132°C (lit. (16) mp 131–132°C). The *cis*-acid (±)-**10** was reduced as described by Noyce and Denny (16) to give the diol (±)-**5**, bp 89°C/0.1 Torr (lit. (16) bp 132–134°C/4 Torr); nmr δ 0.8–2.4 (9H, m), 3.0 (2H, s), and 3.4 (3H, m) ppm.

*Determination of Rates of HLADH-catalyzed Oxidations of **1–5***

The assay method used was as described previously (2*a*, 8) employing the following stock solutions: HLADH, 0.5 mg/ml in 0.05 *M* tris–HCl buffer, p*H* 7.4; NAD^+, 10 mg/ml of 0.05 *M* glycine–NaOH buffer, p*H* 9.0. Substrates, 2×10^{-2} *M* solutions in 0.05 *M* glycine–NaOH buffer, p*H* 9.0.

*HLADH-catalyzed Oxidation of (±)-**1***

The diol (±)-**1** (600 mg, 4.16 mmol) was dissolved at 20°C in 0.05 *M* glycine–NaOH buffer (300 ml, p*H* 9.0) and NAD^+ (235 mg, 0.35 mmol) and FMN (3.11 g, 6.5 mmol) added. The reaction was initiated by adding HLADH (45 mg) and the p*H* periodically readjusted to 9. The oxidation was terminated after 7 h (glc showed 49% conversion) and the p*H* brought to 12 with 1 *M* aqueous sodium hydroxide. Continuous chloroform extraction yielded unchanged diol (287 mg). The aqueous reaction mixture was then acidified to p*H* 3 with

1 *M* aqueous hydrochloric acid and reextracted with chloroform for 20 h. Evaporation of the dried ($MgSO_4$), decolourized (Norite) chloroform extract gave the lactone **6** (146 mg), identical with the sample prepared previously. It had $[\alpha]_D^{27}$ +1.5° (*c* 2.2, MeOH) (lit. (4*a*) for 1*R*,2*R*-**6**, +45.5° (*c* 0.43, MeOH).

HLADH-catalyzed Oxidation of (±)-2

The diol (±)-**2** (700 mg, 4.9 mmol) was oxidized as described above for 10 h after which time glc analysis indicated 50% oxidation. Continuous chloroform extraction of the p*H* 13 solution gave unchanged diol (429 mg) containing some lactone and hemiacetal. The p*H* 3 reaction mixture was then reextracted for 10 h as before to give the lactone **7**, which after chromatography on Woelm alumina (activity I, ether elution) gave material, spectrally identical with the racemate prepared above, $[\alpha]_D^{27}$ +5.78° (*c* 1.07, MeOH) (lit. (4*a*) for 1*R*,2*S*-**7** $[\alpha]_D$ +28° (*c*, 0.6, MeOH).

HLADH-catalyzed Oxidation of (±)-3

This experiment was performed using the general procedure described above with diol (±)-**3** (630 mg, 4.4 mmol). After 10 h, when glc showed 52% oxidation, the reaction was worked-up as described above to give recovered diol (400 mg, containing some lactone and hemiacetal) and lactone **8** (130 mg), $[\alpha]_D^{27}$ −0.033° (*c* 0.23, MeOH). The lactone in ethyl acetate (50 ml) was hydrogenated in the presence of 10% Pd-on-C. Work-up gave the saturated lactone **6** (107 mg), identical with (±)-**6** except that it had $[\alpha]_D^{27}$ +1.96° (*c* 1.07, MeOH) (lit. (4*a*) for 1*R*,2*R*-**6**, $[\alpha]_D$ +45.5° (*c* 0.43, MeOH).

HLADH-catalyzed Oxidation of (±)-4

The diol (±)-**4** (700 mg, 3.7 mmol) was oxidized at 20°C in the usual way. After 48 h (33% oxidation) a further quantity of HLADH (15 mg) was added. After a total reaction time of 72 h (51% oxidation) the mixture was basified (p*H* 13) and continuously extracted with chloroform to give a mixture of recovered diol and lactone **9** (520 mg). The acidified (p*H* 3) mixture was then continuously reextracted to give an oil (140 mg) which, after chromatography on a short column of acidic alumina (ether elution), gave *cis*-tetrahydroactinodiolide **9** mp 80–81°C $[\alpha]_D^{22}$ −8.8° (*c* 1.34, $CHCl_3$) (lit. (6) for 1*S*,2*R*-**9**, mp 81–82°C, $[\alpha]_D^{22}$ +64.5° ($CHCl_3$)).

HLADH-catalyzed Oxidation of (±)-5

Oxidation of the 1,3-diol (±)-**5** (700 mg, 5.4 mmol) was performed as described above, with additional HLADH (30 mg) added after 24 h. The reaction was terminated after 50 h (30% oxidation). Continuous chloroform extraction at p*H* 13 for 3 days gave mainly unchanged **5** (511 mg). Subsequent continuous ethyl acetate extraction at p*H* 3 yielded the racemic hydroxy acid (±)-**10** mp 131–132°C (lit. (16) and previous mp 131–132°C).

The conformation of a ten-membered ring: the crystal and molecular structure of *trans-syn-trans*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane

ARIS TERZIS,[1] T. BRUCE GRINDLEY,[1] AND J. BRIAN FAUGHT

Received December 13, 1976

ARIS TERZIS, T. BRUCE GRINDLEY, and J. BRIAN FAUGHT. Can. J. Chem. **55**, 2692 (1977).

The crystal structure of *trans-syn-trans*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane (**1**) has been determined by X-ray diffraction. The crystals are monoclinic, $a = 10.995(2)$, $b = 5.291(1)$, $c = 12.241(2)$ Å, $\beta = 114.68(1)°$, $P2_1/c$, with $Z = 2$. The structure was solved by the application of symbolic addition procedures and refined with anisotropic thermal parameters for all atoms to a final R value of 0.039 (R_w 0.062) for 1135 independent reflections.

The ten-membered tetraoxecane ring is present in the crystal in a boat–chair–boat (BCB) conformation, which is somewhat different in geometry than the BCB conformations observed for cyclodecane derivatives. The causes of these differences are discussed. Intramolecular non-bonded interactions cause one CH_2 group to be significantly distorted from local C_{2v} symmetry.

ARIS TERZIS, T. BRUCE GRINDLEY et J. BRIAN FAUGHT. Can. J. Chem. **55**, 2692 (1977).

On a déterminé la structure cristalline du *trans-syn-trans*-biscyclohexano-4,5:9,10 tétraoxécane-1,3,6,8 (**1**) par diffraction de rayons-x. Les cristaux sont monocliniques $a = 10.995(2)$, $b = 5.291(1)$, $c = 12.241(2)$ Å, $\beta = 114.68(1)°$, groupe d'espace $P2_1/c$ et $Z = 2$. On a résolu la structure par l'application des méthodes d'addition symbolique et on l'a affinée avec des paramètres thermiques anisotropiques pour tous les atomes jusqu'à une valeur finale de R de 0.039 ($R_w = 0.062$) pour 1135 réflexions indépendantes.

Le cycle tétraoxécane à dix chaînons existe dans le cristal sous la conformation bateau–chaise–bateau (BCB) qui est quelque peu différente, de par sa géométrie, des conformations BCB observées pour les dérivés du cyclodécane. On discute des causes de ces différences. Des interactions non-liées intramoléculaires font que des groupes CH_2 sont passablement déformés de la symétrie C_{2v} au niveau local.

[Traduit par le journal]

Introduction

Strain minimization calculations on cyclodecane, carried out by a large number of workers (1–4), have shown that there are a number of conformations which may be of comparable energy in the gas phase. An electron diffraction study (1) at 130° suggested that the following conformations were present: the boat–chair–boat[2] (BCB, 49%); the twist–boat–chair (TBC, 35%); the twist–boat–chair–chair (TBCC, 8%), and the boat–chair–chair (BCC, 8%), although some possibilities including the conformation calculated to be the most stable by Engler *et al.* (4), the twist–chair–chair–chair (TCCC), were not considered. In view of the above results, it is not surprising that there is little known about the conformational preference of cyclodecane itself in solution.

In the solid state, the conformation suggested to be most stable in the gas phase by the electron diffraction study (1), the BCB, is strongly preferred (5, 6) for cyclodecane derivatives. The BCB conformation has C_{2h} symmetry which results in three different types of carbon atoms, termed I, II, and III. Other conformations have been observed only for derivatives (7, 8) with substituents which strongly disfavor this conformation. 1,3,5,7,9-Pentaoxecane (8), the only ten-membered ring previously examined which contained a number of oxygen atoms, is one of the exceptions and it adopted the twist–chair–boat–chair (TCBC) conformation. Interestingly, nmr spectral evidence suggests that a sugar derivative which has a 1,3,6,8-tetraoxecane ring fused to two tetrahydropyran rings also adopts this TCBC conformation (9) in solution.

A dynamic nmr study showed (10) that the 10-membered ring in *trans-syn-trans*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane (**1**) exists in solution in two degenerate sets of two diastereomeric BCB conformations termed BCB1 and BCB2 (see Fig. 1) which are formally neighbours (2) on the BCB pseudorotation itinerary. BCB1

[2]The nomenclature used is that devised by Hendrickson (2).

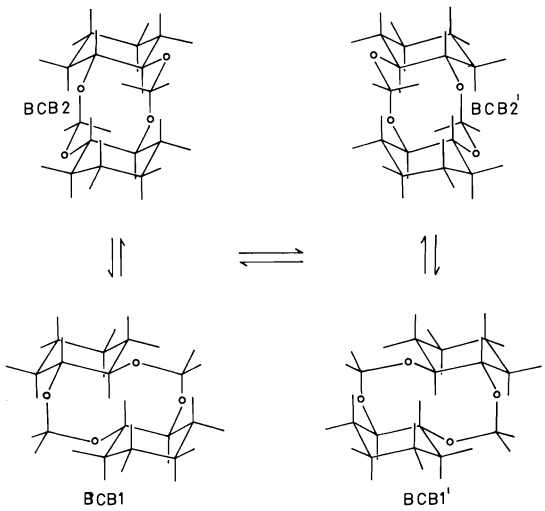

FIG. 1. The conformations observed for *trans-syn-trans*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane in solution.

is dominant at low temperatures in solution (below −30°C), while BCB2 is favoured at room temperature. Recently there has been considerable interest in the effects of the interactions between polar groups on conformations (11, 12) and BCB's 1 and 2 differ in the stereochemical relationships between their polar groups. In BCB1, models suggest that the two COCO torsional angles in each COCOC group are both 60° and equal in sign whereas in BCB2, the torsional angles in each COCOC group are 180° and 60°. Jeffrey *et al.* (11) have calculated that the latter arrangement would be 4.4 kcal/mol less stable than the former and have made predictions about bond length distortions expected in the two arrangements. In this publication we report the structure of *trans-syn-trans*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane in the solid state.

Experimental

trans-syn-trans-4,5:9,10-Biscyclohexano-1,3,6,8-tetraoxecane (**1**) was prepared according to the procedure of Brimacombe *et al.* (13). Crystals suitable for study were obtained by recrystallization from ethanol and had mp 167–168°C (lit. (13) mp 166–167.5°C). Crystal data are

$C_{14}H_{24}O_4$ fw = 256.35

Monoclinic, $a = 10.995(2)$, $b = 5.291(1)$, $c = 12.421(2)$ Å, $\beta = 114.68(1)°$, $V = 656.51$ Å^3, $Z = 2$, $\rho_{calcd} = 1.296$ g cm^{-3}, $\rho_{obs} = 1.28$ g cm^{-3} (18°C, CuK$_\alpha$, $\lambda = 1.54051$ Å).

Preliminary photographic data showed the crystals to be monoclinic with the following systematic absences: $h0l$, $l = 2n + 1$; $0k0$, $k = 2n + 1$, which indicated that the space group was $P2_1/c$.

A crystal (0.33 × 0.41 × 0.45 mm) was mounted with the *b* axis nearly parallel to the φ axis of a Picker FACS-1 automatic diffractometer with a graphite monochromator. Data were collected by the θ–2θ scan technique from a point 0.95° below the calculated 2θ position for CuK$_{\alpha 1}$ to 0.95° above the position calculated for CuK$_{\alpha 2}$ at a rate of 1° min^{-1}. Stationary-crystal stationary-counter background counts of 20 s were recorded at each limit of the scan range. During the data collection, three standard reflections were measured at a period of 30 reflections. Their intensities decreased uniformly by 4%. A total of 1170 intensity measurements were made in the form $\pm h, k, l$ in the region $2\theta < 127°$ and reduced to a set of 1135 independent reflections. The integrated intensity was calculated as

$$I(\text{net}) = I(\text{scan}) - 0.5\frac{t_T}{t_B}(B_1 + B_2)$$

where I(scan) is the number of counts over the scan range, t_T is the scan time, t_B is the time for each background count B_1 and B_2. The standard deviations $\sigma(I)$ were calculated according to the expression

$$\sigma_{(I)} = [N_T + 0.25t_T/t_B(B_1 + B_2) + C(I)^2 + 0.03^2(I - I_c)^2]^{1/2}$$

where N_T is the total net integrated scan count obtained in time t_T, C is a factor to account, among other things, for instrumental instability during data collection (for this structure, C was 0.04), I is the net intensity, and I_c is I corrected for absorption. The last term in the expression is a factor accounting for errors in the absorption correction.

An absorption correction[3] (9) was applied and the calculated transmission coefficients based on a linear absorption coefficient of 7.7 cm^{-1} for CuK$_\alpha$ radiation ranged from 0.698 to 0.802. Lorentz and polarization corrections were applied. 1098 reflections with $I > 2\sigma(I)$ were used in the refinement of the structure.

Solution and Refinement

The structure was determined by the application of symbolic addition procedures (18). The 9 non-hydrogen atoms were found in the *E*-map and a structure factor calculation based on this model gave a conventional *R* factor 0.276 where $R = (\Sigma||F_o| - |F_c||)/\Sigma|F_o|$. Temperature and scale factors were taken from the Wilson plot. Four cycles of block-diagonal least-squares refinement with unit weights and isotropic thermal parameters for the non-hydrogen atoms converged at $R = 0.116$. The twelve hydrogen atoms were located in a difference Fourier synthesis calculated at this point. Block diagonal refinement was continued with anisotropic thermal parameters for the non-hydrogen atoms and isotropic parameters for the hydrogens. A weighting scheme was introduced ($w = 1/[\sigma^2(F_o)]$) as well as a secondary extinction correction (19). The *R* factor at convergence

[3]The computer programs used were locally modified versions of the following: F. R. Ahmed and C. P. Huber, NRC-2 (data reduction) (14); F. R. Ahmed and B. Singh, NRC-3 (absorption correction) (14); A. Zalkin, FORDAP (Fourier, Paterson maps) (15); R. V. Doedens and J. A. Ibers, NUCLS (least-squares refinement with black-diagonal option introduced by J. Sygusch) (16); C. K. Johnson, ORTEP (drawings) (17).

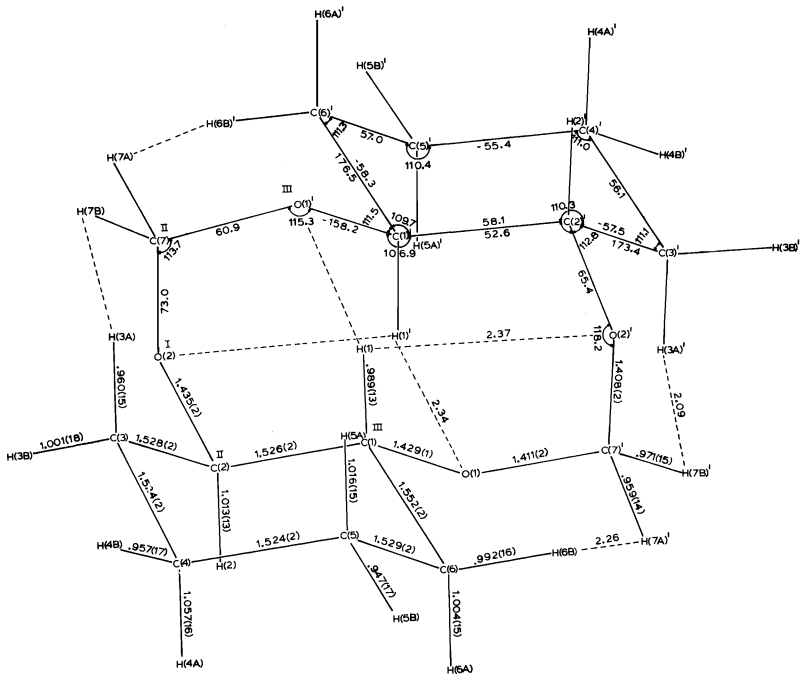

FIG. 2. Numbering and structural parameters for *trans-syn-trans*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane. Bond lengths (Å), with their errors in parentheses (10^3 Å), and the more significant calculated short intramolecular distances (- - -) are shown on the bottom half of the diagram. Bond angles (deg) and torsional angles (deg) between heavy atoms are shown on the top half. All errors in angles were 0.1°. Roman numerals indicate the locations of the three different types of BCB positions on the structure.

was 0.041. Inclusion of anisotropic thermal parameters for the hydrogen atoms reduced R to 0.039 after 4 cycles of refinement and $R_2 = ([\Sigma(w|F_o| - |F_c|)^2]/[\Sigma w|F_o|^2])^{1/2}$ to 0.062 for observed and unobserved data. The maximum shifts in the final least-squares refinement were 0.4 σ. The final 'goodness of fit', defined as $([\Sigma w(|F_o| - |F_c|)^2]/(m - n))^{1/2}$ was 2.88, where m = number of observations and n = number of refined parameters. The scattering factors for all atoms were from Cromer and Mann (20).

Results and Discussion

Atomic positions and thermal parameters for **1** are given in Table 1. The structure factor table and Table 2, which contains the bond angles involving hydrogen were put on deposit.[4] Numbering, bond lengths, bond angles, torsional angles, and short intramolecular distances are shown in Fig. 2. To facilitate comparison with results from strain minimization calculations, the short intramolecular distances involving H were recalculated using a C—H bond length of 1.1 Å.

[4]This information can be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada KIA 0S2.

Figure 3 shows an ORTEP diagram of the crystal structure of **1**.

Since compound **1** is centrosymmetric, the *syn* configuration previously (21) assigned for the relative orientations of the cyclohexane rings in **1** on the basis of its nmr spectrum is correct. In the solid state, **1** adopts the BCB conformation referred to as BCB1 in the Introduction and this conformation appears to have similar geometry to the average BCB conformation of cyclodecane derivatives (4, 6) although there are a number of important differences which will be discussed below.

Bond Angles and Torsional Angles

Bond angles in cyclodecane derivatives are normally large (see Table 3) presumably to relieve transannular non-bonded interactions between opposing hydrogen atoms. Since in this conformation of compound **1**, all of the transannular non-bonded CH–CH interactions have been replaced by CH–O interactions, the angles at all carbons but particularly those at BCB type I and II carbons in **1** should be smaller than in

TABLE 3. Comparison of bond angles and torsional angles between **1** and cyclodecane derivatives

BCB position type	Atoms involved	Angle (deg)		
		Compound **1**	Average value in cyclodecane*	Difference
Bond angles				
I	COC	118.2	118.6 (±2)	−0.4
II	OCC	113.7	117.7 (±4)	−4.0
III	COC	115.3	114.5 (±3)	+0.8
III	OCC	106.9	114.5 (±3)	−7.6
II	CCO	114.3	117.7 (±4)	−3.4
Torsional angles				
I and II	COCO	73.0	65.8 (±6)	+7.2
II and III	OCOC	60.9	55.5 (±4)†	+5.4
III and III	COCC	−158.2	−152.4 (±1.6)	−5.8
III and II	OCCO	52.6	55.5 (±4)†	−2.9
II and I	CCOC	65.4	65.8 (±6)	−0.4

*Average of values from refs. 5 and 6.
†Two values were observed outside this range in an intramolecularly H-bonded molecule (6).

cyclodecane. Table 3 compares the bond angles in **1** to those of cyclodecane and the observed bond angles at type II positions in **1** are both smaller, as predicted above. Although the COC angle at the type I carbon is not smaller, in compound **1** there is an intramolecular non-bonded interaction between C(7) and C(3) similar to the type between an axial methyl and the —OCH_2O— groups in 4-methyl-1,3-dioxane (evaluated at 2.8 or 2.9 kcal/mol (22)) and this interaction presumably maintains the size of this angle at approximately the value observed in cyclodecane. In a closely related compound where this interaction is not present, the bond angle decreased in magnitude by 1.7° to 116.5° (23).

The most notable difference between **1** and cyclodecane is the CCO bond angle of 106.9° at a BCB type III position. CCO bond angles are often small. For instance, in diethyl ether (24), CCO bond angles vary from 107.8° to 108.3°, in 1,5,9,13-tetraoxacyclooctadecane four CCO bond angles are below 109.6° with the smallest being 106.4° (25). In the present case, intramolecular non-bonded interactions appear to be the main cause of the small bond angle, since a decrease in bond angle allows increase of both of the short intramolecular distances, H(7A)—H(6B)′ and H(7B)—H(3A).

The torsional angles of **1** are compared to those of cyclodecane in Table 3 and all of the *gauche* torsional angles fall within the ranges observed for cyclodecane derivatives or are just outside. The one *anti* torsional angle (−158.21°), about the two BCB type III carbons, is considerably outside the observed range. The larger size of this angle contributes to the general narrowing of this tetraoxecane ring as compared to cyclodecane and is caused by the relief of transannular non-bonded interactions, particularly between hydrogens on opposing type III carbons.

TABLE 4. Extraannular intramolecular non-bonded interactions

Atoms	Involved	Distance (Å)†	Distance (Å)‡	E (kcal/mol)*
C(7)	C(6)′	3.138 (0.002)		0.02
C(7)	H(6B)′	2.937 (0.017)	2.934	−0.03
H(7A)	C(6)′	2.848 (0.015)	2.830	0.02
H(7A)	H(6B)′	2.365 (0.024)	2.263	0.28
	Total interactions between $C(7)H_2$ and $C(6)'H_2$			0.29

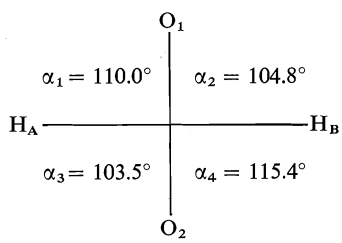
	Total interactions between $C(7)H_2$ and $C(3)H_2$			1.05

*Calculated using the force field of Hilderbrandt *et al.* (1).
†From the X-ray structural determination.
‡Calculated using observed C positions and CCH or OCH bond angles but with the C–H distance assumed to be 1.10 Å.

Intramolecular Interactions

The shortest intramolecular transannular interactions are shown in Fig. 2. Since no force fields are available with parameters for oxygen, the interactions shown in Fig. 2 have been evaluated qualitatively by consideration of the van der Waals radii of Pauling. The van der Waals radii are 2.0, 1.4,[5] and 1.2 Å,[5] for CH_3, O, and H respectively. The shortest O—O transannular distances are about equal to the sum of their van der Waals radii so non-bonded interactions between oxygens should not make a large contribution to the energy. The shortest O—H distances are somewhat less (~0.2 Å) than the sum of their van der Waals radii. Dale (27) has suggested that this latter type of interaction is not repulsive and is perhaps attractive where the hydrogen is on a carbon adjacent to oxygen and therefore acidic. However, recent evidence (28) shows that hydrogens geminal to methoxy groups on a carbon are only very slightly more acidic than those geminal to methyl groups. It therefore appears more likely that the conformational effects observed by Dale (27) who compared ethers to alkanes are simply a consequence of the change of the sum of the van der Waals radii from 4.0 to 3.4 Å when CH–CH interactions were replaced by CH–O interactions. Accordingly, it is likely that the O–H interaction in **1** is slightly repulsive; a H–H interaction 0.2 Å less than the sum of the van der Waals radii can be evaluated at 0.4 kcal/mol using the force field of Hilderbrandt *et al.* (1) and this O–H interaction is probably also small. The sum of the van der Waals radii of CH_3 and O is 3.4 Å, while the short C—O distances observed in **1** are ~2.9 and 3.0 Å. However, here the oxygen is staggered between the atoms on the carbon, so this interaction is probably also only slightly repulsive.

Compound **1** also possesses intramolecular extraannular non-bonded interactions between each OCH_2O group in the ring (*i.e.* C(7)) and one methylene group on each cyclohexane ring (*i.e.* C(3) and C(6)′). Table 4 gives the distances between the atoms in these groups and the corresponding repulsive energies calculated using the force field of Hilderbrandt *et al.* (1). The larger part of the non-bonded repulsion arises from interaction between the hydrogen atoms on C(3) and C(6)′ and different hydrogen atoms on C(7). Since the interactions are with different hydrogen atoms, the effect of the resulting torque should be observable in distortion of the CH_2 group from local C_{2v} symmetry. Distortion of this sort can be conveniently discussed (6) in terms of the following linear combinations of the four HCO-angles, α_1, α_2, α_3, α_4, where m, w, r, and t stand for mean, wag, rock, and twist.



$$m = (1/4)(\alpha_1 + \alpha_2 + \alpha_3 + \alpha_4)$$
$$w = (1/2)(\alpha_1 + \alpha_2 - \alpha_3 - \alpha_4)$$
$$r = (1/2)(\alpha_1 - \alpha_2 + \alpha_3 - \alpha_4)$$
$$t = (1/2)(\alpha_1 - \alpha_2 - \alpha_3 + \alpha_4)$$

[5]Other values have been suggested including shorter (11) and longer (26) values for hydrogen and longer (11) values for oxygen.

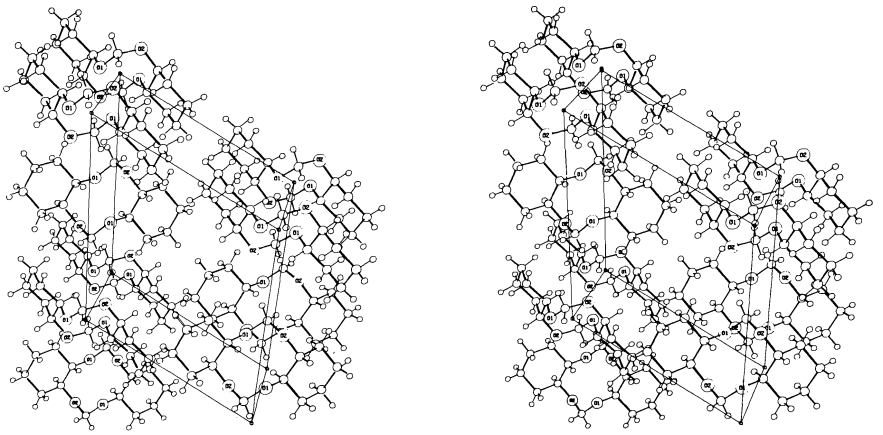


FIG. 4. Stereoscopic view of the molecular packing.

The four angles of α_1, α_2, α_3, and α_4 have values as shown and yield m, w, r, and t values of 108.4°, −2.0°, −3.4°, and 8.6° respectively. For other cyclodecane derivatives, wagging and rocking distortions (but only slight twisting) of up to 4° at types I and III positions are common (6) to relieve non-bonded interactions but little distortion of any type has been observed at the relatively unhindered type II carbons. This observation of the distortion of the $C(7)H_2$ groups (primarily twisting) confirms the importance of these extraannular interactions. It suggests that OCH_2O groups are fairly easily distorted and that force field calculations which assume local C_{2v} symmetry in CH_2 groups will give erroneous results. Each of the interactions of these hydrogens is also similar to that between the OCH_2O group and an axial methyl in 4-methyl-1,3-dioxane.

Polar Effects

The conformation adopted by compound **1** is the BCB conformation (BCB1) in which both torsional angles about C—O bonds in each OCH_2O group are *gauche* and of the same sign; an arrangement calculated (11) to be 4.4 kcal/mol more stable than the *gauche*, *anti* relationship in the other BCB conformation observed in solution (BCB2). The C—O bond lengths observed for this arrangement (1.411 and 1.408 Å) are, as predicted (11), significantly shorter than normal C—O bonds (1.429 and 1.435 Å in this molecule) and approximately equal in length.

Intermolecular Interactions

The packing diagram for compound **1** is shown in Fig. 4. It is unlikely that intermolecular interactions affected the observed conformation to a large extent since there are only 5 intermolecular distances shorter than the sum of the van der Waals radii, none of which are H–H interactions and none of which are energetically important (>0.1 kcal/mol) when the energy is calculated by the force field of Hilderbrandt *et al.* (1).

Nuclear analogs of β-lactam antibiotics. III. Synthesis of 1,3-dimethyl-Δ^3-*O*-2-isocephems[1]

TERRENCE WILLIAM DOYLE,[2] BING-YU LUH, AND ALAIN MARTEL[3]

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received February 16, 1977

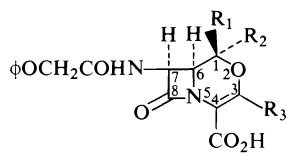
TERRENCE WILLIAM DOYLE, BING-YU LUH, and ALAIN MARTEL. Can. J. Chem. **55**, 2700 (1977).

The synthesis of 1-α-methyl and 1-β-methyl isomers of 7-β-phenoxyacetamido-1,3-dimethyl-Δ^3-*O*-2-isocephem-4-carboxylic acids (**14***a* and **14***b*) is described. Treatment of amine **2** with methacrolein followed by cycloaddition gave **4** which was ozonolyzed to yield the methyl ketones **6**. Upon reduction of **6** there was obtained a mixture of isomeric alcohols **8** which were resolved by column chromatography, converted to their mesylates **9**, and hydrolyzed to yield **10***a* and **10***b*. Conversion of each isomer to the corresponding *O*-2-isocephems **11***a* and **11***b* followed by azide reduction, coupling of the amines to phenoxyacetic acid, and removal of the ester blocking groups gave **14***a* and **14***b*. An attempt to prepare the *gem*-dimethyl compound failed. The structural assignments to **14***a* and **14***b* are discussed.

TERRENCE WILLIAM DOYLE, BING-YU LUH et ALAIN MARTEL. Can. J. Chem. **55**, 2700 (1977).

On décrit la synthèse des acides isomères méthyl-1 α et méthyl-1 β des acides phénoxyacétamido-7 β diméthyl-1,3-Δ^3 isocéphem-*O*-2 carboxyliques 4 (**14***a* et **14***b*). La réaction de l'amine **2** avec de l'aldéhyde méthacrylique, suivie par une cycloaddition, conduit à **4** qui peut être ozonolysé pour conduire aux méthyl-cétones **6**. La réduction de **6** fournit un mélange d'alcools isomères **8** qui peut être résolu par chromatographie sur colonne et chacun des alcools peut alors être transformé dans son mésylate **9** et hydrolysé pour conduire à **10***a* et **10***b*. On fait suivre la conversion de chacun des isomères en isocéphem-*O*-2 correspondants **11***a* et **11***b* par une réduction de l'azide, un couplage des amines avec l'acide de phénoxyacétique et l'enlèvement des groupes esters bloqueurs pour donner **14***a* et **14***b*. Un essai en vue de préparer le composé *gem*-diméthylé n'a pas réussi. On discute des attributions de structure de **14***a* et de **14***b*.
[Traduit par le journal]

In the previous paper of this series the syntheses of a number of *O*-2-isocephem systems (Fig. 1, wherein $R_1 = R_2 = H$ and $R_3 = H$,



1

$R_1 = R_2 = H$ $R_3 = H, CH_3, CH_2\phi, CH_2CH_2\phi$
$R_1 = H$ $R_2 = R_3 = CH_3$
$R_2 = H$ $R_1 = R_3 = CH_3$

FIGURE 1

Me, $CH_2\phi$, $CH_2CH_2\phi$) were described (1). Encouraged by the promising biological activity of these systems the synthesis of 1-substituted *O*-2-isocephems was attempted next. In this paper we report the synthesis of the 1-α,3-dimethyl- and 1-β,3-dimethyl-*O*-2-isocephems **1** ($R_1 = H$, $R_2 = R_3 = CH_3$ and $R_2 = H$, $R_1 = R_3 = CH_3$).[4]

Treatment of amine **2** (Scheme 1) (1) with an excess of methacrolein in the presence of a catalytic amount of the hydrochloride of **2** gave the Schiff base **3** in 90% yield. The catalysis was necessary to ensure rapid formation of **3**. Compound **3** was then treated with azidoacetyl chloride followed by triethylamine to yield β-lactam **4** (82.5%) as a mixture of diastereoisomers (epimeric about the $N—\overset{*}{C}(CO_2Bz)$-center). The isomers could be partially separated by column chromatography on silica gel using benzene as eluent. The nmr spectra of the two isomers (Table 1) indicated that the azido and isopro-

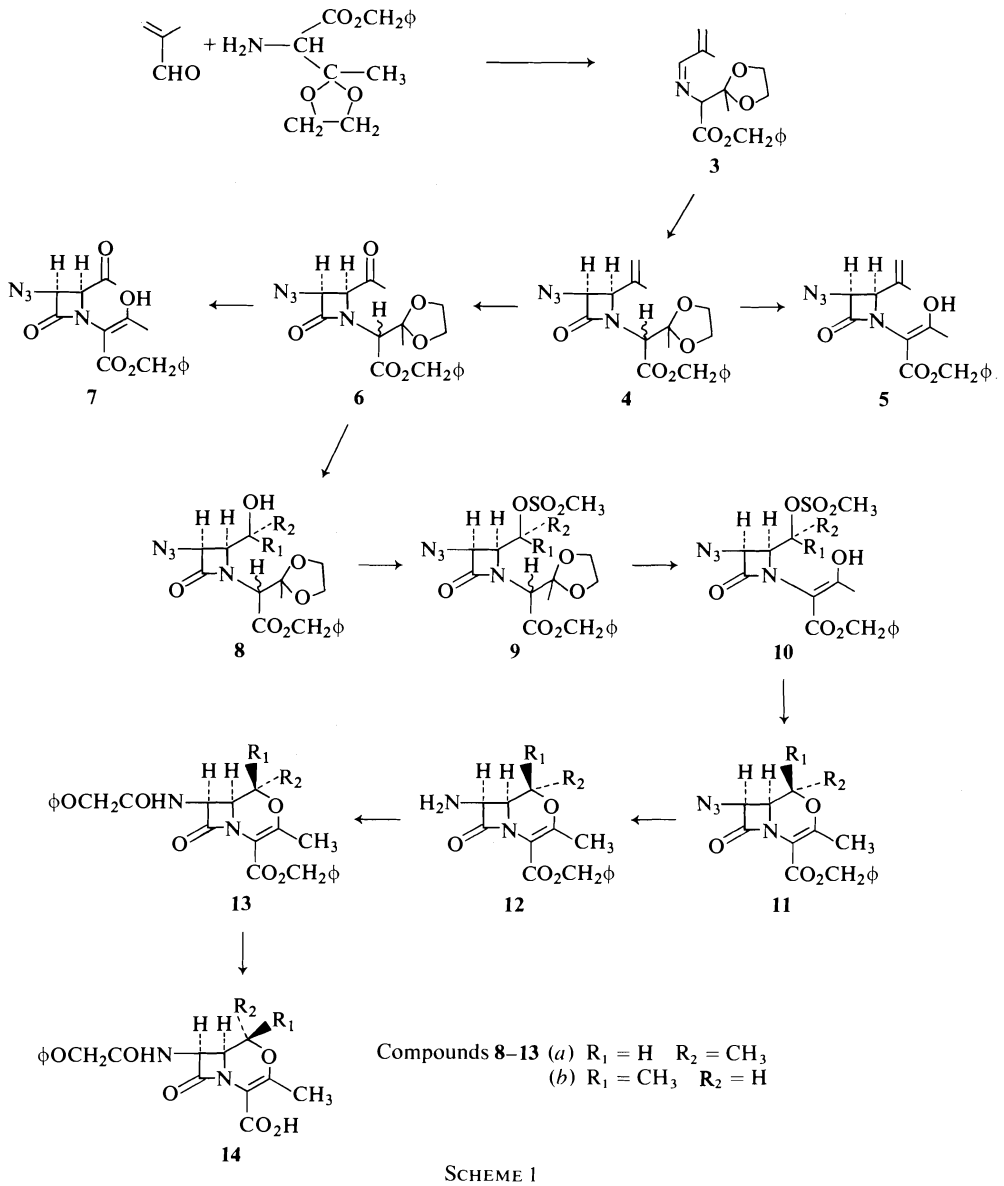

SCHEME I

penyl groups were *cis* to one another as shown by the coupling constants for the protons at C_3 and C_4 in the azetidinone ring (3) J = 5.3 Hz.[5] Hydrolysis of either isomer of **4** gave a single enol **5** (82%). No trace of the *trans* isomer of **5** could be detected by nmr spectroscopy.

Ozonolysis of **4** (1:1 isomer mixture) and decomposition of the ozonide gave a mixture of methyl ketones **6** in 95% yield. The product was chromatographed on silica gel with chloroform as eluent to give each isomer as a crystalline solid. When the isomer of **4** which was eluted first from the column was ozonized a single methyl ketone corresponding to the ketone which eluted second from the column was isolated. The stereochemistry of the isomers of **4** and **6** about the chiral center in the side chain attached to the nitrogen has not been deter-

[5]The order of addition of azidoacetyl chloride and triethylamine to the Schiff base **3** had no effect on the stereochemistry of the products. The procedure described was found to be cleaner (4).

[o]The protons C*H*—C*H*OHCH_3 are obscured under the ketal resonance. [p]Assigned to O—SO_2CH_3. [q]Assigned to C*H*OMesCH_3. [r]Assigned to C*H*—CHOMesCH_3. [s]Assigned to C_1-α-CH_3 and C_1-β-*H*. [t]Assigned to C_6-H. [u]Assigned to C_3-CH_3. [v]Assigned to C_1-β-CH_3 and C_1-α-*H*. [w]Assigned to φOCH_2. [x]Recorded in $CDCl_3$–DMSO-d_6. [y]After D_2O exchange.

mined. Hydrolysis of either isomer of **6** with 95% trifluoroacetic acid gave a single enol **7** as a crystalline solid in 97% yield.

Reduction of **6** (either as single isomers or isomer mixtures) with sodium borohydride led to complex mixtures of alcohols. Invariably the reduction of ketone isomer 2 was more sluggish than that of isomer 1.[6] Reduction of a 1:1 mixture of ketone isomers **6** gave, after chromatography, a recovery of ~10% ketone isomer 2, a mixture of alcohols **8***a* in 43% yield, and a single isomer **8***b* as a crystalline solid in 9.8% yield. The assignment of configuration to the alcohol mixture **8***a* and the single isomer **8***b* was made retrospectively on the basis of the subsequent reactions of **8***a* and **8***b*. Reduction of the isomeric ketones **6** separately also gave complex mixtures, presumably due to epimerization under the reaction conditions.

Treatment of **8***a* with methane sulfonyl chloride and triethylamine gave **9***a* as a mixture of diastereoisomers in 89% yield. Hydrolysis of the ketal with 95% trifluoroacetic acid gave **10** (65%) as a mixture of **10***a* and **10***b* (9:1). Similarly **8***b* was converted to **9***b* (99%) and hydrolyzed to yield **10***b* exclusively in 96% yield.

Treatment of **10***a* with sodium hydride in dimethyl sulfoxide gave **11***a* (38%) contaminated with ~10% **11***b*. Recrystallization from ether gave pure **11***a* (33%). When **10***b* was refluxed with 1 equiv. of triethylamine in chloroform there was obtained **11***b* in 80% yield. The assignments of configuration to **11***a* and **11***b* have been made on the basis of their nmr spectra (Table 1). Compound **11***a* exhibits a coupling constant of 8.5 Hz between the C_6 and C_1 protons. The only configuration which would be predicted to show such a *J* value is that illustrated in Fig. 2

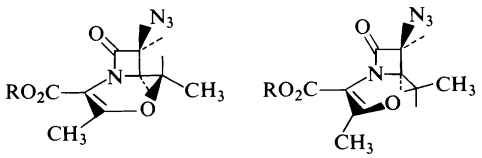

FIGURE 2

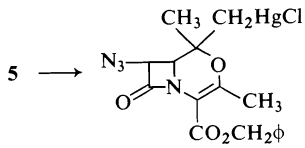
for **11***a* in the conformation shown. The coupling constant for compound **11***b* was J_{16} = 3.7 Hz which could be accommodated by either of the two possible conformations for the Δ^3-*O*-2-isocephem system (illustrated in Fig. 2). It is more probable, however, that **11***b* adopts the conformation shown in Fig. 2 as this would relieve the steric interaction between the azido group at C_7 and the 1-β-methyl group.

Reduction of the azido function in **11***a* with hydrogen sulfide – triethylamine (2) followed by coupling of the amine **12***a* to phenoxyacetic acid using *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) (5) gave the amide **13***a* in 60% yield from **11***a*. Similarly compound **11***b* was reduced to the amine **12***b* (74%) and coupled with phenoxy acetic acid to give **13***b* in quantitative yield.

Hydrogenolysis of the benzylesters **13***a* and **13***b* over 20% $Pd(OH)_2/C$ in ethyl acetate gave the corresponding acids **14***a* and **14***b* in 84 and 73% yields, respectively. Both **14***a* and **14***b* exhibited antibacterial activity the details of which will be published separately.

The synthesis of the 1,1,3-trimethyl-Δ^3-*O*-2-isocephem was attempted next via oxymercuration of compound **5** (Scheme 2). Treatment of **5**



15

SCHEME 2

with mercuric acetate in tetrahydrofuran (6) gave **15** in 66% yield. All attempts to reduce **15** to the desired 1,1,3-trimethyl-Δ^3-*O*-2-isocephem failed, compound **5** being isolated in its stead.

Experimental

The infrared spectra were recorded on a Unicam SP-200G grating, ir spectrometer. The nmr spectra were determined on a Varian A60-A spectrometer using tetramethylsilane as an internal standard. Melting points are uncorrected and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, IL.

cis-N-(α-Carbobenzyloxy-β,β-ethylene ketal propyl)-3-azido-4-isopropenyl-2-azetidinone ***4***

(A) Preparation of Schiff Base ***3***

To a mixture of 50.0 g (0.20 mol) aminoketal **2** and 35.0 g (0.5 mol) freshly distilled methacrolein in 300 ml methylene chloride was added 1.0 g of the amine hydrochloride. To this was added a large excess of anhydrous sodium sulfate (100 g) and the whole vigorously stirred with a magnetic stirrer. After 45 min an aliquot was removed and evaporated to dryness. The nmr spectrum of the residual oil indicated complete formation of the desired Schiff base. The remaining solution was filtered and the filtrate

[6]The terms isomer 1 and isomer 2 refer to their order of elution on chromatography.

passed through a pad of activity III silica gel (Woelm, 50–100 g) to remove the amine hydrochloride. The filtrate was evaporated to dryness to yield 54.90 g (90.5%) of pale yellow oil, the nmr spectrum of which was consistent with the assigned structure; ir (film): 1740, 1640, 1617 cm^{-1}.

(B) β-Lactam Formation

The freshly prepared Schiff base **3** (54.90 g, 0.182 mol) in 500 ml dry methylene chloride was cooled to −15°C (in a methanol–ice bath). To this was added 21.60 g (0.182 mol) azidoacetyl chloride over 5 min. Following this 18.2 g (0.182 mol) TEA in 125 ml dry methylene chloride was added dropwise over 1 h while the temperature was maintained at 0–5°C for 18 h and then evaporated at reduced pressure. The residual oil was triturated with 300 ml ether and the TEA hydrochloride removed by filtration. The filtrate was washed successively with 10% hydrochloric acid (100 ml), saturated sodium bicarbonate (100 ml), and brine (100 ml), dried over sodium sulfate, and filtered. This filtrate was in turn filtered through a pad of 150 g silica gel. The filtrate was evaporated to yield 57.8 g (82.5%) of the desired β-lactam **4** as a mixture of diastereoisomers. A sample of the crude **4** was chromatographed on silica gel (15% water, w/w) using benzene as the eluting solvent to give each of the isomers ~90% pure; ir ($CHCl_3$): 2110, 1773, 1750 cm^{-1}. *Anal.* calcd. for $C_{19}H_{22}N_4O_5$: C 59.06, H 5.74, N 14.50; found: C 59.20, H 5.84, N 14.23.

cis-N-(α-Carbobenzyloxy-β,β-ethyleneketalpropyl)-3-azido-4-acetyl-2-azetidinone ***6***

A solution of 15.18 g (0.0394 mol) β-lactam **4** in 100 ml of methanol was prepared and cooled to −78°C in an acetone – dry ice bath. Ozone was passed through the solution until a distinct blue color due to excess ozone was observed. The solution was purged of excess ozone with a stream of dry nitrogen and 15 ml of dimethyl sulfide (large excess) were added. The solution was allowed to come to ambient temperature (~22°C) and evaporated at reduced pressure. The residue was taken up in ether and washed with water (50 ml) and brine (200 ml in 4 portions). The organic layer was dried over Na_2SO_4, filtered, and evaporated to yield 14.5 g of an oil (95%), the nmr spectrum of which indicated that a mixture of two diastereoisomeric ketones **6** had been obtained. Trituration of this oil with ether induced solidification of the mixture.

A small sample of the mixture was chromatographed on silica gel (15% water, w/w) using chloroform as the eluting solvent. Each of the ketones was isolated as a crystalline solid. Isomer 1 (eluted first) had mp 96–96.5°C after recrystallization from chloroform–ether; ir ($CHCl_3$): 2105, 1780, 1740, 1733(s) cm^{-1}. Isomer 2 had mp 91–91.5°C after recrystallization from benzene–ether, ir ($CHCl_3$): 2110, 1775, 1740, 1735(s) cm^{-1}. *Anal.* calcd. for $C_{18}H_{20}N_4O_6$: C 55.66, H 5.19, N 14.43; found (for isomer 1): C 55.47, H 5.25, N 14.44; found (for isomer 2): C 55.76, H 5.23, N 14.53.

Hydrolysis of Compound ***4***

To 3.70 g (10 mmol) of compound **4** (either isomer) was added 20 ml of 95% trifluoroacetic acid at 25°C. The solution was let stand 45 min at 25°C and poured into brine (100 ml). The solution was extracted with methylene chloride (3 × 50 ml), the extracts washed with water (2 × 50 ml) and brine (50 ml), and dried over sodium sulfate. The extracts were evaporated and the residual oil taken up in 200 ml of ether. The organic layer was then extracted with 2% sodium hydroxide (3 × 25 ml) and the aqueous layer acidified to p*H* ~ 3 with 10% hydrochloric acid. The solution was extracted into ether (3 × 50 ml), the extracts dried over sodium sulfate, filtered, and evaporated to dryness. Trituration of the residual oil with ether – petroleum ether induced crystallization of the oil and gave 2.73 g (82%) of **5**, mp 74–75°C. ir: 2115, 1780, 1740, 1665, 1615 cm^{-1}. *Anal.* calcd. for $C_{17}H_{18}N_4O_4$: C 59.64, H 5.30, N 16.37; found: C 59.53, H 5.15, N 16.14.

Hydrolysis of Compound ***6***

To 1.75 g (4.7 mmol) of **6** (1:1 isomer mixture) was added 10 ml 95% trifluoroacetic acid at 25°C. The solution was stirred 20 min at 25°C and worked-up as in the above example to yield 1.495 g (97%) of compound **7**, mp 108–110°C after recrystallization from benzene – petroleum ether (30–60°C); ir ($CHCl_3$): 2120, 1782, 1738, 1660, 1615 cm^{-1}. *Anal.* calcd. for $C_{16}H_{16}N_4O_5$: C 55.81, H 4.68, N 16.27; found: C 55.77, H 4.72, N 16.17.

Reduction of Compound ***6***

To a solution of 11.16 g (0.0288 mol) of ketone mixture **6** (~1:1) in 100 ml THF (4% H_2O) at 22°C was added 0.450 g (0.0118 mol, 0.047 *N* in hydride) sodium borohydride and the solution was stirred 35 min. To the solution was added 10% HCl to p*H* 4 and the solution was evaporated to dryness. The residue was taken up in ether, washed with 10% HCl and brine, and dried over Na_2SO_4. Evaporation of the filtrate gave 10.0 g of an oil, the nmr spectrum of which indicated that the oil contained ~15% of ketone isomer **2**. Thin layer chromatography of the mixture (on silica gel using φH–EtOAc, 3:2) showed 4 spots at R_f's 0.22, 0.29, 0.44, and 0.51 the first and last of which were minor. The sample was coated on 50 g silica gel and chromatographed on 1 kg silica gel (preequilibrated with 100 ml φH–EtOAc, 3:2) via dry column technique (7) using φH–EtOAc, 3:2 as eluent. The column was eluted, 5 ml fractions being taken. The fractions corresponding to the R_f 0.51 spot (1.33 g) consisted of ketone isomer **2** and benzyl alcohol. The fractions corresponding to the R_f 0.44 spot (4.80 g) consisted of a mixture of alcohols epimeric about the ester —CH linkage, the relative configuration of which about the secondary alcohol was subsequently shown to be as in **8*a***. The yield of mixture **8*a*** was 43%. An intermediate fraction consisting of the spots R_f 0.44 and 0.29 (0.75 g) was collected. Finally, 1.10 g (10%) of crystalline alcohol R_f 0.22 was collected, the configuration of which corresponded to **8*b***. A total of 8 g was eluted from the column.

The ir and nmr spectra of the crystalline alcohol were compatible with a single isomer, **8*b***. The configuration about the secondary alcohol was shown by subsequent reactions although the ester function's relative configuration is unknown. Compound **8*b*** was recrystallized from φH–ether, mp 105–106°C. *Anal.* calcd. for $C_{18}H_{24}N_4O_6$: C 55.38, H 5.68, N 14.38; found: C 55.45, H 5.76, N 14.21. The ir and nmr spectra of **8*a*** were compatible with a mixture of isomeric alcohols. The subsequent reactions of **8*a*** indicate it to have the configuration about the secondary alcohol shown. This mixture was not analyzed but was used as such in the next reaction.

Preparation of ***9a***

To a solution of 4.80 g (0.0123 mol) of **8*a*** in 50 ml

CH_2Cl_2 at 0–5°C was added 2.10 ml (0.015 mol) of TEA followed by 1.77 g (0.0156 mol) of methane sulfonyl chloride in 15 ml CH_2Cl_2 over 15 min. The solution was allowed to stand 5 h at room temperature (~22°C), washed once with 10% HCl once with brine, dried over Na_2SO_4, filtered, and evaporated to yield 5.15 g (89%) of crude mesylate **9***a*. The ir and nmr spectra of **9***a* were compatible with the assigned structure. The oil was used as such in the next step without further purification.

Preparation of **9***b*

To a solution of 370 mg (0.00095 mol) of crystalline alcohol **5***b* in 10 ml CH_2Cl_2 at 0–5°C was added 0.154 ml (0.0011 mol) TEA followed by 0.125 g (0.0011 mol) methane sulfonyl chloride. The solution was allowed to stand 18 h at 22°C, washed with 10% HCl and brine, dried over Na_2SO_4, filtered, and evaporated to yield an oil which crystallized on trituration with ether to give 445 mg (99%) pure mesylate **9***b*. A small sample was recrystallized from benzene–ether, mp 89–90°C. *Anal.* calcd. for $C_{19}H_{24}N_4O_8S$: C 48.71, H 5.16, N 11.96, S 6.84; found: C 48.79, H 5.17, N 11.93, S 6.65.

Hydrolysis of **9***a*

Compound **9***a* (5.15 g, 0.011 mol) was hydrolyzed with 95% trifluoroacetic acid as in the procedure given for the hydrolysis of **4** to yield 3.05 g (65%) of **10***a* contaminated with ~10% **10***b*; ir ($CHCl_3$): 2115, 1780, 1660, 1620 cm^{-1}. The oil was not purified further but was used as such in the next step.

Hydrolysis of **9***b*

From 570 mg (1.21 mmol) of **9***b* was obtained 510 mg (96%) of the enol **10***b* upon hydrolysis with trifluoroacetic acid; ir ($CHCl_3$): 2110, 1781, 1670, 1620 cm^{-1}. The oil was used as such in the subsequent experiment.

Benzyl 1-α,3-Dimethyl-7-β-azido-Δ³-O-2-isocephem-4-carboxylate ***11a***

To a suspension of 0.33 g sodium hydride (55% mineral oil dispersion washed three times with petroleum ether) in 25 ml DMSO was added 3.05 g (0.0072 mol) of enol **10***a*. The solution was stirred for 1 h at 22°C at the end of which time all gas evolution had ceased. To this a solution of 10 ml 10% HCl in 100 ml brine was added with cooling (exothermic). The solution was extracted with 200 ml CH_2Cl_2 in four portions and the extracts washed twice with brine. The extracts were dried over Na_2SO_4 and concentrated to yield an oily residue, which on chromatography on silica gel (20 g) with benzene yielded 900 mg (38%) of crystalline **11**. A sample was recrystallized from ether, mp 121–122°C; ir ($CHCl_3$): 2120, 1782, 1715, 1615 cm^{-1}; uv (EtOH, 3.5 mg/125 ml) λ_{max} 268 nm (ε 11 100). *Anal.* calcd. for $C_{16}H_{16}N_4O_4$: C 58.53, H 4.91, N 17.06; found: C 58.64, H 5.01, N 17.14.

Benzyl 1-β,3-Dimethyl-7-β-azido-Δ³-O-2-isocephem-4-carboxylate ***11b***

To a solution of 852 mg (0.002 mol) enol mesylate **10***b* in 25 ml $CHCl_3$ was added 202 mg (0.002 mol) TEA. The solution was refluxed 3 h and let stand 18 h at 22°C. The solution was washed with 10% HCl and brine, dried over Na_2SO_4, filtered, and evaporated. The residue was filtered through 3 g silica gel with benzene and the eluent evaporated to yield 520 mg (80%) of crystalline **11***b*. A sample was recrystallized from ether, mp 119–120°C; ir ($CHCl_3$): 2115, 1780, 1715, 1613 cm^{-1}; uv (EtOH, 3.4 mg/125 ml) λ_{max} 266 nm (ε 13 900). *Anal.* calcd. for $C_{16}H_{16}N_4O_4$: C 58.53, H 4.91, N 17.06; found: C 58.50, H 4.91, N 17.02.

Benzyl 1-α,3-Dimethyl-7-β-(aminophenoxyacetoyl)-Δ³-O-2-isocephem-4-carboxylate ***13a***

To a solution of 470 mg (0.00143 mol) of **11***a* in 20 ml CH_2Cl_2 was added 0.5 ml TEA. A stream of H_2S gas was bubbled in over 5 min and the solution let stand 30 min at 22°C. The solution was washed with water (100 ml) and $NaHCO_3$ (saturated) (3 × 20 ml portions), dried over Na_2SO_4, and concentrated to give 430 mg (100%) crude amine. The ir and nmr spectra of **12***a* were compatible with the assigned structure. Compound **12***a* was used as such in the next step.

To a solution of the above oil in 25 ml CH_2Cl_2 was added 220 mg (0.00143 mol) phenoxyacetic acid and 360 mg (0.00143 mol) EEDQ. The solution was allowed to stand 18 h at 0–5°C, washed with 10% HCl, dried over Na_2SO_4, and evaporated to yield an oil. The oil was chromatographed on 10 g silica gel using benzene – ethyl acetate (3:2) as eluent to yield 372 mg (59.5%) of **13***a*, mp 120–121°C recrystallized from ether–cyclohexane; ir ($CHCl_3$): 3430, 1778, 1770(s), 1703(s), 1695, 1615, 1604, 1522, 1495 cm^{-1}; uv (EtOH, 1.6 mg/50 ml) λ_{max} 269 (ε 11 100), 275 nm (ε 10 800). *Anal.* calcd. for $C_{24}H_{24}N_2O_6$: C 66.04, H 5.54, N 6.42; found: C 65.87, H 5.57, N 6.40.

Benzyl 1-β,3-Dimethyl-7-β-amino-Δ³-O-2-isocephem-4-carboxylate ***12b***

To a solution of 590 mg (0.0018 mol) of **11***b* in 25 ml CH_2Cl_2 was added 0.5 ml TEA. A stream of H_2S gas was passed through the solution for 2 min. Vigorous nitrogen evolution was observed. The solution was let stand 10 min at 22°C and evaporated to dryness. The residue was partitioned between CH_2Cl_2 and 10% HCl. The aqueous layer was neutralized with Na_2CO_3 and extracted into CH_2Cl_2. The extracts were dried and evaporated to yield 392 mg (74%) of a water white oil which crystallized on trituration with ether, mp 96–97°C; ir ($CHCl_3$): 3430, 1770, 1712, 1615 cm^{-1}. *Anal.* calcd. for $C_{16}H_{18}N_2O_4$: C 63.56, H 6.00, N 9.27; found: C 63.40, H 6.05, N 9.31.

Benzyl 1-β,3-Dimethyl-7-β-(aminophenoxyacetoyl)-Δ³-O-2-isocephem-4-carboxylate ***13b***

To a solution of 370 mg (0.00123 mol) of **12***b* in 25 ml CH_2Cl was added 185 mg (0.00123 mol) phenoxyacetic acid and 302 mg (0.00123 mol) EEDQ. The solution was let stand at 25°C and monitored by tlc (silica gel – ether) every 15 min. The reaction was complete in 45 min. After 1 h the solution was washed once with 20 ml 10% HCl, dried over Na_2SO_4, and concentrated to yield 535 mg (100%) crystalline amide **13***b*, mp 129–130°C recrystallized from benzene–cyclohexane; ir ($CHCl_3$): 3440, 1780, 1770, 1715, 1695, 1615, 1600, 1520, 1500 cm^{-1}; uv (EtOH, 1.5 mg/50 ml) λ_{max} 270 (ε 12 300), 275(s) nm (ε 11 600). *Anal.* calcd. for $C_{24}H_{24}N_2O_6$: C 66.04, H 5.54, N 6.42; found: C 66.02, H 5.43, N 6.45.

1-α,3-Dimethyl-7-β-(aminophenoxyacetoyl)-Δ³-O-2-isocephem-4-carboxylic Acid ***14a***

A suspension of 332 mg (0.00076 mol) of **13***a* and 300 mg 20% $Pd(OH)_2/C$ in 40 ml ethyl acetate was shaken under hydrogen at 50 psi for 54 min. The suspension was

filtered through Celite and evaporated. The residue crystallized on trituration with ether. Filtration of the solid gave 220 mg (84%) of **14***a*, mp 220°C (with decomposition) recrystallized from $CHCl_3$; ir ($CHCl_3$): 3440, 1780, 1695, 1600, 1525, 1495 cm^{-1}. *Anal.* calcd. for $C_{17}H_{18}N_2O_6$: C 58.95, H 5.24, N 8.09; found: C 58.85, H 5.32, N 8.01.

1-β,3-Dimethyl-7-β-(aminophenoxyacetoyl)-Δ^3-O-2-isocephem-4-carboxylic Acid ***14b***

A suspension of 500 mg (0.00115 mol) of **13***b* and 400 mg 20% $Pd(OH)_2/C$ in 50 ml ethyl acetate was shaken under hydrogen at 60 psi for 45 min. The suspension was filtered through Celite and evaporated to yield an oily residue which crystallized on trituration with ether to which a few drops of CH_2Cl_2 had been added. Filtration gave 282 mg (73.5%) acid **14***b*, mp 154–155°C (with decomposition) recrystallized from CH_2Cl_2–Et_2O; ir ($CHCl_3$): 3440, 1775, 1695, 1600, 1520, 1495 cm^{-1}. *Anal.* calcd. for $C_{17}H_{18}N_2O_6$: C 58.95, H 5.24, N 8.09; found: C 59.10, H 5.25, N 8.03.

Preparation of ***15***

To a solution of 102 mg (0.3 mmol) of **5** in 2 ml tetrahydrofuran was added 104 mg (0.3 mmol) mercuric acetate in 2 ml of water at 0–5°C. The cooling was removed and the solution stirred at 25°C for 3.5 h. The solution was poured into 30 ml of brine and extracted with chloroform (5 × 15 ml). The extracts were washed with water (10 ml) and brine (25 ml), dried over magnesium sulfate and concentrated to give 115 mg (66%) of an oil which crystallized from chloroform–ether, mp 130–132°C; ir (Nujol): 2110, 1785, 1715, 1600 cm^{-1}. *Anal.* calcd. for $C_{17}H_{17}ClHgN_4O_4$: C 35.36, H 2.96, N 9.70; found: C 35.24, H 3.02, N 9.55.

Nuclear analogs of β-lactam antibiotics. IV. Synthesis of 1-oxo-Δ^3-*O*-2-isocephems[1]

TERRENCE WILLIAM DOYLE,[2] ALAIN MARTEL,[3] AND BING-YU LUH

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received February 16, 1977

TERRENCE WILLIAM DOYLE, ALAIN MARTEL, and BING-YU LUH. Can. J. Chem. **55**, 2708 (1977).

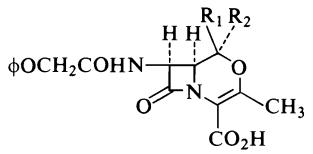
The synthesis of 7-β-phenoxyacetamido-3-methyl-1-oxo-Δ^3-O-2-isocephem-4-carboxylic acid **14** is described. Condensation of amine **2** followed by β-lactam formation and ozonolysis gave the acid **5**. This was converted to its trichloroethyl ester **8** and the ketal was hydrolyzed to give **9**. Reduction of the azido function followed by amide formation gave **11**. The trichloroethyl group was removed and the enol acid **12** closed to yield **13**. Hydrogenolysis of the benzyl ester gave **14**. The structural assignments to the compounds are discussed.

TERRENCE WILLIAM DOYLE, ALAIN MARTEL et BING-YU LUH. Can. J. Chem. **55**, 2708 (1977).

On décrit la synthèse de l'acide phénoxyacétamido-7 β méthyl-3 oxo-1 Δ^3 isocéphem-*O*-2 carboxylique-4 **14**. La condensation de l'amine **2** suivie par la formation d'un β lactame et d'une ozonolyse, conduit à l'acide **5**. Celui-ci peut être transformé en ester trichloroéthylé **8** et le groupement cétal peut être hydrolysé pour conduire à **9**. La réduction du groupe azido, suivie par la formation de l'amide, donne **11**. On a éliminé le groupe trichloroéthyle et on a cyclisé l'anol acide **12** pour fournir **13**. L'hydrogénolyse de l'ester benzylique conduit à **14**. On discute des attributions de structure de ces composés.

[Traduit par le journal]

In the previous paper of this series the syntheses of the 1-α and 1-β isomers of the 1,3-dimethyl-Δ^3-*O*-2-isocephem systems (Fig. 1, wherein R_2 = H, R_1 = Me and R_1 = H, R_2 = Me) were described. In order to further explore the effect of substituents at C_1 on the biological activities of the *O*-2-isocephem system the synthesis of the lactone, 1-oxo-Δ^3-*O*-2-isocephem ($R_1 = R_2 = O$), was examined next.[4] In addition to any purely steric effects of substituting the one position by a carbonyl, considerable enhancement of β-lactam reactivity due both to ring strain and electronic (conjugative) effects is to be expected.



R_1 = H R_2 = CH_3
R_1 = CH_3 R_2 = H
$R_1 = R_2 = O$

FIGURE 1

Condensation of amine **2** (Scheme 1) (3) with a slight excess of furfural gave the Schiff base **3** in quantitative yield. Treatment of compound **3** with an excess of azidoacetyl chloride and triethylamine gave *cis*-β-lactam **4** in 93% yield as a mixture of diastereoisomers.[5] The nmr spectrum of the isomer mixture indicated that no detectable amounts of *trans* isomer had been formed in the cycloaddition. Silica gel chromatography of the mixture using benzene as eluent gave partial separation of the two isomers, the nmr spectra of which are recorded in Table 1.

Ozonolysis of **4** in acetic acid at 20–25°C gave, after work-up, the carboxylic acid **5** as a mixture of diastereoisomers (1:1) in 63.5% yield (9). Hydrolysis of **5** using 95% trifluoroacetic acid gave compound **6** in 94% yield as the enol, as was shown by the singlet in the nmr spectrum at δ 8.90 integrating for one proton. A number of attempts to convert enol acid **6** to the lactone via the mixed anhydride of the acid failed; *e.g.* treatment of **6** with 1 equiv. of triethylamine and either methyl or isobutyl chloroformate gave the methyl and isobutyl esters of **6** respectively, rather than the desired lactone **7**. Attempted ring closure via reaction of the acid with dicyclohexylcarbodiimide in pyridine also failed (4) as

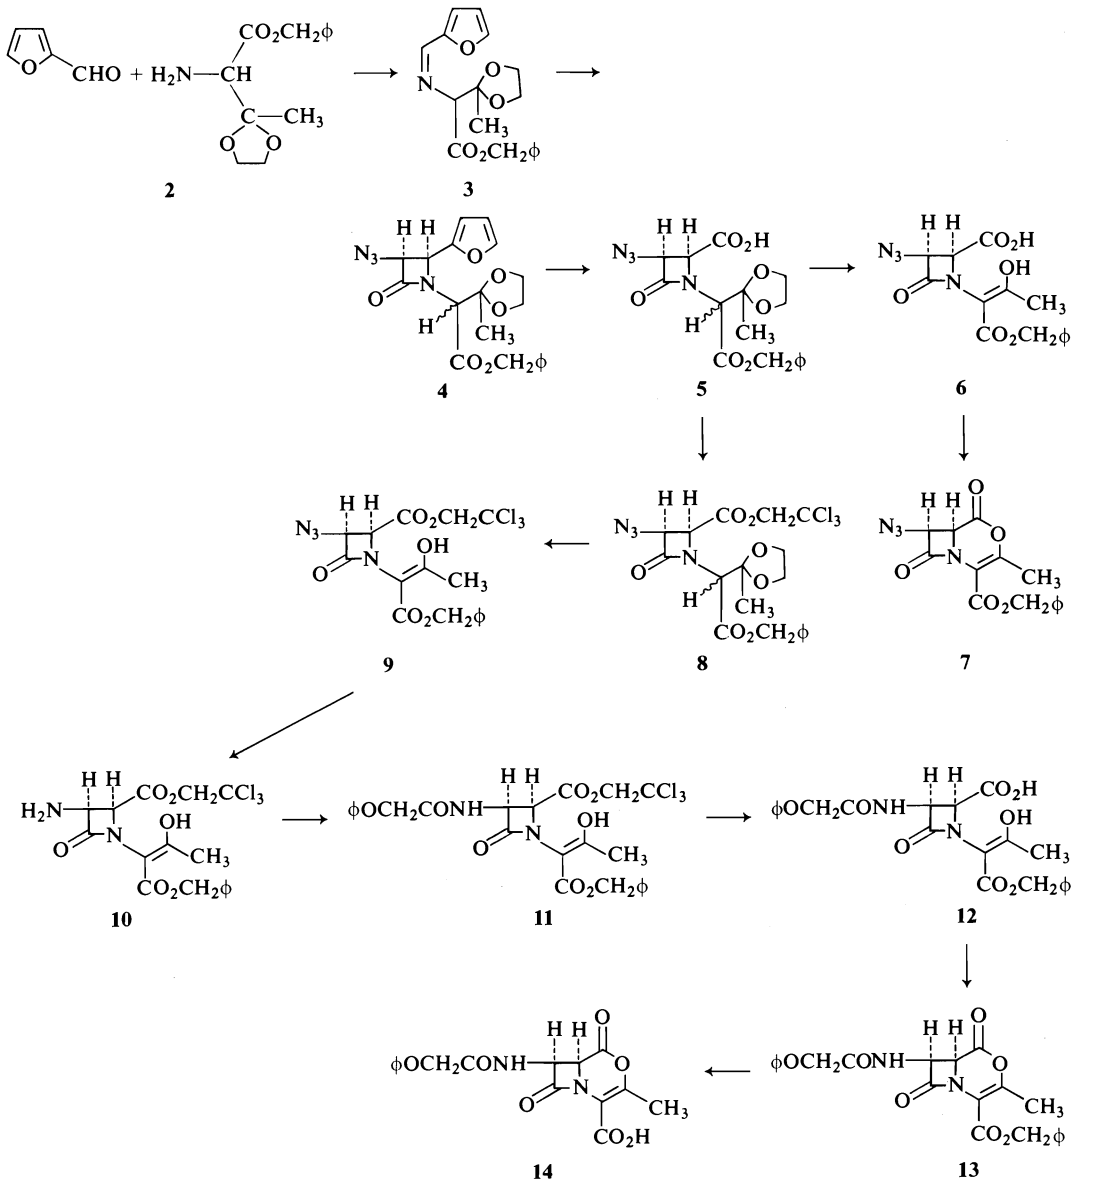
[4]For an explanation of the trivial nomenclature used throughout this series of papers and a review of the literature pertaining to the syntheses of nuclear analogs of β-lactam antibiotics see ref. 2.

[5]While the compounds are illustrated as single entities they are, of course, racemic mixtures.



SCHEME 1

did refluxing **6** in benzene with a catalytic amount of *p*-toluene sulfonic acid. The cyclization of **6** to **7** was finally achieved via conversion of **6** to its acid chloride using thionyl chloride. Treatment of the acid chloride with 1 equiv. of triethylamine gave the desired lactone **7** as an oil. That compound **7** was indeed the lactone was shown by its infrared and nmr spectra. In the ir there were two high frequency carbonyl bands at 1785 and 1800 cm^{-1} which we assign to the lactone and β-lactam, respectively, although these might conceivably be reversed. As a model for the position of the lactone carbonyl resonance we have used the lactone (Fig. 2) 1-dehydro-10-deoxy-7,8-dihydrogenepin. This lactone is reported to have the lactone carbonyl resonance at 1773 cm^{-1} (5). A shift to

higher frequency of 10–12 cm^{-1} for this resonance in compound **7** due to ring strain imparted to **7** by the fused β-lactam would not be unexpected. Similarly the β-lactam carbonyl resonance would be expected to be shifted to higher frequency than in the parent *O*-2-isocephem. We have previously reported (3) the β-lactam carbonyl resonance in the parent system to come at 1780 cm^{-1}. The shift to 1800 cm^{-1} with the substitution of the polar carbonyl group for the methylene at C_1 is as would be expected on the basis of electronic and steric grounds.[6] The nmr spectrum of compound **7** showed doublets at 5.22 and 4.25 δ (J = 5.0 Hz) which we assign to H_7 and H_6, respectively. The coupling constant of 5 Hz is diagnostic of *cis* stereochemistry (6). Examination of the data in Table 1 shows that the proton α to the azido function underwent a shift of +0.38 δ on ring closure (compare **6** and **7**). Similar shifts to lower fields were observed for the proton α to

[6]For a discussion of factors influencing β-lactam carbonyl resonance positions see ref. 7.

TABLE 2. Chemical shift changes for N_3—C*H* upon ring closure[a]

[a]All spectra were recorded in $CDCl_3$ at 60 MHz using TMS as an internal standard.

the azido function upon ring closure in our earlier work (Table 2).

Compound **7** proved to be somewhat unstable, extensive decomposition occurring upon standing at ambient temperature for a week. Attempts were made to reduce the azido function in **7** to no avail; instead polymerization occurred. In view of these problems it was decided to couple the eventual 7-side chain prior to ring closure.

Treatment of **5** with thionyl chloride gave the corresponding acid chloride which was then converted to its 2,2,2-trichloroethyl ester as a mixture of diastereoisomers. The yield of **8** from **5** was 99%. Hydrolysis of the ketal gave the enol **9** as a crystalline solid in 89% yield. The reduction of the azido function in **9** was carried out using hydrogen sulfide – triethylamine. In view of the potential amphoteric nature of the amino compound **10** only catalytic amounts of the base were used along with extended reaction times (2). The crude amine **10** was coupled to phenoxyacetic acid using *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) (7) to give the amide **11** in 70% overall yield from **9**. Cleavage of the 2,2,2-trichloroethyl ester **11** using zinc in acetic acid gave **12** as a crystalline solid in quantitative yield (8). The conversion of enol acid **12** to the lactone **13** proceeded in 63% yield via the acid chloride. In view of the instability demonstrated by **7**, compound **13** was characterized by its ir and nmr spectrum and its subsequent conversion to **14**. Hydrogenolysis of the benzyl ester in **13** using 20% $Pd(OH)_2/C$ in ethyl acetate gave the acid **14** in 56% yield as a crystalline solid. The structure of **14** was shown via its ir, nmr, and uv spectra.

As was expected compound **14** showed enhanced β-lactam reactivity as was indicated by the high β-lactam carbonyl at 1800 cm^{-1}. This could also be seen from the uv spectrum in ethanol. The characteristic bands at 268 (ε 5500) and 275 nm (ε 5300) disappeared rapidly with time indicating a half life of approximately 1 h for **14** in ethanol. That the decomposition of **14** did not involve primary lactone ring opening was shown by the fact that appearance of a uv absorption at 257–262 nm did not occur concomitantly with loss of the absorptions at 268 and 273 nm as would have been expected if **14** were decomposing by lactone ring opening.

The nmr spectrum of **14** was also in accord with assigned structure (Table 1).

Experimental

The infrared spectra were recorded on a Unicam SP-200G grating ir spectrophotometer. The uv spectra were determined on a Unicam SP-800 uv spectrophotometer. The nmr spectra were determined on a Varian A60-A spectrometer using tetramethylsilane as an internal standard. Melting points are uncorrected except where noted and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, IL.

cis-N-(α-Carbobenzyloxy-β,β-ethyleneketalpropyl)-3-azido-4(-2'-furyl)-2-azetidinone ***4***

A. Preparation of Schiff Base

A mixture of 28.0 g (0.113 mol) of amine **2** and 11.6 g (0.12 mol) furfural in 150 ml methylene chloride was boiled at reflux for 5 min. After the initial reflux period, 500 ml of methylene chloride was distilled (with the simultaneous addition of 500 ml methylene chloride) over 1.5 h (azeotrope with water). The residue was dried over Na_2SO_4, filtered, and evaporated to dryness. The oil was heated at 40°C at 0.1 Torr pressure. The solid residue was used in the next step without further purification. The

nmr spectrum of **3** indicated that Schiff base formation was quantitative; ir ($CHCl_3$): 1743, 1643, 1495 cm^{-1}.

B. β-Lactam Formation

A solution of Schiff base (0.113 mol) in 300 ml methylene chloride was cooled to 0–5°C in an ice bath. To this was added 13.3 g (0.131 mol) TEA. A solution of 14.4 g (0.12 mol) azidoacetyl chloride in 100 ml methylene chloride was added over 1 h. An aliquot was removed, washed with water, dried over Na_2SO_4, and concentrated. The nmr spectrum of the residual oil indicated that the reaction was incomplete. To the reaction mixture was added a second equivalent of TEA followed by 12.0 g (0.10 mol) azidoacetyl chloride in 100 ml methylene chloride as before. After the addition was complete, the solution was evaporated to near dryness and the residue triturated with 300 ml ether. The TEA hydrochloride was removed by filtration. The filtrate was treated with 2 g activated charcoal, filtered, washed with water (twice) and brine (twice), and dried over Na_2SO_4.

The suspension was filtered and the solvent removed at reduced pressure to yield 42.6 g (93%) of β-lactam **4** as a mixture of diastereoisomers. The material was sufficiently pure to be used as such in the subsequent steps. A small sample was chromatographed on silica gel (deactivated with 15% w/w water) using benzene as an eluent to give a pale yellow oil; ir ($CHCl_3$): 2120, 1775, 1748, 1640, 1625 cm^{-1}. *Anal.* calcd. for $C_{20}H_{20}N_4O_6$: C 58.25, H 4.89, N 13.59; found: C 58.07, H 4.82, N 13.51.

cis-N-(α-Carbobenzyloxy-β,β-ethyleneketalpropyl)-3-azido-2-azetidinone-4-carboxylic Acid ***5***

A solution of 17.0 g (0.0422 mol) β-lactam **4** in 200 ml glacial acetic acid was prepared. A stream of ozone was passed through the solution for 2 h, while maintaining the temperature between 20–25°C. The solution was evaporated at reduced pressure, and the residue taken up in ether and extracted with 10% sodium bicarbonate. The aqueous layer was acidified with 10% hydrochloric acid and extracted several times with ether. The ethereal extracts were dried over Na_2SO_4 and concentrated to give 10.2 g (63.5%) of a heavy oil which crystallized on scratching with a little ether. An analytical sample was recrystallized from ether, mp 114–115°C. This material was a 1:1 mixture of diastereoisomers; ir ($CHCl_3$): 2800–3600, 2120, 1782, 1742 cm^{-1}. *Anal.* calcd. for $C_{17}H_{18}N_4O_7$: C 52.31, H 4.65, N 14.35; found: C 52.29, H 4.74, N 14.62.

Hydrolysis of ***5***

Ketal **5** (3.5 g) was treated with 95% TFA for 0.5 h at room temperature. The mixture was cooled to 0°C and diluted with brine. It was extracted with CH_2Cl_2 (3 × 30 ml). The methylene chloride extracts were combined, washed with brine (2 × 20 ml), dried over Na_2SO_4, and evaporated to give the desired enol **6** in 94% yield (2.9 g); ir ($CHCl_3$): 2500–3600, 2120, 1780, 1745, 1660, 1620 cm^{-1}.

Benzyl 1-Keto-3-methyl-7-β-azido-Δ³-O-2-isocephem-4-carboxylate ***7***

To a solution of 377 mg enol acid **6** in 25 ml dry CH_2Cl_2 at 0–5°C was added dropwise 0.152 ml TEA in 3 ml CH_2Cl_2. The mixture was stirred at room temperature for 60 min, then treated dropwise with a solution of 0.079 ml $SOCl_2$ in 5 ml CH_2Cl_2. It was stirred at 0°C for 1 h and refluxed for 5 h. After cooling to 0°C, 0.152 ml TEA in 10 ml CH_2Cl_2 was added over a 20 min period. The mixture was allowed to warm slowly to room temperature and stirred for 18 h. The solvent was partially evaporated and the residue was diluted with ether. TEA·HCl was removed by filtration and the solvent was evaporated to give the desired lactone in 63% yield (225 mg) as an oil; ir (film): 2120, 1800, 1785, 1725 (s 1715), 1645 cm^{-1}.

2,2,2-Trichloroethyl-cis-N-(α-carbobenzyloxy-β,β-ethyleneketalpropyl)-3-azido-2-azetidinone-4-carboxylate ***8***

A solution of 10.0 g (0.0256 mol) acid **5** and 10 ml thionyl chloride in 200 ml methylene chloride was refluxed 3 h. The solution was evaporated to dryness. The last traces of thionyl chloride were removed by pumping the residue at 0.1 Torr pressure, for 15 min; ir (film): 1790, 1780(s), 1740 cm^{-1}.

The residue was taken up in 200 ml dry methylene chloride and 5.0 g (0.033 mol) trichloroethanol was added at 0–5°C. To this was added a solution of 5 ml TEA in 25 ml methylene chloride over 0.5 h. The reaction was allowed to stand 60 h at 0–5°C, washed twice with 10% HCl and twice with 10% $NaHCO_3$ brine, and dried over Na_2SO_4. Evaporation of the filtrate gave 13.30 g (99%) of **8** as a mixture of diastereoisomers. An analytical sample was purified by chromatography on silica gel using benzene as the eluent; ir (neat): 2120, 1785 (1770s), 1745 cm^{-1}. *Anal.* calcd. for $C_{19}H_{19}Cl_3N_4O_7$: C 43.74, H 3.67, N 10.74, Cl 20.38; found: C 43.61, H 3.57, N 10.65, Cl 20.24.

Hydrolysis of ***8***

A solution of 13.0 g (0.0249 mol) of ketal **8** in 50 ml of 95% trifluoroacetic acid was let stand 1 h at room temperature. The solution was diluted with 500 ml brine and extracted three times with ether. The organic phase was washed several times with 10% $NaHCO_3$ and once with brine, dried over Na_2SO_4, and evaporated to give 10.60 g (89%) of crystalline enol **9**. An analytical sample was recrystallized from ether, mp 81.5–82.5°C; ir ($CHCl_3$): 2120, 1780, 1663, 1618 cm^{-1}; uv (EtOH) λ_{max} 258 nm (ε 5800). *Anal.* calcd. for $C_{17}H_{15}Cl_3N_4O_6$: C 42.74, H 3.16, N 11.73, Cl 22.27; found: C 42.61, H 3.07, N 11.89, Cl 22.09.

Preparation of ***11***

A. Azide Reduction

A solution of 2.46 g (0.00515 mol) of azide **9** in dry CH_2Cl_2 (50 ml) was treated with a stream of H_2S gas for 20 min at 0–5°C. To this was added 3 drops TEA and the mixture was allowed to stand 3 h at room temperature. The above process was repeated and the mixture allowed to stand an additional 3 h. The solution was evaporated to give an oil which showed no azide absorption in the ir and exhibited an absorption band for NH_2; ir (neat) 3340, 1770(b), 1660, 1615.

B. Side Chain Coupling

To the crude amine in 50 ml CH_2Cl_2 was added 0.88 g (0.0058 mol) phenoxyacetic acid and 1.40 g (0.0057 mol) EEDQ at 0–5°C. The solution was allowed to stand 16 h at 4°C, washed once with 10% HCl, 10% $NaHCO_3$, and brine, and dried over Na_2SO_4. The residue obtained on evaporation of the solvent was chromatographed on

silica gel (20 g, 15% w/w, water) using benzene as eluent to give 2.18 g (70%) of amide **11**; mp 140–140.5°C recrystallized from ether; uv (EtOH), λ_{max} 222 (ε 8900), 262 nm (ε 10 000); ir ($CHCl_3$): 3410, 1780, 1770s, 1695, 1663, 1620, 1600, 1530, 1500 cm^{-1}. *Anal.* calcd. for $C_{25}H_{23}Cl_3N_2O_8$: C 51.26, H 3.96, N 4.78, Cl 18.16; found: C 51.03, H 3.92, N 4.71, Cl 18.06.

Preparation of ***12***

To a solution of 200 mg (0.352 mmol) of **11** in 10 ml of 90% acetic acid was added 1 g activated zinc dust at 5°C. The suspension was stirred 4 h, filtered through Celite, and diluted with 40 ml ether. The solution was washed seven times with 10 ml portions of brine and dried over Na_2SO_4. Evaporation gave 170 mg (100%) of crystalline **12**. An analytical sample was recrystallized from acetone–ether; mp 142–143°C; uv (EtOH) λ_{max} 219 (ε 8500) 257 nm (ε 7400); ir ($CHCl_3$): 3410, 3600–2500, 1780 (s 1770), 1745, 1695, 1665, 1620, 1605, 1535, 1500 cm^{-1}. *Anal.* calcd. for $C_{23}H_{22}N_2O_8$: C 60.79, H 4.88, N 6.16; found: C 60.54, H 4.85, N 6.10.

Benzyl 1-Keto-3-methyl-7-(β-phenoxyacetamido)-Δ³-O-2-isocephem-4-carboxylate ***13***

To a solution of 380 mg (0.838 mmol) enol acid **12** in 80 ml dry CH_2Cl_2 was added 80 mg (0.802 mmol) TEA at 0°C. The solution was let stand 1 h. A solution of 0.12 ml (1.676 mmol) thionyl chloride in 3 ml CH_2Cl_2 was added dropwise over 15 min. The solution was stirred 2 h at 0°C then refluxed 15 min. The solution was cooled to 0°C and a solution of 0.140 ml (1.0 mmol) TEA in 5 ml CH_2Cl_2 was added dropwise over 20–30 min until the color of the solution darkened. The solution was stirred 17 h at room temperature, partially evaporated to 5–10 ml volume, and diluted with 50 ml dry ether. The suspension was stirred 15 min with 200 mg charcoal, filtered through Celite, and evaporated to yield an oily residue. The residue was chromatographed on silica gel (activity I) (200 mg) using dry CH_2Cl_2 as eluent to yield 230 mg (63.3%) of lactone **13** as an oil. No further attempts to purify **13** were made and it was used as such in the next step; ir ($CHCl_3$): 3410, 1805, 1790, 1725, 1690, 1650, 1609, 1525, 1495 cm^{-1}.

1-Keto-3-methyl-7-(β-phenoxyacetamido)-Δ³-O-2-isocephem-4-carboxylic Acid ***14***

Compound **13** (230 mg, 0.528 mmol) and 400 mg 20% $Pd(OH)_2/C$ in 50 ml ethyl acetate were shaken under H_2 for 45 min at 50 psi. The suspension was filtered through Celite and evaporated to dryness. The residue crystallized from CH_2Cl_2–Et_2O (1:1) to yield 100 mg (56%) of acid **14**. An analytical sample was recrystallized from acetone–ether, mp 161–161.5°C; uv (EtOH) λ_{max} 268 (ε 5500), 275 nm (ε 5300); ir (Nujol): 3360, 1800, 1785, 1705, 1690, 1625, 1598, 1515, 1495 cm^{-1}. *Anal.* calcd. for $C_{16}H_{14}N_2O_7$: C 55.49, H 4.08, N 8.09; found: C 55.58, H 4.09, N 8.20.

Nuclear analogs of β-lactam antibiotics. V. Synthesis of a benzo[3,4]-*O*-2-isocephem[1]

TERRENCE WILLIAM DOYLE[2]

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received February 16, 1977

TERRENCE WILLIAM DOYLE. Can. J. Chem. **55**, 2714 (1977).

The synthesis of 7-β-phenoxyacetamido-4′-hydroxybenzo[3,4]-*O*-2-isocephem **14** is described. Condensation of **5** with cinnamaldehyde gave **6** which was converted to the 3-azido-4-styrrylazetidinone **7**. Ozonolysis and reduction of the resulting aldehyde **8** gave **9**. Compound **9** was converted to the mesylate **12** by reduction of the azide to the amine **10**, coupling of **10** with phenoxyacetic acid to give **11**, and mesylation of **11**. Removal of the benzyl groups of **12** by hydrogenolysis and base catalyzed ring closure of the phenol gave **14**.

TERRENCE WILLIAM DOYLE. Can. J. Chem. **55**, 2714 (1977).

On décrit la synthèse du phénoxyacétamido-7 β hydroxy-4′ benzo[3,4]isocéphem-*O*-2 **14**. La condensation de **5** avec le cinnamaldéhyde conduit à **6** qui peut être transformé en azido-3 styrryl-4 azétidinone **7**. L'ozonolyse et la réduction de l'aldéhyde **8** qui en résulte donne **9**. On peut tranformer le composé **9** en son mésylate **12** par réduction de l'azide conduisant à l'amine **10**, le couplage de **10** avec l'acide phénoxyacétique qui donne **11** et par mésylation de **11**. L'enlèvement des groupes benzyles de **12** par hydrogénolyse et la cyclisation, catalysée par les bases du phénol conduit à **14**.

[Traduit par le journal]

The previous papers of this series have described the syntheses of a number of *O*-2-isocephem systems (Fig. 1). In order to further explore structure activity relationships in this series the synthesis of a [3,4]benzo fused cephalosporin analog was carried out.[3]

FIGURE 1

Thus nitration of dibenzylhydroquinone **3** according to the procedure of Burton and Praill (3) gave the desired nitro derivative **4** in 98% yield. Reduction of the nitro group to the amine was accomplished in 93% yield using aluminum amalgam in tetrahydrofuran. The efficient conversion of the amine **5** to the Schiff base **6** required the use of a sixfold excess of cinnamaldehyde. Trituration of the reaction mixture with petroleum ether induced crystallization of the Schiff base and led to recovery of the excess aldehyde. The yield of compound **6** was 80%.

Treatment of Schiff base **6** with azidoacetyl chloride in the presence of triethylamine gave **7** in 70% yield. The nmr spectrum of **7** did not permit an assignment of stereochemistry due to overlap of the signals of the protons on the azetidinone. The assignment of *cis* stereochemistry was made retrospectively. Thus ozonolysis of compound **7** followed by treatment of the ozonide with dimethyl sulfide gave the aldehyde **8** as a crystalline solid in 60% yield. Compound **8** had carbonyl bands in the infrared spectrum at 1770 and 1740 cm^{-1}. The nmr spectrum of **8** (Table 1) indicated the stereochemistry of the 3-azido and 4-formyl functions to be *cis* inasmuch as the proton α to the azido function appeared as a doublet with a coupling constant of 6 Hz (4). By inference, therefore, the stereochemistry of compound **7** was also *cis*.

Compound **9** was prepared directly from compound **7** without isolation of the intermediate aldehyde **8**. Ozonolysis of **7** in methylene chloride – methanol followed by removal of the solvent, redissolution of the residual oil in ethanol, and reduction using sodium borohydride gave the desired alcohol **9** in 65% overall yield. As we contemplated removal of the benzyl groups by

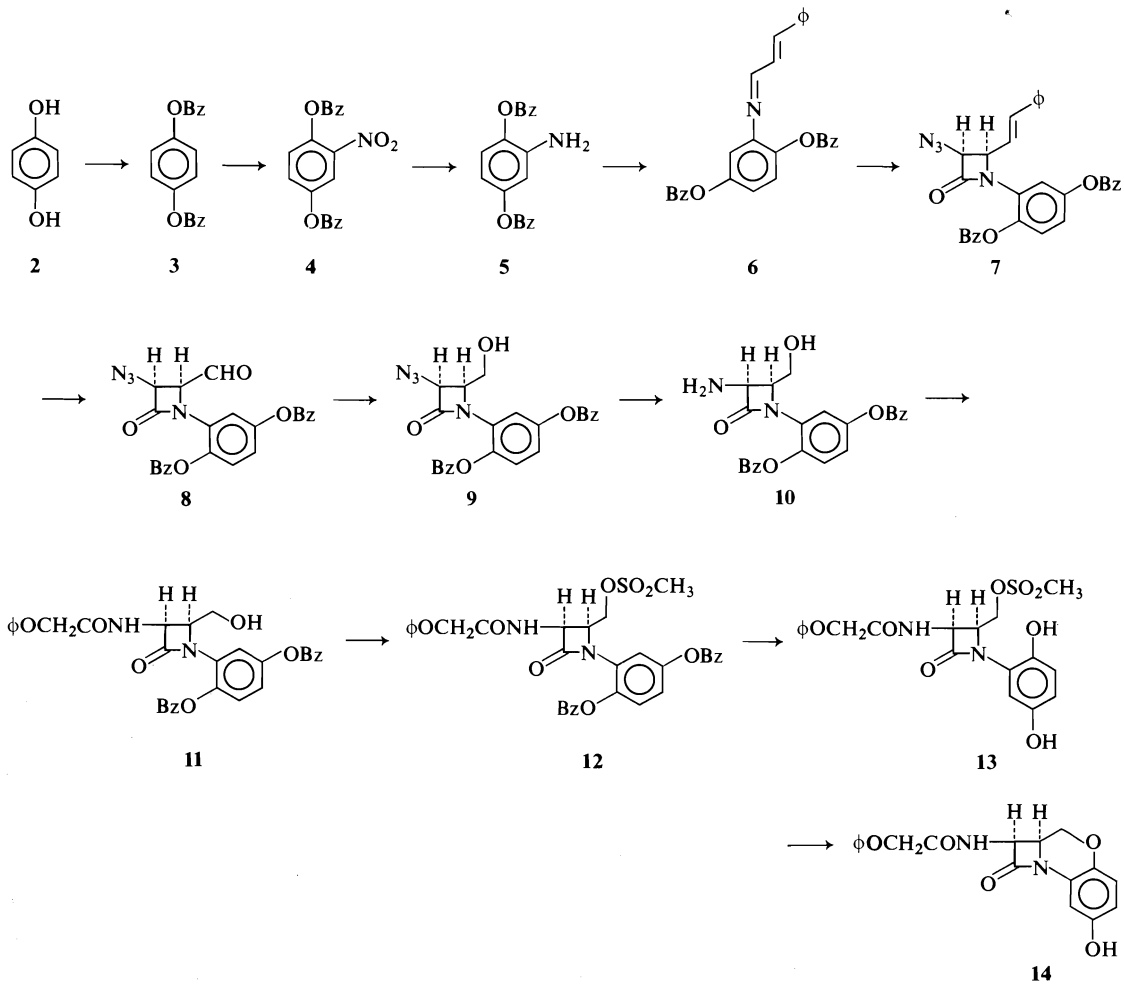
[3]For an explanation of the trivial nomenclature used throughout this series of papers and a review of the literature pertaining to the syntheses of nuclear analogs of β-lactam antibiotics see ref. 2.



SCHEME 1

hydrogenolysis it was decided to introduce the amido side chain at this time. Accordingly the azido function in **9** was reduced using triethylamine – hydrogen sulfide (2) to give the amine **10** in 91.5% yield. Coupling of the amine **10** with phenoxyacetic acid was achieved using *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline(EEDQ) in 65% yield (5). Mesylation of alcohol **11** proceeded in 82% yield to give **12**. Hydrogenolysis of **12** using palladium hydroxide on carbon in acetic acid gave the substituted hydroquinone **13** in 78% yield. Finally treatment of **13** with 1,5-diazobicyclo[4.3.0]non-5-ene (DBN) in dimethyl sulfoxide followed by silica gel chromatography afforded 7-β-phenoxyacetamido-4′-hydroxybenzo[3,4]-*O*-2-isocephem **14** in 47% yield.

Compound **14** was only weakly biologically active.

Experimental

The infrared spectra were recorded on a Unicam SP-200 G grating ir spectrophotometer. The nmr spectra were determined on a Varian A60-A spectrometer using tetramethylsilane as an internal standard. Melting points are uncorrected except where noted and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, IL.

Dibenzyl 2-Nitrohydroquinone **4**

(*A*) To a solution of 110 g hydroquinone (1 mol) and 280 ml benzyl chloride (2.05 mol) in 1 ℓ of ethanol at reflux was added 80 g sodium hydroxide in 600 ml water. Reflux was continued for 4 h and the solution was allowed to stand at 25°C for 18 h. The suspension was filtered and the filter cake washed with benzene. The filtrate was evaporated to a volume of 1 ℓ at reduced pressure and extracted with ether (5 × 100 ml). The extracts were dried over sodium sulfate and concentrated to give a white solid. The combined solids from filtration and ex-

traction were taken up in 1 ℓ of hot benzene and decanted from the residual sodium chloride. The benzene solution was reduced to 800 ml in volume by evaporation at reduced pressure. Following this, the solution was brought to reflux and 300 ml petroleum ether (60–90°C boiling range) added slowly. On cooling white plates crystallized out of solution to give 230 g (68%) pure dibenzyl ether, mp 127.5–128°C (lit. (6) mp 128–129°C).

(*B*) To a suspension of 38.7 g dibenzyl ether **2** (0.1145 mol) in 400 ml glacial acetic acid at 18°C was added 39 ml concentrated nitric acid (sg = 1.42 g/ml) dropwise over 15 min. The temperature was maintained below 20°C with ice cooling.

The solution was stirred 45 min, diluted to 1.5 ℓ with water, and extracted into methylene chloride (5 × 100 ml). The extracts were washed with water (4 × 100 ml), brine (2 × 100 ml), dried over sodium sulfate, filtered, and concentrated to give a yellow solid. The solid was triturated with 200 ml ether and 50 ml petroleum ether (30–60°C boiling range) and filtered to give 43.1 g (98%) of the desired 2-nitro-1,4-dibenzyloxy benzene **4**, mp 81–82.5°C; ir ($CHCl_3$): 1540, 1508, 1463, 1390, 1360 cm^{-1}. *Anal.* calcd. for $C_{20}H_{17}NO_4$: C 71.63, H 5.11, N 4.18; found: C 71.81, H 5.09, N 4.16.

2-Amino-1,4-dibenzyloxybenzene ***5***

Aluminum amalgam was prepared from 14.0 g aluminum foil according to Vogel (see ref. 2). The amalgam was layered with 150 ml tetrahydrofuran and 20.0 g nitro compound **3** (60 mmol) added in 450 ml THF. After an induction period of 20 min, a vigorous reflux ensued which abated somewhat after 30 min. The suspension was stirred an additional hour and filtered. The filtrate was dried over sodium sulfate, filtered, and evaporated to yield 16.6 g (93%) crystalline amine **5** as white plates, mp 101.5–102°C (on trituration with ether); ir ($CHCl_3$): 3460, 3380, 1670, 1680, 1520, 1460, 1387 cm^{-1}. *Anal.* calcd. for $C_{20}H_{19}NO_2$: C 78.66, H 6.27, N 4.59; found: C 78.76, H 6.27, N 4.64.

cis-N-(2′,5′-Dibenzyloxyphenyl)-3-azido-4-styryl-2-azetidinone ***7***

To 46.0 g (151 mmol) crystalline amine **5** dissolved in 500 ml methylene chloride was added 93.0 ml cinnamaldehyde. To this was added 50 g magnesium sulfate (not sodium sulfate!) and the suspension was stirred 1.5 h at 25 °C. The suspension was filtered and the filtrate was evaporated. To the oil was added 1 ℓ petroleum ether (30–60°C) with vigorous stirring in two portions. The layers were separated and the petroleum ether fraction set aside for recovery of the excess cinnamaldehyde. The residue was slurried with petroleum ether (500 ml) which induced crystallization. The suspension was filtered and following pressing of the filter cake it was washed once with 50 ml of petroleum ether – ether (4:1). Pure crystalline Schiff base **6** (45.4 g) was obtained. An additional 5.1 g was obtained from the mother liquors. The combined yield was 80%.

To a solution of 23.5 g (0.0505 mol) of Schiff base **6** in 200 ml dry methylene chloride at −10°C was added 7 ml triethylamine (0.096 mol). To this was added a solution of 6.0 g (0.0504 mol) azidoacetyl chloride in 100 ml methylene chloride dropwise over 30 min. The solution was allowed to come to 25°C over 30 min and evaporated. The residue was taken up in methylene chloride – ether, washed with water (3 × 100 ml), dried over sodium sulfate, and evaporated. The residual oil was taken up in 250 ml benzene and filtered through a pad of silica gel (activity III, 200 g). The residue after evaporation of the filtrate was triturated with 50–100 ml of ether and filtered to give 17.0 g (63.5%) pure **7**, mp 105–106°C. The mother liquors from trituration were chromatographed on silica gel (100 g, activity III) with chloroform as eluent to yield an additional 1.71 g (6.4%) of **7**; ir ($CHCl_3$): 2110, 1760, 1595, 1515 cm^{-1}. *Anal.* calcd. for $C_{31}H_{26}N_4O_3$: C 74.09, H 5.21, N 11.15; found: C 74.28, H 5.29, N 11.13.

cis-N-(2′,5′-Dibenzyloxyphenyl)-3-azido-4-formyl-2-azetidinone ***8***

A solution of 275 mg (0.55 mmol) of **7** in 25 ml methylene chloride was cooled to −78°C in a dry ice – acetone bath and an excess of ozone bubbled in over 3 min. To the solution was added 1 ml dimethyl sulfide. The solution was evaporated to dryness and the residue taken up in 10 ml ether. On standing 18 h at room temperature, the aldehyde crystallized out. Filtration gave 140 mg tan crystals, mp 137–138°C (with decomposition); ir ($CHCl_3$): 2110, 1770, 1740 cm^{-1}. *Anal.* calcd. for $C_{24}H_{20}N_2O_4$: C 67.27, H 4.71, N 13.08; found: C 67.38, H 4.91, N 12.80.

cis-N-(2′,5′-Dibenzyloxyphenyl)-3-azido-4-hydroxymethyl-2-azetidinone ***9***

A solution of 5.38 g (10.7 mmol) of **7** in 50 ml methylene chloride – 2 ml methanol was ozonized at −78°C (excess of ozone). The solution was evaporated to dryness and the residual oil taken up in 100 ml ethanol and cooled to 0–5°C in an ice bath. To this was added 400 mg sodium borohydride. The solution was stirred for 1 h. To the solution was added 10 ml 10% hydrochloric acid. The solution was evaporated to dryness and the residue partitioned between water and methylene chloride. The organic layer was dried over sodium sulfate, filtered, and passed through a pad of silica gel (activity III, 25 g). The filtrate was evaporated and the residual oil triturated with 10 ml ether. Filtration gave 3.0 g (65%) crystalline alcohol, mp 114–115°C, recrystallized from benzene – petroleum ether; ir ($CHCl_3$): 2115, 1760 cm^{-1}. *Anal.* calcd. for $C_{24}H_{22}N_4O_4$: C 66.96, H 5.15, N 13.02; found: C 67.09, H 5.16, N 12.90.

cis-N-(2′,5′-Dibenzyloxyphenyl)-3-amino-4-hydroxymethyl-2-azetidinone ***10***

To a solution of 430 mg (1.0 mmol) azide **9** in 20 ml methylene chloride was added 0.20 ml triethylamine. Hydrogen sulfide gas was passed through this solution for 2 min and a vigorous gas evolution was observed. The orange solution was let stand for 20 min (gas evolution ceased) and then was evaporated to dryness at reduced pressure. The residue was taken up in 50 ml of methylene chloride and washed with water (1 × 50 ml) then brine (2 × 50 ml). The organic layer was dried over sodium sulfate, filtered, and evaporated to yield 370 mg (91.5%) solid amine on trituration with ether, mp 136–137°C; ir ($CHCl_3$): 3400, 1750 cm^{-1}. *Anal.* calcd. for $C_{24}H_{24}N_2O_4$: C 71.27, H 5.98, N 6.93; found: C 70.78, H 6.01, N 6.65.

cis-N-(2′,5′-Dibenzyloxyphenyl)-3-phenoxyacetamido-4-hydroxymethyl-2-azetidinone ***11***

To 370 mg (0.915 mmol) amine **10** in 20 ml methylene chloride was added 139 mg (0.915 mmol) phenoxyacetic acid followed by 226 mg (0.915 mmol) EEDQ. The solu-

tion was let stand for 2 h at 25°C following which it was washed with 10% hydrochloric acid (10 ml), saturated sodium bicarbonate (10 ml), and brine (25 ml). The organic layer was dried over sodium sulfate, filtered, and passed through a pad of silica gel (activity III, 5 g). The solution was evaporated and the residue triturated with ether. Filtration gave 320 mg (65%) of **11**, mp 155–156°C, recrystallized from benzene; ir ($CHCl_3$): 3380, 1760, 1685, 1600, 1520, 1500 cm^{-1}. *Anal.* calcd. for $C_{32}H_{30}N_2O_6$: C 71.36, H 5.61, N 5.20; found: C 71.20, H 5.58, N 5.07.

cis-N-(2′,5′-Dibenzyloxyphenyl)-3-phenoxyacetamido-4-mesyloxymethyl-2-azetidone ***12***

To 2.45 g alcohol **11** (4.55 mmol) in 100 ml methylene chloride was added 0.75 ml TEA. To this 0.40 ml (5.0 mmol) mesyl chloride was added. The solution was allowed to stand 18 h at 25°C. The solution was washed with 10% hydrochloric acid, saturated sodium bicarbonate, and brine. It was dried over sodium sulfate, filtered, and evaporated. The residue was triturated with 15 ml ether and the resulting crystals filtered to yield 2.30 g (82%) of **12**, mp 125–126°C after recrystallization from ethanol; ir ($CHCl_3$): 3420, 1760, 1690, 1600, 1520, 1500 cm^{-1}. *Anal.* calcd. for $C_{33}H_{32}N_2O_8S \cdot H_2O$: C 62.44, H 5.39, N 4.42, S 5.05; found: C 62.10, H 5.04, N 4.35, S 4.80.

cis-N-(2′,5′-Dihydroxyphenyl)-3-phenoxyacetamido-4-mesyloxymethyl-2-azetidinone ***13***

A suspension of 1.70 g (2.76 mmol) dibenzyl ether **12** and 0.50 g 20% Pd $(OH)_2$/C in 50 ml acetic acid was hydrogenated at 25°C and atmospheric pressure for 1 h. The suspension was filtered and evaporated. The residual gum was triturated with ethyl acetate and the crystals filtered to give 0.94 g (78%) of the desired material **13**, mp 155–156°C (with decomposition). *Anal.* calcd. for $C_{19}H_{20}N_2O_8S$: C 52.28, H 4.62, N 6.42, S 7.35; found: C 52.23, H 4.76, N 6.68, S 7.24.

7-β-Phenoxyacetamido-4′-hydroxybenzo[3,4]-O-2-isocephem ***14***

To a solution of 436 mg (1 mmol) of **13** in 5 ml dry dimethyl sulfoxide at 25°C was added 124 mg (1 mmol) 1,5-diazobicyclo[4.3.0]non-5-ene in 1 ml dimethyl sulfoxide. The solution was stirred 1.5 h and diluted to 50 ml with water. The solution was extracted into methylene chloride. The organic phase was washed with brine and dried over sodium sulfate. The residue obtained on evaporation was chromatographed on 5 g silica gel (activity III) using methylene chloride as eluent followed by acetonitrile. The desired material eluted in the methylene chloride fraction. The residue on evaporation was recrystallized from acetonitrile–ether to give 160 mg (47%) of **14**, mp 212–213°C; ir (CH_3CN): 3380, 1780, 1695, 1604, 1540, 1515 cm^{-1}. *Anal.* calcd. for $C_{18}H_{16}N_2O_5$: C 63.52, H 4.73, N 8.23; found: C 63.37, H 4.79, N 8.24.

Nuclear analogs of β-lactam antibiotics. VI. Synthesis of *N*-2-isocephems[1]

TERRENCE WILLIAM DOYLE,[2] BING-YU LUH, DANIEL TIM-WU CHU,[3] AND BERNARD BELLEAU

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received February 16, 1977

TERRENCE WILLIAM DOYLE, BING-YU LUH, DANIEL TIM-WU CHU, and BERNARD BELLEAU. Can. J. Chem. **55**, 2719 (1977).

The syntheses of *N*-methyl and *N*-carboethoxy-7-β-phenoxyacetamido-Δ^3-*N*-2-isocephem-4-carboxylic acids **17***a* and **17***b* are reported. Treatment of aldehyde **3***c* with methylamine followed by reduction of the Schiff base gave **4***d* which was converted to its trifluoroacetamide **5***c*. Acid catalyzed elimination of a mole of ethanol from **5***c*, gave **8***b* which was converted to the enol **10***b* via the vinylogous pyrrolidino amide **9***b*. Reductive removal of the trifluoroacetamide function led to spontaneous ring closure to give **11***b*. Alternatively treatment of bis-mesylate **12***b* with ammonia or methylamine gave **13***a* and **13***b*, respectively. Treatment of **13***b* with sodium hydride in DMSO gave **11***b*. Attempted acylation of **13***a* gave **14**. Reduction of the azido functions in **11***b* and **14** followed by coupling of the amines to phenoxyacetic acid and reductive removal of the benzyl esters gave **17***a* and **17***b*, respectively. The structural assignments are discussed.

TERRENCE WILLIAM DOYLE, BING-YU LUH, DANIEL TIM-WU CHU et BERNARD BELLEAU. Can. J. Chem. **55**, 2719 (1977).

On rapporte la synthèse des acides *N*-méthyl et *N*-carboéthoxy phénoxyacétamido-7 β Δ^3 isocéphem-*N*-2 carboxyliques-4 **17***a* et **17***b*. Le traitement de l'aldéhyde **3***c* avec la méthylamine, suivi par une réduction de la base de Schiff, donne **4***d* qui est transformé en trifluoroacétamide **5***c*. L'élimination acido-catalysée d'une mole d'éthanol de **5***c* donne **8***b* qui est transformé en énol **10***b* par l'intermédiaire de la pyrrolidino amide vinylogue **9***b*. L'enlèvement réducteur de la fonction trifluoroacétamide conduit à la fermeture spontanée de cycle pour donner **11***b*. On peut aussi traiter le bis-mésylate **12***b* avec de l'ammoniac ou de la méthylamine pour obtenir respectivement **13***a* et **13***b*. Le traitement de **13***b* avec de l'hydrure de sodium dans le DMSO donne **11***b*. Lorsque l'on à essayé d'acyler **13***a*, on a obtenu **14**. Les réductions des fonctions azido de **11***b* et **14** suivi par un couplage des amines avec l'acide de phénoxyacétique et l'enlèvement réducteur des groupes benzyles, conduisent respectivement à **17***a* et **17***b*. On discute des attributions de structures.

[Traduit par le journal]

The preceding papers of this series have described the preparation by total synthesis of a number of *O*-2-isocephem systems (1, 2).[4] The high level of antibiotic activity in these systems encouraged us to explore the extension of this work to other systems in which the oxygen atom is replaced by another heteroatom. In this paper we wish to report the synthesis of the *N*-2-isocephem systems **1***h* and **1***i* (Fig. 1).

Our first approach to the syntheses of these compounds involved conversion of the aldehydes **3***a–c* (2*a*, *b*) to the appropriate 4-aminomethyl-2-azetidinones **4** followed by ring closure of these

SCHEME 1

mine followed by reduction gave **4***b* in 55.5% yield. Attempts to prepare the primary amine (R_3 = H) via displacement of the mesylate or tosylates of **2** with azide ion followed by reduction failed.

A number of attempts were made to convert compounds **4***a* and **4***b* to the cyclic enamines **7** by direct hydrolysis of the acetal followed by ring closure. In the case of **4***a* either complete decomposition of starting material occurred with no isolable product being produced or the starting material was recovered unchanged. Treatment of **4***b* with 70% trifluoroacetic acid gave a new product in approximately 10% yield which proved to be very unstable. Attempts to improve the yield or to isolate the material in a pure state led to extensive decomposition. We have tentatively assigned structure **7** to this material based on its ir and nmr spectra. The ir spectrum of **7** showed bands at 2110, 1755, and a weak band at 1620 cm^{-1}. The nmr spectrum of **7** (Table 1) showed the proton α to the azide as a doublet (J = 5.0 Hz). If rupture of the β-lactam had occurred the coupling constant for this proton as well as its chemical shift would be expected to be considerably different. In addition the appearance of a pair of protons in the olefinic region as doublets (J = 6.0 Hz) with loss of the signals in **4***b* for the $CH_2CH(OCH_3)_2$ side chain and a shift of the signal of the benzyl group to lower field are all supportive of the assignment of structure **7** to the compound.

In view of the low yield of **7** from **4***b* an attempt to prepare **7** via an alternate sequence was made. Treatment of **4***b* with trifluoroacetic anhydride gave the trifluoroacetamide **5***a* in 84% yield. Hydrolysis of **5***a* using 90% trifluoroacetic acid gave the aldehyde **6** which proved to be rather unstable. Attempts to prepare **7** via base catalyzed hydrolysis of the trifluoroacetamide in **6** with concommitant ring closure gave only tars. Attempts to introduce functionality at C_4 via enamine condensation reactions of **7** led only to decomposition of **7** with no isolable product being formed.[5] Consequently, this approach was abandoned.

Our second approach was to start with the eventual 4-carboxyl group incorporated into the nitrogen side chain of the azetidinone. As in the case of **4***a* and **4***b* the desired amines **4***c* and **4***d* were prepared via the aldehydes **3***b* and **3***c* (*2a*, *b*). Thus condensation of either **3***b* or **3***c* with methylamine followed by reduction of the Schiff

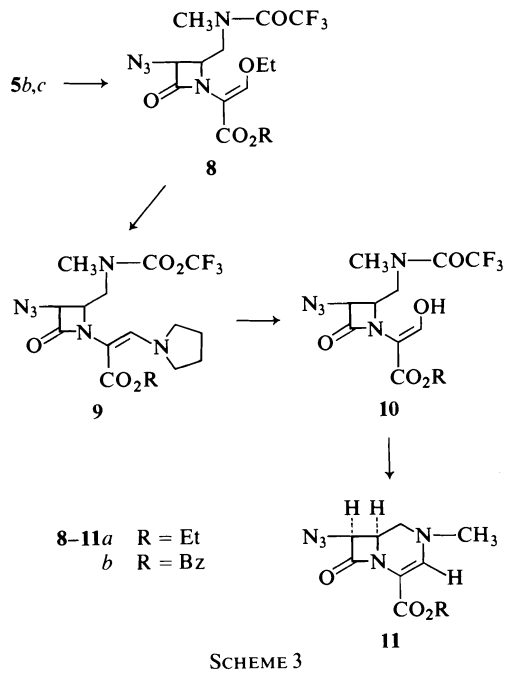
bases **3***f* or **3***g* with sodium borohydride gave **4***c* or **4***d* in 59 and 43% yield, respectively.

Treatment of **4***c* with a suspension of zinc chloride in trifluoroacetic anhydride gave the

[5] *e.g.* The condensation of crude **7** with ethyl chloroformate failed to give any of the 4-carboethoxy-*N*-2-isocephem.



SCHEME 3

amide **8***a* presumably via the acetal **5***b*. The yield of **8***a* from **4***c* was 66.5%. On treatment of **4***d* with zinc chloride – trifluoroacetic anhydride the reaction stopped at the intermediate stage giving **5***c* in 82.5% yield. Prolonged reaction times gave **8***b* from **5***c* in 76% yield.

Our earlier work (2*b*) had shown that the β-ethoxy acrylate system in compounds similar to **8** could be readily converted to the β-hydroxy acrylates via the pyrrolidine derivatives. Thus treatment of **8***a* with pyrrolidine acetate in refluxing benzene gave **9***a* in 97% yield. Similarly **8***b* was converted to **9***b* in 90% yield. Hydrolysis of **9***a* with acetone – 10% hydrochloric acid gave the enol **10***a* in 60% yield. Attempted removal of the *N*-trifluoroacetyl group using the methods of Newman and Wolfrom and Bhat (3) failed, the starting material being recovered unchanged. Accordingly the reductive cleavage of the *N*-trifluoroacetyl group with sodium borohydride according to Weygand was used (4). Treatment of **10***a* with sodium borohydride in ethanol gave **11***a* upon work-up. Similarly hydrolysis of **9***b* to **10***b* (53%) followed by reductive cleavage of the amide gave **11***b*. The yield in this latter case was only 14% and could not be improved upon.

In view of the poor yield of **11***b* and our desire to prepare an analog of **11***b* unsubstituted on the nitrogen atom a third approach to the synthesis of these molecules was made (Scheme 4).

We had available to us a number of useful intermediates from our earlier work (2*b*). The enol mesylate **12***c* was converted to the bismesylate **12***b* in 81% yield by treatment with mesyl chloride and triethylamine. Alternatively **12***b* could be prepared in 80% yield from the diol **12***a* by the same procedure. Treatment of **12***b* with ammonia in dimethyl sulfoxide gave the amine **13***a* in 92% yield. Alternatively compound **13***a* could be prepared from **12***d* (2*b*) by treatment with ammonium acetate in chloroform in 57% yield. The nmr spectrum of **13***a* indicated it to consist of a single isomer the geometry of which has not been determined. Treatment of **12***d* with monomethyl ammonium acetate in benzene gave **13***b* in 81% yield as a mixture of geometrical isomers in the ratio of ~1:1. The isomers were separated by silica gel chromatography. We have tentatively made assignments to each of these isomers on the basis of their spectral characteristics. A comparison of the positions of the vinyl and amino protons between **13***a* and isomer 2 of **13***b* indicate that these compounds very likely have the same configuration.[6] We have assigned the configurations shown in Fig. 2 to each of these isomers of **13***b* on the basis of the following evidence. In the nmr spectra of isomer 1 the vinyl proton appears at δ 6.96 while the nitrogen proton is at δ 7.69. In contrast the vinyl protons of **13***b* isomer 2 and **13***a* appear at δ 7.40 and 7.54, respectively, while the nitrogen protons appear at δ 5.68 and 5.52 respectively. One would predict that the vinyl proton in the *Z* configuration would appear at higher field than that in the *E* configuration. In addition, one would also predict that the nitrogen protons in the *Z* configuration would appear at lower field than those in the *E* configuration (5). Thus, compounds **13***a* and **13***b* isomer 2 are assigned the *E* configuration while **13***b* isomer 1 is assigned the *Z* configuration. The ir spectra of compounds **13***a* and the 2 isomers of **13***b* support this assignment. While **13***a* and isomer 2 of **13***b* show both free and hydrogen bonded NH bands (at 3500 and 3330 cm^{-1} for **13***a* and at 3415 and 3335 cm^{-1} for isomer 2 of **13***b*) isomer 1 of **13***b* exhibited only hydrogen bonded NH bands in the ir (at 3340 cm^{-1}).

[6]The terms isomer 1 and isomer 2 with reference to **13***b* indicate their order of elution from a silica gel column.

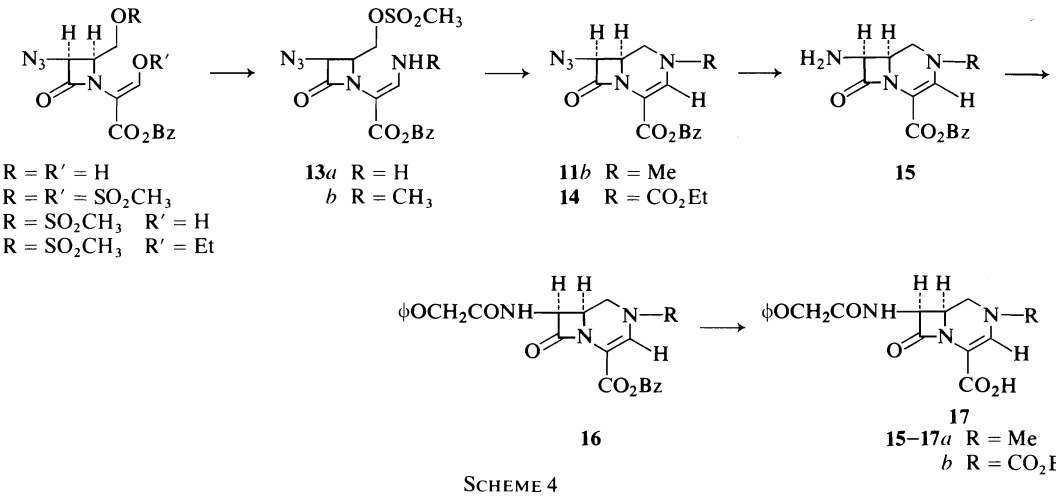
Treatment of **13***b* (as a 1:1 mixture of isomers) with sodium hydride in dimethyl sulfoxide gave **11***b* in 7.65% yield after chromatography. In a second experiment the yield was 16.7%. The material obtained by this method was identical in all respects with that obtained earlier. All attempts to improve the yields beyond the low levels reported failed. An attempt to ring close **13***a* to give the corresponding *N*-demethyl *N*-2-isocephems also failed.

In order to increase the acidity of the NH bond and presumably improve the chances of obtaining the ring closure an attempt was made to acylate **13***a* with ethyl chloroformate and triethylamine in chloroform. The only isolable product proved to be the *N*-carboethoxy *N*-2-isocephem **14** which was formed in 26.8% yield.

Presumably compound **14** arose via formation of the intermediate urethane and subsequent ring closure of this urethane to **14** (Fig. 3). Attempts to isolate the intermediate have failed.

The structures of compounds **11***a*, **11***b*, and **14** were assigned on the basis of their mode of preparation, elemental analyses, and spectral characteristics. Formation of **11***b* from both **10***b* and **13***b*, the shift of the proton α to the azido group from δ ~4.90 to 5.10, and the bathochromic shift in the uv from 280 to 307 nm on ring closure establish the structure of **11***b* as benzyl *N*-methyl-7-β-azido-*N*-2-isocephem-4-carboxylate. Earlier we have shown in the case of the *O*-2-isocephems that ring closure invariably led to a shift of from 20–50 Hz to lower field for the proton α to the azido function (2*d*).



12*a* R = R′ = H
b R = R′ = SO_2CH_3
c R = SO_2CH_3 R′ = H
d R = SO_2CH_3 R′ = Et

13*a* R = H
b R = CH_3

11*b* R = Me
14 R = CO_2Et

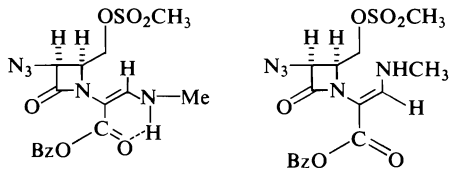
17
15–17*a* R = Me
b R = CO_2Et

SCHEME 4

Similarly ring closure leads to a bathochromic shift of ~30 nm in the *O*-2-isocephem series (2*b*). While the nmr spectra of **11***a* and **11***b* do not permit a conformational assignment to the *N*-2-isocephem ring system (due to overlap of the C_1 and C_6 protons), the nmr spectrum of **14** was first order and permits one to assign the 'A'



Z configuration *E* configuration

13*b*

FIGURE 2

conformation to this molecule (Fig. 4). The pattern of coupling constants for $C_{1\alpha}$, and $C_{1\beta}$ and C_6 protons (Table 1) is consistent with that predicted from the Karplus relationship for conformer A (6).[7]

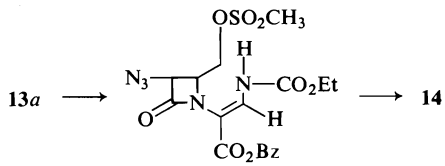


FIGURE 3

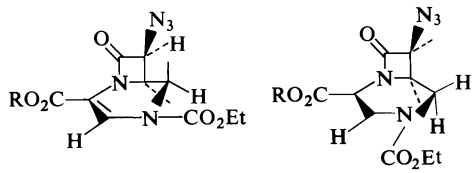
The conversion of **11***b* to the appropriately substituted cephalosporin analog was carried out in the following manner. Reduction of the azido group in **11***b* was accomplished using 10% palladium-on-carbon as catalyst. This gave **15***a* in 76% yield. The amine was converted to the phenoxyacetamide **16***a* using *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDG) and phenoxyacetic acid in 60.5% yield. On reduction of **16***a* with 20% palladium hydroxide on carbon there was obtained a 36% yield of **17***a* as an unstable solid. The spectral characteristics of **17***a* were in accord with the assigned structure. Attempts to purify **17***a* led to decomposition The sample was screened for antibiotic activity as such even though it was estimated (by the extinction coefficient of the band at 308 nm) to be only 30–40% pure. The compound exhibited only a low order of antibiotic activity.

The conversion of **14** to **17***b* was carried out analogously. Thus reduction of the azide gave **15***b* in 90% yield. Coupling of **15***b* with phenoxyacetic acid using EEDQ gave the amide **16***b* as an oil in 37% yield after chromatography. Reduction of **16***b* using 20% palladium hydroxide on carbon gave **17***b* as a solid in 58% yield. Compound **17***b* proved to be relatively stable, nevertheless attempts to recrystallize **17***b* to obtain a sharp melting solid failed. The ir, nmr, and uv spectra of **17***b* were in accord with the assigned structure. Compound **17***b* was active as an antibiotic. Details of the antibiotic spectrum will be published separately.



A B

FIGURE 4

[7]For a detailed assignment in the case of the *O*-2-isocephem systems see refs. 2*b* and 2*c*.

The instability of compounds **17***a* and **17***b* (to a lesser extent) may be due to a greater tendency towards decarboxylation inasmuch as these compounds are vinylogous carbamates.

Experimental

The infrared spectra were recorded on a Unicam SP-200G grating, ir spectrometer. The nmr spectra were determined on a Varian A60-A spectrometer using tetramethylsilane as an internal standard. Melting points are uncorrected and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, IL.

cis-N-(β,β-Dimethoxyethyl)-3-azido-4-anilinomethyl-2-azetidinone **4***a*

To a solution of 400 mg (1.75 mmol) of **3***a* in 20 ml benzene was added 0.5 ml of aniline. The solution was boiled at reflux and the water formed in the reaction was collected in a Dean–Stark trap. After 2.5 h the solution was evaporated to dryness to yield **3***d* as an oil. The oil was taken up in 15 ml of dioxane and 200 mg sodium borohydride added at 15°C. The solution was stirred for 1 h and an aqueous ammonium chloride solution was added. The solution was partitioned between water and methylene chloride and the methylene chloride was dried over sodium sulfate. Evaporation of the organic extracts gave an oil which was chromatographed on 10 g alumina (activity III) with chloroform as eluent. There was obtained 287 mg (49.5%) of an oil which crystallized on standing, mp 54.5°C; ir ($CHCl_3$): 3420, 2120, 1765, 1601 cm^{-1}. *Anal.* calcd. for $C_{14}H_{19}N_5O_3$: C 55.07, H 6.27, N 22.94; found: C 55.13, H 6.30, N 23.02.

cis-N-(β,β-Dimethoxyethyl)-3-azido-4-benzylamino-methyl-2-azetidinone **4***b*

In a manner analogous to that given for **4***a* treatment of **3***a* (300 mg, 1.31 mmol) with benzylamine (0.30 ml) followed by reduction of the intermediate **3***e* with sodium borohydride (100 mg) gave 244 mg (55.5%) of **4***b* after chromatography; ir (neat): 2120, 1710 cm^{-1}. *Anal.* calcd. for $C_{15}H_{21}N_5O_3$: C 56.42, H 6.62, N 21.94; found: C 56.26, H 6.65, N 21.75.

Preparation of **5***a*

A solution of 82 mg (0.257 mmol) of **4***b* in 1.5 ml trifluoroacetic anhydride was let stand 15 min at room temperature. The excess trifluoroacetic anhydride was removed at reduced pressure to give 95 mg of crude amide. The amide was filtered through a pad of alumina (activity III) in CH_2Cl_2 and evaporated to yield 90 mg of **5***a* as an oil; ir ($CHCl_3$): 3520, 3420, 2120, 1780, 1770 1700 cm^{-1}. *Anal.* calcd. for $C_{17}H_{20}F_3N_5O_4$: C 49.17, H 4.85, N 16.86, F 13.72; found: C 48.68, H 4.71, N 16.73, F 13.82.

cis-N-(α-Carboethoxy-β,β-diethoxyethyl)-3-azido-4-methylaminomethyl-2-azetidinone **4***c*

A mixture of 11.5 g (34.6 mmol) of **3***b* and 120 mmol of anhydrous methylamine in 60 ml benzene was stirred 18 h over 10 g magnesium sulfate. The suspension was filtered and evaporated to dryness to yield 12.4 g of crude **3***f* as an oil.

The crude Schiff base was taken up in 50 ml absolute ethanol and 1.31 g sodium borohydride added. The solution was stirred for 0–5 h at 0.5°C followed by 0.5 h at 25°C. To this was added 10 ml 10% hydrochloric acid, following which the solvent was evaporated at reduced pressure. The oily aqueous residue was adjusted to pH 8 with sodium bicarbonate and extracted with chloroform (5 × 25 ml). The extracts were dried (sodium sulfate) and evaporated to give an oil which was chromatographed on 100 g alumina (activity III) using chloroform as the eluting solvent. A total of 7.1 g (59%) of the desired **4***c* was obtained as an oil; ir ($CHCl_3$): 2120, 1770 cm^{-1}. *Anal.* calcd. for $C_{14}H_{25}N_5O_5$: C 48.97, H 7.33, N 20.40; found: C 49.50, H 7.03, N 21.70.

cis-N-(α-Carbobenzoxy-β,β-diethoxy)-3-azido-4-methylaminomethyl-2-azetidinone **4***d*

A mixture of 4.0 g (10.02 mmol) crude compound **3***c* and 80 mmol anhydrous methylamine in 80 ml dry benzene was stirred with 10 g anhydrous magnesium sulfate at 25°C for 2 h. The drying agent was removed by filtration and the filtrate was evaporated to dryness to yield 4.0 g (98%) crude Schiff base, **3***g*. To a solution of 4.0 g (9.8 mmol) of **3***g* in 50 ml absolute ethanol at 0–5°C was added 500 mg (13.13 mmol) sodium borohydride. The solution was stirred 1 h and acidified to p*H* 4 with 10% HCl. The solution was then adjusted to p*H* 8 with saturated sodium bicarbonate and solid sodium chloride added to saturation. The solution was extracted with chloroform (3 × 30 ml). The chloroform extracts were washed with brine, dried over $MgSO_4$, filtered, and evaporated to give 3.7 g of an oil which was chromatographed on 80 g silica gel (15% water) with chloroform then chloroform – 5% methanol as eluent to yield 600 mg of pure amine **4***d* (15%); ir ($CHCl_3$): 2120, 1770 cm^{-1}. An additional 1.4 g of amine contaminated with an unidentified impurity was also obtained. This material contained ~80% of **4***d*. The total yield was 43%.

Preparation of **8***a*

A suspension of 2.45 g (7.4 mmol) of **4***c* and 1.2 g zinc chloride in 10 ml trifluoroacetic anhydride was refluxed for 1 h. The solvent was removed at reduced pressure and the residual oil taken up in chloroform (40 ml). The solution was washed with water (10 ml) and brine (3 × 20 ml) and the organic phase was dried (sodium sulfate) and evaporated. The residue was filtered through a pad of Florisil (5 g) and the filtrate (CH_2Cl_2 solution) evaporated to give 1.9 g (66.5%) of **8***a* as an oil; ir ($CHCl_3$): 2110, 1777, 1698, 1647 cm^{-1}.

Preparation of **8***b*

Upon treatment of 600 mg (1.46 mmol) of **4***d* with 0.245 g zinc chloride in 8 ml trifluoroacetic anhydride as in the above example there was obtained 618 mg (82.5%) of **5***c*; ir ($CHCl_3$): 2110, 1770, 1695 cm^{-1}.

The oil was taken up in 6 ml trifluoroacetic anhydride and treated with 310 mg zinc chloride for an additional 72 h at 25°C. Work-up as in the previous example and chromatography of the resultant oil gave 427 mg (76%) of **8***b* as an oil; ir ($CHCl_3$): 2120, 1780, 1700, 1645 cm^{-1}. *Anal.* calcd. for $C_{19}H_{20}F_3N_5O_5$: C 50.11, H 4.43, N 15.38; found: C 49.74, H 4.47, N 14.98.

Preparation of **9***a*

A solution of 1.45 g (3.75 mmol) of **8***a*, 293 mg (4.13 mmol) pyrrolidine and 248 mg (4.13 mmol) acetic acid in 30 ml benzene was refluxed for 18 h. The solution was washed with water (25 ml) and brine (25 ml) and dried over magnesium sulfate. On evaporation there

was obtained 1.50 g of **9***a* (97%) as an oil; ir ($CHCl_3$): 2400, 2110, 1770, 1695, 1630, 1610 cm^{-1}.

Preparation of ***9b***

A solution of 427 mg (0.93 mmol) compound **8***b*, 110 mg (1.5 mmol) pyrrolidine and 100 mg (1.5 mmol) glacial acetic acid was refluxed in 20 ml benzene for 18 h. The solvent was evaporated and the residue partitioned between chloroform (30 ml) – water (5 ml). The chloroform solution was washed with water (5 ml) and brine (5 ml), dried over Na_2SO_4, filtered, and evaporated to give an oil which was filtered through 3 g silica gel (15% water) with chloroform to yield 347 mg (90%) compound **9***b*; ir ($CHCl_3$): 2110, 1770, 1695, 1625 (s, 1612) cm^{-1}.

Ethyl N-Methyl-7-β-azido-Δ³-N-2-isocephem-4-carboxylate ***11a***

A solution of 1.50 g (3.65 mmol) of **9***a* in 10 ml acetone – 5 ml 10% hydrochloric acid was boiled at reflux for 15 min. The acetone was evaporated at reduced pressure and the oily aqueous residue extracted with chloroform (3 × 20 ml). The organic extracts were washed with water (20 ml) and brine (2 × 20 ml), dried over sodium sulfate, and evaporated. The residual oil was taken up in 30 ml of ether and the ethereal solution was extracted with saturated sodium bicarbonate solution (3 × 10 ml). The basic extracts were adjusted to p*H* 5 with 10% hydrochloric acid and extracted with chloroform (5 × 20 ml). The extracts were dried over magnesium sulfate, filtered, and evaporated to yield 788 mg (60%) of **10***a*; ir ($CHCl_3$): 2110, 1778, 1695, 1630(w) cm^{-1}.

To a solution of 447 mg (1.28 mmol) of **10***a* in 7 ml ethanol – 0.5 ml water was added 110 mg sodium borohydride at 25°C. The solution was warmed to 40–45°C for 1.5 h following which the p*H* was adjusted to 4 with 10% HCl to decompose the excess sodium borohydride. After 10 min, the solution was adjusted to p*H* 8 with sodium bicarbonate and diluted to 50 ml with brine. The solution was extracted with chloroform (4 × 10 ml). The extracts were dried over magnesium sulfate and evaporated to yield 247 mg of an oil which was chromatographed on 2 g of silica gel (15% water, w/w) using chloroform. There were obtained 120 mg (40%) of **11***a* as a crystalline solid, mp 147–148.5°C after recrystallization from chloroform–ether; ir ($CHCl_3$): 2110, 1778(s), 1768, 1690, 1680, 1618 cm^{-1}. *Anal.* calcd. for $C_{10}H_{13}N_5O_3$: C 47.80, H 5.22, N 27.88; found: C 47.71, H 5.17, N 28.13.

Benzyl N-Methyl-7-β-azido-Δ³-N-2-isocephem-4-carboxylate ***11b***

A solution of 347 mg (0.78 mmol) compound **9***b* was refluxed for 15 min in 3 ml acetone – 3 ml 10% HCl. The reaction mixture was treated with 20 ml salt solution and extracted with chloroform (3 × 15 ml). The chloroform layer was washed with water and evaporated to dryness. The residual oil was dissolved into 10 ml ethyl ether. The ethyl ether solution was then extracted with saturated sodium bicarbonate solution (4 × 5 ml). Finally, the bicarbonate extract was acidified to p*H* ~ 5 with 10% hydrochloric acid. Extracted with chloroform (3 × 10 ml), dried over $MgSO_4$, the drying agent was filtered off, and the filtrate was evaporated to dryness to yield 175 mg (0.41 mmol) (53%) of compound **10***b* as an oil; ir ($CHCl_3$): 2110, 1775, 1695, 1630(w) cm^{-1}. *Anal.* calcd. for $C_{17}H_{16}F_3N_5O_5 \cdot \frac{1}{2}H_2O$: C 46.79, H 3.93, N 16.05; found: C 46.56, H 3.82, N 15.63.

To 174 mg (0.41 mmol) of compound **10***b* in 4 ml ethanol – 0.25 ml water was added 60 mg (1.58 mmol) of sodium borohydride at 25°C with stirring. After 5 min, the solution was placed into a warm water bath (45–54°C) for 1 h. The solution was acidified with 10% HCl to p*H* ~ 4, rebasified with sodium bicarbonate to p*H* ~ 8, diluted with water (25 ml), and extracted with chloroform (3 × 10 ml). The chloroform layer was washed with water and brine, dried over magnesium sulfate, filtered, and evaporated to yield 18 mg crystalline material (14%).

The solid was recrystallized from ether–chloroform, mp 166–168°C; ir (CH_3Cl_3): 2115, 1775, 1695, 1615 cm^{-1}; uv (EtOH, 0.3 mg/12.5 ml) λ_{max} 307 nm (ε 12 850). *Anal.* calcd. for $C_{15}H_{15}N_5O_3$: C 57.50, H 4.83, N 22.35; found: C 57.40, H 4.95, N 22.21.

From ***13b***

A solution of 2.80 g (6.85 mmol) of **13***b* (as a mixture of isomers) in 10 ml dimethyl sulfoxide was added to a suspension of 165 mg sodium hydride (6.85 mmol). The solution was stirred at 25°C for 1 h at the end of which time all of the sodium hydride had reacted. The mixture was poured into a 1% hydrochloric acid solution (50 ml at 0°C) and the whole extracted with chloroform (3 × 30 ml). The extracts were washed with brine (50 ml) and dried over magnesium sulfate. The solvent was evaporated to yield a dark red oil which was chromatographed on 15 g of silica gel (15% water w/w) to yield 162 mg (7.65%) of **11***b* identical in all respects with that obtained from **10***b*. In another experiment on smaller scale, the yield was 16.7%.

Preparation of ***12b***

From ***12a***

To a solution of 2.40 g (7.55 mmol) of **12***a* in 50 ml of methylene chloride was added 3.14 ml triethylamine (22.65 mmol) at 0–5°C. To this was added 2.58 g (22.65 mmol) mesyl chloride in 5 ml methylene chloride over 10 min. The solution was stirred 20 min at 25°C. The solution was diluted to 150 ml with ether and washed with 10% hydrochloric acid and brine. The solution was dried over sodium sulfate and evaporated. The residual oil was chromatographed on silica gel (15% water w/w) (50 g) using benzene (200 ml) then ether as eluent. The ethereal fractions from the column contained 2.85 g (80%) of **12***b* as a mixture of two isomers; ir (film): 2110, 1780, 1620, 1640 cm^{-1}; uv (EtOH, 7.0 mg/50 ml) λ_{max} 242 nm (ε 6300).

From ***12c***

Treatment of 13.37 g (33.7 mmol) of **12***c* with 11.1 ml triethylamine (66 mmol) and 7.50 g (66 mmol) of methane sulfonyl chloride as in the above example furnished 12.80 g (81%) of **12***b*.

Preparation of ***13a***

From ***12d***

A solution of 201 mg (0.475 mmol) of **12***d*, 30 mg glacial acetic acid, and 20 mg ammonia in 10 ml of chloroform was heated in a Parr pressure vessel at 48–52°C for 18 h. The solution was washed with water (10 ml) and brine (10 ml), dried over magnesium sulfate, and evaporated to yield an oil which was taken up in methylene chloride and filtered through a pad of silica gel to give 107 mg (57%) of **13***a*; ir ($CHCl_3$): 3500, 3330, 2110, 1770, 1760, 1695, 1650 cm^{-1}.

*From **12b***

To a solution of 2.30 g (4.85 mmol) of **12*b*** in 30 ml of DMSO was added a stream of dry ammonia for 10 min at 25°C. The solution was let stand 30 min at 25°C, poured into brine (100 ml) and extracted with chloroform (5 × 20 ml). The extracts were washed with water (2 × 20 ml) and brine (2 × 20 ml). The extracts were dried over magnesium sulfate and evaporated to yield 1.75 g (92%) of **13*a***.

*Preparation of **13b***

A solution of 5.25 g (12.4 mmol) of **12*d***, 560 mg (18.6 mmol) monomethylamine, and 110 mg acetic acid in 50 ml benzene was heated to 46°C for 18 h in a Parr pressure vessel. Work-up as in the previous example (preparation of **13*a***) gave an oil which was chromatographed on 30 g of silica gel (5% water, w/w) using chloroform as the eluting solvent. A total of 4.1 g (81%) of **13*b*** was obtained in three fractions, 1.3 g of isomer 1 (elutes first), 1.0 g of isomer 2, and 1.8 g mixed fraction (~1:1). Isomer 1: ir ($CHCl_3$): 3340, 2110, 1777, 1769, 1680, 1649, 1625 cm^{-1}; uv (EtOH, 0.3 mg/10 ml) λ_{max} 284 nm (ε 21 100); isomer 2: ir ($CHCl_3$): 3415, 3335, 2110, 1770 (1777sh), 1682, 1650, 1630 cm^{-1}; uv (EtOH, 0.3 mg/10 ml) λ_{max} 280 nm (ε 16 200).

*Benzyl N-Carboethoxy-7-β-azido-Δ³-N-2-isocephem-4-carboxylate **14***

To a solution of 1.75 g (4.43 mmol) of **13*a*** in 40 ml of chloroform was added 1.50 g (13.8 mmol) of ethyl chloroformate followed by 2.02 g (20 mmol) of triethylamine in 5 ml chloroform over 5 min at 25°C. An exothermic reaction was observed. The reaction mixture was let stand at 25°C for 18 h, following which it was washed with water (25 ml) and brine (25 ml). The solution was dried (magnesium sulfate) and evaporated. The oil which resulted was chromatographed on 30 g silica gel using chloroform as eluent to give 440 mg (26.8%) of **14** as a crystalline solid, mp 133.5–134.5°C; ir ($CHCl_3$): 2110, 1780, 1727, 1710, 1625 cm^{-1}; uv (EtOH, 1.4 mg/50 ml) λ_{max} 288 nm (ε 14 600). *Anal.* calcd. for $C_{17}H_{17}N_5O_5$: C 54.98, H 4.61, N 18.86; found: C 54.74, H 4.64, N 18.85.

*Benzyl 7-β-(Aminophenoxyacetoyl)-N-methyl-Δ³-N-2-isocephem-4-carboxylate **16a***

A suspension of 313 mg (1 mmol) of **11*b*** and 100 mg 10% Pd/C in 50 ml ethyl acetate was shaken under hydrogen at 55 psi and 25°C for 1.5 h. Filtration of the suspension through diatomaceous earth and evaporation of the filtrate gave an oil which was filtered through a pad of silica gel (5% water, w/w) (2.0 g) in methylene chloride. Evaporation of the filtrate gave 220 mg (76.5%) of **15*a*** as an oil; ir ($CHCl_3$): 1764, 1685, 1615 cm^{-1}.

Treatment of 204 mg (0.71 mmol) of **15*a*** with 178.2 mg (0.75 mmol) EEDQ and 110 mg (0.75 mmol) phenoxyacetic acid in 30 ml methylene chloride gave after work-up (2*a*) 181 mg (60.5%) of **16*a***, mp 180–182°C, recrystallized from chloroform–ether; ir ($CHCl_3$): 3410, 1767, 1695, 1685, 1615 cm^{-1}; uv (EtOH, 0.9 mg/50 ml) λ_{max} 308 nm (ε 18 300). *Anal.* calcd. for $C_{23}H_{23}N_3O_5$·0.05$CHCl_3$: C 64.77, H 5.43, N 9.83; found: C 64.82, H 5.44, N 9.92.

*Benzyl 7-β-(Aminophenoxyacetoyl)-N-carboethoxy-Δ³-N-2-isocephem-4-carboxylate **16b***

Reduction of 420 mg (1.13 mmol) of **14** with 200 mg 10% Pd/C in 40 ml ethyl acetate at 25°C at 57 psi and for 1.5 h gave 350 mg (90%) of **15*b*** as an oil; ir ($CHCl_3$): 3000–3500b, 1777, 1725, 1712, 1625 cm^{-1}.

Treatment of 315 mg (0.92 mmol) of **15*b*** with 242 mg (0.92 mmol) EEDQ and 140 mg (0.92 mmol) phenoxyacetic acid in 10 ml methylene chloride gave after work-up (2*a*) **16*b*** as an oil. This oil was chromatographed on silica gel using chloroform – 3% acetone as eluent to give 164 mg pure **16*b*** as an oil; ir ($CHCl_3$): 3410, 3330, 1782, 1728, 1712, 1692, 1625, 1602, 1505 cm^{-1}.

*7-β-(Aminophenoxyacetoyl)-N-methyl-Δ³-N-2-isocephem-4-carboxylic Acid **17a***

A suspension of 158 mg (0.38 mmol) of **16*a*** and 290 mg 20% $Pd(OH)_2$/C in 50 ml ethyl acetate was shaken under hydrogen (58 psi) at 20°C for 3 h. The suspension was filtered through diatomaceous earth and the filtrate evaporated to yield an oil. Trituration of the oil with methyl isobutyl ketone gave 45 mg of a tan solid which decomposed above 158°C; ir ($CHCl_3$): 3420, 2500–3600(CO_2H), 1757, 1680, 1613, 1530, 1495 cm^{-1}; uv (EtOH, 0.4 mg/10 ml) λ_{max} 302 (ε 6200), 275 (ε 5700), 268 nm (ε 5600).

The material proved to be unstable, darkening rapidly on standing.

*7-β-(Aminophenoxyacetoyl)-N-carboethoxy-Δ³-N-2-isocephem-4-carboxylic Acid **17b***

A suspension of 158 mg (0.33 mmol) of **16*b*** and 390 mg 20% $Pd(OH)_2$/C in 40 ml ethyl acetate was shaken under hydrogen (57 psi) at 25°C for 1.5 h. Work-up as in the above example yielded an oil which upon trituration with ether solidified, 74 mg. The solid failed to give a sharp melting point decomposing over the range 107–134°C; ir ($CHCl_3$): 3410, 2500–3600b CO_2H, 1780, 1728, 1710, 1694, 1628, 1600, 1520, 1495 cm^{-1}; uv (EtOH, 1.7 mg/50 ml) λ_{max} 284 nm (ε 17 750). *Anal.* calcd. for $C_{18}H_{19}N_3O_7$: C 55.52, H 4.92, N 10.79; found: C 55.45, H 5.21, N 10.64.

The phosphorescence emission and electron spin resonance spectra of methyl mesitoate (**1**) and mesitonitrile (**2**) have been studied in order to assess the steric effect (inhibition of resonance) in the former. The triplet energy of **1** (80.5 kcal mol^{-1}) is considerably higher than that of **2** (74.2 kcal mol^{-1}) while the zero-field splitting parameters are very similar (**1**, D/hc = 0.127 cm^{-1}, E/hc = 0.013 cm^{-1}; **2**, D/hc = 0.127 cm^{-1}, E/hc = 0.006 cm^{-1}). The triplet energy and zero-field splitting parameters of *o*-, *m*-, and *p*-methyl toluate and *o*-, *m*-, and *p*-tolunitrile are also reported.

D. R. ARNOLD, J. R. BOLTON, G. E. PALMER et K. V. PRABHU. Can. J. Chem. **55**, 2728 (1977).

On a étudié les spectres d'émission phosphorescence et de résonance paramagnétique électronique du mésitoate de méthyle (**1**) et du mésitonitrile (**2**) afin de déterminer l'effet stérique (inhibition à la résonance) dans le premier. L'énergie de l'état triplet de **1** (80.5 kcal mol^{-1}) est beaucoup plus élevée que celle de **2** (74.2 kcal mol^{-1}) alors que les paramètres de couplage à champ zéro sont très similaires (**1**, D/hc = 0.127 cm^{-1}, E/hc = 0.013 cm^{-1}; **2**, D/hc = 0.127 cm^{-1}, E/hc = 0.006 cm^{-1}). On rapporte aussi l'énergie de l'état triplet et les paramètres de couplage à champ zéro pour les *ortho*-, *méta*- et *para*-toluates de méthyle et les *ortho*, *méta* et *para*-tolunitriles.

Introduction

Electron spin resonance (esr) spectroscopy can give useful information about the effects (steric and electronic) of substituents on electronically excited triplet states (1). The zero-field splitting parameters (D and E) obtained from the esr spectrum are intrinsic properties of the triplet. Furthermore, in the best of cases, hyperfine splitting may be discernible in which case information about the unpaired electron distribution can be obtained. In contrast, other sources of information, for example, singlet–triplet absorption, phosphorescence emission, and triplet–triplet absorption, of course, involve transitions between two states and substituent effects on these spectra result from perturbations of both initial and final states. The usefulness of esr for providing information on the effect of substituents on stable (ground state) triplet molecules is also well established (2).

We have reported (1*c*) results of a study on the esr and phosphorescence emission spectra of methyl benzoates with electron-withdrawing substituents (cyano- and carbomethoxy-) from which it was possible to conclude that the lowest triplet of these compounds has π,π^* character. It was also clear, from the relatively small value of D (compared with that for benzene for example) that considerable spin density was distributed onto the carbomethoxy and cyano groups. We have now extended this study to include methyl mesitoate and mesitonitrile in an attempt to assess the steric-effect (inhibition of resonance) on the zero-field splitting parameters and triplet energy.

It is well known that the carboxyl carbonyl of methyl mesitoate cannot be coplanar with the phenyl ring in the ground state and therefore resonance interaction is reduced.[4] On the other hand, the nitrile function, being linear, is not prevented from being planar with the ring in mesitonitrile and resonance and inductive interaction with the ring are uninhibited. This classic concept, established over thirty-five years ago, has

[1]Contribution No. 167 from the Photochemistry Unit.

[3]Present address: Solar Laboratories, Inc., Costa Mesa, CA.

[4]X-Ray analysis of mesitoic acid (hydrogen-bonded dimer) indicates the carboxyl group is twisted out of plane of the ring by 48.4° (3) while *o*-toluic acid (hydrogen-bonded dimer) is almost planar (4).

been used to explore the importance of steric effects in several diverse systems (5).

An example of the difference in steric interaction in methyl mesitoate and mesitonitrile which is most pertinent to the present discussion is the comparison of the ultraviolet absorption spectra of these compounds, first reported by Fehnel and Wepster (6). These spectra are shown in Figs. 1 and 2. Figures 1*a* and 1*b* allow a comparison of the absorption spectra of methyl benzoate and cyanobenzene

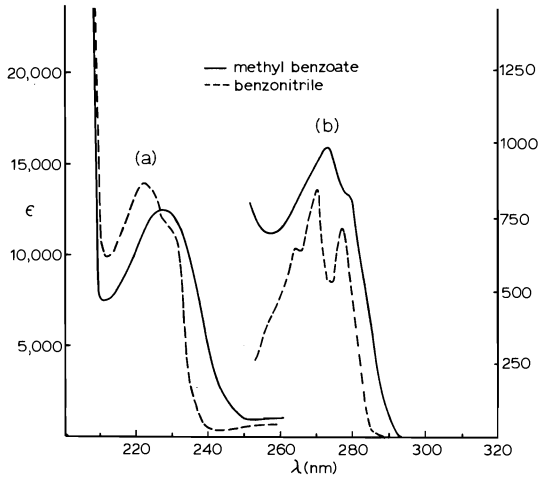

FIG. 1. The primary band (*a*, left axis of ordinates) and secondary band (*b*, right axis of ordinates) of the ultraviolet absorption spectra of methyl benzoate and benzonitrile in ethanol solution.

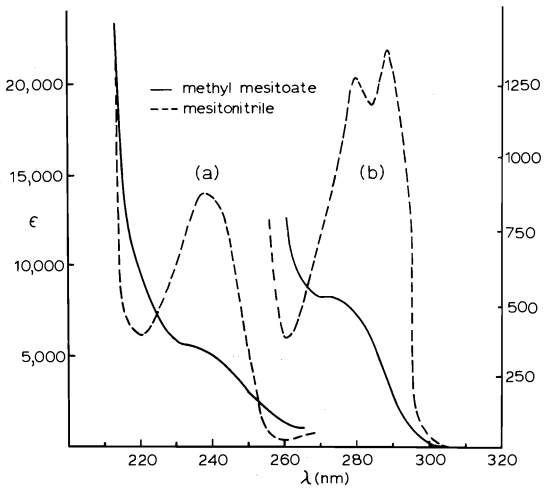

FIG. 2. The primary band (*a*, left axis of ordinates) and secondary band (*b*, right axis of ordinates) of the ultraviolet absorption spectra of methyl mesitoate and mesitonitrile in ethanol solution.

in the primary (^1L_a) and secondary (^1L_b) absorption band regions. The similarity of the spectra indicates a resonance interaction involving the carbomethoxy and cyano substituents in both compounds. Figures 2*a* and 2*b* show the same absorption regions for methyl mesitoate and mesitonitrile. While the spectrum of mesitonitrile still indicates the strong resonance interaction between the cyano group and the phenyl ring, the spectrum of methyl mesitoate is very different from that of methyl benzoate and reflects the diminished resonance interaction. The lowest triplet has the ^1L_a configuration; therefore, the steric effect on the corresponding singlet evident in Fig. 2*a* should be compared with that on the triplet (7).

Results and Discussion

The spectral (electron spin resonance and phosphorescence emission) characteristics of the triplet states of the substituted methyl benzoate esters and cyanobenzenes studied here are summarized in Table 1.

It is apparent, from the overall similarity of the data, that a π,π^* triplet is involved in every case. In particular, the phosphorescence lifetime which varies between 1 and 5 s is too long for an n,π^* state. We assume, therefore, that the differences that do exist can be considered as substituent effects on the ^3L_a (or $^3B_{1u}$) state (7).

Since the triplet energy of methyl benzoate (77.9 kcal mol^{-1}) and cyanobenzene (77.0 kcal mol^{-1}) are similar, the difference in the triplet energy of methyl mesitoate (80.5 kcal mol^{-1}) and mesitonitrile (74.2 kcal mol^{-1}), that is, 6.3 kcal mol^{-1}, can be attributed to the steric effect in the former. The triplet energy of methyl mesitoate is in fact comparable to that of mesitylene (79.8 kcal mol^{-1}) or isodurene (79.6 kcal mol^{-1}) (8).

The observed steric effect upon the absorption and emission spectra are, of course, the combined influence on both the ground state and on the excited singlet and triplet states, respectively. The increase in triplet energy of methyl mesitoate relative to mesitonitrile and methyl benzoate is interpreted to mean that while the ground state energy of methyl mesitoate may be raised by the lack of resonance interaction, the excited state energy is raised even more and the result is a net increase in the transition energy.

TABLE 1. Zero-field splitting parameters and phosphorescence energies for the triplet of some substituted methyl benzoates and cyanobenzenes

We look next to the zero-field splitting parameters for direct evidence on the structure of the triplet.

The decrease in the D value from that for benzene (0.158 cm^{-1} (9)) to that for methyl benzoate (0.133 cm^{-1}) is taken as an indication of the greater average separation of the electrons in the triplet of methyl benzoate. Assuming the point dipole approximation, the D value of benzene is equivalent to an average separation of the electrons of 2.02 Å; while that of methyl benzoate is equivalent to 2.14 Å.[5] The same increase in the average separation of the electrons is observed with cyanobenzene. The trend to lower D values continues with mesitonitrile indicative of the ability of a methyl substituent to take on spin density.

If the carbomethoxy moiety is prevented from becoming coplanar with the phenyl ring in the triplet of methyl mesitoate, the D value should increase relative to that of mesitonitrile and approach that of mesitylene itself. Such is not the case; methyl mesitoate has the same D value as mesitonitrile (within experimental error) and the value is considerably smaller than that for mesitylene ($D/hc = 0.140$ cm^{-1} (10)).

[5]The average separation of the electrons in the triplet was estimated using the equation $D = (3/4)g^2\beta^2 \times (1/r^3)$ (ref. 1*a*).

There are several possible explanations for this result; one is that in the triplet the carbomethoxy moiety is able to twist enough toward the plane of the phenyl ring so that electron delocalization can occur. That is, the steric interactions may not be severe enough to prevent the triplet of methyl mesitoate from becoming planar enough to allow delocalization of the electrons to an extent similar to that of mesitonitrile. This, of course, would be at the expense of energy reflected in the increased triplet energy. To test this possibility we attempted to obtain the esr spectrum from the triplet of methyl 1,3,5-tri-*tert*-butylbenzoate. However, the esr spectrum and the phosphorescence emission spectrum of this compound indicate that more than one species is present; we believe this ester to be photochemically reactive, and have thus far been unable to characterize the triplet.

Experimental

The procedure and apparatus used have been described previously (1*c*, 2*c*).

La pyrolyse de poly(adipate de butylène-1,4)

FRANÇOIS MESSIER ET DON C. DEJONGH[1]

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal, (Qué.), Canada H3C 3V1

Reçu le 29 novembre 1976

FRANÇOIS MESSIER et DON C. DEJONGH. Can. J. Chem. **55**, 2732 (1977).

Le poly(adipate de butylène-1,4) (**1**) a été pyrolysé dans un bateau de porcelaine placé à l'intérieur d'un tube de quartz chauffé à l'aide d'un four externe. Les produits volatils ont été entraînés dans un courant d'azote et conduits à l'extérieur de la zone chauffée. Le polyester **1** fut pyrolysé près de l'entrée de la zone chauffée ainsi que près de la sortie de la zone chauffée à des températures de 500 et 700°C avec ou sans vide. L'acide adipique (**2**) et la cyclopentanone (**4**) ainsi qu'un mélange de mono (**5**) et diesters (**6**) du monomère, du dimère et du trimère furent isolés comme produits de pyrolyse.

La pyrolyse de **1** à 500°C près de la sortie de la zone chauffée à la pression atmosphérique, a donné un rendement de 14% de **2**, 10% de **4**, 40% de **5** et 18% de **6**; **5** était constitué de 26% du monoester du monomère et 74% du monoester du dimère, tandis que **6** était constitué de 63% du diester du monomère et 37% du diester du dimère. Par contre, à 700°C sous vide (0.2–0.3 Torr) avec le polymère **1** près de l'entrée de la zone chauffée, le rendement de **2** était plus élevé (~35%), et les trimères étaient trouvés dans les monoesters **5** et les diesters **6**, avec les dimères et monomères.

FRANÇOIS MESSIER and DON C. DEJONGH. Can. J. Chem. **55**, 2732 (1977).

Poly(1,4-butylene adipate) (**1**) was pyrolyzed in a porcelain boat placed in a quartz tube heated by a furnace. Volatile products were carried out of the heated zone into traps by a flow of nitrogen. Polyester **1** was pyrolyzed both near the entrance and near the exit of the heated zone, at 500 and 700°C with and without a vacuum. Adipic acid (**2**), cyclopentanone (**4**), and a mixture of mono (**5**) and diesters (**6**) of the monomer, dimer, and trimer, were isolated as products of the pyrolyses.

The pyrolyses of **1** at 500°C near the exit of the heated zone at atmospheric pressure gave 14% of **2**, 10% of **4**, 40% of **5**, and 18% of **6**; **5** consisted of 26% monoester of monomer and 74% monoester of dimer, whereas **6** consisted of 63% diester of monomer and 37% diester of dimer. At 700°C, 0.2–0.3 Torr, with **1** near the entrance of the heated zone, the yield of **2** was higher (~35%), and trimers were found in the monoesters **5** and diesters **6**, along with dimers and monomers.

Introduction

Plusieurs méthodes existent pour caractériser des polymères (1); par exemple, on peut citer la spectroscopie infrarouge, qui est une des principales techniques pour connaître la structure physique et chimique du polymère, et la spectroscopie de résonance magnétique nucléaire (rmn), qui permet de déterminer la tacticité du polymère ainsi que sa distribution séquentielle. Il existe également des méthodes de caractérisation en solution telles que la mesure de la viscosité, ainsi que l'osmométrie, qui permettent de connaître la masse moléculaire moyenne ($\overline{M}_n$) des polymères (2). On peut aussi faire l'étude de polymères à l'état solide à l'aide de la diffraction des rayons-X (1), méthode qui donne un aperçu de la cristallinité des polymères. Une autre méthode permettant de caractériser un polymère et d'avoir une idée sur sa stabilité thermique est la thermogravimétrie (1).

Une méthode apparentée à la thermogravimétrie existe pour déterminer la stabilité thermique d'un polymère, la pyrolyse. Dans ce cas, on étudie les produits formés lors de la pyrolyse, contrairement à ce qui se passe pour la thermogravimétrie. Avec cette dernière méthode, l'étude se porte sur le résidu, c'est-à-dire la perte de poids en fonction de l'augmentation de température.

Depuis quelques années, on se sert du patron obtenu lors de la pyrolyse d'un polymère pour l'identifier. En couplant un chromatographe en phase gazeuse (cpg) au pyrolyseur, les produits de la pyrolyse sont séparés et analysés par cpg. La distribution des produits vue sur le chromatogramme devient une caractéristique du produit de départ (3, 4). Il existe de nombreuses références impliquant cette méthode d'analyse

[1]A qui toute demande d'information devra être adressée.

a(δ 1.8,m,2H), *b*(δ 2.5,m,1H), *c*(δ 4.2,m,1H)

de polymères. On peut citer, à propos de ce présent travail, l'analyse par cpg des produits de la pyrolyse du poly(éthylacrylate d'éthylène), du poly(vinylacétate d'éthylène) (5), du poly(méthacrylate de *n*-butyle) (6) et du poly(méthacrylate de méthyle) (7). Nombreuses autres références concernant la pyrolyse de polymères se trouvent dans la littérature (8).[2]

Dans nos laboratoires on possède une vaste expérience de la pyrolyse en phase gazeuse de molécules aromatiques et volatiles (9, 10). Nous voulions acquérir de l'expérience dans la pyrolyse de polymères, et, à cette fin, nous avons décidé de mettre au point la pyrolyse de polymères avec nos appareils en effectuant la pyrolyse du poly(adipate de butylène-1,4) (**1**). En général, la pyrolyse d'ester donne lieu à la formation d'acide carboxylique et d'oléfine via l'intermédiaire d'un cycle à six membres (11). Par exemple, la dégradation thermique du poly(oxycarbonyléthylène) donne en premier lieu la formation de deux fragments, un contenant un site d'insaturation et l'autre une fonction acide en bout de chaîne (12). La partie portant la fonction acide en bout de chaîne se fragmente à nouveau, toujours par le même mécanisme, pour donner lieu à la formation de l'acide acrylique.

Des dégradations thermiques de polyesters aromatiques et aliphatiques ont été effectuées aussi directement dans la source d'ionisation d'un spectromètre de masse (13), sans passer par la cpg. Les polyesters de l'acide téréphtalique et diols aliphatiques se dégradent par une élimination-*cis*, ce qui donne l'acide téréphtalique. Dans le cas des polyesters des acides dicarboxyliques aliphatiques, ce sont les liaisons O—CO et CO—CH_2 qui se brisent. De plus, une petite quantité de trimère cyclique a été trouvée dans un échantillon commercial de poly(téréphtalate d'éthylène) (14); ce trimère se volatilise à 190°C, tandis que la pyrolyse du polyester commence vers 300°C.

Aux différents exemples cités où la pyrolyse se fait dans un pyrolyseur, l'appareil admet une quantité d'un microgramme à un milligramme de produits, et est directement couplé à un appareil de cpg. Au contraire, dans notre cas, on isole le mélange de produits. Puis, on les identifie et on en détermine le rendement, ce qui demande une quantité de polymères au départ d'environ $\frac{1}{2}$ g à 1 g.

Partie théorique

Caractérisation du poly(adipate de butylène-1,4) (1)

Nous avons déterminé la masse moléculaire moyenne ($\overline{M}_n$) du poly(adipate de butylène-1,4) (**1**) par la tonnométrie (15). Une masse moyenne de 4700 g/mol a été trouvée, correspondant à 24 pour le nombre moyen d'unités de répétition ($\bar{x}$). Il faut préciser que la tonnométrie ne donne aucune indication sur la courbe de distribution des molécules de différentes masses présentes dans le polymère. Le spectre rmn du polymère **1** ne révèle que trois pics, c'est-à-dire qu'il n'y a pas de pics provenant d'un groupe hydroxyle ou d'impuretés.

Méthode de pyrolyse

Dans les cas des produits de départ volatils, il s'agit d'abord de les sublimer, et, puis, à l'aide d'un courant d'azote de les amener dans un four pour y être pyrolysés (9, 10). Dans le cas de **1**, au lieu de sublimer l'échantillon dans un courant d'azote, on le place dans un bateau de porcelaine, et puis, il est amené dans la zone chauffée à l'aide d'un déplacement manuel (voir la fig. 1), ou d'une tige de fer et d'aimants. Par cette méthode, le polymère sera pyrolysé en phase

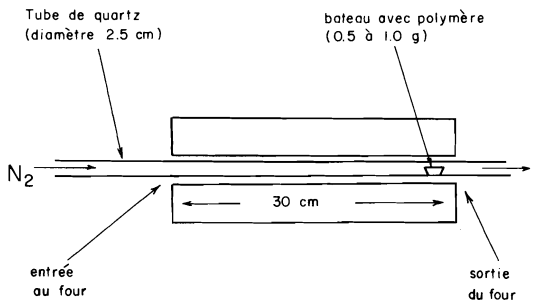

FIG. 1 L'introduction du polymère dans la zone chauffée.

[2]N.B.: cette dernière référence contient au-delà de 500 références.

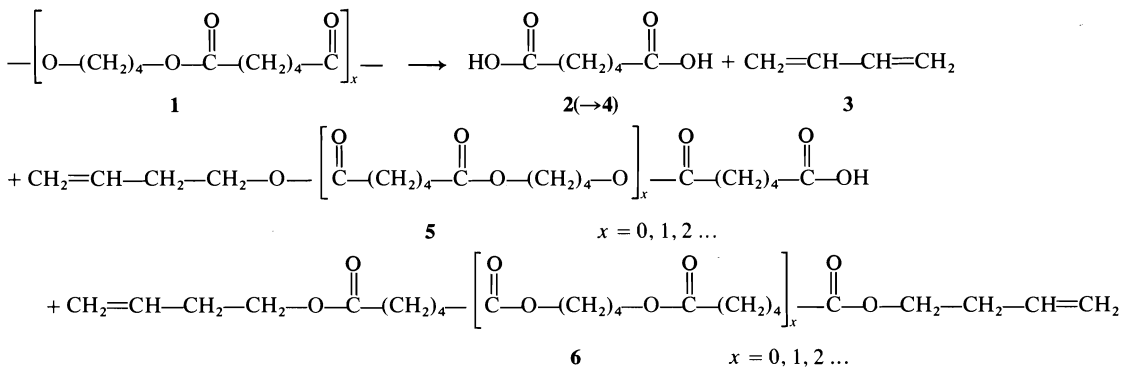

SCHÉMA 1

solide, mais dès qu'il y aura formation de produits volatils, ceux-ci seront entraînés dans le courant d'azote et amenés à l'extérieur de la zone chauffée. Si les produits primaires sont pyrolysés en route, on obtiendra des produits primaires, secondaires, etc, de pyrolyse.

Il y a plusieurs paramètres pouvant influencer la formation et la distribution des produits, tels que la pression, la température et le débit d'azote. En plus, il y a l'endroit où est placé le bateau dans la zone chauffée. Lorsque la pyrolyse est effectuée près de l'entrée, la zone chauffée parcourue par les produits dans le courant d'azote est beaucoup plus longue, environ 30 cm, que lorsque cette pyrolyse est effectuée près de la sortie (environ 10 cm). De ce fait, dans les mêmes conditions de température, de pression et de débit d'azote, la pyrolyse est plus complète lorsque celle-ci est effectuée près de l'entrée plutôt que près de la sortie de la zone chauffée.

*Pyrolyse du polymère **1** près de la sortie de la zone chauffée*

Le polyester **1** est amené dans la zone chauffée pour y être pyrolysé à une température de 700°C à la pression atmosphérique. Un léger débit d'azote permet aux produits formés d'être balayés de la zone chauffée et récupérés dans une série de trappes. Le mélange de produits obtenu est formé de l'acide adipique (**2**), du butadiène-1,3 (**3**), de la cyclopentanone (**4**), ainsi que de deux groupes d'esters, soit les monoesters **5** et les diesters **6** de butène-3 (schéma 1). La cyclopentanone (**4**) se forme de la pyrolyse de l'acide adipique (16).

En injectant ce mélange brut de produits sur un chromatographe en phase gazeuse, nous avons pu isoler le monomère du monoester (**5** où $x = 0$). Sa formule et ses fragmentations caractéristiques ont été déterminées à l'aide de ses spectres de masse à haute et basse résolution (tableau 1).

Le spectre rmn permettait également l'élucidation de la structure du monomère **5** ($x = 0$).

De plus, nous avons pu isoler le monomère du diester (**6** où $x = 0$) par cpg. La structure du diester **6** fut élucidée à l'aide de son spectre de masse ainsi que par son spectre rmn. Cette fois-ci, l'ion moléculaire est présent à *m/e* 254, mais en faible abondance relative, et les fragmentations sont les mêmes que celles du monoester **5** (tableau 1): *m/e* 254(1%), 183(57%), 129(50%), 111(52%), 101(15%), 83(13%), 55(100%) et 54(77%).

Nous avons pris aussi le spectre rmn du mélange brut obtenu de la pyrolyse, après l'élimination de l'acide adipique par précipitation. Ce spectre rmn était identique à la superposition de ceux des monomères, sauf que la valeur de l'intégration obtenue était beaucoup plus élevée que celle attendue pour la présence des monomères seuls. Le spectre de masse de ce

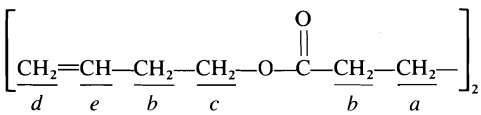
[e]Cette formule n'était pas déterminée.

mélange brut contenait des pics correspondant aux monomères, et, de plus, des pics indiquant le même genre de fragmentations observées dans le cas des monomères, mais à des masses plus élevées de 200 unités. Ces pics devaient être dûs à un mélange du monomère ($x = 0$), du dimère ($x = 1$), du trimère ($x = 2$), etc., de structures **5** et **6**.



6 ($x = 0$)

a(δ 1.7,m,2H), *b*(δ 2.4,m,4H), *c*(δ 4.2,t,2H), *d*(δ 5.2,m,2H), *e*(δ 5.7,m,1H)

Vu que rien de plus grand que les monomères (**5** et **6**, $x = 0$) ne sortait du chromatographe en phase gazeuse, nous avons décidé de séparer par extraction les monoesters **5** des diesters **6** et d'en déterminer les masses moyennes. Les rendements de l'acide adipique (**2**), de la cyclopentanone (**4**) et des esters **5** et **6**, ainsi que la valeur de la masse moyenne des monoesters **5** et des diesters **6**, sont présentés au tableau 2.

Les valeurs obtenues pour les masses moyennes indiquent que les monoesters et les diesters **5** et **6** consistent surtout en monomère et en dimère, car ces valeurs se situent entre la masse du monomère, qui est de 200 (**5**, $x = 0$) ou 254 g/mol (**6**, $x = 0$), et celle du dimère, qui est de 400 (**5**, $x = 1$) ou 454 g/mol (**6**, $x = 1$). De plus, les valeurs d'intégration des protons apparaissant sur les spectres rmn ne correspondent pas au monomère ou au dimère simplement et sont trop faibles pour correspondre au trimère. Les valeurs d'intégration se situent entre celle du monomère et celle du dimère, confirmant l'énoncé que les esters **5** et **6** consistent d'un mélange monomère–dimère dans ce cas.

Le partage en monomère et en dimère dans les mélanges de **5** et **6** fut déterminé par la méthode de tâtonnement à partir de la masse moyenne trouvée expérimentalement. Pour commencer, on choisissait un pourcentage du monomère et le pourcentage complémentaire en dimère, d'une façon arbitraire. En multipliant le pourcentage par la masse moléculaire du monomère ou du dimère selon le cas, on obtenait alors une masse moléculaire moyenne que l'on comparait à celle obtenue expérimentalement. On procédait ainsi jusqu'à ce que la masse moyenne correspondant aux pourcentages de monomère et dimère soit égale à celle obtenue expérimentalement. Les différents pourcentages en monomère ($x = 0$) et dimère ($x = 1$) des mélanges de **5** et de **6** déterminés de cette façon sont également présentés dans le tableau 2.

Nous avons alors pris les spectres rmn des monoesters **5** et des diesters **6**. D'après les pourcentages en monomère et dimère des esters **5** et **6**, tels que présentés dans le tableau 2, l'intégration des protons correspondant à chacun des pics devant apparaître sur les spectres rmn pouvait être prédite. Il s'agissait de multiplier les pourcentages de $x = 0$ et de $x = 1$ par le nombre de protons présents dans le monomère et le dimère et de les additionner. Les intégrations trouvées dans ces spectres rmn étaient très voisines de celles déduites des pourcentages de monomère et dimère.

Une autre pyrolyse du polyester **1** fut effectuée mais à une température de 500°C et avec un léger débit d'azote. Les resultats obtenus pour cette

[a]Ce rendement est calculé en supposant que tout le polymère est transformé en ce produit.
[b]Ce rendement est calculé en faisant le rapport de la quantité de **5** et **6**, selon le cas, sur la quantité de polymère de départ.
[c]Les masses moyennes ($\overline{M}_n$) sont déterminées par tonnométrie; g/mol.
[d]Ces résultats sont les moyennes déterminées de trois pyrolyses; les erreurs indiquées représentent les écarts types.

température sont pratiquement les mêmes que ceux obtenus à 700°C. Les rendements sont présentés au tableau 2 et sont reproductibles.

Lorsque la pyrolyse est effectuée sous vide (0.2–0.3 Torr) à une température de 700°C, la formation de l'acide adipique est pratiquement nulle et on ne remarque que la formation des mono et diesters **5** et **6**. En prenant le spectre rmn du mélange de la pyrolyse, nous avons constaté que les abondances des pics dûs aux protons oléfiniques (*d* et *e*) étaient très faibles. La masse moyenne de ce mélange était déterminée sans au préalable séparer les monoesters **5** des diesters **6**. La valeur de la masse moyenne obtenue est de 733 g/mol, ce qui indiquerait une dominance de trimères ($x = 2$) et de tétramères ($x = 3$) dans le mélange de la pyrolyse.

En effectuant la pyrolyse sous vide (0.2–0.3 Torr) à 500°C, nous avons remarqué que les résultats sont les mêmes que pour la pyrolyse précédente. La masse moyenne du mélange des monoesters et des diesters **5** et **6**, sans au préalable avoir été séparé, est de 702 g/mol comparativement à 733 g/mol pour la pyrolyse sous vide à 700°C.

Les résultats sont reproductibles. Il semble que la différence de température n'ait pas un effet très grand sur les rendements des produits. Par contre, la pression joue un rôle très important sur la grosseur des molécules formées. Sous vide, les molécules de plus haute masse sont rendues volatiles, et, la nécessité d'une repyrolyse des grosses molécules, afin de former des plus petites molécules volatiles, est éliminée.

*Pyrolyse du polyester **1** près de l'entrée de la zone chauffée*

Après avoir constaté l'effet que la pression à laquelle la pyrolyse est effectuée peut avoir sur la formation des produits, nous voulions ensuite connaître l'effet de la longueur de la zone chauffée. Par conséquent, la pyrolyse du poly(adipate de butylène-1,4) (**1**) était refaite dans les mêmes conditions de température et de pression que précédemment, mais cette fois-ci près de l'entrée de la zone chauffée. Encore, les produits volatils étaient entraînés dans les trappes par un courant d'azote. Nous avons donc amené le polymère à 700°C à la pression atmosphérique, et le seul produit que nous avons pu récupérer est la cyclopentanone, dans un rendement de 32%. A une température de 500°C à la pression atmosphérique, il n'y avait pas d'esters **5** et **6** formés non plus, mais, contrairement à la pyrolyse précédente (à 700°C), nous avons noté la formation de l'acide adipique avec un rendement de 32%, en plus de la cyclopentanone dont le rendement a baissé à 18%.

Ensuite, la pyrolyse a été faite dans les conditions d'une température de 700°C sous vide (0.2–0.3 Torr) avec un courant d'azote. Les produits récupérés à la fin de cette pyrolyse sont les mêmes que ceux trouvés lorsque la pyrolyse est effectuée près de la sortie de la zone chauffée et à la pression atmosphérique (voir le schéma 1). Les masses moyennes, ainsi que les rendements de l'acide adipique, de la cyclopentanone et des esters **5** et **6** sont présentés au tableau 3 pour quatre pyrolyses.

Les rendements de l'acide adipique et de la cyclopentanone sont reproductibles. Le rendement de l'acide adipique est important dans ces conditions-ci, alors qu'il était nul lorsque la pyrolyse était effectuée près de la sortie et sous vide. Il y a des variations d'une expérience à l'autre dans les masses moyennes des monoesters

TABLEAU 3. Résultats de la pyrolyse de **1** près de l'entrée de la zone chauffée à 700°C sous vide (0.2–0.3 Torr)

Composé	Pyrolyse	Rendt (%)	$\overline{M}_n$[c] [monomère, dimère, trimère]
2	1	37[a]	
	2	36	
	3	40	
	4	29	
4	1	7[a]	
	2	7	
	3	8	
	4	5	
5	1	31[b]	482(x = 1, 59%; x = 2, 41%)
	2	19	343(x = 0, 29%; x = 1, 71%)
	3	17	321(x = 0, 40%; x = 1, 60%)
	4	33	468(x = 1, 66%; x = 2, 34%)
6	1	9[b]	511(x = 1, 71%; x = 2, 29%)
	2	29	562(x = 1, 46%; x = 2, 54%)
	3	19	514(x = 1, 70%; x = 2, 30%)
	4	12	483(x = 1, 85%; x = 2, 15%)

[a]Ces rendements sont calculés en supposant que tout le polymère est transformé en ce produit.
[b]Ces rendements sont calculés en faisant le rapport de la quantité de **5** et **6** selon le cas sur la quantité de polymère au départ.
[c]Les masses moyennes sont déterminées par tonnométrie, g/mol.

5 et des diesters **6** ainsi que dans leurs rendements.

Dans ces cas aussi, nous avons déterminé les différents pourcentages de monomère (x = 0), de dimère (x = 1) et de trimère (x = 2) pour les esters **5** et **6** en procédant de la même façon que décrite pour les résultats présentés dans le tableau 2. Dû aux valeurs de ces masses moyennes qui sont assez élevées, nous avons calculé les pourcentages en termes du dimère et du trimère excepté pour la formation des monoesters **5** dans les pyrolyses 2 et 3 où nous avons déterminé les pourcentages en termes du monomère et du dimère. Ces résultats sont également présentés au tableau 3. En prenant les spectres rmn de ces esters **5** et **6**, nous étions capables de vérifier les pourcentages en monomère, dimère et trimère déterminés à partir des masses moyennes.

A une température de 500°C, sous vide (0.2–0.3 Torr), nous avons isolé de l'acide adipique (7%), de la cyclopentanone (9%), ainsi que les esters **5** et **6**. La détermination de la masse moyenne du mélange des monoesters et des diesters donne une valeur de $\overline{M}_n$, de 518 g/mol. Ce résultat laisse supposer la présence surtout de trimères. Aussi, si on regarde le spectre rmn de ce mélange, on constate que les abondances des pics *d* et *e* sont très faibles devant les pics *c*, *b* et *a*.

Discussion

On peut expliquer l'origine des différents produits lors de la pyrolyse du poly(adipate de butylène-1,4) (**1**) par la transposition de l'hydrogène-γ. Ce mécanisme très bien connu lors de la pyrolyse d'esters a permis l'explication de la formation de l'acide acrylique lors de la dégradation thermique du poly(oxycarbonyléthylène) (12). Le mécanisme de la formation des produits lors de la pyrolyse du composé **1** est donné au schéma 2.

Le groupe carbonyle active les atomes d'hydrogènes adjacents, ce qui permet de passer par un état de transition quasi-cyclique à six membres. Par la suite, l'hydrogène-γ est transposé sur l'oxygène du groupe carbonyle pour donner lieu à la formation de deux fragments: l'un comportant un site d'insaturation à la fin de la chaîne et l'autre fragment portant un groupement carboxyle en fin de chaîne. Ce mécanisme explique très bien la formation de l'acide adipique (**2**), ainsi que celle des monoesters **5** et des diesters **6**, et également, celle du butadiène-1,3 (**3**). La cyclopentanone (**4**) proviendrait de la cyclisation de l'acide adipique (**2**).

Dans les publications sur la pyrolyse de polymères à l'aide d'un pyrolyseur directement couplé au chromatographe en phase gazeuse, on ne note que la présence de monomères (6, 7, 17). Si les oligomères ne sortent pas de la

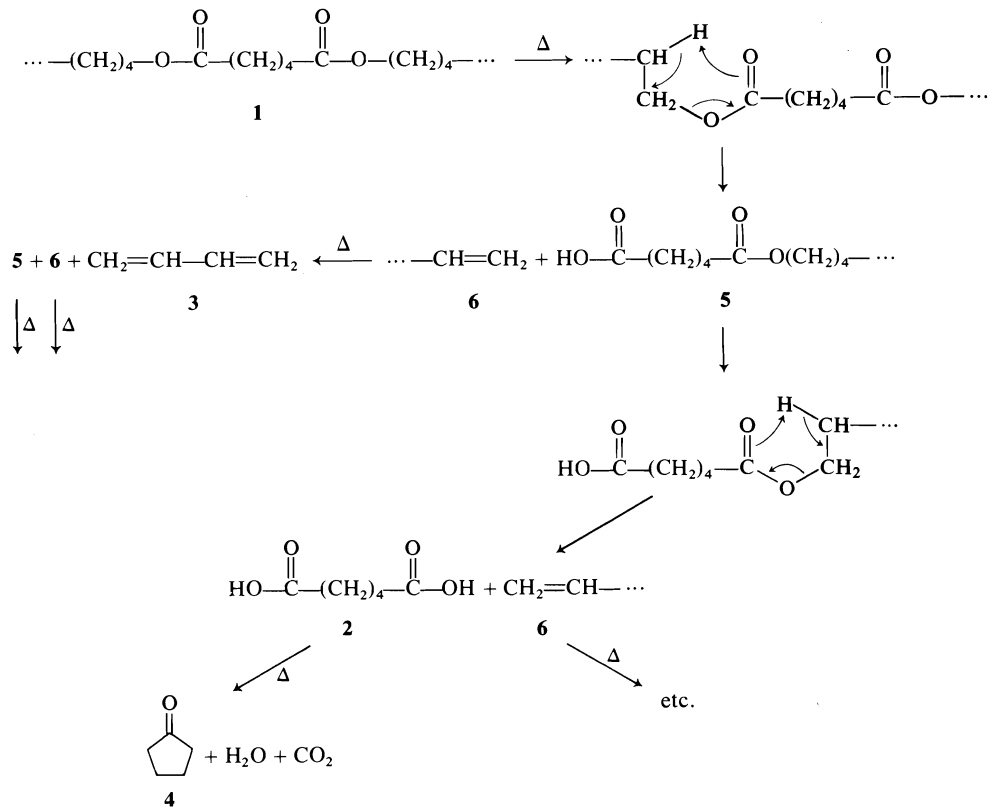

SCHÉMA 2

colonne, ou se dégradent sur la colonne, il devient impossible de savoir s'ils se sont formés. Par contre, un avantage de notre méthode est la mise en évidence de grosses molécules par les spectres rmn et de masse, ainsi que par les déterminations des masses moyennes.

Dans nos interprétations des spectres et des masses moyennes, nous avons présumé que la distribution des oligomères soit déterminée par leurs volatilités, c'est-à-dire, par leurs masses. Il serait également possible d'interpréter ces résultats en proposant la formation de monomère et de trimère, ou même de tétramère, mais au détriment, par exemple, du dimère. D'après le mécanisme de pyrolyse d'esters, nous n'avons pas de raison de préférer cette dernière interprétation et nous pensons que la première est plus probable. De toute façon, nous voulons souligner que les oligomères se forment avec notre méthode et ne sont pas perdus dans le traitement. Il serait possible de les étudier en détail si on le désirait.

La quantité du polymère employée est très petite (~50 μg) avec un pyrolyseur couplé au chromatographe, alors que nous pouvons faire la pyrolyse sur des quantités pouvant aller jusqu'à 1 g de polymère. Ce paramètre est très important surtout si on avait l'intention de se servir de la pyrolyse pour la préparation d'oligomères. Par contre, cet avantage peut devenir un dèsavantage lorsqu'il n'y a qu'une petite quantité du polymère disponible. Une autre comparaison que l'on peut faire de notre méthode par rapport à celle où le pyrolyseur est directement couplé au chromatographe concerne le temps nécessaire pour faire une pyrolyse et pour analyser les produits. Alors que dans notre cas ceci prend plusieurs heures, avec le pyrolyseur cela ne prend que quelques minutes. Donc, si on fait la pyrolyse de polymères dans le but de former et d'étudier les grosses molécules obtenues de la pyrolyse, la méthode mise au point dans ce laboratoire est beaucoup plus avantageuse dû à la quantité du polymère que l'on peut pyrolyser à la fois.

Partie expérimentale

Le point de fusion a été déterminé à l'aide d'un appareil Buchi: la valeur rapportée n'est pas corrigée. Le spectre infrarouge a été enregistré sur un spectrophotomètre

Beckmann modèle IR-8 à double faisceau. Les spectres de résonance magnétique nucléaire ont été pris sur des spectromètres de 60 MHz Varian modèle T-60-A et JEOL modèle C-60-H. Les déplacements chimiques rapportés sont exprimés en ppm, le tétraméthylsilane étant utilisé comme référence interne. Ces spectres furent pris dans le $CDCl_3$. Les spectres de masse ont été pris sur un spectromètre AEI modèle MS-902 et/ou Hitachi–Perkin-Elmer modèle RMU-6-D selon le cas. Les analyses par chromatographie en phase gazeuse ont été faites sur un chromatographe analytique modèle Hewlett-Packard 5750 muni d'un détecteur à conductivité thermique. Les mesures des masses moyennes en nombre ($\overline{M}_n$) par tonométrie (15) ont été faites à l'aide de l'appareil 301A vapor pressure osmometer de la compagnie Hewlett-Packard. Le poly(adipate de butylène-1,4) provient de la compagnie Eastman Kodak.

Méthode de pyrolyse

(a) Pyrolyse près de l'entrée de la zone chauffée

Le polymère (environ 900 mg) est placé dans un bateau de porcelaine (8.5 × 1 × 0.8 cm) et gardé sous un courant d'azote à l'intérieur d'un tube de quartz non-garni (60 cm de long et 2.5 cm de diamètre interne) qui est placé dans un four. Lorsque le four, de marque Linberg Hevi-Duty SB Type 167, a atteint la température désirée pour la pyrolyse, le bateau est amené à l'intérieur de la zone chauffée à l'aide d'une tige de fer et d'aimants. A la sortie de la zone chauffée par le four, il y a trois trappes afin de récupérer les produits de la pyrolyse; la première est refroidie à l'air ambiant alors que les deux autres sont refroidies à l'azote liquide. Lorsque la pyrolyse est faite sous vide, il y a une pompe à vide et une jauge McLeod placées à la suite des trois trappes. Le débit d'azote est réglé à l'aide d'un régulateur placé au début du système. D'habitude, le débit d'azote est ajusté à 0.2 ℓ/min.

En faisant la pyrolyse de cette façon, les produits ont une longueur d'environ 30 cm de la zone chauffée par le four à parcourir.

(b) Pyrolyse près de la sortie de la zone chauffée

Cette fois-ci, le bateau est placé à l'extérieur du four dans le tube de quartz (voir la fig. 1). Lorsque la température désirée du four est atteinte, le tube de quartz est poussé de façon à ce que le bateau de porcelaine contenant le polymère se retrouve maintenant à l'intérieur de la zone chauffée par le four, mais cette fois-ci, près de la sortie. Dans ce cas, le polymère dans le bateau est placé environ 10 cm à l'intérieur de la zone chauffée, ceci étant par conséquent la distance maximum parcourue par les produits volatils de pyrolyse.

(c) Traitement des produits de la pyrolyse

Lorsque la pyrolyse est terminée et que la température du four est en deçà de 100°C, les produits se trouvant dans le tube de quartz à la sortie du four ainsi que dans les trappes sont recueuillis à l'aide de solvants appropriés. La colonne ainsi que les trois trappes sont lavées avec du $CHCl_3$. Le $CHCl_3$ est par la suite évaporé mais pas complètement. Déjà l'acide adipique commence à précipiter; ce précipité est filtré et la solution mère est placée au réfrigérateur afin de continuer la précipitation de l'acide adipique qui demeure en solution. Après avoir filtré à nouveau l'acide adipique, la solution restante est amenée à 10 ml en ajoutant du $CHCl_3$. Cette solution est, par la suite, analysée sur un chromatographe en phase gazeuse contenant une colonne de 9 pied × 0.25 po. de SE-54 10% sur Chromosorb W et programmée de 80 à 260°C à un taux de 10°C par min. La température est maintenue à 260°C durant 10 min environ. La température d'injection est de 260°C alors que celle du détecteur est de 300°C; le débit d'hélium est de 100 ml/min.

Analyse des produits

(a) Cyclopentanone

L'analyse quantitative de la cyclopentanone est effectuée en injectant une quantité connue d'une solution standard de cyclopentanone, et en comparant la surface enregistrée pour ce composé sur le chromatogramme à celle obtenue en injectant une quantité connue de la solution de pyrolyse.

(b) Butadiène-1,3

Pour mettre en évidence la présence du butadiène-1,3, la troisième trappe est refroidie à l'azote liquide afin d'isoler ce produit. La première trappe est toujours refroidie à l'air alors que la seconde trappe est refroidie à l'aide d'un mélange acétone – glace sèche qui laisse passer le butadiène-1,3. Le butadiène-1,3 était identifié par son spectre de masse qui correspond bien avec celui dans la littérature (18).

(c) Acide adipique

L'acide adipique est obtenu sous forme de cristaux blancs: pf 152–153°C (litt. (19) pf 153°C) (recristallisé dans l'eau). Le spectre infrarouge pris dans une suspension de KBr révèle une bande s'échelonnant entre 3300 et 2500 cm^{-1} caractéristique des acides carboxyliques. Une bande C=O à 1700 cm^{-1} est notée également. Le spectre rmn fut pris dans la pyridine-d_6, et il est similaire à celui donné dans la littérature (20). Le spectre de masse, qui montre un pic de base à m/e 100 ($C_5H_8O_2^{+\cdot}$), concorde bien avec celui donné dans la littérature (18).

*(d) Esters **5** et **6***

Lorsque l'acide adipique est enlevé par précipitation, le $CHCl_3$ est évaporé autant que possible, ainsi que la cyclopentanone. Le résidu, environ 500 mg, contenant les esters **5** et **6** est dissous dans 20 ml d'éther. Après l'avoir extraite trois fois avec 5 ml d'une solution de $NaHCO_3$ saturée, la phase organique est séchée sur du $MgSO_4$, puis évaporée pour donner le mélange de diesters **6**. La phase aqueuse est acidifiée, puis extraite au $CHCl_3$, afin de récupérer le mélange de monoesters **5**.

Nous présentons aux tableaux 2 et 3 les pourcentages de produits récupérés. Comme il nous a fallu déterminer les masses moyennes des esters **5** et **6**, nous présentons ces valeurs pour chacune des pyrolyses.

Remerciements

Hydride transfer reactions. Oxidation of *N*-methylacridan by π acceptors[1]

ALLAN K. COLTER, GUNZI SAITO, AND FRANCES J. SHAROM

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received February 25, 1977

ALLAN K. COLTER, GUNZI SAITO, and FRANCES J. SHAROM. Can. J. Chem. **55**, 2741 (1977).

The oxidation of *N*-methylacridan (**1**) to *N*-methylacridinium ion (**2**) by the π acceptors *p*-benzoquinone (BQ), 7,7,8,8-tetracyanoquinodimethane (TCNQ), *p*-chloranil (CA), tetracyanoethylene (TCNE), and 2,3-dicyano-1,4-benzoquinone (DCBQ) has been investigated. Second-order rate constants in acetonitrile (AN) vary by a factor of more than 10^7 for this series. The rate of reaction of **1** with BQ increases 45-fold as the solvent composition is varied from AN to 50% (v/v) AN–water, but is insensitive to changes in buffer ratio or concentration in 75% AN. Spectroscopic evidence for charge-transfer complexing between the reactants was obtained with BQ and CA, and kinetic evidence for complexing was obtained with BQ in 75% AN. The primary isotope effect, p, calculated from the rates of oxidation of **1**, **1**-*9-d*, and **1**-*9,9-d*$_2$ (**1**(HH), **1**(HD), and **1**(DD)) in AN varied from 4.5 (TCNE) to 13 (BQ), while the secondary isotope effect, s, was approximately constant (~1.1). Values of the isotope partitioning ratio, *ipr* (the ratio of **2**(D) to **2**(H) formed in reaction of **1**(HD)) were determined for BQ in three AN–water mixtures and for CA, TCNE, and DCBQ in AN. For all systems studied, except BQ in 90% AN, where determination of the *ipr* is complicated by isotopic exchange between unreacted **1** and product (**2**), the *ipr* agrees with p/s from the kinetic measurements. These results are discussed in terms of mechanism and compared with those of other hydride transfer reactions involving dihydronicotinamide donors.

ALLAN K. COLTER, GUNZI SAITO et FRANCES J. SHAROM. Can. J. Chem. **55**, 2741 (1977).

On a étudié l'oxydation du *N*-méthylacridane (**1**) en ion *N*-méthylacridinium (**2**) par des accepteurs π comme la *p*-benzoquinone (BQ), le tétracyano-7,7,8,8 quinodiméthane (TCNQ), le *p*-chloranil (CA), le tétracyanoéthylène (TCNE) et le dicyano-2,3 benzoquinone-1,4 (DCBQ). Les constantes de vitesse du deuxième ordre dans l'acétonitrile (AN) varient par un facteur de plus de 10^7 pour cette série. La vitesse de réaction de **1** avec le BQ augmente par 45 fois lorsque l'on fait varier la composition de solvant de AN jusqu'à un mélange de 50% (v/v) de AN–eau; toutefois cette vitesse de réaction est insensible à des changements dans des rapports de tampons ou de concentrations dans AN à 75%. On a pu obtenir des données spectroscopiques indiquant qu'il y a une complexation de transfert de charge entre les réactifs avec BQ et CA et des données cinétiques suggérant qu'il s'effectue une complexation avec BQ dans AN à 75%. L'effet isotopique primaire, p, calculé à partir des vitesses d'oxydation de **1**, **1**-*9-d*, et de **1**-*9,9-d*$_2$ (**1**(HH), **1**(HD) et **1**(DD)) dans AN varie de 4.5 (TCNE) jusqu'à 13 (BQ) alors que l'effet isotopique secondaire, s, est approximativement constant (~1.1). On a déterminé les valeurs de rapport de partition d'isotopes (*ipr*) (le rapport de **2**(D) à **2**(H) formé lors de la réaction de **1**(HD)) pour BQ dans trois mélanges de AN–eau et pour CA, TCNE et DCBQ dans AN. Dans tous les systèmes étudiés, excepté BQ dans AN à 90% où la détermination de *ipr* est compliquée par un échange isotopique entre le composé **1** qui n'a pas réagit et le produit **2**, les valeurs de *ipr* sont en accord avec les valeurs de p/s obtenues à partir de mesures cinétiques. On discute de ces résultats en termes de mécanisme et on les compare avec ceux d'autres réactions de transfert d'hydrure impliquant la dihydronicotinamide comme donneur.

[Traduit par le journal]

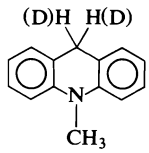
Oxidations of dihydropyridines and related compounds by hydride acceptors are of interest as models for biological oxidation–reduction reactions involving the pyridine nucleotide coenzymes (2), and as reactions of π donors with π acceptors (3). Although generally viewed as one-step hydride transfers, several mechanisms involving sequential transfer of one or two electrons and a hydrogen atom or proton are possible in theory. In fact, arguments for a mechanism involving electron transfer followed by hydrogen atom transfer have been made (4), and evidence for free radical (5) and free radical chain (6) mechanisms has been reported for certain systems. More recently, isotope effects requiring one or more intermediates in the oxidation of N-substituted-1,4-dihydronicotinamides by trifluoroacetophenone (7), *N*-methylacridinium ion

[1]For a preliminary account of a portion of these results, see ref. 1.

(8), and the Zn^{2+} complex of 1,10-phenanthroline-2-carboxaldehyde (9) have been reported. The kinetic deuterium isotope effect in these reactions is substantially smaller than that demanded by the isotope partitioning ratio (*ipr*) (*i.e.*, the ratio of hydrogen to deuterium transferred in reaction of the 4-*d*-dihydronicotinamide) for a one-step mechanism.

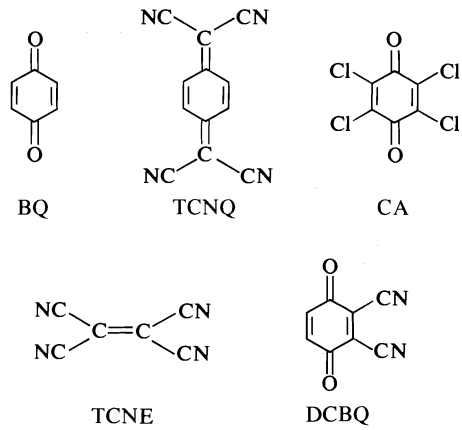
While it is clear that oxidation of dihydropyridines by compounds capable of reacting as either hydride or electron acceptors sometimes occurs by a stepwise mechanism, we know of no reaction where all of the evidence *requires* a synchronous transfer of a proton and two electrons. For example, kinetic deuterium isotope effects which establish C—H bond breaking in the rate-determining step (1, 7–10) are equally consistent with hydrogen atom transfer within a reversibly-formed radical ion pair. We have undertaken a systematic study of the oxidation of dihydropyridine analogs with π acceptors with the aim of elucidating the mechanisms of these reactions and the dependence of the mechanism on structural and environmental variables.

For our initial studies we have chosen *N*-methylacridan (**1**) as hydride donor. This choice



1(HH), **1**(HD), **1**(DD)

was based on several considerations. It is experimentally much simpler than the more extensively studied dihydronicotinamides, which are chemically more labile and in which there is a possibility of concurrent scrambling of deuterium between the 2-, 4-, and 6-positions (11). More importantly, both the lower ionization potential of **1** (below) and the smaller gain in resonance energy accompanying loss of hydride (compared to the dihydropyridines) (12) was expected to increase the lifetime of a radical ion pair intermediate. This paper describes an investigation of the products and stoichiometry, kinetics, solvent effects, and deuterium isotope effects in reaction of **1** with the acceptors *p*-benzoquinone (BQ), 7,7,8,8-tetracyanoquinodimethane (TCNQ), *p*-chloranil (CA), tetracyanoethylene (TCNE), and 2,3-dicyano-1,4-benzoquinone (DCBQ). An



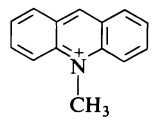
BQ TCNQ CA

TCNE DCBQ

earlier kinetic study of the oxidation of **1** with 2,6-dichloroindophenol has appeared (13).

Results

The products of oxidation of **1** by the five acceptors were identified by direct spectral examination of reaction mixtures under conditions similar to those of the kinetic studies (below), and by spectral and elemental analysis of isolated crystalline products. In agreement with earlier work (13, 14), the oxidation product in all cases is the *N*-methylacridinium ion (**2**), identi-



2

fied by spectral comparison with authentic *N*-methylacridinium salts (λ_{max} = 359 nm), and by isolation as the chloride or perchlorate salt. Reaction of 1:1 molar quantities of **1** and BQ in buffered 90% (v/v) acetonitrile–water (90% AN) followed by addition of hydrochloric acid afforded $\mathbf{2}^+Cl^-$, along with hydroquinone, as the only isolable products. Reaction of **1** (2×10^{-4} *M*) with TCNQ (1.5×10^{-2} *M*) in AN was accompanied by the appearance of absorption maxima at 670 and 740 nm characteristic of the radical anion $TCNQ^{\cdot-}$ (15). The spectra (above 400 nm) of solutions of the products of reaction of **1** with excess CA are consistent with those expected for mixtures of CA and its hydroquinone monoanion, CAH^- in equilibrium with the radical anion $CA^{\cdot-}$ (λ_{max} 415–420, 435–440 nm) (16). With TCNE and DCBQ the principal reduction products as indi-

cated by uv–visible spectra are the corresponding radical anions $TCNE^{\cdot-}$ (17), and $DCBQ^{\cdot-}$ (18), respectively. Similar results have been reported by Wallenfels *et al.* (19) in reaction of dihydropyridines with TCNE. In the reactions of **1** with TCNQ, TCNE, and DCBQ the corresponding crystalline radical ion salts of **2** can be isolated in high yield, however the $DCBQ^{\cdot-}$ salt rapidly decomposes on exposure to air. Details of the application of this method to the preparation of radical anion salts of quaternary heterocyclic cations will be published separately.

Based on these observations, the stoichiometry of these reactions is best represented by [1] for

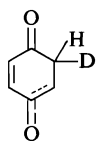
[1] $$\mathbf{1} + A \rightarrow \mathbf{2}^{+} + AH^{-}$$

BQ; with the other four acceptors the equilibrium represented by [2] (16, 20) occurs to vary-

[2] $$2AH^{-} + A \rightleftharpoons 2A^{\cdot-} + AH_2$$

ing extents. With TCNQ, TCNE, and DCBQ the complete oxidation of 1 mol of **1** requires approximately 1.5 mol of acceptor.

Hydroquinone isolated from reaction of **1**(HD) with BQ in 90% AN contained no excess deuterium (mass spectral analysis) indicating that the hydrogen is transferred to an oxygen rather than to a carbon. Intermediate formation of **3**, as might be expected by analogy with other



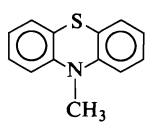
3

nucleophilic additions to quinones (21) would, in isomerizing to the hydroquinone monoanion, retain some excess deuterium bound to carbon. A second control experiment in which **1**(DD) was oxidized by BQ in 90% AN led to **2**(D) having no detectable H in the 9-position, demonstrating the absence of any exchange of the hydrogens at this position with solvent during the course of the oxidation. This result rules out mechanisms in which the hydrogen is transferred as a proton from any intermediate of reasonable lifetime.

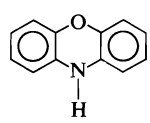
Mixing of separate solutions of BQ and **1** in benzene, chloroform, ether, or AN is accompanied by instantaneous appearance of a new broad long wavelength absorption band (λ_{max} in benzene 505 nm) which disappears as the components react. A transient long wavelength absorption could be observed for several other acceptors as well, but measurement of its position becomes increasingly difficult with increasing acceptor reactivity. In benzene solvent, in which the subsequent reaction is slowest, measurement of λ_{max} was possible with CA and less reactive acceptors. With acceptors more reactive than CA, the band was masked by absorption due to the rapidly-formed acceptor radical anion.

In order to confirm that the new maxima were charge-transfer absorptions, λ_{max} was measured for a series of five acceptors with the donors **1**, pyrene, and perylene (Table 1). Plots of the absorption frequencies for **1** *vs.* those for the corresponding pyrene and perylene complexes describe reasonably good straight lines with slopes of 0.95 ± 0.07 (pyrene) and 0.97 ± 0.07 (perylene).

It is noteworthy that the donor strength of **1** (as measured by charge-transfer frequencies) is much closer to that of 10-methylphenothiazine (**4**) and phenoxazine (**5**) than diphenylamine. For example, the charge-transfer frequencies for complexes of **4**, **5**, and diphenylamine with CA



4



5

are, respectively, 14.4×10^3 cm^{-1} (AN) (22), 13.7×10^3 cm^{-1} (AN) (22), and 15.4×10^3 cm^{-1} (chloroform) (23), compared to 13.7×10^3 cm^{-1} (benzene) for **1**.

Spectroscopic evidence for charge-transfer complexing between the reactants in hydride transfer reactions involving dihydropyridine donors has been reported previously (10*c*, 10*e*, 24). While no quantitative comparison of the donor strengths of **1** and *N*-alkyl-1,4-dihydronicotinamides is presently available, *N*-2,4,6-trimethylbenzyl-1,4-dihydronicotinamide was shown to be a weaker donor than **1**. Mixtures of TNB and **1** in chloroform showed a well-defined maximum at 515 nm, while chloroform solutions of the dihydronicotinamide and TNB showed no evidence for charge-transfer absorption above 500 nm.

[a]Concentrations: **1**, $1.0–1.3 \times 10^{-4}$ *M*; BQ, $1.01–1.09 \times 10^{-2}$ *M*. Temperature, 25.07°C unless otherwise indicated.
[b]Percentage acetonitrile (v/v, 25°C).
[c]Pseudo first-order rate constant ÷ stoichiometric BQ concentration. Averages of two rate runs with average deviation.
[d]Values in parentheses corrected to exactly 75% (v/v) acetonitrile–water.
[e]Temperature, 54.95°C.

All rate measurements were carried out under pseudo first-order conditions using a large excess of acceptor. The progress of the reaction was followed spectrophotometrically utilizing the acridinium absorption at 359 nm (BQ, TCNE) or 420 nm (CA, DCBQ) or that of the radical anion (TCNQ, 680 nm). The TCNE and DCBQ rates were measured using stopped flow spectrophotometry. The kinetics are first-order in each reactant within experimental error at sufficiently low acceptor concentrations, with small deviations from strict second-order behaviour at higher acceptor concentrations (below).

The first kinetic studies with BQ were carried out in buffered AN–water mixtures. Because of the possibility of general acid catalysis, the influence of small changes in buffer ratio and concentration was examined with acetic acid – sodium acetate buffers. Within the limited ranges studied, second-order rate constants (Table 2) vary only slightly with buffer ratio or concentration. A similar insensitivity to p*H* and ionic strength has been observed in oxidations of *N*-alkyl-1,4-dihydronicotinamides with thiobenzophenone (10*a*), BQ (25), and trifluoroacetophenone (26), all in mixed aqueous solvents. The difficulty in demonstrating general acid catalysis in mixed aqueous solvents has been noted (27) and our limited investigation does not exclude the possibility of a very small contribution from acid catalysis. The small decrease in second-order rate constant with increasing buffer concentration is most likely a result of a salt-induced medium effect (28). The activation parameters for reaction of **1** with BQ in 75.12% AN, calculated from runs *1* and *6*, are $\Delta H^{\ddagger} = 11.7 \pm 0.3$ kcal mol^{-1} and $\Delta S^{\ddagger} = -29.4 \pm 1.2$ cal deg^{-1} mol^{-1}.

The rate measurements with BQ are complicated by its photochemical instability, which becomes more serious with decreasing ratio of acetic acid to sodium acetate and increasing percent AN (slower rates). In the absence of a proton source the kinetic behaviour in 100% AN is complex. For these reasons, most of the subsequent rate measurements were carried out in the presence of 0.01 *M* acetic acid.

Because of the expectation of molecular complexing between the reactants, second order rate constants (pseudo first-order rate constant ÷ stoichiometric acceptor concentration) were measured at several concentrations of BQ in

75% AN (Table 3). The reproducibility of independently-determined rate constants is about ±2% (*e.g.*, compare runs *11* and *12*). Nevertheless, a fairly regular decrease in k with increasing BQ concentration is clearly discernible. Similar results have been observed in the oxidation of *N*-alkyl-1,4-dihydronicotinamides with flavins (10*c*, 24*c*) and *N*-methylacridinium ion (24*d*).

The data are consistent with any of several mechanisms involving equilibrium complexation of the reactants, *e.g.*, [3], where DH is the

$$\text{DH} + \text{A} \underset{}{\overset{K}{\rightleftharpoons}} \text{DH}\cdot\text{A} \xrightarrow{k_c} \text{Products} \qquad [3]$$

donor and A the acceptor. Under conditions where the acceptor is in large excess, this mechanism leads to [4] (3), where k is the

$$1/k = 1/k_cK + c_A/k_c \qquad [4]$$

observed second-order rate constant at a stoichiometric concentration of A = c_A. A plot of the kinetic data in Table 3 according to [4] leads, by least-squares analysis, to $K = 0.19\ M^{-1}$ (standard deviation 0.03) and k_cK (the true second-order rate constant based on uncomplexed reactants) = $5.88 \pm 0.05 \times 10^{-3}\ M^{-1}\ s^{-1}$. Exclusion of the point for run *13*, which lies furthest from the best fit straight line, leads to $K = 0.20 \pm 0.02\ M^{-1}$ and $k_cK = 5.88 \pm 0.04 \times 10^{-3}\ M^{-1}\ s^{-1}$.

While the kinetic results are consistent with 1:1 complex formation between the reactants with an association constant of *ca.* $0.20\ M^{-1}$, this interpretation must be viewed with some caution because of the very small decreases in k. Nonspecific medium effects resulting from 0.5 *M* BQ might easily produce changes in k comparable to those observed.

[a]Temperature, 25.0°C. Concentrations: **1**, $0.7–1.2 \times 10^{-4}$ *M*; BQ, 0.0986 *M*.
[b]Percentage AN (v/v, 25°C), 0.01 *M* acetic acid.
[c]Energy of the interionic charge-transfer band of 1-ethyl-4-carbomethoxypyridinium iodide, 25°C (29).

The effect of solvent on the rate of reaction of **1** with BQ was examined in AN–water mixtures covering the range 50 to 100% AN (Table 4). In order to obtain a more quantitative measure of the sensitivity of the rate to changes in ion-solvating ability, Z values (29) were measured for five of the seven solvents. Direct measurement of Z is not possible for AN–water mixtures containing more than about 30% water (29). A plot of log k *vs.* Z is reasonably linear; least-squares analysis leads to [5] (corr. coef. 0.985),

$$\log k = 8.11 \pm 0.64 \times 10^{-2}\, Z - 9.12 \pm 0.52 \qquad [5]$$

where the stated uncertainties are standard deviations.

An increase in rate with increasing ion-solvating ability has been noted previously in reactions of various 1,4-dihydropyridines with thiobenzophenone (10*a*), riboflavin (10*b*), pyridoxal (30), and hexachloroacetone (10*e*). The most extensive study of solvent effects is that of van Eikeren and Grier (26) who found that the rate of oxidation of *N*-propyl-1,4-dihydronicotinamide by trifluoroacetophenone in dimethyl sulfoxide – water and 2-propanol–water mixtures depended only on the mole fraction of water. If the same is true of AN–water mixtures (AN and dimethyl sulfoxide have almost identical Z values) then log k for the reaction of **1** with BQ is about 0.7 times as sensitive to solvent changes as log k for the reaction of van Eikeren and Grier, between $X_{H_2O} = 0.50$ to 0.75. In contrast, solvent effects in the oxidation of *N*-propyl-1,4-dihydronicotinamide with BQ in AN–water mixtures at 23.5°C[2] are practically identical to those found in the present work.

[a]Temperature, 25.0°C. Concentration of **1**, $0.8–2.0\times10^{-4}$ M. Rate constants reproducible to ±1% with BQ, TCNQ, and CA; ±3% with TCNE and DCBQ.
[b]Containing 0.01 M acetic acid.

We next carried out a less detailed investigation of the kinetics of reaction of **1** with the four stronger π acceptors in AN. Under the conditions studied, the five acceptors cover a 1.5 × 10^7-fold range of reactivity (Table 5). With TCNQ, CA, TCNE, and DCBQ a proton source is not required for good pseudo first-order kinetics, however the presence of 0.01 M acetic acid was shown to have no significant effect on the observed rate with TCNQ (Table 5). Spectroscopic evidence for complexing between the reactants was observed with CA and complexing is expected for the other acceptors as well. However, at the low concentrations of acceptor used in the rate measurements, the calculated second-order rate constants were shown to be very close to the true second-order rate constants for uncomplexed reactants. For example, k for reaction of **1**(HH) with 5.0×10^{-3} M TCNQ is 2.38×10^{-1} M^{-1} s^{-1}, close to the value observed with 1.5×10^{-2} M TCNQ (Table 5). Similarly, a tenfold increase in TCNE concentration led to no significant change in k.

Also listed in Table 5 are rate constants for reaction of **1**(HD) and **1**(DD) with BQ in three AN–water mixtures and with all five acceptors in AN.

Any mechanism in which the hydrogen is transferred in a rate-determining step involving the reactants or an intermediate in equilibrium with reactants leads to the relationships summarized in [6]. The rate constants k_{HH}, k_{HD}, and k_{DD} are the experimental rate constants for **1**(HH), **1**(HD), and **1**(DD), respectively; k_H, k_H', k_D, and k_D' are the corresponding rate constants for transfer of the four types of hydrogen and deuterium. The primary isotope effect, p, and the secondary isotope effect, s, defined by [7] and [8], are related to the experimental rate

[6]

$$\mathbf{1}(HH) \xrightarrow{2k_H} \mathbf{2}(H) \qquad k_{HH} = 2k_H$$

$$\mathbf{1}(HD) \xrightarrow{k_H'} \mathbf{2}(D) \qquad \mathbf{1}(HD) \xrightarrow{k_D} \mathbf{2}(H) \qquad k_{HD} = k_H' + k_D$$

$$\mathbf{1}(DD) \xrightarrow{2k_D'} \mathbf{2}(D) \qquad k_{DD} = 2k_D'$$

[7] $$p = k_H/k_D = k_H'/k_D'$$

[8] $$s = k_H/k_H' = k_D/k_D'$$

[9] $$k_{HH}/k_{DD} = p \times s$$

[10] $$k_{HD}/k_{DD} = (p + s)/2$$

constants by [9] and [10]. Primary and secondary isotope effects, calculated from the data in Table 5 using [9] and [10], are listed in Table 6. With BQ, the experimental rate constants are slightly smaller than the true second-order rate constants (above). However, barring extraordinarily large secondary isotope effects on the complexation constants, K, such corrections will have a negligible effect on the calculated values of p and s.

For any of the mechanisms for which the relationships in [6] hold, the isotope partitioning ratio (*ipr*) that is, the ratio of **2**(D) to **2**(H) formed from reaction of **1**(HD), is given by k_H'/k_D, or p/s. Values of the *ipr* were determined for four of the acceptors by mass spectral analysis of isolated *N*-methylacridinium chloride (**2**$^+$Cl$^-$) and are listed for comparison with the kinetically-determined values of p/s in Table 6.

TABLE 6. Kinetic isotope effects and isotope partitioning ratios

Acceptor	Solvent	Kinetic isotope effects[a]			
		p	*s*	*p*/*s*	*ipr*[c]
BQ	60% AN[b]	8.95±0.41	1.08±0.06	8.3±0.6	8.1±1.4
BQ	75% AN[b]	11.0 ±0.5	1.04±0.05	10.6±0.7	9.1±1.9
BQ	90% AN[b]	11.8 ±0.5	1.02±0.05	11.6±0.8	9.4±2.0
BQ	AN[b]	13.3 ±0.6	1.06±0.05	12.6±0.8	—
TCNQ	AN	6.20±0.32	1.16±0.07	5.3±0.4	—
CA	AN	7.66±0.37	1.14±0.06	6.7±0.7	6.2±0.7
TCNE	AN	4.76±0.33	1.10±0.09	4.4±0.5	4.5±1.4
DCBQ	AN	5.37±0.35	1.09±0.08	4.9±0.5	4.7±0.1

[a]Calculated from the data in Table 5 using [9] and [10]; errors based on ±1% uncertainties in k_{HH}, ±3% in k_{HD}, and ±2% in k_{DD} for BQ, TCNQ, and CA, and ±3% in all rate constants for TCNE and DCBQ (See Experimental).
[b]Containing 0.01 *M* acetic acid.
[c]Ratios of acceptor to **1** were 1000 with BQ, 50 with CA, 20 with TCNE and DCBQ. Averages of two to nine determinations, listed with standard deviations. The *ipr*'s are corrected for contamination of **1**(HD) by **1**(HH).

With BQ the measured *ipr* was found to increase toward an upper limit as the ratio of BQ to **1** was increased. For example, in 90% AN the *ipr* increased from 2.9 at 1:1 BQ–**1**, to approximately 9.4 at 1000:1 BQ–**1**. This variation is believed to be a result of isotopic exchange involving unreacted *N*-methylacridan, **1**, and the *N*-methylacridinium ion, **2**, produced in the reaction, *e.g.*, [11].

$$\mathbf{1}(HD) + \mathbf{2}(D) \rightleftharpoons \mathbf{1}(DD) + \mathbf{2}(H)$$
$$\mathbf{1}(HD) + \mathbf{2}(H) \rightleftharpoons \mathbf{1}(HH) + \mathbf{2}(D) \quad [11]$$

Reactions of this type provide a mechanism for conversion of unreacted **1**(HD) to a mixture of **1**(HH), **1**(HD), and **1**(DD). Such scrambling of deuterium will have the effect of reducing the measured *ipr*, and if the true *ipr* is large even a very small amount of scrambling will cause a large error. The *N*-methylacridinium ion is expected to be a much more reactive acceptor than BQ.[3] The occurrence of rapid exchange was directly confirmed by nmr spectroscopic monitoring of solutions containing isotopically labelled **1** and **2**. Complications due to isotopic scrambling are expected to become more serious with increasing percent AN since the rates of the exchange reactions should be less sensitive to solvent ion-solvating ability than that of the BQ reaction. In fact, it was not possible to completely suppress scrambling in 90 and 100% AN, even at a 1000 to 1 ratio of BQ to **1**. Higher ratios are impractical because of the consequent difficulty of isolating the product. Lower ratios of acceptor to **1** were required with the more reactive acceptors. In theory, exchange reactions [11] leading to isotopic scrambling should lead to curvature in the first-order rate plots for **1**(HD). However, under the conditions of the rate measurements no significant curvature was observed.

The most significant results of the isotope effect studies are the uniformly high primary isotope effects and the agreement between *p*/*s* derived from kinetic measurements and product analyses. Both results stand in striking contrast to those for the dihydronicotinamide oxidations cited earlier (7–9). Dittmer *et al.* (10*e*) also found approximate agreement between kinetic and product isotope effects in oxidation of *N*-benzyl-1,4-dihydronicotinamide with hexachloroacetone, pentachloroacetone, and *s*-tetrachloroacetone. Significantly, the agreement between kinetic and product isotope effects in the present work holds for acceptors covering a 1.5×10^7-fold range in reactivity, and in spite of considerable variation in the primary isotope effect. The very high primary isotope effects observed with BQ suggest a contribution from quantum mechanical tunneling (32). This possibility is under investigation. Secondary isotope effects are normal, and approximately constant. Although *s* appears to be somewhat smaller with BQ than with the more reactive acceptors, the difference may well be less than the combined experimental uncertainties.

Discussion

The kinetic isotope effects observed in the

[3]For example, Hajdu and Sigman (31) found CA to be only 29 times as reactive as **2** in oxidation of *N*-benzyl-1,4-dihydronicotinamide in AN, while the reactivity of CA relative to BQ observed in the present work is approximately 2×10^4.

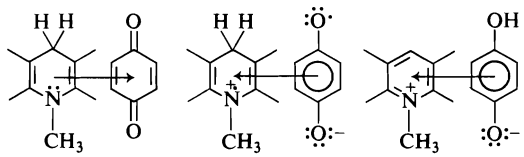
present work require a mechanism in which the C—H bond is broken in a step which is both rate- and product-determining. Two such mechanisms, which we will describe as one-step hydride transfer and sequential electron–hydrogen atom transfer mechanisms, are represented by [12] and [13]. DH represents hydride

$$[12]\quad DH + A \underset{}{\overset{\text{Rapid}}{\rightleftharpoons}} \underset{\text{Charge-transfer complex}}{DH\cdot A} \xrightarrow[\text{of } H:^-]{\text{Slow transfer}} D^+ + AH^-$$

$$[13]\quad DH + A \overset{\text{Rapid}}{\rightleftharpoons} DH\cdot A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{\text{Radical-ion pair}}{DH^{\ddagger}A^{\mp}} \xrightarrow[\text{Slow transfer of H}\cdot]{k_2} D^+ + AH^-$$

donor and A the hydride (or π) acceptor. Since some dihydronicotinamide oxidations require an intermediate such as $DH^{\ddagger}A^{\mp}$ (7–9) it is of interest to examine the extent to which the present results can be accomodated by a mechanism such as [13].[4]

The reactants are in rapid equilibrium with a charge-transfer complex and it is at least reasonable to assume that subsequent electron or hydride transfer proceeds by way of a transition state resembling the complex in relative orientation of the donor and acceptor. Substantial donor–acceptor interaction is expected between the two reactants (**6**) and the products of either electron (**7**) or hydride (**8**) transfer, the donor



6 **7** **8**

and acceptor roles reversing in the process. Although any charge-transfer interaction may be weaker in the transition state than in the reactants (**6**) or products (**7** or **8**), a face-to-face orientation will also be favored by electrostatic interaction between the developing positive and negative charges. However, further work is required to establish the orientation of the donor and acceptor in the transition state.

The somewhat smaller solvent effects in the oxidation of *N*-propyl-1,4-dihydronicotinamide[2] (or **1**) with BQ than with trifluoroacetophenone (26) may be a result of greater delocalization of the developing negative charge, or to donor–acceptor or electrostatic interaction in the transition state for the BQ reaction. It is instructive to compare our solvent effects with those in the anchimerically-assisted ionization of *p*-methoxyneophyl *p*-toluenesulfonate at 75°C (k_{ion}) (33). Using the extensive comparisons of the common solvent polarity parameters published by Reichardt and Dimroth (34), we can estimate that

$$[14]\quad \log k\ (\mathbf{1} + BQ, 25°C) \approx 0.58 \log k_{ion} + \text{constant}$$

The observation that log k for reaction of **1** with BQ is less sensitive to ion-solvating ability than log k_{ion} seems more consistent with partially developed charges in the rate-determining transition state (as in [12]) than with fully developed positive and negative charges (as in [13]).

The isotope effects observed in the present work and those reported by Chipman and Sigman and their co-workers in oxidations of *N*-alkyl-1,4-dihydronicotinamides (7–9) can both be accomodated by mechanism [13] ($k = k_1k_2/(k_{-1} + k_2)$) provided that $k_{-1} \gg k_2$ for oxidation of **1** but that $k_{-1} \approx k_2$ for the dihydronicotinamide oxidations. *A priori* we expect both k_{-1} and k_2 to be smaller, and k_1 to be larger, for the oxidation of **1** than for oxidation of a dihydronicotinamide with the same acceptor under similar conditions. This prediction follows from the lower ionization potential of **1** and the smaller gain in resonance energy accompanying aromatization. More specific comparisons of the present systems with those of Chipman and Sigman are difficult because of the different acceptors and solvents used. However, the reactivity of *N*-propyl-1,4-dihydronicotinamide is approximately 10^3 times that of **1** for reaction with BQ in aqueous AN.[2] If both reactions proceed according to [13], then given the relative magnitudes of k_1 and $(k_{-1} + k_2)$ for the two systems (above), this difference in reactivity must reflect a *greater* than 10^3-fold difference in k_2 in the expected direction.

It is more difficult to understand the large variation in p on the basis of [13]. The acceptors studied are of two types: those in which hydro-

[4]While it is convenient to picture [12] and [13] as discrete mechanisms for the purposes of this discussion, a continuous spectrum of mechanisms intermediate between [12] and [13] is possible.

gen is transferred to oxygen (BQ, CA, DCBQ) and those in which hydrogen is presumably transferred to carbon (TCNQ, TCNE). Within each group, p decreases with increasing reactivity. To reconcile these results with [13] the transition state for the hydrogen transfer step must vary substantially from $BQ^{\bullet-}$ to $DCBQ^{\bullet-}$. Specifically, since the hydrogen transfer step in [13] would have to be highly favorable energetically, the observed trends in p seem to require that k_2 increase in the order $BQ^{\bullet-} < CA^{\bullet-} < DCBQ^{\bullet-}$. While the observed dependence of the rate on acceptor and solvent are in line with expected changes in k_1/k_{-1}, there is less reason to expect k_2 to be greatly different for $BQ^{\bullet-}$, $CA^{\bullet-}$, and $DCBQ^{\bullet-}$, or for $BQ^{\bullet-}$ in the four solvents investigated. However, a more complete understanding of the dependence of the rate on acceptor structure is required before we can comment further. On the other hand, the variation in p is easily accomodated by [12], where the large differences in reactivity result from differences in the rate of the step in which the C—H bond is broken.

Either mechanism predicts a correlation of acceptor reactivity with the stability of AH^- relative to A. Unfortunately, no independent measure of hydride acceptor strength is presently available. Acceptor reactivity parallels the ease of one-electron reduction (as measured, for example, by the polarographic half-wave potentials, $\varepsilon_{1/2}$ (red), for reversible one-electron reduction) within each group but not necessarily when comparing a cyanocarbon to a quinone. For example, the reactivities of CA and TCNQ are in the opposite order to that predicted by their ease of one-electron reduction ($\varepsilon_{1/2}$ (red) = +0.01 and 0.19 V, respectively, *vs.* S.C.E. in AN) (35). A more extensive investigation of reactivity as a function of acceptor structure is in progress.

In summary, the results of the present investigation are completely consistent with a one-step hydride transfer mechanism [12]. While the results do not conclusively exclude a sequential electron–hydrogen atom transfer mechanism such as [13], solvent effects and trends in primary isotope effects are less easily accomodated with such a mechanism.

Experimental

Reagents and Solvents

N-Methylacridan, **1**(HH), was prepared by reduction of *N*-methylacridinium chloride, iodide, or perchlorate with sodium borohydride. In a typical reaction, a solution of 0.386 g (0.01 mol) of sodium borohydride (98%) in 15 ml of water was added dropwise to a stirred, cooled (0°C), solution of 2.30 g (0.01 mol) of $\mathbf{2}^+Cl^-$ in 25 ml of methanol. After stirring for 1 h at 0°C and 3 h at room temperature, the methanol was evaporated under reduced pressure and the product extracted into ether. The combined extracts were dried over K_2CO_3, filtered, and the ether evaporated to yield **1** in quantitative yield. The product was purified by crystallization from absolute ethanol or methanol and sublimation, to give colourless crystals, mp 89–91°C (lit. (36) mp 95°C). The *p*-toluenesulfonate and iodide salts of **2** were prepared by standard methods (37). The chloride salt was prepared by heating an aqueous solution of $\mathbf{2}^+I^-$ with an excess of AgCl in suspension, filtration, and evaporation to dryness under reduced pressure. The residue was dissolved in ethanol, precipitated by addition of ether, and recrystallized from 80:20 ethyl acetate – ethanol, mp 165–168°C. The perchlorate salt was obtained by dropwise addition of 70% perchloric acid to a solution of 5 g of the *p*-toluenesulfonate salt in 30 ml of ethanol until precipitation was complete, filtration and crystallization from methanol, mp 243–247°C (dec.).

N-Methylacridan-*9-d*, **1**(HD), was prepared and purified as described for **1**(HH) using $NaBD_4$ (> 98% isotopic purity). The product ordinarily contained about 5% **1**(HH) (nmr).

N-Methylacridan-*9,9-d*$_2$ was prepared from **1**(HD) by oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), isolation as $\mathbf{2}^+ClO_4^-$, re-reduction with $NaBD_4$, and so on. In a typical oxidation, a solution of 1.71 g (7.5×10^{-3} mol) of DDQ in 125 ml of ether was added dropwise to a stirred solution of 1.42 g (7.2×10^{-3} mol) of **1** in 25 ml of ether, at room temperature. Addition of 2 ml of 70% perchloric acid resulted in precipitation of $\mathbf{2}^+ClO_4^-$, which was filtered, washed with ether, and dried. Yield, 2.14 g (100%). Starting from 7.03 g of **1**(HD), six oxidations and six reductions, followed by crystallization from methanol, led to **1** in 26% overall yield, containing 98.8% D at the 9-position, *i.e.*, 97.6% **1**(DD). The product was sublimed before use.

BQ, TCNQ, CA, and TCNE were obtained from commercial sources and were carefully purified before use. BQ was purified by repeated crystallization from CCl_4 and sublimation, TCNQ was crystallized three times from AN and once from tetrahydrofuran, CA was crystallized four times from benzene, and TCNE was sublimed twice. DCBQ was prepared as described by Brook (38) and purified by sublimation, mp 177–179°C (lit. (38) mp 178–180°C).

Pyrene, perylene, 1,3,5-trinitrobenzene, and 2,3-dichloro-1,4-naphthoquinone were obtained from commercial sources and, where necessary, purified by crystallization and/or sublimation until their melting points agreed with published values. 2,3-Dichloro-5-nitro-1,4-naphthoquinone was prepared by nitration of 2,3-dichloro-1,4-naphthoquinone following the procedure of Wilbur and Day (39), and purified by crystallization from $CHCl_3$, mp 175.5–176°C (lit. (39) mp 174–175°C). 1-Ethyl-4-carbomethoxypyridinium iodide was prepared by refluxing a benzene solution of methyl isonicotinate and ethyl iodide in 1:4 molar ratio, filtration, and crystallization from acetone, mp 109–110°C (lit. (29) mp 111–112°C).

Reagent grade acetonitrile was purified by successive

distillations over sodium hydride, concentrated sulfuric acid, phosphorus pentoxide, and anhydrous potassium carbonate, and stored over a molecular sieve (40). Water and reagent grade acetic acid were further purified by distillation over potassium permanganate.

Tracer Studies

A solution containing **1**(HD) (0.100 g, 5.1×10^{-4} mol) and BQ (0.0554 g, 5.1×10^{-4} mol) in 20 ml of 90% AN, 0.01 *M* in acetic acid and sodium acetate, was allowed to stand at room temperature, protected from light, for approximately 24 h. The AN was evaporated under reduced pressure, 5.1 ml of 0.1 *M* hydrochloric acid and 5 ml of water added, and the resulting mixture extracted several times with ether. The combined ether extracts were washed with aqueous bicarbonate, dried, filtered, and the ether evaporated off. The solid residue was dissolved in 20 ml of 0.1 *M* aqueous NaOH and the alkaline mixture washed several times with ether to remove unreacted **1** and BQ. After acidification with hydrochloric acid, the hydroquinone was isolated by extraction into ether, drying, filtration, and evaporation. The solid residue was sublimed yielding about 10 mg of pure hydroquinone. Mass spectral analysis (comparison with hydroquinone) revealed no excess deuterium. As a control, a sample of hydroquinone containing 67.1% of the hydrogen replaced by deuterium was taken through the reaction and isolation procedure. Mass spectral analysis showed no loss of deuterium.

In a similar reaction of equimolar amounts of **1**(DD) and BQ in buffered 90% AN, the aqueous solution remaining after the first ether extraction was evaporated to dryness under reduced pressure, and the residue dissolved in the minimum amount of 95% ethanol and cooled to deposit yellow crystals of $\mathbf{2}^+Cl^-$ which were washed with ether and dried. The product contained no detectable hydrogen at the 9-position (nmr, D_2O).

Spectroscopic Measurements

Charge-transfer maxima were measured using a Cary model 116 recording spectrophotometer. *Z* values were determined from the average of four or five successive measurements of the wavelengths of the absorption maxima of freshly prepared solutions of 1-ethyl-4-carbomethoxypyridinium iodide (1.66×10^{-2} *M*) in the appropriate solvent. Standard deviations in λ_{max} measurements were 0.4 nm or less.

Kinetic Measurements

Kinetic measurements utilized Guilford model 200 and Cary model 116 spectrophotometers, with thermostatted cell compartments, for the BQ, TCNQ, and CA rates, and a Durrum stopped flow spectrophotometer for the TCNE and DCBQ rates. The progress of the reaction was followed at 359 nm (BQ, TCNE), 420 nm (CA, DCBQ), or 680 nm (TCNQ). Measurements were carried out under pseudo first-order conditions using a 20 to 5000-fold molar excess of acceptor (Table 5). First-order rate plots were linear through at least 3 half-lives and pseudo first-order rate constants were determined both graphically and by computer. Duplicate rate measurements utilizing the same stock solutions of **1** and acceptor were reproducible to $\pm 1\%$ (BQ, TCNQ, CA) or $\pm 3\%$ (TCNE, DCBQ), while completely independently-determined rate constants were reproducible to ± 2–3%. Errors in k_{HD} and k_{DD} due to contamination of **1**(HD) and **1**(DD) by **1**(HH) and **1**(HD), respectively, were minimized by calculation of the rate constant from the limiting slopes after at least one half-life. Such errors are most serious for k_{HD}, where, for example, the rate constant calculated from the average slope between 50 and 75% reaction would be approximately 1.9% high. In calculation of the uncertainties in *p* and *s*, uncertainties in k_{HD} and k_{DD} were therefore taken as $\pm 3\%$ and $\pm 2\%$, respectively, for BQ, TCNQ, and CA.

Isotope Partitioning Ratios

Isolation of $\mathbf{2}^+Cl^-$ was carried out as follows. The reaction mixture was evaporated under reduced pressure in a flask protected from light. The acridinium salt was dissolved by addition of hydrochloric acid and the unreacted quinone removed by repeated ether extractions. The $\mathbf{2}^+Cl^-$ was isolated by evaporation and purified by repeated solution in methanol followed by addition of ether. The proportions of **2**(D) and **2**(H) were determined by mass spectral analysis of $\mathbf{2}^+Cl^-$ at 40 and 70 eV, utilizing the relative intensities of the *m/e* 194 and 195 peaks and the *m/e* 179 and 180 peaks, by comparison with the mass spectra of a series of known mixtures containing 0 to 25% $\mathbf{2}(H)^+Cl^-$. The measured ratios of **2**(D) to **2**(H) were corrected for contamination of the **1**(HD) starting material by **1**(HH).

The crystal structure of *tert*-butyl ethyldiazoacetate mercury(II)

R. A. SMITH, M. TORRES, AND O. P. STRAUSZ

Department of Chemistry, University of Alberta, Edmonton, Alta, Canada T6G 2G2

Received January 12, 1977

R. A. SMITH, M. TORRES, and O. P. STRAUSZ. Can. J. Chem. **55**, 2752 (1977).

tert-Butyl ethyldiazoacetate mercury(II) is monoclinic with the following unit cell data at 20°C: $P2_1/n$, $a = 8.089(3)$, $b = 18.720(10)$, $c = 7.893(3)$ Å, $\beta = 93.20(3)°$, $V = 1193.3$ Å^3, $\rho_o = 2.09(1)$, $\rho_c = 2.06$, $Z = 4$. The structure was solved by heavy atom methods and refined to $R = 6.6\%$ for 1003 reflections. The diazoacetate portion is planar; the CN_2 portion is linear.

R. A. SMITH, M. TORRES et O. P. STRAUSZ. Can. J. Chem. **55**, 2752 (1977).

Le *tert*-butyle diazoacétate d'éthyle mercure(II) est monoclinique et les paramètres de la maille à 20°C sont: $P2_1/n$, $a = 8.089(3)$, $b = 18.720(10)$, $c = 7.893(3)$ Å, $\beta = 93.20(3)°$, $V = 1193.3$ Å^3, $\rho_o = 2.09(1)$, $\rho_c = 2.06$, $Z = 4$. On a résolu la structure par la méthode des atomes lourds et on l'a affinée jusqu'à une valeur de $R = 6.6\%$ pour 1003 réflexions. La portion diazoacétate est planaire; la portion CN_2 est linéaire.

Introduction

Photolysis of $Hg(CN_2CO_2Et)_2$, **1**, has been reported to be a usable source of the novel carbon radical carbethoxymethyne and detailed mechanistic studies have been reported for the photolysis of **1** in olefins and paraffins (1), chloroalkanes (2), and pentacarbonyl manganese bromide (3).

Recently, the photolysis of the source compound *tert*-butyl ethyldiazoacetate mercury(II), **2**, has been investigated (4). The ir spectrum of **2** in CCl_4 solution exhibits bathochromic shifts of *ca.* 75 cm^{-1} in the diazo and carbonyl stretching regions of the spectrum, relative to ethyldiazoacetate. Similar shifts are observed in mercurybis-(α-diazoketones) (5), indicative of large electron delocalization in these portions of the molecule.

Little is known about the crystal structures, molecular geometries, or the nature of the bonds in these diazomercurials. This kind of information, apart from its inherent interest, would be helpful in the elucidation and interpretation of the chemical reactivity of this class of molecules. For this reason an X-ray diffraction study of **2** has been undertaken, the details of which are reported here.

Experimental

The title compound was prepared following the method reported for the methyl analog (6). The resulting prismatic yellow crystals were suitable in terms of size and shape for an X-ray study.

$C_8H_{14}HgN_2O_2$ fw = 370.8

Monoclinic, $P2_1/n$, $a = 8.089(3)$, $b = 18.720(10)$, $c = 7.893(3)$ Å, $\beta = 93.20(3)°$, $V = 1193.3$ Å^3, $\rho_o = 2.09(1)$, $Z = 4$, $\rho_c = 2.06$ (20°C; $MoK_{\alpha 1}$ $\lambda = 0.7093$ Å).

Preliminary photographs showed systematic absences, $h0l$, $h + l = 2n + 1$, $0k0$, $k = 2n + 1$, the non-standard space group was maintained since the standard setting had a β value close to 60°. Twelve high angle reflections were carefully centered on a Picker FACS 1 diffractometer ($MoK_{\alpha 1}$ radiation, no monochromator) and accurate cell constants were derived.

A unique set of data with $0 < 2\theta \leq 47°$ (MoK_α radiation, graphite (002) monochromator) was collected by the coupled $\theta/2\theta$ scan method. The crystals decomposed rapidly under the experimental conditions and three separate crystals were necessary to collect all the data. Decomposition was monitored by measurement of standards every 100 reflections. A total of 1840 reflections were measured and corrected for Lorentz-polarisation, decomposition, and absorption (7) (μ, $MoK_\alpha = 121$ cm^{-1}; crystal *1*, 0.13 × 0.06 × 0.06 mm; crystal *2*, 0.13 × 0.10 × 0.06 mm; crystal *3*, 0.10 × 0.08 × 0.06 mm) and then merged to one data set on the basis of common reflections. The data were reduced to F, $\sigma(F)$, and $\sigma(I)$ using a p value of 0.06 (8). Using an acceptance criterion $I \geq 3\sigma(I)$, 1003 reflections had significant intensity and were used in subsequent calculations.

Conventional heavy atom methods were used to locate the mercury atom. A difference Fourier map for data of the form $h + k + l = 2n$ showed the expected molecule and one related to it by a two-fold axis along b and passing through the mercury atom, but none of the peaks overlapped and an immediate distinction between real peaks and their symmetry-related ones was possible for all non-H atoms. Using full-matrix least-squares procedures on all 1003 reflections, R was reduced to 6.6% with anisotropic thermal parameters for all atoms. A weight of $4F^2/\sigma^2(F^2)$ was applied to every reflection. Scattering

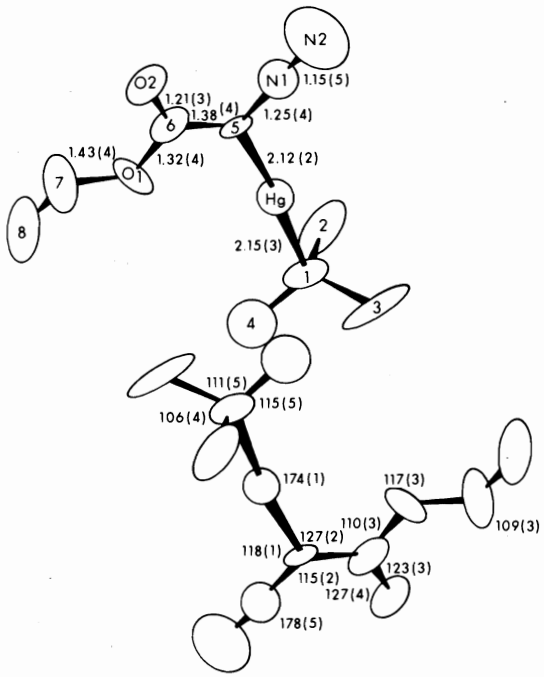

FIG. 1. Atomic numbering, bond angles, and distances in *tert*-butyl ethyldiazoacetate mercury(II).

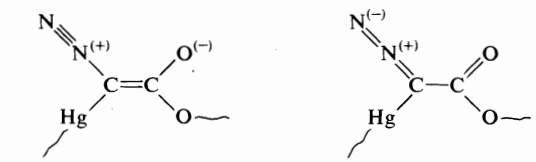
factors for neutral atoms were used (9) and anomalous dispersion corrections were applied to the mercury atom (10). A final difference Fourier map was calculated and contained peaks of the order of 1.0 e/Å^3 in the vicinity of the mercury atom and up to 0.75 e/Å^3 elsewhere. Consequently no attempt was made to determine the hydrogen atom positions.

Results and Discussion

The atomic numbering scheme and important bond angles and distances are given in Fig. 1. Final atom parameters are given in Table 1 and the table of structure factors has been placed in the Depository of Unpublished Data.[1]

It is interesting to note the planar *cis* structure with respect to the carbonyl and azo groups of the diazoacetate because this configuration which is generally more stable than the *trans* (11), has been claimed for diazoketones which are capable of undergoing the Wolff rearrangement (12) yet mercury diazo compounds do not isomerize to ketenes (13). All 7 atoms of the $HgCN_2CO_2$ portion of the molecule lie within 0.02 Å of the mean plane. The standard deviations for the observed bond lengths and angles are, as expected, nearly twice as large as those for similar molecules reported recently (14) because the data from three separate crystals had to be merged. This precludes detailed discussion of the bonding scheme, but it is probably a resonance hybrid of the structures shown below.



[1]The Structure Factor Table is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Bis(ethyldiazoacetate) mercury(II) is currently under investigation, it will be interesting to compare the azocarbonyl moiety in this compound to that found in the title compound.

Theoretical studies of the chemistry of singlet and triplet species. II. Cycloaddition reaction[1]

R. F. W. BADER, M. E. STEPHENS,[2] AND R. A. GANGI[3]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 11, 1977

R. F. W. BADER, M. E. STEPHENS, and R. A. GANGI. Can. J. Chem. **55**, 2755 (1977).

Ab initio SCF potential energy surfaces for the cycloaddition reactions $C_2H_4(^1A_{1g}) + O(^1D, ^3P)$ are reported. The lowest energy singlet path corresponds to the symmetric, concerted addition reaction yielding ethylene oxide. The lowest energy triplet path corresponds to an asymmetric approach of the reactants to form an open ring adduct ($\angle CCO = 105°$). The spatial distribution of the spin density in this adduct conforms to that expected for a diradical. The barrier to internal rotation of the terminal methylene is calculated to be ~ 5 kcal mol^{-1}. The lowest intersystem crossing from the triplet to the singlet surface, as required for ring closure to yield ground state product, is found to occur ~ 36 kcal mol^{-1} above the energy of the triplet reactants.

The differences in singlet and triplet charge distributions and energies for similar approach geometries may be rationalized in terms of the additional restraints imposed on the course of the triplet reaction by the Pauli principle, restraints which are made evident by the spatial distribution of the spin density. Two principal mechanisms of spin polarization, spin unpairing and spin decoupling, are found to provide a rationale for the observed differences of singlet and triplet reactants in abstraction, insertion and addition reactions. The favoured course of a triplet reaction is found to be governed by the axiom that localized distributions of spin density are to be maximally separated in space.

R. F. W. BADER, M. E. STEPHENS et R. A. GANGI. Can. J. Chem. **55**, 2755 (1977).

On rapporte des surfaces d'énergie potentielle calculées par la méthode SCF *ab initio* pour les réactions de cycloaddition de $C_2H_4(^1A_{1g}) + O(^1D,^3P)$. Le chemin singulet d'énergie la plus basse correspond à la réaction d'addition concertée symétrique conduisant à l'oxyde d'éthylène. Le chemin triplet de plus basse énergie correspond à une approche asymétrique des réactifs pour former un adduit à cycle ouvert ($\angle CCO = 105°$). La distribution spatiale des densités de spin dans cet adduit est en conformité avec celle attendue pour un diradical. On a calculé que la barrière à la rotation interne du méthylène terminal est d'environ 5 kcal mol^{-1}. La conversion intersystème la plus basse entre la surface triplet et la surface singulet, telle que requise pour la fermeture du cycle conduisant à un produit dans l'état fondamental, se produirait environ 36 kcal mol^{-1} au dessus de l'énergie des réactifs triplets.

On peut rationaliser les différences dans les distributions de charge des états singulet et triplet et les énergies pour les géométries d'approches similaires en termes de contraintes additionnelles imposées sur l'évolution de la réaction triplet par le principe de Pauli, restrictions qui sont rendues évidentes par la distribution spatiale des densités de spin. On a trouvé que deux mécanismes principaux de polarisation de spin, de dépairage de spin et de découplage de spin peuvent fournir une explication rationnelle pour les différences observées dans les réactions d'enlèvement d'insertion et d'addition des réactifs singulet et triplet. On a trouvé que le chemin favorisé pour une réaction à l'état triplet est gouverné par l'axiome voulant que les distributions localisées de densité de spin doivent être séparées au maximum dans l'espace.

[Traduit par le journal]

Introduction

This paper presents a theoretical study and comparison of the mechanisms of the addition of singlet and triplet states of a reactant to a double bond. *Ab initio* SCF potential surfaces are reported for the cycloaddition reactions of $O(^1D, ^3P)$ with $C_2H_4(^1A_{1g})$. In a previous publication (1) we obtained a qualitative interpretation of the differing tendencies of singlet and triplet species to undergo insertion and abstraction reactions in terms of the spatial distributions of the electronic charge density $\rho(r)$, and spin density $\sigma(r)$. It was observed that the spin density of a triplet adduct is spatially localized in separate

[1]For paper I, see ref. 1.

[2]Centre de Mecanique Ondulatoire Appliquee, 23, rue du Maroc, 75019 Paris, France.

[3]Gloucester County College, Sewell P.O., NJ, U.S.A. 08080.

distributions on neighbouring nuclei in a manner dictated by the molecular geometry. There is a characteristic pattern for the polarization and localization of $\sigma(\boldsymbol{r})$ induced by the approach of a triplet species along the bisector of a singlet, bonded pair of atoms (insertion approach), a pattern which is different from that obtained when the triplet species approaches one atom of the bonded pair to yield an abstraction reaction. The present study shows that the same two patterns of polarization and localization of the spin density are operative for the corresponding geometries of approach of a triplet species to a doubly bonded pair of atoms. The differences in singlet and triplet charge distributions and energies for motion along reaction paths of identical nuclear geometries may be rationalized in terms of the additional restraints imposed on the course of the triplet reaction by the Pauli principle, restraints which are made evident by the spatial distribution of the spin density. The favoured course of a triplet reaction is found to be dictated by the simple axiom that localized distributions of spin density (of the same sign) are to be maximally separated in space.

Since the studies of Skell *et al.* (2) on methylene addition of olefins, much debate has ensued over the relationship between the reaction mechanisms and the spin-multiplicity of open-shell reactants (3, 4).

It has been experimentally established, for instance, that $O(^1D)$ (5), $S(^1D)$ (6), and $CH_2(^1A_1)$ (7) insert into paraffinic CH bonds, while $O(^3P)$ (8) and $CH_2(^3\Sigma_g^-)$ only abstract H atoms and $S(^3P)$ is unreactive with paraffins under the same conditions. The three singlet species add stereospecifically to olefin double bonds (7, 9–11), whereas triplet oxygen or methylene addition results in some loss of the reactant's geometrical isomeric purity. Thus studies on olefin–oxygen reactions in gas (12), liquid (13), and solid (14) phases indicate an electrophilic character (12) of triplet oxygen and temperature-dependent stereospecificity of triplet addition (15). Addition to *cis*-2-butene is non-stereospecific at 77 K and 300 K, but addition to *trans*-2-butene produces *trans*- and *cis*-1,2-dimethyloxirane in the ratio of 17:1 at 77 K (liquid phase) but only 2:1 at 300 K (gas phase).

The most detailed theoretical studies of the potential surfaces for the reactions of CH_2 (3), S (16), and NH (17) all indicate clearly differentiable energetically preferred symmetric lowest singlet and asymmetric lowest triplet paths (with a barrier to rotation of the terminal methylene in the sulphur case sufficient to preserve reactant stereochemistry).

The qualitative interpretation of the CH_2 results originally proposed by Skell (2) has been extended to the other cases as well (8, 12). Briefly, his description is as follows. The singlet species insert into paraffinic CH bonds through concerted formation of CX and XH bonds (X = ^1O, ^1S, or $^1CH_2$), and add to olefinic double bonds through concerted formation of two CX bonds. The triplet species, on the other hand, cannot undergo such a 'spin-forbidden' concerted formation of two bonds in either case, and instead initially forms only one bond to an exposed paraffinic hydrogen or to an olefinic carbon (forming an open-ring diradical capable of internal rotation around the now formally 'single' carbon–carbon bond). The result is H-atom abstraction from paraffins and non-stereospecific cycloaddition to olefins (after intersystem crossing from the triplet to singlet surface).

These mechanisms have been criticized (4) and an alternate, symmetric path for the triplet cycloaddition reaction proposed on several theoretical grounds (18–20). The existence of an open-ring triplet diradical in the cycloaddition reactions has been proposed (12) to account for the loss of stereospecificity, to provide paths to the other reaction products observed, and as an explanation for the observed increased production of addition at the expense of fragmentation products for larger substituted olefins (9, 13).

Pauli Principle and Localization of Spin and Charge Densities

The Hamiltonian used in the calculation of molecular energies (in the absence of external magnetic fields or spin–orbit coupling) is independent of the spin variables of the electrons. Yet the energy so calculated is dependent upon the spin multiplicity of the system. The reason for this result is, of course, a consequence of the antisymmetry requirements imposed on the wave function of the system by the Pauli exclusion principle. The Pauli principle exerts a strong influence on the allowable charge and spin (21) distributions for states of a molecule. One may interpret the effect of the Pauli principle on a system as being one which imposes a correlation

on the motions of electrons with identical spins, the so-called Fermi correlation.

In particular it has been shown that the extent to which some number of electrons $N(\Omega)$ are localized in a well-defined region of real space Ω is determined by the fraction of the total Fermi correlation contained in this same region of space (22). One finds the degree of localization of the charge density to be significantly greater along the triplet than along the corresponding singlet reaction paths. The increased localization of the total charge density of the triplet is reflected in the even more localized nature of the density of the unpaired electrons, *i.e.*, of the spin density. Since the course of a triplet reaction may be rationalized in terms of the extent and separation of localized regions of spin density, it is necessary to understand fully the origin of the localization and its effect upon the energy of a system.

An oft-quoted statement of the Pauli principle is that no electron can occupy the same spatial point as that of another electron with the same spin. However, the restrictions of the exclusion principle are not confined to the single point in space occupied by a given electron. Rather, the probability of finding other electrons with the same spin as that of the reference electron is decreased from the uncorrelated distribution by varying amounts throughout all of space. When this decreased probability is expressed in terms of a decrease in the value of the corresponding pair density referenced to the position of a single electron, it is called the Fermi hole. As the reference electron moves through space, the Fermi hole changes in shape and spatial extent. However, the magnitude of the hole (*i.e.*, the total reduction in the number of pairs over all space) remains equal to one. Thus by its definition, the net effect of the Fermi correlation is to correct for the pairing of an electron with itself. The Fermi hole integrated over all space therefore, equals -1 per electron or $-N$ for a system containing N electrons.

The antisymmetry requirement on the wave function corrects for this self-pairing of the electrons in a very special and nontrivial manner. What one finds is that in certain systems, the Fermi hole is very localized around the position of the reference electron and it remains so for motion of the reference electron throughout a given region (Ω) of space (22). If the Fermi hole for an electron is so localized that it integrates to -1 over just the region (Ω), rather than over all space, for any position of the reference electron within the region (Ω), then this electron is totally localized within the region (Ω). Thus an electron has a doppelgänger, its Fermi hole, which goes wherever the electron goes. Conversely, the electron may go only to regions of space in which its Fermi hole is non-vanishing. If the Fermi hole is localized to a given region of space, so is the electron (22).

In summary, if we label the magnitude of the total Fermi correlation (or Fermi hole) of a region (Ω) as $|F(\Omega,\Omega)|$, then $L(\Omega)$, the percentage localization of the $N(\Omega)$ electrons in (Ω), is given by (22)

$$L(\Omega) = 100 \times |F(\Omega,\Omega)|/N(\Omega)$$

corresponding to 100% localization of the $N(\Omega)$ electrons in (Ω) when $|F(\Omega,\Omega)|$ obtains its maximum value of $N(\Omega)$.

Consider the ethylene molecule, in its $^1A_{1g}$ ground and $^3B_{3u}$ excited states, to be bisected by a planar surface at the bond midpoint to yield two methylene fragments, each with an average population of 8 electrons. An integration of the Fermi hole over such a CH_2 fragment in the ground state molecule indicates that the charge in each fragment is 86% localized. If there were no Fermi correlation (over and above the simple statistical correction for self-pairing) then the charge would be equally localized in each fragment, *i.e.*, there would be no preferred spatial localization.

The localization of the charge in a CH_2 fragment increases to 92% when the molecule is excited to its triplet state, retaining the planar geometry, and undergoes a further increase to 94% when the triplet molecule is twisted into its lowest energy geometry of D_{2d} symmetry. This increase in the localization of the electronic charge in each of the CH_2 fragments on excitation from a singlet state of one electronic configuration to the triplet state of another is the result of the very localized nature of the distributions of the unpaired electrons.

The spin density at a point $\boldsymbol{r}$ in positional space is equal to the excess density of the α or β electrons at that point

$$\sigma(\boldsymbol{r}) = \rho^{\alpha}(\boldsymbol{r}) - \rho^{\beta}(\boldsymbol{r})$$

When $\sigma(\boldsymbol{r}) > 0$, there is an excess of α spins at $\boldsymbol{r}$

and when $\sigma(r) < 0$, there is an excess of β spins at r. The integral of $\sigma(r)$ over all space yields the total number of unpaired α electrons N^{α}, or minus the total number of unpaired β electrons N^{β}, in the molecule.

$$\int \sigma(r)\, dr = N^{\alpha} \text{ (or } -N^{\beta})$$

The spin densities portrayed in this paper are obtained from (spin) unrestricted SCF wave functions, wave functions which allow different orbitals for different spins. This extra variational flexibility is necessary to obtain good representations of $\sigma(r)$, and is essential for a prediction of the polarizations within the spin distribution. In a restricted SCF calculation, $\sigma(r)$ for the $M_s = 1$ component of a triplet reduces to the sum of the densities of the two singly occupied orbitals which describe the excess α electrons. In this approximation $\sigma(r)$ is everywhere greater than zero for a $M_s = 1$ state. In a spin unrestricted calculation, all of the orbital densities contribute to $\sigma(r)$, from both the α and β sets of electrons, and $\sigma(r)$ may exhibit negative values, corresponding to a local predominance of β spin density in a system with a net excess of α spins, *i.e.*, there is a polarization of $\sigma(r)$.

The difference in the descriptions provided by the restricted and unrestricted methods of calculation are illustrated by the example of the lowest triplet ($^3B_{3u}$) state of ethylene. Figures 1 *d* and *e* portray the spin density distributions for this molecule from an unrestricted calculation for the $M_s = 1$ component. The spin density distribution contains significant differences from that obtained from a RHF calculation.

This state of ethylene may, in simplest terms, be considered to result from a simple $\pi^* \leftarrow \pi$ excitation from the $^1A_{1g}$ ground state of the molecule. To a first approximation, the unpaired spin density is due to the occupation of the π and π* molecular orbitals by one α-electron each. Considering the spin density map Fig. 1*d*, one sees a distribution which is an apparent sum of such orbital densities. However, considering the second plot, Fig. 1*e*, that of the spin density in the plane of the nuclei, other features are seen. Surrounding each hydrogen nucleus is a region of excess β-density, and this in a molecule constrained to have a net spin excess of two α-electrons. Integration over the regions of excess α-density would yield a total of more than two α-electrons. There has been a 'polarization' of the molecular spin density with excess α-density being localized on the two carbons and excess β-density on the four hydrogens (and to a small extent along the line joining the two carbon nuclei). The polarization effects predicted by UHF functions have been shown (1) in several examples to agree qualitatively with the results of more detailed calculations. The maps reported here may be expected to faithfully reproduce the pattern of the primary spin polarizations operative in the system studied. Since the spin distributions for the levels of an electronic term differ only by a multiplicative constant (23), M_s/S, we base our interpretation on the properties of the distribution for the (computationally convenient) level of highest M_s value (= 1 for the triplet term).

The excess α spin density is very localized in the region about each carbon nucleus (Fig. 1*d*). In the plane perpendicular to the plane of the nuclei, only contours of relatively low value (less than 0.02 au) encompass both nuclei. For comparison with a related but delocalized two-electron system, one finds that contours with values in excess of 0.04 au encompass both nuclei in the density distribution derived from the π orbital of ground state ethylene. Thus the increase in the degree of localization of the charge in each (CH_2) fragment upon excitation of ethylene to its triplet state may be explained in terms of the mutual avoidance of the two α spin distributions, as shown by the separate localization of the spin density on each of the two carbon atoms. The mutual avoidance of the two localized α spin distributions is maximized, as is the extent of localization of the total charge in each CH_2 fragment, when the triplet molecule is twisted into its lowest energy geometry of D_{2d} symmetry (Fig. 1*f*). The behaviour of the spin density in the twisting motion of ethylene illustrates the axiom that the geometry of lowest energy is the one which maximizes the spatial separation of localized spin distributions of like sign.

The increased localization of the Fermi correlation on excitation to a triplet is reflected in a corresponding increase in the spatial localization of the charge density. Figure 1*a* shows a wide belt of density, defined by the 0.2 au contour, encompassing the carbon nuclei in ground state ethylene. This same contour is very much reduced in width between the same nuclei in the triplet state in both planar (Fig. 1*b*) and twisted (Fig. 1*c*) geometries, indicating a significant re-

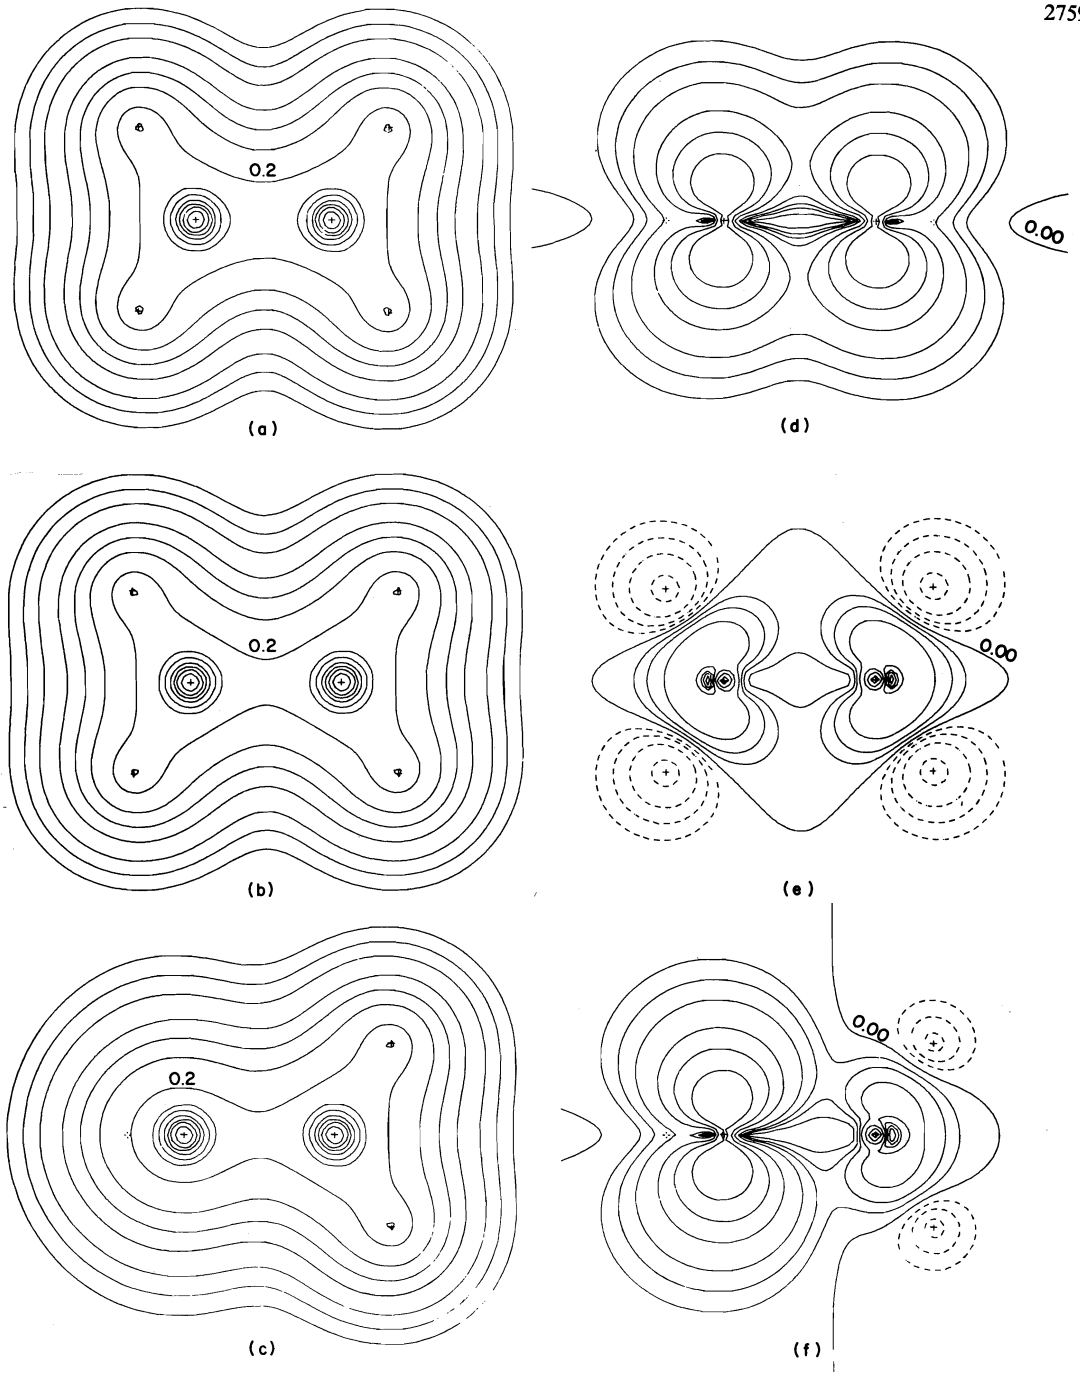

FIG. 1. Total electronic charge, $\rho(\boldsymbol{r})$, and spin, $\sigma(\boldsymbol{r})$, distributions for ethylene. (*a*) $\rho(\boldsymbol{r})$ for ground state ($^1A_{1g}$) in plane containing protons. R(C—C) = 2.5304 au. (*b*) $\rho(\boldsymbol{r})$ for lowest triplet state ($^3B_{3u}$) in plane containing protons. R(C—C) = 2.8346 au, the calculated equilibrium separation. (*c*) $\rho(\boldsymbol{r})$ for lowest energy (twisted) geometry of triplet state ($^3A_{2u}$). R(C—C) = 2.8346 au. (*d*) $\sigma(\boldsymbol{r})$ for $^3B_{3u}$ in plane containing C—C, perpendicular to plane of protons. (*e*) $\sigma(\boldsymbol{r})$ for $^3B_{3u}$ in plane containing protons. (*f*) $\sigma(\boldsymbol{r})$ for $^3A_{2u}$. In all charge density maps, the contours increase in value from the outer contour, in steps of 2×10^n, 4×10^n, 8×10^n au for increasing integer n starting at $n = -3$. In all spin density maps, the contours vary similarly, regions of excess α-density being denoted by solid contours and excess β-density by dashed contours. The first solid contour adjacent to a dashed one is the zero contour line.

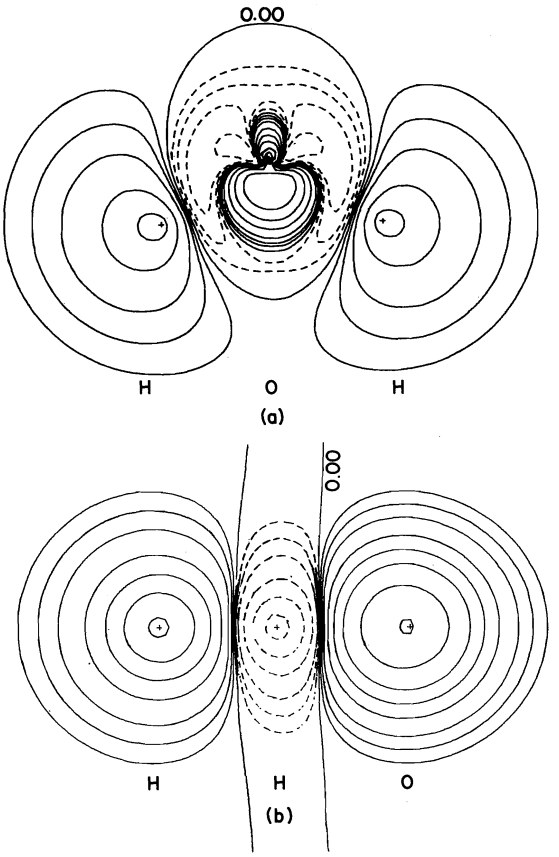

FIG. 2. Spin density maps for the $O(^3P) + H_2(^1\Sigma_g^+)$ system (1). (*a*) Illustrative of the spin unpairing mechanism, is for the symmetric insertion approach at a point where the separation between oxygen and the mid-point of H—H equals 1.11 au, the separation in ground state water. (*b*) Illustrative of the spin uncoupling mechanism, is for the abstraction approach.

duction in charge density and in binding between them. In the $^1A_{1g}$ ground state the value of the charge density at the midpoint of the C—C internuclear axis (the point of maximum $\rho(\boldsymbol{r})$ in the partitioning surface) is 0.3187 au. In the $^3B_{3u}$ excited state this value decreases to 0.2350 au and in the twisted equilibrium geometry, it decreases further to 0.2345 au. *Thus the localization of identical net spin densities on two neighbouring nuclei in a molecule leads to a decrease in the density accumulation, and hence to a decrease in the binding, between them.*

The same axiom and associated observations on the behaviour of the total charge density apply to the determination of the geometries of lowest energy which define the triplet reaction path. This is illustrated by the spin distributions in Fig. 2 for the reaction of $O(^3P)$ with $H_2(^1\Sigma_g^+)$. They illustrate the two basic patterns of spin polarization which characterize triplet reaction paths (1). Figure 2*a* is representative of the spin polarization obtained for triplet insertion, the *spin unpairing mechanism*. The spin density is for a point on the symmetric reaction path for insertion of $O(^3P)$ into $H_2(^1\Sigma_g^+)$. The approach of the oxygen causes an unpairing of the initially paired electrons binding the hydrogen nuclei. As the reaction proceeds the degree of unpairing increases and the resulting spin density becomes increasingly separately localized in the region about each proton. In effect, the spin polarization caused by the approach of $O(^3P)$ corresponds to a quasi-excitation of H_2 from its singlet ground state to its unbound $^3\Sigma_u^+$ state, a state characterized by a localization of $\rho(\boldsymbol{r})$ on each nucleus and to a depletion of the charge density in the region between the nuclei. Indeed $\sigma(\boldsymbol{r}) > 0$ in the regions of all three nuclei, and the electronic charge is depleted in all three internuclear regions (relative to the singlet state in the same geometry) corresponding to an intermediate in which the substrate bond has been broken and no new bonds to the oxygen have been formed. Thus the triplet insertion approach is one of rapidly increasing energy, the energy rising monotonically to a value 124 kcal mol^{-1} above that of singlet ground state water at the equilibrium position of the latter.

The second spin polarization is that characteristic of triplet abstraction, the spin *uncoupling mechanism*. In this case the initial (α,β) substrate bonding pair is polarized so as to localize separate α and β spin distributions on the two centres of the substrate; the spins are uncoupled. Because of the alternation in the sign of the localized spin distributions, increased binding between O and the adjacent H proceeds simultaneously with the decrease in binding in the substrate and the reaction proceeds with a much smaller energy of activation. Thus the spin uncoupling mechanism is the preferred mechanism of spin polarization for the approach of a triplet reactant to a singlet substrate. The same mechanisms of spin polarization with the same energetic consequences are found to apply to the approach of $O(^3P)$ to a doubly bonded system in cycloaddition reactions.

SCF Calculations

The HF method requires three determinants to provide a limiting description of $O(^1D)$ of cor-

rect spatial symmetry (1, 24), but only one determinant for the final product, ethylene oxide in its ground state. In this study, a limited three-state configuration (CI) was included wherever technically possible to take this into account.

The $O(^3P)$ reaction species can be consistently described by one determinant throughout the paths (1). However, because of the UHF approximation used, there is a possibility of 'contamination' of the triplet wavefunction by states of higher multiplicity. The degree of contamination was monitored by evaluation of $\langle S^2 \rangle$ for all points computed on the surface. For the symmetric cycloaddition path, $\langle S^2 \rangle$ is approximately 2.023 for all points, and for the asymmetric path, $\langle S^2 \rangle$ decreases from 2.43 at long range to approximately 2.08 for geometries approaching the equilibrium bond lengths of the ground state ethylene oxide product. The unwanted contributions from quintet, etc., states are thus negligible for the compact geometries of most interest.

The LCAO-SCF wavefunctions were calculated in a basis set derived from the *sp*-gaussian set used by Basch *et al.* (25) in studies of the low-lying electronic states of several small molecules. The basis is of best-atom double-zeta quality. Preliminary studies indicated that the addition of more diffuse orbitals to the basis was necessary to satisfactorily describe the highest occupied molecular orbitals of the three lowest-lying excited triplet states of possible interest. This was accomplished by the addition of three *s*- and one set of three *p*-type functions (left uncontracted) per heavy nucleus, continuing the trend in the ratio of the orbital exponents in the original set. The final basis set used for the surfaces is reported in Table 1. The net contraction is (13 6/4) → [7 3/2] yielding a 56-function set. A basis of this size may be expected to reproduce rotational barriers to within 1 kcal mol^{-1} (26) and charge densities to $\pm 10\%$ (27).

The Potential Surfaces

The energy hypersurfaces for the seven-nucleus C_2H_4 + O system are functions of 15 internal coordinates. Accordingly, a complete geometry search could not be contemplated. Instead, restricted searches were made to answer several specific questions. The first was whether or not the energetically preferred singlet and/or triplet cycloaddition paths are symmetric with respect to the carbon nuclei of the substrate olefin. An alternative is an unsymmetrical binding to one carbon only. In the former case a symmetric ring product may be expected, and in the latter an open-ring product or intermediate. The second question was the height of the energy barrier to rotation of the terminal methylene for open-ring geometries, as this may determine the degree of retention of stereochemistry of a final closed-ring product. Finally, the minimum energy barrier (assumed to be rate-determining) leading to

TABLE 2. Experimental bond lengths and bond angles of ground state ethylene (28) and ethylene oxide (29)

	Value	
Parameter (au or deg)	Ethylene	Ethylene oxide
$R_{CO}(=R2)$	—	2.7164
$R_{CC}(=R1)$	2.5304	2.7817

$\angle CCO(=\alpha)$	—	59.2
$\angle HCH$	117.6	116.7

a transition or intermediate state on the singlet and triplet paths was to be determined.

Each of these questions necessitated a geometry search with respect to variation of one or more of four independent nuclear geometry parameters of the C_2H_4 + O adduct: $R1$, the carbon–carbon distance; $R2$, the shorter of the two carbon–oxygen distances; α, the angle between $R1$ and $R2$; and γ, the torsion angle of the terminal methylene group. For a symmetric oxygen approach (along the bisector of the carbon–carbon axis), it was useful to further define $R3$, the distance between the oxygen nucleus and midpoint of the carbon–carbon axis. The geometries of the two methylene groups were assumed to vary between the (very similar) limiting geometries of reactant ground state ethylene (28) and product ground state ethylene oxide (29). (See Table 2.) The difference in energy caused by this assumption is less than 5 kcal mol^{-1}.

Symmetric Path

The variations in total singlet and triplet energies versus $R3$ were followed for oxygen approaching the olefin in the plane perpendicular to that of the ethylene nuclei and equidistant from the carbons (C_{2v} approach).

The paths computed are presented in Fig. 3 and define the following symmetric cycloaddition reactions:

[1] $C_2H_4(^1A_{1g}) + O(^1D) \rightarrow C_2H_4O(^1A_1)$
$\Delta E = -55$ kcal mol^{-1}

[2] $C_2H_4(^1A_{1g}) + O(^3P) \rightarrow C_2H_4O(^3B_1)$
$\Delta E = +145$ kcal mol^{-1}

The singlet surface is seen to be strongly 'downhill' attractive leading to the potential well around the ground state equilibrium geometry. The triplet surface is purely repulsive. The energy increase quoted for reaction 2 is for the formation of the (unstable) triplet adduct with the equilibrium geometry of the singlet adduct, C_2H_4O. This differing behaviour of the singlet and triplet potential energy curves for the symmetric addition of oxygen is the same as that obtained for the corresponding symmetric insertion of $O(^1D)$ and $O(^3P)$ into $H_2(^1\Sigma_g^+)$; the singlet curve being monotonically decreasing, leading to the formation of stable ground state water and the triplet being repulsive, crossing the singlet curve at a value of $R3$ greater than its equilibrium value in the ground state (1, 24). For several values of $R3$, the singlet energy was optimized with respect to $R1$. A smooth increase from the limiting value of 2.53 au (for reactant ethylene) to 2.78 au (for product ethylene oxide) was found for decreasing $R3$, reflecting the weakening of the carbon–carbon binding with approach of the oxygen. The singlet path is accurate to better than ± 5 kcal mol^{-1} with respect to $R1$ variation along the complete range of $R3$ values.

The effects of the configuration interaction correction to the singlet is also shown in Fig. 3. For the extended geometry with $R3 = 10$ au, wavefunctions for the lowest singlet state were computed by three methods. The lowest single determinantal energy is -152.68075 au. A CI was performed using as a basis the three lowest individually converged SCF closed-shell functions at this geometry. The lowest CI energy was found to be -152.72013 au, only 0.08 kcal mol^{-1} less than the sum of the energies of separated $C_2H_4(^1A_{1g})$ (-78.00643 au) and $O(^1D)$ (-74.71357 au) when the $O(^1D)$ energy is itself obtained from a separate three-state CI. The $O(^1D)$ energy is from a basis of reconverged SCF functions, yielding an $O(^1D) - O(^3P)$ energy difference of 53 kcal mol^{-1}. The spectroscopic energy difference between the oxygen ^1D and ^3P terms is 45 kcal mol^{-1}. Finally, a CI was performed using a virtual orbital (VO) description of the first and second excited closed-shell states. This yielded a lowest singlet energy of -152.68888 au, 18 kcal mol^{-1} above the previous CI result and recovering only 6 kcal mol^{-1} of the 24 kcal mol^{-1} error incurred by the description of $O(^1D)$ by a single determinantal function.

The importance of configurational mixing is expected to decrease as the nuclear structure closes to that of the equilibrium ground state of ethylene oxide. (There the energies of two of the three determinants diverge from that of the low-

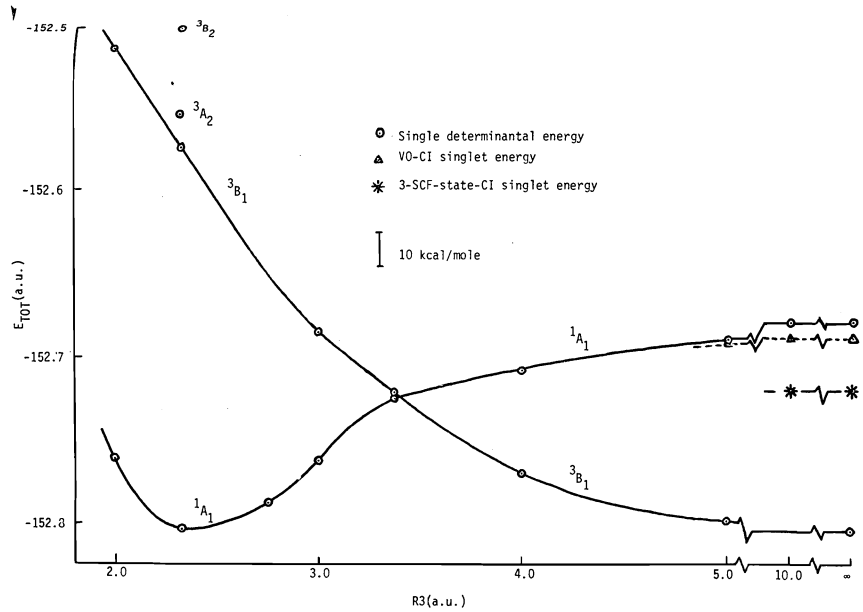

FIG. 3. Symmetric singlet and triplet potential energy paths.

est determinantal function and thus become unimportant contributors to the description of the lowest state.) At $R3 = 5$ au, a VO-CI calculation yielded an energy decrease of 1.3 kcal mol^{-1}. Assuming a roughly proportional relationship of the energy corrections recovered by the VO and reconverged-function basis CI's, there may thus exist an activation barrier to the singlet reaction of the order of 10 kcal mol^{-1} at $R3 = 5$ au.

The symmetric triplet path consists of a smooth energy increase on approach of the reactants. For each value of $R3$, the UHF triplet function was computed for the optimal $R1$ value of the singlet.

Figure 4 displays the singlet and triplet charge distributions for three points on the symmetric surfaces. For $R3 = 4.0$ au, the charge distributions for both states show apparently similar overlap of the reactant charge densities. At $R3 = 3.0$ au, while the regions of high density in the binding regions of the ethylene moiety in the two states are still almost superimposable, the charge density of this fragment in the triplet state has extended into its nonbonded region in the form of a diffuse distribution. For $R3 = 2.31$ au (ground state equilibrium geometry), the singlet distribution contains wide belts of high (>0.2 au) density in the binding regions between the three heavy nuclei indicative of the strong ring binding of the conventional bond description. In contrast, the triplet density plot shows much lower charge between the nuclei. The 0.2 au contours are still separately localized around the oxygen and ethylene fragments indicating the lack of any significant binding between oxygen and the carbons of ethylene. Furthermore, the 0.2 au contour encompassing the carbon nuclei at this geometry has contracted indicating a substantial decrease in the charge density in the C—C internuclear region and hence a decrease in the C—C binding. These observations regarding the charge distributions of the symmetrical singlet and triplet adducts apply equally to the corresponding insertion reactions of oxygen with H_2 (1).

The potential energy and molecular charge distribution exhibit the same characteristic properties along the singlet path for both the insertion and addition reactions, and both differ from the corresponding triplet paths in identical ways with regards to the behaviour of the potential energy and charge density distributions. The differences between the singlet and triplet paths may in each case be related to a common cause, the *added restrictions* placed on a system with two or more unpaired electrons. In the description of a singlet pair of electrons, the antisymmetry requirement is imposed in spin space. For a triplet pair, the spin function is symmetric and the consequences of the antisymmetry are

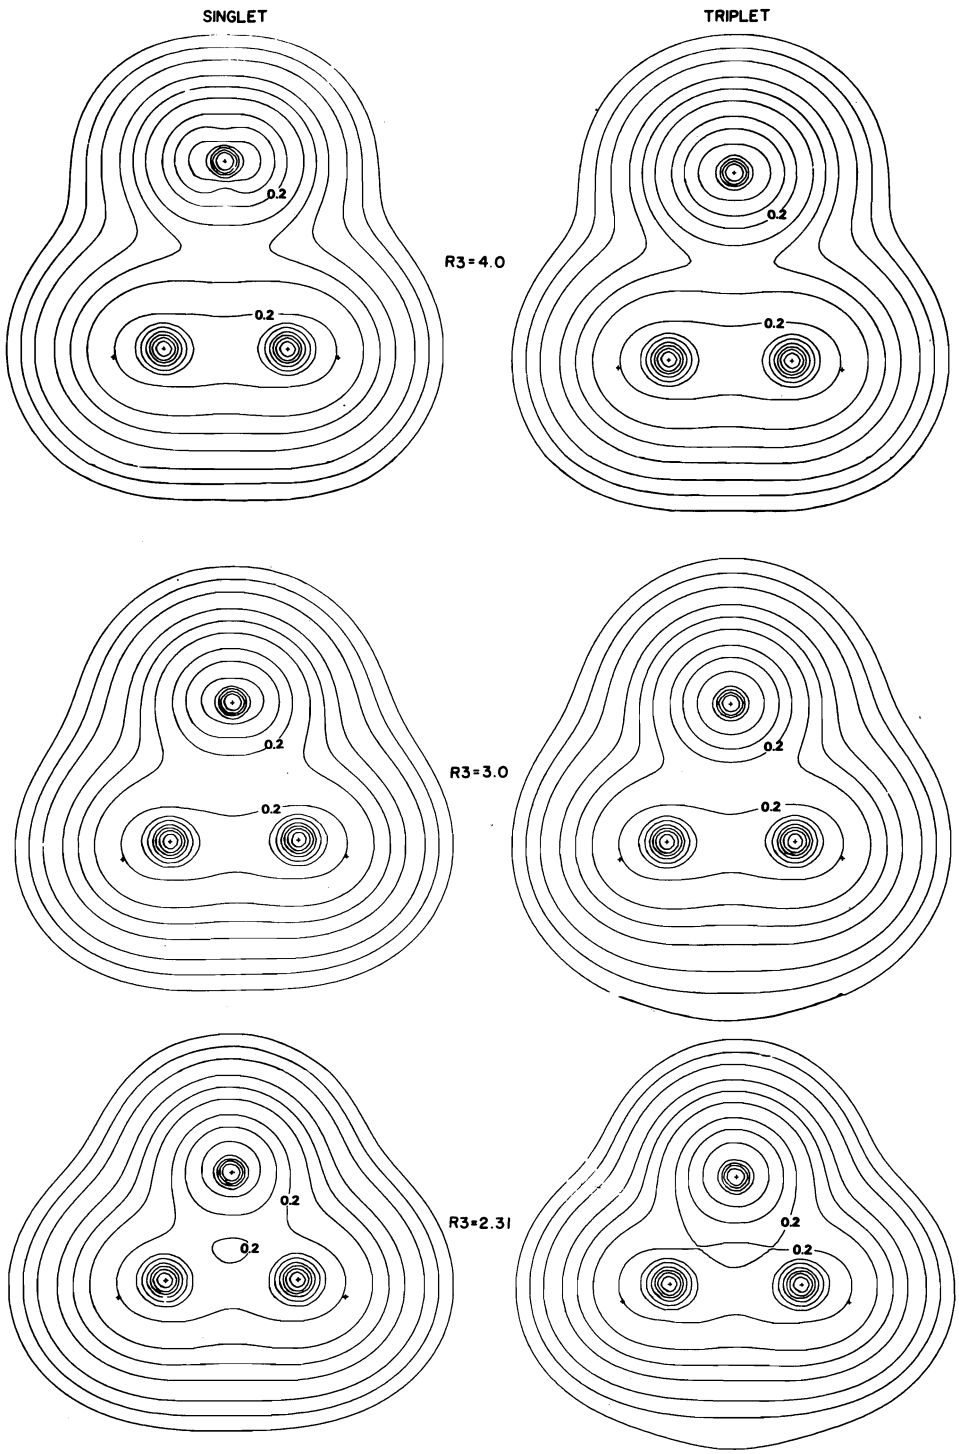

FIG. 4. Total singlet and triplet charge distributions (in the plane of the heavy nuclei) for the symmetric path.

made manifest in real space. Its effect on the energy and charge distribution may be understood and predicted in terms of the spin density, the spatial distribution of which provides a direct display of the consequences of the antisymmetry requirement in real space.

Figure 5 contains plots of $\sigma(r)$ for the first two points of Fig. 4, based on the $M_s = 1$ UHF wavefunctions. One of two unpaired electron distributions remains largely localized on the oxygen, in the plane perpendicular to the plane illustrated. At $R3 = 4.0$ au, a spin 'polarization' is already apparent. There is a π-like distribution of α-density on the ethylene carbons and small regions of excess β-density near the oxygen. For $R3 = 3.0$ au, these effects are more pronounced, and in addition a small region of excess β-density appears between the carbons. A large α-density excess has been localized in the carbon π-regions. The polarization pattern is strongly reminiscent of that of the triplet ethylene molecule (Fig. 1*d*) modified, of course, by the presence of the oxygen. Thus, as in the insertion approach of $O(^3P)$ into $H_2(^1\Sigma_g^+)$, the spin polarization obtained in the symmetric addition approach of triplet oxygen corresponds to the quasi-excitation of the singlet substrate to its lowest triplet, with the related consequences on its charge density and energy. The spin polarization at $R3 = 3.0$ au is characteristic of the spin unpairing mechanism illustrated in Fig. 2*a* for the symmetrical triplet insertion. They differ only in the spatial nature of the electron pair so affected, a σ pair in one case, a π pair in the other.

Thus a symmetric approach to a pair of bonded 'π' electrons results in a localization of spin density of like sign on each nucleus, with the consequence that charge density cannot be accumulated in any of the internuclear regions. The binding between the carbon atoms arising from the charge density in the π-like distribution is reduced and no new binding with the approaching oxygen is possible. The symmetric approach is an energetically unfavourable one for both triplet addition and triplet insertion.

As the angle of approach of the oxygen as measured by β is increased, the spin polarization changes smoothly from that characteristic of a spin unpairing (for $\beta = 90°$) to that characteristic of a spin decoupling. The latter polarization, since it yields an alternation in the signs of the localized spin distributions, in this case C(α)—C(β)—O(2α), allows for simultaneous binding between all three nuclei. Thus one finds a CCO angle such that an uncoupling, that is, a spatial separation of the spin densities of the α,β bonded pair is obtained. This occurs at an angle $\alpha(= \angle CCO)$ equal approximately to the tetrahedral angle (Fig. 8).

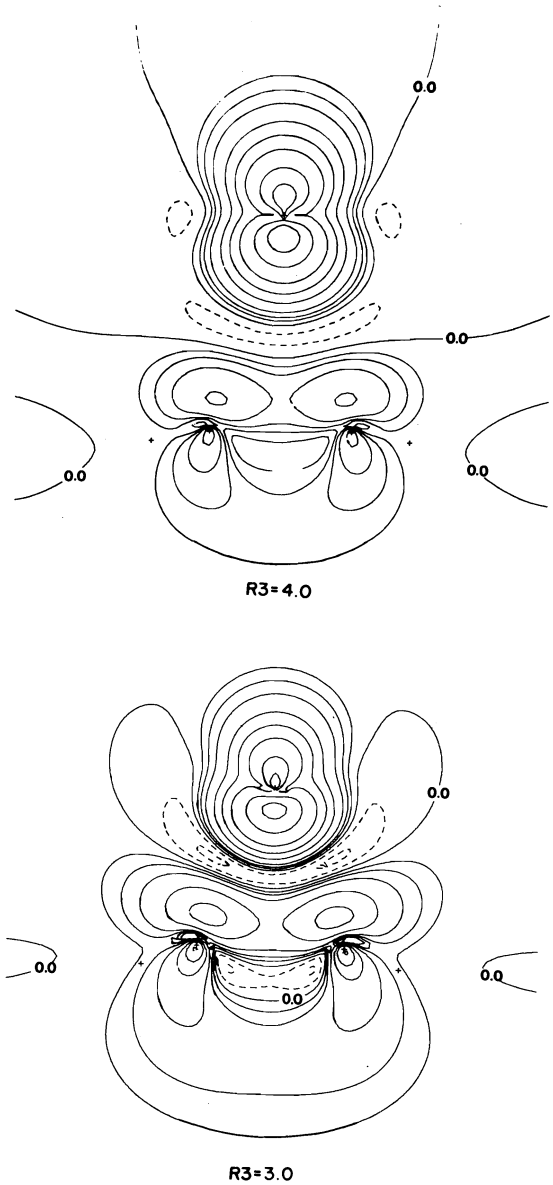

FIG. 5. Triplet spin density distributions (in the plane of the heavy nuclei) for the symmetric oxygen approach points of Fig. 4.

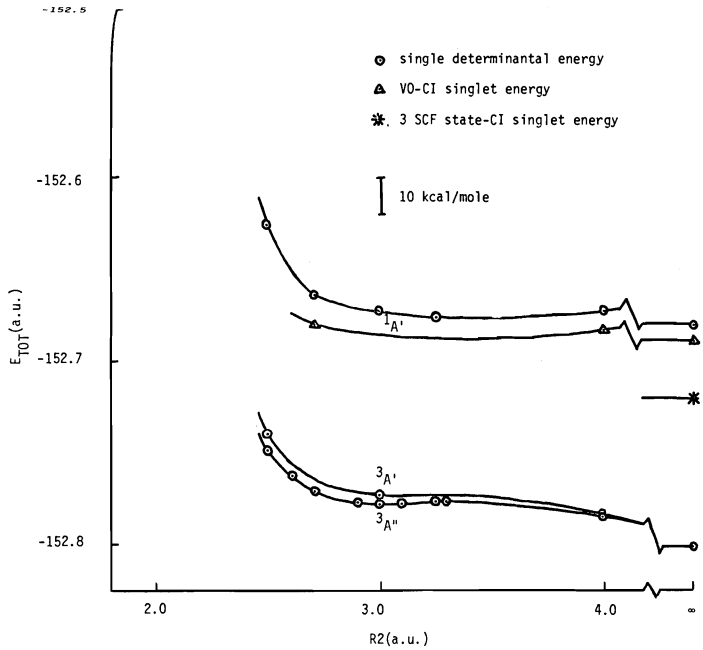

FIG. 6. C_s ($\alpha = 109.47°$) singlet and triplet potential energy paths.

Asymmetric Path and Spin Transfer

To define the energetics of unsymmetrical oxygen approach, which has been variously (2, 8, 30) suggested to be a particularly likely path for the triplet reaction, computations of the singlet and triplet energy variation versus $R2$ were made for α fixed at 109.47° (tetrahedral C—C—O angle). The oxygen was constrained to lie in the plane containing the carbon–carbon axis perpendicular to that of the ethylene nuclei. The terminal methylene was fixed in its planar geometry in ethylene, and the internal methylene given the almost tetrahedral geometry of the ground state ethylene oxide equilibrium geometry. For such molecular geometries, the point group is C_s and the lowest singlet and triplet states are now $^1A'$ and $^3A''$ respectively.

The paths computed are shown in Fig. 6. The lowest (closed-shell) singlet state is repulsive to the extent of 30 kcal mol^{-1} at ground state ethylene oxide equilibrium bond lengths, 25 kcal mol^{-1} with inclusion of VO-CI. For $R2 =$ 2.814 au, the energy of the lowest open-shell $^1A'$ state was computed (by addition of the 2K energy difference to the lowest $^3A'$ RHF state (24, 25)) to be 18 kcal mol^{-1} above that of the lowest single-determinantal closed-shell $^1A'$ state. A VO-CI calculation (including the lowest open-shell $^1A'$ state as well as the lowest three closed-shell determinants) showed only negligible contributions to the single-determinantal description of the lowest singlet, and left the singlet path still repulsive to the extent of 20 kcal mol^{-1} at the ground state equilibrium bond lengths. (This is equivalent to finding the lowest singlet state to have no significant diradical character at such geometries.)

There are two triplet states, slightly repulsive (15 kcal mol^{-1} at the ground state equilibrium bond lengths) and designated $^3A'$ and $^3A''$ (the latter lower by 1–3 kcal mol^{-1} over the whole path). Because of the shallow minimum found at $R2 = 3.0$ au, the path in that region of the surface was optimized with respect to α, then with respect to $R1$ for fixed α at $R2 = 3.5$ and 3.0 au. The originally observed dip, less than 1 kcal mol^{-1}, is not meaningful in itself because of the approximations and constraints imposed by the method of calculation used. However, the α- and $R1$-optimizations defined the lowest energy approach angle to be $104 \pm 2°$ and $R1 = 2.75 \pm 0.05$ au, respectively, in this $R2$ range with the remainder of the molecular geometry rigid. The full curves are possibly within 2 kcal mol^{-1}, and

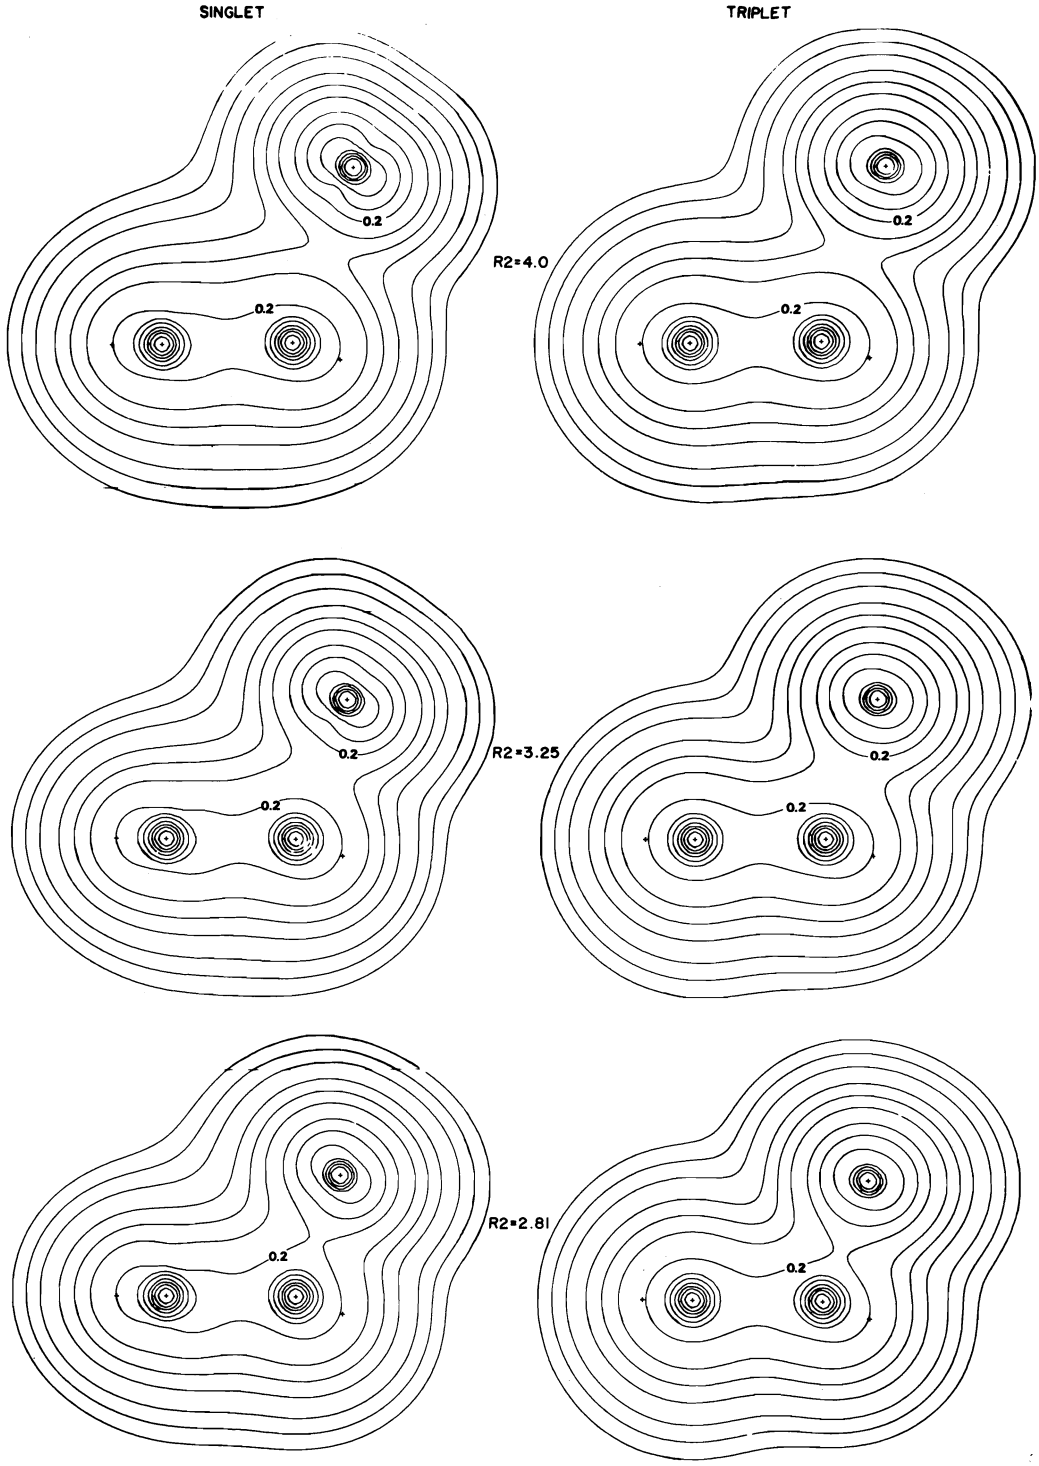

FIG. 7. Total singlet and triplet charge distributions (in the plane of the heavy nuclei) for asymmetric ($\alpha = 109.47°$) oxygen approach to C_2H_4.

certainly 10 kcal mol^{-1}, of the unconstrained path. The singlet asymmetric surface is energetically downhill to the symmetric path for all $R2 <$ 4.0 au. In contrast, the triplet surface is uphill for α both higher and lower than 105° all along the path.

The singlet and triplet charge distributions for three points on this unsymmetric path are shown in Fig. 7. For $R2 = 4.0$ au the oxygen and ethylene fragment distributions are still clearly identifiable. For $R2 = 2.81$ au the 0.2 au contour encircles all the heavy nuclei in both the singlet and triplet adducts, indicating some degree of CO bonding. However, not only is there binding between just one carbon and the oxygen in this region of the singlet surface, the binding which is present is very weak. This is reflected in the ellipsoidal nature of the distribution of charge along the C—O axis.[4] In the triplet plot for $R2 =$ 2.81 au the charge distribution in the region of the terminal methylene is essentially superimposable on that of triplet ethylene (Fig. 1*c*).

Figure 8 shows the spin density for three points along the triplet surface; in the CCO plane (first column) and in the plane perpendicular to this one along the C—O axis. Even for $R2 = 4.0$ au, a spin polarization is strongly in evidence. In addition to the (slightly perturbed) oxygen atom containing an α-density torus (around the CO axis) there are large $p\pi$-like accumulations of excess α- and β-density on the terminal and internal methylene carbons, respectively. The approach of oxygen is accompanied by an 'uncoupling' of the α,β-density of the ethylene. The mechanism of spin polarization is the same as that for the linear abstraction reaction (1) (Fig. 2*b*). Throughout the path there is less β-density induced on the internal carbon than α-density on the terminal carbon. Thus there has also been a net transfer of α-spin from oxygen to terminal methylene. The transfer effect increases along the reaction path until for $R2 = 2.81$ au, the excess α-spin distribution near the terminal methylene is essentially superimposable on that of the ethylene triplet state (Fig. 1*d*).

By referring as well to the second column of plots in Fig. 8 one sees that for large C—O separations the distribution of spin density on oxygen has a directional character (*p*-like) directed along the C—O axis and near spherical character in the perpendicular plane. As the C—O separation is decreased the amount of α spin density in the nuclear plane and its directed nature along the C—O axis are decreased and the spin distribution becomes increasingly localized and directed in the perpendicular plane. Clearly, as the localization of excess α spin density on the terminal carbon increases, the remaining spin density on oxygen is increasingly localized along an axis which is perpendicular to the axis of localization on the terminal carbon. In this manner the two localized distributions of α spin density are maximally separated in space.

The first two columns of Fig. 9 contain the triplet charge and spin density maps for three planes of an asymmetric geometry with $R2$ further reduced to 2.71 au. At this geometry, the triplet has an energy only 22 kcal mol^{-1} above that of the separated reactants (compared to 148 kcal mol^{-1} for the corresponding symmetrical geometry). There is a charge accumulation between the oxygen and internal methylene almost as great as for the singlet equilibrium geometry (Fig. 4), indicative of strong CO bonding. The three planes illustrate the localization of alternating regions of excess α- or β-density on all the nuclei in the incipient molecule. Thus there has been a spin polarization of the σ-bonding density of the reactant ethylene. The amounts of β-density induced on the internal carbon and of α-density remaining on the oxygen in the C—C—O plane are smaller than at long range (*cf.* Fig. 8) corresponding to a short-range spin 'recoupling' and formation of paired CO binding density. The dominant spin structure in the resulting molecule consists of two

[4]The three states of the $O(^1D)$ term which describe the state of oxygen which interacts with ethylene, yield an ellipsoidal charge distribution with its major axis perpendicular to the axis of approach (see Figs. 4 and 7); there is a deficit of charge along the direction of approach. In an orbital description of this 'prepared' state, there are one and two-third orbital vacancies in the plane containing the carbon and oxygen nuclei and one-third of a vacancy in the oxygen orbital perpendicular to this plane. In the symmetric approach, these vacancies are filled by the π electrons of ethylene and the deficit in charge density along the C_2 symmetry axis is not present in the equilibrium geometry. However, in a corresponding close approach in an asymmetric geometry, the ellipsoidal nature of the charge distribution on oxygen is still very much in evidence, indicating that the orbital vacancies in this plane are not filled and that considerably less density is accumulated along one C—O axis than in the symmetric geometry.

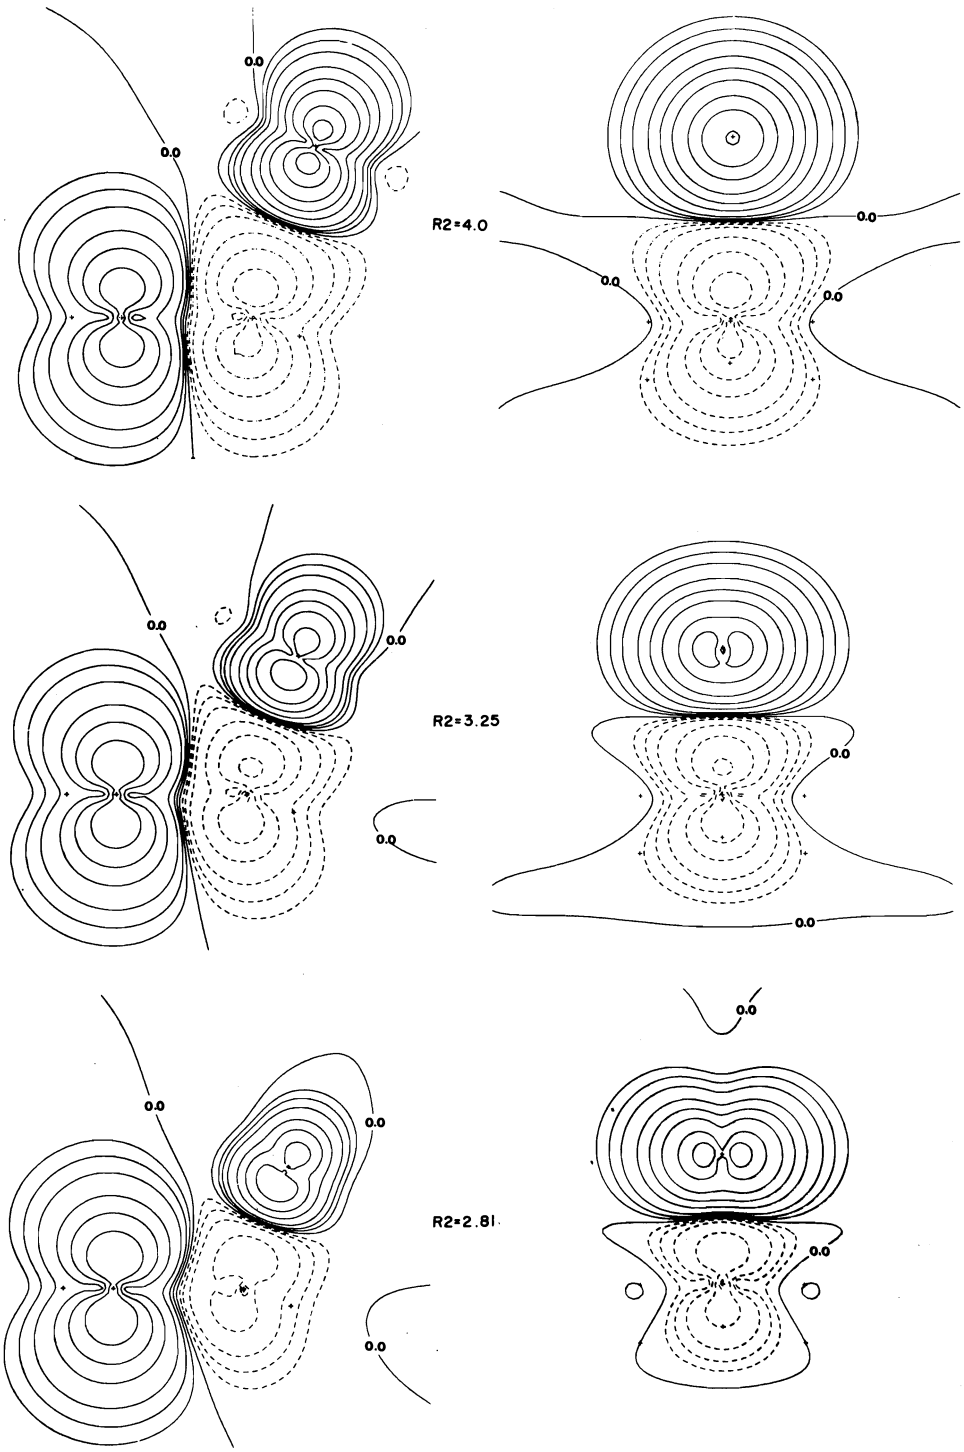

FIG. 8. Triplet spin density distributions; (*a*) in the plane of the heavy nuclei and (*b*) the plane perpendicular to (*a*) and also containing the CO axis, for the points on the triplet asymmetric path in Fig. 7.

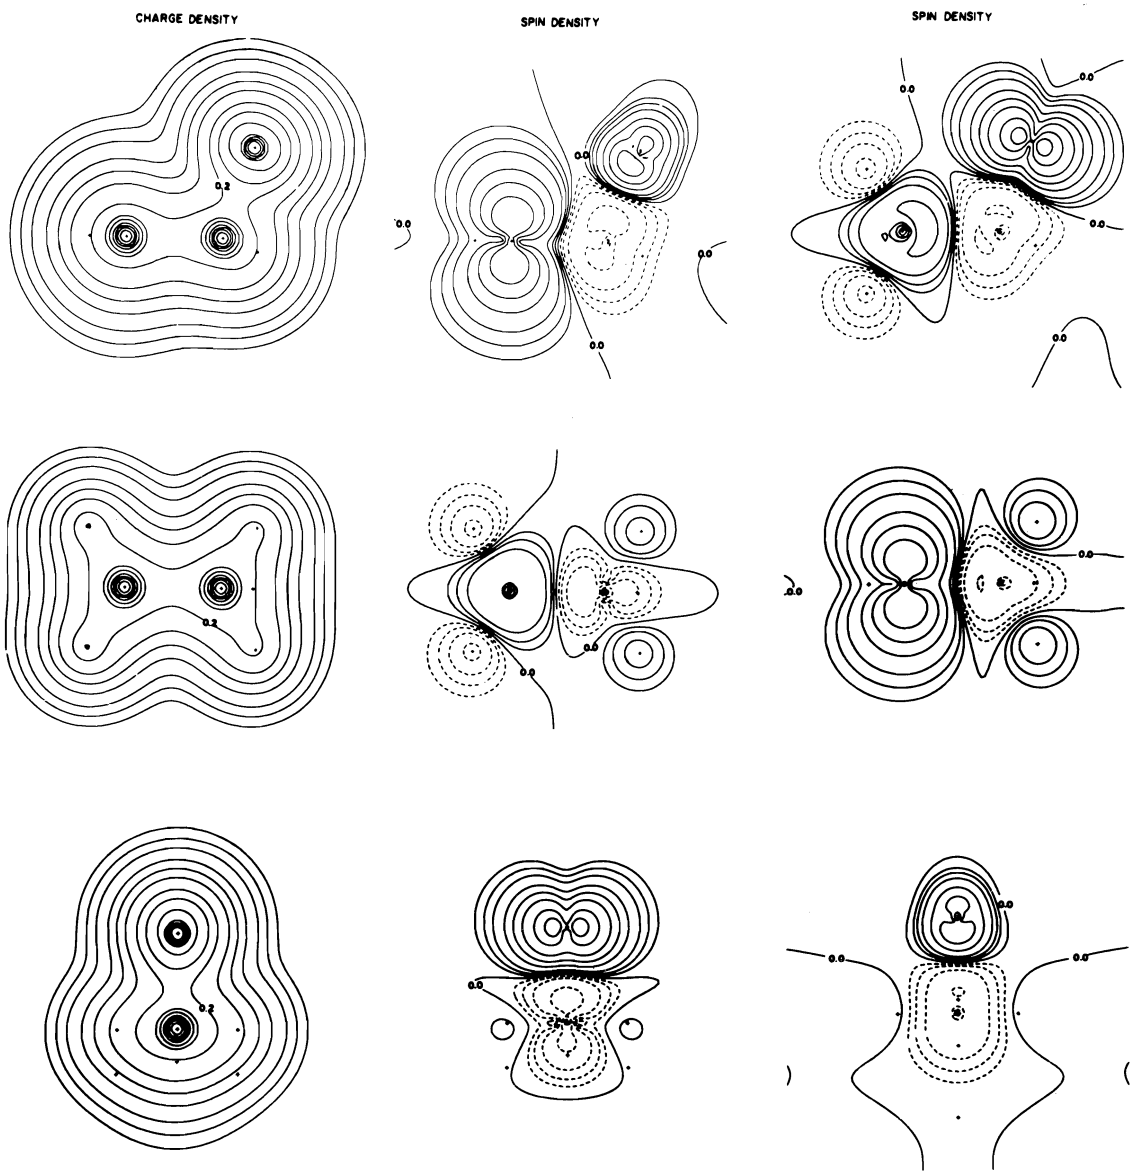

FIG. 9. Total charge and spin density distributions for ethylene oxide $^3A''$ state at $R2 = 2.71$ au. The first column contains charge plots for (from top to bottom) the plane containing the three heavy nuclei, the plane containing the carbons and terminal hydrogen nuclei, and the plane containing the internal carbon–oxygen bond and also perpendicular to the first plane. The second column contains the corresponding spin distributions. The third column contains the spin density plots in the same three planes for the same state and geometry, except that the terminal methylene group is rotated into the plane of the heavy nuclei.

separate distributions of excess α-spin with the axes of their maxima mutually perpendicular; a $p\pi$-like distribution on the terminal methylene and another such distribution on the oxygen directed along an axis perpendicular to that of the former. Also shown, in the third column of Fig. 9, are the spin distributions for the same three planes of the molecule with the same geometry, except that the terminal methylene has been rotated 90°. It can be seen that the perpendicularity

of the two terminal α-density distributions persists. That is, *the rotation of the terminal methylene group induces a rotation of the localized spin distribution on oxygen, such that the mutual avoidance of the two localized α spin distributions is maintained.* Recalling that the distribution of charge and spin density localized on the terminal methylene is essentially superimposable on that for the same fragment of triplet ethylene, the triplet adduct described here has the characteristics of a diradical of the form $CH_2(\alpha)$—C—O(α) with the added understanding that the localized α spin distributions are localized in mutually orthogonal directions.

For these open-ring structures, the barrier to rotation of the terminal methylene around the carbon–carbon axis (*i.e.* variable γ) was computed to be 6 kcal mol^{-1} for $\alpha = 109.47°$ and 5 kcal mol^{-1} for $\alpha = 90°$, a maximum for $\gamma = 90°$ in both cases.[5] This barrier is nearly twice the value for rotation about the C—C bond in ethane.

The spin polarization accompanying an asymmetric triplet reaction path can be described as proceeding in the following manner; (*i*) initial uncoupling of the olefin π-bonding density and counter-migrations of the α- and β-components to the two carbon nuclei, accompanied by a decrease in the carbon–carbon binding density and thus weakening of the carbon–carbon bonding; (*ii*) recoupling of the β-density on the internal carbon to the α-distribution on the oxygen nucleus, associated with accumulation of carbon–oxygen binding density, hence bonding; (*iii*) localization of the two excess α-spins in two mutually perpendicular distributions of one α-spin each at opposite ends of the structure; (*iv*) simultaneous counterpolarization of the σ-binding density on adjacent nuclei throughout the resultant open-chain structure similar to that of the triplet state of ethylene itself. Thus the decrease in the extent of carbon–carbon binding occurs simultaneously with an increase in the extent of carbon–oxygen binding, thereby accounting for the much lower energy barrier to asymmetric rather than symmetric triplet attack.

[5]The rotation barrier for ethylene in its lowest triplet state was computed to be 15 kcal mol^{-1} (for $R1 = 2.961$ au) in the basis set used, the energy for $\gamma = 90°$ being a minimum. The experimental (28) barriers for singlet and triplet ethylene are respectively 66 kcal mol^{-1} (minimum for coplanar methylenes) and 31 kcal mol^{-1} (minimum for perpendicular methylenes).

The lowest energy triplet reaction path is the one which allows for a polarization of the spin density corresponding to the spin uncoupling mechanism: abstraction or ring-opened adduct.

All along the asymmetric path the incipient molecule is unstable to redissociation into $C_2H_4 + O$; it is thus not a chemical intermediate. This path is the lowest triplet reactive channel found. To reach the (dilute, gas-phase) product of interest, ethylene oxide in its ground state, the triplet species must at some point undergo a radiationless transition to the singlet surface. To obtain an estimate of the triplet activation barrier, it suffices to find the geometry of lowest energy at which the singlet and triplet surfaces cross. The singlet surface lies below that of the triplet for symmetric geometries for $R2 < 3.6$ au (Fig. 3); for the asymmetric path ($\alpha = 109.47°$, Fig. 6), the triplet surface lies below that of the singlet for all values of $R2$. Thus the surfaces must cross at intermediate α-values and at $R2 < 3.6$ au, linking the surfaces at a lower crossing energy than on the symmetric path. Optimization of the crossover energy (31) with respect to $R2$ (with the remainder of the molecule fixed in the geometry of Fig. 9) yielded an energy barrier of 36 ± 2 kcal mol^{-1} above the energy of the separated reactants for $R2 = 2.9$ au and $\alpha = 83°$. In comparison, for the symmetric approach, the triplet encounters a barrier of 49 ± 5 kcal mol^{-1} (Fig. 3) before intersecting the singlet surface.

Conclusions

The potential energy surfaces computed for the singlet cycloaddition reaction are in accord with the suggestions of Cvetanović (32); that singlet oxygen undergoes a symmetric, concerted reaction to form an ethylene oxide ring product. The conclusions that the triplet reaction proceeds via the formation of an open-ring diradical with concurrent rotation of the terminal methylene followed by a ring-closing cross-over to the singlet surface are also in agreement with the experimentally based suggestions of Cvetanović (32, 33). We do not find a potential minimum on the triplet surface which would correspond to the formation of an intermediate π-complex as postulated by Cvetanović (34). Our calculated results for the triplet path differ from the experimental findings in one important aspect. The experimental results are interpreted as indicating that $O(^3P)$ adds

to olefins with small (<2 kcal mol^{-1}) energies of activation (12, 33, 34), while the lowest crossover from the triplet to singlet surfaces to yield ground state ethylene oxide is calculated to occur at an energy $\sim$36 kcal mol^{-1} above the energy of the reactants. Thus while the geometry, behaviour, and properties of the theoretically determined triplet adduct agree well with the experimentally based proposals regarding the mechanism of triplet addition, theoretical and experimental proposals of the activation energies are in serious disagreement. In both the $O(^3P) + H_2(^1\Sigma_g^+)$ (1) and $O(^3P) + C_2H_4(^1A_{1g})$ calculations, we did not find an approach geometry which was not repulsive with regards to energy.

It is the principal purpose of this investigation to draw attention to the potential use of the spin density in the understanding of the mechanisms of reactions involving unpaired electrons. A more complete knowledge of the manner in which the spatial localization of the spin density varies with nuclear geometry in systems of experimental interest would provide a theoretical and physical basis for predicting the course of a reaction for a system with a net spin angular momentum.

BRIAN ALSPACH and S. ARONOFF. Can. J. Chem. **55**, 2773 (1977).

The number of structural isomers obtainable from all possible substitutions in an alicyclic hydrocarbon is found by the use of Burnside's Lemma. Four classes of compounds exist according to the number of vertices of the ring, and the number and type of substituents on the carbons. The theory is also applicable to other types of compounds in which paired substituents occur, *e.g.* in the biologically-synthesisable porphyrins. Where the pairing is not mandatory, Polya's Theorem is utilized for enumeration. Examples are provided for each of the classes of compounds.

BRIAN ALSPACH et S. ARONOFF. Can. J. Chem. **55**, 2773 (1977).

Le nombre d'isomères de structure que l'on peut obtenir par toutes les substitutions possibles dans un hydrocarbure alicyclique peut être obtenu en utilisant le Lemma de Burnside. Il existe quatre classes de composés suivant le nombre de sommets du cycle et le nombre et le type de substituants sur les carbones. On peut aussi appliquer la théorie à d'autres types de composés dans lesquels des substituants existent sous forme de paires, par exemple dans des porphyrines, qui peuvent être synthétisés d'une façon biologique. Quand l'existence sous forme de paires n'est pas obligatoire, le théorême de Polya peut être utilisé pour l'énumération. On fournit des exemples pour chacune des classes des composés.

[Traduit par le journal]

For purposes of stereoisomer calculations, alicyclic hydrocarbons may be considered as polygons analyzable by graph theory (1). The use of graph theory has been employed in chemical enumeration (2, 3), using exhaustive techniques to produce all possible isomers with a given generic formula. These are then searched (*e.g.*, by computer) to find those with certain prescribed properties. In this paper we count directly the number of isomers with prescribed properties.

Let the polygon have n vertices. Then the carbon at each vertex will be homo- or heterosubstituted (=CXX or =CXY, respectively). Each n-gon will then have m_i homosubstitutents (*e.g.* m_1 of =CXX, m_2 of =CYY, and m_s of =CZZ. Similarly, among the heterosubstituents, there will be k_1 of =CXY (or its enantiomer, =CYX), k_2 of =CXZ (or its enantiomer, =CZX), etc. Then, if $K = k_1 + ... + k_r$, $n = K + m_1 + ... + m_8$, the n-gons may be described by the notation $(k_i,k_j; m_i,m_j)$, so that chlorobromocyclohexane would be (1,1;4), and 1,1-dimethylcyclopentane would be (0;1,4).

Equation 1 is based on Burnside's Lemma (4) (*cf.* below) involving the number of elements in a permutation group and the number of configurations left fixed on making all possible permutations.

It can be shown (see the Appendix) that the number of isomers, F, is given by

$$[1] \qquad F = \frac{1}{2n}\left(\sum_{d|g} \frac{\phi(d)(n/d)!2^{K/d}}{(k_1/d)! \ldots (k_r/d)!(m_1/d)! \ldots m_s/d)!} + L\right)$$

where the following definitions stand. $\phi(n)$ is the number of positive integers *relatively prime* to n in the interval (1, ..., n). In the set (1,2,3,4,5,6), the integers 1 and 5 are prime to 6 so that $\phi(6) = 2$. g is the *greatest common divisor (gcd)* of the set of integers (a_1, ..., a_m). The *gcd*(2,6) is 2 (2 divides 2 and 6), while that of (3,6) is 3 (3 divides 3 and 6). d is a divisor of g. If $g = 6$, $d = 1$, 2, 3, and 6.

The residual term, L, has values depending upon whether n, k, and m are even or odd. Four categories may be distinguished:

Category 1

n is odd; one of the m_i's (say m_j) is odd; all the other m_i's and k_i's are even.

In this case,

$$L = \frac{n[(n-1)/2]!2^{K/2}}{(k_1/2)! \ldots (k_r/2)!(m_1/d)! \ldots (m_{j-1}/2)!(m_{j+1}/2)! \ldots (m_s/2)!}$$

Category 2

n is even; all of the k_i's are even; two of the m_i's (say m_h, m_j) are odd.

In this case, the value of the numerator is identical with that of category 1, but the denominator has the value

$$(k_1/2)! \ldots (k_r/2)!(m_1/2)! \ldots (m_{h-1}/2)!(m_h/2)!(m_{h+1}/2)! \ldots (m_{j-1}/2)!(m_j/2)!(m_{j+1}/2)! \ldots (m_s/2)!$$

Category 3

n is even; all k's and m's are even.

In this case the value of the denominator is identical with that of category 1, but the numerator has the value

$$(n/2)(n/2)!2^{K/2} + (n/2)[(n-2)/2)!(n/2) - (K/2)]2^{K/2}$$

Category 4

In all other cases, $L = 0$.

In the above, where m's are absent by virtue of the generic description of the molecule or its formal deletion (*e.g.*, if $m_j = 1$, then $m_{j-1} = 0$), the formulae are abbreviated accordingly, *i.e.*, the m's are not formal zeros.

The following examples illustrate the application of this equation.

Example 1

Find the number of isomers of hexahydroinositol, i.e., 1,2,3,4,5,6-hexahydroxyhexane. The isomerism arises, of course, from the axial or equatorial position of the substituent on each carbon.

The molecule is described generically as $F(6,0;0)$ or simply as $F(6;0)$, as the k's are single-valued and the m's are vacant. Then as *n and k are even*, we are in category 3. The *gcd* is 6 and the divisors, d, of 6 are 1, 2, 3, and 6. The numerical equivalence of n and K results in the existence of only a single numerator for L. Then

$$\text{For } d = 1, \phi(1) = 1, F_1 = \frac{(1)(6/1)!2^{6/1}}{(6/1)!} = 2^6 = 64$$

$$\text{For } d = 2, \phi(2) = 1, F_2 = \frac{(1)(6/2)!2^{6/2}}{(6/2)!} = 2^3 = 8$$

$$\text{For } d = 3, \phi(3) = 2, F_3 = \frac{(2)(6/3)!2^{6/3}}{(6/3)!} = 2 \times 2^2 = 8$$

$$\text{For } d = 6, \phi(6) = 2, F_6 = \frac{(2)(6/6)!2^{6/6}}{(6/6)!} = 2 \times 2^1 = 4$$

and

$$L = \frac{(6/2)(6/2)!2^{6/2}}{(6/2)!} = 3 \times 2^3 = 24$$

Consequently,

$$F(6;0) = (1/2 \times 6)(64 + 8 + 8 + 4 + 24) = 108/12 = 9$$

Example 2

Find the number of stereoisomers of the myoinositols, i.e., the trihydroxycyclohexanes. The molecule is $F(3;3)$, $g = 3$, and L is category 4.

$$F(3;3) = (1/2 \times 6)\left[\frac{(1)(6/1)!(2^{3/1})}{(3/1)!(3/1)!} + \frac{(2)(6/3)!(2^{3/3})}{(3/3)!(3/3)!}\right] = 14$$

Example 3

Find the number of stereoisomers of 1,2,3,4,5-pentachlorocyclopentane. Here, $L = 0$, $g = 5$, and $d = 1, 5$.

$$F(5;0) = (1/2 \times 5)\left[\frac{(1)(5/1)!(2^{5/1})}{(5/1)!} + \frac{(4)(5/5)!(2^{5/5})}{(5/5)!}\right] = 4$$

Example 4

Find the number of isomers of tetrachlorocyclopentane. In this case, $n = 5$, $k = 4$, *and* $m = 1$, so that the generic description is $F(4;1)$ and L is category 1. Then,

$$F(4;1) = (1/2 \times 5)\left[\frac{(1)(5/1)!(2^{4/1})}{(4/1)!(1/1)!} + \frac{(5)(4/2)!(2^{4/2})}{(4/2)!}\right] = 10$$

Example 5

Find the number of stereoisomers of 1,1-dimethyltetrachlorocyclohexane. In this case, the generic description is $F(4;1,1)$, and where $g = 1$, $d = 1$, L is category 2. Consequently,

$$F(4;1,1) = (1/2 \times 6)\left[\frac{(1)(6/1)!(2^{4/1})}{(4/1)!(1/1)!(1/1)!} + \frac{(6)(4/2)!(2^{4/2})}{(4/2)!}\right] = 42$$

Example 6

Find the number of stereoisomers of mesoporphyrin. The mesoporphyrins are tetramethyl, diethyl, dipropionic acid porphines. In this example we distinguish between two possible classes, (*a*) those in which the substituents are not constrained with regard to pairing at the β,β′-positions, and (*b*) those where, as in mesoporphyrins of possible biologic origin, the ethyls and propionic acids are each accompanied by methyl groups. In all of the 15 known isomers of this class (5, 6), each pyrrole ring is substituted by either a methyl (*m*), ethyl (*e*), or a methyl, propionic acid (*p*). If the porphyrin is thought of as a square plane, then there is formal substitution at the vertices of a rectangle. The isomerism arises from the position of substitution of *m*, *e*, and *p*, recognizing that the order of substitution must be considered, *i.e.* that $m,e \neq e,m$.

We first consider the porphyrins of possible biological origin. The generic description is $F(2,2;0)$, with L in category 3, $g = 2$ and $d = 1$. Then,

$$F(2,2;0) = (1/2 \times 4)\left[\frac{(1)(4/1)!(2^{4/1})}{(2/1)!(2/1)!} + \frac{(2)(2/1)!(2^{4/2})}{(2/2)!(2/2)!} + \frac{(4/2)(2/2)!(4/2 - 4/2)(2^{4/2})}{(2/2)!(2/2)!} + \frac{(1)(4/2)!(2^{4/2})}{(2/2)!(2/2)!}\right]$$

$$= (1/8)(96 + 16 + 0 + 8) = 15$$

In contrast with the biologically-possible mesoporphyrins, the chemically-possible mesoporphyrins involve no constraint of the *m*, *e*, and *p* substituents. In this case there are 60 isomers (5), a result which can be derived from Polya's Theorem as follows.

If the cyclic decomposition of a permutation is the product of α_k cycles of length k, then the term $x_1^{\alpha_1}, x_2^{\alpha_2}, \ldots x_m^{\alpha_m}$ corresponds to the permutation. The corresponding terms for all the permutations are added together and divided by the order of the group, to form what is called the *cycle index* (7) of the group. For example, the cycle index of a square (P_4) is $(1/8)(x_1^8 + 5x_2^4 + 2x_4^2)$. Thus, the four 2-cycles (x_2^4) may undergo four reflections and one 90° rotation, providing the coefficient, 5. Similar reasoning leads to the coefficients of x_1^8 and x_4^2.

Assume that the porphyrin is such a square, with the β,β′ substituents meeting at each of the four

vertices. At each vertex we may substitute *any* pair of methyl, ethyl, or propionic acid. We may have, as an extreme, octamethylporphine or, less extremely, tetramethyl, tetraethylporphine. We want to know how many exist as tetramethyl, diethyl, dipropionic acid-substituted. According to Polya's Theorem, this number is the coefficient of the $m^4e^2p^2$ term in the expansion of the cycle index polynomial where $(m + e + p)$ is substituted for x_1, $(m^2 + e^2 + p^2)$ for x_2, and $(m^4 + e^4 + p^4)$ for x_4, to give

$$(1/8)[(m + e + p)^8 + 5(m^2 + e^2 + p^2) + 2(m^4 + e^4 + p^4)]$$

Obviously, the term $m^4e^2p^2$ cannot arise from the last term. The number arising from the second term is 4!/2!, and from the first is 8!/4!2!2!. The coefficient of $m^4e^2p^2$ is then

$$(1/8)[(8!/4!2!2!) + 5(4!/2!)] = 60$$

as noted earlier (5).

Appendix

When discussing permutations we have used the so-called *cyclic* notation. For example, (1 3 4 5)(2 6)(7) denotes the permutation in which 1 goes to 3, 3 goes to 4, 4 goes to 5, 5 goes to 1, 2 goes to 6, 6 goes to 2, and 7 goes to itself. We say that this permutation is a product of a 4-cycle, a 2-cycle, and a 1-cycle (a 1-cycle is also called a *fixed-point*). We are particularly interested in the cycle structure of the powers of a given permutation σ when σ is an n-cycle. For example, in cyclohexane, where σ = (1 2 3 4 5 6), then σ^2 = (1 3 5)(2 4 6), σ^3 = (1 4)(2 5)(3 6), etc. Notice that $gcd\{2,6\} = 2$ and σ^2 is a product of two 3-cycles while $gcd\{3,6\} = 3$ and σ^3 is a product of three 2-cycles. This pattern holds in general. If σ is an n-cycle, then σ^r is a product of g (n/g)-cycles if $g = gcd\{r,n\}$.

Let P_n denote a regular n-gon. At each of the vertices of P_n we shall substitute one of the ordered pairs a_1A_1, A_1a_1, a_2A_2, A_2a_2, ..., a_rA_r, A_ra_r, x_1x_1, x_2x_2, ..., x_sx_s. The resulting structure will be called a *configuration*. Arbitrarily label the vertices of P_n as 1, 2, ..., n in a clockwise manner.

Consider the group D_n on P_n consisting of σ = (1 2 ... n) and its distinct powers and the n reflections of P_n about the central axes. D_n is commonly called the *dihedral group of degree n* and contains $2n$ permutations. We shall say two configurations are *equivalent* if one can be obtained from the other under the action of D_n. By an *isomer* we shall mean a collection of configurations all of which are equivalent to each other and none of which are equivalent to any configuration not in the collection. In terms of permutation groups an isomer is an orbit of D_n acting on the set of all configurations.

Under a power of σ the order of an ordered pair is not altered; however, a reflection sends an ordered pair of the form aA to Aa. For example, 1-*aA*,2-*bB*,3-*XX*,4-*bB*cyclobutane, under the reflection (1)(3)(2 4) goes to 1-*Aa*,2-*Bb*,3-*XX*,4-*Bb*cyclobutane. Under the rotation (1 3)(2 4), it goes to 1-*XX*,2-*bB*,3-*aA*,4-*bB*cyclobutane. A further restriction placed on the configurations relates to the number of paired substituents. We specify that altogether there must be k_1 of a_1A_1, k_2 of a_2A_2, ..., k_r of a_rA_r and A_ra_r, m_1 of x_1x_1, m_2 of x_2x_2, ..., and m_s of x_sx_s, appearing on the n-gon with k_1, k_2, ..., k_r, m_1, ..., m_s each at least one.

The proof of the theorem is based on a counting result known as Burnside's Lemma [4], which states that if G is a permutation group, the number of orbits of G is given by the formula

$$\frac{1}{|G|}\sum_{\sigma \in G} f(\sigma)$$

$|G|$ denotes the number of elements in G, $f(\sigma)$ is the number of objects left fixed by the permutation

σ, and the summation is taken over all σ in G. Since the order of D_n is $2n$, the $1/2n$ is accounted for in the formula (1). It now remains to count the number of configurations left fixed by each of the $2n$ permutations.

Let $\sigma = (1\ 2\ 3\ \ldots\ n)$, that is, σ is the rotation of the n-gon through an angle of $2\pi/n$. We saw earlier that any power of σ is a product of n/d d-cycles for some divisor d of n. Such a permutation will leave a configuration fixed if, and only if, each substitution in a given d-cycle is the same. Hence, d must divide each of $k_1, \ldots, k_r, m_1, \ldots, m_s$, that is, d must divide g. Now we need to choose k_1/d d-cycles to give us k_1 of a_1A_1 and A_1a_1, k_2/d d-cycles to give us k_2 of a_2A_2 and A_2a_2, etc. Thus we can choose the d-cycles to fill up with a_iA_i's or A_ia_i's and X_jX_j's in

$$\begin{bmatrix} \frac{n}{d} \\ \frac{k_1}{d} \end{bmatrix}\begin{bmatrix} \frac{n}{d} - \frac{k_1}{d} \\ \frac{k_2}{d} \end{bmatrix}\cdots\begin{bmatrix} \frac{n}{d} - \frac{k_1}{d} - \cdots - \frac{m_{s-1}}{d} \\ \frac{m_s}{d} \end{bmatrix} = \frac{\left(\frac{n}{d}\right)!}{\left(\frac{k_1}{d}\right)!\cdots\left(\frac{k_r}{d}\right)!\left(\frac{m_1}{d}\right)!\cdots\left(\frac{m_s}{d}\right)!}$$

ways. But for each choice of k_1/d d-cycles we can put either all a_1A_1 or all A_1a_1 in each d-cycle. This can be done in $2^{k_1/d}$ ways. Similarly for a_2A_2 or A_2a_2 through a_rA_r or A_ra_r. Thus there are

$$2^{k_1/d} \times 2^{k_2/d} \cdots 2^{k_r/d} = 2^{K/d}$$

ways of filling up any selection of d-cycles. Moreover, there are exactly $\phi(d)$ powers of σ that are products of d-cycles. Therefore, the first term in formula 1 is accounted for and the n permutations that are powers of σ have been considered.

We now consider the n reflections of P_n. If n is odd, then every reflection has its axis passing through a single vertex, that is, the cycle structure is $(n-1)/2$ 2-cycles and a fixed vertex. So a reflection leaves a configuration fixed if, and only if, there is a substitution of the form XX at the fixed vertex, aA is substituted at one vertex of a 2-cycle when Aa is substituted at the other, and YY is substituted at one vertex of a 2-cycle when YY is substituted at the other. First of all we see that exactly one of the m_i's is odd (say m_j) and all other m_i's as well as all k_i's are even if $L \neq 0$ is to be possible. If all except m_j are even, then there are

$$\begin{bmatrix} \frac{n-1}{2} \\ \frac{k_1}{2} \end{bmatrix}$$

ways of choosing 2-cycles for the substitution of a_1A_1 and A_1a_1. Moreover, the a_1A_1 and A_1a_1 can be put into the $k_1/2$ 2-cycles in 2 ways. Similarly, there are

$$\begin{bmatrix} \frac{n-1}{2} - \frac{k_1}{2} \\ \frac{k_2}{2} \end{bmatrix}$$

ways of choosing 2-cycles for a_2A_2 and A_2a_2 and $2^{k_2/2}$ ways of putting them into the 2-cycles. Continuing in this way we find that any reflection fixes

$$\frac{\left(\frac{n-1}{2}\right)!2^{K/2}}{\left(\frac{k_1}{2}\right)!\cdots\left(\frac{k_r}{2}\right)!\left(\frac{m_1}{2}\right)!\cdots\left(\frac{m_{j-1}}{2}\right)!\left(\frac{m_j}{2}\right)!\left(\frac{m_{j+1}}{2}\right)!\cdots\left(\frac{m_s}{2}\right)!}$$

configurations. As there are n such reflections, the formula for L in category 1 follows.

The formulas for L in categories 2 and 3 follow from the fact that, when n is even, half of the reflections have an axis passing through no vertices and the remaining reflections have an axis passing through two opposite vertices. The rest of the calculations are similar to the above.

Molecular orbitals from group orbitals. IV. Quantitative perturbational molecular orbital analysis of the methyl rotational barriers in $(CH_3)_2X$ molecules. Effect of the fragmentation mode upon the results of the analysis

MYUNG-HWAN WHANGBO[1] AND SAUL WOLFE

Received February 21, 1977

MYUNG-HWAN WHANGBO and SAUL WOLFE. Can. J. Chem. **55**, 2778 (1977).

A quantitative perturbational molecular orbital (PMO) analysis has been performed on *ab initio* SCF-MO wavefunctions associated with the rotation of the methyl groups in a series of $(CH_3)_2X$ molecules (X = CH_2, O, S, C=O, C=CH_2). Two fragmentation modes have been investigated: Method *a*, in which the system is dissected into X and $(CH_3)_2$; and Method *b*, in which the system is dissected into CH_3X and CH_3. Both fragmentation modes reproduce the principal property of these molecules, viz., that the more crowded *SS* conformation is preferred. However, whether this conformational preference is controlled by two-electron stabilizing effects or four-electron destabilizing effects is found to depend upon both the mode of fragmentation and the nature of the substituent X. The quantitative results are supplemented by a detailed qualitative description of the nature of the group orbitals associated with the two fragmentation modes and the various types of orbital interactions. It is shown that orbital energy differences control the qualitative discussion of Method *a*, and overlap effects control that of Method *b*. Although the final result, i.e., the preference for the *SS* conformation, and the behaviour of individual orbital interactions are anticipated correctly by the qualitative arguments, these are unable to assess the relative contributions of the stabilizing and destabilizing interactions.

MYUNG-HWAN WHANGBO et SAUL WOLFE. Can. J. Chem. **55**, 2778 (1977).

On a effectué une analyse quantitative d'orbitale moléculaire perturbationnelle (OMP) à l'aide de fonctions d'onde SCF-MO *ab initio* associées avec la rotation des groupes méthyles dans une série de molécules $(CH_3)_2X$ (X = CH_2, O, S, C=O, C=CH_2). On a étudié deux modes de fragmentation: méthode *a*, dans laquelle le système est divisé en X et $(CH_3)_2$; la méthode *b* dans laquelle le système est divisé en CH_3X et CH_3. Les deux modes de fragmentation reproduisent la propriété principale de ces molécules à savoir que la conformation *SS* la plus empêchée est celle qui est préférée. Toutefois, on trouve que la conformation préférentielle qu'elle soit contrôlée par des effets stabilisants dus à deux électrons ou des effets déstabilisants dus à quatre électrons dépend à la fois du mode de fragmentation et de la nature du substituant X. On a ajouté un complément aux résultats quantitatifs en faisant une description qualitative détaillée de la nature des groupes d'orbitales associés avec les deux modes de fragmentation et les divers types d'interaction entre orbitales. On a montré que les différences d'énergie entre les orbitales contrôlent la discussion qualitative de la méthode *a* et que les effets de recouvrement contrôlent celle de la méthode *b*. Quoique les résultats finals, à savoir la préférence de la conformation *SS* et le comportement des interactions orbitales individuelles, peuvent être anticipés d'une façon correcte par des arguments qualitatifs, ces derniers ne permettent pas de déterminer les contributions relatives des interactions stabilisantes et déstabilisantes.

[Traduit par le journal]

Introduction

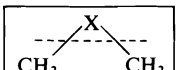
In Part III of this series (1), a method was developed for the quantitative perturbational molecular orbital (PMO) analysis of *ab initio* SCF-MO wavefunctions. This PMO method reproduces rather well the total energy rotational behaviour of the small hydrocarbon molecules ethane and propylene.

Regardless of the details of the procedure employed, any PMO analysis of a conformational effect begins with a dissection of the molecule into fragments. Although there is, in principle, no restriction concerning the specific fragmentation scheme which should be used, in practice it is customary to work within the framework of chemically 'reasonable' functional groups. Thus, for example, it is 'reasonable' to dissect ethane into two methyl fragments, and to dissect propylene into methyl and vinyl fragments. However, for larger molecules, more than one 'reasonable' fragmentation scheme can

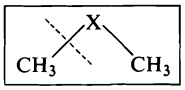
[1]Present address: Department of Chemistry, Cornell University, Ithaca, NY, U.S.A. 14853.

often be conceived. In such a case, it is important to know whether the results of the PMO analysis depend upon the mode of fragmentation of the system. The purpose of the present paper is to examine this problem by a consideration of the rotational behaviour of systems $(CH_3)_2X$ (X = CH_2, O, S, C=O, C=CH_2). A detailed examination of four of these compounds at the 4-31G level has been presented by Pople and co-workers (2). To rationalize their results, these workers have suggested that a π-electron or hyperconjugative effect is operative in these molecules and leads to aromatic stabilization involving bonding between methyl groups when the central atom is a π-donor (as in dimethyl ether), and to a corresponding antiaromatic destabilization when the central atom is a π-acceptor (as in acetone). These qualitative ideas have been developed further by Epiotis and Yates (3), in the course of a study of overlap repulsion as a contributor to aromaticity.

The present quantitative PMO analysis has been performed using two different fragmentation modes: Method *a*, in which the system is dissected into X and $(CH_3)_2$; this is the method employed by Epiotis and Yates (3). In Method *b* the system is dissected into CH_3X and CH_3. The first objective of the work is to determine whether both methods lead to the same conclusions concerning the total energy behaviour of $(CH_3)_2X$ molecules. Since this behaviour is calculated by a summation of the contributions of stabilizing and destabilizing π-type orbital interactions, a second objective of the work is to determine whether one or the other of these is the major contributor to the total energy. A third and most important objective is to demonstrate that the quantitative results can be understood in terms of simple qualitative arguments. Such a demonstration would generate considerable confidence in the use of such arguments for the discussion of conformational effects.

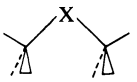


a

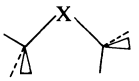


b

It is known (ref. 2 and references cited therein) that $(CH_3)_2X$ molecules exist in the more crowded *SS* conformation, and that the observed rotational barriers refer to the process $SS \rightleftarrows SE$.



SS



SE

The present discussion has, therefore, been restricted to these two conformations.

Results and Discussion

Ab initio SCF-MO calculations were performed using the STO-3G basis set (4) of Gaussian 70 (5). The methyl rotational barriers of the various $(CH_3)_2X$ molecules refer to the process $SS \rightarrow SE$, and were obtained by rigid rotation of one methyl group. The PMO analysis was performed after each SCF-MO calculation by evaluation of the two-electron stabilizing and four-electron destabilizing interaction energies. These energy terms are defined by eqs. 1 and 2 respectively (1).

$$[1] \quad \Delta e_{ij} = 2(\Delta_{ij} - e_i^0 \tilde{S}_{ij})^2/(e_i^0 - e_j^0)$$

$$[2] \quad \Delta e_{ij} = \frac{2\tilde{S}_{ij}\,[-2\Delta_{ij} + (e_i^0 + e_j^0)\tilde{S}_{ij}]}{(1 - \tilde{S}_{ij}^2)}$$

where Δ_{ij} is the interaction matrix element between the fragment orbitals ϕ_i^0 and ϕ_j^0, and $\tilde{S}_{ij}$ is the overlap integral between them. In the discussion which follows, only interactions between π-type fragment orbitals have been taken into account.

Table 1 summarizes the results of the present SCF-MO calculations. The experimental values for the rotational barriers of these systems and the results of Pople's 4-31G computations (2) are included for comparison. The agreement between calculated and experimental barriers is reasonable. In particular, variations in the barrier as X is varied are reproduced by the computations.

Quantitative Analysis by Method a

The results of the PMO analysis based upon Method *a* are summarized in Tables 2–4. The π-type fragment orbitals of X and $(CH_3)_2$ on which the analysis is based are shown schematically in Fig. 1. The butadiene-like character of the $(CH_3)_2$ group orbitals is clearly evident, and their nodal properties can be regarded as the result of in-phase (leading to π_+ and π_+*) and out-of-phase (leading to π_- and π_-*) combinations of methyl π and π* group orbitals.

The orbital energies e_i^0 collected in Table 2 reveal that the energy gap between π_+ and π_-

TABLE 1. Computed total energies and methyl rotational barriers of $(CH_3)_2X$ molecules[a]

X	Total energy (au)		Rotational barrier (kcal/mol)	
	SS	*SE*	Calculated	Experimental

and between π_+* and π_-* is greater in the *SS* conformation, as expected (3) from a recognition that the overlap between the methyl groups is greater in the *SS* conformation. A comparison of the e_i^0 values of π_X and π_X* reveals that the X fragment orbitals are nearly transferable from one conformation to the other within the same molecule.

The gross populations Q_i collected in Table 3 are consistent with the assumption that, prior to orbital interaction, the fragment orbitals π_+, π_-, and π_X are doubly occupied, and π_+*, π_-*, and π_X* are unoccupied. With this assignment of electron occupancies, the orbital interaction energies Δe_{ij} can be calculated, using eqs. 1 and 2, to give the results summarized in Table 4.

In the *SS* conformations, interactions ($\pi_X - \pi_-$), ($\pi_X - \pi_-$*) and (π_X* − π_-) are zero by symmetry. Although this symmetry restriction is removed in the *SE* conformations, these three interactions remain small. In each molecule, the sum of the four-electron destabilizing interactions is more positive, and the sum of the two-electron stabilizing interactions is less negative in the *SE* conformation. This is in harmony with the qualitative prediction by Epiotis and Yates (3) that the *SS* conformation will be more stable because it is stabilized more by the two-electron interaction and destabilized less by the four-electron interactions. For X = CH_2, C═O, and C═CH_2, the four-electron factor is greater than the two-electron factor. In dimethyl sulfide, the two effects are almost the same; however, in dimethyl ether, the two-electron effect is greater.

The differences in the total orbital interaction energies, $\sum\Delta e_{ij}$, of the *SS* and *SE* conformations are 2.68, 2.14, 0.80, 1.20, and 2.18 kcal/mol, for X = CH_2, O, S, C═O, and C═CH_2, respectively. The corresponding methyl rotational barriers obtained from the total energies of the SCF-MO computations are 3.75, 2.98, 1.80, 1.20, and 2.18 kcal/mol, respectively.

Qualitative Analysis by Method a

Our calculations reveal that, for a given interaction, $-\Delta_{ij}$ and $\tilde{S}_{ij}$ vary in the same way.[2] Therefore, it is valid to approximate Δ_{ij} by $k\tilde{S}_{ij}$, with k a negative constant. It then follows, from eqs. 1 and 2, that the magnitude of an interaction energy Δe_{ij} increases as S_{ij}^2 increases, regardless of whether such an interaction is stabilizing or destabilizing. On the other hand, the orbital energy dependence of an interaction energy depends upon the nature of the interaction. A two-electron stabilizing interaction increases as the orbital energy difference ($e_i^0 - e_j^0$) decreases; and a four-electron destabilizing interaction increases as the absolute value of the orbital energy sum ($e_i^0 + e_j^0$) decreases. These qualitative simplifications are, of course, well known (3).

Since π_+ and π_+* lie lower in the *SS* conformation than in the *SE* conformation, an argument based upon orbital energies predicts that the destabilizing interaction ($\pi_+ - \pi_X$) will

[2]More detailed data concerning Δ_{ij}, $\tilde{S}_{ij}$, and other quantities generated in the quantitative PMO analysis, are available from the authors.

be smaller, and the stabilizing interaction ($\pi_X - \pi_+^*$) will be larger in the *SS* conformation. This is confirmed for all X. When X is CH_2, C═O, or C═CH_2, there is also a ($\pi_+ - \pi_X$) stabilizing interaction; the orbital energy argument now predicts greater stabilization in the *SE* conformation. This is observed when X is C═O and C═CH_2, but not when X is CH_2.

The discrepancy is caused by the (secondary) overlap effect, which is difficult to assess qualitatively when X is a single atom, but cannot be ignored when X is a group. As shown in Fig. 2, the ($\pi_+ - \pi_X$) overlap is smaller in the *SS* conformation, but the ($\pi_X - \pi_+^*$) and the ($\pi_+ - \pi_X^*$) overlap is smaller in the *SE* conformation.[3] An overlap argument would, therefore, predict more stabilization and less destabilization in the *SS* conformation. Thus, for the destabilizing ($\pi_+ - \pi_X$) and the stabilizing ($\pi_X - \pi_+^*$) interactions, the overlap and the energy gap arguments operate in the same direction. However, in the case of the stabilizing ($\pi_+ - \pi_X^*$) interaction, they lead to different predictions, and qualitative arguments alone cannot determine which of the two effects should be dominant. Nevertheless, it can be predicted that the conformational dependence of this ($\pi_+ - \pi_X^*$) interaction should be small, as is observed.

It follows from the discussion just presented that the most appropriate qualitative rationalization of the *total energy* behaviour of $(CH_3)_2X$ molecules within the framework of fragmentation Method *a* is the one that emphasizes the energy gap argument (3), because this approach encompasses all X. However, it is not possible with such a procedure to probe the relative contributions of the stabilizing and destabilizing interactions.

Quantitative Analysis by Method b

The orbital interaction energies Δe_{ij} calculated by Method *b* are summarized in Table 5. The π-type fragment orbitals of CH_3X and CH_3 that are employed in this analysis are shown schematically in Fig. 3.

[3]A possible conceptual problem arises at this point, since one might reasonably ask why a repulsive $CH_3 \ldots CH_3$ interaction, greater in the *SS* conformation than in the *SE* conformation, can be ignored. The reason for this is that Method *a* treats $CH_3 \ldots CH_3$ as a single unit (group), and only interactions *between* the $(CH_3)_2$ and X groups are meaningful in the PMO analysis. Furthermore, the $CH_3 \ldots CH_3$ interaction has already been taken into account in the energy gap argument.

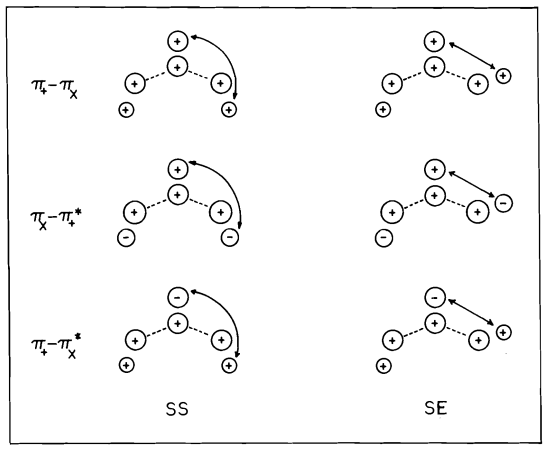

FIG. 2. The overlap between the $(CH_3)_2$ and X groups in the *SS* and *SE* conformations. Several stabilizing and destabilizing interactions are shown. The primary overlap between the fragments is shown as a dotted line. Secondary overlap is indicated by a double-headed arrow.

The nature of the CH_3X group orbitals requires comment. When X is oxygen or sulfur, the nodal property of the CH_3X group is like that of the allyl system, because the two methyl hydrogens, the methyl carbon, and X each contribute one *p*-type atomic orbital. The lowest-lying CH_3X group orbital (π_α) is the in-phase combination of π_{CH_3} and p_X, and the highest occupied CH_3X group orbital (π_β) is the out-of-phase combination of π_{CH_3} and p_X. Since π_{CH_3} lies lower than p_X, it has greater weight in π_α, and p_X has greater weight in π_β. The unoccupied CH_3X group orbital, designated π_γ^*, is mainly the out-of-phase combination of $\pi_{CH_3}^*$ and p_X, and is, therefore, weighted heavily on carbon and hydrogen.

When X is CH_2, C=O, or $C{=}CH_2$, the nodal property of CH_3X is like that of butadiene, because four *p*-type atomic orbitals are used to form the group. The two occupied CH_3X orbitals (π_α and π_β) result mainly from the in-phase and out-of-phase combinations of π_{CH_3} and π_X; the two unoccupied CH_3X orbitals (π_γ^* and π_δ^*) result mainly from the in-phase and out-of-phase combinations of $\pi_{CH_3}^*$ and π_X^*.

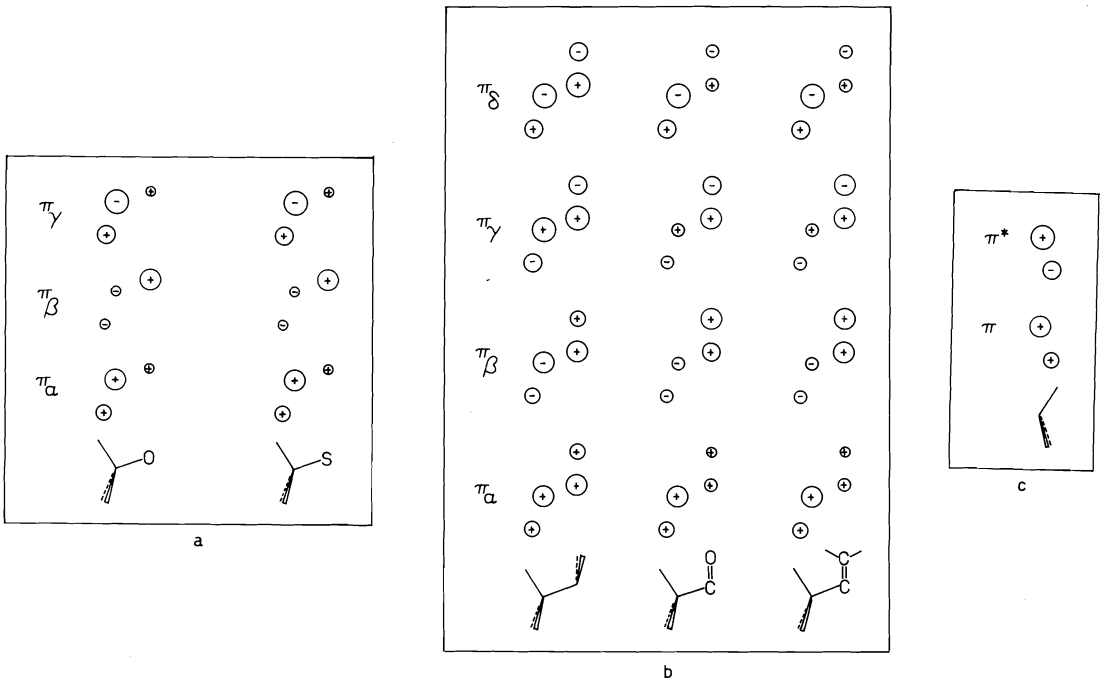

FIG. 3. The π-type fragment orbitals in the CH_3X and CH_3 groups of $(CH_3)_2X$ molecules: (*a*) the CH_3X group, when X = O, S; (*b*) the CH_3X group, when X = CH_2, CO, and C=CH_2; (*c*) the CH_3 group.

Since the energies of π_{CH_3} and $\pi_{CH_3}{}^*$ are not very different from those of π_{CH_2} and $\pi_{CH_2}{}^*$, respectively, the weights on CH_3 and CH_2 in the four CH_3CH_2 group orbitals are all about the same. However, when X is C=O or C=CH_2, π_X lies higher than π_{CH_3} and $\pi_X{}^*$ lies lower than $\pi_{CH_3}{}^*$. Consequently, π_α and $\pi_\delta{}^*$ are weighted in favour of CH_3, and π_β and $\pi_\gamma{}^*$ are weighted in favour of X.

In each molecule, the sum of the two-electron stabilizing interactions is less negative in the *SE* conformation, as in the analysis by Method *a*. However, in contrast to the analysis by Method *a*, the sum of the four-electron destabilizing interactions is more positive *in the SS conformation* in dimethyl ether and dimethyl sulfide. The differences in the total orbital interaction energies of the *SS* and *SE* conformations indicate that the *SS* is more stable by 1.98, 0.82, 0.26, 0.64, and 1.64 kcal/mol for X = CH_2, O, S, C=O, and C=CH_2, respectively.

Qualitative Analysis by Method b

We begin this discussion with the observation that the methyl group orbitals (π and π* of Fig. 3 and Table 5) are almost quantitatively transferable from *SS* to *SE* in each of the five molecules, since the $e_j{}^0$ values calculated for these two orbitals are almost exactly the same in the two conformations.[2] Therefore, the qualitative description of fragmentation Method *b* will be based upon overlap considerations.

The ($\pi - \pi_\alpha$) Interaction

This interaction is shown in Fig. 4. Figure 4 *a* and *b* indicates that the overlap **1** is large in *SS*, and the overlap **2** is large in *SE*. A prediction requires knowledge of which of these two overlaps is larger. This is not possible in the case of X = CH_2 without quantitative results. However, for X = CO and C=CH_2, overlap **2** in *SS* will be greater than overlap **1** in *SE*, because the π_α orbital is more heavily weighted on the methyl group of CH_3X. Figure 4*c* also shows that the overlap is greater in the *SS* conformation. Four of the five molecules are therefore predicted to exhibit greater destabilization in the *SS* conformation in terms of the ($\pi - \pi_\alpha$) interaction.

The ($\pi - \pi_\beta$) Interaction

This interaction is shown in Fig. 5. In this case, Fig. 5 *a* and *b* leads to the same prediction, viz., that the overlap in *SS* is less than that in *SE*, because overlap **2** in *SS* is negative, and

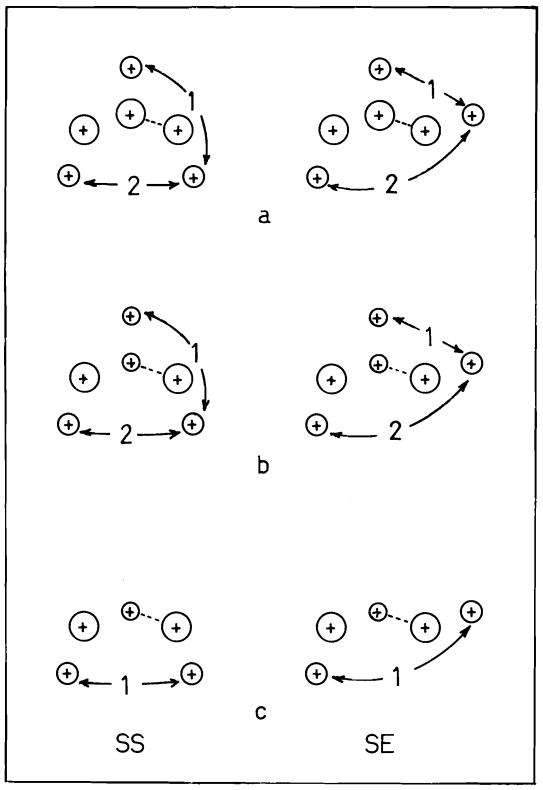

FIG. 4. The phase relationships between the CH_3X and CH_3 fragment orbitals in the *SS* and *SE* conformations for the $(\pi - \pi_\alpha)$ interaction: (*a*) X = CH_2; (*b*) X = CO, C=CH_2; (*c*) X = O, S. The primary overlap between the fragments is shown as a dotted line. Secondary overlap is indicated by a double-headed arrow.

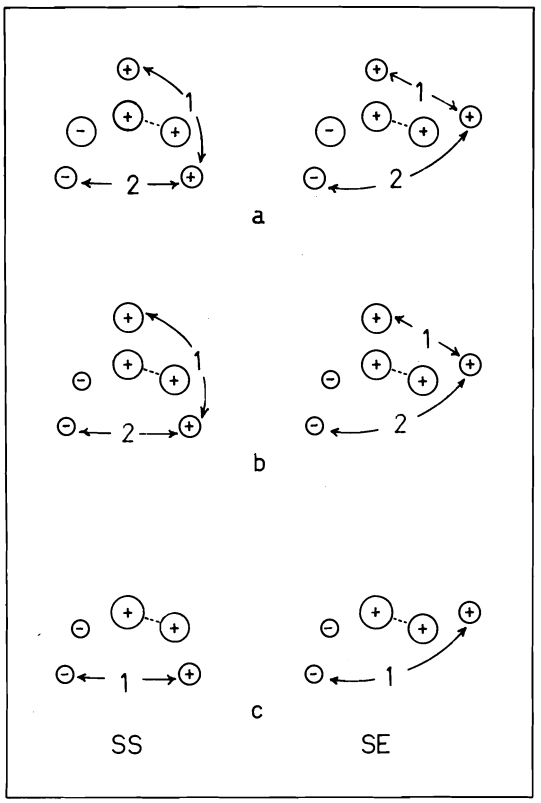

FIG. 5. The phase relationships between the CH_3X and CH_3 fragment orbitals in the *SS* and *SE* conformations for the $(\pi - \pi_\beta)$ interaction: (*a*) X = CH_2; (*b*) X = CO, C=CH_2; (*c*) X = O, S. The primary overlap between the fragments is shown as a dotted line. Secondary overlap is indicated by a double-headed arrow.

overlap **1** in *SE* is positive. Figure 5*c* also shows a more negative contribution from overlap **1** in the *SS* conformation. In terms of the $(\pi - \pi_\beta)$ interaction, all five molecules are predicted to exhibit greater destabilization in the *SE* conformation. In the cases of CH_3O and CH_3S, the $(\pi - \pi_\alpha)$ interaction outweighs the $(\pi - \pi_\beta)$ interaction because the methyl group of CH_3O and CH_3S is more heavily weighted in π_α than in π_β. Thus, the net destabilization is greater in the *SS* conformation in these two molecules, even though the higher orbital energy of π_β would lead to the opposite prediction, as is found in the other three molecules.

The $(\pi - \pi_\gamma^*)$ Interaction

This interaction is shown in Fig. 6. Figure 6 *a* and *b* shows that the overlap **2** is smaller in *SS*, and the overlap **1** is smaller in *SE*. As with the $(\pi - \pi_\alpha)$ interaction, no qualitative prediction is possible in the case of X = CH_2. However, for X = CO and C=CH_2, the negative overlap in *SS* will be less than that in *SE*, i.e., the total overlap will be larger in *SS*, because the π_γ^* orbital is more heavily weighted on the X group of CH_3X. Figure 6*c* also shows that the overlap is greater in the *SS* conformation. Thus, four of the five molecules are predicted to show greater stabilization in the *SS* conformation.

The $(\pi_\beta - \pi^*)$ Interaction

This interaction is shown in Fig. 7. In all cases, the overlap is greater in the *SS* conformation. The $(\pi_\beta - \pi^*)$ interaction therefore predicts greater stabilization in the *SS* conformation.

The $(\pi_\alpha - \pi^*)$ and $(\pi - \pi_\delta^*)$ Interactions

These interactions can be depicted and analysed in an analogous manner, but it is already clear that the qualitative PMO analysis based

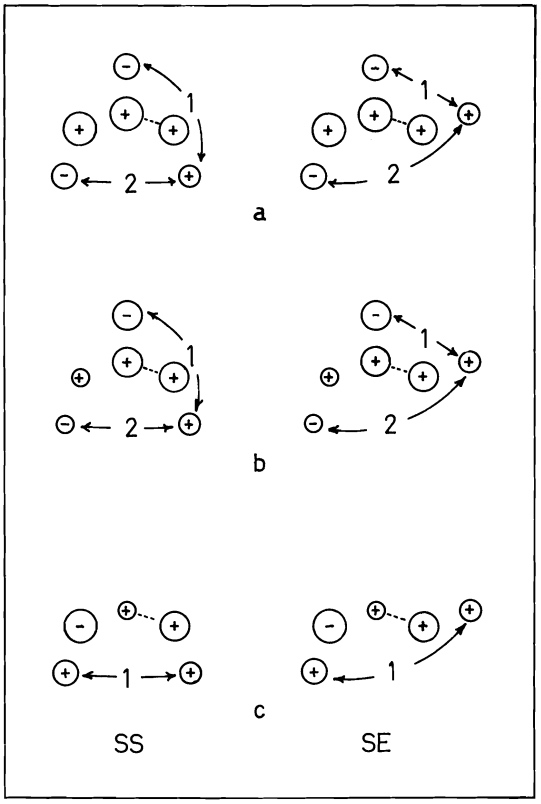

FIG. 6. The phase relationships between the CH_3X and CH_3 fragment orbitals in the *SS* and *SE* conformations for the $(\pi - \pi_\gamma)$ interaction: (*a*) X = CH_2; (*b*) X = CO, C=CH_2; (*c*) X = O, S. The primary overlap between the fragments is shown as a dotted line. Secondary overlap is indicated by a double-headed arrow.

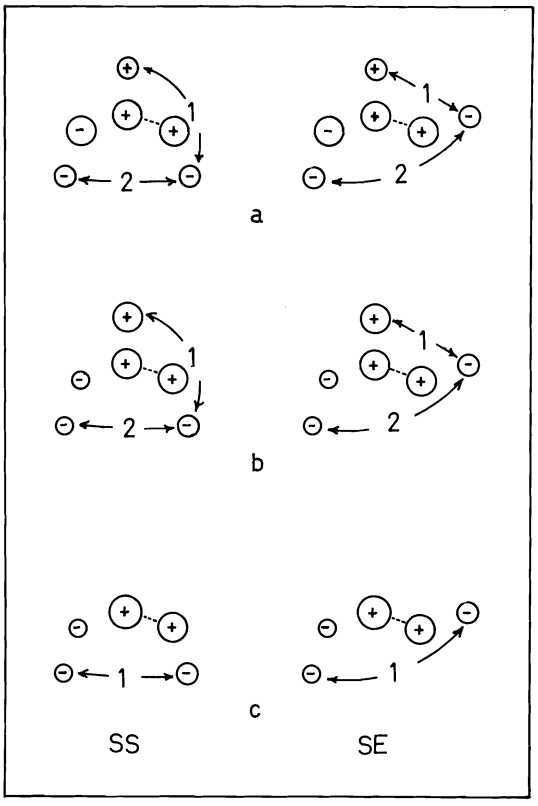

FIG. 7. The phase relationships between the CH_3X and CH_3 fragment orbitals in the *SS* and *SE* conformations for the $(\pi_\beta - \pi^*)$ interaction: (*a*) X = CH_2; (*b*) X = CO, C=CH_2; (*c*) X = O, S. The primary overlap between the fragments is shown as a dotted line. Secondary overlap is indicated by a double-headed arrow.

upon Method *b* is much more cumbersome than that based upon Method *a*. A simplifying assumption seems to be necessary for Method *b* to be useful as a qualitative procedure. A reasonable simplifying assumption is that only interactions associated with the frontier orbitals be considered, i.e., interactions $(\pi - \pi_\beta)$, $(\pi_\beta - \pi^*)$, and $(\pi - \pi_\gamma^*)$. With this simplification it is readily shown that the *SS* conformation is more stable than the *SE* conformation for all X. However, as with Method *a*, it is not possible using qualitative arguments alone to state the relative contributions of the stabilizing and destabilizing interactions to the overall result.

Conclusions

Both fragmentation modes reproduce the principal fact, that the SS conformation is more stable than the SE conformation in $(CH_3)_2X$ molecules. In terms of the orbital interaction energies, the total energy behaviour of these molecules is reproduced more closely by Method *a*. However, neither mode of analysis supports the notion (3) that overlap repulsion effects play a dominant role in deciding the conformational behaviour of dimethyl ether and dimethyl sulfide.

Regardless of the mode of fragmentation, the sum of the gross populations Q_i of all π-type fragment orbitals in a $(CH_3)_2X$ system is 6. It is understandable, therefore, that an analogy has been drawn (2, 3) between the greater stability of an *SS* conformation and the aromaticity of cyclic 6π-electron systems. However, as has been noted, whether such 'aromaticity' is caused by a minimization of repulsive effects or a maximization of attractive effects depends on X.

On the blue complexes of ruthenium. Part II. The structure of *fac*-trichlorotriammineruthenium(III)

FRANK BOTTOMLEY

Department of Chemistry, University of New Brunswick, P. O. Box 4400, Fredericton, N.B., Canada E3B 5A3

Received December 21, 1976

FRANK BOTTOMLEY. Can. J. Chem. **55**, 2788 (1977).

The structure of $[RuCl_3(NH_3)_3]$ prepared from the blue chloro-ammine complex of ruthenium is described. The crystals are orthorhombic, $a = 9.933(3)$, $b = 6.522(2)$, $c = 5.475(2)$ Å, $Z = 2$, space group $Pmn2_1$. The structure analysis used 283 observed reflections, whose intensity was measured on a Picker FACS-1 diffractometer. The structure was refined (full-matrix) to $R = 0.029$. The crystal is composed of chains of *fac*-$[RuCl_3(NH_3)_3]$, and is disordered, approximately 10% of the chains being reversed in direction and displaced one-half in z. The Ru–ligand distances and angles are normal.

FRANK BOTTOMLEY. Can. J. Chem. **55**, 2788 (1977).

On décrit la structure du $[RuCl_3(NH_3)_3]$ préparé à partir du complexe bleu de chloreammine du ruthénium. Les cristaux sont orthorhombiques $a = 9.933(3)$, $b = 6.522(2)$, $c = 5.475(2)$ Å, $Z = 2$ groupe d'espace $Pmn2_1$. L'analyse structurale a fait appel aux 283 réflexions observées dont l'intensité a été mesurée sur un diffractomètre Picker FACS-1. On a affiné la structure par la méthode des moindres carrés (matrice complète) jusqu'à une valeur de $R = 0.029$. Le cristal est composé de chaînes de *fac*-$[RuCl_3(NH_3)_3]$ et est désordonné; environ 10% des chaînes sont dans une direction renversée et déplacée de moitié suivant l'axe des z. Les distances et les angles du ruthénium avec le ligand sont normaux.

Introduction

In a previous paper we outlined our investigations of the blue species obtained by treating hexaammineruthenium(II) with hydrohalic acids (1). We found that the blue complexes were ruthenium(II)–ruthenium(III) dimers of empirical formula $Ru_2X_5(NH_3)_6H_2O$ (X = Cl, Br), and suggested the dimeric cation contained a single halo-bridge, *i.e.* had a formula $[Cl_2(NH_3)_3RuClRu(H_2O)(NH_3)_3Cl]^+$. Later work by Mercer and Gray on the chloro-complex confirmed the dimeric Ru(II)–Ru(III) nature of the cation, and suggested a triply chloro-bridged structure, *i.e.* a formula $[(NH_3)_3RuCl_3Ru(NH_3)_3]^{2+}$ (2). To finally confirm the structure we repeatedly attempted to obtain crystals of the blue cation with various anions but obtained microcrystalline material at best. In the absence of these crystals we turned our attention to $[RuCl_3(NH_3)_3]$, which was the product obtained when the blue chloro-complex was treated with HCl. Our tentative conclusion, on the basis of the infrared spectrum, was that this product had the *mer*-configuration, a structure incompatible with a triple chloro-bridge (1). Mercer and Gray concluded $[RuCl_3(NH_3)_3]$ was *cis*- (*fac*-), which geometry, while compatible with either bridging structure, is clearly more probable from reaction of a triply chloro-bridged cation (2). Hence the structure of $[RuCl_3(NH_3)_3]$ provides good evidence for the structure of the blue complex. We were also interested in this structure in connection with our studies of the *trans*-influence in octahedral complexes of this type (3, 4).

Experimental

$[RuCl_3(NH_3)_3]$ was obtained, as long needles, from $Ru_2Cl_5(NH_3)_6H_2O$ by the method described previously (1). Crystal data are as follows

$[RuCl_3(NH_3)_3]$ mw = 258.5
Orthorhombic, $a = 9.933(3)$, $b = 6.522(2)$, $c = 5.475(2)$ Å, $U = 354.7$ Å^3, $D_c = 2.49$ for $Z = 2$, $D_m = 2.46$ g cm^{-3} (by flotation in $CHCl_3/C_2H_2Br_4$); Zr-filtered Mo-K_α radiation, $\lambda = 0.70926$ Å; μ (Mo-K_α) = 31.7 cm^{-1}. $h0$-$2l$ Weissenberg and 0–$2kl$ and hk0–2 precession photographs showed systematic absences compatible with space groups $Pmn2_1$, $P2_1nm$, or $Pmnm$. The first is correct from the refinement.

The crystal used for the intensity determination was the tip cut from a long needle, and had dimensions 0.08 × 0.35 × 0.15 mm. It was mounted with shellac in a glass tube with the b axis deliberately mis-set with respect to the ϕ axis of the Picker FACS 1 diffractometer. Cell dimensions were determined from 12 accurately centered reflections of $2\theta > 30°$. Data were collected using the following instrumental settings: Zr-filtered Mo-K_α

radiation; 2.0° scan, corrected for $K_{\alpha 1}$–$K_{\alpha 2}$ dispersion; ω–2θ scan of rate 1° min^{-1} in 2θ in the range $2 < 2\theta < 50°$; stationary 20 s background counts on either side of the peak; take-off angle 2.0°; pulse-height analyser set for 97% of the Mo-K_α window; no attenuators needed since count rate was always less than 1×10^4 s^{-1}; the 121 reflection was monitored every 20 reflections as standard; its intensity varied by about 6% during data collection, and this was corrected for in processing. A group of reflections of high h could not be measured because of the position of the crystal in the tube; their presence or absence (less than minimum observable intensity), was established from the photographic record, but they were treated as unobserved and not used in the refinement. In processing, the data reflections having a net count less than 20 or less than 0.05 times the background count were considered unobserved. The processing, including Lorentz and polarisation corrections, gave 88 unobserved and 283 observed reflections. A trial absorption calculation showed the transmission factors varied from 68 to 76%, and hence no absorption correction was applied. In the refinement, which minimized $\Sigma w(|F_o| - |F_c|)^2$, scattering factor curves for Ru(3+), Cl^-, and N were taken from refs. 5 and 6 and were corrected for both the real and imaginary parts of the anomalous dispersion. A weighting scheme of the form given earlier (7) with $A = 35$, $B = 0.02$, and $C = 1.0 \times 10^{-5}$ was used. All calculations used the XRAY 76 package (8).

Results and Discussion

A Patterson function was readily interpretable in terms of Ru^{3+} and three Cl^- ions in space group $Pmn2_1$. Because of the short c axis no solution in $P2_1nm$ was chemically reasonable (there was no room for the Cl^- ions along z). The Patterson solution was confirmed by a Fourier phased on Ru^{3+} alone; this showed the three Cl^- ions and four light atoms, three of which, with the Cl^-, completed a *facial* octahedral co-ordination around the Ru^{3+}. The fourth was sandwiched between the three Cl^- ligands of one $[RuCl_3(NH_3)_3]$ molecule and the three NH_3 of the next. Neither microanalysis (Found: Cl 40.2, N 16.1. Calcd. for $Cl_3H_9N_3Ru$: Cl 41.1, N 16.2) nor the infrared spectrum of the crystals indicated the presence of water of crystallization, but as a preliminary model the additional atom was assumed to be oxygen. Full matrix refinement of this model with all atoms having isotropic temperature factors proceeded to $R = 0.12$. At this stage it was clear that the additional atom was apparently octahedrally coordinated by the three Cl^- and three NH_3, with a co-ordination geometry very similar to that of the ruthenium. The atom was approx. 2.7 Å from the ruthenium. The only reasonable explanation for this unlikely geometry was a disordered crystal. A large number of disordered models were tested, reasonableness of the thermal parameters, R value, bond distances, and chemical sense being used to evaluate the results. The model finally adopted may be visualised, with the aid of Fig. 1, as chains whose *fac*-$[RuCl_3(NH_3)_3]$ links are connected together by hydrogen bonds (because of the disorder no attempt was made to find the hydrogen atoms in the structure analysis, but the intermolecular N. . .Cl distances within the chains are 3.25 (N(1). . .$Cl(1_1)$); 3.53 (N(1′). . .$Cl(2_1)$); and 3.56 (N(2). . .$Cl(1_1)$) Å (for numbering scheme see Fig. 1) indicative of hydrogen bonding (9). There are two almost linear chains running through the unit cell with the idealized threefold axis of *fac*-$[RuCl_3(NH_3)_3]$ (which passes through the midpoints of the trichloro and triammine faces) parallel to c, one chain at $x = 0$, $y = 0.2773$ and the other at $x = 0.5$, $y = 0.7227$. The two chains are held together by hydrogen bonds (the interchain N. . .Cl distances are 3.39 (N(2). . . Cl(1)); 3.51 (N(1). . .Cl(2)); and 3.54 (N(1). . . Cl(1)) Å. For both chains the vector running along the threefold axis from Cl through Ru to NH_3 points in the direction $-z$ to $+z$. The disorder arises because about 10% of the chains are displaced 0.5 in z (the ruthenium, Ru(2), now being at position A in Fig. 1), and they run in the opposite direction (the vector points from $+z$ to $-z$), so that the NH_3 and Cl^- ligands are approximately coincident in position with the NH_3 and Cl^- of the 90% of 'undisordered' chains. The 10% figure was arrived at after refining models with various percentages of the displaced chains, and allowing them to run in both directions. The site occupancy of the Ru^{3+} of the 'undisordered' chains (Ru(1)) was held invariant at 0.9, and of the Ru^{3+} of the 'disordered' chains (Ru(2)) invariant at 0.1. This model, with anistropic thermal parameters for Ru(1) and the three Cl^- ions, and isotropic thermal parameter for the N and Ru(2) atoms refined to a final R of 0.029 ($R_2 = 0.044$). Finally, since $Pmn2_1$ is a polar space group refinement of a model using the data in the $\bar{h}k\bar{l}$ form was tried. This made no significant difference, as would be expected since the Ru(3+) ions are extremely close to being centric, and the same applies to the Cl(2) atom in the special position. A final difference Fourier synthesis showed nothing unusual, neither did statistical tests on R and R_2. The final parameters are listed in

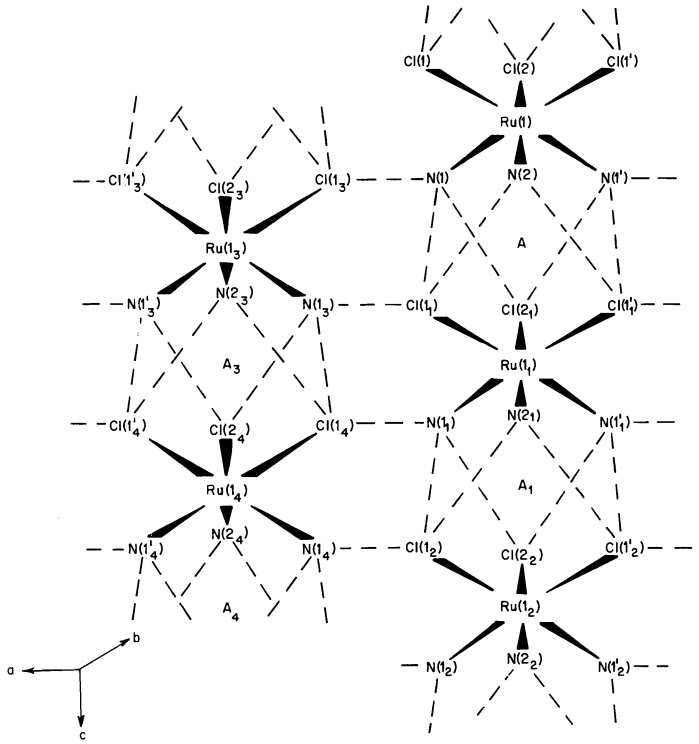

FIG. 1. The chains of *fac*-$[RuCl_3(NH_3)_3]$ projected onto a plane normal to *b* containing Ru(1). Dashed lines indicate hydrogen bonding. The asymmetric unit is the *fac*-$[RuCl_3(NH_3)]$ (containing 9/10 Ru) and the 1/10 Ru at position A. Subscripted atoms belong to repeat asymmetric units (*e.g.* Cl(1) and $Cl(1_1)$). Superscripted atoms are related to the corresponding non-superscripted ones by space group symmetry (*e.g.* (Cl(1) and Cl(1′)).

Table 1, and the final table of F_o and F_c (Table 2) has been deposited.[1]

The results show definitively that the product of the reaction of HCl with $Ru_2Cl_5(NH_3)_6H_2O$ is *fac*-$[RuCl_3(NH_3)_3]$, and not the *mer*-isomer. While this is compatible with from one to three bridging Cl^- in the blue complex, it tends to support the triply chloro-bridged structure proposed by Mercer and Gray rather than the other possibilities. We also note that we have now prepared the blue salts $[Ru_2Cl_3(NH_3)_6]I_2 \cdot H_2O$ and $[Ru_2Cl_3(NH_3)_6]ZnCl_4$, characterised by conductivity, analysis, spectroscopy, and reactions, which provide further and almost conclusive evidence for a triple chloro-bridge (10).

The intramolecular dimensions in $[RuCl_3(NH_3)_3]$ are listed in Table 3. Because of the disorder only the distances and angles around Ru(1) can be compared to those in other ruthenium complexes, and even then no detailed comparison is worthwhile. The ruthenium ion is octahedrally co-ordinated, with angles acceptably close to 90°, by the three Cl^- and three NH_3 groups. The Ru—N distances (2.10(1) and 2.13(1) Å) are similar to those observed in $[Ru(NH_3)_6](BF_4)_3$ (2.104(4) Å (11)) and $[Ru(en)_3]Cl_3 \cdot 3H_2O$ (en = ethylenediamine; 2.10(2) and 2.12(2) Å (12)), and the Ru—Cl distances (2.37(1) and 2.39(1) Å) are in the same region (2.34–2.38 Å (13)) as observed previously for such bond distances.

It is interesting to speculate briefly on the reason for the disorder. The intramolecular distance between the trichloro and triammine faces of the *fac*-$[RuCl_3(NH_3)_3]$ unit (2.5 Å) is similar to the intermolecular distance between the same faces (2.9 Å). This must be the consequence of the strong $NH_3 \ldots Cl$ hydrogen bonding. The disorder arises because the initial orientation of a *fac*-$[RuCl_3(NH_3)_3]$ is determined

Double salts of indium trichloride with the alkali chlorides, with ammonium chloride, and with indium sulfate

ELINOR M. KARTZMARK

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received January 31, 1977

ELINOR M. KARTZMARK. Can. J. Chem. **55**, 2792 (1977).

From a determination of the phase diagrams, at 25°C, the following double salts were shown to exist: $3LiCl{\cdot}InCl_3{\cdot}8H_2O$ in the system LiCl–$InCl_3$–H_2O, $2KCl{\cdot}InCl_3{\cdot}H_2O$ and $3KCl{\cdot}InCl_3{\cdot}2H_2O$ in the system KCl–$InCl_3$–H_2O, $2RbCl{\cdot}InCl_3{\cdot}H_2O$ in the system RbCl–$InCl_3$–H_2O, $2CsCl{\cdot}InCl_3{\cdot}H_2O$ in the system CsCl–$InCl_3$–H_2O, $2NH_4Cl{\cdot}InCl_3{\cdot}H_2O$ in the system NH_4Cl–$InCl_3$–H_2O, $In_2(SO_4)_3{\cdot}InCl_3{\cdot}(17 \pm 1)H_2O$ in the system $In_2(SO_4)_3$–$InCl_3$–H_2O. No double salt was found in the system NaCl–$InCl_3$–H_2O, studied previously (1). All the double salts except the two involving potassium chloride are congruently saturating at 25°C.

ELINOR M. KARTZMARK. Can. J. Chem. **55**, 2792 (1977).

A partir de déterminations de diagrammes de phase à 25°C, on a démontré que les sels doubles suivants existent: $3LiCl{\cdot}InCl_3{\cdot}8H_2O$ dans le système LiCl–$InCl_3$–H_2O, $2KCl{\cdot}InCl_3{\cdot}H_2O$ et $3KCl{\cdot}InCl_3{\cdot}2H_2O$ dans le système KCl–$InCl_3$–H_2O, $2RbCl{\cdot}InCl_3{\cdot}H_2O$ dans le système RbCl–$InCl_3$–H_2O, $2CsCl{\cdot}InCl_3{\cdot}H_2O$ dans le système CsCl–$InCl_3$–H_2O, $2NH_4Cl{\cdot}InCl_3{\cdot}H_2O$ dans le système NH_4Cl–$InCl_3$–H_2O, $In_2(SO_4)_3{\cdot}InCl_3{\cdot}(17 \pm 1)H_2O$ dans le système $In_2(SO_4)_3$–$InCl_3$–H_2O. On n'a trouvé aucun sel double dans le système NaCl–$InCl_3$–H_2O qui avait été étudié antérieurement (1). Tous les sels doubles à l'exception des deux impliquants le chlorure de potassium se saturent d'une façon congruente à 25°C.

Introduction

Many double salts between indium trichloride and the alkali metal halides were reported in the early literature but no systematic study of the aqueous systems has been undertaken. Only a systematic phase rule study can prove the existence or non-existence of compounds in a given system and this is the reason for the present work.

Two of the binary salt systems were studied by Kley (2) using a microscopic technique which did not involve a proper analysis: the double salts Rb_3InCl_6 and Cs_3InCl_6 were reported. An analogous compound K_3InCl_6 was found by Fedorov (3) who did a thermal analysis which also showed the existence of a double salt, K_2InCl_5.

Meyer (4) reported a compound between lithium chloride and indium trichloride, but did not determine its composition. Ensslin *et al.* (5) gave this double salt the formula $3LiCl{\cdot}InCl_3{\cdot}9H_2O$. An incongruently saturating compound of formula $K_3InCl_6{\cdot}2H_2O$ was found by Wallace (6). He also studied the rubidium chloride, cesium chloride, and ammonium chloride systems with indium trichloride and water and reported compounds of formulae $M_2InCl_5{\cdot}H_2O$. He failed to find an analogous compound with potassium chloride which in the present study has been found to occur with an excess of indium trichloride. It is incongruently saturating and decomposes with addition of water to form the compound $K_3InCl_6{\cdot}2H_2O$, found by Wallace. The compound $(NH_4)_2InCl_5{\cdot}H_2O$ was also reported by Klug, Kummer, and Alexander (7).

In the earlier papers by this author on the double salts of indium trichloride the assumption was made that the stable hydrate of indium trichloride, at 25°C, was the trihydrate, since it was reported as such on the label from the BDH supplier. A paper by Ensslin *et al.* (5), which gave the formula $InCl_3{\cdot}4H_2O$ was discounted because of their experimental method: they refer to removing the solid phase by filtration, pressing it dry with filter paper, and analysing. Recently, however, Wignacourt (8) gave the formula as the tetrahydrate and based a Raman study on that formula. This caused the author of this paper to pay more particular attention to this matter. The problem arises because the invariant point on the indium trichloride side of the ternary

systems usually has less than 5% of the second salt and the tie-lines through the "wet residue" do not have sufficient slope to distinguish between three and four moles of water on a total molecular weight near 300. The system: indium trichloride – indium sulfate – water, was chosen in the hope that the invariant point would lie nearer to the middle of the diagram. This system has not previously been studied but Seward (9) gave the formula $In_2(SO_4)_3 \cdot 9H_2O$ to the hydrate of indium sulphate.

Experimental

Materials

Indium trichloride was obtained from Cominco in the form of a concentrated solution in water. To study the indium-rich regions, anhydrous indium trichloride obtained from J. T. Baker was used. The alkali chlorides and ammonium chloride were reagent grade and used without further purification. Anhydrous indium sulfate was obtained from Alfa Inorganics of Beverly, MA.

Analysis

Systems were equilibrated by stirring at 25.00°C for a period of 2 to 3 days. The indium-rich solutions were very viscous and required lengthy stirring to ensure equilibrium. The phases were separated by filtration through sintered glass and were analysed for chloride by precipitation as silver chloride and for alkali halide using a Perkin-Elmer flame photometer, Model 146, which gave an accuracy of ±1%. The presence of indium trichloride affects this estimation, so the indium trichloride was removed by adding ammonia and centrifuging to settle the indium hydroxide. Ammonium ion was estimated to ±1% by distillation from strong sodium hydroxide solution and absorption in boric acid solution, followed by conductimetric titration with standard hydrochloric acid. Indium chloride was determined by difference.

The technique of separation of the phases in the indium trichloride – indium sulfate – water system had to be changed because filtration proved to be impossible. The saturated solution together with solid phase was transferred to a closed centrifuge tube and rotated for from 5 to 6 h. The clear solution was decanted and the remaining wet residue treated as described below. The centrifuging was done at room temperature, 24 ± 1°C. Sulfate was determined as barium sulfate, with an accuracy of ±1%.

The composition of the compounds was obtained by the method of the 'wet rest'. This method requires that the solid phase and the adhering mother liquor be as dry as possible, without preferential loss of water. The simple procedure of placing it, after filtration, between pads of filter paper and submitting it to hydraulic pressure produced a 'wet rest' whose composition was so close to that of the compound, that error in extrapolation was minimized. This is important in high molecular weight compounds containing water if the true degree of hydration is to be obtained.

The experimental data are summarized in Table 1 which gives the composition of invariant solutions and nature of the solid phases for the six systems. The complete solubility data are to be found in the Depository.[1] The data are plotted in Figs. 1 to 6.

Discussion

The system indium trichloride – lithium chloride – water shows the existence of a congruently saturating double salt containing 3 mol of lithium chloride to 1 mol of indium trichloride (Table 1*a*). This salt was reported by Ensslin to have 9 mol of water of hydration but none of the compressed wet solids with compound as solid phase contained this amount of water (31.8%). The six pairs of points containing compound as solid phases were plotted on a triangular diagram, 55 cm to a side, using a width of tie-line equal to ±1%. The intersections of the six tie-lines enclosed a circle of 3 percentage points in diameter, centred at 29.5% water. The salt ratio is undoubtedly 3LiCl to $1In(Cl)_3$: the water content of the circle corresponds to 7 to 9 mol of water. The formula $3LiCl \cdot InCl_3 \cdot 8H_2O$ represents 29.2% water and in all probability is the correct formula of the double salt.

A second interesting feature of this phase diagram (Fig. 1) is the appearance of anhydrous lithium chloride in equilibrium with solution of very high indium trichloride content. This dehydration of a salt hydrate by a second salt is not uncommon. (Under normal laboratory conditions lithium chloride monohydrate loses its water of hydration around 98°C.)

The three systems of indium trichloride with ammonium chloride, rubidium chloride, and cesium chloride present very similar phase diagrams (Figs. 2, 3, 4): the congruently saturating double salts $2RbCl \cdot InCl_3 \cdot H_2O$ and $2CsCl \cdot InCl_3 \cdot H_2O$ occupy the major area of the diagrams, the invariant points lying very close to the water-salt edges and the solubilities being quite small. The double salt $2NH_4Cl \cdot InCl_3 \cdot H_2O$ is also congruently saturating but the solubility is much greater. Thus the double salts first reported by Wallace are the only ones to be found in these systems.

The potassium chloride – indium trichloride – water system (Fig. 5) features two double salts. The first, of formula analogous to those above,

water and g $InCl_3$ per 100 g water. This treatment may be found in the Depository of Unpublished Data.[1]

This system has recently been studied by Wignacourt (8) who also finds the two double salts from a phase rule study at 21°C. He gives the formula $InCl_3 \cdot 4H_2O$ to hydrated indium trichloride and draws an analogy between it and thallium trichloride tetrahydrate. The tie-lines in his phase diagram are not conclusive as to the degree of hydration of indium trichloride, because the wet residue contained a large amount of mother liquor.

Figure 6, which gives the phase diagram at 24 ± 1°C, for the system indium trichloride – indium sulfate – water, shows without doubt that the formula of the hydrate of indium trichloride is $InCl_3 \cdot 4H_2O$. This system also shows the existence of a hydrated double salt of indium trichloride and indium sulfate, in the molar ratio of 1:1. The exact degree of hydration of the double salt cannot be obtained by this method, because the molecular weight is so high; it has been estimated as $17 \pm 1H_2O$. The indium sulfate side of the diagram has been taken from Seward (9) because, as with the double salt, the hydration of indium sulfate cannot be firmly established by the wet residue method.

In conclusion, indium trichloride forms at least one double salt with all of the alkali metal chlorides (except sodium chloride) and with ammonium chloride. Also, the stable hydrate at 25°C, of indium trichloride is $InCl_3 \cdot 4H_2O$.

Mechanism of L-ascorbic acid oxidation and dehydro-L-ascorbic acid reduction on a mercury electrode. I. Acid medium

JUAN JOSÉ RUIZ, ANTONIO ALDAZ,[1] AND MANUEL DOMÍNGUEZ
Departamento de Química Física, Facultad de Ciencias, Universidad de Sevilla, Spain

Received January 21, 1977

JUAN JOSÉ RUIZ, ANTONIO ALDAZ, and MANUEL DOMÍNGUEZ. Can. J. Chem. **55**, 2799 (1977).

A polarographic study of the oxidation mechanism of L-ascorbic acid and of the reduction mechanism of dehydro-L-ascorbic acid was carried out in an acid medium.

For L-ascorbic acid, the oxidation process involves a two electron transfer and obeys the overall reaction

$$AH_2 \rightarrow B + 2e + 2H^+$$

The polarographic curve shows that the limiting current is governed by diffusion. On the rising portion of the wave, the two electron oxidation process consists of two consecutive one electron transfers, the second being the rate determining step (rds). The reaction orders, together with the Tafel slopes, were calculated.

The reduction of dehydro-L-ascorbic acid at the limiting current is kinetically controlled and involves a two electron transfer. The reaction kinetic pathways were studied and the reaction orders and Tafel slope were calculated. It is deduced that, for low overvoltages, the second one electron transfer is the rate determining step.

JUAN JOSÉ RUIZ, ANTONIO ALDAZ et MANUEL DOMÍNGUEZ. Can. J. Chem. **55**, 2799 (1977).

On a effectué, dans un milieu acide, une étude polarographique du mécanisme d'oxydation de l'acide L-ascorbique et du mécanisme de réduction de l'acide déhydro-L-ascorbique.

Pour l'acide L-ascorbique, le processus d'oxydation implique un transfert de deux électrons et est soumis à la réaction générale

$$AH_2 \rightarrow B + 2e + 2H^+$$

La courbe polarographique montre que le courant limitant est gouverné par la diffusion. Sur la portion montante de la vague, le processus d'oxydation à deux électrons implique deux transferts successifs d'un électron, le deuxième étant l'étape déterminante de la vitesse de la réaction. Les ordres de la réaction ainsi que les pentes de Tafel ont été calculés.

La réduction de l'acide déhydro-L-ascorbique, à courant limitant, est contrôlée cinétiquement et implique un transfert de deux électrons. On a étudié les chemins réactionnels cinétiques et on a calculé les ordres de la réaction et la pente de Tafel. On en déduit qu'à de bas survoltages, le deuxième transfert d'un électron est l'étape déterminante de la vitesse de la réaction.

[Traduit par le journal]

Introduction

Several studies have been carried out (1–4) on the electrochemical oxidation of L-ascorbic and dehydro-L-ascorbic acids on a mercury electrode.

However, as far as we know, there exists no detailed study on the mechanism of these reactions. The aim of this study is, therefore, to determine the reaction mechanism for the two acids using direct current polarography.

Experimental

Apparatus

The *i–E* curves were registered either automatically or traced point by point using a PO4 Radiometer with the damping circuit completely suppressed. The potentials were measured vs. s.c.e. with a Beckman Research potentiometer, which was also used as a p*H*-meter.

Electrolysis was carried out with an Amel potentiostat, model 541.

Cells and Electrodes

The polarographic measurements were carried out using a thermostated Radiometer V519 cell. A saturated calomel reference electrode was used. The working electrode was a mercury capillary with the following characteristics: $m = 2.005$ mg/s, $t = 4.32$ s, open circuit, in our buffered solution at pH 1.80 and $h = 40$ cm.

Electrolysis was carried out using a mercury electrode as a working electrode and a platinum auxiliary electrode.

Solutions, Products, and Measurements

All reagents used were Merck p.a. grade. As a supporting electrolyte solution, a buffered solution was used with the following components and concentrations: 0.04 *M* acetic acid, 0.04 *M* phosphoric acid, 0.04 *M*

[1]Present address: Departamento de Investigaciones Químicas, Centro Coordinado del C.S.I.C., Universidad Autónoma, Canto Blanco, Madrid 34, Spain.

ammonium nitrate, and 0.2 *M* NaOH which were mixed in varying proportions according to the p*H* desired. The ionic strength was adjusted with $NaNO_3$ to 0.2 *M* for the ascorbic acid study and to 0.5 *M* for the dehydro-L-ascorbic acid study.

All measurements were carried out in an atmosphere of nitrogen and at a temperature of 25 ± 0.05°C.

The Mapson and Partridge technique (5) was used to identify products by paper chromatography.

The Tafel curves were taken on the rising portion of the polarographic wave ($i/i_{lim} < 0.2$) and, to avoid depleting the solution, the maximum current for plotting the polarographic curve point by point was taken with each first drop (6).

Results

General Behaviour

The L-ascorbic acid oxidizes over the DME producing either one or two polarographic waves depending on the p*H* of the solution. The first wave is visible throughout the p*H* range 2–14, whilst the second is only visible from p*H* 8. Only the first wave was studied to p*H* 7.

The dehydro-L-ascorbic acid gives a stable reduction in an acid medium (p*H* 0.5–6), Fig. 2, only for solutions much more concentrated than those normally used in polarography; *e.g.* for a concentration of 4×10^{-2} *M* currents of less than 1 μA are obtained. This is due to the fact that the acid in solution forms a polarographically active hydrate (1).

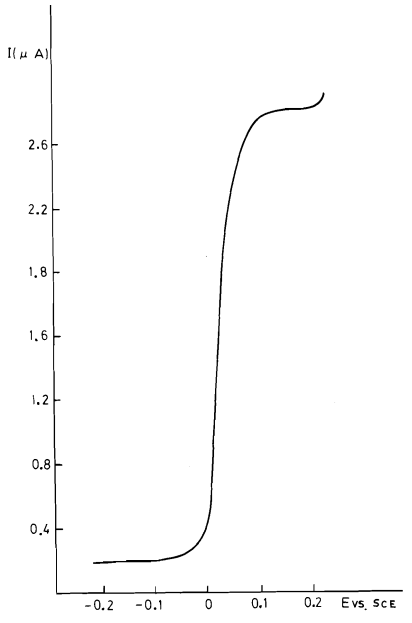

FIG. 1. First wave of L-ascorbic acid. Concentration 5×10^{-4} *M*. p*H* = 5.24.

Microcoulometric Measurements

The number of electrons taking part in the overall reaction was calculated from the decrease of the limiting current with the time of electrolysis (7). The average value obtained was 1.8.

Polarographic Behaviour

In the case of L-ascorbic acid, the limiting current is independent of the p*H* whilst $E_{1/2}$ varies with the p*H*. The values of the slopes of the linear sections were −59 and −27 mV/H^+ decade.

$E_{1/2}$ is independent of the concentration of the L-ascorbic acid. The logarithmic analysis of the polarographic wave gave straight lines with a slope of 30 mV per decade that are practically independent of the p*H*.

The limiting current is controlled by diffusion as: log i_{lim} vs. log *h* (corrected for the back pressure) is linear with a slope of 0.5; i_{lim} has a temperature coefficient of 1.1% per °C, and is proportional to the concentration of the L-ascorbic acid in the bulk of the solution.

In the case of dehydro-L-ascorbic acid, the limiting current is independent of the p*H* and the variation of $E_{1/2}$ with the p*H* is shown in Fig. 4. The values of the slopes were −44 and −72 mV/H^+ decade.

The limiting current is controlled kinetically (i_{lim} independent of *h* and with an elevated temperature coefficient).

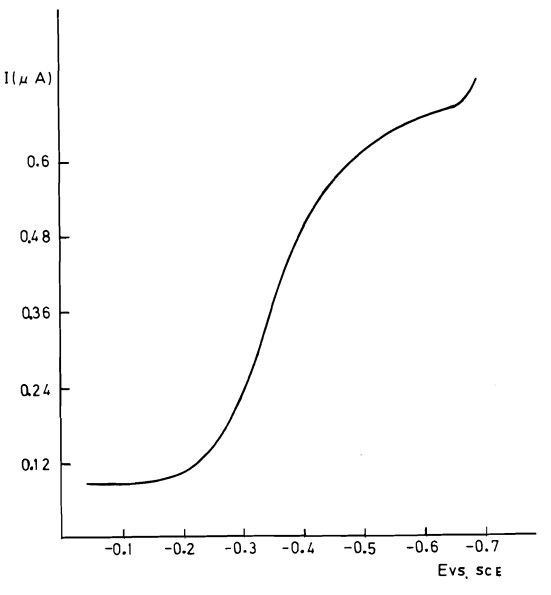

FIG. 2. Wave of dehydro-L-ascorbic acid. Concentration 4×10^{-2} *M*. p*H* = 2.81.

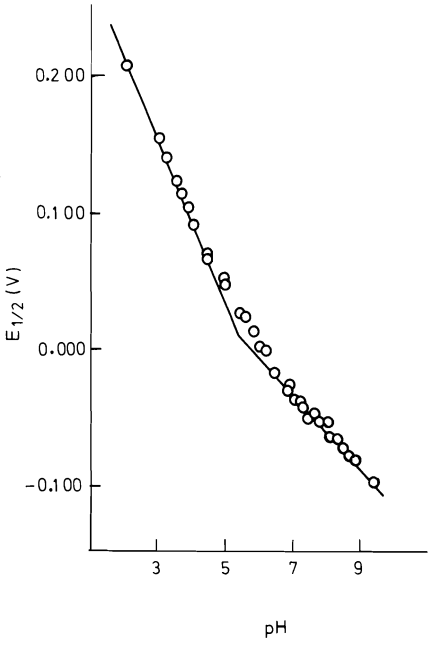

FIG. 3. L-Ascorbic acid. Variation of $E_{1/2}$ with pH.

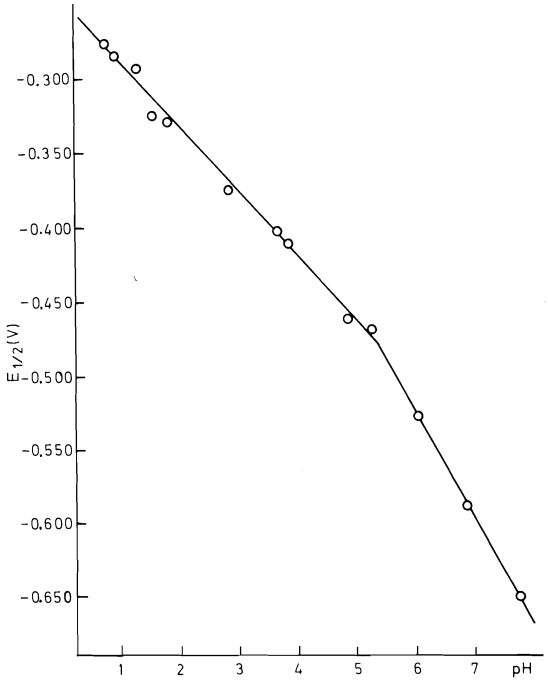

FIG. 4. Dehydro-L-ascorbic acid: variation of $E_{1/2}$ with pH.

Tafel Curves and Reaction Orders

(*a*) Influence of pH. With L-ascorbic acid, the Tafel curves are independent of the pH and their slopes have an average value of 34 mV per decade.

The reaction orders with respect to the H^+ concentration are:

pH	$\left(\frac{\partial \log i_j}{\partial \log H^+}\right)_{E,T,C_{i\neq j}}$
2–3	−1.9
7–8	−0.9

The order is independent of the potential in the area where Tafel's law is obeyed.

For dehydro-L-ascorbic acid, the Tafel slopes are equally independent of the pH with a mean value of 43 mV. The reaction orders with respect to the H^+ concentration are:

pH	$\left(\frac{\partial \log i_j}{\partial \log H^+}\right)_{E,T,C_{i\neq j}}$
0.5–5	1.1
5–7	2.0

(*b*) Influence of the concentration. The reaction order with respect to the concentration of the depolarizing agent was 1 in the case of both acids and was independent of the potential at which measurements were taken.

Electrolysis and Identification of Products

The first product of the oxidation of L-ascorbic acid was identified by paper chromatography of a solution of L-ascorbic acid at pH 4 which had undergone electrolysis at a controlled potential.

From the chromatogram, two zones were observed with the R_f characteristics (0.07 weak and 0.49 strong) of dehydro-L-ascorbic acid. As the position of the weak zone coincides exactly with that assigned to 2,3-diketogulonic acid, it can be assumed that there is a rupture of the lactone ring of the dehydro-L-ascorbic acid during the period of the electrolysis or during the chromatography.

Conclusion

In previous papers (2–4) it appeared to be established that the overall oxidation mechanism of L-ascorbic acid takes place through a reversible transfer of charge followed by a rapid chemical reaction of the product formed with water to form a very stable hydrate.

Our polarographic results confirm that the first

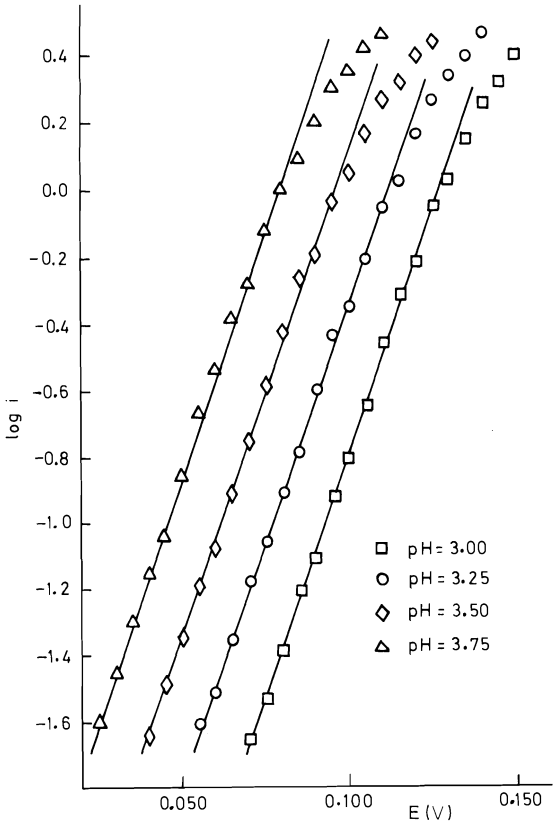

FIG. 5. L-Ascorbic acid: representation of Tafel's law.

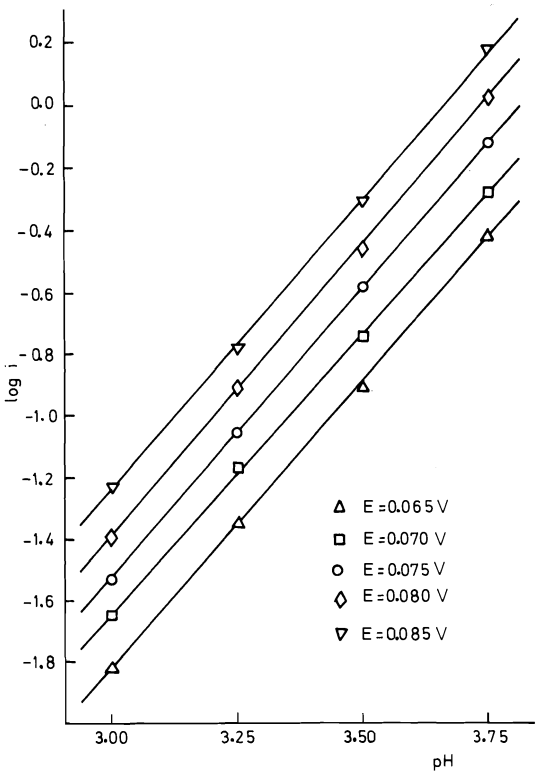

FIG. 6. L-Ascorbic acid: reaction orders.

wave of L-ascorbic acid is produced by a polarographically reversible two electron transfer (Tomes slope 30 mV/H^+ decade) in which two protons intervene in the interval pH 2–5 (slope -59 mV/H^+ decade) and another between pH 5–9 (slope -27 mV/H^+ decade). Thus, the overall reaction in the pH 2–9 interval would be:

$$AH_2 \rightleftarrows B + 2H^+ + 2e$$
$$\downarrow$$
$$C$$

substituting AH_2 by AH^- for pH's larger than the pK_1 of L-ascorbic acid.

The presence of a free radical (8) in the oxidation process of L-ascorbic acid clearly indicates that the transfer of two electrons is realized electron by electron.

With the aforementioned conclusions, the mechanism can be represented by the following reaction kinetic pathways, as shown in Fig. 7 where reaction 1 represents the dissociation of H^+ from the carbon 3, reactions 2 and 3 represent the one electron transfers with the formation of a free radical. Reactions 4 and 5 represent the normal hydration mechanism of carbonyl groups (9).

Assuming reaction 3 as being the rds and applying the approximation of equilibrium state, the value of the anodic current intensity on the rising portion of the wave can be expressed as (taking the electrokinetic potential to be negligible):

$$[1] \quad i = 2Fk_3K_1K_2 \times \frac{C_T}{K_1C_H + C_H^2} \exp((2 - \beta)FE/RT)$$

where C_T is the total concentration of L-ascorbic acid in the bulk of the solution; C_H is the concentration of the H^+ ions; K_1 and K_2 are the equilibrium constants of reactions 1 and 2; k_3 is the rate constant of the rate controlling step. Table 1 gives a comparison between the theoretical values deduced in the aforementioned reaction kinetic pathways and the experimental

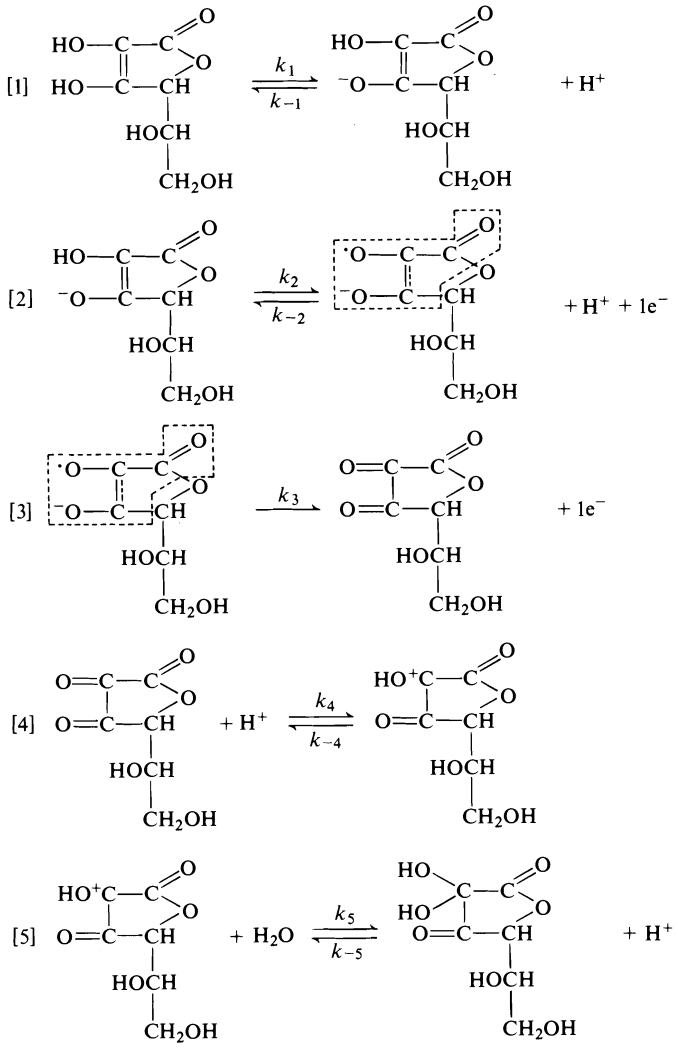

FIG. 7. L-Ascorbic acid: reaction kinetic pathways.

TABLE 1. Comparison between theoretical values (based on mechanisms in Fig. 7) and experimental results

Parameter	Value	
	Theoretical ($\beta \simeq 0.5$)	Experimental
Tafel slope	39 mV	34 mV
Order with respect to L-ascorbic acid concentration	1	1
Order with respect to H^+ ion	-2 for $K_1 \ll C_H$ -1 for $K_1 \gg C_H$	-1.9 (pH 2–4) -0.9 (pH 6–9)

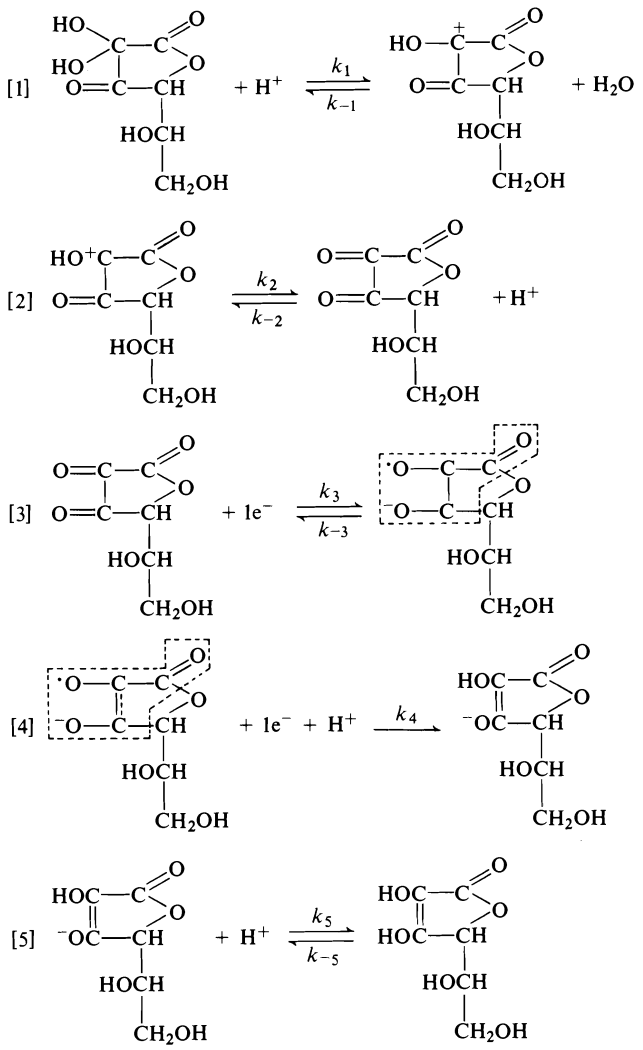

FIG. 8. Dehydro-L-ascorbic acid: reaction kinetic pathways.

results (where β is assumed to have a value of 0.5).

As is logical, in the case where pK_1 is less than the pH of the medium, the reaction:

$$AH_2 \rightleftarrows AH^- + H^+$$

should not be taken into account.

The close agreement between the experimental and theoretical results clearly indicates that the oxidation process takes place as shown in Fig. 7.

Dehydro-L-ascorbic Acid

The polarographic study shows that the reduction process includes a chemical stage which precedes the electron transfer and which controls the reaction rate at those potentials corresponding to the limiting current.

The electron transfer is not a reversible process as no linearity is observed in the plot E vs. log $i/(i_L - i)$.

The low value of i_L (<1 μA) compared with the dehydroascorbic acid concentration (4×10^{-2} M) indicates that the preceding reaction is shifted towards the formation of an electrochemically inactive substance. This substance could be the compound produced during the hydration of one of the two carbonyl groups of the dehydroascorbic acid (1, 2).

From these results and granted that, in this case, it is virtually impossible for a simultaneous

TABLE 2. Comparison between theoretical values (based on mechanisms in Fig. 8) and experimental results

Parameter	Value	
	Theoretical	Experimental
Tafel slope	−39 mV	−43 mV
Order with respect to dehydro-L-ascorbic acid concentration	1	1
Order with respect to H^+ ion	1 for $1 \gg K_1C_H$ 0 for $1 \ll K_1C_H$	1.1 (pH 0.5–5)

TABLE 3. Comparison between theoretical values (based on mechanism in Fig. 9) and experimental results

Parameter	Value	
	Theoretical	Experimental
Tafel slope	−39 mV	−43 mV
Order with respect to dehydro-L-ascorbic acid concentration	1	1
Order with respect to H^+ ion	2 for $1 \gg (1+K_2K_3)K_1C_H$	2

two electron transfer to take place by the tunnel effect (the probabilities being extremely low), reduction mechanism is proposed as shown in Fig. 8, where reactions 1 and 2 represent the dehydration of the carbonyl group, 3 and 4 the one electron transfers, and 5 the recombination with the H^+ ion to form L-ascorbic acid.

Assuming reaction 4 as the rds, the function $i = f(E)$ in the rising portion of the wave would be:

$$[2] \quad i = 2Fk_4K_1K_2K_3 \frac{C_TC_H}{1 + K_1K_2 + K_1C_H} \times \exp(-(1 + \beta)FE/RT)$$

where C_T = total concentration of L-ascorbic acid, C_H = concentration of hydrogen ions, K_1, K_2, K_3 = equilibrium constants, k_3 = rate constant.

Table 2 shows the close agreement between the theoretical and experimental results and permits us to assume that our mechanism is correct.

Near pH 5 a variation in the slope of the $E_{1/2}$ vs. pH plot (Fig. 2) is observed together with a change in reaction order with respect to the H^+ ion which varies from 1.1 to 2. A potentiometric titration of dehydro-L-ascorbic acid gives a first point of complete neutralization at pH 5.3. It is assumed that this is caused by the rupture of the lactone ring of the dehydro-L-ascorbic acid and produces the 2,3-diketogulonate anion according to (9). Therefore, after this pH, the dehydro-L-ascorbic acid in solution is in the form of the 2,3-diketogulonate and the first reaction of the reduction mechanism would be as shown in Fig. 9.

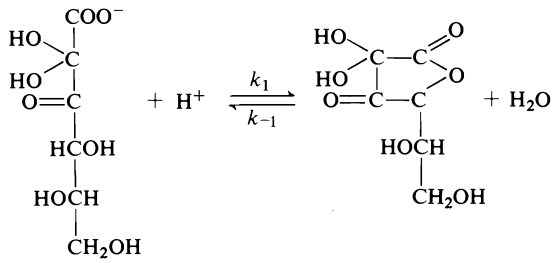

FIG. 9. First reaction on the reduction mechanism of the dehydro-L-ascorbic acid for pH > 5.

Once the dehydro-L-ascorbic acid is formed, the subsequent reactions will occur as before.

Assuming, once again, the last transfer reaction to be the rds, the i–E function is now expressed by:

$$[3] \quad i = 2Fk_5K_1K_2K_3K_4 \times \frac{C_TC_H^2}{K_1K_2C_H^2 + (K_2K_3 + 1)K_1C_H + 1} \times \exp(-(1 + \beta)FE/RT)$$

Table 3 shows the complete agreement between the theoretical and experimental results.

Complex formation between sulfur dioxide and halide ions

ETELA MILANOVA AND ROBERT L. BENOIT

Département de chimie, Université de Montréal, C.P. 6210, Montréal (Qué), Canada H3C 3V1

Received February 28, 1977

ETELA MILANOVA and ROBERT L. BENOIT. Can J. Chem. **55**, 2807 (1977).

Complex formation between sulfur dioxide and iodide ions in acetonitrile (AN) has been studied by vapour pressure measurements. The enthalpy changes ΔH^0 for 1:1 association reactions between SO_2 and halide (X^-) ions in AN and between SO_2 and Cl^- in dimethylsulfoxide (DMSO) have been determined at 25°C by calorimetry. The ΔH^0 values (kcal mol^{-1}) are respectively -4.1 (Cl^-), -3.4 (Br^-), -3.0 (I^-) in AN and -0.7 (Cl^-) in DMSO. In contrast to previous literature data there is a linear relationship between these ΔH^0 and reported ΔG^0 values for the formation of the SO_2X^- complexes in AN. The difference between the ΔH^0 values for SO_2Cl^- in the solvents AN and DMSO is accounted for by the more exothermic enthalpy of solution of SO_2 in DMSO which is the more basic solvent, and by the expected minor difference in the enthalpies of transfer of Cl^- and SO_2Cl^- from AN to DMSO, both dipolar aprotic solvents. Some of the problems connected with the stability order of the SO_2X^- complexes are discussed in relation to solvent effects and properties of X^-.

ETELA MILANOVA et ROBERT L. BENOIT. Can. J. Chem. **55**, 2807 (1977).

On a étudié par mesure de pression de vapeur la formation de complexes entre l'anhydride sulfureux et les ions iodures dans l'acétonitrile (AN). On a déterminé par calorimétrie à 25°C les changements d'enthalpie ΔH^0 des réactions d'association 1:1 entre SO_2 et les ions halogénures X^- dans l'AN et entre SO_2 et Cl^- dans le diméthylsulfoxyde (DMSO). Les valeurs de ΔH^0 (kcal mol^{-1}) sont respectivement -4.1 (Cl^-), -3.4 (Br^-), -3.0 (I^-) dans l'AN et -0.7 (Cl^-) dans le DMSO. Contrairement aux données publiées, on observe une relation linéaire entre ces valeurs de ΔH^0 et les valeurs connues de ΔG^0 pour la formation des complexes SO_2X^- dans l'AN. La différence entre les valeurs de ΔH^0 pour SO_2Cl^- dans les solvents AN et DMSO s'explique par une chaleur de solution de SO_2 plus exothermique dans le DMSO, le solvent le plus basique, et une faible différence, comme prévu, des enthalpies de transfert de Cl^- et SO_2Cl^- entre l'AN et le DMSO, tous deux des solvants dipolaires aprotoniques. On examine quelques uns des problèmes liés à l'ordre de stabilité des complexes SO_2X^- en relation avec l'effet de solvant et les propriétés de X^-.

Early studies on sulfur dioxide solvates of salts, and data on solubility of salts in liquid sulfur dioxide (refs. 1, 2 and references cited therein) suggested specific interactions between SO_2, a Lewis acid, and basic inorganic anions. Complex formation between SO_2 and halide ions X^- in non-aqueous solvents is also evidenced in the presence of a strong uv absorption band which, in turn, is indicative of the charge transfer nature of the $SO_2 - X^-$ interaction. Spectrophotometric data were used to determine formation constants K for some SO_2X^- complexes in acetonitrile (AN) (3, 4) and in dimethylsulfoxide (DMSO) (4). The corresponding enthalpies of complex formation ΔH^0 in AN were also derived from values of K between 15 and 35°C (3, 4).[1] The rather poor agreement between both sets of reported ΔH values in AN is not too surprising in view of first, the difficulties involved in the use of the Benesi–Hildebrand equation to interpret the spectral data and second, the propagation of experimental errors from K to ΔH^0 in the narrow temperature range used. A direct calorimetric method should give more reliable ΔH^0 values.

We are therefore presenting here the results of a calorimetric determination of the enthalpy change $\Delta H^0(s)$ for reaction 1 in two dipolar aprotic (dpa) solvents s.

$$[1] \qquad SO_2(s) + X^-(s) \rightleftharpoons SO_2X^-(s)$$

where X = Cl, Br, I with s = AN, and X = Cl with s = DMSO. This work is of further interest because it extends our current study of the solvent influence on anion–molecule type reactions. We have recently discussed the effect of solvent on two related reactions, namely that between HR, Brønsted acids, and Cl^- (5), and that between I_2, a Lewis acid, and I^- (6). Although in principle calorimetric data on a reaction such as [1] could yield simultaneously ΔH^0 and K (7, 8), this was not the case here as the volatility

[1]The ΔH^0 values reported are not corrected for thermal expansion of the solvent (20).

of SO_2 made it difficult to vary the SO_2/X^- ratio over a wide range, a condition necessary to get meaningful ΔH^0 and K values. The values of K needed to obtain ΔH^0 were taken from Norris *et al.* (3). We also estimated K from SO_2 vapour pressure measurements in the case of SO_2I^- in AN as a check on conflicting reported values.

Experimental

Materials

Tetraalkylammonium halides and tetraethylammonium perchlorate were Eastman Kodak white label products. The salts were dried under vacuum in presence of phosphorus pentoxide for several weeks. The solutions were prepared by weighing. The solvents were reagent grade acetonitrile (Fisher) and dimethylsulfoxide (BDH). Both solvents were dried and stored over activated 4A molecular sieves. Concentrated solutions of SO_2 in AN and DMSO were prepared by bubbling anhydrous (99.98%) gas (Canadian Liquid Air). The stock solutions were then diluted as required.

Apparatus and Procedure

The LKB Model 8725-2 isoperibol calorimeter and the calorimetric procedure have been described previously (8). The heats of mixing of 0.2–3.0 M SO_2 solutions with 27 ml of 0.1–0.2 M halide solutions were determined at 25°C. The volume of SO_2 solution (0.3–0.8 ml) in the glass ampoules was obtained from the density of the solvent and the weight of solution. The concentration of these SO_2 solutions was determined by addition of a known volume dispensed from a Gilmont micropipette to an excess of aqueous standard iodine solution, and back titration with standard thiosulfate. The SO_2 concentration was checked at the end of the calorimetric runs and the runs were discarded if the final SO_2 concentration was more than 3% lower than the calculated 'initial' concentrations.

Total vapor pressures were measured with a quartz spiral (Texas Instruments). The apparatus and procedure used have been described elsewhere (9).

Results

The vapor pressure data for acetonitrile solutions containing SO_2 and/or electrolytes at 25°C are given in Table 1. The SO_2 partial pressures P_{SO_2} are calculated from the experimental total pressures P by subtracting the solvent partial pressures P_{AN}. These latter pressures are derived from the pure solvent vapor pressure P_{AN} = 88.63 mm Hg by assuming that Raoult's law applies for the solute mole fractions used ($x \leq 0.033$). The P_{AN} data for 0.2–0.4 M NBu_4I solutions in absence of SO_2 do not support fully this assumption. However, looking at the solutions containing 0.1 M or 0.2 M NEt_4ClO_4 and SO_2, when we subtract P_{AN} calculated by using Raoult's law, we obtain P_{SO_2} values such that the corresponding Henry's law constant $H = P_{SO_2}/(SO_2)$ (atm/$M\ell^{-1}$) agrees within 1% with the same constant (0.104) determined for six (0.3–1.5 M) SO_2 solutions in absence of electrolyte. This result brings some justification to our method of calculation of P_{AN} and also implies that the salting effect of 0.1–0.2 M NEt_4ClO_4 on solute SO_2 is negligible. We have then assumed that these conclusions could be extended to NBu_4I solutions containing SO_2 so that we attributed the observed lowering of P_{SO_2} in these latter solutions to complex formation between SO_2 and I^-. Values of K, the formation constant of SO_2I^-, given in Table 1, are calculated from the known total concentrations

C_{SO_2} and C_{I^-}, the two corresponding mass balance equations and $[SO_2]$, the free SO_2 concentration deduced from P_{SO_2} and Henry's law constant H.

The usefulness of the vapour pressure method to study reaction 1 in AN proved to be limited for the following reasons. First, because the SO_2X^- complexes are relatively stable and because the presence of $(SO_2)_nX^-$ species cannot be ruled out, the range of C_{SO_2} and C_{X^-} concentrations studied was restricted to values of C_{SO_2}/C_{X^-} near 1. Second, owing to the high

solvent vapour pressure P_{AN}, C_{SO_2} and hence C_{X^-}, had to be relatively high to obtain meaningful values of $P_{SO_2} = P - P_{AN}$, but then the calculation of P_{AN} was approximate because the solutions were no longer dilute. The use of DMSO instead of AN, as solvent, was precluded because though this time P_{DMSO} is favourably low, P_{SO_2} values are also unfavourably low, the Henry's law constant H being now only 0.0076.

The calorimetric results are presented in Table 2. The measured heat effects, Q_{exp}, correspond to the reaction between 0.3–0.8 ml (0.2–3.0 M) SO_2 solutions with a known excess of halide solutions. The final SO_2 concentrations varied between 3×10^{-3} and 4×10^{-2} M whilst the halide concentrations ranged from 9×10^{-2} to 5×10^{-1} M. The lower limits for the SO_2 concentrations were dictated by the magnitude of the ΔH^0 and K values for the particular reaction investigated and the fact that the values of Q_{exp} once corrected had to be reasonably accurate. Since the heat changes observed are relatively small, corrections for dilution effects were applied. For this purpose, the molar heats of dilution of SO_2 were estimated from data obtained on separate calorimetric runs in which SO_2 solutions were mixed with the pure solvents. The minor heat effect on mixing of pure solvent with the halide solutions was also taken into account. The corrections Q_{dil} are entered in Table 2. The enthalpies ΔH^0(s) for reaction 1 were then obtained from corrected heat effects, the SO_2X^- concentrations calculated from mass balances, and the values of the equilibrium constant K listed in Table 3 (3).

Attempts to study the SO_2–F^- system in AN proved unsuccessful because of the very low solubility of dried $(CH_3)_4NF$ and KF.

Discussion

First we will discuss briefly our K values for SO_2I^- in AN, as determined from vapour pressure measurements. Considering the assumptions involved in the calculation of P_{SO_2} and $[SO_2]$, there is a fair agreement between our average value, 33, and the values of Norris *et al.*, 21.4, and of Wasif *et al.*, 38. These latter values were deduced from spectrophotometric data for very dilute solutions ($8 \times 10^{-4} - 5 \times 10^{-3}$ M). Our P_{SO_2} data for two solutions with a high ratio C_{SO_2}/C_{I^-} lead either to a high value for K or a value of $\bar{n}$, the average number of SO_2 moles bound per mole of I^-, which is above 1. These results are thought to be indicative of the presence in these SO_2-rich solutions of an additional species $(SO_2)_2I^-$. In this respect, it is worth noting that solid SO_2 solvates of halide salts containing up to $4SO_2$ per halide are known (1).

The formation of SO_2I^- and SO_2Br^- in aqueous solution has been reported, although the available supporting data are sketchy (4, 10). Taking into account the known decrease in stability of related complexes such as I_3^- and HCl_2^- when passing from a dipolar aprotic solvent, such as AN, to water (8, 11), the quoted stability of SO_2I^- in aqueous media was unexpected. We therefore attempted to estimate a value for $K_{SO_2I^-}$ in water from our $K_{SO_2I^-}$ value in AN. The procedure used followed that which led us to account for the known weak stability of HCl_2^- in water (8). Combining the AN values $K_{SO_2I^-} = 30$ and $P_{SO_2} = 0.104[SO_2]$, gives $[SO_2I^-]/[I^-] = 300 \times P_{SO_2}$. If we now assume that the free energies of transfer of the related anions SO_2I^- and I_2I^-, from water to AN, are about the same, then the calculated ratios $[I_3^-]/[I^-] = K_{I_3^-} \times S_{I_2} = 10^{7.3} \times 10^{-0.3}$ in AN (S_{I_2} is the I_2 solubility) and $[I_3^-]/[I^-] = K_{I_3^-} \times S_{I_2} = 10^{2.9} \times 10^{-2.9}$ in water (11), lead to $[SO_2I^-]/[I^-] \sim 300 \times P_{SO_2} \times 10^{-7.0}$. Since for aqueous solutions $P_{SO_2} = 0.80[SO_2]$ at 25°C (12), we finally get $K_{SO_2I^-} = [SO_2I^-]/[SO_2]\,[I^-] \sim 10^{-4.6}$. This very low value is to be contrasted with much higher values obtained from spectrophotometric data, respectively 0.35 (4) and 0.8

(10). We tend to attribute the large discrepancy to difficulties in the spectrophotometric measurements, possibly due to the susceptibility to oxidation of I^- (catalyzed by light) (13), and of SO_2. That the determinations on the system SO_2–I^- may be subject to errors, even in AN, has been pointed out (3) and it is also apparent when the spectrophotometric data of Wasif *et al.* (4) are compared with those of Norris *et al.* (3). It is difficult to predict from our results in AN what the SO_2X^- complexes stability order is in water. Considering the small differences in the K values in AN, the stability order in water might well be reversed, $SO_2I^- > SO_2Br^- > SO_2Cl^-$. We have shown that for the related series I_2X^-, the order is $I_3^- \sim I_2Br^- = I_2Cl^-$ in sulfolane (14) another dpa solvent but $I_3^- > I_2Br^- > I_2Cl^-$ in water (11). These changes in relative stabilities, when passing from dpa solvents to water, are mainly due to the increasingly stronger solvation by water of the halide ions in the order $I^- < Br^- < Cl^-$.

Turning now to our enthalpy data (Tables 2 and 3), the ΔH^0 values for reaction 1 in AN are, as expected, at variance with those derived indirectly from spectral data at 15, 25, and 35°C (3, 4). The exothermicity of [1] decreases slightly from X = Cl to Br and I just as the stability constants K do. The relationship between ΔH^0 and $\Delta G^0 = -RT \ln K$ is approximately linear as is often the case for donor–acceptor type reactions (15). The enthalpy-based halide basicity order $Cl^- > Br^- > I^-$ we observe here in AN, with SO_2 as the acid A, is the same as that obtained in sulfolane, another dpa solvent with A = HCl (8). From estimates of solvation enthalpies of gaseous ions X^- and AX^- (8), it is expected that the halide basicity order for A = SO_2 remains the same in the gas phase, with differences between the three individual ΔH^0 values larger in the gas phase than in AN.

The analysis of the solvent effect on reaction 1 (X = Cl) from our ΔH^0 values in AN and in DMSO, respectively -4.1 and -0.7 kcal mol^{-1}, is best carried out by taking into account the basicity-related solvent interaction with SO_2. We have therefore calculated ΔH^0(s,g) for

[2] $$SO_2(g) + Cl^-(s) \rightleftharpoons SO_2Cl^-(s)$$

by adding to ΔH^0(s) the heat of solution of gaseous SO_2 in AN and DMSO, respectively -6.8 and -11.5 kcal mol^{-1} (16). The obtained ΔH^0(s,g) values are -10.9 (AN) and -12.2 kcal mol^{-1} (DMSO). The difference, $\Delta\Delta H^0$(s,g), between these values, which is equal to 1.3 kcal mol^{-1}, represents the difference of the enthalpies of transfer between both solvents of the anions pair Cl^-–SO_2Cl^-. The value found for $\Delta\Delta H^0$ (s,g), 1.3 kcal mol^{-1} is in line with what we expected since we have recently established that the differences between the enthalpies of transfer of a number of pairs of anions X^-–AX^- are small and mainly governed by non-coulombic interactions when the transfers are between dpa solvents (6). These results make it possible to estimate, within 1–3 kcal mol^{-1}, the enthalpy change ΔH^0(s) of any X^-–A anion–molecule reaction such as [1] in a dpa solvent, from the value of ΔH^0(s,g) in a reference dpa solvent and the value of the enthalpy of solution of A in the dpa solvent of interest. We can now relate the acid strength of SO_2 to that of I_2, another Lewis acid, by comparing both ΔH(s,g) values for the reaction $A(g) + I^-(s) \rightleftharpoons AI^-(s)$ where s is AN. The corresponding ΔH^0(s,g), -9.8 kcal mol^{-1} (A = SO_2), and -20.0 kcal mol^{-1} (A = I_2) (6), indicate that in the gas phase SO_2 is a much weaker acid than I_2, with respect to the base I^-. The ΔH^0(s) values in AN for $A(s) + I^-(s) \rightleftharpoons AI^-(s)$, -3.0 kcal mol^{-1} (A = SO_2), -9.7 kcal mol^{-1} (A = I_2), give the same acidity order. Drago's compilation of data (17) also rank SO_2 as a weaker acid than I_2 with respect to any molecular base in inert media, since the enthalpy of adduct formation between a base B and an acid A is given by the four-parameter equation: $\Delta H = E_A E_B + C_A C_B$ with $E_A = C_A = 1$ for A = I_2 and $E_A = 0.92$, $C_A = 0.81$ for A = SO_2.

Finally, in view of the probable charge-transfer (CT) character of the SO_2X^- complexes, it is interesting to see to what extent these complexes follow some of the general correlations relating properties of such donor–acceptor complexes with those of the donors or acceptors. A linear relationship has been established (3) between the energies $h\nu_{max}$ corresponding to the frequencies of the uv–visible absorption maxima of the three SO_2X^- complexes and the ionization potentials (I_d) of the donors X^-. However, this linear correlation raises some unanswered questions. First, as pointed out by Norris *et al.* (3), the slope has not the expected unit value, and the calculated differences in binding energies between ground and excited states have a sign which is opposite to that found for CT complexes between

neutral species. Second, because of the abnormal value of the electron affinity of F in the halogen series which gives $I_d = 3.45$ eV for F^-, the linear correlation would predict for SO_2F^- an absorption band ($\lambda_{max} \sim 310$ nm) between those of SO_2Br^- and SO_2Cl^- whilst Norris *et al.* found no such band above 220 nm but a tail of an absorbance band at shorter wavelengths (3). Another type of general correlation sought for CT complexes involving a series of structurally related donors and a common acceptor is that between the stability of the complexes and the donor ionization potential I_d (15). The trend observed here for the SO_2X^- complexes is an increase in stability, as measured with ΔH^0 or K, in the order $SO_2I^- < SO_2Br^- < SO_2Cl^-$ which is the order of increasing I_d, $I^- < Br^- < Cl^-$. Surprisingly this trend is opposite to that usually observed for CT complexes with neutral donors in non-polar solvents (15). This reversal cannot be attributed to the polar nature of the solvent AN since we have seen that the stability order of the SO_2X^- complexes would be the same in the gas phase. The observed order is that of the proton affinity of the halides and is in line with predictions made from Drago's equation and the E_BC_B values calculated for gaseous X^- from gas phase ionic reactions (18). The sequence $Cl^- > Br^- > I^-$ is also that of nucleophilic reactivity of halides in dpa solvents but, interestingly enough, not in liquid SO_2 (19).

NOTE ADDED IN PROOF: The ΔH^0(g) value for $SO_2(g) + Cl^-(g) = SO_2Cl^-(g)$ has recently been found to be about -19.1 kcal mol^{-1} (21, 22). Thus the acidity order, with respect to the base Cl^-, is $HCl > SO_2 > H_2O$ both in the gas phase and in acetonitrile and sulfolane, two dpa solvents of similar basicity.

Received February 21, 1977

HELMUT BEIERBECK, JOHN K. SAUNDERS, and JOHN W. APSIMON. Can. J. Chem. **55**, 2813 (1977).

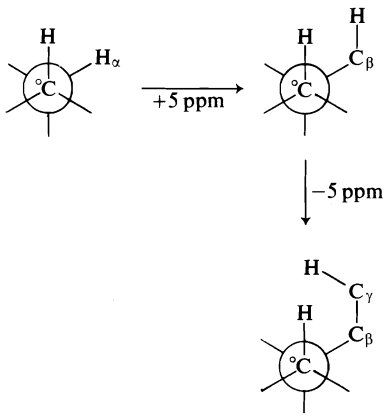
Substituent parameters were derived for the semiempirical determination of ^{13}C chemical shifts in saturated hydrocarbons, alcohols, amines, ketones, and olefins. The olefin parameters are valid for six-membered rings and the remaining parameters for six-membered rings in chair conformations. The use of these parameters for the calculation of carbon resonances is illustrated with a number of examples.

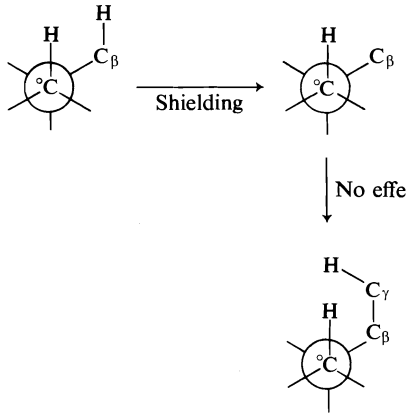
HELMUT BEIERBECK, JOHN K. SAUNDERS et JOHN W. APSIMON. Can. J. Chem. **55**, 2813 (1977).

On a pu dériver des paramètres pour les substituants permettant la détermination semiempirique des déplacements chimiques du carbone 13 d'hydrocarbures saturés, d'alcools, d'amines, de cétones et d'oléfines. Les paramètres des oléfines sont valables pour les cycles à six chaînons et les autres paramètres pour des cycles à six chaînons dans des conformations chaises. On présente des exemples de l'utilisation de ces paramètres pour le calcul des résonances du carbone dans un certain nombre d'exemples.

[Traduit par le journal]

We have shown that β-carbon substituent effects on ^{13}C resonances are related to the number of hydrogen–carbon (HC) and carbon–carbon (CC) *gauche* interactions (1). Similarly, β-heterosubstituent effects depend on the number of hydrogen–heterosubstituent (HX) and carbon–heterosubstituent (CX) *gauche* interactions (2). If a *gauche* γ-substituent is added to an HC configuration, one observes a displacement which is equal in size, but opposite in sign, to the HC shift increment. An investigation of double bond substituent effects suggested that the γ-group has not introduced a new shielding mechanism which fortuitously cancels the HC shift increment, but rather that it has eliminated the HC shift contribution (3).[1] In other words, the observed *gauche* γ-effect is not associated with the γ-group but with the elimination of the





[1]After submission of our manuscript (ref. 3) we became aware of a publication by Boaz (4), in which the author shows that downfield shifts in ^{13}C and upfield shifts in proton spectra are related to the number of 1,3-diaxial hydrogen alignments.

β-hydrogen. This conclusion is based on the following observations (3).

(1) Elimination of γ-hydrogens by γ,δ-double bond formation has no noticeable effect on carbon resonances, i.e. nonbonded interactions with a γ-hydrogen cannot be responsible for the *gauche* γ-effect.

(2) The *gauche* γ-substituent effect is virtually independent of the nature of the γ-group X.

(3) The substituent effect of a β,γ-double bond depends on the number of displaced 1,3-diaxial hydrogen interactions.

(4) β-heterosubstituent shifts are found to depend on bond polarity, if 1,3-diaxial hydrogen alignments $H-^{0}C-C_{\alpha}-X_{\beta}-H_{\beta}$ are taken into account.

(5) Deviations from the cyclohexane chair conformation in heterocyclic systems lead to large *anti* γ-shifts only at carbons which are engaged in 1,3-diaxial hydrogen interactions, presumably because the HC shift contribution is sensitive to changes in hydrogen alignment.

(6) It seems more reasonable that the more severe *syn*-axial δ-interaction should give rise to larger shifts than the *gauche* γ-interaction. In the original interpretation of *gauche* γ-effects the γ-parameter was larger than the δ-parameter.

The general β-parameter HX therefore has to be redefined as the sum of contributions from 1,3-diaxial hydrogen interactions and from the C—X bond polarity. A *gauche* γ-parameter is now only required if the observed *gauche* γ-shift exceeds the magnitude of the eliminated HC contribution. With this revision the additivity parameters for saturated hydrocarbons, alcohols, and amines were redetermined, and new parameters were derived for ketones and olefins.

Results

The experimental data used in the derivation of the predictive parameters are found in Tables 1–5. The first two entries in Table 2 may serve to explain the symbols and abbreviations in the tables. Items 1/**32** and 2/**32** refer to carbons C(1) and C(2) in substrate **32**, 1β-hydroxy-*trans*-decalin. There are two parameter sets:

1/**32**—300 T 10000

2/**32** S 200—02000

The first sequence indicates hydrocarbon parameters and the second block functional group parameters, in this case hydroxyl parameters. The references for sp^2 and heterosubstituted sp^3 carbons are indicated by letters at the beginning of the second parameter sequence. For example C(1) in **32** is a tertiary carbinyl carbon and the hydroxyl parameter series therefore begins with the letter T. The remaining carbon references are indicated at the beginning of the hydrocarbon parameter series. Thus, C(2) in **32** is an unsubstituted secondary sp^3 carbon and the hydrocarbon parameter sequence therefore begins with the letter S. The reference shifts, like the structural parameters, were treated as variables. The number sequences indicate the number of occurrences of structural features. The hydrocarbon parameters are given in the sequence HC, CC, and δ, the hydroxyl parameters in the sequence OC, HO, CO, γ, and δ, etc. The definitions of the references and structural parameters, their numerical values, and standard errors are found in Table 6, in the same sequence as in Tables 1–5. The parameter sequences are also indicated in the footnotes of Tables 1–5. The symbols δ_{obs} and $\delta_{obs} - \delta_{calc}$ indicate observed resonances and deviations between observed and calculated shifts. The carbon and compound numbers, and the literature references for the experimental data are given in Chart 1. Experimental results which were obtained in this laboratory are collected in Table 7.

The hydrocarbon, hydroxyl, amine, and carbonyl parameters were derived from, and are only valid for, six-membered rings in chair conformations. The olefin parameters are valid only for six-membered rings. The eventual extension of this predictive scheme to the derivation of ^{13}C resonances in other conformations will require reference shifts, γ- and δ-parameters which are explicit functions of dihedral angles etc., similar to the generalized β-parameters $2 \times HX \times \cos\phi$ and $2 \times CX \times \cos\phi$ (2).

The use of these parameters for the derivation of ^{13}C resonances will now be demonstrated with a few examples.

Hydrocarbon Parameters

The hydrocarbon parameters in Table 6 are derived from the data in Table 1. P, S, T, and Q are the starting values for the derivation of primary, secondary, tertiary, and quaternary carbon resonances. The HC shift increment is associated with 1,3-diaxial hydrogen–hydrogen interactions, the CC parameter with exocyclic carbon–carbon *gauche* interactions, and the δ parameter with *syn*-axial δ-interactions.

[a]For carbon numbering, substrate number, and literature references see Chart 1.
[b]Parameter definitions: first sequence gives hydrocarbon parameters (see footnote *b*, Table 1), second block gives carbonyl parameters: C = carbonyl reference. Numbers: n_β, $n_{\gamma s}$, $n_{\gamma a}$. Root-mean-squares deviation between calculated and observed resonances is 1.79 ppm.

A few examples may serve as illustration. The C(19) resonance in saturated steroids, e.g. item 19/**15** in Table 1, is calculated to be 7.44 + 4.55 = 12.0 ppm, since C(19) is a primary carbon and there is one HC contribution from the *gauche* interaction between a methyl C—H and the C—H(1e) bonds. In lanostanol the C(19) methyl group has a *syn*-axial δ-interaction with the C(30) methyl group, as well as the *gauche* HC interaction. The C(19) resonance in lanostanol, item 19/**23**, is therefore predicted to be 7.44 + 4.55 + 2.56 = 14.5 ppm. The steroidal C(9) resonance (item 9/**15**) is calculated to be 24.17 + 5 × 4.55 + 3 × 1.85 = 52.5 ppm, since C(9) is a tertiary carbon and there are five HC and three CC shift contributions. The five HC contributions arise from the alignment of the C(9)—H bond with the axial C—H bonds at positions 1, 5, 7, 12, and 14. The three exocyclic carbon–carbon *gauche* interactions are C(11)–C(9)–C(10)–C(1), C(11)–C(9)–C(10)–C(19), and C(8)–C(9)–C(10)–C(19).

Hydroxyl Parameters

The hydroxyl parameters in Table 6 are based on the data in Table 2. Only resonances for secondary alcohols are included in the table and therefore only a reference shift T for tertiary carbinyl carbons was derived. The OC, HO, and CO shift increments are associated with oxygen–carbon, hydrogen–oxygen, and carbon–oxygen *gauche* interactions. The γ parameter is used for *gauche* as well as for *anti* γ-interactions, provided the *anti* γ-hydroxyl group is equatorial. The δ parameter refers to *syn*-axial δ-interactions.

In monofunctional substrates the carbinyl carbon may only be engaged in HC, CC, or δ hydrocarbon interactions and in OC interactions. Of these structural features the HC interactions are the single most important factor determining the position of carbinyl carbon resonances, since the HC parameter has the largest value. For example, the axial C(2)—H bond in 2α-hydroxy,-10-methyl-*trans*-decalin is engaged in one HC interaction with the axial C(4)—H bond, and the C(2) signal is found at 66.9 ppm (item 2/**38**). The axial C(2)—H bond in 2α-hydroxy-*trans*-decalin is engaged in two HC interactions, with the axial C(4)—H and C(10)—H bonds, and the C(2) resonance is found at 70.2 ppm (item 2/**34**).

[a]For carbon numbering, substrate number, and literature references, see Chart 1.
[b]Parameter definitions: first group gives hydrocarbon parameters (see footnote *b*, Table 1), second block gives olefin parameters: T and Q = tertiary and quaternary sp^2 carbon references. Numbers: n_R, n_β, $n_{\gamma s}$, $n_{\gamma a}$. Root-mean-squares deviation between calculated and observed resonances is 2.19 ppm.

δ 2.56 0.39		HNC −0.80 0.45		
				
		γ −2.04 0.34		
				

The axial C(1)—H bond in 1β-hydroxy-*trans*-decalin has three HC interactions, with the axial C(3)—H, C(5)—H, and C(9)—H bonds, plus the O(1)–C(1)–C(10)–C(9) OC *gauche* interaction, and the C(1) resonance occurs at 74.6 ppm (item 1/**32**).

The 2α- and 2β-hydroxy,10-methyl-*trans*-decalins may serve to illustrate the use of the β-, γ-, and δ-hydroxyl parameters. In the 2α isomer both C(1) and C(3) experience two HO *gauche* interactions, in addition to the hydrocarbon contributions (items 1/**38** and 3/**38**). C(4) and C(10) experience an *anti* γ-hydroxyl interaction (items 4/**38** and 10/**38**). In the 2β isomer both C(1) and C(3) are engaged in one HO and one CO interaction (items 1/**39** and 3/**39**), C(4) in

a *gauche* γ-interaction (item 4/**39**), and the methyl group in a *syn*-axial δ-interaction (item Me/**39**).

Amine Parameters

The amine parameters in Table 6 are based on the data in Table 3. The P, S, T, and Q parameters in the second block of parameters in Table 3 are the references for primary, secondary, tertiary, and quaternary nitrogen-bearing carbons. The HN parameter denotes a shift increment associated with a hydrogen–nitrogen *gauche* β-interaction, if a hydrogen or a lone pair electron at the nitrogen atom is aligned with a hydrogen on the carbon in question. However, if the 1,3-diaxial group is a carbon atom, the parameter HNC is used. The CN parameter denotes an increment associated with exocyclic carbon–nitrogen *gauche* β-interactions. The γ-parameter denotes the γ-nitrogen effect at both *gauche* and *anti* positions, exocyclic as well as endocyclic.

The derivations of the *N*-methyl, C(2) and C(10) resonances in *N*-methyldecahydroquinoline and of the C(10) resonance in 10-methylquinolizidine start from the P, S, T, and Q references, respectively (items Me/**72**, 2/**72**, 10/**72**, and 10/**63**). The remaining shift contributions arise from hydrocarbon interactions. For example, the alignment of the methyl C—H bonds with the two C(2)—H groups and with C(10)—H adds 3 × 4.55 ppm to the *N*-methyl reference of 28.82 ppm, for a total value of 42.5 ppm (item Me/**72**).

The C(3), C(5), and C(9) resonances in decahydroquinoline and its *N*-methyl and *N*,9α-dimethyl derivatives may illustrate the application of the HN and HNC parameters. It is assumed that the *N*-methyl group is exclusively equatorial in the monomethyl compound and exclusively axial in the dimethyl derivative. The HN interaction contributes 1 × 4.01, 1 × 4.01, and 2 × 4.01 ppm to the C(3), C(5), and C(9) resonances in decahydroquinoline, since the axial C—H bonds in positions 3 and 5 and both C—H bonds at position 9 are aligned either with a lone pair or a hydrogen on nitrogen (items 3/**64**, 5/**64**, and 10/**64**). In the *N*-methyl derivative the alignment of the axial C(9)—H bond with the lone pair on nitrogen again contributes one HN increment, but the equatorial C(9)—H bond is now aligned with an N—C bond, resulting in an HNC contribution (item 9/**72**). The calculation of the C(3) and C(5) resonances is unchanged by the introduction of the equatorial *N*-methyl group. In the 9α,*N*-dimethyl derivative the C(3), C(5), and C(9) resonances each receive an HNC contribution since all three axial C—H bonds are aligned with the axial N—C bond. In addition the exocyclic Me(9)–C(9)–C(10)–N carbon–nitrogen *gauche* interaction adds one CN increment to the C(9) resonance (items 3/**75**, 5/**75** and 9/**75**). The γ increment is added, for example, to the resonances of C(4) in decahydroquinoline (item 4/**64**, endocyclic *gauche* γ-interaction), to the methyl resonance in the 3β-methyl derivative (item Me/**68**, exocyclic *gauche* γ-interaction), to the C(6) resonance in decahydroquinoline, and to the methyl resonance in the 3α-methyl derivative (items 6/**64** and Me/**67**, *anti* γ-interactions).

Carbonyl Parameters

The carbonyl parameters in Table 6 are based on the data in Table 4. The parameter C is the reference for the carbonyl carbons. There is only one β parameter, but a *syn* and an *anti* γ parameter, γ_s and γ_a.

Since the carbonyl carbons do not bear any hydrogen, the only hydrocarbon interactions which may occur are the CC interactions. Thus, the parameter C itself is the predicted shift for the carbonyl carbons in the 2, 3, 4, 6, 7, and 11-ketosteroids. The carbonyl resonances in the 1- and 12-ketosteroids, on the other hand, receive additional downfield shift contributions of 1.85 ppm from the exocyclic C(2)–C(1)–C(10)–C(19) and C(11)–C(12)–C(13)–C(18) carbon–carbon *gauche* interactions, respectively (items 1/**50** and 12/**57**). The β increment of 14.70 ppm is added to the resonances of all carbons adjacent to the carbonyl group. The *syn* γ-interaction γ_s occurs, for example, at C(9) in 1-ketoandrostane (item 9/**50**) and at C(10) in 11-ketoandrostane (item 10/**56**). The *anti* γ_a interaction may occur at exocyclic or endocyclic carbons. C(19) in 1-ketoandrostane and C(18) in 12-ketoandrostane are examples for the exocyclic case (items 19/**50** and 18/**57**), and C(3) and C(5) in the 1-ketone for the endocyclic case. There are obviously two γ_a positions in every cyclohexanone ring.

Olefin Parameters

The olefin parameters in Table 6 are based on the data in Table 5. The parameters T and Q are the references for tertiary and quaternary sp^2 carbons. The increment R is added to the references T and Q if the second sp^2 carbon is

quaternary. There is only one β parameter, but there is a *syn* and an *anti* γ parameter. The β and γ parameters are not applied at quaternary sp^3 and sp^2 carbons. The hydrocarbon parameter HC is used for all 1,3-diaxial hydrogen interactions, whether the hydrogen is on an sp^2 or an sp^3 carbon. Exocyclic carbon–carbon *gauche* interactions at angles close to 0° are taken to make two CC contributions, in accordance with the cos φ dependence of the generalized β parameters 2 × HC × cos φ and 2 × CC × cos φ on the dihedral angle φ (2). Exocyclic carbon–carbon *gauche* interactions at angles $\phi \geq 90°$ are ignored (2).

A few examples may serve to demonstrate the derivation of sp^2 carbon resonances.

Item	Calculated resonances	Obsvd.
7/**17**	125.99−8.47+0×4.55=117.5	117.1
7/**12**	125.99−8.47+1×4.55=122.1	121.6
14/**14**	125.99−8.47+2×4.55=126.6	128.1
8/**12**	137.80 +0×1.85=137.8	135.2
5/**20**	137.80 +1×1.85=139.6	141.7
8/**18**	137.80 +2×1.85=141.5	140.4
9/**19**	137.80 +3×1.85=143.3	143.4

Carbons 7/**17**, 7/**12**, and 14/**14** are tertiary sp^2 carbons and therefore the reference shift of 125.99 ppm is used. The second sp^2 carbon, C(8) in all three cases, is quaternary and the R increment of −8.47 ppm is added. The sp^2 C—H bond at C(7) in cholest-7-en-3β-ol is not engaged in HC interactions (item 7/**17**). The sp^2 C—H bond in the Δ^7-pimaradiene has one HC interaction with the equatorial C(14)—H bond (item 7/**12**), and in the $\Delta^{8(14)}$-pimaradiene it has two HC interactions, with the equatorial C(7)—H and one C(17)—H bond (item 14/**14**). Items 8/**12**, 5/**20**, 8/**18**, and 9/**19** are examples of quaternary sp^2 carbons and the reference value of 137.80 ppm is used. In these four examples the second sp^2 carbon is tertiary and the R parameter is not required. The only hydrocarbon parameters which may contribute to quaternary sp^2 carbon resonances are the CC shift increments. C(8) in the Δ^7-pimaradiene is not engaged in exocyclic carbon–carbon *gauche* interactions along any of its three CC-bonds, and the predicted shift is simply equal to the reference value (item 8/**12**). The 60° C(6)–C(5)–C(10)–C(19) interaction in cholesta-3,5-diene makes one CC contribution to the C(5) resonance item (5/**20**). The segment C(7)–C(8)–C(14)–C(15) forms an angle of close to 0° and two CC contributions are added to the C(8) resonance in cholesta-5,7-dien-3β-ol (item 8/**18**). Segment C(11)–C(9)–C(10)–C(1) in cholesta-7,9-dien-3β-ol forms a dihedral angle of close to 0°, contributing two CC increments to the C(9) resonance, and the 60° C(8)–C(9)–C(10)–C(19) fragment accounts for the third CC parameter (item 9/**19**). In spite of obvious conformational problems in the olefin series the experimental values reflect this downfield shift with increasing number of HC and CC interactions.

The β parameter is added to the resonances of carbons adjacent to C=C double bonds, with the exception of quaternary or other sp^2 carbons. For example, the β parameter is included in the calculation of the C(2) and C(7), but not the C(4), C(5), or C(10) resonances in cholesta-3,5-diene (items 2/**20**–10/**20**). The γ_s and γ_a increments are also not used for quaternary and sp^2 carbons. For example, a γ_s contribution is added to the tertiary C(9), but not to the quaternary C(8) resonance in β-amyrin (items 8/**29** and 9/**29**). The two *anti* positions are treated as being equivalent. For example, the geometric relation of C(19) relative to the double bond in lanost-9-en-3β-ol is essentially equivalent to the orientation of C(5) or C(7) relative to the same bond. C(7) and C(19) are therefore taken to receive the same γ_a contributions (items 7/**25** and 19/**25**).

The data bases for the substituent parameters require some comments. The assignments in Table 7 are based on off-resonance decoupling, relaxation and shift reagent experiments, and on comparison with related compounds. Our assignments for lanost-8(9)-en-3β-ol and lanost-9-en-3β-ol differ from those in ref. 17 by the interchange C(7) → C(16), C(12) → C(7), and C(16) → C(12). Our β-amyrin assignments agree with ref. 17 and ref. 23 (according to our own results and those in ref. 24, the C(8) shift for β-amyrin in ref. 17 is in error by 1 ppm).

The C(3) and C(4) resonances of cholesta-3,5-diene in ref. 15 are interchanged (items 3/**20** and 4/**20** in Table 5). C(3) is neither engaged in HC or CC *gauche* interactions, nor is the parameter R required. Its predicted shift is therefore equal to the tertiary sp^2 carbon reference of 126.0 ppm, and the 124.6 ppm band, rather than the 129.9 ppm signal, is assigned to C(3).

The assignment of C(4) and C(7) of hydroxydesoxycholic acid in ref. 16 is also interchanged (items 4/**22** and 7/**22** in Table 2). Introduction of an equatorial hydroxyl group at position 6 in steroids with *cis* A/B ring junctions causes the

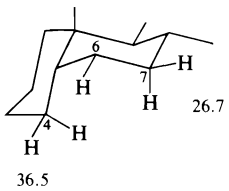
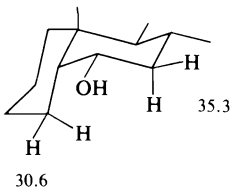
[a]The spectra were recorded on a Bruker HX 90 FT nmr spectrometer, with 0.1 *M* solutions in $CDCl_3$. The chemical shifts are given in ppm relative to internal TMS.
[b]Entries marked with * may be interchanged.
[c]For chemical structures, see Chart 1.

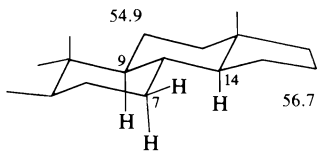
following changes at C(4) and C(7). At C(4) the HC interaction between C(4)—H(4β) and C(6)—H(6α) is eliminated and one *gauche* γ-hydroxyl interaction is introduced, for a substituent effect of $-4.55 + (-1.28) = -5.8$ ppm. At C(7) two HO interactions are introduced for

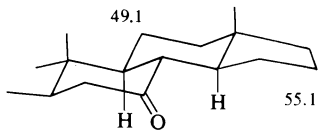




a substituent effect of $2 \times 4.41 = 8.8$ ppm. Therefore the signal at 30.6 ppm is assigned to C(4) and the 35.3 ppm band to C(7).

Finally, the assignment of C(9) and C(14) of 7-cholestanone in ref. 19 is interchanged (items 9/**55** and 14/**55** in Table 4). Introduction of the carbonyl group at C(7) eliminates the HC interaction between C(9)—H and C(7)—H(7α) and introduces an *anti* γ-carbonyl shift, for a substituent effect of $-4.55 + 5.16 = +1.6$ ppm. At C(14) the HC interaction between C(14)—H and C(7)—H(7α) disappears, but here a *gauche* γ-carbonyl interaction is added, for a substituent shift of $-4.55 + (-0.22) = -4.8$ ppm. There-





fore the 55.1 ppm band is due to C(9), and the 49.1 ppm signal is assigned to C(14).

Discussion

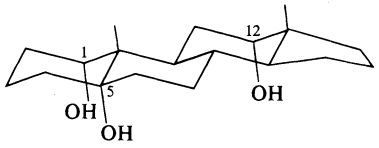
In the diamond lattice all α- and all β-positions, relative to any given lattice point, are equivalent. There are two nonequivalent γ- and four nonequivalent δ-positions, etc. The simplest possible parameter set for the derivation of ^{13}C resonances in saturated hydrocarbons would therefore consist of one reference value, one α-, one β-, two γ-, four δ-parameters, etc. Such a parameter set is insufficient for several reasons. Firstly, α-substituent effects are not additive. Thus, the shift increments caused by the successive replacement of the methane hydrogens by methyl groups are not constant. The simplest parameter modification to allow for this lack of additivity is the replacement of the one reference and one α-parameter by four separate reference values for primary, secondary, tertiary, and quaternary carbons. Secondly, the β-substituent effect depends on the α-substitution pattern at the carbon under observation. The simplest parameter modification to allow for this interdependence is the replacement of the one β-parameter by two parameters associated with hydrogen–carbon and carbon–carbon *gauche* interactions. Thirdly, the shifts observed upon replacement of a directly bonded hydrogen by an α-carbon, an α-hydrogen by a β-carbon, a β-hydrogen by a γ-carbon, a γ-hydrogen by a δ-carbon, etc., are in principle differences between shifts associated with the incoming group and increments associated with the eliminated hydrogen. The distinction between the two contributions is obviously important for an understanding of the relation between chemical structure and ^{13}C resonances. However, this question is particularly difficult to resolve since two steps, namely the removal of a hydrogen and the insertion of a methyl group, give rise to only one observation. An investigation of shielding in ketones and olefins led us to believe that the shift caused by the replacement of a β-hydrogen by a *gauche* γ-methyl group is essentially entirely due to the removal of the β-hydrogen (3). If the second step, the introduction of the *gauche* γ-methyl group, is of no consequence, it follows that the shift due to the replacement of a γ-hydrogen by a *syn*-axial δ-methyl group is associated with the δ-methyl group and not with the removal of the γ-hydrogen. The effect of removal of directly bonded and α-hydrogens on the observed α- and β-carbon shifts has not been investigated yet, but will undoubtedly become of considerable importance for an understanding of the conformational dependence of ^{13}C resonances.

In alcohols, amines, ketones, and olefins, polar and double bond effects create further complications. These contributions are equally difficult to resolve since they again increase the number of parameters without increasing the number of observations. Furthermore, polar and double bond substituents are more likely to cause substantial conformational changes, which in turn may lead to complex changes in chemical shifts. Thus, some of the parameters in Table 6 presumably represent combinations of (de)-shielding effects.

In the alcohol series the β-parameters HO and CO very likely contain polar shift contributions which are impossible to extract at this level of approximation. The *anti* γ-hydroxyl parameter is almost certainly a function of conformation. It seems that only equatorial hydroxyl groups cause upfield shifts at *anti* γ-carbons, whereas axial and bridgehead substituents give rise to downfield shifts (3). Since bridgehead substituents are least likely to cause conformational changes, for reasons of symmetry, the *anti* γ-shift in bicyclic compounds would be expected to correspond most closely to the genuine substituent effect, i.e. the *anti* γ-effect is probably positive. However, the antiperiplanar $^{0}C–C_{\alpha}–C_{\beta}–O_{\gamma}$ arrangement occurs most frequently in equatorially substituted rings, since there are always two ring carbons in an *anti* orientation. Therefore, a negative *anti* γ-hydroxyl parameter is required for most predictive purposes. All examples of *anti* γ-hydroxyl shifts in Table 2 occur in equatorially substituted rings. The γ_a parameter was found to be close to the γ_g value and the *gauche* and *anti* γ-hydroxyl parameters were combined to a general γ-hydroxyl parameter. It was noted (6) that the *anti* γ-hydroxyl shift is positive in tertiary hydroxides. However, axial hydroxyl groups in the secondary 1α- and 12α-hydroxysteroids also shift the methyl carbon resonances downfield (12).

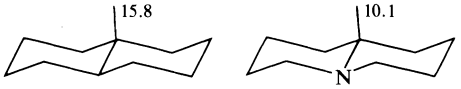
The β-nitrogen parameters HN and CN, like the HO and CO parameters, presumably contain polar shift contributions. One would expect

different HN parameters for secondary and tertiary amines, since 1,3-diaxial hydrogen alignment is only possible in secondary amines. However separate analyses of chemical shifts for



1α—OH	C(19)	+0.6 ppm
5α—OH	C(19)	+3.9 ppm
12α—OH	C(18)	+1.1 ppm

secondary and tertiary amines did not lead to significantly different HN parameters, and therefore no distinction between hydrogen–hydrogen and hydrogen–lone pair alignments is made in the present scheme. The expected parameter difference is possibly obscured by conformational effects. The HNC parameter has the following origin. If C(5) in 10-methyl-*trans*-decalin is replaced by nitrogen, the methyl carbon resonance is shifted upfield from 15.8 ppm (9) to 10.1 ppm (20). One might have



expected the insertion of the more electronegative nitrogen to deshield the angular methyl carbon. In other words, the magnitude of this shielding effect, whatever its origin, should exceed the observed upfield shift by the size of any dipolar nitrogen substituent effect. It is tentatively assumed that such a shielding effect arises whenever a ^{0}C—H bond is aligned with an N_β—C_γ bond.

The γ-carbonyl parameters are open to a number of interpretations. For example, it is possible that the carbonyl group only causes a downfield shift at the *anti*, but not at the *gauche* γ-position. It is equally possible that the keto group causes a general downfield shift at both *gauche* and *anti* γ-positions, of the order of magnitude of the γ_a parameter, and that an additional shielding mechanism in the *gauche* configuration cancels this general γ-effect. A distinction between these different interpretations is not possible at this moment.

The most striking observation in the olefin series is the apparent insensitivity of quaternary carbon resonances to the presence of β- or γ-double bonds. It is possible to find some dependence of quaternary carbon resonances on γ-double bond orientation, within a series of isomeric olefins (3). However, an examination of a larger number of olefins, and particularly the resonances of carbons adjacent to C=C bonds, suggests that, to a first approximation, quaternary carbon resonances may be assumed to be unaffected by the presence of olefinic double bonds. A plausible explanation for this observation might be that the double bond does not affect carbon nuclei directly, but rather C—H bonds. In other words, β-and γ-olefin substituent effects seem to depend on the presence and orientation of ^{0}C—H bonds relative to the C=C group.

Conformational effects have been invoked a number of times in the discussion, and there is little doubt that conformational changes influence chemical shifts. However, it is obviously difficult to demonstrate that a given substituent effect is conformational in origin. Nevertheless, there is an important difference between a (de)shielding substituent effect and a conformational substituent effect which in turn modifies other (de)shielding mechanisms. The analysis of conformational effects on carbon resonances requires the development of substituent parameters which are explicit functions of internal coordinates such as dihedral angles. Conformational effects will then be expressed by modifications of these (de)shielding parameters, and parameters which only represent conformational effects will disappear.

Etude en résonance magnétique nucléaire du ^{13}C des paramètres de substitution de la fonction azide

A. PANCRAZI, I. KABORÉ, B. DELPECH, A. ASTIER, Q. KHUONG-HUU ET G. LUKACS

Institut de Chimie des Substances Naturelles du C.N.R.S., 91190 Gif/Yvette, France

Reçu le 16 février 1977

A. PANCRAZI, I. KABORÉ, B. DELPECH, A. ASTIER, Q. KHUONG-HUU et G. LUKACS. Can. J. Chem. **55**, 2829 (1977).

En rmn du ^{13}C, les différents effets-α, β, γ et δ de 16 azido-stéroïdes ont été mesurés. Les effets-α ont été évalués à 33.6 et 31.2 ppm pour des azides cyclohexaniques de configurations bloquées, équatoriale et axiale. Les effets-γ ainsi que les effets-δ ont des amplitudes voisines de ceux des groupes OH et NH_2. Par contre, l'effet-β des azides est sensiblement plus faible que celui des hydroxyles ou amines, son amplitude étant atténuée par un effet-γ du second atome d'azote de l'azide; cet effet-γ supplémentaire est fonction de la disposition spatiale de la liaison Cβ—H et du groupe azide.

A. PANCRAZI, I. KABORÉ, B. DELPECH, A. ASTIER, Q. KHUONG-HUU, and G. LUKACS. Can. J. Chem. **55**, 2829 (1977).

The various effects (α, β, γ and δ) on the ^{13}C nmr of azido steroids have been measured. For cyclohexane azides constrained to equatorial and axial configurations, the α-effects were determined to be 33.6 and 31.2 ppm. Both γ- and δ-effects have magnitudes near those for OH and NH_2 groups. On the other hand, the β-effect of the azides is slightly smaller than those of hydroxyls or amines as its magnitude is reduced by a γ-effect of the second nitrogen atom of the azide group. This additional γ-effect is a function of the spatial arrangement of the Cβ—H bond with respect to the azide group.

[Journal translation]

Les composés qui possèdent une fonction azide constituent des intermédiaires importants du point de vue de la synthèse de produits naturels complexes (amino-sucres, amino-stéroïdes et alcaloïdes). La rmn du ^{13}C est une technique de choix pour l'étude structurale de ces composés; cette méthode nécessitant une bonne connaissance des différents effets de type α, β, γ et δ de la fonction azide, nous avons entrepris une étude systématique d'un certain nombre d'azido-stéroïdes antérieurement synthétisés (1)[1].

Résultats et discussion

Azides saturés

Les déplacements chimiques en rmn du ^{13}C des azido-stéroïdes de **1** à **10** sont indiqués dans le tableau 1. L'attribution des signaux a été effectuée selon les règles générales de la rmn du ^{13}C (2), appuyée par des expériences de découplage partiel; l'interprétation des résultats est obtenue également par comparaison avec les spectres de modèles bien connus: androstane-5α (3*b*, 4), cholestane-5α (3*a*, 5), cholestane-5β (4, 6) et hydroxy-5α et -5β pregnane (7).

L'examen du tableau 1 permet de dégager les conclusions suivantes.

(*A*) L'effet-α d'un azide équatorial (**1** α = +33.5 ppm) est plus important que celui d'un azide axial (**2**, α = +31.1 ppm) (cf. tableau 1); la différence entre les deux effets $\Delta(\delta\alpha(\text{eq.}) - \delta\alpha(\text{ax})) = 2.4$ ppm semble être toutefois légèrement inférieure à celle observée dans le cas des alcools $\Delta(\delta\alpha(\text{eq.}) - \delta\alpha(\text{ax.})) = 4.6$ ppm (3, 5).

Il est à remarquer dans le cas de l'azido-6β pregnane-5α, **10**, un effet-α de 34.3 ppm relativement important pour un azide axial, ce qui est à rapprocher de l'effet-α d'un groupe hydroxyle en 6β (3*b*), également au dessus de la valeur attendue pour une fonction alcool axiale, ce qui doit être en rapport avec un changement de géométrie de la molécule.

En ce qui concerne les azides-17α et 17β, **5** et **6**, l'effet-α est pratiquement identique pour les deux épimères (31.2 et 30.9 ppm respectivement) alors que pour les deux hydroxy-17α et -17β la différence entre les deux effets-α est de 2 ppm environ (3b).

En position tertiaire les effets-α des azides

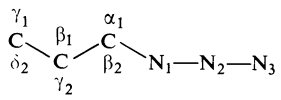
*[a], [b], [c], les attributions à l'intérieur d'une colonne verticale peuvent être inversées.

5α, **4** et 5β, **3** sur le carbone quaternaire C-5 sont respectivement de 22.6 et 24.4 ppm donc considérablement atténués par rapport aux azides secondaires ou primaires; dans le cas des hydroxy-5α et -5β prégnanes (7), ces effets sont également très atténués (26.0 et 29.9 ppm respectivement).

Pour les azides aliphatiques comme les azido-20(*R*), **7**, et -20(*S*) prégnane **8**, on observe des effets de 35.9 et 37.8 ppm; il semble donc que l'effet-α soit plus important en série aliphatique qu'en série alicyclique.

(*B*) L'effet-β dû à un groupe azide est en général nettement plus faible que celui dû à une fonction alcool ou amine de stéréochimie identique. Cette observation s'explique aisément en considérant que l'effet-β dû à l'azote fixé au site de substitution est atténué par un effet-γ dont l'origine est l'azote central de l'azide.



En série équatoriale, cet effet-β est de 4.9 à 5.4 ppm et d'environ 2.5 à 3.5 ppm en série axiale (cf. tableau 2).

La différence $\Delta(\delta\beta_{OH} - \delta\beta_{N_3})$ est de 3.9 à 4.2 ppm pour une substitution équatoriale et de 3.2 à 3.4 ppm en série axiale, ceci apparaissant comme constant dans tous les modèles étudiés.

Néanmoins, dans certains cas très particuliers, l'effet-γ supplémentaire de l'azote central est inexistant, l'effet-β observé se trouve alors voisin et même parfois supérieur à l'effet-β de l'hydroxyle de stéréochimie identique.

C'est ainsi que, pour l'azide-6β, **10**, l'effet sur le C-7 est de 4.3 ppm, soit un $\Delta(\delta\beta_{OH} - \delta\beta_{N_3}) = 3.1$ ppm, ce qui est attendu pour une substitution axiale, mais en C-5, l'effet-β de l'azide est de 2.5 ppm, ce qui correspond à un $\Delta(\delta\beta_{OH} - \delta\beta_{N_3})$ de 0.2 ppm.

De la même façon, pour les azido-17α et -17β androstane-5α, **5** et **6**, la différence $\Delta(\delta\beta_{OH} - \delta\beta_{N_3})$ au niveau du C-16 est de 3.7 et 3.9 ppm respectivement, donc en accord avec les valeurs attendues, mais pour le C-13 le $\Delta(\delta\beta_{OH} - \delta\beta_{N_3})$ est de −1.4 et −0.6 ppm respectivement, ce qui conduit à admettre un effet-β plus important pour l'azide que pour l'hydroxyle.

Au niveau des azides tertiaires-5α et -5β

prégnanes **4** et **3**, les effets observés en C-4 et C-6 ont des valeurs attendues (tableau 3) mais en C-10, les valeurs de $\Delta(\delta\beta_{OH} - \delta\beta_{N_3})$ sont respectivement de 0.4 et 0.6 ppm.

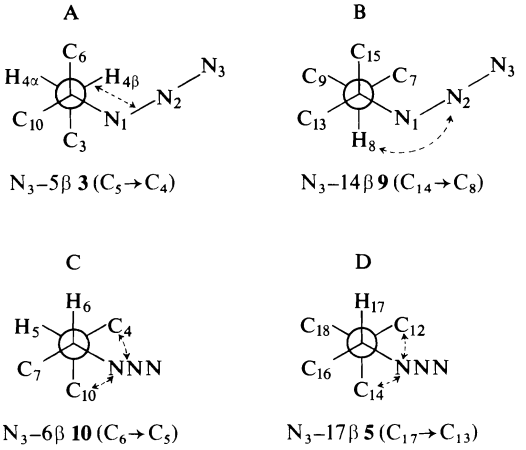
Compte-tenu que d'un point de vue purement stérique, l'enchaînement des atomes d'azote de l'azide doit être dirigé vers l'extérieur du reste stéroïdique, donc de façon "*exo*", (8), des conformations privilégiées de l'azide sont à envisager. A l'examen des modèles moléculaires et des projections de Newman, les faits suivants apparaissent le long des différents axes Cα–Cβ.

Lorsque le carbone-β possède un atome d'hydrogène tel que la liaison C-β—H se trouve parallèle à la liaison N_1—N_2, l'effet-γ supplémentaire de l'azote central est maximum (situation *A*); cet effet peut être apparenté à un effet-γ d'origine stérique; cette situation est déterminée par les conformations privilégiées du groupe azide, par rapport au stéroïde, qui imposent essentiellement un enchaînement des trois atomes d'azote dérivé vers l'extérieur du stéroïde, donc de façon '*exo*' (8).

C'est ainsi que dans le cas ou il existe un hydrogène sur le carbone-β, et que les conformations privilégiées du groupe azide ne permettent pas que les liaisons Cβ—H et N_1—N_2 soient parallèles (situation *B*: azido-14β **9** C-14 → C-8), l'effet-γ supplémentaire observé est d'amplitude plus faible que dans la situation A ($\Delta(\delta\beta_{OH} - \delta\beta_{N_3}) = 1.9$ en C-8).

Pour les autres situations dans lesquelles le carbone-β présente un atome d'hydrogène antipériplanaire à l'azide (situation *C*), ou que le carbone-β ne présente aucun atome d'hydrogène (situation *D*), l'effet-γ supplémentaire ne s'exerce plus; ceci est tout à fait comparable à l'interprétation des effets stériques de type δ, le remplacement d'une liaison Cγ—H par une liaison Cγ—Cδ ayant pour conséquence de supprimer l'effet de blindage sur le carbone-γ (9).

Dans les situations *A* et *D*, le nombre d'exemple présenté est suffisamment important pour l'interprétation du phénomène; par contre, pour les situations *C* et *B* notre explication ne repose que sur un seul cas et doit donc être confirmée par l'analyse spectrale d'autres composés.



(*C*) L'effet-γ de type 1–3 diaxial de la fonction azide est tout à fait comparable à celui d'un groupe hydroxyle ou amine, les faibles variations observées devant être attribuées à des modifications mineures de la géométrie de la molécule; l'effet-γ antipériplanaire (10) (−1.5 à −2 ppm) est également observé dans nos exemples et possède la même amplitude que pour les alcools (3*b*).

Un nouvel effet-γ antipériplanaire provoqué par un groupement X en position tertiaire a été récemment observé par Stothers et ses collaborateurs (11); cet effet déblinde le C-19 de +3.2 ppm dans le cas de l'azide-5α, **4** et pour l'azide-5β, **3**, un déblindage des C-7

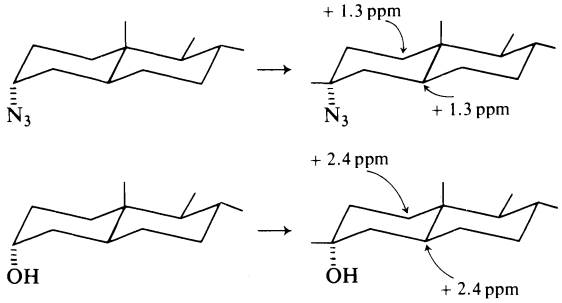
C-19	19.1	19.2	18.4	18.8	15.7	12.5	12.1	12.6	12.4	12.5	19.3	19.0

*Les déplacements chimiques des carbones de C-11 à C-18 et de C-20 et C-21 sont en accord avec des valeurs attendues pour un squelette non substitué.

et C-9 de 1.8 et 2.9 ppm[2] est observé; cet effet est général et son amplitude varie entre les groupes —CH_3, —OH, —NH_2 et —N_3.

Il a été vérifié sur d'autres exemples la validité de l'effet observé par Stothers.

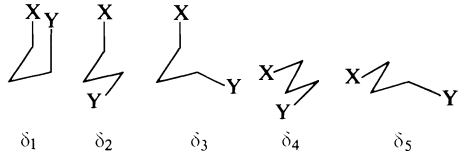


(*D*) Les effets de type-δ définis par Stothers (12) pour les hydroxyles se retrouvent également pour les azides; on notera par exemple un effet-δ_1 (effet stérique de type *syn*-diaxial) de +2.8 ppm sur le C-19 de l'azide-6β, **10** et un δ_2 de +1.8 ppm sur le C-1; pour l'azide 3β, les effets-δ_4 en C-6, δ_5 en C-10 sont de −0.5 ppm et −0.8 ppm; pour l'azide-3α, **2**, l'effet-δ_2 en C-6 est de −0.7 ppm et en C-10 l'effet-δ_3 est d'environ −0.2 ppm.

Azides allyliques et homoallyliques

Pour les azides homoallyliques, les déplacements chimiques sont comparables à ceux des alcools homoallyliques (13), compte-tenu des particularités de la fonction azide, précédemment définies.

Dans le cas d'azides allyliques (cf. tableau 4), on pourra observer pour le carbone-β, éthylénique, un déplacement vers les champs forts, par rapport à l'alcool allylique correspondant (effet-β des azides); par contre, le carbone-γ éthylénique subit un déblindage de 3 à 4 ppm.



[2]Variation en ppm par rapport au dérivé non substitué X = H.

Cette propriété surprenante des azides stéroïdiques s'observe pour tous les composés étudiés sauf **19**; cette influence due à l'azote central de l'azide est un effet de type-δ de déblindage et pourrait être apparenté à l'effet de "l'acétylation allylique", de direction et de dimension tout à fait comparables (14).

Conclusion

L'effet-β des azides est inférieur à celui des groupes OH et NH_2 et présente une variation $\Delta(\delta\beta_{OH} - \delta\beta_{N_3})$ de 3.9 à 4.2 ppm en série équatoriale et 3.2 à 3.4 ppm en série axiale; ceci est expliqué par l'existence d'un effet-γ supplémentaire dû à l'atome d'azote central de l'azide. Il apparaît sans conteste à l'examen des modèles moléculaires que cet effet-γ supplémentaire n'existe que si le carbone-β considéré possède un hydrogène au voisinage du groupe azide.

Long-range spin–spin coupling constants as an indicator of conformational preferences in ethyl and trifluoroethyl vinyl ethers

TED SCHAEFER AND WILLIAM J. E. PARR[1]

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received March 7, 1977

TED SCHAEFER and WILLIAM J. E. PARR. Can. J. Chem. **55**, 2835 (1977).

The observed and calculated, negative, long-range spin–spin coupling constants over five bonds between olefinic and methylene protons in ethyl vinyl ether and in 2,2,2-trifluoroethyl vinyl ether are consistent with predominant *s-cis* planar conformations. The five-bond couplings are sensitive to the proximity of the bonds containing the coupled nuclei and are unobservably small in 1-butene where the H,H distances are somewhat larger than in the ethers. The present results concur with the arguments based on other spectroscopic techniques.

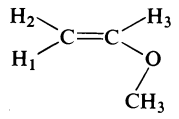
TED SCHAEFER et WILLIAM J. E. PARR. Can. J. Chem. **55**, 2835 (1977).

Les constantes négatives observées et calculées pour les constantes de couplage spin–spin à longue distance à travers cinq liaisons entre les protons oléfiniques et méthyléniques de l'éthoxy-éthylène et du trifluoro-2,2,2 éthoxy-éthylène sont en accord avec des conformations prédominantes *s-cis*-planaires. Les couplages à travers cinq liaisons sont sensibles à la proximité des liens contenant le noyau couplé et sont trop faibles pour être observés dans le butène-1 où les distances H,H sont passablement plus grandes que dans les éthers. Les résultats obtenus dans le présent travail sont en accord avec les arguments basés sur d'autres techniques spectroscopiques.

[Traduit par le journal]

Introduction

The stable conformation of methyl vinyl ether is the *s-cis* form, **1**, defined by a dihedral angle,

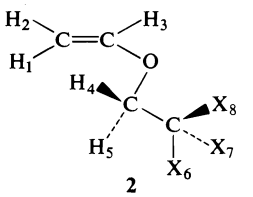


θ(C=C—O—C) = 0°

1

θ, of 0° (1–3). A second, skew, conformation is described by a θ of 90 ± 10°. In the liquid form **1** has a lower enthalpy than the skew form of about 1.5 kcal/mol (3). Consequently **1** is present to about 90% on the assumption that the entropies of the two conformers are equal.

Again, infrared (1, 3) and low resolution microwave (5) data are consistent with a stable form, **2**, for ethyl vinyl ether (EVE) and for



X = H or F
θ(C=C—O—C) = 0°
φ(C—O—C—CX_3) = 180°

2

2,2,2-trifluoroethyl vinyl ether (F_3-EVE). **2** has coplanar carbon and oxygen atoms and is defined by the two dihedral angles, θ and φ, *i.e.* by 0,180. Other plausible conformations would be described by 0,60; 180,180; and 180,0.

The vibrational spectra imply the additional presence of two other conformers for EVE in the liquid and gaseous states (3). Their enthalpies are again higher than that of **2** by about 1.5 kcal/mol (3). It was suggested on the basis of normal frequency calculations that the less stable forms both correspond to θ = 120° and that φ = 120° and 180° distinguishes these two isomers. In any event, the conformer **2** is predominant.

The microwave spectrum of F_3-EVE corresponds to 0,180, *i.e.* form **2**. No other species is observed and therefore the 180,180 conformation can be excluded. The dipole moment and the liquid phase spectra are consistent with this exclusion (4). Any other species in the vapor would be relatively nonpolar, having φ < 90° (5).

In summary, the most stable forms of all three ethers in the liquid and gaseous states are those in which the carbon and oxygen atoms are coplanar and θ = 0°, φ = 180°. In this conformation the C—H bonds of the methylene group in EVE and F_3-EVE are staggered about the O—C= bond. In the proton magnetic resonance spectrum of methyl vinyl ether the proximity of the C—H bonds and the C—H_1

[a]In Hz at 100 MHz and 305 K to low field of internal tetramethylsilane; 10 mol% solutions in CS_2.
[b]In Hz, numbers in parentheses representing the standard deviations in the last place.
[c]Subscripts *c*, *t*, *g*, and *v* represent *cis*, *trans*, geminal, and vicinal, respectively; subscripts 4 and 5 refer to CH_2 and $CH_3(CF_3)$ groups, respectively.
[d]These are the couplings from Table 2, averaged over the values calculated for protons or fluorine nuclei within the CH_2CH_3 or CH_2CF_3 group for conformation **2** of the text, $\theta = 0°$, $\phi = 180°$.
[e]For $\theta = 120°$, $\phi = 180°$.

bond is thought to account for the relatively large, negative, spin–spin coupling, $^5J_c^{H,CH_1}$, of −0.32 Hz (6). The INDO–MO–FPT calculations of the long-range couplings involving the methyl protons are in semiquantitative agreement (6) with the hypothesis that $^5J_c^{H,CH_1}$ contains a contribution from a direct coupling mechanism arising from interactions between electrons in the orbitals of the C—H bonds containing the coupled nuclei. For the *trans* conformation, $\theta = 180°$, $^5J_c^{H,CH_1}$ is calculated as positive.

It follows that $^5J_c^{H,CH_1}$ should be negative in EVE and in F_3-EVE if the conformer populations based on vibrational and microwave spectroscopy are correct. In this paper, full analyses of the proton magnetic resonance spectra of EVE and F_3-EVE in CS_2 solution are reported. The long-range couplings between the olefinic protons and the protons or fluorine nuclei in the saturated fragments are discussed in terms of the conformational preferences and are compared with the couplings calculated by INDO–MO–FPT.

Experimental

Solutions (10 mol%) of EVE and F_3-EVE in CS_2, containing a small amount of tetramethylsilane, were degassed by the freeze–pump–thaw technique. Proton magnetic resonance spectra were calibrated in the frequency sweep mode on an HA 100 spectrometer at 305K. Double resonance experiments (7, 8) established the relative signs of the coupling constants.

Results and Discussion

Spectral Analysis

The spectra were analyzed with the computer program LAME (9, 10), extended to cope with an 8 spin system. The spectral parameters are given in Table 1. The signs of the coupling constants assume that the vicinal couplings are positive. The standard deviations in the coupling constants imply an accuracy of 0.01 to 0.02 Hz in their magnitudes.

INDO–MO–FPT Calculations (11)

Because of the previous experimental data (3–5) and of the expense of these calculations, the latter were carried out for the $\theta = 0$, $\phi = 180$ conformations of EVE and F_3-EVE; and for one other form of EVE, that described by $\theta = 120$, $\phi = 180$. The calculated long-range coupling constants involving the olefinic protons are given in Table 2. The average values involving the protons of fluorine nuclei within a CH_2, CH_3, or CF_3 group correspond to the observed couplings in Table 1 and are tabulated there. The $\theta = 120$, $\phi = 180$ conformer of EVE is calculated as 0.67 kcal/mol less stable than **2**, in qualitative agreement with the vibrational data (3).

TABLE 2. INDO–MO–FPT coupling constants in ethyl vinyl ether and in 2,2,2-trifluoroethyl vinyl ether

	Value[b]				Value[b]

[a]For the numbering see structure **2** in the text.
[b]These are proton–proton couplings in Hz, and, if starred, are proton–^{19}F couplings.

The Long-range Couplings to the Methylene Protons

The agreement between observed and calculated $^5J_c^{H,CH_2}$ and $^5J_t^{H,CH_2}$ is satisfactory for **2** (Table 1), the more negative value of $^5J_c^{H,CH_2}$ arising from the proximity of the coupled protons in **2**. In view of the calculated values for θ = 120, φ = 180 and of the previous calculations on methyl vinyl ether, in which negative values of these couplings were obtained only for θ values near 0 (6), it may be concluded that the coupling constant data and the INDO–MO–FPT calculations concur with the other spectroscopic conclusions that **2** is the predominant form for EVE and F_3-EVE in the liquid and gaseous states.

The observed and calculated values of $^4J^{H,CH_2}$ for **2** are in quantitative agreement for EVE but differ by 0.2 Hz for F_3-EVE. For θ = 120, φ = 180 in EVE, $^4J^{H,CH_2}$ is calculated as much larger than that observed.

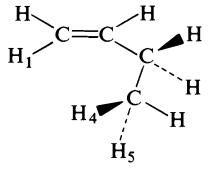
The Long-range Couplings to Methyl Protons and Fluorine Nuclei

$^5J^{H,CH_3}$ and $^5J^{H,CF_3}$ are considerably smaller than their calculated magnitudes for **2**. The large predicted values can be attributed to the overestimate involving H_6 and F_6 (Table 2), INDO–MO–FPT being known to exaggerate couplings over five bonds in the all-*trans* arrangement (12, 13).

The calculations reproduce the positive signs of $^6J_{c,t}^{H,CH_3}$ and of $^6J_{c,t}^{H,CF_3}$ but underestimate the magnitudes by about 0.1 Hz, except for $^6J_c^{H,CF_3}$.

Comparison with Butene-1

$^5J_c^{H,CH_3}$ and $^5J_t^{H,CH_3}$ are both ±0.02 Hz or less in butene-1 (6), yet the microwave data (14) suggest that **3** is populated to a significant extent. It is interesting to note that INDO–MO–FPT calculations for the microwave geometry of **3** yield a $^5J_c^{H,CH_3}$ of −0.01 Hz. The contrast with



3

the corresponding couplings in **1** and **2** is attributable to the different H_1,H_4 distances. In **3**, the H_1,H_4 distance is 2.4 Å and is less than 2.0 Å in **1** and **2**. The direct interactions (6, 15–18) giving rise to a net negative $^5J_c^{H,CH_3}$ are very sensitive to these distances. The observation and calculation of $^5J_c^{H,CH_3}$ for 1-butene can be taken as a partial corroboration of the conformational deductions based on this coupling for the vinyl ethers.

On a isolé la physciosporine, une nouvelle depsidone chlorée, à partir du lichen *Pseudocyphellaria physciospora* et on l'a identifiée comme étant le chloro-2 formyl-4 dihydroxy-3,8 triméthyl-1,6,9 oxo-11 11*H* dibenzo[*b*,*e*][1,4]dioxépincarboxylate-7 de méthyle (chloro-5 virensate de méthyle), **1**.

[Traduit par le journal]

Introduction

Our survey for unusual lichen constituents in the genus *Pseudocyphellaria* by means of two-directional thin layer chromatography (1, 2) revealed the presence of several unidentified constituents reacting with *p*-phenylenediamine (PD). One of these, tentatively named physciosporin, gave a deep orange color with this reagent and was found in two species of the Southern Hemisphere, *P. physciospora* (Nyl.) Malme and *P. granulata* (Bab.) Malme. Physciosporin was extracted and purified in amounts sufficient for chemical identification from thalli of *P. physciospora* collected on Campbell Island, N.Z., on the occasion of the Swedish-Antarctic Expedition 1929, by the late Professor G. Einar DuRietz of the University of Uppsala and Dr. Margareta DuRietz.

Results

Physciosporin, **1**, was isolated in a yield of 5.3% of the dry lichen via column chromatography in benzene. The compound was slightly soluble in 5% sodium bicarbonate solution and readily so in 5% sodium carbonate, although excessive saponification occurred, especially in the latter case. The two absorption maxima in the ultraviolet spectrum (in dioxane) at 248 and 323 nm are typical of depsidones. The presence of a non-bonded ester carbonyl in the ir spectrum (in CCl_4) at 1748 cm^{-1}, as well as ester bond cleavage via methanolysis or saponification to give the corresponding biphenylether derivatives **2** and **3**, respectively, confirmed this conclusion. The mass spectrum showed the presence of one chlorine atom and an apparent molecular formula of $C_{19}H_{15}ClO_8$ confirmed by elemental analysis. The ^{1}Hmr spectrum (in $CDCl_3$) revealed three aromatic methyls, one methoxyl, and three sharp one-proton singlets attributable to an aldehyde function and either two hydroxyls or one hydroxyl and one carboxyl. The assumption of the presence of at least one aldehyde group is consistent with the PD+ reaction as well as the presence, in the ir spectrum (in CCl_4), of an absorption at ν 1647 cm^{-1} (H-bonded aromatic aldehyde C=O). An *ortho* hydroxyaldehyde grouping would also account for the solubility in sodium bicarbonate solution which is normally indicative of carboxylic acids. Short methylation of physciosporin with diazomethane resulted in the formation of a product, **4**, which was completely insoluble in sodium bicarbonate solution and gave an extra methoxyl signal in the ^{1}Hmr spectrum at δ 3.95, replacing the OH singlet at δ 12.81 observed in the ^{1}Hmr spectrum of physciosporin. High resolution mass spectrometry showed that this derivative, $C_{20}H_{17}ClO_8$, no longer had the chlorinated fragments at *m/e* 211 (corresponding to $C_9H_4ClO_4$) and 213 (corresponding to $C_9H_6ClO_4$) obtained from physciosporin, but a fragment at *m/e* 227 corresponding to $C_{10}H_8ClO_4$. On the other hand, the non-chlorinated fragment at *m/e* 194 (corresponding to $C_{10}H_{10}O_4$) was the same as in the parent

compound. Significantly, the biphenylether **3** obtained by cleavage of the depsidone bond gave molecular and daughter ions corresponding to $C_{19}H_{17}ClO_9$ and $C_{18}H_{17}ClO_7$ ($M - 44$), respectively, together with the chlorinated fragment ions found in the spectrum of physciosporin and a nonchlorinated fragment at *m/e* 212 (corresponding to $C_{10}H_{12}O_5$). The smaller ions may be interpreted as shown in Fig. 1*a–e* or as isomers thereof. The *m/e* 211 and 213 ions resemble those found in the mass spectrum of pannarin, **5** (3), a closely related monochlorodepsidone known from species of *Pannaria*, *Bombyliospora* and *Lecanora* (4, 5). Ions *a–c* would thus be derived from ring A and ion radicals *d* and *e* from ring B of a depsidone, clearly accounting for all functional groups implied by the spectral data and in particular ruling out the presence of a free carboxyl group in ring B. The observation of a loss of 32 mass units from the molecular ion of physciosporin supports a carboxymethyl substituent adjacent to a free hydroxyl and/or methyl group (6), and the relatively strong ion at *m/e* 44 (CO_2, 9% of the base peak) must then arise by fragmentation from the depside linkage. The biogenetically correct position of the phenolic hydroxyl in ring B of physciosporin follows from the positive calcium hypochlorite reaction of the saponified product in which the hydroxyl group must be located *meta* to that liberated from the ester bond (7). Typical absorption for an intramolecularly hydrogen-bonded ester function at 1665 cm^{-1} in the ir spectrum (in CCl_4) provides supporting evidence for the proposed locations of substituents on ring B.

On the basis of the above evidence, as well as on biogenetic grounds, physciosporin was likely to possess structure **1**. All presently known monochloro derivatives of naturally occurring depsides and depsidones (3, 5) have the chlorine in position 5 of ring A. However, alternative structures are possible, such as the 3-chloro, 5-formyl isomer, **6**.

Catalytic hydrogenation of physciosporin using platinum oxide as a catalyst and tetrahydrofuran as a solvent yielded hypophysciosporin, **7** or isomer, as the main product, as well as small amounts of the corresponding alcohol intermediate dihydrophysciosporin, **8** or isomer, and of deschlorohypophysciosporin, **9** or isomer. Hypophysciosporin was quantitatively converted to deschlorohypophysciosporin by hydrogenolysis using 10% palladized charcoal as a catalyst, triethylamine to neutralize the hydrochloric acid

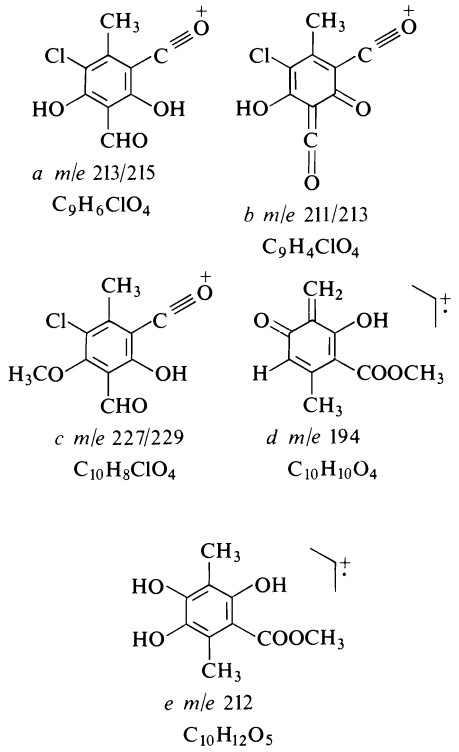

FIG. 1. Composition of important ions in the electron impact mass spectrum of physciosporin.

formed, and methanol as a solvent. The correct structure of deschlorohypophysciosporin was established by comparison with methyl hypoprotocetrarate, **9**, prepared by methylation of naturally occurring hypoprotocetraric acid, **10**, according to Culberson (8), by catalytic hydrogenation and subsequent methylation of fumarprotocetraric acid, **11**, isolated from *Cladonia rangiferina*, as well as by catalytic hydrogenation of the methylester of virensic acid, **12** (9). The physical data of all of these reduction products were in close agreement with each other and they all gave identical 4-*O*-methyl derivatives, **13**, and permethyl derivatives, **14**. The latter showed no depression of their melting points when mixed. Furthermore, the structure of naturally occurring 4-*O*-methylhypoprotocetraric acid, **15**, has recently been verified by synthesis (10) and shown to yield the methylester **13** (11). A comparison of 4-*O*-methyldeschlorohypophysciosporin with the methylester prepared from synthetic 4-*O*-methylhypoprotocetraric acid revealed their identity on the basis of an undepressed mixture mp and ^{1}Hmr spectroscopical data.

The conversion of physciosporin to the tetramethyl depsidone **9** confirmed a regular β-orcinol type of substitution pattern for rings A and B of physciosporin and fixed the chlorine and hydroxyl groups of ring A at the C-5 and C-4 positions, respectively. As a consequence, the intramolecularly hydrogen-bonded aldehyde group had to be placed on C-3 as usual. This assignment accounts for the loss of hydrogen bonding of the aldehyde C=O upon methylation of the C-4 hydroxyl group (ν_{max} for KBr 1700 cm^{-1} in **4** instead of 1648 cm^{-1} in **1**) and was substantiated by ^{1}Hmr studies as follows. Seven-bond spin–spin coupling between the two methyl groups (δ 2.28, 2.58) on ring B of **1** was visible in the ^{1}Hmr spectrum and confirmed by spin-decoupling experiments. Irradiation of the signal at δ 2.58 resulted in a nuclear Overhauser enhancement (25%) of the resonance for the hydrogen of the aldehyde group. This result requires that C-3 bears the aldehyde group, and permits the methyl groups at C-3′ (δ 2.28), C-6′ (δ 2.58), and C-6 (δ 2.60) to be assigned. Physciosporin is therefore firmly identified as methyl 5-chlorovirensate, **1**.

Experimental

Infrared (ir) spectra were recorded on a Perkin-Elmer model 521 spectrometer, ultraviolet (uv) spectra on a Unicam SP 8000 instrument, nmr spectra on a Varian HA-100D nmr spectrometer and mass spectra on a DuPont 21-491 or (for high resolution work) DuPont 21-110 B spectrometer. Chemical shifts are reported downfield from tetramethylsilane used as an internal standard. Precise mass measurements were obtained by the peak matching method using a suitable ion in the spectrum of perfluorokerosene as a standard. For chromatography, silicic acid (Mallinckrodt) and silica gel (Merck 60 F-254 plates) were used.

Methyl 2-Chloro-4-formyl-3,8-dihydroxy-1,6,9-trimethyl-11-oxo-11H-dibenzo[b,e][1,4]dioxepin-7-carboxylate (1, Physciosporin)

Thalli of *Pseudocyphellaria physciospora* were selected that contained a bright greenish yellow fluorescent, PD+ orange constituent. These (21 g, air dry) were extracted exhaustively with benzene. The benzene solution was chromatographed on silicic acid. The main crystalline fraction eluted with benzene (1.12 g or 5.3%) was recrystallized from chloroform–ether and acetone–ether to give fluffy colorless needles, mp 201–202°C; λ_{max}(dioxane) 248 (log ε 4.52), 323 (log ε 3.75), 351 (sh) nm, λ_{min} 229, 296 nm; ν_{max}(KBr) 2994w (br, OH), 2956w and 2929w (CH), 2850 sh(CHO?), 1739 (depsidone C=O), 1658 (H-bonded ester C=O), 1648 (H-bonded aldehyde C=O) cm^{-1}; ν_{max}($CHCl_3$) 1739, 1655 sh, 1643 cm^{-1}; ν_{max}(CCl_4) 1748, 1665 sh, 1647 cm^{-1}; δ ($CDCl_3$) 2.28, 2.58 and 2.60 (3 aromatic CH_3), 3.97 (1 $COOCH_3$), 10.73 (1 CHO), 11.41 and 12.81 (2 OH); *m/e* 408 (M^+, 34%), 406 (M^+, 100, found 406.0448, calcd. for $C_{19}H_{15}{}^{35}ClO_8$ 406.0456), 376(15), 374(40), 348(24), 346(73, found 346.0242, calcd. for $C_{17}H_{11}{}^{35}ClO_6$ 346.0245), 321(10), 319(29, found 319.0003, calcd. for $C_{15}H_8{}^{35}ClO_6$ 319.0010), 308(13),

*Methyl 2-Chloro-4-formyl-8-hydroxy-3-methoxy-1,6,9-trimethyl-11-oxo-11H-dibenzo[b,e][1,4]dioxepin-7-carboxylate (**4**, 4-O-Methylphysciosporin)*

Physciosporin (180 mg) was dissolved in acetone and treated with ethereal CH_2N_2 for 1 min. Excess reagent was destroyed by the addition of a few drops of acetic acid, and concentration of the solvent afforded a massive crystalline precipitate which was filtered off and washed with a minimum of ice-cold acetone to give **4** (100 mg), mp 242–243°C. Further purification via column chromatography raised the mp to 244°C (with slight decomposition); ν_{max}(KBr) 3010w, 2955m, 2880w and 2860w (CH), 1732 (depsidone C=O), 1700 (non-bonded aldehyde C=O), 1671 (H-bonded ester C=O) cm^{-1}; δ ($CDCl_3$) 2.25, 2.50 and 2.57 (3 aromatic CH_3), 3.95 and 3.97 (2 OCH_3), 10.64 (1 CHO, non-bonded), 11.45 (1 OH); *m/e* 422(M^+, 34%), 420(M^+, 100), 390(19), 388(43), 362(28), 361(20), 360(79), 335(11), 333(27), 322(14), 320(43), 308(16), 306(50), 229(5), 227(16, *anal.* calcd. for $C_{10}H_8{}^{35}ClO_4$: 227.0112; found 227.0111), 225(8), 194(33), 83(36), 67(22), 44(16), 28(24). *Anal.* calcd. for $C_{20}H_{17}ClO_8$ (mw 420.81): C 57.09, H 4.07, Cl 8.43, O 30.42; found C 56.84, H 4.11, Cl 8.69, O 29.85.

*3-Chloro-5-formyl-4-hydroxy-2-methyl-6-(3′-carbomethoxy-4′,6′-dihydroxy-2′,5′-dimethyl)phenoxybenzoic Acid (**3**, Saponified Physciosporin)*

When the ether extract from 5 g lichen was carefully fractionated into sodium bicarbonate, sodium carbonate, and neutral fractions as usual (2), physciosporin was isolated from the sodium bicarbonate fraction via column chromatography although only in poor yield (25 mg or 0.5% of the air-dry lichen). The sodium carbonate fraction consisted of 240 mg **3** which formed a very slow moving band on columns as compared to physciosporin. The same compound was obtained in quantitative yield by treatment of pure physciosporin with 5% aqueous solutions of either sodium carbonate or sodium hydroxide at room temperature for 10 min, followed by acidification. It was recrystallized from chloroform, mp 225°C dec. (with foaming); ν_{max}(KBr) 3471s (non-bonded OH), 3135 (br, COOH), 3075w, 3005w, and 2955m (CH), 2850sh (CHO?), 1724 (non-bonded carboxyl C=O), 1656sh (H-bonded ester C=O), 1643 (H-bonded aldehyde C=O) cm^{-1}; δ (THF-d_8) 2.03, 2.30 and 2.32 (3 aromatic CH_3), 3.87 (1 $COOCH_3$), 8.87 (br, 1 non-bonded OH), 10.43 (1 CHO), 11.83 and 12.63 (2 OH), COOH not found; *m/e* 426(M^+, 2%), 424(M^+, 6, found 424.0567, calcd. for $C_{19}H_{17}{}^{35}ClO_9$ 424.0561), 408(4), 406(11), 394(2), 392(4), 382(11), 380(30, found 380.0665, calcd. for $C_{18}H_{17}{}^{35}ClO_7$ 380.0662), 376(7), 374(20), 351(8), 350(26), 349(20), 348(64), 346(31), 321(9), 319(18), 308(5), 306(15), 294(9), 292(23), 215(4), 213(11, found 212.9954, calcd. for $C_9H_6{}^{35}ClO_4$ 212.9955), 212(12, found 212.0684, calcd. for $C_{10}H_{12}O_5$ 212.0685), 211(9), 194(9), 186(29), 185(39), 184(26), 180(26), 165(37), 164(36), 136(24), 85(51), 83(83), 77(34), 67(63), 51(36), 44(100), 43(29), 39(36), 32(16), 31(64), 29(26), 28(33).

*Methyl 3-Chloro-5-formyl-4-hydroxy-2-methyl-6-(3′-carbomethoxy-4′,6′-dihydroxy-2′,5′-dimethyl)phenoxybenzoate (**2**)*

Short treatment of saponified physciosporin, **3** (384 mg), with ethereal CH_2N_2 in acetone (1 min at room

temperature) gave a mixture of products which was separated over silicic acid. From the first fraction eluted with chloroform, **2** (115 mg) was obtained as colorless needles after two recrystallizations from ether, mp 226–227°C dec. (melt dark brown;[4] ν_{max}(KBr) 3280 (br, non-bonded OH), 2950w, 2846 sh, 1708 (non-bonded ester C=O), 1650 sh (H-bonded ester C=O), 1638 (H-bonded aldehyde C=O) cm^{-1}; δ ($CDCl_3$) 2.16, 2.28 and 2.31 (3 aromatic CH_3), 3.45 and 3.93 (2 $COOCH_3$), 6.44 (1 OH, non-bonded), 10.35 (1 CHO), 11.73 and 12.68 (2 OH, bonded); *m/e* 440(M^+, 7%), 438(M^+, 18), 408(15), 406(35), 348(41), 346(100). *Anal.* calcd. for $C_{20}H_{19}ClO_9$ (mw 438.82): C 54.74, H 4.36, Cl 8.08, O 32.81; found C 54.94, H 4.56, Cl 8.02, O 32.79.

The main fraction from this methylation (236 mg, mp 162.5–163°C) has not been fully characterized yet and will be reported elsewhere.

The methyl ester **2** was also formed upon methanolysis of physciosporin. The latter (100 mg) was suspended in 10% methanolic potassium hydroxide (50 ml) and stirred with heating for 30 min. The solution obtained was poured into ice-cold 10% hydrochloric acid (100 ml). The crude crystalline product was filtered off and dissolved in ether, which was shaken with a cold 5% sodium bicarbonate solution and then with dilute hydrochloric acid. Evaporation of the ether and purification by column chromatography gave creamy yellow needles (35 mg) from chloroform, mp 207°C (melt initially yellow, needles formed after cooling melted at 221–223°C with decomposition). Two recrystallizations from ether afforded a colorless product, mp 226–227°C dec. (melt dark brown).[4] Infrared, nmr, and mass spectral data were in good agreement with those of **2** prepared via saponified physciosporin (mixture mp undepressed).

Catalytic Hydrogenation of Physciosporin

Physciosporin (137 mg) was dissolved in tetrahydrofuran (300 ml) and the solution stirred for 5 h in a hydrogen atmosphere in the presence of platinum oxide (50 mg). After removal of the catalyst and evaporation of the solvent, the mixture of products was applied to a short (10 cm) silicic acid column packed in chloroform. Elution with chloroform gave the following fractions in the order mentioned: starting material, hypophysciosporin, **7** (incompletely separated from the former), and several constituents that moved slowly as a glossy band. The mixture of physciosporin and hypophysciosporin was fully resolved by rechromatography on a longer column (30 cm), yielding a total of 25 mg and 53 mg, respectively. The constituents from the glossy band were separated by preparative tlc in benzene – dioxane – acetic acid 90:25:1. Three bands were formed as detected by ultraviolet light (2200 Å). They were scraped off and eluted with acetone. After evaporation of the filtrates, the residues were redissolved in chloroform. The solutions thus obtained were washed with water, dried over anhydrous sodium sulphate, and passed through beds of silicic acid. The tlc eluate from the upper band thus purified gave 4 mg of an unidentified material, that from the middle band 9 mg deschlorohypophysciosporin, **9**, and that from the lower band 22 mg dihydrophysciosporin, **8**.

[4]One recrystallization of highly purified **2** from boiling chloroform gave the lower mp (207°C without decomposition) due to the formation of traces of a yellowish decomposition product not detectable in the nmr spectrum and preferentially soluble in ether. Mass spectrometry of the ether mother liquor gave ions at *m/e* 404 and 372 in addition to those obtained from highly purified **2**.

*Methyl 2-Chloro-3,8-dihydroxy-1,4,6,9-tetramethyl-11-oxo-11H-dibenzo[b,e][1,4]dioxepin-7-carboxylate (**7**, Hypophysciosporin)*

Colorless crystals were obtained from chloroform and washed with ether, mp 240–241°C dec.; ν_{max}(KBr) 3413s (OH), 2954w, and 2925w (CH), 1721 (depsidone C=O), 1656 (H-bonded ester C=O) cm^{-1}; δ (acetone-d_6, assignments on the basis of decoupling experiments) 2.20 (1 aromatic CH_3, ring B), 2.45 (2 aromatic CH_3, both on ring A), 2.68 (1 aromatic CH_3, ring B) 4.01 (1 $COOCH_3$), hydroxyl protons not found; *m/e* 394(M^+, 21%), 392(M^+, 56), 362(24), 360(59), 335(10), 334(40), 333(28), 332(98), 307(22), 306(24), 305(61), 304(43), 294(21), 292(65), 280(26), 279(23), 278(74), 277(30), 276(37), 267(11), 265(25), 199(17, ring A fragment), 198(11), 194(40, ring B fragment), 170(11), 166(35), 91(22), 89(20), 83(100), 77(31), 67(61), 65(24), 63(24), 55(25), 51(28), 44(18), 43(27), 39(41), 28(47). *Anal.* calcd. for $C_{19}H_{17}ClO_7$ (mw 392.80): C 58.10, H 4.36, Cl 9.03, O 28.51; found C 57.90, H 4.50, Cl 9.04, O 28.84.

Hydrogenolysis of Hypophysciosporin

Hypophysciosporin, **7** (39.2 mg or 0.1 mmol) was dissolved in methanol (150 ml). 10% Palladized charcoal (40 mg) was added and an excess of triethylamine (2 equiv. or 28 μl) for neutralization of the hydrochloric acid to be formed. The reaction mixture was stirred for 5 h in an atmosphere of hydrogen. The catalyst was filtered off and washed with methanol, and the combined filtrates were taken down to dryness. The residue was recrystallized from chloroform to give deschlorohypophysciosporin, **9** (30 mg).

*Methyl 3,8-Dihydroxy-1,4,6,9-tetramethyl-11-oxo-11H-dibenzo[b,e][1,4]dioxepin-7-carboxylate (**9**, Deschlorohypophysciosporin)*

The compound isolated from among the products of catalytic hydrogenation of physciosporin and the hydrogenolysis product from hypophysciosporin gave identical physical data; mp 264–265°C dec. (melt dark reddish brown); ν_{max}(KBr) 3346s (OH), 2958w and 2926w (CH), 1703 (depsidone C=O), 1663 (H-bonded ester C=O) cm^{-1}; δ (acetone-d_6, assignments by decoupling experiments) 2.19 (1 aromatic CH_3, ring B), 2.35 (2 aromatic CH_3, both on ring A), 2.67 (1 aromatic CH_3, ring B), 3.98 (1 $COOCH_3$), 6.70 (1 aromatic H), hydroxyl protons not found; δ (THF-d_8) 2.18, 2.31, 2.35 and 2.65 (4 aromatic CH_3), 3.92 (1 $COOCH_3$), 6.45 (1 aromatic H), hydroxyl protons not found; *m/e* 358(M^+, 57%), 326(53), 298(100), 271(53), 270(41), 258(56), 244(62), 243(37), 242(38), 231(33), 194(19), 149(34), 91(39), 83(63), 67(39), 44(9), 43(21), 39(38), 28(30).

*Methyl 2-Chloro-3,8-dihydroxy-4-hydroxymethyl-1,6,9-trimethyl-11-oxo-11H-dibenzo[b,e][1,4]dioxepin-7-carboxylate (**8**, Dihydrophysciosporin)*

Colorless crystals were obtained from chloroform and washed with *n*-hexane, mp 181–182°C; ν_{max}(KBr) 3200 (OH), 2958w and 2830 (CH), 1700 (depsidone C=O), 1664 (H-bonded ester C=O) cm^{-1}; δ ($CDCl_3$, assignments based on decoupling experiments and similar derivatives) 2.25 (C-3′ methyl), 2.50 (C-6 methyl), 2.64 (C-6′ methyl), 3.95 (1 $COOCH_3$), 4.48 (br, 1 OH, non-

bonded), 5.14 (2H, CH_2OH), 7.51 (1H, CH_2OH), 11.42 (1 OH, bonded); *m/e* 408(M − 2, 6%), 406(M − 2, 15), 394(M − 16, 6), 392(M − 16, 13), 348(8), 346(18), 334(12), 332(29), 308(6), 307(7), 306(15), 305(15), 294(9), 292(27), 280(7), 278(20), 194(16), 44(41), 38(57), 36(100), 32(19), 31(28), 28(37). *Anal.* calcd. for $C_{19}H_{17}ClO_8$ (mw 408.80): C 55.83, H 4.19; found C 55.34, H 4.36.

Methylation of Deschlorohypophysciosporin

Deschlorohypophysciosporin, **9** (30 mg), in acetone was treated with ethereal CH_2N_2 for 10 h. After evaporation of the solvent, the residue was taken up in chloroform and passed through a column of silicic acid. The 4-*O*-methyl derivative **13** (10 mg) was eluted first and then the fully methylated product **14** (21 mg).

*Methyl 8-Hydroxy-3-methoxy-1,4,6,9-tetramethyl-11-oxo-11H-dibenzo[b,e][1,4]dioxepin-7-carboxylate (**13**, 4-O-Methyldeschlorohypophysciosporin)*

The crystals obtained from chloroform were washed with a minimum of ether–*n*-hexane, mp 211–213°C, and recrystallized from benzene, mp 219°C, mixture mp with synthetic methyl 4-*O*-methylhypoprotocetrarate (mp 219°C) undepressed; ν_{max}(KBr) 2960 sh, 2927m and 2852w (CH), 1742 (depsidone C=O), 1656 (H-bonded ester C=O) cm^{-1}; δ ($CDCl_3$, assignments on the basis of decoupling experiments) 2.25 (C-3′ methyl), 2.32 (C-3 methyl), 2.49 (C-6 methyl), 2.65 (C-6′ methyl), 3.84 (1 OCH_3), 3.94 (1 $COOCH_3$), 6.56 (1 aromatic H), 11.42 (1 OH, bonded); *m/e* 372(M^+, 48%), 340(47), 312(100).

*Methyl 3,8-Dimethoxy-1,4,6,9-tetramethyl-11-oxo-11H-dibenzo[b,e][1,4]dioxepin-7-carboxylate (**14**, Fully Methylated Deschlorohypophysciosporin)*

The crystals obtained from chloroform were washed with a minimum of ether–*n*-hexane, mp 140–142°C (needle form, lit (8) mp 144–145°C), and recrystallized from methanol, mp 171–172°C (rhombic plate form, lit (8) mp 172–173°C), mixture mp with fully methylated hypoprotocetraric acid (mp 171–172°C) prepared from virensic acid as well as from fumarprotocetraric acid (9) undepressed; ν_{max}(KBr) 3000w, 2980w, 2960m, 2935m, and 2851w (CH), 1740s (depsidone C=O) and 1730s (non-bonded ester C=O), 1671w, 1612 cm^{-1}; δ ($CDCl_3$) 2.29, 2.31, 2.38, and 2.50 (4 aromatic CH_3), 3.74, 3.86, and 3.91 (3 OCH_3), 6.58 (1 aromatic H); *m/e* 386(M^+, 56%), 358(67), 180(100).

Acknowledgments

We are greatly indebted to Dr. Margareta DuRietz for the generous donation of the lichen, and to Dr. Chicita Culberson and Dr. John A. Elix for gifts of hypoprotocetraric acid, isolated from *Ramalina hypoprotocetrarica*, and synthetic 4-*O*-methylhypoprotocetraric acid, respectively. The spectral data were obtained through Messrs D. Embree, G. McCully, and J. Van Ingen.

Photoisomerization of some bicyclooctanones in solution

SUSAN C. CRITCH[1] AND ALEX G. FALLIS

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1C 5S7

Received November 24, 1976

SUSAN C. CRITCH and ALEX G. FALLIS. Can. J. Chem. **55**, 2845 (1977).

The ketene derived products and unsaturated aldehydes produced upon solution photolysis of a series of bicyclooctanones (bicyclo[2.2.2]octan-2-one (**1**), bicyclo[3.2.1]octan-2-one (**6**), 1,8,8-trimethylbicyclo[3.2.1]octan-2-one (**12**)) are reported. Estimated strain energies of the approximate transition states involved and conformational analysis are utilized as guides to rationalize the results. This approach should assist more accurate predictions of photolysis products from related systems in the same solvent(s). The product ratios are solvent sensitive and preliminary experiments indicate that a primary amine (cyclohexylamine) in the photolysis solution enhances the production of ketene derived product.

SUSAN C. CRITCH et ALEX G. FALLIS. Can. J. Chem. **55**, 2845 (1977).

On rapporte les produits dérivés de cétènes et les aldéhydes non-saturés qui sont formés par photolyse en solution d'une série de bicyclooctanones (bicyclo[2.2.2]octanone-2 (**1**), bicyclo-[3.2.1]octanone-2 (**6**) et triméthyl-1,8,8 bicyclo[3.2.1]octanone-2 (**12**)). On utilise les énergies de tension estimées des états de transition approximatifs impliqués et l'analyse conformationnelle comme guide pour rationaliser les résultats. Cette approche devrait permettre de meilleures prédictions concernant les produits de photolyse de systèmes qui sont reliés dans les mêmes solvants. Les rapports de produits sont très sensibles aux solvants et des expériences préliminaires indiquent qu'une amine primaire (cyclohexylamine) dans des photolyses en solution augmente la production de produit dérivé de cétène.

[Traduit par le journal]

Introduction

The photochemical reactions of saturated cyclic ketones in solution have been studied extensively (for pertinent reviews see ref. 1), nevertheless many facets are still imperfectly understood, and as Chapman and Weiss have pointed out "the factors determining the relative yields of aldehyde to ester are ... subtle (and) small changes in molecular structure ... cause drastic alterations in product ratios" (2). Thus, due in part to the difficulty of predicting product ratios accurately, the use of simple, photoinduced cleavage reactions of cycloalkanones in organic synthesis has been limited.

It is well established that photochemical α-cleavage (Norrish type I) of most cyclic ketones affords discrete acyl-alkyl diradicals (3) which partition themselves between three major pathways: (*i*) disproportionation to yield alkenal(s), (*ii*) disproportionation to yield ketene, and (*iii*) recoupling to yield ground state ketone. The relative importance of recombination (ring closure) *vs.* hydrogen abstraction is influenced by radical stability and the ease of formation of the transition states required for hydrogen transfer. Thus substituents and conformational preferences exert a significant influence on the product distribution. This product ratio is also sensitive to solvent and these effects may alter conformational factors. The study of relatively rigid bridged-ring ketones facilitates a better understanding of the conformational factors which influence aldehyde and ketene formation (4). We report herein a study of the product distributions upon photolysis of bicyclo[2.2.2]octan-2-one (**1**), bicyclo[3.2.1]octan-2-one (**6**), and 1,8,8-trimethylbicyclo[3.2.1]octan-2-one (**12**, homocamphor) in methanol and tetrahydrofuran–water solutions. Since completion of this study investigations of closely related systems have been published. Agosta and Wolff (5) have utilized a series of bicyclo[3.2.1]octan-6-ones and Hammond and Yeung (6) have examined a deuterated bicyclo[2.2.2]octan-2-one.

Results

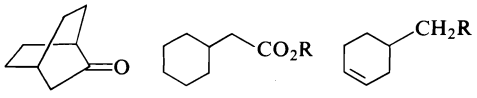
Photolysis of *endo*-5,6-dideuteriobicyclo-[2.2.2]octane-2-one in benzene containing added methanol was recently reported (6) to afford the aldehyde as the only isolated product, while under similar conditions (benzene containing 3.5% methanol) others (5) detected both ester **2**

[1]Taken in part from the M.Sc. Thesis of S. C. Critch, Memorial University of Newfoundland, 1975.

TABLE 1. Relative product formation on the photolysis of **1**, **6**, and **12**

Ketone	Solvent	Relative yields		
		Aldehyde		Ketene
1 	MeOH	4		1
	$THF-H_2O$	10		1
		syn-8	*endo-7*	
6 	MeOH	7	2	1
	$THF-H_2O$	8	2	1
12 	MeOH		4	1
	$THF-H_2O$		30	1

and aldehyde **4** upon photolysis of bicyclo[2.2.2]-octan-2-one (**1**). Under our conditions using either methanol or tetrahydrofuran–water, both the ketene derived product **2** (7) or **3** (8) and the unsaturated aldehyde **4** (9) were produced. Irradiation of **1** in methanol afforded the aldehyde **4** and ester **2** in a 4:1 ratio. The structure of the aldehyde was confirmed by silver oxide oxidation to 3-cyclohexenylacetic acid (**5**), a sample of which was prepared by homologation of 3-cyclo-

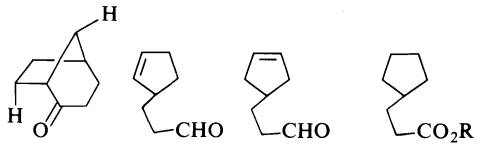


1 **2** R = CH_3, **3** R = H, **4** R = CHO, **5** R = CO_2H

hexenylcarboxylic acid (10).[2] It may be seen from Table 1 that photolysis of **1** in tetrahydrofuran–water (1:1) afforded an aldehyde–acid (**4**:**3**) ratio of 10:1.

Irradiation of a 0.1 *M* methanol solution of bicyclo[3.2.1]octan-2-one (**6**) gave a mixture, shown by glc analysis to contain three components in a ratio of 7:2:1 (8:2:1 in $THF-H_2O$) which were separated by preparative glc. The ^{1}Hmr spectrum of the major component (an aldehyde) possessed a triplet (J = 2 Hz) at δ 9.74 due to an aldehydic proton adjacent to a methylene group and a multiplet representing two protons at δ 5.63 indicating the presence of two vinyl hydrogens.

The second component displayed similar ^{1}Hmr characteristics, a triplet at δ 9.75 and a signal at δ 5.55 suggesting two equivalent vinyl protons in a symmetrical environment. Thus



6 **7** **8** **9** R = H, **10** R = CH_3

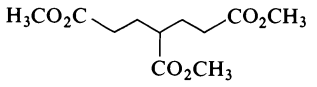
tentatively the major aldehyde can be assigned structure **7** and the second component structure **8** (9). Silver oxide oxidation of **7** followed by hydrogenation (5% Pd/C) provided 3-cyclopentylpropionic acid (**9**) (11). This was repeated on a mixture of **7** and **8** and confirmed that these photoproducts were cyclopentene isomers arising from the same mode of α-cleavage. The minor component from the photolysis mixture was identified as the methyl ester **10** (12).

The exact position of the double bond in the aldehyde isomers, to prove which hydrogen was abstracted preferentially after α-cleavage, was established as follows. The benzene induced solvent shifts indicate that the vinyl hydrogens of **8** are in a symmetrical environment and also experience less shielding than those in **7** due to their greater separation from the carbonyl function. Additional support for the non-identity of the olefinic hydrogens in **7** was provided by the ^{1}Hmr spectrum recorded in the presence of a molar equivalent of $Eu(fod)_3$.

Ozonolysis of **7** followed by oxidative work-up

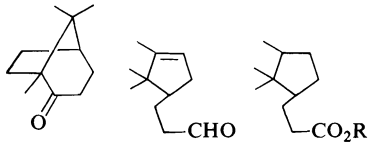
[2]We are grateful to E. R. Benson for preparing this sample.

(30% H_2O_2) and *in situ* methylation with diazomethane provided the ester **11** (13) which was identified by comparison with an authentic sample prepared from pentane-1,3,5-tricarboxylic acid (13), confirming the structural assignment.



11

Prior to this work the only photochemical study of a bicyclo[3.2.1]octan-2-one was that of homocamphor (**12**) (14). Irradiation of homocamphor in diethyl ether containing cyclohexylamine had afforded only the ketene derived product (as the amide) and no aldehyde was detected. Based on the results above one would anticipate that the aldehyde **13** should be the major product upon photolysis of homocamphor in methanol. We have found this to be the case.



12 **13** **14** R = CH_3
15 R = H

The ^{1}Hmr spectrum of the total photolysis mixture contained a triplet at δ 9.67 ($J \sim 1.5$ Hz) due to the aldehydic proton and a singlet at δ 3.60 due to the methoxyl function. Integration of these signals indicated an aldehyde–ester ratio (**13**:**14**) of 4:1. As in the previous cases the THF–H_2O solvent system resulted in an enhancement of the aldehyde–ketene ratio (30:1). In view of these results it is surprising that in the earlier photolytic study of homocamphor in diethyl ether – cyclohexylamine no aldehyde was encountered (14). This solvent effect is very marked, for no aldehyde was detected when the photolysis was repeated under Quinkert's conditions nor was it present as the imine. In a preliminary study, with diethyl ether – cyclohexylamine, bicyclo[3.2.1]octan-2-one afforded an aldehyde–amide ratio of 1:1, and bicyclo[2.2.2]-octan-2-one, a ratio of 1:2. The aldehydes are partly converted to their imines as indicated by the ^{1}Hmr spectrum of the total crude photolysis mixture and could be freed by washing with aqueous acid. This solvent effect which enhances the production of ketene derived product (as the amides) should be of synthetic utility although further work is required and the exact role of amine is not clear at present.

Discussion

As expected, photolysis products arise from these ketones by cleavage of the bond between the carbonyl group and the bridgehead carbon to afford the most stable of the two possible acyl-alkyl diradicals. In these short lived 1,6-diradical systems the accurate prediction of their behaviour is difficult because of the multiple reaction pathways available. Their fate is also influenced by a variety of steric, conformational, and electronic factors. Nevertheless to rationalize the product distribution and to help improve the predictability and synthetic potential for photoinduced α-cleavage it is instructive to examine the conformational preferences of these intermediates. Chart 1 lists estimated 'strain energies' for the approximate transition states involved. Used in concert with steric considerations they provide a guide for predicting the major product from a given photolysis *in the same solvent system.*

For bicyclo[2.2.2]octan-2-one (**1**), as pointed out recently (5), neither product "can arise from the stable chair conformation of the biradical" since for hydrogen abstraction to be geometrically feasible the acyl side chain must be axial. The aldehyde **4** is the expected major product since α-cleavage releases the cyclohexane ring of **1** from its enforced boat conformation placing one of the geometrically equivalent *syn*-hydrogens in close proximity to the acyl radical for facile abstraction (**A**). The geometry of this system is clearly more easily achieved (less strained) than the competing transition state **B** for ketene formation which requires a boat cyclohexane incorporated into a bicyclo-octane-heptane type intermediate bearing an acyl substituent (Chart 1).

Similarly for bicyclo[3.2.1]octan-2-one it is apparent that the major aldehyde will arise from a hydrindanone type intermediate **C** which clearly involves less strain than either of the two competing pathways **D** and **E** (R = H). Cycloheptanones and bicyclo[3.3.1]nonan-3-one are known to be more stable than their parent hydrocarbons (1.5–3.4 kcal) (17). This feature increases the stability of **D** due to the presence of the carbonyl function while the axial acyl substituent in **E** introduces a destabilizing nonbonded interaction. In addition, the reduced freedom of the side chain increases the difficulty of approach to the

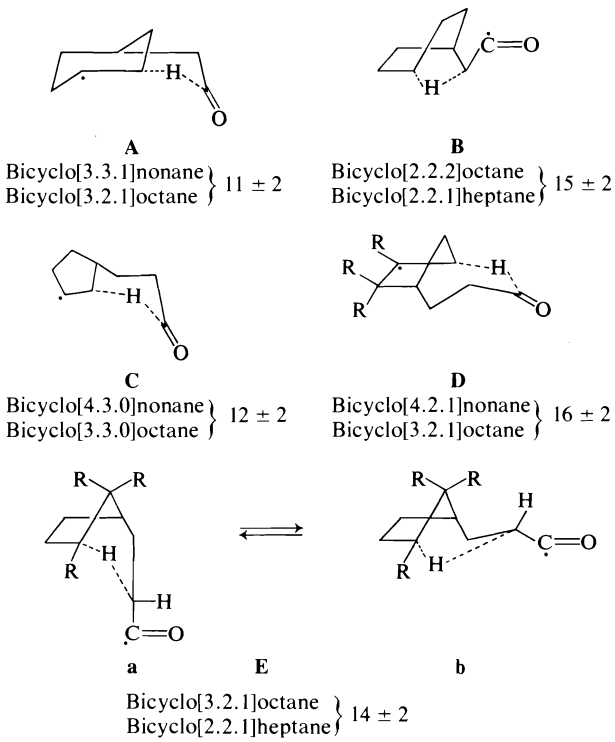


CHART 1. Estimated strain energies (kcal/mol); based on averages of hydrocarbon strain energies determined by Allinger (15), Schleyer (16), and their co-workers for the two bicyclic hydrocarbons being considered.

planar alkyl radical confined in the cyclopentane, and makes ketene formation more difficult. Indeed molecular models suggest that the required conformation is less easily achieved than diagram **E** implies. Thus in total these influences appear sufficient to tip the balance in favour of aldehyde formation via **D** over ketene formation via **E**.

Homocamphor (**12**) provides a measure of the direct competition between these aldehyde and ketene pathways. In this case also, product from **D** (R = CH_3) predominates, enhanced slightly by the *syn*-C_8 methyl function which introduces a further 1,3 interaction which appears more severe in **E** than **D**.

These considerations therefore account for the predominance of aldehydes over ketenes upon photolysis of these bicyclic ketones in methanol and THF–water solvents. The solvent plays a separate role from structure in radical disproportionations and generally the effects are poorly understood. It is possible that the amine solvates the acyl radical preferentially so that it is not able to abstract hydrogen as readily, permitting the ketene pathways to compete more efficiently. However as pointed out above, further work is required with simpler systems in order to fully understand this phenomenon. Bicyclo[5.2.1]decan-10-one may represent a previous example of this 'amine effect' (18).

A referee has recommended inclusion of a general conclusion to facilitate future predictions of major ketone photolysis products. There is at present insufficient data and understanding for predictions of this sort to be made with complete assurance. However based on this study and related examples in the literature (1–5) the following guidelines may be given for comparisons of photolyses of *bridged-ring ketones in the same solvent system*. The diradical intermediates will disproportionate preferentially by the lowest energy pathway consistent with the most geometrically feasible transition state for hydrogen abstraction. As a guide to determining the preferred conformation for the transition state it is useful to consider the approximate strain energy of the system, steric influences of substituents and their non-bonded interactions, the preferred orientation of the acyl radical side chain, and conformational equilibria. In addition the first

example of stereoelectronic control in a hydrogen transfer leading to aldehyde has recently been reported (19). This preference for abstraction of axial hydrogen adjacent to a radical centre may operate in other systems as well but its presence can only be ascertained at present by studying specifically deuterated ketones.

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus or with a Thomas–Hoover Uni-Melt apparatus and are uncorrected. Elemental microanalyses were performed by Alfred Bernhardt, West Germany.

Infrared spectra were recorded on a Perkin-Elmer 237B grating spectrometer, and were calibrated against the 2850 and 1601 cm^{-1} bands of polystyrene film. Nuclear magnetic resonance spectra were determined with a Varian model A-60, Varian model EM-360, or Varian model HA-100 spectrometer; band positions are reported in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra were recorded on a Hitachi–Perkin-Elmer model RMU-6E mass spectrometer at an ionization potential of 70 eV unless otherwise specified.

Gas–liquid chromatographic analyses were conducted on a Varian Aerograph model 1720 gas chromatograph using helium as the carrier gas. Column A refers to an 8 ft × ¼ in., 13% SE-30 column supported on Chromosorb W (AW-DMCS) (70–80 mesh); column B refers to a 8 ft × ¼ in., 20% Carbowax 20M column supported on Chromosorb W (AW-DMCS) (70–80 mesh).

Irradiations were carried out in stoppered Pyrex containers, using a water-cooled Hanovia 450-W medium pressure mercury arc lamp, on solutions (~0.01 *M*) which had been thoroughly flushed with nitrogen.

Solutions in organic solvents were dried over anhydrous magnesium sulphate and evaporated by means of a Büchi rotary evaporator under reduced pressure.

Bicyclo[2.2.2]octan-2-one (**1**) mp 177–178°C (lit. (20) mp 178.5–179°C) was prepared from bicyclo[2.2.2]oct-2-ene (Chem. Sample Co.) by hydroboration and oxidation with chromic acid (21).

*Photolysis of Bicyclo[2.2.2]octan-2-one (**1**)*

(i) In Methanol

A solution of bicyclo[2.2.2]octan-2-one (0.200 g, 0.0016 mol) in absolute methanol (20 ml), to which sodium bicarbonate (0.020 g) had been added, was irradiated for 4 h. After removal of the solvent and addition of petroleum ether, the solution was filtered and concentrated to afford a colourless oil (0.200 g, 100%). Gas–liquid chromatographic analysis indicated essentially complete reaction of the ketone. Comparison of aldehyde and methoxyl peaks of the nmr spectrum indicated an aldehyde–ester ratio of 4:1; ^{1}Hmr (CCl_4) δ 2.62 (s, 3H, OCH_3), 9.68 (t, $J \sim 2$ Hz, 1H, CHO) ppm.

A sample (0.167 g) from the methanol photolysis was added to a solution of silver nitrate (0.0170 g, 0.001 mol) and sodium hydroxide (0.080 g, 0.002 mol) in water (3 ml). After stirring at room temperature for 1.5 h, the solution was filtered, the residue washed several times with hot water, and the filtrate extracted with ether (twice). The combined organic extracts were washed with water, dried, filtered, and concentrated. The methyl ester **2** (7) was isolated as a colourless oil (0.045 g, 36%) which was purified by tlc on silica gel (5% ether – petroleum ether); ir (CCl_4): 1735 cm^{-1}; ^{1}Hmr (CCl_4): δ 3.60 (s, 3H, OCH_3) ppm.

The combined aqueous layers were acidified and extracted with ether to yield the unsaturated carboxylic acid **5** (0.075 g, 53.5%) which was purified by tlc on silica gel (30% ether – petroleum ether); ir (CCl_4): 3500–2400 (br OH), 1710 (C=O) cm^{-1}; ^{1}Hmr (CCl_4): δ 1.1–2.5 (complex), 5.57 (br s, 2H, CH=CH), 11.77 (br s, 1H, COOH) ppm. An authentic sample was prepared by Arndt–Eistert homologation of 3-cyclohexenyl carboxylic acid (10).

(ii) In Tetrahydrofuran–Water

A solution of bicyclo[2.2.2]octan-2-one (0.278 g, 0.0022 mol) in a 1:1 mixture of THF–water (22 ml) was irradiated for 7 h and extracted with ether (twice). The combined extracts were washed with aqueous 10% sodium bicarbonate solution (twice) and water, dried, filtered, and concentrated to provide the aldehyde **4** (0.243 g, 87.5%) (9) which was further purified by preparative glc (column B, 200°C); ir (CCl_4): 2700 (CHO), 1725 (C=O) cm^{-1}; ^{1}Hmr (CCl_4): 5.57 (br s, 2H, CH=CH), 9.63 (t, $J = 2$ Hz, 1H, CHO) ppm.

The combined aqueous layers were acidified and extracted with ether to yield 3-cyclohexylacetic acid (**3**) (0.013 g, 4.15%) (8) which was homogeneous by glc analysis (column A, 150°C); ir (CCl_4): 3500–2400 (br OH), 1705 (C=O) cm^{-1}; ^{1}Hmr (CCl_4): 5.60 (br s, 2H, CH=CH), 11.35 (br s, 1H, CO_2H) ppm. An authentic sample was prepared by the hydrogenation (5% Pd/C, EtOAc) of synthetic **5**. Treatment of **3** with ethereal diazomethane afforded the ester **2** (7).

*Photolysis of Bicyclo[3.2.1]octan-2-one (**6**)*

(i) In Methanol

A solution of bicyclo[3.2.1]octan-2-one (0.150 g, 0.0012 mol, Aldrich) in absolute methanol (13 ml), to which sodium bicarbonate (0.040 g) had been added, was irradiated for 6 h. After removal of the solvent, carbon tetrachloride was added and the solution filtered and concentrated to yield a colourless oil. Gas–liquid chromatographic analysis (column A, 140°C) revealed two major peaks in a ratio of 9:1. Analysis on column B allowed a resolution of the principal peak into two components in a ratio of 7:2 (**7**:**8**) which were separated by preparative glc (column B, 207°C). The major product **7** had the following spectral properties: ir (CCl_4): 2810 (CHO), 2705 (CHO), 1725 (C=O) cm^{-1}; ^{1}Hmr (CCl_4): δ 9.74 (t, $J = 2$ Hz, 1H CHO), 5.63 (m, 2H CH=CH); (benzene-d_6): 5.53 (m, 2H CH=CH), 9.25 (br s, 1H CHO); (CCl_4 + $Eu(fod)_3$ mol equiv.): δ 9.74 (t, $J = 6.5$ Hz, 2H), 6.68 (m, 1H), 6.43 (q, $J = 6.5$ Hz, 2H), 5.50 (m, 1H), 5.07 (br m, 1H), 4.10 (t, $J = 7$ Hz, 1H), 3.88 (d, $J = 6$ Hz) ppm. This material was further characterized as its semicarbazone derivative mp 126–126.5°C. *Anal.* calcd. for $C_9H_{15}ON_3$: C 59.63, H 8.35, N 23.19; found: C 59.65, H 8.16, N 23.37.

The minor aldehyde **8** (9), collected by preparative glc as a colourless oil, had the following spectral properties: ir (CCl_4): 1710 (CHO), 1725 (C=O) cm^{-1}; ^{1}Hmr (CCl_4): δ 9.75 (t, $J = 2$ Hz, 1H, CHO), 5.55 (s, 2H, CH=CH);

(benzene-d_6): 5.58 (br s, 2H, CH=CH), 9.70 (br s, 1H, CHO) ppm. The material was further characterized as its semicarbazone derivative mp 123–123.5°C. *Anal.* calcd. for $C_9H_{15}ON_3$: C 59.63, H 8.35, N 23.19; found: C 59.55, H 8.43, N 23.34.

Methyl 3-cyclopentylpropionate (**10**) (12) was also collected from the glc; ir (CCl_4): 1738 (C=O) cm^{-1}; ^{1}Hmr (CCl_4): δ 3.60 (s, 3H, OCH_3) ppm. An authentic sample was prepared from 3-cyclopentylpropionic acid (Aldrich) by esterification with ethereal diazomethane and purified by glc (column A, 140°C).

(ii) In Tetrahydrofuran–Water

A solution of bicyclo[3.2.1]octan-2-one (8.0 g, 0.064 mol) in a 1:1 mixture of THF–water (64 ml) was irradiated until glc analysis indicated the photolysis was 85% complete. The solution was extracted twice with diethyl ether and the combined organic layers washed with aqueous 10% sodium bicarbonate solution and water until the washings were neutral, dried, and concentrated to give a mixture of isomeric aldehydes, **7** and **8**, and starting ketone as a colourless oil (6.2 g, 78%). Gas–liquid chromatographic analysis indicated the aldehydes were present in a ratio of 8:2 (**7**:**8**).

The combined aqueous layers were acidified and extracted with ether to yield an acid (0.6 g, 7.5%) which was purified by preparative tlc on silica gel (30% ether – petroleum ether) and identified as 3-cyclopentylpropionic acid (11) by comparison with an authentic sample; ir (CCl_4): 3500–2400 (br OH), 1710 (C=O) cm^{-1}.

Silver Oxide Oxidation of Aldehyde 7

A cold (0°C) aqueous solution (5 ml) of silver nitrate (0.350 g, 0.002 mol) and sodium hydroxide (0.04 g, 0.01 mol) was added to a dioxane solution (5 ml) containing the aldehyde **7** (0.100 g, 8.1 mmol). The reaction was stirred for 24 h at room temperature, filtered, and the residue washed with hot water until these washings were neutral. The filtrate was extracted with ether, acidified with 6 *N* hydrochloric acid, and extracted with ether (twice). These latter extracts were combined, washed with water, dried, filtered, and concentrated. The oil so obtained was purified by tlc on silica gel (1% acetic acid – benzene) to give 2-cyclopenten-1-propionic acid, (0.091 g, 80%) (22); ir (CCl_4): 3400–2400 (br, OH), 1710 (C=O) cm^{-1}; ^{1}Hmr (CCl_4): 5.50 (m, 2H, CH=CH), 10.45 (br s, 1H, COOH) ppm.

Hydrogenation of this material (5% Pd/C, EtOAc) afforded 3-cyclopentylpropionic acid. The same result was obtained when the oxidation and reduction were conducted on a mixture of **7** and **8**.

*Ozonolysis and Methylation of 2-Cyclopenten-1-propionic Acid: Formation of Dimethyl 4-Carbomethoxyheptane-1,7-dioate (**11**)*

A methanol–dichloromethane solution (1:1) containing 2-cyclopenten-1-propionic acid (0.090 g, 6.5 mmol) was cooled to −78°C (solid CO_2 – acetone bath) and a stream of oxygen containing ozone (~6%) passed through the solution until it retained a blue colour. The reaction mixture was allowed to warm to room temperature, aqueous 30% hydrogen peroxide (0.5 ml) added, and the solution stirred for 12 h. An ethereal solution of diazomethane was then added at 0°C until the solution retained a yellow colour and the solvent was removed under reduced pressure. Water and ether were added and the ether extract washed with water, dried, filtered, and concentrated to give the triester (0.138 g, 86%) which was purified by preparative glc (column A, 150°C).

This material was identified as dimethyl 4-carbomethoxyheptane-1,7-dioate (**11**) (13) by comparison with an authentic sample prepared by treating 1,3,5-pentanetricarboxylic acid (Aldrich, recrystallized from CH_3CN, mp 112.5–113°C; lit. (13) mp 113–114°C) with ethereal diazomethane at 0°C; ir (CCl_4): 1740 cm^{-1}; ^{1}Hmr (CCl_4): δ 1.86 (br t, $J \sim 6.5$ Hz, 4H, CH_2-), 2.1–2.6 (m, 5H, α to C=O), 3.61 (s, 6H, CH_3O), 3.65 (s, 3H, CH_3O) ppm.

Similar ozonolysis of the mixture of cyclopentenylpropionic acids from **7** and **8** afforded a 7:1 mixture (glc, column A, 180°C) of two triesters and permitted identification of the minor component as dimethyl-3-(carbomethoxymethyl)pentane-1,5-dioate.

*Photolysis of 1,8,8-Trimethyl[3.2.1]octan-2-one (Homocamphor) (**12**)*

(i) In Methanol

A solution of homocamphor (0.055 g, 3.2 mmol) (**12**) in absolute methanol (3.5 ml) containing sodium bicarbonate (0.010 g) was irradiated for 7 h. After evaporation of the solvent and the addition of petroleum ether, the solution was filtered and concentrated to yield a colourless oil (0.054 g, 99%), shown by glc analysis (column A, 187°C) to be a mixture of two new components (ratio 4:1) in addition to **12** (~10%). The aldehyde–ester ratio of 4:1 was confirmed by the ^{1}Hmr spectrum (CCl_4): 3.60 (s, OCH_3), 9.67 (t, $J \sim 1.5$ Hz, CHO) ppm.

(ii) In Tetrahydrofuran–Water

A solution of homocamphor (0.035 g, 2 mmol) in 1:1 THF–water (2 ml) was irradiated for 4 h. Gas–liquid chromatographic analysis (column A, 185°C) indicated an aldehyde–acid ratio of 30:1. After extraction with diethyl ether (twice), the combined extracts were washed with aqueous 10% sodium bicarbonate solution (twice), then water until the washings were neutral. The extracts were then dried, filtered, and concentrated to afford a colourless oil (0.028 g, 80%), from which the aldehyde was separated by tlc on silica gel (10% ether–hexane); ir (CCl_4): 2710 (CHO), 1720 (C=O) cm^{-1}; ^{1}Hmr (CCl_4): δ 0.80 (s, 3H, CH_3), 1.00 (s, 3H, CH_3), 1.60 (br s, 3H, CH_3C=C), 5.16 (br s, 1H, CH=C), 9.67 (t, 1H, $J \sim 1.5$ Hz, CHO) ppm.

Acidification of the combined aqueous phases (6 *N* HCl) followed by extraction with ether, washing the combined extracts with water until the washings were neutral, drying, filtering, and concentrating provided the carboxylic acid **14** (0.008 g, 2.1%) (23) which was homogeneous by glc (column A, 150°C); ir (CCl_4): 3500–2400 (br, OH), 1712 (C=O) cm^{-1}.

*Isolation of (±)-Homocamphor (**12**)*

To a 1:1 mixture of (±)-homo- and (±)-homoepicamphor (1.01 g, 0.006 mol) obtained by ring expansion of (±)-camphorquinone (24) followed by reduction (24) was added aqueous semicarbazide hydrochloride solution (1.5 ml, 0.5 mol equiv.) and enough methanol (~3 ml) to produce a clear solution. After the addition of pyridine (0.38 ml, 0.005 mol), the mixture was heated gently on a steam bath for 10 min, cooled, and the semicarbazone filtered. The filtrate was acidified with 6 *N* hydrochloric acid, the layers separated, and the aqueous layer ex-

tracted with ether (twice). The combined organic extracts were washed with water until the washings were neutral, dried, filtered, and concentrated to afford a colourless oil which crystallized on the addition of a few drops of benzene. Purification of homocamphor was achieved by preparative glc (column A, 187°C) or by thin layer chromatography on silica gel (10% ether-hexane). The melting point of (±)-homocamphor was 178–179°C (sealed tube) (lit. (24) (−)-homocamphor mp 187–190°C);[3] ir (CCl_4): 1706 cm^{-1}; ^{1}Hmr (CCl_4): δ 0.79 (s, 3H, CH_3), 0.85 (s, 3H, CH_3), 0.88 (s, 3H, CH_3) ppm.

*Photolysis of Ketones **1** and **6** in Diethyl Ether – Cyclohexylamine*

Solutions (~0.3 *M*) of the individual ketones were prepared in diethyl ether – cyclohexylamine (20:1), flushed with nitrogen, and irradiated in Pyrex containers until glc analysis indicated 20–30% of the original ketone had reacted. (Prolonged irradiation altered the ratios, the aldehydes giving rise to a more volatile component, presumably oxetane(s), and the amide afforded nitrile.) The ether was removed under reduced pressure and the ^{1}Hmr spectra recorded, the imine hydrogens appearing as triplets $J \sim 5$ Hz at δ 7.50 and 7.49 for **1** and **6**, respectively. These samples were dissolved in chloroform, washed with dilute aqueous hydrochloric acid, dried, and the spectra rerecorded. The imine signals had disappeared and the characteristic triplets for the aldehydic protons were now present. Integration of these signals and the amide N-C-H signals indicated an aldehyde–amide ratio of 1:2 for **1** and 1:1 for **6**. The accuracy of this determination was compared with a synthetic mixture in the case of **6** prepared from the aldehydes **7** and **8** and authentic cyclohexylamide prepared below. The individual components from the photolyses were separated by tlc on silica gel (30% ether–hexane).

3-Cyclopentylpropionatecyclohexyl amide was prepared from 3-cyclopentylpropionic acid (Aldrich) via its acid chloride (thionyl chloride) and recrystallized from ethanol–water mp 99–101°C; ir ($CHCl_3$): 3425 (N—H), 3300 br (N—H), 1665 (C=O), 1515 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$): δ 3.73 (br complex, 1H, H-C-N), 5.48 (br, 1H, N-H) ppm.

Acknowledgments

We are grateful to Memorial University of Newfoundland and the National Research Council of Canada for financial support of this research, the Newfoundland Provincial Government for a fellowship (to S.C.C.), and the referees for their comments.

σ-Complexes as biophysical and biochemical probes. Part II.[1] Transformations of σ-complex intermediates from reaction of 4-nitrobenzofuroxan and methoxide ion

ERWIN BUNCEL, NOEMI CHUAQUI-OFFERMANNS, BRIAN K. HUNTER, AND ALBERT R. NORRIS

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received November 15, 1976

ERWIN BUNCEL, NOEMI CHUAQUI-OFFERMANNS, BRIAN K. HUNTER, and ALBERT R. NORRIS. Can. J. Chem. **55**, 2852 (1977).

Reaction of 4-nitrobenzofuroxan with methoxide ion in methanolic dimethyl sulphoxide solution gives rise to 7-hydroxy-4-nitrobenzofurazan (as the anion) and 7-methoxy-4-nitrobenzofurazan (as the methoxide C-7 adduct); the proposed reaction mechanism invokes the formation of several transient intermediates. The results bear on the postulated mechanism for the antileukemic activity of 4-nitrobenzofuroxan.

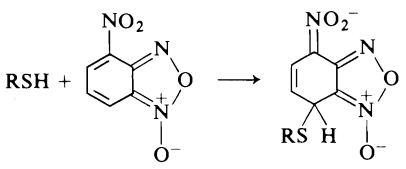
ERWIN BUNCEL, NOEMI CHUAQUI-OFFERMANNS, BRIAN K. HUNTER et ALBERT R. NORRIS. Can. J. Chem. **55**, 2852 (1977).

La réaction du nitro-4 benzofuroxanne avec l'ion méthylate dans une solution de diméthylsulfoxyde méthanolique conduit à l'hydroxy-7 nitro-4 benzofurazanne (sous forme d'anion) et au méthoxy-7 nitro-4 benzofurazanne (sous forme d'adduit méthylate en C-7); le mécanisme proposé pour la réaction implique la formation de plusieurs intermédiaires de courte durée de vie. Ces résultats ont des implications sur le mécanisme postulé pour l'activité antileucémique du nitro-4 benzofuroxanne.

[Traduit par le journal]

Introduction

The discovery (2) that certain benzofuroxan and benzofurazan derivatives act as powerful inhibitors of nucleic acid and protein biosynthesis in many types of animal cells has heightened interest in these classes of compounds (3–11). Especially noteworthy was the observation that 4-nitrobenzofuroxan exhibits a toxic effect on the metabolism of leukocites *in vitro* (3), suggesting the possibility that such compounds may act as potential antileukemic and immunosuppressive drugs. Since 4-nitrobenzofuroxan readily formed Meisenheimer type σ-complexes with nucleophiles, and since drug action was abolished by preincubation with aliphatic thiols, it was concluded (2) that drug action was related to the interaction of 4-nitrobenzofuroxan with intracellular thiol groups, leading to σ-complex formation (10–12).



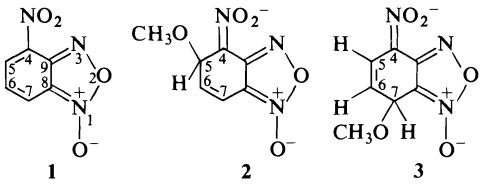
[1]For part I see ref. 1.

In our studies of the interaction of aromatic nitro compounds with bases, we have elucidated the structures of a variety of σ-complexes and have also derived kinetic and thermodynamic parameters relating to their formation and decomposition (13–19). Thus, we have extended these studies to the 4-nitrobenzofuroxan – methoxide ion system in dimethyl sulfoxide – methanol. Unexpectedly, we have discovered that the initially formed σ-complexes undergo some unusual transformations which lead, overall, to deoxygenation of the *N*-oxide function and to substitution of an aromatic hydrogen by the methoxy or hydroxy function.

Results

The interaction of 4-nitrobenzofuroxan (**1**) with potassium methoxide in methanolic dimethyl sulphoxide solution was investigated over a temperature range between −20 and +35°C. Five minutes after mixing, when the first spectrum could be taken, the solution of **1** (0.40 *M*) and CH_3OK (0.44 *M*) in DMSO-d_6–CH_3OD (70:30 v/v) at −20°C showed the absence of signals characteristic of **1**, and the appearance of a species which is identified as **2**. The identification was made on the basis of the following assignment for the ABC spin system (chemical

shifts, δ, quoted in ppm, relative to tetramethylsilane as internal standard, coupling constants in Hz): H-5 5.52, H-6 6.43, H-7 6.68; $J_{5,6}$ 4.7, $J_{5,7} < 1$, $J_{6,7}$ 9.8. On further monitoring of the reaction solution at −20°C new resonances developed which after 30 min were found to be sufficiently intense to allow for their identification as resonances due to complex **3**. The nmr spectrum presented an ABC pattern which was assigned as follows: H-5 7.19, H-6 5.23, H-7 5.32; $J_{5,6}$ 10.3, $J_{5,7} < 1$, $J_{6,7}$ 4.4. The computer simulated spectra (20) of **2** and **3** agreed well with the experimentally obtained nmr spectra.[2] Our data are also in agreement with the work of Simonnin and co-workers (10).



1 **2** **3**

Further changes in the nmr spectrum are observed on allowing the temperature of the solution to rise, first to −10°C (25 min) then to 0°C, corresponding to the formation of a new species, **X**; after 5 min at 0°C the species **2**, **3**, and **X** are present in about equal concentrations. A further rise in temperature causes the signals due to **2** to disappear entirely so that after 45 min at 10°C only **3** and **X** are present, in about equal concentration. When the temperature is then raised to 35°C for 10 min, **3** also disappears and **X** remains as the sole product. The species **X** is identified as the nitronate derivative **4**. The nmr spectrum consisted of a simple AX doublet, assignable as H-5 at 7.27 and H-6 at 5.70 ($J_{5,6}$ = 8), and in addition there was a signal at low field (δ 10.5) assignable to the NOH function. The CH_3O resonance is obscured by the methanol of the medium.

The reaction solution on standing 24 h at 30°C developed new sets of peaks in the nmr spectrum, this process becoming complete after 48 h at 30°C. The new resonance signals could be identified unambiguously as resulting from a mixture of the substances **7** and **9** (present in ratio of 3:1), both of which were prepared by authentic routes (7, 9) and were found to have concordant spectral characteristics under the reaction conditions. For **7**, H-5 occurs at 8.35 (d) and H-6 at 5.90 (d), $J_{5,6}$ = 10. For **9**, H-5 appears at 7.32 (d) and H-6 at 5.32 (d), $J_{5,6}$ = 11 (see Experimental section for complete characterization of **7** and **9**).

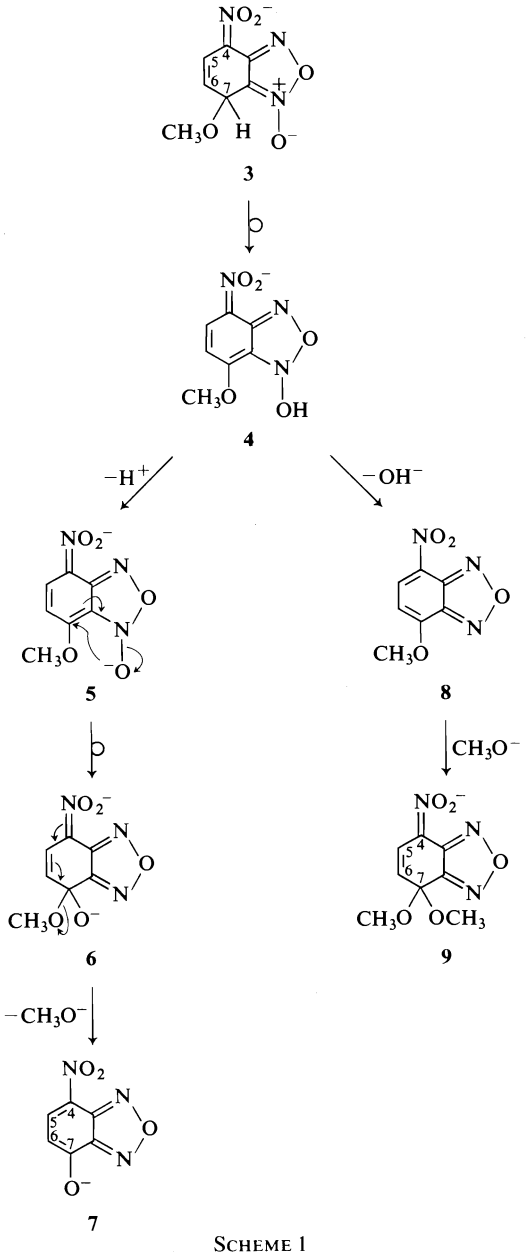
Discussion

The results which we have observed are interpreted as follows. Addition of methoxide ion to **1** leads to the initial formation of complex **2** as the product of a kinetically controlled reaction (21–26). In time **2** is replaced by complex **3** which is the thermodynamically controlled product.[3] The latter is unstable, as shown by further changes in the nmr spectra, and the products which are formed can be explained by the mechanisms given in Scheme 1. Initially there is a transfer of the sp^3 hydrogen in **3** to the *N*-oxide function yielding the nitronate derivative **4**. This intermediate is also unstable and becomes the precursor of the observed reaction products **7** and **9**. The former arises essentially via an intramolecular shift of the O^- function following deprotonation of **4**, *i.e.* **5** → **6**. This process is analogous to the Smiles rearrangement (for a review see ref. 28), though to our knowledge such has not been observed previously in the benzofuroxan system. The product **7** is obtained by loss of CH_3O^- from **6**. The second product, **9**, is obtained from **4** by expulsion of OH^- from the furoxan ring to yield **8**, followed by addition of CH_3O^-. Alternatively, attack of CH_3O^- on C-7 of **4** with concerted expulsion of OH^- would yield **9** directly.

In previous work on the interaction of **1** with methoxide ion, the complexes **2** (10) and **3** (2, 10) have been identified, but not their subsequent transformations. It is noteworthy that formation of complexes analogous to **3**, derived by attack of intracellular sulfhydryl and/or amino groups at C-7 of **1**, has been invoked in order to account for the observed antileukemic reactivity of 4-nitrobenzofuroxan (2, 3). This hypothesis must be reexamined in view of our findings that the complex **3** is unstable and decomposes through

[2]The species **3** could be obtained essentially free of **2** (and also of X) when the experiment was performed under the conditions [4-nitrobenzofuroxan] = [CH_3OK] = 0.2 *M*. However this solution on standing developed a green color, with concurrent loss of the proton resonances. Initial studies show that the course of the reaction is strongly influenced by the ratio of substrate to base and this aspect will be further investigated.

[3]Alternatively, it is possible that the transformation of **2** to **3** occurs by means of the Boulton–Katritzky rearrangement (27). This possibility is currently being investigated.



SCHEME 1

the involvement of several transient intermediates. An examination of the possible biological activity of all the species implicated in the present study is thus indicated, since it might be one or more of these intermediates or products and not 4-nitrobenzofuroxan itself which is responsible for the activity of this compound.

Experimental

Materials and Preparations

Dimethyl sulfoxide was distilled from barium oxide or calcium hydride under nitrogen. Methanol was distilled from magnesium metal. The deuterated solvents were dried over molecular sieves. A stock solution of CH_3OK/CH_3OD was prepared from freshly cut potassium metal and CH_3OD, stored under nitrogen, and standardized immediately before use.

4-Nitrobenzofuroxan was prepared according to ref. 4 (method *B*) mp 143°C. 7-Methoxy-4-nitrobenzofurazan was prepared from 7-chloro-4-nitrobenzofurazan and sodium methoxide, mp 115–116°C (29). Reaction of 7-methoxy-4-nitrobenzofurazan with hot aqueous NaOH yielded 7-hydroxy-4-nitrobenzofurazan, mp 200°C (29). The uv–visible spectrum of this compound was obtained in DMSO–methanol (70:30 v/v) containing trifluoroacetic acid (2.2 *M*): $\lambda_{max(1)}$ 395 nm, ε 9500; $\lambda_{max(2)}$ 285 nm, ε 5000 M^{-1} cm^{-1}. The spectrum of the anion (**7**) was obtained in this medium with added CH_3ONa: $\lambda_{max(1)}$ 466 nm, ε 20 000; $\lambda_{max(2)}$ 366 nm, ε 11 000 M^{-1} cm^{-1}. The nmr spectrum of 7-hydroxy-4-nitrobenzofurazan in DMSO-d_6: H-5 8.60, H-6 6.72 ($J_{5,6}$ 8 Hz), OH 11.6.

Complex **9** was obtained as a yellow-orange solid on treatment of 7-methoxy-4-nitrobenzofurazan in acetonitrile solution with sodium methoxide in methanol. Spectral data: nmr in DMSO-d_6: H-5 7.25, H-6 5.18 ($J_{5,6}$ 11 Hz), OCH_3 3.30; uv in DMSO–methanol (80:20 v/v): λ_{max} 354 nm, ε 22 000. Acidification of the solution (CF_3CO_2H) regenerated 7-methoxy-4-nitrobenzofuran: λ_{max} 380 nm, ε 11 500 M^{-1} cm^{-1}.

Methods

The reaction of 4-nitrobenzofuroxan (**1**) with methoxide ion was performed in DMSO-d_6–CH_3OD by the following procedure. A solution of **1** (72.4 mg) in 0.60 ml of DMSO-d_6–CH_3OD (70:30 v/v) was placed in a 5 ml round bottom flask sealed with a rubber septum, the flask immersed in a cryostat bath at −20°C, and the contents were stirred magnetically. To this cooled, stirred, solution 0.40 ml of a 1.1 *M* potassium methoxide solution in DMSO-d_6–CH_3OD (70:30 v/v) was added very slowly by means of a cooled syringe. A 0.5 ml portion of the resulting deep orange coloured solution was transferred under nitrogen to an nmr tube, which was then cooled to −80°C and stored until the nmr measurements could be made. A Bruker 60 MHz HFX-60 instrument was used, varying the temperature of the probe between −20 and +35°C.

RONALD T. COUTTS and ABDEL-MONAEM EL-HAWARI. Can. J. Chem. **55**, 2856 (1977).

1′,2′-Dihydro-3-methyl-1-phenylspiro[[2]pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**8***q*), the structurally related 1,3-diphenylspiro[pyrazolone–quinoline] **8***r* and numerous 2′-substituted derivatives of **8***q* and **8***r* are readily accessible from catalytic reduction of 3-methyl-1-phenyl- or 1,3-diphenyl-4-(2-nitrobenzyl)-2-pyrazolin-5-one (**1***a*, **1***b*, respectively) in alcohols (with the incorporation of the alkylidene moiety) or by interaction of the corresponding 2-aminobenzyl precursors (**3***a*, **3***b*) with appropriate aldehydes and ketones. All spiro compounds were characterized by mass, ir, and ^{1}Hmr spectra. The products obtained by reducing the spiro compounds with sodium borohydride and with lithium aluminum hydride are described. Reduction of **1***a* and **1***b* with zinc and acetic acid gave 3-methyl-1-phenyl- and 1,3-diphenyl-1*H*-pyrazolo-[3,4-*b*]quinoline (**2***a*, **2***b*, respectively).

RONALD T. COUTTS et ABDEL-MONAEM EL-HAWARI. Can. J. Chem. **55**, 2856 (1977).

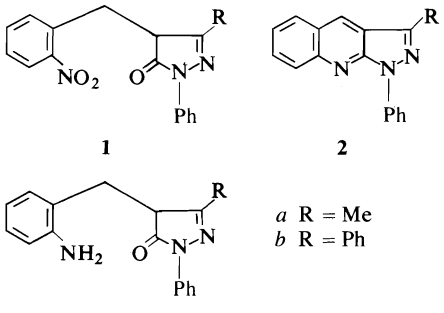
La dihydro-1′,2′ méthyl-3 phényl-1 spiro[[2]pyrazoline-4,3′(4′*H*) quinoline] one-5 (**8***q*), la diphényl-1,3 spiro[pyrazolone–quinoline] qui lui est reliée d'une façon structurale (**8***r*) et plusieurs dérivés substitués en position 2′ de **8***q* et **8***r* sont facilement accessibles par la réduction catalytique des méthyl-3 phényl-1 ou diphényl-1,3 (nitro-2 benzyl)-4 pyrazolin-2 ones-5 (**1***a*, **1***b* respectivement) dans l'alcool (avec l'incorporation de la portion alkylidène) ou par interaction des précurseurs amino-2 benzyle correspondants (**3***a*, **3***b*) avec les aldéhydes ou cétones appropriés. On a caractérisé tous les composés spiro par spectrométrie de masse, ir ou rm^{1}H. Les produits obtenus en réduisant les composés spiro avec le borohydrure de sodium et l'hydrure double de lithium et d'aluminium sont décrits. La réduction de **1***a* et de **1***b* avec le zinc et l'acide acétique conduit aux méthyl-3 phényl-1 et au diphényl-1,3 1*H*-pyrazolo[3,4-*b*]-quinolines (**2***a* et **2***b* respectivement).

[Traduit par le journal]

Our previous studies (1, 2) have shown that the products of palladium–charcoal catalyzed sodium borohydride reductions of 3-methyl-4-(2-nitrobenzyl)-1-phenyl-2-pyrazolin-5-one (**1***a*), the 3-phenyl analog **1***b*, and structurally related 2-nitrobenzylidene compounds, vary according to the nature of the solvent employed. In further attempts to prepare cyclic hydroxylamines or related nitrones, we have continued our studies on the reduction of **1***a* and **1***b* using alternative reducing systems.

Initially, the 3-phenylpyrazolone **1***b* was reduced with zinc and acetic acid and yielded a yellow crystalline product, $C_{22}H_{15}N_3$, the ir spectrum of which lacked NH, OH, and CO absorption bands. The mass spectrum of the product had a strong molecular ion (*m/e* 321) and only three additional ions of appreciable intensity of *m/e* 320, 244, and 218, which resulted from the expulsion of a hydrogen atom, a phenyl radical, and a phenyl cyanide molecule, respectively, from the molecular ion. The product's ^{1}Hmr spectrum showed no signals other than those of aromatic protons. The compound, $C_{22}H_{15}N_3$, is identified, therefore, as the hitherto unknown 1,3-diphenyl-1*H*-pyrazolo[3,4-*b*]quinoline (**2***b*).

When the 3-methyl analog **1***a* was similarly reduced with zinc and acetic acid, the product obtained proved difficult to purify but possessed



[1]For part IV, see ref. 3.

properties similar to those described for **2***b* and is identified as 3-methyl-1-phenyl-1*H*-pyrazolo-[3,4-*b*]quinoline (**2***a*) which was obtained previously (4) by heating together 5-chloro-4-formyl-3-methyl-1-phenylpyrazole and aniline. The mechanism of formation of **2***a* and **2***b* from **1***a* and **1***b* proceeds presumably via the amines **3***a*,*b* since prolonged heating of solutions of these amines in acetic acid produced **2***a* and **2***b*.

Catalytic hydrogenation of the *o*-nitrobenzylpyrazolone derivatives **1***a* and *b* was then attempted to determine whether *N*-hydroxy compounds could be obtained by this route. Reduction was initially carried out using platinum oxide or palladium–charcoal as a catalyst and absolute ethanol as solvent. When the 3-phenylpyrazolone **1***b* was reduced under these conditions, the product obtained, $C_{24}H_{21}N_3O$, designated compound A, was not the expected one. It was a weak base, but, unlike compound **3***b*, product A was insoluble in dilute sodium hydroxide solution. Its ir spectrum showed NH and C=O absorption bands, the latter at 1712 cm^{-1}. The presence of C=O absorption at this frequency in addition to the insolubility of product A in dilute alkali solution, indicated that the pyrazolone ring was no longer capable of enolization, i.e. the hydrogen atom α to the C=O group was no longer present. The ^{1}Hmr spectrum of compound A indicated the presence of a $CHCH_3$ group which undoubtedly originated from the ethanol employed as the solvent in the catalytic reduction of **1***b*. To verify this, the same reaction was repeated in dioxane, in methanol, in propanol, and in benzyl alcohol. With dioxane, 4-(2-aminobenzyl)-1,3-diphenyl-2-pyrazolin-5-one (**3***b*) was obtained in good yield, but when the other solvents were employed, the products obtained (B–D) in each case differed, and elemental analyses suggested that the alkyl or aryl group of the alcohol used had been incorporated into the molecule. The ir spectra of all products (A–D) were very similar. Their ^{1}Hmr and mass spectra confirmed that the alcohols used as solvents were involved in the formation of A–D.

From all these data, each of the compounds A–D was suspected to be a 2′-substituted-1′,2′-dihydro-1,3-diphenylspiro[[2]pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**4**). A mechanism for the formation of spiro[pyrazolone–quinoline] (**4**) can be envisaged (Scheme 1). The nitro compound **1***b* is partially reduced to a hydroxylamine (**5**) which then interacts with the alcohol present; the former is reduced to the amine **3***b* while the latter is oxidized to the aldehyde. Both the amine and the aldehyde react to form a carbinolamine (**6**) which cyclizes to the spiro[pyrazolone-quinoline] derivatives (**4**). This suggested oxidation–reduction process, and subsequent interaction of the products, is another example of solvent/product interactions known to occur during catalytic hydrogenation (5).

SCHEME 1

The spiro[pyrazolone–quinoline] structure (**4**; Scheme 1) is isomeric with the imine (Schiff base) structure **7** but the ir and ^{1}Hmr data from compounds A–D are not compatible with these compounds being imines. Further evidence of the suitability of structure **4** was obtained from an analysis of the mass spectra of the four compounds A–D. None fragmented under electron impact in the manner that Schiff bases do. Mass spectral studies of some Schiff bases have recently been reported (6) and it has been shown that the molecular ion undergoes simple fission at the ring-nitrogen and ring-carbon bonds, the former fragmentation being more facile than the latter. No fragment ions due to ring-nitrogen fission were present in the mass spectra of any of the products isolated. On the other hand, the fragment pathways observed were reminiscent of the behaviour of tetrahydroquinoline derivatives under electron impact (7) (Scheme 2).

A final argument against the imine structure **7** was based on the fact that such a structure should not be isolated under these reduction conditions. Schiff bases are known to be reduced in virtually quantitative yields either by catalytic hydrogenation or by chemical reagents (8) and accordingly, the imine if it were formed would be reduced to the related secondary amine. The imine, however, may have a transitory existence in the formation of the spiro-compounds (**4**) (see Scheme 1). It is possible that the aldol **6** dehydrates directly to the spiro-compound, but literature evidence is available (9) in support of a Schiff base intermediate. The formation of the spiro-compounds (**4**) thus involves the addition of a C—H group to the C=N function of the Schiff base. Similar cyclizations of Schiff bases involving the addition of O—H across the C=N group to give 2*H*-1,3-benzoxazines, and the addition of S—H across the C=N group to yield thiazolidines have been reported (10, 11).

If the postulated mechanism depicted in Scheme 1 is factual, numerous compounds of general structures **8** and **9** could be prepared in the manner shown (Scheme 3) and this has proved possible. Eighteen spiro[pyrazolone–quinoline] derivatives (Table 1) were obtained from the interaction of the amines **3***a* and **3***b* and an appropriate aldehyde or ketone in refluxing ethanolic solution. The phenolic compounds **8***d*, *e*, *f*, *g* and *o* and the carboxylic acid derivatives **8***k* and *p* were prepared in particular because of their ability to dissolve in dilute

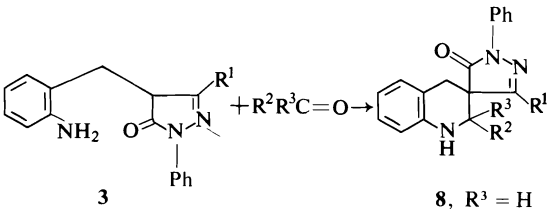
*These compounds are included for completeness and are identical with compounds A, C, and D respectively (see Scheme 1).

alkaline solution, a property which was required to facilitate a planned pharmacological evaluation.

Aliphatic ketones are known to react with amines more slowly than aldehydes to form imines. This was the case here; it necessitated the use of higher reaction temperature and longer reaction times to obtain the spiro-derivatives **9***a* and **9***b* in the absence of catalyst or dehydrating agent. Attempts to crystallize the isolated product **9***a* were unsuccessful, but the ir and ^{1}Hmr spectra of this product agreed with the proposed structure. The reaction between the phenyl analog **3***b* and acetone was more facile and the product **9***b* was easily characterized.



3 **8**, R^3 = H; **9**, R^3 = Me

SCHEME 3

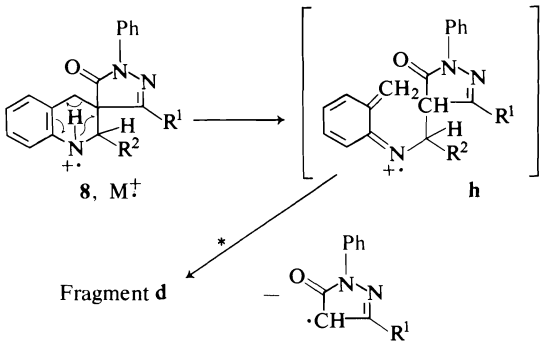
When the amines **3***a* and **3***b* were reacted with formaldehyde, they failed to form spiro-compounds. The required spiro[pyrazolone–quinolines] (**8***q*, **8***r*) were readily obtained, however, when the nitro compounds **1***a*, *b* were catalytically hydrogenated over platinum using methanol as a solvent.

All the spiro-compounds (**8**, **9**) prepared in this study were identified by their correct elemental analysis and by the similarities between their ir and ^{1}Hmr spectra and those described earlier for compounds A—D. The mass spectra of some of these derivatives were recorded and possible fragmentation pathways are suggested in Scheme 2. Deuteration of compound **8***c* as well as an examination of the spectrum of 1′,2′-dihydro-2′,2′-dimethyl-1,3-diphenylspiro[[2]pyrazoline-4,3′(4′*H*)-quinoline]-5-one **9***b* were helpful in accounting for the origin of some of the fragment ions. Each compound gave a strong molecular ion which expelled a hydrogen atom as well as the radical (R^2) from C-2 of the tetrahydroquinoline ring giving rise to weak fragment ions (Scheme 2).

An interesting fragment found in all the spectra (except the dimethyl derivatives **9***a*, *b*) was due to the expulsion of an OH radical from the molecular ion. This expulsion was supported by metastable ions present at appropriate *m*/*e* values in most spectra. The origin of this ion is not known. Deuterium labelling ruled out any contribution from the amine proton since the ion at *m*/*e* 350 in **8***c* was located at *m*/*e* 351 in the deuterated compound.

A strong fragmentation ion (**d**) was present in the spectra of all compounds. This resulted from the expulsion of a pyrazolone radical from the molecular ions; appropriate metastable ions were present in the spectra in support of this assertion. Depending on which hydrogen is involved in the expulsion of the pyrazolone radical, three structures (**d**′–**d**‴) can be en-

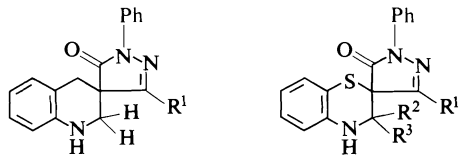
visaged for the ion formed. It seems, however, that the amine hydrogen is more involved in the proposed migration than a C-2′ or a C-4′ hydrogen atom. That was indicated by examining the spectra of both the deuterated compound (**8***c*, N—D replaces N—H) and the 2′,2′-dimethyl derivative **9***b*. The former showed a major loss of 174 mass units from the molecular ion instead of 173 mass units lost in the non-deuterated compound **8***c*. The 2,2-dimethyl derivative **9***b* molecular ion also expelled a pyrazolone radical to give a fragment ion at *m/e* 146 (which retained both C-2′ methyl groups) thus implicating migration of the NH hydrogen atom, or alternatively, a hydrogen atom from the ring methylene group. Non-involvement of the protons at C-4′ was suggested, however, by the presence of similar strong ions resulting from the loss of a pyrazolone radical in the spectra of structurally related spiro-dihydrobenzothiazines (**10**)[2] in which the methylene group is replaced by a sulfur atom. Mechanisms for the formation of ions **d′**–**d‴** are readily suggested. The mechanism preferred, for the reasons just expounded, is given in Scheme 4.



SCHEME 4

Another diagnostic fragmentation pathway is the decomposition of the molecular ion to give ions identified as **f** and **g** in Scheme 2. The intermediate ion **h** (Scheme 4) is also thought to be the origin of the fragment **e** which is present in relatively high abundance in the mass spectra of spiro[pyrazolone–quinolines] which possess aromatic substituents at the C-2′ position. A comparison of the spectrum of **8***c* with *N*-deuterated **8***c* confirmed that the amine hydrogen atom was expelled in the formation of this ion. Of the two possible structures for this ion (**e′** and **e″**), the latter is preferred since **e** is located at *m/e* 131 in the spectrum of **9***b*, indicating the loss of a methyl radical from C-2′ in its formation.

A difference between the *o*-aminobenzylpyrazolone **3***a* and its phenyl analog **3***b* was demonstrated in their reactions with salicylaldehyde. Whereas **3***a* was successfully converted to a spiro[pyrazolone-quinoline] (**8***e*), the phenyl analog reacted to give a yellow crystalline product $C_{29}H_{23}N_3O_2$, which had an ir spectrum that was devoid of both the lactam C=O and NH absorptions present in the spectra of all the spiro-compounds (**8**). The spectrum contained absorption bands comparable to those in the ir spectrum of the Schiff base, salicylideneaniline (**11**) which was prepared for comparison pur-



8 **10**

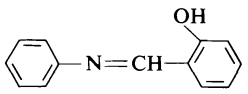
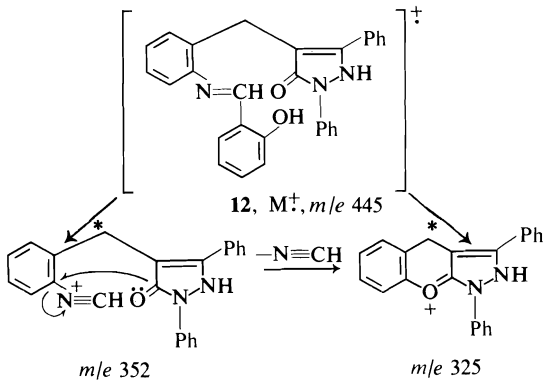
r R^1 = Ph (product B)



11

poses. Accordingly, the Schiff base structure **12** is suggested for the compound $C_{29}H_{23}N_3O_2$. Its mass spectrum was in agreement with the proposed structure. Although this spectrum displayed some similarities with the spectra of the spiro[pyrazolone–quinoline] (**8***e*), it also showed strong fragment ions resulting from cleavage at ring-nitrogen or ring-carbon bonds of the imine group (Scheme 5). Both these fissions are known

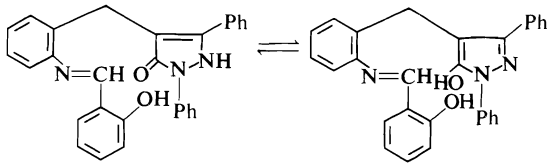


SCHEME 5

[2]R. T. Coutts and A.-m. El-hawari, work to be published.

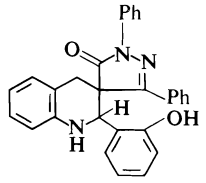
(6, 12) to occur in the mass spectra of Schiff bases.

Reduction of **12** by means of sodium borohydride in aqueous dioxane did not yield a crystalline product. Methylation with dimethyl sulfate gave an alkali-insoluble product which was difficult to purify. The mass spectrum of the

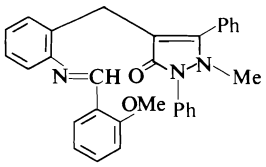


12

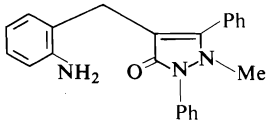
crude methylated product displayed a weak molecular ion at *m/e* 473 which indicated a dimethyl derivative in agreement with a Schiff base precursor (**12**) rather than a spiro-compound (**13**), since in **12**, methylation of the pyrazolone nucleus, could also occur. Interpretation of the ir and mass spectra of the isolated products showed that methylation occurred at the N-2 position of the pyrazolone ring. The ir spectrum displayed a C=O band at 1660 cm^{-1} which is expected only when the pyrazolone nucleus has an α,β-unsaturated carbonyl group (13). The mass spectrum displayed, in addition to the $M - 1$ and $M - 15$ ions, a fragment ion (the base peak) at *m/e* 118. A similar ion was identified earlier (1) in the mass spectrum of the N-2 methylated pyrazolone **15** as the fragment ($Ph—C\equiv\overset{+}{N}—CH_3 \leftrightarrow Ph—\overset{+}{C}=N—CH_3$). Accordingly, the structure **14** was assigned to the dimethyl derivative obtained from **12**.



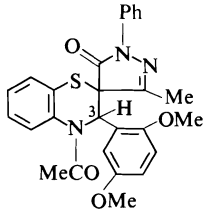
13



14



15



17

The Schiff base **12** is readily cyclized to the isomeric spiro-compound **13**. When the former was dissolved in DMSO-d_6 for a ^{1}Hmr study, a spectrum very similar to that of the spiro[pyrazolone–quinoline] **8***o* was obtained. In particular, the spectrum displayed a doublet of doublets for the methylene group. Such a signal was demonstrated, throughout the present study, solely in spiro-compounds (**8**). This case of conversion (**12** → **13**) supports the earlier suggestion that Schiff bases are intermediate products in the formation of spiro[pyrazolone–quinolines] in the manner illustrated in Scheme 1. Cyclization also occurred when the Schiff base **12** was acetylated. This is discussed further below.

In order to characterize further the spiro-compounds described in this study, some (**8***b*, *c*, *e*, *n*, and *o*) were acetylated with acetic anhydride. Compound **8***n* was converted to a monoacetyl derivative identified as **16***a*. This structure was confirmed by elemental analysis ($C_{31}H_{25}N_3O_2$), ir (carbonyl bands 1666 and 1720 cm^{-1}), and ^{1}Hmr spectra. When **8***e* was acetylated, it yielded a diacetylated product identified as **16***b*. It analyzed correctly for $C_{28}H_{25}N_3O_4$ and its ir spectrum showed three C=O absorption bands at 1766 (ester), 1700 (lactam), and 1670 cm^{-1} (cyclic amide). The nmr spectrum of this compound had three methyl signals at δ 0.78, 1.86, and 2.18. The first of these signals was surprisingly far upfield, a position not expected for any of the methyl groups in compound **16***b*. In order to assist in deciding its origin, the acetyl derivatives **16***c* and **17**[2] were prepared. The results of a ^{1}Hmr study on these compounds are summarized in Table 2 and indicate that it is the

methyl group on the pyrazolone ring which produces the upfield methyl signal in compound **16***b*. A tentative explanation, based on an examination of Dreiding models, is that the N=C—CH_3 group is forced to align itself on top of the phenyl ring at C-2 of the tetrahydroquinoline ring (or C-3 of the dihydrobenzothiazine ring in **17**) and thus is greatly shielded. In addition, the hydrogen atom attached to the same carbon atom as the phenyl ring is forced into the plane of this phenyl ring, adopting 'aromatic-like' character and therefore a downfield position. This explanation is supported by a study of the spectrum of the acetyl derivative **16***f* which lacks an aromatic substituent at C-2 of the tetrahydroquinoline ring. In the ^{1}Hmr spectrum of this compound, the pyrazolone methyl signal came to resonance at δ 1.74. This signal was found to be at δ 1.88 in the non-acetylated tetrahydroquinoline **8***b*.

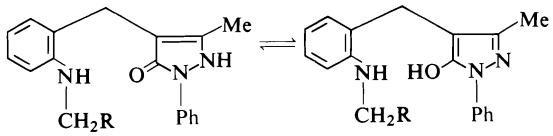
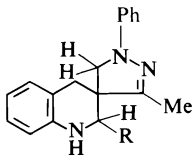
Compound **16***e* (Table 2) was the product obtained when the Schiff base **12** was acetylated with acetic anhydride, again indicating the ease with which **12** is cyclized to **13**. Analysis ($C_{33}H_{27}N_3O_4$) confirmed the diacetate structure. Similarities in the ir and ^{1}Hmr spectra of the isolated product and the isomeric diacetate **16***d* obtained from **8***o* suggested two related structures. The ir spectrum of **16***d* had three carbonyl absorption bands at 1765 (ester), 1715 (lactam), and 1668 cm^{-1} (cyclic amide) which are closely related to those in the ir spectrum of acetylated **12**. The ^{1}Hmr spectrum of **16***d* displayed two methyl signals at δ 2.10 ($OCOCH_3$) and at 2.23 ($NCOCH_3$), a doublet of doublets centered at 3.37 (CH_2), and an aromatic multiplet which included the C-2 proton signal. The corresponding signals in acetylated **12** were located at δ 1.93, 2.24, and 3.26.

To complete this study on spiro[pyrazolone–quinolines] the effect of reducing these compounds was investigated. Whereas sodium borohydride reduction of the amine **12** in aqueous dioxane gave no crystalline products, similar reductions of the isomeric spiro-compounds (**8***a*, *b*, and *c*) yielded amphoteric products which analyzed correctly for $C_{18}H_{18}N_3OR$. The ease of solubility of these products in aqueous sodium hydroxide suggested the presence of an enolizable hydrogen at C-4 of the pyrazolone nucleus. Structure **18** is suggested for the reduction products; this suggestion is supported by the ir spectral characteristics. Their ir spectra displayed an N—H absorption band around 3300 cm^{-1}, lacked C=O absorption, and showed broad absorption between 2100 and 3300 cm^{-1} which could be attributed to a bonded OH stretching band. The ^{1}Hmr spectra of these products were very informative. In addition to the pyrazolone methyl signal and the aromatic signal, two deuterium-exchangeable protons and two methylene signals were also present in all spectra. One methylene signal was a singlet while the other was a singlet or multiplet depending on the adjacent substituent R. The mass spectra of the amphoteric products were also indicative of the suggested structure **18**. Important fragment ions in these spectra (i.e. molecular ion and three fragment ions of greatest mass) are identified in Scheme 6. The presence of ions **i** and **j** are of special interest since both contained an intact $NHCH_2R$ unit. Unlike compounds **18***a* and *b* which expelled the substituent R as a radical and gave fragment **k**, compound **18***c* lacked this ion, but instead expelled a C_7H_7 radical to give an ion of *m*/*e* 278.



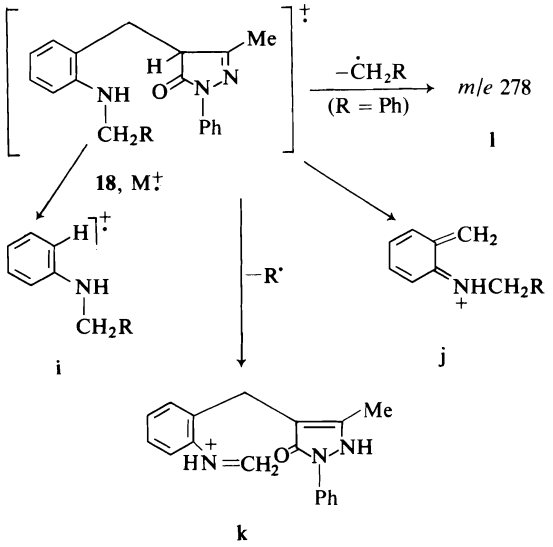
(NH-form) **18** (OH-form)



19

a R = Me
b R = Et
c R = Ph

Reductions of the spiro-compounds **8***a*, *b*, and *c* were also performed using lithium aluminum hydride in ether. Two products were isolated from each reduction mixture; the minor product



SCHEME 6. Percentage relative abundance of ions:

	R	$M^{+\cdot}$	i	j	k	l
18*a*	Me	21	46	100	3	—
18*b*	Et	34	50	100	12	—
18*c*	Ph	24	32	43	—	18

was basic while the major one was amphoteric. The proportion of these compounds was virtually reversed when the reduction of **8***a* was carried out in tetrahydrofuran. In contrast, only the amphoteric product was obtained, when **8***c* was reduced with lithium aluminum hydride/aluminum chloride in ether.

The amphoteric products were identical to the compounds obtained by sodium borohydride reduction of **8***a*, *b*, and *c*, respectively. The basic products analyzed for $C_{18}H_{18}N_3R$ (R = CH_3, C_2H_5, or Ph) and their mass spectra displayed molecular ions at appropriate *m/e* values for these formulae. This indicated that the lactam C=O groups in **8***a–c* had been reduced by the action of lithium aluminum hydride, a reagent which is known to reduce pyrazolones to pyrazoline and pyrazolidine derivatives (14–17). The basic properties, the elemental analyses, and the mass spectra of these products suggested that they were pyrazoline derivatives (**19**). Their ir spectra lacked carbonyl absorption bands but each had two absorption bands near 3400 (sharp band) and 3300 cm^{-1} (broad band) which is a puzzling observation since only one N—H stretching band was expected. The identity of the basic products, $C_{18}H_{18}N_3R$, as compounds **19***a–c* is therefore tentative until further studies of these compounds are made.

Experimental

Infrared spectra were recorded for Nujol mulls with a Beckman IR-10 spectrophotometer. Proton magnetic resonance spectra were recorded with a Varian A60 spectrometer, with tetramethylsilane as internal standard, and mass spectra were measured with an A.E.I. MS9 spectrometer at 70 eV (direct insertion technique). Melting points (capillary) are uncorrected. Deuterated compounds were prepared by repeated crystallization of the non-labelled precursor from dioxane–D_2O. Where elemental analyses are indicated, analytical results obtained for those elements were within ±0.45% of the theoretical values. Complete analyses are compiled in two tables (Table 3: elemental analyses of spiro[pyrazolone–quinolines] and related compounds; Table 4: elemental analyses and physical properties of spiro-[[2]pyrazoline-4,3′(4′*H*)-quinoline]-5-ones (**8**, **9**) prepared by a general method) which are available from the Depository of Unpublished Data.[3]

*Reduction of 1,3-Diphenyl-4-(2-nitrobenzyl)-2-pyrazolin-5-one (**1***b*)*

(*a*) Zinc dust (1.0 g) was added in small quantities to a stirred solution of the title compound (1) (2.0 g) in boiling glacial acetic acid (20 ml). The mixture was heated under reflux for 6 h then filtered. On cooling, a yellow solid (0.8 g), mp 158–160°C crystallized from the filtrate. An additional quantity (0.5 g) of product was obtained by diluting the filtrate with water. Crystallization from ethanol gave 1,3-diphenyl-1*H*-pyrazolo[3,4-*b*]quinoline (**2***b*), mp 162–163°C; ir ν_{max} 1618 (C=N) cm^{-1}, NH and OH bands absent; ^{1}Hmr ($CDCl_3$) δ 7.00–8.90 (aromatic protons); ms *m/e* (% relative abundance) 321(M^+, 100), 320(30), 244(11), 218(9). *Anal.* ($C_{22}H_{15}N_3$) C,H,N.

The same product (**2***b*) was obtained by heating a solution of 1,3-diphenyl-4-(2-aminobenzyl)-2-pyrazolin-5-one (1) (**3***b*, 0.5 g) in glacial acetic acid (10 ml) for 2 h. On cooling, 1,3-diphenyl-1*H*-pyrazolo[3,4-*b*]quinoline (0.35 g) separated as yellow crystals, mp 158–160°C, with properties identical to those described immediately above.

(*b*) The title compound (1.0 g) in methanol (200 ml) was hydrogenated over platinum oxide (30 mg) at room temperature and atmospheric pressure. When the calculated amount of hydrogen was taken up, the catalyst was filtered off and the solvent evaporated to give a yellow solid. Crystallization from methanol yielded pale-yellow crystals (0.35 g) of 1′,2′-dihydro-1,3-diphenylspiro[[2]pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**8***r*, product B), mp 188–189°C; ir ν_{max} 1700 (C=O), 3365 (NH) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 3.34 (2H, s, CH_2), 3.57 (2H, br s, CH_2), 3.95 (1H, br s, NH), 6.50–8.30 (14H, m, aromatic protons); ms: see Scheme 2 caption; measured mass 118.0653 (calcd. for C_8H_8N, 118.0657). *Anal.* ($C_{23}H_{19}N_3O$) C,H,N.

(*c*) Reduction of **1***b* by method *b* was repeated except that ethanol (200 ml) was used as solvent. This gave 1′,2′-

[3]Copies of Tables 3 and 4 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

dihydro-1,3-diphenyl-2′-methylspiro[[2]pyrazoline-4,3′-(4′*H*)-quinoline]-5-one (**8***l*, product A) (0.75) g), as colorless crystals, mp 174–175°C; ir ν_{max} 1712 (C=O), 3405 (NH) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 1.15 (3H, d, J = 6.5 Hz, CH_3), 3.50 (2H, d of d, J = 17 Hz, CH_2), 3.60 (1H, q, J = 6.5 Hz, CH), 3.63 (1H, br s, D-exchangeable, NH), 6.40–8.30 (14H, m, aromatic protons); ms: see Scheme 2 caption; measured masses 367.1680 (calcd. for $C_{24}H_{21}N_3O$, 367.1685), 352.1450 (calcd. for $C_{23}H_{18}N_3O$, 352.1450), 132.0813 (calcd. for $C_{19}H_{10}N$, 132.0813). *Anal.* ($C_{24}H_{21}N_3O$) C,H,N.

(*d*) Reduction of **1***b* by method *b* was repeated except that propanol (200 ml) was the solvent. This gave 1′,2′-dihydro-1,3-diphenyl-2′-ethylspiro[[2]pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**8***m*, product C) (0.59 g) as colorless crystals, mp 159–160°C; ir ν_{max} 1710 (C=O), 3415 (NH) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 0.90–1.50 (5H, m, J = 6.5 Hz, CH_2CH_3), 3.35 (2H, d of d, J = 17.5 Hz, CH_2), 3.64 (1H, br s, D-exchangeable, NH), 6.35–8.30 (14H, m, aromatic protons); ms *m/e* (% relative abundance) 381(M^+, 100), 364(2), 352(42), 146(78); measured masses 381.1837 (calcd. for $C_{25}H_{23}N_3O$, 381.1841), 146.0966 (calcd. for $C_{10}H_{12}N$, 146.0970). *Anal.* ($C_{25}H_{23}N_3O$) C,H,N.

(*e*) Reduction of **1***b* by method *b*, but using benzyl alcohol (200 ml) as solvent gave 1′,2′-dihydro-1,2′,3-triphenylspiro[[2]pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**8***n*, product D) (0.28 g) as a pale yellow solid, mp 207–209°C; ir ν_{max} 1698 (C=O), 3380 (NH) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 3.45 (2H, d of d, J = 17 Hz, CH_2), 4.68 (1H, s, CH), 4.07 (1H, br s, D-exchangeable, NH), 7.00–7.80 (19H, m, aromatic protons); ms *m/e* (% relative abundance) 429(M^+, 100), 412(2), 352(3), 194(67), 193(25). *Anal.* ($C_{29}H_{23}N_3O$) C,H,N.

(*f*) Reduction of **1***b* by method *b* was repeated using dioxane (100 ml) as solvent and 4-(2-aminobenzyl)-1,3-diphenyl-2-pyrazolin-5-one (0.78 g, mp 151–152°C) was obtained as colorless crystals. The properties of this product were identical to those reported earlier (1).

*Reduction of 3-Methyl-4-(2-nitrobenzyl)-1-phenyl-2-pyrazolin-5-one (**1a**)*

(*a*) When the title compound (1) (2.0 g) was reduced with zinc dust in glacial acetic acid as described in the preparation of **1***b* by method *a*, a yellow solid (1.33 g), mp 166–168°C (from aqueous ethanol) was obtained and is identified as 3-methyl-1-phenyl-1*H*-pyrazolo[3,4-*b*]-quinoline (**2***a*) (lit. (4) mp 178°C); ir ν_{max} 1618 (C=N) cm^{-1}, NH and OH bands absent; ^{1}Hmr ($CDCl_3$) δ 2.78 (3H, s, CH_3), 7.30–9.05 (10H, m, aromatic protons); ms *m/e* (% relative abundance) 259(M^+, 100), 258(27), 244(33), 218(21). *Anal.* ($C_{17}H_{13}N_3$) N.

(*b*) The same product (**2***a*) was obtained in low yield (0.15 g) when 4-(2-aminobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one (1) (**3***a*, 0.5 g) was heated under reflux in glacial acetic acid (10 ml) for 3 h.

(*c*) A solution of the title compound (1.0 g) in methanol (150 ml) was hydrogenated in the manner described in the reduction of compound **1***b*, method *b*. Crystallization of the product from methanol gave colorless crystals (0.28 g), mp 153–154°C, of 1′,2′-dihydro-3-methyl-1-phenylspiro[[2]pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**8***q*); ir ν_{max} 1692 (C=O), 3425 (NH) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 2.01 (3H, s, CH_3), 3.00 (2H, d of d, J = 17.5 Hz, CH_2), 3.91 (1H, br s, D-exchangeable, NH), 6.60–8.30 (9H, m, aromatic protons); ms: see Scheme 2 caption. *Anal.* ($C_{18}H_{17}N_3O$) C,H,N.

*General Method of Preparing 1′2′-Dihydrospiro-[[2]pyrazoline-4,3′(4′H)-quinoline]-5-ones (**8**, **9**)-(See Tables 1 and 4)*

A hot solution of the 4-(2-aminobenzyl)-1-phenyl-2-pyrazolone **3***a* or **3***b* (1) (0.5 g) in either methanol or ethanol (15 ml) was mixed with a quantitative amount of the appropriate aldehyde. The reaction mixture was heated under reflux for 1 h. Upon cooling, many of the title compounds separated and were recrystallized from ethanol. In some cases, the reaction mixture was concentrated to about half its volume then diluted with water. The precipitate was washed with water, dried, and recrystallized from either methanol or ethanol as colorless crystals.

A similar reaction was carried out using acetone instead of an aldehyde. In this instance, the solvent used was either ethanol or butanol. Suitable reaction times were found to be 24 h when ethanol was the solvent, or 4–6 h when butanol was employed.

The compounds prepared by this method were obtained in 73–96% yields. Melting points are listed in Table 1. Individual yields and elemental analyses of all compounds are compiled in Table 4.[3] Their ir spectra displayed N—H absorption bands around 3400 and C=O bands around 1700 cm^{-1}. Each ^{1}Hmr spectrum showed, in addition to the signals ascribable to the aromatic protons and the different substituents at C-3 of the tetrahydroquinoline ring, a 2-proton doublet of doublets around δ 3.2 with J value ~ 17 Hz (CH_2), a one proton signal near δ 4.5 (-C*H*R) and a D-exchangeable N-H signal of variable chemical shift. The spectra of 3-methylpyrazolone derivatives also contained a methyl signal around δ 2.0. The mass spectra of some of these compounds were recorded and interpreted (see Scheme 2).

*Preparation and Reactions of 1,3-Diphenyl-4-[2-(2-hydroxybenzylidene)aminobenzyl]-2-pyrazolin-5-one (**12**)*

(*a*) *Preparation*

A solution of 4-(2-aminobenzyl)-1,3-diphenyl-2-pyrazolin-5-one (1) (**3***b*, 0.5 g) and salicylaldehyde (0.18 g) was heated under reflux for 1 h during which time the solution turned dark yellow. On cooling, a yellow solid separated from solution. Crystallization from ethanol gave the title compound (0.55 g), mp 199–200°C; mass spectrum *m/e* (% relative abundance) 445(M^+, 100), 444(44), 428(4), 352(18), 325(20), 248(7), 220(13), 210(41), 209(26); see also Scheme 5. *Anal.* ($C_{29}H_{23}N_3O_2$) C,H,N.

(*b*) *Isomerization*

A solution of **12** in DMSO-d_6 gave ^{1}Hmr δ 3.30 (2H, d of d, J = 16 Hz, CH_2), 5.31 (1H, s, CH), 6.20 (1H, br s, D-exchangeable, NH), 6.50–8.25 (18H, m, aromatic protons), 9.38 (1H, br s, D-exchangeable, OH), consistent with the formation of 1′,2′-dihydro-1,3-diphenyl-2′-(2-hydroxyphenyl)spiro[[2]-pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**13**).

(*c*) *Methylation*

To an ice-cooled solution of the title compound (0.5 g) in dilute sodium hydroxide (15 ml), dimethyl sulfate (1.0 ml) was added dropwise with stirring and then the mixture was heated on a water bath for 1 h. The resulting oil which separated was extracted into chloroform. This

extract was washed with dilute sodium hydroxide then with water and dried. Evaporation of the organic solvent yielded an off-white solid (0.45 g), mp 128–132°C, which could not be purified by fractional crystallization from various solvents but which consisted mainly of 1,3-diphenyl-4-[2-(*o*-methoxybenzylidene)aminobenzyl]-2-methyl-3-pyrazolin-5-one (**14**); ir ν_{max} 1660 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 2.98 (3H, s, NCH_3), 3.37 (2H, s, CH_2), 3.87 (3H, s, OCH_3), 6.40–7.90 (18H, m, aromatic protons); ms *m/e* (% relative abundance) 473(M^+, 4), 472(9), 458(8), 383(80), 118(100).

(*d*) *Acetylation*

A solution of the title compound (0.3 g) in acetic anhydride (5 ml) was heated under reflux for 15 min then poured into ice-water (30 ml). The resulting precipitate was crystallized from ethanol and yielded 1′-acetyl-2′-(2-acetoxyphenyl)-1′,2′-dihydro-1,3-diphenylspiro[[2]-pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**16***e*) as colorless needles (0.22 g), mp 240–241°C; ir ν_{max} 1764 (ester C=O), 1720 (lactam C=O), 1666 (amide C=O) cm^{-1}; ^{1}Hmr (DMSO-d_6) δ 1.93 (3H, s, $OCOCH_3$), 2.24 (3H, s, $NCOCH_3$), 3.26 (2H, d of d, J = 15 Hz, CH_2), 6.30–8.30 (14H, m, C-2′ proton and aromatic protons). *Anal.* ($C_{33}H_{27}N_3O_4$) C,H,N.

*Reactions of 1′,2′-dihydrospiro[[2]pyrazoline-4,3′(4′H)-quinoline]-5-ones (**8**)*

(*a*) *Acetylation*

Each of the spiro[pyrazolone–quinolines] (**8***b*, *c*, *e*, *n*, and *o*) (0.3 g) was acetylated in the manner described above for the acetylation of compound **12**. Products were **16***f*, mp 220–221°C; **16***c*, mp 223–224°C; **16***b*, mp 205–206°C; **16***a*, mp 218–219°C; and **16***d*, mp 188–189°C, respectively. They were crystallized from ethanol as colorless compounds in 78–91% yields. Elemental analyses of the acetylated products are listed in Table 3.[3] The ir spectra of all five acetamides contained C=O absorption bands near 1665 (cyclic amide) and 1710 cm^{-1} (lactam) and were devoid of N—H bands. Compounds **16***b* and **16***d* contained an additional C=O band near 1765 cm^{-1} (ester). Important signals in the ^{1}Hmr spectra of these acetyl derivatives are listed in Table 2.

(*b*) *Reduction with Sodium Borohydride*

(*i*) A solution of 1′,2′-dihydro-2′,3-dimethyl-1-phenylspiro[[2]pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**8***a*, 0.5 g) in dioxane (15 ml) was added dropwise to a stirred solution of sodium borohydride (0.5 g) in water (5 ml). After addition was completed, stirring was continued for 30 min then the reaction mixture was acidified with dilute acetic acid and diluted with water. Crystallization of the resulting precipitate from ethanol gave 4-(2-ethylaminobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one (**18***a*) as a white crystalline powder (0.33 g), mp 181–182°C; ir ν_{max} 2100–3500 (OH) with maximum at 3380 (NH), 1620 (bonded C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 1.02 (3H, t, CH_3), 1.91 (3H, s, CH_3), 3.40 (2H, s, CH_2), 3.62 (2H, q, CH_2), 6.40–7.40 (11H, m, aromatic protons overlapping NH and pyrazoline ring protons); ms, see Scheme 6. *Anal.* ($C_{19}H_{21}N_3O$) C,H,N.

(*ii*) 1′,2′-Dihydro-2′-ethyl-3-methyl-1-phenylspiro[[2]-pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**8***b*, 0.5 g) was similarly reduced to give 3-methyl-1-phenyl-4-(2-*n*-propylaminobenzyl)-2-pyrazolin-5-one (**18***b*, 0.31 g) as white crystals, mp 149–150°C; ir ν_{max} 2040–3400 with maximum at 3380 (OH and NH), 1617 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 0.70–1.75 (5H, m, CH_2CH_3), 2.05 (3H, s, CH_3), 3.30 (2H, s, CH_2), 3.45 (2H, t, NCH_2), 6.30–7.60 (10H, m, aromatic protons and pyrazoline ring proton), 9.02 (1H, br s, D-exchangeable, NH); ms, see Scheme 6. *Anal.* ($C_{20}H_{23}N_3O$) C,H,N.

(*iii*) 1′,2′-Dihydro-1,2′-diphenyl-3-methylspiro[[2] pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**8***c*, 0.5 g) was similarly reduced and yielded 4-(2-benzylaminobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one (**18***c*, 0.39 g) as white crystals, mp 155–156°C; ir ν_{max} 2000–3360 with maximum at 3305 cm^{-1} (OH and NH), 1612 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 1.88 (3H, s, CH_3), 3.33 (2H, s, CH_2), 4.25 (2H, s, CH_2), 6.40–7.80 (16H, m, aromatic protons overlapping NH and pyrazoline ring protons); ms, see Scheme 6. *Anal.* ($C_{24}H_{23}N_3O$) C,H,N.

(*c*) *Reduction with Lithium Aluminum Hydride*

(*i*) A solution of 1′,2′-dihydro-2′,3-dimethyl-1-phenylspiro[[2]pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**8***a*, 0.75 g) in ether (50 ml) was slowly added, with stirring, to a mixture of lithium aluminum hydride (0.15 g) and ether (20 ml). After heating under reflux for 10 h, water was added dropwise to the cooled reaction mixture until the evolution of hydrogen ceased. The solution was made alkaline by the addition of 30% aqueous sodium hydroxide (~20 ml) then the mixture was extracted with ether (2 × 50 ml). Evaporation of the dry (Na_2SO_4) combined ether extracts gave a white powder which crystallized from ethanol as a white solid (0.14 g), mp 178–179°C. This compound is tentatively identified as 1′,2′-dihydro-2′,3-dimethyl-1-phenylspiro[[2]pyrazoline-4,3′(4′*H*)-quinoline] (**19***a*); ir ν_{max} 3470, 3390 br, 1595 (NH) cm^{-1}, C=O absorption absent; ms *m/e* (% relative abundance) 291(M^+, 2), 263(97), 248(10), 171(100). *Anal.* ($C_{19}H_{21}N_3$) C,H,N.

The basic aqueous solution which remained was neutralized with dilute sulfuric acid then extracted with ether (3 × 50 ml). The combined ether extracts were dried (Na_2SO_4) and evaporated to give 4-(2-ethylaminobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one (**18***a*, 0.29 g), identical (mp, ir, mass spectrum) to the product obtained by reducing **8***a* with sodium borohydride as described above.

(*ii*) 1′,2′-Dihydro-2′-ethyl-3-methyl-1-phenylspiro[[2]-pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**8***b*, 0.8 g) was reduced with lithium aluminum hydride in a manner similar to reaction *i* above. The basic product was a white solid (0.12 g), mp 170–171°C and is tentatively identified as 1′,2′-dihydro-2′-ethyl-3-methyl-1-phenylspiro[[2] pyrazoline-4,3′(4′*H*)-quinoline] (**19***b*); ir ν_{max} 3405, 3290 br, 1600 (NH) cm^{-1}, C=O absorption absent; ms *m/e* (% relative abundance) 305(M^+, 25), 303(9), 276(13), 274 (34), 263(43), 171(65), 118(100). *Anal.* ($C_{20}H_{23}N_3$) C,H,N.

The product isolated from neutral solution was 3-methyl-1-phenyl-4-(2-*n*-propylaminobenzyl)-2-pyrazolin-5-one (**18***b*, 0.21 g), identical (mp, ir, mass spectrum) to the product formed by reducing **8***b* with sodium borohydride (see above).

(*iii*) Reduction of 1′,2′-dihydro-1,2′-diphenyl-3-methylspiro[[2]-pyrazoline-4,3′(4′*H*)-quinoline]-5-one (**8***c*, 1.0 g) with lithium aluminum hydride as described in reaction *i* gave basic material which was fractionally crystallized from ethanol and yielded starting material (**8***c*, 0.21 g) and another product (0.09 g), mp 205–206°C

which is tentatively identified as 1′,2′-dihydro-1,2′-diphenyl-3-methylspiro[[2]pyrazoline-4,3′(4′*H*)-quinoline] (**19***c*); ir ν_{max} 3380, 3290 br, 1597 (NH) cm^{-1}; ms *m/e* (% relative abundance) 353(M^+, 7), 351(100), 350(29), 336(8), 274(22), 193(36); accurate mass measurements: 353.1888 ($C_{24}H_{23}N_3$ requires 353.1892), 351.1730 ($C_{24}H_{21}N_3$ requires 351.1736). *Anal.* ($C_{24}H_{23}N_3$) C,H,N.

The product (0.32 g) isolated from the neutralized solution was identical (mp, ir) to the previously identified (see above) 4-(2-benzylaminobenzyl)-3-methyl-1-phenyl-2-pyrazolin-5-one (**18***c*).

P. MEUNIER et G. PFISTER-GUILLOUZO. Can. J. Chem. **55**, 2867 (1977).

Les dithiéno[*c,e*] dihydro azépines, oxépinnes et thiépinnes ont fait l'objet d'une étude par spectroscopie photoélectronique. L'analyse de ces données expérimentales a permis de conclure pour ces composés, à l'existence en phase vapeur d'une conformation croisée.

P. MEUNIER and G. PFISTER-GUILLOUZO. Can. J. Chem. **55**, 2867 (1977).

Dithieno[*c,e*]dihydroazapines, oxepines, and thiepines have been studied by photoelectron spectroscopy. The results of this work are reasonably well interpreted in terms of a twisted conformation in the vapor phase.

Introduction

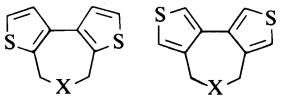
Les dithiéno[*c,e*] dihydro azépines, oxépinnes et thiépinnes peuvent être considérées soit comme des dérivés de substitution des dihydro-2,7 azépine, oxépinne et thiépinne, soit comme des bithiényls hétéropontés.

Selon la préférence conformationnelle de l'hétérocycle à sept chaînons (forme "semi-bateau" ou "croisée"), et l'encombrement stérique provoqué par la substitution, le squelette bithiénylique présentera une conformation *cis*, plane ou twistée.

A notre connaissance, les dihydro "épinnes" envisagées n'ont pas été isolées. Seules les données de diffraction électronique recueillies pour leur homologue carboné, le cycloheptadiène-1,3 (1, 2) avaient permis de conclure en la prépondérance en phase vapeur de la forme "semi-bateau" de ce composé. Par contre, le cycloheptadiène-1,3 et diverses dihydro "épinnes" benzo substituées ont fait l'objet d'une étude rmn (3, 4). Les auteurs proposent pour tous ces dérivés l'existence d'une forme "croisée" en solution, les barrières d'inversion étant d'environ 15 kcal/mol.

Des travaux récents ont mis en évidence l'apport de la spe à l'étude de nombreux problèmes conformationnels (5). Dans ce travail, nous avons appliqué cette technique à une série de dithiéno "épinnes" de type **1** et **2** afin d'en préciser la conformation privilégiée à l'état vapeur. Nos conclusions sont vérifiées par l'examen de certains de ces composés *gem* diméthylés en α et α′ de l'hétéroatome.

Dérivés de type **1** et **2**



1 **2**

X = NR,O,S

Composés de type 1

Ces composés peuvent être considérés comme des dérivés du bithiényl-3,3′ hétéropontés en position 2 et 2′.

Pour le bithiényl-3,3′ lui-même (5*f*), nous avons attribué les potentiels d'ionisation à 8.2, 9.15 et 10.03 eV à l'ionisation des électrons π des quatre orbitales moléculaires schématisées sur la fig. 1. Celles-ci correspondent respectivement aux combinaisons antisymétrique et symétrique des deux orbitales A_2 et B_1 du thiophène. Les écarts observés (approximativement 1 eV et 0.9 eV) correspondent à une interaction moyenne entre les deux noyaux qui s'interprète bien compte tenu de l'angle de twist d'environ 30° déterminé par diffraction électronique (6).

Pour les composés de type **1**, on peut envisager des interactions similaires entre les deux noyaux thiophéniques liées directement à la conformation du cycle heptagonal. Ces interactions sont ainsi attendues nettement plus importantes pour

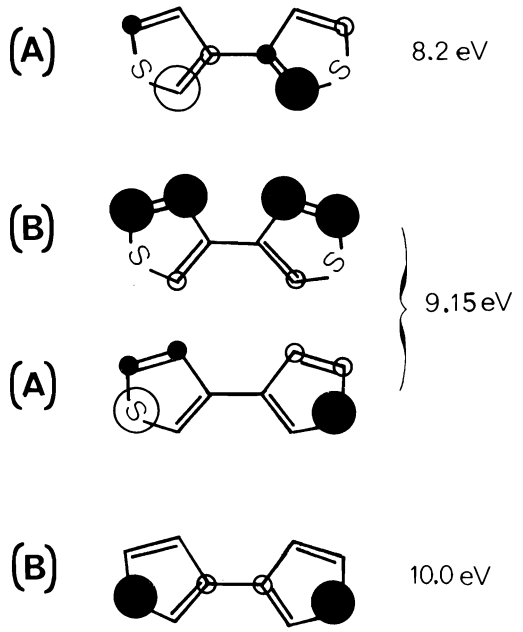


FIG. 1. Orbitales moléculaires du bithiényl-3,3′.

une conformation "enveloppe" que pour une conformation "croisée".

Par ailleurs, la présence de l'hétéroatome X entraine un léger effet de polarisation auquel doit s'ajouter compte tenu de la symétrie de la molécule, une interaction possible entre la paire π de cet hétéroatome et les combinaisons symétriques des orbitales A_2 et B_1 du thiophène (notamment cette dernière, compte tenu du recouvrement entre la paire π de l'hétéroatome et les paires π des atomes de soufre dans les cycles thiophéniques relativement plus important).

Spectres expérimentaux

Les spectres sont reportés dans les figs 2 à 5, et les valeurs des potentiels d'ionisation verticaux ont été rassemblées dans le tableau 1 avec celles observées pour le bithiényl-3,3′.

On note pour tous les composés étudiés des spectres dont l'allure est très voisine de celle du spectre du bithiényl-3,3′. La présence de l'hétéroatome se traduit par une bande supplémentaire dont nous précisons la position avant de discuter des bandes caractéristiques du système bithiényl.

Dithiéno[2′,3′-c;3″,2″-e] 4H, 5 éthyl, 6H azépine et dithiéno[2′,3′-c;3″,2″-e] 4H, 5 phényl, 6H azépine

Dans le cas du dérivé *N*-éthylé, on observe une bande à 8.3 eV qui peut être associée à l'ionisation de la paire libre de l'atome d'azote. Cette valeur peut être rapprochée de celle observée à 8.5 eV dans la triméthylamine (7).

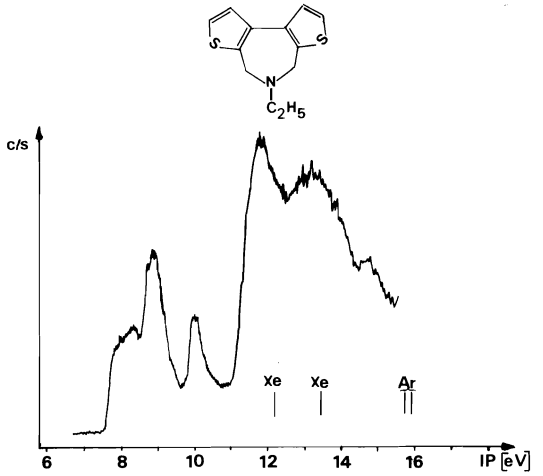

FIG. 2. Spectre photoélectronique du dithiéno[2′,3′-*c*; 3″,2″-*e*] 4*H*, 5 éthyl, 6*H* azépine.

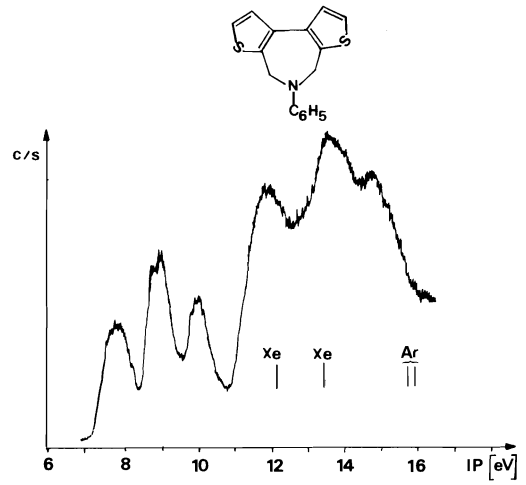

FIG. 3. Spectre photoélectronique du dithiéno[2′,3′-*c*; 3″,2″-*e*] 4*H*, 5 phényl, 6*H* azépine.

Pour le dérivé *N*-phénylé on observe comme pour les dérivés de l'aniline (8) une interaction entre la paire libre de l'azote et les orbitales dégénérées e_{1g} du benzène. Ces ionisations sont à l'origine (*i*) de l'élargissement de la première bande à 7.9 eV, (*ii*) d'une bande dans la région de 10 eV comme pour la *N*,*N*-diméthylaniline, (*iii*) de la bande à 9 eV (ionisation des électrons de l'orbitale e_{1g} antisymétrique).

Dithiéno[2′,3′-c;3″,2″-e] 4H, 6H oxépinne

Pour ce composé, l'ionisation d'un électron de

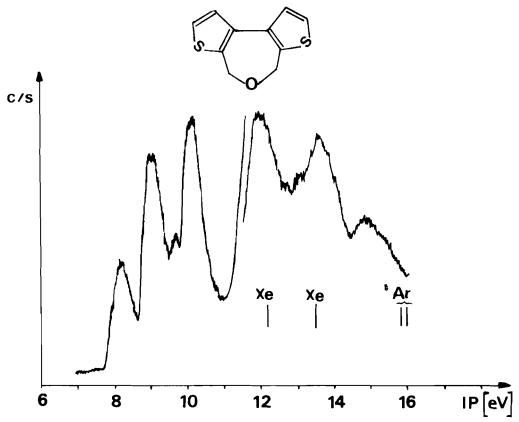

FIG. 4. Spectre photoélectronique du dithiéno[2′,3′-*c*; 3″,2″-*e*] 4*H* 6*H* oxépinne.

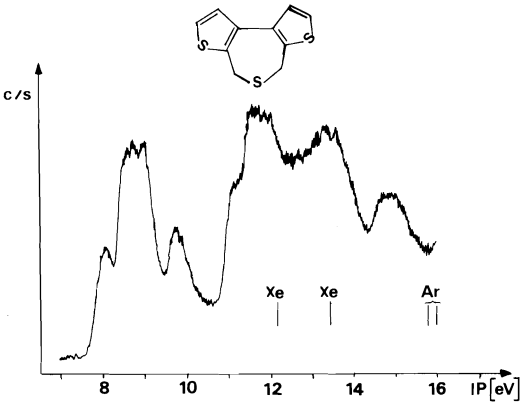

FIG. 5. Spectre photoélectronique du dithiéno[2′,3′-*c*; 3″,2″-*e*] 4*H* 6*H* thiépinne.

la paire π de l'oxygène correspond à la bande large et intense observée à 10.1 eV, valeur à rapprocher de celle observée à 10.04 eV dans le diméthyl éther (9).

Dithiéno[2′,3′-c;3″2,″-e] 4H, 6H thiépinne

L'ionisation de la paire π de l'atome de soufre intervient dans la même région que les deuxième et troisième bandes du système bithiényl. Le massif est large et l'on peut observer trois potentiels d'ionisation verticaux à 8.65, 8.75 et 9.05 eV.

L'ionisation de la paire π de l'atome de soufre intervenant à 8.7 eV dans le diméthyl sulfure (9) et 8.5 eV dans le pentaméthylène sulfure (10), il semble raisonnable de proposer pour les premières et deuxième bandes du bithiényl, celles à 8.15 et 8.75 eV. L'ionisation de la paire π du soufre interviendrait donc à 8.65 eV.

On observe de plus dans ce cas une bande de faible intensité apparaissant à 11.2 eV sous forme d'un épaulement d'une bande plus intense. On peut associer cette bande à l'ionisation des paires σ des atomes de soufre thiophéniques. Nous en apporterons d'ailleurs une confirmation ultérieurement.

Discussion des résultats

Les positions respectives des quatre potentiels d'ionisation associés au système bithiényl s'interprètent de façon qualitative par les interactions mises en jeu entre les paires libres de l'hétéroatome central et les combinaisons symétriques des orbitales des noyaux thiophéniques. Celles-ci sont schématisées sur la fig. 6.

L'effet de polarisation du pont CH_2—X—CH_2 tend à destabiliser les premières bandes du spectre de façon similaire.[1] Pour les trois composés, l'écart entre les premier et deuxième potentiels d'ionisation en première approximation permettra d'évaluer l'angle existant entre les deux noyaux thiophéniques.

Ces écarts sont de 0.9, 0.85 et 0.6 eV respectivement pour l'azépine, l'oxépinne et la thiépinne.

Si l'on rapproche ces données de celles recueillies pour le bithiényl-3,3′ (écart entre le premier

[1]Cet effet varie dans l'ordre NR > S > O, il peut être estimé pratiquement négligeable dans le cas de l'oxépinne.

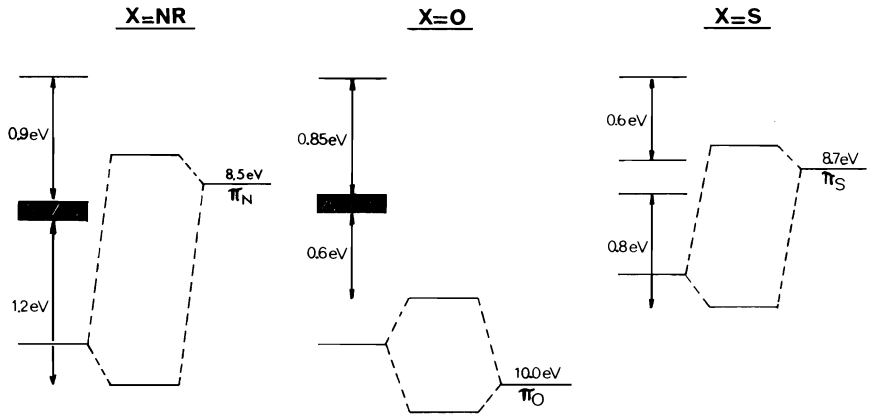

FIG. 6. Diagramme qualitatif des interactions orbitalaires mises en jeu entre le système bithiényl et l'hétéroatome X.

TABLEAU 2. Potentiels d'ionisation verticaux du bithiényl-3,3′ et des dérivés de type **2**

Attributions	Symétrie	Bithiényl-3,3′	Composés type **2**		
			X = NC_6H_5	X = O	X = S
$\pi_{C=C}$	A	8.2	8.15	8.3	8.4
$\pi_{C=C}$	B	9.15	8.9	8.9	8.9
π_S	A	9.15	8.9	8.9	8.9
π_S	B	10.0	10.0	9.5	9.75
π_X	B		7.5	10.0	8.4
n_S	A		8.9	11.2	11.1

et le deuxième potentiels d'ionisation: approximativement 1 eV) présentant en phase vapeur un angle twist d'environ 30° (6), on remarque que, dans le cas de l'azépine et de l'oxépinne, les éclatements observés sont sensiblement du même ordre, quoique un peu plus faibles, ce qui laisse présumer d'un angle de twist entre les deux noyaux de 30 à 40°. Pour la thiépinne, les faibles éclatements observés ne s'interprètent que par une rotation plus importante des cycles.

Dans tous les cas, l'existence privilégiée d'une forme "semi bateau" du cycle heptagonal où les deux cycles thiophéniques seraient coplanaires conduirait à une interaction plus forte entre les cycles thiophéniques que celle observée dans le bithiényl-3,3′, hypothèse incompatible avec les valeurs expérimentales observées.

Composés de type 2

Les spectres sont reportés dans les figs 7, 8 et 9 et les valeurs des potentiels d'ionisation verticaux sont rassemblés dans le tableau 2.

L'ionisation des électrons des paires libres des hétéroatomes du cycle heptagonal peut être associée aux bandes suivantes:

7.5 eV pour l'azépinne

10.0 eV pour l'oxépinne

Dans le cas de la thiépinne, la forte intensité de la première bande à 8.4 eV laisse présumer du recouvrement de deux ionisations. Compte tenu de la légère destabilisation observée pour les paires de l'oxygène et de l'azote comparativement aux dérivés de type **1**, il semble bien que l'on puisse attribuer à l'ionisation des électrons de la paire libre du soufre une valeur aux environs de 8.4 eV.

Dans le cas de l'azépine, la bande correspondant à l'ionisation des électrons du cycle benzénique (e_{1g} antisymétrique) peut être attribuée à celle observée à 8.9 eV, cette bande résultant du recouvrement de trois ionisations.

Discussion des résultats

Comme dans le cas des dérivés de type **1**, les éclatements observés entre les deux premiers potentiels d'ionisation associés aux orbitales A_2 du thiophène suivent le même classement: NR >

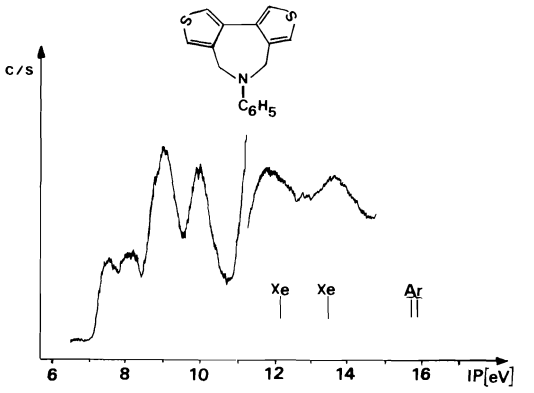

FIG. 7. Spectre photoélectronique du dithiéno[3′,4′-*c*; 3″,4″-*e*] 4*H*, 5 phényl, 6*H* azépine.

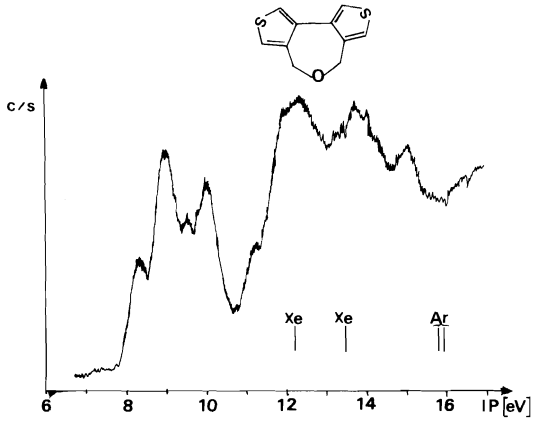

FIG. 8. Spectre photoélectronique du dithiéno[3′,4′-*c*; 3″,4″-*e*] 4*H*, 6*H* oxépinne.

O > S. Cet éclatement est nettement plus faible que pour les dérivés de type **1**: 0.75, 0.6 et 0.5 eV. Les interactions entre les orbitales semi-localisées du thiophène qui sont liées à la position différente des cycles thiophéniques ne permettent pas d'interpréter à elles seules ces données. Il semble logique de conclure pour les composés de type **2** à un angle de torsion légèrement plus important entre les deux cycles thiophéniques que pour les dérivés de type **1**. Comme précédemment l'azépinne et l'oxépinne auraient un angle de torsion voisin tandis que la thiépinne serait sensiblement plus twistée.

Composés tétraméthyles

Afin de compléter cette étude, nous avons examiné les spectres des composés dérivés des oxépinnes précédentes et substitués en α et α′ de l'oxygène par deux groupements méthyles.

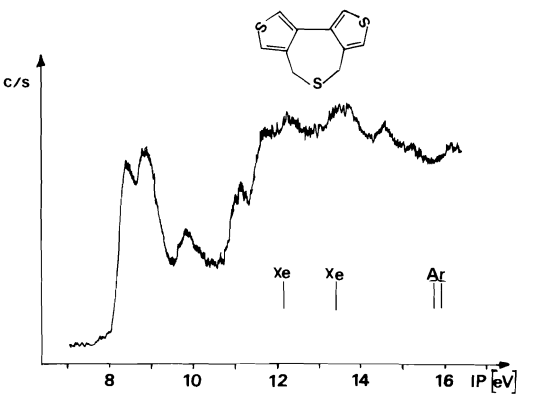

FIG. 9. Spectre photoélectronique du dithiéno[3′,4′-*c*; 3″,4″-*e*] 4*H*, 6*H* thiépinne.

Les spectres sont reproduits sur les figs 10 et 11 et les valeurs des potentiels d'ionisation sont rassemblées dans le tableau 3.

On constate pour les deux composés étudiés: (*i*) une destabilisation de toutes les premières bandes du spectre, (*ii*) une destabilisation plus importante (0.5 à 0.6 eV) de la dernière bande associée aux électrons σ des atomes de soufre thiophéniques. Dans ce cas, on n'observe plus un épaulement mais une bande bien définie.

Pour ces deux composés, l'allure des spectres et les éclatements observés conduisent à conclure à l'existence d'une conformation très voisine de celle existant pour les dérivés non méthylés. Le fait que ces composés fortement encombrés stériquement présentent le même type de conformation que ceux non substitués est cohérent avec les conclusions que nous avons

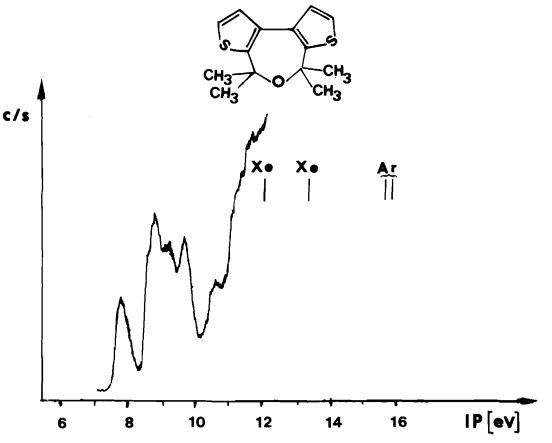

FIG. 10. Spectre photoélectronique du tétraméthyl-4,4,6,6 dithiéno[2′,3′-*c*;3″,2″-*e*] 4*H*, 6*H* oxépinne.

formulées précédemment quant à l'existence d'une forme "croisée" en phase gazeuse.

Conclusion

L'analyse des spectres photoélectroniques des diverses dihydroépinnes étudiées met en évidence pour tous les composés une interaction entre les deux systèmes thiophéniques plus faible que celle observée dans le cas du bithiényl-3,3′. Ce composé présentant d'après les données de diffraction électronique un angle de twist d'environ 30°, il semble raisonnable de proposer pour tous les composés examinés une conformation privilégiée en phase gazeuse correspondant à une forme "croisée". Cette hypothèse est confirmée par l'examen des spectres d'oxépinnes substituées par des groupements méthyles en position αα′ pour lesquels une forme semi bateau n'est pas envisageable compte tenu de l'encombrement stérique.

De façon qualitative on peut estimer que pour les composés de type **1** l'angle de torsion entre les cycles est sensiblement identique (de l'ordre de 30 à 40°) pour les dérivés azotés et oxygénés et comparable à celui observé pour le bithiényl-3,3′ tandis que cet angle est nettement supérieur pour les dérivés sulfurés.

Par contre la conformation des dérivés pour lesquels les thiophènes sont reliés par leur chaînon (*c*) présente vraisemblablement un angle de torsion des cycles supérieur.

Conditions expérimentales

Les spectres ont été enregistrés sur un spectrophotomètre Perkin-Elmer PS 18 muni d'une source à hélium I (584 Å, 21.21 eV). L'étalonnage a été effectué avec les pics $^2P_{1/2}$ et $^2P_{3/2}$ du xénon (12.127 et 13.427 eV) et de l'argon (15.755 et 15.933 eV).

Les potentiels d'ionisation théoriques ont été calculés à l'aide de la méthode CNDO/S (11) dans le cadre du théorème de Koopmans (12).

Les orbitales *d* des atomes de soufre n'ont pas été prises en considération.

Les paramètres géométriques utilisés sont ceux déterminés théoriquement par optimisation énergétique à l'aide de la méthode PCILO (13).

Nuclear analogs of β-lactam antibiotics. VII. Synthesis of 2-isocephems[1]

TERRENCE WILLIAM DOYLE,[2,3] JAMES LESLIE DOUGLAS,[2] BERNARD BELLEAU, JACQUES MEUNIER, AND BING-YU LUH

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received March 17, 1977

TERRENCE WILLIAM DOYLE, JAMES LESLIE DOUGLAS, BERNARD BELLEAU, JACQUES MEUNIER, and BING-YU LUH. Can. J. Chem. **55**, 2873 (1977).

The synthesis of 7-β-phenoxyacetamido-3-methyl-Δ^3-2-isocephem-4-carboxylic acid **14***b* and its corresponding α-sulfoxide **15** and sulfone **17** is described. Treatment of the bismesylates **4***a*, **4***b*, and **10** with hydrogen sulfide triethylamine gave the corresponding 7-β-amino-Δ^3-2-isocephems **12***a–c* which were coupled with phenoxyacetic acid to yield the amides **13***a–c*. Hydrogenolysis of **13***b* and *c* gave the acids **14***a–b* which were active as antibiotics. Compound **14***b* was oxidized to its sulfoxide **15** with sodium metaperiodate and to its sulfone **17** with *m*-chloroperbenzoic acid. Conversion of **13***c* to its sulfoxide **16***b* followed by halogenation gave the 1α-chloro sulfoxide **18** which was converted to the acid **19**. The stereochemical assignments in the 2-isocephem series are discussed.

TERRENCE WILLIAM DOYLE, JAMES LESLIE DOUGLAS, BERNARD BELLEAU, JACQUES MEUNIER et BING-YU LUH. Can. J. Chem. **55**, 2873 (1977).

On décrit la synthèse de l'acide phénoxyacétamino-7β méthyl-3 Δ^3 isocéphem-2 carboxylique-4 (**14***b*) et de ses sulfoxyde α (**15**) et sulfone **17** correspondants. La réaction des bismésylates **4***a*, **4***b* et **10** avec le sulfure d'hydrogène dans la triéthylamine conduit aux amino-7β Δ^3 isocéphems-2 (**12***a–c*) correspondants qui peuvent réagir avec l'acide phénoxyacétique pour produire les amides **13***a–c*. L'hydrogénolyse de **13***b* et de **13***c* fournit les acides **14***a–b* qui sont actifs comme antibiotiques. On a oxydé le composé **14***b* en sulfoxyde **15** à l'aide du métapériodate de sodium et en sulfone **17** en faisant appel á l'acide métachloroperbenzoique. La transformation de **13***c* en sulfoxyde correspondant **16***b* suivie par une halogénation donne le chloro-1α sulfoxyde **18** qui peut être transformé en acide **19**. On discute des attributions stéréochimiques dans la série des isocéphems-2.

[Traduit par le journal]

In our earlier communications the synthesis of a number of *O*-2-isocephems and *N*-2-isocephems were described (1, 2). We now wish to describe the synthesis of the 2-isocephem system as well as its sulfoxide and sulfone (Fig. 1, X = S, SO, SO_2, Y = CH_2, R = ϕOCH_2, R_2 = H, R_3 = H, CH_3).[4]

To date there has been only one report of a synthesis of the 2-isocephem system by Brunwin and Lowe (4). They have described the synthesis of the 7-α-methyl-7-β-phenylacetamido-2-isocephem-4-carboxylic acid **1** (R_1 = ϕCH_2, R_2 = CH_3, R_3 = H, Y = CH_2, X = S). This material was reported to be devoid of antibiotic activity, which result was not surprising in view of the fact that substitution of the 6 position in penicillins or the 7 position in cephalosporins by a methyl group results in extensive loss of activity (5). In addition Woodward and co-workers have reported the syntheses of a number of cephalosporins containing disulfide linkages (**1**, X = Y = S) in which biological activity has been retained (6).

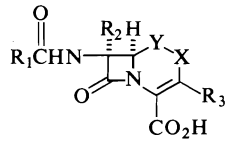

FIGURE 1

Our approach to these compounds is an extension of our synthesis of the *O*-2-isocephem system which we have reported earlier (2*b*). The key intermediates in our synthesis were the bismesylates **4***a*, **4***b*, and **10**. Compounds **4***b* and **10** were prepared in the same manner as **4***a* (1) (Scheme 1). Thus treatment of **2***a* (2*b*) with *p*-nitrobenzyl chloroformate followed by heating

[1]For part VI of this series see ref. 1.

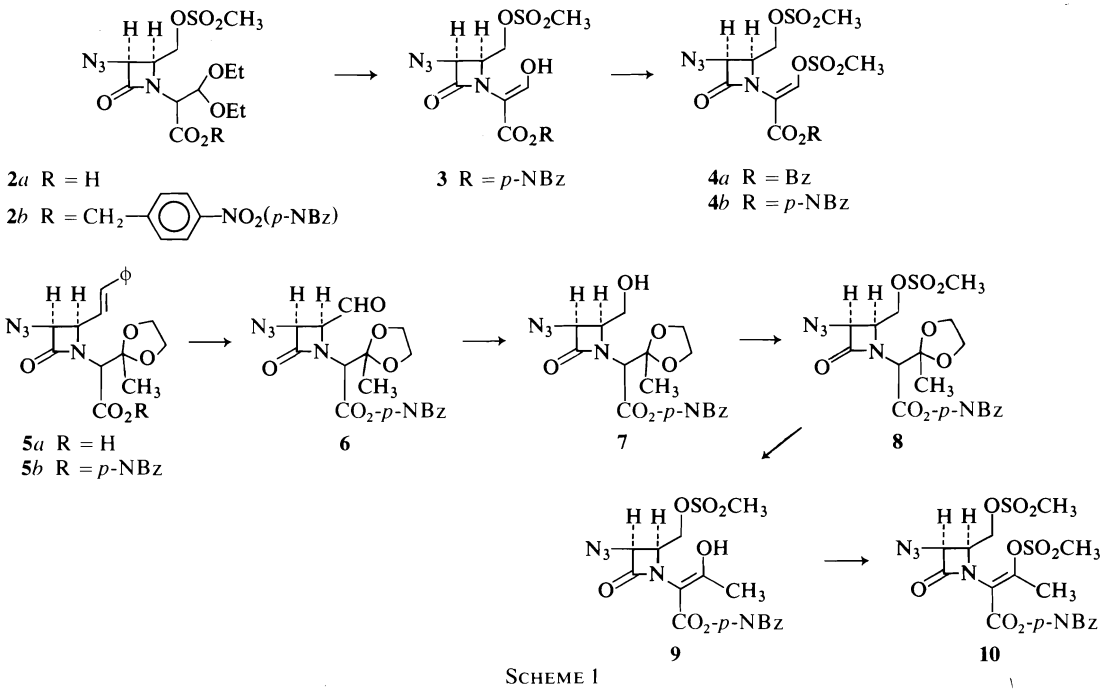
[4]For an explanation of the trivial nomenclature used in this series of papers see ref. 2. Alternatively the nomenclature suggested by Bose might be used. Under such nomenclature the Δ^3-2-isocephem system would be named as a 2-thia-3-octem (3).



SCHEME 1

gave the ester **2***b* in 85% yield. Hydrolysis of the acetal function using 95% trifluoroacetic acid gave the enol **3** in 36% yield. Treatment of the enol **3** with methane sulfonyl chloride and base gave the desired bismesylate **4***b* in 93% yield.

The synthesis of **10** was carried out as follows. Treatment of the acid **5***a* (2*b*) with *p*-nitrobenzyl chloroformate followed by heating as in the preparation of **2***b* gave the ester **5***b* in quantitative yield. Ozonolysis of **5***b* followed by decomposition of the ozonide with dimethyl sulfide gave the aldehyde **6** in 41% yield when isolated. Generally the crude aldehyde was directly reduced with sodium borohydride in tetrahydrofuran at low temperature to give **7**. The crude alcohol was converted to its mesylate **8** which was isolated as a solid in 36% overall yield from **5***a*. Hydrolysis of **8** with trifluoroacetic acid (95%) gave the enol **9** in quantitative yield. Finally treatment of **9** with methane sulfonyl chloride – triethylamine gave the desired bismesylate **10** as an oil (85%).

Our initial experiment on the ring closure of bismesylate to 2-isocephem was carried out on **4***a*. Treatment of **4***a* with potassium acid sulfide in dimethyl sulfoxide gave **11***a* in 44% yield as a crystalline solid. The structure of **11***a* was indicated by its ir, nmr, and uv spectra as well as its correct elemental analysis. The nmr spectrum of **11***a* in $CDCl_3$ was deceptively simple (Table 1) showing a simple doublet of triplets for the C_6 proton and a doublet for the C_1 protons. When the spectrum was recorded in either deuterodimethyl sulfoxide or deuterobenzene the more complex ABX spectrum for these three protons was observed. An analysis of the coupling constants for the C_6, C_1, and C_3 protons of **11***a* permits one to assign each proton as well as to determine the conformation of **11***a* in solution. An examination of Dreiding models of the 2-isocephem system showed that **11***a* could exist in either of two possible conformations A or B (Fig. 2). The coupling constants of $H_{1\alpha}$–H_6 and $H_{1\beta}$–H_6 are 3.5 and 9.5 Hz, respectively, in (C_6D_6). Conformer A is the only conformer consistent with this observation. In addition the 1 Hz long range coupling constant between H_3 and $H_{1\alpha}$ confirms this assignment, these protons being properly aligned in the W configuration in this particular conformation (7). This assignment is in accord with that reached in the *O*-2-isocephem and *N*-2-isocephem systems (1, 2*b*). The uv spectrum of **11***a* showed a band at 303 nm with an extinction coefficient of 13 400. This is in contrast to the value of 296 nm with an extinction coefficient of 4300 reported by Lowe (3) for his 2-isocephem **1** (Fig. 1, X = S, Y = CH_2, R_1 = ϕCH_2, R_2 = Me, R_3 = H). It is apparent

FIGURE 2

that the material obtained by these workers cannot have been of much greater than 33% purity inasmuch as it is highly unlikely that substitution of the 7α-proton by methyl would produce such a difference in the extinction coefficient for the two compounds. The values for the extinction coefficients for all 2-isocephems prepared in this work ranged from 11 400 to 15 000.

Reduction of the azido function **11***a* was accomplished using hydrogen sulfide – triethylamine to give **12***a* in 77% yield. The amine was coupled to phenoxyacetic acid using *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline(EEDQ) (8) to give **13***a* (78%). Attempted conversion of the ester to the desired acid **14***a* by hydrogenolysis failed due to poisoning of the catalyst. Accordingly it was decided to prepare **14***a* via the *p*-nitrobenzyl ester.

Treatment of **4***b* with hydrogen sulfide and 2.2 equiv. of triethylamine followed by immediate work-up gave the desired 2-isocephem **11***b* in 55.5% yield. Reduction of **11***b* with triethylamine – hydrogen sulfide gave the amine **12***b* in quantitative yield. Coupling of **12***b* and phenoxyacetic acid with EEDQ proceeded in 64% yield to give **13***b*. The preparation of the 3-methyl substituted 2-isocephem was carried out similarly. Thus treatment of the bismesylate **10** with hydrogen sulfide – triethylamine for an extended period (45 min vs. 10 min) accomplished both the ring closure and azide reduction in one step giving the amine **12***c* in 77% yield from **10**. The conversion of the amine **12***c* to its phenoxyacetamide was carried out in the usual fashion to give **13***c* in 74% yield.

Hydrogenolysis of **13***b* over palladium-on-carbon gave the desired acid **14***a* in 40.5% yield. Similarly hydrogenolysis of **13***c* gave **14***b* in 70% yield. The structures of **14***a* and **14***b* were established by their mode of synthesis, elemental analyses, and spectral properties. Both **14***a* and **14***b* exhibited significant antibiotic activity.

Treatment of **14***b* with 1 equiv. of sodium metaperiodate gave the sulfoxide **15** in 77% yield as a single isomer. Alternatively **15** could be prepared by conversion of **13***c* to its sulfoxide **16***b* using *m*-chloroperbenzoic acid followed by reduction of **16***b* to **15** on 10% palladium-on-carbon. The overall yield of **15** from **13***c* was 84%. The material was identical in all respects with that obtained from **14***b*, thus indicating the stereochemistry of the sulfoxide to be the same in each case. Treatment of **14***b* with an excess of *m*-chloroperbenzoic acid gave the sulfone **17** in 25% yield.

Chlorination of the sulfoxide **16***b* using *tert*-butyl hypochlorite gave the monochloro derivative **18** as a single isomer in 67% yield. Compound **18** was converted to the acid by hydrogenolysis over 10% palladium-on-charcoal. Thus **19** was prepared in 56% yield.

Inasmuch as only a single sulfoxide isomer was produced in the oxidations of **14***b* to **15**, **13***a* to **16***a*, and **13***c* to **16***b* the assignment of configuration to these compounds (**15**, **16***a*, **16***b*) rests upon the assumption that oxidation of the sulfur should occur from the least hindered face of the molecule thus producing the α-sulfoxide in each instance. Unfortunately the nmr spectra of compounds **15**, **16***a*, **16***b* did little to resolve the question of their stereochemistry although the down field shift of the C_6 proton was suggestive of the formation of an α-sulfoxide with the pseudoaxial configuration (Fig. 3).

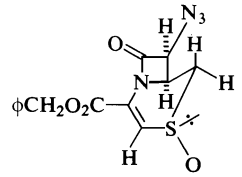

FIGURE 3

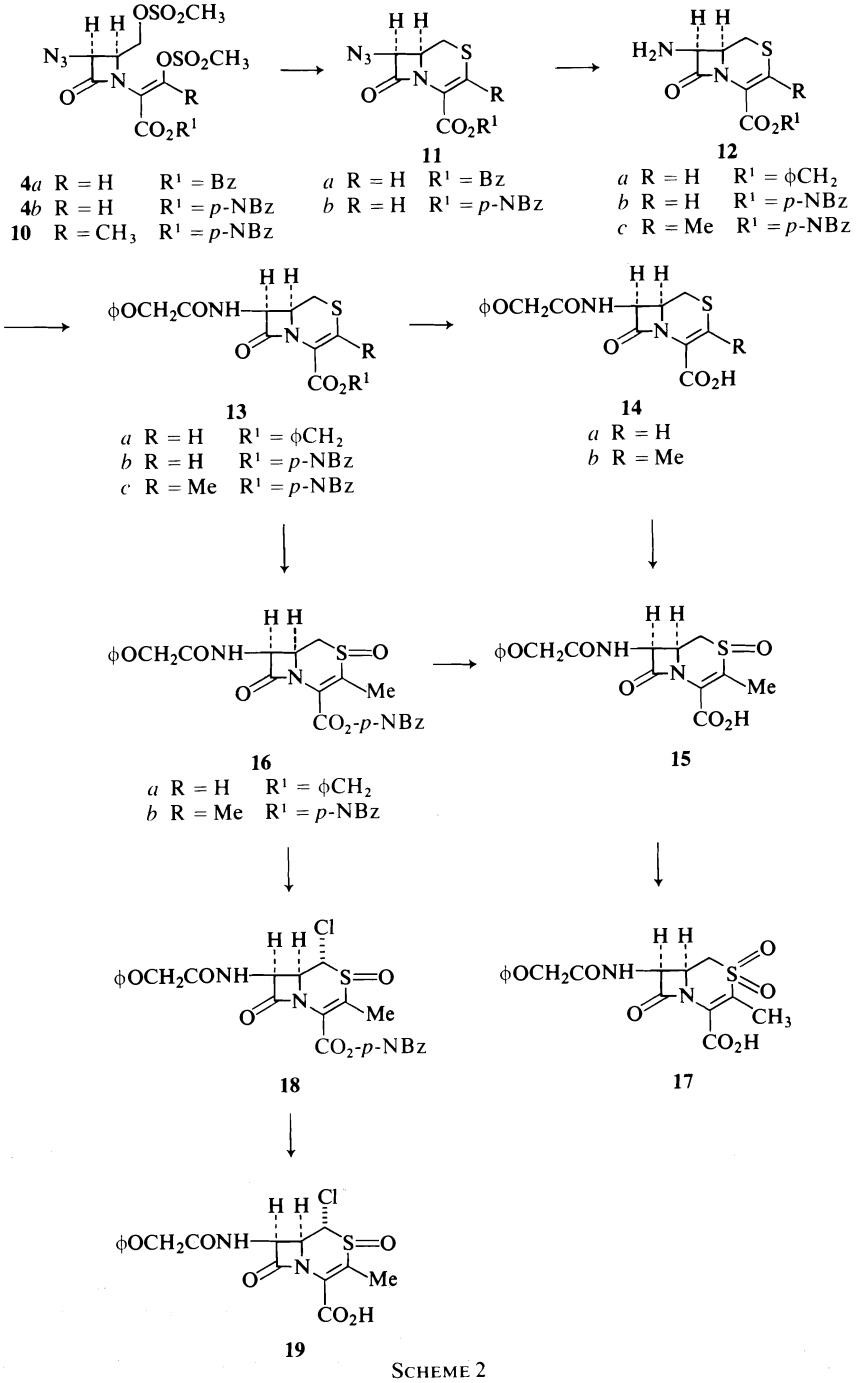
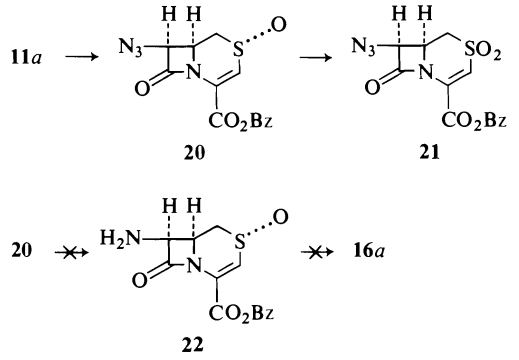
In order to help resolve this question the oxidation of **11***a* to its sulfoxide **20** was carried out. Treatment of **11***a* with 1 equiv. of *m*-chloroperbenzoic acid gave **20** in 74% yield as a single isomer. Prolonged treatment of **11***a* with an excess of *m*-chloroperbenzoic acid gave the sulfone **21** in 86% yield. Several attempts to convert **20** to **16***a* via the amine **22** failed.

A comparison of the nmr spectra of compounds **11***a*, **20**, and **21** permits the configurational assignment to **20** to be made and by inference to **15**, **16***a* and **16***b*. In the nmr spectrum of **20** a down field shift of 0.35 ppm for the C_6 proton was observed typical of the shift usually observed for a proton *syn*-axial to an axial sulfoxide group (9). Conversion of **20** to **21** results



SCHEME 2

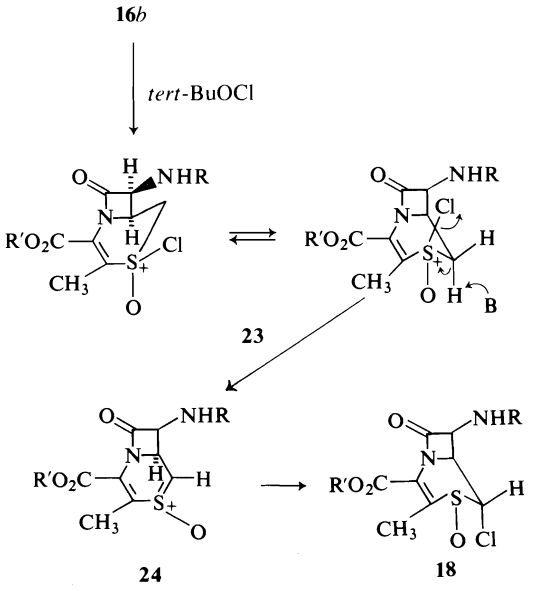
in no shift of the C_6 proton. From the coupling constants for the $C_{1\alpha}$ and $C_{1\beta}$ protons to the C_6 proton both **11***a* and **20** are in the same conformation as shown for **20** in Fig. 3. Thus based on the down field shift of the C_6 proton the α-sulfoxide configuration is assigned to **20**. This is also borne out by the size of the geminal coupling constant for $C_{1\alpha}$ and $C_{1\beta}$ protons in **20** vs. **11***a*. In compound **11***a* J_{gem} = 12.5 Hz while in **20** J_{gem} = 14.5 Hz. The increased J_{gem} is diagnostic



SCHEME 3

of an axial sulfoxide (10) although in the absence of the β-isomer this assignment must be viewed cautiously.

The stereochemical assignment to the α-chlorosulfoxide **18** is uncertain. Recent reports on the stereochemistry of α-halogenation of sulfoxides (11) and the mechanism of the reaction suggest that the chlorination of **17** probably proceeds via the intermediates **23** (Scheme 4) and **24**. A priori one would expect attack of the chloride ion on **24** to proceed from the less hindered α face to give the α-chloro sulfoxide. The nmr spectrum of **18** is in accord with this expectation, there being an ~1.5 Hz coupling constant between the proton α to chlorine and the C_6 proton. The only isomer in which such a small coupling is to be expected is the α-chloro isomer in the conformation shown.



SCHEME 4

While the configuration of the α-chloro group may be thus assigned that of the sulfoxide is less certain. α-Halogenation has been shown to involve both retention and inversion of configuration at sulfur depending on the nature of the sulfoxide and the halogenating agent (11). Spry has reported that α-chlorination of the β-sulfoxide **25** proceeded with retention of configuration at sulfur although no details of the stereochemical assignment were given (12). Inasmuch as this chlorination of **25** probably proceeds via an intermediate **26** similar to **24**, by

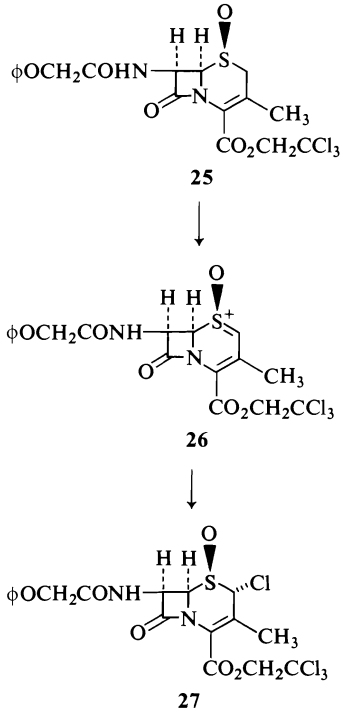


FIGURE 4

analogy the conversion of **16*b*** to **18** may well involve retention at sulfur (Fig. 4).

Experimental

The infrared spectra were recorded on a Unicam SP-200G grating, ir spectrometer. The nmr spectra were determined on a Varian A60-A spectrometer using tetramethylsilane as an internal standard. Melting points are uncorrected and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, IL.

Preparation of 4b

To a solution of 23.0 g crude acid **2*a*** in 150 ml CH_2Cl_2 at 0–5°C was added 15.4 g *p*-nitrobenzylchloroformate. A solution of 8.5 ml triethylamine in 50 ml CH_2Cl_2 was added dropwise. Vigorous gas evolution and darkening of the solution was observed. The solution was refluxed 15

min and diluted to 300 ml with ether. The solution was washed with 10% HCl (2 × 50 ml), 1% NaOH (1 × 50 ml), and brine (100 ml), dried over Na_2SO_4, and filtered through a pad of activity 3 alumina (~50 g). The filtrate was evaporated to give 26.6 g of crude *p*-nitrobenzyl ester **2***b*.

The crude *p*-nitrobenzyl ester **2***b* was taken up in 100 ml of 95% TFA and evaporated to dryness at 50°C under vacuum (rotary evaporator). This procedure was repeated once and the residual oil taken up in CH_2Cl_2. The solution was washed with brine (3 × 100 ml), dried over Na_2SO_4, filtered, and evaporated. The residual oil was taken up in ether and extracted with 1% NaOH. The aqueous fractions were acidified and extracted into ether – methylene chloride (3 × 100 ml). The extracts were dried over Na_2SO_4, filtered, and evaporated to give 8.0 g of enol **3**; uv (EtOH) λ_{max} 238 (ε 9900).

To a solution of 6.5 g (14.7 mmol) of **3** and 224 ml triethylamine in 75 ml CH_2Cl_2 was added 1.25 ml methanesulfonyl chloride in 10 ml CH_2Cl_2 at 0–5°C. The solution was stirred at 0–5°C for 30 min, washed with 10% HCl, saturated $NaHCO_3$, and brine, dried over Na_2SO_4, filtered, and evaporated to yield 7.08 g (93%) of **4***b*. The nmr and ir spectra of **4***b* were compatible with the assigned structure (as a mixture of geometrical isomers). The oil was used without further purification in the next step.

Preparation of ***10***

A solution of the acid **5***a* (89.5 g, 0.25 mol) and triethylamine (27.8 g, 0.275 mol) in 1.35 ℓ of CH_2Cl_2 was placed in a 2 ℓ flask equipped with magnetic stirrer, a nitrogen inlet, and a dropping funnel. A solution of *p*-nitrobenzylchloroformate (59.3 g, 0.275 mol) in 275 ml of CH_2Cl_2 was added slowly while the reaction mixture was maintained at 0–5°. After completion of the addition, the reaction mixture was maintained at 25°C for 30 min, then heated under reflux until gas evolution ceased (45 min). The resulting solution was washed with brine, 10% HCl (2 × 500 ml), and brine, then dried (Na_2SO_4) and evaporated *in vacuo* (35°C) to give ester **5***b* as an orange oil, 123 g (100%) which was used in subsequent reactions without purification.

A solution of compound **5***b* (123 g, 0.25 mol) in 1.7 ℓ of CH_2Cl_2 was cooled to −78°C and ozone passed through until a blue color persisted (3 h). The excess ozone was flushed out with nitrogen. Dimethyl sulfide (100 ml) was added over 30 min to the solution at −78°C, which was then allowed to come to 25°C over 1 h. The solution was evaporated *in vacuo* and the residue redissolved in 1.7 ℓ of CH_2Cl_2. This solution was washed with brine (2×), dried (Na_2SO_4), filtered through a pad of alumina (500 g, grade III), and evaporated *in vacuo*. The final evaporation was done at 40–45°C and 0.3 Torr for 24 h. The resulting oil, 93.3 g, was shown by nmr to be approximately 35% benzaldehyde and 65% aldehyde **6** (mol%). The oil was triturated with cold ether and the resulting solid was collected by filtration to give 42.5 g of **6** as a white solid, mp 143–146°C; ir (neat) 1785, 1735 cm^{-1}. *Anal.* calcd. for $C_{17}H_{17}N_5O_8$: C 48.69, H 4.09, N 16.70; found: C 48.71, H 4.16, N 16.52.

The crude aldehyde was generally used as such in subsequent reactions.

Sodium borohydride (4.2 g, 0.111 mol) was added in three portions to a stirred solution of crude aldehyde **6** (93.3 g, 0.222 mol) in 775 ml of THF at −5 to −10°C. The reaction was maintained at −5 to −10°C for 2 h, then acidified to p*H* 3 with 10% HCl, saturated with NaCl, and evaporated *in vacuo* (35°C). The resulting residue was mixed with 500 ml of brine and extracted (3 × 400 ml) with CH_2Cl_2. The extracts were dried (Na_2SO_4), filtered through a pad of alumina (500 g, grade III), and evaporated *in vacuo* to give a yellow oil, 80.0 g. The nmr and ir spectra of this oil were consistent with the major portion of the oil being the desired alcohol **7** plus some impurities, including benzyl alcohol.

A solution of 80.0 g (0.19 mol) of alcohol **7** and 30.7 g (0.304 ml) of triethylamine in 825 ml of CH_2Cl_2 was cooled to 0°C and a solution of methane – sulfonyl chloride (32.6 g, 0.285 mol) in 240 ml of CH_2Cl_2 was added over 45 min. The reaction mixture was stirred at 25°C for 5 h, then washed with brine (3 × 500 ml) and 10% HCl (3 × 500 ml). The resulting solution was dried (Na_2SO_4) and evaporated *in vacuo* to a red oil. The oil was crystallized from benzene–ether to give pure mesylate **8** as a colorless solid, 44.5 g, mp 133–136°C. The overall yield from **5***a* to **8** was 36%; ir (Nujol mull) 2110, 1775, 1742 cm^{-1}. *Anal.* calcd. for $C_{18}H_{21}N_5O_{10}S$: C 43.29, H 4.24, N 14.02, S 6.42; found: C 42.85, H 4.38, N 14.24, S 6.35.

A solution of ketal **8** (43.4 g, 87 mmol), trifluoroacetic acid (380 ml), and water (20 ml) was left at 25°C for 2.5 h, then evaporated *in vacuo* at 35°C. The residue was mixed with 400 ml of brine and extracted (3 × 200 ml) with CH_2Cl_2. The organic extract was washed (2 × 100 ml) with brine, dried (Na_2SO_4), and evaporated *in vacuo* to give the enol **9** as a yellow oil, 44.8 g; ir (neat) 2110, 1785, 1755, 1660, 1605 cm^{-1}.

A solution of enol **9** (32.0 g, 74 mmol) and methanesulfonyl chloride (9.32 g, 81.4 mmol) in 950 ml of CH_2Cl_2 was added over 1 h. The reaction mixture was stirred another 1 h at 0°C, then washed with brine (2 × 500 ml), 10% HCl (2 × 500 ml), and brine (500 ml). The solution was dried (Na_2SO_4), filtered through a pad of alumina (200 g, grade III), and evaporated *in vacuo* (35°C) to give the dimesylate **10** as an orange oil, 33.45 g; ir (neat) 2110, 1780, 1735, 1645, 1610 cm^{-1}.

Benzyl 7-β-Azido-Δ³-2-isocephem-4-carboxylate ***11a***

To a solution of 497.5 mg (1.05 mmol) of compound **4***a* in 9 ml dry DMSO at 25°C was added a solution of 160 mg (2.10 mmol) potassium acid sulfide in 5 ml DMSO in a dropwise fashion. As each drop was added a transient green color was observed. After approximately 50% of the KSH solution had been added, the green color faded to yellow (rather than colorless as previously observed). Addition was stopped and the solution was stirred 5 min. The solution was poured into 50 ml of brine to which 10 ml 10% HCl had been added. The solution was extracted with CH_2Cl_2–Et_2O, the extracts washed with water (3 × 50 ml) and brine (1 × 25 ml), dried over Na_2SO_4, filtered, and evaporated to yield 255 mg partially crystalline oil. The oil was passed through 2 g silica gel with CH_2Cl_2 and evaporated. Trituration with ether (5 ml) and filtration gave 145 mg of **11***a*, mp 97°C; ir ($CHCl_3$): 2110, 1782, 1715, 1580 cm^{-1}; uv (EtOH) λ_{max} 303 (ε 13 400). *Anal.* calcd. for $C_{14}H_{12}N_4O_3S$: C 53.15, H 3.82, N 17.71; found: C 53.19, H 3.75, N 17.94.

p-Nitrobenzyl 7-β-Azido-Δ³-2-isocephem-4-carboxylate ***11b***

Into a solution of 2.90 g (5.6 mmol) bismesylate **4***b* in 50 ml CH_2Cl_2 was bubbled H_2S gas for 3 min. To this

was added 1.35 g (13.3 mmol) triethylamine in 10 ml CH_2Cl_2 dropwise over 10 min. The solution was purged with a stream of N_2 and washed with 10% HCl, $NaHCO_3$, and brine. The solution was dried over Na_2SO_4 and concentrated. Trituration of the oil with CH_2Cl_2 induced crystallization. Filtration gave 1.12 g (55.5%) crystalline **11***b*, mp 187.5–188.5°C; uv (EtOH) λ_{max} 303 (ε 14 970); ir ($CHCl_3$): 2110, 1782, 1720, 1608, 1573, 1525 cm^{-1}. *Anal.* calcd. for $C_{14}H_{11}N_5O_5S$: C 46.53, H 3.07, N 19.38, S 8.87; found: C 46.69, H 3.07, N 19.65, S 9.18.

Benzyl 7-β-Amino-Δ³-2-isocephem-4-carboxylate ***12a***

To a solution of 316 mg (1 mmol) of **11***a* in 20 ml methylene chloride was added 101 mg (1 mmol) triethylamine. A stream of hydrogen sulfide was passed through the solution for 3 min and the solution was let stand 1 h at 25°C. The solvent was evaporated at reduced pressure and the residue was partitioned between 10% hydrochloric acid and ether. The aqueous layer was neutralized using sodium bicarbonate and extracted with methylene chloride. The extracts were dried over sodium sulfate and evaporated to yield 223 mg (77%) of **12***a*, mp 119–120°C, recrystallized from benzene; ir ($CHCl_3$): 3400, 1770, 1715, 1577 cm^{-1}; uv (EtOH) λ_{max} 305 (ε 14 060). *Anal.* calcd. for $C_{14}H_{14}N_2O_3S$: C 57.91, H 4.86, N 9.65, S 11.04; found: C 58.32, H 4.81, N 9.70, S 11.17.

p-Nitrobenzyl 7-β-Amino-Δ³-2-isocephem-4-carboxylate ***12b***

Reduction of 525 mg (1.45 mmol) of **11***b* in methylene chloride using triethylamine – hydrogen sulfide as in the above example gave 486 mg (100%) of **12***b*, mp 181.5–183°C recrystallized from acetonitrile–ether; ir ($CHCl_3$): 1775, 1720, 1610, 1580, 1530 cm^{-1}; uv (EtOH) λ_{max} 301 (ε 15 200). *Anal.* calcd. for $C_{14}H_{13}N_3O_5S$: C 50.14, H 3.91, N 12.53, S 9.56; found: C 49.85, H 3.85, N 12.67, S 9.59.

p-Nitrobenzyl 3-Methyl-7-β-amino-Δ³-2-isocephem-4-carboxylate ***12c***

Hydrogen sulfide was passed into a solution of dimesylate **10** (4.4 g, 8.24 mmol) in 90 ml of CH_2Cl_2 at 0–5°C for 15 min. With the temperature maintained at 0–5°C, a solution of triethylamine (2.5 g, 24.7 mmol) in 50 ml of CH_2Cl_2 was added over 10 min. The reaction mixture was stirred at 25°C for 45 min. The resulting solution was washed with brine (2 × 100 ml), dried (Na_2SO_4), treated with charcoal, and evaporated *in vacuo* to give a yellow oil. The oil was dissolved in a minimum volume of CH_2Cl_2 (an insoluble gum was removed by filtration) and saturated with HCl (gas). Ether was added to near opalescence and the solution was cooled to 0°C. The hydrochloride salt of **12***c* was obtained as a pale yellow solid, 2.5 g (77%), mp 194–195°C (dec.). The amine **12***c* was stored as its HCl salt; the free base was prepared as follows. The salt was suspended in water, $NaHCO_3$ added until basic, and the mixture extracted (3×) with CH_2Cl_2. The extracts were dried, treated with charcoal, and evaporated *in vacuo* to give the free base **12***c* as a pale yellow foam; ir (Nujol mull on HCl salt): 1782, 1695, 1610, 1580, 1530 cm^{-1}. *Anal.* calcd. for $C_{15}H_{15}N_3O_5S \cdot HCl$: C 46.70, H 4.18, N 10.89, Cl 9.19, S 8.31; found: C 46.50, H 4.20, N 10.85, Cl 9.08, S 8.18.

Benzyl 7-β-(Phenoxyacetamido)-Δ³-2-isocephem-4-carboxylate ***13a***

To a solution of 223 mg (0.77 mmol) of **12***a* in 25 ml methylene chloride was added 123 mg (0.81 mmol) phenoxyacetic acid followed by 200 mg (0.81 mmol) EEDQ. The solution was let stand 18 h at 25°C and washed with 10% hydrochloric acid, 5% sodium bicarbonate, water, and brine. After drying over sodium sulfate, the extracts were evaporated and the residual oil triturated with ether–chloroform. There was obtained 254.5 mg (78%) of **13***a*, mp 184–185°C with decomposition; ir ($CHCl_3$): 3430, 3350, 1770, 1712, 1690, 1601, 1590, 1575, 1530, 1500 cm^{-1}; uv (EtOH) λ_{max} 303 (ε 12 850). *Anal.* calcd. for $C_{22}H_{20}N_2O_5S$: C 62.26, H 4.75, N 6.60, S 7.55; found: C 62.32, H 4.98, N 6.63, S 7.50.

p-Nitrobenzyl 7-β-(Phenoxyacetamido)-Δ³-2-isocephem-4-carboxylate ***13b***

The coupling of 335 mg (1 mmol) of **12***b* with phenoxyacetic acid using EEDQ as in the above example gave 295.7 mg (64%) of **13***b*, mp 180°C after recrystallization from benzene; ir ($CHCl_3$): 3420, 1778, 1720, 1692, 1598, 1573, 1523, 1492 cm^{-1}; uv (EtOH) λ_{max} 302.5 (ε 15 060). *Anal.* calcd. for $C_{22}H_{19}N_3O_7S$: C 56.28, H 4.07, N 8.95, S 6.83; found: C 55.93, H 4.06, N 9.05, S 6.62.

p-Nitrobenzyl 3-Methyl-7-β-(phenoxyacetamido)-Δ³-2-isocephem-4-carboxylate ***13c***

Treatment of 4.0 g (11.4 mmol) of **12***c* with phenoxyacetic acid and EEDQ as in the above example gave after work-up **13***c* as a foam. The foam was recrystallized from benzene to yield 4.75 g (74%) of **13***c* as a beige solid; ir (Nujol mull): 3340, 3310, 1755, 1715, 1680, 1600, 1590, 1575 cm^{-1}. *Anal.* calcd. for $C_{23}H_{21}N_3O_7S$: C 57.14, H 4.38, N 8.69; found: C 57.46, H 4.44, N 8.20.

7-β-(Phenoxyacetamido)-Δ³-2-isocephem-4-carboxylic Acid ***14a***

Compound **13***b* (469 mg, 0.001 mol) in 2 ml DMF and 20 ml methanol (to which 5 drops 10% HCl had been added) were stirred with 700 mg of 10% Pd/C at atmospheric pressure and ambient temperature (20°C) under hydrogen. Rapid uptake of 3 equiv. of hydrogen was observed (35 min). The uptake of the fourth equivalent of hydrogen required an additional 2 h. The suspension was filtered through Celite (filter cake washed with CH_2Cl_2) and the filtrate evaporated. The residue was taken up in 50 ml CH_2Cl_2 and the filtrate evaporated. The solution was dried over Na_2SO_4 and filtered. The filtrate was evaporated to give a yellow solid. Trituration with 5 ml ether and filtration gave 135 mg (40.5%) of **14***a*, mp 209–210°C with decomposition (after recrystallization from acetone–ether); ir (KBr disc): 2400–3600, 3340, 1770, 1750, 1665, 1575 cm^{-1}; uv (EtOH) λ_{max} 298 (ε 12 750). *Anal.* calcd. for $C_{15}H_{14}N_2O_5S$: C 53.87, H 4.22, N 8.37, S 9.59; found: C 53.43, H 4.23, N 8.45, S 9.38.

3-Methyl-7-β-(Phenoxyacetamido)-Δ³-2-isocephem-4-carboxylic Acid ***14b***

A solution of **13***c* (2.0 g, 3.57 mmol) in dioxane (50 ml) and methanol (25 ml) containing 1.0 g of 10% palladium-on-charcoal was hydrogenated on a Parr shaker at 25°C and 50 psi for 3 h. The catalyst was filtered off and the solution evaporated to dryness *in vacuo*. The residue was dissolved in ethyl acetate (EtOAc) and washed with 10% HCl (3×), then with brine. The aqueous layers were extracted (2×) with EtOAc and each extract washed with brine. The combined organic layers were treated with charcoal and evaporated *in vacuo* to a solid. The solid was dissolved in very dilute $NaHCO_3$ containing slightly more

than 1 equiv. of base. This aqueous solution was washed with EtOAc, acidified to p*H* 2 with 10% HCl, and extracted 2× with EtOAc. The organic solution was dried (Na_2SO_4) and evaporated *in vacuo* to give the acid **14***b* as an off-white solid, 865 mg (70% yield). The product could be recrystallized from EtOAc, mp 219–220°C; ir (Nujol mull): 3340, 1755(s), 1745, 1705, 1660, 1590 cm^{-1}; uv (MeOH) λ_{max} 294 (ε 11 400). *Anal.* calcd. for $C_{16}H_{16}N_2O_5S$: C 55.16, H 4.63, N 8.04, S 9.20; found: C 55.03, H 4.62, N 7.98, S 9.07.

Benzyl 2-Oxido-7-β-(Phenoxyacetamido)-Δ³-2-isocephem-4-carboxylate ***16a***

To a solution of 215 mg (0.51 mmol) of **13***a* in 15 ml of methylene chloride was added 107 mg (~0.51 mmol) of *m*-chloroperbenzoic acid in 5 ml methylene chloride at 0–5°C over 15 min. The solution was stirred 15 min at 25°C and washed with 5% sodium bicarbonate solution. The solution was dried over sodium sulfate and concentrated to yield a semisolid which crystallized on trituration with ether to give 157.0 mg (70%) of **16***a*, mp 203–204°C; ir ($CHCl_3$): 3410, 1795, 1735, 1695, 1609, 1595, 1520, 1495 cm^{-1}. *Anal.* calcd. for $C_{22}H_{20}N_2O_6S$: C 59.98, H 4.58, N 6.36, S 7.27; found: C 59.91, H 4.40, N 6.44, S 7.05.

p-Nitrobenzyl 2-Oxido-3-methyl-7-β-(phenoxyacetamido)-Δ³-2-isocephem-4-carboxylate ***16b***

A solution of *m*-chloroperbenzoic acid (103 mg, containing 0.505 mmol) in 11 ml of CH_2Cl_2 was added over 75 min to a stirred solution of **13***b* (280 mg, 0.50 mmol) in 11 ml of CH_2Cl_2 at 0°C. After a further 15 min at 0°C, the solution was washed (3×) with 10% $NaHCO_3$ containing several drops of Na_2CO_3, dried, and evaporated *in vacuo* to give the sulfoxide **16***b* as a colorless foam, 281 mg.

2-Oxido-3-methyl-7-β-(phenoxyacetamido)-Δ³-2-isocephem-4-carboxylic Acid ***15***

From ***14b***

The isocephem **14***b* (454 mg, 1.30 mmol), 45 ml of water, $NaHCO_3$ (110 mg, 1.31 mmol), and sodium metaperiodate (280 mg, 1.30 mmol) were stirred together at 25°C for 24 h. The resulting solution was saturated with NaCl and 10% HCl added until p*H* 2 reached. This mixture was extracted (3×) with EtOAc containing some MeOH. The combined extracts were washed with brine, dried, and evaporated *in vacuo* to give the sulfoxide **15**, 363 mg (77% yield), as a beige solid. Recrystallization from EtOAc–MeOH gave a colorless solid, mp 229–232°C (dec.); ir (Nujol mull): 3360, 3310, 1775, 1720, 1635, 1600, 1595, 1545, 1495 cm^{-1}; uv (MeOH) λ_{max} 270, 275 (ε 9100). *Anal.* calcd. for $C_{16}H_{16}N_2O_6S$: C 52.75, H 4.43, N 7.69, S 8.80; found: C 52.65, H 4.45, N 7.64, S 8.60.

From ***16b***

A mixture containing the sulfoxide ester **16***b* (280 mg, 0.485 mmol), THF (28 ml), dioxane (14 ml), MeOH (2.8 ml), and 10% palladium-on-charcoal was hydrogenated on a Parr shaker at 25°C and 50 psi for 4 h. The catalyst was filtered off and the solution evaporated *in vacuo*. The residue was mixed with EtOAc and ½ ml of 10% HCl and enough MeOH added to make a nearly homogeneous solution. The filtered solution was extracted (2 × 20 ml) with 1% $NaHCO_3$. The aqueous layer was acidified with 10% HCl, saturated with NaCl, and extracted (2×) with EtOAc/MeOH. The organic layers were washed with brine, dried, and evaporated *in vacuo* to give 149 mg (84%) of **15**, the ir and nmr spectra of which were identical with the sample prepared from **14***b*.

2,2-Dioxo-3-methyl-7-β-(phenoxyacetamido)-Δ³-2-isocephem-4-carboxylic Acid ***17***

A solution of *m*-chloroperbenzoic acid (542 mg, containing 2.66 mmol) in 5 ml of EtOAc was added to a slurry of isocephem **14***b* (440 mg, 1.26 mmol) in 44 ml of EtOAc. The mixture was stirred at 25°C for 40 h, then evaporated to dryness under a nitrogen stream. The resulting solid was triturated with small volumes of EtOAc several times, then recrystallized from EtOAc–MeOH (3×) to give the sulfone **17** as a colorless solid, mp 203–204°C (dec.), 118 mg (25% yield); ir (Nujol mull): 3380, 2400–3600, 1795, 1735, 1665, 1620, 1600, 1590, 1520, 1495 cm^{-1}; uv (MeOH) λ_{max} 267 (ε 11 100). *Anal.* calcd. for $C_{16}H_{16}N_2O_7S$: C 50.53, H 4.24, N 7.37, S 8.43; found: C 50.38, H 4.25, N 7.38, S 8.60.

p-Nitrobenzyl 1-α-Chloro-2-oxido-3-methyl-7-β(phenoxyacetamido)-Δ³-2-isocephem-4-carboxylate ***18***

To a slurry of sulfoxide **16***b* (889 mg, 1.78 mmol) and potassium acetate (465 mg, 4.74 mmol) in 70 ml of CH_2Cl_2 at 0°C was added a solution of *tert*-butyl hypochlorite (0.213 ml, 1.92 mmol) in 4 ml of CH_2Cl_2. The mixture was stirred at 0°C for 3.5 h. Water (70 ml) was added and the mixture shaken and separated. The water was extracted with more CH_2Cl_2 and the combined organic layers were washed with brine, dried (Na_2SO_4), and evaporated *in vacuo* to give a yellow oil. A $CHCl_3$ solution of the oil deposited crystals on standing 24 h. The mother liquors were chromatographed on silica (15% water) with $CHCl_3$, the second fraction giving desired product and the third fraction, starting material. Total yield of chlorosulfoxide **18** was 635 mg (67%). The product could be recrystallized from $CHCl_3$ to give material with mp 182–184°C (dec.); ir (Nujol mull): 3330, 1780, 1733, 1675 cm^{-1}. *Anal.* calcd. for $C_{23}H_{20}ClN_3O_8S$: C 51.74, H 3.78, N 7.87, Cl 6.63, S 6.01; found: C 51.47, H 3.66, N 7.74, Cl 6.48, S 5.85.

1-α-Chloro-2-oxido-3-methyl-7-β-(phenoxyacetamido)-Δ³-2-isocephem-4-carboxylic Acid ***19***

A mixture of **18** (600 mg, 1.125 mmol), 10% palladium-on-charcoal (600 mg), dioxane (30 ml), and methanol (15 ml) was hydrogenated on a Parr shaker at 50 psi and 25°C for 3.5 h. The catalyst was filtered off and the filtrates evaporated *in vacuo*. The resulting oil was dissolved in ethyl acetate and this solution was washed with 10% HCl (2 × 50 ml) and brine (2 × 50 ml) and then extracted with 10% $NaHCO_3$ (3 × 50 ml). The basic extracts were washed with ether (2×), acidified to p*H* 3 with 10% HCl, and extracted with ethyl acetate (3 × 75 ml). The combined extracts were washed with brine, dried (Na_2SO_4), and evaporated *in vacuo*. The resulting oil was crystallized from ethyl acetate to give the acid **19**, 250 mg (56%), mp 204–205°C (dec.); ir (Nujol mull): 3400, 3600–2400, 1790, 1778, 1710, 1670, 1660 cm^{-1}; uv (MeOH) λ_{max} 275 (ε 9500) 286 (ε 9400). *Anal.* calcd. for $C_{16}H_{15}ClN_2O_6S$: C 48.19, H 3.79, N 7.02, Cl 8.89, S 8.04; found: C 48.11, H 3.77, N 6.95, Cl 8.77, S 7.94.

Benzyl 2-Oxido-7-β-azido-Δ³-2-isocephem-4-carboxylate ***20***

To a solution of 2.005 g (6.35 mmol) of compound **11***a*

in 45 ml $CHCl_3$ at 0–5°C was added 1.35 g (6.45 mmol) of *m*-chloroperoxybenzoic acid (85%) in 25 ml $CHCl_3$ over 15 min. Thin layer chromatography showed complete reaction after addition was complete. The solution was stirred 15 min, diluted to 400 ml with $CHCl_3$, extracted with Na_2CO_3 (2 × 50 ml of saturated aqueous solution), dried over Na_2SO_4, and concentrated to give compound **20** as a solid. Trituration with 25 ml Et_2O and filtration gave 1.5 g sulfoxide **20** (74%); mp 159–160°C (dec.) recrystallized from $CHCl_3$–Et_2O; ir ($CHCl_3$) 2110, 1800, 1738, 1580 cm^{-1}; uv (EtOH) λ_{max} 279 (ε 12 100). *Anal.* calcd. for $C_{14}H_{12}N_4O_4S$: C 50.59, H 3.64, N 16.86; found: C 50.28, H 3.34, N 16.81.

Benzyl 2,2-Dioxido-7-β-azido-Δ^3-2-isocephem-4-carboxylate ***21***

To a solution of 158 mg (0.5 mmol) of **11***a* in 20 ml methylene chloride was added 220 mg (1.10 mmol) of 85% *m*-chloroperbenzoic acid. The solution was stirred at 25°C for 18 h and then washed with 5% sodium bicarbonate solution. The organic phase was dried over sodium sulfate and evaporated to give an oil which crystallized on trituration with ether. Filtration gave 150 mg (86.5%) of **21**, mp 113.5–114.5°C after recrystallization from chloroform–ether; ir ($CHCl_3$) 2110, 1803, 1740 cm^{-1}; uv (EtOH) λ_{max} 274 (ε 10 100). *Anal.* calcd. for $C_{14}H_{12}N_4O_5S$: C 48.27, H 3.47, N 16.09, S 9.21; found: C 48.38, H 3.31, N 16.08, S 9.42.

Approaches toward the conformational analysis of carbocyclic hydroxyphosphono compounds: ^{13}C–^{31}P couplings and carbon shieldings[1]

GERALD W. BUCHANAN AND FREDERICK G. MORIN
Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received February 18, 1977

GERALD W. BUCHANAN and FREDERICK G. MORIN. Can. J. Chem. **55**, 2885 (1977).

^{13}C nmr chemical shifts and ^{13}C–^{31}P couplings through one, two, and three bonds are reported for twelve carbocyclic hydroxyphosphonates and alkyl derivatives with all ring sizes from four to twelve, except the cyclodecyl system. On the basis of the vicinal couplings and carbon shieldings, inferences regarding preferred conformations are drawn. Evidence for ring flattening in some cyclohexyl compounds is presented. For a given ring size, it is demonstrated that $^1J_{CP}$ becomes less positive as the degree of steric congestion about the C—P bond increases.

GERALD W. BUCHANAN et FREDERICK G. MORIN. Can. J. Chem. **55**, 2885 (1977).

On rapporte les déplacements chimiques en rmn du ^{13}C et les constantes de couplage ^{13}C–^{31}P á travers un, deux et trois liens pour douze hydroxyphosphonates carbocycliques et pour leurs dérivés alkylés; les cycles de toutes les grandeurs allant de quatre á douze chaînons sont représentés á l'exception du système cyclodécyle. Sur la base des constantes de couplage vicinales et des blindages des carbones, on tire des conclusions concernant les conformations privilégiées. On présente des données concernant l'aplatissement du cycle dans quelques composés cyclohexaniques. Pour une grandeur de cycle donnée, on démontre que $^1J_{CP}$ devient plus positive à mesure que le degré de congestion stérique autour du lien C—P augmente.

[Traduit par le journal]

Introduction

Recent publications from these laboratories (1, 2) have dealt with the stereochemical dependence of ^{13}C–^{31}P couplings and ^{13}C chemical shifts for phosphonates of known geometry. For the direct ^{13}C–^{31}P interactions, some indications of a configurational dependence are evident (2), and there appears to be a Karplus-type relationship for the ^{13}C–C–C–^{31}P couplings, except when transmitted through a three-membered ring (1). Electronegative groups such as OH bonded to the carbon bearing the phosphorus have been shown to reduce the absolute value of J_{CCCP} substantially.

Presently we report the results of an investigation of twelve carbocyclic hydroxyphosphono compounds and some methylated derivatives with ring sizes ranging from four to twelve. Using ^{13}C–^{31}P couplings and ^{13}C chemical shifts as stereochemical probes, attempts to define preferred ring geometries are made. Where possible, comparisons with available X-ray data are presented.

[1]Presented in part at the International Symposium on Stereochemistry, Kingston, Ont., Canada. June 27 – July 2, 1976.

Results and Discussion

Spectral Assignments

Routinely the carbon spectra were obtained using complete ^1H noise decoupling. Subsequently the single frequency off-resonance decoupling technique was employed to identify CH_3, CH_2, CH, and quaternary carbons. Selective ^1H decoupling was used occasionally. Approximate signal intensities were an aid in cases where the molecules possessed obvious symmetry properties. Also the model compounds studied previously (1, 2) were valuable in many instances. The chemical shift data are collected in Table 1, while the one, two, and three bond ^{13}C–^{31}P J's are presented in Tables 2, 3, and 4 respectively.

Conformational Implications

In general the ^{13}C shifts and the vicinal couplings are the most useful for obtaining insight into conformational preferences. For the cyclobutyl system **1**, it is instructive to compare the C-3 shift (δ 13.4) with that of cyclobutane itself (δ 22.1) (3). In a puckered 1,1-disubstituted cyclobutane (4), one of the functions will be axial and one equatorial. The axial substituent experiences two *gauche*-butane type interactions

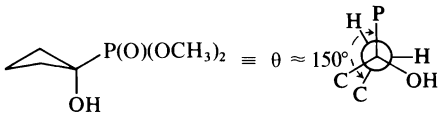
*0.2–0.3 *M* solutions in $CDCl_3$.

with the C-3 ring carbon and should, therefore, induce substantial upfield shifts at this site (5). Our recent work (1, 2) indicates that an axial $P(O)(OCH_3)_2$ function induces a *gauche*-γ shielding effect of 2–3 ppm at C-3,5 of a cyclohexane, whereas an axial OH causes a shielding of 5–6 ppm at these sites (6). On this basis, it appears that the preferred conformer of **1** has an axial OH and an equatorial dimethylphosphono group. This is consistent with the observation in cyclohexyl systems that dialkylphosphono groups are sterically bulky ($-\Delta G^0 \geq 3$ kcal/mol) (2).

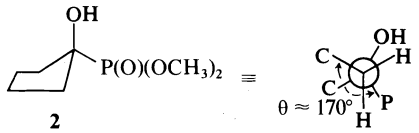
Electron diffraction of cyclobutane (7) gives a dihedral angle of 157° between C-3 and the equatorial H at C-1. In **1**, the ring may well be flattened more than in the hydrocarbon due to the axial OH, and the vicinal *J* of 6.5 Hz reflects this. The expected ^3J for θ = 180° is about 16 Hz (see discussion below). If the phosphorus were axial, the dihedral angle would be nearly 90° and minimal (<0.6 Hz) coupling is predicted (1).

For the cyclopentyl compound **2**, the chemical shifts at C-2,5 and C-3,4 are similar to those for cyclopentanol (36.0 and 24.1, respectively) (8) and C-3,4 of **2** are close to cyclopentane (25.3) (3). The large vicinal coupling of 13.0 Hz



1

suggests that the conformer with equatorial phosphorus is highly favoured. In this form, the dihedral angle can be estimated from models at ca. 170°.



2

The fact that the axial OH of **2** does not perturb the γ-ring carbon shifts of cyclopentane has been noted earlier (8) and is attributed to the lesser amount of ring puckering in the five-membered case than in cyclohexane. Furthermore it is apparent that the influence of the equatorial dimethylphosphono moiety on C-2,5 is minor (presumably due to the offsetting effect of the β-phosphorus atom and the γ-oxygens bonded to it).

For the *cis*-dimethylcyclopentyl compound **3**, the large three-bond *J* from ^{31}P to C-3,4 (16.1 Hz) suggests additional ring puckering to permit the CH_3's to become staggered with respect to the OH and the dimethylphosphono group. We envisage the preferred form of **3** to be that

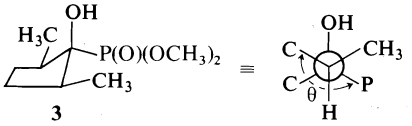
*$^{13}CH_3$–O–^{31}P *J*'s for **1**–**12** are all 7.2 ± 0.4 Hz, and are not listed individually.

depicted below. In such a conformation, the dihedral angle between phosphorus and C-3,4 is approximately 180° and accordingly the enhanced ^3J is noted. The population of the ring inverted form of **3** should be even lower than for **2** since 1,3-diaxial CH_3---CH_3 interactions would arise.



The non-resolvable coupling between phosphorus and the C-2,5 CH_3's of **3** ($\theta \approx 60°$) is reminiscent of the results for 4-*tert*-butylcyclohexylhydroxyphosphonates with axial phosphorus where no coupling to C-3,5 of the ring was found (1). It is notable that the CH_3's of **3** are shielded by 2 ppm relative to the CH_3 of *cis*-2-methylcyclopentanol (8, 9) as a consequence of the *gauche*-γ $P(O)(OCH_3)_2$ group in **3**.

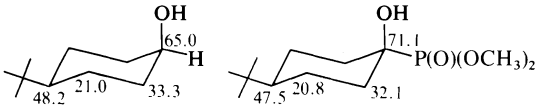
11	$^{3,10}C$–C–C–P	6.7
12	$^{3,11}C$–C–C–P	5.7

For the series of cyclohexyl compounds **4**–**7** the magnitudes of the vicinal coupling between the C-3 and C-5 ring positions and ^{31}P indicate the predominance of conformers with equatorial phosphorus. The methyl stereochemistry in **5**, **6**, and **7**, however, remains to be elucidated. Our approach to this problem involves the use of the methylcyclohexanols (6) as models and consideration of the effect of introducing an equatorial $P(O)(OCH_3)_2$ moiety on the chemical shifts. Comparison of *cis*-4-*tert*-butylcyclohexanol and the corresponding dimethylphosphono compound yields a set of substituent parameters outlined below (1, 6).



α = +6.1 ppm γ = −0.2 ppm
β = −1.2 ppm δ = −0.7 ppm

Model compounds selected were the *cis*-2-methyl, *trans*-3-methyl and *cis*-4-methylcyclohexanols. Equilibration data (10) indicate that the latter two exist at least 85% with axial OH and equatorial CH_3. Assuming approximate additivity of conformational energies (11), the 2-methyl case should be similar. With the alcohol data (6) and the α, β, γ, and δ effects of the equatorial dimethylphosphono group, predicted values for **5**, **6**, and **7** (assuming equatorial CH_3) are presented in Table 5. Observed shifts are in parentheses. Clearly, agreement is excellent for **6** and **7**, between predicted and observed

TABLE 5. Predicted and observed* ^{13}C shifts

	C-1	C-2	C-3	C-4	C-5	C-6
 5	77.5 (74.6)	34.9 (36.2)	29.4 (29.9)	23.8 (25.8)	21.6 (20.5)	30.9 (33.4)

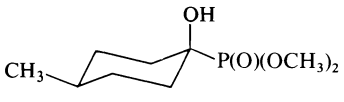
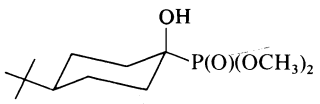
*In parentheses.

parameters, lending credence to our conformational assignments. Poorer agreement at all positions except C-3,5 is noted for **5**.[2] For the alcohol model, for which no equilibration data are available, there may be more axial CH_3 than predicted using additivity of $-\Delta G^0$ values. If this were the case, the axial 2-CH_3 which tends to shield C-4,6 (12) would lead to predicted shifts which are too high field (too low δ) for C-4,6 of **5** than would be the case if the CH_3 were exclusively equatorial in the alcohol.

The most interesting result in the series **4**–**7** is the vicinal coupling of 15.6 Hz in **7** which is 3 Hz larger than that found in the corresponding 4-*tert*-butylcyclohexyl compound (1) and 3–4.5 Hz larger than in **4**, **5**, or **6**. In view of the results for



$^3J_{CCCP} = 15.6$



$^3J_{CCCP} = 12.6$

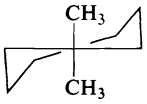
3, we interpret the findings for **7** as indicative of close to 180° dihedral angle between C-3,5 and the equatorial phosphorus. The attenuated coupling in the 4-*tert*-butyl compound can be attributed to ring flattening induced by the bulkier substituent at C-4, which may reduce the dihedral angle to near 170°.

Compound **4** which has been discussed previously (2) is no doubt a mixture of conformers, but the 11.1 Hz vicinal coupling of C-3,5 to phosphorus suggests a preponderance of the conformer with equatorial phosphorus. For **5** the vicinal couplings of 11.2 and 11.6 Hz to C-3 and C-5, combined with the 1.8 Hz vicinal coupling to the CH_3 indicate either ring flattening or measurable contributions from the ring inverted form. Low temperature experiments have been performed and we have not detected two conformers, thus we favor the former rationale. Similar arguments apply to the 3-methyl compound **6**, although it is interesting to observe that there appears to be more ring flattening in the vicinity of the substituent (^3J to C-3 is 11.9) than at the other vicinal carbon (^3J to C-5 is 12.7).

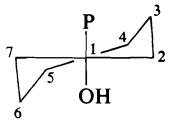
For the cycloheptyl compound **8**, variable temperature experiments (to −100°C) gave no spectral changes. It can be argued, however, that none would be expected until much lower temperatures since the substituent sites in seven-membered rings are known to equilibrate rapidly by pseudorotation and ring inversion even at very low temperatures (13). In fact, no nmr techniques have succeeded in freezing out conformers of cycloheptane to date (13). Several conformational energy calculations have been published for cycloheptane (13–15) and Hen-

[2]Comparing the predicted and observed shifts for **5**, **6**, and **7** at *all* sites indicates comparable differences. Carbons of **5** are, on the average, slightly less shielded than predicted, whereas carbons of **6** and **7** are slightly more shielded than predicted.

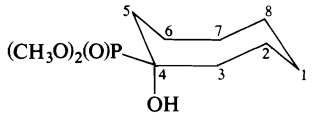
drickson (16) has carried out calculations for several methyl-substituted cycloalkanes. The latter results are most relevant for our purposes since the molecule of interest here is a *gem*-disubstituted cycloheptane. There seems to be general agreement (13–16) that the twist chair form represents an energy minimum. When methyl groups are considered in the calculations (16) the lowest energy form is the twist chair shown.



Recently[3] we have determined the X-ray crystal structure of **8**. The results indicate that the major form ($93 \pm 1\%$) is a twist chair, depicted below, in which the dihedral angles P–C_1–C_7-C_6 and P–C_1–C_2–C_3 are $-168.7°$ and $+90.0°$, respectively. In addition, a minor contribution ($7 \pm 1\%$) from a chair form of **8** is present, for which the angles P–C_1–C_2–C_3 and P–C_1–C_7–C_6 are $-168.7°$ and $-173.0°$. On the basis of the crystal structure and using models for coupling through angles of 90° (J ca. 0.5 Hz) and 170° (J ca. 13 Hz), the 'predicted' value for **8** is near 7 Hz. The observed value of 10.9 Hz suggests that in solution there may be an increase in the amount of chair cycloheptane leading to the enhanced vicinal ^{13}C–^{31}P coupling. It is notable that Hendrickson's calculations (14) give an energy difference of only 1.4 kcal/mol between twist chair and chair cycloheptane. Subtle factors of solvation in **8** may lead to a substantially larger amount of chair form in solution than in the solid phase.



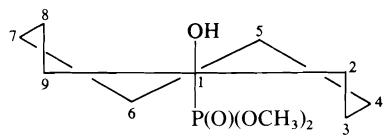
The situation for the cyclooctyl derivative **9** will also be complicated by ring inversion and pseudorotation. The latter process has a very low barrier, measured to be 4.9 kcal/mol in the 1,1-difluoro derivative of cyclooctane (17). Although several conformations will be populated appreciably at room temperature, it is most likely that the favored ring geometry is a boat–chair form (18). Hendrickson (16) calculated that the methyl strain energies are lowest in the 4a,4e(6a,6e) sites of the boat-chair form (each 0.5 kcal/mol). If one assumes that these sites will also be favored for the introduction of the OH and $P(O)(OCH_3)_2$ functions then a low energy form of **9** would be the boat–chair depicted.[4] In this form the dihedral angles



9

P–^{4}C–^{5}C–^{6}C and P–^{4}C–^{3}C–^{2}C are ca. 175° and 75°, respectively. Using models discussed earlier ^3J for $\theta = 175°$ can be estimated at ca. 14–15 Hz and that for 75° at ca. 0.5 Hz. On this basis the predicted ^3J is 7–8 Hz, in reasonable agreement with the observed value of 8.8 Hz. The possibility that the phosphorus and the OH have reversed stereochemistry cannot be disregarded since the calculations (16) indicate no difference in methyl strain energy between the 4a and 4e positions. In this conformer, the dihedral angles P–^{4}C–^{5}C–^{6}C and P–^{4}C–^{3}C–^{2}C are ca. 55° and 165°, respectively. For θ ca. 60°, J is less than 1 Hz (1, 2) while for 165° no reliable models exist, except perhaps a highly flattened cyclohexyl case ($J \approx 11$ Hz). Using these crude models, the ^3J for this conformer would be predicted to be somewhat smaller than for the first case, i.e. in poorer agreement with experiment. To date we have not been able to slow down ring inversion of **9** sufficiently at low temperature to obtain spectra of separate conformers, but efforts to do so are continuing. This should be feasible since ring inversion barriers are ca. 7–8 kcal/mol in cyclooctyl compounds (18).

For the cyclononanyl system **10** the X-ray crystal structure determination has been carried out (19) and the preferred form is the twist-boat–chair (TBC) shown which possesses D_3 symmetry. In this form, the dihedral angles P–^{1}C–



10

[3]Unpublished observations with G. I. Birnbaum.

[4]The numbering scheme used above denotes particular positions of Hendrickson's boat–chair form. Data in Tables 1–4 for **9** are based on the IUPAC numbering system.

^{9}C–^{8}C and P–^{1}C–^{2}C–^{3}C are 176° and 56°, respectively. Employing models for these angles, namely ca. 14–15 Hz and 0.5 Hz, again the predicted value for ^{3}J is 7–8 Hz in reasonable agreement with the experimental value of 6.7 Hz. Of course the usual problem of extrapolation of crystal structures to solution phase applies here.

The fact that only five ring carbon resonances are obtained in the ^{13}C spectrum of **10** is consistent with rapid ring inversion occurring at room temperature. From high frequency ^{1}H nmr (251 MHz) and ^{13}C (63 MHz) at low temperature, Anet and Wagner have measured a barrier of ca. 6 kcal/mol in the hydrocarbon (20). The high field position for the C-3,8 resonance of **10** (δ 18.1 ppm) reflects the averaged *gauche*-γ relationship of these positions to the OH and $P(O)(OCH_3)_2$ groups in the preferred conformer.

For the cycloundecanyl compound **11**, the observation of only six ring carbon resonances again indicates rapid conformational interconversions. In the hydrocarbon the ^{13}C spectrum is still one line at −135°C indicating rather low barriers (21). Dale (22) has calculated that there are four conformations of cycloundecane within 1 kcal/mol of each other. Accordingly for the hydroxyphosphonate **11** we feel that it is not meaningful to attempt to analyze the ^{3}J value of 6.5 Hz in terms of any preferred form.

The X-ray structure of the cyclododecyl compound **12** has been published (23). The molecule adopts a 'square' conformation in the crystal, with the substituents at a corner position. Observation of seven ring carbon signals again indicate rapid conformational interconversion. For the hydrocarbon (21), the 'square–square' interconversion barrier has been determined as 7.3 kcal/mol. The square form of **12** as found in the crystal (23) is depicted in Fig. 2. In the crystal, the dihedral angles P–^{1}C–^{2}C–^{3}C and P–^{1}C–^{12}C–^{11}C are 56° and 172°, respectively. Employing 0.5 Hz as a value for 56° and ca. 12–13 for the latter, the predicted vicinal coupling is 6–7 Hz, compared to the experimental value of 5.7.

To summarize, it is evident that vicinal ^{13}C–^{31}P couplings provide a useful, albeit somewhat local, probe for molecular conformations in these systems. The major drawback at present is the paucity of compounds with well defined geometries to serve as models.

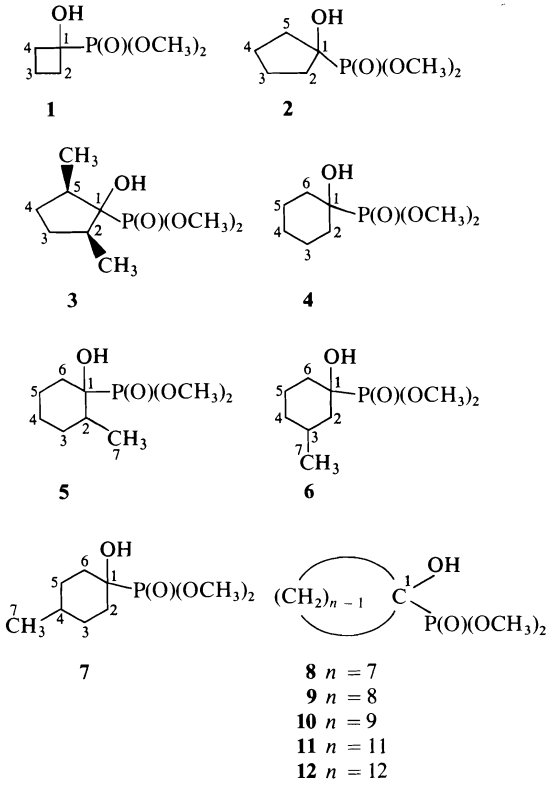


FIG. 2. The square form of **12** as found in the crystal.

Direct Couplings and Steric Congestion

From the data for compounds **2–7** in Table 2 and those published earlier (2), it is evident that for a given ring size, $^{1}J_{CP}$ is to some extent a measure of steric crowding about the C—P bond. It was noted earlier (2) for cyclohexylphosphonates and hydroxyphosphonates that $^{1}J_{CP}$ for compounds with axial phosphorus is 5–7 Hz less than when the dialkylphosphono function is equatorial. Comparing **4** and **5** it is clear that introduction of the 2-methyl group equatorially (i.e. *gauche* to the C—P bond) reduces $^{1}J_{CP}$ substantially. For **6** and **7** when the methyl is more remote, the $^{1}J_{CP}$ values increase, although the value for **7** seems anomalously low.

For the cyclopentyl systems **2** and **3**, $^{1}J_{CP}$ is reduced by 4.9 Hz in **3** where there are *gauche* interactions between phosphorus and the neighbouring methyl groups.

It is interesting that in P^{III} compounds steric hindrance about the phosphorus also reduces $^{1}J_{CP}$ (25). For example in trimethyl phosphine, $^{1}J_{CP}$ is −13.6 Hz, while in the tri-*tert*-butyl

phosphine, $^1J_{CP}$ is -33.9. For hydroxyphosphonates, $^1J_{CP}$ is positive (24), therefore the trends upon increase in steric congestion are consistent in P^{III} and P^{V} systems.

Recently Gorenstein (28) has noted the generality of such trends in directly bonded couplings as a function of stereochemistry. An interpretation involving the Fermi-contact mechanism and bond angle distortions was presented.

Experimental

Spectra

^{13}C spectra were obtained by techniques described previously (1), with the exception that sample tube size was 5 mm in the present study.

Materials

*1-Dimethylphosphono-1-hydroxycyclobutane (**1**)*

To cyclobutanone (0.5 g, 7.1 mmol) and dimethyl phosphite (0.9 g, 8.2 mmol) dissolved in benzene (2 ml) was added 2 drops of a saturated sodium methoxide solution. The reaction mixture was left at room temperature for 1 week and the solvent removed by rotary evaporator. The oily product was placed under vacuum before spectra were taken. The product remained an oil but showed no extraneous peaks in ^1H or ^{13}C nmr. Previously reported (26) as an oil, $\eta_D^{20} = 1.4630$.

*1-Dimethylphosphono-1-hydroxycyclopentane (**2**)*

Cyclopentanone (1.5 g, 17.8 mmol), dimethylphosphite (2.2 g, 20.0 mmol), and 15 drops of sodium methoxide solution were refluxed in benzene (10 ml) overnight and the solvent removed by rotary evaporator. The product was recrystallized (cyclohexane) mp 74.0–75.5°C (lit. mp 78°C) (27); yield 0.91 g (26%).

*1-Dimethylphosphono-1-hydroxy-cis-2,5-dimethylcyclopentane (**3**)*

2,5-Dimethylcyclopentanone (a mixture of *cis*- and *trans*-isomers, 5.0 g, 44.6 mmol), dimethyl phosphite (5.0 g, 45.4 mmol), and 10 drops of sodium methoxide solution were refluxed for 3 days. The reaction mixture was chromatographed on 100 g silica gel (Baker Analyzed Reagent 60–200 mesh) using benzene as eluent. The small amount of hydroxy phosphonate obtained was shown to be the one isomer by ^{13}C nmr. The product remained an oil and could not be crystallized, but was characterized by nmr and ir spectra; ^1H nmr ($CDCl_3$): δ 1.08 (d, $J = 6.5$ Hz, CH_3), 1.3–2.7 (bm, ring -CH_2-), 3.84 (d, $J = 10.3$ Hz, CH_3O-P).

*1-Dimethylphosphono-1-hydroxycyclohexane (**4**)*

The synthesis has been previously described (1).

*1-Dimethylphosphono-1-hydroxy-2-methylcyclohexane (**5**)*

2-Methylcyclohexane (2.0 g, 18.0 mmol), dimethyl phosphite (2.2 g, 20.0 mmol), and 10 drops of a saturated sodium methoxide solution were refluxed in benzene (5 ml) for ½ h. At this point five more drops of base were added and reflux continued for another ½ h. The solvent was removed and the flask placed in a freezer to induce crystallization of the resulting oil. The crystals obtained were recrystallized (ethyl acetate) mp 114–115°C. ^1H nmr ($CDCl_3$): δ 1.04 (d, $J = 6$ Hz, CH_3-), 1.3–2.3 (massive, ring -CH_2-), 3.1 (bs, -O*H*), 3.88 (d, $J = 11.1$ Hz, CH_3-O-P). *Anal.* calcd. for $C_9H_{19}O_4P$: C 48.64, H 8.62; found: C 48.63, H 8.54.

*1-Dimethylphosphono-1-hydroxy-3-methylcyclohexane (**6**)*

3-Methylcyclohexanone (6.0 g, 53 mmol), dimethyl phosphite (6.6 g, 60 mmol), and 25 drops of a saturated $NaOCH_3$ solution were refluxed in benzene (15 ml) for 1 h at which time 10 more drops of base were added. Reflux was continued overnight (ca. 18 h). The product obtained was recrystallized (ethyl acetate) mp 121.5–123°C; yield 10.1 g (86%); ^1H nmr ($CDCl_3$): δ 0.90 (d, $J = 6$ Hz, CH_3-), 1.4–2.3 (massive, ring -CH_2-), 3.3 (bs, -O*H*), 3.88 (d, $J = 10.6$ Hz, CH_3O-P). *Anal.* calcd. for $C_9H_{19}O_4P$: C 48.64, H 8.62; found: C 48.76, H 8.70.

*1-Dimethylphosphono-1-hydroxy-4-methylcyclohexane (**7**)*

The same procedure and amounts were used as for **6** to yield 3.6 g (31%) of the product, recrystallized (ethyl acetate) mp 120–122°C. ^1H nmr ($CDCl_3$): δ 1.0 (d $J = 6$ Hz, CH_3-), 1.3–2.4 (massive, ring -CH_2-), 4.02 (d, $J = 10.9$ Hz, CH_3O-P), 4.4 (bs, -O*H*). *Anal.* calcd. for $C_9H_{19}O_4P$: C 48.64, H 8.62; found: C 48.70, H 8.72.

*1-Dimethylphosphono-1-hydroxycycloheptane (**8**)*

Cycloheptanone (2.24 g 20.0 mmol), dimethyl phosphite (11.0 g, 100 mmol), and 20 drops of a saturated $NaOCH_3$ solution were refluxed in benzene (10 ml) overnight. The product was recrystallized (ethyl acetate) mp 106.0–107.5°C; yield 1.2 g (27%); ^1H nmr ($CDCl_3$): δ 1.4–2.5 (massive, ring -CH_2-), 4.00 (d, $J = 10.8$ Hz, CH_3O-P), 5.0 (bs, -O*H*). *Anal.* calcd. for $C_9H_{19}O_4P$: C 48.64, H 8.62; found: C 48.50, H 8.54.

*1-Dimethylphosphono-1-hydroxycyclooctane (**9**)*

Cyclooctanone (3.8 g, 30 mmol), dimethyl phosphite (3.6 g, 33 mmol), and 15 drops of a saturated $NaOCH_3$ solution were refluxed in benzene (10 ml) for 3 h. The solvent was removed to give a liquid residue. After 1 week in a freezer at −25°C, white crystals had formed. Recrystallized (cyclohexane) mp 92–93°C; yield 0.42 g (6%); ^1H nmr ($CDCl_3$): δ 1.5–2.1 (massive, ring -CH_2-), 3.95 (d, $J = 10.8$ Hz, CH_3O-P), 3.7 (bs, -O*H*). *Anal.* calcd. for $C_{10}H_{21}O_4P$: C 50.84, H 8.96; found: C 50.78, H 8.91.

*1-Dimethylphosphono-1-hydroxycyclononane (**10**)*

To cyclononanone (0.25 g, 1.78 mmol) dissolved in a minimum amount of benzene was added dimethyl phosphite (0.22 g, 2.00 mmol) and 1 drop of a saturated $NaOCH_3$ solution. The mixture turned pale yellow and then faded after 1 h, at which time another drop of base was added. This resulted in no colour change and the reaction mixture was placed in a freezer. The crystals that formed (66 mg, 15%) had mp 106.5–107.5°C (lit. (19) mp 105–106°C).

*1-Dimethylphosphono-1-hydroxycycloundecane (**11**)*

To cycloundecanone (1.14 g, 6.8 mmol) and dimethyl phosphite (1.77 g, 16 mmol) dissolved in benzene (3 ml) was added 10 drops of saturated $NaOCH_3$ solution. The mixture was placed in a freezer for 5 min until cool and the solvent removed by rotary evaporator to leave a liquid residue. After several days in a freezer crystals had formed. Recrystallized (cyclohexane) mp 79.0–80.5°C; yield 0.66 g (35%); ^1H nmr ($CDCl_3$): δ 1.4–2.1 (massive, ring -CH_2-), 4.02 (d, $J = 10.8$ Hz, CH_3O-P), 4.0 (bs,

-O*H*). *Anal.* calcd. for $C_{13}H_{27}O_4P$: C 56.09, H 9.78; found: C 56.13, H 9.85.

*1-Dimethylphosphono-1-hydroxycyclododecane (**12**)*

To cyclododecanone (3.1 g, 17 mmol) and dimethyl phosphite (2.2 g, 20 mmol) dissolved in benzene (5 ml) was added 15 drops of a saturated $NaOCH_3$ solution. This mixture was placed in a freezer until cool, and then removed. After 5 min at room temperature, **12** crystallized. Recrystallized (cyclohexane) mp 131–132.5°C (lit. (26) mp 127°C); yield 3.1 g (62%).

Electron mobilities in fluids through the liquid and critical regions: isomeric butenes[1]

JEAN-POL DODELET AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 2, 1977

JEAN-POL DODELET and GORDON R. FREEMAN. Can. J. Chem. **55**, 2893 (1977).

Electron mobilities are similar in all four isomeric butenes near the critical region, ~ 10 cm^2/V s at ~ 420 K, and again in the low temperature liquids, $\sim 10^{-3}$ cm^2/V s at ~ 150 K, but not at intermediate temperatures. The Arrhenius temperature coefficient of the mobility decreases with increasing temperature in *cis*-butene-2 and isobutene, and increases with temperature in butene-1 and *trans*-butene-2. This difference in behavior is reflected in the temperature dependence of the dispersion parameter σ in the assumed Gaussian distribution of transition energies between localized and extended states. The extreme cases are *trans*-butene-2, for which $d\sigma/dT = 0$, and *cis*-butene-2, for which $d\sigma/dT \approx (2kC_p)^{1/2}$. Mobilities in mixtures of *cis*- and *trans*-butene-2 do not display ideal solution behavior; the transition energies E_0 go through a maximum. The mobility in liquid *cis*-butene-2 under its vapor pressure goes through a maximum value of 17 cm^2/V s at 426 K, decreases to 14 cm^2/V s at $T_c = 433$ K, then increases with temperature in the constant density supercritical gas. Maxima are not observed in the other butenes. Electron migration in each of the supercritical gases is an activated process with an activation energy of ~ 0.3 eV. The present results emphasize the large role played by phase structure in electron migration.

JEAN-POL DODELET et GORDON R. FREEMAN. Can. J. Chem. **55**, 2893 (1977).

Les mobilités électroniques des quatre isomères du butène sont semblables près de la région critique: ~ 10 cm^2/V s à ~ 420 K, ainsi qu'en phase liquide à basse température: $\sim 10^{-3}$ cm^2/V s à ~ 150 K. Toutefois, ces mobilités diffèrent dans la région des températures intermédiaires. Pour ces mobilités, le coefficient de température d'Arrhénius décroît en augmentant la température du *cis*-butène-2 et de l'isobutène tandis qu'il augmente en élevant la température du butène-1 et du *trans*-butène-2. Cette différence de comportement se reflète dans la variation de σ avec la température. σ est le paramètre de dispersion dans la distribution, supposée gaussienne, des transitions entre les états localisés et étendus d'énergie. Les cas extrêmes sont le *trans*-butène-2 pour lequel $d\sigma/dT = 0$ et le *cis*-butène-2 pour lequel $d\sigma/dT \approx (2kC_p)^{1/2}$. Les mobilités dans les mélanges de *cis*- et *trans*-butène-2 ne présentent pas le comportement d'une solution idéale; les énergies de transition E_0 passent par un maximum. La mobilité dans le *cis*-butène-2 liquide, sous sa propre tension de vapeur, passe par un maximum de 17 cm^2/V s à 426 K pour ensuite décroître à 14 cm^2/V s à $T_c = 433$ K. Dans le gaz supercritique, à densité constante, cette mobilité augmente avec la température. Aucun maximum n'est observé pour les autres butènes. La migration électronique pour tous ces gaz au dessus de la température critique est un processus accompagné d'une énergie d'activation de ~ 0.3 eV. Ces résultats mettent l'accent sur le rôle joué par la structure de la phase dans la migration électronique.

Introduction

The Arrhenius temperature coefficient of electron migration in liquids is temperature dependent (1–6). The causes of the temperature dependence in different types of systems are not all the same (2, 5, 6), although none is understood in detail. To obtain more information about this phenomenon, electron mobilities have been measured in the isomeric butenes over a wide range of temperatures, from near the melting point to beyond the critical temperature. The butenes were chosen because of the extraordinary difference between the mobilities in *cis*- and *trans*-butene-2 at room temperature (7).

[1]Assisted by the National Research Council of Canada.

Experimental

Materials

The hydrocarbons were Phillips Research Grade, with initial purities 99.82% for butene-1, 99.57% for isobutene, 99.94% for *cis*-butene-2, and 99.92% for *trans*-butene-2. They were treated in a vacuum apparatus as follows: stirred several hours with lithium aluminum hydride powder and sodium hydroxide pellets, then degassed and distilled onto sodium–potassium alloy, stirred for several hours, then degassed and condensed into the conductance cell at 77 K. The cell was sealed after reducing the gas pressure in it to $< 5 \times 10^{-6}$ Torr.

Apparatus and Techniques

The conductance cell and temperature bath used for studies above room temperature were similar to those described in ref. 6. The cell could contain a pressure of 60 atm.

The cell used at low temperatures had larger electrodes

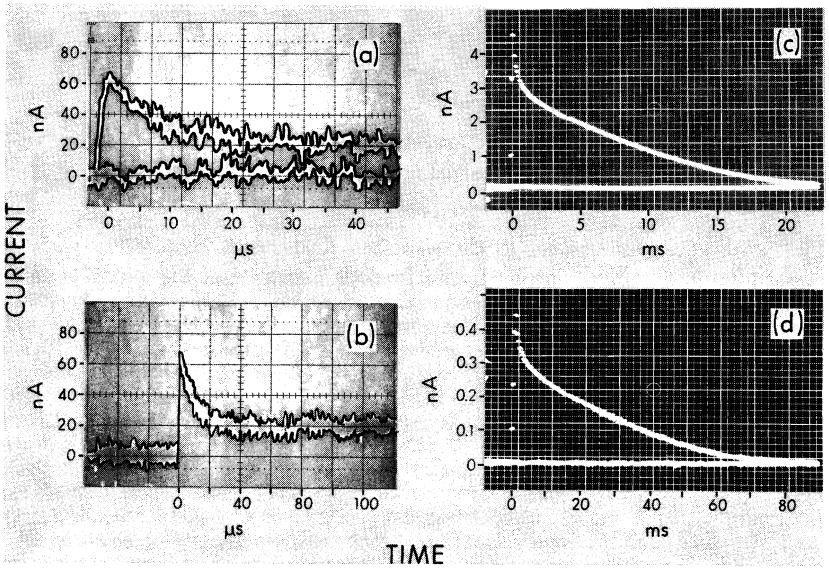

FIG. 1. Oscilloscope traces of transient electron and ion conductances in butene-1 after a 1 μs pulse of X rays. Dose/pulse $\approx 5 \times 10^{10}$ eV/g. (*a*) and (*b*) show the decay of the electron conductance on two time scales; applied field = 34 kV/cm, $T = 216$ K. (*c*) and (*d*) show the decay of the ionic conductance at 17 kV/cm averaged over 16 pulses; $T = 293$ and 192 K, respectively.

to compensate for the lower mobilities and lower ion yields. It was described earlier (8).

The low temperature bath was a Styrofoam box with walls 3 cm thick and a net inner volume $\sim$(10 cm)^3. Cold nitrogen gas from a 50 ℓ Dewar flask was piped into the center of the bottom of the box through a 13 mm diameter stainless steel tube that was insulated with a 5 cm layer of polystyrene. The cold gas was generated by putting controlled electric power into a 600 W heating element immersed in liquid nitrogen. The heater was fixed in a 20 cm long metal pipe attached to the bottom of a 5 cm diameter PVC tube. The pipe was near the bottom of the Dewar and the plastic tube conducted the cold gas up through the 10 cm wide neck.

Temperature gradients were reduced by having the cold nitrogen hit a 1 cm thick Styrofoam false bottom of the box with holes in the four corners, and by having the gas exit through a 15 mm inside diameter, 30 cm high chimney on the flanged lid of the box. The cell sat on the false bottom and was supported by Styrofoam projections from the sides of the box.

The Styrofoam box was placed inside an aluminum (0.5 mm thick) Faraday cage.

Two copper–constantan thermocouples were glued to the cell with silicone rubber. One thermocouple was connected to the temperature controller (LFE Corp. model 226-A21), and the other to a digital thermometer (Fluke 2100A). The best copper and constantan wire came from Thermoelectric Co., and it conformed to the 1974 ASTM standards.

The technique for measuring electron mobilities is described in refs. 7 and 9. The electron mobilities in the low temperature butenes are nearly as small as those of the heavy ions. The method of measurement gives the sum $(u_- + u_+)$, where u_- is the average mobility of the negative species and u_+ is that of the positive species. Immediately after the 1 μs radiation pulse u_- corresponds to the electron mobility u_e. The electron conductance transient decayed in microseconds (Fig. 1 *a,b*), probably due to reaction of the electrons with trace impurities. The remaining ion conductance transient decayed in milliseconds (Fig. 1 *c,d*).

Values of the sum $(u_- + u_+)$ for the heavy ions were obtained from the signal remaining at the right hand ends of pictures such as 1*a* and *b*. If the signals in 1*c* and *d* had decayed in two linear portions it would have been possible to obtain separate values of u_- and u_+ (5). The curvature in these traces indicates the presence of more than two types of ion. However, the total decay time t_d at high field strengths is the time required for the slowest ion to drift the distance $l = 0.30$ cm between the two electrodes. The value of u_{slowest} was obtained from [1].

$$[1] \qquad u_{\text{slowest}} = l^2/Vt_d$$

where V is the applied voltage. Comparing this to the value of $(u_- + u_+)$ just after the decay of the electron transient, the ratio $[(u_- + u_+)/u_{\text{slowest}}] \approx 3$ at 400–200 K, then appeared to increase to $\sim$5 at 140 K. The apparent increase may not have been real. There was considerable uncertainty in the ion mobility values at the lowest temperatures.

An Arrhenius plot of $(u_- + u_+)$ is not linear at the higher temperatures (Fig. 2). The upward curvature is probably associated with the decreasing liquid density and concomitant increasing fluidity (inverse viscosity) as the critical temperature is approached. The Arrhenius temperature coefficient of the ion mobilities is similar to that of the fluidity (10), 1.1 ± 0.2 kcal/mol, where the two types of measurement have been made over the same temperature range (Fig. 2).

The mobilities of the slowest ions may be roughly

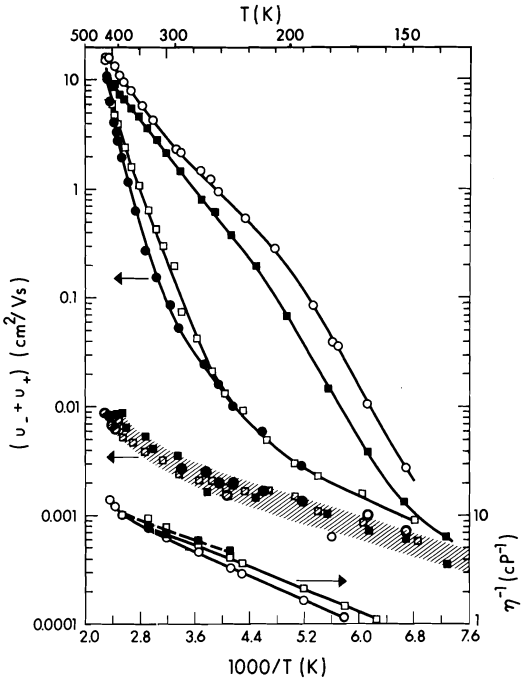

FIG. 2. Plots of $(u_- + u_+)$ and inverse viscosity against T^{-1}. Liquid phase only. For the upper curves the negative species is the electron, while in the hatched region it is a heavy negative ion. ○, *cis*-butene-2; ●, *trans*-butene-2; □, butene-1; ■, isobutene. The viscosities of *cis*- and *trans*-butene-2 are the same (10).

approximated by [2]

$$[2] \qquad u_{\text{slowest}} \approx 0.01 \exp(-700/T)$$

Physical Properties of the Liquids

The densities d were obtained from refs. 10 and 11.

The dielectric constants ε of the three polar butenes were calculated from Onsager's formula (12*a*):

$$[3] \qquad \frac{(\varepsilon - n^2)(2\varepsilon + n^2)}{\varepsilon(n^2 + 2)^2} = \frac{4\pi N d \mu^2}{9MkT}$$

where n is the refractive index, N is Avogadro's number, μ is the dipole moment (13), M is the molar weight, k is Boltzmann's constant, and T is the absolute temperature. The value of n at a given temperature was obtained from ref. 14 and the variation with temperature was calculated from the Lorenz–Lorentz equation (12*b*). The dielectric constant of *cis*-butene-2 was measured at temperatures between 197 and 296 K (15) and the values are 1% greater than those given by [3]. The latter were used in the present work for the sake of consistency over the entire liquid range and through the critical region.

The dielectric constant of *trans*-butene-2, which is nonpolar, was taken equal to n^2, with n determined in the manner described above.

The critical properties of the butenes are summarized in Table 1.

TABLE 1. Critical and other properties of the butenes*

Butene	T_c (K)	P_c (atm)	d_c (g/cm³)	ε_c†	n_c^2†	μ (D)‡
Isobutene	418	39.5	0.234	1.33	1.27	0.50
Butene-1	419	39.7	0.233	1.29	1.27	0.34
trans-Butene-2	428	41.5	0.238	1.28	1.28	0.0
cis-Butene-2	433	40.5	0.238	1.30	1.28	0.3

Results

The pressure on the liquids was the vapor pressure and the density of the supercritical gases was equal to the critical density.

Pure Compounds

Electron mobilities are similar in all four isomeric butenes near the critical region (~420 K) and again in the low temperature liquids (~150 K), but not at intermediate temperatures (Fig. 2). The behavior in isobutene is similar to that in *cis*-butene-2, while in butene-1 it is similar to that in *trans*-butene-2. The mobilities range from $\sim 10^{-3}$ cm²/V s at ~150 K to ~10 cm²/V s at ~420 K.

The relatively high melting point of *trans*-butene-2, 168 K, prevented measurements from being made at the lowest temperatures in that liquid.

The mobility in liquid *cis*-butene-2 goes through a maximum value of 17 cm²/V s at 426 K, decreases to 14 cm²/V s at the critical temperature 433 K, then increases with temperature in the supercritical gas (Fig. 3). Mobilities in the other butenes increase continuously with temperature, although there appears to be a change of slope when the system attains constant density in the supercritical gas (Fig. 3).

The mobilities were independent of field strength up to 30 kV/cm at $T < 300$ K and up to 10 kV/cm at the highest temperatures. Experimental difficulties prevented measurements at higher fields.

Mixtures of cis- and trans-Butene-2

To investigate the cause of the great difference between the behavior in *cis*- and *trans*-butene-2, mobilities were measured in mixtures of the two isomers. Addition of *trans*- to *cis*-butene-2 has a relatively greater effect on electron mobility at low than at high temperatures (Fig. 4).

As expected the ion mobilities in the solutions

were similar to those in the pure compounds (Fig. 4).

Discussion

To obtain values of the electron mobilities it was necessary to subtract u_+ from $(u_e + u_+)$. The value of u_+ was taken as one third of the sum of the heavy ion mobilities $(u_- + u_+)$. This is consistent with reports that $u_-/u_+ \approx 2$ for ions in many hydrocarbons (6, 16, 17). Although there is some doubt about the validity of this approximation in the butenes at $T < 200$ K (see earlier), shifting the fraction to reach $u_+ \approx 0.2(u_+ + u_-)$ at 140 K would have increased the estimated values of u_e only slightly.

The model of electron mobilities that was derived for ether solvents (18) has been applied to the present results. The model involves two types of transport, one important at low temperatures and another at higher temperatures. The low temperature type has been called ion-like, because the activation energy is similar to that for heavy ions and the magnitude of the mobility is a small factor greater than that of anions.[2] The transport mechanism at higher temperatures appears to involve electron transitions to a higher mobility state. The equations are as follows (18).

$$[4] \quad u_e = (1 - \chi)u_{i1}^0 \exp(-E_{i1}/kT) + \chi u_h^0$$

where χ is the fraction of electrons that are in the higher mobility state at a given instant, u_{i1}^0 and E_{i1} are respectively the pre-exponential factor and activation energy for ion-like mobility, k is Boltzmann's constant, T is the absolute temperature, and u_h^0 is the mobility in the higher state.

The fraction χ is given by [5].

$$[5] \quad \chi = \int_{-\infty}^{\infty} N(E)[1 + \exp(E/kT)]^{-1}\,dE$$

where $N(E)\,dE$ is the fraction of solvated electrons that require energies between E and $(E + dE)$ to be excited into the high mobility state, and $[1 + \exp(E/kT)]^{-1}$ is the fraction of electrons, for which the transition energy is E, that occupy the upper state. It has been assumed for simplicity that the entropy change of the transition is negligible.

The distribution function $N(E)$ is assumed to be a Gaussian with a most probable energy E_0 and a dispersion parameter σ.

$$[6] \quad N(E) = \pi^{-1/2}\sigma^{-1} \exp[-(E - E_0)^2/\sigma^2]$$

The present data permit evaluation of u_{i1}^0 and E_{i1} for butene-1 only. Similar values of these parameters were used in the four butenes, because the mobilities of heavy ions are similar in all the liquids (Fig. 2).

It was assumed that E_0 and σ vary linearly with temperature (6, 18).

$$[7] \quad E_0 = E(0) - \alpha T$$

$$[8] \quad \sigma = \sigma(0) + \beta T$$

where $E(0)$ and $\sigma(0)$ are the values extrapolated to zero Kelvin. Finally, u_h^0 was assumed to vary inversely as the temperature and the square of the fluid density (6).

$$[9] \quad u_h^0 = u_{ref}^0 \left(\frac{d_{ref}}{d_T}\right)^2 \frac{T_{ref}}{T}$$

where u_{ref}^0 is the value of u_h^0 at density d_{ref} and temperature T_{ref}.

Unique values of the parameters E_0, σ, and u_{ref}^0 cannot be obtained by fitting eq. 4 to the

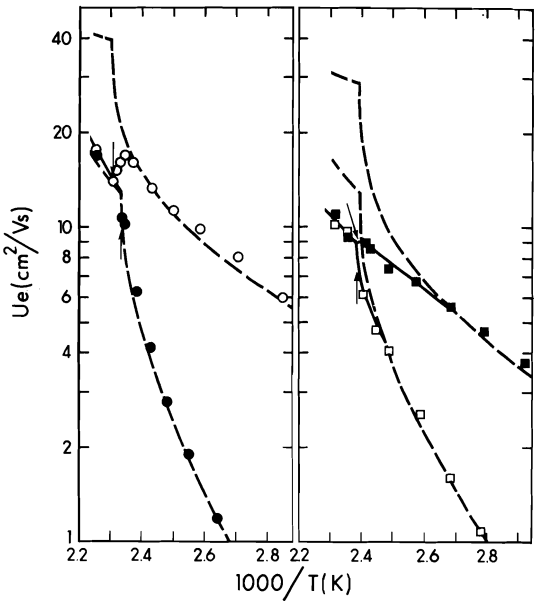

FIG. 3. Electron mobilities in the isomeric butenes near the critical region. The arrows mark T_c^{-1}. ○, *cis*-butene-2; ●, *trans*-butene-2; □, butene-1; ■, isobutene. The dashed lines were calculated from eqs. 4–9, using the parameter values in Table 2. Where the calculated curve deviates greatly from the experimental the latter is indicated by a full curve.

[2]The ion-like mechanism is conceptually similar to thermally assisted tunnelling to nearest neighbor centers (19) and small polaron hopping (20). It does not involve migration of the solvation shell of the electron.

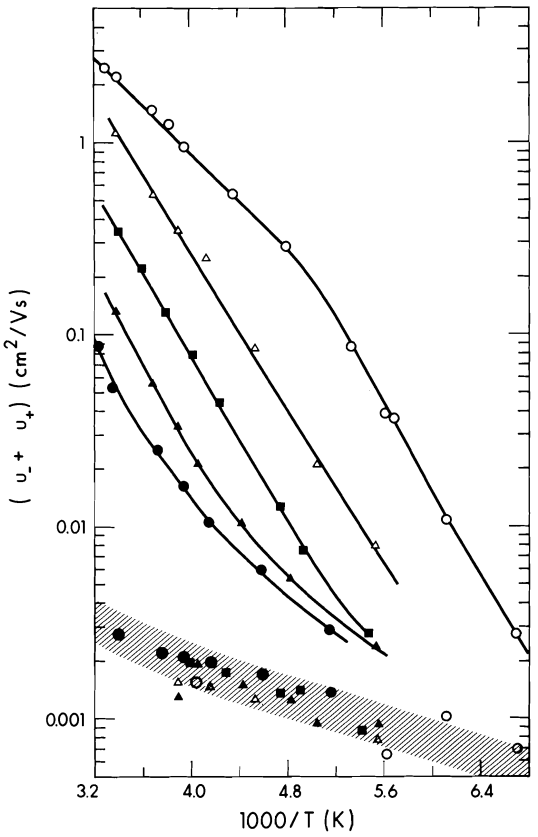

FIG. 4. Plots of $(u_- + u_+)$ against T^{-1} for mixtures of *cis*- and *trans*-butene-2. For the upper curves the negative species is the electron, while in the hatched region it is a heavy negative ion. ○, *cis*-butene-2; ●, *trans*-butene-2; △, 25 mol% *cis*; ■, 50 mol% *cis*; ▲, 75 mol% *cis*. observed mobilities, but lower limits can be estimated. Below certain values of the parameters, disagreement between the calculated and observed mobility curves becomes progressively greater. Thus for $T_{ref} = 295$ K we obtained $u_{ref}{}^0 \gtrsim 15$ cm^2/V s for isobutene, butene-1, and *trans*-butene 2, and $\gtrsim 30$ cm^2/V s for *cis*-butene 2. Lower limits of $E(0)$ and α were 0.5 eV and 0.001 eV/K in *trans*-butene-2 and butene-1, and about 0.3 eV and 0.0005 eV/K in isobutene and *cis*-butene-2. Corresponding values of σ were such that the ratio E_0/σ equalled 3–4 at 150 K and 0.5–1.3 at 400 K, depending on the liquid. As long as the minimum acceptable values of the parameters are equalled or exceeded, the electron mobility – temperature plot is governed mainly by the value of E_0/σ and its variation with temperature, and to a smaller extent by the absolute magnitude of E_0.

To facilitate comparison of the relative values of the parameters we chose for all the liquids $u_{ref}{}^0 = 30$ cm^2/V s at $T_{ref} = 295$ K, and $E(0) = 0.6$ eV. This makes the values of E_0 similar to the optical absorption energies of electrons in hydrocarbons at the lower temperatures (21, 22). The values of $E(0)/\alpha$ that were required to fit the mobilities in the butenes were similar to the ratio of the analogous parameters for the optical absorption energies of electrons in alkyl ethers (18), $E(0)/\alpha \approx 600$ K.

Within the framework of the present model, the change of shape of the mobility curves in Fig. 5 is embodied mainly in the temperature dependence of σ (Table 2). In *cis*-butene-2 σ has the form that would be expected if the width of the distribution of electron trap depths were governed by thermal energy fluctuations in the liquid (23, 24):

$$[10] \qquad \beta \approx (2kC_p)^{1/2}$$

*u_{ref}^0 = 30 cm^2/V s at T_{ref} = 295 K was used for all liquids.
†Assumed, by comparison with butene-1.
‡These values are not unique, but have been placed at slightly larger than the minimum acceptable value for butene-1. To obtain larger values that fit the results $E(0)$, α, σ(0), and β are multiplied by approximately the same factor.
§The calculated curve is essentially the same as that in Fig. 5 of ref. 6.
‖75% *cis* + 25% *trans*-butene-2 mixture.

where C_p is the constant pressure heat capacity of the "cell" that contains the electron and exchanges energy with it. The magnitude of β for *cis*-butene-2, 1.08 meV/K, is equivalent to the thermal fluctuations in a cell that contains about four butene molecules.[3] At the other extreme, σ in *trans*-butene-2 appears to be independent of temperature. This implies that the localized state is more stable in *trans*- than in *cis*-butene-2, perhaps through anion formation in the former. However, the full implications are not known. The stability might be related more to entropy changes than to enthalpy changes.

Equation 9 for u_h^0 was devised to approximate the mobility in *n*-pentane (6), which increases rapidly as the critical temperature is approached. It is also adequate for the results in *trans*-butene-2 and butene-1 (Fig. 5). It does not however, reproduce the maximum and subsequent decrease of the mobility in high temperature *cis*-butene-2 (Fig. 3). The decrease is presumably due to the break up of the conduction band, caused by the rapidly decreasing fluid density in this region (4, 6). A similar process must occur also in isobutene, because the calculated mobilities are much too high in the critical region (Fig. 3). All of the approximations [7]–[9] might be expected to fail at the high temperatures where the liquid density changes rapidly. However, in *trans*-butene-2 the net effect of the approximations remains reasonable right through the critical region (Fig. 3). An alternative to [9] is required for *cis*-butene-2 and other liquids which display a maximum in the plot of electron mobility against temperature.

It should be stressed that electron migration in each of the supercritical gases is an activated process with an activation energy of ~0.3 eV. The similarity of behavior in the supercritical gases, and the great difference of that in the liquids at 300 K, emphasizes the large role played by phase structure.

Mixtures of cis- and trans-Butene-2

The experimental and calculated values of the

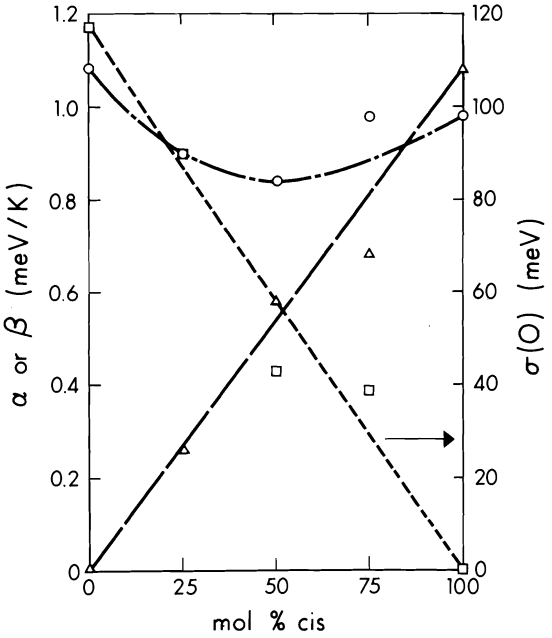

FIG. 6. Mobility parameter values in mixtures of *cis*- and *trans*-butene-2. ○, α; △, β; □, σ(0).

[3]The number of butene molecules that interact appreciably with an electron in the liquid is probably 10–20, so the solvated electron "cell" would be that large. The σ for the electronic state would be smaller than that for the total thermal energy fluctuation in the cell.

mobilities are compared in Fig. 5. The parameter values are listed in Table 2.

Although one cannot obtain the absolute values of E_0 and σ from mobility measurements alone, the relative values provide interesting information. The temperature coefficients of E_0 for the 100%, 75%, 50%, 25%, and 0% *cis* solutions are, respectively, α = 0.98, 0.98, 0.84, 0.90, and 1.08 meV/K. The lack of a linear variation between the two pure compounds indicates that the solutions are not ideal.

The parameters that change the most with solution composition are $\sigma(0)$, which ranges from 0 to 117 meV, and β, which ranges from 1.08 to 0.00 meV/K (Fig. 6).

The results from the mixtures confirm the unexpected behavior of σ. More work is needed to interpret it.

Kinetics and mechanism of the oxidation of several ketones by tris(1,10-phenanthroline)Fe(III) in aqueous acid medium

FLORA T. T. NG AND PATRICK M. HENRY

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received August 16, 1976[1]

FLORA T. T. NG and PATRICK M. HENRY. Can. J. Chem. **55**, 2900 (1977).

The kinetics of the oxidation of acetone, 2-butanone, 2,4-dimethyl-3-pentanone, 3-methyl-2-butanone, and 3-pentanone by tris(1,10-phenanthroline)Fe(III) (ferriin) were determined in aqueous solutions containing either sulphuric or perchloric acid in the presence or absence of air. The kinetics are consistent only with a mechanism involving oxidation of the enol tautomer by ferriin. The rate constants of enolization calculated from this kinetic analysis agree well with the literature values. Relative reactivity of the four enols from symmetrical ketones were found to be in the order: 2,4-dimethyl-3-pentanone > 3-pentanone > cyclohexanone > acetone. The rate of oxidation of the enol form of 2,4-dimethyl-3-pentanone is approximately 1000 fold larger than that of the enol form of acetone, indicating that electron-donating methyl substituents enhance the rate of electron transfer from the enol tautomer to ferriin.

Kinetics of the oxidation carried out in air were generally the same as in its absence; the rates of oxidation were found to be slower by a factor of 2 in most cases. This suggests that the initially formed enol radical reacts with O_2 rather than a second ferriin to give the oxidized product. At high [ferriin] in air, pseudo zero-order kinetics were observed initially as in its absence. However, above about 50% reduction of ferriin, the reaction appears to involve autocatalysis and was not studied further.

FLORA T. T. NG et PATRICK M. HENRY. Can. J. Chem. **55**, 2900 (1977).

On a déterminé, en solutions aqueuses d'acide sulfurique ou d'acide perchlorique en présence ou en absence d'air, les cinétiques d'oxydation de l'acétone, de la butanone-2, de la diméthyl-2,4 pentanone-3, de la méthyl-3 butanone-2 et de la pentanone-3 par le tris(phenanthroline-1,10)-Fe(III) (ferriine). Les données cinétiques sont en accord uniquement avec un mécanisme impliquant l'oxydation du tautomère énolique par la ferriine. Les constantes de vitesse d'énolisation calculées à partir de cette analyse cinétique sont en bon accord avec les valeurs de la littérature. La réactivité relative des quatre énols provenant des cétones symétriques est dans l'ordre suivant: diméthyl-2,4 pentanone-3 > pentanone-3 > cyclohexanone > acétone. La vitesse d'oxydation de la forme énolique de la diméthyl-2,4 pentanone-3 est approximativement 1000 fois plus grande que celle de la forme énolique de l'acétone et ces résultats indiquent que les substituants méthyles électro-donneurs augmentent la vitesse du transfert d'électron du tautomère énolique vers la ferriine.

Les résultats cinétiques des oxydations effectués dans l'air sont généralement les mêmes que pour les réactions effectuées en son absence; on a trouvé que les vitesses d'oxydation sont plus lente par un facteur de 2 dans la plupart des cas. Ces résultats suggèrent que le radical énolique formé initialement réagit avec O_2 plutôt qu'avec une seconde molécule de ferriine pour donner le produit oxydé. A des taux élevés de ferriine dans l'air, on observe initialement un ordre cinétique pseudo zéro; et c'est aussi le cas en l'absence d'air. Toutefois une fois que 50% de la ferriine a été réduite, il semble que la réaction implique une autocatalyse et elle n'a pas été étudiée plus loin.

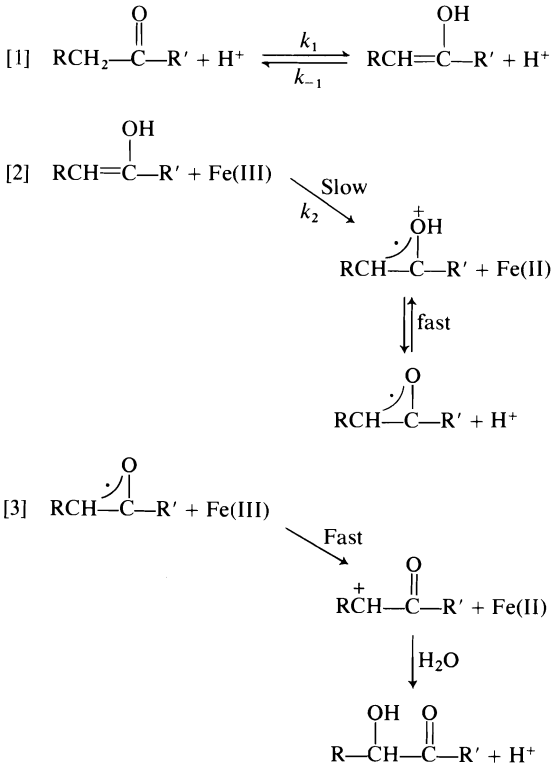
[Traduit par le journal]

Introduction

The oxidation of ketones by two electron oxidants such as Hg(II), Tl(III), Mn(VII), and Cr(VI) has been shown to proceed via the enol tautomer (1–3). However, there has been some discussion as to the mode of oxidation of ketones by one electron oxidants (4, 5). Although it has been suggested that one electron oxidants attack the keto form there is recent kinetic evidence that the oxidation of ketones by $Mn(OAc)_3$ in acetic acid occurs via the enol form (6), a route previously suggested for ketone oxidation by Ce(IV) (7) and Mn(III) pyrophosphates (8). Thus the rate of oxidation of ketone by $Mn(OAc)_3$ is independent of concentration of Mn(III) indicating the rate determining step is the formation of enol. Recently the authors reported similar kinetic evidence indicating that,

[1]Revision received March 25, 1977.

contrary to previous proposals (9), the oxidation of cyclohexanone in aqueous solution by tris-(1,10-phenanthroline)Fe(III) (Ferriin) occurs by way of the enol tautomer (10). The proposed mechanism is given in reactions 1–3.



Thus the complete rate expression is given by [4],

$$[4]\qquad \text{Rate} = \frac{d[\text{Fe(II)}]}{dt} = \frac{2k_1k_2[\text{ketone}][H^+][\text{Fe(III)}]}{k_{-1}[H^+] + k_2[\text{Fe(III)}]}$$

[Fe(III)] = [Ferriin], where k_1 is the rate constant for enolization and k_2 the rate constant for oxidation of enol by Fe(III). This rate expression has two limiting forms. At low [Fe(III)] where $k_{-1}[H^+] \gg k_2[\text{Fe(III)}]$ the rate expression is given by [5] where $k_2' = k_1k_2/k_{-1} = Kk_2$, K being the keto–enol equilibrium constant.

$$[5]\qquad \frac{d[\text{Fe(II)}]}{dt} = \frac{2k_1k_2[\text{Fe(III)}][\text{ketone}]}{k_{-1}} = 2k_2'[\text{Fe(III)}][\text{ketone}]$$

This is the form of the rate expression reported earlier (10).

If high [Fe(III)] and low $[H^+]$ are used such that $k_2[\text{Fe(III)}] \gg k_{-1}[H^+]$ the expression becomes zero order in [Fe(III)] as shown by [6].

$$[6]\qquad \frac{d[\text{Fe(II)}]}{dt} = 2k_1[\text{ketone}][H^+]$$

At low [Fe(III)] and high $[H^+]$ [5] was obeyed while at high [Fe(III)] and low $[H^+]$ [6] was followed. Furthermore, the value of the enolization rate constant, k_1, calculated from these studies agreed with those previously reported. This result requires that the enol tautomer is the reactive species. We also found, by using substituted ferriins, that the rate of electron transfer from the enol to the Fe(III) depended on the reduction potential of the ferriin in the manner predicted by the Marcus relationship (10).

This paper describes a study of the oxidation of several additional ketones. Its main purpose was to see if the enol mechanism held for ketones other than cyclohexanone with different structures and rates of enolization. Also it was hoped to find how k_2 varied with enol structure. Finally we wished to test the effect of oxygen on the reaction mechanism. Earlier it was reported that O_2 increased the rate of cyclohexanone oxidation by ferriin (9), a result which was not duplicated in the later study (10).

Results

The kinetics of reduction of ferriin by acetone, 2-butanone, 2,4-dimethyl-3-pentanone, 3-methyl-2-butanone, and 3-pentanone were determined at 25°C in aqueous solution containing either $HClO_4$ or H_2SO_4. The kinetics were studied with either (*i*) solutions in which the oxygen had been removed by degassing and which were run under a nitrogen and argon atmosphere or (*ii*) with solutions containing air. The H_2SO_4 solutions were employed when high concentrations of ferriin were required, as ferriin is more soluble in aqueous H_2SO_4 than in aqueous $HClO_4$. Actually, it makes little difference which is used, as rates of enolization and oxidation are nearly the same in the two solvents (11).

Air Free System

Kinetic Dependence at Low [Fe(III)] and High [H+]

Kinetic studies were carried out under pseudo first-order conditions with excess ketone. A first-order dependence on [Fe(III)], first-order dependence on [ketone], and zero-order de-

pendence on [H^+] was found. This corresponds to [5]. The values of $2k_2'$ for 2-butanone, 3-methyl-2-butanone, 3-pentanone, and 2,4-dimethyl-3-pentanone are shown in Table 1. 3-Methyl-2-butanone is known to form peroxides readily. However, the same value of k_2' was found for a peroxide free solution under N_2 (Table 1).

The rate of oxidation of acetone by ferriin at high acetone concentration is so slow that the rate of decomposition of ferriin was comparable to the observed rate of oxidation. Thus the rate could not be accurately measured. The value of k_2' was actually measured using 5-chloroferriin which is a more vigorous oxidant than ferriin. A value of 1.3×10^{-3} M^{-1} s^{-1} at 1.3 M H_2SO_4 for $2k_2'$ was found (Table 2). Assuming that the Marcus relationship holds as it does for cyclohexanone, a value of 1.3×10^{-4} M^{-1} s^{-1} can be calculated to be the value of $2k_2'$ for ferriin.

Kinetic Dependence at Low [H^+] and High [Fe(III)]

With excess ketone, pseudo zero-order kinetics were observed for more than 50% of the reaction followed by a gradual decrease in rate. Some reactions were carried out in H_2SO_4 because ferriin is more soluble in H_2SO_4 than in $HClO_4$. The rate expression in the linear region was found to be first-order in [ketone], first-order in [H^+], and zero-order in [Fe(III)]. This corresponds to [6]. Values of $2k_1$ for 2-butanone, 3-methyl-2-butanone, 3-pentanone, and 2,4-dimethyl-3-pentanone are shown in Table 3. No k_1 values for acetone were obtained since the rate expression corresponding to [6] could not be achieved under experimentally accessible conditions (see calculation in Discussion).

†Degassed with argon.

Since the products in the oxidation of ketones by ferriin are known to be 2-hydroxy ketones (initially) which are further oxidized, little product identification study was carried out. However, the oxidation of 2-butanone was shown by vapour phase chromatography to initially give 3-hydroxy-2-butanone. This was further oxidized to 2,3-butanedione.

Air Containing System

Kinetic Data at Low [Fe(III)] and High [H^+]

These runs were carried out essentially in the same way as the air free system except that no attempt was made to remove the air. Runs at low [Fe(III)] and high [acid] gave well behaved kinetics, first-order in [Fe(III)], first-order in [ketone], and zero-order in [H^+]. Values of $2k_2'$, given in Table 4, are usually about one half those in the absence of air (see Table 1). An exception is 3-methyl-2-butanone for which $2k_2'$ was found to be 1.2 M^{-1} s^{-1} or three times larger than in the absence of air.

Kinetic Data at High [Fe(III)] and Low [H^+]

The runs at high [Fe(III)] and low [acid] were

also kinetically well-behaved initially. At a given acid and ketone concentration they gave pseudo zero-order plots for the reduction of [Fe(III)] to [Fe(II)]. However, at about 50% of the reaction the linear rate of [Fe(III)] reduction suddenly increased, giving a reduction plot for the remainder of the reaction which resembled that expected for a reaction first-order in [Fe(III)] (Fig. 1). The latter part of these plots indicate a complicated secondary reaction resulting from the build-up of some reactive species during the course of the ketone oxidation. Since the reaction scheme must be very complicated no kinetic analysis was attempted. Measurement of the initial rate yielded a rate expression corresponding to [6]; first-order in [ketone], first-order in [H^+], and zero-order in [Fe(III)]. Values of $2k_1'$ for all ketones but acetone are given in Table 5.

presence of oxygen would result from formation and decomposition of peroxides in chain reactions they might be expected to be quite complicated. For that reason no product studies were carried out in this system.

Discussion

The air-free system is mechanistically the simplest and will be discussed first. The data are summarized in Table 6. The most important point is that four ketones in addition to cyclohexanone have now been shown to have a rate equation of the form of [4] clearly indicating they are oxidized via the enol mechanism. The five include ketones of quite different structure whose rates of enolization vary by a factor of 170. The agreement between calculated and literature values for the rates of enolization are quite good for cyclohexanone (13) and 2,4-dimethyl-3-pentanone (14) whose rates of enolization are well established (Table 6). The rest were obtained by determining relative rates of enolization as compared with acetone and are probably not as accurate. The values for 3-methyl-2-butanone agree well but those for 2-butanone and 3-pentanone are not as close. However, even with the worst case, 3-pentanone, the difference of a factor of ca. three in the two rates is not unreasonable, considering the difference in method of measurement. However, the value of k_1 for acetone could not be obtained because the limiting case of [4] when k_2[Fe(III)] $\gg k_{-1}$[H^+] is not experimentally accessible. This is readily verified by the following considerations. Values

TABLE 6. Values of k_1 and k_2 for several ketones in air-free aqueous solutions at 25°C*

Ketone	Enolization rate constant† Calcd. (k_1) (M^{-1} s^{-1})	Literature (M^{-1} s^{-1})	$2k_2' = 2Kk_2$ (M^{-1} s^{-1})	K	k_2 (M^{-1} s^{-1})

*All values of k_1 except that for 2,4-dimethyl-3-pentanone were determined in aqueous sulfuric acid. Value of k_1 for this ketone, as well as all values of k_2', were determined in aqueous $HClO_4$.
†Numbers in parentheses are literature references.
‡Data from ref. 10.

of k_2 and k_{-1} were calculated to be 4.3×10^3 M^{-1} s^{-1} and 1.8×10^3 M^{-1} s^{-1} from the literature values of K (1.5×10^{-8}) (15), k_1 (2.7×10^{-5} M^{-1} s^{-1}) (11), and the experimentally determined value of $2k_2'$ (1.3×10^{-4} M^{-1} s^{-1}) (Table 2). Using these values it can be shown that for k_2[Fe(III)] to be 10 times larger than k_{-1}[H$^+$], the ratio of [Fe(III)] to [H$^+$] must be about 4. The lowest [H$^+$] which can be used is 0.2 M since ferriin is readily hydrolyzed at lower [H$^+$] (17). This would require a [Fe(III)] of 0.8 M but it is not possible to make a ferriin solution more concentrated than 0.02 M when [H$^+$] is 0.2 M.

One objective of this work was to establish a correlation between enol structure and reactivity. Fortunately, for the symmetrical ketones, values of the equilibrium constant, K, for enolization have been determined (15). In making such a correlation we will assume that acetone reacts by way of the enol tautomer although this has not been proven kinetically. This is a reasonable assumption since all the other ketones studied are oxidized via the enol tautomer. However, it is possible that acetone is oxidized via the keto tautomer.

The values of the rate constants, k_2, for electron transfer from enol to ferriin are given in Table 6. The order of reactivity, 2,4-dimethyl-3-pentanone > 3-pentanone > cyclohexanone > acetone, indicates a methyl substituent increases the rate of electron transfer from enol. Correlations between enol structure and relative rates are shown in Table 7. This is reasonable if, as previously proposed for the oxidation of cyclohexanone (10), electron transfer occurs to give a radical cation (reaction 2). The electron donating substituents would stabilize such an intermediate. To our knowledge, this is the first quantitative correlation between enol structure and reactivity.

The oxidation rates of the unsymmetrical ketones 2-butanone and 3-methyl-2-butanone are also listed in Table 6. It is of interest to note that the values of $2k_2' = 2Kk_2$ for the two unsymmetrical ketones, 2-butanone and 3-methyl-2-butanone, are similar to the next more substituted symmetrical ketone, 3-pentanone and 2,4-dimethyl-3-pentanone (Table 6). Enols formed from unsymmetrical ketones exist in two tautomeric forms which differ in their degrees of substitution. The rates with symmetrical enols indicate the more highly substituted enol is the more reactive. Thus the rate of oxidation of the ketone will be determined by the rate of reaction of the more substituted enol if its equilibrium concentration is not much less than that of the less substituted enol. The values of K for 3-pentanone and 2,4-dimethyl-3-pentanone are within a factor of two indicating that the equilibrium concentration of enol is not strongly dependent on structure. Actually bromination studies with unsymmetrical ketones (7) suggest that the more substituted enol is the more abundant enol. On the basis of these considerations it would be predicted that the value of $2k' = 2Kk_2$ of unsymmetrical ketones would be close to that of the next more substituted ketone since the reactive enol for both is identical. This is the observed result.

The opposite order of reactivity was found for the oxidation of *para*-substituted benzyl phenyl ketones by $Mn(OAc)_3$ in acetic acid (6). Electron-withdrawing groups increased the rate of oxidation. Also unsymmetrical ketones gave products which indicated that CH_2=C(OH)— was more

TABLE 7. Relative rates of electron transfer from several enols to ferriin

Cyclohexanone		31
Acetone		1

reactive than $(CH_3)_2C{=}C(OH)$—. This system is quite different from the aqueous system considered in this paper and the mechanisms could be quite different. Thus $Mn(OAc)_3$ could be an inner-sphere oxidant and the radical anion could be the more reactive species which would explain the order of reactivity. Also in the $Mn(OAc)_3$ system it is not clear if the rate determining step is the rate of electron transfer from the enol or the rate of enolization.

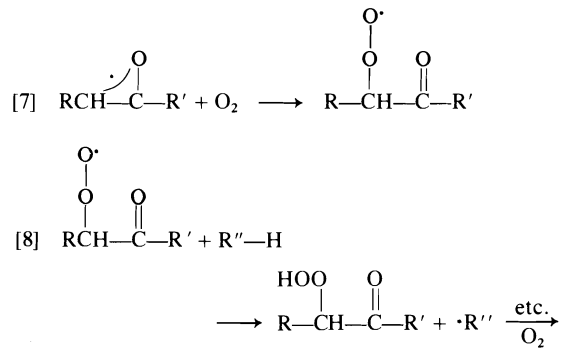
Earlier reports on the rates of oxidation of ketones by other oxidants deserve some comment. Petit found that in the oxidation of a series of methyl ketones by chromic acid, the rate of oxidation increased from acetone to 2-nonanone (18). Shorter found a linear correlation between the apparent rate of oxidation of ketones by ceric sulphate and the rate of enolization. He interpreted this result by suggesting that all enols have approximately the same reactivity since there is likely a Brønsted type of correlation between rate of enolization and the keto–enol equilibrium constant. Acetone was found to react much slower than would be expected on the basis of its rate of enolization. He attributed this lack of stabilization to hyperconjugation in the oxidation product of acetone. No correlation between rates of enolization and rates of oxidation of ketones by Mn(III) pyrophosphate was found; acetone was oxidized faster than 2,4-dimethyl-3-pentanone (8). Ceric sulphate, $Mn(OAc)_3$, chromic acid, as well as Mn(III) pyrophosphate are most likely inner-sphere oxidants and hence not comparable to ferriin. In addition, the rates of oxidation quoted by the above workers includes the keto–enol equilibrium constant and hence do not refer to the reactivity of the enol towards the oxidant.

Although detailed product distribution studies were not carried out, 3-hydroxy-2-butanone and 2,3-butanedione products were the expected ones, if the more substituted enol is reactive. Thus oxidation of 2-butanone by Fe^{3+} (19) and $[Fe(III)(X)(H_2O)phen_2]$ ($X = H_2O$, OH^-) (20) were reported to give 2,3-butanedione as the final product. Almost certainly, this product arose from further oxidation of the hydroxy ketone.

The most striking feature of the values k_1 and k_2 for the air containing system is that they are about the same or lower than those in the air-free system for all ketones but 3-methyl-2-butanone. In fact for three; 2-butanone, 2,4-dimethyl-3-pentanone, and 3-pentanone, the values of both k_1 and k_2 are roughly one-half of the corresponding values in the air-free system. This result can be explained by a change in stoichiometry of the reaction. Thus in the absence of O_2 the reaction would be given by [1] to [3].

In the presence of oxygen [3] could be re-

placed by reactions such as those shown in reactions 7 and 8.



Thus, in the presence of O_2, only one Fe(III) is reduced per electron transfer from enol, i.e. the autoxidation chain reaction must be terminated without further reduction of Fe(III). This would have the effect of halving the rate of Fe(III) reduction. A similar argument has been put forward by Littler and co-workers on the effect of O_2 on rate in the oxidation of cyclohexanone by Ir(IV) (21).

The increase in $2k_2'$ in air for 3-methyl-2-butanone is apparently real. It could be that the rates of the steps in reactions 1–3, 7–8 are different, or alternatively that other reaction paths are operative for this ketone and some species which reduces Fe(III) is produced in high enough concentrations to become important. Thus in the oxidation of 2-butanone by Fe(III), oxygen is reported to increase the rate (19) while in the oxidation of cyclohexanone by Ir(IV), oxygen decreases the rate (21). Thus whether retardation or acceleration is observed will depend on the system and in fact may depend on reaction variables. As discussed next, apparently [Fe(III)] is an important variable.

Since Fe(III) reduction rather than oxygen uptake is measured, no information about the autocatalytic reaction sequence is obtained other than that Fe(III) takes part in the autocatalytic sequence by reacting with some of the products formed. This apparently happens in the runs at high [Fe(III)] and low $[H^+]$ used to measure k_1, since the rate of Fe(III) reduction suddenly departs from linearity at about 50% reduction of Fe(III). Since we were measuring the rate of formation of Fe(II) species the autocatalytic plot shows that in the autocatalytic region, there is a rapid build up of a certain species that is active in reducing Fe(III). The nature of this species is highly speculative; it could be a radical, or peroxide, or even $Fe^{2+}(aq)$[2] formed due to hydrolysis of ferroin (22). On the basis of present evidence further speculation does not seem warranted.

As reported previously, the values of k_1 and k_2 for cyclohexanone are altered little in the presence of air, suggesting Fe(III) reacts very fast with the enol radical (reaction 3) in this case. The value of k_2 for acetone is also little altered by oxygen but because of the uncertainty of mechanism little can be said about this case.

Since the product distribution would likely be very complicated in the air containing systems no product analysis was carried out.

Experimental

Materials

1,10-Phenanthroline, ferrous sulphate heptahydrate, and perchloric acid were purchased from G. Frederick Smith Chemical Company. Sulphuric acid was purchased from Matheson, Coleman and Bell Manufacturing Company.

2-Butanone, 3-pentanone, 3-methyl-2-butanone, and 2,4-dimethyl-3-pentanone were all reagent grade from J. T. Baker Chemical Company and were distilled before use. In some instances, peroxides were removed from the ketone by addition of Fe^{2+} to the ketone before distillation. This treatment did not alter the rates. Acetone was reagent grade from J. T. Baker Chemical Company and was used without purification.

Tris(1,10-phenanthroline)Fe(II) (ferroin) was prepared from a published procedure (23) which consisted of adding 1,10-phenanthroline to a solution of $FeSO_4 \cdot 7H_2O$ in a 3:1 molar ratio. Ferriin was obtained by oxidation of ferroin with PbO_2 in 1 M H_2SO_4. Ferriin was precipitated as a perchlorate salt. Stock solutions of ferriin were made up in concentrated H_2SO_4 or $HClO_4$ medium. Such solutions were diluted with water to appropriate acid strength immediately before each kinetic run.

Kinetic Studies

The rate of oxidation of ketones was monitored by following the increase in optical density at 510 nm with time. Ferroin has an extinction coefficient of 1.1×10^4 M^{-1} cm^{-1} at 510 nm while that of ferriin is 500 M^{-1} cm^{-1} (23). Kinetic studies were carried out on a Durrum stopped-flow spectrophotometer and a Cary 118 spectrophotometer. The reaction was carried out under pseudo first-order conditions with excess ketone. The pseudo first-order rate plots were analyzed by plotting log $(OD_\infty - OD_t)$ against time from which k_{obs} was found.

[2]Ferroin is known to hydrolyze with a rate constant $\sim 10^{-4}$ s^{-1} at 0.2 M $[H^+]$ to give $Fe^{2+}(aq)$. Since oxidations in air are slower than in its absence, we might expect a higher accumulation of $[Fe^{2+}(aq)]$ which subsequently undergoes a rapid outer-sphere electron transfer with ferriin to give ferroin (22) and thus produces autocatalytic behavior.

The k_{obs} values for pseudo zero-order kinetics were obtained by measurement of the slope of the linear region.

Reactions under argon or nitrogen were carried out by degassing solutions of Fe(III) in acid and ketone separately. Reaction was started by injecting the degassed solution of ketone into a solution of Fe(III) in a 1 cm optical cell fitted with a serum cap. Since degassing cannot be performed easily inside a 1 mm cell, such reactions were carried out by degassing solutions of Fe(III) and ketone separately. Mixing and transferring the reactants into the 1 mm cell were carried out under N_2 in a glove box.

The oxidation of acetone was studied at 2.4×10^{-3} *M* ferriin and 0.6 *M* H_2SO_4 and at 6×10^{-5} *M* ferriin and 6.3 *M* H_2SO_4. Even at acetone concentrations of 0.91 *M* and 1.82 *M* and at low [Fe(III)] no change in OD over a 2 h period was observed. At high [Fe(III)] and low [acid], pseudo first-order kinetics were observed with excess [acetone]; k_{obs} is ca. 2×10^{-4} s^{-1} which is about the same as the dissociation rate constant of ferriin in absence of acetone (22). Also, the rates changed little as the acetone concentration was doubled.

The rates of oxidation of acetone by 5-chloroferriin are given in Table 1. From the slope of the k_{obs} vs. acetone plot, k_2' was determined to be 1.3×10^{-3} M^{-1} s^{-1}. If the Marcus relationship is obeyed 5-chloroferriin would be 10 times more reactive than ferriin (10). This gives an oxidation rate of 1.3×10^{-4} M^{-1} s^{-1} for ferriin.

Product Analysis

2-Butanone (0.2 ml) was added to a suspension of 0.008 g of ferriin in 0.1 ml of 2 *M* H_2SO_4. The reaction was carried out under N_2. After stirring the solution for 5 min samples were taken at 1 min intervals for analysis on a Hewlett Packard 5750 research gas chromatograph on a $\frac{1}{4}$ in. diameter 12 ft Carbowax column. Products were identified by retention times. 3-Hydroxy-2-butanone was identified as the initial product. With time, butane-2,3-dione was formed.

Photoreactions of 1- and 2-naphthonitriles with tetramethylethylene in various solvents

JOHN J. MCCULLOUGH, RODERICK C. MILLER, AND WEI-SAI WU
Chemistry Department, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received January 12, 1977

JOHN J. MCCULLOUGH, RODERICK C. MILLER, and WEI-SAI WU. Can. J. Chem. **55**, 2909 (1977).

The photoreactions of 1- and 2-naphthonitriles with tetramethylethylene have been studied in the solvents hexane, benzene, dimethoxyethane, methanol, and acetonitrile. In hexane, benzene, or dimethoxyethane, the exclusive products are the cyclobutanes 1-cyano-7,7,8,8-tetramethyl-2,3-benzobicyclo[4.2.0]octa-2,4-diene (from 1-naphthonitrile and tetramethylethylene), and 6-cyano-7,7,8,8-tetramethyl-2,3-benzobicyclo[4.2.0]octa-2,4-diene (from 2-naphthonitrile). In methanol, products of photoreduction are formed. From 2-naphthonitrile and tetramethylethylene in methanol are obtained 1-(2′-methoxy-1′,1′,2′,2′-tetramethyl)-3-cyano-1,4-dihydronaphthalene, 1-(2′-methoxy-1′,1′,2′,2′-tetramethyl)-2-cyano-2,4-dihydronaphthalene, and 1,2-dihydro-2-naphthonitrile. Deuterium incorporation is observed with CH_3OD as solvent, and the stereochemistry of solvent incorporation is discussed. Reaction in 2,2,2-trifluoroethanol proceeds similarly. In methanol, 1-naphthonitrile and tetramethylethylene give products of reductive dimerization, whose exact structures were not determined. In acetonitrile, both naphthonitriles give complex mixtures of products on reaction with tetramethylethylene. It is proposed that the cyclobutane formation in non-polar solvents involves exciplex intermediates, while in polar media electron transfer occurs and results in photoreduction.

JOHN J. MCCULLOUGH, RODERICK C. MILLER et WEI-SAI WU. Can. J. Chem. **55**, 2909 (1977).

On a étudié les photoréactions des naphtonitriles-1 et -2 avec le tétraméthyléthylène dans l'hexane, le benzène, le diméthoxyéthane, le méthanol et l'acétonitrile comme solvants. Dans l'hexane, le benzène ou le diméthoxyéthane, les produits exclusifs sont les cyclobutanes, cyano-1 tétraméthyl-7,7,8,8 benzo-2,3 bicyclo[4.2.0] octadiène-2,4 (à partir du naphtonitrile-1 et du tétraméthyléthylène) et le cyano-6 tétraméthyl-7,7,8,8 benzo-2,3 bicyclo[4.2.0] octadiène-2,4 (á partir du naphtonitrile-2). Dans le méthanol il y a formation de produits de photoréduction. A partir du naphtonitrile-2 et du tétraméthyléthylène dans le méthanol on obtient le (méthoxy-2′ tétraméthyl-1′,1′,2′,2′)-1 cyano-3 dihydro-1,4 naphtalène, le (méthoxy-2′ tétraméthyl-1′,1′,-2′,2′)-1 cyano-2 dihydro-2,4 naphtalène et le dihydro-1,2 naphtonitrile-2. On observe une incorporation de deutérium lorsque le CH_3OD est utilisé comme solvant et on discute de la stéréochimie de l'incorporation du solvant. La réaction dans le trifluoro-2,2,2 éthanol se produit d'une manière similaire. Dans le méthanol, le naphtonitrile-1 et le tétraméthyléthylène donnent des produits de dimérisation réductive dont on n'a pas déterminé les structures exactes. Dans l'acétonitrile, les deux naphtonitriles conduisent á des mélanges complexes de produits de réaction avec le tétraméthyléthylène. On propose que la formation de cyclobutane dans des solvants non-polaires implique des intermédiaires exciplexes alors que dans des milieux polaires, il se produit des transferts d'électrons et il en résulte une photoréduction.

[Traduit par le journal]

The formation, structure, and behaviour of exciplexes is an area of research attracting considerable current interest. Exciplexes and ion-pairs have been studied by a variety of physical (1–13) and chemical (14–21) approaches, and a great deal is now known about the factors affecting their formation and behaviour. The earlier work employed amino compounds (1–4, 6, 7, 14–16) as electron donors to study the physical and chemical effects of charge transfer. It was also shown, however, that simple alkyl substituted ethylene derivatives could act as electron donors, giving rise to exciplex and ion pair formation with various excited aromatic compounds (8–13, 18–21). We have given preliminary accounts of our physical and chemical investigations on exciplexes and ion pairs from the naphthonitriles and tetramethylethylene (18, 19). In the present paper, we describe the isolation and identification of products of these reactions, run in various solvents. In a later paper, the details of photokinetics and lifetime measurements on these systems will be described.

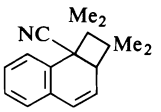
Results

Reactions in Non-polar Solvents

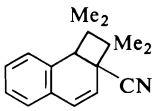
Products and Structural Assignments

Irradiation of 1-naphthonitrile and tetra-

methylethylene in benzene with 313 nm light results in the efficient formation of a 1:1 adduct, **1**. This was separated from residual 1-naphthonitrile by column chromatography and vpc. On sublimation at 1 Torr, crystals, mp 69–71°C were obtained. The nmr spectrum showed resonances as follows. Four singlets at 1.40, 1.32, 1.00, and 0.81 δ (each area 3) were assigned to the methyl groups. A doublet of doublets (area 1) with $J = 4.5$ and 2.0 Hz at 3.20 δ was assigned to the bridgehead methine proton. An AB system at 5.71 δ, $J = 10.0$ and 4.5 Hz and at 6.31 δ, $J = 10.0$ and 2.0 Hz was attributed to the vinylic protons. Protons of the benzene ring gave two multiplets, centered at 7.1 (area 3) and



1



2

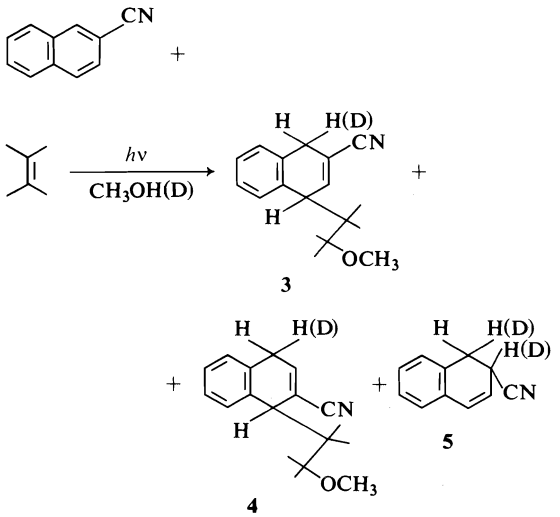
at 6.9 δ (area 1). The ultraviolet spectrum of **1** had λ_{max}(hexane) at 270 nm, log ε = 3.84. This is in good agreement with the spectrum of *endo*-7-cyano-2,3-benzobicyclo[4.2.0]octa-2,4-diene, whose structure is known from X-ray work, which had λ_{max}(hexane) at 268 nm, log ε = 3.86. In contrast, *o*-xylene has λ_{max}(EtOH) at 262 nm, log ε = 2.42. On the basis of this data, the adduct **1** is assigned the structure 1-cyano-7,7,8,8-tetramethyl-2,3-benzobicyclo[4.2.0]octa-2,4-diene. The same adduct was found to be by far the major product of this photoaddition in hexane or dimethoxyethane as solvents.

Irradiation of 2-naphthonitrile and tetramethylethylene in benzene also gave a single 1:1 adduct, **2**. The latter was difficult to separate from 2-naphthonitrile because it was thermally unstable to preparative vpc conditions, and moved at the same rate as 2-naphthonitrile on adsorption chromatography. Purification was achieved by high pressure liquid–liquid chromatography. This adduct is assigned the structure 6-cyano-7,7,8,8-tetramethyl-2,3-benzobicyclo[4.2.0]octa-2,4-diene (**2**). The nmr spectrum agrees with that reported by Cantrell (22). Singlet resonances were noted at 0.78, 1.07, 1.09, and 1.48 δ (each area 3) due to the methyl groups, and at 3.72 δ (area 1), assigned to the methine proton. The vinyl protons showed at 6.52 ($J = 10.0$ Hz) and at 5.72 δ ($J = 10.0$ Hz and 1.5 Hz). The smaller coupling constant is apparently due to coupling with a proton in the benzene ring. The protons of the benzene ring gave multiplets at 7.15 (area 3) and at 6.85 δ (area 1). Note that the product of 1,4-addition to the 2-naphthonitrile would have just one vinyl proton signal in the nmr spectrum. The same adduct was the only significant product of irradiation of 2-naphthonitrile and tetramethylethylene in dimethoxyethane.

Reactions in Polar Solvents

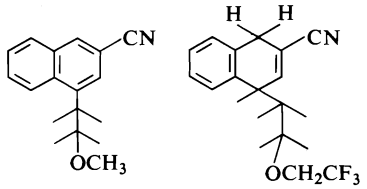
Irradiation of *2-naphthonitrile* and *tetramethylethylene in methanol* gave products assigned the structures **3**, **4**, and **5** shown in Scheme 1.

The products **3** and **4** (ratio 3:2) were isolated by silica gel chromatography. Compound **3** had mp 89.5–91.5°C. The nmr spectrum showed singlet resonances at 3.24 (area 3), due to the methoxy group, and at 0.56, 0.82, 1.10, and 1.26 δ (each area 3), due to the two pairs of diastereotopic methyl groups. The methylene and methine protons gave resonances between 3.30 and 3.80 δ, partly overlapping the singlet at 3.24 δ. A resonance at 7.05 δ was attributed to the vinyl proton, but detail was obscured by the resonance of the benzenoid protons at 7.08 δ (area 4). These resonances did have quite different chemical shifts on treatment with europium tris(dipivaloylmethide) (23). The resonance (area 1) of the vinyl proton showed a doublet, $J = 5.0$ Hz. As a final confirmation of structure, **3** was dehydrogenated with palladium-on-charcoal to give the naphthalene derivative **6**. The latter showed singlet resonances at 3.07 (area 3),



SCHEME 1

of the methoxy group, and at 1.12 and 1.66 δ (each area 6), due to the two pairs of side chain methyl groups. Most of the benzenoid protons resonated between 7.2 and 8.0 δ, except for a multiplet (area 1) at 8.9 δ. The latter is assigned to the proton at the *peri*-position, nearest to the side-chain, because of its low-field position (24). The structure 1-(2′-methoxy-1′,1′,2′,2′-tetramethylethyl)-3-cyano-1,4-dihydronaphthalene is thus assigned to compound **3**.[1]



6 **7**

Compound **4**, mp 96.5–98°C, showed singlet resonances in the nmr spectrum at 7.08, for benzenoid protons (area 4), at 3.24 for the methoxy group (area 3), and at 0.71, 0.73, 1.12, and 1.35 δ (each area 3), for the side-chain methyl groups. A doublet at 3.75 δ, (area 1) with $J = 0.5$ Hz identified the methine proton, while the methylene group gave a multiplet from 3.24–3.50 δ, overlapping the methoxy-group singlet at 3.24 δ. The vinyl proton gave a doublet of doublets at 6.75 δ, (area 1) with $J =$ 7.0 and 3.0 Hz.

Attempted dehydrogenation as described for **3**, resulted in loss of the side-chain to give 2-naphthonitrile. The structure 1-(2′-methoxy-1′,1′,2′,2′-tetramethylethyl)-2-cyano-1,4-dihydronaphthalene is assigned to compound **4**. In the above reaction, there was also formed 1,2-dihydro-2-naphthonitrile **5**. This was isolated by distillation and characterized by its spectral properties.

Reaction of 2-Naphthonitrile and Tetramethylene in Methanol-O-d

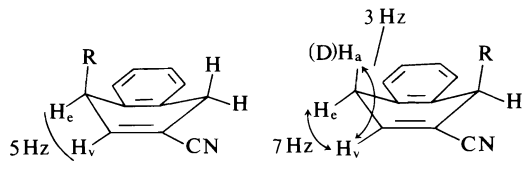
Use of deuteroxylated methanol (CH_3OD) as solvent gave **3**, **4**, and **5** with deuterium incorporated in the methylene groups, as shown in Scheme 1. These labelled products will be referred to as **3**D, **4**D, and **5**D, respectively.

The presence of the deuterium label was evidenced by the weak M^+ ions of **3**D and **4**D with $m/e = 270$ ($C_{18}H_{22}DON$), and by the decrease in areas of the methylene group resonances in the nmr spectra.

By determining which proton–proton coupling constants were affected by the labelling, it was possible to deduce the stereochemistry of the deuterium label in **4**D. It was assumed that the reduced ring of the 1,4-dihydronaphthalene system adopts a shallow boat conformation (25) with the bulky substituent axial, as shown in Fig. 1.

The substituent apparently keeps the dihydronaphthalene system locked in one boat conformation, as shown by the proton spin–spin splitting pattern (25*c*). In **4** (unlabelled) the signal of the vinyl proton (H_v) shows as a doublet of doublets, with $J = 3.0$ and 7.0 Hz. Splitting of the H_v signal by H_a is assumed to have $J =$ 3.0 Hz (25*d*) and the splitting by H_e is assumed to have the larger ($J = 7.0$ Hz) coupling constant (25*c*).

In the spectrum of **4**D the signal of H_v appears as a *doublet* with $J = 7.0$ Hz. Thus, the deuterium in **4**D has apparently replaced H_a and not H_e and the deuterium label is *cis* to the side-chain substituent. Interestingly, the splitting of H_v in **3** has $J = 5.0$ Hz, which is consistent with H_e being equatorial with the bulky substituent axial. The above data are summarized in Fig. 1. Irradiation of *2-naphthonitrile* and *tetramethylethylene* in formic acid – methanol gave the same products as with pure methanol (Scheme 1), although the ratio of **3**:**4** did appear to change. Irradiation of *2-naphthonitrile* and *tetramethylethylene* in 2,2,2-trifluoroethanol gave a mixture of products from which compound **7** was isolated by preparative vpc. This compound had mp 150–152°C, and was identified by its nmr spectrum. This showed singlets at 0.73, 0.87, 1.19, and 1.36 (each area 3), due to the methyl groups, a quartet, $J = 9.0$ Hz (area 2), at 3.79 due to the methylene group of the trifluoroethyl substituent, and a partially resolved doublet at



3 **4**

R = $CH_3OC(CH_3)_2C(CH_3)_2$—

FIG. 1. Conformations of the 1,4-dihydro-2-naphthonitrile derivatives **3** and **4**.

[1]The ultraviolet spectra of **3** and **4** also agreed with these assignments (see Experimental).

7.05 δ due to the vinylic proton. Multiplets at 3.53 (area 1), 3.73 (area 2), and 7.1–7.3 δ (area 4) corresponded to the methine, ring methylene, and aromatic ring protons respectively. The ^{19}F spectrum showed a triplet at 74.6 δ, (J = 9.0 Hz) from $CFCl_3$ confirming the presence of the trifluoroethyl group.

Irradiation of *1-naphthonitrile* and *tetramethylethylene* in methanol gave two crystalline adducts, which were separated by chromatography over silica gel. In spite of an intensive investigation of the structures of these products by chemical and spectroscopic techniques, their structures are still undetermined. They appear to be products of reductive dimerization of the naphthonitrile, and one of them contains the side chain which is present in **3** and **4**. This shows that solvent (methanol) has been incorporated.

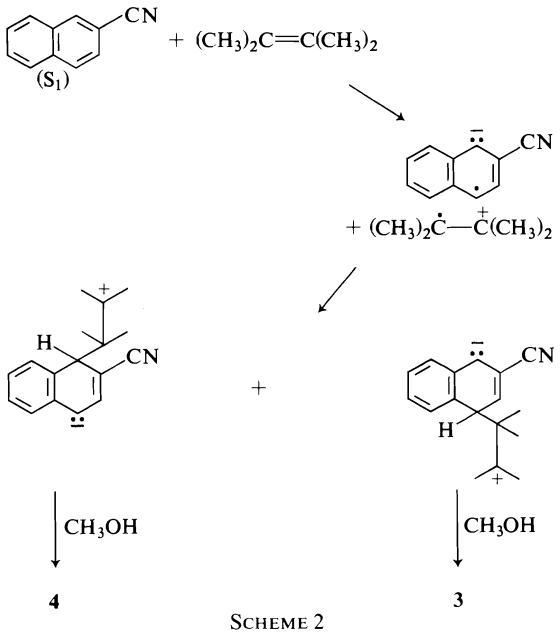
Irradiation of 1- or 2-*naphthonitrile* and *tetramethylethylene* in acetonitrile gave an extremely complex mixture of products, shown by vpc analysis. No attempt was made to separate or characterize these compounds.

Discussion

It is clear from the above results that the photoreactions of the naphthonitriles and tetramethylethylene proceed by quite different mechanisms in the non-polar (hexane, benzene, dimethoxyethane) and polar (alcohols, acetonitrile) solvents. The non-polar media give highly specific reactions, the products being the cyclobutanes, **1** and **2**, formed by a formal $2\pi_S + 2\pi_S$ addition.[2] There is evidence, presented previously, that the cycloaddition involves exciplexes of the naphthonitrile and the olefin (19). The exciplex emission from 1-naphthonitrile and certain olefins is now well-known (10, 11).

Quenching of exciplex emission by polar solvents is also a widely recognized process. This quenching generally gives rise to ion-pairs, which are non-fluorescent. The photoreactions of many amino-compounds in polar solvents have been satisfactorily interpreted in terms of ion pairs, formed by electron transfer.

The products formed from the 2-naphthonitrile and tetramethylethylene in methanol are, by their nature, strongly suggestive of an electron transfer reaction pathway. In fact, all the products in Scheme 1 are dihydronaphthalenes, clearly formed by photoreduction of the naphthalene ring. The following mechanistic scheme (Scheme 2) is suggested to account for these



SCHEME 2

products. The stages are (*i*) electron transfer from olefin to the naphthonitrile ring, forming a pair of radical ions; (*ii*) collapse of the ion pair to a zwitterion; (*iii*) capture of solvent by the zwitterion to give products **3** and **4**. This is a rationale for the reaction, which accounts for the general features, e.g., it explains the formation of 1,2-dihydro-2-naphthonitrile which could be formed by escape of the radical anion from the ion-pair (26).[3]

We have one piece of evidence which gives insight into the timing of the above steps in the reaction. The *cis* arrangement in **4** of the proton (deuterium label) which comes from the solvent, and the side chain means that protonation cannot precede formation of the new carbon–carbon bond. If it did, a mixture of *cis* and *trans* deute-

[2]In a recent communication, Yang *et al.* (27) report the formation of 1-azetines on irradiation of the naphthonitriles or benzonitrile with olefins. We did not observe these products. However, as the authors point out (27), the cyclobutane ring system of **1** and **2** is photochemically labile (17), and under their reaction conditions (high conversion of reactant, Corex filter) the labile cyclobutanes are gradually replaced by the apparently stable 1-azetines. In contrast, our reactions giving **1** and **2** were always taken to low conversion, and Pyrex filters and 300 nm light were used. Under these conditions the initially formed cyclobutanes would be stable.

[3]Libman has observed reduction of 1-naphthonitrile on photoreaction with phenylacetic acid derivatives (26).

rium labelled **4** would result. Apparently, protonation *cis* to the bulky substituent (axial protonation) occurs preferentially.

The formation of **7** in trifluoroethanol may mean that this solvent, in spite of its much lower nucleophilicity, can be captured in the same way as methanol. This is consistent with the ion-pair mechanism, since the radical cation should be a powerful electrophile. Alternatively, protonation of the naphthonitrile ring may precede bonding of the side chain in this solvent (in contrast to methanol). We also note that the reduction product 1,2-dihydro-2-naphthonitrile **5** appears to be formed in trifluoroethanol. A final point can be made concerning product **5**. Since **5** is formed by reduction of the naphthonitrile, there must be an equivalent amount of products, from oxidation of the tetramethylethylene. We have not characterized these products, but note that Sakurai and co-workers (13) have reported a dimeric ether derivative in the photoreaction of 9-cyanophenanthrene with tetramethylethylene in methanol.

The reaction in acetonitrile is very complex, many products being formed, and a detailed analysis would involve an extensive investigation.

In conclusion, the results are consistent with the proposal (18, 19) that cycloaddition in nonpolar solvents proceeds via exciplexes, while electron-transfer in polar media leads to a totally different spectrum of photoreduction products. This scheme has been used to interpret the widely-studied photochemistry of amines and related compounds (14).

Experimental

Instruments

The nuclear magnetic resonance spectra were obtained with a Varian HA-100 or A-60 spectrometer. The chemical shifts are given as ppm (δ) and tetramethylsilane (δ = 0) was used as internal standard. Infrared and ultraviolet spectra were determined with a Perkin-Elmer 521 and Cary model 14 spectrophotometer respectively. Mass spectra were recorded on a Hitachi–Perkin-Elmer RMU 6A or a CEC 21-110B instrument. The vapor-phase chromatography (vpc) was performed, unless otherwise specified, with a Varian 204B dual column instrument with the flow rate of helium 30 ml/min. Two kinds of silica gel (Grace, 923, 100–200 mesh, and MN-silica gel G) were used as adsorbents in the adsorption column chromatography. For thin layer chromatography (tlc), Eastman plastic sheet precoated with silica gel was used. Melting points were measured on a Kofler hot stage and are uncorrected. Nitrogen was Canadian Liquid Air, certified grade. Preparative scale irradiations were generally performed either with a 450 W Hanovia type L mercury vapor lamp, using a Pyrex filter, or in sealed, deaerated Pyrex ampoules, irradiated with RPR-3000 Å lamps in a Rayonet reactor.

Microanalyses were determined by the Spang Microanalytical Laboratory, Ann Arbor, MI, by the Gygli Microanalysis Laboratory, Toronto, or by Galbraith Laboratories, Inc., Knoxville, TN.

Materials

All solvents for reactions were distilled before use.

1-Naphthonitrile from Eastman Organic Chemicals was recrystallized from light petroleum, mp 36.5–37°C. 2-Naphthonitrile was also from Eastman Organic Chemicals and was crystallized from 95% ethanol, mp 67–68°C. Tetramethylene was from Aldrich Chemicals ("Gold Label" grade) and was distilled at atmospheric pressure, bp 70.5°C. Deuterium oxide was from Columbia Organic Chemicals, and was specified at 99.7% D_2O. Dimethyl carbonate was from the British Drug Houses, Ltd., and was used to prepare methanol-*OD* by the method of Streitwieser *et al.* (28).

Photoaddition of 1-Naphthonitrile and Tetramethylethylene in Benzene

1-Naphthonitrile (3.0 g, 0.020 mol) and tetramethylethylene (8.0 g, 0.095 mol) in benzene (420 ml) were irradiated under argon with the Hanovia 450 W lamp for 50 h. The extent of reaction was determined from the nmr spectrum. The mixture was filtered through a 7 × 3 cm column of Grace 923 silica gel, using 1 ℓ of benzene to elute, and the solution was evaporated. The residue was chromatographed on a 3 × 35 cm column of silica gel (Machery–Nagel, type G) which was eluted with ether – benzene – light petroleum mixture in the ratio 15:15:70. The first 300 ml were discarded, and 25 ml fractions were collected. Fractions 1–10 contained mainly 1-naphthonitrile; fractions 11–70 contained a mixture of 1-naphthonitrile and cyclobutane **1**. The residue from fractions 11–70 was distilled at 0.1 Torr, at 110°C (oil bath). The distillate (0.621 g) when combined with fractions 1–10 gave 1.495 g of 1-naphthonitrile (50%). The residue from this distillation was chromatographed on 3 × 10 cm of silica gel, and 25 ml fractions were collected. Fractions 1–5 contained 1-naphthonitrile, while fractions 11–70 contained mixtures of 1-naphthonitrile and the cyclobutane **1**. The latter fractions were evaporated and a sample of **1** was isolated by preparative vpc on 10 ft × ¼ in. of 30% SE-30 on Chromosorb W at 210°C. The sample crystallized on cooling in ice, and the crystals were used to seed the residue from fractions 11–70. An analytical sample of **1** (0.420 g) mp 69–71°C from methanol, was obtained. *Anal.* calcd. for $C_{17}H_{19}N$: C 86.03, H 8.07, N 5.90; found: C 86.22, H 8.29, N 5.90.

Photoaddition of 2-Naphthonitrile and Tetramethylethylene

A solution of 2-naphthonitrile (0.536 g, 3.5 mmol) and tetramethylethylene (6.312 g, 0.075 mol) in benzene (50 ml) was degassed by three freeze–pump–thaw cycles and was sealed in a Pyrex tube. The sample was irradiated for 48 h using the Rayonet reactor and 11 RPR-3000 lamps. Analysis on 5 ft × ⅛ in. of 5% SE-30 on Chromosorb W at 175°C showed one major peak of retention time 5.1 min. In these runs, approximately half of the 2-naphthonitrile was unreacted. The adduct **2** was separated from 2-naphthonitrile by 'reverse phase' high pressure liquid chromatography. A Waters Associates

ALC-100 instrument was used with a 4 ft × $\frac{3}{8}$ in. column of Durapak *n*-octane/Porasil C. Elution was with 50:50 acetonitrile–water at 700 psi and elution rate of 2.0 ml/min. The 2-naphthonitrile was eluted first; the fractions containing the second component **2** were collected, extracted with methylene chloride, and dried over Na_2SO_4. Evaporation gave an oil (115 mg) which declined to crystallize. Analytical vpc showed one peak corresponding to photolysis product. This showed a parent ion of *m/e* 237.1515, corresponding to $C_{17}H_{19}N$. The structure was established from the nmr spectrum (22).

Irradiation of 2-Naphthonitrile and Tetramethylethylene in Methanol

A methanolic solution (400 ml) of 2-naphthonitrile (6.0 g, 0.039 mol) and tetramethylethylene (18.0 g, 0.214 mol) was irradiated under nitrogen with a Hanovia type L 450 W lamp (Pyrex filter) for 36 h. The progress of the addition was monitored by nmr spectroscopy and by vpc on 10 ft × $\frac{1}{8}$ in. of 5% QF-1 at 200°C. Two products were observed with retention times of 10 min and 8.3 min in a ratio of 60:40. The solvent was removed, and the crude mixture (8.14 g) was chromatographed on silica gel (Grace, 923), in a 27 × 3 cm column, slurry packed in and eluted with 30% ether – light petroleum, bp 30–60°C, and 400 ml fractions were collected. Fractions 1 and 2 contained 0.136 g of unidentified material; fractions 3 and 4 were 2-naphthonitrile (3.34 g), and fractions 5–10 contained products **3** and **4** (4.20 g), determined by vpc analysis. Fractions 5–10 were combined and chromatographed on a second column of silica gel (MN-silica gel G), (65 × 4.0 cm); elution was with a mixture of ether, benzene, and light petroleum in the ratio 10:10:80. The first litre of eluate was discarded, and thereafter 20 ml fractions were collected. Fractions 1–9 contained 0.355 g of unidentified material; fractions 13–23 contained a 50:50 mixture of **3** and **4** (2.128 g); fractions 24 and 25 were **4** contaminated with **3** (0.198 g), and fractions 26–37 contained **4** (1.184 g). The latter fractions were combined and crystallization from ethanol afforded **4**, 0.351 g, mp 96.5–98°C. *Anal.* calcd. for $C_{18}H_{23}NO$: C 80.25, H 8.61, N 5.20; found: C 80.38, H 8.62, N 5.22.

Fractions 13–23 from the above column were combined and chromatographed on a third column of MN-silica gel G (25 × 3.0 cm), and elution was with 3% ether – light petroleum, bp 30–60°C. Fractions of 25 ml were collected, and fractions 15–25 contained **3** and **5** (1.064 g) which gave **3**, 0.387 g, mp 89.5–91.5°C, from ethanol. *Anal.* calcd. for $C_{18}H_{23}NO$: C 80.25, H 8.61, N 5.20; found: C 80.31, H 8.55, N 5.31. The ultraviolet spectrum of **3** showed λ_{max}(EtOH) at 263 nm, log ε = 2.52, and that of **4** had λ_{max}(EtOH) 270 nm, log ε = 2.42 (compare *o*-xylene, above). The mother liquors from the crystallization of **3** were evaporated and distilled at 0.05 Torr (oil bath temperature 130°C) to afford **5**, (0.723 g) as an oil.

For the deuterium labelling experiment, the above reaction was repeated using methanol-*OD* as solvent. Deuterated **3**, **4**, and **5** were isolated as above and characterized by mass and nmr spectra.

Irradiation of 2-Naphthonitrile and Tetramethylethylene in 2,2,2-Trifluoroethanol

A solution of 2-naphthonitrile (77 mg, 0.5 mmol) and tetramethylethylene (2.1 g, 25 mmol) in freshly distilled trifluoroethanol (50 ml) was transferred to a Pyrex ampoule and degassed by purging with argon. The sample was irradiated at 300 nm for 25 h using 16 RPR-3000 Å lamps in the Rayonet reactor. Analysis by vpc on 5 ft × $\frac{1}{8}$ in. of SE-30 at 180°C showed peaks with retention times 1.6, 2.0, 7.6, 9.2, 11.5, and 17.5 min. The peak of longest retention time was isolated by preparative vpc on 8 ft × $\frac{1}{4}$ in. of 15% SE-30 on Chromosorb W at 197°C. This gave compound **7** as a yellow solid from which crystals, mp 150–152°C were obtained from ethanol. The mass spectrum showed *m/e* = 337.1663 corresponding to $C_{19}H_{22}NOF_3$. *Anal.* calcd. for $C_{19}H_{22}NOF_3$: C 67.64, H 6.57, N 4.15; found: C 67.43, H 6.63, N 4.30.

The two peaks at shortest retention time were collected together and the nmr spectrum showed that 1,2-dihydro-2-naphthonitrile and 2-naphthonitrile were present.

Irradiation of 2-Naphthonitrile and Tetramethylethylene in Acetonitrile

Irradiation of 2-naphthonitrile (2.0 g, 13 mmol) and TME (6.0 g, 71 mmol) in acetonitrile in the same way as for methanol, for 12 h resulted in the formation of many products, according to vpc analysis (10 ft × $\frac{1}{8}$ in. of 5% SE-30 at 185°C), and the mixture was not investigated further.

Dehydrogenation of Compound 3

A mixture of 0.2 g of compound **3** and 0.15 g 10% palladium–charcoal in 15 ml *p*-xylene was refluxed for 3 days. The catalyst was filtered and the solution distilled under aspirator pressure. The residue was crystallized from ethanol–water. The dehydrogenation product **6**, mp 124–126°C, was obtained (0.06 g, 30% yield). *Anal.* calcd. for $C_{18}H_{21}NO$: C 80.86, H 7.92, N 5.24; found: C 80.88, H 7.99, N 5.24.

Dehydrogenation of Deuterio-5

Deuterio-**5** and 10% palladium–charcoal (0.2 g) in 10 ml toluene were refluxed for 8 h. The solvent was removed and the residue chromatographed on a silica gel (MN-silica gel G) column (7 × 3 cm). First elution was with 0.5 ℓ light petroleum and this was discarded. Elution with 5% ether in light petroleum (1 ℓ) gave a residue which crystallized, giving 2-naphthonitrile, mp 65–68°C (lit. (29) 66°C) on removal of solvent. The product consisted of a 50:50 mixture of 2-naphthonitrile and 1-deuterio-2-naphthonitrile according to nmr and mass spectral analyses.

Pyrromethenes in the synthesis of polypyrranes[1]

AREND ROWOLD AND S. FERGUSON MACDONALD
Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received April 18, 1977

AREND ROWOLD and S. FERGUSON MACDONALD. Can. J. Chem. **55**, 2916 (1977).

A new method makes appropriate 5-bromo-5′-methoxymethyl-pyrromethenes available for synthesizing polypyrranes related to uroporphinogens. In chloroform at 20°C, they react with α-free pyrroles (normally) and with 5-free pyrromethanes (losing the methoxymethyl-pyrrole ring) to give tripyrrenes which reduce to unblocked tripyrranes. Likewise, but in dioxane at 20°C and more cleanly, 5-bromo-5′-methylpyrromethenes convert pyrromethanes to tripyrrenes, and a tripyrrane to a tetrapyrrene (bilene).

AREND ROWOLD et S. FERGUSON MACDONALD. Can. J. Chem. **55**, 2916 (1977).

Une nouvelle méthode permet de préparer quelques bromo-5 méthoxyméthyl-5′ pyrrométhènes utilisés dans la synthèse de polypyrranes apparentés aux uroporphinogènes. Les pyrrométhènes réagissent (normalement) dans le chloroforme à 20°C avec des pyrroles de position α libre et avec des pyrrométhanes de position 5 libre (perdant le cycle méthoxyméthyl-pyrrole) conduisant à des tripyrrènes lesquels sont réduits en tripyrranes non empêchés. De la même façon, les bromo-5 méthyl-5′ pyrrométhènes, dans le dioxane à 20°C, transforment plus proprement les pyrrométhanes en tripyrrènes et un tripyrrane au tétrapyrrène (bilène).

[Traduit par le journal]

The unknown 5-bromo-5′-bromomethyl-pyrromethene (**2**) was promising for the synthesis of porphyrins via a,c-biladienes, and of aminomethyl-polypyrranes related to uroporphinogens. It was obtained from the pyrrole **1**[2] and bromine in ethanol-free chloroform at 0°C, a new method, and converted to the more stable methoxymethyl-pyrromethene **3** in methanol at 20°C. Three analogues of both, with alternating substituents (PAPA, MePMeP, and the known PMePMe (1)), were obtained likewise.

Pyrromethane-5-carboxylic acids with analogues of **3** in boiling benzene had given tetrapyrrenes (bilenes) and mixtures of porphyrins (2, cf. ref. 3). It was suggested that the latter were formed through an intermediate like **11** (R = CH_2OMe) which lost two pyrroles then self-condensed to the porphyrin.

In chloroform or methanol at 20°C, the bromomethyl- and methoxymethyl-pyrromethenes **2** and **3** both condensed rapidly with the α-free pyrrole **4**. The resulting tripyrrene was isolated as its free base **5** (≤40%),[3] which was reduced to the tripyrrane **6**. Unexpectedly, the methoxymethyl-pyrromethene **3** and the 5-free pyrromethane **7** in chloroform also gave **5**, but this retained some impurity (possibly the expected tetrapyrrene, cf. **10**). In boiling benzene, **3** and the 5-carboxylic acid of **7** again gave **5** (tlc), but still less cleanly.

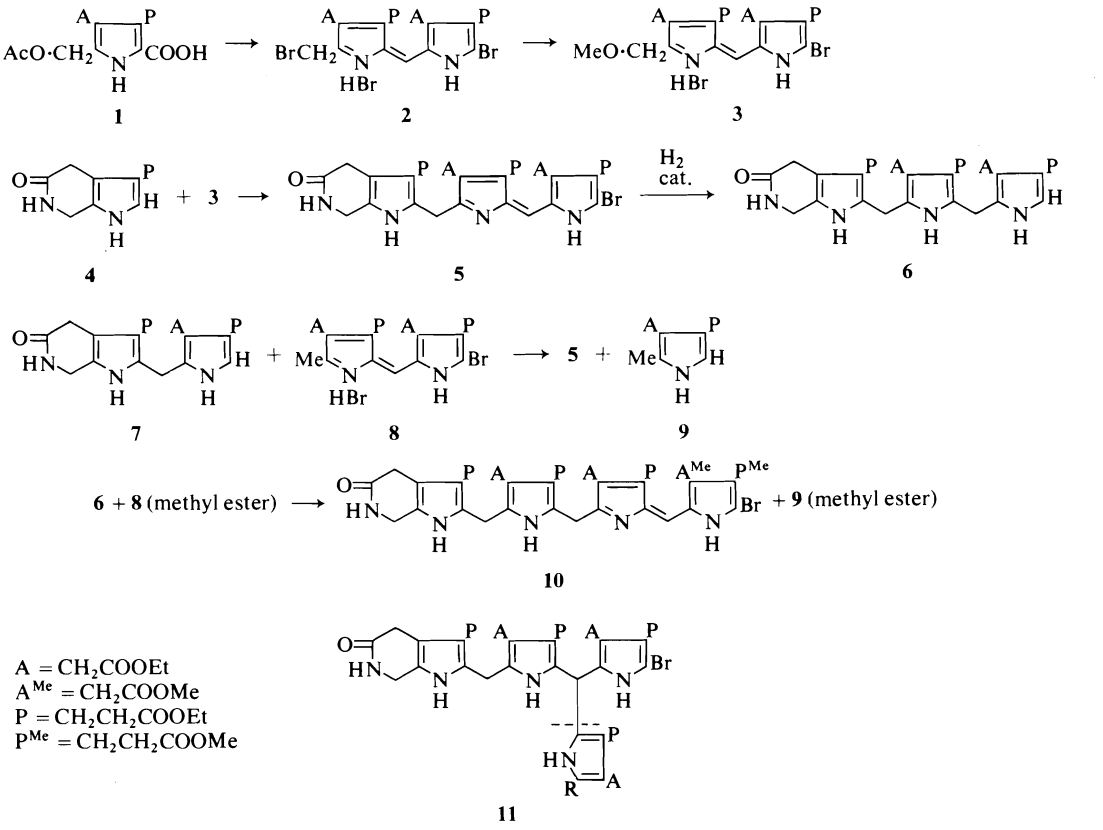
On the face of it, the second electrophilic center in **3** reacted with **7**, resulting in **11** (R = CH_2OMe) and thence **5**. As suggested by this, the 5′-methylpyrromethene **8** (!) and **7** gave **5** exclusively. This reaction was slow in chloroform, and the tripyrrene was hard to separate from unreacted **7**. In dioxane, still at 20°C, the reaction was fast and pure **5** (≤30%) easily obtained. The methyl ester corresponding to **8** and the tripyrrane **6** gave the tetrapyrrene **10** (20%) analogously.

Thin layer chromatography of the products from **7** and **8** showed a pyrrole spot (cold Ehrlich's reaction: red) running as both **9** and its methyl ester. In the more complex and now devalued reaction between **7** and **3** the lost

[1]Issued as NRCC No. 16087.

[2]When it is not indicated that identification was by tlc or ^{1}Hmr, all compounds gave satisfactory analyses, etc.

[3]Such reactions were followed by tlc on alumina (MN, Brinkmann cat. 66130207) with $CHCl_3$–MeOH, ca. 95:5. Concentrated solutions of the products in $CHCl_3$ were filtered through alumina (Woelm, grade 1), washing with reagent $CHCl_3$, eluting with ca. 97:3 $CHCl_3$–MeOH. The dried residue usually crystallized when stirred with methanol.



pyrrole was not accounted for. However, the ^{1}Hmr spectra of tripyrrenes from methoxymethyl-pyrromethene methyl esters and pyrromethane ethyl esters showed that it was the methoxymethyl-pyrrole ring in the former which was lost.

If isoporphobilinogen derivatives behave like those of porphobilinogen, the above reactions may represent general routes to the tripyrranes (from pyrroles or pyrromethanes via tripyrrenes) and the tetrapyrranes (from tripyrranes via tetrapyrrenes). Other routes to the relevant polypyrranes have all required acid-catalyzed condensations (4–7), and usually an element of symmetry (4) or the removal of carbobenzoxy groups (5, 6).

These reactions of **8** are typical pyrrole redistribution reactions. Although long indispensable in the rationalization of mishaps, such reactions have been useless in rational synthesis with one possible exception: the use of formylpyrroles as substitutes for formic acid (8).

N-Nitromethylphthalimide. A formyl anion equivalent[1]

FRANK G. COWHERD,[2] MARIE-CARMEN DORIA, EDVIGE GALEAZZI, AND JOSEPH M. MUCHOWSKI[3]

Research Laboratories, Syntex, S. A., Apartado Postal 10-820, Mexico 10, D.F.

Received July 27, 1976[4]

FRANK G. COWHERD, MARIE-CARMEN DORIA, EDVIGE GALEAZZI, and JOSEPH M. MUCHOWSKI. Can. J. Chem. **55**, 2919 (1977).

It is shown that the exclusive 1,4-addition of *N*-nitromethylphthalimide **4***a* to unhindered α,β-unsaturated ketones and esters can be effected by non-nucleophilic bases, such as sodium hydride or potassium fluoride, in dimethyl sulfoxide. The phthalimido moiety can be removed from the adducts with hydroxylamine or 1,2-dianilinoethane to give the oximes or diphenylimidazolidines of 1,4-ketoaldehydes. The ethylene ketal **5** of 3-formylcyclohexanone could easily be recovered from the imidazolidine **10**, but it was not possible to transform **11** into 3-formylcyclohexanone under similar conditions. It is further shown that reactions, such as the Knoevenagel condensation, or the Paal–Knorr synthesis of pyrroles, can be achieved directly on the adducts without the need for isolating the unstable 4-formyl carbonyl compounds. *N*-Nitromethylphthalimide thus serves as a new formyl anion equivalent.

FRANK G. COWHERD, MARIE-CARMEN DORIA, EDVIGE GALEAZZI et JOSEPH M. MUCHOWSKI. Can. J. Chem. **55**, 2919 (1977).

On démontre que l'addition-1,4 exclusive de la *N*-nitrométhylphtalimide **4***a* aux cétones et aux esters α,β-non-saturés non-empêchés peut être effectué par des bases non-nucléophiles telles que l'hydrure de sodium ou le fluorure de potassium dans le diméthylsylfoxyde. La portion phtalimido peut être enlevée des adduits avec l'hydroxylamine ou le dianilino-1,2 éthane pour conduire aux oximes ou aux diphénylimidazolidines de cétoaldéhydes-1,4. On peut récupérer facilement l'éthylène cétal **5** de la formyl-3 cyclohexanone à partir de l'imidazolidine **10** mais il n'est pas possible de transformer **11** en formyl-3 cyclohexanone dans de telles conditions. On montre de plus que des réactions, telles que la condensation de Knoevenagel ou la synthèse de Paal–Knorr des pyrroles, peuvent être réalisées sur les adduits sans qu'il soit nécessaire d'isoler les composés formyl-4 carbonylés instables. La *N*-nitrométhylphtalimide sert donc de nouvel équivalent de l'anion formyle.

[Traduit par le journal]

1,4-Diketones are compounds of immense synthetic importance and numerous useful procedures have been devised for the preparation of such substances (1–4, and refs. therein). A considerable number of 4-keto aldehyde syntheses (2, 3, 5–11, and refs. therein) have also been reported, but many of these are inconvenient and new practical syntheses of these useful intermediates are required. A conceptually very attractive route to the latter class of compounds is based on the conjugate addition of a formyl anion (4), or an equivalent thereof (2, 8–10), to an α,β-unsaturated carbonyl moiety. Nitromethane (9) and hydrogen cyanide (10), which historically are two of the oldest known formyl

[1]Contribution No. 473 from the Syntex Institute of Organic Chemistry.

[2]Syntex post-doctoral fellow, 1972–1973.

[3]Author to whom enquiries should be addressed.

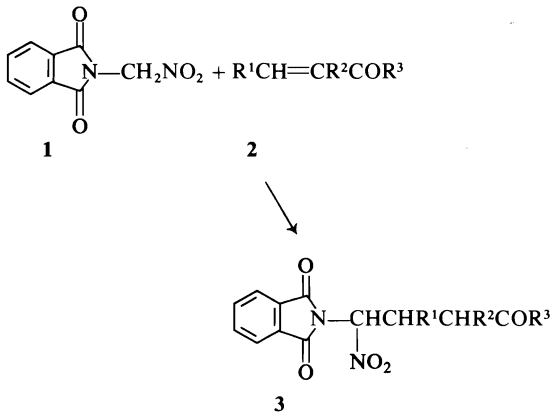
[4]Revision received April 25, 1977.

anion equivalents, still remain the most versatile members of this group of reagents to be used for the synthesis of 4-keto aldehydes. An important characteristic of both of these reagents is that 1,4-addition to an α,β-unsaturated carbonyl system generally occurs in preference to 1,2-addition, even when the latter might be expected to be competitive (e.g., for nitromethane see ref. 12). To be useful, any new formyl anion equivalent should retain this desirable property, and in addition, the latent formyl group should be easily unmasked after the desired reaction has been effected. It was with these points in mind that a study of *N*-nitromethylphthalimide **1** as a formyl anion equivalent was undertaken.[5]

N-Nitromethylphthalimide has previously been prepared in 27% yield from the corresponding *N*-bromomethyl compound and silver nitrite in acetonitrile solution (13). The yield of this product was more than doubled when the reaction was effected with sodium nitrite in acetone solution (this work).

A convenient source of the nitro compound was thus at hand, and consequently a study was undertaken to determine the optimum conditions for the Michael addition of this substance (1 equiv.) to activated olefins (1 equiv.) such as cyclohexenone and methyl vinyl ketone. For these acceptors it was found that the 1,4-addition of **1** occurred most readily in dipolar aprotic solvents (preferably dimethyl sulfoxide) in the presence of weakly nucleophilic bases (1 equiv.) such as sodium hydride or potassium fluoride. These conditions (see Experimental section) were then applied to the preparative scale (5–100 mmol) reaction of **1** with various activated olefins **2**.

The data presented in Table 1 show that the addition of **1** to α,β-unsaturated ketones and esters occurred in satisfactory yields in those cases where the acceptor was unhindered. These yields are particularly notable in view of the fact that a 1:1 olefin–nitro compound ratio was utilized in all of the experiments. Non-cyclic β-substituted acceptors (e.g., benzalacetone and methyl crotonate) reacted rapidly with the anion of **1** to give an equilibrium mixture of the product and the reactants which was strongly in favour of the latter. The expected Michael adducts were isolable in low yields from the reaction mixtures, More highly substituted acceptors such as mesityl oxide, 1-acetylcyclohexene, neosterol, and neosterol acetate did not react at all with **1**, undoubtedly for steric reasons.



Whereas α,β-unsaturated ketones gave the best adduct yields when the anion of **1** was generated with sodium hydride, α,β-unsaturated esters and acrylonitrile, under the same conditions, gave complex mixtures which did not contain the desired products. The expected adducts were formed with α,β-unsaturated esters when the reaction was initiated with potassium fluoride, but no characterizable products were isolable when acrylonitrile was the acceptor, even though **1** was rapidly consumed. The addition of **1** to acrylonitrile was not examined further.

The adducts derived from the cyclic enones and the other β-substituted acceptors were obtained as mixtures of *threo* and *erythro* isomers. This was evident both from the broad melting points and the nmr spectra (see Table 3) of the crude products. For example, the nmr spectrum of the crude adduct from cyclohexenone showed a pair of doublets, of approximately equal intensity, centered at δ 6.24 and 6.25 (J = 10.6 and 8.4 Hz, respectively) for the proton α to the nitro group. In some cases (adducts from benzalacetone and methyl crotonate) one of the isomers could be obtained pure by fractional crystallization, and in one instance (ethylene ketal of adduct from cyclohexenone), both isomers were isolated in pure form by this technique. The resolution of these mixtures is, of course, unimportant because the centre of asymmetry which was created during the formation of the adducts is destined for destruction when the formyl group is unmasked.

[5]Presented in part at the 57th Canadian Chemical Conference of the Chemical Institute of Canada, Regina, Saskatchewan, June 1974.

Phthalimido protecting groups can be removed under basic or acidic conditions (14), but since the latter are generally very vigorous the use thereof was not considered feasible for the deprotection of the compounds described herein. In order to avoid the problems potentially associated with the use of basic reagents such as methylamine (pyrrole formation) or alkaline carbonates (internal aldolization), the enone adducts were converted into the corresponding ethylene ketals (Table 2) for the initial deprotection studies. The ketalized adduct **4***a* reacted rapidly with aqueous methanolic potassium carbonate at room temperature, boiling aqueous methanolic potassium bicarbonate, or aqueous methylamine (15) at room temperature, but in no case was the desired aldehyde **5** isolated after work-up, presumably because of the instability (e.g., aldolization) of this substance under the basic conditions of these reactions. Compound **4***a* was therefore subjected to the action of alkaline sodium borohydride with the expectation that the liberated aldehyde would be reduced before self condensation could occur. A mixture of products was then obtained, but the alcohol **6** was not present therein. The spectral properties and the elemental analysis of the major component of the mixture were fully consistent with the carbinolamide **7***a*. The yield of this compound was considerably improved when the reduction was effected in the absence of external alkali. This substance was considered to have been formed by the reduction of the very reactive acyl imine **9**, the intermediate occurrence of which is readily explicable by the loss of the elements of nitrous acid from the primary reduction product **8***a*. The above observations suggested that the removal of the phthalimido group might be achieved by the inclusion of a weakly basic,

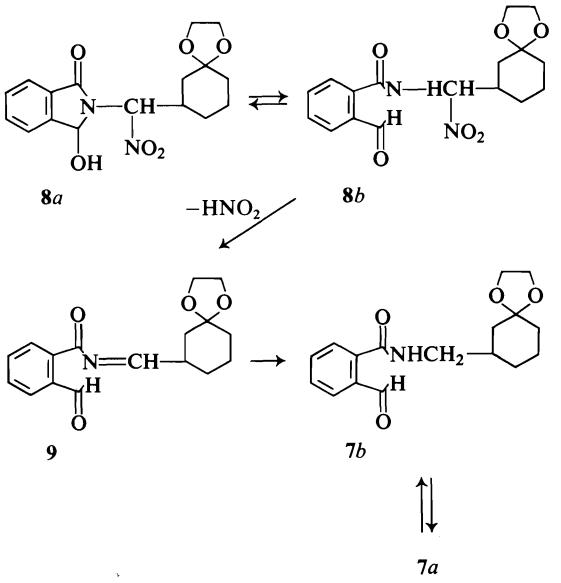
[d]Isomer with mp 151–152°C.

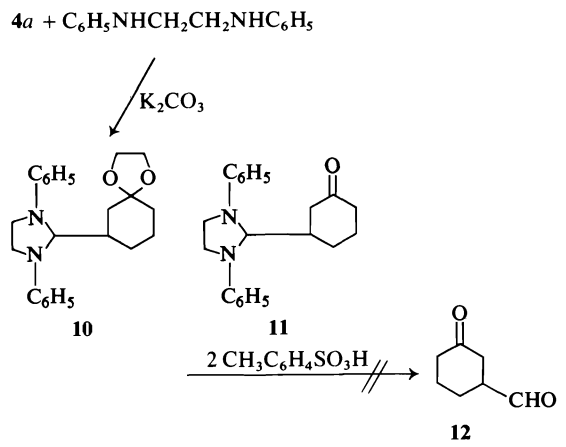
nucleophilic, aldehyde trapping agent, such as the Wanzlick base (16; dianilinoethane), in the hydrolytic medium. This supposition was confirmed by the rapid formation of the imidazolidine derivative **10** when an aqueous methanolic solution of **4*a*** (1 mol), dianilinoethane (1.5 mol), and potassium carbonate (1.1 mol) was stirred at room temperature. The application of these conditions to the other adducts gave the corresponding imidazolidine derivatives (Table 4) in acceptable yields. Even sodium bicarbonate (at reflux temperature) could be used for the transformation, but dianilinoethane alone did not effect the cleavage of the phthalimido compounds.

The aldehyde **5** was easily recovered in good yield by treatment of **10** with 2 equiv. of *p*-toluenesulfonic acid monohydrate in dichloromethane–acetone (1:1) solution at 10°C. Decomposition of the imidazolidine **11** under the same conditions did not give a trace of the 4-ketoaldehyde **12**, even though the bis-toluenesulfonic acid salt of dianilinoethane was formed in high yield. The results were similar when the decomposition of **11** was effected at −30°C. The failure to isolate **12** under such mild conditions prob-



ably is a reflection of the known[6] instability of this type of 1,4-dicarbonyl compound.

Hydroxylamine could also be used to remove the phthalimido moiety from the adducts. For



example, the oximes **13***a* and **13***b* were readily formed from **4***a* and **4***b*, and a method was devised whereby these oximes were transformed into the stable primary alcohols **14***a* and **14***b* without isolation of the intermediate aldehydes. This was accomplished by the addition of the oxime bisulfite adducts (17) to aqueous sodium carbonate containing sodium borohydride, the aldehydes thus being reduced immediately upon liberation from the bisulfite addition products.

[6]Professor B. Fraser-Reid (personal communication), University of Waterloo, also has observed that 1,4-keto-aldehydes are exceedingly unstable substances.

The alcohols (43–66% overall from the oximes) were characterized as the crystalline 4-nitrophenylazobenzoates **15** (18).

The intermediacy of the acyl imines implied

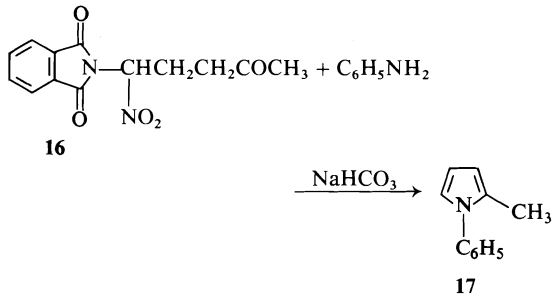
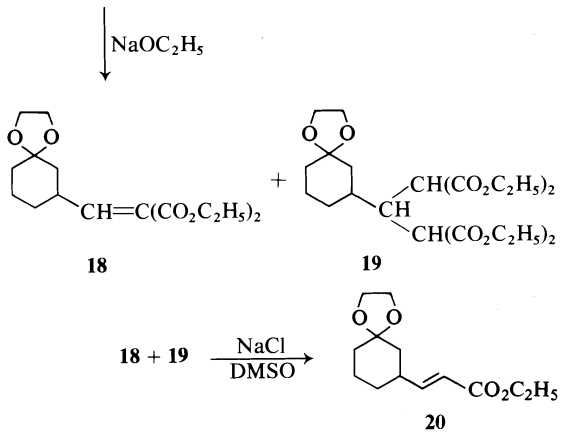
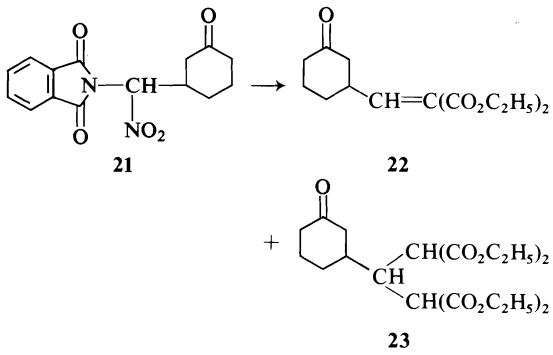
that for some reactions the isolation of the aldehyde would be unnecessary. This was confirmed by the direct formation of 1-phenyl-2-methylpyrrole **17** from the adduct **16** and aniline in the presence of sodium bicarbonate. Furthermore, it



was possible to effect a Knoevenagel type condensation (19) of diethyl malonate with ***4a*** in the presence of sodium ethoxide. A mixture, which consisted of the expected unsaturated ester **18** and the Michael adduct **19** thereof with diethyl malonate, was obtained. The structures of the components of this mixture were assured by transformation into a single unsaturated ester **20** with sodium chloride in hot dimethyl sulfoxide (20). A Knoevenagel condensation of **21** with diethyl malonate gave a mixture of **22** and **23** analogous to that described above.



In summary, it has been shown that *N*-nitromethylphthalimide can be used as a formyl anion equivalent, but that the utility thereof is severely limited by the fact that 1,4-addition is successful only to those activated olefins which are unhindered. Nevertheless, the information described herein can be used as a basis upon



which the design of new formyl anion equivalents, devoid of the above limitation, can be commenced.

Experimental

The melting points were determined in a Mel-Temp melting point apparatus and are corrected. The ir spectra were measured with a Perkin-Elmer model 237 grating infrared spectrophotometer. The uv spectra were recorded with a Perkin-Elmer 402 uv spectrophotometer as solutions in methanol. The nmr spectra were measured with a Varian T-60 spectrometer. The mass spectrum was measured with an Atlas CH-4 spectrometer.

All of the activated olefins except *n*-hexyl vinyl ketone were purchased from commercial sources. The above mentioned unsaturated ketone was prepared from *n*-heptanoic acid and vinyl lithium (21) and was used without purification.

N-Nitromethylphthalimide ***2***

Sodium nitrite (12.5 g, 0.181 mol) was added at 0°C with stirring to a solution of *N*-bromomethylphthalimide (22) (25.0 g, 0.104 mol) in acetone (250 ml). After 0.5 h at this temperature, the reaction was left at room temperature for 1.5 h and then it was poured into water (500 ml). The product was extracted with ether (5 × 100 ml) and the extract was evaporated *in vacuo*. Benzene was added to the residue and the resultant was evaporated *in vacuo* (to remove water). The residue was purified by column chromatography on silica gel using 2.5% ether in benzene as the eluant. The product thus obtained (12.5 g, 58%) had mp 108–110°C (lit. (13) mp 110.5–111°C) after crystallization from benzene–hexane; λ_{max} 218, 237, 293.5 nm (ε 45 700, 9560, 2900); ν_{max} ($CHCl_3$) 1790, 1740, 1580, 1370 cm^{-1}; δ ($CDCl_3$) 6.10 (s, 2H), 8.07 (s, 4H). *Anal.* calcd. for $C_9H_6N_2O_4$: C 52.43, H 2.93, N 13.59; found: C 52.29, H 2.98, N 13.61.

Reaction of N-Nitromethylphthalimide with Activated Olefins

(a) Sodium Hydride as the Base

To a stirred mixture of sodium hydride (10 mmol; from a 50% suspension in mineral oil which had been washed with dry hexane) and anhydrous dimethyl sulfoxide (50 ml), maintained in an atmosphere of dry nitrogen, was added *N*-nitromethylphthalimide (9.7 mmol). After 1 h at room temperature gas evolution had ceased and the solution was cooled to 18°C. The α,β-unsaturated ketone (9.8 mmol) was added in one portion (exotherm

in some cases) and the solution was then left at room temperature until the reaction no longer advanced or the starting nitro compound was absent (see Table 1), as judged by thin layer chromatography (tlc) on silica gel. The solution was poured into a large excess of 10% hydrochloric acid and the product was extracted into ethyl acetate. The extract was washed with water until neutrality was achieved, it was dried over sodium sulfate, and then evaporated *in vacuo*. The adducts derived from cyclohexenone, cyclopentenone, and methyl vinyl ketone were purified by column chromatography on Fluorisil using benzene–ether (5:1) as the eluant. The adducts from benzal acetone and *n*-heptyl vinyl ketone were obtained pure by tlc on silica gel using hexane–ether (1:1) as the developing solvent. The yields and physical constants of these compounds are recorded in Tables 1 and 3.

(b) Potassium Fluoride as the Base

To a stirred solution of potassium fluoride (5.5 mmol, dried *in vacuo* at 60°C for 24 h) in dry dimethyl sulfoxide (30 ml), maintained in an atmosphere of nitrogen, was added the nitro compound (5.0 mmol) and then the α,β-unsaturated ester (5.5 mmol). The reactions were followed and worked-up as described for sodium hydride as the base. The methyl acrylate adduct was purified by column chromatography on Fluorisil using benzene as the eluant. The product from methyl crotonate was obtained pure by tlc on silica gel using benzene–ether (80:20) as the developing solvent. The yields and physical constants of the adducts are recorded in Tables 1 and 3.

Preparation of the Ketals

The adduct (5 g), ethylene glycol (10 ml), and *p*-toluenesulfonic acid (0.125 g) were heated in benzene solution at reflux temperature for 1–3 h. The water evolved was collected in a Dean–Stark apparatus. The solution was left to cool, pyridine (2.0 ml) was added, and the solution was washed successively with water, 10% hydrochloric acid solution, and water. The solution was dried over sodium sulfate and the solvent was removed *in vacuo*. The residue was crystallized from a suitable solvent. The ketal of the adduct from cyclohexenone **4***a* was separated into two isomers by crystallization first from ether. The substance which separated from solution was recrystallized from the same solvent to give an isomer with mp 151–152°C. The mother liquors from these crystallizations were evaporated *in vacuo* and the residue was crystallized from hexane to give the isomer with mp 127–128.5°C. The physical constants of these compounds are recorded in Tables 2 and 3.

*Reduction of **4***a* with Sodium Borohydride*

To a stirred solution of the ketal **4***a* (1.038 g, 3.0 mmol) in dry tetrahydrofuran (60 ml) was added sodium borohydride (0.150 g, 4 mmol). After 6 h at room temperature the mixture was poured into water and the products were extracted into ethyl acetate. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue (0.910 g) was separated by tlc (hexane – ethyl acetate; 1:1) into a less and a more polar fraction. The more polar fraction (**7***a*, 0.370 g) was crystallized from ether to give a solid mp 142–145°C. This material had λ_{max} 220, 228, 250 nm (ε 9120, 6620, 4370); ν_{max} 3585, 3340, 1690, 1622 cm^{-1}; δ ($CDCl_3$) 0.5–2.40 (m, 8H; H-2,4,5,6 of cyclohexane), 2.87–3.33 (m, 3H; H-3 of cyclohexane and N-CH_2), 3.80 (m, 4H; OCH_2CH_2O), 4.42 (d, 1H, J = 11.3 Hz, OH, exchanged with D_2O), 5.72 (d, 1H, J = 11.3 Hz, *CH*-OH, singlet with D_2O), 7.50 (m, 4H; aromatic H's). *Anal.* calcd. for $C_{17}H_{21}NO_4$: C 67.31, H 6.98, N 4.62; found: C 67.39, H 7.05, N 4.73.

Synthesis of the Diphenylimidazolidine Derivatives

(a) Potassium Carbonate as the Base

A solution of the nitro compound (1 mmol), dianilinoethane (1.5 mmol), and potassium carbonate (1.1 mmol) in methanol (25 ml) and water (5 ml) was stirred at room temperature for the time specified in Table 4. The imidazolidine derivative which had separated from solution was collected by filtration, washed with water, dried, and then crystallized from a suitable solvent. The yields and physical constants of these compounds are given in Table 4.

(b) Sodium Bicarbonate as the Base

A solution of the nitro compound (1 mmol), dianilinoethane (1.5 mmol), and sodium bicarbonate (1.1 mmol) in methanol (25 ml) and water (5 ml) was boiled under reflux for 45 min. The solution was cooled and the crystalline product was separated by filtration.

*Synthesis of the Aldehyde **5** by Decomposition of the Imidazolidine **10***[7]

To a solution of the imidazolidine **10** (1.00 g, 2.5 mmol) in 1:1 dichloromethane–acetone (100 ml), cooled to 10°C, was added *p*-toluenesulfonic acid monohydrate (1.06 g, 5.6 mmol). After 7 min the precipitated solid was removed by filtration, it was washed with dichloromethane (20 ml), and the combined filtrates were evaporated *in vacuo*. Ether was added to the residue, the resultant was washed with dilute sodium bicarbonate solution and then with water. The organic phase was dried over sodium sulfate, and evaporated *in vacuo*. The residual oil was purified by tlc on silica gel using ether–hexane (70:30) as the developing solvent. The oily aldehyde (0.32 g, 69%) was distilled *in vacuo* at 86–88°C/0.05 Torr; ν_{max} ($CHCl_3$) 2720, 1715 cm^{-1}; δ ($CDCl_3$) 1.20–2.12 (m, 8H; H-2,4,5,6), 2.48 (m, 1H; H-3), 3.80 (s, 4H; OCH_2CH_2O), 9.54 (s, 1H; CHO); ms (relative intensity) 170(1), 142(7), 141(33), 113(7), 99(29), 86(7), 73(100), 55(11), 45(19), 41(15). Even though this substance appeared to be pure by tlc and nmr a satisfactory microanalysis could not be obtained. *Anal.* calcd. for $C_9H_{14}O_3$: C 63.50, H 8.28; found: C 62.73, H 8.10. The identity of this substance nevertheless was assured by sodium borohydride reduction to the alcohol **14***a* (88%) which was converted into the crystalline 4-(4-nitro)phenylazo benzoate **15***a* (80%) described below.

*Conversion of **4***a* and **4***b* into the Alcohols **14***a* and **14***b*

*(a) Synthesis of the Oximes **13***a* and **13***b*

A solution of **4***a* (1.384 g, 4 mmol) in methanol (75 ml) and water (15 ml) containing hydroxylamine hydrochloride (0.562 g, 8.1 mmol) and potassium carbonate (1.133 g, 8.2 mmol) was boiled under reflux for 2 h. The solution was concentrated to a small volume *in vacuo*, ethyl acetate was added, and the resultant was washed with water. The organic phase was dried over sodium sulfate and evaporated *in vacuo*. The residue was purified by tlc on silica gel using benzene–ether (75:25) as the developing solvent. The oxime was obtained as an oily mixture of *syn* and *anti*

[7]We thank Dr. G. Jones for providing us with these experimental details.

isomers **13***a* in 70–100% yield; ν_{max} ($CHCl_3$) 3605, 3350, 1660 cm^{-1}; δ ($CDCl_3$) 1.12–2.00 (m, 8H; H-2,4,5,6), 2.50 (m, 1H; H-3), 3.90 (s, 4H; OCH_2CH_2O), 6.52, 7.31 (d's, total 1H, J = 6.8 and 5.4 Hz, respectively; CH=N), 8.31 (m, 1H, W_H = 24 Hz; N-OH). *Anal.* calcd. for $C_9H_{15}NO_3$: C 58.36, H 8.16, N 7.56; found: C 58.24, H 8.20, N 7.37.

Compound **4***b* was transformed into the oxime mixture **13***b* in 57% yield in the manner described for **4***a*. This material was used directly in the next step.

*(b) Synthesis of the Alcohols **14***a and **14***b*

A solution of the oxime (1.3 mmol) and sodium bisulfite (1.8 mmol) in 50% aqueous ethanol (20 ml) was boiled under reflux for 2 h. The solvent was evaporated *in vacuo* and the residue was dissolved in methanol (10 ml). This methanol solution was added slowly to a stirred solution of sodium borohydride (3 mmol) and sodium carbonate (1.2 mmol) in water (2 ml). After 1.5 h at room temperature, the solution was poured into a saturated sodium chloride solution and the product was extracted into ethyl acetate. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*.

The alcohol **14***a* was obtained in 43–65% yield; ν_{max} ($CHCl_3$) 3640, 3490 cm^{-1}; δ ($CDCl_3$) 0.68–2.00 (m, 10H, H-2,3,4,5,6, OH), 3.46 (d, 2H, J = 5.4 Hz; CH_2-OH), 3.89 (s, 4H; OCH_2CH_2O). This alcohol was converted into the crystalline 4-(4-nitro)phenylazo benzoate **15***a* for analysis in the manner described below.

The alcohol **14***b* was prepared in 57% yield; ν_{max} ($CHCl_3$) 3635, 3480 cm^{-1}; δ ($CDCl_3$) 1.08–2.92 (m, 7H; H-2,3,4,5), 2.17 (s, 1H; OH, exchanged with D_2O), 3.52 (d, 2H, J = 5.6 Hz; CH_2OH), 3.87 (s, 4H; OCH_2CH_2O). This alcohol was converted into the 4-(4-nitro)phenylazo benzoate **15***b* for analysis.

*(c) Synthesis of the 4-(4-Nitro)phenylazo Benzoates **15***a and **15***b*

To a stirred solution of the alcohol (1.0 mmol) in dry benzene (50 ml) containing pyridine (2.0 mmol) was added 4-(4-nitro)phenylazo benzoyl chloride (1.0 mmol). After 1.5 h at room temperature the solvent was removed *in vacuo*, the residue was taken up in benzene and passed through a short column of alumina (Fluka, neutral, Activity I). Evaporation of the solvent gave a red solid which was crystallized from a suitable solvent.

The ester **15***a* had mp 129–131°C after crystallization from hexane; λ_{max} 329.5 nm (ε 30 200); ν_{max} 1719, 1610, 1527, 1346 cm^{-1}; δ ($CDCl_3$) 0.75–2.52 (m, 9H; H-2,3,4,5,6), 3.93 (s, 4H; OCH_2CH_2O), 4.22 (d, 2H, J = 5.6 Hz; CH_2), 7.48–8.40 (m, 8H; aromatic H's). *Anal.* calcd. for $C_{22}H_{23}N_3O_6$: C 62.10, H 5.44, N 9.87; found: C 62.28, H 5.41, N 9.86.

The ester **15***b* had mp 130–133°C after crystallization from hexane; λ_{max} 329 nm (ε 30 200); ν_{max} ($CHCl_3$) 1720, 1610, 1528, 1346 cm^{-1}; δ ($CDCl_3$) 1.48–2.78 (m, 7H; H-2,3,4,5), 3.89 (s, 4H; OCH_2CH_2O), 4.27 (d, 2H, J = 6.4 Hz; CH_2), 7.84–8.40 (m, 8H; aromatic H's). *Anal.* calcd. for $C_{21}H_{21}N_3O_6$: C 61.30, H 5.14, N 10.21; found: C 60.99, H 5.26, N 10.67.

*1-Phenyl-2-methylpyrrole **17***

A solution of the adduct from methyl vinyl ketone **16** (4.45 g, 16.0 mmol) in methanol (400 ml) and water (80 ml) containing aniline (2.22 ml, 24.0 mmol) and sodium bicarbonate (1.47 g, 17.0 mmol) was boiled under reflux in an atmosphere of nitrogen for 30 min. The solution was concentrated to a small volume *in vacuo* and the residue was diluted with 10% hydrochloric acid. The product was extracted into ethyl acetate and the extract was washed with water and dried over sodium sulfate. The solvent was removed *in vacuo* and benzene was added to the residue. The mixture was filtered to remove phthalimide, silica gel was added to the residue, and the mixture was evaporated to dryness *in vacuo*. This solid was placed on top of a column of silica gel (250 g) and the column was developed with hexane (500 ml) and hexane–benzene (95:5, 750 ml). The product (0.500 g, 19.8%) was found in the hexane–benzene eluate; λ_{max} 241 nm (ε 9330); δ ($CDCl_3$) 2.17 (s, 3H; CH_3), 5.97 (m, 1H; H-3), 6.08 (t, 1H, ΣJ = 3.5 Hz; H-4), 6.64 (m, 1H; H-4), 7.24 (m, 5H; phenyl H's). This compound had previously been prepared by Yurev and Minkina (23).

*Reaction of **4***a with Diethyl Malonate*

To a stirred solution of sodium ethoxide (prepared from 50% sodium hydride in mineral oil (0.610 g, 12.7 mmol)) in absolute ethanol (50 ml) was added diethyl malonate (2.02 g, 12.7 mmol) and then the adduct **4***a* (2.2 g, 6.35 mmol). After 3 h at room temperature the solvent was removed *in vacuo*, water was added to the residue, and the mixture was extracted with ethyl acetate. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. Benzene was added to the residue, the phthalimide was filtered off, and the solvent was evaporated *in vacuo*. The residual oil was chromatographed on a column of Fluorisil (200 g). The column was first eluted with benzene (200 ml) and then the product was removed with benzene–ether (1:1). The product (1.90 g) was then evaporatively distilled at 100°C/0.02 Torr. This oil was a 1:3 mixture of **18** and **19**. The separation of these esters was achieved by tlc on silica gel using hexane – ethyl acetate (85:15) as the developing solvent. In this way, samples of **18** and **19** of about 90% purity were obtained.

Compound **18** had the following spectral characteristics: λ_{max} 214 nm (ε 7220); ν_{max} ($CHCl_3$) 1733 cm^{-1}; δ ($CDCl_3$) 1.27 (m, 6H; ester CH_3's), 1.65 (m, 8H; ring CH_2's), 3.55 (m, 1H; allylic CH), 3.89 (s, 4H; OCH_2CH_2O), 4.22 (m, 4H; ester CH_2's), 6.68 (d, 1H, J = 10 Hz; olefinic CH). This material was not characterized further.

Compound **19** had the following spectral properties: ν_{max} ($CHCl_3$) 1757, 1734 cm^{-1}; δ ($CDCl_3$) 1.25 (m, 12H; ester CH_3's), 1.77 (m, 8H; ring CH_2's), 3.02 (m, 2H; —CH—CH—), 3.73 (m, 2H; CH-α-to ester), 3.85 (s, 4H; OCH_2CH_2-O), 4.14 (m, 8H; ester CH_2's). This ester was not characterized further.

*Preparation of the Unsaturated Ester **20***

A solution of the mixture of **18** and **19** (0.47 g) in dimethyl sulfoxide (10 ml) containing sodium chloride (0.064 g) and water (0.036 g) was heated at 150–170°C for 5 h. The solution was poured into water and the product was extracted into ethyl acetate. The extract was washed with saturated sodium chloride solution, dried over sodium sulfate, and evaporated *in vacuo*. The residue (0.280 g) was purified by tlc on silica gel using hexane – ethyl acetate (75:25) as the developing solvent. The oil (0.080 g) thus obtained was evaporatively distilled at

85°C/0.02 Torr to give an oil with λ_{max} 214 nm (ε 12 300); ν_{max} ($CHCl_3$) 1711, 1652, 972 cm^{-1}; δ ($CDCl_3$) 1.28 (t, 3H, J = 7.2 Hz; CH_3), 1.68 (m, 8H; ring CH_2's), 2.43 (m, 1H allylic CH), 3.92 (s, 4H; OCH_2CH_2O), 4.15 (q, 2H, J = 7.2 Hz; ester CH_2's), 5.72 (q, 1H, J = 1.3; O ‖ 16.0 Hz; =CH—C—), 6.84 (q, 1H, J = 16.0, 6.6 Hz; —CH—*CH*=). *Anal.* calcd. for $C_{13}H_{20}O_4$: C 64.98, H 8.39; found: C 65.11, H 8.49.

*Reaction of **4c** with Diethyl Malonate*

This reaction was carried out in the same manner as described for **4a**. The crude product was separated into its components by tlc on silica gel (benzene–ether; 4:1). The bis adduct **22** was purified (15–22% yield) further by tlc on silica gel (hexane – ethyl acetate; 3:1); ν_{max} ($CHCl_3$) 1731 cm^{-1}; δ ($CDCl_3$) 1.27 (t, 12H, J = 7.4 Hz; CH_3's), 2.12 (m, 9H; ring H's), 3.00 (m, 1H; CH), 3.73 O ‖ (d, 2H, J = 5.8 Hz); CH—C), 4.16 (q, 8H, J = 7.4 Hz; ester CH_2's). *Anal.* calcd. for $C_{21}H_{32}O_2$: C 58.86, H 7.52; found: C 58.85, H 7.69.

A study involving the biodegradation of (+)-usnic acid (**1**) by the microorganism *Mortierella isabellina* is described. Three metabolic products, 6-acetyl-8,9bα-dimethyl-1,9b,2,3-tetrahydro-1α,7,9-trihydroxy-3-oxodibenzofuran (**2**, (+)-1α-hydroxy-2-desacetylusnic acid), (+)-2-desacetylusnic acid (**3**), and (+)-6-acetyl-8,9bα-dimethyl-1,9b-dihydro-2-acetoxy-3,7,9,trihydroxy-1-oxodibenzofuran (**4**, (+)-2-acetoxyusnic acid) are isolated and characterized. By means of radioactively labelled precursors, some information about the biodegradation sequence is derived.

On décrit une étude impliquant la biodégradation de l'acide (+) usnique (**1**) par le microorganisme *Mortierella isabellina*. On a isolé et caractérisé trois produits métaboliques soit l'acétyl-6 diméthyl-8,9bα tétrahydro-1,9b,2,3 trihydroxy-1α,7,9 oxo-3 dibenzofuranne (**2**, l'acide (+) hydroxy-1α désacétyl-2 usnique), l'acide (+) désacétyl-2 usnique (**3**) et le (+) acétyl-6 diméthyl-8,9bα dihydro-1,9b acétoxy-2 trihydroxy-3,7,9 oxo-1 dibenzofuranne (**4**, l'acide (+) acétoxy-2 usnique). Faisant appel à des précurseurs marqués par des radioisotopes actifs, on a obtenu quelques informations sur les chemins de biodégradation.

[Traduit par le journal]

As part of our studies on the microbial degradation of the lichen antibiotic (+)-usnic acid (**1**) (1, 2) the fungal isolate *Mortierella isabellina* (Oudemans and Konig, 1902) (3, 4), a microorganism originally screened by Bandoni and Towers (5), was chosen as a promising candidate for a more comprehensive examination.

Thus a sample of the isolate identified as *Mortierella isabellina* (UBC culture collection #129) was used for the present study. The actual fermentation was carried out over a 10 day period at room temperature in shake culture flasks employing 3–4 day old cultures of the isolate. The representative extraction procedure indicated in Fig. 1 was developed in order to separate the complex product mixture into two main categories: (*i*) Neutral Fraction, and (*ii*) Acid Fraction. Moreover, this procedure allows for the facile recovery of any unreacted starting material by benzene extraction of the filtered solids.

Although the presence of several usnic acid-derived materials has been detected in both the Neutral and Acid Fractions, at the present time only those components which have been fully characterized will be discussed. Furthermore, approximately one-third (by weight) of the total biodegradation mixture resides in the Neutral Fraction, with the remaining two-thirds appearing in the Acid Fraction, as can be seen from Table 1.

In the initial phase of our program, experiments designed to evaluate the sequential production of metabolites according to varying time periods were performed in the hope that the results would allow a differentiation of the several possible biodegradation pathways which

[1]Part VII. See ref. 18.

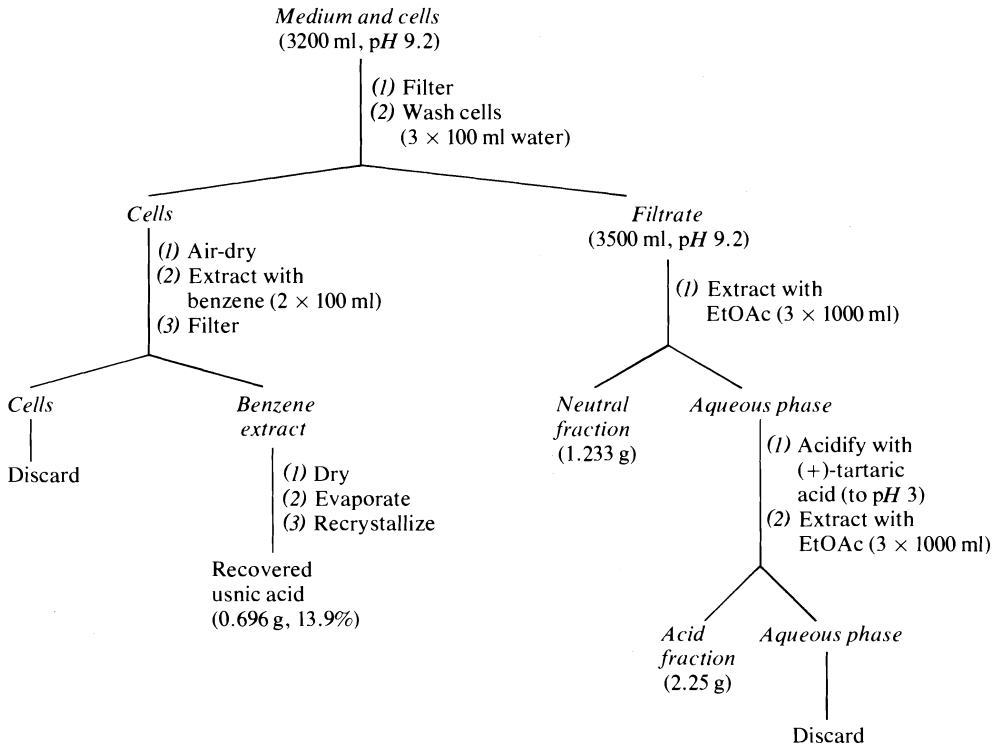

FIG. 1. A representative extraction procedure for the biodegradation of (+)-usnic acid (**1**) by *Mortierella isabellina*.

TABLE 1. Representative product distribution for the biodegradation of (+)-usnic acid (**1**) with *Mortierella isabellina**

Neutral fraction		Acid fraction	
Component	Weight (g)	Component	Weight (g)
FA(N)	0.940	FA(A)	1.250
A(N)	0.075	A(A)	0.060
B(N)	0.124	B(A)	0.700
C(N)	0.010	C(A)	0.150
	Total: 1.149		Total: 2.160

*Starting amount of (+)-usnic acid (**1**) = 5.0 g; FA = fatty acid ester residue; A, B, C = components (according to polarity).

may be involved. Our results indicate (Tables 2 and 3) that after a brief induction period of about 1–2 days, some biodegradation products begin to appear in the fermentation broth, which grows increasingly alkaline until days 9–10 when it reaches its final p*H* value of ~9.20. Whereas (+)-usnic acid (**1**) is being effectively incorporated throughout the time interval considered (20 days) (Fig. 2), the first product observed is the compound coded as B(A) (see Table 1) appearing initially on the second day (Table 3). After 5 days, detectable amounts of A(A) can be isolated from the growth medium (Table 3). It is interesting to note that the composite sequential production of these two materials approximately accounts for the overall behavior of the total Acid Fraction, as seen from Figs. 2 and 3. On the other hand, the Neutral Fraction, consisting mainly of two components, increases more slowly and seems to be at least partially dependent on the behavior of the Acid Fraction, with both reaching a maximum almost simultaneously about the 12–14 day period. Although it was not possible at this stage of the investigation to put forward a biodegradation pathway that would incorporate all the observations at hand, subsequent experiments with radioactively labelled precursors (see later) did shed some light on this aspect.

Purification of the Neutral Fraction afforded besides a fatty acid ester residue (see Table 1), which was not further studied at this time, two main components. The least polar of them, coded as A(N), has not been fully characterized due to its great instability although there appears little question of its derivation from usnic acid. The second component, designated as B(N), was

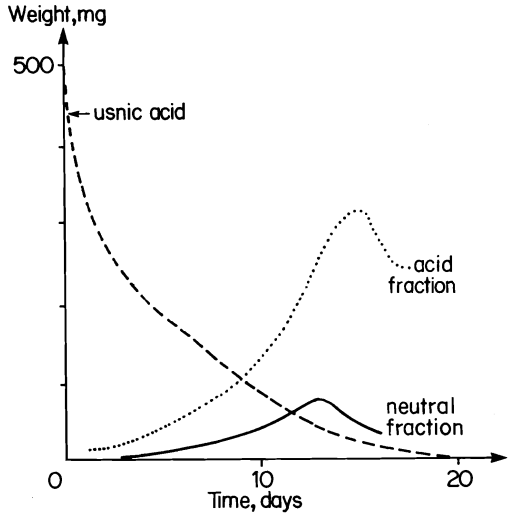

FIG. 2. Sequential study on the biodegradation of (+)-usnic acid (**1**) by *Mortierella isabellina*.

obtained crystalline, mp 236–238°C, $[\alpha]_D^{26}$ +187° (CH_3CN), and had the molecular formula $C_{16}H_{16}O_6$, the latter differing from that of usnic acid ($C_{18}H_{16}O_7$) by 40 mass units. While its ultraviolet spectrum ($\lambda_{max}(CH_3OH)$ 324, 282, 215 nm) suggested the presence of a methylphloroacetophenone system, its infrared spectrum indicated chelated hydroxyl groups (3300–3000 cm^{-1}) and a chelated *o*-hydroxyaryl-methyl ketone group (1625 cm^{-1}), in addition to a new band at 1658 cm^{-1} attributed to an α,β-unsaturated ketone system. At this point it became clear that the normal bands assigned to the ring C β-triketone system (1680 and 1540 cm^{-1}) of the usnic acid series were absent, thus

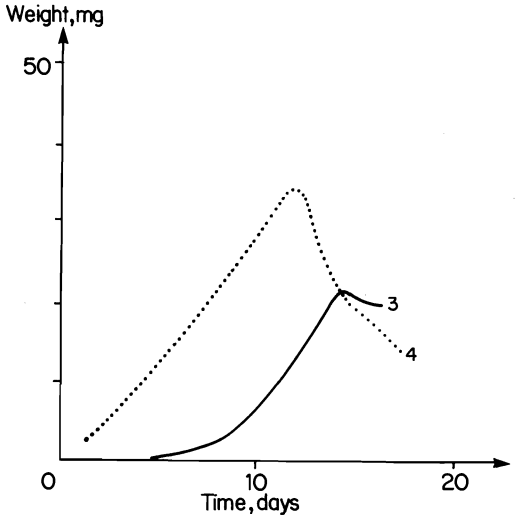

FIG. 3. Product distribution in the acid fraction of the biodegradation of (+)-usnic acid (**1**) by *Mortierella isabellina*.

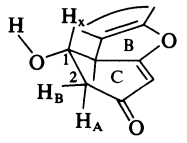
providing the first firm indication that the microbial transformation involves ring C of the usnic acid molecule.

The ^{1}Hmr spectrum of B(N) showed, as expected, the characteristic signals corresponding to the angular and aromatic methyl groups and the aromatic methyl ketone at δ 1.48, 2.04, and 2.66 ppm, respectively, although that corresponding to the angular substituent had experienced a considerable upfield shift. The one-proton singlet at δ 5.75 ppm was in agreement with an olefinic proton at the α-position of an α,β-unsaturated ketone while the low field region of the spectrum indicated the presence of three hydroxyl groups, two of which appeared as a very broad band centered at δ 8.76 ppm and the other being typical of the chelated hydroxyl group at the 7-position (δ 13.32 ppm) in the usnic acid series.

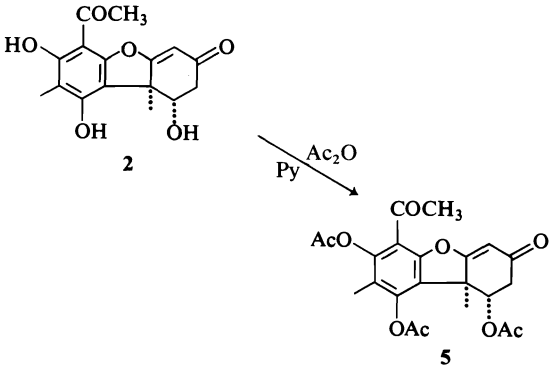
The remaining proton signals in the ^{1}Hmr spectrum of B(N) were observed in the δ 2.50–4.30 ppm region and were clearly due to protons in ring C of an usnic acid derivative. The splitting patterns approximated an ABX system and the coupling constants obtained suggested the stereochemical assignment made to the C_2- and C_1-protons as shown in A. Thus the methylene protons H_A and H_B at C_2 (δ 2.82, J = 16.5 Hz) appear as a multiplet and are coupled to the methine proton at C_1 (δ 4.41, q, J = 16.5 Hz) with the magnitude of the coupling constant being consistent with a pseudoaxial orientation for the latter proton as shown.



A

A previous detailed mass spectrometric investigation of a large number of usnic acid derivatives (6) was invaluable in applying this technique to the structural elucidation of B(N). The nature of the functionality in ring C of this metabolite, as suggested above, was fully substantiated by the fragmentation pattern observed and summarized in Fig. 4. The complete assignment of structure for B(N) or (+)-1α-hydroxy-2-desacetylusnic acid as shown in **2** was now possible.

Confirmation of this structural assignment was obtained when **2** was converted to a triacetate **5**, mp 92–93°C, $[\alpha]_D^{26}$ +152° (CH_3CN). This substance revealed the expected infrared absorptions for both phenolic (1770 cm^{-1}) and saturated acetate (1720 cm^{-1}) groups while in its ^{1}Hmr spectrum new signals at δ 2.23, 2.33, and 2.40 ppm were assigned to the $C_{1\alpha}$-, C_9-, and C_7-acetate groups, respectively. The proton at C_1 in **5** was observed at δ 5.50 ppm (J = 16.5 Hz, q) and as expected had shifted downfield in the conversion to the acetate derivative (δ 4.41 in **2** → δ 5.50 in **5**).



We then turned our attention to the structure elucidation of the metabolites present in the Acid Fraction. The least polar component designated as A(A) was crystalline mp 221–222°C, $[\alpha]_D^{26}$ +630° (CH_3CN), with molecular formula $C_{16}H_{14}O_6$. This compound proved to be identical with (+)-2-desacetylusnic acid (**3**) iso-

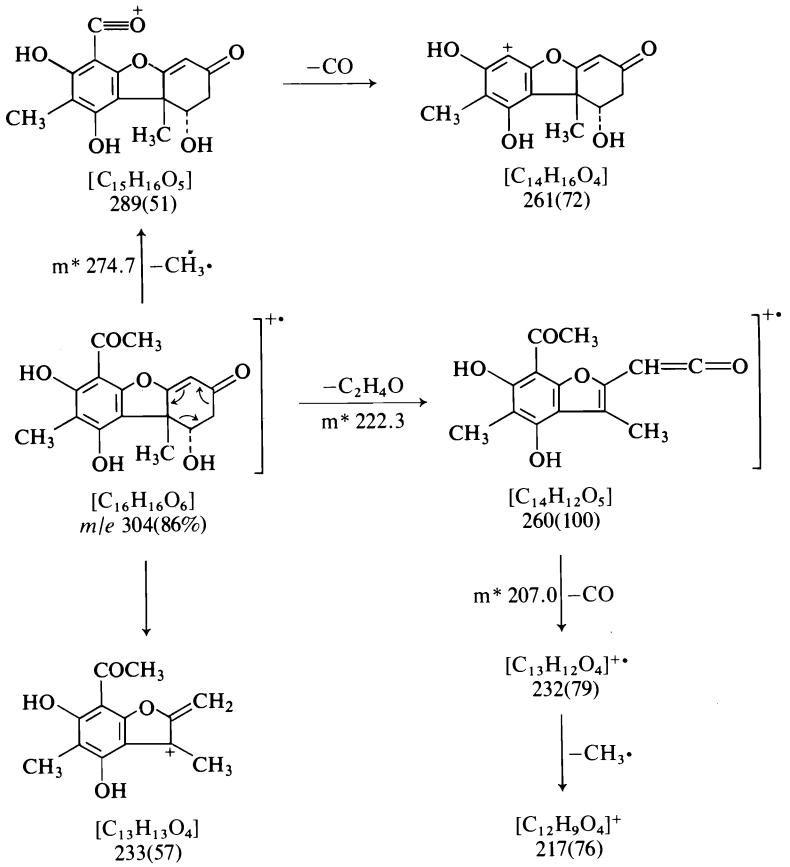


FIG. 4. Postulated fragmentation pattern for (+)-1α-hydroxy-2-desacetylusnic acid (**2**).

lated and characterized in a complementary series of investigations involving fermentations with *Mucor globosus* (7).

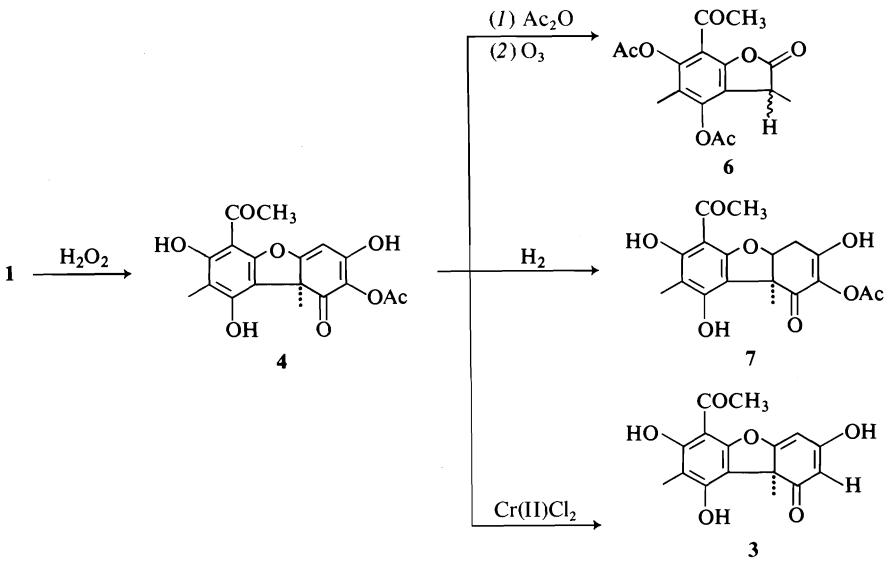
After successive purifications the second component, B(A), was isolated as an unstable bright yellow glassy material with molecular formula $C_{18}H_{16}O_7$, or 16 mass units higher than (+)-usnic acid (**1**). It was shown that the ultraviolet, infrared, and mass spectral data of B(A) were identical with those of synthetic (+)-2-acetoxyusnic acid (**4**), a compound which had already been prepared in our laboratory during studies relating to the synthesis of (+)-2-desacetylusnic acid (**3**) (7).

Further chemistry which substantiated the structural assignment **4** and which would be required for future experiments with radioactively labelled precursors was also developed. Acetylation of **4** and ozonolysis of the acetate provided the known (8, 9) α-coumaranone derivative **6**, thereby revealing that ring A of the usnic acid system had not been modified during the microbial transformation. Hydrogenation of **4** afforded the dihydro derivative **7** while chromous chloride reduction (11) allowed the conversion to the known (+)-2-desacetylusnic acid (**3**), thus providing a facile chemical interrelation between these two metabolites.

The conversion of usnic acid (**1**) to the metabolite **4** can be effectively carried out by reaction of **1** with hydrogen peroxide whereupon **4** is obtained in 83% yield. This latter experiment suggested a possible biological relationship between **1** and **4** (see later).

The above experiments have provided some evidence concerning the microbial degradation of usnic acid (**1**) with *Mortierella isabellina* (Fig. 5) and it was now desirable to substantiate these results and to define more accurately the sequential nature of the biodegradation pathway by the use of radioactively labelled precursors.

The preparation of appropriately labelled



usnic acid and related derivatives, quite unexpectedly, became a difficult chemical problem. The most desired site of label in the usnic acid system was ring A since, as indicated above, the metabolic products retain this portion of the molecule. The most direct synthetic route was the introduction of the aromatic methyl ketone side chain via a Friedel–Crafts reaction or Fries rearrangement employing 6-desacetylusnic acid (**8**) as starting material, as shown in the sequence, **8** → **9**. Although the extensive chemistry of the usnic acid series was recorded in the literature, the earlier workers had not recognized the facile rearrangement of the 'normal' usnic acid series, as shown above, to the 'iso' or isousnic series. In the numerous experiments which followed, it became essential to reinvestigate and clarify the chemistry relating to the synthesis of **8** and the results thus obtained form the subject of a number of recent publications (12–18). Fortunately the desired synthesis of **8** was eventually achieved in an efficient manner *without* the complicating

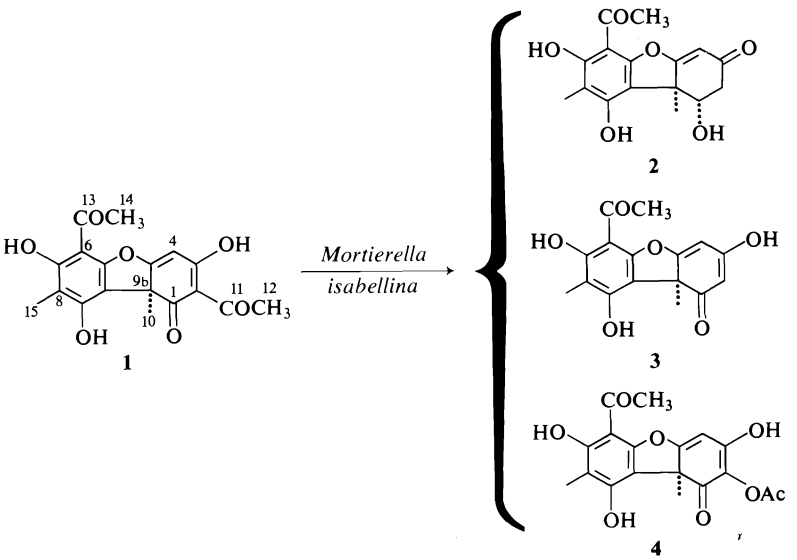


FIG. 5. A summary of metabolic products obtained from the biodegradation of usnic acid (**1**) with *Mortierella isabellina*.

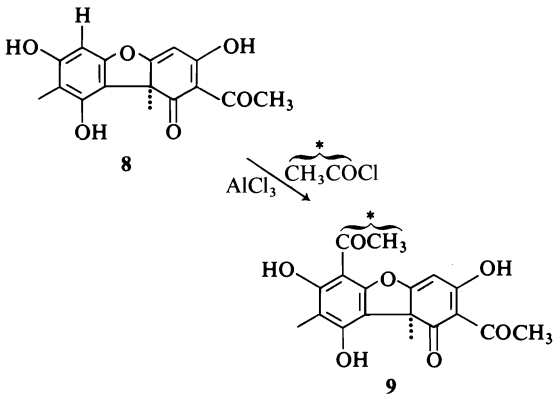
rearrangement to the 'iso' series and the conversion of **8** to (+)-usnic acid (**1**) via the Fries method could be effectively employed (18). Repetition of this latter stage with acetyl chloride-*2*-^{14}C provided the desired usnic acid (**9**) with label in the methyl group of the aromatic ketone side chain (see Experimental). This material was then employed in the fermentation studies with *Mortierella isabellina*.



Various fermentations with [6-$^{14}CH_3CO$]-(+) usnic acid as the precursor were performed and, in each instance, the three metabolites (**2**, **3**, and **4**) were carefully purified and their radioactivity evaluated. These results left no doubt that these compounds were derived from (+)-usnic acid in the biodegradation process. The efficiency of utilization of this precursor by the microorganism varied depending upon the rate of shaking, volume of growth medium, and time period (usually 11–16 days). Under optimum conditions high levels of conversion (generally 70–90%) were obtained (see Experimental).

As mentioned earlier, the chemical conversion of (+)-usnic acid to (+)-2-acetoxyusnic acid (**4**) could be achieved in high yield by an oxidative process (hydrogen peroxide). Such a process could have significance in the biological transformation as well and therefore **4** could be an early stage metabolite serving as a precursor for **2** and/or **3**. For this purpose, radioactively labelled **4** obtained from a synthetic conversion of radioactive **1** and hydrogen peroxide, was added to the fermentation broth in the normal manner. Isolation and separation of the fermentation mixture provided unchanged **4** as a major component (about 60%) and an insignificant amount of the other metabolites.

In order to eliminate the possibility that the fungus requires usnic acid to induce the formation of enzymes responsible for the observed biodegradation, a fermentation experiment with radioactive **4** in the presence of non-radioactive usnic acid was carried out. Again no detectable amounts of the metabolites **2** and **3** were found. On this basis it is assumed that (+)-2-acetoxyusnic acid (**4**) does not serve as a precursor for **2** or **3**.

The relationship between **2** and **3** could be conclusively established from fermentation experiments with radioactive forms of these metabolites. When radioactive **3** was employed as the precursor it could be demonstrated that radioactive **2** is formed. On the other hand fermentation with radioactive **2** produces no evidence of active **3**. In summary these results provide definitive information about the biodegradation pathways involved. It appears that two independent pathways have been recognized, one involving the sequence, **1** → **4**, and the other, **1** → **3** → **2**. The intermediates involved in these conversions have not been established and further experiments will be required. The chemical instability associated with the anticipated intermediates may provide considerable difficulty since the instability of **4** has already prevented any more detailed studies with this metabolite.

Experimental

Melting points were determined on a Kofler block and are uncorrected.

Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer in methanol solution (unless otherwise noted). The wavelength of the absorption maxima are reported in nanometres (nm).

Infrared (ir) spectra were measured routinely on a Perkin-Elmer model 710 spectrophotometer. Analytical or comparison spectra were recorded on a Perkin-Elmer model 457 spectrophotometer using matched cells with a cell path of 0.2 mm in chloroform solution. Calibration was achieved using the 1601 cm^{-1} absorption band of polystyrene. The absorption maxima are quoted in wave numbers (cm^{-1}).

Proton magnetic resonance (^{1}Hmr) spectra were measured at 60 or 100 MHz in deuterochloroform ($CDCl_3$) solution (unless otherwise indicated) at room temperature. Line positions are given in the δ (ppm) scale using tetramethylsilane (TMS) as internal standard. The integrated peak areas, multiplicity, and proton assignments are indicated in parentheses.

Low resolution mass (ms) spectra were determined on either an AEI-902 or an Atlas CH-4B mass spectrometer, with high resolution mass spectra being recorded exclusively on an AEI-MS-902 mass spectrometer.

Optical rotations ($[\alpha]_D$) were measured on a Perkin-Elmer model 141 polarimeter at the sodium D line in

chloroform solution (unless otherwise noted) using cells with a 0.1 dm path.

Microanalyses were performed by Mr. P. Borda of the Microanalytical Laboratory, University of British Columbia.

Merck silica gel G (acc. to Stahl) impregnated with oxalic acid (2%) and with 2% fluorescent indicator added, was used as adsorbent for thin layer chromatography (tlc), unless otherwise noted. The tlc plates were activated in an oven at 90°C for 4 h before use. For qualitative chromatography, layers of 0.3 mm thickness were used and the spots were visualized by viewing under ultraviolet (uv) light or spraying with a 1% ethanolic ferric chloride solution. For preparative (plc) chromatography, large (20 × 20 and 20 × 60 cm) plates with a thicker layer (0.7 mm) were used. The developing systems were *A*, petroleum ether (30–60°C) – acetone (4:1), and *B*, chloroform – ethyl acetate (3:2), unless otherwise indicated.

Column chromatography was performed on either Mackerey–Nagel (0.2–0.5 mm grain size) or Merck 60 (0.063–0.2 mm grain size) silica gel.

(+)-Usnic acid was obtained from Koch-Light Laboratories, England.

In experiments involving radioactive precursors, the radioactivity was determined by the liquid scintillation counting method utilizing a Nuclear-Chicago Mark II Scintillation Counter. All specimens were counted in duplicate.

A sample of the isolate used and identified as *Mortierella isabellina* #129 was maintained on modified malt agar plates (18) by transfer every 2 weeks from a two-week old agar plate growth to a fresh sterile plate.

Maintenance, Growth, and Fermentation Conditions

A 'stock culture' of the purified fungal isolate was stored on modified malt agar in culture tubes placed in the refrigerator.

Aseptic techniques were used throughout in handling the cultures. To ensure proper aeration, the volume of the nutrient solution (18) should never exceed about two-fifths of the total volume of the flask.

Media and stock solutions utilized have been fully reported in ref. 18.

Fermentation Conditions and Extraction Procedure

Inoculation of *shake* culture flasks is carried out by transferring a small segment (about $\frac{1}{4}$ in. square) of active growth (not older than 2 weeks) and agar to a sterile Erlenmeyer flask containing an appropriate volume of nutrient medium.

Large scale production of biodegradation products is carried out in 6 ℓ Erlenmeyer flasks, each containing 3 ℓ of growth medium. Inoculation of these flasks is achieved by transferring the contents of a liquid culture of *Mortierella isabellina* (200 ml) which had been grown for 3–4 days in a shake culture flask (*vide supra*) and crystalline (+)-usnic acid (5 g, 14.534 mmol) into each fermentation flask. The flasks were then agitated on a rotary shaker at room temperature for 10 days. A typical extraction procedure routinely employed is summarized in Fig. 1.

Neutral Fraction

Purification by column chromatography on silica gel Woelm (activity II, 50 g) produced the following components.

Component FA(N)

Fatty acid ester(s) (940 mg). Not investigated.

Component A(N)

Usnic acid derived unstable compound (75 mg). Not investigated.

Component B(N): (+)-1α-Hydroxy-2-desacetylusnic Acid (2) (6-Acetyl-8,9bα-dimethyl-1,9b,2,3,-tetrahydro-1α,7,9-trihydroxy-3-oxodibenzofuran)

Colorless plates from acetone – petroleum ether (30–60°C) (124 mg, 0.408 mmol; 3%), mp 236–238°C; $[\alpha]_D^{26}$ (CH_3CN) +187° (*c* 0.123); uv: λ_{max} (log ε) 324 (3.74), 282 (4.13), 215 (4.19); ir: ν_{max} 3300–3000 (OH, chelated), 1658 (C=O, α,β-unsaturated), 1625 (C=O, chelated aromatic acetyl; C=C); ^{1}Hmr: δ 1.48 (3H, s, C_{9b}-CH_3), 2.04 (3H, s, C_8-CH_3), 2.60 (1H, ABX q, J_{AB} = 18 Hz, C_2-*H* (axial)), 2.66 (3H, s, C_6-$COCH_3$), 2.82 (1H, ABX q, J_{AB} = 18 Hz, C_2-*H* (equatorial)), 4.30 (1H, ABX q, $J_{AX} + J_{BX}$ = 16.5 Hz, C_1-*H* (axial)), 5.75 (1H, s, C_4-H), 8.76 (2H, b, C_1-O*H* and C_9-O*H*), 13.32 ppm (1H, s, C_7-O*H*); ^{1}Hmr (60 MHz, CD_3OD) δ 1.58 (3H, s, C_{9b}-CH_3), 2.13 (3H, s, C_8-CH_3), 2.76 (3H, s, C_6-$COCH_3$), 2.82 (2H, ABX multiplet, $J_{AX} + J_{BX}$ = 16.5 Hz, C_2-H_2), 4.41 (1H, ABX q, $J_{AX} + J_{BX}$ = 16.5 Hz, C_1-*H* (axial)), 5.98 ppm (1H, s, C_4-*H*); ms: *m/e* 304 (M^+), 289, 261, 260 (base peak), 247, 243, 233, 232, 217, 205, 115, 91, 83, 77, 69, 43. *Anal.* calcd. for $C_{16}H_{16}O_6$: C 63.15, H 5.30; found: C 63.05, H 5.28. High resolution molecular weight determination calcd.: 304.095; found: 304.096.

Component C(N)

Base line material (10 mg). Not investigated. Total weight of recovered materials from Neutral Fraction is 1.149 g.

Acid Fraction

Upon concentration of the ethyl acetate extract a yellow crystalline solid precipitated and was filtered. This material (40 mg) constitutes component A(A) and was combined with the one obtained during the purification of the mother liquors by preparative layer chromatography (silica gel – oxalic acid, 20 × 60 cm plates, solvent system *A*, developed three times). The following components were obtained.

Component FA(A)

Fatty-acid ester(s) (1.250 g). It showed an identical ^{1}Hmr spectrum with the one obtained for component FA(N) of the Neutral Fraction; ir: ν_{max} 1720, 1700, 1680, 1610, 1500, 1410. It was subsequently shown with radioactively labelled precursors that this component is *not* derived from usnic acid and it was not investigated further.

Component A(A): (+)-2-Desacetylusnic Acid (3)

Bright yellow plates from ethyl acetate (60 mg, 0.198 mmol; 1.5%), mp 221–222°C; mixture mp with an authentic sample of (+)-2-desacetylusnic acid (7), 220–222°C; $[\alpha]_D^{26}$ (CH_3CN) +630° (*c* 0.0755). This sample showed identical chromatographic and spectroscopic properties with those of the authentic product; uv: λ_{max} (log ε) 330 (3.53), 287 (4.02), 219 (4.33); ir (Nujol): ν_{max} 3300–2300 (OH, chelated), 1670 (C=O, enone system), 1630 (C=O, chelated aromatic acetyl; C=C), 1600 (C=C); ^{1}Hmr: δ 1.71 (3H, s, C_{9b}-CH_3), 2.02 (3H, s, C_8-CH_3), 2.65 (3H, s, C_6-$COCH_3$), 5.37 (1H, d, *J* = 2 Hz, C_2-*H*), 5.88 (1H, d, *J* = 2 Hz, C_4-*H*), 11.94

(1H, b, C_9-O*H*), 13.32 ppm (1H, s, C_7-O*H*); ms: *m/e* 302 (M^+), 287, 260 (base peak), 233, 232, 217. *Anal.* calcd. for $C_{16}H_{14}O_6$: C 63.57, H 4.67; found: C 63.51, H 4.72. High resolution molecular weight determination calcd.: 302.079; found: 302.077.

Component B(A): (+)-2-Acetoxyusnic Acid (4) (6-Acetyl-8,9bα-dimethyl-1,9b-dihydro-2-acetoxy-3,7,9-trihydroxy-1-oxodibenzofuran)

After three successive purifications by preparative chromatography (silica gel – oxalic acid plates, solvent *A*, developed twice) this material presented the following characteristics.

Unstable yellow glassy material that could not be induced to crystallize (700 mg, 1.944 mmol; 15.5%); $[\alpha]_D^{26}$ (CH_3OH) +392° (*c*, 0.025); uv: λ_{max} (log ε) 335 (3.35), 291 (3.83), 221 (4.15); ir: ν_{max} 3400–2500 (OH, chelated), 1765 (C=O, acetate), 1720, 1690 (C=O, β-diketone), 1625 (C=O, chelated aromatic acetyl; C=C); ^{1}Hmr: δ 1.80 (3H, s, C_{9b}-C*H*$_3$), 2.06 (3H, s, C_8-C*H*$_3$), 2.30 (3H, s, C_2-OCOC*H*$_3$), 2.65 (3H, s, C_6-COC*H*$_3$), 5.85 (1H, s, C_4-*H*), 9.00 (2H, b, C_3-O*H* and C_9-O*H*), 13.26 ppm (1H, s, C_7-O*H*); ms: *m/e* 360 (M^+), 318, 302, 290, 272, 262, 260 (base peak), 232, 217, 88, 73, 70, 60. High resolution molecular weight determination calcd. for $C_{18}H_{16}O_8$: 360.084; found: 360.083. This compound seems to be stable for 1–2 weeks if stored at 0°C in ethyl acetate solution.

Compound C(A)

Unstable usnic acid derived product (150 mg). Not investigated. Total weight of recovered materials from Acid Fraction is 2.160 g.

Formation of (+)-1α-Hydroxy-2-desacetylusnic Acid Triacetate (5) (6-Acetyl-8,9bα-dimethyl-1,9b,2,3-tetrahydro-1α,7,9-triacetoxy-3-oxodibenzofuran)

A solution of (+)-1α-hydroxy-2-desacetylusnic acid (**2**) (20 mg, 0.065 mmol) in a 1:1 mixture of pyridine – acetic anhydride (1 ml) was allowed to stand at room temperature for 5 h. The resulting pale brown reaction mixture was then poured onto crushed ice (10 g) and extracted with chloroform (3 × 5 ml). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to yield a colorless semi-crystalline glass (22.8 mg). Purification by preparative layer chromatography (silica gel plates, (4:1) chloroform – ethyl acetate) produced pure (+)-1α-hydroxy-2-desacetylusnic acid triacetate (**5**) (16 mg, 0.0372 mmol; 57%). Although this material could not be induced to crystallize, upon sublimation (190°C, 0.03 Torr) colorless droplets (mp 93–95°C) were obtained; $[\alpha]_D^{26}$ (CH_3CN) +152° (*c* 0.052); uv: λ_{max} (log ε) 272 (3.87), 246 (3.78), 208 (4.29); ir: ν_{max} 1770 (C=O, aromatic acetates), 1720 (C=O, saturated acetate), 1690 (C=O, aromatic acetyl), 1660 (C=O, α,β-unsaturated ketone), 1605 (C=C), 1240 (C—O, saturated acetate), 1205 (C—O, aromatic acetates); ^{1}Hmr: δ 1.60 (3H, s, C_{9b}-C*H*$_3$), 1.94 (3H, s, C_8-C*H*$_3$), 2.23 (3H, s, C_1-α OCOC*H*$_3$), 2.33 (3H, s, C_9-OCOC*H*$_3$), 2.40 (3H, s, C_9-OCOC*H*$_3$), 2.51 (1H, ABX q, J_{AB} = 18 Hz, C_2-*H* (axial)). 2.63 (3H, s, C_6-COC*H*$_3$), 2.98 (1H, ABX q, J_{AB} = 18 Hz, C_2-*H* (equatorial)), 5.50 (1H, ABX q, $J_{AX} + J_{BX}$ = 16.5 Hz, J_{AX} = 10 Hz, J_{BX} = 6.5 Hz, C_1-*H* (axial)), 5.86 ppm (1H, s, C_4-*H*); ms: *m/e* 430 (M^+), 388, 346, 328, 317, 313, 302, 287, 286, 271, 260 (base peak), 232, 217, 83, 74, 59, 43. *Anal.* calcd. for $C_{22}H_{22}O_9$: C 61.39, H 5.15; found: C 61.14, H 5.33. High resolution molecular weight determination calcd.: 430.126; found: 430.128.

Ozonolysis of (+)-2-Acetoxyusnic Acid (4). Isolation of (±)-7-Acetyl-4,6-dihydroxy-3,5-dimethylcoumaran-2-one Diacetate (6)

Freshly isolated (+)-2-acetoxyusnic acid (**4**) (60 mg, 0.166 mmol) was dissolved in a 1:1 mixture of pyridine – acetic anhydride (2 ml) and allowed to stand at room temperature overnight. The resulting solution was poured onto ice (10 g), extracted with ethyl acetate (3 × 5 ml), and the combined extracts washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to produce an orange glass (67 mg). The residue was dissolved in dry carbon tetrachloride (8 ml), cooled to 0°C (ice bath), and ozonized oxygen (26 mg O_3/min) bubbled through until a pale blue color was observed. The reaction mixture was diluted with distilled water (10 ml) and heated to reflux in a steam bath for 20 min. The organic layer was then separated, washed with 2.5% sodium bicarbonate solution and water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The residue was recrystallized from ethyl alcohol – water to produce (±)-7-acetyl-4,6-dihydroxy-3,5-dimethylcoumaran-2-one diacetate (**6**) (20 mg, 0.0625 mmol; 37%), colorless crystals, mp 131–132°C (lit. (2) mp 130–132°C); mixture mp with authentic material, 131–132°C. The sample showed identical chromatographic and spectroscopic properties with those of the material obtained from (+)-usnic acid.

Preparation of (+)-Dihydro-2-acetoxyusnic Acid (7) (2-Acetoxy-6-acetyl-8,9bα-dimethyl-1,9b,4,4a-tetrahydro-3,7,9-trihydroxy-1-oxodibenzofuran)

(+)-2-Acetoxyusnic acid (**4**) (110 mg, 0.305 mmol) in absolute ethyl alcohol (10 ml) was hydrogenated at room temperature and atmospheric pressure over 5% platinum-on-carbon catalyst (50 mg). After the uptake of 1 mol equiv. of hydrogen (7.45 ml H_2 at 25°C) the reaction mixture was filtered through Celite, the Celite cake washed with absolute ethyl alcohol (2 × 5 ml), and the combined filtrates evaporated under reduced pressure to afford a colorless foam (83 mg). Purification by preparative layer chromatography (silica gel – oxalic acid plates, solvent *A*) yielded (+)-dihydro-2-acetoxyusnic acid (**7**) (41.3 mg, 0.114 mmol; 37%), colorless glassy material that could not be induced to crystallize $[\alpha]_D^{26}$ (CH_3OH) +45° (*c* 9.11); uv: λ_{max} (log ε) 322 (3.66), 286 (4.30), 222 (4.15); ir: ν_{max} 3500–3100 (OH, chelated), 1775 (C=O, acetate), 1730 (C=O, β-diketone), 1630 (C=O, chelated aromatic acetyl; C=C); ^{1}Hmr: δ 1.67 (3H, s, C_{9b}-C*H*$_3$), 2.03 (3H, s, C_8-C*H*$_3$), 2.20 (3H, s, C_2-OCOC*H*$_3$), 2.54 (3H, s, C_6-COC*H*$_3$), 3.06 (2H, d, J = 5 Hz, C_4-*H*$_2$), 4.84 (1H, t, J = 5 Hz, C_{4a}-α*H*), 7.13 (2H, b, C_3-O*H* and C_9-O*H*), 13.20 ppm (1H, s, C_7-O*H*); ms: *m/e* 362 (M^+), 334, 320, 305, 260, 233, 220, 219, 217, 215, 205, 201, 191, 149, 91, 83, 69, 57, 55, 43 (base peak). High resolution molecular weight determination calcd. for $C_{18}H_{18}O_8$: 362.100; found: 362.098.

The Chromium(II) Chloride Reduction of Natural (+)-2-Acetoxyusnic Acid (4). Isolation of (+)-2-Desacetylusnic Acid (3)

A solution of (+)-2-acetoxyusnic acid (**4**) (21 mg, 0.0583 mmol) in dry acetone (10 ml) was saturated at

0°C (ice bath) with carbon dioxide and treated under a stream of carbon dioxide with a freshly prepared chromium(II) chloride solution (10 ml). The reaction flask was properly sealed to exclude air (Parafilm) and allowed to stand at room temperature in the dark for 3 days. The resulting green reaction mixture was then concentrated under reduced pressure, diluted with distilled water (10 ml), and extracted with ethyl acetate (3 × 5 ml). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The yellow semicrystalline residue (18 mg) was purified by preparative layer chromatography (silica gel – oxalic acid plates, solvent *A*) to produce (+)-2-desacetylusnic acid (**3**) (13 mg, 0.043 mmol; 73%), bright yellow crystals from ethyl acetate, mp 220–222°C; mixture mp with authentic material, 221–222°C. The sample showed identity with the authentic material in all spectroscopic and chromatographic properties.

*Sequential Biodegradation of (+)-Usnic Acid (**1**) by Mortierella Isabellina*

A sequential study of the biodegradation of (+)-usnic acid (**1**) by *Mortierella isabellina* was set up by using 20-1000 ml Erlenmeyer flasks, each containing an adequate volume of growth medium (250 ml) and crystalline (+)-usnic acid (**1**) (500 mg, 1.453 mmol). Inoculation of these flasks was carried out by transferring aliquots (25 ml) from a 6-day old liquid culture of *M. isabellina* (500 ml).

Extraction of the fermentation mixture according to the scheme outlined in Fig. 1 was performed every day by processing the contents of one flask. The variations of p*H*, amount of recovered usnic acid, total weight of the Neutral and Acid Fraction, and individual weight of components present in each fraction were recorded. The results are presented in Tables 2 and 3.

Synthesis of [6-$^{14}CH_3CO$]-(+)-Usnic Acid

To a solution of aluminum chloride (63.1 mg) and [2-^{14}C]acetyl chloride (29.5 μl; total activity 1.0 mCi) in anhydrous nitrobenzene (1.2 ml) was added 6-desacetylusnic acid (30.3 mg) and the mixture was stirred for 1.5 h at 60°C under a nitrogen atmosphere. After cooling with ice, the mixture was diluted with chloroform (5 ml) and freshly prepared 1 *N* sodium hydroxide solution (5 ml) and stirred at room temperature for a further 0.5 h. The two layers were separated and the organic layer was extracted with 1 *N* sodium hydroxide (5 ml). The combined aqueous layers were carefully acidified with 1 *N* hydrochloric acid and thoroughly extracted with ethyl acetate (3 × 15 ml). These extracts were washed with brine, then with water, dried over anhydrous sodium sulfate, and evaporated *in vacuo* to provide the crude product (25.6 mg). Preparative layer chromatography (silica gel, 2% oxalic acid, petroleum ether – acetone 4:1) and crystallization from chloroform – ethyl alcohol afforded the radioactive usnic acid (11.0 mg). This material was diluted with inactive usnic acid to give a specimen (74.0 mg) with activity of 1.23 × 10^6 dpm/mg.

For the large scale fermentations this sample could be further diluted with inactive usnic acid to provide the required quantities and activities as noted below.

*Fermentation with [6-$^{14}CH_3CO$]-(+)-Usnic Acid (**1**)*

Radioactive usnic acid (4.55 g, activity 1.56 × 10^4 dpm/mg) was reacted in eight flasks innoculated with *Mortierella isabellina* and fermented in the manner already described earlier. Isolation according to the earlier described procedure provided a Neutral Fraction (654 mg) and an Acid Fraction (1.20 g).

Purification of the Neutral Fraction by preparative layer chromatography afforded radioactive **2** (30.2 mg, activity 1.78 × 10^4 dpm/mg) while the Acid Fraction afforded **3** (77.7 mg, activity 1.78 × 10^4 dpm/mg) and **4** (355 mg, activity 1.68 × 10^4 dpm/mg). In addition, 1.3 g of usnic acid was recovered.

This type of experiment was repeated on numerous occasions to provide similar results.

*Fermentation with [6-$^{14}CH_3CO$]-(+)-2-Desacetylusnic Acid (**3**)*

Radioactive (+)-2-desacetylusnic acid **3** (159.8 mg activity 0.57 × 10^3 dpm/mg) was exposed to fermentation in the normal manner over a 17 day period. Isolation of the resultant mixture provided a Neutral Fraction (63.4 mg) and an Acid Fraction (98.6 mg).

Purification of the Neutral Fraction provided an inactive oily material (19.6 mg) which was not characterized further and radioactive **2** (activity 0.60 × 10^3 dpm/mg). Blank experiments with inactive **2** gave values of 81 dpm/mg.

The Acid Fraction, upon purification, afforded unchanged **3** (27.5 mg, activity 0.50 × 10^3 dpm/mg) as the only radioactive components.

*Fermentation with [6-$^{14}CH_3CO$]-(+)-1α-Hydroxy-2-desacetylusnic Acid (**2**)*

Radioactive (+)-1α-hydroxy-2-desacetylusnic acid **2** (162 mg, activity 1.46 × 10^3 dpm/mg) was exposed to fermentation over a 2 week period. Isolation of the mixture afforded a Neutral Fraction (96.3 mg) which upon thin layer chromatographic purification gave unreacted **2** (74 mg) and an Acidic Fraction (31 mg) which on tlc revealed only very polar material. No detectable amounts of any of the other metabolites (**3** or **4**) were observed.

*Synthesis of [6-$^{14}CH_3CO$]-(+)-2-Acetoxyusnic Acid (**4**)*

[6-$^{14}CH_3CO$]-(+)-Usnic acid (500 mg, activity 1.35 × 10^4 dpm/mg) was dissolved in warm pyridine (8.5 ml) and treated at room temperature with 30% hydrogen peroxide (0.35 ml). After stirring for 1 h, the reaction mixture was cooled to 0°C, acidified with 0.1 *N* hydrochloric acid, and then extracted with ethyl acetate (3 × 35 ml). The extract was washed with water, dried over anhydrous sodium sulfate, and evaporated *in vacuo* to provide a brown oily residue. Thick layer chromatography (silica gel – oxalic acid, petroleum ether – acetone (3:1)) of the latter provided pure **4** (480 mg, activity 1.29 × 10^4 dpm/mg).

*Fermentation with [6-$^{14}CH_3CO$]-(+)-2-Acetoxyusnic Acid (**4**)*

Radioactive **4** (350 mg, activity 1.29 × 10^4 dpm/mg) was exposed to fermentation over a 2 week period. Isolation and purification of the Acid Fraction (315 mg) provided unreacted **4** (210 mg) while the Neutral Fraction (11.5 mg) did not reveal any of the expected metabolites **2** or **3**.

*Fermentation with [6-$^{14}CH_3CO$]-(+)-2-Acetoxyusnic Acid (**4**) in the Presence of Non-radioactive Usnic Acid*

Radioactive **4** (128 mg, activity 1.29 × 10^4 dpm/mg)

and non-radioactive usnic acid (150 mg) were exposed to fermentation over a 2 week period. Preparative layer chromatography of the Neutral Fraction (30 mg) provided only unchanged **4** (78 mg) and no evidence of the other metabolites. The normal unlabelled metabolites **2** and **3** formed from the non-radioactive usnic acid were noted in the medium.

Transition state determination by the X-method

PAUL G. MEZEY, MICHAEL R. PETERSON, AND IMRE G. CSIZMADIA
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received December 17, 1976

PAUL G. MEZEY, MICHAEL R. PETERSON, and IMRE G. CSIZMADIA. Can. J. Chem. **55**, 2941 (1977).

A simple direct procedure to locate saddle points (transition states) on energy surfaces is described. The advantage of the method is that it may utilize effective unconstrained optimization techniques while convergence may occur only to saddle points and not to minima. Thus no further tests are needed to decide the nature of the critical point located. Both the simplex and conjugate gradients optimization techniques were applied within the framework of the proposed method (the X-method) and numerical tests were carried out on both 'mathematical' and 'chemical' model surfaces.

PAUL G. MEZEY, MICHAEL R. PETERSON et IMRE G. CSIZMADIA. Can. J. Chem. **55**, 2941 (1977).

On décrit une méthode directe et simple pour localiser les points d'énergie maximale (états de transition) sur des surfaces d'énergie. L'avantage de la méthode est qu'elle peut utiliser des techniques d'optimisation non-contraintes et effectives alors que la convergence peut n'apparaître qu'au niveau maximum sans apparaître au niveau minimum. Il n'est donc pas nécessaire d'avoir d'autres vérifications pour décider de la nature du point critique localisé. On a appliqué les méthodes simplex et conjuguées d'optimisation des gradients dans le cadre de la méthode proposée (la méthode X) et on a effectué plusieurs vérifications numériques sur les surfaces modèles 'mathématiques' et 'chimiques'. [Traduit par le journal]

Introduction

The determination of saddle points is of considerable importance in chemistry as they represent transition states between the stable species, which occur at local minima on energy surfaces. The energy difference between the transition state and the minimum is the energy barrier of the reaction.

Transition states are extremely difficult to observe experimentally and hence only few transition state geometries are even approximately known. The theoretical determination of saddle points also presents great difficulties (1–6), as the calculation of the total energy of a chemical system using the Hartree–Fock method is itself a laborious procedure. In addition, traditional geometry optimization methods, that is, direct unconstrained minimization of the calculated total energy, can lead only to minima of energy hypersurfaces. While these minima are characterized by a positive definite Hessian matrix **H** with elements

$$[1] \qquad H_{ij} = \frac{\partial^2 E}{\partial x_i \partial x_j}$$

i.e., all eigenvalues of **H** are positive, for saddle points an indefinite Hessian is characteristic with one (or for higher order saddle points several negative eigenvalues). Consequently, at a saddle point **H** has at least one eigenvector along which the energy decreases, hence any unconstrained energy optimization should fall back into one of the minima (7).

Constrained optimization of the energy can be utilized if the reactant and product of the reaction or conformational change are of a symmetry different from the symmetry of the transition state, as for the planar (D_{3h}) transition state for the pyramidal inversion of ammonia (C_{3v}). The energy may be minimized within a given symmetry which may lead to a saddle point (or a minimum). However, this method is not generally applicable.

One previously proposed method (3, 6) is based on the fact that all saddle points are among the solutions of the equation

$$[2] \qquad S_g \equiv \sum_{i=1}^{3N-6} \left(\frac{\partial E}{\partial x_i}\right)^2 = 0$$

To find these solutions, a direct minimization method may be applied to S_g. The difficulty with this method, however, is that any critical point (i.e. any point where grad $E = 0$) is a solution of [2], and **H** must also be evaluated to decide whether the solution found is a minimum, saddle point of some order, or a maximum. The method requires many energy and (more costly) grad E evaluations.

Method

The method of the present paper was designed to utilize the effectiveness of direct optimization methods, assuring, however, that convergence may occur to saddle points only.

The basic idea of the method is intuitively transparent and simple. After suitable rotation and translation of the coordinate frame, the equation of the simplest saddle surface, the hyperbolic paraboloid, shown in Fig. 1, becomes

$$[3] \qquad f(x_1,x_2) = \frac{x_1^2}{a^2} - \frac{x_2^2}{b^2} = cx_3$$

At the saddle point $x_1 = x_2 = 0$ and $f(0,0) = 0$. For all points with $x_3 = 0$ eq. 3 becomes

$$[4] \qquad \frac{x_1^2}{a^2} - \frac{x_2^2}{b^2} = \left(\frac{x_1}{a} - \frac{x_2}{b}\right)\left(\frac{x_1}{a} + \frac{x_2}{b}\right) = 0$$

Consequently, there are two horizontal lines that lie completely on the surface:

$$[5] \qquad \frac{x_1}{a} = \frac{x_2}{b} \quad \text{or} \quad \frac{x_1}{a} = -\frac{x_2}{b}$$

The crossing point of these lines is the saddle point, $x_1 = x_2 = 0$. This result is general for any quadratic saddle surface. Taking coordinate x_3 as the calculated energy, the horizontal lines are of constant energy. Also there is only one pair of horizontal lines that lie wholly on the surface, necessarily the pair that cross at the saddle point. Consequently, the determination of the saddle point is equivalent to the determination of the best fitting horizontal line pair on the surface, which can be accomplished by simple least square fitting.

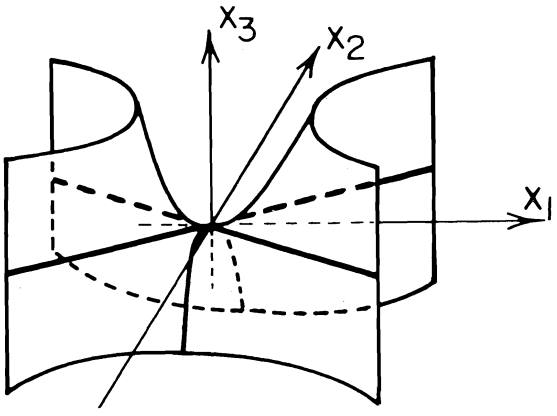

FIG. 1. Hyperbolic paraboloid: $x_1^2/a^2 - x_2^2/b^2 = cx_3$; horizontal lines: $x_1/a = \pm x_2/b$.

For saddle surfaces of chemical reactions only a neighbourhood of the saddle point can be regarded as quadratic, consequently the fit of line pairs is not perfect. As may be seen from Fig. 2, which is a contour plot of Fig. 1, two horizontal line segments that form an X (hence the name X-method) are needed to fit onto the surface. An attractive feature of the method is the fact that, after finding the two line segments, one of the two bisectors of the X gives a tangent to the reaction path. Consequently, a single determination of the saddle point also gives the direction of the reaction path at this point.

The concept of $n - 1$ linearly independent horizontal lines fitting to the saddle point is general for quadratic hypersurfaces in n dimensions (8), and may be utilized for the determination of saddle points. In this paper we present a simplified formulation of the general technique (8), that is suitable for the chemically most important $n = 3$ case, i.e. for saddle surfaces.

The actual formulation of the method for the determination of ordinary saddle points is outlined below. In the case of three dimensional saddle surfaces the energy may be written as

$$[6] \qquad \text{Energy} = E(\boldsymbol{x}) = E(x_1,x_2)$$

To define two line segments a reference vector $\boldsymbol{x}^0$ (the coordinates of the crossing point) and two direction vectors, $\boldsymbol{v}(\alpha)$ and $\boldsymbol{v}(\beta)$ are required. Let 'reference energy' E^0 be the energy of the crossing point. For any point of the 'horizontal X' the coordinate $x_3 = E^0$. The deviation of the line segment from the surface point $E(\boldsymbol{x})$ is

$$[7] \qquad d = E(\boldsymbol{x}) - E^0$$

The points $\boldsymbol{x}^{p_\alpha}$ and $\boldsymbol{x}^{p_\beta}$ along the arms of X are

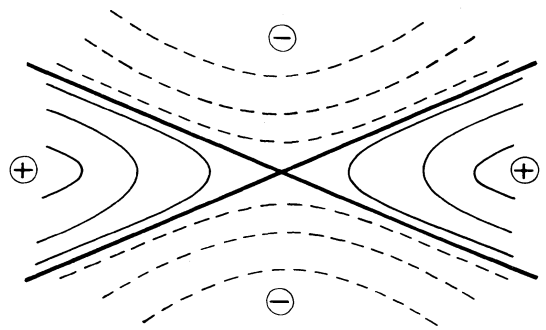

FIG. 2. Contour plot of a hyperbolic paraboloid showing the X of constant energy.

defined as

$$[8] \qquad \boldsymbol{x}^{p_\alpha} = \boldsymbol{x}^0 + p_\alpha z \boldsymbol{v}(\alpha)$$

$$[9] \qquad \boldsymbol{x}^{p_\beta} = \boldsymbol{x}^0 + p_\beta z \boldsymbol{v}(\beta)$$

Vectors $\boldsymbol{v}(\alpha)$ and $\boldsymbol{v}(\beta)$ are unit vectors, z is a suitably chosen positive scalar. The factors p_α and p_β give the multiples of $z\boldsymbol{v}(\alpha)$ and $z\boldsymbol{v}(\beta)$ to add to $\boldsymbol{x}^0$ in order to obtain a set of points on the lines defined by angles α and β with respect to the x_1 coordinate axis. The vectors $\boldsymbol{v}(\alpha)$ and $\boldsymbol{v}(\beta)$ may be generated by simple rotations,

$$[10] \qquad \boldsymbol{v}(\alpha) = \begin{pmatrix} \cos\alpha \\ \sin\alpha \\ 0 \end{pmatrix}$$

$$[11] \qquad \boldsymbol{v}(\beta) = \begin{pmatrix} \cos\beta \\ \sin\beta \\ 0 \end{pmatrix}$$

In order to fit an X to the saddle region of a surface the following function is to be minimized:

$$[12] \quad D = D(\boldsymbol{x}^0,\alpha,\beta) = \sum_{p=-k}^{k} \{[E(\boldsymbol{x}^{p_\alpha}) - E^0]^2 + [E(\boldsymbol{x}^{p_\beta}) - E^0]^2\}$$

where p_α and p_β take on values between $-k$ and k (k integer). The reference energy $E^0 = {x_3}^0$ may be restricted to $E^0 = E({x_1}^0,{x_2}^0)$, although faster convergence was achieved leaving ${x_3}^0 = E^0$, a free parameter just as the coordinates of points $\boldsymbol{x}^{p_\alpha}$ and $\boldsymbol{x}^{p_\beta}$. For quadratic surfaces, if $\boldsymbol{x}^0$ converges to the saddle point the reference energy E^0 becomes $E({x_1}^0,{x_2}^0)$, for intermediate $\boldsymbol{x}^0$ points, however, E^0 may deviate from $E({x_1}^0,{x_2}^0)$. For non-quadratic saddle surfaces, even if ${x_1}^0$ and ${x_2}^0$ are the coordinates of the saddle point, the E^0 value of the best fitting line segments is not necessarily equal to $E({x_1}^0,{x_2}^0)$. Since $\boldsymbol{x}^0$ involves three parameters, with α and β there are five parameters to be optimized.

In the course of the optimization the two angle parameters α and β must be different, since $\alpha = \beta$ would correspond to two coincident lines, that is, the X would collapse into one single line. If this single horizontal line fits onto the surface then the saddle point must fall on this line, nevertheless, the location of the saddle point along this line is still undetermined. Consequently, if the two angles approach each other beyond a preset limit, e.g. $|\alpha - \beta| < 1°$, then the optimization should be restarted with at least one of the angles altered. The choice of $\alpha_{new} = \alpha_{old}$, $\beta_{new} = \alpha_{old} + 90°$ appears to be appropriate, since then one well fitting line, $\boldsymbol{v}(\alpha)$, is preserved while the second line, $\boldsymbol{v}(\beta)$, fits rather poorly on the surface. The expected result of the new β in the next step is a translation along $\boldsymbol{v}(\alpha)$.

Two procedures to optimize these parameters were used: the simplex method (9) and the method of conjugate gradients (10–12). As the latter method requires the gradient of D, the following partial derivatives must be calculated:

$$[13] \qquad \frac{\partial D}{\partial {x_i}^0}, \frac{\partial D}{\partial \alpha}, \frac{\partial D}{\partial \beta}$$

Note that a similar application of the conjugate gradient method for the minimization of S_g (eq. 2) would require the evaluation of the *second derivatives* of the energy. For economy, during the testing of the X-method, the surfaces used were fitted by an analytic equation generated by a least-squares fitting procedure,[1] therefore, the explicit forms of [13] were available.

Results and Discussion

As would be expected, the conjugate gradients method generally converged to the minimum of D, i.e. to the saddle point in fewer function evaluations than the simplex method. However, in the simplex optimization procedure there is no need to evaluate the gradients and the actual optimization procedure follows a rather simple alogorithm. Consequently the conjugate gradient method appears to be more efficient in the most common cases of chemical applications, i.e., whenever the function evaluation is by far the most time consuming step. However, for functions that are readily calculable the simplex method is recommended. It appears that a rather crude approximation to the saddle point, based on chemical intuition, may yield a satisfactory starting point for the X-method.

As may be seen from Fig. 3, there are two additional 'parameters' in the X-method: (*1*) the number of points (NP) taken along each line segment, and (*2*) the distance (z) between those points. Both of these factors control the size of the X. A judicious choice of NP and z is necessary for, if the X is too small it may fit onto the surface reasonably well almost everywhere, while

[1]Programs SURFIT and SURFPLOT are available from the authors.

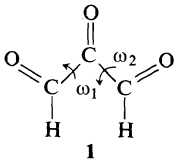
[b]One 'D evaluation' includes calculation of both D and grad D.

if it is too large, the approximation that the surface can be represented by a hyperbolic paraboloid is, in general, no longer valid.

As a chemical example, the calculated rotation–rotation surface of propanetrione (13), a surface of two coordinates, were taken. The conformational surface was calculated using the CNINDO program (14). An actual analytic approximation of this $E(\omega_1,\omega_2)$ surface by trigonometric functions is published elsewhere (13). The $\omega_1 = \omega_2 = 0$ conformation is defined by **1**. One saddle point occurs for ω_1 and ω_2 equal 1.5928 and 3.1950 rad (91° and 183°), respectively,[2] with a 90° angle between the arms of the X. The (91°,91°) and (89°,271°) conformations are minima.



1

The results for this molecule are summarized in Table 1. They bear out the conclusions drawn above. It is also apparent from the table that the X-method performs almost equally well for NP = 3 or NP = 5, indicating that the number of function evaluations may be reduced to 3 per line. A proper choice for z seems to be important since for a z value of 0.02 the angle between the arms of the X is about 25° too small. For larger z, however, the correct angle was obtained consistently.

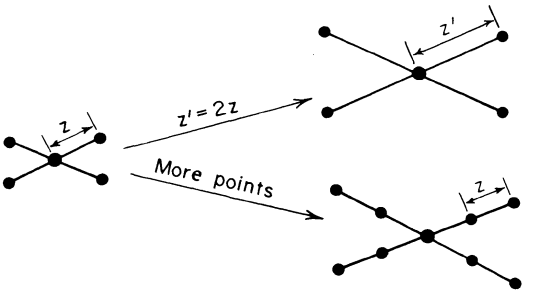


FIG. 3. Dependence of the size of the X on (*a*) the distance between the points and (*b*) the number of points per line segment.

Due to the large number of D evaluations, each involving 5 (for NP = 3) or 9 (for NP = 5) energy calculations, the computational costs appear too high to apply the method as an integral part of *ab initio* MO programs, such as the GAUSSIAN 70 program system (15). Instead, determination of saddle points on analytic surfaces fitted to the points calculated by such *ab initio* programs is recommended.

[2]The saddle point has been determined previously by the S_g method.

The interaction of 1-hydroxy-9,10-anthrahydroquinones (1-HOAHQ) with boric acid in aqueous borate buffer solutions at p*H* 9.5 causes a decrease in the anodic limiting current of the 1-HOAHQ and the simultaneous appearance of a new diffusion-controlled anodic wave at more positive potentials. This is attributed to the formation of a cyclic borate ester of the 1-HOAHQ involving the peri-hydroxyl groups. Ester formation is much slower but still complete when the boric acid – borate to 1-HOAHQ molar ratio exceeds 10–15. These esters are most stable at p*H* 7.5–9.5 and completely unstable above p*H* 12. 1,2-Dihydroxy-9,10-anthraquinones (1,2-diHOAQ) react with boric acid to give cyclic esters involving the 1- and 2-hydroxyl groups, but of lower stability than those from 1-HOAHQ. On reduction of a 1,2-diHOAQ in the presence of boric acid at p*H* 9.5, cyclic borate esters involving the peri-hydroxyl groups are rapidly produced in preference to those involving the ortho-hydroxyl groups.

ARTHUR D. BROADBENT, W. DONALD HEWSON, HEATHER A. MCDONALD et RONALD J. MELANSON. Can. J. Chem. **55**, 2946 (1977).

L'interaction d'hydroxy-1 anthraquinones-9,10 (1-HOAHQ) avez de l'acide borique en solutions aqueuses de borate tamponées à un p*H* de 9.5 produit une diminution du courant limitant anodique du 1-HOAHQ et l'apparition simultanée d'une nouvelle vague anodique contrôlée par la diffusion à des potentiels plus positifs. On attribue ces résultats à la formation d'un ester borate cyclique du 1-HOAHQ impliquant les groupes hydroxyles en péri. La formation d'ester est beaucoup plus lente mais elle demeure complète quand les rapports molaires acide borique – borate/1-HOAHQ dépassent 10–15. Ces esters sont les plus stables à des p*H* allant de 7.5–9.5 et complètement instables au dessus d'un p*H* 12. Les dihydroxy-1,2 anthraquinones-9,10 (1,2-diHOAQ) réagissent avec l'acide borique pour conduire à des esters cycliques impliquant les hydroxy-1 et -2 mais ces derniers ont une stabilité plus faible que ceux du 1-HOAHQ. Lors de la réduction d'un 1,2-diHOAQ en présence d'acide borique à un p*H* 9.5, des esters boriques cycliques impliquant les groupes hydroxyles en périe se forment rapidement de préférence à ceux impliquant les groupes hydroxyles en ortho.

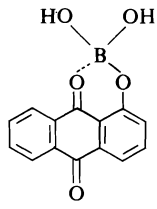
Introduction

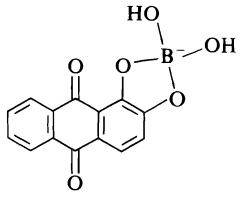
The formation of chelated esters of boric acid and 1,2-diols is well-known (1–3). The rings in the cyclic esters are limited to five or six atoms, and the boron:diol ratio is usually 1:1 or 1:2.

1-Hydroxy-9,10-anthraquinones (1-HOAQ) form esters with boric acid in H_2SO_4 solution, but the esters readily hydrolyze in the presence of water, despite chelation between the boron and carbonyl oxygen atoms as in **1** (4). Russian workers have reported formation of chelated esters of boric acid and 1,2-dihydroxy-9,10-anthraquinones (1,2-diHOAQ) in aqueous solution, chelation occurring between the ortho-hydroxy groups as in **2** (5, 6).

Specific interaction between boric acid or borate ion and AQ derivatives was proposed by Furman and Stone (7) to account for anomalous polarographic results, but was subsequently repudiated by Gill and Stonehill (8), who observed normal polarographic behavior for such compounds in borate buffers. Polarographic studies of 1-HOAQ-4-SO_3H in ethanolamine and borate buffers of identical p*H*, and of the corresponding 9,10-anthrahydroquinone obtained by reduction (1-HOAHQ-4-SO_3H), indicated that

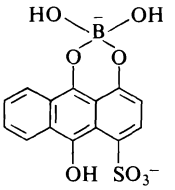


1



2

the AQ did not interact with boric acid while the AHQ gave an anodic wave at more positive potentials in the borate buffers attributed to oxidation of the ester **3** (9).



3

The purpose of the present study was to undertake a broader and more detailed study of the effect of boric acid on the polarography of hydroxyanthraquinone derivatives.

Results

The polarographic behavior of various 1-HOAQ, and the corresponding 1-HOAHQ generated by reduction with $Na_2S_2O_4$, was examined in borate and ethanolamine buffers of identical p*H*. After reduction of the AQ in borate buffer, or after addition of borate to an ethanolamine buffer solution of the AHQ, the anodic limiting current (i_d) for polarographic oxidation of the AHQ of half-wave potential ($E_{1/2}$) identical to that for polarographic reduction of the AQ, decreased with increasing time and simultaneously an anodic wave appeared at more positive potentials. The decrease in i_d for the 1-HOAHQ and the appearance of the new anodic wave were usually quite rapid in the borate buffer solution, total reaction taking only a few minutes or less with a 780-fold molar excess of boric acid – borate (except for 1-HOAHQ-4-SO_3H). The conversion was much slower but still complete when a 10–15-fold molar excess of boric acid – borate was added to the 1-HOAHQ. For ethanolamine buffer solutions of the 1-HOAHQ containing an equimolar quantity of boric acid – borate, the decrease in i_d for the 1-HOAHQ was very slow and when i_d became stable after several hours, both the anodic wave of the AHQ and the new anodic wave could be observed, the $E_{1/2}$ of the latter being about 10–20 mV more positive than in the presence of excess boric acid.

In the case of 1,5-diHOAHQ, no anodic wave was observed in the presence of excess borate buffer but the yellow solution had an intense green fluorescence. On adding a 10-fold molar excess of boric acid – borate to an ethanolamine buffer solution of 1,5-diHOAHQ (2.0×10^{-4} mol dm^{-3}), its anodic limiting current ($E_{1/2} = -581$ mV) decreased with simultaneous appearance of a new anodic wave with $E_{1/2} = -438$ mV. However, as i_d for the AHQ approached zero the limiting current of the new anodic wave ceased increasing and then gradually decreased to zero with development of the green fluorescence, indicating a stepwise reaction.

For every 1-HOAHQ, the decrease of i_d for the AHQ in the presence of borate buffer was accompanied by simultaneous changes in the visible absorption spectrum (Table 2). These changes were only slight and did not result in any observed colour changes. For 1,5-diHOAHQ, a stepwise reaction was again evident since addition of borate buffer to an ethanolamine buffer solution of the AHQ resulted in an initial increase in absorption at 399 nm followed by a decrease in absorption at this wavelength.

Addition of 2 mol $K_3Fe(CN)_6$ per mol of 1-HOAHQ in the borate buffer caused immediate oxidation and disappearance of the new anodic wave. The only observed oxidation product within 10 s was the corresponding 1-HOAQ, detected by its characteristic cathodic wave and absorption spectrum.

For the 1-HOAQ in borate buffer, and for both the 1-HOAQ and 1-HOAHQ in ethanolamine buffer, graphs of log $(i_d - i)/i$ vs. E were linear, but the slopes, although all constant for a given compound, were usually larger than the 29.7 mV expected for an electrode process involving transfer of 2 electrons per molecule, which was indicative of semiquinone formation (8, 9). For the ethanolamine buffer solutions, $E_{1/2}$ was identical with E_0' determined by redox potentiometry. Similar logarithmic analysis of the new anodic waves for the 1-HOAHQ in borate buffer gave linear graphs but the slopes were quite variable ranging from 29 mV for 1,8-diHOAHQ up to 45 mV for 1-HOAHQ-6-SO_3Na. In all cases, observed limiting currents were found to be directly proportional to the initial concentration of the 1-HOAQ and to the square root of the effective mercury height above the dropping mercury electrode.

Previous polarographic studies (10) indicated that 2-HOAQ and 2-HOAHQ and derivatives do not interact with boric acid as described above, and a similar result was found for

TABLE 1. Polarographic data for 1-HOAQ (2.0×10^{-4} mol dm^{-3}) and 1,2-diHOAQ (1.0×10^{-3} mol dm^{-3}) derivatives in ethanolamine and borate buffer solutions (p*H* 9.55, 25°C)

1-NH_2AHQ-6-SO_3Na (Table 1). It was observed that 1-NH_2AHQ-6-SO_3Na is not stable at p*H* 9.55 and its i_d decreases slightly with increasing time to a lower steady value with simultaneous appearance of two new cathodic waves with $E_{1/2}$ of -1124 and -1285 mV. This behavior is typical of tautomerism of the AHQ to the corresponding 10-hydroxy-9-anthrone derivative (10, 11) and no new anodic wave at potentials below 680 mV was observed in the presence of boric acid.

The variation of i_d for the new anodic wave with change in p*H* was examined for one compound (Fig. 1) and the optimum p*H* for its formation was established as 7.5–9.5. The $E_{1/2}$ data also provided information on acidic dissociation constants.

The rate of decrease of i_d for 1-HOAHQ-4-SO_3H, in the presence of a large molar excess of boric acid – borate, was sufficiently low that it could be conveniently measured. Graphs of log i_d vs. time were linear. The preliminary pseudo first order rate constant increased with increasing concentration of borate buffer at constant p*H*

and decreased on increasing the p*H* of the borate buffer in the range 8.9–10.3, with the tentative conclusion that the rate is first order with respect to boric acid.

The polarographic behavior of the 1,2-diHOAQ in the ethanolamine buffer appears quite normal. In the borate buffer, the 1,2-diHOAQ exhibits two overlapping cathodic waves, but only a single anodic wave was observed after reduction and this had $E_{1/2}$ corresponding to the first cathodic wave for the AQ. For the 1,2-diHOAQ in both buffer solutions, the total limiting current is diffusion controlled and corresponds to the transfer of two electrons per molecule. The first of the two cathodic waves observed in borate buffer, however, has a pronounced positive temperature coefficient, while the second cathodic wave decreases slightly with increasing temperature.

A more detailed examination of the polarography of 1,2-diHOAQ-3-SO_3Na in the borate buffer established that the first of the two cathodic waves ($E_{1/2} = -652$ mV) was only present in concentrated borate buffer solutions (Table 3). Such solutions of 1,2-diHOAQ-3-SO_3Na are yellow-range, while solutions in the ethanolamine buffer are violet (Table 2). In the solution composed of 60% of the ethanolamine buffer mixed with 20% of the borate buffer, 1,2-diHOAQ-3-SO_3Na did not give an observable cathodic wave at $E_{1/2} = -655$ mV, even though visible absorption spectra showed 50% conversion of the violet AQ to the yellow-orange chelated borate ester, e.g. **2**. Reduction of the AQ in this solution, however, gave a single anodic wave at $E_{1/2} = -650$ mV. With a 10-fold molar excess of boric acid – borate present, the visible absorption spectrum of 1,2-diHOAQ-3-SO_3Na was essentially identical with that of an ethanolamine buffer solution of the AQ with boric acid absent, but after reduction to the AHQ the spectrum of the latter rapidly changed to that typical of the AHQ in the presence of excess borate buffer. This coincided with a decrease in i_d of the AHQ anodic wave at $E_{1/2} = -735$ mV and the simultaneous growth of the new anodic current at $E_{1/2} = -655$ mV.

Discussion

The decrease of i_d of the AHQ, and the simultaneous appearance of a new anodic wave at more positive potentials, occurs only for 1-HOAHQ in the presence of boric acid. The

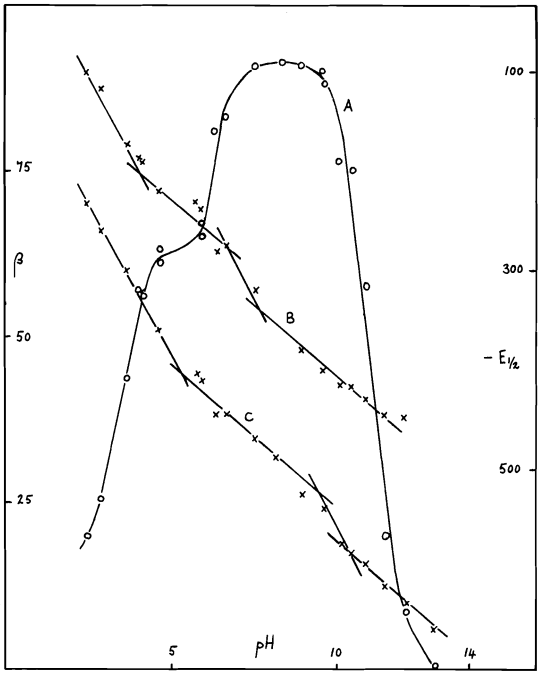

FIG. 1. Dependence of $E_{1/2}$ on pH for 1-HOAQ-6-SO_3Na (2.0×10^{-4} mol dm^{-3}) at 25°C (C) and the effects of pH on $E_{1/2}$ for the cyclic borate ester of 1-HOAHQ-6-SO_3Na (B) and upon the conversion (β) of 1-HOAHQ-6-SO_3Na to the ester (A) in the presence of boric acid – borate (2.0×10^{-3} mol dm^{-3}). $\beta = 100\ i_{ester}/i_{anodic}$.

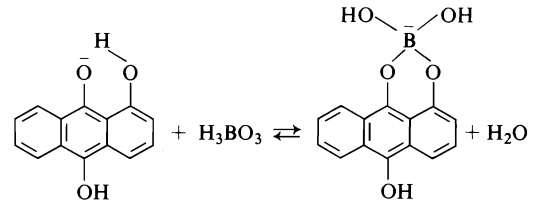
new wave most probably arises because of anodic oxidation of a chelated borate ester (reaction 1).



4 **5**

Chelated esters of *o*-diols are well-known but some involving peri-diols have been reported (12, 13). Polarographic and spectrophotometric examination of 1-HOAQ in the ethanolamine and borate buffers did not reveal any measureable interaction between the 1-HOAQ and boric acid. Borate esters of 1-HOAQ (e.g. **1**) are readily hydrolyzed in aqueous solution (4).

Reduction of a 1-HOAQ in the presence of excess borate buffer results in complete conversion of **4** into **5** and the observed changes in polarographic behavior of the 1-HOAHQ are quite specific for these compounds. The i_d of the new anodic wave is controlled by diffusion of **5** to the electrode surface but the electrode process is not polarographically reversible, possibly because the product of anodic oxidation of **5**, **1**, is rapidly hydrolyzed to the 1-HOAQ on the electrode surface.

Additional support for reaction 1 is provided by the observation of the analogous interaction of 1-HOAHQ-6-SO_3Na with benzene boronic acid, and by the obvious stepwise reaction of 1,5-diHOAHQ with boric acid, this being the only AHQ for which two rings involving boron could form. The observation of fluorescence towards completion of the reaction between boric acid and 1,5-diHOAHQ would be consistent with the rigid polycyclic structure of a dichelated ester.

In solutions containing equimolar boric acid, the formation of esters with a 1:2 boron: 1-HOAHQ ratio is possible, but no significant change in $E_{1/2}$ was observed.

The 1-NH_2AHQ-6-SO_3Na did not react with boric acid, in agreement with Böeseken's observations on *o*-aminophenols (14). There was also no indication of reaction of boric acid with reduced 1,4-diHOAQ. In strongly alkaline solution, the polarographic results for this compound seem quite normal, but at pH 9.5 1,4-diHOAHQ presumably exists as the tautomer 1,4-dioxo-1,2,3,4-tetrahydro-9,10-dihydroxyanthracene (15), which would account for the irregular behavior at this pH.

The variation of $E_{1/2}$ with changing pH for 1-HOAHQ-6-SO_3Na gave pK_a values of 5.2 and 10.2 for the AHQ and 9.4 for the AQ, these values being very similar to those found for 1-HOAHQ-4-SO_3H and 1-HOAQ-4-SO_3H (9). A pK_a of 5.33 for 1,8-dihydroxynaphthalene-3,6-disulfonate has been reported (16). Peri-diphenols exhibit enhanced acidity because of intramolecular hydrogen bonding, the non-hydrogen bonded proton at position 1 or 8 being most acidic.

Changes in slope in the plot of $E_{1/2}$ vs. pH for the chelated borate ester of 1-HOAHQ-6-SO_3Na (Fig. 1) must be considered with caution because of the polarographic irreversibility of the anodic oxidation process. These data did not give reliable pK_a values for the borate ester, which would have been valuable for interpretation of the dependence of the degree of chelate formation (β) on pH (Fig. 1). For 1-HOAHQ-6-

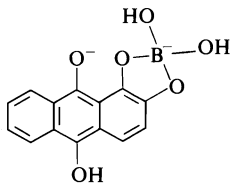
*% by volume.

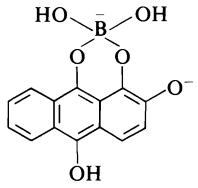
SO_3Na, optimum formation of **5** occurs at pH 7.0–8.5, where the maximum concentrations of **4** and boric acid exist. The decreased concentration of boric acid at pH > 9 must contribute to the decrease in β in alkaline solution. The stepwise decrease in β at pH < 7 must be a consequence of the acid–base equilibria of the reaction partners and products, or possibly of a noncyclic borate ester, which is a likely intermediate in the formation of **5**. Since β was determined using only a 10-fold molar excess of boric acid – borate, the values may be influenced by formation of chelate esters with a 2:1 AHQ:boron ratio.

Spectrophotometric measurements on the 1,2-diHOAQ showed that relatively high boric acid concentrations were required to give the chelated ester **2**. For 1-HOAHQ, total conversion to **5** was found at much lower boric acid concentrations. These results indicated that chelated esters such as **5** are formed more readily than **2**. An identical result was found for chelated esters of 1,8-dihydroxynaphthalene, when compared with those of 2,3-dihydroxynaphthalene (13, 16). The polarographic behavior of the 1,2-diHOAQ and 1,2-diHOAHQ can be interpreted in terms of the difference in stability of 1,2- (**6**) and 1,9-chelated borate esters (**7**) of 1,2-diHOAHQ. Reduction of **2** in the presence of boric acid results in preferential formation of **7** rather than **6** because in **7** the 1,9-oxygen atoms are closer together than the 1,2-oxygen atoms in **6**. The ester **7** is more stable as its formation involves less strain.

In the presence of a 10-fold molar excess of boric acid – borate, the 1,2-diHOAQ gave a single cathodic wave, with $E_{1/2}$ essentially identical to that in the ethanolamine buffer. On reduction, i_d for the 1,2-diHOAHQ rapidly decreased with simultaneous increase in the i_d for the anodic wave at more positive potentials, a process which proceeded to completion at boric acid concentrations insufficient to give detectable formation of **2**. The new anodic wave can be attributed to oxidation of **7** rather than **6**.



6



7

The occurrence of two cathodic waves on polarography of 1,2-diHOAQ at higher borate buffer concentrations can also be related to preferential formation of **7**. In such solutions, the 1,2-diHOAQ exist largely as **2**, but both species are polarographically active, being reduced to 1,2-diHOAHQ and **6**, respectively, with essentially identical $E_{1/2}$ values (−740 mV). At potentials corresponding to the foot of the first cathodic wave (−640 mV), the Nernst equilibrium concentration of 1,2-diHOAHQ at the electrode surface is very low, but, at high boric acid concentrations rapid conversion to **7** would disturb the redox equilibrium and result in further elec-

tron transfer to **2**. Thus, a significant current can arise at potentials more positive than anticipated. At lower boric acid concentrations, the rate of conversion of 1,2-diHOAHQ to **7** is insufficient to disturb the Nernst equilibrium. The pronounced positive temperature coefficient for the first cathodic wave indicates that its limiting current is controlled by a reaction rate. Although the exact pathway leading to **7** cannot be distinguished, the conversions **2** to 1,2-diHOAQ, **6** to 1,2-diHOAHQ or 1,2-diHOAHQ to **7** could be rate-controlling, assuming rapid electron transfer at the electrode surface. The $E_{1/2}$ of the first cathodic wave corresponds to that of the 1,2-diHOAHQ in borate buffer because of the redox equilibrium between **7** and its oxidation product. The situation is somewhat analogous to that where adsorption of the electrode product results in a polarographic wave at more positive potentials.

Experimental

The compounds examined were available from previous studies (18) or were commercial samples which were purified by chromatography on Al_2O_3 and recrystallization from ethanol and/or acetic acid. Solutions of the hygroscopic sulfonates were standardized by potentiometric titration of the AHQ with $K_3Fe(CN)_6$ solution.

Ethanolamine was dried by distillation of added benzene and purified by vacuum distillation. The buffer solutions were composed of 0.200 mol dm^{-3} ethanolamine/0.100 mol dm^{-3} HCl and of 0.078 mol dm^{-3} B_2O_3/0.100 mol dm^{-3} NaOH.

A known aliquot of the AQ solution was placed in the flat-bottomed, flanged reaction vessel, which was clamped to an aluminum plate fitted with sealed-in DME, salt bridge to the SCE, N_2 inlets and outlet for anaerobic operation, and burettes for N_2-saturated titrant solutions. The AQ were reduced by titration with freshly prepared, concentrated $Na_2S_2O_4$ solution in the appropriate buffer. HOAQ insoluble at p*H* 9.5 was dissolved in NaOH or NaOH–ethanolamine solution and, after reduction, the solutions were buffered to p*H* 9.5 by addition of B_2O_3 or HCl solution.

Polarograms were recorded on a Sargent Model XV1 polarograph at 25°C.

Effect of the hexadecapole moment on the translational vibrational absorption by carbon-dioxide-type crystals[1]

E. WHALLEY
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received February 14, 1977

E. WHALLEY. Can. J. Chem. **55**, 2953 (1977).

The effect of a hexadecapole moment on the absorption by the translational vibrations of carbon-dioxide-type crystals has been calculated. If the qudrupole and hexadecapole moments have the same sign the absorption is relatively insensitive to the hexadecapole moment and the hexadecapole moment may reduce the integrated absorptivity to a minimum of about 0.85 of the value for the quadrupole moment alone. If the moments have opposite signs, the absorptivity can be increased significantly by a hexadecapole moment of the expected magnitude.

E. WHALLEY. Can. J. Chem. **55**, 2953 (1977).

On a calculé l'effet d'un moment hexadécapolaire sur l'absorption par des vibrations de translation de cristaux de type dioxyde de carbone. Si les moments quadrupolaires et hexadécapolaires ont le même signe l'absorption est relativement insensible au moment hexadécapolaire; le moment hexadécapole peut réduire l'absorptivité intégrée vers une valeur minimale d'environ 0.85 de la valeur du moment quadrupolaire seul. Si les moments ont des signes opposés, il peut y avoir une augmentation importante de l'absorptivité par un moment hexadécapolaire de grandeur attendue.

[Traduit par le journal]

A part of the interaction between molecules at relatively large distances is frequently described as being due to the permanent electrostatic moments acting according to classical laws. The electric field of dipole and successively higher moments decreases with increasing distance r from the molecule by the factors r^3, r^4, r^5, etc. Most observable effects are due either to the square of the field, when the observed effects should decrease by the factors r^6, r^8, r^{10}, etc., or to the square of the field gradient, when the effects should decrease by the factors r^8, r^{10}, r^{12}, etc. A particularly elegant way of studying this interaction is to measure the intensity of absorption of electromagnetic radiation by the translational vibrations of the molecules. For some crystals, such as those having the carbon-dioxide or halogen structures, symmetry requires that only the non-spherical part of the intermolecular interaction can contribute to the intensity, and so it can be studied in isolation.

Schnepp (1) has worked out the theory for the infrared intensity of crystals having the carbon-dioxide structure assuming that the quadrupole moment dominates, and it seems to agree reasonably well with experimental measurements on carbon dioxide (2, 3), although the experimental absorption intensity of solid nitrogen (4) is about one quarter of the calculated value, perhaps (4) because the large vibrational motion reduces the effective quadrupole moment. The theory is not adequate for all molecular crystals; for example, the absorption intensity of crystalline chlorine is (5) about 94 times that calculated by the theory adapted to the halogen structure.[2] This paper is concerned only with the crystals for which the multipole moment theory is an adequate approximation.

It is not clear that the multipole expansion converges rapidly at the intermolecular distances in the crystals, as the following arguments show. For approximate purposes, the charge distribution in a linear molecule like carbon dioxide can be represented by two equal and opposite point dipoles of moment μ, counted as positive if the positive end is on the inside, situated on the axis, and parallel to it a distance a from the center of the molecule. The nth moment of charge for such a distribution, when n is even, is characterized by the quantity $-2na^{n-1}\mu$. The integrated infrared intensity due to the nth even

[1]NRCC No. 16002.

[2]The calculations in this paper were made with the inaccurate published quadrupole moment of chlorine. A corrected value (6) results in the experimental integrated absorption intensity being 94 times greater instead of the published 35 times.

TABLE 1. Field derivatives (1) for carbon-dioxide-type crystals due to hexadecapole moments[a]

$$\frac{\partial E_x^i(p,q)}{\partial x(p,q)} = -\frac{H}{8r^7}(1365d_1^2d_3'^4 - 2520d_1d_3'^3l_1 - 315d_3'^4 - 90d_1^2d_3'^2 + 420d_3'^2l_1^2 + 840d_1d_3'l_1 - 75d_1^2 + 210d_3'^2 - 60l_1^2 - 15)_{p,q}$$

$$\frac{\partial E_y^i(p,q)}{\partial x(p,q)} = \frac{\partial E_z^i(p,q)}{\partial x(p,q)} = -\frac{H}{8r^7}(1365d_1d_2d_3'^4 - 1260d_1d_3'^3l_2 - 1260d_2d_3'^2l_1 - 90d_1d_2d_3'^2 + 420d_3'^2l_1l_2 + 420d_1d_3'l_2 + 420d_2d_3'l_1 - 75d_1d_2 - 60l_1l_2)_{p,q}$$

[a] r is the nearest-neighbor distance and the other symbols are defined by Schnepp (1).

moment is (1) $4n^2a^{2(n+1)}\mu^2/r^{2(n+2)}$ where r is the intermolecular distance, apart from an angular factor of the order unity and the product of some fundamental parameters. The ratio of the intensities due to, say, the quadrupole and hexadecapole moments, without the angular factor, is $4(a/r)^4$. An intermolecular distance is typically twice an intramolecular distance, and so this ratio is about $\frac{1}{4}$. The effects of quadrupole and hexadecapole moments may therefore be of the same magnitude. Furthermore, because the fields due to quadrupole and hexadecapole moments on the same molecule interfere destructively in some regions of space and constructively in others, it is not clear whether the effect of adding a hexadecapole moment is to increase or decrease the absorptivity from that of a quadrupole alone.

To determine if the hexadecapole moment of carbon dioxide and related molecules contributes significantly to the absorption intensity it is therefore necessary to work out the theory. This has been done following Schnepp's (1) procedure for the effect of the quadrupole moment. The derivatives of the field at the center of a molecule, due to the hexadecapole moment H of a linear neighboring molecule, with respect to the displacement of the molecule, are given in Table 1. The symmetry coordinates for the infrared-active vibrations of carbon-dioxide-type crystals are (7)

$$S_4(T_u) = \tfrac{1}{2}(x_1 - x_2 + x_3 - x_4)$$

$$S_7(T_u) = \tfrac{1}{2}(x_1 - x_2 - x_3 + x_4)$$

where x_q is the x cartesian displacement of molecule q, and molecules 1, 2, 3, and 4 are on the sites 000, $\frac{1}{2}\frac{1}{2}0$, $0\frac{1}{2}\frac{1}{2}$, and $\frac{1}{2}0\frac{1}{2}$. The derivatives of the fields at the centers of the molecules q are listed in Table 2, and the sums of the derivatives caused by the quadrupole (1) and hexadecapole moments are listed in Table 3.

If the moments have the same sign, the contributions of the quadrupole and hexadecapole moments to the field derivatives $\partial E_y/\partial S_4$ have opposite signs, and the contributions to $\partial E_z/\partial S_4$ and $\partial E_y/\partial S_7$ have the same sign. If the relatively small effect of the anisotropy of the polarizability is neglected, the integrated intensity A of the two bands is

$$[1]\quad A \propto 308160^2 + 286511H^2/r^4 - 733870H/r^2$$

where r is the nearest-neighbor distance. For a given θ, this expression has a minimum value as a function of H at

$$H/r^2 = 0.128070\theta$$

and the minimum value is $26\ 112\theta^2$ or 0.8475 of the absorption with zero hexadecapole moment. The experimental intensity for nitrogen is about one fourth of the calculated intensity (1, 4) and it appears that the effect of the hexadecapole moment cannot lower the absorption enough to account for more than a small fraction of the discrepancy. The integrated intensity is within 15% of the value for zero hexadecapole moment if $H/\theta r^2$ is between -0.27369 and $+0.78597$.

The intensity of absorption due to the quadrupole moment of a molecule with an insignificant hexadecapole, and that due to the hexadecapole moment of a molecule with an insignificant quadrupole, are equal, if the distance r is the same in both cases, when

$$H/\theta r^2 = 0.32795$$

A typical intermolecular distance in a crystal of small molecules is 4 Å, and then a pure hexadecapolar molecule having a moment of 5.25×10^{-42} esu cm^4 would have the same absorption intensity as a pure quadrupolar molecule having a moment of 10^{-26} esu cm^2. If the same molecule has a hexadecapole moment between -4.4 and 12.6×10^{-42} esu cm^4 its absorption intensity would be within 15% of that of the quadrupole acting alone.

The quadrupole moment of nitrogen is (8) -1.4×10^{-26} esu cm^2 and the hexadecapole

$\frac{\partial E_z^q}{\partial S_7}$	0	0	0	0

moment is (9) about $\pm 3 \times 10^{-42}$ esu cm^2. If these acted independently, the hexadecapole would cause an absorption intensity of 0.1656 of the quadrupole, but if the two moments have the same sign the intensity due to the combined moments is 0.8454 of that of the quadrupole alone, which is nearly the smallest possible, and if they have the opposite sign, the absorptivity is 1.486 of the quadrupole acting alone. The quadrupole moment of carbon dioxide is -4.1×10^{-26} esu cm^2, and if the charge distribution is represented by two point dipoles located on the oxygen atoms the hexadecapole moment is $2a^2\theta$ where a is the C=O distance. The estimated hexadecapole moment is therefore -14×10^{-42} esu cm^4. The intensity of the combined quadrupole and hexadecapole moments is then 0.922 of that of the quadrupole alone. If the hexadecapole moment were 14×10^{-42} esu cm^4, the intensity would be about twice as high. An

accurate measurement of the intensity should therefore determine the sign of the hexadecapole moment if the effective quadrupole moment (4) were known.

The principal conclusions of this note are: (*1*) The hexadecapole moments of molecules like nitrogen and carbon dioxide contribute significantly to the fluctuation of the electric fields at the molecular centers in the crystal, but if the quadrupole and hexadecapole moments have the same sign, interference of the fields can reduce the absorption intensity of the translational vibrations to about 85% of that due to the quadrupole alone. The hexadecapole moment cannot therefore explain the difference between the experimental and theoretical absorption intensity of crystalline nitrogen. (*2*) Accurate infrared intensity measurements should allow the hexadecapole moment to be determined if $H/\theta r^2$ is significantly less than about -0.3 or greater than about 0.8.

ESCA investigations of Group IV derivatives. Part III. Binding energies for methyl substituted disilyl and digermyl chalcogenide series

JOHN E. DRAKE, CHRIS RIDDLE, H. ERNEST HENDERSON, AND BORIS GLAVINČEVSKI

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received February 3, 1977

JOHN E. DRAKE, CHRIS RIDDLE, H. ERNEST HENDERSON, and BORIS GLAVINČEVSKI. Can. J. Chem. **55**, 2957 (1977).

Core-level binding energies of all atoms are reported for the methyl substituted disilyl and digermyl chalcogenides, $(Me_nMH_{3-n})_2E$; where M = Si, Ge; E = O, S, Se, Te; n = 0, 1, 2, 3. Binding energies are also reported for the dimethyl series Me_2E; where E = O, S, Se, Te; for the hydrides H_2E; where E = O, S, Se; and for the methylhydrides MeEH; where E = O, S. Binding energy trends throughout these closely related series of compounds are discussed. The similarity of atomic charge patterns, deduced from the binding energies, for all molecules of a given silicon or germanium series are consistent with their ability to redistribute charge. The bonding mechanisms that make this possible are assessed.

JOHN E. DRAKE, CHRIS RIDDLE, H. ERNEST HENDERSON et BORIS GLAVINČEVSKI. Can. J. Chem. **55**, 2957 (1977).

On rapporte les énergies des liaisons au niveau du noyau de tous les atomes pour les chalcogénicides de disilyl et de digermyl substitués par des méthyles, $(Me_nMH_{3-n})_2E$; où M = Si, Ge; E = O, S, Se, Te; n = 0, 1, 2, 3. On rapporte aussi les énergies de liaisons pour les séries diméthyles Me_2E; où E = O, S, Se, Te; pour les hydrures H_2E où E = O, S, Se; et pour les méthylhydrures MeEH; où E = O, S. On discute des tendances des énergies des liaisons à travers toutes ces séries de composés extrêmement reliés. La similarité dans les répartitions des charges atomiques, déduite des énergies de liaison pour toutes ces molécules d'une série donnée de silicium ou de germanium, est en accord avec leur habilité à redistribuer les charges. On évalue les mécanismes de liaison qui rendent ces propriétés possible.

[Traduit par le journal]

Introduction

In earlier publications (1, 2) we reported core-level binding energies for various halogeno(methyl)-germanes and -silanes. Few ESCA studies of related Group VI B derivatives have appeared in the literature. Van Wazer *et al.* (3) reported silicon 2*p* level binding energies of several silicon–oxygen containing species and of the polymeric sulfide $(SiS_2)_\infty$; all recorded with solid or liquid samples. Their work was extended to similar derivatives of other Group IV B elements (4). Unfortunately, correlations between data collected from condensed phase samples are liable to be poor. Perry and Jolly have made extensive correlations between vapor-phase determined binding energies and calculated charge (5). In discussing the importance of *d*-orbital participation they concluded that "the data offer little support for the participation of *d*-orbitals in the bonding of silicon and germanium compounds" (6). Although they mainly reported binding energies for simple hydrides and halides, two Group VI derivatives, Me_2O and $(SiH_3)_2O$, were included (5, 6).

A communication by Pignataro *et al.* (7) reported sulfur $2p^{3/2}$ binding energies for a series of compounds C_6H_5—S—MMe_3 (M = C, Si, Ge, Sn, Pb). These were compared with the ^{13}C nmr chemical shifts of the ring carbon attached to sulfur. The authors concluded that the concept of ($p \rightarrow d$) π-bonding, from sulfur to the metal, M, is supported because the ionization energy of the sulfur $2p^{3/2}$ level increases along the series Si < Ge < Sn < Pb. However, the value of the binding energy of sulfur for C_6H_5—S—CMe_3 falls between those of the germanium and tin derivatives.

The hydrides $(MH_3)_2E$ (M = C, Si, Ge; E = O, S, Se, Te) have been the subject of a PES study (8) which assigned the observed bands to expected valence shell levels and concluded that the results were consistent with the existence of ($p \rightarrow d$) π-bonding for all compounds where M = Si or Ge. Glidewell (9) reconsidered these data, taking into account that the ionization energies for the lone-pairs of the Group VI B atoms increase in the order $(CH_3)_2E > (GeH_3)_2E > (SiH_3)_2E$. This leads him to conclude that the

SiH_3 and GeH_3 groups are not electron acceptors by means of ($p \rightarrow d$) π-interactions but are, in fact, net electron donors, relative to hydrogen. He suggested that a π-perturbation, caused by mixing of the $p\pi$ lone-pair orbital of M with another, more tightly bound, orbital of π-symmetry, is operative.

Bock *et al.* have published the results of extensive molecular orbital calculations assigning the PES of the two series $(CH_3)_n$—E—$(SiH_3)_{2-n}$; where n = 2, 1, 0 and E = O (10) and S (11). For the ether series they concluded that conformational changes are surprisingly important and that the bond-angle widening on substitution of silyl groups "may as much be a mechanism to relieve coulombic repulsions ... as it is partially a result of oxygen–silicon $p\pi$–$d\pi$ interaction" (10). For the sulfide series, they conclude that ($p \rightarrow d$) π-interactions from sulfur to silicon play a significant role in increasing the binding-energy of the sulfur "lone-pair" in the $2b_1$ molecular orbital; also the concentration of localized charge in the sulfides is far less critical than in the ethers (11).

With this limited background of ESCA and related studies, we decided to investigate a large number of silicon and germanium derivatives of Group VI B. As in our previous work (1, 2) we have measured core-level binding energies of *all* atoms in closely related series of compounds. In this way we can study the changes in binding energy and thence in charge throughout each molecule, as stepwise substitutions of atoms or groups occur. The series reported in this paper are the methyl substituted disilyl and digermyl chalcogenides, $(Me_nMH_{3-n})_2E$; where M = Si or Ge; E = O, S, Se, Te; n = 0, 1, 2, 3. Binding energies are also reported for the dimethyl series Me_2E; where E = O, S, Se, Te; for the hydrides H_2E; where E = O, S, Se; and for the methyl hydrides MeEH; where E = O, S.

Results and Discussion

Table 1 gives a complete listing of the binding energies observed in this work. The previously reported values for H_2O, MeOH, H_2S (12) and for Me_2O and $(SiH_3)_2O$ (5, 6) agree well with our values, allowing for minor calibration differences.

The quality of the peaks observed was dependent upon the stability of the samples under the instrumental operating conditions. All the tellurides had a tendency to decompose in the instrument and frequent cleaning of the system was necessary. Peak quality suffered slightly, due to the count rates being reduced. It is possible, however, that some of the minor anomalies in the data result from the effects of sample decomposition. Digermyl ether is known to be of low stability (13) and we were only able to obtain a weak spectrum, unsuitable for computer treatment, but of sufficient intensity to be able to fix the peak positions to ± 0.2 eV.

The most striking feature of the binding energy data is the *lack* of any substantial shifts. Intuitively, large differences might be expected between binding energies of oxygen compounds and those of the other Group VI B elements; or at least consistent trends along the series. Such is not generally the case.

Consider first the carbon 1*s* levels. Although it is true that in these levels the least change might be expected; along any series the value of the C 1*s* binding energy hardly varies, regardless of the nature of E. For example, in the series $(Me_3Ge)_2E$ the C 1*s* values are: 289.79 (E = O); 289.81 (S); 289.82 (Se); 289.84 eV (Te). A few individual values do vary within some series. For example, the sulfur compound has a value *ca.* 0.15 eV higher ($\Delta = +0.15$ eV) than the mean in the $(MeSiH_2)_2E$ series; the oxygen compound has $\Delta = -0.13$ for the $(Me_3Si)_2E$ series and $\Delta = +0.23$ for the $(Me_2GeH)_2E$ series. The few exceptions are random and could result from aberrations in the experimental determinations. Thus, the postulate that the R_3Ge— and R_3Si— groups (R = Me or H) behave as invariant moieties regardless of whether they are attached to oxygen, sulfur, selenium, or tellurium is generally upheld. Any changes in partial charges with a change in the central atom should therefore be most noticeable in the changing binding energies of the M and E atoms that are involved in mutual bonding. (The slight general increase in the value of the C 1*s* level as H atoms replace methyl groups in the R_3M moieties is possibly the result of changes in relaxation effects. In our studies on Me_3MX (X = Cl, Br, I) compounds (1) we noted a small but consistently higher value for corresponding C 1*s* levels when M = Ge compared with M = Si. In these Group VI B series, of the twelve possible corresponding pairs of compounds, the germanium compound has the higher C 1*s* value in all *four* $(Me_3M)_2E$ pairs of compounds, in three of the $(Me_2MH)_2E$ pairs, but only in *one* of the $(MeMH_2)_2E$ pairs.

TABLE 1. Observed binding energies of Group VI B derivatives

General formula	Core level*	E

	E	536.02	167.84	60.07	46.07

*The core levels observed and their average widths (eV) at half maximum height are: Si 2*p* (1.52), Ge 3*d* (1.53), C 1*s* (1.26), O 1*s* (1.21), S $2p^{3/2}$ (1.04), Se 3*d* (1.68), and Te 4*d* (1.35).
†These values compare with the following reported in Siegbahn *et al.* (10): H_2O, O 1*s* 539.7; MeOH, C 1*s* 292.3, O 1*s* 538.9; H_2S, S $2p^{3/2}$ 170.2.
‡These values compare with the following reported by Perry and Jolly (5, 6) and referenced to Ar $2p^{3/2}$ at 248.46 eV: Me_2O, C 1*s* 292.14, O 1*s* 538.86; $(SiH_3)_2O$, Si $2p^{3/2}$ 107.68, O 1*s* 538.46.

This could be related to the changes noted above on the introduction of H atoms into the R_3M moiety.)

In the Me_2E series the C *1s* binding energies are close for E = S, Se, Te but for E = O a considerably higher value results $\Delta = +1.5$ eV. A large shift, $\Delta = +1.0$ eV, occurs between MeOH and MeSH also. This is discussed later.

We next consider the silicon 2*p* and germanium 3*d* binding energies. Again, along a series, there is no dramatic change or general trend. All sixteen silicon values are contained within a 1.2 eV spread and all the germanium values are within a 1.4 eV spread. Thus for the $(Me_3Si)_2E$ series the experimental value for Si 2*p* is constant for E = O, S, and Se and rises for E = Te, whereas for the $(MeSiH_2)_2E$ series it is lowest for E = Te. The normal expectation, based on the relative Pauling electronegativities of O, S, Se, and Te would be for the silicon or germanium atoms to be relatively the most positive when attached to oxygen and therefore to have the highest binding energy for the $(R_3M)_2O$ species with a fairly regular decrease along the series $(R_3M)_2O \gg (R_3M)_2S > (R_3M)_2Se > (R_3M)_2Te$. Clearly the relative electron-withdrawing powers of the Group VI B elements are being equalized by some mechanism. Our studies on the halogeno(methyl)-silanes and -germanes also led to the conclusion that the halogens (Cl, Br, and I) all 'behave' as though they had similar electronegativities. On the basis of simple charge calculations, we rationalized that this comes about by the halogen *s*-orbitals being utilized to

varying degrees in the bonding between the halogen and the Group IV B element. Indeed, if the *s*-orbital participation is only *ca.* 5% greater for Cl than for Br and a further 3-5% greater for Br than for I, then the similarity of binding energies of the Me_nMX_{3-n} series can be explained (1, 2). It seems reasonable to assume a similar argument applies to the Group VI B elements. The increase in *s*-character would not be so large as to require a dramatic increase in the M—E—M angle, although it would require an angle greater than 90°. For example, the introduction of 10% *s*-character requires an increase in angle from 90 to 96°, which is approximately the angle at S or Se where known (12).

The same mechanism cannot be used for the $(R_3M)_2O$ compounds. It is well established (12) that the M—O—M bond angles are appreciably *larger* than the corresponding M—E—M angles (E = S, Se, Te). This wide angle requires an even larger involvement of the *s*-orbital of oxygen and hence a much higher binding energy is expected for the silicon and germanium atoms. However, bond angles of 120° and more are those required to maximize $(p \rightarrow d)$ π-bonding (10, 11, 14, 15). Where this is extensive, a significant redistribution of charge back from oxygen to silicon and germanium is expected, thus reducing the electropositive nature of the atoms and hence the value of their binding energies; exactly the situation that we have here. The fact that the binding energies are so close is possibly fortuitous because relaxation effects have been ignored. Nonetheless, a model that suggests that there are varying degrees of small *s*-orbital participation by S, Se, and Te to make the binding energies similar in $(R_3M)_2E$ compounds, without invoking *d*-orbital participation, is consistent with the observations. However, for $(R_3M)_2O$ species, where *s*-orbital participation must be large, the occurrence of $(p \rightarrow d)$ π-bonding appears to be the most logical rationalization. In the compounds MeOH and Me_2O, where $(p \rightarrow d)$ π-bonding cannot occur, there are indeed considerable binding energy shifts, the carbon atom being considerably more electropositive in the oxides than in the sulfides, selenides, or tellurides.

Finally, we examine the binding energies of the central atoms themselves. With three exceptions, $(MH_3)_2S$, $(Me_3M)_2S$, and $(Me_3M)_2Te$), all of the silicon compounds have higher binding energies for the core-level of the Group VI B elements than do the germanium analogues. In this respect the results parallel those found for the lone-pair orbitals in the two series $(SiH_3)_2E$ and $(GeH_3)_2E$ (E = O, S, Se) (5). Within the silicon and germanium compounds, as hydrogen atoms successively substitute for methyl groups, within the R_3M moieties, there is a corresponding general increase in the binding energies of all levels measured. Such changes could be the result of relaxation effects, however, the changes are as predicted if it is assumed that the hydrogen atom is 'behaving' as a weakly electronegative halogen atom. This is not unreasonable as the Si—H and Ge—H bonds are polarized with $H^{\delta-}$ (16). Thus the successive introduction of the more electronegative hydrogen atom increases all the binding energies within the molecule. For example, the binding energy increases in the $(R_3Si)_2O$ column as R = Me → H are: Δ O $1s = +1.07$; Δ Si $2p = +1.22$; and Δ C $1s = +0.70$ eV. With few exceptions, all columns show the same trend. This is exactly as we found for the Me_nGeX_{4-n} (X = Cl, Br, I) series (1, 2).

The collected data do not allow a definitive analysis of bonding mechanisms in the Group VI B compounds. Assuming that the changes in binding energy reflect the *overall* changes in charge distribution that result from a variety of competing 'mechanisms', such as $(p \rightarrow d)$ π-bonding, varying *s*-orbital participation, and inductive effects, then only the dominant mechanism, and not the relative importance of competing mechanisms, will be reflected in the data.

Experimental

Core-electron binding energies were determined on a McPherson ESCA-36 photoelectron spectrometer using magnesium K_α X-radiation (1253.6 eV) for photoelectron excitation. Samples were introduced in the vapor phase at pressures close to 5×10^{-5} Torr. Argon gas was bled in to form 20% of the total sample. Binding energies in excess of 120 eV were referenced to the argon $2p^{3/2}$ level at 248.63 eV (17). All other binding energies were referenced indirectly, via Ar $2p^{3/2}$, to the neon 2*s* level at 48.47 eV (17).

Details of the data accumulation procedures adopted and of the curve-fitting program used to compute the binding energies are given in Part I (1). The reproducibility from separate runs was such that binding energies are quoted to ± 0.05 eV for C 1*s*, Si 2*p*, O 1*s*, and S $2p^{3/2}$ and to ± 0.10 eV for Ge 3*d*, Se 3*d*, and Te 4*d*.

The observed binding energies are listed in Table 1.

Materials

Hexamethyldisiloxane and hexamethyldisilthiane were obtained commercially (Petrarch Systems) as were dimethyl ether (Matheson Gas Products), dimethyl sulfide,

methanol, methanethiol (Aldrich Chemical Co.), dimethyl selenide, and dimethyl telluride (Research Organic/Inorganic Chemical Corp.). Hydrogen sulfide, hydrogen selenide, and hydrogen telluride were prepared by hydrolysis of the corresponding aluminum compound, Al_2E_3 (E = S, Se, Te) (18, 19). The remaining methyl substituted disilyl and digermyl chalcogenides, $(Me_nMH_{3-n})_2E$ (M = Si, Ge; E = O, S, Si, Te; n = 0, 1, 2, 3) were prepared *either* by reaction of the corresponding silyl or germyl halide with a solution of the requisite lithium salt, Li_2E (20–23), *or* by cleavage of the corresponding bismethylgermanium carbodiimide with the appropriate Group VI hydride, H_2E (21, 24, 25).

All samples were distilled on the vacuum line and their purity checked by ir, Raman, and nmr spectroscopy. Where appropriate, vapor pressure determinations were also made.

Liquid-junction potentials in ethylenediamine: Attempted calculations and evaluations using concentration cells

SURAJ P. MAKHIJA[1]

Department of Chemistry, Indiana University, Bloomington, IN, U.S.A. 47401

Received December 17, 1976

SURAJ P. MAKHIJA. Can. J. Chem. **55**, 2962 (1977).

Concentration cells of the type M(Hg)|MX(1)||MX(2)|M(Hg), where M(Hg) is potassium amalgam or sodium amalgam, were investigated with three electrolytes, potassium bromide, potassium iodide, and sodium iodide. An attempt was made to determine the necessity and magnitude of liquid-junction potential corrections. Only in the case of sodium iodide are the ionic mobilities of cation and anion quite different in ethylenediamine, and liquid-junction potential corrections are necessary to obtain agreement between observed and calculated data. The limiting equations of Nernst and of Lewis and Sargent were found to be appropriate for calculating liquid-junction potentials in ethylenediamine, provided that calculated activities were used in these equations.

SURAJ P. MAKHIJA. Can. J. Chem. **55**, 2962 (1977).

On a étudié, à l'aide des trois électrolytes, bromure de potassium, iodure de potassium et iodure de sodium, des cellules de concentration de types M(Hg)|MX(1)||MX(2)|M(Hg), où M(Hg) est un amalgame de potassium ou de sodium. On a effectué des essais pour déterminer la nécessité et l'amplitude des corrections pour les potentiels de jonction-liquide. Il n'y a que dans le cas de l'iodure de sodium où les mobilités ioniques du cation et de l'anion sont très différentes dans l'éthylènediamine et où des corrections de potentiel de jonction-liquide sont nécessaires pour obtenir une bonne concordance entre les valeurs observées et les valeurs calculées. On a trouvé que les équations limites de Nernst et de Lewis et Sargent sont appropriées pour calculer les potentiels de jonction-liquide dans l'éthylènediamine à condition que l'on utilise une activité calculée dans ces équations.

Introduction

Whenever solutions containing various electrolytes are brought into contact a potential develops at the interface. This potential is known as liquid-junction potential, E_j, and develops due to mobilities of various ions across the interface. There are three types of liquid junctions. The simplest of all involves the same electrolyte at different activities, such as 0.1 *M* NaBr|0.01 *M* NaBr. Both sodium and bromide ions diffuse from more concentrated to less concentrated solution with a driving force proportional to the concentration gradient: the sign and magnitude of E_j are independent of which ion of the salt is involved in the electrode reaction.

This type of liquid-junction potential is approximated by an equation due to Nernst

$$[1] \qquad E_j = (1 - 2t^-)\frac{RT}{F}\frac{(M^+)_1}{(M^+)_2}$$

where t^- is the transference number of the anion, $(M^+)_1$ and $(M^+)_2$ are the activities of the cation in the two solutions, and the other terms have their usual meanings. It is obvious from the above equation that $E_j = 0$ if $t^- = 0.5$.

Various concentration cells of the type

M(Hg)|MX(I)||MX (2)|M(Hg)

were studied and an attempt was made to estimate the necessity and magnitude of corrections for liquid-junction potentials in non-aqueous solvents. Three electrolytes, KBr, KI, and NaI, were investigated.

The overall potential of a concentration cell is the difference between the potentials of the two electrodes, i.e.,

$$E_1 = E_{m+m(Hg)} + \frac{RT}{nF}\ln (M^+)_1$$

and

$$E_2 = E_{m+m(Hg)} + \frac{RT}{nF}\ln (M^+)_2$$

Therefore

$$[2] \quad E_{cell} = E_1 - E_2 = \frac{RT}{nF}\ln\frac{(M^+)_1}{(M^+)_2} - E_j$$

[1]Present address: Department of Chemistry, Alabama State University, Montgomery, AL, U.S.A. 36101.

The potential of the concentration cell is thus seen to be independent of the standard potentials of the electrodes, but to depend upon the ratio of the activities of metal ion in the two solutions and the liquid-junction potential.

In this study, an attempt was made to test out theories for the calculation of activities and liquid-junction potentials. If the exact expressions (1) for ionic activities are substituted into eq. 2, we get

$$[3]\quad E_{obs} = E_{cell} - E_j = E_1 - E_2 - E_j = \frac{RT}{nF} \times \ln \frac{(1 + 4\sum_{MX(1)} K_{mx} f_i^2)^{1/2} - 1}{(1 + 4\sum_{MX(2)} K_{mx} f_i^2)^{1/2} - 1} \times \frac{f_{i(2)}}{f_{i(1)}} - E_j$$

in which $\sum_{MX}$ is the stoichiometric concentration of 1:1 electrolyte, f_i is the activity coefficient, and K_{mx} is the ion-pair association constant. Conductance studies (2) have shown that the cations and anions of KBr and KI have approximately equal ionic mobilities in ethylenediamine, while NaI has a cation and anion with appreciably different mobilities. If the theories for liquid-junction potentials are correct, then only sodium iodide among the above three electrolytes should require liquid-junction potential corrections in order to obtain a reasonable fit of the experimental data to theoretically calculated curves.

As the system

$$M(Hg)|MX\ (1)||MX\ (2)|M(Hg)$$

involves only the simple type liquid-junction potential, the corrections were made using eq. 1. Since $t^+ \simeq t^-$ for K^+, Br^-, and I^- ions and t^+ and $t^- = 1$, eq. 1 shows that the E_j correction will approach zero for solutions containing KBr or KI. In case of Na^+ and I^-, however, $t^+ < t^-$ and the E_j corrections become significant.

Experimental

Material

Commercially available 98–100% ethylenediamine was doubly distilled from calcium hydride under reduced pressure in an atmosphere of purified nitrogen and was stored in a glass stoppered bottle. All alkali metal halides were of analytical reagent grade quality and were dried for 6 to 8 h in a vacuum at approximately 100°C. Sodium amalgam and potassium amalgam (both two-phase) were prepared by electrolyzing 5% solutions of NaOH or KOH in methanol with a mercury pool as cathode and a platinum wire as anode. Excess hydroxides were washed with methanol.

The dissolution of alkali metal halides was hastened by grinding the salts finely and using a rotatory disk for continuous shaking of the solution.

The reference electrodes were prepared by adding an ethylenediamine solution containing a fixed concentration of the alkali metal halide into compartments of the demountable H-shaped cell which also contained the two-phase alkali metal amalgam.

Instruments and Cells

An H-shaped cell of the following type was used for carrying out the experimental work.

M(Hg), MX(*i*)	MX	MX	MX(*ii*), M(Hg)
Reference	Salt bridge 1	Salt bridge 2	Indicating compartment

In the above cell, M refers to potassium or sodium and X to bromide or iodide. MX(*i*) denotes the potassium or sodium salt solution having a constant concentration while MX(*ii*) refers to the solution with varying con-

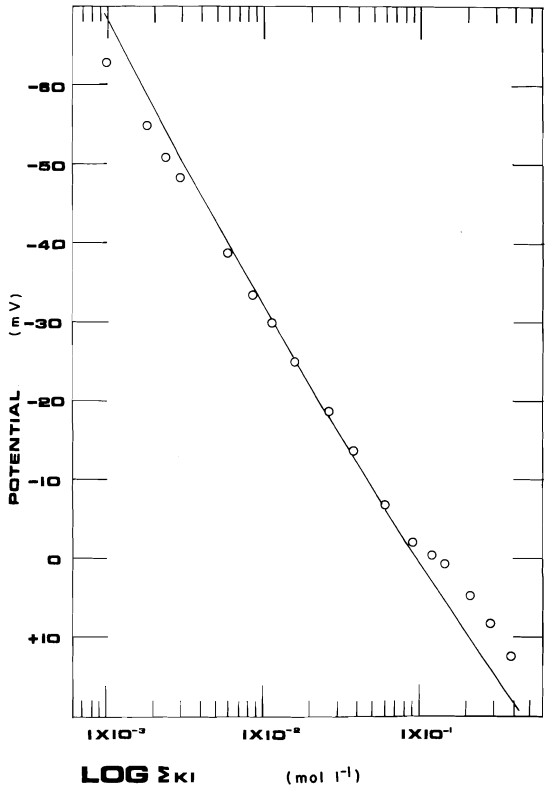

FIG. 1. Plot of potential (mV) of concentration cell K(Hg)|KI(1)||KI(2)|K(Hg) as a function of log Σ_{KI}. Open circles: experiment; solid line: potentials calculated with eq. 3.

centration of MX. Contact to the metal amalgam in the reference and indication electrode compartments were made by fusing a platinum wire through the glass at the bottom of each compartment

The indicating electrode and reference electrode were separated by two salt bridges, one of which (S.B.1) contained a standard solution of alkali metal halide in ethylenediamine and the other of which (S.B.2) contained the same stoichiometric concentration of alkali metal halide as the indicating electrode. The concentrations of the alkali metal halide in salt bridge 2 and in the indicating electrode compartment were changed simultaneously and equally by adding appropriate amounts of a concentrated solution of MX to both compartments with a buret. Two bridges containing MX were introduced in order to avoid any direct mixing of the solutions in the reference and indicating electrode compartments. Dry, prepurified nitrogen gas was bubbled through the indicating compartment to achieve good mixing and to remove any oxygen which might have been dissolved.

A null-type Rubicon potentiometer was used to measure all the potentials. A Honeywell high-gain electronic null-indicator, Model No. 104 WIG, was used with the potentiometer.

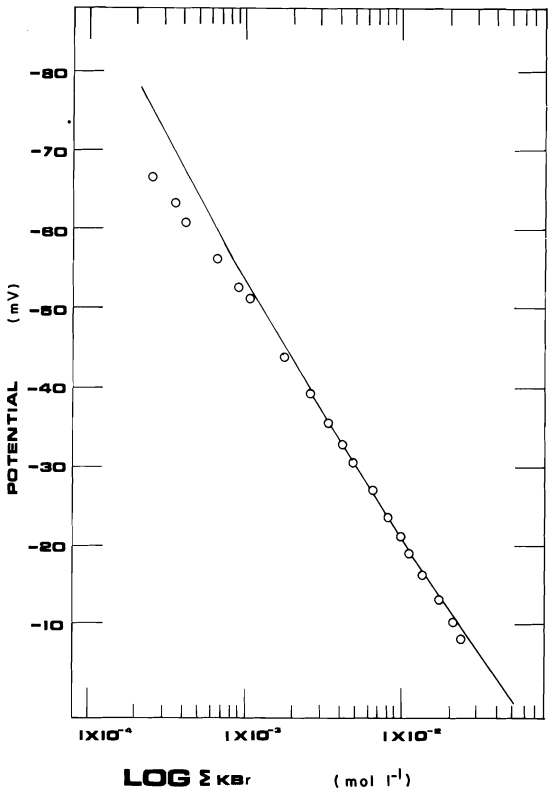

FIG. 2. Plot of potential (mV) of concentration cell K(Hg)|KBr(1)||KBr(2)|K(Hg) as a function of log Σ_{KBr}. Open circles: experiment; solid line: potential calculated with eq. 3.

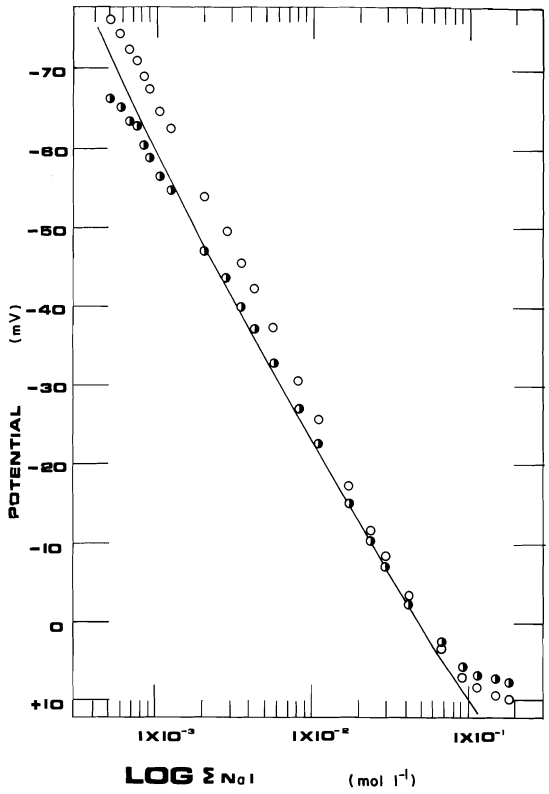

FIG. 3. Plot of potential (mV) of concentration cell Na(Hg)|NaI(1)||NaI(2)|Na(Hg) as a function of log Σ_{NaI}. Open circles: experimentally observed potentials; half-shaded circles: experiment corrected for liquid-junction potentials; solid line: potential calculated with eq. 3.

Results and Discussion

The potentials obtained with KI, KBr, and NaI were measured over a wide range of concentration.[2] Theoretical potentials, E_{calc}, are shown as solid lines in Figs. 1, 2, and 3 and were calculated as a function of electrolyte concentrations using eq. 3.

Experimental points as observed and after correction for liquid-junction potential, if any, are plotted for comparison with theoretical points. It is observed that liquid-junction potential corrections are necessary in the case of sodium iodide, i.e., for a concentration cell in which the cations and anions have different mobilities. In the cases of potassium bromide and iodide, where t^+ and t^- are very close

[2]Complete set of the actual experimental data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

to 0.50, the liquid-junction corrections are not necessary and good agreement between the theoretical lines and uncorrected experimental points is observed over a reasonably wide range of concentration.

A careful examination of Figs. 1, 2, and 3 shows that calculated curves fit the experimental data best at intermediate stoichiometric concentrations (between 1×10^{-3} to 1×10^{-1} M) of alkali metal halides. Deviations at higher concentrations (i.e., 1×10^{-1} M) are an indication of the probable formation of triple and perhaps quadruple ions (3).

Oxygen-18 isotope effects in the liquid water–pyridine system as a probe of intermolecular forces

ROBERT H. BETTS, JAN BRON, WAYNE D. BUCHANNON, AND KWOK-YING D. WU

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received March 11, 1977

ROBERT H. BETTS, JAN BRON, WAYNE D. BUCHANNON, and KWOK-YING D. WU. Can. J. Chem. **55**, 2966 (1977).

Oxygen-18 exchange between gaseous carbon dioxide and water in liquid water–pyridine mixtures is used as a probe for changes in intermolecular forces when the composition of the system is changed from pure water to pure pyridine. In agreement with results obtained previously by other methods, it is found that the interaction energy of an 'average' water molecule with the medium decreases when the mole fraction of pyridine is varied from zero to unity. The experimental results are related to the vapour pressure isotope effect, $P(H_2{}^{18}O)/P(H_2{}^{16}O)$, of the binary mixtures. The utility of the Stern – Van Hook – Wolfsberg equation for vapour pressure isotope effects has been investigated. In addition, a plot of the equilibrium constant of the oxygen-18 exchange reaction vs. the mole fraction of pyridine presents no evidence of the formation of stoichiometric pyridine–water complexes.

ROBERT H. BETTS, JAN BRON, WAYNE D. BUCHANNON et KWOK-YING D. WU. Can. J. Chem. **55**, 2966 (1977).

On utilise l'échange d'oxygène-18 entre le dioxyde de carbone et l'eau dans des mélanges liquides eau–pyridine comme sonde pour des changements dans les forces intermoléculaires alors que la composition du système varie de l'eau pure jusqu'à la pyridine pure. En accord avec les résultats obtenus antérieurement par d'autres méthodes, on a trouvé que l'énergie d'interaction d'une molécule "moyenne" avec le milieu diminue quand la fraction molaire de pyridine varie de zéro jusqu'à unité. On relie les résultats expérimentaux à l'effet isotopique de pression de vapeur, $P(H_2{}^{18}O)/P(H_2{}^{16}O)$ des mélanges binaires. On a étudié l'utilité de l'équation de Stern – Van Hook – Wolfsberg pour les effets isotopiques de la tension de vapeur. De plus, une courbe de la constante d'équilibre de la réaction d'échange de l'oxygène-18 par rapport à la fraction molaire de la pyridine ne présente pas de données permettant de conclure à la formation de complexe stoechiométrique pyridine–eau.

[Traduit par le journal]

Introduction

The properties of liquid mixtures of water and pyridine have been the subject of numerous investigations. Amongst the properties examined have been the vapour pressures of binary mixtures (1) and the infrared (2, 3) and Raman (4) spectra. A recent very comprehensive paper by Chan and Van Hook (5) reports vapour pressure isotope effects for the C_5D_5N–H_2O and C_5H_5N–H_2O systems. An earlier related study by Rabinovich (6) involved measurements of enthalpy of mixing of water (both H_2O and D_2O) with pyridine, as well as a comparison of the relative vapour pressures of the H_2O–C_5H_5N and D_2O–C_5H_5N systems. In addition there have been many papers published of systems involving the H_2O–pyridine pair in which a third component is present as the solvent (7–9). Much of this latter work is summarized in a review by Christian *et al.* (10). While three-component systems are of intrinsic interest, they are not directly relevant to our investigations and we shall not enlarge on this aspect.

Broadly speaking, the following picture emerges from earlier work. The system is characterized by complete miscibility over the entire range of composition and over all temperatures examined above the melting points of the pure components. Positive deviations from Raoult's law are observed, i.e., the *excess* Gibbs free energy of mixing is positive, whilst ΔG(mixing) is of course negative. The latter quantity reaches a minimum value at 65 mol% of pyridine. Rabinovich (6) suggests that this minimum corresponds to the formation of molecular complexes involving hydrogen bonding of two pyridine molecules to a single water molecule. Similar conclusions are drawn by Chan and Van Hook from their vapour pressure isotope effect measurements. Spectral studies, usually involving a third component, also support the view that complexes containing two pyridine molecules per water mol-

ecule are present, especially for systems rich in pyridine relative to water (2, 8). The recent spectral work of Bonner and Choi (3) provides particularly strong evidence for the 1 : 1 complex as well. These authors interpret the absorption spectra in terms of a water molecule, singly hydrogen bonded to the π electrons of the aromatic ring. This conclusion is supported by experimental and theoretical studies by Hussein *et al.* (11) of the three component system water – pyridine – carbon tetrachloride.

Some years ago, O'Neil and Adami (12) measured the distribution of ^{18}O between gaseous CO_2 and liquid water in a search for evidence of discrete polymolecular species of water in the liquid phase. At that time, certain temperature dependent anomalies, or "kinks", in the physical properties of water were suspected and O'Neil and Adami indicated how ^{18}O distribution studies could be used to learn more about these anomalies and the molecular complexes responsible. We have adapted their method to the pyridine–water system in an attempt to learn more about the molecular interactions in this system.

The purpose of this paper is twofold: (*1*) To apply and test ^{18}O isotope effects as a probe of intermolecular forces and changes therein; abrupt changes, due to formation of complexes of definite composition, will lead to discontinuities in plots of physical properties vs. mole fraction. (*2*) To examine the general applicability of the SVHW (13) equation for vapour pressure isotope effects. For example, Chan and Van Hook found that a 15% decrease in the external frequencies for water on solution in pyridine could explain their results (5). Therefore, since the SVHW equation should be generally applicable and independent of the isotopes involved, measurements of the ^{18}O isotope effects in the water–pyridine system should give results which are consistent with the data in (5).

Experimental

Pyridine (0.04% water, Baker Analyzed Reagent) was distilled from *p*-toluene sulfonyl chloride to remove secondary and tertiary amines, and then redistilled from calcium hydride to remove final traces of water. It was stored over Linde Type 3A molecular sieve. A single supply of doubly-distilled water was used in all experiments.

Mixtures of pyridine and water of the desired composition were prepared by weight in a clean dry equilibration flask of approximately 110 ml volume. The flask was attached to a vacuum line, and the contents outgassed by repeated cycles of freezing, pumping, and thawing, using liquid nitrogen as a refrigerant.

A single batch of carbon dioxide was used for all experiments. It was first freed of permanent gases and water by distillation between traps using liquid nitrogen and dry ice – acetone as the refrigerants.

The same amount (0.00055 mol) CO_2 was added to each flask of pyridine–water, after which the flask was transferred to a water bath maintained at 298.1 K. The flasks were shaken mechanically for at least 9 h, a time found sufficient to reach isotopic equilibrium amongst the oxygens of CO_2 and H_2O.

After equilibration was complete, the CO_2 was removed quantitatively from the system by vacuum transfer, and freed from traces of pyridine and water by trap-to-trap distillation. We emphasize that all the CO_2 was collected, i.e., the CO_2 in the gas phase, as well as that dissolved in the pyridine–water liquid phase. This was done to avoid possible errors arising from fractionation of the isotopic carbon dioxides between the two phases; such effects are likely to be small, but have been observed in other liquid–vapour distributions involving CO_2 (14).

Both the H_2O and CO_2 used in this work were of normal isotopic composition.

A Varian-Mat GD-150 isotope ratio mass spectrometer was used for isotopic analysis of the recovered CO_2.[1] The relative abundance of ^{18}O in each sample was measured as the ratio of mass 46 ($^{12}C^{16}O^{18}O$) to the sum of masses (44 + 45 + 47 + 48). The relative ^{18}O content of each sample was compared repeatedly with that in the original purified but unequilibrated CO_2, which was taken as a reference. This is discussed further below.

Results

This isotope exchange equilibrium we are concerned with may be written as

$$H_2{}^{18}O(\ell) + \tfrac{1}{2}\,C^{16}O_2(g) \rightleftharpoons H_2{}^{16}O(\ell) + \tfrac{1}{2}\,C^{18}O_2(g)$$

and the equilibrium constant, K, has the form

$$[1] \qquad K = \frac{[C^{18}O_2]^{1/2}[H_2{}^{16}O]}{[C^{16}O_2]^{1/2}[H_2{}^{18}O]}$$

The square brackets denote the number of moles of the indicated species at equilibrium. Provided that the isotopes ^{16}O and ^{18}O are distributed statistically amongst $C^{16}O_2$, $C^{16}O^{18}O$, and $C^{18}O_2$, which may be confidently expected, the following relation applies:

$$[2] \quad \frac{[C^{18}O_2]^{1/2}}{[C^{16}O_2]^{1/2}} = \frac{2[C^{18}O_2] + [C^{16}O^{18}O]}{2[C^{16}O_2] + [C^{16}O^{18}O]}$$

[1]This spectrometer measures the ratio of the abundance of mass 46 ($^{12}C^{16}O^{18}O$) to the sum of the abundances of the masses ± 2 mass units on each side of mass 46, i.e., masses (44 + 45 + 47 + 48). The first two of these terms contribute >99.5% of the denominator, whilst the last term is negligibly small. In the text we refer to this ratio as R. Variations in R faithfully reflect variations in the $^{18}O/^{16}O$ ratio of the CO_2.

The expression on the right hand side of [2] is clearly a quantitative measure of the ratio $^{18}O/^{16}O$ in CO_2.

We now proceed to relate K, which is defined by [1], to measured quantities. The mass spectrometrically determined ratio R, where

$$R = \text{Mass}(46)/\text{Mass}(44 + 45 + 47 + 48)$$

is a good measure of the ratio shown in [2]. Let $R_{st} = {}^{18}O/{}^{16}O$ for reference CO_2 and $R_g = {}^{18}O/{}^{16}O$ for CO_2 after equilibrium with H_2O in pyridine. If δ_g is defined as

$$\delta_g = (R_g/R_{st} - 1)1000$$

it follows that

$$R_g = (1 + \delta_g/1000)R_{st}$$

Let R_l be equal to

$$R_l = [H_2{}^{18}O]/[H_2{}^{16}O]$$

and let δ_l be defined by

$$\delta_l = (R_l/R_{st} - 1)1000$$

it then follows that

$$R_l = (1 + \delta_l/1000)R_{st}$$

The equilibrium constant K can now be expressed in the following way

$$[3] \qquad \alpha = \frac{R_g}{R_l} = \frac{1 + (\delta_g/1000)}{1 + (\delta_l/1000)} \simeq K$$

the factor R_{st} cancelling out. An equation identical to [3] was used by O'Neil and Adami in the work already cited (12). In the following we shall use α as a measure of K.

In each experiment δ_g is a measured quantity from which α can be evaluated by means of [3], provided that we know δ_l. This latter quantity is obtained in the following way. For the H_2O–CO_2 system alone at 298 K, α is equal to 1.04073 (12) and measurement of δ_g for this system therefore gives directly δ_l for the equilibrated water (see entry 1 in Table 1). From this information, the value of $\delta_l{}^0$, where the superscript refers to the value of this quantity for our stock water *before* its equilibration with CO_2, is obtained from [4]

$$[4] \quad 2n_{CO_2}\delta_g{}^0 + n_{H_2O}\delta_l{}^0 = 2n_{CO_2}\delta_g + n_{H_2O}\delta_l$$

In [4], n refers to the number of moles; $\delta_g{}^0$ is of course equal to zero by definition.

In summary, to evaluate α for each CO_2–pyridine–H_2O system investigated, we measure δ_g, and from [4] evaluate δ_l, since $\delta_l{}^0$ is known. With these quantities, α is calculated by means of [3]. The relevant data are given in Table 1 and summarized in Fig. 1.

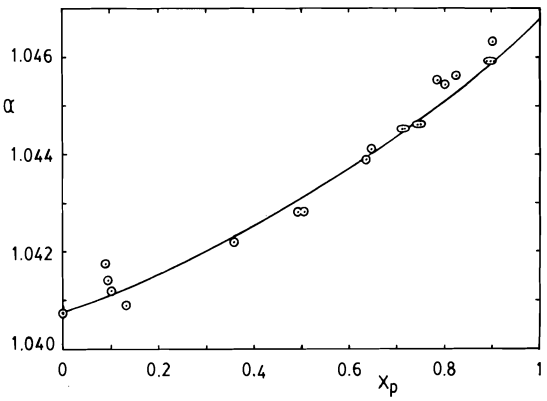

FIG. 1. A plot of α, defined by [1] in text, vs. the mole fraction of pyridine, X_p, at 298 K.

Discussion

Figure 1 displays the results of measurements of α as a function of the mole fraction, X_p, of pyridine. It may be observed that, within experimental error, no 'kinks' in the estimated line connecting the experimental points occur and that this line shows slight curvature. In order to

explain the variation of α with X_p a theoretical digression is required.

The equilibrium constant α can be written in terms of molecular partition functions

$$[5] \qquad \alpha = (q'/q)^{1/2}(\bar{q}/\bar{q}') = k^{1/2}r$$

In [5] the prime refers to the ^{18}O labelled species. The *molecular* canonical partition function for CO_2 in the ideal gas phase is q. The relationship between q and the *total* partition function, Q, is $q = (N!Q)^{N^{-1}}$. The partition function $\bar{q}$, which refers to the condensed phase of H_2O, is the *average* partition function as defined by Bigeleisen (15): $\bar{q} = Q^{N^{-1}}$. The constant k is equal to (q'/q) and r is equal to $(\bar{q}/\bar{q}')$. It is possible to calculate k, within the harmonic approximation, from the data for CO_2 given by Bottinga (16). At 298 K, k is equal to 1.783. Therefore, from a knowledge of α and k, r can be calculated by means of [5]. The value obtained for r will then be an 'experimentally observed' quantity; it quantifies the partition function ratio of the average isotopic water species in the *condensed* phase.

A relationship between r and α and the vapour pressure isotope effect can be obtained readily. Bigeleisen and Mayer (17) defined a reduced partition function as

$$[6] \qquad f = (q/q')\Pi_i(m_i'/m_i)^{3/2}$$

A similar definition has been given for $\bar{q}$. By using [6] and after making several simplifying assumptions SVHW (13) obtained an expression for the vapour pressure isotope effect:

$$[7] \qquad P'/P = f_l/f_g$$

In this case the subscripts l and g refer to the condensed and gas phase of water respectively. The vapour pressure ratio P'/P is then $P(H_2{}^{18}O)/P(H_2{}^{16}O)$. Note the following relationships

$$[8] \qquad f_l = r(18/16)^{3/2} \quad \text{and} \quad f_g = [(q/q')/(18/16)^{3/2}]_g^{(H_2O)}$$

The reduced partition function f_g may be calculated from literature data (18): at 298 K f_g is equal to 0.940. It follows, by means of [5], [6], [7], and numerical values for the quantities required, that

$$[9] \qquad P(H_2{}^{18}O)/P(H_2{}^{16}O) = 0.951\alpha$$

Hence, P'/P is directly proportional to α and, in this case, almost equal to α. By means of [9] and the experimental results for α, it can be concluded that the vapour pressure of $H_2{}^{18}O$ increases, relative to $P(H_2{}^{16}O)$, as X_p increases.

The variation of P'/P or α as a function of X_p can be explained as follows. Application of the SVHW expression and the assumption that the *ratios* of the internal partition functions of the $H_2{}^{16}O$ and $H_2{}^{18}O$ species in the condensed phase do not change considerably in going from pure water to pure pyridine, results in the following expression

$$[10] \qquad P'/P = \text{constant} \times \prod_{i=1}^{6} \frac{(\frac{1}{2}u_i)\sinh(\frac{1}{2}u_i')}{(\frac{1}{2}u_i')\sinh(\frac{1}{2}u_i)}$$

In [10] the number 6 represents the six external degrees of freedom: three hindered translations and three librations. The quantities u_i are equal to $hc\omega_i/kT$, in which all symbols have their usual meaning. Equation 10 states that the variation in P'/P at a particular temperature with X_p is caused only by a change in the six frequencies corresponding to the external degrees of freedom. Since the values of u_i are usually small at room temperature, [10] can be written as (19)

$$[11] \qquad P'/P \simeq A\sum_{i=1}^{6}\Delta u_i^2 + B$$

The constants A and B are positive. The difference Δu_i^2 is equal to $(u_i'^2 - u_i^2)$.

The change in the sum $\sum\Delta u_i^2$ accounts for variations in P'/P as the medium is changed from pure water to pure pyridine. As P'/P is linearly related to α and a plot of α vs. X_p is almost linear, the sum $\sum\Delta u_i^2$ should be an (almost) linear function of X_p. The sum $\sum\Delta u_i^2$ is always negative in the condensed phase, since Δu_i^2 is always negative or zero. It may be noted that Δu_i^2 can only be zero for some librational modes. The sign of Δu_i can be rationalized in the following way (13, 20). For translation

$$[12] \qquad \Delta u_t^2 = (h/kT)^2\sum_{i=1}^{3}(\nu_i'^2 - \nu_i^2) = (h/2\pi kT)^2 \times (M - M')(MM')^{-1}\nabla^2 V^{(t)}$$

The force constant of hindered translation is $\nabla^2 V^{(t)}$. It has been assumed that $\nabla^2 V^{(t)}$ is independent of isotopic substitution. Because by definition $M' > M$ and $\nabla^2 V^{(t)} > 0$, Δu_t^2 for the hindered translational modes is always negative. It can be shown by similar arguments that for the three librational modes the contributions to the sum in [11] must be negative or zero.

For the experimental results and [11] to be

consistent, $\sum\Delta u_i^2$ must increase with increasing X_p. Since the sum is always negative it should, therefore, become less negative (approach zero from the negative direction) when X_p is changed from zero to unity. The sum in [11] can only change via the (positive) force constants of hindered translation and libration and it may be concluded that these force constants for the average water molecule should decrease with increasing X_p. Also, a decrease in force constants of the external modes of vibration signifies a decreased interaction energy of the water molecule with the medium.

From [9], [11], and the experimental results it can be deduced that in our work we 'observed' a 15% increase in the sum $\sum\Delta u_i^2$, which is not the same result as the one by Chan and Van Hook (see above) but points in the same direction: a lowering of the force constants of the external degrees of freedom. It follows from [9] and the data in Table 1 that the vapour pressure ratio $P(H_2{}^{18}O)/P(H_2{}^{16}O)$, in solutions where X_p approaches unity, is 0.995 (0.951 × 1.046). This value is virtually the same as that reported by O'Neil and Adami (12) for concentrated dioxane–water mixtures. Hence, the external forces on the water molecule, when $X_p \simeq 1$, should be very similar in these two solutions.

Finally, by considering Fig. 1, the spread of experimental results does not allow us to draw any firm conclusions about the ambience of discrete molecular complexes of pyridine and water. Thus there are no plateaus or peaks in the values of α, corresponding to unique values of this quantity for particular molecular entities. This is perhaps not entirely unexpected, as there are undoubtedly a very large number of co-existing molecular environments for water and the nature and proportions of these will change as pyridine is added. Only some of these can be described as stoichiometric complexes. The ^{18}O equilibration method is evidently responding to the weighted chemical environment of all the water molecules in the system.

Received January 5, 1977

MARK SALOMON. Can. J. Chem. **55**, 2971 (1977).

The rates of the catalysed hydrolysis of bis(trifluoroethyl)sulfite have been measured in concentrated acid solutions at 25 and 35°C in water and in an aqueous mixture containing 60.7% *p*-dioxane by weight. The results are analyzed in terms of a solvation model similar to that proposed by Bunnett, and the kinetic medium effect. The data indicate that the mechanism of the acid-catalysed hydrolysis is bimolecular and that catalysis by halide ions occurs only in acidified solutions.

MARK SALOMON. Can. J. Chem. **55**, 2971 (1977).

On a mesuré les vitesses d'hydrolyse catalysée des sulfites de bis(trifluoroéthyle) dans des solutions acides concentrées, à 25 et 35°C, dans l'eau et dans des mélanges aqueux contenant 60.7% de *p*-dioxanne par poids. On analyse les résultats en termes d'un modèle de solvatation similaire à celui proposé par Bunnett et d'un effet cinétique de solvant. Les données indiquent que le mécanisme de l'hydrolyse acido-catalysée est bimoléculaire et que la catalyse par des ions halogénures ne se produit que dans des solutions acidifiées.

[Traduit par le journal]

Introduction

The acid/base-catalysed hydrolysis of alkyl sulfites has been studied in detail by Bunton and co-workers (1), Tillett (1, 2), and Davis (3). The overall reaction has been shown to be

[1] $$(RO)_2SO + H_2O \rightarrow 2ROH + SO_2$$

which occurs by cleavage of the S—O bond in both acid and base. The mechanism of reaction 1 has been determined by these investigators to be bimolecular (Type A-2): i.e. in acid solution,

[2*a*] $(RO)_2 + H^+ \rightleftharpoons (RO)_2SOH^+$ rapid equilibrium

[2*b*] $(RO)_2SOH^+ + H_2O \rightarrow$ products slow

The unimolecular or A-1 mechanism, which has not been confirmed for any of the alkyl sulfites, can be written as

[3*a*] $(RO)_2SO + H^+ \rightleftharpoons (RO)_2SOH^+$ rapid equilibrium

[3*b*] $(RO)_2SOH^+ \rightarrow$ products slow

The present paper is concerned with the hydrolysis of bis(trifluoroethyl)sulfite, $(CF_3CH_2O)_2SO$, in water and in an aqueous–dioxane mixture containing 60.7% *p*-dioxane by weight. The objective of this study is to elucidate the mechanism of the hydrolysis of this fluorinated ester by investigating the dependence of the rate upon (*1*) the concentrations of various solutes, (*2*) the effect of temperature, and (*3*) the effect of solvent composition.

Experimental

(a) Materials

All salts and the ester $(CF_3CH_2O)_2SO$ were purified as described previously (4). The ester was stored in an argon-filled dry box and all salts were stored in a desiccator over P_2O_5. Reagent grade *p*-dioxane was distilled from activated alumina and type 4A molecular sieves. Reagent grade acids were used as received. Acid solutions for the water–dioxane mixture were prepared by mixing standard (aqueous) acid with the purified dioxane such that the wt% of dioxane was always 60.7 (this corresponds to the 60.0 vol% mixture used in related studies 2*b*, 5). The acid solutions were analyzed by titration with Fisher certified standard alkali. All titrations, both for standardization and product analysis (see below), were carried out at 25°C using water-jacketed burets.

(b) Rates of Hydrolysis

Since the acid hydrolysis of sulfite esters results in the production of SO_2 (cf. reaction 1), the rate of reaction is conveniently measured by iodometric titration (1–3). A hydrolysis cell with ~10 ml capacity is shown in Fig. 1. In each run, 3–5 cells were thermostated in series to within ±0.1°C. 5.0 ml of ester + acid solution were pipetted into each cell and, at specified times, the solutions were rapidly drained by N_2 pressure into small flasks containing excess 0.01 *N* I_2 (as I_3^-). The excess I_3^- was back-titrated with 0.01 *N* $Na_2S_2O_3$ and the first order rate constant was calculated from

[4] $$k^1 = \{\ln [a/(a - x)]\}/t$$

where *a* is the initial concentration of $(CF_3CH_2O)_2SO$

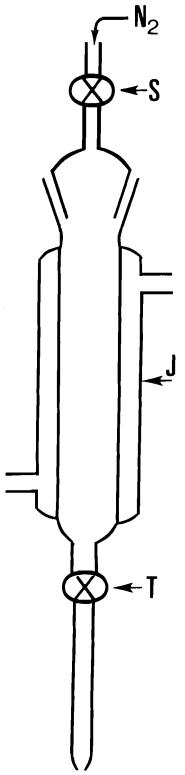

FIG. 1. Diagram of the hydrolysis cell. S = greased micro-stopcock, J = water jacket, T = Teflon micro-stopcock.

and x is the mol of SO_2 liberated after t min. The experimental k^1 values were reproducible to within $\pm 3\%$. Zero time for the kinetic runs was taken at the start of mixing the ester with the acid solutions. Typical initial concentrations of the sulfite ester in water were around 5×10^{-3} M and around 3×10^{-2} M in 60.7% dioxane. Several runs were carried out at 35°C and the majority of the runs were carried out at 25°C.

(c) Results

The results are summarized in Tables 1–5.[1] In Tables 2, 4, and 5, the rate constant k_x^1 is the observed rate constant for the acid–halide-catalysed reaction, and is obtained from the observed first order rate constant, k^1, by subtracting the value the rate constant would have in the absence of halide; i.e. as in $HClO_4$ solutions. Denoting this latter quantity as $k^1(HClO_4)$, we have

$$[5] \qquad k_x^1 = k^1 - k^1(HClO_4)$$

The values of $k^1(HClO_4)$ were obtained either graphically by interpolation or from a least squares fit to a suitable rate equation (see eqs. 11 and 14 below). Additional data given in these tables are the acidity functions, H_0, for $HClO_4$ in water (6) and 60.7% dioxane (5), and for HCl in water (6) and 60.7% dioxane (7). The molar activity coefficients, $y_\pm$, for HCl in water and 60.7% dioxane were obtained from Harned and Owens' compilations (8) (the latter values were interpolated from the data for 20, 45, 70, and 82% dioxane solutions). Values of $y_\pm$ for aqueous $HClO_4$ solutions and the activity of water in these solutions were obtained from the molal activity coefficients, $\gamma_\pm$, of Robinson and Baker (9). The density data of Markham (10) were used to make the conversions to the molar scale.

There are additional kinetic data in 60.7% dioxane which were not placed in the tables. In neutral solutions containing 0.274 and 0.512 M LiCl, the first order rate constant was too small to be determined by the present method ($k^1 < 10^{-5}$ min^{-1}); in 0.407 M KOH the second order rate constant was much too large to be accurately determined ($k^2 > 10$ ℓ mol^{-1} min^{-1}).

The enthalpies of activation, $\Delta H^\ddagger$, were estimated from the data at 25 and 35°C, and the entropies of activation were calculated from the data at 25°C using the relation

$$[6] \quad \Delta S^\ddagger = R \ln (k/T) + \Delta H^\ddagger/T - 47.216$$

where k is in units of s^{-1}. The results are given in Table 6 along with those for diethylsulfite (1*b*, 2*b*) which are presented for comparison.

Discussion

(a) Overall Kinetics

The observed rate constant may be written as

$$[7] \quad k^1 = k_N + k_H[H^+] + k_x[H^+][X^-] + k_{OH}[OH^-]$$

where k_N is the rate constant in neutral solution and k_{OH} is that for alkaline solution which, for the present experimental conditions, need not be considered. The data in Tables 1–5 indicate: (*1*) there is specific catalysis by H^+; (*2*) there is no catalysis by Li^+, Na^+, or ClO_4^-; and (*3*) there is catalysis by halide ions only in the presence of H^+. The existence of catalysis by halide ions appears to be unique as no such behaviour is observed for the hydrolysis of carboxylic esters (11). The reason for the existence the k_x term in eq. 7 is due to the fact that the sulfinyl sulfur is highly electrophilic (12, 13). It has also been suggested (14) that the sulfinyl sulfur can be classified as a hard Lewis acid in the Pearson sense (15), and on this basis, one would expect its reactivity towards anions would decrease according to $OH^- > Cl^- > Br^- > ClO_4^-$. The alkaline hydrolysis of alkyl sulfites and of $(CF_3CH_2O)_2SO$ is faster than the H^+—X^--catalysed hydrolysis, but the latter decreases according to $Br^- > Cl^-$ which suggests that the sulfinyl sulfur is a soft Lewis acid (4, 12). This acidic behaviour of the sulfinyl sulfur originates partly from an inductive effect (4) and partly from the possibility that the sulfinyl sulfur

[1]Tables 1–5 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

	60.7% diox	$HClO_4$	1.500			18.91	−10.75

*$\Delta H^{\ddagger}$ units are kcal/mol; $\Delta S^{\ddagger}$ units are eu.

possesses *d* orbitals of low enough energy to undergo *d–p* π-bonding and *d–d* back-bonding with suitable anions (i.e. of appropriate symmetry) such as the halides, but not with ClO_4^- (12, 14). The two major terms involving k_H and k_x in eq. 7 are discussed below.

(b) The Acid-catalysed Reaction

For acid-catalysis, the first order rate constants for the A-1 and A-2 mechanisms are given by

$$[8]\quad \log k_{A\text{-}1}{}^{1} = \log k^0 + \log a_{H^+} + \log(y_s/y^{\ddagger})$$

and

$$[9]\quad \log k_{A\text{-}2}{}^{1} = \log k^0 + \log([H^+]a_w) + \log(y_{\pm}y_s/y^{\ddagger})$$

In these equations, *y* is the true (measurable) molar activity coefficient for the indicated species: s for the substrate $(RO)_2SO$, and ‡ for the activated complex. Explicit forms of eqs. 8 and 9 can be derived by using theoretical and/or empirical relations for the activity coefficients (16). One such relation is the extended Debye–Hückel equation

$$[10a]\quad \log y_i = -Az_i^2\mu^{1/2}/(1 + \mu^{1/2}) + b_i\mu$$

When the species *i* is a molecule ($z_i = 0$), eq. 10*a* reduces to

$$[10b]\quad \log y_i = b_i\mu$$

Substituting eqs. 10 into eq. 9 gives

$$[11a]\quad \log\{k^1/[H^+][H_2O]\} = \log k^0 + b'\mu$$

where $b' = b_{H^+} + b_{H_2O} + b_s - b^{\ddagger}$. For the range of concentrations over which eqs. 10 are valid, the variation in $[H_2O]$ is small and the log $[H_2O]$ term can be incorporated into the log k^0 term: i.e.

$$[11b]\quad \log(k^1/[H^+]) = \log k' + b'\mu$$

where

$$[12]\quad k' = k^0\chi_w$$

The thermodynamic reference state for ions and uncharged solutes is the hypothetical 1 *M* solution, whereas the reference state for the solvent is, by convention, that of the pure solvent: thus the terms in $[H_2O]$ in the above equations can be replaced by the mole fraction of water, χ_w.

A major problem associated with the use of eqs. 10 over a large range of concentrations is that the constant *b* is not constant. The variation in *b* for infinitely dilute aqueous solutions to 0.5 *M* solutions is ~25%, and from 1.0 to 3.0 *M*, *b* changes by ~9%. Bunnett (17) has shown that in concentrated solutions, satisfactory empirical relations for the activity coefficients should account for ionic/molecular hydration. In aqueous solutions for concentration ≤6 *M*, an accurate rate equation can be derived by use of the empirical equation (18)

$$[13]\quad \log y_i = -\frac{Az_i^2\mu^{1/2}}{1 + Ba_0\mu^{1/2}} - \bar{n}\log a_w - \log\left\{\frac{1}{d_0}[d - 0.001(36.03 - MW)c]\right\}$$

where $\bar{n}$ is the average solvation number, d_0 and *d* are, respectively, the densities of pure water and the solution, MW is the molecular weight of the solute whose concentration is *c* mol/ℓ, and all other terms have their usual significance. Combining eqs. 9 and 13 yields

60.7% diox; HCl	17	0.938	−0.102	0.024

*Based on data in solutions for which $[HClO_4] \leq 3\ M$.
†To obtain k^0 from this intercept, k' is divided by χ_w (0.760) for the pure solvent (cf. eq. 12) which yields $\log k^0 = -3.402$.

[14] $$\log (k^1/[H^+]) + \log \left\{\frac{1}{d_0}[d - 0.001(36.03 - MW)[H^+]]\right\} = w^* \log a_w + \log k^0$$

where w^* is the "Bunnett" slope defined by

[15] $$w^* = 1 + n^{\neq} - n_{H^+} - n_s$$

Taking $n_{H^+} = 4$ (19) and $n^{\neq} - n_s \simeq 0$, 1, the slope w^* is expected to have values around −2 to −3. The above treatment assumes that the average solvation number is constant over the entire concentration range studied. This is a reasonable assumption for solutions in which there are an excess of solvent molecules, but for concentrations greater than 2 to 3 *M*, this assumption is not valid (20).

(c) The Acid–Halide-catalysed Reaction

This reaction can be treated in a simple fashion since the mechanism appears to be (cf. also ref. 3*b*)

[16*a*] $(RO)_2SO + H^+ \rightleftharpoons (RO)_2SOH^+$ rapid equilibrium

[16*b*] $(RO)_2SOH^+ + X^- \rightarrow ROSOX + ROH$ slow

[16*c*] $ROSOX + H_2O \rightarrow ROH + H^+ + X^- + SO_2$ fast

Since both the substrate and activated complex are neutral species, it is assumed that $y_s/y^{\neq} = 1$ and the first order rate constant (i.e. the observed quantity) can be written as

[17] $$\log k_x^1 = \log k^0 + \log a_{\pm}^2$$

The data for hydrolysis in acidified Cl^- and Br^- solutions (Tables 2, 4, and 5) show that eq. 17 is obeyed within experimental error: i.e. $\log (k^1/a_{\pm}^2)$ is constant.

(d) Analysis of the Data

The data for hydrolysis in $HClO_4$ solutions can be analyzed in several ways as shown in Table 7. The data for 25°C in this table were treated by the least squares method and the σ's are the statistical standard deviations in $\log k^1$. In aqueous solution, the Bunnett slope w^* (eqs. 14, 15) is −2.5 which leads to the reasonable values of $n^{\neq} \simeq 1$ and $n_s \simeq 0$. An attempt was made to determine if the rates of these reactions could be fit to a first order mechanism. Use was made of the Zucker–Hammett (21) relation

[18] $$\log k^1 = \log k^0 - H_0$$

and the Bunnett (17) relation

[19] $$\log k^1 + H_0 = w \log a_w + \log k^0$$

and the results are also given in Table 7. The rate data for the fluorinated ester studied here are complementary to those for the non-fluorinated esters (1–3): i.e. the reaction mechanism appears to be bimolecular in both cases.

The energetics of the catalysed hydrolysis of $(RO)_2SO$ can offer additional insights as to the mechanism. Using the data in Table 7 for the k^0 terms,[2] the standard enthalpies and entropies of activation ($\Delta H_0^{\neq}$ and $\Delta S_0^{\neq}$) have been evaluated and are presented in Table 8 with corresponding data for $(CH_3CH_2O)_2SO$. These

[2]It is to be noted that $k^0 = k^2 K_e$, where k^2 is the true second order rate constant in units of $\ell\ mol^{-1}\ min^{-1}$ and K_e is the equilibrium constant for protonation of the substrate (eqs. 2*a* and 16*a*).

TABLE 8. Standard enthalpies and entropies of activation for the hydrolysis of $(CF_3CH_2O)_2SO$ and $(CH_3CH_2O)_2SO$

Sulfite	Solvent	Acid	Salt	$\Delta H_0^{\neq}$	$\Delta S_0^{\neq}$	k^0 (25°C)
$(CF_3CH_2O)_2SO$	H_2O	$HClO_4$		17.9	−19.3	1.79×10^{-3}
	H_2O	HCl		11.0	−39.0	0.0101
	60.7% diox	$HClO_4$		15.4	−30.5	3.98×10^{-4}
	60.7% diox	$HClO_4$	LiCl	14.6	−19.6	0.419
	60.7% diox	HCl		12.8	−23.6	1.036
$(CH_3CH_2O)_2SO$	H_2O	$HClO_4$		17.9	−14.7	0.0180
	H_2O	$HClO_4$	NaCl	18.9	−8.2	0.0857
	H_2O	$HClO_4$	NaBr	18.8	−5.5	0.377
	60.7% diox	$HClO_4$		19.2	−12.5	5.81×10^{-3}

data are not completely unambiguous, but several factors can be used to lend support to the A-2 mechanism. The fact that $\Delta S_0^{\neq}$ and $\Delta S^{\neq}$ are large and negative has been interpreted by Long and co-workers (22) as being due to the large loss in entropy on forming the activated complex which, by virtue of its mechanism, is more solvated than its A-1 counterpart. Considering the hydrolysis of $(CF_3CH_2O)_2SO$, Tables 6 and 8 indicate that in aqueous solution, $\Delta S^{\neq}$ is more negative for the H^+—Cl^--catalysed hydrolysis than it is for the acid-catalysed reaction; the reverse behaviour is noted in 60.7% dioxane. In aqueous HCl, the loss in entropy in forming the activated complex, $(RO)_2SOHCl$, may be augmented by a large net ordering effect of the solvent since in the initial state, Cl^- is a "structure-breaking" ion and the large activated complex may embody the "structure-making" properties typical of large non-polar solutes (23). In 60.7% dioxane, the increase in $\Delta S^{\neq}$ for the H^+—Cl^--catalysed reaction compared to the acid-catalysed reaction is almost certainly due to the more negative entropy of solvation of the Cl^- ion in the mixed solvent. This follows from the general observations of Criss and co-workers that entropies of ions are most positive in those solvents which have a greater degree of internal order in the pure state (24–26). For the aqueous $(CH_3CH_2O)_2SO$ system, $\Delta S_0^{\neq}$ is larger for the acid-catalysed reaction than for the H^+—Cl^--catalysed reaction. The reason for this is not clear, but may be attributed to a combination of effects such as a weaker S–Cl interaction compared to that involving $(CF_3CH_2O)_2SO$, and (2) the activated complex $(CH_3CH_2O)_2SOHCl$ may be a structure-breaker since it is expected to be more polar than its fluorinated analog. It is of course possible that this decrease in $\Delta S_0^{\neq}$ for $(CH_3CH_2O)_2SO$ hydrolysis in the presence of halide is an artifact of the extrapolations used to obtain k^0, but a large error seems unlikely since the differences cannot be attributed to experimental error.

Despite several uncertainties in the above treatments, there is no evidence supporting the A-1 mechanism. Another straightforward approach in mechanism confirmation involves the medium effect. In general, the ratio of standard rate constants for reactions in water (k_w^0) to that in solvent s (k_s^0) is given by (26*b*)

$$[20]\quad k_w^0/k_s^0 = \exp\{[\Delta G_t^0(\neq) - \textstyle\sum \Delta G_t^0(r)]/RT\}$$

where $\Delta G_t^0(\neq)$ and $\Delta G_t^0(r)$ are, respectively, the standard free energies of transfer of the activated complex and reactants from water to solvent s. For large neutral molecules or for large ions where the charge is diffusely distributed over the molecule, ΔG_t^0 approaches zero (27, 28) and eq. 20 can be greatly simplified. From eqs. 8 and 9 for the A-1 and A-2 mechanisms in the absence of halide, eq. 20 reduces to

$$[21]\quad (k_w^0/k_s^0)_{H(A\text{-}1)} = \exp\{-\Delta G_t^0(H^+)/RT\}$$

and

$$[22]\quad (k_w^0/k_s^0)_{H(A\text{-}2)} = \exp\{[-\Delta G_t^0(H^+) - \Delta G_t^0(H_2O)]/RT\}$$

For the H^+—Cl^--catalysed reaction, eq. 20 reduces to

$$[23]\quad (k_w^0/k_s^0)_{x(A\text{-}2)} = \exp\{-\Delta G_t^0(HCl)/RT\}$$

The terms in $\Delta G_t^0(HCl)$ and $\Delta G_t^0(H_2O)$ can be unambiguously evaluated from emf studies on cells of the type H_2/HX (in solvent s)/AgX,Ag (8, 29–31), and from equilibrium constants for the ionization of H_2O in water and mixtures with *p*-dioxane (32, 33) and the activities of water in these mixtures (34). For the transfer from water to 60.7% dioxane, the values of $\Delta G_t^0(HCl)$ and $\Delta G_t^0(H_2O)$ are, respectively, 2.45 and 3.96 kcal/mol. The evaluation of $\Delta G_t^0(H^+)$ requires

an extrathermodynamic assumption which is always subject to uncertainty (26–29). The method of Feakins and co-workers (29, 35) appears to be consistent with other techniques (26) and using the emf data (8, 29–31), it is found that $\Delta G_t^0(H^+) = -6.0$ kcal/mol. Substituting these values into the above equations yields

$$(k_w^0/k_s^0)_{H(A\text{-}1)} = 2.6 \times 10^4$$

$$(k_w^0/k_s^0)_{H(A\text{-}2)} = 33.0$$

$$(k_w^0/k_s^0)_{x(A\text{-}2)} = 0.016$$

Experimentally the specific rate ratios for $(CF_3CH_2O)_2SO$ hydrolysis are $(k_w^0/k_s^0) = 4.5$, and $(k_w^0/k_s^0)_x = 0.010$. Similarly, for the hydrolysis of $(CH_3CH_2O)_2SO$, it is found that $(k_w^0/k_s^0)_H = 3.1$.

Summary and Conclusions

The mechanism of the acid–halide catalytic hydrolysis of $(CF_3CH_2O)_2SO$ follows closely that of $(CH_3CH_2O)_2SO$: both are bimolecular, characterized by a large negative value for the entropy of activation, and exhibit analogous behaviour when the medium is changed from water to an aqueous–dioxane mixture. The observations that the acid–halide-catalysed reactions are faster for $(CH_3CH_2O)_2SO$ than for $(CF_3CH_2O)_2SO$ is attributed to a large inductive effect at the carboxylic oxygens which are the sites of the initial protonation (cf. eqs. 2*a*, 16*a*). A large inductive effect at the sulfinyl sulfur would lead to a stronger S–Cl interaction with the fluorinated ester which might conceivably lead to more rapid kinetics. There is some evidence that there is a stronger S–Cl interaction with the fluorinated ester: for the hydrolysis of $(CF_3CH_2O)_2SO$ in water, $\Delta S^{\neq}$ and $\Delta S_0^{\neq}$ are smaller for the acid–halide-catalysed reaction than it is for the acid-catalysed reaction. The reverse behaviour is observed for the hydrolysis of $(CH_3CH_2O)_2SO$ as seen in Tables 6 and 8. The effect of fluorination of diethyl sulfite thus appears to give rise to two major effects: the decrease in electron density at the carboxylic oxygens and the sulfinyl sulfur results in a decrease in K_e (the equilibrium constant for protonation of the substrate) which acts to decrease the rate of hydrolysis, while the increase in the S–Cl interaction acts in an opposing fashion.

Molar excess enthalpies of acetonitrile + chloroform and of acetonitrile + chloroform-d_1 at 298 K

YASH PAUL HANDA[1] AND DAVID EDWARD JONES[2]
Department of Chemistry, University of Otago, Dunedin, New Zealand
Received February 10, 1977

YASH PAUL HANDA and DAVID EDWARD JONES. Can. J. Chem. **55**, 2977 (1977).

Molar excess enthalpies of acetonitrile + chloroform and of acetonitrile + chloroform-d_1 were measured at 298 K. The results for the former system were discussed in terms of an ideal associated solution model and the deuterium isotope effect was discussed.

YASH PAUL HANDA et DAVID EDWARD JONES. Can. J. Chem. **55**, 2977 (1977).

On a mesuré, à 298 K, les enthalpies molaires d'excès de l'acétonitrile + chloroforme et de l'acétonitrile + chloroforme-d_1. On discute des résultats obtenus dans le premier système en termes d'un modèle de solutions associées idéales et on discute de l'effet isotopique du deutérium.

[Traduit par le journal]

Introduction

There has been a revival of interest recently in the thermodynamic study of liquid mixtures of A and B in which association takes place. Often, the "physical" contribution, $X^E_{m,phys}$ and the "chemical" contribution, $X^E_{m,chem}$ to the molar excess function X^E_m are assumed independent (there is experimental evidence for this assumption (1)) i.e.

$$[1] \qquad X^E_m = X^E_{m,phys} + X^E_{m,chem}$$

If $X^E_{m,phys}$ is negligibly small compared with $X^E_{m,chem}$ or, alternatively, if $X^E_{m,phys}$ can be estimated (see, for example, ref. 2), the mixture can be treated as an ideal associated solution. The application of this model to calorimetric measurements on mixtures with AB association has been reviewed (3).

Triethylamine + chloroform and diethyl ether + chloroform have been exhaustively investigated by thermodynamic methods as a result of independent evidence for AB association in these systems. The earlier calorimetric studies in the former system at 298 K (4, 5) have been supplemented by vapour pressure measurements at 283 K (6) and 298 K (7) and by measurements of the molar excess volumes at 298 and 308 K (8). The ideal associated solution model has been extended and applied to these results. Similarly, the ideal associated solution model has been applied (3) to the results of calorimetric measurements at 298 K (9), to vapour pressure measurements at 298 K (7), and to the results (10) for the temperature dependence of the molar excess volumes of diethyl ether + chloroform (7).

For the system acetonitrile + chloroform vapour pressures at 313 K (11), constant pressure vapour liquid equilibria (12) and molar excess volumes at 293 and 313 K (13) have been measured. Spectroscopic measurements on this system (14, 15) have been interpreted in terms of AB association and the values of the equilibrium constants at 299 and 310.5 K have been calculated. However, it appears that the AB associated model is too simple and that a model which includes self-association (see accompanying paper) is required to interpret the thermodynamic results. We have measured the molar excess enthalpies of acetonitrile + chloroform at 298 K.

The deuterium isotope effect on thermodynamic measurements in liquid mixtures has been reviewed (16). The molar excess enthalpies of triethylamine + chloroform and of triethylamine + chloroform-d_1 at 298 K (17) have been interpreted in terms of a larger value of the equilibrium constant for the former system and a more exothermic enthalpy of AB association for the latter, assuming no difference in the physical contributions in the respective systems. No deuterium isotope effect was detected from comparison of the molar excess enthalpies of

[1]Present address: Department of Chemistry, Wright State University, Dayton, OH, U.S.A. 45431.

diethyl ether + chloroform and of diethyl ether + chloroform-d_1, and this may be attributed to a compensation of the respective differences in the equilibrium constants and the standard enthalpies of AB association (17). In order to assess the deuterium isotope effect in this study, we report the molar excess enthalpies of acetonitrile + chloroform-d_1 at 298 K.

Experimental

Materials

Chloroform (B.D.H. Analar) was purified as reported previously (7).

Chloroform-d_1 (Merck, for spectroscopy) was purified by a procedure similar to that for chloroform (7) except that the initial shaking with water (to remove ethanol) was omitted. A high amplification nmr study indicated a purity of 99.7 mol%, with chloroform being the only proton-containing impurity.

Acetonitrile (B.D.H. Analar) was refluxed over phosphorous pentoxide for 4 h, and subsequently fractionally distilled in a dry and oxygen-free nitrogen atmosphere using a column of 15 theoretical plates at a reflux ratio of 20. The distillation apparatus was wrapped in black cloth to exclude light. The middle fraction was degassed by vacuum sublimation (18) and the degassed sample was stored over freshly activated molecular sieve (Union Carbide, type 13X) in a sealed ampoule. A high amplification nmr study indicated that the sample was at least 99.5 mol% pure.

Calorimeter

The calorimeter was similar to that described by Larkin and McGlashan (19) and has been described elsewhere (20). Tests with the I.U.P.A.C. recommended system *n*-hexane + cyclohexane have previously been carried out and compared with literature values (22).

Results

The molar excess enthalpies, H_m^E of acetonitrile + chloroform and of acetonitrile + chloroform-d_1 at 298 K are given in Table 1. The results were fitted by a least-squares computer program to the expression

$$[2]\quad H_m^E/\text{J mol}^{-1} = x_A x_B \sum_{i=1}^{k} h_i(1 - 2x_B)^{i-1}$$

where x_B is the mole fraction of chloroform or of chloroform-d_1. For both systems the results in Table 1 were adequately fitted with $k = 3$ in eq. 2. The parameters h_i and their respective standard deviations are given for both systems in Table 2. Table 2 also gives the standard deviations $\sigma(H_m^E)$ defined by

$$[3]\quad \sigma(H_m^E) = \left\{\sum (H_m^E(\text{calcd}) - H_m^E(\text{expt}))^2/(N - k)\right\}^{1/2}$$

where H_m^E(calcd), H_m^E(expt) are respectively the calculated (from the parameters h_i given in Table 2) and experimental values of the molar excess enthalpies for N experimental values.

TABLE 1. Molar excess enthalpies H_m^E of $x_A CH_3CN + x_B CHCl_3$ and of $x_A CH_3CN + x_B CDCl_3$ at 298 K

Discussion

Both the magnitude and asymmetry of the H_m^E results suggest the inadequacy of the AB association model used to interpret the nmr results. There is evidence (21) for self-association in acetonitrile for which Trouton's constant is 96.4 J mol^{-1} K^{-1}. In addition, the results for G_m^E are positive (11) which is not consistent with an AB association model. Hence, it appears that a more complex model is required to interpret the thermodynamic results for this system (see accompanying paper).

At 313 K $G_m^E(x_B = \frac{1}{2}) = 131$ J mol^{-1} and use of the Gibbs–Helmholtz equation gives $G_m^E(x_B = \frac{1}{2}) = 164$ J mol^{-1} and $TS_m^E = -974$ J mol^{-1} at 298 K.

From constant pressure liquid vapour equilibrium results (12) it appears that G_m^E is slightly more positive at higher temperatures and consequently that H_m^E changes sign. This is in accordance with the expectation that $C_{p,m}^E$ will be positive for mixtures in which AB association takes place. Consequently, measurements of $C_{p,m}^E$ would be of interest.

Both V_m^E and $(\partial V_m^E/\partial T)_p$ are negative (13), the former fact consistent with AB association and the latter as observed for triethylamine + chloroform (8).

Although there is no significant deuterium

TABLE 2. Coefficients in eq. 2, the standard deviations of these coefficients, and standard deviations $\sigma(H_m^E)$ defined by eq. 3

System	h_1	h_2	h_3	$\sigma(H_m^E)$/J mol^{-1}
Acetonitrile + chloroform	-3250 ± 11	1505 ± 21	319 ± 52	4.8
Acetonitrile + chloroform-d_1	-3317 ± 16	1611 ± 39	153 ± 97	6.8

isotope effect on V_m^E (13), the molar excess enthalpies of acetonitrile + chloroform-d_1 are more exothermic (by 16 J mol^{-1} at $x_B = \frac{1}{2}$) than those of acetonitrile + chloroform. The difference is beyond the experimental uncertainty (Table 2) and is therefore consistent with the idea that the strength of the hydrogen bond in the AB associated system is increased on substitution by deuterium. However, a different value of the physical contribution in the hydrogen and deuterium systems (23) may account for such a small difference in the values of H_m^E. It appears that there will be some interest in similar experimental results for acetonitrile-d_3 + chloroform and acetonitrile-d_3 + chloroform-d_1.

Further treatment of the thermodynamic results for the binary systems formed by carbon tetrachloride, chloroform, and acetonitrile will be found in the following paper.

Thermodynamics of complex formation in binary liquid mixtures: application to systems containing acetonitrile

JOHN W. LORIMER AND DAVID E. JONES[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 10, 1977

JOHN W. LORIMER and DAVID E. JONES. Can. J. Chem. **55**, 2980 (1977).

Equations for enthalpies and volumes of mixing are derived from thermodynamic association theory for complex binary liquid mixtures containing self-associating species and binary complexes. The various species can interact through general non-specific interactions of the simple mixture type.

The equations, along with equations for the excess Gibbs energy, are applied to experimental data on excess Gibbs energies, heats, and volumes of mixing for the three binary systems formed from acetonitrile, carbon tetrachloride, and chloroform. The data require a theoretical model that involves two types of self-association of acetonitrile, one type of self-association of chloroform and formation of a binary complex $CH_3CN{\cdot}2CHCl_3$. Thermodynamic parameters for the various types of association and interaction are derived by constrained least-squares methods, and provide a unified picture of the thermodynamic properties of these mixtures.

JOHN W. LORIMER et DAVID E. JONES. Can. J. Chem. **55**, 2980 (1977).

On a dérivé des équations pour les enthalpies et les volumes de mélange à partir de la théorie d'association thermodynamique pour des mélanges liquides binaires complexes contenant des espèces auto-associées et des complexes binaires. Les diverses espèces peuvent interagir par l'intermédiaire des interactions générales non spécifiques d'un type de mélange simple.

Les équations de même que les équations pour l'énergie d'excès de Gibbs peuvent être appliquées à des données expérimentales concernant les énergies d'excès de Gibbs, les chaleurs et les volumes de mélanges pour les trois systèmes binaires formés à partir de l'acétonitrile, du tétrachlorure de carbone et du chloroforme. Les données nécessitent un modèle théorique qui implique deux types d'auto-association de l'acétonitrile, un type d'auto-association du chloroforme et la formation d'un complexe binaire $CH_3CN{\cdot}2CHCl_3$. On a pu dériver les paramètres thermodynamiques pour les divers types d'association et d'interaction par la méthode des moindres carrés restreints et l'on obtient ainsi une image unifiée des propriétés thermodynamiques de ces mélanges.

[Traduit par le journal]

Introduction

Much recent interest in formation of complexes in binary liquid mixtures has emphasized the extraction of thermodynamic parameters from heats and volumes of mixing for systems in which simple complexes are assumed to form between non-associating components (1). In systems such as mixtures of alcohols and alkanes, self-association is extensive and it has proved difficult to construct a quantitative theory that correlates the experimental data (2). Recently, Lorimer *et al.* (3) combined thermodynamic association theory (4–6) with experimental Gibbs energies to find thermodynamic parameters for systems that involve self-association, formation of binary complexes, and non-specific interactions among the various species present. The theory, except in the case of simple complex formation between two non-associating components (4), has not been extended to include heats and volumes of mixing. This extension is described in the first part of this paper.

Extensive data are available for the three binary mixtures formed from acetonitrile, carbon tetrachloride, and chloroform. Handa and Jones (7) and Handa (8) have presented data on the heats and volumes of mixing for mixtures of acetonitrile and chloroform, and excess Gibbs energies have been obtained from measurements of total vapour pressures (9). Excess Gibbs energies (10, 11), heats of mixing (11, 12), and volumes of mixing (10, 11) have been measured for the systems acetonitrile – carbon tetrachloride and carbon tetrachloride – chloroform. Interpretation of the properties of liquid mixtures containing acetonitrile must take into account the high degree of association in pure

[1]Present address: Ministry of the Environment, P.O. Box 487, Bracebridge, Ont., Canada P0B 1C0.

acetonitrile, evidence for which has been summarized by Saum (13). It has also been considered that chloroform is an associated liquid (14) and that acetonitrile and chloroform form complexes (9, 15, 16). There is no evidence for formation of complexes between acetonitrile and carbon tetrachloride in the solid–liquid phase diagram (17); the phase diagram for acetonitrile–chloroform (18) will be discussed below. Association theory would appear, therefore, to be a reasonable approach to a comprehensive theory of the thermodynamic properties of these binary mixtures, an approach that is discussed in the second part of this paper.

Theory

(a) General Relations and Excess Gibbs Energies

Saum (13) has indicated that both antiparallel and head-to-tail association of acetonitrile dipoles is significant, with a larger energy of association for the antiparallel case. Thus, two association reactions for acetonitrile are assumed: a one-step association (corresponding to roughly antiparallel alignment of CN bond dipoles):

$$[1] \qquad 2A_1 = A_2' \qquad K_A' = x_{A_2}'/x_{A_1}^2$$

and chain association (corresponding to head-to-tail alignment of acetonitrile dipoles) with the same association constant for all steps (3, 6):

$$[2] \qquad A_1 + A_i = A_{i+1} \qquad K_A = x_{A_{i+1}}/x_{A_1}x_{A_i}, \quad i \geq 1$$

Chloroform molecules (B) are assumed to associate in chains, with the same equilibrium constant for each association step:

$$[3] \qquad B_1 + B_i = B_{i+1} \qquad K_B = x_{B_{i+1}}/x_{B_1}x_{B_i}$$

Acetonitrile and chloroform molecules are assumed to form simple complexes containing one or two $CHCl_3$ molecules:

$$[4] \qquad B_1 + AB_i = AB_{i+1} \qquad K_{i+1} = x_{AB_{i+1}}/x_{AB_i}x_{B_1}, \quad i = 0, 1$$

The symbols A_i and B_i represent i-mer molecules, x_{A_i}, x_{B_i} are the species mole fractions based on the total amount of all species in the mixture and x_{A_2}' refers to head-to-head dimers. These various species are assumed to form a mixture that is ideal except for a general non-specific interaction term involving all species (3–5). The quantities K_{i+1}, K_A', K_A, K_B are mole fraction equilibrium constants.

The stoichiometric mole fractional activity coefficients can be calculated by methods described elsewhere (3, 6), and are given by (cf. ref. 3):

$$[5] \qquad x_{A_1}{}^* f_A \exp(-wx_B^2) = x_{A_1}/x_A = Q(x_{A_1}, x_{B_1})/\{x_{B_1}K_1(1 + x_{B_1}K_2) + 2x_{A_1}K_A' + 1/(1 - x_{A_1}K_A)^2\}$$

$$[6] \qquad x_{B_1}{}^* f_B \exp(-wx_A^2) = x_{B_1}/x_B = Q(x_{A_1}, x_{B_1})/\{x_{A_1}K_1(1 + 2x_{B_1}K_2) + 1/(1 - x_{B_1}K_B)^2\}$$

where

$$[7] \qquad Q(x_{A_1},x_{B_1}) = 2x_{A_1}K_A' + x_{A_1}x_{B_1}K_1(2 + 3x_{B_1}K_2) + x_{A_1}/(1 - x_{A_1}K_A)^2 + x_{B_1}/(1 - x_{B_1}K_B)^2$$

Here, $x_{A_1}{}^*$, $x_{B_1}{}^*$ are the mole fractions of monomers in the pure liquids A, B respectively, and the exponential terms allow for non-specific interactions among all species. The species mole fractions are related by

$$[8] \qquad x_{A_1}^2K_A' + x_{A_1}/(1 - x_{A_1}K_A) + x_{B_1}/(1 - x_{B_1}K_B) + x_{A_1}x_{B_1}K_1(1 + x_{B_1}K_2) = 1$$

Equations 8 with either [5] or [6] constitute two simultaneous equations in x_{A_1} and x_{B_1} that may be solved by iteration if the interaction parameter w and the equilibrium constants are known. To estimate these parameters, it is convenient to use the limiting values of the activity coefficients (3):

[9] $$l_A^{(g)} \equiv \lim_{x_A \to 0} f_A = e^w / x_{A_1}^* x_{B_1}^* \{1 + x_{B_1}^* K_1 (1 + x_{B_1}^* K_2)\}$$

[10] $$l_B^{(g)} \equiv \lim_{x_B \to 0} f_B = e^w \{2 x_{A_1}^{*3} K_A' + (1 - x_{A_1}^{*2} K_A')^2\} / x_{A_1}^* x_{B_1}^* (1 + x_{A_1}^* K_1)$$

In deriving these limiting relations, the following relations derived from eq. 8 have been used (3):

[11] $$K_A = 1/x_{A_1}^* - 1/(1 - x_{A_1}^{*2} K_A')$$

[12] $$K_B = 1/x_{B_1}^* - 1$$

Note that, if $K_A = 0$, eq. 11 becomes

[13] $$K_A' = (1/x_{A_1}^* - 1)/x_{A_1}^*$$

If experimental data on excess Gibbs energies are fitted to the usual polynomial expansion

[14] $$G_m^E / RT = x_A x_B \sum_{r=1}^{n} g_r (x_A - x_B)^{r-1}$$

where R is the ideal gas constant and T the thermodynamic temperature, then it is found that (3)

[15] $$l_A^{(g)} = \exp \left\{ \sum_{r=1}^{n} (-1)^{r-1} g_r \right\}$$

[16] $$l_B^{(g)} = \exp \left\{ \sum_{r=1}^{n} g_r \right\}$$

It will be shown below how experimental values of $l_A^{(g)}$ and $l_B^{(g)}$ can be used to find values of the association parameters. Once these have been found, data on excess enthalpies and volumes can be analyzed.

(b) Excess Enthalpies

Well-known thermodynamic relations (19) give

[17] $$R \ln f_A = G_m^E / T - x_B \partial (G_m^E / T) / \partial x_B$$

and

[18] $$H_A - H_A^* = H_m^E - x_B \partial H_m^E / \partial x_B$$

where H_m^E is the molar excess enthalpy and H_A, H_A^* are the partial molar enthalpies of A in the mixture of composition x_B and in the pure liquid, respectively. Analogous equations for component B are found by interchanging the subscripts A and B. Differentiation of eq. 17 with respect to $1/T$ gives eq. 18. It follows that

[19] $$l_A^{(h)} = R \, \partial \ln l_A^{(g)} / \partial (1/T)$$

and that a similar relation holds for $l_B^{(h)}$, where $l_A^{(h)}$, $l_B^{(h)}$ are the limiting partial molar heats of mixing of components A and B. From eqs. 9, 10, and 19,

[20] $$l_A^{(h)} = u - \Delta H_A^* - \{1 + x_{B_1}^* K_1 (2 + 3 x_{B_1}^* K_2)\} \Delta H_B^* / \{1 + x_{B_1}^* K_1 (1 + x_{B_1}^* K_2)\} + x_{B_1}^* K_1 \{(1 + x_{B_1}^* K_2) \Delta H_1^{\ominus} + x_{B_1}^* K_2 \Delta H_2^{\ominus}\} / \{1 + x_{B_1}^* K_1 (1 + x_{B_1}^* K_2)\}$$

[21] $$l_B^{(h)} = u - \Delta H_B^* - \Delta H_A^* - x_{A_1}^* K_1 (\Delta H_A^* - \Delta H_1^{\ominus}) / (1 + x_{A_1}^* K_1) + 2 x_{A_1}^{*2} K_A' \{(1 - x_{A_1}^* K_A' - x_{A_1}^*) \Delta H_A'^{\ominus} + (3 x_{A_1}^* + 2 x_{A_1}^* K_A' - 2) \Delta H_A^*\} / Q'$$

where

[22] $$Q' = 2 x_{A_1}^{*3} K_A' + (1 - x_{A_1}^{*2} K_A')^2$$

In these equations, standard values of ΔH (indicated by superscript $\ominus$) are the usual derivatives $-R\partial/\partial(1/T)$ of the appropriate equilibrium constants. The starred quantities are (cf. (3))

[23] $$\Delta H_A^* = R\partial \ln x_{A_1}^*/\partial(1/T)$$

[24] $$\Delta H_B^* = R\partial \ln x_{B_1}^*/\partial(1/T) = (1 - x_{B_1}^*)\Delta H_B^{\ominus}$$

and

[25] $$u = R\partial w/\partial(1/T)$$

The enthalpy terms connected with self-association of acetonitrile are connected by the following relation derived from eq. 11:

[26] $$x_{A_1}^* K_A \Delta H_A^{\ominus} = \{1 + 2x_{A_1}^{*3} K_A'/(1 - x_{A_1}^{*2} K_A')^2\}\Delta H_A^* - x_{A_1}^{*3} K_A' \Delta H_A'^{\ominus}/(1 - x_{A_1}^{*2} K_A')^2$$

For the special case $K_A = 0$, eqs. 26 and 13 give:

[27] $$\Delta H_A^* = (1 - x_{A_1}^*)\Delta H_A'^{\ominus}/(2 - x_{A_1}^*)$$

From eq. 14, the experimental enthalpies can be represented as a series

[28] $$H_m^E = x_A x_B \sum_{r=1}^{n} h_r (x_A - x_B)^{r-1}$$

and from eq. 17,

[29] $$h_r = R\partial g_r/\partial(1/T)$$

From [28], [15], and [16],

[30] $$l_A^{(h)} = \sum_{r=1}^{n} (-1)^{r-1} h_r$$

[31] $$l_B^{(h)} = \sum_{r=1}^{n} h_r$$

The limiting partial molar heats of mixing can therefore be obtained from experimental data expressed in the form of eq. 28, and it will be shown below how these values can be used to evaluate the enthalpy parameters for association.

Once the enthalpy parameters have been determined, the excess enthalpy – composition curve can be calculated as follows. From eqs. 5, 6, 17, and 18,

[32] $$H_A - H_A^* = R\partial \ln x_{A_1}/\partial(1/T) - \Delta H_A^* + u x_B^2$$

and similarly for component B. The molar excess enthalpy is then

[33] $$H_m^E = x_A(H_A - H_A^*) + x_B(H_B - H_B^*)$$

Differentiation of eqs. 5 (or 6) and 8 gives two simultaneous linear equations in the temperature derivatives of x_{A_1} and x_{B_1}, with solutions

[34] $$\partial x_{A_1}/\partial(1/T) = (Q_2 Q_6 - Q_3 Q_5)/(Q_1 Q_5 - Q_2 Q_4)$$

[35] $$\partial x_{B_1}/\partial(1/T) = (Q_3 Q_4 - Q_1 Q_6)/(Q_1 Q_5 - Q_2 Q_4)$$

where

[36] $$Q_1 = x_B(1 + x_{A_1}K_A)/(1 - x_{A_1}K_A)^3 + 4x_B x_{A_1} K_A' + x_{B_1} K_1(2x_B - 1) + x_{B_1}^2 K_1 K_2(3x_B - 2)$$

[37] $$Q_2 = -x_A(1 + x_{B_1}K_B)/(1 - x_{B_1}K_B)^3 + x_{A_1} K_1(2x_B - 1) + 2x_{A_1} x_{B_1} K_1 K_2(3x_B - 2)$$

[38] $$\begin{aligned} RQ_3 = {} & -2x_B x_{A_1}^2 K_A \Delta H_A^{\ominus}/(1 - x_{A_1}K_A)^3 + 2x_A x_{B_1}^2 K_B \Delta H_B^{\ominus}/(1 - x_{B_1}K_B)^3 \\ & - 2x_B x_{A_1} K_A' \Delta H_A'^{\ominus} - (2x_B - 1)x_{A_1} x_{B_1} K_1 K_2 \Delta H_1^{\ominus} \\ & - (3x_B - 2)x_{A_1} x_{B_1}^2 K_1 K_2 (\Delta H_1^{\ominus} + \Delta H_2^{\ominus}) \end{aligned}$$

[39] $$Q_4 = 1/(1 - x_{A_1}K_A)^2 + 2x_{A_1} K_A' + x_{B_1} K_1(1 + x_{B_1} K_2)$$

[40] $$Q_5 = 1/(1 - x_{B_1}K_B)^2 + x_{A_1}K_1(1 + 2x_{B_1}K_2)$$

[41] $$RQ_6 = -x_{A_1}{}^2K_A\Delta H_A{}^{\ominus}/(1 - x_{A_1}K_A)^2 - x_{B_1}{}^2K_B\Delta H_B{}^{\ominus}/(1 - x_{B_1}K_B)^2 - x_{A_1}{}^2K_A{}'\Delta H_A{}'^{\ominus} - x_{A_1}x_{B_1}K_1\Delta H_1{}^{\ominus} - x_{A_1}x_{B_1}{}^2K_1K_2(\Delta H_1{}^{\ominus} + \Delta H_2{}^{\ominus})$$

For each pair of calculated values of x_{A_1} and x_{B_1}, the derivatives and the excess enthalpy can be calculated.

The significance of $x_{A_1}{}^*$, $x_{B_1}{}^*$, $\Delta H_A{}^*$, $\Delta H_B{}^*$ (and, as defined below, $\Delta V_A{}^*$ and $\Delta V_B{}^*$) should be recalled (3): $RT \ln x_{A_1}{}^*$ is the change in molar Gibbs energy for formation, in the pure liquid, of the equilibrium distribution of self-associated complexes from monomers, and $\Delta H_A{}^*$, $\Delta V_A{}^*$ are the accompanying changes in enthalpy and in volume. The standard quantities (superscript $\ominus$) specify as usual that all species are in their reference states, here the hypothetical pure liquid for each species in the mixture.

(c) Excess Volumes

Equations analogous to [17] to [19] may be derived by differentiating with respect to pressure instead of temperature. Thus,

[42] $$V_A - V_A{}^* = V_m{}^E - x_B\partial V_m{}^E/\partial x_B$$

where $V_m{}^E$ is the molar excess volume and V_A, $V_A{}^*$ are the partial molar volumes of A in the mixture of composition x_B and in the pure liquid, respectively. Differentiation of eq. 17 with respect to pressure p gives eq. 42. It follows that

[43] $$l_A{}^{(v)} = RT\partial \ln l_A{}^{(g)}/\partial p$$

and that a similar equation holds for $l_B{}^{(v)}$, where $l_A{}^{(v)}$, $l_B{}^{(v)}$ are the limiting partial molar volumes of mixing of components A and B. Analogues of eqs. 20 through 41 hold for the excess volumes, and are obtained from these equations by replacing H with V, h_r with v_r, u with v, and $R\partial/\partial(1/T)$ with $RT\partial/\partial p$.

Although the relations above have been developed for a specific model for association, analogous relations can be developed by the same method for other models.

(d) The Non-specific Interaction Parameters

Relations among the interaction parameters are useful for interpretation of available data on systems involving acetonitrile. If the interaction parameters w_{ij} refer to simple mixtures, the approximate relation of Malesinski (9, 20) connecting the values of w_{ij} for the three different binary systems that can be formed from components 1, 2, 3 is

[44] $$w_{23} = w_{13} - w_{12}$$

From this equation and eq. 25 it follows that (9)

[45] $$u_{23} = u_{13} - u_{12}$$

and that, analogously, $v = RT\partial w/\partial p$, giving

[46] $$v_{23} = v_{13} - v_{12}$$

For a series of systems that show formation of complexes between components 2 and 3, Kreglewski (9) assumed that w_{12} and w_{13} could be replaced by the appropriate experimental values of $4G_m{}^E/RT$ (i.e., at mole fraction $\frac{1}{2}$), and argued that self association effects for one component (3, say) would largely cancel. The value of w_{23} calculated in this way was taken to be the contribution of non-specific interactions to the total excess Gibbs energy of mixtures of components 2 and 3. However, it is clear from eqs. 5 and 6 that the effects of self-association and binary association are not additive, and here relations [44]–[46] are considered to apply only to the interaction parameters, and not to the excess Gibbs energies at mole fraction $\frac{1}{2}$.

McGlashan *et al.* (21) discussed formation of simple complexes from the point of view of lattice theory, pointing out that wRT is a Gibbs energy and that for many simple mixtures $w = A/T^2$ and $u = 2wRT$ hold approximately, where A is a constant. Bertrand (22) assumed that a non-specific interaction term existed for each species in a mixture containing simple complexes, and by a series of approximations reduced the problem to finding a single w that was estimated from solubility parameters. Bertrand's method is clearly a crude version of the correct lattice theory that ignores entropic contributions to w and that cannot be applied either to self-associating components or to polar molecules (23).

Applications and Discussion

(a) Excess Gibbs Energies

For analysis of complexes in mixtures of

acetonitrile and chloroform, available data on binary mixtures of carbon tetrachloride, chloroform, and acetonitrile are used, where it is assumed that carbon tetrachloride takes no part in complex formation, but that both chloroform and acetonitrile are self-associated. The three possible systems are indicated by Roman numerals: CCl_4–$CHCl_3$(I), CH_3CN–CCl_4(II), CH_3CN–$CHCl_3$(III), and the first-named component is component A. For these three systems, eight parameters $w_{12}, w_{13}, w_{23}, x_{A_1}^*, x_{B_1}^*, K_1, K_2$, and K_A' appear in eqs. 9 and 10.

Excess Gibbs energies have been calculated from isothermal liquid–vapour equilibrium data for both CCl_4–$CHCl_3$ (11) and CH_3CN–CCl_4 (10). For CCl_4–$CHCl_3$, a one-constant equation of type [14] represents the data, with $g_1 = h_1/RT + g_0$. The value of h_1 is that recommended by McGlashan *et al.* (11), and its standard deviation was estimated from the summary of heats of mixing given by them. The constant g_0 and its standard deviation were found from least-squares evaluation of the G_m^E data at three temperatures; its value differs slightly from that of McGlashan *et al.* (11). For CH_3CN–CCl_4, the data (10) were fitted by least squares to an equation of type [14] in order to find estimated standard deviations. The coefficients differ slightly from those given by Brown and Smith (10).

Excess Gibbs energies for CH_3CN–$CHCl_3$ have been obtained at 40°C from measurements of total vapour pressures (9) by Barker's method (24), and by neglecting the second virial cross-coefficient for the vapour. It is known (3) that this coefficient is of considerable importance, and the data have been recalculated using virial coefficients estimated by the method[2] of Prausnitz *et al.* (25, 26). The necessary data (26) give the values $B_{AA} = -3256$, $B_{AB} = -698$, $B_{BB} = -1115$ cm^3 mol^{-1} at 40°C (A-acetonitrile) on calculation. The values for B_{AA} and B_{BB} are in good agreement with the average of tabulated values (27). The results of all recalculations of g_r are given in Table 1, along with estimated standard deviations σ. Correlation coefficients for the g_r values are necessary to find standard deviations for derived quantities such as activity coefficients, but are not listed here. The coefficients for CH_3CN–$CHCl_3$ at 45°C were estimated from the values at 40°C and the enthalpies of mixing (7), assuming that the enthalpies of mixing are independent of temperature over this range. For each system, the number of coefficients g_r tabulated is the number that gave the smallest standard deviation or that gave a variance ratio that indicated the minimum number of coefficients required.

Since the limiting activity coefficients for CCl_4–CH_3Cl are equal, there are only five limiting activity coefficients that can be used to find the eight association parameters. Estimation of the parameters proceeds as follows. For system II (CH_3CN–CCl_4), $K_1 = K_2 = K_B = 0$ and the ratio $l_B^{(g)}/l_A^{(g)}$ (eqs. 9, 10) gives a quadratic equation in K_A' for a given value of $x_{A_1}^*$. The value of $x_{A_1}^*$ is a maximum for $K_A = 0$, and, for this value of K_A, determines the values of K_A' and w_{13} through eqs. 9 and 13. These parameters are then used for an iterative solution of eqs. 5 and 8 by computer to find x_{A_1} and x_{B_1}, using initial values of these quantities found by setting the stoichiometric activity coefficients equal to unity. The activity coefficients and G_m^E are then calculated. The parameters found in this way reproduced the experimental G_m^E–x_B curve very well, the maximum deviation being only 4.2% at $x_B = 0.5$. Calculations of the enthalpy of mixing (see below) using these parameters were less successful, and, in fact, a better fit to the excess Gibbs energies was found by using a non-zero value of K_A. Values of K_A' were chosen, and the corresponding values of $x_{A_1}^*$,

[2]The sign of the association term in the equation for the virial coefficients is incorrect in refs. 25, 26, but correct in the computer program in ref. 26.

w_{13}, and K_A were found from eqs. 9, 10, and 11. The value of K_A' that gave the minimum χ^2 for nine values of G_m^E calculated from the experimental polynomial at equally-spaced mole fractions was taken as the final value (Table 4). The estimated standard deviation in K_A' was found by finding the values of K_A' that produced twice the minimum χ^2, while the standard deviations in K_A and in x_{A_1}* were calculated from this value and (through eqs. 9 to 11) the error matrix for the experimental polynomial. Agreement between the theoretical and experimental excess Gibbs energy curves (Fig. 1) is excellent, with an estimated standard deviation (28) of only 19 J mol^{-1}.

Non-specific interactions contribute 718 J mol^{-1} to G_m^E at mole fraction one-half. The remaining positive contribution to the almost symmetrical curve is due to self-association. Kreglewski's method (9) gives the much larger value 1082 J mol^{-1} for non-specific interactions at equal mole fractions.

Saum (13) has estimated x_{A_1}* = 0.04 at 30°C by consideration of heats of vapourization and viscosities of a homologous series of nitriles. His value of the enthalpy of association gives x_{A_1}* = 0.12 at 45°C from eqs. 23 and 27, in reasonable agreement with the value found here when the highly approximate nature of Saum's estimate is considered.

For mixtures of CH_3CN and $CHCl_3$, the relation of Malesinski (eq. 44), the ratio $l_A^{(g)}(III) \times l_A^{(g)}(I)/l_A^{(g)}(II)$ and the corresponding ratio for the $l_B^{(g)}$-values give an equation that relates x_{B_1}* to x_{A_1}*, if $K_2 = 0$. Numerous trials showed that $K_2 < K_1$ was a condition that was incompatible with the experimental data, that K_1 was at least 100 times smaller than K_2, and that x_{B_1}* was smaller than unity. The final values of the parameters and their standard deviations were found by the constrained least-squares procedure outlined above, this time setting $K_1 = 0$ and choosing a value of x_{B_1}* that gave a minimum χ^2. Agreement between the theoretical and experimental G_m^E-composition curves is again excellent, with a standard deviation of 3.9 J mol^{-1} (Fig. 1).

Non-specific interactions contribute −215 J mol^{-1} to G_m^E at equal mole fractions. This contribution and the negative contribution from complex formation are overbalanced by self-association of acetonitrile. The skewness of the curve results mainly from formation of a complex containing two molecules of $CHCl_3$. Use of volume fractions instead of mole fractions in the non-specific interaction term would also skew the curve in the same direction. However, the heat of mixing curve (Fig. 2) is skewed in the opposite direction.

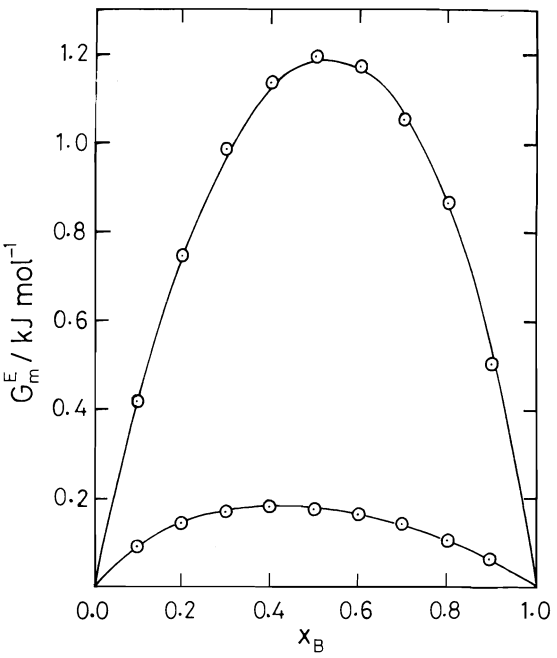

FIG. 1. Excess Gibbs energies at 318 K. Upper curve: CH_3CN–CCl_4; lower curve: CH_3CN–$CHCl_3$. Lines: experimental polynomials; open circles: values from association theory.

Values of K_1 for formation of AB-type complexes between acetonitrile and chloroform have been derived from nmr measurements (15, 16) by assuming that only these complexes are formed and that self-association of acetonitrile does not affect the calculations, or is included in a solvent shift. The nmr data, however, can be interpreted equally well by assuming that only an AB_2 complex is formed. The method of doing this is outlined in the Appendix, and gives $K_2 = 1.9$ at 297 K, which is the same value found for this temperature by extrapolation from 318 K using the enthalpy of complex formation (Table 4). From the constants in Tables 1 and 4 it is calculated that the fraction of CH_3CN molecules that is self-associated is 0.73 at $x_B = 0.336$ (the most concentrated solution of $CHCl_3$ used by Lin and Tsay (16)) and 0.86 at $x_B = 0$, while the fraction of CH_3CN molecules in AB_2 complexes varies from 0.063 to zero over the same range of

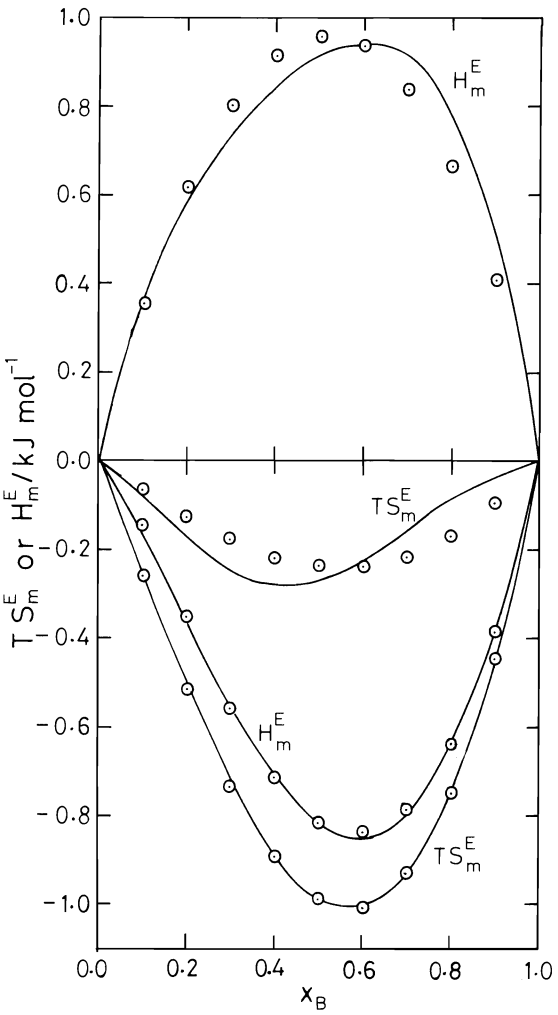

FIG. 2. Excess enthalpies and entropies (as TS_m^E). Upper curves: CH_3CN–CCl_4, 318 K; lower curves: CH_3CN–$CHCl_3$, 298 K for H_m^E, 318 K for TS_m^E. Lines: experimental polynomials; open circles: values from association theory.

composition. At $x_B = 0.0290$ (the lowest concentration of Lin and Tsay (16)), a fraction 0.85 of CH_3CN molecules are self-associated and a fraction 8.8×10^{-4} is in AB_2 complexes. Even at this low concentration it is estimated that the mole fraction of AB complexes is not more than one-quarter that of AB_2 complexes. The assumptions that self-association of acetonitrile is roughly constant and that AB complexes are negligible over the range of composition used in the nmr studies thus appears to be justified.

The solid–liquid phase diagram for $CHCl_3$–CH_3CN (18) shows no evidence for complex formation, while $CHCl_3$–propionitrile shows an AB complex and $CHCl_3$–butyronitrile shows both AB and AB_2 complexes. Murray and Schneider (18) proposed that self-association in acetonitrile was so extensive that formation of binary complexes was prevented. This question can be investigated by extrapolating the coefficients in Tables 1 and 4 to 183 K (where a solid compound might exist) and calculating the fraction of acetonitrile molecules that are self-associated. This fraction varies from 0.9 at $x_B = 0$ to 0.74 at $x_B = 0.5$ to 0.46 at $x_B = 0.67$ and is probably an overestimate; the enthalpy terms have been assumed independent of temperature, but there is probably a significant positive heat capacity of association. Thus, there should be sufficient opportunity for binary compounds to form at low temperatures, and a reinvestigation of the phase diagram is desirable.

The coefficient g_1 for CCl_4–$CHCl_3$, with the value of x_{B_1}*, yields the value of w_{12} in Table 2. This non-specific interaction term contributes 60 J mol^{-1} to G_m^E at equal mole fractions of $CHCl_3$ and CCl_4, or 61% of the total. Proton nmr measurements (14) give $K_B = 0.16$ for a one-step self-association of chloroform at 25°C, a value that corresponds to x_{B_1}* = 0.88. At 45°C, the value of x_{B_1}* should be closer to unity, and at the normal boiling point (61°C) the Trouton constant $\Delta S_1^v/R = 10.67$ has the "normal" value for an unassociated liquid (3). The value x_{B_1}* = 0.94 (Table 4) is in good agreement with these considerations. The fact that CCl_4–$CHCl_3$ mixtures have equal limiting activity coefficients in the range 298–328 K is incompatible with the assumption made in interpreting the nmr data that only $CHCl_3$ dimers are formed.

(b) Enthalpies of Mixing

In Table 2, the least-squares coefficient in the polynomial equation [28] is taken from values in the literature for CCl_4–$CHCl_3$ (11). For CH_3CN–$CHCl_3$ the tabulated coefficients (7) were recalculated to find the error matrix, and for CH_3CN–CCl_4 (12) the data were fitted to a least-squares polynomial. The same number of coefficients for polynomials [28] and [14] was found to give satisfactory fits in all cases and all coefficients are given in Table 2. It is assumed that, for CH_3CN–$CHCl_3$ mixtures, the enthalpies of mixing are independent of temperature between 25 and 45°C. This is a good assumption

TABLE 2. Coefficients for calculation of excess enthalpies (eq. 28) in J mol^{-1}

System	T/K	h_1	$\sigma(h_1)$	h_2	$\sigma(h_2)$	h_3	$\sigma(h_3)$	h_4	$\sigma(h_4)$
CCl_4–$CHCl_3$	289–328	930	2	—	—	—	—	—	—
CH_3CN–CCl_4	318.15	3636	40	−966	152	1657	154	−274	371
CH_3CN–$CHCl_3$	298.15	−3250	11	1505	21	319	52	—	—

for some associated mixtures (e.g., olefin–SO_2 (3)), but for others (e.g., aromatic hydrocarbons – CCl_4 (21)), the heat of mixing at $x_B = 0.5$ can vary as much as 30 J mol^{-1} over a range of 20 K.

Equations 20 and 21, when applied to CH_3CN–CCl_4 mixtures, give a single equation in $\Delta H_A'^{\ominus}$ and ΔH_A^*. A value of $\Delta H_A'^{\ominus}$ was chosen which, with the values of $x_{A_1}^*$, K_A', and K_A found previously, determines ΔH_A^*, $\Delta H_A^{\ominus}$, and u_{13}. These parameters were then used to find H_m^E from eqs. 32–41, along with values of x_{A_1} and x_{B_1} calculated from the experimental polynomial for G_m^E and eqs. 5 and 6. The value of $\Delta H_A'^{\ominus}$ was then varied until a minimum χ^2 was found, and the resulting parameters $\Delta H_A'^{\ominus}$, $\Delta H_A^{\ominus}$, ΔH_A^*, and u_{13} are given in Table 4. The theoretical curve is less skewed than the experimental curve (see Fig. 2), and deviations are considerably larger than the estimated random errors in the experimental polynomial. The standard deviation for the fit is 78 J mol^{-1}. However, only two experimental values of H_m^E are available for $x_B > 0.5$; more experimental values could alter the shape of the curve considerably. Use of volume fractions instead of mole fractions in the non-specific interaction term would skew the calculated curve in the wrong direction. Non-specific interactions amount to 653 J mol^{-1} at equal mole fractions.

Saum (13) estimated the energy of parallel dipole interaction in acetonitrile to be −28 kJ mol^{-1}, if the C—N distances between adjacent molecules are equal to the sum of the van der Waals' radii. This value is close to the value −23 kJ mol^{-1} estimated from the electrostatic reaction field (29) and to −22 kJ mol^{-1} estimated by Lambert *et al.* (30) from the virial coefficients of acetonitrile vapour. Meyer and coworkers (31, 32), on the other hand, estimated that induction forces contribute −11 kJ mol^{-1} to the cohesive energy of acetonitrile, and −4 kJ mol^{-1} to the orientation energy. Their calculation was based essentially on the curvature of heats of vaporization as a function of chain length in a homologous series of nitriles. The ΔH_A parameters presumably are measures of orientation energy, since they refer to formation of complexes from a hypothetical liquid consisting only of monomers. The "mean" enthalpy change, ΔH_A^*, has a value close to Meyer's value of orientation energy. Dipole–dipole attractions (13) at distances larger than the van der Waals' radii or at angles between adjacent dipoles of less than 180° (18) could account easily for the values of $\Delta H_A'^{\ominus}$ and $\Delta H_A^{\ominus}$.

For CH_3CN–$CHCl_3$ mixtures, values of the parameters for acetonitrile were used, and choosing ΔH_B^* then determines $\Delta H_2^{\ominus}$ and u_{23} through eqs. 20 and 21. The same constrained least-squares procedure then yielded the values in Table 4. The agreement between calculated and observed values is excellent with a standard deviation of 13 J mol^{-1}. The point of inflection at $x_B = 0.1875$ is reproduced well by the theory. As with the excess Gibbs energies, the main contribution to skewness is the formation of complexes containing two molecules of $CHCl_3$. The non-specific interaction term contributes −81 J mol^{-1} at equal mole fractions, a rather small value because of the large positive contribution from acetonitrile interactions. Use of volume fractions in the non-specific term would skew the curve in the wrong direction.

For CCl_4–$CHCl_3$ mixtures, the value of ΔH_B^* and eq. 20 determines the value of u_{12}. The calculated reaction field energy in chloroform is −0.75 kJ mol^{-1} (29), again larger than the value of ΔH_B^*, which presumably reflects orientation energy. Non-specific interactions contribute 200 J mol^{-1} or 22% of the heat of mixing at equal mole fractions.

(c) Excess Entropies

Excess entropies of mixing were calculated from both the experimental and theoretical values of G_m^E and H_m^E, and are shown in Fig. 2. As expected, the errors in the model or in the data for H_m^E are emphasized in taking differences between H_m^E and G_m^E, so that the agree-

TABLE 3. Coefficients for calculation of excess volumes (cf. eq. 28) in $cm^3\ mol^{-1}$

System	T/K	v_1	$\sigma(v_1)$	v_2	$\sigma(v_2)$	v_3	$\sigma(v_3)$	v_4	$\sigma(v_4)$
CCl_4–$CHCl_3$	297.15	0.695	0.036	—	—	—	—	—	—
CH_3CN–CCl_4	298.15	−0.533	0.025	0.016	0.078	0.391	0.054	−0.269	0.124
CH_3CN–$CHCl_3$	313.15	−1.265	0.002	0.838	0.005	−0.072	0.010	—	—
	318.15	−1.302	0.002	0.856	0.005	−0.076	0.010	—	—

ment between the experimental and theoretical curves for CH_3CN–CCl_4 is only qualitative. The most striking discrepancies are that the curves are skewed in opposite directions and that the two points of inflection in the experimental curve are not found by theory. Non-specific interactions account for -65 J mol^{-1} at equal mole fractions, so that there is a large negative contribution from self-association.

For CH_3CN–$CHCl_3$, the calculated and experimental curves agree closely. Non-specific interactions contribute -535 J mol^{-1} at equal mole fractions, and there is a negative contribution due to self-association and complex formation that is considerably larger than in CH_3CN–CCl_4. The excess entropy for CCl_4–$CHCl_3$ is always positive. At equal mole fractions, non-specific interactions contribute 140 J mol^{-1} to TS_m^E, or 104% of the total, leaving a contribution of -5 J mol^{-1} for self-association of chloroform.

Standard entropy changes can be calculated for each corresponding equilibrium constant and enthalpy of association, and are given in Table 4. It has been suggested (5, 6) that the decrease in entropy on association arises mainly from the loss of orientational degrees of freedom, i.e.,

$$[47] \qquad q = \exp(-\Delta S^{\ominus}/R)$$

where q is the number of nearest-neighbour contacts that are lost by a monomer on association. The values of q calculated from the data in Table 4 are 3 for reaction 1, 14 for reaction 2, 2 for reaction 3, and 27 for reaction 4, compared to the value of 6–10 expected for freely-rotating molecules in a liquid. Clearly, other contributions to the entropy of association are present, among them a change in entropy involving dipole orientation.

(d) Volumes of Mixing

Polynomial least-squares fits according to the volume analogue of eq. 28 were recalculated on the data for excess volumes of CCl_4–$CHCl_3$ (11) and CH_3CN–$CHCl_3$ (8) in order to estimate errors. For CH_3CN–CCl_4, excess volumes were calculated from density data (10) and fitted to a least-squares polynomial. The coefficients of all polynomials are given in Table 3.

Analysis of the experimental data by association theory proceeds exactly as for the analysis of the heats of mixing. For CCl_4–$CHCl_3$ and CH_3CN–CCl_4, the experimental data are for 298 K, and values of the required association parameters were calculated at this temperature using the enthalpy data in Table 4. For CH_3CN–$CHCl_3$, data are available at 293 and 313 K (8), permitting a linear extrapolation (33) to 318 K. The resulting parameters are given in Table 4. The volume changes for association are all negative, and are small compared to the molar volumes of the components (52.9, 97.1, and 80.7 $cm^3\ mol^{-1}$ at 298 K for CH_3CN, CCl_4, and $CHCl_3$, respectively). The theoretical excess volume–composition values (Fig. 3) agree well with the experimental values; the standard deviations are 0.011 $cm^3\ mol^{-1}$ for CH_3CN–CCl_4, and 0.015 $cm^3\ mol^{-1}$ for CH_3CN–$CHCl_3$. The predominantly negative excess volume for CH_3CN–CCl_4 becomes zero at $x_B = 0.962$, then reaches a positive maximum of 9.9×10^{-4} $cm^3\ mol^{-1}$ at $x_B = 0.982$, according to the polynomial equation (cf. 10, 33). One positive value has been measured (10): $V_m^E = 0.0015$ $cm^3\ mol^{-1}$ at $x_B = 0.9535$. The association theory curve also shows reversal of sign, which occurs at $x_B = 0.994$ and reaches a maximum of 1.6×10^{-4} $cm^3\ mol^{-1}$ at $x_B = 0.997$. While the quantitative agreement between these two sets of values is poor, they are both subject to large errors. The limiting partial molar volume of mixing is negative at $x_B = 0$ and positive at $x_B = 1$, so that the theoretical curve is constrained to undergo a change in sign. That this change in sign occurs at a mole fraction close to the experimental value is an indication of the high degree of consistency among the theoretical

TABLE 4. Association and interaction parameters for binary liquid mixtures containing carbon tetrachloride (1), chloroform (2,B), and acetonitrile (3,A)*

Parameter	Value	Parameter	Value	Parameter	Value	Parameter	Value

w_{12}	0.091(0.091)	u_{12}	0.801(0.020)	s_{12}	1.76(0.80)	v_{12}	0.667(0.044)
w_{13}	1.09(0.15)	u_{13}	2.6(1.6)	s_{13}	−0.82(1.2)	v_{13}	−0.73(0.77)
w_{23}	0.33(0.18)	u_{23}	−3.0(1.9)	s_{23}	−12.2(6.1)	v_{23}	−0.94(1.2)

*Parentheses show estimated standard deviations. Enthalpies in kJ mol^{-1}, entropies in J K^{-1} mol^{-1}, volumes in cm^3 mol^{-1}. T = 318 K except for volume parameters subscripted A, v_{12}, and v_{23}, which are for 298 K.

FIG. 3. Excess volumes. Upper curve: CH_3CN–CCl_4, 298 K; lower curve: CH_3CN–$CHCl_3$, 318 K. Lines: experimental polynomials; open circles: values from association theory.

parameters for the excess Gibbs energy and the excess volume. For this system, non-specific interactions contribute −0.183 cm^3 mol^{-1} at equal mole fractions, the contribution from self-association being positive.

The excess volume–composition curve for CH_3CN–$CHCl_3$ has a point of inflection at $x_B = 0.2367$ that is reproduced well by the theory. Non-specific interactions contribute −0.235 cm^3 mol^{-1} at equal mole fractions, the balance being the net result of self-association (positive contribution) and complex formation (negative contribution).

For CCl_4–$CHCl_3$, non-specific interactions contribute 0.167 cm^3 mol^{-1} or 96% of the excess volume at equal mole fractions. The remaining positive contribution is from self-association of chloroform. For all three systems, the product pV_m^E is negligible compared to G_m^E or H_m^E.

(e) Relations Among the Parameters

The data in Table 4 indicate clearly that eqs. 44–46 are poor approximations; the correct sign for the 2–3 interaction is obtained only for the volume interaction term v_{23}. The ratios u_{ij}/RTw_{ij} have the values 3.32, 0.91, and 3.49 for CCl_4–$CHCl_3$, CH_3CN–CCl_4, and CH_3CN–$CHCl_3$, respectively, all of which are close to the average value of 2 suggested by McGlashan *et al.* (21). The values of $\Delta S^{\ominus}$ for self-association decrease roughly linearly with $\Delta H^{\ominus}$; it follows that $\Delta G^{\ominus}$ increases roughly linearly with $\Delta H^{\ominus}$. The values found for chain self-association of SO_2 (3) fit these correlations as well, and are very close to the values for chain self-association of acetonitrile.

(f) General Remarks

The power series equations and association theory both represent the experimental data well (except for the heats of mixing of CH_3CN–CCl_4), and both representations satisfy the Gibbs–Duhem equation. The two representations are not, however, identical. The limiting curvatures of the excess Gibbs energy – composition curves can be calculated from association theory and from the series equations. Despite the exact agreement imposed on the limiting slopes, and the general good agreement between experiment and theory at intermediate compositions, the calculated and experimental curvatures differ markedly in magnitude but have the same sign. The association theory equations for heats and volumes of mixing involve derivatives of G_m^E, and thus resemble the equations for the curvature. Enthalpies and volumes of association and complexing are available as disposable parameters, however, so that the temperature and pressure derivatives of the limiting slopes are chosen to agree with experiment.

Hildebrand and Scott (34) have pointed out that in many cases both association theory and regular solution theory give equally satisfactory fits to experimental data. A similar equivalence between association theory and Barker's statistical mechanical theory of associated mixtures (35, 36) has been found by Smith and Brown (2) for alcohol–alkane mixtures. From a rigorous statistical mechanical point of view, it would be desirable to calculate thermodynamic properties from suitable molecular interaction parameters and then to look for statistical mechanical interpretation of the parameters found from thermodynamic association theory. In this paper, the separation of interactions into specific and non-specific types is to some extent arbitrary, and thus simple correspondences between molecular and thermodynamic parameters may not exist. This problem will be the subject of future work. We note, however, that association theory gives a self-consistent, if limited, picture of interactions in these complex systems.

Acknowledgement

The authors wish to thank Dr. Y. P. Handa for supplying data on molar volumes of acetonitrile–chloroform mixtures in advance of publication.

Appendix

If only AB_2-type complexes form, the nmr data can be analyzed by standard methods (16). If Δ is the observed chemical shift of complexed chloroform relative to that of pure chloroform, δ_B, and $\Delta_{AB_2} = \delta_{AB_1} - 2\delta_B$ is the relative chemical shift of the complex, then it is found readily that

$$[48] \quad K_2 = \Delta(1 - 2x_B\Delta/\Delta_{AB_2})/(1 - 2\Delta/\Delta_{AB_2})^2 \times (x_A - x_B\Delta/\Delta_{AB_2})$$

This equation can be rearranged in the form of the equation for AB complexes (16):

$$[49] \quad (1 + 4K_2)\Delta/(1 - x_B) = K_2(\Delta_{AB_2} + 4\Delta_0^2/\Delta_{AB_2}) + 3K_2x_B\Delta/(1 - x_B) + 2x_B\Delta^2(1 - 2K_2\Delta/\Delta_{AB_2})/\Delta_{AB_2}(1 - x_B) + 4K_2\{\Delta^2/(1 - x_B) - \Delta_0^2\}/\Delta_{AB_2}$$

where Δ_0 is the value of Δ at $x_B = 0$. If $K_2 \sim 2$, $\Delta_{AB_2} \sim -0.6$, the third and fourth terms in eq. 49 have opposite signs, and at the highest x_B used by Lin and Tsay (16) total about 20% of the second term. Thus, approximately, $\Delta/(1 - x_B)$ is a linear function of $x_B\Delta/(1 - x_B)$. This is indeed the case for the results of Lin and Tsay (16), and the slope and intercept yield $K_2 = 1.87$, $\Delta_{AB_2} = -0.60$. The latter value is close to the value $\Delta_{AB} = -0.65$ (16). Inclusion of a solvent shift would alter these values slightly (16). The nmr data cannot, therefore, discriminate between the two cases $K_1 \ll K_2$ and $K_2 \ll K_1$ unless chemical shifts are measured over the whole range of compositions of the mixture.

C-Nucleosides and related compounds. XIII. Synthesis of D,L-2′-deoxyshowdomycin (1*d*)

Received September 23, 1976[1]

GEORGE JUST and MU-ILL LIM. Can. J. Chem. **55**, 2993 (1977).

Starting from the Diels–Alder adduct of furan and methyl β-nitroacrylate, the synthesis of the title compound is described.

GEORGE JUST et MU-ILL LIM. Can. J. Chem. **55**, 2993 (1977).

Partant de l'adduit de Diels–Alder du furanne avec le β-nitroacrylate de méthyle, on décrit une synthèse du composé mentionné dans le titre.

[Traduit par le journal]

We have recently described the synthesis of the 2′-epimer **1***b* of D,L-showdomycin **1***a* (1), and of the carbocyclic analogues of D,L-showdomycin **1***c* (2) and D,L-2′-deoxypyrazofurin A (3), starting from the Diels–Alder adducts of methyl β-nitroacrylate and furan or β-bromoacrylic acid and cyclopentadiene, respectively.

We now should like to describe a similar sequence of reactions leading to D,L-2′-deoxyshowdomycin **1***d* (see Scheme 1).

Because of some variability in the ratio of adducts **2** and **3** obtained in the initial Diels–Alder reaction, the reaction was studied in some detail. At 45°C, the concentration of the *endo*-nitro adduct **2** reached a maximum after 8 h (**2**:**3** = 2). After 4 days, an equilibrium was reached in which the *exo*-nitro adduct **3** predominated (**2**:**3** = 0.5).

Konig and co-workers reported the similar result that the *endo*-nitro isomer predominated in early stages of the Diels–Alder reactions of furan or 2,5-dimethyl furan with nitroethylene (4).

Hydroboration of the *exo*-nitro adduct **3** and oxidation of the resulting organoborane with alkaline hydrogen peroxide (5) was unsatisfactory. However, reaction of **3** with diborane in tetrahydrofuran at 0°C, followed by oxidation with triethylamine *N*-oxide dihydrate as reported by Kabalka and Hedgecock (6), resulted in the formation of the isomeric mixture of the alcohols **4***a* in 42% yield after chromatography on silicic acid.

The resulting isomeric alcohols **4***a* could not be separated. Direct acetylation of the alcohol using acetic anhydride and *p*-toluenesulfonic acid monohydrate afforded the acetates **4***b* in good yield. All attempts to separate the isomeric acetates failed. It is interesting to note here that acetylation with acetic anhydride in pyridine led to decomposition products, as already noted for similar bicyclic systems (1).

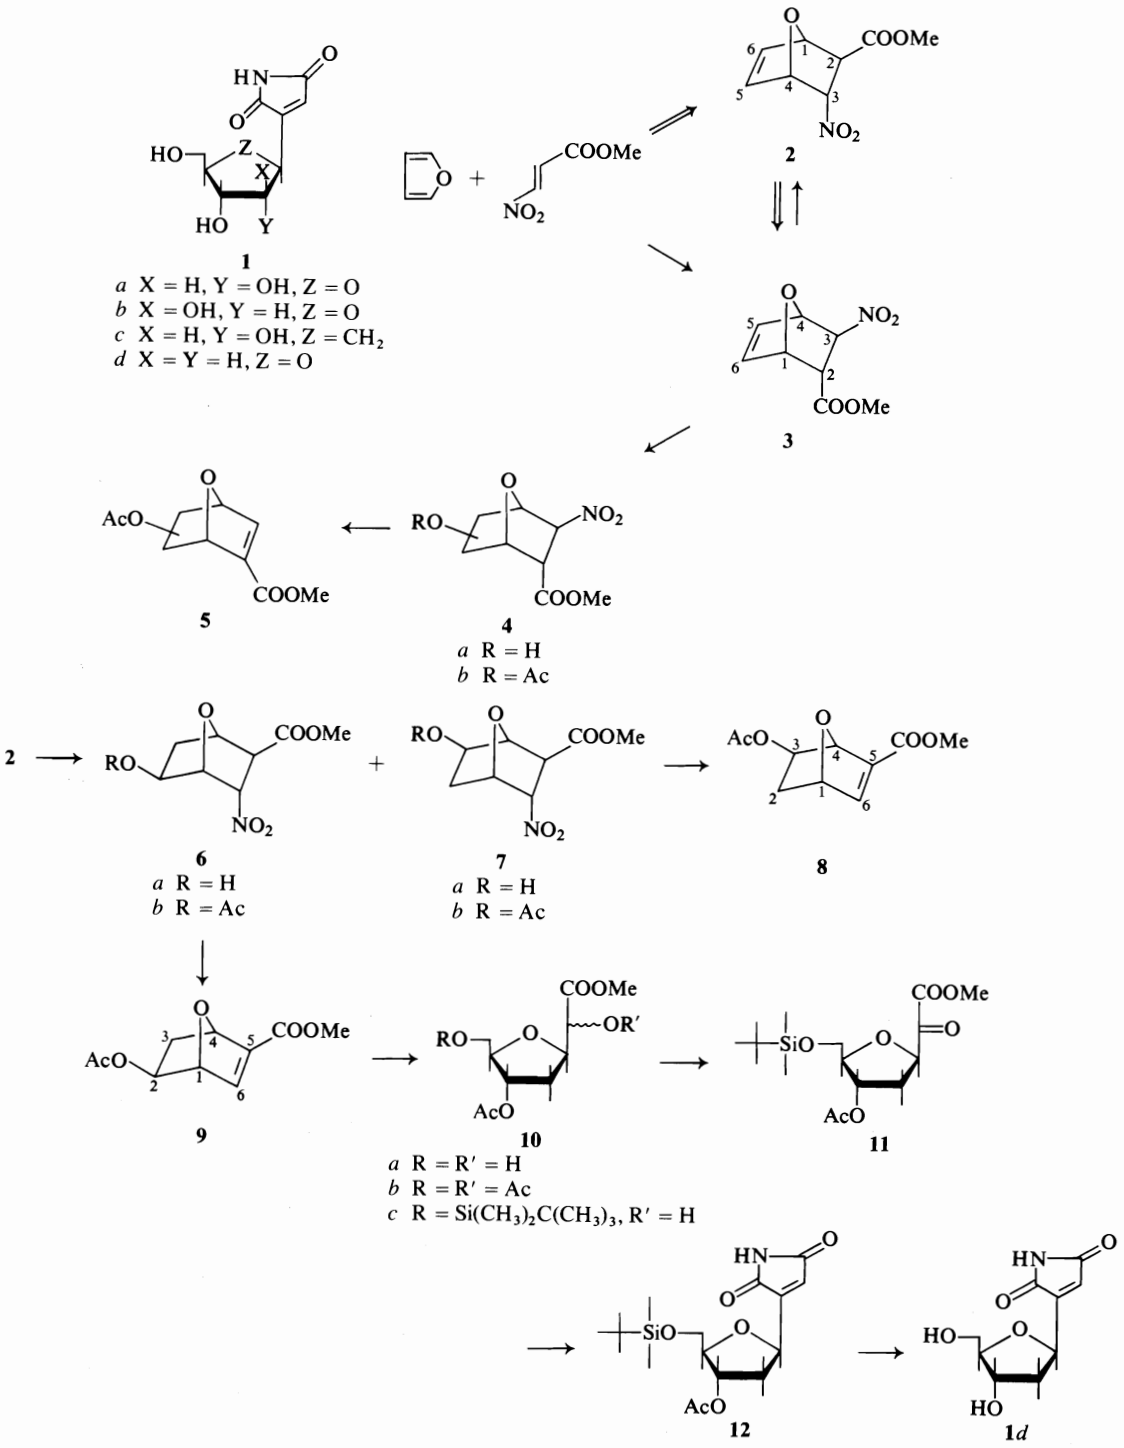
The acetates **4***b* were treated with diazabicyclo[5.4.0]undec-5-ene (DBU) in methylene chloride under reflux for 1 h to give the olefin esters **5** (7). The products consisted of a 1:1 mixture of isomers according to the nmr spectral data and could not be separated.

The above synthetic route was repeated starting with the *endo*-nitro adduct **2**. Hydroboration of **2** and oxidation of the resulting borane with triethylamine *N*-oxide dihydrate, under conditions identical to those described above, gave the isomeric alcohols **6***a* and **7***a* which were obtained in 46% yield after column chromatography on silicic acid. Without separation of the isomers, the mixture was acetylated with acetic anhydride and *p*-toluenesulfonic acid monohydrate in 82% yield. Both isomers were formed in approximately equal amounts, based on the nmr spectral data of **6***b*, **7***b*.

It was possible to separate the two isomers by fractional crystallization from hexane – carbon tetrachloride. One isomer, mp 113–114°C, was later identified to be the desired acetate **6***b* and the other, mp 67–68°C, to be the undesired acetate **7***b*. At this stage, we were unable to confirm the structures by nmr spectroscopy.

Elimination of nitrous acid from the acetate **6***b* by means of DBU in refluxing methylene chloride gave the 2-acetate olefin ester **9** in 91% yield. Using the same conditions as above,

[1]Revision received April 21, 1977.



SCHEME 1

nitrous acid elimination from the acetate **7***b* afforded, after chromatography, a good yield of the 3-acetate olefin ester **8**. Both isomers had virtually identical ir and mass spectra but different nmr spectra.

In the nmr spectrum of the 2-acetate **9**, the C-4 proton gave a doublet at δ 5.16 (J = 4 Hz) due to coupling with the C-3 *exo* proton. A doublet for the C-6 proton at δ 6.92 resulted from $J_{6,1}$ = 2 Hz. Decoupling of the C-6 proton readily allowed identification of the C-1 proton at δ 5.00 (J = 2 Hz) because irradiation of the doublet for the C-6 proton collapsed the doublet for the C-1 proton to a singlet. The C-2 proton signal was split into a doublet of doublets with $J_{2,3endo}$ = 6 Hz and $J_{2,3exo}$ = 2 Hz (X part of AMX). The C-3 protons appeared as a complex multiplet at δ 1.73–2.20. The remaining two singlets for the carbomethoxy and acetyl protons were found at δ 3.70 and 2.03, respectively.

In the case of the acetate **8**, a singlet for the C-4 proton could be expected since there is no coupling between the C-4 proton and C-3 *endo* proton. In fact, a one-proton singlet overlapped with a one-proton multiplet at δ 4.90–5.10. Irradiation of the multiplet collapsed a doublet for the C-6 proton at δ 7.03 (J = 2 Hz) to a singlet. Therefore, it was obvious that a singlet arose from the C-4 proton and a multiplet from the C-1 proton which coupled with the C-6 and C-2 protons. Like the C-2 *endo* proton in the 2-acetate, the C-3 *endo* proton showed a doublet of doublets with $J_{3,2endo}$ = 6 Hz and $J_{3,2exo}$ = 2 Hz.

Ozonolysis of the olefin ester **9** in methylene chloride at low temperature, followed by mild reduction with dimethyl sulfide (7), afforded the crude aldehydo keto ester and its hydrated form in a ratio of 1:3, as established by nmr.

Since we knew from previous experience that the aldehyde could not be reduced selectively (1), the aldehydo keto ester was treated with 4 equiv. of lithium tri-*tert*-butoxyaluminum hydride in tetrahydrofuran at 0°C for 4 h to give the diol ester **10***a* in 62% yield after column chromatography on silicic acid. The structure of the diol ester was confirmed by acetylation to **10***b*.

Selective silylation of the diol ester **10***a* with 1 equiv. of *tert*-butyldimethylsilyl chloride and imidazole in dimethylformamide (9) at room temperature for 20 h provided the hydroxy ester **10***c* in 77% yield after purification by column chromatography on silicic acid.

Several different methods were examined for the oxidation of the hydroxy ester **10***c* to the keto ester **11**. By far the best results were obtained using dimethyl sulfoxide – acetic anhydride (10).

The keto ester **11** obtained by oxidation with dimethyl sulfoxide – acetic anhydride was treated with 1 equiv. of carbamoylmethylenetriphenylphosphorane (11) in chloroform at room temperature for 2 h. The reaction gave a single major product together with a considerable amount of polar products. By chromatography of the products on silica gel plates, the maleimide **12** was isolated in an overall yield of 38% from the hydroxy ester **10***c*. In agreement with the maleimide structure, this product showed a strong uv absorption characteristic for the maleimide chromophore at 222 nm in ethanol. The ir spectrum showed a broad absorption at 3420 cm^{-1} (NH) and the typical absorptions at 1780, 1740, 1725, and 1655 cm^{-1} (C=O, C=C). In the mass spectrum the major peak was found at m/e 312 ($M^+ - C(CH_3)_3$). The nmr spectrum displayed a single NH proton at δ 6.55. Similar reaction sequences in related systems indicate that no epimerization took place at the 'anomeric' center.[2]

The protected 2′-deoxyshowdomycin **12** was subjected to treatment with 0.1 *N* methanolic hydrochloric acid at room temperature for 26 h to remove the acetyl and silyl groups. Subsequent purification by a column of silicic acid using acetone – ethyl acetate (3:7) led to crystalline D,L-2′-deoxyshowdomycin **1***d*, mp 122–124°C, in 68% yield. Kalvoda (13) and Nakagawa *et al.* (14) used the same conditions to remove the acetyl groups of 2′,3′,5′-tri-*O*-acetylshowdomycin. The mass spectrum clearly indicated the complete removal of the protecting groups. A molecular ion was found at m/e 213 (M^+) and a major fragment corresponding to loss of water from the molecular ion at m/e 195 ($M^+ - H_2O$). The uv spectrum showed an absorption at 222 nm (log ε 4.18) like showdomycin and 2′-epishowdomycin and the molar extinction coefficient was also in accordance with that of known examples (1, 14), thus confirming the structure of the aglycon moiety of **1***d*. Furthermore, the elemental analysis confirmed the purity of the final product.

The synthetic route described seems to be

[2]From ref. 12 and unpublished results of T. J. Liak.

quite simple and straightforward, and should be applicable to other 2′-deoxy-analogues of *C*-nucleosides. No further work is at present being undertaken in this area.

Experimental

Melting points were determined on a Gallenkamp block and are uncorrected. Mass spectra were obtained on an AE1-MS-902 mass spectrometer at 70 eV using a direct-insertion probe. Nuclear magnetic resonance spectra were recorded on a Varian Associates T-60 spectrometer. Infrared spectra were obtained on a Unicam SP1000 and a Perkin-Elmer 257 ir spectrophotometer. Ultraviolet spectra were determined with a Unicam SP-800 spectrophotometer. Microanalyses were carried out by Dr. C. Daessle, Montreal.

*A Mixture of 2-exo-Carbomethoxy-5-exo-hydroxy-3-endo-nitro-7-oxabicyclo[2.2.1]heptane and 2-exo-Carbomethoxy-6-exo-hydroxy-3-endo-nitro-7-oxabicyclo[2.2.1]heptane (**6a**, **7a**)*

A solution of **2** (858 mg, 4.3 mol) in dry tetrahydrofuran (10 ml) was cooled to 0°C by means of an ice-water bath. To the reaction mixture was added 3 ml of 1 *M* diborane solution (3 mmol) in tetrahydrofuran and the mixture was stirred for 2.5 h under nitrogen. After evaporation to dryness *in vacuo* the residue and triethylamine *N*-oxide dihydrate (658 mg, 4.3 mmol) were dissolved in dry tetrahydrofuran (20 ml). The reaction mixture was heated under reflux for 2.5 h. The solvent was evaporated and the residue was dissolved in ethyl acetate, washed with 0.1 *N* hydrochloric acid, water, and with brine, dried, and evaporated. Chromatography of the residue on a column of silicic acid using chloroform afforded 416 mg (46%) of the isomeric mixture of **6***a* and **7***a* as an oil; ir ($CHCl_3$) 3650, 3500 (OH), 1735 (C=O), 1735 (C=O), 1578 cm^{-1} (NO_2); nmr ($CDCl_3$) δ 1.33–2.40 (m, 2H), 2.90 (m, 1H), 3.26 (m, 1H), 3.73 (s, 3H), 4.03 (m, 1H), 4.60–5.10 (m, 2H), 5.10–5.30 (m, 1H). *Anal.* calcd. for $C_8H_{11}NO_6$: C 44.24, H 5.11, N 6.45; found: C 44.35, H 5.10, N 6.78.

*5-exo-Acetoxy-2-exo-carbomethoxy-3-endo-nitro-7-oxabicyclo[2.2.1]heptane (**6b**) and 6-exo-Acetoxy-2-exo-carbomethoxy-3-endo-nitro-7-oxabicyclo[2.2.1]-heptane (**7b**)*

A mixture of the isomeric alcohols **6***a* and **7***a* (504 mg, 2.32 mmol) and acetic anhydride (4 ml) containing 1 equiv. of *p*-toluenesulfonic acid monohydrate was stirred overnight at room temperature. The reaction mixture was evaporated to dryness and the residue was dissolved in chloroform, washed with water, and dried over sodium sulfate. Following evaporation of the solvent chromatography of the residue on a column of silicic acid using chloroform afforded 495 mg (82%) of the isomeric mixture of **6***b* and **7***b* as an oil.

One isomer, the 5-acetoxy heptane **6***b*, was crystallized from hexane–carbon tetrachloride to give 220 mg, mp 113–114°C; ir (KBr) 1735 (C=O), 1550 cm^{-1} (NO_2); nmr ($CDCl_3$) δ 1.70–2.60 (m, 5H), 3.36 (d, 1H, J = 4 Hz), 3.70 (s, 3H), 4.70–5.03 (m, 3H), 5.30 (m, 1H); ms *m/e* 228 ($M^+ - OCH_3$), 213 ($M^+ - HNO_2$), 171, 153, 128, 43. *Anal.* calcd. for $C_{10}H_{13}NO_7$: C 46.33, H 5.06, N 5.40; found: C 46.53, H 5.26, N 5.43.

Upon evaporation the residue contaminated with **6***b* was chromatographed on a column of silicic acid using chloroform–hexane (1:1), giving 121 mg of the 6-acetoxy heptane **7***b* as an oil. The product solidified on standing, mp 67–68°C; ir (KBr) 1735 (C=O), 1550 cm^{-1} (NO_2); nmr ($CDCl_3$) δ 1.70–2.30 (m, 5H), 3.37 (d, 1H, J = 4 Hz), 3.70 (s, 3H), 4.70–5.06 (m, 3H), 5.20 (m, 1H); ms *m/e* 228 ($M^+ - OCH_3$), 213 ($M^+ - HNO_2$), 169, 127, 81. *Anal.* calcd. for $C_{10}H_{13}NO_7$: C 46.33, H 5.06, N 5.40; found: C 46.23, H 5.30, N 5.21.

*2-exo-Acetoxy-5-carbomethoxy-7-oxabicyclo[2.2.1]hept-5-ene (**9**)*

A solution of **6***b* (605 mg, 2.34 mmol) and DBU (444 mg, 281 mmol) in methylene chloride (20 ml) was refluxed for 1.5 h. The mixture was diluted with methylene chloride, washed with 0.1 *N* hydrochloric acid and water, dried, and evaporated. Chromatography of the residue on a column of silicic acid using chloroform–hexane (3:1) afforded 453 mg (91%) of **9** as an oil which solidified on standing, mp 62–63°C; ir (KBr) 1725, 1710 (C=O), 1610 cm^{-1} (C=C); nmr ($CDCl_3$) δ 1.73–2.20 (s + m, 5H), 3.70 (s, 3H), 4.76 (q, 1H, J = 3 Hz, H-2), 5.00 (d, 1H, $J_{1,6}$ = 2Hz, H-1), 5.16 (d, 1H, $J_{4,3exo}$ = 4 Ha, H-4), 6.92 (d, 1H, $J_{6,1}$ = 2 Hz, H-6); ms *m/e* 212 (M^+), 181 ($M^+ - OCH_3$), 169 ($M^+ - COCH_3$), 152 ($M^+ - CH_3COOH$), 137, 127, 109. *Anal.* calcd. for $C_{10}H_{12}O_5$: C 56.50, H 5.70; found: C 56.45, H 5.36.

*3-exo-Acetoxy-5-carbomethoxy-7-oxabicyclo[2.2.1]hept-5-ene (**8**)*

A mixture of **7***b* (189 mg, 0.73 mmol) and DBU (122 mg, 0.8 mmol) in methylene chloride was heated under reflux for 1.5 h. After the usual work-up chromatography of the residue on a column of silicic acid using chloroform–hexane (3:1) gave 108 mg (70%) of **8** as an oil which was crystallized from hexane–carbon tetrachloride, mp 119–120°C; ir (KBr) 1725, 1710 (C=O), 1610 cm^{-1} (C=C); nmr ($CDCl_3$) δ 1.70–2.10 (s + m), 3.70 (s, 3H), 4.75 (q, 1H, J = 3 Hz, H-3), 4.90–5.10 (s + m, 2H, H-4 and H-1), 7.03 (d, 1H, $J_{6,1}$ = 2 Hz, H-6); ms *m/e* 197 ($M^+ - CH_3$), 181 ($M^+ - OCH_3$), 169 ($M^+ - COCH_3$), 152 ($M^+ - CH_3COOH$), 127, 95, 43. *Anal.* calcd. for $C_{10}H_{12}O_5$: C 56.50, H 5.70; found: C 56.46, H 5.58.

*Methyl 2-(3-O-Acetyl-2-deoxy-β-D,L-ribofuranosyl)-glycolate (**10a**)*

To a solution of **9** (483 mg, 2.28 mmol) in dry methylene chloride at −78°C was bubbled ozone until a blue color persisted. Excess ozone was flushed with nitrogen and dimethyl sulfide (0.5 ml) was added. The reaction mixture was allowed to come to room temperature over a period of 5 h. The solution was then washed with brine three times, dried over magnesium sulfate, and evaporated. To a solution of the residue in dry tetrahydrofuran (20 ml) at 0°C was added lithium tri-*tert*-butoxyaluminum hydride (2.3 g, 9.1 mmol). The reaction mixture was stirred at 0°C for 4 h and a solution of ammonium sulfate (1.5 g) in water (2 ml) was added. After filtration over a layer of Celite and evaporation, the residue was dissolved in ethyl acetate, washed with water, dried, and evaporated. The residue was chromatographed on a column of silicic acid using chloroform–ethyl acetate (1:2), giving 349 mg (62%) of **10***a* as an oil; ir ($CHCl_3$) 3500 (OH), 1750 cm^{-1} (C=O); nmr ($CDCl_3$) δ 1.73–

2.56 (s + m, 5H), 3.43–4.16 (m, 7H), 4.16–4.80 (m, 3H), 5.10 (m, 1H). *Anal.* calcd. for $C_{10}H_{16}O_7$: C 48.38, H 6.50; found: C 48.49, H 6.28.

*Methyl 2-O-Acetyl-2-(3,5-di-O-acetyl-2-deoxy-β-D,L-ribofuranosyl)glycolate (**10***b*)*

The diol **10***a* (157 mg) was acetylated with acetic anhydride (1 ml) and pyridine (2 ml). After the usual work-up chromatography of the crude product on a column of silicic acid using chloroform–hexane (1:1) afforded 149 mg (70%) of **10***b* as an analytically pure oil; ir (neat) 1745 cm^{-1} (C=O), no hydroxyl group; nmr (CCl_4) δ 1.80–2.70 (m, 11H), 3.63 (m, 3H), 3.76–4.06 (m, 3H), 4.30 (m, 1H), 4.73–5.06 (m, 2H); ms *m/e* 332 (M^+), 301 ($M^+ - OCH_3$), 273 ($M^+ - CH_3COO$), 259, 201, 152, 81. *Anal.* calcd. for $C_{14}H_{20}O_9$: C 50.60, H 6.07; found: C 50.38, H 6.26.

*Methyl 2-(3-O-Acetyl-5-O-tert-butyldimethylsilyl-2-deoxy-β-D,L-ribofuranosyl)glycolate (**10***c*)*

To a solution of **10***a* (242 mg, 0.98 mmol) in dimethylformamide (5 ml) was added *tert*-butyldimethylsilyl chloride (148 mg, 0.98 mmol) and imidazole (166 mg, 2.45 mmol). The reaction mixture was stirred at room temperature for 20 h. The solvent was evaporated *in vacuo*. The residue was dissolved in chloroform, washed with water, dried over sodium sulfate, and evaporated. Chromatography of the residue on a column of silicic acid using chloroform gave 276 mg (77%) of **10***c* as an oil; ir (neat) 3450 (OH), 1740 cm^{-1} (C=O); nmr ($CDCl_3$) δ 0.13 (s, 6H), 0.93 (s, 9H), 1.76–2.53 (s + m, 5H), 3.23 (m, 1H), 3.53–3.97 (m, 6H), 4.10–4.46 (m, 2H), 5.03 (m, 1H). *Anal.* calcd. for $C_{16}H_{30}O_7Si$: C 53.04, H 8.29; found: C 53.27, H 8.05.

*2-(3-O-Acetyl-5-O-tert-butyldimethylsilyl-2-deoxy-β-D,L-ribofuranosyl)maleimide (**12**)*

A mixture of **10***c* (152 mg, 0.42 mmol) and acetic anhydride (1 ml) in dry dimethyl sulfoxide (4 ml) was stirred overnight at room temperature. The mixture was diluted with chloroform and washed with an aqueous sodium bicarbonate solution, water, and brine. The organic layer was dried over magnesium sulfate and evaporated to dryness, leaving the crude keto ester **11** as an oil which was contaminated with minor amounts of impurities. Without any further purification this material was directly used in the next step. A solution of the resulting keto ester and carbamoylmethylenetriphenylphosphorane (121 mg, 0.38 mmol) in dry chloroform was stirred at room temperature for 2 h. The solvent was then evaporated. The residue was chromatographed on a silica gel plate using ethyl ether – hexane (1:1), giving 58 mg (38% from **10***c*) of **12** as an oil; ir ($CHCl_3$) 3420 (NH), 1780, 1740, 1725 (C=O), 1645 cm^{-1} (C=C); uv λ_{max} (EtOH) 222 nm; nmr ($CDCl_3$) δ 0.06 (s, 6H), 0.86 (s, 9H), 1.70–2.76 (s + m, 5H), 3.70–3.90 (m, 2H), 4.10 (m, 1H), 4.83–5.23 (m, 1H), 5.33 (m, 1H), 6.55 (t, 1H, C=CH), 8.20 (m, 1H, NH); ms *m/e* 312 ($M^+ - C(CH_3)_3$), 253, 129, 117, 75, 73. *Anal.* calcd. for $C_{17}H_{27}NO_6Si$: C 55.28, H 7.32, N 3.79; found: C 55.12, H 7.35, N 3.68.

*2-(Z-Deoxy-β-D,L-ribofuranosyl)maleimide (**1***d*)*

A solution of **12** (102 mg, 0.28 mmol) in 0.1 *M* methanolic hydrochloric acid (15 ml) was stirred at room temperature for 26 h. After evaporation to dryness, chromatography of the residue on a column of silicic acid using acetone – ethyl acetate (3:7) afforded 40 mg (68%) of **1***d* as an oil which was crystallized from acetone–benzene; mp 122–124°C; ir (KBr) 3510, 3320, 3280, 3100 (OH, NH), 1770, 1700 (C=O), 1640 cm^{-1} (C=C); uv λ_{max} (EtOH) 222 nm (log ε 4.18); ms *m/e* 214 ($M^+ + 1$), 213 (M^+), 195 ($M^+ - H_2O$), 182, 165, 153, 136, 124, 81, 53, 44, 43, 39, 31, 29. *Anal.* calcd. for $C_9H_{11}NO_5$: C 50.70, H 5.20, N 6.57; found: C 50.85, H 5.40, N 6.64.

C-Nucleosides and related compounds. XIV. The synthesis of a nitrogen analogue of showdomycin[1]

GEORGE JUST AND G. PAUL DONNINI[2]

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3C 3G1

Received February 9, 1977

GEORGE JUST and G. PAUL DONNINI. Can. J. Chem. **55**, 2998 (1977).

Starting from teloidinone **5***a*, 2-(2′α,3′α-dihydroxy-4′β-hydroxymethyl-*N*-carbomethoxypyrrolidin-1β-yl)maleimide **1***b*, a showdomycin analogue in which the ribofuranosyl ring oxygen is replaced by an *N*-carbomethoxy group, has been synthesized in 7% overall yield.

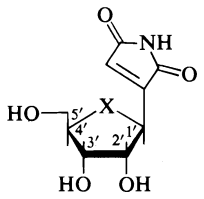
GEORGE JUST et G. PAUL DONNINI. Can. J. Chem. **55**, 2998 (1977).

Utilisant la téloidinone **5***a*, on a synthétisé, avec un rendement global de 7%, la (dihydroxy-2′α,3′α hydroxyméthyl-4′β *N*-carbométhoxypyrrolidinyl-1β)-2 maléimide **1***b*, un analogue de la showdomycine dans lequel l'oxygène du cycle ribofurannosyle est remplacé par un groupe *N*-carbométhoxy.

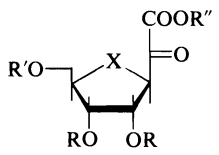
[Traduit par le journal]

We wish to report the synthesis of an analogue of showdomycin (**1***a*), in which the ring oxygen is replaced by an *N*-carbomethoxy group. This ring oxygen seems to play an important role in the mechanism of action of showdomycin and pyrazofurin A, since its replacement by a methylene group leads to virtually complete disappearance of antiviral, antibacterial, and antifungal activity (1). The transformation of a ketoester of type **2** to showdomycin (**1***a*) (2) or its analogues (1, 3) being a relatively simple matter using Moffatt's procedure (2), we set out to synthesize the analogous ketoester **3** or **4**. However, the Diels–Alder approach that had been used successfully in the synthesis of the carbocyclic analogue of showdomycin (1) and other nucleoside analogues (4, 5) failed in this instance due to the unreactivity of N-substituted pyrroles towards the appropriate dienophiles.

Accordingly, we prepared the known teloidinone acetonide **5***b* (6) from teloidinone **5***a* (7).



1*a* X = O
1*b* X = N—COOMe
1*c* X = N—H



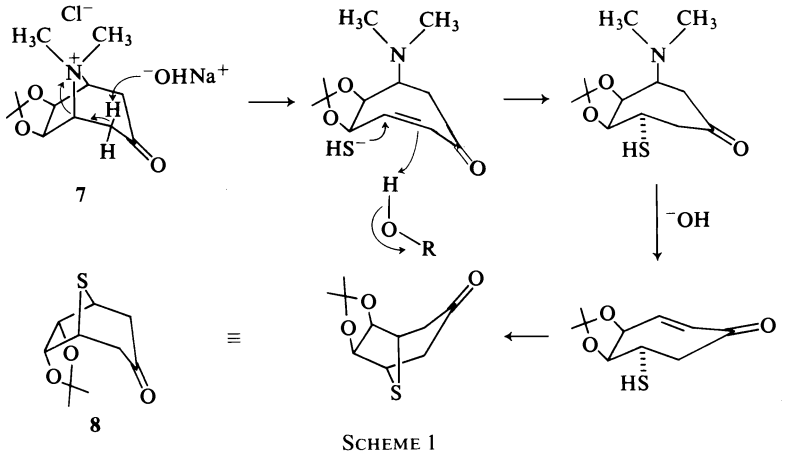
2 X = O
3 X = N—R‴
4 X = N—H

[1]Abstracted from the Ph.D. thesis of G. P. Donnini.
[2]Holder of an NRCC postgraduate scholarship, 1973–1976.

It was hoped that by selective oxidation, the two methylene groups adjacent to the carbonyl function could be differentiated. Thus, in order to protect the tertiary amine in **5***b* against oxidation, it was converted in high yield to the ethyl carbamate **6***a* by boiling with excess ethyl chloroformate (8) in toluene. An analogous reaction with methyl chloroformate in benzene gave, in addition to a 75% yield of the expected methyl carbamate **6***b*, a 15–20% yield of methochloride **7**. The structure of these products was supported by the usual spectroscopic and analytical data. Methochloride **7** could also be converted cleanly to the 8-thiatropan-3-one **8** by treatment with sodium sulphide in aqueous ethanol. The ^{1}Hmr spectrum of **8** clearly indicated a reversal of stereochemistry at C-6 and C-7. This arose from a double displacement of the nitrogen bridge of **7**, and attack by the sulfhydryl group from the least hindered side of the bicyclic system, as shown in Scheme 1. The methyl carbamate **6***b* was further characterized by hydrolysis with aqueous trifluoroacetic acid to diol **9***a*, which was converted to the diacetate **9***b*.

Oxidation of **9***b* with thallium trinitrate (9) gave the α-hydroxy ketone **10** in 40% yield. However, all attempts to oxidize **10** to an α-diketone by means of $Cu(OAc)_2 \cdot H_2O$ (10), DMSO – acetic anhydride (11), or RuO_2–KIO_4 (12) met with failure. Direct oxidation of the carbamate **6***b* with such reagents as selenium dioxide (13) was not attempted, because of the low yields of such transformations (13).

We next tried to form an α-monofurfurylidene



SCHEME 1

ketone derivative in order to ozonize it to an α-diketone. Unfortunately, all such attempts (14) afforded the di-substituted derivatives (**11** and **12**), even when only 1 equiv. of furfuraldehyde was utilized. We also prepared the morpholine enamines **13***a*, **13***b*, and **13***c* in the hope of converting them to α,β-unsaturated ketones of type **14** by the method of Birkofer *et al.* (15). The enamines were formed in high yield with a $TiCl_4$ catalyst (16), but once isolated they proved to be quite unstable, and they did not undergo clean reactions.

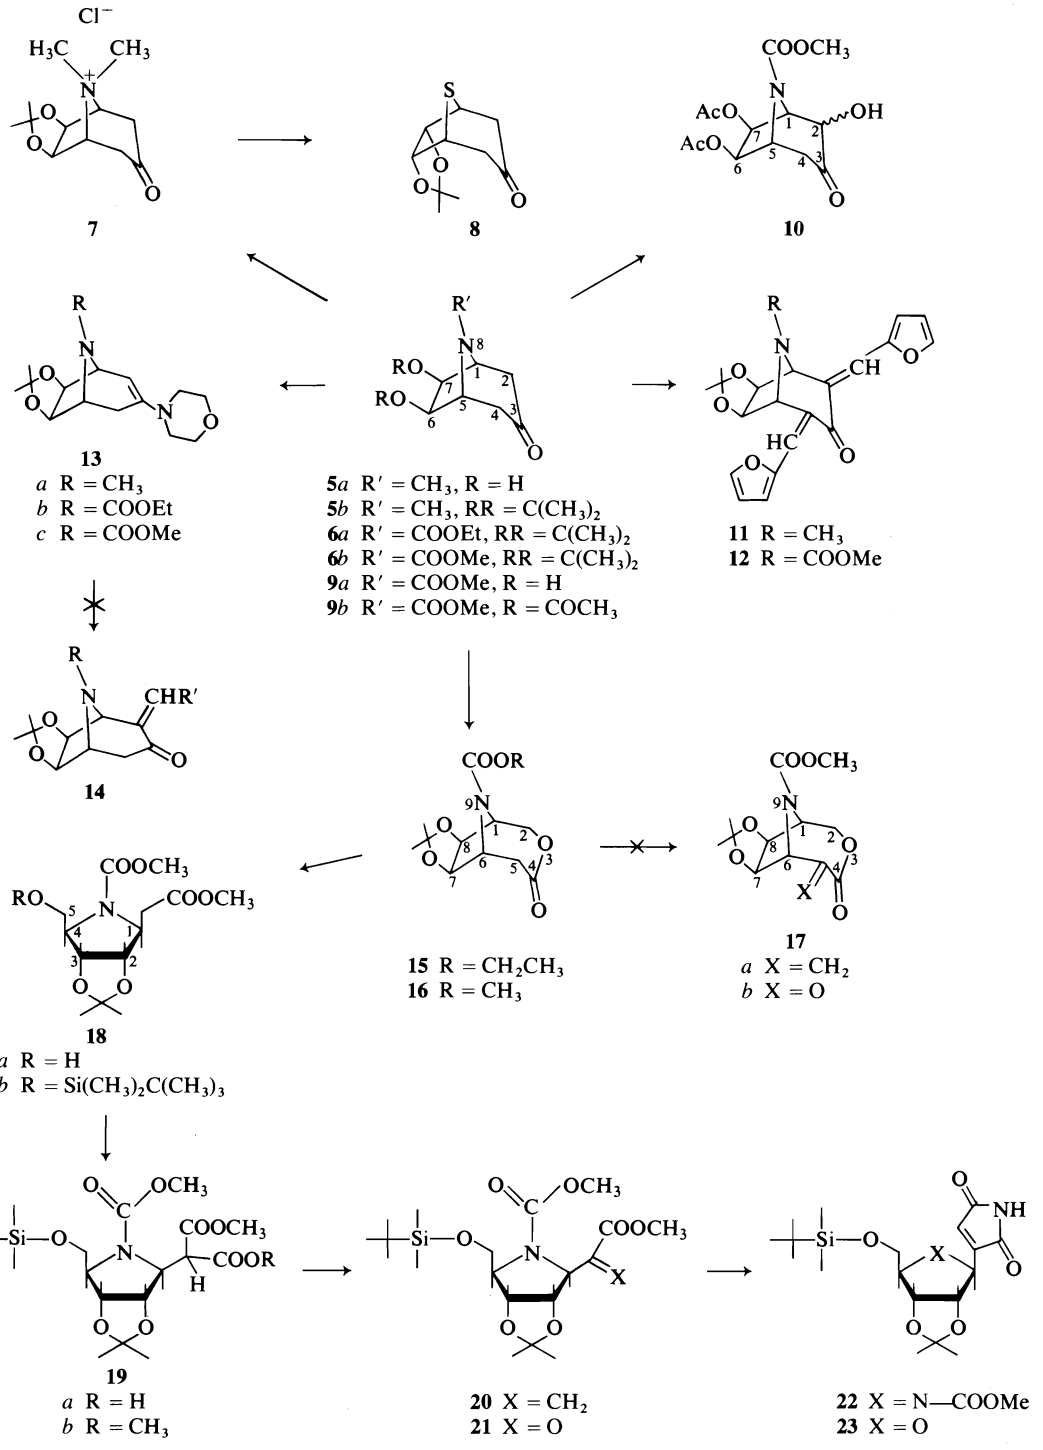
We next attempted to carry out a Baeyer–Villiger oxidation of ketone **6***a*. Prolonged treatment (36 h, 90°C) of ethyl carbamate **6***a* with *m*-chloroperbenzoic acid (MCPA) in refluxing 1,2-dichloroethane in the presence of a free radical inhibitor (17) gave impure lactone **15** in relatively good yield, as established by ^{1}Hmr, ir and mass spectra. However, it proved difficult to isolate in the pure state. On the other hand, the methyl carbamate **6***b* could be oxidized cleanly by treatment with MCPA at 60°C for 22 h. The crystalline D,L-lactone **16** was isolated in about 60% yield. It appears that the ethyl group in **6***a* possesses enough steric bulk to impede the approach of the oxidizing agent to the carbonyl group. This finding precluded the use of bulkier, more selectively removable N-protecting groups such as benzyl (18), phenyl (18, 19), and 2,2,2-trichloroethyl (20) carbamates.[3]

[3]We feel that this problem may be circumvented by the use of trifluoroperacetic acid (21). Unfortunately, 90–98% hydrogen peroxide used for its routine preparation is not commercially available anymore, thus precluding, for the time being, the synthesis of showdomycin analogue **1***c* by the scheme outlined.

Since conversions of lactones to their α-methylene derivatives with lithium diisopropylamide (22) have been reported to proceed in high yields, we hoped to convert lactone **16** to the α-methylene lactone **17***a*. The latter could be oxidized to the α-keto lactone **17***b*, which would be formally equivalent to the desired α-ketoester **3**. When the reaction of **16** with lithium diisopropylamide was carried out, substantial decomposition occurred, probably due to ring opening of the bicyclic structure. Thus, it was decided to open up the lactone and attempt to form an α-ketoester from the resulting ester.

Accordingly, lactone **16** was treated at room temperature with 1 equiv. of sodium methoxide in methanol, producing the hydroxy methyl ester **18***a*. The alcoholic function of **18***a* was protected with *tert*-butyldimethylsilyl chloride (23), affording the oily silyl ether **18***b* in greater than 85% yield, based on the lactone. This ether **18***b* was then treated with lithium diisopropylamide and carbon dioxide (22). The resulting malonic acid **19***a* could either be isolated as its methyl ester **19***b* (24) or directly decarboxylated in aqueous formaldehyde and diethylamine (22). In this way, an 80% yield of the α-methylene ester **20** was obtained, based on ether **18***b*. The ir spectrum of **20** exhibited a strong, broad carbonyl band between 1735 and 1720 cm^{-1}, plus a weaker olefinic absorption at 1650 cm^{-1}. Its ^{1}Hmr spectrum displayed two well-separated olefinic multiplets at δ 6.10 and 5.70 ppm, two carbomethoxy methyl singlets at 3.72 and 3.60, as well as *gem*-dimethyl singlets at 1.45 and 1.29 ppm.

Ozonolysis of the olefinic bond of **20** at −78°C, followed by reductive work-up with di-



SCHEME 2

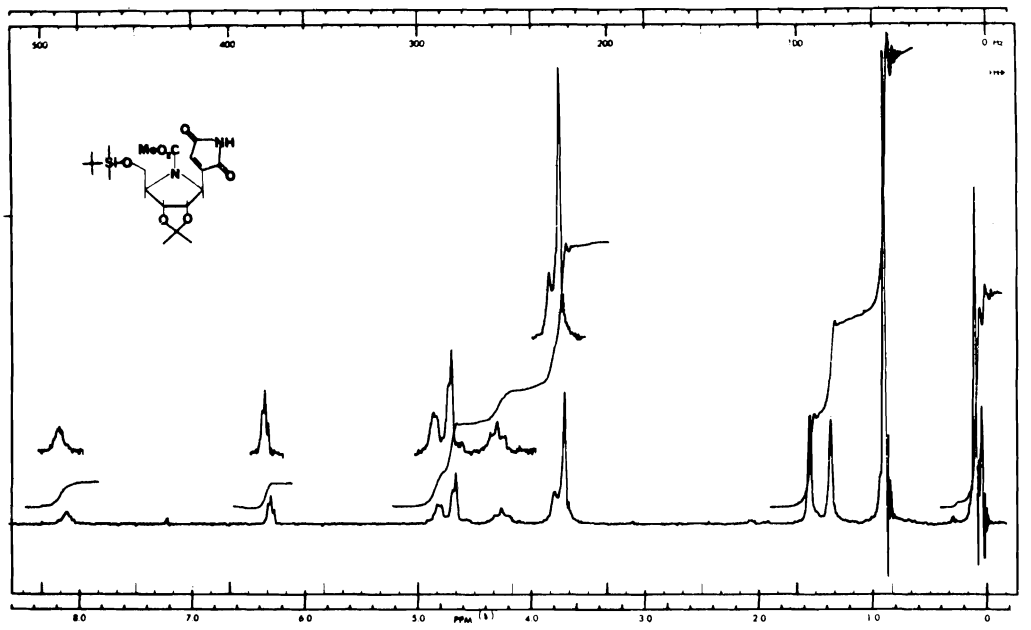


FIG. 1. ^{1}Hmr spectrum of the blocked azacyclic analogue **22** of showdomycin in deuterochloroform.

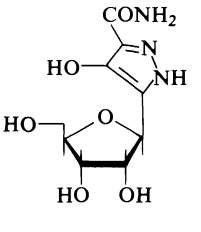
methyl sulphide (25), afforded the crude α-keto-ester **21**. This was reacted directly with carbamoylmethylenetriphenylphosphorane (2) in chloroform, yielding maleimide **22** in 40% yield based on the α-methylene ester **20**. The crystalline product (**22**) displayed ultraviolet and infrared absorptions extremely similar to those of showdomycin itself (26), and a ^{1}Hmr spectrum (Fig. 1) that was nearly superimposable on that of authentic, similarly blocked showdomycin **23**[4] (Fig. 2). The presence of an *N*-carbomethoxy methyl absorption at δ 3.66 ppm was the only major difference. Furthermore, the similarity of the separation between the *gem*-dimethyl singlets (0.18 ppm in Fig. 1 and 0.22 ppm in Fig. 2) supported the correct stereochemistry at C-1′ (27).

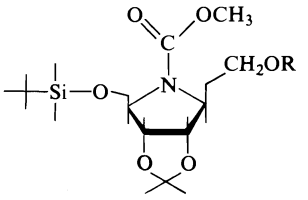
The protected maleimide **22** was deblocked with 50% aqueous trifluoroacetic acid, affording the triol **1***b* in 75% yield after purification by preparative thin layer chromatography. The product would not crystallize, but all spectral data supported the proposed structure. Biological testing of this compound has not yet been undertaken.

[4]Prepared by T. J. Liak. Removal of the protecting groups afforded showdomycin identical to that obtained in ref. 2.

Since malonic esters were known to undergo condensation with ethyl diazoacetate to produce 4-hydroxypyrazoles (28), we attempted to convert malonic ester **19***b* to an analogue of pyrazofurin A (**24**) by this scheme. However, no such conversion was observed. Substantial decomposition of the starting material always occurred. It should be noted, however, that Ohrui and Fox (29) successfully utilized a similar malonic ester of a *C*-glycoside to produce an analogue of pseudouridine.



24



25*a* R = H
25*b* R = SO_2CH_3

Finally, we selectively reduced the ester function of ester **18***b* with borane–tetrahydrofuran, isolating the oily alcohol **25***a* in good yield. This was converted quantitatively to the mesylate **25***b*. But all attempts to eliminate methanesulphonic acid from this compound, in order to

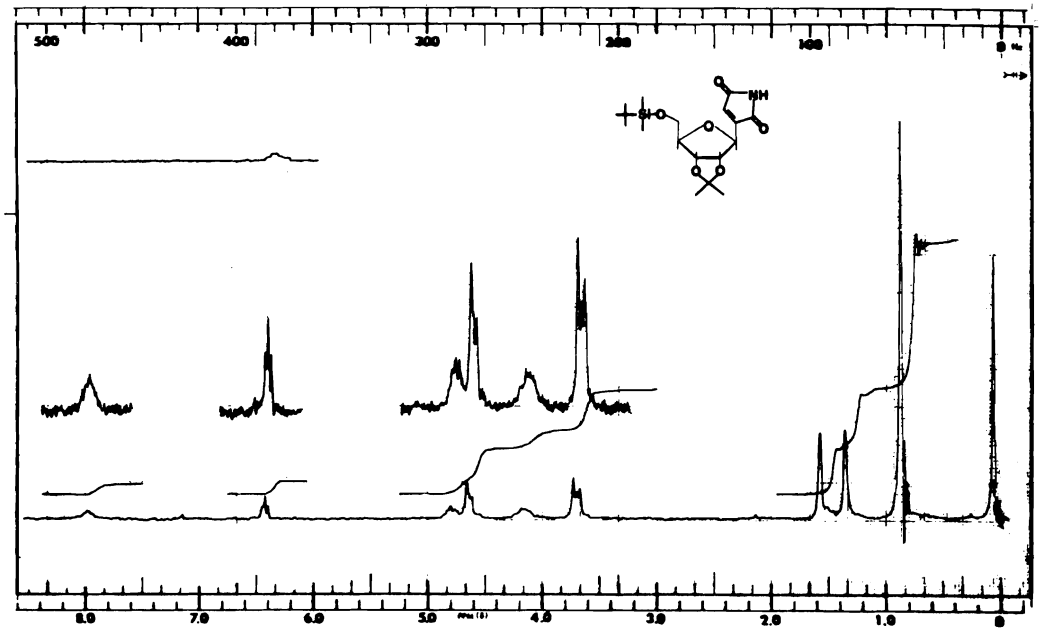


FIG. 2. ^{1}Hmr spectrum of blocked showdomycin **23** in deuterochloroform. Top scan is 100 Hz offset.

form a terminal olefin, failed. A terminal olefin would be an extremely useful dipolarophile for the production of many heterocyclic bases via 1,3-dipolar additions.

We have also been unable to remove efficiently the *N*-carbomethoxy group from any of our compounds, and as yet a reagent capable of cleaving simple *N*-carbalkoxy groups has not been reported in the literature.

Preliminary evaluation of the showdomycin analogue **1***b* failed to show any activity against 15 strains of bacteria and four strains of fungi up to levels as high at 256 μg/ml. Nine viral strains, including both DNA and RNA types, were not significantly affected by these drugs in tissue culture.

Experimental

Solvents were reagent grade unless otherwise specified. All evaporations were done under reduced pressure (water aspirator) with a bath temperature of 25–45° C unless otherwise noted.

Melting points were determined on a Gallenkamp block in open capillary tubes and are uncorrected. Mass spectra were obtained on an AEI-MS-902 mass spectrometer at 70 eV using a direct insertion probe. Infrared (ir) spectra were obtained on a Unicam SP1000 and a Perkin-Elmer 257 spectrophotometer. Ultraviolet (uv) spectra were obtained on a Unicam SP-800 and a Cary 17 spectrophotometer. Proton magnetic resonance (^{1}Hmr) spectra were recorded on a Varian T-60 instrument using tetramethylsilane (TMS) as an internal standard unless otherwise stated. Chemical shifts are given in the δ scale in parts per million (ppm). Doublets (d), triplets (t), quartets (q), and multiplets (m) were recorded at the centre of the peaks; other abbreviations used: singlet (s) and broad (b).

Analytical thin layer chromatography (tlc) was performed on silica gel-coated plates (Eastman Kodak or Machery-Nagel Polygram G) and on a preparative scale (plc) on silica gel (Merck $UV_{254,366}$) coated glass plates. Woelm alumina (neutral) and silica gel were used for column chromatography.

Elemental analyses were performed by C. Daessle, Montreal, and Heterocyclic Chemical Corporation, Missouri.

*6β,7β-Dihydroxy-O-isopropylidene-tropan-3-one (Teloidinone Acetonide) (**5b**)*

To a suspension of 4.71 g (27.5 mmol) teloidinone **5***a* (7) in 500 ml acetone was added 19.0 ml concentrated hydrochloric acid with vigorous stirring. This mixture was stirred at room temperature for 20 h, by which time it had become a clear, yellow solution. It was then neutralized by bubbling in anhydrous ammonia (to p*H* 8–9), and the resulting ammonium chloride filtered off. The precipitate was washed with another 100 ml acetone, and the filtrates were evaporated to dryness *in vacuo*. The yellow solid residue was recrystallized from petroleum ether (60–80° C); the product was obtained as white needles, mp 84–86°C (lit. (6) mp 87–90°C). The yield was 5.25 g (90%) in three crops; ^{1}Hmr ($CDCl_3$) δ 1.34 (s, 3H), 1.55 (s, 3H), 2.06 (bs, 0.67H), 2.34 (bs, 1.33H), 2.61 (d, 1.33H), 2.75 (s, 3H), 2.87 (d, 0.67H), 3.55 (m, 2H), 4.41 ppm (s, 2H); ir (KBr) 3025, 2980, 2945, 1720 (C=O), 1395 and 1390 (*gem*-dimethyl), 1220, 1080, 1055, 873 cm^{-1}; ms *m/e* 211 (M^+), 196 ($M^+ - CH_3$).

*6β,7β-Dihydroxy-O-isopropylidene-N-carbethoxy-tropan-3-one (**6a**)*

Freshly distilled ethyl chloroformate (6.2 ml, 76.3

mmol) was added to a solution of 805 mg (3.8 mmol) of teloidinone acetonide **5***b* in 15 ml dry toluene. This solution was heated to gentle reflux for 30 h, then evaporated to dryness under reduced pressure. The solid residue was recrystallized from petroleum ether (60–80°C) – ether, affording an 85% yield of white crystals, mp 77–78°C; ^{1}Hmr ($CDCl_3$) δ 1.23 (s, 3H), 1.27 (t, 3H), 1.40 (s, 3H), 2.48 (bm, 4H), 4.15 (q, 2H), 4.40 (s, 2H), 4.46 ppm (bm, 2H); ir (KBr) 1720 (ketone), 1705 (urethane), 1395 and 1385 cm^{-1} (*gem*-dimethyl); ms *m/e* 269 (M^+), 254 ($M^+ - CH_3$), 169, 168. *Anal.* calcd. for $C_{13}H_{19}NO_5$: C 57.98, H 7.11, N 5.20; found: C 57.82, H 7.09, N 5.22.

*6β,7β-Dihydroxy-O-isopropylidene-N-carbomethoxy-tropan-3-one (**6b**)*

Freshly distilled methyl chloroformate (29.6 ml, 0.384 mol) was added to a solution of 4.05 g (0.0192 mol) of teloidinone acetonide **5***b* in 50 ml dry benzene. This solution was warmed to 60°C and stirred for 20 h. Then the white precipitate (methochloride **7**) was filtered off, and the filtrate was evaporated to dryness. The white solid residue was recrystallized from anhydrous ether, mp 123–123.5°C. Further crops were obtained by adding petroleum ether (30–60°C) until the solvent was a 1:1 mixture. Total yield 3.6 g (75%) in four crops; ^{1}Hmr ($CDCl_3$) δ 1.30 (s, 3H), 1.46 (s, 3H), 2.56 (bm, 4H), 3.79 (s, 3H), 4.47 (s, 2H), 4.52 ppm (bm, 2H); ir (CCl_4) 2980, 2950, 2890, 1730 (C=O's), 1460, 1395 and 1385 cm^{-1} (*gem*-dimethyl); ms (150°C) *m/e* 255 (M^+), 240 ($M^+ - CH_3$), 155, 154. *Anal.* calcd. for $C_{12}H_{17}NO_5$: C 56.46, H 6.71, N 5.49; found: C 56.34, H 6.66, N 5.52. Evaporation of the last filtrate left 275 mg (6.3%) unreacted starting material.

6β,7β-Dihydroxy-O-isopropylidene-tropan-3-one Methochloride (7)

The side product isolated above was quite pure, and it was obtained in 17% yield (875 mg). An analytical sample was prepared by dissolving in methanol and adding anhydrous ether until partial reprecipitation had occurred, then cooling; mp 168–170°C with charring; ^{1}Hmr (D_2O) δ 1.53 (s, 3H), 1.79 (s, 3H), 2.80 (bs, 0.67H), 3.14 (bs, 1.33H), 3.43 (d, 1.33H), 3.60 (s, 3H), 3.70 (bm, 0.67H), 3.80 (s, 3H), 4.70 (d, 2H), 5.25 ppm (bs, 2H); ir (KBr) 3120, 3025, 3005, 2950, 1730 (C=O), 1395 (*gem*-dimethyl), 1215, 1160, 1065 cm^{-1}; ms (150°C) *m/e* 225 (M^+ – HCl, Hofmann elimination), 210 (M^+ – HCl – CH_3), 167. *Anal.* calcd. for $C_{12}H_{20}NO_3Cl$: C 55.06, H 7.70, N 5.35; found: C 55.01, H 7.52, N 5.07.

*6α,7α-Dihydroxy-O-isopropylidene-8-thiatropan-3-one (**8**)*

Sodium sulphide hydrate ($Na_2S \cdot 9H_2O$, 1.04 g, 4.3 mmol) was dissolved in 15 ml ethanol–water (2:1), and to this was added 378 mg (1.44 mmol) methochloride **7** in 15 ml ethanol–water (2:1). The solution was heated 30 min at 50°C, then stirred 1 h at room temperature. The ethanol was removed under reduced pressure, and the resulting aqueous mixture was extracted with methylene chloride (3 × 15 ml). Drying (Na_2SO_4) and evaporation afforded 200 mg of a yellow solid which consisted of a 6:1 mixture of 8-thiatropan-3-one **8** and teloidinone acetonide **5***b* by ^{1}Hmr. Purification by chromatography on 20 × 20 cm silica gel plates, using ether–hexanes (3:2) as the solvent system, afforded 145 mg (47%) of a white powder, mp 114–115.5°C. An analytical sample was obtained by recrystallization from petroleum ether (60–80°C), mp 115.5–116.5°C; ^{1}Hmr ($CDCl_3$) δ 1.35, 1.37 (s, s, 6H), 2.40 (d, 0.4H), 2.69 (d, 1.6H), 2.87 (d, 1.6H), 3.16 (d, 0.4H), 3.46 (bm, 2H), 4.88 ppm (q, 2H); ir (KBr) 3000, 2940, 1720 (C=O), 1390 and 1383 cm^{-1} (*gem*-dimethyl); ms (130°C) *m/e* 214 (M^+), 199 ($M^+ - CH_3$). *Anal.* calcd. for $C_{10}H_{14}O_3S$: C 56.07, H 6.59; found: C 56.10, H 6.53.

*6β,7β-Diacetoxy-N-carbomethoxy-tropan-3-one (**9b**)*

Urethane **6***b* (255 mg, 1 mmol) was dissolved in 10 ml 30% trifluoroacetic acid – water and heated to 55°C. After 4 h, its ^{1}Hmr spectrum showed the almost complete disappearance of the isopropylidene group, so the solution was evaporated to dryness, using benzene as chaser. Acetylation of the resulting diol **9***a* was carried out with 1 ml pyridine and 1 ml acetic anhydride for 4 h at room temperature. The solution was then evaporated to dryness and passed through a small silica gel column, eluting with methylene chloride. The eluate was evaporated to near dryness, and excess ethyl ether was added to precipitate the product **9***b*. Cooling the filtrate afforded a second crop; total yield 175 mg, 60%; mp 157–159°C; ^{1}Hmr ($CDCl_3$) δ 2.03 (s, 6H), 2.61 (bm, 4H), 3.73 (s, 3H), 4.47 (bm, 2H), 5.02 ppm (s, 2H); ir (KBr) 1755–1745 (acetates), 1720–1710 cm^{-1} (urethane and ketone); ms (150°C) *m/e* 299 (M^+), 239 ($M^+ - CH_3COO$), 197, 154. *Anal.* calcd. for $C_{13}H_{17}NO_7$: C 52.17, H 5.73, N 4.68; found: C 52.03, H 5.51, N 4.73.

*2-Hydroxy-6β,7β-diacetoxy-N-carbomethoxy-tropan-3-one (**10**)*

Diacetate **9***b* (205 mg, 0.685 mmol) was dissolved in 2 ml glacial acetic acid, and a solution of thallium trinitrate trihydrate (400 mg, 0.9 mmol) in 1.3 ml acetic acid was added. Five drops of concentrated nitric acid were then added, and the solution was stirred overnight at room temperature. The solid was filtered off, and the filtrate was neutralized with 10% sodium bicarbonate and with solid sodium bicarbonate. The resulting mixture (approximately 35 ml) was allowed to stand at room temperature overnight, then the precipitate was filtered off. The aqueous filtrate was extracted with 3 × 30 ml methylene chloride. Drying ($MgSO_4$) and evaporation afforded a white foam. This was dissolved in carbon tetrachloride and excess ethyl ether was added. On cooling, 80 mg (38% yield) of a white powder was recovered, mp 160–161.5°C; ^{1}Hmr ($CDCl_3$) δ 2.06 (s, 3H), 2.15 (s, 3H), 2.70 (m's, 2H), 3.88 (s, 3H), 4.60 (m, 1H), 4.82–5.63 ppm (m's, 5H; 1H at 5.4 moved downfield by CF_3COOH); ir (KBr) 1780 and 1760 (acetates), 1720 and 1705 (urethane), 1650 cm^{-1} (α-hydroxy ketone); ms (155°C) *m/e* 315 (M^+), 314 ($M^+ - H$), 272 ($M^+ - H - CH_2CO$), 235.7 (M*, 314 → 272), 212, 196, 184. *Anal.* calcd. for $C_{13}H_{17}NO_8$: C 49.52, H 5.44, N 4.44; found: C 49.38, H 5.21, N 4.49.

*2,4-Difurfurylidene-6β,7β-dihydroxy-O-isopropylidene-tropan-3-one (**11**)*

Teloidinone acetonide **5***b* (422 mg, 2 mmol) was dissolved in 4 ml of 95% ethanol and cooled in ice. A solution of 88 mg (2.2 mmol) sodium hydroxide in 1 ml water was added, followed by a solution of 200 mg (2.1 mmol) freshly distilled furfuraldehyde in 1 ml ethanol. A yellow precipitate was soon formed. The mixture was stirred 30 min, 5 ml water was added, and the precipitate was harvested. The bright yellow product was recrystallized from chloroform – absolute ethanol as yellow crystals in 50% yield, mp 218–221°C with charring; ^{1}Hmr ($CDCl_3$)

δ 1.34 (s, 3H), 1.66 (s, 3H), 2.50 (s, 3H), 4.60 (s, 2H), 4.86 (s, 2H), 6.58 (q, 2H), 6.80 (d, 2H), 7.66 ppm (bm, 4H); ir (KBr) 3160, 3120, 1675 (ketone), 1615, 1590, 1550, 1480 cm^{-1}; ms (200°C) *m/e* 367 (M^+), 352 ($M^+ - CH_3$), 267, 238.

*7β,8β-Dihydroxy-O-isopropylidene-N-carbomethoxy-3-oxa-9-azabicyclo[4.2.1^{1,6}]nonan-4-one (**16**)*

Ketone **6***b* (2.52 g, 9.9 mmol) was dissolved in 60 ml 1,2-dichloroethane, and to this was added 5.0 g (25 mmol) of 85% *m*-chloroperbenzoic acid and 20 mg 2,4,6-tri-(*tert*-butyl)phenol. This mixture was heated to 55°C and followed by gas chromatography (Hewlett-Packard 700 Laboratory Chromatograph, SE-30 Ultraphase (10% w/w) with Chromosorb W support in 6 ft × $\frac{1}{8}$ in. column). After 22 h the starting material had disappeared, and the solution was cooled to −15°C for 30 min to precipitate out most of the *m*-chlorobenzoic acid. The acid was filtered off, and the filtrate was washed successively with cold 10% sodium bisulphite (15 ml), cold 10% sodium bicarbonate (3 × 15 ml), and saturated salt solution (20 ml). The organic phase was dried ($MgSO_4$) and evaporated off, leaving a partially solidified oil. This was dissolved in anhydrous ether and allowed to crystallize out at −15°C, mp 117–118°C. More product was obtained by adding petroleum ether (30–60°C) and cooling, total yield 1.6 g (60%); ^{1}Hmr ($CDCl_3$) δ 1.26 (s, 3H), 1.40 (s, 3H), 2.93 (m, 2H), 3.73 (s, 3H), 4.33 (bm, 4H), 4.53 (d, 1H), 4.86 ppm (d, 1H); ir (CCl_4) 3000, 2960, 1755 (lactone), 1725 (urethane), 1455, 1392 and 1382 cm^{-1} (*gem*-dimethyl); ms (150°C) *m/e* 271 (M^+), 256 ($M^+ - CH_3$), 240 ($M^+ - CH_3O$), 214 ($M^+ - CH_3 - CH_2{=}C{=}O$), 179.0 (M*, 256 → 214), 142. *Anal.* calcd. for $C_{12}H_{17}NO_6$: C 53.13, H 6.32, N 5.16; found: C 53.29, H 6.41, N 5.11.

*Methyl-2-(2α,3α-dihydroxy-O-isopropylidene-4β-hydroxymethyl-N-carbomethoxypyrrolidin-1β-yl)-acetate (**18***a*)*

The lactone **16** (2.38 g, 8.8 mmol) was dissolved in 40 ml dry methanol under an atmosphere of dry nitrogen, and to this was added a solution of 223 mg (9.7 mmol) sodium in 20 ml dry methanol. The resulting yellow solution was allowed to stand at room temperature for 18 h, then cooled in ice and neutralized with 5 *N* hydrochloric acid. The resulting solution was evaporated to dryness, and the residue triturated with methylene chloride. The inorganic salt was filtered off and washed well, and the filtrate was dried ($MgSO_4$) and evaporated to dryness. The oily orange residue (2.4 g) was quite pure by ^{1}Hmr, and was used directly in the next step. ^{1}Hmr ($CDCl_3$) δ 1.30 (s, 3H), 1.47 (s, 3H), 2.71 (d, 2H, CH_2-COOMe), 3.50 (bm, 2H, exch. with D_2O), 3.70 (s, 6H, 2 × $COOCH_3$), 3.70 (bm, 2H), 3.92–4.85 ppm (m's, 4H); ir (film) 3480 (O—H), 1740–1710 (C=O's), 1460, 1390 cm^{-1}; ms (110°C) *m/e* 303 (M^+), 288 ($M^+ - CH_3$), 286 ($M^+ - OH$), 285 ($M^+ - H_2O$), 272 ($M^+ - CH_3O$), 256, 240, 230.

*Methyl-2-(2α,3α-dihydroxy-O-isopropylidene-4β-tert-butyldimethylsiloxymethyl-N-carbomethoxypyrrolidin-1β-yl)acetate (**18***b*)*

The crude alcohol **18***a* (2.4 g, 8 mmol) was dissolved in dry *N*,*N*-dimethylformamide (15 ml), and to this was added 1.6 g (10.5 mmol) *tert*-butyldimethylsilyl chloride (23) and 1.43 g (21 mmol) imidazole. This solution was stirred at room temperature overnight, then evaporated to dryness *in vacuo*. The residue was partitioned between methylene chloride (35 ml) and water (25 ml), and the organic layer was further washed with water (3 × 20 ml), dried ($MgSO_4$), and evaporated. The crude silyl ether was purified by passage through a short silica gel column, eluting with ethyl ether. The product was obtained as a slightly yellow oil, yield 3.0 g (85% based on lactone **16**); ^{1}Hmr (CCl_4, external TMS) δ 0.14 (s, 6H, dimethylsilyl), 0.96 (s, 9H, *tert*-butylsilyl), 1.30 (s, 3H), 1.46 (s, 3H), 2.55 (m, 2H, CH_2COOMe), 3.66 (s, 6H, 2 × $COOCH_3$), 3.68 (bm, 2H), 3.77–4.66 ppm (m's, 4H); ir (film) 2960, 1750 (ester), 1720 (urethane), 1460, 1390 cm^{-1}; ms (100°C) *m/e* 402 ($M^+ - CH_3$), 386 ($M^+ - CH_3O$), 360 ($M^+ - (CH_3)_3C$), 302, 272, 228. *Anal.* calcd. for $C_{19}H_{35}NO_7Si$: C 54.65, H 8.45, N 3.35; found: C 54.52, H 8.27, N 3.38.

*Methyl-2-(2α,3α-dihydroxy-O-isopropylidene-4β-tert-butyldimethylsiloxymethyl-N-carbomethoxypyrrolidin-1β-yl)acrylate (**20**)*

A three-necked 50 ml flask equipped with a septum, stopcocks, and a mercury bubbler was flushed with dry nitrogen and charged with 11.5 ml of a 0.26 *M* solution of lithium diisopropylamine in dry tetrahydrofuran. This was cooled to −78°C in an acetone – dry ice bath, and a solution of 1.015 g (2.45 mmol) of ester **18***b* in 15 ml tetrahydrofuran was added with a syringe over a 3 min period. The flask was allowed to slowly warm up to −25°C, and then dry carbon dioxide was bubbled into the solution for 10 min via a syringe needle. The resulting yellow solution was neutralized to p*H* 6 with 10% hydrochloric acid, and the precipitated diisopropylamine hydrochloride was filtered off. The filtrate was evaporated to dryness, and the residue **19***a* was used in the next reaction without further purification.

The crude malonic acid was heated to 50°C with 1.3 ml (12.25 mmol) diethylamine and 2.5 ml of 37% aqueous formaldehyde for 30 min, then 250 mg sodium acetate and 2.5 ml glacial acetic acid was added. The mixture was heated to 50°C for 20 min, then allowed to cool. Water (20 ml) was added, and the aqueous mixture was extracted with methylene chloride (3 × 25 ml). The organic extracts were dried ($MgSO_4$) and evaporated, and the crude product was chromatographed on silica gel. Elution with ether–hexane (2:1) afforded the product as a clear, colorless oil in 80% yield. An analytical sample was obtained by preparative tlc on a 20 × 20 cm silica gel plate using ether–hexane (1:1) as the solvent system; ^{1}Hmr (acetone-d_6) δ 0.12 (s, 6H), 0.92 (s, 9H), 1.29 (s, 3H), 1.45 (s, 3H), 3.60 (s, 3H), 3.72 (s, 3H), 3.75 (bm, 1H), 3.83–4.33 (m's, 2H), 4.40–4.85 (m's, 3H), 5.70 (m, 1H, C=C—*H*), 6.10 ppm (m, 1H, C=C—*H*); ir (film) 2975, 2950, 2875, 1735–1720 (C=O's), 1650 (C=C), 1460, 1390 cm^{-1}; ms (130°C) *m/e* 414 ($M^+ - CH_3$), 398 ($M^+ - CH_3O$), 372 ($M^+ - (CH_3)_3C$), 360. *Anal.* calcd. for $C_{20}H_{35}NO_7Si$: C 55.92, H 8.21, N 3.26; found: C 55.65, H 8.44, N 3.47.

*2-(2′α,3′α-Dihydroxy-O-isopropylidene-4′β-tert-butyldimethylsiloxymethyl-N-carbomethoxypyrrolidin-1′β-yl)maleimide (**22**)*

The olefin ester **20** (280 mg, 0.65 mmol) was dissolved in 45 ml dry ethyl acetate and treated with ozone at −78°C. Dry nitrogen was bubbled through the solution to remove excess ozone, and dimethyl sulphide (0.1 ml,

1.3 mmol) was added. The mixture was stirred for 30 min at −60°C, then allowed to warm up to room temperature and stand 5 h. It was washed with 3 × 25 ml of saturated salt solution, dried (Na_2SO_4), and evaporated to dryness. The residue (270 mg) displayed no olefinic absorption in the ir spectrum, but appeared impure by ^{1}Hmr.

The crude product was dissolved in 10 ml dry chloroform and 208 mg (0.65 mmol) of carbamoylmethylenetriphenylphosphorane (2) was added. The yellow solution was stirred for 3 h at room temperature, then evaporated to dryness. The oily residue was separated on 20 × 20 cm silica gel plates using ether–hexane (3:1) as the solvent system, and 150 mg of a clear, colorless oil was recovered. The product was crystallized from ether–hexane, mp 88–89°C in 40% overall yield based on olefin ester **20**; ^{1}Hmr ($CDCl_3$) δ 0.07 (s, 6H), 0.87 (s, 9H), 1.33 (s, 3H), 1.52 (s, 3H), 3.66 (s, 3H), 3.72 (bm, 2H), 4.22 (m, 1H), 4.50–4.90 (m's, 3H), 6.25 (t, 1H, C=C—*H*), 8.06 ppm (bm, N—*H*); ir (KBr) 3250 (maleimide N—H), 2970, 2950, 2870, 1787, 1738, 1695 (urethane), 1655 (maleimide C=C), 1460, 1390 cm^{-1}; uv (EtOH) λ_{max} 221.3 nm (ε 18 000), shoulder ~275 nm (ε 1000); ms (170°C) *m/e* 425 ($M^+ - CH_3$), 383 ($M^+ - (CH_3)_3C$), 325 ($M^+ - (CH_3)_3C(CH_3)_2Si$). *Anal.* calcd. for $C_{20}H_{32}N_2O_7Si$: C 54.52, H 7.32, N 6.36; found: C 54.54, H 7.52, N 6.50.

*2-(2′α,3′α-Dihydroxy-4′β-hydroxymethyl-N-carbomethoxypyrrolidin-1β-yl)maleimide (**1b**)*

Blocked showdomycin analogue **22** (130 mg, 0.30 mmol) was dissolved in 3 ml of 50% aqueous trifluoroacetic acid. After standing at room temperature for 5 min, the solution was evaporated to dryness. Separation on a 20 × 20 cm silica gel plate, eluting with ethyl acetate, afforded 70 mg (75%) of a clear colorless oil which would not crystallize; ^{1}Hmr (acetone-d_6, external TMS) δ 3.15 (bm, 2H), 3.60 (s, 3H), 3.65–4.80 (bm's, 7H), 6.60 (d, 1H), 9.5 ppm (bm, 1H); ir (film) 1780, 1730–1700, 1650 cm^{-1} (C=O, C=C), 3350 cm^{-1} (OH); ms (150°C) *m/e* 268 ($M^+ - H_2O$), 255 ($M^+ - CH_3O$), 237 ($M^+ - CH_3O - H_2O$), 220 (M*, 255 → 237), 205, 117, 59.

*Methyl-2-(2α,3α-dihydroxy-O-isopropylidene-4β-tert-butyldimethylsiloxymethyl-N-carbomethoxypyrrolidin-1β-yl)malonate (**19b**)*

The crude malonic acid **19***a* in 30 ml ethyl ether was esterified with etheral diazomethane generated from nitrosomethylurea (24). After reaction for 1 h at room temperature, the solution was evaporated to dryness, and the residue was purified by chromatography on a silica gel column, eluting with ether–hexane (1:1). The oily product was obtained in 60% yield based on methyl ester **18***b*. ^{1}Hmr spectrum ($CDCl_3$) δ 0.11 (s, 6H), 0.93 (s, 9H), 1.30 (s, 3H), 1.43 (s, 3H), 3.60–3.70 (3 × s, 9H), 3.7–4.3 (m's, 4H), 4.3–4.7 ppm (m's, 3H); ir (film) 2920, 2890, 2820, 1730 (malonic ester), 1700 (urethane), 1440, 1375 cm^{-1}; ms (160°C) *m/e* 460 ($M^+ - CH_3$), 444 ($M^+ - CH_3O$), 418 ($M^+ - Me_3C$), 386 ($M^+ - Me_3C$ – MeOH), 360 ($M^+ - Me_3C(Me_2)Si$), 356.5 (M*, 418 → 386), 228, 189. *Anal.* calcd. for $C_{21}H_{37}NO_9Si$: C 53.03, H 7.84, N 2.95; found: C 52.74, H 8.05, N 2.98.

*3,4-O-Isopropylidene 2β-(2′-Hydroxyethyl)-5β-tert-butyldimethylsiloxymethyl-N-carbomethoxypyrrolidine-3α,4α-diol (**25a**)*

Ester **18***b* (526 mg, 1.26 mmol) was dissolved in 10 ml dry tetrahydrofuran in a 50 ml 3-neck flask equipped with septum, stopcocks, and mercury bubbler. The apparatus was flushed with nitrogen, cooled to 0°C, and 4.2 ml of a 1 *M* borane–THF solution was added with a syringe. The ice was allowed to melt, and the solution was allowed to stand at room temperature for 2 days. Then 1 ml methanol was added, and the solution was evaporated to dryness. Coevaporation with methanol (2 × 15 ml) left an oily residue which was chromatographed on silica gel. Elution with ethyl acetate – methylene chloride (1:5) recovered unreacted ester, then elution with a 1:1 mixture of the same solvents afforded 350 mg (70% yield) of alcoholic product as a clear, colorless oil; ^{1}Hmr (CCl_4) δ 0.08 (s, 6H, dimethylsilyl), 0.91 (s, 9H, *tert*-butylsilyl), 1.27 (s, 3H), 1.42 (s, 3H), 1.60 (bm, 2H, CH—C*H*$_2$—CH$_2$), 3.24–4.17 (bm's, 7H, 1H exch. with D_2O at about 3.5), 3.60 (s, 3H), 4.24 (bd, 1H, C*H*—O), 4.51 ppm (bd, 1H, C*H*—O); ir (film) 3490 (O—H), 1710 and 1695 (urethane), 1460, 1390 cm^{-1}; ms (95°C) *m/e* 374 ($M^+ - CH_3$), 332 ($M^+ - Me_3C$), 300 ($M^+ - Me_3C - CH_3OH$), 274 ($M^+ - Me_3C$-$(CH_3)_2Si$), 271.0 (M*, 332 → 300).

*3,4-O-Isopropylidene 2β-(2′-Mesyloxymethyl)-5β-tert-butyldimethylsiloxymethyl-N-carbomethoxypyrrolidine-3α,4α-diol (**25b**)*

To a solution of 100 mg (0.257 mmol) of alcohol **25***a* in 6 ml dry methylene chloride was added 2.35 ml of a 0.167 *M* solution of triethylamine in dry dichloromethane. This solution was cooled to −50°C (dry ice – acetone), and 0.92 ml of a 0.32 *M* solution of methanesulphonyl chloride in methylene chloride was added to it dropwise. The solution was allowed to warm up to room temperature then stirred 1 h. It was then washed with 2 × 10 ml cold water. The organic layer was dried ($MgSO_4$) and evaporated, leaving the clear, colorless mesylate in nearly quantitative yield; ^{1}Hmr (CCl_4) δ 0.09 (s, 6H), 0.92 (s, 9H), 1.29 (s, 3H), 1.42 (s, 3H), 1.97 (bm, 2H), 2.93 (s, 3H, OSO_2CH_3), 3.60 (bm, 2H, C*H*$_2$OSi), 3.62 (s, 3H), 3.7–4.6 ppm (m's, 6H); ir (film) 1710 (urethane), 1460, 1365 and 1180 cm^{-1} (mesylate); ms (130°C) *m/e* 410 ($M^+ - Me_3C$), 322 ($M^+ - Me_3C(CH_3)_2SiOCH_2$). *Anal.* calcd. for $C_{19}H_{37}NSO_8Si$: C 48.80, H 7.97, N 3.00; found: C 48.52, H 7.81, N 2.83.

A critical evaluation of Lennard–Jones and Stockmayer potential parameters and of some correlation methods

FRANK M. MOURITS AND FRANS H. A. RUMMENS

Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received November 10, 1976[1]

FRANK M. MOURITS and FRANS H. A. RUMMENS. Can. J. Chem. **55**, 3007 (1977).

Published values for the potential parameters σ and ε/k of the Lennard–Jones (12–6) and Stockmayer (12–6–3) potentials as based on viscosity measurements are reviewed, with particular reference to the problem of indeterminacy inherent to such calculations. A number of correlation techniques, calibrated on viscosity-based potential parameters, are critically reviewed; where possible, priority rules for the use of these correlations have been developed. In addition, several other criteria (i.e. not based on viscosity data) for the acceptance or rejection of σ and ε/k parameter values are also discussed. Upon application of the various criteria and priority rules it has been possible to give recommended σ and ε/k parameter values for 75 molecules.

FRANK M. MOURITS et FRANS H. A. RUMMENS. Can. J. Chem. **55**, 3007 (1977).

On passe en revue les valeurs publiées pour les paramètres σ et ε/k des potentiels de Lennard–Jones (12–6) et de Stockmayer (12–6–3); les potentiels sont basés sur des mesures de viscosité et on tient particulièrement compte des problèmes d'indéterminations inhérents aux tels calculs. On fait aussi une revue critique d'un certain nombre de techniques de corrélation, calibrées sur des paramètres de potentiel basés sur la viscosité; on a développé, dans les cas qui s'y prêtent, des règles de priorité pour l'utilisation de ces corrélations. De plus, on discute de plusieurs autres critères (qui ne sont pas basés, c'est-à-dire, sur la viscosité) pour l'acceptation ou le rejet de valeurs des paramètres σ et ε/k. Par l'application de divers critères et de règles de priorité, il est possible de présenter des valeurs recommandées pour les paramètres σ et ε/k pour 75 molécules.
[Traduit par le journal]

Introduction

The prediction of bulk properties of matter from molecular level models appears to be a well-developed science. Particularly in gases, properties like the second virial coefficient, viscosity, thermal conductivity *et cetera* can be molded into a unifying framework based on molecular pair interactions (see in particular Hirschfelder, Curtiss, and Bird's book (1*a*)). These models of pair interactions all start with the assumption that there exists a general potential function, different only for the various different molecules through one, two, or more parameters. Many such functions have been proposed (1*b*), but perhaps the one most commonly used is the Lennard–Jones (12–6) function of [1]:

$$[1] \qquad V(\text{pair}) = 4\varepsilon\left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6}\right]$$

where r is the distance between the centres of mass of the two molecules, ε is the maximum depth of the potential well, and σ is the distance at which $V(\text{pair}) = 0$. Equation 1 can, strictly speaking, only be used for non-polar molecules, but in practice [1] is also used for polar molecules. However, for the latter the Stockmayer (12–6–3) potential of [2] should be preferred:

$$[2] \quad V(\text{pair}) = 4\varepsilon\left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6} - \delta\left(\frac{\sigma}{r}\right)^{3}\right]$$

where $\delta = \zeta\,\mu^2/4\sigma^3\varepsilon$, $\zeta(\theta_1,\theta_2,\phi)$ being a function to describe the angular dependence of the dipole–dipole interaction energy. Used in their proper integrated forms, [1] or [2] can lead to expressions for transport properties (1*c*) and equation of state and thermodynamic properties (1*d*); data-fitting with accurate experimental data on these properties can be used to determine the parameters ε/k and σ. Mixing rules exist (1*e*) to predict macroscopic properties of binary mixtures. Particularly in engineering the possibility of calculating transport properties of gases has been explored and applied extensively. In our own attempts to construct a molecular model to account for the medium nmr shift of gases and liquids (see following paper (2)) we

[1]Revision received May 11, 1977.

have been confronted (as have many others before us) with several major drawbacks of the above outlined approach.

(*i*) Methods to extract the parameters ε/k and σ from different macroscopic properties often lead to substantially different values; this may happen even if the same property is employed.

(*ii*) All too often the ε/k and σ for the molecules of interest are not known, and even the required macroscopic properties may not have been measured. In these cases one has to resort to estimation methods, of which a bewildering collection is available in the literature, thus leaving one with the difficult task of deciding which approximation to believe most.

In this paper we will exclusively discuss ε/k and σ parameters either directly obtained from gas viscosities or estimated by correlation methods which have been calibrated on such viscosity-based parameters. This restriction is a pragmatic one; more parameters are known from viscosity than from all other sources combined. Second virial coefficients apply to a state of equilibrium and therefore potential parameters based on second virial coefficients should, in principle, be more relevant to nmr medium shift applications than those based on viscosity. Second virial coefficient data fits are, however, very sensitive to the choice of potential; in particular shape- and higher-order polarity terms are needed to obtain physically meaningful parameters (3). At present only Lennard–Jones parameters have been calculated from 2nd virial coefficients in any great number and these are notably poor for polar and large non-polar molecules (1*f*).

Directly viscosity-based parameters and their reliability are discussed first. Next some of the more prominent correlation methods will be discussed and several priority rules for the use of these will be proposed. A few extra tests will also be discussed; these are crude correlation guides for ε/k and σ which are nevertheless useful because even the best of the correlation techniques can on occasion produce extremely erroneous results. Finally, this critical analysis has enabled us to recommend best values for σ and ε/k. A list of such recommended parameters for 75 molecules concludes this paper.

Discussion

ε/k and σ Parameters Directly Obtained From Gas Viscosities

Before comparing in detailed fashion the various sets of parameters, it should be pointed out that for some molecules greatly varying parameter values have been reported. Reid and Sherwood (4*a*) have already discussed this in connection with the parameter values for *n*-butane as calculated by Flynn and Thodos and by Svehla, whose calculations were based on the *same* experimental viscosity data.

The explanation of these erratic results has recently been given by Kim and Ross (5). These authors noted that the Lennard–Jones collision integral $\Omega^{(2,2)*}$ in the reduced temperature range $0.4 < T^* < 1.4$ reduced to $1.604(T^*)^{-1/2}$ with an error of less than 0.7%. This has the effect (since $T^* = kT/\varepsilon$) that the Chapman–Enskog equation for the viscosity η is reduced to a simple proportionality with T, out of which only the *product* $\sigma^2\varepsilon^{1/2}$ can be deduced:

$$[3] \qquad \eta = \frac{266.95 \times 10^{-7}(MT)^{1/2}}{\sigma^2\Omega^{(2,2)*}} = \frac{166.43 \times 10^{-7}T(Mk)^{1/2}}{\sigma^2\varepsilon^{1/2}} \text{ (P)}$$

Reichenberg (6) has also studied this matter, reaching virtually the same conclusion, albeit with a slightly different indeterminacy range of $0.39 < T^* < 1.55$. Halkiadakis and Bowrey (7) have applied the same ideas to the Stockmayer potential and its parameters; they found that the range of indeterminacy increases slowly with polarity to become $0.2 < T^* < 1.8$ when δ_{max} reaches $\delta_{max} = 2.5$ ($\delta_{max} = \frac{1}{2}\mu^{*2}$, where $\mu^{*2} = \mu^2/\sigma^3\varepsilon$). Our own analysis confirmed the above, but it was found that in the indeterminate range $\Omega^{(2,2)*}$ for polar molecules reduces to $A(T^*)^{-n}$, where A and n depend strongly on the value of δ_{max}, with the result that η then becomes inversely proportional to the product $P(n) = \sigma^2(\varepsilon/k)^n$. Such indeterminacy is not really serious when viscosities are recalculated; any combination σ, ε/k such that the product $P(n)$ is equal to the experimental value will reproduce viscosities to good precision. Greater errors occur when viscosities of *mixtures* or other properties are calculated. Such errors take on catastrophic dimensions when a property like the nmr Van der Waals intermolecular shift σ_w is calculated, because σ_w is approximately proportional to $\sigma^{-3}\varepsilon$ (8); a σ which is too large combined with too small an ε now add up to give a much too small σ_w value.

Kim and Ross (5) also showed that the collision integral $\Omega^{(2,2)*}$ in the range $0.9 < T^*$

< 5 can be written, with an error of less than 0.1%, as:

$$[4] \qquad \Omega^{(2,2)*} = 0.7616\left(1 + \frac{1.09}{T^*}\right)$$

Equation 4 makes the Chapmann–Enskog equation (eq. 3) equivalent to the empirical Sutherland formula, which can be written as follows:

$$[5] \qquad \eta = \frac{266.95 \times 10^{-7}(MT)^{1/2}}{{\sigma_T}^2}$$

$$[5] \qquad {\sigma_T}^2 = {\sigma_\infty}^2\left(1 + \frac{C}{T}\right)$$

In the above stated T^* range the parameters in [3] and [5] are thus related as follows:

$$[6] \qquad \sigma = 1.146\sigma_\infty \quad \varepsilon/k = 0.917C$$

Through [6], therefore, the large compilation by Franck (9) of σ_∞ and C parameters can be converted to σ and ε/k parameters; the latter being just as much subject to indeterminacy, however, as when obtained directly through [3].

The indeterminacy problem thus obliges one to make a judgement on the quality of the experimental viscosity data. In Table 1 the viscosity-based parameters σ are listed as originating from Franck (abbrev. F) (9), Hirschfelder *et al.* (abbrev. HCB) (1*f*), Flynn and Thodos (abbrev. FT) (10), Svehla (abbrev. S) (11), Tee, Gotoh, and Stewart (abbrev. TGS) (12), Linakis and Bowrey (abbrev. LB) (13), and Halkiadakis and Bowrey (abbrev. HB) (7). In the column marked HB we have also indicated the total number of viscosity points (N_t) used by HB as well as the number (N_e) of viscosity points *outside* the indeterminate range. The parameters values of HCB and FT were obtained by a multiple two-point numerical fitting technique, whereas those given by S, TGS, LB, and HB were obtained by direct least-squares fitting on [3]. In Table A the corresponding ε/k values are listed.[2]

For polar molecules (Tables 2 and B)[2] a distinction must be made between parameters calculated following a Lennard–Jones potential [1], and those calculated according to a Stockmayer potential [2]. Only Monschick and Mason (referred to as MM), using a graphical curve-shifting procedure, have used [1] and [2] on the *same* set of viscosity data (14).

[2]Copies of Tables A, B, and C are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Because of the important role of the product $P(n) = \sigma^2(\varepsilon/k)^n$, the values of $P(n)$ for all parameter sets listed in Tables 1, 2, A, and B have been calculated; these are given in Tables 3 and 4. In Table 4 the calculated $P(n)$ values based on the Stockmayer potential are given both for the correct value of n (varying between 0.49 and 0.54) as well as for $n = 0.50$. The latter allows comparison with the Lennard–Jones based products $P(n)$, where $n = 0.50$. As will be shown, these products $P(n)$ can be used as a guide in analyzing and judging the various parameter sets. As expected, the $P(n)$ values for indeterminate parameter sets are fairly constant ($\pm 1\%$ or less), although the individual σ and ε/k parameters may vary strongly between the various authors. For determinate situations $P(n)$ is only constant, when the individual σ and ε/k parameters are the same. The $P(n)$ values based on the data of Franck (eq. 6 and ref. 9) were found to be systematically higher than all other $P(n)$ values; hence the corresponding σ and ε/k values were omitted from further consideration.

For the noble gases, N_2, O_2, CO_2, CH_4, C_2H_6, and H_2O the viscosities are known over a very large temperature range; therefore a high percentage of viscosity points falls outside the indeterminate range. Indeed the parameters from HCB, FT, S, TGS, and MM show a good mutual agreement for these molecules. The σ parameters of LB and HB seem to be systematically lower for the noble gases, N_2, O_2, and CO_2 in spite of a high percentage determinacy. We have traced this discrepancy back to their use of presmoothed viscosity data (15), even extrapolating outside the original experimental temperature range (O_2). In the HB study viscosity points outside the indeterminacy range were given a statistical weight 10 times larger than those inside the range, whereas in the LB study virtually the same data points were used but with *equal* statistical weight. The product $P(n)$ is a useful quantity to discuss the differences between the results of HB and LB. As the tables show, for highly determinate cases the products $P(n)$, as well as the individual σ and ε/k parameters are very similar in the HB and LB studies. The tables show also that the HB and LB products $P(n)$ are almost the same, but with widely different individual σ and ε/k values, for those molecules where the parameters are indeterminate. For molecules whose experimental points are partly inside, partly outside the indeterminate range, several sub-cases

need to be considered. If the HB and LB procedures result in substantially different products $P(n)$, then the set of experimental points favored by the HB weighting method (normally the high-temperature points) is inconsistent with the complete set. In fact in such a case the HB parameters should be considered less reliable since even their product $P(n)$ does not optimally fit the

data points in the indeterminate range. On the other hand the LB *product* $P(n)$ is more reliable. It would have been better to employ the HB method, but with the LB product $P(n)$ kept as a fixed constant. Examples are C_3H_8, C_2H_4, N_2O, NH_3, and SO_2. If the HB and LB products $P(n)$ are essentially the same, when the individual σ and ε/k parameters are different, then one should prefer the HB parameters. Examples are F_2 and CCl_4. If the HB and LB products $P(n)$ and the σ and ε/k parameters are virtually the same, then apparently the case is already effectively determinate (noble gases, N_2, O_2, CO_2, NO). The fourth possibility relates to cases where N_e is very small. If these few points fall in a *narrow* T^* range (as they normally will do), then the extracted HB parameters may become effectively indeterminate (constant $P(n)$) again, as was pointed out already by Reichenberg (6). Examples are CH_3Cl, $CHCl_3$, C_2H_5OH, CH_3OH, and $(C_2H_5)_2O$. Although the degree of indeterminacy as indicated in Tables 1 and 2 refers, strictly speaking, only to the work of HB, it gives in general also a good indication of the indeterminacy of the parameters of the *other* authors for these same molecules, since the sources of viscosity data were largely the same. In addition, the latter data are for the most part

fairly old and are consequently not likely to be more accurate than 0.7%. It should be kept in mind, however, that recent viscosity data, particularly when measured with the rotating disc technique may be as precise as 0.1% (15), thereby narrowing or even eliminating the indeterminacy range. Except for the noble gases, N_2, O_2, and CO_2 no such accurate data appear to be available at this time.

As far as the fit on viscosity data of polar molecules is concerned, no significant improvement is obtained by replacing the Lennard–Jones

(12–6) potential by a Stockmayer (12–6–3) potential (14). Indeed as MM stated (14), even more primitive potentials would have been equally successful. Klein and Hanley (16) analyzed this problem from a theoretical viewpoint and came to the important conclusion that within the range $2.0 < T^* < 5.0$ little can be learned about the precise nature of the potential function. One must have viscosity data of at least 0.5% accuracy and then either at $T^* < 2.0$ or $T^* > 5.0$ or both in order to distinguish between the various proposed potential func-

tions. The above does not imply, however, that the *parameter* sets for the Lennard–Jones and Stockmayer potentials would have to be the same. Inspection of the two MM columns of Tables 2 and B reveals in fact considerable, but non-systematic differences. Comparing each of the corresponding MM $P(n)$ values with the other $P(n)$ values for the same potential (Table 4), it is evident that all cases except SO_2 are effectively indeterminate. Although therefore no conclusion can be drawn regarding the relative merit of the two potentials with respect to their σ and ε/k parameters, it is evident from Table 4 that the Stockmayer $P(n)$ values are systematically smaller than the Lennard–Jones $P(n)$ values. Analysis of the collision integral $\Omega^{(2,2)*}$ as a function of δ_{max} has shown us that there are, to a good approximation, explicit relations between Stockmayer and Lennard–Jones parameters. Up to $\delta_{max} = 0.25$ the differences are negligible. Going from $\delta_{max} = 0.25$ to $\delta_{max} = 2.5$ the Stockmayer σ values decrease up to 5%, while the Stockmayer ε/k values decrease up to 51% relative to the Lennard–Jones ε/k; as a result Stockmayer $P(n)$ values are substantially smaller than Lennard–Jones $P(n)$ values for $\delta_{max} > 0.25$. This latter trend can be clearly observed in Table 4. The general conclusion therefore is, that, apart from indeterminacy problems, Stockmayer potential parameters are to be preferred for molecules with δ_{max} larger than 0.25.

ε/k and σ Parameters Obtained by Correlation Techniques

Stiel and Thodos (abbrev. ST) (17) have developed the following empirical relationship for non-polar molecules:

$$[7] \qquad \sigma = 0.1866 V_c^{1/3} Z_c^{-6/5}, \quad \varepsilon/k = 65.3 T_c Z_c^{18/5}$$

and similarly for polar, but non-hydrogen bonding molecules (18):

$$[8] \qquad \sigma = 0.785 V_c^{1/3}, \quad \varepsilon/k = 0.897 T_c$$

Here V_c is the critical volume (cm^3), T_c is the critical temperature (K) and Z_c is the critical compressibility. Selected values for Z_c, V_c, P_c, T_c, as well as for the dipole moment μ are given in Table C.[2] Equation 7 was calibrated on the viscosity-based Lennard–Jones (12–6) parameters of FT (10) and of HCB (1*f*). Equation 8 was calibrated on the viscosity-based Stockmayer parameters of MM (14). More recently, HB (7) have developed similar relations. For non-polar molecules only, they find:

$$[9] \qquad \sigma = 0.386 V_c^{1/3} Z_c^{-0.59}, \quad \varepsilon/k = 2.80 T_c Z_c^{0.97}$$

whereas for non-polar and polar molecules combined, they find:

$$[10] \qquad \sigma = 0.813 V_c^{1/3}, \quad \varepsilon/k = 0.404 T_c Z_c^{-0.53}$$

HB calibrated [9] and [10] on their own set of calculated viscosity-based Lennard–Jones (12–6) and Stockmayer (12–6–3) potential parameters.

For non-polar molecules an alternative was recently introduced by TGS (12). The method does not require knowledge of the often inaccurate V_c parameter, but utilizes P_c, T_c, and Pitzer's acentric factor ω, where ω is defined by

$$[11] \qquad \omega + 1 = -\log_{10} \frac{P}{P_c}\bigg|_{T_r = 0.7}$$

with P being the vapour pressure at the reduced temperature $T_r = 0.7$. Calibrating on their own set of viscosity-based Lennard–Jones (12–6) parameters, they found:

$$[12] \qquad \sigma = (2.3454 + 0.2972\omega)(T_c/P_c)^{1/3}$$
$$\varepsilon/k = (0.8082 - 0.4504\omega) T_c$$

The parameter ω can be calculated (eq. 11) from vapour pressure data or, if the latter are not available, be estimated within 5% from the following semi-empirical relation (19):

$$[13] \qquad \omega + 1 = \frac{3\theta}{7(1-\theta)} \log_{10} P_c, \quad \theta = T_b/T_c$$

where T_b (K) is the boiling point temperature.

Malek and Stiel (abbrev. MS) (20) have attempted to expand the TGS method to *polar* compounds, introducing a fourth parameter x to account for the polar interactions:

$$[14] \qquad x = \log_{10} \frac{P}{P_c}\bigg|_{T_r = 0.6} + 1.70\omega + 1.552$$

Calibrating on MM's set of Stockmayer parameters (14), they obtained the following relations:

$$[15] \qquad \sigma = (2.3454 + 0.2972\omega - 40.4271x + 61.7675\omega x - 15.8248x^2 - 0.9706\omega^2)(T_c/P_c)^{1/3}$$
$$\varepsilon/k = (0.8082 - 0.4504\omega + 27.3866x - 48.9402\omega x - 48.7293x^2 + 0.8784\omega^2) T_c$$

We have calculated ω and x values for all molecules concerned, directly from the best vapour pressure data available. These are given in Table 5. The right-hand side of Tables 1–4, A and B show calculated values of σ, ε/k and $P(n)$ as based on the critical values of Table C and our own set of ω and x parameters of Table 5.[2]

Critical Comparison of ε/k and σ Parameter Values

In Tables 1–4, A, and B we have italicized those values which we have used to arrive at the *recommended* values. For the values of σ(visc) and ε/k(visc) this judgement was arrived at by searching the original literature on the viscosity measurements as used by the various authors. Generally, when about 30% or more of the experimental points were outside the indeterminate range, the parameters were considered reliable, at least if and when the latter conformed with the criteria regarding $P(n)$ as discussed in the previous section. These preferred σ(visc) and ε/k(visc) values form a basis set against which the σ(calcd) and ε/k(calcd) can be compared.

Discussing first the non-polar molecules (Table 1), it may be seen that the σ(calcd) values according to [7] are not unreasonable but nevertheless slightly too large on the average. It is believed that this is due to the calibration of [7], which included many σ(visc) values now considered to be unreliable. Re-calibrating would be a possibility, but at this stage this would be rather unsatisfactory due to the lack of reliable σ(visc) data for *larger* molecules. Furthermore the strong dependence on the, usually inaccurately known, parameter V_c makes the ST method less attractive, particularly since the TGS method (see below) does not require V_c at all. The correlations given by HB (eqs. 9 and 10) show a lesser dependence on V_c. The σ(calcd) values obtained by [9] are reasonable, but in general somewhat too small. Equation 10 has in principle the great advantage of avoiding the discrimination between polar and non-polar molecules, but for non-polar molecules at least the results are often much too low.

The TGS results (eq. 12) show a very good agreement with our selected σ(visc) and ε/k(visc) parameters despite the fact that the original TGS calibration included some indeterminate parameters. Since the TGS method does not require knowledge of V_c but rather of the vapour pressure, which is usually accurately known, we prefer the TGS method over those of ST and HB. Based on this preference we have accepted as best values for those molecules, for which no sufficiently determinate σ(visc) and ε/k(visc) were available, the σ(calcd) and ε/k(calcd) calculated with [12]. The last two columns of Table 1 show the selected parameters σ and ε/k for all non-polar molecules; the ε/k values have, in all instances, been selected in conformity with the selection of σ values (see Table B).[2] Where more than one acceptable value was available, the *average* of these is given.

For slightly polar molecules (i.e. $\mu^* \leq 0.3$) [7] gives σ(calcd) values which are too high (as was already noticed for non-polar molecules), whereas the σ(calcd) values according to [8] are too low. Taking the *average* of the results of [7] and [8] gives good agreement for this μ^{*2} range. However, the HB method of [9] gives also good results, comparable with the above mentioned average. For polar molecules with $\mu^{*2} > 0.3$ reasonably good values are obtained with [8]. This is rather remarkable since the calibration of [8] included only one molecule (SO_2) with a large degree of determinacy in its parameters. Equation 10, being a correlation for non-polar and polar molecules combined shows systematic deviations; σ(calcd) is generally too low for slightly polar molecules and too high for polar molecules. It follows therefore that it is impossible to find a universal correlation based on critical constants, which gives good results for molecules of both low and high polarity. The claim of HB that [10] is superior to ST's [7] is irrelevant as far as polar molecules are concerned because the latter equation is designed to correlate non-polar molecules only!

The ω,x method of MS (eq. 15) is potentially the most powerful correlation, since it relates directly the potential parameters to the size and the degree of polarity of the molecule. However, because of the way in which ω and x are defined, these size and polarity factors are not separated, resulting in the need for a cross-term ωx and higher order terms such as ω^2. Ideally, such a method with well-separated parameters would correlate polar and non-polar molecules without discontinuity. However, because of the noted non-separation, one has to arbitrarily set ω^2 and x equal to zero for non-polar molecules (to reduce [15] to [12]), but also for slightly polar

[a]The molecular parameters ω for the hydrocarbons were calculated from the API-44 vapour pressure data (28). The ω parameters for the inorganic gases, taken from Reid and Sherwood's tabulation (4b) are experimentally determined or calculated. Their value for CO_2 (ω = 0.420) is clearly in error. [b]K.S. FIG. 1. Empirical correlation between the molar volume V_m^{25} and σ^3(rec) values of Tables 1, 2, and 6. σ(rec) values, based on determinate σ(visc) values are indicated by ▲; filled circles ● indicate σ(rec) values based on correlation techniques. Solid lines tie points within classes of compounds.

molecules (the limit appears to be at $\mu^{*2} = 0.3$). Another disadvantage of the MS method is that it requires extremely accurate vapour pressure data (*vide infra*). Finally it appears that for molecules with $|x| > 0.035$ grossly erroneous results may occur. Examples are HF, HCN, CH_3NO_2, and CH_3CN. In conclusion we prefer the MS method of [15] for polar molecules with $\mu^{*2} > 0.3$ whenever very accurate vapour pressure data are available. If with [15] physically unacceptable results are obtained according to supplementary tests (*vide infra*) (for example due to inaccurate vapour pressure data), it is recommended to use the ST method of [8]. For slightly polar molecules ($\mu^{*2} \leq 0.3$) it is recommended to use the TGS method of [12], to be consistent with the preference expressed with respect to non-polar molecules. Based upon the above recommendations, preferred σ and ε/k values (or their average) are given in the last columns of Table 2. Table B gives all the corresponding ε/k values for polar molecules.[2]

In Table 3 (non-polar molecules) P(av) is the average of all P(visc) values (except those of F), while P(rec) is the product based on σ(rec) and ε/k(rec). For the indeterminate cases (where η is only a function of $P(n)$), P(av) will give the best fit on all viscosity data combined. The deviation of P(rec) from P(av) is therefore a direct measure of the error if viscosities were recalculated on the basis of P(rec). These percentage deviations have been given in the last column of Table 3. In the determinate cases P(rec) is always taken from one or more P(visc) data and therefore will, of course, already constitute the best fit over the combined viscosity data.

For polar molecules (Table 4) with $\delta_{max} \leq 0.25$, P(av) is the average over the Lennard–Jones and Stockmayer P(visc) values; Stockmayer P(visc) values were used to calculate P(av) when $\delta_{max} > 0.25$. For reasons of consistent comparison all P(calcd), P(av), and P(rec) values have been calculated with $n = 0.50$. It should be noted that for indeterminate cases the determinate product $P(n)$ *may* have a value of n, different from 0.50; in these cases also P(visc) values for $n = 0.50$ were calculated to make comparison possible. As before, the % dev. column indicates the error

level in viscosities, recalculated on the basis of the recommended parameters.

Supplementary Test Methods for σ

In addition to already existing non-viscosity-based correlation techniques (1, 11) we have found three additional estimation methods. Figure 1 shows that there is a reasonable correlation between σ^3(rec) and V_m^{25}, the molar volume at 25°C. In fact, for chemically closely related molecules (such as the *n*-alkanes, the methyl benzenes and the *n*-alkan-1-ols) very good straight-line relationships exist. In principle a correlation between σ^3 and V_m^b (molar volume at boiling point) would be better; however, V_m^b is not available in many cases, whereas V_m^{25} is much more often available from literature sources. For low-boiling compounds the reverse is often true. An application of the above correlations is ethyl acetate which with the MS method appeared to give too high a value for σ. Using Fig. 1, an estimated σ(rec) = 5.65 was arrived at. Points which would fall clearly outside the indicated correlation band of Fig. 1 must be considered erroneous. In fact this criterion was used in the foregoing discussions; it did confirm that certain σ(visc) values (such as for mesitylene, *n*-hexane, neopentane, cyclohexane, CCl_4, and propanal) were not only indeterminate, but indeed erroneous.

A second test is based on the σ and ε/*k* parameters obtained by Wilhelm and Battino (abbrev. WB) (21) from the solubility of certain gases (He, Ne) in liquids. As Fig. 2 shows, there is an excellent straight-line relation between the WB σ values and our σ(rec) values. This relation formed an additional argument to accept the TGS method, particularly because of the excellent correlation for the higher *n*-alkanes. The only deviating point is that for acetone; since σ(rec) is based on highly accurate P_c, T_c, and vapour pressure data and since in Fig. 1 acetone falls well inside the correlation band, it is suspected that this deviation is caused by an error in the solubility measurements. The WB method in principle provides also ε/*k* values, but these seem to be rather inaccurate.

A third test is provided by the σ values, obtained by Goldman (22) by fitting a thermodynamic perturbation theory to experimental vapour pressure data. Figure 3 shows an excellent correlation between Goldman's σ and our σ(rec) values.

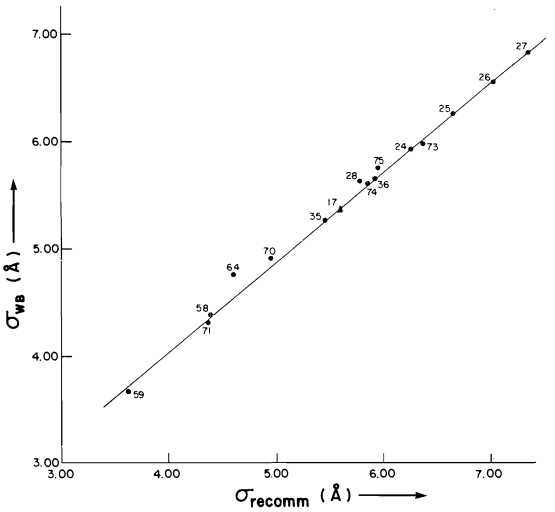

FIG. 2. Empirical correlation between the σ values based on noble gas solubility as given by Wilhelm and Battino (21) and the σ(rec) values of Tables 1, 2, and 6. σ(rec) values, based on determinate σ(visc) values are indicated by ▲; filled circles ● indicate σ(rec) values based on correlation techniques.

Whenever these test methods are used to *estimate* σ values, the problem of finding the corresponding ε/*k* value still remains. However, in these cases an accurate product $P(n)$ may be available, from which, in combination with the estimated σ value, the ε/*k* value can be abstracted (example: ethyl acetate).

Auxiliary Parameters

In all correlation techniques discussed above, critical constants are needed. Compilations of experimental critical constants are available (23–26). For molecules where such experimental data are not available, these can be calculated with good precision according to a method described by Curl and Pitzer (27). This method requires knowledge of the boiling temperature, the temperature at which the vapour pressure is 100 Torr and the density at some temperature below the boiling point, all of which data are usually easily accessible.

The TGS and MS methods require in addition knowledge of vapour pressures for the calculation of ω (and *x*). The potential parameters calculated according to TGS are not very sensitive to small (±5%) changes in ω. Therefore almost any source of vapour pressures (26, 28–32) at $T_r = 0.7$ is normally accurate enough as are values of ω estimated with the Edmister formula [13]. The situation is more complicated,

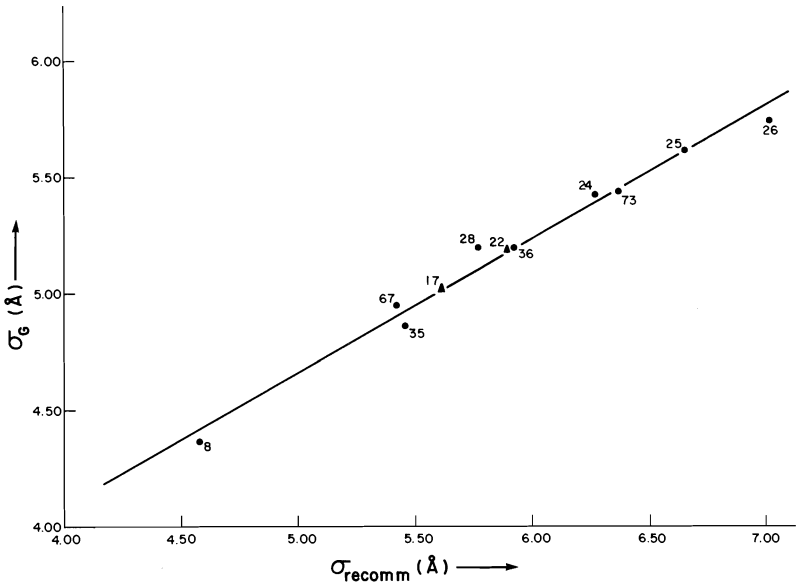

FIG. 3. Empirical correlation between the σ values of Goldman (22) and the σ(rec) values of Tables 1, 2, and 6. σ(rec) values based on determinate σ(visc) values are indicated by ▲; filled circles ● indicate σ(rec) values based on correlation techniques.

however, when the ω and x parameters of the MS method are to be determined. In their original paper, MS calculated Stockmayer parameters for 13 molecules for which, in their words, "reliable values of ω and x were available", without disclosing either their methods or their sources. In Table 5 we have listed the most recent values of ω and x used in other work of Stiel and co-workers. The fact that some of these values were revised several times reflects already the problems encountered when determining such parameters. With the above ω and x parameters we calculated σ and ε/k according to [15], but many of these were clearly unacceptable on the basis of the V_m^{25} or V_m^{b} test (example ethanal) or on the basis of a lacking consistency in homologous series (for example the σ(MS) for HBr and HCl). Partly because of the above we felt compelled to re-evaluate the ω,x method and to develop suitable criteria. Extensive trials have shown us that, in order to obtain reasonable σ and ε/k parameters through the MS method, one needs vapour pressures accurate to ±0.01 Torr (corresponding to a temperature accuracy of ±0.001°C), over an extended pressure range (normally between 0.1 and 2 atm) covering at least the $T_r = 0.6$ point but preferably also the $T_r = 0.7$ point. The requirement of highly accurate vapour pressure data is a direct result of the extreme sensitivity of σ and ε/k towards ω and x. In order to find the needed vapour pressures at reduced temperatures $T_r = 0.6$ and $T_r = 0.7$, it is necessary to fit experimental data into a vapour pressure equation. One of these is the Antoine equation [16]:

$$[16] \qquad \log_{10} P = A - \frac{B}{t + C}$$

Several compilations of Antoine parameters are available (28, 29, 31). The closeness of the data fit over the experimental range should be ±0.03% or less and the calculated critical pressure should be about 8% too low (33). If raw vapour pressure data were available, or if the Antoine equation was not adequate, we have successfully employed the following expression:

$$[17] \quad \log_{10} P = A - \frac{B}{T} + C \log T + DT$$

In our experience, [17] is at least equivalent in quality to the Antoine equation and in certain cases (such as alcohols) definitely superior; in addition, [17] is more easily adaptable to computerized least-squares fitting. Most of our own ω,x values (last two columns of Table 5) were obtained through the vapour pressure equation [17].

Some Further Applications

As mentioned above, for many molecules of interest no viscosity-based potential parameters are available at all. In such cases one has to rely exclusively on the correlation techniques as recommended in this paper. For some molecules, which were of particular interest to our nmr intermolecular interaction studies, we have thus calculated σ and ε/k values as given in Table 6.

Intermolecular interactions in nuclear magnetic resonance. XI. The ^{13}C and proton medium shifts of CH_4 in the gas phase and in solution

FRANS H. A. RUMMENS AND FRANK M. MOURITS

Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received September 23, 1976[1]

FRANS H. A. RUMMENS and FRANK M. MOURITS. Can. J. Chem. **55**, 3021 (1977).

The ^1H and ^{13}C resonances of methane have been measured at 298 K, both as pure CH_4 in the gas phase as function of the density as well as at low concentration in solution, using polar, non polar, isotropic, as well as magnetically anisotropic solvents. It is found that both the gas and the solution proton shift data can be readily understood in terms of the Van der Waals shielding σ_w and the mean-square field due to the dispersive interactions: $\sigma_w = -B\overline{F^2}$. Either a macroscopic reaction field model or a binary collision statistical mechanical model for $\overline{F^2}$ can be used with an approximately equal degree of success. Whereas the ^{13}C gas phase shifts of CH_4 are also proportional to the density, the ^{13}C gas-to-solution shifts indicate that, apart from σ_w, there exists even in non-polar isotropic solvents another effect which is not proportional to $\overline{F^2}$. The present study also includes a new proposal regarding $\overline{F^2}$, a discussion of anisotropy shielding σ_a in magnetically anisotropic solvents and a discussion of the effective B parameters (^1H and ^{13}C) of CH_4 in the gas and the solution state.

FRANS H. A. RUMMENS et FRANK M. MOURITS. Can. J. Chem. **55**, 3021 (1977).

On a mesuré les résonances de ^1H et ^{13}C du méthane à 298 K sous forme de CH_4 pur en phase gazeuse en fonction de la densité ainsi qu'à faible concentration en solution utilisant des solvants polaires, non-polaires, isotropes aussi bien que magnétiquement anisotropes. On a trouvé que les données de déplacement chimique des protons pour le gaz et les solutions peuvent être facilement expliquées en termes du blindage de Van der Waals σ_w et du moyen du carré du champ dû à des interactions dispersives: $\sigma_w = -B\overline{F^2}$. On peut utiliser soit un modèle de champ de réactions macroscopiques ou un modèle de méchanique statistique par collision binaire pour $\overline{F^2}$ et l'on a alors des chances approximativement égales de succès. Alors que les déplacements ^{13}C en phase gazeuse du CH_4 sont aussi proportionnels à la densité, les déplacements de ^{13}C qui se produisent lorsque l'on passe du gaz vers des solutions indiquent qu'il existe, en plus de σ_w, même dans des solvants isotropes non-polaires, un autre effet qui n'est pas proportionnel à $\overline{F^2}$. L'étude actuelle inclut aussi une nouvelle proposition concernant $\overline{F^2}$ soit une discussion du blindage anisotropique σ_a dans des solvants magnétiquement anisotropes et une discussion des paramètres B effectifs (^1H et ^{13}C) du CH_4 à l'état gazeux et en solution.

[Traduit par le journal]

Introduction

Solvent effect studies on nmr shifts have been studied hitherto mostly by proton spectroscopy. In view of the recent tremendous expansion of ^{13}C nmr it is surprising that very few ^{13}C solvent studies have appeared (for brief reviews see ref. 1 and the literature cited in ref. 2 therein). Apart from very recent work by Tiffon and Doucet (2) on ^{13}C gas-to-liquid shifts of *n*-pentane and by Cans *et al.* (3) on the ^{13}C solution shifts of a number of olefins, no other systematic study seems to have been undertaken. This situation appears precarious, because ^{13}C solvent shifts can now be estimated as being of very considerable magnitude; lack of knowledge of these effects can well precipitate errors of interpretation in general ^{13}C work. It was decided to study the medium shift effects of CH_4 to help fill in the aforementioned gap. Methane was chosen for several specific reasons. Firstly, it allows a study in the gas phase as function of density as well as in the liquid phase as gas-to-solution shifts. Secondly, the carbon being at the centre of mass, the site factor complications (ref. 4; see also pp. 46–50 of ref. 1 for a further discussion of this effect) are eliminated for the ^{13}C shifts. Finally, by measuring at the same time the proton shifts, a comparison between nuclear species would be feasible.

In general one can write for the shielding of a molecule in a medium:

$$[1] \quad \sigma = \sigma_0 + \sigma_b + \sigma_w + \sigma_a + \sigma_{E^2} + \sigma_{Ez} + \ldots$$

where the symbols have their usual meaning (5).

[1]Publication was delayed at the author's request.

The medium shift can be defined as $\sigma_m = \sigma - \sigma_0 - \sigma_b$; σ_m then contains exclusively the intermolecular effects. Since CH_4 is non polar, the reaction field term σ_{Ez} will be taken as zero. In addition the term σ_{E^2}, the direct field effect of polar solvents will also be taken as zero, since it has been estimated (6) that this effect, if it exists at all, is negligible in comparison to σ_w, at least for non polar solutes. For the Van der Waals term σ_w, most present theories start with Stephen's proposal (7) that σ_w is proportional to the mean-square electric field due to the spontaneous moments; $\sigma_w = -B\overline{F^2}$. Of these only the binary collision statistical mechanical model of Raynes, Buckingham, and Bernstein (abbreviated RBB) (5) and the macroscopic reaction field model of Rummens (6) have shown quantitative promise. In the latter model one has:

$$[2] \quad \sigma_w = -\frac{6KB\alpha_1 I_1}{a^6}\left(\frac{n_2^2 - 1}{2n_2^2 + 1}\right)^2 \frac{1}{(1 - q^2)^3}$$

The cavity radius a can be estimated from $a^3 = 3V_1/4\pi N_A$ but this has been shown (6) to be a poor approximation. Using proton shifts, Rummens has used the above model in reverse to determine the cavity radius; with a value of $KB(^1H) = 4.71 \times 10^{-18}$ esu he found $a^3(CH_4) = 13.9 \times 10^{-24}$ cm^3.[2] The site factor $(1 - q^2)^{-3}$ contains the parameter q which is defined as $q = d/r_{12}$, d being the distance from nuclear site to the centre of mass of the solute while $r_{12} = r_1 + r_2$, r_1 and r_2 being molecular radii. For ^{13}C of CH_4, $d = 0$ and therefore the site factor is unity. The parameter B is certainly much larger for ^{13}C than for ^1H; the parameter K contains only model approximations and can be expected to be independent of the nuclear species investigated. Following [2] one has therefore

$$[3] \quad \frac{\sigma_w(CH_4) \times (1 - q_H^2)^3}{\sigma_w(CH_4)} = \frac{B(^1H)}{B(^{13}C)}$$

In the virial model of RBB, and allowing only binary interactions, one has (5)

$$[4] \quad \sigma_w = \frac{\sigma_{1w}}{V} = \frac{1}{V}\int (\sigma_w)\text{pair} \exp(-u/kT)\, d\tau$$

where u is the intermolecular potential, for which the Lennard–Jones (6–12) potential is conveniently chosen:

$$[5] \quad u = 4\varepsilon\left\{\left(\frac{r_0}{r}\right)^{12} - \left(\frac{r_0}{r}\right)^6\right\}$$

The same authors (5) took as mean-square field on the solute the field of a (solvent) molecule at distance r

$$[6] \quad \overline{F}^2(\text{RBB}) = \frac{3\alpha_2 I_2}{r^6}$$

Rummens *et al.* (4, 8) introduced a site factor, which in the integrated form of [4] is given by

$$[7] \quad S_6^g = 1 + 5q_0^2\frac{\mathscr{H}_8(y)}{\mathscr{H}_6(y)} + 14q_0^4\frac{\mathscr{H}_{10}(y)}{\mathscr{H}_6(y)} + 30q_0^6\frac{\mathscr{H}_{12}(y)}{\mathscr{H}_6(y)} + 55q_0^8\frac{\mathscr{H}_{14}(y)}{\mathscr{H}_6(y)} \ldots$$

where $q_0 = d/r_0$. Using (σ_w) pair $= -B\overline{F^2}$, [4] combined with [5] and [6] becomes

$$[8] \quad \sigma_w = \frac{-\pi K_6^g B N_A \alpha_2 I_2}{r_0^3 V_2 y^4}\mathscr{H}_6(y) S_6^g$$

where $y = 2(\varepsilon/kT)^{1/2}$ and $\mathscr{H}_6(y)$ is an integral whose numerical values are known (9). For gas-phase work $K_6^g = 1$ by definition. A value of $K_6^g = 1.46 + 0.0064t$ has been proposed (8) for gas-to-liquid shifts. Apparently σ_w in liquids or in high pressure gases can be understood in terms of an *effective* binary collision, higher order collision contributions being apparently proportional to the binary effect. In this interpretation K_6^g represents this proportionality constant; its value should be independent of nuclear species. Analogous to [3], this model therefore predicts that

$$[9] \quad \frac{\sigma_w(CH_4)/S_6^g(H)}{\sigma_w(CH_4)} = \frac{B(^1H)}{B(^{13}C)}$$

Theory

A modification in the use of the binary collision model will be discussed here. It concerns the mean-square field $\overline{F^2}$, several criticisms having been made recently (ref. 1, pp 41–42) regarding the approach of [6]. At the rather short distances of interest (σ_w is nearly entirely determined by the nearest neighbors), it would seem that solute and solvent molecule would interact and that therefore a field in empty space would not be adequate For the dispersion energy ϕ^{disp} of two

[2]The value $a^3 = 34.3$ given in ref. 6 is in error; also the $(r_{01}/2)^3$ value quoted should read 6.80×10^{-24} cm.

molecules one may write;

$$[10] \qquad \phi^{disp} = -\frac{3\alpha_1\alpha_2 I_1 I_2}{2r^6(I_1 + I_2)}$$

This follows from the Drude model, but the same result can be obtained by London's perturbational method (10) or by variational methods (11, 12).

The energy of a polarizable particle in an electric field being $-\alpha E^2/2$, one has for a system of two particles in each other's mean-square field:

$$[11] \qquad \phi^{pol} = -\tfrac{1}{2}\alpha_1\overline{F^2}_{1(2)} - \tfrac{1}{2}\alpha_2\overline{F^2}_{2(1)}$$

where $F_{i(j)}$ is the field at i, caused by j. Equating [10] and [11], one has as a possible solution:

$$[12] \qquad \overline{F^2}_{1(2)} = \frac{3\alpha_2 I_1 I_2}{2r^6(I_1 + I_2)}$$

together with a similar expression for $\overline{F^2}_{2(1)}$.

For σ_w this results in:

$$[13] \qquad \sigma_w = \frac{-\pi N_A K_6{}^g B\alpha_2 I_1 I_2}{2r_0{}^3 V_2(I_1 + I_2)y^4}\mathscr{H}_6(y)S_6{}^g$$

Comparing [12] and [6] one notes that I_2 has been replaced by $I_1I_2/2(I_1 + I_2)$, so that even if the ionization potentials are equal, [12] gives a 4× smaller field and therefore a 4× smaller σ_w.

Many approximations were made in the derivation of the London dispersion energy, given by [10]. One may well wonder if its use is justified. Hirschfelder *et al.* (16) compared the sum of the first three terms in the dispersion energy with the r^{-6} coefficient in the Lennard–Jones potential as determined from viscosity and found that the latter coefficients were between 1.5 and 2.0 times larger. However, if one compares the r^{-6} coefficients of [10] with the results of other quantum-mechanical calculations, such as the variational methods of Slater and Kirkwood (11) and Buckingham (12), the uncoupled Hartree–Fock calculations of Karplus and Kolker (13) or the coupled version of Dalgarno and Victor (14), one can generally see a reasonable agreement. As Dalgarno and Davison have pointed out (15), one should not compare the r^{-6} coefficients based on viscosities, because the viscosity data are usually obtained at temperatures where the short-range repulsion forces play a significant role. One should extrapolate these viscosity data to absolute zero in order to get correct results. Atomic beam small-angle scattering at thermal energies is potentially the most valuable source of information about long-range forces. The few results obtained so far agree well with the above mentioned calculations (15). Bell (17) has calculated the r^{-6} coefficients for a number of gases, using a semi-empirical method which can be considered the best available. His results are somewhat larger than those of [10], but only about 5 to 20%. Thus, we have decided to adopt [10] because of its general applicability and its relatively good accuracy. As a corollary, [12] then must also be assumed correct, but this can be checked in an independent manner. If one takes the r^{-6} coefficient of $\sigma_w = -B\overline{F^2}$ with $\overline{F^2}$ as *per* [6] and equate this to the r^{-6} coefficient of σ_w for two interacting H atoms, as calculated by Marshall and Pople (18), one arrives at $B = 0.20 \times 10^{-18}$ esu for an H atom, in poor agreement with $B = 0.74 \times 10^{-18}$ esu for an H atom in an electric field, as calculated also by Marshall and Pople (19). However, if [12] is used rather than [6] then a value of $B = 0.80 \times 10^{-18}$ esu emerges, which shows a very good correspondence with the direct calculation of an H-atom in a field. In addition it has also been established empirically by Mohanty and Bernstein in their ^{19}F gas phase work (20) and by Rummens and De Meyer (ref. 1, p. 45) on gas-to-liquid shifts of $X(Me)_4$ that a form $I_1I_2/(I_1 + I_2)$ or, what is almost the same, $\sqrt{I_1I_2}$, gives much better coherence of σ_w data than does I_2 alone. Also a considerable improvement in constancy of B (though not enough) would be obtained if the data of Jameson *et al.* on ^{129}Xe in various solvent gases (21) would be treated according to [12] rather than [6].

The replacement of [6] by [12] has an effect that all B parameters obtained from gas phase studies would have to be recalculated; they will all become larger by a factor close to 4.

Experimental and Calculational Details

The ^1H and ^{13}C spectra were recorded on a Bruker HX-90 spectrometer by pulse Fourier transform techniques, using a ^{19}F field lock. Hexafluoroacetone – 1.6 D_2O (HFA) in a separate capillary was employed as the locking compound. The CH_4 proton resonance frequencies were derived directly from the offset frequency and from the spectral width employed. The ^{13}C resonance frequencies of $^{13}CH_4$ were measured relative to the ^{13}C resonance of HFA. The ^{13}C spectra were narrow-band proton decoupled. The probe temperature was maintained at 298 ± 0.5 K for all spectra. The CH_4 used for all gas phase measurements was supplied by Matheson of Canada, Ltd. (ultra high purity, CH_4 > 99.95%); for the

solution measurements, enriched $^{13}CH_4$ was used, supplied by Merck, Sharp and Dohme Canada, Ltd. (90 at.% ^{13}C). The various solvents were high purity chemical reagents, used without further purifications. A single nmr tube was used for all experiments. Its design followed closely that of Mohanty and Bernstein (20). A 5 mm od medium wall nmr tube (Wilmad Glass Co. Inc. #524-PP) was used, the open end of which was joined to the glass body of a Fischer and Porter Teflon valve, the side arm of the latter having been removed. The original Teflon valve was replaced by a modified valve which has an axial hole for the passage of the gas and a top designed to fit a 10/30 female glass joint on the vacuum system. A capillary (1.5 mm o.d.) containing the lock and reference compound HFA was placed in the nmr tube before the latter's assemblage; it was permanently centered by two Teflon washers. Tests have shown us that this kind of tube assembly can withstand pressures of over 100 atm. Alignment of the tube assembly on a precision lathe was found to be necessary in order that it will spin smoothly.

In order to enable the calculation of the CH_4 density in the nmr tube, a gas transfer system, which included a Toepler pump, was constructed. The design and operation of such systems have been described by Meinzer (22) and by Mohanty and Bernstein (20). Once all volumes concerned (nmr tube, Toepler pump, and manifold line) were calibrated, the amount of gas transferred could be calculated from its pV product.

The proton gas phase spectra of CH_4 were recorded on samples ranging in density from 1.5 mg cm^{-3} to 35 mg cm^{-3} (*i.e.* 2.4–53 atm). Below 2.4 atm the proton resonance line became too broad (because of spin–rotation relaxation) to be accurately measured. The corresponding ^{13}C spectra (of the natural abundancy CH_4) in the gas phase were recorded in the density range 5.9–35 mg cm^{-3}, the lower limit being determined by the low signal strength. The accuracy of the calculated gas densities was checked gravimetrically and found to be within 0.1%. The limits of error of the chemical shift measurements were ± 0.5 Hz for ^1H and ± 1.2 Hz for ^{13}C. For the gas-to-solution measurements the ^1H and ^{13}C shifts of $^{13}CH_4$ (90%) were determined in 18 solvents, which are listed in Table 1. The preparation of these samples was similar to the method described by Rummens and Louman (23); the solvent is brought into the nmr tube; it is then degassed by several freeze–pump–thaw cycles, followed by condensing an amount, equivalent to a pressure of 5 atm at 298 K, of $^{13}CH_4$ into the tube. The $^{12}CH_4$ proton resonance frequency was found by taking the center of the recorded doublet of the $^{13}CH_4$ and correcting this value for the isotope effect of 0.002 ppm. (This technique is more accurate than using the weak central line due to the 10% $^{12}CH_4$.)

The chemical shifts of CH_4 in the gas phase were found to be linear to the density, both for ^1H and ^{13}C. Extrapolation to $\rho = 0$ gave the values of $\sigma_0(^1H)$ and $\sigma_0(^{13}C)$, while the slopes provided the parameters $\sigma_1(^1H)/M$ and $\sigma_1(^{13}C)/M$, respectively.

Table 1 lists the physical properties used in the calculation of the medium shifts. All temperature dependent parameters were calculated at the temperature of the experiment. In the calculation of the site factors $d = 1.09$ Å was taken. Values of r_1 of CH_4 of $r_1 = 2.442$ Å for CH_4 (obtained by extrapolation on a plot of $V^{1/3}$ *vs.* r_0 for the halomethanes)[3] and r_2 (Å) = [0.293 V_2 (ml)]$^{1/3}$ (8) were used in the calculation of $q = d/r_1 + r_2$). The r_0 and ε/k parameters used have been given in the foregoing paper (31). Mixing rules (32) ($r_0^{(12)} = (r_0^{(1)} + r_0^{(2)})/2$ and $\varepsilon_{12} = \sqrt{\varepsilon_1\varepsilon_2}$ were used. A Hewlett Packard model 97 calculator was used for all calculations.

Results and Discussion

Gas Phase Measurements

Both for ^1H and ^{13}C the medium shift was found to be proportional to the density ρ. The results are given in Table 2. The experimental σ_1 value for $^1H(CH_4)$ compares well with earlier data (ref. 1, p. 34). The ratio $B(^{13}C)/B(^1H)$ is equal to 52 according to Table 2. This is reasonably close to similar ratios $B(Ne)/B(He)$ of 75 and 25 as calculated by Jameson *et al.* (21) and Kromhout and Linder (24), respectively. The large value for $B(^{13}C)$ indicates that σ_w is likely dominated by the paramagnetic shielding term.

Gas-to-solution Measurements

Table 3 gives the zero-pressure gas-to-solution shifts. The proton data can be compared with those at 30°C of Buckingham *et al.* (25). In general there is reasonable agreement, although there are sizeable differences. This is due in part to our extrapolation to zero gas pressure (in (25) a 10 atm CH_4 sample was used as the zero point) and to better χ_m data in the present study. Differences remain even after these corrections; our present results indicate σ_m values which are still 0.01 to 0.06 ppm larger. This systematic difference could be due to the lower probe temperature (25°C) of the present study.

A plot of $-\sigma_m(H)$ for 'isotropic' solvents vs. $(n^2 - 1)^2/(2n^2 + 1)^2(1 - q^2)^3$ for the proton data is given in Fig. 1. An unbiased least-squares straight line fit gave an intercept well below the standard deviation limit; a best straight line forced through the origin resulted in a slope of 8.05 ppm which is slightly different from a similar slope published earlier (6); this new slope value is henceforth adopted. A similar plot of $-\sigma_m(H)$ *vs.* $\sigma_w/K_6{}^gB$ of [13] gives also a reasonable straight line through the origin (see Fig. 2) although with somewhat larger scatter. However, if the binary collision model is subsequently used to extract σ_a values for the anisotropic solvents (by taking the difference of the experimental σ_m

[3]This value is different from the earlier used $r_1 = 2.068$ (6) because of re-calibration using better r_0 values (28).

values and σ_w contributions calculated on the basis of the straight line of Fig. 2), quite unacceptable values for σ_a result (see column 3 of Table 4). The σ_a values for acetone, acetonitrile, and nitromethane seem much too high, the one for acetonitrile even having the wrong sign, whereas those for the aromatics appear unrealistically low. The aberrations appear outside the limit of the errors due to uncertainties in r_0 and ε/k, but no alternate explanation can be offered. Because of this we have used the σ_a data based on [2] and the best straight line of Fig. 1; they are given in column 2 of Table 4.

The $\sigma_m(^{13}C)$ data were corrected, using this newly adopted set of σ_a values, (note that the site effect for σ_a is unity for spherical solutes (26, 27), independent of nuclear species) and subsequently tested against the expressions of [2] and [13]. As Figs. 3 and 4 indicate, neither of these plots goes through the origin while in addition the scatter is very large. The possibility of model or parameter errors can be eliminated by plotting $(\sigma_m - \sigma_a)$ for ^{13}C against $(\sigma_m - \sigma_a)$ or $(\sigma_m - \sigma_a)/S_{con}$ for ^1H. As [9] and [3] indicate this should result in perfect straight lines through the origin with a scatter no larger than that due to experimental error (note that $S_6{}^g$ and S_{con} are close to unity in this particular case). As Fig. 5 shows, however, this is not the case at all (using S_{con} rather than $S_g{}^6$ results in an almost identical plot). This can only mean that $\sigma_w = B\overline{F^2}$ is not a sufficient basis for the Van der Waals shifts of

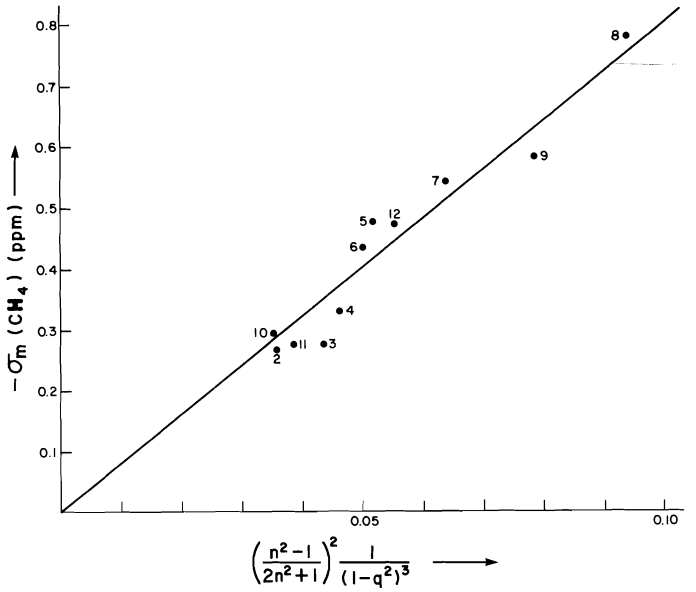

FIG. 1. Proton gas-to-solution shifts at 25°C of CH_4 corrected for σ_b, plotted against $f(n,q)$ of [2] for isotropic solvents. Slope of solid line is 8.05 ppm; standard deviation is ±0.045 ppm.

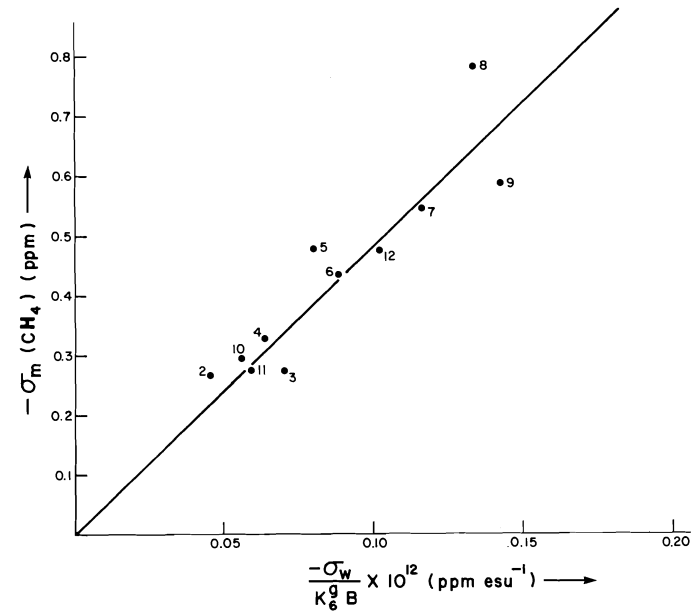

FIG. 2. Proton gas-to-solution shifts at 25°C of CH_4, corrected for σ_b, plotted against σ_w/BK_6^g, calculated according to [13]. Slope of solid line is $K_6^g B = 4.92 \times 10^{-18}$ (esu); standard deviation is ±0.07 ppm

^{13}C. Beyond dispersion forces there is clearly another effect at work, which is not proportional to $\overline{F^2}$. Apart from the suggestion that repulsive forces may be at the origin of this problem no definite explanation of this new effect can be offered at this stage.

The slope of Fig. 2 $K_6^g B = 4.92 \times 10^{-18}$ esu is in very satisfactory agreement with $KB =$

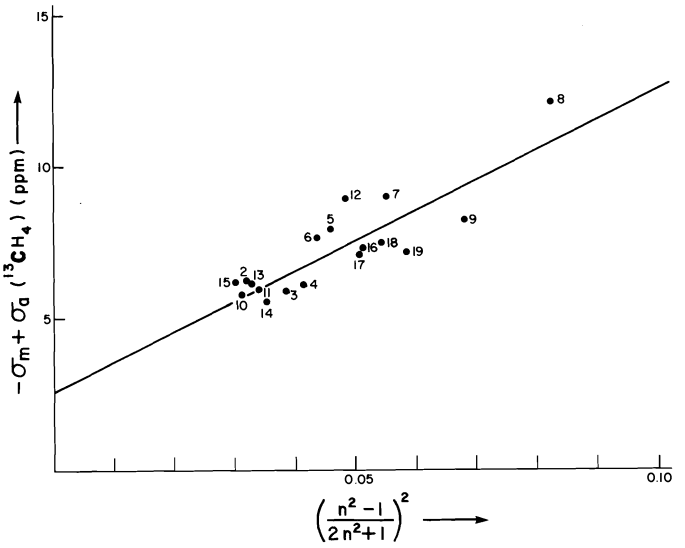

FIG. 3. ^{13}C gas-to-solution shifts at 25°C of $^{13}CH_4$, corrected for σ_b and σ_a, plotted against $f(n)$ of [2]. Best straight line is given by $y = 99.5x + 2.61$ ppm with a standard deviation of ± 0.84 ppm. Best line through the origin is $y = 151.4x$ with a standard deviation of ± 1.15 ppm.

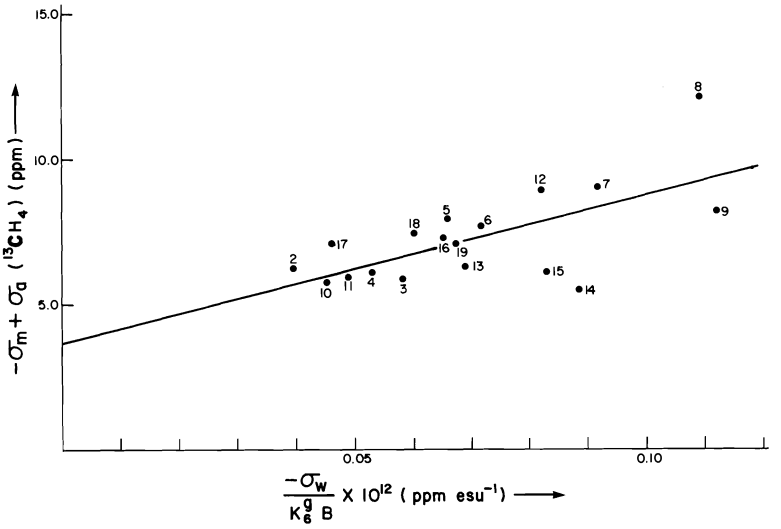

FIG. 4. ^{13}C gas-to-solution shifts at 25°C of $^{13}CH_4$, corrected for σ_b and σ_a, plotted against $\sigma_w/K_6^g B$ calculated according to [13]. Equation of solid line is $y = 50.0x + 3.74$ ppm; standard deviation is ± 1.28 ppm. Best line through the origin is $y = 99.4x$ with a standard deviation of ± 1.69 ppm.

4.71×10^{-18} esu determined previously (6). With a value of $B(CH_4) = 1.68 \times 10^{-18}$ esu (Table 2), this leads to $K = 2.80$ and $K_6^g = 2.93$. Although both these figures are somewhat larger than the $K_6^g(25°C) = 1.62$ (8), the close agreement shows again that both the continuous model and the binary collision model are essentially measuring the same property. Using the 'forced-through-the origin' lines of Figs. 3 and 4, combined with $B(CH_4) = 88.1 \times 10^{-18}$ esu (Table 2) one finds $K = 1.01$ and $K_6^g = 1.13$ respectively. Again the two K values are very similar but both are substantially lower than when determined from the proton shifts. If the slopes of the nonbiased best straight lines are used, the discrepancy becomes worse ($K = 0.66$

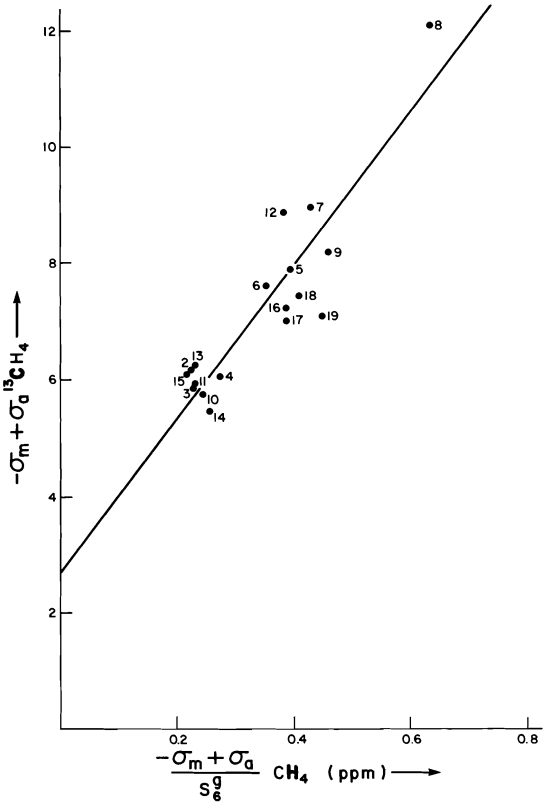

FIG. 5. ^{13}C Van der Waals shift $(-\sigma_m + \sigma_a)$ of $^{13}CH_4$ plotted against site-factor corrected proton Van der Waals shifts of $^{13}CH_4$. Best straight line is $y = 2.77 + 12.92x$; standard deviation is ± 0.71 ppm. Best line through the origin is $y = 20.2x$ with a standard deviation of ± 1.14 ppm.

and $K_6^g = 0.57$, respectively). This shows that the unidentified contribution to the ^{13}C Van der Waals shifts is not a constant term, but is definitely solvent dependent but with a dependency which is neither a smooth function of solvent refractive index, nor of the combined solvent factor of the binary collision model. Another way to look at the consistency between the models and the experimental facts is to calculate the $B(^{13}C)/B(^1H)$ ratios (eqs. 3 and 9). This ratio is 18.9 for the continuum model, 20.2 for the binary collision model, and 20.2 for the experimental ratio as given by Fig. 5.

In the ^{13}C work of Tiffon and Doucet on *n*-pentane (2) no nonzero intercepts, larger than the standard deviation, were observed in plotting σ_m *vs.* $(n^2 - 1)^2/(2n^2 + 1)^2$. This is probably due to the fact that these medium shifts are much smaller than for $^{13}CH_4$, but it also is possible that the particular choice of solvents has played a role in this. Calculating the site factors for pure *n*-pentane as S_{con} $(CH_3) = 1.67$, $S_{con}(CH_2) = 1.20$ and $S_{con} = 1.00$ for the central carbon respectively and dividing these into the observed slopes (see above), shows that the two types of CH_2 groups must have virtually the same KB values, whereas that for the CH_3 group must still be substantially larger. Using $\alpha_1 = 10.12 \times 10^{-24}$ cm^3, $I_1 = 16.9 \times 10^{-12}$ erg and $a^3 = 34.5 \times 10^{-24}$ cm^3 (this is actually the value for neopentane (6)) the *KB* parameters can be calculated using [2]. The σ_m *vs.* $(n^2 - 1)^2/(2n^2 + 1)^2$ slopes reported by Cans *et al.* (3) on the ^{13}C shifts of a number of olefinic hydrocarbons are not so easy to interpret because of the variety of solute molecular shapes. Taking the *average* observed slopes, assuming all $\alpha_1 I_1/a^6$ to be constant, assuming also a site factor for CH_3 groups, which is $1.2\times$ larger than for all other aliphatic groups, the ratios of *KB* factors $KB(CH_3R) : KB(CH_2R_2) : KB(CHR_3) : KB(CR_4)$ can be found, however. The first ratio, $KB(CH_3R) : KB(CH_2R_2)$, agreed very well with that same ratio found for *n*-pentane (see above). Anchoring on the *n*-pentane data, the *KB* values for the other aliphatic groups could thus be obtained. The final results are as follows

$$KB(CH_4) = 89 \times 10^{-18} \text{ esu}$$

$$KB(CH_3R) = 55 \times 10^{-18} \text{ esu}$$

$$KB(CH_2R_2) = 27 \times 10^{-18} \text{ esu}$$

$$KB(CHR_3) = 17 \times 10^{-18} \text{ esu}$$

$$KB(CR_4) = 38 \times 10^{-18} \text{ esu}$$

Although some of the above assumptions may seem drastic, the *qualitative* aspects of the above data are, in our opinion, nevertheless beyond reasonable doubt. The general trend of decreasing *KB* with increasing alkylation shows that this is not caused by a decrease in a presumed intermolecular repulsion effect (such an effect would have the opposite direction; see above), but that it is more likely a real bond effect. However, as the result for CR_4 shows, this cannot be the only effect. The three carbon types CH_3R, CH_2R_2, and CHR_3 are non-symmetrical, however, which makes these groups susceptible to electric field effects. Whereas the σ_{Ez} term cancels out to zero for CH_4 and CR_4, there could be a residual reaction field term σ_{Ez} in the other three substitution types.

Reaction of xenon difluoride. Part III. Oxidative-fluorination and α-fluorination of sulfur(II) compounds

RONALD KIRK MARAT AND ALEXANDER F. JANZEN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received March 14, 1977

RONALD KIRK MARAT and ALEXANDER F. JANZEN. Can. J. Chem. **55**, 3031 (1977).

The reaction of XeF_2 with aryl and alkyl sulfides and thiols has been investigated. Oxidative-fluorination of diphenyl sulfide and *tert*-butylphenyl sulfide gives diphenylsulfur difluoride and *tert*-butylphenylsulfur difluoride, respectively. The presence of an α-hydrogen substituent leads to α-fluorination and, in some cases, to olefin formation while reaction of XeF_2 with thiols gives disulfides. HF catalyzed decomposition of products and intermolecular fluorine exchange is inhibited by the addition of $[(CH_3)_3Si]_2NH$.

RONALD KIRK MARAT et ALEXANDER F. JANZEN. Can. J. Chem. **55**, 3031 (1977).

On a étudié la réaction de XeF_2 avec des sulfures et des thiols d'aryles et d'alkyles. La fluoration oxydative du sulfure de diphényle et du sulfure de *tert*-butylphényle conduisent respectivement au difluorure de diphénylsulfure et au difluorure de *tert*-butylphénylsulfure. La présence d'un hydrogène comme substituant en α conduit à une α fluoration et dans quelques cas à la formation d'oléfine; la réaction de XeF_2 avec les thiols conduit aux disulfures. La décomposition catalysée par HF des produits et l'échange intermoléculaire du fluorure sont inhibés par l'addition de $[(CH_3)_3Si]_2NH$.

[Traduit par le journal]

Introduction

Xenon difluoride readily converts phosphorus(III) to phosphorus(V) (1, 2) and iodine(I) to iodine(III) (2–4) derivatives. We now report a similar oxidative-fluorination of sulfur(II) compounds. The presence of an α-hydrogen leads to α-fluorination and, in some cases, to olefin formation while reaction with thiols gives disulfides. Very recently, Zupan reported the XeF_2 fluorination of $C_6H_5SCH_3$ to $C_6H_5SCFH_2$ and $C_6H_5SCHF_2$ and the dehydrogenation of thiopyrone and thiochromanone (5). Previous methods of fluorination of sulfides include electrolytic fluorination in anhydrous HF and fluorination with F_2 or metal fluorides (6). α-Fluorination, accompanied by oxidative-fluorination, is often encountered in such reactions, as illustrated by the electrochemical conversion of CH_3SCH_3 to CF_3SF_5 and $CH_3SF_4CFH_2$ (7) and the formation of $CSHF_7$ (CHF_2SF_5?) (8) and $C_4H_8FSF_3$ ($C_3H_7CHFSF_3$?) (9) during fluorination of CH_3SH and $(n\text{-}C_4H_9S)_2$. Perfluoroalkyl-sulfides, -disulfides and -sulfenyl chlorides react with ClF to give sulfur(IV) and sulfur(VI) derivatives (10). Sulfides and CF_3OF give sulfur(IV) and sulfur(VI) derivatives, e.g. $(C_6H_5)_2SF_2$ and $(C_6H_5)_2SF_4$ (11).

Results and Discussion

XeF_2 and Diphenyl Sulfide and t-Butylphenyl Sulfide

Oxidative-fluorination of diphenyl sulfide occurred under mild conditions, eq. 1, to give diphenylsulfur difluoride which is stable indefinitely at room temperature if stored in a Teflon container. The product was characterized by elemental analysis, ^1H, ^{19}F, and ^{13}C nmr and by its hydrolysis to $(C_6H_5)_2SO$. The absence of

$$[1]\quad (C_6H_5)_2S + XeF_2 \xrightarrow[CH_3CN]{-5^\circ C} (C_6H_5)_2SF_2 + Xe$$

intermolecular fluorine exchange in $(C_6H_5)_2SF_2$ was confirmed by ^{13}C nmr since ring carbons C_1, C_2, and C_4 showed triplet fine structure due to carbon–fluorine coupling.

Under the mild conditions employed in this study, $(C_6H_5)_2SF_2$ was found to be stable towards further oxidative-fluorination by XeF_2.

Reaction of *t*-butylphenyl sulfide with XeF_2 gave $C_6H_5SF_2C(CH_3)_3$, identified by ^1H and ^{19}F nmr. The product was too unstable for elemental analysis.

XeF_2 and Alkyl Sulfides

The presence of methyl, ethyl, isopropyl, or

benzyl substituents prevented the isolation of dialkylsulfur difluorides; instead, the products were α-fluorinated sulfides, eq. 2, as listed in Tables 1 and 2.

[2] $RSCHR_2 + XeF_2 \rightarrow RSCFR_2 + HF + Xe$

Some reactions of $C_6H_5SCH(CH_3)_2$ produced only $C_6H_5SCF(CH_3)_2$ but others gave olefin, $C_6H_5SC(CH_3)=CH_2$, as well. The ratio of α-fluoride to olefin depended on reaction conditions; lower temperature (−10°C) favoured α-fluoride while higher temperature (0°C) favoured olefin. Once formed, the ratio of α-fluoride to olefin did not appear to vary, even at +40°C, suggesting that the olefin is not formed by simple loss of HF from $C_6H_5SCF(CH_3)_2$.

XeF_2 and Thiols

Reaction of XeF_2 with CH_3SH, $(CH_3)_2CHSH$, or C_6H_5SH (thiol:XeF_2 = 2:1) gave the corresponding disulfide, HF, and Xe as the only detectable products, eq. 3.

[3] $2RSH + XeF_2 \rightarrow RSSR + 2HF + Xe$

If the reaction is carried out with thiol:XeF_2 = 1:1 the same products are formed but only half of the XeF_2 is consumed. CH_3SSCH_3 is stable in the presence of excess XeF_2, however, after 3 days decomposition gives a very complex mixture of products.

Thiophene did not react with XeF_2 below +80°C; above that temperature decomposition occurred to give a black residue.

HF Catalyzed Decompositions and Exchange Reactions

The technique of removing HF by chemical reaction with silicon-nitrogen compounds, eq. 4, thereby slowing down HF catalyzed decom-

[4] $[(CH_3)_3Si]_2NH + 2HF \rightarrow 2(CH_3)_3SiF + NH_3$

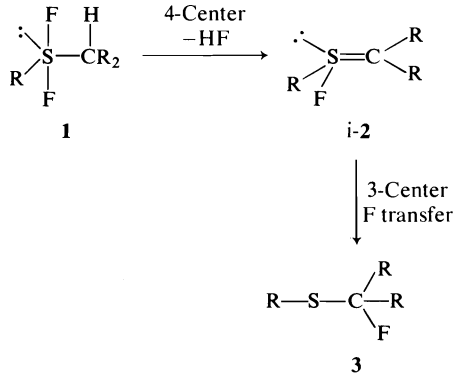
positions and exchange reactions (12), proved useful in this work. For example, $(C_6H_5)_2SF_2$ gave a broad ^{19}F nmr signal on several occasions, however, the addition of a small amount of $[(CH_3)_3Si]_2NH$ produced a sharp peak; at the same time some of the $[(CH_3)_3Si]_2NH$ was converted to $(CH_3)_3SiF$ thereby strongly suggesting that HF catalyzed intermolecular fluorine exchange, perhaps involving intermediates $(C_6H_5)_2SF_3H$ or $(C_6H_5)_2SF^+FHF^-$, was the cause of line broadening.

Initial attempts to prepare $C_6H_5SF_2C(CH_3)_3$ were unsuccessful because of rapid decomposition, however, when the procedure was modified to include the addition of a small amount of $[(CH_3)_3Si]_2NH$ immediately after the reaction of XeF_2 with $C_6H_5SC(CH_3)_3$ then the product was stable for at least 3 h at +40°C.

The reaction of XeF_2 with sulfides produced equivalent amounts of HF, eq. 2, but the α-fluorinated sulfides $RSCFR_2$ decomposed in the presence of HF, for example, $CH_3CH_2SCFHCH_3$ decomposed within 15 min at +40°C while $C_6H_5CH_2SCFHC_6H_5$ decomposed after one week at −20°C. If a stoichiometric amount of $[(CH_3)_3Si]_2NH$ was added to remove HF, then the products appeared to be stable indefinitely.

Possible Intermediates in Fluorination Reactions

Our results are consistent with initial oxidative-fluorination of diaryl(alkyl) sulfides to give sulfur(IV) difluorides which are stable unless an α-hydrogen is present. Perhaps HF is lost via a 4-center step to give intermediate(i) i-**2** followed



1 i-**2** **3**

by fluorine transfer via a 3-center step to give α-fluorinated sulfide **3**. Since the olefin $C_6H_5SC(CH_3)=CH_2$ is not formed by simple loss of HF from **3**, it is possible that **1** or i-**2** is the olefin precursor. Other intermediates could also be formed by reaction of HF with **1** or i-**2**, in that case, the mechanism of α-fluorination would be more complex than indicated here.

Attempts to identify intermediates in the reaction of XeF_2 with thiols were unsuccessful.

Experimental

Safety Note

Although no violent reactions were encountered in this work, the technique of destroying excess HF with $[(CH_3)_3Si]_2NH$ at the completion of the XeF_2 reactions is potentially hazardous because XeF_2 reacts explosively with some silicon-nitrogen compounds (2).

TABLE 1. Reaction of XeF_2 with sulfur(II) compounds

Sulfur(II) compound (mmol)		XeF_2 (mmol)	Reaction conditions	Products
$(C_6H_5)_2S$	1.09	1.09	−5°C, 10 min	$(C_6H_5)_2SF_2$, Xe
$C_6H_5SC(CH_3)_3$	0.42	0.42	0°C, 10 min	$C_6H_5SF_2C(CH_3)_3$, Xe
$(CH_3)_2S$	0.80	0.66	−20°C, 10 min	CH_3SCFH_2, Xe, HF
$(CH_3CH_2)_2S$	0.40	0.40	−5°C, 3 min	$CH_3CH_2SCFHCH_3$, Xe, HF
$(C_6H_5CH_2)_2S$	0.40	0.40	0°C, 5 min	$C_6H_5CH_2SCFHC_6H_5$, Xe, HF
$C_6H_5SCH(CH_3)_2$	0.40	0.40	−10°C, 30 min	$C_6H_5SCF(CH_3)_2$ (>90%), Xe, HF
	0.40	0.40	−5°C, 10 min	$C_6H_5SCF(CH_3)_2$ (60%), $C_6H_5SC(CH_3)=CH_2$ (40%)
	0.40	0.40	0°C, 2 min	$C_6H_5SC(CH_3)=CH_2$ (>90%)
Thiophene	0.45	0.45	+20 to +80°C	No reaction; dec. above +80°C
$(CH_3)_2CHSH$	0.55	0.27	−10°C, 20 min	$[(CH_3)_2CHS]_2$, Xe, HF
C_6H_5SH	0.59	0.55	0°C, 10 min	$[C_6H_5S]_2$, Xe, HF
CH_3SH	0.45	0.43	+20°C, 10 min	$[CH_3S]_2$, Xe, HF
$(CH_3)_3CSH$	0.80	0.80	−10°C, 30 min	$(CH_3)_3CF$, Xe, HF, S_8
CH_3SSCH_3	0.35	0.35	+20°C, 60 min	No reaction; very complex mixture after 3 days

[a]Proton and carbon chemical shifts are relative to internal $(CH_3)_4Si$; fluorine chemical shifts are relative to internal $CFCl_3$. Positive values indicate shifts to high field.
[b]Sample for proton-decoupled ^{13}C nmr spectrum contained 1.0 mmol $(C_6H_5)_2SF_2$ and 10 μl $[(CH_3)_3Si]_2NH$ in CD_2Cl_2.

General

XeF_2 (PCR), CD_3CN (Aldrich), $[(CH_3)_3Si]_2NH$ (Aldrich), thiols, and dialkyl and diaryl sulfides were commercial samples and were used without further purification. Volatile compounds were handled in a conventional glass vacuum system. $C_6H_5SCH(CH_3)_2$ and $C_6H_5SC(CH_3)_3$ were prepared on a 0.1 mol scale (13). *tert*-Butanol, instead of isobutene, was used in the $C_6H_5SC(CH_3)_3$ synthesis.

Proton and fluorine nmr spectra were recorded on a Varian A-56/60A spectrometer and carbon nmr spectra were obtained on a Varian CFT-20 spectrometer (8 mm probe). Mass spectra were recorded on a Finnigan 1015 quadrupole mass spectrometer coupled to a Varian 1700 gas chromatograph. Thiols, sulfides, sulfoxides, S_8, HF, and Xe were identified by nmr and/or gc-ms by comparison with authentic samples. $C_6H_5SC(CH_3)=CH_2$ was identified by its known nmr and mass spectrum (14).

Elemental analyses were carried out by Alfred Bernhardt Laboratories, West Germany.

Diphenylsulfur Difluoride and tert-Butylphenylsulfur Difluoride

Diphenyl sulfide, in a microsyringe, was added to a solution of XeF_2 in CH_3CN (quantities given in Table 1) at −30°C in a 100 ml Teflon bottle. Reaction occurred on warming to about −5°C. After 10 min, all volatile components were removed under vacuum and the white residue (slightly purple coloured) was washed with three 10 ml portions of isopentane. The solid was again dried under vacuum to give $(C_6H_5)_2SF_2$, white needle-like crystals, mp 66–74°C, isolated yield 74%. Hydrolysis gave $(C_6H_5)_2SO$. *Anal.* calcd. for $C_{12}H_{10}SF_2$: C 64.27, H 4.49, F 16.94; found: C 64.20, H 4.62, F 16.71.

Using the procedure above, *t*-butylphenyl sulfide was added to XeF_2 in CH_3CN. Reaction occurred on warming to 0°C. After 10 min, 5 μl $[(CH_3)_3Si]_2NH$ was added and the solution transferred to a silylated and dried (210°C) quartz nmr tube. The nmr spectra were recorded at −20°C and the product was stable indefinitely at −20°C but decomposed within 18 h at +20°C to give

mainly $(CH_3)_3CF$, $C_6H_5SC_6H_5$, $(C_6H_5S)_2$, and $(C_6H_5)_2SO$.

Reaction of XeF_2 with Sulfides and Thiols

In a typical reaction, a solution of XeF_2 in CD_3CN was placed into a 2 ml vial, sealed with a Teflon lined septum cap and cooled to $-40°C$ with the aid of a Thermoelectrics Stir-Kool SK-31 apparatus. The sulfide or thiol was then added with a microsyringe and the temperature allowed to increase until reaction commenced. A 5 or 10 ml glass syringe was connected to the reaction vial and the reaction was conveniently monitored by observing the rise of the syringe plunger as Xe gas was liberated. Reaction with volatile CH_3SCH_3 and CH_3SH was carried out in a vacuum line by condensing reagents onto a XeF_2/CD_3CN solution. Reaction conditions and products are listed in Tables 1 and 2. The products were formed in essentially quantitative yield, as determined by nmr integration.

HF was observed in the proton nmr at about -7.8 ppm (half-height width ~ 4 Hz) and in the fluorine nmr at about $+170$ ppm (half-height width ~ 50 Hz).

The kinetics of the reaction of boric acid with salicylic acid

ALAN QUEEN

Parker Chemical Laboratory, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received May 10, 1976[1]

ALAN QUEEN. Can. J. Chem. **55**, 3035 (1977).

Salicylic acid forms a 1:1 complex with boric acid, the reaction involving both the fully protonated ligand, and the salicylate ion. The kinetics of this reaction have been studied by the stopped-flow method. The stability constant for the reaction involving salicylate ion has been calculated from measurements of the absorbances of solutions at equilibrium and is the same as that obtained from the kinetic data. The kinetic results at p*H* values in the range 3.45–4.63 suggest that, when salicylic acid is the ligand, the complex is formed in two steps. A similar process may also occur with salicylate ions.

ALAN QUEEN. Can. J. Chem. **55**, 3035 (1977).

L'acide salicylique forme un complexe 1:1 avec l'acide borique; la réaction implique et le ligand complètement protoné et l'ion salicylate. On a étudié la cinétique de la réaction par la méthode des flux stoppés. On a calculé la constante de stabilité pour la réaction impliquant l'ion salicylate; ces calculs ont été effectués à partir de mesures d'absorption de solutions en équilibre et cette constante de stabilité est la même que celle obtenue à partir de données cinétiques. Les résultats cinétiques, à de valeurs de p*H* allant de 3.45 à 4.63, suggèrent que lorsque l'acide salicylique agit comme ligand, le complexe se forme en deux étapes. Un processus similaire peut aussi se produire avec les ions salicylates.

Introduction

Boric acid forms 1:1 and 1:2 complexes with *cis* diols (1, 2), α-hydroxy acids (3), dicarboxylic acids (4) and nucleosides (5) as well as other compounds such as α-diketones (6). Most of the previous work has been concerned with equilibrium studies but recently Pizer and his coworkers have published the results of a series of kinetic studies of the reactions of boric acid with tartaric acid and phenylboronic acid with lactic, oxalic, and malonic acids (4, 7–10). The appearance of this work prompts the publication of results that have been obtained using boric and salicylic acids.

Pizer has interpreted his data in terms of several factors that influence the rate of complex formation. These are the acidity of the ligand and interactions that stabilize a four coordinate species. The first of these effects seems to be well established but the other effects are less easily identified. In particular, a proposal that in some cases there may be attractive interactions between the aromatic ring of phenylboronic acid and the carboxylate group of the ionized ligand is quite vague.

Salicylic acid was chosen for the present studies because complex formation could be followed spectroscopically in the absence of indicators and because the rates could be conveniently measured by the stopped-flow method.

Experimental

Salicyclic acid and boric acid were Fisher Certified Reagents and were used without further purification after drying *in vacuo* over phosphorus pentoxide.

Buffered solutions were made up by volume from standard solutions of acetic acid, sodium acetate, and sodium chloride, the final volume of the mixture being adjusted to give an ionic strength of 0.1 *M*. These solutions were used to prepare solutions of salicyclic acid and boric acid of known strength. p*H* measurements were carried out at 25°C on mixtures of equal volumes of the salicylic acid and boric acid solutions.

All kinetic experiments were carried out at 25°C, using a stopped-flow apparatus that has been described previously (11), except that it was fitted with a quartz cell having a bore of 2 mm square section and length of 20 mm. The flexible light pipes were discarded and light was passed from the monochromator to the cell by means of mirrors. By changing the position of a mechanical shutter, either transmitted light or fluorescence could be measured. In the fluorescence mode, light measurements were made at right angles to the exciting beam, which illuminated a 12 mm length of the reaction cell, starting 8 mm from the mixing chamber. Rate measurements were carried out by following the changes in fluorescence intensity using exciting light at a wavelength of 335 nm. Somewhat larger changes in fluorescence were observed when the exciting light was at 320 nm, but a better signal-to-noise ratio was obtained at the longer wavelength, where the output of the 200 W quartz–iodine lamp was

much greater. The apparatus used a Bausch and Lomb high intensity monochromator set at a bandwidth of 15 nm. It was shown that identical rate constants were obtained using either fluorescence or absorbance measurements. The fluorescence method was preferred because considerable loss of transmitted light occurs in our apparatus below 400 nm, resulting in a poor signal-to-noise ratio. The rate constants were calculated by an on-line method (12) and the results are summarized in Table 1. Each value is the mean of at least ten independent experiments. Good first-order rates were obtained over at least four half lives.

Results

Stability constants, K_{H_2A} and K_{HA^-}, for the formation of the complex **1** from salicylic acid and salicylate ion, respectively, are defined according to [1] and [2]. Values of K_{HA^-} have been obtained at 322 and 332 nm from the measurements of the absorbances of ten different solutions of boric acid and salicylic acid. The pH of the solutions was 5.34 and measurements were made at 25°C using a Gilford spectrophotometer, model 2400-2. For these conditions less than 0.5% of the ligand is in the protonated form. Calculations were based on the method of Rose and Drago (13) and the results are summarized in Table 2. The average value of $K_{HA^-} = 10.6$ can be compared to the approximate value of 17 ± 3, previously obtained at an ionic strength of 3 M and an unknown temperature using infrared data (14). Rose and Drago's method assumes that only two absorbing species are present in solution. Support for this assumption is gained from the convergence of the $K_{HA^-}^{-1}$ values in the Rose–Drago plots and from the

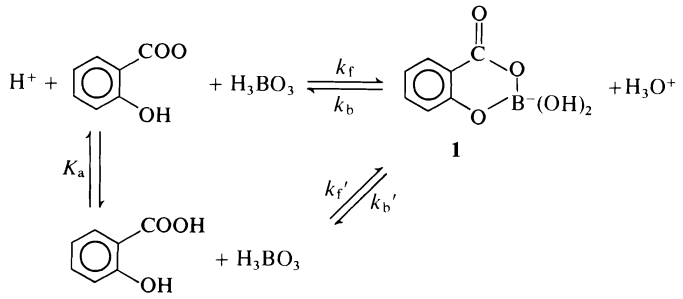
fact that excellent isosbestic points were observed at 258 and 299 nm when the pH of the solutions was 5.34.

[1] $$K_{H_2A} = \frac{[\text{complex}][H^+]}{[H_2A][\text{boric acid}]}$$

[2] $$K_{HA^-} = \frac{[\text{complex}]}{[HA^-][\text{boric acid}]}$$

Within the range of pH used, boric acid is virtually undissociated and only the first ionisation of salicyclic acid needs to be considered. The boric acid was always in large excess over salicyclic acid but at concentrations where the formation of dimers and larger aggregates could be neglected (15). For these conditions, the simplest reaction scheme is given by [3]. It can

[3]



be readily shown that the observed rate constants are given by [4].

[4] $$k_{obs} = (k_b + k_b'[H^+]) + \left(\frac{k_f K + k_f'[H^+]}{K + [H^+]}\right)[H_3BO_3] = A + B[H_3BO_3]$$

In agreement with this scheme, plots of k_{obs} against boric acid concentration at constant pH were linear. The slopes and intercepts of these plots were obtained by a least-squares method and the values are given in Table 3. The values of the intercepts, A, varied linearly with hydrogen ion concentration, as required by [4]. The corresponding slopes, B, also increased linearly with hydrogen ion concentration, within the limits of the experimental errors, which is not inconsistent with [4], depending on the values of the constants and the range of hydrogen ion concentrations used. K_a, the acidity constant of salicylic acid, has been accurately measured in these laboratories by Dunn and Kung (16) at 25°C and an ionic strength of 0.1 M, the value being 1.02×10^{-3}. Values of k_b and k_b' were obtained from the variation of A with hydrogen ion concentration by a least squares method. k_f was similarly calculated from the hydrogen ion dependence of B. Values of k_b, k_b', and k_f obtained in these ways are shown at the bottom of Table 3. The results obtained at pH 5.29 were not included in these calculations, being used instead to check the validity of using [4] to obtain k_b and k_f. It can be seen that the values of these rate constants are in good agreement with those of A and B, respectively, obtained at low hydrogen ion concentration (pH = 5.29). Using these values of the rate constants, the ratio $k_f/k_b = 10.7 \pm 0.8\ M^{-1}$ is in good agreement with the value of K_{HA^-} given in Table 2. If k_f/k_b is calculated from the data obtained at pH 6.29, it equals $11.1 \pm 0.3\ M^{-1}$. The best value of k_f' leading to calculated values of B in agreement with those observed is $135\ s^{-1}\ M^{-1}$.

Discussion

The simple mechanism shown in [3] requires that $K_a = k_f'k_b/k_b'k_f = 1.02 \times 10^{-3}$. However, the rate constant quotient equals 2.8×10^{-3}, which suggests that the simple mechanism is either incorrect or incomplete. A logical expansion of this scheme allows for stepwise formation of the final complex **1** from both salicylate ion **2** and salicylic acid **4**, as shown in [6].

It might be argued that k_4 and k_{-4} should be associated with the quantities k_f' and k_b', so that K_a in [4] should be replaced by a composite-K_a', possibly equal to $k_{-3}K_a/k_3$. However, it is not possible to choose a value for K_a* which will simultaneously yield k_f' and a fit to the observed values of B. We have not attempted a full kinetic treatment of [6]. Instead we have preferred to argue from a consideration of a treatment in-

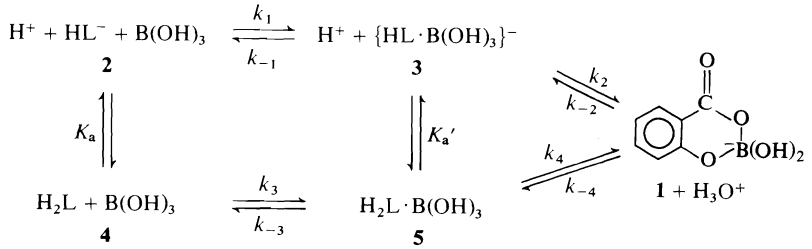
[a][Salicylic acid] = 1.5×10^{-3} *M*, $K_a = 1.02 \times 10^{-3}$, $k_b = 3.62 \pm 0.08\ s^{-1}$, $k_f = 38.9 \pm 2.6\ s^{-1}\,M^{-1}$, $k_b' = 4483 \pm 360\ s^{-1}\,M^{-1}$, $k_f' = 135\ s^{-1}\,M^{-1}$.

[6]



volving only the species **1**, **2**, and **3**; i.e. for the situation that would hold when the p*H* > 5.

If all three species change concentration simultaneously, then they will also contribute to the changes in fluorescence. It can then be shown that the value of k_{obs} is given by [7].

$$[7]\quad k_{obs} = \frac{1}{t}\ln\left\{\frac{(Y_e + Z_e)}{(Y_e + Z_e) - (Y + Z)}\right\} + \frac{1}{t}\ln\left\{\frac{P - (QY_e + RZ_e)/(Y_e + Z_e)}{P - \dfrac{Q(Y_e - Y) + R(Z_e - Z)}{(Y_e + Z_e) - (Y + Z)}}\right\}$$

In this equation, $Y_e = (C_2^e - C_2^0)$, $Y = (C_2^t - C_2^0)$, $Z_e = (C_1^e - C_1^0)$. The *C* values are concentrations at times 0, *t*, and equilibrium, as indicated by the superscripts 0, *t*, and e, respectively. The quantities *P*, *Q*, and *R* are the fluorescence coefficients of the species **2**, **3**, and **1**, respectively. These are likely to be different at a given wavelength and to change differently with wavelength. Hence, k_{obs} would be expected to vary with the wavelength of the incident light in a given experiment where the boric acid concentration and p*H* are fixed. If the reaction is followed by monitoring changes of absorbance,

the P, Q, and R values are extinction coefficients. It is likely that there will not be a 1:1 relation between these quantities for fluorescence and absorbance, so that k_{obs} might be expected to vary depending on the method used to measure it. The data in Table 1 show that neither of these differences are observed when the pH is 5.29. Indeed, the values of k_{obs} are independent of wavelength at pH 4.63, where the salicylic acid/salicylate ion ratio is 0.023. This suggests either that the complex **3** is not formed at all or that it reaches a low steady-state concentration early in the course of the reaction. The possibility that Q and R are equal is considered to be less likely. When the concentration of the complex **3** is small, Y and Y_e are small causing the second term of [7] to become zero. The steady state approximation may be applied to complex **3** and k_{obs} is then given by [8].

$$[8] \quad k_{obs} = \frac{k_{-1}k_2}{k_{-1} + k_2} + \frac{k_1k_2}{k_{-1} + k_2}[\text{boric acid}]$$

Hence,

$$k_b = \frac{k_{-1}k_2}{k_{-1} + k_2}, \quad k_f = \frac{k_1k_2}{k_{-1} + k_2}$$

$$K_{HL^-} = \frac{k_f}{k_b} = \frac{k_1k_2}{k_{-1}k_{-2}} = K_1K_2$$

This is consistent with the observation that the kinetic and equilibrium values of K_{HL^-} are the same.

The conclusion that complex **3** does not contribute significantly to changes in fluorescence suggests that the inequality of K_a and the quotient $k_f'k_b/k_b'k_f$ may require that complex **5** is not in low or steady state concentration during the course of the reaction. If this is so, the values of k_{obs} at low pH, when no salicylate ion is present, should be given by an equation similar to [7] and so should be wavelength dependent. No changes in light absorption or fluorescence could be detected at pH 1 and were too small to be useful at pH 2. A similar, but more complicated equation than [7] should apply to k_{obs} for intermediate pH values where both salicylic acid and salicylate ion react with boric acid. Table 1 shows that k_{obs} is indeed wavelength dependent at pH 3.45. It is therefore proposed that the results for the boric acid, salicylic acid system support a stepwise formation of the complex **1** from salicylic acid and probably from salicylate ion also. For this system, complex **3** is in low concentration during the reaction but complex **5** is not.

Pizer has previously assumed the formation of complexes corresponding to **3** and **5** in the reactions he has studied. However, he also assumes that these intermediates are formed at diffusion controlled rates, so that k_f and k_f' are considered to measure the rates of ring closure on loss of H_2O and H_3O^+, respectively. Although the present data have not been interpreted in the same way, mechanism [6] would appear to be capable of accommodating a variety of different possibilities since the various steps would be expected to be sensitive to the effects of substituent groups in the ligands. Indeed, it may be possible on this basis to explain the fact that k_f is larger than k_f' for the complexation of lactic and boric acids, this reaction being the only one so far reported where the fully protonated acid reacts more slowly than its conjugate base. It is worth noting that lactic acid is the only ligand having an electron donating group close to the reaction sites. Moreover, it is not certain that the same group acts as the nucleophile towards the boron atom in all cases. It may well be that the phenolic group acts in this way in the fully protonated ligands but that the carboxylate group is the reactive centre in the corresponding ionized ligands, at least in some cases.

The virial partitioning of a molecular electronic charge distribution, $\rho(\boldsymbol{r})$, divides a molecule into a collection of chemically identifiable atomic-like fragments. When two fragments interact strongly the distribution of charge in the region between their nuclei contains a saddle point ($\nabla\rho(\boldsymbol{r}) = 0$). The gradient paths (paths of steepest ascent through $\rho(\boldsymbol{r})$, as traced by the vectors $\nabla\rho(\boldsymbol{r})$) which *terminate* at this internuclear saddle point, define the virial partitioning surface which lies between the fragments. The two gradient paths which *originate* at the internuclear saddle point and terminate at each of the fragment nuclei define a *bond path*: the path which follows the ridge of maximum charge density between a pair of bonded nuclei. When the internuclear axis does not coincide with a symmetry axis, the internuclear stationary point will, in general, lie off the axis, and the bond path joining the nuclei will deviate or curve from this axis. The magnitude and direction of this 'bond curvature' as determined by the bond path agrees well with chemical expectations.

G. R. RUNTZ, R. F. W. BADER et R. R. MESSER. Can. J. Chem. **55**, 3040 (1977).

La départition virielle d'une distribution de charge électronique moléculaire, $\rho(\boldsymbol{r})$, divise une molécule en une collection de fragments du genre atomique qui sont identifiables d'une façon chimique. Lorsque deux fragments interagissent fortement la distribution de la charge dans la région entre les noyaux contient un point selle ($\nabla\rho(\boldsymbol{r}) = 0$). Les chemins gradients (les chemins qui ont la pente d'ascension la plus grande pour $\rho(\boldsymbol{r})$, lorsqu'on les trace en fonction des vecteurs $\nabla\rho(\boldsymbol{r})$) qui *aboutissent* à ce point maximal internucléaire, définissent la surface de départition virielle qui existe entre les fragments. Les deux chemins gradients *qui prennent origine* au point selle internucléaire et qui se terminent aux noyaux des fragments définissent un *chemin de liaison*: le chemin qui suit les hauteurs maximales de densité de charge entre une paire de noyaux liés. Quand l'axe internucléaire ne coïncide pas avec l'axe de symétrie, le point stationnaire internucléaire ne se situera généralement pas sur l'axe et le chemin de liaison joignant les noyaux déviera ou sera en courbe par rapport à cet axe. L'amplitude et la direction de cette 'courbature de liaison', telles que déterminées par le chemin de liaison, sont en bon accord avec les résultats attendus sur une base chimique.

[Traduit par le journal]

Introduction

In the virial partitioning of a molecular system and its properties the topographical features of the (observable) molecular charge distribution $\rho(\boldsymbol{r})$ define the partitioning surfaces (1–4). Specifically, $\rho(\boldsymbol{r})$ is partitioned by those *closed* surfaces through which the flux of $\nabla\rho(\boldsymbol{r})$ is *everywhere* zero,

$$[1] \qquad \nabla\rho(\boldsymbol{r})\cdot\boldsymbol{n}(\boldsymbol{r}) = 0 \quad \forall \boldsymbol{r} \in S(\boldsymbol{r})$$

where $\boldsymbol{n}(\boldsymbol{r})$ is the vector normal to the surface $S(\boldsymbol{r})$. Equation 1 is derived as a boundary condition through the application of the variational principle in the definition of a quantum subspace (5). The virial partitioning of a molecular system is obtained by constructing for the system all surfaces which satisfy eq. 1. This set of surfaces divides a molecule into a collection of chemically identifiable atomic-like fragments. Each fragment so defined possesses a unique set of quantum properties; the hypervirial and virial theorems are obeyed and all properties of the fragment, including its *total* energy are rigorously defined. Thus any property of the total system may be equated to a sum of contributions from spatially defined fragments. The properties of the fragments coincide with expectations based on experimental chemistry (2–4, 6).

In this attempt to find a quantum mechanical basis for the observations upon which descriptive chemistry is founded, the unit which emerges as the fundamental carrier of chemical information is atomic-like in nature and not bond-like. Thus the subspace variational principle demonstrates that the physical basis for additivity and near constancy of (functional) group properties has

[1]To whom correspondence should be addressed.

its origin in a constancy or near constancy, respectively, of the charge distribution and properties of the atomic-like (virial) fragments as defined in real space (5, 7). The only property of the observable charge distribution of a molecular system which is 'bond-like' in nature (that is, of bi-nuclear character) is the path defining the line of maximum charge density linking certain pairs of neighbouring nuclei. This paper is concerned with the definition of such a 'bond path' and with the delineation of its properties.

Topography of a Molecular Charge Distribution

The bond path linking two nuclei is defined in terms of the same topological property of the charge distribution used to define the virial partitioning surface which lies between the same two nuclei. For this reason we first discuss and illustrate the general topological features of a molecular electronic charge distribution.

Stationary Points

Stationary points in a charge distribution $\rho(\boldsymbol{r})$ are points at which $\nabla\rho(\boldsymbol{r}) = 0$. In an isolated molecule, these are generally *saddle points* (i.e., points at which $\rho(\boldsymbol{r})$ is a minimum with respect to certain directions, and a maximum with respect to others). There are two types: *internuclear* and *ring* saddle points. Internuclear saddle points normally occur on or near the internuclear axes joining pairs of so-called 'bonded' nuclei. Such stationary points are illustrated in Fig. 1 for the cyclopropane molecule, labelled as A, B, and C. When the internuclear axis is a rotational symmetry axis, the saddle point lies on the axis and is coincident with the density minimum on it. Otherwise it normally lies off the axis a short distance from this minimum. For example, the internuclear stationary point C lying between the out-of-plane carbons is displaced by 0.11 au from the point of intersection of the corresponding C—C internuclear axis with the σ_v plane (Fig. 1). Ring saddle points lie at or near the centres of ring compounds (e.g., point D in Fig. 1).

Stationary points at which $\rho(\boldsymbol{r})$ is a minimum or maximum with respect to all directions are less common. An example of true minima would be the intermolecular stationary points in $\rho(\boldsymbol{r})$ for a collection of molecules (i.e., in a liquid or a solid). Another example, as pointed out by Collard and Hall (8), is the density minimum near the centre of a cage compound. As far as we are aware[2] there are no examples of stationary points which are true maxima in $\rho(\boldsymbol{r})$. One must remember that the maxima which occur at nuclei are not stationary points, as $\rho(\boldsymbol{r})$ exhibits a cusp at a nuclear position and hence $\nabla\rho(\boldsymbol{r})$ is undefined (9).

Gradient Paths

A single gradient path (GP) passes through each point $\boldsymbol{r}_k$ in $\rho(\boldsymbol{r})$, providing $\nabla\rho(\boldsymbol{r}_k)$ is both defined and non-zero (i.e., providing $\boldsymbol{r}_k$ is not a nuclear cusp or a stationary point). The GP through $\boldsymbol{r}_k$ is the combination of the path of steepest *ascent* with the path of steepest *descent* from that point (as traced by the vectors $\nabla\rho(\boldsymbol{r})$ and $-\nabla\rho(\boldsymbol{r})$, respectively).

A number of GP's are illustrated in Figs. 1 and 2. Such two-dimensional representations of GP's are possible only in symmetry planes (as $\nabla\rho(\boldsymbol{r})$ has a zero component perpendicular to symmetry planes). In this case, GP's always intersect contour lines at right angles. The more general three-dimensional picture may be mentally constructed if one visualizes shells of constant density instead of contours. GP's can then be readily visualized as they must run *normal* to all density shells.

All GP's must *originate* and *terminate* at either a nuclear cusp (where $\nabla\rho(\boldsymbol{r})$ is undefined) or at a stationary point (where $\nabla\rho(\boldsymbol{r}) = 0$). (By *origin* and *terminus* of a GP we refer to the points of minimum and maximum $\rho(\boldsymbol{r})$, respectively, on that path.) In an isolated molecule most GP's originate at infinity (where both $\rho(\boldsymbol{r})$ and $\nabla\rho(\boldsymbol{r})$ tend to zero) and terminate at nuclei (e.g., all GP's represented by solid lines in Fig. 1). It is those which do not that are of particular interest.

Definition of Molecular Fragments and Bond Paths

In the virial partitioning of a molecular system, molecular fragments are objectively and unambiguously defined by those *closed* surfaces through which the flux of $\nabla\rho(\boldsymbol{r})$ is everywhere zero (7). The restriction that the flux of $\nabla\rho(\boldsymbol{r})$ be

[2]The only known possible exception is $Li_2(X^1\Sigma_g^+)$ for which the Hartree–Fock $\rho(\boldsymbol{r})$ exhibits a maximum at the bond midpoint (10). This molecule has an extremely long equilibrium bond length ($\sim$5.0 au) and apparently has a double minimum in $\rho(\boldsymbol{r})$ along the internuclear axis. Whether this is a true feature of the charge distribution, or simply a shortcoming of the approximate wavefunction, is not known.

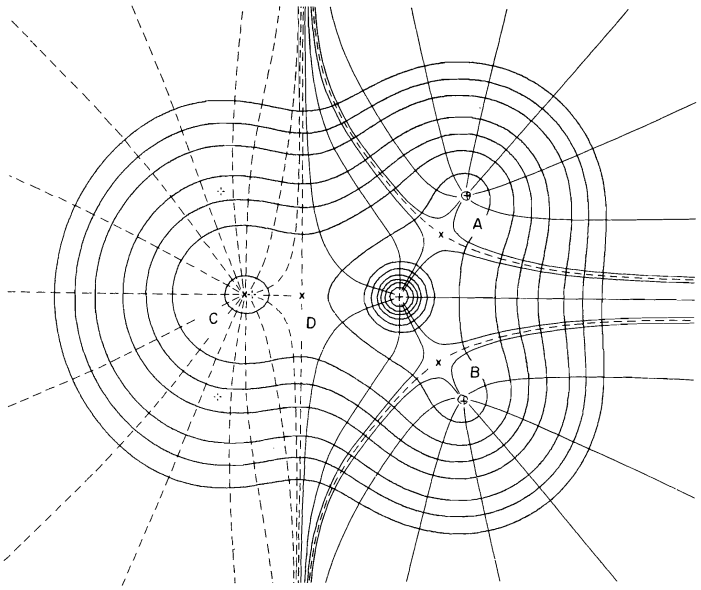

FIG. 1. Contour plot of the charge distribution in a σ_v symmetry plane of C_3H_6. Nuclei in the plane are denoted by plusses (+), and out-of-plane nuclei by broken plusses. The stationary points in $\rho(\boldsymbol{r})$ in this plane are denoted by × and labelled A through D. All gradient paths of $\rho(\boldsymbol{r})$ which lie in a partitioning surface are denoted by dashed lines; the two unique pairs of gradient paths which terminate at A and B denote the intersection with the σ_v plane of the partitioning surface between (C) and each (H); the gradient paths which terminate at stationary points C and D denote the partitioning surface between the out-of-plane carbons. All other gradient paths terminate at a nucleus. The contours increase inwards in the steps 2×10^n, 4×10^n, 8×10^n with n beginning at -3 and increasing in steps of unity.

everywhere zero is important in that it excludes surfaces which contain nuclei, since $\nabla\rho(\boldsymbol{r})$ is undefined there (9). The closure condition simply ensures a well-defined (not open-ended) fragment. Partitioning surfaces in an isolated molecule are generally closed by the zero-flux surface at infinity, where both $\rho(\boldsymbol{r})$ and $\nabla\rho(\boldsymbol{r})$ tend to zero.

The portions of the partitioning surfaces which occur at finite values of the coordinates are traversed by GP's which originate *and* terminate (both conditions are important) at stationary points in $\rho(\boldsymbol{r})$. Thus, a virial partitioning surface may be equivalently defined by *the collection of all gradient paths which both originate and terminate at stationary points in* $\rho(\boldsymbol{r})$. In Fig. 1, GP's which have this property are indicated by dashed lines. The GP's which terminate at stationary points A and B define the intersection with the σ_v symmetry plane of the partitioning surfaces which lie between the carbon and hydrogen fragments. There are actually six such surfaces. Only two of them intersect the plane illustrated. Those GP's which originate at infinity and terminate at stationary points C and D, together with the single gradient path which originates at D and terminates at C, define the partitioning surface which lies between the two out-of-plane carbon nuclei. There are actually three such surfaces. The two GP's which terminate at point D lie along the common intersection of these three surfaces (the C_3 rotational symmetry axis). The GP's denoted by dashed lines in Fig. 2 lie along the intersection of these surfaces with the σ_h symmetry plane.

Gradient paths may be used to define *bond paths* which link certain pairs of nuclei, as well as the partitioning surfaces which separate them. In a molecule, an internuclear saddle point may exist between a pair of neighbouring nuclei. The gradient paths which *terminate* at this saddle point define the partitioning surface which lies between them. The two gradient paths which *originate* at this same saddle point and terminate at each of the two nuclei define the *bond path*. Thus, whereas the paths of steepest descent from an internuclear saddle point define the partitioning surface, the two paths of steepest ascent from

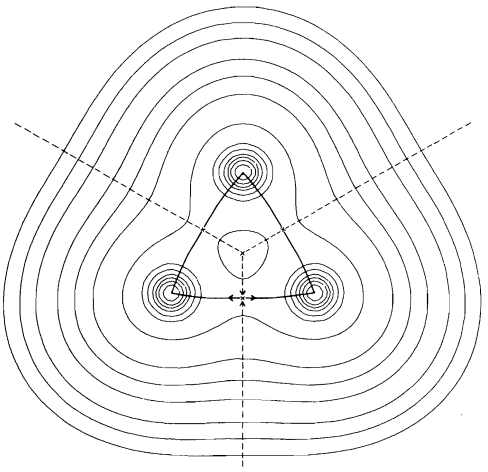

FIG. 2. Contour plot of $\rho(\boldsymbol{r})$ in the plane of the carbon nuclei in C_3H_6. Partitioning surfaces are denoted by dashed lines, the bond paths by solid lines joining the nuclei, and stationary points by ×. The directions of steepest ascent along the gradient paths in the partitioning surface and in the bond path are denoted by arrows for one pair of nuclei.

this same point to the nuclei define the *bond path*: *the path which follows the ridge of maximum charge density between a pair of bonded nuclei*. In those cases where an internuclear axis does not coincide with an axis of symmetry, the internuclear stationary point will not, in general, lie on the axis, and the bond path joining the two nuclei will deviate or curve from the internuclear axis. The magnitude and direction of this 'bond curvature' as reported below for a number of examples, agrees well with chemical expectations.[3]

Properties of the Bond Path

In cyclopropane (Fig. 2) the internuclear stationary points do not lie on the C—C internuclear axes. They are displaced outwards by 0.11 au. The line from a carbon nucleus to such a stationary point is called the *bond direction*, and the angle α formed by this line and the internuclear axis is 4.46°. The bond paths are curved out in this example. An experimental $\Delta\rho_{X-N}$ density difference map shows that the *bond density* (10*b*) in a three-membered ring compound peaks outside the nuclear triangle (13). Stevens *et al.* (14) have also noted that the ridge of maximum charge density obtained from an SCF wavefunction for cyclopropane is outwardly displaced from the internuclear axis.

The concept of 'ring strain', introduced to account for the increased reactivity of small ring compounds relative to that of their acyclic analogues, is given physical embodiment in the observed behaviour of the bond path in cyclopropane. The binding between a pair of nuclei is maximized when the bond path is coincident with the internuclear axis (10*b*, 15). In this case, the forces of attraction exerted on the nuclei by the charge density are maximized, as is the binding energy. In cyclopropane, not only does the ridge of maximum charge density lie off the internuclear axis, thereby resulting in a decrease in the binding energy, its displacement is such that it exerts a component of force on the nuclei tending to open the ring.

A ring structure may also exhibit an enhanced stability relative to its acyclic analogue. All nuclei comprising the ring are simultaneously attracted and bound by charge density lying within the geometrical boundary of the ring (16). If the bond path is displaced off each internuclear axis towards the interior of the ring, each nucleus will experience an increase in the force required to open the ring. An example of this behaviour is found for the benzene molecule, where the internuclear stationary points of the carbon ring are displaced off the axes towards the interior of the ring by 0.012 au with bond directions of 0.51°.

The recognition and definition of a bond path in an electronic charge distribution, together with the obvious electrostatic consequences its behaviour has on the forces which the electronic charge density exerts on the nuclei, provide a *common* explanation for the differing behaviour of cyclic compounds relative to their acyclic analogues: from 'ring strain energy' to 'resonance stabilization energy'.

In general, the bond direction (and its implied

[3]Martenson and Sperber (11) have previously suggested that one define "bond lines" as tracks of maximum charge density. However, no analytical definition of bond line was given and the authors expressed uncertainty as to which "density" function should be used to determine it. Qualitative bond lines were traced for cyclopropane using the density of a single bonded molecular orbital, and using the density difference distribution obtained from the valence electrons only. Neither distribution exhibits features common to the total charge distribution. Thus Martenson and Sperber found two maxima in these density functions lying off a C—C internuclear axis. These maxima determined the direction of the bond line. They concluded that any definition of bond line would be arbitrary. The definition of the bond path as given here in terms of a particular topological property of the *total* electronic charge distribution is nonarbitrary.

angle, α), as defined here in terms of a property of the charge density, is not expected to yield values as large as those obtained by models which both define and equate a 'bond' to some property of a localized or hybrid orbital. In their classic paper dealing with strain energy in cyclopropane, Coulson and Moffitt (17) obtained a value of 22° for the angle formed between the direction of the maximum in a hybrid orbital on carbon and the carbon–carbon internuclear axis.

There *are* preferred directions of bonding in a polyatomic system. The behaviour of the bond path offers a direct, quantitative measure of the importance, and with further study, of the energetic consequences of such geometrical restraints on the formation of a molecule.

The bond path, since it measures the real response of the electronic charge distribution to a particular nuclear arrangement, is not limited in its applicability or usefulness to systems where one postulates on *a priori* grounds the presence of strain or enhanced stability. Thus one finds the internuclear stationary points in the equilibrium geometries of H_2O and NH_3 to be displaced towards the interiors of these molecules, and their bond paths curved inwards. The bond direction, as measured in terms of the angle α with O or N at the apex, is 0.25° for H_2O and 0.24° for NH_3. In BH_3 with tetrahedral HBH angles, the bond paths are curved outwards and α, with B as apex, equals 6.26°.

The equilibrium geometry of BH_3 is planar and the charge distribution of pyramidal BH_3 is such that the ridge of maximum density is displaced off each B—H axis in a direction so as to exert an electrostatic force opening the bond angle. In H_2O (or NH_3), which is bent (or pyramidal) because of its ability to concentrate charge density in the binding region between the nuclei (16, 18), the ridge of maximum density is displaced so as to oppose an increase in the bond angles. Thus, information paralleling the relaxation of $\rho(\boldsymbol{r})$ caused by a change in bond angle, whether it facilitates or retards such a motion, is built into the static charge distribution as determined by the bond paths (19, 20).

If two fragments interact strongly within a molecular system, $\rho(\boldsymbol{r})$ in the region between their nuclei will exhibit a saddle point, and the nuclei will be linked by a bond path. This link will exist whether the strong interaction is a bonded one or a repulsive one, as in He_2 for example. Thus the existence of a bond path is a necessary (but not sufficient) condition for two atomic fragments to be bonded to one another.[4] In the charge distribution of H_2O for example, there are only two stationary points: internuclear saddle points between oxygen and each hydrogen. Thus, bond paths link the oxygen nucleus to each proton but no such link exists between the protons. The hydrogen fragments are not bonded to one another in the equilibrium water molecule. Alternatively, the two hydrogen fragments in H_2O do not share a common partitioning surface (12).

Bond path and bond direction are further examples of how chemically important concepts may be given rigorous definitions in terms of a property of the observable charge distribution.

Calculations

The electronic charge distributions used in the present study were calculated from the following wavefunctions: C_3H_6: a double-zeta function obtained by Snyder and Basch (21); C_6H_6: a minimal Slater function obtained by Stevens *et al.* (14); H_2O: a function of near Hartree–Fock quality obtained by Neumann and Moskowitz (22); NH_3: a function of near Hartree–Fock quality obtained by Rauk *et al.* (23); BH_3: a function of near Hartree–Fock quality obtained by Runtz and Bader (6).

2. R. F. W. BADER and P. M. BEDDALL. J. Am. Chem. Soc. **95**, 305 (1973).

[4]NOTE ADDED IN PROOF: It is possible that the sign of $\nabla^2\rho(\boldsymbol{r})$ at the saddle point $\boldsymbol{r}_s$ may be used to determine whether a given interaction is attractive or repulsive. It has been shown (24) that when $\nabla^2\rho(\boldsymbol{r}_s) < 0$, the potential energy density attains large negative values in the binding region while the kinetic energy density simultaneously is reduced in value. At an internuclear saddle point the curvature of $\rho(\boldsymbol{r}_s)$ parallel to the internuclear axis, $d^2\rho/dz^2 > 0$ while the perpendicular components, $d^2\rho/dx^2 = d^2\rho/dy^2 < 0$. When electronic charge is concentrated in the binding region as required for a bound state, the parallel curvature is decreased, the perpendicular values increased and hence $\nabla^2\rho(\boldsymbol{r}_s) < 0$. (In H_2 and N_2, $\nabla^2\rho(\boldsymbol{r}_s) = -1.27$ and -3.17 au at their respective R_e values.) In a repulsive state, charge density is removed from the binding region around $\boldsymbol{r}_s$, the parallel curvature of $\rho(\boldsymbol{r}_s)$ is greatly increased and $\nabla^2\rho(\boldsymbol{r}_s) > 0$. (In He_2 at $R = 2$ au, $\nabla^2\rho(\boldsymbol{r}_s) = +1.22$ au.) The stronger the binding, the more pronounced are the differing behaviours of the parallel and perpendicular curvatures of $\rho(\boldsymbol{r}_s)$. Thus the magnitude of $\nabla^2\rho(\boldsymbol{r}_s)$ is greater for N_2, than for C_2, than for Li_2.

The influences of nitrogen, hydrogen, and pyridine on the conversion of 3-carene into various products over chromia catalyst at 450°C and over chromia–alumina at 400°C have been investigated. Nitrogen acts as a diluent over these catalysts; hydrogen at low partial pressures enhances the formation of cymenes over chromia, but suppresses its formation over chromia–alumina. Increase of the partial pressure of hydrogen increases the proportion of menthanes over chromia–alumina, but decreases it over chromia catalyst. Pyridine suppresses the over-all conversion of 3-carene and the formation of cymenes over chromia and chromia–alumina; however, it increases the formation of menthadienes over chromia–alumina. These observations are explained in terms of the acidity of chromia and chromia–alumina, the diluting effects of nitrogen, hydrogen, and pyridine, and their ability to adsorb and desorb over the catalyst surfaces.

V. KRISHNASAMY et L. M. YEDDANAPALLI. Can. J. Chem. **55**, 3046 (1977).

On a étudié l'influence de l'azote, de l'hydrogène et de la pyridine sur la conversion des carènes-3 en divers produits par passage sur un catalyseur de chrome à 450°C et sur un catalyseur de chrome–alumine à 400°C. L'azote agit comme un diluant sur ces catalyseurs; l'hydrogène, à des pressions partielles peu élevées, augmente la formation des cymènes sur le chrome mais supprime leur formation sur les complexes de chrome–alumine. Une augmentation de la pression partielle d'hydrogène augmente la proportion des menthanes sur le catalyseur de chrome–alumine mais la diminue sur le catalyseur de chrome. La pyridine supprime la conversion globale des carènes-3 et la formation des cymènes sur les catalyseurs de chrome et de chrome–alumine; toutefois elle augmente la formation des menthadiènes sur les catalyseurs de chrome–alumine. On explique ces observations en termes d'acidité des catalyseurs de chrome et de chrome–alumine, des effets diluant de l'azote, de l'hydrogène et de la pyridine et de leur habilité à s'adsorber et à se désorber sur les surfaces des catalyseurs.

Introduction

Alumina, chromia, and chromia–alumina catalysts and their modified forms obtained by treating with hydrofluoric acid, potassium nitrate, sodium carbonate, etc. have been employed in this laboratory for the vapour-phase catalytic transformation of terpene hydrocarbons from Indian turpentine, with a view to convert them into stable useful intermediates. Isomerization and aromatization of β- and α-pinenes were already reported (1–4). Recently, the dehydrogenation of 3-carene over chromia and chromia–alumina catalysts, impregnated with potassium and fluoride ions, has been reported (5) with special reference to the ratio of *p*-cymene to *m*-cymene formed from 3-carene. The present study deals with the effect of nitrogen, hydrogen, and pyridine on the dehydrogenation of 3-carene. In the presence of these added substances the ratio between the cymenes does not show any appreciable change from that obtained in their absence; hence, this aspect is not reported here.

Experimental

Preparation of Materials

Alumina

Alumina was prepared by hydrolysing aluminium isopropoxide with distilled water (6). The precipitated aluminium hydroxide was filtered, washed thoroughly with water, and dried at 120°C for 24 h. It was activated at 500°C in dry air for 24 h, crushed into powder, and made into 4 × 4 mm cylindrical pellets.

Chromia Gel

The chromia gel catalyst was prepared and activated according to procedure described elsewhere (4, 7). The activated material was powdered and pelletized (4 × 4 mm cylindrical size). Prior to each run, the catalyst was reactivated by heating for 8 h in a current of dry air at 500°C until no oxides of carbon were detected in the exit

[2]Deceased.

gas, and then reduced by passing pure dry hydrogen for 6 h at the same temperature.

Chromia–Alumina

Chromia–alumina was prepared according to the methods of Selwood and Eischens (8) and Yeddanapalli *et al.* (9). The %Cr was estimated (9) to be 5.78.

3-Carene

First-quality Indian turpentine oil (Government Turpentine and Rosin Company, Bareilly, India) containing 50% 3-carene, 40% α-pinene, and 10% β-pinene was used. 3-Carene was obtained from this oil by fractionation at 10 mm, using a 152 cm glass column packed with stainless steel helices equivalent to 22 theoretical plates. The purity was found by gas chromatography to be better than 99%.

Pyridine

Analar pyridine (E. Merck) was refluxed over KOH pellets and fractionally distilled with careful exclusion of moisture, and the material distilling at 115.5°C/760 mm was collected. Its purity by gas chromatography was found to be better than 99%.

Nitrogen and Hydrogen

Nitrogen and hydrogen (Indian Oxygen Co.) were purified by passing successively through a silica gel drying tower, a tube containing freshly reduced copper turnings at 400°C, another silica gel tower, and finally through a trap cooled in liquid oxygen.

Apparatus and Procedure

The reactions were carried out at atmospheric pressure in a fixed-bed flow-type reactor. The catalyst (5 g) was placed in a Pyrex reaction tube, 25 cm long and 3 cm internal diameter. Above the catalyst bed, Pyrex glass beads (4 mm diameter) were placed to a height of 5 cm. The tube was inserted into the furnace, a cylindrical steel tube of internal diameter 4 cm, coated with a thin layer of asbestos and wound uniformly with nichrome wire, and heated electrically to the required temperature. 3-Carene was passed over the catalyst using a constant feed rate syringe pump that could be operated at different feed rates. The hydrogen and nitrogen supplies were controlled through precision 'Hoke' valves, and their flow rate was measured initially using a soap bubble flow meter, which was cut off during the experiment to avoid contamination of the catalyst with moisture. The flow rate was checked again at the end of the experiment. Various partial pressures of pyridine were achieved by mixing pyridine and 3-carene in different proportions.

The liquid products collected for the first 15 min of each run, which normally covers an hour, were discarded, and analysis was made only of the products collected after this time. This was done to ensure the attainment of a steady state for the reaction over the catalyst, and also to allow any temperature fluctuations due to the starting of the reaction to dissipate. After the reaction, the catalyst was regenerated as described earlier.

The liquid products of dehydrogenation were identified and estimated using a Perkin-Elmer Infracord Model-137 and a Perkin-Elmer Vapour Fractometer Model 154-D. Products other than cymenes were quantitatively estimated by a Perkin-Elmer Column K, consisting of a 2-m column of carbowax on chromosorb. The column temperature for the best resolution within a reasonable time was found to be 115°C with a hydrogen inlet pressure of 15 psi. *Para*- and *meta*-cymenes were separated and estimated in a specially prepared 2-m column filled with 40–60 mesh acid-washed kiesulguhr, coated with the stationary liquid, consisting by weight of 9% Bentone-34 and 4% Apiezon-L, heated at 108°C with hydrogen passed at a pressure of 28 psi.

For the identification of different peaks in a chromatogram, retention times for the different compounds were found by introducing pure substances kindly donated by Hercules Powder Company, U.S.A. For quantitative analysis, exactly reproducible quantities of synthetic mixtures containing the different compounds in varying proportions were introduced, and calibration curves relating the concentration with the peak heights were drawn. Since the peaks obtained were sharp and symmetrical, peak heights were used as a measure of concentration. Initial experiments, in which both peak heights and the total areas were compared using mixtures of known concentrations, gave identical results. The formation of the various products in this investigation can be accounted for by schemes presented earlier (5).

Results and Discussion

Results obtained over chromia and chromia–alumina in the presence of nitrogen, hydrogen, and pyridine are given in Figs. 1 to 3. To estimate the extent to which hydrogen and pyridine inhibit or enhance the over-all conversion of 3-carene, as well as the distribution of the products, the results were compared with those obtained using nitrogen as a diluent. The effects of partial pressures of nitrogen, hydrogen, and pyridine on the conversion of 3-carene over chromia and chromia–alumina are presented in Fig. 1. Figure 2 illustrates the influence of these substances on the formation of cymenes over chromia and chromia–alumina. The proportions of menthadienes and menthanes formed over these catalysts are shown in Fig. 3.

When 3-carene mixed with nitrogen at various partial pressures was passed over chromia gel catalyst, its conversion and product formation were reduced. The same effect of nitrogen was observed over chromia–alumina catalyst, but the formation of menthadienes increased directly with the partial pressure of nitrogen. The total acidities of chromia and chromia–alumina were 0.14 and 0.64 milliequivalent of *n*-butylamine, respectively (5). The higher acidity of chromia–alumina may be responsible for the increased formation of menthadienes.

Effect of Hydrogen

The increase in partial pressure of hydrogen, like that of nitrogen, decreased the total conversion of 3-carene. But, the decrease due to hydrogen was less pronounced at all partial

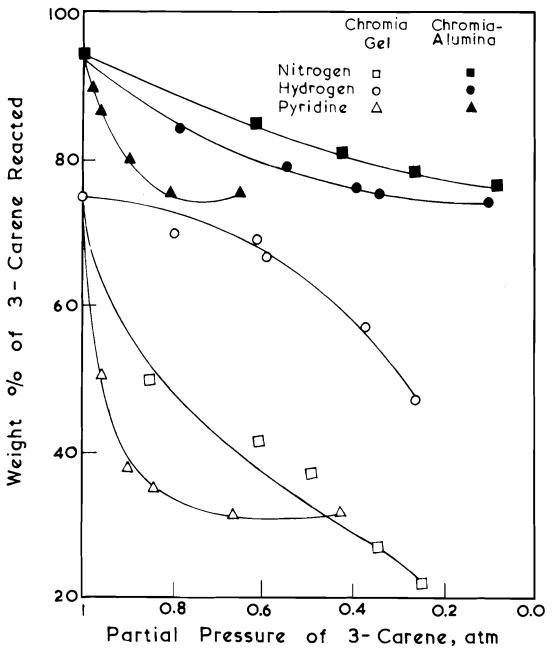

FIG. 1. Effect of partial pressure of nitrogen, hydrogen, and pyridine on the overall conversion of Δ^3-carene over chromia gel catalyst at 450°C and over chromia–alumina catalyst at 400°C. LHSV = 2.

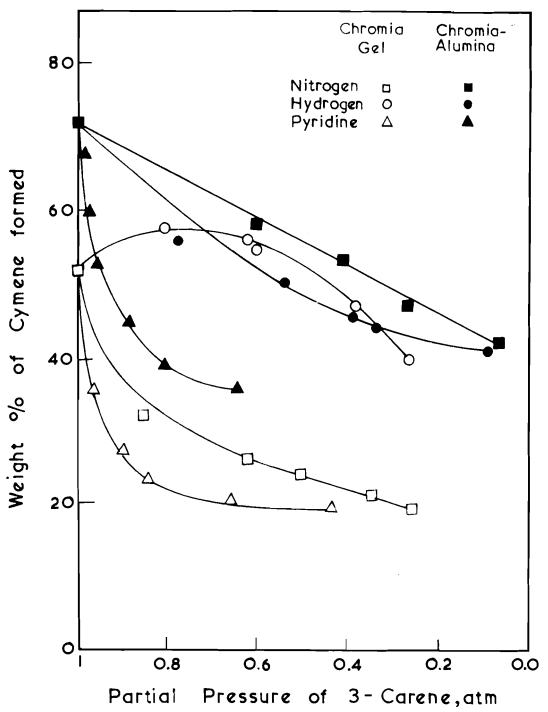

FIG. 2. Effect of partial pressure of nitrogen, hydrogen, and pyridine on the formation of cymenes from Δ^3-carene over chromia catalyst at 450°C and over chromia–alumina catalyst at 400°C. LHSV = 2.

pressures, as compared to nitrogen (Fig. 1). It may be noted that the formation of cymenes increases even though there is a decrease in the conversion of 3-carene.

The above observations may be explained as follows. Hydrogen over chromium oxide is easily desorbed (10) and therefore its presence on the surface of the catalyst does not seriously affect the conversion of 3-carene. It is presumed that hydrogen reduces the unsaturated compounds that precede the formation of polymers and of coke which would deposit on the active centers of the catalyst as in an earlier scheme (5). On suppressing the formation of polymers and coke, the formation of cymenes goes up. The fall in the activity of chromia at higher partial pressures of hydrogen may be due to further reduction of catalyst surface available for reaction.

Hydrogen has a different effect over chromia–alumina compared to chromia. Hydrogen decreases both 3-carene conversion and the formation of cymenes, but the level of reduction is much below that due to nitrogen (Figs. 1 and 2). Formation of menthadines does not vary significantly, but that of menthanes increases with the partial pressure of hydrogen. The decrease in the conversion of 3-carene and the formation of cymenes may be attributed to the preferential adsorption over chromia–alumina of hydrogen compared to 3-carene. The observed results are in agreement with the findings of Selwood (11) and Greensfelder (12). Presumably the adsorbed hydrogen is transferred to the adsorbed menthadines and hydrogenates them to menthanes, thus increasing the yield of menthanes.

Effect of Pyridine

Pyridine markedly reduces the conversion of 3-carene over chromia while only a small reduction is noted over chromia–alumina. In either case, the poisoning influence of pyridine is greater compared to nitrogen as diluent. These observations can be related to the acidity of these two catalysts. The alumina used as a support for chromia in this investigation was found (13) to contain strong, medium, and weak acid sites. Pyridine being a strong base can neutralise the strong and medium sites preferentially, without affecting the weak sites, which are still capable of isomerizing 3-carene to menthadienes. Parry (14) has also reported that pyridine does not affect the weak sites on alumina. The acid sites in chromia possibly may not be active in an

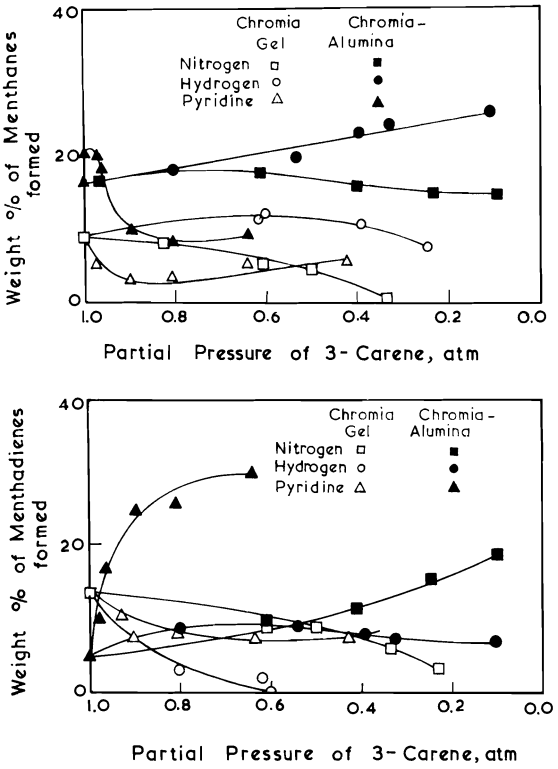

FIG. 3. Effect of partial pressure of nitrogen, hydrogen, and pyridine on the formation of menthadines and menthanes from Δ^3-carene over chromia catalyst at 450°C and chromia–alumina catalyst at 400°C. LHSV = 2.

atmosphere of pyridine, thus accounting for the observed reduction in the conversion of 3-carene.

Though there is a notable difference in the conversion of 3-carene over chromia and chromia–alumina, as discussed above, there is not much difference in the reduction of cymenes over these catalysts. For instance, cymenes formed over chromia and chromia–alumina in the absence of pyridine are 52 and 76% respectively; the amounts are reduced to 35 and 56% when the partial pressure of pyridine is 0.04 atm (Fig. 2). This effect may be attributed to the tendency of pyridine to interact with the chromium ions. This is supported by the findings of Stanislaus and Yeddanapalli (4) on the dehydrogenation of α-pinene over chromia–alumina. Quinoline is also found to reduce the dehydrogenation and the dehydration activity of chromia (15).

Over chromia pyridine suppresses the formation of both menthanes and menthadienes, but over chromia–alumina it favours the formation of menthadienes; menthanes, however, show only an initial increase. Heats of combustion (16) and of hydrobromination (17) show that cyclopropane ring has double bond character, and that the ring may undergo fission via addition. Hence, the cyclopropane ring in 3-carene can isomerize (5) to *p*- and *m*-menthadienes by the weak acid sites, which are left unaffected by pyridine. The menthadines formed may not possibly be dehydrogenated, since the dehydrogenation sites may have interacted with the pyridine molecules as mentioned above. Krishnasamy and Yeddanapalli (5) have observed a similar increase of menthadienes in the presence of potassium ions.

Pyridine at low concentrations may catalyse hydrogen transfer reactions among the menthadienes to form menthanes. Pines and Kolobielski (18) have also noted hydrogen transfer reactions among cyclic diolefins in the presence of base catalysts.

Transition state activity coefficients in the acid-catalyzed hydrolysis of amides

TOMASZ A. MODRO, KEITH YATES, AND FRANÇOISE BEAUFAYS
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received March 8, 1977

TOMASZ A. MODRO, KEITH YATES, and FRANÇOISE BEAUFAYS. Can. J. Chem. **55**, 3050 (1977).

The transition-state activity coefficient ($f_{S\neq}$) approach has been applied to the acid-catalyzed hydrolysis of benzamide and its *N*-alkyl derivatives. For all systems (with the exception of the *N-tert*-butyl derivative which reacts via carbon–nitrogen bond cleavage) a uniform type of medium dependence of log $f^*_{S\neq}$ is observed. The reaction shows a pronounced destabilization of $S^{\neq}$ over the whole region of acidity studied, practically identical to that found for the A_{Ac}-2 type of ester hydrolysis. This is interpreted in terms of an A_OT2 mechanism of amide hydrolysis, that is the rate-determining formation of the oxonium-type tetrahedral intermediate from the O-protonated form of substrate conjugate acid.

TOMASZ A. MODRO, KEITH YATES et FRANÇOISE BEAUFAYS. Can. J. Chem. **55**, 3050 (1977).

On a appliqué le coefficient d'activité des états de transition ($f_{S\neq}$) à l'hydrolyse acido-catalysée de la benzamide et de ses dérivés *N*-alkylés. Pour tous les systèmes (à l'exception du dérivé *N-tert*-butylé qui réagit par l'intermédiaire d'une coupure du lien carbone–azote), on a observé un type uniforme de relation entre le milieu et le log $f^*_{S\neq}$. La réaction présente une déstabilisation prononcée de $S^{\neq}$ à toutes les valeurs d'acidité étudiées et cette déstabilisation est pratiquement identique à celle trouvée pour l'hydrolyse d'esters de type A_{Ac}-2. On interprète ces résultats en termes d'un mécanisme A_OT2 pour l'hydrolyse des amides qui implique la formation, dans l'étape déterminante, d'un intermédiaire tétraédrique de type oxonium à partir de la forme O-protonée de l'acide conjugué du substrat.

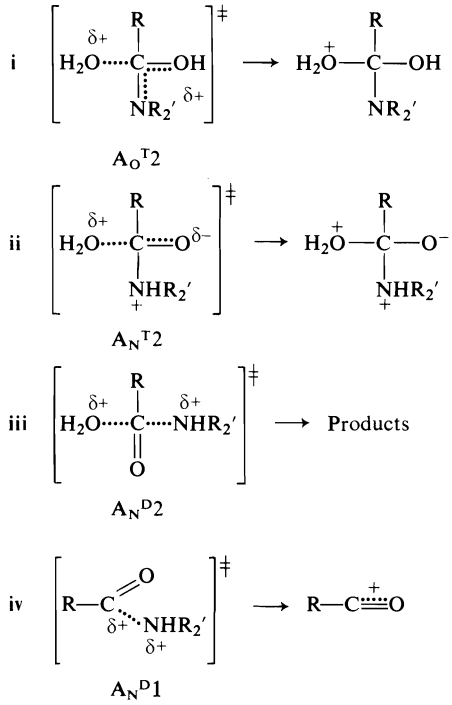
[Traduit par le journal]

The controversial question of the predominant protonation site in amides now seems to be definitely resolved in favour of oxygen-protonation;[1] this holds in both regions of moderate and low concentrations of aqueous acids (1). The O-protonated conjugate acid probably represents the major intermediate on the reaction path in the acid-catalyzed hydrolysis of amides, but this is not established. Recent results of Williams (2) on the acidic hydrolysis of *N,N*-dialkylacetamides indicate that the percentage of reaction proceeding via the N-protonated form of conjugate acid (existing in very low concentration but possibly highly reactive) is less than 0.02%. However, this conclusion involves necessary assumptions about the compounds used as models for N-protonated amides. The only reported example of amide hydrolysis via S_N2 displacement in the N-conjugate acid is a special case of acid-catalyzed collapse of *N*-nitrosoamides (3).

The present work concerns the hydrolysis of benzamide and a series of its *N*-alkyl and *N,N*-dialkyl derivatives in moderately concentrated aqueous sulfuric acid, and was undertaken to provide possible support for the mechanism involving O-protonated amide as the reactive intermediate. The approach used has been successfully applied previously in mechanistic studies of acid-catalyzed ester hydrolysis (4) and aromatic substitution (5). It is based on expected differences in solvation requirements of different types of transition state and involves examination of the behaviour of the activity coefficients of transition states as a function of the acidity (or water activity) of the reaction medium. For the acid-catalyzed hydrolysis of amides there are principally four distinct mechanistic schemes that have to be taken into account (6). Three of them involve bimolecular rate-determining nucleophilic attack of water on the substrate conjugate acid (A-2 mechanisms). The fourth scheme represents unimolecular rate-determining cleavage of the N-protonated amide (A-1 mechanism). The first of the A-2 reaction paths (designated as the A_OT2 mechanism (6)) involves rate-determining formation of the tetrahedral intermediate from the O-protonated substrate; in the second (designated as A_NT2) the tetrahedral intermediate is formed in a rate-determining step from the N-protonated substrate. The mechanism designated as A_ND2 involves a rate-

[1]See however the recent article of M. Liler in ref. 18.

determining, synchronous displacement of ammonia (or amine) by water from the N-protonated conjugate acid, and the last scheme (designated as A_N^D1) involves a unimolecular rate-determining cleavage of the N-protonated substrate to give the ammonia (or amine) molecule and an acylium ion. The possible transition states (and intermediates which directly follow them) for these four mechanistic schemes can be represented by the structures **i**–**iv**. Since the reactivity of the amides studied is



very low, on the basis of the Hammond postulate a 'late' transition state can be assumed for the hydrolysis pathway. The transition states **i**, **ii**, and **iv** would be therefore expected to resemble the intermediates which follow (tetrahedral structures or acylium ion); for **iii** a high degree of charge dispersion would be expected. The A_O^T2 scheme corresponds closely to the $A_{Ac}2$ mechanism of acid-catalyzed ester hydrolysis (4) and the transition state, due to advanced charge localization and a considerable degree of oxonium ion character, should be characterized by strong requirements for hydrogen-bonding type of solvation. By analogy with the $A_{Ac}2$ process (4), the transition state for A_O^T2 mechanism should exhibit a marked salting-out effect (or destabilization) when the availability of water in the reaction medium is decreased. By contrast, in the A_N^D2 and A_N^D1 mechanisms, the corresponding transition states are characterized by significant charge dispersion and at least partial ammonium ion character. This should result in much lower hydration requirements and therefore in lower sensitivity to changes in the composition of the reaction medium. Moreover, since the nitrogen in **iii** and **iv** has a partially ammonium ion character, it would be expected to show different hydration (hydrogen bonding) requirements depending on the number of hydrogen atoms present on nitrogen (R′ = H or alkyl). In consequence, a decrease in the salting-out effect should be observed in the series primary > secondary > tertiary amides (7).

It is difficult to predict the behaviour of the transition state corresponding to the polycharged intermediate **ii** in the A_N^T2 process. At any rate, it should be distinctly different from that for the A_O^T2 mechanism, for which a close resemblance to the transition state of the bimolecular ester hydrolysis is expected. In summary, essentially different behaviour is anticipated for the transition state activity coefficients for the alternative hydrolysis mechanisms as a response to the variation of the aqueous acid composition.

The transition state activity coefficient $f^*_{S\neq}$ (relative to a standard tetraethylammonium ion)[2] can be expressed as a sum of the following quantities (4):

$$[1]\quad \log f^*_{S\neq} = \log k_0 - \log k_\psi^{corr} + pK_{SH^+} + \log f_S + \log a^*_{H^+}$$

In [1] k_0 is the rate constant for the slow step and the log k_0 term can be separated as the intercept of a plot of log $(f^*_{S\neq}/k_0)$ vs. acid concentration. k_ψ^{corr} is the observed pseudo-first-order rate constant, corrected for partial protonation of the substrate; i.e. $k_\psi^{corr} = k_\psi^{obs}(1 + I)$, where I is the ionization ratio $[SH^+]/[S]$. pK_{SH^+} is the amide acidity constant and can be obtained from conventional ionization ratio measurements. f_S represents substrate activity coefficient and can be determined by means of solubility or distribution measurements. Finally, $a^*_{H^+}$ is the proton activity (expressed as relative

[2]Since the activity coefficients of single ionic species are not directly accessible, they are usually expressed as relative to the standard, tetraethylammonium ion (8): $f^*_{Z^+} \equiv f_{Z^+}/f_{TEA^+}$.

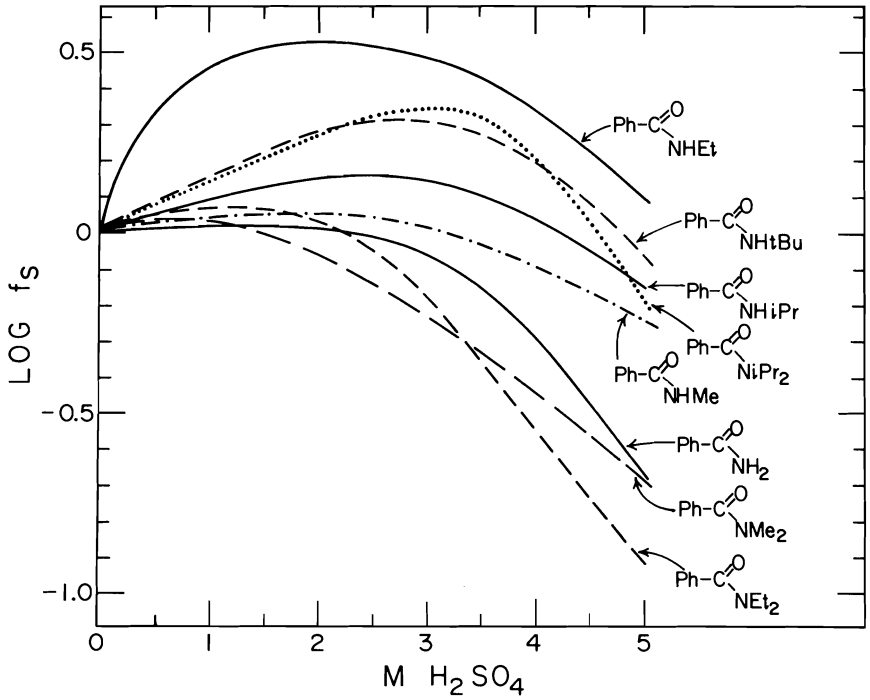


FIG. 1. Activity coefficient variation for benzamides.

to the TEA^+ ion) and its values are available (9) for various aqueous acid solutions.

We have determined the required quantities (eq. 1) for some amides of the structure PhC(O)-NRR′ (R,R′ = H, alkyl) in order to examine the log $f^*_{S\ddagger}$ dependence on the acidity of the reaction medium and to compare this behaviour with that of log $f^*_{S\ddagger}$ for related reactions and of log f_+* of some stable model cationic species.

Results and Discussion

Activity Coefficient Data

The distribution method (7) was employed in all cases, using chloroform as the inert organic solvent. The distribution coefficients were corrected for the partial ionization of amides in the aqueous phase. The activity coefficients determined for eight benzamides at different concentrations of sulfuric acid are represented graphically in Fig. 1.[3] For all compounds, similar behaviour was observed; an initial mild salting-out (destabilization) followed by a moderate salting-in (stabilization) effect. The variations in the individual values of f_S over the acidity range employed never exceed one logarithmic unit (usually ca. 0.5 log unit) and therefore the log f_S term in [1] does not contribute very significantly to the over-all calculation of the transition state activity coefficients.

Basicity of Amides

Ionization ratios ($I = [SH^+]/[S]$) for the five *N*-alkyl derivatives of benzamide were obtained spectrophotometrically by conventional methods (10). Plots of log I values against the amide acidity function H_A showed good linearity (correlation coefficients >0.99) over a wide range of acidity. The slopes m and intercepts of those plots for the series of benzamides discussed are presented in Table 1. The values of the slope m show significant deviations from 'ideal' behaviour (slope of unity) for some of the *N*-alkyl derivatives. For secondary amides these deviations are not large, although slightly greater than those (m = 1.03–0.93) reported by Barnett and O'Connor (12) for a series of ring-substituted *N*-alkylbenzamides. For the *N*,*N*-dialkyl substituted system, a systematic decrease in the d log I/d($-H_A$) value was observed with an increase of the size of the alkyl groups (0.90, 0.73,

[3]The values of activity coefficients (Table 4) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

[a]Taken from ref. 11.

0.57, respectively). The reason for this steric effect on the acidity dependence of the ratio f_{SH^+}/f_S (which increases with diminishing water activity more rapidly for bulky tertiary than for primary and secondary amides) is not quite clear. In the conjugate acid Ph—$C(OH)NR_2^+$ the oxonium-like OH group is always syn to one of the alkyl groups R and its solvation is probably subject to significant steric hindrance. When water is removed from the medium, the (partly) compensating solvation by bisulfate ions may be less effective for steric reasons and the cation is more rapidly salted-out relative to the conjugate acids derived from primary and secondary amides.[4]

Rate Constants

Rates of hydrolysis were measured spectrophotometrically by a conventional method (13). For all compounds there is a sufficiently large difference in the uv spectrum of the substrate and product (benzoic acid) for the reaction to be followed by measuring the change of the absorbance of the reaction mixture in the range 210–240 nm. The hydrolysis is slow and all kinetic runs were carried out at elevated temperatures. In Table 2 are listed pseudo-first-order rate constants for the five amides as a function of acidity. In Fig. 2 some typical rate profiles, determined at 70.9°C, are displayed, together with data previously obtained (13) for benzamide and its *N,N*-dimethyl derivative, interpolated to the same temperature. All compounds show similar rate–acidity dependence, with a broad rate maximum at about 30% H_2SO_4, typical of amide hydrolysis in acidic solutions (cf. ref. 14). The only exception is *N-tert*-butylbenzamide, which will be discussed later. The overall hydrolysis rate is markedly suppressed by alkyl substitution at nitrogen particularly for the *N,N*-dialkyl derivatives. A systematic decrease in k_ψ values with an increase of the bulk of the alkyl groups is observed with the *N,N*-diisopropyl derivative being 3 to 4 × 10^3 times less reactive than the parent benzamide. This sensitivity of the rates to steric effects in itself argues against the mechanistic models of hydrolysis involving C—N bond cleavage in the rate-determining step (mechanisms A_N^D2 and A_N^D1). If these mechanisms were operating, some rate enhancement due to the relief of steric crowding would be expected with increasing substitution at nitrogen.

The behaviour of *N-tert*-butylbenzamide is quite different; spectrophotometrically measured rate constants increase with acidity more rapidly than those for other substrates, and at ca. 40% H_2SO_4 the rate profile merges into that of benzamide itself. Close similarity of rate profiles for acid-catalyzed hydrolysis of 4-chlorobenzamide and its *N-tert*-butyl derivative has also been observed by Hyland and O'Connor (15). It was demonstrated some time ago by Lacey (16) that the hydrolysis of various *N-tert*-alkyl substituted amides in strong mineral acids proceeds with an alkyl carbon – nitrogen bond fission, giving first the tertiary alcohol and unsubstituted amide. We have confirmed this observation for the *N-tert*-butylbenzamide; the nmr analysis of the reaction mixture showed the exclusive formation of *tert*-butyl alcohol, no *tert*-butylamine being detected in the products. In this case the hydrolysis can be therefore described by [2*a*] and [2*b*]. The uv spectro-

[4]Since the value of pK_{SH^+} is included in [1] as a constant, any possible error in its determination does not affect the behaviour of log f_+* as a function of acidity.

photometric method enables one to follow only step [2*b*], since the spectroscopic changes accompanying the conversion secondary → primary benzamide are insignificant. It can be seen from the rate profiles in Fig. 2 that up to ca. 40% H_2SO_4 the step [2*a*] (de-*tert*-butylation) is slower than step [2*b*] (benzamide hydrolysis) whereas this order is reversed above that acidity. The alkyl–nitrogen cleavage step [2*a*] can be followed by nmr due to the different chemical shifts for the *tert*-butyl hydrogens of the substrate and the alcohol. We have determined the half-life of *N*-*tert*-butylbenzamide in 96% H_2SO_4 by the nmr method, and the corresponding value of k_ψ at 25°C is ca. 1.9×10^{-4} s^{-1}. This value can also be estimated indirectly from the uv measurements. From the rates determined at three different temperatures (Table 2), the corresponding rate profile for the hydrolysis of *N*-*tert*-butylbenzamide at 25°C could be obtained. The linear section of this log k_ψ – acidity plot (up to 30% H_2SO_4) has been extrapolated to higher acidities, giving approximate value of k_ψ (25°C) in 96% H_2SO_4 equal 2×10^{-4} s^{-1}. The good agreement with k_ψ value obtained by nmr indicates that the spectrophotometrically (uv) determined rate profile at acidities below 40% H_2SO_4 (Fig. 2) indeed corresponds to the acid-catalyzed de-*tert*-butylation step [2*a*]. Hydrolysis involving prior alkyl–nitrogen cleavage seems to operate only for tertiary alkyl derivatives. Nuclear magnetic resonance analysis of the reaction mixture for the hydrolysis of *N*,*N*-diisopropylbenzamide (the least reactive member of the series) showed the formation of diisopropylamine as the exclusive product, that is by the 'normal' acyl–nitrogen cleavage pathway.

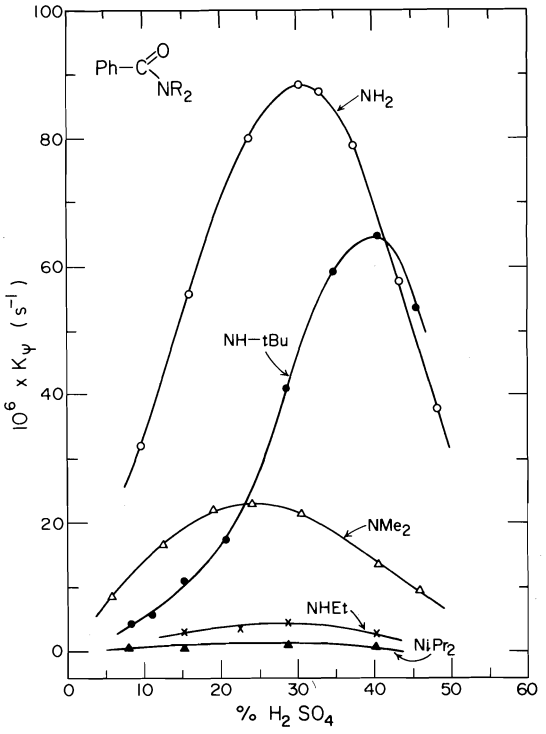

FIG. 2. Rate profiles for hydrolysis of benzamides.

The hydrolysis of the *N*-*tert*-butylbenzamide

must be considered as a distinct type of acid-catalyzed cleavage of an amide system. This process by itself presents some interesting mechanistic problems, such as the role of water in the dealkylation step, and the structural requirements for the mechanistic change from the acyl–nitrogen to the alkyl–nitrogen bond fission pattern. These questions can only be answered by more comprehensive studies on the rate–acidity and rate–structure dependence for this type of hydrolysis and work on acid-catalyzed amide hydrolysis proceeding via alkyl–nitrogen cleavage is in progress in this laboratory. For the purpose of this work, however, the *N-tert*-butyl derivative has been excluded from the transition state activity coefficient treatment.[5]

Log $f^*_{S\ddagger}$ for Amide Hydrolysis

Values of log $f^*_{S\ddagger}$ as a function of sulfuric acid concentration have been calculated for benzamide and its *N*-methyl, *N*,*N*-dimethyl, and *N*-isopropyl derivatives. These models have been chosen in order to examine the behaviour of the log $f^*_{S\ddagger}$ values for primary, secondary, and tertiary systems, as well as for secondary amides substituted at nitrogen by alkyl groups of different size. The necessary rate data at 25°C were available for benzamide (13), and for remaining substrates were obtained by extrapolating the Arrhenius plots determined at higher temperatures. The values of log $f^*_{S\ddagger}$ (eq. 1) in the 0.5–5.0 M sulfuric acid region are listed in Table 3.

The data in Table 3 show the remarkable similarity in log $f^*_{S\ddagger}$ values for all four substrates over the whole range of acidity, despite the large variations in observed rate. This is evidence of the close structural parallel of the transition states involved, which in turn implies a uniformity of mechanism of hydrolysis for these derivatives. Since all systems are salted-out (destabilized) with an increase of acidity to approximately the same extent, it appears that the number of hydrogen atoms present at the nitrogen is not important in determining the overall solvation requirements of the transition state. Such a result indicates that only a minor fraction of the positive charge is localized on the nitrogen in the transition state. In Fig. 3, values of log $f^*_{S\ddagger}$ are plotted as a function of water activity in the aqueous solutions of sulfuric acid. The behaviour of log $f^*_{S\ddagger}$ for the amide hydrolysis is compared in Fig. 3 with the behaviour of the activity coefficients of some relevant systems, the transition state for the $A_{Ac}2$ type of ester hydrolysis (4) and two stable cationic species: the conjugate acids of alcohols (17) (oxonium ion with localized charge and high hydration requirements) and amides (7). The values of log $f^*_{S\ddagger}$ for benzamide and its *N*-alkyl derivatives parallel closely the plot characteristic for the $A_{Ac}2$ mechanism of ester hydrolysis. This is well illustrated by comparison of the behaviour of one of the amides studied with the log $f^*_{S\ddagger}$ – acidity plot for the hydrolysis of *p*-nitrobenzyl

[5]It is worth pointing out that the log $f^*_{S\ddagger}$ values for the *N-tert*-butylbenzamide calculated from the rate data up to 35% H_2SO_4 (Fig. 2) show that the transition state activity coefficient behaviour is indeed different from that of remaining amides. A weaker salting-out effect is observed, as might be expected for the essentially different mechanism not involving an oxonium ion-like transition state. However, this log $f^*_{S\ddagger}$ behaviour for the *N-tert*-butyl derivative is also different from that of *tert*-butyl acetate hydrolysis (4) indicating that the reaction does not represent the typical A-1 process in which the formation of the *tert*-butyl carbonium ion constitutes the rate-determining step.

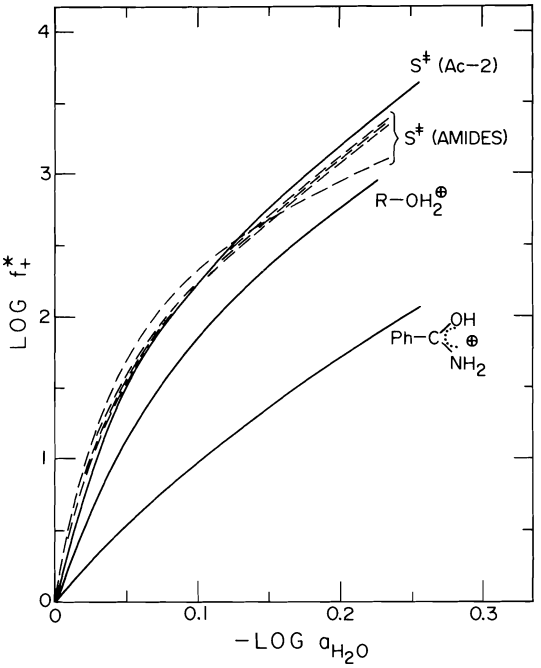

FIG. 3. Activity coefficients of cationic molecules and transition states (relative to TEA^+).

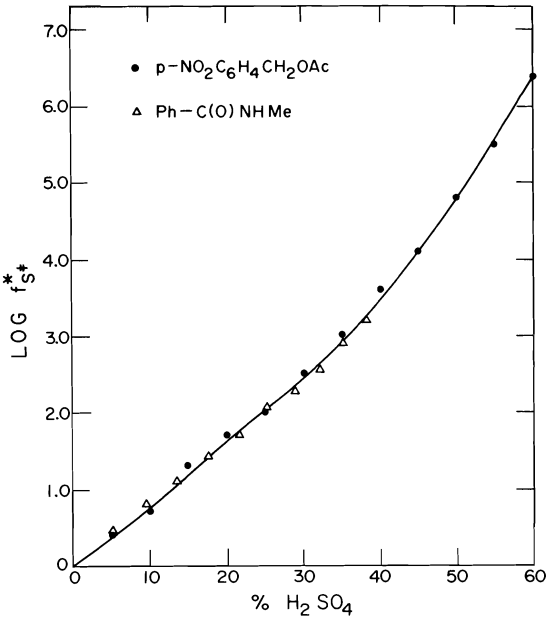

FIG. 4. Transition state activity coefficients for hydrolysis of *p*-nitrobenzyl acetate and *N*-methylbenzamide.

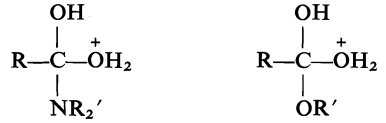
acetate, an ester which is believed to react according to the $A_{Ac}2$ mechanism over the whole range of sulfuric acid concentrations (4). Such a comparison, made for the *N*-methylbenzamide, is presented in Fig. 4. An examination of the log $f^*_{S^{\ddagger}}$ behaviour for hydrolysis of amides and esters leads to the obvious conclusion that for both systems the transition states must resemble each other very closely in solvation requirements, and in the degree of development of oxonium ion character. This can be interpreted in terms of highly advanced transition states, resembling in both cases the corresponding tetrahedral intermediate:



We believe therefore that the generally observed behaviour of the log $f^*_{S^{\ddagger}}$ for amide hydrolysis as a function of medium composition is only compatible with the $A_O{}^T2$ mechanistic pattern.

Experimental

Materials

N,N-Diethylbenzamide was prepared from benzoyl chloride and diethylamine in benzene; bp 99°C/0.6 Torr. *Anal.* calcd. for $C_{11}H_{15}NO$: C 74.54, H 8.53, N 7.90; found: C 74.64, H 8.55, N 7.93. Remaining amides were commercially available, and were purified by recrystallization.[6] Acid solutions were prepared by diluting the concentrated sulfuric acid with distilled water. The concentrations of these solutions were determined from their densities; densities were measured with a DMA 02C digital precision density meter at 25.0°C.

Activity Coefficient Measurements

All activity coefficients were determined by the distribution method (7): a 10^{-2}–10^{-3} *M* solution of the amide in chloroform (ACS Grade) was shaken mechanically with 5 ml of water or the aqueous sulfuric acid solution for 5 min in a thermostatically controlled (25 ± 0.5°C) box. The aqueous layer was transferred to the uv cell and the absorbance of the amide was measured at the wavelength maximum (Table 5), using a Cary 14 spectrophotometer. The concentration of the amide in acidic solution was corrected for partial ionization of the substrate. The values of the activity coefficients were calculated from the ratio of the distribution coefficient in pure water to that in an acid solution.

Measurements of Basicity Constants

A stock solution of the substrate in methanol (0.5 µl) was introduced into 3.0 ml of the aqueous acid in a uv cell by means of a Hamilton Precision Syringe, and the uv spectrum was measured immediately. The range of acid concentrations generally included at least ten

[6]The uv characteristics of the substrates and their conjugate acids (Table 5) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

samples in the region $-1.0 \leq \log I \leq 1.0$, as well as solutions in which the substrate is unprotonated and fully protonated.

Rate Determinations

A stock solution of amide was prepared in the appropriate sulfuric acid and 12–14 samples were prepared for each kinetic run by sealing 3 ml of the solution in glass ampoules. The ampoules were allowed to equilibrate in an oil bath thermostatted to ± 0.1°C, and were quenched in ice when withdrawn. Runs were followed to ca. 2 half-lives. Infinity points A_∞ were obtained in duplicate or triplicate and were reproducible to $\pm 1.0\%$. Rate constants were obtained in the usual way from plots of $\ln (A_t - A_\infty)$ vs. time.

Product Determination

The substrate was dissolved in aqueous sulfuric acid and the hydrolysis was followed by recording the nmr spectrum of the solution in the range of 0–3 δ. For the *N-tert*-butylbenzamide the initial signal of the *tert*-butyl group (δ ~ 1.8) disappeared gradually and was replaced by the signal corresponding to the *tert*-butyl group of *tert*-butyl alcohol (δ ~ 1.1); no signal corresponding to the *tert*-butylamine was detected. The cleavage product was identified by adding authentic samples of *tert*-butyl alcohol and *tert*-butylamine to the sample tube. Similar experiments for *N,N*-diisopropylbenzamide demonstrated exclusive formation of diisopropylamine; no traces of 2-propanol were observed.

The rate of the de-*tert*-butylation of *N-tert*-butylbenzamide was determined in a similar way. The progress of reaction was followed by measuring the ratio of the integrated peak areas for the *tert*-butyl group of the substrate and product as a function of time.

Comment: Lifetimes of the solvated electron in liquid alcohols

J. H. BAXENDALE AND PETER WARDMAN[1]

Chemistry Department, University of Manchester, Manchester M13 9PL, England

Received February 22, 1977

J. H. BAXENDALE and PETER WARDMAN. Can. J. Chem. **55**, 3058 (1977).

The solvated electron, e_s^-, decays with first-order kinetics in pulse-irradiated aliphatic alcohols, attributed to reaction 1: $e_s^- + ROH \rightarrow$ products. It is suggested that a recent report of curved Arrhenius plots for the temperature dependence of the rate constants for reaction 1 can be ascribed to reaction of e_s^- with impurities.

J. H. BAXENDALE et PETER WARDMAN. Can. J. Chem. **55**, 3058 (1977).

Dans des alcools aliphatiques irradiés par pulsation, l'électron solvaté e_s^- se décroît avec une cinétique du premier ordre par une réaction attribuée á: $e_s^- + ROH \rightarrow$ des produits [1]. On attribue à la réaction de e_s^- avec des impuretés la nature recourbée des traces d'Arrhénius, décrivant la relation entre les constantes de vitesse et la temperature, pour la réaction 1 qui ont été rapportées dans un travail récent.

[Traduit par le journal]

Recently, Bolton, Jha, and Freeman (1) measured the lifetimes of the solvated electron produced by pulse radiolysis of liquid alcohols, and compared their values of the first-order rate constants, k_1

[1] $$e_s^- + ROH \rightarrow \text{products}$$

at various temperatures with the data previously reported by Baxendale and Wardman (2). Bolton *et al.* (1) observed an order of magnitude shorter lifetimes of e_s^- at low temperatures than Baxendale and Wardman, and also shorter lifetimes than are predicted from the Arrhenius extrapolation of their higher temperature values. In fact, their Arrhenius plots were curved, and they stated that "the earlier reported linearity (2) is questionable". No basis for this statement was given.

Our data were published (2) in the form of the equation

[2] $$k_1 = A_1 \exp(-E_1/RT)$$

with values of $\log_{10}(A/s^{-1})$ and E_1/kJ mol^{-1} together with the least-squares standard deviations from measurements at 12–15 temperatures between ca. 170 and 340 K. We present some details in Fig. 1, which shows that for changes in k_1 of three orders of magnitude, "Our direct measurements.....are closely described by the Arrhenius expression....." (2).

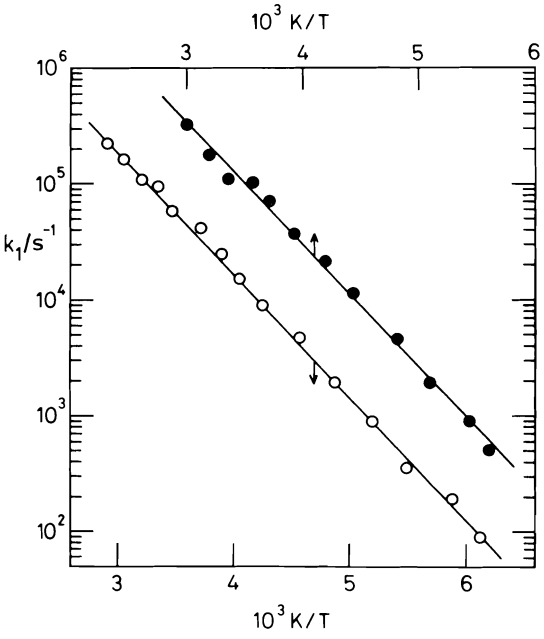

FIG. 1. Arrhenius plots for the exponential decay of e_s^- in alcohols containing 1 mmol dm^{-3} sodium alkoxide. ○, ethanol (lower abscissa). ●, methanol (upper abscissa).

Electron decay studies in 'pure' liquids have always been bedevilled by the question of liquid purity and hence we would hesitate to claim that our results are the last word on this matter. However, we found that impurities which shorten the lifetime of e_s^- had relatively more effect at lower temperatures, i.e. the apparent E_1 increased with purification. Clearly, curved

[1]Present address: Cancer Research Campaign Gray Laboratory, Mount Vernon Hospital, Northwood, Middlesex HA6 2RN, England.

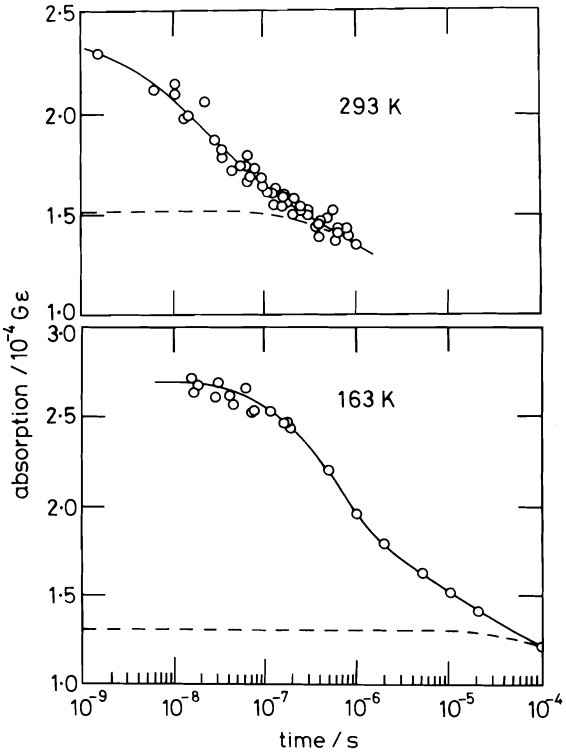

FIG. 2. Absorption of e_s^- after nanosecond pulse radiolysis of ethanol at 163 and 293 K. Dose ~600 rad.

Arrhenius plots may also arise in this way and the higher values of k_1 at low temperatures reported by Bolton *et al.* (1) suggest that impurities in the alcohols are the reason for their curves. We purified ethanol by the borohydride technique (3) and methanol by fractional distillation from basic solution under nitrogen.

Our values of k_1 were derived from analysis of the final, exponential portion of the decay of e_s^- after nanosecond pulse radiolysis of alcohols containing 1 mmol dm^{-3} base. Prior to this exponential 'free ion' decay, there is a more rapid decay process due to recombination with geminate ions or radicals in the spur. We showed (2) that in pure alcohols at low temperatures the whole of the 'free' and 'spur' e_s^- could be observed, and presented time–concentration data for methanol and 1-butanol at 187 K demonstrating the amounts of these two contributions. In Fig. 2 we give the corresponding data for ethanol at 163 and 293 K. The dotted line is the 'free ion' contribution to the total e_s^-, obtained by extrapolation of the exponential decay. The kinetic separation of 'free' and 'spur' ions can easily be made at both temperatures even in neutral alcohols, and is made easier by the addition of base. Values of k_1 and the ratio of geminate to free ions (2) were obtained from analyses of the final, exponential portion of the decay of e_s^-, over ca. 3 half-lives. The initial ~10% of the free-ion decay was ignored in this analysis (i.e. the whole of the data in Fig. 2 would be excluded) to eliminate possible contributions from a small amount of spur decay still occurring on this timescale.

Reply: Lifetimes of the solvated electron in liquid alcohols

GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 7, 1977

GORDON R. FREEMAN. Can. J. Chem. **55**, 3059 (1977).

A reply is given to the preceding Comment concerning the kinetics of the decay of e_s^- in alcohols.

GORDON R. FREEMAN. Can. J. Chem. **55**, 3059 (1977).

On fait une réponse au commentaire qui précède concernant la cinétique de la décroissance du e_s^- dans des alcools.

The preceding comment by Baxendale and Wardman (1) focusses attention on the important and difficult problem of interpreting data when the kinetics of the reaction are not simple. The decay of electrons in irradiated alcohols follows nonhomogeneous kinetics inside the spurs and homogeneous kinetics outside the spurs. The decay outside the spurs is generally accepted to occur by pseudo-first-order reactions which, in a purified alcohol, are much slower than the spur reactions. The rate of the former is obtained from the tail of the optical absorption signal at long times. However, it is not always clear at what point the contribution of spur electrons to the absorption signal becomes negligible (see Fig. 2 of ref. 1). The earlier (2) discussion of this problem may have been obscured by the mass of other data in that paper.

As a basis for questioning the linearity of the Arrhenius plots (1) we gave a full column of discussion (2). It is also difficult to assess data for which the pulse dose has not been given. Qualitatively, Wardman lowered the dose as the temperature was lowered, because the longer decay times permitted greater electronic smoothing.[1] The resulting smaller amount of secondary reaction at lower pulse doses might tend to straighten the Arrhenius plot of the electron decay rate. On the other hand, we have stated (2) and Wardman has emphasized (1) that artifacts might also have caused the curvature we observed.

Solution to the problem requires further work.

Erratum: Electronic excited states of small ring compounds. IV. Bicyclo[2.1.0]pentanes by the photocycloaddition of cyclopropenes to olefins

D. R. ARNOLD AND R. M. MORCHAT

The Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received May 19, 1977

(Ref.: Can. J. Chem. **55**, 393 (1977))

Our inconsistent use of units on page 398 may cause confusion. The rate constants listed in Table 1 are given in units of s^{-1} as indicated. In the Arrhenius plot (Fig. 5) and for the kinetic parameter given, the rate constants are in units of min^{-1} (not indicated). The preexponential term is $\log A = 12.9 \pm 0.4\ s^{-1}$.

A template synthesis of nickel 6,8,15,17-tetramethyldibenzo[*b*,*i*][1,4,8,11]-tetraazacyclotetradeca-2,4,7,9,12,14-hexaene

A. R. CUTLER AND D. DOLPHIN

Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received April 21, 1977

A. R. CUTLER and D. DOLPHIN. Can. J. Chem. **55**, 3062 (1977).

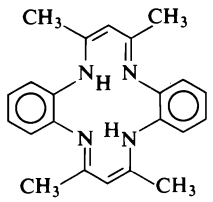
The title macrocyclic nickel complex has been conveniently prepared in moderate yield using 2,5-dimethyl-3*H*-1,5-benzodiazepine, or a mixture of *o*-phenylenediamine and pentane-2,4-dione in a template synthesis using nickel salts. The previous low yield synthesis of this macrocycle required condensation of nickel bisacetylacetonate in molten *o*-phenylenediamine.

A. R. CUTLER et D. DOLPHIN. Can. J. Chem. **55**, 3062 (1977).

Le complexe macrocyclique du nickel du titre est préparé avec un rendement moyen en utilisant la diméthyl-2,5 benzo[3*H*]diazépine-1,5 ou un mélange de *o*-phénylènediamine et de pentanedione-2,4 dans une synthèse modèle faisant intervenir des sels de nickel. La synthèse antérieure, à bas rendement de ce macrocycle, consiste en la condensation du bis-acétylacétonate de nickel dans la *o*-phénylènediamine fondue.

[Traduit par le journal]

Metal complexes of the fully conjugated macrocycle (**1**) are but one example of synthetic tetraaza macrocyclic complexes (1) that have gained importance as metalloporphyrin models (2). Synthetic entry into complexes of type **1** has



1

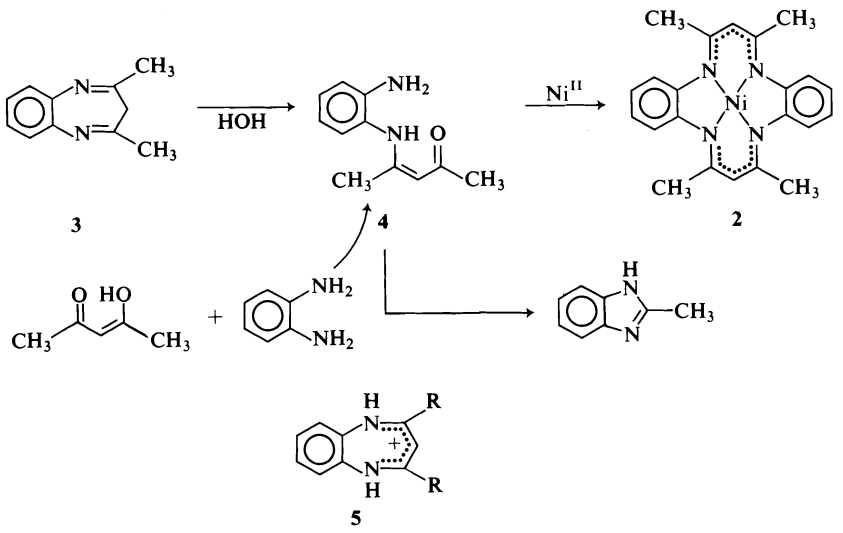
been limited by the availability of its nickel complex (**2**), which had previously been prepared in low yield from the reaction of nickel bisacetylacetonate in excess *molten* *o*-phenylenediamine (3). Removal of the nickel from **2** with acid, followed by remetallation, has then provided other metal complexes of **1** (4). We report here a convenient template synthesis of **2**.

The reaction of 2,4-dimethyl-3*H*-1,5-benzodiazepine (**3**) (5) and nickel(II) acetate (2:1) in refluxing aqueous ethanol gave a 31% yield of the emerald green nickel complex (**2**). Removal of solvent from this reaction mixture and washing with water left a green residue containing **2** and a magenta filtrate which contained nickel complexes of 2-methylbenzimidazole (6).[1] Similar work-up of a refluxing aqueous ethanol solution of *o*-phenylenediamine, pentane-2,4-dione, and nickel(II) acetate (2:2:1) provided a somewhat lower yield (15%) of **2**.

Similar reactions between the 2,4-dimethyl-1,5-benzodiazepinium salt (**5**) (R = CH_3) and nickel salts afforded only nickel complexes of 2-methylbenzimidazole. In contrast, the parent benzodiazepinium salt (**5**) (R = H) has been shown to undergo a stepwise template reaction, via the uncyclized nickel tetradentate complex of *N*,*N*′-di-(*o*-aminophenyl)-1-amino-3-iminopropene, to give the related nickel macrocyclic complex of 6,8,15,17-tetramethyldibenzo[*b*,*i*]-[1,4,8,11]tetraazacyclotetradeca-2,4,7,9,12,14-hexaene.

Formation of the nickel macrocyclic complex (**2**) under the above critical conditions involves two competing pathways via the monoanil intermediate (**4**). The monoanil (**4**) is the postulated intermediate for both the hydrolytic ring con-

[1]The yield of this reaction was evidently concentration dependent. Thus a decrease in the concentration of the reagents from that in the Experimental section greatly diminished the yield of **2**. In addition the choice of solvolytic conditions was critical and although this had not been optimized, substitution of either ethanol or water alone afforded only minor amounts of **2**.



traction of **3** to 2-methylbenzimidazole as well as for the condensation of *o*-phenylenediamine and pentane-2,4-dione to **3** (5, 8). Thus the monoanil (**4**) generated in our reactions either degrades to 2-methylbenzimidazole or undergoes a metal template cyclization to **2**.

It is hoped that the straightforward template synthesis of **2** and analogous macrocyclic complexes (7, 9) will increase their availability.

Experimental

Nickel acetate (12.443 g, 0.050 *M*) was added as a hot aqueous solution (40 ml) to an ethanolic solution of 2,4-dimethyl-3*H*-1,5-benzodiazepine (17.223 g, 0.100 *M*). The resulting magenta solution changed to an emerald green suspension after refluxing 4 h. Removal of solvent under reduced pressure and washing the greenish brown residue with water (200 ml) afforded a green solid. After air drying, the green solid, in a minimum volume of methylene chloride (60 ml), was added to a column of dry alumina (18 × 6 cm; Camag neutral, activity I, 160 g). Elution of this column with methylene chloride cleanly removed a dark green band containing the desired nickel macrocycle (**2**) (6.323 g, 31.5%). The nmr spectrum of the highly soluble **2** was especially diagnostic, $CDCl_3$(TMS) δ 2.19 (s, 12H, CH_3), 4.73 (s, 2H, CH), 6.61 (multiplet, 8H, Ar-H).

Crystal and molecular structure of 1,1′-bi(3,3,4,4-tetrafluoro-2-diphenylphosphinocyclobutene)

STEVEN J. RETTIG AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received February 2, 1977

STEVEN J. RETTIG and JAMES TROTTER. Can. J. Chem. **55**, 3065 (1977).

Crystals of 1,1′-bi(3,3,4,4-tetrafluoro-2-diphenylphosphinocyclobutene) are monoclinic, a = 10.398(1), b = 18.484(1), c = 15.984(1) Å, β = 107.76(1)°, Z = 4, space group $P2_1/c$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to a final R of 0.042 and R_w of 0.057 for 4226 reflections with $I \geq 3\sigma(I)$. The molecule has a *cisoid* configuration about the central C—C bond, the angle between the two cyclobutene rings being 34.3°. The overall molecular symmetry is approximately C_2 with a P...P separation of 3.661(1) Å. Bond lengths and angles in the molecule are generally in good agreement with accepted values.

STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **55**, 3065 (1977).

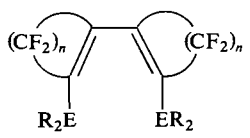
Les cristaux du bis-(tétrafluoro-3,3,4,4 diphénylphosphino-2 cyclobutène)-1,1′ sont monocliniques, a = 10.398(1), b = 18.484(1), c = 15.984(1) Å, β = 107.76(1)°, Z = 4, groupe d'espace $P2_1/c$. On a résolu la structure par les méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.042 et de R_w 0.057 pour 4226 réflexions avec $I \geq 3\sigma(I)$. La molécule a une configuration *cisoide* autours du lien C—C central; l'angle entre les deux cyclobutènes est de 34.3°. La symétrie moléculaire globale est approximativement C_2 avec une séparation P...P de 3.661(1) Å. Les longueurs de liens et les angles dans la molécule sont généralement en bon accord avec les valeurs acceptées.

[Tradiut par le journal]

Introduction

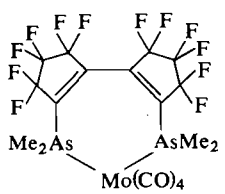
The preparation and physical properties of a series of ditertiary phosphines and arsines with bialicyclic, 'butadiene', bridging groups, **1**, have recently been reported (1). This work was initiated by the discovery that a complex with this type of bridging group can be isolated when $[(CH_3)_2AsC{=}CAs(CH_3)_2CF_2CF_2]Co_2(CO)_6$ is warmed in solution (2, 3). Several metal carbonyl complexes were obtained from these new ligands and one of them, $(bif_{12}fars)Mo(CO)_4$, **2**, has been characterized by X-ray analysis (1).

Compound **1***b*, the ditertiary phosphine, has the unusual property of photochromism in the solid state. In the dark, the crystals are yellow, but turn bright orange-red when exposed to sunlight. The process is reversible (at a slower rate) provided the exposure has not been too great. A crystal structure analysis of **1***b* has been undertaken in the hope that the photochromic nature of the molecule might be explained by some feature of the structure.



1

a $R_2E = (CH_3)_2As$, $n = 2$
b $R_2E = (C_6H_5)_2P$, $n = 2$
c $R_2E = (CH_3)_2As$, $n = 3$



2

Experimental

The crystal chosen for study was mounted with (1 0 −6) normal to the goniostat axis and had dimensions of ca. 0.4 × 0.5 × 1.0 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least squares on 2 sin θ/λ values for 21 reflections measured on a diffractometer with CuKα radiation (λ = 1.5418 Å). Crystal data (at 22°C) are:

$C_{32}H_{20}F_8P_2$ fw = 618.5
Monoclinic, a = 10.398(1), b = 18.484(1), c = 15.984(1) Å, β = 107.76(1)°, V = 2925.4(4) Å^3, Z = 4, ρ_c = 1.4041(2) g cm^{-3}, $F(000)$ = 1256, μ(CuKα) = 20.1 cm^{-1}. Absent reflections: $h0l$, $l \neq 2n$ and $0k0$, $k \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with nickel-filtered CuKα radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 4° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed; 10 s background counts were measured at each end of the scan. Data were measured to 2θ = 146°. The intensities of the check reflections, measured every 50 reflections throughout the data collection, decreased uniformly to final values which were 80% of the initial values. Lorentz and polarization corrections and batch check reflection scaling were applied, and the structure amplitudes were derived. No absorption correction was made (maximum error in $|F_o|$ about 5%, apart from a few planes with extreme path lengths). Of the 5846 independent reflections measured, 4246 (73%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + B + (dS)^2$ with S = scan count, B = time averaged background count, and d = 0.06 (the relatively high value of d was required to give a satisfactory weighting scheme in the final refinement).

The structure was solved by direct methods. Eight sets of signs for 500 reflections with $|E| \geq 1.69$ were determined by a computer program which uses Sayre relationships in an iterative procedure (4). One set of signs was outstanding in that it converged in six cycles to a set having the highest consistency index (0.93). Forty of the 42 non-hydrogen atoms were located on an E map calculated from this set of signs.

The 40 atoms located on the E map were refined by full-matrix least-squares procedures giving R = 0.179. An electron density difference map gave the positions of the two remaining carbon atoms. All 42 non-hydrogen atoms were refined isotropically for two cycles, and then anisotropically for two cycles reducing R to 0.065. A second difference map, calculated at this point, gave positions for all 20 hydrogen atoms which were included in all subsequent cycles of refinement with isotropic temperature factors. The entire structure (460 variables, full-matrix) was refined for four cycles giving a final R of 0.042 and R_w of 0.057 for 4226 reflections with $I \geq 3\sigma(I)$ (20 reflections which had $|F_o| - |F_c| > 3\sigma(F)$ were treated as unobserved in the final stages of refinement; instrumental error was suspected for these reflections, but it seemed unwise to bias the data by remeasuring them; none of the disagreements were exceptionally bad). For all 5846 reflections R = 0.060 and R_w = 0.066.

The least-squares refinement was based on the minimization of $\Sigma w[|F_o| - |F_c/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was 6.3 × 10^{-8}. The scattering factors of ref. 5 were used for the non-hydrogen atoms and those of ref. 6 for the hydrogen atoms. Anomalous scattering factors from ref. 7 were used for the non-hydrogen atoms. The weighting scheme $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

On the final cycle of refinement some parameter shifts (particularly for hydrogen atoms associated with the C(27)—C(32) phenyl ring) were significant. The mean error in an observation of unit weight was 1.277. A final difference map showed maximum fluctuations of ±0.28 e Å^{-3} in the vicinity of the phosphorus atoms and ±0.16 e Å^{-3} elsewhere. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation (**T**), libration (**L**), and screw (**S**) motion (8) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0015 Å^2. Analyses were physically reasonable for the four phenyl groups C(9)—C(14) and P(1), C(15)—C(20) and P(1), C(21)—C(26) and P(2), and C(27)—C(32) and P(2) (rms ΔU_{ij} = 0.0017, 0.0023, 0.0020, and 0.0031 Å^2 respectively) and for the 10 atom group P(1), P(2), C(1)—C(8) (rms ΔU_{ij} = 0.0029 Å^2).

The appropriate bond distances have been corrected for libration (9, 10), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3[1] along with the uncorrected values.

Results and Discussion

Figure 1 shows a general view of the molecule with the crystallographic numbering scheme and Fig. 2 shows the packing arrangement viewed along a^*. Bond angles are given in Table 4[1] and deviations of atoms from weighted least squares mean planes in Table 5.[1] Selected inter- and intramolecular non-bonded distances are listed in Table 6.[1]

The 1,1′-bi(3,3,4,4-tetrafluoro-2-diphenylphosphinocyclobutene) molecule, **1***b*, has a *cisoid* configuration about the central C(2)—C(6) bond, the angle between normals to the two cyclobutene mean planes being 34.3°. The over-

[1]The structure factor table and Table 2 (thermal parameters), 3*b* (bond distances involving hydrogen), 4*b* (bond angles involving hydrogen), 5 (mean planes), and 6 (non-bonded distances) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

all molecular symmetry is approximately C_2, the most obvious departure from C_2 symmetry being the orientation of the phenyl rings (torsion angles about the P—Ph bonds are: C(1)[P(1)—C(9)]C(14), 34.5(2), C(1)[P(1)—C(15)]C(20), 77.3(2), C(5)[P(2)—C(27)]C(32), 12.1(2), and C(5)[P(2)—C(21)]C(26), −75.8(2)°). The arsine ligand in **2** has exact C_2 symmetry and an As... As separation of 3.636 Å, close to the value of 3.661(1) Å for the P...P distance in the present structure.

Both cyclobutene rings are slightly, but significantly, nonplanar (see Table 5), with bond angles ranging from 85.9 to 94.8°. The mean[2] bond lengths (averaged assuming C_2 symmetry) in the cyclobutene rings (1.362(1), 1.490(4), 1.537(3), and 1.507(1) Å) may be compared to those in gaseous perfluorocyclobutene (1.342(6), 1.508(3), and 1.595(assumed) Å) (11). The C(sp^3)—C(sp^3) single bond (1.537 Å) is short compared to the values of 1.55–1.60 Å usually found in four-membered rings (see e.g. ref. 12 for numerous examples). The mean C—F bond distance of 1.350(5) Å is as expected. The geometry of the bi(cyclobutene) moiety indicates essentially localized double bonds. The shortening of the C(2)—C(6) (1.445(3) Å), C(1)—P(1) (1.804(2) Å), and C(5)—P(2) (1.798(2) Å) bonds relative to the distances of 1.485 and 1.828 Å (13) usually expected for C(sp^2)—C(sp^2) and C(sp^2)—P(tertiary) single bonds is believed to result primarily from σ-hybridization effects (14).

One of the four phenyl rings is rigorously planar within experimental error while the other three show small, but significant, deviations from planarity (see Table 5). Bond lengths and angles in the C_6H_5P groups are equal, within experimental error, to the mean values quoted for phenyl derivatives of trivalent phosphorus and their coordination compounds (13). The mean C(ar)—H distance of 0.95(8) Å is as expected for X-ray data.

The crystal structure of 1,1′-bi(3,3,4,4-tetrafluoro-2-diphenylphosphinocyclobutene) (see Fig. 2) consists of well-separated molecules. The shortest intermolecular distances (listed in Table 6) correspond to normal van der Waals interactions.

[2]Here and elsewhere in this paper, mean values refer to weighted means with rms deviations from the mean in parentheses.

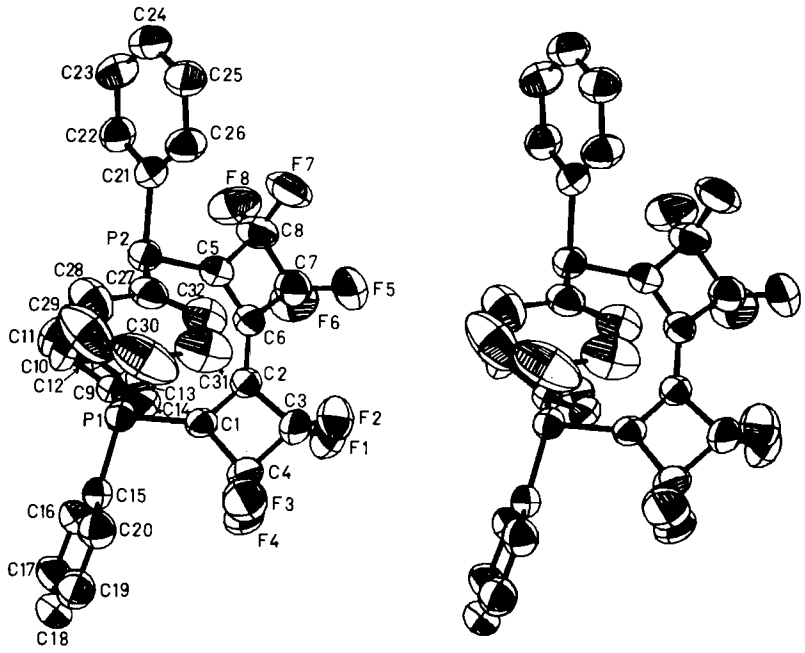

FIG. 1. A stereo view of the 1,1′-bi(3,3,4,4-tetrafluoro-2-diphenylphosphinocyclobutene) molecule; 50% ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been omitted for clarity.

The crystal structure reveals no unusual features which could definitely explain the photochromic behavior of the compound. Crystals of the orange-red material obtained by irradiation (with light or X rays) gave the same diffraction pattern as the original yellow crystals, so that any structural change must be small. One of the phenyl rings, C(27)—C(32), exhibits fairly large thermal vibration, which might suggest a possible rotation of the four-membered rings about the C(2)—C(6) bond, with consequent increase in electron delocalization, and hence color change. The lone-pair electrons of P(1) point towards the phenyl group, and the bis(phosphine oxide) of **1***b* is colorless, suggesting that the phosphorus lone pairs are involved. However, it is not yet understood why the compound should be colored at all (1).

Acknowledgments

We thank Prof. W. R. Cullen and Dr. A. W. Wu for suggesting the problem, providing the sample, and helpful discussion. We are indebted to the University of British Columbia Computing Centre for assistance and to the National Research Council of Canada for financial support.

Crystal and molecular structure of phenylboronic acid, $C_6H_5B(OH)_2$

STEVEN J. RETTIG AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received April 1, 1977

STEVEN J. RETTIG and JAMES TROTTER. Can. J. Chem. **55**, 3071 (1977).

Crystals of phenylboronic acid are orthorhombic, $a = 17.9049(7)$, $b = 15.3264(5)$, $c = 9.8113(2)$ Å, $Z = 16$, space group *Iba*2. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to a final R of 0.031 and R_w of 0.041 for 1409 reflections with $I \geq 3\sigma(I)$. The asymmetric unit consists of two independent molecules linked by a pair of O—H...O hydrogen bonds. Each dimeric unit is also hydrogen bonded to four other such units (at $z \pm \frac{1}{2}$) to form an infinite array of layers which stack along the c axis. Mean bond lengths corrected for libration (rms deviations from the mean in parentheses) are: O—B, 1.371(7), B—C, 1.565(3), and C—C(phenyl), 1.394(11) Å.

STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **55**, 3071 (1977).

Les cristaux de l'acide phénylboronique sont orthorhombiques, $a = 17.9049(7)$, $b = 15.3264(5)$, $c = 9.8113(2)$ Å, $Z = 16$, groupe d'espace *Iba*2. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.031 et R_w de 0.041 pour 1409 réflexions avec $I \geq 3\sigma(I)$. L'unité asymétrique comprend deux molécules indépendantes liées par une paire de ponts hydrogène O—H...O. Chaque unité dimère est aussi liée par des ponts hydrogène à quatre autres unités semblables (avec $z \pm \frac{1}{2}$) pour former un arrangement infini de couches qui sont superposées le long de l'axe c. Les longueurs moyennes de liaison corrigées pour la libration (les déviations rms à partir de la moyenne sont entre parenthèses) sont O—B, 1.371(7), B—C, 1.565(3) et C—C(phényle), 1.394(11) Å.

[Traduit par le journal]

Introduction

The structures of a number of esters and other derivatives of the organoboron acids R_2BOH and $RB(OH)_2$ have recently been reported (1–9). Two of these structures contain trigonally coordinated boron atoms (1, 2) while the other molecules feature tetrahedrally coordinated boron, occurring via intramolecular N → B (3, 4, 6, 8, 9) or O → B (5, 7) interactions. There is, however, little structural information available on the parent acids. Only one structure, that of $4\text{-}BrC_6H_4B(OH)_2$ (10), has been determined, but the presence of bromine obscures the structural details of the boron coordination group. In order to provide accurate geometrical parameters for a free organoboron acid the crystal structure of phenylboronic acid, $C_6H_5B(OH)_2$, has been determined.

Experimental

Crystals of phenylboronic acid (Alfa Inorganic) suitable for X-ray analysis were obtained by recrystallization from water. The crystal chosen for study was mounted with c parallel to the goniostat axis and had dimensions of ca. 0.36 × 0.40 × 0.93 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least squares on 2 sin θ/λ values for 17 reflections measured on a diffractometer with CuKα radiation (λ = 1.5418 Å). Crystal data (at 22°C) are:

$C_6H_7BO_2$ fw = 121.93

Orthorhombic, $a = 17.9049(7)$, $b = 15.3264(5)$, $c = 9.8113(2)$ Å, $V = 2692.4(1)$ Å^3, $\rho_m = 1.18$ (flotation in aqueous KI), $Z = 16$, $\rho_c = 1.203$ g cm^{-3}, $F(000) = 1024$, $\mu(CuK\alpha) = 7.18$ cm^{-1}. Absent reflections: hkl, $h + k + l \neq 2n$; $0kl$, $k \neq 2n$; and $h0l$, $h \neq 2n$. Space group *Iba*2 (C_{2v}^{21}, No. 45).

Intensities were measured with nickel-filtered CuKα radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 4° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed; 10 s background counts were measured at each end of the scan. Data were measured to 2θ = 160°. The intensities of two check reflections, measured every 50 reflections throughout the data collection, decreased slowly to a value which was 0.91 times the initial value. Lorentz and polarization corrections and batch check reflection scaling were applied, and the structure amplitudes were derived. An absorption correction was applied by a computer program using a Gaussian integration method (11, 12). Transmission factors ranged from 0.631 to 0.794. Of the 1563 independent reflections measured, 1419 (91%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time averaged background count. These reflections were used in the solution and refinement of the structure.

The systematic absences allow space groups *Iba*2 or

Ibam, the former being indicated by the E statistics. The structure was solved by direct methods (13–15). The positions of the 18 non-hydrogen atoms were located among the 19 highest peaks on an E map calculated from the set of phases with the lowest value of R_k.

Two cycles of isotropic followed by three cycles of anisotropic full-matrix least-squares refinement of the non-hydrogen atoms gave $R = 0.064$. The z coordinate of O(1) was fixed to determine the origin. The positions of all 14 hydrogen atoms were located on a difference map at this point. The entire structure (including hydrogen atoms with isotropic thermal parameters) was refined for six cycles giving a final R of 0.031 and R_w of 0.041 for 1409 reflections with $I \geq 3\sigma(I)$ (10 reflections which had $|F_o| - |F_c| > 3\sigma(F)$ were treated as unobserved in the final stages of refinement; for all 1563 reflections $R = 0.036$ and $R_w = 0.044$).

The least-squares refinement was based on the minimization of $\Sigma w[|F_o| - |F_c/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was $9.0(6) \times 10^{-8}$. The scattering factors of ref. 16 were used for the non-hydrogen atoms and those of ref. 17 for the hydrogen atoms. Anomalous scattering factors from ref. 18 were used for the non-hydrogen atoms. The weighting scheme: $w = 1.0$ if $|F_o| < 10.0$, $w = (10.0/|F_o|)^2$ if $|F_o| \geq 10.0$, and $w = 0.0625$ for the unobserved reflections gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

On the final cycle of refinement the mean parameter shift was 0.09σ, with no shift greater than 0.65σ. The mean error in an observation of unit weight was 0.3556. A final difference map showed maximum fluctuations of ± 0.3 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The positive z direction (for the particular crystal used) has been determined through the anomalous scattering of the non-hydrogen atoms. Structure A is represented by the coordinates in Table 1 referred to a right-handed axial system and structure B, the mirror image of A, was generated by changing the z coordinates of A to $1 - z$. Both structures were refined and Hamilton's test (19) applied to the resulting R factor ratios. The ratios (B/A) and the percentage probabilities that A is the correct structure are: 1.0009 (90%) for R (all data), 1.0002 (50%) for R (3σ data), 1.0017 (95%) for R_w (all data), and 1.0017 (95%) for R_w (3σ data).

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation (**T**), libration (**L**), and screw (**S**) motion (20) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0011 Å^2. Analyses were successful for each of the two independent molecules (rms $\Delta U_{ij} =$ 0.0024 and 0.0025 Å^2 for molecules 1 and 2 respectively).

[1]The structure factor table and Tables 2 (thermal parameters), 3*b* (individual bond lengths involving H), and 4*b* (individual angles involving H) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

The appropriate bond distances have been corrected for libration (21, 22), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3[1] along with the uncorrected values. Corrected bond angles differ by less than 1 standard deviation from the uncorrected values listed in Table 4.[1]

Results and Discussion

Figure 1 shows a view of the asymmetric unit with the crystallographic numbering scheme and Fig. 2 shows a view down b of the basic repeating structural unit. Details of the hydrogen bonding scheme are given in Table 5.

The asymmetric unit (Fig. 1) consists of two molecules of phenylboronic acid linked by a pair of O—H...O hydrogen bonds. Each of these dimeric units is hydrogen bonded to four other such units (at $z \pm \frac{1}{2}$) to form an infinite array of layers which stack along c. The basic repeating structural unit, including the interlayer hydrogen bonding, is shown in Fig. 2. The two dimeric units which make up each layer are related by the

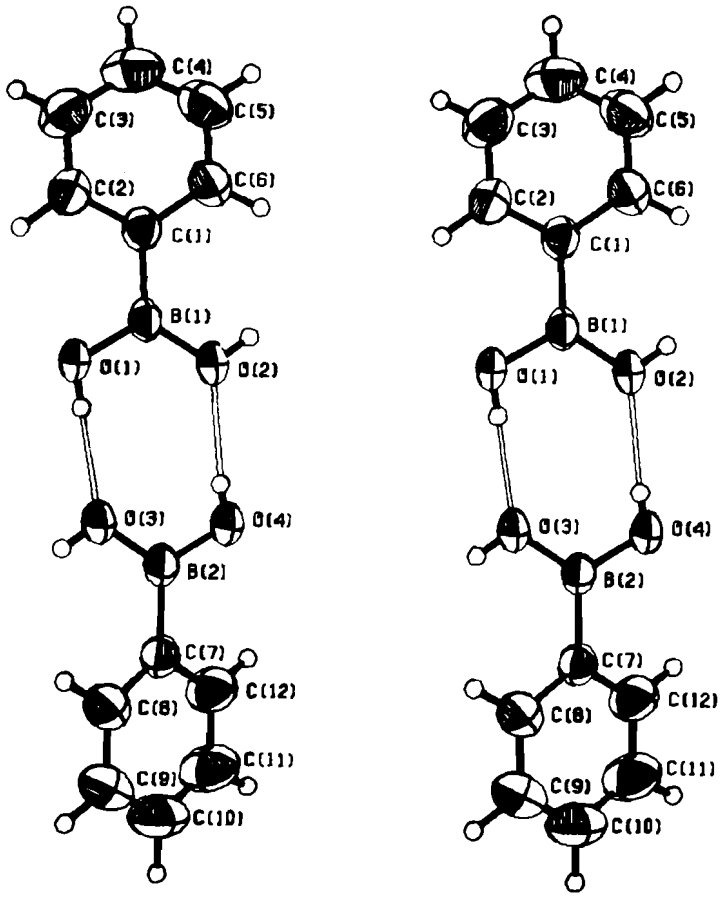

FIG. 1. A stereo view of the asymmetric unit of phenylboronic acid; 50% ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

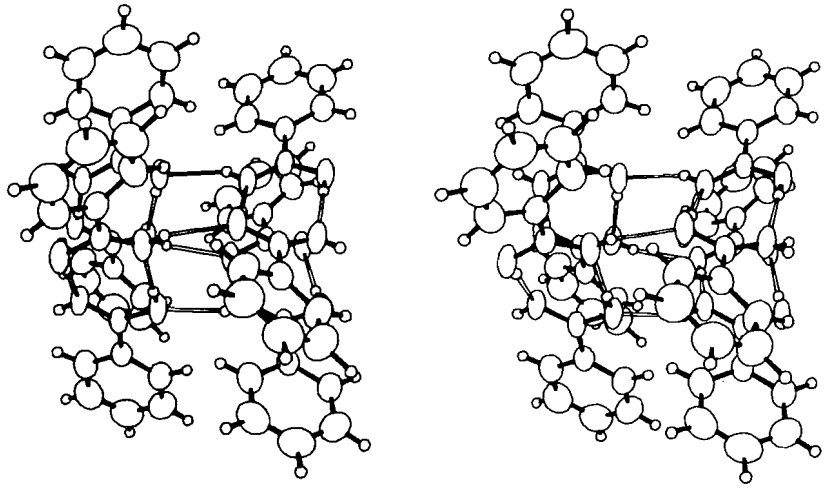

FIG. 2. The basic repeating structural unit of phenylboronic acid viewed down *b*. Unshaded bonds represent hydrogen bonds.

*Superscripts refer to atoms at positions: [1] $x, 1-y, \frac{1}{2}+z$; [2] $1-x, y, z-\frac{1}{2}$.

twofold axis ($\frac{1}{2}$, $\frac{1}{2}$, z) and are not directly hydrogen bonded to one another. Alternate layers are related by *c* glide planes and the dimers in each layer are bridged (via hydrogen bonds) by both dimers in the adjacent layers. There are two well-separated 'stacks' of molecules in the unit cell, related by the *I* centering.

The most obvious difference between the two molecules is in the orientation of the phenyl ring, twisted 6.6° with respect to the boron co-

ordination group in molecule 1 and 21.4° in molecule 2. The phenyl rings and boron coordination groups of both molecules are slightly, but significantly, nonplanar. B(1) and B(2) deviate by 0.009(2) and 0.012(2) Å from the respective OOC planes, and by 0.061(2) and 0.021(2) Å from the phenyl mean planes.

The bond angles at the trigonal planar boron atoms are distorted from ideal values in a manner which makes all of the hydrogen bonds more linear. The C(1)—B(1)—O(1) and C(7)—B(2)—O(4) angles (118.7(2) and 119.7(2)°) are significantly smaller than C(1)—B(1)—O(2) and C(7)—B(2)—O(3) (125.0(2) and 124.0 (2)°). The two independent O—B—O angles (116.3(2) and 116.2(2)°) are equal within experimental error. The two B—O distances in molecule 1 are significantly different while those in molecule 2 are not. The mean[2] B—O distance of 1.371(6) Å is somewhat shorter than the bond in 2-phenyl-1,3,2-benzodioxaborol (1.394(3) Å (1)), between the values of 1.337(2) and 1.404(2) Å in 8,8-dimethyl-3,5-diphenyl-2,4,6-trioxa-1-azonia-3-bora-5-boranatabicyclo[3.3.0]octane (2), and in good agreement with the mean value of 1.36 Å in $BrC_6H_4B(OH)_2$ (10). The B—C distances in the present structure (1.563 and 1.568 Å) lie between those in the above-mentioned molecules (1.537(6), 1.557(2), and 1.54 Å respectively) and those in Ph_3B (23) of 1.571(3) and 1.589(5) Å.

The corrected C—C distances in the phenyl rings range from 1.374(5) to 1.410(3) Å with a mean value of 1.394 Å. As in related molecules (e.g. ref. 2), the bond distances in the phenyl rings decrease as they are removed from the boron substituent (mean values are 1.405(4), 1.392(3), and 1.381(6) Å). This variation of bond lengths, as well as the pattern of bond angles in the phenyl rings, is consistent with that in related compounds (24). Distances and angles involving hydrogen atoms are as expected for X-ray data.

^{125}Te Mössbauer spectra of the polyatomic cations of tellurium

C. H. W. JONES

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received March 14, 1977

C. H. W. JONES. Can. J. Chem. **55**, 3076 (1977).

^{125}Te Mössbauer data for frozen solutions of tellurium in HSO_3F and in oleum are reported together with data for solid samples which may have contained the Te_4^{2+}, Te_n^{n+}, and Te_6^{2+} cations. The data demonstrate that the quadrupole splitting reflects the sequential oxidation of the tellurium through the steps Te → Te_4^{2+} → Te_n^{n+} → Te(II) → Te(IV) → TeO_2. The quadrupole splittings for samples identified as containing Te_4^{2+} are consistent with a unit quadrupole splitting of 12 mm s^{-1} for ^{125}Te.

C. H. W. JONES. Can. J. Chem. **55**, 3076 (1977).

On rapporte des données de Mössbauer du ^{125}Te pour des solutions congelées de tellure dans HSO_3F et dans l'oléum de même que des données pour des échantillons solides qui pourraient contenir des cations Te_4^{2+}, Te_n^{n+} et Te_6^{2+}. Les données démontrent que les couplages quadrupolaires sont un reflet de l'oxydation en séquence du tellure par l'intermédiaire des étapes Te → Te_4^{2+} → Te_n^{n+} → Te(II) → Te(IV) → TeO_2. Les couplages quadrupolaires pour les échantillons qui sont identifiés comme contenant du Te_4^{2+} sont en accord avec un couplage quadrupolaire unitaire de 12 mm s^{-1} pour le ^{125}Te.

[Traduit par le journal]

Introduction

The formation and properties of the polycations of the Group VI elements have been reviewed by Gillespie and Passmore (1, 2). In particular, tellurium is known to form the red cation Te_4^{2+} in sulphuric and fluorosulphuric acid solutions (3, 4) and also on reaction with sulphur trioxide (5). Crystallographic studies of $Te_4(AlCl_4)_2$ and $Te_4(Al_2Cl_7)_2$ have established that the Te_4^{2+} ion is square-planar in geometry (6). On oxidation of the Te_4^{2+} ion in acid solution or in SO_3, a yellow diamagnetic ion Te_n^{n+}, which is possibly Te_4^{4+}, Te_6^{6+}, or Te_8^{8+}, is formed. Further oxidation produces a colorless Te(IV) species in solution and finally, in sulphuric acid solution, TeO_2 precipitates out (3). More recently the preparations and crystal structures of the compounds $Te_2Se_8(AsF_6)_2 \cdot SO_2$ and $Te_{3.7}Se_{6.3}(AsF_6)_2$ have been reported (7).

The reaction of tellurium with arsenic and antimony pentafluorides yields a number of solid derivatives of the Te_4^{2+} and Te_n^{n+} ions (3, 4) and the compound with the empirical formula Te_3AsF_6 has also been identified. The latter is diamagnetic and hence may be formulated as $Te_6^{2+}(AlF_6^-)_2$ (3). A single crystal X-ray diffraction study (8) of the compound $Te_6(AsF_6)_4 \cdot 2AsF_3$ has shown the presence of the cation Te_6^{4+}, which is a trigonal prismatic cluster cation.

The study of the phases formed in the system Te–$TeCl_4$–$AlCl_3$ has led to the identification (6) of the compounds $Te_4(AlCl_4)_2$ and $Te_4(Al_2Cl_7)_2$ referred to above and also to that of the compound $Te_6(AlCl_4)_2$ (9).

The present work was initiated to determine whether or not ^{125}Te Mössbauer spectroscopy could be used to distinguish between these different tellurium polycations and perhaps throw some light on the nature of the bonding in the Te_n^{n+} and Te_6^{2+} ions. The Mössbauer parameters for the Te_4^{2+} ion were also of some considerable interest because the structure of this ion is known and it was important to establish whether or not the data for this simple ion would support the previous models that we have used in interpreting quadrupole splittings in ^{125}Te Mössbauer spectra (10, 11).

Results and Discussion

Typical spectra are shown in Fig. 1 and the computed Mössbauer parameters are given in Table 1. Where more than one result is reported for any one compound or ion these represent independent measurements on separately prepared samples. For the solutions of tellurium in HSO_3F, the first sample prepared gave rather broad line-widths and the subsequent samples studied were prepared with less ^{125}Te present. This was also the case for the spectrum of the oxidation product of tellurium formed on warming in oleum.

It is clear from Table 1 that on dissolving tellurium in cold HSO_3F, the Mössbauer spec-

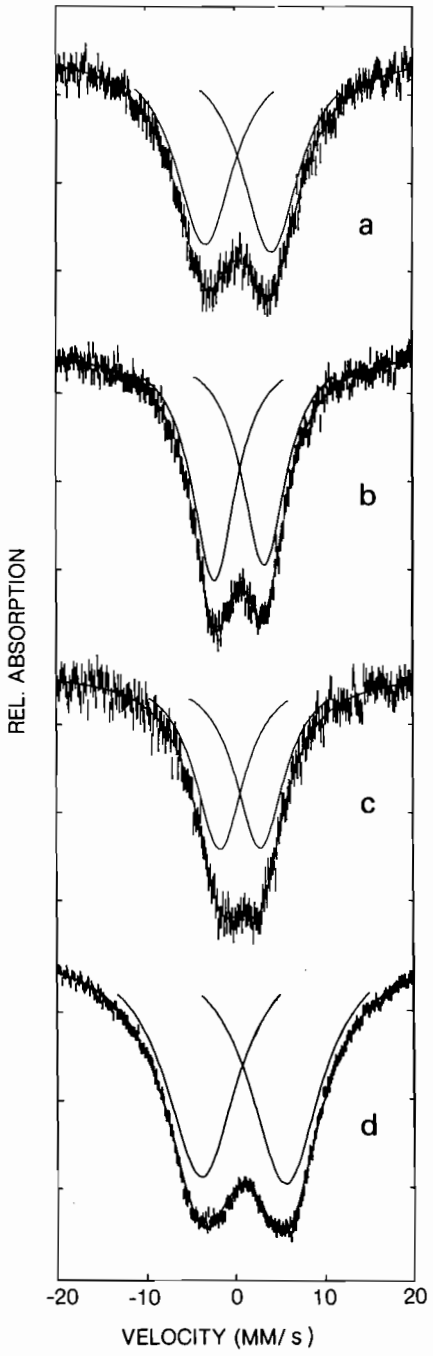

FIG. 1. ^{125}Te Mössbauer spectra for (*a*) Te, (*b*) Te in HSO_3F (Te_4^{2+}), (*c*) Te in 45% oleum (Te_n^{n+}), (*d*) Te in 45% oleum on warming (Te(II)).

trum of the frozen solution was significantly different from that of the elemental tellurium itself. Within the errors, the observed parameters for $Te_4(Sb_2F_{11})_2$, $Te_4(AlCl_4)_2$, and $Te_4(AsF_6)_2$ were in reasonable agreement with those of the HSO_3F frozen solutions.

Taking the average of the values for the HSO_3F solutions and the solids containing the Te_4^{2+} ion, the values $\delta = +0.44$ and $\Delta = 6.1$ mm s^{-1} for the Te_4^{2+} ion are arrived at. The Te_4^{2+} ion in $Te_4(AlCl_4)_2$ and $Te_4(Al_2Cl_7)_2$ is known (6) to be square-planar with bond-angles very close to 90° and bond-lengths of ca. 2.66 Å, which are shorter than those in elemental tellurium (2.864 Å). A simple description of the bonding would suggest that each tellurium contributes one 5*p* electron to each σ-bond in the (*xy*) plane, and that each tellurium possesses on average 1.5 electrons in the $5p_z$ orbital directed out of the plane, the p_z orbitals participating in π-bonding around the ring. This picture would suggest that V_{zz} the principal component of the efg tensor would be negative in sign and that in the Townes and Dailey theory the *p*-orbital imbalance, U_p, would be −0.5. Since Δ is 6.0 mm s^{-1} for Te_4^{2+} it follows that the quadrupole splitting for an imbalance of one 5*p* electron in ^{125}Te should be 12.0 mm s^{-1}. This value is in excellent agreement with our previous estimate of this parameter based on an analysis of the isomer shifts of the TeX_6^{2-} ions (X = Cl, Br, I) and the δ and Δ values of the Te(II) thiourea complexes (10, 11).

The isomer shift of Te_4^{2+} is a little more positive than that of elemental tellurium. Removal of 5*p*-electron density from tellurium results in deshielding of the 5*s*-electrons from the nucleus and increases the isomer shift by ca. +0.4 mm s^{-1} per 5*p* electron, while removal of 5*s*-electron density directly decreases δ (10). Assuming that the bonding in elemental tellurium is itself predominantly *p* in character, the removal of *p*-electron density on oxidation of Te^0 to $Te^{+1/2}$ would be expected to have only a small effect on the isomer shift, and, within the large errors, this appears to be the case.

A solution of tellurium in cold H_2SO_4 yielded a Mössbauer spectrum with a significantly smaller quadrupole splitting than Te_4^{2+}. The parameters for the H_2SO_4 solution were subsequently found to be very similar to those of solid derivatives thought to contain the yellow Te_n^{n+} cation. Solutions of tellurium in H_2SO_4 always contain both Te_4^{2+} and Te_n^{n+} and it would appear that, while the solutions were red in color, the yellow Te_n^{n+} ion predominated in the present case. There was no evidence in the spectrum for the presence of appreciable amounts of Te_4^{2+}. A solution of tellurium in

§χ^2 divided by the number of degrees of freedom, N.

oleum, which on prolonged standing turned orange, also gave a quadrupole splitting comparable with the H_2SO_4 solution and this is again tentatively identified as corresponding to the Te_n^{n+} ion. There is little question that the quadrupole splittings of these latter samples were all consistently smaller than those corresponding to the Te_4^{2+} ion, and that the isomer shift was consistently more positive, corresponding to an increase in oxidation state and a net removal of 5*p*-electron density from the tellurium.

A number of possible structures for the Te_n^{n+} ion are discussed in ref. 3. In the light of the known structure of the Te_6^{4+} ion, which is a trigonal prismatic cluster cation, it has been proposed that Te_n^{n+} is probably Te_6^{6+} and has the structure shown in Fig. 2*i*. The presence of a small quadrupole splitting in the Mössbauer spectrum is not inconsistent with that structure. The 60% bond angles within the triangular ring suggests the presence of bent bonds which lie off the interatomic axes. The bonding could be predominantly *p* in character and the small *p*-orbital imbalance would derive from the difference between the bonding within and between the triangular rings. The small increase in δ over that in tellurium and the Te_4^{2+} cation is consistent with the presence of predominantly *p*-character in the bonds.

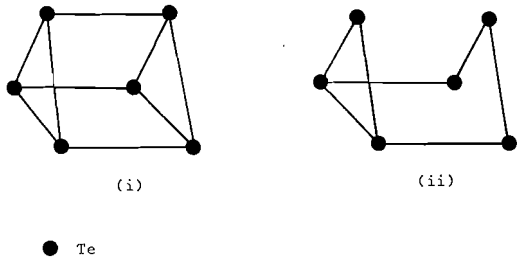

FIG. 2. Proposed structures (8) for Te_n^{n+} (i.e. Te_6^{6+}) and Te_6^{2+}. For the latter, 3 resonance forms may contribute to the structure.

On warming a solution of tellurium dissolved in oleum, a very marked increase in the quadrupole splitting was observed for the frozen solution, together with an increase in line-width. Attempts to fit the spectra to more than one pair of doublets yielded poorer fits to the data than that reported here. The broad line-widths and the poor χ^2 values suggest the presence of a spectrum of products with varying hyperfine parameters. The increase in Δ is consistent with oxidation of the tellurium to a Te(II) derivative, compounds which in general exhibit quadrupole splittings from 10 to 15 mm s^{-1}.

Following further heating, the spectrum of the frozen solution exhibited a significant decrease in Δ and an increase in δ, consistent with further oxidation of the tellurium to a Te(IV) species.

The decrease in Δ reflects the participation of all three 5*p* orbitals in bonding, in contrast with Te(II) compounds, and the increase in δ the increased withdrawal of *p*-electron density and a concomitant increase in the *s*-electron density at the nucleus.

Finally, TeO_2 precipitated out and the somewhat smaller isomer shift for this compound is consistent with that generally found for Te(IV) oxides and oxyanions in the solid state, reflecting some stereochemical activity of the 5*s* electrons (10).

From these experiments it appears that the Mössbauer quadrupole splitting reflects the step by step oxidation of the tellurium:

$$Te \rightarrow Te_4^{2+} \rightarrow Te_n^{n+} \rightarrow Te(II) \rightarrow Te(IV) \rightarrow TeO_2$$

	Value					
Parameter	Te	Te_4^{2+}	Te_n^{n+}	Te(II)	Te(IV)	TeO_2
Δ (mm s^{-1})	7.8	6.1	4.6	10.3	6.0	6.2
δ	+0.35	0.43	0.58	0.70	0.96	0.67

The isomer shifts for ^{125}Te are small because of the small value of $\Delta R/R$ for this transition. As a result the changes in δ are less useful in characterizing the change in chemical form of the tellurium. However, with the exception of TeO_2, the δ values show a trend to increasing (more positive) δ values with increasing oxidation state. This suggests that the 5*s* electrons are predominantly stereochemically inactive and that the electrons removed are primarily 5*p* in character.

Prince *et al.* (9) have prepared the compound $Te_6(AlCl_4)_2$ through the reaction

$$11Te + TeCl_4 + 4AlCl_3 \rightarrow 2Te_6(AlCl_4)_2$$

A ^{125}Te enriched sample prepared in this way yielded the parameters shown in Table 1. The quadrupole splitting is again significantly different from that of the other tellurium ions studied. While the line-width was rather broad, there is no conclusive evidence for the presence of more than one tellurium site in the sample. The broad line-width for this sample may have arisen from the presence of tellurium. A structure which has been suggested for this ion is shown in Fig. 2*ii*.

A crystal structure of Te_6^{2+} has not been reported but $Te_2Se_4^{2+}$ and $Te_3S_3^{2+}$ have been demonstrated (12) to have a six-membered boat-shaped ring structure with a Te—Te cross-ring bond, similar to that of Fig. 2(*ii*). The Te_6^{4+} ion may be viewed as a boat-shaped ring with two cross-ring bonds (8). In the Te_6^{2+} ion three resonance structures of the form shown in Fig. 2*ii* may contribute to the structure, in which case all six tellurium atoms would have similar environments. A similar situation has been found to hold for Te_6^{4+} (12).

The isomer shift of +0.3 mm s^{-1} (Table 1) is consistent with a small charge on the tellurium. The quadrupole splitting of 8.7 mm s^{-1} is greater than that proposed for tellurium in the Te_n^{n+} ion. Assuming the Te_n^{n+} and Te_6^{2+} ions to have the structures shown in Fig. 2(*i*) and (*ii*) respectively, a greater *p*-orbital imbalance would be expected for Te_6^{2+}.

With regard to the experiments where frozen solutions were studied, there is clearly some uncertainty as to whether the species being studied was present in a frozen glass or whether a compound had crystallized out of solution. However, since the Mössbauer parameters for ^{125}Te appear to be primarily determined by the valence orbital populations of the tellurium, and that lattice terms do not appear to be important, the similarity between the results for the frozen solutions and the solid compounds for the same tellurium cation was to be expected.

Experimental
