Discussion

G. A. Kenney-Wallace: In a recent laser photolysis study of optical absorption coefficients for e_s^- in a series of alcohols, at the absorption maximum for electrons solvated in methanol we find a value of about 10 700 M^{-1} cm^{-1}, in agreement with Freeman's value of 10 200 M^{-1} cm^{-1}, Ward's value of 10 000 M^{-1} cm^{-1}, and the data of Dorfman *et al.* if the higher free ion value is used. Therefore your relatively high absorption coefficient implies to me that the free ion value you determine is possibly too low.

G. A. Salmon: The question of $G(e_s^-)_{fi}$ and $\varepsilon_{\lambda max}$ is, of course, intrinsically related since by pulse radiolysis one can only measure the product. Therefore, if you believe $G(e_s^-)_{esc} = 2.0$ you will of course obtain a lower ε. However, I should point out that the low values of ε (high $G(e_s^-)_{fi}$) imply very low values for the oscillator strength. Nevertheless, your approach using laser generation of e_s^- sounds interesting and I should be pleased to hear further details: for example, how you determine $\phi(e_s^-)$.

U. Schindewolf: In water and ammonia there is some evidence of increased light absorption in the near uv. Could you observe an increase of absorption below 230 nm?

G. A. Salmon: Our detection system does not allow us to make accurate measurements below 230 nm.

L. G. Christophorou: Why do you not consider the $C(NO_2)_4^-$ parent ion, but rather the fragment ion $C(NO_2)_3^-$?

G. A. Salmon: In water and alcohols the stable $C(NO_2)_3^-$ ion can be prepared by hydrolysis of $C(NO_2)_4$. The absorption spectrum of the product of reaction of e_s^- (and $^{\cdot}CH_2OH$) with TNM is compatible with that of $C(NO_2)_3^-$. This has been demonstrated by several groups of workers. For references, see our ref. 1.

J. W. Hunt: I would mention that we are also studying the yields of e_{sol}^- in water, alcohols, and mixtures at picosecond and microsecond times with test scavengers such as cadmium perchlorate, sodium salicylate, and biphenyl. The electron adducts were observed. Our results are consistent with a higher free ion yield of e_{solv}^- in methanol ($G(e_{sol})_{fi} \sim 1.9$), and total yields of electron adducts are at least 4.8 to 4.2 per 100 eV. I would like to have your comments.

G. A. Salmon: The high yields of product at high concentrations of solute and short times is compatible with our view that presolvated and spur electrons can be scavenged by high solute concentrations. However, the difficulty arises with the yields which you have observed on microsecond time scales. I can only say that to interpret microsecond yields it is necessary to know the chemistry of the radicals with the solute and of the radical anion. Your yields of biphenyl radical anion on microsecond time scale seem to be at variance with those measured by Sauer *et al.* (M. C. Sauer, S. Arai, and L. M. Dorfman. J. Chem. Phys. **42**, 708 (1965)) and Janovsky (I. V. Janovsky. Ph.D. Thesis. University of Leeds, Leeds, England. 1969).

J. H. Baxendale: Don't you have a problem with increases in the free ion yield due to spur scavenging by saturated N_2O?

G. A. Salmon: The total radical yield as measured by TNM increases from 5.63 for argon saturated solution to 6.45 in nitrous oxide solution (1). We have taken this increase in $G(R^{\cdot})$ into account in partitioning the uv absorption by addition of N_2O.

On the existence of H^- in γ-irradiated matrices at 77 K

A. BERNAS AND T. B. TRUONG

Received September 27, 1976

A. BERNAS and T. B. TRUONG. Can. J. Chem. **55**, 2044 (1977).

A band peaking around 1050 nm in the stimulated neutralization luminescence spectrum of γ-irradiated glassy EtOH, pure crystalline and alkaline glassy ices has recently been attributed to H^-. Further results on EtOH glass and on EtOH–H_2O mixtures are now presented which support our previous interpretation.

A shuttle of the electron from the presumed H^- to a matrix trapped state and back to H with restoration of the 1050 nm band can be induced in, and only in, alcohol–water mixtures where it has been shown that, contrary to either of the two pure solvents, H atoms can be trapped (H_t). Further, the intensity of the regenerated stimulated band is found to be maximum for the mixture composition which leads to the highest H_t yield.

It is noted that the red limit of the H^- stimulated band, which corresponds to a photodetachment energy threshold, is close to the electron affinity value of the isolated H atom. This observation seems to imply that, contrary to expectation, the solvation energy of H^- in these matrices is quite low.

A. BERNAS et T. B. TRUONG. Can. J. Chem. **55**, 2044 (1977).

La glace pure cristallisée, les glaces alcalines vitreuses, l'éthanol vitreux irradiés aux Rγ à 77 K donnent lieu à une luminescence de neutralisation dont le spectre d'excitation présente une bande centrée à 1050 nm. Il a été récemment suggéré que celle-ci était associée à H^-. De nouveaux résultats relatifs à EtOH vitreux et aux mélanges EtOH–H_2O sont maintenant présentés qui confirment cette interprétation.

Il est en effet observé qu'un transfert réversible des électrons de l'espèce X^- vers des pièges physiques puis vers X avec reconstitution de la bande X^- à 1050 nm n'est possible que dans les mélanges EtOH–H_2O où les atomes H sont stabilisés (H_t). L'intensité de la bande 1050 nm ainsi régénérée est trouvée maximale pour la composition du mélange qui conduit à un rendement maximum en H_t.

On note enfin que la limite vers le rouge de la bande de stimulation de H^- qui correspond à une énergie seuil de photodétachment est très voisine de la valeur de l'affinité électronique de H gazeux. Ceci semble impliquer que dans les matrices considérées l'énergie de solvatation de H^- est très faible.

Introduction

It is well known that after γ-irradiation of rigid matrices at low temperatures and stabilization of neutral and charged intermediates, solvated electrons may be detrapped or bleached by a suitable optical excitation. A deferred luminescence designated as 'stimulated' luminescence (SL) is then generally associated with the subsequent cation–electron neutralization (1, 2).

The emission spectrum, $I_{SL} = f(\lambda_{an})$, obtained upon bleaching the trapped electron at constant wavelength λ_b and recording the luminescence at variable wavelength $\lambda_{analysis}$, may give information on the neutralization mechanism, dissociative or not, and on the emitting electronic state (3).

On the other hand, the luminescence excitation spectrum or 'stimulation' spectrum, giving the neutralization luminescence intensity as a function of the bleaching wavelength, $I_{SL} = f(\lambda_b)$, characterizes the negative species, whether anions or solvated electrons (2–5).

This technique has recently been applied to γ-irradiated glassy ethanol and the results have led to the suggestion that H^- was present (6). The present study deals with γ-irradiated ethanol and ethanol–water mixtures at 77 K where hydrogen atoms are known to be stabilized, although trapped H (H_t) is not observed in either pure component (7).

Experimental Results and Discussion

The experimental set-up has been described elsewhere (4, 5). It mainly consists of a slightly modified commercial spectrofluorimeter in which the xenon source and excitation monochromator are used to release the trapped electrons in the pre-irradiated sample. The neutralization lumin-

escence is simultaneously recorded by a RCA IP 28 photomultiplier through the analyzing monochromator. The stimulation spectra have been corrected for the trapped electron consumption under successive bleachings and for the variation of the excitation light flux with bleaching wavelength λ_b.

EtOH

Emission Spectrum

For pure ethanol glasses γ-irradiated at 77 K, the observed neutralization emission spectrum is given in Fig. 1, curve *A*. The same emission spectrum peaking at 345 nm is recorded, whatever the bleaching wavelength: 500 or 1000 nm.

The nature of the emissive center has been much debated for irradiated alkane glasses, with no conclusive assignment, however, and the emitter is also unidentified in the alcohol case. For the former, Brocklehurst (8) has recently proposed a radiative tunneling mechanism so that there would be no emitter as such; the luminescence would be a property of the ion pair.

For alcohol, it can only be stated that neither alcohol impurities (curve *B*) nor stable radiolysis products (curve *C*) are responsible for the 345 nm emission band.

Stimulation Spectrum

However, whatever the origin of the emission, the luminescence excitation or stimulation spectrum provides an electron photodetachment efficiency curve. If $\lambda_{analysis}$ is fixed at 345 nm, the stimulation spectrum shown in Fig. 2 is obtained. The visible region of the spectrum appears quite similar to the previously reported (9, 10) bleaching efficiency curves relating the decrease in trapped electron optical density to the bleaching wavelength λ_b. An extra band, absent in the bleaching curves is, however, present in the stimulation spectrum peaking at about 1050 nm with a low energy threshold at about 1500 nm (0.86 eV). The intensity of the 1050 nm band decreases as the γ-dose increases as illustrated in Fig. 3.

An analogous band appears in the stimulation spectra of pure (11) or alkaline (12) ices. If present in the stimulation spectra of irradiated alkane glasses, it would be masked (6) by the

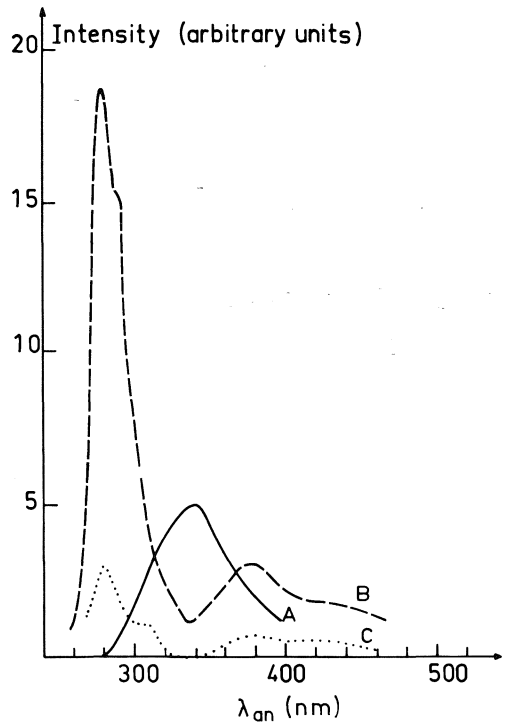

FIG. 1. Neutralization emission spectrum in γ-irradiated EtOH glass at 77 K. (*A*) Stimulated emission spectrum, $I_{SL} = f(\lambda_{an})$ of γ-irradiated EtOH glasses, (10^{19}eV g^{-1}), upon bleaching with λ_b = 1000 nm. (*B*) Emission spectrum of unpurified EtOH glass, upon excitation at λ_{exc} = 254 nm. (*C*) Emission spectrum of the γ-irradiated sample (10^{19} eV g^{-1}) subjected to one melting–freezing cycle, and excited with λ_{exc} = 254 nm.

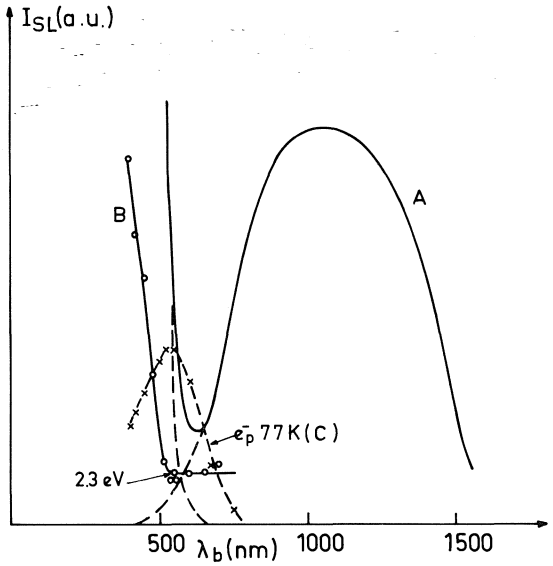

FIG. 2. Neutralization stimulation spectrum in γ-irradiated EtOH at 77 K. (*A*) Stimulation spectrum $I_{SL} = f(\lambda_b)$, λ_{an} = 345 nm. (*B*) Bleaching efficiency curve $(-D_{opt}) = f(\lambda_b)$ (9). (*C*) Absorption spectrum of solvated electrons in γ-irradiated EtOH glass (9).

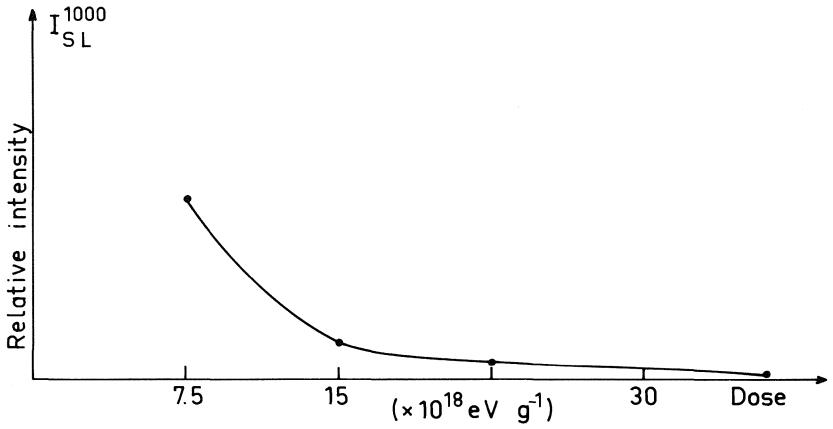

FIG. 3. Intensity of stimulated luminescence in γ-irradiated EtOH glass *vs.* γ-dose; λ_{an} = 345 nm, λ_b = 1000 nm.

broad trapped electron band peaking at 1600 nm. It has been observed (6), however, that the bleaching rate at 1600 nm for MCH or 3-MP glasses is much lower after large γ-doses ($>10^{20}$ eV g^{-1}), that is, when the trapped electron contribution is lower. Such a difference in the bleaching kinetics between physical and chemical electron traps has been pointed out before (13, 4). This observation would favour the conclusion that the 1050 nm band originates from an anion.

Absorption bands in the same spectral region have been reported previously.

In the case of alkaline aqueous glasses, the 1000 nm band has been attributed to dielectrons (14). In the case of ethanol irradiated and investigated at 4 (15) or 6 K (10), the ir band apparently originates from electrons located in shallow wells, non-relaxed traps. For *n*-propanol and higher aliphatic alcohols the shoulder observed in the near ir region would correspond to traps formed, at least partly, by alkyl groups (16).

None of these interpretations can apply to our experimental findings, however. A dielectron attribution cannot be considered since the 1050 nm band appears at low doses for irradiated ices (11) and since its intensity decreases as the γ-dose increases in the ethanol case (Fig. 3). As to the shallow traps, they are known to be stabilized at 4–6 K but to become fully relaxed as the temperature rises to 77 K (17) with a correlative shift of the absorption band maximum to higher energies. Besides, the 1050 nm band does not exist in the SL spectrum of photoionized tryptophane dispersed in ices or ethanol glasses (6). Electrons which would be solvated not only by OH dipoles but also by alkyl groupings might exist in alcohols but not in pure or alkaline ices. Again, we are led to suggest that the 1050 nm band is associated with an anion X^-.

OH radicals, and possibly OH^-, are stabilized in pure radiolyzed ice, O^- in alkaline ices, but the most plausible radiolysis product X^-, common to alcohols and ices, seems to be H^-.

EtOH–H_2O Mixtures

It is well known that no H atom signals have been recorded through esr in alcoholic matrices neither at 77 nor even at 4 K, even though much indirect evidence exists that hydrogen atoms are produced during radiolysis. In pure ice, H atoms are stable at 4 K but begin to diffuse and combine in the temperature range 20–50 K.

On the other hand, Hase and Kevan (*7a*) and Chandra (*7b*) have identified trapped hydrogen atoms through the characteristic esr doublet signal of H in irradiated MeOH–H_2O, EtOH–H_2O, and PrOH–H_2O mixtures at 77 K. Since the H_t yields as a function of the mixture composition show a striking correlation with the excess enthalpy of mixing of the alcohol–water mixtures, it was considered that both effects are related to alcohol–water complex formation, and that the simplest trapping site structure was a hydrogen bonded trimer of one alcohol and two water molecules (*7a*).

Neutralization luminescence has now been examined for these systems and the following observations have been made.

Emission Spectrum

For the EtOH–H_2O mixtures (10 to 50 mol% of EtOH), the stimulated emission spectrum

gives a λ_{max} at 360–365 nm under bleaching at 1000, 390, or 254 nm. This emission is red-shifted as compared with the stimulated emission of pure EtOH (λ_{max} = 345 nm) and blue-shifted with respect to the main neutralization luminescence band in pure irradiated ice (λ_{max} = 380 nm).

It is not clear at the present time whether the 365 nm emission is an envelope of the two pure solvents' emission bands or is due to a different emissive entity.

Stimulation Spectrum

The stimulation spectrum has the same shape as the EtOH stimulation spectrum (Curve *A*, Fig. 2) but, in the irradiated EtOH–H_2O mixtures, the 1050 nm band appears more intense than for either of the two pure solvents.

The 1050 nm band due to X^- can be completely bleached off under λ_b = 1000 nm. Then, by exciting the sample with a light frequency which is absorbed by the solvated electrons and not by X^-, *i.e.* at λ_b = 400 nm (6) the 1050 nm band is partially regenerated. This restoration of the X^- band is observed in the EtOH–H_2O mixtures but in neither one of the pure solvents. That is, the X^- band can be reproduced only in the systems where H atoms are stabilized, in which case one can induce the reversible electron transfer:

$$[1] \qquad e_{solv}^- + h\nu \rightarrow e_m^- \xrightarrow{H} X_t^-$$

$$[2] \qquad X_t^- + h\nu \rightarrow e_{solv}^-$$

Moreover, as shown in Fig. 4, the intensity of the regenerated X^- band appears maximum for a mixture containing 20 mol% EtOH. This is precisely the mixture composition which, from Hase and Kevan experiments (7*a*), leads to the maximum concentration of trapped hydrogen atoms, following γ-radiolysis or after a subsequent e_{solv}^- optical bleaching.

Similarly, the intensity of the regenerated X^- band increases with increasing γ-dose within a range where H_t concentration was found to be linear with dose: curve *A* (γ-dose = 0.6 Mrad) as compared with curve *B* (γ-dose = 0.32 Mrad).

The restored X^- band appears more intense for λ_b = 254 nm rather than λ_b = 390 nm which may reflect a higher e_{solv}^- photobleaching efficiency at shorter wavelengths (curves *B* and *C*).

These qualitative and quantitative features

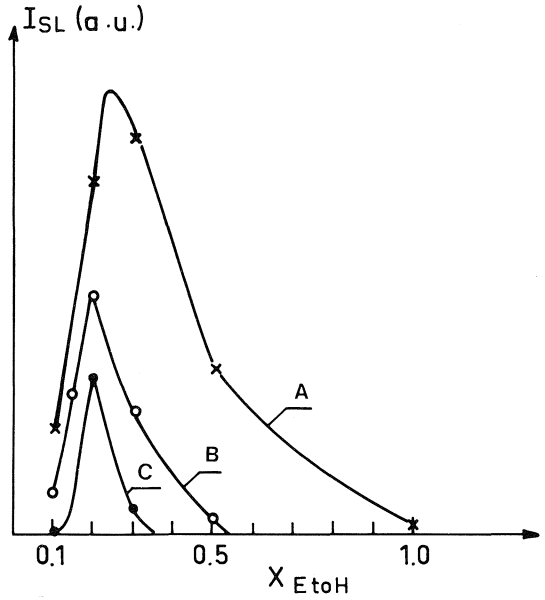

FIG. 4. Intensity of the regenerated 1050 nm band *vs.* EtOH mole fraction in EtOH–H_2O mixtures: (*A*) γ-dose = 0.6 Mrad, λ_b = 254 nm, (*B*) γ-dose = 0.32 Mrad, λ_b = 254 nm, (*C*) γ-dose = 0.32 Mrad, λ = 390 nm.

indicate that X^- anion is effectively the hydride ion, as previously suggested (6).

It is also worth mentioning that H^- has been detected in solar atmosphere (18) and that its calculated and observed absorption spectrum appears at the same spectral position, as illustrated in Fig. 5.

The decrease of the H^- stimulated band with increasing γ-dose for pure EtOH may be compared with the observed decrease with dose of the molecular hydrogen yield $G(H_2)$. It may be similarly explained by a competition between the H forming reactions 3 and 4

$$[3] \qquad e_m^- + C_2H_5OH_2^+ \rightarrow C_2H_5OH + H$$

$$[4] \qquad e_m^- + C_2H_5OH \rightarrow C_2H_5O^- + H$$

and the electron attachment on acetaldehyde, which is a good electron scavenger and whose concentration increases with dose (19).

$$[5] \qquad e_m^- + CH_3CHO \rightarrow CH_3CHO^-$$

A competition may also intervene between reactions 5 and 6:

$$[6] \qquad e_m^- + H \rightarrow H^-$$
$$R^\bullet \rightarrow R^-$$

where $R^\bullet$ is a radiation produced solvent radical.

Various modes for H^- formation may be envisaged depending on the matrix:

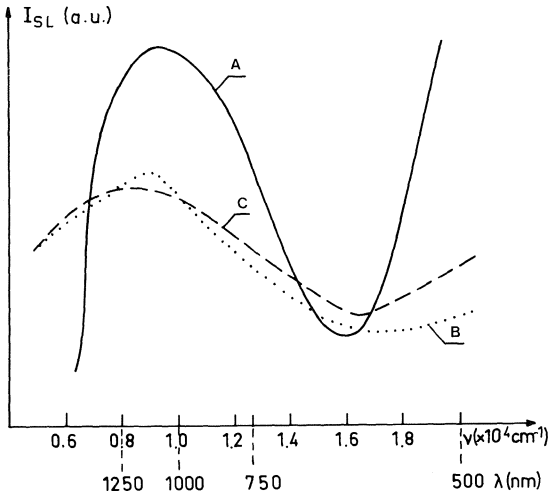

FIG. 5. Absorption spectrum of gaseous H^-: (*A*) Stimulation spectrum $I_{LS} = f(\lambda_b)$ of γ-irradiated EtOH glass, γ-dose = 10^{19} eV g^{-1}, λ_{an} = 345 nm, (*B*) Observed absorption spectrum of H^- (18), (*C*) Calculated absorption spectrum of H^- (18).

(*a*) In water vapor, the dissociative electron attachment [7] is well established (20)

[7] $$e^- + H_2O \rightarrow H^- + OH$$

Even though at higher pressures ion–molecule reaction 8

[8] $$H^- + H_2O \rightarrow OH^- + H_2$$

is known to occur, reaction 7 may be operative and H^- might be solvated and stabilized in condensed phase.

(*b*) In the EtOH–water mixtures, electron attachment may clearly occur on preformed, trapped hydrogen atoms

[9] $$e_m^- + H_t \rightarrow H_t^-$$

besides their possible formation during radiolysis through reaction 10.

(*c*) In pure radiolyzed solid alcohol, where hydrogen atoms are not trapped, the latter may diffuse toward the solvated immobile electrons and become trapped as H_t^-:

[10] $$H + e_{solv}^- \rightarrow H_t^-$$

Reaction 10 would thus provide another path for the decay of H atoms, besides the combination reaction 11

[11] $$H + H \rightarrow H_2$$

and the abstraction reaction 12:

[12] $$H + CH_3CH_2OH \rightarrow H_2 + CH_3CHOH$$

Reaction 10 has been previously suggested by Shirom and Willard (21) to account for the decrease in solvated electron concentration with increasing dose in hydrocarbon glasses. It was shown later (22) that reaction 10 was not responsible for the observed decrease in $G(e_{solv}^-)$; there is no indication, however, that reaction 10 does not take place in hydrocarbon glasses or other radiolyzed systems.

As to the occurrence of reaction 9, it is not easy to demonstrate. Electron spin resonance analyses of the γ-irradiated EtOH–H_2O mixtures have shown (7*a*) that, upon bleaching the solvated electrons, the H atom concentration increases due to H production through H_3O^+ (mostly) and $C_2H_5OH_2^+$ neutralization. Such an increase apparently overcomes the decrease which would be associated with electron attachment on H. The fact that the decrease in e_t^- is found to exceed the correlative increase in H (7*a*) indicates that some of the bleached electrons do not recombine with positive holes. This may be due to reaction 9 but also to electron attachment on other radiolysis products, attachment which, if dissociative, would not give rise to H.

Conclusion

We wish to conclude with two remarks.

The low energy limit of the H^- stimulated band, which corresponds to a photodetachment energy threshold, appears very close to the value of the electron affinity of the isolated H atom (0.7–0.8 eV). This observation is contrary to expectation. It would seem to imply that the influence of the matrix molecules, *i.e.* the solvation energy of H^- in these matrices, is quite low. As pointed out to us,[1] this could possibly be correlated to the helium-like, close-shell configuration of the hydride ion.

Finally, we want to stress again that recording the stimulation spectrum of the neutralization luminescence is a detection technique which is both sensitive and specific of negatively charged species. It may thus supplement optical absorption spectroscopy when the sensitivity of the latter is too low or when cations and anions have indistinguishable spectra. It may also replace esr spectroscopy in the search for nonparamagnetic anions.

Discussion

L. G. Christophorou: Could the fact that H^- is a closed-shell system explain the absence of a profound medium effect (on the photodetachment threshold)?

A. Bernas: This is indeed a very interesting comment and suggestion but before drawing such a conclusion I would prefer that our experimental work be extended to other anions, *e.g.* Cl^-.

R. S. Dixon: H^- is thought to react rapidly with H_2O in the gas and liquid phases. Would you expect reaction with neighboring water molecules in the glass?

A. Bernas: I agree that at high pressures the ion–molecule reaction $H^- + H_2O \rightarrow OH^- + H_2$ is known to occur. However, H^- may be formed in a trapped state through $H + e_{solv}^- \rightarrow H^-_{trapped}$.

N. K. Kestner: I am also concerned that the spectral shifts of the H^- spectrum are so small in the glass; H^- is a rather large system, compared to H. H^- is only stable relative to $H + e^-$ by 0.75 eV while the correlation energy is over 1 eV. In order for H^- to be stable the size of the orbitals in H expand. Thus I might expect larger spectral shifts for H^- than for H when present in condensed phases.

A. Bernas: As I just mentioned we were also puzzled that the photodetachment threshold in the glass appears close to the electron affinity of H in the gas, and so far we have no explanation to offer. As to the size of the H orbitals permitting H^- stability, it seems difficult to say anything in the case of condensed media.

R. Catterall: When the solvated electrons in γ-irradiated water–alcohol solutions are photobleached, the esr signal from e_{solv}^- disappears. Does the H atom esr signal also decrease?

A. Bernas: The experiment has been done but the data are not conclusive with regard to H^- formation. (*a*) The initial (*i.e.* before e_{solv}^- bleaching) H concentration is low as compared to that of e_{solv}^-. (*b*) Upon e_{solv}^- bleaching various reactions will modify the H concentration in opposite directions: neutralization of H_3O^+ or attachment on ethanol molecules will increase [H] whereas electron attachment on H will decrease it.

U. Schindewolf: Our attempts to dissolve alkali hydrides, *e.g.* in THF with the aid of crown-compounds, to complex the alkali ion failed. We hoped in this way to get H^- ions into solution. Has H^- even been observed in liquid solution as Na^-, K^-, etc. have been?

A. Bernas: Not to my knowledge, even though it has been suggested many times, in particular a long time ago by Platzman.

Low energy electron ranges in liquids: determination by nonhomogeneous kinetics[1]

J.-P. DODELET[2]

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 27, 1976

J.-P. DODELET. Can. J. Chem. **55**, 2050 (1977).

Free ion yields have been measured in four hydrocarbon liquids: *n*-pentane, cyclopentane, neopentane, and neohexane. Each liquid has been studied from room temperature or below up to the critical temperature. Theoretical curves have been calculated using the relation between the free ion yields and the external field strength derived by Terlecki and Fiutak on the basis of an equation by Onsager. Two popular electron range distribution functions, Gaussian and exponential, have been shown not to be an adequate representation of the reality as far as the model used for the calculations is concerned. In order to fit experimental points, both range distribution functions would require a drastic increase in the total ionization yield, G_{tot}, with temperature increase. This would mean an unrealistic decrease of the ionization potential of the molecule from the melting point up to the critical temperature.

It is possible to keep G_{tot} quite constant and within the range of values obtained by other techniques by extending the Gaussian range distribution function with a $(\text{range})^{-3}$ probability tail. The most probable range can be normalized for the liquid density. This parameter has been used to obtain information about the behaviour of epithermal electrons in the four alkane liquids from the melting point up to the critical temperature.

(*1*) Normalized penetration ranges of epithermal electrons are dependent on the structure of the molecule in the entire liquid range but differences are smaller at critical than at low temperatures.

(*2*) Normalized penetration ranges of epithermal electrons pass through a maximum in the liquid phase for neopentane, neohexane, and cyclopentane. No maximum is observed for *n*-pentane.

(*3*) There is no drastic change in the behaviour of epithermal electrons in these alkanes at the critical temperature.

J.-P. DODELET. Can. J. Chem. **55**, 2050 (1977).

Les rendements en ions libres ont été mesurés dans quatre hydrocarbures liquides: le *n*-pentane, le cyclopentane, le néopentane et le néohexane. Chaque hydrocarbure a été étudié depuis une température égale ou inférieure à celle du laboratoire jusqu'à la température critique. Les courbes théoriques ont été calculées en utilisant la relation, déduite par Terlecki et Fiutak d'après une équation d'Onsager, entre les rendements en ions libres et le champ électrique appliqué. Deux distributions des parcours électroniques, l'une de type gaussien, l'autre exponentiel, très populaires dans la littérature, ont été utilisées dans les calculs et n'ont pas donné satisfaction dans le cadre de ce modèle. En effet, pour ces deux distributions, une bonne coincidence entre les calculs et l'expérience requerrait, lorsque la température augmentait un accroissement considérable du rendement total en ions, G_{tot}, ce qui aurait signifié une diminution constante, très peu probable, du potentiel d'ionisation de la molécule à partir du point de fusion jusqu'à la température critique.

Il est possible de maintenir G_{tot} relativement constant et dans le domaine des valeurs obtenues par d'autres techniques, en prolongeant artificiellement la distribution gaussienne des parcours électroniques par une distribution du type $(\text{parcours})^{-3}$. Le parcours le plus probable peut alors être normalisé en tenant compte de la densité du liquide. Ce paramètre a été utilisé pour obtenir des renseignements sur le comportement des électrons épithermiques injectés dans les quatre alcanes liquides étudiés, depuis leur température de fusion jusqu'à leur température critique.

(*1*) Les parcours normalisés des électrons épithermiques dépendent de la structure des molécules sur l'ensemble de la phase liquide mais les différences, importantes à basse température, s'amenuisent en allant vers la température critique.

[2]Present address: Département de Chimie-Biologie, Université du Québec à Trois Rivières, Case postale 500, Trois Rivières (Qué.), G9A 5H7.

(*2*) Les parcours normalisés des électrons épithermiques présentent un maximum dans la phase liquide pour le néopentane, le néohexane et le cyclopentane. Aucun maximum n'est observé pour le *n*-pentane.

(*3*) A la temperature critique il n'y a pas de changement brusque dans le comportement des électrons épithermiques injectés dans ces alcanes.

Introduction

Injection of low energy electrons into liquids can be done in various ways. The most popular methods are electron photoinjection (1, 2) and the use of pulsed ionizing radiation (3–5).

When an ionizing radiation like a pulse of X rays penetrates into a liquid, a random distribution of ionized atoms or molecules is produced. These primary electrons will generate a branching out of ionization events along their tracks. After the last ionization takes place, the liquid contains a number of low energy electrons and their parent positive ions. These epithermal electrons will become thermalized at some distance from their parent ions by transferring their surplus energy to the medium.

The important factors which govern the penetration ranges of low energy electrons are the energy loss processes when the electron energy is below the lowest electronic excitation potential of the medium (2, 6, 7). If their interactions with the medium at those energies are small, their penetration ranges will be large.

Once the electrons become thermalized, they become involved in reactions with the positive ions. These reactions can be described by nonhomogeneous kinetics. Nonhomogeneous qualifies the relative distribution of equal numbers of positive ions and electrons in the liquid. If a positive ion is chosen as a reference, there is a much larger probability to find an electron as its nearest charged neighbour than another positive ion, in contrast with homogeneous kinetics, where there is an approximately equal chance to find either a positive or a negative charge closest to the reference ion.

Once an electron is thermalized, at a distance designated y from its parent ion, it is submitted to the thermal agitation of the medium which tends to counteract the Coulombic attraction toward the parent ion. The probability that electrons escape geminate neutralization is given by the equation

$$[1] \qquad P_{fi} = \exp(-q^2/\varepsilon kTy)$$

where q is the charge of the electron, k is the Boltzmann constant, T is the absolute temperature, and ε is the dielectric constant of the medium. The derivation of this equation is due to Onsager (8).

The experimentally measurable quantity is G_{fi}, the number of pairs of free ions created by every 100 eV of energy absorbed by the liquid. It is related to the escape probability by the relation

$$[2] \qquad G_{fi} = P_{fi}G_{tot}$$

where G_{tot} is the total number of ion pairs created per 100 eV of energy absorbed by the liquid. G_{tot} depends among other things on the ionization potential of the medium.

The average energy, W, required to form an ion pair in the gas phase has been measured for rare gases and many organic molecules (9, 10). In the liquid phase, the W value is unknown and the gas phase value is often used.

However, recently Takahashi *et al.* (11) measured the average energy expended per ion pair in liquid Xe using ^{207}Bi as an internal source of electrons. They obtained W(liq. Xe) = 15.6 $\pm$ 0.3 eV, a value considerably smaller than the gas phase value (21.5–21.9). In earlier publications (12, 13) they reported W(liq. Ar) = 23.6 eV which is also lower than the gas phase value (26.4 eV). If this trend is confirmed with a molecular medium, it is possible that the total ionization yield in liquids is larger than the usually used gas phase value.

Experimental

Techniques

If some ions become free they can be collected on electrodes. In order to collect and integrate a current, a constant external voltage must be applied on the electrodes. Therefore, only dielectric liquids can be used with this technique.

A charge clearing technique is used (14). The ions are generated by a pulse of 1.7 MeV X rays. For a 1 μs pulse duration, the energy absorbed by the sample is of the order of 10^{10} eV/g. The transient current produced by the ion collection is integrated and the collected charge is measured. The radiation pulse intensity is also integrated.

[3] $$G_{fi} \propto \frac{\text{collected charge}}{\text{absorbed dose} \times \text{collection volume}}$$

The measurements are repeated at several electric field strengths E to obtain a series of values designated $G_{fi}{}^{E}$.

Material

The hydrocarbons used in this paper are three C_5 hydrocarbons (*n*-pentane, cyclopentane, neopentane) and neohexane. These Research Grade hydrocarbons were obtained from Phillips Petroleum Co. Their purity is > 99.9%.

In order to see an electron conductance transient in these liquids (15), further purification is required. The same purification technique was used for all four hydrocarbons. (*1*) 24 h shaking with sulfuric acid; (*2*) after separation, 1 h stirring with $BaCO_3$; (*3*) introduction in the vacuum system through a column of NaOH pellets; (*4*) degassing; (*5*) 24 h stirring on $LiAlH_4$ under their own vapor pressure; (*6*) at least 48 h stirring on Na–K alloy under their own vapor pressure; (*7*) introduction into the conductance cell under a remaining pressure of the order of 10^{-7} torr.

Conductance Cells

Two kinds of conductance cell were used for these experiments. The low pressure cell has been described in detail elsewhere (14). For high pressure experiments a cell able to support a pressure of 100 atm was used (15). In order to get good signals, the high pressure cell has to be baked at a temperature higher than the critical temperature of the hydrocarbon under investigation. Both cells were coated with carbon black. This provided an efficient grounding of the cell body. At high temperatures the high voltage source drives excessive current through glass coated with a conducting material and this may cause breakage. Because of this, the high voltage arm was not coated with carbon black.

Temperature Control

The low temperature system has been described earlier (14). For higher than room temperatures, the high pressure cell was positioned in a clear Dewar and air at the desired temperature was blown on the sample with a heat gun. One thermocouple was used to drive the temperature controller and another recorded the temperature. Both thermocouples were placed inside the guard electrode side-arm as close as possible to the body of the cell. The meniscus disappearance signified the critical point and this was observed through a window left uncoated on the cell body.

Physical Properties of the Liquids

Densities, d, for low temperature *n*-pentane and for neohexane from 0°C to 25°C have been obtained from Timmermans (16). Low temperature densities for neohexane were assumed to change linearly with temperature from 25°C to the melting point. Gallant (17) provided the densities for high temperature pentane and cyclopentane up to critical temperature. The density curve up to critical temperature is not available for neopentane or neohexane. For these alkanes the densities at 20°C and critical temperature are provided by Timmermans (16). The density variations of neopentane and neohexane were assumed to be similar to the density variations for *n*-butane and *n*-pentane respectively (17).

TABLE 1. Critical data

Liquid	T_c (°C)	d_c (g/cm³)
n-Pentane	197.2	0.2323
Cyclopentane	238.6	0.270
Neopentane	160.6	0.221
Neohexane	216.2	0.240

Critical temperatures and densities for the four hydrocarbons are given in Table 1.

The dielectric constants used for the various temperatures were calculated with the Debye formula using $\mu = 0.06$ D (18) for *n*-pentane and neohexane and $\mu = 0.0$ D for cyclopentane and neopentane. Refractive indices of these hydrocarbons were found in the Handbook of Chemistry and Physics (19). At 20°C the calculated values of ε are in good agreement with the literature values (19).

The Model

The field strength E produced by the external voltage is in competition with the field strength due to the Coulombic interaction. In other words the external field will help the ions to become free and this effect will be larger, the larger the voltage. The relation between the free ion yield and the external field strength is given by the relation calculated by Terlecki and Fiutak (20).

[4] $$G_{fi}{}^{E} = P_{fi}[1 + \psi(u_0, s)]G_{tot}$$

[5] $$\psi(u_0, s) = e^{-u_0} \sum_{n=1}^{\infty} \frac{{u_0}^n}{(n+1)!} \times \sum_{j=0}^{n-1} (n-j) \frac{s^{j+1}}{(j+1)!}$$

where $u_0 = Eqy/300kT$, $s = q^2/\varepsilon kTy$. This calculation is based on Onsager's escape probability in the presence of an external electric field (8).

This relation assumes a unique spur population: one positive ion and one electron only. It has been shown by Mozumder and Magee that a certain amount of energy deposition appears in the form of multiple ion spurs (21). However, the majority of spurs are single pair spurs when X radiation is used (21). Introduction of spurs with multiple ion population into the calculation highly complicates the problem, especially if the repulsion between the same charged species is to be taken into consideration.

The expressions [4] and [5] are derived for an electron penetration range y. It would be fortuitous if all the electrons would thermalize at the same distance y from the parent ion. A

distribution function of penetration ranges is more realistic but such a function is unknown and the problem is left for speculation.

Two distribution functions of penetration ranges have been used in many calculations. The first one is based on the random walk model (22) and is a three dimensional Gaussian (8, 23, 24). We will call it YG.

$$[6] \qquad F(y) = \frac{4y^2}{\pi^{1/2} b_G{}^3} \exp(-y^2/b_G{}^2)$$

where b_G is the Gaussian dispersion parameter. It is also the most probable value of y. The second range distribution function is a simple exponential (25), based on the wave nature of the electron motion (26). We will call it YE.

$$[7] \qquad \begin{aligned} F(y) &= 0 && y < y_0 \\ F(y) &= b_E{}^{-1} \exp -((y - y_0)/b_E) && y \geq y_0 \end{aligned}$$

where b_E is the exponential dispersion parameter and y_0 is an arbitrary truncation distance. It has been taken equal to 5 Å by Abell and Funabashi (25) as the distance at which neutralization occurs. The electron propagates through the liquid as a plane wave with $b_E{}^{-1}$ as attenuation coefficient. Both distributions are normalized and

$$\int_0^\infty F(y)\, dy = 1$$

With the use of a distribution function, [4] becomes

$$[8] \qquad G_{fi}{}^E = G_{tot} \int_{y=0}^{\infty} F(y) P_{fi}[1 + \psi(u_0, s)]\, dy$$

Results and Discussion

Model Calculations with YG and YE Range Distribution Functions

As stated previously, the exact value of the total ionization yield, G_{tot}, in the liquid phase is not known but it is a reasonable approximation that the ionization potential of a molecule in the liquid phase will remain constant when the temperature of the liquid varies. Therefore G_{tot} should remain approximately constant as well.

In order to test the model, the two range distribution functions YG and YE were used to fit the experimental free ion yields of *n*-pentane and neopentane at various temperatures, going from −123°C to 209°C for *n*-pentane and from 25°C to 174°C for neopentane. For each temperature G_{tot} was used as an adjustable parameter to fit the experimental free ion yields. For each value of G_{tot}, the value of b_G or b_E necessary to perform the calculation of $G_{fi}{}^E$ (eq. 8) was computed from the 'experimental' $G_{fi}{}^0$ using [1] and [2]. This 'experimental' $G_{fi}{}^0$ is obtained by extrapolation of the experimental $G_{fi}{}^E$ to 0 V. If this extrapolation is not obvious, a range of possible $G_{fi}{}^0$ is tested and the best value is chosen.

In the fitting process by computer, an error between calculated and experimental points is computed on the basis of the relation

$$[9] \qquad \text{error} = \frac{1}{n} \sum_{E=E_1}^{E_n} |G_{fi}{}^E{}_{calc} - G_{fi}{}^E{}_{exp}|$$

where n is the number of experimental points.

Figures 1 and 2 display the best fit obtained with YE and YG for the lowest and highest experimental temperatures of *n*-pentane and neopentane respectively. Using YE, the best fit value of G_{tot} goes from 4.3 at −123°C to 9.2 at 209°C for *n*-pentane and from 4.6 at 25°C to 8.2 at 174°C for neopentane. Using YG, the best fit value of G_{tot} goes from 1.2 at −123°C to 5.1 at 209°C for *n*-pentane and from 3.4 at 25°C to 5.5 at 174°C for neopentane.

The field strength dependence of $G_{fi}{}^E$ is never a straight line when the voltage range is large enough. Even in *n*-pentane at −123°C the curvature in the experimental and calculated lines are clearly visible (Fig. 1).

The best fit values of G_{tot} at intermediate temperatures are displayed in Fig. 3 for *n*-pentane and in Fig. 4 for neopentane. The credibility range of the best fit is given by 1.1 times the error on both sides of the best fit error curve.

For both distributions the best fit method would require an increase of G_{tot} when temperature increases. This would correspond to a decrease of the ionization potential. As we have made the reasonable assumption that the ionization potential remains constant when the liquid temperature varies, we can conclude that a pure Gaussian or exponential range distribution function is not an adequate representation of the reality as far as this model is concerned.

Amending the Distributions

The goal is to obtain by calculation a constant total ionization yield for the four alkanes for

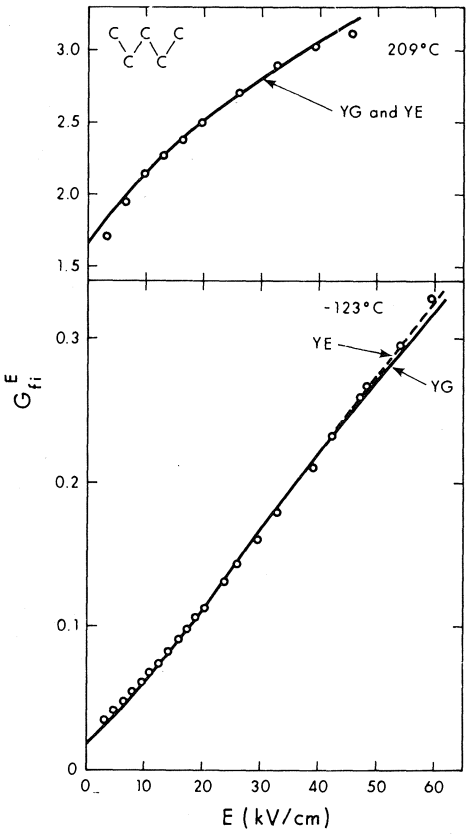

FIG. 1. Variation of the free ion yield $G_{fi}{}^{E}$ with field strength in *n*-pentane at −123°C and 209°C. The best fit lines are calculated using [8] with two range distribution functions, YE and YG. At −123°C, $G_{tot} = 4.3$ for YE and 1.2 for YG. At 209°C, $G_{tot} = 9.2$ for YE and 5.1 for YG.

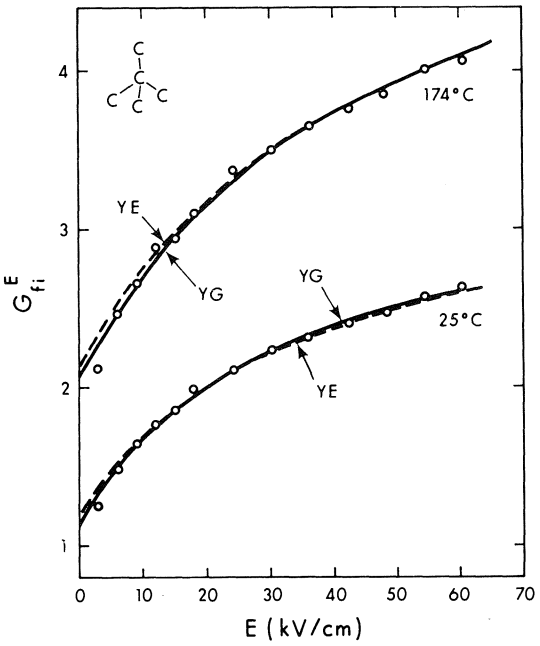

FIG. 2. Variation of the free ion yield $G_{fi}{}^{E}$ with field strength E in neopentane at 25°C and 174°C. The best fit lines are calculated using [8] with two range distribution functions YE and YG. At 25°C, $G_{tot} = 4.6$ for YE and 3.4 for YG. At 174°C, $G_{tot} = 8.2$ for YE and 5.5 for YG.

the entire range of temperatures. By using larger thermalization ranges than the ones allowed by YG or YE it is possible, when $G_{fi}{}^{0}$ is small, to increase the value of G_{tot} used to fit the experimental points.

Let us demonstrate why the best fit value of G_{tot} obtained with YG is small when $G_{fi}{}^{0}$ is small. At low temperature $G_{fi}{}^{0}$ in *n*-pentane, for example, is small. The only ions able to become free are the ones with large thermalization ranges. In order to provide large y values, the dispersion parameter of the Gaussian, b_G, which is also the most probable value of y, must be large. Equations 1 and 2 show that this is equivalent to saying that the escape probability is large. But $G_{fi}{}^{0}$ is given by extrapolation of experimental $G_{fi}{}^{E}$. A large escape probability requires therefore a small G_{tot} value.

To obtain larger thermalization ranges for a small portion of the electrons, we used a Gaussian tailed by a power probability function in y^{-3}. This combined function, called YGP, extends to much larger y values than YG. The tail contains the outermost 6% of the distribution function. It seemed to give quite good results in the past and has the following mathematical form (14).

$$F(y) = 0.96\text{YG} \qquad y < 2.4b_{GP}$$
$$F(y) = 0.96\text{YG} + 0.48(b_{GP}{}^{2}/y^{3}) \qquad y \geq 2.4b_{GP} \qquad [10]$$

The G_{tot} variation with temperature obtained with the YGP distribution function is displayed for *n*-pentane in Fig. 5 and the variation of G_{tot} with YG is displayed on the same graph for comparison. The curve obtained with YGP still shows some tendency to curve up, but it tends to make G_{tot} more constant on the entire temperature range. A value of $G_{tot} = 4 \pm 1$ could be accepted. A similar extension of the exponential range distribution function gave an apparent value around 7.5 for G_{tot}.

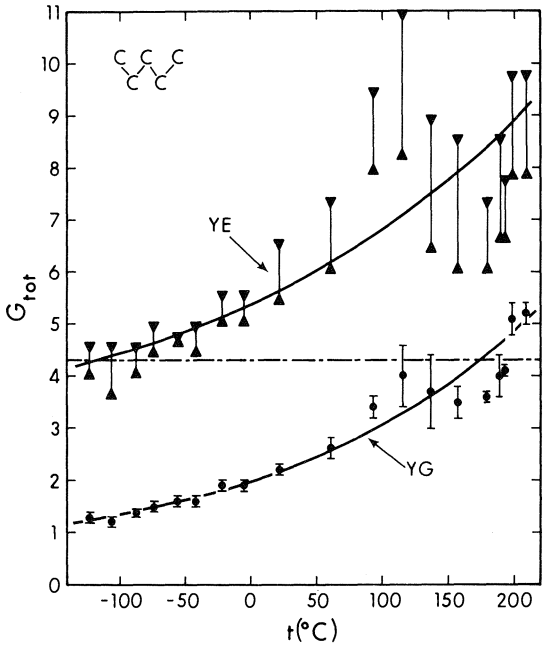

FIG. 3. Temperature variation of G_{tot} (with credibility gap) giving the best calculated fit for $G_{fi}{}^{E}$ *vs.* E in *n*-pentane for two range distribution functions YE (upper curve) and YG (lower curve). Increasing y_0 from 5 to 20 Å in YE did not shift the curve appreciably. The dotted line is the G_{tot} gas phase value.

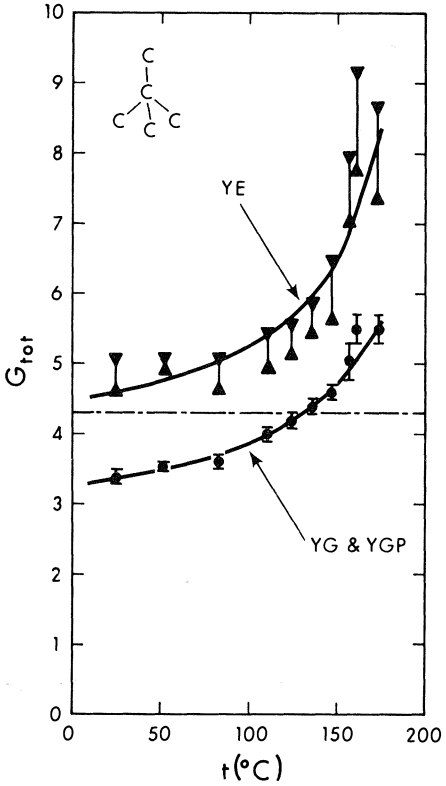

FIG. 4. Temperature variation of G_{tot} (with credibility gap) giving the best calculated fit for $G_{fi}{}^{E}$ *vs.* E in neopentane for three range distribution functions YE (upper curve), YG and YGP (lower curve). The dotted line is the G_{tot} gas phase value.

The adjunction of a power tail to both functions has nearly no effect when $G_{fi}{}^{0}$ and the escape probability are large. This can be seen in Fig. 5 for high temperature *n*-pentane and on Fig. 4 for neopentane on the entire temperature range studied. With these conditions the main contribution to the escape probability is from y values belonging to the Gaussian or exponential parts of the functions. The curvature observed on the variation of G_{tot} with temperature remains unchanged and suggestions are open for a better improvement on the range distribution functions.

It is possible to rationalize the existence of large thermalization ranges like the ones used in the tail of the YGP range distribution function. Some of the energy released by the primary electrons creates heavily populated spurs (21). After recombination of the inner electrons with parent positive ions, there would remain a single ion pair separated by a relatively large distance. The tail is an artifact inherent to a model treating only single ion pair spurs.

By assuming the generally accepted point that G_{tot} is almost independent of temperature over the entire liquid range, we have shown that conductivity results can be fit with a Gaussian type distribution function using $G_{tot} = 4 \pm 1$ *or* with an exponential type distribution function using $G_{tot} = 7.5 \pm 1$.

Previous attempts have been made (14, 25, 27) to decide whether an exponential or a Gaussian range distribution function better describes the reality. Another approach was used for these studies: G_{tot} was maintained constant at an arbitrary value (usually the gas phase value), different distribution functions were used, and their fit was compared. There are two approaches because there are two unknowns: the total ionization yield and the range distribution function. As long as the total ionization yield for these liquids remains unknown and until an adequate multipair spur model is devised, it will be impossible to chose by the conduction

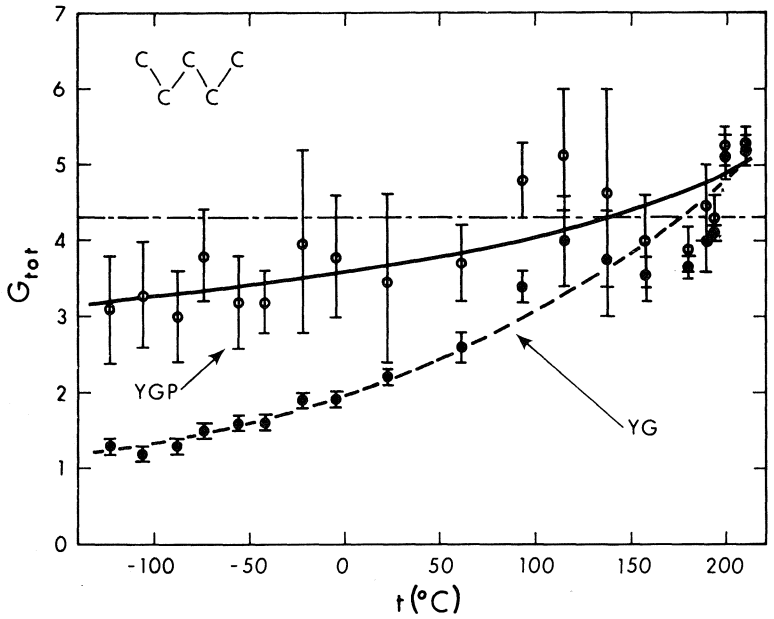

FIG. 5. Temperature variation of G_{tot} (with credibility gap) giving the best calculated fit for $G_{fi}{}^{E}$ *vs.* E in *n*-pentane for the YGP range distribution function (upper curve). YG (lower curve) is displayed for comparison. The dotted line is the G_{tot} gas phase value.

method alone between a Gaussian or an exponential type range distribution function. Even going to a very high field strength is not the answer, as has been shown by Mathieu and co-workers (28). The distinction between the two range distribution functions remains a problem.

Scavenging experiments are another way of getting information about the total ionization yield, but this technique also has its problems. For example: (*1*) A good scavenger should react with the electrons only. There should be no side reactions, as seems to be the case for all known scavengers. (*2*) In order to scavenge all the electrons produced by the irradiation the scavenger concentration must be high. Therefore, the liquid under investigation is far from being a single component system.

Having pointed out these limitations, scavenging experiments usually give values between 4 (29) and 6 (30) for the total ionization yield in the hydrocarbons. This would be consistent with the value of G_{tot} (4 ± 1) obtained from YGP ranges.

Deductions from Calculated Curves Performed with YGP

It seems that for hydrocarbons, the gas phase value can be used as an approximation for the liquid phase. Therefore, $G_{tot} = 4.3$ (9) was used for *n*-pentane, cyclopentane, neopentane, and neohexane. This value falls in the credibility gap of 4 ± 1 deduced earlier for a YGP range distribution function.

The voltage and temperature effects on the free ion yield are displayed in Figs. 6 and 7 for *n*-pentane at low and high temperatures respectively. Results for several temperatures are shown for cyclopentane in Fig. 8, neohexane in Fig. 9, and neopentane in Fig. 10. All calculations were done with a YGP range distribution function giving for each experimental temperature a most probable thermalization range, b_{GP}. At high temperatures, the calculated curves do not give a good fit to the data points in the low (<10 kV/cm) field strength region. This could be an artifact because the cell glass becomes slightly conducting at high temperatures, therefore allowing a voltage drop through the cell envelope. Fortunately this effect is not ohmic and seems not to affect higher voltages. In order to compare the ranges calculated for the four hydrocarbons, they must be multiplied by the density at the appropriate temperature.

A plot of the normalized most probable penetration ranges for the four compounds under

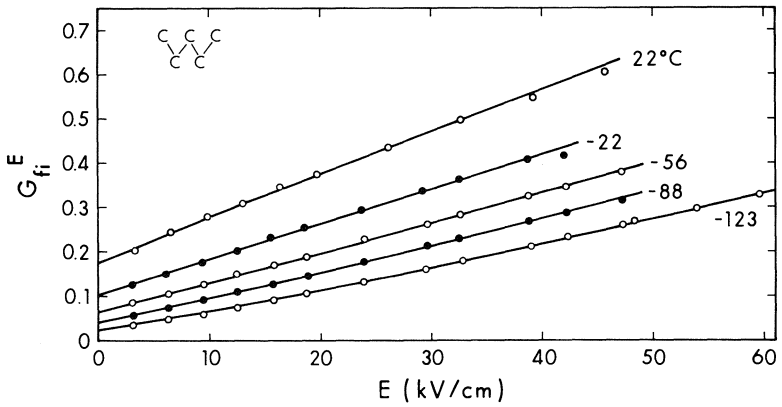

FIG. 6. Free ion yields at field strength E in liquid n-pentane at various temperatures. The lines are calculated using [8] with the YGP range distribution function and a total ionization yield, $G_{tot} = 4.3$.

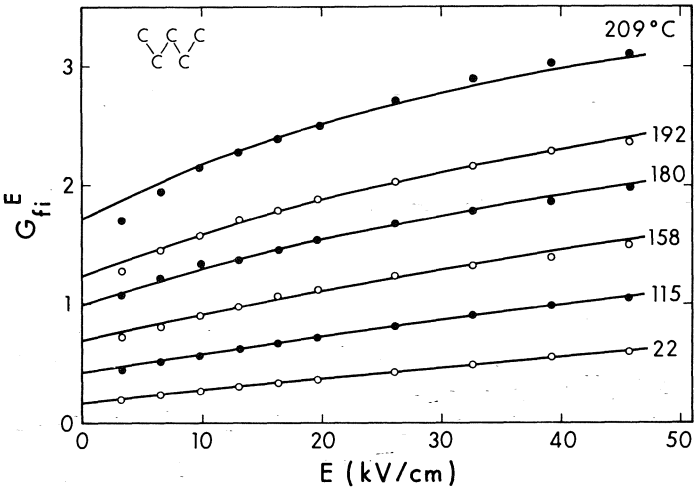

FIG. 7. Free ion yield $G_{fi}{}^{E}$ at field strength E in liquid at various temperatures and upper critical gas (209°C) in n-pentane. The lines are calculated using [8] with the YGP range distribution function and a total ionization yield, $G_{tot} = 4.3$.

investigation is displayed in Fig. 11. Three major conclusions can be deduced from this plot.

(*1*) The normalized mean penetration range is not the same for all hydrocarbons. It is dependent on the structure of the molecule. This has already been shown for part of the liquid range (23, 31). It remains true up to the critical temperature but differences are smaller at the critical than at lower temperatures.

(*2*) The normalized penetration range is not constant for the complete liquid range. Neopentane, neohexane, and cyclopentane curves go through a maximum. This maximum in the mean penetration range occurs at a temperature very close to the temperature where the mobility of thermal electrons in these liquids also goes through a maximum (15). The mean penetration ranges curve of n-pentane does not go through a maximum in the liquid phase. Nor is a maximum observed for the thermal electron mobility in n-pentane.

The observation of parallel behaviour between epithermal and thermal electrons is not new. It has already been pointed out (31) that the inelastic scattering cross sections of alkanes for both thermal and epithermal electrons are affected by the same factors, and only the relative magnitudes of the effects are different. The present work necessitates some elaboration

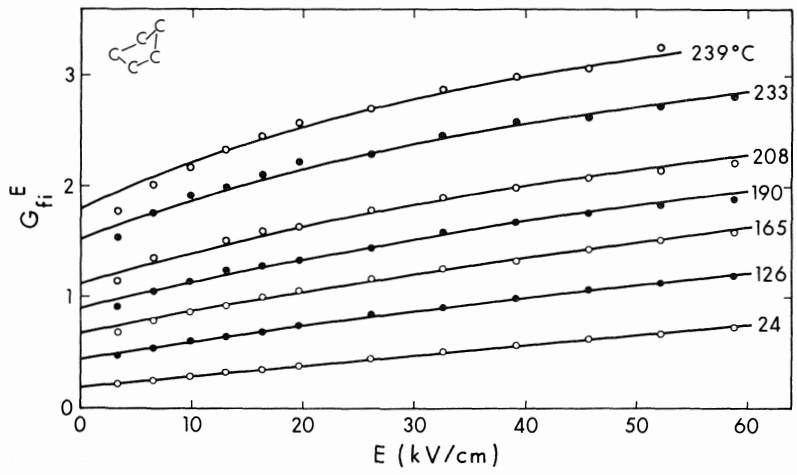

FIG. 8. Free ion yield $G_{fi}{}^{E}$ at field strength E in liquid at various temperatures and critical gas (239°C) in cyclopentane. The lines are calculated using [8] with a YGP range distribution function and a total ionization yield, $G_{tot} = 4.3$.

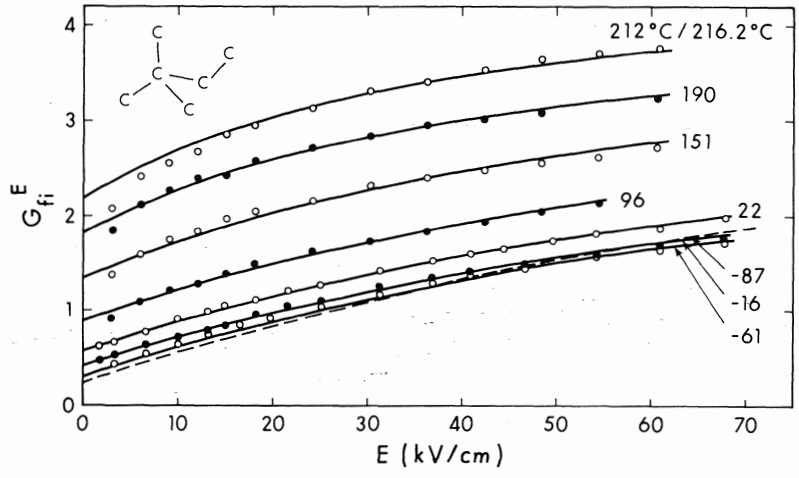

FIG. 9. Free ion yield at field strength E in liquid at various temperatures and critical gas (216.2°C) in neohexane. The lines are calculated using [8] with a YGP range distribution function and a total ionization yield, $G_{tot} = 4.3$. The experimental points are not plotted for −87°C and 216.2°C to avoid confusion.

of this point. The thermal electron mobility, in neopentane for example, first increases then decreases with an increase of temperature (15). This decrease in the mobility is interpreted by a breaking down of conduction bands resulting from a drastic decrease of the liquid density approaching the critical region. If the epithermal electron is also sensitive to the breaking of conduction bands, it seems logical to deduce that it has to travel in these conduction bands when its energy is very close to thermal. One can therefore suspect that the sensitivity of epithermal electron penetration ranges to molecular structure is due to the presence of well defined conduction bands in some liquids and their absence in others.

(*3*) At temperatures above critical, the density of the gas enclosed in the cell volume remains constant and an increase of temperature is associated with an increase of electron mean penetration range. This is shown in the present work for *n*-pentane and neopentane and has been measured for other hydrocarbons (32). At subcritical temperatures, a temperature in-

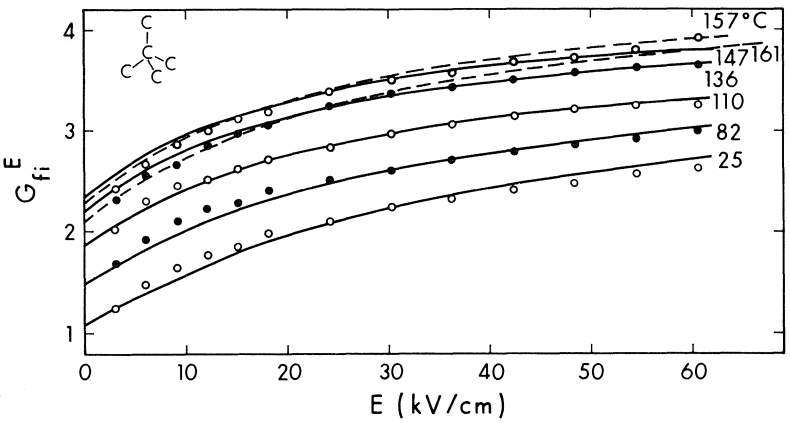

FIG. 10. Free ion yield $G_{fi}{}^{E}$ at field strength E in liquid at various temperatures and critical gas (161°C) in neopentane. The lines are calculated using [8] with a YGP range distribution function and a total ionization yield, $G_{tot} = 4.3$. The experimental points are not plotted for 157°C and 161°C to avoid confusion.

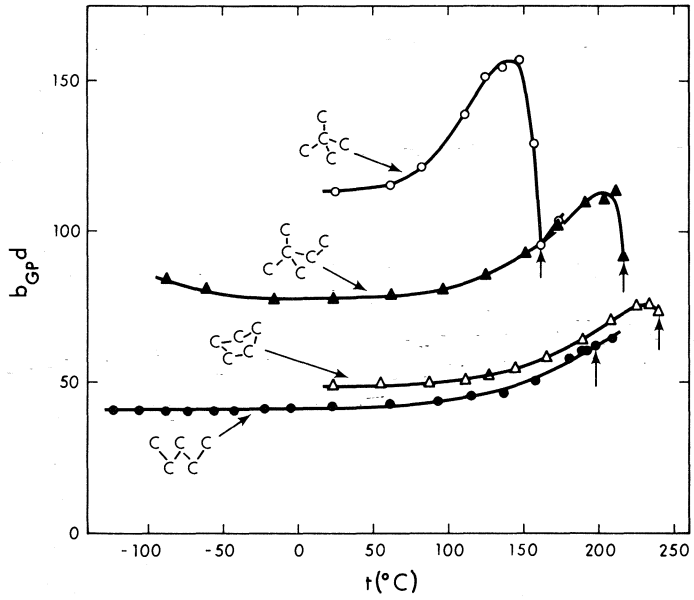

FIG. 11. Variation of normalized mean penetration ranges $b_{GP}d$ with temperature for *n*-pentane, cyclopentane, neohexane, and neopentane. The vertical arrows indicate the critical temperature of the alkanes.

crease goes with a density decrease. It is difficult to dissociate the relative effect of both factors on the electron mean penetration range. The maxima in the penetration ranges do not occur at the critical temperatures but at lower temperatures where the alkanes are still liquid and where the densities of neopentane, neohexane, and cyclopentane are about the same (0.390 g/cm^3). This tends to demonstrate that nothing special happens at the critical temperature, contrary to what had been anticipated from theory for electron mobilities (33). Consistent with the observations on electron ranges, the electron mobility in Xe did not undergo a transition in the critical region (34) nor in the four alkanes studied (15).

Acknowledgments

I wish to thank the staff of the Radiation Research Center for help with the electronics.

I am also grateful for discussions with Dr. G. R. Freeman and T. G. Ryan.

Discussion

J. Jortner: An important mechanism for energy loss of electrons in liquid hydrocarbons may originate from inelastic electron–molecule scattering followed by vibrational excitation. Now, these hydrocarbons are characterized by low vibrational frequencies which may be thermally excited. Collision of an electron with a vibrationally excited molecule will provide a more effective energy loss mechanism than collision with a ground state molecule. It is possible that the maximum observed in the initial separation lengths b_{GP} *vs.* temperature originates from thermal vibrational excitations? This question will be settled by whether the maximum in b_{GP} originates essentially from a density effect or from a temperature effect. In the latter case the mechanism proposed herein may be relevant.

J.-P. Dodelet: The fact that a maximum appears in some liquids at about the same temperature for epithermal electron thermalization ranges and thermal electron mobilities indicates that the electron finds it difficult to lose energy when its energy is just above thermal. Therefore I do not think that vibrationally excited molecules provide a good explanation of the maximum appearing in thermalization lengths. A density effect seems to provide a better explanation. This is underlined by the fact that the density (g/cm^3) at the maximum thermalization length is the same for the three liquids in which this maximum appears.

G. R. Freeman: The data presented by Dodelet seem to indicate that the main part of the thermalization range in a liquid hydrocarbon is attained by the electrons when they are in the conduction bands not much above thermal energy. Scattering cross sections are relatively small in the conduction bands, so electron de-energization is inefficient in them. Conduction bands are less well defined in *n*-pentane than in neopentane, so electron scattering is greater and the range is shorter in the former than in the latter. Conduction bands seem to be more clearly defined in liquids that are made up of more spherelike molecules. The difference between density and temperature effects will be more clearly seen in our mobility paper in the last session of the conference.

L. G. Christophorou: In connection with Dr. Freeman's comment on the importance of the low-energy region in determining the size of the penetration range, I wish to point out that measurements of the rate of energy loss by subexcitation electrons for a number of polyatomic *gases*, including hydrocarbon vapors, (L. G. Christophorou, K. S. Gant, and J. K. Baird. Chem. Phys. Lett. **30**, 104 (1975)) show that the rate of energy loss varies greatly from one

compound to another in the region of vibrational excitation threshold ($\lesssim$0.5 eV), but it changes little for energies 1–2 eV. This clearly shows the importance of energy loss processes in the very low energy range ($\lesssim$0.5 eV) in determining the particle's range (or thermalization time).

G. R. Freeman: The effect is amplified in the liquid phase because conduction bands do not exist in low density gases. For example, the large difference between the ranges in neopentane and *n*-pentane in the liquids would not be expected in the gas phase.

K. Funabashi: The concept of 'thermalization' distance is sufficiently vague to warrant a detailed quantitative fit of experiment with any formula with more than one parameter. Energy loss for a subexcitation electron undoubtedly involves multiphonon processes besides single-phonon processes. In view of the fact that cross sections for elastic scattering in large alkane molecules are much (orders of magnitude) larger than those for inelastic processes, we have reason to believe that the so-called initial distribution is *mainly* determined by elastic scattering of the medium which is particularly important for very low-energy electrons.

G. R. Freeman: The difference in magnitude of the ranges in the liquids *n*-pentane and neopentane indicates that inelastic scattering is important. It appears to us that the range distributions are mainly determined by inelastic processes at electron energies not much above thermal.

E. O. Forster: What is the meaning of a "thermalized electron"?

J.-P. Dodelet: A "thermalized electron" is an electron having the same average kinetic energy as the molecules of the liquid.

E. O. Forster: Could one not readily associate the value of b_{GP} with the trap depth deduced from molecular structure? Neopentane has the most shallow trap and *n*-pentane is deepest. Hence a "thermalized" electron will be trapped more readily in a shorter distance in *n*-pentane than in neopentane.

J.-P. Dodelet: Yes. Alternatively, the magnitude of the thermalization length of epithermal electrons in liquids may be dependent upon the presence or absence of well-defined extended states. If the extended state is well defined it is because the trap depth is shallow.

E. O. Forster: How do you explain the decrease in b_{GP} near the critical point? Could the intense density fluctuations account for this phenomenon? Again, light scattering near the critical point suggests that such fluctuations might be worth considering.

J.-P. Dodelet: The decrease in b_{GP} near the critical point in some liquids is explained in terms of breaking down of extended states due to the density decrease. If the molecules become too far apart, their excited orbitals no longer overlap to produce an extended state.

J. L. Magee: I would like to congratulate Dr. Dodelet, Professor Freeman, and the Alberta group on the large amount of good work they have done on this problem. However, I have been thinking about this matter for a long time and I do not believe that we have a model which is ready for fine-tuning. There are several difficulties that are very troublesome, for example the multi-ion-pair neglect which Dr. Dodelet mentioned. Dr. Mozumder recently called my attention to another effect which may be of considerable importance, that the mobility of electrons in hydrocarbons is not constant, *i.e.*, the drift velocity is not proportional to the first power of the field strength. Mozumder has recalculated several free ion yields taking this effect into account and found that the initial distributions necessary to obtain given values are not those obtained from use of the Onsager equation. (He will publish a short paper on this topic.) There may be even other effects which have not been considered.

G. R. Freeman: Whether or not the electron mobility in a liquid hydrocarbon varies with the field strength depends on the hydrocarbon structure and density and on the field magnitude. It is up to the theoreticians to fine tune the model and up to the experimentalists to point the way. There are many shortcomings in our calculations, but we think that the similarities between the $b_{GP}d$ and mobility plots illustrate your early prediction that the electron ranges are attained mainly after the electrons have reached energies of a few tenths of an electronvolt.

J. M. Warman: We have calculated (J. M. Warman and M. C. Sauer. J. Chem. Phys. **62**, 1980 (1975)), from experimentally determined thermalization times in gases, the expected values of bd for neopentane and *n*-hexane (presumed similar to *n*-pentane). These values were 32 and 61 g Å cm^{-3}, respectively. The values of bd in the liquid phase at close to the critical temperature would therefore appear to be approaching the values expected in the gas phase. Secondly, since a decrease in mobility, as observed in neopentane, corresponds to a decrease in the scattering mean free path then this might be taken to directly indicate a decrease in the thermalization range as observed, if a random walk model is accepted. The correlation between μ and b has, however, been found to be rather weak when different liquids at normal densities are compared.

G. R. Freeman: We are now studying the gases at low and high densities. The density normalized ranges in the critical region are similar to, but not the same as, those in the low density gases. However, your estimated values are lower than ours. In answer to the second comment, although we have found fine structure in the correlation between μ and b_{GP} in different families of liquids (Can. J. Chem. **53**, 2714 (1975); **54**, 744 (1976)), I would not call the correlation weak. We must remember that μ in most liquids is strongly dependent upon three parameters (structure, density, and temperature), while b_{GP} depends mainly on the first two.

A. O. Allen: The many calculations on the subject of free ion yields which have appeared during the long period I have been interested in the subject, have in my opinion added little to our understanding. Looking at the data in a commonsense way, we see that those liquids which show thermally-activated mobilities have low free ion yields. This immediately suggests that the probability of an electron escaping the field of the positive ion depends on the

chance of its falling into a trap on the way out. A calculation made on this picture might provide a useful correlation between mobility and free ion yield.

J.-P. Dodelet: To my knowledge all fluid hydrocarbons display a thermally activated electron mobility if it is measured over a large enough temperature range. This includes neopentane and neohexane. The behavior of electron mobility in these hydrocarbons will be discussed in the last paper of this conference (Dodelet and Freeman). I agree that around room temperature and below, electron mobility in neopentane displays nearly no energy of activation, but at higher temperatures the mobility is quite sensitive to change of temperature. Furthermore, a high free ion yield is observed in *n*-pentane at temperatures close to critical and the electron mobility in *n*-pentane in the same temperature range is thermally activated. The picture is not simple.

G. R. Freeman: It is true that calculations are often more enlightening to those who make them than to others. I think that the large ranges in hydrocarbons are attained mainly by the epithermal electrons travelling in the conduction bands. Liquids comprised of less spherelike molecules are more efficient energy sinks (scatterers) and contain deeper traps. Dr. Allen's picture is qualitatively similar to ours.

L. Onsager: As we approach the critical point, fluctuations get large, which tends to reduce any benefit that the electron free path may obtain from Ramsauer effects.

G. R. Freeman: The density fluctuations characteristic of the critical region are long range. They appear to have little effect on the electron behavior. This was demonstrated for electrons in xenon by the work of Kimura (J. Chem. Phys. **60**, 4081 (1974)). However, I agree that the maxima observed in the range–density and mobility–density plots are related to Ramsauer effects.

Nonhomogeneous charge neutralization kinetics in nonpolar organic solids (Extended Abstract)

K. K. AMETOV, E. L. FRANKEVICH, G. F. NOVIKOV, AND B. S. YAKOVLEV
Institute of Chemical Physics, Academy of Sciences USSR, 142432 Chernogolovka, USSR

Received November 22, 1976

It is known that the bulk of electrons generated by ionizing radiation in organic nonpolar amorphous solids and liquids are thermalized in the vicinity of geminate positive ions, where the Coulomb energy is greater than the thermal energy. Such electrons form pairs correlated with positive ions and have a significant probability of recombination with 'their own' ions or ions of their track. This recombination process (so called 'geminate' recombination) cannot be described by applying homogeneous kinetics. Most of the theoretical approaches to geminate recombination in nonpolar liquids have been based on considerations of the diffusion of a classical charged particle. These approaches may prove to be unjustified for electron–ion geminate recombination in organic solids where electrons may be captured by structural traps for a time commensurable with the characteristic time of measurement.

To describe the kinetics of geminate recombination in this case we neglected a tunnelling mechanism of recombination and used a distribution function $Y(N)$ (1). This function gives the probability for an electron to recombine after N trapping events. The case was considered when a transition of an electron from one localized state, e_{tr}^-, to another can be characterized by a single relaxation time τ. Then the probability for the electron to undergo N captures by traps for the time t is the Poisson function

$$[1] \qquad \omega_N(t) = (t/\tau)^{N-1}\, e^{-t/\tau}/(N-1)!$$

and the rate of recombination is

$$[2] \qquad W(t) = \frac{1}{\tau}\sum_{N=1}^{\infty} Y(N)\omega_N(t)$$

This dependence was compared with experimental data on photo- and thermostimulated processes in 3-methylpentane (3-MP) glasses γ-irradiated at 77 K. For photostimulated recombination we used $\tau = (\sigma L)^{-1}$, where σ is the known photo-detrapping cross-section and L is the light intensity. For isothermal recombination at 77 K a good fit with experiment was obtained by using $\tau = 26$ min (1). A comparison of equation 2 with the decay of the photostimulated recombination luminescence of 3-MP at 77 K illustrated in Fig. 1 shows a satisfactory agreement for

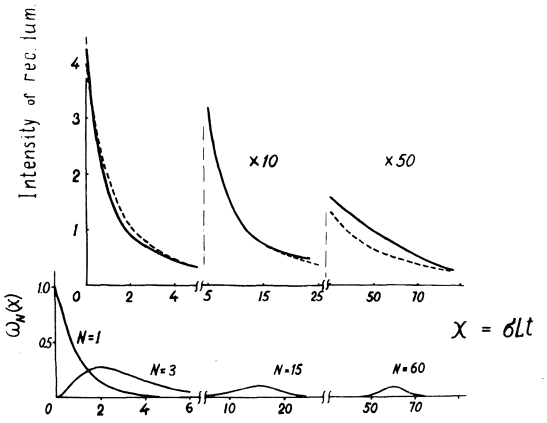

FIG. 1. Dependence of photostimulated luminescence in γ-irradiated 3-methylpentane at 77 K on ir-bleaching time; dose 3×10^4 rad; the ir light was switched on 36 min after e_{tr}^- generation. Dashed curve is calculated from [1]–[3]. The functions $\omega_N(x)$ are shown for $N = 1$, 3, 15, and 60.

$$[3] \qquad Y(N) = \begin{cases} 2.5 & \text{at } N = 1 \\ N^{-3/2} & \text{at } N > 1 \end{cases}$$

Such a distribution function has also been used to describe the decay of photoconductivity, isothermal recombination luminescence, quantum yield of e_{tr}^- bleaching (1), electric polarization of electron-ion pairs (2) in 3-MP at 77 K, and the radiothermoluminescence kinetics of 3-MP (3). For example, Fig. 2 shows the experimental (4) and calculated dependences of the quantum yield of e_{tr}^- bleaching, φ, on the optical density of e_{tr}^-, D. The latter was obtained from the equation:

$$[4] \qquad \varphi = \frac{1}{D}\frac{dD}{dx}$$

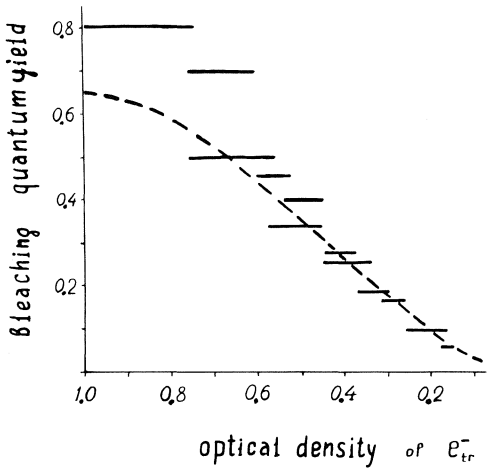

FIG. 2. Comparison of the calculated dependence of the quantum yield of bleaching of e_{tr}^- on the optical density of e_{tr}^- with experimental data (4) for 3-methylpentane: — Hamill's data; --- calculated.

where $x = \sigma Lt$, and

$$[5] \quad D \sim [e_{tr}^-] \sim \sum_{N=1}^{\infty} Y(N) \sum_{i=1}^{N} \omega_i(t)$$

At $t \gg \tau$, [5] may be written as

$$[6] \quad [e_{tr}^-] \sim (t)^{-1/2}$$

Such a relationship is known to be justified for geminate recombination of electrons in liquids and corresponds to the diffusion theory of recombination at longer times ($t \gg \lambda^{-1}$) (5). This result may be understood if one assumes the same space distribution of thermal electrons in both liquid and solid hydrocarbons because at $t \gg \tau$ the electron motion in solids may be described by a diffusion equation.

Discussion

A. C. Albrecht: (*1*) We have found that the decay of infrared stimulated recombination luminescence in 3-MP at 77 K can be fit to two exponentials and a second-order equation. The second order is interpreted through a simple distribution of unimolecular (one-jump) rate constants. The rate constant distribution is transformed to a radial distribution by making an assumption on how the rate constant depends on charge separation through the Coulomb field. Over 95% of the recombination events are accounted for in this way. As usual such a procedure represents simply another model which can be made to fit the data. The multiple hopping model seems to predict a polarization current which provides an interesting additional check on that model at least.

(*2*) A simple way of distinguishing polarization events from bulk transport is to see whether when electrodes are blocked the observed signal is altered. Polarization events within the Coulomb well should not be affected by blocking. Bulk current flow should be on an appropriate time scale. We have tried this for the 3-MP system at 77 K producing electrons photolytically. We found that blocking converts the normal ultraviolet dc photocurrents into polarization spikes, indicating that bulk flow is the major source of photocurrent in that system. However the photocurrent signals obtained when visible (or near infrared) light is used to excite previously produced electrons were not thus tested.

Electric field perturbed electron tunnelling in nonpolar organic glasses

A. J. DOHENY AND A. C. ALBRECHT

Department of Chemistry, Cornell University, Ithaca, NY, U.S.A. 14853

Received October 22, 1976

A. J. DOHENY and A. C. ALBRECHT. Can. J. Chem. **55**, 2065 (1977).

Isothermoluminescence (ITL) and electrophotoluminescence (EPL) resulting from electron–cation recombination are measured in a 2-methylpentane–methylcyclohexane glass. The ITL is more characteristic of quantum-mechanical tunnelling and the EPL signal is markedly stronger in this new glass than previous measurements in 3-methylpentane. Quantum-mechanical tunnelling theory is used to predict recombination rates of electrons in the potential field of a cation plus an applied field. Numerical integration of the nonhomogeneous kinetic equations resulting from a distribution of cation–electron separations leads to qualitative and quantitative predictions of the EPL signal that are observed experimentally. Fitting of the theory to experiment supports the conclusions that the angular distribution of the photoelectrons about the cations is close to isotropic, that the electrons active in ITL and EPL on the time scale of minutes are separated about 50 Å from their parent cation, and that the trap ionization potential in this nonpolar hydrocarbon glass is in the range of 0.5 to 0.7 eV.

A. J. DOHENY et A. C. ALBRECHT. Can. J. Chem. **55**, 2065 (1977).

On a mesuré l'isothermoluminescence (ITL) et l'électrophotoluminescence (EPL) qui se produit à partir de recombinaisons électron–cation dans des verres de méthyl-2 pentane et de méthylcyclohexane. L'ITL est plus caractéristique d'un tunnel de mécanique quantique et le signal EPL est beaucoup plus fort dans ce nouveau verre que ceux mesurés antérieurement dans le méthyl-3 pentane. On utilise la théorie des tunnels de mécanique quantique pour prédire les vitesses de recombinaison des électrons dans le champ potentiel d'un cation plus un champ appliqué. L'intégration numérique des équations cinétiques non-homogènes résultant des distributions des séparations cation–électron conduit à des prédictions qualitatives et quantitatives du signal EPL qui sont observées expérimentalement. L'ajustement de la théorie avec les expériences supporte les conclusions voulant que la distribution angulaire des photoélectrons autours de cations est près de l'isotropique, que les électrons actifs dans l'ITL et l'EPL sur une échelle de temps de minutes sont séparés par environ 50 Å de leur cation parent et finalement que le potentiel d'ionisation de piège dans ce verre hydrocarboné non-polaire est d'environ 0.5 à 0.7 eV.

[Traduit par le journal]

Introduction

When low temperature glasses are exposed to ionizing radiation, electrons are produced which subsequently may be chemically scavenged by other species of suitable electron affinity produced during the same irradiation (or added to the system before forming the glass). In many glasses, the electrons may be physically trapped in the medium for times much longer than the irradiation time, forming a trapped or solvated electron. In this temporary trapped state, they may be studied by conventional spectroscopies and over times ranging from nanoseconds to years depending on the natures of the glass and of the scavenging species.[1] In cases such as those described herein, where the scavenger is a radical cation, the neutralization of the charge pair can produce an electronically excited molecule; the intensity of the luminescent decay of this molecule is then a good measure of the rate of change of the trapped electron concentration. This isothermoluminescence (ITL) is a measure of the rate of charge neutralization only when this is slow compared to electronic relaxation times and is realizable only when it is fast enough to give a detectable flux of photons.

Quantum-mechanical tunnelling of an electron from its trapping site to the scavenger is thought to be the rate determining process in trapped-electron decay, at least in very hard ($\gtrsim 10^{12}$ P) glasses (2–4). However, ITL in 3-methylpentane (3MP) glasses at 77 K shows many effects not to be expected from a tunnelling process. The ITL is apparently quite temperature dependent (3, 5) and its fall-off with time is approximately $1/t^2$ at long times (3, 5), as compared with a $1/t$ law predicted and encountered in other cases of

[1] A general review of the subject with extensive reference is given in ref. 1.

ITL where tunnelling is the major mode of trapped-electron decay (3). In addition, strong electric fields (10^5 to 10^6 V/cm) applied to a 3MP glass which is undergoing ITL cause an enhancement of the electron decay rate, giving rise to a burst of light termed electrophotoluminescence (EPL) analogous to the Gudden–Pohl effect in inorganic phosphors (6). The EPL effect in 3MP was qualitatively and quantitatively explained (except at short times) by a one-parameter equation relating the EPL effect to the ITL. The parameter was found to be exponential in applied fields suggesting that the decay of any particular electron was governed thermally by a simple Arrhenius activation energy model (6).

Ott (5) and Bullot *et al.* (7) obtained an apparent activation energy for ITL in 3MP of about 0.67 eV, which corresponds to the activation energy of viscosity in 3MP obtained by Ling and Willard (8). Further, Ott (5) found that the temperature dependence of ITL in 3MP disappeared and that the ITL had a $1/t$ dependence below 72 K, consistent with the results of Kieffer *et al.* (3). This leads one to conclude that a mechanism similar to that of Pilling and Rice (9) is operative in the electron–cation recombination in 3MP at 77 K for times in the order of 10 min, *i.e.*, a trapped electron diffuses towards its parent cation at a viscosity-mediated rate until it reaches the point at which tunnelling becomes fast compared with further inward diffusional motion. Thus neither a pure tunnelling nor a pure thermal model can be adequate to explain the EPL phenomenon in 3MP at 77 K.

Instead of adapting a serial diffusion-tunnelling model to the EPL phenomenon, in the present work we report EPL in a hydrocarbon glass similar to but enough harder than 3MP so as to move the time scale of the viscosity-mediated effects beyond the time scale of the EPL experiment. Tunnelling theory is extended to the EPL experiment, whereupon it is found that the EPL effect in the harder glass is qualitatively predictable from a reasonable tunnelling model. Furthermore, it is found that the quantitative agreement between the model and the EPL experiment can be forced by variation of the parameters in the tunnelling calculations, but that only a limited range of trap depths is compatible with reasonable values of the other parameters and that a spherical distribution of electrons about their respective cations gives a significantly better fit to the experimental data than does an angularly anisotropic distribution.

Experimental Results

The experiments described herein have been carried out essentially as described previously by Bullot and Albrecht (6). *N,N,N′,N′*-Tetramethylparaphenylene diamine (TMPD) was obtained from Aldrich Chemical Company and purified by vacuum sublimation. Hydrocarbons were obtained from Phillips Petroleum Company. Hydrocarbon solutions of TMPD were frozen between two electrodes in a Dewar originally designed by Cadogan (10) for photoconductivity studies.

Exceptions to the method previously described (6) are that the back electrode is made of highly polished stainless steel, the irradiating light is passed through a filter consisting of two Corning 7-56 filters plus 2 cm of the hydrocarbon composing the glass, and the phototube is covered with a Corning 7-60 filter so that only the fluorescence of TMPD is monitored. Samples, once frozen between the electrodes, are allowed to relax at least 4 h before irradiation. Irradiation is for 1 min, following which the phototube is locked into place with the photomultiplier window approximately 5 cm from the window on the outside wall of the Dewar. Ott (5) found that the ITL in 3MP was apparently uncomplicated by viscosity for times up to 25 min at temperatures of 72 K or less. If we extrapolate the viscosity of 3MP below its glass transition using published data (8), we find that this temperature corresponds to a viscosity of about 3×10^{15} P. This figure is within an order of magnitude of that given by Hutzler *et al.* (11) for a 1:1 (v/v) mixture of 2-methylpentane (2MP) and methyl cyclohexane (MCH) at 77 K, which figure is also an extrapolation from measurements at higher temperatures.

Approximately millimolar solutions of TMPD in this solvent mixture were examined for the EPL effect. Most often the glasses cracked before attaining thermal equilibrium, but although they were thus unsuitable for the EPL experiment, ITL's determined with these cracked glasses exhibit ITL $\propto 1/t$ for times of 25 min or longer (Fig. 1).

One sample did resist cracking at 77 K, and sustained applied fields up to 5×10^5 V/cm. In this sample the EPL effect was measured at different fields in both polarities. In addition various sequences of field on and off and polarity reversals were tried. The qualitative results are summarized pictorially in Fig. 2. They are in every gross feature qualitatively

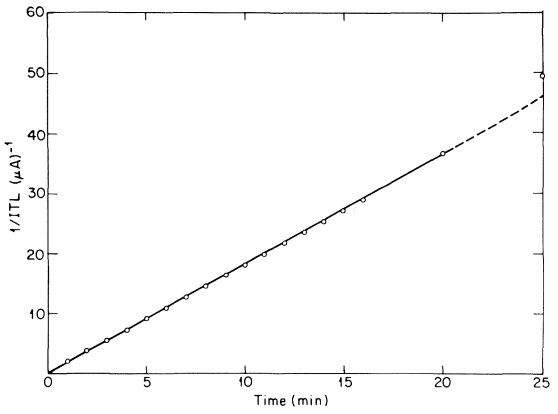

FIG. 1. Plot of $(ITL)^{-1}$ *vs.* time in 2MP/MCH (μA at anode of photomultiplier).

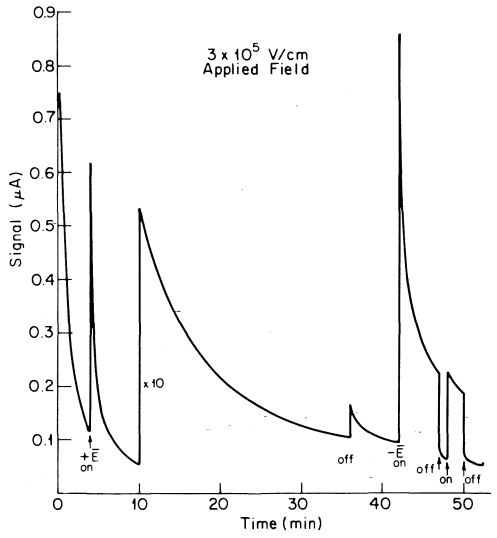

FIG. 2. Plot of EPL signals in 2MP/MCH.

identical with the EPL effects reported before for 3MP glasses (6). However, the relative height of the EPL spike and the time taken for the EPL signal to decay to the level of the ITL both appear to be about an order of magnitude larger in this glass than in the previous 3MP glasses. Further experiments established that the enhanced EPL effects in this glass could not be due to the infrared-stable, field-sensitive state of TMPD previously investigated in this laboratory (12) in 3MP glasses, for no evidence of this state was found in the harder glass of this work.

Theory

The recombination of a trapped electron with its geminate cation can be treated as a radiationless transition from an extreme charge-transfer state into an isoenergetic, near continuum of Rydberg-type states, the time dependence of which transition derives from the Fermi golden rule. The final state must be buried in a near continuum, since the total energy of the initial charge-transfer state in nonpolar glasses is at most only an electron volt or so below complete ionization in the nonpolar condensed phase, at which level molecular energy densities are quite large.

An apparently alternative approach is to treat the problem as the tunnelling of a trapped electron through a potential barrier from some trapping potential to the Coulomb well of the cation. This is not a real alternative, however, since in either view the recombination rate can be reduced to a frequency factor weighted by the probability that an electron initially trapped at a distance R from its parent cation can be found at the much shorter distance, r_0, from the cation where the electron emerges from the nonclassical into the classical region of the potential. These two approaches are distinguished only in their detailed interpretation of the frequency factor, which difference is related as much to the implicitly different choice of zeroth order states as to anything else.

The probability part of the recombination or transition rate must include tunnelling in the nuclear coordinates of the solvent cation system, *i.e.*, a Franck-Condon factor, as well as in electronic coordinates. For the present we will subsume this Franck–Condon factor as well as a geometric factor (13) into a generalized frequency ν; an appropriate and reasonable choice of this frequency, we intend to show, will theoretically duplicate the experimental EPL effect.

Theoretical Electron-tunnelling Rates

The electron space part of the probability can be derived from the semiclassical or WKBJ approximation to the electron wave function in the nonclassical region of the potential (14). Thus for the recombination rate of a cation–electron pair separated by a distance R we simply write

$$[1] \quad k(R) = \nu \exp\left[-2/\hbar \int_{r_0}^{r_1} (2m|U(r)|)^{1/2}\, dr\right]$$

In [1], m is the mass of the electron, r_0 and r_1 are the classical turning points of the motion, *i.e.*, the zeros of $U(r)$ which defines the energy

deficit of the electron below the top of the barrier, and the R dependence on the rhs is implicit. The frequency factor ν, in either approach to the transition rate, must have as an upper limit the frequency associated with a weakly bound electron or about 10^{14} to 10^{15} s^{-1}.

For the sake of concreteness, we may take the trapping potential of the electron to be a spherical square well of radius a and depth V_0. Then the barrier presented to a trapped electron in the Coulomb field of a monovalent cation in a medium of dielectric constant ε is shown in Fig. 3. V_0 and a determine the local binding energy or ionization potential of the electron, I_0, and the distance tunnelled by the electron to recombine with the cation is L^0. Figure 3 was drawn roughly to scale for a well of diameter 2.5 Å and ionization potential 0.5 eV, located at 47.5 Å from a cation in a medium of $\varepsilon = 2.3$. From the barrier potential of Fig. 3, we set $U(r)$ in the integrand of [1] to be simply $I_0 + (e^2/\varepsilon R) - (e^2/\varepsilon r)$.

Then [1] has the analytical result

$$[2]\quad k(R) = \nu \exp\left\{\frac{-2a}{\hbar}\sqrt{\frac{2me^2}{\varepsilon a}} \times \left[X_2\sqrt{\frac{1}{X_1}-\frac{1}{X_2}} - \frac{\sqrt{X_1}}{2} \times \ln\left(\frac{1+\sqrt{1-\frac{X_1}{X_2}}}{1-\sqrt{1-\frac{X_1}{X_2}}}\right)\right]\right\}$$

where

$$X_2 = \frac{r_1}{a} = \frac{R-a}{a}$$

and

$$X_1 = \frac{R}{a}\left(1 + \frac{RI_0\varepsilon}{e^2}\right)^{-1}$$

Equation 2 is similar to previously published results (3, 13, 15–17) the differences owing to the fact that the potential used includes a trap radius (18). Evaluation of [1] from its analytic form (eq. 2) and by numerical integration using a double-precision 32 point Gaussian quadrature give identical results, which in turn agree with Mikhailov's (16) numerical results when the same values of the parameters are used. Equation 2 predicts that to a good approximation,

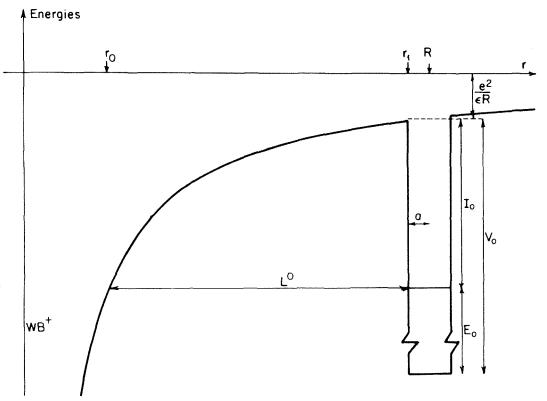

FIG. 3. Potential-barrier model for an electron in a spherical square well in the Coulomb field of a cation. WB^+ is Wurster's blue cation of TMPD. Symbols are defined in text.

$$[3]\quad \frac{\mathrm{d}\ln k(R)}{\mathrm{d}R} \simeq \frac{-2\sqrt{2mI_0}}{\hbar}$$

exactly as one would get from a square-barrier (*i.e.*, non-Coulomb) approximation to the integral. However, the square-barrier approximation introduces large absolute errors into $k(R)$ which can only be partially compensated by using L^0 or some other effective tunnelling length in a square-barrier formula. The major effect of the Coulomb field, as pointed out by Mikhailov (16), is that electrons decaying at a particular rate may be as much as 30% further from the cation in a low dielectric, small I_0 glass, than a square-barrier calculation would require them to be. This in turn has major ramifications on the theory of the EPL effect.

The shape of the potential when an applied electric field is superimposed on a Coulomb field is shown in Fig. 4. The energy scale is the same as in Fig. 3, but the horizontal scale has been halved to show the same trap as in Fig. 3 on both sides of the cation with respect to the internal field, which in the scale of the figure is 4×10^5 V/cm. When the potential barrier of Fig. 4 is used in [1], one obtains

$$[4]\quad k(R,\theta) = \nu \exp\left[\frac{-2}{\hbar}\sqrt{\frac{2me^2a}{\varepsilon}} \times \int_{X_1}^{X_2}\left(\frac{1}{X_1} - X_1\mathcal{E} - \frac{1}{Q} + Q\mathcal{E}\right)^{1/2}\mathrm{d}Q\right]$$

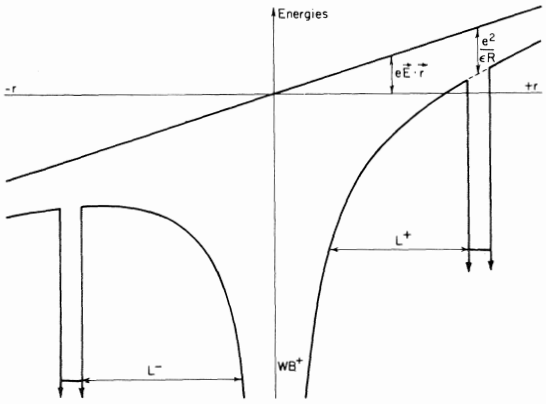

FIG. 4. Potential barriers resulting from application of an electric field to the potential of Fig. 3.

where $Q = r/a$, X_2 is defined as in [2], $\mathcal{E} = \varepsilon a^2 E \cos\theta/e$, and X_1 is the positive root of

$$X_1^2\left(\frac{\mathcal{E}R}{a}\right) + X_1\left\{1 + \frac{I_0\varepsilon R}{e^2} - \mathcal{E}\left(\frac{R}{a}\right)^2\right\} - \frac{R}{a} = 0$$

Fowler and Nordheim (19) encountered the tunnelling integral of [4] in a similar context, *i.e.*, the field emission of metals, and expressed the result as an elliptic integral. The same authors (19) and later Brocklehurst (2) evaluated [4] without including the angular dependence or the Coulomb field. Hagston (17) has derived an angle-dependent approximation to [4] when the field is so small as to give no experimentally observable effects. Instead, we employ the same numerical procedure that gives exact agreement with the analytical expression in the zero-field case. Qualitatively, the results of these calculations can be seen in graphs like Fig. 5 which shows $\log_{10} k(R, \theta)$ as a function of θ measured from the field vector. The internal field is 4.3×10^5 V/cm, $I_0 = 0.7$ eV, $\nu = 10^{15}$ s^{-1}, and $a = 1$ Å. The solid apple-shaped curves are for field-on conditions, with the more negative log scale in parentheses corresponding to the cation–trap separation of 60 Å. The dotted circles intersecting at 90° and 270° are the logs of the corresponding field-off rates which are of course angle independent. The field-off rate at 50 Å is approximately 3000 times faster than that at 60 Å. With the field on the recombination rate of an electron at 60 Å and directly upfield from the cation is increased by a factor of 250, while

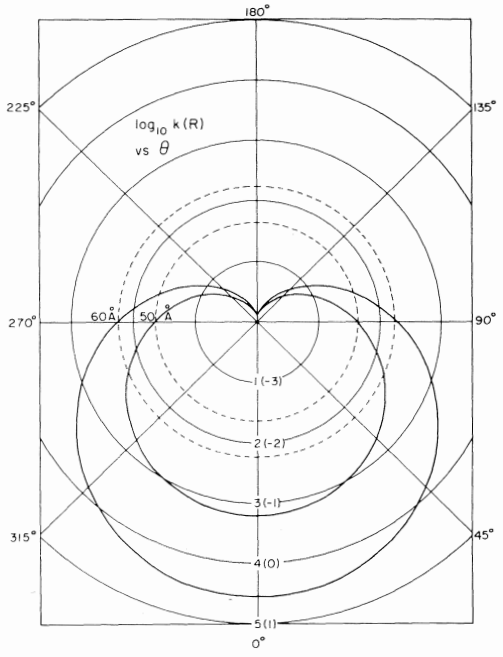

FIG. 5. Plot of log $k(R)$ *vs.* θ (measured from the positive field direction) for $I_0 = 0.7$ eV, $\nu = 10^{15}$ s^{-1}, $a = 1$ Å, and an internal field of 4.3×10^5 V/cm. The scales are explained in the text; but as an example, at 60 Å separation, the field-off rate is about 0.02 s^{-1} while with the field on the rate at 0° is about 5 s^{-1}.

an electron at 50 Å experiences a rate enhancement of only 30. In addition, Table 1 gives the ratio of the field-on rate to the field-off rate at different trap depths, internal fields, and cation–electron separations.

From consideration of Fig. 4, one can see that in the limit of large fields, shallow traps, or large cation–trap separations, all upfield electrons tunnel through virtually the same triangular barrier regardless of their distance from the cation. On the other hand, the tunnelling distance either downfield from the cation or even without the field is much more dependent on R. Therefore any comparison between field-on and field-off tunnelling rates will be highly R dependent. These observations give us warning that in calculating any EPL effect, we must exercise extreme caution in retaining any factors which affect the separation between the fastest remaining electrons and their cations at the instant the field is turned on.

Calculation of Isothermoluminescence and Electrophotoluminescence

Once we can predict field-dependent tunnelling

TABLE 1. $k_{\pm}/k$ for various I_0, E, and R (a = 1 Å)

	60	0.0039	0.060	18.5	363

rates at a particular cation–electron distance, we must apply them to the calculation of ITL and EPL effects. Since the tunnelling rate is such a strong function of the charge-pair separation, only a virtual δ-function distribution of separations (and of the other parameters) can lead to a simple exponential decay. Instead, even for a relatively narrow distribution of separations, say 10 Å wide, tunnelling rates varying over three to four orders of magnitude can be encountered. Hence we treat each electron–cation pair as a separate chemical species (which is valid up to ionic concentrations in the order of 10^{-2} M), each reacting at its own unimolecular rate, but all leading to the same product, and it is the rate of appearance of the product that we measure in ITL and EPL.

The development of the concentration, ITL, and EPL integrals where there exists a zero-time distribution of charge pairs having decay rates dependent upon the pair separation and orientation is standard in the recent literature (4, 17, 20, 21) and need not be repeated here. For our purposes a recapitulation of these integrals using the symbols of this work will suffice.[2]

If R is the charge-pair separation and θ the angle between the electron position vector (with origin at the cation) and the eventual field direction, then the number of pairs remaining at time t, $N(t)$, is given by

$$[5]\quad N(t) = \int_0^{\infty}\int_0^{\pi} n_0(R,\theta) \times e^{-k(R)t} \sin\theta\, d\theta\, dR$$

[2]Further details are to be found in the Ph.D. Thesis of Doheny (22) of which this work constitutes a part.

where $n_0(R,\theta)$ is a linear density of charge pairs and $k(R)$ is the zero-field tunnelling rate of [2]. The ITL signal is

$$[6]\quad \mathrm{ITL}(t) \propto \int_0^{\infty}\int_0^{\pi} n_0 k(R) \times e^{-k(R)t} \sin\theta\, d\theta\, dR$$

while the EPL signal resulting from applying an electric field at time t' to a sample undergoing ITL is

$$[7]\quad \mathrm{EPL}(t', t) \propto \int_0^{\infty}\int_0^{\pi} n_0\, e^{-k(R)t'} k_{\pm}(R,\theta) \times e^{-k_{\pm}(R,\theta)(t-t')} \sin\theta\, d\theta\, dR$$

where $k_{\pm}(R,\theta)$ is the angle-dependent field-on rate of [4]. One assumes that the proportionality in [6] and [7], involving instrumental and quantum-yield factors is field independent and hence identical for both ITL and EPL. The linear density $n_0(R,\theta)$ is motivated by the R^{-2} dependence of photoelectron flux in the limit of no electron scattering following isotropic photoionization.

Equations 6 and 7 have been integrated by various authors (4, 17, 20, 21) using the square-barrier approximation to $k(R)$, *i.e.*, $k = \nu e^{-AR}$. Most often used for n_0, where one has correlated charge pairs, is a constant distribution or a slowly decaying exponential. When a real experiment covers only a few, maybe up to four, orders of magnitude in time, the constant distribution assumption is not so restrictive. The rate constant k is such a strong function of R that only about 10 or 15 Å (not many molecular diameters) are being swept out in an experiment. Practically speaking n_0 must be constant only

over such a range. Since the field-on rates for the upfield electrons are less sensitive to their separation from the cation (than the field-off rates) the electric field will bring into the time domain of the experiment larger separations than are practically seen in ITL. Thus at long times the assumption of constancy of n_0 with R might fail in the field-on case. In any event any real distribution must be integrable on $R \subset (0, \infty)$, so that eventually the tail of the distribution must fall off at least as fast as e^{-R}.

Equation 6, when integrated with the square-barrier rate constant and a slowly decaying exponential distribution, e^{-BR}, where $B \ll A$, gives a simple power law decay at long times

$$[8] \qquad \mathrm{ITL}(t) \propto t^{-m}$$

where (20) $m = 1 + (B/A)$. For a constant distribution, one may take $B = 0$ in [8] or integrate [6] directly (17, 20, 21). In either case

$$[9] \qquad \mathrm{ITL}(t) = C_0/t$$

As already mentioned, the functional form of [9] has been observed in this work and in other glasses independently of temperature (3), but not in 3MP glasses at 77 K (3, 5). Of course, ITL at the experimental time zero is not infinite, but instead a plot of $1/\mathrm{ITL}(t)$ *vs.* experimental time will intersect the x axis sometime during the irradiation period.

In order to integrate [5]–[7] with the full form of the Coulomb well plus electric field barrier, a numerical integration procedure has been devised analogous to that used to perform the integral appearing in the rate constant. The logic of the numerical procedure is briefly outlined in the Appendix.[2] In every case investigated, the distribution $n_0(R,\theta)$ is assumed to be independent of R, but two types of angular distribution have been explored: isotropic and $\sin^2\theta$. The second distribution (in the coordinate system referred to the electric field) corresponds to that to be expected when the photoemissive state is spherically symmetric and the photoelectron ejection direction is governed by the electric field of the incoming photon with no subsequent angular scattering (23).

Theoretical Isothermoluminescence

In Fig. 6 are plotted the theoretical values of the inverse ITL *vs.* time for electrons tunnelling in the Coulomb field of a cation, for two different values of I_0 and an isotropic distribution of initial trapping sites. The integration method gives the same results for anisotropic distributions, which serves as a check on the numerical integration procedure. The differences between the curves are more an artifact of the normalization (*cf.* Appendix), for if the calculation were performed for the same density of traps in R space, the 0.7 eV curve would fall about 20% above the other.

As anticipated by Pilling and Rice (18), the inclusion of the Coulomb field has little effect on the observable ITL kinetics. The actual data for Fig. 6 show deviations from linearity of 0.5%/decade for $I_0 = 0.7$ eV and 1%/decade for $I_0 = 0.5$ eV, but these effects of the Coulomb field on ITL are so small as to be easily buried by the consequences of a nonconstant $n_0(R,\theta)$ (17). However, as noted previously the Coulomb field will determine both the R value whence virtually all the ITL originates at a given time, and, consequently, the magnitude of the EPL effect. Illustrating this are the numbers attached to the curves of Fig. 6, which are the separations in angstroms at times 1, 10, and 100 min where $n(R,\theta,t) = (1/e)n_0(R,\theta)$ for the case with the Coulomb field included and, in parentheses, without Coulomb distortion of the barrier.

Theoretical Electrophotoluminescence

The theoretical EPL effect was calculated for

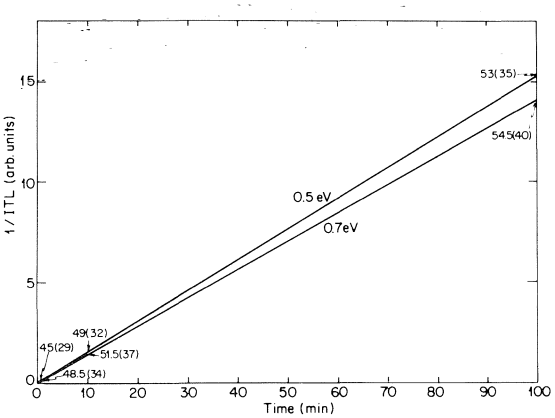

FIG. 6. Plot of $(\mathrm{ITL})^{-1}$ *vs.* time for two different values of ionization potential. For the 0.5 eV curve, $\nu = 3.6 \times 10^9\ s^{-1}$, and for the 0.7 eV curve, $\nu = 6 \times 10^{12}\ s^{-1}$. The numbers attached to the curves are the separations of the active electrons at the given time with and, in parentheses, without the Coulomb field. The fact these are smaller for 0.5 eV is the result of the smaller frequency factor. Note that the rate at which the active separation region increases with time is faster for a 0.5 eV ionization potential.

different fields, angular distributions, values of ν, and field-on times. The calculated EPL signal depends on the R value of the ITL active region and the number density of electrons in this region at the time the field is turned on. Both of these factors necessarily vary with the choice of parameters (the number density through our normalization protocol). However, to eliminate the proportionality in [6] and [7], we prefer to work with the ratio, $P_E(t)$, which we define as EPL(t)/ITL(t) where ITL(t) is the isothermoluminescence intensity which is theoretically predicted at time t in the absence of a field for the identical set of parameters. $P_E(t)$ is plotted *vs.* the logarithm of time, not for any theoretical reason, but simply because the values of this ratio vary dramatically at short times and much less so at longer times.

When plotted in this manner, all cases examined give remarkably similar curves, differing only in the height of the initial rise and their placement on the log (time) axis. Figure 7 is a plot of $P_E(t)$ *vs.* log t calculated for a trap with I_0 = 0.6 eV, when a 4.3 × 10^5 V/cm internal field is applied at 4 min. These curves in general can be described as consisting of an initial spike and then a slower decay until the ratio drops below 1 (*i.e.*, the signal in the presence of a field is eventually less than that expected had the field not been applied at all), reaches a minimum in the neighborhood of 0.9, and turns back toward 1.

Table 2 lists $P_E(t)$ information for traps having I_0 = 0.7 eV. If the field is turned on at

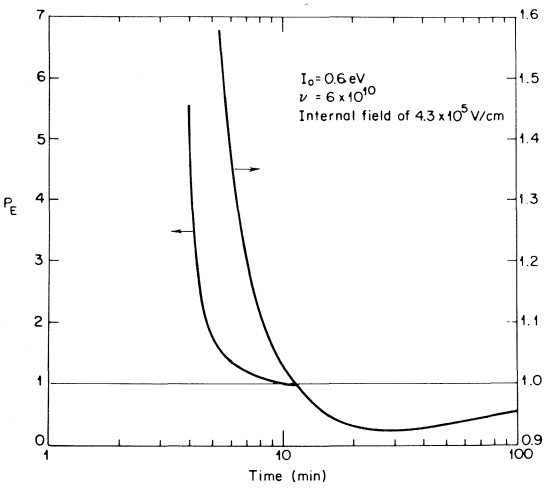

FIG. 7. Plot of $P_E(t)$ *vs.* log t for the indicated parameters. The field-on time, t', is 4 min and the crossing time, t_1, is about 11 min.

t', the initial peak value is $P_E(t')$ and is identified as P_E' in the table. To capture the sense of decay $P_E(1.1t')$ is also given, and thirdly the approximate time, t_1, at which $P_E(t)$ first reaches unity. Corresponding experimental data for two different experimentally applied fields are also given in Table 2. From Table 2 we see that as far as the peak ratio P_E' is concerned, an isotropic distribution is about as field sensitive as an anisotropic distribution having a 100-fold greater frequency factor. From additional calculations, it is established that the theoretical value of P_E' is an almost exponential function of field in this range. P_E' increases with greater values of t', *i.e.*, the later the field is turned on, reflecting the slightly greater cation–electron distance of the charge pairs which remain at the longer time.

Even though the P_E' values vary dramatically for the parameters in Table 2, the values of $P_E(1.1t')$ are fairly tightly grouped within each distribution, and are primarily affected by the internal field. In addition when a family of $P_E(t)$ curves differing only in field-on time are plotted as in Fig. 7, the curves are parallel from values of $P_E(t)$ between 2 and 1, but are displaced on the log-time axis. The curves coincide in this range of $P_E(t)$ if they are plotted as a function of their reduced time, t/t'. The implication is that whatever characteristic time is extracted from the slow decay of $P_E(t)$ from about 2 down to 1, it would be found that these times would then be a fairly linear function of the field-on time. The most remarkable example of this is simply the time t_1 defined by $P_E(t_1)$ = 1. From Table 2, we see that t_1 is very linear in field-on times, and only weakly affected by the applied field. Further calculations show that this crossing time is also insensitive to I_0.

The theoretical prediction that a simple t' scaling of time makes the family of curves coincide is somewhat understandable. The time at which the field is turned on selects the R value of the ITL-active electrons at that time. Accordingly, it determines the rate of decay and the electric field rate enhancement at the inside edge of the distribution of remaining electrons, which edge is receding from the cation as fast as log(t) is increasing. This is an area for further experimental testing of the model (22).

Discussion

We now wish to compare the theoretical EPL

effect with that experimentally found in the 2MP/MCH glass. What we hope to find is an internally consistent set of parameters that can produce quantitative agreement with the measurable experimental facts of EPL.

Determination of the Angular Distribution

When an anisotropic distribution ($\sin^2$ θ), a frequency factor ν of 10^{12} s^{-1}, and an ionization potential I_0 of 0.7 eV are used in the calculations (Table 2), the theoretical P_E' values at internal fields of 4×10^5 and 6×10^5 V/cm are close to those determined at the experimentally applied fields of 3×10^5 and 4×10^5 V/cm (Table 2). However, with so few points in the parameter space explored, it cannot be said that these parameters are in any sense a best fit set of parameters to experiment. Now we have already mentioned that P_E' is exponential in the internal field in the range of fields we have used. This is confirmed experimentally when the logarithm of the experimental P_E' values is plotted as a function of the applied field (Fig. 8). This plot is linear over the range studied, although the slope must change at lower fields so that P_E' is 1 at zero field. The logarithm of the theoretical P_E' plotted *vs.* the applied field is also linear, but the slope of the line and the extrapolated intercept are both functions of the parameters ν, I_0, t', n_0, and $g(\varepsilon)$ which scales the applied field to the internal field. As an example, for Lorentz scaling

$$g(\varepsilon) = (2 + \varepsilon)/3 \qquad [10a]$$

$$\boldsymbol{E} = g(\varepsilon)\boldsymbol{E}_{app} \qquad [10b]$$

In the laboratory only t' and E_{app} are under effective experimental control, and in this work, t' is fixed at 4 min while E_{app} ranges from 2×10^5 to 5×10^5 V/cm. What we seek, therefore, is a set of parameters which makes the theoretical and experimental curves for log P_E' *vs.* applied field coincide. In practice, we look for a set $\{\nu, I_0, n_0, g(\varepsilon)\}$ which forces coincidence between the experimental and theoretical values of P_E' at 3×10^5 V/cm and predicts P_E' at 4×10^5 V/cm. Such correspondence between theory and experiment is tested by the ratio $P_E'(4 \times 10^5$ V/cm$)/P_E'(3 \times 10^5)$, which is proportional to the slope of the log P_E' *vs.* E_{app} plot.

Variation of any parameters in our set will in general change both the slope and intercepts of these log P_E' *vs.* applied field curves. However, it quickly becomes apparent that one can fine-tune the calculated P_E' value at any applied field (in particular at 3×10^5 V/cm) to the experimental value by adjustment of the frequency factor ν. This is undestandable in that ν determines the R value of the closest remaining electrons at t'.

Table 3 gives the theoretical and experimental values of P_E' at two applied fields for different choices of I_0 and $g(\varepsilon)$ using both anisotropic and isotropic distribution. These are all for cases where adjustment of ν has forced coincidence at the lower of the two fields. The column labeled R' is the approximate cation–electron separation at which $n(R,\theta,t')$ has decayed to $(1/e)$ $n_0(R,\theta)$ at the time t'.

The data in Table 3 show that, for both kinds of angular distribution, the predicted value of P_E' at the higher field is independent of I_0 and $g(\varepsilon)$, once the frequency factor has been adjusted so that the calculated P_E' at the lower field matches experiment. The values of I_0 represented in Table 3 correspond to the probable extremes of those possible in this glass consistent with the tunnelling model of the EPL effect, as we discuss below. In addition the factor $g(\varepsilon)$ has been chosen to represent the extremes of no scaling and Lorentz scaling of the internal field (with $\varepsilon = 2.3$).

From Table 3 we see that the isotropic

distribution predicts correctly the observed P_E' at the high field while the anisotropic distribution is apparently incapable of doing so in the range of parameters explored. Further we may conclude that the electrons active in ITL and EPL in the time scale of minutes and at the chosen ionization potentials are in the order of 50 to 55 Å from the parent cation. Since the estimated uncertainty in the experimental ratio of the P_E' values at the two different applied fields is about 5%, a slight anisotropy in the angular distribution is not ruled out. Experiments conducted with the field applied obliquely to the ionizing radiation will be necessary to establish any small anisotropy in the angular distribution.

Figures 9 and 10 show the theoretical $P_E(t)$ for the parameters taken from the first two lines of Table 3. The circled points in Figs. 9 and 10 are experimental values of $P_E(t)$ for applied fields of 3×10^5 and 4×10^5 V/cm respectively. The fit, while good, suffers in that the experimental $P_E(t)$ goes through unity somewhat later than predicted and becomes smaller than predicted on the time scale of these experiments.

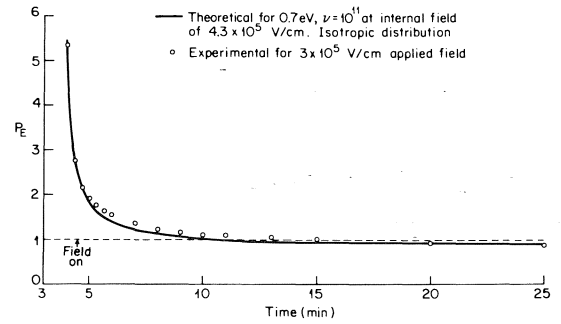

FIG. 9. Plot of P_E *vs.* time, experimental points and theoretical curve for 3×10^5 V/cm.

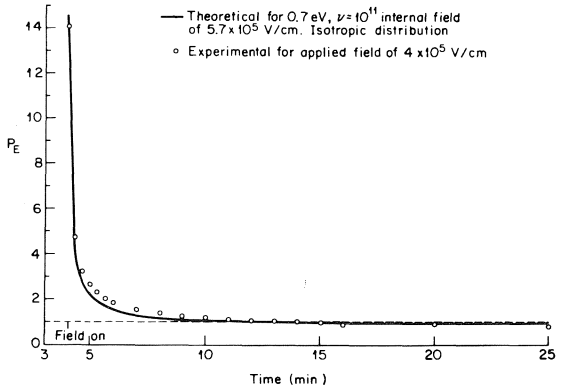

FIG. 10. Plot of P_E *vs.* time, experimental points and theoretical curve for 4×10^5 V/cm.

The model is apparently qualitatively predictive, and in some cases measurable experimental parameters are quantitatively predictable and indicate that the angular distribution of electrons is isotropic. Further, as Table 3 shows, the experimental facts about which the model is quantitatively accurate are insensitive to the other major unknown input parameters of the model, ionization potential and field scaling. The model at this point cannot be improved in any respect by changing these input parameters. Therefore the choice of the 'best' fit input parameters depends upon a discussion of the internal consistency of the set.

Reasonable Estimates of Internally Consistent I_0, ν, and $g(\varepsilon)$

So far we have been using the frequency factor ν as a totally free parameter, which for a given set of energy input parameters can be adjusted so that at a given field-on time, the inside edge of the distribution is far enough away from the cation as to produce a given field effect. In actuality, the factor ν, and for that matter the ionization potential I_0, ought to agree with the physical picture of the trapped electron derived from other sources.

The maximum in the trapped electron absorption spectrum in glassy hydrocarbons occurs at about 0.7 eV with a low energy onset of about 0.5 eV (24). In addition Miller and Willard (25) have reported photodetachment of the trapped electron at energies of 0.53 eV while Novikov and Yakovlev (26) estimate the photoionization threshold to be even as low as 0.4 to 0.44 eV. Hence, we have restricted ourselves to the investigation of trap ionization potentials in the range 0.5 to 0.7 eV.

However, there are some arguments to be made from the calculated EPL effect that place the barrier height, I_0, in the range we have been using. Previously we mentioned in passing that the frequency factor ν should not exceed the zero point frequency of a weakly bound electron. If, for definiteness, we use the zero point energy E_0 of a spherical square well trap to estimate the upper bound of ν, ν_{max}, we calculate from Funabashi's (27) parameterization of the ground state energy level that $\nu_{max} \simeq 6 \times 10^{14}\ s^{-1}$ for a trap radius of 2.5 Å, independently of the ionization potential (*i.e.*, E_0 in Figs. 3 and 4 is 2.5 eV no matter what V_0 and hence I_0 we use). For a trap of only 1 Å radius (which has been used throughout the kinetic calculation for

scaling convenience and to keep $R \simeq r$), ν_{max} becomes $3 \times 10^{15}\ s^{-1}$ and at $a = 5$ Å it is $2 \times 10^{14}\ s^{-1}$. Now the upper limit of ν should only apply for an electron completely surrounded by cations, but recalling that only a single direction of tunnelling can produce recombination, we ought really to reduce ν_{max} by a probability factor calculated from reasonable, if not rigorous, geometrical arguments (4, 9, 13, 21). We seek the fraction of all possible tunnelling directions that allow the electron to emerge into the Coulomb well without tunnelling a distance, $L^0 + \delta r$, much greater than the minimum tunnelling distance, L^0. If the radius r_0 of the Coulomb well at the emergence energy increases, the tunnelling rate falls off less drastically with the intra-pair separation, R. Hence, if we restrict ourselves to off-axis tunnelling directions that decrease the tunnelling rate by a small factor (less than 2) owing to an increase in the barrier width of approximately δr, we find that $\delta r/r_0$ is in the order of 5–10% and independent of I_0 and therefore r_0. The steric factor $P(R)$ is therefore the fractional solid angle subtended by a spherical lens with radius of curvature r_0 and thickness $\delta r \simeq 0.05 r_0$, at an electron a distance $L^0 \simeq R\text{-}r_0$ away. The result is simply (22)

$$[11] \qquad P(R) \simeq \frac{1}{2}\left(\frac{r_0}{L^0}\right)^2 \frac{\delta r}{r_0}$$

As an example, for $R = 50$ Å, $I_0 = 0.7$ eV, and $\delta r = 0.05 r_0$, we obtain a $P(R)$ of 8×10^{-4}.

We further estimate the Franck–Condon factor, which heretofore is also implicit in our use of ν and reflects the readjustment of the nuclei of the cation and all the intervening and surrounding solvent molecules, to be in the order of unity. This is because the transition, as mentioned previously, is essentially from charge-transfer to Rydberg-type states. In addition the initial and final states are surely degenerate within the band width of the final states for reasons previously discussed so that a lack of resonance should not further reduce ν_{max} to any extent. Thus we estimate that a reasonable effective frequency, ν, for these trap parameters is somewhere in the range of 5×10^{10} to 10^{12} s^{-1} ($\sim \nu_{max} P(R)$). Considering the oversimplifications in the model of the trapping potential, it is gratifying that such a rough estimate of the frequency factor is well within an order of magnitude of that needed to fit the experimental data at these trap parameters for an isotropic distribution.

If we ask now what would be the effect of a larger ionization potential, we can extrapolate from the data of Table 3 that it would require an effective frequency factor about two orders of magnitude larger to fit the experimental EPL effect for each 0.1 eV increase in I_0, yet the probability factor calculated as before would decrease since ν_{max} is insensitive to I_0 while the point at which the tunnelling electron emerges from the barrier is closer to the cation. These considerations enable us to put an upper limit of 0.7 eV on the trap ionization potential.

A lower limit to the ionization potential is not so easy to assign. Values of I_0 lower than 0.7 eV again lead to ν's about two orders of magnitude smaller for each 0.1 eV decrease in I_0 while $P(R)$ increases slightly. However, lower trap ionization potentials down to about 0.5 eV do fit the experimental EPL data slightly better in the 5 to 15 min range. In addition, there may be some as yet unexplored mechanisms involving the solvation sphere of the electron that could lower ν_{max} still further to fit the EPL data at a smaller I_0. For now we are content to accept a lower limit of about 0.5 eV to the trap ionization potential, consistent with the photoionization data. Given the limits on the trap ionization potential and more importantly the reasons for setting these limits, we can say little more about the appropriate internal field scaling except that Lorentz scaling appears to be favored at ionization potentials of 0.7 eV (since a $g(\varepsilon)$ of 1 would require $\nu \simeq 10^{13}$–$10^{14}\ s^{-1}$), but at smaller ionization potentials there is no clear choice. Kriebel (28) has determined that in low dielectric constant fluids there is no clear choice among various dielectric field-scaling models; in fact the magnitude of the internal field at a dielectric constant of about 2 varies little with the choice of the model. If we accept Lorentz scaling, or something of similar magnitude, as appropriate to the internal field, we are led to favor trap ionization potentials closer to 0.7 eV, since at lower I_0, Lorentz scaling leads to rather small values of ν (Table 3).

Prospects for Quantitative Improvement of the Model

Once we use a geometrical argument to rationalize the effective frequency factors obtained by a theoretical fit to the experiment, we

should re-examine some previous conclusions in light of this argument. In fact, qualitatively, the EPL effect arises predominantly from the up-field shortening of the tunnelling length which consequently increases the effective cation size. This means that there is a potentially significant field dependence in $P(R)$ as we have estimated it; and especially for the case of an isotropic angular distribution, this could alter the ratio of the P_E' values at two different fields, which is presently the main justification for assuming that the distribution is isotropic. We plan to re-calculate the EPL effect with a field-dependent $P(R)$, but preliminary estimates predict that the ratios previously calculated for the isotropic distribution may at worst be diminished by about 5%, not enough at present to reject the isotropic distribution. It is conceivable that including the field effect in $P(R)$ may also improve the match between theory and experiment at times between about 5 and 20 min.

The experimental fact that $P_E(t)$ becomes smaller than theoretically predicted may also be a result of not including field effects in $P(R)$. We must remember, however, that the assumption of a constant distribution in R may not be as harmless in calculating EPL as it is in ITL, for the field brings much larger R values into the purview of the experimental time scale. Since experimentally, the 1/ITL curves deviate from linearity at long times, there is some reason to suspect an effective limit on the R distribution and this should lower $P_E(t)$ at times greater than 20 min.

Conclusion

The calculations and experimental data on the EPL effect presented herein generally support the role of quantum-mechanical tunnelling in the decay of trapped electrons in very hard glassy hydrocarbons. From the field dependence of the EPL effect, the model indicates that the distribution of trapped photoelectrons about their parent cations is angularly isotropic. Furthermore reasonable quantum-mechanical limits on the largest possible frequency parameter of the tunnelling model put an upper limit of the trap ionization potential of about 0.7 eV, and at this value the magnitude of the EPL effect is consistent with Lorentz scaling of the internal field and electron–cation separations of about 50 to 55 Å. It is still a source of wonder to the authors that the model, which totally neglects the graininess of matter on the scale of angstroms and predicts order-of-magnitude effects on the scale of molecular diameters, is still qualitatively and even quantitatively in harmony with the observations. This is in all likelihood due to the statistical nature of the electron distribution. The success of the theory implicitly supports the notion of electrons trapped at distances from the cation great enough so that the radial correlation function of the solvent molecules has become constant on the same scale of separations.

Appendix

A distribution which is constant in R space is set up between limits determined as follows: (*a*) at the first time point calculated, all the ITL from the region of the minimum R has ceased; (*b*) at the last time point calculated and at the highest internal fields expected, the concentration of electrons remaining near the maximum R is still greater than 90% of that specified by the starting distribution. It is desired to make this range as small as possible to minimize errors resulting from too coarse a grid in the integration, without introducing other errors resulting from time running off either distribution edge.

Once the distribution range of trapped electrons is decided it is possible to calculate the rate constants, both with and without field, for each of 2^{10} points in the range $R \subset (R_{min}, R_{max})$, $\theta \subset (0, \pi)$. The points are spaced in both directions according to the nonhomogeneous intervals appropriate to 32-point Gaussian integration. An additional 32 by 32 matrix is set up for the same points in R,θ space to contain the numerical value of the distribution $n_0(R,\theta)$. For convenience, these numbers are scaled so that $N(0) = 1$. At each value of t, Gaussian integration is carried out over $R \subset (R_{min}, R_{max})$ and the resulting number is used simply as a function value in a subsequent Gaussian integration over θ. In cases where an applied field effect is to be calculated, the distribution matrix is updated to the turn-on time, t', using $n(R,\theta,t') = n_0(R, \theta)e^{-k(R)t'}$ before calculating EPL from [7].

Confidence in the integration procedure is established by obtaining in every case the preselected normalization value of the integral [eq. 5] at zero time, independently of the angular distribution. In addition, the computer-generated ITL points are identical for isotropic and nonisotropic distributions when scaled for the R-distribution range, as long as other parameters remain unchanged. Finally, intermediate output can be compared with the analytic forms obtained in the square-barrier case, to see that local concentrations of electrons about cations are varying qualitatively as in the simpler cases (9, 17, 20).

Discussion

G. R. Freeman: You observed a rather narrow band of R in the vicinity of 50 Å. Could you estimate the fraction of the total number of electrons that was involved? Perhaps the light emitted prior to the EPL measurement could be integrated, and the sample could be warmed afterwards to measure the remaining emission. Measurement of the free ion yield in X irradiated liquid 3-methylpentane, as a function of applied electric field strength, indicates that only about 10% of the thermalized electron–ion pairs would have R values between 50 and 60 Å.

A. C. Albrecht: (*a*) The 'initial' distribution of geminate cation–electron pairs is inevitably complicated by the immense range of lifetimes of such pairs in rigid glasses. If charge pairs are generated by an energy pulse of duration τ s then, at the end of the pulse, those pairs having lifetimes, τ_p, much shorter than τ will have reached photostationary state concentrations, while the number of those pairs with τ_p much longer than τ will still be growing linearly with irradiation time. Thus, suppose the rate of generating geminate pairs having a separation R is $g(R)$ (s^{-1}). Then the distribution in R of pairs having $\tau_p \ll \tau$ is given by $g(R)\tau_p$ where, as we have seen, τ_p is an exponentially strongly increasing function of R, so that for such pairs the dominant factor in their distribution is $\tau_p(R)$ not (R). Furthermore in the context of rigid nonpolar organic systems this precludes finding geminate pairs having $R < 20$ Å even when viewing on the nanosecond time scale of the fluorescence process itself. On the other hand for $\tau_p \gg \tau$, the distribution of charge pairs goes as $g(R)\tau$ and will accurately reflect the function $g(R)$ itself. It must be remembered that τ_p represents the lifetime of the charge pair during irradiation. Particularly for charge pairs having very long dark lifetimes, their τ_p might well be governed by the radiative pathways for recombination. The competing time constant for such a path is just $I\sigma$, where I is the flux of incident radiation and σ is the cross section for an ion pair to absorb this energy and recombine. In summary, it is clear that no simple distribution function of geminate pairs in R space can be expected under practically any condition of excitation.
(*b*) What fraction of all geminate pairs is located in the

50 Å $\leq R \leq$ 60 Å range which is the active range in our experiments? In the Ph.D. Thesis of Robert Ott (ref. 5), the methods you suggest were employed, although not combined with an EPL measurement. The total photons received after various ITL periods were compared to the total possible recombination photons as measured in a separate experiment, where under otherwise identical conditions the sample was warmed about 4° above the glass point and the total *thermoluminescence* curve was collected. By this measure the first 30 min of ITL after 1 min irradiation (in 3-methylpentane) at 77.3 K corresponds to the collapse of about 80% of all geminate pairs. However, as we have emphasized, at 77 K in 3MP there is a considerable temperature component to the recombination process (it is not pure tunnelling). At 68 K in 3MP where only tunnelling is active, R. Ott finds that in 30 min of ITL about 29% of all possible recombination events are seen. This latter situation should presumably carry over to our tunnelling-only case in the hard MCH–2MP glass at 77 K, which we have used in our present paper. If so then a reasonable choice of parameters (in tunnelling calculation) tells us that geminate pairs having τ_p (dark) from 1 to 30 min will lie in the range 48 Å $< R <$ 53 Å, and to this range we we should assign 29% of all geminate pairs. If the radial distribution is assumed to be constant, it would then need to extend to about 65 Å to account for the total of possible recombination events. The same tunnelling calculations show that pairs with separations of 65 Å will have $\tau_p \simeq$ 30 min in the presence of 6×10^5 V/cm internal field. We conclude that in the distribution we prepare, the majority of geminate pairs will lie in the 50 Å $< R <$ 60 Å range. It is conceivable that X-ray produced electrons are distributed more broadly. Our experiment would still be sensitive only to the same small separation range corresponding to the 1 to 30 min time scale, but it would then constitute a smaller fraction of the total pair production.

G. R. Freeman: As you mentioned, the assumption that $n_0(R)$ = constant is acceptable for a narrow slice of the R distribution. An alternative to an exponential over-all distribution is a Gaussian. The latter might be the more probable in strongly scattering media such as 3-methylpentane and methylcyclohexane.

Temperature and solvent dependence of electron scavenging efficiency in polar liquids: water and alcohols

JOHN W. HUNT AND W. JOHN CHASE

The Ontario Cancer Institute and Department of Medical Biophysics, University of Toronto, 500 Sherbourne Street, Toronto, Ont., Canada M4X 1K9

Received October 18, 1976

JOHN W. HUNT and W. JOHN CHASE. Can. J. Chem. **55**, 2080 (1977).

High concentrations of electron scavengers reduce the initial yield of e_{sol}^- and its precursor, e_t^-. The scavenging efficiency of a solute is inversely proportional to its C_{37} value, the solute concentration required to reduce the initial electron yield to 37% of the yield with no scavenger present. Over a range of 40 to $-60°C$ the C_{37} value for a given scavenger is almost constant, and is the same for e_{sol}^- and e_t^-. In water and alcohols, the C_{37} value is not correlated with the time required for solvation of the electron, τ_s, or the static dielectric constant, ε_s, but rather with the concentration of oxygen atoms in the solvent. These results support the model in which the scavenging of a mobile electron occurs before the electron is trapped in the solvent.

JOHN W. HUNT et W. JOHN CHASE. Can. J. Chem. **55**, 2080 (1977).

Des grandes concentrations de pièges d'électrons réduisent le rendement initial de e_{sol}^- et de son précurseur e_t^-. L'efficacité d'un soluté comme piège est inversement proportionnelle à sa valeur C_{37}, la concentration de soluté requise pour réduire le rendement initial d'électron jusqu'à 37% du rendement obtenu en l'absence de piège. A des températures allant de 40 à $-60°C$, la valeur C_{37} d'un piège donné est pratiquement constante et est la même pour e_{sol}^- et e_t^-. Dans l'eau et les alcools, il n'y a pas de corrélation entre la valeur C_{37} et le temps requis pour la solvatation de l'électron, τ_s, ou la constante diélectrique statique, ε_s, mais plutôt avec la concentration des atomes d'oxygène dans le solvant. Ces résultats sont en accord avec le modèle dans lequel le piégeage d'un électron mobile se produit avant que l'électron soit piégé dans le solvant.

[Traduit par le journal]

Introduction

From the breakdown of the competition reaction between the scavenging of and formation of e_{aq}^- in concentrated solutions, Hamill and co-workers (1–3) suggested that the 'dry' electron, e^-, is chemically reactive. Picosecond pulse radiolysis experiments in our laboratory also support this conclusion. In aqueous and alcoholic solutions, high concentrations of electron scavengers reduce the initial yield of solvated electron, e_{sol}^-, (4–7) and its precursor, e_t^-, (7) an electron trapped in a shallow potential well. The initial electron yield, $[e_x^-]$, decreases as the scavenger concentration, [S], increases according to

$$[1] \qquad [e_x^-]/[e_x^-]_0 = \exp(-[S]/[C_{37}])$$

where e_x^- can be e_t^- or e_{sol}^-, $[e_x^-]_0$ is the initial electron yield with $[S] = 0$, and $[C_{37}]$ is the scavenger concentration which reduces the yield of e_x^- to 1/e (37%). The C_{37} value of a scavenger is thus inversely proportional to its scavenging efficiency.

Two general categories of models have been proposed to explain the reduction of the initial yield of electrons. In one category, as secondary electrons diffuse through the liquid they can react with neighboring scavenger molecules before they become localized (4, 5, 8). In the other category, the electron becomes localized and then reacts with scavenger molecules. The encounter-pair model of Czapski and Peled (9), the electron-tunnelling model of Miller (10), and the time-dependent rate constant theory of Schwarz (11) fall into this category. Although these models predict the exponential dependence of electron yield on the scavenger concentration of [1], Lam and Hunt (7) showed that they could not explain the magnitude of the observed effect.

Lam and Hunt (7) observed that, *for a given scavenger*, the C_{37} value was the same for e_{sol}^- and e_t^-, and the C_{37} value changed systematically with the polarity of the solvent. They noted an apparent correlation of the C_{37} values with the time for solvation of the electron, τ_{sol}, and with the static dielectric constant, ε_s. The reduced yield of e_{sol}^- could be explained by a tunnelling process, in which the rate of reaction

TABLE 1. Correlation of C_{37} values with parameters of solvent

Solvent	$[C_{37}]$ of acetone[a] (mol dm^{-3})	τ_{sol} (296 K)[b] (ps)	ε_s (298 K)[c]	[O] (mol dm^{-3})
H_2O	1.4	<2	78.5	55.5

1-Butanol	0.25	34	17.1	10.9
1-Hexanol	0.3		13.3	8.0

[a]Reference 7.
[b]References 15, 16.
[c]Reference 27.

will be faster from a shallow than from a deep trap (10). Since τ_{sol} indicates the time spent by an electron in a shallow trap, the C_{37} value might decrease as τ_{sol} increases. Alternatively, the reduced initial yield of e_{sol}^- from solvent to solvent might be due to the different attractive forces between the electrons and the positive ions in the radiation spur. The attractive force between ions separated by a distance r is proportional to $1/(\varepsilon r^2)$ and this force could alter the range of the low energy electron as it diffuses through the media. The probability of an electron, and thus the C_{37} value might depend on ε_s.

This paper shows that the correlation of the C_{37} values with τ_{sol} and ε_s at room temperature is only fortuitous. However, a correlation with the concentration of oxygen, [O], in different solvents supports the model of a mobile electron.

Experimental

The reactions of e_{sol}^- and e_t^- in concentrated solutions of electron scavengers were observed using the stroboscopic pulse radiolysis (spr) system previously described (12–14). The spr system has been modified so that the temperature of the flowing liquid in the radiation cell can be varied from 40 to −60°C (15, 16). The initial electron yield was obtained from picosecond kinetic absorption traces by extrapolating back along the absorption curve to the middle of the pulse (for slow decays) or by using a computer convolution technique (15, 16) (for fast decays).

Results

Table 1 summarizes the C_{37} values of acetone in various polar solvents, at 298 K, with an attempt to correlate the C_{37} values with different parameters. As noted in the Introduction, there is a general relationship between the C_{37} value, τ_{sol}, and ε_s (7). A much more significant result is shown in the last column, where there is a correlation with the concentration of oxygen atoms in the solvent, [O]. For all of the solvents considered except ethylene glycol, [O] (or [OH]) is the same as the concentration of pure solvent, whereas for ethylene glycol, there are two oxygen atoms per molecule, and [O] is twice the concentration of pure solvent.

For acetone and carbon tetrachloride, as shown in Table 2, the C_{37} value is almost independent of temperature and is the same for e_{sol}^- and e_t^- within experimental error. This agrees with the preliminary results of Lam and Hunt (7). The fact that the C_{37} value is the same for e_{sol}^- and e_t^- over a wide range of temperature indicates that a precursor of e_{sol}^- and e_t^- is being scavenged.

In Table 3, τ_{sol} and ε_s are compared to the C_{37} values of carbon tetrachloride, acetone, and toluene in 1-propanol. At room temperature carbon tetrachloride and acetone are efficient scavengers while toluene is quite an inefficient scavenger. As was the case in ethanol, the C_{37} values for these first two scavengers are almost independent of temperature. The C_{37} value of toluene, on the other hand, shows a marked temperature dependence, decreasing by more than a factor of 10 from 25 to −123°C. We are not sure of the reason for this behavior, but it would appear that toluene scavenges

electrons by a different mechanism than the more efficient scavengers, such as carbon tetrachloride and acetone.

As shown in Table 3, as the temperature is changed from 25 to −123°C, τ_{sol} increases by a factor of 1000 while the C_{37} values for the *efficient* scavengers decrease by only a factor of two. While this change is in the same direction as in Table 1, the large size of the change in τ_{sol} seems to rule out a direct relationship between τ_{sol} and the C_{37} values, even for toluene. As the temperature is changed from 25 to −123°C, ε_s increases while C_{37} decreases, the opposite to what was found in Table 1. This certainly rules out any direct correlation between the C_{37} value and ε_s.

If the C_{37} value is related to the concentration of oxygen atoms in the solvent, [O], the C_{37} value should be independent of temperature. When the C_{37} values are corrected for the solvent density the values are almost constant over the range from 25 to −60°C. To further examine a possible correlation, various mixtures of water and ethanol were used for the solvent. As shown in Fig. 1, the C_{37} values are proportional to [O], although the proportionality is not exact, since the lines drawn through the points do not pass exactly through the origin. It is also striking that the C_{37} values of acetone and CCl_4 in viscous ethylene glycol are similar to those obtained in nonviscous H_2O–ethanol mixtures.

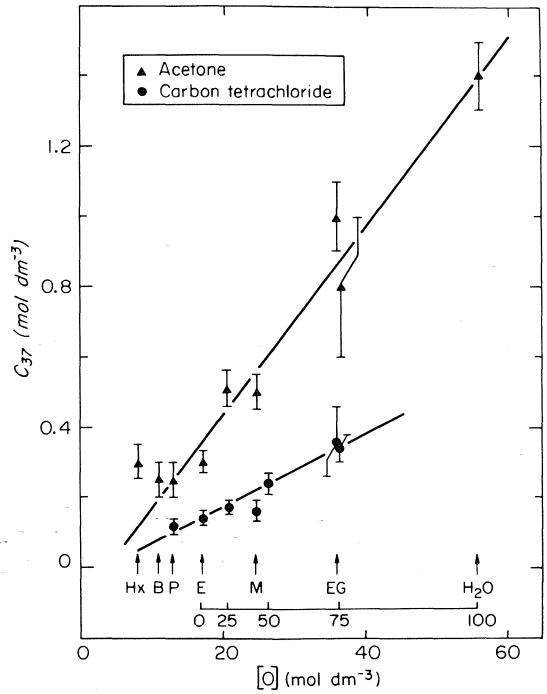

FIG. 1. C_{37} values for acetone (▲) and carbon tetrachloride (●) *vs.* the concentration of oxygen atoms in the solvent. The scales at the bottom identify the solvent used: H_2O, water; EG, ethylene glycol; M, methanol; E, ethanol; P, 1-propanol; B, 1-butanol; and Hx, 1-hexanol. The numbers are the mol% of water in the ethanol–water mixtures.

Discussion

Many models have been proposed to explain the reduction of the initial electron yield, such as dry or mobile electrons (1–5), encounter pairs (9), electron tunnelling (10), and time-dependent specific rates (11). These models have been considered in detail in previous papers (7, 17). For the solutions in this paper, a calculation shows that for the worst case (acetone in water)[1] the effect of the time dependence of the specific rates on the C_{37} values is about 10%, and that corrections for the time-dependent specific rates are much smaller in alcohols and cold solutions. The possible effect of electron tunnelling is

[1]At the concentrations and temperatures used, acetone in water has the highest rate of reaction with e_{sol}^-, and thus the time dependence of the specific rate will be largest for this reaction.

strongly dependent on the particular parameters used and competes with the time dependence of the specific rates (18), and thus it is difficult to estimate the contribution of electron tunnelling to the initial electron reactions. However, we feel that electron tunnelling is not *the* major factor in these reactions, since, as noted by Lam and Hunt (7), it cannot account for the systematic changes in the C_{37} values from solvent to solvent. Another attempt to explain the result is the encounter-pair concept of Czapski and Peled (9), in which the electron is localized very near a solute molecule. This encounter pair might react very quickly. This concept is difficult to evaluate, particularly in the case of nondiffusion-limited reactions such as e_{aq}^- + acetone. A calculation for this reaction shows that less than 20% of the prompt electron reactions are due to encounter pairs. As well, Lam and Hunt (7) showed that the encounter-pair concept does not explain the solvent-to-solvent variation of the C_{37} values for a given scavenger.

Because of the difficulties in making accurate corrections to the data, we have not attempted to do so. Instead, we have concentrated on the mobile electrons, which give the most lucid explanation of the prompt electron reactions.

Wolff *et al.* (4) and Aldrich *et al.* (5) obtained [1] by assuming that mobile electrons can react with scavenger molecules before the electrons reach thermal energies. In this model, the electron undergoes a random walk, colliding with solvent and solute molecules until it becomes thermalized. Bolton *et al.* (8) have proposed a similar model, although there are some differences (see below). The probability that the electron does *not* react with the scavenger molecule before it reaches thermal energies is given by

$$[2] \qquad [e_x^-]/[e_x^-]_0 = (1 - cP)^n$$

where c is the mole fraction of scavenger molecules (*i.e.* [S]/[solvent]), P is the probability of a mobile electron reacting with a scavenger, and n is the total number of collisions of the electron with solvent and scavenger molecules before the electron is thermalized. Since $cP < 1$ and, as noted by Aldrich *et al.* (5), $n \geq 150$ for efficient scavengers, [2] can be written as

$$[3] \qquad [e_x^-]/[e_x^-]_0 = \exp(-cPn)$$

Comparing this to [1], the terms in parentheses yield

$$[4] \qquad \frac{[S]}{[C_{37}]} = cPn = \frac{[S]}{[solvent]} Pn$$

and solving for $[C_{37}]$,

$$[5] \qquad [C_{37}] = [solvent]/Pn$$

This simple *theory* predicts that the C_{37} value is proportional to the solvent concentration, while *experimentally* the C_{37} value is proportional to [O]. For all of the solvents considered *except* ethylene glycol [O] = [solvent] and [5] can be written as

$$[6] \qquad [C_{37}] = [O]/Pn$$

For ethylene glycol, [O] = 2[solvent] and thus

$$[7] \quad [C_{37}] = \frac{[O]}{Pn} = \frac{2[solvent]}{Pn} = \frac{[solvent]}{Pn'}$$

where $n' = n/2$ is the actual number of electron–molecule collisions in ethylene glycol.

The mobile electron hypothesis implies that the energy loss per collision is inversely proportional to the number of collisions, n. For all of the solvents except ethylene glycol, a common value for n suggests that the energy loss per collision is the same, which in turn implies a common mechanism of energy loss, *i.e.* the oxygen atom (or the hydroxyl group) absorbs the energy. In ethylene glycol, the number of collisions is half that in the other solvents, suggesting that an ethylene glycol molecule either absorbs twice as much energy per collision or has two separate and independent modes of accepting energy (*i.e.* two oxygen atoms).

In a review article, Mozumder (19) noted that the range and the mechanism of energy loss of low energy electrons are only poorly known. Mozumder (19) considered mechanisms of energy loss in water, and Funabashi (20), several organic solids at 77 K, but no satisfactory theory for all solvents is available. Dodelet and Freeman (21) studied the effect of molecular structure of alkanes on the density-normalized range secondary electrons. They noted a correlation between the efficiency of energy loss and the relative inductive effect of the functional groups of the molecules, as indicated by the Taft coefficient, σ^* (22). The oxygen atom is highly electron affinic and the OH group has a much higher σ^* of 0.66 (23) than the methyl group with $\sigma^* = 0.0$. Thus, if our theory relating the slowing down of the mobile electron to the C_{37} values is correct, it is not surprising that

there is a good correlation between the C_{37} values and [O]. In solvents not containing oxygen, it may be possible to estimate the C_{37} value of a scavenger relative to that in other solvents by considering the Taft coefficient, σ^*, and the size of the solvent molecules.

The exponential function for the relative electron yield, derived using a fixed value of n (equation 3), describes the experimental data quite well. In reality, n does not have a single fixed value but a distribution of values. If a Gaussian distribution for n is assumed, with a mean value, $\bar{n}$, of 150 and a standard deviation, σ, as large as 50, the calculated electron yield fits an exponential function within our experimental error (5%). A minimum value for $\bar{n}$ can be obtained by considering the most efficient scavenger by assuming $P = 1$ and solving for n in [5]. Cd^{2+} has a C_{37} value of 0.39 mol dm^{-3} (5), yielding a value for n of 140. CrO_4^{2-} has a C_{37} value of 0.2 mol dm^{-3} (7), giving a value of 275 for n. Miller (10*c*) has shown that electrons tunnel to CrO_4^{2-} in NaOH glass. Because electron tunnelling (or time dependence of the specific rates, or encounter pairs) could contribute to electron scavenging, we estimate the minimum value of $\bar{n}$ to be 150. A Gaussian distribution for n implies that, although the electron can be scavenged at any time, it can only be localized when it has lost most of its energy.

Bolton *et al.* (8) described a different model than the one considered in our work, in which the probability of an electron being localized is constant along its path, or that scavenging is possible only "during the *last few* collisions of the epithermal electron prior to localization."[2] The resulting distribution function has a maximum value for n equal to 6 (the number of molecules in the solvation shell) and decreases slowly with increasing n. Bolton *et al.* (8) obtained good fits to their data using a value of 30 for $\bar{n}$, obtained from benzene, a relatively inefficient scavenger. However, we argue that the minimum value of $\bar{n}$ should be calculated from efficient scavengers. Using a value of 150 for $\bar{n}$, the relative electron yield calculated using the formulation of Bolton *et al.* (8) deviates considerably from an exponential function. Therefore, we feel that the formulation of Bolton *et al.* (8) disagrees with the picosecond studies, and that the electron can be scavenged before it can be localized.

The C_{37} value of toluene shows a marked temperature dependence, whereas those of carbon tetrachloride and acetone do not. Buxton *et al.* (24) and Hase and Kawabata (25) have recently observed an absorption at infrared wavelengths due to an electron in a very shallow trap. If the main mechanism of the initial yield reduction in toluene were tunnelling of the electrons from these very shallow traps at very short times (< 1 ps), rather than mobile electron scavenging, then the temperature dependence of the C_{37} value might be accounted for by assuming that either the number of electrons in these very shallow traps, or that the time spent there, is also temperature dependent. Another possibility is that the value of P in [3] is temperature dependent. Fueki *et al.* (26) calculated that the energy of the quasi-free electron state, V_0, decreases as the temperature increases. If the ground state of the toluene anion is near V_0, the temperature dependence of V_0 could change P in [2]. For carbon tetrachloride and acetone, the ground state of the anion might be sufficiently lower than V_0 that small changes in V_0 would not affect P.

Conclusion

For carbon tetrachloride and acetone, but not toluene, the C_{37} value is almost independent of temperature and is the same for e_{sol}^- and e_t^- in ethanol and propanol. In water and the alcohols, for a given scavenger the C_{37} value is proportional to [O], the concentration of oxygen atoms in the solvent. In the mobile electron hypothesis, the number of scavenger molecules that the electron collides with before solvation is determined by the electron range. The range is controlled by the efficiency of energy transfer from the mobile electron to the solvent molecules, which is in turn related to the electron affinity and the relative inductive effect of functional groups of the solvent molecules. In water and the alcohols, oxygen has the highest electron affinity and thus controls the range and therefore the C_{37} value.

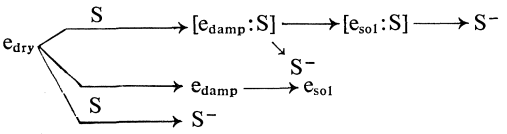
Discussion

G. Czapski: The general scheme of the fate of e_{dry} is



where $[e_{damp}:S]$ and $[e_{sol}:S]$ describe encounter pairs of e_{damp} and e_{sol} with S respectively, with an encounter radius R. In your studies the extrapolation of the yield of e_{sol} into the pulse assumes pseudo first order decay of $e_{sol} + S \rightarrow S^-$. This treatment neglected two essential corrections, the time dependence of the rate constant of the reaction $e_{sol} + S$ and the initial formation of encounter pairs. It was previously shown by Czapski and Peled (9) that by making the above-mentioned corrections for most of the solutes used in your earlier studies in water, the full initial yield of e_{sol} can be obtained by this procedure.

In the present studies you did not make these corrections and conclude from values of C_{37} for various solutes and solvents that e_{dry} reacts with the solutes. Even if this assumption would be true, you have to make these corrections, as $k_{e_{sol}+S}$ is time dependent and $[e_{sol}:S]$ are formed. Doing so at the concentration C_{37}, you would have found that the extrapolated yield of e_{sol} would be much larger than 37% and in some cases could give the full yield of e_{sol}, although in several systems there will still be a missing yield of e_{sol}. Even in the systems where with the appropriate corrections the initial yield is too low, it is not essential to assume the reaction of dry electrons with the solute.

Assuming electrons are 'trap diggers', the following solvation sequence occurs in the solvation site

$$e_{dry} \rightarrow e_{damp} \rightarrow e_{sol}$$

It is obvious that damp electrons also are partially formed as encounter pairs. It is reasonable to assume that the encounter radius, R, of damp electrons with S will exceed that of solvated electrons with S. With these assumptions the following behaviour is expected.

1. As the solvation time of the electron in H_2O is less than 10^{-12} s, the lifetime of the encounter pair of S with e_{damp} may be too short and e_{damp} may solvate prior to the formation of S^- from the encounter pair $[e_{damp}:S]$. This will not apply to the alcohols where the solvation times exceed by far the lifetime of $[e_{damp}:S]$.

2. For a given solute and solvent C_{37} will be temperature independent, as $R_{[e_{damp}:S]}$ and $R_{[e_{sol}:S]}$ should not vary with temperature. This is in accordance with your results.

3. You observed that C_{37} is the same for e_{damp} and e_{sol} in a given solvent. This is evident as the solvated electrons are formed from those damp electrons which did not disappear in $[e_{damp}:S]$.

4. You found that C_{37} for a given solute depends on the solvent and decreases the larger the solvation time in that solvent. This behaviour may be due to an additional correction which should be made. In these solvents some of e_{damp} disappear within $\sim 10^{-12}$ s in $[e_{damp}:S]$ while the rest are initially separated from S. The damp electron has a larger encounter radius than the solvated electron, and therefore it will also have a larger rate constant in the reaction with S. Therefore in addition to the usual time dependence of diffusion-controlled rate constants, another time dependence will occur. The longer the solvation time of e_{damp} is in a given solvent, the faster will S react. Therefore the lower values of C_{37} for solvents with longer solvation time is expected in accordance with your observations.

From this analysis it is concluded that for most systems you studied it is not necessary to postulate reactions of dry electrons. Benzene on the other hand appears to react with dry electrons.

W. J. Chase: I agree with Dr. Czapski that corrections for the time dependence of the specific rates and the formation of encounter pairs should be made to the C_{37} values. These corrections are difficult to assess but are not large for the solutions and experimental conditions that we used. In alcohols, the relaxation of the trapped electron, $e_t^- \rightarrow e_{sol}^-$, is faster than the reaction $e_t^- + S \rightarrow S^-$, and thus masks any time dependence of the latter specific rate. Both of these processes are slow in cold solutions; little extrapolation is needed to obtain the initial yield of e_t^- and thus time dependence of the specific rates is not important. For the solutions considered in this paper, time dependence of the specific rate will have its largest effect on the reaction of e_{aq}^- with acetone at room temperature. Using the same extrapolation technique as was used in the paper, and the formulation of Jonah *et al.* (J. Phys. Chem. **79**, 2705 (1975)), the correction to the C_{37} value for this nondiffusion-controlled reaction is only about 10%.

The correction for encounter pairs is more difficult to assess, since the encounter-pair concept is not well understood for nondiffusion-controlled reactions. For such reactions the top arm of Czapski's reaction scheme should include the escape of e_t^- from the encounter pairs, as in

$$e_{dry}^- \rightarrow [e_t^-:S] \rightarrow [e_{sol}^-:S] \rightarrow S$$
$$\swarrow \quad \searrow \qquad \swarrow \quad \searrow$$
$$S^- \quad e_t^- + S \qquad e_{sol}^- + S$$

$$(e_t^- \equiv e_{damp}^-)$$

Thus, nondiffusion-controlled reactions are explained if not every encounter pair forms S^-, but rather some leave e_t^- and S unreacted. Using an encounter radius of 0.5 nm, and the formulation of Jonah *et al.*, we estimate that the effect of the encounter pair is small (< 20%) in water, and smaller in alcohols. Thus, the total corrections due to time-dependent specific rates and encounter-pair formation does not account for the observed C_{37} values. Dr. Czapski also assumed that the encounter radius of e_t^- with S is larger than that of e_{sol}^- with S. However, esr measurements on electrons in ethanol glass of Hase *et al.* (J. Chem. Phys. **57**, 1039 (1972)) suggest that the radius of e_t^- is only 0.1 nm larger than that of e_{sol}^-, in general agreement with the theoretical work of Fueki *et al.* (J. Chem. Phys. **56**, 5351 (1972)).

Based on the assumption of a larger encounter radius for e_t^-, Dr. Czapski makes four predictions about the effect of scavengers, the last two of which I disagree with. Concerning point *3*, not all of the e_{sol}^- are formed from e_t^-. In fact, *some* are formed almost immediately, apparently because the electrons have become localized initially in a deep trap. Thus an immediate absorption is observed at short wavelengths (16, 29). Concerning point *4*, since we have measured the *initial* yield of e_t^-, the solvation time, as long as it is more than ~10 ps, should have very little to do with the reduction of the initial yield. And in fact it does not, since the C_{37} value remains the same when the solvation time is increased by lowering the temperature.

Lam and Hunt (7) and Hunt (17) showed that there is a serious inconsistency when the encounter-pair concept is used to explain the empirical relationship observed by Lam and Hunt (7),

$$[1] \qquad C_{37} = Q/k_{obs}$$

where Q is a constant for each scavenger. This equation can be explained, using the Smoluchowski equation as formulated by Jonah *et al.* and equation 6 from our paper. Thus we feel the C_{37} values obtained in various solutions can be explained best by changes in the rate of reaction of the mobile or dry electron.

G. R. Freeman: Scavenging of electrons prior to their solvation, mentioned by Chase, and scavenging in initial encounter pairs, mentioned by Czapski, are both treated in a recent article by Bolton, Jha, and myself (Can. J. Chem. **54**, 1497 (1976)).

W. J. Chase: As mentioned in the paper we agree that a stochastic model in the paper mentioned above might explain certain aspects of the precursors of the e_{solv}^-. However, we feel that our older approach (4) explains the results more accurately. That is, the subexcited electrons (the 'dry' electrons) lose energy relatively slowly and collide with solvent and solute molecules. In a pure solvent, a relatively constant number of collisions (~150) will occur before they reach energies low enough to be trapped. A low number and wide range of collisions, as

suggested by Bolton *et al.*, does not agree with the observed data. Of course, encounter-pair corrections must also be considered in a more accurate assessment as mentioned by Czapski, but they only account for a small part of the process.

G. R. Freeman: The basic stochastic model dates back to the mid-sixties and improves with time. In some systems the plots of log (initial absorbance) against solute concentration are not linear. The degree of linearity can be adjusted by choosing suitable values for the minimum number of encounters and the probability of localization per collision.

C. Jonah: I question the exponential dependence on solute using Freeman's model for scavenging *vs.* trapping.

W. J. Chase: I haven't looked at this myself, but I would expect that the departure from exponential behaviour would depend upon the particular distribution function used for n, the number of collisions. Qualitatively, I would expect that the sharper the distribution of n around a mean value, $\bar{n}$, the better the agreement with exponential behaviour. The experimental data do seem to follow the exponential behaviour quite well. In fact, Dr. Hunt looked at this years ago, and found that using a Gaussian distribution for n with a mean value, $\bar{n}$, of 150 and a width, α, of about 25 collisions there was little departure from linearity for the semilogarithmic plot.

Electron scavenging in the radiolysis of supercritical butenes[1]

Electron scavenging reactions with N_2O have been studied in γ-irradiated supercritical butenes in the density range 0.25–0.48 g/cm^3 at 170 ± 1°C. Free ion yields were estimated as a function of density from the nitrogen yields by means of the 'square root' model. The estimated G_{fi} in butenes increased with the decrease in density, and were in the order *cis*-2-butene ≳ isobutene > *trans*-2-butene at a given density. The density-normalized range of electrons estimated from G_{fi} values was independent of density over the density range studied. The magnitude of the reactivity parameter A in *trans*-2-butene was much larger than that in other butenes studied, but it generally increased with a decrease in density. An analysis of the parameter on the basis of the Nernst–Einstein relationship indicates that the trend is related to the change in the encounter efficiency of the reaction $e^- + N_2O$.

MASARU NISHIKAWA et YOH-ICHI YAMAGUCHI. Can. J. Chem. **55**, 2088 (1977).

On a étudié des réactions de piégeage d'électrons par N_2O dans des butènes supercritiques irradiés par des radiations γ à des densités allant de 0.25–0.48 g/cm^3 à 170 ± 1°C. On a déterminé les rendements en ions libres en fonction de la densité à partir des rendements en azote en faisant appel à un modèle de "racine carré". Les G_{fi} évalués dans le butène augmentent avec une diminution de la densité et pour une densité donnée sont dans l'ordre de butène-2 *cis* ≳ isobutène > butène-2 *trans*. Les pénétrations d'électrons normalisées pour la densité, évaluées à partir de valeurs de G_{fi}, sont indépendantes de la densité à toutes les densités étudiées. La grandeur du paramètre de réactivité A du butène-2 *trans* est beaucoup plus grande que celle observée avec les autres butènes étudiés mais elle augmente d'une manière générale avec une diminution de la densité. L'analyse des paramètres sur la base d'une relation de Nernst–Einstein indique que la tendance est reliée au changement dans l'efficacité de la réaction $e^- + N_2O$.

[Traduit par le journal]

Introduction

Recent charge scavenging studies in supercritical hydrocarbons demonstrated that they are amenable to quantitative interpretation in terms of the 'square root' model (1, 2). The interpretation led to the estimation of free ion yields and the kinetic parameters for the reaction of electrons with N_2O in various hydrocarbons in the supercritical state. Freeman and coworkers (3, 4) found in the liquid phase that both the free ion yield and the electron mobility are anomalously low in *trans*-2-butene compared to those in other isomeric butenes. In the present study the observations are extended to the supercritical state in order to observe the resulting effects on the kinetics of electron scavenging.

Experimental

Phillips Research Grade *cis*-2-butene (99.98%), *trans*-2-butene (99.78%), and isobutene (99.9%) were purified further by circulating overnight through traps filled with KOH and NaK alloy by means of an electromagnetically operated pump. Takachiho Research Purity nitrous oxide (99.9%) was used after bulb-to-bulb distillation.

Methods of sample preparation, irradiation in a ^{60}Co source, and product analysis were described previously (1). The irradiation was carried out at 170 ± 1°C. The dose rate was 5.26×10^{18} eV g^{-1} h^{-1} in Fricke solution and appropriate corrections were made for the electron density ratios. Total dose per sample did not exceed 6×10^{18} eV/g.

The critical temperatures are *cis*-2-butene, 160.0°C; *trans*-2-butene, 155.0°C; isobutene, 144.73°C (5). Dielectric constants at different densities and 170°C were calculated by the Clausius–Mosotti equation from the data given in ref. 4.

Results and Discussion

Free Ion Yields

The yields of nitrogen from γ-radiolysis of *cis*-2-butene – nitrous oxide, *trans*-2-butene – nitrous oxide, and isobutene – nitrous oxide mixtures at 170 ± 1°C in the density range from 0.24 to 0.48 g/cm^3 exhibit features quite similar to those observed for other hydrocarbons in the supercritical state (1, 2). Firstly, they can be quantitatively described by the square root model, $G(N_2) = G(N_2)_{fi} + G(N_2)_{gi}(A[N_2O])^{1/2}$;

[1]Partially supported by a Grant-in-Aid from the Ministry of Education.

secondly, $G(N_2)_{fi}$ decreases with increase in density for each butene studied (Figs. 1–3). The values of $G(N_2)_{fi}$ obtained in the liquid phase agree quite well with those obtained by electrical measurements (4). It was previously argued that $G(N_2)_{fi}$ can be assumed to be equal to the free ion yields, G_{fi} (2). The G_{fi} values in the supercritical butenes in the density range studied are in the decreasing order *cis*-2-butene $\gtrsim$ isobutene > *trans*-2-butene (Table 1). The trend is in agreement with the finding that G_{fi} in liquid *trans*-2-butene is much smaller than in other isomer liquids (4).

Electron Ranges

By inserting the G_{fi} values into [1], electron ranges were estimated.

$$[1] \quad G_{fi} = G_{tot} \int_0^\infty f(r) \exp(-r_c/r)\, dr$$

where G_{tot} is the total ionization yield calculated from W values in the gas phase, $f(r)$ is the distribution function of ion–electron separation distances, and r_c is the Onsager distance ($e^2/\varepsilon kT$) (1, 2, 4). The distribution function $f(r)$ was taken to have the form composed of a Gaussian core and a power function tail (eq. 2):

$$f(r) = 0.96(4r^2/\pi^{1/2}b_{gp}^3) \exp(-r^2/b_{gp}^2) \qquad r < 2.4b_{gp}$$

$$[2] \quad f(r) = 0.96\{(4r^2/\pi^{1/2}b_{gp}^3) \exp(-r^2/b_{gp}^2) + 0.5(b_{gp}^2/r^3)\} \qquad r > 2.4b_{gp}$$

where b_{gp} is the most probable value of r. Although this form has been found to give an accurate description of electric field dependence of the free ion yields (4, 6, 7), the use of [2] in the present study is for the sake of comparison with values obtained by other methods (4) because it has not yet been possible to determine the most satisfactory form of $f(r)$ (6, 7). The value of b_{gp} has been found to be practically identical to that of the parameter b in the simple Gaussian form when $G_{fi} > 0.3$ (4). Thus most of the b_{gp} values in the present study are equal to b values; b_{gp} in butenes increased only gradually with decrease in density. The behavior is similar to that observed for C_3 and C_4 hydrocarbons in the supercritical state (1, 2).

The independence of the density-normalized electron ranges has been noted previously both in the liquid phase (4) and in the supercritical state (1, 2). This is again the case with the supercritical butenes. The values of $b_{gp}d$ in the present study agreed quite well with those obtained by electrical measurements in the corresponding liquids (4). The discussion based on the independence of the density-normalized ranges in the supercritical state may be premature before it can be confirmed by direct measurements. It might also be possible that the trend is susceptible to the form of $f(r)$ used in [1].

Scavenging Efficiency Parameter

The scavenging efficiency parameters, A, were evaluated from the slope of the square root plot in Figs. 1–3. They were found to increase regularly with decrease in density for each butene studied. This is different from the behavior observed in other C_3–C_4 hydrocarbons where they showed no definite trend (1, 2). A values in *cis*-2-butene and in isobutene were much smaller than those in *trans*-2-butene (Table 1).

It has been shown that the parameter A is given by

$$[3] \qquad A = k_s/\lambda$$

where k_s is the rate constant for charge scavenging, and λ is a constant for a given solvent and represents the rate of recombination of geminate ion-electron pairs (8). The Nernst–Einstein relationship has been found to be a good approximation for the geminate recombination (9), so that λ can be adequately expressed as (10)

$$[4] \quad \lambda = 3(D_e + D_+)r_c/b_{gp}^3 \simeq 3D_e r_c/b_{gp}^3$$

where D_e and D_+ are the diffusion coefficients

of the electrons and the positive ions, respectively. By combining [3] and [4], k_s is now given by

$$[5] \qquad k_s = 3D_e A r_c / b_{gp}^3$$

The encounter efficiency of a reaction is defined as the ratio of k_s to that in the diffusion-controlled case, *i.e.*, $4\pi R D_e$ in the present case. One notes that by using [5] the efficiency is quite generally given by

$$[6] \qquad f = \frac{3Ar_c}{4\pi R \cdot 6 \times 10^{20} b_{gp}^3}$$

where 6×10^{20} is the conversion factor from cm³ molecule^{-1} s^{-1} to l mol^{-1} s^{-1}. The values of f calculated by taking arbitrarily 5 Å for the reaction radius R are summarized in Table 2 where values for *n*-butane are included for comparison. Although there are some exceptions, f is generally seen to decrease with decrease in density. The large A values in *trans*-2-butene are apparently related to similarly large f values.

A correlation between the encounter efficiency for the reaction $e^- + N_2O$ and electron mobilities μ_e has been found in liquid rare gases and in several liquid hydrocarbons (11). This correlation also seems to exist in the liquid butenes

§Estimated from critical volumes in ref. 5.

when f values are compared with the measured values of electron mobilities taken from ref. 4. It would therefore be of some interest to see if this correlation extends into the supercritical state. Unfortunately, measurements of the mobilities have not been carried out in the gas phase in the density range of interest. Previously, a relationship $k_s \propto \mu_e^{1/2}$ observed in some hydrocarbon liquids (12, 13) was assumed for the estimation of μ_e in the supercritical state from scavenging data (2), but this relation appears to be of a more limited applicability than was originally thought (14–16). Instead, a correlation of apparently more fundamental nature has been noted recently between k_s and the energy of the electron in its conducting state V_0 in an assortment of hydrocarbon and rare gas liquids containing solutes including N_2O (15, 16). If one assumes the validity of the correlation in the supercritical state, then the problem is to find V_0 values.

The Springett *et al.* model (17) has been used to calculate V_0 in liquid hydrocarbons, and the agreement with experiment has been found to be remarkably good (18, 19). The calculation is based on the hard core radius a, the polarizability, and density. Since a is considered to be density- and temperature-independent within the framework of the present V_0 theory, it seems justifiable to employ the method for the calculation of V_0 in the supercritical hydrocarbons. The values of a to be used in the calculation were determined either from V_0's when experimental values were available in the corresponding liquid, or by the relationship $a = 0.305 V_{crit}^{1/3}$ where V_{crit} is the critical volume (20). Since V_0 is relatively sensitive to a, the V_0 values obtained by using the estimate of a from the relationship may be subject to large errors.

The values of a so obtained and V_0 calculated by the model are listed in Table 2. It is interesting to note that V_0 apparently passes through a minimum on going from the liquid to the low density region. This trend is quite reasonable, as V_0 must return to zero in low pressure gases, and seems to indicate the validity of the model for the calculation of V_0 in the supercritical state.

With the V_0 values one can find k_s from the

experimentally obtained relationship between V_0 and k_s (15), and thence μ_e by eq. 5 and $\mu_e = eD_e/kT$.[2] The μ_e values so estimated steadily increase with decreasing density (Table 2). Thus the decrease in the encounter efficiency is accompanied by the increase in electron mobilities. This is in keeping with observations in liquid hydrocarbons and rare gases (11). This behavior was accounted for in terms of the dependence of reaction probability on the electron–reactant interaction time per encounter (11).

Direct measurements of both k_s and μ_e in the supercritical state are desirable.

Acknowledgments

We wish to thank Dr. K. Fueki for valuable discussion, and Mr. Y. Kaneko for his assistance in a part of the study.

[2]There is also an empirical relation that connects V_0 directly to μ_e noted for the neopentane–*n*-hexane mixture (21). μ_e's obtained by this relation are very much larger than those estimated by the method described in the text; moreover they begin to decrease in the intermediate density region.

Discussion

G. R. Freeman: The mobilities of electrons in the supercritical butenes at the critical density have been measured, but we haven't published them yet. They are about 10–20 cm^2 V^{-1} s^{-1}. How does this compare with the values you estimated?

M. Nishikawa: Our estimated values at $d \simeq 0.25$ g/ml and 170°C are 15 to 20 cm^2 V^{-1} s^{-1} for *cis*-2-butene and isobutene, in fair agreement with your values.

Effect of a magnetic field on the fluorescence produced in irradiated anthracene solutions[1]

The effect of an applied magnetic field on the fluorescence from radiolytic ion recombination has been studied for anthracene in some hydrocarbon solvents. In pulse-irradiated anthracene (10^{-2} mol dm^{-3}) in squalane, the fluorescence intensity following the pulse increases as a function of applied magnetic field in the range studied, 0 to 0.3 T (0 to 3000 G). At a constant magnetic field strength, the field-induced enhancement of the fluorescence intensity varies with time after the pulse. At high field strengths (0.3 T) the enhancement reaches a maximum of ~45% about 50 ns after the pulse. Similar effects are observed in cyclohexane but the enhancement is smaller than that in squalane. In benzene solutions the effect is extremely small. These findings are confirmed by observations in continuously gamma-irradiated solutions. In gamma-irradiated solutions of anthracene (10^{-2} mol dm^{-3}) in squalane, the fluorescence intensity increases with increasing magnetic field and approaches ~13% enhancement at high fields (>0.1 T). The enhancement is smaller (~3%) in cyclohexane and very small (<1%) in benzene solutions. 9,10-Dimethylanthracene gives a larger enhancement and anthracene-d_{10} a smaller enhancement than the parent anthracene at high fields. The results are in general agreement with recent theoretical predictions based on the effect of a magnetic field on the loss of spin correlation of geminate ions pairs prior to recombination.

On a étudié l'effet d'un champ magnétique appliqué sur la fluorescence provenant de la recombinaison ionique radiolytique de l'anthracène dans quelques solvants hydrocarbonés. Dans le cas de l'anthracène irradié par pulsation (10^{-2} mol dm^{-3}) dans le squalane, l'intensité de la fluorescence à la suite de la pulsation augmente en fonction du champ magnétique appliqué dans les intervalles étudiés soit de 0 à 0.3 T (0 à 3000 G). A une force constante du champ magnétique, l'augmentation, induite par le champ, de l'intensité de la fluorescence varie avec le temps après la pulsation. A des forces de champ plus élevées (0.3 T), l'augmentation atteint un maximum d'environ 45% environ 50 ns après la pulsation. On observe des effets similaires dans le cyclohexane mais l'augmentation est plus faible par rapport à celle observée dans le squalane. Dans des solutions benzéniques, l'effet est extrêmement faible. Ces découvertes sont confirmées par des observations dans des solutions irradiées d'une façon continue par des radiations gamma. Pour l'anthracène en solution dans le squalane (10^{-2} mol dm^{-3}) et irradié par des rayons gamma, l'intensité de la fluorescence augmente avec une augmentation du champ magnétique et atteint environ 13% d'augmentation en haut champ (>0.1 T). L'augmentation est plus faible (~3%) dans le cyclohexane et très faible (<1%) dans des solutions benzéniques. Comparé à l'anthracène, le diméthyl-9,10 anthracène donne des augmentations plus grandes alors que l'anthracène-d_{10} donne des augmentations plus faibles à des hauts champs. Ces résultats sont en accord général avec les prédictions théoriques récentes basées sur l'effet d'un champ magnétique sur la perte de corrélation de spin de paires d'ions géminés avant leur recombinaison.

Introduction

Large yields of cations and electrons are produced following absorption of radiation by a liquid. In nonpolar liquids most of the electrons and parent cations recombine geminately (1), *i.e.* the separated charges remain coupled by electrostatic attraction and the electron recombines with its original counter ion. In

[1]Issued as AECL No. 5660.

solutions of an aromatic hydrocarbon in an alkane solvent, geminate recombination of solute radical ion pairs is thought to be a major source of solute excited state formation (2–6). Consequently much attention has focused on the ion recombination process and the production and yields of excited states in such systems (1–12).

For geminately recombining radical ions, the electron on the anion was initially paired in a singlet state with the odd electron in the cation. If the spins remain correlated (*i.e.* if the relative orientations and phase of the two electrons stay the same), excited singlet states will be produced, whereas if the correlation is lost, this will lead to the formation of triplet states. Statistically, ion recombination is expected to lead to a triplet:singlet (T/S) ratio of 3. However, measurements of triplet and singlet yields (9, 11, 12) show T/S ratios between 1 and 2, after correction for intersystem crossing. Although the picture may be complicated by energy transfer from excited singlet alkane molecules (10, 12) and excitation of solute triplet states by electrons with insufficient energy to excite the solvent (3), the experimental yields suggest that spin correlation may be partly, but not completely, lost.

The question of the mode and rate of loss of spin correlation was first discussed (13, 14) in terms of the spin relaxation times T_1 and T_2, as used in electron spin resonance (15). Since it was assumed that the loss of correlation would occur in times comparable with T_1 and T_2, it was predicted that a magnetic field would affect the loss of spin correlation when the ion recombination time T_G was longer than the spin–spin relaxation time T_2 but shorter than the spin–lattice relaxation time T_1. Since T_1 and T_2 occur in μs and T_G is ~1–100 ns in mobile liquids, no magnetic field effect would be expected under these conditions. However, if T_G could be increased by the use of viscous solvents, an effect might be seen.

On the basis of these arguments, solutions of fluorene in the viscous solvent squalane were pulse-irradiated and a magnetic field effect on the fluorescence intensity following the pulse was observed (16). The effect was confirmed in gamma-irradiated solutions (17). However, the pulse experiments showed the effect to develop on a shorter time scale than predicted and it was clear that a much more rapid process than spin relaxation was taking place. While the early arguments regarding T_1 and T_2 are still valid, it would be difficult experimentally to detect such an effect because of the low sensitivity.

Further developments in the theory led to predictions of a magnetic field effect on a nanosecond time scale (18, 19). It was shown that loss of spin correlation could occur because of the hyperfine interactions, a, between the unpaired electrons and the hydrogen nuclei of the ions M^+ and M^-. The rate of loss of correlation is mainly determined by the magnitude of a and the number of nuclei. The recent theory stresses the importance of the relative orientations of the spins of the two electrons on M^+ and M^-, which are in different nuclear spin environments. In a strong magnetic field, the electrons on M^+ and M^- precess at different rates about the total field. This difference in the rates of precession leads to conversion of the ion pair from a singlet to a triplet spin state. In principle, the probability of forming a singlet or triplet state should cycle between 1 and 0 but, in practice, it has been shown (18, 19) that the presence of several nuclei tends to mask this and a steady decay from singlet to a mixture of singlet and triplet is predicted. At zero field, the ion pair states S_0, T_0, T_+, and T_- are degenerate and mixing occurs between the singlet and all three triplet states. At high fields, T_+ and T_- have different energies because of the Zeeman splitting, hence mixing takes place only between S_0 and T_0 states. The latter is calculated to be slower and the limiting value for the ratio of singlet to triplet states to be larger than that at zero field. Thus the rate of loss of spin correlation is predicted to be lower in a strong magnetic field than at zero field. Further, the time scale for loss of spin correlation is predicted to correspond not to the esr line width (~100 kHz) but to the spectral width (~100 MHz). This leads to spin correlation changes on a nanosecond time scale.

The original experiments (16, 17) used fluorene because of its short fluorescence decay time (~10 ns) (20) and high fluorescence quantum yield (0.54) (21) and squalane because of its high viscosity. This paper describes the magnetic field effects found on anthracene fluorescence in both pulse-irradiated and continuously irradiated solutions in squalane, cyclohexane, and benzene and compares the results with theoretical predictions.

Experimental

The experimental arrangement for studying the magnetic field effect following pulse radiolysis is shown in Fig. 1. The electron beam flight tube of a 4 MV Van de Graaff accelerator was extended axially through the electromagnet of a Varian 4500 esr spectrometer by means of a hole which passed through the yoke, the pole piece, and the pole cap. The flight tube then passed into a pulse radiolysis cell block assembly at the centre of the electromagnet, and terminated in a 0.03 mm thick brass window located 1 mm from the face of the cell. The Suprasil cell was part of a flow system for ease of sample changing. The magnetic field strength was measured by a Hall effect probe. Since the field affected the beam focusing, the latter was adjusted to minimize this effect. Details of the effect of field strength on the dose per pulse measured by KCNS dosimetry are described elsewhere (22). In the present experiments, conditions were such that the magnetic field had no effect on the dose below 0.1 T and only ~5% at 0.3 T. The dose per pulse was $\sim 10^{-2}$ J. For experiments with the magnetic field off, a small residual field of $\sim 10^{-3}$ T (~10 G) remained when the magnet was turned off. To eliminate this, a small reverse dc current was applied to the magnet such that the magnetic field was a minimum in the direction of the Hall crystal. The field at the minimum was $< 10^{-4}$ T. A conventional optical detection system was used with a 1P28 photomultiplier tube and a Hewlett-Packard 183A oscilloscope. To facilitate measurements at long times after the pulse, a pulse generator with a variable delay was used to trigger the oscilloscope. Initially a Jarrell-Ash 0.25 m monochromator was used, but once the fluorescence spectrum was established, this was removed for greater sensitivity.

The experimental arrangement for studying the magnetic field effect on continuously irradiated solutions is shown in Fig. 2. Solutions were irradiated in a Suprasil cell, which was part of a flow system, by gamma rays from a movable Iridium-192 source. The dose rate was $\sim 6 \times 10^{-5}$ J g^{-1} s^{-1} ($\sim 4 \times 10^{14}$ eV g^{-1} s^{-1}) as measured by the Fricke dosimeter. A small electromagnet provided the magnetic field up to 0.5 T. A permanent magnet, used in a few experiments, gave the same results. Measurement of the field strength and zeroing of the field were as described for the pulse experiments. The magnetic field had no effect on the photomultiplier tube (RCA 1P28) or on the emission intensity from a cell containing solvent only. However, it was necessary to correct for the effect of the gamma rays on the photomultiplier tube. The light emitted from the cell was focused by a lens onto the photomultiplier tube and the level displayed on a recorder. The identity of the emitting species was assumed to be the same as that in the pulse radiolysis experiments.

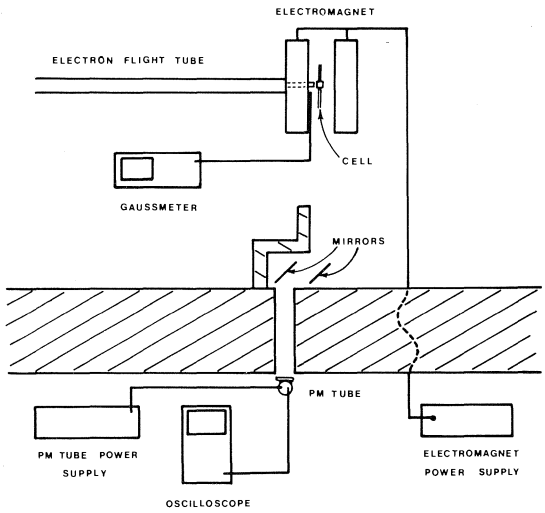

FIG. 1. Schematic of the apparatus for studying the effect of an applied magnetic field on the fluorescence from pulse-irradiated solutions.

Cyclohexane (Fisher or Matheson Spectroquality), benzene (Fisher certified), anthracene (Hinton, zone refined), anthracene-d_{10} (Merck, Sharpe, and Dohme 98% D), and dimethylanthracene (Aldrich) were used as received. Squalane was purified by repeated passes through a silica gel column until the absorption edge, measured spectrophotometrically, remained constant.

Results

(a) Pulse Radiolysis

The fluorescence from pulse-irradiated anthracene in squalane persists to hundreds of nanoseconds after the pulse, and the intensity increases in the presence of an applied magnetic field (Fig. 3). The field has little or no effect on the in-pulse intensity. The emission enhancement following the pulse was found to be both time and field strength dependent. The effect of field strength at ~100 ns following the pulse is shown in Fig. 4 for 10^{-2} mol dm^{-3} anthracene. The enhancement was found to increase rapidly with increasing field strength up to 0.1 T, followed by a much slower increase at higher fields. The behaviour was similar for times in the range 0–400 ns after the pulse. The time dependence of the enhancement at a field of 0.3 T is shown in Fig. 5 for 10^{-2} mol dm^{-3} anthracene. The enhancement increases rapidly with time, reaching a plateau of ~45% some 50 ns after the pulse. The enhancement may decrease slightly at longer times but the emission is small and the measurement less precise. Within the limits of experimental error, we saw no concentration effect in the range 10^{-3} to 10^{-2} *M* anthracene up to ~200 ns after the pulse, but at longer times the 10^{-2} *M* solution showed less enhancement than the 10^{-3} *M* solution.

Similar behaviour was seen in solutions of anthracene in cyclohexane but the magnetic

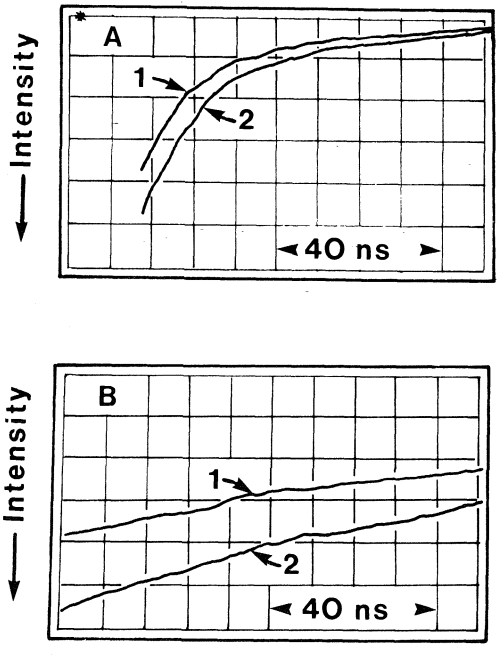

FIG. 3. Typical oscilloscope traces showing the effect of an applied magnetic field on the fluorescence intensity from 10^{-2} mol dm^{-3} anthracene in squalane following a 5 ns pulse: (*A*) $t = 0$ to 100 ns following start of pulse; (*B*) $t = 300$ to 400 ns following start of pulse (sensitivity × 150); curve *1*, no magnetic field; curve *2*, 0.3 T (3000 G).

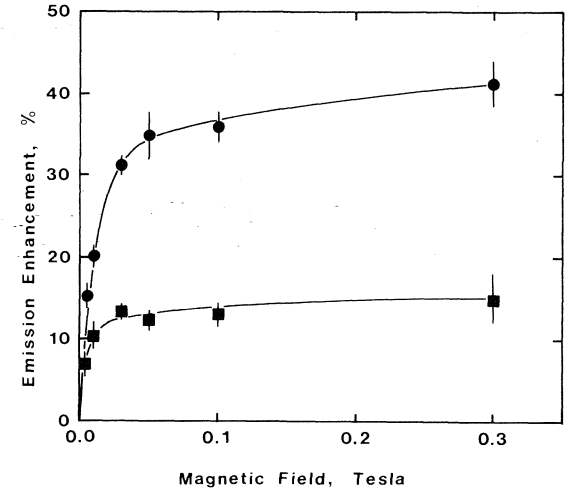

FIG. 4. Effect of applied magnetic field on the fluorescence intensity from 10^{-2} mol dm^{-3} anthracene in squalane (●) and cyclohexane (■): $t = 100$ ns following start of pulse.

field effect was smaller than in squalane (Figs. 4 and 5). For example, the maximum emission enhancement following the pulse was only ~20% at high fields (Fig. 5) at an anthracene concentration of 10^{-2} mol dm^{-3}.

In benzene the emission intensity was large but we found no measurable field effect up to ~100 ns following the pulse. However, there

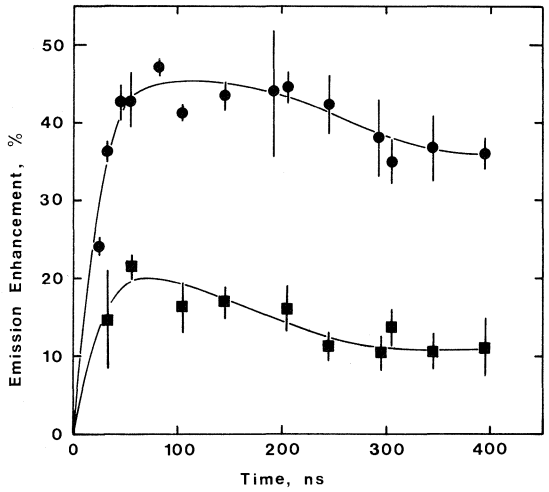

FIG. 5. Magnetic field induced increase in fluorescence intensity as a function of time following a 5 ns pulse for 10^{-2} mol dm^{-3} anthracene in squalane (●) and cyclohexane (■): magnetic field = 0.3 T.

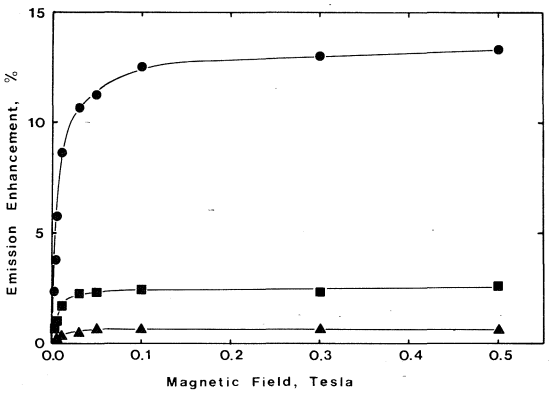

FIG. 6. Effect of applied magnetic field on the fluorescence intensity from gamma-irradiated 10^{-2} mol dm^{-3} anthracene in squalane (●), cyclohexane (■), and benzene (▲).

may be a small enhancement ($\leq 5\%$) in the range 100–200 ns following the pulse, but we could not make precise measurements because of lack of sensitivity.

(b) Continuous γ Radiolysis

The effect of solvent on the emission enhancement from anthracene solutions in an applied magnetic field is shown in Fig. 6. The enhancement is in the order squalane > cyclohexane > benzene, the effect being very small in benzene. In squalane solutions, the enhancement was also found to increase slightly with concentration in the range 5×10^{-4} *M* to 10^{-2} *M*, but

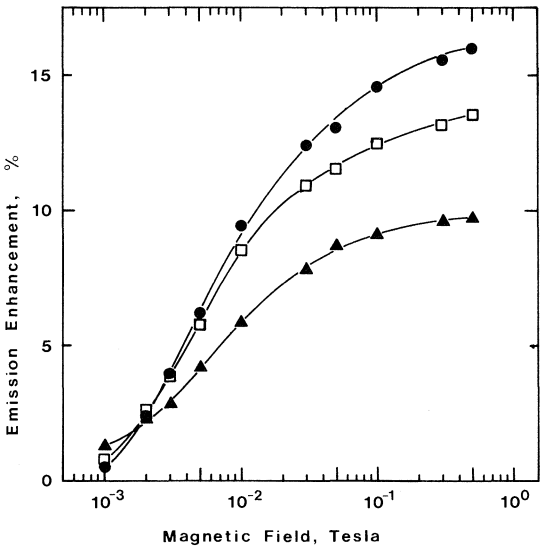

FIG. 7. Effect of applied magnetic field on the fluorescence intensity from some gamma-irradiated anthracenes (10^{-2} mol dm^{-3}) in squalane: (●) 9,10-dimethylanthracene; (□) anthracene; (▲) anthracene-d_{10}.

at higher concentrations it began to decrease slightly. The effect of magnetic field on the fluorescence from anthracene, perdeuteroanthracene, and 9,10-dimethylanthracene in squalane is shown in Fig. 7. Deuteration gives a smaller enhancement and methylation a larger enhancement than the parent anthracene at higher fields.

Discussion

(a) Pulse Radiolysis

Although there is still considerable debate on the possible mechanisms of excited state formation, their relative contributions, and the time scales over which they are important, ion recombination is thought to be a major source of excited states in irradiated systems. In nonpolar solvents, most of the ion pairs do not separate completely but undergo geminate recombination (1). The pertinent reactions occurring in solutions of an aromatic hydrocarbon, M, in an alkane, S, will be

[1] $$S \rightsquigarrow S^+ + e^-$$

[2] $$S^+ + M \rightarrow M^+ + S$$

[3] $$e^- + M \rightarrow M^-$$

[4] $$M^+ + e^- \rightarrow M^*$$

[5] $$S^+ + M^- \rightarrow M^* + S$$

[6] $$M^+ + M^- \rightarrow M^* + M$$

where M* can be an excited singlet or triplet state. At high solute concentrations, reaction 6, involving reaction of solute radical ions, will be the major process for ion recombination.

Figure 8 shows the decay of the fluorescence from 10^{-2} mol dm^{-3} anthracene in squalane following a 5 ns pulse. The fluorescence persists to longer times and decays much more slowly than would be expected from the photofluorescence decay time (4.9 ns in cyclohexane (20)), *i.e.* neglecting the effects of self-quenching, quenching by radiolysis products, etc. At short times following the pulse, a major fraction of the fluorescence arises from 'prompt' singlets (whether formed by energy transfer, ion recombinations, or other mechanisms) and the decay time is ~15 ns. At longer times the fluorescence arises mainly from slower ion recombinations, which explains the much slower fluorescence decay with increasing time.

The enhancement of the fluorescence intensity in the presence of a magnetic field increases with time following the pulse and reaches its maximum ~50 ns after the end of the pulse (Fig. 5). In his theory of magnetic field effects on excited singlet state formation, Brocklehurst describes approximate time regions following the pulse where different field effects are predicted (18, 19). At times <5 ns, there is no loss of spin correlation in the rapidly recombining ions and no magnetic field effect. At times >5 ns, loss of spin correlation occurs faster at zero field because the singlet can mix with all three degenerate triplets, whereas at high field only the singlet and T_0 states mix because of the Zeeman effect. At these times, the field effect is predicted to be large. On the basis of these predictions, we would expect no field effect during the pulse and a rapidly rising effect immediately following the pulse. The enhancement should reach a maximum when the 'prompt' fluorescence contribution has become negligible. These general features of the theory are found in our experimental results (Fig. 5).

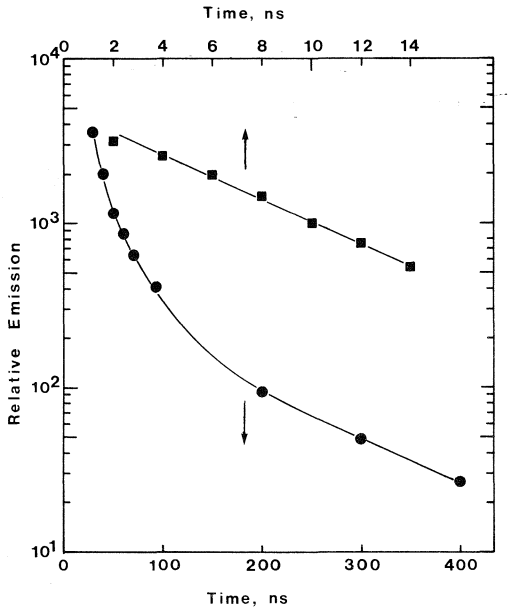

FIG. 8. Decay of the fluorescence from pulse-irradiated 10^{-2} mol dm^{-3} anthracene in squalane (●) and benzene (■).

The theoretical calculations predict a maximum in the field effect at ~10–20 ns after the pulse (18, 19). Maxima have been observed in this time region in studies of magnetic field effects on scintillations from geminate ion recombination (23, 24). We do not observe a maximum at this time but a somewhat longer time (~50 ns). However, our results are more complicated because of the width of the pulse and because of the fluorescence lifetime. The latter is particularly important since, at shorter times after the pulse, a considerable fraction of the total emission comes from 'prompt' fluorescence, which exhibits no magnetic field effect. If the prompt fluorescence contribution were subtracted from the total emission, the emission enhancement would reach its maximum in a shorter time. Qualitatively this has been shown to be the case for fluorene in squalane (22), assuming that the in-pulse emission is all prompt fluorescence and using the literature value for its decay time. This is not strictly true since the in-pulse emission includes Cerenkov emission, etc., but it does indicate that the field effect on ion recombination in the present system probably reaches its maximum at a time shorter than 50 ns after the pulse.

In cyclohexane solutions, ion recombination will be much faster than in squalane because of the lower viscosity. Thus a greater fraction of the geminately recombining ions will not be affected by a magnetic field, but the behaviour of the remaining ions should be similar to that in squalane. The overall decay of the fluorescence is similar to that found in squalane, but the magnetic field effect is smaller. In the simplest theoretical case, the magnetic field enhancement is calculated to reach a factor of 2 at longer

times (18, 19). The maximum enhancement which we have observed is about half of this, both in the present work and in other systems (16, 22). There are several possible reasons for the discrepancy. In discussing excited state yields, Magee and Huang (25) considered the formation of triplet ion pairs by cross-recombination in multiple ion pair spurs and by spin reversal of a secondary electron when it excites a solvent molecule to the triplet state. If these processes are significant in the present system, triplet ion pairs may reduce the extent of the magnetic field effect. In addition, the calculated limiting probabilities of 0.5 and 0.25 for singlet state formation in the presence and absence of a magnetic field may not be reached except at very long times (19). Finally the yields of excited states may depend not only on spin but on the energy level densities, *i.e.* Franck–Condon factors (14). Contributions from any of these factors may lead to an emission enhancement which is smaller than the maximum theoretical value. Nevertheless, it appears that some additional or alternative factor is involved in the case of cyclohexane solutions. A factor which is likely to be much more important in cyclohexane than in squalane is the effect of the prompt fluorescence decay. In cyclohexane the prompt fluorescence will be much larger and the emission from slower ion recombinations much smaller than in squalane. Consequently the prompt fluorescence contribution, which shows no magnetic field effect, will be larger and much more important than in squalane. This will lead to a smaller enhancement in cyclohexane than in squalane at short times after the pulse, though it appears doubtful that this can still be operative out to the longest times which we have measured.

Results in benzene are considerably different from those in squalane and cyclohexane since we see a large emission but no magnetic field effect during the first 100 ns after the pulse. Although excited state yields are high in benzene (2, 3), solute ions have not been observed. This implies that solute excited states arise from energy transfer from solvent excited states, fast ion recombination, or some other rapid process, none of which would be expected to exhibit a magnetic field effect, according to theory (18, 19). The fluorescence decay was found to be exponential (Fig. 8) with a lifetime of 6.4 ns, compared to the lifetime of 4.9 ns from photochemical measurements in cyclohexane (20). This comparison is reasonable since the lifetime under our experimental conditions may be increased by reabsorption and by any ion recombination contribution. At times in the range 100–200 ns after the pulse, we did observe a small magnetic field effect ($\leq 5\%$) at an applied field of 0.3 T. While measurements in this region were subject to large experimental uncertainty, they, together with the results from continuously irradiated benzene, do suggest a small contribution from slower ion recombinations and a small magnetic field effect.

(b) Continuous Radiolysis

The effects of a magnetic field on continuously gamma-irradiated solutions of anthracene in squalane, cyclohexane, and benzene are qualitatively similar to those found in pulse-irradiated solutions. Increasing the magnetic field intensity increases the fluorescence enhancement rapidly for fields up to 0.1 T but much more slowly at higher fields (Figs. 6 and 7). The enhancement is again larger in squalane than in cyclohexane and only a small enhancement ($< 1\%$) is seen in benzene solutions (Fig. 6). The enhancement in continuously irradiated solutions is smaller than that found in pulse-irradiated solutions, as expected. In the continuous radiolysis we are seeing the prompt emission, whether from energy transfer, fast ion recombination, or other processes, superimposed on the emission from slower ion recombinations. Since only the latter is expected to exhibit a magnetic field effect, the effect will be smaller than the maximum seen in pulse-irradiated solutions after most of the prompt emission has decayed. The enhancement in squalane solutions is expected to be larger than that in cyclohexane solutions because of the viscosity differences. In general, the range of ion recombination times in cyclohexane is smaller than in squalane, leading to a greater fraction of singlet excited states which exhibit no magnetic field effect. The enhancement is, however, smaller than expected on the basis of results from other solutes in cyclohexane (17, 22). This appears to be further evidence that some other process is contributing to the overall effects in both pulse-irradiated and continuously irradiated anthracene in cyclohexane. In benzene, excited state yields are high (2, 3) but solute ions have not been observed. This implies that the major mechanism of solute excited state formation in benzene involves energy transfer,

very fast ion recombination, or some other rapid process, none of which would be expected to show a magnetic field effect. This is confirmed by our experimental results (Fig. 6). Nevertheless, we do see a small, but positive, field effect which suggests that some solute excited states in benzene may be formed by slow ion recombinations.

The effect of deuteration and methylation at high field (Fig. 7) provides some support for the theory (18, 19). The ion recombination rate for the three anthracenes will be little affected by substitution and not at all by the magnetic field. The different effects of substitution must therefore be due to the effect on the rate of loss of spin correlation. A major reason for the decay of the spin correlation, *i.e.* the rate of conversion of singlet ion pairs to triplet pairs, is the electron–nuclear coupling in the respective radical ions. Decreasing the coupling constant should decrease the rate of loss of spin correlation, leading to an increase in excited singlet state formation, and vice versa. Anthracene-d_{10} has a smaller coupling constant than anthracene because of the smaller magnetic moment of the deuteron. Thus the rate of loss of spin correlation will be smaller for anthracene-d_{10}, resulting in a corresponding increase in the probability of excited singlet state formation and a smaller magnetic field effect. Conversely, 9,10-dimethylanthracene will have a larger coupling than anthracene because of the increased number of protons. This will lead to an increase in the rate of loss of spin correlation, *i.e.* a decrease in the probability of forming singlet excited states and a larger magnetic field effect, as is found (Fig. 7).

At low fields ($\sim 10^{-3}$ T) the reverse effect occurs, *i.e.* the enhancement is highest for anthracene-d_{10}. This is because, to be effective in preventing mixing between S_0 and $T_{\pm}$, the field must be $\gtrsim$ the spread of the hyperfine levels. This is smallest for anthracene-d_{10}, so a smaller field is required to give an enhancement.

(c) Other Considerations

We have attributed the magnetic field induced enhancement of the fluorescence to an increase in the fraction of geminate ion recombinations leading to excited singlet state formation. In principle, other mechanisms may be possible. We have ruled out a field effect on the fluorescence lifetime since, in benzene, the fluorescence is little affected by a magnetic field either in pulse-irradiated or continuously irradiated solutions. We assume the same to hold in squalane and cyclohexane. Studies on delayed fluorescence by triplet–triplet annihilation in both crystals (26–28) and fluid solutions (29, 30) and on electrochemically generated luminescence (31, 32) have shown the importance of magnetic field effects on this process. A magnetic field was found to decrease both the rate of the triplet–triplet reaction and the rate of triplet quenching by radical ions. However, we consider the contribution from these mechanisms to be small, if any, for several reasons. At the low dose rates used in our continuous radiolysis experiments, triplet–triplet annihilation is unlikely to be a major source of fluorescence, yet a large magnetic field effect can be seen. Conversely, in pulse-irradiated benzene solutions, we found little magnetic field effect even though triplet yields in benzene are high (2, 3). In our pulse radiolysis experiments, the dose rate is much higher than in the continuous radiolysis, but the results suggest that triplet–triplet annihilation is not of major importance in any solvent studied. In cyclohexane we found triplet anthracene to decay by a first order process with $k = 3.0 \times 10^4\ s^{-1}$, independent of magnetic field. Evidence from the literature shows similar triplet decays. In the pulse-irradiated viscous solvent liquid paraffin, biphenyl triplets were seen to decay by a first order process and little or no second order contribution was found (33). At the high doses used (0.15 J) the decay was attributed to quenching by radicals. In pulse-irradiated cyclohexane and benzene solutions (34), anthracene triplet decayed by a first order process for doses up to $0.02\ J\ g^{-1}$, which is similar to the doses used in the present work. Finally, the field effects on singlet state production from triplet–triplet annihilation should show no isotope effect since the processes depend on the fine structure of the triplet state (zero-field splitting) rather than the hyperfine interaction. Thus, although magnetic field effects on delayed fluorescence from triplet–triplet annihilation now appear well-established, our evidence suggests that their contribution in the present work is not of major importance.

Conclusions

An applied magnetic field increases the fluorescence intensity from pulse-irradiated and continuously irradiated solutions of anthracene

in squalane and cyclohexane. Only a small effect is seen in benzene solutions. The results are in qualitative agreement with theoretical predictions based on the effect of a magnetic field on the rate of loss of spin correlation of separated ion pairs prior to their geminate recombination. Both the effect of solvent and of substitution in the solute molecule support the theory. The results also provide evidence for the importance of geminate ion recombination in the formation of solute excited states in radiolysis.

Discussion

A. C. Albrecht: Can triplet–triplet annihilation be easily excluded in this work?

R. S. Dixon: Magnetic fields are known to decrease both the rate of triplet–triplet annihilation and the quenching of triplets by radical ions. The former would lead to a decrease in excited singlet formation and the latter to an increase. We cannot definitely exclude a contribution from these mechanisms but we consider it to be small for several reasons. Firstly, the field effect in benzene solutions is small even though triplet state yields in benzene are high. Secondly, at the low dose rates used in the continuous radiolysis, triplet–triplet annihilation is unlikely to be a major source of fluorescence. Thirdly, in pulse-irradiated anthracene in cyclohexane, we found a first order decay for the triplet with no measurable field effect. A first order triplet decay has been observed in similar studies in the literature. However, I should point out that, because of the long triplet lifetime, triplet decay measurements were necessarily made at much longer times (μs) than the fluorescence measurements.

Time resolved magnetic modulation of ion recombination in organic solutions: spin motion in radical ion pairs

JEAN KLEIN AND RENÉ VOLTZ

Centre de Recherches Nucléaires et Université Louis Pasteur, Laboratoire de Physique des Rayonnements et d'Electronique Nucléaire, F 67037, Strasbourg, Cedex, France

Received September 27, 1976

JEAN KLEIN and RENÉ VOLTZ. Can. J. Chem. **55**, 2102 (1977).

The evolution of the singlet character of correlated ion radical pairs, prepared by high energy impact (β particles) in organic liquid and solid solutions, is monitored by nanosecond time resolved solute recombination fluorescence. Results obtained show that the relative variations $[I^B(t) - I^0(t)]/I^0(t)$ of the luminescence intensity in presence $I^B(t)$ and in absence $I^0(t)$ of magnetic fields ($B \leq 5$ kG) decrease exponentially with time, according to a field and solute concentration dependent rate, in liquid but not in solid solutions; in the case of 2b PPD as solute, a damped oscillating component could be observed. The results are interpreted in terms of hyperfine interaction induced coherent singlet–triplet mixing and of field and solute concentration dependent spin–lattice relaxation.

JEAN KLEIN et RENÉ VOLTZ. Can. J. Chem. **55**, 2102 (1977).

L'évolution du caractère singulet de paires de radicaux-ions corrélés, créés dans des solutions organiques liquides et solides par une excitation brève (particule β), a pu être suivie dans le domaine de la nanoseconde par l'intermédiaire de la fluorescence de recombinaison résolue dans le temps. Les résultats obtenus montrent que les variations relatives $[I^B(t) - I^0(t)]/I^0(t)$ de l'intensité de la luminescence en présence $I^B(t)$ et en absence $I^0(t)$ de champs magnétiques ($B \leq 5$ kG) décroissent exponentiellement avec une constante de temps qui dépend du champ et de la concentration en soluté dans les solutions liquides mais non dans les solides; dans le cas de 2b PPD comme soluté, on observe de plus une composante oscillante. Ces résultats sont interprétés à l'aide d'un modèle impliquant d'une part un mélange cohérent entre états singulet et triplet induit par des interactions hyperfines, d'autre part des processus de relaxation spin–réseau dépendant du champ et de la concentration en soluté.

A radical ion pair model, where spin motion of the two unpaired electrons under the hyperfine structure and Zeeman interaction is responsible for time variations of the total spin state, has been used to describe a variety of phenomena in organic solutions, *e.g.*, (*i*) chemically induced dynamic nuclear and electronic polarization (1, 2); (*ii*) geminate ion pair recombination in polar and nonpolar solvents (3–8); (*iii*) hyperfine structure modulation of dye-sensitized fluorescence in organic crystals (9, 10).

In the present work, we analyse the time resolved magnetic field dependence of ion recombination luminescence in organic solutions excited by high energy radiation (11). The method allows one to follow in detail the behavior of the ion pair singlet character, on the nanosecond time scale, so that new and direct information on the general ion pair model is obtained (8). Here, special attention will be given to the influence of the phase of the solvent as well as the nature and concentration of the solutes on coherent motion and relaxation of the radical pair spin in liquid and solid solutions.

Experimental Set-up and Conditions

The block-diagram of the set-up is shown in Fig. 1. The sample (S) to be studied is placed between the poles of an electromagnet (M), supplying magnetic fields up to 5000 G. The fields are measured by placing the Hall effect probe of a gaussmeter at the position of the sample. In order to obtain 'zero field', a small reverse current in the electromagnet is used to cancel the residual (hysteresis and earth magnetic field) so that values less than 0.2 G are obtained. The luminescence of the solutions can be excited by light flashes or high energy particles. A photomultiplier (PM) detects a major part of the light emitted by the sample, and acts as a monitor giving the reference time t_0. The second photomultiplier (PEU) works under single photon counting conditions: per light pulse, it delivers at most one electric signal, corresponding to the extraction at a time t ($t \geq t_0$) of a single photoelectron from the cathode; at any time t, the probability of extraction of this electron is proportional to the light intensity $I(t)$ at the cathode (12). The time-to-amplitude converter (TAC) yields signals with amplitudes proportional to $\Delta t = t - t_0$, which are finally analysed by the multichannel analyser (MCA); the resulting counts in the

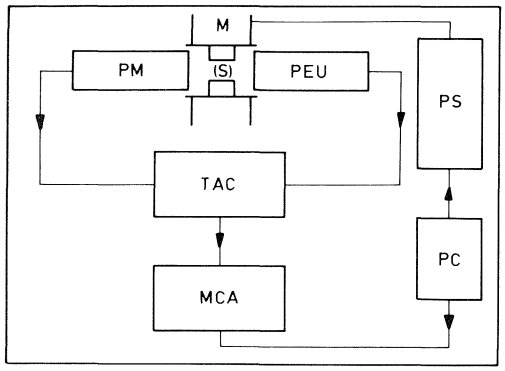

FIG. 1. Block-diagram of magnetic modulated time resolved luminescence measurement apparatus (S: sample; M: electromagnet and PS its power supply; PM and PEU: photomultipliers; TAC: time-to-amplitude converter; MCA: multichannel analyser; PC: periodic commutator).

memory of MCA are accumulated as long as necessary to get a histogram of Δt with a sufficient statistical precision.

To minimize eventual errors due to slow electronic jitter, the measurements with and without magnetic fields are performed successively, for a short time (10 s) by means of a periodic commutator (PC), switching alternatively on and off the magnetic power supply (MP) and the corresponding way-in of MCA; the results are stored in two separate parts of the MCA memory.

With this set-up, the luminescence intensity $I(t)$ can be followed between 0 and microseconds with a time resolution of 0.5 ns under very weak excitation intensity conditions. The results are similar to those previously published and discussed in detail (11).

In the present experiments, the luminescence is excited by β particles from a 0.1 μCi source of ^{90}Sr–^{90}Y plunged into the solutions. Samples are contained in cylindrical Pyrex cells and have been degassed by the usual freeze–pump–thaw technique. For the liquids, the solvents used are benzene, cyclohexane (Merck, "uvasol"), and methylcyclohexane (MCH) (Prolabo, "for spectroscopy"), with the following solutes which are used without special purification: *para*-terphenyl (*p*TP) (Progil), bis-2,5-(4-butylphenyl)-1,3,4-oxadiazole (2b PPD) (Ciba[1]), and 2,5-diphenyl-1,3-oxazole (PPO) (Nuclear Entreprise). The polystyrene solutions were prepared by thermal polymerization of styrene (Merck) purified by double distillation under vacuum. Solid glass solutions of MCH were obtained by freezing samples in liquid nitrogen in a dewar device having an optical tail which is placed in the magnetic field.

Results

If we denote respectively by $I^B(t)$ and $I^0(t)$ the luminescence intensities at time t measured in the presence and in the absence of an external magnetic field B, we can represent the relative field variation by the time dependent quantity $\Delta I/I = [I^B(t) - I^0(t)]/I^0(t)$. Figures 2*a* and 2*b* show the observed variations of $\Delta I/I$ with time, for various field strengths, in liquid cyclohexane solutions at room temperature (Fig. 2*a*) and solid MCH solutions at 77 K (Fig. 2*b*). Each of these two sets of curves may be taken as representative of the liquid and solid systems, since similar results were obtained in the other comparable cases.

We may first note that, on the time scale, each graph exhibits two regions where the magnetic field effect is different: the first time period, from 0 (maximum of the $I(t)$ curve) to about 30 ns, where the 'prompt' component radioluminescence is known to be dominant (11, 13); a second one, for times longer than 30 ns where only the 'delayed' component, due to ion recombination, is present (11).

In the case of the liquid solutions of 2b PPD in cyclohexane, the results of Fig. 2*a* suggest considering the time dependence of $\Delta I/I$ as the sum of a damped oscillatory term and a monotonic decreasing component. The former term exhibits an oscillation period of the order of 120 ns; but its observability strongly depends on the nature of the solute since no clear evidence for its occurrence could be found with other solutes like anthracene, *para*-terphenyl, and PPO (*cf.* Fig. 2*a*). On the other hand the second component was observed in all the liquid systems investigated: its decay is exponential with a rate constant k (s^{-1}) depending on the external field B and the solute concentration C_s as

$$[1] \qquad k = k' + k''(B, C_s)$$

where k' is constant, while k'' increases with C_s and decreases for increasing fields around $B \approx 10^2$ G. The results for the 2b PPD solutions in cyclohexane are represented in Fig. 3. In the case of the solid solutions, by contrast, no such variations could be observed on the time scale explored, where $\Delta I/I$ remained constant.

Discussion

We only consider the slow luminescence component arising from geminate recombination of solute ion pairs. Initially these pair states may be taken as prepared in a singlet spin state by high energy impact excitation. By recombination, these ion pairs produce fluorescing excited solutes

[1]2b PPD was kindly supplied by Ciba (Basel) as a specimen.

Time dependence of relative fluorescence intensity $\Delta I/I$ upon application of magnetic fields B for (*a*) 1.5×10^{-3} M solutions of 2b PPD and PPO in cyclohexane at room temperature and (*b*) 10^{-3} M solution of *p*TP in methylcyclohexane glass at 77 K; excited by β rays from a 0.1 μCi ^{90}Sr–^{90}Y source.

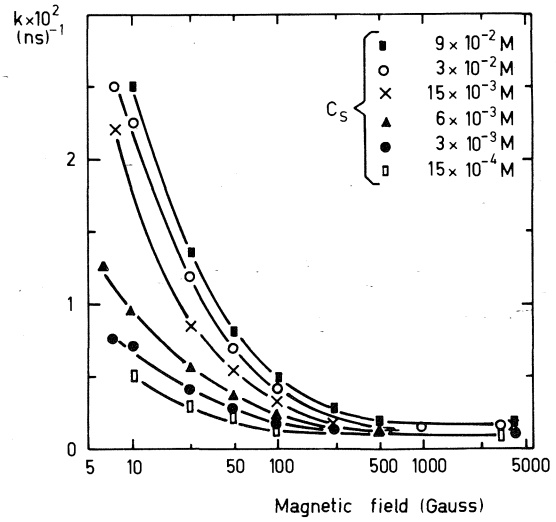

FIG. 3. Influence of the field strength B and the solute concentration C_s on the decay rate k of exponentially decreasing $\Delta I/I$ for 2b PPD solutions in cyclohexane at room temperature.

provided they are singlet at the neutralization time; recombination luminescence may thus be used to monitor the singlet character of the solute ion pair states between initial sudden preparation and final recombination. Denoting by $\rho_s(t)$ the probability of the correlated solute ion pair to be singlet at time t, one has

$$[2] \qquad \frac{\Delta I}{I} = \frac{\rho_s^B(t) - \rho_s^0(t)}{\rho_s^0(t)}$$

where $\rho_s^B(t)$ and $\rho_s^0(t)$ are the quantities in the presence and the absence of the magnetic field.

The time variations of $\rho_s^B(t)$ may be derived by taking for the unpaired electrons (1) and (2) a spin Hamiltonian involving a Zeeman and a hyperfine structure interaction term ($\hbar = 1$)

$$[3] \quad H = g\beta \boldsymbol{B}[\boldsymbol{S}(1) + \boldsymbol{S}(2)] + a(1)\boldsymbol{I}(1)\cdot\boldsymbol{S}(1) + a(2)\boldsymbol{I}(2)\cdot\boldsymbol{S}(2)$$

where $\boldsymbol{S}(i)$ and $\boldsymbol{I}(i)$ represent respectively the electronic and nuclear spins on the two radicals labelled $i = 1, 2$; $a(i)$ denotes the hyperfine isotropic coupling constant and β the Bohr magneton; nearly identical g values are assumed for the two ions. In order to define the representation in which the total spin $\boldsymbol{S} = \boldsymbol{S}(1) + \boldsymbol{S}(2)$ is diagonal, we split H into two terms which are symmetric and antisymmetric with respect to the interchange of the electronic spin indices on the two radicals:

$$[4] \quad H_0 = \left[g\beta \boldsymbol{B} + \tfrac{1}{2}\sum_i a(i)\boldsymbol{I}(i) \right][\boldsymbol{S}(1) + \boldsymbol{S}(2)]$$
$$H_1 = \tfrac{1}{2}[a(1)\boldsymbol{I}(1) - a(2)\boldsymbol{I}(2)][\boldsymbol{S}(1) - \boldsymbol{S}(2)]$$

The symmetric part H_0 defines the representation in which the total electronic spin $\boldsymbol{S}$ of the ion pair is diagonal. The basis eigenvectors are written as the direct products $|SM_s; n\rangle$ of electronic and nuclear spin eigenvectors: the former (SM_s) in-

clude the singlet S_0 and the triplet (T_0, T_{+1}, T_{-1}) eigenstates of $\boldsymbol{S}$; the nuclear spin states $|n\rangle$ are products of the eigenstates of $\boldsymbol{I}(1)$ and $\boldsymbol{I}(2)$: $|n\rangle = |I(1), M(1); I(2)M(2)\rangle$; their total number is $N = [2I(1) + 1][2I(2) + 1]$. The corresponding energy spectrum is (*cf.* Fig. 4)

$$E(S_0, n) = E(T_0, n) = 0$$

$$[5] \qquad E(T_\pm, n) = \pm \left[g\beta \boldsymbol{B} + \tfrac{1}{2} \sum_i a(i)M(i) \right]$$

The antisymmetric operator H_1 has only non-diagonal matrix elements, which couple the different $\boldsymbol{S}$ levels. For each nuclear $|n\rangle$ the two degenerate $|S_0 n\rangle$ and $|T_0 n\rangle$ states are hence submitted to resonance interaction, which gives rise to coherent oscillations between these $M = 0$ states (*cf.* Fig. 4), with a characteristic frequency

$$[6] \qquad \Omega_n = \langle T_0 n|H_1|S_0 n\rangle = \tfrac{1}{2}[a(1)M(1) - a(2)M(2)]$$

Damping is introduced by the spin-flip transitions between the ($M = 0$, n) states and the non-isoenergetic ($T_\pm$, $n \mp 1$) levels; these transitions are made possible by spin–lattice relaxation and are all assumed to have equal rate constants Γ.

Under these conditions the spin density matrix element $\langle S_0 n|\rho(t)|S_0 n\rangle$ representing the population of the $|S_0 n\rangle$ levels is given by (8)

$$\rho_s^{(n)}(t) = \langle S_0 n|\rho(t)|S_0 n\rangle$$

$$[7] \qquad \rho_s^{(n)}(t) = \frac{1}{2N} \cos(2\Omega_n t) \exp(-2\Gamma t) + \frac{1}{4N}[1 + \exp(-4\Gamma t)]$$

if one assumes that initially only the $|S_0 n\rangle$ states are formed with equal populations of the N possible nuclear states: $\rho_s^{(n)}(0) = N^{-1}$. From this, the quantity $\rho_s(t)$ which is the total population of the S_0 states, $\rho_s(t) = \sum_n \rho_s^{(n)}(t)$, is obtained as

$$[8] \qquad \rho_s^{B}(t) = \frac{1}{2N} \sum_n^N \cos(2\Omega_n t) \exp(-2\Gamma t) + \tfrac{1}{4}[1 + \exp(-4\Gamma t)]$$

The field dependence is due to the relaxation rates Γ which must be related to the experimental parameter k of [1]. For $B = 0$, this constant is maximum and equilibrium is attained after relaxation times ≤ 10 ns; under the present experimental conditions, we can hence take $\rho_s^0(t) = \frac{1}{4}$, so that one gets the expression

$$[9] \qquad \frac{\rho_s^B(t) - \rho_s^0(t)}{\rho_s^0(t)} = \frac{2}{N} \sum_n^N \cos(2\Omega_n t) \times \exp(-2\Gamma t) + \exp(-4\Gamma t)$$

which describes the principal features of the experimental data for $\Delta I/I$.

In Fig. 2*a*, the above-mentioned damped oscillatory part exhibited by the curves for the 2b PPD solutions is interpreted by the first term in expression [9]: a periodic behavior clearly appears, with a frequency of 8 MHz, which is indeed of the order of the isotropic hyperfine interaction in organic radicals (14) as expected from [6]. Periodicity requires that the various Ω_n values in [9] are multiples of a common frequency which implies following [6] that the hyperfine coupling constants $a(1)$ and $a(2)$ on the positive and negative ions are not too different. Also the spectrum of the sets of equivalent nuclei should be as simple as possible: this appears to be the case for 2b PPD where the two equivalent nitrogen nuclei form a single set which may be suspected to dominate hyperfine structure; in PPO, one of the nitrogen nuclei is replaced by a C—H group leading to a more complicated hyperfine structure spectrum, so that the time interference effects should be difficult to observe, in accord with the experiments (Fig. 2*a*).

The other monotonic decreasing component of $\Delta I/I$ in Fig. 2*a* is described by the second exponentially decaying term of expression [9]. The experimental quantities k of [1] are given by 4 Γ, with (8)

$$[1'] \qquad \Gamma = \Gamma' + \Gamma''(B, C_s)$$

i.e., two different contributions to spin–lattice relaxation. The first term Γ' is due to the rotational fluctuations of anisotropic magnetic interactions within the two radicals, and may be

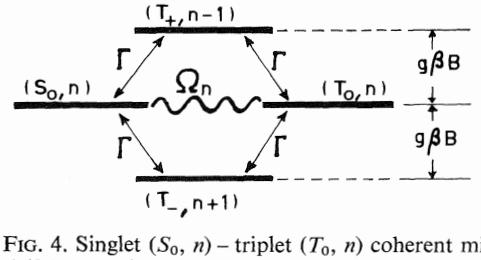

FIG. 4. Singlet (S_0, n) – triplet (T_0, n) coherent mixing and ($M_s = 0$, n) $\leftrightarrow$ ($M_s = \pm 1$, $n \mp 1$) states relaxation scheme for a radical ion pair in a magnetic field B (Ω_n frequency of the oscillations, Γ relaxation rate).

expected to be of the order of the $(T_1)^{-1}$ constants for the isolated radicals; indeed a value near 10^6 s^{-1}, in agreement with T_1 for organic radicals (15), is found in liquid solutions in the high field case (*cf.* Fig. 3). The second relaxation mechanism is attributed to time modulations of the isotropic hyperfine interactions by electron transfer from the radical ions to neutral solute molecules encountered during diffusion in the liquid (16). The field and solute concentration dependence of the corresponding rate constant Γ'' is justified with the help of the general expression (17, 18) $\Gamma'' = \alpha\langle\delta\omega\rangle^2 J(\Delta\omega)$, where $\langle\delta\omega\rangle$ is the interaction energy matrix element and $\Delta\omega$ the transition energy which according to [5] increases linearly with B; $J(\Delta\omega)$ represents the power spectrum of the fluctuating perturbation with correlation time τ_c: $J(\Delta\omega) = 2\tau_c/[1 + (\Delta\omega \cdot \tau_c)^2]$ decreases for increasing B in the 10^2 G range provided $\tau_c \approx 1$ ns, which is reasonable for intermolecular electron transfer (14). Finally α is the fraction of time during which the perturbation is operative: in terms of the mean times during (τ_1) and between (τ_2) the radical–neutral molecule encounters, α is of the form $\alpha = \tau_1/(\tau_1 + \tau_2)$ or, since τ_2 is proportional to ${C_s}^{-1}$, $\alpha = \tau_1\eta C_s/(1 + \tau_1\eta C_s)$ with $\tau_2 = (\eta C_s)^{-1}$, which shows that Γ'' increases with C_s. With data from Fig. 3 one can verify that $1/\Gamma''$ increases linearly with $1/C_s$ as predicted. In the solid solutions, no diffusion of radicals takes place so that only the field and concentration independent part Γ' may be important, which again agrees with experimental observations in Fig. 2*b*.[2]

As a concluding remark, we may note that the present experimental approach is particularly useful to focus attention on time development in spin subspace, independently from the kinetics of recombination luminescence itself, which has been considered elsewhere (11, 19).

Discussion

R. S. Dixon: I want to point out that, in his calculations of ρ_s, the probability of forming a singlet state, Brocklehurst predicted a coherent oscillation of the overall wavefunction between singlet and triplet, which might be seen in some simple systems. In our system, the large number of protons on M^+ and M^- would smear out the oscillation effect. We concluded that relaxation was unimportant because it occurred on a longer time scale (μs) than that over which we observed the field effect (ns). Your work implies that relaxation is important on a nanosecond time scale. Is this the case?

J. Klein: Yes that is the case, but only in liquid solutions where, besides the usual spin–lattice relaxation processes (T_1) you have an additional relaxation process which we attributed to diffusion controlled electron transfer between ions and neutral solute molecules.

Field-assisted photo-stimulated charge transfer across photoconductor–dielectric liquid interfaces

Field-assisted photo-stimulated charge transfer across a photoconductor–dielectric liquid interface has been studied by a high sensitivity signal averaging transient measurement technique. The effects of both the temperature and electric field (below 2×10^5 V/cm) have been investigated. Experimental results were analyzed using an interface model developed earlier to describe the charge transfer kinetics. We have found evidence of direct and indirect transfer of charge across the interface and we have identified the controlling parameters for the desorption rate of charge carriers from the interface into the fluid.

On a étudié le transfert de charge photostimulé et assisté par le champ à travers l'interface entre un photoconducteur et une liquide diélectrique en faisant appel à une technique de grande sensibilité mesurant les phénomènes transitoires par une methode qui établit la moyenne des signaux. On a étudié les effets de la température ainsi que du champ électrique (en bas de 2×10^5 V/cm). On a analysé les résultats expérimentaux en faisant appel à un modèle d'interface qui a été développé antérieurement pour décrire la cinétique de transfert de charge. On a trouvé des preuves de transferts de charges directs et indirects à travers l'interface et on a identifié des paramètres qui contrôlent la vitesse de désorption des transporteurs de charges allant de l'interface vers le fluide.

[Traduit par le journal]

Introduction

The phenomenon of photo-assisted charge transfer across a photoconductor–dielectric liquid interface has been studied in this experiment. Evidence of charge transfer from a photoconductor into nonpurified dielectric liquids has been reported earlier (1) for high electric fields, and a phenomenological model was developed to describe this process. The experimentally observed transient current pulse was found to depend primarily on two important parameters; the release rate of charge from surface traps on the photoconductor into the lowest vacant state of a neutral impurity molecule adsorbed on the surface, and the desorption rate of the ions from the interface into the liquid. The electric field dependence of the two rates was examined previously for the range 2×10^5 to 10^6 V/cm. Here we investigated the validity of the charge-transfer model further by measuring the thermal activation energies of the rates, and by extending the measurements to lower electric fields (10^4–10^5 V/cm).

Experimental Approach and Charge Transfer Model

We used a typical capacitor cell arrangement for our experiment. The electrodes were SnO_2 coated glass, overcoated with a thin film of SiO (thickness 1000 Å) to prevent charge injection directly from the electrodes. Metal-free phthalocyanine was vacuum deposited (thickness 1300 Å) onto one of the SiO coated electrodes. The photoconductor was separated from the other electrode by a Teflon spacer, forming a cell which was filled with practical grade decane. The liquid was obtained directly from the supplier's container and was not further purified. The thickness of the liquid was 120 μm and the electrode area was 1 cm^2.

A Xenon flash lamp (3 μs duration), in conjunction with a band-pass filter (400–800 nm), was used to illuminate the cell. The photogenerated current pulse moved through the photoconductor layer in about 10^{-9} s (2), which was shorter than the response time of our instruments (2 μs). The charge then transferred into the liquid. The current in the liquid increased as the charge carriers desorbed from the photoconductor surface, and decreased as carriers began arriving at the other electrode. The peak of the current trace, shown in Fig. 1, corresponds to the average transient time τ for carriers to move through the liquid. A typical

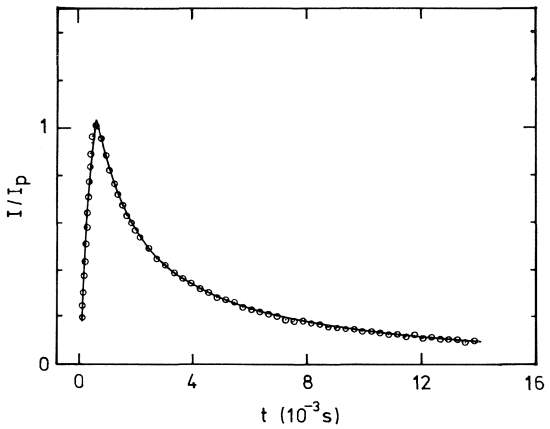

FIG. 1. The least squares fit (solid line) of the single surface trap interface model to a typical transient current pulse (circles) for negative charge transfer from phthalocyanine into decane. The current is normalized by the peak current I_p at $t = \tau$.

value of τ was 10^{-3} s. In terms of the drift mobility μ of the charge carrier, we have

$$[1] \qquad \tau = d/\mu E$$

where d is the fluid thickness and E is the electric field in the liquid. The magnitude of the carrier mobility as determined from [1] was of the order of 10^{-4} cm^2 V^{-1} s^{-1}, indicating that the carriers were ions (3).

As mentioned earlier, we restricted ourselves to the low field region between 4×10^4 and 2×10^5 V/cm. The signal in this field range was always below the noise level and the conventional single transient measurement technique was found to be inadequate for this case. We circumvented this problem by using a signal averaging technique. Each of our data points represents the average of a few hundred to a few thousand current traces taken at the same temperature and field. By using this technique, the signal-to-noise ratio is improved by a factor $\sqrt{n}$, where n is the number of current traces averaged. As a check, the average transit time obtained by this technique was plotted as a function of $1/E$, and good agreement with [1] was found.

The temperature in the cell was monitored by a micro-temperature sensor embedded in the dielectric liquid. The temperature was varied from 0 to 100°C and was stabilized to better than ± 1°C. At 100°C the sublimed phthalocyanine started to separate from the glass substrate, and the data points obtained at this temperature have only a qualitative significance.

According to the phenomenological model, the transfer of charge from the photoconductor into the liquid requires the presence of an unoccupied state whose energy (relative to the vacuum level) lies below the conduction band energy of the photoconductor. This state can be conveniently supplied by the lowest vacant state of an impurity molecule adsorbed on the photoconductor surface. Direct transfer into the liquid is unlikely because the energy level of the extended electronic state is a fraction of a volt (4), and is well above the conduction band energy of the photoconductor (3.2 eV). As shown in Fig. 2, charge in the photoconductor can either transfer to a neutral molecule directly or via surface traps at a release rate r_2. In the process of desorbing from the photoconductor, the ionized impurity molecule must overcome the potential barrier resulting from the image potential and the applied electric field in the liquid, *i.e.*

$$[2] \quad U(x) = -\frac{\alpha e}{x} - eEx \qquad \text{for } x \geq a$$

where a has the dimension of the ion radius, e is the electronic charge, and $\alpha = (3/16\pi\varepsilon_f)(\varepsilon_p - \varepsilon_f)/(\varepsilon_p + \varepsilon_f)$, where ε_p and ε_f are the dielectric constants of the photoconductor and fluid, respectively. The position and magnitude of the potential barrier can be evaluated from [2] for different fields.

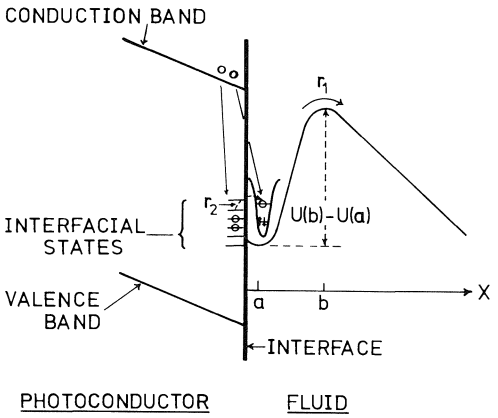

FIG. 2. Schematic of the kinetics of charge transfer from the photoconductor into the fluid. Energy levels of electrons are shown to the left of the interface and the potential well of the ionized impurity molecule in the fluid is shown to the right of the interface. r_1 is the desorption rate of ions from the interface into the liquid and r_2 is the release rate of charge from surface traps into the lowest unoccupied energy level of the molecule adsorbed onto the photoconductor surface.

The expression for the transient current pulse in the liquid has been shown to have the following form (1),

$$[3]\quad I(t) = \begin{cases} i(t) & t < \tau \\ i(t) - i(t-\tau) & t > \tau \end{cases}$$

where

$$[4]\quad i(t) = A[1 - \exp(-r_1 t)] + B[1 - \exp(-r_2 t)] + \frac{Br_2}{r_1 - r_2} \times [\exp(-r_1 t) - \exp(-r_2 t)]$$

Expressions for the constants A and B are given in ref. 1, and are not used in the present investigation. The desorption rate of carriers into the fluid is r_1, and r_2 is the release rate from surface traps. The functional dependence of r_1 on electric field and temperature is given by (1),

$$[5]\quad r_1 = CE^{3/4} \exp(-U_t/k_B T)$$

where C is a constant, k_B is Boltzmann's constant, and the total activation energy U_t consists of two parts; the potential barrier height $U(b) - U(a)$ (where $x = b$ corresponds to the potential maximum) and the ion mobility activation energy U_μ, *i.e.*,

$$[6]\quad U_t = U(b) - U(a) + U_\mu$$

The $E^{3/4}$ part of the prefactor in [5] arises from the change in the curvature at the maximum of the potential barrier as the field is varied.

The temperature and field dependence of the trap release rate r_2 have not been calculated because of lack of information about the physical nature of the surface traps.

Results and Discussion

The charge transfer model was checked by measuring the transient current as a function of the electric field and temperature, and comparing with [3]. The measured current traces were fitted to [3] by a nonlinear least squares computer routine. As mentioned earlier, each current trace used for comparison with the theory represented an average of many traces taken under identical conditions of electric field and temperature. Thus, the relative error of the data points depends primarily on the number of traces used for averaging, and is typically below 5% for most of our traces. The uncertainty in the temperature is less than $\pm 0.5\%$, and the uncertainty in the value of the electric field is $\pm 2\%$. Figure 1 shows an averaged current trace and the computer fit to [3]. It is evident that [3] describes the shape of the current pulse quite well.

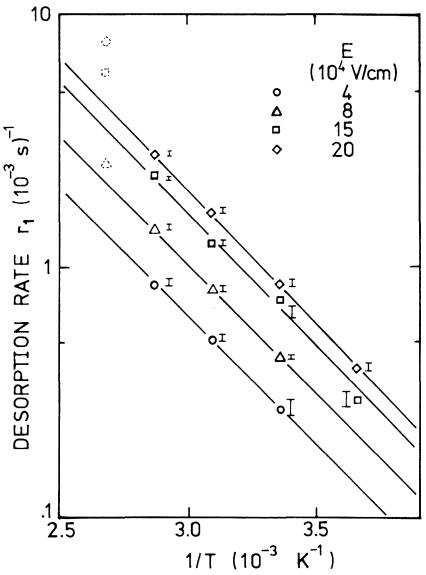

FIG. 3. Temperature dependence of the desorption rate r_1 for four different fields. The slopes at each field are almost identical and give a total activation energy of 0.21 ± 0.01 eV. Data points at 100°C are not very reliable because the photoconductor had partially separated from the substrate.

In Fig. 3 the logarithm of the desorption rate r_1 is plotted as an inverse function of temperature for four different electric fields. It should be noted that all data points for the same field lie on a straight line and the lines for the different fields are nearly parallel to one another. This implies that the desorption process of charge carriers is thermally activated, as described by the Boltzmann factor in [5], and the activation energy U_t is not very sensitive to the electric field for the low field range. The rate r_1 is shown in Fig. 4 as a function of the electric field. The data points for the different temperatures all follow the power law $E^{3/4}$ which is shown by the solid lines. This again indicates that the contribution to the field dependence of r_1 from the exponent in [5] is negligible. The experimental value of U_t, as deduced from the slope of the straight lines in Fig. 3, is 0.21 ± 0.01 eV. U_μ can be obtained from the temperature dependence of the charge carrier mobility, shown in Fig. 5. The slope of this line gives an activation energy of 0.17 ± 0.01 eV. The potential barrier height, $U(b) - U(a)$, is thus determined to be 0.04 ± 0.02 eV, with no measured field depen-

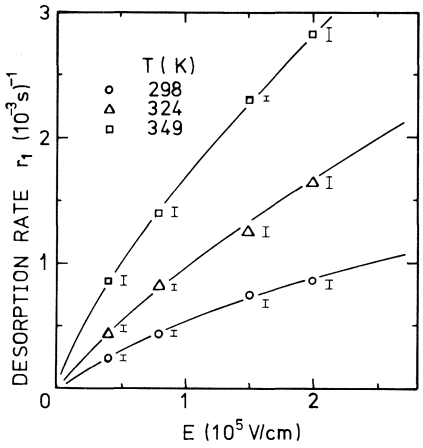

FIG. 4. Electric field dependence of the desorption rate r_1 for three different temperatures. The solid line is a fit to the theoretical expression given by [5].

dence. The value of $U(b)$ estimated from [2] for $E = 2 \times 10^5$ V/cm is about -0.02 eV, which cannot be resolved in our experiment. The barrier height is probably dominated by the ion binding energy at the interface, $U(a)$.

The trap release rate r_2 is plotted as an inverse function of temperature in Fig. 6. As one would expect, the detrapping of charge increases with increasing temperature. Unfortunately, the data for r_2 cannot distinguish whether the charge is released from surface traps or from bulk traps

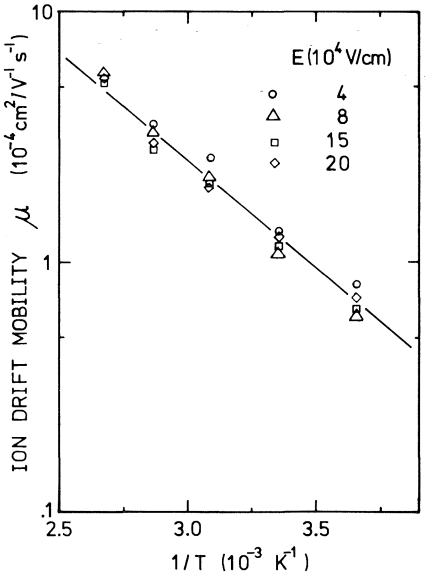

FIG. 5. Temperature dependence of ion mobility for four different fields. The mobility activation energy obtained from the slope is 0.17 ± 0.01 eV.

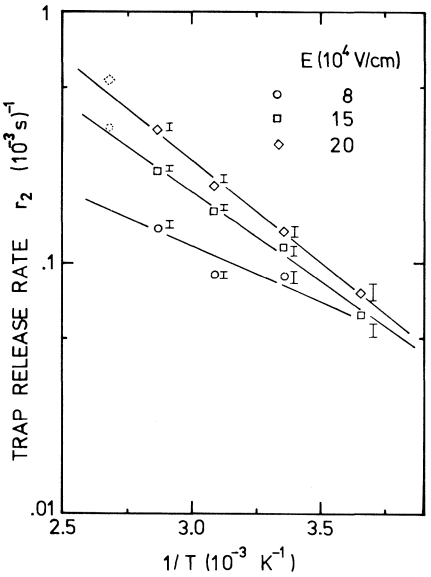

FIG. 6. Temperature dependence of the trap release rate r_2 for three different electric fields.

near the surface. However, we have observed that the charge transfer from different phthalocyanine thin films gives different values of r_2 for identical values of temperature and field. The reason for this variation could be that slightly different film evaporation conditions may result in different surface morphology and different surface states. A more precise control on the vacuum deposition conditions is required to study this effect. For consistency, all measurements presented here were performed on one sample. The field dependence of r_2 shown in Fig. 6 cannot be interpreted at this time because of insufficient knowledge about the physical nature of the traps.

Finally, the effective radius of the charge carrier, a, was determined by two different methods. The value calculated from [2], using the value of $U(a)$ estimated earlier from the activation energy of r_1, is $a \simeq 8$ Å. The corresponding value from Stokes' law, $\mu = e/6\pi\eta a$, where μ is obtained from the transit time data and $\eta = 0.88$ cp for decane at 25°C is $a \simeq 7.4$ Å. The agreement between these two methods of determining a indicates that the small value of the binding energy at the interface is indeed due to the large effective radius of the charge carrier.

In conclusion, we summarize our findings as follows: the phenomenological model proposed earlier (1) gives a good description of the transfer

of photogenerated charge from a photoconductor into a dielectric fluid under an applied electric field. The charge carriers in the fluid are ions, as indicated by the small value of the observed mobility, and charge transfer requires the presence of an impurity molecule with its lowest vacant energy level lower than the conduction band energy of the photoconductor. Both the desorption r_1 of ions from the interface and the release rate r_2 from surface traps are thermally activated. The rate r_1 has a power law field dependence which arises from the effect of the applied field on the curvature of the image potential barrier near its maximum. The variation of the height of the potential barrier with field is very small and is not observed for the low field range investigated. The origin of the field dependence of r_2 is not understood at present. An investigation of the effect of various impurity molecules on the charge transfer is presently in progress.

Discussion

A. C. Albrecht: We very much appreciate the nice analysis you have presented for the transfer of charge at a semiconductor–fluid interface. We have studied this very system with chlorophyll acting as the semiconducting film and see both the fast and the slow signal. Your model should be very useful in analyzing these results too. An interesting qualitative effect we have seen is that as we add chlorophyll monomer to the fluid phase the slow signal is greatly enhanced. Chlorophyll seems to mediate the discharge at the interface. The actual charge carrier in the fluid phase, though, is very likely a smaller molecule according to mobility estimates.

J. Noolandi: We would be very interested in applying the analysis to your experiment.

Electron reactivity as a function of phase

A. HENGLEIN

Received September 27, 1976

A. HENGLEIN. Can. J. Chem. **55**, 2112 (1977).

Reactions of free electrons in the gas phase, of quasi-free electrons and solvated electrons in dielectric liquids, of hydrated electrons in water, and of electrons originating from an electrode in contact with a solution are among the great variety of electronic processes in chemistry. It is the purpose of this paper to describe a few phase effects. Reactions of electrons in dielectric liquids will be discussed with respect to the corresponding processes in the gas phase. Furthermore, certain aspects in the transfer of an electron from a hydrocarbon phase into the aqueous phase will be dealt with. The processes will be described in terms of electronic redox level distributions of the acceptor redox systems.

A. HENGLEIN. Can. J. Chem. **55**, 2112 (1977).

Les réactions d'électrons libres en phase gazeuse, d'électrons pratiquement libres et d'électrons solvatés dans des liquides diélectriques, d'électrons hydratés dans l'eau et d'électrons ayant leur origine dans une électrode en contact avec une solution sont parmi la grande variété des processus électroniques de la chimie. Le but de ce travail est de décrire quelques effets de phases: on discutera des réactions des électrons dans des liquides diélectriques par rapport aux processus correspondants en phase gazeuse. De plus on examinera certains aspects du transfert d'un électron d'une phase hydrocarbonée à une phase aqueuse. On décrira les processus en termes des distributions des niveaux redox-électroniques des systèmes redox-accepteurs.

I. Abnormal Kinetic Phenomena in the Reactions of Electrons in Dielectric Liquids

Excess electrons in dielectric liquids are very mobile and often react with dissolved substances with rate constants as high as 10^{12} to 10^{15} M^{-1} s^{-1}. However, unlike normal fast reactions their rate constants often do not bear a simple relationship to the diffusion characteristics of the reactants. This may be recognized from Figs. 1 and 2 which show the dependence of the bimolecular rate constant k on various variables such as the energy V_0 (energy of the delocalized electron in a solvent with respect to an electron in the gas phase), the nature of the acceptor molecule, the electron mobility, and the strength of a strong electric field across the solution.

Figure 1 shows how k varies with V_0 if the reaction of an acceptor molecule is studied in different solvents. V_0 is known to span the range from -0.6 to $+0.1$ eV for most of the dielectric liquids at room temperature. The mobility μ of the excess electron varies over several orders of magnitude in these solvents as can be seen from the upper abscissa in Fig. 1. In *n*-hexane which has a high V_0 value all acceptor molecules with the exception of molecular oxygen react with rate constants of the order of 10^{12} M^{-1} s^{-1}. For oxygen k is only 9.1×10^{10} M^{-1} s^{-1} at room temperature. In tetramethylsilane which has a low V_0 value some acceptors such as sulphur hexafluoride and carbon tetrachloride react extremely rapidly ($k \sim 10^{14}$ M^{-1} s^{-1}) while others such as nitrous oxide and ethyl bromide react even slower than in *n*-hexane. The two latter acceptors react fastest in solvents of intermediate V_0. Oxygen is a relatively poor acceptor in all these solvents (1)[1].

The activation energy of reaction has also been determined from the temperature dependence of the rate constant in various solvents. In *n*-hexane, many acceptors react with a positive activation energy (3). It amounts to 3.49 kcal mol^{-1} in the case of good acceptors, a value close to the activation energy of the mobility of the electron in *n*-hexane (4.30 kcal mol^{-1}). The reaction $e^- + O_2 \rightarrow O_2^-$, however, has a smaller activation energy of 2.29 kcal mol^{-1}, although this reaction is slower than those of the other acceptor molecules. In the case of the solvent 2,2,4-trimethylpentane, the activation energy can be positive (SF_6), almost zero (N_2O), or even switch from a positive value at low temperatures to a negative one at higher temperatures (C_2H_5Br) (1). In the case of tetramethylsilane, the reactions of N_2O and ethyl bromide occur

with small negative activation energies, the reactions of oxygen and carbon tetrachloride with small positive activation energies (1). Figure 2 shows the dependence of the rate constant for various acceptors in liquid xenon as a function of the strength of a superimposed electric field. The mean kinetic energy with which excess electrons move under the influence of the electric field is given at the top of the figure. While the rate constant decreases for SF_6 and O_2 with increasing electron energy, that for N_2O goes through a maximum at about 0.6 eV of the mean kinetic energy (4).

II. Concepts from Ordinary Reaction Kinetics

The effects described above can be qualitatively explained by combining the concepts of ordinary reaction kinetics with data from electron impact on gas molecules and with concepts from the theories of electron transfer (7). A normal chemical reaction is said to be diffusion-controlled if the encounter time τ_e during which the two reactants are kept close together in the cage of the surrounding solvent molecules is longer than the time τ_r required for the reaction to occur after the reactants had come into this close contact. The bimolecular rate constant is given by the expression

$$[1] \quad k_d = \frac{4\pi N \Delta R}{10^3} M^{-1}\,s^{-1} \quad \text{for } \tau_e \gg \tau_r$$

where Δ is the total diffusion coefficient, R the collision diameter of the reactants, and $N = 6.02 \times 10^{23}$; τ_r may be expressed in terms of a frequency factor γ_r and a chemical activation energy E_r:

$$[2] \quad \tau_r = \frac{\exp(E_r/kT)}{\gamma_r}$$

τ_e may be written as

$$[3] \quad \tau_e \sim \tfrac{1}{2} R^2/\Delta$$

The activation energy of a diffusion-controlled reaction is given by that of the diffusion coefficient Δ.

On the other hand, if $\tau_e < \tau_r$, the probability p of the reaction per encounter is lower than unity and the bimolecular rate constant may now be expressed as

$$[4] \qquad k = k_d p$$

Putting p equal to τ_e/τ_r (for $\tau_e \ll \tau_r$) one obtains from [1], [2], and [4]

$$[5] \qquad k \propto \gamma_r \exp(-E_r/kT)$$

The measured activation energy of the reaction is now equal to the chemical activation energy E_r and the rate constant is independent of the rate of diffusion. In the case of the reaction of an electron, the movement of the acceptor molecule may be neglected and Δ is practically equal to the diffusion coefficient Δ_{el} of the electron

$$[6] \qquad \Delta_{el} = \mu kT/e$$

where μ is its mobility and e the amount of its charge. If the expression

$$[7] \qquad \mu = \mu_0 \exp(-E_\mu/kT)$$

describes the temperature dependence of the mobility of the electron, the rate constant of a diffusion-controlled reaction should be proportional to $T \exp(-E_\mu/kT)$. The measured activation energy of a diffusion-controlled reaction should therefore be slightly higher than E_μ, provided that R is not dependent on the temperature. The interaction radius R may be as large as the de Broglie wavelength λ of the electron. In a strong electric field the mean velocity $\bar{v}$ of the electron increases with field strength F and the interaction radius R may be expected to decrease. In liquid xenon, for example, $\bar{v}$ is proportional to $F^{0.32}$ and R should be proportional to $F^{-0.32}$ (5).

The time which an electron spends close to an acceptor molecule will become shorter with increasing mobility of the electron. We may thus talk in terms of an encounter time τ_e for reactions of electrons, although this concept which is based on a random-walk type of motion is very approximate for solvents of high electron mobility. Recent measurements of the rate constants for electron capture by sulphur hexafluoride in liquid rare gases indicate that R is close to $\lambda = \hbar/m\bar{v}$ (5, 6). The diffusion coefficient of the electron at room temperature amounts to 2.3×10^{-3} cm^2 s^{-1} in *n*-hexane and 2.3 cm^2 s^{-1} in tetramethylsilane. If R is of the order of 10^{-7} cm, the respective encounter times of [3] are of the order of 10^{-10} s (*n*-hexane), and 10^{-13} s (TMS). The rate constant k_d for diffusion-controlled processes in these solvents is of the order of 10^{12} M^{-1} s^{-1} (*n*-hexane) and 10^{15} M^{-1} s^{-1} (TMS) as calculated from [1]. The highest k values which have been measured in these solvents are indeed of this magnitude and the activation energies for such rapid reactions agree fairly well with those for the electron mobility (1, 3). τ_r is regarded as the time required for the acceptor molecule to reach a certain atomic configuration (including the solvation shell) at which the electron can be accepted.[2] In molecular photochemistry, Franck–Condon transitions to a higher electronic state of a molecule are associated with various transition energies depending on the actual interatomic distances in the molecule at the moment of light absorption. Similarly, the capture of an electron by a molecule can occur with a distribution of transition energies.

III. Concepts from Electron Impact in the Gas Phase and Electron Transfer Theories

Electron transfer reactions generally have a free energy of activation which is not zero even if the free energy of the reaction is negative. The activation of the reacting system has to occur in order to bring the reactants into the appropriate molecular configuration (including the solvation shells of the reactants). In this configuration, the energy of the system before the electron jumps is equal to that after the jump and the products are finally deactivated to their states of lowest energy. The theories of Marcus (8) and Levich (9) describe the properties of the activated states in electron transfer reactions in solution. We shall make use of the simpler treatment of Gurney (10) and Gerischer (11) in which the distributions of the electronic redox levels of the two redox systems involved in a transfer reaction are compared with each other. Although this treatment does not describe electron transfer reactions in the most exact manner, it readily leads to a semiquantitative explanation of the observed reaction rates. The density of states functions of the activated complexes are simply

[2]Since τ_r can hardly be shorter than 10^{-13} s, *i.e.* the encounter time in tetramethylsilane, the above-mentioned k_d value of 10^{15} M^{-1} s^{-1} for this solvent represents a general upper limit for the rate constant of reaction of e^- in solution (at room temperature).

substituted by those of the separated reactants (*i.e.* extremely weak interaction is assumed) and electron transfer is postulated to occur only from occupied electronic redox levels of the donor system to unoccupied ones of the acceptor system of equal energy. Such transitions are represented by vertical transitions between the potential curves of the systems $A + e^-$ and A^-.

Vertical transitions in reactions of electrons in dielectric liquids with solutes have been postulated in earlier papers (1, 7, 12). It is an intriguing feature of such considerations that reactions of electrons with molecules in the gas phase, where the kinetic energy of the electrons can be varied, may be compared with the reactions in dielectric solvents, where the total energy of the electrons can be varied by choosing solvents of different energy V_0 or by heating up the electrons in an electric field.

The energy of the electron in a liquid is characterized by the energy V_0 if the reaction of a delocalized electron is to be considered. We shall assume in the following treatment that the electron is in the V_0 level at the moment of reaction. This assumption is probably fulfilled in the case of liquids of high electron mobility where the electron spends most of its time in the delocalized state. It should, however, not be excluded that trapped electrons may also be able to react with a solute molecule before they are thermally released into the V_0 level. This may occur in liquids of low mobility in which the electron spends most of its time in the trap and where its optical absorption has even been observed (13, 14). Reactions of a localized electron may occur via tunneling to the acceptor molecule. The energy levels which are occupied by localized electrons lie below the level V_0. Trap depths of the order of 0.4–0.5 eV have recently been reported (15).

As the energy V_0 refers to that of an electron in the gas phase, one has to choose the same reference point for the energy ε with which the electron is bound in the acceptor molecule. ε is the energy which is liberated in the theoretical process $e^-(g) + A(s) \rightarrow A^-(s)$ where $e^-(g)$ is an electron in the gas phase and A(s) the acceptor molecule in solution. This energy liberated must be equal to V_0, if the reaction $e^-(s) + A(s) \rightarrow A^-(s)$ of an electron $e^-(s)$ in solution occurs as a vertical transition. Let us study the following cycle of processes in which all species are meant to be in their lowest state of internal energy:

$$[8] \qquad A(s) \rightarrow A(g) \quad -\Delta H_s(A)$$

$$[9] \qquad e^-(g) + A(g) \rightarrow A^-(g) \quad -EA(A)$$

$$[10] \qquad A^-(g) \rightarrow A^-(s) \quad \Delta H_s(A^-)$$

$$[11] \qquad e^-(g) + A(s) \rightarrow A^-(s)$$

$$\varepsilon_0 = -EA(A) + \Delta H_s(A^-) - \Delta H_s(A)$$

ΔH_s denotes the energy of solvation and EA the gas phase electron affinity. ε_0 is the energy liberated if all species are in thermodynamic equilibrium with their surroundings. $\varepsilon_0 - V_0$ is the energy of reaction ΔH_r of an electron in the V_0 level with an acceptor in solution.

In a vertical transition $e^-(g) + A(s) \rightarrow A^-(s)$, however, the anion $A^-(s)$ is generally not formed in its lowest state of internal energy but with a certain amount of excess energy. This excess energy has a distribution and consequently the transition energy ε has a distribution too. It will peak at some energy above ε_0. This distribution of transition energies may be called the density of unoccupied electronic levels $D_{unocc}(\varepsilon)$ of the redox system $A(s)/A^-(s)$.

The spontaneous ejection of an electron from the anion A^- into the V_0 level of the liquid may now be considered. If the electron is not to change its energy during the process, the energy for removal of the electron into the gas phase according to the theoretical process

$$[12] \qquad A^-(s) \rightarrow A(s) + e^-(g)$$

must be equal to $-V_0$. The energy for removal of the electron is equal to $-\varepsilon_0$ (eq. 11), if all particles are considered in their lowest states of internal energy (including their solvation shells), *i.e.* if the process occurs adiabatically. However, in a vertical transition, the product A(s) will generally be formed with excess energy. The energy for the removal of the electron into the gas phase will thus be larger than $-\varepsilon_0$. We may expect a distribution of energies for removal of the electron. The corresponding energies ε characterize the occupied electronic levels of the redox system $A(s)/A^-(s)$ and their distribution function may be designated $D_{occ}(\varepsilon)$. It will peak below ε_0.

The energies where the maxima of the functions D_{unocc} and D_{occ} are located differ more from ε_0 the more the atomic structures of A and A^- and their solvation shells differ from each other. In nonpolar solvents, solvation is mainly

due to electronic polarization of solvent molecules which is little dependent on their orientation. The width of the distribution functions will therefore mainly be determined by the changes in the equilibrium distances of the atoms in A and A^-.

Our model is the most simple-minded one: the solvent is regarded as a homogeneous dielectric medium. All processes are excluded in which part of the energy of reaction is channeled into internal degrees of freedom of the solvent. Furthermore, the effect of nuclear tunneling discussed in the theory of electron transfer (8) is disregarded. These processes, however, may play an important role in slow reactions of electrons, *i.e.* in reactions where the density of unoccupied levels of the acceptor system at the energy V_0 is low.

IV. Simple Acceptor Molecules

Potential functions of simple acceptor molecules such as N_2O, C_2H_5Br, CCl_4, and O_2 have been published in the literature (16–19). They are shown in the diagrams of Fig. 3. Consider diagram (*b*) for carbon tetrachloride: The curve for the system $CCl_4(s) + e^-(g)$ was obtained by shifting that for the system $CCl_4(g) + e^-(g)$ by the small amount of the solvation energy of carbon tetrachloride. Similarly, the curve for $CCl_4^-(g)$ was shifted downwards by the larger amount of the solvation energy of the anion to obtain the curve for $CCl_4^-(s)$. The upward pointing arrow indicates the most probable transition $e^-(g) + CCl_4(g) \rightarrow CCl_4^-(g)$ which requires an electron energy of 0.3 eV. Transitions with smaller and much higher energies are also possible in the Franck–Condon range. CCl_4^- immediately dissociates to form Cl^- whose ionization efficiency curve (cross section *vs.* electron energy) determined by mass spectrometry gives information about the spectrum of transition energies in the gas phase. The downward pointing arrow in Fig. 3*b* indicates the most probable transition of the theoretical process $e^-(g) + CCl_4(s) \rightarrow CCl_4^-(s)$. The energy ε of this transition differs from that of the corresponding gas phase process by $\Delta H_s(A^-) - \Delta H_s(A)$, provided that the anion is formed in its solvation state of lowest energy. In a vertical transition, this condition will generally not be fulfilled since the anion will be formed with the structure of the solvation shell of the neutral molecule. As mentioned before, this effect will

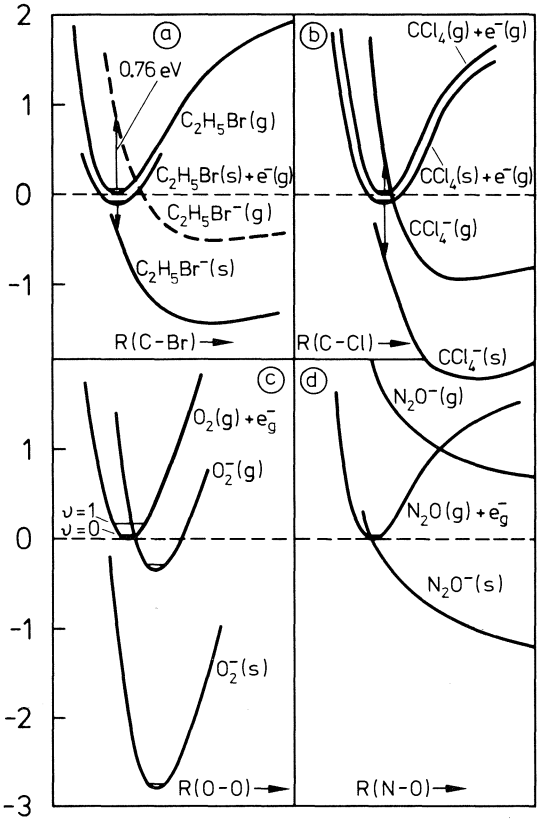

FIG. 3. Potential curves of various redox systems in the gas and liquid phase: (*a*) Christophorou *et al.* (16); (*b*, *d*) Wentworth *et al.* (17, 18); (*c*) Schultz (19).

not be too pronounced in dielectric liquids. We take this effect into account by adding only $0.8[\Delta H_s(A^-) - \Delta H_s(A)]$ to the transition energy in the gas phase to obtain that of the process $A(s) + e^-(g) \rightarrow A^-(s)$.

The problem lies in the calculation of the difference $\Delta H_s(A^-) - \Delta H_s(A)$. The free energy for charging a sphere of radius r with the elementary charge e in a medium of dielectric constant ϑ is (20)

$$[13] \qquad \Delta G_p = -\frac{e^2}{2r}\left(1 - \frac{1}{\vartheta}\right)$$

The free energy of solvation of an anion of radius r is then $\Delta G_p + \Delta G_s(A)$ where $\Delta G_s(A)$ is the free energy of solvation of the neutral molecule (21). The energy of polarization is

$$[14] \qquad \Delta H_p = -\frac{e^2}{2r}\left(1 - \frac{1}{\vartheta} - \frac{T}{\vartheta^2}\frac{d\vartheta}{dT}\right)$$

and the energy of solvation of an anion is

$\Delta H_p + \Delta H_s(A)$. The above-mentioned difference $\Delta H_s(A^-) - \Delta H_s(A)$ is therefore equal to ΔH_p.[3]

Since $d\vartheta/dT < 0$, $\Delta H_p < \Delta G_p$. ϑ has practically the same value for the various dielectric liquids, *i.e.* ΔG_p or ΔH_p can be regarded as independent of the nature of the solvent. The effective radius r is often calculated from the molar volume of the neutral molecule in its condensed state:

$$[15] \qquad \tfrac{4}{3}\pi r^3 = \frac{1}{N}\frac{M}{d}$$

where M = molecular weight, d = density of A (see, for example, ref. 23). This procedure yields reliable values of ΔG_p for large molecules. In the case of small molecules or molecules in which the charge is not uniformly distributed, too small amounts of the solvation energy are obtained. One must make a plausible estimate of r in these cases. The charge in the anion N_2O^-, for example, is strongly localized at the oxygen atom. The radius r calculated from the molar volume of liquid N_2O is certainly an upper limit, while a radius equal to half the sum of the NN and NO distances in this molecule can be taken as a lower limit.

The largest cross section for electron capture by ethyl bromide is observed at an electron energy of 0.76 eV in the gas phase. $0.8\Delta H_p$ is calculated as -1.06 eV for the anion. The energy of the electron in the most probable transition $e^-(g) + C_2H_5Br(s) \rightarrow C_2H_5Br^-(s)$ is obtained as $0.76 - 1.06 = -0.3$ eV. The function D_{unocc} drawn in Fig. 4 therefore peaks at $\varepsilon = -0.3$ eV. The shape of the curve roughly corresponds to that of the ionization efficiency curve of Br^- found in the gas phase reaction. The half width was broadened by 0.2 eV to account for the various reorganization energies of the solvation shell.

Similar functions are shown in Fig. 4 for the other systems in Fig. 3. Carbon tetrachloride is expected to have the highest density of unoccupied redox levels at $\varepsilon = -0.7$ eV. In the system $O_2(s)/O_2^-(s)$, the most probable transition energy is expected to be very negative, *i.e.* about -1.8 eV. This is due to the rather large value of the solvation energy of this small molecule. The energy ε_0 is calculated as about -2.8 eV.

[3]In earlier calculations of various authors (7, 22), small errors were introduced by regarding ΔG_p as equal to $\Delta G_s(A^-)$, and ΔH_p as equal to $\Delta H_s(A^-)$.

The system $N_2O(s)/N_2O^-(s)$ is characterized by a most probable transition energy of 2.2 eV in the gas phase. However, as mentioned before, the value of $0.8\Delta H_p$ is rather large in this case because of the concentration of the charge on the small oxygen atom. One can expect the function $D_{unocc}(\varepsilon)$ to peak at an ε value close to zero.

Figure 4 also shows the energies V_0 of the excess electron in various liquid hydrocarbons and in tetramethylsilane. The reaction of an electron–acceptor encounter pair will be fast, if the density of unoccupied electronic levels of the system $A(s)/A^-(s)$ is high at $\varepsilon = V_0$. With decreasing temperature, V_0 of most of the liquid hydrocarbons increases (24) while the increase in the dielectric constant causes the functions $D_{unocc}(\varepsilon)$ to shift downwards. Let us now discuss the experimental observations in Section I from these points of view.

(a) Dependence of the Rate Constant on V_0 or μ

Tetramethylsilane may first be regarded as a solvent of high electron mobility. Since $\tau_e \ll \tau_r$, only molecules where the distribution of unoccupied levels is peaking close to $V_0 = -0.6$ eV are expected to react rapidly with the electron in this solvent. Carbon tetrachloride is a typical example. Acceptor molecules whose distribution of unoccupied levels is peaking far above or far below $\varepsilon = -0.6$ eV are expected to react much slower. Ethyl bromide and nitrous oxide are examples of the first case and oxygen of the latter one.

In *n*-hexane, the condition $\tau_e > \tau_r$ is fulfilled

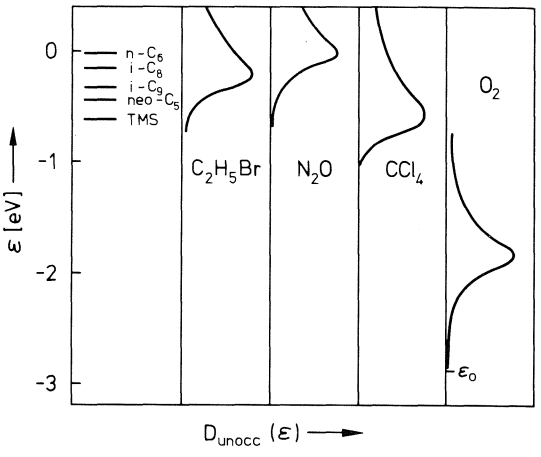

FIG. 4. Estimated distributions of unoccupied electronic redox levels of the system A/A^- of Fig. 3 and the energy levels V_0 of the electron in various hydrocarbons.

for many acceptor molecules even if their distribution of unoccupied levels does not peak close to $\varepsilon = 0$, *i.e.* close to V_0 in this solvent. One may thus understand why most of the solutes react with a diffusion-controlled rate constant in this solvent. Only in the case of oxygen, the density of unoccupied levels at $\varepsilon = 0$ is so low that the condition $\tau_e > \tau_r$ is no longer fulfilled. The reaction, therefore, is not diffusion-controlled.

That oxygen is able to react with a rate constant of about $10^{11}\ M^{-1}\ s^{-1}$ may be explained by one of the effects which we have excluded in the simple-minded model. (*1*) Reaction may occur at a suitable configuration of the solvent shell of the O_2 molecule which allows the flow of part of the energy of reaction into internal degrees of freedom of the solvent molecules. Such a configuration may be obtained during the thermal fluctuations of the system with little activation energy. (*2*) Reaction may occur via internal conversion of $O_2 + e^-$ into O_2^-. This process will be slow since internal conversion in diatomic molecules generally is not fast. Both explanations would be in agreement with the rapid attachment–detachment equilibrium $e^- + O_2 \rightleftharpoons O_2^{-*}$ postulated by Baxendale *et al.* (3).

The maxima for the rate constants of N_2O and C_2H_5Br in Fig. 1 can also be explained. In going from *n*-hexane to solvents of increased electron mobility such as neopentane, two opposing effects affect the rate of reaction. (*1*) The increased mobility causes an increase in the rate constant as long as $\tau_e > \tau_r$. (*2*) The density of unoccupied levels in these two acceptor molecules decreases with increasing μ (or decreasing V_0) for solvents of low V_0. This effect will lead to a decrease in the rate constant as soon as the condition $\tau_e > \tau_r$ is no longer valid.

In the case of oxygen, the reaction is slower in all the solvents than expected for a diffusion-controlled process. The increase in rate with decreasing V_0 (or increasing μ) of the solvent is not due to the increased mobility but to the increase of the density of unoccupied states at the V_0 level of the electron.

In tetramethylsilane, three cases may be distinguished.

(*1*) The acceptor system has a high density of unoccupied states at $\varepsilon = V_0 = -0.6$ eV. According to (a) the reaction is almost diffusion-controlled. A small positive activation energy almost equal to that of the mobility of the electron can be expected. A typical example is carbon tetrachloride.

(*2*) The acceptor system has its center of unoccupied levels at much lower ε values. A decrease in temperature leads to a smaller value of the function D_{unocc} at $\varepsilon = V_0$, *i.e.* to a lower rate. A positive activation energy will therefore be observed as well as a low rate of reaction. Oxygen is a typical example for this case.

(*3*) The acceptor system possesses a distribution of unoccupied levels far above -0.6 eV. The rate constant will again be low. A decrease in temperature leads to an increased value of $D_{\text{unocc}}(\varepsilon)$ at $\varepsilon = V_0$. The rate increases, *i.e.* a negative activation energy will be observed. Examples are nitrous oxide and ethyl bromide.

In solvents of intermediate V_0, such as 2,2,4-trimethylpentane, the condition $\tau_e > \tau_r$ will be fulfilled at low temperatures for almost all acceptors. Diffusion-controlled reactions with a positive activation energy will be observed. If the acceptor system has a high density of unoccupied levels at $\varepsilon = V_0$, the activation energy will still be positive at higher temperatures. However, if the density of states peaks at high ε values, the condition $\tau_e < \tau_r$ is reached at higher temperatures and the rate determined by the value of $D_{\text{unocc}}(\varepsilon)$ at $\varepsilon = V_0$. A negative activation energy will now be observed. This explains the maximum of the rate constant for C_2H_5Br in 2,2,4-trimethylpentane (1).

(c) Dependence of the Rate Constant on Electrical Field Strength

The electrons are mainly moving in a level with the energy $\varepsilon = V_0 + \bar{E}_K$, where $\bar{E}_K$ is the mean kinetic energy picked up by acceleration in the electric field. The decrease in ε with increasing field strength causes the interaction radius R to decrease. This effect will generally contribute to a decrease in the rate constant with increasing field strength. However, if the acceptor system possesses a distribution of unoccupied levels at energies higher than V_0, the increase in field strength will result in a higher value of the function $D_{\text{unocc}}(\varepsilon)$ at the energy $\varepsilon = V_0 + \bar{E}_K$. This effect may counterbalance or even surpass the decrease in the interaction radius and thus lead to an increase in the rate constant with increasing field strength. A typical example for this behavior is nitrous oxide. The rate constant passes through its maximum value with in-

TABLE 1. Thermodynamic and kinetic data on the equilibrium $A(s) + e^-(s) \rightleftharpoons A^-(s)$ for various acceptors in tetramethylsilane (22, 26) (all energies in kcal mol^{-1})

Acceptor	Electron affinity (gas phase)	Attachment reaction				Detachment reaction rate constant (s^{-1})
		ΔH_r	$298\Delta S_r$	ΔG_r	Rate constant ($M^{-1}\ s^{-1}$)	
Triphenylene	6.5	−17.6	−6.1	−11.5	$2.5\times10^{12}\exp(0.72/RT)$	$1.3\times10^{17}\exp(-16.9/RT)$
Phenanthrene	7.1	−16.8	−6.6	−10.2	$4.7\times10^{12}\exp(0.68/RT)$	$5.1\times10^{17}\exp(-16.1/RT)$
Naphthalene	3.5	−16.1	−8.5	−7.6	$2.6\times10^{12}\exp(0.78/RT)$	$4.7\times10^{18}\exp(-15.4/RT)$
Styrene	−0.2	−15.4	−9.6	−5.4	$4.6\times10^{12}\exp(0.77/RT)$	$1.2\times10^{18}\exp(-14.6/RT)$
α-Methylstyrene	−1.2	−16.0	−11.6	−3.9	$3.0\times10^{12}\exp(1.01/RT)$	$1.4\times10^{20}\exp(-15.0/RT)$
Carbon dioxide	−9.2	−21.1	−13.7	−7.4	$2.7\times10^{10}\exp(0.94/RT)$	$3.2\times10^{20}\exp(-20.2/RT)$

creasing field strength when the energy $\varepsilon = V_0 + \bar{E}_K$ of the electron is about equal to the energy at which the $D_{unocc}(\varepsilon)$ function of the acceptor peaks.

In the foregoing discussion, only those distributions of unoccupied electronic levels were considered which result from transitions from the vibrational ground state of the molecule to the anion. The influence of thermal activation of the acceptor molecule to higher vibrational states was neglected. Excitation of the O_2 molecule into the first vibrational excited state, for example, would enhance the probability of transitions which are accompanied by small transition energies, *i.e.* the function $D_{unocc}(\varepsilon)$ would become wider and larger at low ε values. However, this effect does not seem to play any role in *n*-hexane as the activation energy found by Baxendale *et al.* (3) is much lower than the energy of 4.6 kcal mol^{-1} of a vibrational quantum in oxygen. In the case of polyatomic molecules, thermal excitations may occur more frequently and influence the distribution of unoccupied electronic redox levels. Thermal fluctuations in the solvent shell are of great importance in electron reactions and slow electron transfer reactions in strongly polar media, and internal excitation of the reactants may play an important role in slow electron transfer reactions.

V. Aromatic Acceptor Molecules and Carbon Dioxide

The anions of aromatic compounds are stable with respect to atomic dissociation. They may, however, spontaneously lose the electron. Equilibria of the type

[16] $$A(s) + e^-(s) \rightleftharpoons A^-(s)$$

in tetramethylsilane have been studied (25, 26) by measuring the rate constant of the forward reaction as well as the constant of the equilibrium

[17] $$K = \frac{[A^-(s)]}{[e^-(s)][A(s)]}$$

at various temperatures. Table 1 shows thermodynamic data derived from the measurements as well as expressions for the temperature dependence of the rate constants.

All these aromatic acceptors react with about the same energy ΔH_r although they have different electron affinities in the gas phase. Small molecules have a low electron affinity but they are more strongly solvated. $\varepsilon_0 = -EA + \Delta H_p(A^-)$ is about 23 kcal mol^{-1} in all these cases. The differences in the free energy of reaction ΔG_r are caused by the reaction entropy ΔS_r which is the more negative for the smaller (*i.e.* more solvated) molecules.

Electron capture occurs with a small negative activation energy, which changes little for the various acceptor molecules. The preexponential factor of the rate constant has almost the same value in all the cases studied. The rate constant amounts to about $1 \times 10^{13}\ M^{-1}\ s^{-1}$ at room temperature. It is slightly smaller than the rate constants of sulfur hexafluoride and of carbon tetrachloride (Fig. 1). These findings suggest that the distribution of unoccupied redox levels of the aromatic acceptors is centered slightly above $V_0 = -0.6$ eV in tetramethylsilane.

The activation energy for electron detachment is slightly lower than $-\Delta H_r$, *i.e.* close to 21 kcal mol^{-1} for all the aromatic anions. The rate constant at room temperature generally amounts to 10^5 to $10^{10}\ s^{-1}$. That these detachment processes are so fast despite their large activation energy is due to the large preexponential factor of the rate constant which is of the order of 10^{17}

to $10^{20}\ s^{-1}$. Such large preexponential factors are known for a number of unimolecular reactions of polyatomic molecules in solution. They are observed if many internal degrees of freedom of the molecule participate in the process of activation and they are expressed by

$$10^{13}\left(\frac{E}{RT}\right)^{n-1}\frac{1}{(n-1)!}$$

where n is the number of active internal degrees of freedom and E the activation energy (see, for example, ref. 27).

The activated state of the detachment reaction is thought to be an activated molecular anion in which the energy ε of the electron (with respect to the energy of an electron in the gas phase) is equal to the energy V_0. It can thus readily escape into the solvent. The preexponential factor of the rate constant may be presented as the product $10^{13}\exp(\Delta S^*/R)$ where ΔS^* is the activation entropy ($10^{13}\ s^{-1}$: collision frequency). The ΔS^* values calculated from the preexponential factors of Table 1 are practically identical with the reaction entropy ΔS_r (26). Since the latter is equal to the entropy of polarization of the medium by the anion, one may suppose that the high entropy of the activated complex of the detachment reaction is due to little polarization of the solvent. If this supposition is correct, one must conclude that the electron is rather diffuse in the activated complex.

The electron attachment–detachment equilibrium of CO_2 has been studied in various solvents (22). The kinetic and thermodynamic data for tetramethylsilane are included in Table 1. The activation energy for detachment is clearly higher than that for the aromatic anions. The rate of detachment, however, is about the same as that of the aromatic anions, since the preexponential factor is correspondingly higher for CO_2^-. The high activation entropy for detachment is again explained by changes in the solvation shell of CO_2^-.

CO_2 is linear and CO_2^- is bent (134°) (28). Vertical electron attachment or detachment in the gas phase will lead to products with a lot of excess energy. It has recently been shown by *ab initio* calculations (29) that a series of extended Rydberg-like orbitals exist for an electron which is added to CO_2 in its linear configuration. The more extended the orbital, *i.e.* the higher its quantum number, the lower is the energy of the CO_2^- anion formed. On the other hand, the state of lowest energy of CO_2^- in its bent equilibrium configuration is the one in which the electron is located in the orbital of lowest quantum number. It is difficult to predict how the potential functions of these excited states will change upon dissolution of the molecules. It is, however, conceivable that these states play a role in both the attachment and detachment process.

VI. Heterogeneous Electron Transfer: Electronic States in Water

Electrons can be accepted by water from excited states of anions (30). Ultraviolet-light excitation of the ferrohexacyanide anion, for example, leads to a very rapid detachment of an electron. The dynamics of the later stages of its solvation have been studied using picosecond detection techniques (31). However, it could not be decided in this experiment whether the electron was initially injected into the conduction band of water or into a localized state below the level V_0. The excitation of ferrohexacyanide by 4.75 eV quanta leads to a state characterized by $\varepsilon = -0.1$ eV on our energy scale ($\varepsilon = 0$ for the electron in the gas phase). According to the present theoretical considerations, V_0 in water may lie somewhere between -0.5 and $+1.0$ eV.[4]

It has recently been found that molecules of low gas phase ionization energy (~ 6.5 eV) such as phenothiazine (33) and tetramethylbenzidine (34) can be ionized by 3.56 eV quanta (frequency doubled ruby laser) if they are irradiated in the lipoidic interior of anionic micelles in aqueous solution. Immediately after the 10 ns laser flash, the spectrum of the hydrated electron and that of the cation of the solubilized molecule could be seen. The interfacial potential of -0.5 V between the hydrocarbon-like part of the micelle and the aqueous phase facilitates the ejection of the electron from the first excited singlet state of the molecule formed by light absorption. The electron is transferred to the aqueous phase through the electric double layer at the surface of the micelle and the negative overall charge of the micelle prevents a fast neutralization of the ion pair produced.

The energetics of the process are shown in Fig. 5. The levels of the redox couples $P^+/P(S_0)$, $P^+/P(S_1)$, and $P^+(T_1)$ in the micelle are shown on the left side (S,T: singlet and triplet states of phenothiazine). Excitation by 3.56 eV quanta

[4]J. Jortner. Private communication.

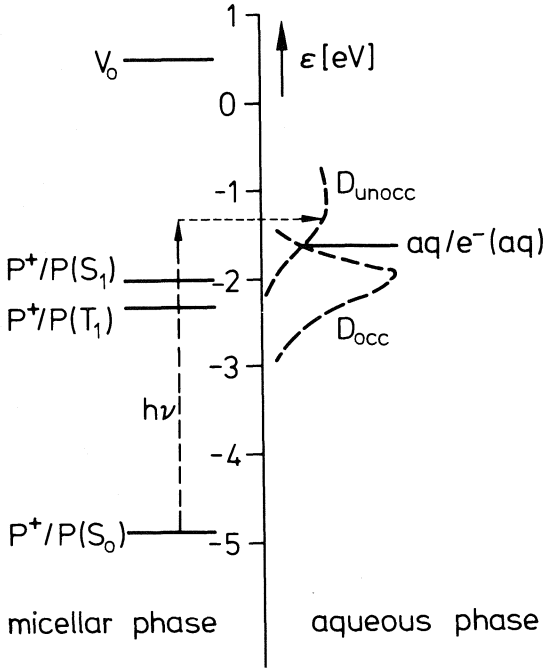

FIG. 5. ε^0 values of various redox systems of phenothiazine in anionic micelles and of the redox system aq./e_{aq}^-. The distribution functions of unoccupied and occupied electronic levels of the latter system are also indicated. Their exact shapes are not known.

leads to a vibrational level of the first excited singlet state at a position slightly above the thermodynamic level $\varepsilon^0 = -1.63$ eV of the hydrated electron (right side of Fig. 5). The electron can easily move into the aqueous phase at an energy ε which is far below the energies at which electrons are generally detached from CTTS states of anions.

Two explanations for this phenomenon may be given. The author prefers an explanation which is pictured by the functions D_{unocc} and D_{occ} on the right side of Fig. 5. The V_0 level is believed to be high (at about -0.2 eV (35)). Below this level, water may accept electrons into clusters of suitable structure present in the thermal fluctuations in the liquid. The electronic energies of these clusters(aq.) are characterized by the function $D_{unocc}(\varepsilon)$. After acceptance of the electron, reorganization of the solvent shell to reach the state of lowest energy will take place. The clusters(aq.) and the hydrated electron e_{aq}^- may thus be considered to be the oxidized and reduced forms of a redox couple. A function $D_{occ}(\varepsilon)$ below $\varepsilon^0 = -1.63$ eV must exist describing the distribution of occupied electronic levels of this redox system (*i.e.* the distribution of negative energies required to move the electron in a sudden process from e_{aq}^- into the gas phase). The shape of the two distribution functions is not known.

On the other hand, it has been shown in photoelectrochemical experiments that electrons can be ejected from a light irradiated electrode into water at energies $\varepsilon < -1.3$ eV (2, 32). The effects were explained by injection into the conduction band of water and thus V_0 should be equal to -1.3 eV. It should be mentioned that under these circumstances the maximum in the absorption spectrum of e_{aq}^- must be attributed to the transition to a bound state e_{aq}^{-*} which lies above the level V_0. No theoretical reasoning for the existence of such an excited state has yet been given. One may, however, also postulate that the electron can be transferred from an electrode into unoccupied electronic levels below V_0 as described above. A clear distinction between the two explanations does not seem possible at the present time.

Discussion

G. R. Freeman: Part of the high value of the apparent frequency factor (10^{20} s^{-1}) for detachment reactions in TMS might be due to a negative temperature coefficient of the enthalpy of activation $E_a \approx \Delta H^{\ddagger}(0) - \gamma T$, where $\Delta H^{\ddagger}(0)$ is the activation enthalpy extrapolated to zero Kelvin and γ is the temperature coefficient. We have observed a similar behavior for electron mobilities in olefins at low temperatures, where transient negative ions seem to form. It has also been observed in several semiconductors. A value of $\gamma \approx 10^{-3}$ eV/K will increase the apparent frequency factor by about 10^5.

$$k = A \exp(-E_a/RT) = A \exp(\gamma/R) \exp(-\Delta H^{\ddagger}(0)/RT)$$

The effect seems to be due to temperature dependence of the solvation free energy of the transient anion.

A. Henglein: I agree that this could be a contribution for the high preexponential factor. However, let me emphasize the fact that the calculated activation entropies always are equal to the energy of polarization of the anions. I do not think that this happens by chance.

G. R. Freeman: How accurately are the temperature dependences of the energies of polarization of anions known in TMS?

A. Henglein: Energies derived from the temperature dependence of the equilibrium constant can be regarded to be more accurate than 0.1 eV. Since equilibria of this type can only be observed within a relatively small temperature range, no data have been obtained for the temperature dependence of the energy of reaction.

A. C. Albrecht: The state from which you propose electron ejection appears to be an excited vibrational level of the first excited singlet state. The ejection or charge transfer process must therefore compete with picosecond type decay channels. The yield for transfer out of the micelle might for this reason be extremely low. How is this problem rationalized?

A. Henglein: The ejection should indeed be very rapid. However, the energy of the first excited state in phenothiazine is not known accurately. It might be higher by a few tenths of an electronvolt than shown in this figure. It could therefore be that the ejection of the electron occurs from the ground vibrational level of the first excited singlet. This question should be solved by looking at the process under conditions of picosecond time resolution.

Y. Hatano: Concerning the discussion of electron attachment to a molecule, *e.g.* O_2, in liquids based upon the knowledge of that in the gas phase, I would like to show some recent data on the effect of a third body on thermal electron attachment to O_2 in the gas phase, $e_{th}^- + O_2 + M \xrightarrow{k_M} O_2^- + M$, as studied by a microwave cavity technique combined with pulse radiolysis, where k_M is a three-body rate constant which is shown in the table for various medium gases (H. Shimamori and Y. Hatano Chem. Phys. Lett. **38**, 242 (1976); Chem. Phys. **12**, 439 (1976); Chem. Phys. To be published). The difference in these values is ascribed to the difference in the efficiency of collisional stabilization of vibrationally excited O_2^-*. This stabilization process may be classified into two cases depending on whether the vibrational relaxation is effected by V–T transitions or V–V transitions. Concerning the stability of a vibrationally excited negative ion, *i.e.*, an effective attachment rate of electrons in condensed media such as liquids or rigid matrices, it appears interesting now to take additionally into account V–phonon interactions.

M	k_M ($\times 10^{-30}$ cm^6/s)	M	k_M ($\times 10^{-30}$ cm^6/s)

J. C. Thompson: What is the nature of D_{unocc} levels in H_2O into which e^- moves from the excited state of the micelle.

A. Henglein: These are configurations of water molecules which can localize an electron. They are characterized by the energy liberated if an electron is put into them in a sudden process from the gas phase. The distribution D_{unocc} is the distribution of these transition energies.

L. G. Christophorou: Negative ions, as neutrons, have a number of excited, higher states which often are closely spaced. In the gas phase a large number of molecules, such as the ones you considered, have two or three negative ion states within 0.5–1 eV of 0 eV. When such systems are placed in a liquid, especially when their electron affinity is large, there will be cases where two or more negative ion states will lie below 0 eV. In such cases, the electron can be captured in not only the lowest negative ion state as you described, but also in these higher states as well. Will this change your picture?

A. Henglein: They will complement the picture. I considered them at an earlier occasion (7).

Numerical investigation of tunnelling contributions to electron scavenging reactions in liquids at short times

P. Robin Butler, Michael J. Pilling,[1] Stephen A. Rice,[2] and Timothy J. Stone

Physical Chemistry Laboratory, South Parks Road, Oxford, England 0X1 3QZ

Received September 27, 1976

P. Robin Butler, Michael J. Pilling, Stephen A. Rice, and Timothy J. Stone. Can. J. Chem. **55**, 2124 (1977).

Fick's second diffusion equation, with an added exponential sink term, is integrated numerically to simulate the decay of electrons at short times in the presence of scavengers. The time dependence of the scavenger concentration profile, the scavenging rate constant, and the electron concentration are illustrated graphically. Using the experimental results of Buxton *et al.* and Jonah *et al.* It is shown that the Smoluchowski equation is valid within their experimental time ranges provided the cage encounter distance is replaced by R_{eff}, where R_{eff} can be evaluated explicitly in terms of reaction parameters. It is also shown that tunnelling from relaxed traps may make a significant contribution to ultra-short time electron scavenging.

P. Robin Butler, Michael J. Pilling, Stephen A. Rice et Timothy J. Stone. Can. J. Chem. **55**, 2124 (1977).

On intègre d'une façon numérique la deuxième équation de diffusion de Fick avec un terme de piège exponentiel afin de simuler la décroissance des électrons à des temps courts en présence de pièges. On illustre d'une façon graphique la relation qui existe entre le temps et la contribution du piège au profil ainsi que la constante de vitesse de piègeage et la concentration d'électrons. Utilisant les résultats expérimentaux de Buxton *et al.* et de Jonah *et al.*, on montre que l'équation de Smoluchowski est valide à l'intérieur des écarts de temps expérimentaux pourvu que l'on remplace la distance de rencontre en cage par R_{eff}, où R_{eff} peut être évalué explicitement en termes des paramètres de la réaction. On montre aussi que la réaction tunnel provenant de pièges relaxés peut apporter une contribution importante au piégeage d'électrons à des temps extrêmement courts.

Introduction

The involvement of tunnelling in reactions of solvated electrons in rigid glasses is now well documented (1, 2) although there is some disagreement about the detailed mechanism of such reactions (3). Tunnelling has also been postulated in liquids, but the evidence is less convincing. Hart and Anbar (4) noted that the rate constants of some diffusion-controlled reactions of the hydrated electron are larger than would be expected on the basis of 'crystallographic' radii and the known diffusion coefficients of the reacting species. They suggested that the electrons react at large distances by a tunnelling mechanism. An analysis of the steady-state diffusion equation with an exponential sink term confirmed that the magnitude of the increase in the encounter distance is compatible with tunnelling parameters as derived from studies of glasses (5). Buxton *et al.* (6) and Jonah *et al.* (7) studied diffusion-controlled reactions in the time-dependent zone (8) prior to establishment of the steady state. They analysed their data using the time-dependent Smoluchowski equation or a variant which employs the so-called radiation boundary condition (8), neither of which takes account of any long range nature of the reaction. They were able to determine the effective encounter distance, R_{eff}, and the diffusion coefficient, D, independently. In both investigations reactive systems were found which gave R_{eff} greater than the 'crystallographic' values and a tunnelling mechanism was invoked.

The present paper presents a numerical integration of the time-dependent diffusion equation containing an exponential sink term and examines the validity of the conclusions of Buxton *et al.* (6) and Jonah *et al.* (7). A numerical analysis (9) of the same equation has been reported previously, but no specific application of the results was made.

Experimental studies have also been made of very short time (<30 ps) electron scavenging and various mechanisms, involving dry electrons

[1]To whom correspondence should be addressed.

[2]Present address: Department of Chemistry, Wayne State University, Detroit, MI, U.S.A. 48202.

or tunnelling, have been proposed (10–12). An analysis of the likely effects of tunnelling in this time regime is also presented.

Diffusion Equation

The rate of a fast reaction of the solvated electron depends on the mutual diffusion of the reactants. Provided the reaction occurs by a contact mechanism, the change in the ensemble averaged concentration of scavengers around electrons ($S(r,t)$) may be described by the diffusion equation derived from Fick's second law:

$$[1a] \qquad \frac{\partial S(r,t)}{\partial t} = \frac{D}{r}\frac{\partial^2 S(r,t)r}{\partial r^2}$$

Spherical symmetry is assumed and r is the electron scavenger distance, t is the time, and D is the relative diffusion coefficient of the reactants. If reaction occurs on every encounter of scavenger and electron, then the Smoluchowski boundary conditions may be applied

$$[2] \qquad S(r,t) = 0 \qquad r < R,\ t \geq 0$$

$$[3] \qquad S(r,t) = S_0 \qquad r > R,\ t = 0$$

$$[4] \qquad S(r,t) \rightarrow S_0 \qquad r \rightarrow \infty,\ t \geq 0$$

where R is the encounter (reaction) distance and S_0 is the bulk scavenger concentration. At zero time, the scavenger distribution is assumed random. The reaction depletes the region around $r = R$ of scavengers and provides a concentration gradient which promotes the diffusion of scavengers from larger distances. A steady-state concentration profile is eventually set up, with diffusive supply balancing reactive depletion and the equation becomes time independent. By evaluating the radial flux of scavengers, the steady-state rate constant for the reaction may be shown to be $4\pi RD$ (8). For reactions which are not quite so fast, the radiation boundary condition is introduced, modifying [2] and reducing the rate constant (8).

Pilling and Rice (5) modified [1a] in order to describe reactions, such as electron scavenging, which take place by a long range mechanism whose probability falls off exponentially with distance. They introduced an exponential sink term:

$$l_s(r) = \alpha' \exp\left[-\beta(r - R)\right]$$

into [1a], to give

$$[1b] \qquad \frac{\partial S(r,t)}{\partial t} = \frac{D}{r}\frac{\partial^2 S(r,t)r}{\partial r^2} - l_s(r)S(r,t)$$

and employed the boundary conditions [2]–[4]. $l_s(r)$ is the first order rate constant for reaction of an electron and scavenger held at a distance r, and may be derived from the Gamow equation (2). It describes tunnelling of an electron through the potential energy barrier separating it from the scavenger. α' is a frequency term and β is related to the height of the potential barrier (or, equivalently, to the depth of the electron trap). Alternatively, and more realistically, $l_s(r)$ may be derived using Fermi's golden rule; α' is now related to the electronic transition moment for the electron transfer process and to Franck–Condon factors, whilst β is determined by the radial dependence of the electron wavefunction. An analysis of electron scavenging in aqueous glasses showed that $\alpha' \sim 10^{14}\ s^{-1}$ and $\beta \sim 10^{10}\ m^{-1}$ (equivalent to a trap depth of 1 eV) (2).

Pilling and Rice (5) solved [1b] analytically and showed that the steady-state rate constant is given by

$$k = 4\pi R_{eff} D$$

where

$$[5] \qquad R_{eff} = R + \frac{1}{\beta}\left[2\gamma + \ln\frac{w_0^2}{4} + \frac{2K_0(w_0)}{I_0(w_0)}\right]$$

γ is Euler's constant (0.57721...), $w_0^2 = 4\alpha'/\beta^2 D$, and $I_0(w_0)$ and $K_0(w_0)$ are the modified first and second kind Bessel functions of zero order and argument w_0. They also derived steady-state concentration profiles ($S(r,\infty)$ *vs.* r) and showed that the reaction may be adequately described by placing an absorbing barrier at $r = R_{eff}$, which is greater than R for an efficient scavenger. They were unable to solve [1b] analytically in the time-dependent region; the present paper uses a numerical approach.

Numerical Solution

Equation 1b may be transformed into a reduced equation more suited to computation using the following substitutions:

$$x = \beta r/2 \qquad Y = xS(r,t)/S_0 \qquad \tau = \beta^2 Dt/4$$
$$\lambda = w_0^2 \exp(\beta R)$$

giving

$$[1c] \qquad \frac{\partial Y}{\partial \tau} = \frac{\partial^2 Y}{\partial x^2} - \lambda^2 Y \exp(-2x)$$

with suitably modified boundary conditions. Equation 1c was then solved numerically, using a modified Crank–Nicolson method (13) (see Appendix).

Scavenger Concentration Profiles

Figure 1 shows the computed scavenger profiles, $\rho(r,t) = S(r,t)/S_0$, as a function of time, for typical parameters:

(*a*) $\alpha' = 0$, $D = 10^{-8}$ m^2 s^{-1}, $R = 0.5$ nm, *i.e.*, for solution of the Smoluchowski equation with no tunnelling (eq. 1*a*).

(*b*) $\alpha' = 10^{14}$ s^{-1}, $\beta = 10^{10}$ m^{-1}, $D = 10^{-8}$ m^2 s^{-1}, $R = 0.5$ nm.

(*c*) $\alpha' = 10^{14}$ s^{-1}, $\beta = 10^{10}$ m^{-1}, $D = 0$, $R = 0.5$ nm, *i.e.*, the pure tunnelling case considered by Dainton *et al.* (2).

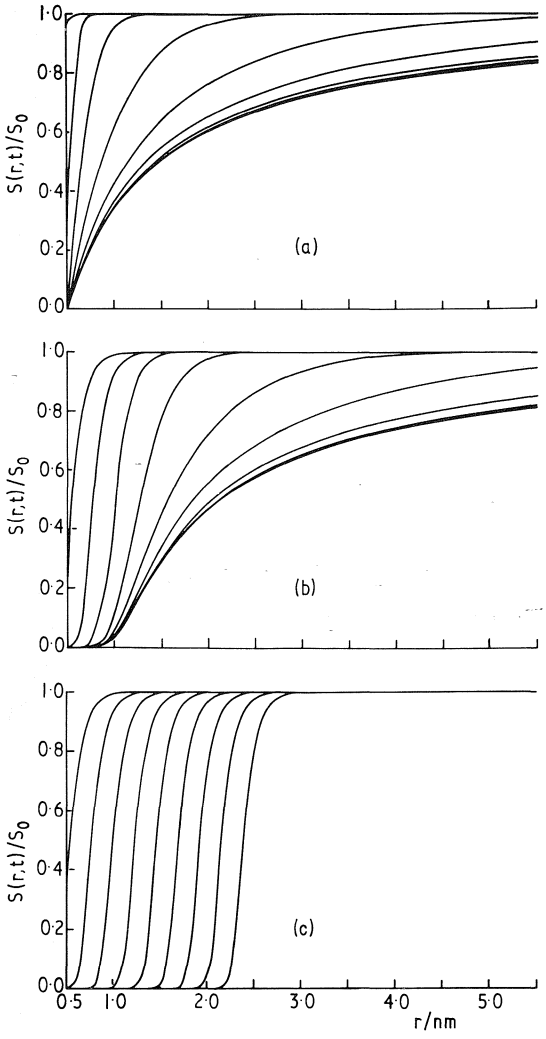

FIG. 1. Scavenger profiles (*a*) Smoluchowski: $\alpha' = 0$, $D = 10^{-8}$ m^2 s^{-1}, $R = 0.5$ nm; (*b*) tunnelling and diffusion: $\alpha' = 10^{14}$ s^{-1}, $\beta = 10^{10}$ m^{-1}, $D = 10^{-8}$ m^2 s^{-1}, $R = 0.5$ nm; (*c*) pure tunnelling $\alpha' = 10^{14}$ s^{-1}, $\beta = 10^{10}$ m^{-1}, $D = 0$, $R = 0.5$ nm. The profiles are shown at decadic time intervals from 10^{-14} to 10^{-6} s, with that for 10^{-14} s at the extreme left.

Figure 1*a* shows the relaxation of the scavenger distribution from a random form to the steady-state form, over a period of 10^{-7} s for case (*a*). Figure 1*c* shows the expansion of the volume depleted of scavengers when a tunnelling reaction takes place but diffusion is unable to replenish the local scavenger concentration (2). Figure 1*b* shows the time dependence most relevant to the present discussion. At short times ($t < 10^{-12}$ s) reaction occurs predominantly by static tunnelling and the quasi-steps in Fig. 1 *b* and *c* recede with time in a similar manner. At longer times diffusion makes good some of the local scavenger depletion and after $\sim 10^{-7}$ s the steady state is established. A comparison of Fig. 1 *a* and *b* shows, however, that the tunnelling reaction at small r occurs too rapidly for effective scavenger replenishment and $\rho(r,t)$ is small out to $r \sim R_{\text{eff}}$. The computed steady-state concentration profile agrees well with the analytical form given by Pilling and Rice (5). The same general conclusions could be made from the numerical results obtained with a range of diffusion and tunnelling parameters although the time regimes for pure tunnelling and steady-state behaviour are, of course, altered.

Rate Constants

Pilling and Rice (5) showed that the total scavenging rate constant, $k(t)$, is the sum of diffusive ($k_D(t)$) and tunnelling ($k_T(t)$) rate constants, where the former relates to reaction on encounter and the latter to reaction from all distances greater than R. They are given by:

$$[6] \qquad k_D(t) = 4\pi R^2 D \left.\frac{\partial \rho(r,t)}{\partial r}\right|_R$$

$$[7] \qquad k_T(t) = \int_R^\infty 4\pi r^2 \alpha' \rho(r,t) \times \exp[-\beta(r - R)]\, dr$$

$$[8] \qquad k(t) = k_D(t) + k_T(t)$$

The Appendix describes how $k_D(t)$ and $k_T(t)$ were obtained numerically from the computed scavenger concentration profiles.

Figure 2 shows computed rate constants, $k(t)$, for $\alpha' = 10^{14}$ s^{-1}, $\beta = 10^{10}$ m^{-1}, $D = 10^{-8}$ m^2 s^{-1}, and $R = 0.5$ nm, as a function of time. For all $t > 10^{-14}$ s, $k_T(t)$ is several orders

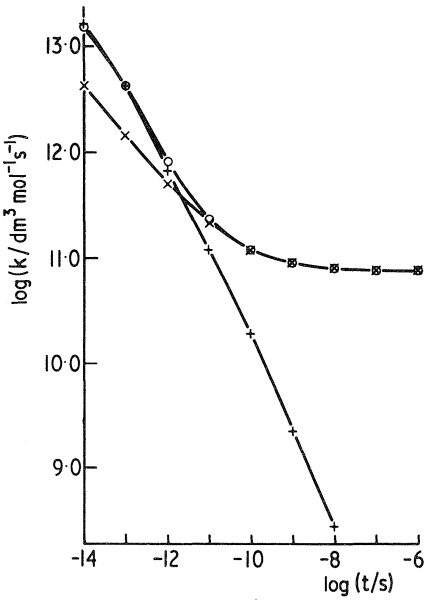

FIG. 2. Time dependence of rate constants: × Smoluchowski with R replaced by R_{eff}; ○ numerical results based on [1*b*], including both tunnelling and diffusion; + pure tunnelling. The parameters are: $\alpha' = 10^{14}$ s^{-1}, $\beta = 10^{10}$ nm^{-1}, $D = 10^{-8}$ m^2 s^{-1}, $R = 0.5$ nm.

of magnitude greater than $k_D(t)$, *i.e.*, $k(t) \simeq k_T(t)$. The origin of this effect may be illustrated by reference to Fig. 1*b*, which shows that the concentration gradient at $r = R$ is very small, even at short times: the exponential sink term at distances close to R is so large that this region is rapidly depleted of scavengers. In consequence only a very small fraction of the reaction occurs by the purely diffusive mechanism required by [7]; the majority of reactive events occurs with $r > R$.

Equation 1*a* may be solved analytically to give the Smoluchowski time-dependent rate constant, $k_S(t)$ (8):

$$[9] \qquad k_S(t) = 4\pi RD[1 + R/(\pi Dt)^{1/2}]$$

Buxton *et al.* (6) and Jonah *et al.* (7) assumed that [9] is applicable, with a suitably increased encounter distance, even when tunnelling takes place, *i.e.*, when [1*b*] applies. Figure 2 also shows $k_S(t)$, calculated from [9], but with R replaced by R_{eff} (eq. 5). The rate constant for pure tunnelling ($D = 0$) is shown in addition. This is defined by [7], with the profile derived from [1*b*] with $D = 0$.

At short times, the rate constant, $k(t)$, is close to the value obtained for pure tunnelling, as would be expected from Fig. 1 *b* and *c*; in this time region the concentration profiles recede in a similar manner and diffusion has little effect. For $t > 10^{-11}$ s, diffusion begins to play a part and the pure tunnelling rate constant falls below the composite value which in turn acquires good agreement with the Smoluchowski rate constant equation, [9], with R replaced with R_{eff}. This effect stems from the strong distance dependence of the sink term. It falls off so rapidly at longer distances that diffusive transport is more effective and scavengers approach R_{eff} with little reactive depletion: the system approximates closely one with an absorbing boundary at R_{eff} (*cf.* Fig. 1*b*).

The changeover from pure tunnelling to tunnelling/diffusion behaviour is in agreement with the perturbation treatment of Pilling and Rice (14) which predicts that the electrons react by static tunnelling for times less than t_D:

$$t_D = 1/\beta^2 D$$

At times longer than this they suggested that diffusion plays a role in electron transport. For the parameters considered in Fig. 2, $t_D \sim 10^{-12}$ s.

Figure 2 shows that [5] was applied down to times of 10^{-14} s, whilst the Brownian approximation, implicit in Fick's laws, is generally felt to fail for times less than 10^{-12} s. This failure is seen to be unimportant in the present system, since in this time regime the diffusive contribution is negligible.

At long times, the numerical results show the required approach to a steady-state value, which agrees well with the analytical value $4\pi R_{eff}D$.

Variable α'

Dainton *et al.* (2) suggested that α' is r-dependent and is given by $\alpha' = \alpha\sigma^2/4r^2$, where σ is the electron capture radius of the scavenger and α is an r-independent frequency term. In order to obtain an analytical solution to the diffusion equation in the steady state Pilling and Rice (2) set $\alpha' = \alpha\sigma^2/4\langle r\rangle^2$ where $\langle r\rangle$ is a 'mean' tunnelling distance. They suggested that in the steady state the exponential dependence of the sink term swamps any r-dependence of α' and they assumed $\langle r\rangle = R_{eff}$. Figure 3 shows a comparison of numerical rate constants for $\alpha' = 10^{14}$ s^{-1} and $\alpha' = (10^{-3}$ m$^2/4r^2)$ s^{-1}. The latter value of $\alpha\sigma^2$ was determined so that

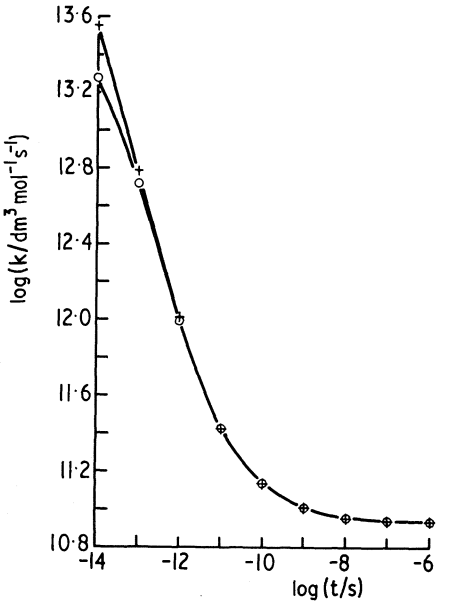

FIG. 3. A comparison between r-dependent and r-independent frequency factors: ○ $\alpha' = 10^{14}$ s^{-1}; + $\alpha' = (10^{-3}$ m$^2/4r^2)$ s^{-1}.

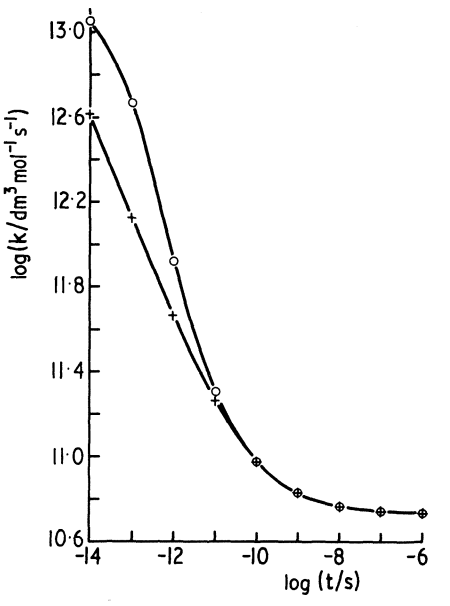

FIG. 4. A comparison of the numerically evaluated rate constant (○) and that calculated from the Smoluchowski equation with R replaced by R_{eff} (+), designed to simulate the data of Jonah *et al.* (7), for scavenging by IO_4^-. $\alpha' = 5.37 \times 10^{13}$ s^{-1}, $\beta = 10^{10}$ m^{-1}, $D = 6.5 \times 10^{-9}$ m^2 s^{-1}, $R = 0.5$ nm.

both forms gave the same computed steady-state solution. For $t > 10^{-12}$ s the results are identical, suggesting that the assumptions made by Pilling and Rice are at least operationally valid over the whole of the experimentally accessible time scale. The two forms for α' require $\langle r \rangle = 1.55$ nm, whilst $R_{eff} = 1.07$ nm.

Specific Fits to Experimental Data

(*i*) Jonah *et al.* (7) studied electron scavenging in water over the time scale 50–3500 ps. They were unable to analyse explicitly for time-dependent rate constants but instead determined the half-life, $t_{1/2}$, for electron decay. By varying the scavenger concentration they were able to vary the time scale of the reaction and so the mean rate constant, $\langle k \rangle$, for scavenging. For IO_4^- they found that $t_{1/2}$ and $\langle k \rangle$ could be adequately described by the Smoluchowski equation, with $R_{eff} = 1.06$ nm and $D = 6.5 \times 10^{-9}$ m^2 s^{-1}. Taking $\beta = 10^{10}$ m^{-1}, on the basis of low temperature studies, the data require $\alpha' = 5.37 \times 10^{13}$ s^{-1}. Figure 4 shows the numerically determined rate constant as a function of time; the time dependence of the Smoluchowski rate constant, $k_S(t)$, with R replaced by R_{eff} (*i.e.*, as used by Jonah *et al.*) is also shown. Significant differences occur only for $t < 10^{-11}$ s, which is outside the experimental time scale.

(*ii*) Buxton *et al.* (6) studied electron scavenging in 10 M aqueous hydroxide and 9.5 M aqueous LiCl solutions over the temperature range 190–240 K. The viscosity is so high at these temperatures that they were able to study the electron decay under non-steady-state conditions on a microsecond time scale and make a full analysis of the time dependence. They found several instances of large encounter distances and concluded that tunnelling is important. Before a numerical analysis is made, their data may be reinterpreted to obtain further confirmation of tunnelling. The steady-state model of Pilling and Rice (5) requires that the effective encounter distance increases as the diffusion coefficient falls, whilst Buxton *et al.* (6) reported no evidence for this. They obtained the temperature dependence of the steady-state rate constant

$$k(t \rightarrow \infty) = A \exp \{-B_k/(T - T_0)\}$$

where B_k is an experimental parameter and T_0 is the temperature of zero mobility of the glass forming solvents. They also determined the temperature dependence of the diffusion coefficient:

$$D = D_0 \exp \{-B_D/(T - T_0)\}$$

Since $k(t \rightarrow \infty) = 4\pi R_{eff} D$

$$R_{eff} = (A/4\pi D_0) \exp \{-(B_k - B_D)/(T - T_0)\}$$

There were large uncertainties in the values of B_D and B_k, but, with only two exceptions out of eight, $B_D > B_k$, suggesting that R_{eff} increases with decreasing temperature (*i.e.* with increasing viscosity) in line with the model of Pilling and Rice (5). For example, taking the mean values of B_D and B_k for CrO_4^{2-} in 10 *M* hydroxide, $R_{eff}(240\text{ K}) = 1.47$ nm and $R_{eff}(190\text{ K}) = 2.8$ nm. Using the CrO_4^{2-} values of R_{eff} and D, together with $\beta = 10^{10}\text{ m}^{-1}$, $R = 0.5$ nm requires $1.53 \times 10^{13} < \alpha' < 3.87 \times 10^{15}\text{ s}^{-1}$. Once again the Smoluchowski and numerical rate constants agree well for $t > 10^{-9}$ s at both 190 and 240 K. Figure 5 shows the computed and Smoluchowski time dependent rate constants at 240 K.

These numerical analyses show that, at both low and high viscosities, the Smoluchowski equation adequately represents a diffusion-controlled reaction with a tunnelling mechanism provided the encounter distance is replaced by R_{eff}. They thus confirm the validity of the conclusions reached by Jonah *et al.* (7) and Buxton *et al.* (6). It must be emphasized that the present treatment has been applied only to very efficient scavengers. A reduction in α' reduces R_{eff} and moderates the effect of tunnelling. For a sufficiently small α', reaction takes place only on encounter and the analytical form contained in the radiation boundary method (8) may be employed.

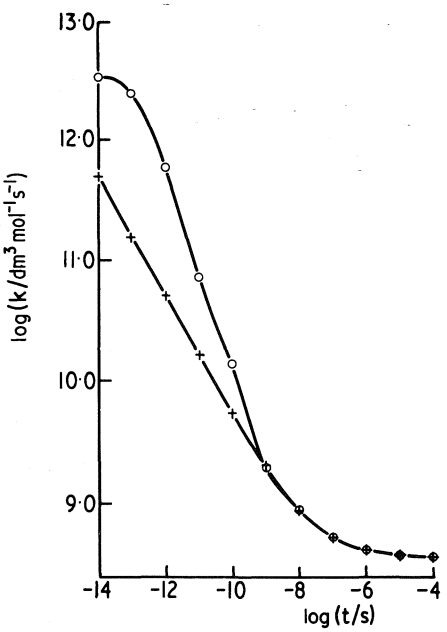

FIG. 5. A comparison of the numerically evaluated rate constant (○) and that calculated from the Smoluchowski equation with R replaced by R_{eff} (+), designed to simulate the data of Buxton *et al.* (6) for scavenging by CrO_4^{2-} in 10 *M* OH^- at 240 K. $\alpha' = 3.87 \times 10^{15}\text{ s}^{-1}$, $\beta = 10^{10}\text{ m}^{-1}$, $D = 3.08 \times 10^{-11}\text{ m}^2\text{ s}^{-1}$, $R = 0.5$ nm.

Short Time Studies

Hunt and co-workers (10–12) made a systematic study of short time ($t < 30$ ps) electron scavenging. They defined a parameter, S_{37} (in our notation), which is the scavenger concentration required to reduce the electron yield at zero time to $1/e$ of its value at the same time in the absence of a scavenger. The zero time yield was obtained by extrapolation of data obtained for $t > 30$ ps. They found a good correlation between S_{37} and the value of the rate constant, $\langle k \rangle$ measured at times greater than 30 ps (11).

$$[10] \qquad S_{37} \langle k \rangle = 10^{10}\text{ s}^{-1}$$

They did not specify the scavenger concentration at which $\langle k \rangle$ was determined and, since the rate constants are time dependent in this time regime, there is some uncertainty about the exact physical significance of $\langle k \rangle$.

Several mechanisms of short time scavenging have been proposed, including tunnelling from relaxed and partially relaxed traps and dry electron scavenging (10). The numerical technique allows us to examine the feasibility of the relaxed trap model.

The electron concentration at time t, $C(t)$, is obtained by integration of the pseudo-first-order equation:

$$dC(t)/dt = k(t)S_0C(t)$$

whence

$$[11] \quad C(t) = C_0 \exp\left[- \int_0^t k(t)S_0\, dt \right]$$

where C_0 is the true electron concentration at zero time. Because of the strong time dependence of the rate constant, extrapolation to zero time based on $\langle k \rangle$ underestimates C_0:

$$[12] \qquad C(t) = C_0' \exp(-\langle k \rangle S_0 t)$$

where C_0' is the extrapolated zero time electron concentration. Equating [11] and [12]

$$\frac{C_0}{C_0'} = \exp\left\{ S_0 \left[\int_0^t k(t)\, dt - \langle k \rangle t \right] \right\}$$

The parameter defined by Hunt *et al.* (11), S_{37}, is obtained when $C_0/C_0' = e$, whence

[13] $$S_{37} = \left[\int_0^t k(t)\,dt - \langle k \rangle t \right]^{-1}$$

where $t = 30$ ps.

CrO_4^{2-} was chosen as a model scavenger, since it has responded well to tunnelling treatments and also because it has the smallest S_{37} value and thus represents the most severe test. Using the tunnelling parameters derived from the short time rate data of Jonah *et al.* (7) ($4\pi R_{eff}D = 3 \times 10^{10}$ dm^3 mol^{-1} s^{-1}) together with $D = 5.5 \times 10^{-9}$ m^2 s^{-1} and $R = 0.5$ nm, and defining $\langle k \rangle$ by its 100 ps value, a value of 0.55 mol dm^{-3} was calculated for S_{37}. This is in fair agreement with the experimental value of 0.2 ± 0.05 mol dm^{-3}. The calculation is quite crude, however, and does not preclude the possibility of dry or damp electron scavenging. There is uncertainty in the value of $\langle k \rangle$ and charge effects (15) and trap relaxation have been neglected. The calculations do show, however, that tunnelling, even from fully relaxed traps, can account for a significant amount of scavenging at very short times. This observation applies only to the more efficient scavengers. The extreme dependence of the rate constant on time occurs only if α' is large.

If we assume that the short time scavenging may be ascribed exclusively to tunnelling, then [10] and [13] require that

$$\int_0^t \frac{k(t)\,dt}{\langle k \rangle} - t = 10^{-10} \text{ s}$$

for $t = 30$ ps. If we assumed that $\langle k \rangle$ is defined by its 100 ps value, and if we take the form shown in Fig. 2 for $k(t)$, then the left-hand side of this equation is equal to 5×10^{-11} s.

Charge Effects

The effect of scavenger charge and of ionic strength have been entirely neglected throughout the present calculations. Jonah *et al.* (7) showed that ionic strength had no effect on the scavenging of CrO_4^{2-} and IO_4^- and they ascribed this to the large effective encounter distance and to the consequently small Coulombic interaction. This argument will be even more valid at the low temperatures and high ionic strengths at which Buxton *et al.* (6) performed their experiments. The effects of scavenger charge in the time-dependent region and at the steady state have been considered by Butler and Pilling (16).

Conclusion

In fluid systems containing electrons in fully relaxed traps, the decay of the electrons can be divided into two well defined regions. For $t < t_D$ ($t_D = 1/\beta^2 D$), the electrons decay almost exclusively by static tunnelling (2). For $t \gtrsim 10t_D$ the decay occurs by combined diffusion and tunnelling with a rate constant:

$$k(t) = 4\pi R_{eff} D(1 + R_{eff}/(\pi Dt)^{1/2})$$

For electrons in water at 300 K, $t_D \sim 10^{-12}$ s.

Appendix

The (x,τ) space (eq. 1*c*) was divided into a mesh of points separated by equal increments, δx and $\delta\tau$, and labelled by subscripts i and j, respectively. The $Y(i,0)$ array was defined from the boundary condition [3]. Condition [4] was redefined to give $Y(n,j) = x$; $i = n$ corresponds to the maximum value of the distance variable, defined by $x = \beta R_{max}/2$. $\partial Y(i,j)/\partial\tau$ was approximated by a forward difference relation and $\partial^2 Y(i,j)/\partial x^2$ by the mean of its finite difference approximations on the jth and $(j + 1)$th rows (13). The distance dependent sink term was

similarly averaged. This procedure allowed the $(j + 1)$th row of Y to be evaluated for all i from the predetermined values of $Y(i,j)$. It gave $(n - 1)$ simultaneous differential equations, which may be expressed in matrix form as:

$$\mathbf{D} \cdot \mathbf{Y} = \mathbf{K}$$

where $\mathbf{D}$ is a $(n - 1) \times (n + 1)$ matrix with elements

$$D_{l,k} = -1/2(\delta x)^2 \qquad k = l, l + 2$$
$$= 1/\delta\tau + 1/(\delta x)^2 + (\lambda^2/2) \exp(-2x_l) \qquad k = l + 1$$
$$= 0 \qquad k < l, k > l + 2$$

$\boldsymbol{Y}$ is an $(n + 1)$ dimensional column vector with elements $Y(i,j + 1)$ for $i = 0, 1, \ldots, n$ and $\boldsymbol{K}$ is an $(n - 1)$ dimensional column vector with elements

$$K(i) = Y(i + 1,j)/[2(\delta x)^2] + Y(i,j)(1/\delta\tau - 1/(\delta x)^2 - (\lambda^2/2) \exp(-2x_i)) + Y(i - 1,j)/[2(\delta x)^2]$$

for $i = 1, 2, \ldots, n - 1$. This generates $(n - 1)$ equations with $(n + 1)$ unknowns; the additional conditions $Y(0,j + 1) = 0$ and $Y(n,j + 1) = \beta R_{max}/2$ were employed and the equations solved by established computational techniques. Because of the large change in gradient at short times, the technique was modified to enable a change in the distance step, δx_1 to δx_2, to be made for integration at a given time. This required modifications in the equations defining $\partial^2 Y/\partial x^2$ at the changeover point from δx_1 to δx_2. Typically $\delta\tau$ was taken initially as 10^{-14} s and was then increased by a factor of 10 after 10 increments; this procedure was repeated until the profile became invariant (*i.e.* until the steady state was established). δx was taken as 0.2 nm for the first 25 steps in the space coordinate and then increased to 3.0 nm until R_{max} was reached. R_{max} was generally taken as 50.5 nm, although larger values were also used to test convergence. At very short times, some variation in δx was required to obviate oscillation.

The equations defining the rate constants ([6] and [7]) necessitated the generation of continuous profiles from the numerically evaluated mesh points. In order to avoid interpolations based on the extreme variations in $\rho(= S/S_0)$, a function Z was defined:

[A1] $$Z = \ln(\rho + 10^{-6})$$

which remains finite as $\rho \to 0$. The Z values at any distance between the mesh points were determined from a cubic fit. ρ was then found by inverting [A1]. Tunnelling rate constants were evaluated from [7] using Gauss's approximation (17), with an upper limit at R_{max}. Variation of the upper limit was used to check convergence. Gauss's approximation was also used to evaluate the electron decay. The diffusive rate constants were determined by evaluating the gradients of chords from the encounter distance to points on the concentration profile at decreasingly small distances from R. An approximate value of $\partial S/\partial r|_R$ was then obtained by extrapolation and hence $k_D(t)$ determined from [6].

Discussion

C. Jonah: What sort of change would one expect if one used the Waite or Noyes theory for reaction?

S. A. Rice: I do not know! I surmise that a good guess would be to replace the true (crystallographic) encounter distance by R_{eff}, for reactions which are only partially activation controlled. However, as the activation process becomes slower, so would I expect that electron tunnelling would also decrease in importance.

G. A. Salmon: Simple tunnelling models as applied to glassy systems have difficulties in accounting for differences between solutes. Does this present difficulties in computing rate constants for the fluid phase?

S. A. Rice: Providing this electron tunnelling model is treated as a phenomenological approach, the rigid glass and fluid regions are mutually consistent. Furthermore, the difficulties alluded to above refer, I believe, to comments of Buxton and Kemsley whose model of trap-to-trap tunnelling has very serious deficiencies. See also reply to J. Jortner.

P. K. Watson: A basic assumption in this work is that the motion of an electron diffusing towards a scavenger molecule is characterized by a constant diffusion coefficient. It is important to question whether a constant D is appropriate at molecular distances, where an electron will strongly polarize its environment, and nonhomogeneous surroundings will result in asymmetrical local fields. Presumably as an electron diffuses in the environment of a polarizable molecule there is an approach distance at which the self-induced field due to the electron will be large enough to complete with the motion due to kT, and in this case a biased random walk of the type discussed by Chandrasekhar will be appropriate. An extension of this idea is to consider the effect of local traps on the electron motion (one envisages this trap as being due to local polarization). Calculations by Scher and Montroll on stochastic hopping transport have described the motion of a charged particle in a trapping environment, with an applied electric field. They

show that carrier motion can be described by a diffusion-like process defined by a distribution of waiting time $\psi(t)$ between hops and in which the average jump distance $\bar{l}$ is field-dependent. This model has been very successful in describing, for example, the motion of a carrier packet moving in high fields in amorphous semiconductors.

S. A. Rice: The diffusion motion of charged species in water has been shown to be a reasonable approach for times of picoseconds or more. Polarization of solvent molecules and of scavenger by an electron is probably insignificant in highly ionic aqueous systems which have been alluded to above. Dainton studied the effect of ionic strength on electron – ionic scavenger reaction rates and found accord with the Bronsted–Bjerrum theory; for short times the electron can react without a relaxed ionic solvation shell and so is not so strongly screened. In ethers and alkanes solvent and scavenger polarization effects may have to be considered, I concede.

J. Jortner: I would like to comment on the interesting suggestion regarding the possible applicability of the Montroll–Scher theory to diffusion controlled reactions of the solvated electron. Montroll and Scher address themselves to electron–hole recombination in an amorphous semiconductor where the transport process involves thermal excitation to the mobility edge. In the case of the solvated electron transport occurs via a "hydrodynamic drag" and solvent short-range configurational charges. It is thus questionable whether the amorphous semiconductor recombination is directly applicable to the problem at hand.

There is, however, one analogy between the two systems which deserves serious consideration. The electron–hole recombination in amorphous semiconductors involves a multiphonon process. The same picture should be applied to describe the reactions of the solvated or trapped electron. The electron tunnelling picture applied by S. A. Rice, J. Miller, and A. C. Albrecht provides a grossly oversimplified picture for such reactions. As is well known, configurational nuclear charges have to be explicitly introduced in the electron transfer process and the electron follows adiabatically the motion of the nuclei. Such a picture for electron-transfer bears a close analogy to small polaron motion in solids. The Forster–Dexter intermolecular energy transfer and intramolecular radiationless transitions can be described within the framework of a unified approach which rests on the theory of multiphonon processes. The dependence of the electron transfer transition probability or the separation r of the solvated or trapped electron and of the electron acceptor is of the functional form $\exp(-\beta r)$, which is, of course, identical to that obtained from the tunnelling argument. However, the pre-exponential factor (and temperature dependent factors) in the general correct theory involve Franck–Condon vibrational overlap terms, which cannot and should not be disregarded in quantitative application.

S. A. Rice: While the approach of Kestner, Logan, and Jortner to electron transfer processes is elegant, it does not seem to reproduce the observed transfer probability as a function of electron-scavenger distance. The pre-exponential factor α' (containing information about Franck–Condon factor, density of states, and electronic coupling) does not appear to depend on the identity of the electron scavenger. Surprisingly, far better agreement between theory and experiment is obtained if β is dependent on the scavenger, and α is held constant at 10^{14} Hz (Rice and Pilling). Until this paradox is resolved advances in a quantitative description of the electron transfer probability are in danger of stagnating.

K. Funabashi: When the electronic energy separation between the initial and final states is much greater than their interaction energy, the electron transfer cannot be termed as 'tunnelling' which implies the driving force is essentially electronic. Apart from this semantic objection, long-range transfer process over 50 Å is not realistic in molecular solids. An alternative mechanism may involve some hopping motion of localized electrons in disordered or random lattice (Sher, Montroll, Ambegaoker, Halpern).

S. A. Rice: That an enhancement to the Smolchowski rate constant in liquids appears to correlate with electron tunnelling in glasses, suggests that the long-range (non-diffusive) motion of the electron is not associated with the thermally activated mobility of electrons discussed by Scher and Montroll.

Kinetics of electron capture by SF_6 in solution[1]

Received September 27, 1976

JAMES K. BAIRD. Can. J. Chem. **55**, 2133 (1977).

We present a theory of the rate constant for electron capture by SF_6 when it is dissolved in liquid hydrocarbon and condensed rare gas solvents. The theory includes the effects of diffusion and solvation on the observed rate. Also included is the effect of the long-range polarization force acting between the electron and the SF_6 molecule. The role of the solvent molecules in modifying this force is taken into account by use of a dielectric screening function. The theory is applied with semiquantitative success to electron capture data in the solvents: methane, ethane, propane, butane, *n*-pentane, neopentane, *n*-hexane, cyclohexane, isooctane, tetramethylsilane, argon, and xenon.

JAMES K. BAIRD. Can. J. Chem. **55**, 2133 (1977).

On présente une théorie de la constante de vitesse de la capture de l'électron par SF_6 quand il est dissout dans un hydrocarbure liquide et dans des gas rares condensés agissant comme solvant. La théorie inclut les effets de diffusion et de solvatation sur les vitesses observées. On inclut aussi l'effet de la force de polarisation à longue distance agissant entre l'électron et la molécule de SF_6. On tient compte du rôle des molécules de solvant dans la modification de cette force en faisant appel à une fonction d'écran diélectrique. On a appliqué la théorie avec des succès semiquantitatifs pour des données de capture d'électron dans les solvants méthane, éthane, propane, butane, *n*-pentane, néopentane, *n*-hexanne, *c*-hexanne, isooctane, tétraméthylsilane, argon et xénon.

[Traduit par le journal]

Introduction

A number of measurements have recently been reported of the rate of electron capture by sulfur hexafluoride dissolved in various liquid hydrocarbons and condensed rare gases (1–3). Electrons were introduced into the solutions by the method of pulse radiolysis. In the experiments of Sowada *et al.* and Bakale *et al.*, for example, it was found that the electron current in the solutions decreased with time at a rate which was proportional to the sulfur hexafluoride concentration. The decay was taken to be evidence for a bimolecular reaction between an electron and a sulfur hexafluoride molecule. In discussion of these measurements, it is helpful to summarize first the relevant information which is known concerning the process whereby SF_6 captures electrons in the gas phase.

The often-proposed mechanism for the gas phase process is

$$[1a] \qquad e^- + SF_6 \underset{\tau^{-1}}{\overset{k}{\rightleftarrows}} SF_6^{-*}$$

$$[1b] \qquad SF_6^{-*} + M \xrightarrow{k_1} SF_6^- + M$$

$$[1c] \qquad SF_6^{-*} \xrightarrow{k_2} SF_5^- + F$$

where M is any third body, k is the rate constant for the formation of the compound negative ion SF_6^{-*}, τ is the autodetachment lifetime of SF_6^{-*}, k_1 is the rate constant for collisional stabilization, and k_2 is the rate constant for dissociative attachment. If the steady-state approximation $d[SF_6^{-*}]/dt = 0$ is applied, these equations give rise to an expression for the overall disappearance of the electrons

$$[2] \qquad \frac{1}{[e^-]}\frac{d[e^-]}{dt} = \frac{k(k_2 + k_1[M])[SF_6]}{\tau^{-1} + k_2 + k_1[M]}$$

The experimental value of the autodetachment lifetime, τ, of SF_6^{-*} is strongly dependent upon the conditions of measurement. Electron beam experiments, in which the electrons have an energy distribution with a width of about 0.1 eV, yield a lifetime of the order of 30 μs (4). Ion cyclotron resonance experiments where the electrons can have even lower energies, however, give a lifetime in the range 0.3–2 ms (5). The dissociative attachment rate constant k_2 is

[1] By acceptance of this article, the publisher or recipient acknowledges the U.S. Government's right to retain a non-exclusive, royalty-free license in and to any copyright covering the article.

characterized by an activation energy of approximately 0.43 eV (6) and is thus negligibly small for capture experiments carried out near room temperature. In experiments where a buffer gas M is present at a pressure of approximately 1 Torr or greater, the rate of collisional stabilization (eq. 1*b*) dominates the other rates leading to the destruction of SF_6^-*. Under this circumstance $k_1[M] + k_2 \gg \tau^{-1}$, so that

$$[3] \qquad d[e^-]/dt = -k[SF_6][e^-]$$

Thus, the forward reaction in [1*a*] is the rate-determining step, and the observed rate constant is equal to k. Experiment has shown that k is independent of temperature in the range 293 to 523 K (4, 6). The arithmetic mean of 23 reported experimental values is $k = (2.1 \pm 0.6) \times 10^{-7}$ cm^3/s (4, 6, 7). A careful analysis of the present state of our understanding of the SF_6 gas phase electron capture process has been given recently by Klots (8).

When the attachment experiment is run with sulfur hexafluoride dissolved in a liquid solvent, the solvent becomes the third body in the highest concentration capable of collisionally stabilizing the compound negative ion. Since collisions of SF_6^-* with the molecules of the solvent can be expected to be very frequent, the forward reaction in [1*a*] can be expected to remain the rate-determining step. This will be a basic assumption in what follows. Aside from this similarity between the gas and liquid phase attachment mechanisms, one can imagine at least two differences. (*1*) The rate of diffusion of electrons through the solvent may be slow enough to affect the observed values of the forward and backward rates in [1*a*]. (*2*) Assuming for the moment that the equilibrium constant of [1*a*] could be measured, the position of equilibrium will be shifted in the liquid phase toward the side of the reaction with the smaller Gibbs free energy of solution.

In the following sections of this paper, we will examine in detail these two effects.

Effect of Diffusion on Kinetics

The significance of diffusion may be seen by comparing (*a*) the electron velocity correlation length with (*b*) the distance which an electron travels before it meets a sulfur hexafluoride molecule. The velocity correlation length λ is the distance which an electron must travel in order to have suffered a sufficient number of collisions with the solvent molecules that its velocity is no longer correlated with its initial velocity. We let the correlation length serve as a measure of scale. A process which requires for its completion a dimension large compared with λ is considered to be macroscopic; otherwise, microscopic. An equation for λ is

$$[4] \qquad \lambda \approx (2\mu/e)(mk_BT)^{1/2}$$

where k_B is the Boltzmann constant, T the absolute temperature, and e, m, and μ are, respectively, the charge, the mass, and the mobility of the electron (9).

Calculation with measured values of the mobility (1, 2) shows that for ethane, propane, butane, *n*-pentane, *n*-hexane, and cyclohexane (hereafter called 'group 1 liquids'), λ is less than 1 Å. This distance is smaller than one molecular diameter and probably indicates that the electron spends part of its time in potential traps in these solvents as has often been postulated (10). For the solvents isooctane, neopentane, tetramethylsilane, methane, argon, and xenon (hereafter called 'group 2 liquids') under the conditions of the capture experiments (1, 2, 3), λ lies in the range 1.7 to 1074 Å. If we assume a uniform distribution of molecules in the solution, each SF_6 molecule finds itself at the center of spherical volume of solvent of radius $R = (3/4\pi[SF_6])^{1/3}$. In the experiments of Allen *et al.* (1) the SF_6 concentration varied little from 10^{-7} *M*. In the experiments of Bakale *et al.* (2) and Sowada *et al.* (3), the SF_6 concentration was adjusted so that in each solvent the electron current decayed with a characteristic time θ of approximately 30 ns. Hence, since $[SF_6] \gg [e^-]$, we have $k_s[SF_6] = \theta^{-1}$, where k_s is the observed rate constant. Numerical evaluation of R readily shows that $\lambda < R$ for all the experiments. We may conclude, therefore, that the capture of an electron takes place on a macroscopic scale and choose to describe its transport by use of diffusion theory.

Our analysis of diffusion follows the methods first introduced by Smoluchowski to treat the problem of coagulation of colloids and later extended by Debye to the problem of reaction kinetics in ionic solutions (11, 12).

Differential Equations

We begin by establishing a coordinate frame with center at the nucleus of the sulfur atom in SF_6. The SF_6 molecule is assumed to occupy

the spherical region $0 \leq r \leq \rho$, where r is the radial coordinate, and ρ is the SF_6 molecular radius. The region $\rho < r < \infty$ outside this sphere is assumed to be occupied by the solvent. An electron is regarded as being generated in the solvent at time $t = 0$ and diffusing toward the SF_6 molecule. Under the assumption that there are no sinks nor sources of electrons within the region $\rho < r < \infty$, Fick's laws of diffusion take the form

$$[5a] \qquad \frac{\partial c(\boldsymbol{r}, t)}{\partial t} + \nabla \cdot \phi(\boldsymbol{r}, t) = 0$$

$$[5b] \qquad \phi(\boldsymbol{r}, t) = -D\nabla c(\boldsymbol{r}, t) + c(\boldsymbol{r}, t)\boldsymbol{w}(\boldsymbol{r})$$

where $c(\boldsymbol{r}, t)$ is the electron concentration, $\phi(\boldsymbol{r}, t)$ is the electron flux, and $\boldsymbol{w}(\boldsymbol{r})$ is the electron drift velocity specified by

$$[6] \qquad \boldsymbol{w}(\boldsymbol{r}) = -\mu\nabla V(\boldsymbol{r})$$

In [6], $V(\boldsymbol{r})$ is the electrostatic potential of interaction of the electron with the SF_6 molecule. Since the center of coordinates lies at the center of the SF_6 molecule, the diffusion coefficient D in [5*b*] is given by

$$[7] \qquad D = D_{SF_6} + D_e$$

where D_{SF_6} is the coefficient for diffusion of a molecule of SF_6 through the solvent, and D_e is the coefficient for diffusion of an electron (13, see especially p. 61). For the solvents and temperatures we shall consider $D_{SF_6} \simeq 10^{-5}$ cm^2 s^{-1}, while $D_e > 10^{-4}$ cm^2 s^{-1}. Hence, we may conclude $D \simeq D_e$.

An analytical solution of [5] and [6] including both space and time dependence has yet to be obtained (11). However, a simplification can be achieved by reasoning as follows. Soon after the production of electrons by the pulse radiolysis, the initial electron concentration distribution dissipates, and the electron capture process reaches a steady state specified by $\partial c(\boldsymbol{r}, t)/\partial t = 0$. The time required for the approach to the steady state to be complete is of the order of $R^2/4D$ (11). Using experimental values for D (1, 2, 3), we find that in all experiments the steady state is achieved in times no longer than a few nanoseconds. These times are to be compared with $\theta = 1/k_s[SF_6]$. In the experiments of Bakale *et al.* (2) and Sowada *et al.* (3), for example, we noted previously that $\theta = 30$ ns. Since $\theta \gg R^2/4D$, we are fully justified in ignoring all explicit dependence on the time in [5]. In the steady state, substitution of [5*b*] into [5*a*] leads to

$$[8] \qquad \nabla^2 c(\boldsymbol{r}) + (1/k_B T)\nabla U(\boldsymbol{r}) \cdot \nabla c(\boldsymbol{r}) + (1/k_B T)c(\boldsymbol{r})\nabla^2 U(\boldsymbol{r}) = 0$$

which has been simplified by using the Nernst–Einstein relation

$$[9] \qquad \mu/D = e/k_B T$$

and by making the identification $U(\boldsymbol{r}) = e \cdot V(\boldsymbol{r})$. For the case of a sulfur hexafluoride molecule in the field of an electron, the leading term in the potential energy is

$$[10] \qquad U(r) = -\frac{1}{2}\frac{\alpha e^2}{r^4} f$$

where α is the SF_6 polarizability, and f is a screening function that expresses the diminution of the interaction between the SF_6 molecule and the electron due to the presence of the solvent (14, 15). The next lowest term in the potential energy is due to the interaction of the electron with the permanent hexadecapole moment of SF_6 and is the order of $1/r^5$ (16). This term, however, depends also upon the angular coordinates represented in $\boldsymbol{r}$ and leads to additional mathematical complications. Hence in what follows we shall ignore the hexadecapole term.

Inasmuch as $U(\boldsymbol{r})$ in [10] represents a central potential (depends only upon the magnitude of $\boldsymbol{r}$), eq. 8 simplifies to

$$[11] \qquad \frac{d}{dr}\left[r^2 \frac{dc(r)}{dr}\right] + \left(\frac{1}{k_B T}\right)\frac{d}{dr} \times \left[c(r)\left(r^2 \frac{dU(r)}{dr}\right)\right] = 0$$

Boundary Conditions

For the solution of [11], two boundary conditions are required. The first is

$$[12] \qquad \lim_{r \to \infty} c(r) = c(\infty)$$

where $c(\infty)$ is the bulk concentration of electrons, *i.e.*, that concentration measured at large distance from the SF_6 molecule. The second boundary condition is either of the two equations

$$[13a] \qquad 4\pi\rho^2\phi(\rho) = -k(\rho)c(\rho)$$

$$[13b] \qquad \lim_{r \to \infty} 4\pi r^2\phi(r) = -k(\infty)c(\infty)$$

where $k(\infty)$ is the scavenger rate constant observed at $r = \infty$, and $k(\rho)$ is a rate constant

determining the disappearance of electrons at $r = \rho$. Since there are no sources nor sinks of electrons within the region $\rho < r < \infty$, the quantity $4\pi r^2\phi(r)$ must be a constant independent of r. Hence,

$$[14] \qquad k(\rho)c(\rho) = k(\infty)c(\infty)$$

Relation Between $k(\rho)$ and $k(\infty)$

Subject to the above boundary conditions, the solution to [11] is

$$[15] \quad c(r) = c(\infty)\exp(-U(r)/k_BT) - \frac{k(\infty)c(\infty)}{4\pi D}\exp(-U(r)/k_BT) \times \int_r^\infty \exp(U(x)/k_BT)x^{-2}\,dx$$

We may use [14] and [15] to eliminate the ratio $c(\rho)/c(\infty)$ to obtain the relation

$$[16] \quad \frac{1}{k(\infty)} = \frac{1}{4\pi D\rho^*} + \frac{1}{k(\rho)\exp(-U(\rho)/k_BT)}$$

where ρ^* is the 'effective capture radius' (12) given by

$$[17] \quad \frac{1}{\rho^*} = \int_\rho^\infty \exp(U(x)/k_BT)x^{-2}\,dx$$

If in [10], $f > 0$, then $\rho > \rho^*$; if $f < 0$, then $\rho < \rho^*$.

In the limit that the reaction is diffusion controlled ($D \to 0$), $k(\infty)$ takes on the value k_d

$$[18] \qquad k_d = 4\pi D\rho^*$$

In the limit that the kinetics are homogeneous ($D \to \infty$), *i.e.*, the rate of reaction is determined by the rate of encounters between electrons and SF_6 molecules, $k(\infty)$ takes on the value k_h

$$[19] \qquad k_h = k(\rho)\exp(-U(\rho)/k_BT)$$

Condition of Equilibrium

The condition of equilibrium is attained when each separate elementary reaction in the mechanism is at equilibrium (17). Consider [1*a*] occurring in the liquid phase. We introduce lifetimes $\tau(\rho)$ and $\tau(\infty)$ to account for any difference between lifetimes evaluated at $r = \rho$ and at $r = \infty$, respectively. At equilibrium

$$[20a] \qquad k(\rho)\tau(\rho) = \frac{[SF_6^-{}^*]}{[SF_6]c(\rho)}$$

$$[20b] \qquad k(\infty)\tau(\infty) = \frac{[SF_6^-{}^*]}{[SF_6]c(\infty)}$$

At equilibrium there can be no net electron flux anywhere in the solution. Setting $\phi(r, t)$ to zero in [5*b*] and using the boundary condition [12], we find that

$$[21] \qquad c(r) = c(\infty)\exp(-U(r)/k_BT)$$

which is a Boltzmann distribution.

Combination of [16], [20], and [21] gives

$$[22] \quad \tau(\infty) = \tau(\rho)\left[1 + \frac{k(\rho)\exp(-U(\rho)/k_BT)}{4\pi D\rho^*}\right]$$

which is an expression relating the lifetimes, $\tau(\infty)$ and $\tau(\rho)$. Since the second term within the bracket in [22] is positive definite, we have $\tau(\infty) > \tau(\rho)$. Physically interpreted, this result means that the rate at which electrons appear at $r = \infty$ is much less than the rate at which they are produced at $r = \rho$ by autodetachment from $SF_6^-{}^*$. When an electron is emitted at $r = \rho$, there is a certain probability that it will be recaptured, since to reach $r = \infty$, it must diffuse against the action of the polarization potential $U(r)$. Hence, [22] evaluates the effect of 'secondary recombination' (32) on the decay of $SF_6^-{}^*$.

Effect of Solvation

By use of a thermodynamic cycle (29), one may show

$$[23] \quad \frac{k_h}{k} = \frac{\tau}{\tau_h}\exp[(\Delta G_s(e^-) + \Delta G_s(SF_6) - \Delta G_s(SF_6^-{}^*))/k_BT]$$

where we have defined

$$[24] \qquad \tau_h = \lim_{D\to\infty} \tau(\infty) = \tau(\rho)$$

as the lifetime for the case of homogeneous kinetics, and $\Delta G_s(e^-)$, $\Delta G_s(SF_6)$, and $\Delta G_s(SF_6^-{}^*)$ are the free energies for solution of e^-, SF_6, and $SF_6^-{}^*$, respectively. The gas phase quantities k and τ were previously defined by [1*a*]. Hence, we see that, the effects of diffusion aside, [1*a*] is shifted in the liquid phase toward the side of the reaction having the smaller Gibbs free energy of solution.

Comparison with Experiment

Calculation of ρ^* and k_h

To calculate ρ^* from [10] and [17], we need to establish the values of certain parameters. For ρ, the SF_6 radius, we take the value 2.92 Å, which is the sum of the S—F bond distance (1.57 Å) and the fluorine atom Van der Waal's radius (1.35 Å) (26, 27).

We may take for the polarizability of SF_6 either the static value $\alpha = 6.545$ Å^3 (28*a*) or the optical value $\alpha = 4.515$ Å^3 (28*b*) which was determined for electromagnetic radiation at 5460 Å. To establish the relevant value, we estimate the length of time during which the polarization interaction dominates the electron's motion through the solvent. The reciprocal of this time should be the order of magnitude of the natural frequencies of the sulfur hexafluoride molecule which are involved in interacting with the electron. The potential energy $U(r)$ becomes important when it equals the electron kinetic energy, $\frac{3}{2}k_BT$. From [10] we find that $|U(r)| = \frac{3}{2}k_BT$ at $r = r_c$, where

$$[25] \qquad r_c = \left(\frac{\alpha e^2 f}{3k_BT}\right)^{1/4}$$

The drift velocity of the electron is given by

$$[26] \qquad w = -\mu\frac{dV}{dr} = \frac{2\alpha e f}{r^5}\mu$$

The average drift velocity between r_c and ρ is

$$[27] \quad \bar{w} = 2\alpha e f\mu\left[\int_\rho^{r_c} r^{-5}\,dr\right]\left[\int_\rho^{r_c} dr\right]^{-1} = \frac{\alpha e f\mu}{2}\left(\frac{1}{r_c - \rho}\right)\left(\frac{1}{\rho^4} - \frac{1}{r_c^4}\right)$$

The time required for the electron to drift from $r = r_c$ to $r = \rho$ is

$$[28] \qquad t = \frac{r_c - \rho}{\bar{w}} = \frac{2\rho^2}{3D}\frac{[(r_c/\rho) - 1]^2}{[(r_c/\rho)^4 - 1]}$$

where we have used [9] to put μ in terms of D. For the temperatures we are considering (85–323 K) and either value of α, we find $r_c \sim 5$ to 7 Å. Taking $r_c \sim 6$ Å and applying [28], we find for group 1 liquids, $1/t \sim 10^{11}$ to 10^{13} s^{-1}. For these liquids, we choose to calculate ρ^* using the static value of α. For group 2 liquids, $1/t \sim 10^{14}$ to 10^{16} s^{-1}, so we choose the optical value of α.

To calculate ρ^*, we also need a formula for the electric dipole screening function, f. For a single component, nonpolar liquid without structure, Lekner has proposed the formula

$$[29] \qquad f = f_L = (1 + \tfrac{8}{3}\pi N_0\alpha_0)^{-1}$$

where α_0 and N_0 are, respectively, the electric dipole polarizability and number density of the molecules (14). In applying [29] to a solution, we assume that a solute molecule experiences the same dielectric screening as a solvent molecule. We identify the quantities N_0 and α_0 with the solvent molecules.

By use of the Clausius–Mossotti equation, the Lekner screening function may be put in the form

$$[30] \qquad f_L = (\varepsilon + 2)/3\varepsilon$$

where ε is the dielectric constant. We verified the validity of this substitution by testing the accuracy of the Clausius–Mosotti equation for the liquids under consideration. The densities of the liquids are known (18–20). Except for Ar and Xe, the electric dipole polarizabilities were calculated by addition of the appropriate atomic refractions (Landolt's rule) (21, 22). The polarizabilities of Ar and Xe are given in ref. 20. We used experimental values of the static dielectric constant ε or the sodium D line refractive index n_D ($n_D^2 = \varepsilon$, approximately for the hydrocarbons and the liquid rare gases) (23–25). We found that the Clausius–Mossotti equation was obeyed to within a few percent by all of the liquids except methane at 93 K where the error was 10%. Hence, we concluded that the replacement of $(8\pi/3)N_0\alpha_0$ in [29] by $(2\varepsilon - 2)/(\varepsilon + 2)$ was justified. For dilute solutions, the dielectric constant of the solution is very closely equal to the dielectric constant of the pure solvent; hence, in evaluating [30] for a solution, we identify ε with the dielectric constant of the solvent.

A screening function based upon a continuum dielectric model for a liquid has recently been proposed (15). It takes the form

$$[31] \quad f = f_1(u_1, \varepsilon) = \left(\frac{1}{u_1\varepsilon}\right) \times \left[\frac{u_1(\varepsilon + 2) - (\varepsilon - 1)}{(2\varepsilon + 1) - 2u_1(\varepsilon - 1)}\right]$$

This equation was also originally developed for a single component fluid. The parameter u_1 in that application referred to the properties of a single molecule, and the dielectric constant ε was taken to be that of the bulk fluid. In applying it to electron diffusion in solutions, we shall identify u_1 with the properties of the SF_6 molecule and take ε to be the dielectric constant of the pure solvent. We have $u_1 = \alpha/\rho^3$. The unit subscript was used in the original work to distinguish $f_1(u_1, \varepsilon)$ from the induced electric quadrupole screening function $f_2(u_2, \varepsilon)$, which was also derived, but which finds no immediate application here since the induced quadrupole potential is proportional to $1/r^6$.

The Lekner screening function, f_L, is positive definite, but $f_1(u_1, \varepsilon)$ is positive only for $\varepsilon < (1 + 2u_1)/(1 - u_1)$. When the screening function is positive, the integral in [17] can be related to the incomplete gamma function. When the screening function is negative, special techniques are required. The details of these calculations are given in the Appendix.

In [16], we identify $k(\infty)$ with the experimentally measured rate constant k_s and replace $k(\rho) \exp(-U(\rho)/k_B T)$ by k_h according to [19] to obtain

$$[32] \qquad \frac{1}{k_h} = \frac{1}{k_s} - \frac{1}{4\pi D\rho^*}$$

In what follows, we shall attempt to calculate k_h using experimental values of k_s and D in conjunction with values of ρ^* calculated on the basis of the Lekner and the continuum screening theories, respectively. We note that k_h, in contrast to k_s, contains none of the effects of diffusion.

Data Analysis Based on the Lekner Screening Function f_L

Our calculations based on the Lekner screening function (eq. 30) are summarized in Figs. 1 and 2.[2] For all liquids and conditions (1–3), we found that q defined by [A4] was greater than 10. Hence, ρ^* could be calculated to a high degree of accuracy from [A10*b*].

For the group 1 liquids (electron mobilities less than 1 $cm^2\ V^{-1}\ s^{-1}$), it was found that $4\pi D\rho^*$ was less than the experimental value of k_s. Hence, it made no sense to attempt to use [32] to calculate $1/k_h$, which must of necessity be positive definite. We assumed, instead, that in these liquids the reaction was diffusion controlled, *i.e.*, $k_s = k_d$. We calculated values of ρ^* from the experimental values of k_s and D using [18] and compared them with values of ρ^* calculated according to [A10*b*] as follows. From [A10*b*], it is clear that a plot of $\log_{10}(\rho^* f^{-1/4})$ as a function of $\log_{10} T$ forms a straight line of slope $-1/4$. For the liquids and range of temperatures under consideration (110 to 297 K), f as given by [30] is a weak function of ε, and hence T. Consequently, plots of $\log_{10} \rho^*$ *vs.* $\log_{10} T$ should also very nearly form straight lines. From Fig. 1, one may see that [A10*b*] reproduces the qualitative trend of the experimental data, but the calculated slope of $-1/4$ is smaller than the slope of the experimental data, which was determined by the method of least squares to be -1.2.

In Fig. 2, we have summarized our results for the group 2 liquids (electron mobility is greater than 1 $cm^2\ V^{-1}\ s^{-1}$). For these solvents we found that $4\pi D\rho^*$ was greater than k_s, so that it was possible to obtain a positive value for $1/k_h$ from [32]. The points are badly scattered, and the few trends that can be perceived are indicated by connecting the relevant points by curves.

Data Analysis Based on the Continuum Screening Function $f_1(u_1, \varepsilon)$

Our calculations based on the continuum screening function (eq. 31) are shown in Figs. 1 and 2.

Again, we found for the group 1 liquids that $4\pi D\rho^*$ was less than k_s. Hence, we chose to plot $\log_{10} \rho^*$ *vs.* $\log_{10} T$ under the assumption that the reaction was diffusion controlled. In most cases, we found q to be less than 3, so that ρ^* had to be calculated according to [A5] and [A7]. The theoretical points lie along straight lines because $I(q)$ is a rapidly converging series which is fairly well approximated by its first two terms only. A separate line is obtained for each liquid because $f_1(u_1, \varepsilon)$ is a much stronger function of ε than f_L (15), and the values of ε are different for different liquids. It is seen that the theoretical points derived from the continuum function lie along lines with positive slope while the experimental points show a trend characterized by a negative slope.

Our results for the group 2 liquids are shown in Fig. 2. In most cases, we found $f_1(u_1, \varepsilon) < 0$, and in a few cases were we able to determine a positive value for $1/k_h$. Because the continuum screening function in general predicts a less attractive polarization potential than does the Lekner screening function, we found that ρ^* was smaller when calculated from $f_1(u_1, \varepsilon)$ than when calculated from f_L. Hence, the values of k_h predicted by the continuum function are larger than those predicted by Lekner's function.

Discussion

We have seen that when we use the Lekner screening function, we are more often able to calculate a positive value of k_h than when we use the continuum screening function. Assuming

[2]A detailed summary of the relevant experimental data and all intermediate calculated quantities has been compiled in the form of tables. A complete set of tables is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

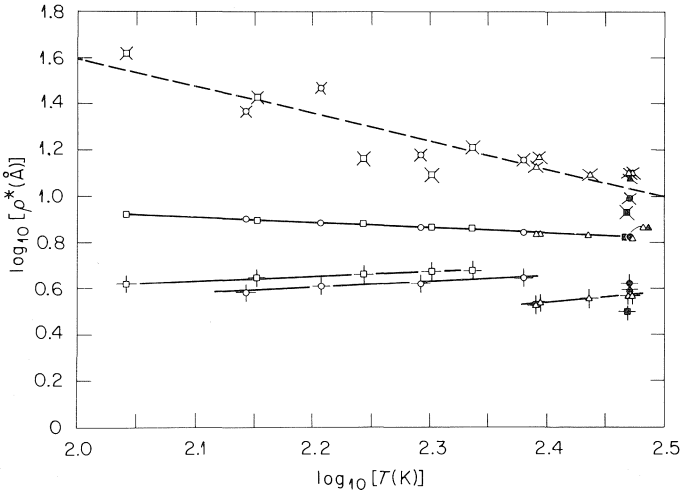

FIG. 1. Effective capture radius as a function of absolute temperature: □, ethane; ○, propane; ●, butane; ▲, *n*-pentane; △, *n*-hexane; and ■, cyclohexane. The plain symbols are points calculated from [A10*b*] with f given by the Lekner function (eq. 30). The symbols bearing crosses are points calculated from [A5] and [A7] with f given by the continuum function (eq. 31). In all calculations $\alpha = 6.545$ Å^3 and $\rho = 2.92$ Å. The symbols bearing the ×'s are based solely on experimental data (refs. 1–3) with ρ^* calculated from $\rho^* = k_s/4\pi D$.

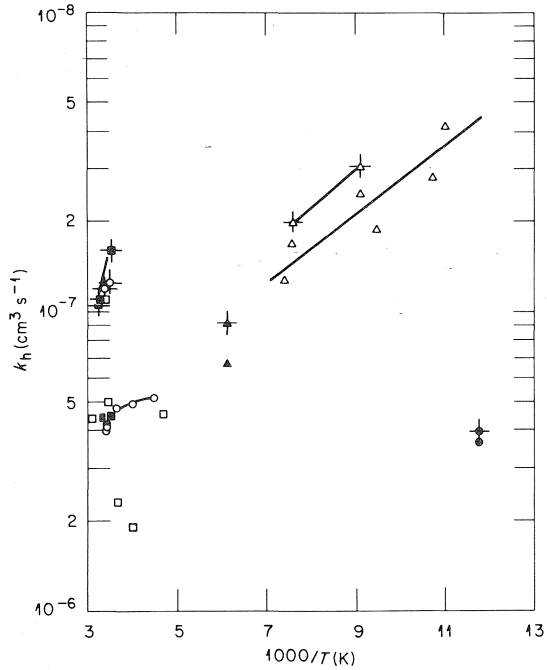

FIG. 2. Homogeneous rate constant as a function of absolute temperature: □, isooctane; ■, neopentane; ○, tetramethylsilane; △, methane; ●, argon; and ▲, xenon. All values of k_h were determined from [32] and experimental values of D and k_s (refs. 1–3). The plain symbols are points for which ρ^* was calculated using Lekner's screening function, while the symbols bearing the crosses are points calculated using the continuum screening function. In all calculations $\alpha = 4.515$ Å^3 and $\rho = 2.92$ Å.

that the capture rate is diffusion controlled in the group 1 liquids, we find that the Lekner screening function predicts a value of ρ^* which is uniformly too low, however. The values of ρ^* calculated on the basis of the continuum screening function are lower still. One may show that, even assuming the strongest attractive polarization potential possible ($f = 1$), eq. A10*b* gives values for ρ^* smaller than those observed experimentally. There are at least two possible causes. (*1*) The multipole expansion of the potential of interaction of the electron with the SF_6 molecule, of which $-\frac{1}{2}\alpha e^2 f/r^4$ is the leading term, may break down for values of r of the order of ρ; and (*2*) when the electron gets near the SF_6 molecule, it may tunnel through the solvent into the region $r < \rho$. Such a tunneling mechanism has already been proposed by Pilling and Rice (30). Until the role played by these two effects is examined, it would seem premature to rule in favor of the Lekner screening function.

Comparison of Different Scavengers

For the group 1 liquids, the electron mobility satisfies the empirical relation

$$[33] \qquad \mu = \mu_0 \exp(-E/k_B T)$$

where μ_0 is a constant independent of temperature and E is an activation energy (1). Assuming that the electron capture reaction is diffusion controlled, we may combine [A10*b*], [33], and

[9] to obtain for the case $q \geq 3$ the semiempirical equation

$$[34] \quad k_d = 4\pi D\rho^* = \frac{8\pi\sqrt[4]{8}}{\Gamma(1/4)}\mu_0 T^{3/4} \times (\alpha f_L k_B{}^3/e^2)^{1/4} \exp(-E/k_B T)$$

for k_d. For dilute solutions, the Lekner screening function depends upon properties of the solvent alone. Hence, if S_1 and S_2 are two different electron scavengers which interact with electrons at long range principally through the polarization force, one finds from [34] that for a given solvent and temperature

$$[35] \quad k_d(S_1)/k_d(S_2) = (\alpha(S_1)/\alpha(S_2))^{1/4}$$

where $k_d(S_1)$, $k_d(S_2)$, $\alpha(S_1)$, and $\alpha(S_2)$ are the respective polarizabilities and diffusion-controlled rate constants. Since $k_d(S_1)/k_d(S_2)$ depends upon the fourth root of $\alpha(S_1)/\alpha(S_2)$, one would expect to observe little difference in the scavenging power of S_1 and S_2.

Fluid Structure

For the case of liquid argon, Lekner's work provides us an opportunity to assess the role played by a fluid structure in determining ρ^*. Let us consider for the moment pure liquid argon and establish a coordinate system with origin at the nucleus of one of the atoms in the liquid. Call the radial distance from this atom to any other point in the fluid, r. Since the intermolecular force tends to attract a number of atoms into a coordination layer around any given atom in the fluid, the screening function will depend upon r. Lekner has shown that this screening function $f(r)$ satisfies an integral equation (eq. 11 of ref. 14) which involves the pair correlation function for the fluid. He took for his pair correlation function a form calculated from the Percus–Yevick equation for hard spheres. Lekner solved the integral equation for the screening function by numerical methods and obtained the plot shown in Fig. 3. Note that as r/β increases, where β is the Ar hard-core radius, that $f(r)$ approaches f_L (eq. 30). Remember that f_L is the screening function for a fluid without structure, *i.e.*, a fluid for which the pair correlation function $g(r)$ satisfies

$$[36] \quad g(r) = \begin{cases} 0, & r < 2\beta \\ 1, & r > 2\beta \end{cases}$$

The asymptotic relationship in Fig. 3 between $f(r)$ and f_L is due to the fact that there is no long-range order in the fluid.

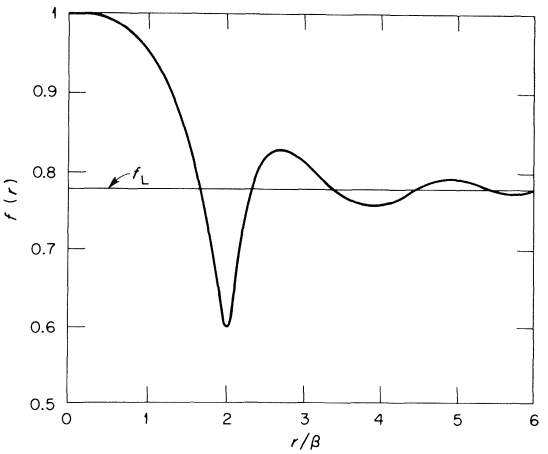

FIG. 3. Screening function $f(r)$ for liquid argon at 85 K. Hard-core radius $\beta = 1.72$ Å.

We now turn our attention to the case of sulfur hexafluoride dissolved in argon. The density of argon atoms in the vicinity of the SF_6 molecule is not known. In the absence of this information, we will make the following assumption. Although the SF_6 radius (2.92 Å) is significantly larger than the Ar hard-core radius (1.72 Å), we will assume that the radial distribution function which applies to an Ar atom in the pure liquid also applies to the SF_6 molecule. Consequently, we will assume that the screening function appropriate to an SF_6 molecule dissolved in liquid Ar is given by the $f(r)$ in Fig. 3 with $\beta = 2.92$ Å.

With this assumption, we have replaced f in [10] by $f(r)$ and evaluated the integral in [17] numerically. For comparison, we have plotted in Fig. 4 the integrand in [17] with f set equal to $f(r)$ and set equal to f_L, respectively. The small differences in these curves are due to the oscillations in $f(r)$. The areas under the two curves are nearly identical. When $f = f(r)$, we found $\rho^* = 8.42$ Å, while when $f = f_L$, we found from [A10*b*] $\rho^* = 8.45$ Å. Thus, we see that the liquid structure produces sizable oscillations in $f(r)$ which, however, tend to compensate each other in the calculation of ρ^* by [17]. Within the limitations of our assumption, we may conclude that the details of the liquid structure play no important role in determining the value of ρ^*.

Solvation

At this point it would be quite interesting to make a quantitative comparison between k_h and k using [23] and the results in Fig. 2. This comparison requires a knowledge of the free

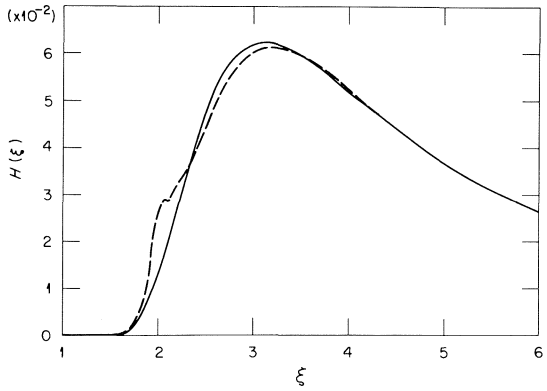

FIG. 4. Plot of the integrand of the ρ* integral (eq. 17) with potential given by [10]. The abscissa is $\xi = x/\rho$, and the ordinate is

$$H(\xi) = \xi^{-2} \exp(-p\xi^{-4} f(\xi))$$

where

$$\rho/\rho^* = \int_1^\infty H(\xi)\, d\xi, \quad p = (\alpha e^2/2k_B T\rho^4)$$

$\alpha = 4.515$ Å^3, $\rho = 2.92$ Å, and $T = 85$ K. Solid curve: $f(\xi) = f_L = (\varepsilon + 2)/3\varepsilon$ with $\varepsilon = 1.51$. Dashed curve: $f(\xi)$ is given by the curve in Fig. 3 with β set equal to ρ.

energies $\Delta G_s(SF_6)$, $\Delta G_s(SF_6^{-*})$, and $\Delta G_s(e^-)$. Methods of calculating these have been proposed recently by Henglein (33) and by Holroyd *et al.* (29). Quantitative evaluation of [23] is frustrated, however, because most of these estimates contain errors large compared with $k_B T$. Suffice it to say, however, that only k_h (not k_s) bears thermodynamic comparison with k. This is because diffusion is an inherently nonequilibrium process. According to [32], the effect of diffusion, which gives rise to the term $1/4\pi D\rho^*$, must be subtracted from $1/k_s$ before a result is obtained which depends only upon the equilibrium properties of solvent and solute.

Comparison with Other Theories

Henglein has given an electrochemical theory of electron capture in liquids (33). In this theory, the rate constant depends upon (*1*) the rate of encounters between the electrons and scavenger molecules, (*2*) the number of electrons per unit energy, and (*3*) the density of unoccupied electron acceptor levels in the scavenger. Henglein's rate constant most closely approximates k_h in the present theory.

Funabashi and Magee have used the Fermi golden rule of quantum mechanics to calculate the liquid phase rate constant for dissociative attachment of electrons to the solutes C_2H_5Br and CCl_4 (31). They have chosen to ignore the effects of diffusion on the rate constant and have thus limited their attention to solvents in which the electron mobility is much greater than 1 cm^2 V^{-1} s^{-1}. In cases where dissociative attachment is the rate-determining step, their calculation also represents an evaluation of a rate constant closely analogous to k_h in our theory. Both C_2H_5Br and CCl_4 interact with the electron through noncentral potentials, so that the treatment of diffusion we have used does not apply. It would be of interest, however, to combine the theory of Funabashi and Magee with a treatment of electron diffusion in a noncentral potential to give a general theory of dissociative attachment in the liquid phase.

Holroyd *et al.* (29) studied the kinetics of electron attachment to CO_2 in solution. In their theoretical analysis, they chose not to take into account the effect of the long-range interaction of the charge of the electron with the permanent quadrupole moment of the CO_2 molecule. They did, however, include the effect of the drift of the electron in an external electric field, a phenomenon not included by the present theory. A theory of electron diffusion combining the effects of the external field and the long-range electron–molecule forces is possible in principle. It would require, however, that noncentral potentials be dealt with as mentioned above.

Acknowledgements

The author would like to thank Dwight Russell for his help in preparing the tables and the figures. He would like to acknowledge some helpful discussions of the theory with C. E. Klots and V. E. Anderson.

Appendix: Calculation of ρ^*

Case I, $f > 0$

In order to evaluate the integral

$$[A1] \quad \frac{1}{\rho^*} = \int_\rho^\infty \exp\left(U(x)/k_B T\right) x^{-2}\, dx$$

where

$$[A2] \quad U(x) = -\frac{1}{2}\frac{\alpha e^2}{x^4} f$$

we let

$$[A3] \quad y = \frac{\alpha e^2 f}{2k_B T x^4}$$

and

$$[A4] \quad q = \frac{\alpha e^2 f}{2k_B T \rho^4} = \frac{|U(\rho)|}{k_B T}$$

The result of making these substitutions in [A1] is

$$[A5] \quad \rho^*/\rho = 4q^{1/4}/I(q)$$

where

$$[A6] \quad I(q) = \int_0^q y^{-3/4} e^{-y}\, dy$$

is an integral related to the incomplete gamma function. Values of $I(q)$ may be readily generated, however, without reference to the incomplete gamma function by expanding the exponential in the integrand and integrating term by term. The resulting sum is

$$[A7] \quad I(q) = 4q^{1/4} \sum_{n=0}^{\infty} \frac{(-1)^n q^n}{(4n+1)n!}$$

For $q \lesssim 10$, this sum converges after the evaluation of a few dozen terms. However, for $q \gtrsim 3$, $I(q)$ differs insubstantially from $\Gamma(1/4) = 3.6256....$ Consider

$$[A8] \quad \Gamma(1/4) = \int_0^\infty y^{-3/4} e^{-y}\, dy = I(q) + \int_q^\infty y^{-3/4} e^{-y}\, dy$$

Now

$$[A9] \quad \int_q^\infty \frac{e^{-y}}{y^{3/4}}\, dy < \int_q^\infty \frac{e^{-y}}{q^{3/4}}\, dy = q^{-3/4} e^{-q}$$

For $q = 3$, $q^{-3/4} e^{-q}$ has the value 0.022. Hence, for most practical purposes, we may conclude that for $q \gtrsim 3$,

$$[A10a] \quad \rho^*/\rho = 4q^{1/4}/\Gamma(1/4) = 1.103q^{1/4}$$

By combining [A4] and [A10*a*], we find that ρ^* is in fact independent of ρ and given by

$$[A10b] \quad \rho^* = \frac{4}{\Gamma(1/4)}\left(\frac{\alpha e^2 f}{2k_B T}\right)^{1/4}$$

Case II, $f < 0$

For this case, we let

[A11] $$q = \frac{\alpha e^2 |f|}{2k_B T \rho^4}$$

and

[A12] $$\rho^*/\rho = 4q^{1/4}/J(q)$$

where

[A13] $$J(q) = \int_0^q y^{-3/4} e^y \, dy$$

which is no longer equal to a gamma function as q goes to infinity. Hence, we rely on the series representation

[A14] $$J(q) = 4q^{1/4} \sum_{n=0}^{\infty} \frac{q^n}{(4n+1)n!}$$

to calculate $J(q)$.

Discussion

G. R. Freeman: We have recently estimated that the reaction of electrons with SF_6 in alcohols is not quite diffusion controlled. Does that agree with what you would predict?

J. K. Baird: I have difficulty in answering the question in the affirmative, because alcohols belong to the class of polar solvents. The theories of dielectric screening presently available (see refs. 14 and 15) refer exclusively to nonpolar liquids. A theory of dielectric screening in a polar solvent is conceivable, however.

A. O. Allen: Would your treatment account for the very high rate of reaction of solvated electrons (in water or alcohol) with iodine (I_2), which corresponds to a reaction radius of the order of 10 Å?

J. K. Baird: No. The reason is that I_2 possesses a permanent electric quadrupole moment which would give rise to the leading term in its interaction with the electron. The quadrupole gives rise to a noncentral potential and consequently introduces an angle variable into the Debye–Smoluchowski equation. The angular and radial parts of this equation might not be separable in such cases, which of course would constitute a major obstacle in finding its solution. I have thought about this problem but as of yet not had the opportunity to investigate it in detail.

J. M. Warman: Have you looked at other spherical molecules such as CCl_4 which has an attachment rate constant similar to that for SF_6 in the gas phase but displays different temperature behaviour to SF_6 in both the gas and liquid (TMS) phases?

J. K. Baird: Carbon tetrachloride has a permanent electric octupole moment which would compete with the molecular polarizability in attracting the electron. The octupole moment is likely to raise the same difficulty in solving the Debye–Smoluchowski equation as was indicated in my answer to Dr. Allen's question. However, like you, it is clear to me that an attack on the problem of diffusion of electrons in multipolar fields (especially the field of a permanent dipole) is necessary if the theory is to be compared with the bulk of the experimentally known rate constant values.

Electron reactivity in liquid hydrocarbon mixtures

TOSHINORI WADA, KYOJI SHINSAKA, HIDEKI NAMBA, AND YOSHIHIKO HATANO

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152, Japan

Received October 4, 1976

TOSHINORI WADA, KYOJI SHINSAKA, HIDEKI NAMBA, and YOSHIHIKO HATANO. Can J. Chem. **55**, 2144 (1977).

The electron current in neopentane–*n*-hexane mixtures, produced by a few nanoseconds X-ray pulse in the presence of external electric field, has been observed in the nanosecond–microsecond range. The form of the time dependence of the electron current has been shown to vary with dose per pulse and is analysed accordingly. The electron mobilities μ_e are thereby determined in the mixtures. The rate constant of electron–ion recombination, k_r, is proportional to the mobility over the wide range of μ_e. The rate constant for electron scavenging, k_s, by CCl_4 varies with $\sqrt{\mu_e}$; k_s for C_2H_5Br shows a maximum for a mixture with the mole fraction of *n*-hexane, $x_h = 0.48$. The results for k_s obtained for the mixtures agree with those by Allen and co-workers for various neat hydrocarbons. Further, the mechanism of electron transport in non-polar liquids is discussed. Using experimental results for V_0 and E_a for the mixtures (the energy of the electron in its quasifree state and the activation energy of μ_e, respectively) V_0 is expressed by a linear function of E_a: $V_0 = -0.42 + 2.6E_a$ at room temperature and μ_e is correlated with V_0 as an empirical formula $\mu_e = 125/[1 + 360 \exp(15V_0)]$ based on a trapping model.

TOSHINORI WADA, KYOJI SHINSAKA, HIDEKI NAMBA et YOSHIHIKO HATANO. Can. J. Chem. **55**, 2144 (1977).

On a observé le courant d'électrons qui se produit, dans l'écart de nanosecond–microsecond dans des mélanges de néopentane–*n*-hexane soumis à une pulsation de quelques nanoseconds de rayon-X en présence d'un champ électrique externe. On a démontré que la forme de la relation qui existe entre le temps et le courant d'électrons varie avec la dose par pulsation et on l'a analysée en conséquence. On a déterminé les mobilités électroniques, μ_e, des mélanges. La constante de vitesse de la recombinaison électron–ion, k_r, est proportionnelle à la mobilité sur un grand écart de μ_e. La variation de la constante de vitesse, k_s, pour le piégeage des électrons par CCl_4 est pratiquement proportionnelle à $\sqrt{\mu_e}$; k_s pour C_2H_5Br présente un maximum pour un mélange avec une fraction molaire de *n*-hexane $x_h = 0.48$. Les résultats obtenus pour k_s pour les mélanges sont en accord avec ceux de Allen et coll. pour divers hydrocarbures à l'état pur. De plus, on discute du mécanisme de transport d'électrons dans des liquides nonpolaires. Utilisant des résultats expérimentaux pour V_0 et E_a pour des mélanges, qui sont respectivement l'énergie de l'électron dans son état pratiquement libre et l'énergie d'activation de μ_e, on peut exprimer V_0 par une fonction linéaire de E_a: $V_0 = -0.42 + 2.6E_a$ à la température de la pièce et μ_e est relié avec V_0 par une formule empirique $\mu_e = 125/[1 + 360 \exp(15V_0)]$ qui est basée sur un modèle de piégeage.

[Traduit par le journal]

Introduction

Recently the behavior of electrons in non-polar liquids, especially in liquid hydrocarbons, has received great attention among radiation chemists, mainly with respect to electron transport phenomena (1–4) and electron reactivities (5–9).

The mobility μ_e has been measured for a large number of liquid hydrocarbons. It has been found that μ_e depends strongly upon the molecular structure of the solvent molecule: μ_e in neopentane is about three orders of magnitude greater than that in *n*-hexane. It has been suggested by Freeman and co-workers (4) that the electron mobility tends to be larger when the solvent molecule is more spherical. The temperature dependence of μ_e has also been investigated and it provides important information about the mechanism of electron transport in liquid hydrocarbons (1, 2). In addition the energy required to inject an electron from the vacuum into the liquid, V_0, has been measured by Holroyd *et al.* (10) for various hydrocarbons. The quantity V_0 is assumed to be the electron potential energy in the conducting state with respect to that *in vacuo* and it has been correlated with the electron mobility. It has generally been accepted that the mechanism of electron transport in liquid hydrocarbons can be explained in terms of two essentially different states for

electrons: a localized or trapped state and a delocalized or quasifree state. A suitable configuration of a group of molecules at a particular site in the liquid provides a region of low potential energy for an electron, where the electron is localized until it is thermally activated into the quasifree state. The electron transport takes place through a succession of migrations from one trap to another as a conduction electron. This mechanism has been referred to as a trapping model (1, 2).

The rates of electron scavenging and of electron–ion recombination have been measured in liquid hydrocarbons with different molecular structures. It has been found that the reactivity of the electron toward scavengers differs significantly from one solvent to another. In cyclohexane the absolute rate constants of free electron scavenging, k_s, as well as the efficiencies of geminate electron scavenging reported by Klein and Schuler (11), depend very little upon the nature of the scavengers (7, 8). In neopentane, on the other hand, a noticeable difference among the relative values of k_s was first observed by Hatano and co-workers (12) from experiments on the competitive free electron scavenging of N_2O with various scavengers. Allen and co-workers (8) have also pointed out that in neopentane and tetramethylsilane the value of k_s is largely dependent upon scavengers. Beck and Thomas (6*a*) have correlated k_s for biphenyl in several hydrocarbons with the electron mobility and found that k_s varies rather closely with the square root of μ_e. Allen *et al.* (8*b*) have correlated k_s for various scavengers in different hydrocarbons and tetramethylsilane with the quantity V_0, where CCl_4 and C_2H_5Br show the two typical correlations of k_s *vs.* V_0. The value of k_s for CCl_4 increases monotonically with decreasing V_0 (or increasing μ_e), while k_s for C_2H_5Br exhibits a maximum for a characteristic value of V_0. To elucidate theoretically these apparent anomalies Funabashi and Magee (13) have proposed a model where electron scavenging in high-mobility liquids is treated as an electron capture process which is completely analogous to the gas phase process.

In most experiments carried out so far the quantities μ_e, V_0, and k_s have been determined for various *neat* hydrocarbons with different molecular structures and correlated with each other as mentioned above. For hydrocarbon *mixtures*, on the other hand, the values of k_s are almost unknown, although the quantities μ_e (2*b*) and V_0 (10*d*) have already been determined as a function of the mole fraction of the component. In this work we have determined, using conductivity techniques, the values of k_s for CCl_4 and C_2H_5Br in neopentane–*n*-hexane mixtures, where μ_e and k_r, the rate constant of electron–ion recombination, are also measured. By mixing a suitable amount of the two hydrocarbons, one can obtain a solution adjusted to a desired μ_e or V_0. Further, the mechanism of electron transport in non-polar liquids is discussed on the basis of the experimental results obtained for the mixtures.

Experimental

Materials

Neopentane (>99.94 mol% pure) and *n*-hexane (>99.99 mol% pure) were Phillips Research Grade. These were used after further treatment as follows. Each hydrocarbon was stirred under vacuum with concentrated H_2SO_4 for 20 h, with NaOH pellets for 4 h, with $LiAlH_4$ powder for 4 h, and with Na–K alloy for 20 h, then transferred into a measuring cylinder with which the volume of the liquid was measured at room temperature. Known volumes of each hydrocarbon were transferred into a vessel and mixed together. After a final purification with Na–K alloy for 10 h, the mixture was introduced under high vacuum ($\sim 10^{-6}$ torr) into a conductance cell.

Carbon tetrachloride (Merck, 99.8%) and ethyl bromide (Tokyo Kasei, >99%) were used as solutes after the usual degassing.

Conductance Cell[1]

Circular plates of stainless steel were placed in parallel, having an interelectrode distance of 3.5 mm. The collecting electrode had an area of 7.8 cm^2 and was protected by a guard ring from edge effects. The electrodes were sealed in a glass envelope which had a reservoir of 50 ml and a side arm with several break-seals. The conductance cell was coated on the outside surface with Ag paint to shield it from electromagnetic effects.

Conductivity Measurements

The apparatus used for conductivity measurements is schematically shown in Fig. 1. The conductance cell containing a sample was set in the shielded box. A potential difference of -1000 V, unless otherwise mentioned, was supplied to the high voltage electrode by a FLUKE 415B high voltage power supply through a low pass filter (8 kHz). The sample between the electrodes was irradiated with a few nanosecond pulse of X-rays through a window surrounded by lead bricks of 5 cm thickness. The single pulse of X-rays was generated by an impinging pulse of 0.6 MeV electrons from a Febetron 706 accelerator on 0.1 mm tungsten foil (14). The electron current induced in the external circuit of the cell was observed by an oscilloscope (Tektronix 454A MOD 163D,

[1]The conductance cell used in this experiment is the same type as illustrated in ref. 4*c* except for some modification.

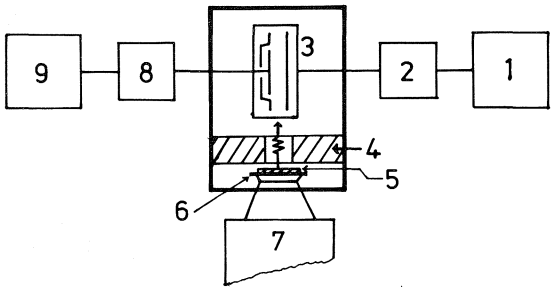

FIG. 1. Schematic representation of the apparatus: (*1*) high voltage power supply, (*2*) 8 kHz low pass filter, (*3*) conductance cell, (*4*) lead brick of 5 cm thickness, (*5*) lead plate of 0 to 8 mm thickness, (*6*) tungsten foil, (*7*) Febetron 706 accelerator, (*8*) 1 MHz amplifier, (*9*) 60 MHz oscilloscope.

150 MHz) through a signal filter (3 MHz) if necessary, or by an oscilloscope (Tektronix 5403-D44, 60 MHz) with an amplifier (Tektronix 5A26, 1 MHz) for measurements of the smaller current. The oscilloscope was connected to the collecting electrode by a coaxial cable with a 50 Ω termination. The conductivity measurements were carried out at room temperature (296 ± 3) K.

Dosimetry

The conductance cell was placed 11 cm from the tungsten foil. The dose absorbed by the sample was measured by a film-badge or a thermoluminescent dosimetry. Since the pulse intensity at a charging voltage of 25 kV varied from pulse to pulse with about ±10% fluctuation, the absorbed dose and the conductivity were determined by averaging the results of several runs. It should be noted that a single pulse of X-rays from Febetron 706 delivers a large dose to the sample in comparison with that from other accelerators. The highest pulse dose obtained in this experiment was 160 mrad. We could obtain any pulse dose desired by attaching a lead plate of 0 to 8 mm thickness to the tungsten foil (Fig. 1).

Addition of Solutes

A small space (1.24 ml) between two valves was filled with vapor (0.1 torr) of CCl_4 or C_2H_5Br. This small amount of the additive was transferred onto the frozen mixture in the conductance cell through the side arm. Then the cell was sealed off. After melting, the cell was inverted several times to dissolve the solute in the solvent. The method for additive transfer to the cell was checked by gas chromatography using a flame ionization detector. To prepare samples of various concentrations additional solute was added after each run to the mixture of 30 ml. It was assumed that the added solute dissolved completely in the liquid phase.

Results and Discussion

Rate Constants of Electron–Ion Recombination in Pure Neopentane and in Neopentane–n-Hexane Mixtures

The decay of the conductivity signal shown in Fig. 2 was observed when neopentane was irradiated with a pulse of X-rays at the highest pulse dose (160 mrad). Reducing the absorbed dose D, the initial half-life of decay $t_{1/2}$ becomes longer in proportion to log $(1/D)$, and at a pulse dose below 10 mrad it assumes a constant value (475 ± 15 ns) as shown in Fig. 3.

The electron current $I_e(t)$ observed following a pulse of X-rays is given by

$$[1] \qquad I_e(t) = \frac{eA\mu_e E}{d}\int_0^d n_e(x,t)\,dx$$

where e is the electron charge, A the area of the collecting electrode, d the distance between electrodes, E the applied field strength, and n_e the electron concentration at the distance x from the collecting electrode. The change in the electron concentration should be described by

$$[2] \quad -\left(\frac{\partial n_e}{\partial t}\right) = \mu_e E\left(\frac{\partial n_e}{\partial x}\right) + k_{tr}n_e + k_r n_e n_+ + k_s[S]n_e$$

The first term on the right hand side of [2] represents the contribution due to drifting of electrons to the collecting electrode in the presence of an external field. The second term is due to conversion of high-mobility electrons to negative charge carriers of lower mobility with the rate constant k_{tr}, possibly by attachment to residual impurities which might remain even after rigorous purification described in the Experimental section. The third is due to electron–ion recombination with the rate constant k_r, where n_+ is the concentration of positive ions. The last term is due to electron scavenging by a solute S with the rate constant k_s. In case of neopentane, the last term of [2] is eliminated. Reducing the pulse dose makes the contribution of the third term of [2] to the observed decay rate less important, because both n_+ and n_e become smaller in proportion to the absorbed dose. At the lower dose rate where $t_{1/2}$ assumes a constant value, the observed decay may be ascribed to only the first two terms of [2].

If only the first two terms of [2] contribute to the decay, the electron current is given by

$$[3] \quad I_e(t) = I_0\left(1 - \frac{\mu_e E t}{d}\right)\exp(-k_{tr}t)$$

where I_0, the peak current at the end of the pulse, is equal to $eA\mu_e E n_0$, where n_0 is the initial concentration of free electrons. The most suitable

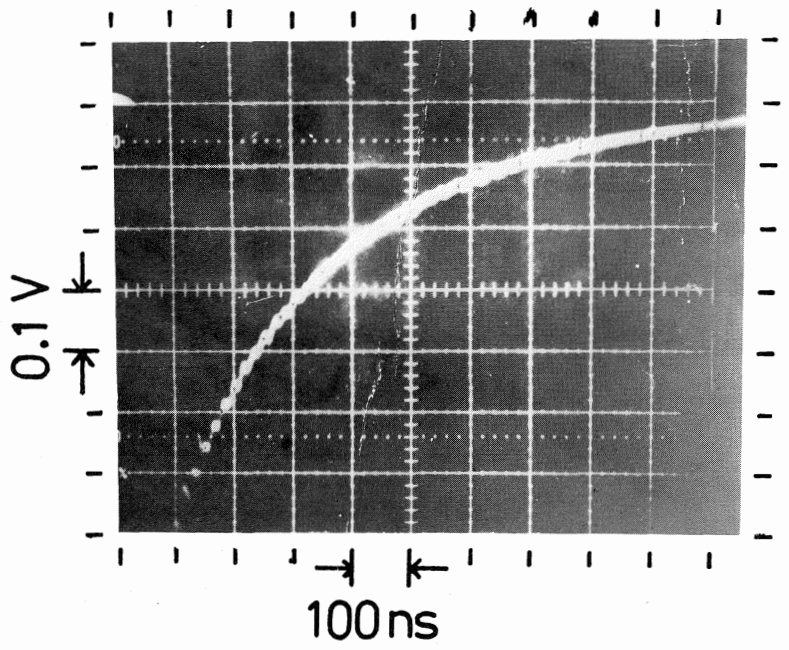

FIG. 2. Decay of the conductivity signal in neopentane: pulse dose = 160 mrad, E = 2.8 kV/cm.

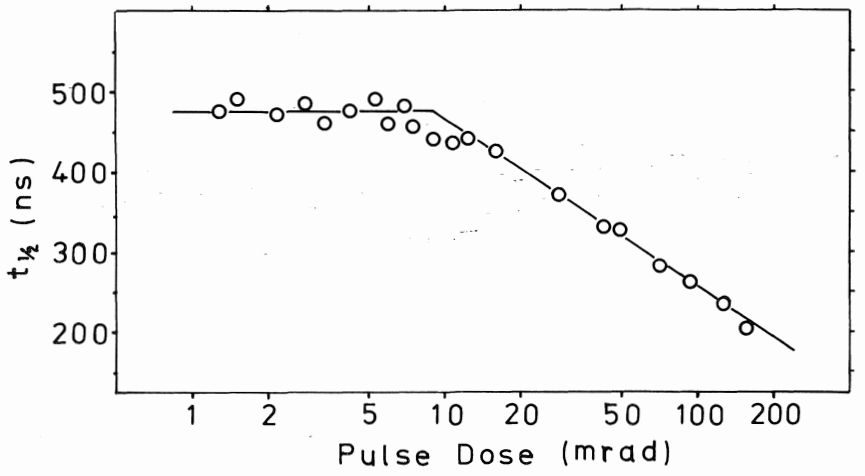

FIG. 3. Effect of dose rate on the initial half-life $t_{1/2}$ of the electron decay in neopentane.

value for μ_e is that in which the plot of $[I_e(t)/(1 - \mu_e Et/d)]$ is reduced to the exponential decay $I_0 \exp(-k_{tr}t)$. The electron mobility in neopentane is thus determined to be (60 ± 3) $cm^2\ V^{-1}\ s^{-1}$ from the analyses of decay plots at low pulse doses for several neopentane samples.

At the highest pulse dose, electron–ion recombination should compete with the first and the second processes of [2] and the electron current may be given approximately by

$$[4] \quad I_e(t) = I_0 \frac{(1 - \mu_e Et/d)}{(1 + n_0 k_r t)} \exp(-k_{tr}t)$$

The value of k_r can be so chosen as to fit [4] to the experimental result. In the actual calculation to find the value of k_r, [5], which is derived by combining [4] with [3], is used

$$[5] \quad 1 + (n_0)_h k_r t = \left(\frac{I_e(t)}{I_0}\right)_l \Big/ \left(\frac{I_e(t)}{I_0}\right)_h$$

where subscripts l and h represent the low and the high doses, respectively. Substituting two sets of $I_e(t)/I_0$ into [5], one can determine the value of $(n_0)_h k_r$ with an error of $\pm 10\%$. The initial concentration of free electrons at high pulse dose, $(n_0)_h$, is obtained from either the peak current I_0 using $\mu_e = 60\ cm^2\ V^{-1}\ s^{-1}$ or the absorbed dose using the field-enhanced free electron yields $G^E = 1.3$ (4*d*) at $E = 2.8$ kV/cm in neopentane. Thus the rate constant of electron–ion recombination in neopentane is determined to be $(2.8 \pm 0.3) \times 10^{16}\ M^{-1}\ s^{-1}$ at room temperature. In order to ensure that the drifting process is the only decay mechanism at low pulse doses, the external field strength is increased to 7.1 kV/cm. The electron current decays linearly with time and is given by

$$[6] \qquad I_e(t) = I_0\left(1 - \frac{\mu_e E t}{d}\right)$$

The signal decay time, t_d, corresponds to the time required for an electron to drift the distance between the electrodes. The electron mobility determined from t_d is 61 $cm^2\ V^{-1}\ s^{-1}$, which is in good agreement with that determined from the analysis of the decay plot at lower electric field. The value of μ_e also agrees well with those already reported (1–4, 8).

The mobilities of electrons in mixtures of neopentane–*n*-hexane have been determined from the peak current at the end of the pulse using the equation $I_0 = eA\mu_e E n_0$. The initial concentration of free electrons in the mixture is given by $n_0 = 6.25 \times 10^{11} D d_{mix} G_{mix}{}^E$, where D is the dose in rads and d_{mix} is the density of the mixture. The free electron yield in the mixture in the presence of the applied field E is calculated from [7] using a single-pair-spur model (4*c*, 15).

$$[7] \qquad G_{mix}{}^E = G_{tot} \int_0^\infty F(y)\phi(y,E)\ dy$$

where G_{tot} is the total ionization yield which is assumed to be 4.3, $\phi(y,E)$ is the probability that a thermalized electron–ion pair with initial inter-pair separation distance y will escape geminate recombination and become a free electron in the presence of the applied field E, and $F(y)$ is the initial separation distance distribution function. The escaping probability $\phi(y,E)$ is approximated by the initial four terms of a polynomial expression (4*c*). The distribution function $F(y)$ is given by the three dimensional Gaussian function

$$(4y^2/\pi^{1/2} b_{mix}{}^3) \exp(-y^2/b_{mix}{}^2)$$

where b_{mix} is the most probable value of y in the mixture. The value of b_{mix} is calculated using b values for neopentane and *n*-hexane from the relation found by Schmidt and Allen (16). The values of b_{neo} and b_h are determined so as to fit $G_{mix}{}^E$ calculated from [7] to the experimental plots of G^E *vs.* E reported by Freeman and co-workers (4*c*,*d*). The electron mobilities determined in this manner are plotted *vs.* the mole fraction of *n*-hexane, as shown in Fig. 4. For neopentane and a mixture of $x_h = 0.16$ the values of μ_e determined from the peak current are, respectively, in good agreement with those determined from the analysis of the decay plot within the experimental error. For *n*-hexane the peak current has not been accurately measured owing to the low ratio of signal to noise. The extrapolation of the curve in Fig. 4 to $x_h = 1$ gives 0.08 $cm^2\ V^{-1}\ s^{-1}$, which is in good agreement with that already reported (1, 2, 8).

The plot of log μ_e *vs.* x_h yields a straight line,

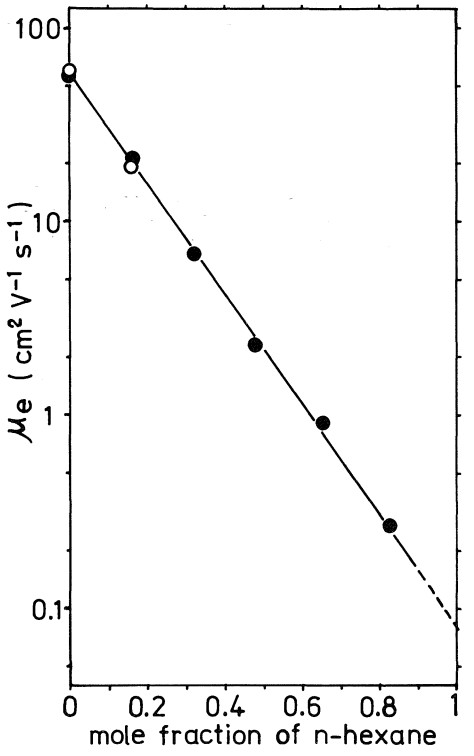

FIG. 4. The electron mobility μ_e as a function of mole fraction of *n*-hexane, x_h in the mixture. (○) determined from the analysis of the electron current decay; (●) determined from the peak current at the end of the pulse.

indicating that the electron mobility in the mixture μ_{mix} is expressed by

$$[8] \qquad \mu_{mix} = \mu_{neo}^{x_{neo}} \mu_h^{x_h}$$

where μ_{neo} and μ_h are the electron mobilities in neopentane and *n*-hexane, respectively, and x_{neo} is the mole fraction of neopentane in the mixtures. It is seen from [8] that by suitably mixing neopentane and *n*-hexane one can obtain a solvent of any desired electron mobility which lies between μ_{neo} and μ_h. The above relation has been found by Minday *et al.* (2*b*) for the same hydrocarbon mixtures using a time-of-flight method. They have also investigated the temperature dependence of μ_{mix} and found that the electron mobility in the mixtures, as in the cases of the pure components, can be expressed by the Arrhenius type expression,

$$[9] \qquad \mu_{mix} = \mu_f \exp(-E_{mix}/RT)$$

where μ_f is assumed to be the mobility of the electron in the quasifree state. The activation energy in the mixture, E_{mix}, increases with x_h and is given by a linear function of composition.

$$[10] \qquad E_{mix} = E_{neo}x_{neo} + E_h x_h$$

where E_{neo} and E_h are the activation energies in neopentane and *n*-hexane, respectively. It has been concluded (2*b*) that neopentane and *n*-hexane form an 'ideal' mixture in which the localized state or the trap for electrons is made up by a group of molecules which is weighted according to composition.

The rate constants for recombination of electrons with positive ions in the mixtures are determined in the same way as in the case of neat neopentane. A noticeable difference between the electron half-life at high pulse dose, $(t_{1/2})_h$ and that at low pulse dose, $(t_{1/2})_l$ has been observed in the mixtures. However, the electron current decay in the mixtures of large x_h exhibits pseudo-first-order behavior under both dose conditions. In this case [5] is reduced to

$$1 + (n_0)_h k_r t = \exp\{0.693[(t_{1/2})_h^{-1} - (t_{1/2})_l^{-1}]\}$$

Figure 5 shows a plot of the recombination rate constant k_r *vs.* the electron mobility. Our data obtained for the mixtures of $x_h = 0$, 0.16, 0.32, and 0.48 are represented together with those reported by Allen and Holroyd (8*a*) for *n*-hexane, *n*-pentane, and tetramethylsilane and by Baxendale and co-workers (7) for *n*-hexane and cyclohexane. All of these rate constants are proportional to the electron mobilities over a wide range of μ_e and lie on the straight line obtained from the reduced Debye equation

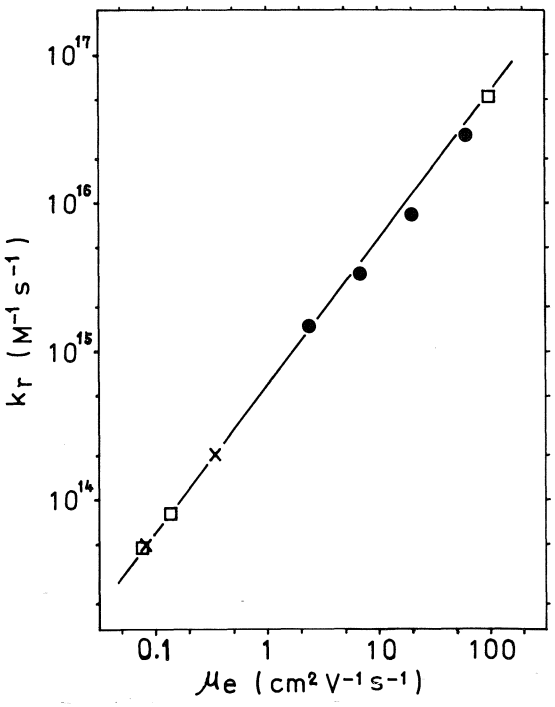

FIG. 5. The rate constants of electron–ion recombination, k_r, as a function of the electron mobilities, μ_e, in the mixtures (●) and in neat hydrocarbons (×) and tetramethylsilane (□) from refs. 7 and 8. The solid line is calculated from the reduced Debye equation [11].

$$[11] \qquad k_r = \frac{4\pi e}{\varepsilon}\mu_e$$

Figure 5 shows, therefore, that electron–ion recombination in non-polar liquids, where the electron mobility varies by three orders of magnitude, is a diffusion-controlled process.

It is generally considered that the reduced Debye equation, derived from the motion of ions which is essentially characterized by random diffusion, may be appropriate for low-mobility liquids such as *n*-hexane where the electron seems to reside in the spatially localized state for a long period of time and to move from one localized site to another as a conduction electron. In Fig. 5, however, [11] is also applicable for electron–ion recombination in high-mobility liquids such as neopentane where the electron seems to be extensively delocalized. Although the extent of delocalization of the electron in

high-mobility liquids seems not to have been estimated, it may be considerably smaller than the effective reaction radius of electron–ion recombination, ρ_r, which is close to 300 Å in liquids of low dielectric constant. The delocalized electron may stay in the vicinity of the positive ion for a time which is considerably longer than the vibrational period for nuclear motion and the recombination reaction may occur with a probability of unity whenever the electron enters into the effective reaction radius. If so, the rate constant of electron–ion recombination remains diffusion controlled even in high-mobility liquids.

Rate Constants of Electron Scavenging in the Mixtures

The time dependence of the electron current in the mixtures has exhibited pseudo-first-order behavior and the observed half-life $t_{1/2}$ is related to a rate constant, k_0. The exponential decay may be attributed to the relatively small contributions of electron drift and of electron–ion recombination processes in the mixtures. Addition of small amounts of CCl_4 or C_2H_5Br considerably increases the decay rate of the electron current, which still exhibits pseudo-first-order behavior with an effective rate constant k_e. The large increment in the decay rate caused by addition of solute may be exclusively attributed to electron scavenging by the solute. Then the effective decay constant k_e in the presence of the solute may be given by $k_e = k_0 + k_s[S]$, where k_s is the rate constant of electron scavenging by the solute. Typical examples are shown in Fig. 6 for a mixture of $x_h = 0.32$, where, as required in this treatment, k_e is linear with the solute concentration and the slopes of these lines yield k_s for CCl_4 and C_2H_5Br with errors of $\pm 10\%$.

The rate constants obtained in this way for electron scavenging in mixtures are plotted in Fig. 7. Data for *n*-hexane are those reported by Allen and Holroyd (8*a*). The mole fraction x_h is translated into the energy of the quasifree electron in the mixtures, $V_{0\,mix}$, using the relation found by Holroyd and Tauchert (10*d*),

$$[12] \qquad V_{0\,mix} = V_{0\,neo}x_{neo} + V_{0\,h}x_h$$

where $V_{0\,neo}$ and $V_{0\,h}$ are the energies of the quasifree electron in neopentane and *n*-hexane, respectively. The plot of log k_s for CCl_4 *vs.* x_h yields a straight line: k_s for CCl_4 is expressed

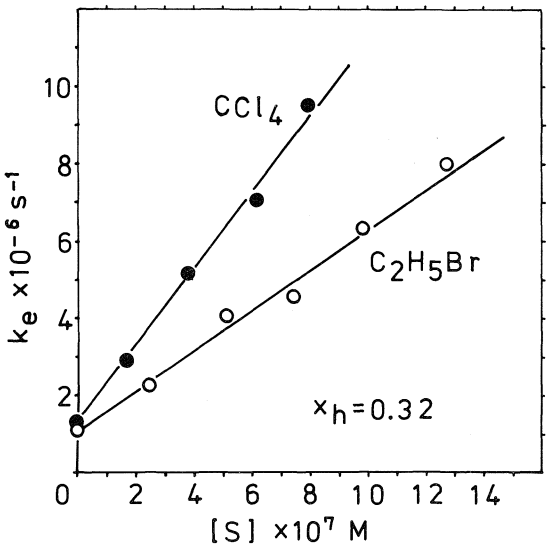

FIG. 6. The effective rate constants, k_e, of electron scavenging in the mixture of $x_h = 0.32$ as functions of the concentrations of CCl_4 (●) and C_2H_5Br (○).

fairly well by $4 \times 10^{12}\mu_e^{0.5}\ M^{-1}\,s^{-1}$. On the other hand, k_s for C_2H_5Br shows a maximum at $x_h = 0.48$ where $V_0 = -0.15$ eV. The results of k_s for CCl_4 and C_2H_5Br determined for the neopentane–*n*-hexane mixtures agree with those by Allen *et al.* (8*b*) for various neat hydrocarbons. The agreement of the results for neopentane–*n*-hexane mixtures and for various neat hydrocarbons indicates that the electron reaction with scavengers does not depend on the solvent molecular structure itself but only on the quantities μ_e and V_0 of the medium.

If electron scavenging is diffusion controlled, the rate constant should be proportional to the electron mobility and given by

$$[13] \qquad k_s = \frac{4\pi k T \rho_s}{e}\mu_e$$

where ρ_s is the effective reaction radius of electron scavenging. The broken line in Fig. 7 is the result of [13], assuming that ρ_s has a constant value of 5 Å in mixtures of any composition. In relatively low-mobility mixtures the reaction of electron scavenging appears to be a diffusion-controlled process. The data of k_s for a large number of scavengers in cyclohexane and *n*-hexane reported by Baxendale and co-workers (7) and Allen and co-workers (8) depend little on scavengers and agree closely with [13] for the respective solvents. In high-mobility mixtures,

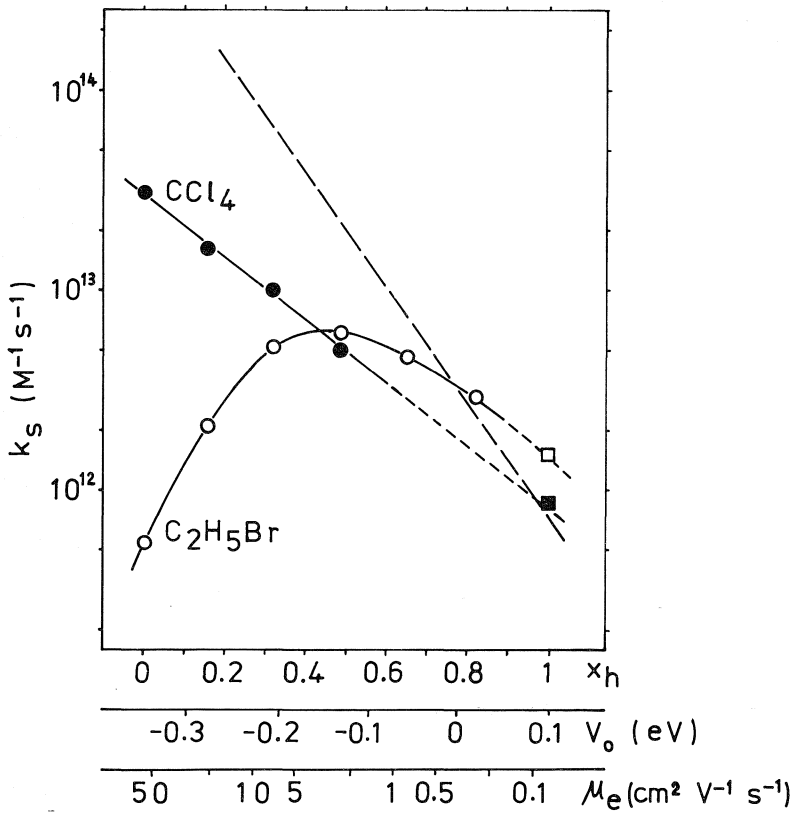

FIG. 7. The rate constants of electron scavenging, k_s by CCl_4 (●) and C_2H_5Br (○) as functions of x_h, V_0, and μ_e in the mixture. The data for neat *n*-hexane (■, □) are cited from ref. 8. The broken line is calculated from [13].

on the other hand, the rate constants k_s do not follow [13]. Electron scavenging in high-mobility mixtures is not diffusion controlled. This appears to hold particularly for the case of C_2H_5Br, since k_s decreases with increasing μ_e in the higher mobility region. For CCl_4, however, k_s might have something to do with [13], because its specific rate varies rather closely with the square root of the electron mobility over the wide range of μ_e.

It has been suggested that diffusion kinetics expressed by [13] is not necessarily valid for processes of electron scavenging in liquid hydrocarbons, especially in high-mobility liquids. In neopentane, Hatano and co-workers (12) have first indicated that the relative values of k_s are largely dependent upon scavengers and are correlated with the rate constants of thermal electron attachment in the gas phase, suggesting that a new theoretical approach taking account of 'gaseous character' (12) of liquid neopentane may be necessary instead of diffusion kinetics. Allen *et al.* (8*b*) have correlated k_s in various hydrocarbons and tetramethylsilane with the energy of the quasifree electron, V_0, and proposed that a characteristic value of V_0 at which k_s becomes a maximum can be predicted using the resonant energy maximum in the attachment cross section for electron reaction with the scavenger in the gas phase. For high-mobility liquids, Funabashi and Magee (13) have proposed a model where the process of electron scavenging is completely analogous to the gas phase process of electron attachment. Thus the 'gaseous character' (12) of the high-mobility liquid commonly has been emphasized to explain the non-diffusion-controlled behavior of k_s.

Let us here consider the situation in which diffusion kinetics is valid. When the following two requirements are satisfied, electron reactions in liquids may be described by diffusion

kinetics. The first is that the electron undergoes high-frequency diffusive displacements of the random walk type in a relatively small area compared with the effective reaction radius of interest, even if the electron wavefunction is somewhat extended over several solvent molecules. The second is that the electron reaction has a low or no activation energy: the rate is determined by the diffusion of the electron towards the reacting species rather than by the final reaction itself. The first requirement may be related to the electron mobility and the second to the quantity V_0. When either of the requirements is not satisfied, electron reactions in liquids may exhibit non-diffusion-controlled behavior.

In the high-mobility mixtures these requirements may not be met in the reactions of electrons with CCl_4 and C_2H_5Br shown in Fig. 7. For C_2H_5Br, in the high-mobility mixtures having V_0 lower than -0.15 eV, the final reaction of electron capture seems to require an activation energy, as suggested by Allen and co-workers (8), so it becomes the rate determining step. For CCl_4, on the other hand, the quasifree electron in the mixtures of any composition seems to have energies which are high compared with that required for the final reaction of electron capture. As μ_e becomes larger, the diffusive displacements of the electron become large compared with the effective reaction radius of electron scavenging, ρ_s. In other words, the more the electron wavefunction extends, the smaller its overlap with the orbitals of CCl_4 molecule becomes. For the reaction of electron scavenging, therefore, ρ_s may decrease with decreasing overlap (or increasing μ_e). Assuming that ρ_s for CCl_4 is tentatively equal to $r_s/\sqrt{\mu_e}$, where r_s is the geometrical radius of the CCl_4 molecule, [13] is reduced to $k_s = (4\pi kTr_s/e)\sqrt{\mu_e}$, which accounts for the result in Fig. 7.

Both μ_e and V_0 are important with respect to the rate of electron scavenging in liquid hydrocarbons. The details of the factors which determine the reaction rate k_s, however, still remain obscure. Further measurements of k_s for various scavengers in mixtures of hydrocarbons clearly are required.

Electron Transport in Non-polar Liquids

The mechanism of electron transport in non-polar liquids has been described in terms of three quantities: electron mobility, μ_e, its activation energy, E_a, and electron energy in its quasifree state, V_0. The temperature dependence of μ_e as is expressed by [9] may imply that the electron transport takes place through a succession of migrations from one trap to another as a conduction electron. This mechanism has generally been referred to as a trapping model (1, 2), which is *apparently* similar to a phonon-assisted hopping model proposed to explain the electron transport in amorphous semiconductors (17). The correlation between μ_e and V_0 received attention originally by Holroyd and Allen (10*a*). Recently Schiller and co-workers (18), Kestner and Jortner (19), and Freeman and co-workers (20) have theoretically calculated μ_e as a function of V_0 based on, respectively, a partial localization model, an effective medium model, and an activation model. The activation energy E_a has also been calculated from the theories. Then the experimental data of μ_e and E_a have been correlated with V_0 to test predictions from theories.

Turning to the experimental results on these three quantities for neopentane–*n*-hexane mixtures, which are expressed by [8], [10], and [12], it is seen that the correlations of μ_e *vs.* V_0 and V_0 *vs.* E_a can be expressed by simple formulae. The electron mobility, μ_{mix}, is expressed by a function of the mole fraction of components. Both $V_{0\,mix}$ and E_{mix} are linearly dependent on composition. Substituting [12] into [8], μ_{mix} is expressed by an exponential function of $V_{0\,mix}$,

$$[14] \qquad \mu_{mix} = 0.35 \exp(-15\, V_{0\,mix})$$

which is calculated using $\mu_{neo} = 60$, $\mu_h = 0.08$ $cm^2\ V^{-1}\ s^{-1}$, $V_{0\,neo} = -0.35$ (10*d*), and $V_{0\,h} = 0.10$ eV (10*d*). This relation was first reported by Holroyd and Tauchert (10*d*). Comparing [12] with [10], $V_{0\,mix}$ is expressed by a linear function of E_{mix}

$$[15] \qquad V_{0\,mix} = -0.42 + 2.6E_{mix}$$

at room temperature, which is calculated using $E_{neo} = 0.024$ (the average of refs. 4*a* and 2*b*) and $E_h = 0.20$ eV (the average of refs. 1, 2, and 8*b*). Equation 15 is an empirical formula derived from the experimental results on the mixtures and correlates the energy of the trapped state with that of the quasifree state quantitatively. Figure 8 shows a plot of V_0 *vs.* E_a for various hydrocarbons and tetramethylsilane for which both quantities have been reported. Equation 15, represented by the solid line, seems to hold for

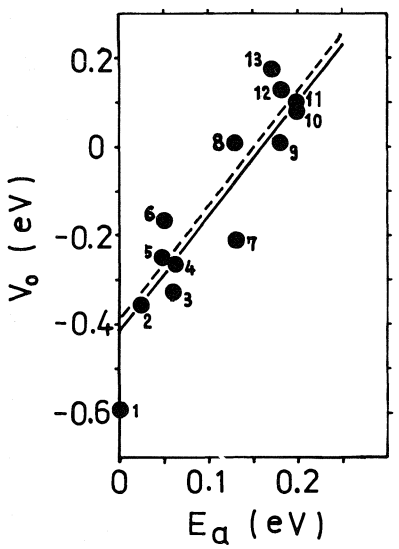

FIG. 8. Plot of V_0 *vs.* E_a in liquid hydrocarbons and tetramethylsilane. All values are experimental near 296 K. Values of V_0 are from ref. 10*e*. Values of E_a are the average of those in refs. 1, 2, 4, and 8. The solid and dotted lines are from [15] and its modification, respectively. The numbers labeling the points are: (*1*) tetramethylsilane, (*2*) neopentane, (*3*) 2,2,4,4-tetramethylpentane, (*4*) 2,2-dimethylbutane, (*5*) 2,3-dimethylbutene-2, (*6*) 2,2,4-trimethylpentane, (*7*) cyclopentane, (*8*) cyclohexane, (*9*) *n*-pentane, (*10*) methylcyclohexane, (*11*) *n*-hexane, (*12*) *n*-octane, (*13*) *n*-decane.

many hydrocarbons but not for tetramethylsilane. In order to elucidate the relationship more completely, it will be necessary to determine theoretically the composition dependence of E_{mix} as well as $V_{0\,mix}$ (21) in the mixtures.

The observed electron mobility is expressed by the mobility of the quasifree electron, μ_f, multiplied by the fraction of the time that the electron exists in the quasifree state. Using Frommhold's formula (22), the electron mobility is given by

$$[16] \qquad \mu_e = \frac{\mu_f}{1 + \nu\tau_t}$$

where ν is the frequency of trapping collisions of the quasifree electron and τ_t is the mean time that the electron resides in the trapped state. It was suggested by Davis and co-workers (2*a*) that τ_t depends on the activation process and so it can be expressed by $\tau_t = \tau_0 \exp(E_a/RT)$, where τ_0 is approximately the period of a vibrational oscillation. It is also assumed that $\nu\tau_0 \approx 1$ (23). The electron mobility is then expressed as

$$[17] \qquad \mu_e = \frac{\mu_f}{1 + \exp(E_a/RT)}$$

using the activation energy. Using [15] and taking 180 $cm^2\,V^{-1}\,s^{-1}$ for μ_f, the electron mobility can be expressed as

$$[18] \qquad \mu_e = \frac{180}{1 + 520\exp(15V_0)}$$

at room temperature. The value of μ_f is so determined that [18] is reduced to [14] for relatively high values of V_0. Figure 9 shows a plot of log μ_e *vs.* V_0 for various hydrocarbons

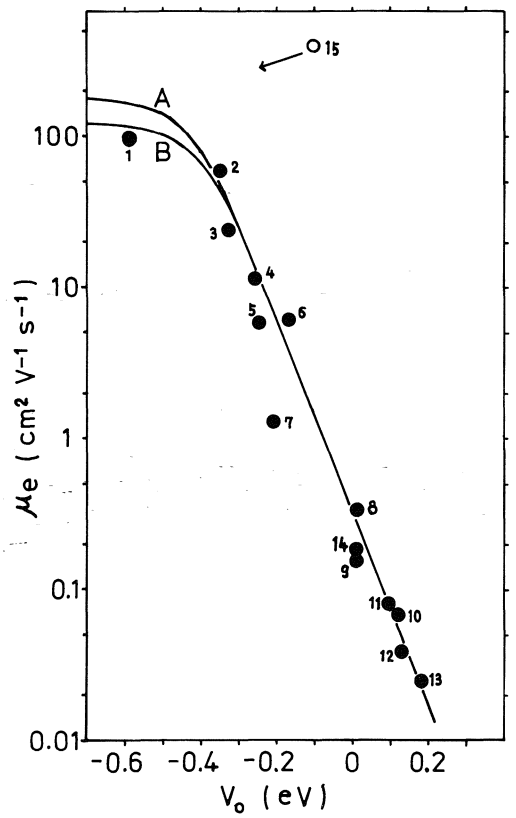

FIG. 9. Plot of μ_e *vs.* V_0 in liquid hydrocarbons and tetramethylsilane. All data are near 296 K except for liquid methane (○), near 110 K. Values of μ_e are the average of those in refs. 1–4, 8, 24, and 25. Values of V_0 are from refs. 10*e*, 24, and 26. The curves of *A* and *B* are calculated from [18] and [19], respectively. The numbers labeling the points are the same as in Fig. 8 except for: (*14*) 3-methylpentane, (*15*) methane. The arrow shows the expected direction of shift of the open circle with increasing temperature because μ_e in liquid methane has a negative temperature coefficient (24, 25) in the range of 90 to 140 K and V_0 may decrease with increasing temperature (10, 26).

and tetramethylsilane for which both quantities have been reported. It is seen that [18], denoted by curve *A*, expresses suitably the correlation between μ_e and V_0 for many hydrocarbons except tetramethylsilane, cyclopentane, and methane. Here, if [19] is used in place of [18],

$$[19] \qquad \mu_e = \frac{125}{1 + 360 \exp(15V_0)}$$

we can obtain curve *B* in Fig. 9, which passes near the point for tetramethylsilane. Equation 19 is obtained from the equation $V_0 = -0.39 + 2.6E_a$ (the dotted line in Fig. 8) in place of [15], which is a trivial modification. The value of μ_f results in 125 $cm^2\ V^{-1}\ s^{-1}$. The curve *B* in Fig. 9 appears to fit well to the theoretical curve obtained from Freeman's activation model (20) while not to those obtained from Schiller's (18) and Kestner and Jortner's models (19) over the entire mobility range.

As mentioned above, using the experimental results on the quantities μ_e, E_a, and V_0 for neopentane–*n*-hexane mixtures and a trapping model on electron transport, we have presented empirical formulae which express suitably the correlations of V_0 *vs.* E_a (eq. 15) and μ_e *vs.* V_0 (eq. 19) for many hydrocarbons and tetramethylsilane at room temperature. While [15] seems not to be valid for tetramethylsilane, [19] appears to hold for the highest mobility liquid such as neopentane and tetramethylsilane where the quasifree electron is considered to be dominant. A theoretical consideration of [15] clearly is required. It is also necessary to consider the connection between the empirical formula (eq. 19) and theoretical expressions (18–20).

It has been shown in this work that experiments using hydrocarbon mixtures give us a better understanding of behavior of electrons in non-polar liquids.

Discussion

J. Jortner: Concerning the relations between μ_e and V_0, which many of us have been using, it appears now that the experimental data of Schmidt and colleagues on liquid ethane provide a striking exception to this rule.

Y. Hatano: I think so. But, the temperature effect of μ_e and V_0 should be noted as that indicated in Fig. 9 for liquid methane.

J. M. Warman: We have measured the temperature dependence of the mobility of the negative charge carrier(s) in liquid TMS containing low concentrations of the temporary electron trap biphenyl (J. M. Warman, M. P. DeHaas, and A. Hummel, Proc. 5th International Conference on Conduction and Breakdown in Dielectric Liquids, Noordwykerhout, The Netherlands, July 1975). Such a solution corresponds to a low mobility liquid in which the mobility is known to be controlled by equilibrium between a trapped and quasi-free state, of which the quasi-free mobility is known (100 $cm^2\ V^{-1}\ s^{-1}$). If the observed temperature dependence of the mobility in such a 'trap doped' solution is plotted in an Arrhenius fashion corresponding to $\mu = A \exp(-B/RT)$, then the value of B found from the slope (even up to mobilities quite close to the quasi-free mobility) is very close to the known (*i.e.* measured) value of ΔH for the trapping process. The preexponential parameter, A, determined from such a plot is, however, many orders of magnitude greater than the known quasi-free value of 100. These experiments were carried out deliberately to illustrate that the association of A with μ_0 is of dubious validity.

Scavenging of localized and quasifree electrons in liquid hydrocarbons (Extended Abstract)

A. A. BALAKIN, I. A. BORIEV, E. L. FRANKEVICH, L. V. LUKIN, AND B. S. YAKOVLEV
Institute of Chemical Physics, Academy of Sciences USSR, 142432 Chernogolovka, USSR
Received November 22, 1976

Excess electrons in liquid hydrocarbons are believed to be either in a localized or in a quasifree state. In what state are electrons which are scavenged by acceptor molecules? As an approach to this question we examined the values of rate constants k obtained for electron scavenging reactions in liquid hydrocarbons with highly different electron mobilities, μ. Scavenging by aromatic hydrocarbons and oxygen molecules has been studied.

The rate constant measured is a combination of partial rate constants for scavenging of localized and quasifree electrons. The contribution of the quasifree or localized state is assumed to be proportional to the time spent by electrons in this state, *i.e.*

$$k = k_1 P + k_f(1 - P) \qquad [1]$$

where k_f and k_1 are the rate constants for scavenging of a quasifree and localized electron; $1 - P$ is the fraction of time which an electron spends in a quasifree state and is equal to μ/μ_0 for the conventional model of trap-limited transfer of excess electrons; μ_0 is the mobility of the quasifree electron.

Figure 1 shows the dependence of k for pyrene molecules on the diffusion coefficient of excess electrons, D, obtained from Einstein's relationship by using μ.

For liquids with $D \lesssim 10^{-3}$ cm^2/s an assumption of the predominant capture of quasifree electrons leads to $k \lesssim k_0$, where k_0 is the maximum possible attachment rate constant for a thermal free electron at $\mu_0 \lesssim 20$ cm^2 V^{-1} s^{-1}. Such a value seems to be too low for quasifree electrons; therefore we suppose the localized electron scavenging process to be more adequate for liquids with small D. In this case a large effective radius of the reaction $R \approx 17$ Å obtained (1) for these liquids can be connected either with the localized electron radius (1) or with the electron transfer tunnelling mechanism

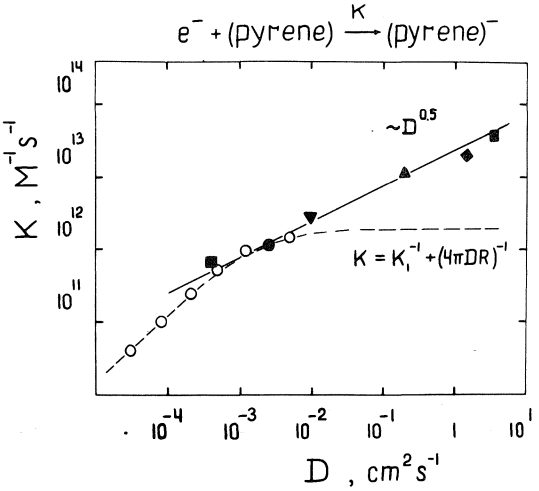

FIG. 1. The dependence of the rate constant of electron scavenging by pyrene in nonpolar dielectric liquids on the diffusion coefficient of excess electrons: pentadecane (■), *n*-hexane (●), cyclohexane (▼), isooctane (▲), neopentane (◆), and tetramethylsilane (■) at $T = 296$ K; *n*-hexane (○) at different temperatures (1).

(the latter gives $R \approx 17$ Å if we take the localized electron radius as 5 Å, the value usually used for the electron tunnelling theory parameter (2) $\alpha' \approx 10^{13}$ s^{-1}, and the parameter $\beta \approx 10^7$ cm^{-1} corresponding to a trap depth of 0.2 eV for localized electrons). Figure 1 illustrates the dependence $k(D)$ derived from the general expression of Noyes $k^{-1} = (4\pi DR)^{-1} + k_1^{-1}$, which agrees with the experiment for $D < 6 \times 10^{-3}$ cm^2 s^{-1}. For liquids with $D > 0.1$ cm^2 s^{-1} such a simple approach gives values of k lower than experimental. Two possible effects might lead to this result: (*1*) an increase of the 'genuine' rate constant, k_1, when going to liquids with larger D (for example, due to lowering of the tunnelling barrier); (*2*) an increase of a quasifree electron contribution.

For scavenging of excess electrons by oxygen molecules in liquid hydrocarbons with $\mu < 10$

$cm^2\ V^{-1}\ s^{-1}$ at $T = 296$ K the values of k proved to be about equal ($k \approx 5 \times 10^{10}\ M^{-1}\ s^{-1}$ (3)) though values of μ and, as expected, of $1 - P$ varied over a range of 10^2 in different liquids. These results permit, in view of [1], the description of scavenging as a capture of localized electrons. The rate constant k has been shown to increase when going to liquids with $\mu > 10\ cm^2\ V^{-1}\ s^{-1}$. This is believed to be due to a capture of quasifree electrons. On this assumption we obtained $k_f = 6 \times 10^{11}\ M^{-1}\ s^{-1}$ at 296 K and an activation energy $E_f \lesssim 0.01$ eV (3, 5) for scavenging quasifree electrons in neopentane and tetramethylsilane.

We compared the values of k_f and E_f with gas-phase data assuming a compound negative ion $(O_2^-)^*$ to be involved in the quasifree electron scavenging process, *i.e.*

$$e_f^- + O_2 \rightleftarrows (O_2^-)^* \rightarrow O_2^-$$

In gases the cross section of $(O_2^-)^*$ formation consists of series of spikes at energy values, $\varepsilon_{v'}$, corresponding to vibrational levels of O_2^- with the quantum number $v' \geq 4$ and $\Delta\varepsilon = \varepsilon_{v'+1} - \varepsilon_{v'} \approx 0.1$ eV (4). The formation of $(O_2^-)^*$ was proposed to proceed in liquids at kinetic energies of quasifree electrons of about

$$[2] \qquad \tilde{\varepsilon}_{v'} = \varepsilon_{v'} + V_p - V_0$$

where V_p is the polarization energy of the $(O_2^-)^*$ ion in the liquid and V_0 is the lowest level of e_f^-.

Aside from this one can imagine at least two differences between the gas and liquid phase attachment mechanisms: (*1*) different widths, $\Gamma_{in}^{v'}$, for decay into the ground state of O_2 plus a free electron, (*2*) because of a distribution of V_p in liquids, the quasifree electrons with a given energy can lead to the formation of $(O_2^-)^*$ with different vibrational levels. (As V_p is defined by the local density near an O_2 molecule just before electron attachment, then due to the density fluctuation one may expect a rather wide (~ 1 eV) distribution function $P(V_p)$ in liquid hydrocarbons (5). Therefore the thermal electron can form $(O_2^-)^*$ with v' from ~ 10 to ~ 20.)

In these circumstances we have

$$[3] \quad k_f = \sum_{v'} \int_{V_p^0}^{0} k_{v'}(V_p) w(\tilde{\varepsilon}_{v'}) P(V_p)\, dV_p$$

where V_p^0 is the lowest value of V_p and is about -2.1 eV for liquid isooctane (5); $w(\tilde{\varepsilon}_{v'}) = \tau_v^{-1}/(\tau_v^{-1} + \Gamma_{in}^{v'}/\hbar)$ is the stabilization probability of $(O_2^-)^*$ in a v' state; τ_v is the vibrational relaxation time for $(O_2^-)^*$ ions in liquids; $k_{v'}(V_p)$ is the rate constant of $(O_2^-)^*$ formation in the v' state if the polarization energy has a value V_p.

The relationship [3] may be simplified if we accept that, for the *d*-wave resonant scattering involved in the present reaction, as for a gas (6), $\Gamma_{in}^{v'} = B\tilde{\varepsilon}_{v'}^{5/2}$ and $\int \sigma_{v'} d\varepsilon = A\Gamma_{in}^{v'}/\tilde{\varepsilon}_{v'}$, where $A = (4/3)\pi^2(\hbar^2/2m)$, $\sigma_{v'}(\varepsilon, V_p)$ is the cross section for $(O_2^-)^*$ formation in the v' state, and m is the mass of the electron. Then for $B = 1.2 \times 10^{-1}\ eV^{-3/2}$ (the latter corresponds to $\hbar/\Gamma_{in}^4 = 2 \times 10^{-12}$ s (7) for the life time of $(O_2^-)^*$ with $v' = 4$ in the gas), we have $\hbar/\Gamma_{in}^{v'} \gtrsim 10^{-11}$ s for v' from ~ 10 to ~ 20 and consequently $w(\tilde{\varepsilon}_{v'}) \approx 1$ if $\tau_v \approx 10^{-13}$ s, and

$$[4] \quad k_f = \sum_{v'} P(V_0 - \tilde{\varepsilon}_{v'}) \int_0^\infty \frac{u}{\varepsilon} f(\varepsilon) A\Gamma_{in}^{v'}\, d\varepsilon \approx B(2\pi\hbar kT)^2/\Delta\varepsilon \cdot m^{3/2}$$

where u is the velocity of the quasifree electron with kinetic energy ε; $f(\varepsilon)$ is the Maxwellian energy distribution for excess electrons. The relationship [4] leads to $k_f = 3 \times 10^{11}\ M^{-1}\ s^{-1}$ and $E_f = 5 \times 10^{-2}$ eV at $T = 300$ K. These results are in rather good agreement with the experiment.

Discussion

L. G. Christophorou: Your lifetime of 10^{-12} s for $(O_2^-)^*$ as well as your value of $4 \times 10^{11}\ M^{-1}\ s^{-1}$ or k_F are very consistent with our own values for $(O_2^-)^*$ derived from high-pressure electron attachment studies. We estimated (R. E. Goans and L. G. Christophorou, J. Chem. Phys. **60**, 1036 (1974)) a value of $\sim 2 \times 10^{-12}$ s for the lifetime of $(O_2^-)^*$ and a value for $k_F = 3.3 \times 10^{11}\ M^{-1}\ s^{-1}$ for the reaction $e_{thermal} + O_2 \rightarrow (O_2^-)^*$, when our data on the $e_{thermal}$, O_2 system in dense ethylene gas were extrapolated to liquid-ethylene density.

J. Jortner: You have estimated the rate constant for $O_2 + e$ reaction in solution in terms of a sum of Lorentzians involving the width $\hbar/\tau_{vib}$ where τ_{vib} is the $v \rightarrow v - 1$ medium induced vibrational relaxation time of O_2^-. This approach assumes sequential electronic coupling followed by vibrational relaxation. This approach is identical to the Robinson–Frosch theory of molecular radiationless transitions. An alternative physical picture involves the participation of medium phonons superimposed on the molecular vibrational levels v of the final state, which will provide a dissipative sink. Another modification of your theoretical rate constant should involve the vibrational nuclear overlap Franck–Condon factor between the appropriate states of O_2 and of O_2^-.

E. L. Frankevich: You are right but to date we have only approximate determinations of k_F (rate constant for reaction of quasifree electrons with O_2) in a liquid phase. This makes it impossible to compare the results of more advanced approaches and to choose the best one.

Comparison of solvated electron reaction rates in water and ammonia

U. SCHINDEWOLF AND P. WÜNSCHEL

Institut für Physikalische Chemie und Elektrochemie, Universität Karlsruhe, Germany

Received October 4, 1976

U. SCHINDEWOLF and P. WÜNSCHEL. Can. J. Chem. **55**, 2159 (1977).

New and literature data of solvated electron reactions in ammonia with some inorganic ions and organic neutral molecules are compared with corresponding data in water. In ammonia only a few reactions with aromatic molecules are diffusion controlled and therefore faster than in water ($k \approx 1 \times 10^{11}$ and 1×10^{10} M^{-1} s^{-1}, respectively). After correcting for the electrostatic contribution to the rate constant of the other reactions it is concluded that in general the reactivity of the solvated electron in ammonia is appreciably lower than in water. For the slow reactions of ammoniated electrons with acetonitrile and dimethylsulfoxide we find activation energies of 7 to 9 kcal/mol and activation volumes of -40 to -60 ml/mol. In these reactions it is suggested that the rate determining step is associated with the collapse of the large electron cavity in liquid ammonia.

U. SCHINDEWOLF et P. WÜNSCHEL. Can. J. Chem. **55**, 2159 (1977).

Des données nouvelles et des données trouvées dans la littérature concernant les réactions d'électrons solvatés dans l'ammoniac avec quelques ions inorganiques et des molécules organiques neutres sont comparées avec celles disponibles pour l'eau. Dans le cas de l'ammoniac, il n'y a que quelques réactions avec les molécules aromatiques qui sont contrôlées par la diffusion et qui sont donc plus rapides que dans l'eau ($k \approx 1 \times 10^{11}$ et 1×10^{10} M^{-1} s^{-1} respectivement). Si l'on fait la correction pour la contribution électrostatique à la constance de vitesse d'autres réactions, on peut conclure qu'en générale la réactivité des électrons solvatés dans l'ammoniac est beaucoup plus faible que celle dans l'eau. Pour des réactions lentes d'électrons solvatés dans l'ammoniac avec l'acétonitrile et le diméthylsulfoxyde, on trouve des énergies d'activation de 7 à 9 kcal/mol et des volumes d'activation de -40 à -60 ml/mol. Dans ces réactions, on suggère que l'étape déterminante de la réaction est associée avec la disparition de la grande cavité de l'electron dans l'ammoniac liquide.

[Traduit par le journal]

Introduction

Extensive studies of rates of solvated electron (e_s^-) reactions in water have been carried out (1). Little is known about their rates in ammonia, although a wealth of information about the physical properties of the ammoniated electrons is available (2–6). The most striking difference in kinetic behavior is the high stability of the ammoniated electron e_{am}^- in contrast to that of the hydrated electron e_{hyd}^-.

In 50 mol% water ammonia mixtures (7) the solvated electron lifetime is at least 10^3 times the value in pure water. Assuming the normal bimolecular rate law and a solvent independent rate constant the lifetime of the electron should only be increased by a factor of two, due to the twofold dilution of the reacting water. Considering the equilibrium $H_2O + NH_3 \rightleftarrows NH_4^+ + OH^-$ does not help to interpret the large observed lifetime increase. Neither does consideration of the electrostatic contribution to the rate constant (8) arising from the different dielectric constants of ammonia and water ($\varepsilon = 17$ and 78, respectively). This behavior should be contrasted with that in ethyl alcohol and water or their mixtures, where the observed small changes in rate constant with, for example, nitrate or zinc ions, can be solely explained by the electrostatic correction (9).

In this paper we demonstrate that after correcting for the electrostatic contribution (8) the reactivity of solvated electrons in ammonia is several powers of ten smaller than in water. The argument is based on published results (10) and new kinetic data of electron reactions in ammonia with inorganic anions, cations, and organic neutral molecules. The corresponding data in water were taken from literature (1). The experimental details, mainly concerning pulse radiolysis at high pressure, have been described before (7).

Results and Discussion

Inorganic Ions

Table 1 shows a comparison for water and ammonia of the experimental rate constants

TABLE 1. Kinetic data for the reaction of solvated electrons with inorganic ions in water and ammonia

Ion	Water*		Ammonia	
	Rate constant† (M^{-1} s^{-1})	Activation energy (kcal/mol)	Rate constant† (M^{-1} s^{-1})	Activation energy (kcal/mol)
NO_3^-	8.6×10^9	3.9	3.9×10^6	2.9
NO_2^-	2.7×10^9	3.4	1.7×10^5	3.3
BrO_3^-	1.6×10^9	4.5	7.5×10^4	2.3
CN^-	$<4 \times 10^6$	—	<1	—
CNO^-	$<1.0 \times 10^6$	—	<1	—
ClO_3^-	$<1.3 \times 10^6$	—	<1	—
Cd^{2+}	9.8×10^{10}	—	6.2×10^9	—
Ni^{2+}	3.9×10^{10}	—	3.5×10^{10}	—
Co^{2+}	2.0×10^{10}	—	4.2×10^{10}	—

Mn^{2+}	7.7×10^7	—	5.5×10^9	—

*Reference 1.
†Extrapolated to zero ionic strength.

measured at 22°C and extrapolated to zero ionic strength (8) for the reaction of e_s^- with monovalent NO_3^-, NO_2^-, and BrO_3^- anions and the divalent Cd^{2+}, Ni^{2+}, Co^{2+}, Zn^{2+}, and Mn^{2+} cations. (At the substrate concentration $<10^{-4}$ M complete dissociation of the electrolytes even in ammonia can be assumed; the extrapolation yields half a power of ten decrease and one power of ten increase of the measured rate constants of anion and cation reactions, respectively; it is not decisive for the following discussion.) The anion rate constants in ammonia are three to four powers of ten lower than in water. On the other hand some cation rate constants (Mn^{2+}, Zn^{2+}, Co^{2+}) are increased whilst others (Cd^{2+}, Ni^{2+}) are decreased by up to a factor of ten in ammonia as compared to in water. These results can be separated into diffusion and nondiffusion controlled reactions.

Diffusion Controlled

In this case the calculated second order rate constant is given by the Debye equation [1] (8).

$$k_{\text{diff}} = \frac{4\pi a N_L D}{1000} \frac{Q}{\exp Q - 1} \qquad [1]$$

$$Q = \frac{N_L z_1 z_2 e_0^2}{\varepsilon a R T}$$

where N_L is Avogadro's number, R the gas constant, T the absolute temperature, D the diffusion coefficient $= D_1 + D_2$, z_1 and z_2 the charge number of e_s^- and the solute, respectively, ε the dielectric constant, e_0 the electronic charge, and a the collision diameter (distance of closest approach which leads to reaction). Q describes the electrostatic contribution of the ions to the rate of diffusion controlled reactions. In the limiting case for noncharged solutes where $z_2 \to 0$ the rate constant is given by the first term.

Figure 1 shows the diffusion controlled rate constant according to [1] as a function of the collision parameter between 1 and 9 Å for the electron reactions with divalent cations ($z_2 = 2$) and with monovalent anions ($z_2 = -1$) in ammonia and water. For reactions with cations k_{diff} is essentially independent of the collision diameter but with anions increases rapidly with increasing values of a. Diffusion coefficients $D = 5 \times 10^{-4}$ and 5×10^{-5} cm^2/s (22°C) were taken as averaged values for ammonia and for water, respectively, as computed from the known mobilities of the species in the two solvents (11, 12). The ratio of the diffusion coefficients in ammonia and water reflects the inverse ratio of the viscosity of the two solvents which is close to 9 at 25°C.

From the experimental data and theoretical curves of Fig. 1 it may be concluded that the e_s^- reactions with Cd^{2+}, Ni^{2+}, and Co^{2+} are diffusion controlled in water whereas this is not the case in ammonia. Of the anions only the NO_3^- ion might be diffusion controlled in water with a collision diameter around 5 Å. For the other two anions the collision diameter for a diffusion controlled reaction would be <3 Å, which hardly seems acceptable. As argued for the cations none of the anion reactions in ammonia are diffusion controlled, unless again

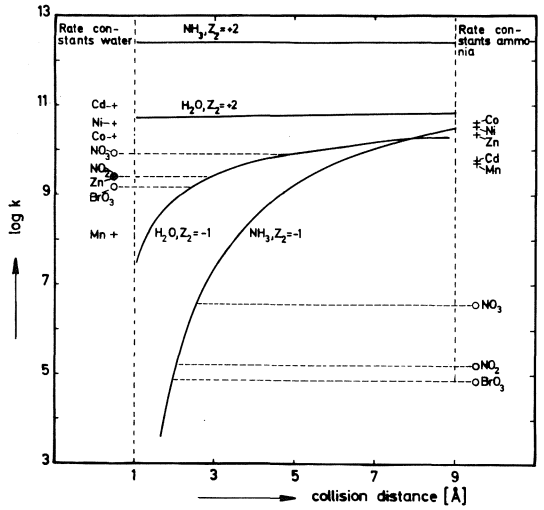

FIG. 1. Calculated rate constants for diffusion controlled reactions of solvated electrons with monovalent anions ($z_2 = -1$) and divalent cations ($z_2 = 2$) in water and ammonia; abscissa collision diameter. The experimental rate constants are given on the sides.

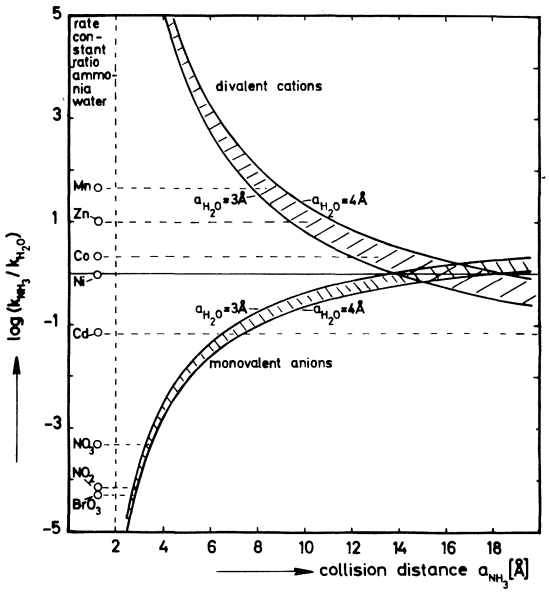

FIG. 2. Calculated ratio of the rate constants of electron reactions in ammonia and water with monovalent anions and divalent cations, considering the electrostatic contribution only (k_∞ independent of solvent); abscissa collision diameter in ammonia; collision diameter in water 3–4 Å. Experimental ratios are given on the side.

we assume an unreasonably small collision diameter (<2 Å). This is even less likely in ammonia than in water because of the larger effective radius r_e of the solvated electron cavity having values of 3.2 Å in ammonia (2–6) and <1.4 Å in water (13, 14).

Nondiffusion Controlled

If the ion reactions are not diffusion controlled, the rate constant can be calculated by the Brönsted–Christiansen–Scatchard equation (8)

$$[2] \qquad k = k_\infty \exp -Q$$

with Q from [1], describing the correction of the rate due to Coulomb interaction, and k_∞ being the rate constant in the absence of Coulomb forces ($\varepsilon \to \infty$). Assuming that the rate differences in the two solvents are caused only by the Coulomb term, *i.e.* k_∞ is solvent independent, then the ratio of rate constants in ammonia and water is given by

$$[3] \quad \ln\frac{k_{NH_3}}{k_{H_2O}} = \frac{N_L z_1 z_2 {e_0}^2}{RT} \times \left(\frac{1}{a_{H_2O}\varepsilon_{H_2O}} - \frac{1}{a_{NH_3}\varepsilon_{NH_3}}\right)$$

Figure 2 shows a plot of k_{NH_3}/k_{H_2O} according to [3] with a reasonable collision distance in water, a_{H_2O} = 3 to 4 Å (9), as a function of the collision distance in ammonia a_{NH_3}. The experimental rate ratios are given on the left hand side. For anions a fit is obtained only for a_{NH_3} of 2 to 3 Å, which appears too small considering the rather large effective radius of the ammoniated electron. For the cations, on the other hand, a_{NH_3} seems too large ranging from 8–20 Å. Varying a_{H_2O} does not yield a better value for a_{NH_3}. Therefore we conclude that k_∞ cannot be independent of the solvent.

Variations in k_∞ were computed from [2] using the experimental rate constants k and taking a_{H_2O} = 3–4 Å (9) and a_{NH_3} = 5–6 Å (because of the larger electron radius in ammonia). For both anions and cations it is found that k_∞ in ammonia is roughly three powers of ten smaller than in water. A smaller a_{NH_3}, or larger a_{H_2O}, gives smaller ratios of $k_{\infty H_2O}/k_{\infty NH_3}$ for anions and larger for cations and vice versa.

Therefore, excluding the electrostatic contribution to the rate constant, we conclude that the electron in ammonia has a lower reactivity than the electron in water. This may be due to the energy as well as the entropy factor determining the rate constant (8)

$$[4] \qquad k \propto \exp(\Delta S^{\ddagger}/R) \exp(-\Delta H^{\ddagger}/RT)$$

where $\Delta S^{\ddagger}$ = activation entropy and $\Delta H^{\ddagger}$ =

activation enthalpy. However, since we find activation energies for the three anions in ammonia only slightly smaller than those reported for water (Table 1) it must be the entropy factor which in this case is responsible for the decreased reactivity of e_{am}^-.

In contrast to the foregoing discussion it should be mentioned that in water, ethanol, or their mixtures the variation of the rate of the e_s^-–NO_3^- and of the e_s^-–Zn^{2+} reaction (9) can be explained solely on the basis of the Coulomb term of [2] with constant collision distance and constant k_∞.

Organic Molecules

Table 2 gives collected rate constants for the reaction of solvated electrons with organic molecules in water and ammonia. Again we can try to distinguish between reactions which are diffusion and which are nondiffusion controlled.

Diffusion Controlled

The bimolecular rate constant follows from [1] with $z_2 \rightarrow 0$ (8):

$$[5] \qquad k_{diff} = 4\pi a N_L D/1000$$

With the same diffusion constants and collision parameters as given before the diffusion controlled rate constants in water and ammonia should be $1.1\text{–}1.5 \times 10^{10}$ and $1.9\text{–}2.3 \times 10^{11}$ $M^{-1}\,s^{-1}$. It is seen that rate constants of this order of magnitude are obtained for the electron reactions with biphenyl, naphthalene, anthracene, and nitrobenzene. Consequently there is no doubt that these reactions are diffusion controlled in water as well as in ammonia.

Nondiffusion Controlled

All other reactions are slower in ammonia by two to seven powers of ten as compared to those in water, showing again that the electron in ammonia is less reactive than in water or alcohol (9). This is true even if the different electrostatic contributions to reactions of an ion with a neutral particle are included (8). This would account for a rate constant ratio in ammonia and water of 0.2 to 3 depending only on whether the radius of the solvated electron is smaller or larger than that of the activated complex.

TABLE 2. Rate constants for the reaction of solvated electrons with organic molecules in water and ammonia

Molecule	Water*	Ammonia
Benzene	$<7 \times 10^6$	<1
Toluene	1×10^7	<1
Biphenyl	7×10^9	8×10^{10}†
Naphthalene	5.4×10^9	1.1×10^{11}†
Anthracene	—	3.5×10^{11}†
Nitrobenzene	3×10^{10}	2.8×10^{11}†
Acetone	6×10^9	9×10^7
1-Bromopropane	8×10^9	8×10^6
1-Chloropropane	7×10^8	3×10^6
Acetonitrile	3×10^7	2
Dimethylsulfoxide	1.7×10^6	2.5×10^2

*Reference 1.
†Reference 10.

Activation Energy and Activation Volume

For further studies of the activation energy and activation volume of the solvated electron reactions (temperature- and pressure-dependence of reaction rate) we chose acetonitrile and dimethylsulfoxide, which react with solvated electrons in ammonia 10^7 and 10^4 times slower than in water. The large differences in rate constants definitely rule out a major contribution from the Coulomb effect. The activation energies and activation volumes of the electron reactions in ammonia are 7.0 and 9.0 kcal/mol and -60 and -45 ml/mol for acetonitrile and dimethylsulfoxide, respectively. The higher activation energies in ammonia as compared to those in water (which are around 5 kcal/mol (1)) cannot explain the differences in rate. Again it is concluded that the entropy factor of [4] is decisive for the slow electron reactions in ammonia.

The large negative activation volume in ammonia reflects the large molar volume of solvated electrons in ammonia as was found previously (7) ($\approx$65 ml/mol according to density measurements on metal ammonia solutions (2–6)). Together with the larger activation energy it proves that the rates of these two reactions in ammonia are controlled by a reaction step involving charge transfer to the substrate and collapse of the cavity of the ammoniated electron.

In pure water, however, where the molar volume of the electrons is small, the pressure effect on the rates also is small (13, 14).

Conclusions

After correction for the electrostatic contribution it is shown that (besides the few diffusion controlled reactions with neutral molecules) the electron reaction rates in ammonia are by several powers of ten slower than in water. This is

considered due to the entropy factor of the rate expression [4]; this includes that the entropy of the 'large' solvated electrons in ammonia is larger than that of the 'small' solvated electrons in water. A high molar entropy of the ammoniated electrons has been assumed before (15, 16) and also can be deduced from several e_s^--equilibrium reactions (*e.g.* $C_6H_6 + e_{am}^- \rightleftarrows C_6H_6^-$) (17) in ammonia which too exhibit pronounced pressure effects ($\Delta V = -60$ ml/mol). Therefore the high entropy of the ammoniated electron is associated with its large volume, so that all differences in rates of the electrons in water and in ammonia may be due to structural effects. They reflect the different interaction of the electron with an HN- or an HO-group of the solvent. Consequently there are no kinetic differences of the electron reactions in water and alcohol (after correction of the electrostatic contribution) since in alcohol the electron also is solvated by an HO-group.

NOTE ADDED IN PROOF

Very recently Farhataziz and Cordier (J. Phys. Chem. **80**, 2635 (1976)), working on a time scale 100 to 1000 times faster than we did, reported rate constants of ammoniated electron reactions with some inorganic ions which are 10 to 100 times larger than ours. It might be that Farhataziz data are too high because of interfering reactions of electrons with other radiation products like $H^\bullet$ or $NH_2^\bullet$ which Farhataziz did not remove but which we very effectively scavenged with methylate ions (electron half-times in our solutions with added scavengers but without substrates were far above 1 s). Another explanation could be given on the basis of an equilibrium reaction

$$e^- + M^{2+} \underset{k_2}{\overset{k_1}{\rightleftarrows}} M^+$$

followed by the slower reaction

$$M^+ \xrightarrow{k_3} \text{products}$$

Then on the fast time scale Farhataziz might have observed the rate constant of the electron attachment k_1, whereas we measured on the slow time scale a complex rate constant involving k_1, k_2, and k_3. Or, finally, the methylate scavenger might lead to complexed cations which are less reactive than the ammoniated cations. In the two latter cases some of our arguments have to be revised. Anyhow, it seems necessary to collect more data of solvated electron reactions in non-aqueous solutions to get to an understanding of their kinetics.

Discussion

G. R. Freeman: The reaction of inefficient scavengers such as acetonitrile with electrons in alcohols is followed by protonation.

[1, −1] $$e_{solv}^- + M \rightleftarrows M_{solv}^-$$

[2] $$M_{solv}^- + ROH \rightarrow MH + RO_{solv}^-$$

The activation volume of [2] is negative and contributes to the total observed activation volume of the electron capture reaction. Perhaps the protonation reaction also con-

tributes to the negative activation volume in liquid ammonia, and the low rate constant might be partly limited by the slowness of protonation of the anion by ammonia.

U. Schindewolf: I do not think that [2] would have the large negative activation volume we observed. However, it would contribute if [2] really is rate determining. But in the equilibrium reactions mentioned above the large pressure dependence definitely is to be attributed to volume change which is due to the large molar volume of the ammoniated electron disappearing in the reaction. In most cases people working in kinetics restrict themselves to the observation of the disappearing of the electrons. It seems now that the electron attachment–detachment equilibrium as you state it is to be considered in many cases, because it obscures the kinetics. The negative activation energy of the e_{am}^- + C_6H_5F reaction we observed in ammonia, and of many other reactions, is due to such an equilibrium.

W. Seddon: Would you care to comment or speculate on the magnitude of the rate constant for the ammoniated solvated electron with alkali metal cations?

U. Schindewolf: I am not sure about the evidence that e_{am}^- reacts with alkali cations. As we know the equilibrium $e^- + K^+ \rightleftarrows (K^+e^-)$, which might lead to an ion pair, in the low concentration solutions is far on the left side. I would suggest pulse radiolysis – conductivity experiments to find out whether the electron is 'trapped' this way. If the reaction occurs, it should be diffusion controlled.

Electron states in liquid metals: especially optical and magnetic properties

N. H. MARCH[1]

Department of Physics, The Blackett Laboratory, Imperial College, London, England SW7 2BZ

Received October 4, 1976

N. H. MARCH. Can. J. Chem. **55**, 2165 (1977).

The theory of optical absorption of the simple liquid metals (*e.g.* the alkalis) is outlined. At not too large frequencies, the Drude theory is regained. The relaxation time is that given by the weak scattering (Ziman) theory of electrical resistivity. For high frequencies, the relaxation time, however, becomes frequency dependent. Appreciable structure enters the theory, arising from collective excitations. The relation to recent ellipsometric measurements on liquid Na is briefly discussed. The optical conductivity and density of states in the divalent metals Hg and Be is then discussed, followed by the relation between photoemission and soft X-ray experiments and current electron theory. Specific attention is given to the evidence for a pseudo-gap in the divalent metals and to changes in the electron states which occur on melting the noble metals.

The second major area treated is concerned with the magnetic properties of liquid metals. The theory of orbital and spin magnetism in simple liquid metals is reviewed and confronted with experiment. It is clear that the electron–electron enhancement effects have a dominant influence on the trend of the spin susceptibility of simple liquid metals as a function of density. However, electron–ion interactions must be introduced as corrections to the interacting electron gas values and in a metal like Li the nearly free electron theory fails to do this adequately. Knight shift results are summarized, and some attention is given to a recent experiment on the Knight shift of expanded fluid Hg. Difficulties for the theory in relation to transport and the pseudo-gap are pointed out. Finally, new theoretical calculations are reported on the relation between the magnetic properties of the liquid rare earth metals and their electrical conductivity. Mathiessen's rule is shown to break down because of very strong potential scattering. A recent theory of this by Parrinello *et al.* shows that in the strong scattering limit the magnitude of the localized spin carried by the rare earth ion drops out of the transport theory, as required by the experiments of Güntherodt *et al.*

N. H. MARCH. Can. J. Chem. **55**, 2165 (1977).

On décrit la théorie de l'absorption optique des métaux liquides simples (par exemple les alcalis). A des fréquences qui ne sont pas trop grandes, on retrouve la théorie de Drude. Le temps de relaxation est celui prévu par la théorie (Ziman) de dispersion faible de la résistivité électrique. Pour des fréquences élevées, il existe toutefois une relation entre le temps de relaxation et la fréquence. Un degré appréciable de structure, provenant d'excitations collectives, entre dans la théorie. On discute de la relation qui existe avec les mesures ellipsométriques effectuées récemment sur du sodium liquide. On discute alors de la conductivité optique et de la densité d'états dans les métaux divalents Hg et Be; le tout est suivi par la relation qui existe entre les expériences de photoémission et de rayons-X doux et la théorie électronique prévaut actuellement. On porte une attention spéciale aux preuves concernant un pseudo-gap dans les métaux divalents et à un changement dans les états électroniques qui se produisent lorsque l'on fait fondre des métaux nobles.

La deuxième section importante qui sera traitée concerne les propriétés magnétiques des métaux liquides. On passe en revue la théorie des magnétismes orbital et de spin dans des métaux liquides simples et on la compare avec l'expérience. Il est évident que l'influence des effets de rehaussement électron–électron est dominante sur la tendance de la susceptibilité de spin des métaux liquides simples en fonction de la densité. Toutefois, des interactions électron–ion doivent être introduites pour corriger les valeurs des électrons interagissant en phase gazeuse; toutefois dans un métal comme le lithium la théorie d'électron presque libre ne parvient pas à l'expliquer d'une façon adéquate. On donne un sommaire des résultats de déplacement de Knight et on accorde une certaine attention à une expérience récente sur le déplacement de Knight par du Hg fluide gonflé. On met en relief les difficultés que la théorie rencontre pour expliquer le transport et le pseudo-gap. Finallement on rapporte de nouveaux calculs théoriques sur la relation qui existe entre les propriétés magnétiques des métaux de terres rares liquides et leur conductivité électrique. On montre que la règle de Mathiessen ne tient

pas à cause de la grande dispersion du potentiel. Une théorie récente à ce sujet par Parrinello et ses collaborateurs montre que dans la limite d'une forte dispersion, l'amplitude du spin localisé transporté par un ion de terre rare disparaît de la théorie du transport tel qu'il est requis par les expériences de Guntherodt et ses collaborateurs.

[Traduit par le journal]

Introduction

The theory of liquid metals divides usefully into two sections:

(*1*) Simple metals (*e.g.* Na, Al, Pb, etc.)

Here, almost free conduction electrons are scattered off ions by a weak electron–ion interaction. The basic ingredients in the theory are: (*a*) the liquid structure factor $S(k)$ and (*b*) a weak pseudopotential $U(k)$, representing the electron–ion interaction.

The nearly-free electron theory of transport (Ziman theory) then gives for the dc electrical resistivity the result (see, for example, ref. 1)

$$[1.1]\quad \rho = (3\pi^2/e^2\hbar v_f^2)\Omega \int_0^{2k_f} |U(k)|^2 S(k) k^3 \, dk = (ne^2\tau/m)^{-1}$$

where v_f and k_f are the Fermi velocity and wave number, respectively, while Ω is the atomic volume and τ the relaxation time. This formula can explain a lot of the general properties of transport in pure liquid metals. Valency is simple (Table 1) and the Hall effect confirms the number of free electrons per atom as equal to the valency (Na 1, Al 3, Pb 4, etc.).

(*2*) Strong scattering liquid metals (*e.g.* transition and rare earth metals: divalent metals, Be, Hg, Ba, etc.).

Here, theory to date generalizes [1.1] using again the measured structure factors but replacing $U(k)$ by the appropriate object (the so-called **t** matrix) describing the strong scattering off a single ion. Though this theory has had some successes (*e.g.* explaining why the dc resistivity of Ba is ~ 300 $\mu\Omega$ cm) the theory is less well based, because for strong scattering, higher order correlations between atoms enter the theory and we do not presently know how to either measure or calculate these with any certainty.

TABLE 1. Effective number of free electrons per atom in liquid metals

Metal	Valency	n^*
K	1	1.0
Ag	1	1.1
Cd	2	2.1
Ga	3	2.9
Sn	4	4.6
Pb	4	4.7
Sb	5	6.1
Bi	5	5.3

With this as background we turn to the first of the two major topics of this review, the optical properties of liquid metals. Subsequently, we shall deal with magnetic properties as the second topic. The link between the two is structure, both electronic and atomic.

(A) Optical Properties

2. *Theory of Optical Absorption of Simple Liquid Metals*

2.1. Drude Theory

The most elementary theory of high frequency conductivity, going back to Drude, writes the real part of the complex conductivity as

$$[2.1]\quad \sigma(\omega) = \frac{\sigma(0)}{1 + \omega^2\tau^2} = \frac{ne^2\tau}{m(1 + \omega^2\tau^2)}$$

where at $\omega = 0$ this reduces to the above formula [1.1], an explicit expression for τ resulting in terms of the structure factor and pseudo-potential.

Equation 2.1 adequately represents the ac conductivity of numerous liquid metals with $\omega\tau$ found to be ~ 1 in the visible, to be contrasted with the case of solids where $\omega\tau \sim 1$ lies in the far infrared. Equation 2.1 is, of course, the real part of the complex conductivity, the imaginary part being derivable from it, in principle, using the Kramers–Kronig relations.

The values obtained experimentally for n, the effective number of free electrons per unit volume, are shown in Table 1. The results are given per atom, for direct comparison with the valency.

The data available on the optical properties of liquid metals are seen to accord well with free-electron theory, a notable exception, however, being liquid Hg which does not obey the Drude formula [2.1].

We refer briefly at this point to two approaches to the basic theory, one of the principal aims being to get limits of validity for the Drude formula [2.1]. The first approach (see, for example, Sturm and Pajanne (2)) attempts to make direct contact with the Ziman theory, though it shows that, while τ in the denominator

of [2.1] can be correctly calculated from the Ziman theory for low frequencies, for high frequencies the relaxation time becomes frequency dependent. Appreciable structure then enters the theory, arising from collective excitations (see below for a short summary of the theory).

A second, more formal, approach is that of Parrinello and co-workers (3) who treat the liquid metal from the outset as a two-component system of positive ions and itinerant electrons, with correlation functions between each pair of particles. The connection of their approach with the Drude formula is also briefly referred to below.

2.2 Weak Scattering Theory of Optical Absorption

If one treats the simple liquid metals (*e.g.* the alkalis) in which it is appropriate to assume a weak effective electron–ion interaction, then the Drude formula results (see, for example, Sturm and Pajanne (2)) provided $\hbar\omega/E_f \ll 1$ but $\omega\tau \gg 1$. Furthermore the constant relaxation time is indeed given by the Ziman formula, as anticipated above.

The basic theory starts out from the general expression for the real part of the optical conductivity tensor, which, within linear response theory, is given by Pethick (4)

$$[2.2]\quad \mathrm{Re}\,\sigma^{\mu\nu}(\omega) = \frac{1}{2}\frac{e^2/m^2}{\hbar\omega^3}\int_{-\infty}^{\infty} dt(e^{-i\omega t} - e^{i\omega t})\frac{1}{N^2}\sum_{KK'} K^{\mu}K'^{\nu}U_K U_{K'} \times \langle \rho_K^{el}(0)\rho_{-K}^{ion}(0)\rho_{K'}^{el}(t)\rho_{-K'}^{ion}(t)\rangle$$

Here U_K is the Fourier component of the potential of a single ion, while the electronic and ionic density fluctuations are defined as

$$[2.3]\quad \rho_{\boldsymbol{K}}^{el}(t) = \sum_i e^{i\boldsymbol{K}\cdot\boldsymbol{r}_i(t)}$$

and

$$[2.4]\quad \rho_{\boldsymbol{K}}^{ion}(t) = \sum_j e^{i\boldsymbol{K}\cdot\boldsymbol{R}_j(t)}$$

$\boldsymbol{r}_i$ and $\boldsymbol{R}_j$ denoting electronic and ionic coordinates, respectively.

The important simplification which arises if we now calculate Re $\sigma^{\mu\nu}(\omega)$ to second-order in the potential is that the correlation function decouples to yield

$$[2.5]\quad \langle \rho_{\boldsymbol{K}}^{el}(0)\rho_{-\boldsymbol{K}}^{ion}(0)\rho_{\boldsymbol{K}'}^{el}(t)\rho_{-\boldsymbol{K}'}^{ion}(t)\rangle \simeq \langle \rho_{\boldsymbol{K}}^{el}(0)\rho_{\boldsymbol{K}'}^{el}(t)\rangle\langle \rho_{-\boldsymbol{K}}^{ion}(0)\rho_{-\boldsymbol{K}'}^{ion}(t)\rangle$$

In lowest order, $\langle \rho_{\boldsymbol{K}}^{el}(0)\rho_{\boldsymbol{K}'}^{el}(t)\rangle$ is the electronic density–density correlation function of jellium (Sommerfeld model of a metal). Therefore we have

$$[2.6]\quad \langle \rho_{\boldsymbol{K}}^{el}(0)\rho_{\boldsymbol{K}'}^{el}(t)\rangle \neq 0$$

only if $\boldsymbol{K}' = -\boldsymbol{K}$.

Furthermore, this is directly related to the frequency-dependent dielectric function $\varepsilon(K,\omega)$ of the electron gas by

$$[2.7]\quad \int_{-\infty}^{\infty} dt\langle \rho_{\boldsymbol{K}}^{el}(0)\rho_{-\boldsymbol{K}}^{el}(t)\rangle(e^{-i\omega t} - e^{i\omega t}) = \frac{\hbar^2K^2}{2\pi e^2}\,\mathrm{Im}\left(\frac{-1}{\varepsilon(K,\omega)}\right)$$

Also the (dynamic) structure factor is given by

$$[2.8]\quad S(\boldsymbol{K},t) = \frac{1}{N}\langle \rho_{-\boldsymbol{K}}^{ion}(0)\rho_{\boldsymbol{K}}^{ion}(t)\rangle$$

As the ions move slowly compared with the electronic motion we can put $t = 0$ since on the time scale defined by the frequency of the light, electrons see essentially a static distribution of ions.

Since $S(K)$ is isotropic for a liquid metal, we then obtain

$$[2.9]\quad \mathrm{Re}\,\sigma(\omega) = (24\pi^3 nm^2\omega^3)^{-1}\int dKK^6|U_K|^2S(K)\,\mathrm{Im}\,(-1/\varepsilon(K,\omega))$$

Introducing a formal definition of relaxation time through

$$[2.10]\quad \mathrm{Re}\,\sigma(\omega) = \frac{ne^2}{m}\frac{1}{\tau(\omega)\omega^2} \qquad \text{for } \omega\tau \gg 1$$

we obtain

$$[2.11] \qquad \frac{1}{\tau(\omega)} = (24\pi^3 n^2 m e^2 \omega)^{-1} \int dK K^6 |U_K|^2 S(K) \, \mathrm{Im}\,(-1/\varepsilon(K,\omega))$$

(a) Connection with Ziman Theory—Provided $\hbar\omega/E_f \ll 1$ we can write

$$[2.12] \qquad |U_K|^2 \, \mathrm{Im}\left(\frac{-1}{\varepsilon(K,\omega)}\right) \simeq \left|\frac{U_K}{\varepsilon(K,0)}\right|^2 \mathrm{Im}\,\varepsilon(K,\omega)$$

The Lindhard expression for Im $\varepsilon(K,\omega)$ for small frequencies is

$$[2.13] \qquad \mathrm{Im}\,\varepsilon(K,\omega) = \frac{3\pi}{2}\frac{\omega_p{}^2\omega}{K^3 v_f{}^3}$$

where ω_p is the plasma frequency and v_f the Fermi velocity.

Substituting this result in [2.11] we obtain the reciprocal relaxation time τ^{-1} as

$$[2.14] \qquad \tau^{-1} = \frac{m}{12\pi^3\hbar^3 n^2}\int_0^{2k_f} dK K^3 S(K)|U_K/\varepsilon(K,0)|^2$$

where U_K is normalized such that $U_{K=0}/\varepsilon(0,0) = -\frac{2}{3}E_f$. This is precisely the form given by the Ziman theory. Sturm and Pajanne (2) have made numerical calculations for Na at 100°C with the Ashcroft (5) empty core model potential

$$[2.15] \qquad U(r) = \begin{cases} -e^2/r & r > R_c \\ 0 & r < R_c \end{cases}$$

with $R_c = 1.66a_0$, a_0 being the Bohr radius. They use a hard sphere model for $S(K)$, with a hard sphere diameter 3.30 Å.

Figure 1 shows the real part of $\sigma(\omega)$ (full curve) from their calculations compared with the Drude (constant relaxation time) result (dashed curve). The most striking feature is the peak arising from the collective excitations (plasmons).

Comparison with experiment is still difficult, but it seems that for photon energies $\sim E_f$ the optical absorption is considerably greater than the Drude value, in general accord with theory. Measurements on liquid Al between about 0.8 and 4 eV (6) show essentially Drude behaviour. This is in agreement with theory, since for $\hbar\omega/E_f \ll 1$ the Drude formula should be valid.

(b) Ellipsometric Measurements on Na—Rather than attempt to survey earlier experiments (see, for example, Faber (7) for both experiment and theory), we shall conclude this discussion of optical absorption in the simple metals by referring to the accurate ellipsometric measurements on free surfaces of liquid Na at 120°C between 0.6 and 3.8 eV, recently reported by Inagaki *et al.* (8).

They find that the optical conductivity below 2.2 eV agrees well with the Drude formula [2.1]. Above 2.2 eV the optical conductivity exhibits a weak absorption, which they suggest is analogous to the interband absorption in the solid phase.

Their measurements of the optical conductivity, related to the imaginary part ε_2 of the dielectric constant by $\sigma = \omega\varepsilon_2/4\pi$, where ω is the angular frequency of the incident photons, are shown in Fig. 2, along with the Drude result. The free-carrier density of 2.405×10^{22} cm^{-3} at 120°C plus the measured dc conductivity $\sigma(0) = 8.607 \times 10^{16}$ s^{-1} lead to a relaxation time $\tau = 1.653 \times 10^{-14}$ s. This is obtained by taking an effective mass m^* of $1.17m$, which was deduced from the experimental values of the real part of the dielectric function in the infrared region.

The results for ε_1, the real part of the dielectric function, are plotted in Fig. 3, as a function of the square of the wavelength λ in μm. Inagaki *et al.* (8) analyzed these data by using the conventional form

$$[2.16] \qquad \varepsilon_1 = 1 + 4\pi n_0\alpha - ne^2\lambda^2/\pi m^* c^2$$

where n_0 is the atomic density and α is the ion-core polarizability. This gives $m^* = (1.17 \pm 0.01)m$ below 2.2 eV and $(1.10 \pm 0.01)m$ above 2.2 eV, a plasma energy, defined by $\varepsilon_1 = 0$, at 5.70 ± 0.05 eV, and $4\pi n_0\alpha = -0.05 \pm 0.05$. The result for m^* below 2.2 eV is comparable to that obtained by Mayer and Hietel (9) at 100°C, namely $m^* = 1.19m$, despite the substantial differences in σ recorded in Fig. 2.

3. Strong Scattering Liquid Metals

3.1. Summary of Two-component Theory

As remarked above, in ref. 3 an approach to liquid metals which treats them, from the outset,

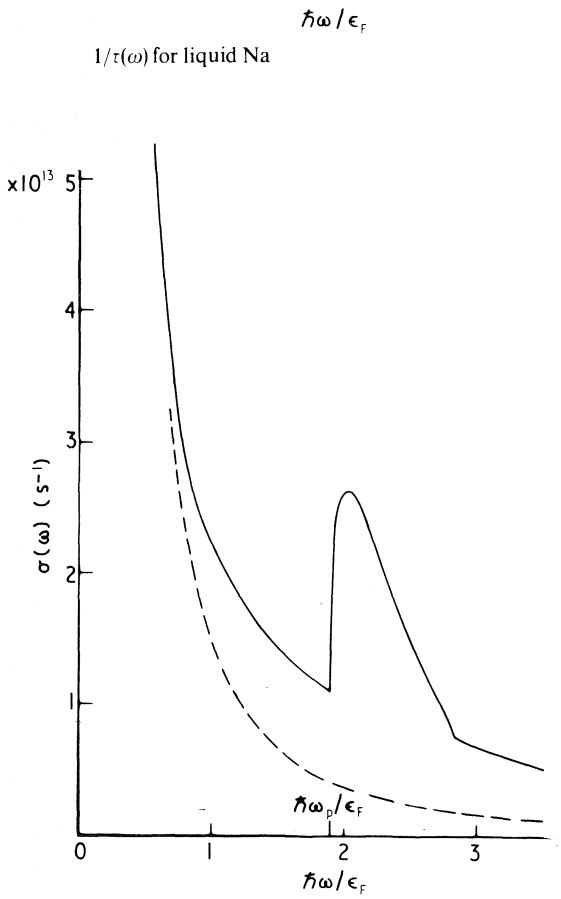

FIG. 1. High frequency conductivity of liquid Na: — calculated from [2.11], --- result of Drude theory. (Reprinted with permission from the Journal of Physics F: Metal Physics, **3**, 199 (1973). Copyright by The Institute of Physics.)

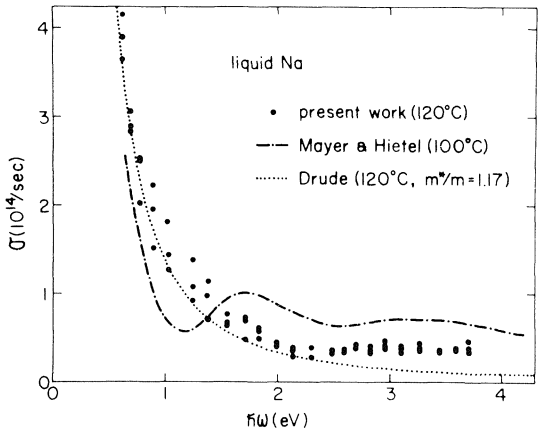

FIG. 2. High frequency conductivity of liquid Na. (Reprinted with permission from Physical Review Section B: Solid State, **13**, 5610 (1976). Copyright by The American Physical Society.)

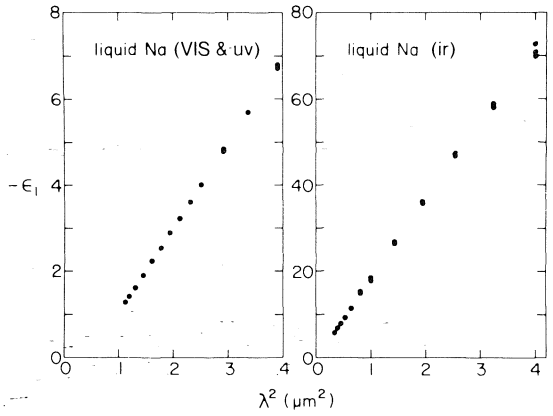

FIG. 3. Real part of dielectric constant for liquid Na. (Reprinted with permission from Physical Review Section B: Solid State, **13**, 5610 (1976). Copyright by The American Physical Society.)

as two-component systems, with three partial structure factors, has been developed, which may eventually afford a route to the strong scattering theory.

Optical properties are then described by a formula for the conductivity in the long wavelength limit $k \to 0$, namely

$$[3.1] \quad \sigma(k=0,\omega) = \frac{n_e e^2}{m_e} \times \frac{M/m_i}{-i\omega + M\gamma(\omega)/n_e m_i m_e}$$

where $M = m_i + Zm_e$, Z being the valence and e and i denoting electrons and ions, respectively.

The Drude theory, which, as we saw in section 2, is very useful for liquid metals, follows if $\gamma(\omega)$ in [3.1] is assumed to vary only slowly with frequency over the range of interest. Both theoretical predictions and empirically derived forms of $\gamma(\omega)$ for simple liquid metals are discussed in ref. 3. $\gamma(\omega)$ involves the electron–ion interaction and the functional derivative with respect to the electron current of the ion-density – electron-density correlations: to date no convincing approach to this object in the presence of strong scattering exists. Reference should also be made here to the work of Jones (10) on frequency-dependent conductivity.

In view of these difficulties in the theory for strong scattering, we shall restrict ourselves to a brief discussion of the optical properties of the divalent metals, Hg and Be, and the relation of these properties to the density of electronic states.

3.2. Optical Conductivity and Density of States in Divalent Metals

Divalent elements such as Be and Hg form metallic crystals below their melting temperatures because of band overlap. If this overlap is sufficiently small, it is evident that in the crystal the density of electronic states will pass through a minimum in the region where the bands overlap.

The question now arises, whether such a minimum in the density of states (often referred to as a pseudogap) will persist, when the long-range order in such a divalent metal is destroyed by melting.

(a) Liquid Mercury—Mott (11) has suggested that, if there is a pseudogap near the Fermi level, as depicted in the density of states $N(E)$ drawn in the lower part of Fig. 4, then the high frequency conductivity should have the form shown in curve *2* of the upper part of Fig. 4. The behaviour without a pseudogap should have the Drude form as in curve *1*. The reason why there should be a peak away from zero frequency in $\sigma(\omega)$, according to Mott's argument, is indicated by the available transitions for low and high frequency in the lower part of Fig. 4.

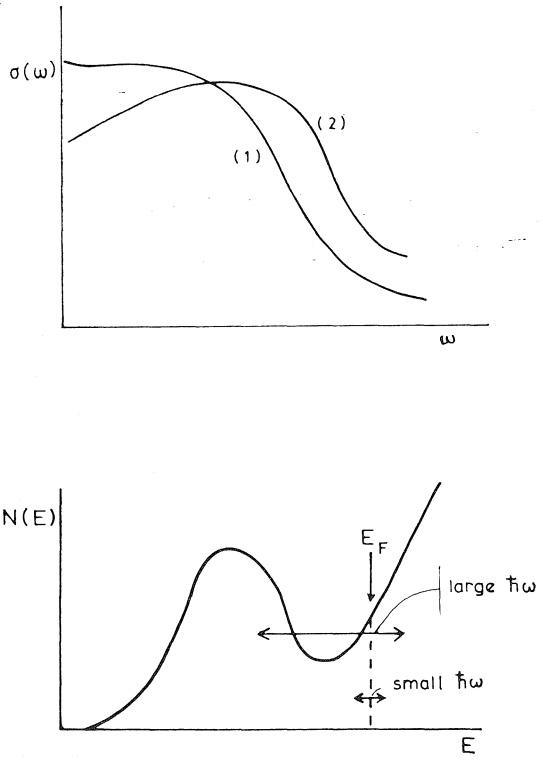

FIG. 4. Upper diagram: high frequency conductivity with (curve *2*) and without (curve *1*) a pseudogap. Lower diagram: density of states with pseudogap.

Subsequently, the optical conductivity and electronic density of states for liquid Hg have been discussed by Chan and Ballentine (12) using low-order perturbation theory. They found a dip near the Fermi energy in the density of states $N(E)$, which was less pronounced than that suggested by Mott, and which they found too small to alter the optical conductivity appreciably from Drude form.

Experimentally it is not clear that $\sigma(\omega)$ behaves like curve *2* of Fig. 4 (actually Hodgson (13) has found a shape like this for liquid Te). Thus, for liquid Hg, Guggenheim (14) finds such an effect, which disappears on alloying. Comins (15) comes to a similar conclusion, both these experiments being carried out using ellipsometric methods. In contrast, Boiani and Rice (16) get good accord with the Drude formula over a wide frequency range, using direct reflection methods. Bloch and Rice (17) maintain that the differences can be reconciled if a surface layer with different electrical properties from the bulk is assumed.

We shall return to the question of the existence of a pseudogap in liquid Hg several times. However, there has also been a small amount of work done on liquid and amorphous Be, another divalent metal, and we turn now to summarize the findings on this metal.

(b) Amorphous Beryllium—Rousseau *et al.* (18) have reported a calculation of the electronic density of states of liquid Be, in which the basic building block is the partition function of a single screened ion in a Fermi gas. This is treated by strong scattering, not by low-order Born approximation, and the partition function of the liquid metals is then built up from such screened ions (pseudoatoms) assuming independence, that is

$$[3.2] \qquad pf_{\text{liquid}} = \Pi pf_{\text{screened ions}}$$

The electronic density of states can be derived from, essentially, the inverse Laplace transform of the partition function. Rousseau *et al.* (18) conclude that there is considerable similarity between the liquid and the crystal and that some dip remains in the liquid density of states. It would, of course, be of considerable interest to apply the more modern methods of electronic structure calculations, briefly summarized in the Appendix, to this metal.

To our knowledge, there is no experiment as yet available relating to the optical properties of liquid Be. However, Hunderi and Myers (19) have measured the optical absorption of evaporated Be films, which they believe to be in a disordered state. They find, as can be seen from Fig. 5, that their data are quite similar to the spectrum obtained on bulk single crystal Be by Weaver *et al.* (20). Their findings are consistent with the view that the electronic structure of crystalline as well as disordered Be is governed largely by short-range order. The theoretical work of Rousseau *et al.* (18) supports this view. In particular, both experiment and theory lend some support to the view discussed above for Hg also, that a minimum in the density of electronic states near the Fermi level, known to exist in crystalline Be, will persist in the presence of disorder.

4. Soft X-Ray and Photoemission Experiments on Molten Metals

Within the general area of optical properties, we turn next to a class of experiments containing potentially much richer information on electronic states in liquid metals than ac conductivity.

Since the early days of the band theory of metals, it has been clear that experiments on soft X-ray emission, in which an electron falls from a conduction band state into a core hole (*e.g.* in Li from p states in the $2s$–p conduction band into the ($1s$) K shell state) must reflect the density of states in the conduction band. But, of course, matrix elements also come in, and only if these are slowly varying in energy can one extract the electronic density of states $N(E)$ from the intensity of the soft X-ray emission. Nevertheless, this class of experiment remains very important, and we shall discuss recent results by Hague (21) on the metals Fe, Ni, and Co. Passing reference will also be made to earlier work on Al.

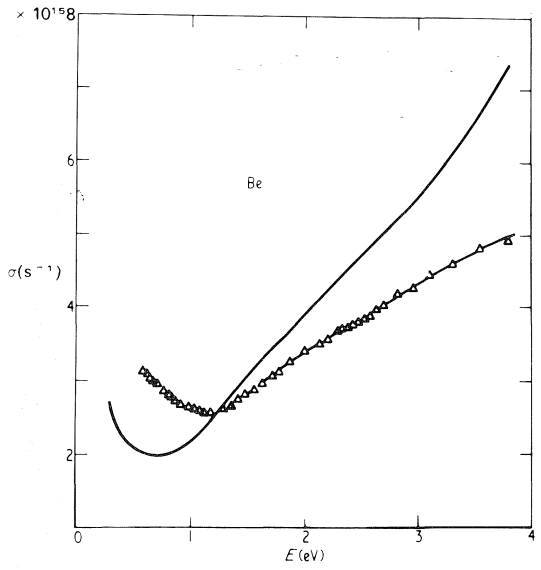

FIG. 5. Optical conductivity of crystalline Be (full curve) after Weaver *et al.* (20). Other results, conductivity of Be deposited and measured at 20 K. (Reprinted with permission from the Journal of Physics F: Metal Physics, **4**, 1088 (1974). Copyright by The Institute of Physics.)

The other very important approach to the experimental study of the electronic density of states is afforded by photoemission. We shall consider in some detail the experiments by Williams and Norris (22) on liquid noble metals as well as the work of Cotti *et al.* (23) on liquid Hg. Again, we make no claim to completeness. Theoretical approaches to the calculation of the electronic density of states in a liquid metal will be briefly referred to, and some of the principal conclusions confronted with the above experiments.

4.1. Photoemission and Electronic Band Structure

Williams and Norris (22) have observed ultraviolet photoemission (21.2 eV) from liquid Cu samples. Figure 6 shows their photoelectron energy distribution curves (EDC's) obtained for liquid Cu, and for comparison they show results from the same sample immediately after freezing and after being held for several days at 1000 K. The energy scale is such that the zero corresponds to the Fermi level.

The primary distribution of photoemitted electrons can be expressed as a sum over initial (i) and final (f) states, namely as

$$[4.1]\quad \mathcal{N}_{\text{primary}}(E,\hbar\omega) = \sum_{i,f} |\langle f|H'|i\rangle|^2 \times \delta(E_f - E_i - \hbar\omega)\delta(E - E_f)$$

where H' is the interaction describing both the probability of photoexcitation and escape into the vacuum.

For disordered systems such as liquids, in which non-direct transitions are possible, it may be argued that the matrix element is not a dominant function and can be removed from the summation to yield

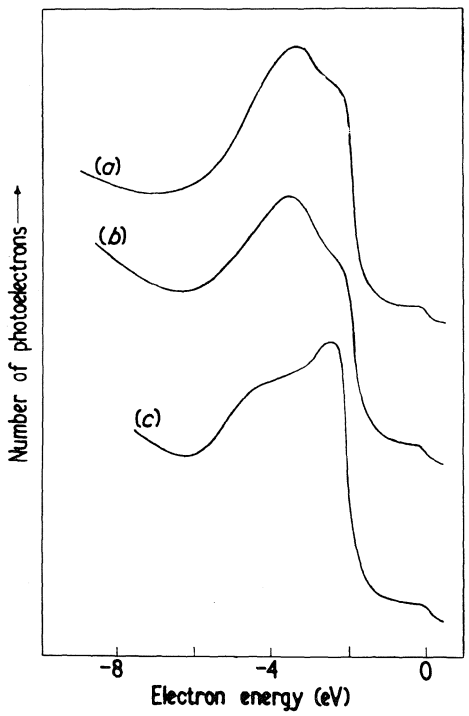

FIG. 6. Energy distribution curves for Cu (*a*) liquid, (*b*) solid immediately after freezing, and (*c*) solid after annealing. (Reprinted with permission from the Journal of Physics F: Metal Physics, **4**, L175 (1974). Copyright by The Institute of Physics.)

$$[4.2] \qquad \mathcal{N}(E,\hbar\omega) = BN(E - \hbar\omega)N(E)$$

as a product of initial and final density of states.[2]

Figure 7 shows a comparison between the measured result for liquid Cu and the result of a cluster calculation for liquid Cu by Keller *et al.* (25). Also plotted is the density of states computed by Mueller (26) for the face-centred cubic crystal.

There is substantial agreement between the shape of the 3*d* band and the cluster calculation. However, the agreement between the measured shape and the 3*d* band of the crystal is much poorer than was found for liquid and solid Au by Eastman (27). The explanation (*cf.* ref. 22) seems to lie in the fact that in Au there is greater *s–d* hybridization with correspondingly less sensitivity to the local order than is the case for Cu. The high energy peak at −2.5 eV in Cu is associated with an unhybridized level in the solid

[2]Refinements of this expression are discussed by Schaich and Ashcroft (24).

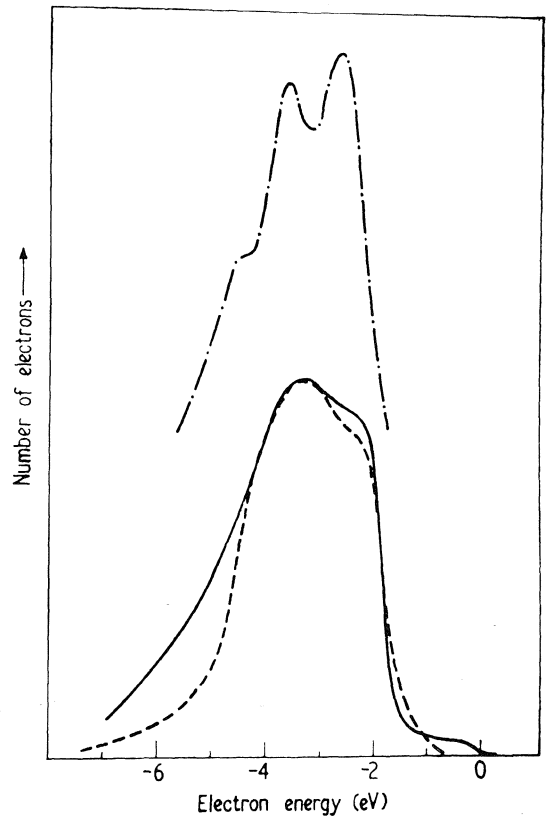

FIG. 7. Density of states of liquid Cu: -·-·- Mueller's calculation for fcc Cu, — experiment on liquid, --- cluster calculation. (Reprinted with permission from the Journal of Physics F: Metal Physics, **4**, L175 (1974). Copyright by The Institute of Physics.)

and would therefore be expected to weaken considerably, as Williams and Norris (22) observe, when the crystal melts and the long-range order is lost.

In connection with the above cluster calculation, it is of interest that House and Smith (28) found for crystalline Cu that a cluster calculation using only a single face-centred-cubic unit cell was in good agreement with the band structure result.

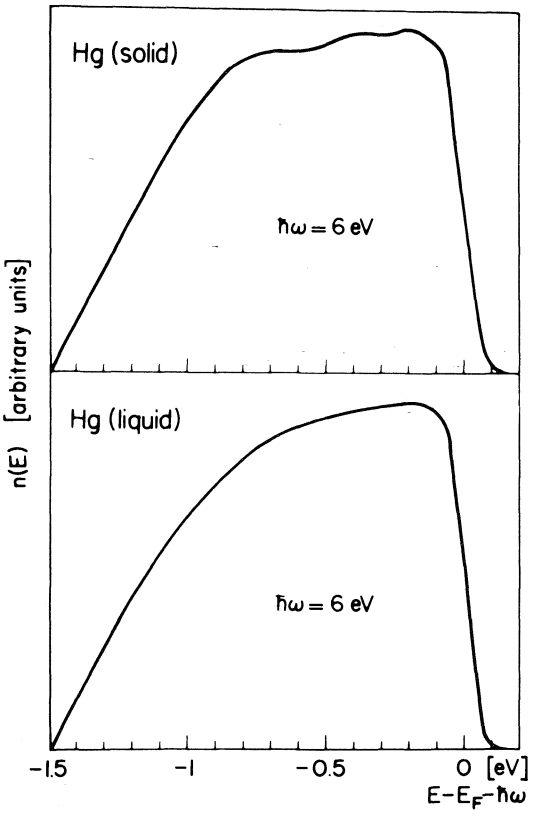
(a) Photoemission from Liquid Hg—Because of a possible pseudogap referred to previously, Hg has attracted considerable attention and Cotti *et al.* (23) have reported measurements of the energy distribution of photoemitted electrons from both the liquid and solid.

As remarked above, in connection with Cu, provided that $\boldsymbol{k}$-conservation is not an effective selection rule, as is the case for a liquid metal,

then the EDC's may be regarded as reflecting the density of states.

In Fig. 8, the EDC's show clearly that liquid and solid Hg exhibit the same general behaviour, though the solid curve has a little more structure, probably arising from direct transitions at critical points. Figure 9 shows a comparison of the liquid results with the predictions of nearly-free electron theory. The agreement is much poorer than for say potassium (23) and therefore Cotti *et al.* (23) claim that their results indicate the presence of a pseudogap (or minimum in the density of states) in liquid Hg, first suggested by Mott (11, 29). Such a minimum in the density of states was consistent with the experiments of Hunderi and Myers (19) discussed above for disordered divalent Be.

We have reproduced in Fig. 10 the density of states in a divalent liquid metal according to the proposal of Mott (ref. 29; compare $N(E)$ for Be from Rousseau *et al.* (18)). Part *a* would be the result of low order perturbation theory, curve *b* the suggested form for liquid Hg. Curve *c* is a form suggested for Hg at densities such that the conductivity lies in the range 300–2000 Ω^{-1} cm^{-1}, while *d* is the curve expected at low densities. Curve *d* is indeed what seems to be required by the low density experiments of Hensel and Franck (30) and Schmulzter (31). It is relevant in this context to refer to the work of Overhof *et al.* (32) who have attempted to explain the optical properties of expanded fluid Hg using a quasi-crystalline model with non-direct transitions. They also make a critical examination of discrepancies between optical and electrical transport data for fluid Hg but we must refer the reader to their paper for further details (see also refs. 36 and 39).



Comparison of EDC's for solid and liquid mercury.

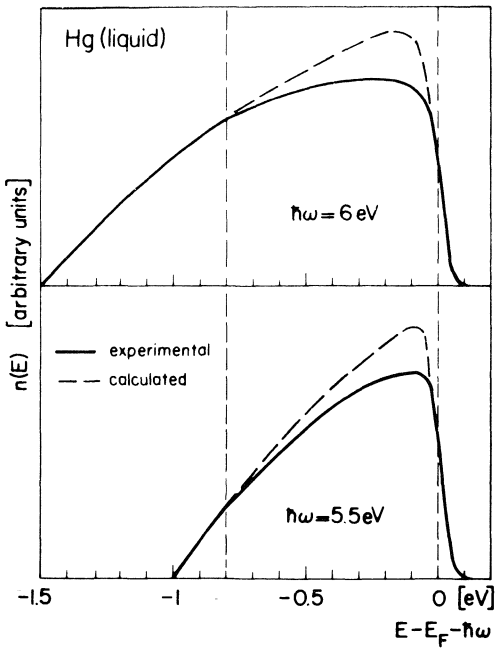

FIG. 9. Comparison of calculated and measured EDC's for liquid Hg. (Reprinted with permission from Solid State Communications, **12**, 635 (1973). Copyright by Pergamon Press Ltd., Oxford.)

(b) Other Results by Ultraviolet Photoemission Spectroscopy—Some other valence band results have been obtained by ultraviolet photoemission spectroscopy (ups). It seems that these techniques can provide a better resolution of the densities of states, if a sufficiently monochromatic excitation

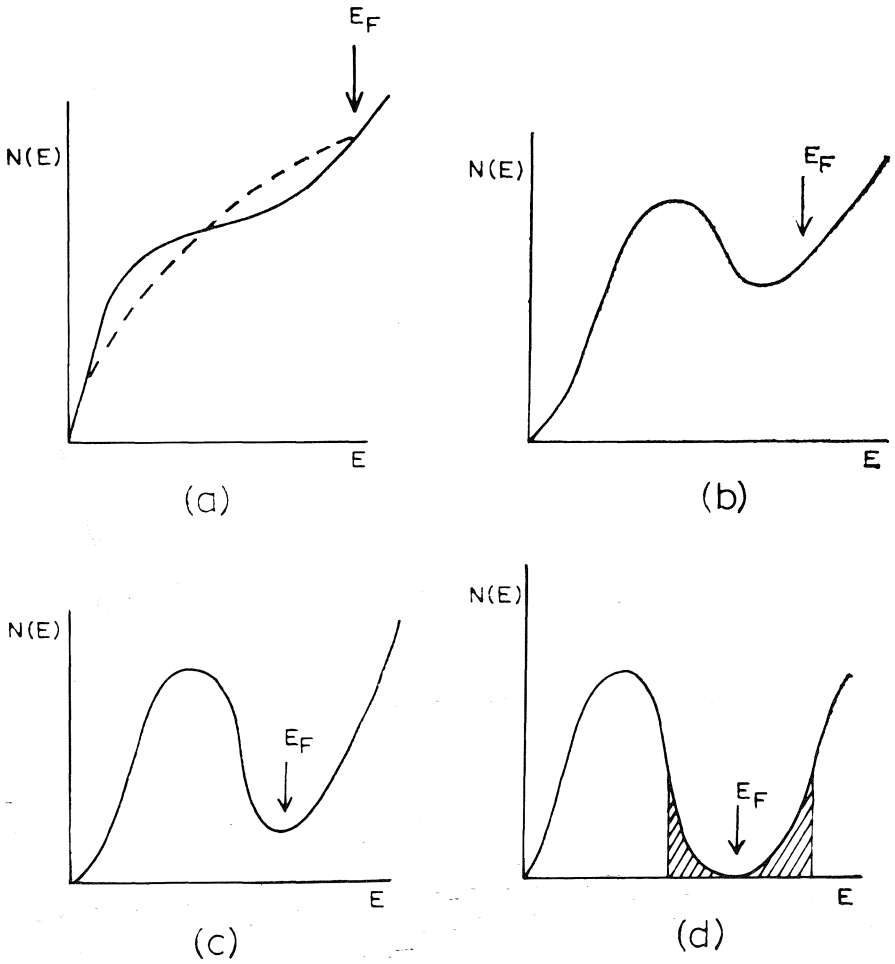

FIG. 10. Densities of states for liquid Hg at different densities: (*a*) high density, dashed curve is free electron result; (*b*) overlapping bands of divalent metal at intermediate density; (*c*) development of pseudogap at lower density; (*d*) shaded regions indicate localized states. radiation is employed (33, 27, 22, and 34). However, they are more subject to surface contamination and secondary effects than soft X-ray spectroscopy (sXs) (21).

Also, photoemission measurements, notably for Sn and In (Norris *et al.* (35); Norris and Rodway[3]) suggest considerably more structure in the electron density of states than calculations based on such a low-order approximation would imply (see Fig. 11).

The conclusion for the simpler metals, especially Sn, In, and Pb, is that the liquid density of states retains quite a few features in common with the crystalline phase, the nearly free electron approximation being almost always too crude.

Following this summary of photoemission results, we shall next consider what we can learn about electronic structure of liquid metals from soft X-ray experiments. We shall focus largely on the very recent work of Hague (21) on the iron group.

4.2. Soft X-Ray Band Spectra of Liquid Metals

Hague (21) has reported the L_3 emission and absorption spectra in liquid Fe, Co, and Ni and we shall briefly discuss his results and their qualitative interpretation.

(a) Emission Spectra—Hague (21) actually measured the L_3 emission curves at two excita-

[3]C. Norris and D. C. Rodway, private communication.

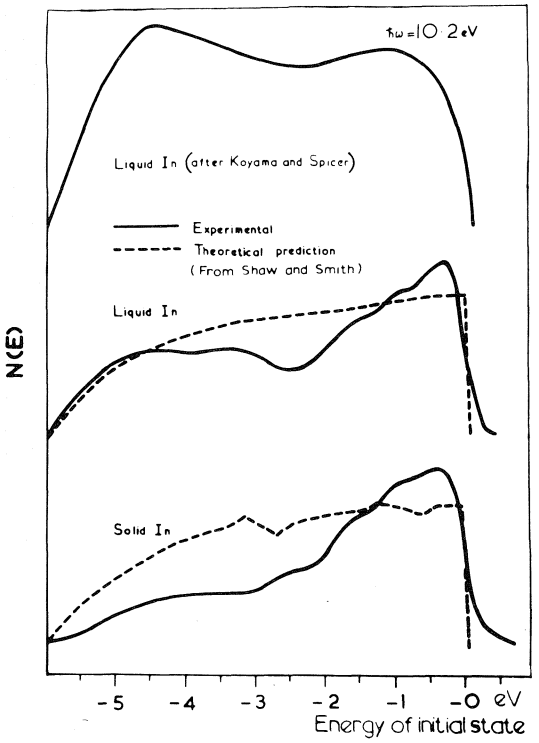

FIG. 11. Densities of states from photoemission for liquid In. (Reprinted with permission from ref. 35.)

tion voltages; only the curves for the 2.5 kV voltage are reproduced in Fig. 12. In Ni, comparison between solid and liquid results turns out to be difficult, because as Hague points out surface oxidation very probably exists in the solid phase (not in the liquid phase).

For Co the differences between solid and liquid emission spectra turn out to be small, though these may again be somewhat masked by some contamination in the solid. Finally, the Fe results are found by Hague to be slightly different from the other two liquid metals. Some modification in the electron states between liquid and solid Fe was observed by Hague in the data at 5 kV.

(b) Absorption Spectra for Fe, Co, and Ni— The experimental results shown in Fig. 12 are for the liquid phase. Curves for the solid phase are considered by Hague (21) to be unreliable because of self-absorption. Therefore, the absorption spectra from solid thin films are given for comparison purposes.

It can be seen that, for Ni, the resemblance between the self-absorption curve and the thin film result is close. Parratt (38) has shown that in

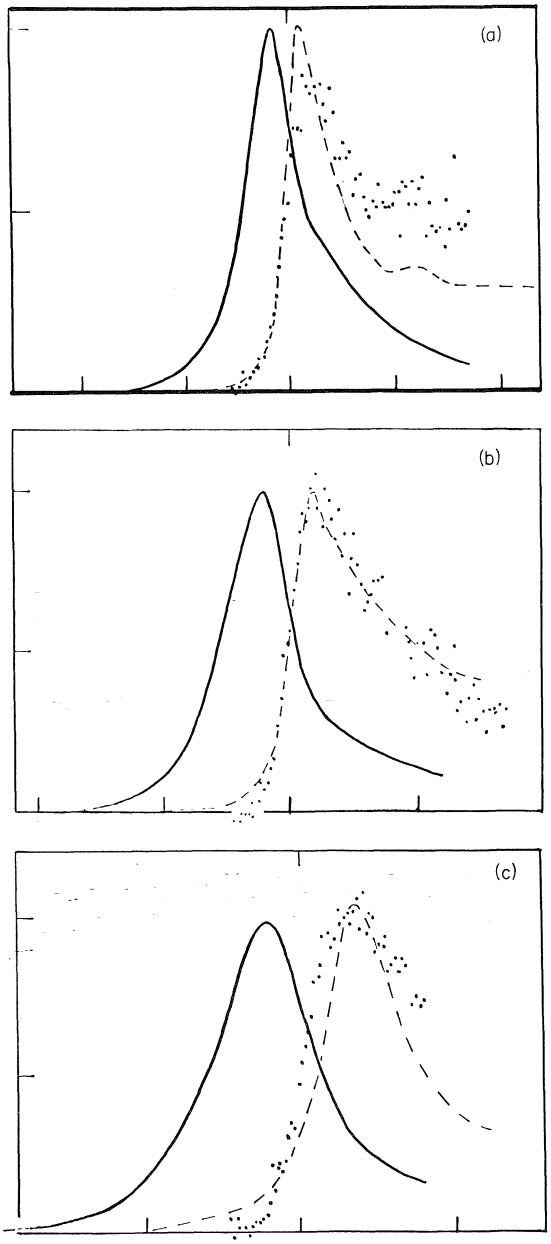

FIG. 12. L_3 emission curves of liquid metals at 2.5 kV—; L_3 self-absorption curves of liquid metals ···; and thin solid film L_3 absorption curves (*a*) Ni, (*b*) Co, (*c*) Fe. (From work of C. Hague; see also ref. 21.)

the case of a sharp peak representing the empty *d* states in the conduction band, as in this case, the amplitude of the maximum is very dependent on the thickness of the absorbant. Hague (21) suggests this as an explanation of the attenuation observed in the peak in the liquid spectrum.

For Co, in view of some arbitrariness in normalization of the absorption curves, the agreement between the liquid and solid thin film curves is good, and the small deviation occurring at high energy may not be significant.

Finally, for Fe, the absorption spectra show appreciable differences. However, the thin film spectrum, as Hague (21) points out, is most likely perturbed by an anomalous reflection in the analysing crystal containing Fe, which occurs close to the Fermi level. Hague (21) finds that the solid self-absorption curve follows closely that of the liquid result.

Summing up, it seems reasonable to expect that the L emission spectra in transition metals reflect somewhat closely the density of states $N(E)$ of the d states in the valence band. Also the peak in the absorption curve close to the Fermi level is characteristic of the unfilled d states in the conduction band.

Because there is little change in the interatomic distances or coordination number of these metals in the liquid state, modifications in the density of states can be expected to be small. The cluster calculations of House and Smith (28) referred to above, and perhaps also the hard sphere description of Gaspard[4] bear this out.

Hague's (21) soft X-ray spectra do not reveal the presence of any extra structure close to the Fermi level, and neither do the K spectra obtained by Garg and Kallne (40). This is in agreement with the theoretical work of Olsen (41).

Hague (21) stresses that, despite the blurring effect on fine structure due to inner level broadening, the soft X-ray band spectra should be capable of exposing quite small alterations in the electronic structure. Evidence exists, in his measurements, that the non-close-packed metal in the solid, namely Fe, already shows changes in the electronic states on melting.

(c) Soft X-Ray Spectra of Other Liquid Metals—Other measurements of similar type to those of Hague (21) were made on the L emission spectrum of liquid Al (42), its K emission spectrum (43, 44), and more recently on the K emission of liquid Cu and Fe (40).

In the X-ray region, the results for Al diverge for the K and L X-ray emission (44, 42). Catterall and Trotter (42) demonstrate that the L_{23} emission spectrum obtained from liquid Al shows some resemblance to the solid, though the peak characteristic of the zone overlaps is rather less pronounced. Again, the result shows that the short-range arrangement of atoms is playing a more important role than the long-range order. Fisher and Baun (44) find that near the melting point the K bands for solid and liquid differ only slightly. However, at a temperature several hundred degrees above the melting point, they find a markedly different result, which, they suggest, may be due to the liquid surface or to a dense vapour layer close to the liquid Al surface.

Garg and Kallne (40) study the K emission band (valence band $\rightarrow 1s$) and the emission lines $K\beta_{1,3}$ ($3p_{3/2,1/2} \rightarrow 1s$) for Fe and Cu. The main conclusion is that the K X-ray spectra of the transition metals Cu and Fe are unaffected by melting, within the accuracy of the experiment.

For Fe and Cu the density of states has been calculated by the cluster method (45). For liquid and solid Fe the calculation gives a broad $3d$ band almost split into two parts. For Cu, the $3d$ band is single and narrow, but with much fine structure. The band width predicted is the same for solid and liquid within 5%. Thus, the experiments agree in general terms with the calculations, although the experiment could not detect the splitting of the Fe $3d$ band due to limitations imposed by (*a*) the spectrograph and (*b*) the mode of detection.

Clearly, this is an area in which a good deal of effort is worthwhile, especially if the theoretical work on electron states could be brought to a state of refinement in which the observed intensities could be calculated, not just the electronic densities of states.

(B) Magnetic Properties

5. *Spin and Orbital Magnetism in Simple Liquid Metals*

We begin the discussion of magnetic properties by summarizing briefly the results of spin and orbital susceptibility, in a band theory framework, at first neglecting electron–electron correlations.[5]

If we start out from free electrons (certainly a good approximation for liquid sodium) then the Pauli spin paramagnetism is given by

$$[5.1] \qquad \chi_{\text{Pauli}} = \frac{3}{2} n_0 \mu_B{}^2 \frac{1}{E_f}$$

[4]J. Gaspard, private communication to C. F. Hague; see ref. 21.

[5]This neglect is not justified for quantitative work; see below.

where n_0 is the number of conduction electrons per unit volume, μ_B is the Bohr magneton, and E_f is the Fermi energy. Since $n_0 = k_f^3/3\pi^2$, where k_f is the Fermi wave number, then it follows from [5.1] that $\chi_{Pauli} \propto E_f^{1/2}$ since $E_f \propto k_f^2$. The rather obvious generalization of this to an energy band with density of states $N(E)$ is $\chi_{Pauli} \propto N(E_f)$, the free electron density of states being proportional to $E_f^{1/2}$.

For free electrons, as Landau first demonstrated, the orbital diamagnetism is the negative of $\frac{1}{3}\chi_{Pauli}$.

As already mentioned, the effect of electron–electron interactions on these formulae is important, χ_{Pauli} being relatively strongly enhanced by the interactions in the range of electron density appropriate to the simple liquid metals.

Formulae for liquid metals have been written down to second-order in the pseudopotential and we shall refer briefly to these. Naturally, as in the resistivity in the weak scattering regime, the liquid structure factor $S(q)$ enters the theory of both spin and orbital susceptibility. For liquid Na, the electron–ion interaction contribution to χ_{Pauli} appears to be small compared with the effects of electron–electron interaction, which we discuss below. For further references to pseudopotential work the reader may wish to consult the work of Borchi and De Gennaro (46). Some later references to pure liquid metal studies are given by Dupree and Sholl (47), though their main concern is with alloys.

5.1. Total and Spin Susceptibilities of Liquid Metals

Dupree and Seymour (48) have plotted values of the total volume susceptibility for liquid metals at their melting points against the mean interelectronic spacing r_s defined such that $\frac{4}{3}\pi r_s^3$ is the volume/conduction electron. Their results are shown in Fig. 13 in cgs volume units, r_s being measured in atomic units.

Writing the total susceptibility χ in the usual way as the sum of an ion-core contribution χ_i, an orbital susceptibility χ_d, and the spin susceptibility χ_p, namely

$$[5.2] \qquad \chi = \chi_i + \chi_p + \chi_d$$

Dupree and Seymour use χ_i from the work of Angus (49).[6] For χ_d they take the interacting

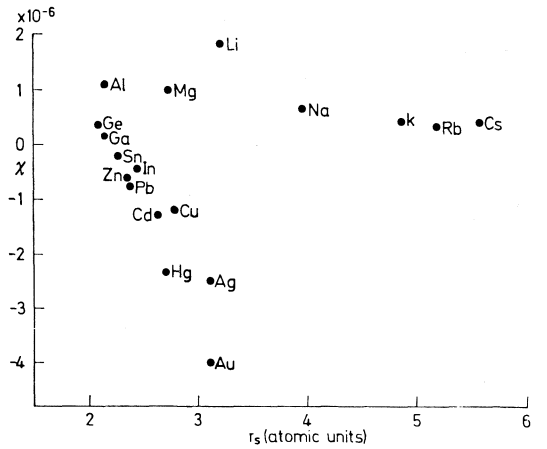

FIG. 13. Total volume susceptibilities of liquid metals. (Reprinted with permission from Physik der Kondensierten Materie, **12**, 97 (1970). Copyright by Springer-Verlag, Berlin.)

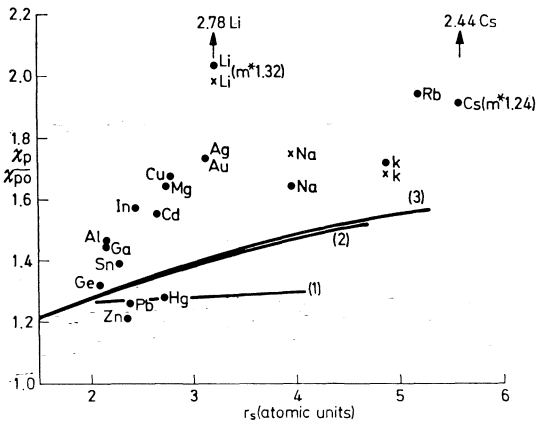

FIG. 14. Spin susceptibilities of liquid metals, extracted from experimental results of Fig. 13. Lines *1*, *2*, and *3* correspond to different choices of the Landau Fermi liquid parameters in [5.4]. (Reprinted with permission from Physik der Kondensierten Materie, **12** 97 (1970). Copyright by Springer-Verlag, Berlin.)

electron gas result of Kanazawa and Matsudaira (50; see also ref. 51), which, in units of the Landau free electron susceptibility χ_L may be written:

$$[5.3] \qquad \frac{\chi_d}{\chi_L} = 1 + \frac{\alpha r_s}{6\pi}\left[\ln r_s + 4 + \ln\left(\frac{\alpha}{2\pi}\right)\right]$$

where $\alpha = (4/9\pi)^{1/3}$.

Figure 14 gives the values of χ_p/χ_{Pauli} thus obtained. Here χ_{Pauli} is again the non-interacting free electron result, with effective mass $m^* = m$.

The following points are noteworthy (*cf.* 48):

(*i*) In spite of the large variation in χ in

[6]For the reasons for this choice, the reader may refer to Dupree and Seymour (48).

Fig. 13 all values of χ_p lie in the fairly narrow range 0.9 to 2.1 $\times$ 10^{-6}.

(*ii*) Direct determinations of χ_p, using conduction electron spin resonance techniques, are shown for Li, Na, and K (crosses). The measurements were made in each case for the solid metal: for Li and Na no significant change was found on melting and for K there is very little change in total susceptibility through the melting point. So it seems unlikely in that case that χ_p changes for K either. The direct measurements of χ_p are seen from Fig. 14 to be in good agreement with the values deduced from the total susceptibility. It is relevant here to refer to the very recent measurement of χ_p for Li through the melting point by Hanabusa *et al.* (52).

(*iii*) The curves *1–3* shown in Fig. 14 are from the theory of an interacting electron gas. In the Landau Fermi liquid theory, χ_p can be written in terms of the Landau parameters A_1 and B_0 (see, for example, Jones and March (53)) as

$$[5.4] \qquad \frac{\chi_p}{\chi_{Pauli}} = \frac{1 + A_1}{1 + B_0}$$

The different curves *1–3* in Fig. 14 correspond to different ways of approximating A_1 and B_0 in the many-electron problem (actually A_1 is considerably smaller in magnitude than B_0, which is negative). More refined theories for χ_p/χ_{Pauli} are given by Hamann and Overhauser (54) and Dupree and Geldart (55), the results being in reasonable overall agreement with the trends of χ_p/χ_{Pauli} shown in Fig. 14. If one wishes to do better and get quantitative results for individual metals, obviously electron–ion interaction and the liquid structure must be introduced, as we discuss briefly below.

(a) Possible Effects of Electron–Ion Interaction—Timbie and White (56), following early work of Baltensperger (57), have calculated the effect of electron–ion interaction on the orbital susceptibility χ_d, as also have later workers, *e.g.* Takahashi and Shimizu (58).

Whereas Baltensperger (57) estimates that for Na, χ_d increases (*i.e.* becomes less diamagnetic) by 20%, Timbie and White (56) estimate a correction smaller by an order of magnitude. The corrections found in no way alter the above conclusion that electron–electron interactions play a dominant role in the theory of the magnetic properties of the simple liquid metals.

Takahashi and Shimizu (58), as well as Timbie and White (56), also estimate the electron–ion corrections to the spin susceptibility. Though their expressions in terms of the liquid structure factor $S(k)$ and pseudopotential $U(k)$ agree, their numerical estimates differ somewhat. The results may be summarized by saying that electron–ion corrections cause only small deviations from electron gas values, when calculated by such a nearly free-electron approach.

While the above discussion indicates that, for the orbital diamagnetism, such corrections are indeed small, it does not seem possible for a metal like Li, which is not free-electron-like in the solid, to treat the electron–ion interaction in the spin susceptibility in the above manner. Presumably, because of the similarity of χ_p in solid and liquid, more structural information must go into the liquid theory than the pair correlation function. Thus, one should not use the nearly free-electron theory, without considerable caution, for correcting the electron gas results for the spin susceptibility, the similarity between liquid and solid results being a much better guideline.

6. Nuclear Magnetic Resonance

Nuclear magnetic resonance has been observed in some 20 liquid metals. Seymour (59) has reviewed the data on Knight shifts at the melting points in liquid metals, and Table 2 is taken from his paper.

6.1. Knight Shifts in Liquid Metals

Ignoring transition metals, one can write the Knight shift K in the usual way as

$$[6.1] \qquad K = (8\pi/3)\Omega P_F \chi_p$$

Here Ω is the atomic volume, P_F is the probability density at the nucleus for conduction electrons at the Fermi surface, while χ_p is the conduction electron (volume) spin susceptibility discussed extensively above.

For the electron contact density factor ΩP_F, expressions have been given by Faber (60), Cyrot-Lackmann (61), and Watabe *et al.* (62), with modifications given by Perdew and Wilkins (63). Unfortunately, the Knight shifts remain difficult to interpret in a really convincing way.

Seymour (59) also reviews the temperature coefficient of K and the change in the Knight shift on melting and we refer the reader to his paper for details, as well as (briefly) Knight shifts in alloys. Broadly, in alloys, one often finds that the shifts for both constituents of a binary alloy

TABLE 2. Experimental Knight shifts for liquid metals at their melting points (theoretical values shown are obtained from a single orthogonalized plane wave treatment)

	K (%)			K (%)	
Metal	Experimental	Theory	Metal	Experimental	Theory
Li	0.026	0.09	In	0.786	0.79
Na	0.116	0.15	Sn	0.73	0.75
Al	0.162	0.18	Sb	0.72	0.72
K	0.265	0.41	Te	0.38	0.70
Cu	0.264	0.52	Cs	1.44	1.63

As	0.32	0.52	Tl	1.48	1.31
Rb	0.662	0.82	Pb	1.49	1.34
Ag	0.575	0.74	Bi	1.41	1.32
Cd	0.795	0.77			

change roughly linearly with atomic concentration and in approximately parallel fashion (but a lot of exceptions occur). Fractional changes $\Delta K/K$ across the composition range are typically 5–20% except for alkali metal alloys where they are most often 20–50%: they are not very dependent on temperature except for transition metal solutes.

In concluding this discussion on Knight shifts, we return to the question of the existence of a pseudogap, and the change in electronic structure of liquid Hg as the density is varied.

(a) Knight Shift in Expanded Liquid Hg—El-Hahany and Warren (64) have reported measurements of the Knight shift in liquid Hg from the normal liquid density to less than 8 g/cm^3 at 1730 K and 1411 bar. An abrupt metal–nonmetal transition between 9 and 8 g/cm^3 is preceded by ranges of roughly linearly decreasing shift ($11 < \rho < 13.6$ g/cm^3) and constant shift ($9 < \rho < 11$ g/cm^3).

Theories by Mott (65) and Friedman (66) for conductivity and Hall coefficient would require that $N(E_f)$, the density of states at the Fermi level, would drop by a factor of 3 between 11 and 9 g/cm^3. The Knight shift remains constant as seen in Fig. 15 and it would appear at first sight that this could only be reconciled with the strong scattering model if a decrease in $N(E_f)$ is compensated almost precisely by a corresponding rise in ΩP_F in [6.1]. However, as demonstrated above, electron–electron interaction enhancement is so important that the above treatment of χ_p via $N(E_f)$ is obviously too primitive. For further discussion, the reader is referred to El-Hanany and Warren (64; see also Cohen and Jortner (67)). Obviously, the problem of the nature of the electronic states, and the transport processes, in liquid Hg is far from solved as yet.

6.2. Nuclear Quadrupole Relaxation

As Seymour (59) emphasizes, there is some interest in liquid metals in a relaxation rate T_{1Q}^{-1} involving coupling (for nuclei with $I > \frac{1}{2}$) of the nuclear electric quadrupole moment Q with the fluctuating electric field gradient produced by thermal motion of the ions. The effect can be isolated when there is a pair of isotopes with differing ratios of magnetic moments and of electric quadrupole moments (*e.g.* ^{69,71}Ga, ^{121,123}Sb, etc.).

An approximate relation for T_{1Q} is

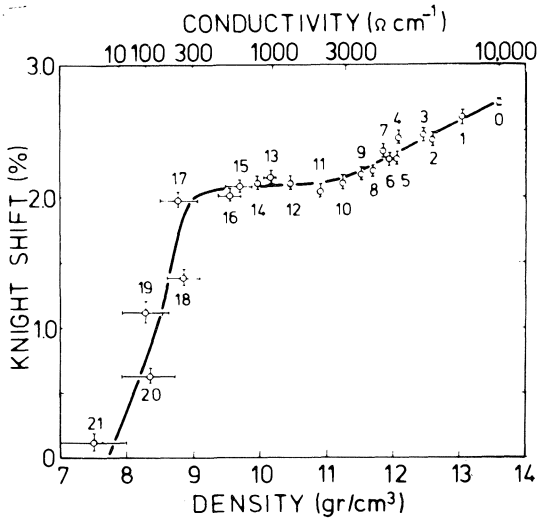

FIG. 15. Knight shift in liquid Hg as function of fluid density. (Reprinted with permission from Physical Review Letters, **34**, 1276 (1975). Copyright by The American Physical Society.)

$$[6.2]\quad \frac{1}{T_{1Q}} = \frac{3(2I+3)}{40I^2(2I-1)}\frac{e^4Q^2\overline{q^2}}{\hbar^2}\tau_i$$

where $\overline{q^2}$ is the mean square field gradient at a nucleus, and is assumed to be characterized by an autocorrelation function which decays exponentially with time constant τ_i. One might expect τ_i to vary inversely as the self-diffusion coefficient D. While this is qualitatively correct, the relationship to the diffusion constant is not as simple as that.

Coupling to the diffusional motion has been treated theoretically by Sholl (68) and extended to alloys by Claridge *et al.* (69) and by Jolly and Titman (70).

The three-body correlation function $g^{(3)}$ for the ions enters the theory, which is of some interest in view of the central position this function occupies in the statistical theories of liquids (see, for example, March (1)).

Sholl's (68) result for a metal is approximately (*cf.* Seymour (59))

$$[6.3]\qquad 1/T_{1Q} = (C/D)(I_1 + I_2)$$

and for species A in concentration c in an AB alloy

$$[6.4]\quad 1/T_{1Q} = (C/D)\{cI_1 + (1-c)a^2I_1 + c^2I_2 + a^2(1-c)^2I_2 + 2c(1-c)aI_2\}$$

Here a is the ratio of field gradients of A and B ions, D is assumed the same for A and B, and C has absorbed the constant terms. I_1 involves the nucleus interacting separately with the field gradients produced by other ions, while I_2 contains $g^{(3)}$. The equation shows the observed parabolic dependence for $I_2 \simeq -0.9I_1$; it is clear that such cancellation is going to occur on general grounds.

The conclusion here is that a large amount of nmr data for liquid metals can be understood in terms of a nearly free-electron model. We have not referred here to the Korringa relation, but this shows up the role of electron–electron interactions (see the discussion of Seymour (59)).

In conclusion, Gabriel and Schirmacher (71) have given a theory of nuclear quadrupole relaxation in liquid metals in terms of the usual effective ion–ion potential plus the van Hove function $S(k\omega = 0)$ for elastic scattering. This latter quantity is available from neutron experiments for some liquid metals (see, for example, Barker *et al.* (72)).

Rather than attempting a survey of a wide area of magnetic behaviour in other than the simpler liquid metals discussed above in detail, we shall focus most attention in the remainder of this article on one group, the liquid rare earth metals. Here, the basically new feature that appears is the existence of very localized magnetic moments on the ions. After surveying briefly their magnetic properties, we conclude by discussing the relation between dc conductivity and the magnetic moments.

7. Liquid Rare Earth Metals

We shall, therefore, first summarize the magnetic properties of liquid rare earth metals briefly (see also Güntherodt *et al.* (73)). The main point to be made immediately is that the magnetic susceptibility of liquid rare earths is rather similar to the solid state behaviour.

Below room temperature, the solid state susceptibility of Ce, Pr, and Nd obey a Curie–Weiss law. The effective magnetic moment is associated with localized $4f$ electrons, 1 for Ce, 2 for Pr, and 3 for Nd. At higher temperatures and beyond the melting point, a deviation to larger values of the magnetic susceptibility occurs. Figure 16 gives the magnetic susceptibility of Ce above room temperature and in the liquid state.

The deviations from the Curie–Weiss law can be explained as due to occupancy of low-lying $4f$ states above the ground state. This ionic contribution can be handled satisfactorily by the usual van Vleck theory.

At high temperatures, the ionic $4f$ contribution becomes small and the contribution from conduction electrons has to be taken into account. An estimate of this contribution can be made by considering the susceptibility of La, and χ^{-1} of Ce at high temperatures. La has no magnetic moment and one sees the Pauli paramagnetism, enhanced though by a factor of 10 compared with simple liquid metals. No change is observed at the temperature T_p of the fcc–bcc phase transition in Ce, whereas small changes have been detected at the melting point of Ce as well as at the melting point and the temperature T_p of the phase transition of La (see also Fig. 16).

7.1. Relation between Transport and Localized Spins

The electrical resistivity of some liquid rare earth metals, namely Dy, Ho, Gd, and Tb has been measured by Güntherodt *et al.* (74), samples of their results being shown in Fig. 17 for Ho, over the temperature range up to 1600°C.

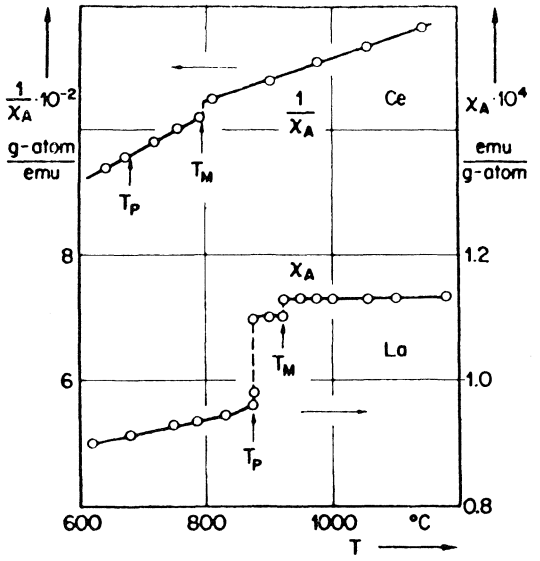

FIG. 16. Magnetic susceptibilities of Ce and La *vs.* *T*. (Reproduced from a preprint kindly supplied by Dr. H. U. Künzi; see also ref. 73.)

With regard to the comparison between the different materials, the electrical resistivities are about 10% higher for Dy and Ho than the values for the preceding rare earths, Gd and Tb. This is very different from the behaviour at room temperature, where Gd has the highest resistivity of all the rare-earth metals, as can be seen from data for all the rare earths, both solid and liquid, in Fig. 18.

As a function of temperature, the electrical resistivities for both Dy and Ho remain constant in the liquid state. The same temperature independence is found in Gd. However, for liquid Tb the electrical resistivity is found to increase by $1.5 \times 10^{-8}\ \Omega\,\text{cm}\ ^\circ\text{C}^{-1}$.

The absolute magnitude of the electrical resistivities is large compared with other liquid metals, *e.g.* for Gd 195 μΩ cm and Tb 190 μΩ cm, at their respective melting points. These values are 10 times larger than that for liquid Cu, though, for instance, as remarked above, liquid Ba has a resistivity of 300 μΩ cm.

The fact that the 4*f* states are far below the Fermi energy, as follows from recent XPS measurements by Bear and Busch (75; see Güntherodt *et al.* (74)), and have atomic character, suggests that the main contribution to the electrical resistivity is due to the 5*d* resonance scattering.

As Güntherodt *et al.* (74) point out, an additional contribution to the electrical resistivity due to spin disorder scattering which dominates at low temperatures is in question, since the resistivities of Dy and Ho at high temperatures and in the liquid state are larger than for Gd. It is to this point (*a*) plus (*b*) and (*c*) below that Parrinello *et al.* address themselves,[7] as we shall now discuss.

The main points on which this theoretical study focuses, stemming from the experiments of Güntherodt *et al.* (73, 74), are: (*a*) There is no obvious relation of the resistivity ρ at the freezing points of the liquid rare earth metals to the magnitude of the localized spins on the ions. Yet, as Fig. 18 shows, in the solid state at room temperature the resistivity has its maximum at Gd, with a spin of 7/2. (*b*) The resistivities are large, and for four of the heavy rare earths there is practically no temperature dependence. (*c*) As emphasized by Güntherodt *et al.* (73, 74), and shown in Fig. 19, there is a correlation between the resistivity ρ and θ_D^2, θ_D being the Debye temperature in the solid.

(a) Weak Scattering Theory—It is clear that, for weak scattering from an assembly of ions, each ion carrying a localized spin, we can invoke Mathiessen's rule to write the inverse of the total relaxation time τ as

$$[7.1] \qquad \frac{1}{\tau} = \frac{1}{\tau_d} + \frac{1}{\tau_m}$$

where τ_d^{-1} is the contribution from scattering off the ionic density fluctuations while τ_m^{-1} is the magnetic term. Following de Gennes and Friedel (76), for weak scattering $\tau_m^{-1} \propto S(S+1)$, where S is the spin (7/2 for Gd, etc). This explains the peaking of ρ in the solid at 25°C in Fig. 18, when the spin has its largest value, namely at Gd.

As the temperature is increased, the scattering increases for a strong ionic potential. Mathiessen's rule begins to break down, and therefore in the liquid rare-earths, Parrinello *et al.*[7] propose as the zeroth order theory the extreme strong scattering limit in which the single-centre scattering is so strong that the scattering off successive ions is incoherent. If the **t**-matrix for single-ion scattering is denoted by t, then the total scattering in this limit is given by Nt^2, N being the total number of scatterers.

(b) Strong Scattering Limit—It should be emphasized that, whereas when we transcend

[7]M. Parrinello, M. P. Tosi, and N. H. March, unpublished results.

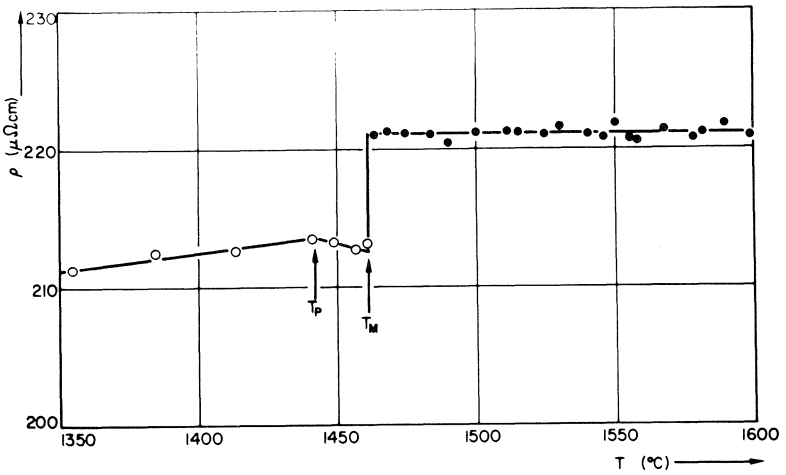

FIG. 17. Resistivity of liquid and solid Ho *vs. T.* (Reprinted with permission from ref. 74*b*; see also ref. 73.)

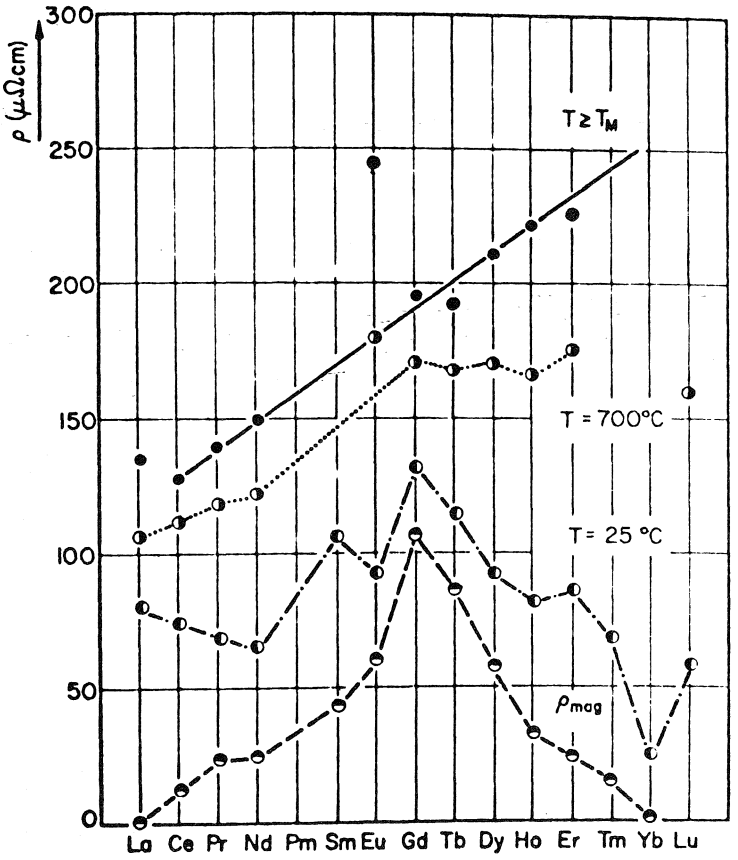

FIG. 18. Resistivities of rare earth metals at different temperatures in solid and liquid states. In the lowest curve labelled ρ_{mag} the spin disorder contribution to the resistivity has been separated from the total resistivity. (Reprinted with permission from Phys. Lett. A, **50**, 313 (1974); see also ref. 73.)

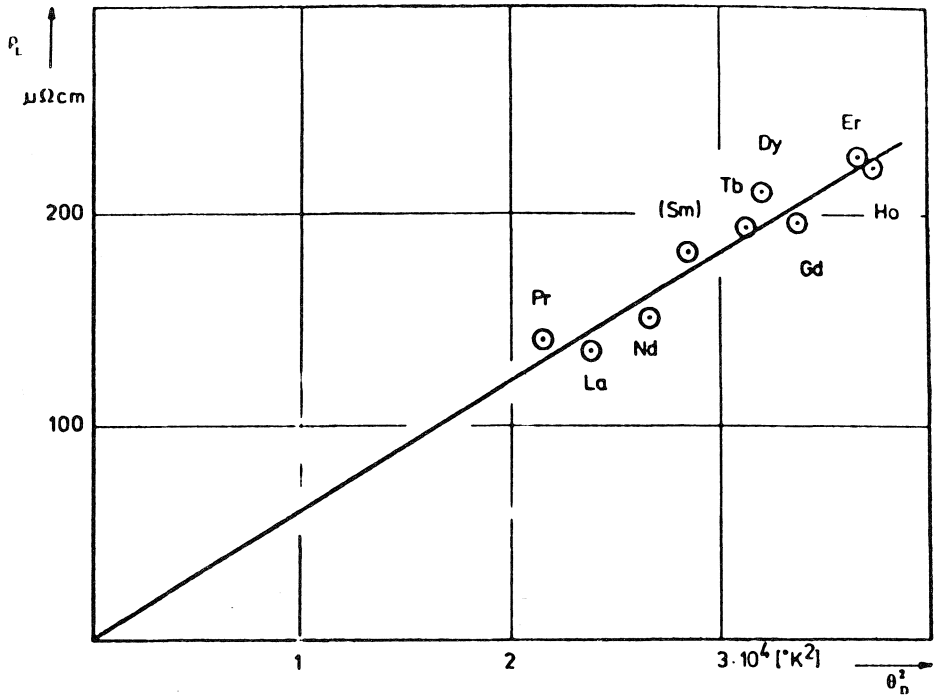

FIG. 19. Resistivities of liquid rare earth metals *vs.* square of Debye temperature. (Reprinted with permission from Phys. Lett. A, **50**, 313 (1974); see also ref. 73.)

the lowest order Born approximation, in which the radial distribution (pair) function only enters the theory through the static structure factor $S(k)$ (see [1.1]), higher order atomic correlation functions enter the theory (*e.g.* the three-body function $g^{(3)}$ referred to in section 6.2) of the resistivity, yet for sufficiently strong single-centre scattering the structure drops out of the theory, and with it the essential temperature dependence characteristic of weak scattering theory.

We can then utilize the well known result for the **t**-matrix for one ion in terms of phase shifts. Assuming that the *d*-wave phase shift is dominant, it is readily shown that the resistivity ρ is then

$$[7.2] \quad \rho = \frac{4\pi\hbar}{Ze^2k_f}\frac{5}{2S+1} \times [(S+1)\sin^2\eta_2^{+} + S\sin^2\eta_2^{-}]$$

where η_2^{+} and η_2^{-} are the *d*-wave phase shifts for the two spin directions. If we assume the conduction electron spin polarization round a single ion is small, then $\eta_2^{+} = \eta_2^{-}$ and equal to $\pi Z/10$ from the Friedel sum rule, Z being the valency. Then the spin S drops out of the theory and we find

$$[7.3] \quad \rho_0 = \frac{20\pi\hbar}{Ze^2k_f}\sin^2(\pi Z/10)$$

To refine this zeroth order result, we introduce *s* and *f* wave phase shifts. The resistance is substantially reduced by the interference between *d* and *f* phase shifts, the result being

$$[7.4] \quad \rho/\rho_0 = [\sin^2\eta_0 + 5\sin^2\eta_2 + \tfrac{1}{7}\alpha^2\sin^2\eta_3 - \tfrac{6}{7}\alpha\sin\eta_2\sin\eta_3 \times \cos(\eta_2 - \eta_3)]/[5\sin^2(\pi Z/10)]$$

with sum rule

$$[7.5] \quad \pi Z/2 \simeq \eta_0 + 5\eta_2 + \alpha\eta_3$$

We have written the multiplicity α, rather than 7, for Matthias and Zachariesen (77) have analyzed the melting points of the rare earths to conclude how much *f* contribution there is to the valence band charge density through the series. They conclude that $\alpha \doteqdot (14 - n_f)/2$, n_f being the number of *f* electrons and we find then an estimate of the *f* phase shift η_3 as $0.025\pi Z$. For two choices of η_0, zero and $0.2\pi Z/2$ (see

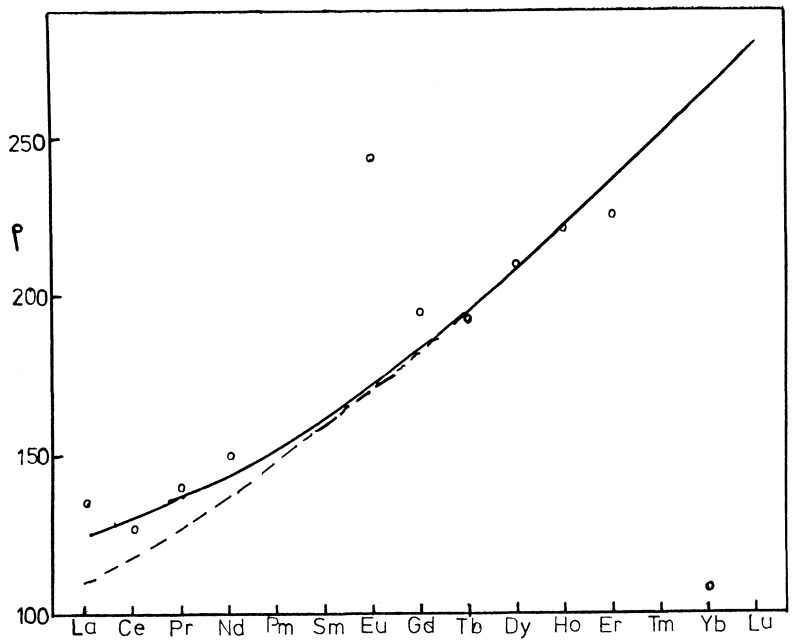

FIG. 20. Resistivities of rare earths at freezing point from theory and experiment.

Parrinello *et al.*[7]) we get the two curves shown in Fig. 20. There is a scale factor of 1.29 applied to the case $\eta_0 \neq 0$ to make the curve pass through the right value for Ho. This, we believe, is a manifestation of some residual liquid structure remaining in the theory, though the extreme incoherent limit is almost quantitative for the liquid rare earths.

The exceptions in Fig. 20, namely Eu and Yb, are easily explained as they are divalent, whereas the other rare earths in Fig. 20 are trivalent. In fact Eu and Yb are better compared with divalent Ba; the resistivities of these three elements then vary regularly. Here then, as emphasized in Parrinello *et al.*[7], we have a somewhat dramatic demonstration of the breakdown of Matthiessen's rule.

Finally, the relation of α, and the resistivity, to the number n_f of $4f$ electrons can be combined with the results of Matthias and Zachariesen (77) that the melting temperature T_m also is linearly dependent on n_f to get the correlation of resistivity with T_m shown in Fig. 21. Invoking Lindemann's law of melting, T_m is proportional to the square of the Debye temperature θ_D, and thus this is the origin of the correlation of the resistivity ρ with θ_D^2 shown in Fig. 19.

8. Concluding Comments on Magnetic Properties

The simple metals in the liquid state reflect the magnetic properties of a strongly interacting electron gas. The electron–electron interactions determine the general trend of the spin susceptibility with mean interelectronic separation. However, to get quantitative agreement for a liquid metal like Li, it is not adequate to include electron–ion interaction by nearly free-electron theory, the similarity with the solid indicating that higher order atomic correlation functions must come in.

Secondly, some of the features of the rare earth metals in the liquid state can be understood using a theory of strong potential scattering from ions carrying localized spins. Matthiessen's rule breaks down and it has been shown that the spin largely disappears from the electrical resistivity. The weak temperature dependence of the resistivity also follows naturally from the strong scattering limit.

It is interesting in this connection that the resistivity of liquid Fe, Co, and Ni have recently been measured by Güntherodt *et al.* (78). These resistivities are smaller than for the rare earths and it is satisfying that some contribution from spin disorder scattering is required.

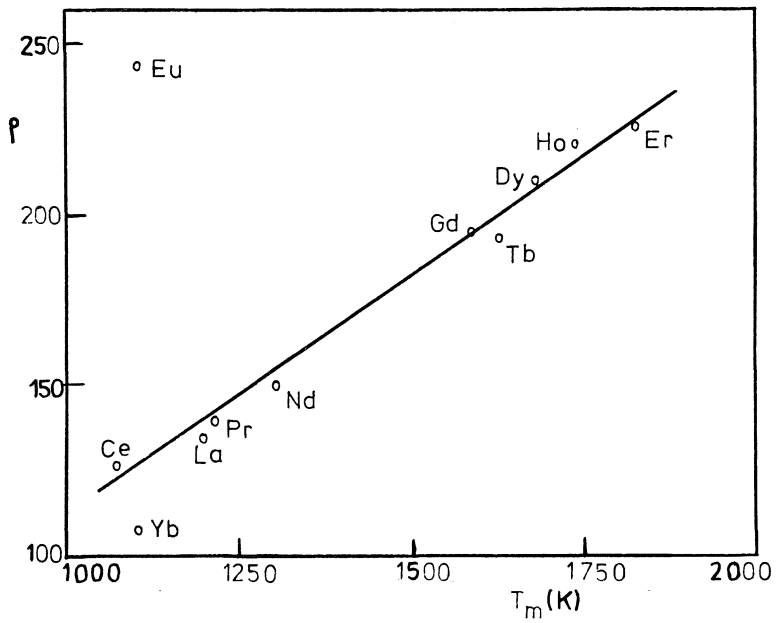

FIG. 21. Resistivities of liquid rare earths *vs.* melting temperature.

In connection with the magnetic moments in the liquid transition metals, it is worth remarking that neutron scattering has been recently studied from both Ni (79) and liquid Fe.[8] Whereas there is no marked spin disorder scattering contribution observed from liquid Ni, the results for liquid Fe show a significant component of magnetic scattering.

In the same context, a magnetic form factor for liquid Ce has recently been determined (80) by comparing the differential scattering cross section for thermal neutrons for liquid Ce with that for liquid La. The form factor is consistent with the dipole approximation and a $2F_{5/2}$ spectroscopic state for Ce^{3+}, roughly 20% of the Ce ions in the liquid state behaving as though they are instantaneously magnetically inactive. The coexistence in liquid Ce of two types of Ce ion, one of which has lost its f electron by a process associated with a resonating bond, is implicit in several qualitative discussions of the bonding properties of the lanthanides (81).

Progress, both experimental and theoretical, is to be expected in this general area in the fairly near future.

Acknowledgments

Many people, directly or indirectly, have helped in preparing this article. I want especially to thank my colleagues, Professor M. P. Tosi and Dr. M. Parrinello for many invaluable discussions on the whole area covered in this article. Thanks are also due to Drs. R. Dupree, P. J. Grout, B. L. Gyorffy, C. Hague, and C. Norris for supplying me with results and/or critical comments on their various areas of expertise. (Special thanks are due to Dr. Hague for supplying Fig. 12 prior to publication.) Needless to say, however, I alone am responsible for the final form and the point of view expressed here.

Finally, I wish to acknowledge support from the Science Research Council for the research programme on liquid metals at Imperial College, as well as partial contractual support from the US Army through its European Research Office.

Electronic Structure of Liquid Metals: Strong Scattering Theories

We shall briefly summarize here without mathematical detail some recent work on the electronic structure of liquid metals, with strong scattering. The nearly free-electron theory has been discussed fully elsewhere and we shall omit that here.

Roth (82) used the tight-binding or linear combination of atomic orbitals (LCAO) methods to study electronic states in disordered systems. The work is restricted to a simple one-orbital model of a liquid metal.

Refinements of this approach are discussed by Roth (83). There, an equation is derived for a one-electron continuum Green function, from which the density of electron states can be obtained. Utilizing an analogy between this Green function and the **T** matrix of multiple scattering theory, Roth obtains approximations corresponding, respectively, to (*a*) the quasi-crystalline approximation (QCA) of Lax (84) and (*b*) the self-consistent approximation (SCA) of Schwartz and Ehrenreich (85).

What Roth (83) shows, by calculations using random and hard-sphere pair functions, is that the QCA is inadequate, while the SCA, though a considerable improvement, involves a questionable approximation to the three-body distribution function. Unfortunately, to date, direct comparison with experiment is hardly possible and will probably necessitate the generalization to more than one orbital.

In later work, an effective-medium approximation for liquid metals has been discussed by Roth (86) and a tight-binding version of this theory worked out. This follows the early work of Faulkner (87) on a random liquid, and a generalization by Gyorffy (88) (see also Korringa and Mills (89)) to include the liquid pair correlation function. These approaches have been taken further by Yonezawa and Watabe (90) (see also Watabe and Yonezawa (91)) and reviews are given by these workers in ref. 92, so that further details will not be given here. However, the reader interested in this area should be able to build up the full background by making use of the references given here.

It is obviously important that the progress in fundamental theory of strong scattering liquid metals in these papers should be turned into numerical calculations of densities of states which can then be confronted with the photoemission and soft X-ray experiments reviewed in the body of the text.

Discussion

E. D. Crozier: Regarding your calculation of $N(E)$ for liquid Be, would you comment on the main differences between your method and the weak scattering approach involving Green functions.

N. H. March: Our method calculates the single-centre scattering essentially exactly. Higher order atomic correlation functions come in and are approximated by a modification of the Kirkwood assumption. Weak scattering methods do not include $g^{(3)}$, etc.

E. D. Crozier: The slide for the $N(E)$ as deduced from pes for Hg did not show a dip close to E_F as indicated in the earlier work of Norris. Would you comment?

J. E. Enderby: The data of Norris *et al.* were taken under conditions of higher photon energy so that a better resolution of the spectra could be obtained.

J. K. Baird: From your partition function, how did you invert the required Laplace transform to obtain the density of states function?

N. H. March: As we had numerical values of the partition function as a function of $\beta = (k_B T)^{-1}$ only over a finite range of the real axis, it was necessary to parametrize the density of electronic states and to determine the parameters by fitting to the partition function.

J. C. Thompson: There are data on both susceptibility and optical constants of M—NH_3 solutions in the metallic regime, but at larger r_s values than even Cs which may be used to test the models you have discussed.

N. H. March: It would be interesting to try this. Difficulties could arise in interacting homogeneous electron gas theory at such low electron densities due to instabilities (*e.g.* spin density wave and(or) charge density wave states), which the metal–ammonia system would inhibit.

The far-infrared reflectivity of liquid Mg–Bi alloys (Extended Abstract)

E. D. Crozier, R. W. Ward, and B. P. Clayman
Department of Physics, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received November 22, 1976

The fluid and electronic structures of liquid binary alloys which display semiconducting behaviour are not well understood. The bulk of the experimental work has concentrated on measurement of thermodynamic and dc electron transport properties. Most of the alloys are characterized by a composition-dependent dc conductivity $\sigma(0)$ which displays a pronounced minimum near a stoichiometric composition. Taken together, the experimental results indicate that marked short range order exists near these critical stoichiometric compositions.

Mg–Bi is a representative system. The dc conductivity decreases from typical metallic values for the pure liquids Mg and Bi to a pronounced minimum of $\sim 45\ \text{ohm}^{-1}\ \text{cm}^{-1}$ at Mg_3Bi_2 (1, 2). In the narrow composition range about 60 at.% Mg the alloys display semiconducting behaviour. The thermoelectric power undergoes a change of sign (2) and the Hall coefficient[1] shows an increase at Mg_3Bi_2. These properties imply a decrease in the number of conduction electrons as the stoichiometric composition is reached. The concentration–concentration correlation function in the long wavelength limit $S_{cc}(0)$ shows a minimum near the composition 60 at.% Mg. Reasonable agreement with $S_{cc}(0)$ has been obtained in model calculations (3, 4) in which it was assumed that molecules of Mg_3Bi_2 existed with finite lifetimes. The molecules were assumed to be weakly bonded; the Gibbs free energy of formation was $\sim -15kT$/molecule.

The far-infrared reflectivity measurements discussed in this paper were initiated to test specifically for vibrational modes that could be associated with molecules of Mg_3Bi_2. In addition our reflectivity measurements, which span the range 3 to 300 cm^{-1} (9×10^{10} Hz to 9×10^{12} Hz), are in a frequency range where hopping processes may be important. According to the Mott pseudogap model when $\sigma(0) < 200\ \text{ohm}^{-1}\ \text{cm}^{-1}$ a dip develops in the density of electronic states near the Fermi energy E_F, states near E_F become localized, and electronic conduction occurs via thermally activated hopping processes.

Using high resolution Fourier transform spectroscopy the reflectivity of liquid Mg–Bi alloys was measured as a function of temperature and composition. Typical reflectivity results obtained with a resolution of $2.6\ \text{cm}^{-1}$ and normalized to the reflectivity of Cu at room temperature are shown in Fig. 1 for different compositions at temperatures slightly above the liquidus temperatures of the alloys. The normalized reflectivity is accurate to within 10%.

There is no evidence in the reflectivity spectra of absorption due to molecular vibrational modes. Within experimental error, for all compositions investigated the reflectivity decreases monotonically with increasing frequency.

Note that the reflectivity of 60 at.% Mg approaches unity. On the basis of the free electron model the reflectivity should be significantly less. The anomalous composition dependence of the reflectivity is emphasized in Fig. 2 which shows the reflectivity at the fixed frequency of 100 cm^{-1} as a function of at.% Mg.

The reflectivity data of Fig. 1 can be fitted using the Drude nearly free electron model wherein the ac conductivity is given by

$$\sigma(\omega) = \sigma(0)_{opt}/(1 - i\omega\tau)$$

provided the relaxation time τ and $\sigma(0)_{opt}$ are treated as adjustable parameters. The rapid increase of the reflectivity near Mg_3Bi_2 leads to a value of $\sigma(0)_{opt}$ which is enhanced by a factor of ~ 100 relative to the dc value of $\sim 45\ \text{ohm}^{-1}\ \text{cm}^{-1}$.

The reflectivity data of Fig. 1 can also be fitted by a simple Debye model with a single frequency of hopping between localized states. However, the parameters obtained in fitting the data are questionable. A physically plausible hopping frequency results in an anomalously high value of $\varepsilon_0 - \varepsilon_\infty$ the difference between the low and high frequency dielectric constants.

The reflectivity data imply the existence of localized states near the Fermi energy in a restricted composition range near 60 at.% Mg.

[1]U. Even. Private communication.

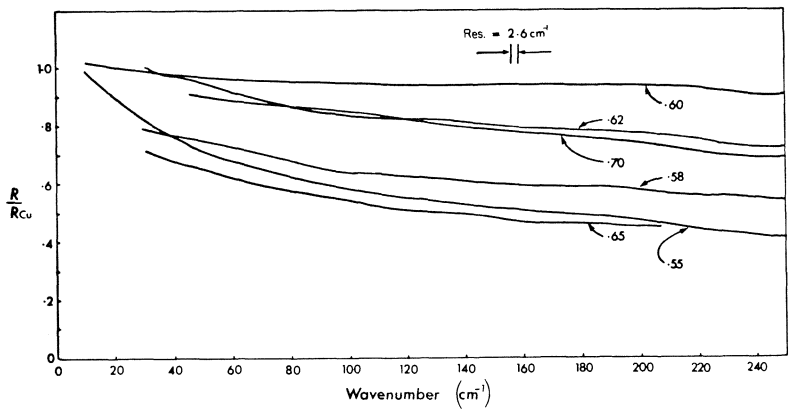

FIG. 1. The reflectivity of liquid Mg–Bi alloys. The reflectivity is normalized to the reflectivity of Cu at room temperature. The resolution is 2.6 cm^{-1}. The numbers represent the composition in at.% Mg. The temperature of the reflectivity curves are 832°C (60), 813°C (62), 790°C (58), 783°C (65), 770°C (70), 687°C (55).

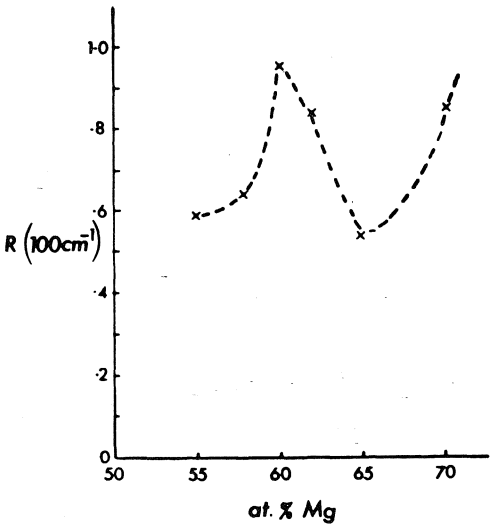

FIG. 2. Reflectivity of liquid Mg–Bi alloys at temperatures near the liquidus temperatures. The data were taken from Fig. 1 for the fixed frequency of 100 cm^{-1}.

However, the physical origin of the enhanced reflectivity is not understood.

Discussion

M. Cutler: In view of the large difference in electronegativity, one might expect a high degree of ionicity in Mg_3Bi_2. Have you considered the possibility of interpreting your reflectivity results in terms of an ionic structure?

E. D. Crozier: Yes. However, to my knowledge ionic liquids such as LiF have a reflectivity in the far infrared which is less than 0.75.

M. Cutler: The idea that hopping occurs when the conductivity $\sigma < 200$ ohm^{-1} cm^{-1} is a misleading concept which has frequently appeared in the literature. A more accurate description of the situation is as follows. The value 200 ohm^{-1} cm^{-1} characterizes the value of $\sigma(E)$ at the mobility edge E_c. For $E < E_c$, one has hopping transport with $\sigma_h(E) \lesssim 1$ ohm^{-1} cm^{-1}. The value of σ is obtained from

$$\sigma = -\int \sigma(E) \frac{\partial f}{\partial E} \, dE$$

where f is the Fermi–Dirac factor. When the Fermi energy $E_f > E_c$, $\sigma \gtrsim 200$ ohm^{-1} cm^{-1}. When $E_f < E_c$,

$$\sigma \cong \sigma_h(E_f) + \sigma(E_c) \exp\left[-(E_c - E_f)/kT\right]$$

the second term representing the contribution to transport by electrons excited thermally to the mobility edge. Therefore, in the range of σ between 1 and 200 ohm^{-1} cm^{-1}, the second term dominates. Only when $\sigma \lesssim 1$ ohm^{-1} cm^{-1} (below the minimum σ for Mg_3Bi_2) should one expect a major contribution by hopping.

J. C. Thompson: How does the reflectivity of the solid compare with that of the liquid?

E. D. Crozier: Reflectivity measurements were made on the solid alloys existing when the liquid alloys were cooled about 50 deg below their liquidus temperatures. In all cases the reflectivity of the liquid was greater than that of the solid (measurements were made on more than 30 alloys). For example at 60 at.% Mg at 100 cm^{-1} the reflectivity of the liquid was 16% higher than the solid.

Chemical potentials and fluctuations in indium–iodine solutions

KAZUHIKO ICHIKAWA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo, Japan

Received September 22, 1976

KAZUHIKO ICHIKAWA. Can. J. Chem. **55**, 2190 (1977).

The composition dependence of the relative chemical potential of In in liquid In–I alloys was determined from emf data obtained over the range of composition from In to InI_3. Electrical conductivities were also measured for a limited number of concentrations. The specific conductance of the InI_3 composition differs from that of pure liquid In by almost five orders of magnitude; *i.e.*, at 600°C that for InI_3 is 0.104 while that for the pure metal is $2.16 \times 10^4\ \Omega^{-1}$ cm^{-1}. At the long-wavelength limit the concentration correlation function $S_{cc}(0)$, which was calculated from the chemical potential data, exhibits large composition fluctuations on the In-rich side and minimal compositional disorders in the vicinity of the intermediate compositions InI, InI_2, and InI_3. The mean square compositional fluctuation is developed to discuss the crude short range ordering, ΔN_α, and the role of charge transfer, Δe_α, in a general statistical mechanical theory of solutions. The large peak in $S_{cc}(0)$ at the indium-rich side provides crucial evidence of large concentration fluctuations, accompanied by microscopic inhomogeneities in the electronic structure, if a bimodal distribution is assumed. The limit $\Delta N_\alpha \rightarrow 1$ near the InI, InI_2, and InI_3 compositions shows that a preference exists for unlike nearest neighbors because of the ionic or covalent character in the chemical bonding. It is proposed that over the In–InI range there is the relationship between a gradual metal–nonmetal transition and the large concentration fluctuations which are associated with microscopic inhomogeneities in the electronic structure.

KAZUHIKO ICHIKAWA. Can. J. Chem. **55**, 2190 (1977).

On rapporte des données sur la relation qui existe entre la composition et le potentiel chimique relatif de l'indium dans des alliages liquides de In–I pour des compositions allant de In–InI_3; on a obtenu ces potentiels pour diverses compositions allant de In à InI_3 en faisant appel à des données de fem. On a aussi mesuré les conductivités électriques pour un nombre limité de concentrations. La conductivité spécifique de InI_3 diffère de celle de In par presque cinq ordres de grandeur; c'est-à-dire à 600°C celle de InI_3 est de 0.104 alors que celle de l'indium métallique à l'état pur est de $2.16 \times 10^4\ \Omega^{-1}\ cm^{-1}$. A la limite de longues longueurs d'onde, la fonction de corrélation de concentration $S_{cc}(0)$, qui a été calculée à partir de données de potentiel chimique de l'indium, démontre l'existence de grandes fluctuations dans la composition du côté riche en indium et des désordres au niveau de la composition qui sont minimes autour des compositions intermédiaires de InI, de InI_2 et InI_3. On a développé la fluctuation de composition quadratique moyenne afin de pouvoir discuter de l'arrangement brut à faible distance, ΔN_α, et le rôle du transfert de charge, Δe_α, par rapport à une théorie des solutions basée sur la mécanique statistique générale. Le pic important dans $S_{cc}(0)$ au niveau de la section riche en indium est une preuve critique des grandes fluctuations de concentration qui accompagnent les inhomogénéités microscopiques dans la structure électronique lorsque l'on fait l'hypothèse qu'il existe un mode de distribution bimodale. La limite $\Delta N_\alpha \rightarrow 1$ près des concentrations InI, InI_2 et InI_3 montre qu'il existe une préférence pour des voisins les plus près qui sont dissemblables à cause d'un caractère ionique ou covalent dans la liaison chimique. On propose qu'il existe dans la région In–InI une relation entre une transition graduelle métal–non-métal et les grandes fluctuations de concentration qui sont associées avec des inhomogénéités microscopiques dans la structure électronique.

[Traduit par le journal]

Introduction

A general statistical mechanical theory of solutions has been developed with the aid of the theory of composition fluctuations in the grand canonical ensemble (1). At temperatures above the Debye temperature and in the long-wavelength limit the concentration correlation function, $S_{cc}(0)$, represents the mean square fluctuations in concentration, and is linearly related to the partial structure factors, $a_{\alpha\beta}(q \rightarrow 0)$ (2). The values of $a_{\alpha\beta}(0)$ cannot be extracted from measurements at a finite wavevector because of the poor experimental resolution. The limits are, however, given in terms of measurable thermodynamic quantities, namely the density, compressibility, and chemical potential (2). Thus the long-wavelength partial structure factors provide a measure of detailed structure in the

binary mixtures such as $S_{cc}(0)$ and the crude short range ordering (3), ΔN_α.

A physical picture was recently advanced for the continuous metal–nonmetal (MNM) transition in a binary solution including a nonmetallic component such as metal–ammonia solutions. The concentration fluctuates locally about either of two well-defined regimes, a metallic propagation regime and a nonmetallic regime (4). Further, it was proposed that the large concentration fluctuations (5) near a consolute concentration of the metal–ammonia solutions originate from the microscopic inhomogeneities in bonding configurations which are distinct from critical fluctuations (4).

Nuclear magnetic resonance (nmr) provides information at the microscopic level on the electronic structure (6, 7). This is because the apparent Knight shift increases monotonically with increasing metal concentration for the metal–nonmetal solutions such as alkali metal – NH_3 (8, 9) and Bi–BiI_3 (10), while conductivity measurements demonstrate the continuous metal–nonmetal transition induced by a simple change in concentration (11, 12). A careful examination of the experimental data is required to discuss the MNM transition in view of microscopically inhomogeneity in electronic structure (7).

The present paper reports relative chemical potential and electrical conductivity measurements of the system indium–iodine. In the phase diagram of the In–I system (13, 14), a miscibility gap was assumed over the In–InI region and the exact consolute point is not yet known. The stoichiometric compounds of InI, InI_2, and InI_3 were examined at temperatures below their melting points. The mean square concentration fluctuations (or $S_{cc}(0)$) are determined from the concentration derivative of the chemical potential for indium and developed to estimate the terms ΔN_α and Δe_α which refer to crude short range atomic configuration and chemical bonding at the intermediate compositions of InI, InI_2, and InI_3, respectively. The relationship between a gradual metal–nonmetal transition and a large peak of $S_{cc}(0)$ resulting from a bimodal distribution is discussed for indium–iodine solutions.

Experimental

Electromotive force measurements are briefly reported, and are described in detail elsewhere. Determination of the activity of In has been carried out using a ZrO_2 (+CaO) solid electrolyte. A concentration cell without transference was employed:

$$W|In, InO||ZrO_2(+CaO)||In—I, InO|W$$

The emf, ε, of such a cell is related to the activity of In,

$$\varepsilon = -\frac{RT}{2F} \ln a_{In}$$

where O^{2-} transport can be regarded as the mechanism of conduction in the zirconia solid electrolyte. The emf of the cell was measured on a dc potentiometer. The electrical conductance measurements were made with the aid of a dc four-terminal potentiometric method for the indium-rich region and with an ac Jones type bridge (15) for the intermediate region.

Materials

The indium used was 99.999% pure. Guaranteed reagent grade InI_3 was purified by distillation *in vacuo*.

Results

Figure 1 shows the emf, ε, as a function of concentration at 600°C. The points shown in Fig. 1 are taken from the smoothed curves of the emf *vs.* the temperature at a given concentration. Some of the emf data in Fig. 1 are shown as a dotted line over the 70–90 at.% In region across a consolute concentration where the correct consolute point has not yet been determined. The specific conductance increases continuously and monotonically with increasing metal composition; *i.e.*, at 600°C, 0.104 Ω^{-1} cm^{-1} for the InI_3, 0.419 Ω^{-1} cm^{-1} near the InI_2, 2.17×10^4 Ω^{-1} cm^{-1} for 0.9985, 2.225×10^4 Ω^{-1} cm^{-1} for 0.9991, and 2.285×10^4 Ω^{-1} cm^{-1} for the pure In.

Discussion

Relationship among Metal–Nonmetal Transition and Concentration Fluctuations

In Fig. 2 the concentration fluctuations, $S_{cc}(0)$, directly determined from the emf data of Fig. 1 (2, 5, 16), show a large peak over the whole range of In–InI throughout which the conductivity, σ, can be expected to change by almost five orders of magnitude. It remains almost constant in the iodine-rich region between InI and InI_3 solutions. Thus the continuous metal–nonmetal transition induced by concentration changes takes place at the In-rich side where there are large composition fluctuations.

Bimodal and Unimodal Distributions

A bimodal distribution in an α–β liquid alloy occurs when one component, *e.g.* α, has two different electronic structures resulting from microscopic inhomogeneities. In the case of a

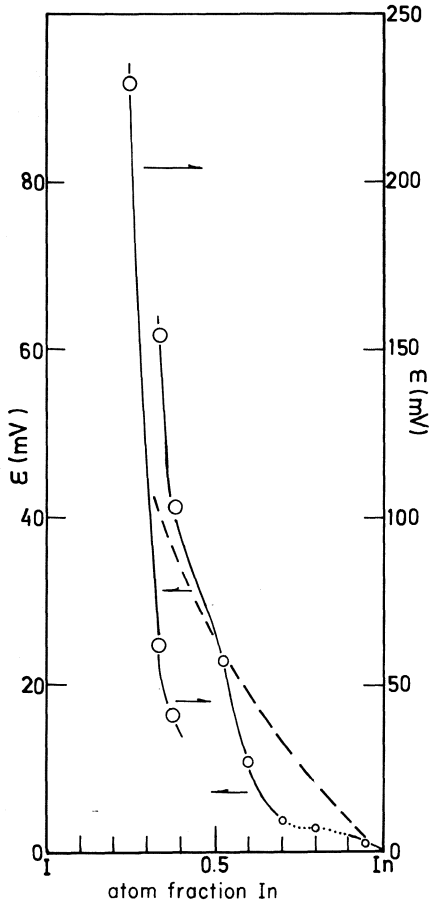

FIG. 1. The measured emf for In–I mixtures is shown by the open circle. All data were taken at 600°C. Ideal behaviour for ε is shown by the broken line.

unimodal distribution there is a single electronic state for each component. Whether the concentration fluctuations are bimodally or unimodally distributed should be experimentally determinable. The quantity

$$[1] \qquad \Delta N_\alpha \equiv x_\alpha[a_{\beta\alpha}(0) - a_{\alpha\alpha}(0)]$$

means the difference between the total number of α species surrounding a β species and the total number of α species surrounding an α species, and provides a crude measure of the short range ordering in a binary system (3). Here,

$$a_{\beta\alpha}(0) = 1 + \rho \int d\mathbf{r}[g_{\beta\alpha}(r) - 1]$$

From standard arguments of composition fluctuations in statistical thermodynamics (1) [1] can be expressed in terms of $S_{cc}(0)$ as follows (7),

$$[2] \qquad \Delta N_\alpha = 1 - (1+\delta x_\alpha)S_{cc}(0)/x_\alpha x_\beta$$

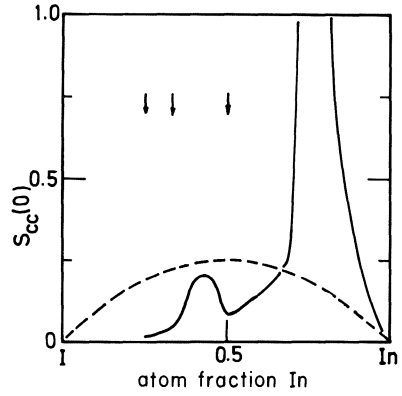

FIG. 2. The concentration correlation function $S_{cc}(0)$ for In–I mixtures at 600°C. The dashed curve is ideal.

where δ is a dilation factor defined by $v_m^{-1}\partial v_m/\partial x$ with a molar volume, v_m. The concentration dependences on ΔN_α for a variety of binary liquid alloys such as In–I, Na–NH_3, Ga–Bi, and Al–In are shown in Figs. 3–6. One can definitely classify them into the group in which $\Delta N_\alpha \neq \Delta N_\beta$ over a considerable range corresponding to the miscibility gap for the metal–nonmetal alloys such as In–I and Na–NH_3; in another group, $\Delta N_\alpha \simeq \Delta N_\beta$ for Ga–Bi and Al–In except for the range close to a consolute concentration. If microscopic inhomogeneities originate from ordinary critical fluctuations, that is, a unimodal distribution, the crude short range ordering, ΔN_α, for an α species can be expected roughly to equal ΔN_β for the other species β.

It is proposed that both bimodal distribution and $\Delta N_\alpha \neq \Delta N_\beta$ can occur in various metal–nonmetal liquid alloys. There are several experimental results to support this remark. Recent experiments on small-angle neutron scattering on K–KBr solutions (or K–Br) show that significant concentration fluctuations exist and that their large correlation length extends over a large temperature range above the immiscibility gap (17). It can be deduced from the determination of the three partial interference functions that nonmetal components cannot come in close contact in metal–nonmetal liquids or amorphous alloys. For amorphous Co–P, the experimental results show that a phosphorus atom cannot associate with other phosphorus atoms owing to electrical repulsion (18). For liquid Fe–P systems partial structure factors determined using anomalous scattering of X-rays (19) indicate not only that a phosphorus atom is surrounded by iron atoms but that

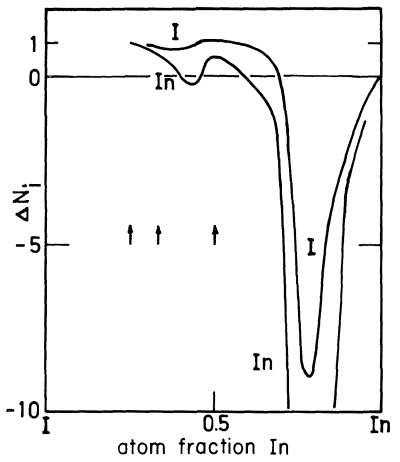

FIG. 3. The parameters ΔN_{In} and ΔN_I computed from [2] for In–I mixtures. For an ideal solution of the same atomic size this parameter is zero. The arrows mark the stoichiometric compositions of InI, InI_2, and InI_3.

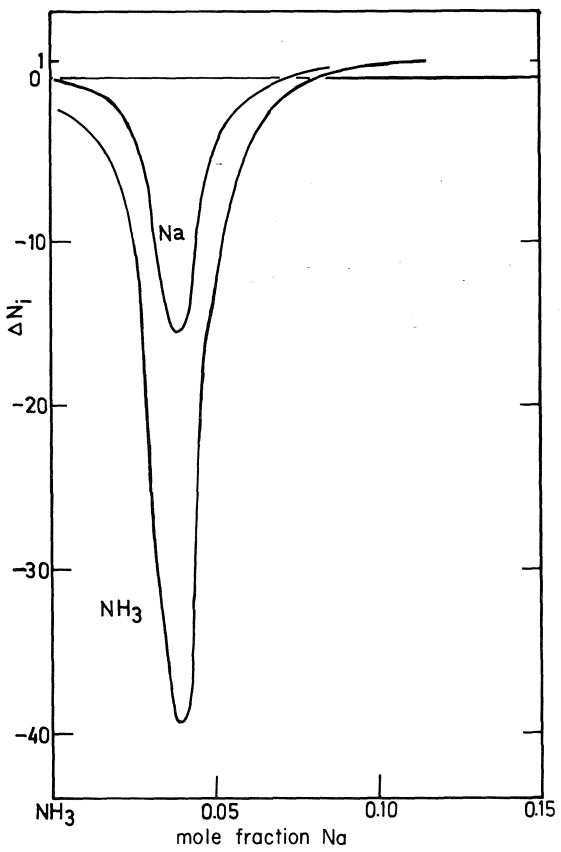

FIG. 4. The parameters ΔN_{Na} and ΔN_{NH_3} computed from [2] for Na–NH_3 solutions (ref. 5).

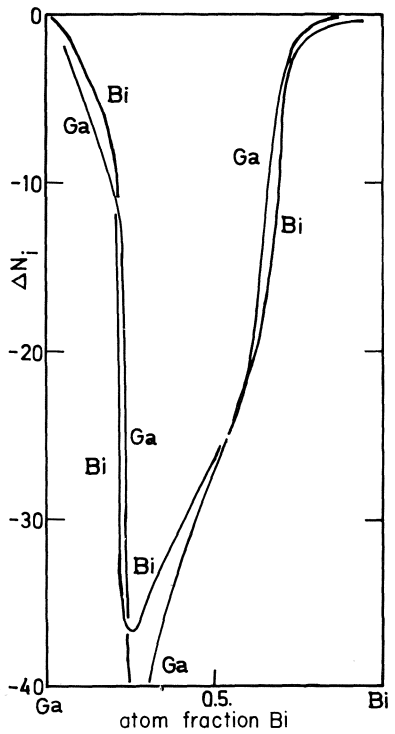

FIG. 5. The parameters ΔN_{Ga} and ΔN_{Bi} computed from [2] for Ga–Bi mixtures (ref. 28).

phosphorus atoms may not come in close contact. Thus, it is expected that in In–I solutions the iodine atoms cannot be brought into contact and that each of them is isolated by indium atoms. The fused salt-like local structure of the In–I pair may bring about aggregation of indium atoms in the indium-rich region. In view of the similarity between In–I (or In–InI) and K–Br (or K–KBr) systems the In–I solutions are also expected to have large amplitude concentration fluctuations which extend over large distances, as shown in Fig. 2. Therefore, the following remarks can be made: over the concentrations of In–InI (*i*) there exist two different local electron states for the indium component: a simple ionic fused salt-like electrostatic potential between In and I, and metallic cohesion among indium atoms, that is, a bimodal distribution; (*ii*) $\Delta N_I \neq \Delta N_{In}$ (in fact, $0 > \Delta N_I > \Delta N_{In}$ has been inferred from emf measurements and [2]). For Na–NH_3 solutions the fact that $0 > \Delta N_{Na} > \Delta N_{NH_3}$ is attributed to the following physical picture. The components may be viewed as positive sodium ions surrounded by a large group of oriented ammonia molecules and free-

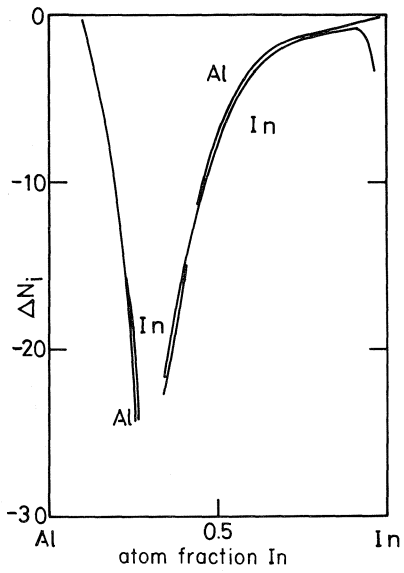

FIG. 6. The parameters ΔN_{Al} and ΔN_{In} computed from [2] for Al–In mixtures (ref. 29).

ammonia molecules which are not bound to a sodium ion (*e.g.* ref. 20). Two different dipoles can be considered for bound and unbound NH_3 molecules. Thus, the large fluctuations in concentration and their extension over large distances confirmed from chemical potential (5) and small-angle neutron scattering (21) studies on Na or Li–NH_3 and Li–ND_3 support the plausibility of a bimodal distribution.

It is proposed that over the In–InI range there is the relationship between metal–nonmetal transition and the large concentration fluctuations which are associated with a bimodal distribution and $0 > \Delta N_{In} \neq \Delta N_I$.

Minimal Compositional Disorder

S_{cc} (0) shows strong negative deviation from an ideal mixture at the InI, InI_2, and InI_3 concentrations for In–I (see Fig. 2). This result indicates minimal compositional disorder and stability at these compositions, which are apparently dominated by the chemical bonding (ionic or covalent) among the constituent atoms. It is worth noting that the values of ΔN_α approach unity at the stoichiometric compositions, InI, InI_2, and InI_3 (see Fig. 3). The facts that $\Delta N_\alpha = 1$ and $x_\alpha = 0.5$ in [1] lead to the conclusions which are quite satisfactory for a simple ionic melt of α^+–β^-, as follows: (*i*) $S_{\alpha\beta}(0) = S_{\alpha\alpha}(0) = S_{\beta\beta}(0)$ (22, 23), where their partial structure factors are defined by

$$S_{\alpha\beta}(0) \equiv (\rho_\alpha\rho_\beta)^{1/2} \int_0^\infty d\boldsymbol{r}\,[g_{\alpha\beta}(r) - 1] + \delta_{\alpha\beta}$$

(*ii*) the electrical neutrality condition (22, 24), and (*iii*) the limit $S_{cc}(0) \to 0$ (23). Therefore, the solutions at the intermediate concentration of InI or $x_{In} = x_I = 0.5$ have a fused salt-like configuration in view of preference for unlike nearest neighbors.

What is the kind of pair potential which brings about a fused salt-like configuration near the stoichiometric composition of InI? It is proposed that for metal–halogen alloys the minimal compositional disorder at this intermediate composition is attributed to a charging process. A new quantity, $(\partial\mu_\alpha/\partial\rho_\alpha)_{T,P}$ is introduced in addition to $S_{cc}(0)$ or $(\partial\mu_\alpha/\partial x_\alpha)_{T,P}^{-1}$ and ΔN_α. The theory of composition fluctuations is subsequently developed to evaluate thermodynamic parameters in terms of the partial correlation functions, $a_{\alpha\beta}(0)$, at the long-wave limits (1, 25). The thermodynamic relation for a binary α–β system at constant P and T

$$[3]\quad \left(\frac{\partial\mu_\alpha}{\partial\rho_\alpha}\right)_{T,P} = \frac{\rho_\beta(\partial\mu_\alpha/\partial\rho_\alpha)_{T,\mu_\beta}(\partial\mu_\beta/\partial\rho_\alpha)_{T,\mu_\alpha}}{\rho_\beta(\partial\mu_\beta/\partial\rho_\alpha)_{T,\mu_\alpha} - \rho_\alpha(\partial\mu_\alpha/\partial\rho_\alpha)_{T,\mu_\beta}}$$

can be expressed in terms of the $a_{\alpha\beta}(0)$ using

$$[4]\quad k_B T\left(\frac{\partial\rho_\alpha}{\partial\mu_\beta}\right)_{T,\mu_{\beta'}} = \frac{\rho_\alpha\rho_\beta}{\rho}[a_{\alpha\beta}(0) - 1] + \rho_\alpha\delta_{\alpha\beta}$$

In fact, substitution of [4] into [3] yields

$$[5]\quad \frac{1}{k_B T}\left(\frac{\partial\mu_\alpha}{\partial\rho_\alpha}\right)_{T,P} = \frac{1}{\rho_\alpha} - \frac{\frac{1}{\rho}[a_{\alpha\alpha}(0) - a_{\beta\alpha}(0)]}{1 + \frac{\rho_\alpha}{\rho}[a_{\alpha\alpha}(0) - a_{\beta\alpha}(0)]}$$

From the definition [1] of the local ordering, ΔN_α, [5] can be rewritten as

$$[6]\quad \left(\frac{\partial\mu_\alpha/k_B T}{\partial\log\rho_\alpha}\right)_{T,P} = 1 + \frac{\Delta N_\alpha}{1 - \Delta N_\alpha}$$

Here, $\Delta N_\alpha/(1 - \Delta N_\alpha)$ ($\equiv \Delta e_\alpha$) is the contribution to the deviation from the laws of ideal solutions. Figure 7 shows that Δe_I for the binary In–I solutions probably has two large peaks in the

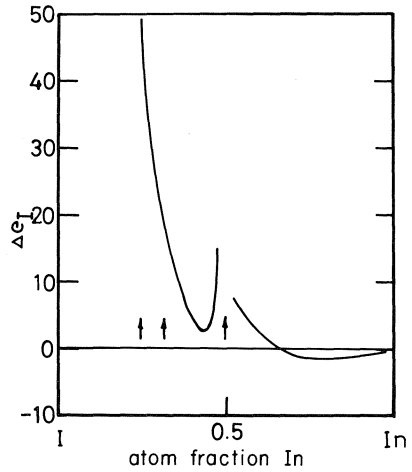

FIG. 7. The parameter Δe_I computed from [10] and [2] for In–I mixtures. For an ideal solution of the same atomic size, this parameter is zero. The arrows mark the stoichiometric composition of InI, InI_2, and InI_3.

vicinity of the intermediate compounds InI, InI_2, and InI_3, where each ΔN_α is close to unity and $S_{cc}(0)$ shows the probable and real minima in compositional disorder. Kirkwood and Buff (1) point out that [5] or Δe_α provides an alternative to the usual charging process encountered in electrolyte theory. According to Onsager (26) the electrostatic contribution, $\Delta F(\text{el})$, to the free energy of a concentrated electrolyte can be given by

$$[7] \qquad \Delta F(\text{el}) = \sum_{\gamma}^{2} \rho_\gamma \int_0^{Z_\gamma|e|} \phi(e_\gamma)\, de_\gamma$$

where $\phi(e_\gamma)$ is average potential due to other ions at the point of an ion with instantaneous charge, e_γ, and ρ_γ is the number density of a γ ion. The corresponding contribution to the chemical potential of an α ion is expressed as follows:

$$[8] \qquad \Delta\mu_\alpha(\text{el}) = \int_0^{Z_\alpha|e|} \phi(e_\alpha)\, de_\alpha + \rho_\alpha \frac{\partial \int_0^{Z_\alpha|e|} \phi(e_\alpha)\, de_\alpha}{\partial \rho_\alpha}$$

It is assumed that for the In–I liquid alloy the deviation from ideality can be attributed entirely to electrostatic forces between unlike ions, near the intermediate concentration, because the Coulomb energy, which is the main contribution to the internal potential in a simple ionic melt of α^+–β^-, is very large compared with the internal energy for a simple liquid metal (*e.g.*, liquid In) and the van der Waals energy for liquified inert gases. The contribution of the Coulomb energy to the deviation from the laws of ideal solutions may mask the contribution resulting from excess entropy and excess volume terms.

Therefore, near the stoichiometric composition of InI the form of $\Delta N_\alpha/(1 - \Delta N_\alpha)$ can be approximately expressed as

$$[9] \qquad \frac{\Delta N_\alpha}{1 - \Delta N_\alpha} = 2 \frac{\rho_\alpha}{k_B T} \frac{\partial \int_0^{Z_\alpha|e|} \phi(e_\alpha)\, de_\alpha}{\partial \rho_\alpha'}$$

by differentiation of [8] with respect to ρ_α and neglect of the second ρ_α derivative of the integrand in [8] for simplification only. Thus, the large positive value of Δe_α at this composition is directly related to the increment of the work of charging one α ion owing to its addition into a given concentration of an α–β alloy. For liquid Cs–Au it was proposed that, near equi-atomic concentration, ionic conduction plays an important role on the hypothesis of charge transfer, that is, the Cs atoms donate one valence electron to each Au atom (27). The system Cs–Au can be expected to have a peak of Δe_α near this equi-atomic concentration.

More detailed studies of the indium–iodine system, in particular, on its thermodynamic functions are clearly required.

Acknowledgments

I thank Professor J. C. Thompson for his encouraging discussions and for his critical reading, and Mr. T. Kiya for technical services.

Received October 4, 1976

WERNER F. SCHMIDT. Can. J. Chem. **55**, 2197 (1977).

A survey is given on the mobility of excess electrons in liquid hydrocarbons and related compounds. It was found that the mobility is strongly influenced by the molecular structure of the liquid, by the temperature, and by the electric field strength. The mobility in hydrocarbons increases as the shape of the molecule approaches a sphere. The temperature coefficient is positive in most liquids over a limited temperature although exceptions have been observed in liquid methane. The field dependence of the mobility in high mobility liquids (>10 cm^2 V^{-1} s^{-1}) showed a decrease of the mobility at higher field strengths while in low mobility liquids (<1 cm^2 V^{-1} s^{-1}) it showed an increase. These results are discussed on the basis of the extended and the localized electron models. The predictions of these theories are compared with the experimental results and conclusions on the validity of the underlying assumptions are drawn.

WERNER F. SCHMIDT. Can. J. Chem. **55**, 2197 (1977).

On présente une revue sur la mobilité des électrons en excès dans des hydrocarbures liquides et d'autres composés qui leur sont reliés. On a trouvé que la mobilité est grandement influencée par la structure moléculaire du liquide, par la température et par la force du champ électrique. La mobilité dans les hydrocarbures augmente à mesure que la forme de molécule approche celle d'une sphère. Le coefficient de température est positif dans la plupart des liquides à l'intérieur de faibles limites de température même si l'on a observé des exceptions dans le méthane liquide. La relation qui existe entre le champ et la mobilité dans des liquides de grande mobilité (>10 cm^2 V^{-1} s^{-1}) présente une diminution de mobilité à des forces de champ élevées alors que dans des liquides de basse mobilité (<1 cm^2 V^{-1} s^{-1}) elle présente une augmentation. On discute de ces résultats sur la base de modèles d'électrons étendus et localisés. On compare les prédictions de ces théories avec les résultats expérimentaux et on tire des conclusions sur la validité des hypothèses de base.

Introduction

The electronic properties of nonpolar liquids have received increasing interest during recent years. From a fundamental point of view nonpolar liquids represent a class of non-crystalline materials; the physical properties and the chemical behavior of excess electrons can be studied since excess charge carries can be injected by various means (1). Radiation chemistry is interested in excess electrons since they represent one product of the interaction of high energy radiation with matter and since their chemical reactivity depends strongly on the liquid surrounding.

From a practical point of view nonpolar liquids have wide applications as insulators in electrical power equipment and the development of a cryogenic high voltage technology requires among other things the investigation of the conduction processes in cryogenic liquids (2).

The discovery of highly mobile electrons in certain nonpolar liquids has opened applications in fast nuclear radiation detectors and in fact right now huge liquid ionization chambers with effective volumes of 5000 ℓ are being built for the detection and the calorimetry of elementary particles in high energy physics (3, 4).

The subject of electron mobility in nonpolar liquids encompasses a wide field. Since over 20 years investigations have been carried out with liquefied rare gases and several reviews have appeared (5–7); this area will not be discussed here. Excess electrons in liquid hydrocarbons were observed first in 1969 independently by several groups (8–11) and since then a lot of experimental information has been gathered.

It is the purpose of this paper to review the experimental data and to discuss the salient features of the excess electron mobility in liquid hydrocarbons and related compounds. Emphasis will be placed on the effects of structure, temperature, and electric field strength. Com-

parison will be made with results from scattering studies of electrons and polyatomic molecules in liquefied rare gases.

Methods for Mobility Measurements

Measurements of excess electron mobility have been carried out mainly with two methods. Either the increase of the conductivity during a short pulse of high energy X rays or electrons is measured or the drift velocity is determined by a time of flight method. Excess charge carriers can also be produced by photoionization of a homogeneously distributed solute as for instance *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine (TMPD) (12).

In the conductivity method use is made of the fact that the mobility of the excess electrons is usually much greater than the mobility of ions so that any change in the conductivity during the pulse is due to excess electrons. The conductivity σ is then given by

$$[1] \qquad \sigma = e_0 n(\mu_{e1} + \mu_+) \approx e_0 n \mu_{e1}$$

where n is the concentration of excess electrons/cm^3 and e_0 the electronic charge. The concentration n can be determined with the radiation yield of electrons $G_{e1}(F)$, which is a function of the applied electric field F and the absorbed dose D, from

$$[2] \qquad n = D \cdot G_{e1}(F) \times 10^{-2}$$

A necessary presumption is that no volume recombination between electrons and positive charge carriers occurs during the pulse. Usually a parallel plate measurement cell (area q, electrode distance l) is employed and the conductivity signal is converted into a voltage signal with a resistor R connected in series with the cell. If $R \ll (\sigma q/l)^{-1}$ than the signal voltage obtained with voltage U, $U_s = \sigma(q/l)UR$, is proportional to the conductivity.

In the time of flight method the drift of a spatial inhomogeneity of the charge carrier density in an electric field is observed. Neutralization of the charge carriers at their respective counter electrode leads to a discontinuity in the current–time signal. The drift time t_d is given by

$$[3] \qquad t_d = l^2/(\mu U)$$

Different methods for the production of this inhomogeneous density distribution are used. In the Hudson method the liquid in a parallel measurement cell is subjected to a step function of X rays and the time of flight is given by the time it takes those electrons generated near the cathode to reach the anode. In the pulse method the liquid volume is irradiated with a short pulse of X rays leading to a constant density of excess electrons. Under the influence of the electric field the electrons move to the anode, become neutralized, and a discontinuity travels across the gap leading to a linear decay. Other methods which have been applied to liquefied rare gases and ionic charge carriers in hydrocarbons were reviewed recently (1).

Both methods have advantages and disadvantages. While the time of flight method gives direct information on the mobility, it requires extremely pure liquids since only small concentrations of excess charge carriers can be generated if space charge effects are to be neglected.

In the conductivity method a higher level of impurities can be tolerated. The determination of the mobility, however, requires the independent determination of $G_{e1}(F)$ and measurement of the radiation dose; the accuracy of the mobility values is determined to a high degree by the accuracy of the dosimetry. Measurements in this laboratory were carried out with a time of flight method and the experimental set-up has been described repeatedly (13).

The Effect of Structure

One of the surprising features of excess electron mobilities in nonpolar liquids is the large variation with the structure of the molecules composing the liquid. This dependence is very much apparent in the liquid hydrocarbons where mobilities ranging from 400 cm^2 V^{-1} s^{-1} for methane at 111 K to 1.3×10^{-3} cm^2 V^{-1} s^{-1} for ethane and the same temperature have been measured. A sample collection of values is compiled in Table 1 where data for liquids at room temperature are given. Research on electron mobilities is being conducted in several laboratories all over the world and virtually hundreds of values have been reported. In order to show the salient features the data of Table 1 have been selected not for the sake of completeness but to give, for liquids where several values have been measured, a value which has been obtained recently and is in agreement with most of the other values.

Although it remains an open question whether comparison at an arbitrary temperature can give insight into the physics of the transport

process some general properties can be extracted by inspection of Table 1. In the normal alkanes we see a decrease of the electron mobility with increasing chain length which levels off at about 5×10^{-2} cm^2 V^{-1} s^{-1} for $C_n > C_6$. The electron obviously is 'myopic' (a description coined by Freeman and his co-workers (16)) being unable to look ahead for more than six CH_2 groups. Branching of the C_n chain leads to an increase of the mobility which is demonstrated by the comparison of the mobility in the isomers of C_4, C_5, and C_6. The greatest values are obtained for compounds which contain a quaternary carbon atom. As the mobility increases in these compounds the energy of activation decreases. The cycloalkanes exhibit higher mobilities than the corresponding *n*-alkanes. Introduction of double bonds into alkanes may lead to a decrease or an increase depending on the position of the double bond. In the case of 2,3-dimethylbutane/2,3-dimethyl-2-butene the double bond is shielded by the CH_3 groups and it may lead to a more compact molecule. A dramatic effect of the isomerization on the mobility is apparent for *cis*- and *trans*-2-butene.

In the cyclic compounds the influence of a double bond is not very clear.

In the aliphatic compounds there is a great influence of the shape of the molecule. The electron mobility is highest in spherical molecules (tetramethylsilane, tetramethylgermanium, tetramethyltin, neopentane) and it increases in the other liquids the more this shape is realized.

As with gas phase mobilities in these compounds (27) it is difficult to correlate the observed liquid values with any specific molecular property. The absence of a permanent dipole leads to short range interactions which are also influenced by the structure of the liquid or in other words by the simultaneous interaction of one electron with several molecules. This may be seen from measurements of the excess electron mobility in mixtures of liquid methane and ethane given in Fig. 1 (28).

While in pure methane at $T = 111$ K the mobility is 400 cm^2 V^{-1} s^{-1} it drops to 1.3×10^{-3} cm^2 V^{-1} s^{-1} in pure ethane at the same temperature. At low ethane concentrations the mobility is reduced due to single scattering while at higher ethane concentration collective interactions of an electron with a group of ethane molecules may take place leading to localization and a low mobility.

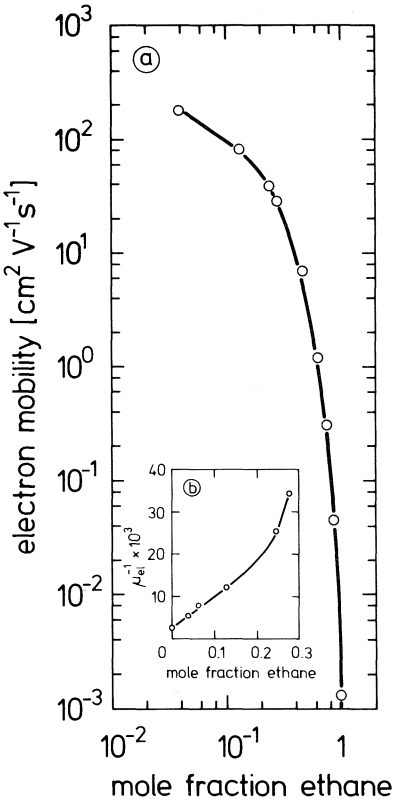

FIG. 1. Dependence of the electron mobility in liquid mixtures of methane and ethane on the ethane concentration (with permission, from ref. 28).

The Effect of Temperature

Electron mobilities in hydrocarbon liquids exhibit in general positive temperature coefficients. The only exception so far seems to be liquid methane where a decrease of the mobility with increasing temperature has been observed (Fig. 2). Very recently these temperature studies have been extended by Engels and van Kimmenade (30). A mobility minimum was found at 135 K and the mobility increased with increasing temperature to a maximum, as in the case of liquid argon (31). Most normal alkanes show an Arrhenius-type dependence of μ_{el} on T (Fig. 3) with activation energies between 0.1 and 0.2 eV. A decrease of the activation energy at higher temperature was obtained for ethane while the data for *n*-pentane show the opposite behavior. These two cases are also typical for a number of other liquids (16, 22, 26).

For the branched alkanes, as for example neohexane or isooctane, smaller activation

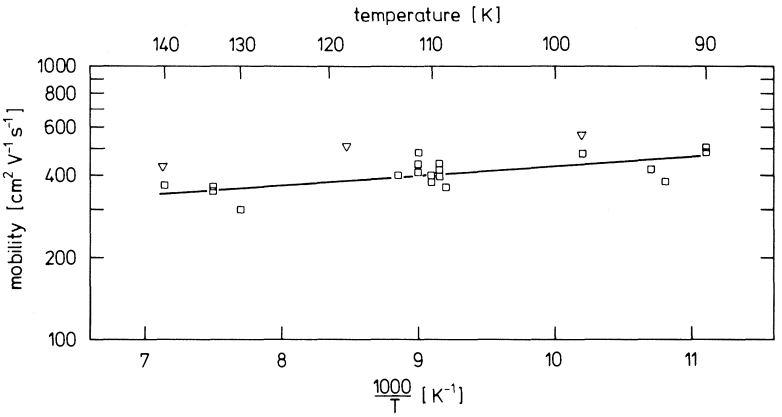

FIG. 2. Temperature dependence of electron mobility in liquid methane: □, from ref. 13; ▽, from ref. 29.

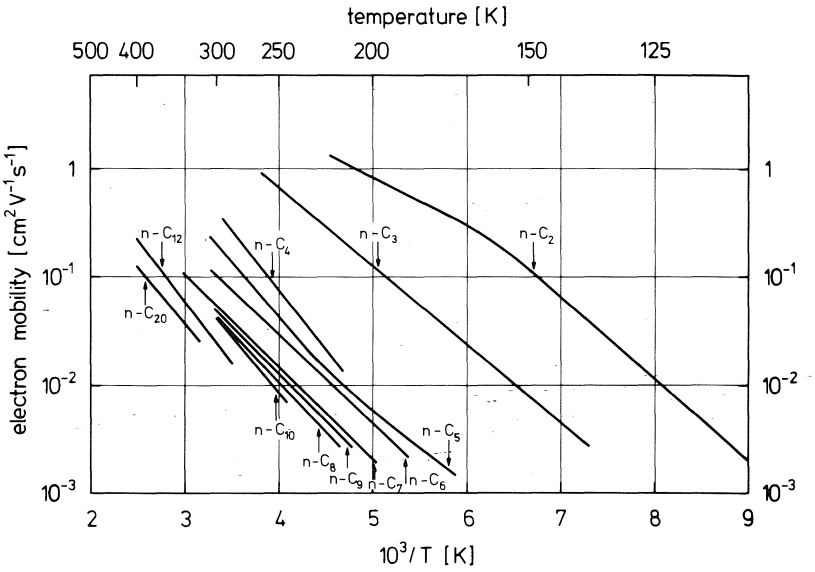

FIG. 3. Arrhenius plot of the electron mobility in *n*-alkanes. Data from refs. 12, 32, 29, 17.

energies were observed and the electron mobility in neopentane or tetramethylsilane was approximately independent of temperature in the range of temperature given in Table 1.

Expressing the dependence of $\mu(T)$ as

$$[4] \qquad \mu(T) = \mu_0 \exp(-E_a/kT)$$

gave values for μ_0 between 100 and 1000 $cm^2 V^{-1} s^{-1}$.

The Effect of an Electric Field

For the determination of the mobility μ_{el} measurements of the drift velocity v_d at different field strengths F are carried out and the usual mobility is the low field limit of the ratio v_d/F, *i.e.*

$$[5] \qquad \mu(T,0) = v_d/F$$

The proportionality between v_d and F extends over an interval of field strength which depends on the type of liquid. A further increase in field strength results in deviations from the proportionality and sublinear and superlinear dependencies have been observed. In Fig. 4 the electron drift velocity as a function of the field strength is shown for some liquids in which electron mobilities greater than 10 $cm^2 V^{-1} s^{-1}$ were observed. A characteristic field strength F_c

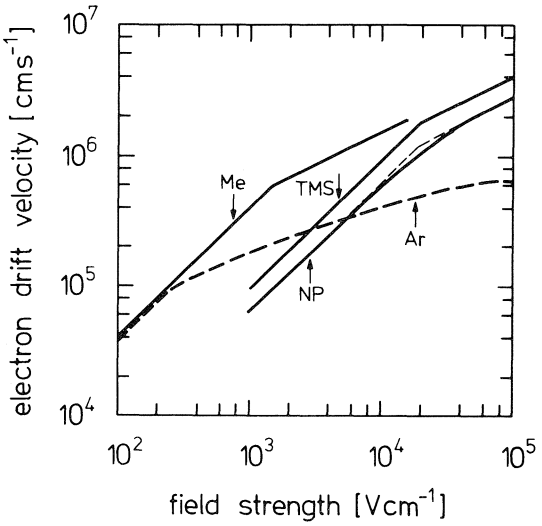

FIG. 4. Electron drift velocity as a function of the electric field strength in high mobility liquids: Me, methane, $T = 111$ K (ref. 13); TMS, tetramethylsilane, $T = 293$ K (ref. 34); NP, neopentane, $T = 295$ K (ref. 35); Ar, argon, $T = 87$ K (ref. 36).

can be found above which a sublinear dependence of v_d on F exists. In those liquids where the measurements have been carried out far enough into this sublinear region the data are consistent with a $v_d \propto F^{0.5}$ dependence which means that the mobility becomes a function of the field strength and decreases as $\mu \propto F^{-0.5}$. This sublinear dependence is generally interpreted as being due to an increase of the mean electron energy above $k_B T$.

Electrons pick up more energy from the field than they lose in subsequent collisions and a new stationary state results with a higher mean energy.

An interesting behavior is observed in methane/ethane mixtures of low ethane concentration where the low field mobility is decreasing with increasing ethane concentration (*cf.* Fig. 1) while the product $v_d = \mu_{el} F_c$ remains constant (*cf.* Fig. 5; the sublinearity sets in at a drift velocity of 5×10^5 cm s^{-1}).

A completely different field strength dependence of the drift velocity was found in hydrocarbons exhibiting a low electron mobility ($\mu_{el} < 1$ cm^2 V^{-1} s^{-1}). Here above a certain field strength a superlinear dependence was observed and data for ethane, propane, and pentane have been published already (32, 34). As examples for this type of behavior in Figs. 6 and 7 the electron drift velocities in liquid butane and cyclopentane are shown. It can be seen that the field strength at which the superlinearity sets in is shifted to lower values the higher the temperature.

A third type of field strength dependence was observed in isooctane at 221 K and in a 50/50 mixture of ethane and methane (Figs. 8 and 9), where the low field mobilities are 3 and 5 cm^2 V^{-1} s^{-1}, respectively.

Above a certain field strength a superlinear region is observed which is followed again at a still higher field strength by a linear region with a higher mobility. At 296 K in isooctane a sublinear dependence is found while at 195 K the drift velocity increases superlinearly with field.

Liquid Argon, Krypton, and Xenon: The Effect of Nonelectronegative Solutes

The interaction of thermal and superthermal electrons with alkane molecules in a condensed medium can be investigated by studying solutions of these compounds and liquefied rare gases (38). Use is being made of the experimental fact that in liquefied argon, krypton, or xenon electrons with mean energies above thermal can be obtained by the application of an electric field (36). Addition of hydrocarbon molecules influences the electron transport in a distinct way leading to a decrease of the low field mobility and to an increase of the high field mobility defined as

$$[6] \qquad v_d(F)/F = \mu(F)$$

at a fixed field strength F as compared to the pure solvent. As an example of this type of experiment in Fig. 10 the dependence of the excess electron drift velocity on the electric field strength is shown for liquid xenon and solution with *n*-butane. It is interesting to note that for low butane concentrations even a drift velocity maximum is obtained and at higher field strength the drift velocity approaches the value of the pure solvent again. Qualitatively these findings can be explained in the following way. At low field strength the electrons are in thermal equilibrium with the solvent and addition of butane molecules introduces new scattering centers for momentum transfer and a smaller mobility results. At the high field strengths the drift velocity is determined by elastic energy losses. Butane molecules act as energy sinks because a molecule can take up more energy

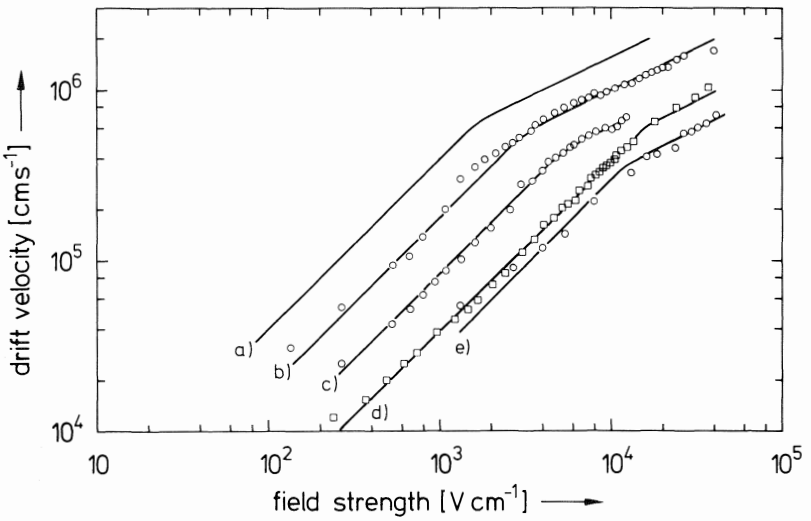

FIG. 5. Field strength dependence of electron drift velocity in methane–ethane mixtures at low ethane concentrations at $T = 111$ K: *a*, pure methane; *b*, 4 mol% ethane; *c*, 13 mol% ethane; *d*, 24 mol% ethane; *e*, 27 mol% ethane (with permission, from ref. 28).

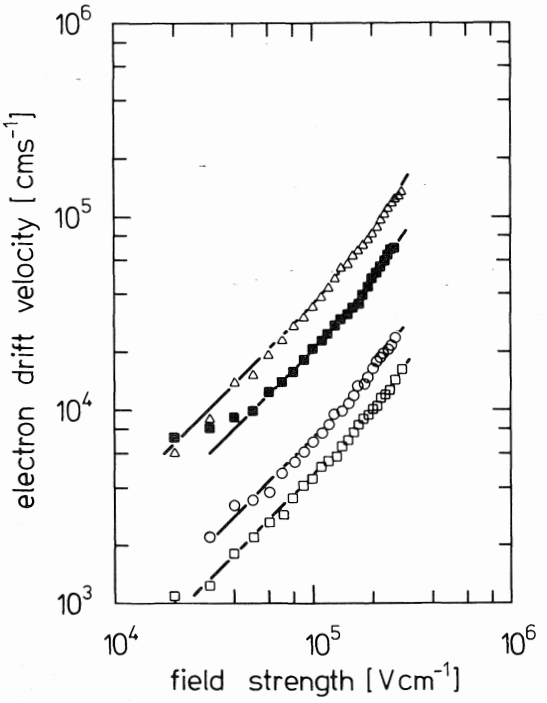

FIG. 6. Electron drift velocity as a function of the electric field strength in liquid butane: △, 297 K; ■, 278 K; ○, 250 K; □, 238 K (ref. 14).

from a colliding electron than a xenon atom. The drift velocity is then determined by the relative magnitude of the elastic loss rate to the inelastic loss rate. A simple analysis of these processes leads to a formula which gives the dependence of the drift velocity v_i on the solute concentration

$$[7] \quad v_i = \mu F_i = \left[\frac{\mu \Delta W \sigma(\varepsilon) N (2\varepsilon/m)^{1/2}}{e_0} + (\mu F_p)^2\right]^{1/2}$$

where F_i and F_p are the field strength in the solution and the pure solvent, respectively, where the same electron mobility μ (defined by eq. 6) exists. ΔW is the energy transferred to the molecule per collision, $\sigma(\varepsilon)$ the energy dependent cross section, N the solute concentration, ε the mean electron energy, m the electron mass, and e_0 the electronic charge. At high field strengths μF_p is constant (saturation velocity in the pure solvent) and for a certain solute concentration a drift velocity maximum occurs at an energy ε_{max} where $\mu\sigma(\varepsilon)\varepsilon^{1/2}$ shows a maximum.

By analyzing data as shown in Fig. 10 the product of $\Delta W\sigma(\varepsilon)$ can be obtained provided $\varepsilon = \varepsilon(F)$ is known. We applied the Cohen–Lekner theory (39, 40) and adjusted the mean free paths for momentum transfer Λ_1 to fit the theoretical dependence of electron drift velocity on field strengths for the pure solvents. Λ_0 values were obtained from V_0 measurements by means of the Springett–Jortner–Cohen theory (41).

Results of this type of analysis are shown in

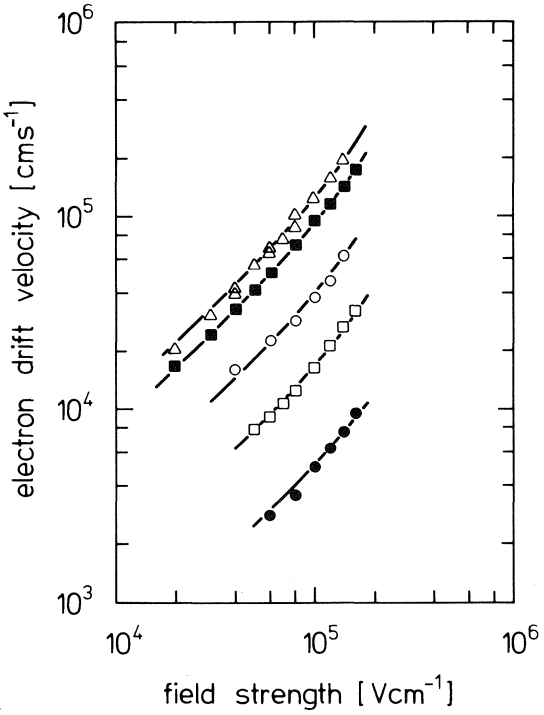

FIG. 7. Electron drift velocity as a function of the electric field strength in liquid cyclopentane: △, 296 K; ■, 278 K; ○, 251 K; □, 222 K; ●, 202 K (ref. 14).

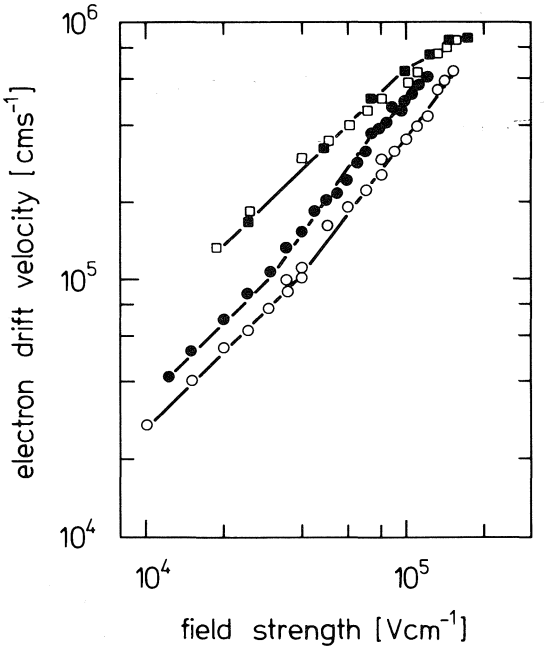

FIG. 8. Electron drift velocity as a function of the electric field strength in liquid 2,2,4-trimethylpentane (14, 24): □, 296 K; ●, 221 K; ○, 195 K. ■, 295 K (data from Balakin and Yakovlev (37)).

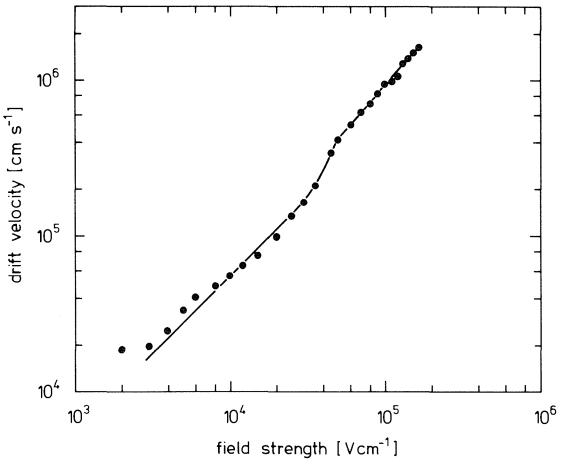

FIG. 9. Field strength dependence of electron drift velocity in an equimolar mixture of methane and ethane at $T = 111$ K (with permission, from ref. 28).

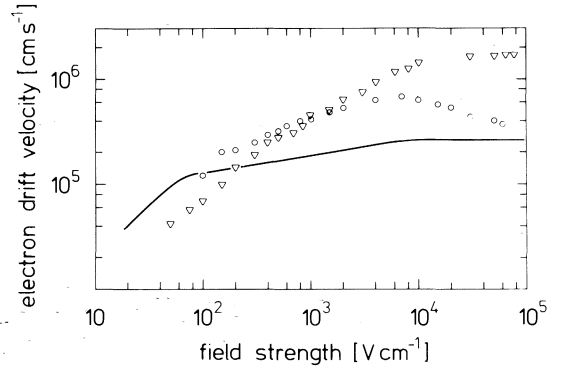

FIG. 10. Electron drift velocity as a function of the electric field strength in liquid xenon and the effect of butane. Butane concentration: ○, 1.26×10^{19} cm^{-3}; ▽, 1.9×10^{20} cm^{-3}; $T = 165$ K, solid line pure xenon (with permission, from ref. 38).

Fig. 11. With the mean electron energy approaching 0.1 eV a steep increase occurs and a maximum is reached between 0.3 and 0.5 eV. Butane is best in taking up energy since with increasing chain length the variety of possible vibrations increases. Hydrogen is effective at much higher energies.

Evaluation of the influence of solutes on the low field mobility has been reported by Sowada *et al.* in this symposium.

Mobility Models

Although no uniform theory exists which would describe all the dependencies mentioned in the foregoing sections some models have been proposed which take into account some of the properties and explain some of the data.

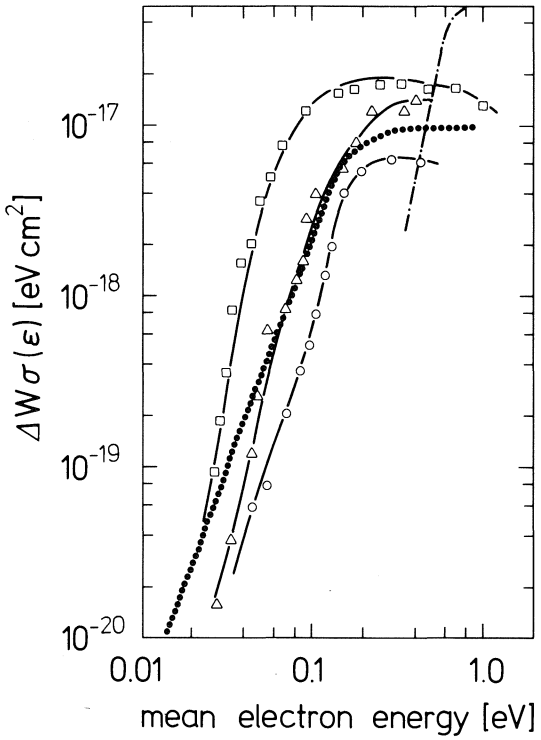

FIG. 11. Product of cross section for inelastic energy loss and loss quantum as a function of the electron mean energy: ●, methane; ○, ethane; △, propane; □, butane; ·-· hydrogen (38).

The simplest explanation for the exponential temperature dependence of the mobility is the trapping model first proposed by Minday *et al.* (42) for the electron mobility in *n*-hexane. The electrons are thought to be trapped by a molecule or a group of molecules for a time τ_t. Thermal activation would promote electrons from the traps into a conducting state with high mobility μ_{cb} where they travel for a time τ_f until retrapping occurs. The observed mobility μ_{el} is then given by

$$[8] \qquad \mu_{el} = \frac{\tau_f}{\tau_f + \tau_t}\mu_{cb} + \frac{\tau_f}{\tau_f + \tau_t}\mu_t$$

Here μ_t denotes the mobility of the trap which in liquid hydrocarbons is probably of the order of ionic mobilities. With the justifiable assumption that $\tau_f\mu_{cb} \gg \tau_t\mu_t$ then for μ_{el} one obtains

$$[9] \qquad \mu_{el} = \mu_{cb}\frac{1}{1 + \tau_t/\tau_f} \approx \mu_{cb}\frac{\tau_f}{\tau_t}$$

It is assumed that $\tau_f \ll \tau_t$ and that the residence time in the trap is temperature dependent

$$[10] \qquad \tau_t = \tau_0 \exp(E_a/k_BT)$$

which with eq. 9 leads to

$$[11] \qquad \mu_{el}(T) = \mu_{cb}(\tau_f/\tau_0) \exp(-E_a/k_BT)$$

The mobility in the extended state may also depend on temperature; however, over a limited temperature range the exponential dependence will be the dominating factor leading to a straight line in an Arrhenius plot. For the trapping model to be applicable it is required that the mean free path between trapping collisions Λ_t is greater than the relaxation length λ associated with the mobility in the extended state.

$$[12] \qquad \mu_{cb} = \frac{e_0}{m}\frac{\lambda}{v_{th}}$$

with v_{th} the thermal velocity of the electrons (e_0, m electronic charge and mass, respectively), or

$$[13] \qquad \tau_f \gg \lambda/v_{th}$$

From the measurement of the temperature dependence of the mobility alone no information on the different parameters of this model can be obtained. Application of a strong electric field leads to a voltage drop across the diameter of the trap a_t thus reducing the trapping energy. Considering classical processes only LeBlanc (43) found that the mobility should vary with field strength as

$$[14] \qquad \mu(F) = \mu_{cb} \exp\left(-\frac{(E_a - e_0a_tF)}{k_BT}\right)$$

or

$$[15] \qquad \frac{\mu(F)}{\mu(0)} = \exp\left(\frac{e_0a_tF}{k_BT}\right)$$

where $\mu(0)$ denotes the low field mobility. Sample calculations have shown that the dependence according to eq. 15 could not be fitted to the experimental data of butane with any value of a_t. Incorporation of quantum mechanical tunneling into the model might improve the situation.

While the trapping model actually requires the participation of extended states (or in the terminology of solid state physics a conduction band) the field strength and temperature dependences in low mobility hydrocarbons can also be described by the hopping model in which it is assumed that the electron moves by jumps from one localized state to another.

If Λ is the mean jump distance and ν_j the jump frequency then the diffusion coefficient is given by

[16] $$D = \Lambda^2 \nu_j$$

The low field mobility is obtained by the Nernst–Einstein relationship

[17] $$\mu(0,T) = \frac{e_0 D}{k_B T} = \frac{e_0}{k_B T} \Lambda^2 \nu_j$$

With the assumption that the transport is an activated process ν_j is

[18] $$\nu_j = \nu_0 \exp(-E_a/k_B T)$$

and the low field mobility becomes

[19] $$\mu(0,T) = \frac{e_0}{k_B T} \Lambda^2 \nu_0 \exp(-E_a/k_B T)$$

The application of an electric field leads to an increase of the mobility and Bagley (44) derived for $\mu(F,T)$

[20] $$\mu(F,T) = \mu(0,T) \frac{\sinh(e_0 \Lambda F/2k_B T)}{e_0 \Lambda F/2k_B T}$$

This equation has been used to analyze our temperature and field strength data by adjusting Λ. Temperature dependent values of Λ were obtained which are shown in Fig. 12. The other parameters of this model are given in Table 2. The temperature dependence of the jump frequency gave linear Arrhenius plots. With the parameters and $\Lambda(T)$, the temperature dependence of the mobility could also be reproduced.

A notable exception is propane, where Λ is independent of temperature and ν_0 is one order of magnitude greater. No reason for this behavior can be given at the present time. Funabashi and Rao (45) have extended the Bagley model for the case of statistically fluctuating barrier heights. Parameter fitting lead to smaller Λ values. A more detailed analysis, however, in three dimensions would be necessary. The temperature and field strength dependence of the mobility given by eq. 20 also follows from the theory of the small polaron (46–49).

An electron moving through a nonpolar liquid is surrounded by a cloud of induced polarization. In ionic crystals this can lead to self-trapping and the resulting entity is called a polaron. Polaron formation can also occur in molecular crystals and Holstein (46) has described the essential properties of this species. Depending on the temperature different modes of transport are thought to exist. At low temperatures a band-type motion is observed while at higher temperatures the polaron states are localized and the motion becomes thermally activated. The electron will jump from one site to another whenever the molecular configurations of the two sites are the same. This situation results from thermal fluctuations and its probability is proportional to $\exp(-E_a/k_B T)$. The jumps occur so rapidly that the polarization well due to molecular orientation remains behind and the electron ceases to exist as a localized polaron until it encounters the new site. The residence time in a trap Δt should be short compared to a tunneling time t_p but long compared to the jump time t_0. Estimates for these times given by Lang and Firsov (48) show that these conditions are indeed fulfilled for ethane and that the small polaron concept seems to be applicable.

Efros (49) derived a temperature and field strength dependence of the mobility as given by eq. 20. Different preexponential factors were obtained, however, for $\eta_2 < 1$ and $\eta_2 > 1$ where

[21] $$\eta_2 = J^2/\hbar w_0 (E_a k_B T)^{1/2}$$

with w_0 the vibration frequency of the molecules. The Efros equation can be written as

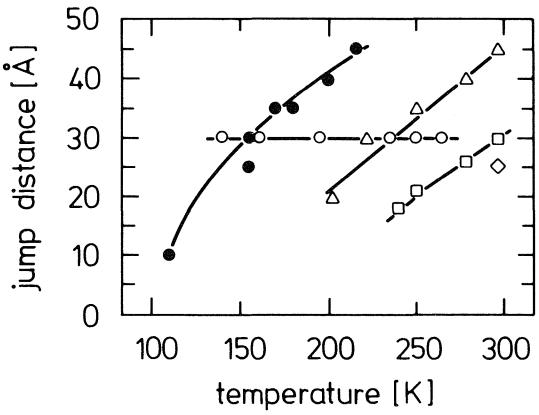

FIG. 12. Dependence of the mean jump distance (hopping model) on the temperature: ●, ethane; ○, propane; □, butane; ◇, pentane; △, cyclopentane (32, 34, 14).

TABLE 2. Parameters of the hopping model

Liquid	ν_0 (s^{-1})	E_a (eV)
Ethane	1.4×10^{13}	0.087
Propane	2×10^{14}	0.155
Butane	1.4×10^{13}	0.13
Cyclopentane	1.4×10^{13}	0.12

$$[22]\qquad \mu(T,F) = \underbrace{A(T)\Lambda^2(T)}_{f_1}\ \underbrace{\exp\left(-\frac{E_a}{k_B T}\right)}_{f_2}\ \underbrace{\frac{\sinh\left(\frac{e_0 F\Lambda}{2k_B T}\right)}{\frac{e_0 F\Lambda}{2k_B T}}}_{f_3}\ \underbrace{\exp\left(-\frac{(e_0 F\Lambda)^2}{16E_a k_B T}\right)}_{f_4}$$

At medium field strengths as applied in our experiments f_4 is negligible and the resulting $\mu(T, F)$ is the same as in the Bagley model.

The factor f_1 depends on η_2 and for $\eta_2 < 1$

$$[23]\qquad f_{11} = \frac{e_0\pi^{1/2}}{2\hbar}\frac{|J|^2}{(E_a k_B{}^3 T^3)^{1/2}}$$

while for $\eta_2 > 1$

$$[24]\qquad f_{12} = w_0 e_0/2\pi k_B T$$

If we take for $w_0 = 2\pi\nu_0$ then f_{12} coincides with the preexponential factor of eq. 19. Fitting our data for ethane and propane with f_{11} yields for the exchange integrals $J = 0.014$ eV and $J = 0.09$ eV, respectively. These values give $\eta_2 < 1$ and, furthermore, $J < E_a$ is fulfilled, the Holstein condition (46) for the small polaron model. A further test can be achieved with measurements at very high fields where f_4 becomes significant.

For liquids with high electron mobilities, notably liquid argon, the free electron theory developed by Cohen and Lekner (39, 40) can be applied. For the low field mobility they derive the Lorentz formula (52)

$$[25]\qquad \mu = \tfrac{2}{3}(2/\pi m k_B T)^{1/2} e_0\Lambda_1$$

with Λ_1 the mean free path for momentum transfer which is related to the structure of the liquid by

$$[26]\qquad \Lambda_1{}^{-1} = 4\pi\bar{a}^2 n S(0)$$

n is the number density of the liquid, $\bar{a}$ the scattering length, and $S(0)$ the structure factor for the limit of zero energy. From eq. 25 mean free paths Λ_1 obtained for the high mobility liquids mentioned in this paper are given in Table 3.

The observed field dependence of the mobility at higher field strengths is related to the way the electrons lose energy picked up from the field between subsequent collisions.

The Cohen–Lekner theory gives the critical field strength F_c at which this field dependence sets in as

$$[27]\qquad f \approx \tfrac{1}{3}(e_0 F_c\Lambda_1)(e_0 F_c\Lambda_0)/(k_B T)^2$$

Here Λ_0 is the mean free path for energy transfer and f the mean fractional energy loss per collision. Λ_0 values can be obtained from V_0 values by means of the Springett–Jortner–Cohen theory (41) and in Table 3 the ratio f/f_{el} derived for these liquids is given ($f_{el} = 2m/M$, with M the mass of an atom or molecule of the liquid). The strong influence of inelastic collisions on the mobility in the molecular liquids is apparent.

In the cases of neopentane and isooctane the applicability of the Cohen–Lekner theory may be doubtful since the necessary presumption that the de Broglie wavelength be smaller than Λ_1 is not fulfilled.

For liquid methane and tetramethylsilane the ratio f/f_{el} could also be derived from the scattering experiments in the liquefied rare gases (39) and similar ratios as given in Table 3 were obtained.

Attempts have been made to develop a general picture of the electron mobility in hydrocarbons. Schiller and co-workers (12, 52) and Dodelet *et al.* (16) extended the equilibrium model of Minday *et al.* (42) by introducing the concept of electron localization due to energy fluctuations in the liquid.

The probability of finding regions of the liquid capable of localizing electrons is given by

$$[28]\qquad P = (2\pi\Sigma^2)^{-1/2} \times \int_{\infty}^{V_0} \exp\left(-(E - E_t)^2/2\Sigma^2\right) dE$$

with E_t the energy of the localized state, V_0 the energy of the extended state, and Σ the energy fluctuation parameter. The observed mobility is then

$$[29]\qquad \mu_{el} = \mu_{cb}(1 - P)$$

Since P depends on V_0 a correlation between

TABLE 3. Critical field strength and velocity and mean fractional energy loss for high mobility liquids

†$v_{th} = (3k_BT/m)^{1/2}$.
‡$f_{el} = 2m/M$.

μ_{el} and V_0 should exist. Some data follow the dependence while others do not (52, 54). Values for μ_{cb} between 100 and 400 cm^2 V^{-1} s^{-1} are obtained (12).

Percolation theory was invoked by Kestner and Jortner (53) and results similar to those of Schiller's were obtained. The experimental data, however, are not in general agreement with the predictions of the theory (54, 33).

Conclusion

Excess electrons in liquid hydrocarbons exhibit mobilities which range over several orders of magnitude.[1] Two limiting cases can be distinguished as seen from the dependence on the electric field strength. In liquids with a high mobility $\gtrsim$ 100 cm^2 V^{-1} s^{-1} the electrons move in an extended state and the magnitude of the mobility is determined by scattering processes. High electric field strength leads to an increase of the mean electron energy and a decrease of the mobility. In low mobility liquids $\lesssim$ 0.1 cm^2 V^{-1} s^{-1} the electrons spend most of their lifetime in localized states and the transport can be described either by a hopping process or a trap controlled band motion. High electric field strength increases changes of place thus leading to a higher mobility.

The further understanding of the electron transport process in nonpolar liquids will depend on the development and exploitation of other sources of physical information.

Discussion

P. K. Watson: The mechanism of hopping transport discussed by the author is described in terms of an attempt frequency and a mean hopping distance between traps. It seems likely however that in a liquid there will be a wide distribution of residence times in traps so that a model based on a single hopping frequency and a single jump distance is an oversimplification. A more appropriate model, which one might use to describe such a hopping process, is of the form described by Scher and Montroll in which the hopping transport is defined in terms of a distribution of waiting times in traps and a field-dependent asymmetry in the jump distance.

W. F. Schmidt: The Scher–Montroll model applies primarily to disordered solid material where a wide distribution of residence times exist. Electrons injected at one electrode travel into the material and get trapped in deeper traps. The current decay shows a long tail. In liquids we get out all electrons injected at almost the same time (only diffusion leads to a smearing out of the density distribution), therefore the application of a mean residence time seems to be justified.

J. Noolandi: I would like to point out that the decay time of the current for the experiments analyzed by the Scher–Montroll theory is typically of the order of milliseconds, not hours.

W. F. Schmidt: I think the important feature of these experiments is the long nonlinear decay of the current after the injection pulse as compared, for instance, to our liquid mobility work.

J. M. Warman: I don't wish to defend any particular mobility mechanism but I do think that the two-state trapping model was not given a fair chance since the effect of field

was considered only on the detrapping process. It is quite possible that the rate of the trapping process is (also?) dependent on field strength if the electron is 'heated up' by the field while residing in the quasifree state. If the trapping rate decreases with electron energy as might be suggested by your results on the attachment to SF_6 in liquid xenon then an increase in the residence time in the quasifree state will occur at high fields and hence an increase in mobility as observed for mobility liquids.

W. F. Schmidt: Your arguments are correct. Only at the present, to my knowledge, there is no theory describing the effect of field on the trapping model and I think besides the points you mentioned field assisted tunnelling out of the trap has to be included.

E. O. Forster: It appears that in discussing the various possible models for liquid hydrocarbons the liquid has been considered to be made up of individual molecules. Indeed the structure of these liquids is more complicated. How do the various models take into consideration (*a*) the clustering caused by induced dipole–dipole interactions and (*b*) the density fluctuations existing at constant temperature on the molecular level.

W. F. Schmidt: Structure of the liquid has been taken into account in the Cohen–Lekner theory of the extended excess electron state. In this conference L. Kevan has presented potential calculations for hydrocarbons with different orientations of the molecules towards the electron. It is clear that theoretical approaches have to include these effects you mention.

E. O. Forster: Have you looked at the values of E_a for viscous flow for the alkanes and alkenes you have studied? It might prove interesting to consider this parameter as a measure of structural effects.

W. F. Schmidt: There does not seem to exist a simple correlation between viscosity and any of the properties we measured. Sowada, in his thesis, has found, however, that the product of jumping distance and viscosity was constant for some liquids.

C. C. Yang: Could you elaborate the physics behind the structure influence on the electronic mobility?

W. F. Schmidt: Not really, since there is no model which could explain the difference in mobility in methane and ethane. From the high field measurements in high mobility liquids it is apparent that in the molecular liquid inelastic losses influence the mobility (see Table 3).

J.-P. Dodelet: (*a*) The activation energies you reported from the literature were often measured around room temperature. They could be very different at lower or higher temperatures as you have shown in ethane and methane. It could therefore be misleading to say that high mobility liquids are characterized by a very low energy of activation. This is true in only a small temperature range. (*b*) How do you explain the two activation energies you reported in ethane?

W. F. Schmidt: (*a*) The statements I made refer to the present status of the field, where, as you pointed out, measurements have been made only over a limited range of temperatures. Changes in activation energy or temperature dependence may indicate a change of the transport mechanism. (*b*) We actually have only one activation energy listed in Table 2. The variation of the mobility as a function of temperature is due to the temperature dependence of the jump distance derived from the Bagley model.

L. Onsager: Could Dr. M. H. Cohen tell us to what extent he looked at phonons, or time dependence of fluctuations, and similar aspects of the problem?

M. H. Cohen: With regard to interpretation of changes of activation energy with temperature, the obvious possibility is a change in mechanism. For example, at elevated temperatures the small polaron is unstable and the electron motion goes over to a diffusive mechanism similar to that I described in my talk which involves the time dependence of the fluctuations. With regard to the observed reduction in mobility caused by molecular asymmetry or by the introduction of double bonds, the obvious interpretation is that the possibility of orientational and polarization fluctuations is introduced, thereby introducing an increased tendency towards Anderson localization and increased possibilities for self-trapping. However optimistic one is about such mechanisms for interpreting the observations reported for drift velocities in complex molecules, the dramatic effect of ethane on mobilities, etc., in methane has to give one pause. There is no drastic increase in polarizability and the asymmetry of the molecule is not great, not nearly as large as in more complex liquids of higher mobilities. This raises the need of paying attention to quite specific properties of individual molecules.

G. R. Freeman: The jump from methane to ethane is enormous because methane is isotropically polarizable and ethane has an appreciable anisotropy.

L. G. Christophorou: Mobility is a gross, all-embracing quantity, *i.e.* the overall result of many processes, elastic, inelastic, capture, etc. I believe that, especially for the case of high field mobility, emphasis should be accorded to the detailed electron energy loss mechanisms, in a manner analogous to that in gases.

W. F. Schmidt: The overall picture has been established; measurements giving information on a microscopic level are necessary. First steps into this direction have been made by us in measuring the influence of molecular solutes on the electron drift velocity in liquid argon (K. Yoshino, U. Sowada, W. F. Schmidt. Phys. Rev. A, **14**, 438 (1976)).

J. Jortner: We have been talking about the role of density and orientational fluctuations of small amplitude configurational changes induced by the electron and of large configurational changes resulting in electron localization. I would like to draw attention to another effect which involves the coupling of the excess electron with a single vibrating solvent molecule. I am referring to the small polaron in the Holstein picture where the two-order picture involves the electron residing on a single molecule. Small polaron effects are exhibited in some diatomic molecular solids such as solid N_2, where the electron mobility studied by Spear is $\sim 10^{-2}$ cm^2 V^{-1} s^{-1}. Such small polaron effects may be responsible for the reduction of electron mobility upon the introduction of double bonds.

Equilibrium model for the interpretation of the conduction properties of metal–ammonia solutions

S. HAHNE, P. KREBS, AND U. SCHINDEWOLF

Institut für Physikalische Chemie und Elektrochemie, Universität Karlsruhe, Germany

Received October 19, 1976

S. HAHNE, P. KREBS, and U. SCHINDEWOLF. Can. J. Chem. **55**, 2211 (1977).

The electrical conductivity of metal–ammonia solutions can be described by an equilibrium of solvated electrons of low mobility and of free electrons of high mobility. With proper choice of the equilibrium constant and its temperature and pressure dependence and of the solvation number of the solvated species the experimental conductivities can be matched in the temperature and pressure range from 240 to 420 K and up to 1000 bar over the entire concentration range from 0.1 mol/ℓ to saturation, also fitting the extrema of the temperature and pressure coefficients of the conductivity around 1 mol/ℓ.

S. HAHNE, P. KREBS et U. SCHINDEWOLF. Can. J. Chem. **55**, 2211 (1977).

On peut décrire la conductivité électrique des solutions métal–ammoniac par un équilibre d'électrons solvatés de mobilité faible et d'électrons libres de grande mobilité. En faisant un choix approprié des constantes d'équilibres et de la dépendance sur la température et sur la pression ainsi que du nombre de solvatation des espèces solvatés, on peut trouver un bon accord avec les conductivités expérimentales à des températures et des pressions allant de 240 à 420 K et jusqu'à 1000 bar à toutes les concentrations allant de 0.1 mol/ℓ jusqu'à la saturation, et qui s'accordent aussi aux extrêmes des coefficients de température et de pression de la conductivité autour de 1 mol/ℓ.

[Traduit par le journal]

Recently we (1) presented experimental data about the electrical conductivity of metal–ammonia solutions (MAS) in the temperature and pressure range from 240 to 420 K and 200 to 1000 bar, respectively. As shown in Fig. 1, in which the equivalent conductance Λ at constant pressure ($\Lambda = \sigma/c$ (Ω^{-1} cm^2 mol^{-1}); σ specific conductivity (Ω^{-1} cm^{-1}), c molar concentration (mol/cm^3)) is plotted *vs.* molar concentration with temperature as parameter, the steep increase of the conductivity is shifted to smaller concentrations with increasing temperature; pressure increase on the other hand leads to a shift to higher concentrations.

No matter what the conduction mechanism in these solutions is and how the nonmetal–metal transition (NMT) is defined the data suggest that this transition is favoured by temperature increase and opposed by pressure increase.

For the interpretation of the NMT in MAS two contrasting theories were presented by Cohen and Jortner (2) and Mott (3), respectively, based on the percolation model and on the concept of the Anderson transition. Although the authors gave a series of arguments to support their concepts it seemed that no general agreement is obtained on the nature of the NMT and the conduction mechanism in moderate to high concentrated solutions. Only for the dilute range ($c < 0.05$ mol/ℓ or 0.1 mol% metal (mpm)) in which the equivalent conductance varies only slightly with concentration (Λ = 500–1000 Ω^{-1} cm^2 mol^{-1} at 240 K) is it not doubted that the electrical current is carried by individual moving solvated electrons and metal cations (4).

In the intermediate range (0.5–2 mol/ℓ or 1–4 mpm, depending on temperature) with the beginning steep conduction increase and the still unexplained maxima of the positive temperature coefficient (5) and the negative pressure coefficient (6) of the conductivity (see also Fig. 3), semiconduction is assumed. This is supported by the peculiar temperature dependence of the thermopower (7, 8) (see also Fig. 4) which in the intermediate range decreases with temperature as is to be expected for activated transport (3), whereas in lower and higher concentrated MAS it increases with temperature.

Besides a more or less quantitative description of the conduction behaviour of the MAS at normal temperature and pressure, no explanation was given or could be given on the basis of the percolation model or the Anderson concept for the observed shifts of the NMT with temperature and pressure.

Two experimental observations prompted us

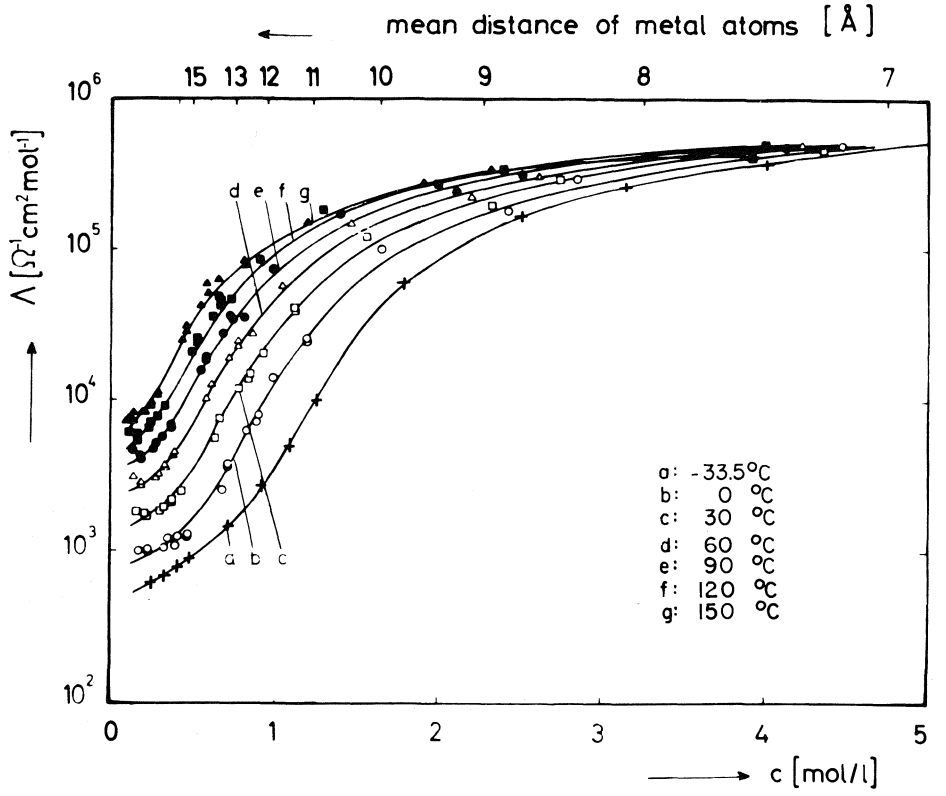

FIG. 1. Equivalent conduction Λ of sodium–ammonia solutions in the temperature and pressure range between 240 and 423 K at 200 bar. (Reprinted with permission from the Journal of Physical Chemistry, **79**, 2922 (1975). Copyright by the American Chemical Society.)

to propose an equilibrium model for the interpretation of the conduction behaviour of MAS, assuming a proper chemical equilibrium between solvated electrolytelike electrons e_s^- of low mobility and unsolvated free electrons e_f^- of high mobility. These observations are: (*1*) electrons photoinjected from a cathode into liquid ammonia exist in two different states, which exhibit low and high mobility (0.03 and 2000 $cm^2\ V^{-1}\ s^{-1}$) (9) and which might be characterized as solvated and free electrons, and (*2*) the absorption spectrum of solvated electrons persists still in higher concentrated solutions, *i.e.* that solvated electrons are present in solutions of metallic character (10). The assumed chemical equilibrium is written in the form

$$[1] \qquad e_s^-(iNH_3) \rightleftarrows e_f^- + iNH_3$$

with i the solvation number of the solvated electrons. The solvated metal cations $M^+(kNH_3)$ with solvation number k cancel in the equilibrium. The equilibrium constant is

$$[2] \qquad K = \frac{[e_f^-][NH_3]^i}{[e_s^-(iNH_3)]}$$

(squared brackets stand for concentration). The charge and material balance are

$$[3] \quad [e_s^-(iNH_3)] + [e_f^-] = [M^+(kNH_3)] = c_M$$

$$[4] \quad i[e_s^-(iNH_3)] + k[M^+(kNH_3)] + [NH_3] = c_A$$

c_M, the overall concentration of dissolved metal, is equal to the concentration of the solvated metal cations, providing complete dissociation; $[NH_3]$ is the concentration of unbound free ammonia, c_A its overall concentration. The combination of [2], [3], and [4] leads to a polynomial of i + 1st degree from which the concentration of solvated electron or free electrons can be obtained as a function of the concentration of dissolved metal.

The specific conductance of the MAS is given by the sum of the conduction of solvated and free

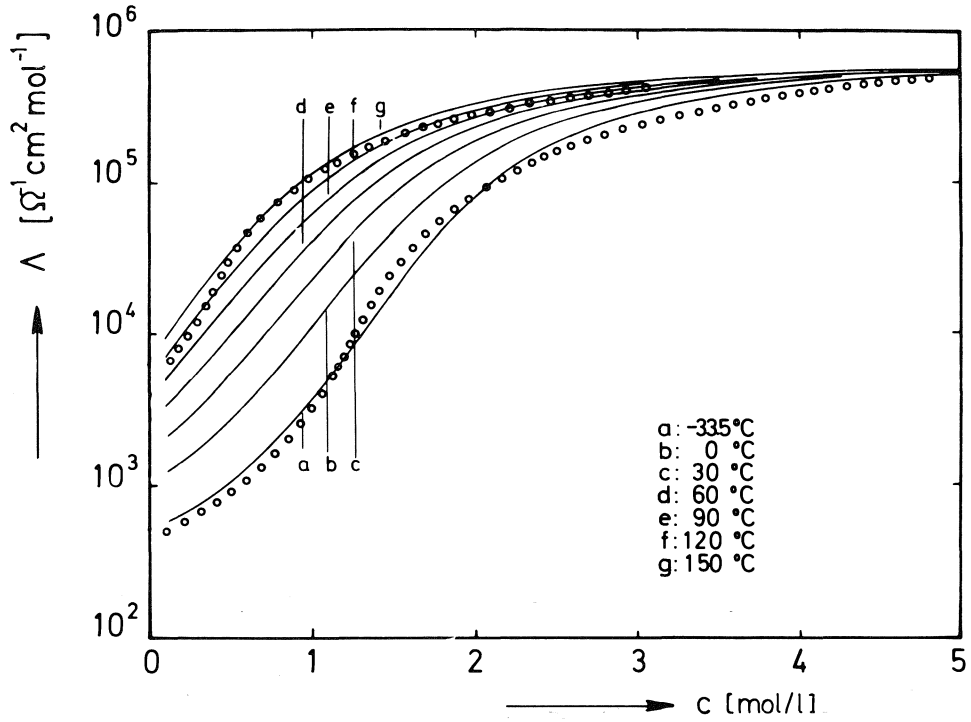

FIG. 2. Simulation of the equivalent conduction of metal–ammonia solutions in the temperature range from 240 to 423 K on the basis of the equilibrium model (experimental data at 240 and 423 K also shown).

electrons and of metal cations

$$\sigma = \sigma_s + \sigma_f + \sigma_{M^+} \quad [5]$$

The contribution of each species is taken as the product of its concentration and its concentration independent mobility (equivalent conduction)

$$\sigma_i = c_i \Lambda_i \quad [6]$$

The molar conduction of the solution follows from

$$\Lambda = \sigma / c_M = \sum c_i \Lambda_i / c_M \quad [7]$$

For evaluation of this concept, mobilities of solvated electrons and cations and of free electrons were taken from experimental conductivity data of very dilute MAS in which all electrons are solvated (electrolytic behaviour) and of saturated MAS, respectively, in which all electrons are assumed to be free (truly metallic solutions): $\Lambda_s + \Lambda_{M^+} \approx 500$, $\Lambda_f = 6 \times 10^5$ Ω^{-1} cm^2 mol^{-1} at 240 K and 200 bar (see lowest curve of Fig. 1). The solvation number of metal cations is taken as $k = 6$ on the basis that the solubility limit of sodium or potassium in ammonia is around 15 mol% metal (roughly 6 mol ammonia per mol of metal). After trial and error a rather good fit of experimental conduction data for 240 K and 200 bar in the concentration range from 0.1 mol/ℓ to saturation could be obtained by setting the solvation number of the solvated electrons $i = 6$ and the equilibrium constant $K = 2.5 \times 10^6$ (mol/ℓ as concentration units).

With the introduction of the normal temperature dependence of the equilibrium constant and of the mobility of the solvated electrons and metal cations

$$K = K_0 \exp\{-\Delta H/RT\}$$
$$\Lambda_s = \Lambda_{s0} \exp\{-E_a/RT\} \quad [8]$$

conductivity data at higher temperatures also could be matched (ΔH molar enthalpy difference between the free state and the solvated state of the electrons; E_a energy of activation of the mobility of the solvated particles; the mobility of the free electrons is in agreement with Fig. 1 taken independent of temperature). Figure 2 shows the results in which in addition

to the other constants given above ΔH was set at 5 kcal/mol and E_a to 2.8 kcal/mol, the latter taken from the literature (5). For comparison the experimental data for 240 and 423 K are also shown.

From Fig. 2, or from its comparison with Fig. 1, it is seen that the numerical evaluation of the proposed model gives a rather good approximation of the trend of the experimental conduction data which vary over three powers of 10 from low concentrated to saturated solutions in the wide temperature range covered by experiments.

Pressure dependences of the conductivity also can be evaluated by introducing the normal pressure dependence of the equilibrium constant and of the mobility

$$\frac{\mathrm{d} \ln K}{\mathrm{d}p} = -\frac{\Delta V}{RT}$$

$$\frac{\mathrm{d} \ln \sigma}{\mathrm{d}p} = -\frac{\Delta V^{\neq}}{RT}$$

(ΔV molar volume difference of the electrons in the free and solvated state, $\Delta V^{\neq}$ activation volume of the mobility of the solvated species). A good fit of the experimental data between 1 and 1000 bar in the temperature range up to 420 K is obtained with $\Delta V^{\neq} \simeq 2$ ml/mol, as taken from literature (6), and $\Delta V = 10$ ml/mol together with the other constants given above (the mobility of the free electrons is taken pressure independent).

In Fig. 3 we plot the calculated temperature and pressure coefficients $(\mathrm{d} \ln \sigma/\mathrm{d}T)_p$ and $(\mathrm{d} \ln \sigma/\mathrm{d}p)_T$ of the conductivity of MAS *vs.* concentration. Also these curves with the maxima of $(\mathrm{d} \ln \sigma/\mathrm{d}T)_p$ and the minimum of $(\mathrm{d} \ln \sigma/\mathrm{d}p)_T$ in the concentration range around 1 mol/ℓ or 2 mpm are in fair agreement with experimental data (dotted lines).

It should be stressed that the treatment given above is only an interpolation of the conduction behaviour of MAS between the two extrema, the electrolytic and the metallic state; only four parameters were chosen arbitrarily, *i.e.* the equilibrium constant K, its temperature and pressure dependence expressed by the reaction enthalpy ΔH and the reaction volume ΔV, and the solvation number i of the solvated electrons, to get a fit of the experimental data in a wide concentration, temperature and pressure range. The other necessary constants *i.e.*, the mobility

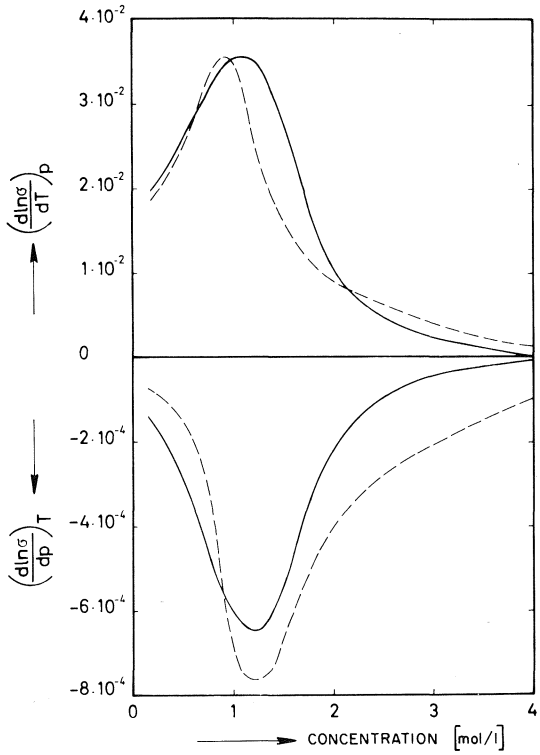

FIG. 3. Simulation of the temperature coefficient and the pressure coefficient of the conductivity of metal–ammonia solutions (240 K) on the basis of the equilibrium model (dotted lines experimental data).

and its temperature and pressure dependence of the solvated species and of the free electrons were taken from experimental data. For the choice of the solvation number of the cations a good argument was given.

Also, the arbitrarily chosen parameters are not unreasonable. The solvation number of solvated electrons $i = 6$ is also used by the theoreticians (11) to obtain a good fit between calculated and observed absorption spectra of solvated electrons in ammonia. The equilibrium constant $K = 2.5 \times 10^6$ at 240 K leads to a change of free energy of $\Delta G = -7$ kcal/mol and in combination with $\Delta H = 5$ kcal/mol to a change of entropy of 40 cal mol^{-1} K^{-1} associated with the transition from the nonmetallic to the metallic state. This entropy increase would not be surprising when a bound electron is converted into a free electron, releasing six ammonia molecules from its solvation shell. The positive ΔV also is not unrealistic, since an increase in the apparent molar volume of dissolved sodium in ammonia in the concentration range

of the NMT was found by density determinations (12) although this increase is not as large as that used here.

Of course one argument against the evaluation of the proposed model is that solutions were treated as ideal, not considering any interactions between particles which might be considerable but which presently are hard to estimate because as Mott (3) states "too many effects have a role for a quantitative theory to be possible". It has been the only aim of this paper to show that the rather simple concept of a chemical equilibrium, which might be more appealing to a chemist than the other theories, can describe the conduction phenomenon of MAS over a wide range of experimental conditions with a minimum number of parameters. Also the general trend of experimental data on thermopower (7, 8) and of the Hall coefficient (13) can be matched with this model.

The treatment given here is analoguous to that of Lelieur *et al.* (14) who also assume two different electronic states of different but strongly concentration dependent mobilities whereas we assumed the two states to have concentration independent mobilities. It also is analoguous to that of Arnold and Patterson (15) who, however, assume in addition for the intermediate concentration range electron jumping from F-centres (solvated electrons) to metal cations.

Appendix: Pressure Dependence of Thermopower

In the preceding section we mentioned older data on MAS, according to which in the concentration range of the steep conduction change, temperature and pressure have an adverse, abnormally large effect on the conductivity. Also it was shown that the thermopower behaves abnormally: in the middle concentration range it decreases with temperature, whereas in the more dilute or more concentrated solutions it increases. We succeeded also in determining the effect of pressure on the thermopower with the following arrangement.

The solution was kept in a U-tube, the two sides of which were connected by a capillary to avoid thermal convection. Both sides of the tube could be heated separately by surrounding heating coils. Two identical thermocouples, each sealed without electrical contact in a thin steel mantel, were immersed in the solutions of the two sides of the U. The thermocouples were connected to the x-axis of an x,y-plotter to record the temperature differences of both solution sides. The steel mantels form together with the solution the thermocouple $(\text{steel/MAS})_{T_1}/(\text{MAS/steel})_{T_2}$, the voltage of which after suitable amplification was fed to the y-axis of the plotter. The absolute thermopower of the steel mantels, as measured against mercury was small enough ($<2\ \mu V/K$) to be neglected.

The assembly was housed in a thermostated autoclave (200–240 K) which was pressurised up to 800 bar with purified nitrogen. All electrical connections were passed in proper leads through the autoclave. For the measurements one side of the U was heated slowly by about 3 deg, and then allowed to cool again; then the other side was heated and cooled. This procedure required a period of 10 min. The plotter directly recorded the voltage of the MAS–steel thermocouple *vs.* the temperature differences of the solutions; the slope of the plot directly gives the thermopower of the solutions. Concentrations of the solutions were obtained by the usual analytical procedures and checked before and after an experiment by conductivity measurements directly in the cell

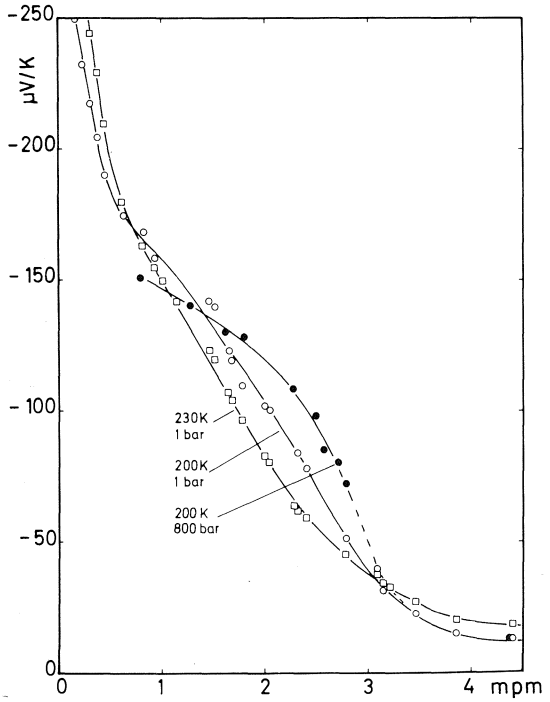

FIG. 4. Thermopower of potassium–ammonia solutions at 200 and 230 K, 1 bar, and 200 K and 800 bar, respectively.

with the two steel mantels as electrodes. The results are given in Fig. 4: the thermopower of the solutions is plotted *vs.* concentration for 1 bar and 800 bar at 200 K and 1 bar at 230 K.

In the intermediate concentration range pressure increases the thermopower very significantly whereas in the more dilute and concentrated ranges the pressure effect is small. It follows that in the intermediate range temperature and pressure also have an adverse effect on the thermopower as shown earlier for the conductivity.

Discussion

M. H. Cohen: All three models will have similar pressure and temperature behavior since all three involve mixtures of two kinds of configurations differing in free energy. All three models then would show temperature variations characterized by an activation energy and pressure variations characterized by an activation volume in roughly the same way. The main difficulty in this problem is that more than one thing is happening. In the theory of Jortner and myself, the metal–nonmetal transition starts at 2.3 mpm. The properties of the nonmetallic state, however, are strongly concentration dependent in the range 1–2.3 mpm, as evidenced by the conductivity, which is electronic and not ionic, and by your thermopower measurements, particularly with regard to the pressure dependence.

Finally, Ichikawa's interpretation of his concentration fluctuation data, reported yesterday, supports the hypothesis of Jortner and myself of bimodally distributed concentration fluctuations. Thus, it seems clear that one can construct a multiplicity of internally consistent models, all of which can be made to fit the data by adroit choice of parameters. What is needed is more microscopic structural data.

U. Schindewolf: I am aware that we can construct any number of models to describe this or another property of metal–ammonia solutions. As long as these models do not neglect the fundamentals of physics, each of them might have some truth in it, even if it considers the phenomena from a different and perhaps, as ours, unconventional point of view.

L. Onsager: Some parts of this I don't like. As long as the carriers interact by Coulomb forces the mobilities must vary with the concentration even when only one kind of electron is present This interaction together with some neutral atom formation and some dimerization of the trapped electrons might well account for the variation of the mobilities at concentrations well below that of the mobility minimum at about 0.03 mol/ℓ. Beyond that, through the concentration where the temperature coefficient peaks, the variation of mobility with concentration and temperature invites interpretation in terms of tunnelling between singly and doubly occupied cavities. More than a very small contribution from very mobile 'unsolvated' electrons at low concentrations can be ruled out on the grounds that their entropy must be large and yet they constitute only a small fraction of the total electron population, from which we must infer a large energy of liberation and a large temperature coefficient for the size of the free population. However, at low concentrations the temperature coefficient of conducitivity hardly differs from that of the fluidity, which now imposes a rather low ceiling on the proportion of the 'free' electrons.

U. Schindewolf: No effort was made to cover the range below 0.1 mol/ℓ where neutral atom formation or dimerization of electrons seems to occur. In this range the equivalent conductivity changes by a factor of two at the most, whereas here we deal with changes of three powers of 10. Of course tunnelling might be assumed as well as hopping and might, as Mott has shown, also explain the observed pressure changes of conductivity on the basis that the cavity has to increase in size when an electron tunnels or hops into it.

The fact that at low concentrations the T and P coefficients of conductivity correspond to that of fluidity of the solvent, implies that the concentration of very mobile unsolvated electrons is low in spite of their large entropy. The postulated equilibrium 'solvated–unsolvated electrons' is at low metal concentration far on the left side, because of the high concentration of the solvating ammonia. According to the model, the contribution of the unsolvated electrons to conductivity becomes important above 1 mol/ℓ only.

High field transport of excess electrons and holes in amorphous SiO_2 (Extended Abstract)[1]

R. C. HUGHES
Sandia Laboratories, Albuquerque, NM, U.S.A. 87115
Received November 22, 1976

High mobility, quasi-free electrons have been found to exist in very pure amorphous SiO_2 (1). Unlike hydrocarbon and inert gas liquids, and glasses, there is considerable ionic character in the bonding of SiO_2 glass. Consequently polar optical mode scattering of the electron controls the mobility, rather than acoustic mode scattering or interaction with other internal modes of the molecules. The mobility is found to be 21 ± 2 cm^2 V^{-1} s^{-1} at 300 K, which is in good agreement with the calculated value (no adjustable parameters) from theories of scattering from the known longitudinal optical (LO) modes in SiO_2. Above 300 K the mobility decreases with increasing temperature as predicted by theory. However, at lower temperatures the mobility becomes almost constant at about 40 cm^2 V^{-1} s^{-1}, which may be a consequence of the disorder in the glass; the mobility is not thermally activated at any temperature studied. At applied fields above 5×10^5 V/cm, the electrons become heated and the drift velocity *vs.* field curve indicates that the primary energy loss mechanism at high electron velocities (highest observed was 1.1×10^7 cm/s) is emission of optical phonons (2). In thin SiO_2 films, stable drift velocities for applied fields of 5×10^6 V/cm have been observed (*i.e.*, electron energy losses to the lattice are 0.05 eV/A) which explains the abnormally high attenuation of electrons passing through thin oxide films. The yield of electron–hole pairs in amorphous SiO_2 for excitation by high energy X-rays as a function of the applied field has also been measured. The short electron lifetime (longest observed was 15 ns) has prevented acquisition of accurate low field yield data which is normally used in testing for phenomena like geminate recombination. However, at the high fields which can be tolerated by SiO_2, the fairly strong field dependence of the yield can be fit approximately by the Onsager geminate recombination theory extended to high fields.

It is now known that the positive counterpart to the excess electron produced by ionization moves as a hole rather than an ion. The best picture that we can construct of the hole and its transport is that it is localized in the oxygen nonbonding $2p$ orbital (*i.e.*, a missing electron in that orbital) and that it hops as a small polaron to one of the six nearest neighbor oxygen $2p$ orbitals (2.6 Å away). It is known from bonding considerations that the nonbonding orbitals have a relatively small overlap with each other, and the band structure calculations which have been done for SiO_2 emphasize this fact by showing that the top of the valence band consists of a 'narrow' band formed mostly from the $2p$ nonbonding orbitals. The band structure calculation alone cannot tell us whether a small polaron forms or what is the origin of the temperature dependence of the mobility. The formation of a small polaron means that the localized hole distorts the equilibrium positions of nearby nuclei in such a way to lower its energy (the polaron binding energy). The main evidence that the hole is a small polaron comes from: (*1*) The fact that the mobility is less than about 1 cm^2 V^{-1} s^{-1} and (*2*) the mobility above 200 K is thermally activated by 0.16 eV, which is a reasonable magnitude for a polaron binding energy. A very strong piece of evidence is the non-Arrhenius temperature behavior, in which a break to lower activation energy is seen at about 200 K; the temperature dependence of the mobility is given by the solid line in Fig. 1. Emin (3) predicted recently that the small polaron should exhibit such behavior at about 1/3 the Debye temperature, which is close to 200 K for SiO_2. (*3*) The field dependence of the mobility was also predicted by Emin (3) for the small polaron at very high fields and for the parameters appropriate to SiO_2, no field dependence is expected up to 6×10^6 V/cm, and this is observed experimentally.

[1]Work supported by U.S. Energy Research and Development Administration.

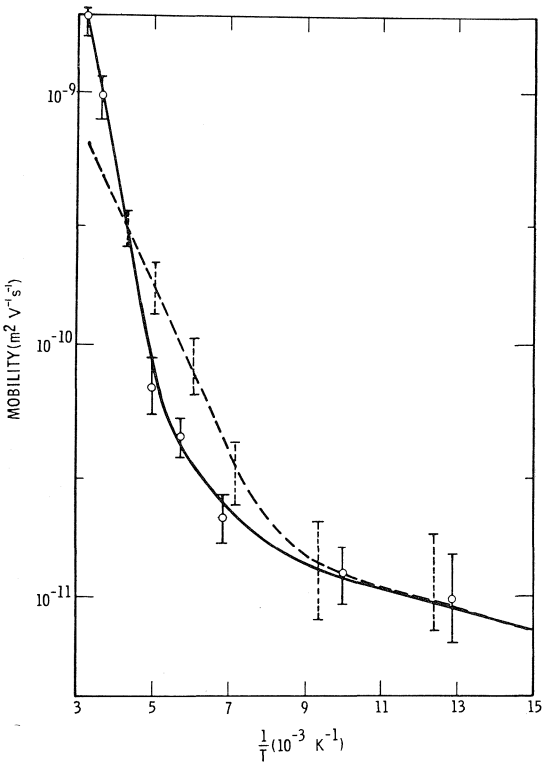

FIG. 1. The temperature dependence of the measured intrinsic hole mobility compared with a mobility calculated from the measured hopping rate of holes between nearest neighbor oxygens in the 'A' color center in quartz.

Another line of evidence concerning the hole transport in SiO_2 comes from detailed knowledge about the 'A' color center in single crystal SiO_2 (quartz). This optically active center is now known to be a hole trapped at an Al^{3+} substitutional (of which there are always a few ppm in quartz). The AlO_4 tetrahedron has the same electronic structure as the ordinary SiO_4 tetrahedron, with the only major difference being that it is negatively charged. Electron paramagnetic resonance studies (4) of the unpaired spin shows that it is localized in the oxygen $2p$ nonbonding orbital and that even at below 200 K the hole is hopping from one oxygen to the next in its own tetrahedron. The Coulomb attraction of the site prevents the hole from hopping to any of the other three nearest neighbor oxygens which are bonded to an Si^{4+}. The rate of hole hopping has been measured directly by dielectric relaxation techniques (4) and the dashed line in Fig. 1 gives the hopping rate with no adjustable parameters converted to a mobility (if v is the hopping rate and a is the hop distance the mobility of a simple random walker is $\mu = va^2/6kT\ m^2\ V^{-1}\ s^{-1}$). The agreement is very good, including the break in activation energy, which leads one to conclude that the hopping mechanism is the same for intrinsic hole transport in pure SiO_2 and the hole hopping within the color center.

In all samples of amorphous SiO_2 which have been studied, the defect concentration is very high, and the holes are trapped at defects after about 100 ns of hopping by the mechanism described above. However, the holes are not completely immobilized by the defects at room temperature and the drift of the holes from defect to defect in high applied fields has been measured (5). Because of the wide range of trapping and detrapping times, the transport of the holes becomes very dispersive, *i.e.*, some holes traverse the sample in times that are orders of magnitude shorter than others. The dispersive transport has been found to agree with the model of Scher and Montoll (6) so that the photocurrent *vs.* time data at any field, sample thickness, and temperature can be predicted from the two experimentally determined parameters of the model.

Discussion

J. Noolandi: How do your experiments on the hole transport agree with the predictions of the stochastic hopping model of Scher and Montroll?

R. C. Hughes: We get good agreement with the Scher–Montroll theory for times long compared with the trapping time of the holes, which is about 100 ns at 300 K. The details will appear soon in Physical Review B.

P. K. Watson: Has the author observed electron trapping in his samples, and if so, what is the order of density of the traps, and can the electron be readily detrapped?

R. C. Hughes: The concentration of electron traps in pure amorphous SiO_2 varies with the method of preparation, but for good samples is about 10^{12}–10^{13} cm^{-3}. The electrons can be photodetrapped with visible light at longer wavelengths than those required for photoemission from the metal electrodes.

W. F. Schmidt: In your drift velocity measurements at higher fields, do the electrons have superthermal energies?

R. C. Hughes: At fields above 5×10^5 V/cm, the electrons are heated by the field so that optical phonons of energy 0.15 eV are emitted. Thus the average kinetic energy of the electrons approaches 0.15 eV as the field approaches 10^7 V/cm.

L. G. Christophorou: The SO_2 molecule has an electron affinity of ~1.1 eV and captures low-energy electrons to form SO_2^-. In SO_2^- the electron is binding with respect to the two oxygen atoms. Is it possible that this happens in your (amorphous) SiO_2?

R. C. Hughes: SiO_2 does not form a molecular solid like CO_2, but is polymerized in three dimensions with each O bonded to two Si. I know of no evidence for negative ion states of the polymer, and the mean free path of quasi-free electrons can be understood quantitatively by scattering from LO phonons; no additional scattering is needed to understand the mobility. However, the nature of electron traps in pure SiO_2 is not known, and may involve lattice bonding defects, like trivalent silicon, which have strong electron affinities.

Negative ion – molecule reactions in liquid argon following electron capture by N_2O

Received September 28, 1976

GEORGE BAKALE, ULRICH SOWADA, and WERNER F. SCHMIDT. Can. J. Chem. **55**, 2220 (1977).

Electrons produced in liquid argon by a short burst of X rays react readily with dissolved N_2O with a bimolecular rate constant of 5.8×10^{-10} cm^3/s or 3.5×10^{11} M^{-1} s^{-1}. The addition of H_2 or CO to the Ar/N_2O solution results in a fast and slower component in the decay of the electron current. We assume that O^- ions are formed in the reaction of electrons with N_2O and then react with H_2 to give

[11] $$O^- + H_2 \rightarrow H_2O + e^-$$

or with CO to give

[12] $$O^- + CO \rightarrow CO_2 + e^-$$

The addition of CH_4 does not regenerate electrons since the reaction

[13] $$O^- + CH_4 \rightarrow CH_3 + OH^-$$

is thought to occur. Reaction 12 is in agreement with the fact that CO_2 does not react with electrons in liquid argon.

GEORGE BAKALE, ULRICH SOWADA et WERNER F. SCHMIDT. Can. J. Chem. **55**, 2220 (1977).

Les électrons produits dans l'argon liquide par une courte émission de rayons-X réagissent facilement avec du N_2O dissout avec une constante de vitesse bimoléculaire de 5.8×10^{-10} cm^3/s ou 3.5×10^{11} M^{-1} s^{-1}. L'addition de H_2 ou de CO à la solution de Ar/N_2O conduit à des composantes rapides et plus lentes pour la décroissance du courant électrique. On fait l'hypothèse qu'il y a formation d'ions O^- lors de la réaction des électrons avec N_2O et qu'ils réagissent avec H_2 suivant l'équation

[11] $$O^- + H_2 \rightarrow H_2O + e^-$$

ou avec CO suivant l'équation

[12] $$O^- + CO \rightarrow CO_2 + e^-$$

L'addition de CH_4 ne regénère pas d'électrons puisque l'on croit que la réaction [13] se produit

[13] $$O^- + CH_4 \rightarrow CH_3 + OH^-$$

La réaction [12] est en accord avec le fait que le CO_2 ne réagit pas avec les électrons de l'argon liquide.

[Traduit par le journal]

Introduction

The growth of interest in excess electrons in nonpolar liquids during the last 8 years is best exemplified by the number of papers on this subject presented at this conference. Within this field of electrons in liquids, techniques have developed from simply measuring the mobilities of electrons (2–4) to measuring field effects on the electron drift velocity (5–7), electron recombination and attachment rates (8–13), and the energy dependence of electron attachment processes (1, 14). In this paper we add to this list of techniques of studying electron-related phenomena in liquids by reporting the first measurements of the rates of associative detachment reactions in nonpolar liquids.

An associative detachment reaction is a special form of an ion–molecule reaction which is characterized by the liberation of an electron from an anion A^- following collisional com-

bination with a molecule M; *i.e.*

[1] $$A^- + M \rightarrow AM + e^-$$

Such reactions are important to the chemistry of the upper atmosphere and have been intensively studied in the gas phase (15). Since most of these studies have been carried out with drift tube, ion cyclotron resonance, or flowing afterglow techniques at pressure below 1 torr, extrapolation of their results to liquid densities is highly questionable and the occurrence of associative detachment in liquid systems remained to be established. However, Warman *et al.* (16) used a microwave conductivity technique to study associative detachment reactions of O^- which was radiolytically generated by dissociative electron attachment to N_2O at pressures up to 260 torr. We employed a similar technique in this study to generate O^- in liquid argon and report upon associative detachment reactions in this liquid of O^- with H_2 and CO and the apparent abstraction of H by O^- from CH_4.

Experimental

The pulsed conductivity technique, in which a pulse of ~12 MeV bremsstrahlung from a linear accelerator irradiates the sample under study in a parallel-plate ion chamber and produces free electrons and positive ions in the solution, has been described previously (5). Oscillographically monitoring the dc current induced by the electrons drifting between the electrodes under the influence of an applied field provides a measure of the electron concentration and the decay of this current permits the evaluation of the electron velocity, attachment rate, and/or recombination rate (1).

Purification of Ar, N_2O, H_2, CO, and CH_4 has been described elsewhere (14, 17). Solutions were prepared by first admitting N_2O to a measured pressure P_1 into a cell of known volume and then adding the second solute (H_2, CO, or CH_4) at a pressure $P_2 \gg P_1$ to prevent escape of N_2O from the cell. The total solute pressure was then measured, the cell was cooled to 77 K, and argon was admitted to and condensed in the cell with the external argon pressure maintained at 800–1100 torr. The condensation at 77 K was continued until the cell was about half filled with the solution and the cell was then warmed to 87 K (liquid argon bath) until filled to a calibrated volume. All rate constant measurements were made at 87 K and with a sufficiently low external electric field to minimize heating of the electrons by the field.

Thermal energy electron attachment to N_2O in liquid argon had been found to occur with an overall rate constant of 5.8×10^{-10} cm^3 s^{-1} at 87 K (1). A typical oscillogram from which this rate constant was derived is shown in Fig. 1*A* for an N_2O concentration of 14 μM. Addition of H_2 to a similar N_2O/Ar solution results in the two-component decay illustrated in Fig. 1*B* in which H_2/N_2O is ~11. Similar two-component electron decays were observed when excess CO was substituted for H_2.

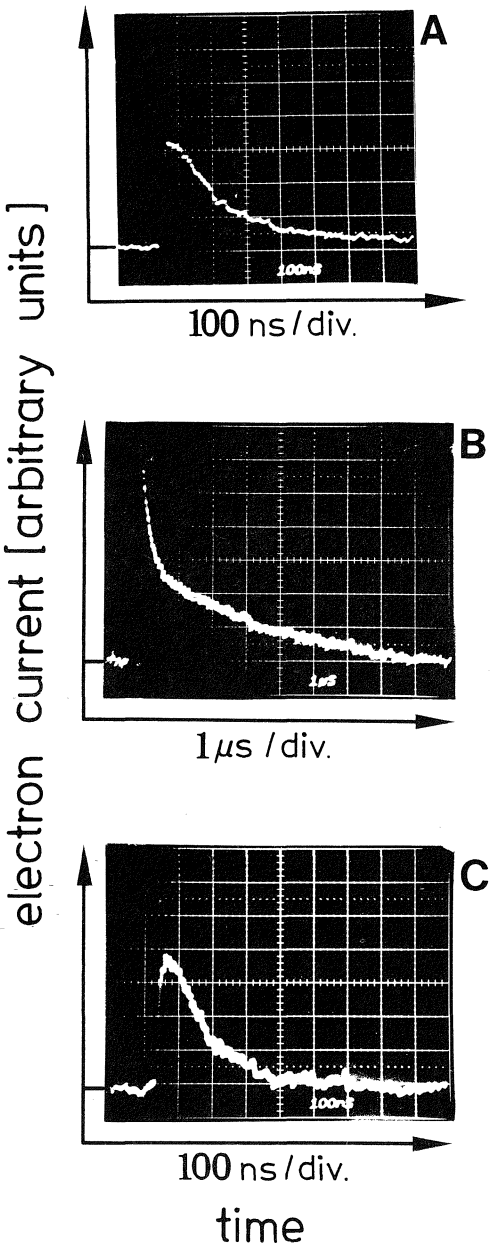

FIG. 1. (*A*) Decay of electron current due to electron attachment to N_2O in liquid argon at 87 K with $[N_2O]$ = 14 μM. (*B*) Decay of electron current due to electron attachment to N_2O (fast component, $t_{1/2} < 0.5$ μs) and electron detachment due to associative detachment of O^- with H_2 (slow component, $t_{1/2} > 2$ μs) in liquid argon at 87 K, $[N_2O]$ = 13.4 μM, $[H_2]$ = 0.15 mM. (*C*) Decay of electron current due to electron attachment to N_2O in liquid argon/methane solution at 87 K, $[N_2O]$ = 13.5 μM, $[CH_4]$ = 9.6 mol%.

With the addition of CH_4 to the N_2O/Ar solution, oscillograms typified by Fig. 1*C* were observed.

Before discussing analysis of the two-component electron decay curves to obtain detachment rate constants, we must first discuss the attachment/detachment mechanism in the next section.

Results and Discussion

Electron attachment to N_2O in the gas phase has recently been reviewed by Caledonia (18) who concludes that dissociative attachment by N_2O, *i.e.*

[2] $$e^- + N_2O \rightarrow N_2 + O^-$$

is followed by a sequence of reactions in which O^- acts as a chain carrier to produce NO^- by

[3] $$O^- + N_2O \rightarrow NO^- + NO$$

which regenerates the electron by the associative detachment reaction

[4] $$NO^- + N_2O \rightarrow NO + N_2O + e^-$$

In addition to these reactions, the chain terminating reactions

[5] $$NO^- + N_2O \rightarrow NO_2^- + N_2$$

[6] $$NO^- + 2N_2O \rightarrow N_3O_2^- + N_2O$$

[7] $$O^- + 2N_2O \rightarrow N_2O_2^- + N_2O$$

were proposed as being consistent with the mass-analyzed results (18).

In the present study as in the high pressure microwave conductivity studies of Warman *et al.* (16), the electron decay in reaction 2 and regeneration in [4] are the only reactions involving a monitorable species; consequently, having no mass analysis capability precludes our detailing the intermediates and products specified in [2]–[7]. Therefore, we are limited to a mechanism which involves only electrons, viz.

[8] $$e^- + N_2O \rightarrow P + X^-$$

[9] $$X^- + N_2O \dashrightarrow P' + e^-$$

[10] $$X^- + N_2O \rightarrow \text{no } e^-$$

where P and P′ are unspecified products and X^- an unidentified anion which may regenerate the electron through more than the one-step process indicated by [9] (*e.g.*, [3], [4]).

With the limitation of no mass analysis we utilized gas phase negative ion chemistry and propose a mechanism for electron attachment to N_2O in liquid argon in which attachment reaction 8 is identified with [2], detachment reaction 9 with [3] and [4], and chain termination [10] with reactions 5–7. Evidence for O^- being X^- in the above reaction sequence is based upon the effects of H_2, CO, and CH_4 on electron regeneration in liquid argon/N_2O solution and the known gas phase reactions

[11] $$O^- + H_2 \rightarrow H_2O + e^-$$

[12] $$O^- + CO \rightarrow CO_2 + e^-$$

[13] $$O^- + CH_4 \rightarrow CH_3 + OH^-$$

The rate constants of these reactions in the gas phase are listed in Table 1 and compared with the liquid phase rate constants which we determined as follows.

To obtain rate constants k_{11} and k_{12} from two-component electron decay oscillograms such as Fig. 1*B*, we assume at low electric field E that the electron current is proportional to the product of electron concentration n_e and electron mobility μ_e (8). We used low dose irradiations and maintained low fields to ensure that recombination and field effects on μ_e were negligible; consequently, any change in the electron current was due to a change in the electron concentration, n_e. Electrons attach to N_2O dissociatively (reactions 2 or 8) forming O^- which then reacts with excess H_2 or CO to regenerate electrons by [11] or [12], respectively. The net effect of this attachment is a reduction of the electron concentration as compared to the case of the pure argon. The electron concentration in the solution $(n_e)_S$ is given by

[14] $$(n_e)_S = (n_e)_{Ar}\, T_f/(T_f + T_a)$$

where $(n_e)_{Ar}$ is the electron concentration in pure argon and T_f and T_a are the electron residence times in the free and attached states respectively, and may be obtained from

[15] $$T_f = 1/k_2\,[N_2O]$$

[16] $$T_a = 1/k_{11,12}\,[S]$$

where $[N_2O]$ and [S] are the N_2O and H_2 or CO concentrations, respectively. Obviously, $(n_e)_{Ar} = (n_e)_S + [A^-]$. Combining [14]–[16] yields

[17] $$(n_e)_S = (n_e)_{Ar}\left(1 + \frac{k_2[N_2O]}{k_{11,12}[S]}\right)^{-1}$$

Since the observed current signal i is proportional to the temporary electron concentration, [17] may be rewritten as

TABLE 1. Liquid, gas, and limiting values of O^- attachment rate constants

Reaction	$k \times 10^{10}$ (cm^3/s) (ref.)			
	Liquid[a]		Gas	
	Obs.	Lim.[b]	Obs.	Lim.[c]
$O^- + H_2 \rightarrow H_2O + e^-$	0.17	0.096	7.5 (19) 8.0 (20) 7.0 (21)	16 (19)
$O^- + CO \rightarrow CO_2 + e$	0.21	0.10	7.5 (19) 7.3 (22)	10 (19)

[a]This work.
[b]Calculated using eq. 20, see text.
[c]Calculated using eq. 19, see text and ref. 25.

$$[18] \qquad \frac{i_{Ar}}{i_{eq}} = \left(1 + \frac{k_2[N_2O]}{k_{11,12}[S]}\right)$$

where i_{Ar} is the initial amplitude of the electron current in liquid argon at the end of the 5 ns X-ray pulse and i_{eq} is the amplitude at times where the attachment and detachment reactions are in equilibrium. Values of k_2 had been measured independently [1] and thus, from [18] k_{11} and k_{12} were obtained at known N_2O and H_2 or CO concentrations by extrapolating i_{eq} to $t = 0$, when the ionizing pulse was applied. (The decay of the slow component in Fig. 1*B* is due to electron neutralization at the electrodes.)

The limiting rate constants of the O^- reactions which we have listed in Table 1 are for a thermal ion colliding with a nonpolar molecule due to long range polarization interaction between the ion and molecule and were calculated (19, 23) using

$$[19] \qquad k = 2\pi e(\alpha/\mu)^{1/2}$$

where e is the electron charge, α the polarizability of the neutral molecule, and μ the reduced mass of the reactant (25). Whereas the measured gas phase values for O^- reacting via associative detachment with H_2 and CO are within a factor of two of the limiting values, the liquid phase values are ~50–100-fold less. This marked difference may result from an increase in the stability of the anion intermediate (H_2O^- or CO_2^-) in the liquid phase due to solvation effects opening a second reaction channel. This explanation seems implausible, however, due to the exceedingly low electron attachment rate of CO_2 in liquid argon of $<10^{-13}$ cm^3/s which we measured in Ar/CO_2 solutions.

An alternative explanation is the increased reduced mass in the liquid of the reactants due to solvation of O^-. This, too, seems unlikely since solvation of O^- by six argon atoms would decrease the limiting rate by only 6% for H_2 and 57% for CO.

Rather than these explanations, we attribute the observed difference in O^- reactivity to the lower diffusivity of O^- in the liquid phase. If we assume that the reactions in both phases are diffusion controlled as [19] implies for the gas phase, the limiting rate constant in the liquid phase may be calculated by application of the Smoluchowski equation (26). For a reactant of unit charge diffusing to a nonpolar molecule, the appropriate form of the Smoluchowski equation is

$$[20] \qquad k = 4\pi(R_A + R_S)(D_A + D_S)$$

where R is the effective encounter radius and D the diffusion coefficient of the reactant anion and solute denoted by the subscripts A and S, respectively. For the radius of O^- we use the radius of atomic oxygen of 0.6 Å (27) and use molecular radii determined from gas phase viscosity data of $R_{H_2} = 1.09$ Å and $R_{CO} = 1.9$ Å (28). Since diffusion coefficients of O^-, H_2, and CO in liquid argon are not available, we resort to the Loveland *et al.* (29) value of the anion mobility in liquid oxygen of 1.35×10^{-3} $cm^2/V\,s$ at 87 K, which is assumed to be O_2^-, and use

the Nernst–Einstein equation to convert this mobility to $D_{O_2^-} = 1.0 \times 10^{-5}$ cm^2/V s. We also assume that the ion (molecule) diffusion coefficient is inversely proportional to the radius of the diffusing species and using the above values of $D_{O_2^-}$ and $R_{O_2} = 1.49$ Å (28) approximate the diffusion coefficients to be $D_{O^-} = 2.5 \times 10^{-5}$, $D_{H_2} = 1.4 \times 10^{-5}$, and $D_{CO} = 0.78 \times 10^{-5}$ cm^2/s.

By substituting the above values of $R_{A,S}$ and $D_{A,S}$ in [20], we estimated the limiting liquid phase associative detachment rate constants listed in Table 1. Although we consider these limiting rate constants to be very approximate, the agreement within a factor of two between the measured and calculated values suggests that associative detachment reactions can occur in liquids at diffusion-controlled rates.

Discussion

J. L. Magee: In the liquid your limiting rates were less than the observed rates. Why did you not reconsider the radii used in the calculations?

G. Bakale: The purpose of the calculated rate constants for the associative detachment reaction in liquid phase and comparison with our data was to illustrate that this process is nearly diffusion controlled. We recognize that the estimate of the limiting rate constant could have been improved by considering the induced dipole interaction but did not feel that this was warranted in view of the rough estimates of the diffusion coefficients that we had to make.

M. Nishikawa: Is your reaction mechanism independent of electron temperature? In other words, is there any evidence that you still get O^- in the presence of CH_4 with its cooling effect?

G. Bakale: Under the conditions of the experiments we observed no effect of electron temperature on the O^- reaction rate. At the lowest field strengths with either H_2 or CO present, we observed the two-component decay indicating that O^- was produced by thermal electron dissociative attachment to N_2O. We assume O^- was also produced in the presence of CH_4, but yielded single-component decay curves due to reaction 13.

Density-, temperature-, and concentration-induced metal–nonmetal transitions in fluids

F. HENSEL

Institute of Physical Chemistry, Philipps-University Marburg, D-3550 Marburg, Auf den Lahnbergen, Germany

Received November 1, 1976

F. HENSEL. Can. J. Chem. **55**, 2225 (1977).

A brief review is given of the continuous metal–nonmetal transition observed in different fluid systems, with special emphasis on recent work by the author and his colleagues. Selected results of a broad experimental survey of the electrical and magnetic properties of fluid binary semiconducting alloys, expanded fluid metals, and fluid selenium are reported. The results are discussed with special emphasis on their relationship to some theoretical areas of controversy, especially the importance of the amount of covalency and ionicity for the electrical and magnetic properties of semiconducting alloys, the role of chemical bond satisfaction in covalent selenium and tellurium for the temperature-induced nonmetal to metal transition, and some speculations concerning the importance of fluctuations and microscopic inhomogeneity for the metal–nonmetal transition in expanded fluid metals. It is concluded that no theory of the metal–nonmetal transition is available which is generally valid for all the fluid systems discussed. It is proposed that measurements of the structure factor and of thermodynamic data of the fluids are necessary to make it possible to formulate a theory which is tested experimentally. The first new results of the structure factor and the compressibility of fluid expanded rubidium are reported.

F. HENSEL. Can. J. Chem. **55**, 2225 (1977).

On présente une brève revue de la transition métal–nonmétal continue observée dans différents systèmes fluides en insistant d'une façon particulière sur les travaux récents de l'auteur et de ses collègues. On rapporte des résultats choisis sur un large éventail expérimental de propriétés électrique et magnétique d'alliages semiconducteurs binaires fluids, de métaux fluides gonflés et de sélénium fluide. On discute des résultats en tenant compte particulièrement de leur relation avec quelques sections théoriques controversées en particulier l'importance du degré de covalence et du caractère ionique sur les propriétés électrique et magnétique des alliages semiconducteurs, le rôle de la satisfaction du lien chimique dans le sélénium et le tellure covalent pour des transitions métal–nonmétal induites par la température et quelques spéculations concernant l'importance des fluctuations et de l'inhomogénéité microscopique pour la transition métal–nonmétal dans des métaux fluides déployés. On conclut qu'il n'y a aucune théorie disponible de la transition métal–nonmétal qui serait valide d'une façon générale pour tous les systèmes fluides discutés. On propose que des mesures de facteurs de structure et de données thermodynamiques des fluides sont nécessaires pour rendre possible la formulation d'une théorie qui pourrait être vérifiée expérimentalement. On rapporte les premiers nouveaux résultats de facteur de structure et de compressibilité d'un rubidium fluide gonflé.

Introduction

Metal–nonmetal transitions (MNT) have been studied in a number of different fluid one-component and two-component systems including expanded liquid and gaseous metals (1–3), fluid selenium at high temperatures (4, 5), liquid Se–Te mixtures (6), solutions of alkali metals in fluid ammonia (7, 8), solutions of electropositive metals in their molten halides (9, 10), and semiconducting liquid alloys (11–15). All these fluids can transform from a metallic to a semiconducting or insulating state under changes of an appropriate thermodynamic parameter, *e.g.* temperature, pressure, density, and composition. The transition from a metallic to a nonmetallic fluid implies that the type of chemical binding or at least of the interatomic interaction changes from metallic to nonmetallic binding. Consequently, a successful model or theory of the MNT must explain not only the nature of the apparently continuous changes of electron transport properties during the course of the transition, but must also account for the changes of chemical bonds, the associated changes in the fluid structure, and changes of the more mechanical and thermodynamic properties, especially the thermal compressibility. Since there is an interdependence of electron–electron screening and the far reaching intermolecular forces, which control

the thermodynamic properties, it is interesting also to prove experimentally whether the thermodynamic critical points will coincide with the MNT.

The aim of the present paper is to review recent experimental results with an emphasis on work from the Institute of Physical Chemistry of the University of Marburg. Selected data will be discussed for all the fluid systems mentioned above except metal–ammonia and metal–molten salt solutions. Recent reviews on these systems are by Thompson (16), Schindewolf (7), and Nachtrieb (17).

Metal–Nonmetal Transition in Semiconducting Alloys

The group of fluid semiconducting alloys provides the most direct evidence that the formation of chemical bonds plays an important role for the MNT. Liquid Mg–Bi (11), Li–Bi (18), Cs–Au (13), Rb–Au (19), and Cs–Sb (20) represent some of the alloys which belong to this group. Although the pure metals Li, Mg, Cs, Rb, Au, and Sb are highly conducting liquid metals, in the neighbourhood of compositions satisfying simple chemical valence requirements the liquid mixtures have conductivities which are definitely outside the range typical for liquid metals. It seems to be clear from this observation that a large change in the bonding characteristics associated with changes in the liquid structure takes place as one proceeds from the pure metal to the stoichiometric concentration. Whereas the structural effect has been discussed in a large number of reviews (12, 21) and articles (22, 23) written mainly by Enderby, relatively little attention has been paid to how the properties of semiconducting alloys depend on the nature of the bonds, *i.e.* on the relative ionicity and covalency of the bonds. But the detailed electronic structure and the electrical transport properties of the molten alloys certainly depend on the character of the chemical bonds. In systems with predominantly ionic bonds ionic species must occur and they must be mobile in liquids, so that their effect may be considerably larger in the electrical transport properties, comparable to metal – molten salt solutions. In the following, recent experimental results for the Cs–Au and Cs–Sb system will be presented with particular emphasis on their relevance to the question raised above.

A rough measure of the relative ionic or covalent character of the bonds in CsAu and Cs_3Sb can be obtained from published tables of electronegativities. The electronegativity difference according to the Pauling scale leads to the suggestion that a high amount of covalent bonding exists in liquid Cs_3Sb, whereas liquid CsAu exhibits predominantly ionic bonding. In order to contrast the behaviour of these two systems the electrical conductivity σ and the molar magnetic susceptibility $\mathscr{H}_m$ of both Cs–Au and Cs–Sb are plotted as a function of the concentration in Fig. 1*a* and Fig. 1*b*. The concentration scale varies between the compound composition on the left and pure Cs on the right. It is obvious that there is a striking difference in the concentration dependence of σ and $\mathscr{H}_m$ for these two systems. σ of Cs_3Sb–Cs rises abruptly within a narrow concentration range of less than 5 at.% excess Cs, whereas σ of CsAu–Cs remains approximately constant up to about 15 at.% excess Cs. For the concentration dependence of $\mathscr{H}_m$, the slope of the curve gets steeper for the Cs–Au system when the compound composition is approached, whereas it is decreasing in the Cs–Sb system. It was recently shown by Freyland and Steinleitner (14, 20) that for liquid Cs_3Sb a logarithmic plot of the electrical conductivity *vs.* the reciprocal temperature gives a straight line over a temperature range of about 200°C. From the slope an activation energy $\Delta E = 0.44$ eV is determined. They concluded from the magnitude of ΔE and from the observed small absolute thermoelectric power of $S \approx -20$ μV K^{-1} that electronic conduction prevails in liquid Cs_3Sb. In addition they found this

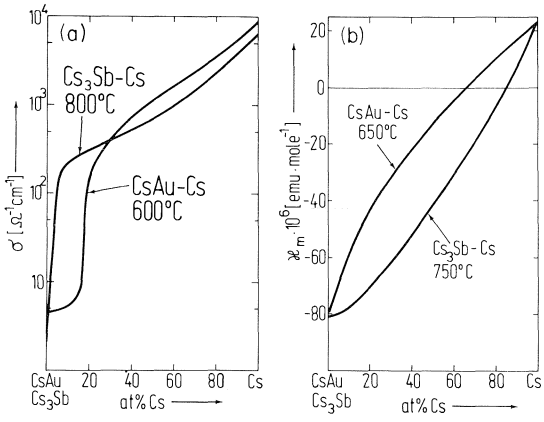

FIG. 1. Comparison of the electrical conductivity σ and the molar magnetic susceptibility $\mathscr{H}_m$ of Cs–Au and Cs–Sb alloys (data from refs. 14, 20, 13).

assumption in agreement with the observed positive temperature dependence of the magnetic gram susceptibility. Assuming that this positive temperature dependence is due to thermally excited electrons and holes and that the activation energy for the charge carrier contribution to the susceptibility $\mathscr{H}_g^c$ is the same as observed for the electrical conductivity, *i.e.* 0.44 eV, they were able to fit the experimental data. In contrast to the behaviour of liquid Cs_3Sb the temperature dependence of the liquid CsAu susceptibility is comparatively small and negative and the molar susceptibility of -81×10^{-6} cm^3 mol^{-1} is consistent with a description in which the liquid is assumed to consist of Cs^+ and Au^-. The latter is consistent with the observed temperature dependence of the conductivity σ of CsAu which is shown in Fig. 2. The 'apparent activation energy' of σ is about 4.5 kcal/mol (about 0.2 eV) for CsAu which is also of the order of the 'activation energies' of ion migration in salts. It must be pointed out, however, that the concept of 'apparent activation energies' of ion migration in liquid salts is based on theories developed for atomic transport in solids. And certainly it is necessary to prove by more accurate measurements over wider temperature intervals whether Arrhenius behaviour is the rule or the exception.

In addition the marked decrease of the conductivity of the alloys on melting (Fig. 3) indicates that the electrical behaviour in the liquid Cs–Au alloys is very different from that in solid Cs–Au alloys. One can contrast the behaviour of CsAu with that of other solid semiconductors, which mostly show a more or less large increase of σ on melting. Two main groups may be distinguished. In the first group of semiconductors, such as Ge, Si, InSb, etc., the coordination number increases on melting and the short range order and the nature of chemical binding drastically change. The conductivity becomes metallic, *i.e.* a semiconductor to metal transition is observed on melting. In the second group, to which semiconductors like Mg_3Bi_2, Se, In_2Se_3, etc. belong, the coordination number changes only slightly and the short range order of the crystal persists to a large extent on melting, *i.e.* a semiconductor to semiconductor transition is observed on melting. As the temperature is considerably increased, the short range order is possibly changed into a completely random atomic configuration which is typical of liquid metals at high temperatures, *i.e.* an abrupt

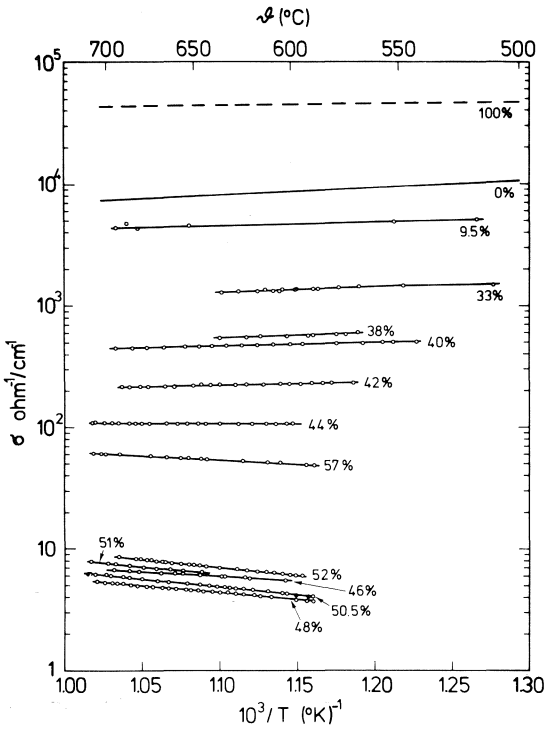

FIG. 2. Logarithm of the conductivity, σ, of liquid Cs–Au alloys as a function of the reciprocal temperature at different constant Au concentrations in at.% (from ref. 13).

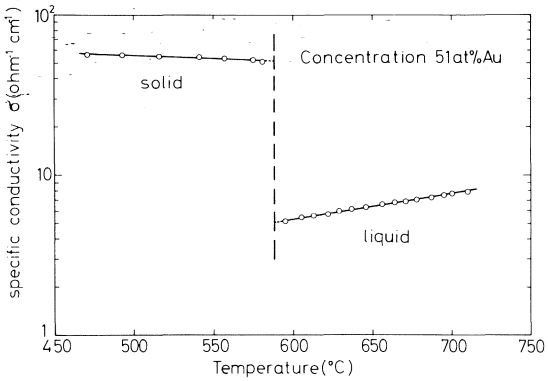

FIG. 3. Conductivity, σ, for a Cs–Au alloy with 51 at.% Au as a function of the temperature in the liquid and solid state (from ref. 13).

semiconductor to semiconductor and a gradual semiconductor to metal transition is observed. The latter was recently investigated for liquid Se (5). It is evident from the results in Fig. 3 that CsAu does not belong to one of the groups mentioned above. Therefore we make the assumption that a further type of solid–liquid

phase behaviour may be shown by semiconductors with a high degree of ionic binding. We believe that for these semiconductors the solid–liquid phase transition coincides with a transition from a solid semiconductor to a liquid mainly ionic conductor. CsAu was the first example of this type. In the meantime a similar behaviour has been observed for RbAu, whereas the system LiAu is metallic in its liquid state (19).

Further evidence for a mainly ionic structure of CsAu stems from the striking similarity in the concentration dependence of σ of the liquid Cs–CsAu system and solutions of electropositive metals in their molten salts as demonstrated by Fig. 4 for the K–KBr system. For comparison Fig. 4 includes also the concentration dependence of σ for the system Mg–Mg_3Bi_2 and Tl–Tl_2Te which in both cases is clearly different from that for the Cs–CsAu system. The poor correlation between the Mg–Mg_3Bi_2 and the Tl–Tl_2Te mixtures, which have both been classified as 'liquid-semiconductors', and the Cs–CsAu mixture and on the other hand the similarity between the K–KBr mixture and Cs–CsAu mixture are consistent with the conclusion that the conduction process in CsAu involves ionic transport.

This conclusion is supported qualitatively also by the relatively high value of the thermoelectric power S of liquid CsAu. As demonstrated by Fig. 5, S of liquid Cs–Au alloys is negative and larger than -1000 μV/K near the equiatomic composition. Probably, the presence of Cs^+ and Au^- ions precludes the n–p transition in S seen in systems with prevailing electronic conduction, *e.g.* Mg_3Bi_2 and Tl_2Te (15). Large values of S are typical for ionic conductors (24). However, it is very difficult to handle quantitatively the thermoelectric power near the equiatomic composition, since there exist different kinds of charge carriers, possibly electrons, cations, and anions, having similar mobilities and transference numbers. Therefore, again it is only possible to contrast the behaviour of the CsAu–Cs system with that of other systems, especially with that of metal – molten salts mixtures. Measurements of the thermoelectric power have been made for the systems $BiCl_3$–Bi, $BiBr_3$–Bi, and BiI_3–Bi (25–27). The results are qualitatively in accord with the observations on Cs–CsAu. When the metal excess is large and the current is mainly due to electrons the thermoelectric power

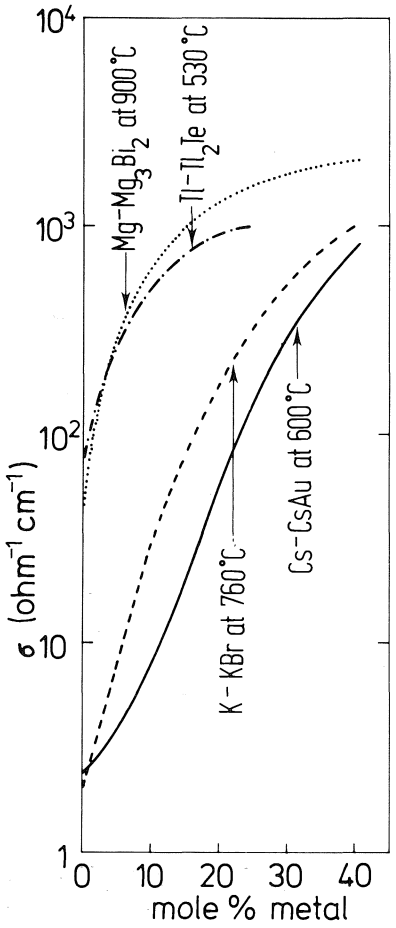

FIG. 4. Influence of excess metal on the conductivity of different compound forming alloys and salts (from ref. 13).

is relatively small, it increases rapidly with decreasing metal concentration, and reaches a maximum value near the pure salt concentration. Thus, the results are again consistent with the assumption that ions in liquid CsAu are movable and that conductivity and thermoelectric power are determined at small metal concentrations by ionic conduction superimposed by a contribution of electronic conduction. Finally there is evidence that enormous electromigration occurs in liquid CsAu. It was shown by Schmutzler and Krüger (28, 29) that Cs drifts to the cathode and Au drifts to the anode. One Cs^+ and one Au^- are transported per elementary charge to the electrodes within the experimental error. This is definitely the value required by Faraday's law for electrolysis in ionic conductors.

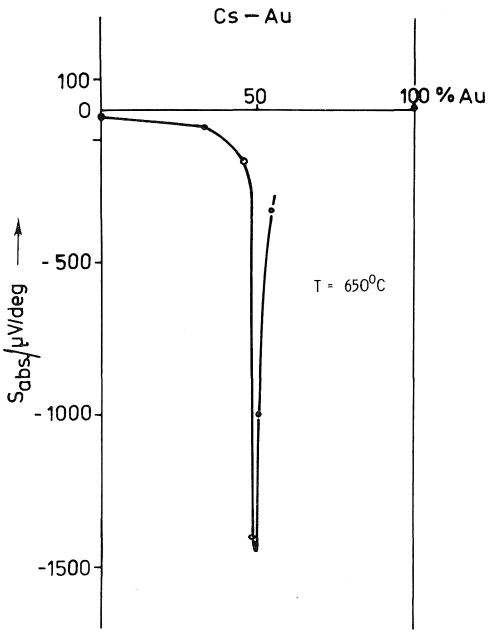

FIG. 5. The absolute thermoelectric power, S_{abs}, of liquid Cs–Au alloys at 650°C as a function of the concentration (from ref. 13).

The Metal–Nonmetal Transition in Elemental Liquid Semiconductors and Expanded Liquid Metals

The transition from metallic to semiconducting-like electronic properties in the alloys discussed above can be understood as a result of the formation of chemical bonds as one proceeds from the pure metal to the stoichiometric concentration. Other examples for the importance of chemical bonds are liquid Se and S which both are nonmetallic near the melting point where their liquid structures are dominated by the presence of molecular species as rings and relatively large chainlike units (30). However, the liquid structure including the local atomic coordination number can change markedly with temperature, pressure, or on alloying with more metallic elements. A gradual change toward a lower resistance liquid is observed due to the dissociation of the liquid chain structure induced by an increase in temperature or pressure (31). A very interesting element among the electronically conducting liquids is liquid selenium. It exhibits a relatively small strongly temperature-dependent electrical conductivity σ at its melting point. Since a logarithmic plot of σ *vs.* the reciprocal temperature shows a linear region in a not too extended temperature range, it is tempting to call selenium a 'liquid semiconductor' (32, 33). However various results suggest a tendency to a more metallic behaviour as the bonding arrangement is altered at very high temperatures (31) or pressures (34). Application of very high temperatures implies that the heating up of the liquid takes place at pressures greater than the liquid–vapour critical pressure p_c. A list of critical pressures p_c together with the corresponding critical temperatures T_c is assembled in Fig. 6 for those liquid chalcogenic and metallic elements which are of interest for the present discussion.

Experimental results are shown for Se (right side) and Hg (left side) in Fig. 7 in the form of conductivity isotherms plotted *vs.* pressure. It is only at temperatures close to the critical temperature that for both liquids the conductivity becomes strongly pressure dependent. This is certainly related to the strong pressure dependence of the density in this region. However, it is obvious from Fig. 7 that the conduction behaviour of selenium sharply differs from the behaviour of the metal mercury. The characteristic feature for Se is a very pronounced effect of the temperature on the conductivity at constant pressure. The conductivity isobars show a very large slope at subcritical conditions, giving a maximum conductivity near the critical temperature in the nearly metallic range 100–1000 ohm^{-1} cm^{-1}, many orders of magnitude larger than the conductivity near the melting point. Above the maximum the conductivity drops rapidly at the highest temperatures. The maximum in the 400 bar isobar lies at 1500°C,

Substance	T_c (K)	p_c (bar)
Hg	1760	1510
Cs	2020	110
Rb	2100	130
K	2200	155
Te	2500*	270*
Se	1760	380
S	1315	180

FIG. 6. Thermodynamic critical points.

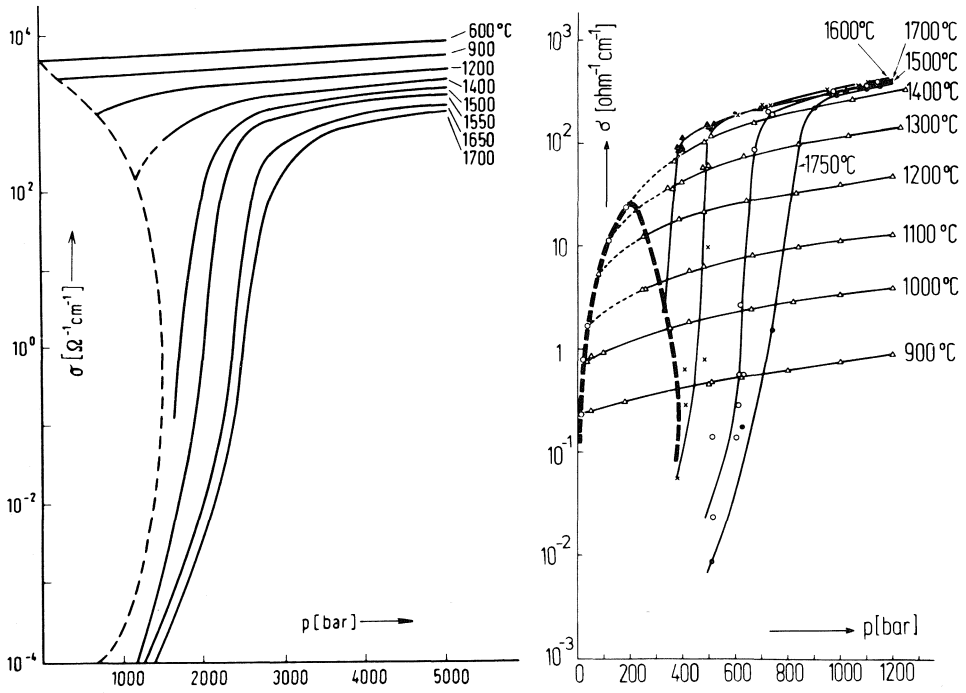

FIG. 7. The electrical conductivity of mercury and selenium at subcritical and supercritical temperatures as a function of pressure.

about 100°C lower than the critical temperature. This indicates that Se is semiconducting or insulating at the critical point (4). The conductivity of molten selenium throughout the entire liquid range at equilibrium pressure is given in Fig. 7 by the curve punctuated in heavy type. It reaches a maximum value of 25 ohm^{-1} cm^{-1} and decreases to a quite small value near the critical point. This small conductivity can be considered consistent with the result of an analysis of the vapour pressure curve of selenium in terms of 'correspondence state theory' which leads to the suggestion that selenium is essentially a molecular fluid in the vicinity of the critical point rather than a metallic one. The transformation to nearly-metallic conductivities can be induced either by increasing temperature in the liquid range (left hand side of the maximum) or by increasing pressure in the vapour (right hand side of the maximum). It is certainly a very complicated system. However, it seems reasonable to suppose that the temperature effect in the liquid results from the combined effects to thermal activation of carriers, increasing coordination number as Se chain- and ring-structure rupture, and decreasing density from thermal expansion. The former two effects should increase the conductivity while the density decrease should decrease the conductivity. The maxima in the isobars can then be understood. The decrease in density at high temperatures leads to a density-induced metal–insulator transition which is similar to those observed in supercritical fluid metals.

Liquid selenium near its melting point has been studied by many investigators both in regard to its electrical properties and its molecular and electronic structure (32). Its behaviour is consistent with the assumption that the chain-like structure, *i.e.* the covalent bonds between atoms in twofold coordination, of crystalline selenium persists to a large extent on melting. This assumption leads to a well-developed energy gap and semiconducting properties. However, if the temperature is increased, the chains rupture and the coordination number increases; the decrease of the chain length goes in the direction of a completely random atomic configuration which is typical for metals. The limitations of the 'semiconductor model' for liquid selenium become apparent at high temperatures. This is demonstrated by Fig. 8 where the logarithm of the conductivity is plotted *vs.* the reciprocal temperature. While it is possible to

identify an activation energy from the slopes below about 1300°C, these values depend on pressure at constant temperature. Moreover, at higher temperatures, the slopes increase and then decrease as the maxima are approached.

Further evidence for the limitations of the 'semiconductor model' for liquid selenium at very high temperatures stems from recent measurements of the absolute thermoelectric power (35). In the current picture of disordered semiconductors the band gap is replaced by a mobility gap (32, 36). Conduction at sufficiently high temperatures proceeds by thermal excitation of carriers across the mobility gap, *i.e.* σ and S are determined by electrons and holes thermally excited to the mobility edge probably for σ as low as about 1 ohm^{-1} cm^{-1}. When one band dominates, then σ and S are related by (32).

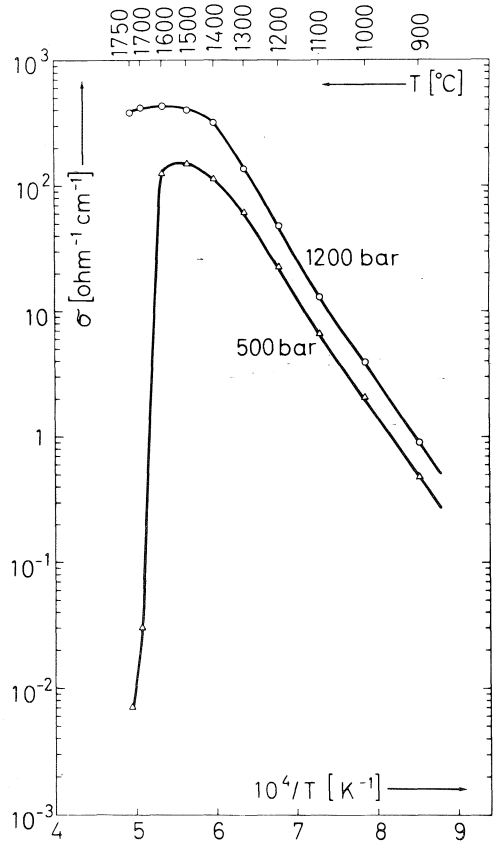

FIG. 8. Logarithmic plot of conductivity isobars of selenium *vs.* reciprocal temperature. Slopes in the range $10^4/T \geq 7.3$ K^{-1} yield 'activation energies' ΔE of roughly 1.8 eV. At higher temperatures, slopes increase to yield ΔE values of roughly 2.2 eV. In both ranges ΔE depends noticeably on pressure.

$$[1] \qquad \sigma = \sigma_0 \exp\left(-\frac{eS}{k} + 1\right)$$

An analysis of the thermoelectric power data shows that relation [1] is not obeyed for Se in the conductivity range between about 8 to 1000 ohm^{-1} cm^{-1}, *i.e.* at very high temperature, whereas it is consistent with the experimental results for smaller than 8 ohm^{-1} cm^{-1}. In respect to its electrical properties liquid tellurium is very different from liquid selenium. It provides an example of an electronically conducting liquid which exhibits some features of both metallic and semiconducting behaviour (37, 38). Its conductivity of about 1000 ohm^{-1} cm^{-1} at the melting point is relatively large and its Knight-shift value is in a range typically observed for liquid metals. On the other hand, the temperature coefficients of the conductivity and of the Knight shift are positive.

Neutron scattering data (39) indicate that the number of atoms in the first coordination shell is about two near the melting point and changes to about three at about 900°C. The twofold (binary) coordination is typical for the helical chainlike structure of selenium, while the threefold (ternary) coordination is similar to that of the arsenic crystal structure. Such a change of coordination was found to be consistent with the Knight-shift measurements (37) and velocity of sound measurements (40). Between the melting point and 900°C the existence of regions of twofold coordination which are semiconducting mixed with regions of threefold coordination which are metallic has been suggested by Cabane and Friedel (41). They assume that the number of free carriers increases with temperature due to the increase of ternary sites.

Since the first coordination number increases to a value larger than five at 1800°C (39), Cabane and Friedel (41) proposed that the local structure of liquid tellurium tends to a more metallic cubic structure like α-polonium with metallic character at high temperature (about 1700°C) or high pressure. This proposal is consistent with recent measurements of the electrical conductivity of liquid tellurium as a function of temperature at various pressures (42). Up to about 900°C the conductivity values along isobars increase and then decrease through broad maxima at about 1000°C. Above 1000°C the values of $(d\sigma/dT)_p$ are almost constant irrespective of pressure. The maxima shift slightly to

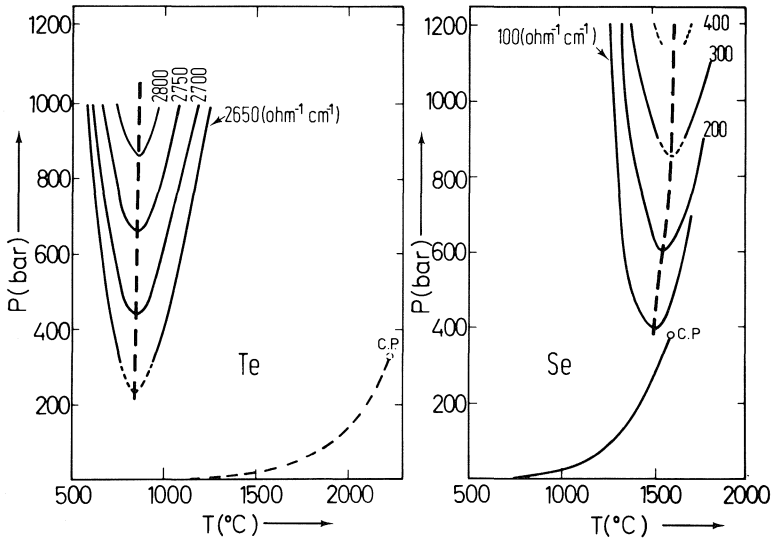

FIG. 9. Plots of pairs of temperature and pressure for constant conductivities for liquid selenium and tellurium. The numbers on the curves denote the value of the conductivity in ohm^{-1} cm^{-1}. The point C.P. is the critical point and terminates the vapour pressure curve.

higher temperatures with increasing pressure (42).

It seems reasonable to suppose that the effect of increasing temperature results from the combined effects of increasing coordination number and decreasing density from thermal expansion. The former effect should increase the conductivity while the latter should work in the opposite direction. A comparison of the temperature dependence of the electrical conductivity of liquid tellurium and liquid selenium both at moderate pressures shows that under the present experimental conditions the conductivity of liquid tellurium is always larger than that of liquid selenium. It is obvious that in both elements the conductivity varies through maxima and the change found in liquid tellurium is much smaller than that in selenium. This is certainly related to the larger stability of the bonds within the chain molecules in selenium. The difference in the pressure and temperature dependence of the conductivity between selenium and tellurium is shown in Fig. 9. It includes plots of pairs of temperature and pressure for constant conductivities. It is obvious from this figure that the maxima in the conductivities, *i.e.* the nearly-metallic conductivities, occur at much higher temperatures for selenium than for tellurium. For selenium the maximum conductivity is observed near the critical temperature of the liquid–vapour phase equilibrium, whereas for tellurium the maxima occur far beyond the critical temperature. The latter was determined by means of the corresponding states principle. In accordance with the rule (43) that any group of substances with effectively similar intermolecular forces should conform themselves to the principle of corresponding states, the correspondence between the vapour pressures of sulphur, selenium, and tellurium was used to determine the critical point of tellurium.

We turn next to the metal-nonmetal transition in low density metallic fluids. As can be seen from Fig. 7 the unavoidable critical temperatures and pressures of the metals are relatively high. Experiments for obtaining data under such extreme conditions are chiefly limited by the reduced strength and increased chemical reactivity of the sample containers at the high temperatures. It was only through the development of a special experimental technique favored by the rapid advances in the production of high-temperature construction materials during the past few years, that a number of experiments have been possible on Hg, Cs, Rb, and K which have critical temperatures lower than 2000°C. The fundamental thermodynamic and electronic properties, density, vapour pressure, critical data, viscosity, electrical conductivity, thermoelectric power, Hall effect, Knight shift, optical absorption, and structure factor, have been measured in some cases.

The metal that has been most intensively studied is mercury. Figure 7 (left side) shows the dc electrical conductivity measured by various groups of workers (44–47) as a function of the pressure for a number of subcritical and supercritical temperatures. The dotted line gives the densities or the conductivities of the coexisting liquid and vapour phases, respectively. Below the critical point, which was found at T_c = 1490°C and p_c = 1510 bar, a phase separation in a low density vapour with a relatively small conductivity and a highly conducting dense liquid is observed. The critical point must be the limit for observing the sharp transition between a highly conducting liquid and a lower conductance vapour, since at this point any distinction between liquid and vapour disappears. Above the critical temperature a steep but continuous increase of the conductivity with increasing pressure is observed. This behaviour of the electrical conductivity in the critical region is qualitatively typical for liquid metals and has been observed for mercury, cesium, and potassium. However, quantitatively a striking difference is observed in the critical behaviour of divalent mercury and monovalent cesium or potassium. Near the critical point the conductivity of mercury (σ_{Hg} is about 10^{-1} ohm^{-1} cm^{-1}) is three orders of magnitude smaller than the conductivity of cesium and potassium (σ_{Cs} is about 200 ohm^{-1} cm^{-1}). In addition the value of the absolute thermoelectric power of mercury, which is about -500 μV/K (47) at the critical point, is very large and certainly nonmetallic, whereas the value for cesium is -60 μV/K at the critical point (48). The latter is relatively small and not unreasonable for a metal. Thus, on the basis of this argument it is tempting to speculate that one observes two different types of critical points. For mercury close to the critical point a type of liquid–vapour phase transition similar to that in nonmetallic liquids is observed, *i.e.* liquid mercury exists in a high density metallic form and a low density nonmetallic form. For cesium (the same is true for potassium) it cannot be excluded that the liquid–vapour phase transition is associated with the metal–nonmetal transition. It must be pointed out, however, that it is not clear whether the existence of a relatively high conductivity at the critical point of cesium and potassium means that the state of these two elements can really be considered as metallic in the critical region, *i.e.* that the forces remain long range compared with an insulating liquid like argon.

For a divalent metal like mercury the Bloch–Wilson model of noninteracting electrons predicts a band-crossing transition. When the distance between the mercury atoms is continuously increased, the overlap between the s-valence band and the p-conduction band decreases, resulting in a metal–nonmetal transition. However, in a fluid the situation is more complicated; the atoms or ions are not rigidly held in position and fluctuations in density can be significant. Therefore in a fluid the singularities in the density-of-states function at the band edges are smeared out; the band edges exhibit tails in the energy region which is forbidden in the corresponding crystalline solid. Thus the gap separating the valence and the conduction band in the solid is replaced in fluid mercury by a minimum in the density of states near the Fermi energy. This is a suggested model, and it is very difficult to prove it experimentally. The difficulty arises because one of the most informative experiments used in crystal physics, optical absorption, disappoints us in fluid systems. In view of the uncertainties concerning the tails in the gap, it is necessary to ask whether it is possible to define an optical gap.

The spectral dependence of the absorption coefficient of mercury at the constant supercritical temperature of 1640°C and densities between 1 g/cm^3 and 4.8 g/cm^3 is shown in Fig. 10. The absorption edges exhibit the expected red shift with increasing density and are found to be exponential in form for values of K up to about 2×10^3 cm^{-1}.

At densities larger than 3 g/cm^3 the absorption curves flatten out to approximately constant values of the absorption coefficient at long wavelengths up to the infrared region. The level of these long wavelength tails increases very rapidly with increasing density and the density dependence is the same as observed for the dc conductivity. This equivalence of the density dependence for the dc conductivity and the optical frequency absorption coefficient is strong, if not conclusive, evidence that the mechanism of both have the same physical reason, *e.g.* free carrier conduction by thermally excited electrons in extended states.

At high enough values of the absorption coefficient ($K > 2 \times 10^3$ cm^{-1}) the linear dependence of log K on the photon energy is no longer observed and the absorption coefficient

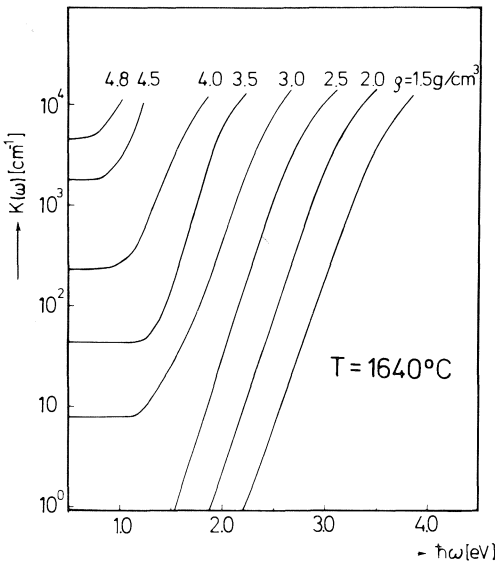

FIG. 10. Optical absorption edges in fluid mercury at different densities and the constant temperature of 1640°C (from ref. 1).

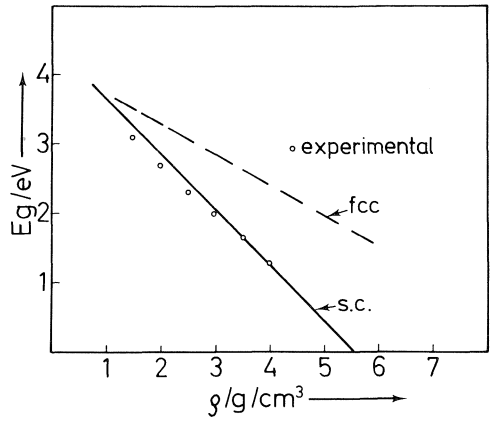

FIG. 11. Optical gap in mercury as a function of density at the constant temperature at 1640°C; the points are the experimental data. The curves give the calculated band edges for sc and fcc crystal structures (calculated values from ref. 50).

increases less steeply. In this region the absorption coefficient K can be described by the relation

$$[2] \qquad K\hbar\omega \propto (\hbar\omega - E_0)^2$$

This relation is of a form similar to that for indirect interband electronic transition in crystalline semiconductors and was derived by Tauc (49). He assumed that the density of states of the conduction and the valence bands not too close to the band edges is of a parabolic form and that the optical matrix element is constant in the energy range under consideration. Moreover the absorption in many semiconducting glasses at high enough absorption levels is observed to obey the relation [2], and the constant E_0 can be used to define an optical gap E_g. However, one fact should be emphasized. If the interpretation of the experimentally observed relation [2] given by Tauc is right then E_g is determined from an extrapolation of the densities of states deeper in the bands. Thus E_g may represent an extrapolated rather than a real zero in the density of states. The widths of the optical gaps E_g derived in this way for mercury at 1640°C as a function of the density are given in Fig. 11. The author feels that not too much physical significance should be given to E_g. Despite this fact, it is surely tempting to compare the density dependence of the optical gap defined in this way with the gap calculated for expanded mercury crystals (50–52). The main result of these calculations is that the energy gap is very sensitive to changes in structure. This is in accordance with the old empirical rule of chemistry that both density and coordination environment determine whether a fluid or amorphous material is metallic or not. In Fig. 11 the calculated band gaps as a function of density for fcc and sc structures are included. The absolute values, as well as the slopes of the curves, are different for each structure. The agreement between the measured gap and that calculated for the sc structure evident from Fig. 11 is extremely close and should be regarded as partly accidental. The plot in Fig. 11 demonstrates that the valence band (the 6s band) and the conduction band (the 6p band) cross at a density between 5 and 6 g/cm^3. At this density the dc conductivity is about 10^{-1} ohm^{-1} cm^{-1} and the thermoelectric power is about -500 μV/deg which are certainly nonmetallic values. This is quite consistent with the current picture of disordered semiconductors. As mentioned above in this picture the band gap of the crystalline solid is replaced by a mobility gap and all the states within the mobility gap are localized. Conduction at sufficiently high temperatures proceeds by thermal excitation of carriers across the mobility gap. The last mechanism leads for thermal excitation of electrons (32) to relation [1] between the thermoelectric power S and the electrical conductivity σ.

Schmutzler and Hensel (2) have shown that σ

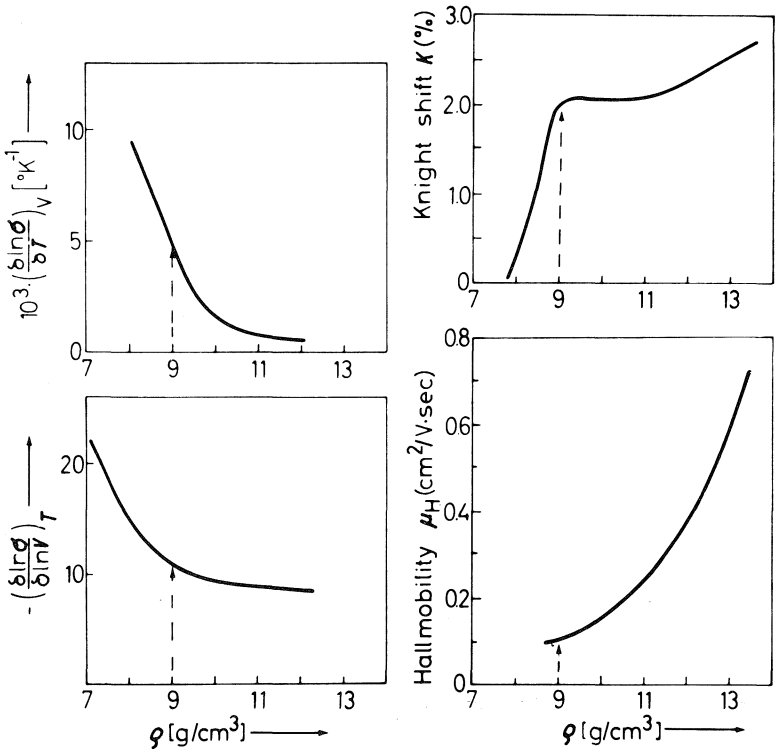

FIG. 12. Temperature and volume coefficient of the conductivity and the Knight shift and the Hall mobility of fluid mercury as a function of the density (from ref. 1).

and S for mercury in the density range between 8 g/cm^3 and 5 g/cm^3 are consistent with [1]; *i.e.* with an excitation of electrons from localized states at the Fermi energy to free states across the critical energy which divides ranges in which states are localized from those in which states are not. On the other hand $(\partial \ln \sigma/\partial \ln V)_T$ (47), $(\partial \ln \sigma/\partial T)_V$ (47), the Hall mobility (53, 54), and the Knight shift (55) indicate a change of the electronic state of mercury for densities around 9 g/cm^3, which is demonstrated by Fig. 12. Therefore, for the density range between 8 g/cm^3 and 9 g/cm^3 Cohen and Jortner (56, 57) have proposed an alternative explanation. They suggested the existence of an inhomogeneous transport regime in mercury between 9 g/cm^3 and 8 g/cm^3. They assumed that the microscopic inhomogeneities arise from density fluctuations. The metal–nonmetal transition in such a system with metallic and semiconducting clusters is then discussed within the framework of percolation theory. This matter is very controversial and up to now it is impossible to decide from the existing experimental results whether the Cohen–Jortner proposal is right. However, recent measurements of the isothermal compressibility χ_T and the thermal expansion coefficient α_p for expanded mercury as a function of the density from our laboratory (58) indicate an enormous increase of χ_T and α_p at densities smaller than 9 g/cm^3. It is certainly interesting to speculate on whether the mutual interdependence of electron–electron screening and interatomic forces necessarily leads to density fluctuations in the metal–nonmetal transition range.

At mercury densities larger than 9 g/cm^3 the analysis of the available electrical transport data, electrical conductivity, Hall effect, and thermoelectric power demonstrates the existence of two distinct regimes of electron transport in this one-component system. For densities between 9 and 11 g/cm^3 Even and Jortner (54) showed by combined conductivity σ and Hall effect R measurements that σ is proportional to $(R_{FE}/R)^2$, whereupon the Hall mobility μ_H follows $\mu_H \propto R_{FE}/R$. In these equations R_{FE} means the free electron value $R_{FE} \equiv (nec)^{-1}$. These experimental relations are in excellent agreement with

the theoretical predictions given by the strong scattering model (32) and Friedman's theory of the Hall effect (59, 60). However, it must be pointed out that expanded mercury is the only example for which the theory is in agreement with the experimental transport data. The recent measurements of the Knight shift by El-Hanany and Warren (55), however, seem inconsistent with the strong-scattering model. More accurate experimental and theoretical work on expanded mercury in the density range between 11 and 9 g/cm^3 is necessary to make it possible to formulate a theory which is in agreement with the experimental results.

For densities between 13.6 and 11 g/cm^3 it is found that the Hall coefficient has the free electron value $R_{FE} \equiv (nec)^{-1}$ and the conductivity exhibits no special relation to R. It is assumed that in this range, where the mean free path L of the conduction electrons exceeds the Fermi wavelength k_F^{-1}, σ is well represented by the nearly-free-electron (NFE) theory (61–63). The latter assumption, that the theory is valid when $L > k_F^{-1}$, has very recently been proved experimentally for fluid rubidium by measurements of the density (64, 65), the electrical conductivity (64, 65), and the structure factor (66, 67) as a function of temperature and pressure. It was found that the density dependence of the electrical conductivity can be well represented by the NFE theory even for an expansion of the fluid metal to a value of 65% of the density at the melting point (see Fig. 13). The experimental results agree satisfactorily with those calculated within the NFE theory using the measured structure factors of expanded rubidium. The latter is shown in Fig. 14 for different temperatures and pressures. Mainly three particular features may be distinguished in these curves. The first peak, which is relatively sharp at low temperatures, broadens appreciably with increasing temperature and its height decreases drastically. This fact illustrates that the 'shell of nearest neighbours' is less well defined and smears out with increasing temperature or decreasing density. At the same time the position of the first maximum is shifted by 10% to lower Q values between 450 K and 1400 K, which simply reflects the expansion of the liquid by about 30% within the above temperature limits. The main overall feature for Q values above 1 Å^{-1} is a considerable flattening of the structure factor.

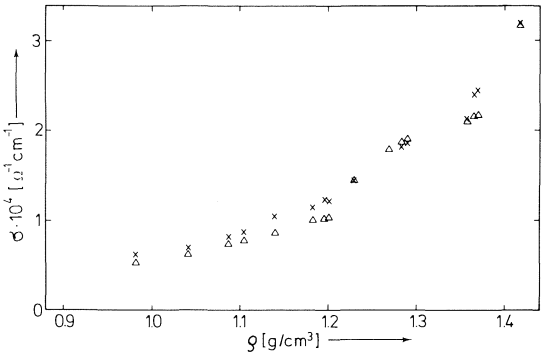

FIG. 13. The electrical conductivity of liquid rubidium: (×) calculated with the Ziman formula using a screened Ashcroft pseudopotential and experimental structure factors; (Δ) values recently reported in refs. 64–66.

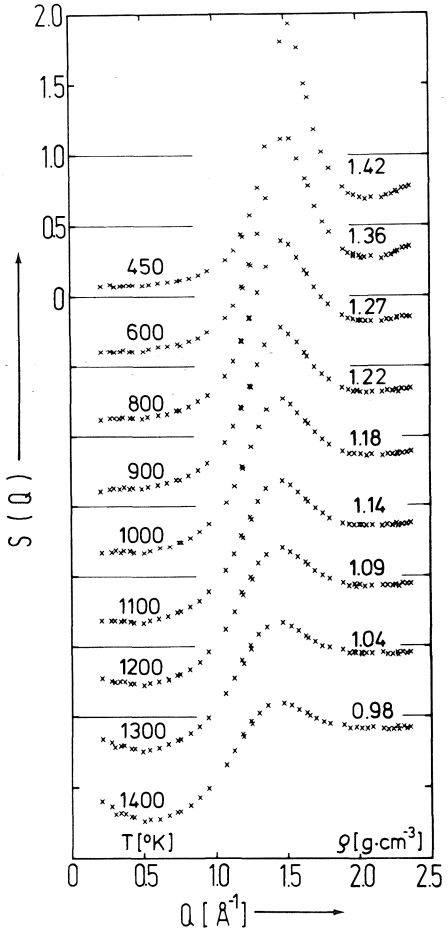

FIG. 14. Measured structure factors of liquid rubidium at nine different densities and temperatures for momentum transfers between 0.2 and 2.5 Å^{-1}.

At Q values below 0.5 $Å^{-1}$ two interesting observations can be made. Whereas for temperatures below 1100 K $S(Q)$ remains constant below $Q \leq 0.6$ $Å^{-1}$, a slight increase of $S(Q)$ with decreasing $Q \leq 0.4$ $Å^{-1}$ starts to show up at 1200 K, and is well pronounced at 1400 K. However, further measurements are necessary to establish this fact. The second interesting finding is that at the smallest Q reached in this experiment, $S(Q)$ increases by almost a factor of five between 450 K and 1400 K. This is consistent with the observed increase in the isothermal compressibility on expansion of fluid rubidium (Fig. 15) (64, 65) which is related to the structure factor at $Q = 0$ $Å^{-1}$ by the well-known equation

$$[3] \qquad S(0) = k_B T \chi_T n$$

where k_B is the Boltzmann constant and n the number density per cm^3. Since the compressibility is determined by the interatomic forces which are depending on the electron–electron screening, again one is tempted to speculate that the metal–nonmetal transition is probably connected with large fluctuations in the density. Further measurements of the structure factor of expanded metals at small wave vectors are necessary to prove this hypothesis. Possibly one can get better evidence by such an experiment for or against the various mechanisms proposed for the metal–nonmetal transition.

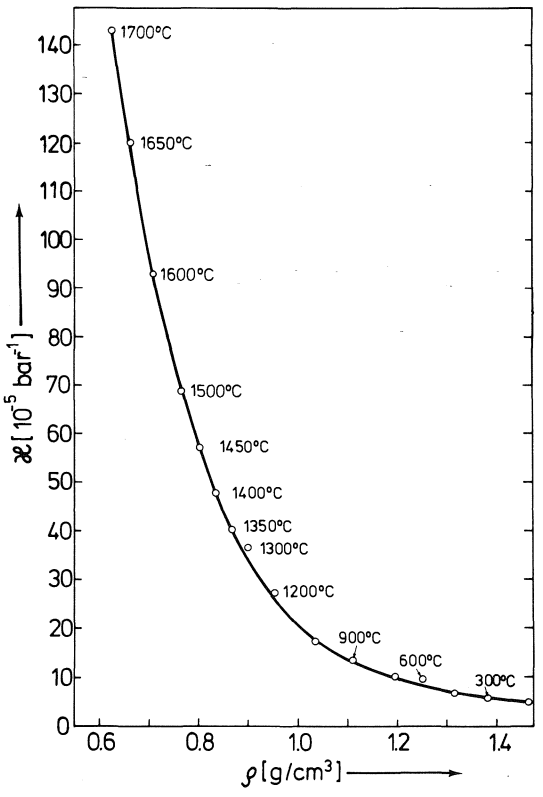

FIG. 15. Isothermal compressibility of expanded fluid rubidium as a function of the density (the points are measured at different temperatures) (data from refs. 64, 65).

Discussion

G. R. Freeman: One may plot the conductances of cesium (Hensel and co-workers) and mercury (Jortner and co-workers) against the number of atoms/cm^3 instead of against temperature, and compare them with a similar plot of the mobility of electrons in liquid xenon against density. One finds the band–nonband transition in xenon sandwiched between the densities of the metal–nonmetal transitions in cesium and mercury. The approximate densities of the transitions are 1×10^{21} atom/cm^3 in cesium, 1.2×10^{22} atom/cm^3 in xenon, and 3×10^{22} atom/cm^3 in mercury. The transition in xenon occurs at a density far above the critical density, which is 5×10^{21} atom/cm^3, so is not associated with critical fluctuations. I suspect that the same is true for the transitions in the metals and other systems you mentioned.

F. Hensel: Your comment is certainly true for mercury, for which we believe the metal–nonmetal transition occurs at a density of 9 g/cm^3 which largely exceeds the thermodynamic critical density of 5.3 g/cm^3. But for the alkali metals the existing electrical and thermodynamic data do not exclude that the phase transition and the metal–nonmetal transition are correlated. If it is a Mott transition one really would expect a correlation between the critical point and the metal–nonmetal transition.

M. H. Cohen: I was intrigued by the rise in the structure factor of liquid Rb at small q for high temperatures. Jortner and I have proposed the existence of density fluctuations in liquid Hg at densities of 9 g/cm^3 and below with q of the order of 15 Å in radius. It has just now occurred to me that such density fluctuations may be a universal concomitance of metal–nonmetal transitions involving the development of a pseudogap and ultimately a gap as the density is decreased. The compressibility is determined by the interatomic in-

teractions which are screened by the electronic dielectric function. For small q, the pseudogap causes a screening reduction, nonmetallic forces, and an increased compressibility. For large q, electrons can be scattered across the pseudogap, and their dielectric response is little affected by it. Thus for larger q one has metallic forces and a smaller compressibility. The compressibility, dielectric function, and structure factor are all directly related in such a way that the physical effect described leads to long wavelength density fluctuations for only those densities in the range where a relatively small pseudogap exists. Thus I would welcome the improved experimental results you promised, and, in return, will attempt the relevant theoretical analysis.

F. Hensel: We are very much interested in these questions, and we certainly will try to measure the isothermal compressibility and the structure factor at lower densities (higher temperatures and pressures), especially in the density range of the metal–nonmetal transition. We are mainly interested in two questions, the role of long range fluctuations and the role of short range order, especially the formation of diatomic molecules of the alkali metals on the nonmetallic side.

Hall effect at the metal–nonmetal transition in metal–ammonia solutions[1]

U. EVEN, R. D. SWENUMSON,[2] AND J. C. THOMPSON

Received October 4, 1976

U. EVEN, R. D. SWENUMSON, and J. C. THOMPSON. Can. J. Chem. **55**, 2240 (1977).

The conductivity and Hall coefficient have been measured for solutions of Li, Na, K, and Cs in liquid NH_3 using a double ac method over a concentration range of 1–10 mol% metal (mpm). The conductivities vary from 10^{-1} to near $10^4\ \Omega^{-1}\ cm^{-1}$ and the Hall coefficients from 10^{-6} to $10^{-9}\ m^3\ C^{-1}$ over the 1–10 mpm range. Hall mobilities vary from 10^{-2} to $10^0\ cm^2\ V^{-1}\ s^{-1}$ over the same range. The mobility for Na–NH_3 solutions shows a maximum at 4 mpm while the others are monotonic. The mobility peak in Na–NH_3 solutions appears to be related to the presence of substantial composition fluctuations in that system.

U. EVEN, R. D. SWENUMSON et J. C. THOMPSON. Can. J. Chem. **55**, 2240 (1977).

Utilisant une méthode à double ca, on a mesuré la conductivité et le coefficient de Hall pour des solutions de Li, Na, K et Cs dans l'ammoniac liquide à des concentrations allant de 1 à 10 mol% de métal (mpm). Les conductivités varient de 10^{-1} jusqu'à près de $10^4\ \Omega^{-1}\ cm^{-1}$ et les coefficients de Hall de 10^{-6} à $10^{-9}\ m^3\ C^{-1}$ aux concentrations allant de 1–10 mpm. Aux mêmes concentrations, les mobilités de Hall varient de 10^{-2} à $10^0\ cm^2\ V^{-1}\ s^{-1}$. La mobilité, dans le cas des solutions Na–NH_3, présente un maximum à 4 mpm alors que dans les autres cas elle est monotonique. Il semble que le maximum dans la mobilité, dans le cas des solutions Na–NH_3, soit relié à la présence de fluctuations importantes dans la composition de ce système.

1. Introduction

A measurement of the Hall coefficient R_H together with the electrical conductivity σ permits one to determine the carrier concentration ($R_H = (nec)^{-1}$, in the free electron approximation) and the Hall mobility ($\mu_H = \sigma R_H$) as well as Mott's g factor (the ratio of density of states to a free electronic density of states, both at the Fermi level, $g = R_H(\text{free})/R_H$). Such measurements are, therefore, central to any study of electronic transport processes and in particular to studies of the metal–nonmetal transition (1). However, there are ambiguities in interpretation of the Hall effect associated with low mobilities (2), and microscopic inhomogeneities (3–5) or fluctuations. One can relate R_H to the free carrier density only when the mean free path is long; should the free path be shortened by strong scattering processes or inhomogeneities then modifications of the conventional relationship ($R_H = (nec)^{-1}$) are required.

There are two current views of how the metal–nonmetal transition must proceed, one attributed primarily to Mott (1) and the other to Jortner and Cohen (3). We shall examine each in turn, though neither will turn out to be entirely satisfactory.

Mott (1) suggests that, in the strong scattering case, one replaces the usual relation by the Friedman (2) formula

$$R_H = C'/necg \qquad [1]$$

where C' is a constant with a value near unity (perhaps 0.7). Under the same circumstances the conductivity is given by

$$\sigma = \sigma_{min} g^2 C'' \qquad [2]$$

where σ_{min} is near $100\ \Omega^{-1}\ cm^{-1}$ and where C'' is a constant depending on the coordination number, with a value near 0.1. Under these circumstances, one expects $\sigma \propto R_H^{-2}$ or

$$\mu \propto R_H^{-1} \qquad [3]$$

Cutler (6) and also Fritzsche (7) have shown that one can write quite general formulae for the conductivity and thermoelectric power S which, in the case of semiconducting materials, reduce to

$$\sigma = \sigma_0 \exp -[(E_c - E_F)/kT] \qquad [4]$$

and

$$S = -(k/e)[(E_c - E_F)/kT + C'''] \qquad [5]$$

[1]Supported in part by the U.S. NSF under grant No. DMR 75-07828 and by the R. A. Welch Foundation of Texas.

[2]R. A. Welch Predoctoral Fellow.

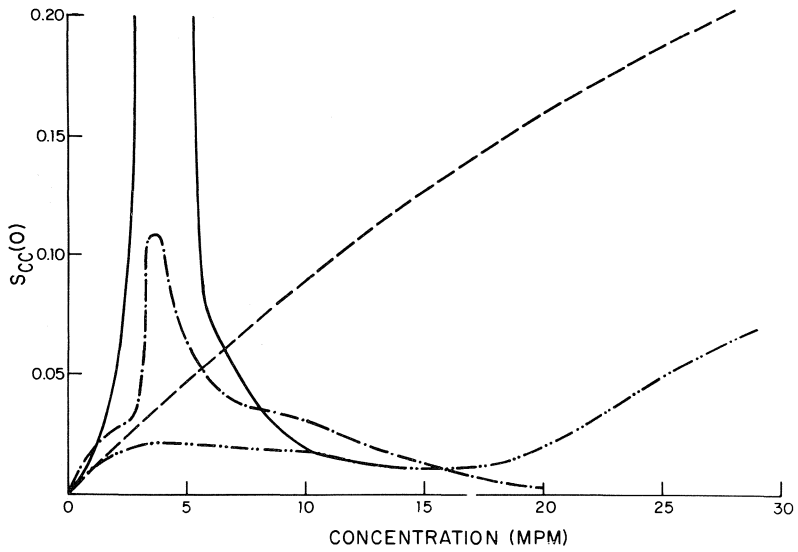

FIG. 1. The concentration correlation function for Li–NH_3 (---), Na–NH_3 (———), and Cs–NH_3 (-·-·-) solutions as a function of concentration is shown. The ideal value is also shown (---). (Reprinted with permission from the Journal of Chemical Physics, **59**, 1680 (1973).)

One therefore expects a model-independent relationship of the form

$$[6] \qquad \ln(\sigma/\sigma_0) = (e/k)S + C''' \qquad$$

where σ_0 and C''' are constants and k is Boltzmann's constant, whenever there is non-degenerate semiconducting behavior, in contrast to the small value of S and a wide variety of values of σ in metallic materials. One may therefore compare values of S and σ to fix the extremes of the metal–nonmetal (M–NM) transitions and use [1]–[3] to describe the transition regime.

If, however, there are microscopic inhomogeneities in the system then Jortner and Cohen (3, 4) suggest that quite a different approach is required. They believe that in many M–NM transitions a fraction C of the material is metallic in nature, containing free electrons in extended states, while the remainder $(1 - C)$ is non-metallic with localized electrons. The various regions are microscopic in size ($\sim$40 Å) and are mixed thoroughly. The problem then becomes one of determining whether a free electron can find a maze-like path from one metallic region to another and thence across the sample. Percolation theory (8) therefore enters. While results have been worked out for simple systems, using computer simulation in the main (4, 5), the problem is immensly complicated, particularly for transport parameters. One has as well to establish the origin of the inhomogeneities.

Since solutions of alkali metals in liquid ammonia (9) have often been used as subjects for the verification of each of the models described above (as well as others), it seems to be worthwhile to determine precisely how the M–NM transition affects σ and R_H in these materials so that a test of the two models can be made.

In Mott's model, we must look for the validity of [1]–[3]. In Cohen's model the test is more complex. If one looks at the phase diagrams of M–NH_3 solutions, it is immediately apparent that Cs–NH_3 solutions differ from the others in that there is no phase separation. This impression is confirmed by an analysis of the metal chemical potentials μ_M. One can calculate the mean square composition fluctuations $\langle(\Delta x)^2\rangle$ from [7],

$$[7] \qquad S_{cc}(0) = \langle(\Delta x)^2\rangle \propto (d\mu_{Na}/dx)^{-1}$$

where x is the metal concentration and $S_{cc}(0)$ is the long wave limit of the concentration correlation function (10). There is no sign in Cs–NH_3 solutions of the large fluctuations one commonly associates with phase separation as may be seen in Fig. 1. Note that there are stronger fluctuations in Na–NH_3 solutions than in the others. The data of Fig. 1 were taken at

$-33°C$ in each case; they are at larger values of $t = (T - T_c)/T_c$ for Li–NH_3 than for Na–NH_3 solutions, where T_c is the consolute temperature. Since fluctuations, and hence the peak in $S_{cc}(0)$, drop off as t increases one might expect the reduced values of $S_{cc}(0)$ for Li–NH_3 solutions. However, the temperature dependence of $S_{cc}(0)$ is not likely to be great enough to explain the total absence of fluctuations in the Cs–NH_3 solutions. This assertion is based on the assumption that the temperature dependence of $S_{cc}(0)$ does not grossly change with solute so that the observed behavior of Na–NH_3 solutions (10) may be taken as indicative of the behavior of solutions with other solutes as well. The absence of a phase separation in Cs–NH_3 solutions (9) is also an indicator of the relative weakness of concentration fluctuations in that system.

The fluctuations seen, say, in Na–NH_3 solutions might well be the origin of inhomogeneities in those solutions (3) while no inhomogeneities from this mechanism (phase separation) are to be expected in Cs–NH_3 solutions. If, indeed, fluctuations are important then clearly Cs–NH_3 solutions should not exhibit the same electrical transport properties in the 1–10 mol% metal (mpm) range as do solutions of the lighter alkalis.

The questions then to be answered by the experiments reported here are the following: (*a*) do all M–NH_3 solutions behave alike and (*b*) do they satisfy the Friedman relations? The next section contains a description of the experiments and the last a discussion of the results.

2. Experimental

The Hall cell was constructed from Pyrex glass plates with tungsten electrodes. A rectangular depression approximately 20 × 5 × 1 mm was ultrasonically milled into one glass plate which was in turn fused to a flat cover plate and the electrodes were then sealed into the edges. Platinum wires were spot-welded to the tungsten on the outside to permit easy soldering of the coaxial cable leads. Lead placement was designed to reduce pick-up. Geometrical constants for conductivity and Hall effect were determined using mercury as a standard. The inside part of the leads was electropolished with a sodium phosphate tribasic solution then electroplated with either gold or silver in a cyanide bath. The cell was rinsed with organic solvents and a dilute HF solution then baked for several hours at 250°C in a vacuum furnace at pressures below 10^{-6} torr. After baking, the cell was taken directly into the glove box to be loaded with metal, closed off, then taken out and attached to the ammonia still.

The lower part of the cell could be heated locally with a 3 W lamp to induce gentle boiling and thus mix the solution. A controlled flow of cold nitrogen vapor was used to maintain the desired low temperature. The nitrogen vapor was obtained as boiloff from a 25 ℓ Dewar containing a 30 W heater in the liquid. A platinum resistance thermometer, placed next to the sample cell, was used to feed a modified temperature controller which powered the heater. Temperature measurement was by a copper–constantan thermocouple attached to the cell; temperature stability and repeatability were ±0.2 K. The gas cooling system has a low heat capacity so that temperature could be changed conveniently.

The conductivity was measured by an ac four-probe method. Current was derived from an audio oscillator (HP 651A) and a 30 W power amplifier (McIntosh MI 75) at 5.2 kHz. The current was measured by a DVM (Keithley 171), and the voltage drop across the sample was measured through a tuned isolation transformer with the same DVM. The precision of the conductivity measurement was better than 2% over five decades of measurement. Accuracy, also near 2%, was limited by the calibration procedure.

The Hall coefficient measuring system uses the double ac method (11–13). The system can be subdivided into seven parts which are described in turn.

(*a*) The laminated iron-core, homebuilt magnet (14) had a field region of 40 × 100 × 100 mm. A series resonance for operation at about 200 Hz was achieved by connecting a 1 μF high-voltage capacitor. When fed by an audio oscillator and power amplifier (McIntosh MI 350) a highly stable (0.1%) 1 kG rms field was established. Stability and harmonic purity (0.1% total harmonic distortion) are essential for this method of measurement. Homogeneity of the field over the volume of the sample was about 1%. Normal air convection cooling of the magnet was sufficient.

(*b*) The sample current, at about 5.2 kHz, was produced as in the conductivity experiment. A 0.1 μF capacitor in series with the power output of the amplifier prevented the low frequency magnetic field pick-up from mixing with the current frequency at the output stage of the amplifier. Otherwise a false Hall signal would have been created.

(*c*) The Hall signal was stepped up by a 50:1 transformer wound on a 'pot-core' ferrite and tuned to resonate at the sum frequencies of field (0.2 kHz) and current (5.2 kHz). A capacitor at the input served as a high-pass filter. The preamplifier was an 'Ortec-Brookdeal 9452 precision ac amplifier' which has the necessary linearity (10 ppm), low noise, and band width needed at this stage.

(*d*) A ferrite-wound L–C circuit connected in a resonance-notch configuration passed the 5.4 kHz signal and attenuated the 0.2 kHz pick-up from the magnet, thus serving as an intermediate stage of filtering.

(*e*) A Brookdeal phase sensitive detector (9412a) referenced to the 5.2 kHz current frequency was used as a first stage demodulator. The Hall signal was thus transformed to 0.2 kHz, while the bothersome misalignment voltage at the current frequency was converted to easily filtered dc. This mode of operation allows large interference at the current frequency without necessitating special filtering or bucking signals. Nevertheless every

effort was made to position the Hall probes so that misalignment voltage was minimum.

(*f*) A PAR lock-in amplifier (128), referenced to the magnetic field frequency, was used as the final demodulator to convert the Hall signal to dc.

(*g*) A simple multiplier circuit, fed by the audio oscillators generating the current and magnetic field, was used to generate a signal of known level at the sum frequency of 5.4 kHz. This signal was injected through a step-down transformer in series with the cell to compensate for the wide variation in conductivity expected in this study.

System parameters and performance may be summarized as follows.

(*1*) sample impedance: 10^{-3}–10^{2} Ω;
(*2*) current at 5.2 kHz: 10^{-3}–10^{0} A (rms);
(*3*) field at 0.2 kHz: 10^{0}–10^{3} G (rms);
(*4*) equivalent noise at input: 0.1 nV at 10 s integration;
(*5*) precision of Hall voltage: 1%;
(*6*) dynamic range: 120 dB.

A portion of the dynamic response curve is given in Fig. 2.

Samples of the required alkali metal were cut from vacuum-packed ampoules (99.99%) inside a helium-filled glove box and loaded into the freshly baked cell. Ammonia gas, passed though a charcoal trap and condensed onto sodium, was then distilled into the cell after it was placed in the magnet. Concentrations were determined to within 0.1 mpm from the weight of the metal and the volume of gas transferred. Successive transfers of NH_3 varied the concentration. All solutions were stable throughout the measurement period with negligible evolution of hydrogen.

In common with previous investigators (11, 14, 15) we have encountered severe electrode problems at concentrations below 5 mpm and particularly below 3 mpm. We have employed a variety of electrodes: Au, W, Ag-plated W, Au-plated W, and Cs-plated W (the latter for solutions containing no Cs). None was satisfactory in every solution and it is abundantly clear that the 'chemistry' of the electrodes in M–NH_3 solutions is controlling. For example, clean W was sufficient in Cs–NH_3 solutions. We presume Cs to be sufficiently reactive to clean the electrode and the oxide (?) sufficiently soluble to be removed from the electrode region. Pure Au electrodes were noticeably reduced in size following an experiment in K–NH_3 solutions.

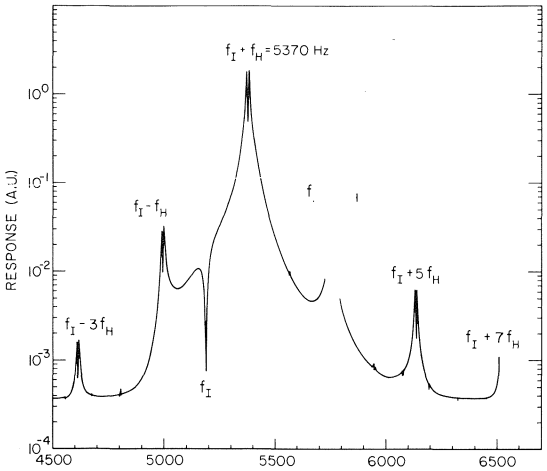

FIG. 2. The dynamic system response for the Hall measurement is shown. Hall data were taken at $f_I + f_H$ = 5370 Hz, where f_I = current frequency and f_H = magnetic field frequency.

In ac Hall effect measurements, the fundamental problem is that any nonlinearity in the electrode–solution interfacial resistance (or in the detection system, see above) can introduce a 'mixing' effect thereby producing a signal at the same frequency (though possibly a different phase) as the Hall voltage itself. The superposition of these two signals will then produce a false Hall voltage. Thus problems arise in measurement of R_H but not in the conductivity. In Li–NH_3 solutions the value of R_H decreases by two orders of magnitude as the electrode is changed from 'clean' W, to W coated with Cs, Ag, or Au. Furthermore, solutions of the lighter alkalis exhibit a reversal in the sign of R_H as the concentration is reduced below 2.5 mpm with noble-metal-coated W electrodes. With Ag-plated W electrodes, the application of a steady state (dc) current between one Hall (+) and one current electrode (−), of several mA for periods of several minutes would cause a further irreversible reduction of the Hall voltage V_H. We took this as an indication of a film coating (possibly oxide) on the Hall electrode and rejected data obtained with such electrodes. Pure Au electrodes were satisfactory in both Li–NH_3 and Na–NH_3 solutions, but were dissolved in K–NH_3 solutions where Ag-plated W was apparently successful.

The data reported here are regarded as 'true' on the basis of the following criteria. (*1*) These results were reproducible from run to run and cell to cell. (*2*) Values of V_H are linear in current and field. (*3*) Values of V_H do not change following prolonged operation of a cell with large dc currents between the Hall and other electrodes. (*4*) If a given concentration is reproduced during the course of a run, the same V_H was obtained. (*5*) Microscopic examination of the electrodes following an experiment failed to reveal any contamination or etching.

All data were taken at the consolute point plus 10 K, except with Cs where the temperature was −55°C.

3. Results and Discussion

We have obtained σ and R_H on solutions of Li, Na, K, and Cs in liquid NH_3 as well as density data for Cs–NH_3 solutions. Figures 3–6 display the measured values of σ and R_H for each solution and, in addition, the Hall mobility derived from the measured parameters. In each case the conductivities range from 10^{3}–10^{-1} Ω^{-1} cm^{-1} over the 10–1 mpm range of the M–NM transitions and are consistent with those of previous workers (9); R_H varies from 10^{3}–10^{0} in units of 10^{9} m^3/C except in Cs–NH_3 solutions where the maximum value is 10^{2}. These data

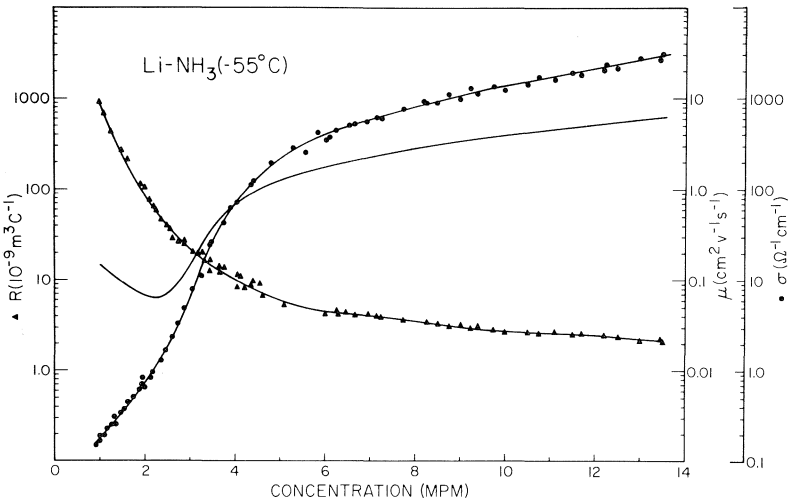

FIG. 3. The conductivity, mobility, and Hall coefficient for Li–NH_3 at −55°C are shown. The conductivity is denoted by ●, R_H by ▲, and μ_H by the solid line.

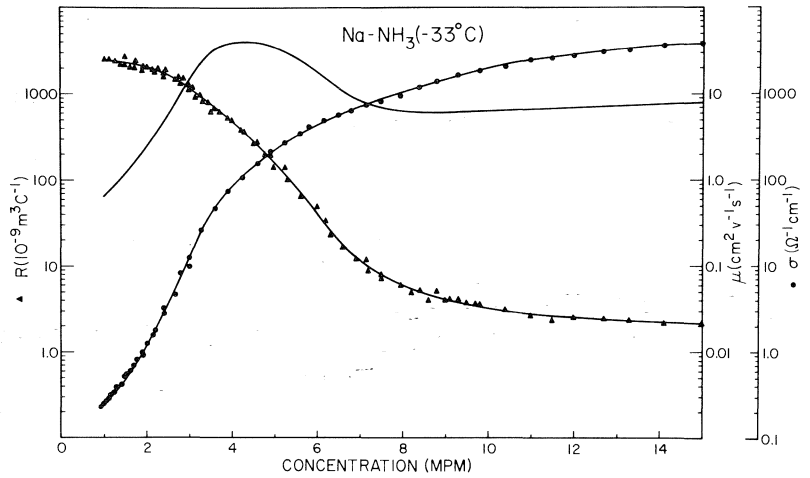

FIG. 4. The conductivity, mobility, and Hall coefficient for Na–NH_3 at −33°C are shown. Legend as in Fig. 3.

are not consistent with the meager data previously reported in the 1–5 mpm range, where electrode problems are most severe, but are in agreement with data reported at higher concentrations. The present data show less scatter and are considerably more extensive than those reported previously (9).

For concentrations above 6 mpm, *all* electrodes gave the same results within our precision of about 5% with no systematic differences. In addition these data are consistent with previous data (9). Below 6 mpm the precision of the data presented in Figs. 3–6 is near 10%. Inasmuch as the rejected data differed from those presented in both magnitude and sign it is difficult to assign absolute error bars. Since the data presented lie close to plausible extrapolations of the curves obtained above 6 mpm and, in particular, the high mobility of the Na–NH_3 solutions is observed above 6 mpm, we infer that the accuracy is also near 10%. Older data in the 1.5–6 mpm range are sufficiently sparse and scattered as to make comparison unrewarding.

The σ data are compared in Fig. 7, and may be seen to be essentially independent of solute.

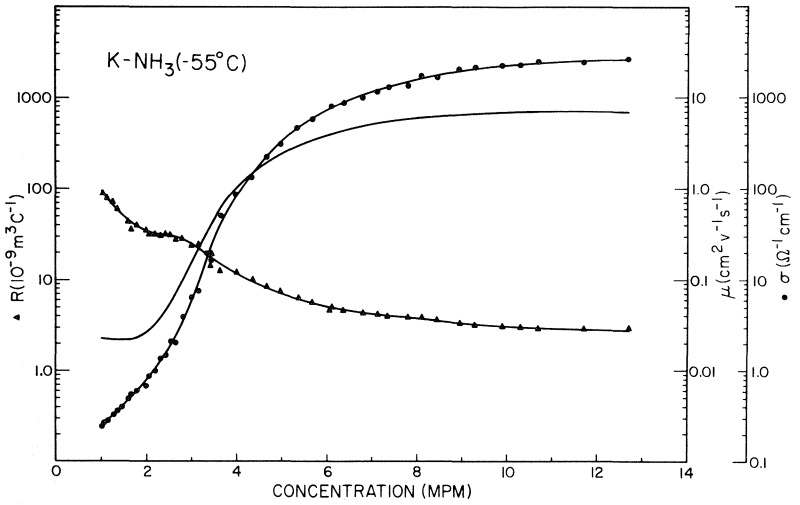

FIG. 5. The conductivity, mobility, and Hall coefficient for K–NH_3 at −55°C are shown. Legend as in Fig. 3.

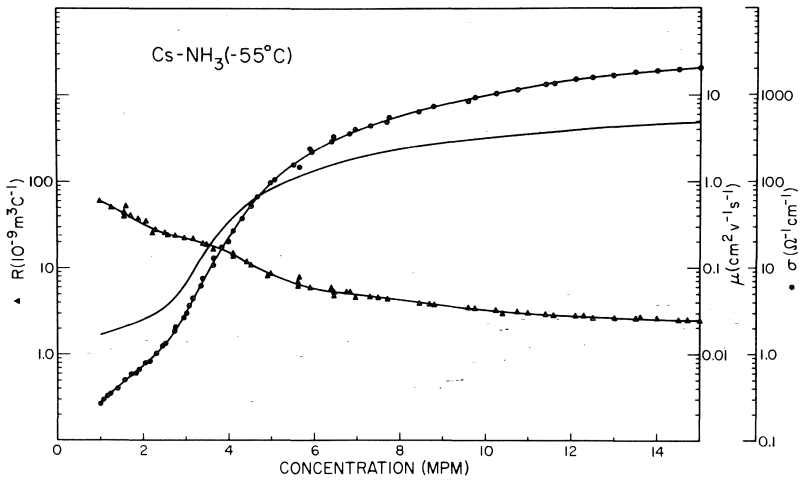

FIG. 6. The conductivity, mobility, and Hall coefficient for Cs–NH_3 at −55°C are shown. Legend as in Fig. 3.

The minimum metallic conductivity[3] σ_{min} of $100\ \Omega^{-1}\ cm^{-1}$ occurs near 4 mpm or at a solute number density of $10^{21}\ cm^{-3}$. Mobilities are compared in Fig. 8, where the Na–NH_3 data may be clearly seen to be different. Note that mobilities are near unity at the concentration for which $\sigma = \sigma_{min}$, except for Na–NH_3 solutions. There is a minimum mobility of $0.06\ cm^2\ V^{-1}\ s^{-1}$ in Li–NH_3 solutions.

If concentrations are normalized to that for which $\sigma = \sigma_{min}$, then the M–NH_3 solutions are even more alike as may be seen in Fig. 9 where σ data (13) for expanded Cs and Hg vapors are also displayed. The M–NH_3 solutions form a class of their own as might be expected from the different scattering mechanisms operative in the pure metal vapors. The nonmetallic states are different in the two (or three) sorts of material and the NH_3 molecules must also have an effect. The pure Cs conductivity is, however, strikingly close to that of the solutions.

Differences among the M–NH_3 solutions are

[3]The relevant concentrations are 10.5 mpm for Na–NH_3 and Cs–NH_3 and 5.4 and 6.2 mpm for Li–NH_3 and K–NH_3, respectively. For Hg, ρ_0 is 11 g cm^{-3}.

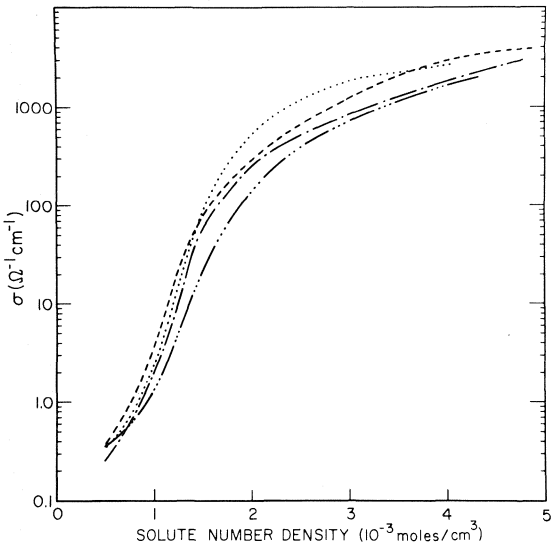

FIG. 7. The conductivities of Li–NH_3 (---), Na–NH_3 (---), K–NH_3 (···), and Cs–NH_3 (·····) solutions as a function of solute number density are shown.

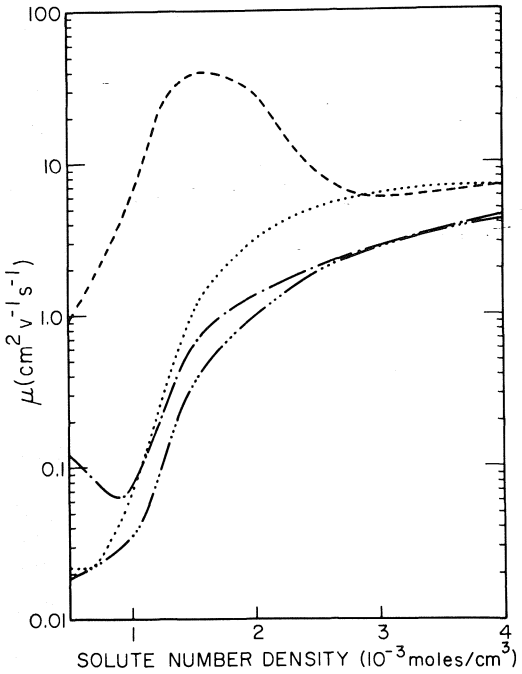

FIG. 8. The mobilities of Li–NH_3, Na–NH_3, K–NH_3, and Cs–NH_3 solutions as a function of solute number density (same notation as Fig. 1) are shown.

most apparent when the ratio of free-electron Hall coefficient to that measured (or the Mott g factor) is plotted against a concentration normalized to $\rho_0(\neq \rho_c)$. The density ρ_0 is defined by the intersection of the linear extension of that portion of the ratio (g) which lies below unity with the $g = 1.0$ line.[3] Here one finds a clear trend in that those solutions with larger fluctuations (as in Fig. 1) have a more rapid decrease of g as ρ/ρ_0 decreases below unity (see Fig. 10). The order is Na, Li, K, Cs. The pure Hg data show a drop-off even more rapid than any of the M–NH_3 solutions.

Mott suggests that the M–NM transition occurs when g falls to $\frac{1}{3}$. In the present instance g never quite reaches that value for the low-fluctuation, most homogeneous solutions of K and Cs. In Na–NH_3 solutions g is $\frac{1}{3}$ at 7 mpm where the conductivity is $700\ \Omega^{-1}\ cm^{-1}$ while in Li–NH_3 solutions the concentration is near 2.5 mpm and σ is only $4\ \Omega^{-1}\ cm^{-1}$. All attempts to reconcile these data with the Friedman formula, eq. 3, have also failed, as have similar efforts with the older data (1, 9).

Though Na–NH_3 solutions behave quite differently from the others so that it is possible to assign a role to the enhanced fluctuations seen in that system, it is nevertheless difficult to assess the details of that role. Certainly the straightforward application of percolation theory (3, 5) cannot reproduce the behavior of Na–NH_3 solutions though Li–NH_3 can be so described.

The mobility for electrons in Na–NH_3 solutions is shown in Fig. 11. Mobility maxima are also found for excess electrons in fluid Ar, Kr, and Xe (16). Those maxima occur at substantially higher *fluid* densities ($10^{22}\ cm^{-3}$) than the *solute* densities of the present experiments. The overall fluid densities are comparable. The maximum mobility in Xe is two orders of magnitude larger than that reported here. In the absence of any real theory of the maxima in the noble gases any relevance of the similarity to Na–NH_3 solutions must be questionable.

In summary our results must be regarded as inconsistent both with the Friedman formula and with the simple inhomogeneous model. The evidence for the importance of fluctuations may be regarded as strong but not yet conclusive. Efforts to confirm the effects of fluctuations are underway.

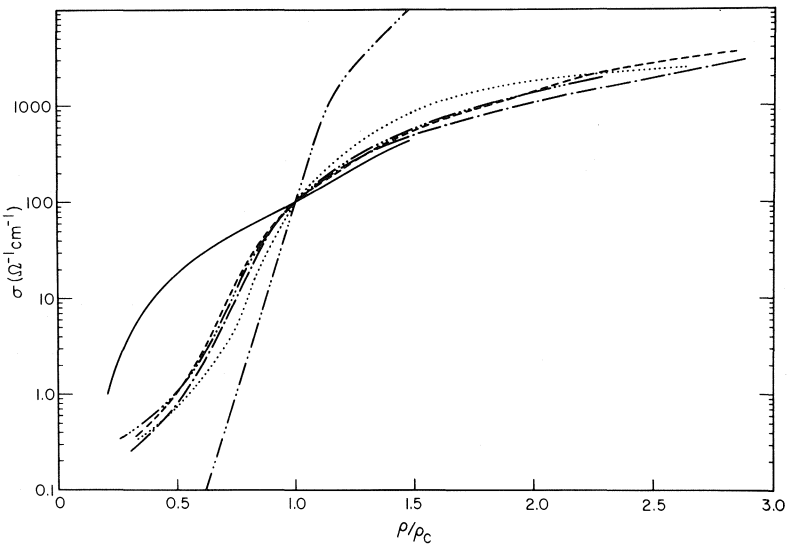

FIG. 9. The conductivities of Li–NH_3, Na–NH_3, K–NH_3, Cs–NH_3 solutions and expanded Cs (———) and Hg (····) systems *vs.* ρ normalized to the value of ρ where $\sigma = 100\,\Omega^{-1}\,cm^{-1}$ are shown.

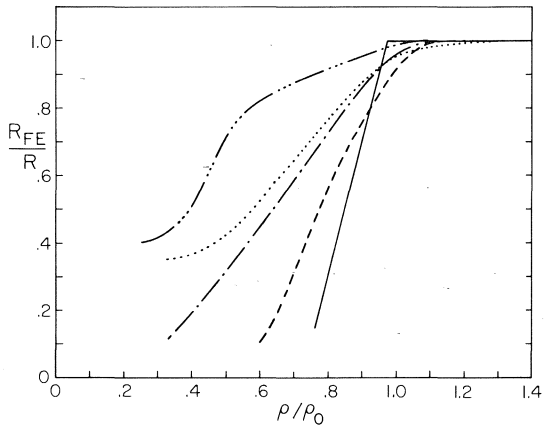

FIG. 10. R_H(free)/R_H for the systems Li–NH_3, Na–NH_3, K–NH_3, Cs–NH_3, and Hg(····) is shown. The value of ρ_0 is given in the text. The abscissa ρ/ρ_0 is defined in the text.

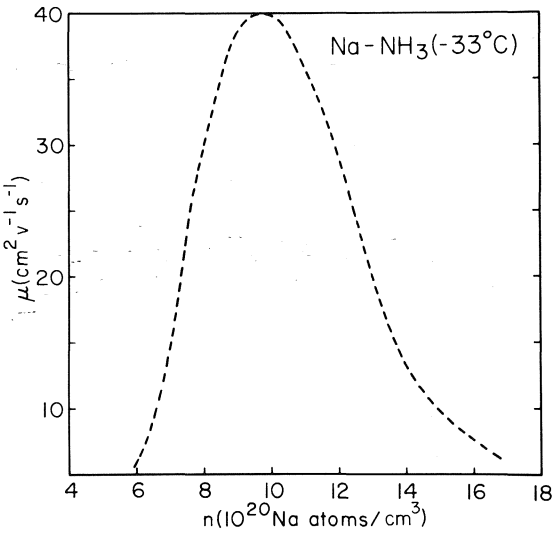

FIG. 11. The mobility of Na–NH_3 solutions at −33°C as a function of the Na number density is shown.

Discussion

G. R. Freeman: Could the difference between the concentration dependences of the conductivities of cesium vapor and the metal–ammonia solutions, at low concentrations, be attributed to the dielectric constant of the ammonia?

J. C. Thompson: I think not. The scattering mechanisms are just too dissimilar to be treated the same way (with or without a dielectric constant) in the metal vapors as in $M–NH_3$ solutions.

G. R. Freeman: The greater slope of the conductance–density plot of liquid mercury might be associated with the fact that mercury atoms contain two paired valence electrons, whereas the alkali metal atoms contain only one valence electron.

J. C. Thompson: There is some evidence for Cs_2 in the vapor. A diatomic molecule is equivalent to a divalent atom. Hence a band-crossing basis for the M–NM transition is possible. Otherwise I would agree that the different valences of Cs and Hg are dominant.

The study of primary and secondary charge carriers in nanosecond pulse irradiated liquid dielectrics using a resonant microwave cavity

A microwave resonant cavity technique for studying changes in conductivity of pulse irradiated dielectric liquids is presented. The sensitivity of the method is such that transient changes in conductivity of 5×10^{-9} ohm cm^{-1} can be measured with a signal to noise ratio of 10 and a response time of approximately 10 ns. The use of the technique is illustrated by a study of primary (excess electron, hole) and secondary (molecular ions derived from solutes) charge carriers in the saturated hydrocarbon liquid *trans*-decalin. The temperature dependences of the mobilities of the excess electron and hole are found to be described quite well by $\mu(-) = 25 \exp(-4500/RT)$ $cm^2\ V^{-1}\ s^{-1}$ and $\mu(+) = 4.0 \times 10^{-3} \exp(500/RT)$. The mobility of the hole is found to exceed that of the electron below approximately 10°C. The sum of the mobilities of the secondary ions at 22°C in a 5×10^{-3} *M* SF_6 plus 10^{-2} *M* benzene solution is 5.2×10^{-4} $cm^2\ V^{-1}\ s^{-1}$. In order to determine the mobilities of even the primary charge carriers consideration had to be given to the presence of geminate ion pairs on the time scale of the observations. The way in which corrections for geminate ion pairs were carried out is fully discussed.

JOHN M. WARMAN, PIERRE P. INFELTA, MATTHIJS P. DE HAAS et ANDRIES HUMMEL. Can. J. Chem. **55**, 2249 (1977).

On présente une technique de cavité résonante de microonde pour l'étude des changements dans la conductivité de liquides diélectriques irradiés par pulsation. La sensibilité de la méthode est telle que des changements temporaires dans la conductivité de l'ordre 5×10^{-9} ohm cm^{-1} peuvent être mesurés avec un rapport de signal à bruit de 10 et un temps de réponse approximatif de 10 ns. On illustre la technique par une étude des porteurs de charges primaires (excès d'électron et trou) et secondaire (ions moléculaires dérivés de solutés) dans la décaline-*trans* qui correspond à un hydrocarbure saturé/liquide. On a trouvé que les relations qui existent entre la température et la mobilité des électrons en excès et des trous peuvent être assez bien décrites par les relations $\mu(-) = 25 \exp(-4500/RT)$ $cm^2\ V^{-1}\ s^{-1}$ et $\mu(+) = 4.0 \times 10^{-3} \exp(500/RT)$. On a trouvé que la mobilité du trou excède celle de l'électron en dessous d'une température approximativement égale à 10°C. La somme des mobilités des ions secondaires à 22°C dans une solution de 5×10^{-3} *M* SF_6 plus 10^{-2} *M* de benzène est de 5.2×10^{-4} $cm^2\ V^{-1}\ s^{-1}$. Afin de déterminer les mobilités même des porteurs de charges primaires, on a dû faire entrer en considération la présence de paires d'ions géminés sur l'échelle de temps des observations. On discute de la manière par laquelle les corrections pour les paires d'ions géminés ont été effectuées.
[Traduit par le journal]

Introduction

The use of microwave techniques to study transient changes in the conductivity of pulse irradiated liquid hydrocarbons on a nanosecond time scale was reported by three of the present authors (1) in 1973. At that time the sensitivity of the apparatus was such that only signals due to relatively high mobility ($\mu \geq 1\ cm^2\ V^{-1}\ s^{-1}$) charge carriers could be detected. Subsequently, improvements in the components used and in the theoretical understanding and design of the experiment resulted in the use of this technique to observe primary positive ions with mobilities on the order of $10^{-2}\ cm^2\ V^{-1}\ s^{-1}$ in liquid cyclohexane and methylcyclohexane (2, 3).

A further increase in sensitivity has recently been achieved by the use of a low *Q* resonant cavity as the irradiation cell. It is the purpose of the present paper to demonstrate how this has resulted in the possibility of studying not only high mobility primary charge carriers but also secondary (molecular) ions on a nanosecond time scale. The use of the method will

be illustrated by results obtained in the saturated hydrocarbon liquid *trans*-decalin (*trans*-decahydronaphthalene).

Experimental

The *trans*-decalin (Merck) was distilled on a 90 theoretical plate column (Fisher "Spaltrohr-system"). The distilled solvent was passed through a column of activated silica gel, bubbled with N_2, degassed on a grease-free vacuum line, and distilled into a bulb containing sodium–potassium alloy (MSA Research Corp.) where it was allowed to stand several days before use. The liquid was transferred from the NaK bulb to a glass bulb attached to the microwave cell by distillation on a heated (*ca.* 60°C) vacuum line. The volume of liquid transferred (*ca.* 16 ml) was determined by weighing the cell before and after filling.

Known amounts of the solutes SF_6, NH_3, and benzene were added by distilling them from calibrated volumes into the cell bulb which was immersed in liquid nitrogen. The pressure of solute in the calibrated volume was measured using a capacitance manometer (MKS Instruments). The concentrations of SF_6 and NH_3 in the liquid phase were calculated using Ostwald solubility coefficients of 0.78 and 2.1 respectively which were measured in our laboratory.

The microwave cell used in the present experiments was designed as an iris coupled, rectangular resonant cavity. The cell consisted basically of a 4 cm length of X-band waveguide (internal dimensions 1 cm × 2.3 cm) which was completely closed at one end with a 1 mm thick copper plate. On the other end was fitted a 0.5 mm thick copper plate with a central coupling hole of 8 mm diameter which was sealed by a thin sheet of mica attached with epoxy cement. The cell was further fitted with a flange for attachment to the waveguide circuit and had a connecting hole in the 'upper' broadwall side to allow admission of liquid from the attached, via a metal–glass transition, glass bulb. The upper broadwall side was reduced to a thickness of 0.5 mm for a length of 3 cm from the completely closed end to allow transmission of the electron beam.

The cell was irradiated with 3 MeV electrons from a Van de Graaff accelerator using pulse widths of 20, 50, and 250 ns. The total charge in the pulse, Q nC, was measured by deflection of the beam onto a 50 ohm coaxial target and integration of the current using a Keithly model 616 electrometer. The dose absorbed by the liquid, under the present conditions, was $8.9 \times 10^{14} Q\rho$ eV cm^{-3} where ρ g cm^{-3} is the density of the liquid. For a 20 ns pulse the total dose absorbed was approximately 1.2×10^{16} eV cm^{-3} (*ca.* 200 rad). For a yield $G(100\text{ eV})^{-1}$ of ion pairs, for which the sum of the ion mobilities is μ, the change in conductivity of the medium will be

$$[1] \quad \Delta\sigma = Ne\mu$$

$$[2] \quad = 1.42 \times 10^{-6} Q\rho G\mu \text{ ohm cm}^{-1}$$

Changes in the microwave power reflected from the cell were measured using microwave circuitry almost identical to that published previously (1). The ac output of the detector diode (AEI 1502F, schottky barrier) was amplified × 100 by a Hewlett Packard 462A amplifier prior to being fed into a Tektronix 7904 transient digitizer and displayed on a Tektronix 604 monitor. The overall response time of the system of 10 to 15 ns was controlled principally by the response time of the cavity.

When filled with decalin ($\varepsilon_r = 2.159$) at 22°C the loaded quality factor, Q_L, of the cavity at its resonance frequency of 8.810 GHz was determined to be 467. At the minimum of the resonance the ratio, R_0, of the microwave power reflected by the cavity to the incident power level was 0.453. For such a cavity, it has been derived[1] that a small change in the conductivity of the medium within the cell, $\Delta\sigma$, will result in a change in the level of the reflected power, P_r, given by

$$[3] \quad \frac{\Delta P_r}{P_r} = \mp \frac{Q_L(1/\sqrt{R_0} \pm 1)}{\pi f_0 \varepsilon_0 \varepsilon_r} \Delta\sigma$$

In [3] f_0 is the resonance frequency, ε_0 is the permittivity of vacuum, and ε_r is the relative dielectric constant of the medium. As can be seen in [3] an increase in conductivity of the medium may result in a decrease in reflected power (absorption) or an increase in reflected power (emission). These two possibilities result from the fact that the cavity may be over or undercoupled respectively at resonance. If an absorption is observed the upper signs in [3] should be used, and for an emission signal the lower.

Equation [3] is based on irradiation of the total length, d, of liquid within the cavity. In most practical cases, including the present, a length d_i at the back of the cavity is irradiated. Taking this into account, the relationship between ΔP_r and the change in conductivity in the irradiated length becomes

$$[4] \quad \frac{\Delta P_r}{P_r} = \mp \frac{Q_L(1/\sqrt{R_0} \pm 1)}{\pi f_0 \varepsilon_0 \varepsilon_r} \times \frac{2\pi n d_i/d - \sin(2\pi n d_i/d)}{2\pi n} \Delta\sigma$$

where n is the number of half wavelengths in the cavity.

In the present case an absorption signal is found on irradiation of decalin within the cavity and substitution for the various parameters either known or measured in [4] gives

$$[5] \quad \Delta P_r/P_r = -1.53 \times 10^3 \Delta\sigma$$

for conductivity in units of ohm^{-1} m^{-1}. The conductivity change in units of ohm^{-1} cm^{-1} may be obtained from the observed change in reflected power using

$$[6] \quad \Delta\sigma = -6.54 \times 10^{-6} \Delta P_r/P_r \text{ ohm}^{-1} \text{ cm}^{-1}$$

From [2] and [6], the product of the ion pair yield and sum of the mobilities may then be obtained from

$$[7] \quad G\mu = -\frac{4.61}{Q\rho} \frac{\Delta P_r}{P_r}$$

[1]P. P. Infelta, M. P. de Haas, and J. M. Warman. Derivation to be published.

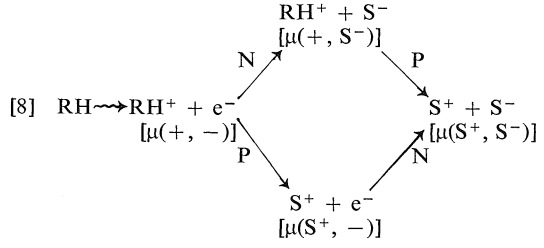
Using signal averaging of 16 pulses the noise level of the present system allows the measurement of a one part per thousand change in P_r with a signal to noise ratio of approximately 10. Conductivity changes of 5×10^{-9} ohm^{-1} cm^{-1} can therefore be accurately measured. This corresponds to a concentration of 3×10^{10} ions cm^{-3} or 5×10^{-11} M of a charge carrier of unit mobility (in cm^2 V^{-1} s^{-1}). Since doses up to 1 krad (50 ns, 1 A pulse) can be deposited in the liquid, values of the product $G\mu$ as low as 5×10^{-5} (100 eV)$^{-1}$ cm^2 V^{-1} s^{-1} can be readily measured.

Conventional dc conductivity methods are in theory two to three orders of magnitude more sensitive than the present method. However, in practice the ultimate sensitivity of dc methods is difficult to attain. This is due to problems of impedance matching of the cell to the transmission line which results in 'ringing' and to spurious transients resulting from 'pick-up' from the pulsed source of radiation. The latter is of considerable importance when the liquid is irradiated directly with electrons. Using microwave methods considerably diminishes this problem since the waveguide used has the effect of filtering out electromagnetic impulses with frequencies other than those which can propagate. The result is that, at least for electron irradiation, the present method is at least as sensitive as dc techniques presently in use.

Results and Discussion

Qualitative Considerations

One of the principal problems in the study of the conductivity of irradiated systems is the determination of the relative contributions to the conductivity of the positive and negative charge carriers. The method used in the present work is based on the knowledge, from radiation chemical studies, that certain compounds are capable of reacting specifically with one or other of the primary charge carriers formed in irradiated hydrocarbon liquids. These reactions lead to the formation of secondary molecular ions with corresponding changes in the total mobility as shown in the following scheme.



Of particular interest is whether or not a primary charge carrier, electron, or hole, has a mobility significantly larger than that of a molecular ion whose motion depends on molecular displacements within the medium. A qualitative answer to this question may be obtained from measurements of the conductivity induced by a given pulse under conditions of added solute(s) corresponding to the different stages in the above reaction scheme.

Such measurements are shown in Fig. 1 for the case of *trans*-decalin at 22°C to which 5×10^{-3} M SF_6 and 7×10^{-3} M NH_3 were added as electron and hole scavengers respectively. The conductivity signal in the case of the fully scavenged system, lowest trace, is seen to be considerably smaller than that in pure decalin, particularly at longer times, indicating that at least one of the primary charge carriers has a mobility considerably larger than that of a molecular ion. The initial rapid decay of the conductivity in the fully scavenged case, which is more fully discussed below, is due to the presence of a large yield of geminate ion pairs on a nanosecond time scale in such systems as is well known from optical pulse radiolysis studies (4, 5). Addition of either SF_6 or NH_3 singly to *trans*-decalin results in a decrease in the conductivity signal by a factor of approximately two in both cases, the remaining signal being considerably larger than that in the fully scavenged system. It may be argued, from these observations, that both of the primary ions in *trans*-decalin have mobilities considerably larger than those of molecular ions and that, at 22°C, the electron and hole mobilities are of the same order of magnitude.

In order to derive absolute values for the mobilities of primary and secondary ions from measured conductivities, it is necessary to know the total yield of ion pairs present at a given time following the pulse. In a previous publication (3), values of the mobilities of the primary charge carriers in some hydrocarbon liquids were estimated based on the assumption that all geminate ion pairs underwent recombination on a time scale much shorter than the pulse length and that therefore the yield of ion pairs present at the end of the pulse was equal to the free ion yield. As mentioned above, on the time scale of the present experiments, this is known not to be the case when both primary ions are scavenged and, even for the singly scavenged systems, the initial somewhat faster decay, shown by the traces in Fig. 1, is indicative of the presence of a significant yield of geminate ion pairs. An analysis of the possible con-

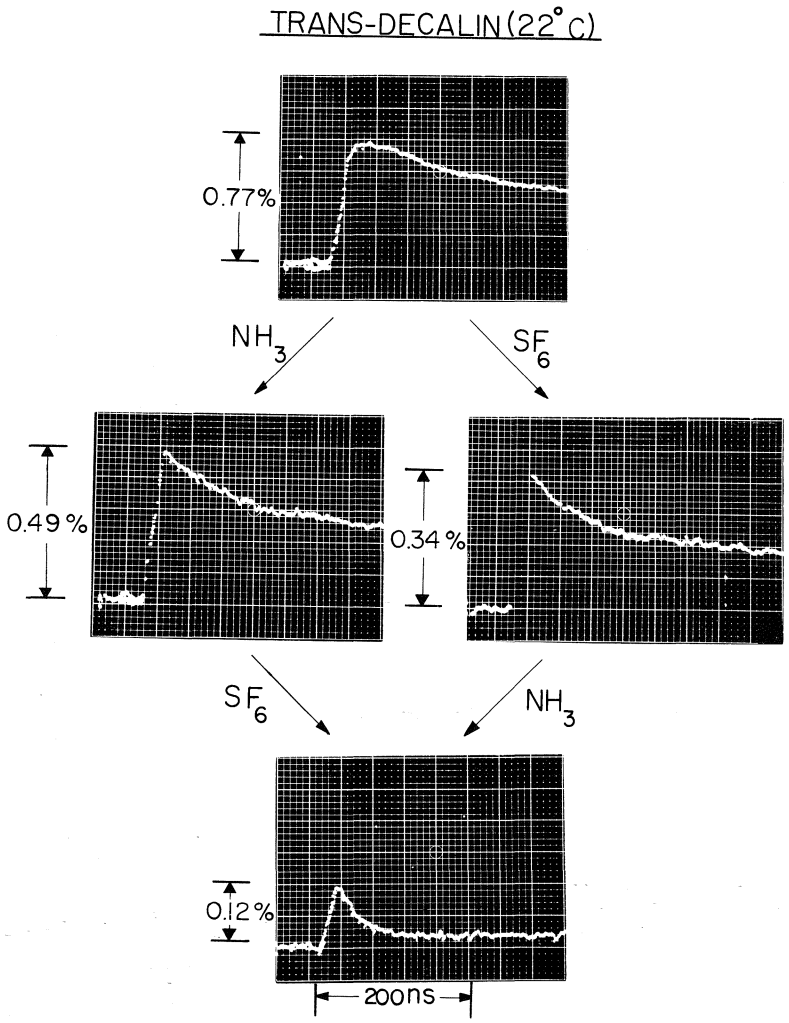


FIG. 1. Monitor traces of the absorption of microwave power resulting from pulse irradiation (20 ns, *ca.* 10 nC) of *trans*-decalin alone and containing 7×10^{-3} *M* NH_3 and 5×10^{-3} *M* SF_6 separately and combined, at 22°C.

tribution of geminate ions is therefore necessary and is presented below.

Decay Kinetics

(a) Pure Liquid

Estimates of the lifetime distribution of geminate ion pairs in irradiated liquid hydrocarbons have been derived from the concentration dependence of electron scavenging in these solvents using the Laplace transform method (6–9). If it is considered that one is dealing with single ion pairs then the WAS scavenging equation (10, 11) leads to the expression

$$[9] \quad F(t) = \exp [\lambda(+, -)t] \operatorname{erfc} [\lambda(+, -)t]^{1/2}$$

for the fraction of geminate ion pairs existing at a time t following an infinitely short pulse of irradiation. In [9], $\lambda(+, -)$ is a constant the reciprocal of which has the units of time and will subsequently be called the 'characteristic lifetime' of geminate ions. The value of $\lambda(+, -)$ can be determined if both the reactivity parameter α and the absolute rate constant k for scavenging of a primary ion by a given solute are known, via the relationship (8, 9)

$$[10] \quad \lambda(+, -) = k/\alpha$$

Based on [10], values of the characteristic lifetime in liquid cyclohexane of approximately 2×10^{-12} s (taking a geminate ion yield of 5.0 $(100\ \text{eV})^{-1}$) have recently been obtained

from measurements of the absolute rate constants of electron (12) and hole (13) scavenging together with the known reactivity values.

For times considerably longer than the characteristic lifetime [9] may be quite accurately approximated[2] by

$$[11] \qquad F(t) = [\pi\lambda(+, -)t]^{-1/2}$$

The observable yield of geminate ion pairs at a time t following a pulse of irradiation should therefore be $G_{gi}[\pi\lambda(+, -)t]^{-1/2}$, for $t \gg \lambda(+, -)^{-1}$. The parameter G_{gi} is an empirical constant in the WAS scavenging equation (10, 11) which, if this equation were known to be valid up to infinitely high solute concentrations, would be equal to the total yield of geminate ion pairs formed.

If the decay of free ions due to homogeneous recombination is negligible on the time scale of the observations then the time dependence of the total ion pair yield at long times following pulse irradiation will be given by

$$[12] \qquad G_i = G_{fi} + G_{gi}[\pi\lambda(+, -)t]^{-1/2}$$

(b) Secondary Ions

Equation [12] is the predicted time dependence of the ion pair yield in the pure solvent. It has been suggested (8, 9), however, that an equation of the same form as [12] may be applicable to recombination under conditions where either one or both of the primary ions has been converted into a secondary ion. This is based on the proposition that, for those ion pairs which have been scavenged, the time scale for geminate recombination will simply be extended compared with that in the pure liquid by a factor which is inversely proportional to the ratio of the total ion mobilities in the scavenged case to that in the pure liquid. For the case that both primary ions have been scavenged, $\lambda(+, -)$ in [12] should therefore be replaced by $\lambda(S^+, S^-)$ which is given by

$$[13] \qquad \lambda(S^+, S^-) = \frac{\mu(S^+, S^-)}{\mu(+, -)}\lambda(+, -)$$

from which the total yield of ion pairs is

$$[14] \qquad G_i = G_{fi} + G_{gi}[\pi\lambda(S^+, S^-)t]^{-1/2}$$

The assumptions on which the replacement of $\lambda(+, -)$ by $\lambda(S^+, S^-)$ are based are (*a*) the primary ion is scavenged on a time scale much shorter than its recombination time, (*b*) the initial separation distribution of the primary ions is not affected by the presence of the scavenger, and (*c*) the recombination time for both primary and secondary ions is dependent on the inverse first power of the mobility. These assumptions are at present being subjected to theoretical and experimental examination. The experimental results on the decay of secondary ions, obtained by optical pulse radiolysis studies (4, 5) and, as mentioned below, by the present method, are in fact found (9) to be described very well by a time dependence of the form given in [14].

For simplicity of presentation a parameter γ given by

$$[15] \qquad \gamma = (G_{gi}/G_{fi})^2/\lambda\pi$$

is introduced which on substitution in [14] leads to

$$[16] \qquad G_i = G_{fi}\{1 + [\gamma(S^+, S^-)/t]^{1/2}\}$$

As can be seen from [16], γ has the physical significance of being the time at which the contributions of free and geminate ion pairs to the total ion pair yield are equal, assuming no decay of free ions. This parameter will subsequently be called the 'equivalent lifetime' of geminate ion pairs.

Taking the sum of the mobilities of secondary ions to be independent of time[3] results in a predicted time dependence of the product of the yield of ion pairs and the total ion mobility given by

$$[17] \qquad G_i\mu = G_{fi}\mu(S^+, S^-)\{1 + [\gamma(S^+, S^-)/t]^{1/2}\}$$

According to [17], plots of $G_i\mu$ against $1/\sqrt{t}$ should be linear with an intercept equal to $G_{fi}\mu(S^+, S^-)$ and a slope to intercept ratio equal to the equivalent lifetime, $\gamma(S^+, S^-)$.

In Fig. 2 are shown plots of $G_i\mu$ *vs.* $t^{-1/2}$ for a solution containing 5×10^{-3} *M* SF_6 and 10^{-2} *M* benzene at -26, 38, and 108°C. The data

[2]The value of $F(t)$ calculated using [11] is larger than that obtained using [9] by 33%, 14%, and 4% for $\lambda t =$ 1, 3, and 10 respectively. Equation [11] is therefore accurate within 5% for $\lambda t > 10$.

[3]This assumption would appear to be reasonable in view of recent measurements (14) of secondary ion mobilities in isooctane and cyclohexane containing different solutes which showed the mobility to be independent of the solute present within the error limits of the measurements. This is taken to indicate that the mobility would remain unchanged even if the nature of a secondary ion should change due to further reactions occurring.

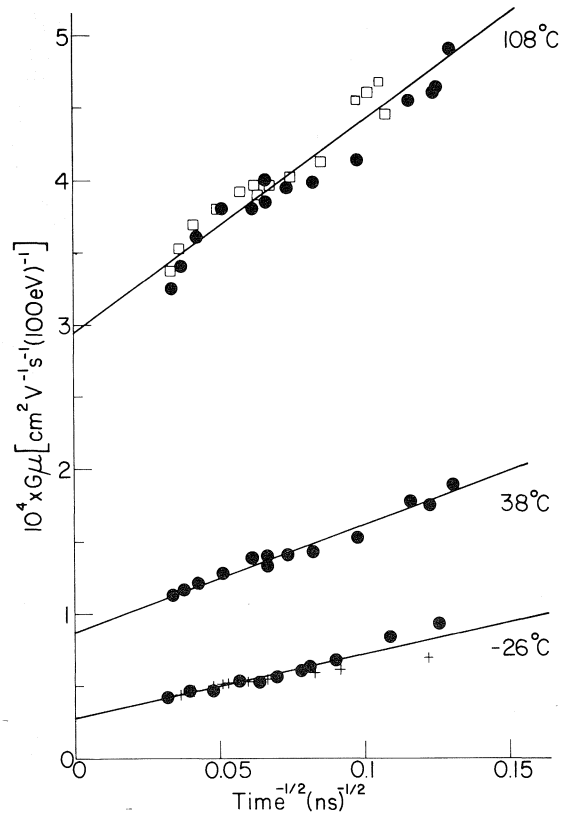

FIG. 2. Plots of the product of the ion pair yield, G (100 eV)$^{-1}$, and the total mobility, μ (cm^2 V^{-1} s^{-1}), against the reciprocal square root of the time for a solution of 1×10^{-2} M benzene plus 5×10^{-3} M SF_6 in *trans*-decalin at the temperatures shown. Pulse width used: □, 20 ns; ●, 50 ns; +, 250 ns.

plotted were taken over a time span from 50 ns to 1 μs from the end of the pulse and as can be seen obey the predicted reciprocal square root of time dependence very well. That no significant decay of free ions occurs over this time scale is shown by the independence of the $G_i\mu$ values on total dose (pulse length). The first half-life of free ions, for the results shown in Fig. 2, estimated using the Debye rate constant, is greater than 10 μs even for the highest conductivity measured.

The values of $\gamma(S^+, S^-)$ obtained from the plots in Fig. 2 and at other temperatures studied are listed in Table 1. Values of $\mu(S^+, S^-)$, obtained from the intercepts by dividing by the free ion yield (see below), are also listed in Table 1.

(c) High Mobility Primary Ions

The same treatment as that given above for secondary ions is usually not applicable to solutions containing a high mobility primary ion. This is due to a problem that frequently occurs which is that the primary ion reacts with impurities inadvertently present in the system. This results in a decrease in the total mobility as well as the yield of ion pairs with time.

In order to illustrate a data analysis procedure which may be carried out in such a case we take as an example the situation in which the electron is scavenged by a high concentration of SF_6 yielding a negative ion of mobility $\mu(S^-)$. If the hole which remains then reacts with an impurity to form a secondary ion of lower mobility, $\mu(S^+)$, the result will be a decrease in the total mobility of the charge carriers present with time according to

$$[18] \quad \mu = [\mu(+) - \mu(S^+)] \exp(-t/\tau) + \mu(S^+, S^-)$$

where τ is the mean lifetime for reaction with the impurity. If τ is considerably longer than the equivalent geminate ion lifetime $\gamma(+, S^-)$ then the total yield of ion pairs will be given by [16] with $\gamma(S^+, S^-)$ replaced by $\gamma(+, S^-)$, and hence the product $G_i\mu$ will be

$$[19] \quad G_i\mu = G_{fi}\{[\mu(+) - \mu(S^+)] \exp(-t/\tau) + \mu(S^+, S^-)\} \times \{1 + [\gamma(+, S^-)/t]^{1/2}\}$$

Rearrangement of [19] gives

$$[20] \quad \frac{G_i\mu}{1 + [\gamma(+, S^-)/t\,]^{1/2}} - G_{fi}\mu(S^+, S^-) = G_{fi}[\mu(+) - \mu(S^+)] \exp(-t/\tau)$$

If the correct value of $\gamma(+, S^-)$ is used then a linear dependence of the logarithm of the left-hand side of [20] on time should be observed with an intecept at $t = 0$ equal to the logarithm of $G_{fi}[\mu(+) - \mu(S^+)]$.

In order to arrive at the value of $\gamma(+, S^-)$ an iterative procedure is adopted. Thus, $\gamma(+, S^-)$ is initially taken to be equal to zero (corresponding to the assumption of the complete absence of geminate ions). A linear least-mean-squares fit to the variables ln $[G_i\mu - G_{fi}\mu(S^+, S^-)]$ and t, using the value of $G_{fi}\mu(S^+, S^-)$ determined as described above, is then carried out. This results in an initial (upper limit) value for $G_{fi}[\mu(+) - \mu(S^+)]$. This value may then be used to obtain a first estimate of $\gamma(+, S^-)$ from the value of $\gamma(S^+, S^-)$, determined as described above, using the relationship (derived from [13] and [15])

TABLE 1. The temperature dependence in liquid *trans*-decalin of the equivalent lifetime (see text for definition) of geminate ion pairs in a SF_6 benzene solution; the free ion yield; the total mobility in a SF_6 benzene solution; the hole mobility; and the excess electron mobility

T (°C)	$\gamma(S^+, S^-)$ (ns)	G_{fi} $(100\ eV)^{-1}$	$\mu(S^+, S^-)$ $(10^{-4}\ cm^2\ V^{-1}\ s^{-1})$	$\mu(+)$ $(10^{-3}\ cm^2\ V^{-1}\ s^{-1})$	$\mu(-)$ $(10^{-3}\ cm^2\ V^{-1}\ s^{-1})$
108	25	0.261	10.8	7.7	71
82	45	0.215	9.6	7.9	39
56	68	0.169	6.8	7.2	28
38	75	0.143	5.8	8.8	15
22	144	0.121	5.2	9.0	13
2	146	0.096	4.8	10.2	7
−15	174	0.076	3.8	8.2	3.2
−26	303	0.066	3.8	14.4	3.5

$$[21]\quad \gamma(+, S^-) = \gamma(S^+, S^-)\frac{\mu(S^+, S^-)}{\mu(+, S^-)}$$

$$[22]\quad = \frac{\gamma(S^+, S^-)}{1 + G_{fi}[\mu(+) - \mu(S^+)]/G_{fi}\mu(S^+, S^-)}$$

The value of $\gamma(+, S^-)$ so obtained is then used to obtain a second value of $G_{fi}[\mu(+) - \mu(S^+)]$ from a fit to the variables $\ln\{G_i\mu/(1 + [\gamma(+, S^-)/t]^{1/2}) - G_{fi}\mu(S^+, S^-)\}$ and t, and hence a second estimate of $\gamma(+, S^-)$. This iterative procedure was in the present case repeated until the value of $G_{fi}[\mu(+) - \mu(S^+)]$ obtained differed by less than 5% from the previous value. This required only three or four iterations in all cases. To illustrate the effects of this treatment on the raw data, in Fig. 3 are shown semilogarithmic plots against time of $G_i\mu$, $G_i\mu - G_{fi}\mu(S^+, S^-)$ and the left-hand side of [20] for a $5 \times 10^{-3}\ M$ SF_6 solution at 22°C. As can be seen, a good straight line semilogarithmic plot is found using the final value of $\gamma(+, S^-)$ obtained.

Values of the hole mobility were derived from the final value obtained for $G_{fi}[\mu(+) - \mu(S^+)]$ by dividing by the value of G_{fi} (see below) and then adding one half of the value determined for $\mu(S^+, S^-)$. The latter operation assumes that the mobilities of the secondary positive and negative ions are the same. This has, in fact, in certain cases been found (14) not to be so. However, since the correction is small, it is considered to be a satisfactory approximation for the present purposes. The values of $\mu(+)$ derived at different temperatures are listed in Table 1.

Of some interest is the magnitude of the value of $G_{fi}\mu(+)$ obtained after correction compared with the end-of-pulse value of $G_i\mu$. In the case of the $5 \times 10^{-3}\ M$ SF_6 solution the ratio of $G_i\mu$ at end-of-pulse to $G_{fi}\mu(+)$ was found to vary from 2.0 to 1.7 in going from −26°C to 108°C thus indicating an approximately equal yield of geminate and free ion pairs at end-of-pulse.

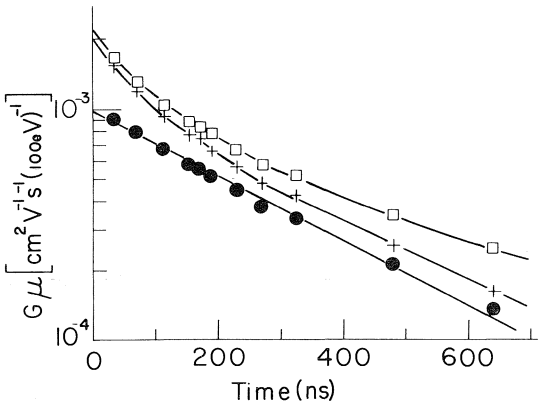

FIG. 3. Illustration of the effect on the raw data of corrections for the presence of secondary ions and geminate ion pairs following pulse irradiation (20 ns) of a $5 \times 10^{-3}\ M$ solution of SF_6 in *trans*-decalin at 22°C: □, experimental $G\mu$ values; +, $G\mu - G_{fi}\mu(S^+, S^-)$; ●, $[G\mu/(1 + [\gamma(+, S^-)/t]^{1/2}) - G_{fi}\mu(S^+, S^-)]$ calculated using the final value of $\gamma(+, S^-)$ obtained by the iterative procedure described in the text.

The same treatment as described above was carried out for solutions containing $7 \times 10^{-3}\ M$ NH_3 in which the excess electron is the primary charge carrier. The values of $\mu(-)$ so obtained are listed in Table 1. As opposed to the rather small change with temperature found for the ratio of $G_i\mu$ end-of-pulse to $G_{fi}\mu(+)$, in the case of the electron the equivalent ratio was found to decrease from 4.6 (*ca.* 80% contribution of geminate ions) at −26°C to 1.2 (*ca.* 20% geminate ion contribution) at 108°C.

The Free Ion Yield

A value of $G_{fi} = 0.04 \pm 0.01$ (100 eV)$^{-1}$ is to be found in the literature; however, in the same article the value of G_{fi} for cyclohexane is given as 0.06 (100 eV)$^{-1}$ which is much lower than the recent values in the range 0.15 to 0.2 (15–17). Since no recent values could be found for decalin we measured this quantity by the method (18, 19) of extrapolating to zero concentration a plot of the methane yield from a methylbromide solution against the square root of the methylbromide concentration. The value obtained was $G_{fi} = 0.12$ (100 eV)$^{-1}$. Using exactly the same method and apparatus we obtained a value of $G_{fi} = 0.15$ (100 eV)$^{-1}$ for cyclohexane which is in good agreement with recently reported values.

Taking a Gaussian form for the distribution function of ion pair separation distances results in the following relationship (15) between the free ion yield and the Gaussian distribution parameter b:

$$[23] \quad G_{fi} = G_{tot} \int_0^{\infty} \frac{4r^2}{\pi^{1/2}b^3} \times \exp\left(-\frac{r^2}{b^2} - \frac{r_c}{r}\right) dr$$

In [23], G_{tot} is the total ion pair yield, taken to be 4.3 (100 eV)$^{-1}$ (15), and $r_c = e^2/\varepsilon_r kT$ is the Onsager escape distance. From the measured free ion yield of 0.12, the value of the product $b\rho$ where ρ is the density of the liquid is found to be 50 Å g cm^{-3} for *trans*-decalin. It has been found (15–17), for the vast majority of liquids studied, that when free ion yield data are analysed using [23] with a constant (temperature independent) value for G_{tot}, then temperature independent values of $b\rho$ are derived, within the temperature range used in the present work. This finding may therefore be used quite empirically, independent of whether or not one accepts the constancy of G_{tot} or a Gaussian range distribution, to calculate G_{fi} values at different temperatures if the relevant value of $b\rho$ is known. The values of G_{fi} for *trans*-decalin at temperatures other than 22°C, listed in Table 1, were therefore calculated using [23] and the above value of $b\rho$ together with the known variation of ε_r and ρ with temperature (20).

Mobilities

As can be seen from the data in Table 1 the electron mobility in *trans*-decalin increases markedly with temperature. As has been found for other liquids, $\mu(-)$ is found to be quite well described by an equation of the form

$$[24] \quad \mu = A \exp(-B/RT)$$

with $A = 25$ cm^2 V^{-1} s^{-1} and $B = 4.5 \pm 0.3$ kcal mol^{-1}. The latter value is similar to that found for the activation energy of the excess electron mobility in other low (<0.1 cm^2 V^{-1} s^{-1}) mobility hydrocarbon liquids (16, 17).

As opposed to the strong temperature dependence of the electron mobility, that of the hole is seen to change very little over the almost 140°C temperature range studied. A slight decrease with increasing temperature is in fact indicated. In terms of [24] values of $A = 4.0 \times 10^{-3}$ cm^2 V^{-1} s^{-1} and $B = -0.5 \pm 0.3$ kcal mol^{-1} are found to give a best fit to the data. This lack of a significant temperature dependence of $\mu(+)$ has also been found in cyclohexane (3). The data previously reported for cyclohexane were not subjected to a correction for the presence of geminate ion pairs. When this is carried out the value of $\mu(+)$ at room temperature in cyclohexane is found to be 0.95×10^{-2} cm^2 V^{-1} s^{-1} (as opposed to the 1.6×10^{-2} cm^2 V^{-1} s^{-1} previously reported) which is close to that found in the present work for *trans*-decalin.

Of particular interest in the present results, as is shown by the data in Table 1, is that at low temperatures the mobility of the hole actually exceeds that of the electron. If the very low activation energies found for hole mobilities in cyclohexane and *trans*-decalin may be taken to represent the general case then a transition from the electron to the hole as major charge carrier would in fact be expected to occur in any liquid displaying a high hole mobility if the temperature could be lowered sufficiently.

The value of the sum of the slow ion mobilities of 5.2×10^{-4} cm^2 V^{-1} s^{-1} at 22°C is in the order of what would be expected for this liquid (viscosity 2.06 cP). Thus, from recent drift-time measurements (14) of secondary ion mobilities in cyclohexane (viscosity 0.93), the sum of the positive and negative ion mobilities has been found to be 7.8×10^{-4} cm^2 V^{-1} s^{-1}. If a simple linear dependence of mobility on fluidity (reciprocal viscosity) were assumed then from this result in cyclohexane a value of $\mu(S^+, S^-)$ of 3.5×10^{-4} cm^2 V^{-1} s^{-1} would be predicted for *trans*-decalin.

Further aspects of the present results such as the relevance of the parameter $\gamma(S^+, S^-)$ and the nature of displacement of the hole will be discussed in future publications.

Discussion

L. G. Christophorou: Are the changes in your conductivity sensitive enough to the masses of the ions for your system to function, basically, as a liquid-state mass spectrometer?

J. M. Warman: We find, unfortunately perhaps, that the sum of the mobilities of molecular positive and negative ions in the liquids studied are very insensitive to the nature (including the mass) of the ions, *i.e.* that the total mobility of the ions is independent of the solutes used to scavenge the electron and hole.

G. R. Freeman: You referred to geminate neutralization in the solutions. Was the scavenger concentration high enough that you would not see the tail of the reaction of scavenger with the free ions?

J. M. Warman: Yes. For example in liquid cyclohexane the SF_6 concentration was 3×10^{-3} *M*, which using a rate constant for electron scavenging of 4×10^{12} M^{-1} s^{-1} corresponds to an electron lifetime of 0.1 ns. This is sufficiently short to ensure that no electrons are present within 10 ns following the pulse.

W. F. Schmidt: How do you correct for a dose rate drop in your sample since you are using 3 MeV electrons as ionizing agent?

J. M. Warman: We carried out our dosimetry by measuring the absorption of the solvated electron in a 10^{-2} *M* NaOH – 1 *M* EtOH solution in water using a He/Ne laser as light source. The cell used for dosimetry was identical to that used in the microwave experiments, but with optical (glass) windows at both ends. By use of the laser we measured the absorbed dose as a function of depth and breadth of the sample. The largest variation was an approximately 40% decrease in going from the top of the cell to the bottom for a 0.8 g cm^{-3} density medium. The absorbed dose was corrected for variations in dose within the cell by averaging over the field intensity of the microwave standing wave pattern.

W. F. Schmidt: Isn't there the possibility that more than one kind of positive charge carriers are formed?

J. M. Warman: This is a possibility which is often voiced. The principal evidence that in cyclohexane > 80% of the positive ions are the parent ions comes from optical absorption studies of the rapid formation of solute positive ions formed by the reaction, $RH^+ + S \rightarrow RH + S^+$. Thus the *G* values found for $TMPD^+$ formation immediately at the end of a 10 ns pulse, for a TMPD concentration of 10^{-4} *M*, is close to the value of the free ion yield in this liquid (0.16 $(100\,eV)^{-1}$), as would be expected if all positive ions were the parent.

Y. Hatano: Did you confirm experimentally the effect of the microwave power on the final signal intensity? I would like to know the input microwave power and the cavity *Q* value which you are using.

J. M. Warman: The microwave power levels we use are on the order of 100 mW, which in a medium of dielectric constant 2 corresponds to a field strength (maximum) of about 2 or 3 V/cm. The *Q*'s of the cavities we use are usually on the order of 400. In the cavity experiments the field strength is considerably larger than in normal reflection experiments, but we obtain identical results for $G\mu$ values where we have obtained them using both methods. This confirms the lack of a field strength (power) effect, as would be expected in molecular liquids for which field effects on electron mobilities are found to occur only above field strengths of 10^3 V/cm.

Metallic condensation of Wannier–Mott impurity states in lithium–hexamethylphosphoramide glasses

A metal to non-metal (MNM) transition observed in frozen solutions of lithium in hexamethylphosphoramide (HMPA) was tentatively interpreted as a Mott transition in which localized Wannier-type impurity states were the source of electrons in the metallic state. In this paper this assertion is examined in greater detail by calculating critical densities (n_c) on the basis of a scaled (variational) form of Mott's original criterion for the onset of localization in a dielectrically screened Coulomb potential, and also on the basis of the Hubbard tight-binding model. Mott's model for the transition is based upon the screening properties of a freely propagating gas of metallic electrons. In the Hubbard regime, however, the phenomenon is viewed from the tight-binding limit; the transition from localized to delocalized states occurs when the bandwidth (Δ) of a regular lattice of isolated centres exceeds the value of the intra-atomic Coulombic repulsion integral (U) associated with electron correlation.

Both electron-gas (Mott) and tight-binding (Hubbard) approaches give calculated critical densities (5.6×10^{18}, 3.2×10^{18} cm^{-3}, respectively) in good agreement with the experimental value ($\sim 3 \times 10^{18}$ cm^{-3}). These results therefore support the earlier suggestion that the MNM transition in frozen lithium–HMPA solutions is a Mott-transition associated with electron-interaction effects.

PETER P. EDWARDS et RON CATTERALL. Can. J. Chem. **55**, 2258 (1977).

On a interprété d'une façon non-définitive une transition métal à non-métal (MNM) observée dans des solutions congelées de lithium dans l'hexaméthylphosphoramide (HMPA) comme une transition de Mott dans laquelle des états d'impuretés du type Wannier localisés sont les sources d'électrons de l'état métallique. Dans cette communication on examine cette affirmation en détail en calculant les densités critiques (n_c) sur la base d'une forme échelonnée (variationnelle) du critère original de Mott pour le début de la localisation dans un potentiel de Coulomb qui est masqué d'une façon diélectrique et aussi sur la base du modèle d'attachement intime de Hubbard. Le modèle de Mott pour la transition est basé sur les propriétés de blindage d'un gaz d'électrons métalliques se propageant librement. Dans le régime de Hubbard, toutefois, on conçoit le phénomène à partir de la limite de l'attachement intime; la transition des états localisés vers les états délocalisés se produit quand la largeur de bande (Δ) d'un réseau régulier de centres isolés excède la valeur de l'intégrale de répulsion Coulombique intra-atomique (U) associée avec la corrélation d'électron.

Les approches d'électron-gaz (Mott) et d'association intime (Hubbard) conduisent respectivement à des densités critiques calculées de 5.6×10^{18} et 3.2×10^{18} cm^{-3}, en bon accord avec la valeur expérimentale qui est approximativement 3×10^{18} cm^{-3}. Ce résultat supporte donc la suggestion antérieure à l'effet que les transitions MNM dans des solutions congelées de lithium dans HMPA sont des transitions de Mott associées avec des effets d'interactions des électrons.

[Traduit par le journal]

Introduction

At the recent Colloque Weyl IV we have reported the observation of a metal–nonmetal (MNM) transition in frozen solutions of lithium in HMPA (1). The transition was found at a metal concentration of the order of $5 \times 10^{-3}\ M$ ($\sim 3 \times 10^{18}$ cm^{-3}). A cursory examination of the results suggested that the transition was of the Mott–Hubbard type, originating in electron-correlation effects. The purpose of this paper is to calculate explicitly the critical concentration for the MNM transi-

[1]This research sponsored by the National Science Foundation under Grant No. MPS 74-21480.

[2]British Fulbright Scholar, 1975–1977.

tion in this system using both the Mott and Hubbard models for the transition.

In the calculations to be outlined below, we have assumed that the system approximates a uniform, homogeneous material; that is, it is devoid of large (bimodal) concentration fluctuations and associated inhomogeneities (2, 3). We have previously reported the simultaneous observation of both delocalized (metallic) and localized (insulating) states in frozen solutions of potassium, rubidium, and cesium in HMPA (1), indicating large concentration inhomogeneities in these low-temperature glasses. In these systems (at least on the macroscopic scale[3]) the possibility of a Mott–Hubbard type transition would appear to be ruled out (4) and a realistic approach would presumably be to interpret the transition in terms of a threshold for continuous percolation (2, 3). However, in frozen lithium–HMPA solutions we have found no evidence for large scale inhomogeneities for the concentration range *ca.* 10^{-4} to 0.1 *M*. We suppose, therefore, that the concept of a Mott transition in this homogeneous system represents a good working hypothesis, and in this paper we calculate critical donor (lithium atom) concentrations.

A Scaled (Variational) Form of the Mott Criterion for the Homogeneous Regime

Mott (5–7) proposed that a MNM transition will take place when an itinerant (metallic) electron becomes localized on a specific centre. The model was originally developed with particular reference to (*i*) a dielectrically screened Coulomb potential for the long range electron–hole interaction and (*ii*) Thomas–Fermi screening by the free electrons. The critical concentration of donors (n_c) is then given (5–7) by

$$[1] \qquad n_c^{1/3} a_H \simeq 0.25$$

Here a_H is the ground state Bohr radius of the lowest localized state with a one-electron wavefunction

$$[2a] \qquad \psi(r) = \{1/(\pi a_H^3)^{1/2}\} \exp(-r/a_H)$$

where

$$[2b] \qquad a_H = \hbar^2 K_{st}/m^* e^2$$

and K_{st} is the static (low-frequency) dielectric constant of the host material and m^* the electron effective mass.

The idea of a *true* Coulomb potential is appropriate only for localized states in which there exists considerable overlap between the donor wavefunction and the electronic wavefunction of the surrounding matrix (8, 9). The electron – parent core interaction is then screened by the low-frequency dielectric constant and the resulting donor levels are truly hydrogenic (9).

Berggren and Lindell (10) have questioned the *direct* use of the Mott criterion in the form [1] for systems other than the high dielectric, large Bohr radius states (of which the doped group IV semiconductors are good examples). They (10) have proposed a modification to the Mott criterion in the form of a simple scaling relation;

$$[3] \qquad n_c^{1/3}(a_H/\gamma) = 0.25$$

where γ is a parameter defined such that the ratio ($a_H/\gamma = a^*$) defines an *appropriate* radius associated with a realistic wavefunction (not necessarily of the type [2*a*] for the isolated centres. Thus, the basis of the present approach is somewhat different from previous attempts at applying the Mott criterion to the MNM transition in metal–ammonia (11, 12) and related (13) systems.

One attractive feature of this scaled form of the Mott criterion is that it allows an independent determination of the radius a^* from *experimental* parameters which characterize the localized state.[4]

A possible criticism of this approach is that the constant in [3] will be sensitive to the particular nature of the donor wavefunction and the choice of the screening potential for the electron gas (14). One purpose of this paper is to show that the scaled criterion [3] may be applied to many experimental systems exhibiting a MNM transition; ranging from the tight binding (Frenkel) states in the rare gas solids (15) (with $a^* \sim 2$ Å) to shallow impurity states in germanium (16) (with $a^* \sim 46$ Å), with good agreement between calculated and experimental critical densities. In Table 1 we have assembled some representative experimental

[3]However, the arguments developed here could also be applied to regions in a microscopically inhomogeneous material which are smaller than the Debye correlation length for concentration fluctuations (2).

[4]In the past, it has been customary to attempt to apply the Mott criterion to non-Coulombic isolated donor states by replacing the low frequency dielectric constant by an arbitrary value reflecting some weighted average of high and low frequency values (see refs. 11–13).

TABLE 1. Critical densities for electron localization on the basis of scaled form of the Mott criterion

System	Nature of isolated centre	$\{a_H/\gamma\} = a^*/Å$	n_c/cm^{-3} Calculated (eq. 3)	n_c/cm^{-3} Observed

[b]Reference 33.
[c]Obtained by fitting optical ($1s \rightarrow 2p$) transition of the isolated (localized) centre to Jortner's polaron model (33).
[d]Characteristic Bohr radii (a^*) for the doped group IV semiconductors were estimated from two approaches: (*a*) The Coulomb result $a^* = e^2/2K_{st}E_{expt}$ where E_{expt} is the experimental (18) ionization energy for the isolated donor state, and (*b*) the quantum defect approach (cited in ref. 25) $a^* = a_H(E_{EM}/E_{expt})$; where a_H and E_{EM} are taken from ref. 18. Values shown in the table are the average of these two values, together with associated error estimates.

values for characteristic Bohr radii (a^*), associated critical concentration (calculated from [3]), and corresponding experimental concentrations of a variety of systems showing a MNM transition. It appears, therefore, that the simple scaled form of the Mott criterion may be applicable to many experimental situations in which the isolated donor potential is not necessarily truly Coulombic.

For the lithium–HMPA system we can obtain an experimental estimate for a^* from the magnetic properties of the isolated centres (1). The isolated donor states in frozen lithium–HMPA solutions closely approximate (1) true Wannier–Mott impurity states in an amorphous medium (9). On the Kohn–Luttinger effective mass (EM) theory (17, 18) the wavefunction of the isolated donor states is constructed mainly from Bloch waves near the bottom of the (host) conduction band. The wavefunction for the lowest energy states is then

$$[4] \qquad \psi(\boldsymbol{r})_{EM} = \sum_{j=1}^{N} \alpha_j F_j(\boldsymbol{r})\phi_j(\boldsymbol{r})$$

where N is the number of conduction band minima in k-space, α_j are numerical coefficients of the appropriate linear combinations of $F_j(\boldsymbol{r})\phi_j(\boldsymbol{r})$, $\phi_j(\boldsymbol{r})$ is the Bloch wave at the jth minima, and the functions $F_j(\boldsymbol{r})$ are hydrogen-like envelope functions similar to those given previously (eq. 2*a*).

$$[5] \qquad F_j(\boldsymbol{r}) = 1/(\pi a_H^3)^{1/2} \exp(-r/a_H)$$

where a_H is given by [2*b*]. Setting $r = 0$ and squaring [5], we have an expression for the unpaired electron spin density at the donor (lithium) nucleus;

$$[6] \qquad |\psi(0)|_{EM}^2 = N|\phi_j(0)|^2|F_j(0)|^2$$

where

$$[7] \qquad |F_j(0)|^2 = 1/\pi a_H^3$$

A slightly different form of [6], first proposed by Kohn (18), allows for possible *minor* deviations from effective mass theory arising from the breakdown of the Coulomb potential in the vicinity of the impurity. On this 'corrected' effective mass (CEM) theory we have (18)

$$[8] \qquad |\psi(0)|_{CEM}^2 = |\psi(0)|_{EM}^2 K$$

where K, the Kohn enhancement factor, represents a measure of the deviation from effective mass formalism. Detailed discussions of K, and its estimation, are presented elsewhere (1, 18). For Li–HMPA we expect (9) negligible deviations from the effective mass theory.[5] For Wannier-type impurity states in lithium–HMPA glasses we have estimated (1) $K \simeq 1.4$ (*cf.* 9.8

[5]Observed unpaired electron spin densities at the alkali nucleus (9) for Wannier–Mott (alkali) impurity states in the M–HMPA glasses are independent of the donor atom. This invariance is predicted by the effective mass theory (eq. 6).

for P:Si (18)), and setting $|\phi_j(0)|^2 = 100$ and $|\psi(0)|^2$(observed) $= 0.061 \times 10^{24}$ cm^{-3} (1) we find $a_H = 14.1$ Å from [6] and [8].

In this particular instance, the form of the isolated donor potential approximates closely the Coulombic potential (1, 9) and we expect $\gamma \sim 1$ and $a^* \sim a_H$. Although the ground state wavefunction for Wannier-type impurity states (eq. 4) differs markedly from the single hydrogenic form over large distances [4], it is dominated by the hydrogenic terms F_j which have a characteristic radius of the magnitude of the Bohr radius a_H (eq. 2*b*).

Substituting for $a^* = 14.1$ Å in the scaled criterion [3] gives a critical donor concentration of 5.6×10^{18} cm^{-3}, in good agreement with the experimental value $\sim 3 \times 10^{18}$ cm^{-3}.

Critical Concentration from the Hubbard (Tight-binding) Model for the Homogeneous Regime

On Mott's model (5–7) the MNM transition occurs when a dielectrically-screened Coulomb (or other) potential starts to give rise to bound states. The Hubbard formulation (19), however, originates in the tight-binding (isolated-donor) limit. It prescribes a transition from the insulating to the metallic state when

$$[9] \qquad \{\Delta/U\} = \text{constant}$$

Here Δ is the unperturbed bandwidth of a regular array of centres and U is the intradonor repulsion energy associated with electron correlation. The magnitude of the constant in [9] depends upon the approximations inherent in any particular interpretation of the Hubbard model (20, 21), but typically it is of the order 1.0 to 1.5.

Berggren (21) has applied the Hubbard tight-binding model to an analysis of the MNM transition in shallow donor states in silicon and germanium. As in the lithium–HMPA system, the isolated donor states in these semiconductors are described by the Kohn–Luttinger effective mass theory (eqs. 4 to 8). When the host conduction band is isotropic,[6] the envelope function is given by [5] and the unperturbed bandwidth is then

$$[10] \qquad \Delta = 2z|T|$$

where z is a co-ordination number of donor states around a given centre and T is the hopping integral between two adjacent orbitals

$$[11] \quad T = \frac{e^2}{K_{st}a^*}\{-\tfrac{1}{2}S - [R/a^* + 1] \times \exp(-R/a^*)\}/\sqrt{N}$$

The overlap integral, S, is given by (21)

$$[12] \quad S = \{1 + (R/a^*) + \tfrac{1}{3}(R/a^*)^2\} \times \exp(-R/a^*)$$

where R is the distance between donors and N is the number of conduction band minima.

Utilising earlier results of Miller and Abrahams (23), Berggren (21) has obtained an expression for the intradonor repulsion energy,

$$[13] \qquad U = \tfrac{5}{8}(e^2/K_{st}a^*)$$

representing the electrostatic energy between two hydrogenic centres with orbital exponents $(1/a^*)$.

Hubbard's original estimate of the constant in [9] was 1.15, but more recent values range from 1.0 to 1.5 (20, 21). However, in the region of the MNM transition the bandwidth changes rapidly over a relatively narrow concentration range and the computed critical density is not particularly sensitive to the exact value of (Δ/U), *as long as it is close to unity* (21). We take Hubbard's value (19) of 1.15 for the value of (Δ/U) at the MNM transition, and for the particular case of Wannier-type donor states in Li–HMPA solutions, we estimate $n_c = 3.2 \times 10^{18}$ cm^{-3} in excellent agreement with the experimental value.

As yet, we have not specified what value of the dielectric constant is appropriate in [11] and [13]. In fact, having specified an appropriate (experimental) Bohr radius (a^*) for the donor state (see previous section), a particular choice of the dielectric constant is unnecessary. For a given value of the impurity Bohr radius, both the unperturbed bandwidth (Δ) and the repulsion energy (U) are inversely proportional to the dielectric constant (see [10] and [13]), but the Hubbard ratio (Δ/U), and therefore the critical donor concentration, is independent of the dielectric constant. This particular aspect gives some insight into the role played by the host matrix in the MNM transition.

[6]We feel this is a reasonable assumption for HMPA for the following reasons: (*i*) the experimental observation (9) of true Wannier–Mott impurity states in alkali metal – HMPA glasses requires that electrons in the host (HMPA) conduction band are free-electron-like (see ref. 31); (*ii*) the energy V_0 of the quasi-free electron state in HMPA has been estimated (22) as $-1.9 < V_0 < 0.3$ eV; based on the Wigner–Seitz model for the quasi-free electron state (32).

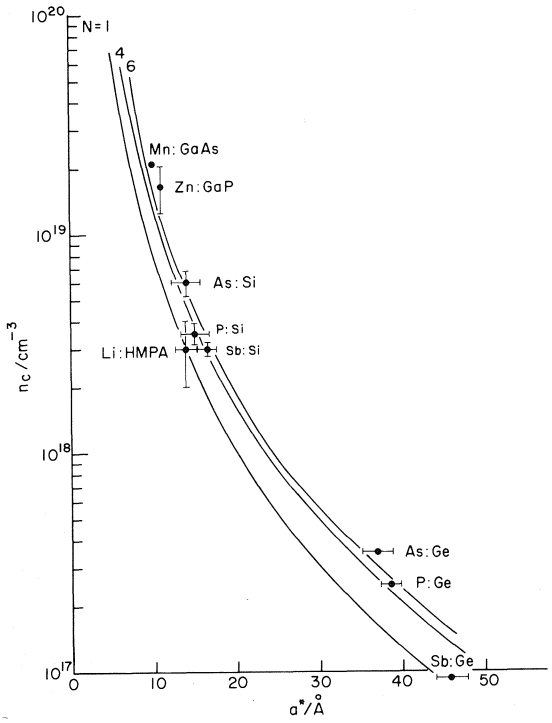

FIG. 1. The MNM transition in Wannier-like impurity states. The solid lines represent the predicted variation of n_c with a^* for Wannier-like states constructed predominantly of Bloch states from the host (matrix) conduction band. Curves are presented for conduction band with 1, 4, and 6 equivalent minima in k-space. The method of calculation based on Berggren's (21) interpretation of the Hubbard Hamiltonian (19), is described in the text. The points, and associated error bounds, are experimental values. No error estimates for n_c (experimental) are available for Mn:GaAs and for group V donors in germanium. For the group V donors in silicon and germanium characteristic radii were determined by the two methods described in the footnote [d] of Table 1. Experimental parameters for acceptor states in GaAs and GaP were taken from refs. 26 and 27.

Low dielectric systems (for example, the rare-gas solids (15)), produce only a small perturbation on the isolated (free) atom eigenstates of the donor, and the matrix-bound states have wavefunctions only slightly expanded relative to their gas-phase counterparts (8). On the other hand, high dielectric systems (for example, Si and Ge (16)) produce significant shielding of the electron – parent core interaction and a correspondingly large Bohr radius for the donor state (9). However, once these modifications to the donor state by the host matrix are taken into account, the subsequent phenomenon of the MNM transition (at finite donor concentrations) reduces to a hydrogen-like problem of competing kinetic and potential energy effects (24) *but with the reference (concentration) axis suitably 'displaced'*.

On this basis, we expect the expressions [9] to [13] to be directly applicable to all systems in which the localized (insulating) states are described in terms of the effective-mass theory.[7] We have computed critical densities for the MNM transition as a function of the Bohr radius (a^*) of the isolated donor states averaged over the three possible configurations of donors. The results of the numerical calculations are compared with experimentally determined values in Fig. 1 for both donor and acceptor states in various matrices.

For materials differing widely in dielectric properties we find good agreement between the experimental results and the predicted variation of n_c with a^*. The slight deviations from the predicted behavior probably arise from our use of an isotropic model for all the various systems; for silicon and germanium, in particular, this must be regarded as only a first approximation in view of the anisotropic nature of the conduction band in these materials (18).

Conclusions

In the preceding sections we have examined two particular models for the MNM transition in lithium–HMPA glasses. Both the Mott (electron-gas) and Hubbard (tight-binding) models predict similar critical concentrations in good agreement with the experimental values, arguing strongly that the transition is indeed driven by electron correlation effects (1) of the Mott–Hubbard type.

The general similarity in predictions for the two models has been recognised for some time (28, 29). In the present context, it follows naturally from the particular formulation (21) of the Hubbard model. The occurrence of a common factor $(e^2/K_{st}a^*)$ in the expressions for both the unperturbed bandwidth (via [11]) and the intradonor repulsion energy (eq. 13) requires that the critical concentration be determined by the dimensionless quantity

[7]In fact, these arguments could possibly be expanded to encompass all manner of matrix-bound states (from Frenkel to Wannier-like states) since the expressions derived by Berggren (21) are essentially hydrogenic (see also Brandow (24)), relating only to bandwidth and repulsion energies for s-like states.

$(R/a^*) \propto (1/n^{1/3}a^*)$, as in the scaled Mott criterion (eq. 3).

Jortner and Cohen (2) have recently proposed that in the absence of bimodal inhomogeneities (*i.e.* at temperatures sufficiently above the consolute temperature) the MNM transition in lithium– and sodium–ammonia solutions is a Mott transition. In addition, Toma *et al.* (13) have tentatively interpreted their recent transport measurements on fluid lithium–methylamine solutions in terms of electron-correlation effects of the Mott–Hubbard type. In the lithium–methylamine system there is experimental evidence (30) to suggest that microscopic inhomogeneities are negligible in the transition region.

It appears, therefore, that for metal solutions in which the only inhomogeneities are the normal, unimodally distributed fluctuations, the MNM transition is a Mott–Hubbard transition.

On a more general theme, we have indicated that both the scaled Mott criterion and the Hubbard model for the MNM transition possess a certain universality which allows their application to a wide range of experimental systems.

Discussion

M. H. Cohen: In the Hubbard criteria you used, the interaction should have been the intra-atomic Coulomb interaction between two electrons of opposite spin in the same 'hydrogenic' orbital. You used instead the Coulomb interaction between two electrons on neighboring sites. The criterion for the M–NM transition based on that interaction is not known in three dimensions. On dimensional grounds it must be of the same form ($T/U \propto$ constant) as that you used. However, the numerical value is unknown, and the coordination number may be associated with U as well as T. Nevertheless, your results are very interesting and quite impressive.

Electron mobilities in alkanes through the liquid and critical regions[1]

JEAN-POL DODELET AND GORDON R. FREEMAN
University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 4, 1976

JEAN-POL DODELET and GORDON R. FREEMAN. Can. J. Chem. **55**, 2264 (1977).

Three properties of electrons in liquids are governed by scattering at low energies and show similar dependence upon liquid density and molecular shape. They are the mobility, the dependence of the mobility upon electric field strength, and the penetration range of low energy (< 10 eV) electrons. The scattering cross sections of hydrocarbons in the liquid phase (near or below the normal boiling point) are smaller when the molecules are more sphere-like. The degree of sphericity of the molecules in the present series decreases in the order 2,2-dimethylpropane (DMPr) > 2,2-dimethylbutane (DMB) > cyclopentane (cP) > *n*-pentane (nP).

Electron mobilities in DMPr and DMB measured as functions of the liquid density pass through maxima similar to those observed earlier in argon and xenon. The magnitudes of the maxima decrease in the order Xe > Ar > DMPr > DMB. The maxima occur at densities approximately double the critical density d_c. There is a small maximum for electrons in cP, but none for those in nP.

The mobilities in the supercritical gases are similar for the four compounds. The Arrhenius temperature coefficients are all 7–10 kcal/mol (0.3–0.4 eV/electron) for temperatures and densities near the critical values. This implies that electrons form localized states in the gases. The extent of localization in supercritical DMPr appears to be greater than that in the normal liquid. The localization is not the critical phenomenon predicted by Lekner.

The mobility in liquid DMPr decreases at high electric field strengths. The magnitude of the field dependence changes with the liquid density and passes through a maximum similar to that of the mobility itself. The field dependence in liquid DMB is smaller than that in DMPr, but it also passes through a maximum at a density about double d_c.

Equations are given that describe the mobility in nP at all temperatures from the triple point through to the supercritical gas. The electrons reside mainly in localized states over the entire temperature range, but transport occurs mainly in extended states to which the electrons are thermally excited.

The penetration range parameter b_{GP} of secondary electrons in these liquids is normalized for comparison by multiplying by the liquid density d. The values of $b_{GP}d$ plotted against d form curves similar in shape to the μ against d curves, but the relative variations in $b_{GP}d$ are much smaller.

JEAN-POL DODELET et GORDON R. FREEMAN. Can. J. Chem. **55**, 2264 (1977).

La mobilité des électrons dans un milieu constitue un outil très sensible pour déterminer la diffusion et le transfert d'énergie des électrons thermiques dans ce milieu. Les sections efficaces pour la diffusion et le transfert d'énergie des hydrocarbures en phase liquide (à proximité et en dessous de la température d'ébullition) sont d'autant moindres que la forme des molécules approche la forme sphérique. La sphéricité des molécules dans la présente série décroît dans l'ordre suivant: le diméthyle-2,2 propane (DMPr) > le diméthyle-2,2 butane (DMB) > le cyclopentane (cP) > le *n*-pentane (nP). Trois propriétes des électrons dans ces liquides à 295 K décroissent également dans cet ordre. Elles sont: la mobilité des électrons thermiques, la variation de cette mobilité en fonction du champ électrique et les distances de pénétration des électrons de 0.1 à 10 eV.

Les mobilités dans le DMPr et DMB, mesurées en fonction de la densité du liquide, passent par un maximum semblable à celui déjà observé dans l'argon et le xenon. Ce maximum apparait à une densité approximativement double de la densité critique d_c. L'amplitude de ce maximum décroît dans l'ordre suivant Xe > Ar > DMPr > DMB. Le maximum est peu visible pour le cP et inexistant pour le nP.

Les mobilités dans les gaz, au delà de la température critique, sont semblables pour les quatre hydrocarbures. Les coefficients de température d'Arrhénius sont tous de 7–10 kcal/mol (0.3–0.4 eV/électron) pour les températures et densités proches des valeurs critiques. Ceci implique que les électrons forment des états localisés dans les gaz et que la localisation au delà du point critique semble être plus importante que dans le liquide en dessous de la temperature d'ébullition. Cette localisation n'est pas le phénomene critique predit par Lekner.

---

[1]Assisted by the National Research Council of Canada.

La mobilité dans le DMPr liquide decroît aux champs électriques élevés. L'amplitude de cette dépendance en fonction du champ varie avec la densité du liquide et passe par un maximum similaire à celui de la mobilité. La dépendance en fonction du champ est plus petite pour le DMB liquide que pour le DMPr et le maximum de cette dépendance se situe également à une densité double environ de la densité critique.

Des équations decrivent la mobilité dans le nP à toutes températures depuis le point triple jusqu'au gaz supercritique. Les électrons resident principalement dans des états localisés mais le transport se fait par des états non localisés vers lesquels les électrons sont excités thermiquement.

Afin de comparer les parcours des électrons secondaires b_{GP} dans ces liquides, ils doivent être multipliés par la densité d. Les valeurs de $b_{GP}d$ portées en graphique en fonction de d présentent des courbes semblables aux courbes de μ en fonction de la densité. Toutefois, l'amplitude des variations de $b_{GP}d$ est de beaucoup inférieure à celle de μ.

Introduction

The mechanism of electron transport in materials undergoes a change when the density (1–9) temperature (10–12), or composition (10, 13, 14) of the material is varied over an appropriate range. Although density and temperature were usually varied together, the change of mechanism in a given system has been mainly attributable to one or the other of the properties.

Many different transport mechanisms have been proposed, each fitted to a certain type of system. A general understanding of electron transport has not been attained. For example electron behavior in amorphous solid silicon (15) is similar to that in liquid ethers (16); perhaps the 'ion-like' mechanism of electron transport in low temperature ethers is actually electron hopping between localized states on the edge of the conduction band as proposed for low temperature amorphous silicon. Results are needed from many more systems before a unified theory of electron transport can be formulated.

Experiments involving wide changes of density have involved monatomic fluids (1–9). The present work reports analogous studies with polyatomic molecules. The compounds were chosen to display a wide range of electron mobilities at room temperature.

Experimental

Materials

The hydrocarbons were Phillips Research Grade with initial purities $\geq 99.9\%$. They were further purified as follows: shake or stir 24 h with concentrated sulfuric acid; separate from acid and stir 1 h with solid barium carbonate; pass the vapor through a column of sodium hydroxide pellets; degas; stir 24 h with lithium aluminum hydride; degas; stir 48 h on sodium/potassium alloy; degas; distil into the conductance cell after the latter had been evacuated to 10^{-7} Torr.

Conductance Cells

Two kinds of conductance cells were used, one for low temperatures and pressures (17) and another for pressures up to 100 atm.

A sketch of the high pressure cell is shown in Fig. 1. The distance between the electrodes was determined by a spacer used during manufacture. The cell constant was determined conductiometrically, using standard potassium chloride solutions. The conductance bridge was designed to keep the guard and collector electrodes accurately at the same ac potential (Fig. 2). The cell constant was independent of frequency, 1–3 kHz.

The body of each cell was coated on the outside with Aqua Dag (GC Electronics TV Tube Coat), which was grounded to the copper braid that shielded the lead to the collector electrode. This minimized interference from conductance in the glass. The glass side arm over the high voltage lead was not covered with Aqua Dag or braid because the high fields thus formed in the glass created stresses in it and caused it to break more easily.

A vertical strip of wall on the front and back of the cell was left clean so that the liquid contents could be observed. It was important to note the occurrence of bubbling, the disappearance of the meniscus, and the appearance and disappearance of critical opalescence.

To degas the metal electrodes, the cells during evacuation were heated to a temperature 50 deg higher than that to which they would be raised when containing a sample.

Temperature Control

The low temperature system was the same as that described earlier (17).

For temperatures greater than ambient the cell was positioned on asbestos supports in a clear walled Dewar. A heat gun (Master Appliance Model H67518) was fitted to a 3 cm diameter glass pipe which passed through the asbestos lid, to the bottom of the Dewar. The fan motor and heating coil of the gun were connected to separate Variacs. The heating coil was connected to an LFE Corp. Model 226-A21 temperature controller. Two thermocouples were placed inside the side arm leading to the guard electrode, as near as possible to the body of the cell. One thermocouple was connected to the temperature controller and the other was used to record the temperature. The thermocouples were calibrated by the temperature at which the meniscus disappeared. During heating of the liquid the meniscus stayed in about the center of the cell, well above the electrodes.

The Dewar was placed in a grounded Faraday cage.

Determination of Mobility μ

Electron mobilities at low temperatures in nP were determined from the magnitudes of the electron conductance transients (ect) and the free ion yields (18). Amplifier model 4 (19), with a signal decay half-life of 75 ns and

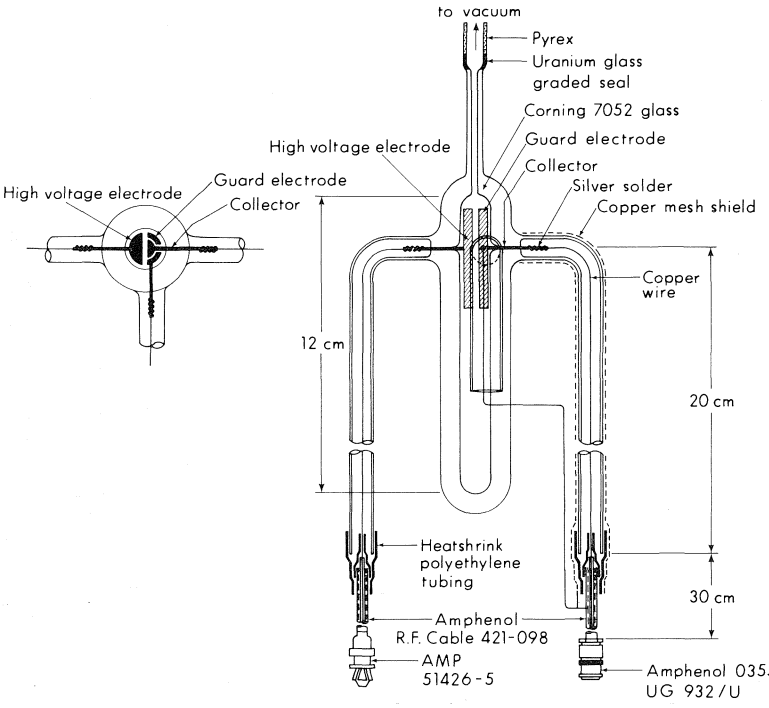

FIG. 1. Conductance cell for studying electrons in critical fluids. The walls were 12 mm thick Corning 7052 borosilicate glass. The electrodes were stainless steel and the pins Kovar. The distance between the electrodes was 3.2 mm and the cell constant 0.125 cm^{-1}.

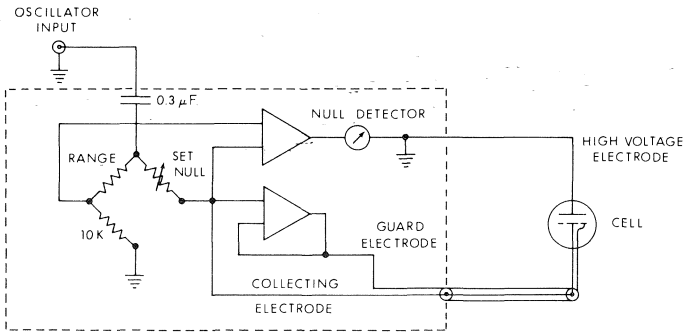

FIG. 2. Bridge circuit used to measure the cell constant. The dashed line represents a metal box which also contained the power supply.

3–97% response time of 200 ns, was used to measure the ect.

At high temperatures in nP and under all conditions in the other hydrocarbons, electron mobilities were obtained from the time of flight between the electrodes (eq. 1).

$$[1] \qquad \mu = l^2/Vt_d$$

where l is the distance between the electrodes, V is the applied voltage, and t_d is the time required for the charged particle to drift the distance l. An example oscilloscope trace for a time of flight measurement is shown in Fig. 3.

Under conditions where both methods could be used, the mobility values agreed within $< 10\%$.

Ion mobilities were determined using [1] and the circuit sketched in Fig. 4.

The radiation pulses were 0.1 or 1.0 μs of 1.7 MeV X rays delivering 0.1 or 1.0×10^{11} eV/g, respectively.

Physical Properties of the Liquids

The densities d for *n*-pentane (nP) and cyclopentane (cP) were obtained from refs. 20–22. Plots of d against T are not available for 2,2-dimethylpropane (DMPr) and 2,2-dimethylbutane (DMB), but the densities at 20°C and the critical temperature T_c are known (20, 21). The variation of d with T for DMPr and DMB were estimated by using the curves for *n*-butane, *n*-pentane, and *n*-hexane (22) as guidelines.

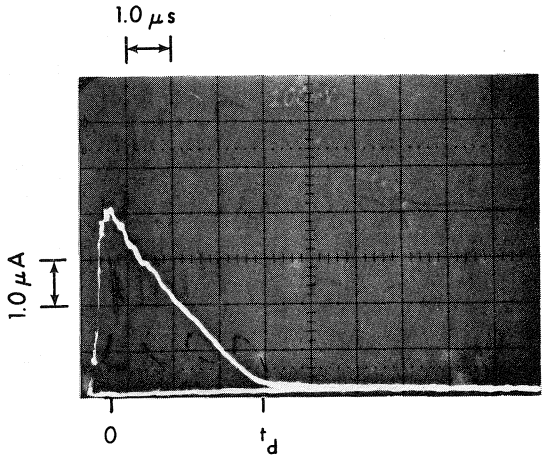

FIG. 3. Oscilloscope trace for an electron time of flight measurement in DMPr at 295 K. Applied voltage = 500 V.

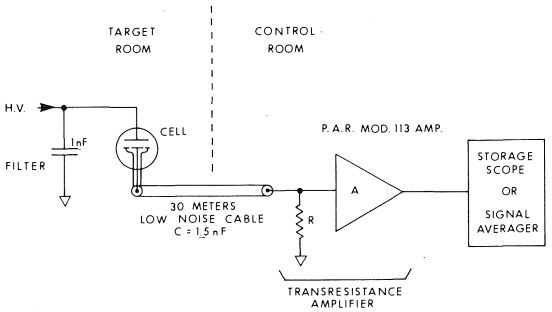

FIG. 4. Apparatus for measuring ion drift times. The 3–97% response time of the input network is $5.2 \times 10^{-9}R$ (s). The transresistance amplifier gain is $R \times A$ (ohm). Typical values of R and A are $10^4\ \Omega$ and 10^4, respectively.

The pressure on the liquid was always its vapor pressure.

The values of the dielectric constant ε at various temperatures were calculated using the Lorenz–Lorentz equation (23*a*) for cP and DMPr, and the Onsager relation (23*b*) for nP and DMB. A dipole moment $\mu = 0.06$ D (24) was used for the last two compounds, but it made $<1\%$ contribution to the dielectric constant even at the lowest temperature. Values of the refractive indices were obtained from refs. 20 and 21.

Results

Temperature Dependence at Low Field Strengths

Electron mobilities ($cm^2\ V^{-1}\ s^{-1}$) in the liquids at 296 K are: nP, 0.12; cP, 1.1; DMB, 11; DMPr, 61. The values for cP, DMB, and DMPr are within 10% of those listed in ref. 25, but there is a scatter of up to ±30% for reported mobilities of electrons in liquid hydrocarbons (11, 18, 25–30). The precision within a given series of experiments is usually <10%. Larger scatter may occur in results from the same laboratory over a period of years and the reason for it remains unknown. However, electron mobilities may differ by several orders of magnitude from one compound to another, so the 30% uncertainty in the absolute magnitudes does not seriously hinder progress in the investigation of electron behavior in liquids.

The mobility of electrons in nP increases continuously with temperature from 150 K through the critical temperature T_c and in the supercritical gas (Fig. 5). By contrast the mobility in DMPr goes through a maximum in the liquid phase at a temperature 29 deg below T_c, and through a minimum at T_c (Fig. 5).

The behaviors in cP and DMB are intermediate between those in nP and DMPr (Fig. 5). In all cases the curves undergo a change of slope at T_c. The validity of the change of behavior is illustrated in Fig. 6 by the error bars marking the upper and lower limits of the measured values at each temperature.

The mobilities in the four critical fluids all lie

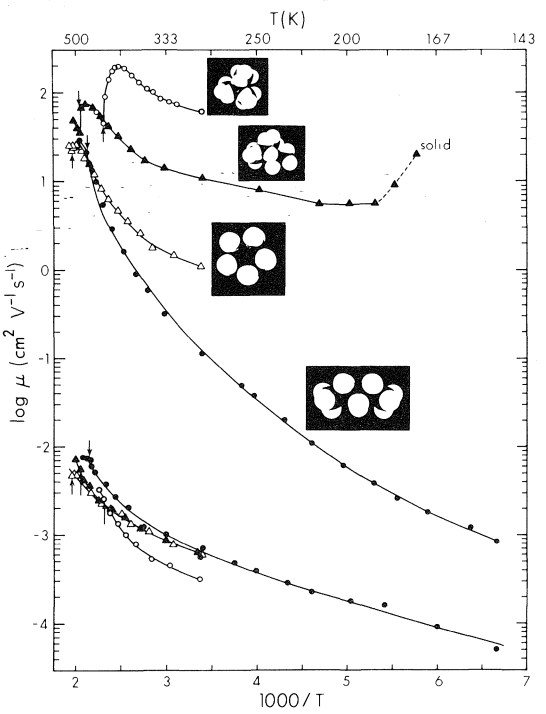

FIG. 5. Effect of temperature on the mobilities of electrons (upper set of curves) and positive ions (lower set) in fluid hydrocarbons. ○, DMPr; ▲, DMB; △, cP; ●, nP. The arrows mark the critical temperatures of the liquids. The curve through the nP points was calculated from eqs. 2–7.

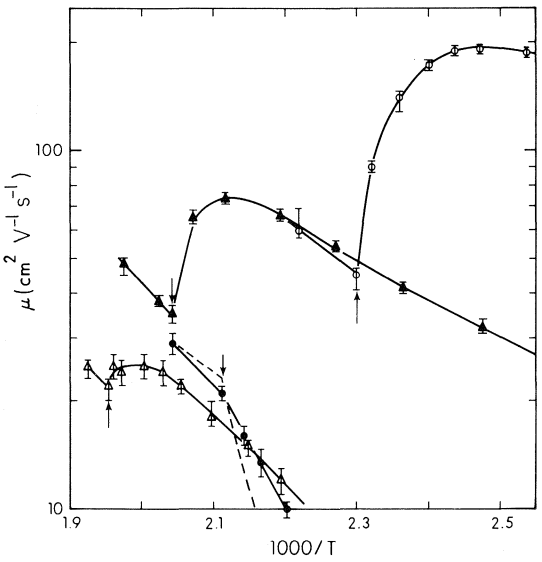

FIG. 6. Behavior of electron mobilities in the vicinity of the critical region in DMPr (○), DMB (▲), cP (△), and nP (●). The error bars mark the upper and lower limits of the measured values at each temperature. The dashed line represents the calculated curve for nP in this region.

within a factor of two of each other, while at 295 K the differences are up to 500-fold.

The mobilities of heavy positive ions increased monotonously with temperature in all the hydrocarbons (Fig. 5). Extrema are therefore characteristic of electron mobilities. The upward curvature of the ion mobility plots for high temperatures is similar to that in the electron mobility plots at temperatures below the mobility maxima.

Anion mobilities were usually not measured because under most conditions the electrons were swept out of the system before becoming attached to an impurity to form an anion. However, anions were obtained in cP and DMB at the lower temperatures. Compared to the positive ion mobilities in Fig. 5, $\mu_-/\mu_+ = 2.0 \pm 0.1$ in cP and 2.1 ± 0.1 in DMB. Similar values of the ratio have been obtained in many hydrocarbons (31–33).

In the high temperature sample of nP and in DMB, slower positive ions than those recorded in Fig. 5 were also observed. The ratio μ_+(fast)/μ_+(slow) had an average value of 2.3 ± 0.2 in nP and 1.9 ± 0.1 in DMB. The slower cations may have been mainly dimers to tetramers of product and impurity olefins.

Electric Field Dependence

In nP and cP the electron mobilities were independent of applied field strength over the range 3–20 kV/cm in liquids and 3–12 kV/cm in the supercritical gases. Experimental difficulties prevented measurements at higher fields at the highest temperatures. The difficulties included amplifier sensitivity and response time and field induced conductance switching in the hot glass (34).[2]

The electron mobility in DMPr at 295 K decreased gently with increasing field strength at $E > 4$ kV/cm. Upon raising the liquid temperature, the mobility and its field dependence increased (Fig. 7). Both the mobility and its field dependence passed through maxima at temperatures near 400 K (Figs. 7 and 8). For a given mobility, the field dependence was smaller on the high than on the low temperature side of the mobility maximum. A few degrees below T_c the field dependence became negligible up to 20 kV/cm and remained so in the supercritical gas (Fig. 8). The mobility passed through a minimum in this temperature region (Fig. 6).

The behavior was similar in DMB (Figs. 9 and 10), but the mobilities and their temperature dependences were smaller than in DMPr.

Cation mobilities were independent of applied field strength in the present region.

Discussion

Electrons in liquid alkanes are distributed among localized and extended states. The measured mobility is an appropriate average of the mobilities characteristic of the states, taken over the distribution of the electrons among the states. These things depend on the temperature and density of the liquid and on the nature of the molecules. The influences of all three factors are visible in Fig. 5.

Effect of the Nature of the Molecules at $T \ll T_c$

The molecules of the present liquids are nonpolar or only slightly polar, with gas phase dipole moments ≤ 0.1 D (24). The potential wells of the localized states of electrons in the liquids are at most a few tenths of an eV deep. The traps tend to be shallower when the molecules are more sphere-like (27). Electrons also appear to be less efficiently localized in traps the

[2]Field induced switching occurs in many amorphous materials such as boron-based glasses (34). Recently, most studies of the phenomenon have been made with chalcogenides (34–36).

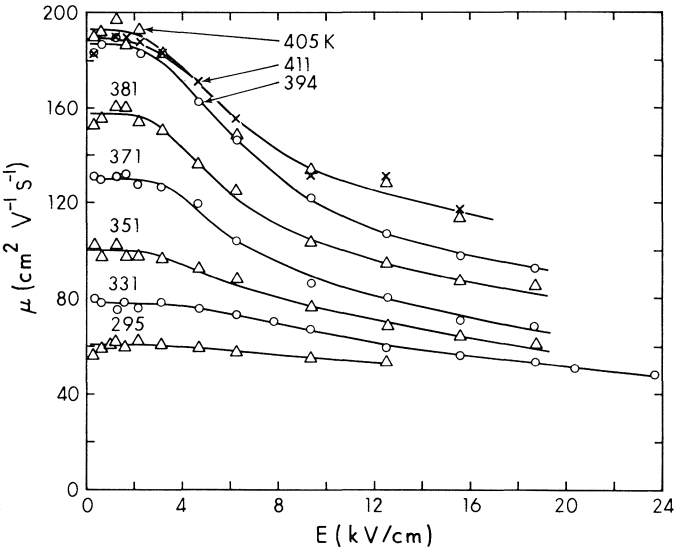

FIG. 7. Electric field dependence of electron mobilities in liquid DMPr at temperatures from 295 K through those at the mobility maximum.

more easily the molecules can rotate in the fluid (18).

The mobilities of electrons in extended states are several orders of magnitude greater than those in localized states. Thus the measured mobilities are greater in liquids of the more sphere-like molecules: nP < cP < DMB < DMPr (Fig. 5).

Effect of Temperature

In nP at the lowest temperature the electron mobility is eightfold greater than that of the anions, and the ratio increases with temperature. The contribution of an ion-like mechanism (12) to electron transport in liquid alkanes therefore appears to be negligible.[3] The mobility and its temperature dependence can be explained in terms of thermal partition of the electrons between localized and extended states, with transport occurring mainly in the latter (38).

The energy states are affected by local fluctuations in the molecular orientation and density of the fluid (39). It is assumed that the distribution of transition energies from localized to extended states is a Gaussian centered about a value E_0, with a distribution parameter σ.

$$[2] \quad N(E) = \pi^{-1/2}\sigma^{-1} \exp\left[-(E - E_0)^2/\sigma^2\right]$$

where $\pi^{-1/2}\sigma^{-1}$ is a normalization factor. The measured mobility μ_e is given by [3], where μ^0 is

$$[3] \quad \mu_e = \mu^0 \int_{-\infty}^{\infty} N(E)[1 + \exp(E/kT)]^{-1}\, dE$$

the mobility in the extended state. It is assumed that the entropy change is small for an electron going from a localized to an extended state and that the energy ranges of the localized and extended states overlap (12).

To calculate μ_e from [3] one requires values of μ^0, E_0, and σ. Unique values of the parameters in a given system are not available, but reasonable limitations can be put on them by comparison with other data. By analogy with the temperature dependences of the optical absorption parameters of solvated electrons (12), one may assume that $dE_0/dT \leq 0$ and $d\sigma/dT \geq 0$. Due to the Franck–Condon requirement of optical transitions and the probability that there are only one or two bound levels per electron trap in a liquid alkane, one may take $E_0 \leq E_{am}$, where E_{am} is the transition energy at the optical absorption maximum. The values of E_{am} in nP over the temperature range 150–

[3]The ion-like mechanism in liquid ethers is conceptually similar to thermally assisted tunnelling to nearest neighbor centers (35) and small polaron hopping (37). It does not involve migration of the solvation shell of the electron (12). The similarity between the activation energies of electron and ion mobilities in polar liquids had been rationalized in terms of the energy requirements of rotational–translational motions of the anisotropic solvent molecules (16). However, the striking resemblance between the behavior of electrons in a specimen of solid, amorphous silicon (37), and that in liquid ethers (16) is difficult to understand.

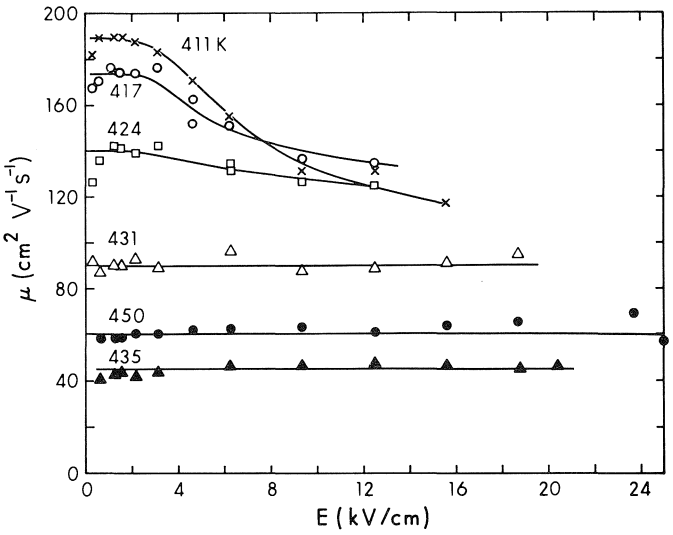

FIG. 8. Electric field dependence of electron mobilities in DMPr at temperatures above that of the mobility maximum. T_c = 434 K. The filled points refer to the gas at a density of 0.242 g/cm³.

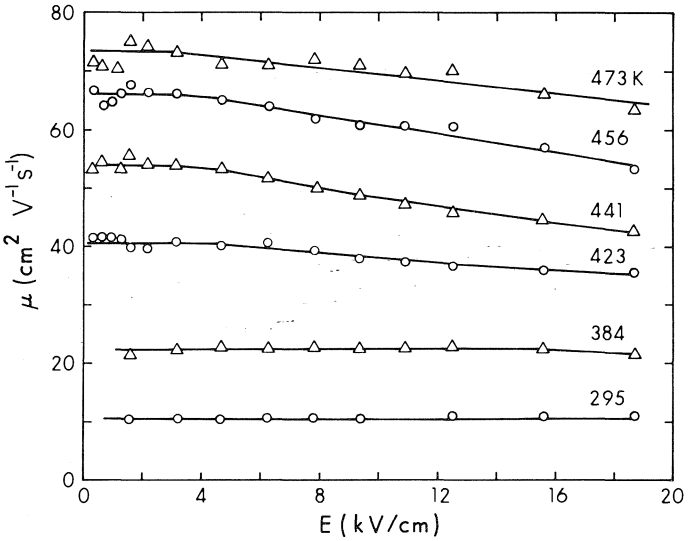

FIG. 9. Electric field dependence of electron mobilities in liquid DMB at temperatures from 295 K to that of the mobility maximum.

500 K are probably near 0.6–0.3 eV (12, 40). The value of $d\sigma/dT$ for the electron transitions is probably not greater than that of the thermal energy fluctuations in the liquid, so $d\sigma/dT \leq (2\ kC_p)^{1/2} \approx 5 \times 10^{-4}$ eV/K in nP at $T < 400$ K (22, 38).

In earlier studies over more limited temperature ranges μ^0 has usually been taken to be independent of temperature (12, 25, 28, 30). That approximation is inadequate for the wide ranges of temperature and fluid density in the present work. In particular, the rapid change of density at temperatures approaching T_c should be taken into account, although the way to do it is not straightforward. For electrons in nP it was assumed that the mean free path λ was inversely proportional to the density, and that μ^0 could be represented by [4] (12), where v^0 is the jump

$$\mu^0 = \lambda^2 v^0 e/2kT \qquad [4]$$

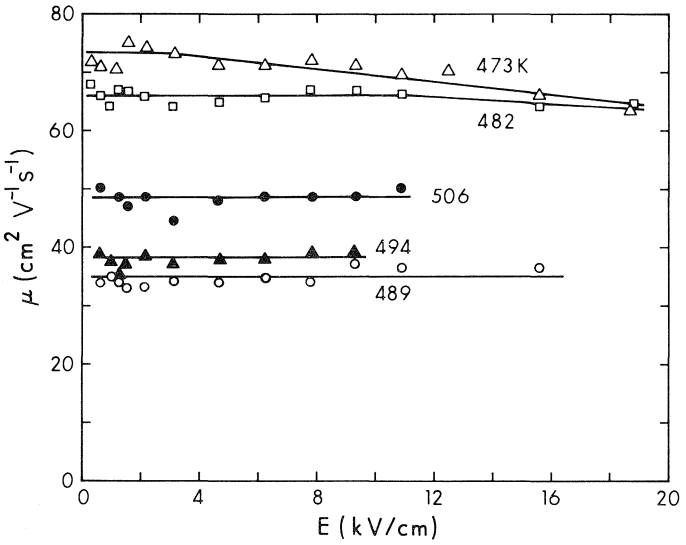

FIG. 10. Electric field dependence of electron mobilities in DMB at temperatures from the mobility maximum to the supercritical region. T_c = 489 K. The filled points refer to the gas at a density of 0.240 g/cm³.

attempt frequency and e is the unit electronic charge.

Within the above limitations we were able to fit the electron mobilities in nP over most of the liquid range and in the supercritical gas (Fig. 5) with the following parameter values.

$$[5] \qquad E_0\,(\text{eV}) = 0.64 - 7 \times 10^{-4}T$$

$$[6] \qquad \sigma\,(\text{eV}) = 0.15 + 8 \times 10^{-5}T$$

$$[7] \quad \mu^0\,(\text{cm}^2\,\text{V}^{-1}\,\text{s}^{-1}) = \mu^0{}_{\text{ref}}\left(\frac{d_{\text{ref}}}{d_T}\right)^2\left(\frac{T_{\text{ref}}}{T}\right) = 250\left(\frac{0.623}{d_T}\right)^2\left(\frac{295}{T}\right)$$

where $\mu^0{}_{\text{ref}}$ and the density d_{ref} are the values at the reference temperature T_{ref}. The fit is adequate over the entire 350 deg range of temperature except for a 30 deg region just below the critical temperature (Figs. 5 and 6). In this region the density changes rapidly and nonlinearly with temperature, so [5] and [6] become inadequate representations of E_0 and σ, respectively.

The transition energy E_0 is equal to $(V_0 - \overline{V})$, where V_0 is the energy of an electron in the lowest extended state relative to the vacuum level, and $\overline{V}$ is the mean energy of electrons in localized levels (38, 39, 41–43). Preliminary treatments of electron mobilities by fluctuation theories (39, 41) neglected the temperature dependence of E_0 and, based upon thermal energy fluctuations, assumed $d\sigma/dT$ = 6–11 × 10^{-4} eV/K for C_5 and C_6 hydrocarbons. However, to fit the temperature dependence of the mobilities using such large values of $d\sigma/dT$ would require that dE_0/dT be *positive* and of similar magnitude (38). Positive values of dE_0/dT are unlikely, so the temperature coefficient of σ must be much smaller than that of the dispersion parameter of thermal energy fluctuations.

Holroyd and co-workers (42, 43) have measured the photoinjection of electrons from metal surfaces into liquids and into a vacuum as functions of photon energy and applied electric field strength. From the difference between the injection energy into a liquid and into a vacuum they derived an energy that was equated to V_0. They obtained $dV_0/dT = -2.2 \times 10^{-3}$ eV/K for nP (43), which is much greater in magnitude than the temperature coefficient of E_0 in [5]. This implies that the energies of the localized and extended states in alkanes are affected similarly when the liquid temperature is changed. Thus V_0 and $\overline{V}$ in alkanes appear to be affected mainly by the changing density; $(dV_0/dd) \approx (d\overline{V}/dd)$ = positive, which multiplied by the negative (dd/dT) gives the observed results. There would be a positive contribution from $(d\overline{V}/dT)$ due to decreased orientational polarization at higher temperatures, but it would be relatively small in hydrocarbons.

The direct effect of density on electron energy

levels in liquids, distinct from its secondary effect through the dielectric constant, has also been detected through the influence of pressure on optical absorption energies in alcohols (44–46), and through the influence of temperature on V_0 in hydrocarbons (43).

Electron migration in nP remains in the thermally activated regime even in the supercritical gas. The mobility increases monotonously with temperature. By contrast, the mobility in DMPr goes through a maximum (Fig. 5). The maximum occurs at a temperature 29 deg below T_c, so the decrease in mobility at high temperatures is not a critical phenomenon. The behavior is reminiscent of that in argon (2) and xenon (5), where the electrons were presumed to normally reside in the lowest extended state (47). Changes in mobility would then reflect changes in μ^0. However, μ_e increases with temperature in the supercritical gas of DMPr at constant density, just as it does in nP (Fig. 6). It appears that electron transport in supercritical DMPr occurs by a two state mechanism and that the decrease of μ_e at $T > 405$ K is due to the formation of localized states. The Arrhenius activation energies of μ_e in all four of the present supercritical gases are 7–10 kcal/mol (0.3–0.4 eV/electron). They are about double that in liquid nP at room temperature, where the two state mechanism is generally accepted.

The mobilities and their temperature dependences in DMB and cP are intermediate between those in nP and DMPr (Fig. 5). Assuming that the values of σ are similar in the four hydrocarbons, the variations of μ_e with temperature indicate that the relative values of E_0 at a given temperature at $T \ll T_c$ decrease in the order nP > cP > DMB > DMPr. Measured values of V_0 at $\sim$296 K lie in the same order (42, 48).

An adequate interpretation of mobility maxima in fluids has not yet been found (2, 49), so theoretical curves are not offered for the DMPr, DMB, and cP results in Fig. 5.

Effect of Density

The mobilities are displayed as functions of the liquid densities in Fig. 11. Points for solid DMPr (29) and DMB are included.

The increase in mobility on going from the liquid to the crystalline solid is due to the smaller amount of scattering in the more ordered medium (represented by a smaller structure factor (50)). The continued increase of μ_e with increasing density of the solid is actually due to the decreasing temperature of the samples (29), and thereby reduced scattering of the electrons by phonons (51).

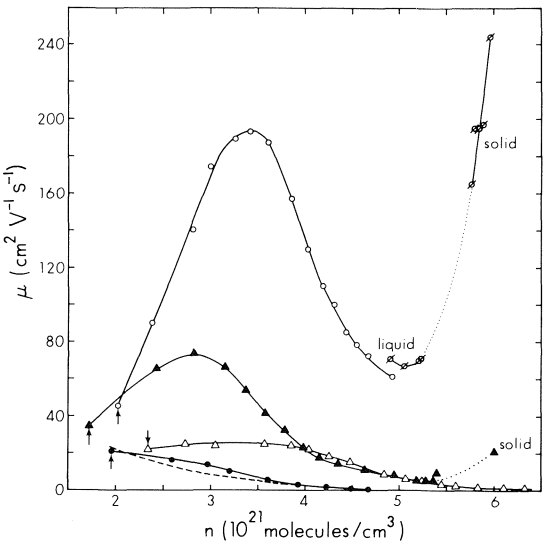

FIG. 11. Electron mobilities in DMPr (○), DMB (▲), cP (△), and nP (●) plotted against the molecular density of the medium. The arrows mark the critical fluids. The liquid and solid phase results for DMPr from ref. 29 are also included (ϕ). Dotted lines mark the liquid–solid transition. The dashed line for nP represents the mobilities calculated from eqs. 2–7. The densities were changed by changing the temperature of the samples under their vapor pressure.

Upon decreasing the density of liquid DMPr from that at the triple point, the mobility passes through a minimum. The increase of μ_e with decreasing density is attributed to a decreasing scattering length. The molecules in the normal liquid are so close together that an electron passing between them suffers mainly repulsion from the hard cores (Hartree fields) of the molecules (51). As the density decreases the molecules move farther apart and the electron experiences more of the attractive polarization interactions, which tend to counteract the hard core repulsions. The scattering length thereby decreases. The attractive interaction continues to increase with decreasing fluid density and at some point cancels the hard core repulsion, and the scattering cross section is a minimum. Upon further reducing the density the attractive polarization dominates the electron–molecule interaction, the scattering length becomes negative, and the scattering cross section increases again. The mobility therefore decreases. This model has been used to interpret the mobility maximum in

liquid argon (47). However, there are quantitative difficulties with the model (2, 49). Some other process contributes to limiting the mobility at the maximum and on the low density side of the peak. The present results from fluid hydrocarbons indicate that the other process is electron localization. Lekner and Bishop (4) proposed that localization would take place in simple fluids near the critical point. An effect that is peculiar to the critical region does not occur (5), but localization does take place over a broader range of densities.

The data in Table 1 and in Fig. 11 of ref. 2 indicate that electron migration in fluid argon gradually changes to a thermally activated two state mechanism at densities below 1.4×10^{22} atom/cm^3. The mobility maximum occurs at 1.2×10^{22} atom/cm^3. At 1.0 and 0.7×10^{22} atom/cm^3 the Arrhenius temperature coefficients of the mobilities are each 3 kcal/mol. Thus the formation of localized states could make a major contribution to limiting the mobility in this density region.

The maxima in DMB and DMPr occur at 2.8 and 3.4×10^{21} molecules/cm^3, which are 1.7 times the respective critical densities. The mobility maxima in argon and xenon occur at 12×10^{21} molecules/cm^3 (2, 5), which are respectively 1.5 and 2.4 times d_c.

The mobility in nP appears to be approaching a maximum at the critical point (Fig. 11). The complex behavior in all the hydrocarbons at densities $<4 \times 10^{21}$ molecules/cm^3 indicates why the simple calculations based on [2]–[7] gave poor agreement between calculated and observed mobilities for nP in this region (Fig. 11).

The electron mobility curve for each hydrocarbon in Fig. 5 changes slope abruptly at the critical temperature. The change of slope does not signify a change in electron behavior, but rather a discontinuity in dd/dT. As T_c is approached in the liquid phase the density decreases rapidly and the density effect dominates the change in μ_e. At $T > T_c$ the density remains constant, so the mobility is affected only by the change of T.

TABLE 1. Critical properties of the hydrocarbons

	T_c (K)	P_c (atm)	d_c (g/cm^3)	ε_c
Cyclopentane	512	44.6	0.270	1.29
2,2-Dimethylpropane	434	31.6	0.23	1.27
n-Pentane	470	33.3	0.232	1.27
2,2-Dimethylbutane	489	30.9	0.240	1.27

Ion Mobilities

The temperature dependences of ion mobilities in the liquid alkanes within 100 deg of their critical temperatures are non-Arrhenius (Fig. 5). The same is true of the temperature dependences of the viscosities (22) and self-diffusion coefficients (52). The non-Arrhenius behavior reflects the accelerating value of dV_f/dT in this temperature range, where V_f is the free volume.

The relationship between the positive ion mobility μ_+ (cm^2 V^{-1} s^{-1}) and the viscosity η (cP) for nP between 230 and 450 K is approximately given by [8], while that for cP between 300 and 420 K is [9]. The calculated and experimental results are displayed in Fig. 12. The mobility–viscosity relationship varies with the structure of the solvent molecules, but is similar for alkanes and ethers (16). Ions in cyclo-solvents have higher mobilities than those in *n*-alkyl solvents of the same viscosity. The mobilities do not fit Walden's rule; the viscosity exponents are -1.1 to -1.3 instead of the predicted -1.0.

$$[8] \qquad \mu_+ = 1.0 \times 10^{-4}\eta^{-1.3}$$

$$[9] \qquad \mu_+ = 2.2 \times 10^{-4}\eta^{-1.1}$$

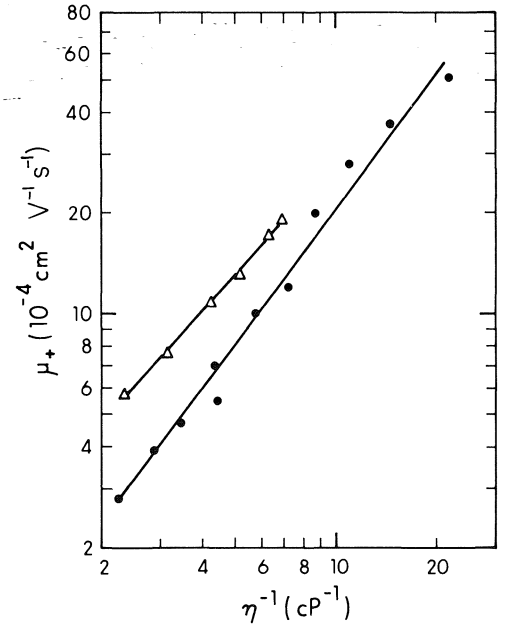

FIG. 12. Ion mobilities in cP (△) and nP (●) as functions of the inverse viscosity. The full lines represent [8] for nP and [9] for cP.

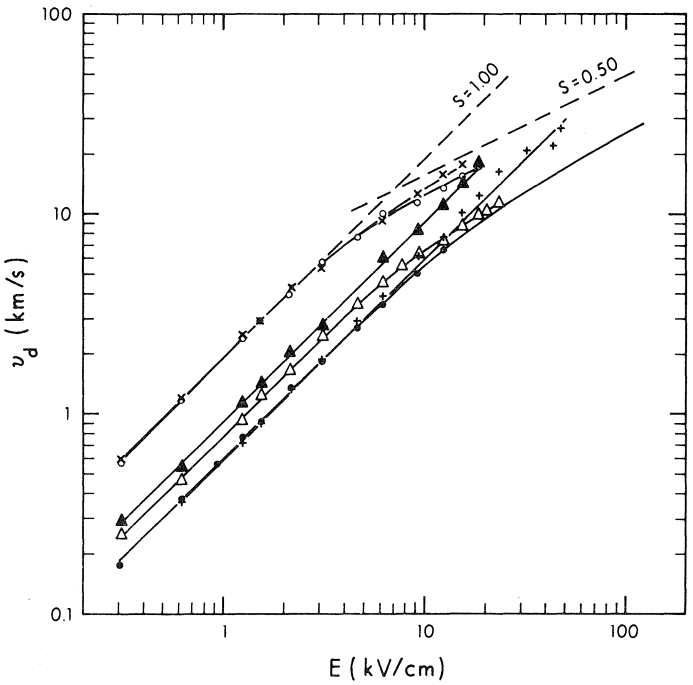

FIG. 13. Electron drift velocity v_d as a function of electric field strength in DMPr at different temperatures. ●, 295 K; △, 331 K; ○, 394 K; ×, 405 K; ▲, 431 K; +, 450 K (gas). T_c = 434 K. The curve beyond 13 kV/cm at 295 K represents results from ref. 56.

Rotational motions of the irregularly shaped solvent molecules are required to facilitate ion migration, to maintain the polarization energy at a reasonably low level while the ion moves. The temperature coefficient of rotational motion E_τ is often greater than that of shear viscosity E_η; for water and for diethyl ether $E_\tau/E_\eta = 1.2$ at 293 K (calculated from data in refs. 53 and 54). Equations 8 and 9 imply that $E_{\mu_+}/E_{\eta^{-1}} = 1.2 \pm 0.1$ in cP and nP, which indicates a correlation between μ_+ and τ^{-1}.

Walden's rule is an approximation, the validity of which stems from the interdependence of rotational and translational motions in these liquids. The rule would be expected to apply more accurately to liquids made up of spherical molecules.

Field Dependence

The electron mobilities in nP and cP are relatively low and they are independent of applied electric field strength up to 20 kV/cm. In DMB and DMPr the mobilities are relatively high and field dependent. The two properties tend to increase together (Figs. 7–10).

The usual way to display field dependence is to make a log–log plot of drift velocity v_d against field strength (Fig. 13). Field dependence occurs where the slope deviates from unity. It means that the energy acquired by the electron from the field is not dissipated efficiently enough, and the average electron energy increases above thermal. The lower the field at which deviation occurs, the less efficient are the energy loss processes.[4]

If deviation occurs when v_d is only about twice the speed of sound in the medium, the electron energy is dissipated mainly to acoustic phonons. At higher drift velocities more efficient processes are important (50, 55).

In DMPr at 295 K the mobility becomes field dependent when v_d exceeds about 3 km/s (Fig. 13). The present result agrees with that of Bakale and Schmidt (56). By extrapolation of data for other alkanes at the same temperature and at the same density (57), the velocity of sound in liquid DMPr at 295 K is 1.0 km/s. As the temperature of the liquid increases the velocity of sound de-

[4]This explains why the penetration ranges of epithermal electrons are greater in systems that show a greater field dependence of the mobility. Density normalized ranges tend to be greater when the energy loss processes are less efficient.

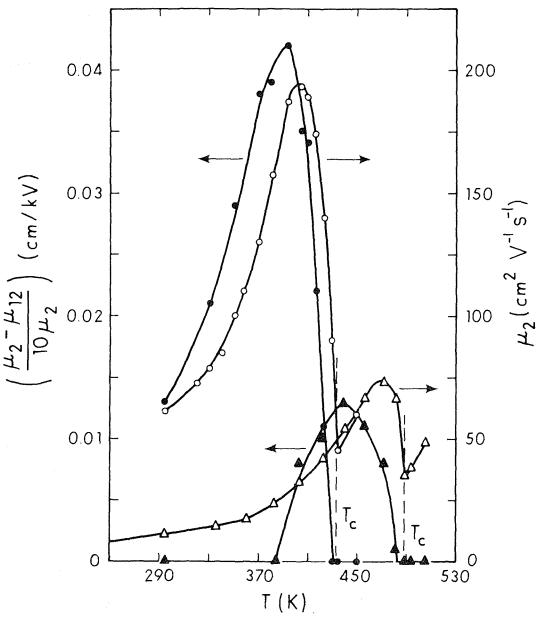

FIG. 14. Electric field dependence of the electron mobilities in DMPr (●) and DMB (▲) as functions of temperature. μ_2 and μ_{12} are the mobilities at 2 and 12 kV/cm, respectively. Values of μ_2 are also plotted so that the peaks can be compared.

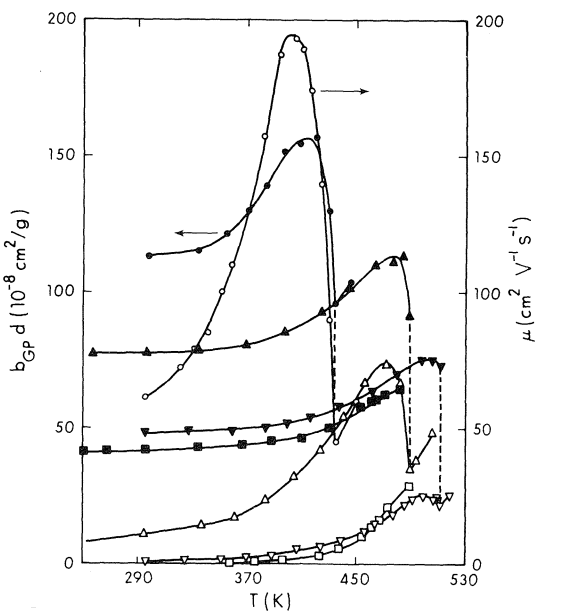

FIG. 15. Density normalized ranges ($b_{GP}d$) of secondary electrons in fluid hydrocarbons as functions of temperature. ●, DMPr; ▲, DMB; ▼, cP; ■, nP; data from ref. 58. The mobilities (open points) are plotted for comparison. The vertical dashed lines mark the critical temperature of each fluid.

creases (57), whereas the threshold drift velocity for field dependence goes in the opposite direction (Fig. 13). Electron thermalization in DMPr and the other hydrocarbons cannot be attributed to interactions with the collective motions of acoustic phonons. It must be due to more efficient interactions with motions of smaller groups of molecules.[5]

Simple theories (50) predict that at high fields the drift velocity will vary as $E^{1/2}$. For this reason it is usual to place reference lines with slopes $s = 1.00$ and 0.50 in graphs like Fig. 13. However, a survey of the literature provides little support for the existence of extended regions where $v_d \propto E^{1/2}$ in liquids. The slope simply becomes different from unity and can become as low as zero.

The field dependence varies with the temperature in a manner similar to the mobility itself. A comparative measure of the field dependence is $\mu^{-1}(d\mu/dE)$. In the present work it may conveniently be represented by $(\mu_2 - \mu_{12})/10\mu_2$, where the subscripts denote the field in kV/cm at which the mobility was measured and the units of the ratio are cm/kV. Values of this ratio peak about 10 deg below the temperature of the mobility maximum in DMPr and about 30 deg below the mobility maximum in DMB (Fig. 14). There is a remarkable coincidence between the relative sizes of the mobility and the field dependence peaks.

The density normalized penetration ranges of the secondary electrons in these liquids also pass through maxima (58). The range maxima occur at temperatures slightly higher than those of the mobility maxima (Fig. 15). The relative magnitudes of the range peaks are much smaller than those of the mobility and field dependence peaks. The major portion of the range is generated by electrons in a higher average energy state, probably a few tenths of an eV, while the mobility and its field dependence are properties of electrons having an average energy of a few hundredths of an eV.

The common factor that influences these three quantities is the electron energy transfer cross section. The cross section in liquids comprised of globular molecules first decreases, then increases as the density of the fluid decreases. The molecules of nP are distinctly nonsphere-like; the

[5]Terms for these motions in liquids are not well defined. They include optical phonons, rotational–translational oscillations, librations, lattice vibrations, and perhaps others.

scattering cross section in that liquid is relatively large and decreases monotonously with decreasing density at high temperatures.

Electron localization occurs when the scattering cross section is large. Localization apparently occurs in the supercritical gases near the critical region.

Discussion

J. K. Baird: I wish to point out that I have integrated the Schrodinger equation numerically for argon with the following potential $V(r)$:

$$V(r) = V_{HF}(r) - \frac{1}{2}\frac{\alpha e^2 f}{(r^2 + r_c^2)^2}$$

where $V_{HF}(r)$ is the Hartree field, α is the polarizability, e the electron charge, f the screening function, and r_c is a cut-off radius. The screening function may be either that due to Lekner (Phys. Rev. **158**, 130 (1967)) or one based on the Onsager reaction field (J. K. Baird. J. Phys. Chem. **79**, 2862 (1975)). The difference is unimportant except to say that $f = 1$ at zero density and decreases toward zero as the density increases. The cut-off radius r_c was determined so that when $f = 1$, the potential predicted an energy dependence of the total scattering cross section in agreement with that observed in numerous experiments on the Ramsauer effect in low pressure gases. The result of using the above potential to calculate the scattering cross section as f decreased from unity was: (*1*) the Ramsauer minimum in the cross section persisted; (*2*) the energy at which the minimum occurred decreased; (*3*) the value of the cross section at the minimum decreased. It is my view that the above potential is the one from which the single atom cross section in the liquid should be calculated. To take into account diffraction effects, I believe that this cross section should be multiplied by the liquid structure factor, as in the Ziman weak scattering theory, to obtain the many atom scattering cross section in the liquid. Hence, since the single atom cross section appears to decrease with increasing density, one is tempted to conclude that the decrease in the screening function may account for the large electron mobility observed in liquid argon.

Y. Hatano: Do you have any experimental data on the hydrogen isotope effect of μ_e, such as μ_e's for CH_4, CH_3D, CH_2D_2, CHD_3, and CD_4, or μ_e's for C_2H_4, C_2H_3D, $C_2H_2D_2$ (*trans*-$C_2H_2D_2$, *cis*-$C_2H_2D_2$, asym-$C_2H_2D_2$), C_2HD_3, and C_2D_4? One may expect to get an interesting feature for the effect of molecular structure of μ_e.

G. R. Freeman: I agree that the isotope effect should exist. We tried to do measurements in the series of deuterated methanes several years ago, but failed due to impurity problems. We are going to try again soon. As a final comment, on several occasions during the conference experimentalists have presented evidence that behavior similar to the (gas phase) Ramsauer–Townsend effect can occur in simple liquids. The opinion of concerned theoreticians seems to be that the Ramsauer–Townsend effect cannot occur in liquids. At this point we must specify conditions more precisely. In mobility experiments the effect appears as a maximum in a plot of electron mobility against applied electric field strength. The mobility maximum occurs in both gaseous and liquid xenon. For the liquid phase, beginning at the critical density and proceeding towards higher densities, the low field mobility increases and the Ramsauer–Townsend maximum becomes less prominent (Kimura and Freeman. To be published). Thus, the Ramsauer–Townsend mobility maximum (scattering minimum) correlates with the density dependence of the mobility at low fields. What we lack is a formal theory that relates the two effects to common underlying properties of the fluid. Lekner's model for the density dependence of the scattering length (Phys. Lett. A, **27**, 341 (1968)) seems an appropriate place to start.

The photoinsertion of tin(II) chloride into the metal–metal bond of hexacarbonylbis(tri-*n*-butylphosphine)dicobalt[1]

PETER F. BARRETT, ARNOLD FOX, AND RAYMOND E. MARCH

Department of Chemistry, Trent University, Peterborough, Ont., Canada K9J 7B8

Received November 12, 1976

PETER F. BARRETT, ARNOLD FOX, and RAYMOND E. MARCH. Can. J. Chem. **55**, 2279 (1977).

The photochemical insertion reaction of $SnCl_2$ into the metal–metal bond of $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$ has been studied in THF at 23.0°C at the irradiating wavelengths 365 nm, 436 nm, and 546 nm. At 365 nm, the quantum yield for the reaction increases with increasing concentration of $SnCl_2$ and approaches a limiting value of 1.0. At 436 nm, however, the quantum yield increases above 1.0 and at 546 nm, quantum yields as high as 6 were measured. The uv–visible absorption spectrum of $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$ shows an intense band at 372 nm and a broad shoulder at about 440 nm. A simple mechanism is proposed to operate on irradiation at 365 nm due to absorption by the intense band, but a more complicated chain mechanism is suggested to operate at 546 nm as a result of absorption by the lower energy shoulder band. It appears that both mechanisms operate on irradiation at 436 nm due to the overlap of the two absorption bands at this wavelength.

PETER F. BARRETT, ARNOLD FOX et RAYMOND E. MARCH. Can. J. Chem. **55**, 2279 (1977).

On a étudié, dans le THF à 23.0°C et faisant appel à des longueurs d'irradiation de 365, 436 et 546 nm, la réaction d'insertion photochimique de $SnCl_2$ dans le lien métal–métal de $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$. A 365 nm, le rendement quantique de la réaction augmente avec une augmentation de la concentration de $SnCl_2$ et approche une valeur limite de 1.0. Toutefois à 436 nm, le rendement quantique augmente au-dessus de 1.0 et à 546 nm, des rendements quantiques aussi haut que 6 ont pu être mesurés. Le spectre d'absorption uv–visible de $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$ indique une bande intense à 372 nm et une épaule large autour de 440 nm. On propose un mécanisme simple qui s'appliquerait pour l'irradiation à 365 nm et qui serait dû à l'absorption par la bande intense; toutefois on suggère un mécanisme en chaîne beaucoup plus compliqué pour expliquer les résultats à 546 nm qui proviendraient d'une absorption par la bande existant sous forme d'épaule à une énergie plus basse. Il semble que les deux mécanismes agissent lors de l'irradiation à 436 nm dû à un recouvrement des deux bandes d'absorption à cette longueur d'onde.

Introduction

There has been a recent surge of interest in the mechanisms of the photochemical reactions of transition metal carbonyl complexes containing metal–metal (M—M) bonds (1–7). The photochemistry of these complexes can be explained on the basis of the homolytic fission of the M—M bond (1), or in solvents of high donicity, on the heterolytic fission of this bond (2). Studies have shown that the lowest excited states of the M—M bonded species produced on absorption of radiation result from an electronic transition which weakens the M—M bond, either by an electron transition from the M—M σ bond orbital to a π* orbital of a ligand (1), or by a transition to the σ* orbital of the M—M bond from a π-*d* orbital

which is essentially non-bonding with respect to the M—M bond (5–7). Cleavage of the M—M bond to form two radicals appears to be the consequence either of these excitations, or of the higher energy process involving the transition of an electron from a σ orbital of the M—M bond to a σ* orbital associated with this bond.

In our studies of the thermal insertion of tin(II) halides into the M—M bonds of a number of complexes (8), we have noted that some of these reactions are greatly accelerated when performed in the presence of laboratory light (9, 10). A preliminary study of the photoinsertion of $SnCl_2$ into the M—M bond of $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$ has previously been reported (10), but we now present the results of a quantitative study of this reaction and discuss two mechanisms which are consistent with the variation in the observed quantum yields with changes in the reactant concentrations, and the intensity and wavelength of the radiation.

Experimental

Materials

Hexacarbonylbis(tri-*n*-butylphosphine)dicobalt and dichlorobis(tricarbonyltri-*n*-butylphosphinecobalt)tin were prepared by the methods outlined in the literature (11). Anhydrous tin(II) chloride was prepared by dehydration of the dihydrate as described previously (8) and stored under nitrogen. Tetrahydrofuran was refluxed over sodium wire and freshly distilled in an atmosphere of dry nitrogen immediately before use.

Determination of Extinction Coefficients

The extinction coefficients of $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$ and $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2SnCl_2$ in THF were measured in the region 350 nm to 560 nm. A small amount of the complex was weighed on a microbalance, transferred to a volumetric flask, and dissolved up to the mark with THF under nitrogen. These solutions were exposed to light only from a 1A Kodak safelight filter, and other solutions of known concentration were prepared by accurate dilution of these stock samples. The absorption spectra were recorded at 23.0°C with a Unicam SP1800 Spectrophotometer using Teflon stoppered 1.0 cm path length cells. Figure 1 shows the spectra of $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$ and $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2SnCl_2$ in THF, and Table 1 lists the extinction coefficients at several wavelengths.

Photolysis Procedures

$SnCl_2$ was weighed into a 25 ml volumetric flask and dissolved up to the mark with THF. Part of this solution was pressure-filtered through dried No. 42 filter paper (using a Sartorius pressure syringe) to fill two 1.0 cm cells to be used as blanks. Another 10 ml portion of the $SnCl_2$ solution was pressure-filtered into a 10 ml volumetric flask containing a weighed quantity of $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$. The weight of $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$ was relatively constant for a series of runs at a given wavelength of irradiation except when the effect of the concentration of this complex on the quantum yield was being studied. This reactant solution was used to completely fill two Teflon

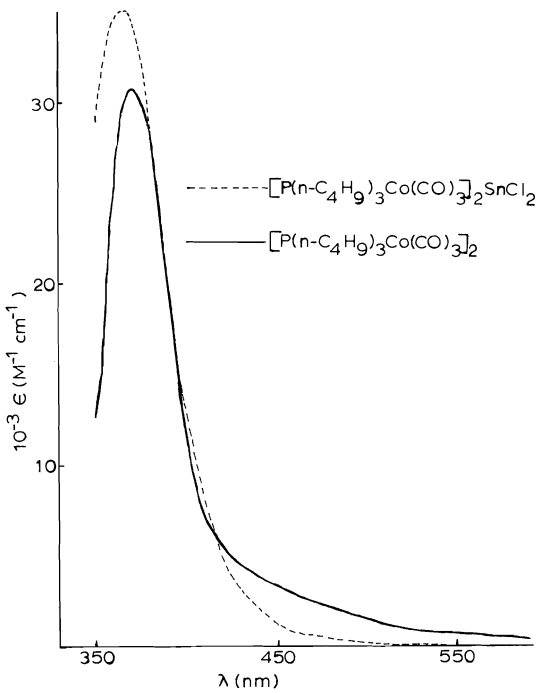

FIG. 1. Electronic absorption spectra of $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$ and $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2SnCl_2$ in THF at 23.0°C.

stoppered 1.0 cm cells. One pair of cells (reactant solution plus blank) was used to study the photochemical reaction while the other was used to monitor any thermal reaction that might occur and whose contribution could therefore be subtracted from the reaction occuring during photolysis.

The cell to be photolyzed was placed in a thermostatted block at 23.0°C and was irradiated by a collimated beam of light which was contained entirely within the boundaries of the cell face. The beam was produced from the radiation of a 100 W medium pressure mercury lamp which had passed through a Heath scanning monochromator E. U. 700 with a slit width of 2.0 mm. The nominal band width resolution of the instrument was found to be 4 nm under these conditions. Controlled diminished light intensities in some runs were achieved either by inserting neutral density filters (Kodak) of known transmittance in front of the reaction cell, or by using different lamps of known intensity.

During illumination, the reaction cell (which contained a small glass bead) was removed from the illuminator at regular intervals and agitated in order to maintain homogeneity of the solution. Absorbances were recorded periodically at convenient monitoring wavelengths (540 nm or 560 nm) by transferring the cell to a Unicam SP1800 spectrophotometer. The irradiation time was stopped and started by using a manual shutter. The solutions were irradiated at 365 nm, 436 nm, and 546 nm, and the intensity of the radiation at these wavelengths was measured by the potassium ferrioxalate actinometric method (12).

The volumes of the reaction cells containing the small glass beads, which were required for the calculations, were calculated by determining the weight of distilled water that could be contained by each cell.

Determination of Quantum Yields

The rate of the photochemical reaction

$$M_2 \xrightarrow{h\nu} M_2^* \xrightarrow{L} MLM$$

is given by eq. 1 (13) when the path length of the reaction vessel is 1.0 cm and the only absorbing species are M_2 and MLM.

$$[1] \quad \frac{-d[M_2]}{dt} = \frac{\phi I_0}{V}(1-10^{-(\varepsilon_{M_2}[M_2]+\varepsilon_{MLM}[MLM])}) \times \frac{\varepsilon_{M_2}[M_2]}{\varepsilon_{M_2}[M_2] + \varepsilon_{MLM}[MLM]}$$

where $M_2 = [P(n\text{-}C_4H_9)_3Co(CO)_3]_2$, $L = SnCl_2$, which is virtually transparent to visible light used in this study, $MLM = [P(n\text{-}C_4H_9)_3Co(CO)_3]_2\text{-}SnCl_2$, ϕ = quantum yield, I_0 = incident light intensity in einsteins h^{-1}, V = volume of the reaction cell in ℓ, ε's are extinction coefficients for the species at the wavelength of the irradiation in M^{-1} cm^{-1}. Equation 1 can be simplified and integrated under two limiting conditions which are applicable in this study.

Condition A

If the solution is almost totally absorbing at the wavelength of irradiation, *i.e.* if

$$\varepsilon_{M_2}[M_2] + \varepsilon_{MLM}[MLM] \geq 2$$

eq. 1 can be simplified and integrated to give eq. 2.

$$[2] \quad (\varepsilon_{M_2} - \varepsilon_{MLM})([M_2]_0 - [M_2]) + \varepsilon_{MLM}[M_2]_0 \ln \frac{[M_2]_0}{[M_2]} = \frac{\phi I_0 \varepsilon_{M_2} t}{V}$$

If the progress of the reaction is monitored spectrophotometrically at a wavelength where absorbances are represented by A and extinction coefficients by ε', eq. 2 can be rearranged to give eq. 3.

$$[3] \quad f(A_t) = -\frac{\phi I_0 \varepsilon_{M_2} t}{V \varepsilon_{MLM}} + C$$

where

$$f(A_t) = \frac{(\varepsilon_{M_2} - \varepsilon_{MLM})A_t}{\varepsilon_{MLM}(\varepsilon_{M_2}' - \varepsilon_{MLM}')} + [M_2]_0 \ln (A_t - A_\infty)$$

and

$$C = \frac{(\varepsilon_{M_2} - \varepsilon_{MLM})A_0}{\varepsilon_{MLM}(\varepsilon_{M_2}' - \varepsilon_{MLM}')} + [M_2]_0 \ln (A_0 - A_\infty)$$

Condition B

If the solution is not totally absorbing at the wavelength of irradiation, but if

$$\varepsilon_{M_2}[M_2] \gg \varepsilon_{MLM}[MLM]$$

eq. 1 can be simplified and integrated to give eq. 4.

$$[4] \quad ([M_2]_0 - [M_2]) + \frac{1}{\varepsilon_{M_2}} \times \log \frac{(1 - 10^{-\varepsilon_{M_2}[M_2]_0})}{(1 - 10^{-\varepsilon_{M_2}[M_2]})} = \frac{\phi I_0 t}{V}$$

which in turn can be rearranged to give [5].

$$[5] \quad F(A_t) = \frac{\phi I_0 \varepsilon_{M_2} t}{V}$$

where

$$F(A_t) = A_0 - A_t + \log \frac{(1 - T_0)}{(1 - T)}$$

and A and T refer to the absorbance and transmittance of the solution at the monitoring wavelength.

According to eqs. 3 and 5, $f(A_t)$ and $F(A_t)$ should be linear functions of time, and quantum

yields can be determined from the slopes of plots of these functions against time.

In this study, the concentration of M_2 was such that condition *A* was applicable for runs at irradiating wavelengths 365 nm and 436 nm, while condition *B* was applicable for irradiation at 546 nm. Reactions were monitored for the first 20–25% of reaction.

Results and Discussion

Plots of $f(A_t)$ and $F(A_t)$ against time were indeed linear and from the slopes of these plots the quantum yields were determined. Figure 2 shows the variation of the quantum yield for the insertion of $SnCl_2$ into the Co—Co bond of $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$ to produce $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2SnCl_2$, as a function of the concentration of $SnCl_2$ at the three wavelengths of irradiation 365 nm, 436 nm, and 546 nm.

Irradiation at 365 nm

Figure 2 indicates that for irradiation at 365 nm, the quantum yield increases with increasing $[SnCl_2]$ but begins to level off at high $[SnCl_2]$. A mechanism which is consistent with these data and which is similar to that proposed by Barrett and Poë (10) is as follows:

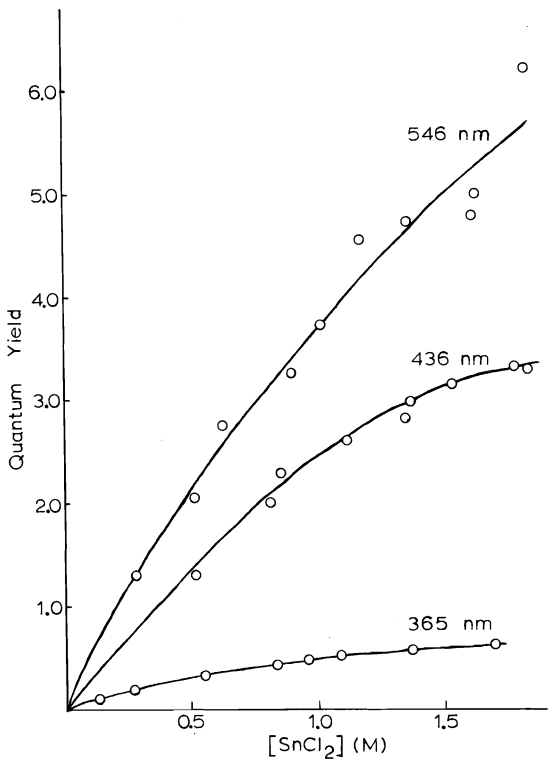

FIG. 2. Dependence of quantum yield on $[SnCl_2]$ for irradiation at 365 nm, 436 nm, and 546 nm.

Mechanism I

$$M_2 \xrightarrow{h\nu} M_2^*$$

$$M_2^* \xrightarrow{k_1} M_2$$

$$M_2^* + L \xrightarrow{k_2} MLM$$

The excited state produced directly on absorption of radiation due to the strong absorption band of $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$, which has a maximum absorption at 372 nm ($\varepsilon_{max} \sim 3.1 \times 10^4$) (Fig. 1), is assumed to be rapidly converted by radiationless processes having unitary efficiency to M_2^*, a lower energy, longer lived excited state which can undergo the chemistry indicated in the mechanism. Although the absorption spectrum also shows a broad shoulder around 440 nm, it is much weaker than the 372 nm band and therefore the bulk of the absorption of the 365 nm radiation would be due to the peak at 372 nm. Making a steady-state approximation for $[M_2^*]$ leads to the following expression for the quantum yield

$$\phi = \frac{k_2[L]}{k_1 + k_2[L]} \quad [6]$$

which can be rearranged to give

$$\frac{1}{\phi} = 1 + \frac{k_1}{k_2[L]} \quad [7]$$

Equation 7 predicts that a plot of ϕ^{-1} against $[L]^{-1}$ should be linear with an intercept of 1.0 and a slope of k_1/k_2. Figure 3 demonstrates the linearity of this plot and gives an intercept of 0.91 ± 0.05, *i.e.* a limiting ϕ at high [L] of 1.10 ± 0.06, and a value of k_1/k_2 of 1.18 ± 0.02. Equation 7 also implies that the quantum yield should be independent of both the intensity of the radiation and the concentration of $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$. Although there is a fair degree of scatter of the data points, Table 2 indicates that these criteria appear to be met.

Irradiation at 436 nm and 546 nm

Figure 1 indicates that photolysis at 546 nm will result in absorption due to the broad band centered at ~440 nm. Since overlap of this band with the strong band at 372 nm is negligible at the photolyzing wavelength of 546 nm, the

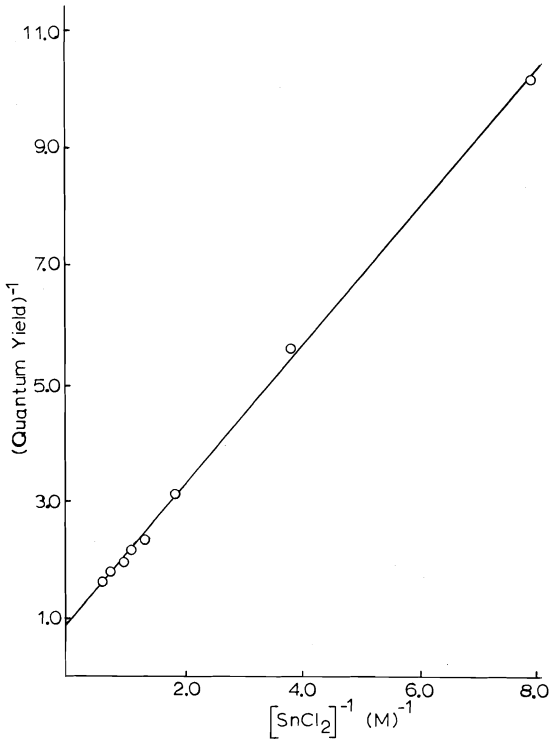

FIG. 3. Plot of ϕ^{-1} against $[SnCl_2]^{-1}$ for irradiation at 365 nm.

excited state produced, M_2*, will be electronically different from that formed from irradiation at 365 nm and could therefore give rise to an entirely different mechanism for the reaction. The fact that the quantum yields are greater than 1.0 (Fig. 2) implies that a chain mechanism is operating and the following scheme is consistent with the data:

Mechanism II

$$M_2 \xrightarrow{h\nu} M_2^*$$

$$M_2^* \xrightarrow{k_3} M_2$$

$$M_2^* + L \xrightarrow{k_4} MLM$$

$$M_2^* + L \xrightarrow{k_5} \cdot ML + \cdot M$$

$$\cdot ML + M_2 \xrightarrow{k_6} MLM + \cdot M$$

$$\cdot M + L \xrightarrow{k_7} \cdot ML$$

$$\cdot M + \cdot ML \xrightarrow{k_8} MLM$$

Applying the steady-state approximation to $[M_2^*]$, $[\cdot ML]$, and $[\cdot M]$, and if I_m = rate of absorption of radiation by M_2 in einsteins ℓ^{-1} h^{-1}, the following expression for the quantum yield can be derived:

$$[8] \quad \phi = \frac{(k_4 + k_5)[L]}{k_3 + (k_4 + k_5)[L]} + \left(\frac{[M_2]}{I_m}\right)^{1/2} \times \left(\frac{k_5 k_6 k_7}{k_3 k_8 + k_8(k_4 + k_5)[L]}\right)^{1/2} [L]$$

TABLE 2. Dependence of ϕ on $[M_2]$ and on the intensity of absorbed radiation I_m at 365 nm, $M_2 = [P(n\text{-}C_4H_9)_3Co(CO)_3]_2$

$[SnCl_2]$ (M)	$[M_2]$ (M)	$10^5 I_m$ (einsteins ℓ^{-1} h^{-1})	ϕ
1.50	4.19	1.93	0.560
1.50	4.07	3.26	0.540
1.50	4.62	5.10	0.681
1.50	3.55	6.85	0.585
1.50	3.25	5.10	0.708
1.50	8.76	5.10	0.766

Because irradiation at 436 nm occurs in a region of overlap of the two absorption bands at 372 nm and ~440 nm, presumably the insertion reaction can occur simultaneously by both mechanisms I and II. The quantum yields observed for irradiation at 436 nm would therefore be expected to fall between those observed for irradiation at 365 nm and 546 nm and this is borne out in Fig. 2. Equation 8 predicts that at constant $[M_2]$ and [L], the quantum yield should be inversely proportional to $I_m^{1/2}$, and that at constant [L] and I_m, ϕ should be directly proportional to $[M_2]^{1/2}$. Figures 4 and 5 show the plots which appear to verify these predictions. The intercept in both figures should lie between 0 and 1.0, but the accuracy of the intercepts is poor because the data points are so far removed from the intercept.

The nature of the excited states M_2* postulated in mechanisms I and II can be understood only if the electronic transitions involved in the two absorption bands in the uv–visible spectrum of $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$ are known. The intense absorption band between 350 nm and 400 nm for complexes of the type $[Co(CO)_3L]_2$, where L = phosphine or phosphite, has been assigned to a σ–σ* transition associated with the cobalt–cobalt bond (14). Although the broad shoulder on the lower energy side of the intense band in these complexes has not been unequivocally assigned, a similar shoulder band in $Mn_2(CO)_{10}$ adjacent to the band due to the

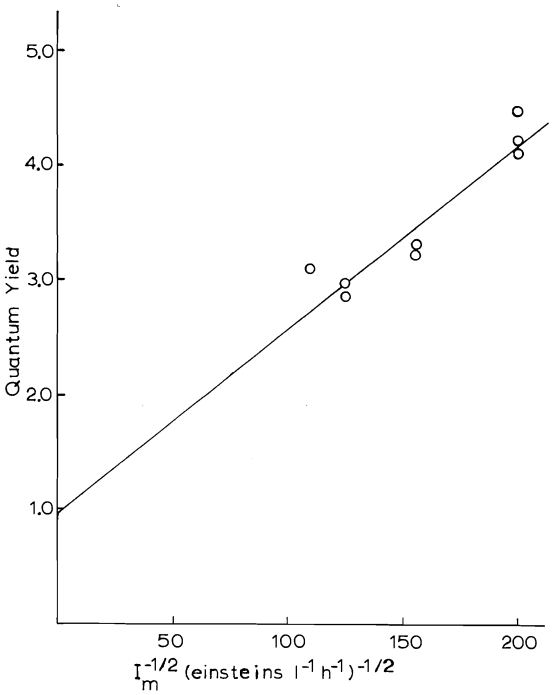

FIG. 4. Plot of ϕ against $I_m^{-1/2}$ for irradiation at 436 nm. $[SnCl_2] = 1.50\ M$.

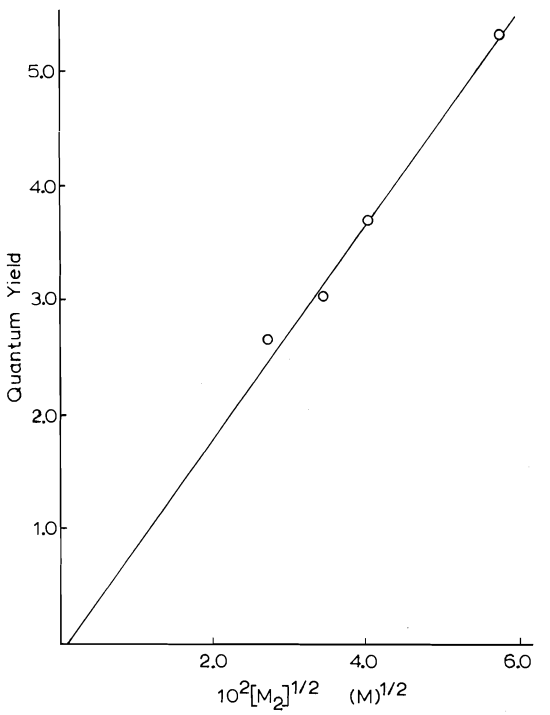

FIG. 5. Plot of ϕ against $[M_2]^{1/2}$ for irradiation at 436 nm. $[SnCl_2] = 1.50\ M$.

σ–σ^* transition has been assigned to a π–σ^* transition (15) and it would appear reasonable to make a similar assignment in the case of the cobalt complexes. Absorption of radiation at 365 nm therefore would result in an electronic transition from the M—M bonding σ orbital to a σ^* orbital. Such a transition would be expected to reduce to zero the bond order between the two halves of the dimeric complex and easily lead to the formation of radicals. No radicals could, however, be detected by esr in the range 3650 $\pm$ 250 G on irradiation of a solution of $[P(n\text{-}C_4H_9)_3Co(CO)_3]_2$ in THF with a 200 W high pressure mercury lamp. Irradiation of $Mn_2(CO)_{10}$ has been reported to result in the formation of Mn(O) radical species which are detectable by esr (16, 17), but these claims appear now to be unfounded (18, 19). Although the limiting quantum yield of 1.0 for irradiation at 365 nm, which is predicted by mechanism I and which is consistent with the data, rules out the possibility of a radical chain mechanism occurring, there still is the possibility that M_2^* could exist as two radicals trapped in a solvent cage.

Absorption of radiation due to the lower energy band at $\sim$440 nm does give rise to a chain mechanism as evidenced by the large quantum yields at 436 nm and 546 nm. The transition involved (π–σ^*) would result in the M—M bond order being reduced to one-half, but it is not clear why a radical propagation mechanism should be favoured here when there is no evidence for such a mechanism occurring with radiation corresponding to the σ–σ^* transition.

Substituent effects on the triplet–singlet energy separation in diphenylmethylene[1]

ROBERT W. R. HUMPHREYS AND DONALD R. ARNOLD[2]

Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received November 23, 1976

ROBERT W. R. HUMPHREYS and DONALD R. ARNOLD. Can. J. Chem. **55**, 2286 (1977).

The electron paramagnetic resonance (epr) spectra of the diarylmethylenes: diphenylmethylene, *p*-cyanodiphenylmethylene, *p*-methoxydiphenylmethylene, *p,p'*-dimethoxydiphenylmethylene, *p,p'*-dicyanodiphenylmethylene, *p*-cyano-*p'*-methoxydiphenylmethylene, have been studied. The zero-field splitting parameters have been determined. The signal intensity as a function of temperature (*ca.* 4–20 K) indicates these methylenes are ground state triplet species.

ROBERT W. R. HUMPHREYS et DONALD R. ARNOLD. Can. J. Chem. **55**, 2286 (1977).

On a déterminé les spectres de résonance paramagnétique électronique (rpe) des diarylméthylènes: diphénylméthylène, *p*-cyanodiphénylméthylène, *p*-méthoxydiphénylméthylène, *p,p'*-diméthoxydiphénylméthylène, *p,p'*-dicyanodiphénylméthylène, *p*-cyano-*p'*-méthoxydiphénylméthylène. On a déterminé les paramètres de couplage à champ zéro. L'intensité du signal en fonction de la température (environ de 4–20 K) indique que ces groupements méthylène existent sous forme d'espèces triplets dans l'état fondamental.

[Traduit par le journal]

Introduction

Diphenylmethylene has been extensively studied over the past fifteen years. In the process, a considerable amount of information about the structure and chemical reactivity of this molecule has been obtained.

Early reports of the electron paramagnetic resonance (epr) spectra of diphenylmethylene, both randomly-oriented in a rigid glass (3*a*) and oriented in a single-crystal matrix (3*b*), indicated that the triplet was the ground state of the molecule. Although one might expect such a triplet methylene to be linear, with the planes of the phenyl rings perpendicular (Fig. 1*a*) (4), the epr studies indicate that this is not the case. Hyperfine coupling data for diphenylmethylene oriented in single crystals of benzophenone, along with molecular orbital calculations (5), and ENDOR experiments on diphenylmethylene in single crystals of 1,1-diphenylethylene (6) suggest that the molecule is non-linear with a dihedral angle (*i.e.* the angle at the divalent carbon) of 140–155°. The ENDOR experiments also suggest that the phenyl rings deviate from coplanarity, but it is possible that the structure is altered somewhat by the crystal packing forces.[3]

The magnitude of the epr zero-field splitting parameter D for diphenylmethylene ($D = 0.4050$ cm^{-1}, $E = 0.0194$ cm^{-1}) (7) is considerably greater than that for the phosphorescent state of an aromatic hydrocarbon such as naphthalene ($D = 0.0992$ cm^{-1}, $E = 0.0143$ cm^{-1}). Thus the two unpaired electrons must be localized at the divalent carbon to a large extent. However, delocalization into the phenyl groups in diphenylmethylene is significant in comparison to phenylmethylene ($D = 0.5098$ cm^{-1}) (7) and methylene ($D = 0.95$ cm^{-1}) (8). It should also be

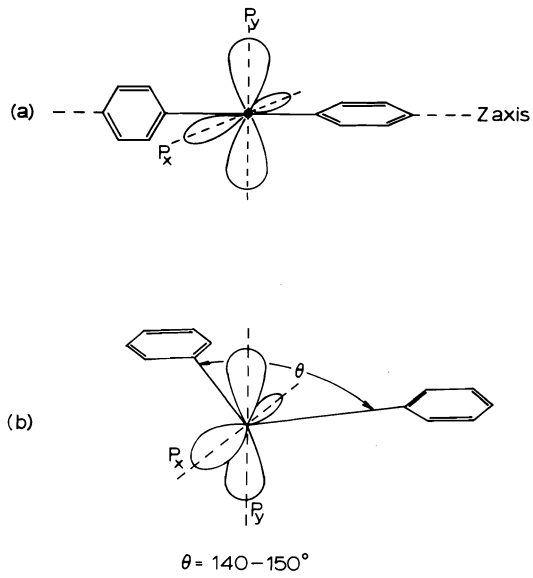

FIG. 1. Models for diphenylmethylene.

[1]Contribution No. 166.

[3]The observed deviation from coplanarity of the phenyl rings in diphenylmethylene is very similar to that known for the host crystal diphenylene from X-ray analysis (6).

noted that E is not equal to zero. This was the first experimental indication that the linear model for diphenylmethylene with the phenyl planes perpendicular was incorrect, since one would expect such a triplet species to have $E = 0$.

The above results lead to a model for triplet diphenylmethylene in which the divalent carbon and phenyl rings are approximately coplanar (7, 9) (Fig. 1*b*). The two half-filled orbitals at the divalent carbon consist of a pure *p*-orbital perpendicular to the phenyl rings, and conjugated with the phenyl π-system, and an orbital occupying the plane of the molecule with considerable *s* character (referred to as the σ-orbital). The unpaired electron occupying the *p*-orbital is, thus, delocalized into the phenyl rings to a certain extent while the unpaired electron in the σ-orbital is localized at the divalent carbon atom.

There is one glaring problem still remaining in the understanding of diphenylmethylene. As has already been pointed out, it is well established that diphenylmethylene is a ground state triplet molecule. The stereospecificity of the addition of diphenylmethylene to *cis*- and *trans*-olefins at room temperature has led to the conclusion that both the singlet and the triplet were reacting and that these species are in thermal equilibrium at this temperature (10*a*). The actual energy gap between the ground triplet state and the first singlet state has been estimated, by a complex kinetic analysis of flash spectroscopic experiments, to be less than *ca.* 3.6 kcal mol^{-1} (10*b*).

Theoretical calculations of the energy separation between the triplet and singlet states of diphenylmethylene are very few due to the large size of the molecule. Extended Hückel calculations by Hoffmann, Zeiss, and Van Dine (11) led these authors to predict the ground state of diphenylmethylene to be the triplet state. However, no estimate of the energy separation between the ground triplet state and the first singlet state can be obtained from these calculations and in fact the prediction of the triplet ground state was based partially on empirical criteria.

It should be mentioned that the absorption and emission spectra of diphenylmethylene have also been studied (9, 12). Unfortunately, only fluorescence emission has been detected. Attempts to detect phosphorescence, which would give the triplet–singlet separation directly, were unsuccessful (9).

In a recent publication (13), we described the determination of the ground state multiplicity of a number of related phenylvinylmethylenes. Our interest centered on the effect of substituents on the ground state multiplicity of the species in question based on theoretical models for the parent vinylmethylene (12, 14). The problem associated with the triplet–singlet energy separation in diphenylmethylene led us to study the effect of substituents on this system.

The possible stabilization of singlet methylene with respect to the triplet has been discussed in some detail by other authors (11, 14*a*, 15, 16), and these concepts can be applied to diphenylmethylene. The basic problem involves removing the degeneracy of the singly occupied *p*-orbitals in linear triplet methylene to the point at which it is more favourable energetically for both electrons to occupy the same orbital. This, of course, involves overcoming the electron–electron repulsion which occurs when both electrons occupy the same orbital. Is it possible, with the proper choice of substituents, to remove the degeneracy of the two singly-occupied orbitals in triplet diphenylmethylene to such an extent that the singlet becomes the ground state?

It is not immediately obvious how the choice of substituents will affect the triplet–singlet energy gap in diphenylmethylene since it is clear that substituents will influence both the triplet and singlet states. Substituent stabilization of the triplet has been discussed by Closs and Goh in the case of *p*-nitrophenylcarbene (17). The zero-field splitting parameter D for *p*-nitrophenylcarbene (0.480 cm^{-1}) is smaller than that for phenylcarbene (0.512 cm^{-1}), indicating increased electron delocalization in the nitro derivative and, thus, some stabilization of the triplet state by the nitro group. However, the known substituent effects on the value of D are generally small and it is not apparent what relationship there is between the D-value and the actual energy of a triplet state, much less the energy separation between the triplet and singlet. We felt that the substituent effect on the triplet–singlet energy separation should be considerably larger than the substituent effect on the stability of the triplet state of diphenylmethylene. This assumption is supported by the very large Hammett ρ-value observed for the gas phase ionization of substituted benzyl radicals (18) and from the relatively small effect of substituents upon the epr spectra of substituted benzyl radicals (19) when con-

sidered with the accepted structure of diphenylmethylene (*i.e.* the triplet state, Fig. 1*b*).

Based on the above rationale, we prepared a series of *p*-cyano and *p*-methoxy substituted diphenylmethylenes (Table 1). We chose these substituents as examples of good resonance electron withdrawing and donating substituents, respectively. The diphenylmethylenes were easily obtained by irradiation of the corresponding diazo compounds in a rigid glass at very low temperatures. The diazo compounds were prepared from the corresponding hydrazones by oxidation with mercuric oxide in the presence of base using a method described in the Experimental section.

The experimental determination of the ground state multiplicity of these species and the attempts to observe the population of an upper state can be a relatively simple matter if the triplet methylene can be detected by epr spectroscopy. For a constant methylene concentration, the signal intensity should vary inversely with temperature. That is, the signal intensity should follow the Curie law. Deviation from this linear relationship indicates one of the following: (*1*) the triplet is reacting as the temperature is raised (this can easily be verified by repeating the temperature cycle on the same sample); (*2*) an upper singlet state is being populated as the temperature is raised, thus depleting the population of triplets; (*3*) the singlet state is the ground state and the triplet state is being populated as the temperature is raised.

The expected behaviour of the signal intensity under conditions (*2*) and (*3*) has been discussed in some detail previously (13). The temperature dependence of the signal intensity for various triplet species have been reported (1). These studies include several examples in which the triplet is the upper state which is thermally populated (1 *a–d*). Species examined by this technique which show singlet–triplet equilibrium behaviour include cyclic, symmetric 4n π-electron systems (1 *a, b*), aromatic dinegative ions (1*c*), and biradicals (1 *d, e*). This behaviour has never been observed for a methylene system.

There are no reported examples of the observation of temperature dependent signal intensity behaviour indicative of thermal population of an upper singlet from a lower energy triplet state (*i.e.* case *2*). This is perhaps not surprising in view of the limitations of this technique to detect this phenomenon (13).

Results

The diphenyldiazomethanes were characterized by ^{1}H nmr, ir, and visible spectroscopy. Examination of the visible absorption maxima for the series indicated a trend in the effect of substituents on the position of the maximum. A good correlation was found for the position of the visible absorption maximum as a function of the Hammett substituent parameter $\sum\sigma_p$. This correlation was useful to confirm the structure of the diphenyldiazomethanes, including other *para*-substituted diphenyldiazomethanes not described here.

Generation of the methylenes (**1–6**) at *ca.* 5 K in a rigid glass proved to be an easy matter. The diazo precursors were irradiated directly with a 1 kW high pressure mercury arc lamp. Once generated, the methylenes seemed to be stable to further irradiation. However, prolonged irradiation was avoided to prevent both excessive sample heating, thereby wasting liquid helium, and a significant increase in the signal due to free radicals in the $g = 2$ region.

The signals due to a triplet species were assigned in terms of the Hamiltonian $\mathcal{H} = g\beta H\cdot\hat{S} + D\hat{S}_z^2 + E(\hat{S}_x^2 - \hat{S}_y^2)$. The zero-field splitting parameters were obtained from the observed spectra by employing an iterative computer program and are summarized in Table 2. The spectral field positions were obtained accurately using an Alpha Scientific Model 675 Gaussmeter. In all cases, only four lines were observed: H_{z_1}; H_{x_2}; H_{y_2}; H_{z_2}.

The observed signal intensity (the peak-to-peak height of the H_{x_2} line was used in every case) as a function of temperature for two of the methylenes studied is shown in Fig. 2. As can be seen, the

plots are linear over the entire temperature range studied (5–20 K). These results were typical of all the diphenylmethylenes (**1–6**) listed in Table 1.

Discussion

On examining the D and E values in Table 2, it is, first of all, obvious that the effect of substituents is not large and, secondly, that there is no trend which is consistent with the Hammett substituent parameters (σ, σ^+, etc.). In general, the observed D value is somewhat lower than that of the parent species, indicating greater electron delocalization in the substituted diphenylmethylenes. This is predictable and has been observed previously (7).

The I *vs.* $1/T$ plots for diphenylmethylenes **1–6** indicate that all follow Curie law dependence over the temperature range studied. We interpret these results to mean that the diphenylmethylenes **1–6** are ground state triplets and the singlet state is not being populated to any discernible extent at the maximum temperature of the experiment. An alternative possibility is that the singlet is the ground state of the species and is separated by such a small energy (<5 cal mol^{-1}) from the upper triplet as to be in thermal equilibrium with this upper state even at the lowest temperatures used. We consider this unlikely for any of the diphenylmethylenes **1–6**.

The expected behaviour of the intensity *vs.* $(\text{temperature})^{-1}$ profile for an upper singlet state being populated from a lower triplet state can be calculated using the expression

$$I = \frac{a}{T}\frac{e^{-\Delta E/RT}}{3 + e^{-\Delta E/RT}}$$

Such calculations indicate that the practical limit for the observation of deviations from Curie law dependence, from a graphical standpoint, seems to be somewhat less than 100 cal mol^{-1} for the case in which the triplet is the ground state. This at least places a lower limit on the triplet–singlet energy separation in all diphenylmethylenes studied here

We conclude that the effects of the p-methoxy and cyano substituents in the derivatives **1–6** are not large enough to invert the order of states in diphenylmethylene. In view of the relatively small energy difference (<3.6 kcal mol^{-1} estimated) (10*b*) between these states in diphenylmethylene, we are reluctant to abandon the substituent effect approach to achieve this objective. We have, therefore, begun a study of the *p-N,N*-dimethylamino and nitro derivatives. Preliminary evidence indicates that the p,p'-bisdimethylamino and the p-dimethylamino derivatives are ground state triplets. Our results from this series will be reported in the near future.

Experimental

General

Electron paramagnetic resonance spectra were obtained from and temperature dependence studies were performed on a Varian E-12 epr spectrometer equipped with an Air Products Model LTD-3-110 "Helitran" liquid helium Dewar and transfer system. Samples were placed in Supersil epr tubes and were irradiated with a Schoeffel 1 kW high pressure mercury arc lamp.

Electron paramagnetic resonance samples were generally prepared by dissolving approximately 6 mg of the appropriate diphenyldiazomethane in 1 ml 4:1 methylcyclohexane-isopentane (MCIP) followed by degassing by the freeze–pump–thaw technique. For samples used in the temperature dependence studies, approximately 6 mg phenylazide was added to the samples. The inclusion of the phenylazide provided an internal check on the temperature readings, since (triplet) signals from phenyl nitrene are known to follow the Curie law.

Temperature readings at liquid helium temperatures were obtained using two chromel *vs.* gold – 0.07% iron thermocouples, one imbedded in the liquid helium Dewar near the sample cavity and one used as a standard at ice–water temperature. The voltage readings were obtained from a Hewlett–Packard 3420B DC differential voltmeter.

Temperature Dependence Studies

The temperature dependence studies were performed in a manner essentially identical to that described in a previous paper (13) and will not be discussed here.

Preparation of Compounds

All diphenyldiazomethanes were prepared by the same method. The general procedure involved the preparation of the corresponding benzophenone hydrazone and subsequent oxidation with yellow mercuric oxide in the presence of base. The preparation of *p,p'*-dicyanodiphenyldiazomethane was typical, with the exception that dry THF was used as the solvent for the oxidation step due to the insolubility of *p,p'*-dicyanobenzophenone hydrazone in diethyl ether. For all of the other diphenyldiazomethanes, the oxidation step was carried out in diethyl ether.

Pertinent spectral data for the diazo compounds are summarized in Table 3.

The preparation of the hydrazones was generally carried out by a method described previously (2). For *p*-cyano- and *p,p'*-dicyanobenzophenone hydrozone, this method was found to produce considerable azine. Therefore, a different method was used for the preparation of the corresponding hydrazones of these ketones and will be described in detail for *p,p'*-dicyanobenzophenone hydrazone.

The preparation of *p,p'*-dicyanobenzophenone is also described due to the improved procedure used.

All ^{1}H nmr spectra were obtained on a Varian T-60 nmr spectrometer using TMS as an internal standard. All ir spectra were obtained on a Beckman IR-5A infrared spectrometer with polystyrene calibration. Visible spectra were obtained on a Cary 118C UV-Visible spectrometer.

p,p'-Dicyanobenzophenone

Dry *N,N*-dimethylformamide (20 ml), *p,p'*-dibromobenzophenone (20 g, 0.059 mol), and cuprous cyanide (12.7 g, 0.142 mol, 20% excess) were placed in a 50 ml round-bottom flask equipped with a magnetic stirring bar, reflux condenser, and drying tube. The mixture was heated to reflux using an oil bath and was allowed to heat for 9 h, at which time the hot, dark brown, granular mixture was poured into hot, 10% aqueous sodium cyanide (500 ml). The sodium cyanide solution was allowed to heat on a steambath for 30 min, at which time an orange solid had separated and come to the top. The sodium cyanide solution was extracted with benzene (3 × 250 ml), the orange solid dissolving in the benzene. The benzene solution was washed three times with water and dried over anhydrous magnesium sulfate.

In some cases, lumps of solid from the reaction mixture may appear and these should be broken up with a glass rod. Periodic manual stirring of the hot sodium cyanide solution also helps and the mixture may be left on the steambath for longer than 30 min. Some solid will remain

which cannot be dissolved in either the benzene or aqueous layers.

After filtration by gravity and removal of the benzene on the rotary evaporator, a yellow solid was obtained, the nmr and ir spectra of which indicated the presence of *p,p′*-dicyanobenzophenone. The crude yield was about 60% (8.2 g). Removal of the yellow colour required column chromatography on silica gel using 9:1 petroleum ether – diethyl ether elution and slowly changing to 6:4 petroleum ether – diethyl ether. Recrystallization of the pure product from chloroform – diethyl ether or benzene afforded needles, mp 159.5–160°C (uncorrected). *nmr (CDCl₃)*: δ 7.82(s); *ir (CHCl₃)*: 3.33(w), 4.47(m), 6.00(s), 7.86(s), 10.77(s).

p,p′-Dicyanobenzophenone Hydrazone

Hydrazine hydrate (3.5 g, 0.069 mol), absolute alcohol (50 ml), and anhydrous sodium sulfate (10 g) were placed in a 250 ml 3-neck round-bottom flask equipped with an addition funnel, stopper, condenser, and drying tube, and the mixture was heated to reflux using an oil bath. A solution of *p,p′*-dicyanobenzophenone (0.805 g, 3.47×10^{-3} mol) in ethanol (50 ml) and benzene (20 ml) was added through the addition funnel over a period of 8 h, at which point the reaction mixture was a light yellow colour. The mixture was allowed to heat at reflux overnight.

After cooling and filtering by gravity to remove the sodium sulfate, all solvent was distilled off under vacuum and the light yellow solid thus obtained was recrystallized from absolute alcohol. Very light yellow crystals of *p,p′*-dicyanobenzophenone hydrazone (0.445 g, 55%) were obtained after two recrystallizations from absolute alcohol. *nmr (CDCl₃)*: δ 5.7 (s, br, 2H), δ 7.74 (m, 6H); *ir (CHCl₃)*: 2.89(w), 3.33(w), 4.39(s), 6.36(m), 6.66(m), 11.90(s).

p,p′-Dicyanodiphenyldiazomethane

p,p′-Dicyanobenzophenone hydrazone (0.127 g, 5.16×10^{-4} mol) was placed in a 25 ml round-bottom flask equipped with a magnetic stirring bar and a drying tube. Spectral grade tetrahydrofuran (20 ml) was added and the hydrazone was allowed to dissolve. Anhydrous sodium sulfate (1.0 g), yellow mercuric oxide (0.450 g, 2.1×10^{-3} mol), and saturated ethanolic potassium hydroxide (0.5 ml) were added and the mixture was allowed to stir vigorously at room temperature in the dark overnight. The reaction mixture was filtered by gravity, with care being taken to exclude all light. The solution was a deep orange colour. Evaporation of the solvent on a rotary evaporator afforded an orange solid, the nmr and ir of which were consistent with the structure of the desired product, *p,p′*-dicyanodiphenyldiazomethane (Table 3).

The internal coordinate Morse oscillator as a means to simplify the anharmonicity problem in the thermodynamics of systems of polyatomic molecules

JAN BRON AND R. WALLACE

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received November 15, 1976

JAN BRON and R. WALLACE. Can. J. Chem. **55**, 2292 (1977).

Two postulates simplify the evaluation and algebraic complexity of the expression for the anharmonic correction to the ground rotational–vibrational energy of a polyatomic molecule. The two postulates are: (*1*) anharmonicity of vibration is associated with bond stretching coordinates only; all other internal coordinates can be represented by harmonic potentials; (*2*) bonds vibrate according to a Morse potential. The result is the replacement of tedious computer calculations by a 'back of an envelope' type of computation. Relationships between anharmonic corrections to the ground state vibrational energies of isotopically different molecules are derived. Good agreement with exact results is obtained. Quantitative and qualitative applications are given.

JAN BRON et R. WALLACE. Can. J. Chem. **55**, 2292 (1977).

Deux postulats permettent de simplifier l'évaluation et la complexité algébrique de l'expression pour la correction anharmonique vers l'énergie rotationnelle vibrationnelle fondamentale d'une molécule polyatomique. Les deux postulats sont: (*1*) l'anharmonicité de la vibration est associée uniquement avec les coordonnées de vibration du lien; toutes les autres coordonnées internes peuvent être représentées par des potentiels harmoniques. (*2*) Les liens vibrent d'après un potentiel de Morse. Le résultat de cette simplification implique le remplacement de calculs complexes par ordinateur par un type de calcul qui peut se faire sur le "dos d'une enveloppe." On a pu dériver des relations entre les corrections anharmoniques vers les énergies vibrationnelles de l'état fondamental de molécules différentes du point de vue isotopique. On a obtenu un bon accord avec les résultats exacts. On donne des applications qualitatives et quantitatives.
[Traduit par le journal]

Introduction

The correction of partition functions and thermodynamic quantities for anharmonicity of vibration has been discussed in detail over the past few years (1–4). It has been found that thermodynamic quantities, calculated by means of the harmonic approximation, may be considerably changed when corrected for anharmonicity. This was especially found to be true for compounds containing hydrogen isotopes (5). Anharmonicity in the ground vibrational–rotational state seems to lead to the largest correction (5).

The anharmonic correction, a multiplicative factor, of the molecular canonical partition function, q, has the form

$$[1] \qquad \text{ANHC} = \exp\left[-(\text{AZPE})/kT\right]$$

The energy quantity, AZPE (5), is the difference between the anharmonic and harmonic vibrational zero-point energy. The expression for AZPE is complex and not easily evaluated (3). The calculation of AZPE requires the use of a large, modern computer. The time needed to calculate AZPE increases enormously when one atom is added to the molecule. For this reason it has proved impossible to study molecules with more than four atoms.

The time consuming part in calculations of AZPE is the transformation of cubic and quartic force constants in internal coordinates to those in dimensionless normal coordinates (6). In a recent paper (7) a theory of nuclear motion in polyatomic molecules based upon the Morse oscillator (bond stretches) has been developed. This theory can be used to evaluate AZPE, eliminating the tedious transformation mentioned above.

In this paper the Morse oscillator approach will be used to attempt to simplify the theory of anharmonicity. Since the anharmonicity correction, ANHC, is largest for compounds containing hydrogen isotopes, this discussion will mainly deal with H, D, and T containing molecules.

Theoretical Considerations

Perhaps the simplest way to evaluate the vibrational partition function, q_{vib}, is to sub-

stitute the harmonic frequencies, obtained by using the best available (harmonic) spectroscopic force field and Wilson's **F**, **G** matrix method (8), into the well known expression

$$[2] \quad q_{\text{vib}} = \prod_{i=1}^{3N-6(5)} e^{-hc\omega_i/2kT}(1 - e^{-hc\omega_i/kT})^{-1}$$

and then multiply q_{vib} by ANHC. In [2], ω_i (cm^{-1}) is the frequency of vibration of the ith normal mode and all other symbols have their usual meaning. It is proposed to estimate ANHC by assuming that the magnitude of AZPE is mainly determined by anharmonicity of vibration of the A—X bond (X = H, D, T; A is any other heavier element). Furthermore, it will be postulated that the bonds vibrate according to a Morse potential. An expression for AZPE can now be derived.

The vibrational Hamiltonian operator in terms of internal (stretching) coordinates, S_i, is (7)

$$[3] \quad \hat{H} = \sum_{i=1}^{m} \hat{H}_i^{(0)}(S_i) - \hbar^2 \sum\sum_{i<j} G_{ij}(\partial^2/\partial S_i \partial S_j)$$

There are m bonds in the molecule. The operator $\hat{H}_i^{(0)}(S_i)$ is defined as

$$[4] \quad \hat{H}_i^{(0)} = -\tfrac{1}{2}\hbar^2 G_{ii}(\partial^2/\partial S_i^2) + V_i(S_i)$$

and G_{ij} is a **G** matrix element defined by Wilson (8). The potential energy, $V_i(S_i)$, is given by the Morse expression

$$[5] \quad V_i(S_i) = D_i[\exp(-2a_iS_i) - 2\exp(-a_iS_i)]$$

where D_i and a_i are the usual Morse parameters for the ith bond. The approximate eigen values of the operator $\hat{H}$ in the vibration–rotational ground state can be found by (non-degenerate) perturbation theory.

Equation 3 can be written as

$$[6] \quad \hat{H} = \hat{H}_0 + \hat{H}^{(1)}$$

where

$$[7] \quad H_0 = \sum_{i=1}^{m} \hat{H}_i^{(0)}(S_i)$$

and the perturbation, $H^{(1)}$, is equal to

$$[8] \quad \hat{H}^{(1)} = -\hbar^2 \sum_{i<j}^{m}\sum^{m} G_{ij}(\partial^2/\partial S_i \partial S_j)$$

The zeroth-order wavefunction, $\psi_0^{(0)}$, is

$$[9] \quad \psi_0^{(0)} = \prod_{i=1}^{m} \phi_i^{(0)}(S_i)$$

The function $\phi_i^{(0)}(S_i)$ is the solution of the ith one-dimensional Morse oscillator problem and corresponds to the lowest eigenvalue (9):

$$[10] \quad E_i^{(0)} = -A_i^{-2}(K_i - \tfrac{1}{2})^2$$

In this equation the quantities A_i and K_i are defined as

$$[11] \quad A_i = (2\mu_i)^{1/2}/a_i\hbar; \quad K_i = A_i D_i^{1/2}$$

In [11], μ_i is the reduced mass of the atoms defining the ith bond. The solution, $E_0^{(0)}$, of the equation

$$[12] \quad H_0\psi_0^{(0)} = E_0^{(0)}\psi_0^{(0)} = \sum_{i=1}^{m} H_i^{(0)}\psi_0^{(0)}$$

is then

$$[13] \quad E_0^{(0)} = -\sum_{i=1}^{m} A_i^{-2}\left(K_i - \frac{1}{2}\right)^2$$

The first and second order contributions to the energy are more difficult to evaluate than for a set of m harmonic oscillators, because the matrix elements of the Morse oscillator do not have a set of well defined selection rules. By means of the eigen functions given in [9], the first order contribution, $E_0^{(1)}$, becomes

$$[14] \quad E_0^{(1)} = -\hbar^2 \sum_{i<j}^{m}\sum^{m} G_{ij}\langle 0|\partial/\partial S_i|0\rangle \times \langle 0|\partial/\partial S_j|0\rangle = -\tfrac{1}{4}\hbar^2 \sum_{i<j}^{m}\sum^{m} a_i a_j G_{ij}$$

The second order correction, $E_0^{(2)}$, to the ground state energy becomes

$$[15] \quad E_0^{(2)} = \sum_{k}' [\langle 0|\hat{H}^{(1)}|k\rangle^2/(E_0^{(0)} - E_k^{(0)})]$$

The prime near the summation sign indicates that the summation is over all states *except* the ground state. The energy $E_k^{(0)}$ is given by the expression (9)

$$[16] \quad E_k^{(0)} = -\sum_{i=1}^{m} A_i^{-2}(K_i - n_i - \tfrac{1}{2})^2$$

The subscript k is a symbol for the values of the quantum numbers n_i in the kth state.

For reasons given above, the summation in [15] will contain an infinite number of terms. However, by analogy with the harmonic oscillator, the term, V_{11}, in the sum that will be largest by far is

$$[17]\quad V_{11} = \hbar^4 \left[\sum_{i<j} \sum G_{ij} \langle 0|\partial/\partial S_i|1\rangle \times \langle 0|\partial/\partial S_j|1\rangle \right]^2 \Big/ \Delta E_{11}{}^{(0)}$$

The difference $\Delta E_{11}{}^{(0)}$ is defined as

$$[18]\quad \Delta E_{11}{}^{(0)} = -A_i{}^{-2}(K_i - \tfrac{1}{2})^2 - A_j{}^{-2} \times (K_j - \tfrac{1}{2})^2 + A_i{}^{-2}(K_i - \tfrac{3}{2}) + A_j{}^{-2}(K_j - \tfrac{3}{2})^2 = 2A_i{}^{-2}(1 - K_i) + 2A_j{}^{-2}(1 - K_j)$$

After evaluation of the matrix elements in [17], the expression for V_{11} becomes

$$[19]\quad V_{11} = (\hbar/2)^4 \left[\sum_{i<j} \sum a_i a_j G_{ij} (2K_i - 1)^{1/2} \times (2K_j - 1)^{1/2} \right]^2 \Big/ \Delta E_{11}{}^{(0)}$$

Expressions for the other terms in the sum can also be found.

Numerical values for [14] and the largest terms in [15] were obtained for several molecules, such as H_2O, HDO, D_2O, NH_3, NH_2D, . . . etc. It was found that they were extremely small compared to $E_0{}^{(0)}$. Therefore, considering the parametric character of the Morse oscillator, which shall be discussed below, $E_0{}^{(1)}$ and $E_0{}^{(2)}$ will be ignored. The ground state energy of the set of m oscillators in the molecule becomes then (*cf.* [13]):

$$[20]\quad E_0 = -\sum_{i=1}^{m} A_i{}^{-2}(K_i - \tfrac{1}{2})^2$$

Equation 20 is the ground state energy of a set of m *uncoupled* Morse oscillators and leads to important simplifications. Equation 20 can now be used to obtain an expression for AZPE in [1]:

$$[21]\quad \text{AZPE} = \sum(-A_i{}^{-2}(K_i - \tfrac{1}{2})^2 + D_i - \tfrac{1}{2}h\nu_i)$$

In [21] the Morse parameter D_i may be *roughly* identified with the depth of the potential well associated with the vibration of the ith bond. The harmonic part in E_0 is removed by subtracting $\frac{1}{2}\sum h\nu_i$. The frequency ν_i is defined as

$$[22]\quad \nu_i = (2\pi)^{-1}(F_i/\mu_i)^{1/2}$$

The force constant F_i can be expressed in terms of a_i and D_i, by differentiating [5] twice with respect to S_i and determining the value of the second derivative at $S_i = 0$. The result is

$$[23]\quad F_i = 2a_i{}^2 D_i \quad \text{or} \quad a_i = +(F_i/2D_i)^{1/2}$$

By means of [21], [22], and [23], AZPE becomes

$$[24]\quad \text{AZPE} = -\sum_{i=1}^{m} (2A_i)^{-2} = -\frac{\hbar^2}{16}\sum_{i=1}^{m} F_i/(\mu_i D_i)$$

It should be noted that [24] is easily evaluated if F_i and D_i are known. A reasonable value for F_i, the bond force constant, can be found in the literature (10) and an estimate for D_i can be obtained from Pauling's empirical formula (11). Results obtained from [24] can be compared with "exact" values (2, 3).

Discussion and Conclusions

The energy AZPE in [24] has been postulated to be a sum of contributions of m bonds in the molecule. It is convenient to define a quantity E(A—X) such that

$$[25]\quad \text{AZPE} = \sum E(\text{A—X})$$

where the summation is over all m bonds A—X. The bond anharmonic energy is then

$$[26]\quad E(\text{A—X}) = -(2A_i)^{-2} = -\hbar^2 F_i/(16\mu_i D_i)$$

Within the Born–Oppenheimer approximation F_i and D_i are the same for bonds differing only in isotopic substitution, therefore,

$$[27]\quad \frac{E(\text{A} - \text{X}')}{E(\text{A} - \text{X})} = \frac{\mu_i}{\mu_i'}$$

The prime denotes isotopic substitution. From [25] follows that AZPE for a molecule AX_mX_n' is

$$[28]\quad \text{AZPE}(AX_mX_n') = mE(\text{A—X}) + nE(\text{A—X}')$$

By means of [27], the above equation reduces to

$$[29]\quad \text{AZPE}(AX_mX_n') = E(\text{A—X}) \times [m + n\mu_i/\mu_i']$$

The relationship [28] has been observed (but not explained) previously (3) in exact calculations of AZPE for the NH_nD_{3-n}, NH_nT_{3-n}, AH_nD_{2-n}, and AH_nT_{2-n} (A = O, S, Se) molecules; also the reduced mass relationship, [27], holds. In the exact calculations, anharmonicity of the bending modes has been taken into account. Bending coordinates *probably*

cannot be related by equations of type [27] and [28]. The assumption that the magnitude of AZPE is mainly determined by anharmonic vibration of the A—X bonds, seems therefore reasonable.

A numerical example may be informative. The exact value for AZPE of NH_3 is -123.3 cm^{-1} (3). It took, by the way, about 50 min for a PDP-10 computer to obtain this number and the program used was the result of a year's work. From [28] follows that E(N—H) is equal to $-123.3/3$ or -41.1 cm^{-1}. By means of [27] and [29], AZPE for NH_2D, NHD_2, and ND_3 can be deduced. The results are -104.1, -85.0, and -65.8 cm^{-1} respectively. The exact values are -104.0, -84.9, and -66.1 cm^{-1}, so the agreement is excellent.

For molecules of the type AX_nX_m', the Morse oscillator approach reduces AZPE from a many to a *two* parameter equation. It may be useful to discuss these parameters, a_i and D_i, in greater detail. As pointed out above a_i and D_i are the same for chemical bonds differing only in isotopic substitution. The dissociation energy can approximately be identified with D_i, but a_i is a more abstract quantity. It is therefore suggested to use [23] and replace a_i by F_i. The force constant F_i is, of course, also the same for bonds only differing in isotopic substitution. The two (Morse) parameters are then only F_i and D_i. If F_i is obtained by spectroscopic means or from tables (10), AZPE depends on only *one* parameter. The remaining parameter D_i cannot be eliminated, since D_i and the bond dissociation energy are not the same. For example, for E(N—H) equal to -41.1 cm^{-1} and F_i equal to 8.454×10^5 dyn cm^{-1} (12) and [26] follows that D_i has the value of 278 kJ/mol. This compares poorly with 407 kJ/mol for the N—H bond (13). However, for molecules for which exact values for AZPE have not been obtained, the dissociation energy may serve as a first estimate of D_i.

Equations 25 and 27 are also useful for qualitative purposes. Recently a paper appeared (14) on *differences* in thermodynamic quantities of various $^x UF_6$ species (x = 238, 235, etc.). These differences are related to the partition function ratios of the $^x UF_6$ molecules. It was anticipated, by means of intuitive arguments, that the anharmonicity corrections for these partition function ratios are small. The equations in this paper can be used to prove this assertion. If, for example, the correction factor for the ratio $q(^{238}UF_6)/q(^{235}UF_6)$ is C, then

$$[30]\quad C = \mathrm{ANHC}(^{238}UF_6)/\mathrm{ANHC}(^{235}UF_6) = \exp\left[-\{\mathrm{AZPE}(^{238}UF_6) - \mathrm{AZPE}(^{235}UF_6)\}hc/kT\right]$$

It has been implied in [30] that the units of AZPE($^x UF_6$) are cm^{-1}. As mentioned above, there is no correction when C is equal to unity. By using [25] and [27], [30] becomes

$$[31]\quad C = \exp\left[-6E(^{238}U—F)(1 - \mu_{238}/\mu_{235}) \times hc/kT\right] = \exp\left[E(^{238}U—F)0.0057hc/kT\right]$$

If D_i(U—F) is equal to 517 kJ/mol (15) and F_i(U—F) is 3.85×10^5 dyn cm^{-1} (16), then C becomes 0.999985. Hence, anharmonicity is unimportant.

As has been implied above, two postulates simplify the evaluation and algebraic complexity of the expression for the anharmonic correction to the ground rotational–vibrational energy of polyatomic molecules. These two postulates are: (*1*) anharmonicity of vibration is primarily associated with bond stretching coordinates; all other internal coordinates can be represented by harmonic potentials: (*2*) bonds vibrate according to a Morse potential. The results obtained, eqs. 27 and 29, successfully relate AZPE for isotopic diatomic, triatomic, and tetratomic molecules (AX, AXY, AXYZ; X, Y, Z = H, D, T). Therefore, it is suggested that [27] and [29] may also be applied to suitable molecules of more than four atoms. It should be noted that [27] and [29] are essentially empirical in character.

The quantity ANHC, eq. 1, corrects only for anharmonicity of the ground state. A correction similar to ANHC can be defined for anharmonicity of the vibrational *excited* states, but it is expected that in that case simple expressions, such as [27] and [29], will not be obtained. However, detailed calculations have revealed (5) that corrections due to anharmonicity of the excited states are much smaller than ANHC at temperatures between 200 and 600 K. For higher temperatures the "local mode" method of Hayward and Henry (17, 18) shows promise to simplify the calculation of the correction for anharmonicity of excited states.

In this paper an attempt has been made to show how the values of AZPE for molecules

differing in isotopic substitution are related. Furthermore, a method has been presented to estimate AZPE, from the Morse parameters F_i (or a_i) and D_i. If precision is required and spectroscopic data are available it is best to calculate AZPE by the exact method and use the above formulae to determine AZPE for isotopic molecules. For larger molecules, containing more than four atoms, the exact method demands too much computer time, and the Morse oscillator approach can be used to gain an impression about the importance of anharmonicity of vibration. Equations 1, 25, and 27 can also be used in chemical kinetics (4).

Comments on "Librations around the C(S)–phenyl bond in *N*-thiobenzoylmorpholines observed by 220 MHz proton magnetic resonance spectroscopy"

ULF BERG

Division of Organic Chemistry 1, Chemical Center, University of Lund, P.O. Box 740, S-220 07 Lund 7, Sweden

Received December 21, 1976

ULF BERG. Can. J. Chem. **55**, 2297 (1977).

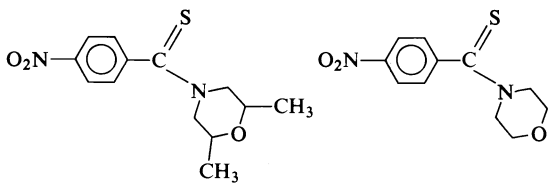
The interpretation of the temperature dependent nmr spectra of the three thiobenzmorpholides **1**–**3** in terms of torsional libration proposed in the title article is criticized. Pure samples of *cis*-**1** and *trans*-**1** have been prepared and studied by dynamic ^1H and ^{13}C nmr. A new interpretation is presented which involves the freezing of the passage over the steric barrier with a planar Ph—C(S)N transition state.

ULF BERG. Can. J. Chem. **55**, 2297 (1977).

On critique l'interprétation proposée dans l'article mentionné dans le titre pour expliquer la dépendance qui existe entre la température et les spectres rmn de trois thiobenzmorpholides **1** à **3** en termes de librations torsionnelles. On a préparé des échantillons purs de **1**-*cis* et de **1**-*trans* et on les a étudiés par rmn dynamique de ^1H et ^{13}C. On présente une nouvelle interprétation qui implique le blocage du passage au-dessus de la barrière stérique avec un état de transition Ph—C(S)N planaire.

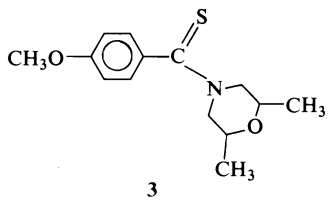
[Traduit par le journal]

Recently an investigation of the temperature dependent ^1H nmr spectrum of the three thiobenzmorpholides **1**–**3** was communicated (1). The



1

2



3

ortho-proton signals of **1** and **3** were reported to be temperature dependent in the region +40 – −50°C at 220 MHz in several solvents, whereas in **2** they remain unchanged under the same conditions.

Fulea and Krueger associate this phenomenon with the rotational process about the Ph—C(S) bond and suggest two energy maxima for this rotation, *i.e.* one steric barrier (E_{steric}) for the process by which *ortho*-protons would pass through the thioamide plane, and one electronic barrier (E_π) for the process by which the phenyl ring passes through a plane perpendicular to the thioamide plane. However, they do not attribute the observed spectral features to the freezing of any of these processes. Instead, the phenomenon is explained by "progressive freezing of the librations of the thioamide group around the Ph—C(S) bond as the temperature is lowered" and with the passages over both the E_{steric} and E_π barriers "frozen" in the relevant temperature region (0 – −50°C). This conclusion was based upon the existence of small sharp peaks in the neighbourhood of the coalescence temperature.

We question this interpretation and wish to present a critical analysis of their theory and a reinvestigation of the nmr spectrum of **1**.

In order to observe an effect on the nmr bandshape of the type shown in Fig. 1, ref. 1, of a set of nuclei interchanging between two (or more) sites, the condition has to be fulfilled that the lifetime of the nuclei in the different sites has to be much longer by far than what can be envisaged for the torsional levels around a local potential energy minimum (see, *e.g.*, ref. 2). In other words, the torsional states would have to be separated by barriers in the order of 11–14 kcal/mol in the present cases.[1] In the absence of such a high barrier, the nuclei in all populated

[1]This argument also contradicts the interpretations in terms of torsional librations in the other papers cited in ref. 1.

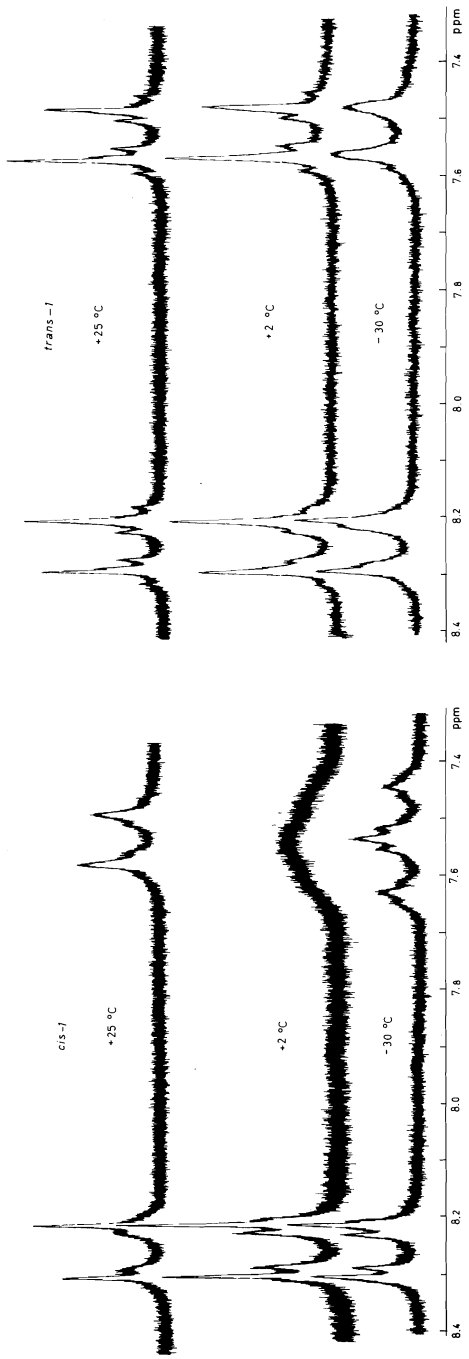


FIG. 1. ^{1}H nmr spectra of the aromatic protons of *cis*-**1** and *trans*-**1** in acetone-d_6 + $CDCl_3$ (1:1).

states give rise to only one chemical shift which is the weighted mean value of the chemical shifts in the different states. This, however, results in only "sharp" signals determined by this chemical shift and the coupling constants.

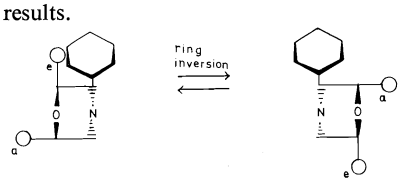
Furthermore, the statement in ref. 1 that passage over the E_π barrier, with a frozen E_{steric} rotation, will average the *ortho*-protons is erroneous in the case of **1** and **3** since the presence of the two methyl groups in the morpholine ring introduces anisochronism to the *ortho*-protons (in principle also to the *meta*-protons) even if the morpholine ring inversion is rapid, provided that the C(S)—N rotation is slow. This is true for both the *cis* and *trans* arrangements of the 2,6-dimethyl substituents.[2] In the absence of methyl substituents in the morpholine ring as in **2**, this anisochronism is lost if the inversion of this ring is rapid on the nmr time scale and the *ortho*-protons are indeed equalized by passage over the E_π barrier.

An analysis of the alternative possibility, *i.e.* that the E_π barrier is frozen, gives at hand that passage over the E_{steric} barrier does not equalize the *ortho*-protons in any of the compounds **1**–**3**. Though no barriers to rotation over the E_π maximum have so far been determined, a very low value for this barrier can be expected by an extrapolation from data on the Ph—C(O) system (3), taking into account the important barrier-lowering effect of the cross conjugation with the nitrogen lone pair as well as the destabilization of the ground state by non-bonded interactions (E_{steric}).

These remarks suggest an alternative interpretation which simply involves the freezing of the rotation about the E_{steric} barrier.

In a reinvestigation, authentic samples of *cis*-**1** and *trans*-**1** were prepared and examined by variable temperature ^{1}H and ^{13}C nmr. The 100

[2]The explanation in terms of torsional oscillations proposed in ref. 1 was just recently commented upon (8) and an interpretation, essentially concurring with ours, was suggested. In conflict with our analysis, however, the authors claimed (ref. 8, note 9) that the *ortho*-protons in the *trans* isomer are symmetrically equivalent. This is not the case as may be visualized by the following schematic formula. The non-equivalence is also verified by our ^{13}C nmr results.



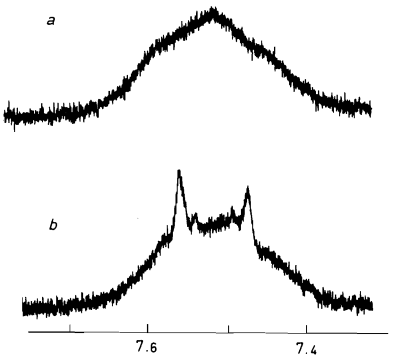


FIG. 2. ^{1}H nmr spectra of the *ortho*-protons at the coalescence temperature: *a*, pure *cis*-**1**; *b*, *cis*-**1** + *ca.* 10% of *trans*-**1**.

MHz ^{1}H nmr signal patterns for the aromatic and the methyl protons of the two isomers are very similar at ambient temperature. The spectra of the morpholine ring protons, however, differ substantially. *Cis*-**1** exhibits three groups of signals (δ 2.7–3.1, 3.5–3.9, 5.3–5.5), the low-field part of which integrates for one proton, which by double resonance was shown to be a N—CH_2 proton and, by analogy with earlier results, assigned to the *Z*-equatorial proton pointing in the direction of the strongly deshielding C=S group (4). In *trans*-**1**, on the other hand, all morpholine ring protons fall in one group of signals (δ 3.0–4.6).

On cooling, the *ortho*-proton part of *cis*-**1** undergoes broadening and at +2°C a decoalescence is observed, whereas for *trans*-**1** only a slight broadening is observed down to −60°C (Fig. 1). Furthermore, the spectrum of *cis*-**1** at +2°C does not contain the sharp peaks amidst the broad band reported in ref 1, but this pattern is perfectly reproduced when a small quantity of the *trans* isomer is added to the sample (Fig. 2). Thus, we conclude that Fulea and Krueger were studying a sample of *cis*-**1** containing a few percent of the *trans* isomer.

In order to acquire further information and to avoid the complication with badly resolved proton spectra a dynamic ^{13}C nmr study was also carried out. The ^{13}C chemical shifts are shown in Table 1. On lowering the temperature the signal assigned to the *ortho*-carbons showed exchange broadening and decoalesced to a symmetrical doublet. This phenomenon was observed for both *cis*-**1** and *trans*-**1**. The coalescence data are reported in Table 2.

So far we have considered the situation with rapid inversion of the morpholine ring. The study

of the nmr spectra of *cis*-**1** and *trans*-**1** at temperatures where this inversion is slow should give information about the *cis–trans* assignments of the isomers of **1**.

Cis-**1** exists in a single conformation with the methyls in diequatorial positions, this conformation being of *ca.* 5 kcal lower energy than the diaxial conformation (5), and one can expect no effect on the nmr spectrum of the freezing of the inversion of this ring.

Trans-**1** on the other hand, exists as an equilibrium between two rapidly interconverting conformations of comparable energy[3] with axial–equatorial methyls. Thus the *trans* isomer should be expected to give rise to decoalescence phenomena when the rate of ring inversion is slow. Accordingly, the ^{13}C nmr spectrum of *trans*-**1** below −80°C displayed exchange broadening of all the six signals from the morpholine carbons as well as those of the two *ortho*-carbons and the single signal of the *meta*-carbons, leaving only the three quaternary carbons (and those of the solvent) as sharp signals (Fig. 3). At −116°C, which unfortunately was the low temperature limit of the apparatus, the first decoalescence was reached corresponding to an upper limit of the barrier of 8.0 kcal/mol (with a δν of 10 Hz).

In previous work it has been found that *N*-

[3]Since the steric interactions between an axial *Z*-methyl and the sulfur might substantially differ in energy from that between an equatorial *Z*-methyl and the sulfur, unequal populations cannot be ruled out.

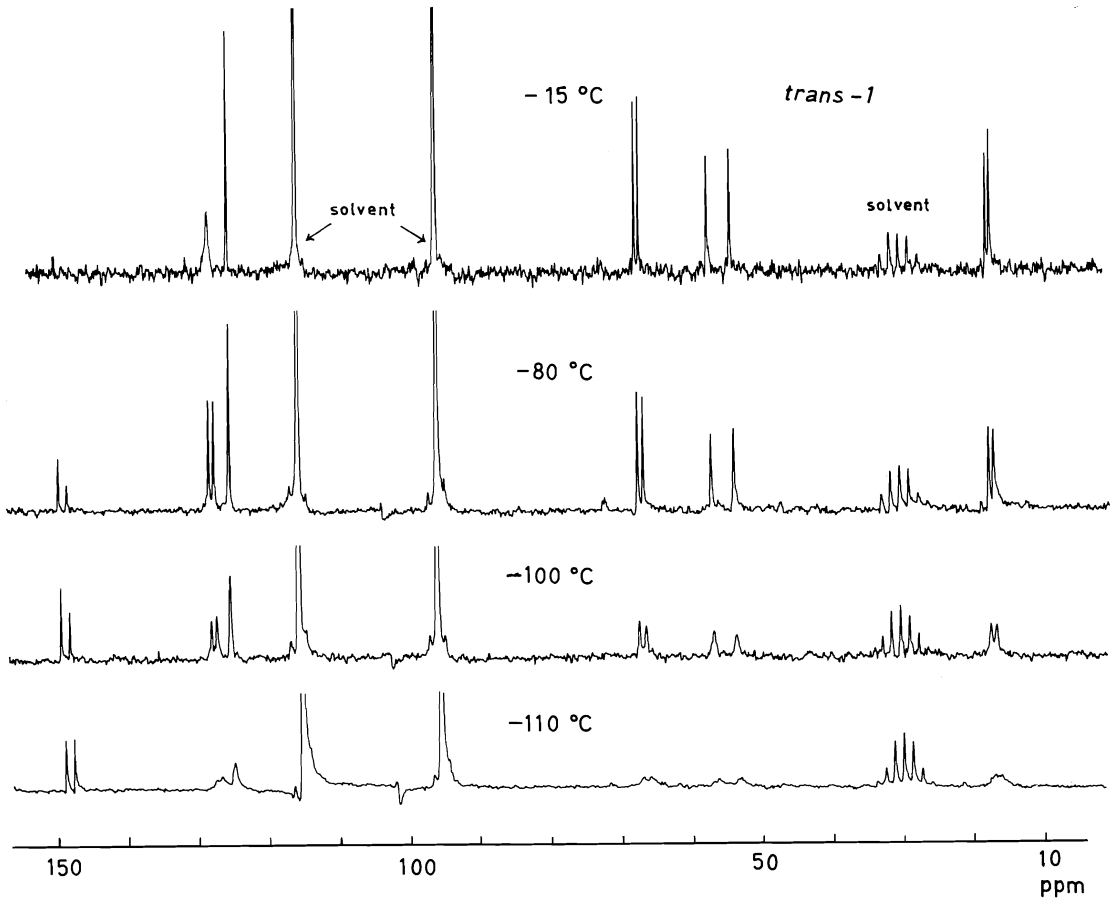

FIG. 3. Proton noise decoupled ^{13}C nmr spectra of *trans*-**1** in $CHCl_2F$ (+20% acetone-d_6).

acylation lowers the inversion barrier of morpholines by 2–3 kcal/mol (6). Thus, reduction of the thiocarbonyl group, giving the corresponding benzylmorpholine, should make the decoalescence accessible. On reaction with sodium borohydride it was found that both the thiocarbonyl group and the nitro group were reduced. The ^1H nmr spectrum of *N*-(*p*-aminobenzyl)-*trans*-2,6-dimethylmorpholine showed the expected decoalescence of the methyl signals as well as of the ring protons and the benzyl ($T_c = -80°C$, $\Delta G^{\ddagger} = 9.4$ kcal/mol), whereas the *cis* isomer remained unchanged at $-105°C$. This unambiguously clarifies the assignment of *cis* and *trans* configurations.

Experimental

Measurements

The ^1H nmr spectra were recorded on a Jeol MH-100 spectrometer utilizing an internal proton lock (TMS) and the ^{13}C nmr spectra on a Jeol FX-60 spectrometer working at 15.03 MHz. A flip angle of 60° was used, the number of data points was 8K and spectral widths were 5000, 2500, and 1000 Hz. The temperature was measured by means of the thermocouple fixed in the normal insert. This thermocouple was calibrated against a second thermocouple held inside the spinning nmr tube. Free energies of activation were estimated by the approximate formula appropriate for a coalescing doublet (7) and the Eyring equation in the form:

$$\Delta G^{\ddagger} = \frac{4.57 T_c}{1000}\left(9.97 + \log\frac{T_c}{\delta\nu}\right) \text{ kcal/mol}$$

Preparations

The *cis* and *trans* isomers of *p*-nitrothiobenz-2,6-dimethylmorpholide (**1**) were prepared by reaction of *p*-nitrobenzaldehyde (7 g), sulfur (4 g), and 2,6-dimethylmorpholine (15 ml, Aldrich, containing *ca.* 30% of the *trans* isomer) for 1.5 h under reflux conditions. The mixture was treated with ice water and extracted with chloroform. Analysis by tlc (silica, chloroform) gave rise to two yellow spots ($R_f = 0.64$; 0.54) in addition to by-products. The two products could be separated by re-

peated column chromatography (silica, Merck 70-230, chloroform) and by recrystallization of the different fractions from ethanol. The products were identified in the order that they were eluted: *cis*-**1**, 2.5 g, mp 165–166°C; *trans*-**1**, 0.5 g, mp 149–150°C. For identification see Discussion. In addition *p*-aminothiobenz-2,6-dimethylmorpholide (2.0 g, mp 135–159°C) was isolated, apparently formed by reduction of the nitro group by sulfide ions generated in the reaction. The *cis–trans* relation was not established for this compound but according to the large temperature interval of melting a mixture of the two isomers seems probable.

Reduction of 1

Each isomer of **1** (200 mg) was treated with sodium borohydride (excess) in ethanol at 50°C for 1 h. Dilute HCl was added to destroy the excess hydride and the solution was made basic with NaOH, extracted with ether, and evaporated. Analysis by gc–ms and nmr showed that the main component (80%) was *N*-(*p*-aminobenzyl)-2,6-dimethylmorpholine. Small amounts of recovered **1** and *p*-aminothiobenz-2,6-dimethylmorpholide could also be identified.

Elemental analyses, mass and nmr spectra were in agreement with the given structures.

Etude expérimentale et théorique des spectres de vibration des dérivés di- et trisubstitués de l'isothiazole[1]

GILBERT MILLE, MICHEL GUILIANO ET JACQUES CHOUTEAU

Université de Droit, d'Economie et des Sciences d'Aix-Marseille, Centre de Spectrographie Infrarouge, Centre st. Charles, 3, Place V. Hugo, F. 13331, Marseille, Cédex 3 France

Reçu le 28 octobre 1976

GILBERT MILLE, MICHEL GUILIANO et JACQUES CHOUTEAU. Can. J. Chem. **55**, 2302 (1977).

Les spectres infrarouges sous différents états (liquide, solution, vapeur) et les spectres Raman en phases condensées d'une série de dérivés di- et trisubstitués de l'isothiazole ont été analysés. Pour certains composés une étude de modes normaux de vibration a également été faite. Une attribution des modes fondamentaux de vibration de ces molécules est proposée et discutée.

GILBERT MILLE, MICHEL GUILIANO, and JACQUES CHOUTEAU. Can. J. Chem. **55**, 2302 (1977).

The infrared absorption spectra in different physical states (liquid, solution, vapor) and the Raman spectra in the liquid or solid state of di- and trisubstituted isothiazole derivatives have been analyzed. For some compounds a study of the normal vibrations has also been done. An assignment of the fundamental modes of vibration of these molecules is given and discussed.

Introduction

Une analyse expérimentale et théorique des spectres de vibration de l'isothiazole (1–3) et de ses dérivés monosubstitués en position 3, 4 et 5 (4–7) vient de faire l'objet de plusieurs mémoires. Dans le prolongement de ces recherches en série isothiazolique, nous nous sommes proposés d'étendre ce travail aux composés di- et trisubstitués de l'isothiazole $C_3NSRR'R''$ (R = H, CH_3, Cl, R′ = H, D, CH_3, CN, NO_2, Br, I et R″ = H, D, CH_3, CD_3, Cl, Br, I) (fig. 1) afin, d'une part de compléter l'attribution fragmentaire existant pour les diméthyl- et triméthyl-isothiazoles (8) et d'autre part, de voir dans quelle mesure les résultats expérimentaux et théoriques relatifs aux dérivés monosubstitués pouvaient être utilisés pour l'interprétation des spectres de vibration des molécules polysubstituées.

Les spectres infrarouges ainsi que les spectres Raman de 14 composés disubstitués et de huit dérivés trisubstitués ont donc été examinés. De plus nous avons pour sept molécules complété l'étude expérimentale par un calcul de modes normaux de vibration.

Les attributions que nous proposons sont limitées aux oscillations propres du cycle isothiazole et des liaisons CX, CY et CZ.[2] Nous ne donnons pas ici une analyse détaillée des vibrations propres aux substituants polyatomiques; celle-ci est indiquée ailleurs (9).

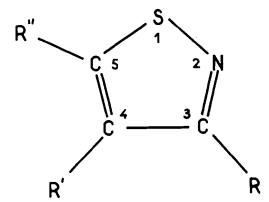

FIG. 1. Isothiazole $C_3NSRR'R''$.

Après le dénombrement et l'activité des vibrations nous donnerons les conditions expérimentales ainsi que les conditions de calcul. Nous indiquerons ensuite les résultats expérimentaux et théoriques qui seront discutés dans une dernière partie.

Dénombrement et activité des vibrations

Dans l'hypothèse où le squelette des dérivés di- et trisubstitués de l'isothiazole est plan, la

[1]Ce travail constitue une partie de la thèse de Doctorat d'Etat, n° d'ordre CNRS A0.10862, de M. Gilbert Mille, soutenue en 1975 à Marseille.

[2]X = R, Y = R′ et Z = R″, dans le cas où les substituants sont monoatomiques. X, Y, Z représente l'atome de carbone ou d'azote directement lié à l'hétérocycle dans le cas de substituants polyatomiques tels que CH_3, CD_3, CN et NO_2. Dans le cas des dérivés disubstitués X, Y ou Z = H, respectivement pour une substitution en position 4 et 5, 3 et 5 ou 3 et 4. Par convention X sera lié au carbone en position 3, Y au carbone en position 4 et Z au carbone en position 5.

symétrie est du type C_s. Dans ce groupe de symétrie les 18 vibrations fondamentales toutes actives en infrarouge et en Raman peuvent se décomposer en 13 mouvements ($7\omega + 1\nu CX + 1\nu CY + 1\nu CZ + 1\delta CX + 1\delta CY + 1\delta CZ$) de symétrie A' et 5 oscillations ($2\Gamma + 1\gamma CX + 1\gamma CY + 1\gamma CZ$) de type A''.[3]

Les vibrations de symétrie A' et A'' doivent pouvoir se caractériser de la même manière que dans les spectres de l'isothiazole (1). En particulier le grand axe d'inertie de ces molécules devant, si elles ont une structure plane, être normal au plan du noyau, on peut s'attendre à ce que dans les spectres infrarouges des composés à l'état vapeur les oscillations de classe A' et A'' donnent lieu à des bandes de vibration–rotation de type A, B ou hybride $A + B$, d'une part et de type C, d'autre part. Les séparations $\Delta\nu_{RP}$ des enveloppes de type A, B ou C doivent évidemment différer des écarts $\Delta\nu_{RP}$ des bandes de même type de l'isothiazole (1). De même que pour l'isothiazole, on doit trouver dans les spectres Raman des dérivés isothiazoliques des bandes de diffusion généralement fortes et polarisées pour les vibrations de symétrie A' et des bandes faibles et dépolarisées pour les modes de classe A''.

Conditions expérimentales

Synthèse

La synthèse des différents composés étudiés a été discutée ailleurs (8, 10).

Spectres infrarouges

Les spectres infrarouges ont été enregistrés sur spectrographes Perkin-Elmer, modèles 125 et 225.

Les composés solides ont été examinés sous forme de pastilles constituées de 2 mg de produit inclus dans 200 mg de bromure de potassium.

Les spectres infrarouges des composés à l'état vapeur ont été réalisés avec une cellule à gaz chauffante Perkin-Elmer de 5 cm d'épaisseur à fenêtres de bromure de potassium ou d'iodure de césium.

A l'état dissous les concentrations étaient voisines de 0.2 *M*. Le tétrachlorure de carbone a été employé dans les régions de 3000 cm^{-1} et de 1500 à 1300 cm^{-1}, le tétrachlorure d'éthylène, le sulfure de carbone et le cyclohexane ont respectivement été utilisés entre 2000 et 1400, 1350 et 450 et entre 450 et 200 cm^{-1}. Les coefficients d'extinction molaire apparents ont été mesurés aux maximums des bandes d'absorption.

Spectres Raman

Les échantillons à l'état liquide ou solide ont été examinés dans des tubes capillaires, avec un spectrographe Raman Coderg, type PH 1, équipé d'un laser He–Ne de 100 mW émettant à 6328 Å. Les facteurs de dépolarisation ont été corrigés d'après la méthode décrite par Bribes et Gaufres (11). Les intensités ont été chiffrées de 0 à 10 par comparaison avec la raie la plus forte de chacun des spectres. Dans les cas où il n'a pas été possible d'obtenir les spectres de diffusion de 3200 à 200 cm^{-1} sans changer les conditions d'enregistrement les intensités des raies Raman ont été estimées à l'aide des lettres F (forte); m (moyenne); f (faible) et ff (très faible). Pour les spectres infrarouges et Raman l'incertitude sur les fréquences est inférieure à 2 cm^{-1} dans la région de 4000 à 1000 cm^{-1} et d'environ 1 cm^{-1} de 1000 à 200 cm^{-1}.

Conditions de calcul

Le calcul des modes normaux de vibration des dérivés di- et trisubstitués de l'isothiazole a été entrepris par la méthode classique de Wilson *et al.* (12) dans l'hypothèse d'un champ de forces de valence du type GVFF. Le programme de calcul utilisé est celui écrit par Schachtschneider (13).

Structure géométrique

Les paramètres structuraux choisis pour les dérivés di- ou trisubstitués de l'isothiazole sont ceux adoptés pour les composés monosubstitués correspondants (7).

Coordonnées internes

Nous avons conservé les coordonnées internes[4] déjà utilisées pour l'isothiazole (3) et ses dérivés monosubstitués (7), pour décrire les différentes vibrations de symétrie A' (fig. 2).

Dans le cas des molécules méthylées, nous avons considéré le ou les substituants méthyle comme des groupements ponctuels de masse $M = 15.035$ g.

Champ de forces

L'analyse vibrationnelle a été menée en admettant qu'en première approximation le champ de forces des dérivés di- et trisubstitués de l'isothiazole résultait de la superposition des champs de forces trouvés pour les dérivés monosubstitués correspondants (7). Un premier calcul effectué dans ces conditions a donné des résultats très satisfaisants. Néanmoins pour améliorer certains écarts entre fréquences observées et fréquences calculées, nous avons introduit des constantes d'interaction du type: $f_{r_i r_{i+1}}$ ($i = 3$,

[3] ν, δ, γ désignant respectivement les vibrations de valence, de déformation dans le plan et hors du plan; ω et Γ les vibrations de déformation du noyau respectivement dans et hors du plan (*cf.* ref 4).

[4] Comme pour l'isothiazole et ses dérivés monosubstitués (3, 7) nous avons adopté pour les déformations angulaires des vibrateurs CX, CY ou CZ des coordonnées de groupe du type: $\beta_i = (\psi'_i - \psi_i)/\sqrt{2}$.

TABLEAU 1. Constantes de force* relatives aux vibrateurs CX, CY, CZ pour les dérivés di- et trisubstitués de l'isothiazole

*Elongation des liaisons (F_{r_i}) en 10^5 dyn cm^{-1}. Déformation des angles (F_{β_i}) en 10^{-11} erg rad^{-2}. Interactions (f) en 10^{-3} dyn rad^{-1}.

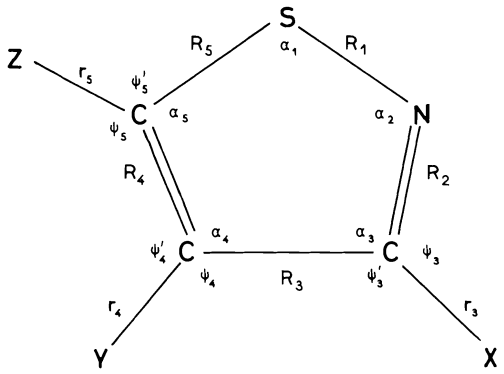

FIG. 2. Les différentes vibrations de symétrie A'.

4 ou 5) lorsque deux ou trois substituants étaient voisins et du type $f_{\beta_i\beta_H}$ (i = 3 et 5) dans le cas des dérivés disubstitués en position 3, 5. Nous indiquons dans le tableau 1 uniquement les constantes de force relatives aux vibrateurs CX, CY et CZ. Toutes les autres constantes de force concernant plus particulièrement le cycle sont identiques à celles de l'isothiazole et de ses dérivés monosubstitués et sont mentionnées dans les réfs 3 et 7.

Résultats expérimentaux et théoriques

Dans le tableau 2[5] sont indiquées les fréquences infrarouges, enregistrées à l'état dissous, des vibrations (ν, δ et γ) des liaisons CH (ou CD) des composés disubstitués de l'isothiazole. Le tableau 3[5] renferme sous forme de suites les fréquences infrarouges et Raman des vibrations fondamentales des hétérocycles C_3NSXYZ.[6] Dans ces deux tableaux les fréquences infrarouges mesurées à l'état dissous sont suivies du coefficient d'extinction molaire et lorsque les composés ont été examinés à l'état de vapeur elles sont précédées de la symétrie de vibration rotation (A, B ou C) des bandes. L'intensité des raies de diffusion, chiffrée de 0 à 10, succède aux fréquences Raman des composés en phase condensée.

Les résultats théoriques obtenus à partir du champ de forces défini précédemment (tableau 1 et réf. 3) sont comparés aux données expérimentales dans le cas des diméthyl isothiazoles (tableau 4), des méthyl-3 bromo-4 et méthyl-3 bromo-5 isothiazoles (tableau 5) des triméthyl 3,4,5 isothiazole et dichloro-3,5 méthyl-4 isothiazole (tableau 6). Dans ces tableaux sont indiquées également les attributions qu'il est possible de formuler d'après l'analyse de la distribution d'énergie potentielle (9).

Discussion des résultats

Nous examinerons en premier lieu, les vibrations des liaisons CH ou CD, puis celles de noyau en distinguant chaque fois les vibrations de type A' de celles de symétrie A''.

I. Vibrations des liaisons CH ou CD

(1) Vibrations de symétrie A′

(a) Vibrations de valence ν(CH ou CD)

Trois séries de fréquences vers 3102 ± 10, 3088 ± 7 et 3048 ± 11 cm^{-1} peuvent être constituées en examinant respectivement les spectres

[5]On peut obtenir les tableaux 2 et 3 à un prix nominal, en s'adressant au Dépôt de données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa, Canada K1A 0S2.

[6]Les fréquences des maximums reliés à des oscillations des substituants ou à des vibrations harmoniques ou de combinaison, sont indiquées pour chacun des composés dans la réf 9.

infrarouges des dérivés de l'isothiazole disubstitués en −3,4, −3,5 et −4,5. Les maximums composant ces suites donnent en Raman des raies faibles mais polarisées. Nous les relions respectivement aux vibrations νC_5H, νC_4H et νC_3H (tableau 2). On peut remarquer que les positions des modes νCH des composés disubstitués sont très proches de celles de l'isothiazole (1). La présence de substituants en position 3,4, 3,5 ou 4,5 a donc peu d'influence sur les mouvements νCH.

Dans le spectre infrarouge du diméthyl-3,5 deutério-4 isothiazole, on observe aucun maximum au-dessus de 3000 cm^{-1}, mais une absorption à 2287 cm^{-1} devant très certainement résulter du mode νC_5D.

(b) Vibrations de déformation δ(CH ou CD)

La fréquence de δC_3H a été situé à 1236 cm^{-1} dans l'isothiazole (1). Par analogie et en accord avec les résultats théoriques (tableau 4 et 5) nous relions les sommets infrarouges vers 1228 cm^{-1} relevés dans les spectres des composés disubstitués en position 4,5 à des mouvements analogues.

Dans les spectres de tous les dérivés substitués en 3,4 ou en 3,5, on observe entre 1200 et 1100 cm^{-1} une absorption forte pour les composés

disubstitués en position 3 et 4 et moyenne pour ceux disubstitués en 3,5 (tableau 2). Ces bandes infrarouges disparaissant dans les spectres des molécules trisubstituées ou dans celui du diméthyl-3,5 deutério-4 isothiazole, doivent donc être rattachées à des vibrations δCH (tableau 2).

On peut noter que les fréquences des modes δC_4H ou δC_5H des dérivés disubstitués sont plus élevées que celles des composés monosubstitués correspondants, alors que la position de la bande δC_3H reste inchangée quel que soit le degré de substitution. Enfin on peut également remarquer que, pour un même type de substitution, la position des bandes dues à des oscillations δC_4H ou δC_5H diffère suivant la nature du substituant (tableau 2). Nous situons la fréquence de δC_4D du diméthyl-3,5 deutério-4 isothiazole à 840 cm^{-1} en raison de l'absence de maximum proche de cette fréquence dans les spectres infrarouge et Raman du diméthyl-3,5 isothiazole.

(2) Vibrations de symétrie A''

Vibrations de déformation γ(CH ou CD)

Les spectres infrarouges des méthyl-3 bromo-4, diméthyl-3,5 et méthyl-3 bromo-5 isothiazoles à l'état de vapeur (9) présentent respectivement à 776, 818 et 819 cm^{-1} des structures de vibration–rotation de type *C* qui doivent résulter d'oscillations γCH de symétrie *A''*. Nous rattachons donc les maximums rangés dans les suites vers 800 ± 21 et 807 ± 14 cm^{-1} respectivement aux mouvements γC_5H et γC_4H des dérivés disubstitués en position 3,4 et 3,5.

Par analogie avec l'attribution proposée pour le mouvement γC_3H du dideutério-4,5 isothiazole (1), on peut situer ce même mode dans les dérivés de l'isothiazole disubstitués en 4,5 vers 882 cm^{-1} (tableau 2). Notons que, dans les spectres Raman de ces composés, on n'observe aucune bande de diffusion dans cette région.

Remarquons enfin que les attributions antérieures proposées pour les mouvements γCH des diméthylisothiazoles (8) sont maintenues.

L'enveloppe de la bande de type *C* observée à 699 cm^{-1} uniquement dans le spectre infrarouge du diméthyl-3,5 deutério-4 isothiazole à l'état vapeur (9) indique que la vibration γC_4D doit être attribuée à cette fréquence pour ce composé. L'accord entre la valeur des produits de Teller–Redlich expérimental et théorique est satisfaisant pour les vibrations de type *A''* (9).

II. Vibrations des squelettes C_3NSXYZ

(1) Vibrations de symétrie A'

Nous examinerons les vibrations de noyau et de valence νC(X,Y ou Z), puis celles de déformation δC(X,Y ou Z).

(a) Vibrations de noyau et de valence νC(X, Y ou Z)

Les suites que nous allons discuter peuvent se décomposer comme pour les dérivés monosubstitués de l'isothiazole, en suites relativement fixes en position: I, II, III, V et VII et en suites variables suivant la nature et la position du substituant: IV, VI, VIII, VIII' et VIII''. Nous examinerons en premier lieu, les fréquences rangées dans les suites fixes, puis celles faisant l'objet des suites variables.

Suites fixes

Comme pour les dérivés monosubstitués de l'isothiazole, les cinq suites I, II, III, V et VII peuvent être rapprochées des vibrations ω_1, ω_2, ω_3, ω_5 et ω_7 de l'isothiazole. Pour les composés disubstitués en position 3,4, on retrouve une suite vers 840 cm^{-1} (tableau 3) pouvant être reliée à un mode de fréquence voisine du mouvement ω_4 de l'isothiazole. L'existence de cette suite avait déjà été mentionnée pour les dérivés monosubstitués soit en 3, soit en 4 (5, 7). Dans chacune des suites les fréquences les plus élevées sont observées dans les spectres des diméthyl et triméthyl isothiazoles et décroissent lorsque la masse du substituant augmente (tableau 3):

$$\nu_{\omega_i CH_3} > \nu_{\omega_i Cl} > \nu_{\omega_i NO_2} > \nu_{\omega_i Br} > \nu_{\omega_i I} \quad (i = 1,2,3,5 \text{ et } 7).$$

Comme pour les dérivés monosubstitués, ce sont les suites II et V qui regroupent les fréquences s'écartant respectivement le moins des fréquences des modes ω_2 à 1390 et ω_5 à 815 cm^{-1} de l'isothiazole. Dans chaque suite, les maximums les moins intenses sont relevés pour les molécules di- ou triméthylées. L'intensité des absorptions augmente généralement lorsqu'on remplace un groupement méthyle par un halogène (Cl, Br ou I) ou un groupement nitro (tableau 3). En Raman, les raies de diffusion correspondant aux maximums rangés dans les diverses suites sont très souvent assez intenses à l'exception toutefois, de celles faisant l'objet de la suite I qui sont généralement faibles et même parfois absentes. Comme pour les dérivés monosubstitués, certains modes de vibration mettent en jeu plus particulièrement, un vibrateur. C'est notamment le cas pour les trois oscillations entre 1500 et 1300 cm^{-1} et de la vibration vers 800 cm^{-1} qui font respectivement intervenir les élongations des liaisons C=C, C=N, C—C et S—N (*cf.* tableaux 4–6).

Les maximums formant la suite VII ont des fréquences plus élevées que ceux rangés dans la suite ayant la même notation pour les dérivés monosubstitués. Pour le diméthyl-3,4 isothiazole et les dérivés trisubstitués de l'isothiazole, les fréquences que nous avons choisies pour la suite VII sont particulièrement élevées. Cependant le fait qu'on observe en Raman vers ces fréquences une bande de diffusion forte et polarisée ne peut laisser de doute au sujet de cette interprétation. De plus, les résultats des calculs de modes normaux de vibration relatifs aux dérivés disubstitués indiquent que la fréquence la plus élevée de la suite VII est effectivement trouvée pour le diméthyl-3,4 isothiazole (tableau 4). Cette élévation de fréquence de la vibration de noyau ω_7 pourrait résulter d'un couplage partiel de cette vibration avec les oscillations $\nu C(X,Y,Z)$. Les résultats des calculs de modes normaux relatifs au triméthyl-3,4,5 isothiazole et au dichloro-3,5 méthyl-4 isothiazole sont en faveur de cette hypothèse (tableau 6).

Notons enfin, que l'attribution que nous avions proposée antérieurement pour les vibrations ω_1, ω_2, ω_3 et ω_5 des diméthylisothiazoles et du triméthylisothiazole est conservée (8).

Suites variables

Par analogie avec les composés de l'isothiazole monosubstitués en 3, 4 ou 5, on devrait retrouver, en analysant les spectres infrarouges et Raman des dérivés de l'isothiazole disubstitués en 3,5 ou 4,5, un premier couplage entre la vibration ω_6 et l'oscillation νC_3X ou νC_4Y et un deuxième couplage entre le mode ω_4 et le mouvement de valence νC_5Z.

Effectivement, les spectres infrarouges et Raman des dérivés disubstitués en position 3,5 ou 4,5 permettent de constituer quatre suites de fréquences variables: IV, VI, VIII et VIII′ qui peuvent s'interpréter suivant les déductions faites de l'analyse des spectres infrarouges et Raman des molécules monosubstituées (4–6). Les fréquences rangées dans ces suites sont proches de celles groupées dans les suites IV, VI et VIII des dérivés monosubstitués. Notons enfin, que pour le dideutério-4,5 isothiazole, où les fréquences νC_4D et νC_5D sont trop élevées par rapport à celles des vibrations de squelette pour que le couplage puisse avoir lieu, on retrouve, pour les mouvements de noyau ω_4 et ω_6, des fréquences proches de celles correspondantes dans l'isothiazole (1).

Les remarques relatives aux vibrations couplées dans les dérivés monosubstitués s'appliquant parfaitement aux composés disubstitués en 3,5 et 4,5, on devrait pour les molécules disubstituées en position 3,4 observer une interaction entre le mouvement de noyau ω_6 et les oscillations de valence νC_3X et νC_4Y. Nous avons déjà constaté pour ces dérivés l'existence de la suite IV formée de maximums ayant des positions voisines du mode ω_4 de l'isothiazole ou de la suite ayant la même notation dans les composés de l'isothiazole monosubstitués en 3 ou 4. De plus, l'examen des spectres infrarouges et Raman de ces hétéro-

cycles disubstitués en 3,4 révèle la présence de trois suites, l'une entre 1120 et 975 cm^{-1} et les deux autres entre 600 et 250 cm^{-1}. L'existence de ces suites ainsi que l'absence de maximum à des fréquences où l'on pourrait attendre les mouvements ω_6 et νC_3X et νC_4Y purs, indiquent effectivement que les résultats déduits de l'étude des dérivés monosubstitués en position 3 ou 4 sont totalement "transférables" aux composés disubstitués en 3,4. Comme dans les dérivés monosubstitués, la suite VI est formée d'absorptions infrarouges moyennes et de raies de diffusion faibles et les suites VIII et VIII′ regroupent des bandes faibles en infrarouge, mais souvent intenses en Raman. On peut également constater (tableau 3) que les fréquences de la suite VI pour un dérivé disubstitué, sont généralement plus élevées que celles choisies pour les composés monosubstitués correspondants. Notons que les résultats des calculs de modes normaux sont en parfait accord avec cette remarque. Ces calculs indiquent en outre que les couplages mettent principalement en jeu les oscillations de valence νC_3X ou νC_4Y et une vibration de déformation angulaire du noyau (δN) (tableaux 4 et 5). Si pour les composés trisubstitués il existe comme pour les dérivés mono- ou disubstitués de l'isothiazole des vibrations couplées on doit pouvoir former cinq suites de fréquences variables suivant la nature et la place du substituant. Effectivement cinq suites, notées IV, VI, VIII, VIII′ et VIII″ peuvent être décelées en examinant les spectres infrarouges et Raman des dérivés trisubstitués de l'isothiazole (tableau 3). Par analogie avec les composés mono- et disubstitués, deux de ces suites (IV et VIII″) résultent du couplage des mouvements ω_4 et νC_5Z et les trois autres (VI, VIII et VIII′) du couplage des oscillations ω_6, νC_3X et νC_4Y.

(b) Vibrations de déformation $\delta C(X,$ Y ou Z)

Les fréquences que nous proposons pour ces vibrations de type *A′* font l'objet de la suite notée $\delta C(X,$ Y ou Z) du tableau 3. Le choix des maximums de cette suite a été dicté par l'examen des spectres Raman au-dessous de 440 cm^{-1} dans lesquels on observe généralement deux bandes assez fortes et polarisées, puis par les fréquences théoriques calculées pour certains composés et enfin, par des comparaisons avec les fréquences reliées à des mouvements analogues dans les isothiazoles monosubstitués correspondants.

La fréquence δCI du méthyl-3 iodo-4 isothiazole doit vraisemblablement être située au-dessous de 200 cm^{-1}. N'ayant pas enregistré le spectre Raman de ce composé, il n'est pas possible de localiser cette vibration. Le méthyl-3 chloro-5 isothiazole n'ayant été examiné qu'à l'état liquide au-dessus de 400 cm^{-1}, nous n'avons pu proposer une attribution pour les oscillations δCC et δCCl de cette molécule.

(2) Vibrations de symétrie A″

Les vibrations de noyau et les mouvements $\gamma C(X,Y,Z)$ seront successivement traités.

(a) Vibrations de noyau

Les fréquences formant la suite IX peuvent être rapprochées de la vibration de noyau Γ_1 de l'isothiazole. Dans les spectres Raman, aucune raie n'apparaît à ces fréquences. Alors que pour le diméthyl-4,5 isothiazole les fréquences des modes ω_8 et Γ_1 étaient très proches, on ne relève pour le méthyl-4 trideutériométhyl-5 isothiazole qu'une seule absorption à 604 cm^{-1} ayant une intensité trop forte pour résulter uniquement du mode ω_8. L'intensité élevée de cette bande peut s'expliquer en admettant que les mouvements ω_8 et Γ_1 sont de même fréquence.

Nous relions à une vibration analogue à l'oscillation Γ_2 de l'isothiazole, les maximums de la suite X qui, lorsqu'ils apparaissent en Raman donnent des raies faibles et dépolarisées et qui possèdent, dans les spectres des composés examinés à l'état vapeur des structures de vibration–rotation de type *C*.

(b) Vibrations de déformation $\gamma C(X,Y,Z)$

Entre 400 et 200 cm^{-1} certains maximums ont déjà été reliés à des mouvements $\delta C(X,Y,Z)$. Nous rattachons dans les spectres des composés étudiés jusqu'à 200 cm^{-1}, les autres pics à des oscillations $\gamma C(X,Y,Z)$ par analogie avec les attributions faites pour des mouvements analogues dans les composés monosubstitués correspondants (4, 5). Les fréquences inférieures à 200 cm^{-1} que nous avons attribuées à des modes $\gamma C(X,Y,Z)$ ont été observées uniquement en diffusion. Notons enfin que certains maximums de la suite $\gamma C(X,Y,Z)$ peuvent résulter simultanément de modes δ et $\gamma C(X,Y,Z)$.

Conclusion

La validité de la "transférabilité" du champ de forces de l'isothiazole aux dérivés monosubstitués que nous avions montré dans le précédent mémoire (7) est à nouveau confirmée par notre

étude des dérivés di- et trisubstitués de l'isothiazole. Cette hypothèse est donc raisonnable et justifie par ailleurs la validité du champ de forces proposé. La nature des mouvements a pu être discutée grâce à l'analyse des distributions d'énergie potentielle. La diversité des composés examinés a permis de suivre l'influence de la nature, de la position et du nombre des substituants sur les vibrations fondamentales du cycle isothiazole. Pour les dérivés di- et trisubstitués de l'isothiazole le calcul des modes normaux de vibration a permis, comme pour les composés monosubstitués, d'apporter une justification et un complément théoriques à l'ensemble des attributions formulées d'après les résultats expérimentaux infrarouges et Raman. On peut noter que cette analyse vibrationnelle a été conduite en utilisant un nombre assez réduit de paramètres et que surtout, ces paramètres permettent de rendre compte de façon très satisfaisante des modes de vibration d'un nombre important de dérivés mono-, di- et trisubstitués de l'isothiazole.

Il est, enfin, remarquable de constater l'existence d'une loi additive, permettant à partir du champ de forces des molécules monosubstituées de préciser correctement la fréquence et la nature des vibrations fondamentales des composés di- et trisubstitués de l'isothiazole.

Remerciements

Nous remercions vivement MM. J. C. Poite et C. Perichaud d'avoir mis gracieusement à notre disposition l'ensemble des produits examinés.

Degenerate rearrangements in solvolytic studies with tri-*p*-tolylvinyl-2-^{13}C bromide

CHOI CHUCK LEE, ANTHONY J. PAINE, AND ERIC C. F. KO

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received October 12, 1976

CHOI CHUCK LEE, ANTHONY J. PAINE, and ERIC C. F. KO. Can. J. Chem. **55**, 2310 (1977).

The acetolysis in the presence of AgOAc of tri-*p*-tolylvinyl-2-^{13}C bromide (**3**-Br-2-^{13}C) gave about 14% scrambling of the label from C-2 to C-1 due to degenerate 1,2-tolyl shifts. This value is compared with the 7 and 20% scramblings previously observed for similar reactions with triphenylvinyl-2-^{13}C and trianisylvinyl-2-^{13}C bromides, and their mechanistic implications are discussed. The trifluoroacetolysis of **3**-Br-2-^{13}C in the presence of CF_3COOAg or CF_3COONa resulted in about 47% scrambling. In the absence of any added salt, the scrambling was found to increase with reaction time and in addition, solvent isotope effects of 1.6 and 2.6, respectively, were observed for $k_{CF_3COOH}/k_{CF_3COOD}$ at 100°C with or without added CF_3COONa. The role of electrophilic addition–elimination and the processes leading to the isotopic scrambling in the reaction with CF_3COOH, with or without added salt, are discussed.

CHOI CHUCK LEE, ANTHONY J. PAINE et ERIC C. F. KO. Can. J. Chem. **55**, 2310 (1977).

A cause de déplacements 1,2 dégénérés des groupes tolyles, l'acétolyse en présence de AgOAc, du bromure de tri-*p*-tolylvinyl-2-^{13}C (**3**-Br-2-^{13}C) conduit à une transposition d'environ 14% du marqueur de la position C-2 vers C-1. On compare cette valeur avec les valeurs de 7 et 20% observées antérieurement pour des réactions similaires des bromures de triphénylvinyl-2-^{13}C et de trianisylvinyl-2-^{13}C et on discute de leurs implications mécanistiques. La trifluoroacétolyse du **3**-Br-2-^{13}C en présence de $AgOCOCF_3$ ou de $NaOCOCF_3$ conduit à environ 47% de transposition. Lorsqu'il n'y a aucun sel d'additionné, on a trouvé que les transpositions augmentent avec le temps de réaction et de plus on a observé respectivement des effets isotopiques de solvant de 1.6 et 2.6 pour $k_{CF_3COOH}/k_{CF_3COOD}$ à 100°C avec ou sans addition de $NaOCOCF_3$. On discute du rôle du mécanisme d'addition–élimination électrophile et des processus conduisant aux mélanges isotopiques dans la réaction de CF_3COOH avec ou sans addition de sel.

[Traduit par le journal]

Reactions of vinyl cations, including rearrangements that gave rise to more stable from less stable cations via 1,2-shifts, have been extensively reviewed (1–3). Degenerate rearrangements arising from 1,2-aryl shifts across the double bond in a number of labeled triarylvinyl cations, with various combinations of phenyl and/or *p*-anisyl as the aryl groups, have been studied in this laboratory using the ^{14}C tracer technique or ^{13}C-labeling coupled with ^{13}C nmr analysis (4–8), and by Rappoport and coworkers using ^{2}H as label coupled with analysis by ^{1}H nmr and mass spectrometry (9–11). The reaction of triphenylvinyl-2-^{13}C bromide (**1**-Br-2-^{13}C) with HOAc in the presence of AgOAc was found to give 6–7% scrambling of the ^{13}C label from C-2 to C-1 (5), while similar studies with trianisylvinyl-2-^{13}C bromide (**2**-Br-2-^{13}C) gave 20 and 50% isotopic scrambling, respectively, for the acetolysis in the presence of AgOAc and trifluoroacetolysis in the presence of CF_3COOAg (6). As an extension of such studies, isotopic scramblings arising from 1,2-tolyl shifts in solvolytic reactions with tri-*p*-tolylvinyl-2-^{13}C bromide (**3**-Br-2-^{13}C) were investigated.

Analogous to the preparation of **1**-Br-2-^{13}C and **2**-Br-2-^{13}C (5, 6), **3**-Br-2-^{13}C was prepared by the following series of reactions:

$$\mathrm{TolCH_2MgCl} \xrightarrow{^{13}CO_2} \mathrm{TolCH_2{}^{13}COOH} \xrightarrow[H^+]{\mathrm{EtOH}}$$

$$\mathrm{TolCH_2{}^{13}COOEt} \xrightarrow{\mathrm{TolMgBr}} \mathrm{TolCH_2{}^{13}C(OH)(Tol)_2} + \mathrm{TolCH{=}{}^{13}C(Tol)_2}$$

$$\xrightarrow[\mathrm{HOAc}]{Br_2} \mathrm{(Tol)_2{}^{13}C{=}CBrTol}$$

3-Br-2-^{13}C

In the initial experiments, the solvolysis of **3**-Br-2-^{13}C was carried out in HOAc containing 1.1 equiv. of AgOAc or in CF_3COOH containing 1.1 equiv. of CF_3COOAg. The product obtained, **3**-OAc-*x*-^{13}C or **3**-$OOCCF_3$-*x*-^{13}C, was reduced twice successively with $LiAlH_4$ (6) to give 1,2,2-tri-*p*-tolylethanol-*x*-^{13}C (**4**-*x*-^{13}C), the ^{13}C nmr spectrum of which was utilized for the determination of the extent of isotopic scrambling from C-2 to C-1. The method, based on the measurement of relative intensities of the C-1 and C-2 absorptions using the CH_3 absorption containing ^{13}C in its natural abundance as an internal

reference standard, is the same as that described previously in the study with **2**-Br-*2*-^{13}C in which the CH_3O absorption served as internal reference standard (6). The ^{1}H-decoupled ^{13}C nmr spectrum of unenriched **4** and the chemical shifts are given in Fig. 1*A* and Table 1. A typical spectrum for **4**-*x*-^{13}C derived from one of the solvolysis experiments is shown in Fig. 1*B*. The relative intensities and the calculated extents of ^{13}C scrambling from C-2 to C-1 are summarized in Table 2. An illustration of the calculations is given in the Experimental section.

The reaction of **3**-Br-*2*-^{13}C with HOAc–AgOAc gave rise to 13–14% isotopic scrambling, a value that is intermediate between the 7 and 20% scrambling found, respectively, in similar reactions with triphenylvinyl-*2*-^{13}C bromide (**1**-Br-*2*-^{13}C) (5) and trianisylvinyl-*2*-^{13}C bromide (**2**-Br-*2*-^{13}C) (6). The relative extents of scrambling arising from degenerate 1,2-aryl shifts in reactions with HOAc–AgOAc for **1**-Br-*2*-^{13}C:**3**-Br-*2*-^{13}C:**2**-Br-*2*-^{13}C would be 7:14:20 or approximately 1:2:3. Another comparison of the scrambling data from the reactions in HOAc–AgOAc may be obtained from consideration of the mechanism shown in Scheme 1. Using the steady state treatment and a method analogous to that employed by Bonner and Collins (12), it can be shown (10) that after complete reaction, the following relationship holds:

$$[\mathbf{5}]/[\mathbf{5r}] = 1 + (k_{SOH}/k_r)$$

Thus when Ar = Ph, Tol, and An, respectively, in **5** and **5r**, k_{SOH}/k_r is calculated to be 12, 5.1, and 3.0.

It is well known that the migratory aptitude of aryl groups follows the order of An > Tol > Ph. From the classical work of Bachmann and Ferguson with symmetrical aromatic pinacols, the migratory aptitude for Ph:Tol:An was found to be 1:15.7:500 (13). Rappoport (11) has also concluded that for the Ph and An groups, the migratory aptitude in vinylic systems resembles that in saturated systems; for example, consideration of the rearrangement data from the 2-anisyl-1,2-diphenylvinyl and triphenylvinyl cations led to the value of 76–120 for the rearrangement ratio for An:Ph (9). If solvolyses of triphenylvinyl, tri-*p*-tolylvinyl, and trianisylvinyl systems were to proceed via classical vinyl cations **6***a*, **7***a*, and **8***a*, bridged structures **6***b*, **7***b*,

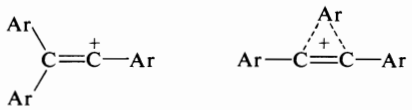
[d]About 5 half-lifes.

and **8***b* may be regarded as models of the transition states for the degenerate 1,2-aryl shifts in these systems. In these three systems, not only the migrating group but also the migration origin and the migration terminus are different from



6*a*, Ar = Ph
7*a*, Ar = Tol
8*a*, Ar = An

6*b*, Ar = Ph
7*b*, Ar = Tol
8*b*, Ar = An

one system to another. Thus a direct comparison of the extents of scrambling or degenerate rearrangement[1] among these systems would reflect not only the effects of the migrating group, such as migratory aptitude, but also the effects of the different non-migrating aryl substituents at C-1 and C-2.

As indicated earlier, the scrambling ratio for the acetolysis of **1**-Br-*2*-^{13}C:**3**-Br-*2*-^{13}C:**2**-Br-*2*-^{13}C is only about 1:2:3. These values are much smaller than what one would expect if migratory aptitudes were the predominant factor. In going from cations **6***a*, **7***a*, and **8***a* to transition states **6***b*, **7***b*, and **8***b*, respectively, the stability of the cations apparently plays an important role. The greater stability of **7***a* over **6***a*, for example, would increase the activation energy for **7***a* → **7***b*, counterbalancing the higher migratory aptitude of the *p*-tolyl group. Thus the scrambling ratio for the acetolysis of **3**-Br-*2*-^{13}C:**1**-Br-*2*-^{13}C is only about 2:1, although the migratory aptitude of tolyl:phenyl in pinacol rearrangements was found to be 15.7:1. Another factor which could also counterbalance the greater migratory aptitudes of the tolyl and anisyl groups is the effect of the α-aryl substituent on the electrophilic character of the migration terminus. As suggested by Bonner and co-workers (14, 15), the delocalization of the positive charge in **7***a* or **8***a* by the α-tolyl or anisyl substituent would decrease the electrophilic character of the migration terminus, hence decreasing the tendency for the tolyl and anisyl migration.

The trifluoroacetolysis of **3**-Br-*2*-^{13}C in the presence of CF_3COOAg gave about 47% scrambling of the label from C-2 to C-1 (Table 2), and this corresponds to k_{SOH}/k_r (Scheme 1) of only 0.13. A similar reaction with **2**-Br-*2*-^{13}C was found to give rise to a complete scrambling of 50% (6). As pointed out previously (4, 6), the extremely low nucleophilicity of CF_3COOH (16, 17) allows the 1,2-aryl shift in the vinyl cation to compete favorably with product forming reaction with solvent, hence much greater extents of scrambling were observed in trifluoroacetolysis than in acetolysis.

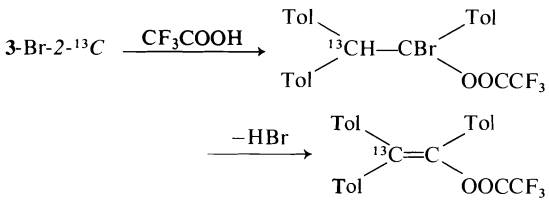
In solvolytic studies with vinylic systems, under acidic conditions such as trifluoroacetolysis, there is the distinct possibility of an electrophilic addition followed by elimination to give the same product as that derived from an S_N1 reaction (18–21). In this laboratory, how-

[1]The percentage rearrangement used by Rappoport and co-workers (9–11) is equal to twice the percentage scrambling reported by us since complete rearrangement via 1,2-shifts in our systems would give rise to 50% scrambling.

ever, CF_3COOH has been used as solvent (4, 6) since the ester product derived from trifluoroacetolysis, for example as in the present work, may be readily converted to **4**-*x*-^{13}C for ^{13}C nmr examination. It has been pointed out that a solvent kinetic isotope effect is a good diagnostic test for electrophilic addition–elimination (20, 21). The rates of reaction of **3**-Br with HOAc or DOAc, and with CF_3COOH or CF_3COOD, without the presence of any Ag salt, were measured by the potentiometric titration of the liberated bromide ion (22). For acetolysis at 150°C, the rate constants in HOAc and DOAc, respectively, were 1.2×10^{-6} and 1.3×10^{-6} s^{-1}, indicating essentially no solvent kinetic isotope effect. Trifluoroacetolysis at 100°C in CF_3COOH and CF_3COOD, however, gave rate constants of 9.0×10^{-4} and 3.5×10^{-4} s^{-1}, respectively, corresponding to a solvent kinetic isotope effect, $k_{CF_3COOH}/k_{CF_3COOD}$, of 2.6.[2] Thus in the absence of Ag salt, electrophilic addition–elimination apparently plays an important part in the reaction of **3**-Br with CF_3COOH. In the presence of 1.1 equiv. of CF_3COOAg, however, the reaction, even at 0°C, was too fast for kinetic measurement by potentiometric titration. Presumably, the Ag salt catalyzes the formation of the vinyl cation via the S_N1 process, and the contribution from electrophilic addition–elimination may be negligible in the presence of Ag salt. When the trifluoroacetolysis was carried out in the presence of 2.5 equiv. of CF_3COONa, the rate constants observed at 100°C for CF_3COOH and CF_3COOD, respectively, were 1.1×10^{-3} and 7.1×10^{-4} s^{-1}, corresponding to $k_{CF_3COOH}/k_{CF_3COOD}$ of 1.6. It appears that for the trifluoroacetolysis in the presence of CF_3COONa, the contribution of the addition–elimination process is of much lesser importance than in the trifluoroacetolysis with no added salt.

Isotopic scrambling in the trifluoroacetolysis of **3**-Br-*2*-^{13}C with the presence of 2.5 equiv. of CF_3COONa or with no added salt were also carried out, and the results are included in Table 2. With added CF_3COONa, after a reaction time of about 2 or 5 half-lifes, the same extent of scrambling (47%), as was found in the reaction with CF_3COOH–CF_3COOAg, was observed. Moreover, the product apparently did not undergo further scrambling since the same result was noted after 2 or 5 half-lifes. Since both reactions with added Ag or Na salt involved capture of the tri-*p*-tolylvinyl cation by CF_3COOH–CF_3COO^-, the same extent of scrambling was observed.

In the reaction of **3**-Br-*2*-^{13}C with CF_3COOH with no added salt, the extent of scrambling was found to increase with increasing reaction time (Table 2), indicating that the initially formed product was unstable and could subsequently ionize and undergo further scrambling. Moreover, the solvent isotope effect of 2.6 for unbuffered CF_3COOH–CF_3COOD suggests a substantial contribution from electrophilic addition–elimination. Such an addition–elimination process would not give rise to any scrambling:



However, the trifluoroacetate product from addition–elimination could subsequently undergo ionization and 1,2-tolyl shift. Thus in CF_3COOH with no added salt, besides the possibility of S_N1 solvolysis with scrambling, addition–elimination also occurs giving rise to an unrearranged product which subsequently may undergo scrambling. A combination of these processes could, therefore, explain the observed scrambling results in the trifluoroacetolysis, with no added salt, of **3**-Br-*2*-^{13}C.

Experimental

*Ethyl p-Tolylacetate-carboxyl-^{13}C (**9**)*

Reaction of $TolCH_2MgCl$ with $^{13}CO_2$ (from $Ba^{13}CO_3$, 90% enriched) in a similar way as in the preparation of labeled *p*-anisylacetic acid (6, 23) gave a 62% yield of $TolCH_2{}^{13}COOH$, mp 91–92°C (lit. (24) mp 94°C), ^1H nmr δ($CDCl_3$) 2.30 (CH_3, s), 3.60 (CH_2, d, $J_{^{13}CCH_2} = 8.0$ Hz), 7.13 (arom, s), and 10.77 (COOH, s). The acid was esterified by the H_2SO_4 catalyzed reaction with absolute ethanol to give an 88% yield of $TolCH_2{}^{13}COOEt$ (**9**), bp 62–63°C/0.1 Torr (lit. (24) bp 240°C), ^1H nmr δ($CDCl_3$) 1.25 (ethyl CH_3, t), 2.35 (CH_3, s), 3.57 (CH_2, d, $J_{^{13}CCH_2} = 8.0$ Hz), 4.15 (ethyl CH_2, q of d's, $J_{^{13}COOCH_2} = 3.3$ Hz), and 7.15 (arom, s).

*Tri-p-tolylvinyl-2-^{13}C Bromide (**3**-Br-*2*-^{13}C)*

The reactions utilized in the synthesis of **3**-Br-*2*-^{13}C are the same as those previously described for the synthesis of **2**-Br-*2*-^{13}C (6). The following is a typical set of experimental procedures.

[2]Similarly, the solvent kinetic isotope effect in the reaction of *cis*- and *trans*-2-phenyl-1,2-di-*p*-tolylvinyl bromides with CF_3COOH and CF_3COOD was found to be 3.4–3.9 (to be published).

A solution of labeled ester **9** (70% enriched, 2.60 g, 14.5 mmol) in 45 ml of tetrahydrofuran (THF) was added dropwise over a period of 1 h to a solution of TolMgBr (from 20 g (120 mmol) of TolBr) in about 100 ml of THF. The mixture was heated under reflux for 48 h, cooled in an ice bath, decomposed with ice and 10% HCl, and then repeatedly extracted with 50-ml portions of ether. The combined extract was dried over $MgSO_4$ and the ether was removed under reduced pressure to give an oil consisting of about a 3:1 mixture (from ^1H nmr) of 1,1,2-tri-*p*-tolylethanol-*1*-^{13}C (**10**) and 1,1,2-tri-*p*-tolylethene-*1*-^{13}C (**11**).

In trials with unlabeled materials, the reaction mixture from the treatment of $TolCH_2COOEt$ with TolMgBr was decomposed with saturated NH_4Cl solution rather than with dilute HCl to minimize elimination. 1,1,2-Tri-*p*-tolylethanol was isolated from the oily product by recrystallization from absolute ethanol, mp 70–71°C (lit. (25) mp 72–73°C), ^1H nmr δ(acetone-d_6) 2.20, 2.23 (CH_3, s's), 3.58 (CH_2, s), 4.03 (OH, s), and 6.9–7.5 (arom, m). When a concentrated solution of this tertiary alcohol in HOAc–Ac_2O was stirred at room temperature for 1 h, the precipitated tri-*p*-tolylethene was collected and repeatedly recrystallized from HOAc–CH_3OH, mp 82–84°C (lit. (25) mp 89–90°C), ^1H nmr δ($CDCl_3$) 2.22, 2.38, 2.42 (CH_3, s's), 6.90 (olefinic H, s), and 7.0–7.3 (arom, m).

The 3:1 mixture of labeled alcohol **10** and olefin **11** obtained above was dissolved in 80 ml of HOAc and a solution of 4.0 g (25 mmol) of Br_2 in 30 ml of HOAc was added dropwise. The reaction mixture was stirred at room temperature for 10 h and the pale yellow product that precipitated was collected by filtration and the filtrate was concentrated under reduced pressure to give more product. The combined solid material was washed with $NaHCO_3$ solution and with water and then recrystallized from CH_3OH to give 2.45 g (45% based on ester **9**) of tri-*p*-tolylvinyl-*2*-^{13}C bromide (**3**-Br-*2*-^{13}C), mp 121–123°C, ^1H nmr δ($CDCl_3$) 2.38, 2.47, 2.55 (CH_3, three s's), and 7.0–7.5 (arom, m). *Anal.* calcd. for $C_{23}H_{21}Br$ (70% ^{13}C enrichment at C-2): C 73.25, H 5.61; found: C 73.82, H 5.68.

Solvolysis Reactions

The acetolysis of **3**-Br-*2*-^{13}C was carried out by heating the substrate under reflux and with stirring for 3 h in HOAc–Ac_2O containing 1.1 equiv. of AgOAc. The trifluoroacetolysis was effected by stirring a mixture of **3**-Br-*2*-^{13}C and 1.1 equiv. of CF_3COOAg in CF_3COOH–$(CF_3CO)_2O$ for 15 min at room temperature. The reaction of **3**-Br-*2*-^{13}C with CF_3COOH containing 2.5 equiv. of CF_3COONa or without the presence of any added salt was carried out at 100°C for different lengths of time as summarized in Table 2. A typical experiment is described below.

A mixture of 1.03 g (2.73 mmol) of **3**-Br-*2*-^{13}C (diluted with **3**-Br to about 33% enrichment) and 500 mg (3.00 mmol) of AgOAc in 16 ml of HOAc containing 2.2 ml of Ac_2O was heated under reflux for 3 h. The AgBr and excess AgOAc were removed by filtration and washed with warm HOAc. The combined filtrate was evaporated at 3–5 Torr to give the crude product, **3**-OAc-*x*-^{13}C as an oil which was directly utilized for two successive treatments with $LiAlH_4$ as described previously (6) to give 1,2,2-tri-*p*-tolylethanol-*x*-^{13}C (**4**-*x*-^{13}C) for ^{13}C nmr examination. The yield of 4-*x*-^{13}C, after recrystallization from EtOH–H_2O, mp 93–94°C, was 0.54 g (62% based on **3**-Br-*2*-^{13}C).

In preliminary trials with unlabeled materials, the crude product, tri-*p*-tolylvinyl acetate (**3**-OAc), was redissolved in ether, washed with 10% K_2CO_3 solution, and dried over $MgSO_4$. Removal of the ether and recrystallization from absolute ethanol gave the pure **3**-OAc, mp 128–130°C, ^1H nmr δ($CDCl_3$) 1.95 (CH_3CO, s) 2.35, 3.40 (CH_3, two s's), and 6.9–7.3 (arom, m). *Anal.* calcd. for $C_{25}H_{24}O_2$: C 84.24, H 6.79; found: C 84.05, H 6.58.

Similarly, the ester product from the trifluoroacetolysis, **3**-$OOCCF_3$, was isolated from trials with unlabeled **3**-Br. Recrystallized from ether–methanol, it melted at 112–113°C; ^1H nmr δ($CDCl_3$) 2.35, 2.40 (CH_3, two s's), and 7.0–7.4 (arom, m). *Anal.* calcd. for $C_{25}H_{21}O_2F_3$: C 73.16, H 5.16; found: C 73.24, H 5.35.

Reduction of **3**-OAc or **3**-$OOCCF_3$ once with $LiAlH_4$ gave an approximately 2:1 mixture of the ketone $(Tol)_2CHCOTol$ and the alcohol $(Tol)_2CHCH(OH)Tol$ (**4**), and after a second treatment with $LiAlH_4$, pure **4** was obtained, mp 93–94°C, ^1H nmr δ($CDCl_3$) 2.03 (OH, s), 2.18, 2.24, 2.28 (CH_3, three s's), 4.19 (C-2 H, d, J = 8.5 Hz), 5.29 (C-1 H, d), and 6.9–7.4 (arom, m). *Anal.* calcd. for $C_{23}H_{24}O$: C 87.30, H 7.64; found: C 86.90, H 7.55.

An illustration of the calculations using the data from **4**-*x*-^{13}C given in Table 2 is as follows.

Let I_1^0 and I_1^*, respectively, be the integrated intensities of the ^{13}C absorption due to the naturally abundant ^{13}C at C-1 and to the ^{13}C enrichment at C-1. Then, from the unenriched **4**, $I_1^0/I_s = 0.578$; from the **4**-*x*-^{13}C derived from one of the trifluoroacetolysis experiments (spectrum given in Fig. 1*B*), $I_1/I_s = (I_1^0 + I_1^*)/I_s = 5.33$. Hence

$$(I_1^0 + I_1^*)/I_1^0 = 5.33/0.578 = 9.22$$

Converting the intensities to percentage ^{13}C

$$(1.1 + I_1^*)/1.1 = 9.22$$

$$I_1^* = 9.0\%$$

Similarly,

$$I_2^0/I_s = 0.578$$

$$I_2/I_s = (I_2^0 + I_2^*)/I_s = 5.86$$

$$(I_2^0 + I_2^*)/I_2^0 = 5.86/0.578 = 10.14$$

$$(1.1 + I_2^*)/1.1 = 10.14$$

$$I_2^* = 10.0\%$$

Therefore, the total ^{13}C enrichment is 9.0 + 10.0 = 19.0% and the scrambling from C-2 to C-1 = (9.0/19.0)100 = 47%.

Kinetic Measurements

The rates of the reaction of **3**-Br with CH_3COOH or CH_3COOD at 150°C and with CF_3COOH or CF_3COOD at 100°C, with or without the presence of 2.5 equiv. of CF_3COONa, were followed by heating the reaction mixtures in sealed ampoules and measuring the liberated bromide ion by potentiometric titration as described in the literature (22).

The reactions of mercaptide anions with chlorinated sulfones

RICHARD F. LANGLER[1] AND JAMES A. PINCOCK

Chemistry Department, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received November 22, 1976

RICHARD F. LANGLER and JAMES A. PINCOCK. Can. J. Chem. **55**, 2316 (1977).

Mercaptide anions react with chlorinated sulfones in two modes, *i.e.* nucleophilic attack on carbon with chlorine as the leaving group and/or nucleophilic attack on chlorine with concomitant carbanion formation. Mercaptide anion pK_b, degree of chlorination of the sulfone substrate, and substituent effects are qualitatively assessed in terms of the propensity for nucleophilic attack at carbon or chlorine.

RICHARD F. LANGLER et JAMES A. PINCOCK. Can. J. Chem. **55**, 2316 (1977).

Les anions mercaptures réagissent avec les sulfones chlorées suivant deux voies: soit une attaque nucléophile sur le carbone impliquant le chlore comme nucléofuge et/ou une attaque nucléophile sur le chlore avec la formation concomitante d'un carbanion. On discute d'une façon qualitative des effets des paramètres suivants sur la facilité avec laquelle l'anion mercapture attaque d'une manière nucléophile au niveau soit du carbone soit du chlore: le pK_b de l'anion mercapture, le degré de chloration de la sulfone agissant comme substrat, et les effets de substituants.

[Traduit par le journal]

In recent papers (1–4), we have reported studies of the chlorination of a variety of sulfide substrates. The initial paper (1) detailed the fate of α-sulfonyl-sulfides upon chlorination in aqueous acetic acid. These α-sulfonyl-sulfides were prepared from the appropriate α-chlorosulfone and thiol anion; for example, from chloromethyl methyl sulfone (**1***a*) and phenylmethanethiol anion (Table 1). In contrast, a variety of non-sulfur nucleophiles do not displace the chlorine atom of an α-chlorosulfone (5–8). We have also shown that both sodium bisulfide and thiourea fail to react with **1***a* in refluxing ethanol (1). Based on these observations a more extensive study of this apparently unusual nucleophilic displacement was undertaken.

We began the study by examining the effect of variations in the structure of the chlorosulfone substrate in the preparation of the sulfone-sulfides **2***b* (R_1 = Ph) and **2***c* (R_1 = $ClCH_2$) (10).

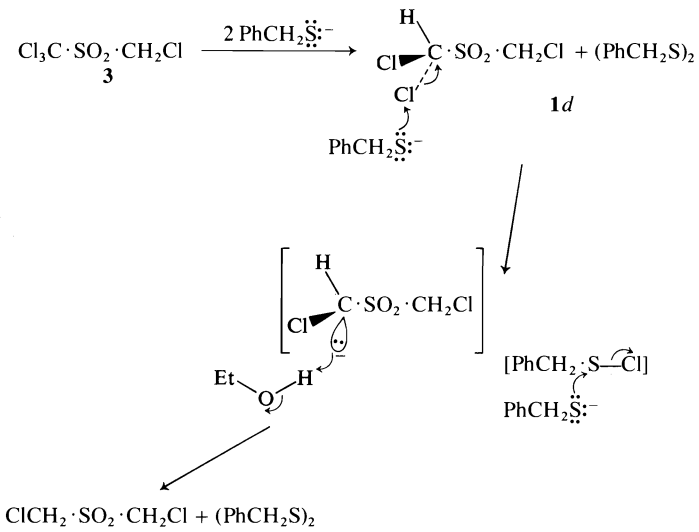
Although both of these reactions were successful,[2] the yields of the sulfone-sulfides **2** obtained with phenylmethanethiol anion changed markedly as a function of the chlorosulfone (percentage yield); chloromethyl methyl, **1***a* (93%) (9), chloromethyl phenyl, **1***b* (22%), and bis-(chloromethyl), **1***c* (14.6%) (10). These results may well indicate a sensitivity to bulky groups in the sulfone substrate which is consistent with the S_N2 mechanism envisioned for this reaction. In contrast, the reaction appears to have little sensitivity to steric hindrance resulting from bulky groups in the mercaptide anion, *e.g.*, chloromethyl methyl sulfone (**1***a*) affords the corresponding sulfone-sulfide upon reaction with the following mercaptide anions (percentage yield); ethyl (55%); phenylmethyl (93%) (9), diphenylmethyl (81%) (1), and triphenylmethyl (43%) (1).

The next system chosen for study was the trichlorosulfone **1***d*. *A priori*, the preparation of the sulfone-sulfide **2***d* presented some points of interest. Firstly, there are two carbon sites for nucleophilic attack of the thiol anion and secondly, the steric and electronic effects of a third chlorine atom could not be easily predicted.

The products from the reaction of **1***d* with phenylmethanethiol anion in refluxing ethanol proved to be bis(chloromethyl) sulfone, dibenzyl disulfide, and unreacted **1***d*. Moreover, treatment of the tetrachlorosulfone **3** with benzyl mercaptide anion furnished the same products. These observations are nicely explained by nucleophilic attack of the mercaptide anion on chlorine rather than on carbon as outlined in Scheme 1. Three factors appear to contribute to the change in mechanism. First, the bulky di-

[1]Author to whom enquiries should be addressed.

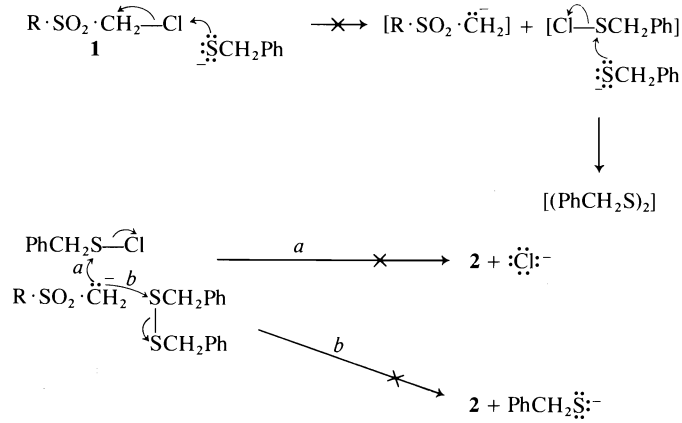
[2]In agreement with the results (1) for the methyl analog **2***a* both sulfone-sulfides **2***b* and **2***c* were successfully converted to the corresponding, α,α-dichloro-α-sulfonyl sulfonyl chlorides and subsequently hydrolyzed to the corresponding dichloromethyl sulfones.



SCHEME 1

chloromethyl group hinders attack of the nucleophile at the chloromethyl carbon; second, the presence of a second chlorine atom on carbon hinders nucleophilic attack at the carbon of the dichloromethyl group; and third, the presence of the second chlorine atom on the carbon adjacent to the sulfonyl group enhances the stability of the departing carbanion.

At this point a reasonable alternate mechanism seemed possible for the 'normal' nucleophilic attack at carbon. These products could arise after attack by the nucleophilic mercaptide anion on chlorine as observed for **1***d* and **3**, if the resulting carbanion (*i*) displaced chlorine from the newly formed sulfenyl chloride or (*ii*) displaced thiol anion from disulfide formed from



SCHEME 2

the reaction of the sulfenyl chloride and mercaptide anion. The net result as outlined in Scheme 2 would then appear to be nucleophilic attack of the mercaptide anion on carbon. We have examined these possibilities with three experiments. No sulfone-sulfide was obtained on treatment of dimethyl sulfone and benzenesulfenyl chloride with ethanol – sodium ethoxide, although methyl chloromethyl sulfone reacts with phenyl mercaptide anion under these conditions to furnish the corresponding sulfone-sulfide.[3] Therefore, sulfenyl chlorides do not function as intermediates in the formation of the

sulfone-sulfides **2**. Furthermore, dimethyl sulfone and dibenzyl disulfide in ethanol – sodium ethoxide failed to furnish any detectable amount of the corresponding sulfone-sulfide, although as shown in Table 1, chloromethyl methyl sulfone (**1***a*) furnishes **2***a* in 93% yield upon reaction with phenylmethanethiol anion. Finally, even the more acidic β-disulfone **9** and dibenzyl disulfide in ethanol – sodium ethoxide failed to give any substitution product. Therefore, disulfides do not function as intermediates in the formation of the sulfone-sulfides **2**. These results confirm our original formulation (1) of the substitution reactions as nucleophilic attack on carbon for **1***a*–**1***c* and the products obtained in the cases of **1***d* and **3** as nucleophilic attack on chlorine.

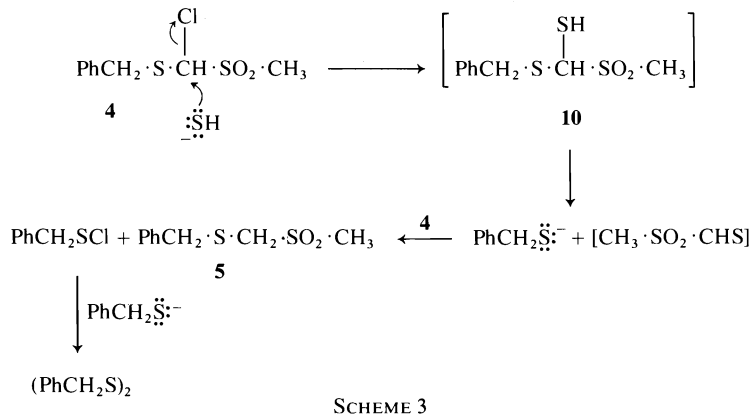
Nucleophilic displacements of carbon by attack on halogens have been observed previously with perhaps the most comparable example being the dechlorination reactions of α-halosulfones by phosphines (11, 12). However, they are sufficiently uncommon that an effort to examine the factors in the substrate and the nucleophile that lead to preferential nucleophilic attack at halogen, was undertaken.

Two cases of substrate variation are shown in Table 1 for **4** and **6**. The dechlorination of the chlorosulfone-sulfide **4** establishes that mercaptide anion nucleophilicity at chlorine can be induced by other groups which enhance the stability of the departing carbanion. The dechlorination of phenyl chloromethanesulfonate (**6**), establishes that the anion-stabilizing group need not be directly attached to the carbon atom involved. As an aside, the sulfonate **6** might have produced sulfene via nucleophilic attack on chlorine with concomitant ejection of phenoxide ion, although the absence of ethyl sulfonate products establishes that such a process did not occur. Clearly, now, from the reactivity of **6**, the preference for mercaptide anion attack at the chlorine of an α-chlorosulfone may be observed in substrates where carbanion stability is enhanced and where steric factors are not substantially different from α-chlorosulfone substrates which are attacked preferentially at carbon.

We subsequently examined variations in the nature of the sulfur nucleophile. As mentioned previously, simple α-chlorosulfones are inert to either substitution or dechlorination by bisulfide ion (1). However, substrates with enhanced carbon leaving group stability are dechlorinated as shown for the cases of **3**, **4**, and **8** (Table 1).

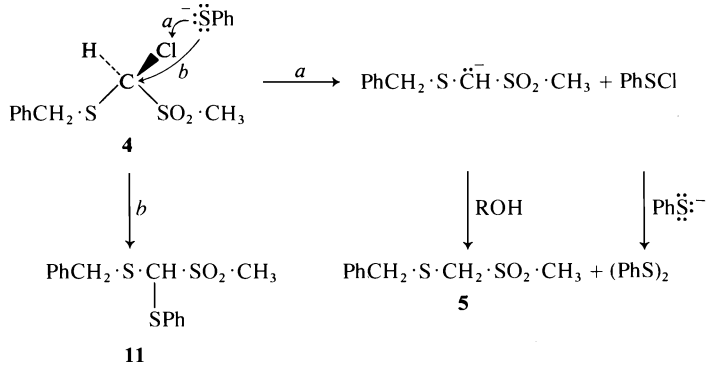
A cursory examination of these reactions would indicate that they appear to be following the pattern expected from the results obtained with the phenylmethanethiol anion. The key difference is the formation of dibenzyl disulfide in the reaction of the α-chloro-α-sulfonyl sulfide **4**. As outlined in Scheme 3, this would seem to require nucleophilic attack by the bisulfide ion on carbon with concomitant ejection of chloride ion resulting in the formation of the unstable intermediate **10**.

It now appears that there are two factors to consider in these nucleophilic reactions. The



SCHEME 3

first is that the propensity for attack on carbon is changed to favour attack on chlorine when the stability of the departing anion is enhanced. The second is that increasing the pK_b of the mercaptide anion (pK_b $PhCH_2S^-$ < pK_bHS^-)[4] shifts the propensity back to nucleophilic attack at carbon. As a consequence of these conclusions we examined the reaction of **4** with a mercaptide anion whose pK_b is closer to that of bisulfide ion than that of phenylmethane thiol anion and



SCHEME 4

which would afford a stable carbon substitution product. Our choice was the phenyl mercaptide ion.[4]

It was with some satisfaction that we isolated from the reaction of **4** with phenyl mercaptide anion (see Scheme 4) both the dechlorinated sulfone-sulfide **5** (43%) along with diphenyl disulfide-sulfone **11** (22%) indicating nucleophilic attack on carbon. This reaction, therefore, represents an adjustment of the two factors which appear to dictate the course of nucleophilic attack of mercaptide anions on chlorosulfone substrates (*i.e.* dechlorinated carbanion stability and mercaptide anion pK_b) to the point where both pathways are observed in the same reaction. Such a system is highly advantageous in order to undertake a more quantitative mechanistic and kinetic study of these pathways which we hope to pursue shortly.

As a final comment on this type of dechlorination reaction, Pierce *et al.* (14) have recently reported the dechlorination of *N*-phenyl-2-chloro-3-oxobutyramide with sodium bisulfide. They proposed an S_N2 displacement of chlorine proceeding through the intermediacy of a thiol-keto-amide which they were unable to isolate. In view of our results it appears that this reaction might be better formulated as a direct attack on chlorine. Such a rationale can be advanced on the grounds that the pK_b of the dechlorinated keto-amide anion formed in this reaction would be expected to be comparable to that of the β-disulfone **9** (which forms via nucleophilic attack on chlorine by bisulfide ion) rather than that of the sulfone-sulfide **4** (which undergoes some

[4]The pK_a of H_2S, PhSH, and $PhCH_2SH$ are approximately 7.0, 8.0, and 12.0, respectively (13).

nucleophilic attack at carbon by bisulfide ion, *vide* Scheme 3).

In conclusion, we have found that α-chlorosulfones undergo nucleophilic attack by sulfur anions at both carbon and chlorine. Increasing the number of chlorine atoms adjacent to the sulfonyl group diverts the nucleophilic attack from carbon to chlorine. Rationales for this result may be found in the increased crowding of both centres adjacent to the sulfonyl group by the introduction of second and third chlorine atoms and in the enhanced stability of the departing carbanion conferred by the additional chlorine atom(s). The latter rationale permits one to anticipate the preferential nucleophilic attack of sulfur anions on chlorine in α-chlorosulfone-sulfides which was also observed. Finally, the preference for nucleophilic attack of sulfur anions at carbon is enhanced as the pK_a of the corresponding thiol decreases. Such an observation is consistent with the increasing polarizability (softness) of the sulfur nucleophile as the pK_a of the corresponding mercaptan diminishes leading to increased rate of reaction with increasing electron deficiency (hardness) at carbon in the substrates.

Experimental

General

The ir spectra were recorded on a Beckman IR-10 grating spectrophotometer and the nmr spectra were obtained on a Varian T-60 instrument using TMS as the internal standard. The mass spectra were recorded on a Dupont 21-490 instrument. Samples were directly introduced and the spectra run at 30 eV with a source temperature of 200°C. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. The tlc was carried out on 5 × 20 cm analytical plates (0.75 mm thickness) spread with silica gel HF-254 (A. G. Merck).

*Preparation of $PhSO_2CH_2SCH_2Ph$ (**2b**) (15)*

Sodium metal (0.67 g) was dissolved in absolute ethanol (100 ml), followed by the addition of phenylmethanethiol (3.6 ml). Phenyl chloromethyl sulfone (5.003 g) was added and the reaction mixture refluxed for 1 h. Water (100 ml) was added and the solution extracted with chloroform (three-100 ml aliquots). The chloroform layers were combined, dried ($MgSO_4$), filtered, and the chloroform rotary evaporated. The residue was crystallized from 95% ethanol furnishing the sulfone-sulfide **2b** (1.610 g, mp 107–109°C) (15). The product had R_F, 0.73 on tlc when developed with chloroform. The ir bands were present at 1320 and 1145 cm^{-1}. The nmr spectrum ($CDCl_3$) showed signals at τ 2.36 (10H, m) 6.06 (2H, s) and 6.26 (2H, s).

Preparation of $CH_3SO_2CH_2SCH_2CH_3$

Sodium metal (9.64 g) was dissolved in absolute ethanol (300 ml) and the solution cooled with ice water. Ethanethiol (9.630 g) and chloromethyl methyl sulfone (20.007 g) (9) were added and the solution refluxed for 1 h. Water (300 ml) was added and the resultant mixture extracted with chloroform (five-100 ml aliquots). The combined organic layers were dried ($MgSO_4$), filtered, and rotary evaporated. The residue was dissolved in $CHCl_3$ (300 ml), washed with 2.5% sodium hydroxide (ten-100 ml aliquots), dried ($MgSO_4$), filtered, and rotary evaporated. The residue was rectified at reduced pressure affording the sulfone-sulfide (13.441 g; bp 146°C/5 Torr). The ir bands were present ($CHCl_3$) at 1315 and 1150 cm^{-1}. The nmr spectrum ($CDCl_3$) showed signals at τ 6.06 (2H, s), 7.00 (3H, s), 7.06 (2H, q), and 8.73 (3H, t). The mass spectrum exhibited ions at *m/e* 154(M^+, 7.5%), 75(100%), and 47(73.5%). *Anal.* calcd. for $C_4H_{10}O_2S_2$: C 31.11, H 6.53; found: C 30.90, H 6.64.

*Reaction of $Cl_2CH{\cdot}SO_2{\cdot}CH_2Cl$ (**1d**) and $PhCH_2SH$*

Metallic sodium (0.680 g) was dissolved in absolute ethanol (100 ml). Phenylmethanethiol (3.5 ml) and 1,1,3-trichloro-2-thiapropane-2,2-dioxide (5.067 g) (16) were added and the solution refluxed for 1 h. Water (100 ml) was added and the resultant mixture washed with chloroform (three-100 ml aliquots). The combined chloroform layers were dried ($MgSO_4$), filtered, and rotary evaporated affording a residue composed of dibenzyl disulfide (3.6 g), 1,3-dichloro-2-thiapropane-2,2-dioxide (2.6 g), and unreacted trichlorosulfone (1.6 g) (composition determined by nmr). A portion of the residue crystallized. The crystals were filtered off and recrystallized from carbon tetrachloride. A portion of this recrystallized material (300 mgm) was chromatographed on preparative tlc plates (100 mgm/plate) using CCl_4 developer. The disulfide bands were detected (uv light) and scraped, washed with chloroform, and the chloroform concentrated to afford dibenzyl disulfide which was identical with authentic material by nmr, tlc, and ir. The remainder of the preparative plate from the lower edge of the disulfide band to the lower edge of the origin was scraped, washed with chloroform, and the chloroform concentrated to afford clean dichlorosulfone which was identical to authentic material by nmr, ir, mp, and mixture mp.

Reaction of $Cl_3C{\cdot}SO_2{\cdot}CH_2Cl$ (3) and $PhCH_2SH$

This experiment was virtually identical to the reaction of **1d** with phenylmethanethiol (detailed above) except that the amounts of Na and $PhCH_2SH$ were four fold molar excess as compared with the tetrachlorosulfone **3** (16).

*Reaction of $PhCH_2SCHClSO_2CH_3$ (**4**) and $PhCH_2SH$*

Sodium metal (0.213 g) was dissolved in absolute ethanol (50 ml). Phenylmethanethiol (1.2 ml) and the chlorosulfone-sulfide **4** (1.150 g) (1) were added and the reaction stirred at ambient temperature for 48 h. Water (100 ml) was added and the reaction mixture washed with chloroform (three-100 ml) aliquots. The combined chloroform layers were dried ($MgSO_4$), filtered, and rotary evaporated affording a crude residue (2.003 g). The residue was composed of the dechlorinated sulfone-sulfide **5** and dibenzyl disulfide (1:1 molar ratio) as confirmed by nmr and tlc.

*Reaction of $ClCH_2{\cdot}SO_2{\cdot}OPh$ (**6**) with $PhCH_2SH$*

Sodium metal (0.669 g) was dissolved in absolute ethanol (100 ml). Phenylmethanethiol (3 ml) and phenyl

chloromethanesulfonate (**6**) (4.999 g) (prepared from chloromethanesulfonyl chloride and phenol) were added and the reaction mixture refluxed for 48 h. Water (100 ml) was added and the resultant mixture washed with chloroform (three-100 ml aliquots). The combined chloroform layers were dried ($MgSO_4$), filtered, and rotary evaporated. The residue (10.9 g) contained phenyl methanesulfonate (7) (22% based on starting chloromethanesulfonate), unchanged phenyl chloromethanesulfonate (78%), and dibenzyl disulfide (22%).

A portion of the residue (0.5 g) was chromatographed on preparative tlc plates (100 mg/plate) using chloroform for development. Bands located (254 nm uv light) at R_F, 0.89 afforded dibenzyl disulfide (0.055 g) which was identical to authentic material by tlc, nmr, and ir. The band at R_F, 0.78 afforded unchanged phenyl chloromethanesulfonate (0.164 g) which was identical to starting material by tlc, nmr, and ir. The bands at R_F, 0.64 afforded phenyl methanesulfonate (0.035 g) which was identical to authentic material by tlc, nmr, and ir.

*Reaction of $Cl_3C{\cdot}SO_2{\cdot}CH_2Cl$ (**3**) with NaHS*

The tetrachlorosulfone **3** (1.001 g), and a solution of *p*-toluenesulfonic acid monohydrate (0.832 g) and sodium sulfide nonahydrate in water (15 ml) were mixed together in methanol (40 ml). The reaction was stirred at room temperature for 48 h. Water (100 ml) was added and the resultant mixture washed with chloroform (three-100 ml aliquots). The chloroform was evaporated yielding a crude solid (0.695 g). The solid was recrystallized and shown to be identical to authentic bis(chloromethyl) sulfone by nmr, ir, and mp.

*Preparation of $PhCH_2{\cdot}SO_2{\cdot}CHCl{\cdot}SO_2CH_3$ (**8**)*

The chlorosulfone-sulfide **4** (1.401 g) (1) was dissolved in glacial acetic acid (5 ml) and the resultant solution added dropwise (5 min) to a cooled mixture of chromium trioxide (1.490 g) in glacial acetic (50 ml). The resultant mixture was maintained between 90 and 100°C for 0.5 h. Water (50 ml) was added and the resultant solution washed with chloroform (four 50 ml aliquots). The combined chloroform layers were washed with 2.5% sodium hydroxide until the aqueous p*H* remained basic. The chloroform was washed with distilled water (50 ml), dried ($MgSO_4$), filtered, and rotary evaporated to yield a brownish oil (1.421 g). The oil was crystallized from 95% ethanol affording colorless crystals (1.084 g; mp 125–128°C). The ir bands were present ($CHCl_3$) at 1350, 1340, 1155 and 1130 cm^{-1}. The nmr spectrum ($CDCl_3$) displayed signals at τ 2.66 (5H, s), 4.80 (1H, s), 5.13 (1H, d, J = 14 Hz), 5.43 (1H, d, J = 14 Hz), 6.73 (3H, s). The mass spectrum[5] exhibited ions at *m/e* 140(2.6%), 138(7.9%) and 91(100%). *Anal.* calcd. for $C_9H_{11}ClO_4S_2$: C 38.22, H 3.92; found: C 38.53, H 3.72.

*Reaction of $PhCH_2SO_2CHCl{\cdot}SO_2CH_3$ (**8**) with NaHS*

A solution of the α-chloro-β-disulfone **8** (1.001 g) in methanol (40 ml) was added dropwise over 20 min to a solution of sodium sulfide nonahydrate (1.719 g) and *p*-toluenesulfonic acid monohydrate (0.820 g) in distilled water (15 ml). The reaction was stirred at ambient temperature for 18 h. Water (100 ml) was added and the solution extracted with chloroform (three-100 ml aliquots). The combined chloroform layers were dried ($MgSO_4$), filtered, and rotary evaporated affording the dechlorinated β-disulfone **9** (741 mgm). The dechlorinated material was recrystallized and shown to be identical to authentic material (9) by nmr, ir, and mp.

*Reaction of $PhCH_2SCHClSO_2CH_3$ (**4**) with NaHS*

A solution of the chlorosulfone-sulfide **4** (1.000 g) in methanol (40 ml) was added dropwise over 10 min to a solution of sodium sulfide nonahydrate (2.170 g) and *p*-toluenesulfonic acid monohydrate (0.964 g) in water (15 ml). The reaction mixture was stirred at ambient temperature for 48 h. Water (100 ml was added and the solution extracted with chloroform (three-100 ml aliquots). The combined chloroform layers were dried ($MgSO_4$), filtered, and rotary evaporated affording a crude residue (0.550 g). A portion of the crude residue (300 mgm) was developed on preparative tlc plates (100 mgm/plates) using carbon tetrachloride. The bands at R_F 0.65 were scraped and washed with chloroform furnishing dibenzyl disulfide (0.400 g) which was identical to authentic material by nmr, tlc, and ms. The bands at the origin were scraped and washed with chloroform yielding dechlorinated sulfone-sulfide **5** (0.150 g) which was identical with authentic material by nmr, tlc, and ms.

*Reaction of $PhCH_2SCHClSO_2CH_3$ (**4**) with PhSH*

Sodium metal (0.216 g) was dissolved in absolute ethanol (50 ml). Benzenethiol (1.018 g) and chlorosulfone-sulfide **4** (1.157 g) were added and the reaction mixture stirred at ambient temperature for 4 days. Water (100 ml) was added and the resultant mixture washed with chloroform (three-100 ml aliquots). The combined chloroform layers were dried ($MgSO_4$), filtered, and rotary evaporated affording a crude residue (1.566 g). A portion of the residue (1.051 g) was chromatographed on silica gel (100 g). The column was eluted with carbon tetrachloride (thirty-50 ml fractions) and then with chloroform (thirty-50 ml fractions). Fractions 6 and 7 were combined and concentrated which furnished diphenyl disulfide (0.196 g) which was identical with authentic material by tlc, nmr, and ms. Fractions 42–46 were combined and concentrated affording, as an oil, the sulfone-disulfide **11** (0.195 g). The sulfone-disulfide **11** exhibited ir bands ($CHCl_3$) 1325 and 1150 cm^{-1}. The nmr spectrum ($CDCl_3$) displayed signals at τ 2.80 (10H, pseudo-doublet), 5.45 (1H, s), 5.76 (1H, d, J = 13 Hz), 6.10 (1H, d, J = 13 Hz), 7.00 (3H, s). The mass spectrum showed ions at *m/e* 245(66.6%), 110(20.3%), 109(11.5%), and 91(100%). *Anal.* calcd. for $C_{15}H_{16}O_2S_3$: C 55.52, H 4.97; found: C 55.36, H 5.03. Fractions 47–51 were combined and concentrated affording the benzylic sulfone-sulfide **5** (0.347 g). The impure material obtained from these fractions was chromatographed on three preparative tlc plates employing chloroform development. The upper band furnished clean sulfone-sulfide **5** (0.260 g) which was identical with authentic material by tlc, nmr, and ms.

[5]The significance of the ions at *m/e* 140, 138 has been discussed in detail (9, 10).

Organic sulfur mechanisms. 20. Sulfenes from 1-haloalkanesulfinic acids: the 'abnormal route' [1,2]

JAMES FREDERICK KING, RODGER PETER BEATSON, AND JOSEPH MAX BUCHSHRIBER

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 15, 1976

JAMES FREDERICK KING, RODGER PETER BEATSON, and JOSEPH MAX BUCHSHRIBER. Can. J. Chem. **55**, 2323 (1977).

1-Haloalkanesulfinic acids react with water, *p*-toluidine, or an enamine in the presence of added base to give products expected from an intermediate sulfene. It is concluded that sulfenes are formed, and hence may be presumed to react, via the 'abnormal route', *i.e.*, loss of a nucleophile from the *carbon* (rather than the sulfur) of the incipient sulfene, or, for the reverse process, addition of a nucleophile to the *carbon* (rather than the sulfur) of the sulfene. Since addition at the sulfur is well precedented, these conclusions indicate that sulfene is an 'ambifunctional' electrophile of a previously unknown kind. The mechanism of the sulfene formation is discussed in the light of deuterium labelling and kinetic experiments.

JAMES FREDERICK KING, RODGER PETER BEATSON et JOSEPH MAX BUCHSHRIBER. Can. J. Chem. **55**, 2323 (1977).

Mis en présence de base, les acides halo-1 alcanesulfiniques réagissent avec l'eau, la *p*-toluidine ou une énamine pour conduire aux produits attendus à partir d'un intermédiaire sulfène. On en conclut qu'il y a formation de sulfènes et qu'on peut donc supposer que ces acides réagissent par l'intermédiaire de la 'voie anormale' c'est à dire perte d'un nucléophile à partir du *carbone* (plutôt que du soufre) du sulfène qui se forme; pour les processus inverses, il y aurait addition d'un nucléophile sur le *carbone* (plutôt que sur le soufre) du sulfène. Puisque des réactions d'addition au niveau du soufre sont bien connues, ces conclusions indiquent que le sulfène est un électrophile 'ambifonctionnel' d'une sorte qui était inconnu jusqu'à maintenant. On discute du mécanisme de formation du sulfène à la lumière d'expériences de marquage au deutérium et de cinétique.

[Traduit par le journal]

Introduction

In all of their reactions known to date simple sulfenes apparently react as electrophiles, and usually the reaction occurs in such a way that an attacking nucleophile or nucleophilic component becomes attached to the sulfur atom, as in [1]. This mode which we call 'normal' addition is illustrated in its various forms by the formation of (*a*) sulfonic esters from reaction with alcohols,

[1] $RR'C{=}SO_2 + Nu^-(+E^+) \rightarrow RR'C(E){-}SO_2{-}Nu$

'Normal' addition

[2] $RR'C{=}SO_2 + Nu^-(+E^+) \rightarrow RR'C(Nu){-}SO_2(E)$

'Abnormal' addition

Nu = nucleophile, E = electrophile (not necessarily present)

where Nu = OR and E = H, (*b*) sulfonamides from ammonia or primary or secondary amines, where Nu = NR^2R^3 and E = H, (*c*) zwitterions from tertiary amines (3), where Nu = $\overset{+}{N}R^2R^3R^4$ and there is no electrophile E, and (*d*) 3-aminothietane 1,1-dioxides from enamines, where Nu = the nucleophilic carbon and E = the electrophilic (nitrogen bearing) carbon of the double bond.[3] As we have pointed out previously (6), there are certain reactions, however, in which it is reasonable to propose, at least formally, a nucleophilic attack on the *carbon* of the sulfene, as in [2]. The product of such an attack, instead of being an alkylsulfonyl compound, is an α-substituted sulfinic acid derivative. Such a mode of reaction, which we term 'abnormal' addition, is perhaps most easily depicted by the formation of α-chlorosulfinate anion, initially suggested (6*a*,*b*) as the second step in

[1]For part 19, see ref. 1.

[2]A preliminary account of this work has appeared; see ref. 2.

[3]For further examples see refs. 4 and 5, especially Table II of the latter. The only apparent anomaly in this list has recently been resolved (1), the reaction with chloral to give β-sultones having been shown to involve the sulfene in an orthodox manner.

the proposed mechanism for the formation of thiobenzoyl chloride *S*-oxides from phenylmethanesulfonyl chloride and tertiary amines as in [3].

[3] $PhCH_2SO_2Cl \xrightarrow{R_3N} PhCH{=}SO_2 \xrightarrow{Cl^-}$

$$PhCHSO_2^- \rightarrow \rightarrow PhC{=}SO$$
$$\quad\;\; | \qquad\qquad\quad\; |$$
$$\quad\;\; Cl \qquad\qquad\quad\; Cl$$

A number of what we regard as possible examples of 'abnormal' attack had been collected (6), but believing that the existence of this reaction was not adequately proved, we decided to attack the problem by examining the reverse process, *i.e.*, by seeing if it were possible to *form* a sulfene by the 'abnormal' route, for example, by simple loss of halide from a 1-haloalkanesulfinate anion.

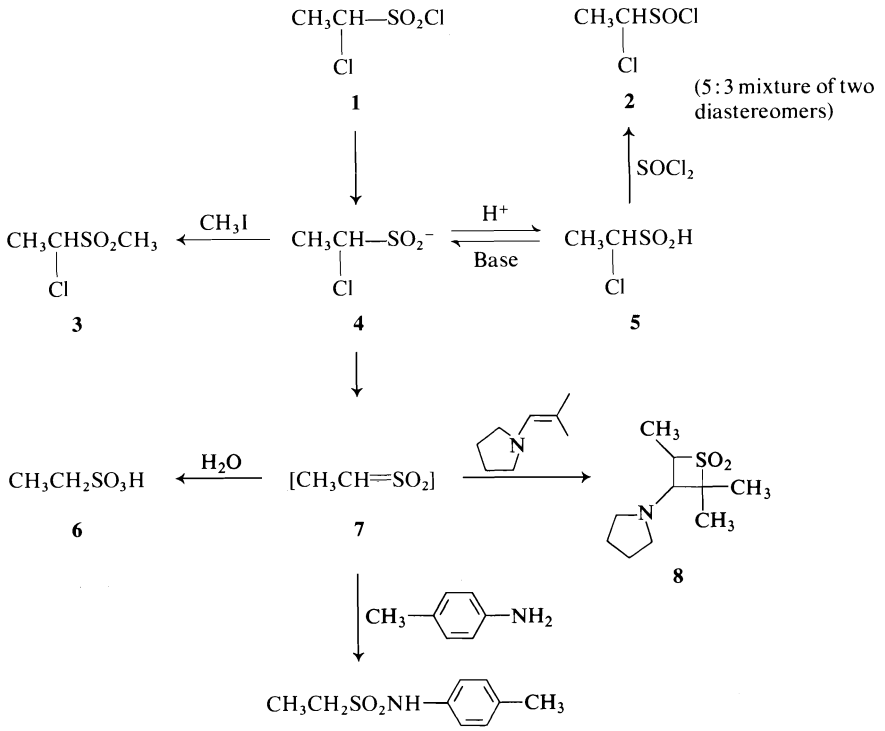
Results and Discussion

Formation of Sulfenes by the 'Abnormal' Route

That such an approach might work was suggested by some observations reported by Müller and Raudenbusch in 1931 (7), who noted, without explanation, that 1-chloroethanesulfonyl chloride (**1**) gave the ethanesulfonate anion on treatment with zinc in the presence of water. This observation is readily explained if one assumes that the zinc effects the usual reduction (8) of the sulfonyl chloride to the sulfinate stage, **4** and (or) **5**, and that this is transformed by the 'abnormal' route to the sulfene **7** which then undergoes 'normal' addition of water to form **6**. We have verified the formation of ethanesulfonate from **1** with zinc and ethanol, though the yields were modest.

Further experiments which gave both better yields and a full confirmation of the existence of the 'abnormal' route are summarized in Scheme 1. Treatment of **1** with sodium sulfite followed by strong acid gave **5** as a colorless oil. Because a careful proof of the structure of this material is essential for the conclusions drawn in this paper, the following data were adduced. The nmr spectrum showed a doublet at 1.75 (3H), a quartet at 4.75 (1H, $J = 7$ Hz), and a singlet at 10.5 ppm (1H), and the infrared spectrum had strong bands at 2900 (broad, OH) and 1080 cm^{-1} (S=O stretch) (9). Redox titration gave a titre corresponding to essentially pure **5**. Potentiometric titration with sodium hydroxide showed **5** to be a strong acid ($pK_a < 2$). We know of no pK_a determinations of any alkanesulfinic acids but pK_a values in the range 1.8 to 2.16 have been reported for benzenesulfinic acid (10). The replacement of a phenyl by a 1-chloroethyl group in the sulfinic acid series might be expected to affect the pK_a in a manner at least roughly parallel to that found with carboxylic acids, *i.e.*, pK_a (benzoic acid) − pK_a (1-chloropropionic acid) = 4.20 − 2.88 = 1.32 (10); this would point to a pK_a of **5** of ~1, a value consistent with our (admittedly limited) observations. Attempts to determine the pK_a of **5** conductometrically also merely confirmed the strong acid character of **5**. Reaction of **4** with methyl iodide gave the crystalline sulfone **3** whereas treatment of **5** with thionyl chloride gave the sulfinyl chloride **2**. The infrared spectrum of **2** displayed the strong absorption at 1160 cm^{-1} characteristic of sulfinyl chlorides, and the nmr spectrum showed this material to be a mixture of diastereomers, having two doublets (respectively at 1.92 and 1.91, both $J = 6.5$) and two quartets (at 5.02 and 5.18 ppm) in the ratio 3:5. Because both chiral carbon and sulfur atoms are present in **2**, such a mixture of diastereomers is expected to be visible in the nmr spectrum, provided that the sulfur atom is capable of maintaining its chirality (on the nmr time scale at the temperature of the instrument). This observation was, in fact, the first reported experimental indication that this is indeed so; further examples have subsequently been described (11).

The formation of methylsulfene (**7**) from **5** is deduced from the following. Reaction of **5** with triethylamine and *p*-toluidine in refluxing acetonitrile gave ethanesulfon-*p*-toluidide (**9**). In refluxing benzene in the presence of the enamine 1-(2-methylpropenyl)pyrrolidine and triethylamine, **5** gave the characteristic enamine-sulfene cycloadduct **8** in 16% yield. Under similar conditions ethanesulfonyl chloride gave **8** in 23% yield (though better yields were obtained at lower temperatures). The structure of **8** follows from its formation from ethanesulfonyl chloride taken with its elemental analysis and spectroscopic properties; the coupling of 9 Hz between the ring hydrogens was suggested in similar examples to be evidence for a *trans* orientation of the substituents (12), though such assignments have subsequently been questioned (13). Reaction of **5** with an excess of aqueous NaOH under reflux for 30 min gave sodium ethanesulfonate. When this reaction was carried out in



SCHEME 1

acetate buffer at 60°C, the pseudo first-order rate constants for p*H* values of 4.0, 5.0, and 5.9 were respectively 2.42, 2.67, and 2.53 × 10^{-5} s^{-1}. This insensitivity to change in p*H* taken with the previously mentioned strong acidity of **5**, fits with the proposal that **7**, **8**, and **9** are formed by unimolecular reaction of the anion **4**, as in Scheme 1. The nature of these products, especially **8**, points to the sulfene **7** as the only reasonable precursor for these materials.

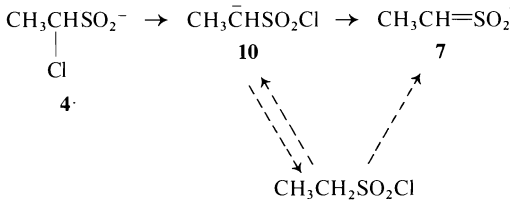
The formation of the sulfene from 1-haloalkanesulfinic acids is presumably a general reaction. We found that 1-bromoethanesulfinic acid was rather unstable at room temperature and did not require heating to afford the *p*-toluidide **9**. Chloromethanesulfinic acid, on the other hand, needed extended refluxing in benzene to give methanesulfon-*p*-toluidide. Since the publication of our preliminary report, two reports of the abnormal route involving the trichloromethanesulfinate anion have appeared (14, 15). Dykman (14) postulated the transformation $Cl_3C—SO_2^- \rightarrow Cl_2C{=}SO_2$ as a step in a mechanism accounting for formation of the complex thiosulfonate ester $Cl_2CHSO_2SCCl_3$ on reaction of Cl_3CSCl with dilute base. Kempe and Norin (15) proposed both 'abnormal' addition and elimination processes, the former in the sequence

$$Cl_2CHSO_2Cl \xrightarrow{Et_3N} Cl_2C{=}SO_2 \xrightarrow{Cl^-} Cl_3CSO_2^-\,Et_3NH^+$$

and the latter to account for halogen exchange, $Cl_3CSO_2^- \rightarrow Cl_2BrCSO_2^-$, in the presence of $Et_3NH^+Br^-$.

Mechanism of 'Abnormal' Sulfene Formation

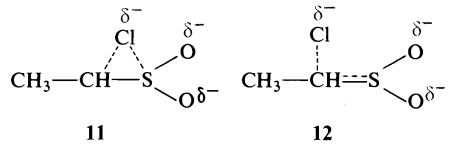
Although simple loss of chloride ion with direct formation of the sulfene is the most direct and the most likely route from the anion **4** to the sulfene **7**, there are less obvious routes which warrant some consideration here. One conceivable possibility, for example, is that the sulfinate anion **4** rearranges to the carbanion **10**, which then either loses chloride ion directly or picks up a proton to form ethanesulfonyl chloride which is transformed in the reaction medium to the sulfene **7** (either directly or via **10**). That ethanesulfonyl chloride cannot have been involved in the formation of **7**, however, is shown by an experiment in which 1-chloro-



ethanesulfinic acid-*d* was treated with triethylamine in the presence of *p*-toluidine-d_2. In such a reaction mixture any ethanesulfonyl chloride formed (via the route **4** → **10** → ethanesulfonyl chloride) would necessarily have been mostly monodeuterated (*i.e.*, CH_3CHDSO_2Cl) since the only important sources of hydrogen ions for converting **10** to ethanesulfonyl chloride are the SO_2D and ND_2 groups. A control experiment with CH_3CHDSO_2Cl and triethylamine and *p*-toluidine-d_2 gave a substantial amount of the dideuterated *p*-toluidide ($CH_3CD_2SO_2NHC_6H_4$-CH_3, after normal work-up), and since there was no clear sign of any of the dideuterated sulfonamide in the reaction starting from **5**, we conclude that ethanesulfonyl chloride is not an intermediate for any significant portion of the reaction **5** → **7**.

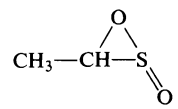
Avoidance of formation of ethanesulfonyl chloride does not preclude involvement of **10**, but does require that the reaction **10** → **7** be very fast, since deuteration of **10** by $Et_3\overset{+}{N}D$ is probably diffusion-controlled (or close to it). In that event the reaction **4** → **10** is presumably rate determining. Our observation of simple first-order decomposition of **4** precludes bimolecular reactions of **4** either with itself or any other reagent not present at the same concentration in each of our experiments at three different p*H* values; this, in effect, would limit the reaction to a simple unimolecular reaction. Consideration of the stereochemistry of a unimolecular rearrangement, however, leads us to question its feasibility. The closest analogies for such a transfer of chlorine would appear to us to be the reaction of sulfinate anions with chlorine to form the sulfonyl chloride, or (in the reverse direction) the reaction of sulfonyl chlorides with carbanionic species such as acetylides (16) or enolates (17). These reactions may be regarded as S_N2 reactions at chlorine, and though the geometric requirements of nucleophilic displacements are not known, such 'endocyclic' S_N2 reactions at carbon are not observed, the preferred route being the intermolecular pathway (18).

One further point may be raised concerning the intermediacy of **10**. Williams and co-workers (19) have suggested that a carbanion of the type $PhCHSO_2Z$ where Z is a good leaving group (*e.g.*, 2,4-dinitrophenoxide) may be so short-lived as to be not a true intermediate but merely a point on the slope from the transition state to the sulfene. If this should be the case with **10**, then the *single* transition state for this reaction would look something like **11**, which differs from the presumed transition state **12** for the direct



elimination from **4** only in that **11** has a partial bond from sulfur to chlorine rather than to carbon. An experimental distinction between **11** and **12** appears too subtle for us to attempt at present, and, in sum, the mechanism proceeding through **10**, to the extent that it is operationally distinguishable from the direct extrusion from **4**, remains a possible route, though in the face of the above points, a rather unlikely one.

A third conceivable route is the process **4** → **13** → **7**. The first step is analogous to the formation of α-lactones from carboxylate anions



bearing a good leaving group in the α-position as proposed initially by Kenyon and Phillips (20). It has been suggested (21) that α-sultines, such as **13**, are intermediates in the formation of aldehydes or ketones from sulfenes on flash thermolysis above 800°C, but their implication in reactions in solution has not been demonstrated. Oxidation of sulfines is known to give ketones (22) and it is attractive to postulate that this reaction may take place via a transient α-sultine, which may be hydrolyzed to the α-hydroxyalkanesulfinic acid which in turn proceeds to the carbonyl product. Such a scheme would suggest that if **13** is an intermediate in the formation of **7** from **4** that one might well find some acetaldehyde (or derivative) also formed in the reaction; none has been observed in our experiments, however, and the possibility that the α-sultine may be formed in this system remains,

but without any basis other than the analogy to α-lactone formation.

The Ambifunctionality of Sulfene

From the above discussion it would appear that the simple direct elimination process is the most likely route for the formation of the sulfene, and it follows, of course, that the reverse reaction is similarly the most likely mechanism for the postulated abnormal addition. If this is so then sulfenes show the apparently hitherto unobserved property of being 'ambifunctional' (23) electrophiles in which the attacking nucleophile may form a bond by simple addition to either of two different nuclei, carbon or sulfur in this case. Ambifunctional electrophiles in which the electrophilic centres are atoms of the same kind are well known (*e.g.* allylic cations and α,β-unsaturated ketones), and, in addition, electrophilic behaviour involving attack at two different atoms in *displacement* (as opposed to addition) reactions is observed, for example, with sulfonyl chlorides, which may yield either a sulfonyl derivative and chloride ion or a chlorinated derivative and sulfinate ion by attack at either the sulfur or the chlorine atoms, respectively. We are unable to call to mind, however, any previously known examples of simple *addition* to either of two different nuclei. Though ambifunctionality often leads to an interesting interplay of kinetic and thermodynamic factors, we prefer not to discuss this aspect of the chemistry of sulfenes until we have more data.

Conclusion

The chief point that we make from these observations is that the transition state for the abnormal route is readily obtainable from an α-substituted alkanesulfinic acid (for 1-chloroethanesulfinate at 60% $\Delta G^{\ddagger} = 26.5$ kcal mol^{-1}) and hence must be regarded as a species which, under some circumstances at least, could be obtained from a sulfene and a nucleophile. To be sure, the normal reaction of a nucleophile in the presence of a proton donor is to form the sulfonic acid derivative, but the 'abnormal' process may be important in certain situations (*e.g.* when the normal route merely leads back to the starting material). The 'abnormal' route would appear to be the mode of reaction in the formation of the thioacyl chloride *S*-oxides (6*a*,*b*; see also ref. 1), and hence the singular 1,3-dipolar addition process suggested by Strating (24) is unnecessary.

A final comment on the synthetic limitations of the formation of sulfenes from α-haloalkanesulfinic acids seems in order. Though the present study provides a new route to sulfenes, it is likely that it will find only occasional synthetic use; neither the yields, which are at best unremarkable, nor the relative inaccessibility of starting materials (at least at present) recommends it for common use. It appears that sulfinic acids (or sulfinate anions) react with sulfenes (to give uncharacterized products) and it is likely that the yields of desired sulfene products obtainable from this route may be limited by the destructive tendency of the sulfene to be consumed by reaction with its precursor. The chief significance of this study lies not so much in its synthetic value but rather in the insight it provides into the mechanisms of sulfene reactions.

Experimental

Infrared spectra were obtained with Beckman IR-10 or IR-20 spectrometers; nuclear magnetic resonance spectra with Varian A-60, T-60, or HA-100 instruments using tetramethylsilane as internal standard. Potentiometric titrations and p*H* determinations were carried out with a Radiometer PHM 25 p*H* meter. Melting points were determined on a Kofler hot stage and are uncorrected. 1,2-Dimethoxyethane (DME) and triethylamine were reagent grade materials distilled from CaH_2.

*Reaction of 1-Chloroethanesulfonyl Chloride (**1**) with Zinc Dust*

1-Chloroethanesulfonyl chloride (**1**) was prepared from trithioacetaldehyde (25) by the method of Müller and Raudenbusch (7); bp 51–53°C/5 Torr, 50% yield; ir (film) ν_{max} 1380 (s), 1170 (s), and 690 (m) cm^{-1}; nmr, δ 2.06 (3H, d, $J = 7$ Hz) and 5.36 (1H, q). The sulfonyl chloride (**1**) (5.8 g, 35 mmol) was dissolved in 24 ml of absolute ethanol; zinc dust was added in small portions until no more heat was evolved. The mixture was filtered and the solvent removed from the filtrate by evaporation. Potassium carbonate solution was added to the liquid residue until it was alkaline and the water evaporated under reduced pressure. A solid was obtained which was dissolved in water and passed through a column of Dowex 50W-X8 (H^+) cation exchange resin, the column being eluted with water until the eluant was no longer acidic. Water was removed from the eluant by evaporation. The residue was refluxed with excess thionyl chloride and the product was distilled under reduced pressure. Ethanesulfonyl chloride (0.36 g, 2.7 mmol, 8%) was obtained. The ir (liquid film) showed peaks at 1500 (w), 1360 (s), and 1160 cm^{-1} (s); the nmr ($CDCl_3$) had peaks at δ 1.6 (3H, t, $J = 7.0$ Hz) and 3.7 (2H, q); both of the spectra matched those of a commercial sample of ethanesulfonyl chloride (Eastman).

*1-Chloroethanesulfinic Acid (**5**)*

1-Chloroethanesulfonyl chloride (3 g, 18.4 mmol) was stirred for 1 h with a solution of sodium sulfite (4.8 g,

38 mmol) in 50 ml of water. The solution was washed with methylene chloride. Sulfuric acid (2 *M*) was added to the aqueous layer and the acidic solution was extracted 6 times with 40 ml portions of ether. The ether extracts were combined, dried ($MgSO_4$), and the solvent evaporated at a low temperature (*ca.* 40°C) to yield 1-chloroethanesulfinic acid (1.8 g, 14 mmol, 60% yield); ir ($CHCl_3$) ν_{max} 2900 (br s), 1080 (s), and 830 cm^{-1} (m); nmr ($CDCl_3$) δ 1.75 (3H, d, J = 7 Hz), 4.75 (1H, q), and 10.5 (1H, s). A sample (0.132 g) was dissolved in 250 ml of water and a 5 ml aliquot pipetted into a beaker; the solution was diluted with 140 ml of distilled water plus 200 ml of 0.1 *M* sodium hydroxide, and titrated potentiometrically (glass and platinum electrodes and a salt bridge) with 0.0066 *M* potassium permanganate solution (26) to an end point of 3.17 ml. After correcting for a blank of 0.035 ml, the titre was 3.135 ml, corresponding to 0.0207 mmol (100.1%) of the acid. Potentiometric titration of 1-chloroethanesulfinic acid with 0.0428 *M* sodium hydroxide gave a titration curve indistinguishable from that given by perchloric acid.

Reaction of 1-Chloroethanesulfinic Acid (5) with p-Toluidine

p-Toluidine (4.28 g, 40 mmol) and triethylamine (1.2 g, 12 mmol) were dissolved in acetonitrile (30 ml) and the solution heated to reflux. 1-Chloroethanesulfinic acid (0.516 g, 4 mmol) dissolved in acetonitrile (20 ml) was added to the refluxing solution over a period of 5 min. Refluxing was continued for a further 30 min, and the acetonitrile solution was allowed to cool to room temperature. The solution was made acidic with 2 *M* hydrochloric acid, and most of the acetonitrile was removed by evaporation.

Extraction of the remaining solution with methylene chloride yielded, after drying ($MgSO_4$) and evaporation of the solvent, ethanesulfon-*p*-toluidide (617 mg, 3.09 mmol, 77.5%). Recrystallization from methylene chloride – petroleum ether gave the ethanesulfon-*p*-toluidide (532 mg, 2.67 mmol, 67% yield), mp 77–80°C. The mp and ir and nmr spectra were identical to those of an authentic specimen prepared (27) from ethanesulfonyl chloride (Eastman).

When the above reaction was carried out in benzene at 45°C the yield of ethanesulfon-*p*-toluidide was 10%, and at 65°C, 32%.

Reaction of 1-Chloroethanesulfinic Acid (5) with 1-(2-Methylpropenyl)pyrrolidine and Triethylamine

Triethylamine (2 g, 20 mmol) was dissolved in acetonitrile (20 ml) and the mixture heated to reflux. A solution of the enamine (28) (7.1 g, 56 mmol) in 10 ml of acetonitrile was added to the refluxing mixture. 1-Chloroethanesulfinic acid (**5**) (713 mg, 5.5 mmol) was dissolved in acetonitrile and added to the stirred, refluxing mixture over a period of 4 min. The reaction was refluxed for a further 35 min. The mixture was allowed to cool and then acidified with 2 *M* sulfuric acid. The acidic solution was washed with methylene chloride, made basic with potassium carbonate, and extracted with methylene chloride. The CH_2Cl_2 layer after drying ($MgSO_4$) and evaporation gave an oil, which after addition of MeOH gave the cycloadduct (**8**) (117 mg, 0.82 mmol, 15%), mp 79–83°C. Recrystallization from MeOH gave the analytical specimen, mp 83.5–85°C. *Anal.* calcd. for $C_{10}H_{19}NO_2S$: C 55.26, H 8.81, N 6.45, S 14.75; found: C 55.01, H 8.89, N 6.42, S 14.89.

Reaction of ethanesulfonyl chloride with the enamine under similar conditions gave **8** (23% yield), mp 83–84°C, mixture mp with the material obtained above, 82.5–83°C; the ir and nmr spectra were identical to those of the above material: ν_{max} ($CHCl_3$), 2970 (m), 2700 (m), 1460 (w), 1300 (s), 1100 cm^{-1} (s); δ ($CDCl_3$) 1.48 (3H, s), 1.58 (3H, d, J = 8 Hz), 1.60 (3H, s), 1.78 (4H, m), 2.50 (4H, m), 2.88 (1H, d, J = 8.7 Hz), and 4.03 (1H, dq, J = 8 and 8.7 Hz).

Preparation of Methyl 1-Chloroethyl Sulfone (3) from 1-Chloroethanesulfinic Acid (5)

Triethylamine (1.2 g, 12 mmol) was added to 1-chloroethanesulfinic acid (**5**) (690 mg, 5.4 mmol) and the mixture stirred while methyl iodide (17.5 ml, 38 g, 270 mmol) was added over a period of 12 min. The mixture was refluxed with continuous stirring for 23 min. Water was added and the mixture extracted with methylene chloride. The extracts were combined, washed with aqueous sodium thiosulfate, dried ($MgSO_4$), and the solvent evaporated leaving methyl 1-chloroethyl sulfone (**3**) (0.589 g, 4.1 mmol). Recrystallization from chloroform – petroleum ether gave white crystals of **3** (0.573 g, 4.0 mmol, 74% yield) mp 56–57°C; reported (29) mp 62°C. The nmr spectrum ($CDCl_3$) showed peaks at δ 1.85 (3H, d, J = 8 Hz), 2.98 (3H, s), and 4.68 (1H, q); ir ($CHCl_3$): ν_{max} 1322 (s), 1145 (s), and 960 cm^{-1} (m). *Anal.* calcd. for $C_3H_7ClSO_2$: C 25.27, H 4.95, Cl 24.86, S 22.48; found: C 25.26, H 5.02, Cl 24.66, S 22.65.

1-Chloroethanesulfinyl Chloride (2)

Thionyl chloride (8.3 g, 70 mmol) was slowly added to 1-chloroethanesulfinic acid (**5**) (1.22 g, 9.5 mmol) at 0°C, and the mixture stirred for 1 h at room temperature. The mixture was then refluxed for 1 h and the excess thionyl chloride distilled off at atmospheric pressure. The product was distilled under reduced pressure. A small amount of 1-chloroethanesulfinyl chloride was obtained as a colorless oil. The ir spectrum (liquid film): ν_{max} 1400 (m), 1375 (m), 1160 (s), and 1035 cm^{-1} (m). The nmr spectrum ($CDCl_3$, HA-100) showed quartets at δ 5.02 and 5.18 (J = 6.5 Hz) with relative areas of 3:5 and doublets at 1.92 and 1.91.

Reaction of 1-Chloroethanesulfinic Acid (5) with Aqueous Sodium Hydroxide

1-Chloroethanesulfinic acid (**5**) (0.73 g, 5.7 mmol) was added to a refluxing solution of sodium hydroxide (0.65 g, 16 mmol) in 20 ml of water. The mixture was stirred under reflux for 35 min and the water removed by evaporation under reduced pressure. The residue was suspended in methylene chloride and phosphorus pentachloride (8.5 g) was added in small portions while swirling the mixture at room temperature. The methylene chloride was decanted, washed with water, dried ($MgSO_4$), and evaporated leaving ethanesulfonyl chloride (0.48 g, 2.9 mmol, 52% yield). The identity of the product was determined by comparing the nmr and ir spectra with those of a commercial sample of ethanesulfonyl chloride (Eastman).

Rate of Release of Chloride Ion from 1-Chloroethanesulfinic Acid (5) in Aqueous Acetate Buffers

A solution of 1-chloroethanesulfinic acid (**5**) (*ca.*

4 mmol) in 0.2 *M* acetic acid – sodium acetate buffer (100 ml) was frozen in liquid N_2 and degassed, and then heated in a water bath at 60.0 ± 0.1°C. Argon was let into the flask which was then fitted with a serum cap. Aliquots (5.00 ml) were removed at intervals and quenched by diluting in cold water (40 ml). The chloride ion content was determined by potentiometric titration (silver and glass electrodes) with 0.01 *M* $AgNO_3$. Good first-order rate plots were obtained as far as the reactions were followed (to about 60% reaction). The rate constants (determined graphically) were as follows: p*H* 4.0, 2.42×10^{-5}; p*H* 5.0, 2.67×10^{-5}; p*H* 5.90, 2.53×10^{-5} s^{-1}.

Reaction of 1-Chloroethanesulfinic Acid-d with p-Toluidine-d_2

1-Chloroethanesulfinic acid (**5**) in ether was shaken with several portions of D_2O. The sulfinic acid obtained after drying ($MgSO_4$) and evaporation of the ether was found by nmr to contain >90% deuteration of the acidic hydrogen. *p*-Toluidine-d_2 was prepared as follows. *p*-Toluidine was recrystallized from ethanol–water and the crystals dissolved in CH_2Cl_2. The CH_2Cl_2 layer was removed from the aqueous layer which formed, dried ($MgSO_4$), and then shaken with several portions of D_2O and dried over anhydrous K_2CO_3. The product remaining upon removal of the solvent showed 96% incorporation of deuterium in the amino group.

Triethylamine (0.7 g, 7 mmol) and *p*-toluidine-d_2 (1.4 g, 13 mmol) were dissolved in 20 ml of acetonitrile and the solution heated to reflux. 1-Chloroethanesulfinic acid-*d* (0.18 g, 1.4 mmol) dissolved in acetonitrile (10 ml) was added to the stirred refluxing mixture over a period of 4 min, and the mixture was refluxed for 35 min. The reaction was cooled and dilute sulfuric acid was added. The acetonitrile was evaporated. The aqueous solution was extracted with methylene chloride. The methylene chloride was dried ($MgSO_4$) and evaporated yielding the toluidide (0.17 g, 0.86 mmol, 61% yield), which was recrystallized from methanol giving a product with mp 81–81.5°C. The nmr spectrum ($CDCl_3$) showed no detectable dideuterated toluidide. The mass spectrum analyzed for undeuterated 21 ± 2%, monodeuterated 77 ± 2%, and dideuterated 2 ± 2% products, corresponding to 6.18 atom % excess D; deuterium analysis gave 6.10 atom % excess D.

Reaction of Ethanesulfonyl-1-d Chloride with Triethylamine and p-Toluidine-d_2

Ethanesulfonyl-*1-d* chloride was prepared by reaction of ethanesulfonyl chloride in dioxane-D_2O with triethylamine and converting the resultant triethylammonium ethanesulfonate-*1-d* to the sulfonyl chloride with PCl_5 in CH_2Cl_2 as previously described (30); deuterium analysis gave 17.65 atom % excess D (calcd. for CH_3CHDSO_2Cl: 20.0 atom % excess D); nmr integration indicated 92% CH_3CHDSO_2Cl and 8% $CH_3CH_2SO_2Cl$. When this sulfonyl chloride was added to a refluxing mixture of triethylamine and *p*-toluidine-d_2 in acetonitrile as described for the experiment with $CH_3CHClSO_2D$, the toluidide (35% yield) was found by examination of the methyl signal at δ 0.9 to consist of 22 ± 5% of undeuterated, 44 ± 5% of monodeuterated, and 34 ± 5% dideuterated toluidide.

1-Bromoethanesulfinic Acid

1-Bromoethanesulfonyl chloride (31) (536 mg, 2.58 mmol) was stirred for 1 h with a solution of sodium sulfite (660 mg, 5.2 mmol) in water (10 ml). The work-up and isolation were performed at less than 10°C. The solution was acidified with sulfuric acid (2 *M*), then extracted with ether (4 × 10 ml). The combined ether extracts were dried ($MgSO_4$) and the solvent removed to give 1-bromoethanesulfinic acid (295 mg, 66%); nmr spectrum ($CDCl_3$): δ 9.3–6.0 (variable br s, combination of water and sulfinic acid proton), 4.41 (1H, q, J = 7 Hz), 1.84 (3H, d, J = 7 Hz). The acid was used within 2 h after isolation. An impurity with δ 3.66 (q, J = 7 Hz), 1.22 (t) was present in varying small amounts.

Reaction of 1-Bromoethanesulfinic Acid, p-Toluidine and Triethylamine

1-Bromoethanesulfinic acid (262 mg, 1.51 mmol) in acetonitrile (10 ml) was added during 5 min to a solution of *p*-toluidine (1.62 g, 15.1 mmol) and triethylamine (0.64 ml, 4.54 mmol) in acetonitrile (20 ml) at 0°C. The resulting pale yellow solution was stirred at room temperature for a further 55 min, then acidified (2 *M* HCl) and the solvent removed *in vacuo*. The acidic solution was extracted with ether (3 × 25 ml). The combined ether extracts were dried ($MgSO_4$) and the solvent removed to give the crude toluidide (**9**) (150 mg, 45%). The mp and nmr spectrum were identical to those of the toluidide prepared from ethanesulfonyl chloride, a mixture mp showed no depression. When the above reaction was carried out for 2 h and 19 h, the yields of ethanesulfon-*p*-toluidide were 50 and 74%, respectively; at 4°C for 10 min and 1 h the yields were 6 and 26%, respectively. Reaction of 1-chloroethanesulfinic acid (**5**) at room temperature for 1 h, as above, gave no toluidide (**9**) detectable by nmr.

Chloromethanesulfinic Acid and its Reaction with p-Toluidine

Chloromethanesulfonyl chloride (32) (3.4 g, 23 mmol) was stirred with an aqueous solution of sodium sulfite (4.8 g in 50 ml) containing $NaHCO_3$. The solution was washed with CH_2Cl_2 and then strongly acidified with 3 *M* H_2SO_4 and extracted with ether. The extracts were dried and the solvent evaporated leaving a pale yellow oil (1.6 g, 61%). *p*-Toluidine (2.0 g) and triethylamine (1.5 g) were dissolved in benzene (30 ml), added to chloromethanesulfinic acid (0.37 g, 3.2 mmol), and the mixture refluxed overnight. The precipitate ($Et_3NH^+Cl^-$) was removed by filtration and the benzene solution washed with dilute HCl, and the dried solvent evaporated leaving the crude methanesulfon-*p*-toluidide (0.3 g, 50%), which on recrystallization from ether – petroleum ether melted at 99–101°C; the infrared and nmr spectra were identical to those of authentic specimen (33) prepared from methanesulfonyl chloride.

Acknowledgments

We thank the National Research Council of Canada for financial support and Mr. S. K. Laurence Li for carrying out the experiment with chloromethanesulfonyl chloride.

Applicability of the H_T acidity function to the protonation of thioamides, thioureas, and thionesters

JOHN T. EDWARD, GARY D. DERDALL, AND SIN CHEONG WONG

Department of Chemistry, McGill University, P.O. Box 6070, Station A, Montreal, P.Q., Canada H3C 3G1

Received August 3, 1976[1]

JOHN T. EDWARD, GARY D. DERDALL, and SIN CHEONG WONG. Can. J. Chem. **55**, 2331 (1977).

The protonation of eleven thioamides, five thioureas, and four thionbenzoates in aqueous sulfuric acid has been found to follow the H_T acidity function with acceptable accuracy. Protonation constants pK_{TH^+} obtained by use of H_T agreed fairly well with pK_{TH^+} values obtained by the Bunnett–Olsen method, but less well with those obtained by the Marziano–Cimino–Passerini procedure. Linear free-energy relationships of pK_{TH^+} values are discussed.

JOHN T. EDWARD, GARY D. DERDALL et SIN CHEONG WONG. Can. J. Chem. **55**, 2331 (1977).

On a observé que la protonation d'onze thioamides, cinq thiourées et quatre thionbenzoates dans de l'acide sulfurique aqueux suit avec une précision convenable la fonction d'acidité H_T. Les constantes pK_{TH^+} établies par l'usage de H_T sont en assez bon accord avec les valeurs établies par la méthode de Bunnett et Olsen, mais pas avec les valeurs établies par la méthode de Marziano, Cimino et Passerini. On discute des relations linéaires de l'enthalpie libre des valeurs pK_{TH^+}.

In a recent paper (1), we have reported values of an acidity function H_T governing the conversion of thiocarbonyl compounds (T) into their conjugate acid forms (TH^+) in aqueous sulfuric acid. This function is defined by

$$[1] \quad H_T = -\log (a_{H^+} f_T / f_{TH^+}) = pK_{TH^+} - \log ([TH^+]/[T])$$

where all symbols have their customary definitions (2). In the present paper we test the applicability of this H_T function, developed by the classical Hammett–Deyrup (H.D.) overlap procedure (3), to the ionization behaviour of 20 other thiocarbonyl compounds, and compare pK_{TH^+} (H.D.) values obtained by its use with pK_{TH^+} values obtained by analysing the experimental data according to the procedures of Bunnett and Olsen (B.O.) (4) or Marziano, Cimino, and Passerini (M.C.P.) (5) which do not require a specific acidity function for each class of compounds.

Experimental

Materials

Thioacetamide (6), 2-phenylthioacetamide (6), thiocyclohexanecarboxamide (6), and 1-methyl-2-thiopyridone (7) were prepared by reaction of the corresponding amides with phosphorus pentasulfide. Their melting points were close to those reported in the literature. Thiopivalamide, a new compound, was similarly prepared: after crystallization from ethanol, it had the properties listed in Table 1.

All substituted thiobenzamides were prepared by reacting the appropriate nitriles with hydrogen sulfide in the presence of triethylamine (8, 9). Melting points and elemental analyses of two new compounds are given in Table 1.

All substituted thioureas were commercial products and were recrystallized to constant melting point.

Substituted thionbenzoates were prepared from the corresponding nitriles via benzimidate hydrochloride intermediates (1, 10). They were purified by chromatography in hexane solution over alumina, followed by distillation under reduced pressure.

Measurement of Ionization Ratios

Ionization ratios ($I = [TH^+]/[T]$) of thiocarbonyl compounds were measured spectrophotometrically, following general procedures already described (1) and are available as supplementary material.[2]

Results and Discussion

Applicability of H_T Function

From equation 1, it is evident that a plot of log I against H_T should give a straight line of unit slope. In practice, it is found that slopes often vary from unity, but their closeness to unity is an indication of the applicability of the acidity function to the particular compounds. Values in the range 0.95–1.05 are desirable, but

[1]Revision received March 1, 1977.

[2]A complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

TABLE 1. Characterization of new compounds

Compound	mp (°C)	λ_{max} (nm) and ε_{max} (parentheses) in EtOH	Formula	Calcd.				Found			
				C	H	N	S	C	H	N	S
Thiopivalamide	116–119	340(55), 269.5(1020)	$C_5H_{11}NS$	51.2	9.5	12.0	27.3	51.2	9.5	12.1	26.9
3-Methoxythiobenzamide	102–103	384(240), 298(8530), 252(5630)	C_8H_9NOS	57.5	5.4	8.4	19.2	57.5	5.4	8.5	19.0
3-Methylthiobenzamide	90–91	384(230), 293(7080), 248(7250)	C_8H_9NS	63.5	6.0	9.3	21.2	63.4	6.0	9.3	21.4

those between 0.9–1.1 are considered acceptable (11).

Table 2 lists the 20 thiocarbonyl compounds investigated, along with the slopes of log I *vs.* H_T. All compounds have slopes within the range 0.9–1.1, with all of the thionesters and most of the thioamides having slopes between 0.95–1.05. The thioureas show a greater scatter in their slopes, probably because their spectra are subject to stronger medium shifts (1). If we include the 16 original H_T indicators (which obviously must have slopes close to unity), a total of 36 thiocarbonyl compounds are found to follow the H_T function, the average slope being 0.992 with a standard deviation of 0.037. The results are comparable to those obtained from the application of H_A to aromatic amides (11) (average slope 1.001, standard deviation 0.051) and of H_0 to substituted anilines (12) (average slope 0.995, standard deviation 0.040). This result is remarkable, considering the diversity of thiocarbonyl types tested, and indicates the H_T function to be generally applicable to the ionization behaviour of thiocarbonyl compounds.

pK_{TH^+} Values

With the applicability of [1] firmly established, the thermodynamic dissociation constant (pK_{TH^+}) of a thiocarbonyl compound may be calculated from either (*a*) the intercept of the plot of log I *vs.* H_T, or (*b*) the average pK_{TH^+} values obtained by application of [1] to log I data at various acid concentrations. The two methods proved to give essentially the same results within 0.02 logarithmic units. pK_{TH^+} (H.D.) values obtained by method *b* are reported in Table 2. The pK_{TH^+} of the strongest base, 1-methyl-2-thiopyridone, was also obtained by extrapolation to zero acid concentration of a plot of log I − log $[H^+]$ against $[H^+]$ for concentrations of perchloric acid between 0.7 and 2.5 M (13). The value of −1.56 agrees with the value obtained from [1], and gives a further proof that the H_T scale has been correctly anchored in dilute aqueous acid.

Also given in Table 2 are pK_{TH^+} values obtained by the B.O. and M.C.P. approaches. While the H.D. values obtained using H_T and [1] are in fair agreement with B.O. values, they are in much poorer agreement with M.C.P. values, obtained using M_C values for different concentrations of sulfuric acid (1) and the

equation

$$[2]\quad pK_{TH^+} = n_T{}^*M_C - \log\frac{[T]}{[TH^+]} - \log[H^+]$$

However, the B.O. values of Table 2 are for the most part in excellent agreement with pK_{TH^+} values obtained by Professors K. Yates and R. A. Cox (private communication) using a more generalized M.C.P. procedure.

Hammett ρσ Relations

A referee has suggested that a comparison of LFER plots using pK_{TH^+} values obtained from H_T with plots using pK_{TH^+} values obtained by B.O. and M.C.P. methods "would give some idea of whether or not it is *necessary* to derive new acidity functions for new compounds".

A good linear correlation (linear regression correlation coefficient $r = 0.993$) was found between Hammett σ values (15) and pK_{TH^+} (H.D.) values of six *meta*- and *para*-substituted thiobenzamides (Fig. 1) which include 4-methoxythiobenzamide and 4-chlorothiobenzamide from the original H_T indicators (1). The correlation with σ^+ values (15) is poor ($r = 0.920$). The ρ value of −1.29 is close to the value of −0.92 for *meta*- and *para*-substituted benzamides, whose pK_{AH^+} values also correlate with σ rather than σ^+ (11). Correlation of σ with pK_{TH^+} (B.O.) ($r = 0.914$) and with pK_{TH^+} (M.C.P.) ($r = 0.827$) is very much poorer.

Similarly, a good correlation exists between pK_{TH^+} (H.D.) values of aliphatic thioamides and pK_a values of corresponding carboxylic acids (16), as shown in Fig. 2. The slope of the straight line is 1.09 ($r = 0.988$). Again, the correlation of pK_{TH^+} (B.O.) ($r = 0.964$) and of pK_{TH^+} (M.C.P.) ($r = 0.967$) with pK_a is much poorer.

Finally, a good linear correlation is found between σ and pK_{TH^+} (H.D.) for eight substituted thionbenzoates, four of them being H_T indicators (1), as shown in Fig. 3 ($\rho - 2.66$; $r = 0.995$). Correlation between σ and pK_{TH^+} (B.O.) ($r = 0.966$) and pK_{TH^+} (M.C.P.) ($r = 0.978$) is poorer. However, correlations of σ^+

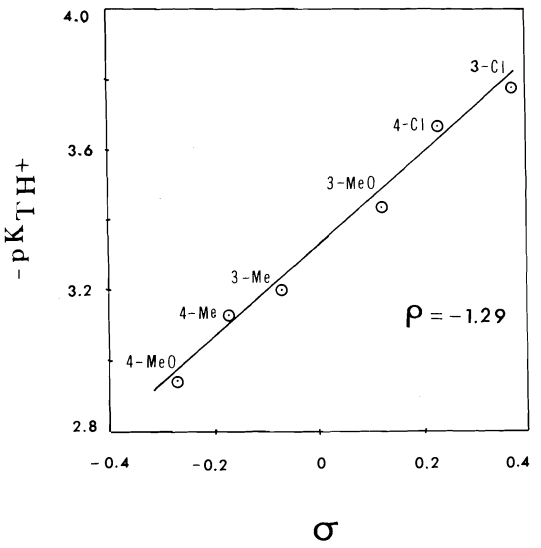

FIG. 1. Hammett ρσ plot for substituted thiobenzamides.

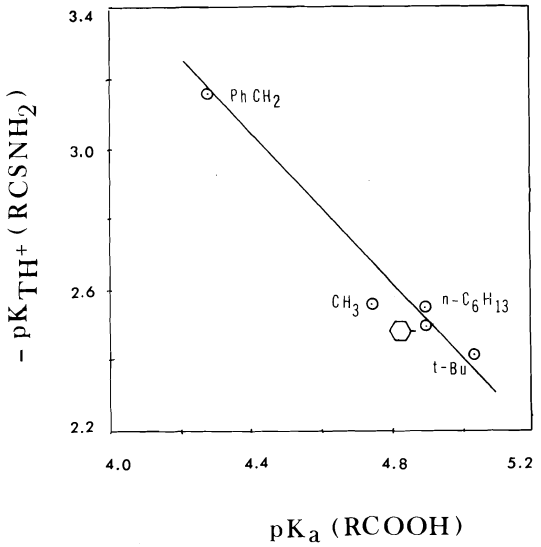

FIG. 2. Linear relation of pK's of carboxylic acids and thioamides.

with pK_{TH^+} (H.D.) (ρ − 2.33; r = 0.990), pK_{TH^+} (B.O.) (r = 0.996), and pK_{TH^+} (M.C.P.) (r = 0.995) are about equally good. (The *p*-methoxy compound was excluded because it is known to show gross deviation in $\rho\sigma^+$ plots for strong acid solutions (17).) The higher ρ values indicate that the ethoxy group of the thionesters is a weaker electron-releasing group than the amino group of the thiobenzamides, so that the extent of delocalization of the positive charge

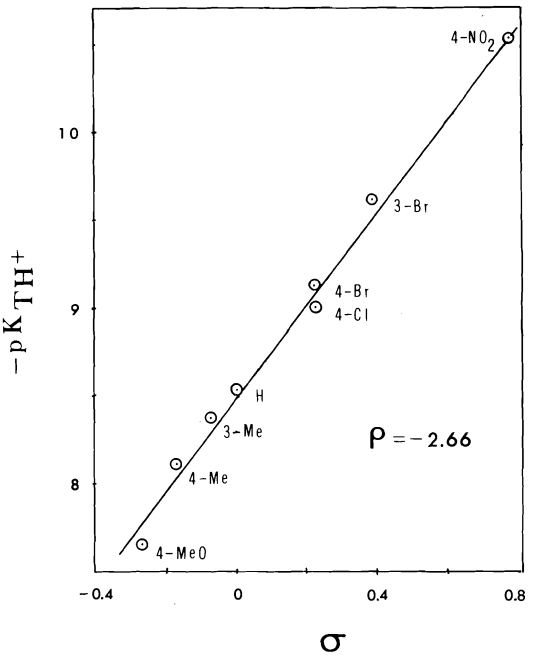

FIG. 3. Hammett ρσ plot for substituted ethyl thionbenzoates.

of the conjugate acid into the benzene ring is greater; this also explains the better correlation of pK_{TH^+} with σ^+.

These results with thionesters indicate that pK_{TH^+} values obtained by the Hammett–Deyrup acidity function method, applied to ionization data in concentrated sulfuric acid, have little or no superiority to pK_{TH^+} (B.O. and M.C.P.) obtained without use of a specific acidity function. However, for bases such as thioamides, ionizing in much more dilute sulfuric acid, the values obtained using H_T are definitely superior to the B.O. and M.C.P. values, as shown by the better correlation with σ and pK_a, and the better agreement with pK_{TH^+} values (ref. 1 and this paper) obtained by Paul's extrapolation procedure.

Received December 20, 1976

JAMES P. KUTNEY, JEFFREY D. LEMAN, PHILLIP J. SALISBURY, IGNACIO H. SANCHEZ, TREVOR YEE, and ROBERT J. BANDONI. Can. J. Chem. **55**, 2336 (1977).

Studies on the biodegradation of (+)-usnic acid (**1**) by a *Pseudomonas* species have revealed a novel aromatic deacylation process. The isolated metabolite, (+)-6-desacetylusnic acid (**2**) is crystalline and its structure is established by means of spectroscopic and chemical methods. The synthesis of **2** from usnic acid (**1**) is also reported and provides conclusive evidence for the structure of this metabolite.

JAMES P. KUTNEY, JEFFREY D. LEMAN, PHILLIP J. SALISBURY, IGNACIO H. SANCHEZ, TREVOR YEE et ROBERT J. BANDONI. Can. J. Chem. **55**, 2336 (1977).

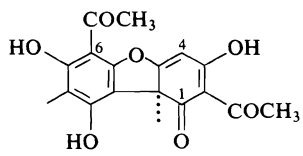
Des études sur la biodégradation de l'acide (+) usnique (**1**) par les espèces *Pseudomonas* ont permis de mettre en évidence un nouveau processus de déacylation aromatique. Le métabolite qui a été isolé, l'acide (+) désacétyl-6 usnique (**2**), est cristallin et sa structure a été établie à l'aide de méthodes spectroscopique et chimique. On rapporte aussi la synthèse de **2** à partir de l'acide usnique (**1**); cette synthèse fournit une preuve concluante de la strucure de ce métabolite.

[Traduit par le journal]

The degradation of organic compounds by microorganisms, an essential biochemical step, has considerable chemical and ecological significance, as can be seen from the increased work in this area (1–8). Our interest in this field centers primarily on the study of the metabolic intermediates involved in the breakdown of various aromatic substrates as a means of elucidating the relevant biodegradation pathways involved (4–8).

In previous preliminary investigations (9) it was shown that various microorganisms have the ability to degrade the lichen antibiotic (+)-usnic acid (**1**) (10–12) and a more detailed study was now warranted. For this purpose a sample of *Pseudomonas* was obtained from surface soil samples collected in the Whistler mountain area of British Columbia and further experiments were undertaken.

The fermentation was carried out at room temperature on a rotary shaker in Erlenmeyer flasks containing an appropriate amount of nutrient medium (see Experimental) with 3–4 day old cultures of the purified bacterial isolate. After 7–10 days, work-up and purification of the crude extract produced a single component, isolated in 57% yield, as yellow crystals, mp 134.5–136°C, in addition to some recovered substrate (32%).



1

Pseudomonas sp. → $C_{16}H_{16}O_6$

2

This material possessed the molecular formula $C_{16}H_{16}O_6$ as shown by high resolution mass spectrometry and elemental analysis, and was optically active $[\alpha]_D^{27}$ +689° (CH_3OH). Its ultraviolet spectrum (λ_{max} (MeOH) 336, 266, 232 nm) showed a hypsochromic shift of the aromatic B band as compared to that of usnic acid

[1]Part VI, J. P. Kutney and I. H. Sanchez, ref. 36.

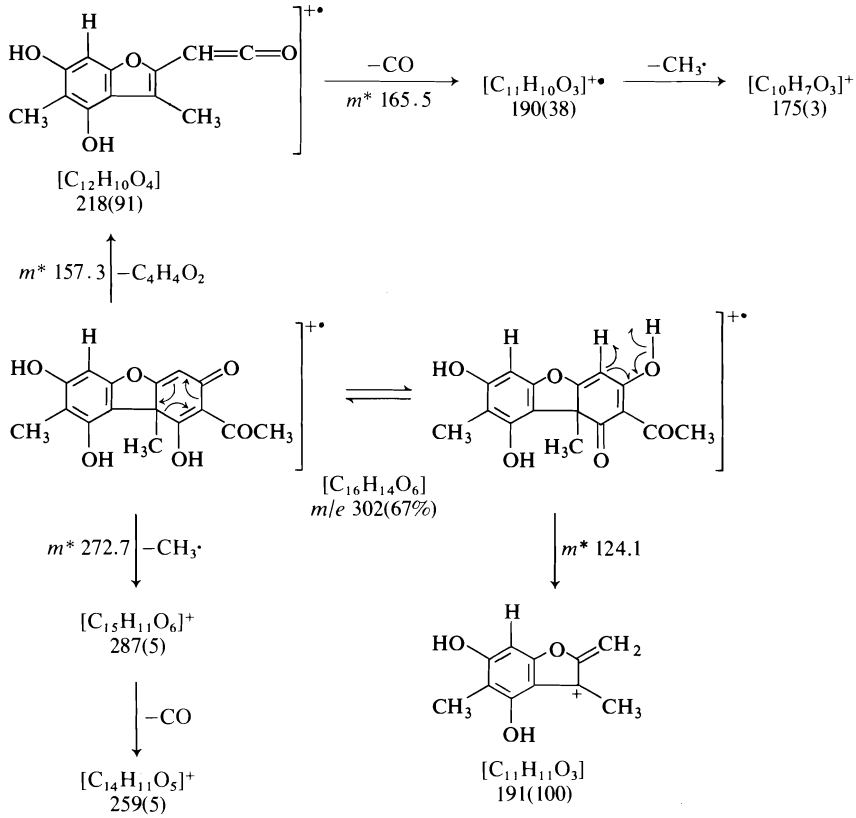


FIG. 1. The postulated fragmentation pattern of (+)-6-desacetylusnic acid in the mass spectrometer.

(285 to 266 nm), strongly suggesting that a change had occurred in the aromatic chromophore (13). Moreover, its infrared spectrum showed, in addition to the chelated hydroxyl groups (ν_{max} 3400–2800 cm^{-1}) similar to those of the parent molecule, the retention of the ring C chelated β-triketone system (14, 15) (1670, 1540 cm^{-1}). However, the reduction in intensity of the 1630 cm^{-1} band (as compared to that in (+)-usnic acid) assigned to the chelated aromatic methyl ketone (14, 15), coupled with a distinct band at 895 cm^{-1} that suggested the presence of a pentasubstituted aromatic ring (16), were strongly indicative of a ring A deacylated material.

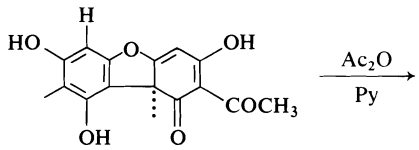
The ^{1}Hmr spectrum of this product showed in addition to three three-proton singlets corresponding to the angular methyl group, the aromatic methyl group, and the ring C methyl ketone (δ 1.70, 2.11, and 2.61 ppm, respectively), characteristic signals for both the chelated enol (δ 18.64) and the C_4 olefinic proton (δ 5.79). However, while the C_9-phenolic absorption remained at its usual position (δ 10.23), two new absorptions were observed, and these could be readily assigned to an aromatic proton (δ 6.26) and a phenolic hydroxyl group (δ 5.67, reveals exchange with D_2O). The shift to higher field shown by the latter clearly indicates the loss of chelation as a result of bacterial deacylation of the aromatic ring.

In its mass spectrum this compound revealed a molecular ion at *m/e* 302 and significant fragments at *m/e* 287 ($M - 15$) and 218 ($M - 84$) characteristic of the usnic acid series (17, 18). The base peak observed at *m/e* 191 ($M - 111$) was again typical of this series. The latter two fragments, which show complete retention of the usnic ring system, appear at values corresponding to 42 mass units lower than the corresponding fragments observed for the parent compound and left no doubt about the absence of the aromatic acetyl side chain in the isolated product. Figure 1 summarizes the postulated fragmentation pattern.

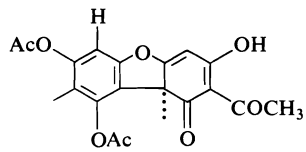
On the basis of the above spectroscopic data,

the metabolite isolated was assigned the structure **2** and the name, (+)-6-desacetyl usnic acid.

Further evidence was obtained through the preparation of the corresponding diacetate **3**. This crystalline derivative, mp 208–209°C, $[\alpha]_D^{26}$ +121° (CH_3OH), showed the molecular formula $C_{20}H_{18}O_8$, and the expected infrared (1750 cm^{-1}) and ^{1}Hmr (δ 2.31 and 2.43 ppm) characteristics for an *O*-diacetyl derivative.



2



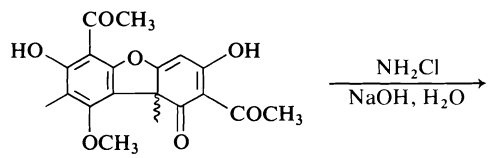
3

Having thus obtained all the required spectroscopic evidence in favor of structure **2**, it was decided to provide a firmer basis for our postulate by means of chemical transformations into known usnic acid derivatives. One of the few such derivatives lacking the aromatic acetyl group is pyrousnic acid (**4**), (19–22) obtained by heating (+)-usnic acid (**1**) to 210°C in 50% sodium or potassium hydroxide under a stream of hydrogen for 10 min (Fig. 2). Under somewhat milder conditions (23) (75% potassium hydroxide at 88–90°C for 1 h) usnetic acid (**6**), a derivative retaining the aromatic methyl ketone is obtained. Thus treatment of metabolite **2** under the latter conditions produced, in 35% yield, crystalline pyrousnic acid (**4**) which was shown to be identical with an authentic sample prepared directly from (+)-usnic acid.

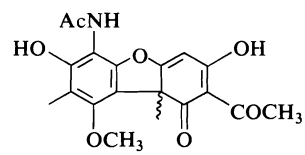
It appeared clear that the biodegradation of (+)-usnic acid (**1**) by a *Pseudomonas* species had resulted in a novel and specific aromatic deacylation process. However, to provide a more conclusive proof for the structural assignment and to obtain synthetic intermediates which would be useful in subsequent studies, an investigation directed at the synthesis of (+)-6-desacetylusnic acid (**2**) was initiated.

In our initial synthetic studies it became clear that alkaline cleavage of the aromatic methyl ketone occurred with concomitant rearrangement (24–26) thus leading to the 'iso' series of usnic acid derivatives. It thus became necessary to investigate a suitable protection for the aromatic carbonyl system in ring A and it appeared that an amide function may satisfy such requirements. It is well known that amide hydrolysis can be accomplished under a variety of conditions (27, 28) and the resulting products, upon deamination (29–33), lead to the desired materials. Moreover, recent experiments on acylarylnitrosoamines (34, 35) have also shown that such transformations can be equally performed directly at the acetanilide stage. In view of these results, and the above mentioned difficulties encountered during our synthetic approaches, we decided to undertake a study of the preparation of ring aminated usnic acid derivatives.

Treatment of the racemic monoether **7** (36) under the conditions described by Chrochet and Kovacic for the conversion of *o*-hydroxyaldehydes and ketones into *o*-hydroxyanilides (37–39) produced selectively, in over 90% yield, the novel acetanilide derivative **8**. This crystalline compound, mp 118–119°C, exhibited in the infrared spectrum, the presence of an associated secondary amide group (3300, 1660, 1550, 1280 cm^{-1}) while its ^{1}Hmr spectrum confirmed the postulated rearrangement with signals at δ 2.34 and 7.70 ppm, assigned to the *N*-acetyl and N-H protons respectively. In the mass spectrometer this compound revealed fragmentations typical of the usnic acid series (40) with fragments containing the ring A amine function.



7



8

Attempted ether cleavage in **8** by means of boron tribromide (41, 42) produced in low yield (12%) the desired (±)-*N*-acetyl-6-aminousnic acid (**10**), mp 228–230°C, showing the expected spectral data (ir: 3460, 1685, 1520, 1260 cm^{-1}; ^{1}Hmr: δ 2.19, 9.97 ppm). The main component, isolated in 60% yield, possessed the amide group (ν_{max} 3280, 1655, 1550, 1270 cm^{-1}) but the methoxyl and angular methyl groups were absent.

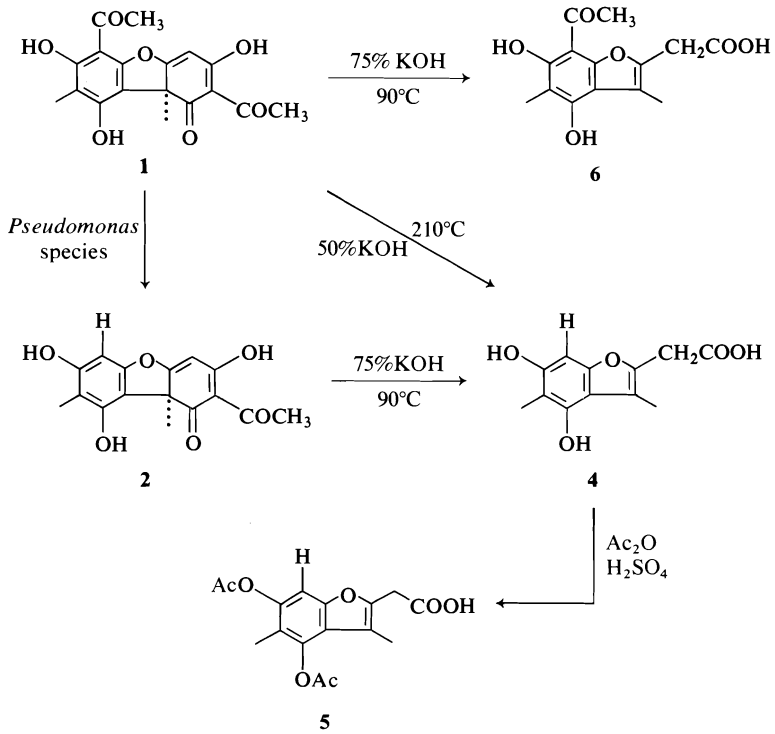


FIGURE 2

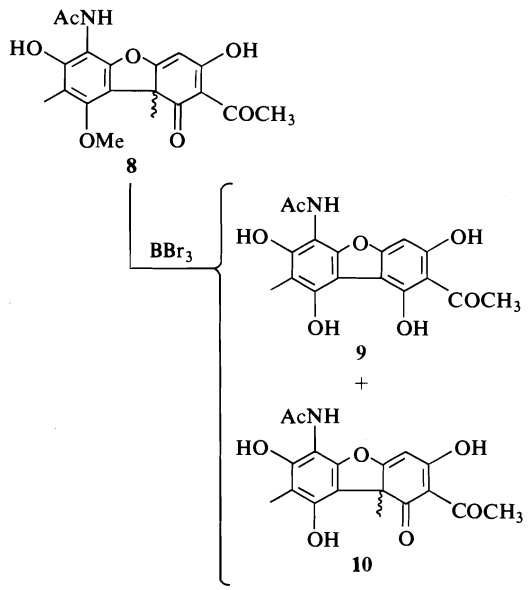
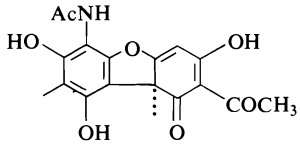
On the basis of spectral data this product was assigned the dibenzofuran structure **9**. Reaction of **8** with anhydrous aluminum trichloride (43, 44) permitted the isolation of **10** in 34% yield, whereas boron trichloride (45–48) in dry dichloromethane produced an 81% yield of the same component.



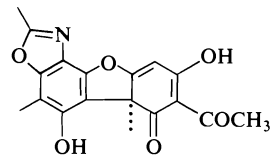
Having thus demonstrated the feasibility of introducing amide functionality into ring A of usnic acid derivatives, we decided to turn our attention to (+)-usnic acid itself. Although treatment of **1** under the conditions of the Schmidt reaction (49) resulted only in recovered starting material, the reaction with monochloramine in 2% methanolic sodium hydroxide or preferably 0.6% aqueous sodium hydroxide produced in 52% yield the optically active amide **11**, mp 230–232°C. This compound was further reacted with thionyl chloride (50) and the corresponding ring A oxazole derivative **12** was obtained in 52% yield.

Unfortunately complications arose when the triketone system (ring C) in the ring A aminated derivatives could not be converted to the isoxazole derivatives by the established procedures (51), a requirement for the synthetic approach envisaged for metabolite **2**.

Attempts to overcome this difficulty by performing the chloramine rearrangement on a preformed ring C isoxazole derivative bearing the C_6 acetyl side chain, similarly met with failure. However success was achieved in this area when the ring A ether derivatives were reacted with hydroxylamine and the resulting



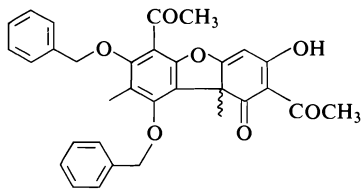
11



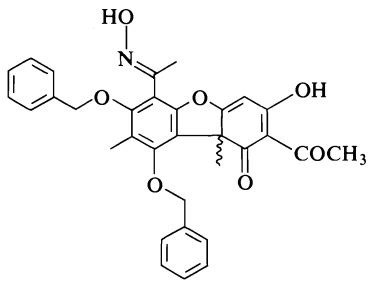
12

oximes exposed to Beckmann rearrangement conditions.

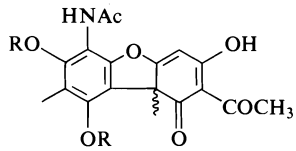
Treatment of the racemic dibenzyl ether **13** (36) with hydroxylamine hydrochloride in 5% methanolic potassium hydroxide – water (2:1) at 50°C resulted in good yields of the corresponding oxime intermediate **14**, which, without purification, was further treated with phosphorus pentachloride (52) in anhydrous ethyl ether at room temperature to produce in 48% yield the racemic dibenzylanilide derivative **15**, mp 168–170°C. Its infrared spectrum indicated clearly the presence of both an amide functionality (3430, 1680, 1520, 1250 cm^{-1}) and the



13



14



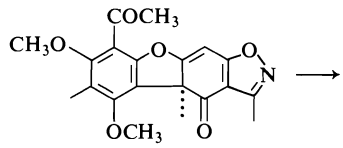
15

R = CH_2—C_6H_5

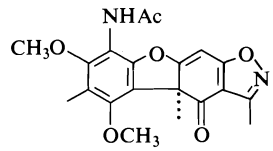
ring C β-triketone system (1680, 1540 cm^{-1}), both of which were confirmed by ^{1}Hmr spectroscopy, with signals at δ 2.27 and 6.87 ppm, assigned to the *N*-acetyl and the secondary amide protons, respectively. An improvement in yield (62%) could be achieved by a thionyl chloride catalyzed rearrangement (53) of the oxime **14**.

In similar fashion, the isoxazole derivative **16** (36) could be converted to the corresponding anilide derivative **17** (70% yield).

The necessary chemistry for the preparation of the required amino usnic acid derivatives was now developed and its utilization in the synthesis



16



17

of the metabolite **2** is discussed presently. A summary of the successful synthetic pathway from usnic acid (**1**) is provided in Fig. 3.

Due to the severe difficulties encountered during the attempted hydrolytic cleavage of the amide C—N bond, it became necessary to find an alternative method for our synthetic objective. The use of acylarylnitrosoamines as intermediates came under serious consideration. Thus Bamberger (54) and Hey *et al.* (55) studied the use of acylarylnitrosoamines as arylating agents, while DeTar (56, 57) and White (58–60) and co-workers studied the decomposition of such compounds, both in the aromatic and aliphatic series, in a variety of solvents. Finally, Denney *et al.* (34) and Cadogan *et al.* (35) demonstrated that the relevant aryl radical formed upon decomposition of the intermediate diazonium cation is able to abstract hydrogen atoms from the solvent to generate the desired H-substituted materials in satisfactory yields.

The preparation of *N*-nitrosoacylaryl (alkyl) amines can be accomplished by a variety of methods (61–66) and the direct arylation of aromatic amines (67) and amides (68) has been performed as well by the use of alkyl nitrites in refluxing benzene or biphenyl, respectively.

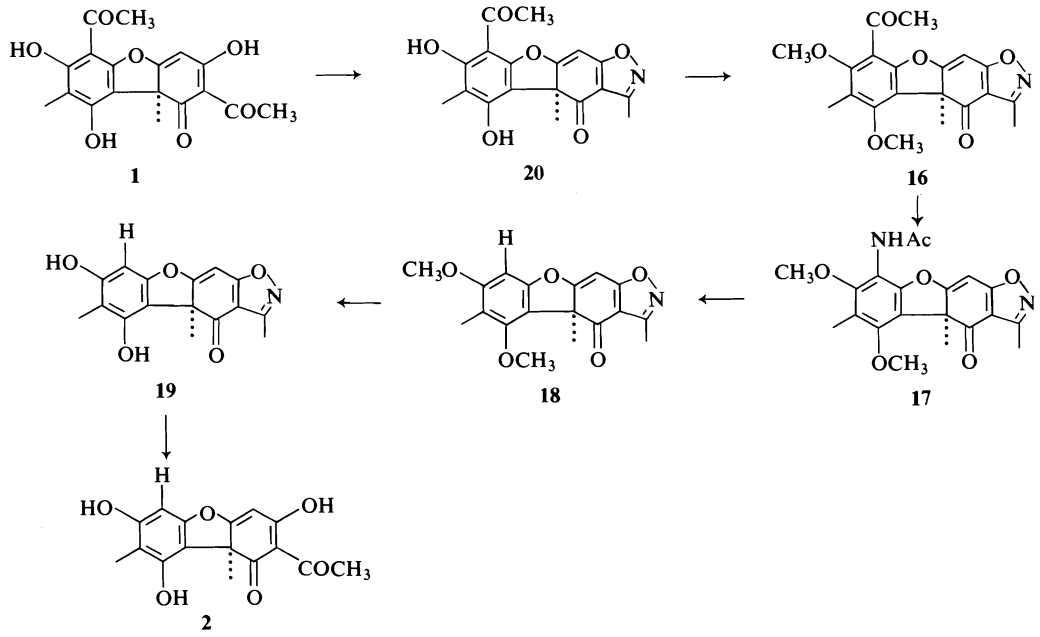


FIG. 3. The synthesis of (+)-6-desacetylusnic acid (**2**) from (+)-usnic acid (**1**).

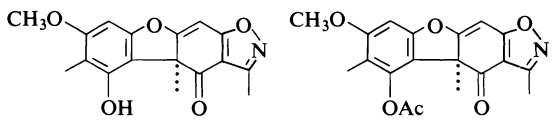
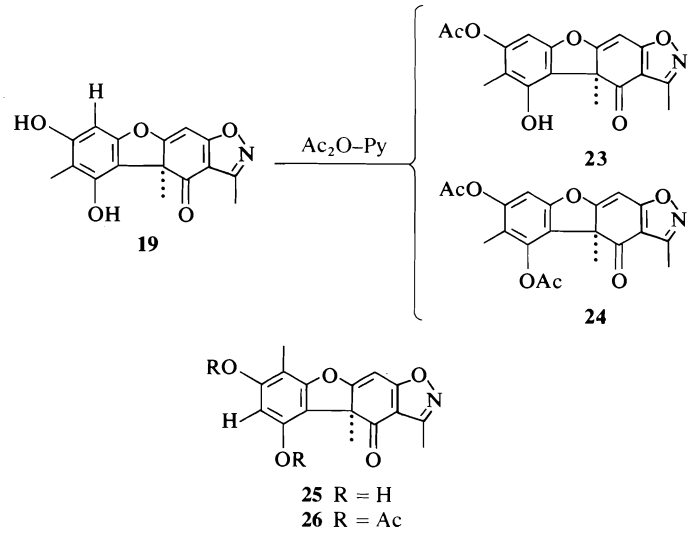
Although all the attempts to prepare the desired *N*-nitroso intermediate by the usual methods (61–66) proved unsuccessful, treatment of the acetanilide **17** with isoamyl nitrite in anhydrous dioxane (32) at 88°C produced, in 78% yield, the crystalline (+)-6-desacetyl-7,9-di-*O*-methylisoxazolo[4,5-*b*]usnic acid (**18**), mp 156.5–158°C. This substance showed in its ^{1}Hmr spectrum, the retention of both ether functionalities (δ 3.78 and 3.96) as well as the new aromatic proton as a sharp singlet at δ 6.43. It must be mentioned, however, that this reaction could not be applied directly to either (+)-usnic acid (**1**) or its isoxazole derivative **20**.

The next step in our synthetic sequence required the removal of the various protecting groups. After several unsuccessful attempts using the normal reagents for cleavage of ether functions (32, 69–73) the use of boron tribromide (74, 75) at −50°C in dry dichloromethane furnished, in 98% yield, the crystalline monoether **21**, mp 167–168°C, arising from selective demethylation at the 9-position. The remaining methoxyl group appeared as a sharp three-proton singlet at δ3.76, while the phenolic proton (exchangeable with D_2O) was seen at δ 9.67. Further corroboration for this structure was obtained by the preparation of the monoacetyl ether **22**, molecular formula $C_{19}H_{17}O_6N$, mp 195–196°C, showing the expected infrared (1770 cm^{-1}) and ^{1}Hmr (δ 2.46, 3.85 ppm) absorptions.



However, when the diether **18** was allowed to react at 10°C with boron tribromide, complete demethylation was observed and the product, (+)-6-desacetylisoxazolo[4,5-*b*]usnic acid (**19**), could be isolated in 87% yield. Acetylation of this material produced in good yield a mixture of the diacetate **24** and the 7-monoacetate **23** as highly crystalline materials, mp 168–170°C and 242–243°C, respectively.

Moreover, the phenol **19** and its diacetate **24** allowed the first direct comparison with the 'iso' series intermediates obtained previously (24, 51, 78). Some of the main differences arose from their infrared spectra, which showed that while the carbonyl group at the 1-position absorbs at 1675 cm^{-1} for the normal series isomer **19**, it appears at 1660 cm^{-1} for the isomer analogue **25**. As expected, ^{1}Hmr spectroscopy allows a facile differentiation between the two series, as seen from Table 1.



A minor product from the boron tribromide demethylation, isolated in 8% yield, was characterized as the bromophenol **27** resulting from the known (76) nuclear halogenation (bromination) of 1,3-diphenolic ethers upon treatment with Lewis acids.

The chemistry for the final steps in the sequence leading to the preparation of metabolite **2** had already been performed with the 'iso' series diacetate **26**, (24, 51, 78) and involved reductive cleavage (PtO_2/H_2) of the isoxazole N—O bond followed by immediate alkaline (1 *N* sodium hydroxide) regeneration of the ring C β-triketone system. Indeed treatment of the diacetate **24** under identical conditions furnished, in 97% yield, the desired (+)-6-desacetylusnic acid (**2**) mp 134.5–136°C, $[\alpha]_D^{26}$ +689° (CH_3OH), identical in all respects with the material isolated from the bacterial degradation. Table 2 indicates the circular dichroism data for the synthetic and natural compounds.

TABLE 1. Proton magnetic resonance data for (+)-6-desacetylisoxazolo[4,5-*b*]usnic acid (**19**) and (+)-6-desacetylisoxazolo[4,5-*b*]isousnic acid (**25**) and their corresponding acetates

C_9-O*H*	9.62	—	8.59	—

A further comparison of the natural and synthetic series was achieved on the corresponding diacetates (**28**).

Finally, the synthetic phenol **2** was converted via a one-step acetylation-aluminum trichloride-catalyzed Fries rearrangement (77) into synthetic (+)-usnic acid (**1**). The latter substance showed identical spectroscopic and chromato-

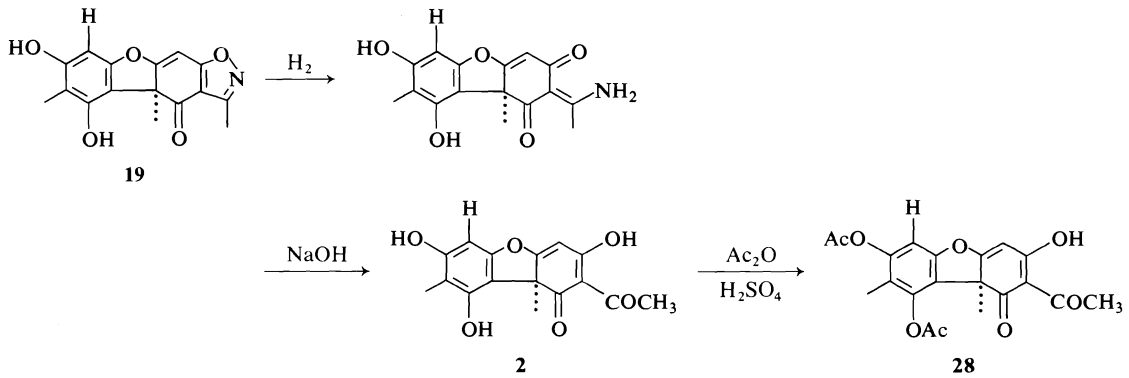
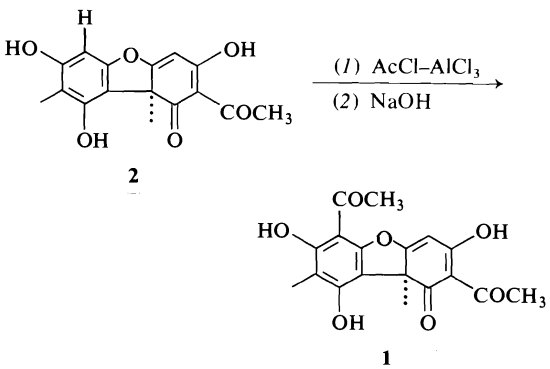


graphic properties to those of the naturally occurring optically active lichen substance.

In conclusion, it has been demonstrated that the biodegradation of (+)-usnic acid (**1**) by a *Pseudomonas* species results in a novel and specific aromatic deacylation process. Further studies are underway to provide a better understanding of this reaction.



Experimental

Melting points were determined on a Kofler block and are uncorrected.

Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer in methanol solution (unless otherwise noted). The wavelength of the absorption maxima are reported in nanometers (nm).

Infrared (ir) spectra were measured routinely on a Perkin-Elmer model 710 spectrophotometer. Analytical or comparison spectra were recorded on a Perkin-Elmer model 457 spectrophotometer using matched cells with a cell path of 0.2 mm in chloroform solution. Calibration was achieved using the 1601 cm^{-1} absorption band of polystyrene. The absorption maxima are quoted in wave numbers (cm^{-1}).

Proton magnetic resonance (^{1}Hmr) spectra were measured in deuterochloroform ($CDCl_3$) solution (unless otherwise indicated) at room temperature. Routine spectra were recorded at 60 MHz on a Varian T-60 spectrometer, and analytical or comparison spectra at 100 MHz on either a Varian HA-100 or a Varian XL-100 spectrometer. Line positions are given in the δ (ppm) scale using tetramethylsilane (TMS) as internal standard. The integrated peak areas, multiplicity, and proton assignments are indicated in parentheses.

Low resolution mass (ms) spectra were determined on either an AEI MS 902 or an Atlas CH-4B mass spectrometer, with high resolution mass spectra being recorded exclusively on an AEI-MS-902 mass spectrometer.

Circular dichroism (cd) spectra were obtained on a Jasco model J-20 spectropolarimeter in methanol solution (unless otherwise indicated). The wavelength of the absorption maxima is reported in nanometers (nm). The differential molar extinction coefficient ($\Delta\varepsilon$) and the sign of the observed Cotton effect are indicated in parentheses.

Optical rotations ($[\alpha]_D$) were measured on a Perkin-Elmer model 141 polarimeter at the sodium D line in chloroform solution (unless otherwise noted) using cells with a 0.1 dm path.

Microanalyses were performed by Mr. P. Borda of the

Microanalytical Laboratory, University of British Columbia.

Merck silica gel G (acc. to Stahl) impregnated with oxalic acid (2%) and with 2% fluorescent indicator added, was used as adsorbent for thin layer chromatography (tlc), unless otherwise noted. The tlc plates were activated in an oven at 90°C for 4 h before use. For qualitative chromatography, layers of 0.3 mm thickness were used and the spots were visualized by viewing under ultraviolet (uv) light or spraying with a 1% ethanolic ferric chloride solution. For preparative (plc) chromatography, large (20 × 20 and 20 × 60 cm) plates with a thicker layer (0.7 mm) were used. The developing systems were *A*, petroleum ether (30–60°C) – acetone (4:1), and *B*, chloroform – ethyl acetate (3:2), unless otherwise indicated.

Column chromatography was performed on either Mackerey-Nagel (0.2–0.5 mm grain size) or Merck 60 (0.063–0.2 mm grain size) silica gel.

The usnic acid utilized throughout the course of this study was obtained from Koch-Light Laboratories, England, as the optically active dextrorotatory isomer, (+)-usnic acid, isolated from lichen sources (*Usnea barbata*).

The numbering system employed is that approved for the dibenzofuran series (79).

The bacterial isolate showing the ability to degrade (+)-usnic acid was obtained by serial dilution of soil in distilled water and plating on modified malt agar (malt–yeast–peptone agar) from surface soil samples collected in the Whistler Mountain area by Dr. J. Leman. The culture has since been purified and identified as a *Pseudomonas* species by one of us (R.J.B.).

Media and Stock Solutions

Constituents for malt–yeast–peptone agar: malt extract 7 g, soytone 1 g, yeast extract 0.5 g, agar 15 g, distilled water to 1000 ml.

Constituents for nutrient medium: dextrose 5 g, asparagine 2 g, KH_2PO_4 1 g, $MgSO_4 \cdot 7H_2O$ 0.5 g, vitamin stock solution 0.2 ml, minerals stock solution 0.2 ml, distilled water to 1000 ml.

Vitamin stock solution: biotin 25 μg, thiamine 500 μg, pyridoxine 500 μg, inositol 25 μg, ethyl alcohol (40%) to 100 ml.

Minerals stock solution: $FeCl_3 \cdot 6H_2O$ 98 mg, $CuSO_4 \cdot 5H_2O$ 78.5 mg, $MnSO_4 \cdot 4H_2O$ 40.5 mg, $ZnSO_4 \cdot 7H_2O$ 88 mg, distilled water to 250 ml.

Maintenance, Growth, and Fermentation Conditions

A 'stock culture' of the purified bacterial isolate was stored on modified malt agar in culture tubes placed in the refrigerator.

Before fermentation could be carried out, the culture was transferred to a fresh sterile plate (Petri dish) containing modified malt agar. Transfers were effected in a clean air station by means of an inoculating loop that had been sterilized by heating to redness in a burner flame, by scraping a few cells from the stock culture onto the *cool* loop, and then rubbing them off onto the fresh agar surface. In order to avoid contamination from air-borne micro-organisms, it is essential to observe all aseptic precautions, including the flaming of mouths of all containers. Prior to inoculation, the flasks and nutrient media were sterilized in an autoclave by heating at 121°C, 15 psi *steam* for about 20 min, and then allowed to cool down to room temperature.

The actual inoculation of *shake* culture flasks was carried out by transferring a small segment (about $\frac{1}{4}$ in. square) of active growth and agar from a recently inoculated Petri dish (not older than 2 weeks) to a sterile 500 ml Erlenmeyer flask equipped with a rubber foam stopper and containing an adequate nutrient medium (100 ml). To ensure proper aeration, the volume of the 'nutrient solution' should never exceed about two-fifths of the total volume of the flask.

Thus, the newly inoculated liquid culture was allowed to grow for 3–4 days before addition of the substrate (100 mg (+)-usnic acid (0.290 mmol) in 10 ml acetone).

Once the substrate had been incorporated, the flasks were agitated on a rotary shaker at room temperature for the required amount of time (7–10 days), after which the fermentation broth (p*H* 8–8.5) was acidified with tartaric acid to p*H* 4 and thoroughly extracted with ethyl acetate (3 × 30 ml). The organic extracts were then washed with water (2 × 20 ml), dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. The residual broth was autoclaved before disposal.

The yellow residue (125 mg) was then purified by preparative layer chromatography (plc) on silica gel plates impregnated with oxalic acid (2%) using solvent mixture *A* to afford two main components.

*Component A: (+)-Usnic Acid (**1**) (2,6-Diacetyl-1,9b-dihydro-8,9bα-dimethyl-3,7,9-trihydroxy-1-oxodibenzofuran)*

Recrystallization of this material from chloroform–methanol produced bright yellow prisms of (+)-usnic acid (**1**, 32.1 mg, 0.093 mmol) identical in all respects (tlc, mixture mp, ir, ^{1}Hmr) with an authentic sample.

*Component B: (+)-6-Desacetyl Usnic Acid (**2**) (2-Acetyl-1,9b-dihydro-8,9bα-dimethyl-3,7,9-trihydroxy-1-oxodibenzofuran)*

Bright yellow needles (50.0 mg, 0.165 mmol; 57.0%) from chloroform – petroleum ether (30–60°C), mp 134.5–136°C; $[\alpha]_D^{27}$ +689° (*c* 0.1095); uv: λ_{max} 336 (3.15), 266 (3.87), 232 (4.07); ir: ν_{max} 3400–2800 (OH, chelated), 1670 (C=O, dienone system), 1630 (C=C, enol, enol ether and aromatic ring), 1540 (C=O, chelated carbonyl of the enolic triketone system), 895 (C—H, isolated Ar—H); ^{1}Hmr: δ 1.70 (3H, s, C_{9b}–C*H*$_3$), 2.11 (3H, s, C_8-C*H*$_3$), 2.61 (3H, s, C_2-COC*H*$_3$), 5.67 (1H, br s, C_7-O*H*), 5.79 (1H, s, C_4-*H*), 6.26 (1H, s, C_6-*H*), 10.23 (1H, s, C_9-O*H*), 18.64 ppm (1H, br s, C_3-O*H*); ms: *m/e* 302 (M^+), 287 ($M-15$), 218 ($M-84$), 191 ($M-111$, base peak), 161, 147, 135. *Anal.* calcd. for $C_{16}H_{14}O_6$: C 63.57, H 4.67; found: C 63.51, H 4.59. High resolution molecular weight determination calcd.: 302.079; found: 302.081; cd: λ_{max} (Δε) 328 (+9.99), 284 (−6.66), 262 (−3.53), 241 (+13.11); cd (CH_3OH + KOH): λ_{max} (Δε) 345 (+8.11), 310 (+6.86), 285 (+1.66), 264 (−12.90), 236 (+10.19).

*Preparation of (+)-6-Desacetylusnic Acid Diacetate (**3**) (2-Acetyl-7,9-diacetoxy-1,9b-dihydro-8,9b-dimethyl-3-hydroxy-1-oxodibenzofuran)*

(+)-6-Desacetylusnic acid (**2**) (50 mg, 0.165 mmol) was dissolved in a 1:1 mixture of acetic anhydride – pyridine (2 ml) and the solution allowed to stand at room temperature overnight. The reaction mixture was then poured over cracked ice (10 g) and extracted with ethyl ether (3 × 15 ml). The combined ethereal extracts were thoroughly washed with water (4 × 10 ml), dried over anhydrous magnesium sulfate, and evaporated under reduced pressure to yield an orange solid (60 mg) which

was purified by preparative chromatography (silica gel – oxalic acid plates, solvent system *A*) to produce pure (+)-6-desacetylusnic acid diacetate (**3**) (28 mg, 0.072 mmol; 44%), yellow crystals from chloroform – ethyl alcohol, mp 208–209°C; $[\alpha]_D^{26}$ +121 (*c* 0.06525); uv λ_{max} (log ε) 325 (3.26), 280 (3.73), 261 (3.85), 220 (4.00), ir: ν_{max} 1750 (C=O, acetates), 1685 (C=O, enone system), 1620, 1605 (C=C, enol ether, aromatic ring), 1540 (C=O, chelated acetyl of the triketone system); ^{1}Hmr: δ 1.78 (3H, s, C_{9b}-C*H*$_3$), 1.97 (3H, s, C_8-C*H*$_3$), 2.31 (3H, s, C_7-OCOC*H*$_3$), 2.43 (3H, s, C_9-OCOC*H*$_3$), 2.52 (3H, s, C_2-COC*H*$_3$), 5.81 (1H, s, C_4-*H*), 6.81 (1H, s, C_6-*H*), 18.41 ppm (1H, s, C_3-O*H*); ms: *m/e* 386 (M^+, base peak), 244 (*M* − 42), 302, 260, 233, 218, 191. *Anal.* calcd. for $C_{20}H_{18}O_8$: C 62.17, H 4.69; found: C 62.12, H 4.72. High resolution molecular weight determination calcd.: 386.100; found: 386.099.

*Preparation of Pyrousnic Acid (**4**) (2-Carboxymethyl-4,6-dihydroxy-3,5-dimethylbenzofuran)*

*I. From (+)-Usnic Acid (**1**)*

Usnic acid (**1**) (1 g, 2.90 mmol) was dissolved in 50% sodium hydroxide (4 ml) and heated to 210°C in an oil bath under a nitrogen atmosphere for 10 min. The reaction mixture was allowed to cool down to room temperature, poured into ice-cold 2 *N* sulfuric acid (50 ml), and extracted with ethyl acetate (3 × 50 ml). The combined extracts were dried over anhydrous magnesium sulfate and evaporated to yield a brown gum (421 mg). Repeated crystallizations from ethyl acetate – petroleum ether (light) afforded pure pyrousnic acid (**4**) (250 mg, 1.05 mmol; 36%) as tan needles mp 198–200°C (dec.) (lit. (22) mp 199–200°C); $[\alpha]_D^{26}$(CH$_3$OH) 0° (*c* 0.0875); uv: λ_{max} (log ε) 315 (3.03), 253 (3.51); ir (Nujol): ν_{max} 3500–2400 (OH, phenol, carboxylic acid), 1770, 1725, 1440 (C=O, carboxylic acid), 1640 (C=C); ^{1}Hmr (CD$_3$OD): δ 2.10 (3H, s, C_5-C*H*$_3$), 2.30 (3H, s, C_3-C*H*$_3$), 3.63 (2H, s, -C*H*$_2$COOH), 6.46 ppm (1H, s, C_7-H); ms: *m/e* 236 (M^+), 191, 44 (base peak). *Anal.* calcd. for $C_{12}H_{12}O_5$: C 61.01, H 5.12; found: C 61.05, H 5.03. High resolution molecular weight determination calcd.: 236.068; found: 236.068.

*II. From (+)-6-Desacetylusnic Acid (**2**)*

A solution of (+)-6-desacetylusnic acid (**2**) (363 mg, 1.20 mmol) in 75% aqueous potassium hydroxide (2 ml) was heated at 85–90°C under a nitrogen atmosphere for 40 min. After cooling, the reaction mixture was acidified with 1 *N* hydrochloric acid and then extracted with ethyl acetate (3 × 25 ml). The combined extracts were thoroughly washed with water (3 × 20 ml), dried over anhydrous sodium sulfate, and evaporated under reduced pressure to produce a brown oil (150 mg). Crystallization from ethyl acetate – petroleum ether (light) and ethyl alcohol gave pyrousnic acid (**4**) as a tan microcrystalline solid (100 mg, 0.42 mmol; 35%), mp 197–198°C; mixture mp with authentic pyrousnic acid 196–198°C. Chromatographic (silica gel – oxalic acid, solvent system *B*) and spectral (uv, ir, ^{1}Hmr) properties were also identical with those of authentic pyrousnic acid prepared from (+)-usnic acid.

*Preparation of Pyrousnic Acid Diacetate (**5**) (2-Carboxymethyl-4,6-diacetoxy-3,5-dimethylbenzofuran)*

A solution of pyrousnic acid (**4**) (40 mg, 0.169 mmol) in 0.5% concentrated sulfuric acid in acetic anhydride (1.5 ml) was allowed to stand at room temperature overnight. The resulting solution was poured into crushed ice (10 g), extracted with ethyl acetate (3 × 5 ml), and the combined extracts washed with water (2 × 5 ml), dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The residue (59.2 mg) was directly crystallized from ethyl acetate – petroleum ether (30–60°C) to afford pure pyrousnic acid diacetate (48 mg, 0.150 mmol; 88%) as cream coloured needles, mp 206–208°C; mixture mp with authentic pyrousnic acid diacetate, 207–208°C; $[\alpha]_D$(CH$_3$OH) 0° (*c* 0.05725); uv: λ_{max} (log ε) 280 (3.33), 260 (3.79), 218 (4.04), 213 (4.06); ir (Nujol): ν_{max} 3000–2400 (OH, carboxylic acid), 1755 (C=O, acetates), 1705 (C=O, carboxylic acid), 1635, 1600 (C=C), 1420, 1220 (OH, C—O, carboxylic acid dimer); ^{1}Hmr (CDCl$_3$–DMSO-d_6): δ 1.95 (3H, s, C_4-C*H*$_3$), 2.14 (3H, s, C_6-OCOC*H*$_3$), 2.28 (3H, s, C_4-OCOC*H*$_3$), 2.34 (3H, s, C_3-C*H*$_3$), 3.65 (2H, s, C_2-C*H*$_2$-COOH), 5.95 (3H, br, COO*H*·H_2O), 7.03 ppm (1H, s, C_7-*H*); ms: *m/e* (M^+), 278, 236 (base peak), 191, 43. *Anal.* calcd. for $C_{16}H_{16}O_7$: C 59.99, H 5.03; found: C 60.06, H 5.10. High resolution molecular weight determination calcd.: 320.089; found: 320.088.

*Preparation of Usnetic Acid (**6**) (7-Acetyl-2-carboxymethyl-4,6-dihydroxy-3,5-dimethylbenzofuran)*

A solution of (+)-usnic acid (**1**) (1 g, 2.90 mmol) in 75% potassium hydroxide (3 ml) was heated at 88–90°C under nitrogen. After 1 h, when the bubbling had stopped, the reaction mixture was cooled to 10°C and acidified with 1 *N* hydrochloric acid. A solid precipitated and was allowed to stand overnight at 0°C. Water (10 ml) was then added and the mixture filtered to give a pale yellow solid (380 mg) which upon recrystallization from 70% acetic acid produced pure usnetic acid (**6**) (310 mg, 1.11 mmol; 38%), mp 207–208°C (lit. (23) mp 209–210°C); $[\alpha]_D$(CH$_3$OH) 0° (*c* 0.112); uv: λ_{max} 358 (4.20), 308 (3.81), 255 (3.94), 249 (4.00); ir (Nujol): ν_{max} 3605 (OH, free), 3300–2500 (OH, COOH, chelated), 1715 (C=O, carboxylic acid), 1625 (C=O, chelated acetyl grouping; C=C, aromatic ring); ^{1}Hmr (CDCl$_3$–DMSO-d_6): δ 2.06 (3H, s, C_5-C*H*$_3$), 2.26 (3H, s, C_3-C*H*$_3$), 2.67 (3H, s, C_7-COC*H*$_3$), 3.64 (2H, s, -C*H*$_2$-COOH), 6.00 (4H, br, C_4-COO*H*, H_2O), 13.71 ppm (1H, s, C_6-O*H*); ^{1}Hmr (CD$_3$OD): δ 2.09 (3H, s, C_5-C*H*$_3$), 2.31 (3H, s, C_3-C*H*$_3$), 2.68 (3H, s, C_7-COC*H*$_3$), 3.74 ppm (2H, s, -C*H*$_2$-COOH); ms: *m/e* 278 (M^+, base peak), 276, 263, 249, 234, 232, 215, 77, 43. *Anal.* calcd. for $C_{14}H_{14}O_6$: C 60.42, H 5.07; found: C 60.39, H 5.12. High resolution molecular weight determination calcd.: 278.079; found: 278.078.

*Preparation of (±)-N-Acetyl-6-amino-9-O-methylusnic Acid (**8**) (N-Acetyl-2-acetyl-6-amino-1,9b-dihydro-3,7-dihydroxy-8,9b-dimethyl-9-methoxy-1-oxodibenzofuran)*

A cold solution of (±)-9-*O*-methylusnic acid (**7**) (50 mg, 0.139 mmol) in 0.5 *N* sodium hydroxide (3 ml) was added dropwise to a cold freshly prepared stock solution of monochloramine[2] (2.24 ml; 10.75 mg monochloramine,

[2]The stock solution of monochloramine is prepared at 0°C (ice bath) by *carefully* adding an equal volume of a cold ammonium hydroxide solution, prepared by diluting concentrated ammonium hydroxide (7.4 *M*, 9.15 ml) with distilled water (90.85 ml), to cold 5% aqueous sodium hypochlorite solution (commercially available) with occasional shaking. The resulting solution contains 4.8 mg monochloramine/ml and is ready for immediate use.

0.208 mmol) and the resulting solution stirred at 0°C (ice bath) for 3 h. The reaction mixture was then neutralized with 1 *N* hydrochloric acid and extracted with ethyl acetate (3 × 3 ml). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The resulting yellow residue (56.2 mg) was purified by preparative layer chromatography (silica gel – oxalic acid plates, solvent *A*) to produce (±)-*N*-acetyl-6-amino-9-*O*-methylusnic acid (**8**) (47 mg, 0.1258 mmol; 90%), bright yellow prisms from chloroform – ethyl ether, mp 118–119°C; $[\alpha]_D$-($CHCl_3$) 0° (*c* 0.10); uv: λ_{max} (log ε) 305 (3.34), 262 (3.79), 221 (4.01); ir (Nujol): ν_{max} 3300 (NH, associated), 3200–2400 (OH, chelated), 1680 (C=O, enone system), 1660 (C=O, 'Amide I band', associated), 1610 (C=C), 1560 (C=O, chelated triketone system), 1550 (N—H, C—N, 'Amide II band', associated), 1280 (C—N, 'Amide III band', associated); ir: ν_{max} 3450 (NH, free), 3320 (NH, associated), 3200–2400 (OH, chelated), 1690 (C=O, enone system), 1680 (C=O, 'Amide I band', free), 1660 (C=O, 'Amide I band', associated), 1610 (C=C), 1560 (C=O, chelated triketone system), 1550 (N—H, C—N, 'Amide II band', associated), 1520 (N—H, C—N, 'Amide II band', free), 1280 (C—N, 'Amide II band', associated), 1260 (C—N, 'Amide III band', free); ^{1}Hmr: δ 1.78 (3H, s, C_{9b}-CH_3), 2.22 (3H, s, C_8-CH_3), 2.34 (3H, s, N-$COCH_3$), 2.54 (3H, s, C_2-$COCH_3$), 3.99 (3H, s, C_9-OCH_3), 5.62 (1H, s, C_4-*H*), 7.70 (1H, br, N-*H*), 9.43 (1H, br, C_7-O*H*), 18.07 ppm (1H, s, C_3-O*H*); ms: *m/e* 373 (M^+, base peak), 331, 316, 289, 262, 260, 247, 246, 245, 232, 220, 115, 83. *Anal.* calcd. for $C_{19}H_{19}O_7N$: C 61.12, H 5.13, N 3.73; found: C 61.50, H 5.25, N 3.59. High resolution molecular weight determination calcd.: 373.116; found: 373.117.

*Attempted Methyl Ether Cleavage on (±)-N-Acetyl-6-amino-9-O-methylusnic Acid (**8**). Experiment I. Isolation of N-Acetyl-2-acetyl-6-amino-8-methyl-1,3,7,9-tetrahydroxydibenzofuran (**9**)*

A solution of (±)-*N*-acetyl-6-amino-9-*O*-methylusnic acid (**8**) (67 mg, 0.179 mmol) in dry dichloromethane (6 ml) was cooled to −78°C (dry ice – acetone bath), treated with neat boron tribromide (415 mg, 1.62 mmol), and allowed to warm up to room temperature overnight. The resulting brown suspension was carefully poured into saturated sodium bicarbonate solution (10 ml), neutralized with 1 *N* hydrochloric acid and extracted with ethyl acetate (3 × 5 ml). The combined extracts were thoroughly washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to produce a yellowish solid (11 mg). Repeated crystallization of the residue from methanol afforded *N*-acetyl-2-acetyl-6-amino-8-methyl-1,3,7,9-tetrahydroxydibenzofuran (**9**) (37 mg, 0.107 mmol; 59%), pale yellow crystals that decompose without melting at approximately 300°C; uv: λ_{max} (log ε) 305 sh (3.85), 290 (4.11), 280 (4.18), 271 (4.12), 237 (4.04); ir (Nujol): ν_{max} 3370 (OH), 3280, 3105 (N—H, associated), 2800–2500 (OH, chelated), 1655 (C=O, 'Amide I band', associated), 1630 (C=O, chelated ring C acetyl), 1620 (C=C), 1550 (N—H, C—N, 'Amide II band', associated), 1270 (C—N, 'Amide III band', associated); ^{1}Hmr ($CDCl_3$–DMSO-d_6): δ 2.07 (3H, s, C_8-CH_3), 2.18 (3H, s, C_6-NH-$COCH_3$), 2.64 (3H, s, C_2-$COCH_3$), 3.25 (4H, br, C_1-O*H*, C_9-O*H*, H_2O), 6.50 (1H, s, C_4-*H*), 8.95 (1H, s, C_6-N*H*-$COCH_3$), 9.71 (1H, s, C_7-O*H*), 11.55 ppm (1H, br, C_3-O*H*); ms: *m/e* 345 (M^+), 327, 303 (base peak), 302, 286, 285, 44, 43. *Anal.* calcd. for $C_{17}H_{15}O_7N\cdot\frac{1}{4}H_2O$: C 58.36, H 4.46, N 4.00; found: C 58.87, H 4.65, N 3.63. High resolution molecular weight determination calcd. for $C_{17}H_{15}O_7N$: 345.085; found: 345.085.

Preparative layer chromatography (silica gel – oxalic acid plates, petroleum ether (30–60°C) – acetone (3:1)) of the mother liquors afforded the desired product (±)-*N*-acetyl-6-aminousnic acid (**10**) (7.7 mg, 0.0215 mmol; 11%), yellow prisms from chloroform – petroleum ether, mp 227–228°C (dec.). Due to the small amount of sample available from this experiment, characterization was done at this point only by ^{1}Hmr and mass spectroscopy: ^{1}Hmr: δ 1.73 (3H, s, C_{9b}-CH_3), 2.18 (3H, s, C_8-CH_3), 2.31 (3H, s, C_6-NH-$COCH_3$), 2.65 (3H, s, C_2-$COCH_3$), 5.88 (1H, s, C_4-*H*), 9.18 (1H, br, C_2-N*H*-$COCH_3$), 9.93 (1H, s, C_7-O*H*), 10.61 (1H, s, C_9-O*H*), 19.43 ppm (1H, s, C_3-O*H*); ms: *m/e* 359 (M^+, base peak), 317, 275, 248, 233, 232, 206, 43. High resolution molecular weight determination calcd. for $C_{18}H_{17}O_7N$: 359.100; found: 359.103.

*Methyl Ether Cleavage of (±)-N-Acetyl-6-amino-9-O-methylusnic acid (**8**). Experiment II. Isolation of (±)-N-Acetyl-6-aminousnic Acid (**10**) (N-Acetyl-2-acetyl-6-amino-1,9b-dihydro-8,9b-dimethyl-3,7,9-trihydroxy-1-oxodibenzofuran)*

To a solution of (±)-*N*-acetyl-6-amino-9-*O*-methylusnic acid (**8**) (48 mg, 0.128 mmol) in dry dichloromethane (7 ml) was added anhydrous aluminum trichloride (99 mg, 0.745 mmol), and the reaction allowed to proceed at room temperature, under a nitrogen atmosphere for 2.5 h. The reaction mixture was then poured into cold 5% sodium bicarbonate solution (10 ml), neutralized with 1 *N* hydrochloric acid, and extracted with ethyl acetate (3 × 10 ml). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to afford a yellow-brown glass (54 mg). Purification of the residue by preparative layer chromatography (silica gel – oxalic acid plates, petroleum ether – acetone (3:1)) produced (±)-*N*-acetyl-6-aminousnic acid (**10**) (15.6 mg, 0.0434 mmol; 33%), bright yellow prisms from methanol, mp 228–230°C (dec.); $[\alpha]_D$(CH_3CN) 0° (*c* 0.1075); uv: λ_{max} (log ε) 335 (3.33), 265 (3.90), 230 (4.27); ir: ν_{max} 3460 (N—H, free), 3400–2500 (OH, chelated), 1685 (C=O, 'Amide I band', free), 1660 (C=O, enone system), 1630, 1620 (C=C), 1540 (C=O, chelated triketone system), 1520 (N—H, C—N, 'Amide II band', free), 1260 (C—N, 'Amide III band', free); ^{1}Hmr ($CDCl_3$-DMSO-d_6): δ 1.72 (3H, s, C_{9b}-CH_3), 2.08 (3H, s, C_8-CH_3), 2.19 (3H, s, C_6-NH-$COCH_3$), 2.61 (3H, s, C_2-$COCH_3$), 5.90 (1H, s, C_4-*H*), 9.01 (1H, s, C_6-N*H*-$COCH_3$), 9.52 (1H, s, C_7-O*H*), 9.97 (1H, s, C_9-O*H*), 18.63 ppm (1H, s, C_3-O*H*); ms: *m/e* 359 (M^+, base peak), 317, 275, 248, 233, 232, 206, 43. *Anal.* calcd. for $C_{18}H_{17}O_7N$: C 60.16, H 4.77, N 3.90; found: C 60.45, H 4.91, N 3.92. High resolution molecular weight determination calcd.: 359.100; found: 359.105.

*Preparation of (±)-N-Acetyl-6-aminousnic Acid (**10**). Experiment III*

To a cold (−10°C) solution of (±)-*N*-acetyl-6-amino-9-*O*-methylusnic acid (**8**) (50 mg, 0.134 mmol) in dry dichloromethane (6 ml) was added boron trichloride

(147 mg, 1.257 mmol), obtained by condensing the gas at −78°C (dry ice – acetone bath). The reaction mixture was then stirred and under a nitrogen atmosphere allowed to warm up to room temperature over 4 h. The reaction mixture was then poured carefully into cold distilled water (15 ml) and extracted with ethyl acetate (3 × 5 ml). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to afford a yellow glass (54.4 mg). Purification by preparative layer chromatography, (silica gel – oxalic acid plates, petroleum ether – acetone (3:1)) produced (±)-*N*-acetyl-6-aminousnic acid (**10**) (39 mg, 0.108 mmol; 81%), bright yellow prisms from methanol, mp 227–229°C; mixture mp with authentic material from previous experiments, 228–229°C. The spectroscopic and chromatographic properties of both samples are identical.

*Attempted Schmidt Reaction on (+)-Usnic Acid (**1**)*

A solution of (+)-usnic acid (**1**) (34.4 mg, 0.1 mmol) in chloroform (1 ml) and concentrated sulfuric acid (0.5 ml) was cooled to 0°C in an ice-bath. Crystalline sodium azide (7.5 mg, 0.115 mmol) was added over 0.25 h and stirring continued for 1 h. The crude reaction mixture was then poured onto crushed ice (10 g), extracted with chloroform (3 × 5 ml), and the combined extracts thoroughly washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The residue (37 mg) was directly crystallized from chloroform – ethyl alcohol to produce (+)-usnic acid (**1**) (32 mg, 0.093 mmol; 93%), mp 201–202°C; mixture mp with authentic (+)-usnic acid (**1**), 202–203°C. Both samples showed identical spectroscopic and chromatographic properties.

*Reaction of (+)-Usnic Acid (**1**) with Monochloramine. Experiment I. Isolation of (+)-N-Acetyl-6-aminousnic Acid (**11**)*

A cold solution of (+)-usnic acid (**1**) (2.5 g, 7.267 mmol) in 2% methanolic sodium hydroxide (40 ml) and distilled water (60 ml) was added dropwise to a cold (0°C) stock solution of monochloramine (4.8 mg monochloramine/ml, 120 ml; 576 mg NH_2Cl, 11.184 mmol), and the reaction allowed to proceed with external cooling (ice bath) for 4 h. The reaction mixture was then acidified with 1 *N* hydrochloric acid, extracted with ethyl acetate (3 × 25 ml), and the combined extracts washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to produce a dark yellow residue (2.23 g). Purification by column chromatography on silica gel Merck (200 g) using 20% ethyl acetate in benzene as eluent afforded (+)-*N*-acetyl-6-aminousnic acid (**11**) (1.2219 g, 3.403 mmol; 46%), yellow prisms from methanol, mp 230–232°C; $[\alpha]_D^{26}$ (CH_3CN) +437° (*c* 0.17625); uv: λ_{max} (log ε) 335 (3.35), 265 (3.92), 230 (4.27); ir: ν_{max} 3455 (N—H, free), 3400–2400 (OH, chelated), 1685 (C=O, 'Amide I band', free), 1665 (C=O, enone system), 1630 (C=C), 1540 (C=O, chelated triketone system), 1520 (N—H, C—N, 'Amide II band', free), 2160 (C—N, 'Amide III band', free); ^{1}Hmr: δ 1.73 (3H, s, C_{9b}-CH_3), 2.16 (3H, s, C_8-CH_3), 2.30 (3H, s, C_6-NH-COCH_3), 2.65 (3H, s, C_2-COCH_3), 5.86 (1H, s, C_4-*H*), 9.15 (1H, br, C_6-NH-COCH_3), 9.90 (1H, s, C_7-O*H*), 10.62 (1H, s, C_9-O*H*), 19.43 ppm (1H, br, C_3-O*H*); ms: *m/e* 359 (M^+, base peak), 317, 275, 248, 233, 232, 206, 43. *Anal.* calcd. for $C_{18}H_{17}O_7N$: C 60.16, H 4.77, N 3.90; found: C 60.27, H 4.90, N 3.99. High resolution molecular weight determination calcd.: 359.100; found: 359.103.

*Reaction of (+)-Usnic Acid (**1**) with Monochloramine. Experiment II. Isolation of (+)-N-Acetyl-6-aminousnic Acid (**11**)*

A cold solution of (+)-usnic acid (**1**) (5 g, 14.534 mmol) in 0.6% aqueous sodium hydroxide (200 ml) was added dropwise to a cold (0°C) stock solution of monochloramine (4.8 mg NH_2Cl/ml, 240 ml; 1.152 g NH_2Cl, 22.368 mmol), and the reaction allowed to proceed with external cooling (ice bath) for 4 h. The reaction mixture was then acidified with 1 *N* hydrochloric acid, extracted with ethyl acetate (3 × 40 ml), and the combined extracts washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The residue (4.85 g) was purified by column chromatography on silica gel Merck (200 g) using 20% ethyl acetate in benzene as eluent to produce pure (+)-*N*-acetyl-6-aminousnic acid (**11**) (2.731 g, 7.607 mmol; 52%), yellow prisms from methanol, mp and mixture mp with authentic material, 230–232°C.

*Cyclization of (+)-N-Acetyl-6-aminousnic Acid (**11**). Isolation of (+)-Oxazolo[4,5-h]usnic Acid (**12**)*

A solution of (+)-*N*-acetyl-6-aminousnic acid (**11**) (50 mg, 0.139 mmol) in thionyl chloride (3 ml, freshly distilled) was heated at 55°C (oil bath temperature) under a nitrogen atmosphere for 0.5 h. Excess solvent was evaporated under reduced pressure, the residue taken up into ethyl acetate (8 ml), and the organic extract thoroughly washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to yield a yellow glass (53 mg). Purification by preparative layer chromatography (silica gel – oxalic acid, petroleum ether – acetone (3:1)) produced (+)-oxazolo[4,5-*h*]usnic acid (**12**) (26.5 mg, 0.0777 mmol; 55%), yellow prisms from ethyl ether, mp 173–174°C; $[\alpha]_D^{26}$(CH_3CN) +538° (*c* 0.04); uv: λ_{max} (log ε) 335 (3.28), 268 (4.05), 218 (4.29); ir: λ_{max} 3300–2500 (OH, chelated), 1685 (C=O, enone system), 1635 (C=C), 1540 (C=O, chelated triketone system); ^{1}Hmr ($CDCl_3$–DMSO-d_6): δ 1.68 (3H, s, C_{9b}-CH_3), 2.34 (3H, s, C_8-CH_3), 2.60 (6H, s, C_2-COCH_3 and oxazole-CH_3), 5.98 (1H, br s, C_4-*H*), 10.54 (1H, br, C_9-O*H*), 18.72 ppm (1H, br, C_3-O*H*); ms: *m/e* 341 (M^+), 257 (base peak), 230, 229, 186, 43. *Anal.* calcd. for $C_{18}H_{15}O_6N$: C 63.34, H 4.43, N 4.10; found: C 63.39, H 4.52, N 4.01. High resolution molecular weight determination calcd.: 341.090; found: 341.089.

*Preparation of (±)-N-Acetyl-6-amino-7,9-di-O-benzylusnic Acid (**15**) (N-Acetyl-2-acetyl-6-amino-7,9-dibenzyloxy-1,9b-dihydro-8,9b-dimethyl-3-hydroxy-1-oxodibenzofuran). Experiment I*

A solution of (±)-7,9-di-*O*-benzylusnic acid (**13**) (52.4 mg, 0.1 mmol) and hydroxylamine hydrochloride (10.3 mg, 0.148 mmol) in 5% methanolic potassium hydroxide (2 ml) and distilled water (1 ml) was heated at 50°C (oil bath temperature) under a nitrogen atmosphere for 1.5 h. The resulting bright yellow solution was diluted with cold distilled water (10 ml), acidified with 1 *N* hydrochloric acid, and extracted with ethyl acetate (3 × 5 ml). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to afford a bright yellow foam (54 mg). The

crude oxime was dissolved in anhydrous ethyl ether (5 ml), treated with phosphorous pentachloride (72.5 mg, 0.348 mmol) and stirred at room temperature for 1 h. The reaction mixture was then poured onto crushed ice (10 g), extracted with ethyl acetate (3 × 5 ml), and the combined extracts thoroughly washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The yellow residue (57.2 mg) was purified by preparative layer chromatography (silica gel – oxalic acid plates, petroleum ether – acetone (3:1)) to produce (+)-*N*-acetyl-6-amino-7,9-di-*O*-benzylusnic acid (**15**) (26 mg, 0.0482 mmol; 48%), fine yellow needles from ethyl ether, mp 168–170°C; $[\alpha]_D(CHCl_3)$ 0° (*c* 0.1052); uv: λ_{max} (log ε) 330 (3.19), 265 (3.93), 2.5 (4.30); ir: ν_{max} 3430 (N—H, free), 3400–3100 (OH, chelated), 1680 (C=O, 'Amide I band', free; enone system), 1610, 1590 (C=C), 1540 (C=O, chelated triketone system), 1520 (N—H, C—N, 'Amide II band', free), 1250 (C—N, 'Amide III band', free); ^{1}Hmr: δ 1.79 (3H, s, C_{9b}-CH_3), 2.01 (3H, s, C_8-CH_3), 2.27 (3H, s, C_6-NH-COCH_3), 2.46 (3H, s, C_2-COCH_3), 4.82 (2H, AB q, J = 10 Hz, C_7-O-CH_2-C_6H_5), 5.25 (2H, AB q, J = 10 Hz, C_9-O-CH_2-C_6H_5), 5.77 (1H, s, C_4-*H*), 6.87 (1H, br s, C_6-N*H*-COCH$_3$), 7.30–7.70 (10H, m, 2 × C_6H_5), 18.00 ppm (1H, s, C_3-O*H*); ms: *m/e* 539 (M^+), 449, 448, 422, 406 (base peak), 380, 364, 358, 338, 322, 316, 315, 306, 232, 205, 175, 91, 85, 65, 43. *Anal.* calcd. for $C_{32}H_{29}O_7N$: C 70.81, H 5.94, N 2.42; found: C 70.54, H 6.00, N 2.10. High resolution molecular weight determination calcd. for $C_{32}H_{29}O_7N$: 539.194; found: 539.191.

*Preparation of (±)-N-Acetyl-6-amino-7,9-di-O-benzylusnic Acid (**15**). Experiment II*

A solution of (±)-7,9-di-*O*-benzylusnic (**13**) (52.4 mg, 0.1 mmol) and hydroxylamine hydrochloride (10.3 mg, 0.148 mmol) in 5% methanolic potassium hydroxide (2 ml) and distilled water (1 ml) was heated at 50°C (oil bath temperature) under a nitrogen atmosphere for 1.5 h. The resulting solution was diluted with cold distilled water (10 ml), acidified with 1 *N* hydrochloric acid, and extracted with ethyl acetate (3 × 5 ml). The combined extracts were washed with distilled water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The crude oxime (55 mg) was dissolved in dry ethyl ether (5 ml), treated with thionyl chloride (83.5 mg, 0.701 mmol), and stirred at room temperature for 20 min. To the resulting suspension was added a 1:1 mixture of ethyl acetate – water (10 ml), the reaction mixture transferred into a separatory funnel, the organic layer separated, and the aqueous mother liquors extracted with ethyl acetate (2 × 5 ml). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The crude residue (52.3 mg) was purified by preparative layer chromatography (silica gel – oxalic acid plates, petroleum ether – acetone (3:1)) to produce (±)-*N*-acetyl-6-amino-7,9-di-*O*-benzylusnic acid (**15**) (33.4 mg, 0.0619 mmol; 61%), pale yellow needles from ethyl ether, mp 169–170°C; mixture mp with authentic material from previous experiments, 169–170°C. Both samples showed identical spectroscopic and chromatographic properties.

*Preparation of (+)-N-Acetyl-6-amino-7,9-di-O-methylisoxazolo[4,5-b]usnic Acid (**17**) (N-Acetyl-10-amino-6,6a-dihydro-7,9-dimethoxy-5,6aα,8-trimethyl-6-oxoisoxazolo[4,5-b]dibenzofuran)*

A solution of (+)-7,9-di-*O*-methylisoxazolo[4,5-*b*]-usnic acid (**16**) (36) (2.0 g, 5.42 mmol) and hydroxylamine hydrochloride (1.13 g, 16.258 mmol) in dry pyridine (30 ml) was heated at 55°C (oil bath temperature) under a nitrogen atmosphere for 2.75 h. The reaction mixture was then diluted with cold distilled water (100 ml) and extracted with ethyl acetate (3 × 30 ml). The combined extracts were washed with 1 *N* hydrochloric acid, with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The crude oxime (2.1831 g) was dissolved in anhydrous ethyl ether (70 ml), treated with thionyl chloride (950 mg, 7.983 mmol), and the mild exothermic reaction allowed to proceed for 12 min. The reaction mixture was then quenched with a 1:1 mixture of ethyl acetate – water (100 ml), neutralized with 2.5% aqueous sodium bicarbonate solution, and extracted with ethyl acetate (3 × 20 ml). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to afford a yellow-brown foam (2.36 g). Purification by column chromatography on silica gel Merck (150 g) using 20% acetone in benzene produced the following materials.

*Fraction I. (+)-7,9-di-O-methylisoxazolo[4,5-b]usnic Acid (**16**)*

Yellow foam that could not be induced to crystallize (208 mg, 0.563 mmol; 10%). This sample showed spectroscopic and chromatographic characteristics identical with those of the starting material.

*Fraction II. (+)-N-Acetyl-6-amino-7,9-di-O-methylisoxazolo[4,5-b]usnic Acid (**17**)*

Fine yellow needles from ethyl ether (1.302 g, 3.390 mmol; 69%) mp 188–189°C; $[\alpha]_D^{26}$ +354° (*c* 0.0395); uv: λ_{max} (log ε) 364 (3.06), 315 (2.84), 281 (3.15), 253 (3.71), 208 (4.48); ir: ν_{max} 3460 (N—H, free), 3320 (N—H, associated), 1685 (C=O, 'Amide I band', free), 1670 (C=O, enone system), 1650 (C=O, 'Amide I band', associated), 1610, 1590 (C=C), 1550 (N—H, C—N, 'Amide II band', associated), 1535 (N—H, C—N, 'Amide II band', free), 1300 (C—N, 'Amide III band', associated), 1265 (C—N, 'Amide III band', free); ^{1}Hmr: δ 1.78 (3H, s, C_{9b}-CH_3), 2.19 (6H, s, C_8-CH_3, and C_6-NH-COCH_3), 2.43 (3H, s, C_{11}-CH_3), 3.78 (3H, s, C_7-OCH_3), 3.96 (3H, s, C_9-OCH_3), 6.14 (1H, s, C_4-*H*), 7.28 ppm (1H, br s, C_6-N*H*-COCH$_3$); ms: *m/e* 384 (M^+, base peak), 369, 342, 341, 327, 316, 314, 301, 299, 284, 260, 259, 253, 246, 203, 43. *Anal.* calcd. for $C_{20}H_{20}O_6N_2$: C 62.49, H 5.18, N 7.29; found: C 61.98, H 5.18, N 6.77. High resolution molecular weight determination calcd.: 384.132; found: 384.127.

*Preparation of (+)-6-Desacetyl-7,9-di-O-methylisoxazolo-[4,5-b]usnic Acid (**18**) (6,6a-Dihydro-7,9-dimethoxy-5,6aα,8-trimethyl-6-oxoisoxazolo[4,5-b]-dibenzofuran)*

A solution of (+)-*N*-acetyl-6-amino-7,9-di-*O*-methylisoxazolo[4,5-*b*]usnic acid (**17**) (1.4 g, 3.645 mmol) in anhydrous dioxane (45 ml, freshly distilled from lithium aluminum hydride) was treated with excess isoamyl nitrite (10 ml) and heated at 88°C (oil bath temperature) under a nitrogen atmosphere for 8.5 h. The solvent was then evaporated under reduced pressure and the residue (1.32 g) purified by column chromatography on silica gel Merck (150 g) to produce the following component.

*Fraction I. (+)-6-Desacetyl-7,9-di-O-methylisoxazolo-[4,5-b]usnic Acid (**18**)*

Large bright yellow prisms from ethyl alcohol (812 mg, 2.483 mmol; 77%) mp 156.5–158°C; $[\alpha]_D^{26}$(CH_3CN)

+300° (*c* 0.07585); uv: λ_{max} (log ε) 368 (2.95), 305 (2.84), 281 (3.27), 254 (3.67), 211 (4.41); ir: ν_{max} 2940 (C—H, aromatic -OCH_3), 2850 (C—H, aromatic -OCH_3), 1630 (C=O, enone system), 1650 (isoxazole, trisubstituted), 1620, 1600 (C=C); ^{1}Hmr: δ 1.76 (3H, s, C_{9b}-CH_3), 2.12 (3H, s, C_8-CH_3), 2.44 (3H, s, C_{11}-CH_3), 3.78 (3H, s, C_7-OCH_3), 3.96 (3H, s, C_9-OCH_3), 6.12 (1H, s, C_4-*H*), 6.43 ppm (1H, s, C_6-*H*); ms: *m/e* 327 (M^+, base peak), 312, 299, 298, 284, 271, 259, 258, 246, 243, 231, 215, 203, 115. *Anal.* calcd. for $C_{18}H_{17}O_5N$: C 66.05, H 5.23, N 4.28; found: C 66.08, H 5.44, N 4.13. High resolution molecular weight determination calcd.: 327.111; found: 327.112.

*The Demethylation of (+)-6-Desacetyl-7,9-di-O-methylisoxazolo[4,5-b]usnic Acid (**18**). Isolation of (+)-6-Desacetyl-7-O-methylisoxazolo[4,5-b]usnic Acid (**21**) (6,6a-Dihydro-9-hydroxy-7-methoxy-5,6aα,8-trimethyl-6-oxoisoxazolo[4,5-b]dibenzofuran)*

A solution of (+)-6-desacetyl-7,9-di-*O*-methylisoxazolo[4,5-*b*]usnic acid (**18**) (50 mg, 0.1529 mmol) in dry dichloromethane (4 ml) was cooled to −50°C (dry ice – acetone bath) and treated with cold boron tribromide (383 mg, 1.530 mmol). The resulting deep red solution was allowed to warm-up to −30°C over 0.5 h and then poured into ethyl acetate (10 ml) and ice (10 g). The aqueous fraction was extracted once more with ethyl acetate (10 ml) and the combined extracts washed thoroughly with water, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. The residue (51 mg) was crystallized directly from ethyl alcohol to produce pale yellow prismatic needles of (+)-6-desacetyl-7-*O*-methylisoxazolo[4,5-*b*]usnic acid (**21**) (47 mg, 0.150 mmol; 98%), mp 167–168°C; $[\alpha]_D^{26}(CH_3CN)$ +250° (*c* 0.034); uv: λ_{max} (log ε) 372 (2.81), 304 (2.37), 256 (3.50), 214 (4.44); ir: ν_{max} 3500–3100 (OH, chelated), 1660 (C=O, enone system), 1620 (C=C); ^{1}Hmr: δ 1.71 (3H, s, C_{9b}-CH_3), 2.06 (3H, s, C_8-CH_3), 2.46 (3H, s, C_{11}-CH_3), 3.76 (3H, s, C_7-OCH_3), 6.18 (1H, s, C_4-*H*), 6.25 (1H, s, C_6-*H*), 9.67 ppm (1H, s, C_9-O*H*); ms: *m/e* 313 (M^+, base peak), 284, 270, 257, 245, 244, 229, 204, 201. *Anal.* calcd. for $C_{17}H_{15}O_5N$: C 65.17, H 4.83, N 4.47; found: C 65.59, H 4.71, N 4.75. *Acetylation of (+)-6-Desacetyl-7-O-methylisoxazolo[4,5-b]usnic Acid (**21**). Preparation of (+)-6-Desacetyl-7-O-methylisoxazolo[4,5-b]usnic Acid Monoacetate (**22**) (9-Acetoxy-6,6a-dihydro-7-methoxy-5,6aα,8-trimethyl-6-oxoisoxazolo[4,5-b]-dibenzofuran)*

A solution of (+)-6-desacetyl-7-*O*-methylisoxazolo-[4,5-*b*]usnic acid (**21**) (115 mg, 0.367 mmol) in 0.5% concentrated sulfuric acid in acetic anhydride (2 ml) was allowed to stand at room temperature overnight. The resulting yellow-brown solution was poured onto crushed ice (10 g), extracted with ethyl acetate (3 × 5 ml), and the combined extracts thoroughly washed with water, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. The crude residue (90.8 mg) was purified by preparative layer chromatography (silica gel – oxalic acid plates, solvent *A*) to produce (+)-6-desacetyl-7-*O*-methylisoxazolo[4,5-*b*]usnic acid monoacetate (**22**) (42 mg, 0.181 mg; 32%), pale yellow plates from ethyl alcohol, mp 195–196°C; $[\alpha]_D^{26}(CH_3CN)$ +500° (*c* 0.064); uv: λ_{max} (log ε) 365 (3.01), 304 (2.90), 278 (3.44), 251 (3.70), 213 (4.39); ir: ν_{max} 2960, 2860 (C—H, aromatic -OCH_3), 1770 (C=O, acetate), 1690 (C=O, enone system), 1660 (isoxazole,t risubstituted), 1620, 1600 (C=C); ^{1}Hmr: δ 1.76 (3H, s, C_{9b}-CH_3), 2.01 (3H, s, C_8-CH_3), 2.46 (3H, s, C_9-$OCOCH_3$), 2.50 (3H, s, C_{11}-CH_3), 3.85 (3H, s, C_7-OCH_3), 6.20 (1H, s, C_4-*H*), 6.58 ppm (1H, s, C_6-*H*); ms: *m/e* 355 (M^+, base peak), 338, 312, 297, 286, 284, 273, 270, 269, 257, 244, 232, 229, 216, 204, 201. *Anal.* calcd. for $C_{19}H_{17}O_6N$: C 64.22, H 4.82, N 3.94; found: C 64.03, H 4.89, N 3.91. High resolution molecular weight determination calcd.: 355.105; found: 355.104.

*Preparation of (+)-6-Desacetyl-7-O-methylisoxazolo-[4,5-b]usnic Acid Monoacetate (**22**)*

A solution of (+)-6-desacetyl-7-*O*-methylisoxazolo-[4,5-*b*]usnic acid (**21**) (60 mg, 0.191 mmol) in a 1:1 mixture of dry pyridine – acetic anhydride (2 ml) was allowed to stand at room temperature overnight. The resulting yellow solution was poured onto crushed ice (10 g) and extracted with ethyl acetate (3 × 5 ml). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The crude residue (71 mg) was purified by preparative layer chromatography (silica gel – oxalic acid plates, solvent *A*) to produce (+)-6-desacetyl-7-*O*-methylisoxazolo[4,5-*b*]usnic acid monoacetate (**22**) (64.71 mg, 0.1822 mmol; 95%), pale yellow plates from ethyl alcohol, mp 195–196°C. Mixture mp with authentic material from the previous experiment, 195–197°C. Both samples showed identical spectroscopic and chromatographic properties.

*Preparation of (+)-6-Desacetylisoxazolo[4,5-b]usnic Acid (**19**) (6,6a-Dihydro-7,9-dihydroxy-5,6aα,8-trimethyl-6-oxoisoxazolo[4,5-b]dibenzofuran) I*

A solution of (+)-6-desacetyl-7,9-di-*O*-methylisoxazolo[4,5-*b*]usnic acid (**18**) (190 mg, 0.581 mmol) in dry dichloromethane (30 ml) was cooled to −78°C (dry ice – acetone bath) and treated with cold boron tribromide (1.483 g, 5.81 mmol). The resulting deep red solution was allowed to warm-up to 0°C over 1.5 h and then stirred at 10°C for 2.5 h. The reaction mixture was then poured into ethyl acetate (100 ml) – crushed ice (100 g), the organic extract separated and the aqueous phase extracted with ethyl acetate (2 × 30 ml). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The resulting residue was immediately purified by preparative layer chromatography (silica gel – oxalic acid plates, solvent *A*) to afford the diphenol **9** (136 mg, 0.4548 mmol) and a mixture (37 mg) consisting of the monophenol and another material of similar R_f. Recycling this mixture under identical experimental conditions and combining those fractions consisting of pure diphenol produced the following products.

*Compound I. (+)-6-Desacetylisoxazolo[4,5-b]usnic Acid (**19**)*

Pale yellow crystals from chloroform – petroleum ether (30–60°C) (151 mg, 0.505 mmol; 86%), mp 194.5–196°C (dec.); $[\alpha]_D^{26}(CH_3CN)$ +608° (*c* 0.0625); uv: λ_{max} (log ε) 370 (2.53), 319 (2.85), 258 (3.71), 210 (4.41); ir: ν_{max} 3610 (OH, free), 3500–3100 (OH, chelated), 1675 (C=O, enone system), 1640 (isoxazole), 1620 (C=C); ^{1}Hmr ($CDCl_3$-DMSO-d_6): δ 1.70 (3H, s, C_{9b}-CH_3), 2.07 (3H, s, C_8-CH_3), 2.44 (3H, s, C_{11}-CH_3), 6.16 (1H, s, C_4-*H*), 6.28 (1H, s, C_6-*H*), 8.63 (1H, br, C_7-O*H*), 9.62 ppm (1H, s,

C_9-O*H*); ms: *m/e* 299 (M^+, base peak), 284, 271, 270, 256, 243, 231, 230, 218, 202, 201, 190, 83. *Anal.* calcd. for $C_{16}H_{13}O_5N$: C 64.21, H 4.37, N 4.68; found: C 64.27, H 4.42, N 4.50. High resolution molecular weight determination calcd.: 299.079; found: 299.077.

*Compound II. (+)-6-Bromoisoxazolo[4,5-b]usnic Acid (**27**) (10-Bromo-6,6a-dihydro-7,9-dihydroxy-5,6aα,8-trimethyl-6-oxoisoxazolo[4,5-b]dibenzofuran)*

Pale yellow crystals from chloroform – petroleum ether (30–60°C) (17.12 mg, 0.0453 mmol; 7%), mp 209–211°C (dec.); $[\alpha]_D^{26}(CH_3CN)$ +593° (*c* 0.0455); uv: λ_{max} (log ε) 371 (3.01), 324 (2.59), 255 (3.57), 210 (4.53); ir: ν_{max} 3500–3100 (OH, chelated), 1675 (C=O, enone system), 1638 (isoxazole), 1625, 1600 (C=C); ^{1}Hmr ($CDCl_3$–DMSO-d_6): δ 1.72 (3H, s, C_{9b}-C*H*$_3$), 2.32 (3H, s, C_8-C*H*$_3$), 2.45 (3H, s, C_{11}-C*H*$_3$), 6.32 (1H, s, C_4-*H*), 7.96 (1H, br, C_7-O*H*), 9.68 ppm (1H, s, C_9-O*H*); ms: *m/e* 379 (M^+, ^{81}Br, base peak), 377 (M^+, ^{79}Br), 364, 362, 350, 348, 336, 334, 323, 321, 311, 309, 298, 296, 282, 280, 270, 268, 202, 200, 173. *Anal.* calcd. for $C_{16}H_{12}O_5Br$: C 50.80, H 3.20, N 3.70, Br 21.12; found: C 50.91, H 3.40, N 3.49, Br 21.29. *Acetylation of (+)-6-Desacetylisoxazolo[4,5-b]usnic Acid (**19**)*

A solution of (+)-6-desacetylisoxazolo[4,5-*b*]usnic acid (**19**) (32 mg, 0.107 mmol) in a 1:1 mixture of pyridine – acetic anhydride (2 ml) was allowed to stand at room temperature overnight. The resulting deep yellow solution was poured onto crushed ice (10 g) and extracted with ethyl acetate (3 × 5 ml). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The residue (39.7 mg) was purified by preparative chromatography (silica gel – oxalic acid plates, chloroform) to afford two main components.

*Fraction I. (+)-6-Desacetylisoxazolo[4,5-b]usnic Acid Monoacetate (**23**) (7-Acetoxy-6,6a-dihydro-9-hydroxy-5,6aα,8-trimethyl-6-oxoisoxazolo[4,5-b]-dibenzofuran)*

Pale yellow needles from ethyl alcohol (22.7 mg, 0.0665 mmol; 62%), mp 168–170°C; $[\alpha]_D^{26}(CH_3CN)$ +547° (*c* 0.03475): uv: λ_{max} (log ε) 365 (3.09), 315 (2.46), 264 (3.56), 255 (3.63), 214 (4.40); ir: ν_{max} 3300–3100 (OH, chelated), 1760 (C=O, acetate), 1675 (C=O, enone system), 1640 (isoxazole ring), 1620, 1610 (C=C); ^{1}Hmr: δ 1.77 (3H, s, C_{9b}-C*H*$_3$), 2.03 (3H, s, C_8-C*H*$_3$), 2.27 (3H, s, C_7-OCOC*H*$_3$), 2.46 (3H, s, C_{11}-C*H*$_3$), 6.22 (1H, s, C_4-*H*), 6.41 (1H, s, C_6-*H*), 9.99 ppm (1H, s, C_9-O*H*); ms: *m/e* 341 (M^+, base peak), 299, 284, 271, 270, 256, 243, 231, 230, 215, 202, 201, 190, 43. *Anal.* calcd. for $C_{18}H_{15}O_6N$: C 63.33, H 4.43, N 4.10; found: C 63.30, H 4.53, N 3.90. High resolution molecular weight determination calcd.: 341.090; found: 341.091.

*Fraction II. (+)-6-Desacetylisoxazolo[4,5-b]usnic Acid Diacetate (**24**) (7,9-diacetoxy-6,6a-dihydro-5,6aα,8-trimethyl-6-oxoisoxazolo[4,5-b]dibenzofuran)*

Colorless prisms from ethyl alcohol (13.6 mg, 0.0355 mmol; 33%) mp 242–243°C; $[\alpha]_D^{26}(CH_3CN)$ +368° (*c* 0.057); uv: λ_{max} (log ε) 361 (3.09), 310 (2.85), 280 (3.40), 250 (3.69), 210 (4.35); ir: ν_{max} 1765 (C=O, acetates) 1685 (C=O, enone system), 1650 (isoxazole ring), 1620, 1600 (C=C); ^{1}Hmr: δ 1.77 (3H, s, C_{9b}-C*H*$_3$), 1.95 (3H, s, C_8-C*H*$_3$), 2.29 (3H, s, C_7-OCOC*H*$_3$), 2.41 (3H, s, C_9-OCOC*H*$_3$), 2.47 (3H, s, C_{11}-C*H*$_3$), 6.19 (1H, s, C_4-*H*), 6.78 ppm (1H, s, C_6-*H*); ms: *m/e* 383 (M^+), 341, 326, 315, 299 (base peak), 284, 271, 260, 256, 243, 230, 218, 217, 202, 190, 43. *Anal.* calcd. for $C_{20}H_{17}O_7N$: C 62.65, H 4.47, N 3.65; found: C 62.50, H 4.57, N 3.49. High resolution molecular weight determination calcd.: 383.100; found: 383.099.

*Preparation of (+)-6-Desacetylusnic Acid (**2**)*

(+)-6-Desacetylisoxazolo[4,5-*b*]usnic acid (**19**) (56 mg, 0.187 mmol) in absolute ethyl alcohol (10 ml) was hydrogenated over platinum oxide (8 mg) at room temperature and atmospheric pressure. After the uptake of 1 mol equiv. hydrogen was observed (4.58 ml at 25°C) the reaction mixture was filtered through celite, the celite cake washed with absolute ethyl alcohol (3 × 5 ml), and the combined extracts evaporated under reduced pressure. The residue (56 mg) was dissolved in tetrahydrofuran (1 ml) and freshly prepared 1 *N* sodium hydroxide (5 ml) and stirred at room temperature under a nitrogen atmosphere for 1 h. The yellow brown solution was cooled down to 0°C (ice bath), acidified with 1 *N* hydrochloric acid, and extracted with ethyl acetate (3 × 5 ml). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to afford a crystalline residue (57 mg). Recrystallization from chloroform – petroleum ether produced (+)-6-desacetylusnic acid (**2**) (55 mg, 0.182 mmol; 97%) mp 134.5–136°C; mixture mp with authentic (+)-6-desacetylusnic acid (**2**), 134.5–136°C; $[\alpha]_D^{26}$ +689° (*c* 0.06175); uv: λ_{max} (log ε) 335 (3.17), 265 (3.76), 233 (4.08); ir: ν_{max} 3400–2800 (OH, chelated), 1670 (C=O, enone system), 1630 (C=C), 1540 (C=O, chelated carbonyl of the triketone system); ^{1}Hmr: δ 1.67 (3H, s, C_{9b}-C*H*$_3$), 2.09 (3H, s, C_8-C*H*$_3$), 2.59 (3H, s, C_2-COC*H*$_3$), 5.28 (1H, s, C_7-O*H*), 5.78 (1H, br, C_4-*H*), 6.22 (1H, s, C_6-*H*), 10.22 (1H, s, C_9-O*H*), 18.65 ppm (1H, s, C_3-O*H*); ms: *m/e* 302 (M^+), 287, 218, 191 (base peak). *Anal.* calcd. for $C_{16}H_{14}O_6$: C 63.57, H 4.67; found: C 63.53, H 4.72. High resolution molecular weight determination calcd.: 302.079; found: 302.078; cd: λ_{max} (Δε) 328 (+9.42), 283 (−6.06), 260 (−3.59), 239 (+13.24); cd (CH_3OH + KOH): λ_{max} (Δε) 344 (+7.85), 208 (+6.28), 285 (+1.79), 266 (−12.57), 238 (+9.87).

*Acetylation of Synthetic (+)-6-Desacetylusnic Acid (**2**). Isolation of (+)-6-Desacetylusnic Acid Diacetate (**28**)*

A solution of (+)-6-desacetylusnic acid (**2**) (49 mg, 0.162 mmol) in 0.5% concentrated sulfuric acid in acetic anhydride (3 ml) was allowed to stand at room temperature overnight. The light brown reaction mixture was then poured onto ice (10 g) and extracted with ethyl acetate (3 × 5 ml). The combined extracts were thoroughly washed with water, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. The residue (47 mg) was purified by preparative layer chromatography (silica gel – oxalic acid plates, solvent *A*) to produce (+)-6-desacetylusnic acid diacetate (**28**) (25 mg, 0.0647 mmol; 39%), pale yellow fine needles from ethyl alcohol, mp 208–210°C, mixture mp with authentic (+)-6-desacetylusnic acid diacetate (**28**), 208–209°C; $[\alpha]_D^{26}$ +125° (*c* 0.1025); uv: λ_{max} (log ε) 325 (3.24), 280 (3.75), 261 (3.85), 220 (4.02); ir: ν_{max} 1755 (C=O, acetates), 1685

(C=O, enone system), 1620, 1600 (C=C), 1545 (C=O, chelated triketone system); ^{1}Hmr: δ 1.78 (3H, s, C_{9b}-CH_3), 1.98 (3H, s, C_8-CH_3), 2.33 (3H, s, C_7-OCOCH_3), 2.45 (3H, s, C_9-OCOCH_3), 2.55 (3H, s, C_2-COCH_3), 5.83 (1H, s, C_4-*H*), 6.82 (1H, s, C_6-*H*), 18.31 ppm (1H, br s, C_3-O*H*); ms: *m/e* 386 (M^+), 344, 302, 260, 233, 218 (base peak), 191, 190, 78, 43. *Anal.* calcd. for $C_{20}H_{18}O_8$: C 62.17, H 4.69; found: C 62.21, H 4.74. High resolution molecular weight determination calcd.: 386.100; found: 386.097.

Fries Rearrangement on (+)-6-Desacetylusnic Acid (2). Preparation of Synthetic (+)-Usnic Acid (1)

To a solution of anhydrous aluminum trichloride (41 mg, 0.307 mmol) and acetyl chloride (26 mg, 0.331 mmol) in dry nitrobenzene (0.8 ml, distilled from calcium hydride) was added crystalline (+)-6-desacetylusnic acid (**2**) (20 mg, 0.0661 mmol) and the resulting yellow-brown solution heated at 60°C (oil-bath temperature) under a nitrogen atmosphere for 1.5 h. The reaction mixture was cooled in an ice bath, diluted with chloroform (4 ml), and upon addition of freshly prepared 1 *N* sodium hydroxide (8 ml) stirred at room temperature for 0.5 h. The two layers were separated, and the chloroform–nitrobenzene fraction extracted with 1 *N* sodium hydroxide (2 × 3 ml). The combined aqueous extracts were *carefully* neutralized with 1 *N* hydrochloric acid, extracted with ethyl acetate (4 × 10 ml), and the combined extracts washed with water, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. The residue was immediately purified by preparative layer chromatography (silica gel – oxalic acid plates, solvent *A*) to produce (+)-usnic acid (**1**) (10.8 mg, 0.0314 mmol; 47%), yellow prisms from chloroform – ethyl alcohol, mp 201–203°C, mixture mp with authentic (+)-usnic acid (**1**), 202–203°C. The spectroscopic properties of both samples were identical.

Cationic rhodium(I) sulfoxide complexes. Synthesis and spectroscopic properties

BRIAN R. JAMES, ROBERT H. MORRIS, AND KENNETH J. REIMER

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received January 24, 1977

BRIAN R. JAMES, ROBERT H. MORRIS, and KENNETH J. REIMER. Can. J. Chem. **55**, 2353 (1977).

Displacement of the labile acetone ligand from [Rh(diene)(PPh_3)(acetone)]A (diene = 1,5-cyclooctadiene (COD), norbornadiene (NBD); A = PF_6^-, SbF_6^-) allows facile coordination of dialkyl or alkyl aryl sulfoxides, and [Rh(diene)(PPh_3)(sulfoxide)]$^+$ complexes have been synthesized using dimethyl sulfoxide (DMSO), tetramethylene sulfoxide (TMSO), di-*n*-propyl sulfoxide (NPSO), (*S*,*S*;*S*,*R*)-(+)-2-methylbutyl methyl sulfoxide (MBMSO), methyl phenyl sulfoxide (MPSO), (*R*)-(+)-methyl-*p*-tolyl sulfoxide (MPTSO), and (*R*)-*t*-butyl *p*-tolyl sulfoxide (TBPTSO).

Diaryl sulfoxides appear to coordinate in solution but no solid compounds could be isolated. The upfield shifts of the sulfoxide resonances (^1H nmr), reflecting shielding by the adjacent phenyl groups of PPh_3, and the decrease in ν(SO) on coordination, are indicative of O-bonding in all cases. Infrared data indicate that the frequency shift of ν(SO) upon O-coordination is roughly proportional to the strength of the metal–oxygen bond for a range of transition metal DMSO and TMSO complexes.

BRIAN R. JAMES, ROBERT H. MORRIS et KENNETH J. REIMER. Can. J. Chem. **55**, 2353 (1977).

Le déplacement du ligand acétone labile du [Rh(diène)(PPh_3)(acétone)]A {diène = cyclooctadiène-1,5 (COD), norbornadiène (NBD); A = PF^-_6, SbF^-_6} permet une coordination facile des dialkyl- et alkyl aryl sulfoxydes et on a synthétisé les complexes [Rh(diène)(PPh_3)(sulfoxyde)]$^+$ utilisant le diméthyle sulfoxyde (DMSO), le tétraméthylène sulfoxyde (TMSO) le di-*n*-propyl sulfoxyde (NPSO), le (*S*,*S*;*S*,*R*)-(+)(méthyl-2 butyl) méthyl sulfoxyde (MBMSO), le méthyl phényl sulfoxyde (MPSO) et le *R*-(+)-méthyl *p*-tolyl sulfoxyde (MPTSO) et le *R*-*tert*-butyl *p*-tolyl sulfoxyde (TBPTSO).

Il semble que le diaryl sulfoxyde se coordonne en solution mais on n'a pu isoler aucun composé solide. Les déplacements vers les hauts champs de résonances du sulfoxyde (rmn ^1H) suggèrent qu'il y a un blindage par les groupes phényles adjacents du PPh_3; par ailleurs la diminution de la valeur de ν(SO) par coordination indique qu'il y a formation de lien avec l'oxygène dans tous les cas. Des données infrarouges indiquent que le déplacement de la fréquence ν(SO) par coordination avec l'oxygène est approximativement proportionnel avec la force du lien métal/oxygène par un étendue de complexes de métaux de transition et de DMSO et TMSO.

[Traduit par le journal]

Introduction

Other studies from this group have recently described ruthenium complexes containing sulfoxide ligands, and the systems were found effective for homogeneous catalytic hydrogenation of olefins (1); use of a chiral sulfoxide ligand led to catalytic asymmetric synthesis (2). We then became especially interested in attaching sulfoxides, including chiral ones, to a rhodium(I) centre. The catalytic activity of rhodium(I) complexes, commonly with phosphines, is well-documented (3), but there is very little known about the catalytic potential of systems containing sulfoxides (4).

Catalysts derived from the complexes [Rh(diene)L_n]A, **1**, (diene = 1,5-cyclooctadiene (COD), norbornadiene (NBD); L = neutral donor ligand; A = anion) are known to be useful for the hydrogenation of a variety of unsaturated organic substrates (5). The selectivity and efficiency of such reactions (*e.g.*, hydrogenation *vs.* isomerization) is likely dependent on the nature of L, typically a tertiary phosphine or arsine, and suggests that catalytic selectivity might be further controlled by using mixed ligand precursors, [Rh(diene)L^1L^2]A, **2**. Compounds such as **1** are typically prepared (5) by the addition of excess L to [RhCl(diene)]$_2$, a procedure not applicable to the synthesis of **2**, but we have found that the latter are easily obtained from [Rh(diene)L^1(acetone)]A, **3**.

In view of our interest in rhodium sulfoxide complexes and the paucity of such complexes in general (6), and especially compounds of type **2**, we have initially investigated the utility of **3** as a synthetic precursor for [Rh(diene)(PPh_3)(sulfoxide)]A species. An appreciation of the electronic and steric requirements of the [Rh(diene)L^1L^2]$^+$ cation and the properties of sulfoxide derivatives (*e.g.*, O- *vs.* S-bonding) are essential

for an evaluation of such compounds as potential catalysts. During the course of this work, Crabtree (7) reported the use of $[Rh(COD)(PPh_3)(py)]^+$ for hydrogenation of 1-alkynes to 1-alkenes.

Experimental

Synthetic procedures and solution measurements were conducted under argon atmosphere. Spectral grade solvents were stored over molecular sieves (BDH, type 5A) and were vacuum-degassed before use.

Infrared spectra (accurate to $\pm 2\ cm^{-1}$) were recorded on a Perkin Elmer 457 grating spectrometer; solid samples were run as Nujol mulls between CsI plates, and for solutions 0.1 mm NaCl cells were used with $CHCl_3$, or CH_2Br_2, a solvent with a useful "window" from 1070–850 cm^{-1}. ^1H nmr spectra were run on a Varian T-60 spectrometer with tetramethylsilane as an internal reference. Conductivity measurements were made in nitromethane at 25°C using a Thomas Serfass conductivity bridge and cell.

Rhodium(III) trichloride was obtained as the trihydrate from Johnson, Matthey Limited. Silver salts were obtained from Alfa Inorganic and Cationics Inc. The chiral sulfoxides were kindly donated by R. S. McMillan of this group (2), and B. Bosnich and H. Boucher (University of Toronto). The other sulfoxides were obtained commercially (Aldrich, Fisher). Microanalyses were performed by Mr. P. Borda of this department.

Preparation of Complexes

Literature methods (8, 9) were used for the synthesis of $[RhCl(COD)]_2$ and $[RhCl(NBD)]_2$, but for the latter the reaction mixture was stirred at 40°C for 3 h under argon.

[Rh(diene)(PPh$_3$)(acetone)]A; diene = COD, NBD; A = PF$_6$, SbF$_6$

To a CH_2Cl_2 solution (15 ml) of PPh_3 (0.409 g, 1.56 mmol) and $[RhCl(COD)]_2$ (0.384 g, 0.774 mmol) was added dropwise with stirring $AgPF_6$ (0.395 g, 1.56 mmol) dissolved in acetone (10 ml); flocculent white AgCl precipitated. After 10 min the bright orange solution was filtered under argon and concentrated to 5 ml. Gradual addition of ether gave orange crystals which were collected, washed with ether, and dried. Additional product was obtained upon further concentration and addition of ether. The fractions were combined, dissolved in an equivolume acetone/dichloromethane mixture, and crystallized by the addition of ether (yield = 80%). Solvent of crystallization (CH_2Cl_2), usually found in samples so obtained, was removed by prolonged evacuation.

The NBD compound was prepared similarly.

[Rh(COD)(PPh$_3$)(DMSO)]PF$_6$

DMSO (21 μl, 0.29 mmol) and $[Rh(COD)(PPh_3)(acetone)]PF_6$ (0.20 g, 0.29 mmol) were dissolved in CH_2Cl_2 (3 ml) and stirred for 15 min. Addition of ether gave yellow crystals which were recrystallized from dichloromethane/ether, washed with ether, and dried *in vacuo* for several hours.

All of the mixed ligand species (Table 1) were similarly prepared from the appropriate acetone precursor. Yields were typically 80–90%.

Results and Discussion

Acetone Complexes

Facile cleavage (8–12) of the chloride bridge of $[RhCl(diene)]_2$ by a Lewis base, L^1, can give a monomeric derivative $[RhCl(diene)L^1]$, **4**, but excess reactant (especially where L^1 = phosphine or arsine) in a polar solvent may displace the labile chloride forming $[Rh(diene)L^1_n]^+$ (13, 14). The removal of chloride as a silver salt from **4** facilitates the coordination of acetone, a weak and easily displaced ligand (15); reactions 1 and 2.

$$[1] \quad [RhCl(diene)]_2 + 2L^1 \longrightarrow 2[RhCl(diene)L^1]$$

$$[2] \quad [RhCl(diene)L^1] + AgA \xrightarrow[CH_2Cl_2/acetone]{} [Rh(diene)L^1(acetone)]A + AgCl$$

(**4**; **3**)

Although a variety of ligands such as amines (10, 11), arsines (12), phosphines (8, 9), halides (8), etc., have been used to effect reaction 1, we have confined our initial investigation to triphenylphosphine derivatives. This provides a synthetic advantage, as crystalline samples of the acetone cation, **3**, are easily obtained when $L^1 = PPh_3$, as are the subsequently derived sulfoxide complexes. Table 1 gives the microanalytical data. The *in situ* synthesis of other reactive acetone complexes is readily accomplished.

Solid state infrared measurements on **3** show ν(CO) at $\sim 1660\ cm^{-1}$ (Table 2), consistent with a coordinated acetone moiety (15). The extreme lability of the acetone ligand is demonstrated by the replacement of this band by one of the free ligand at $1710\ cm^{-1}$ during the recording of solution infrared in CH_2Cl_2. Furthermore, only a singlet at δ 2.05 for free ligand is present in the ^1H nmr spectra (Table 3) and there is no evidence of coordinated acetone. In contrast, with the cationic complexes $[M(CO)(acetone)(PPh_3)_2]^+$, M = Rh, Ir, the coordinated acetone singlet appears at δ 1.6–1.8, due to diamagnetic shielding by the *cis* phosphines (13, 15, and see below), and free acetone is detected only after several hours (16). Accordingly, samples of **3** must be recrystallized in the presence of excess acetone.

The dissociation of acetone suggests the formation of formally three-coordinate species. Although such species are usually considered to be solvated four-coordinate square planar, evidence has been presented for three-coordinate

TABLE 1. Analytical data for the rhodium(I) complexes

intermediates in reactions of d^8 organometal systems (17). Unsymmetrical T- and Y-shaped configurations were favoured (17*b*) and the former, or solvated four-coordinate species, could account for the inequivalence of the COD olefinic protons in the present system. Two sets of resonances at δ 5.2 and 3.3 are observed in $CDCl_3$ solution (Table 3). A complex spectrum is observed for the NBD analogue in $CDCl_3$, but only a single olefinic signal at δ 4.4 is observed in acetone-d_6; intra- or intermolecular rearrangements are indicated and low temperature nmr studies should clarify the phenomenon. Previous studies (17*a*, 18) have demonstrated differences in the exchange reactions of rhodium(I) diene complexes depending on the nature of the diene, the NBD complexes undergoing rearrangements more readily than the COD analogues. Also relevant here is that for $[Rh(diene)L_n]^+$ complexes, *n* may be 3 for NBD, but only 2 for COD systems (13). The stronger π back-bonding properties of NBD have been invoked to rationalize the reactivity patterns (18).

Infrared data for all of the complexes reported here show that the anions are uncoordinated, since only the characteristic bands of PF_6^- and SbF_6^- are observed at 840 vs, 560 s, and 658 vs, 290 s cm^{-1}, respectively (19).

Sulfoxide Complexes

Despite the somewhat complex solution behaviour of **3**, such solutions react with an equivalent of a sulfoxide to give yellow (COD) or yellow-orange (NBD) crystalline products. Analytical data are presented in Table 1. The complexes are reasonably air-stable in the solid state. In solution the NBD derivatives are very air-sensitive, while the COD derivatives show reactivity only after several hours; the oxidation products are as yet uncharacterized but dioxygen intermediates are a possibility (20). Treatment of the complexes with dihydrogen at 20°C in solution gives metal, and dihydride complexes, readily formed and detected with the biphosphine cations (5, 13), seem likely intermediates. Of interest, a complex $[H_2Ir(diene)(PPh_3)_2]^+$ has recently been reported (21).

For [Rh(COD)(PPh_3)(DMSO)]A (A = PF_6, SbF_6) a molar conductance of 85 mho cm^{-2} is observed in nitromethane, identical to that for [Rh(COD)(PPh_3)$_2$]PF_6, a known 1:1 electrolyte (13). However, solution infrared spectra of these DMSO complexes in nitromethane show that the solution species is probably [Rh(COD)(PPh_3)($MeNO_2$)]$^+$: ν(SO) is detected at 1055 cm^{-1}, that of free DMSO.

The ^{1}H nmr spectra for the COD derivatives in $CDCl_3$ show two signals for the non-equivalent olefinic protons. The downfield resonance at δ ~ 5.2 is assigned to the protons (H_A) *trans* to PPh_3, consistent with previous assignments (22) for the neutral compounds [MCl(COD)PPh_3], M = Rh, Ir; in these, the signal due to the protons *trans* to chloride appears at δ ~ 3, similar to that found here for those (H_B) opposite the sulfoxide ligands.

The down- and up-field shifts of olefinic diene protons *trans* to PPh_3 and sulfoxide, respectively, are further supported by the respective positions of the equivalent olefinic protons at δ 4.6 and 3.9 for the cations [Rh(COD)(PPh_3)$_2$]$^+$ (13) and [Rh(COD)(DMSO)$_2$]$^+$ (18).

The methylene protons of the diene appear as a broad signal between δ 1.8–2.5. The ^{1}H nmr resonances of the olefinic and methine protons of the diene in the NBD–sulfoxide compounds are complex, as in the NBD–acetone complexes. This precludes definitive assignments, but there is no evidence for the dissociation of the sulfoxide ligands from either the NBD or COD complexes in dichloromethane or chloroform at room temperature. All the sulfoxide complexes contain O-bonded sulfoxide (see below).

DMSO and TMSO Complexes

A sharp ^{1}H nmr singlet due to the DMSO methyl protons of [Rh(COD)(PPh_3)(DMSO)]PF_6 appears at δ 2.2, compared to δ 2.6 for the free sulfoxide and δ 2.8 for [Rh(COD)(DMSO)$_2$]BF_4 (18). Downfield shifts of up to 1 ppm are usually characteristic of S-bonded DMSO, while the O-bonded complexes, in which the protons are further removed from the metal,

[c]From SbF_6^- complex, since obscured in the PF_6^- derivative.

show considerably less variation from the free values (23). The proximal phenyl rings of PPh_3 must be responsible for the upfield shifts observed here, and noted previously (24) for $[Ir(CO)(DMSO)(PPh_3)_2]ClO_4$ (δ 1.8). Indeed, space filling models suggest that the most favorable orientation is one where a phenyl group presents a ring centre to the adjacent sulfoxide ligand, and such a conformation will likely persist during the majority of rotational motion.

Addition of excess DMSO to a solution of $[Rh(COD)(PPh_3)(DMSO)]^+$ in $CDCl_3$ gives a sharp resonance at a weighted mean position of the free and coordinated ligand, suggesting that the exchange is fast on the nmr time scale. Interestingly, the COD(—CH=) resonances are not broadened. Facile exchange of O-bonded sulfoxides, less so for S-bonded (1), has been noted by others (23, 25), and this, together with the other nmr and infrared evidence (see below), is consistent with the O-bonded nature of DMSO in the present instance.

The position of the sulfur–oxygen stretching vibration in the infrared spectra of sulfoxide complexes is diagnostic of the bonding mode; S-bonding usually causes an increase of ν(SO) to about 1100 cm^{-1}, whereas a shift to a lower range (1000–900 cm^{-1}) is indicative of donation from oxygen (1, 6, 23, 26–29). However, assignments of ν(SO) for O-bonded sulfoxides with α-methyl groups, are complicated by the presence of methyl rocking vibrations which are similar in energy to the S—O stretch (26, 27, 30, 31).

Bands at 983 and 947 cm^{-1} are observed in the CH_2Br_2 solution infrared of $[Rh(COD)(PPh_3)(DMSO)]A$. The higher frequency band is absent in the spectrum of the DMSO-d_6 analogue (Table 4) indicating that the major contribution to this band is a methyl rocking mode.

By comparison of the infrared spectra of the present compounds with those of other rhodium diene species we have assigned ν(Rh—O) for the TMSO (432 cm^{-1}) and DMSO (450 cm^{-1}) compounds. The latter is shifted to 430 cm^{-1} in the DMSO-d_6 compound, and the frequency ratio 1.046 confirms this assignment and indicates that the vibrational modes are almost pure Rh—O stretches (32).

By means of a deuteration study, we have confirmed the O-bonded nature of the DMSO ligands in $[Rh(COD)(DMSO)_2]^+$; ν(SO) = 950 cm^{-1}, ν(Rh—O) = 473, 465 cm^{-1}. The Rh—O stretches again exhibit the expected deuterium shift of about 1.05 (32).

A correlation seems to exist between the bands assigned as ν(M—O) and the frequency reduction of ν(SO) on coordination of sulfoxide to metals. Data are given in Table 5 for O-bonded DMSO and TMSO in some transition metal complexes. There is sometimes ambiguity in the assignment of the O-bonded SO-stretch within certain of the DMSO complexes because of the methyl rocking modes (27, 31) (two Δν(SO) values are thus given), but nevertheless ν(M—O) increases generally with increasing Δν(S—O). Such a relationship has been suggested (37), but not previously documented. Figure 1 shows the data plotted for systems where there is thought to be no ambiguity. Except for the CrL_6^{3+} complexes (L = DMSO, TMSO), the data fall within a remarkably well-defined band for all the mono-, bi-, and trivalent species. Figure 1 unfortunately does not aid in establishing the

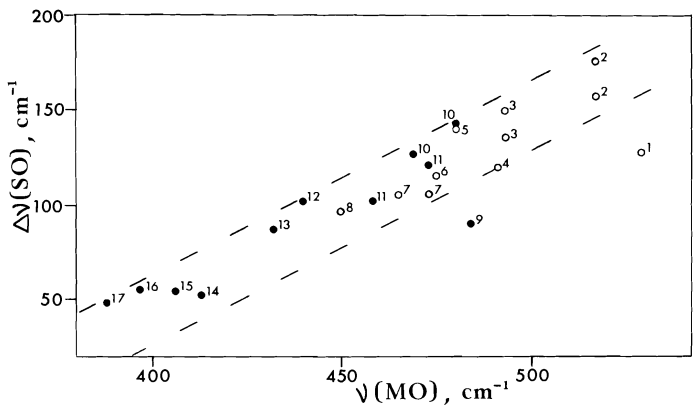

FIG. 1. Plot of frequency shift of ν(SO) on coordination of O-bonded sulfoxide *vs.* ν(MO); ○, dimethylsulfoxide complexes; ●, tetramethylene sulfoxide complexes. Numbers refer to complexes listed in Table 5.

correct assignments for ν(SO) and $\rho_r(CH_3)$ in the $M(DMSO)_6^{2+}$ species ($M = Mn^{II}$, Fe^{II}, Co^{II}, Ni^{II}). However, Fig. 1 likely resolves the corresponding ambiguity in the assignments for ν(SO) in $Cu(DMSO)_4^{2+}$ (940 or 988 cm^{-1}) and *trans*-$CuCl_2(DMSO)_2$ (923 or 980 cm^{-1}); in each case, the lower number giving Δν(SO) values of 115 and 132 cm^{-1}, respectively, is more consistent with the observed trend *vs.* ν(MO).

Other Sulfoxide Complexes

The ^1H nmr data of the other sulfoxide complexes (Table 3) show that, except for *p*-CH_3, all resonances are shifted upfield from the free ligand positions, indicating again a phenyl diamagnetic shielding of O-bonded sulfoxide ligands.

The infrared data in the 900–1000 cm^{-1} region for systems uncomplicated by the presence of α-methyl rocking modes (*i.e.*, for the DMSO-d_6, TMSO, TBPTSO, and NPSO systems) show that the SO stretch shifts by 70–110 cm^{-1} upon coordination to the metal (Table 2). This wide shift range precludes its use in helping assign

ν(SO) in the MBMSO, MPSO, and MPTSO systems which contain the methyl rocking modes; the shift of *both* bands in the region of interest is in the same 70–110 cm^{-1} range (Table 2). Nevertheless, the increased complexity in the 900–1000 cm^{-1} region upon coordination with the α-methyl-containing sulfoxides is consistent with O-bonding. Assignments of ν(Rh—O) were precluded by the multiplicity of infrared bands in the 400–500 cm^{-1} region.

Although diaryl sulfoxides appear to be O-bonded to rhodium (upfield nmr shifts) in solution, we have been unable to isolate discrete complexes, possibly due to unfavorable steric interactions in the solid state; the diaryl sulfoxide ligands studied were diphenylsulfoxide, and *S-o*-tolyl *p*-tolyl sulfoxide.

The choice of S- or O-coordination with a sulfoxide ligand has usually been rationalized in terms of steric effects (25, 38). However, considering that both the DMSO ligands are O-bonded in the unhindered $[Rh(COD)(DMSO)_2]^+$ complex, electronic factors must play a substantial role in the cationic rhodium(I) diene complexes. Attempts to force S-donation using different L^1 ligands, as well as investigation of the catalytic properties of these complexes, are in progress.

Synthesis of 3,5-dihydroxy-2,2-dimethylchroman-4-one and its implications for the structure of the phytotoxin stemphylin[1]

A. N. STARRATT AND A. STOESSL

Agriculture Canada, Research Institute, University Sub Post Office, London, Ont., Canada N6A 5B7

Received February 21, 1977

A. N. STARRATT and A. STOESSL. Can. J. Chem. **55**, 2360 (1977).

3,5-Dihydroxy-2,2-dimethylchroman-4-one was prepared by an unambiguous synthesis. Its spectroscopic properties and those of its methyl ether are incompatible with its identity as the aglycone moiety of the fungal toxin stemphylin.

A. N. STARRATT et A. STOESSL. Can. J. Chem. **55**, 2360 (1977).

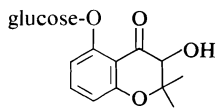
On a préparé la dihydroxy-3,5 diméthyl-2,2 chromanone-4 par une synthèse non-ambigue. Ses propriétés spectroscopiques et celles de son éther méthylique ne correspondent pas à celles de la fraction aglycone de la toxine fungale stemphyline.

[Traduit par le journal]

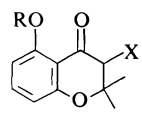
The phytotoxic compound stemphylin was recently isolated from the fungus *Stemphylium botryosum* (1). It was reported as a "chromone glucoside" and assigned structure **1** mainly on spectroscopic evidence (1), the interpretation of which appeared open to doubt. In order to clarify the situation, we prepared chromanone **2**, the aglycone of **1**, and report that its spectroscopic properties render **1** and related structural proposals for stemphylin untenable.

The synthesis of the acetate **3** of chromanone **2** was accomplished in one step by neutral permanganate oxidation of the known chromene acetate **4**. The latter was prepared from the corresponding chroman **5** essentially as described in the literature (2) but also, more conveniently and efficiently, by the oxidation of **5** with dichlorodicyanobenzoquinone.[2] The permanganate oxidation of **4** furnished **3** in 31% yield when 1.6 mol of reagent was used. The mechanism for the formation of ketols from olefins by oxidation with neutral permanganate has been discussed by Wiberg and Saegebarth (3). An oxidation of a chromene to an α-hydroxychromanone has also been reported with osmium tetroxide – sodium periodate (4).

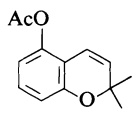
Mild alkaline hydrolysis of acetate **3** gave the 3,5-dihydroxychromanone **2**, mp 61–62°C, whose structure was established by the usual criteria



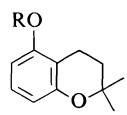
1



2 R = H, X = OH
3 R = Ac, X = OH
6 R = CH_3, X = OH
7 R = Ac, X = Br
8 R = H, X = H
9 R = Ac, X = H



4



5 R = Ac
10 R = H

(see Experimental). This compound absorbs at λ_{max} 215, 275, and 349 nm (ε 11 860, 7900, and 2700) in ethanol as expected, since very similar values are reported in the literature for other 5-hydroxychromanones (5–7). In water at p*H* 5.5, **2** absorbs at λ_{max} 215, 274, and 346 nm (ε 12 300, 8300, and 2500). In contrast, stemphylin was reported (1) to absorb at λ_{max} 218 and 268 nm (ε 19 200 and 7330) in water at p*H* 5.5, with an additional weak maximum at 427.5 nm, but no mention was made of selective absorption near 350 nm. Methylation of **2** with diazomethane gave methyl ether **6** whose uv spectroscopic properties are similar to those of **2**, including an absorption maximum at 331 nm. This band, therefore, is not contingent on the presence of a free hydroxyl group at C-5. On the other hand, it should be noted that the bathochromic shift observed (1) for stemphylin at p*H* 8.9 suggests

[1]Contribution No. 676.

[2]In passing, we draw attention to the use of chlorobenzene as solvent for this oxidation. This refluxes at a temperature comparable to that of xylene but appears to be less subject to oxidation itself than the latter commonly used solvent.

that this substance does, in fact, possess a free phenolic hydroxyl, contrary to the suggested structure. No bathochromic shift was observed when alkali was added to the spectroscopic solution of the methyl ether **6**.

Other significant differences between the properties reported for stemphylin and those of the chromanone **2** are found in the nmr spectra. Particularly striking is the fact that the methyl groups of **2** are differentially shielded by the hydroxyl attached to C-3. This is observed both in chloroform and dimethyl sulfoxide solution and is also the case with acetate **3** and methyl ether **6**. The 3-bromochromanone **7**, prepared as a model, also exhibits this property which is, indeed, expected of any 3-substituted 2,2-dimethylchroman. Only in the absence of substitution at C-3 do the methyl groups at C-2 become equivalent and give rise to singlet absorption as observed in compounds **8** and **9**. Stemphylin shows only singlet absorption in the methyl region (1) and is therefore unlikely to be a 3-substituted 2,2-dimethyl chromanone, irrespective of the oxygenation pattern in the aromatic ring. Further, the low field absorption of stemphylin is broad and in the range δ 6.6–7.2 whereas the aromatic protons of chromanone **2** give rise to well-defined and fully analyzable bands in the noticeably wider range δ 6.3–7.5.

The substitution of glucosyloxy for a hydroxy or methoxy group at C-5 of **2** or **6**, respectively, will not alter their spectroscopic properties to any significant extent. Thus, the data reported in the present communication clearly indicate that the structure of stemphylin must be regarded as unknown. This conclusion is also in accord with the gross divergence between the figures calculated for the elementary composition of **1** and those determined experimentally for stemphylin (1).

Experimental

Melting points were determined on a Kofler hot stage and are uncorrected. Proton magnetic resonance spectra were measured with Varian A-60A or XL-100-12 spectrometers with tetramethylsilane as internal standard and $CDCl_3$ as solvent unless otherwise stated. Chemical shifts of multiplets were measured at the geometric centres and J represents observed splittings. Mass spectra were determined on a Varian MAT 311A mass spectrometer, infrared spectra were recorded using a Beckman IR-20A spectrophotometer, and ultraviolet spectra were recorded using a Beckman DK spectrophotometer. Silicic acid – celite (4:1) was used for column chromatography and separations were monitored by tlc on Kieselgel (Camag). Light petroleum, bp 35–60°C, was used for chromatography and bp 60–80°C for recrystallizations. Samples were sublimed for analysis (Dr. C. Daesslé, Montreal).

2,2-Dimethyl-5-acetoxychroman, **5**

2,2-Dimethyl-5-hydroxychroman (**10**) was synthesized by the method of Verhé *et al.* (8) with the exception that 1,3-cyclohexanedione was reacted with 1-chloro-3-methyl-2-butene for 4 h. The crude chroman was acetylated at room temperature with acetic anhydride – pyridine and the product was purified by column chromatography. Light petroleum – methylene chloride (9:1) eluted material which was recrystallized from ethanol to give chroman acetate **5**, mp 59–61°C (lit. (2) mp 63–63.5°C); nmr δ 1.31 (d, 6H, Me_2C), 1.75 (t, $J \simeq 6.5$ Hz, 2H, CH_2CMe_2), 2.58 (t, $J \simeq 6.5$ Hz, 2H, CH_2Ar), 2.28 (s, 3H, OAc), 6.59 (dd, $J \simeq 1.5$ and 8 Hz, 1H, H-6 or H-8), 6.70 (dd, $J \simeq 1.5$ and 8 Hz, 1H, H-8 or H-6), 7.12 (t, $J \simeq 8$ Hz, H-7).

2,2-Dimethyl-5-acetoxychromene, **4**

(*a*) Chroman acetate **5** (306 mg) was brominated with *N*-bromosuccinimide as described by Fukami and Nakajima (2). Best yields were obtained by monitoring each run by nmr. Typically the product was isolated after 30 min and dissolved in dry benzene (5 ml) containing 1,5-diazobicyclo[5.4.0]undec-5-ene (254 mg). After heating at reflux for 5 min, the solution was washed with dilute HCl and water and the product was purified by column chromatography. Elution with light petroleum – methylene chloride (19:1) gave chromene acetate **4** (146 mg), an oil; nmr δ 1.43 (s, 6H, Me_2C), 2.30 (s, 3H, OAc), 5.64 (d, $J \simeq 10$ Hz, 1H, $CHCMe_2$), 6.37 (d, $J \simeq 10$ Hz, 1H, CHAr), 6.60 (dd, $J \simeq 1.5$ and 8 Hz, 1H, H-6 or H-8), 6.68 (dd, $J \simeq 1.5$ and 8 Hz, 1H, H-8 or H-6), 7.12 (t, $J \simeq 8$ Hz, 1H, H-7).

(*b*) Chroman acetate **5** (220 mg, 1.0 mmol) in chlorobenzene (5 ml) was refluxed with dichlorodicyanobenzoquinone (253 mg, 1.1 mmol) until the reagent was consumed (tlc, 8 h). Column chromatography with light petroleum – methylene chloride (19:1) afforded pure chromene acetate **4** (105 mg; 48%). Ensuing fractions contained a little more chromene (12 mg, estimated by nmr) admixed with increasing amounts of starting material (48 mg). In similar experiments, with carefully purified xylene as solvent, only traces of the desired product were observed although the reagent was rapidly reduced (formation of precipitate).

2,2-Dimethyl-5-acetoxy-3-hydroxychroman-4-one, **3**

A solution of potassium permanganate (278 mg) and magnesium sulfate (211 mg) in water (8 ml) was added dropwise with stirring during 2.5 h to a solution of chromene acetate **4** (240 mg) in ethanol (7.2 ml) at −15 to −20°C. The precipitate was filtered off and washed thoroughly with boiling water. Extraction of the aqueous solution with ethyl acetate yielded the crude product (181 mg) which was purified by chromatography. Elution with light petroleum – methylene chloride (19:1) yielded a small quantity of starting material (tlc). Further elution with light petroleum – methylene chloride (9:1) gave the main product (84 mg) which was recrystallized from ether – light petroleum to yield chromanone acetate **3**, mp 68–70°C; uv (EtOH) λ_{max} 254 and 322 nm (log ε 3.81 and 3.47); ir ($CHCl_3$) 1762, 1687 (C=O) cm^{-1}; nmr δ 1.22 and 1.63 (s, 3H each, Me_2C), 2.38 (s, 3H, OAc), 4.36 (s, 1H, CHOH), 6.67 (dd, $J \simeq 1.5$ and 8 Hz, 1H,

H-6 or H-8), 6.84 (dd, $J \simeq 1.5$ and 8 Hz, 1H, H-8 or H-6), 7.49 (t, $J \simeq 8$ Hz, 1H, H-7) and in DMSO-d_6, 1.19 and 1.46 (s, 3H each, Me_2C), 2.29 (s, 3H, OAc), 4.20 (s, 1H, C*H*OH), 6.72 (dd, $J \simeq 1.5$ and 8 Hz, 1H, H-6 or H-8), 6.90 (dd, $J \simeq 1.5$ and 8 Hz, 1H, H-8 or H-6), 7.57 (t, $J \simeq 8$ Hz, 1H, H-7). *Anal.* calcd. for $C_{13}H_{14}O_5$: C 62.39, H 5.64; found: C 62.19, H 5.80.

2,2-Dimethyl-3,5-dihydroxychroman-4-one, **2**

Chromanone acetate **3** (18 mg) in ethanol (0.4 ml) was treated with a solution of KOH (15 mg) in 80% ethanol (3 ml). After standing under nitrogen at room temperature for 0.5 h, the solution was acidified with 0.1 *N* HCl and the product extracted into ethyl acetate. The product was chromatographed over a short column with light petroleum – methylene chloride (19:1) and recrystallized from light petroleum to give chromanone **2**, mp 61–62°C; uv (EtOH) λ_{max} 215, 275, and 349 nm (log ε 4.07, 3.90, and 3.43); uv (H_2O) λ_{max} 215, 274, and 346 nm (log ε 4.09, 3.92, and 3.40) and, after adjustment of p*H* to 9.5 with 0.1 *N* NaOH, λ_{max} 237, 280, and 372 nm (log ε 4.01, 3.77, and 3.66); ir ($CHCl_3$) 1652 (C=O) cm^{-1}; nmr δ 1.27 and 1.63 (s, 3H each, Me_2C), 4.43 (s, 1H, C*H*OH), 6.40 (dd, $J \simeq 1$ and 8 Hz, 1H, H-6 or H-8), 6.50 (dd, $J \simeq 1$ and 8 Hz, 1H, H-8 or H-6), 7.39 (t, $J \simeq 8$ Hz, 1H, H-7), and in DMSO-d_6, δ 1.26 and 1.48 (s, 3H each, Me_2C), 4.33 (s, 1H, C*H*OH), 6.40 (d, $J \simeq 8$ Hz, 1H, H-6 or H-8), 6.45 (d, $J \simeq 8$ Hz, 1H, H-8 or H-6), 7.40 (t, $J \simeq 8$ Hz, 1H, H-7), 11.27 (s, 1H, ArO*H*, D_2O exchangeable); ms *m/e* calcd. for $C_{11}H_{12}O_4$: 208.0734; found: 208.0733. *Anal.* calcd. for $C_{11}H_{12}O_4$: C 63.45, H 5.81; found: C 63.62, H 5.97.

2,2-Dimethyl-3-hydroxy-5-methoxychroman-4-one, **6**

Chromanone **2** (14 mg) was methylated with ethereal diazomethane and the product was purified by preparative tlc (chloroform–methanol, 99:1). Recrystallization from light petroleum yielded methyl ether **6**, mp 77–78°C; uv (EtOH) λ_{max} 269 and 331 nm (log ε 3.94 and 3.52); nmr δ 1.22 and 1.62 (s, 3H each, Me_2C), 3.93 (s, 3H, OMe), 4.31 (s, 1H, C*H*OH), 6.48 (d, $J \simeq 8$ Hz, 1H, H-6 or H-8), 6.52 (d, $J \simeq 8$ Hz, 1H, H-8 or H-6), 7.40 (t, $J \simeq 8$ Hz, 1H, H-7), and in DMSO-d_6, δ 1.19 and 1.44 (s, 3H each, Me_2C), 3.77 (s, 3H, OMe), 4.08 (d, $J \simeq 4$ Hz, 1H, C*H*OH, s after D_2O exchange), 5.54 (d, $J \simeq 4$ Hz, 1H, OH, D_2O exchangeable), 6.42 (d, $J \simeq 8$ Hz, 1H, H-6 or H-8), 6.54 (d, $J \simeq 8$ Hz, 1H, H-8 or H-6), 7.34 (t, $J \simeq 8$ Hz, 1H, H-7); ms *m/e* calcd. for $C_{12}H_{14}O_4$: 222.0891; found: 222.0888.

2,2-Dimethyl-5-hydroxychroman-4-one, **8**

2,6-Dihydroxyacetophenone (600 mg) in anhydrous ether (10 ml) was slowly added to sodium dispersion (1 g, 5 μm, 40% sodium – 60% xylene) in anhydrous ether (5 ml) under nitrogen. The mixture was then heated at reflux for 1.5 h. After cooling, dry acetone (5 ml) was added slowly and the mixture was stirred for 4 h at room temperature and then heated at reflux for 1 h. Water was added, the solution was acidified with acetic acid, and the product was extracted into ether. Chromatography with light petroleum – chloroform (3:1) yielded a mixture (524 mg) of chromanone and acetone condensation products. Extraction of an ether solution of this material with 1 *N* KOH and isolation of the alkali soluble material yielded chromanone **8** (131 mg), mp 73–74°C (lit. (2) mp 75.5–76°C); nmr δ 1.48 (s, 6H, Me_2C), 2.77 (s, 2H, CH_2), 6.43 (dd, $J \simeq 1$ and 8 Hz, 1H, H-6 or H-8), 6.53 (dd, $J \simeq 1$ and 8 Hz, 1H, H-8 or H-6), 7.42 (t, $J \simeq 8$ Hz, 1H, H-7); ms *m/e* calcd. for $C_{11}H_{12}O_3$: 192.0785; found: 192.0785.

Acetylation of chromanone **8** with acetic anhydride – pyridine yielded chromanone acetate **9**, an oil; nmr δ 1.44 (s, 6H, Me_2C), 2.34 (s, 3H, OAc), 2.65 (s, 2H, CH_2), 6.59 (dd, $J \simeq 1$ and 8 Hz, 1H, H-6 or H-8), 6.82 (dd, $J \simeq 1$ and 8 Hz, 1H, H-8 or H-6), 7.42 (t, $J \simeq 8$ Hz, H-7).

2,2-Dimethyl-5-acetoxy-3-bromochroman-4-one, **7**

2-Carboxyethyltriphenylphosphonium perbromide (9) (266 mg) was added to a stirred solution of chromanone acetate **9** (84 mg) in tetrahydrofuran (5 ml) at room temperature. After 9 h additional reagent (101 mg) was added. Stirring was continued for 3 days when reaction was essentially complete (tlc). The major product (98 mg) was isolated by chromatography with chloroform – light petroleum (1:1). Recrystallization from ether – light petroleum yielded bromochromanone **7**, mp 90–92°C; nmr δ 1.53 and 1.60 (s, 3H each, Me_2C), 2.37 (s, 3H, OAc), 4.32 (s, 1H, CHBr), 6.69 (dd, $J \simeq 1.5$ and 8 Hz, 1H, H-6 or H-8), 6.88 (dd, $J \simeq 1.5$ and 8 Hz, 1H, H-8 or H-6), 7.52 (t, $J \simeq 8$ Hz, 1H, H-7). *Anal.* calcd. for $C_{13}H_{13}O_4Br$: C 49.86, H 4.18; found: C 49.64, H 4.48.

Acknowledgments

We wish to thank Mrs. H. Schroeder for 100 MHz nmr spectra, Mr. D. Hairsine for mass spectra, and Mr. G. L. Rock and Mrs. M. E. Stevens for valuable technical assistance.

Ethyl azidoformate has been allowed to react with 1,4-naphthoquinone, 1,2-naphthoquinone, and 2-methoxy-1,4-naphthoquinone under different thermolytic conditions. A variety of products involving addition, substitution, insertion, and molecular rearrangement have been observed. The nature and yields of these products under different conditions are discussed inrelation to the mechanisms proposed for these reactions.

MOHINDER S. CHAUHAN, DAVID M. MCKINNON et RAYMOND G. COOKE. Can. J. Chem. **55**, 2363 (1977).

On a permis à l'azidoformate d'éthyle de réagir avec les naphtoquinones-1,4, naphtoquinones-1,2 et méthoxy-2 naphtoquinones-1,4 dans diverses conditions de thermolyse. On a observé plusieurs produits impliquant des additions, des substitutions, des insertions et des réarrangements moléculaires. On discute de la nature et des rendements de ces produits sous diverses conditions en relation avec les mécanismes proposés pour ces réactions.

[Traduit par le journal]

Introduction

The reactions of azides with conjugated systems have been investigated by various workers (1–6). The addition of an azide moiety to the double bond initially forms a triazoline derivative which may be stable or undergo oxidation to a triazole (3). Loss of nitrogen to form an aziridine (4, 7–9) or subsequent rearrangement to form an anil (3) is possible. Various aziridines have been reported from the addition of nitrene species to the double bonds of various organic substrates without any isolation of triazoline derivatives (10, 11). The only difference between azide and nitrene mechanisms with respect to the aziridine formation is the time of loss of nitrogen in the reaction sequence. In some cases both mechanisms have been encountered (11) while in others a concerted mechanism involving simultaneous addition of the azide moiety and elimination of a nitrogen molecule has been encountered. Recently much interest has been shown in the reactions of ethyl azidoformate since it is a rigid azide and does not undergo Curtius Rearrangement and is a suitable reagent for the investigation of azide and/or nitrene mechanisms with many organic substrates (9–12). We have studied the reactions of this reagent with various quinones, firstly to elaborate previous findings (13), and secondly, as a method of preparation of azepinone derivatives required in a separate study. Also, aziridinoquinones have potential as anti-tumor agents (14).

Results

Reactions with 1,4-Naphthoquinone

Preliminary experiments on photolysis of ethyl azidoformate in the presence of 1,4-naphthoquinone, as monitored by nitrogen evolution, proceeded at a negligible rate, presumably because of the masking effect of the quinone ($\lambda_{max} < 400$ nm). Accordingly, thermolysis was investigated at various temperatures and times. While at 80°C the reaction proceeded smoothly and products **1***a–c*, **3***a*, and **4–10** were obtained along with some starting material and tar; at 60°C reaction was slow and only compounds **1***a* and **10** were isolated along with the starting material. At 100°C neither **1***a* nor **5** were isolated and relative yields changed considerably (Table 1). At higher temperatures increasing amounts of tar were obtained and at 114°C explosive decomposition was evident. Under a nitrogen atmosphere at 80°C, yields were essentially unchanged except that **5** was not obtained. Separa-

*For each run the amount of ethyl azidoformate used was 54 g. Nine batches of 1 g each were used in each case.
†Conditions: A under atmospheric conditions, B under nitrogen.

tion of the various products was achieved by chromatographic and fractional crystallization techniques.

The structures of the products **1***c* and **8–10** were established from the identity of their spectral data with those of authentic specimens. The monooxime **1***c* was most probably derived from the oxazirane **3***a* during chromatography since pure oxazirane **3***a* when passed through a silica gel column under similar conditions afforded some **1***c*. The structure of the urethane **1***a* was established by spectroscopy and by base-catalyzed hydrolysis to the anticipated 2-hydroxy-1,4-naphthoquinone. The aziridine **2** exhibited a 2H singlet at δ 3.74 due to the protons at the saturated ring junction and a carbonyl absorption at 1689 cm^{-1} in the infrared, consistent with its structure. Although an azide mechanism shown in Scheme 1 could easily account for the formation of the aziridine, this is not entirely consistent with the yields of the products obtained at various temperatures. This will be discussed below. All attempts at ring expansion of **2** with acids were unsuccessful. Only urethane products were obtained, indicating that in **2**, the nitrogen atom, despite its association with the electron-withdrawing carbethoxy group, is much more basic than the oxygen of the carbonyl group. Thus treatment of **2** with various acids in all cases afforded **1***a*, sometimes along with other products, depending on the nature of the acids; **1***e* with concentrated sulfuric acid and 2-hydroxy-1,4-naphthoquinone with hydrochloric acid. Glacial acetic acid afforded only **1***a*. Attempts at thermal rearrangement in refluxing benzene, cyclohexene, or veratrole were unsuccessful.

The oxazirane structure of **3***a* was established from its nmr spectrum which exhibited two doublets due to the olefinic protons at δ 6.75 and 7.46. Also, heating under reflux with acetic acid yielded the nitrone **1***d* and the oxime **1***c* as expected. The nitrone **1***d* itself yielded the oxime **1***c* on heating with acetic acid. A possible mechanism for these conversions is shown in Scheme 2.

The structure of the urethane **4** was proved by alkaline hydrolysis which yielded the expected indan-1,3-dione-2-aldehyde, and that of the diurethane **1***b* was proved from its spectral data and alkaline hydrolysis to the expected 3-amino-2-hydroxy-1,4-naphthoquinone. That **1***b* arises from **1***a* is shown by the relative yield of **1***b* increasing with temperature while that of **1***a* decreases; also, **1***a* when treated with ethyl azidoformate afforded **1***b* as a major product.

The mass spectrum and analysis of **5** were consistent with a 1:1 adduct of carbethoxynitrene and 1,4-naphthoquinone, but with two additional atoms of oxygen. It exhibited carbonyl absorptions at 1751 and 1701 cm^{-1} in the

ir. The latter is higher than that for 1,4-naphthoquinone and suggested some alteration in the quinone ring. The nmr spectrum exhibited two 1H singlets at δ 5.75 and 6.34 as well as four A_2B_2 type aromatic protons. Thus the structure **5** is assigned to this compound. A possible mechanism for its formation is shown in Scheme 3. Treatment of **5** with dilute ethanolic hydrochloric acid afforded intractable tar, but when **5** was treated with water and zinc dust, a small amount of ethyl (2-hydroxy-1,4-naphthoquinone-3-yl)carbamate (**1***e*) was obtained, possibly by the mechanism shown in Scheme 4. The first reduction is analogous to the zinc dust reduction of an ozonide, while the formation of the new carbon–carbon bond in the second reduction stage is analogous to a pinacol formation (15). The oxidation at the final stage most probably occurs during work-up.

Either structure **6** or **7** is consistent with the properties of the last compound isolated. Elemental analysis indicated a 2:1 quinone:nitrene adduct; in addition, a molecular ion at 401.0898 was found in the mass spectrum. The nmr spectrum showed AB type two 1H doublets at δ 6.62 and 7.04 in addition to aromatic and ethyl signals. Attempted hydrolysis with dilute hydrochloric acid yielded only polymeric material. We were unable to detect any 3-amino-2-hydroxy-1,4-naphthoquinone or 1,4-naphthoquinone from it and are thus inclined to favor structure **6** over **7**. Further investigations were abandoned due to lack of material. The compound (**6** or **7**) is probably formed from a dihydro precursor by aerial oxidation during work-up, or reaction with diethyl azodicarboxylate.

Reactions with 1,2-Naphthoquinone

The reaction of 1,2-naphthoquinone with an excess of ethyl azidoformate at 92°C gave products **11***a–d* and **12** along with some **8**, **9**, and **1***e*. The structures of the urethanes **11***a* and **11***b* were established by spectral methods, and in addition, the treatment of the diurethane **11***b* with dilute base afforded the expected imidazolone **11***e*.

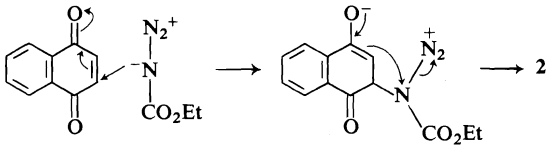
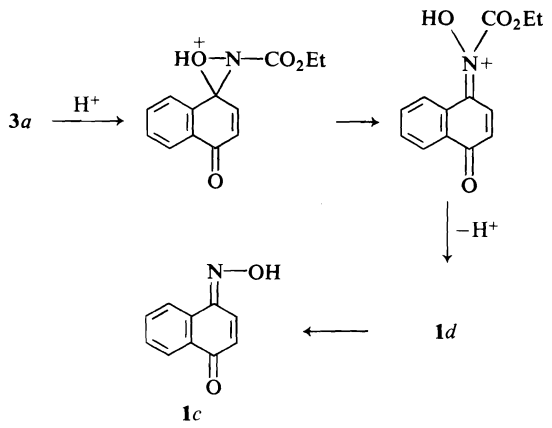
FIGURE 2



SCHEME 1

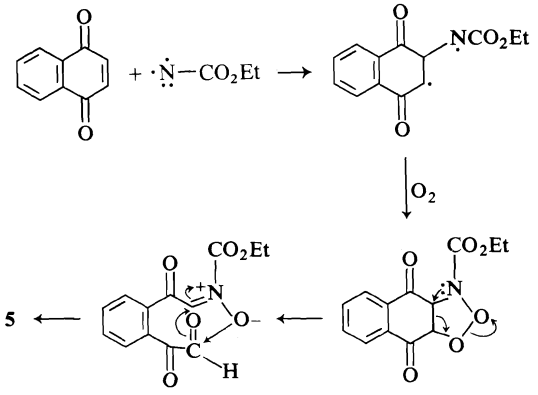
The nmr spectra of the two oxazole products **11***c* and **11***d* were rather similar. Treatment of **11***c* with dilute acid afforded ethyl (2-hydroxy-1,4-naphthoquinone-3-yl)carbamate (**1***e*) as expected. There was insufficient **11***d* to attempt this. While it is difficult to rationalize the formation of **1***e* in terms of reaction between 1,2-naphthoquinone and ethyl azidoformate, it may be explained by the decomposition of either **11***b* or **11***c* during chromatographic analysis of the reaction mixture over silica gel (Scheme 5).



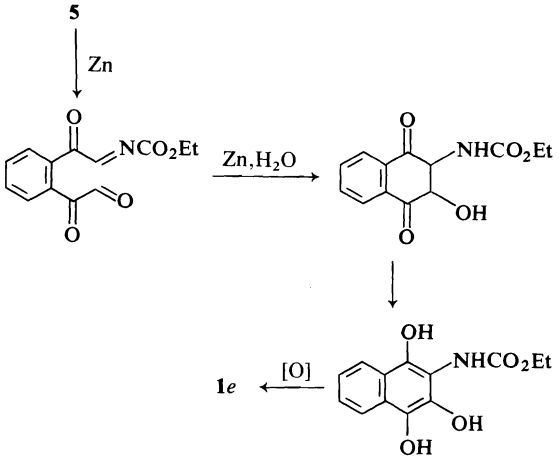
SCHEME 2

Reactions with 2-Methoxy-1,4-naphthoquinone

The reaction between 2-methoxy-1,4-naphthoquinone and ethyl azidoformate at 94°C yielded products **1***f*, **3***b*, and **11***f* along with **9**, **1***e*, and ethyl carbamate (**13**). The structure of the urethane **1***f* was established from its conversion to **1***e* by dilute base, and that of **11***f* by its identity with an authentic specimen. Its formation in the reaction may involve the mechanism shown in Scheme 6. The product **3***b* was a 2:1 adduct of carbethoxynitrene and 2-methoxy-1,4-naphthoquinone. Although the ir and the nmr spectra were consistent with either structures **3***b* or **3***c* the low frequency of the methoxy group (δ 4.48) compared with the corresponding peak in the urethane **1***f* (δ 4.17) favored structure **3***b*. The methoxy group shift in **3***c* would be expected to be closer to the value for that of the methoxy group in **1***f* as a result of their similar environments, whereas that in **3***b*, due to its proximity to the carbethoxy group of the oxaziridine ring would be expected to be shifted to a lower field.



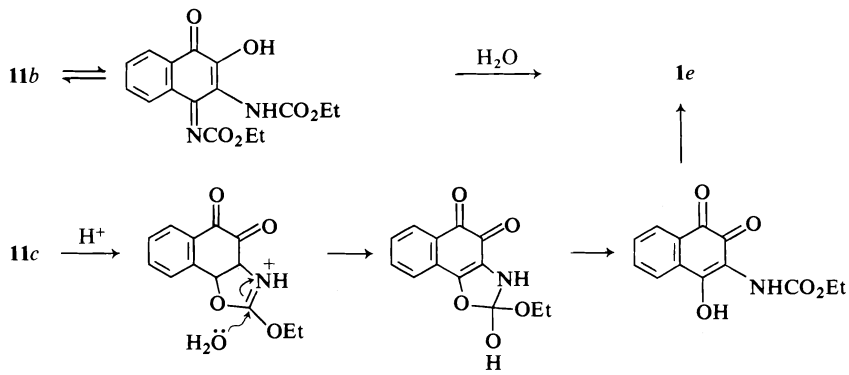
SCHEME 3



SCHEME 4

Compound **1***e* was formed by the demethylation of ethyl (2-methoxy-1,4-naphthoquinone-3-yl) carbamate on the silica gel column as some of it was also obtained by such treatment of the pure compound.

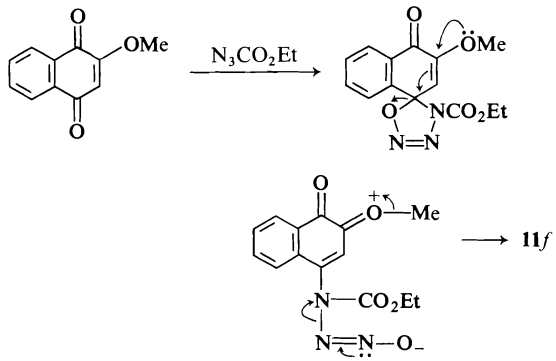
The formation of diethyl azodicarboxylate **14** in the thermolysis of ethyl azidoformate has been shown (16). This ester is a good dehydrogenating agent (17) and has been shown to dehydrogenate both alcohols and amines. Thus it is quite likely that the diurethane **10** may be formed from the hydrogenation of **14** during the reactions and/or chromatographic separation.



SCHEME 5

Indeed, some of the diurethane **10** was formed when pure diethyl azodicarboxylate was run through silica gel under conditions similar to those employed for the various reaction mixtures.

The possibility of the formation of the various urethanes from the reaction of ethyl carbamate with the naphthoquinones was eliminated as none of the products were obtained when these reagents were heated together. Furthermore, that diethyl azodicarboxylate was not involved in the formation of any of the products was shown by the lack of reaction between it and 1,4- and 1,2-naphthoquinone.



SCHEME 6

Discussion

Although the formation of the various products in the above reactions may be explained on the basis of the two electronic states of carbethoxynitrene a closer examination of the results suggests that the azidoester is also involved in the formation of some of the products. A comparison of the yields of **1***a* and the aziridine **2** obtained at 80°C or higher suggests that at these temperatures formation of **2** is favored over **1***a*. In contrast, at 60–65°C no aziridine **2** was observed and **1***a* was the major product. If the urethane had been formed by rearrangement of the aziridine, greater yields of the urethane than the aziridine would also have been expected at higher temperatures. The results suggest that the urethane and aziridine are formed either from different species or from the same species but by different mechanisms. The aziridine **2** may arise via a nitrene mechanism, since at the higher temperatures of its formation, decomposition of ethyl azidoformate will be enhanced, and in turn will lead to an increased rate of nitrene formation and a higher yield of aziridine. On the other hand, it appears unlikely that urethane formation, particularly at low temperatures, involves the participation of nitrenes. Alternatively, the urethane and the aziridine could both be formed from an intermediate triazoline formed by 1,3-dipolar cycloaddition of the azide followed by, because of different temperature coefficients for the two competing reactions, different modes of decomposition of the triazoline at different temperatures.[1]

The formation of the oxazole **11***c* may be explained in terms of a 1,3-dipolar addition of carbethoxynitrene to the quinone double bond to yield an oxazoline derivative and its subsequent dehydrogenation. Oxazole formation by [2 + 0] addition of carbethoxynitrene (1,2-addition) followed by a 1,3-shift is also a possibility. These suggest the need for the presence of a polarized double bond for the formation of oxazole or oxazoline derivatives by 1,3-dipolar

[1]We are grateful to the referees for helpful suggestions on triazoline mechanisms.

addition of carbethoxynitrene. Thus the absence of oxazoline or oxazole derivative in the reaction of 1,4-naphthoquinone may be due to the symmetrical nature of the quinone ring double bond which lacks the tendency to behave as a strong dipolarophile required for such 1,3-dipolar reactions. These results are in agreement with the facile formation of 1,3,4-oxadiazole from the aliphatic nitriles and carbethoxynitrenes (18) and the lack of formation of oxazoline or oxazole derivatives from cyclohexene (19). The reverse will be expected for the formation of the aziridine. This is indicated by the non-occurrence of aziridine in the 1,2-naphthoquinone reaction and it being a major product in the case of 1,4-naphthoquinone. A mechanism involving 1,3-dipolar addition of the azide to the quinone followed by loss of nitrogen and subsequent oxidation of the oxazoline derivative will also lead to oxazole formation, but it is difficult to differentiate between these mechanisms experimentally here.

Both ethyl carbamate and diethyl hydrazodicarboxylate require triplet carbethoxynitrene in their formation (19). The lack of formation of ethyl carbamate in the 1,2- and 1,4-naphthoquinone reactions suggests that the formation of diethyl hydrazodicarboxylate in these reactions did not involve triplet carbethoxynitrene, otherwise some ethyl carbamate formation would also have been observed as in the reaction of 2-methoxy-1,4-naphthoquinone.

Experimental

Melting points were observed with a Kofler block and are uncorrected. Analyses were performed by the Australian Microanalytical service, Melbourne, Australia. Infrared spectra were recorded on a Perkin-Elmer model 137E spectrophotometer using samples in potassium chloride discs. Nuclear magnetic resonance samples were obtained on Varian HR 60 and HA 100 spectrometers and mass measurements were obtained with the A.E.I. M59 spectrometer. Unless otherwise stated light petroleum ether refers to the boiling range 60–80°C fractions.

Thermolysis of Ethyl Azidoformate with 1,4-Naphthoquinone

A mixture of the quinone (1.0 g) and ethyl azidoformate (6.0 g) was heated at 80°C for 24 h. The products of nine such batches were combined and the excess ester removed by distillation under reduced pressure. The residue was dissolved in chloroform, and chromatography on silica gel, using elution with benzene, then benzene with greater concentrations of chloroform gave, in order of elution, 1,4-naphthoquinone, triethyl nitrilotricarboxylate (**8**), di-1,4-naphthoquinone-2-yl (**7**), compound **5**, ethyl (1,4-naphthoquinone-2-yl)carbamate (**1***a*); 3,4-benzo-7-ethoxycarbonyl-7-azabicyclo[4.1.0]-hept-3-ene-2,5-dione (**2**); 4,5-benzo-1-oxa-2-aza-2-ethoxycarbonylspiro[2.5]octa-4,7-diene-6-one (**3***a*); 1,4-naphthoquinone monooxime (**1***c*); 2-(*N*-ethoxycarbonylaminomethylene)indan-1,3-dione (**4**), diethyl 1,4-naphthoquinone-2,3-dicarbamate (**1***b*), compound **6**, and diethyl hydrazodicarboxylate (**10**).

The reaction was also investigated at 80°C under nitrogen, at 60–65°C and 100–103°C. Yields of the various products are shown in Table 1.

Triethyl nitrilotricarboxylate (**9**) was purified by distillation under reduced pressure (1 Torr) when the fraction distilling at 102–105°C was collected (lit. (20) bp 146–147°C/12 Torr). The infrared and nmr spectra of this compound were identical with those of an authentic specimen.

Di-1,4-naphthoquinone-2-yl (**8**) crystallized from ethanol in yellow plates, mp 270°C (lit. (21) mp 273–274°C). It was found to be identical in all respects with an authentic specimen.

Compound **5** crystallized first from a mixture of benzene and petroleum ether and then from ethanol in colourless needles, mp 108–108.5°C. *Anal.* calcd. for $C_{13}H_{11}NO_6$: C 56.32, H 4.00, N 5.05; found: C 56.25, H 4.16, N 5.11. Infrared ν_{max} (cm^{-1}): 1751, 1701, 1610 nmr ($CDCl_3$) δ 7.63–8.38 (m, 4H, A_2B_2 system), 6.34 (s, 1H), 5.75 (s, 1H), 1.37 (t, 3H, J = 7 Hz), 4.35 (q, 2H, J = 7 Hz).

Ethyl (1,4-naphthoquinone-2-yl)carbamate (**1***a*) crystallized from ethanol as yellow plates, mp 163.5°C. *Anal.* calcd. for $C_{13}H_{11}NO_4$: C 63.67, H 4.52, N 5.71; found: C 63.47, H 4.76, N 5.73. *Mol. Diethyl hydrazodicarboxylate (**10**) crystallized from benzene as colourless needles, mp 133°C (lit. (23) mp 133–134°C). The ir and nmr spectra of this compound were identical with those of an authentic specimen. A mixture melting point with the authentic specimen was undepressed.

Reaction of Compound 5 with Zinc Dust and Water

The compound (**5**) (100 mg) was refluxed with zinc dust (100 mg) and water (5 ml) for 30 min. After cooling, the filtrate was acidified with dilute hydrochloric acid and then extracted with ether (3 × 30 ml). The combined ether extracts were washed with water (2 × 30 ml) and dried overnight over anhydrous magnesium sulphate. Evaporation of the ether and crystallization of the residue from petroleum ether yielded ethyl (2-hydroxy-1,4-naphthoquinone-3-yl) carbamate (2 mg). The residue, after removal of ethyl (2-hydroxy-1,4-naphthoquinone-3-yl)carbamate was chromatographed over silica packed in benzene. Elution with benzene, benzene–chloroform (9:1, v:v), and chloroform yielded a yellow gum which could not be crystallized.

Hydrolysis of Ethyl (1,4-Naphthoquinone-2-yl)carbamate (1a) with Sodium Hydroxide

The urethane (100 mg) was heated with 10% sodium hydroxide solution (8 ml) on a steam bath for 30 min. The orange solution was cooled, acidified with dilute hydrochloric acid, and extracted with ether (4 × 40 ml). The yellow ether solution was washed with water (10 ml) and then dried over anhydrous magnesium sulphate. Evaporation yielded a yellow solid residue which crystallized from ethanol to give 2-hydroxy-1,4-naphthoquinone (65 mg), mp 192°C (lit. (24) mp 192°C).

Reaction of 3,4-Benzo-7-ethoxycarbonyl-7-azabicyclo-[4.1.0]hept-3-ene-2,5-dione (2) with Acetic Acid

The aziridine (100 mg) was refluxed with glacial acetic acid (10 ml) for 6 h on an oil bath. The acid was then evaporated and the residue was crystallized from ethanol to give ethyl (1,4-naphthoquinone-2-yl)carbamate (15 mg). Evaporation of the alcohol yielded starting material (75 mg).

When the above reaction was carried out over 15 h there was no change in the nature of the products, although the relative yields of the urethane (55 mg) to the aziridine (35 mg) were changed.

Reaction of 3,4-Benzo-7-ethoxycarbonyl-7-azabicyclo-[4.1.0]hept-3-ene-2,5-dione (2) with Concentrated Sulfuric Acid

Concentrated sulfuric acid (1 ml) was added slowly with shaking over 10 min to the aziridine (300 mg); the colour of the reaction mixture became reddish brown. The shaking was continued for another 30 min and then the reaction mixture was poured over ice. A yellow solid separated out on agitation. This was chromatographed over silica gel as usual to give ethyl (1,4-naphthoquinone-2-yl)carbamate (150 mg) and ethyl (2-hydroxy-1,4-naphthoquinone-2-yl)carbamate (30 mg). The latter was crystallized from ethanol mp 173–174°C. *Anal.* calcd. for $C_{13}H_{11}NO_5$: C 59.77, H 4.24, N 5.36; found: C 59.58, H 4.36, N 5.47. Infrared ν_{max} (cm^{-1}): 3247, 2564, 1669, 1616; nmr ($CDCl_3$): δ 7.41–8.30 (m, 4H), 7.79 (s, NH), 11.82 (s, OH), 1.37 (t, 3H, J = 7 Hz), 4.32 (q, 2H, J = 7 Hz).

Alkaline Hydrolysis of Ethyl (2-Hydroxy-1,4-naphthoquinone-3-yl)carbamate 1e

Ethyl (2-hydroxy-1,4-naphthoquinone-3-yl)carbamate (50 mg) was heated with 10% sodium hydroxide solution (5 ml) on a steam bath for 30 min. The colour of the solution became deep blue. The solution was cooled and acidified with dilute acetic acid to give a deep red solution. It was extracted with ether (3 × 40 ml) and the combined ether extracts were washed with water (2 × 20 ml) and then dried over anhydrous magnesium sulphate. The ether was evaporated on a rotary evaporator and the residue was crystallized from ethanol to give dark brown red needles of 3-amino-2-hydroxy-1,4-naphthoquinone (25 mg) darkening above 138°C (lit. (25) 130–140° dec.). *Mol. Wt.* calcd. for $C_{10}H_7NO_3$: 189.04258; found: 189.04228. Infrared ν_{max} (cm^{-1}): 3472, 3333, 1661 (sh), 1650, 1608; The nmr spectrum (100 MHz, DMSO-d_6) δ 9.48 (s, OH), 7.50–7.98 (m, 4H), 5.90 (s, 2NH).

Reaction of 3,4-Benzo-7-carbethoxy-7-azabicyclo[4.1.0]-hept-3-ene-2,5-dione (2) with Dilute Hydrochloric Acid

The aziridine (200 mg) was added to a 50 ml flask containing aqueous ethanolic hydrochloric acid solution (6 ml concentrated hydrochloric acid and 3 ml ethanol) and the mixture refluxed for 2 h. The solution was cooled and the yellow crystalline compound was collected. This was identified as ethyl (1,4-naphthoquinone-2-yl)carbamate from its melting point (161°C) and infrared spectrum. Yield 120 mg (60%).

The filtrate was concentrated on a rotary evaporator and the residue crystallized from ethanol to give 2-hydroxy-1,4-naphthoquinone (20 mg).

Reaction of 4,5-Benzo-1-oxa-2-aza-2-ethoxycarbonylspiro-[2,5]octa-4,7-diene-6-one (3a) with Acetic Acid

The oxazirane (100 mg) was refluxed with glacial acetic acid (6 ml) for 10 h. The acetic acid was then removed on a rotary evaporator. The residue was heated with petroleum ether (2 × 30 ml) and the solution filtered. The filtrate was cooled to give *N*-carbethoxy-1,4-naphthoquinone monoimine-*N*-oxide (**1***d*, 20 mg) in pale yellow needles, mp 104°C. *Anal.* calcd. for $C_{13}H_{11}NO_4$: C 63.67, H 4.52, N 5.71; found: C 63.51, H 4.90, N 5.65.

Infrared ν_{max} (cm^{-1}): 1786, 1667, 1592; nmr ($CDCl_3$) δ 7.92 (d, 1H, J = 10 Hz), 6.74 (d, 1H, J = 10 Hz), 7.57–7.73 (m, 2H), 8.40 (m, 1H), 8.17 (m, 1H), 1.46 (t, 3H, J = 7 Hz), 4.41 (q, 2H, J = 7 Hz).

The residue insoluble in petroleum was dissolved in benzene and filtered. 1,4-Naphthoquinone monooxime (10 mg), identified as above, crystallized from the cooled solution.

The solvent from the filtrate left after the crystallization of the oxime was evaporated on a rotary evaporator and the residue crystallized from methanol to give the starting material (30 mg).

*Chromatography of Pure 4,5-Benzo-1-oxa-2-aza-2-ethoxycarbonylspiro[2,5]octa-4,7-diene-6-one (**3a**)*

The oxazirane (50 mg) was dissolved in benzene and chromatographed over silica gel. Elution with benzene and benzene–chloroform (9:1, v:v) yielded 5 mg of 1,4-naphthoquinone monooxime along with the starting material.

*Reaction of N-Carbethoxy-1,4-naphthoquinone monoimine-N-oxide (**1d**) with Acetic Acid*

The nitrone (30 mg) was refluxed with glacial acetic acid (6 ml) for 10 h. The acetic acid was evaporated on a rotary evaporator and the residue was crystallized from benzene to give 1,4-naphthoquinone monooxime (15 mg).

*Alkaline Hydrolysis of 2-(N-Carbethoxyaminomethylene)indan-1,3-dione (**4**)*

2-(*N*-Carbethoxyaminomethylene)indan-1,3-dione (20 mg) was heated with 10% sodium hydroxide solution (5 ml) on a steam bath for 30 min. The reaction mixture was cooled, acidified with dilute hydrochloric acid, and extracted with ether (3 × 30 ml). The combined ether extracts were washed with water (2 × 30 ml) and dried over anhydrous magnesium sulphate. The ether was evaporated and the residue crystallized from petroleum ether to give indan-1,3-dione-2-aldehyde as pink crystals, mp 141°C (lit. (26) mp 141–142°C). The infrared and nmr spectra of this compound were identical with those of an authentic sample of indan-1,3-dione-2-aldehyde. A mixture melting point with the authentic specimen was also undepressed.

*Alkaline Hydrolysis of Diethyl-1,4-naphthoquinone-2,3-dicarbamate (**1b**)*

The diurethane (100 mg) was heated with 10% sodium hydroxide solution (5 ml) on a steam bath for 30 min. The colour of the solution became deep blue. The solution was cooled and then acidified with dilute acetic acid to give a deep red solution. It was extracted with ether (3 × 30 ml) and the combined ether extracts were washed with water (40 ml) and then dried over anhydrous magnesium sulphate. The ether was evaporated and the solid thus obtained was crystallized from ethanol to give 3-amino-2-hydroxy-1,4-naphthoquinone (35 mg).

*Attempted Thermal Isomerisation of 3,4-Benzo-7-ethoxycarbonyl-7-azabicyclo[4.1.0]hept-3-ene-2,5-dione (**2**)*

The aziridine (100 mg) was refluxed with benzene (50 ml) for 72 h. The benzene was evaporated and the residue chromatographed over a silica gel column in benzene to give the starting material. No urethane could be detected.

Similarly when the aziridine was refluxed in cyclohexene for 72 h or heated in veratrole to 130°C for 48 h, only starting material was obtained.

*Reaction of Ethyl (1,4-Naphthoquinone-2-yl)carbamate (**1a**) with Ethyl Azidoformate*

The urethane (400 mg) and ethyl azidoformate (5 g) were heated together at 85°C for 8½ h with occasional swirling. The unreacted ethyl azidoformate was removed by distillation under reduced pressure and the residue was chromatographed over silica gel. Elution of the column with benzene, benzene–chloroform (9:1, v:v), and chloroform afforded successively diethyl 1,4-naphthoquinone-2,3-dicarbamate (270 mg) and diethyl hydrazodicarboxylate (80 mg).

*Reaction of Diethylazodicarboxylate (**14**) with 1,4-Naphthoquinone*

Diethylazodicarboxylate (10 g) and 1,4-naphthoquinone (2 g) were heated together at 80°C for 24 h with occasional swirling. The reaction products were dissolved in chloroform and chromatographed over silica gel. Elution with benzene followed by a mixture of benzene–chloroform (9:1, v:v) and finally chloroform yielded successively diethylazodicarboxylate (8 g), 1,4-naphthoquinone (1.965 g) and diethyl hydrazodicarboxylate (150 mg).

When the above reaction was carried out at 60°C for 28 h and the reaction products chromatographed as before diethylazodicarboxylate (8.5 g), 1,4-naphthoquinone (1.97 g), and diethyl hydrazodicarboxylate (140 mg) were obtained.

*Chromatography of the Pure Diethylazodicarboxylate (**14**)*

Diethylazodicarboxylate (5 g) was dissolved in chloroform and then chromatographed over silica gel. Elution with benzene, benzene–chloroform (9:1, v:v), and chloroform afforded diethylazodicarboxylate (4.3 g), an unidentified pale yellow liquid (130 mg), and diethyl hydrazodicarboxylate (70 mg).

Thermolysis of Ethyl Azidoformate with 1,2-Naphthoquinone

Ethyl azidoformate (7.2 g) and 1,2-naphthoquinone (1.0 g) were heated together at 92°C for 8 h. The products of eight such batches were combined, the excess azido ester was removed as before, and the residue was boiled with chloroform (3 × 80 ml) and filtered to give di-1,2-naphthoquinone-4-yl. The chloroform solution was concentrated and chromatography on silica gel with elution by benzene, then benzene with increasing proportions of chloroform, gave successively triethyl nitrilotricarboxylate (**9**) (3.5 g), unchanged 1,2-naphthoquinone (700 mg), ethyl (1,2-naphthoquinone-3-yl)carbamate (**11***a*) (5 mg), ethyl (2-hydroxy-1,4-naphthoquinone-3-yl)carbamate (**1***c*) (20 mg), 2-ethoxynaphtho[1,2-*d*]oxazole-4,5-quinone (**11***c*) (20 mg), 2-ethoxynaphtho[1,2-*d*]oxazole-8,9-quinone (**11***d*) (5 mg), diethyl-1,2-naphthoquinone-3,4-dicarbamate (**11***b*) (120 mg), di-1,2-naphthoquinone-4-yl (**12**) (3 g), and diethyl hydrazodicarboxylate (**10**) (2.5 g).

Ethyl (1,2-naphthoquinone-3-yl)carbamate (**11***a*) crystallized first from a mixture of benzene and petroleum ether and then from ethanol to give violet needles, mp 148°C. *Anal.* calcd. for $C_{13}H_{11}NO_4$: C 63.67, H 4.52, N 5.71; found: C 63.82, H 4.57, N 5.59. Infrared ν_{max} (cm^{-1}): 3300, 1721, 1692(sh), 1672, 1623; nmr ($CDCl_3$)

δ 7.18–7.6 (m, 4H including NH at 7.21), 7.94 (s, 1H), 7.97 (q, 1H, J = 7 and 2 Hz), 1.33 (t, 3H, J = 7 Hz, 4.23 (q, 2H, J = 7 Hz).

2-Ethoxynaphtho[1,2-*d*]oxazole-4,5-quinone (**11***c*) crystallized first from benzene and then from ethanol, mp 195°C. *Anal.* calcd. for $C_{13}H_9NO_4$: C 64.20, H 3.73; found: C 63.92, H 4.06. Infrared ν_{max} (cm^{-1}): 1675, 1631, 1605; nmr ($CDCl_3$) δ 8.07 (q, 1H, J = 7 and 2 Hz), 7.33–7.74 (m, 3H), 1.51 (t, 3H, J = 7 Hz), 4.64 (q, 2H, J = 7 Hz).

2-Ethoxynaphtho[1,2-*d*]oxazole-8,9-quinone (**11***d*) crystallized from a mixture of benzene and chloroform to give violet rods, mp 235°C (dec.). *Anal.* calcd. for $C_{13}H_9NO_4$: C 64.20, H 3.73; found: C 64.08, H 3.99. Infrared ν_{max} (cm^{-1}): 1685, 1639; nmr (TFA) δ 7.59–7.99 (m, 3H), 8.31 (q, 1H, J = 7 and 2 Hz), 1.72 (t, 3H, J = 7 Hz), 4.93 (q, 2H, J = 7 Hz).

Diethyl 1,2-naphthoquinone-3,4-dicarbamate (**11***b*) crystallized first from benzene and then from ethanol to give orange needles mp 180–181°C. *Anal.* calcd. for $C_{16}H_{16}N_2O_6$: C 57.83, H 4.85, N 8.43; found: C 57.84, H 4.76, N 8.27. Infrared ν_{max} (cm^{-1}): 3205, 1698, 1689(sh), 1667, 1613, 1587; nmr ($CDCl_3$) δ 7.34–7.73 (m, 3H), 8.06 (q, 1H, J = 7 and 2 Hz), 8.68 (s, NH), 7.26 (s, NH), 1.32 (t, 3H, J = 7 Hz), 1.37 (t, 3H, J = 7 Hz), 4.26 (q, 2H, J = 7 Hz), 4.43 (q, 2H, J = 7 Hz).

Di-1,2-naphthoquinone-4-yl (**12**) crystallized twice from chloroform, then from dioxane, and finally from a mixture of chloroform and methanol to give an orange crystalline solid mp 290°C (dec.) (lit. (27) 289–290°C dec.). *Mol. Wt.* calcd. for $C_{20}H_{10}O_4$: 314.0579; found: 314.0580. Infrared ν_{max} (cm^{-1}): 1698, 1667; nmr spectrum (TFA) δ 6.80 (s, 2H), 8.30–8.55 (m, 2H), 7.40–7.96 (m, 6H).

Reaction of 2-Ethoxynaphtho[1,2-d]oxazole-4,5-quinone (11c) with Hydrochloric Acid

The oxazole (10 mg) was heated with 5% hydrochloric acid solution (3 ml) on a steam bath for 15 min and the solution filtered. The residue (2 mg) was found to be the starting material. On cooling the filtrate a yellow crystalline solid (2 mg) separated out which was found to be ethyl (2-hydroxy-1,4-naphthoquinone-3-yl)carbamate. The yellow filtrate on ether extraction yielded a further 2 mg of product.

Reaction of Diethyl 1,2-naphthoquinone-3,4-dicarbamate (11b) with Sodium Hydroxide

The diurethane (50 mg) was heated with 10% sodium hydroxide (2 ml) on a steam bath for 20 min. The reaction mixture immediately turned blue and a blue compound separated out after a few minutes. The solution was cooled and filtered leaving a blue residue. This was washed with water (30 ml) to remove any residual sodium hydroxide and crystallized from methanol to give naphtho[1,2-*d*]imidazolone-4,5-quinone (**11***e*) (30 mg). *Mol. Wt.* calcd. for $C_{11}H_6N_2O_3$: 214.03783; found: 214.03715. Infrared ν_{max} (cm^{-1}): 3145, 3205(sh), 3106(sh), 1678, 1623; nmr spectrum (100 MHz, TFA) δ 10.36 (s, 1H), 8.18 (m, 1H), 7.44–7.88 (m, 3H). The signal for the second NH proton was not observed probably due to the very rapid exchange with the strongly acidic solvent.

Reaction of Diethylazodicarboxylate (14) with 1,2-Naphthoquinone

1,2-Naphthoquinone (1 g) and diethylazodicarboxylate (6 g) were heated together at 90°C for 6 h with occasional swirling. The reaction products were dissolved in chloroform and chromatographed over silica gel. Elution with benzene, benzene–chloroform, and finally with chloroform yielded diethylazodicarboxylate (4.4 g), 1,2-naphthoquinone (0.5 g), and diethyl hydrazodicarboxylate (180 mg).

Thermolysis of Ethyl Azidoformate with 2-Methoxy-1,4-Naphthoquinone

Ethyl azidoformate (9.1 g) and 2-methoxy-1,4-naphthoquinone (1.0 g) were heated together at 94°C for 9 h. The combined products from eight batches were separated as before, by distillation of the unchanged azido ester and chromatography of the residue with elution by benzene, chloroform–benzene, chloroform, and finally chloroform–methanol (19:1, v:v) to give successively ethyl carbamate (**13**) (1.6 g), unchanged 2-methoxy-1,4-naphthoquinone (1.5 g), ethyl (2-methoxy-1,4-naphthoquinone-3-yl)carbamate (**1***f*) (5.0 g), (**3***b*) (480 mg), diethyl hydrazodicarboxylate (**10**) (1.5 g), ethyl (1,2-naphthoquinone-4-yl)carbamate (**14**) (120 mg), and ethyl (2-hydroxy-1,4-naphthoquinone-3-yl)carbamate (90 mg).

Ethyl carbamate (**13**) crystallized from petroleum ether as colourless needles, mp 48°C (lit. (28) mp 48–50°C). Its infrared and nmr spectra were found to be identical with those of an authentic specimen of ethyl carbamate. A mixture melting point with the authentic specimen was also undepressed.

Ethyl (2-methoxy-1,4-naphthoquinone-3-yl)carbamate (**1***f*) crystallized from ethanol in yellow needles, mp 140–141°C. *Anal.* calcd. for $C_{14}H_{13}NO_5$: C 61.09, H 4.76, N 5.09; found: C 60.83, H 4.90, N 5.24. Infrared ν_{max} (cm^{-1}): 3165, 2817(sh), 1718, 1689, 1664, 1618; nmr ($CDCl_3$) δ 7.59–8.14 (m, 4H), 6.84 (s, NH), 4.17 (s, 3H), 1.32 (t, 3H, J = 7 Hz), 4.23 (q, 2H, J = 7 Hz).

Compound **3***b* crystallized from ethanol as pale yellow rods, mp 131–132°C. *Anal.* calcd. for $C_{17}H_{18}N_2O_7$: C 56.35, H 5.01, N 7.73; found: C 56.08, H 4.99, N 7.95. Infrared ν_{max} (cm^{-1}): 3279, 1748, 1724, 1672, 1658, 1613; nmr ($CDCl_3$) δ 7.68–8.18 (m, 4H), 7.23 (s, NH), 4.48 (s, 3H), 1.28 (t, 6H, J = 7 Hz), 4.07–4.37 (m, 4H).

Ethyl (1,2-naphthoquinone-4-yl)carbamate (**11***f*) crystallized from chloroform as orange rectangular plates decomposing at 205°C. *Anal.* calcd. for $C_{13}H_{11}NO_4$: C 63.67, H 4.52, N 5.71; found: C 63.44, H 4.45, N 5.40. Infrared ν_{max} (cm^{-1}): 3257, 1727, 1686, 1629(sh), 1618; nmr (DMSO-d_6) δ 7.56–8.19 (m, 4H), 7.10 (s, 1H), 9.98 (s, NH), 1.34 (t, 3H, J = 7 Hz), 4.27 (q, 2H, J = 7 Hz).

Reaction of Ethyl (2-Methoxy-1,4-naphthoquinone-3-yl)carbamate (1f) with Sodium Carbonate

The urethane (20 mg) was heated with 10% sodium carbonate solution (10 ml) on a steam bath until the solution turned red. The solution was cooled and acidified with dilute hydrochloric acid to give ethyl (2-hydroxy-1,4-naphthoquinone-3-yl)carbamate (13 mg).

Alkaline Hydrolysis of Ethyl (1,2-Naphthoquinone-4-yl)carbamate (11f)

The urethane (20 mg) was heated with 10% sodium hydroxide (5 ml) on a steam bath for 15 min. The solution was cooled, acidified with dilute hydrochloric acid, and then extracted with ether (3 × 30 ml). The combined ether extracts were washed with water (10 ml) and then dried over anhydrous magnesium sulphate. The ether

was evaporated and the yellow residue crystallized from ethanol to give 2-hydroxy-1,4-naphthoquinone.

*Preparation of Ethyl (1,2-Naphthoquinone-4-yl)carbamate (**11f**)*

To a mixture of 4-amino-1,2-naphthoquinone (200 mg), pyridine (2 ml), and acetonitrile (70 ml) was added ethyl chloroformate (240 mg) dropwise with constant shaking over 15 min. The solution was shaken for a further 2 h and then refluxed on a steam bath for 1½ h. Cooling and filtration of the solution yielded a violet solid which was found to be unreacted 4-amino-1,2-naphthoquinone. The filtrate was evaporated to dryness and the solid residue from this crystallized from chloroform to give ethyl (1,2-naphthoquinone-4-yl)carbamate (160 mg) in 62% yield.

*Attempted Synthesis of Ethyl (2-Methoxy-1,4-naphthoquinone-3-yl)carbamate (**1f**) and Ethyl (1,2-Naphthoquinone-4-yl)carbamate (**11f**) from 2-Methoxy-1,4-naphthoquinone and Ethyl Carbamate*

2-Methoxy-1,4-naphthoquinone (2 g) and ethyl carbamate (1.5 g) were refluxed in toluene for 48 h. The solvent was evaporated on a rotary evaporator and the residue was dissolved in chloroform and chromatographed over silica gel. Elution with a mixture of benzene–chloroform (9:1, v:v), chloroform, and finally with chloroform–methanol (19:1, v:v), yielded only the starting materials.

*Chromatography of the pure Ethyl (2-Methoxy-1,4-naphthoquinone-3-yl)carbamate (**1f**)*

Ethyl (2-methoxy-1,4-naphthoquinone-3-yl)carbamate (2 g) was dissolved in chloroform and chromatographed over silica gel. Elution with a mixture of benzene–chloroform (9:1, v:v), followed by chloroform, and finally with a mixture of chloroform–methanol (19:1, v:v) yielded the starting material along with a small amount of ethyl (2-hydroxy-1,4-naphthoquinone-3-yl)carbamate (7 mg).

Synthesis and photochemistry of 4,4-diphenyl-γ-pyran. Di-π-methane rearrangement in a new chromophore

DENIS GRAVEL, CHRISTIAN LEBOEUF,[1] AND SERGE CARON

Département de Chimie, Université de Montréal, C.P. 6210, Montréal (Qué.), Canada H3C 3V1

Received January 10, 1977

DENIS GRAVEL, CHRISTIAN LEBOEUF, and SERGE CARON. Can. J. Chem. **55**, 2373 (1977).

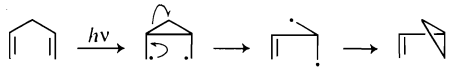
A synthesis of 4,4-diphenyl-γ-pyran (**1**) was elaborated from diphenylmethane. Prolonged irradiation of pyran **1** in *tert*-butyl alcohol led to: *trans-endo*-5,6-diphenyl-2-oxabicyclo[3.1.0]-hexene (**18**), isomeric 3,5-diphenylpenta-2,4-dienals (**6**), *trans-tert*-butyl 3,5-diphenylpent-2-enoate (**7**), *cis-tert*-butyl 3,5-diphenylpent-2-enoate (**8**), and isomeric 3,5-diphenylpent-2-enoic acids (**9**). It was established that the photolysis of γ-pyran **1** yields only one primary photoproduct: the oxabicyclo[3.1.0]hexene derivative **18** via a di-π-methane rearrangement. The other compounds isolated result from further irradiation of the primary product. The results observed are discussed in the light of the di-π-methane rearrangement mechanism.

DENIS GRAVEL, CHRISTIAN LEBOEUF et SERGE CARON. Can. J. Chem. **55**, 2373 (1977).

Une synthèse du diphényl-4,4 γ-pyranne a été élaborée à partir du diphénylméthane. L'irradiation prolongée du pyranne **1**, en solution dans le *tert*-butanol, conduit au: diphényl-5,6-*trans-endo* 2-oxabicyclo[3.1.0]hexène (**18**), diphényl-3,5 pentadièn-2,4 als (**6**) isomères, diphényl-3,5 pentèn-2 oate de *tert*-butyle-*trans* (**7**), diphényl-3,5 pentèn-2 oate de *tert*-butyle-*cis* (**8**) et acides diphényl-3,5 pentènoïques (**9**) isomères. Il fut de plus établi que la photolyse du γ-pyranne **1** conduit à un seul photoproduit primaire: le dérivé oxabicyclo[3.1.0]hexène **18**, via un réarrangement di-π-méthane. Les autres produits isolés résultent tous de l'irradiation subséquente du photoproduit primaire. Les résultats observés sont discutés à la lumière du mécanisme du réarrangement di-π-méthane.

Introduction

Few photochemical reactions have been studied so extensively as the di-π-methane rearrangement (for the latest major contributions to appear in the field see ref. 1*a*,*b*; for a review see ref. 1*c*). This reaction which occurs on photolysis of compounds having two π moieties bonded to a single sp^3-hybridized carbon atom is an extremely general process. It formally involves the migration of one π moiety from the saturated carbon atom to the adjacent sp^2-hybridized carbon atom of the second π moiety with concomitant formation of a three-membered ring (1*c*). Zimmerman, who first named the rearrangement, noted that the skeletal change could be accounted for by one basic qualitative mechanism which is represented below (1*c*).[2]

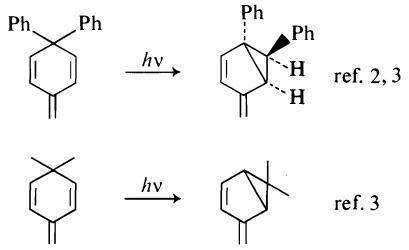


[1]Predoctoral Fellow, Ministère de l'éducation du Québec and National Research Council of Canada: 1973–1977.

[2]It is important to note that the π systems, here represented by vinyl groups, may alternatively include phenyl or carbonyl groups.

The great number of investigations of this rearrangement, largely due to Zimmerman and his co-workers, eventually led to a detailed understanding of (*i*) how the structure affects the excited state multiplicity by which the di-π-methane rearrangement proceeds; (*ii*) how the nature of the substituents on the π moieties controls the regiospecificity of the rearrangement; and (*iii*) the preferred rearrangement stereochemistry (1*c*).

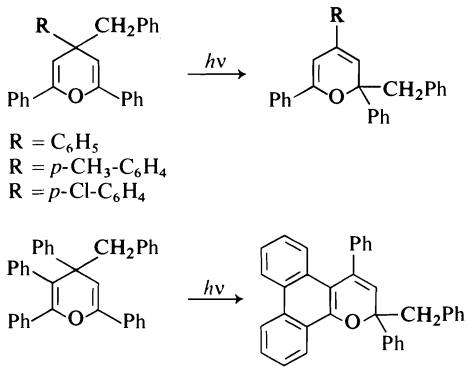
In those cases where the di-π-methane system is comprised in a six-membered ring, the reaction leads to formation of a bicyclo[3.1.0] derivative as shown. When the sp^3-hybridized carbon



bears phenyl groups (which add additional di-π-methane arrangements to the system) the product is formed through phenyl–vinyl bonding

with concomitant phenyl migration, whereas in the case of *gem*-dimethyl substitution the product is formed through vinyl–vinyl bonding.

We were interested in studying some cyclic di-π-methane systems where the two π moieties in the ring would be joined by a heteroatom. Such models should provide further tests to the generality of the rearrangement, provide further insight into its mechanism, and also give access to new hetero bicyclo[3.1.0] systems and their chemistry. To our knowledge the photochemistry of 4,4-disubstituted γ-pyrans has been studied by two groups only (4, 5) and in both instances the compounds studied were of the 4-aryl-4-benzyl type and the sole behavior observed was the isomerization to the corresponding α-pyran with concomitant 1–3-benzyl migration by a probable sigmatropic mechanism. Specific examples are represented in Scheme 1.

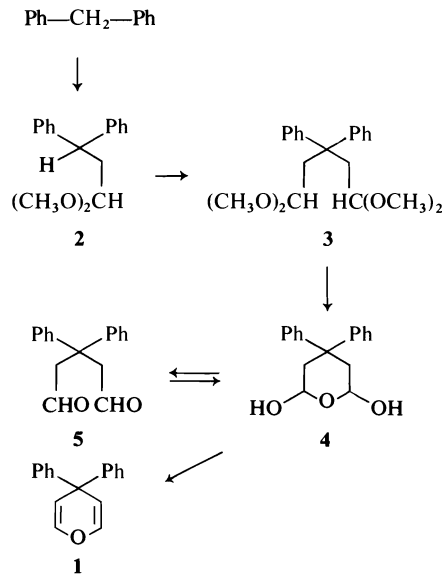


SCHEME 1. Photoisomerization of γ-pyrans to α-pyrans.

In our case, the first model chosen for study was 4,4-diphenyl-γ-pyran (**1**) which should not present the problem of 1–3 sigmatropic shifts.

Synthesis of the Title Compound 1

The synthesis of 4,4-diphenyl-γ-pyran (**1**) was devised starting from diphenylmethane as outlined in Scheme 2. A first alkylation (6) of the anion of diphenylmethane in liquid ammonia using 1,1-dimethoxy-2-chloroethane gave the corresponding 1,1-dimethoxy-3,3-diphenylpropane (**2**) in 67% yield. A second alkylation (6) using the same conditions afforded the tetramethoxy diacetal of 3,3-diphenylglutaraldehyde (**3**) in 50% yield. Hydrolysis of the diacetal **3** in 2 *N* sulfuric acid led to a quantitative yield of an insoluble white powder which appeared to be the hemihydrate of the desired 3,3-diphenylglutaraldehyde (**4**). Although the mass spectrum showed a molecular ion peak at *m/e* 252 which



SCHEME 2. Synthesis of 4,4-diphenyl-γ-pyran (**1**).

corresponds to the dialdehyde, the ir showed hydrogen bonded hydroxyl absorption at 3190 and 3290 cm^{-1} and no carbonyl absorption. The nmr spectrum in DMSO-d_6 was also very revealing in that it showed a well resolved ABMX system where only the A proton showed appreciable coupling to the M proton. The A portion appeared as a pair of doublets centered at 1.68 ppm with J_{AB} = 12.5 Hz and J_{AM} = 10 Hz. The B portion appeared as a doublet at 2.91 ppm with J_{AB} = 12.5 Hz. The M portion of the system appeared as a doublet of doublets centered at 4.65 ppm with J_{AM} = 10 Hz and J_{MX} = 7.5 Hz, due to coupling with the hydroxylic proton. In fact, the addition of D_2O caused the doublet of doublets to collapse to a doublet with J_{AM} = 10 Hz. The X portion of the system, attributed to the hydroxylic proton, appeared as a doublet at 6.48 ppm with J_{MX} = 7.5 Hz; this signal disappeared upon addition of D_2O. Final verification of these assignments was obtained by irradiating the M portion of the system and observing the A proton doublet of doublets collapse to a doublet (J_{AB} = 12.5 Hz). Since the B proton was not appreciably coupled to the M proton the dihedral angle between the two must be close to 90° (7).

In order to chemically substantiate our proposal of the stable crystalline hemihydrate **4**, the compound was heated slightly above its melting point under vacuum for 10 min and the nmr spectrum of the resulting yellowish oil

recorded and shown to be in perfect accord with that expected of 3,3-diphenylglutaraldehyde (**5**). Furthermore, the reverse reaction, *ie* the addition of water, was easily accomplished when the dialdehyde **5** obtained above was heated at 100°C for 30 min in a mixture of DMSO and 10% HCl, 20:1, and the resulting solution diluted with cold water to give hemihydrate **4** as a precipitate whose physical and spectroscopic properties proved identical to those of the original hemihydrate.

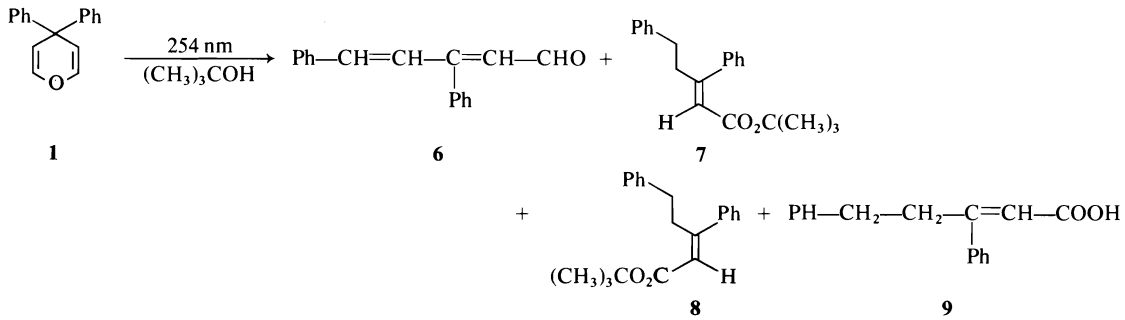
Having demonstrated to a satisfactory degree of confidence the fact that dialdehyde **5** existed in the form of a hemihydrate (**4**) we proceeded to eliminate 2 mol of water from the compound by treating it with tosyl chloride in pyridine at 140°C (8). The product obtained in an 80% yield was shown unambiguously by ir, nmr, uv, and mass spectrometry to be the desired 4,4-diphenyl-γ-pyran (**1**) (see Experimental).

Preparative Scale Photolysis and Spectroscopic Characterization of Photoproducts

The ultraviolet irradiation during 20 h and at 254 nm of 500 ml of a 4.2×10^{-3} *M* solution of 4,4-diphenyl-γ-pyran (**1**) in anhydrous *tert*-butyl alcohol led to a mixture of at least five products as evidenced by thin layer chromatography (tlc). Separation of the mixture was carried out using preparative scale tlc on silica gel. In increasing order of polarity the products isolated were (see Scheme 3): starting material **1** (11%); 3,5-diphenylpentadienal (**6**) (7%), as a mixture of isomers which we did not attempt to separate; *tert*-butyl *trans*-3,5-diphenylpent-2-enoate (**7**) (15%); *tert*-butyl *cis*-3,5-diphenylpent-2-enoate (**8**) (9%) and 3,5-diphenylpent-2-enoic acid (**9**) (8%), as a mixture of *cis* and *trans* isomers. A 13% yield of a highly polar yellow oil was also isolated but not characterized.

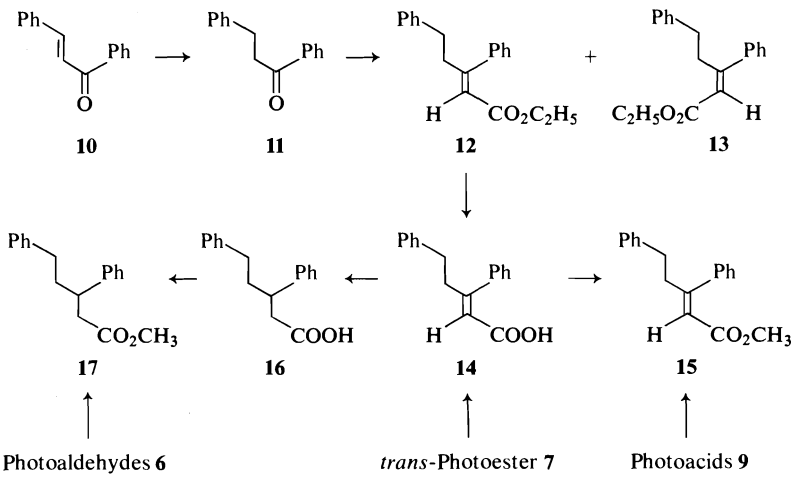
The unsaturated aldehyde **6** was characterized by its mass spectrum which showed a molecular ion at *m/e* 234 (100%) and an important peak (62%) at *m/e* 205 for the loss of CHO, thus showing the product was an isomer of the starting material and was probably an aldehyde. In the ir the product showed the characteristic absorption of an unsaturated carbonyl at 1665 cm^{-1} along with vinyl and aryl absorption at 1610 cm^{-1}. The nmr spectrum showed complex absorption in the vinyl and aryl regions (13H), *i.e.* from 5.8 to 7.5 ppm and two doublets (1H) at 9.2 and 10.0 ppm ascribable to isomeric aldehydes in the mixture. Finally, the uv spectrum had a λ_{max} at 315 nm (ε 1200) with long wavelength absorption extending into the visible, characteristic of extended conjugation. These results, however, give no clue as to the relative position of the phenyl groups on the carbon chain, a point of vital importance in the rearrangement. A definitive and final proof of structure was therefore established by chemical correlation as will be shown below.

The *tert*-butyl ester **7**, on the other hand, could be characterized much more satisfactorily with spectroscopic techniques. The mass spectrum showed a molecular ion at *m/e* 308 indicating the product results from the addition of solvent to an isomer of the starting material, probably a ketene. Fragment ions at $M - 56$, $(M - 56) - 45$, and $(M - 56) - 17$ indicate, respectively, the loss of $(CH_3)_2C{=}CH_2$ by McLafferty rearrangement of a *tert*-butyl ester (9) followed by the loss of COOH or OH. The base peak at *m/e* 91 is characteristic of a $PhCH_2$— moiety in the structure. The ir spectrum showed an intense absorption at 1705 cm^{-1} indicating an α,β-unsaturated ester. In the nmr, a singlet (9H) at 1.55 ppm confirmed the presence of a *tert*-butyl group attached to an oxygen



1 **6** **7** **8** **9**

SCHEME 3. Preparative scale photolysis of 4,4-diphenyl-γ-pyran (**1**).



SCHEME 4. Synthesis of reference compounds and structure correlations.

atom. A symmetrical multiplet (5H) extending from 2.5 to 3.6 ppm could represent the AA′MM′ portion of an AA′MM′X system such as $PhCH_2CH_2—C(=CH—)$. A singlet (1H) at 6.0 ppm is characteristic of a vinyl proton. Finally, two broad singlets (10H) at 7.28 and 7.45 correspond to the aromatic protons. The stereochemical arrangement about the trisubstituted double bond was unambiguously established by nOe experiments (10): irradiation of the methylene signal at 3.37 (downfield portion of the AA′MM′ part of the AA′MM′X system) caused an increase in intensity of 11 to 13% of the vinyl proton signal at 6.00 ppm (X portion of the AA′MM′X system). As will be shown below the other stereoisomeric ester showed no noticeable nOe effect.

Complete characterization of *tert*-butyl ester **8** was also possible using spectroscopic techniques. The mass spectrum and the ir spectrum were characteristic and similar to those of ester **7** (see Experimental). The nmr spectrum on the other hand showed the *tert*-butyl group as a singlet at 1.28 ppm and the AA′MM′ portion of the AA′MM′X system as a deceptively simple widened singlet at 2.76 ppm. This hypothesis was substantiated by the progressive addition of small amounts of $Eu(fod)_3$ to the nmr sample solution (11) and the observation of the evolution from a deceptively simple singlet to a more complex pattern similar to that observed in the case of the other isomer. The vinyl proton appeared as a singlet at 5.93 ppm and the aromatic protons as a broad singlet at 7.34 ppm. Again in this case, nOe experiments (10) were conclusive in showing the stereochemistry about the double bond; indeed, irradiation of the deceptively simple signal at 2.76 ppm caused no noticeable increase in intensity of the singlet at 5.93 ppm while such experiments had caused an 11 to 13% increase in the intensity of the vinyl proton signal in the case of ester **7**.

The diphenylpentenoic acid (**9**) was isolated as a mixture of *cis* and *trans* isomers and was characterized as such. In the ir, characteristic absorptions appeared at 3500, 1725, and 1620 cm^{-1}. In the nmr, the allylic and benzylic methylenes appeared as a multiplet between 2.50 and 3.60 ppm, the vinyl proton as a singlet at 5.90, the aryl protons as a multiplet at 6.80 and 7.80 ppm, and finally the carboxyl proton as a singlet at 11.00 ppm.

Synthesis of Reference Compounds and Structure Correlations

In order to fully characterize the photoaldehydes isolated and also in order to corroborate the structures of the photoacids and esters obtained, the unambiguous synthesis of authentic reference compounds was carried out (see Scheme 4).

A mixture of authentic *trans*- and *cis*-ethyl 3,5-diphenylpent-2-enoate (**12** and **13**) was obtained from chalcone (**10**) by first reducing it to dihydrochalcone (**11**) (12) and then treating it with diethylcarbethoxymethylphosphonate in the presence of sodium hydride (13). Separation of the mixture by preparative tlc yielded samples

of authentic *trans*- and *cis*-ethyl 3,5-diphenylpent-2-enoate (**12** and **13**). Total yield of esters 35%.

Saponification of the *trans* ester **12** using potassium hydroxide in ethanol yielded 75% of recrystallized *trans* acid **14**. This authentic acid was used as reference material in all three chemical correlations to be described below.

Structure Correlation of the trans Photoester 7

Treatment of *tert*-butyl ester **7** with a catalytic amount of *p*-toluenesulfonic acid in refluxing benzene (14) yields a carboxylic acid which is identical in all respects with the authentic *trans* acid **14**.

Structure Correlation of the cis–trans Mixture of Photoacids 9

The reference acid **14** was first esterified with diazomethane (15) to yield authentic methyl ester **15** which was compared by vpc, using two different columns, to the mixture of methyl esters obtained by treating photoacids **9** with diazomethane.

Structure Correlation of Photoaldehydes 6

Authentic methyl 3,5-diphenylpentanoate (**17**) was first prepared from the unsaturated reference acid **14** by catalytic hydrogenation (16) followed by esterification with diazomethane (15). The mixture of photoaldehydes **6** was oxidized with nickel peroxide (17) to the corresponding mixture of acids which was hydrogenated (16) and then esterified with diazomethane (15) to yield a methyl ester identical to authentic methyl 3,5-diphenylpentanoate.[3]

Isolation and Characterization of the Primary Photoproduct 18

Consideration of the structures presented in Scheme 3 reveals that the expected primary photoproduct, a diphenyl-2-oxabicyclo[3.1.0]-hexene (**18** in Table 1), was not isolated from the photolysis. However, it also suggests that photoaldehyde **6** is possibly formed through thermal or photochemical ring opening of the unobserved primary photoproduct **18**. Finally, it is apparent that should the suggested primary photoproduct be formed it must involve the phenyl–vinyl bonding pathway since photoaldehyde **6** shows one of the phenyl groups migrated.

[3]The comparison was carried out on silica gel tlc plates using three different eluting mixtures and by vpc using two different columns.

TABLE 1. Comparison of nmr data of primary photoproduct **18** with those of pertinent models

Structure	Coupling constants	Reference
 **18**	$J_{1,6} = 7$ $J_{3,4} = 2.5$	This work
	$J_{1,6} = 8.5$ $J_{3,4} = 5.5$	3
	$J_{1,6} = 4$ $J_{3,4} = 5.0$	3
	$J_{1,6} = 9.0$ $J_{3,4} = 5.5$	3
	$J_{1,6} = 8.5$	3
	$J_{1,6} = 9$ $J_{3,4} = 5.50$	18
	$J_{2,3} = 2$	19, 20

This hypothesis was fully verified when a small scale photolysis of diphenylpyran **1** was carried out and the reaction monitored by tlc. It was then possible to isolate a 10% yield of a new product which was characterized as *trans-endo*-5,6-diphenyl-2-oxabicyclo[3.1.0]hexene (**18**). In the nmr this compound showed two typical AB systems, one for the cyclopropyl protons and one for the vinyl protons. The first of these is characterized by a doublet centered at 2.50 ppm ($J = 7$ Hz) for the cyclopropyl proton in the 6-position and a second doublet centered at 4.73 ppm ($J = 7$ Hz) for the cyclopropyl proton in the 1-position. This latter signal shows broadening probably due to long range W coupling with the 3-proton. The second AB system has a doublet centered at 5.10 ppm ($J = 2.5$ Hz) for the vinyl proton in the 4-position and a second doublet centered at

5.96 ppm (J = 2.5 Hz) for the vinyl proton in the 3-position. Again, this latter signal shows broadening most probably due to long range W coupling with the 1-proton.

In view of the fact that only one stereoisomer of the primary photoproduct could be isolated in sufficient amount for characterization[4] and also due to the great importance of the primary photoproduct structure and stereochemistry in establishing the intimate detail of the rearrangement (1*c*) we have included for comparison a table of nmr coupling constants for representative model substances (see Table 1).

It is readily apparent from the table that a typical value for $J_{1,6}$*cis* is of the order of 8.5–9 Hz and that a $J_{1,6}$*trans* is of the order of 4 Hz. The value of 7 Hz observed in the case of primary photoproduct **18** is in excellent agreement with a *cis* arrangement of protons 1 and 6 if one takes into consideration the fact that the oxygen in the 2-position should lower the value of the coupling constant between H-1 and H-6 due to an electronegativity effect not present in the other models included for comparison. The phenomenon of the lowering of vicinal coupling constants by electronegative substituents has been amply demonstrated in the case of substituted cyclopropanes (21) and is well documented in the literature generally (22, 23).

In the case of $J_{3,4}$, the value of 2.5 Hz observed for primary photoproduct **18** is considerably lower than that of 5.5 Hz reported for the carbocyclic model compounds. This lowering of the coupling constant is again attributable to the electronegativity effect of the oxygen atom. This assertion is supported by the value of 2 Hz reported for $J_{2,3}$ in 4,5-dihydrofuran (19, 20, 23).

The fact that the primary photoproduct **18** had not been observed in the original preparative scale photolysis is due in part to the fact that under the tlc conditions used to monitor the reaction and separate the products, the primary photoproduct **18** has the same R_f as the starting material, but mostly to the fact that it was present in very small amount since it is not stable under the conditions of photolysis and subsequent manipulations as we shall see below.

[4]Only once have we been able to observe a compound which is presumably the *cis-exo* isomer. It was isolated by preparative tlc in the usual manner but rearranged almost quantitatively to the known mixture of aldehydes **6** during extraction from the silica gel using a Soxhlet continuous extraction apparatus.

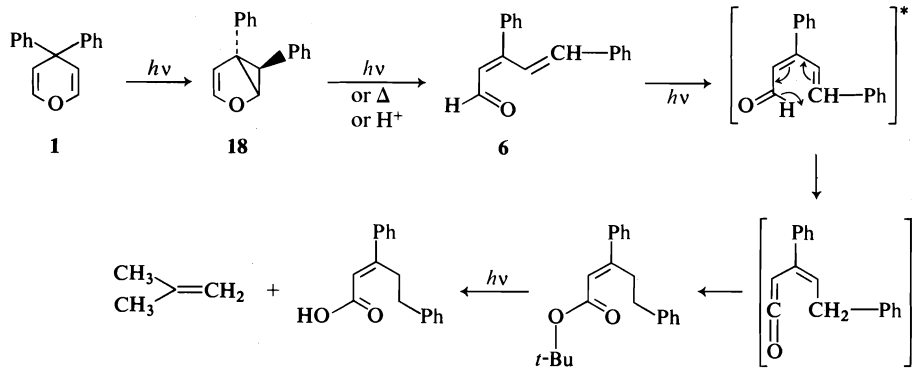
Interrelation Between the Products of Photolysis

In an effort to establish the relationship between the various products formed during photolysis and also to verify that the primary photoproduct **18** isolated was the sole primary product, we carried out the photolysis of each compound isolated (see Scheme 5)

In a first instance, the primary product **18** was applied to three tlc plates (silica gel) and the first plate irradiated for 1 h with 254 nm light; after elution the plate revealed extensive formation of the photoaldehyde **6** already characterized in the preparative scale photolysis, thus showing that aldehyde **6** is possibly formed by subsequent photochemical rearrangement of the bicyclic primary product **18**. The second plate when heated in an oven at 150°C for 10 min showed, after elution, a quantitative rearrangement of the primary product **18** to the photoaldehyde **6**, thus showing that the previously described rearrangement may also be brought about thermally. Finally, the primary product **18** spotted on the third plate showed partial rearrangement to the photoaldehyde **6** when a methanolic solution of *p*-toluenesulfonic acid was applied over the spot and the plate eluted after standing 30 min at room temperature. This result shows that rearrangement of the bicyclic primary product **18** to the aldehyde **6** can not only be initiated photochemically or thermally, but also by acid catalysis.

These findings are, in the end, not surprising in view of the fact that an examination of the literature revealed numerous examples of studies of carbenic additions to furans (24) which show that the 2-oxabicyclo[3.1.0]hex-3-ene initially formed is generally unstable thermally or in presence of acid or photochemically, when the compound has a chromophore with a significant absorption coefficient. In the present case it is therefore readily understandable that the primary photoproduct **18** be unstable and isomerize under the three different sets of conditions to the corresponding open-chain aldehyde **6** as depicted in Scheme 5.

The formation, on the other hand, of esters **7** and **8** during photolysis appears less trivial at first glance, but may be rationalized on the basis of two well known processes. Indeed, it is plausible to envisage that the *tert*-butyl ester is formed by reaction of the solvent on an intermediate ketene which would be formed by a [1,5] sigmatropic shift of the aldehydic hydrogen to the 5 position of the chain. Such photochemical



SCHEME 5. Interrelation between products formed in the photolysis of 4,4-diphenylpyran.

[1,5] shifts are well known in the case of aliphatic conjugated dienes (25*a*) but it appears that this could be the first example involving an unsaturated aldehyde.

It is interesting to point out that Pirkle *et al.* (25*b*) have observed analogous [1,5] hydrogen shifts in the intermediate unsaturated ketene aldehydes formed in the pyrolysis of 2-pyrone derivatives but these shifts did not take place when the intermediate was formed by photolysis.

In order to provide evidence to support our hypothesis of this two-step transformation a 50 mg sample of photoaldehyde **6** was irradiated in *tert*-butyl alcohol-*O-d* and the major *trans-tert*-butyl ester isolated. The mass spectrum showed a molecular ion at *m/e* 309 which indicates that the ester is formed by incorporation of the elements of one molecule of *tert*-butyl alcohol-*O-d* and that no deuterium is present at the 5-positions of the chain since the base peak of the spectrum appears at *m/e* 91 and not *m/e* 92. Unfortunately, the small amount available did not allow the recording of a useful nmr spectrum, Ft technique not being available to us at that time.

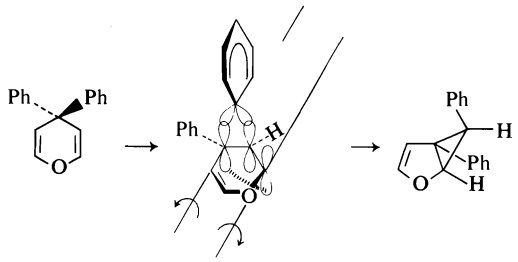
To circumvent this difficulty the starting 4,4-diphenylpyran (**1**) was irradiated in *tert*-butyl alcohol-*O-d* and the *trans* ester isolated and analyzed by both mass spectrometry and nmr. As expected, the mass spectrum proved identical to that obtained in the previous experiment. The nmr spectrum, on the other hand, provided supportive and conclusive evidence concerning the presence and the position of the incorporated deuterium atom. Indeed, whereas the undeuterated *trans* ester showed the vicinal 4- and 5-methylene groups as a multiplet for the AA′MM′ portion of an AA′MM′X system,the spectrum of the deuterated material showed a doublet ($J \simeq 7$ Hz) at 2.60 ppm for the 5-methylene group and a triplet ($J \simeq 7$ Hz) at 3.25 ppm, in excellent accord with a CHD group in the 4-position.

Finally, the relationship between the photoesters and the photoacids was easily established by carrying out the photolysis of a small sample of the *trans-tert*-butyl ester (**7**) and showing by tlc the progressive formation of the previously characterized photoacids (**9**). The photochemical Norrish type II decomposition of *tert*-butyl esters to yield the corresponding acids and isobutylene is well known (26) and the case reported herein is an additional example of this general reaction.

Discussion

Although sensitization and quenching results have not yet been obtained, the evidence thus gathered in the photolysis of 4,4-diphenyl-γ-pyran (**1**) clearly points to a di-π-methane rearrangement in the primary photochemical step. Indeed, the bicyclo[3.1.0] nature of the rearranged product and the *trans-endo* relationship of the phenyl groups are characteristic features of this rearrangement (1*c*). The stereochemistry observed in the phenyl migration is fully in accord with a concerted process involving inversion of configuration at the central ('methane') carbon and where rearrangement occurs in an *anti*-disrotatory mode as represented (1*c*).

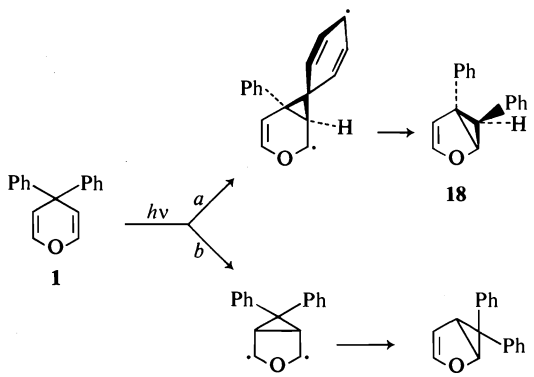
Another observation which may be made pertains to the multiplicity of the reacting excited species. Zimmerman and co-workers have shown (1*c*) that di-π-methane systems having nonconstrained or free π moieties usually give an efficient rearrangement from the excited singlet state, because of an energy dissipation



process available in the triplet state *i.e.* rotation about the excited π-bond or *cis–trans* isomerization. This deactivation process was named the "free rotor effect". In the case of compounds having constrained π-moieties the di-π-methane rearrangement usually proceeds efficiently from the triplet and inefficiently from the singlet, probably due to efficient alternative pathways.

The 4,4-diphenyl-γ-pyran (**1**) studied, being made up of constrained non-free π-moieties, the di-π-methane rearrangement observed should proceed more efficiently from the excited triplet state. However, since compound **1** did not show any primary photoreactivity other than di-π-methane rearrangement, it is possible that part of the rearrangement also originates from the singlet state.

Concerning the absolute regiospecificity observed *i.e.* rearrangement with phenyl–vinyl bridging (path *a* Scheme 6) totally preferred over vinyl–vinyl bridging (path *b*, Scheme 6), it appears, at first glance, that it could be due to the localization of the excitation energy mostly in the phenyl groups. Indeed, the divinyl ether chromophore (in a seven-membered ring) absorbs at 216 nm (ε 3720) and 231 nm (ε 2000) (27) while phenyl absorbs at 255 nm (ε 204) (28). However, it would be very surprising if both



SCHEME 6. Odd-electron representation of *a priori* possible reaction pathways in the 4,4-diphenyl-γ-pyran system.

chromophores were not at least slightly coupled since they are homoconjugated and compound **1** has λ_{max} 240 nm (ε 1050). The excitation energy should then probably be distributed over the entire π system. The situation could, on the other hand, be quite different in the case of the triplet state where energy could be more or less localized in one of the π moieties. Unfortunately we have no data at this time to warrant any further discussion on that aspect.

A more plausible approach to explain the occurrence of path *a* over path *b* would be the relative ease of formation of the cyclopropyl–dicarbinyl-diradical species[5] where that in path *a* has more odd-electron stabilization relative to that in path *b*. Indeed, Zimmerman, in a study of substituent effects in the singlet di-π-methane rearrangement of an acyclic diene has concluded (29) that "bridging is the major process affecting the rate". In addition, one might point out that the diradical species in path *a* should also proceed to final product with greater ease due to the rearomatization of a phenyl ring which constitutes a very favorable driving force. In a comparative study of 1-methylene-4,4-dimethylcyclohexa-2,5-diene and the 4,4-diphenyl analog (*vide supra*), Zimmerman has commented (3) that the results "can be interpreted as an inherent preference for the phenyl participation process with intervention of phenyl migration whenever possible" and that vinyl migration seems to be abnormally inefficient compared to phenyl migration. In view of the present results it would appear that the above remarks apply equally well to the case of 4,4-diphenyl-γ-pyran (**1**).

Finally, if we compare the results reported for the photolysis of 4-phenyl-4-benzyl-γ-pyrans (4, 5) (see Scheme 1) which rearrange to the corresponding 4-phenyl-2-benzyl-α-pyrans via a [1,3] sigmatropic shift, with the results reported herein on 4,4-diphenyl-γ-pyran which gives only di-π-methane rearrangement, we have another remarkable example of the control of excited state processes by substituent effects.

Experimental

The silica gel used for preparative thin layer chroma-

[5]It is important to note here that this rationalization does not require a nonconcerted mechanism. As Zimmerman remarked (1*c*): "the diradical species may just be points on a potential energy surface and not represent minima". This argument has been given ample substance in Zimmerman's recent work (1*a*).

tography was GF-254 from Merck or G/UV 254 from Machery-Nagel. Melting points were taken on a Büchi apparatus and are uncorrected. The ir spectra were recorded on a Beckman model IR-8 apparatus. The nmr spectra were recorded on a Varian model A-60 apparatus or a JEOL model C60-H apparatus using TMS as internal reference. The nOe experiments herein described were performed on a JEOL model JNM-4H-100 apparatus. The letters s, d, t, q, m, meaning respectively singlet, doublet, triplet, quadruplet, and multiplet, are used in the description of the spectra. The uv spectra were recorded in ethanol on a Bausch and Lomb Spectronic 505 spectrophotometer. The mass spectra were obtained from AEI MS902 and Hitachi–Perkin-Elmer RMU6D mass spectrometers. Photolyses were carried out in a Rayonet photochemical reactor equipped with 254 nm lamps.

*1,1-Dimethoxy-3,3-diphenylpropane (**2**) (6)*

A solution of potassium amide in liquid anhydrous ammonia is first prepared by slowly distilling ammonia over anhydrous potassium hydroxide, and condensing it in a 1 ℓ, three necked flask mounted with an acetone – dry ice condenser and mechanical stirrer. When the volume of liquid ammonia has reached 400 ml, a catalytic amount of ferric nitrate (~150 mg) is added and 10.4 g (0.26 mol) of potassium are precautiously dissolved under continuous mechanical stirring. Diphenyl methane (35 g, 0.21 mol) in anhydrous ether (150 ml) is subsequently added over a period of 30 min, giving a dark red solution characteristic of the anion thus formed. A solution of chloroacetaldehyde dimethylacetal (25.8 g, 0.21 mol) is then slowly added to the reaction mixture.

The ammonia is evaporated overnight, the acetone – dry ice condenser having been removed. The remaining ether solution is washed with water, dried over anhydrous magnesium sulfate, and evaporated. The crude mixture is separated by distillation under reduced pressure (~0.3 Torr). Pure 1,1-dimethoxy-3,3-diphenylpropane (**2**) is thus obtained (35.8 g; 67%); bp 138°C/0.3 Torr; mp 58–59°C; ir 1600, 1120, and 1050 cm^{-1}; nmr ($CDCl_3$); δ 7.30 (s, 10H), 4.10 (m, 2H), 3.20 (s, 6H), 2.4 (dd, 2H).

*1,1,5,5-Tetramethoxy-3,3-diphenylpentane (**3**) (6)*

As previously described, 5.6 g of potassium (0.14 mol) are dissolved in 300 ml of anhydrous liquid ammonia, containing a catalytic amount of ferric nitrate (~75 mg) and 1,1-dimethoxy-3,3-diphenylpropane (**2**) (25.6 g, 0.1 mol) in anhydrous ether (150 ml) is slowly added. A solution of bromoacetaldehyde dimethylacetal (16.9 g, 0.1 mol) in anhydrous ether (150 ml) is then added and the reaction mixture allowed to stand overnight while the ammonia is evaporated. The ether solution is washed with water, dried over anhydrous magnesium sulfate, and evaporated. The title compound (**3**) is obtained (17.2 g; 50%) by reduced pressure fractional distillation on a Vigreux column (30 cm): bp 158°C/0.3 Torr; mp 68–69°C; ir ($CHCl_3$), 1050, 1120, and 1600 cm^{-1}; nmr ($CDCl_3$), δ 7.20 (s, 10H), 3.90 (t, 2H), 3.10 (s, 12H), 2.60 (d, 4H).

*2,6-Dihydroxy-4,4-diphenyltetrahydropyran (**4**)*

A fine suspension of 1,1,5,5-tetramethoxy-4,4-diphenylpentane (**3**) (3.0 g, 8.7 mmol) in 60 ml of a 2 *N* solution of sulfuric acid in water is heated under reflux over a period of 1 h. The precipitate thus formed is filtered, crushed, and washed with acetone, then anhydrous ether to yield pure 2,6-dihydroxy-4,4-diphenyltetrahydropyran (**4**); 2.23 g (95%); mp 138–140°C; ir (Nujol) 3290 and 3190 cm^{-1}; nmr (DMSO-d_6), δ 7.21 (complex signal, 10H), 6.48 (d, 2H, J = 7.5 Hz), 4.65 (dd, 2H, J = 10 Hz), 2.91 (d, 2H, J = 12.5 Hz, lowfield portion of the AB system), 1.68 (dd, 2H, J = 10 Hz, J = 12.5 Hz, highfield portion of the AB system). After exchange with D_2O, signal at δ 6.48 disappears (hydroxylic protons) and signal at δ 4.65 collapses to a doublet, J = 10 Hz. Decoupling experiment: signal irradiated at δ 4.65, signal observed at δ 1.68 collapses to a doublet, J = 12.5 Hz.

Further experimental proof to the proposed structure was obtained when a small amount of the title compound was heated for 10 min *in vacuo*, slightly above its melting point, and gave quantitatively the expected corresponding dialdehyde, 3,3-diphenylglutaraldehyde (**5**), as an oil: nmr (DMSO-d_6), δ 9.47 (t, 2H, $J \simeq$ 2.5 Hz), 7.27 (br s, 10H), 4.36 (d, 4H, $J \simeq$ 2.5 Hz). The above dialdehyde (**5**) was heated at 100°C for 30 min in DMSO containing a small volume of 10% HCl (20:1), then diluted with cold water. The precipitate thus formed was filtered, washed with water then acetone, and dried *in vacuo*. All physical and spectroscopic data were identical with the ones reported for the title compound (**4**).

*4,4-Diphenyl-γ-pyran (**1**)*

p-Toluenesulfonyl chloride (4.5 g, 24.7 mmol) is added to a solution of 2,6-dihydroxy-4,4-diphenyltetrahydropyran (**4**) (1.4 g, 5 mmol) in 50 ml of anhydrous freshly distilled pyridine and the mixture heated (8) at 140°C during 20 h under magnetic stirring. The reaction mixture is allowed to cool and is then diluted with ether. The ether solution, washed with a 10% aqueous solution of hydrochloric acid to remove the pyridine, is then washed with water, dried over anhydrous magnesium sulfate, and evaporated to give an oily residue which crystallizes on standing. Pure 4,4-diphenyl-γ-pyran (**1**) is obtained by sublimation *in vacuo* (100°C/0.2 Torr): 1.04 g (80%); mp 56–57°C; mass spectrum, calcd.: 234.1044; found: 234.1050; ir ($CHCl_3$), 1668, 1620, and 1590 cm^{-1}; nmr ($CDCl_3$) δ 7.20 (s, 10H), 5.90 (q, AB, 4H, J = 6 Hz); uv (ethanol), λ_{max} 240 nm (ε 1050).

Typical Irradiation Conditions and Characterization of Photoproducts

A solution of 500 mg of 4,4-diphenyl-γ-pyran (**1**) in 500 ml anhydrous *tert*-butyl alcohol (4.2×10^{-3} *M*) was irradiated for 20 h at 254 nm in a quartz vessel, using a Rayonet reactor. The photochemical products were then separated by preparative thin layer chromatography on silica gel plates (20 × 40 cm) eluted by a 20:80 ether–hexane mixture. Six products were thus obtained and are enumerated here in their increasing order of polarity.

(*a*) Unreacted starting material, γ-pyran (**1**): 55 mg (11%).

(*b*) *trans-tert*-Butyl 3,5-diphenylpent-2-enoate (**7**): 98 mg (15%); mp 55°C (ether–pentane); mass spectrum, molecular ion at *m/e* 308 (<1%), loss of isobutylene at *m/e* 252 (20%), followed by loss of CO_2H at *m/e* 207 (16.7%), and base peak at *m/e* 91 (100%); ir (CCl_4), 1705 and 1620 cm^{-1}; nmr ($CDCl_3$), δ 7.45 (br s, 5H), 7.28 (br s, 5H), 6.00 (s, 1H), 3.50 to 2.50 (m, AA′MM′X, 4H), 1.55 (s, 9H). nOe experiment: the product is dissolved in $CDCl_3$ and the solution degassed several times before sealing the tube. Irradiated signal at 3.37 ppm, lowfield

portion of the AA′MM′X system. Observed signal at 6.00 ppm, vinylic proton singlet shows an increase in intensity of 11 to 13% (10).

(*c*) *cis-tert*-Butyl 3,5-diphenylpent-2-enoate (**8**): 59 mg (9%); clear oil; mass spectrum, molecular ion at *m/e* 308 (1%), loss of isobutylene at *m/e* 252 (30%), followed by loss of CO_2H at *m/e* 207 (20%), base peak at *m/e* 91 (100%); ir ($CHCl_3$), 1700 and 1630 cm^{-1}; nmr ($CDCl_3$), δ 7.34 (m, 10H), 5.93 (s, 1H), 2.76 (br s, 4H), 1.28 (s, 9H). nOe experiment: (*vide supra*) irradiated signal at 2.76 ppm. Observed signal at 5.93 ppm, vinylic singlet, shows no noticeable increase in intensity (10). Contact shift reagent $Eu(fod)_3$: a qualitative study shows that when small amounts of $Eu(fod)_3$ are added to the solution in $CDCl_3$, there is a marked evolution from a deceptively simple singlet at 2.76 ppm, to a more complex AA′MM′X multiplet (10).

(*d*) Isomeric 3,5-diphenylpent-2,4-dienals (**6**): 33 mg (6.5%); yellow oil; mass spectrum, molecular ion at *m/e* 234 (100%), loss of CHO at *m/e* 205 (62%); ir ($CHCl_3$), 1665 and 1610 cm^{-1}; nmr ($CDCl_3$), δ 10.21, 9.47, 9.40 (d, 1H), 7.8 to 6.00 (m, 13H).

(*e*) Isomeric 3,5-diphenylpent-2-enoic acids (**9**): 43 mg (8%); ir ($CHCl_3$), 3500, 1725, and 1620 cm^{-1}; nmr ($CDCl_3$), δ 11.00 (s, 1H), 7.80 to 6.80 (m, 10H), 5.90 (br s, 1H), 3.60 to 2.50 (m, 4H).

(*f*) Unidentified organic polymers: yield measured as percentage starting material (13%).

*trans- and cis-Ethyl 3,5-Diphenylpent-2-enoate (**12** and **13**) (13)*

A solution of diethylcarbethoxymethylphosphonate (13) (2.25 g, 0.01 mol) in 5 ml DME is slowly added to a fine suspension of sodium hydride (0.4 g of a 51% suspension in oil; 8 mmol) in 15 ml of DME. Dihydrochalcone (**11**) (1 g, 4.8 mmol), previously obtained (12) by catalytic hydrogenation of chalcone (**10**), in 15 ml DME is subsequently added at room temperature and the resulting solution heated under reflux for 4 h. The reaction mixture is allowed to cool, 150 ml of water are then added, and both organic and water layers are filtered. The aqueous phase is extracted twice with ether and the organic extracts are combined, dried over anhydrous magnesium sulfate, and evaporated. A mixture (3.2 g) of *trans-* and *cis*-ethyl 3,5-diphenylpent-2-enoate (**12**, **13**) is thus obtained. The esters are separated by thin layer chromatography on silica gel plates (20 × 40 cm), eluted with a 30:70 ether–hexane mixture: total yield in esters, 35%.

trans-Ethyl 3,5-diphenylpent-2-enoate (**12**): mp 36–39°C; mass spectrum, molecular ion at *m/e* 280 (8%), base peak at *m/e* 91 (100%); ir ($CHCl_3$), 1700 and 1620 cm^{-1}; nmr ($CDCl_3$), δ 7.57 (s, 5H), 7.20 (s, 5H) 6.05 (s, 1H), 4.30 (q, 2H), 3.70 to 2.40 (m, AA′MM′X, 4H) 1.30 (t, 3H). nOe experiment: (*vide supra*), irradiated signal at 3.40 ppm, observed signal at 6.05 ppm, 13% increase in intensity (10).

cis-Ethyl 3,5-diphenylpent-2-enoate (**13**): clear oil; mass spectrum, molecular ion at *m/e* 280 (8%), base peak at *m/e* 91 (100%); ir ($CHCl_3$), 1705 and 1635 cm^{-1}; nmr ($CDCl_3$), δ 7.40 (m, 10H), 5.95 (s, 1H), 4.00 (q, 2H), 2.72 (s, 4H), 1.05 (t, 3H). nOe experiment: (*vide supra*), irradiated signal at 2.72 ppm, observed signal at 5.95 ppm, no appreciable increase in intensity (10).

*Authentic trans-3,5-Diphenylpent-2-enoic Acid (**14**)*

trans-Ethyl 3,5-diphenylpent-2-enoate (**12**) (100 mg, 0.4 mmol) is added to a solution of KOH (50 mg, 0.8 mmol) in 3 to 4 ml of 95% ethanol. The resulting mixture is heated to reflux during 75 min. The solution is then acidified by 2 *N* H_2SO_4 and extracted by two 20 ml portions of ether. The organic extracts are combined, washed with water, dried over anhydrous magnesium sulfate, and evaporated. The solid crude product (74 mg) is recrystallized from a pentane–ether mixture: yield 75%, mp 99–101°C; mass spectrum, molecular ion at *m/e* 252 (5%), loss of CO_2H at *m/e* 207 (8%), base peak at *m/e* 91 (100%); nmr ($CDCl_3$), δ 11.30 (s, 1H), 7.56 (s, 5H), 7.36 (s, 5H), 6.24 (s, 1H) 3.80 to 2.60 (m, AA′MM′X, 4H).

*Cleavage of trans-tert-Butyl 3,5-diphenylpent-2-enoate (**7**) (14)*

trans-tert-Butyl 3,5-diphenylpent-2-enoate (**7**) (75 mg, 0.24 mmol) and a catalytic amount of *p*-toluenesulfonic acid monohydrate are dissolved in 5 ml of benzene and the solution heated to reflux for 3 h. The benzene is evaporated and the crude product purified first by column chromatography on silica gel (5 × 15 cm) eluted with a 80:20 ether–hexane mixture, then by recrystallization from ether–pentane to yield *trans*-3,5-diphenylpent-2-enoic acid (**14**): mp 99–101°C. Mixture mp with authentic acid: 100–101°C. All the spectra were taken and are identical to those of the authentic acid **14**.

*3,5-Diphenylpentanoic acid (**16**)*

A solution of 3,5-diphenylpent-2-enoic acid (**14**) (210 mg, 0.8 mmol) in 30 ml of ethyl acetate containing 10 mg of PtO_2 is submitted to catalytic hydrogenation under a pressure of 3 atm for 5 h in Augustine's catalytic hydrogenator (16). After evaporation of the solvent, a yield of 200 mg (95%) of crude product is obtained; mp (ethyl ether – petroleum ether) 100–102°C; mass spectrum, molecular ion at *m/e* 254; nmr ($CDCl_3$); δ 10.90 (s, 1H), 7.20 (br signal, 10H), 3.50 to 1.50 (m, 7H).

*Authentic Methyl 3,5-Diphenylpentanoate (**17**)*

An ethereal solution of diazomethane prepared from Diazald (15) is added dropwise to 30 mg (0.12 mmol) of 3,5-diphenylpentanoic acid (**16**) in 20 ml ether until the evolution of nitrogen ceases and the solution remains yellow. The excess diazomethane is then eliminated by adding 1 to 2 drops of glacial acetic acid. The reaction mixture is washed with 15 ml $NaHCO_3$ (10%) and two portions of water. The solution is dried over magnesium sulfate and the solvent evaporated. Yield 30 mg (95%); colourless oil; nmr ($CDCl_3$), δ 7.00 (br signal, 10H), 3.40 (s, 3H), 3.40 to 1.50 (complex signal, 7H).

*Chemical Transformations of Photoaldehydes (**6**) and Structure Correlation*

A suspension of 50 mg (0.21 mmole) of the photoaldehydes (**6**) in 4 ml of water and 40 mg KOH is treated with nickel peroxide (17) (200 mg). The mixture is heated to reflux for 30 min and maintained at 50°C for 7 h. The reaction mixture is filtered, and extracted with ether. The aqueous layer is acidified and also extracted with ether. The latter ether extracts are dried and evaporated. The acids thus obtained are dissolved in 25 ml ethyl acetate and submitted to catalytic hydrogenation (*vide supra*) for 3 h (16). The solution is then filtered, the solvent evaporated, and the residue taken up in 30 ml of ether. The ethereal solution is treated with a solution of diazomethane in ether (*vide supra*) (15).

The resulting solution of methyl ester is compared to an authentic sample of previously prepared methyl 3,5-diphenylpentanoate (**17**) by tlc, using three different ether–hexane mixtures (10:90, 20:80, 40:60) and by gas chromatography, using the peak enhancement technique on two different columns (SE-30, 3%, 5 ft × 0.25 in. on Chromosorb W 60/80 and OV-1, 3%, 6 ft × 0.25 in. on Varaport).

*Correlation of Structure of the Photoacids (**9**)*

*Authentic trans-Methyl 3,5-Diphenylpent-2-enoate (**15**)*

The title compound is prepared by treating a solution of 50 mg of *trans*-3,5-diphenylpent-2-enoic acid (**14**) (0.2 mmol) in 2 ml of ether with ethereal diazomethane (*vide supra*). Yield 52 mg (100%); colourless oil; nmr ($CDCl_3$), δ 7.07 (br s, 5H), 6.90 (br s, 5H), 5.78 (s, 1H), 3.56 (s, 3H), 3.50 to 2.40 (m, AA′MM′X, 4H).

*Esterification of Photoacids (**9**)*

A mixture of photoacids (25 mg) is dissolved in 2 ml of ether and treated with ethereal diazomethane (15) (*vide supra*). The resulting mixture is compared to authentic *trans*-methyl 3,5-diphenylpent-2-enoate (**15**) by tlc on silica gel using three different ether–hexane mixtures (10:90, 20:80, 40:60) and by gas chromatography using the peak enhancement technique on two different columns (SE-30, 3%, 5 ft × 0.25 in. on Chromosorb W 60/80 and OV-1, 3%, 6 ft × 0.25 in. on Varaport).

*Isolation of the Primary Photoproduct, trans-endo-5,6-Diphenyl-2-oxabicyclo[3.1.0]hexene (**18**)*

Irradiation of 500 mg of 4,4-diphenyl-γ-pyran (**1**) in 100 ml of *tert*-butyl alcohol at 254 nm for 2 h gives 50 mg (10%) of *trans-endo*-5,6-diphenyl-2-oxabicyclo[3.1.0]hexene (**18**), along with all the other expected photoproducts. This product is isolated by preparative thin layer chromatography on silica gel plates (20 × 40 cm), eluted with a 3:97 ether–hexane mixture. The product was extracted from silica gel by washing several times with ether at room temperature. Continuous extraction with ether or chloroform using a Soxhlet yields an appreciable amount of isomeric aldehydes (**6**) by thermal rearrangement, nmr ($CDCl_3$) δ 7.40 (2 s, 10H), 5.96 (d, AB, $J_{AB} \simeq 2.5$ Hz), 5.10 (d, AB, $J_{AB} \simeq 2.5$ Hz), 4.73 (d, $J \simeq 7$ Hz), 2.50 (d, $J \simeq 7$ Hz); ir ($CHCl_3$), 3100, 3080, 3040, 2920, 1590, 1490, 1440, 1140, 690 cm^{-1}.

*Rearrangement of Primary Photoproduct (**18**) to Photoaldehydes (**6**)*

The primary photoproduct **18**, under various experimental conditions, leads to the formation of photoaldehydes (**6**), as evidenced by tlc on silica gel plates. A solution of 3 mg of **18** in 0.5 ml ether is spotted on three silica gel plates 2.5 × 7.5 cm. The first plate when irradiated for 1 h at 254 nm and then eluted by a 20:80 ether–hexane mixture showed extensive formation of aldehydes **6**. The second plate, when heated at approximately 150°C for 10 min showed quantitative rearrangement of **18** into the aldehydes **6** after eluting with a 20:80 ether–hexane mixture. The third plate showed partial rearrangement of the primary photoproduct **18** to the aldehydes **6** when a methanolic solution of *p*-toluenesulfonic acid was spotted over product **18** and the plate eluted by 20:80 ether–hexane mixture after standing 30 min at room temperature.

*Photolysis of 4,4-Diphenyl-γ-pyran (**1**) in tert-Butyl Alcohol-O-d*

Irradiation at 254 nm during 20 h of 500 mg of 4,4-diphenyl-γ-pyran (**1**) in 200 ml of *tert*-butyl alcohol-*O-d* leads to the formation of 11 mg (2.2%) of *trans-tert*-butyl-4-d_1 3,5-diphenylpent-2-enoate (**7**). Mass spectrum, molecular ion at *m/e* 309, loss of isobutylene at *m/e* 253, then loss of OH at *m/e* 236 or loss of CO_2H at *m/e* 208, base peak at *m/e* 91; nmr ($CDCl_3$), δ 7.25 (br s, 5H), 7.08 (br s, 5H), 5.83 (s, 1H), 3.25 (t, 1H), 2.60 (d, 2H), 1.30 (s, 9H).

*Photolysis of Aldehydes (**6**) in tert-Butyl Alcohol-O-d*

Irradiation at 254 nm during 5 h of a 50 mg solution of aldehydes **6** in 30 ml *tert*-butyl alcohol-*O-d* leads to the formation of 2 to 3 mg *trans-tert*-butyl 4-d_1 3,5-diphenylpent-2-enoate (**7**), identified by tlc. Mass spectrum, molecular ion at *m/e* 309 (≪1%), loss of isobutylene *m/e* 253, then loss of OH at *m/e* 236 or loss of CO_2H at *m/e* 208, base peak at *m/e* 91.

*Formation of Photoacids (**9**) from Photoester **7***

Irradiation at 254 nm during 5 h of 2 to 3 mg of *trans-tert*-butyl 2,5-diphenylpent-2-enoate (**7**) in solution in 1 ml *tert*-butyl alcohol leads to the formation of the photoacids, as evidenced by tlc on silica gel plates eluted by a 20:80 ether–hexane mixture.

Two types of localized excess electrons in crystalline D_2O ice[1]

GEORGE V. BUXTON,[2] HUGH A. GILLIS, AND NORMAN V. KLASSEN
Division of Physics, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received January 28, 1977

GEORGE V. BUXTON, HUGH A. GILLIS, and NORMAN V. KLASSEN. Can. J. Chem. **55**, 2385 (1977).

In a pulse radiolysis study of crystalline D_2O ice, an intense infrared absorption band with $\lambda_{max} > 2350$ nm has been found at low temperatures, in addition to the well-known visible absorption band of the trapped electron. The infrared band is also attributed to trapped electrons, partly because of its similarity to the electron absorption band found recently in some D_2O glasses at low temperatures. The effects of temperature, dose per pulse, accumulated dose, and added NH_4F, HF, and ND_3 on the yields and decay kinetics of both bands have been investigated. It is concluded that the electron trap giving rise to the visible band is a vacancy which at low temperatures is radiation-produced by a two-step spur process. At temperatures close to the melting point the vacancy-trap probably exists before the radiation pulse at equilibrium concentration. The electron trap which gives rise to the infrared band is thought to be a cavity that occurs naturally in the perfect lattice. For previously unirradiated samples the infrared band decays by a second order process which is remarkably fast ($k \simeq 4 \times 10^{12}\ M^{-1}\ s^{-1}$ at 76 K). The decay reaction is probably neutralization by D_2O^+. Doping with NH_4F increases the yield of the infrared absorption and greatly decreases its decay rate. The total yield of localized electrons in irradiated crystalline D_2O is higher than has been generally recognized.

GEORGE V. BUXTON, HUGH A. GILLIS et NORMAN V. KLASSEN. Can. J. Chem. **55**, 2385 (1977).

En travaillant à basse température au cours d'une étude sur la radiolyse pulsée d'une glace de D_2O cristalline, on a trouvé une bande d'absorption infrarouge intense avec un $\lambda_{max} > 2350$ nm; cette bande est en surplus de la bande d'absorption visible bien connue pour les électrons piégés. On attribue aussi la bande infrarouge aux électrons piégés; cette conclusion est basée en partie sur sa similarité avec la bande d'absorption d'électrons trouvée récemment dans quelques verres de D_2O à basse température. On a étudié les effets de la température, des doses par pulsation, des doses accumulées et de l'addition de NH_4F, HF et ND_3 sur les rendements et la cinétique de disparition des deux bandes. On en conclut que le piège d'électron donnant lieu à la bande visible est un trou qui, à basse température, est produit par des radiations par un processus spontané à deux étapes dans les grappes. A des températures proches de celle du point de fusion, le piège trou existe probablement à la concentration d'équilibre avant la pulsation de radiation. On croit que le piège d'électron qui donne lieu à la bande infrarouge est une cavité qui se trouve naturellement dans un réseau parfait. Pour des échantillons qui n'ont pas été irradiés antérieurement, la bande infrarouge disparait suivant un processus du second ordre qui est remarquablement rapide ($k \simeq 4 \times 10^{12}\ M^{-1}\ s^{-1}$ à 76 K). La réaction de disparition est probablement une neutralisation par D_2O^+. Le dopage par NH_4F augmente le rendement de l'absorption infrarouge et diminue grandement sa vitesse de décroissance. Le rendement total d'électrons localisés dans du D_2O cristallin irradié est plus élevé que ce qui avait été habituellement observé.

[Traduit par le journal]

Introduction

Several studies of electrons localized in crystalline ice and absorbing in the visible have been reported (1–7). They have been especially concerned with the nature of the electron trap and the mechanism of trapping because self-trapping which occurs in liquid water is unlikely in ice at low temperatures due to its very long dielectric relaxation time. Several years ago it was concluded from the available experimental evidence that the visible band is probably due to an electron trapped in a vacancy in the crystal lattice (8). In one study it was concluded that the electron trap which gives rise to the visible band pre-exists (3). However, in a very recent study it was concluded that the trap involved is a radiation-produced lattice vacancy (7). In this paper we report some new observations on the

[2]This work was carried out while G.V.B. was a Visiting Research Officer at the National Research Council of Canada, June–September, 1974. Permanent address: University of Leeds, Cookridge Radiation Research Centre, Cookridge Hospital, Leeds LS16 6QB, England.

visible-absorbing electron in crystalline D_2O ice which enables us to say something further about the nature of the corresponding trap.

Recently we reported in a preliminary way on a radiation-produced infrared absorption band in crystalline D_2O and three kinds of D_2O glass at low temperatures (9). We assigned the band to a second type of trapped electron. Later we published a more extensive study of this band in the D_2O glasses (10), and here we describe further experiments concerning the infrared band in crystalline D_2O. Very recently the infrared band and an accompanying epr spectrum have been studied in crystalline D_2O at 4 K (11), and also assigned to trapped electrons.

Solids of D_2O, rather than H_2O, are used in these studies because of their greater transparency in the infrared; with samples of 5 mm optical path we can make measurements out to 2350 nm for crystalline D_2O, but only out to 1780 nm for crystalline H_2O.

Experimental

All crystals were made from D_2O (99.7 mol% D) from Merck, Sharp and Dohme which was used as received. The ND_3 was also from Merck, Sharp and Dohme, NH_4F and HF were analytical reagent grade and all three solutes were used without further purification.

Crystals were grown by lowering Pyrex tubes (19 mm id) containing degassed D_2O at a rate of 75 mm/day into a bath which was usually at −4°C. Each tube contained three or four round spacers with diameters slightly smaller than the inside diameter of the tube, which were attached perpendicularly to a rod at either 5 or 9.5 mm intervals. The rod and spacers were normally of brass, but were of Lucite for growing crystals doped with HF or ND_3. The samples were stored in the bath until used. Then an ice column was removed from its tube, an individual cylindrical sample of 5 or 9.5 mm thickness was pushed out from between its spacers, and slowly (in a period of about 5 min) lowered into liquid nitrogen in an irradiation Dewar. The samples were always clear and usually crack-free. We presume that each sample consisted of a few large crystals.

After NH_4F- and HF-doped samples were irradiated, they were melted and analyzed for F^- with an Orion fluoride electrode. Similarly ND_3-doped samples were analyzed with an ammonia electrode. These analyses indicated a somewhat more efficient incorporation of the solute into the crystal than found by Gross *et al.* (12). Thus they measured the distribution coefficient for NH_4F for unstirred systems as around 0.1, independent of concentration. However, we found that the concentration of NH_4F in a crystal was nearly as high as the concentration of the solution from which it was grown.

Samples were irradiated by single 30 or 40 ns pulses of 35 MeV electrons. The dose per pulse was generally in the range 4–9 krad. The irradiation Dewar, equipped with optical windows, was either filled with liquid nitrogen (bubbled with helium) or cold nitrogen gas was flowed through it to provide temperatures higher than 76 K. Temperature was measured with a copper–constantan thermocouple attached to the sample holder. Irradiation of the Dewar and liquid nitrogen but no sample showed that no blank corrections were required.

The dose per pulse was monitored with a secondary emission monitor which was calibrated for each experiment by using O_2-saturated 5 m*M* KSCN solution as a dosimeter. The irradiation cell with dosimeter solution was surrounded with methanol, which has an electron density similar to that of liquid nitrogen, and $G\varepsilon$ was taken as 2.2×10^4 molecules $(100\ \text{eV})^{-1}\ M^{-1}\ \text{cm}^{-1}$ at 475 nm.

In most experiments the light intensity was monitored simultaneously at two wavelengths. In determinations of spectra, one wavelength was fixed as the reference while the other was varied. The following light detectors were used: for $\lambda < 450$ nm, a Phillips XP-1003 photomultiplier; for 450 nm $\leq \lambda \leq$ 1000 nm, an EG & G SHS-100 silicon photodiode; and for $\lambda > 900$ nm a Barnes A-100 room temperature InAs photodiode. The 0–98% response time of the oscilloscope–detector system was < 30 ns for the first two detectors and ~ 60 ns for the last one. The performance of the silicon and InAs photodiodes has been described (13).

Results

(1) Spectrum of Trapped Electrons

The spectrum of trapped electrons (e_t^-) in pure crystalline D_2O at 76 K consists of two bands, as shown in Fig. 1. The low-energy side of the visible band decays much faster than the band as a whole; the band-width at half-height is 0.75 and 0.67 eV at 30 ns and 400 ns, respectively. The band-width following ^{60}Co

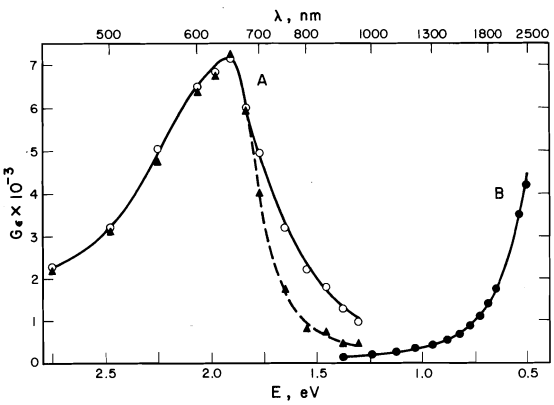

FIG. 1. Absorption spectra at 76 K in crystalline D_2O ice. For the visible band (*A*), points ○ were measured at the end of a 30 ns pulse. Points ▲ refer to measurements made 400 ns after the start of the pulse and multiplied by 1.90. For the infrared band (*B*), the line is a Lorentzian curve fitted to the experimental points ●, which refer to the end of a 30 ns pulse and were obtained by a short extrapolation from 100 ns. Points for both bands between 1.0 and 1.5 eV have been corrected for contributions from the other band (see text).

irradiation is about 0.58 eV (4), so presumably further narrowing occurs after 400 ns. For measurement of the visible band the reference wavelength was 650 nm and the points shown refer to samples which had received no more than 30 krad accumulated dose. This is relevant because not only do the yields for the visible and infrared bands have different dependences on dose (see below), but also in the visible band the ratio of absorption in the quickly-decaying red-edge to that in the main part of the band increases with accumulated dose. Thus it was found that the ratio of optical density at 800 nm to that at 650 nm changed from 0.31 for a previously unirradiated crystal to 0.48 for a crystal that had already received 80 krad.

For measurement of the infrared band of Fig. 1 the reference wavelength was 2300 nm and there was no evidence of a change in the band shape with accumulated dose. The spectrum of irradiated NH_4F-doped ($\sim 4 \times 10^{-3}$ *M*) crystalline-D_2O was found to be very similar to that shown in Fig. 1, but for the doped sample the life-time of the infrared band is much greater than that of the visible band. This permits resolution of the spectrum into the two bands, and the points in Fig. 1 in both bands for energies between 1.0 and 1.5 eV were obtained in this way.

The experimental points for the infrared band fit a Lorentzian function very well; the best fit, shown by the line for the band *B* in Fig. 1, predict $\lambda_{max} = 2950$ nm. By contrast the Lorentzian fit for the infrared band in a $MgCl_2$–D_2O glass at 76 K predicted a λ_{max} of 3600 nm (10). However the imprecision in this method of finding λ_{max} is considerable, so this difference between crystalline and glassy systems may not be experimentally significant. The visible band in the aqueous glasses was found to obey a Gaussian curve on the low-energy side, but this is not true for the visible band shown in Fig. 1.

We measured the spectrum of e_t^- in pure D_2O at 151 K and found that the infrared band has the same shape as band *B* of Fig. 1. The visible band at the end of the pulse at 151 K is intermediate between the 30 ns and 400 ns points of band *A* in Fig. 1, as expected because of the faster decay of the red-edge at the higher temperature.

(2) Decay of e_t^- in Pure Crystalline D_2O

The decay of absorption at 650 nm does not obey simple first or second-order kinetics. As shown in Fig. 2, the decay at 76 K in the pure crystal follows the same curve on a plot of $OD/(OD)_0$ against time for a four-fold variation of initial concentration. This strongly suggests that the species absorbing at 650 nm decays by reaction with a geminate partner.

Absorption in the infrared band for pure crystalline D_2O decays very differently in that the half-life for decay depends strongly on the dose. Figure 3 shows that for previously unirradiated samples the initial decay follows second-order kinetics although deviations from second-order decay occur at later times. What is much more significant is that the initial slopes for the second-order plots are the same within experimental error for a four-fold variation in initial concentration. This means that the decay is due to reaction of species which have a homogenous distribution.

(3) Effects of Accumulated Dose

The effect of repeated pulsing of a D_2O crystal at 76 K on the yields of both bands is shown in Fig. 4*A*. The yields reported here were measured 100 ns after the start of a 40 ns pulse. Accumulated dose also affects the decay rates for both bands. At 650 nm the decay rate increases somewhat with dose. At 2350 nm the initial decay becomes much faster with repeated pulsing but a long tail becomes increasingly significant (see trace *B* of the inset of Fig. 3). The faster initial decay could account for all of the apparent decrease in yield with dose indicated in Fig. 4*A*.

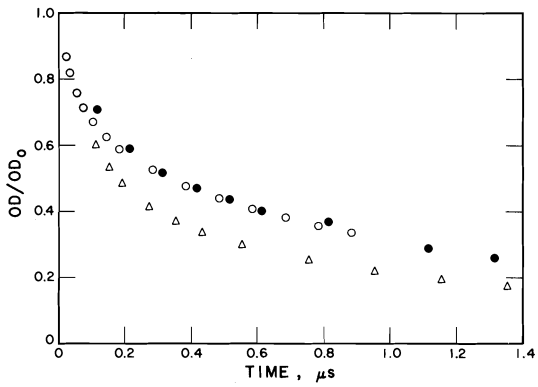

FIG. 2. Decay of absorption at 650 nm in crystalline D_2O ice at 76 K. $(OD)_0$ is OD at mid-pulse, obtained by extrapolation. For ○, no additive and $(OD)_0 = 28.6 \times 10^{-3}$; for ●, no additive and $(OD)_0 = 6.9 \times 10^{-3}$; for △, crystal doped with 9.6×10^{-4} *M* NH_4F, and $(OD)_0 = 25.0 \times 10^{-3}$. Each set of points refers to the first pulse for a sample.

TABLE 1. Electron yields for pure and doped crystalline D_2O at 76 K, for 0 and 50 krads previous dose

Additive	Concentration (M)	$G\varepsilon \times 10^{-3}$ 650 nm (0 krads)	650 nm (50 krads)	2350 nm (0 krads)	2350 nm (50 krads)
None	—	5.7	8.1	3.3	3.1
NH_4F	5.4×10^{-6}	6.2	7.0	4.1	4.4
NH_4F	9.0×10^{-5}	5.8	6.0	5.6	6.5
NH_4F	9.6×10^{-4}	6.4	6.1	9.0	14.5
NH_4F	1.51×10^{-2}	7.1	7.2	13.9	21.8
HF	2.31×10^{-2}	6.1	5.9	5.7	7.8
ND_3	9.8×10^{-5}	5.4	6.1	3.4	3.2
ND_3	1.3×10^{-4}	5.2	—	3.3	—

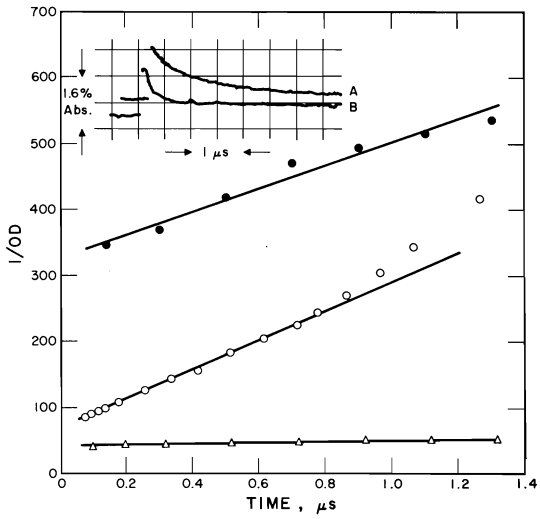

FIG. 3. Decay of absorption at 2350 nm in crystalline D_2O at 76 K, without additives (●) and (○), and doped with 9.6×10^{-4} M NH_4F (△). All three curves are for the first pulse for a sample. Inset: *A*, oscilloscope trace of absorption at 2350 nm for previously unirradiated crystal without additives at 76 K; *B*, oscilloscope trace of absorption at 2350 nm for pure crystal at 76 K that had received an accumulated dose of 100 krads.

(4) Effect of Dose/Pulse

$G\varepsilon$ for both the visible and infrared bands was constant within experimental error (±10%) for a variation of dose/pulse of a factor of 4.5 at a constant pulse width.

(5) Effects of Solutes

The yields of both electron bands for pure and doped crystalline D_2O at 76 K are given in Table 1, both for previously unirradiated samples and for samples that had already received 50 krads. All yields were determined 100 ns after the start of a 40 ns pulse. The yields given for pure D_2O represent the average of values obtained for several samples on different days. Because of uncertainties in positioning samples and dosimeter solutions, the uncertainty in each value given for $G\varepsilon$ is about ±10%, but the uncertainties in the ratio of $G\varepsilon$'s at 650 and 2350 nm and in the change in $G\varepsilon$ on pulsing are smaller.

The effect of 9.6×10^{-4} M NH_4F on electron decay rate for a previously unirradiated sample is shown in Figs. 2 and 3 for the visible and infrared bands, respectively. It is seen that NH_4F drastically decreases the decay rate of the infrared band, and decay was slowest for the most highly doped crystals. For a crystal doped with 6.7×10^{-4} M NH_4F the decay had a half-life of ~25 ms, as measured by using a bandpass filter at 1500 nm in front of the cell to minimize

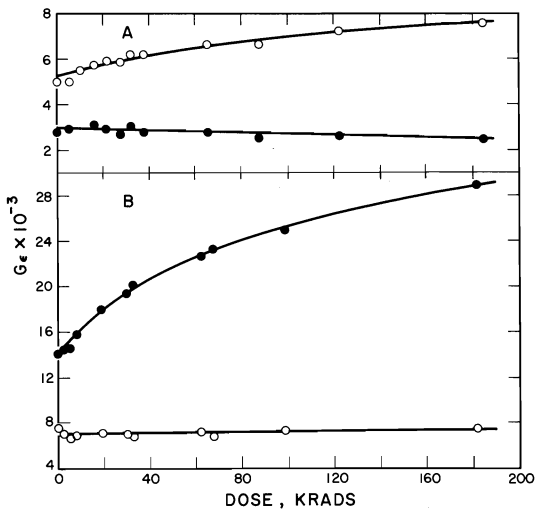

FIG. 4. Effect of accumulated dose on yields of both electron bands in crystalline D_2O at 76 K. *A*, no additives, ○, 650 nm; ●, 2350 nm. *B*, doped with 1.51×10^{-2} M NH_4F: ○, 650 nm; ●, 2350 nm.

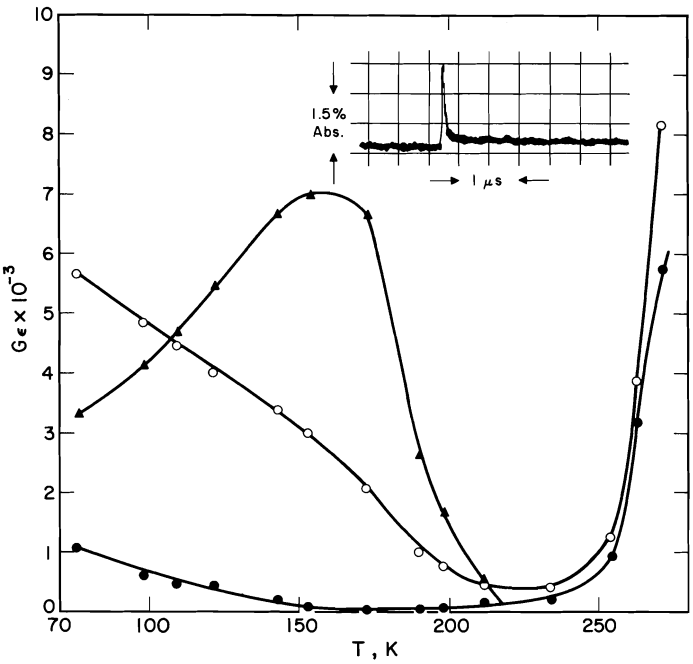

FIG. 5. Effect of temperature on absorption in pure crystalline D_2O. ▲, at 2350 nm, measured 100 ns after the start of a 40 ns pulse; ○, at 650 nm, measured 100 ns after the start of a 40 ns pulse; ●, at 650 nm, measured 3 μs after the start of a 40 ns pulse. Inset: oscilloscope trace showing decay of absorption at 650 nm in a crystal at 212 K.

photobleaching effects. The decay rate of the infrared band was also decreased by HF but not affected significantly by added ND_3.

The effect of dose on the most highly doped NH_4F crystal, 1.51×10^{-2} *M*, is shown in Fig. 4*B*. It is seen that for this sample the yield of infrared absorption doubles as the accumulated dose increases from 0 to 180 krads while the yield of the visible band remains practically constant.

(6) Effects of Temperature

The effect of temperature on yields in both absorption bands is shown in Fig. 5. The decay of absorption at 650 nm at higher temperatures appears to consist of a fast initial decay and a much slower second process, and the second process becomes increasingly important as the temperature is raised from 190 K. The inset to Fig. 5 shows the rapid initial decay and long tail at 212 K. In Fig. 5 the yields at 650 nm at 3 μs at the higher temperatures are roughly the yields of the long-lived absorption, but at temperatures <170 K this absorption at 3 μs appears to be simply the tail of the initial decay process. The effect of temperature on the decay half-life, measured from 100 ns after the start of a 40 ns pulse, is shown for both bands in Fig. 6. It is seen that the half-life for decay of infrared absorption becomes comparable to the detector response-time ($\sim$60 ns) around 180 K, so the decrease in yield at 2350 nm above 160 K, as seen in Fig. 5, is at least partially instrumental. The decay of the infrared band was studied carefully in previously unirradiated samples only at 76 K, but did not seem to obey good second-order kinetics at higher temperatures.

(7) Emission

We observed emission from irradiated crystalline D_2O and 76 K, and the spectrum of this emission is shown in Fig. 7. Corrections for change in the efficiency of the light-gathering system with wavelength have been applied to the points in Fig. 7. The reference wavelength used in determination of the spectrum was 400 nm. The intensity of emission increased considerably with accumulated dose up to a plateau. The intensity at 400 nm approximately tripled in going from an accumulated dose of 20 krads to $\sim$300 krads, and then remained approximately constant with dose up to $\sim$6000 krads. The effect

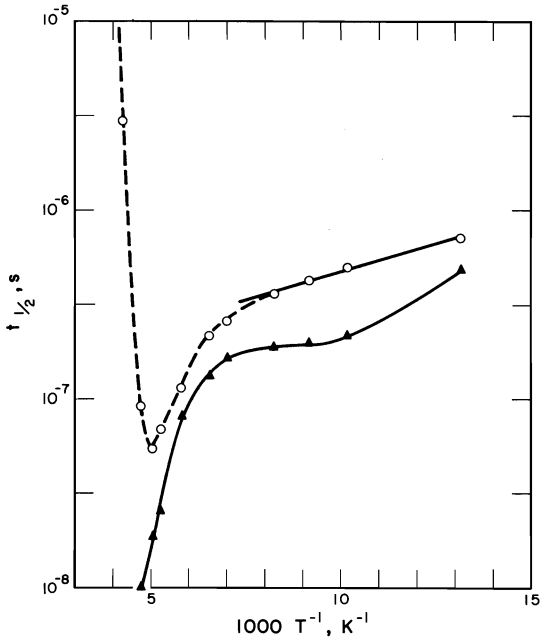

FIG. 6. Effect of temperature on $t_{1/2}$, measured from 100 ns after the start of a 40 ns pulse, for decay of absorption at 650 nm (○), and 2350 nm (▲) in pure crystalline D_2O.

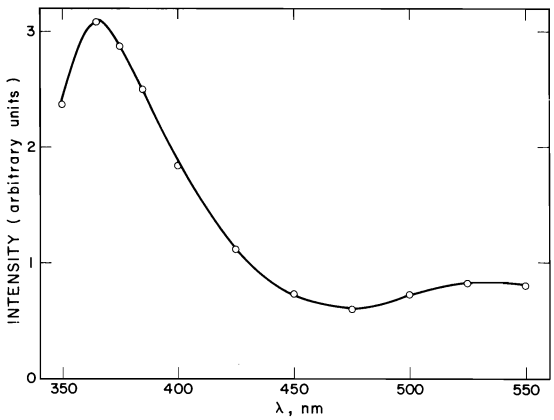

FIG. 7. Spectrum of luminescence from irradiated crystalline D_2O at 76 K, 200 ns after the start of a 400 ns pulse. Corrections for dependence of the efficiency of the light-gathering system on wavelength have been applied.

of dose on the second peak around 525 nm was not studied; in Fig. 7 the points at $\lambda > 450$ nm refer to a dose of ~ 50 krads.

Discussion

(1) Two Types of Excess Electron

The decay rates of the visible and infrared absorption in crystalline D_2O ice are different, and the effects of temperature, dose, and additives on the two bands are different, so they must be due to different species. The partial infrared band we see here is similar in shape and position to the partial infrared band we saw in several D_2O glasses (10), and we found fairly good evidence that the latter is due to a second type of trapped electron. By analogy then we conclude that in crystalline D_2O ice the infrared is also due to a shallowly trapped electron. At 4 K the infrared band decreased with time in the dark while the visible band grew (11); this is further evidence that the infrared band is due to a shallowly trapped electron. Significant infrared absorption was found in only 3 of the 11 D_2O glasses investigated (10), which raised the possibility that high concentrations of particular solutes are required for the production of this band. Finding a similar band in pure D_2O ice clearly removes this possibility.

We shall use the symbols e_{vis}^- and e_{ir}^- to indicate excess electrons which cause the visible and infrared absorption bands.

(2) Trap for e_{vis}^-

Our results can be interpreted on the basis that the visible band is due to an electron trapped in a vacancy in the crystal lattice, as concluded earlier (8). However, at 76 K this vacancy does not exist before a crystal has been irradiated, as indicated by the following calculation. The equilibrium concentration of vacancies at any temperature may be calculated from the Boltzmann equation if the energy required to form a vacancy is known. This energy is not well known but has been estimated as 0.5 eV (ref. 14, p. 162), and as 0.28 ± 0.07 eV (15) around 100 K. Since it is related to the energy of sublimation (14), it would not be expected to depend strongly on temperature. As a crystal is cooled down a temperature will be reached at which vacancies become frozen in, *i.e.* equilibrium is no longer attained. There is evidence that radiation-produced vacancies become mobile and disappear in the region of 100 K (15) or 120 K (11), and therefore equilibrium conditions must hold at higher temperatures. The maximum concentration of vacancies before the first pulse on a crystal at 76 K can then be calculated by using the lower limit of the lower estimate of the energy required to produce a vacancy, 0.21 eV, and by assuming that vacancies become frozen in at 120 K, and this concentration is 8×10^{-8} *M*. If

we assume ε_{650} is the same as ε_{max} in OH^- glasses at 76 K, *i.e.* $2.0 \times 10^4\ M^{-1}\ cm^{-1}$ (16), then for a pulse typical of those used to obtain the data of Fig. 1 the concentration of electrons at the end of the pulse was about $2 \times 10^{-6}\ M$. So the concentration of pre-existing cavities is not high enough to account for our results.

However, there is now fairly direct evidence for the production of vacancies by irradiation of ice (15, 17). We suggest that e_{vis}^- is produced at 76 K by the following mechanism:

$$[1] \qquad 2D_2O \rightsquigarrow (2D_2O^+ + 2e_{qf}^-)$$

$$[2a] \qquad (2D_2O^+ + 2e_{qf}^-) \rightarrow (D + OD + D_2O^+ + e_{qf}^- + \square)$$

$$[2b] \qquad \rightarrow 2D_2O^+ + 2e_{qf}^-$$

$$[3a] \qquad (e_{qf}^- + \square) \rightarrow e_{vis}^-$$

$$[3b] \qquad \rightarrow e_{qf}^- + \square$$

$$[4] \qquad e_{qf}^- + \square \rightarrow e_{vis}^-$$

Here parentheses around reactants are intended to indicate that the reaction takes place in a spur, $\square$ represents a vacancy and e_{qf}^- is the quasi-free electron. The major mechanism for producing e_{vis}^- is the two successive spur reactions 2*a* and 3*a*; the first is a neutralization reaction which produces the vacancy and the second is the trapping of a quasi-free electron in the same spur. A possible alternative to reaction 2*a* which could produce a vacancy in the same spur with e_{qf}^- is decomposition of an excited molecule. We consider that the non-spur reaction 4 is not an important source of e_{vis}^-, but does account for the slight increase in $G(e_{vis}^-)$ with increasing dose. From Fig. 4 it is seen that $G(e_{vis}^-)$ is only about 17% higher for the eighth pulse than for the first pulse for a crystal. It might be argued that most vacancies disappear between pulses (possibly most are destroyed when e_{vis}^- reacts) but that non-spur reactions between e_{qf}^- and vacancies produced in the same pulse are an important source of e_{vis}^-. However, in that case, since e_{qf}^- can undergo an alternative reaction with another kind of trap which is not radiation-produced (see below), one would expect the yield of e_{vis}^- to depend on dose per pulse. As indicated in the Results section, we find otherwise.

As discussed below, $G(e_{vis}^-) \simeq 0.4$ at 76 K, which means that roughly 10% of e_{qf}^- become e_{vis}^-. This seems plausible for the mechanism proposed since the percentage of spurs containing two or more ion pairs in which the successive reactions 2*a* and 3*a* would occur is expected to be rather low.

Kawabata (7) has shown that most of the traps for stable or slowly decaying e_{vis}^- in crystalline D_2O at low temperatures are produced by radiation previously received by a sample. However, he studied only a small percentage of total e_{vis}^-. Thus in pulse experiments he found $G(e_{vis}^-) \simeq 0.01$ in the ms region for the first pulse; our $G(e_{vis}^-)$ at 105 K at 100 ns is about 0.23 (Fig. 5).

The narrowing of the visible absorption band with time, as seen in Fig. 1, is easily explained in terms of a vacancy model. If one water molecule is removed from the tetrahedral structure of ice and an electron occupies this vacancy, then protons from only two of the four water molecules in the first shell point towards the electron. Natori and Watanabe (18) have calculated the optical transition energy for an electron in a vacancy in H_2O ice, and found agreement with experiment only by assuming that two of the molecules at the corners of the tetrahedron can rotate so that four OH bonds point to the center, and by assuming also that the OH bond length and the HOH angles can change from their values in the perfect crystal. Other models also require orientation of the dipoles around the electron in order to get agreement with the observed visible absorption (19, 20). The low-field dielectric relaxation time of water is very long at low temperatures (*e.g.* ~1 s at 165 K) (21). But it has been pointed out that the relaxation time in the high field close to the electron must be very much less than that at low fields (22, 23). Therefore the narrowing of the visible band seen in Fig. 1 is probably a reflection of the orientation of the OD dipoles so that they point towards the center of the vacancy. An increase in absorption at λ_{max} as this spectral shift occurs is not seen because of the rapid decay of e_{vis}^-.

If the vacancy sites for e_{vis}^- are formed by reactions 1–4, then the observed geminate decay of e_{vis}^- at low temperatures is easily explained as a spur reaction with OD or D_2O^+ which probably occurs by a tunnelling process:

$$[5] \qquad (e_{vis}^- + OD) \rightarrow OD^-$$

$$[6] \qquad (e_{vis}^- + D_2O^+) \rightarrow OD + D$$

In Fig. 6 the solid straight-line portion of the Arrhenius plot for e_{vis}^- gives an activation

energy of 0.27 kcal mol^{-1}; such a low activation energy is reasonable for a tunnelling reaction. Other features of the effect of temperature on lifetimes of e_{vis}^- are discussed below. Modest concentrations of solute such as NH_4F would not be expected to have an appreciable effect on the yield of e_{vis}^-, as observed. However, NF_4F seems to increase the decay rate of e_{vis}^- a little, and we cannot explain this. Also in ^{60}Co experiments it has been found that in samples doped with 10^{-2} *M* NH_4F, the yield of e_{vis}^- is about six times that in pure crystalline H_2O (4). However, again these yields refer to the very small fraction of electrons extant at very long times; in the sample doped with 10^{-2} *M* NH_4F, $G(e_{vis}^-)$ was estimated as 3.3×10^{-3}.

(3) Site for e_{ir}^-

In our preliminary account of this work (9) we suggested that an electron captured in a D-defect could give rise to the infrared band. However, this idea does not seem to be in accord with the results of our further studies on the effects of solutes on e_{ir}^- yields. Crystals doped with ND_3, HF, and NH_4F should have higher, lower, and approximately equal concentrations of D-defects, respectively, as compared to the pure crystals (ref. 14. chapt. 7), and one might expect corresponding effects on $G(e_{ir}^-)$ if e_{ir}^- is an electron trapped at a D-defect. Instead, as seen in Table 1, ND_3 has no effect and both HF and NH_4F increase the yields. If it is assumed that orientation of the dipoles surrounding an electron trapped in ice is not possible, then λ_{max} is predicted by the polaron model to be in the infrared (1, 19). This prompts us to suggest that the infrared band in crystalline D_2O is due to electrons trapped in cavities that are natural to the crystal structure and around which little orientational polarization takes place:

[7] $$e_{qf}^- + \text{trap} \rightarrow e_{ir}^-$$

In a crystal of ordinary ice (ice I_h) molecules form sheets of crinkled six-membered rings normal to the *c* axis. Rings from two adjacent sheets form dodecahedral cavities which are joined together along the *c* axis to form long open shafts (see Fig. 1 in ref. 23), and we suggest that electrons trapped in these cavities give rise to the infrared absorption. Fast orientational polarization around these electrons is less likely than around electrons in vacancies for two reasons: (*a*) It would have to work against the strong hydrogen bonding of the crystal, whereas broken hydrogen bonds surround a vacancy. (*b*) There are 12 molecules to be oriented in the first co-ordination shell of the natural cavity, compared to 4 molecules around a vacancy. However, before the infrared band was discovered, Nilsson (23) proposed that electrons trapped in these natural cavities absorb initially in the infrared, but the absorption shifts quickly to the visible as the dipoles of the first co-ordination shell line up with the electric field of the electron. He has developed an equation which enables one to calculate the microscopic relaxation time from the ordinary relaxation time. Use of this equation with data from reference 21 gives a microscopic relaxation time of about 10^{-7} s at 173 K, and of course at 76 K the time would be much longer. Thus Nilsson's treatment is not in accord with our observations that the visible band is present at 30 ns after the pulse and undergoes only a modest narrowing in the next 400 ns, nor with our findings that the effects of dose per pulse, accumulated dose, and solutes on the two bands are uncorrelated.

Earlier we reported finding an infrared absorption band in three D_2O glasses, but not in eight others. We suggest that in the three glasses which give the infrared band the arrangement of D_2O molecules around solute ions or molecules happens to be such that cavities similar to the natural cavities of the crystal are formed.

(4) Decay of e_{ir}^-

The decay of e_{ir}^- is essentially second-order at 76 K for previously unirradiated pure samples, as shown in Fig. 3, and remarkably fast. In order to calculate a rate constant from the slopes of Fig. 3, we estimate an extinction coefficient for e_{ir}^- at 2350 nm by assuming that ε_{1400} is the same for crystalline D_2O as it is for ethylene glycol – D_2O glass, 5.7×10^3 M^{-1} cm^{-1} (10), and by using the ratio of extinction coefficients at 2350 and 1400 nm from Fig. 1. From the estimated $\varepsilon_{2350} = 3.8 \times 10^4$ M^{-1} cm^{-1} and the straight line drawn through the points in Fig. 3, *k* is calculated as 4×10^{12} M^{-1} s^{-1} at 76 K. From this rate constant the sum of the mobilities of e_{ir}^- and its reaction partner can be calculated from the following expression for the rate constant of a diffusion-controlled reaction between particles A and B that are singly and oppositely charged (25):

$$k = \frac{4\pi e(\mu_A + \mu_B)N}{1000D}$$

where N is Avogadro's number, D is the dielectric constant, and μ is the mobility. If we take $D = 3$, the high-frequency dielectric constant of ice (26), then $k = 4 \times 10^{12}\ M^{-1}\ s^{-1}$ corresponds to $(\mu_A + \mu_B) = 1.1 \times 10^{-2}\ cm^2\ V^{-1}\ s^{-1}$. This sum of mobilities is somewhat higher than the sum of about $0.3 \times 10^{-2}\ cm^2\ V^{-1}\ s^{-1}$ expected for normal ions in liquids at room temperature.

We consider that the most likely decay reaction of e_{ir}^- which accounts for homogeneous second-order kinetics in previously unirradiated pure ice is neutralization by D_2O^+:

[8] $\quad e_{ir}^- + D_2O^+ \rightarrow D_2O \text{ or } D + OD + \square$

This requires that e_{qf}^-, the precursor of e_{ir}^-, is trapped sufficiently far from the site of ionization that e_{ir}^- has a homogeneous distribution with respect to D_2O^+. In view of the high mobility of e_{qf}^- and the probability that most spurs contain one ionized molecule, it does not seem unreasonable to expect this requirement to be satisfied in the D_2O crystal. Another possibility is neutralization by D_3O^+, formed from D_2O^+:

[9] $\quad D_2O^+ + D_2O \rightarrow D_3O^+ + OD$

[10] $\quad e_{ir}^- + D_3O^+ \rightarrow D + D_2O$

Reaction 8 seems more likely than reaction 10 for two reasons: (*a*) In aqueous glasses e_{ir}^- does not seem to react with acid (10); (*b*) If reaction 10 is the main decay reaction, e_{ir}^- must have a high mobility because the mobility of D_3O^+ has been measured as only $1 \times 10^{-3}\ cm^2\ V^{-1}\ s^{-1}$ at 95 K and should be rather similar at 76 K (27). (Earlier measurements which were interpreted as indicating a proton mobility so high it could only be explained by tunnelling, are now thought to be unreliable because of deficiencies in experimental technique (28).) However, if e_{ir}^- is very mobile then its long life-time ($t_{1/2} \simeq 25$ ms) in NH_4F-doped crystals is hard to understand; a mobile e_{ir}^- would be expected to react quickly with trapped OD radicals, for example. It seems more reasonable to propose that e_{ir}^- has a low mobility, at least at 76 K, and the large rate constant for decay of e_{ir}^- is due to the movement of D_2O^+ by a resonant charge transfer process. The long tail in the decay curves for e_{ir}^- in crystals that have already been heavily irradiated could be due to trapping of D_2O^+ at radiation-produced defects or impurities. The faster initial decay might be due to reaction of e_{ir}^- with a radiation product by tunnelling from the shallow trap.

(5) Effects of Solutes on e_{ir}^-

One effect of doping ice crystals with NH_4F is to considerably increase $G(e_{ir}^-)$ at 76 K both for previously unirradiated samples and especially for irradiated samples, as indicated in Table 1 and Fig. 4; at the highest concentration used, $1.51 \times 10^{-2}\ M$, a sample that had received 50 krads gave a $G(e_{ir}^-)$ 7 times as great as for a pure ice crystal at the same dose. Another effect of the added NH_4F is to slow down very markedly the decay rate of e_{ir}^- at 76 K, as seen in Fig. 3. The effects of doping with HF are qualitatively similar though not as large as those of NH_4F, and the low concentration of ND_3 that could be incorporated into the crystal had very little effect. To partly explain these effects we propose that D_2O^+, besides reacting with e_{ir}^- (reaction 8) and with e_{qf}^- in a spur (reaction 2*a*), can also react with e_{qf}^- in a non-spur reaction:

[11] $\quad D_2O^+ + e_{qf}^- \rightarrow D + OD + \square$

and can react with added F^-:

[12] $\quad D_2O^+ + F^- \rightarrow D_2O + F$

Removal of D_2O^+ by reaction 12 decreases the rates of reactions 8 and 11. The decrease of the rate of reaction 8 accounts for the longer life-time of e_{ir}^-, and the decrease of the rate of reaction 11 results in an increase in the fraction of e_{qf}^- which undergoes reaction 7 and hence $G(e_{ir}^-)$ is higher. However, we are not able to explain why $G(e_{ir}^-)$ increases with dose for doped crystals.

(6) Effects of Temperature

The dependence of $G(e_{vis}^-)$ on temperature shown in Fig. 5 is similar to that reported earlier (5) except that our yields are somewhat larger because of our shorter electron pulses. Kawabata (7) has argued that the decrease in $G(e_{vis}^-)$ as the temperature is raised from 76 K to 130 K or so is due to a faster recombination of e_{vis}^- or the vacancy with fragments such as D, D^+, and OD at the higher temperatures. However, this seems to account for only part of the temperature effect on yields; $G(e_{vis}^-)$ obtained by extrapolation to mid-pulse, though somewhat imprecise at higher temperatures, still shows a drop between 76 K and 140 K.

Use of estimated extinction coefficients indi-

cates that the sum $G(e_{vis}^-) + G(e_{ir}^-)$ is approximately constant (increases slightly) between 76 K and 140 K which suggests that the decrease in $G(e_{vis}^-)$ and increase in $G(e_{ir}^-)$ are connected mechanistically. One possibility is that reaction of D_2O^+ with D_2O to give D_3O^+, reaction 9, takes place and has a small activation energy. The greater importance of this reaction at higher temperatures would mean a smaller fraction of D_2O^+ available for reaction 2*a* and hence the yield of e_{vis}^- should be smaller. More e_{qf}^- would be available for reaction 7 and hence $G(e_{ir}^-)$ should be larger, as observed. In this argument it is assumed that e_{qf}^-, like e_{ir}^-, does not react efficiently with D_3O^+.

Above 155 K the measured yields of e_{ir}^- become decreasingly representative of the initial yields because of the very rapid decay indicated in Fig. 6. Measurements with a faster detector might reveal very high yields of e_{ir}^- at temperatures higher than 150 K, and possibly the same species exists in the liquid. Rentzepis *et al.* (29) have reported that in water absorption at 1.06 μm is observed within 2 ps after generation of the quasi-free electron, and then the absorption band shifts from lower to higher energies and the normal absorption of the hydrated electron is developed in 4 ps. We suggest that the absorption at 1.06 μm seen by Rentzepis *et al.* could be the same infrared band we see in crystalline ice at low temperatures, though alternatively it could be the rapidly-decaying red edge of the visible band.

At temperatures >140 K, $t_{1/2}$ for both e_{vis}^- and e_{ir}^- become very short (Fig. 6). As indicated above, there is evidence that radiation-produced vacancies become mobile in the region of 100 K (15) or 120 K (11). Therefore, it is possible that e_{vis}^- decays quickly at temperatures >140 K because of migration of their traps. However, in the references cited the time-periods involved were minutes (11) or days (15), whereas we are concerned with $t_{1/2} \simeq 100$ ns, and a high mobility of vacancies would be hard to reconcile with the relatively long-lived e_{vis}^- at temperatures slightly below 0°C. Also a high mobility of vacancies would not explain a rapid decay of e_{ir}^-. A better possibility is that OD radicals become very mobile at temperatures >140 K and react with both e_{vis}^- and e_{ir}^-. Taub and Eiben (3) have observed OH radicals decaying slowly at temperatures as high as 259 K, but at temperatures of 173 K and lower, a fast decay was seen in addition to the slow decay. The fast decay may well be due to reaction with e_{vis}^- and e_{ir}^-, with the slow decay occurring after they have been consumed.

As indicated in the Results section and as shown in the inset of Fig. 5, at temperatures of 212 K and higher the decay curve for e_{vis}^- consists of a spike and a long tail. The tail becomes relatively more important as the temperature is raised from 212 K and the yields also increase sharply with temperature. It seems reasonable to suggest that the spike is due to spur reaction (discussed above), and that the long tail is due to decay of free electrons. However, as pointed out earlier (30), the yield of free e_{vis}^- increases too quickly with temperature above 250 K to be explained directly by the Onsager (31) relation. We suggest that free e_{vis}^- results from e_{qf}^- being captured by pre-existing vacancies, the equilibrium concentration of which would be high enough to accommodate our observed concentrations of e_{vis}^- if 0.3 eV (15) is the correct energy of vacancy formation. On this basis the rapid increase in $G(e_{vis}^-)$ with temperature above 254 K would reflect the increase in equilibrium concentration of vacancies. A plot of log $G(e_{vis}^-)$ against $1/T$ for the three points above 250 K in Fig. 5 gives an energy of 0.6 eV, instead of 0.3 eV, but this determination is quite imprecise because the temperature measurements under our conditions could well have been in error by a few degrees.

At variance with our conclusion that there is an appreciable free electron yield in crystalline ice above 250 K is the conclusion of Schiller (32) based on experiments with polycrystalline H_2O ice doped with tetranitromethane. In neutral ice no nitroform anion (the expected product of electron scavenging) could be found and so it was concluded that free electrons are either absent or do not react with tetranitromethane in ice.

(7) Yields of e_t^-

It is often stated that the yields of trapped electrons in irradiated ice are very low, and it is sometimes said that the yields that are found are to be attributed to electrons trapped in glassy regions in the crystal. Of course the yields of very long-lived electrons that are measured in ^{60}Co experiments are low, but those measured in our experiments at short times are not insignificant. As indicated above, we assume

$\varepsilon_{650} = 2 \times 10^4\ M^{-1}\ cm^{-1}$ for e_{vis}^-, and $\varepsilon_{2350} = 3.8 \times 10^4\ M^{-1}\ cm^{-1}$. Then for a previously unirradiated sample of pure D_2O ice at 76 K, at mid-pulse $G(e_{vis}^-) = 0.41$ and $G(e_{ir}^-) = 0.11$, for a total $G(e_t^-) = 0.52$. For a sample doped with $1.51 \times 10^{-2}\ M$ NH_4F and previously irradiated to the extent of 180 krads, $G(e_{vis}^-) = 0.53$ and $G(e_{ir}^-) = 0.75$ for a total $G(e_t^-) = 1.28$.

(8) Emission

The emission spectrum from irradiated D_2O ice at 76 K is shown in Fig. 7. Steen and Holteng (33) recently reported a very similar spectrum for polycrystalline ice at 77 K, with band maxima at 373 and 534 nm. They found that the ratio of intensities of the two bands depends on dose.

In our study of irradiated deuterated aqueous glasses which show appreciable infrared absorption (10), we found that the emission decay kinetics correlate very well with the decay kinetics of the infrared band, and this led us to suggest that e_{ir}^- decays by reaction with an OD radical to give an OD^-* which fluoresces. In the present study we found no correlation between the decay of emission at 407 nm and the decay of absorption at either 600 nm or 2350 nm, and therefore conclude that emission from the crystal does not result from the same mechanism as in the glass. Bernas and Truong have concluded that OH^- is not responsible for the stimulated luminescence from γ-irradiated crystalline ice (24).

Acknowledgements

The authors are very grateful to Dr. G. J. Trudel for analyzing the doped crystals, and to him and Mr. G. G. Teather for very capable assistance in other aspects of the experimental work.

DOUGLAS M. CHEN, FRED. Y. FUJIWARA, and LEONARD W. REEVES. Can. J. Chem. **55**, 2396 (1977).

A systematic investigation has been made of some lyotropic mesophases (lyomesophases) which macroscopically orient in magnetic fields. These mesophases have been classified into type I which have a positive diamagnetic anisotropy ($\Delta\chi > 0$) and type II with $\Delta\chi < 0$. The mesophase behavior has been observed as a function mainly of electrolyte additions to binary and ternary systems. The electrolyte has a profound effect on the mesophase behavior at extremely low concentrations. It has the effect in the ternary system, sodium decylsulphate/decanol/water, of converting a type I to a type II mesophase with less than 1 wt.% electrolyte. The addition of electrolytes to binary surfactant/water systems had the effect of increasing the mesomorphic region to higher water concentrations. In the case of sodium and cesium decylsulphate, and potassium laurate, these ternary mesophases were of type I and for decylammonium chloride of type II. The method used to distinguish mesophases and determine the degrees of order of water and some hydrocarbon chain segments has been deuterium magnetic resonance.

DOUGLAS M. CHEN, FRED Y. FUJIWARA et LEONARD W. REEVES. Can. J. Chem. **55**, 2396 (1977).

On a fait une étude systématique de quelques mésophases lyotropes (lyomésophases) qui s'orientent d'une façon macroscopique dans les champs magnétiques. On a classifié ces mésophases en type I, celles qui ont une anisotropie diamagnétique positive ($\Delta\chi > 0$), et type II, pour celles où $\Delta\chi < 0$. On a principalement observé le comportement de la mésophase en fonction de l'addition d'électrolytes à des systèmes binaires et tertiaires. L'électrolyte a un effet considérable sur le comportement de la mésophase à des concentrations extrêmement basses. Sur le système tertiaire, décylsulphate de sodium/décanol/eau, l'électrolyte a comme effet de transformer une mésophase de type I en une mésophase de type II avec moins que 1% en poids d'électrolyte. L'effet de l'addition d'électrolytes à des systèmes binaires, agent actif à la surface/eau, est de déplacer la région mésomorphe vers des concentrations d'eau plus élevées. Dans le cas des décylsulphates de sodium et de césium et du laurate de potassium, les phases ternaires sont du type I alors que pour le chlorure de décylammonium elle est du type II. On utilise la résonance magnétique du deutérium comme méthode pour distinguer les mésophases et pour déterminer les degrés d'ordre de l'eau et de quelques segments de chaînes hydrocarbonés.

Introduction

The complex superstructures of lyotropic mixtures of amphiphilic compounds, in water, formed in the regime of concentrated micellar systems, lead to liquid crystalline properties of the resulting fluids (1). These lyomesophases are important both with reference to basic structures of biological membranes and with respect to the aspects of colloid and interface science (2, 3). Phase diagrams have been an active area of study because they are so important in defining the number of liquid crystalline phases which occur in any given system (4–8). In the most thorough studies these mesophases are characterized by their low angle X-ray diffraction pattern. Lyomesophases which can be oriented either spontaneously or by other means offer exceptional advantages for study by any technique where the anisotropy of physical properties is accessible to measurement (9). The fact that a lyomesophase can be oriented in an applied magnetic field was first reported in 1967 (10). This very useful property opens up a research topic in which the chemical flexibility of such lyomesophases comes into question. Should such a variation of the chemistry of these spontaneously orienting lyomesophases be large, then many of

[1]Visiting Professor Universidade de São Paulo 1967–present.

the problems of colloid and interface science can be subjected to the full armament of the nuclear magnetic resonance (nmr) tool (11). In addition, these lyomesophases contain model aspects of the bilayer matrix of biological membranes (2–4).

In previous studies (12–15) the chemical variations which are possible have been investigated in some ternary and quaternary systems. The persistence of lyomesophases which can be oriented when counter ions are exchanged, partly or completely, for a complex ion has led to a new technique for investigating the structure of ions in fluid media (14–16). The behavior of alkali metal decylsulphates in mixtures with decanol and water (13) and the investigation of mixed alkali metal decylsulphates in similar mesophases leads to some important overall generalizations for these systems.

Two types of lyomesophases occur (12). One class, denoted type I, orients with the uniaxial direction (the director) parallel to the magnetic field. Therefore, the diamagnetic susceptibility along the director, $\chi_{\parallel}$, must be algebraically larger than that in the perpendicular direction, $\chi_{\perp}$, and the type I lyomesophases have a positive diamagnetic anisotropy, $\Delta\chi = \chi_{\parallel} - \chi_{\perp}$. In the second class of mesophases, denoted type II, the value of $\Delta\chi$ must be negative since the mesophase aligns with the director perpendicular to the magnetic field direction (12, 13). There is no implication that these lyomesophases can be assigned a single superstructure arrangement in order to achieve either type I or type II behavior. There appear to be several types of lyomesophases leading to the same behavior in magnetic fields.

In pure alkali metal decylsulphate/decanol/water systems the lithium salt has only a very narrow range of type I behavior, the sodium detergent leads to type I phases, while the cesium salt has broad ranges of type II mesophases (13). In lyomesophases of mixed alkali metal detergents, the change from type I to type II can be induced merely by changing lithium or sodium content in the counter ions. The addition of electrolytes to these lyomesophases has not been systematically studied with respect to the behavior of resulting uniaxial fluids in magnetic fields. The present study is an attempt to investigate the effect of added electrolytes in several mesophase systems. Such studies are important as the basis for using lyomesophases for all manner of physical measurements where bulk or molecular anisotropic properties are under scrutiny.

Experimental

Decylammonium chloride was prepared by neutralizing decylamine with hydrochloric acid. The crude product was recrystallized several times from ethanol – petroleum ether. The refined product was dried for several days under vacuum conditions and stored in an evacuated desiccator. Sodium decylsulphate was prepared by sulphation of *n*-decanol with either sulphuric acid in the manner previously reported by Radley *et al.* (12), or with chlorosulphuric acid (17). Recrystallization was repeated several times from 90% ethanol in water mixtures. Cesium decylsulphate was synthesized as previously reported (12) with recrystallization from ethanol – ethyl acetate mixtures. The sodium 3,3,4,4-tetradeuterodecylsulphate was prepared as described previously (18). The 1,1-dideuterodecylammonium chloride was prepared by reducing nonylnitrile with $LiAlD_4$. Purity was checked from the proton magnetic resonance spectra (Varian HA100) using the highest gains available to reveal impurities in aqueous isotropic solutions. Potassium laurate (Baker Chem. Co.) was recrystallized from ethanol. Electrolytes were analytical reagent grade and D_2O was > 99% deuterium from Merck Sharp and Dohme.

Various nmr spectrometers were used to study the various nuclei observed. These were Varian VF16, HA100, HR60, and XL-100 units.

Results

Sodium Decylsulphate/Decanol/Water System

A lyomesophase was prepared with the following composition: 1.53 g H_2O (0.1% D_2O added to give a deuterium nmr signal), 0.21 g decanol, and 1.05 g sodium decylsulphate (SDS). The sodium decylsulphate contained 19.00% of SDS-*3,3,4,4-d*$_4$ so as to provide a strong enough deuterium signal from the hydrophobic component. This lyomesophase falls into the region of type I properties (13). Spectra were taken at 23.7 $\pm$ 0.3°C on a Varian XL100 spectrometer for this series of experiments. The anhydrous sodium sulphate additions were performed with 0.098 to 7.03 wt.% of the total phase. The ^{23}Na and deuterium nmr signals were followed to show that partially averaged nuclear quadrupole splittings behave in a parallel manner. The deuterium doublets for the chain deuterium nuclei on carbon 3 and 4 were often not resolved in samples near the phase transition; the small amount of deuterium in the water appears as a separate doublet. A more complete study of the degree of order profile of the hydrocarbon chain by ^2H nmr has been previously reported (18).

In Fig. 1 the partially averaged quadrupole splittings (in the case of the chain an average for position 3 and 4) are plotted against the weight percent of sodium sulphate in the phases. The separation of two mesophases occurs after addition of 5.1% sodium sulphate.

The initial phase, before additions of sodium sulphate, is of type I and orients, somewhat slowly, in about an hour or so, with the mesophase director parallel to the magnetic field direction. On passing from initial powder pattern to fully oriented mesophase the separation of the quadrupole doublet increased by a factor of two, and when the oriented sample was turned in the magnetic field and a spectrum was obtained before the sample reoriented, the quadrupole splitting followed a $(3\cos^2\Omega - 1)$ dependence with the rotation angle. As shown in Fig. 1, an addition of only 0.272 wt.% sodium sulphate leads to a precipitous change in the deuterium quadrupole splittings which indicates a phase change induced by the addition of electrolyte. After this quantity of sodium sulphate has been added the new lyomesophase formed exhibits type II behavior. The change in the deuterium quadrupole splitting exactly at the critical concentration of the electrolyte for the phase transition is 1.64 for both water and chain deuterium signals. The values are: HOD 372 Hz type I to 227 Hz type II, and chain CD_2 groups 8.30 kHz type I to 5.06 kHz type II. The phase change is accompanied also by a characteristic change in the sign of the slope $(d(\Delta\nu)/dx)$; $\Delta\nu$ = quadrupole splitting and x = concentration of some component, in this case the electrolyte (12). With the assumption of an axially symmetric electric field gradient tensor for the C—D bond axis, the appropriate equation for the degree of order of this axis becomes:

$$[1] \qquad \Delta\nu_D = \tfrac{3}{4}QS_{CD}(3\cos^2\Omega - 1)$$

where $\Delta\nu_D$ is the deuterium quadrupole splitting, Q is the quadrupole coupling constant for deuterium in a C—D bond, Ω is the angle between the phase director and the magnetic field, and S_{CD} is the degree of order of the C—D bond axis.

Using the figure for the ratio at the phase transition, $\Delta\nu_D$(type I)/$\Delta\nu_D$(type II) = 1.64, in [1] gives 0.82 as the ratio S_{CD}(type I)/S_{CD}(type II). The degree of order of the C—D axes in the detergent are thus smaller with respect to the director in the type I phase by a small amount under equilibrium conditions between the two phases. A similar statement applies to all components of the lyomesophase.

The effect of electrolyte addition is more pronounced in producing phase transitions than the changes in the counter ion content investigated previously (12). An approximately 5 mol% substitution of cesium for sodium ion is necessary before the phase change type I to type II is induced.

The effect of adding lithium sulphate in the form $Li_2SO_4 \cdot H_2O$ to a lyomesophase of composition 0.35 g sodium decylsulphate, 0.07 g decanol, and 0.56 g D_2O was also studied. Very similar results were obtained to the sodium sulphate additions reported above. The transition type I to type II lyomesophase occurs at 0.65 wt.% added hydrated lithium sulphate. This concentration is considerably higher than in the case of sodium sulphate, but it is not surprising that the transition should depend on the nature of the added electrolyte. The phase change was followed using ^{23}Na, ^{7}Li, and ^{2}H resonance signals.

The effect of increasing the decanol content in the ternary type I mesophase was also investigated. A series of samples were prepared containing sodium decylsulphate and heavy

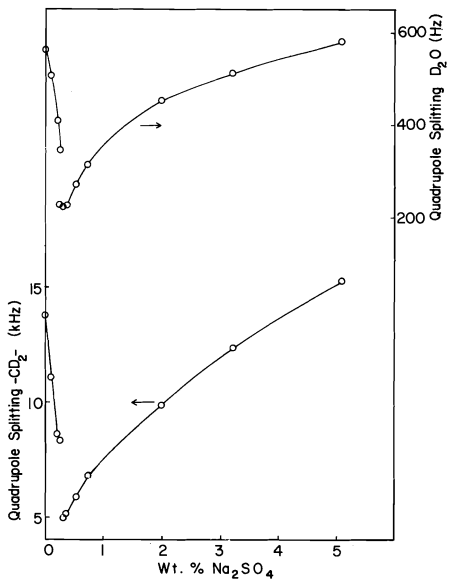

FIG. 1. Partially averaged deuterium quadrupole splittings in HOD and deuterated sodium decylsulphate-*3,3,4,4-d*$_4$ used as components of a lyomesophase described in the text. These splittings are plotted against added weight percent sodium sulphate.

water in the ratio 1:1.600 by weight and the decanol content was varied from 6.35 to 7.7 wt.% of the total sample. In Fig. 2 the sodium quadrupole splitting (measured as the total separation of the triplet) is plotted against the decanol concentration. The quadrupole splitting decreases slightly as the decanol content is increased up to 7.24 wt.% where a phase change occurs resulting in the formation of a second mesophase. This mesophase which is in equilibrium with the type I mesophase over a fairly extensive region does not orient in the magnetic field and results in a powder pattern spectrum. The second mesophase is less dense and samples in this region separate into two layers on standing. By comparison with the phase diagram of the corresponding sodium octylsulphate and sodium dodecylsulphate ternary systems (6), as well as those of similar ionic surfactants (6, 7) it is likely that the mesophase formed at high decanol content is a lamellar phase.

Decylammonium Chloride/Water Binary System

Simple binary mixtures of detergent and water do form birefringent uniaxial mesophases (4, 7), but these are not generally oriented in magnetic fields and the deuterium magnetic resonance spectra take on the powder diagram form (11). Decylammonium chloride/D_2O mixtures were studied between 29.9 wt.% D_2O to 53 wt.% D_2O. (The D_2O used contained 0.1 *N* HCl in order to decrease the rate of exchange of the labile deuteriums.) The temperature of the experiments was 27.8 $\pm$ 0.2°C and deuterium nmr powder signals were followed as a function of water content.

In Fig. 3 the water deuterium doublet splitting

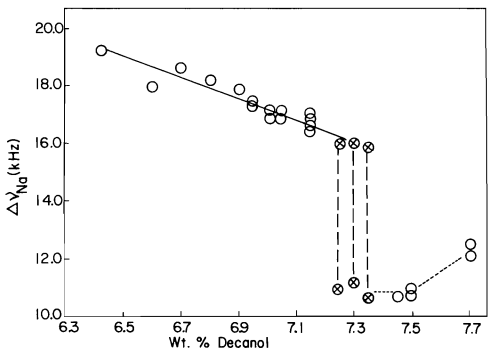

FIG. 2. Variation of the ^{23}Na quadrupole splitting with *n*-decanol content in a ternary SDS mesophase. The points ⊗ represent two splittings observed from the same sample.

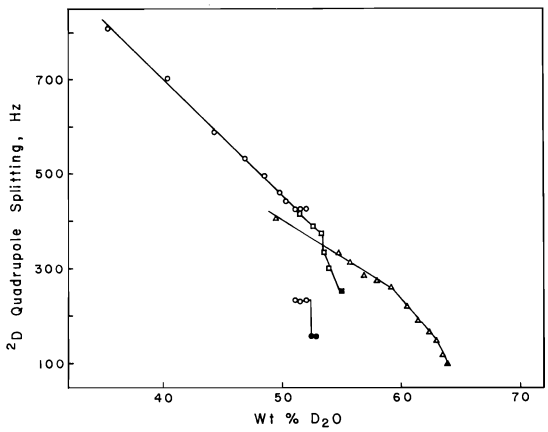

FIG. 3. The mesophase behavior of the binary system, decylammonium chloride/D_2O, with and without added ammonium chloride. The quadrupole splittings of the D_2O are plotted against the weight percent water: ○ the binary phase; □ the ternary system containing an ammonium chloride/decylammonium chloride ratio of 1:46.2; and △ the ternary system containing an ammonium chloride/decylammonium chloride ratio of 1:9.25. The filled points represent partly isotropic two phase samples.

is plotted against weight percent D_2O. Between 29.9 wt.% and 51.1% D_2O there is a linear decrease in D_2O quadrupole splittings with water content from 999 $\pm$ 10 Hz to 426 $\pm$ 1 Hz. The lyomesophases in this concentration range are known to be of lamellar form (4, 7). At 51.1 wt.% D_2O a separation of two birefringent phases occurs. Signals from both phases are doublets, but the new phase which appears in equilibrium with the original lamellar phase does orient in the magnet in a few seconds and appears as a sharp doublet. This second phase orients with the director perpendicular to the magnetic field direction. Fig. 4*A* is a spectrum of this two phase mixture in equilibrium. The co-existence concentration range is 51.1 to 52.3 wt.% D_2O. This appears to be a true equilibrium mixture of two mesophases because on warming to an isotropic medium and allowing the system to cool to 27.8°C again in the magnet, the two signals reappear in the same intensity ratio. When the samples near or in the two phase regions are allowed to cool from an isotropic solution in the magnetic field changes in the appearance of the signals assigned to the original lamellar phase occur. The powder pattern spectra from the lamellar phase become sharper doublets indicating that an orientation process has occurred. An almost completely oriented sample is shown in Fig. 4*B*. The doublet splitting

of the lamellar phase does not change on orientation which indicates that the mesophase directors orient perpendicular to the magnetic field. In the two phase region the ratio of the deuterium quadrupole splitting of the D_2O was 1.83 ± 0.01. Such a result clearly indicates that at least two different mesophases can lead to the same behaviour in a magnetic field.

At 52.3 wt.% D_2O and above a second two phase system occurs, but in this event only the upper one is birefringent. The upper phase is probably identical with the second type II phase indicated above. This upper phase orients in a few minutes and is type II while the lower phase is isotropic with a singlet deuterium spectrum. Above 53.0 wt.% only one isotropic solution remains.

The behavior in the absence of electrolyte is in complete contrast with the ternary system containing added salts. A mixture of ammonium chloride and decylammonium-*1,1-*d_2 chloride in the ratio by weight of 1:9.25 was weighed and to this mixture various percentages by weight of D_2O (containing 0.1 *N* HCl) were added so that composition variations were obtained between 48 and 64 wt.% water. The measurements of deuterium quadrupole splitting in the D_2O component are plotted in Fig. 3 against weight percent D_2O in the ternary mixture. The weight percent of electrolyte in the ternary system decreases somewhat between 48 and 64 wt.% D_2O, but the variation is not a strong one and for convenience of comparison it is included on a binary phase basis. At the lowest water contents the deuterium spectrum remains a powder pattern with no tendency to orientation in the magnetic field. Near 59 wt.% water there is a tendency for the mesophase to orient and at the highest water contents encountered the orientation process is rather rapid. At 59 wt.% there is a distinct break in the linear dependence of the quadrupole splitting of the type II phase on water content. Such a break indicates some structural change, perhaps a second-order type transition. We have obtained a similar subtle modification in a previous study of the same lyomesophase system with temperature (19). An isotropic phase in equilibrium with the type II lyomesophase occurs at 63.87 wt.% D_2O in the ternary mixture. The change in slope of the linear dependence of D_2O deuterium quadrupole splitting on water content was further probed by observing the $—ND_3^+$ and a α-d_2 deuterated chain segment. The $—ND_3^+$ and α-CD_2 deuterium doublets were obtained as a function of water content and this is plotted in Fig. 5. The corresponding subtle break in the linear dependence on water content is found at *ca.* 59% wt.% D_2O. The structural changes in the lyomesophase are transmitted to the degrees of order of both the hydrophilic and hydrophobic compartments. It is possible that interface water undergoes local rearrangements without producing a precipitous alteration of the mesophase superstructure. Low angle X-ray studies are suggested as a means of elucidating these modifications. At 63.87 wt.% water a second isotropic and more dense phase separates in equilibrium with the type II mesophase. At higher water contents the orientation is rapid. The ratio of α-CD_2 deuterium splitting to the $—ND_3^+$ value is constant at 2.33 ± 0.02 over the whole region investigated. The quadrupole couplings of the $—ND_3^+$ head group are linearly dependent on those of the D_2O component, but there is an intercept of 0.7 kHz, showing a discontinuity in extrapolated order between the hydrocarbon and aqueous regions. The experimental relationship found is:

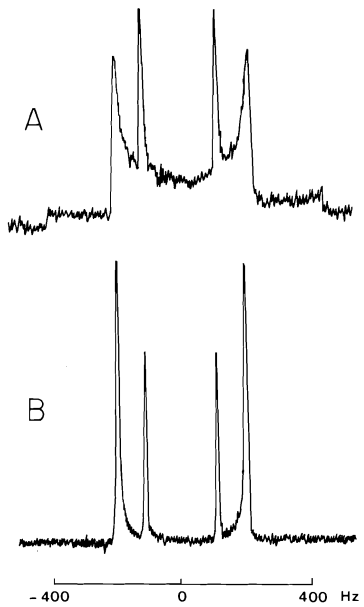

FIG. 4. ^2H spectrum of decylammonium chloride – D_2O samples in the two phase region. A: sample with 51.1% D_2O after leaving overnight in the magnetic field. B: sample with 51.4% D_2O after the sample was heated to an isotropic phase allowed to cool in the magnetic field. The mesophase with the largest splitting becomes almost completely oriented by this cycle.

[2] $$\Delta\nu_{D_2O} = 0.040\Delta\nu_{ND_3^+} - 29$$

where $\Delta\nu_{D_2O}$ and $\Delta\nu_{ND_3^+}$ are the quadrupole splittings in Hz of D_2O and $-ND_3^+$ groups, respectively. This effect has been reported earlier for both D_2O and Cl^- ion in the aqueous compartment (19).

To further investigate the effect of adding an electrolyte to the binary system, another series of samples containing a smaller amount of electrolyte was studied. These samples contained an ammonium chloride to decylammonium chloride ratio of 1:46.2 by weight (the electrolyte made up *ca.* 1% of the sample). The quadrupole splittings of the D_2O in these samples are also shown in Fig. 3.

There is a distinct change in the concentration dependence of the quadrupole splitting at 53.4% D_2O. Samples with D_2O concentrations higher than this amount rapidly orient macroscopically in the magnetic field with the director perpendicular to the field direction. Samples with slightly less than 53.4% D_2O tend to orient perpendicular to the field when they are allowed to cool from an isotropic solution in the magnetic field; the sample with the lowest amount of water (51.5%) showed no appreciable orientation.

Other Ternary Surfactant/Water/Electrolyte Systems

Some further investigations of new ternary systems which will spontaneously orient in magnetic fields have been implemented and the results, though not as comprehensive as those reported above, are worth recording as a guide to others who plan uses for lyomesophases. The ternary systems containing an electrolyte and the sodium or cesium decylsulphate or potassium laurate are in contrast with the corresponding ternary systems based on the decylamine salts described here and elsewhere (15, 19). Unlike the mesophases formed from the decylamine salts, these mesophases orient with the director parallel with the field; *i.e.*, type I behavior. These type I mesophases were found to orient homogeneously after several hours in the magnet.

Sodium decylsulphate/electrolyte/water was prepared in two mesophases of composition: (*a*) 55.7 wt.% D_2O, 39.8% sodium decylsulphate, and 4.5% anhydrous sodium sulphate; (*b*) 53.3% H_2O, 41.9% sodium decylsulphate, and 4.8% Na_2SO_4. Both mixtures formed single birefringent type I lyomesophases. The deuterium splitting in (*a*) at 35°C was 696 Hz and the

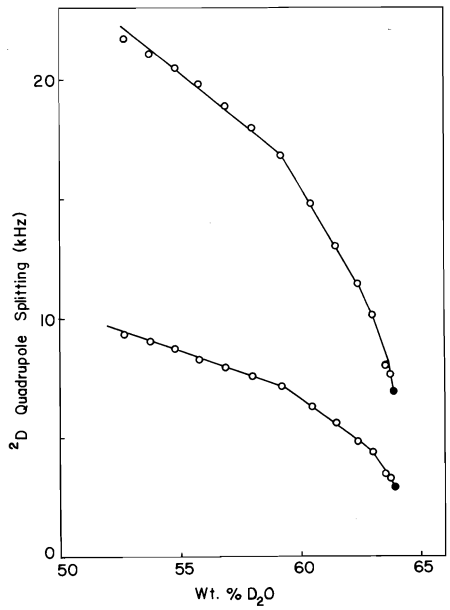

FIG. 5. Deuterium quadrupole splittings of the terminal $-ND_3^+$ group (lower curve) and α-CD_2 group for ternary mixtures ammonium chloride, decylammonium chloride, and D_2O as described in the text.

separation of adjacent peaks of the 3:4:3 triplet of ^{23}Na in mesophase (*b*) was 7.688 ± 0.005 kHz. The angularly dependent peaks were halved in separation on rotation 90° about an axis perpendicular to the magnetic field after sufficient time elapsed to homogeneously orient the sample.

Cesium decylsulphate/water/electrolyte systems were prepared as homogeneous lyomesophases of type I in the following proportions: (*c*) 44.3% D_2O, 52.2% cesium decylsulphate (CsDS), 3.5% Na_2SO_4; (*d*) 49.3% D_2O, 48.8% CsDS, 2.0% Na_2SO_4; (*e*) 49.7% H_2O (containing 0.5% D_2O), 46.6% CsDS, 3.7% $CsNO_3$. The mesophases gave D_2O deuterium splittings of 632 Hz, 545 Hz, and 458 Hz, respectively, at 35°C.

A ternary system potassium laurate (KL)/D_2O/potassium chloride with 65.1, 32.7, and 2.2 wt.%, respectively, with a deuterium (D_2O) doublet of 558 Hz at 35°C proved to be a type I lyomesophase.

Some comments can be added on these three new lyomesophase systems. Both the sodium decylsulphate and potassium laurate mesophases above form two phase mixtures in the absence of added electrolyte, an extremely viscous birefringent mesophase and an isotropic phase. The corresponding binary CsDS/water systems

form a single mesophase which is also extremely viscous. The ternary CsDS mesophases have the unusual physical property that they become extremely viscous on cooling and change into an isotropic phase.

Discussion

Compared to the large number of lyomesophases known, the number which will spontaneously orient in a magnetic field is relatively small. The mesophases which will macroscopically orient are characterized by a lower bulk viscosity. Presumably the forces exerted on these uniaxial liquids by the magnetic field due to their diamagnetic anisotropies are sufficient to overcome the internal viscous forces.

The binary surfactant/water systems containing sodium or cesium decylsulphate, or potassium laurate undergo a phase transition from an isotropic solution to an extremely viscous mesophase as the surfactant concentration is increased. In the case of the potassium laurate and the similar sodium octylsulphate and dodecylsulphate binary systems, these mesophases have been identified as a 'middle' or 'hexagonal' phase composed of cylindrical micelles packed in a hexagonal array (7, 20). These middle phases can incorporate up to *ca.* 10% decanol; at higher decanol concentrations lamellar phases are formed (7).

The addition of an electrolyte, decanol, or both to the binary CsDS, SDS, and KL systems has two marked effects. The liquid crystalline phase is extended to lower surfactant concentrations and there is a drastic reduction in the viscosity. In light of the difference in the behavior of the resulting mesophases, some of these changes must also be accompanied by a phase change. On the addition of only an electrolyte, all three systems form type I mesophases; on the addition of only decanol the SDS forms a type I phase, the CsDS forms a type II mesophase (12), and the KL system remains a viscous middle phase; and on the addition of both electrolyte and decanol all three systems form type II mesophases (21) which also have the most extensive mesomorphic region. However, a quaternary system containing anilinium decylsulphate has been found to be a type I phase (22).

Addition of less than 1 wt.% of electrolyte to the ternary lyomesophase system, sodium decylsulphate/decanol/water provokes a phase change from a uniaxial fluid (with $\Delta\chi > 0$) which orients with the director parallel to a magnetic field direction, to a mesophase (with $\Delta\chi < 0$) which orients with the phase director in all directions perpendicular to the field. It has been suggested that these ternary and quaternary phases are lamellar and hexagonal phases, respectively (23). However, the ratio of the degree of order parameter for the paraffinic chain and for D_2O of type I/type II $= 0.82$ observed at the phase transition is not consistent with such a phase change. A ratio of two would be expected as a result of the additional averaging motion in the hexagonal phase as a result of rapid diffusion around the cylindrical micelles. A factor of approximately two has been observed in the comparison of lamellar and hexagonal mesophases (19, 24). Also, the mesophase resulting from the phase change caused by increasing the decanol concentration of this type I mesophase can be assumed to be a lamellar phase by comparison with other similar surfactant systems (7).

The type II mesophases have been assumed to be of hexagonal type with a sufficiently low viscosity to allow the mesophase to orient in a magnetic field (12, 15, 16, 19). This assumption was mainly based on the fact that the hexagonal phase was the only mesophase which was usually found in the corresponding region of the phase diagrams of a large number of similar surfactants. The discovery of another class of type I mesophases, the surfactant/water/electrolyte system, in addition to the other ternary type I mesophases containing decanol which all have a similar surfactant/water concentration as the type II mesophase, makes comparisons with similar well characterized systems of little use. It is apparent that other data, in particular from low-angle X-ray diffraction studies, are necessary to elucidate the structure of these various mesophases.

The binary system decylammonium chloride/water has a large range of mesophase compositions but these liquid crystals do not spontaneously orient in a high magnetic field. The lamellar mesophase can be heated at the higher water contents to an isotropic fluid, which on cooling in the magnet slowly reforms a lamellar phase in a much more oriented state. This mesophase has a negative diamagnetic anisotropy and exhibits type II behavior with alignment of the director perpendicular to the field

direction. This alignment with the hydrocarbon chains perpendicular to the magnetic field is consistent with the diamagnetic anisotropy of paraffinic chains which is known to be negative (25). An extremely narrow co-existence range with a second type II mesophase occurs and at higher water contents this mesophase co-exists in equilibrium with an isotropic micellar solution. The behavior of this binary system is very similar to the octylammonium chloride systems in which the more extensive mesophase was assigned as lamellar and the other as hexagonal (7). A similar assignment of the mesophases formed with decylammonium chloride is consistent with the ratio of the quadrupole splittings observed; the ratio of 1.83 is close to the value of 2 expected for a lamellar to hexagonal transition. It should be noted that if this second phase is hexagonal, then it orients with the cylinder axis perpendicular to the field. Therefore, the diamagnetic anisotropy of the hydrocarbon chains cannot be the dominant contribution to the anisotropy of the mesophase.

Electrolyte additions provoke profound changes in the mesophase behavior. The presence of an electrolyte extends the mesophase region to much higher water concentrations, but in contrast to the other ternary systems discussed above, the resulting mesophases are of type II. On the addition of *ca.* 1% electrolyte, the mesophase with the lower degree of order has a larger composition range and there appears to be a subtle phase modification which reduces the difference between the two mesophases. At the higher electrolyte concentration (*ca.* 4%) the mesophase which will orient has a much more extensive region and the phase transition almost disappears. It is apparent that the addition of an electrolyte modifies the behavior of both lamellar and hexagonal phases.

The degree of order of solubilized molecules and ions in oriented lyomesophases has been determined at specifically deuterated C—D bond axes from the quadrupole splitting of the deuterium magnetic resonance. Mixtures at low concentration of specifically deuterated alkanes, alcohols, carboxylic acids, and carboxylates of different chain length have been observed in host cationic and anionic lyomesophases. The degree of order of a given C—D position in alcohols increases strongly with chain length up to a length comparable with the host detergent. A broad series of carboxylic acids and carboxylate ions from C_2 to C_{16} have been deuterated in the α position. The α-C—D bond axis in the solubilisate increases in order with chain length, the anion having lower order than the parent acid. An accurately *linear* increase in the degree of order of the α position is observed for intermediate chain lengths. At chain lengths approximately equal to the host chain lengths the α position reaches a limiting value in the degree of order and further segments do not influence the order. At short chain lengths the degree of order is *less* than that predicted from extrapolation of order in the linear region. This has been interpreted in terms of distribution into the aqueous compartment by the solubilisates of short chain length. Acetic acid and the acetate, propionate, butanoate, and pentanoate ions spend an appreciable amount of time in the aqueous region. An estimate has been made of these distributions based on reasonable assumptions.

DOUGLAS M. CHEN, FRED Y. FUJIWARA et LEONARD W. REEVES. Can. J. Chem. **55**, 2404 (1977).

On a déterminé le degré d'ordre des molécules et des ions solubilisés dans des lyomésophases orientées; ces études ont été effectuées par rapport à des axes de liaisons C—D deutérés d'une façon spécifique à partir des couplages quadrupolaires de la résonance magnétique du deutérium. On a observé, dans des lyomésophases cationique et anionique agissant comme hôtes, des mélanges contenant de faibles concentrations d'alkanes, d'alcools, d'acides carboxyliques et de carboxylates de longueurs de chaîne différentes et deutérés d'une façon spécifique. Le degré d'ordre pour une position C—D donnée dans les alcools augmente d'une façon très prononcée avec la longueur de la chaîne jusqu'à une longueur comparable à celle du détergent agissant comme hôte. On a deutéré en position α une grande série d'acides carboxyliques et d'ions carboxylates allant de C_2 à C_{16}. L'ordre de l'axe de liaison α-C—D des molécules solubilisées augmente avec la longueur de la chaîne; l'anion a un ordre plus bas que celui de l'acide qui lui a donné naissance. On observe une augmentation linéaire précise dans le degré d'ordre dans la position α pour des longueurs intermédiaires de la chaîne. A des longueurs de chaîne approximativement égales à celles des longueurs de chaîne de la molécule hôte, la position α atteint une valeur limite dans le degré d'ordre et des segments supplémentaires n'influencent pas l'ordre. Aux courtes longueurs de chaîne, le degré d'ordre est plus faible que celui prédit à partir de l'extrapolation de l'ordre dans la région linéaire. On a interprété ces résultats en termes de distribution dans la phase aqueuse par les molécules qui solubilisent et qui ont de courtes longueurs de chaîne. L'acide acétique et les ions acétate, propionate, butanoate et pentanoate passent une quantité appréciable de temps dans la région aqueuse. On a fait une évaluation de ces distributions qui est basée sur des hypothèses raisonables.

Introduction

In aqueous micellar solutions of soaps and detergents (1, 2), the solubility of all manner of substances is greatly increased. This process of 'solubilization' is known to arise because of micelle formation (2) and the internal division of the stable colloidal dispersion into hydrophobic micelle interiors which are able to occlude organic substances in a similar manner to an organic solvent.

We have been engaged in a series of studies

[1]Visiting Professor, Universidade de São Paulo, 1967–present.

of concentrated micellar solutions which take on the form of uniaxial fluids (3). Many of these uniaxial media have the property of spontaneously orienting with the mesophase directors, either all parallel to a magnetic field direction or in all directions perpendicular to a large magnetic field (3). By using nuclear magnetic resonance methods the degree of order of axes in individual components of the mesophases can be determined with respect to the magnetic field direction (4). In general we may write

$$[1] \qquad S_a = \tfrac{1}{2}\langle 3\cos^2\theta_a - 1\rangle$$

where S_a = degree of order of an axis, θ_a = the angle between that axis and the mesophase symmetry axis (the director), and also

$$[2] \qquad \Delta\nu = \tfrac{3}{2}QS_a\tfrac{1}{2}(3\cos^2\Omega - 1)$$

where $\Delta\nu$ is the quadrupole splitting of the deuterium magnetic resonance doublet, S_a is the degree or order of the C—D, O—D, or N—D bond axis (assuming an axially symmetric nuclear quadrupole coupling tensor), Ω is the angle between the mesophase director and the magnetic field, and Q is the nuclear quadrupole coupling constant of the deuterium nucleus. In the case of parallel alignment of the phase director and the magnetic field the factor $(3\cos^2\Omega - 1)/2$ is $+1$ while with perpendicular direction of the symmetry axis of the mesophase this function has a value $-\frac{1}{2}$.

Being a fluid phase in which freedom of motion of molecules, ions, segments, and head groups is impeded only by uniaxial constraints, then S_a may be interpreted as a local measure of structure and order. Local symmetry must be sensibly used in these situations since the possibility of orientation of an axis about the magic angle $(3\cos^2\theta_a - 1)/2 = 0$ occurs. There is a great deal of heterogeneity of local order, the water O—D bond being almost isotropic in average motion, while the head group ionic region is the most highly ordered segment (4, 5). The degree of order in different parts of the lyomesophase tends to be imposed on any guest molecule or ion dissolved in the system and thus the location of a guest species can be investigated.

It is important to realize that the nuclear magnetic resonance (nmr) signals are averaged over all events which occur with smaller than $\sim 10^{-3}$ s correlation time. In the case of counter ions, added electrolytes, and water there is a rapid exchange between the actual interface and more distant localities in the water compartment and only an average degree of order for all sites is recorded (4).

The act of 'solubilization' implies inclusion in the hydrophobic region of the guest species. The extent to which this is true and what degree of local order is imposed upon a guest molecule or ion, is the object of this study of components solubilized in lyomesophases. The method used has been deuterium magnetic resonance of the guest and some host molecules and ions.

Experimental

Preparation of Deuterated Materials

Alcohols (*n*-propanol through *n*-decanol) deuterated at specific positions were prepared by deuteration of the corresponding alkynols over platinum oxide (Adam's catalyst), (6, 7) by a low pressure deuterogenation reaction. If a terminal acetylenic group was deuterogenated, this was preceded by exchange of the acidic acetylenic proton for deuterium. A typical exchange to form 5-deutero-4-pentyn-1-ol was achieved as follows: 0.4 g of sodium metal was slowly dissolved in 10 ml D_2O, followed by 10 g of 4-pentyn-1-ol. The mixture was stirred for 6 h and the organic layer separated, dried, and distilled (7). About 80% replacement of hydrogen was achieved in one exchange and this was deemed sufficient. In deuterogenation reactions about 90% deuteration was obtained but often a significant and detectable amount of deuterium wandered to the adjacent positions giving a bonus of easily assigned deuterium resonances. Similar procedures were used to deuterogenate alkynes.

A series of α-d_2-carboxylic acids were synthesized by heating the sodium or potassium salts with D_2O containing NaOD in a stainless steel bomb at 150°C (9). The deuterated carboxylic acids were fractionally distilled except those longer than lauric acid.

Spectrometers Used

The measurements in all cases were made at 15.36 MHz for deuterium signals with samples contained in 5 or 10 mm tubes on a Varian XL-100 spectrometer. For alkanes and alcohol solubilization the probe temperature was 26.6 to 26.8°C except where noted. The experiments on solubilization of carboxylic acids and carboxylates were carried out at 34°C. Proton noise decoupling was activated during the observation of deuterium nmr in some cases.

The deuterium nmr signals required accumulation of 6000 to 30 000 transients and in some cases high field and low field spectra were recorded separately because quadrupole couplings exceeded the 12.5 kHz spectral width limit imposed by the spectrometer. No difficulty was encountered in piecing together the two halves of the spectrum by use of the overlap region.

Methods Used to Compare Degrees of Order

In order to compare the degree of order of the components solubilized in a lyomesophase, it was found convenient to allocate in small amount each component to be studied to a single lyomesophase so as to compare them in the same phase at the same temperature. This finality was achieved in stages while taking care that the solubilized components did not appreciably change the

TABLE 1. Deuterium quadrupole splittings of specifically deuterated normal alkanes and alcohols in decylammonium chloride mesophases*

Sample	Solubilisates	Quadrupole splitting (kHz)	$\Delta\nu(CD_n)/\Delta\nu(HOD)$

host mesophase order. An example of this procedure is now given.

In order to compare the deuterium quadrupole couplings in the α-position for the acids, acetic to decanoic, a lyomesophase was prepared first containing all acids with an even number of carbons. The composition of this lyomesophase in our code denoted phase D28 was 50.95 wt.% H_2O (containing 0.1% D_2O and adjusted to p*H* 2), 5.45 wt.% decanol, 38.18 wt.% sodium decylsulphate (SDS), and 4.36% anhydrous sodium sulphate. The balance of mesophase D28 was made up of components of very low concentration, whose relative degree of order along the α-C—D bonds were to be compared. These were 0.11 wt.% C_2, 0.21% C_4, 0.35% C_6, and 0.38% C_8 using the notation C_2 as the 2 carbon acid, etc. The deuterium magnetic resonance spectra gave a series of doublets which could routinely be assigned to the α positions in the various acids and DOH. A second lyomesophase D29 of composition 50.83% H_2O (0.1% D_2O, p*H* = 2), 5.44% decanol, 38.11% SDS, 4.36% Na_2SO_4, 0.22% C_3, 0.24% C_5, 0.29% C_7, and 0.50% C_{10} was also prepared and the deuterium magnetic resonance spectrum of the oriented lyomesophase assigned as for D28. The two mesophases D28 and D29 were mixed to form a single lyomesophase with approximately equal weights of each. The resulting uniaxial fluid has the composition 50.89 wt.% H_2O, 5.45% decanol, 38.14% SDS, 4.36% Na_2SO_4, 0.05% C_2, 0.12% C_3, 0.09% C_4, 0.13% C_5, 0.16% C_6, 0.16% C_7, 0.16% C_8, and 0.28% C_{10}. The information gathered with respect to assignments of the deuterium spectra of D28 and D29 separately, served to assign completely the respective α-CD_2 doublets in the combined and oriented lyomesophase. A sample containing the C_9 to C_{12} acids and another containing the C_{10}, C_{14}, and C_{16} acids were prepared, with the same SDS/decanol/sodium sulfate ratio as in the samples described above, to study the longer chain acids.

The solubilization of the series of α deuterated carboxylate anions added as the sodium salts, was studied in a series of samples corresponding to those described above for the carboxylic acids but with water at p*H* = 10 to assure complete ionization of the carboxylic headgroups. The samples containing the long chain carboxylates were studied as a function of the water content in order to compare these quadrupole splittings with those observed in the samples containing the C_2 to C_{10} salts.

Solubilization studies of the alcohols were made in mesophases of decylammonium chloride/water/ammonium chloride. A typical lyomesophase was: 38.46 wt.% decylammonium chloride, 0.82% NH_4Cl, 56.94% H_2O (0.1% D_2O, p*H* 3), 0.15% methanol-d_3, 0.30% propanol-*2,2,3,3,3-d*$_5$, 1.12% pentanol-*3,3,4,4-d*$_4$, 1.12% heptanol-*3,3,4,4-d*$_4$, and 1.09% nonanol *3,3,4,4-d*$_4$. The alkanes and alcohols in Table 1 were prepared in similar lyomesophases.

The host lyomesophases based on the sodium decylsulphate and decylammonium chloride detergents used in this study macroscopically orient in the magnetic field with the director perpendicular to the field as a result of their negative diamagnetic anisotropy. It was necessary to keep the concentrations of the solubilized species sufficiently low since at higher concentrations a phase change occurs, which usually resulted in a mesophase which will not orient in the magnetic field. In several cases specifically deuterated decylsulphate ions were used and the degree of order profile of its hydrocarbon chain (7) was found to be unaffected by the presence of the small amounts of solubilized components employed.

Results and Discussion

The type II mesophases employed in this study have a fairly extensive liquid crystalline region and are probably 'middle' or 'hexagonal' phases composed of cylindrical micelles packed in a hexagonal array (12). Although the structure of these mesophases which have the ability to orient in magnetic fields have not been unambiguously established, a knowledge of the exact shape and packing of the micelles is not critical in this study of solubilization. Previous studies have indicated that the nature of the hydrocarbon core is not dependent on the shape, whether cylindrical or lamellar, of the micelle (5, 13, 14).

Solubilization of Alcohols and Alkanes in Decylammonium Chloride Mesophases

A typical deuterium nmr spectrum of the solubilized alcohols, methanol to nonanol, in the odd carbon series is present in Fig. 1. The extreme low field section is outside the spectral range but doublets can be discerned for water HOD (w), methanol (m), propanol (p) with a terminal CD_3 group of smaller splitting, pentanol-*3,3,4,4-d*$_4$ (pe) with the smaller doublet splitting associated with the 4,4 position, heptanol (h) with the 3,3 and 4,4 positions overlapping, and nonanol (n) also with the 3,3 and 4,4 positions superposed in the spectrum. The peaks become broader as the quadrupole splittings increase because there are small deviations in the homogeneity of the order and because dipole–dipole couplings between the deuterium nuclei and with adjacent protons (not completely decoupled) become larger as the order parameter increases.

Additional samples containing the same alcohols labelled in other positions were studied, as well as the corresponding samples containing the even carbon series of alcohols. The various samples were not directly comparable because of small differences in sample compositions. However it was observed that over the small range of compositions used the ratio of the deuterium quadrupole splitting of any labelled alcohol to that of the HOD was constant to within *ca.* 1%. In Fig. 2 these ratios for various deuterated positions are plotted against the length of the solubilized alcohol. The quadrupole splittings of the HOD were in the range from 221 to 246 Hz.

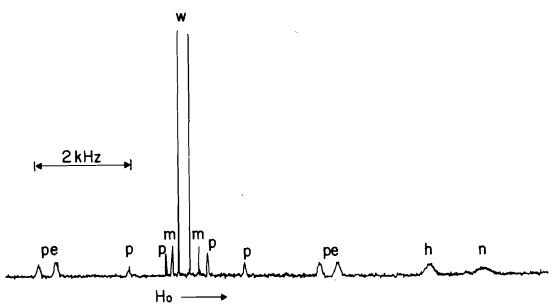

FIG. 1. Varian XL-100 F.t. spectrum of a decylammonium chloride mesophase containing: (*1*) methanol-d_3 (m), (*2*) propanol-*2,2,3,3,3-d*$_5$ (p), (*3*) pentanol-*3,3,4,4-d*$_4$ (pe), (*4*) heptanol-*3,3,4,4-d*$_4$ (h), (*5*) nonanol-*3,3,4,4-d*$_4$ (n). The sample composition is given in the experimental section. A total of 6000 transients were accumulated. Probe temperature was not determined accurately but was estimated to be around 32°C. Since the maximum spectral width was 12 kHz, and since this is in the range of the larger quadrupole splittings of the longer chain alcohols, the spectrum was offset so as to display only the high field peaks for splittings larger than 5 kHz.

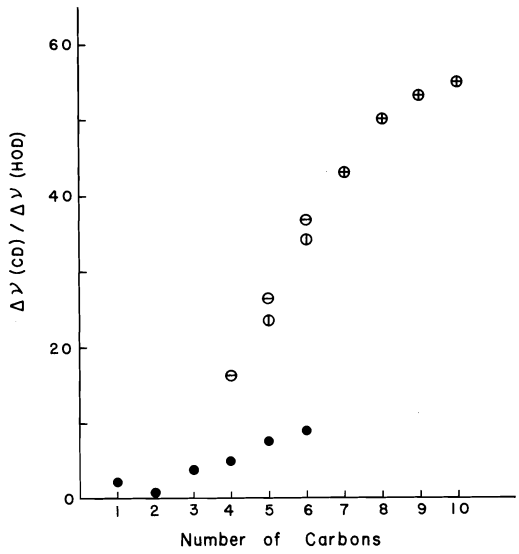

FIG. 2. The ratio of the deuterium quadrupole splitting of specifically deuterated alcohols to that of the HOD in the same mesophase plotted against the length of the alcohol chain. The following symbols indicate the position deuterated: ● terminal methyl group, ⊖ carbon 3, ⓘ carbon 4 and ⊕ average value for carbons 3 and 4.

Some general trends are noteworthy. The longer the chain the alcohol has, the larger the ratio for increase in degree of order over that of the water component, for any given —CD_2— in the chain. For example, factors for the 3,3-CD_2 position are 16.2 for butanol, 25.9 for pentanol, 37.0 for hexanol, 43.0 for heptanol, 50.1 for octanol, 53.0 for nonanol, and 57.5 for decanol. Terminal methyl CD_3— groups are always of lower degree of order than the —CD_2— segments of the chain. We have discussed in earlier papers the ratio of —CD_2— to —CD_3 couplings in terminal —CD_2—CD_3 groups (7, 10, 11). The ratios experimentally observed in this work are 13.2 ethanol, 2.8 propanol, 3.3 butanol, 3.0 pentanol, and 3.5 hexanol. The increase in degree of order at any segment with chain length could be connected with the exchange of the alcohol with the aqueous compartment in which its degree of order is expected to be low. In this case, the mean degree of order measured would be the time weighted average of the more and less ordered environment. Kinoshita *et al.* (15) mea-

sured the solubility of alcohols butanol to decanol in water. Using the degree of order ratios for the CD_2 3,3-position in decanol and butanol of 56.0 and 16.2, respectively, compared to the water, the butanol would appear to be largely in the water compartment. The solubility measurements (15) indicate a distribution of only ~2% of the butanol in water.

These results are, however, so disparate that it is clear the mean degrees of order measured at a given chain segment in this series, except for the very short chain alcohols, do not reflect in any way the distribution of the alcohol between aqueous and hydrocarbon chain regions. The change in degrees of order at a given position away from the head group in alcohol chains of increasing length embedded as guest molecules in a host bilayer probably reflect the increased freedom for conformational equilibria in the chain as it becomes shorter.

The data for deuterium quadrupole couplings on solubilized alkanes in the decylammonium chloride mesophase are summarized in Table 1. The table enables a comparison to be made with the solubilized alcohol of the same chain length in the same mesophase. For example, for heptane deuterated at 3,3,4,4 only one doublet was resolved and the degree of order in the corresponding alcohol positions is about six times larger. The head group thus seems to act as an anchor in the interface greatly restricting the motion of the chain at the 3,3,4,4 positions. The effect of the polar head group is evident even at the end of the hydrocarbon chain. The degree of order of the terminal CD_3 group of octane is much smaller than that expected (by extrapolating the results shown in Fig. 2) for the corresponding position of octanol.

Solubilization of Carboxylic Acids and the Carboxylate Ion

In this series of experiments, the α-CD_2 group of the solubilized components was observed. The host mesophases were always a water, sodium decylsulfate, decanol, and sodium sulfate system in which the ratio of the last three components was kept constant. Typical mesophase compositions are given in the experimental section. The solubilisates were studied in three groups; the carboxylic acids or carboxylates from C_2 to C_{10} with the exception of C_9 were studied in one sample and the longer chain solubilisates were studied in samples containing the C_9 to C_{12} or C_{10}, C_{14}, and C_{16} acids or carboxylates. Since the nature and amounts of added solubilisates does affect the average degree of order of the mesophase, the results from different samples were compared in the following manner. In the case of the carboxylic acids, the quadrupole doublet of the α-CD_2 signal of decanoic acid was found to be identical to those of the higher homologues. The line width of the overlapping peaks arising from the C_{10}, C_{11}, and C_{12} or C_{10}, C_{14}, and C_{16} acids were not significantly broader than the signal due only to C_{10} acid. The results for the carboxylic acids are shown in Fig. 3.

The α-CD_2 quadrupole doublets for the C_9 to C_{12} carboxylate anions were resolved. On varying only the water content the ratio of the quadrupole splittings, C_9:C_{10}:C_{11}:C_{12}, was found to be constant to within 0.5%. In the concentration range studied, the quadrupole splitting for lauric acid-α-d_2 varied from 17.64 to 10.96 kHz; the mesophase was stable on the addition of more water but the peaks could no longer be resolved. A similar behavior was observed in the samples containing the C_{10}, C_{14},

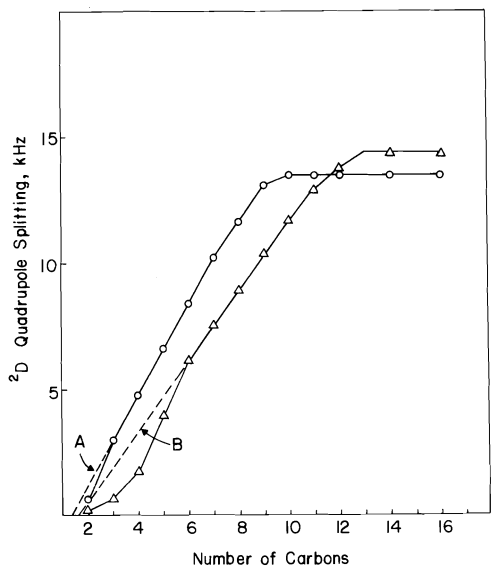

FIG. 3. Deuterium quadrupole splittings for the α-CD_2 position of solubilized carboxylic acids and carboxylates in a quaternary lyomesophase sodium decylsulphate, decanol, water, and sodium sulfate. These are plotted as a function of the chain length of the solubilisate. The carboxylic acids are denoted by ○ and carboxylates by △. In both cases linear portion of the dependence is extrapolated back to shorter chains by dotted curves A and B.

and C_{16} carboxylates. This constant ratio observed for the C_9 to C_{16} carboxylates was used to normalize these results to those observed in the sample containing the shorter homologues. In Fig. 3 the quadrupole splittings at the α-CD_2 positions are plotted against the length of the solubilized chain for both carboxylate and carboxyl systems.

The dependence of the degrees of order of a chain position with chain length for the carboxylic acids and the carboxylate anions appears to be very similar to that of the alcohols. There is an increase in the degree of order of the α-CD_2 group with chain length up to a length comparable to the host decylsulphate chain. This increase in degree of order with chain length reaches a saturation where additional —CH_2— groups have no effect. The carboxylic acids reach a maximum order at the α position at close to half the bilayer thickness of 10 carbon atoms, while the anionic carboxylate detergent ions reach a steady degree of order at the α position at a 13 or 14 carbon chain. A comparison between the degrees of order in the limiting regions cannot be made from these data because of differences in sample composition. Work is presently in progress to compare the degree of order of the α positions in these long chain carboxylic acids and anions with that of the host decylsulphate chains. However the results in Fig. 3 show that there is a considerable difference in order at the α-C—D bonds between anions and acids at all chain lengths below those in the limiting region, the carboxylate ion head group provoking the smaller degree of order.

The short chain carboxylates are much more soluble in water than the parent acids and low degrees of order are consequently observed for acetate and propionate ions because of a distribution into the water compartment of a significant fraction of the solubilized ion. Both the carboxylic acids and carboxylates from C_3 to C_9 and C_6 to C_{11}, respectively, increase in degree of order at the α position in a linear fashion. The linearity of the dependence of α position order on chain length is quite a precise one from C_3 to C_7 for the acids and C_6 to C_{10} for the detergent anions (Fig. 3). This experimental fact encourages an explanation of the degrees of order of the shorter chains in terms of an equilibrium distribution model. Linear extrapolations from the longer chains give the dashed lines A for acids and B for anions in Fig. 2. The degrees of order of shorter chain species always fall below the extrapolated linear dependence on chain length; furthermore, the extrapolations indicate a degree of order zero at a chain length approximately one carbon in length, this carbon being the carboxyl carbon. It is reasonable to assume therefore that for those acids or anions which are included completely in the bilayer the increase in order at the α-CD_2 position is a linear function of the chain length. The linear section of the degree of order dependence can be expressed:

$$[3] \qquad \Delta\nu_D = 1.401n_c - 2.294$$

for carboxylates, and

$$[4] \qquad \Delta\nu_D = 1.809n_c - 2.461$$

for carboxylic acids

The correlation coefficient for [3] is 0.9998 and for [4] 0.99996. '$\Delta\nu_D$' is the deuterium nuclear quadrupole splitting in the α-CD_2 positions in kHz and n_c is the number of carbons in the molecule or ion.

The experimental degree of orders measured for acetic acid-d_3, acetate-d_3, propionate-d_2, butanoate-d_2, and pentanoate-d_2 are smaller than those extrapolated from longer chains. Let us assume that there is a rapid exchange process which leads to this deviation from the above equations. The measured degree of order becomes:

$$[5] \qquad S_{obs} = x_D S_D + (1 - x_D)S_W$$

S_{obs} is the observed degree of order, S_D the degree of order while located in the hydrophobic bilayer, and S_W the value while located in the water compartment; x_D is the mole fraction of the solubilized component in the bilayer and thus $(1 - x_D)$ is that fraction in the aqueous region. Since degrees of order are proportional to the quadrupole splittings we may work with the latter. $\Delta\nu_{obs}$, $\Delta\nu_D$, and $\Delta\nu_W$ may be used to symbolize [3] and [4] in terms of quadrupole splittings. The value for $\Delta\nu_W$ must be very small compared to $\Delta\nu_D$. For example $\Delta\nu_W$ for the acetate ion must be less than 0.18 kHz. Let us assume that $\Delta\nu_W$ for both acids and ions is 0.15 kHz and that it has the same sign as $\Delta\nu_D$. The value of $\Delta\nu_D$ can be obtained from the extrapolated linear region with an appropriate n_c, while the value $\Delta\nu_{obs}$ is taken in each case from the values used for Fig. 3. The mole fractions x_D can be computed from [5]. The results obtained are the following: 0.298 for

propionate ion, 0.511 for butanoate ion, 0.831 for pentanoate ion, and 0.468 for acetic acid molecules. The uncertainty in the estimation of $\Delta\nu_W$ renders the calculations especially subject to large errors for acetic acid and consequently corrections for the difference between the methyl group methylene group motions was neglected. The mole fractions of these species calculated for the bilayer are in accord with the increasing hydrophobicity. The greater dispersion of carboxylate ions from the bilayer into the water is rational in terms of the existence of a counter ion and the aqueous solubility of the salts. The increase in order at the α position in the linear region per $-CH_2-$ segment is larger for a neutral carboxylic acid than the anion indicating a more effective packing of the neutral species in the host bilayer. Two types of chain motions can be identified which can account for the increase in the degree of order of the α position in the intermediate chain length region: (*1*) a decrease in the freedom of conformational motions as the chain becomes longer and (*2*) a decrease in the amplitude of the oscillations of the average chain axis about the normal to the interface. The second of these averaging motions could be expected to decrease and reach a limiting value with increasing chain length as a result of the increasing intermolecular interactions of the dilute guest hydrocarbon chain with host chain matrix. A quantitative analysis of the chain motions is needed to account for the observed linear dependence in the intermediate chain length region.

In the limiting region the degree of order of the chain segments near the head group appears to be dominated by conformational motions which are not affected by increased chain lengths. A study of the degree of order profile along the hydrocarbon chain of these solubilisates is currently in progress.

Broad band absorption of solutes in liquid solutions and in polystyrene

C. K. McLellan and S. Walker

Department of Chemistry, Lakehead University, Thunder Bay, P, Ont., Canada P7B 5E1

Received December 23, 1976

C. K. McLellan and S. Walker. Can. J. Chem. **55,** 2411 (1977).

Broad band absorptions in the frequency range 20 to 100 cm^{-1} arising from four polar solutes in polystyrene matrices have been observed at 302 K and compared with those in liquid benzene or cyclohexane solutions. A broad band was also found for 1,4-diacetylbenzene in a polystyrene matrix at 124 K. The broad band absorption still occurs in the far-infrared region when group and/or molecular relaxation(s) occur in appreciably lower frequency regions. The significance of these absorptions is discussed in terms of some models which account for the origins of broad band absorptions.

C. K. McLellan et S. Walker. Can. J. Chem. **55,** 2411 (1977).

Travaillant à 302 K, on a observé de larges bandes d'absorption aux fréquences allant de 20 à 100 cm^{-1} et dérivant de quatre solutés polaires dans des matrices de polystyrène. On a comparé ces absorptions avec celles obtenues dans des solutions liquides de benzène ou de cyclohexane. On a aussi trouvé une bande large pour le diacétyl-1,4 benzène dans une matrice de polystyrène à 124 K. La bande d'absorption large existe encore dans la région de l'infrarouge lointain quand les relaxations du groupe et/ou de la molécule se produisent dans des régions de fréquence qui sont beaucoup plus faibles. On discute de l'importance de ces absorptions en termes de quelques modèles qui tiennent compte des origines des absorptions des bandes larges.

[Traduit par le journal]

Introduction

Broad band absorptions in the frequency range 10 to 100 cm^{-1} have been shown to exist for both polar and non-polar liquids (1–6). The effects of pressure, temperature, and solvents have been studied (7–11), and these bands have also been shown to exist in solid phases permitting molecular rotation (9, 10). Brot (12) has recently discussed the work on broad band absorption.

Hill (13) proposed a model in which a particular polar molecule in a liquid was temporarily confined to a "cage" of neighbours which provided potential energy wells encountered by the trapped molecule during its rotation. Rotation through large angles from one well to another corresponded to the well-known Debye dielectric relaxation process. Small-angle oscillations within one well in response to an applied field would account for the broad band absorption. Hill stated that the damping of this latter resonant process "cannot here be attributed to collisions. Instead the damping must arise from the lack of rigidity of the cage of neighbours, which allows a transfer of energy from the central molecule to the cage" (13).

Chantry and Gebbie felt that the experimentally-observed broad band might be composed of a number of overlapping absorption lines, the widths of which "would be determined by the lifetime of the pseudo-lattice state" (2) which they expected would be of the order of the dielectric relaxation time.

We have undertaken a study at room temperature of four polar solute molecules each dissolved in benzene and in polystyrene matrix. In the latter state the relaxation times of the molecules and of their substituent groups are very much longer than in liquid solutions. Studies of the dielectric relaxation processes of polar molecules in polystyrene matrices have been reported (14–17), and we have previously carried out such studies for the four solutes (acetophenone, 1,4-diacetylbenzene, 4-acetylbiphenyl, and 4-nitrobiphenyl) used in the present work (18).

Experimental

All far-infrared spectra have been recorded via Fourier transform interferometry by the use of a modular cube interferometer of the N.P.L. type for the frequency range 20 to 200 cm^{-1}. The details have been reported previously (5, 9, 11, 19, 20).

The polystyrene matrix samples were measured as disks without cell windows. No change of weight of the sample occurred as a result of the experiment.

For the polystyrene matrix containing 1,4-diacetylbenzene as solute we have also recorded spectra at 298 K

and 124 K using a cell which allowed temperatures to be controlled to within ±1 K anywhere in the range from 115 K to 340 K.

The absorption spectra of benzene and polystyrene are shown in Fig. 1. To obtain the absorption spectrum resulting from the presence of the solute a point-by-point subtraction of solvent from solution absorption was carried out. We have calculated from the solute absorption the maximum absorption cross-section σ_{max} (cm^2 mol^{-1}) via eq. 1 in which c is the solute concentration in mol ℓ^{-1} and α_{max} is the maximum value of the absorption coefficient.

$$[1] \qquad \sigma_{max} = \frac{\alpha_{max}}{c} \times 1000$$

A small difference between solution and solvent absorption curves means that a relatively large error must be associated with the difference. This applies particularly to the benzene solution of 4-acetylbiphenyl.

The error in the frequency of maximum absorption, $\bar{\nu}_{max}$, was typically ±4 cm^{-1} for the broad band absorption. The error estimate for the band width at half height, $\Delta\bar{\nu}_{1/2}$, was about ±10 cm^{-1} in most cases. Normally, we have found the error in α_{max} to be of the order of ±10%. However, when the absorption is weak the error could well be ±15% or worse, while the error in σ_{max} could be ±30% or even larger than this in cases where the difference is small compared to the absorptions of the solution and pure solvent.

Results

The far-infrared absorption spectra are presented as graphs of α (cm^{-1}) *vs.* $\bar{\nu}$ (cm^{-1}), with three curves representing solution, solvent, and difference spectra on each. In the case of acetophenone in cyclohexane only one curve is shown, since the solvent absorption is negligibly small in comparison with that of the solute (21). Parameters derived from these spectra are summarized in Table 1.

In polystyrene matrices at 302 K, the acetyl group relaxation times in the ketones investigated were: acetophenone, 9.8 × 10^{-10} s; 1,4-diacetylbenzene, 2.0 × 10^{-10} s; and 4-acetylbiphenyl, 4.0 × 10^{-10} s. Under these conditions the molecular relaxation time of 4-acetylbiphenyl also was 2.2 × 10^{-3} s, and that of 4-nitrobiphenyl was 3.7 × 10^{-4} s (18). This means that the frequency of maximum dielectric absorption due to acetyl group relaxation was lower than 2.6 × 10^{-2} cm^{-1}, and that dielectric absorption due to molecular relaxation of the two larger molecules was at frequencies lower than this by a factor of about 10^7. By contrast, the maximum absorption of the broad band in far-infrared spectra is usually observed at frequencies of about 50 cm^{-1}. Thus, there is a separation of dielectric absorption in the polystyrene matrix solutions from any absorption in the far-infrared region by a factor of 2 × 10^3 for group relaxation and about 10^9 for relaxation for the biphenyl molecules.

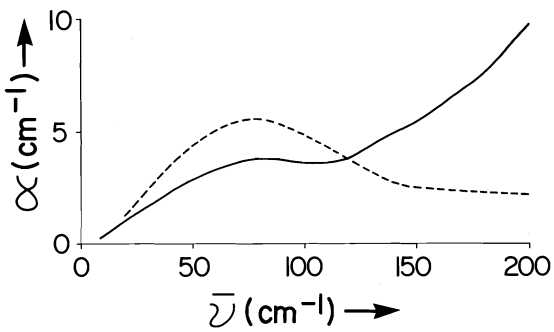

FIG. 1. Far-infrared spectra of pure benzene (- - -) and pure polystyrene (—) at 302 K.

Figures 2, 3, and 4 show the far-infrared absorption spectra of acetophenone as a 10% solution in cyclohexane, a 5% solution in benzene, and a 10% solution in polystyrene, respectively. The numerical data in Table 1 demonstrate that the peak frequencies and half-height widths are virtually the same in benzene and polystyrene solutions, with some reduction of maximum absorption cross-section in the polystyrene matrix solution. Solutions of 1,4-diacetylbenzene in benzene (Fig. 5) and polystyrene (Fig. 6) showed agreement of peak frequency, width, and absorption cross-section, both for the lower-frequency broad band and for the band around 160 cm^{-1}. This higher-frequency peak is not part of the broad band absorption, and infrared work by Varsányi (22) and Raman studies by Mross and Zundel (23) indicate that the C_{ar}—$COCH_3$ out-of-plane vibration occurs at this frequency.

Figures 7 and 8 give the spectra of solutions of 4-acetylbiphenyl in benzene and polystyrene, and there is very good agreement between the two spectra for the peak frequency, width, and maximum absorption cross-section of the low-frequency broad band (see Table 1). The 165 cm^{-1} band appeared to have a greater intensity in polystyrene than in benzene, and this could be related to the considerable overlap of the two peaks. As a result of the low solute concentration the intensity of this peak in the benzene solution is only slightly greater than that of benzene itself. Hence, the intensity of the difference may be in considerable error.

Thus, the broad band absorption spectra of

TABLE 1. Far-infrared absorption spectra parameters for pure solvents and for residual (solution–solvent) absorptions at 302 K except for one specified case

acetophenone, 1,4-diacetylbenzene, and 4-acetylbiphenyl all appear not to have been altered appreciably by a change from benzene liquid solutions to polystyrene matrices. Yet, the molecular relaxation process would be very much slower in polystyrene than in benzene, and their molecular translational motions should also be substantially reduced.

It seems unlikely that the absorption may be due solely to the rotating acetyl groups since it is clear that the rates of rotation of the acetyl groups in polystyrene solutions are markedly slower than those in benzene solutions while the far-infrared absorptions appear unaffected by the change of solvent. For 4-nitrobiphenyl the group relaxation process would not be detectable, and this yielded broad band absorption in polystyrene (see Fig. 9) even though the molecular relaxation time was longer by a factor of about 10^7 than would be the case in liquid solutions.

The spectra of the matrix containing 1,4-diacetylbenzene as solute at two temperatures are shown in Fig. 10. The relaxation times for the acetyl group in a polystyrene matrix were about 10^{-10} s at 298 K and about 5×10^{-3} s at 124 K (18). In this solute molecule the dipole moments along the axis cancel so that in the absence of stable *cis* and *trans* forms the only relaxation process would be of the group type. A recent

study by McLellan and Walker has shown this to be the case (18). Thus, dielectric absorption due to the molecular relaxation process itself is not a factor which could be considered as a contributor to broad band absorption in this case at least. Further, for this molecule in a polystyrene matrix the rate of translational motion and therefore the resultant frequency of molecular collisions is expected to be considerably less at 124 K than at 298 K.

The spectra for 1,4-diacetylbenzene shown in Fig. 10 do not differ greatly. At the lower temperature, the broad band peak occurs at 93 cm^{-1} frequency compared to 90 cm^{-1} at 298 K. This difference is of the order of experimental error and is less than the resolution (approximately 7 cm^{-1}) at which the spectra have been recorded. The maximum intensity of the 93 cm^{-1} band is about 10% greater at the lower temperature, whereas very much larger changes of both peak height and frequency have been reported in pure liquid and rotator solid phases of other materials (5, 8–10). The dielectric absorption maximum has been shifted to lower frequency by a factor of about 10^7 at 124 K compared to 298 K, and yet the frequency, intensity, and shape of the far-infrared broad band do not appear to have been altered. Thus, the existence of this broad band absorption appears not to be due simply to the motion ascribed to acetyl group relaxation.

Discussion

Several procedures have been employed to increase molecular and intramolecular relaxation

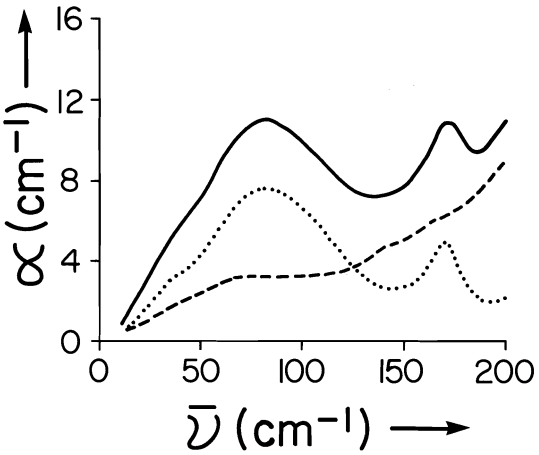

FIG. 8. 4-Acetylbiphenyl (0.533 *M*) in polystyrene at 302 K. Key as for Fig. 4.

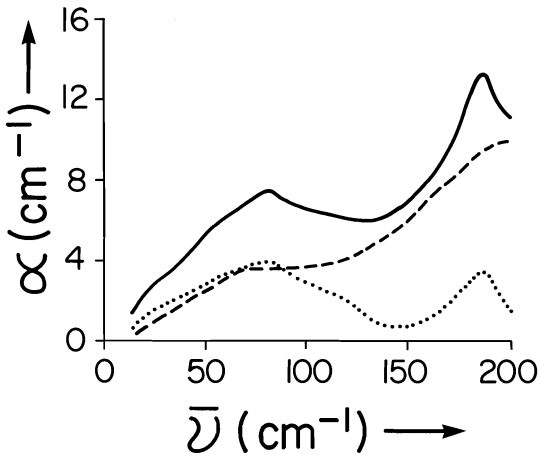

FIG. 9. 4-Nitrobiphenyl (0.539 *M*) in polystyrene at 302 K. Key as for Fig. 4.

times. Solid phases which allow some rotation of nearly spherical molecules have been examined (9, 10). Chantry *et al.* (24, 25) have reported the existence of a broad band absorption due to the presence of the slowly re-orienting polar acetate groups in vinyl acetate – ethylene copolymers. Thus, both in this work and our own in polystyrene broad band absorption has been found despite slow molecular relaxation and reduced translational motions. However, it has been shown (1, 2, 9, 10) that in solid phases lacking molecular rotational freedom one observes in the far-infrared region rather a different absorption spectrum consisting of intense narrow bands attributed to lattice modes.

It is apparent that the rates of molecular and substituent group relaxation are not critical for the existence of a broad absorption band in the

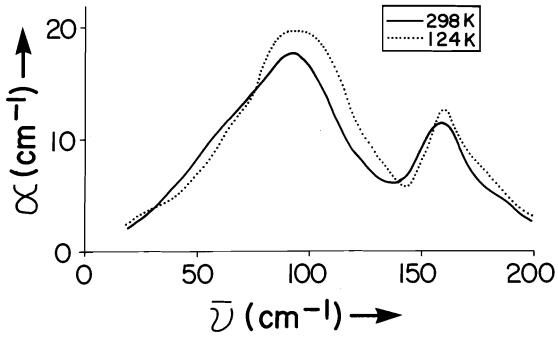

FIG. 10. 1,4-Diacetylbenzene (0.652 *M*) in polystyrene at two temperatures as indicated.

far-infrared region. Moreover, this absorption appears to arise from some process which is completely separate from that of dielectric absorption.

Haffmans and Larkin (10, 26), Minami and Ohno (27), and Higasi *et al.* (28) have considered the Hill model (13, 29, 30) and a square-well potential model, finding that the latter was more successful in fitting experimental data than a single resonant frequency of the Hill type subject to appreciable damping. However, Higasi *et al.* (28) pointed out that the fit of the Hill model would be improved if a distribution of resonant frequencies were employed.

In the square-well model the shape of the absorption band is influenced by time-dependent fluctuations of the surrounding cage. Since this model uses elastic librator-cage collisions, these cage fluctuations must arise from distortions of the cage produced by external collisions and/or by dielectric relaxation of the central molecule. The present work suggests that, even when the rate of collision-induced fluctuations of the cage is very much slower than in room-temperature liquid phase studies, a typical broad band absorption exists and is, furthermore, very much like that found in room-temperature studies in benzene solutions.

Conclusions

The polystyrene matrix solution technique offers a means of removing from the low-frequency side of the broad band possible contributions from dielectric relaxation processes (10, 26). In this regard it is interesting to note that on passing from benzene solutions to polystyrene matrices we have found no evidence of a decreased absorption intensity at frequencies down to 20 cm^{-1}, and the characteristic parameters of the broad band remain unchanged for

systems which are capable of the following types of relaxation (*a*) molecular, (*b*) group, (*c*) both molecular and group. It is apparent that the broad band absorption is not merely a higher-frequency band due solely to the molecular and intramolecular relaxation processes which give rise to dielectric absorptions at frequencies in the microwave region and lower. It would appear that the broad band absorption arises from some separate class of molecular motion such as has been proposed in theories involving a "cage" surrounding a central molecule which has at least some limited freedom to rotate. The rates of molecular and group relaxation processes and of translational motion do not appear critically important in the absorption process. It would seem likely that the relaxation time and the cage lifetime are not the dominant factors in governing the intensity of the broad band absorption for the systems reported here. Further, since the solutes are monomolecularly dispersed in the matrix (15), the concept that broad band absorption arises from lattice bands in local molecular structure would seem unlikely.

The main requirements for broad absorption would seem to be that the (solute) molecule is enclosed by other molecules or segments of them and that it is capable of limited rotation (oscillation) and possibly of translational motion. In such an environment the polar molecule could undergo small angle oscillations in response to the applied field leading to broad band absorption. In this Hill type process (13, 29, 30) it may well be that a distribution of resonant frequencies (28–30) is more important than time-dependent fluctuations of the surroundings of individual molecules in determining the appearance of the broad band. Certainly for these matrix systems the Fuoss–Kirkwood distribution parameter values ranging between 0.18 and 0.20 for the molecular relaxation processes of 4-nitro- and 4-acetylbiphenyl bear out that the solute molecules experience a wide variety of local environments and this could lead to a distribution of resonant frequencies.

A relationship between correlation energies and sizes: the series of beryllium- and neon-like ions

FERNANDO BERNARDI
Istituto di Chimica Organica dell' Universita, Bologna, Italy
PAUL G. MEZEY AND IMRE G. CSIZMADIA

Received January 20, 1977

FERNANDO BERNARDI, PAUL G. MEZEY, and IMRE G. CSIZMADIA. Can. J. Chem. **55**, 2417 (1977).

A simple empirical relation for the estimation of the correlation energy (E_{corr}) is found to be valid for the isoelectronic series of Be- and Ne-like ions to a very good accuracy. Although originally such a relation was proposed for the He-like ions, the present results indicate that it is applicable for layer systems as well. Thus the interelectron pair correlation in systems such as Be or Ne does not affect adversely the accuracy of the relation:

$$E_{corr} = \frac{K}{Z_{eff}^2 \langle r^2 \rangle}$$

where the denominator is the size $\langle r^2 \rangle$ weighted by the square of the effective nuclear charge Z_{eff}.

FERNANDO BERNARDI, PAUL G. MEZEY et IMRE G. CSIZMADIA. Can. J. Chem. **55**, 2417 (1977).

On a trouvé qu'une relation empirique simple permettant d'évaluer l'énergie de corrélation (E_{corr}) peut être appliquée pour des séries isoélectroniques d'ions du type Be et Ne avec une très bonne précision. Même si une telle corrélation avait été originalement proposée pour des ions du type He, les résultats actuels indiquent qu'elle peut être appliquée aussi bien pour des systèmes plus grands. Donc la corrélation de la paire interélectronique dans des systèmes tels que le Be ou le Ne n'affecte pas d'une façon adverse la précision de la relation:

$$E_{corr} = \frac{K}{Z_{eff}^2 \langle r^2 \rangle}$$

où le dénominateur est la grandeur $\langle r^2 \rangle$ pondérée par le carré de la charge nucléaire effective Z_{eff}.

[Traduit par le journal]

Introduction

It is of great importance to obtain reliable estimates for correlation energies of both atomic and molecular systems. Most of the previous attempts were based on estimating the correlation energies from Hartree–Fock density matrices (1). In this paper a conceptually simpler empirical relationship is proposed for multielectronic systems.

In earlier studies on helium and the helium-like ions (2) a simple empirical relationship was found between the correlation energy E_{corr}, effective nuclear charge Z_{eff}, and the size of the electron pair (3) as expressed by the expectation value of the spherical quadratic operator, $\langle r^2 \rangle$. It was observed that for the helium-like ions E_{corr} is inversely proportional to the product $Z_{eff}^2 \langle r^2 \rangle$ to a very good approximation. Since the correlation energy E_{corr} is expected to increase as the volume available for the electrons decreases, such a result may easily be interpreted in the qualitative sense.

The correlation energy E_{corr} may be expressed as the difference between the non-relativistic energy E_{NR} and the Hartree–Fock limit E_{HF} of the system:

$$[1] \qquad E_{corr} = E_{NR} - E_{HF}$$

Studies on a large number of isoelectronic systems (series of the He-, Be-, Ne-, and Mg-like ions) indicated that a relatively simple relation holds between the sizes and energies of localized orbitals (4):

[2] $$\frac{1}{e_i} = m\langle r^2\rangle^{\gamma} + \frac{1}{e_0}$$

where m, γ, and e_0 are adjustable parameters. The energy term for orbital i was defined as

[3] $$e_i = 2h_i + \sum_{j}^{\text{all pairs}} g_{ij}$$

As all these calculations were carried out using rather large gaussian basis sets, one may expect that the observed relations are valid at the Hartree–Fock limit, possibly with slightly different numerical parameters m, γ, and e_0. The essentially reciprocal dependence of the energy on $\langle r^2\rangle$ is expected to be retained for E_{HF}. If E_{corr} shows a similar dependence on $\langle r^2\rangle$, one should be able to express the 'size dependence' of E_{NR} on the basis of eq. 1. In the present study the functional relation of the size dependence of E_{corr} is analysed for polyelectronic atoms and a simple method proposed for the calculation of correlation energies that may possibly be extended to the molecular cases.

Results and Discussion

One may expect that in the family of isoelectronic series of atom-ions the Be- and Ne-like ions already exhibit some features related to electron pair – electron pair interactions that may result in a somewhat more general correlation energy-size relation. Therefore, in addition to the simplest series of He-like ions previously studied (2), in our present study we concentrate on the analysis of the Be- and Ne-like isoelectronic series of ions.

Earlier studies indicated that the calculated total size, $\langle r^2\rangle$, shows only insignificant change if instead of a correlated wavefunction a near Hartree–Fock wavefunction is used (2). Since in the Hartree–Fock framework the total size $\langle r^2\rangle_{HF}$ may be given in terms of orbital contributions,

$$\langle r^2\rangle_{HF} = \sum_i \langle r^2\rangle_i$$

the true expectation value $\langle r^2\rangle_{corr}$ may also be approximated by such a sum.

In Table 1 the Hartree–Fock energies, correlation energies, and total sizes are listed for the He-, Be-, and Ne-like ions. The rather large gaussian basis sets used in calculating total sizes are specified in an earlier paper (4).

For the helium-like ions the correlation energy E_{corr} may be approximated by the empirical formula (2),

[4] $$E_{corr} = \frac{K}{(Z-\sigma)^2\langle r^2\rangle}$$

that may be converted into a linear dependence between the nuclear charge Z and the quantity $(-E_{corr}\langle r^2\rangle)^{-1/2}$. Such a relation when plotted gives a straight line with slope $(-K)^{-1/2}$ and x-intercept σ, the screening constant.

In Table 2, the best fit K and σ values are given along with the calculated correlation coefficients. The results of Table 2 may be restated in terms of correlation energies calculated using empirical formula [4], the calculated total sizes and the optimized parameters K and σ. These calculated E_{corr} values are listed in Table 3. It is apparent from these values and the excellent correlation coefficients that eq. 4 is applicable for all three series to a very good approximation. Though the relative deviations are significantly larger for the second and third series, the inter-electron-pair correlation in the series of Be- and Ne-like ions does not affect adversely the fit to relation [4] originally proposed for the two-electron systems of the He-like ions.

The present results indicate that the total size as weighted by Z_{eff} is the most important single factor in determining correlation energies for isoelectronic atom-ions. Regarding relation

$$E_{\text{corr}} = F(Z,\langle r^2\rangle)$$

this function does not contain essential terms depending on Z or $\langle r^2\rangle$ separately. This proposition is supported not only by the excellent fit to eq. 4, but also by the fact that the small deviations in all three series show a systematic slight 'bending'. This systematic pattern of deviations suggests that the small errors are mostly due to the simplicity of the relation

$$E_{\text{corr}} = F(Z_{\text{eff}}{}^2\langle r^2\rangle)$$

rather than the somewhat arbitrary pairing of variables Z_{eff} and $\langle r^2\rangle$. If correction terms depending on Z_{eff} and $\langle r^2\rangle$ separately would be important, then larger and less systematic deviations from eq. 4 could be expected.

The present results also lend hopes that in series of analogous molecules similar relationships may exist between sizes of molecular orbitals and correlation energies and may be utilized for approximate determination of molecular correlation energies.

Metal complex catalyzed reactions of anils. II. Transimination

A. R. BOATE AND D. R. EATON
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 19, 1976

A. R. BOATE and D. R. EATON. Can. J. Chem. **55**, 2426 (1977).

The exchange of aromatic residues between anilines and anils (transimination) has been shown to be efficiently catalyzed by metal complexes of thiourea. This reaction can be conveniently studied by nmr spin saturation transfer techniques. Experiments of this type using both CW and FT nmr spectrometers are reported. The rate of the reaction is about two orders of magnitude greater than the rates of reactions involving anil formation and hydrolysis with the same substrates and catalysts. The effectiveness of the catalysts vary in the same manner as they do for anil formation and the reaction is similarly subject to inhibition by competing ligands. The rate of exchange of the two inequivalent methyl groups in acetone anils is similarly catalyzed and may be studied by spin saturation transfer experiments. The lifetime of an anil molecule for methyl group exchange is approximately twice that for transimination suggesting that the rate determining process for transimination results in free rotation about the C—N bond so that the methyl groups have an equal probability of retaining or exchanging their environments.

A. R. BOATE et D. R. EATON. Can. J. Chem. **55**, 2426 (1977).

On a démontré que l'échange de résidus aromatiques entre des anilines et des anils (transimination) est catalysé d'une façon efficace par des complexes métalliques de la thiourée. Cette réaction peut être étudiée facilement par les techniques de transfert de saturation de spin en rmn. On rapporte des expériences de ce type faisant appel à des spectromètres rmn, CW et FT. La vitesse de la réaction est pratiquement deux ordres de grandeur plus grande que les vitesses de réactions impliquant la formation d'anil et l'hydrolyse avec les mêmes substrats et les mêmes catalyseurs. L'efficacité des catalyseurs varie de la même manière que pour la formation de l'anil et la réaction est aussi sujette à une inhibition par des ligands en compétition. La vitesse d'échange de deux groupes méthyles non-équivalents dans des anils de l'acétone est aussi catalysée d'une façon similaire et peut être étudiée par des expériences de transfert de saturation de spin. Le temps de vie d'une molécule d'anil par rapport à l'échange du groupe méthyle est approximativement deux fois plus grand que celui de la transimination; ces résultats suggèrent que le processus déterminant la vitesse pour les transiminations provient d'une rotation libre autour du lien C—N d'une façon telle que les groupes méthyles ont une probabilité égale de retenir ou d'échanger leur environnement.

[Traduit par le journal]

Introduction

The initial paper in this series (1) described experiments demonstrating the metal complex catalyzed formation and hydrolysis of anils, *e.g.*

[1] $C_6H_5NH_2 + (CH_3)_2CO \rightleftharpoons C_6H_5N{=}C(CH_3)_2 + H_2O$

Similar reactions occur with a variety of substituted anilines and aliphatic ketones and are very efficiently catalyzed by small concentrations of thiourea and substituted thiourea complexes of cobalt, nickel, and zinc. A subsequent paper will describe detailed studies of the kinetics and mechanisms of these reactions. There is, however, a second reaction occurring concurrently, namely, transimination. Transimination results in the exchange of aromatic residues between the aniline and the anil, *e.g.*

[2] 
where X and Y may be different or identical substituents. It is very probable that the mechanisms for anil formation and for transimination are closely related. In the present paper we will therefore describe a number of experiments demonstrating catalyzed transimination before returning to a discussion of the mechanistic aspects of all of these reactions in the third paper of this series.

Most of the reactions to be discussed below are quite rapid. Typically the average lifetime of a reactant is a few seconds. A very useful tech-

nique for studying reactions on this timescale is provided by nmr experiments involving spin saturation transfer (SST). The theory involved in experiments of this type has been given by Forsen and Hoffman (2, 3) who used the method to measure keto–enol isomerization rates of acetylacetone. There have been relatively few quantitative applications. Van Leeuwen and Praat (4) have measured exchange rates in π allyl palladium complexes. Sherrod *et al.* (5) have studied kinetic isotope effects in metaparacyclophanes and Kabakoff and Namanworth (6) have used the method to measure a rotation barrier in the dimethylcyclopropylcarbinyl cation. Some interesting recent applications are provided by the work of Creelmore and Reilly (7) in determining the exchange rates for water with an ion exchange resin and that of Redfield and coworkers (8) in studying rates of electron transfer and ligand exchange for cytochrome *c* enzymes. A review by Faller (9) provides examples of more qualitative applications.

Briefly, the experiment involves choosing a pair of resonances (A and B) involved in an exchange process, saturating one (B) by applying a strong RF field and observing the effect on the second resonance A. When equilibrium has been reached the magnetization at site A ($M_\infty{}^A$) will be less than the value in the absence of the saturating field ($M_0{}^A$) since nuclei with their spin populations equalized will have been transferred from site B to site A. Forsen and Hoffman showed that:

$$M_\infty{}^A = M_0{}^A \frac{\tau_{1A}}{T_{1A}} \quad [3]$$

where

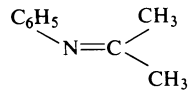
$$\frac{1}{\tau_{1A}} = \frac{1}{T_{1A}} + \frac{1}{\tau_A} \quad [4]$$

In these equations T_{1A} is the spin–lattice relaxation time and τ_A is the lifetime for chemical exchange of the A nuclei. If T_{1A} is known τ_A can be found and since

$$\frac{\tau_A}{\tau_B} = \frac{M_0{}^A}{M_0{}^B} \quad [5]$$

this leads to τ_B. In principle T_{1A} can be found either from the decay in the magnetization at A after applying the saturating field or from its recovery after removing the saturating field. In practice it is often more convenient to measure T_{1A} in an independent experiment. This is particularly the case if an FT instrument is available since T_1's for all nuclei in an exchanging system can be measured easily and routinely. It should be noted that T_2 is affected by chemical exchange but T_1 is not.

The utility of this technique to transimination reactions may be seen by reference to eq. 2. If X = Y in this equation, transimination will exchange the substituent between aniline and anil and spin saturation transfer effects may be anticipated if either the anil or the aniline resonance is irradiated and the other site observed. On the other hand the methyl peaks of the anil are in identical sites in the reactants and products. Only anil formation and hydrolysis will lead to exchange of methyl groups with the acetone present. A third process is however possible. The two CH_3 peaks are not equivalent, *e.g.*



If the N=C bond is broken or weakened during the transimination reaction exchange between the methyl groups *cis* and *trans* to the aryl group may be anticipated.

^{19}F *Spin Saturation Transfer Experiments*

There are a number of practical limitations to the application of the spin saturation transfer technique. It is essential that there be no direct effect of the saturating field at frequency B on the observed resonance at frequency A. If A and B are too close together in frequency interference will occur. Experimentally it was found that a minimum separation of ~20 Hz is necessary if a CW instrument is used. Much smaller separations (3 or 4 Hz) are possible if an FT instrument is used. Initial experiments were therefore carried out on the ^{19}F resonances of *p*-fluoroaniline and its acetone anil. These resonances are separated by 400 Hz at 56.4 MHz and direct interference of the irradiating field is negligible. In the absence of catalyst, irradiation of either the aniline or anil peak produced no effect on the other peak. In the presence of either $Zntu_2Cl_2$ or $Zntu_4(ClO_4)_2$ spin saturation transfer was readily observed. The ^{19}F nuclei in both compounds are coupled to the aromatic protons. For quantitative work it is necessary to decouple

these protons by applying a strong RF field at 60 MHz.

It is necessary to position the observing frequency on the exact centre of one of the resonances and to observe the intensity at this frequency as the saturating field is switched on and off. An automatic device for switching the various fields was used and the results of a number of switching cycles accumulated in a Computer of Average Transients (CAT) to optimize the signal to noise ratio. The results of such an experiment involving *p*-F aniline and its acetone anil with $Zntu_4(ClO_4)_2$ as the catalyst and Freon 112 present for locking purposes are shown in Fig. 1. The *Y* axis represents intensity at the centre of the decoupled anil resonance (site A) and the *X* axis represents time. The time for one complete cycle was 100 s and this low noise level was achieved by accumulating 100 cycles. At point A the saturating field was switched off and the signal recovered to its full intensity at B. The observing signal was then switched off to obtain a base line reading. However, idiosyncrasies in the electronics results in a false base line reading and the true position was obtained by jumping the observing frequency (still at zero power) several hundred Hz off resonance at point C of Fig. 1. At point D the observing frequency reverted to the resonance position and was switched on. At point E the saturating frequency was switched on and the decay of the signal to its original value has occurred at point F. The value of $M_\infty{}^A/M_0{}^A$ can be obtained directly from this plot. From the decay of the magnetization commencing at point E a plot of $\ln [M_z{}^A(t) - M_\infty{}^A]$ against t has a slope of τ_{1A}. This information suffices to determine both T_{1A} and τ_A. If τ_A is relatively

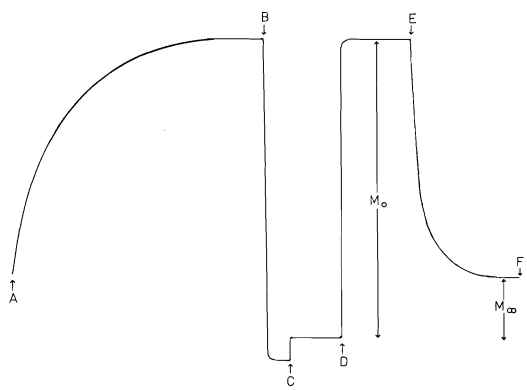


FIG. 1. Output from ^{19}F spin saturation transfer experiment. See text for explanation.

short compared to T_{1A} it is also possible to determine T_{1A} from the recovery curve commencing at point A. A third alternative is to measure $M_\infty{}^A/M_0{}^A$ and then find T_{1A} for *p*-F aniline independently using the saturation recovery technique. This last method has the inherent disadvantage that the environment of the *p*-F aniline in the reacting mixture is not the same as in a simple solution of *p*-F aniline and hence the T_1 obtained may not be appropriate.

In a typical experiment, values of τ_A (aniline) of 1.5 s, of τ_B (anil) of 0.5 s, of T_{1A} 9.5 s, and of T_{1B} 8.0 s were obtained. The T_1'*s* in this case were obtained from observation of the decay of magnetization. Although quite reproducible these T_1's agreed poorly with direct determinations of the T_{1A} for *p*-fluoroaniline. It must be concluded that T_{1A} is sensitive to the environment (probably water and catalyst concentrations are the determining factors) and that determination of T_1 in the reacting solution is necessary.

The experimental problems involved in these experiments, most notably the difficulty in maintaining ^{19}F and ^1H decoupling oscillators to the requisite 0.1 Hz frequency stability, limit the accuracy of quantitative data obtained using CW spectrometers. The results obtained with an FT instrument, described below, are much more reliable. However, a number of qualitative experiments served to better define the catalytic system. Thus it was shown that the metal salts and complexes, previously reported (1) to catalyze anil formation, also catalyze transimination. Using $Zntu_4(ClO_4)_2$ as a catalyst addition of excess thiourea decreased the spin saturation transfer showing inhibition by thiourea. In another experiment using $Ni(ClO_4)_2.6H_2O$ as a catalyst almost complete inhibition by ortho phenanthroline and terpyridine was demonstrated. The stability of the catalysts was also investigated. Thus a solution of $Zntu_4(ClO_4)_2$ lost approximately 8% of its catalytic activity as measured by the ratio $M_0{}^A/M_\infty{}^A$ in 6 h and transimination had ceased after the solution had stood for 1 week. In all these respects the catalysis of transimination shows essentially the same characteristics as does that of anil formation and hydrolysis.

^1H *Spin Saturation Transfer Experiments*

Using CW instruments it is difficult to examine transimination directly by proton nmr

since the aniline and anil peaks are usually not sufficiently separated. In these cases interference from the saturating field and Bloch-Seegert shifts of the observing resonance preclude spin saturation transfer experiments. However, it is possible to examine exchange between the two inequivalent methyl peaks since these are separated by 38 Hz at 100 MHz. It was noted that the addition of $Zntu_4(ClO_4)_2$ to a solution of the acetone anil of *p*-F anil caused a slight broadening of these methyl resonances suggesting that an exchange process might be occurring. Figure 2 illustrates SST experiments on this system. Trace A shows the methyl peaks of the anil together with a small peak due to acetone and solvent peaks (CD_2HCN). Irradiation of the high field CH_3 has no effect on either the low field CH_3 or the acetone (trace B). Addition of $Zntu_4(ClO_4)_2$ catalyst causes slight broadening (trace C). Irradiation of the low field CH_3 peak in the catalyst containing solution clearly causes spin saturation transfer to the low field CH_3 but not to acetone (trace D).

It is of interest to compare the rate of exchange of anil CH_3 peaks with the rate of transimination and with the rate of anil hydrolysis. For this purpose a sample containing an equilibrium mixture of *p*-F aniline and its acetone anil was first examined by both ^1H and ^{19}F SST. In both cases no effect was observed. $Zntu_4(ClO_4)_2$ was then added and the SST experiments repeated. Transfer of spin saturation was now observed and using the methods described above the ^{19}F experiment yielded lifetimes for the anil (τ_{anil}) of 0.72 s and for the aniline ($\tau_{aniline}$) 1.73 s. From the ^1H experiment we obtain $\tau_A = \tau_B = 1.55$ s. The lifetime of an anil molecule for interchange of the methyl groups is therefore greater than its lifetime for the transimination reaction by a factor of 2.1. The same sample was then split into two portions and the equilibrium for anil formation or hydrolysis displaced by adding acetone to one portion and water to the other portion. Return to equilibrium was monitored by measuring the change in intensity of the acetone and anil CH_3 peaks as a function of time. In the case of the sample with water added the reaction could be followed rather easily and the results are shown in Fig. 3. It may be noted that it took approximately 30 min to reach equilibrium so that anil hydrolysis is obviously considerably slower than transimination. From the slope of the curve in Fig. 3 an initial rate of 3×10^{-3} mol/ℓ s is obtained. This may be compared with the rate for transimination at equilibrium, *i.e.*

$$\text{Rate} = \frac{[\text{anil}]}{\tau_{anil}} = \frac{0.66}{0.74} = 0.9 \text{ mol}/\ell\text{ s}$$

Transimination is faster than anil hydrolysis by a factor of at least 10^2.

All of the experiments described above have involved transimination reactions in which the anil substituent and the aniline substituent are the same, *i.e.* X = Y in eq. 2 so that there is no net reaction. It seemed worthwhile to illustrate the generality of the reaction by demonstrating rapid transimination in a case where $X \neq Y$. The following experiment served this purpose. A sample of *p*-toluidine (0.2 *M*) in acetone was

FIG. 2. ^1H nmr spin saturation transfer experiment with the acetone anil of *p*-F aniline in CD_3CN. See text.

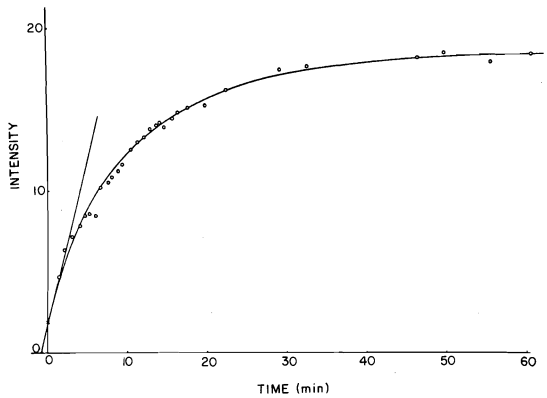

FIG. 3. Intensity of acetone peak as a function of time after addition of water to an equilibrium solution of *p*-F aniline and its acetone anil in CD_3CN. Catalyst $Zntu_4(ClO_4)_2$.

prepared, a little $Zntu_4(ClO_4)_2$ added and anil formation monitored by measuring the intensities of the p-CH_3 peaks of p-toluidine and its anil as a function of time. After 30 min the reaction had proceeded roughly 66% to completion. At this point sufficient aniline was added to the sample to make it 0.4 M in aniline. The first nmr sweep through the methyl region after the addition of aniline showed that the ratio

$$\frac{[p\text{-toluidine anil}]}{[p\text{-toluidine anil}] + [p\text{-toluidine}]}$$

had changed from 0.40 to 0.13. This occurred in less than 1 min. The added aniline has reacted with the p-toluidine anil by a transimination reaction, *i.e.*

[6] 
This has increased the concentration of p-toluidine and decreased that of p-toluidine anil to produce the change in the ratio noted above. Again the indication is that this reaction is faster than anil formation by a factor of at least 10^2. Reaction 6 does not occur in the absence of catalyst.

Fourier Transform Spin Saturation Transfer Experiments

There are two major advantages in using an FT instrument for SST experiments, namely, (*a*) a much smaller separation of peaks is necessary, and (*b*) the required T_1's can be measured directly in the presence of chemical exchange. This latter factor is of some significance. Thus the T_1 for the methyl group of p-toluidine changed from 3.0 s to 2.4 s as the concentration of $Zntu_2Cl_2$ was increased from 0.15 M to 0.45 M. Unfortunately an FT instrument was available only in the final stages of the present work. We report, however, some initial measurements on transimination reactions involving p-toluidine since this amine was used for many of the studies on anil formation and hydrolysis and a comparison with transimination is of interest. The p-CH_3 peaks of p-toluidine and its acetone anil are approximately 9 Hz apart at 90 MHz and it was shown that this separation was sufficient to allow SST experiments to be carried out on a Brucker WH 90 instrument. Some results are shown in Table 1. The $Zntu_2Cl_2$ used as a catalyst is a rather poor catalyst for anil formation and is also a relatively poor catalyst for transimination hence the rather high catalyst concentrations. The ratio R shown in the last column should be equal to 1 and provides a check on the experiment. An approximate comparison may be made between these lifetimes and the rate of anil formation with the same catalyst. For the same initial concentration of p-toluidine and for a catalyst concentration of 0.02 mol/ℓ the initial rate of anil formation was found to be 1.6×10^{-4} mol/ℓ s. This corresponds to an aniline lifetime of 1200 s. Since rate has been shown to be proportional to catalyst concentration this would give a lifetime of 120 s at 0.2 M compared to 4 s for transimination. A number of factors, however, make this comparison inaccurate. Thus the initial rate measurements were carried out at 35°C and the SST experiments at 27°C. The initial rate experiments used p-toluidine-d_2 and the SST experiments p-toluidine-h_2. The SST experiments refer to the rate at equilibrium rather than the initial rate. All three factors would tend to increase the difference between the rate of anil formation and that of transimination. The true ratio of rates is therefore most probably greater than the factor of 30 indicated and is likely to be of the order 10^2 as found for p-F aniline.

TABLE 1. FT spin saturation transfer experiments[a]

Concentration of catalyst (mol/ℓ)	T_1 (s)	τ_{anil} (s)	$\tau_{aniline}$ (s)	R^b

0.39	2.4	4.0	2.2	1.16

[a]Initial solution 0.2 M p-toluidine in acetone. Catalyst $Zntu_2Cl_2$. Temperature 28°C. Frequency 90 MHz.
[b]$R = (M_0^{anil}/M_0^{aniline})/(\tau_{anil}/\tau_{aniline})$.

Discussion

The spin saturation transfer experiments described above have clearly demonstrated a metal complex catalyzed reaction which exchanges aniline and anil substituents. This could be accomplished by reaction 1 involving the formation and hydrolysis of the anil. If this were so exchange between acetone and anil should occur at the same rate as between aniline and anil. Since the former exchange is approximately two orders of magnitude slower we conclude that the

exchange between aniline and anil proceeds by the transimination reaction 2. Except for its greater rate, the characteristics of this catalyzed reaction are very similar to those of the anil formation reaction. A catalyst which is effective for anil formation is effective for transimination and vice versa. Both reactions are inhibited by excess thiourea and by chelating ligands.

It has also been shown that the exchange of the non-equivalent anil methyl groups is metal complex catalyzed. It has been reported that the nmr spectrum of *N*-isopropylidene aniline shows coalescence of these methyl peaks at 126°C (10). In the absence of catalyst there is no indication of exchange at room temperature. The lifetime for methyl exchange is twice that for transimination. A hypothesis which satisfactorily accounts for these observations is that rotation about the C—N bond takes place during and only during transimination. If there were free rotation about this bond there would be an equal probability of a given CH_3 retaining or exchanging its environment in the product anil. Hence the lifetime for methyl exchange should be twice that for transimination. The agreement of the experimental ratio of 2.1 with this prediction is possibly fortuitous but it seems clear that the rate determining steps in both processes are closely related and that any proposed mechanism for these reactions must be consistent with this observation.

Experimental

The preparation and purification of the reagents and catalysts used in these studies have been described previously (1).

The nmr instruments used were a Varian HA 100 (probe temperature 34.5–35.0°C), a Varian DP 60 (probe temperature 27°C), and a Brucker WH 90 (probe temperature 26.5°C). The DP 60 operated at 56.4 MHz for ^{19}F studies and was modified for proton decoupling by supplying 60 MHz radiation from a crystal controlled frequency generator (General Radio Co.) amplified with an operational amplifier (Model 805, RF Communications Inc.) and fed into two specially tuned coils fitted in the spectrometer probe. The decoupled ^{19}F signal of *p*-F aniline had a line width of less than 0.5 Hz. An automatic device for switching the various fields required in the SST experiments and triggering the CAT was built. The main component of this device was an accurate variable speed electric motor driving a plastic disc to activate appropriate micro switches. On the WH 90 homonuclear decoupling may be accomplished using either a pulsed or gated decoupler. Both methods were used with the gated decoupling being rather more satisfactory since it produced less distortion near the decoupling frequency. A necessary condition for using this decoupling for SST experiments is that either $T_2^* \ll T_1$ or $\tau_A > T_{1A}$. These conditions were adhered to. Since the internal computer routines for intensity and area calculations are unreliable in the vicinity of the saturating frequency, intensities were measured directly from the spectra relative to a standard reference peak (usually TMS).

Metal complex catalyzed reactions of anils. III. Kinetic and mechanistic studies

A. R. BOATE AND D. R. EATON

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received October 4, 1976

A. R. BOATE and D. R. EATON. Can. J. Chem. **55**, 2432 (1977).

The kinetics of the homogeneously catalyzed formation and hydrolysis of anils in non-aqueous solution have been studied. The catalysts used are zinc complexes of thiourea. It is shown that all the evidence obtained, kinetic and otherwise, is consistent with a model in which the rate determining step for anil formation is nucleophilic attack by an aniline held in the second coordination sphere of the metal complex on an acetone molecule directly bound to the metal atom. Analogous mechanisms are suggested for anil hydrolysis and for transimination.

A. R. BOATE et D. R. EATON. Can. J. Chem. **55**, 2432 (1977).

On a étudié la cinétique de la formation, catalysée d'une façon homogène, et l'hydrolyse d'anils dans des solutions non-aqueuses. Les catalyseurs utilisés sont des complexes de zinc de la thiourée. On montre que toutes les données obtenues, soit cinétiques ou autres, sont en accord avec un modèle dans lequel l'étape déterminante de la réaction pour la formation de l'anil est une attaque nucléophile par une aniline maintenue dans la seconde sphère de coordination du complexe métallique d'une molécule d'acétone directement liée à l'atome métallique. On suggère des mécanismes analogues pour l'hydrolyse de l'anil et pour la transimination.

[Traduit par le journal]

Introduction

Previous papers (1) in this series have demonstrated that reactions involving anil formation, anil hydrolysis, and transimination are effectively catalyzed by a variety of metal complexes, particularly a series of thiourea and substituted thiourea complexes of cobalt, nickel, and zinc. The present paper describes kinetic and mechanistic studies of these reactions.

Anil Formation

(i) Dependence on Catalyst Concentration

The reaction of interest is the formation of an anil from an aniline, *e.g.*, *p*-toluidine and a ketone such as acetone, *i.e.*

[1] $p\text{-}CH_3C_6H_4NH_2 + (CH_3)_2CO \rightleftharpoons p\text{-}CH_3C_6H_4\cdot N{=}C(CH_3)_2 + H_2O$

At low concentrations of catalyst this reaction can be conveniently followed by repetitively scanning the methyl region of the ^1H nmr spectrum and observing the decrease of the $p\text{-}CH_3$ of the toluidine and the increase in intensity of the corresponding anil peak. A typical experimental trace is shown in Fig. 1. The fraction of anil formed, *i.e.* [Anil]/[Anil] + [Aniline]) can be found as a function of time from the measured intensities. The initial rate of the reaction can be obtained graphically. Alternatively since the reaction can be followed to equilibrium the complete reaction curve can be fitted to the equation:

$$\frac{d[Anil]}{dt} = k_1[Aniline] - k_2[Anil]$$

using a standard computer programme (2). The experimental data of Fig. 1 gave $k_1 = 0.136$ min^{-1} with a standard deviation of 0.0021 compared with the value $k_1 = 0.132$ min^{-1} obtained graphically. The plot of residuals from the computer fit was completely random. We estimate that rates obtained by this experimental method are accurate to at least $\pm 10\%$.

Table 1 presents data illustrating the dependence of rate on catalyst concentration. An excellent linear dependence is observed with the very small intercept showing that the rate of the uncatalyzed reaction is negligible. A plot of log (initial rate) against log (catalyst concentration) has a slope of 0.94 confirming that the reaction is indeed first order in catalyst.

(ii) Dependence on Aniline Concentration

The dependence of the initial rate on aniline concentration may be determined in essentially the same manner as described above. There is however one complication. The acetone-d_6 used contains D_2O as an impurity and this will rapidly exchange with the NH_2 protons. The

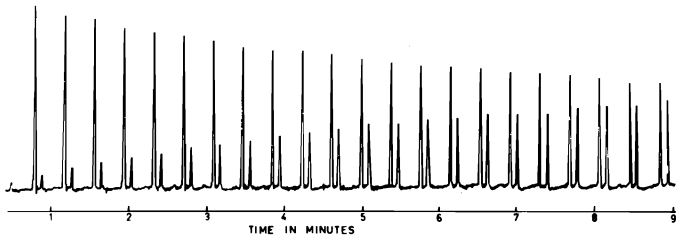

FIG. 1. Repeated scans of the methyl nmr peaks showing the diminution of the *p*-toluidine peak and the growth of the anil peak.

extent of deuteration will vary with the concentration of *p*-toluidine used. If there is a significant kinetic isotope effect (see below) this factor will influence the apparent dependence of the rate on *p*-toluidine concentration. This problem was avoided by using *p*-toluidine-d_2 for the initial rate experiments. The results of a series of such measurements are shown in Table 2. The dependence on *p*-toluidine concentration is not linear as shown in Fig. 2*a*. The shape of this curve is reminiscent of the results obtained in many studies of enzyme kinetics in which there is a rapid pre-equilibrium between the enzyme and substrate followed by a rate determining reaction of the enzyme–substrate complex (Michaelis–Menton kinetics) (3). In such cases a linear plot is obtained by plotting the reciprocal of rate against the reciprocal of substrate concentration (a Lineweaver–Burk plot). Such a plot is indeed linear (Fig. 2*b*), suggesting a rapid pre-equilibrium leading to Michaelis–Menton kinetics or some more complex scheme which reduces to the same general mathematical form. The data in Table 2 show results for two catalysts. It may be noted that the catalyst concentrations differ by two orders of magnitude. In both cases the dependence of rate on substrate concentration was essentially the same.

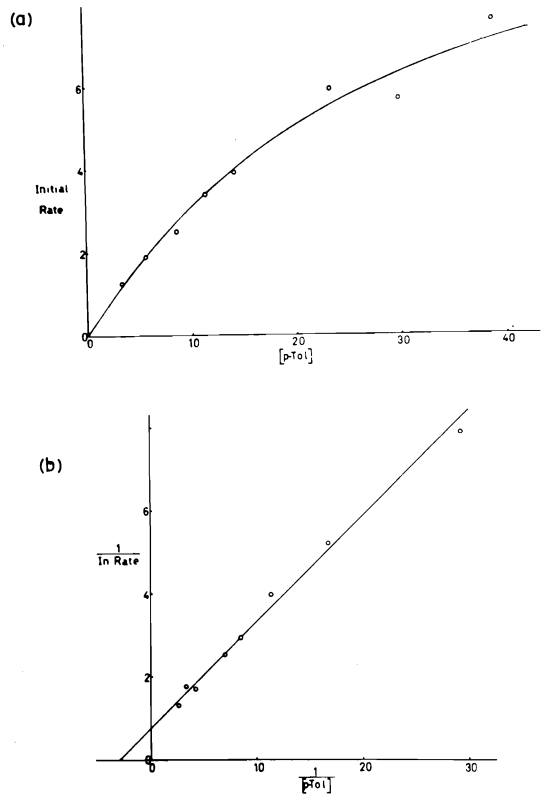

FIG. 2. (*a*) Dependence of initial rate of anil formation (mol/min × 10^6) on concentration of *p*-toluidine-d_2 (mol × 10^5); (*b*) double reciprocal plot of these data.

(iii) Overall Concentration Dependence

Since the anil formation reaction is carried out using acetone-d_6 as a solvent it is not feasible to directly examine the effect of varying the acetone concentration on the initial rate. An alternative experiment is to investigate the effect on the rate of dilution with an 'inert' solvent. In this context an 'inert' solvent is one which is incapable of functioning as a ligand in the metal complex. The concentrations of the various metal complex species in solution are controlled by equilibria

of the type:

$$ML_n + X \rightleftharpoons ML_{n-1}X + L$$

If a fraction α of ML_n has reacted, at equilibrium the concentrations of the various species will be determined by:

$$[2] \qquad \frac{m^2\alpha^2}{m(1-\alpha)(x-m\alpha)} = K$$

where m is the initial concentration of ML_n and x is the initial concentration of X. If the solution is now diluted by a factor V the initial concentration of ML_n becomes m/V and x becomes x/V. However, the fraction α is independent of V since there are an equal number of concentration terms in the numerator and denominator of eq. 2. It follows therefore that providing all metal complex species in solution have the same coordination number and providing the diluting solvent does not participate in any of the ligand exchange equilibria, dilution by a factor V will reduce the concentration of each species in solution by this factor but will not affect the relative concentrations of any of the species. In the present case carbon tetrachloride was used as a diluting solvent since it seems unlikely that it could function as a ligand. There is also evidence that both Co(II) and Zn(II) remain tetrahedral and four coordinate (4, 5) in all these systems so that the above conditions are met.

The results of such a dilution experiment are shown in Table 3. In this experiment the reacting mixture of *p*-toluidine and acetone was progressively diluted with carbon tetrachloride and a quantity of catalyst sufficient to make the solution 1.0×10^{-4} *M* in catalyst added to each sample. It is apparent that the initial rate of anil formation measured by the method described above is independent of dilution. The significance of this result will be discussed below.

(iv) Dependence on Thiourea Concentration

From the experiments described above and in a previous paper (1) it is very likely that these catalysts function by dissociation of thiourea and coordination of one or more of the substrate molecules to the metal ion. In this case excess thiourea should inhibit the reaction. This is indeed the case. Table 4 presents data showing the effect of excess thiourea on the initial rate of formation of *p*-toluidine anil. A plot of initial rate against the reciprocal of thiourea concentration passes through the origin showing that the complete repression of thiourea dissociation

results in complete inhibition of the reaction. In these experiments the added thiourea ranges from ten to one hundred times the thiourea present in the $Zntu_4(ClO_4)_2$ catalyst so that total thiourea equals added thiourea to a good approximation. No catalysis attributable to thiourea itself rather than to a metal complex was noted in these experiments.

Anil Hydrolysis

(i) Dependence on Anil Concentration

The reverse reaction of [1] is anil hydrolysis. As it must be, this reaction is also catalyzed by thiourea complexes of zinc and cobalt. Since the anil can be prepared indirectly the kinetics of its catalyzed hydrolysis can also be studied using the nmr method described above. In this case, a double reciprocal plot of the data has a pronounced curvature. In enzyme kinetics such a curvature is often interpreted as arising from inhibition by the substrate itself (3). This is not unreasonable in the present case. The equilibrium constant for the formation of a metal anil complex is higher than for all other ligands except thiourea (1). At high anil concentrations the metal could therefore tend to become saturated with anil to the exclusion of the other substrate water. Inhibition would then result.

(ii) Dependence on Water Concentration

The dependence of the initial rate of anil hydrolysis on water concentration was also studied. D_2O was used for this study to avoid kinetic isotope effects. The amount of water present in the acetone-d_6 was found from the position of the final equilibrium. The double reciprocal plot for these data is linear.

(iii) Overall Concentration Dependence

The effect of dilution with an inert solvent (carbon tetrachloride) on the initial rate for anil hydrolysis has also been examined. This experiment was carried out in a slightly different manner to the corresponding experiment for anil formation. A stock solution of anil in acetone-d_6 with a little D_2O added was prepared and diluted with CCl_4 to make up five samples. Catalyst solution was added to each of these samples sufficient to keep the relative concentrations of anil and catalyst constant in each sample. This procedure differs from that used in the anil formation experiment in that the concentration of the catalyst as well as those of the substrates was progressively diminished. The results are shown in Table 5 in terms of the relative initial rates. It is apparent that the initial rate decreases in direct proportion to the fraction of carbon tetrachloride in the mixture. Since it has already been shown that the initial rate is proportional to catalyst concentration this result is exactly equivalent to the result obtained for anil formation, *i.e.* that initial rate was independent of dilution of the reactants.

The Kinetic Isotope Effect

In general isoptopically substituted molecules do not react at the same rates. The effect of substituting deuterium for hydrogen are particularly marked since the mass ratio of these two isotopes is greater than that of any other pair. The magnitude of the kinetic isotope effect depends on the nature of the rate determining step (6). If this step involves proton transfer a large primary kinetic isotope effect may be anticipated. If it does not involve proton transfer a smaller, secondary effect is predicted. We have already presented indirect evidence that proton transfer steps are too rapid to be rate determining in the present catalytic reactions (1). Since, however, this is a mechanistically impor-

TABLE 5. Dependence of initial rate of anil hydrolysis on dilution with carbon tetrachloride[a]

0	1.00	1.00
0.20	0.80	0.72
0.40	0.60	0.57
0.60	0.40	0.41
0.80	0.20	0.18

[a]Catalyst 1.13×10^{-3} *M* $Zntu_4(ClO_4)_2$, 0.27 *M* *p*-toluidine anil, $T = 35°C$.

tant conclusion it seemed worthwhile to obtain direct kinetic evidence on this point.

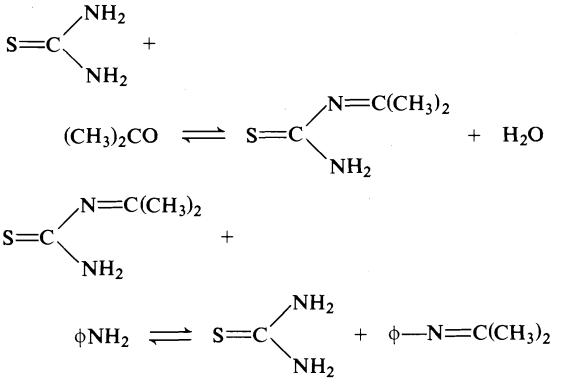
The experiment is somewhat complicated by the presence of D_2O in the acetone-d_6 used as solvent. As a result of this, as discussed previously, rapid exchange leads to partial deuteration of the NH_2 group of *p*-toluidine-h_2. The samples for this experiment were therefore made up in pairs, one containing *p*-toluidine-h_2 (A) and the other an equal concentration of *p*-toluidine-d_2 (B). The *p*-toluidine-d_2 was deuterated to the extent of 95% on the amino group. The initial rate of formation of anil was then measured over a range of *p*-toluidine concentrations. The ratios, rate A/rate B, increase steadily with concentration since the extent of deuteration of the *p*-toluidine-h_2 due to exchange with D_2O decreases with increasing *p*-toluidine concentration. At infinite *p*-toluidine concentration this effect would be negligible. To obtain the true kinetic isotope effect it is therefore necessary to extrapolate to infinite *p*-toluidine concentration. It may be shown that:

$$\ln \frac{X - X_\infty}{1 - X_\infty} = -kY$$

where X is the ratio of rates at a concentration of *p*-toluidine Y and X_∞ is the kinetic isotope effect at infinite *p*-toluidine concentration. The data were therefore fitted to this equation using a range of values for X_∞ and a least squares fitting procedure. The value of X_∞ chosen was that which led to a minimum in the standard deviation for the constant k. In this way we obtain a value for X_∞ (the kinetic isotope effect) of 1.55. This is probably a secondary effect and supports the conclusion that proton transfer is not involved in the rate determining step.

The Mechanism of Catalysis

It has been shown that anil formation, anil hydrolysis, and transimination are homogeneously catalyzed by metal complexes, specifically thiourea complexes of cobalt and nickel. The most effective catalysts are those which dissociate to the greatest extent in acetone (1). The rate of reaction is proportional to catalyst concentration and the reaction is inhibited by chelating ligands and by excess thiourea. All of this evidence suggests that one or more of the substrate molecules must be complexed to the metal for catalystis to occur. It is however possible to envisage mechanisms not involving substrate complexation. Thus for example one such possibility would be imine formation with thiourea followed by transimination, *i.e.*,



We reject this possibility on the grounds: (*a*) Thiourea alone is ineffective as a catalyst. (*b*) There is no evidence for imine formation between thiourea complexes and acetone in the absence of anilines. (*c*) Both $Zn(DMTu)_2Br_2$ and $Zn(TMTu)_2Br_2$ are very effective catalysts (DMTu $\equiv$ *N*,*N*′-dimethyl thiourea, TMTu $\equiv$ *N*,*N*,*N*′,*N*′-tetramethyl thiourea). In these cases the NH_2 groups necessary for imine formation are not present.

Given, then, the necessity for substrate complexation the question arises as to whether one or both substrates must be complexed. For the case of catalysis by metal ions in aqueous solution arguments have been advanced in favour of both these possibilities (7, 8). Our original interpretation of the results of the experiments involving dilution with carbon tetrachloride favoured the model with both substrates complexed.

The argument is as follows. For anil formation the rates of ligand exchange for both acetone and aniline are too rapid to allow complex formation to be a rate determining step. The observed rapid proton exchange and the measured kinetic isotope effect prelude proton transfer steps as being rate determining. Therefore the rate must be determined by the rate of attack of aniline on acetone. If both the substrates were complexed the rate would be proportional to the concentration of a binary complex, *i.e.*

$$\text{Rate} = k[\text{M.Ac.An}]$$

If only one of the substrates were complexed, then

$$\text{Rate} = k[\text{M.Ac}][\text{An}] \text{ or } k[\text{M.An}][\text{Ac}]$$

(An = aniline, Ac = acetone). However dilu-

[a]Catalyst 0.0219 *M* $Zntu_2Cl_2$, acetone concentration 13.65 *M*, equilibrium constants K_1(tu) = 1.0, K_2(An) = 0.036, K_3(Ac) = 0.000107.
[b]A = ([$MtuAcCl_2$] + [$MAnAcCl_2$])[An].
[c]B = ([$MtuAnCl_2$] + 2[$MAnAnCl_2$] + [$MAnAcCl_2$]).
[d]It is only meaningful to correlate these concentrations with initial rates if it is assumed that An has not significantly displaced Ac in the second sphere.

tion with carbon tetrachloride reduces the concentration of all species in direct proportion to the degree of dilution (see above). Therefore in the first case dilution by a factor of two would half the rate and in the second case it would reduce it by a factor of four since both reactant concentrations are halved. The experimental results clearly favour the first alternative. The argument for the back reaction (anil hydrolysis) is exactly analogous and the experimental results are equally unambiguous.

However, more detailed analysis does not sustain this argument. Equilibrium constants are available for the complexation of each of the substrates with cobalt thiourea compounds. The above rate data have been obtained with zinc thiourea catalysts, hence we would not expect to be able to perform quantitative calculations using the equilibrium constants for the cobalt compounds. We would however expect correct qualitative predictions regarding the variation of rate with substrate concentrations. A set of equilibria of the type:

$$ML_jL_e + L_i \rightleftharpoons ML_jL_i + L_e$$

may be written involving Mtu_2X_2 catalysts in which L_i, L_j, and L_e are all possible combinations of thiourea, aniline, acetone, anil, and water. It may be shown that the concentration of any given species, say ML_2L_3 is given by the expression:

$$[ML_2L_3] = \frac{2mK_2K_3[L_2][L_3]}{(K_1[L_1] + K_2[L_2] + K_3[L_3])^2}$$

In this expression m is the total catalyst concentration and K_1, K_2, K_3 etc. are the equilibrium constants for the replacement of thiourea (L_1) by other ligands. The expressions for the case with four replacable ligands *e.g.*, $Mtu_4(ClO_4)_2$ are exactly the same except that the numerical factor is equal to 12 rather than 2. Knowing the equilibrium constants and the initial concentrations the set of equations of the above type may be solved by an iterative procedure. An appropriate computer programme was found to converge rapidly when m was small compared to any product $K_i[L_i]$. If complexed aniline reacts with complexed acetone then for a catalyst Mtu_2X_2:

$$\text{Rate} \propto [MAcAnX_2]$$

For a catalyst such as $Mtu_4(ClO_4)_2$ the rate will be proportional to the sum of the concentrations of all complexes containing both Ac and An. Some calculations giving the dependence of [$MAcAnX_2$] on aniline concentration are shown in Table 6 and compared with the experimental data for the rate of anil formation at the same aniline concentrations. The calculated concentrations of the binary complex decrease with increasing concentration, whereas the rates increase. The same result is obtained for $Mtu_4(ClO_4)_2$ catalysts. Examination of the calculations shows that the concentration [$MAnAcX_2$] will not increase with aniline concentration unless $K_3[Ac] \gg K_2[An]$. Although the equilibrium constants used for the replacement of thiourea by acetone (K_3) and by aniline (K_2) may not be accurate the above condition is clearly unrealistic and this model must be rejected.

It is therefore necessary to examine the significance of the experiments involving dilution with carbon tetrachloride more closely. The experimental results demand that both substrates be bound to the catalyst in such a manner that the addition of carbon tetrachloride will not dissociate the resulting adduct. It is not necessary

that they be both held in the first coordination sphere of the complex. It is recognized that ligands may be weakly held in the second coordination sphere of metal complexes (9) and that such entities may have kinetic significance. Thus in ligand exchange reactions associative (A) mechanisms may be distinguished from interchange (I_A) mechanisms in which the rate determining step involves interchange of a first sphere and a second sphere ligand (10). In the present case we may write a rapid pre-equilibrium involving the replacement of acetone by aniline in the second sphere: *i.e.*,

$$[3]\quad \mathrm{MtuAcCl_2{\cdot}(Ac)} + \mathrm{An} \overset{K'}{\rightleftharpoons} \mathrm{MtuAc{\cdot}Cl_2{\cdot}(An)} + \mathrm{Ac}$$

$MtuAcCl_2{\cdot}(An)$ is now the reactive species together with analogous complexes such as $MAnAc{\cdot}Cl_2{\cdot}(An)$ and $MAc_2Cl_2{\cdot}(An)$. The last term can be neglected since K_3 is small and the rate will be given by:

$$[4]\quad \text{Rate} \propto [\mathrm{MtuAcCl_2{\cdot}(An)}] + [\mathrm{MAnAc{\cdot}Cl_2{\cdot}(An)}]$$

By arguments analogous to those presented above the equilibrium 3 will not be affected by dilution with carbon tetrachloride providing CCl_4 does not compete with aniline or acetone for second sphere sites. Experimental evidence with other metal complexes does indeed indicate that CCl_4 is a very poor second sphere ligand (11). The rate expression 4 above will give the observed result in the dilution experiments.

Equations 3 and 4 predict that the initial rate be proportional to $([\mathrm{MtuAcCl_2{\cdot}(Ac)}]+[\mathrm{MAnAcCl_2{\cdot}(Ac)}][\mathrm{An}]$. Calculated values for this quantity are shown in column A of Table 6. They are plotted against the initial rate data in Fig. 3. A satisfactory linear dependence is obtained showing that this mechanism is consistent with experiment. There is another possibility, namely, that aniline be held in the first sphere and acetone in the second sphere. This is chemically less likely (see below) but cannot be entirely ruled out on kinetic grounds. The appropriate concentrations are shown in column B of Table 6. The hydrolysis of the anil would involve a mechanism in which anil is held in the first sphere and subject to nucleophilic attack by second sphere water. The kinetic implications of this mechanism are entirely analogous to those discussed above for anil formation.

It remains to be shown that the above model

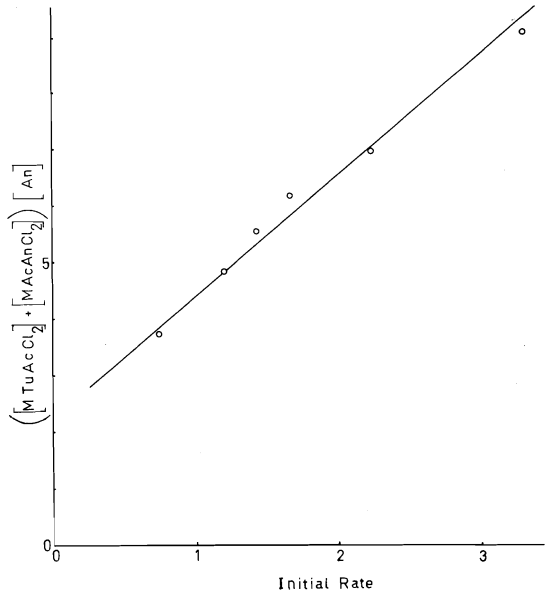

FIG. 3. Comparison of observed initial rate (mol/ℓ s $\times 10^4$) with calculated concentrations of reactants (mol^2/ℓ^2 $\times 10^5$).

satisfactorily accounts for the remaining kinetic data. All of the models predict a linear dependence of rate on catalyst concentration as is experimentally observed. It may be shown that for the Mtu_2X_2 catalysts to a good approximation:

$$\frac{1}{\text{Rate}} = \frac{\sqrt{K_2}}{2kK'K_3\sqrt{m}} \cdot \frac{1}{\sqrt{\text{An}}} + \frac{K_2}{2kmK'K_3}$$

Hence the reciprocal of rate should be linear with the reciprocal of the square root of aniline concentration. An appropriate plot is shown in Fig. 4 and is satisfactorily linear. A slight curvature is predicted in the Lineweaver–Burk double reciprocal plots but calculation of sample theoretical curves showed that the experimental scatter of the data is too great to reveal the curvature. The situation with $Mtu_4(ClO_4)_2$ catalysts is mathematically more complicated but numerical calculations confirm that 1/rate should be proportional to 1/[An] within the accuracy of the experiments. For the experiments involving inhibition with thiourea it is predicted that:

$$\frac{1}{\text{Rate}} = a[\mathrm{tu}] + b$$

Figure 5 shows an appropriate plot of the experimental data. It may be noted that the model involving the coordination of both acetone and

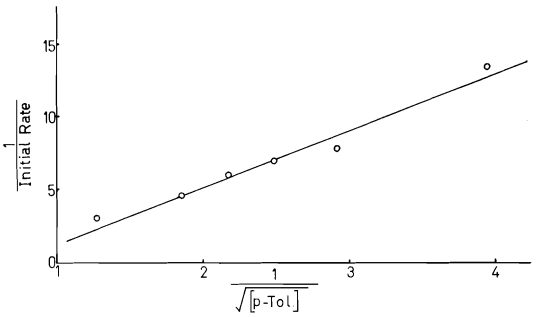

FIG. 4. Plot of (initial rate)$^{-1}$ (ℓ s/mol $\times 10^{-3}$) for anil formation against $[p\text{-tol}]^{-1/2}$ ($\ell^{1/2}$ mol$^{-1/2}$).

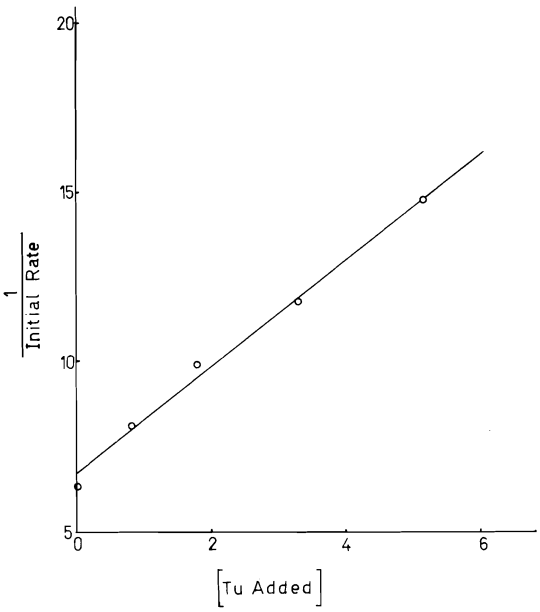

FIG. 5. Plot of (initial rate)$^{-1}$ (ℓ s/mol $\times 10^{-1}$) for anil formation against [tu] (mol/$\ell \times 10^2$) added.

aniline predicts that 1/rate will vary as $[tu]^2$ at high thiourea concentrations. Figure 5 shows no indication of this behaviour.

The Nature of the Rate Determining Step

On the basis of the evidence discussed above the reaction scheme shown in Fig. 6 is suggested. The steps shown are preceded by rapid pre-equilibria establishing the distribution of ligands in the first and second coordination spheres of the metal complex and are followed by further rapid equilibria re-establishing this distribution with the product anil and water molecules. Anil hydrolysis proceeds by the reverse of these reactions. A similar scheme for transimination may be readily written by replacing the acetone molecule with an anil.

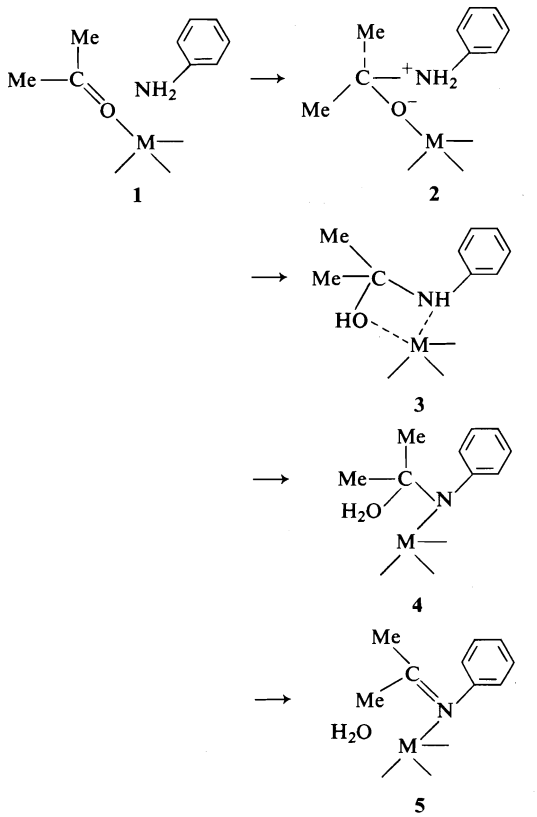

FIG. 6. Suggested mechanism for anil formation.

In this scheme steps **2** → **3** and **3** → **4** involve proton transfer. The observations of rapid exchange on the nmr time-scale and of a small kinetic isotope effect show that these steps are not rate determining. If step **4** → **5** were rate determining the carbinolimine should be a stable intermediate and as such observable by nmr. It is therefore suggested that step **1** → **2**, the nucleophilic attack of a second sphere aniline on a coordinated acetone molecule is the rate determining step in anil formation. For anil hydrolysis the rate determining step is the attack of second sphere water on coordinated anil.

For the transimination reaction the corresponding scheme has a higher symmetry since the forward and backward reactions are identical. Similar arguments suggest that attack of second sphere aniline on coordinated anil is rate determining. In this case nmr spin saturation transfer experiments provide additional evidence (1). The lifetime for exchange of *cis* and *trans* methyl groups is twice that for transimination indicating the two rates are determined by the

same process and suggesting facile rotation or inversion about the C—N bond during nucleophilic attack.

The above mechanism is also chemically attractive. Complexation of acetone or anil will withdraw negative charge from the molecule leaving the carbon more susceptible to nucleophilic attack (12) *e.g.*

On the other hand complexation of aniline or water involves utilization of the lone pair electrons and would make these molecules less effective nucleophiles (13). For this reason the above model with acetone in the first sphere and aniline in the second sphere is preferred over the kinetically similar model with aniline in the first sphere and acetone in the second sphere.

It cannot be unambiguously determined whether the aniline occupies a true second sphere site or is weakly bound to the metal to give a five coordinate complex. We prefer the first alternative. Binding to the metal would deactivate the nucleophile. There is no evidence for any stable five coordinate complexes with these ligands although such complexes may exist as intermediates in ligand exchange reactions. There is a fair amount of evidence for second sphere complexes involving anilines with binding energies of the order of 4 or 5 kcal/mol (14). If the aniline were primarily held by hydrogen bonding it would be activated as a nucleophile. There is a clear analogy between the mechanism suggested above and the I_A mechanism for ligand exchange. In an I_A mechanism a second sphere ligand is available for nucleophilic attack on the metal ion. In the reactions discussed above the nucleophilic attack is on a ligand atom.

Finally we summarize some of the factors which make these metal complexes particularly effective catalysts for the reactions discussed. The thiourea ligands are readily replaceable by substrate ligands but serve to prevent the precipitation of insoluble complexes. The availability of NH_2 groups on the periphery of the molecule may well serve a role in providing hydrogen bonding sites for second sphere coordination. The solubility in non-aqueous solvents implies that substrates such as acetone which could not compete with water as ligands in aqueous solution can complex the metal atom to a sufficient degree to react. Finally the role of the catalysts in bringing together the reactants should be mentioned. This has been referred to as the "promnastic" effect (15) and is undoubtedly a factor in any reaction which without catalysis would be bimolecular in nature.

Experimental

The preparation and purification of the chemicals used in this study has been described previously (1).

Initial rates were measured using a Varian HA 100 NMR spectrometer (probe temperature 35°C). The reaction was followed by using a voltage controlled frequency generator (Wavetek) to provide the sweep frequency so that the area of interest in the spectrum was repetitively scanned while the pen recorder was running. The sample containing the aniline or anil and a little TMS to provide a locking signal was placed in the probe and allowed to come to thermal equilibrium. The sample was then rapidly removed, catalyst solution injected with a syringe, a stopwatch started, and the tube shaken and replaced in the probe. The lock signal was relocated and the pen recorder started. This whole operation could be carried out in about 25 s and the first spectra were obtained about 30 s after the reaction had commenced. The fraction [Anil]/([Aniline] + [Anil]) is obtained from the measured intensities. Since the denominator is always constant, measurements of this quantity are insensitive to small changes in the homogeneity of the magnetic field or in the gain of the amplifier circuits. In the case of the measurements on the hydrolysis of anil the fraction [Aniline]/([Aniline] + [Anil]) was plotted against time, but the curve was extrapolated to meet the time axis where the concentration of aniline would be zero. This was necessary because the *p*-toluidine anil contained ~5% *p*-toluidine and the initial rate of formation of aniline must be determined where the aniline concentration is zero. Zinc thiourea complexes were used in these initial rate experiments to avoid complications arising from broadening of the nmr lines by the paramagnetic cobalt complexes.

p-Toluidine-d_2 was prepared by dissolving *p*-toluidine in diethyl ether and stirring together with successive portions of D_2O. The ether layer was dried with Na_2SO_4, the solvent removed on a vacuum line and the *p*-toluidine-d_2 sublimed *in vacuo*. It was kept in a glove bag under a dry nitrogen atmosphere. Integration of the nmr spectrum showed the material to be 95% deuterated.

Some methods for the preparation of α-alkylated vinylphosphonium salts and their use in 2,5-dihydrothiophene synthesis

JOHN M. MCINTOSH AND RICHARD S. STEEVENSZ

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received February 7, 1977

JOHN M. MCINTOSH and RICHARD S. STEEVENSZ. Can. J. Chem. **55**, 2442 (1977).

The preparation of a series of vinyltriphenylphosphonium salts, all of which bear a substituent on the carbon attached to phosphorus, is described. Yields are generally poor unless a symmetrical secondary allylic halide can be used. The use of these salts in the preparation of substituted 2,5-dihydrothiophenes has been examined. In general, reaction times are increased and product yields decreased relative to the reactions of the unsubstituted salts previously reported. This result is ascribed to steric inhibition of the intramolecular Wittig reaction.

JOHN M. MCINTOSH et RICHARD S. STEEVENSZ. Can. J. Chem. **55**, 2442 (1977).

On décrit la préparation d'une série de sels de vinyltriphénylphosphonium qui portent tous un substituant sur le carbone attaché au phosphore. Les rendements sont généralement mauvais à moins que l'on puisse utiliser un halogénure allylique secondaire symétrique. On a évalué les possibilités d'utiliser de tels sels pour la préparation de dihydro-2,5 thiophènes substitués. D'une façon générale, les temps de réaction augmentent et les rendements en produits diminuent par rapport aux réactions des sels non substitués qui avaient été rapportés antérieurement. On attribue ce résultat à une inhibition stérique de la réaction de Wittig intramoléculaire.

[Traduit par le journal]

In recent years, a number of research groups have demonstrated the usefulness of vinylphosphonium salts in the synthesis of a wide variety of acyclic (1), carbocyclic (2), polycyclic (3), and heterocyclic (4) compounds. Initially, most of the work was concerned with the use of vinyltriphenylphosphonium bromide because of its ready availability and unambiguous structure. Subsequently, we demonstrated (5) the simple conversion of primary allylic phosphonium salts **1** into their vinyl isomers (**2**), which allowed the use of the readily available **1** directly in the reactions and thereby provided facile formation of products derived from β-substituted salts (eq. 1).[1] Application of this technique to heterocyclic synthesis has afforded a wide range

[1] 
1 **2** **3**

of substituted dihydrothiophenes, (5, 6), dihydrothiopyrans (7), and products derived therefrom.

Reports of the synthesis and reactions of α-substituted vinyl salts (**3**) are much less frequent. Seyferth and Fogel (8) prepared **4** by a method which required initial quaternization of triphenylphosphine with an α-haloketone (eq. 2), a type of reaction well known to afford very low yields of phosphonium salts (see ref. 9 for a list of references). However, this route offers the possibility of complete generality if the alkylated salts **4** could be prepared more efficiently. Schweizer and co-workers (10) prepared several α-substituted salts **3** by routes which either did not appear to be general or afforded impure products or which led to substituents other than phenyl on the phosphorus atom. Another route, due to Vedejs *et al.* (11), also gives alkyl-substituted phosphorus atoms; difficulties encountered in the utilization of these compounds (10*b*) prompted us to develop other alternatives.

The importance of **3**, particularly those compounds bearing a functional group α to phosphorus, lies in their use in the synthesis of conjugated dienes by the route already outlined (5, 6) (eq. 3). The case of carboxy- or ether-substituted **3** would be particularly important in

[2] 
4

[1]The counterion for all salts in this paper is Br^- unless otherwise noted.

[3] 
the preparation of rather inaccessible (12) dienes for use in the Diels–Alder reaction.

With these facts and ideas in mind, we set out to explore improved routes to **3** and their applications in synthesis.

Results and Discussion

Synthesis of α-Substituted Vinyl Salts

Considering our success in preparing simple vinyl salts **2** by the isomerization of **1**, we first investigated the feasibility of applying this technique to salts derived from secondary allylic halides. That the method was successful was shown by the isomerization of cyclohex-3-en-1-yl-triphenylphosphonium bromide to its vinyl isomer (**5**) using the usual pyridine–triethylamine system (5). However, a major difficulty frequently arises during the preparation of the allylic salts required as starting materials. This is illustrated in [4]. Identical phosphonium

[4] 
salts were obtained, starting with either 3-chloro-1-butene or 1-chloro-3-butene. In all cases of this type, the intervention of extensive allylic rearrangement during quaternization introduces ambiguity into the structure of both the allylic and vinyl salts and therefore into that of the products derived from them. Only in the case of primary or symmetrical halides can this possibility be discounted.

An alternative to quaternization for the preparation of the required secondary allylic salts involved the alkylation of primary allylic salts (eq. 5). Alkylation of both carbonyl-stabilized

[5] 
(13) and unstabilized phosphoranes (14) is a well-documented reaction. However, the use of **1** presents the possibility of both α- and γ-alkylation leading to **7** and **8**. While the ylide **6** is well known to react at the α-position in the Wittig reaction (15), it has been pointed out that γ-attack may well be an undetected reaction (γ-attack on **6** by ethyl chloroformate has been documented; see ref. 16). The observation of γ-attack on **6** in some specific instances (17) supports this possibility. However, we were confident that the α/γ alkylation ratio could be controlled by the use of the proper cation in the alkylation (see, for example, ref. 18). It should also be noted that the alkylation of the corresponding allyl phosphonate at the α-position has been reported (19).

When **6** was generated, either with *n*-butyllithium or under saltfree conditions (20), and mixed with a large excess of alkylating agent (methyl iodide, ethyl bromide etc.), no visible quenching of the red ylide colour could be detected, even upon addition of 10% HMPA as cosolvent. Addition of acid immediately quenched the colour and the allylic salt was reisolated in high yield. Also, addition of carbonyl compounds to the ylide solution led to a rapid Wittig reaction, confirming the presence of the ylide.

We are unable to offer an explanation for this result. However, it should be noted that the related sulfonium ylide is also very unreactive to alkylating agents, although it does react well with carbonyl compounds (21).

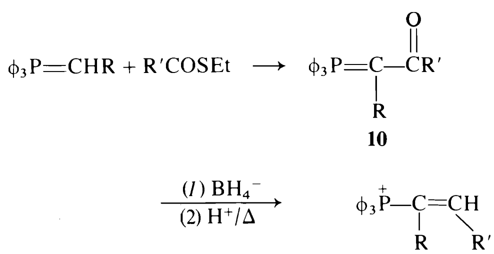
An alternative method for the preparation of the allylic salts **1** lay in the reported (22) addition of triphenylphosphine hydrobromide to conjugated dienes. Evidence is available that this addition proceeds well when the diene is symmetrical (eq. 6) or when a steric problem at one terminus of the diene system prevents attack of the bulky triphenylphosphine at that position (eq. 7) (6).

[6] 
[7] 
When the starting diene is readily available, this can be the method of choice for the preparation of **1**.

As previously mentioned, the work of Seyferth and Fogel (8) indicated that α-alkyl-β-keto-

phosphoranes **10** were a good source of vinyl salts. A possibly improved method for the preparation of **10** lay in the work of Bestmann (13) who had shown that simple phosphoranes could be acylated using thioesters (eq. 8).

[8]



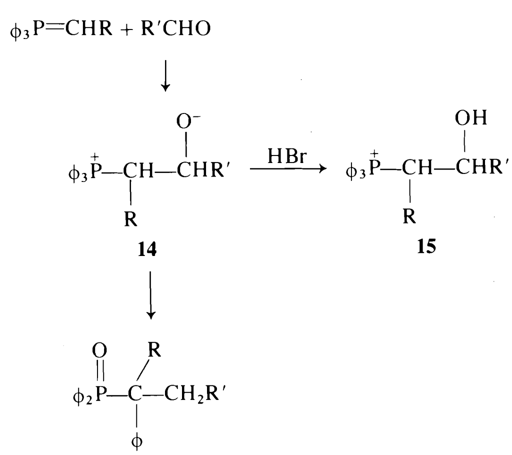
10

11 R = R′ = Me
12 R = Et, R′ = Me
13 R = Pr, R′ = Me

We were able to prepare **11–13** by this method, but both the yields (~20%) and the necessity of preparing the thiolesters detracted from this approach. However, it must be noted that, unlike the work described below, salts **11–13** were obtained as pure crystalline materials.

The major problem in the thioester approach lay in the formation of **10**. Therefore, an alternative appeared desirable and it occurred to us that interception of the betaine intermediate **14** of the normal Wittig reaction might overcome this difficulty and at the same time remove the necessity for reduction of **10**. It is well established (23) that the decomposition of **14** is slow at low temperature and by quenching the reaction with hydrobromic acid at 0°C, the oily β-hydroxyphosphonium salts **15** could be isolated (eq. 9). Unfortunately, **15** was contaminated with varying amounts of another product which we presume to be **16** derived by

[9]



14 **15**

16

rearrangement (24) of either **14** or **15** which reduced the yields of **15** considerably. Its presence was inferred from the low-field region of the nmr spectrum and the infrared spectrum. Removal of **16** was accomplished by recrystallization.

Difficulties arose when the preparation of salt **15** bearing two bulky groups (R and R′) was attempted. In these cases little or none of the desired **15** could be obtained.

Dehydration of **15** in concentrated hydrobromic acid (8) led to the formation of the vinyl salt. Other methods for the dehydration did not prove effective. Thus, reaction of **15** with acetylchloride afforded the β-acetoxyphosphonium salt, but elimination of acetic acid using LDA gave only the olefin expected from normal Wittig reaction. Similarly untoward results were obtained when mesylation or tosylation of **15** was attempted. Finally, dehydration using phosphorous oxychloride or thionyl chloride also proved unsatisfactory.

The acid-catalyzed dehydration of **15** afforded material which was contaminated with up to 50% of another unidentified product. Separation using chromatographic techniques was unsuccessful and recrystallization led to large losses of material. Therefore, we decided to carry these impure materials on to the dihydrothiophene synthesis, as it was felt that the contaminants would be more easily removed at that stage.

The vinyl salts prepared are listed in Table 1. The yields for those prepared by method *D* are those of partially purified materials, whose purity is estimated (nmr) to be in excess of 65%. The nmr spectral data for new vinylphosphonium salts is given in Table 2.[2] These were obtained on small amounts of extensively purified material. The β-hydroxyphosphonium salts **15** were prepared and their nmr spectra are shown in Table 3. In addition to nmr analysis the presence of the desired salts was confirmed by the use of field-desorption mass spectrometry (25).

It should be noted that for the dehydration to be successful, a homogeneous acid phase must be attained while the solution is refluxing. Heterogeneous mixtures led to the formation of black tars.

[2]Tables 2 and 6 showing nmr and analytical data have been deposited in the Depository of Unpublished Data. Copies of these tables may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Synthesis of Dihydrothiophenes from α-Alkylvinylphosphonium Salts

The accepted mechanism for the formation of dihydrothiophenes is shown in [10]. The final step in this sequence is a Wittig reaction and as we have pointed out (5) we know of no examples of the formation of a tetrasubstituted double

[10] 
bond using this reaction. Also, Schlosser (26) has estimated that the presence of an α-alkyl substituent reduces the rate of betaine decomposition by a factor of ten. Therefore, our initial investigations utilized mercaptoaldehydes **24–26** (Table 4). Subsequently, ketones **27–29** were also included. While not all the salts listed in Table 1 were used, the reactions reported here illustrate the effects which determine the relative success of the method.

The reactants, products, yields, and reaction times are summarized in Table 4 and the spectral characteristics of the products in Table 6.[2] The yields indicated are based on an assumed 100% purity of the vinyl salts. As has already been pointed out, except for **5**, **9**, **12–14**, and **17**, this was known to be incorrect and therefore the yields indicated are minimum values.

As can be seen from Table 4, drastically reduced yields and increased reaction times are encountered relative to the simpler cases already reported (5, 6, 27). These were expected on the basis of earlier reports (7, 10) and the steric arguments mentioned above. In particular, the use of either acyclic ketones and α-substituted salts (products **46–48**, Table 4) or salts which have substituents larger than methyl at both the α- and β-positions (products **34**, **41**, **42**, Table 4) react very poorly. In some cases, the long reaction times caused the formation of some thiophene products derived from air oxidation of the dihydrothiophenes (7). Schweizer *et al.* have attributed the lower reactivity of the α-substituted vinyl salts to a steric inhibition of the initial conjugate addition reaction (10*b*). However, in view of the results of Schlosser and our previously demonstrated ability to form dihydrothiophenes from β,β-disubstituted vinyl salts, we prefer to attribute the results to inhibition of the Wittig cyclization.

The ability to form dihydrothiophenes from aldehydes and less hindered salts allows a degree of flexibility in synthetic planning as many can now be prepared from two different sets of reactants. For example, **37** can now be prepared as shown in [11].

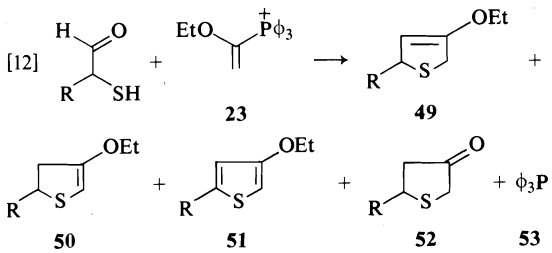
Reactions Using 1-Ethoxyvinyltriphenylphosphonium Bromide (23)

We have reported (28) the formation of **23** and the fact that it does function as a Michael acceptor. When this salt was utilized in the dihydrothiophene-forming reaction, unexpected results were obtained (eq. 12). In addition to the



expected dihydrothiophene **49**, three other sulfur-containing products **50**–**52** were produced. The hydrolysis product **52** is unexceptional but the presence of thiophene **51** cannot be explained on the basis of air oxidation of **49** and **50**, since both of these are stable after isolation. The concomitant formation of triphenylphosphine (**53**) suggests another mechanism may be operating. We have previously noted (29) the formation of **53** and thiophene products in the reaction of butadienyltriphenylphosphonium salts and it appears possible that a mechanism similar to the one proposed in that case may be operating here (Scheme 1). The presence of an anion-destabilizing substituent might well favour the proton migration over the direct cyclization to **49** and account for the observed results.

Products of type **50** have not been observed previously by us. We presume they are formed by isomerization of **49**, a process which would be much more favourable in this case than in the alkyl-substituted dihydrothiophenes because of the increased ease of protonation of the double bond of the enol ether relative to the simple alkene. The products obtained from **23** are shown in Table 5 and their spectral characteristics are included in Table 6.[2]

Conclusions

From the results, it is apparent that, except in some specific cases, we have not successfully solved the problems associated with the preparation of the α-substituted vinylphosphonium salts. Furthermore, the feasibility of using dihydrothiophenes bearing substituents at both the 3- and 4-positions as synthetic intermediates appears to be very limited and we do not plan any further investigations in this area.

Experimental

Nuclear magnetic resonance spectra were run on Varian EM 360 or JEOLCO C60HL instruments and are reported in ppm downfield from TMS as internal standard. Infrared spectra were obtained on a Beckmann IR 12 and mass spectra on a Varian-MATCH-5DF spectrometer under the control of an INCOS computer. Gas chromatography was performed on an F and M Model 720 instrument, utilizing the following columns: 6 ft × 0.25 in. 10% Carbowax 20M on Chromosorb W; 10 ft × 0.375 in. 10% Carbowax 20M on Chromosorb W.

Microanalyses were performed by A. B. Gygli, Microanalysis Laboratory, Toronto, Ontario.

Cyclohex-3-en-1-yltriphenylphosphonium Bromide

A mixture of 10 g (6.2 mmol) of 3-bromocyclohexene (30) and 16.3 g (6.2 mmol) of triphenylphosphine in 160 ml of acetonitrile was heated at reflux for 10 h. The cooled solution was reduced in volume to about 100 ml and poured into ether. After stirring for 0.5 h, the solution was filtered and the residue recrystallized from methylene chloride–ethyl acetate to give 18.0 g of product (69%), mp 222–224°C; nmr ($CDCl_3$) 8.1–7.4 (15H, m), 6.1–5.35 (3H, m), 2.1–1.25 (6H, m). *Anal.* calcd. for $C_{24}H_{24}BrP$: C 68.10, H 5.72, Br 18.89; found: C 68.01, H 5.64, Br 19.02.

Carrying out the reaction in ether solvent gave no reaction, whereas the use of benzene led to extensive decomposition. Dissolution of the salt in pyridine containing triethylamine (method *A*) led to complete isomerization to the vinyl isomer (**5**) as evidenced by the nmr spectrum.

Preparation of ***9***

To a solution of 7.0 g (0.02 mol) of triphenylphosphine hydrobromide (31) in 50 ml of acetonitrile was added 3.6 g of 2,4-hexadiene and the solution was refluxed for 18 h. The solvent was evaporated to afford a quantitative yield of the light yellow glassy allylic phosphonium salt which was quantitatively (nmr) isomerized to **9** by treatment with pyridine–triethylamine.

Preparation of Vinyl Salts via β-Ketophosphoranes (Method C)

To a toluene solution of the required phosphorane generated under salt-free conditions (20) was added 1.1 equiv. of the desired thioester. The mixture was refluxed for 18 h, filtered hot, and the α-alkyl-β-ketophosphorane isolated by filtration of the cooled solution. Recrystallization was effected from ethyl acetate – petroleum ether. Since borohydride reduction of these materials was difficult, they were converted to their phosphonium salts by reaction with gaseous hydrogen bromide in benzene solution.

To a solution of the phosphonium salt in methanol (25 ml per gram of salt) was added solid sodium borohydride (1.5 g per gram of salt) over a period of 2 h at 0°C. After 1 h, the excess hydride was decomposed with water. The methanol was evaporated and the aqueous phase extracted with chloroform. Evaporation of the dried extract gave the β-hydroxyphosphonium salt **15** which was recrystallized from ethyl acetate – chloroform. Yields and spectral data for the products can be found in Table 3.

The hydroxy salt was dissolved in 48% hydrobromic acid (15 ml per gram of salt) and heated at reflux for 3 weeks (shorter reaction times gave incomplete reaction). The cooled solution was diluted with an equal volume of water and extracted with methylene chloride. The combined organic extracts were washed with water, dried, and evaporated. The oil obtained was dissolved in the minimum amount of hot methylene chloride and ethyl acetate was added slowly to the cloud point. The cooled solution was filtered and the product recrystallized from methylene chloride – ethyl acetate. Products, yields, and spectral data are listed in Tables 1 and 2.[2]

Direct Formation of the β-Hydroxyphosphonium Salts (Method D)

To a suspension of the required phosphonium salt (0.05 mol) in 150 ml of dry ether under nitrogen was added 0.05 mol of *n*-butyllithium. After 1 h, the solution was cooled to 0°C and the desired aldehyde (0.07 mol) added slowly without stirring. A thick, white precipitate formed, to which was added 100 ml of 5% hydrobromic acid. This caused the formation of three layers. The upper ether layer was separated and the middle aqueous layer was extracted with methylene chloride. The combined organic layers were dried and evaporated. Precipitation of the product from methylene chloride solution using ethyl acetate afforded the β-hydroxyphosphonium salts **15** which crystallized over a 24 h period at 0°C. Using this method, salts **15** of about 90% purity could be obtained which were dehydrated using 48% hydrobromic acid as previously described.

Preparation of 2,5-Dihydrothiophenes

A solution of the vinyl salts (0.01 mol) and mercaptocarbonyl compound (0.015 mol) in 50 ml of pyridine containing 0.015 mol of triethyl amine was heated at reflux under a nitrogen atmosphere for the time indicated in Table 4. Water (600 ml) was added to the cooled solution and the mixture was extracted twice with 100 ml of ether and twice with 100 ml of pentane. The combined organic layers were washed with 10% hydrochloric acid until the washing was acidic, dried, and evaporated. The oil thus obtained was chromatographed on acidic alumina using pentane as the eluant. Evaporation afforded the dihydrothiophene in the yields shown in Tables 4 and 5 and it was shown to be at least 95% pure by glc. Analytical samples were collected from glc. The refractive indices and nmr spectral data are given in Table 6.[2] Except for the lack of carbonyl absorption, the ir spectra were uninformative.

By-products (thiophenes and positional isomers **53** and **54**) were also collected by glc where possible and the data for these are included in Table 6.[2]

Use of ^{13}C in biosynthetic studies. Incorporation of ^{13}C-labeled acetate into chartreusin by *Streptomyces chartreusis*[1]

P. L. CANHAM AND L. C. VINING
Biology Department, Dalhousie University, Halifax, N.S., Canada B3H 4J1

Received October 29, 1976

P. L. CANHAM, L. C. VINING, A. G. MCINNES, J. A. WALTER, and J. L. C. WRIGHT. Can. J. Chem. **55**, 2450 (1977).

Examination by ^{13}C nuclear magnetic resonance spectroscopy of chartreusin produced in cultures of *Streptomyces chartreusis* supplemented with [1-^{13}C] and [2-^{13}C]acetate showed that the 19-carbon aglycone component was derived entirely from acetate. In the spectrum of chartreusin enriched from [1,2-^{13}C]acetate the signals for 16 of the carbon atoms were accompanied by satellites due to spin–spin coupling of intact ^{13}C—^{13}C units. The coupled pairs were matched with the aid of homonuclear single ^{13}C-frequency decoupling. Of the uncoupled carbon atoms, two were derived from methyl groups of acetate and the third came from an acetate carboxyl group. The arrangement of paired and unpaired ^{13}C atoms in chartreusin suggests that the aglycone is derived from a single 22-carbon polyketide chain. Cyclization to a benzpyrene-like intermediate followed by ring cleavage and loss of three carbon atoms provides a plausible route from the polyketide to the substituted isocoumarin structure of the aglycone.

P. L. CANHAM, L. C. VINING, A. G. MCINNES, J. A. WALTER et J. L. C. WRIGHT. Can. J. Chem. **55**, 2450 (1977).

L'examen des spectres rmn du ^{13}C de la chartreusine produite dans les cultures de *Streptomyces chartreusis* additionnées de [1-^{13}C] et [2-^{13}C]acétate montre que le composant aglycone contenant 19 atomes de carbone provient entièrement de l'acétate. Dans le spectre de la chartreusine enrichie à partir de [1,2-^{13}C]acétate, les signaux de 16 des atomes de carbone sont accompagnés par des satellites dus à un couplage spin–spin des unités ^{13}C–^{13}C intactes. On a pu comparer les paires couplées à l'aide d'un découplage de fréquence ^{13}C homonucléaire et simple. Des atomes de carbone non-couplés, deux proviennent des groupes méthyles de l'acétate et le troisième d'un groupe carboxyle de l'acétate. L'arrangement des atomes de carbone ^{13}C pairés et non-pairés dans la chartreusine, suggère que l'aglycone dérive d'une seule chaîne polykétide contenant 22 atomes de carbone. Une cyclisation conduisant à un intermédiaire ressemblant à du benzpyrène suivie par une fermeture de cycle et la perte de trois atomes de carbone fournit une route possible menant d'un polykétide à la structure isocoumarine substituée de l'aglycone.

[Traduit par le journal]

Introduction

Streptomyces chartreusis produces a glycosidic antibiotic, chartreusin, the aromatic dilactone component of which has been reported to originate from acetate (1, 2). Schmid located the carbon atoms derived from the methyl and carboxyl groups of acetate as shown in Fig. 1, but no experimental evidence was provided (1). Brown *et al.* (2) examined the distribution of ^{14}C-labeled carbon atoms in chartreusin enriched by growing cultures of *S. chartreusis* on diethyl [1-^{14}C] or [2-^{14}C]malonate. By chemical degradation of the aglycone they were able to confirm that C-3 and C-9 originated with the carboxyl and methylene carbons of malonate, and that the relative specific activities of substituted phthalic acids containing the carbon atoms of rings A and C were consistent with the distribution of label reported by Schmid. However, no complete chemical dissection of the labeled molecule has been described. Even if the proposed labeling pattern is assumed to be correct, the manner in which acetate and malonate units are assembled to generate chartreusin aglycone is not obvious. As observed by Brown and his colleagues, the carbon skeleton cannot be formed directly by the folding of a single polyketide chain; either an intermediate

[1]NRCC No. 15895.

of single-chain origin undergoes rearrangement or more than one polyketide chain is involved.

To obtain information on the assembly of two-carbon units in chartreusin we have prepared the antibiotic from cultures supplemented with ^{13}C-enriched acetate and measured the incorporation of isotopic label by ^{13}C nuclear magnetic resonance (^{13}C nmr) spectroscopy. A preliminary account of these experiments has already been reported (3). We present here the evidence supporting ^{13}C nmr assignments, biosynthetic labeling patterns, and our conclusion that chartreusin aglycone is derived from a single polyketide chain of 22 carbon atoms.

Biosynthetic Labeling

Of three isolates of *S. chartreusis* (strains K-180, ATCC 14922, and X-465) compared on defined (2) and complex (4) media for chartreusin production, strain X-465 gave the highest titre. Yields of 80–100 mg/ℓ were obtained at first, but deteriorated rapidly when the stock culture was transferred. To maintain good production we found it necessary to select a high-producing variant and prepare inocula for biosynthetic labeling experiments directly from stock cultures preserved by lyophilization. The culture medium favouring chartreusin formation was adapted from that of Berger *et al.* (4). An appropriate concentration of sodium acetate supplement, and suitable times for adding the supplement and harvesting the cultures to obtain optimum isotopic enrichment of the antibiotic, were selected in pilot experiments. Incorporation of radioactivity from sodium [2-^{14}C]acetate was used as a measure of isotopic enrichment.

The ^{13}C nmr spectra of chartreusin from cultures supplemented with sodium [1-^{13}C] acetate, [2-^{13}C]acetate, and [1,2-^{13}C]acetate are compared in Fig. 2 with the spectrum of the antibiotic at natural abundance. Signals at δ 15 (CH_3), 100 (anomeric carbon), and in the range 55–80 ppm (hydroxymethine carbons) could be assigned to the glycosidic moiety. They were enhanced to only a small extent in the spectra of samples enriched from ^{13}C-labeled acetate. Chartreusin derived from singly labeled acetate showed marked enhancement of a reciprocal series of signals, *i.e.* all of the non-glycosidic signals not intensified in the sample labeled from [1-^{13}C]-acetate were enhanced in the sample from [2-^{13}C]acetate. This result verifies the earlier deductions based on radiotracer studies that all of the aglycone carbon atoms are derived from acetate (1, 2). In the spectrum of the sample labeled from [1,2-^{13}C]acetate, signals for 16 of the 19 aglycone carbons were accompanied by satellites due to ^{13}C–^{13}C coupling between covalently bonded ^{13}C carbon atoms.

Assignment of ^{13}C Resonances

Aglycone resonances in the ^{1}H broad-band decoupled pulse Fourier transform ^{13}C nmr spectrum of chartreusin were assigned from chemical shift trends (5), direct and long-range spin–spin couplings to hydrogen ($^{n}J_{CH}$, which were more easily measured in the high resolution (HR) spectra of samples labeled with [1-^{13}C] and [2-^{13}C]acetate), and unambiguous pairing of carbons that were spin–spin coupled ($^{1}J_{cc}$) in the spectrum of the [1,2-^{13}C]acetate-labeled metabolite. Values for chemical shifts and spin–spin coupling constants are presented in Table 1.

Chemical shift values and a characteristic one-bond ^{13}C–^{13}C coupling of 43.5 Hz identified the aglycone methyl carbon (δ_c 21.6 ppm) and the adjacent C-5′ quaternary aromatic carbon atom (δ_c 138.5 ppm). The HR signal for C-5′ was probably a doublet of quartets due to coupling with H-3′ and the methyl hydrogens ($^{2}J_{CH}$) but spectral resolution was insufficient to permit the small couplings to be measured. Signals for the five aromatic methine carbon atoms were easily recognized in the HR spectrum from the splitting due to one-bond ^{13}C–H couplings (5). Those for C-5 and C-7 could be distinguished by the additional splitting caused by three-bond ^{13}C–H coupling to H-7 and H-5. The carbon atom resonating at δ_c 116.2 ppm was assigned to C-5 because it was ^{13}C–^{13}C coupled ($^{1}J_{cc}$ 56.2 Hz) to a quaternary aromatic carbon (C-4a) at δ_c 126.0

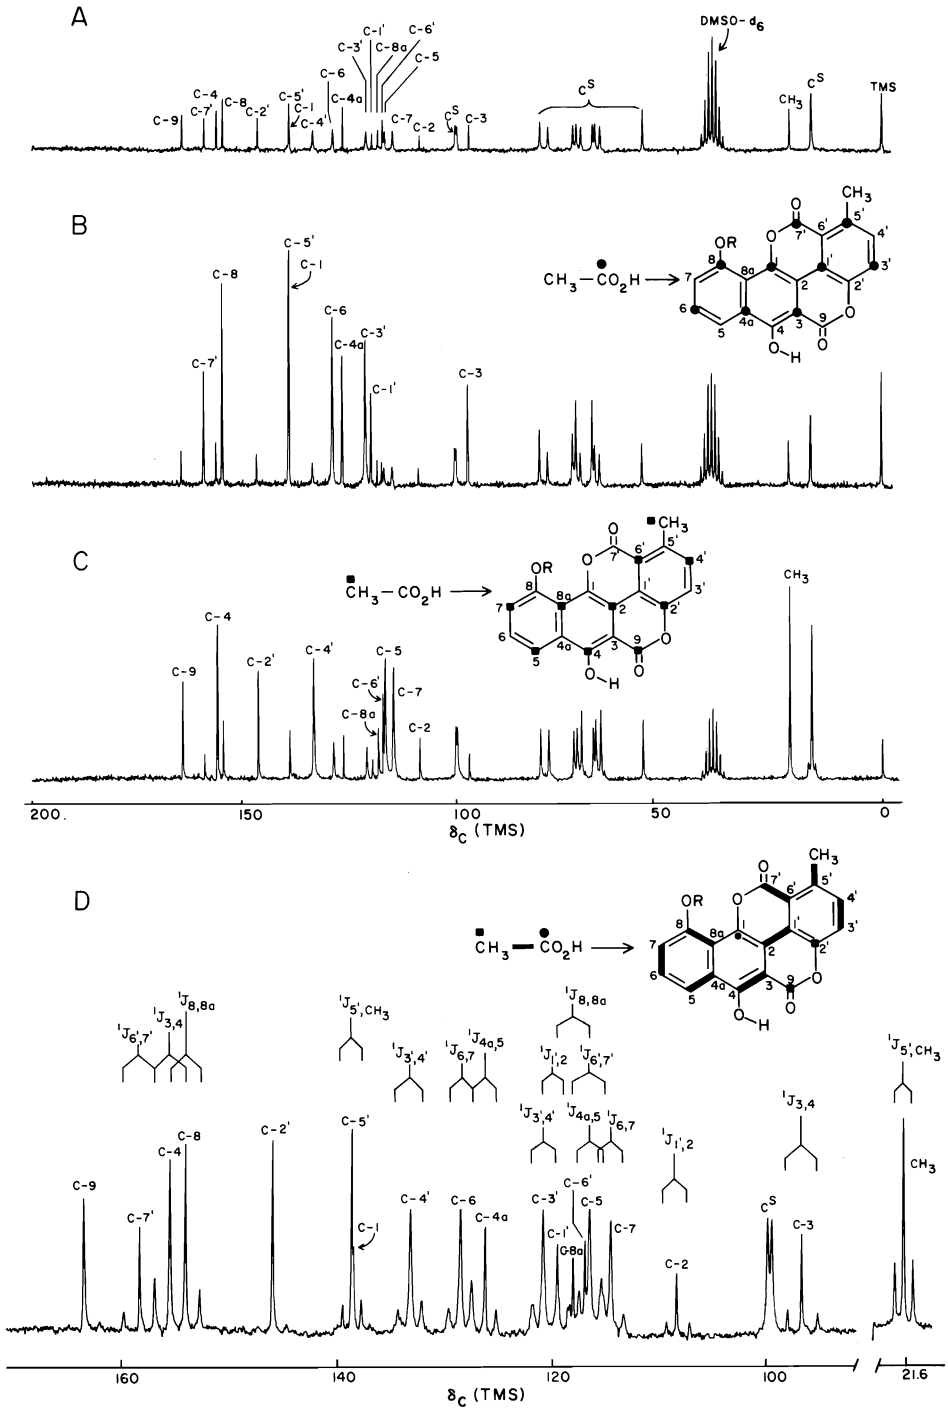

FIG. 2. ^{13}C nmr spectra (broadband (^1H)-decoupled) of chartreusin at natural abundance ^{13}C concentration (A), and from cultures supplemented with [1-^{13}C]acetate (B), [2-^{13}C]acetate (C), and [1,2-^{13}C]acetate (D). In D regions containing resonances of the aglycone carbon atoms are expanded and show satellites due to ^{13}C–^{13}C spin–spin coupling ($^1J_{cc}$). C^s denotes the glycosidic resonances.

ppm which in turn was long-range coupled to an aromatic hydrogen (H-6, $^{3}J_{CH}$ 8.7 Hz) as well as to a hydroxyl hydrogen ($^{3}J_{C(OH)}$ 6.9 Hz). Replacing the hydroxyl hydrogen with deuterium removed the $^{13}C(OH)$ coupling. The signal at δ_c 114.4 ppm was allocated to C-7, since this carbon atom was ^{13}C–^{13}C coupled ($^{1}J_{cc}$ 53.9 Hz) to an aromatic methine carbon atom at δ_c 128.3 ppm which could only be C-6. The remaining carbons bearing hydrogen, namely C-3′ (δ_c 120.6 ppm) and C-4′ (δ_c 133.1 ppm), were also derived biosynthetically from an intact [1,2-^{13}C]acetate unit ($^{1}J_{cc}$ 54.5 Hz). The higher field resonance was assigned to C-3′ because the oxygen substituent at C-2′ would be expected to shield it, but not C-4′ (5). Consistent with those assignments the HR resonance attributed to C-4′ was a doublet of quartets due to coupling with H-4′ and the methyl hydrogens, whereas that for C-3′ was a sharp doublet due to coupling with H-3′ only. There was not sufficient spectral resolution to measure the small $^{3}J_{CH}$ values.

Resonances could be assigned to C-4 (δ_c 155.4 ppm, $^{2}J_{C(OH)}$ 4.1 Hz) and C-3 (δ_c 96.5 ppm, $^{3}J_{C(OH)}$ 3.5 Hz) because both carbon atoms (like C-4a) were spin–spin coupled to hydroxyl hydrogens, belonged to a ^{13}C–^{13}C unit ($^{1}J_{cc}$ 70.6 Hz), and possessed chemical shifts consistent with one (C-4) being deshielded and the other (C-3) being shielded by a hydroxyl substituent (5). Supporting these assignments, the resonance attributed to C-3 was enhanced in the spectrum of the metabolite enriched with [1-^{13}C]acetate, as predicted from the radiotracer study (2) which established that C-3 was derived from the carbonyl carbon of acetate. The long-range coupling ($^{3}J_{CH}$ 3.1 Hz) at C-4 must involve H-5.

Of the nine ^{13}C resonances still unassigned the five at lowest field were allocated to the two carbonyl carbon atoms (C-7′ and C-9) and the three aromatic carbon atoms bonded to oxygen (C-1, C-8, and C-2′). In HR spectra the signals at δ_c 154.0 and 145.8 ppm could be distinguished within this group as belonging to C-8 and C-2′ since they were present as doublets due to coupling with H-6 and H-4′, respectively. Of the three other resonances, those at δ_c 138.4 and δ_c 158.3 ppm were enhanced in the spectrum of chartreusin biosynthesized from [1-^{13}C]acetate whereas the carbon atom with a chemical shift of δ_c 163.6 ppm was derived from the methyl group of acetate. Since the earlier radiotracer study (2) established that C-9 was labeled by

[2-^{14}C]malonate the δ_c 163.6 ppm resonance was assigned to this carbon atom. Such an assignment is consistent with chemical shift expectations (5) and also with the absence of ^{13}C–^{13}C satellites at this resonance in the spectrum of chartreusin labeled by [1,2-^{13}C]acetate. Since C-3 and C-4 were incorporated as an intact two-carbon unit, C-9 is necessarily a product of acetate C—C bond fission. The signal at δ_c 158.3 ppm was attributed to C-7′, which should have a chemical shift similar to that of C-9. Moreover, it was ^{13}C–^{13}C coupled ($^1J_{cc}$ 74.1 Hz) to an aromatic quaternary carbon atom with δ_c 116.7 ppm, which should be C-6′ as it was also ^{13}C–H coupled to an aromatic hydrogen (H-4′) and to the hydrogens of the methyl group bonded to C-5′. The signal at δ_c 138.4 ppm was assigned to C-1, the only remaining carbon atom bonded to oxygen but not ^{13}C–H coupled; its chemical shift value is primarily accounted for by the shielding effect of substituents at C-4 and C-8 (6, 7).

The ^{13}C nmr spectrum of chartreusin labeled from [1,2-^{13}C]acetate showed that C-1, like C-9, was one of the three carbons in the aglycone not derived from an intact ^{13}C—^{13}C unit. The third such carbon atom resonated at δ_c 145.8 ppm and was one of the two low-field carbon atoms (C-2′ and C-8) that appeared as a doublet in HR spectra. The signal was assigned to C-2′, because C-8, with C-8a, comprised a ^{13}C—^{13}C pair ($^1J_{cc}$ 68.4 Hz) incorporated intact from [1,2-^{13}C]acetate. C-8 was assigned the resonance at δ_c 154.0 ppm and C-8a the one at δ_c 117.8 ppm. Confirming these assignments, HR spectra showed that the latter signal was coupled to two aromatic hydrogens (H-5 and H-7) as expected for C-8a, whereas signals attributed to C-8 and C-2′ were each coupled to one hydrogen (H-6 and H-4′, respectively). The carbon atoms at C-2 and C-1′, each shielded by lactone oxygens on adjacent carbons, were expected to resonate at high field. Of the two unassigned signals given by chartreusin, that at δ_c 119.2 ppm was a doublet ($^3J_{CH}$ 2.5 Hz) in HR spectra. It was assigned to C-1′ because this carbon should be spin–spin coupled with H-3′, whereas the other resonance, at δ_c 108.1 ppm, was a singlet and was more appropriately assigned to C-2. In samples labeled from [1,2-^{13}C]acetate the signals were coupled ($^1J_{cc}$ 53.9 Hz), confirming that the two carbon atoms to which they were assigned were adjacent.

Labeling Pattern

Inspection of the ^{13}C nmr spectra of chartreusin enriched from [1-^{13}C] and [2-^{13}C]acetate in the light of ^{13}C resonance assignments established the origin of the aglycone carbons (Table 2). Enrichments were approximately 6 and 3%, respectively, and were thus large enough to show the labeling pattern unequivocally. The distribution of carbon atoms derived from the carboxyl and methyl groups of the precursor was identical with that proposed earlier by Schmid (1) and partially confirmed by Brown and colleagues (2). However, evidence from ^{13}C–^{13}C coupling between carbons of chartreusin enriched from [1,2-^{13}C]acetate (Table 1) revealed that only eight two-carbon precursor units had been incorporated intact into the antibiotic. This result, together with the information on origin and location of the remaining three carbon atoms of chartreusin aglycone that were not coupled, exclude all previous biogenetic schemes based on a 20-carbon polyketide chain intermediate.

A plausible alternative, consistent with all of the ^{13}C nmr evidence for the labeling pattern as well as the arrangement of bonded and single carbon units, is shown in Fig. 3. In this a polyketide chain (**1**) with 22 carbon atoms derived by head-to-tail condensation of acetate and malonate units is condensed to a polycyclic aromatic intermediate (**2**) of the benzpyrene type. Oxidative cleavage of two rings, with elimination of three carbon atoms by decarboxylation, would generate the phenylnaphthalene dicarboxylic acid derivative (**3**). Rotation of the phenyl ring would orient the substituents to facilitate formation of the dilactone (**4**) with the labeling pattern observed in chartreusin aglycone. Attachment of sugars at the C-8 hydroxyl could take place at any stage after formation of the polyketide, but by analogy with the sequence of biosynthetic steps shown for other glycosidic antibiotics of *Streptomyces* species (8–10), it is probably a terminal step.

If chartreusin is derived from a single-chain 22-carbon polyketide as suggested, it is the first example of a metabolite in this biogenetic subgroup (11). Hitherto, the 24-carbon metabolite, siphulin (12), was the only compound of apparent polyketide derivation formed by participation of more than ten acetate units. Although the measurement of ^{13}C enrichment is subject to appreciable error the results obtained suggest that each precursor enriched uniformly those

chartreusin aglycone carbon atoms that it labeled. This is consistent with biosynthesis via a single-polyketide-chain intermediate, but it should be noted that the experimental conditions were not designed to test multichain alternatives. Precursors were added intermittently during growth of the cultures to produce a sustained isotopic enrichment of the acetate pool, the objective being to obtain maximum ^{13}C incorporation. To examine the possibility that chartreusin aglycone is formed from more than one polyketide chain a single-pulse addition of precursor would have been more informative, since it might have made it possible, from differences in enrichment at different positions in the molecule, to distinguish between chain-initiating units derived directly from acetate and chain-extending units derived via malonate. The limiting factor in such experiments is likely to be the accuracy with which small differences in enrichment can be detected and our results indicate that the use of doubly labeled acetate would be advantageous.

If chartreusin aglycone is derived from a single-chain-polyketide intermediate we see no reasonable alternative to the folding pattern and processing steps proposed in Fig. 3. In speculating about a multichain origin one might include a variation of this pathway in which the initial polyketide folding pattern is retained but the single-chain intermediate (**1**) is replaced by two or more shorter chains, assembled and condensed head-to-tail to form the same polycyclic aromatic intermediate (**2**). Clearly a large number of such short-chain variations can be entertained. Other routes, beginning with the condensation of two or more polyketide chains folded in different patterns, are conceivable. Since the presence in chartreusin aglycone of acetate-derived carbon atoms which are no longer part of bonded two-carbon units implies that processing reactions occur after the initial polyketide condensation, and since the nature of these reactions are not known at present, it is possible to construct and modify polyketide precursors with a variety of chain lengths and

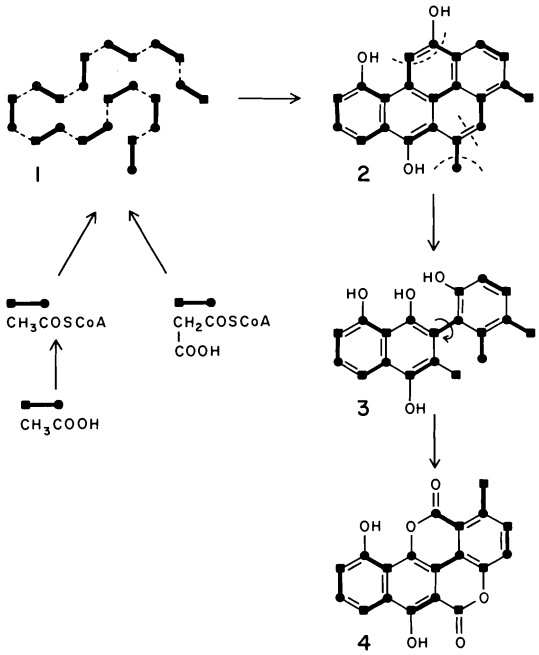

FIG. 3. Suggested biogenesis of chartreusin aglycone.

folding patterns to fit the labelling results. However, none of these alternatives appear to be more plausible than the route we have proposed.

Experimental

Labeled Compounds

Sodium [1-^{13}C]acetate, [2-^{13}C]acetate, and [1,2-^{13}C]acetate, all 90% enriched, were obtained from Merck, Sharp and Dohme, Pointe Claire, Quebec. An authentic sample of chartreusin was obtained from Dr. G. Whitfeld, the Upjohn Co., Kalamazoo, Mich.

Production, Extraction, and Purification of Chartreusin

In early experiments a sporulated slant of *S. chartreusis* X-465-4222 from Hoffmann-LaRoche, Nutley, NJ, maintained on a medium of Heinz Tomato Paste (2%), Heinz Baby Oatmeal (2%), and agar (1.5%), was used to seed 50-ml portions of a medium containing glucose (6%), soybean meal (2%), dipotassium hydrogen phosphate (0.1%), calcium carbonate (0.3%), zinc sulphate heptahydrate (0.001%), cupric sulphate pentahydrate (0.0002%), manganese sulphate tetrahydrate (0.0002%), and ferrous sulphate heptahydrate (0.001%) in 250-ml Erlenmeyer flasks. For later experiments it was necessary to plate spores of strain X-465-4222 and select a chartreusin-producing variant from the population. The variant was propagated on tomato paste – oatmeal agar and a spore suspension, subdivided into ampoules, was lyophilized and stored at −20°C. One of the lyophilized spore preparations was used to seed the liquid medium. Cultures seeded by either method were incubated in the dark for 2 days at 26°C on a shaker platform rotating at 220 rpm with an eccentricity of 3.8 cm, and used in 2-ml portions as a vegetative inoculum for chartreusin production medium. Cultures for producing chartreusin were grown under the same conditions as the vegetative inoculum.

In separate experiments, sterile solutions containing 10 mmol of sodium [1-^{13}C]acetate, sodium [2-^{13}C]acetate or sodium [1,2-^{13}C]acetate were added in aliquots to each of 20 flask cultures. The supplement was given in two portions, one on the fourth and one on the fifth day after inoculation. Cultures were harvested on the sixth day and extracted using the following adaption of previously described methods (4, 13). The broth was acidified to p*H* 5.5, centrifuged, and finally filtered through Whatman No. 5 paper to remove fine particles. Culture solids removed in this process were heated to boiling successively with three 100-ml portions of 80% aqueous acetone. The filtered extracts were combined with the culture filtrate and the mixture was extracted with an equal volume of acetone – methylene chloride (1:1) to completion. The combined extracts, evaporated and dried *in vacuo*, were redissolved in chloroform and applied to a column (2.6 × 25 cm) of silicic acid. The column was washed with acetone–chloroform (1:9) and chartreusin was eluted with acetone–chloroform (2:3). It was crystallized from methylene chloride and ethanol in yields ranging from 53 to 199 mg per litre of culture; the identity and purity of the samples was established by thin-layer chromatography (silica gel treated with citric acid, irrigated with chloroform–methanol, 9:1), ultraviolet absorption spectroscopy, and the absence of extraneous peaks in its ^{13}C nmr spectrum. Samples were compared with a reference specimen of chartreusin.

Spectra of chartreusin (50 to 120 mg samples dissolved in dimethyl sulfoxide-d_6) were obtained with a Varian XL-100/15 Fourier transform spectrometer under the following conditions: frequency 25.16 MHz, acquisition time 0.8 or 1.6 s (data accuracy ±0.6 or ±0.3 Hz), spectral width 5120 Hz, flip angle 40°, internal ^{2}H lock to solvent, temperature *ca.* 30°C, internal reference to tetramethylsilane. Broadband (^{1}H)-decoupling was achieved by phase modulation of the decoupling field ($\gamma H_2/2\pi$ 3800 Hz) from 0° to 180° at 150 Hz (14). During the acquisition of high-resolution spectra the nuclear Overhauser enhancement was maintained by applying this field for *ca.* 1.7 s between acquisition periods. For homonuclear (^{13}C) decoupling, a 25.12 MHz signal from a General Radio model 1061 frequency synthesizer was fed continuously via a tuned RF amplifier and BNC T connector to the transmitter coil of the probe. The higher frequency sideband of this signal, generated by the 40.96 KHz modulation field, was used to irradiate the resonance to be decoupled, the effective $\gamma H_2/2\pi$ being *ca.* 40 to 70 Hz. Coupled ^{13}C–^{13}C pairs of resonances were located from either direct irradiation of resonances or from the residual couplings caused by off-resonance decoupling effects.

The distribution of isotopic label in chartreusin from cultures supplemented with [1-^{13}C] or [2-^{13}C]acetate was determined by comparing ^{13}C nmr spectra of the enriched and natural abundance compounds recorded under identical experimental conditions. The ratio, *R*, of the intensity of each resonance to that of a reference peak known not to be enhanced was calculated for each spectrum. Spectra were compared via the ratio, *r*, for each peak, where $r = R$ (labeled compound)/R (natural

abundance compound). Thus $r \gg 1.0$ for peaks corresponding to enriched carbons; otherwise $r \simeq 1.0$. The percentage ^{13}C at each site was obtained by multiplying r for that carbon by the factor required to scale the average r for unenriched carbons to 1.108%. This procedure clearly distinguished enhanced peaks at the levels of enrichment encountered, and should detect enrichments $\geq 0.4\%$ above natural abundance. Errors stem mainly from the variation in r for unenhanced peaks, which places a limit on the accuracy of 'scaling' to natural abundance ^{13}C concentration. The measuring errors shown in the footnote to Table 2 are related to the standard deviation Δr in r for unenhanced peaks: error = $\Delta r/r \times$ average enrichment. In both cases the standard deviation (SD) of the enrichments is very similar to this error, showing that the relative variation in resonance intensity, due to factors other than enrichment, is almost the same for unenriched and enriched carbons. The method is independent of the choice of a reference peak for calculating R: if a peak enhanced by enrichment were chosen $r \ll 1$ for those peaks not enhanced. The percentage enrichment at labeled positions in chartreusin produced from doubly labeled acetate was calculated from the equation $1.1I_s/(I_c - fI_s)$, where I_s is the sum of the intensities of the two satellite resonances, I_c the intensity of the central peak, and f is the ratio of the concentrations of appropriate singly and doubly labeled precursors present in the doubly enriched acetate (15).

Fluorinated alkoxides. Part X. Template syntheses leading to fluorinated β-imino-alkoxy complexes of four- and five-coordinate nickel(II) and copper(II)

JOHN W. L. MARTIN AND CHRISTOPHER J. WILLIS

Chemistry Department, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 6, 1977

JOHN W. L. MARTIN and CHRISTOPHER J. WILLIS. Can. J. Chem. **55**, 2459 (1977).

Hexafluorodiacetonealcohol, HFDA, $HOC(CF_3)_2CH_2COCH_3$, is sufficiently acidic to coordinate to metal ions in an ionized form as a chelating, uninegative ligand. Complexes of Ni^{2+} and Cu^{2+} may be isolated, most conveniently by using a tridentate nitrogen-containing macrocycle as co-ligand so that five-coordinate unipositive compounds are produced.

In the presence of metal ions, HFDA readily undergoes template condensation reactions with diamino-ethane or -propane to give complexes of ionized β-imino alcohols, *e.g.* $^-OC(CF_3)_2$-$CH_2C(CH_3):N(CH_2)_2N:C(CH_3)CH_2C(CF_3)_2O^-$; these complexes are neutral and square planar but become five-coordinate by solvation in, *e.g.*, pyridine. The use of triamines H_2N-$(CH_2)_nNH(CH_2)_nNH_2$ (where $n = 2$ or 3) in template syntheses with HFDA gives complexes in which the metal ion is five-coordinate; these do not undergo solvation.

JOHN W. L. MARTIN et CHRISTOPHER J. WILLIS. Can. J. Chem. **55**, 2459 (1977).

L'hexafluorodiacétonealcool, HFDA, $HOC(CF_3)_2CH_2COCH_3$, est suffisamment acide pour se coordonner avec des ions métalliques sous une forme ionisée agissant comme ligand chélatant mononégatif. On a pu isoler les complexes du Ni^{2+} et du Cu^{2+}, particulièrement en faisant appel à des macrocycles tridentates contenant de l'azote comme co-ligand; de cette façon des composés monopositifs pentacoordonnés ont pu être obtenus.

En présence d'ions métalliques, HFDA subit facilement des réactions modèles de condensation avec les diamino éthane ou propane pour donner des complexes de β iminoalcools ionisés comme par exemple $^-OC(CF_3)_2CH_2C(CH_3):N(CH_2)_2N:C(CH_3)CH_2C(CF_3)_2O^-$; ces complexes sont neutres et sont plan-carrés mais deviennent pentacoordonnés par solvatation par exemple avec de la pyridine. L'utilisation de triamines $NH_2(CH_2)_nNH(CH_2)_nNH_2$ (où $n = 2$ ou 3) dans des synthèses modèles avec HFDA conduit à des complexes dans lesquels l'ion métallique est pentacoordonné; ceux-ci ne subissent pas de solvatation.

[Traduit par le journal]

Previous studies have shown that stable complexes of a variety of elements are given by highly fluorinated di-tertiary alcohols and related molecules, in which the enhanced acidity of the $-C(CF_3)_2OH$ group leads to coordination in the ionized form. The doubly ionized perfluoropinacolato ion, $^-OC(CF_3)_2C(CF_3)_2O^-$ (PFP^{2-}), has proved the most generally useful ligand, giving a variety of stable complexes with both main-group (1) and transition elements (2–4). Although anionic complexes such as $Ni(PFP)_2^{2-}$ are readily prepared, the more stable complexes are neutral compounds formed by the incorporation of one PFP^{2-} and neutral ligands containing nitrogen or phosphorus donor atoms, *e.g.* $L_2Ni(PFP)$. A further point of interest in the last type of complex is that, with a suitable choice of the ligand L, an additional ligand will coordinate in solution to give five-coordinate nickel species (4).

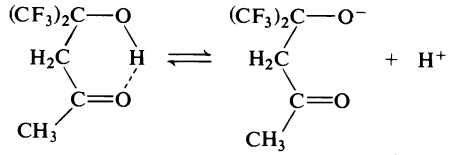
In the present study, we present several further instances of complexes in which an initially

square-planar, four-coordinate, nickel(II) ion, surrounded by two nitrogen and two oxygen donors, becomes five-coordinate by solvation. However, instead of mixing PFP^{2-} and nitrogen donor ligands to achieve the necessary environment, we have incorporated both the fluorinated tertiary alcohol grouping, $—C(CF_3)_2OH$, and the nitrogen donor sites into a number of polydentate ligands by template synthesis routes.

Results and Discussion

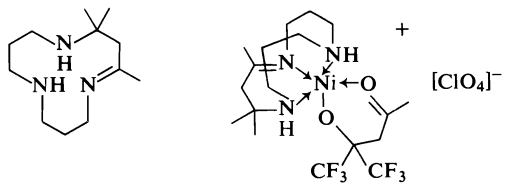
Preparation of Ligands and Complexes

The starting point for these syntheses was 5,5,5-trifluoro-4-trifluoromethyl-4-hydroxy-2-pentanone, more conveniently known as hexafluorodiacetonealcohol (HFDA), **1**, a known compound prepared by the reaction of hexafluoroacetone with acetone (5). The loss of a proton from this compound gives the anion (**2**) with the potential of acting as a bidentate, uninegative ligand:

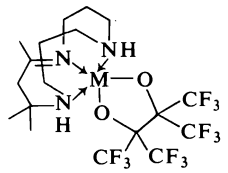


1 **2**

The carbonyl group is not a strong donor (in the absence of stabilization through delocalization of charge, as in acetylacetone complexes), and we have not yet been successful in preparing neutral complexes of the type $M^{2+}[CH_3COCH_2C(CF_3)_2O^-]_2$. However, through the use of the tridentate macrocycle **3** (abbreviated to [12]-ene-3) we have prepared the cationic, five-coordinate, nickel complex **4** and, for comparison in our assignment of this geometry to nickel, the neutral PFP^{2-} derivative **5***a*.



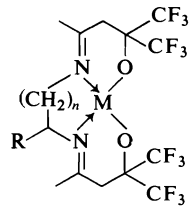
3 **4**



5*a*, M = Ni^{2+}
5*b*, M = Cu^{2+}

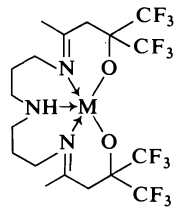
The greater utility of HFDA, however, was in the preparation of multidentate β-imino-alkoxy ligands, containing the $—C(CF_3)_2OH$ grouping, by its condensation with nitrogen bases in the presence of the metal ion. Template syntheses of this type are known to be successful in the case of the unfluorinated analogue, diacetonealcohol (6), but the ligands produced in that case coordinated by an un-ionized hydroxyl group because of the lower acidity found in the absence of fluorination. Our hope was that the fluorinated ligands would be dinegative through ionization and therefore more strongly coordinating ligands, and this proved to be the case.

In the presence of either Ni^{2+} or Cu^{2+}, HFDA underwent ready condensation with either 1,2- or 1,3-diamines, and neutral, square-planar complexes were formed of general structure:



6 *n* = 1, R = H, M = Cu^{2+}
7 *n* = 1, R = H, M = Ni^{2+}
8 *n* = 1, R = CH_3, M = Ni^{2+}
9 *n* = 2, R = H, M = Ni^{2+}

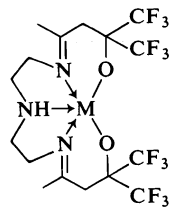
A similar condensation reaction using dipropylenetriamine, $NH_2(CH_2)_3NH(CH_2)_3NH_2$, led to the formation of neutral, five-coordinate complexes of structure:



10 M = Ni^{2+}
11 M = Cu^{2+}

Previous workers (6) had found that, when diacetonealcohol was condensed with this triamine in the presence of nickel ions, an octahedral, cationic, hydrated complex formed.

The analogous condensation reaction of HFDA with diethylenetriamine, $NH_2CH_2CH_2NHCH_2CH_2NH_2$, also led to the formation of neutral, five-coordinate complexes, the structure being:



12 M = Ni^{2+}
13 M = Cu^{2+}

The ready condensation of this triamine with HFDA differs markedly from its behaviour towards unfluorinated diacetonealcohol, where no condensation was observed under these conditions (6).

Attempts to form any of the fluorinated β-imino alcohols by condensation reactions in the absence of metal ions were not successful, illustrating again the power of the template technique. The readier reactions undergone by HFDA, as opposed to the unfluorinated analogue, are clearly due to its much greater tendency to coordinate to the metal ion (in the ionized, anionic, form) simultaneously with the amine. It would seem unlikely that the ease of condensation of the carbonyl group is materially influenced by the fluorination of the two methyl groups, which are remote from it in the molecule.

Solvation Effects and Five-coordinate Nickel

In the solid state and in methanol solution, the nickel complexes **7**–**9** were four-coordinate, square planar, and diamagnetic, but more strongly coordinating solvents caused an increase in coordination. Water and other oxygen-containing donors were without effect, but adduct formation occurred with pyridine and amines. For example, **7**, an orange solid, gave an orange solution in methanol but a yellow-green solution in pyridine associated with the appearance of a strong absorption at 26 000 cm^{-1}. Spectra of **7**, **8**, and **9** in methanol–pyridine mixtures showed two isosbestic points, indicating the presence of only two species. Pronounced thermochroic behaviour was also noted for these solutions, *e.g.*, a solution of **7** in methanol/pyridine which was yellow at 25°C became green at −20°C and orange at +35°C; the absorption at 21 000 cm^{-1} characteristic of the square-planar complex diminished in intensity on cooling.

These visible spectra indicated the presence of five-coordinate nickel in solution. The ratio of solvated to unsolvated species in the methanol/pyridine solutions was found, from optical densities, to be directly proportional to the concentration of pyridine, as would be expected for 1:1 adducts. Strong support for five-coordinate nickel here was given by comparison with the spectra of the model compounds **4** and **5**, which showed characteristic absorption at 27 200 and 26 200 cm^{-1} respectively and other similarities in the lower frequency regions of their spectra (Table 1). Similarly, these spectra may be compared with those reported previously (4) and other instances where five-coordination has been unambiguously established (7, 8).

In the case of the PFP^{2-} complexes, we ascribed the formation of five-coordinate solvates (rather than the more common six-coordinate adducts) to the steric hindrance offered at the sixth coordination by the combination of the bulky PFP^{2-} ligand and a bulky substituted diamine. In the present work, it would appear that the approach of the fifth ligand caused some distortion of the essentially planar β-imino-alcohol complex giving an essentially square pyramidal structure which was not further solvated.

Concentration of pyridine solutions of **7** and **8** precipitated green crystals, presumably of the pyridine adducts, but removal of solvent led to rapid reversion to the orange, unsolvated, complexes.

None of the chelated five-coordinate nickel complexes prepared in this study (that is, **4**, **5***a*, **10**, or **12**) showed any evidence of accepting an additional donor molecule in the sixth coordination site, their spectra being unchanged in pyridine solution.

This is in sharp contrast to the unfluorinated analogue of **10**, which, as mentioned above, is only known as an octahedral hydrate. Although steric hindrance offered by the trifluoromethyl groups may be a contributing factor here, a major reason for this difference probably lies in the charge on each species. Since the weakly acidic unfluorinated $—C(CH_3)_2OH$ ligand coordinates without ionization, the resulting ligand is neutral overall and the nickel complex carries a 2+ charge. The complex as a whole, and the metal ion in particular, would therefore be much more likely to attract a nucleophilic water molecule than would be the case in the neutral fluorinated complex.

Solvation of Copper Complexes

The blue copper complex **6** showed a single, broad, intense absorption band (ε = 170) in both

†m = methanol, py = pyridine, d = dichloromethane.

dichloromethane and methanol solution (Table 1). In pyridine, a small shift of the band maximum to lower energy was observed, along with a considerable reinforcement (shoulder) on the low-energy side. The latter features were present in the spectrum of the complex **11** (expected to be five-coordinate on the basis of its known stoichiometry and analogy with the nickel complex **10**) in both methanol and pyridine solution, so we suggest that the initially four-coordinate **6** becomes five-coordinate in pyridine solution in the same way as its nickel analogue. However, the possible coordination of an additional solvent molecule at the sixth position cannot be excluded.

The model copper compound ***5b*** provided confirmation of the above suggestion. Use of the tridentate macrocyclic ligand **3** is known to produce many five-coordinate complexes (6) and the PFP^{2-} derivative showed a visible spectrum very similar to those of known examples. The band appearing as a shoulder in the pyridine solvates above was resolved in ***5b***, appearing as a discrete peak at 10 200 cm^{-1}.

The diethylenetriamine condensation complex of copper, **13**, showed slightly different properties from the other complexes. It crystallized as a stable hydrate, whereas other copper complexes were normally anhydrous, and the anhydrous material showed a very broad, almost flat-topped, visible absorption band in both methanol and dichloromethane solution. Because of the extended nature of this peak, the apparent shift in the absorption maximum (Table 1) may be misleading, but the geometry around copper does appear to be rather different from the very similar complex **11**. Some degree of solvent interaction at the sixth coordination site in **13** is possible, although this would be expected to be minimal in dichloromethane solution. Alternatively, the change in spectrum could arise from a distortion in the geometry caused by the decrease in size of two of the chelate rings between **11** and **13**.

Infrared Spectra

Important infrared absorption bands are shown in Table 2. All complexes of HFDA contained additional strong, characteristic, absorption in the region 1150–1250 cm^{-1} associated with the trifluoromethyl groups.

The absorption associated with the imino link appeared in the region 1640–1680 cm^{-1}, and additional confirmation that condensation of the primary amine had occurred was found in the absence of bands characteristic of the $—NH_2$ group.

The coordinated carbonyl group present in **4** gave rise to an absorption at 1690 cm^{-1}, which, as would be expected, is lower than that found in

*Diamagnetic.

the free ligand **1** (1730 cm^{-1}) or the ion **2** (as the potassium salt, 1713 cm^{-1}).

Magnetic Data

As expected, the orange to red colored complexes **7**, **8**, and **9** were diamagnetic. The proposed five-coordinate nickel complexes had magnetic moments in the range 3.10–3.31 BM (Table 3), comparing well to the value for (DETA)Ni(PFP) (4), and in the range previously observed for five-coordinate nickel complexes (10). The copper complexes were paramagnetic as expected for one unpaired electron.

Conclusion

We conclude that the template condensation technique offers a valuable route to fluorinated complexes of a variety of metals because of the ready availability of a variety of carbonyl derivatives of the fluorinated alcohols. The production of metal complexes in which the steric requirements of the ligand are dominant leads to a well-defined geometry of coordination about the metal ion and, in particular, adds to recent accumulating evidence that five-coordination is by no means uncommon.

Experimental

General

Volatile compounds were handled in a conventional vacuum system. Infrared spectra were recorded on a Perkin-Elmer 621 instrument and visible spectra on Cary 14 and Cary 118 spectrometers. Microanalyses (Table 3) were performed by Alfred Bernhardt Laboratories, West Germany.

Hexafluorodiacetonealcohol (HFDA)

The preparation varied from that published (5) in that 20 g of hexafluoroacetone and 20 ml of dry acetone were allowed to react for 4 days in a sealed tube (100 ml) at 135°C. The distilled product had bp 150–153°C (lit. bp 150–151°C).

Nickel Complexes

The same general procedure was used for the five β-imino fluorinated alkoxy complexes prepared. In a typical preparation, nickel(II) chloride hexahydrate (2.37 g, 10 mmol) in warm ethanol was added to ethylenediamine (1.22 g, 20 mmol) in ethanol, followed by an ethanolic solution containing hexafluorodiacetonealcohol (4.48 g, 20 mmol) and potassium hydroxide (1.12 g, 20 mmol). The solution was cooled to 0°C and filtered to remove potassium chloride, refluxed for 4 h, then left at 25°C for 16 h. The resulting orange-red solution was filtered and concentrated to yield the solid product **7**; orange-red crystals from methanol.

The same method, using the appropriate amine, gave **8**, using 1,2-diaminopropane; orange needles from ethanol; **9**, using 1,3-diaminopropane; red needles from ethanol; **10**, using dipropylenetriamine; blue-green needles from ethanol.

Some **8** was produced by reaction of 1,2-diaminopropane present as impurity in the triamine; it was readily removed through its lower solubility. **12**, using diethylenetriamine; green crystals from 2-propanol/ether.

Copper Complexes

The same general route was used as described above for nickel, except that the ratio of metal chloride to amine was 1:1 rather than 1:2. Thus prepared were: **6**, using ethylenediamine; blue needles from ethanol; **11**, using dipropylenetriamine; blue plates from methanol; **13**, using diethylenetriamine; blue crystals of the hydrate from ethanol. Dehydrated by heating *in vacuo* 80°C/4 h.

Macrocyclic Ligand Complexes

The starting material for complexes incorporating the tridentate macrocycle **3** (abbreviated to [12]-ene-3) was the cationic hydroxo-complex $[M_2([12]\text{-ene-}3)_2(OH)_2](ClO_4)_2$ where $M = Cu^{2+}$ or Ni^{2+}. This was prepared as described previously (11); it should be noted that the postulated structure shown in that report has since been revised and bridging hydroxide ions and two 12-membered macrocyclic rings in a binuclear complex cation are now known to be present (6, 9).

The PFP^{2-} complexes, M([12]-ene-3)PFP, were prepared by the addition of perfluoropinacol, prepared as described previously (4), in methanol, to the appropriate hydroxo-complex in methanol, using a molar ratio of 2.02:1. Concentration of the solution yielded the products, which were recrystallized from ethanol to give the green nickel complex (**5***a*) and the blue copper complex (**5***b*).

The HFDA complex of nickel, **4**, was prepared by the same route, using HFDA in place of H_2PFP; green plates from ethanol.

Fluorinated alkoxides. Part XI. Studies on highly fluorinated amino-alcohols and their metal derivatives[1]

IN-SOON CHANG AND CHRISTOPHER J. WILLIS

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 20, 1977

IN-SOON CHANG and CHRISTOPHER J. WILLIS. Can. J. Chem. **55**, 2465 (1977).

We describe the synthesis of a number of difunctional molecules in which the fluorinated tertiary alcohol grouping, $-C(CF_3)_2OH$, is combined with a nitrogen donor site such as an amino-group or a pyridine ring. In all cases, zwitterionic behaviour in solution is found resulting from intramolecular proton transfer from the acidic fluorinated alcohol to the nitrogen, and this sometimes persists in the solid state, *e.g.* $NH_2CH_2CH_2C(CF_3)_2OH$ exists as the dipolar ion $^+NH_3CH_2CH_2C(CF_3)_2O^-$. Measurements of p$K$ values suggest that the behaviour of the fluorinated amino-alcohols may be compared with that of the amino-acids, subject to changes to be expected from the lower acidity of the $-C(CF_3)_2OH$ group.

Metal complexes of the fluorinated amino-alcohols form readily; specifically, neutral complexes of Co^{2+}, Ni^{2+}, and Cu^{2+} of formula $M(L)_2$, where L is an ionized amino-alcohol chelating through the ionized hydroxy group and the nitrogen atom. Measurements of formation constants show that the six-membered chelate rings are the most stable, while a comparison of the stabilities of fluorinated amino-alkoxy complexes with those of analogous amino-acids shows that the former are less stable: this is attributed to the steric influence of the trifluoromethyl groups.

IN-SOON CHANG et CHRISTOPHER J. WILLIS. Can. J. Chem. **55**, 2465 (1977).

On décrit la synthèse d'un certain nombre de molécules difonctionnelles dans lesquelles le groupe alcool tertiaire fluoré $-C(CF_3)_2OH$ est combiné avec un azote agissant comme site donneur tel qu'un groupe aminé ou un cycle pyridine. Dans tous les cas, on trouve que le comportement zwitterionique en solution résulte d'un transfert de proton intramoléculaire provenant de l'alcool fluoré acide vers l'azote et que quelquefois ce transfert persiste à l'état solide; par exemple $NH_2CH_2CH_2C(CF_3)_2OH$ existe sous forme d'ion dipolaire $^+NH_3CH_2$-$CH_2C(CF_3)_2O^-$. Des mesures de valeur de pK suggèrent que le comportement des alcools aminés fluorés peuvent être comparé avec celui des acides aminés si l'on tient compte des changements auxquels on doit s'attendre à cause de l'acidité plus faible du groupe $-C(CF_3)_2OH$.

Les complexes des alcools aminés fluorés se forment rapidement; d'une façon spécifique, il y a formation des complexes neutres du Co^{2+}, Ni^{2+} et Cu^{2+} de formule $M(L)_2$ où L est un amino alcool ionisé chélatant par l'intermédiaire du groupe hydroxy ionisé et de l'atome d'azote. Des mesures sur les constantes de formation indiquent que les cycles chélatés à six chaînons sont les plus stables alors qu'une comparaison des stabilités des complexes amino alcool fluorés avec ceux des acides aminés analogues montrent que les premiers sont beaucoup moins stables; on attribue ce résultat à une influence stérique des groupes trifluorométhyles.

[Traduit par le journal]

We have previously shown (1) that metal complexes of highly fluorinated alkoxy ligands in which there is a second donor site (specifically, an imino nitrogen) in the molecule may be conveniently prepared by template synthesis routes. Although a powerful synthetic method, this approach has the disadvantage that the ligand molecule itself is not prepared and studied in the absence of the metal ion.

In the present work, we report the preparation of a number of molecules which contain the fluorinated tertiary alcohol grouping $-C(CF_3)_2$-OH in conjunction with a second potential donor site in the form of a primary amine, secondary amine, or pyridine group. These have been successfully used as ligands towards transition metal ions, chelation occurring by attachment of the amino-group and the ionized alkoxy group, $-C(CF_3)_2O^-$. The size of the chelate ring depends on the separation of these two sites in the ligand molecule, and we have prepared complexes having either five- or six-membered rings.

[1]Presented in part at the 8th International Symposium on Fluorine Chemistry, Kyoto, Japan, August 1976.

Results and Discussion

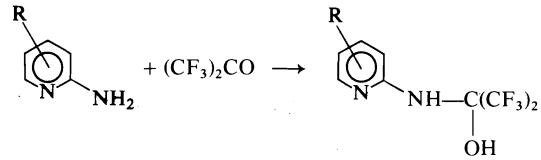
Preparation of Ligand Molecules

The easiest general route to the preparation of compounds containing the grouping $-C(CF_3)_2$-

OH is through the addition of hexafluoroacetone to an active hydrogen site (2).

$$R—H + (CF_3)_2CO \rightarrow RC(CF_3)_2OH$$

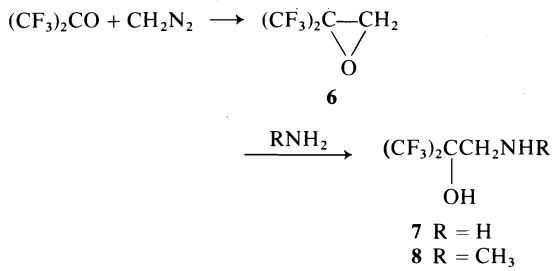
The addition across O—H or N—H is frequently reversible, while that across C—H is generally irreversible. In view of the excellent ligand properties of the pyridine ring system, we began this study by reacting hexafluoroacetone with 2-aminopyridine and with methyl-substituted 2-aminopyridines. Ready addition to give a stable product occurred in each case.



1 R = H
2 R = 3-methyl
3 R = 4-methyl
4 R = 5-methyl
5 R = 6-methyl

Ligands containing primary or secondary amino groups were prepared by two general methods, ring-opening reactions of fluoroepoxides with ammonia or amines, or catalytic reduction of fluorinated tertiary nitriles.

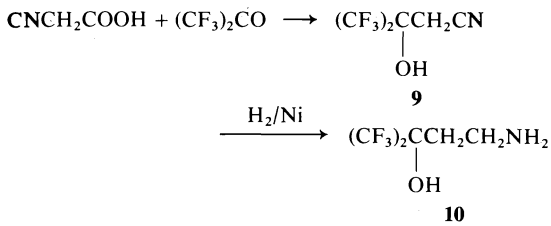
The addition of diazomethane to hexafluoroacetone gives the fluorinated epoxide **6** (3) and the ring may be broken across the $—CH_2—O—$ bond by ammonia or primary amines to yield fluorinated amino-alcohols



7 R = H
8 R = CH_3

This direction of ring opening is that which would be expected if reaction occurred by nucleophilic attack of the amine on the methylene group which, by attachment to the oxygen atom and the fluorocarbon residue, should be the most electrophilic point in the ring. To confirm this, we reacted the epoxide **6** with methylmagnesium iodide, when the product formed was $(CF_3)_2C(OH)C_2H_5$ by nucleophilic attack on the ring by the methyl group. A similar result has been reported with other partially fluorinated epoxides (4), although the reaction sequence is more complex when the ring is fully fluorinated (5).

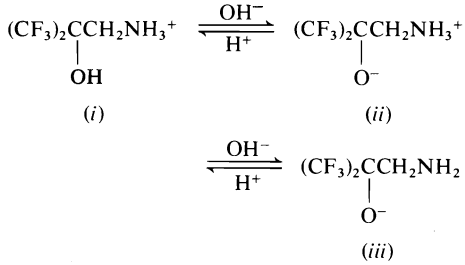
The C—H bond in cyanoacetic acid is known (6) to be sufficiently reactive that ready addition to hexafluoroacetone occurs, followed by decarboxylation to give the fluorinated cyanoalcohol **9**. We have catalytically hydrogenated this to the amino-alcohol **10**.



This reduction went readily in good yield, but the corresponding reduction of hexafluoroacetone cyanohydrin, $(CF_3)_2C(OH)CN$, giving the amino-alcohol **7**, required much more severe conditions and gave only poor yields.

Properties of the Ligands; Zwitterionic Behaviour

The four ligands studied in this work all have the potential for internal proton transfer to give zwitterions, in view of the acidity of the fluorinated tertiary alcohol group, and the fluorinated amino-alcohols may therefore be likened to amino-acids, *e.g.*



Titration of the compounds confirmed that this behaviour was occurring in solution in each case. Two pK_a values were determined, corresponding to the two steps in the above equilibrium, and these are recorded in Table 1, together with isoelectric point values; figures for glycine are added for comparative purposes. In comparing these figures with pK_a values for other fluorinated alcohols such as $(CF_3)_3COH$ (pK_a = 5.4 (7)) or $CH_3C(CF_3)_2OH$ (pK_a = 9.6 (8)) it should be remembered that, for the species studied in the present work, $pK_a(1)$ represents the ionization of the hydroxylic proton in the protonated species (*i*), whereas $pK_a(2)$ represents the ionization of the proton on the amine group in the

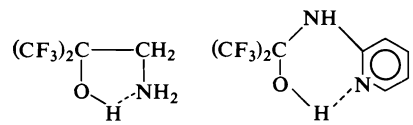
TABLE 1. pK_a and isoelectric point values for zwitterionic ligand molecules

Ligand	$pK_a(1)$	$pK_a(2)$	Isoelectric point
Glycine, NH_2CH_2COOH	2.34	9.60	5.97
1 	5.71	6.91	6.31
7 $(CF_3)_2CCH_2NH_2$ | OH	5.35	8.63	6.99
8 $(CF_3)_2CCH_2NHCH_3$ | OH	5.61	8.96	7.29
9 $(CF_3)_2CCH_2CH_2NH_2$ | OH	6.39	9.46	7.93

zwitterionic species (*ii*). This leads to an apparent enhancement of the acidity of the hydroxyl group in the fluorinated alcohol, just as the apparent acidity of the carboxylic acid in glycine is considerably greater than that of acetic acid ($pK_a = 4.74$).

The general features of this behaviour may be readily explained. All the fluorinated amino-alcohols have $pK_a(1)$ values 3–4 units greater than glycine, a difference similar to that found between fluorinated alcohols and carboxylic acids. The $pK_a(2)$ values of **7**, **8**, and **9**, which contain $—CH_2NH_2$ or $—CH_2NHR$, are similar to that of glycine, whereas that of the pyridine derivative **1** is notably less. This is consistent with the expected lower basicity of both the nitrogen atoms in **1**; that in the pyridine ring, and that in the side-chain, which is attached to the electronegative $—C(CF_3)_2O^-$ group.

In the solid state, infrared spectral studies showed a considerable difference between the compounds (Fig. 1). The γ-amino alcohol **10** showed neither O—H nor NH_2 absorptions, but very broad absorption in the region 2200–3000 cm^{-1} characteristic of $—NH_3^+$ and very similar to that of glycine. This alcohol would therefore appear to have the zwitterionic structure in the solid state and should be written $^-O—C(CF_3)_2-CH_2CH_2NH_3^+$. The β-amino alcohols, on the other hand, showed fairly sharp N—H absorptions at 3330 and 3400 cm^{-1} in $(CF_3)_2C(OH)-CH_2NH_2$ (**7**) and at 3380 cm^{-1} in $(CF_3)_2C(OH)-NH(C_5H_4N)$ (**1**), with much reduced absorption in the 2500–3000 cm^{-1} region. This suggests that the structures of these molecules in the solid state are not zwitterionic, but probably contain intramolecular hydrogen-bonding:



7 **1**

The marked difference between **7** and **9** in these solid-state structures is presumably associated with the different ring sizes required for internal hydrogen-bonding, the five-membered ring being more easily formed. However, this effect would not seem to operate in solution.

Metal Complexes of Amino-alcohols

In view of the resemblances between fluorinated amino-alcohols and amino-acids, noted above, we expected that chelation to metal ions as uninegative ligands would occur, and this proved to be correct. For each amino-alcohol ligand, neutral metal complexes of general formula $M(L)_2$ formed, where $M = Co^{2+}$, Ni^{2+}, or Cu^{2+}. In a square-planar environment, either a *cis*- or *trans*-configuration would be possible, as shown in Fig. 2.

The general environment of the metal in these complexes is very similar to that in complexes which we have previously studied (9) in which the

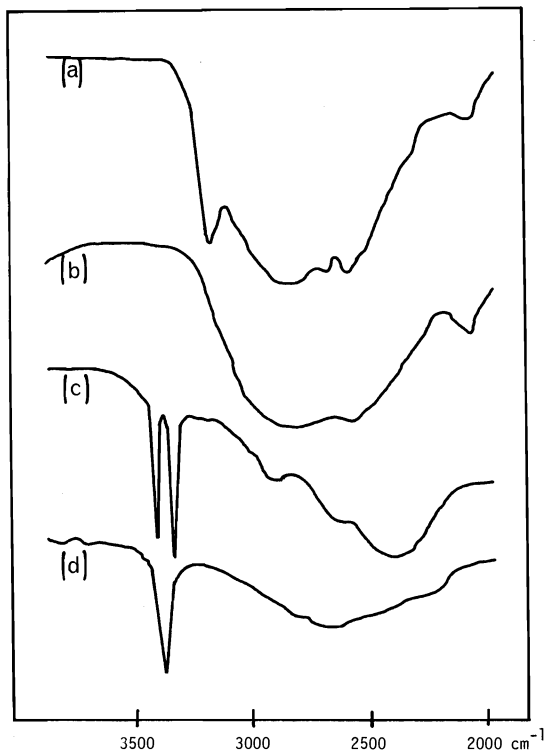


FIG. 1. The infrared spectra of some fluorinated amino-alcohols: (*a*) glycine, (*b*) ligand **9**, (*c*) ligand **7**, (*d*) ligand **1**.

ligands are a perfluoropinacolato dianion and a chelating diamine, so we would expect similar structures to prevail. This was the case, with the nickel complexes all being square-planar and diamagnetic.

With the substituted pyridine ligand **1**, the metal complexes both showed a strong sharp N—H absorption in the infrared spectrum at 3380 cm^{-1}, unchanged from its position in the free ligand. This shows that coordination is occurring from the nitrogen of the pyridine ring, rather than from the side-chain —NH— group; the latter would of course be most unlikely to form a chelate with oxygen, as a four-membered ring would be required. This result also shows that the —NH— nitrogen atom is not involved

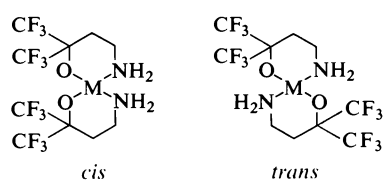

FIG. 2. *cis*- and *trans*-configuration of metal complexes of amino acids.

in zwitterion formation and supports the internally hydrogen-bonded model given above.

Present evidence does not allow us to distinguish between *cis*- and *trans*-configurations in these complexes. The local symmetry of the metal is C_{2v} for the *cis*- and C_{2h} for the *trans*-isomer, which should affect the infrared spectrum in the metal–oxygen and metal–nitrogen vibrational region (300–500 cm^{-1}) but the presence of other groups in the molecule complicates the spectrum and makes an unambiguous assignment impossible.

The magnetic moments and visible absorption spectra of most of the copper complexes were in the ranges previously found (9) for complexes of this type, to which we had assigned approximately square-planar geometry. However, the complex with ligand **5**, the derivative of 2-amino-6-methylpyridine, had a significantly higher magnetic moment of 2.12 BM, where the others were in the range 1.75–1.85 BM. The maximum in the visible absorption spectrum of this compound was also at slightly longer wavelength (626 nm against 550–610 nm) with a greater intensity ($\varepsilon = 142$ against $\varepsilon = 50$–70) than the other complexes. This behaviour is consistent with some degree of distortion from a square-planar arrangement being present in complexes of ligand **6**, associated with the steric hindrance offered by the methyl group in the 6-position on the pyridine ring.

Only restricted studies of cobalt(II) complexes of the fluorinated amino-alcohols were possible, since they had a very limited stability in solution. However, ligand **7** formed a cobalt complex, stable in the solid state, whose analysis corresponded to the dihydrate $Co[NH_2CH_2C(CF_3)_2O]_2(H_2O)_2$, which had a magnetic moment of 4.38 BM and a visible absorption spectrum with peaks at 480 and 570 nm (diffuse reflectance); properties consistent with octahedral cobalt(II). The water was easily removed *in vacuo*, but the properties of the compound were hardly changed at all. The magnetic moment was 4.36 BM, the visible absorption spectrum was almost identical, and the infrared spectrum was largely unchanged except for the loss of a sharp —OH absorption at 3860 cm^{-1}. It would appear, therefore, that the two water molecules are not coordinated to the cobalt ion but are simply present elsewhere in the lattice. The octahedral coordination of the cobalt is presumably achieved by extension of the coordination of the oxygen atoms

TABLE 2. Formation constants of metal complexes

Ligand	log K* Cu^{2+}	Ni^{2+}	Co^{2+}
1 	13.83	9.56	7.95
glycine, NH_2CH_2COOH (11, 12)	15.67	12.13	10.04
7 $(CF_3)_2CCH_2NH_2$ | OH	13.16	9.08	7.88
β-alanine, $NH_2CH_2CH_2COOH$ (13)	12.50	8.12	3.58†
9 $(CF_3)_2CCH_2CH_2NH_2$ | OH	10.09	8.11	4.21†

*$K = [M(L)_2]/[M^{2+}][L^-]^2$.
†K is for the formation of the 1:1 complex $M(L)^+$ only, due to the limited stability of the 1:2 amino-alcohol complex in solution.

in the ligand to form bridges between the cobalt ions and a polymeric structure, a tendency we have not previously observed with $-C(CF_3)_2O^-$ ligands, but the point cannot be definitely established without more detailed structural data.

The compound $(CH_3)_2NNHC(CF_3)_2OH$ was readily prepared by the addition of hexafluoroacetone to 1,1-dimethylhydrazine. Although this has the potential of acting as a chelating ligand, forming a five-membered ring similar to that in the amino-pyridine derivatives described above, we could find no indication of complex formation with metal ions. This is presumably due to steric hindrance from the relatively bulky dimethylamino group, whose coordination is less favourable than that of the pyridine ring.

Formation Constants

The isolation of a variety of metal complexes established that the fluorinated amino-alcohols were in all cases coordinating as the anionic form (*iii*). We were therefore able to determine overall formation constants for the reactions

$$M^{2+} + 2L^- \rightleftharpoons M(L)_2$$

for most of the amino-alcohols, by potentiometric titration in methanol/water mixtures (10). Solubility limitations prevented direct measurement in pure water, but values obtained in methanol/water were extrapolated to water in order to allow comparison with the known values of comparable constants for amino-acids; the results are summarized in Table 2.

In most cases where a direct comparison between similarly structured complexes is possible, that is, between **7** and glycine and between **9** and β-alanine, the amino-alcohol complex has the lower formation constant. This may be explained in terms of the greater steric crowding of the $-C(CF_3)_2O^-$ group, as compared with the carboxylate group. It is also clear by a comparison of **7** with **9** that the formation of complexes with 5-membered chelate rings is, as is usually found, more favourable that that of those with 6-membered rings. The pyridine derivative, **1**, gives the most stable complexes of any of the amino-alcohols studied, despite the formation of a 6-membered chelate ring; this may be ascribed to the greater donor strength of the pyridine nitrogen as compared with that of an amino-group.

Within a series of metal complexes of the same ligand, the stability in each case follows the usual Irving-Williams order $Cu^{2+} > Ni^{2+} > Co^{2+}$.

Solvate Formation

We have previously demonstrated (9) the existence of exclusively 5-coordinate solvate formation when complexes of nickel with PFP^{2-} and a bidentate diamine are dissolved in pyridine or a primary amine. In view of the similarity of the environment of the metal atom

in the compounds in the present study, particularly in respect of the steric hindrance presented by the four bulky trifluoromethyl groups, it is not surprising that these behave similarly. The nickel complexes, because of their characteristic visible spectra, show the effect best.

The nickel complex of the ligand **7**, initially square-planar and red, dissolved in pyridine to give a green solution from which a green solid solvate could be isolated. Analysis showed this to be a 1:2 adduct, $Ni[(C_5H_4N)NHC(CF_3)_2O]_2$-$(C_5H_5N)_2$, but it was clear from its visible spectrum that only one of the two solvent molecules had coordinated to the nickel. The strong sharp absorption near 380 nm with a weaker peak at 640 nm characteristic of 5-coordinate nickel(II) were present in both solid and solution spectra and a series of spectra run in methanol/pyridine mixtures gave two well-defined isosbestic points, similar to those found in our previous studies, confirming that only one solvate had formed. Furthermore, the spectrum of the solvate was virtually superimposable on that found for nickel(II) complexed by PFP^{2-} and the tridentate amine, diethylenetriamine (9). We conclude that the second pyridine molecule in the solid solvate is fortuitously included in the lattice without interacting with the metal ion.

With the other nickel(II) complexes of amino-alcohols, visible spectra in methanol/pyridine mixtures showed behaviour very similar to that noted above, showing that solvation to give 5-coordinate adducts was occurring, but no solid products could be isolated.

When the analogous copper complex of ligand **1**, in methanol, was treated with pyridine, it was clear that solvation was occurring, but no stable solid adduct could be isolated. The visible absorption maximum shifted from 550 to 600 nm with one isosbestic point, indicating that only one solvated species was present. That this was a 5-coordinate 1:1 adduct of the copper complex with pyridine may reasonably be suggested, by analogy with the nickel studies, but the visible spectra of copper in different environments are not sufficiently distinctive to allow a definite assignment to be made.

Conclusion

Our study of these difunctional molecules confirms that there is a valid analogy between the properties of a highly fluorinated tertiary

alcohol and a carboxylic acid. The acidity of the former is sufficient to undergo intramolecular proton transfer when a suitable basic site is present and to coordinate in an ionized form to a transition metal ion, giving isolable complexes. However, the greater bulk of the fluorinated alcohol results in steric hindrance around the metal, such that the coordination number of the metal appears to be limited to five.

Experimental

General

Volatile materials were handled by standard vacuum-line techniques. Infrared spectra were recorded on a Perkin-Elmer model 621 instrument and visible spectra on Cary model 14 and 118 spectrophotometers. A Corning model 12 p*H* meter was used for potentiometric titrations. Magnetic moments were determined by the Gouy method.

Microanalyses were performed by Alfred Bernhardt Laboratories, West Germany. All analytical data are given in Table 3.

Hexafluoroacetone (Matheson) was purified by trap-to-trap distillation. Other starting materials were reagent grade chemicals purified by standard methods.

*N-(2-Pyridyl)-2-aminohexafluoropropane-2-ol (**1**)*

2-Aminopyridine in dry benzene was maintained near 10°C while gaseous hexafluoroacetone was passed in through a bubbler below the surface with continuous stirring. Uptake was followed by weight gain to an equimolar ratio. The product crystallized on partial removal of solvent and was recrystallized from benzene. The yield was essentially quantitative; mp 122–124°C.

Use of the various methyl-substituted amino-pyridines in the same method gave the methyl-substituted products.

The copper complex was prepared by treating a methanolic solution of the ligand (30 mmol) and copper sulfate (10 mmol) with methanolic potassium hydroxide to p*H* 9. The solution was evaporated to dryness and extracted with tetrahydrofuran to remove potassium sulfate, then concentrated, and 30–60°C petroleum ether added to the cloud point. Crystals of the desired complex separated on cooling.

With nickel and cobalt, the method was very similar, with the metal nitrates used as a source of metal ions. The cobalt reaction was carried out using degassed solvents under a nitrogen atmosphere.

1,1,1-Trifluoro-2-trifluoromethyl-3-aminopropane-2-ol (7)

(a) By Ring Opening of an Epoxide

The known epoxide $(CF_3)_2\overline{CCH_2O}$ was made by the reaction of diazomethane with hexafluoroacetone as described previously (3), employing precautions usual to the handling of diazomethane. In a typical reaction, diazomethane was prepared from nitrosomethylurea (14) and distilled in ether into a cooled receiver containing ether over potassium hydroxide pellets. Based on the expected 65–70% yield, about 5.6 g (0.13 mol) diazomethane was present and hexafluoroacetone (33 g, 0.20 mol) was slowly passed in while maintaining the temperature at −10°C. Without separation of the epoxide, which has bp 39°C, the flask was fitted with a condenser at −78°C and excess gaseous ammonia bubbled through while the contents were slowly allowed to warm to reflux temperature. The final solution was filtered and evaporated and the solid product recrystallized from ether/hexane, mp 76–77°C.

(b) By Catalytic Hydrogenation

Hexafluoroacetone cyanohydrin (15) proved difficult to hydrogenate over Raney nickel, but pressures of 500 psi gave a satisfactory yield (75%) of product identical with that obtained by the ring-opening route.

Metal complexes were prepared by the method described above for ligand **1**. The nickel complex had very low solubility in all solvents tried, and was recrystallized from very dilute ether/hexane solution.

*1,1,1-Trifluoro-2-trifluoromethyl-3-(methylamino)-propane-2-ol (**8**)*

The ring-opening reaction on the epoxide, described above, was repeated with the substitution of methylamine for ammonia. Removal of solvent gave a white solid from which the product was isolated by recrystallization from ether/hexane, mp 73°C.

An alternative route to this compound is available through the reduction of the known dioxolane $(CF_3)_2\overline{COC(CF_3)_2OCNCH_3}$, made by the addition of hexafluoroacetone to methyl isocyanide (16). When 20 g of this compound was heated under reflux with lithium tetrahydridoaluminate (5 g) for 24 h, the mixture cooled and decomposed with water and aqueous alkali, the lithium salt of the *N*-methylamino alcohol was obtained in poor yield on evaporation. Previous workers reported that a similar reduction and workup procedure on the *N*-ethyl analogue gave the *N*-ethylamino alcohol, rather than its salt.

The copper complex of **8** was prepared by the same method used for **7**.

*1,1,1-Trifluoro-2-trifluoromethyl-4-aminobutane-2-ol (**9**)*

The hydroxy-nitrile $(CF_3)_2C(OH)CH_2CN$ was prepared by the addition of hexafluoroacetone to cyanoacetic acid (6). In the hydrogenation, 48 g (0.23 mol) of the purified hydroxy-nitrile was dissolved in anhydrous ether (250 ml) with 28 g of anhydrous sodium acetate and 10 g of Raney nickel, pre-treated with acetic anhydride. After shaking under an initial hydrogen pressure of 50 psi for 18 h, the mixture was filtered, the solvent removed, and the product recrystallized from ether/hexane, mp 82–83°C. The yield was essentially quantitative.

Complexes of cobalt, nickel, and copper were prepared by the same method described above for ligand **1**.

Fluorosulfates of palladium

K. C. LEE AND F. AUBKE[1]

Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received February 1, 1977

K. C. LEE and F. AUBKE. Can. J. Chem. **55**, 2473 (1977).

The syntheses of $Pd(SO_3F)_2$ and $Pd(SO_3F)_3$ by the reactions of palladium with $BrOSO_2F$ and $S_2O_6F_2$ are described. Structural information on both compounds is based on infrared, Raman, diffuse reflectance, and electronic mull spectra as well as magnetic measurements from $\sim$300 to $\sim$100 K. Palladium bisfluorosulfate is found to have a polymeric structure with the fluorosulfate group acting as a tridentate ligand. As a consequence, an octahedral environment is found for Pd^{2+} with a $^3A_{2g}$ ground state, a μ_{eff}^{298} value of 3.39 BM and the ligand field parameter $Dq = 1177\ cm^{-1}$ and $B = 633\ cm^{-1}$. $Pd(SO_3F)_3$ is best regarded as $Pd^{II}[Pd^{IV}(SO_3F)_6]$.

K. C. LEE et F. AUBKE. Can. J. Chem. **55**, 2473 (1977).

On décrit la synthèse du $Pd(SO_3F)_2$ et du $Pd(SO_3F)_3$ par les réactions du palladium avec $BrOSO_2F$ et $S_2O_6F_2$. Les informations concernant la structure des deux composés sont basées sur les spectres infrarouges, Raman, de réflexions diffuses et électroniques de même que des mesures magnétiques de $\sim$300 à $\sim$100 K. On a trouvé que le bis(fluorosulfate) de palladium existe sous forme de polymère dans lequel un groupe fluorosulfate agit comme ligand tridentate. En conséquence on trouve un environnement octaédrique pour Pd^{2+} avec un état fondamental $^3A_{2g}$, une valeur de μ_{eff}^{298} de 3.39 BM et un paramètre de champ de ligand $Dq = 1177\ cm^{-1}$ et $B = 633\ cm^{-1}$. La meilleure façon de considérer $Pd(SO_3F)_3$ est $Pd^{II}[Pd^{IV}(SO_3F)_6]$.

[Traduit par le journal]

Introduction

Divalent palladium has a d^8 electronic configuration and is, much like divalent platinum, found in diamagnetic square planar, low spin complexes (1). The only notable exception is palladium difluoride (2) and some of its derivatives like $CsPdF_3$ (3) or $Pd^{II}[M^{IV}F_6]$ (4), with M = Ge, Sn, or Pd. The difluoride is found to have a rutile structure (5), and an octahedral environment is indicated for palladium also by the observed paramagnetism of the complex fluorides.

This study describes the syntheses of two new, strongly paramagnetic fluorosulfates of palladium, $Pd(SO_3F)_2$ and $Pd(SO_3F)_3$, and their structural characterisations by magnetic measurements, vibrational and electronic spectra.

Experimental

Chemicals

Peroxydisulfuryl difluoride, $S_2O_6F_2$ (6), and bromine(I)-fluorosulfate, $BrOSO_2F$ (7), were synthesised according to literature reports. Palladium powder of 60 mesh and of 99.95% purity was supplied by the Ventron Corp. Perfluoro-octyl sulfurylfluoride, $C_8F_{17}SO_2F$, was obtained as a gift from Dr. H. Niederpruem, Farbenfabriken Bayer, Leverkusen, W. Germany.

Instrumentation

Raman spectra were obtained with either a Cary 81 or a Spex Ramalog 5 spectrophotometer fitted with a He–Ne (635.5 nm) and an argon ion (514.5 nm) laser respectively. Solid samples were contained in Pyrex tubes. Infrared spectra were recorded on a Perkin-Elmer 457 spectrophotometer. Silver chloride or bromide was used as window material. Due to the reactivities of the palladium fluorosulfates, mulling agents such as Nujol and HCB could not be used and spectra were recorded on thin films of the solids. Electronic spectra were obtained on powdered samples using a Bausch and Lomb Spectronic 600 spectrophotometer (diffuse reflectance) and on samples mulled in $C_8F_{17}SO_2F$ (perfluoro-octyl sulfurylfluoride) using a Cary 14 spectrophotometer. Magnetic susceptibilities were measured using the Gouy apparatus described earlier (8). The coil current of the magnet was regulated to give a field of approximately 4500 G. The temperature of the sample was controlled by the rate of evaporation of N_2 around the chamber. Calibration was achieved using $HgCo(SCN)_4$ (9). Diamagnetic corrections of 25×10^{-6} for Pd^{2+}, 22×10^{-6} for Pd^{3+}, 18×10^{-6} for Pd^{4+}, and 40×10^{-6} for SO_3F^- were made (1, 10). All values are in cgs units.

All reactions were performed in Pyrex reaction vials of about 40 ml contents, fitted with Kontes Teflon stem valves. Volatile materials were handled using vacuum line techniques. Solids were handled in a Vacuum Atmospheres Corp. "Dri Lab" Model No. HE-43-2, filled with purified dry nitrogen and equipped with a "Dri-Train" Model No. HE-93-B circulating unit.

Preparations of $Pd(SO_3F)_2$

Palladium metal (508 mg, 4.77 mmol) was allowed to react at 110°C (oil bath) for about 14 days with a large excess (about 12 to 15 g) of $BrOSO_2F$. The completion of the reaction was indicated by the consumption of all metal and the appearance of an insoluble purple solid.

[1]To whom correspondence should be addressed.

Removal of all volatile material yielded 1437 mg (4.72 mmol) of palladium bisfluorosulfate. $Pd(SO_3F)_2$ is a light purple, hygroscopic solid, thermally stable up to +250°C. Above this temperature thermal decomposition according to

$$Pd(SO_3F)_2 \rightarrow PdF_2 + 2SO_3$$

was observed.

Synthesis of $Pd(SO_3F)_3$

A large excess of peroxydisulfuryl difluoride, $S_2O_6F_2$ (about 10 to 15 g), was added to 398 mg (1.31 mmol) of $Pd(SO_3F)_2$. An immediate reaction was noted, evidenced by the gradual darkening of the solid reactant. The mixture was heated overnight at 80°C. After removal of all volatiles, 518 mg (1.28 mmol) of $Pd(SO_3F)_3$ were obtained. $Pd(SO_3F)_3$ is a dark brown, hygroscopic solid, thermally stable up to 180°C at atmospheric pressure.

Analysis

Chemical analyses were performed by A. Bernhardt, Elbach, West Germany. The results are listed in %.

	Pd		S		F	
Compound	Calcd.	Found	Calcd.	Found	Calcd.	Found

$Pd(SO_3F)_3$	26.36	26.54	23.83	23.68	14.12	14.01

Results and Discussion

Synthesis

The direct reaction of bromine-(I)-fluorosulfate with palladium powder according to:

$$[1]\quad Pd + 2BrOSO_2F \xrightarrow[14\ days]{+110°C} Pd(SO_3F)_2 + Br_2$$

was found to be a most convenient route to palladium(II) fluorosulfate. The formation reaction has two precedents: interaction of $BrOSO_2F$ with gold and platinum is reported to yield $Au(SO_3F)_3$ and $Pt(SO_3F)_4$ (11). However, there are some important differences. Palladium metal was far less reactive than either gold or platinum as indicated by the higher reaction temperature and the longer reaction time. The oxidation reaction proceeded exclusively to the +2 oxidation state and the resulting product was seemingly insoluble in excess $BrOSO_2F$ even at +110°C, whereas both $Au(SO_3F)_3$ and $Pt(SO_3F)_4$ dissolved readily in $BrOSO_2F$ and complete removal of the bromine-(I)-fluorosulfate required elevated temperatures. The purple $Pd(SO_3F)_2$ was also insoluble in HSO_3F and thermally stable up to 250°C. All these features are consistent with a polymeric structure for palladium bisfluorosulfate.

Oxidation to form palladium trisfluorosulfate was readily accomplished with peroxydisulfuryl difluoride. The resulting brown $Pd(SO_3F)_3$ decomposed quantitatively at +160°C *in vacuo* to yield $S_2O_6F_2$ and $Pd(SO_3F)_2$ in a reversal of the formation reaction:

$$[2]\quad 2Pd(SO_3F)_2 + S_2O_6F_2 \underset{+160°C}{\overset{+80°C/12\ h}{\rightleftharpoons}} 2Pd(SO_3F)_3$$

The formation of $S_2O_6F_2$ by pyrolysis of a metal fluorosulfate was unprecedented, but xenon bisfluorosulfate and the fluoride-fluorosulfates of $FXeSO_3F$ and F_5XeSO_3F have been reported to yield peroxydisulfuryl difluoride (12–14).

The direct reaction of $S_2O_6F_2$ with palladium powder proceeded extremely slowly, yielding only incompletely oxidised brown products. The successive oxidation by $BrOSO_2F$ and $S_2O_6F_2$ appeared to be a better route to $Pd(SO_3F)_3$.

The existence of $Pd(SO_3F)_3$ as a stable species with the metal in the +3 oxidation state would be rather surprising. Whereas both $Pd^{II}(d^8)$ and $Pd^{IV}(d^6)$ are rather common oxidation states for palladium, no evidence for $Pd^{III}(d^7)$ in stable binary compounds has been reported and PdF_3 is better regarded as $Pd^{II}[Pd^{IV}F_6]$ (4). A similar formulation may very well apply to the palladium trisfluorosulfate and both vibrational spectra and magnetic measurements should provide some structural insights.

Vibrational Spectra

The infrared and Raman data in cm^{-1} for $Pd(SO_3F)_2$ are found as follows, with Raman data in parentheses: 1240 s, b (1231 m); 1090 ms (1111 ms); 860 s (869 m); 610 s (612 w); 565 m (552 w, sh) and 421 m (430 m, 354 vw). The relatively simple spectrum with only six ir and Raman active vibrational modes indicates that the fluorosulfate group has C_{3v} symmetry.

Similar infrared spectra have been reported for a number of fluorosulfates of the type $M(SO_3F)_2$, with M = Mg, Ca, Zn, Cd, Hg, Fe, Co, and Ni, by Thompson and co-workers (10, 15). These authors have postulated a tridentate, oxygen bridged fluorosulfate group in these compounds rather than ionic groups, where the

point group C_{3v} would predict the same number and type of fundamental vibrations. The argument is based on frequency shifts, affecting all six fundamentals. In particular ν_2 the S—F stretch is found $\sim 100\ cm^{-1}$ higher than commonly observed for ionic fluorosulfates (16–18).

$Pd(SO_3F)_2$ also falls into this group. The fact that none of the degenerate modes appears to be split, leads one to expect a regular octahedral environment for palladium, rather than a distorted one as suggested for $Cu(SO_3F)_2$ (15, 16).

Vibrational information for $Pd(SO_3F)_3$ is obtained from the Raman spectrum using the He–Ne laser. The more powerful argon ion laser was found to cause decomposition of the sample evidenced by the appearance of lines due to $Pd(SO_3F)_2$. The extreme reactivity of the compound prevented us from recording any reliable infrared spectra.

The observed Raman shifts are tabulated in Table 1 and compared to previously reported data for $K_2[Sn(SO_3F)_6]$ (19). As can be seen from the table, a useful comparison between this complex and $Pd(SO_3F)_3$ can indeed be made, providing initial support for a formulation as $Pd^{II}[Pd^{IV}(SO_3F)_6]$. The SO_3 stretching frequencies are assigned to bands at 1400, 1220, and 1000 cm^{-1}, with all bands split into two or three components due to solid state splitting.

The similarities between $[Sn(SO_3F)_6]^{2-}$ and $[Pd(SO_3F)_6]^{2-}$ continue into the lower frequency range, suggesting approximately monodentate fluorosulfate groups with coordination via oxygen for both compounds. A more detailed vibrational assignment appears not very useful due to the observed complexity of the Raman spectrum.

Electronic Spectra

The vibrational spectrum had indicated a regular octahedral environment for palladium(II) in $Pd(SO_3F)_2$ and the magnetic results, to be discussed subsequently, support a high spin configuration and hence a $^3A_{2g}$ ground state. A three line ligand field spectrum is therefore expected and indeed observed. The mull spectrum shows bands at 850 and 575 nm and a shoulder at ~ 370 nm. The diffuse reflectance spectrum shows only bands at 575 nm and ~ 380 nm because the region beyond 700 nm was not accessible with the spectrometer used. The three bands are assigned as follows:

ν_1 at 850 nm (11 770 cm^{-1}), $^3A_{2g} \rightarrow {}^3T_{2g}$

ν_2 at 575 nm (17 400 cm^{-1}), $^3A_{2g} \rightarrow {}^3T_{1g}(F)$

ν_3 at 370 nm (27 000 cm^{-1}), $^3A_{2g} \rightarrow {}^3T_{1g}(P)$

Hence, 10 Dq is 11 770 cm^{-1}. The ligand field parameter, B, of 633 cm^{-1} is obtained from the measured ν_2/ν_1 ratio using Tanabe–Sugano diagrams as suggested by Lever (20). The position of ν_3 at 370 nm is confirmed by this method. Some pertinent ligand field parameters for $Pd(SO_3F)_2$, $Ni(SO_3F)_2$ (21), and $Co(SO_3F)_2$ (10) are listed in Table 2.

The comparison shows, that the three bands observed for $Pd(SO_3F)_2$ are best explained as

ligand field bands for Pd^{2+} in a regular octahedral environment. The increase in Dq, and the decrease in B/B^0 when going from $Ni^{2+}(3d^8)$ to $Pd^{2+}(4d^8)$ are expected. Since the spectrum of PdF_2 seems not to have been investigated and all other palladium(II) compounds give spectra typical for square planar environments, no further meaningful comparisons can be made.

No useful electronic spectra could be obtained for $Pd(SO_3F)_3$. A very intense featureless band, presumed to be a charge transfer band, extended over most of the visible region. Any ligand field bands were most likely obscured.

Magnetic Measurements

Both $Pd(SO_3F)_2$ and $Pd(SO_3F)_3$ are paramagnetic. The observed magnetic moments for both compounds are listed in Table 3, together with magnetic information on related compounds. For $Pd(SO_3F)_2$, a μ_{eff} value of 3.39 BM at room temperature is observed, indicative of two unpaired electrons and in good agreement with the magnetic moment for $Ni(SO_3F)_2$ (21, 23). However, the μ_{eff} value for PdF_2 (2, 24) is considerably lower, obviously due to antiferromagnetic coupling via super exchange. The absence of such coupling for the fluorosulfate down to ~100 K is evident from the temperature dependent study.

The linear $1/\chi_M^{corr}$ *vs.* temperature plot indicates Curie–Weiss law behaviour with a Weiss constant of $\theta = +13 \pm 4$ K. Similar magnetic moments and negative Weiss constants are reported for numerous octahedral Ni^{2+} complexes (1), not altogether inconsistent with a $^3A_{2g}$ ground state. Some small variation of μ_{eff} with temperature is within the limit of experimental accuracy and probably not very significant.

The knowledge of 10 Dq for $Pd(SO_3F)_2$ allows one also to correct for contributions from the temperature independent paramagnetism (TIP) to the observed magnetic susceptibilities. The resulting TIP-corrected value of μ_{eff} is listed in Table 3, and the indication is that only a small TIP contribution is thus detected. Due to the

lack of spectroscopic data for $Pd(SO_3F)_3$ and the palladium fluorides, no such corrections are possible for these compounds.

The observed magnetic moment for Pd^{2+} in the fluorosulfate is noticeably higher than the 'spin-only' value of 2.83 BM. Since no orbital contribution is expected for an ion with a $^3A_{2g}$ ground state and the TIP contributions are rather small, the increase must be caused by spin–orbit coupling. The spin–orbit coupling constant, λ, for Pd^{2+} is unknown but is expected to be negative and hence should lead to a higher μ_{eff} value (22). It is also doubtful, whether spin–orbit coupling would follow the Russel Saunders coupling scheme for an ion as heavy as Pd^{2+} (22), and any further analysis of the magnetic data for $Pd(SO_3F)_2$ seems therefore not reasonable.

A reasonable interpretation of the magnetic results for $Pd(SO_3F)_3$ is possible when the formulation as $Pd^{II}[Pd^{IV}(SO_3F)_6]$ is used. Pd(IV) with a d^6 electron configuration should be diamagnetic, (*e.g.* in $K_2Pd^{IV}F_6$ (3)) and all paramagnetism should be due to the Pd^{2+} ion. The μ_{eff} value at room temperature now becomes 3.45 BM, and the $1/\chi_M^{corr}$ *vs.* T plot indicates a Weiss constant $\theta = +10 \pm 2$ K. Again the μ_{eff} values between 334 and 107 K show only a slight variation and it can be concluded that Pd^{2+} in both $Pd^{II}(SO_3F)_2$ and $Pd^{II}[Pd^{IV}(SO_3F)_6]$ must be in very similar environments. This would imply that the fluorosulfate group is coordinated strongly to Pd^{IV} and rather weakly to Pd^{II} with the metal in an octahedral environment each time. The noted complexity of the vibrational spectrum may be caused in part by such weak coordination to Pd^{II}.

The magnetic results are thus consistent with the conclusions reached earlier when analysing the vibrational spectrum, and the suggested formulation of PdF_3 as $Pd^{II}[Pd^{IV}F_6]$ (4, 24). The slightly lower μ_{eff} values for Pd^{2+} in the fluoride and the reported Weiss constant of $\theta = -28$ K indicate a different magnetic behaviour and perhaps some intermolecular antiferromagnetic interaction (25).

Conclusions

The investigation on palladium fluorosulfates has shown that an octahedral rather than a square planar environment for Pd^{II} is found in fluorosulfates as well as in fluorides, thus pointing to the similarities of SO_3F^- and F^- as weak field ligands. It is hoped that this analogy can be extended to other 4*d*- and 5*d*-block element fluorosulfates.

Kinetics and mechanism of the decarboxylation of pyrimidine-2-carboxylic acid in aqueous solution

GERALD E. DUNN, EDWARD A. LAWLER, AND A. BRIAN YAMASHITA

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received January 17, 1977

GERALD E. DUNN, EDWARD A. LAWLER, and A. BRIAN YAMASHITA. Can. J. Chem. **55,** 2478 (1977).

Pseudo-first-order rate constants for the decarboxylation of pyrimidine-2-carboxylic acid have been determined at 65°C in aqueous solution over the acidity range pH = 2 to H_0 = −9.5. Rate constants increase rapidly from pH = 2 to H_0 = −3, then remain constant. This behaviour can be accounted for by a Hammick-type mechanism in which monoprotonated pyrimidine-2-carboxylic acid loses carbon dioxide to form an ylide (stabilized by the adjacent positively charged nitrogens) which rapidly converts to pyrimidine.

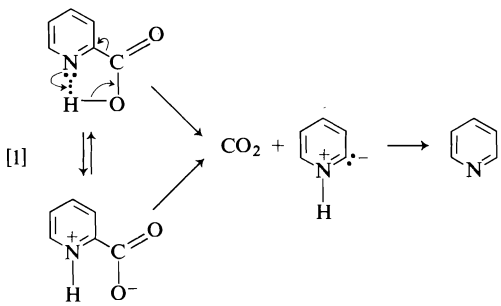
GERALD E. DUNN, EDWARD A. LAWLER et A. BRIAN YAMASHITA. Can. J. Chem. **55,** 2478 (1977).

Travaillant à 65°C, en solution aqueuse et à des acidités allant d'un pH = 2 jusqu'à H_0 = −9.5, on a déterminé les constantes de vitesse de pseudo premier ordre pour la décarboxylation de l'acide pyrimidinecarboxylique-2. Les constantes de vitesse augmentent rapidement du pH = 2 jusqu'à une valeur de H_0 = −3 et elles demeurent ensuite constantes. On peut expliquer ce comportement par un mécanisme du type Hammick dans lequel l'acide pyrimidinecarboxylique-2 monoprotoné perd une molécule de CO_2 pour conduire à un ylure (stabilisé par les azotes adjacents chargés positivement) qui se transforme rapidement en pyrimidine.

[Traduit par le journal]

Introduction

Earlier papers from this laboratory have reported on the decarboxylation of various substituted pyridine-2-carboxylic acids in aqueous solution (1, 2). They appear to decarboxylate by the Hammick mechanism, reaction 1, in which the developing carbanionic center at position 2



[1]

of the transition state is stabilized by the electron-withdrawing nitrogen at position 1 (3). Thus quaternization of the nitrogen increases the rate of decarboxylation by factors of about 100 in aqueous solution (1) and 700 in ethylene glycol (4). Substituents in the 3-position have a much larger effect on the rate than in the 4-, 5-, or 6-positions (1) and appear to exert their influence by a mixture of electronic and steric effects. Thus, a 3-methyl substituent increases the rate of decarboxylation by a factor of about 4, whereas 3-benzoyl, 3-carboxyl, and 3-nitro increase the rate by several orders of magnitude (2). It seemed, therefore, of interest to examine the effect of an electron-withdrawing 3-substituent of minimal steric requirements, such as the second ring nitrogen of pyrimidine-2-carboxylic acid. The decarboxylation of pyrimidine carboxylic acids is also of more general interest because it is sometimes involved in both the bio- and laboratory syntheses of pyrimidine-based nucleic acids (5).

Experimental

Pyrimidine-2-carboxylic Acid

4,6-Dihydroxy-2-methylpyrimidine (Aldrich) was converted to 4,6-dichloro-2-methylpyrimidine (6) which was dehalogenated to 2-methylpyrimidine (7). After several unsuccessful attempts to oxidize the methyl group with $KMnO_4$ or CrO_3, pyrimidine-2-carboxylic acid was obtained by selenium dioxide oxidation using a modification of the procedure developed by Jerchel *et al.* for oxidation of picolines (8).

2-Methylpyrimidine (1.5 g) and selenium dioxide (3.6 g) were heated for 2.5 h in 30 ml of refluxing pyridine. The deep red solution was filtered hot and the residue was washed with three 10 ml portions of pyridine, then with 20 ml of water. The filtrate was steam distilled to remove most of the pyridine, reduced to a volume of 70 ml on a rotary evaporator, and filtered into a solution of 5 g of cupric acetate in 50 ml of water. A blue-green pre-

cipitate was collected by filtration and combined with two additional crops obtained by further concentration and filtration over a period of several days. Hydrogen sulfide was passed into a suspension of the combined solids in 150 ml of water at 40°C for about 40 min, cupric sulfide was filtered off, and the pale blue filtrate was treated again with hydrogen sulfide. The final, colourless filtrate, taken to dryness on the rotary evaporator, left 350 mg of a brownish solid, mp 176–185°C. Vacuum sublimation yielded 250 mg (13%) of colourless crystals mp 193–197°C (lit. (9) mp 199°C); mass spectrum, *m/e*: 124, 107, 80.

Kinetic Measurements

The decarboxylation was followed spectrophotometrically by recording the decrease with time in the absorbance of pyrimidine-2-carboxylic acid at 220 nm using a Varian Techtron model 635 spectrophotometer.

For each kinetic run 3.5 ml of a stock solution of pyrimidine-2-carboxylic acid (8.8×10^{-2} *M*) was made up to 25 ml with the appropriate mineral acid. At p*H*'s greater than 1, the mineral acid was a buffer made from HCl, KCl, and NaH_2PO_4; at p*H*'s less than 1 it was a mixture of water and H_2SO_4. For buffer solutions the p*H* was measured on an Orion model 801, p*H* meter; for sulfuric acid solutions the density of the solution was determined in triplicate with a 5 ml pycnometer and from this the percent sulfuric acid and H_0 values were obtained (10). Ten 2-ml samples of this solution were sealed in ampoules and placed in the thermostat at 65 ± 0.01°C. At intervals samples were quenched in ice, diluted to 10 ml with distilled water, and analyzed in the spectrophotometer. In each case the uv spectrum of the product coincided precisely with that of pyrimidine. Reactions were carried to more than three half-lives of the faster runs; the very slow ones to only one half-life. The average standard deviation of experimental points from the first-order regression lines was 1.7%, and reproducibility of rate constants was ±2%. Results are shown in Table 1.

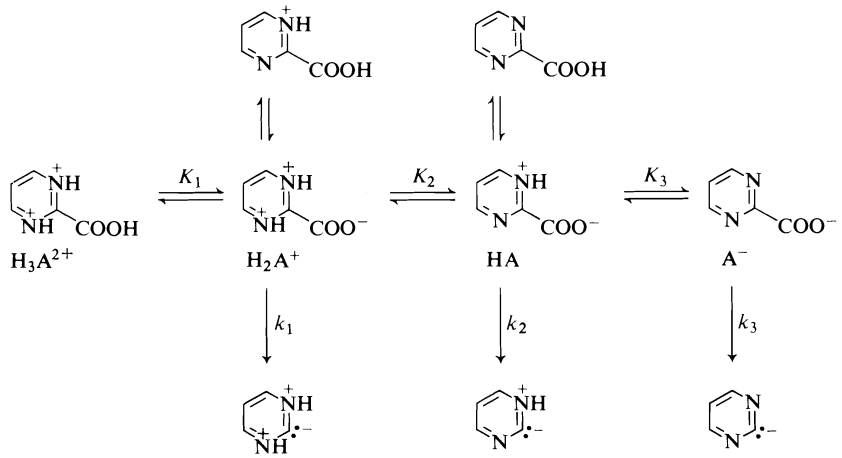
TABLE 1. First-order rate constants for decarboxylation of pyrimidine-2-carboxylic acid in aqueous acid at 65°C

p*H* (or H_0)	Acid	$k \times 10^4$
2.04	HCl	0.0023
1.07	HCl	0.025
0.92	H_2SO_4	0.025
−0.059	H_2SO_4	0.157
−1.01	H_2SO_4	0.821
−1.94	H_2SO_4	1.41
−2.61	H_2SO_4	2.12
−3.51	H_2SO_4	3.01
−4.83	H_2SO_4	3.45
−5.19	H_2SO_4	3.46
−5.87	H_2SO_4	3.76
−6.79	H_2SO_4	4.44
−7.78	H_2SO_4	4.15
−8.81	H_2SO_4	3.65
−9.48	H_2SO_4	3.60

Discussion

The ionization equilibria and Hammick mechanism for decarboxylation of pyrimidine-2-carboxylic acid are shown in reaction 2. In aqueous solution the anion and ylides shown as products would be rapidly converted to pyrimidine or its conjugate acid. Mason gives for pyrimidine-2-carboxylic acid $pK_2 = -1.13 \pm 0.05$ and $pK_3 = 2.85 \pm 0.02$ without specifying the temperature (11). Since the p*K*'s would probably change by less than one p*K* unit between room temperature and 65°C, one may conclude from the data in Table 1 that the species decarboxylating at $H_0 < -2$ is H_2A^+ and that its rate of decarboxylation is much greater than that of HA. Furthermore, since the rate does not decrease significantly at very high acidity, although previous experience suggests that the unionized carboxyl group does not decarboxylate easily (1, 12), it appears that very little H_3A^{2+} is present even at $H_0 = -9.5$ (~98% H_2SO_4), so that pK_1 is probably less than −10. This conclusion is perhaps not

[2]



surprising since pK_1 for pyrimidine is *ca.* -6.3 (13), and it is reinforced by the observation that the ultraviolet spectrum of the acid does not change significantly from $H_0 = -2$ to $H_0 = -9.5$.

Accordingly, it may be assumed, at least as a first approximation, that, in the pH range studied, the only species present in significant concentration are H_2A^+ and HA, that the only important ionization constant is K_2, and that k_2 is negligible. These assumptions are expressed in [3], [4], and [5] which may be combined to give [6].

$$[3] \qquad [H_2A^+] + [HA] = [C]$$

$$[4] \qquad \frac{[H^+][HA]}{[H_2A^+]} = K_2$$

$$[5] \qquad \frac{d[CO_2]}{dt} = k_{obs}[C] = k_1[H_2A^+]$$

$$[6] \qquad k_{obs} = \frac{k_1[H^+]}{[H^+] + K_2}$$

At $H_0 < -4$, $[H^+] \gg K_2$, so that $k_{obs} = k_1$. The average value of k_{obs} at these high acidities is $3.8 \times 10^{-4}\ s^{-1}$, which may be taken as an estimate of k_1 at 65°C. At p$H > 0$, $[H^+] < K_2$ so that $k_{obs} = k_1[H^+]/K_2$. The first points of Table 1 give a value of $2.2 \times 10^{-5}\ s^{-1}$ for k_1/K_2, corresponding to a value of 17 for K_2 (p$K_2 = -1.23$) at 65°C, which may be compared with the literature value (11) of p$K_2 = -1.13$ (presumably at 25°C).

Figure 1 shows a plot of log k_{obs} *vs.* H_0 and pH. The solid line shows the rate constants calculated from [6] using the values of k_1 and K_2 estimated in the preceding paragraph. It is clear that the calculated k_{obs} are too large in the region where k_{obs} varies with H_0, which suggests that H_0 may not be the appropriate acidity function to represent the protonation of pyrimidine-2-carboxylic acid. Since most acidity functions are proportional to H_0 (14), one may plot log k_{obs} against nH_0. For this purpose [6] is modified to [7].

$$[7] \qquad k_{obs} = \frac{k_1 h_0^{\,n}}{h_0^{\,n} + K_2}$$

The optimum value for n is about 0.55, and the dotted line in Fig. 1 shows the rate constants calculated from [7] using $n = 0.55$ and the previously estimated values of k_1 and K_2. The fit is good, which suggests that the protonation

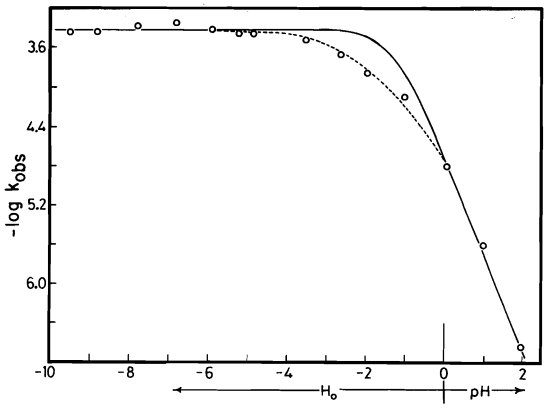


FIG. 1. The effect of changing acidity on the first-order rate constant for decarboxylation of pyrimidine-2-carboxylic acid in aqueous solution at 65°C. Circles represent experimental points, the solid and dotted lines represent [6] and [7], respectively, with $k_1 = 3.8 \times 10^{-4}\ s^{-1}$, $K_2 = 17$, and $n = 0.55$.

of pyrimidine-2-carboxylic acid follows an acidity function which increases about half as fast with acidity as does H_0. This description fits the amide acidity function, H_A (15) reasonably well, since a plot of H_A *vs.* H_0 has a slope of 0.53 (16). It is noteworthy in this connection that the second protonation of pyrimidine is reported to follow H_A (13).

Thus it is possible to account for the acidity dependence of the decarboxylation of pyrimidine-2-carboxylic acid by the Hammick mechanism using ionization constants and an acidity function in reasonable agreement with the literature. It is necessary, however, to assume that the rate constant for decarboxylation of protonated substrate (k_1) is at least a thousand times greater than that for the substrate itself (k_2). This emphasizes the importance of electronic (inductive and field) effects in stabilizing the transition state leading to ylide in the Hammick mechanism. In pyridine-2-carboxylic acids 3-substituents were found to have an accelerating effect that is at least partly steric (2), but in the present case steric effects should be negligible.

In the pyridine series 3-substituents inhibit the decarboxylation of pyridine-2-carboxylate ions, again by a steric effect, presumably (2). It would therefore be of particular interest to examine the decarboxylation of the pyrimidine-2-carboxylate ion (k_3), where steric effects are reduced but electronic effects should be favorable. Since k_2 is very small at 65°C and k_3 would be smaller still,

attempts were made to study the decarboxylation at 95°C. However, the product of decomposition at 95°C and pH = 5 (where the substrate should be over 99% in the form of A^-) had an ultraviolet spectrum quite different from that of pyrimidine. Pyrimidine itself behaved similarly, so it is apparent that the anion or its decarboxylation product undergoes some other reaction under conditions where A^- might be expected to decarboxylate.

Acknowledgments

Thermal and photochemical reactivity of cyclopropene derivatives: a semi-empirical molecular orbital study

J. A. PINCOCK AND R. J. BOYD

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received December 23, 1976

J. A. PINCOCK and R. J. BOYD. Can. J. Chem. **55**, 2482 (1977).

The MINDO/3 semi-empirical MO method has been used to study the conversion of cyclopropene to vinyl carbene. In particular, the surfaces of the ground state and the first excited singlet and triplet states have been calculated. Additional calculations, including geometry optimization, have been carried out on vinyl substituted cyclopropenes. In general, the results are consistent with the known thermal and photochemical reactivities of cyclopropenes and the results of the few *ab initio* calculations on these species.

J. A. PINCOCK et R. J. BOYD. Can. J. Chem. **55**, 2482 (1977).

On a utilisé la méthode semi-empirique MINDO/3 MO pour étudier la conversion du cyclopropène en vinylcarbène. On a calculé en particulier les surfaces de l'état fondamental et des premiers états exités singulet et triplet. Des calculs additionnels incluant une optimisation de la géométrie ont été réalisés sur des cyclopropènes substitués par un groupe vinyle. D'une façon générale, ces résultats sont en accord avec les réactivités thermiques et photochimiques bien connues des cyclopropènes et les résultats des quelques calculs *ab initio* sur ces espèces.

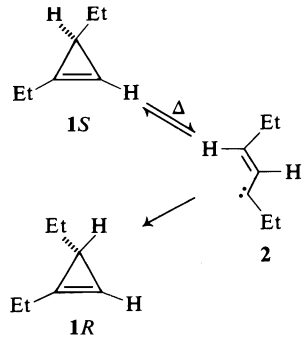
Introduction

The chemistry of cyclopropene derivatives has attracted considerable interest (1) mainly because of the high strain energy (~53 kcal/mol in the ground state (2)) associated with the unsaturated three-membered ring. Studies on their unimolecular behaviour in either the ground state (thermal chemistry) or the excited states (singlet and triplet photochemistry) have been used as an indirect method of gaining an understanding of the effect of bonding on reactivity. These results will be briefly summarized here.

The most extensive study of the thermal behaviour of cyclopropenes is the work of Bergman and co-workers (3) on the pyrolysis of racemic and optically active 1,3-diethylcyclopropene as shown in reaction 1. The formation of isomeric 2,4-heptadienes and 3-heptyne was nicely explained in terms of hydrogen migrations for the vinyl carbene intermediate **2**. The activation energy for this process (32.2 kcal/mol) agreed well with estimates made by the usual group equivalent and bond energy values for the heat of formation of **2**. Moreover, optically active **1** was shown to racemize (**1***S* ⇄ **1***R*) about nine times as fast as it was converted to products, making the case for the intervention of **2** even stronger. Note as well that the cyclopropene **1** has apparently reacted, as expected, by cleavage of the more highly substituted σ bond. However,

[1]



$CH_3CH{=}CH{-}CH{=}CH{-}Et$

3

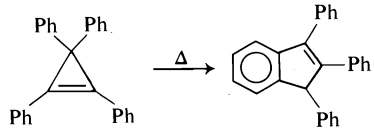
+

$CH_3CH_2C{\equiv}CCH_2CH_2CH_2CH_3$

4

as Bergman points out, this type of substituent effect is not observed in all cases. Thus, tetraphenylcyclopropene, **5**, rearranges to the indene **6** (presumably via the isoindene), but the reported activation energy of 40 kcal/mol (4) is surprisingly high. Since the estimated value for the

[2]



5 **6**

thermal cleavage of a σ bond in **5** is approximately 11 kcal/mol (3), the phenyl groups are clearly affecting the single bond energy in an unprecedented manner.

The photochemistry of cyclopropene derivatives has been shown to be remarkably dependent on the multiplicity of the excited state involved. As in thermal reactions, excited singlets give products also consistent with σ bond cleavage to vinyl carbenes (5) whereas triplet states dimerize by a $2\pi + 2\pi$ cycloaddition (6). For example (7), direct irradiation (excited singlet) of methyl 1-methyl-2-phenylcyclopropene-3-carboxylate, **7**, gives 2-methoxy-5-methyl-4-phenylfuran, **8**; in contrast, sensitized irradiation gives the tricyclic dimer **9** (reactions 3 and 4). Further,

[3] 
7 8

[4] 
7 9

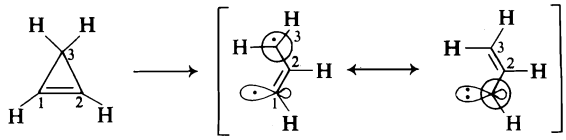
photolysis of optically active **7** demonstrated that racemization was occurring in the excited singlet state about four times as fast as conversion to **8**, whereas no racemization could be detected in the sensitized irradiations. Considering the high strain energy of the cyclopropene, plus the added energy from electronic excitation, the surprising feature of these observations is not that the excited singlet opens to a vinyl carbene but that the triplet state is long-lived enough as a three-membered ring to react by a bimolecular path.

This paper examines some of these properties of cyclopropene compounds by a quantum mechanical approach using the semi-empirical SCF–MO MINDO/3 method (8) on model systems. The particular features we wished to examine were the nature of the three surfaces (ground, excited singlet, and triplet) in the conversion of cyclopropene to vinyl carbene and the effect of substituents on the ground state surface. The choice of the MINDO/3 method was based on the fact that complete geometric minimizations along a reaction surface can be made for molecules of a reasonable size at a moderate cost. Further, although the technique has already been successful for a variety of thermal reactions (9), at least one experimental case (1,3-migration in vinyl cyclopropanes) is not predicted correctly (10). More tests of the method are therefore desirable before its general applicability to organic reactions is appreciated. Finally, for these systems, a limited number of *ab initio* calculations of both the valence bond (11) and the molecular orbital method (12)[1] have appeared and so comparison with the MINDO/3 approach is possible.

Results

Cyclopropene to Vinyl Carbene: Ground State

The conversion of **10** to **11** was studied taking the length of the σ bond as the reaction coordinate (C_1—C_3) and minimizing all other geometric variables. Initially, we reproduced Dewar's (13) previously reported result for the energy and equilibrium geometry of cyclopropene. As shown in Fig. 1 (circles), calculations using cyclopropene as the starting point and increasing the C_1—C_3 bond length gave a surface with the energy increasing continuously. (At C_1—C_3 greater than 2.4 Å the C_3H_4 system dropped in energy drastically by migrating a hydrogen atom and forming methyl acetylene.) There was no indication of rotation of the methylene group towards planarity and the intermediate **11**. In contrast, when the starting point for the calculations was a flat intermediate like



10 11

11 and the C_1—C_3 value was decreased, the points shown as triangles in Fig. 1 were obtained. At C_1—C_3 = 2.0 Å the two calculated structures coincided both in energy and geometry. This is an example of what Dewar calls "chemical hysteresis" (9) and results from the intersection of the surfaces of two states. As Salem *et al.* have discussed in considerable detail (14), the crossing

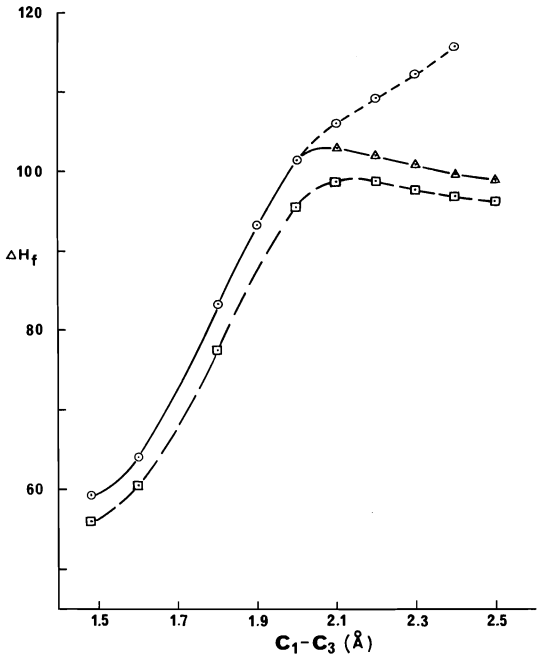

FIG. 1. Ground state surfaces for the conversion of **10** to **11**: starting point cyclopropene **10**, ⊙; starting point vinyl carbene **11**, △; including CI, ⊡.

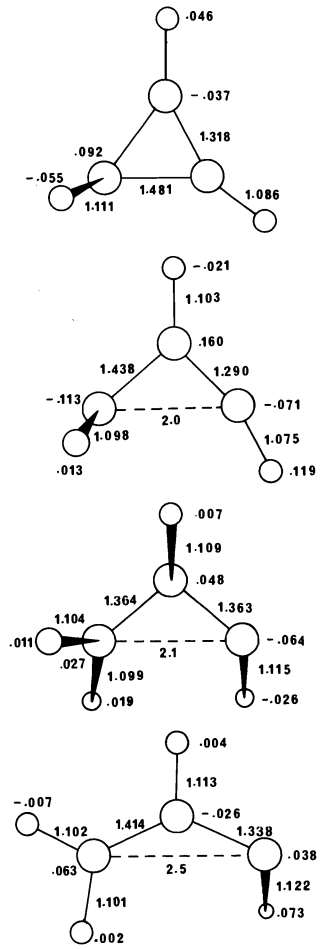

FIG. 2. Geometries and atomic charges of intermediates in the conversion of **10** to **11**: cyclopropene, minimized (59.3 kcal/mol); C_1—C_3 = 2.0 Å; C_1—C_3 = 2.10 Å; C_1—C_3 = 2.50 Å.

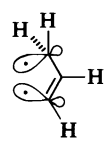
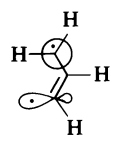
should be, but is not avoided because the crudeness of the method does not allow for mixing of the ionic and covalent configurations of each state. In our case the crossing is avoided in one direction (**11** → **10**) but not in the other (**10** → **11**). Despite these problems, we assume that the solid line in Fig. 1 represents an approximation to the true surface in the opening of cyclopropene to the vinyl carbene. Geometries including bond lengths and atomic charges for cyclopropene and three of the calculated points (C_1—C_3 = 2.0, 2.1, and 2.5 Å) are shown in Fig. 2. Comparison of charges in the two structures at 2.0 and 2.1 Å indicates the decrease in polarity as the crossing point is passed.

The MINDO/3 program has the option of including a limited CI with mixing of the first doubly excited configuration. As Dewar has pointed out (8), inclusion of CI should significantly lower heats of formation for species that are biradical in character and therefore a check must be made in bond dissociations of the type involved in the **10** → **11** conversion. As shown (squares in Fig. 1), inclusion of CI lowers the surface by an approximately constant amount independent of the bond length when compared with the results in the absence of CI. Since the CI option does make the calculations longer and since there seems to be no large improvement by its inclusion, we have elected to omit it for the remainder of our work in these systems.

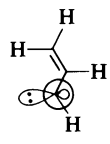
A preliminary report of Generalized Valence Bond (GVB) calculations using assumed geometries has recently been published for several key intermediates on the **10** to **11** surface (11). These intermediates (**12**, **13**, and **14**) are shown



12
(42.6 kcal/mol)



13
(38.9 kcal/mol)



14
(36.6 kcal/mol)

with the calculated energies relative to cyclopropene as zero. Cyclopropene correlates through the open but non-planar biradical **12** to the planar vinyl carbene state represented by **13** ($^1A''$). (Note that **14** ($^1A'$) is the lowest singlet state of vinyl carbene.) Comparison of these GVB results with the MINDO/3 results indicates that the two are actually very similar.

Thus, the calculated barriers to ring openings of cyclopropene are: GVB 42.6 kcal/mol; MINDO/3 43.6 kcal/mol; MINDO/3 + CI 43.0 kcal/mol. The difference of ~11 kcal/mol from the experimental value of 32.2 kcal/mol (3) for 1,3-diethylcyclopropene is explained at least in part by alkyl group stabilization of a ring-opening transition state. A value of 35.2 kcal/mol has been reported for the conversion of cyclopropene to methyl acetylene (15). By MINDO/3 the ground state of cyclopropene does not correlate with the lowest energy state of **11** (note the crossing in Fig. 1), but remains as a non-planar diradical. The lowest singlet state of **11** is a near-planar structure (note C_1—C_3 = 2.5 Å in Fig. 2), the major deviation being the hydrogen at the carbene carbon.

Vinylcyclopropenes to Vinylcarbenes

Encouraged by the success of the MINDO/3 method in examining the conversion of cyclopropene **10** to vinyl carbene **11**, we next approached the larger problem of the effect of phenyl substituents on the barrier to ring opening. Despite the advantage the semi-empirical method has over the *ab initio* methods for large molecules, tetraphenylcyclopropene is too large even for MINDO/3. However, with the assumption that the effect of the phenyl groups would mainly be a result of conjugative interactions, we chose to examine vinyl cyclopropenes as analogues of phenylcyclopropenes.

Three substitution patterns are possible as shown in reactions 5, 6, and 7. These are: 1-vinylcyclopropene with cleavage of the C_1—C_3 bond (**15** → **16**); 1-vinylcyclopropene with cleavage of the C_2—C_3 bond (**15** → **17**); 3-vinylcyclopropene with cleavage of the C_1—C_3 bond (**18** → **19**). In order to minimize computation

[5] 
15 **16**

[6] 
15 **17**

[7] 
18 **19**

time, our first approach was to keep the vinyl group (—CH=CH_2) in a fixed geometry throughout the calculations (C=C = 1.33 Å; C—H = 1.10 Å; all angles 120°). All other geometric variables were minimized at each reaction coordinate value.

Here a comment on one problem associated with the conformations of these species is appropriate. In each case the vinyl group has freedom of rotation about the single bonds. If more than one minimum exists for the rotation of the vinyl groups, then the possibility arises that the barriers for ring opening of the cyclopropenes may be incorrectly calculated. This is true, despite the fact that the rotational angle is one of the geometric variables, since the MINDO/3 geometry optimization is based on an efficient steepest-descents approach rather than a more tedious search of the entire surface. Accordingly the optimized value for a rotational angle may depend on the starting point for the geometry search. For this reason additional calculations to determine whether or not a lower minimum exists are advisable.

We first checked these conformational aspects with the cyclopropenes **15** and **18**. The calculated results for rotation about the single bond are shown in Figs. 3 and 4. The main feature of these plots is the very small difference in energy between the various conformations; 0.3 kcal/mol between the most and least stable for **15** and 1.0 kcal/mol for **18**. As Dewar has demonstrated, MINDO/3 predicts conformational minima reasonably well but usually underestimates the barriers (13). Therefore these values may be somewhat too low but are probably of the right order of magnitude. We next examined conformational preferences in the open carbenes **16**, **17**, and **19** in all cases with a

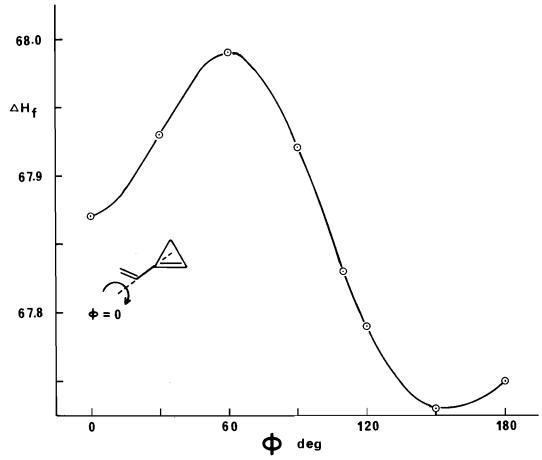


FIG. 3. Rotational surface for 1-vinylcyclopropene, **15**.

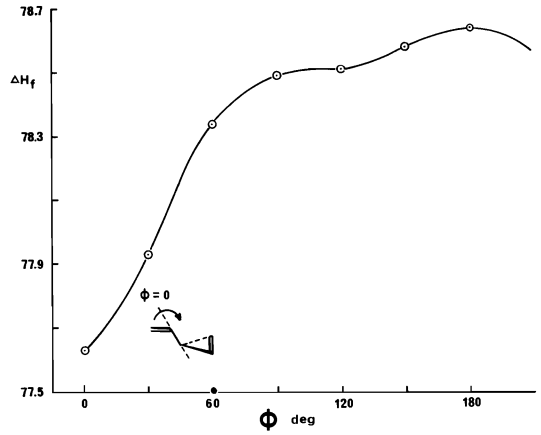

FIG. 4. Rotational surface for 3-vinylcyclopropene, **18**.

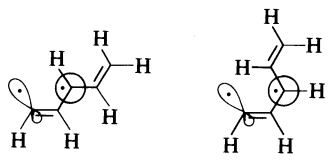
reaction coordinate C—C bond of 2.5 Å. Again, the energy differences between conformations were small, the largest being 0.81 kcal/mol between **19** and **20** as shown. Based on these



19 (112.81 kcal/mol) **20** (113.62 kcal/mol)

results, we felt confident that any errors that occurred because of incorrect conformational choices would be small and therefore not interfere with the general conclusions of the calculations.

Based on our experience with the cyclopropene to vinyl carbene conversion (*i.e.*, the crossing of states) we chose as starting points for these three sets of calculations the open carbenes **16**, **17**, and **19** in the conformations shown. The results are listed in Table 1 and plotted in Fig. 5. The geometries, including bond lengths and atomic charges, for some points along the surface are shown in Figs. 6, 7, and 8. No bond lengths are shown for the vinyl groups which are of fixed geometry.

The simplest feature to discuss in these results is the activation barrier for the three conversions: 41.1 kcal/mol (**15** → **16**); 51.8 kcal/mol (**15** → **17**) and 37.4 kcal/mol (**18** → **19**). In order to confirm that, despite the fixed vinyl group, these values were reasonable estimates of the activation energies, we repeated the calculations for both the starting vinylcyclopropenes and the transition states in the three cases, allowing complete geometric minimization. These results are shown in

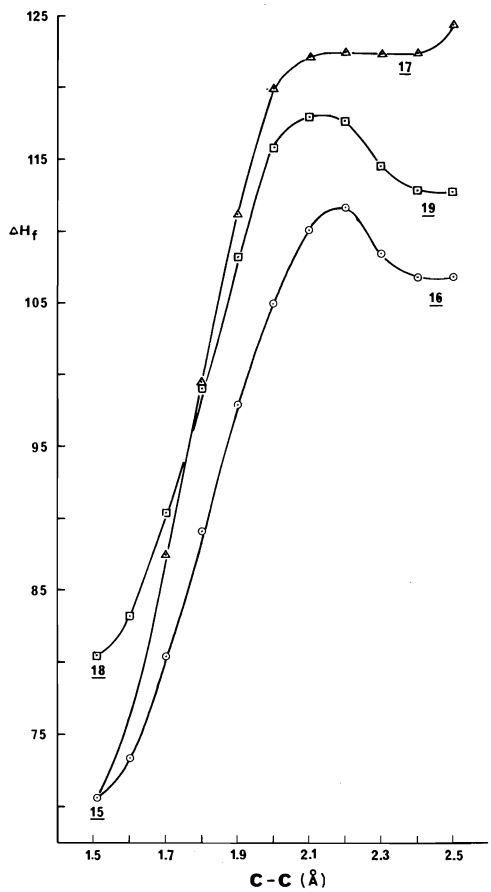


FIG. 5. Ground state surfaces for the thermal conversion of vinylcyclopropenes to vinylcarbenes.

parentheses in Table 1 and lead to the following activation energies: 41.2 kcal/mol (**15** → **16**); 52.3 kcal/mol (**15** → **17**) and 38.1 kcal/mol (**18** → **19**). Clearly, the differences are so small that restriction of the geometry of the vinyl group is unlikely to affect the general conclusions reached from a discussion of the results for these vinyl cyclopropenes.

On comparison with the value calculated for cyclopropene itself (43.6 kcal/mol) we note that the position of the vinyl group has a remarkable effect on the barrier to ring opening. As expected on the basis of conjugate effects with the developing radical center, a vinyl group on C-3 of cyclopropene lowers (by 6.2 kcal/mol) the activation barrier. A vinyl group at C-1 (C_1—C_3 bond breaking) also decreases (by 2.5 kcal/mol) the barrier. In contrast, a vinyl group at C-1 (C_2—C_3 bond breaking) actually raises the barrier by 8.2 kcal/mol. Qualitatively, an explanation is now available for the very high activation energy for tetraphenylcyclopropene pyrolysis (note reaction 2). The key feature is expected to be the presence of the phenyl group on the double bond carbon opposite to the σ bond that is breaking. In order to confirm that this destabilization of the transition state is still dominant when other stabilizing vinyl groups are present we have briefly examined divinyl cyclopropenes. Two point potential energy surfaces were obtained for 1,2-divinylcyclopropene (reaction 8) and 1,3-divinylcyclopropene (reaction 9) estimating the transition state energy by single calculations at a σ bond distance of 2.15 Å. This value was chosen based on the maxima in Fig. 5. In both cases the destabilizing effect of the vinyl group on the carbon opposite to the breaking σ bond is greater than any stabilizing effect that results from vinyl groups on the carbons of the bond involved. This

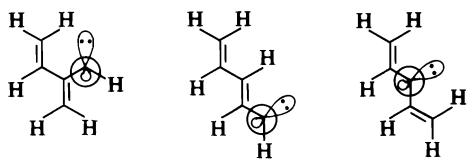
ΔH_{act} 48.0 kcal/mol

destabilization, which should be enhanced even more by phenyl groups, could be checked experimentally by a systematic study of the pyrolysis of phenyl substituted cyclopropenes.

Although we feel these results indicate the main feature in the surprising stability of tetraphenylcyclopropene, the reason for this stabilizing effect is less obvious. An examination of the intermediate carbenes for the three systems suggests an explanation. In both cases where the effect of the vinyl group is stabilizing (*i.e.*, substituted on the bond breaking) the intermediate becomes almost planar (note Fig. 6, C_1—C_3 = 2.2 Å and Fig. 8, C_1—C_3 = 2.5 Å). Thus **16** is essentially divinyl carbene and **19** is butadienyl carbene. Moreover the electron density of the carbene carbons is concentrated almost exclusively in the plane of the molecule; the sum of the squares of the coefficients of the carbene carbon orbital in the HOMO is 0.685 and 0.923 with a π-contribution of 0.004 and 0.000 for **16** and **19** respectively. Therefore the π system itself is essentially cation-like. In contrast, **17** (the intermediate that is destabilized by vinyl substitution) never becomes planar (note Fig. 7, C_2—C_3 = 2.4 Å). In fact, the carbene center remains somewhat isolated from the π-system of the developing butadiene fragment. This carbene is then actually less stabilized than that formed from cyclopropene; that is, conjugation of the second vinyl group with the developing double bond of the vinyl carbene prevents stabilization of the carbene itself. This is seen clearly in the potential energy surface for conversion of **15** to **17** in Fig. 5 where lack of stabilization prevents the appearance of a true minimum.

This explanation raises the question as to why **17** does not become planar. A qualitative answer is suggested by examination of planar **17** which, by analogy to the other cases, would have a π-system similar to the 2-methylenebutadienyl cation. In contrast, planar **16** and **19** are similar to pentadienyl cation (see above). Cross con-



Planar **17** Planar **19** Planar **16**

jugated systems like **17** are less stable than linearly conjugated systems like **16** (**19**) as evidenced by the simple Hückel energy difference of 0.24β in favour of pentadienyl over 2-methylenebutadienyl. Therefore **17** is less stable than the intermediates from the other vinyl carbenes because its energy is not significantly decreased in a planar geometry.

Cyclopropene to Vinyl Carbene: Excited States

Our main objective in examining the excited state behaviour of these species was to find an explanation for the experimental observation that excited singlet states of cyclopropene derivatives open to vinyl carbene intermediates, whereas triplet states are surprisingly stable and long lived. Since, to our knowledge, no application of the MINDO/3 technique to excited state processes has appeared, this seemed an ideal small molecule to test the method.

Our initial calculations were simply of the excited singlet (182.5 kcal/mol) and triplet (125.0 kcal/mol) in the equilibrium ground state geometry of cyclopropene. The first value should give an estimate (182.5 − 59.2 = 123.3 kcal/mol) of the vertical excitation energy and therefore can be compared with the π–π* electronic absorption band at 58 000 cm^{-1} (166 kcal/mol) reported for cyclopropene (16). The comparison is rather poor and is certainly not as good as those obtained by *ab initio* SCF techniques: 173 kcal/mol (16) and 167 kcal/mol (12). No experimental value is known for the vertical ground state–triplet splitting (125.0 − 59.2 = 65.8 kcal/mol) but again results from *ab initio* calculations are considerably higher; 119.9 kcal/mol by the GVB technique (11) and 92.8 kcal/mol by an MO method (12). This poor agreement between MINDO/3 and *ab initio* results for excited state species suggests that attempts to obtain quantitative information on the cyclopropene to vinyl carbene surface may be difficult. However, hopefully the qualitative behaviour of the surfaces will still be acceptably reliable.

Thus in Fig. 9 the excited singlet and triplet surfaces are shown for the conversion of cyclopropene (**10**) to vinyl carbene (**11**) along with the ground state surface for comparison. Figures 10 and 11 show, respectively, geometries of some of the points along the excited singlet and triplet surfaces.

A problem was encountered obtaining the singlet surface. The solid line shown is drawn through the minimum calculated values at any given C_1—C_3 bond distance. Depending on the geometry used as the starting point to obtain the minimized structure, quite different energies and

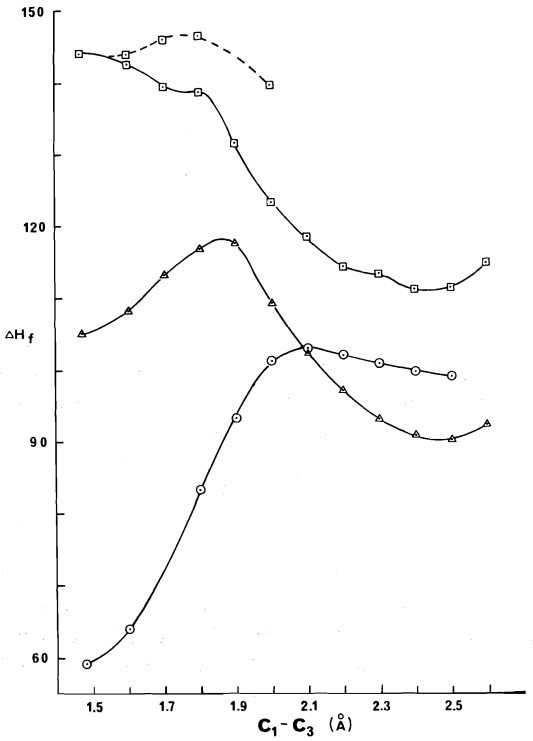


FIG. 9. Ground state, triplet state, and excited singlet state surfaces for the conversion of **10** to **11**: ground state ⊙; triplet state △; excited singlet state ⊡.

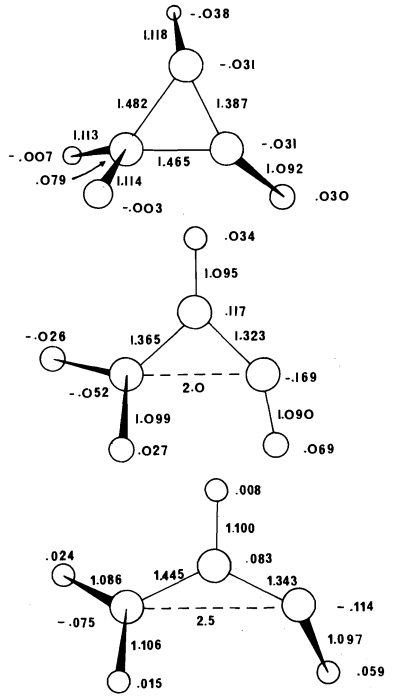

FIG. 10. Geometries and atomic charges of intermediates in the conversion of excited singlet **10** to **11**.

geometries were obtained. This may again reflect the inability of the MINDO/3 program to complete geometric minimizations adequately when there are intersecting surfaces for several states. (Note Fig. 2, ref. 12.) As an example, the points shown on the upper solid line in Fig. 9 were obtained starting at C_1—C_3 = 2.3 Å and shortening the C_1—C_3 distance. The points on the dotted line were obtained starting at C_1—C_3 = 1.48 Å and lengthening the bond. This same type of behaviour was previously encountered on the ground state surface (Fig. 1). The other irregularities in the excited singlet surface may again be a result of the inability of MINDO/3 to find a true minimum. Again we assumed that the solid lines shown on Fig. 9 are the best approximation that MINDO/3 can make for the excited state surfaces.

First, in agreement with previous calculations, we note that the most stable state of vinyl carbene is the triplet (11, 12). More interesting is the very different behaviour of the excited singlet and triplet surfaces. The singlet opens in an unactivated process whereas the triplet has a barrier of ~13 kcal/mol. This observation is,

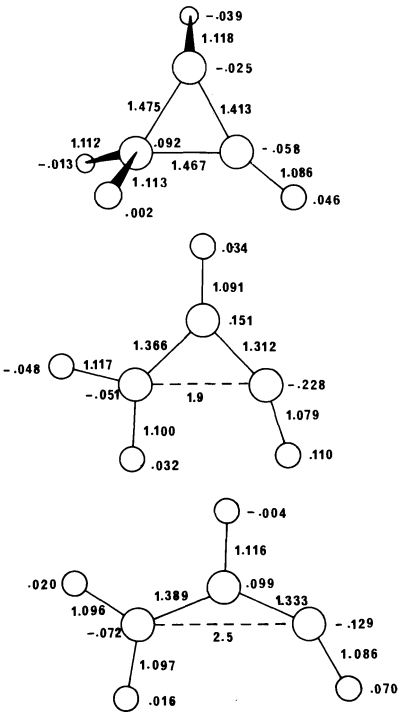

FIG. 11. Geometries and atomic charges of intermediates in the conversion of triplet **10** to **11**.

then, an explanation for the experimental results of cyclopropene photochemistry; the triplet states have a barrier to ring opening and are therefore long-lived enough to encounter another ground state molecule leading to dimerization. This also prevents photochemical racemization. The behaviour of the singlet state surface agrees well with the "funnel theory" of excited state to ground state conversions as outlined principally by Michl (17). Close approach of the two surfaces greatly enhances internal conversion and therefore gives a route for excited singlet cyclopropene to open to vinyl carbene and then return to ground state cyclopropene. Presumably there is a competition between this process leading to racemization of the cyclopropene and other processes leading to photoproducts.

Anchoring of the amide acidity function in dilute aqueous acid: a corrected H_A scale

JOHN T. EDWARD AND SIN CHEONG WONG

Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, P.Q., Canada H3A 2K6

Received February 10, 1977

JOHN T. EDWARD and SIN CHEONG WONG. Can. J. Chem. **55**, 2492 (1977).

Amide indicators ionizing over the range 0–30% sulfuric acid indicate that values of the H_A scale established by Yates *et al.* (Can. J. Chem. **42**, 1957 (1964)) should be corrected by +0.33 unit.

JOHN T. EDWARD et SIN CHEONG WONG. Can. J. Chem. **55**, 2492 (1977).

En utilisant trois amides comme indicateurs ionisant dans la région 0–30% H_2SO_4, on découvre que les valeurs de H_A de Yates *et al.* (Can. J. Chem. **42**, 1957 (1964)) doivent être corrigées par +0.33 unité.

Introduction

The various acidity functions H_R', H_0''', H_I, H_0, etc. all start out in dilute aqueous solution equal to pH (by definition), but diverge in sulfuric acid solutions more concentrated than about 1%. This shows up in a fanning out of curves for H_R', H_0''', and H_0 above $H_x \simeq 0.5$ in Fig. 1. The same behaviour might be expected (1) of the amide acidity function H_A of Yates *et al.* (2); however these authors, unable to find amide indicators ionizing over the range 0–16% sulfuric acid, chose to use 4-nitroaniline and 2-nitroaniline (indicators numbers 1 and 2 of Table 1), in effect making H_A coincident with H_0 over this concentration range. Bunnett and Olsen (3), on the basis of their LFER method of determining pK_{AH^+} values of amides, suggested that the H_A scale of Yates *et al.* was too negative by about 0.3 unit. This suggestion has the merit of lowering the H_A curve of Fig. 1 so that it diverges from the other curves at about the point to be expected. However, so far attempts to confirm the suggestion have been contradictory. Johnson *et al.* (4) claimed that pyridine-1-oxides followed the H_A acidity function, and used indicators 4, 5, and 6 of Table 1 to reassess the H_A scale in the lower acidity regions. They asserted that this investigation only confirmed the old scale. On the other hand, using the *N*-oxide indicators 7, 8, and 9 of Table 1, Homer and Johnson (1) changed the scale by 0.2 unit. However, none of these compounds are amides, and the parallelism between the logarithm of their ionization ratios with that of succeeding amide indicators is not very good. We have now investigated the ionization in 0–30% sulfuric acid of the amide indicators 10, 11, and 12 of Table 1 (2-hydroxynicotinic acid should exist preponderantly as the 2-pyridone tautomer (5)). We find that the H_A scale should indeed be shifted to the extent suggested by Bunnett and Olsen.

TABLE 1. Indicators used in attempts to establish the H_A scale in 0–25% aqueous sulfuric acid

Indicator (ref.)	$-\mathrm{d}\log I/\mathrm{d}H_0$
1. 4-Nitroaniline (2)	1.00
2. 2-Nitroaniline (2)	1.00
3. Pyrrole-2-carboxamide (2)	0.79
4. 3,5-Dimethyl-4-nitropyridine-1-oxide (4)	1.02
5. 3,5-Dichloropyridine-1-oxide (4)	0.77
6. 2,6-Dimethyl-4-nitropyridine-1-oxide (4)	0.82
7. 3-Chloropyridine-1-oxide (1)	0.91
8. 5-Nitroquinoline-1-oxide (1)	0.79
9. 8-Nitroquinoline-1-oxide (1)	0.79
10. 1-Methyl-2-pyridone (this work)	0.80
11. 5-Chloro-2-pyridone (this work)	0.78
12. 2-Hydroxynicotinic acid (this work) (2-pyridone-5-carboxylic acid)	0.77

Experimental

Materials

1-Methyl-2-pyridine, 5-chloro-2-pyridone, and 2-hydroxynicotinic acid (2-pyridone-5-carboxylic acid) were all commercial products.

Sulfuric acid and perchloric acid solutions were prepared by diluting commercial concentrated acids. Their final concentrations were determined by volumetric titration.

Ionization Measurements

Ionization ratios (I) of all three compounds (numbers 10, 11, and 12 of Table 1) in sulfuric acid, and of the first two compounds in perchloric acid were determined spectrophotometrically following standard procedures (6). Medium effects were corrected by characteristic vector analysis (7). Results are deposited as supplementary

TABLE 2. Ionization constants of 2-pyridone indicators

Compound	Δ log I	pK_{AH^+}	
1-Methyl-2-pyridone	—	0.38[a]	
5-Chloro-2-pyridone	0.35±0.04	0.03[b]	(−0.01)[a]
2-Hydroxynicotinic acid (2-pyridone-5-carboxylic acid)	0.67±0.03	−0.64[b]	
Pyrrole-2-carboxamide[c]	0.26±0.06	−0.90[b]

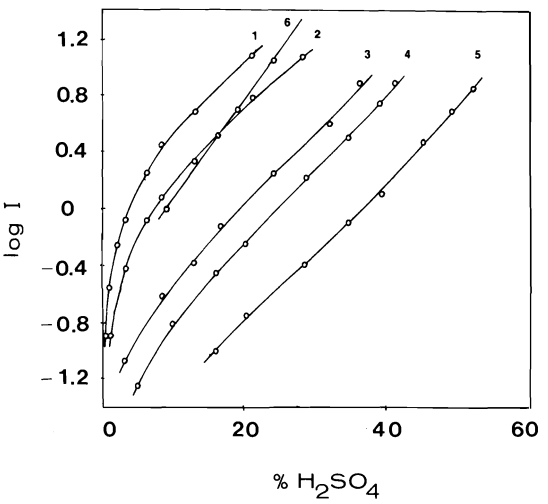

FIG. 2. Ionization of amide indicators in aqueous sulfuric acid: (*1*) 1-methyl-2-pyridone, (*2*) 5-chloro-2-pyridone, (*3*) 2-hydroxynicotinic acid, (*4*) pyrrole-2-carboxamide, (*5*) 3,4,5-trimethoxybenzamide, and (*6*) 2-nitroaniline.

material with the NRCC,[1] and were used to obtain the data of Table 1 and Fig. 2.

Results and Discussion

The parallelism in ionization ratios of the 2-pyridone indicators of Table 1 with those of the most basic amide indicators of Yates *et al.* (2), and hence their applicability in re-anchoring the H_A function, are shown by the plots of Fig. 2. The parallelism is good. Furthermore, indicators 10–12 have about the same slopes of log I against H_0 (Table 1) as pyrrole-2-carboxamide, the most basic indicator of Yates *et al.*, in contrast to some of the *N*-oxide indicators (numbers 4–9) used previously to anchor the H_A scale.

The pK_{AH^+} of the most basic amide, 1-methyl-2-pyridone, was obtained by a graphical method due to Paul (8). Examining [1]:

$$[1]\quad \log\frac{[AH^+]}{[A]} - \log[H^+] = pK_{AH^+} + \log f_A + \log\frac{f_{H^+}}{f_{AH^+}}$$

(the symbols being defined in ref. 2), since both log f_A (9) and log f_{H^+}/f_{AH^+} (8, 10, 11) can be expected to increase linearly with molar concentration of electrolyte, a plot of log I − log [H^+] against [H^+] should give a straight line with the intercept equal to pK_{AH^+} for a standard state of infinite dilution in water. In fact, 1-methyl-2-pyridone gave a straight line (linear regression

[1]The ionization data are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

TABLE 3. Revised H_A scale

% H_2SO_4	H_A	% H_2SO_4	H_A
2.5	0.58	45	−1.91
5	0.25	50	−2.18
7.5	0.02	55	−2.44
10	−0.15	60	−2.77
12.5	−0.28	65	−3.05
15	−0.40	70	−3.41
20	−0.67	75	−3.82
25	−0.92	80	−4.29
30	−1.17	85	−4.69
35	−1.41	90	−5.24
40	−1.67		

correlation coefficient 0.998) indicating a pK_{AH^+} of 0.38 ± 0.01.

The pK_{AH^+} values of the other indicators were calculated according to the overlap procedure (12). They are reported in Table 2 along with the differences in log I values (Δ log I) used in calculating them. A pK_{AH^+} value of −0.90 is obtained for pyrrole-2-carboxamide, as opposed to the value of −1.23 reported by Yates *et al.* (2). Thus, the original H_A scale is 0.33 unit too negative for sulfuric acid concentrations from 16.1% up. For 0–16.1% H_2SO_4, H_A values have been calculated from pK_{AH^+} and log I values of the indicators, according to the equation: $H_A = pK_{AH^+} + \log I$. The revised H_A scale is given in Table 3.

Received January 10, 1977

ANTONIO MARIO TAMBURRO and ANGELO SCATTURIN. Can. J. Chem. **55**, 2495 (1977).

The circular dichroism spectra of Z-Val-$(Ala)_3$-OEt in different solvents are reported. In dioxane the spectrum shows a negative band at 228–229 nm and a positive band at 212–213 nm, features which are consistent with the presence of some population of tetrapeptide molecules in a β-bend conformation. The infrared spectrum of Z-Val-$(Ala)_3$-OEt in KBr suggests an association of the molecules in an antiparallel β-structure in the solid state.

ANTONIO MARIO TAMBURRO et ANGELO SCATTURIN. Can. J. Chem. **55**, 2495 (1977).

On rapporte les spectres de dichroïsme circulaire de Z-Val-$(Ala)_3$-OEt dans différents solvants. Dans le dioxanne, le spectre montre une bande négative à 228–229 nm et une positive à 212–213 nm indiquant que des molécules du tétrapeptide existent dans la conformation β-bend. Le spectre infrarouge de Z-Val-$(Ala)_3$-OEt dans le KBr indique qu'à l'état solide il existe une association des molécules en structure β antiparallèle.

The so called β-bend folded conformation (1–4) is of paramount importance in the structure of small cyclic peptides (5) and it has also been found in some linear tetrapeptides (6, 7). Moreover, it has been suggested (2, 8) to play a particular role as a nucleation site in protein folding, although different points of view are possible (9, 10). Therefore we started with a wide-range project concerning structural investigations on linear tetrapeptides in order to elucidate the short-range forces responsible for the stabilization of this particular structure. In the present paper we report our results on the conformation of benzyloxycarbonyl-L-valyl-L-alanyl-L-alanyl-L-alanyl ethyl ester (Z-Val-$(Ala)_3$-OEt) which are of interest in connection with the recent finding of a β-bend type conformation in alanine tetrapeptide derivatives (6).

Experimental

The tetrapeptide was synthesized in a stepwise manner by the *p*-nitrophenyl ester method. The unprotected tripeptide L-alanyl-L-alanyl-L-alanine ethylester hydrobromide (11) was coupled with benzyloxycarbonyl-L-valine *p*-nitrophenylester (12) to give Z-Val$(Ala)_3$-OEt, mp 233°C. *Anal.* calcd. for $C_{24}H_{36}N_4O_7$: C 58.51, H 7.35, N 11.37; found: C 58.60, H 7.72, N 11.45. The cd spectra were recorded on a Cary 6002 dichrograph. The calibration was based upon $[\theta]_{290} = 7840$ deg cm^2 dmol^{-1} for a purified sample of *d*-10-camphosulfonic acid (Fluka, Bucks) in 0.1% aqueous solution (13). Samples were examined at concentrations ranging from 0.2 to 5 mg/ml using quartz cylindrical cells with optical paths of 0.01, 0.05, and 0.1 cm. The data are expressed in terms of $[\theta]_M$, the molar ellipticity in units of deg cm^2 dmol^{-1}. Infrared spectra were measured in the form of KBr pellets on a Perkin Elmer 21 spectrophotometer. Nujol spectra showed no significant variations.

Results and Discussion

Shown in Fig. 1 are the cd spectra of the protected tetrapeptide in TFE at three concentrations and in HFIP. Only minor concentration effects are found on both negative bands centered at 198 and 223–224 nm. Less polar solvents, such as water and ethylene glycol, induce a red shift and a decrease in the intensity of the bands (Fig. 2). As shown in Fig. 3, the alteration in the cd spectra, as a consequence of a change in solvent composition, could reflect a simple solvent effect and/or a conformational transition. However, when the apolar solvent dioxane is used (Fig. 4) a positive band appears around 212–213 nm. The spectrum under these

[1]Abbreviations used: cd, circular dichroism; ir, infrared; Z, benzyloxycarbonyl; Val, L-valine; Ala, L-alanine; OEt, ethyl ester; TFE, 2,2,2-trifluoroethanol; HFIP, 1,1,1,3,3,3-hexafluoropropan-2-ol; EG, ethylene glycol.

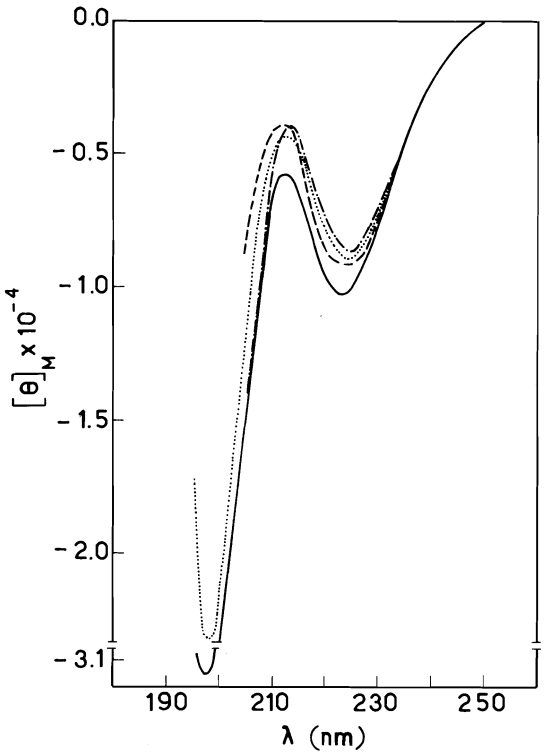

FIG. 1. Circular dichroism of Z-Val-$(Ala)_3$-OEt at 25°C in TFE at three concentrations and in HFIP: ··· HFIP, 0.2 mg/ml; --- 5 mg/ml; ·---· 0.5 mg/ml; — 0.2 mg/ml.

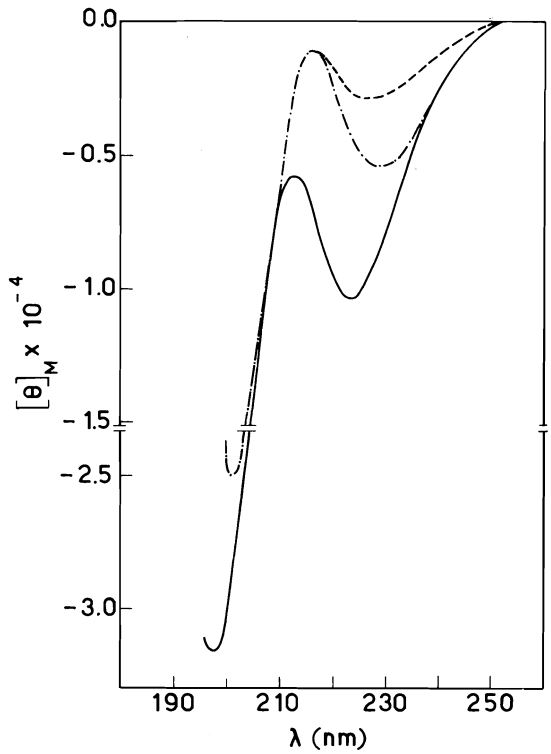

FIG. 2. Circular dichroism of Z-Val-$(Ala)_3$-OEt at 25°C in: — TFE; ·---· EG/TFE (90:10 v/v); --- H_2O/TFE (90:10 v/v). Peptide concentration was 0.2 mg/ml.

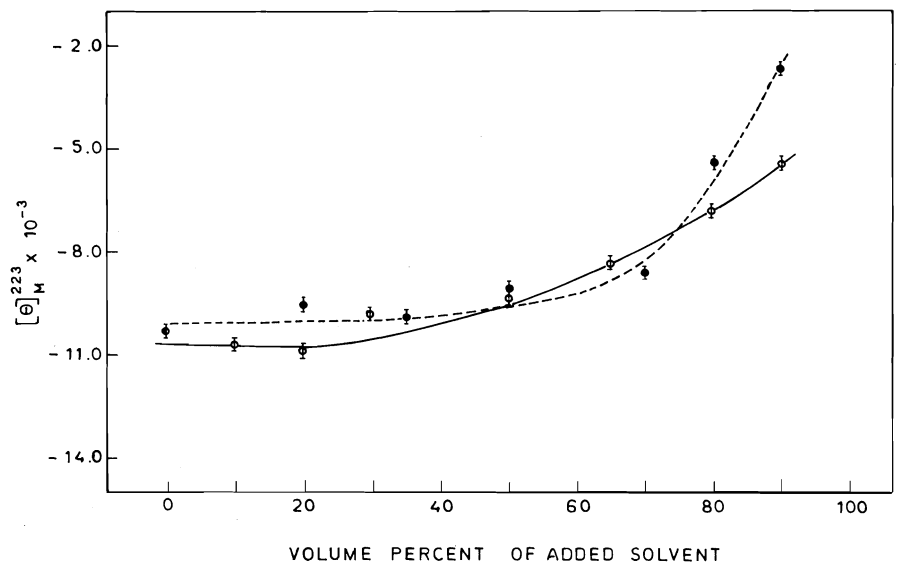

FIG. 3. Plot of $[\theta]_M$ at 223 nm of Z-Val-$(Ala)_3$-OEt at 25°C *vs.* percentage (v/v) of EG (○) in TFE and H_2O (●) in TFE. Peptide concentration was 0.2 mg/ml.

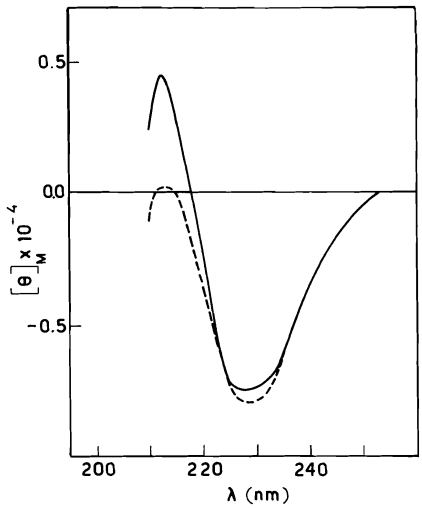

FIG. 4. Circular dichroism of Z-Val-$(Ala)_3$-OEt at 25°C in: — TFE/dioxane (30:70 v/v); --- TFE/dioxane (50:50 v/v). Peptide concentration was 0.2 mg/ml.

conditions looks similar to the one which is believed to be typical of β-bends (14). According to these results, we propose that on decreasing the solvent polarity, and therefore its hydrogen-bonding potential, the tetrapeptide is undergoing a conformational transition so that a significant fraction of the total population of its conformations exists in a chain-reversal (β-bend) conformation.

It is to be noted that, in principle, the presence of the phenyl ring in the protecting group could affect the 210 nm region of the cd spectrum. Therefore, we recorded cd spectra in TFE–dioxane mixtures in the region 250–300 nm in order to detect possible dichroic bands associated with the aromatic chromophore.

As a matter of fact, no such bands were observed even using long optical paths and sensitivities at the limit of the instrument adopted. Accordingly, we are confident that the cd changes observed in the far uv are not attributable to solvent-dependent aromatic bands.

The ir spectrum (Fig. 5) of the tetrapeptide in KBr shows the frequencies of Amide A, B, I, II, and V bands positioned at 3320, 3080, 1685 and 1630, 1530, and 690 cm^{-1}, respectively. All bands but one are fully consistent with the presence, in the solid state, of the antiparallel β-structure. The exception is represented by the Amide A frequency at 3320 cm^{-1} which is about 40 cm^{-1} higher than that observed for the anti-

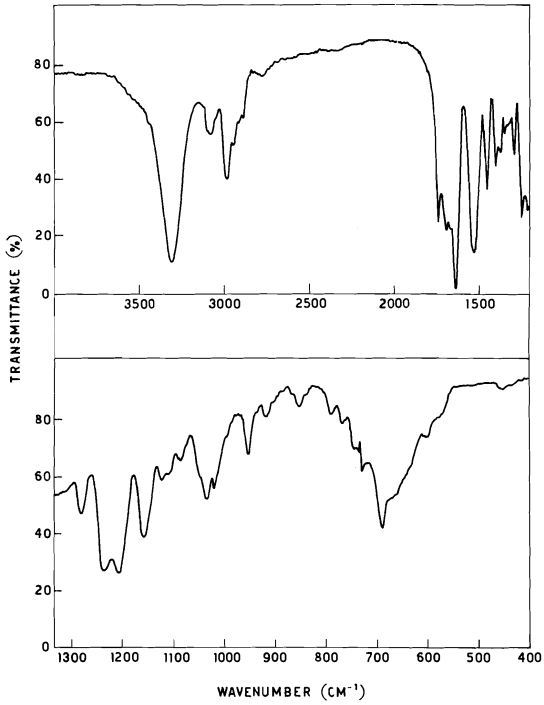

FIG. 5. Infrared spectrum of Z-Val-$(Ala)_3$-OEt in KBr pellets.

parallel β-form (15). In principle this higher NH-stretching frequency of hydrogen-bonded amides could arise from unusually long and/or very nonlinear hydrogen bonds. Peptides assuming 'bent' or 'folded' forms with intramolecular hydrogen bonds, show high Amide A frequencies (16, 17), probably because the groups involved are sterically prevented from adopting the optimal angles for hydrogen bond formation (15). In light of this, we suggest that for the Z-Val$(Ala)_3$-OEt chain folding is also occurring in the solid state with association of the molecules in an antiparallel fashion. A possible model would be the side-by-side aggregation postulated for protected tetraalanine at high concentrations in chloroform (6).

Solubilities of the silver halides in propylene carbonate mixtures with bis(trifluoroethyl)sulfite

MARK SALOMON

Power Sources Technical Area, U.S. Army Electronics Technology and Devices Laboratory (ECOM), Fort Monmouth, NJ., U.S.A. 07703

Received January 5, 1977

MARK SALOMON. Can. J. Chem. **55**, 2499 (1977).

The complex solubilities of AgCl, AgBr, and AgI have been measured in several mixed solvents containing propylene carbonate and bis(trifluoroethyl)sulfite. The results indicate that a large inductive effect destabilizes the solvation of silver ions whereas the halide ions appear to be stabilized by coordination with the sulfinyl sulfur. Several physio-chemical properties of pure bis(trifluoroethyl)sulfite are reported.

MARK SALOMON. Can. J. Chem. **55**, 2499 (1977).

On a mesuré les solubilités de complexes de AgCl, AgBr et AgI dans plusieurs solvants mixtes contenant du carbonate de propylène et du sulfite de bis(trifluoroéthyle). Ces résultats indiquent qu'un effet inductif important déstabilise la solvatation des ions argent alors que les ions halogénures semblent être stabilisés par une coordination avec le soufre du groupe sulfinyle. On rapporte plusieurs propriétés physicochimiques du sulfite de bis(trifluoroéthyle) à l'état pur.

[Traduit par le journal]

Introduction

In previous papers (1) the complex solubilities of the silver halides, AgX (X = Cl, Br, I), were studied in a series of pure and mixed aprotic, sulfur-containing solvents. The reactions studied were

$$[1] \qquad AgX \rightleftharpoons Ag^+ + X^- \qquad K_{s0}$$

$$[2] \qquad Ag^+ + nX^- \rightleftharpoons AgX_n^{1-n} \qquad \beta_n$$

$$[3] \qquad AgX + X^- \rightleftharpoons AgX_2^- \qquad K_{s2}$$

The previous studies were concerned with the effect of solvent composition on the magnitudes of these equilibrium constants which, in turn, were used to interpret the nature of the ion–solvent interactions. For example, the magnitude of the solubility product, K_{s0}, is determined by the solvent interactions with Ag^+ and X^- whereas the magnitude of K_{s2} is governed by the relative interactions between the solvent and the ions X^- and AgX_2^-. In those solvents containing a sulfinyl, sulfonyl, and sulfenyl atom, the magnitude of K_{s2} was, in part, found to be dependent upon the electronic configuration at the sulfur which reflects the nature of the solvent–X^- interaction. The magnitudes of K_{s0} and K_{s2} could also be used to determine the specific solvent–Ag^+ interaction: *i.e.* whether Ag^+ interacts with a sulfur or with an oxygen atom.

The present paper is an extension of our related studies (1), being concerned with the solubilities of the silver halides in several mixed solvents composed of propylene carbonate (PC) and bis(trifluoroethyl)sulfite, $(CF_3CH_2O)_2SO$. One of the major aims of this study is to determine the effect of fluorine substitution on the above equilibria. Another objective is to determine some of the important physio-chemical properties of bis(trifluoroethyl)sulfite which shows promise as a new dipolar aprotic solvent for use in the study of medium effects.

Experimental Section

(a) Materials

Tetrapropylammonium perchlorate, chloride, bromide, and iodide (Pr_4NClO_4, Pr_4NCl, Pr_4NBr, and Pr_4NI) were purified by the methods described by Mann (2). Purified PC was used as received from Burdick and Jackson Laboratories. Bis(trifluoroethyl)sulfite was prepared by a method similar to that described by DeMarco *et al.* (3). A 1:1 alcohol:amine adduct was prepared at −10 to 0°C from 2,2,2-trifluoroethanol and triethyl amine. A stoichiometric quantity of $SOCl_2$ was condensed, under vacuum, onto the adduct at −196°C and the mixture was allowed to warm to room temperature overnight. The sulfite ester was distilled at ~1 Torr and 100–130°C and collected in an acetone/CO_2 bath. The middle 3/5 fraction was retained and placed over purified Hg and stirred for 24 h to insure that any monosubstituted sulfite, $CF_3CH_2OS(O)Cl$, had further reacted to yield the desired product (3, 4). The solvent was fractionated two more times from activated alumina and the middle 3/5 fraction retained in each step. A typical ele-

mental analysis, performed by PCR, Inc., gave the following. *Anal.* calcd.: C 19.52, H 1.64, S 13.00, F 46.30; found: C 19.91, H 1.98, S 13.05, F 46.52. All solvents and salts were stored in an argon-filled dry box (O_2 and H_2O content $\leq$ 1 ppm).

(b) Measurements of Dielectric Properties

The static dielectric constants of pure $(CF_3CH_2O)_2SO$ and its mixtures with PC were measured by the comparison method (5) at a fixed frequency of 2 MHz. The cell, provided by Payne (6), consisted of concentric brass electrodes threaded onto a Teflon base which also formed part of a water jacket. The cell capacitance was measured by a substitution method using a General Radio 1606-B bridge and Type 722-D and 1422-ME precision variable capacitors. The cell constants were determined from measurements made with air (7), benzene (8), PC (6), and dimethylsulfoxide (9). A least-squares fit gave

$$C = 5.626\varepsilon + 2.952 \ (15°C)$$
$$C = 5.634\varepsilon + 2.980 \ (25°C) \quad [4]$$
$$C = 5.657\varepsilon + 2.957 \ (35°C)$$

where C is the measured capacity and ε is the static dielectric constant.

The dipole moment of pure $(CF_3CH_2O)_2SO$ was determined at 25°C with the above apparatus by measuring the dielectric constants of five benzene solutions in which the mole fraction of $(CF_3CH_2O)_2SO$ was varied from 0.0028 to 0.2060. The dipole moment, μ_0, was calculated from the limiting molar polarization of the solute as described by Smyth (10). The Kirkwood "g" factor was calculated from the Kirkwood–Frölich equation (11)

$$[5] \quad g = \frac{9kT}{4\pi n_2 \mu_0} \times \frac{(2\varepsilon + \varepsilon_\infty)(\varepsilon + 2)}{3\varepsilon(\varepsilon_\infty + 2)} \times \left\{\frac{\varepsilon - 1}{\varepsilon + 2} - \frac{\varepsilon_\infty - 1}{\varepsilon_\infty + 2}\right\}$$

where all terms have their usual significance. The high frequency dielectric constant, ε_∞, was calculated from the optical index of refraction assuming a 10% increase in the total induced polarizability between optical and microwave frequencies (*e.g.* see ref. 12): *i.e.* $\varepsilon_\infty = 1.10n_D^2$. Refractive indices, n_D, were measured with a Bausch and Lomb model 8006 refractometer. Temperature control for all measurements was $\pm$0.1°C.

(c) Solubility Studies

The solubility and stability constants were obtained from potentiometric titration data as described previously (1). Three mixed solvents were studied in which the mole fractions of $(CF_3CH_2O)_2SO$, χ_{-so}, in PC were 0.3483, 0.6831, and 0.7960. Studies were not carried out in pure $(CF_3CH_2O)_2SO$ because $AgClO_4$ is not soluble to any appreciable extent in this solvent. $AgClO_4$ was only moderately soluble in the solution where χ_{-so} = 0.7960 and which therefore necessitated the reduction of its concentration. All solutions were of a constant ionic strength, μ: for χ_{-so} = 0.3483, 0.6831, and 0.7960, respectively, μ = 25.0, 10.0, and 5.0 mM (millimolar). The titrant was therefore either 25.0, 10.0, or 5.0 mM $AgClO_4$ in the respective solvent and the titrate was a solution of $Pr_4NX + Pr_4NClO_4$, the latter salt being used to maintain the required ionic strength. The titration cell is identical with the one described earlier (1) and consisted of an etched, coiled silver indicator electrode and a silver wire reference electrode in 25.0, 10.0, or 5.0 mM $AgClO_4$: the reference electrode was separated from the titrate by a salt-bridge. The cell and 10 ml of titrate was fitted with a Gilmont 2 ml microburet containing the titrant, removed from the dry box, and placed in a water bath at 25 $\pm$ 0.1°C. Magnetic stirring was maintained throughout the titration and all emf's were measured with a Fluke Model 8800A digital multimeter.

Results

Several physio-chemical properties of pure $(CF_3CH_2O)_2SO$ and its mixtures with PC are given in Table 1. The data for the χ_{-so} = 0.7960 solution were interpolated either graphically or by a power series least-squares fit. All other data are based upon experimental measurements. Although pure $(CF_3CH_2O)_2SO$ has a relatively low dielectric constant, it has a relatively large dipole moment ($\mu_0 = 2.55 \times 10^{-18}$ esu-cm) and a Kirkwood "g" value of 1.4 which indicate that the liquid is moderately associated and that the O—S(O)—O pyramidal angle is substantial. The temperature dependence of ε for pure $(CF_3CH_2O)_2SO$ is given by

$$[6] \quad \varepsilon = \frac{5070.89}{T} - 6.604(\pm 0.06)$$

where the temperature is in K.

The stability constant, β_2, was calculated by by an iterative least-squares technique (1) and the standard deviation of β_2 was calculated by Sillén's pit-mapping method (13). The K_{s0} values are averages calculated by a Newton–Raphson iteration for each point in the saturated solutions. Electromotive force values were generally stable to within $\pm$0.5–1.0 mV and formal potentials had standard deviations of $\pm$2–3 mV. Attempts to generate the equilibrium constants β_1 and β_3 by the least-squares method failed (*i.e.* convergence of the iterations was not achieved) and it was therefore assumed that they are of minor significance. The results for β_2, K_{s0}, and K_{s2} are given in Table 2. The equilibrium constants in Table 2 were adjusted to the state for zero ionic strength (Table 3) by using the Davies equation (14) to calculate the activity coefficients:

TABLE 1. Properties of PC/$(CF_3CH_2O)_2SO$ solutions at 25°C*

χ_{-SO}	M_{-SO}	n_D	d	ε	A
0.3483	3.1428	1.3782	1.3738	39.71	1.4165
0.6831	5.0640	1.3510	1.4861	21.52	3.5506
0.7960	(5.56)	(1.343)	(1.516)	(18.0)	(4.642)
1.0	6.3495	1.3308	1.5628	10.33	10.676

*χ_{-SO} and M_{-SO} are the mole fraction and molarity, respectively, of $(CF_3CH_2O)_2SO$ in solution; n_D is the optical refractive index measured at the sodium D line; d is the density in g/ml; A is the Debye–Hückel constant ($\ell^{1/2}$ mol$^{-1/2}$); data in parentheses are extrapolated values.

[7] $$\log y_{\pm} = \frac{-A\mu^{1/2}}{1 + \mu^{1/2}} + 0.3A\mu$$

Included in Table 3 are corresponding data for pure PC (16) and $(CF_3CH_2O)_2SO$, the latter obtained by a non-linear extrapolation. The standard deviations for the mixed solvents are not included in Table 2 but are expected to be about 10% higher than those in Table 2: the standard deviations in pure $(CF_3CH_2O)_2SO$ are however much larger (±2 log units), because of the non-linear extrapolations used to obtain these quantities.

In previous papers (1, 15), we have used the approximate extrathermodynamic assumption of

$$\Delta G_t^0(AgCl_2^-) = -\Delta G_t^0(AgBr_2^-)$$

to calculate the free energies of transfer of single ions from water to an organic solvent (ΔG_t^0(ion)). The ΔG_t^0(ion) values for the ions involved in the present study were calculated using this assump-

TABLE 4. Standard free energies of transfer of single ions from water to a nonaqueous solvent*

Solvent	ΔG_t^0(ion) (kcal/mol)					
	Ag^+	Cl^-	Br^-	I^-	$AgCl_2^-$	AgI_2^-
PC	5.5	8.7	5.9	1.0	1.3	−8.2
PC/$(R_fO)_2SO$ $\chi_{-SO} = 0.348$	7.5	4.6	3.7	1.6	1.0	−4.8
PC/$(R_fO)_2SO$ $\chi_{-SO} = 0.683$	10.9	4.6	3.5	1.9	1.6	−3.2
PC/$(R_fO)_2SO$ $\chi_{-SO} = 0.796$	13.2	5.6	4.0		1.0	
$(R_fO)_2SO$	22.5	6.8	4.0		1.0

DMSO	−8.9	10.0	6.6	2.8	1.7	−6.2
PC/THT $\chi_{THT} = 0.05$	−5.7	8.8	6.0	2.6	1.4	−5.0

*All data are based on molar units at 25°C. $(R_fO)_2SO$ = $(CF_3CH_2O)_2SO$; $(MeO)_2SO$ = dimethylsulfite; DMSO = dimethylsulfoxide; THT = tetrahydrothiophene.

tion and are presented in Table 4 along with those determined earlier (1).

Discussion

The data shown in Tables 3 and 4 reveal that the effects of $(CF_3CH_2O)_2SO$ additions to PC are to (*i*) greatly destabilize the energy of solvation of Ag^+ and (*ii*) to stabilize the energy of solvation of the X^- ions. In several solvents containing a sulfur atom, the Ag^+ ion – solvent interaction energy is often stabilized by π-bonding which is, in part, evident from the magnitude of $\Delta G_t^0(Ag^+)$: *e.g.* for the transfer from water to dimethylformthioamide, dimethylsulfoxide, PC/SO_2 mixtures, $\Delta G_t^0(Ag^+)$ has values of −23.8, −8.9, and −3.0 kcal/mol, respectively (1, 17). In those aprotic solvents containing only C, H, and O, $\Delta G_t^0(Ag^+)$ values are generally positive (~5 kcal/mol) which indicates that the soft Ag^+ coordinates with a hard oxygen atom. Since the alkyl sulfite esters are pyramidal, Ag^+ coordination might be expected to occur at the soft basic S-center. However, as shown earlier, the large positive values of $\Delta G_t^0(Ag^+)$ suggest that coordination occurs at an oxygen due to the high (positive) charge on the sulfur (1*c*). The value of 22.5 kcal/mol for $\Delta G_t^0(Ag^+)$ is unexpectedly large in view of the value of 5 kcal/mol found for the transfer from water to dimethyl- and ethylenesulfite, and because the transmission of electronic effects through two σ-bonds are usually small. The result of fluorine substitution appears to primarily affect the electronic structure at the oxygens (rather than the sulfur as discussed below). The decrease in basicity of the oxygen produced by fluorine substitution (separated by two σ-bonds) has previously been reported by Parker *et al.* (17) who determined that $\Delta G_t^0(Ag^+) = 11.7$ kcal/mol for the transfer from water to 2,2,2-trifluoroethanol.

Concerning the nature of anion solvation, the present results show little or negligible differences in the S—X^- interaction between $(CF_3CH_2O)_2SO$ and $(CH_3O)_2SO$ or $(CH_2O)_2SO$. The data for the mixed solvents clearly indicate this ($\log K_{s2} \simeq -1$) whereas the data for pure $(CF_3CH_2O)_2SO$ suggest a decreased interaction ($\log K_{s2} \simeq 0$). The data for pure $(CF_3CH_2O)_2SO$ are, however, less reliable owing to the large errors (±2 log units) in $\log K_{s2}$ which resulted from the non-linear extrapolations. It is concluded that the interaction of halide ions with $(CF_3CH_2O)_2SO$ is, essentially, the same as that with the unsubstituted alkyl sulfites: *i.e.* the halide ions' interaction with the sulfinyl sulfur is augmented by π-bonding (*cf.* 1*c*).

Acknowledgments

The author would like to thank Dr. R. DeMarco for his advice in the preparation of $(CF_3CH_2O)_2SO$, and Dr. R. Payne for providing the dielectric cell.

The intramolecular hydrogen bond in some β-nitroalcohols. Chemistry of nitroalkanes. Part CXIX

E. LIPCZYŃSKA-KOCHANY AND T. URBAŃSKI

Chemical Faculty, Technical University (Politechnika), 00-662 Warszawa, Poland

Received December 29, 1976

E. LIPCZYŃSKA-KOCHANY and T. URBAŃSKI. Can. J. Chem. **55**, 2504 (1977).

New experimental evidence is given on the existence of an intramolecular hydrogen bond in β-nitroalcohols between the nitro and hydroxylic groups. The conclusion is based on examination of $n_a \rightarrow \pi^*$ and infrared absorption bands and nmr spectra.

E. LIPCZYŃSKA-KOCHANY et T. URBAŃSKI. Can. J. Chem. **55**, 2504 (1977).

Des nouvelles preuves sont fournis sur l'existence de la liaison hydrogène interne dans les β-nitroalcools entre les groupes nitrique et hydroxylique. La conclusion est basée sur l'examination de la bande d'absorption $n_a \rightarrow \pi^*$, spectres d'absorption infrarouge et spectres nmr.

Introduction

A suggestion on the existence of an intramolecular bond between the alcoholic and nitro groups in aliphatic β-nitroalcohols was given by one of the authors of the present paper and his co-workers between 1951 and 1959. The suggestion was based on the chemical reactivity of the compounds (1), on ultraviolet (2, 3, 6, 7) and infrared (4, 7) spectroscopy and on measurement of dipole moments (5). The latter substantiated the earlier work of Lumbroso and Lauransan (8).

At first the suggestion was met with sharp criticism (9). However a number of later papers (10–15) have supported the view of the existence of a weak hydrogen bond and the latter appears now to be accepted (16). In view of the weakness of the bond, it seemed desirable to collect more information by using different methods. A more detailed spectroscopic analysis is reported in the ultraviolet and infrared regions and by the nmr technique. We have examined 2-methyl-2-nitropropane-1-ol (**1**), its methyl ether (**8**), 2-alkyl-2-nitropropane-1,3-diols (**2–7**), and alcohols without the nitro group: 2-methylpropane-1-ol (**9**) and 2,2-dimethylpropane-1,3-diol (**10**).

Dipole moments were also measured and calculated and the results will be reported elsewhere (17).

Experimental

2-Methyl-2-nitropropane-1-ol (**1**) and 2-alkyl-2-nitropropane-1,3-diols (**2–7**) were prepared from the corresponding nitroalkanes and formaldehyde by known procedures (18). The methyl ether of 2-methyl-2-nitropropane-1-ol was obtained by methylation of the alcohol by means of methyl sulphate (19). 2-Methylpropane-1-ol (**9**) from the Eastman Kodak Company, Rochester (Spectro Grade), was dried over $MgSO_4$ and distilled. 2,2-Dimethylpropane-1,3-diol was prepared from isobutyl aldehyde and formaldehyde by a known method (20).

Benzene and dioxane were of analytical grade from E. Merck, Darmstadt and Xenon, Łódź, Poland, respectively. They were purified by the method described previously (21). Their densities at 20°C were 0.8740 g/cm^3 and 1.0337 g/cm^3, respectively. Carbon tetrachloride for spectroscopy made by Chemapol, Prague, Czechoslovakia was dried over P_2O_5. Hexane for spectroscopy UCB, Bruxelles, Belgium was dried over $MgSO_4$. Methanol for spectroscopy made by Chemapol, Prague, was used.

Ultraviolet spectra were measured with a VSU-2P spectrometer, Carl Zeiss, Jena. A hydrogen lamp was used as the source of uv light; measurements were taken every 1 nm. Series of solutions of various concentrations were

TABLE 1. Ultraviolet spectra: the intensity* and the wavelength of the $n_a \rightarrow \pi^*$ band

	Compound	In hexane		In CCl_4		In methanol		In dioxane	
		λ_{max}	ε_{max}	λ_{max}	ε_{max}	λ_{max}	ε_{max}	λ_{max}	ε_{max}

prepared for each compound and solvent. The results were extrapolated to infinite dilutions (Table 1). All extrapolations show plots of ε_{max} as linear functions of concentrations with extrapolation to zero concentrations. The compound **8** does not show change of ε_{max} with the concentration. All other compounds show a fall of ε_{max} with decreasing concentration. The fall of ε_{max} is particularly prominent in diols (**2–7**), in non-polar solvents. The slope of the linear dependence of ε_{max} on concentration is 0.3640–0.4663 for diols in non-polar solvents. Typical absorption curves of diols and monols are presented in Figs. 1 and 2, respectively. The ether **8** gave a curve similar to that of the monol (Fig. 2).

Infrared spectra were taken with a Perkin-Elmer PE-577 spectrometer in cells of NaCl in the region of $\nu_{s(OH)}$. Solutions in carbon tetrachloride were made to concentrations 0.005–0.003 mol/ℓ. Sharp peaks, broader peaks, and shoulders could be determined to the accuracy of ± 1 cm^{-1}, ± 2 cm^{-1}, and ± 4 cm^{-1}, respectively. The data are collected in Table 2 and the typical absorption spectra at different concentrations are given in Figs. 3 and 4.

Nuclear magnetic resonance spectra were determined with a 100 MHz JEOL spectrometer in carbon tetrachloride using tetramethylsilane as internal reference. Solutions of various concentrations were the same as used in infrared spectroscopy. Values of frequencies were taken from the frequency meter with an accuracy of ± 0.05 Hz. The values of chemical shifts of OH protons were extrapolated to infinitive dilution by the method of least squares. The accuracy of the chemical shift measurements was of the order of 0.3 Hz. The data are collected in Table 2, some parts of the spectra are shown in Figs. 5, 6 and a diagram of the extrapolation of δ for compound **1** at various temperatures in Fig. 7. Similar linear dependence of δ on concentration were observed with compounds **2–7**. The spectral parameters were obtained from the experimental transitions using the iterative procedure of the LAOCOON program (22).

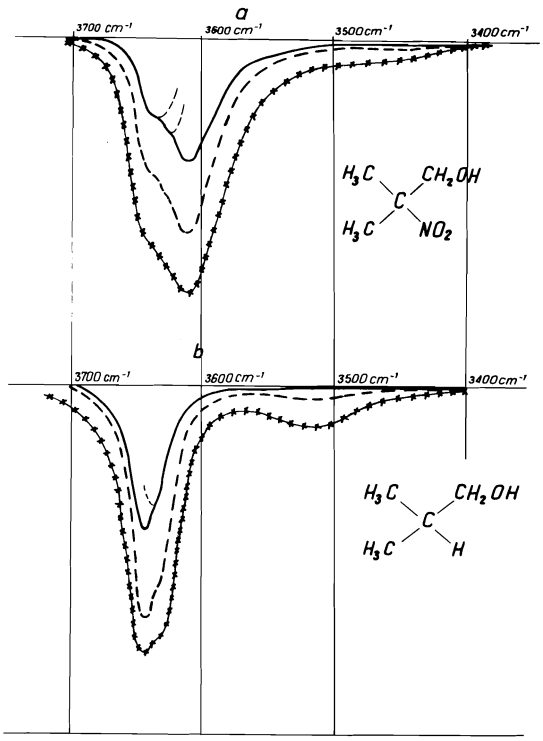

FIG. 3. Infrared spectra of 2-methyl-2-nitropropane-1-ol (**1**) and 2-methylpropane-1-ol in the $\nu_{S(OH)}$ regions; $d = 1$ cm. (*a*) — $c = 0.00428$ mol/ℓ, --- $c = 0.00925$ mol/ℓ, × × × $c = 0.0180$ mol/ℓ; (*b*) — $c = 0.00540$ mol/ℓ, --- $c = 0.01650$ mol/ℓ, × × × $c = 0.0256$ mol/ℓ.

Discussion

Ultraviolet Spectra

The previous finding (2, 6) on the shape of the curves of nitroalcohols in aqueous solutions is now confirmed: diols **2** to **7** do not show definite maxima (Fig. 1) but only well pronounced shoulders. On the contrary, the monol (**1**) (Fig. 2) shows a maximum. The spectra of the aqueous solution of its methyl ether (**7**) could not be taken owing to a very low solubility of the substance in water.

The molar absorption coefficients of the maxima in ethanol are approximately the same for all the compounds. The molar absorption coefficients for 2-methyl-2-nitropropane-1-ol (**1**) and its methyl ether (**7**) in dioxane are equal. If the hydrogen bond in this nitroalcohol exists, it seems to be weak and readily broken by dioxane and hence the shape of the absorption of both compounds is identical.

The absorption of nitrodiols (**2–7**) in dioxane is much lower compared to that of **1** and **8**, and approximately equal to the absorption of nitrodiols in methanol. No change in the intensity of the $n_a \rightarrow \pi^*$ absorption band in the spectra of these nitrodiols measured in CCl_4 and dioxane were observed. In carbon tetrachloride the absorption coefficients of nitrodiols (**2–7**) and of monol (**1**) were equal. Considerable weakness of the absorption band in the spectra of the 2-methyl-2-nitropropane-1-ol (**1**) and nitrodiols (**2–7**) in carbon tetrachloride as compared to that of the methyl ether (**8**) of 2-methyl-2-nitropropane-1-ol were observed. A comparison of the spectra of **1** and **8** in hexane also shows the weakness of the $n_a \rightarrow \pi^*$ absorption band of the alcohol **1**.

The presence of hydroxyl groups causes a bathochromic shift of the absorption band as compared to the spectra of the ether **8**. For all compounds examined we observed the following influence of the solvent on the wavelength of the $n_a \rightarrow \pi^*$ absorption band:

$$\lambda_{Methanol} < \lambda_{Dioxane} < \lambda_{Hexane} < \lambda_{CCl_4}$$

The change of the absorption coefficients of **1**

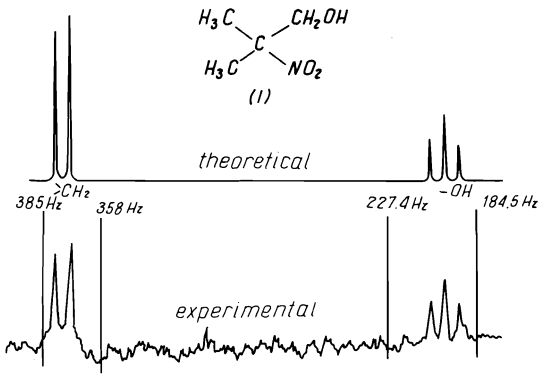

FIG. 5. Part of the nmr spectrum (experimental and theoretical) of 2-methyl-nitropropane-1-ol (**1**). c = 0.008 mol/ℓ; temperature +32°C. $\delta(1)$ = 376.42 Hz, $J(1,2)$ = 0.00 Hz; $\delta(2)$ = 376.42 Hz, $J(1,3)$ = 7.23 Hz; $\delta(3)$ = 200.00 Hz, $J(2,3)$ = 7.23 Hz.

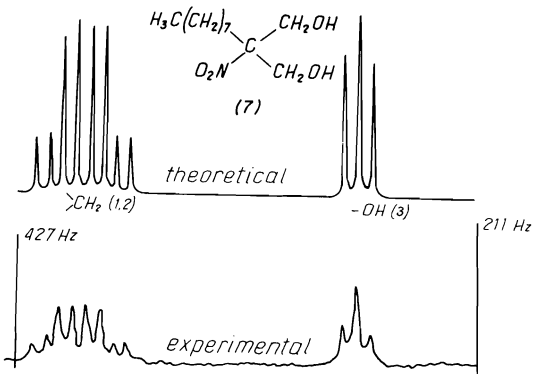

FIG. 6. Part of the nmr spectrum (experimental and theoretical) of 2-octyl-2-nitropropane-1,3-diol (**7**); c = 0.020 mol/ℓ, temperature +32°C. $\delta(1)$ = 408.00 Hz, $J(1,2)$ = −12.54 Hz; $\delta(2)$ = 385.38 Hz, $J(1,3)$ = +6.96 Hz; $\delta(3)$ = 230.50 Hz, $J(2,3)$ = +6.51 Hz.

and **8** with dilution gives an insight into the possible influence of the solvent upon the internal hydrogen bond. It seems that in polar solvents such as methanol and dioxane, the bond is broken whereas in non-polar solvents (carbon tetrachloride and hexane) the bond exists. This is particularly evident when comparing the ε_{max} values of the alcohol **1** with that of its ether **8**.

As noted above, the decrease of ε_{max} with dilution was particularly prominent in diols, when carbon tetrachloride and dioxane were used, whereas in methanol and water the decrease was less pronounced. This was probably due to a

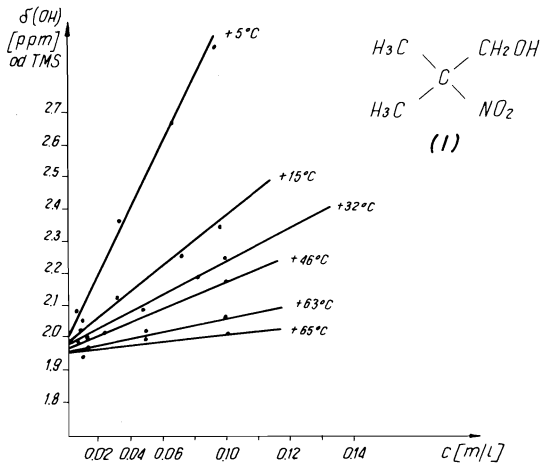

FIG. 7. Extrapolation of $\delta_{(OH)}$ of 2-methyl-2-nitropropane-1-ol (**1**) to infinite dilution at various temperatures.

competition between the intermolecular hydrogen bond in these solvents and the solute containing hydroxylic groups.

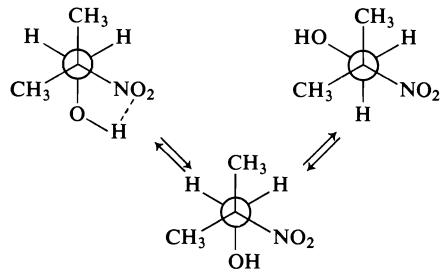
Infrared Spectra

All alcohols examined in solution show a band and a shoulder at frequencies between 3646 and 3628 cm^{-1}. This is in agreement with the fact already recorded in the literature for *all* primary and secondary alcohols in solutions with the exception of methanol. It is assigned to the existence of *two conformers* with "free" unbonded OH groups (23, 24).

With regard to the infrared spectra of β-nitroalcohols the existing data (4, 7, 9–16) are not fully consistent, although most of the authors admit the presence of the intramolecular hydrogen bond between the nitro and hydroxylic groups. Various conformations seem to be stabilized by internal hydrogen bonds as pointed out by Schleyer and co-workers (11) and Giguère and Tokiji (14).

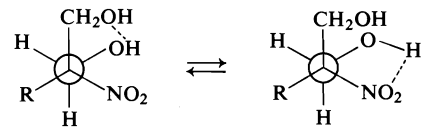
Two series of experiments were carried out to elucidate the role played by the nitro group in the formation of the hydrogen bond: (*1*) Comparative examination of spectra of 2-methylpropane-1-ol (**9**) and its derivative containing the nitro group (**1**). (*2*) Examination of spectra of the diol (**10**) and its derivatives and homologues with a nitro group (**2** to **7**).

The spectrum of 2-methylpropane-1-ol shows a maximum at 3646 cm^{-1}, a shoulder at 3636 cm^{-1}, and a broad, low intensity band at 3520 cm^{-1} which disappeared on dilution. The latter is due to OH groups bonded through intermolecular hydrogen bonds. The former are two bands which should be assigned to two conformers of the monomer. The 2-nitroderivative (**1**) shows a main peak at 3612 cm^{-1} and two shoulders: 3640 and 3632 cm^{-1}. The former is probably produced by the OH group internally bonded to the NO_2 group and the latter by "free" (unbonded) OH groups. Both shoulders should be assigned to two conformers in agreement with existing views. An equilibrium is suggested between "bonded" and "unbonded" forms as shown on Scheme 1.



SCHEME 1

Comparison of the spectra of the diols gives a clearer picture. In Fig. 4 the difference can be seen in the spectra produced by the presence of the nitro group. Diol (**10**) shows two maxima 3642 and 3550 cm^{-1}, whereas all diols with the nitro group (**2–7**) give two maxima: at 3606 and 3560 cm^{-1} and a shoulder at 3636 cm^{-1}. The maxima at about 3550 cm^{-1} are clearly due to the internal hydrogen bonds between two OH groups, whereas the main peak at 3642 cm^{-1} and the shoulder at 3636 cm^{-1} in spectra of diol (**10**) and nitrodiols (**2–7**) respectively, are most likely produced by "free" (unbonded) OH groups. Consequently a broad maximum at 3606 cm^{-1} in (**2–7**) should be assigned to the hydroxyls bonded with the nitro group (Scheme 2).



SCHEME 2

We did not examine the bands of the nitro group. It was shown earlier (4) that the frequencies of the nitro group are unchanged under the action of hydrogen bonds.

Nuclear Magnetic Resonance Spectra

There is a rather prominent influence of the presence of the NO_2 group in alcohols on the

chemical shift. The chemical shifts (δ) of protons of the hydroxyl groups of monohydroxylic alcohols and diol (**10**) are 0.5–0.8 and 1.56 ppm, respectively. The nitro group increases the value of $\delta_{(OH)}$ to 1.990 and 1.995 ppm in monohydroxylic nitroalcohols (**1**) and nitrodiols (**5–7**), respectively. This is in agreement with findings already published on the nmr spectra of nitrophenols (26–29) where the chemical shift of the OH proton was brought to considerably lower values of τ (ppm), *i.e.* higher values of δ (ppm) by virtue of the intramolecular hydrogen bond.

Received December 31, 1976

PAUL FRANCIS ALEWOOD, MICHAEL BENN, JOHN WONG, and ALAN J. JONES. Can. J. Chem. **55**, 2510 (1977).

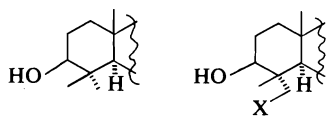
Thermolyses of the azidoformate derivatives of 1,1,4a-trimethyl-*trans*-decalin-2β-ol, lanostanol-3β, and Δ^8-lanosten-3β-ol yield the perhydro-1,3-oxazin-2-one products of nitrene insertion into the adjacent α-oriented methyl groups, as well as oxazolidinones and ketones.

PAUL FRANCIS ALEWOOD, MICHAEL BENN, JOHN WONG et ALAN J. JONES. Can. J. Chem. **55**, 2510 (1977).

La thermolyse des dérivés azidoformates du triméthyl-1,1,4a décalinol-2β *trans*, du lanostanol-3β et du Δ^8-lanostenol-3β conduit à des produits perhydrooxazin-1,3 ones-2 provenant d'une insertion de nitrène dans les groupes méthyles adjacents orientés en α, ainsi qu'à des oxazolidinones et à des cétones.

[Traduit par le journal]

We describe here (1) the results of a study directed towards achieving the *in situ* functionalization of the 4α-methyl group in 4,4-dimethyl-3β-ol-5α-steroids, *i.e.* the transformation **1** → **2**.



1 **2**

A reaction of this type is known to occur during the biosynthesis of cholesterol from lanosterol, where the oxidative removal of the geminal methyl groups from ring A involves an initial hydroxylation of the 4α-group (2). The same reaction is presumably also involved in the biosynthesis of such other triterpenes as 23-hydroxy betulin (3) from betulin, and hederagenin (4) from β-amyrin.

These biological oxidations might plausibly be considered to involve complexing of the substrate with a mixed-function oxidase through a 3β-hydroxy group – metal cation interaction, with the 4α-methyl group held in position for attack by an oxidant also complexed with the metal ion. However, some exploratory experiments directed along these lines, employing conditions similar to those recently described by Groves and van der Puy (5), were unpromising, so we decided to concentrate upon achieving the functionalization in a 'non-biological' way.

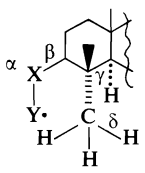
The bulk of functionalizations of 'remote', chemically unactivated sites have been achieved by intra-molecular[2] radical abstraction reactions: a radical is generated, abstracts a hydrogen atom from a geometrically favoured position, and thus produces a carbon radical which is functionalized in some trapping reaction (6).

The 3β-hydroxy function of **1** represents an obvious and attractive anchor-point for setting up a system to give an intramolecular attack on the C-4 methyls, but since the abstraction reactions are known to strongly favour attack on δ-located hydrogens (via a six-membered cyclic transition state) (6), this would require modification of **1** to set up a system like **3**.

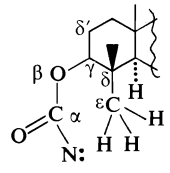
We considered such possibilities, but were impressed by the observation that azidoformates could be decomposed thermally or photolytically to yield nitrenes, which could then un-

[1]A preliminary account of this work has been published in ref. 1*a*, and was presented, in part, at the 10th International Symposium on the Chemistry of Natural Products, IUPAC, Dunedin, N. Z., 1976. See also ref. 1*b*.

[2]Intermolecular radical abstraction reactions favour attack on tertiary sites and are thus in any case not suited to methyl group functionalization.

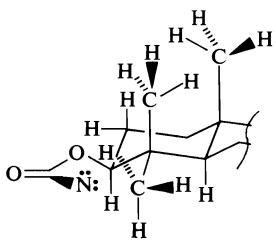


3

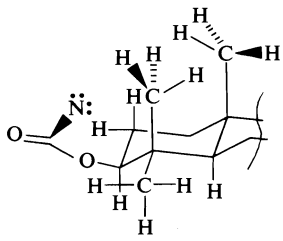


4

dergo intramolecular insertion reactions into accessible C_δ—H bonds to an extent that compared favourably with insertion into C_ε—H bonds. Indeed, as recounted earlier (7), we found that we could establish conditions for the thermolysis of acyclic azidoformates in which the yields of the tetrahydro-1,3-oxazin-2-ones (ε-insertion products) exceeded those of the oxazolidin-2-ones (δ-insertion products). Thus it appeared reasonable to expect the nitrene **4** to yield products arising from insertion into the methyl groups, as well as into the C(2)—H bonds (δ′-insertion). Furthermore it seemed likely that non-bonded interactions should disfavour conformations leading to attack on the 4β-methyl group (*cf.* **5** *vs.* **6**), and similarly (though less clearly) that insertion into the equatorial $C_{2\alpha}$—H bond should be preferred over the axial $C_{2\beta}$—H.



5

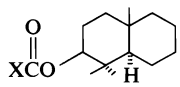


6

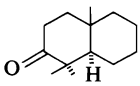
These considerations, together with the attractiveness of the ready preparation of azidoformates from alcohols via the corresponding chloroformates, induced us to investigate the thermolysis of **1**-azidoformates as a route to 4α-methyl functionalized products.

Thermolysis of 1,1,4a-trimethyl-*trans*-decalin-2β-yl azidoformate (**7**) in carbon tetrachloride, followed by column chromatography, yielded a trace of the carbamate **8**, some ketone (**9**), and two other products (homogeneous by tlc analysis) *A* and *B* which were identified as the oxazolidinone **10** and the tetrahydro-1,3-oxazin-2-one **11** on the basis of the following evidence.

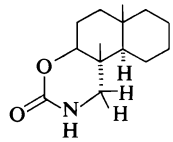
The mass spectra of both compounds revealed an apparent molecular ion at *m/e* 237 amu which was proven to have composition $C_{14}H_{23}NO_2$ by high-resolution mass measurements. Among the differences in their mass spectra, that of *A* contained a prominent ion at *m/e* 178 amu, corresponding to the loss of $CHNO_2$, while instead of this in the spectrum of *B* there was an ion at 164 amu corresponding to the loss of $C_2H_3NO_2$. The infrared spectrum of *A* contained a strong absorption at 1750 cm^{-1}, while



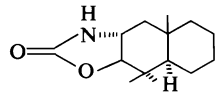
7 X = N_3
8 X = NH_2



9



11



10

for *B* this appeared at 1700 cm^{-1}; and the ^{1}Hmr spectrum of *A* contained signals for three methyl groups, while that for *B* had only two. Thus we concluded that *A* was **10** and *B* was **11**. The ^{13}Cmr and 270 MHz ^{1}Hmr evidence which substantiated these conclusions and provided proof for the 4α-methyl functionalization, as well as the stereochemistry of the oxazolidinone – ring A fusion, is described below.

Similarly we thermolyzed lanostan-3β-yl azidoformate (**12**) and lanost-8-en-3β-yl azidoformate (**13**) and obtained from them products whose mass, infrared, and 100 MHz ^{1}Hmr spectra were consistent with their formulation as oxazolidin-2-ones (**14** and **16**) and tetrahydro-1,3-oxazin-2-ones (**15** and **17**). The 3-ketones analogous to **10** were also usually obtained, a matter to which we return later.

[a]The numbering system employed for these compounds in this table is analogous to that conventionally used for triterpenes.

In order to check these assignments and, in particular, to attempt to determine which methyl group has been functionalized, we turned to ^{13}Cmr (^{13}C magnetic resonance) investigations. The ^{13}C chemical shifts of 1,1,4α-trimethyl-*trans*-decalin-2β-ol, lanostan-3β-ol, and the compounds **10–12**, **14**, and **15** are given in Table 1. *Note that for the convenience of presentation in the table and intercomparison between the decalin and triterpenoid derivatives we have, in this table, numbered the carbon sites in the decalins to correspond with those of the analogous sites in the triterpenes.* The chemical shifts of lanostan-3β-ol have been assigned previously, though in the recent literature some uncertainty in the assignments given for the carbon atoms C-5 and C-9 and C-12, C-15, and C-16 has been implied (8–10). In the present work we have established the assignment of the carbons C-5 and C-9 and have followed the assignments recently determined by Lukacs and co-workers (9) for the carbons C-12, C-15 and C-16 in a series of cycloartenol derivatives in which simple monosubstituent effects facilitated identification. A variety of conventional techniques were used to assign individual carbon atoms to specific resonances in all the compounds studied, including gated decoupling (11) and modulated off-resonance (12) methods and chemical shift additivity relationships (8–10, 13) as particularly applied to structurally related compounds. The chemical shifts of some of the methyl groups (excluding C-29 and C-30) must remain tentative, though we have followed the order established by Knight (8) for these carbon atoms.

The methyl ^{13}C chemical shifts in 1,1,4α-trimethyl-*trans*-decalin-2β-ol and **10** help characterize the assignments in the more complex triterpenes. That is, the shift of the axial methyl group (C-30 ≡ 4β-CH_3) (14.5 ± 1 ppm) is

13 ppm to high field of the equatorial methyl group (C-29 ≡ 4α-CH_3) (27.6 ± 0.4 ppm), the consequence of the well-characterized 1,3-*syn*-axial or γ-steric effect (14). This shift difference was recently used most effectively in revising the structure of the related tetracyclic triterpenoid *Buxus* alkaloids (15). The methyl group functionalization in the oxazinones **11** and **15** is established by the observation that the equatorial C-29 resonance shifts to 54 ± 0.4 ppm now representing a substituted methylene group, while the slightly high field of the axial C-30 methyl carbon (12 ppm ± 0.4) is attributable to steric effects in both of these compounds. The *trans*-stereochemistry of the junction of the heterocyclic and A rings in **11** and **15** is also established by the high field shift (compared to the corresponding alcohols) of the C-4 carbon, −4.5 and −2.7 ppm, respectively, in these compounds (15). The γ-effect (−1.7 ppm) observed at C-5 in **11**, and **15** (−2.8 ppm) not only indicates substitution at the 4α-methyl site, but also confirms the assignment of the carbon C-5 in contrast to C-9 (8–10) in the triterpenoid systems. Note that formation of the tetrahydrooxazinone ring is also characterized by the down-field shift (3.4 ppm) at C-3 in both **11** and **15**.

The oxazolidinone structures **10** and **14** were further supported by the typical ^{13}C substituent shifts (compared to the precursor alcohols) at the α-carbon C-2 (25 ppm) and the β-carbons C-1 and C-3 (4 and 12.8 ppm).[3] The α-shift resembles that resulting from *exo*-amino substitution in norbornane (25.3 ppm) (16), but differs from that in the corresponding *endo*-derivative (23.3 ppm) (16). It is tempting to use this data to invoke the *trans*-stereochemistry at the junction of the heterocyclic and A rings. Particularly since if the alternative *cis*-stereochemistry were adopted, large γ-shieldings would be expected at C-4 and C-10 (*cf.* ref. 17): no such shifts are observed. Fortunately we did not need to rely on this argument for analysis of the 270 MHz proton spectrum of the oxazolidinone **10** established the *trans*-stereochemistry of the ring fusion: the H-3 proton signal exhibited a typical ABXX′ pattern at 3.82 ppm. Equivalent *trans*-couplings (10.8 Hz) (18) with the axial H-2 and H-4 protons, and a smaller *cis*-coupling (3.4 Hz) with the equatorial H-4 proton, give rise to this pattern. The magnitude of the coupling between H-3 and H-2 thus indicates the *trans*-stereochemistry of this oxazolidinone. Unfortunately, in the case of **14** and **16** overlapping C-2 and C-3 proton signals could not be resolved, even at 270 MHz, and thus our tentative assignment of a *trans* ring fusion of the heterocyclic system in these compounds rested on the assumption that it would be as in **10**. Vindication of this has been provided by a recent publication describing studies similar to ours in which chemical evidence was provided which established the *trans*-ring fusion in **16** (19).[4]

An aspect of the reaction which, in our hands, proved to be poorly reproducible, was the formation of ketonic side products. (In some thermolyses of lanostenyl azidoformate considerable amounts of the 3-ketone were formed while in other runs we did not obtain this compound.) Such by-products have not been commonly noted in the thermolysis or photolysis of azidoformates, perhaps because in simple alkyl systems the nitrogen-free carbonyl products are sufficiently volatile and non-polar to have escaped notice.

Interestingly Edwards and Paryzek observed ketone formation in the thermolysis of steroidal 7α- and 7β-azidoformates (20), and although Hora reported only carbamate arising from insertion into cyclohexane solvent when 3β-acetoxy-5-androsten-17β-yl azidoformate was photolyzed (21), we have found thermolysis of this substrate in methylene chloride to give substantial yields of the 17-one (together with products arising from intra-molecular nitrene cyclization).

It might be postulated that the ketones arise from fragmentation of the azidoformates or the nitrenes formed from them (20). We noted that in reactions where the ketones were formed in appreciable amount there was invariably accompanying formation of a high (but indistinctly) melting solid, insoluble in the thermolysis solvent, the infrared spectrum of which closely resembled that of cyanuric acid. We therefore write the reaction as one involving HNCO loss from the alkoxycarbonyl nitrene. A plausible

[3]A referee comments that the large downfield shift of C-3 in **10** (12.9 ppm) and **14** (12.8 ppm) resulting from two β-shifts is also diagnostic of the ring size.

[4]Since this paper was submitted for publication a report of the thermolysis of **7** has appeared (23). The conclusions were similar to ours, and confirmation of the structures of **10** (and **11**) was very nicely provided by chemical synthesis.

alternative is elimination of HNCO from an intermediate alkoxyisocyanate (19).

Conclusions

The thermolysis of the azidoformate derivatives of systems such as **1** provides a means for functionalizing the adjacent equatorial methyl group. In the steroid–triterpene field this procedure seems to complement the nitroxide photolysis procedure recently shown to functionalize the 4β-methyl group (21). It is clear that ^{13}Cmr spectroscopy provides the most facile route for establishing the stereochemistry of these reactions.

Experimental

Melting and boiling points are uncorrected. The proton magnetic resonance spectra were measured on 100 and 270 MHz instruments and chemical shifts are reported on the δ (ppm) scale downfield from an internal tetramethylsilane reference. Standard abbreviations are used to describe signal multiplicities. ^{13}C magnetic resonance spectra were measured on a Bruker HFX-270 instrument at 67.89 MHz in the Fourier mode and are similarly described.

All thin layer chromatography was performed on 0.2 mm thick Silica Gel G, with iodine vapour for spot detection. The solvent systems employed are as specified.

1,1,4α-Trimethyl-trans-decalin-2β-ol Chloroformate

A solution of 1,1,4α-trimethyl-*trans*-decalin-2β-ol[5] (3.09 g) in toluene (100 ml) containing pyridine (5.0 ml) was added dropwise over 1 h to an ice-cold solution of phosgene in toluene (100 ml of a 20% w/v solution). The reaction mixture was allowed to warm to room temperature and after 20 h was then shaken with ice water. The organic phase was separated, dried ($MgSO_4$), and the solvent removed under reduced pressure to yield a colourless oil (3.51 g, 90%), ν_{max} (film) 1770 cm^{-1}, and no OH stretch absorption. This material was immediately used for the preparation of the azidoformate.

1,1,4a-Trimethyl-trans-decalin-2β-yl Azidoformate

Dimethylformamide (200 ml) containing sodium azide (4.0 g) and the chloroformate from above was stirred magnetically and heated to 60°C. After 4 h the reaction mixture was diluted with cold water (400 ml) and extracted with diethyl ether (3 × 150 ml). The combined ether extracts were washed with water (5 × 100 ml) and then dried ($MgSO_4$). Removal of solvent left a residual light yellow oil (3.48 g), which crystallized on storage at 0°C. This material had mp 53–55°C, and was homogeneous by tlc (benzene–chloroform 2:1 v/v, R_F 0.60), ν_{max} (film) 2180, 2130, 1750, 1725, 1395, 1370, 1230, 980, and 750 cm^{-1}; δ ($CDCl_3$) 0.86 (3H, s), 0.93 (3H, s), 0.98 (3H, s), 1.0–2.0 (13H, br m), 4.52 (1H, dd, J_1 = 6.5 Hz, J_2 = 8 Hz); *cf.* data for **7** in ref. 23.

[5]This alcohol was prepared from 1,1,4a-trimethyl-Δ^8-2-decalone (22) by sequential reduction with sodium borohydride in 2-propanol and catalytic hydrogenation in ethanol over 10% palladium-on-charcoal.

Thermolysis of the Azidoformate (7)

A solution of the azidoformate **7** (1.02 g), in carbon tetrachloride (100 ml) under an atmosphere of nitrogen, was heated at 120°C in a thick-walled sealed tube for 24 h. Removal of solvent left a light yellow oil, $\nu_{max}(CCl_4)$ 3430, 3250, 1770 sh, 1755, 1710; tlc (diethyl ether) revealed six components R_F 0.1–0.8.

The mixture was chromatographed on silica gel (Merck for column chromatography) in ether and collected as *ca.* 5 ml fractions every 15 min. The individual fractions were evaporated, analyzed by tlc, and grouped accordingly. By this means six fractions were obtained. Fraction I (tubes 7 and 8) (79 mg) was a nearly colourless oil; R_F 0.68; >95% one component by glc; ν_{max} (film) 1700 cm^{-1}; δ 0.96 (3H, s), 1.01 (3H, s), 1.06 (3H, s); *m/e* 194 (70) ($M^{+\cdot}$), 137(45), 123(20), 109(90), 108(100) amu, all consistent with this being 1,1,4α-trimethyl-*trans*-decalin-2-one, from which it was indistinguishable by glc analysis.

Fraction II (tubes 13 and 14) (25 mg); mp 175–177°C; R_F 0.47; ν_{max} (KBr) 3540, 3430, 1715, 1245, 1050 cm^{-1}; δ 0.80 (3H, s), 0.88 (3H, s), 0.93 (3H, s), 4.2–4.9 (*ca.* 3H, br); *m/e* 178(75) (M − 61), 163(100); consistent with this material being 1,1,4a-trimethyl-*trans*-decalin-2-yl carbamate (**8**), and it proved to be identical with an authentic specimen prepared by treating the chloroformate with ammonia.

Fraction III (tubes 16–22); 381 mg; mp 187–187.5°C; R_F 0.35; ν_{max} (KBr) 3440 and 1750 cm^{-1}; δ 0.93 (3H, s), 1.04 (3H, s), 1.08 (3H, s), 1.81 (1H, m), 3.37–4.0 (2H, m), and 6.24 (1H); *m/e* calcd. for $C_{14}H_{23}NO_2$: 237.1729 ($M^{+\cdot}$); found: 237.1725, consistent with this being the oxazolidinone **10**.[6]

Fraction IV (tubes 26–37); 55 mg; mp 205–210°C; R_F 0.26; ν_{max} (KBr) 3440 and 1750 cm^{-1}; *m/e* 237(15), 178(12), 161(10), and 150(100), was apparently a mixture and was not investigated further.

Fraction V (tubes 40–55); 25 mg; mp 138–145°C; R_F 0.16; ν_{max} (KBr) 3460, 1745, and 1030 cm^{-1}; δ 1.05 (3H, s), 1.09 (3H, s), 1.13 (3H, s), 4.0–4.5 (2H, m), and 5.58 (1H, s); *m/e* 237; consistent with this being an oxazolidinone, however, and it was not investigated further.

Fraction VI (tubes 64–88); 184 mg; mp 185–188°C; R_F 0.05; ν_{max} (KBr) 3450, and 1700 cm^{-1}; δ 0.96 (3H, s), 1.0 (3H, s), 2.75–3.15 (2H, J_{AB} = 11 Hz, J_{ANH} = 4 Hz, J_{BNH} = 0 Hz), 6.16 (1H, dd, $J_{2\alpha,3}$ = 6 Hz, $J_{2\beta,3}$ = 6 Hz) and 6.5 (1H, br); *m/e* calcd. for $C_{14}H_{23}NO_2$: 237.1729; found: 237.1727(45), 164(95), 149(100), all consistent[6] with this being the tetrahydro-1,3-oxazin-2-one (**11**).

Lanostan-3β-yl Chloroformate

A solution of lanostan-3β-ol (1.6 g) in benzene (65 ml) containing pyridine (2.5 ml) was added over 1 h to an ice-cold solution of phosgene (10 g) in benzene (80 ml), and the reaction mixture was stirred overnight. Work-up was essentially as described for the preparation of the decalin system, but extracting with benzene gave a crystalline product which was recrystallized from acetone to yield colourless needles, mp 129–131°C (1.44 g, 78%); homogeneous by tlc analysis, *m/e* calcd. for $C_{31}H_{53}{}^{35}ClO_2$: 492.3734; found: 492.3732.

[6]See discussion for further analysis of this data and the ^{13}Cmr spectrum.

*Lanostan-3β-yl Azidoformate (**12**)*

The chloroformate (1.17 g) was added to a stirred solution of sodium azide (1.17 g) in dry dimethylformamide (100 ml). Benzene (15 ml) was added to give a homogeneous solution. After 4 h the reaction mixture was cooled, diluted with water (500 ml), and worked-up as described for **7** (benzene rather than diethyl ether being used for the extractions) to yield a colourless crystalline solid, which was recrystallized from acetone to yield lanostan-3β-yl azido formate mp 135–136°C (1.06 g, 89%); homogeneous by tlc analysis; *m/e* calcd. for $C_{31}H_{53}N_3O_2$: 499.41377; found: 499.41367.

*Thermolysis of Azidoformate **12***

The azidoformate **12** (1.0 g) was dissolved in methylene chloride (100 ml, purified by passage through a silica gel column), and the solution was thermolyzed at 125°C overnight as described for **7**. Some solid had separated from solution and after evaporating the reaction mixture to small volume, this was collected by filtration. Further concentration of the filtrate then yielded a pale yellow solid residue (971 mg) shown by tlc (chloroform) to contain two major, and at least seven minor, products. This mixture was chromatographed on Woelm Alumina grade III, 16 cm × 2.5 cm). Benzene eluted crystalline material (119 mg); R_F 0.45; mp 130–131°C; ν_{max} (KBr) 1695 cm^{-1}; *m/e* 428. This product was initially identified as 3-lanostanone from its ir spectrum and this was confirmed by comparison (ir and glc) with authentic material.

Benzene – diethyl ether (9:1 and 4:1 v/v) next eluted crystalline material (305 mg), R_F 0.08. Recrystallization from methylene chloride – methanol gave material mp 283–285°C; ν_{max} (KBr) 3450, 1780, and 1755 cm^{-1}; 0.7–1.1 (8 methyl signals), 3.55 (2H, br m), and 5.8 (1H, br s); *m/e* calcd. for $C_{31}H_{53}NO_2$: 471.40763; found: 471.40756, all consistent[6] with structure **14**.

Diethyl ether alone and with methanol (2% v/v) eluted the final major product as a colourless solid (392 mg) which was, however, amorphous. Attempts to crystallize this material from a variety of solvents gave solutions which gelled upon cooling, the gel yielding colourless solid upon drying, homogeneous on tlc; R_F 0.78 (MeOH–$CHCl_3$, 1:4); ν_{max}(KBr) 3450, 1725, and 1700; 0.7–0.9 (7 methyl groups), 2.85 (2H, m), 2.85 (1H, br m), and 6.12 (1H, d, J = 2 Hz) (the signal at 3.85 was an AB quartet J_{AB} = 12 Hz, with the low field pair of lines showing a second coupling of 2 Hz; addition of D_2O removed the 6.12 signal and converted the 2.85 absorption to a clean AB quartet); *m/e* calcd. for $C_{31}H_{53}NO_2$: 471.40763; found: 471.40679. This data is consistent with this substance being the perhydro-1,3-oxazin-2-one (**15**).

*Lanost-8-en-3β-yl Azidoformate (**13**)*

This compound was prepared from lanost-8(9)-en-3β-ol, via the chloroformate (mp 125–126°C) and obtained in 80% yield as a colourless crystalline solid mp 105–106°C (from methanol), ν_{max}(Nujol) 2200, 2140, 1740, and 1240 cm^{-1}; *m/e* 497, 482, 411, 395 (base). *Anal.* calcd. for $C_{31}H_{51}N_3O_2$: C 74.70, H 10.42; found: C 74.87, H 10.41.

Thermolysis of Lanostenyl Azidoformate

A solution of **13** (905 mg) in methylene chloride (120 ml) was thermolyzed in a sealed tube at 125°C/for 22 h. Removal of solvent left a pale yellow solid (845 mg) which was shown to contain at least four components by tlc analysis (benzene). Column chromatography on silica gel with benzene – ethyl acetate (4:1 v/v) as eluant yielded four substances.

The first (477 mg) was obtained as a crystalline solid mp 255–260°C (from methanol), ν_{max}($CHCl_3$) 3440 and 1755 cm^{-1}; *m/e* calcd. for $C_{31}H_{51}NO_2$: 469.3918; found: 469.3904; δ ($CDCl_3$) 0.8–1.20 (8 methyls), 3.7 (2H, br m), 5.3 (1H, br NH), all consistent[4] with this being the oxazolidinone **16**.

The second fraction (44 mg) was a colourless solid, mp 125–150°C, ν_{max}($CHCl_3$) 3440 and 1758 cm^{-1}, apparently impure oxazolidinone; while the third fraction (25 mg) similarly gave a colourless solid with an indistinct mp 140–150°C, ν_{max}($CHCl_3$) 3440, 1760, and 1705 cm^{-1} and was seemingly a mixture of oxazolidinone and tetrahydro-1,3-oxazinone. These materials were not investigated further.

The fourth fraction (140 mg) gave a colourless solid, mp 255–258°C, ν_{max}($CHCl_3$) 3440 and 1705 cm^{-1}; *m/e* calcd. for $C_{31}H_{51}NO_2$: 269.3918; found: 469.3909; δ 0.8–1.1 (7 methyl groups), 2.7–3.3 (2H, J_{gem} = 11 Hz, J_{He-NH} = 3 Hz), 3.85 (1H, dd, J = 7 and 3 Hz), 5.95 (NH, br, J = 3 Hz), all consistent[6] with this product being the tetrahydrooxazinone (**17**)

The Cyanuric Acid-like Side Product

In some thermolyses a highly insoluble white powder deposited on the walls of the sealed tube. This substance had mp > 300°C, essentially insoluble in water, ethanol, or chloroform, and had ν_{max}(KBr) 3450, 3420, 3330, 3150, 3050, 2730, 1720, 1650, and 1610 cm^{-1}, *m/e* 129(100) and 61(80) with no other major ions above 50 amu. Cyanuric acid (Eastman Chem. Co.) had a very similar but non-identical infrared, and mass spectrum.

Luminescence différée d'une solution organique vitreuse photoactivée et transition vitreuse

D. CECCALDI

Laboratoire de Physico-chimie des Rayonnements, associé au CNRS, Université de Paris-Sud, centre d'Orsay, 91 Orsay, France

Reçu le 17 juin 1976[1]

D. CECCALDI. Can. J. Chem. **55**, 2517 (1977).

Une théorie cinétique générale est utilisée pour interpréter la réponse d'un système luminescent à des sauts thermiques rapides ($\Delta T \sim 1$ K, $\Delta t \sim 1$ s). Les systèmes luminescents étudiés sont des solutions organiques vitreuses photoactivées de TMPD/MCH 10^{-3} *M* et TMPD/3-MP 10^{-3} *M*. L'étude est faite dans un domaine de température (63–91 K) situé de part et d'autre de la transition vitreuse. On montre qu'il y a diffusion lente des électrons piégés vers le cation et compétition entre dépiégeage thermique et dépiégeage par effet tunnel. La proportion d'effet tunnel Y est indépendante du temps au cours d'une cinétique de luminescence isotherme et dépend peu de la température lorsque $T \leq T_y$; T_y est très proche de la température de transition vitreuse. Pour $T > T_y$, Y décroit rapidement. L'énergie d'activation du dépiégeage thermique passe par un maximum à $T_m \simeq T_g$. On peut définir la température de transition vitreuse par:

$$T_g = \tfrac{1}{2}(T_y + T_m) \quad (\simeq T_y \simeq T_m)$$

Enfin on mesure un temps τ de relaxation de la matrice vitreuse. τ décroit avec la température.

D. CECCALDI. Can. J. Chem. **55**, 2517 (1977).

A general kinetic theory is used to explain the shapes of photoionized sample luminescence curves perturbed by thermal jumps ($\Delta T \sim 1$ K, rise time ~ 1 s). The samples studied are photoactivated organic vitreous solutions of TMPD/MCH 10^{-3} *M* and TMPD/3-MP 10^{-3} *M*. The experiments are performed within a temperature range (63–91 K) which includes the glass transition temperature T_g. It is shown that there is a slow diffusion of the trapped electrons towards the cation and competition between thermal detrapping and tunneling. The tunneling/thermal detrapping ratio Y is not time dependent during an isothermal luminescence and is only slowly temperature dependent if $T \leq T_y$. T_y is very close to T_g. For $T > T_y$, Y decreases rapidly with T. The activation energy for thermal detrapping shows a maximum when the temperature reaches $T_m \simeq T_g$. The glass transition temperature T_g may therefore be defined empirically as:

$$T_g = \tfrac{1}{2}(T_y + T_m) \quad (\simeq T_y \simeq T_m)$$

Finally we obtain a glassy matrix relaxation time, τ, which decreases with T.

Introduction

Dans un récent article (1), on a présenté une nouvelle méthode expérimentale pour étudier la luminescence de recombinaison électron–cation consécutive à la photoionisation d'une solution organique vitreuse. On applique, au cours de la luminescence isotherme (ITL), des sauts thermiques rapides ($\Delta T \sim 1$ K, $\Delta t \sim 1$ s) et on analyse la réponse du signal de luminescence à ces sauts thermiques en utilisant une théorie cinétique. Dans le cas du TMPD[2] piégé dans un verre de 3-MP[3] ou de MCH[4] à 77 K on a montré qu'il y a diffusion lente des électrons piégés vers le cation et compétition entre dépiégeage thermique et athermique (effet tunnel). On a mesuré l'énergie d'activation E du dépiégeage thermique et la proportion d'effet tunnel Y. La théorie cinétique permet en effet de montrer que, si on effectue un saut thermique rapide ΔT, la luminescence passe de I à I' et l'on a:

$$\frac{I'}{I} = \frac{\exp\left(\dfrac{\Delta T}{T}\dfrac{E}{kT}\right) + Y}{1 + Y}$$

Cette loi a été vérifiée expérimentalement en fonction de ΔT à 77 K. A cette température le verre est au point de transition vitreuse pour le 3-MP ($T_g = 77$ K) et en dessous de la transition vitreuse dans le cas du MCH ($T_g = 84$–89 K). Dans ce présent travail on poursuit cette étude

[1]Revision reçue le 21 mars 1977.

[2]TMPD = *N,N,N′,N′*-tétraméthyl *para*-phénylènediamine.

[3]3-MP = 3-méthylpentane.

[4]MCH = méthylcyclohéxane.

expérimentale en étendant la gamme de température de 63 à 91 K pour les verres de MCH et 3-MP. On explore donc un domaine de température de part et d'autre de la température de transition vitreuse (89 et 77 K) trouvée par calorimétrie (2, 3). On peut ainsi chercher à déterminer la variation de E et Y avec la température et à savoir s'il y a encore diffusion des électrons piégés. On peut aussi espérer caractériser la transition vitreuse comme par la mesure de la chaleur spécifique, du coefficient de dilatation thermique, du volume ou de la viscosité (4). On verra que ceci est possible et qu'on trouve aussi une méthode pour mesurer un temps τ de relaxation de la matrice vitreuse.

Rappels sur la théorie cinétique

On a défini précédemment (1) des états de configuration "j" pour l'ensemble "cation–électron piégé–solvant". L'ensemble évolue par une suite de transitions j–j'. Ces transitions sont des réarrangements moléculaires thermiques du solvant (avec en général diffusion de l'électron) ou des passages par effet tunnel de l'électron d'un site j à un site j' proche. On appelle $K_{jj'}$ la constante de vitesse correspondante. Pour chaque état j on a une vitesse de recombinaison avec le cation:

$$[1] \qquad k_j(T) = k_j{}^{\mathrm{th}}(T) + k_j{}^{\mathrm{tu}}$$

avec

$$[2] \qquad k_j{}^{\mathrm{th}}(T) = f_j(T)\exp(-E_j/kT)$$

(En général le dépiégeage thermique et le dépiégeage par effet tunnel sont en compétition.) Dans ces conditions, la vitesse d'évolution d'une population $N_j(t)$ est:

$$[3] \quad -\frac{\mathrm{d}N_j(t)}{\mathrm{d}t} = k_jN_j(t) + \sum_{j'} K_{jj'}N_j(t) - K_{j'j}N_{j'}(t)$$

La cinétique de luminescence, exprimée en nombre de recombinaisons par unité de temps s'écrit:

$$[4] \qquad I(t) = -\sum_j \frac{\mathrm{d}N_j(t)}{\mathrm{d}t} = \sum_j k_jN_j(t)$$

(Expérimentalement on observe la fluorescence de recombinaison de durée de vie 10^{-8} s.)

Saut thermique

Ecrivons la cinétique de luminescence $I(t)$ en décomposant la partie thermique et la partie tunnel:

$$[5] \qquad I(t) = I^{\mathrm{th}}(t) + I^{\mathrm{tu}}(t)$$

$$[6] \qquad I^{\mathrm{th}}(t) = \sum_j k_j{}^{\mathrm{th}}(T)N_j(t)$$

$$[6'] \qquad I^{\mathrm{tu}}(t) = \sum_j k_j{}^{\mathrm{tu}}N_j(t)$$

Si au cours d'une cinétique ITL on passe brusquement de la température T à la température $T + \Delta T$ la cinétique $I(t)$ devient $I'(t)$ et on montre que:

$$[7] \quad \frac{I'(t)}{I(t)} = X(t) = \frac{\left\langle \exp\left(\frac{\Delta T}{T}\frac{E_j}{kT}\right)\right\rangle + Y(t)}{1 + Y(t)}$$

La valeur moyenne est prise pour tous les électrons qui se recombinent au temps t. $Y(t)$ est la proportion d'effet tunnel:

$$[8] \qquad Y(t) = \frac{I^{\mathrm{tu}}(t)}{I^{\mathrm{th}}(t)}$$

Méthode expérimentale

Les systèmes étudiés sont des solutions (10^{-3} M) de TMPD dans MCH ou 3-MP. Les hydrocarbures saturés sont purifiés par ébullition sur tamis moléculaire (13X-5A) et distillation. La TMPD est photoionisée à basse température par irradiation uv (raie 313 nm, H_g HP). La cellule qui permet d'effectuer des sauts thermiques est formée de deux plaques de pyrex rectangulaires (40 × 50 × 4 mm^3) séparées de 0.4 mm par un joint de Mylar (rectangle ouvert). Les deux faces intérieures de la cellule sont rendues conductrices par un dépôt de SnO_2 transparent. Ce dépôt conducteur est traversé par un courant i qui dissipe une énergie calorifique par effet joule. La cellule contenant la solution étant immergée dans l'azote liquide, la solution devient un verre en contact avec les faces chauffantes de la cellule. La température est mesurée par un thermocouple Cu–constantan de 0.2 mm, isolé et piégé dans le verre. Avec une forme de signal convenable $i(t)$ on obtient une variation $T(t)$ désirée dans l'échantillon. Le temps d'équilibre thermique entre le thermocouple et l'échantillon est très rapide (si on effectue un pic δ de courant, le thermocouple et la luminescence répondent avec un décalage dans le temps inférieur à 1/10 s). L'homogénéité du dépôt de SnO_2 est contrôlée par une méthode de pont. On obtient la gamme de température 63–77 K en pompant sur l'azote liquide.

Diffusion lente des électrons et dépiégeage

Diffusion lente

Si on effectue des sauts thermiques identiques à différents temps t_n au cours d'une luminescence isotherme ITL à une température T donnée (63–91 K), le rapport $X(t_n) = I'(t_n)/I(t_n)$ est indépendant du temps t_n (figs 1*a* et

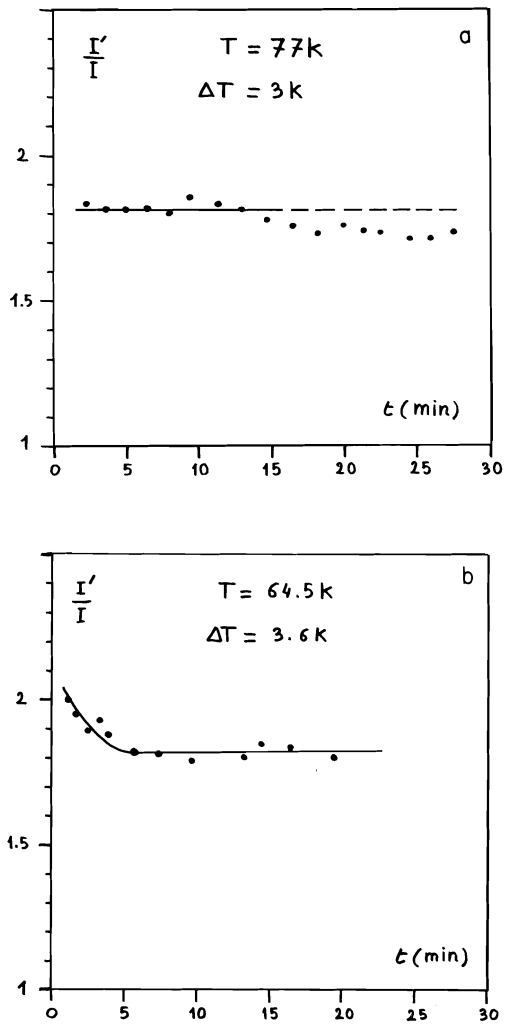

FIG. 1. Si on effectue des sauts thermiques rapides ΔT identiques au cours d'une ITL à la température T, le rapport I'/I est indépendant du temps à toute température T. Mais dans le MCH pour $T \lesssim 77$ K il y a décroissance légère pendant un temps $\tau_{uv} \gtrsim 5$ min. τ_{uv} décroit avec la température: (*a*) TMPD/MCH 10^{-3} M à 77 K; le léger écart des points à la droite horizontale peut être attribué à un phénomène secondaire (relaxation de la matrice); (*b*) TMPD/MCH 10^{-3} M à 64.5 K; le rapport I'/I décroit un peut pendant 5 min.

1*b*). En fait, dans le MCH pour $T \lesssim 77$ K, X décroit un peu pendant un temps $\tau_{uv} \lesssim 5$ min. Ce temps τ_{uv} diminue avec T et dépend de la dose d'irradiation. (On verra par la suite que c'est un temps d'équilibre d'état stationnaire dans la zône d'effet tunnel.)

D'après les formules [7] et [8] on doit avoir simultanement:

$$[9] \qquad \left\langle \exp\left(\frac{\Delta T}{T}\frac{E_j}{kT}\right)\right\rangle = \text{constante} = \exp\left(\frac{\Delta T}{T}\frac{E}{kT}\right)$$

$$[10] \qquad Y(t) = \text{constante} = Y$$

La deuxième égalité de [9] est légitime. En effet, en admettant une distribution gaussiènne pour les énergies d'activations E_j, centrée sur la valeur E, on montre par un calcul sur ordinateur que la formule [9] est correctement vérifiée si la gaussiènne a une largeur $\delta E/E \lesssim 1/7$ lorsque $E \leq 0.7$ eV et $\Delta T \lesssim 3$ K. D'après l'éq. 10 le dépiégeage thermique et le dépiégeage par effet tunnel donnent des intensités de luminescence dans un rapport constant. Ceci n'est possible que si la zône d'effet tunnel $\sum$ et la zône de dépiégeage thermique $\sum'$ sont constamment repeuplées avec la même vitesse. Il y a donc diffusion lente des électrons vers le cation. D'après les éqs 9 et 10 le rapport X de l'éq. 7 devient:

$$[11] \qquad X = \frac{\exp\left(\frac{\Delta T}{T}\frac{E}{kT}\right) + Y}{1 + Y}$$

Dépiégeage thermique. Effet tunnel

X et Y ne dépendent pas du temps au cours d'une ITL mais de la température T. A une température donnée T, on vérifie que la fonction:

$$[12] \qquad F(\Delta T) = X(\Delta T)(1 + Y) - Y$$

varie bien exponentiellement avec ΔT ou:

$$[13] \qquad kT^2 \ln(F) = E\Delta T$$

En fait il est plus pratique, au cours d'une cinétique isotherme d'effectuer des sauts thermiques ΔT_i ($i = 1, 2$, ou 3) croissants et de recommencer la séquence ΔT_i plusieurs fois, plutôt que d'effectuer une séquence ΔT_i longue ($i = 1, 2, \ldots, N$) unique. On prends alors la moyenne des X_i pour i donné (figs 2*a* et 2*b*). On montre expérimentalement que les deux méthodes sont équivalentes.

La variation de E et Y est donnée (figs 3*a* et 3*b*). L'énergie d'activation E passe par un maximum à une température T_m proche de la température de transition vitreuse T_g. La proportion d'effet tunnel Y dépend peu de la température et décroit brutalement à partir de $T_y \simeq T_g$. De 77 à 91 K, la vitesse de chauffage par paliers (entre deux cinétiques) est d'environ 2 K par

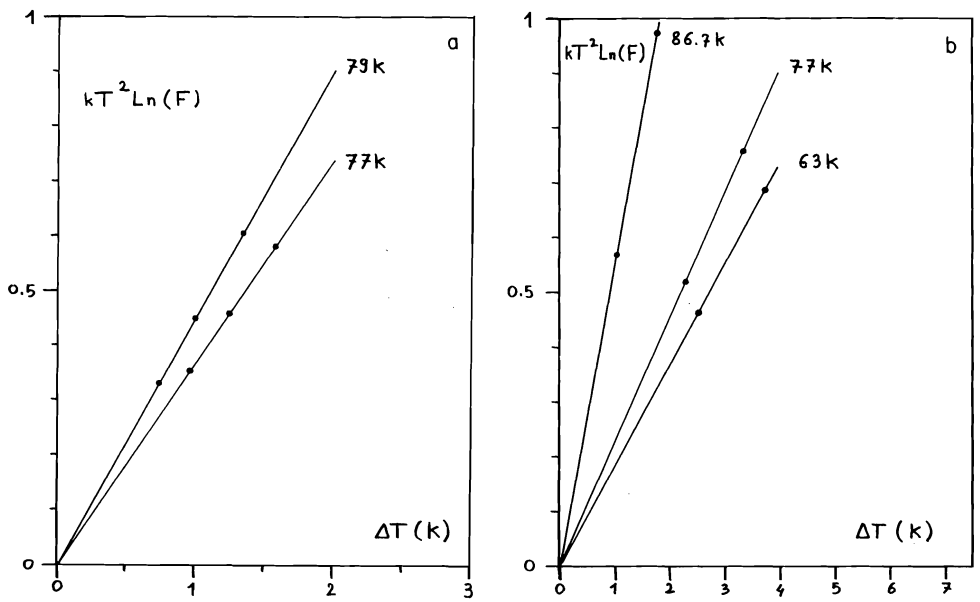

FIG. 2. La fonction F varie exponentiellement avec ΔT. La pente de la droite est l'énergie d'activation E du dépiégeage thermique. (*a*) TMPD/3-MP 10^{-3} *M*. (*b*) TMPD/MCH 10^{-3} *M*.

heure. La gamme de température 63 K $\leq T \leq$ 77 K est faite séparément.

Interprétation

Il existe une autre grandeur physique pour laquelle l'énergie d'activation passe par un maximum à la transition vitreuse. C'est la viscosité η. Prod'homme (5) pose:

$$\eta = AT \exp(E/kT)$$

L'énergie d'activation de la viscosité passe par un maximum à $T \simeq T_g$. Ceci a été vérifié sur différents types de verres (minéraux et organiques). D'autre part, à la transition vitreuse la chaleur spécifique passe aussi par un maximum lors du réchauffement (6); le maximum de C_p dans le MCH est situé vers 94 K. Dworkin (2), prenant le point d'inflection de C_p trouve T_g = 89 K. On sait qu'il est difficile de définir exactement T_g. Par notre méthode on peut poser:

$$T_g = \tfrac{1}{2}(T_m + T_y) = 88.5\ \text{K} \quad (\simeq T_m \simeq T_y)$$

Dans le MCH la proportion d'effet tunnel est pratiquement constante de T = 77 K à T_y = 87 K. On va voir que ceci est justifié s'il y a diffusion lente des électrons piégés. On a défini deux zônes sphèriques $\sum$ et $\sum'$ entourant le cation à l'intérieur desquelles il y a respectivement dépiégeage par effet tunnel et dépiégeage thermique; on appelera $\sum''$ la sphère de provenance des électrons qui, par une transition j''–j se trouvent dans un état j de $\sum$. Le nombre d'électrons piégés dans chacune de ces zônes est appelé respectivement $N_\Sigma(t)$, $N_{\Sigma'}(t)$, $N_{\Sigma''}(t)$.

Ecrivons l'approximation de l'etat stationnaire à la zône d'effet tunnel $\sum$ qui est constamment repeuplée par diffusion:

$$[14] \qquad \frac{dN_\Sigma(t)}{dt} \simeq 0$$

Or par définition:

$$[15] \qquad N_\Sigma(t) = \sum_{j\in\Sigma} N_j(t)$$

La notation $j \in \sum$ signifie que j est un état de piégeage dans la zône d'effet tunnel $\sum$. En tenant compte des éqs 3 et 15, la relation 14 devient:

$$[16] \qquad \frac{dN_\Sigma(t)}{dt} = -\sum_{j\in\Sigma}(k_j^{th}(T) + k_j^{tu} + K_j(T))N_j(t) + \sum_{j\in\Sigma, j''\in\Sigma''} K_{j''j}N_{j''}(t) = 0$$

On a posé $K_j(T) = \sum_{j'} K_{jj'}(T)$. Les éqs 5, 6, 6′ séparent la partie de la luminescence qui provient du dépiégeage thermique $I^{th}(t)$ de celle qui provient du dépiégeage par effet tunnel $I^{tu}(t)$.

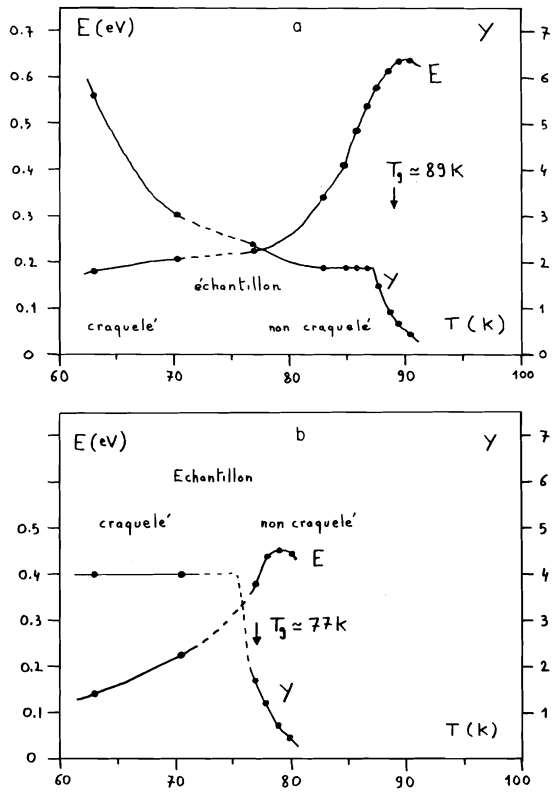

FIG. 3. L'énergie d'activation E du dépiégeage thermique passe par un maximum à T_m. La proportion d'effet tunnel Y décroit rapidement avec T à partir de T_y. On peut définir la température de transition vitreuse par: $T_g = \frac{1}{2}(T_y + T_m)$ ($\simeq T_y \simeq T_m$): (*a*) TMPD/MCH 10^{-3} *M*. (*b*) TMPD/3-MP 10^{-3} *M*.

Donc la relation [16] permet de calculer la proportion d'effet tunnel $Y(t) = I^{tu}(t)/I^{th}(t)$:

$$I^{tu}(t) = \sum_{j\in\Sigma, j''\in\Sigma''} K_{j''j}(T)N_{j''}(t) - \sum_{j\in\Sigma} (k_j^{th}(T) + K_j(T))N_j(t)$$

$$[17] \quad Y(t) = \frac{\langle K_{j''j}(T)\rangle N_{\Sigma''}(t)}{\langle k_j^{th}(T)\rangle N_{\Sigma'}(t)} - \frac{\langle k_j^{th}(T) + K_j(T)\rangle N_\Sigma(t)}{\langle k_j^{th}(T)\rangle N_{\Sigma'}(t)}$$

Il n'est donc pas illogique que Y soit indépendant de la température en dessous de la transition vitreuse. En effet, la température agit sur des constantes de diffusion et de dépiégeage thermique, mais elles apparaissent sous forme de rapport. On peut écrire Y de manière rigoureuse, en tenant compte des éqs 5, 6, 6′:

$$[18] \quad Y = \frac{\sum_j k_j^{tu} N_j(t)}{\sum_j k_j^{th}(T)N_j(t)} = \frac{\langle k_j^{tu}\rangle N_\Sigma(t)}{\langle k_j^{th}(T)\rangle N_{\Sigma'}(t)}$$

Y semble apparaitre sous forme d'une loi activée thermiquement et donc l'éq. 18 serait en contradiction avec le fait que Y est indépendant de T. Mais ce paradoxe s'explique facilement. Les électrons diffusent vers la zône d'effet tunnel $\sum$. Dans cette zône si un état j est tel que $k_j^{tu} \ll k_j^{th}(T)$, l'électron sera dépiégé par effet thermique. Si au contraire $k_j^{tu} \gg k_j^{th}(T)$, on aura, en appelant V_j la vitesse de peuplement de l'état j:

$$[19] \quad k_j^{tu} N_j(t) = V_j$$

Si la diffusion est thermique la vitesse V_j augmente avec la température comme k^{th}. Donc dans l'éq. 18, Y ne dépend pratiquement pas de la température.

Dans le MCH, $Y(T)$ décroit avec T de 63 à 77 K; cela peut provenir d'une diffusion par effet tunnel qui devient négligeable pour $T > 77$ K ($V_j = V_j^{th}(T) + V_j^{tu}$).

Lorsqu'on se rapproche de la température de transition vitreuse T_g, la proportion d'effet tunnel décroit brusquement pour $T \geq T_y$. L'augmentation de la mobilité moléculaire près de T_g doit modifier les processus thermiques et la zône de dépiégeage thermique doit s'agrandir de telle manière que le rapport $N_\Sigma(t)/N_{\Sigma'}(t)$ diminue avec T.

Décalage thermique et temps de relaxation de la matrice

On a vu que si on effectue des sauts thermiques ΔT au cours d'une ITL (à la température T), le rapport I'/I est constant (fig. 4*a*). Mais, si au cours d'une ITL on passe de la température T' à la température T au temps t_0, et si on effectue des sauts thermiques ΔT a la température T, ($t > t_0$), le rapport I'/I est plus grand et décroit vers sa valeur d'équilibre (fig. 4*b*). On mesure donc un temps τ (T', T) de relaxation de la matrice. Ce temps décroit avec la température (tableau 1).

On peut trouver une interpretation cinétique de ce phénomène. I'/I est donné par l'éq. 11; l'énergie E dépend un peu de la température; d'autre part la proportion d'effet tunnel Y (éq. 16) décroit brusquement quand on passe de T' à T. Y doit retrouver sa valeur d'équilibre $Y(T) \sim Y(T')$; il faut donc qu'il s'effectue une

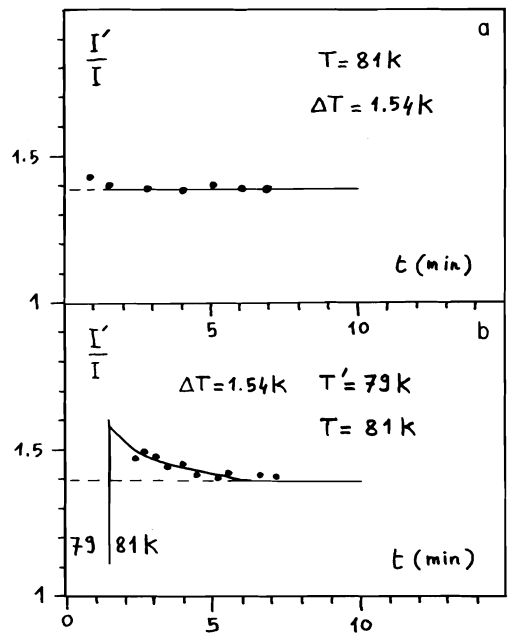

FIG. 4. (*a*) à $T = 81$ K le rapport I'/I est constant. (*b*) Le rapport I'/I n'est plus constant à $T = 81$ K si la photoionisation a été faite à $T' = 79$ K (avec décalage thermique 79–81 K au temps $t_0 = 1.4$ min). On mesure un temps $\tau(T',T)$ de retour à l'équilibre du système. Ici $\tau = 3.5$ min.

TABLEAU 1. La décroissance de τ avec la température

T' (K)	T (K)	τ (min)
70	77	7 ± 1
79	81	3.5 ± 0.5
81	83	1.2 ± 0.3
—	≥ 85	0 ± 0.5

nouvelle distribution des populations $N_j(t)$ qui s'obtient par relaxation thermique du système. On mesure donc un temps $\tau(T', T)$ de relaxation de la matrice; néanmoins ce temps n'est peut être pas un temps de relaxation pur de cette matrice car l'électron sélectionne des mouvements particuliers de la matrice et de plus il perturbe le milieu par sa présence (pression électronique, polarisation électrique).

5-Allyl-9-oxobenzomorphans. Part 4.[1] Synthesis of 3-hydroxy-8-oxyisomorphinans, 5-allyl-9α-hydroxy-6,7-benzomorphans, and related tetrahydrofuranobenzomorphans

YVON LAMBERT,[2] JEAN-PAUL DARIS, AND IVO MONKOVIĆ
Bristol Laboratories of Canada, Candiac, Quebec, P.Q., Canada J5R 1J1

Received January 17, 1977

YVON LAMBERT, JEAN-PAUL DARIS, and IVO MONKOVIĆ. Can. J. Chem. **55**, 2523 (1977).

A series of 3-hydroxy-8-oxyisomorphinans (**11**, **16**) has been synthesized from the corresponding 5-allyl-9β-hydroxy-6,7-benzomorphans (**7**, **12**) via a hydroboration, oxidation, mesylation, and cyclization sequence of reactions. Selective reduction of and methylmagnesium iodide addition to 5-allyl-2′-methoxy-2-methyl-9-oxo-6,7-benzomorphan (**1**) gave the respective 9α-hydroxy-6,7-benzomorphans (**17**). These were transformed to a number of 2-substituted-5-allyl-2′,9β-dihydroxy-6,7-benzomorphans (**22**) and corresponding methyltetrahydrofurano analogs (**24**).

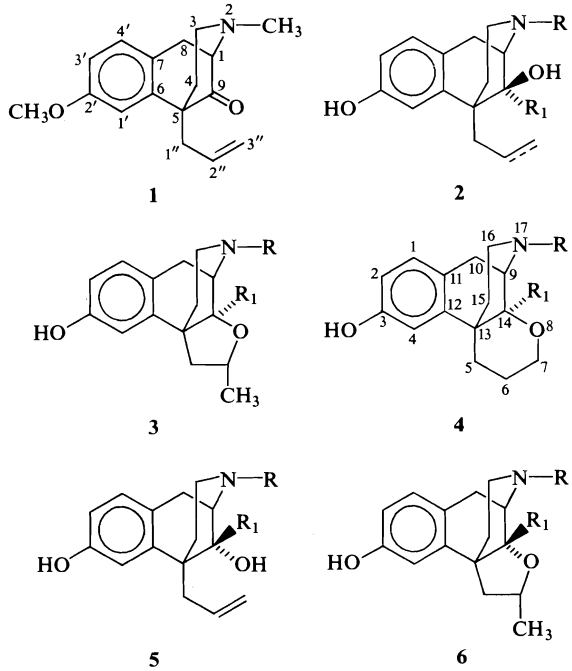
YVON LAMBERT, JEAN-PAUL DARIS et IVO MONKOVIĆ. Can. J. Chem. **55**, 2523 (1977).

On a synthétisé une série d'hydroxy-3 oxy-8 isomorphanes (**11** et **16**) à partir des allyl-5 hydroxy-9β benzo-6,7 morphanes (**7**, **12**) correspondants par l'intermédiaire d'une hydroboration, d'une oxydation, d'une mésylation et d'une cyclisation. La réduction sélective et l'addition d'iodure de méthylmagnésium à l'allyl-5 méthoxy-2′ méthyl-2 oxo-9 benzo-6,7 morphane (**1**) conduisent respectivement aux hydroxy-9α benzo-6,7 morphanes (**17**) correspondants. Ceux-ci peuvent être transformés en un grand nombre d'allyl-5 dihydroxy-2′,9β benzo-6,7 morphanes (**22**) substitués en position 2 et de leurs analogues méthyltétrahydrofuranno correspondants (**24**).

[Traduit par le journal]

Introduction

In part 3 of this series (1) we have described the synthesis of a number of 5-propyl- and 5-allyl-2′,9β-dihydroxy-6,7-benzomorphans **2** as well as the corresponding tetrahydrofurano analogs **3**, via stereoselective reduction of, or organometallic addition to, 5-allyl-2′-methoxy-2-methyl-9-oxo-6,7-benzomorphan **1** (Scheme 1). In view of the fact that some of the compounds **2** have been found to possess high levels of analgesic and/or narcotic antagonist activities, comparable to reference agents in laboratory animal tests, we thought it desirable to explore the synthesis and pharmacological properties of isomeric 9-hydroxy-derivatives **5** in which orientation of the hydroxyl group is away from the nitrogen atom or α with respect to the aromatic ring. In addition, it was of interest to continue the investigation of C-ring oxygen-containing systems in both series, such as 8-oxyisomorphinans **4** and tetrahydrofuranobenzomorphans **6**.



SCHEME 1

Results and Discussion

The synthesis of 8-oxyisomorphinans **11** is shown in Scheme 2. 5-Allyl-9β-hydroxybenzomorphans **7***a* and **7***b* were converted to the corresponding diols **8***a* and **8***b* in good yields via a hydroboration and oxidation reaction

[1]For part 3, see ref. 1.

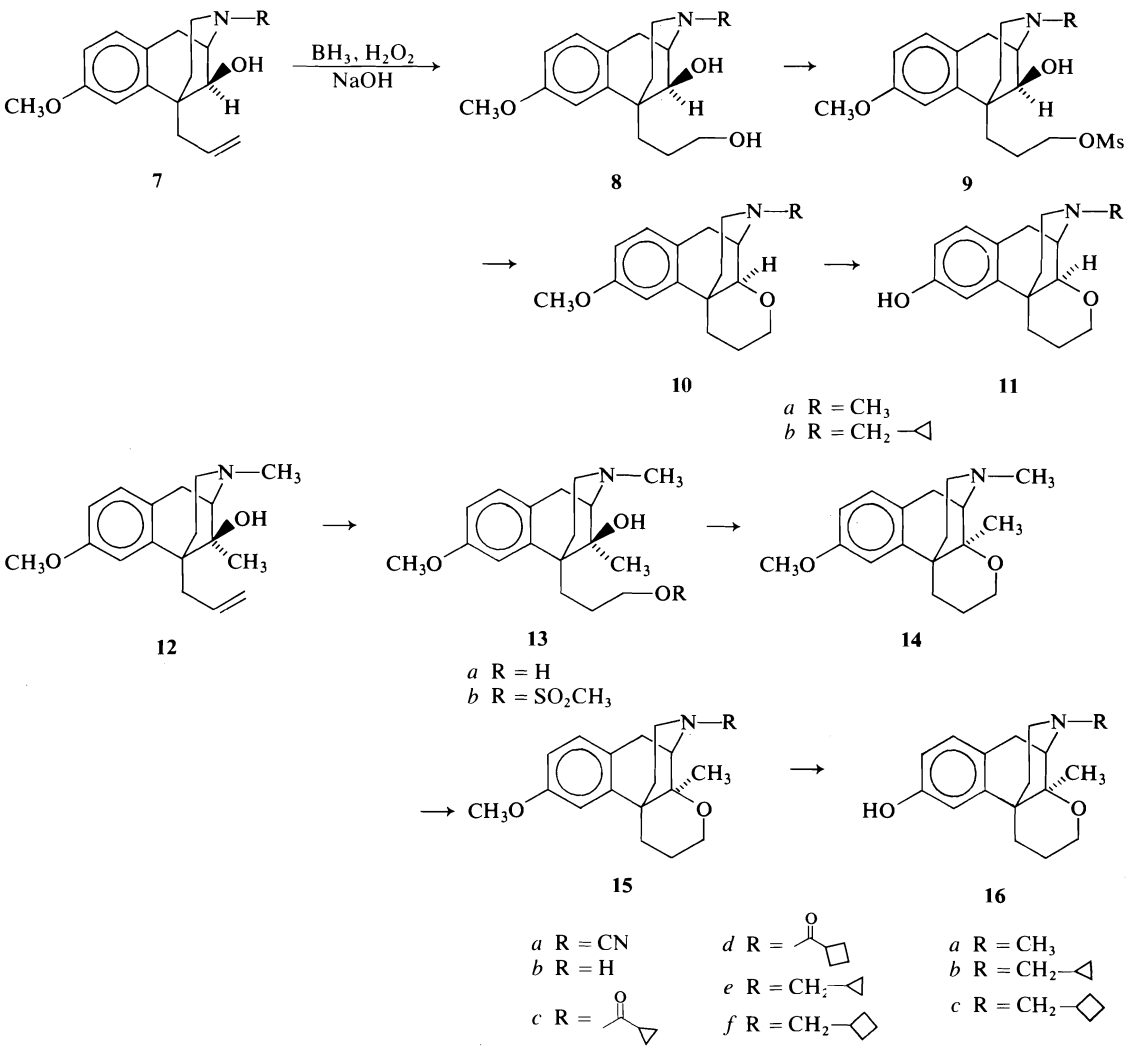
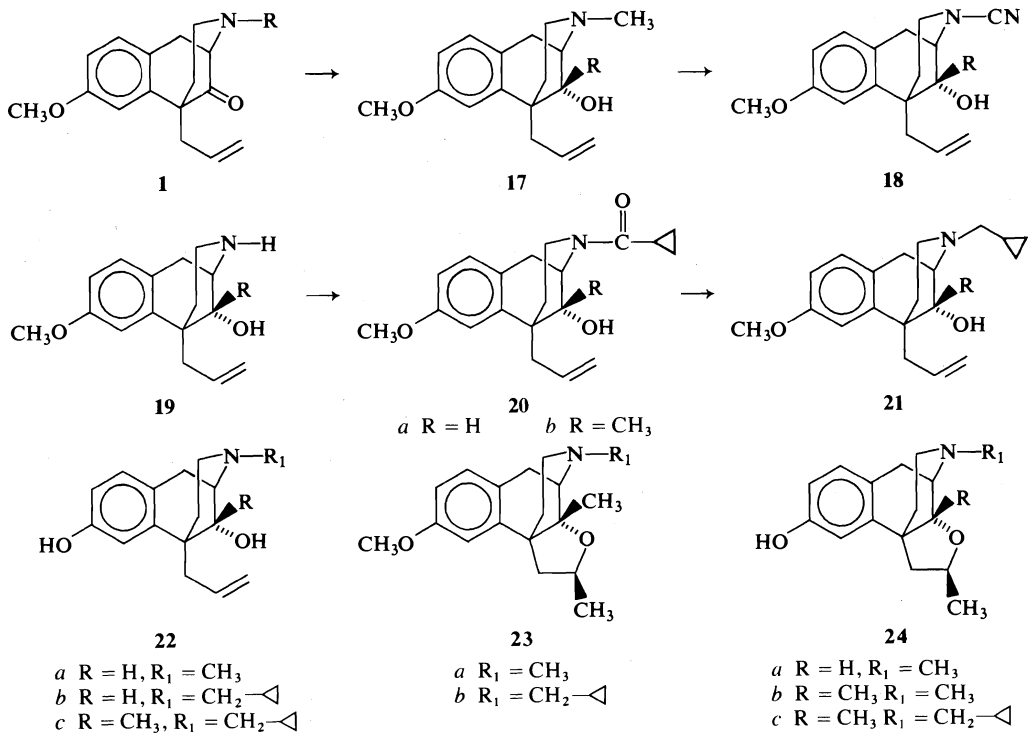


SCHEME 2

sequence. However the problem of formation of stable borane–nitrogen complexes required our attention. The complexed borane was decomposed thermolytically in a suitable hydroxylic solvent. The most convenient solvent was found to be ethylene glycol in which a reaction mixture was heated until hydrogen evolution ceased. The dihydroxy intermediates (**8***a* and **8***b*) were treated with methanesulfonyl chloride to give methanesulfonyl esters **9***a* and **9***b*, which were treated *in situ* with sodium hydride in DMF to give the respective 8-oxyisomorphinans **10***a* and **10***b*. These were demethylated by treatment with boron tribromide in dichloromethane to give **11***a* and **11***b*.

In a similar reaction sequence **12** was converted via **13***a* and **13***b* to the 3-methoxy-14-methyl-8-oxyisomorphinan **14**. A conversion of **14** to **15***e* and **15***f*, respectively, proceeded as expected via a well defined reaction sequence of von Braun demethylation, reduction, acylation, and again reduction. Demethylation of **14**, **15***e*, and **15***f* with boron tribromide gave poor yields of the corresponding phenolic products **16**, presumably due to opening of the tetrahydropyran ring. Better results were obtained with sodium thioethoxide in boiling DMF (2) or lithium diphenylphosphide in boiling THF (3).

Although a number of compounds in the 9α-hydroxy series have been prepared by May and



SCHEME 3

co-workers (4, 5) both by reduction and organometallic addition to tertiary amino ketones, from the start we were confronted with the following problems; firstly, catalytic reduction which is known to give α-alcohols could not be applied in our synthesis since it would be expected to reduce the double bond as well, which we need preserved. Secondly, addition of methyllithium to **1** has been demonstrated (1) to give selectively **12** instead of the expected **17***b* (Scheme 3). Consequently we had to investigate systematically these reactions in order to achieve the desired selectivity. We soon discovered that reduction of **1** with diisobutyl aluminum hydride does indeed give selectively **17***a* (better than 96% stereochemical purity) in quantitative yield.

While addition of methyllithium in ether to **1** gave selectively **12** (1) we observed that methylmagnesium iodide in the same solvent added to **1** to give a mixture of 45% **12** and 55% **17***b* as determined by nmr spectroscopy; in addition to a singlet at δ 1.1 due to **12**, a new singlet appeared at δ 1.58 due to **17***b*. Furthermore, the selectivity was lost when addition of methyllithium to **1** was conducted in a mixture of ether and petroleum ether (bp 30–60°C) 1:10, as observed by the product ratio of 60% **17***b* and 40% **12**, indicating, in addition to the observed large effect of the inorganic part of the organometallic reagent, a large solvent effect. These results also pointed a way in which further investigation should be directed; addition of the Grignard reagent in nonpolar solvent (petroleum ether) was expected and indeed found to give almost exclusively **17***b* (better than 95%).

In a recently published review article on the stereochemistry of organometallic compound addition to cyclic ketones Ashby and Laemmle (6) concluded that the stereochemical outcome of the addition is primarily a function of the entering groups and steric requirements of the particular ketone, which are controlled by steric and torsional strain in the transition state. Factors such as solvent, nature of the metal to which the entering group is attached, and others, result in only minor changes in overall observed stereochemistry. If this generalization is valid, it seems reasonable to assume that large metal and solvent effects observed by us must be related to the fact that our ketone is an amino ketone and therefore probably susceptible to a complexation with organometallic reagents via

a nitrogen lone electron pair. That such complexation would be more pronounced in a nonpolar solvent and consequently conducive to an intramolecular addition to give selectively *trans* amino alcohol (**17***b*) is not surprising, since a polar solvent could be expected to compete effectively with the bulky tertiary amine for the complexation of organometallic reagent. That complexation of a Grignard reagent is more effective than that of an organolithium compound is already known (7).

It is also conceivable that complex formation or lack of it plays an important role in the selective reduction of **1**. In a related study, Stevens *et al.* (8) concluded that primary and secondary 2-amino-2-phenylcyclohexanones form stable complexes with hydride reducing agents to give *trans* amino alcohols by an internal hydride transfer.

A conversion of **17***a* and **17***b* to **21***a* and **21***b* was accomplished by the standard reaction sequence shown in Scheme 3. Demethylation of **17***a*, **21***a*, and **21***b* (EtS^- or lithium diphenylphosphide) gave dihydroxybenzomorphans **22**. Compound **24***a* was obtained by hydrochloric acid-catalyzed cyclization of **22***a* (9) while **24***b* was obtained in two steps from **17***b*. Hydrochloric acid-catalyzed cyclization gave intermediate **23***a* which was demethylated to **24***b*. Similarly **24***c* was prepared from **21***b* via **23***b*.

Compounds **11**, **16**, **22**, and **24** were tested for analgesic and narcotic antagonist activities, and found to be considerably less active than corresponding compounds in the 9β-hydroxy series (1). Biological results will be discussed in more detail in another paper.

Experimental

The melting points were determined on Gallenkamp apparatus, and are uncorrected. The infrared (ir) spectra were recorded on a Unicam SP-200G grating ir spectrometer. The nmr spectra were recorded on a Varian A-60A spectrometer using deuterochloroform. The chemical shifts are expressed in δ values using tetramethylsilane as internal reference. Microanalyses were performed by Micro-Tech Laboratories Inc., Skokie, IL.

9β-Hydroxy-2′-methoxy-2-methyl-5-[3′′-(1′′-hydroxypropyl)]-6,7-benzomorphan ***8a***

To a cooled (ice–salt bath) stirred solution of 5-allyl-9β-hydroxy-2′-methoxy-2-methyl-6,7-benzomorphan (**7***a*) (1) (2.24 g, 8.2 mmol) in THF (12 ml) was added dropwise a 1 *M* borane solution in THF (30 ml) and the mixture allowed to stand for 3 h at −10°C followed by 16 h at room temperature. This was cautiously treated with water (5 ml), followed by 20% sodium hydroxide (5 ml, 30 mmol) and 30% hydrogen peroxide (0.92 g, 8 mmol). The whole was stirred for 3 h and then extracted with chloroform (3 × 20 ml). The extract was concentrated *in vacuo* and the residue was boiled briefly with ethylene glycol (10 ml) to decompose a borane complex, cooled, diluted with water, and made basic with sodium hydroxide. The product, an oil, was isolated by extraction with chloroform, drying, and concentration *in vacuo*. The oil crystallized from ether – petroleum ether to give 1.34 g (50%) of **8***a*, mp 96–98°C. Another 15% of **8***a* was obtained from mother liquors by chromatography (Al_2O_3, $CHCl_3$ – 10% CH_3OH). An analytical sample was obtained by recrystallization from ether, mp 98–100°C; nmr δ 6.6–7.2 (3H, m), 3.8 (3H, s, O—CH_3), 3.5–4.0 (3H, m, 9-H and 3′′-H_2), 2.7–3.5 (3H, m), 2.37 (3H, s, N—CH_3), 1.0–2.7 (8H, m). *Anal.* calcd. for $C_{17}H_{25}NO_2$: C 70.07, H 8.65, N 4.81; found: C 70.16, H 8.79, N 4.79.

2-Cyclopropylmethyl-9β-hydroxy-2′-methoxy-5-[3′′-(1′′-hydroxypropyl)]-6,7-benzomorphan ***8b***

The diol **8***b* (an oil) was similarly prepared from **7***b* in 62% yield isolated as a hydrochloride salt. An analytical sample crystallized with ½CH_3OH of crystallization from methanol–acetone; mp 202–203°C. *Anal.* calcd. for $C_{20}H_{29}NO_3 \cdot HCl \cdot \frac{1}{2}CH_3OH$: C 64.13, H 8.40, N 3.65; found: C 64.50, H 8.35, N 3.49.

3-Methoxy-17-methyl-8-oxyisomorphinan ***10a***

To a cooled (ice bath) solution of **8***a* (1.08 g, 3.7 mmol) in dry CH_2Cl_2 (5 ml) was added a 1 *M* solution of methanesulfonyl chloride in benzene (4 ml) and the whole allowed to stand at room temperature for 1 h. Then the reaction mixture was concentrated *in vacuo* and the residue was stirred with a suspension of sodium hydride (420 mg of 50%, 9 mmol, washed with benzene) in DMF (6 ml) for 16 h at room temperature and then for 30 min at 60–70°C. After the usual work-up the crude product was chromatographed on an alumina column. Elution with chloroform gave an oil, which crystallized from ether – petroleum ether to give 0.53 g (62%) of **10***a*, mp 104–105°C; nmr δ 6.7–7.3 (3H, m), 4.05–4.5 (1H, m), 3.84 (3H, s, O—CH_3), 2.5–4.0 (7H, m), 2.44 (3H, s, N—CH_3), 0.8–2.5 (6H, m). *Anal.* calcd. for $C_{17}H_{23}NO_2$: C 74.69, H 8.48, N 5.12; found: C 74.74, H 8.58, N 5.11.

17-Cyclopropylmethyl-3-methoxy-14-methyl-8-oxyisomorphinan ***10b***

This compound (an oil) was similarly prepared from **8***b* in 65% yield, isolated as its oxalate salt. An analytical sample crystallized from methanol–acetone with ½MeOH of crystallization, mp 181–183°C. *Anal.* calcd. for $C_{20}H_{27}NO_2 \cdot C_2H_2O_4 \cdot \frac{1}{2}CH_3OH$: C 64.42, H 7.44, N 3.34; found: C 64.47, H 7.57, N 3.22.

3-Hydroxy-17-methyl-8-oxyisomorphinan ***11a***

To a cooled (ice bath) solution of **10***a* (547 mg, 2 mmol) in dry CH_2Cl_2 (8 ml) was added a 1 *M* boron tribromide solution in CH_2Cl_2 (5 ml) and the mixture allowed to stand at room temperature for 3 h. The excess boron tribromide was carefully decomposed with water. The mixture was made basic with ammonium hydroxide and layers were separated. The water layer was extracted with CH_2Cl_2 and the combined organic phase was dried and concentrated *in vacuo*. The residual orange colored solid

was recrystallized from acetone–CH_2Cl_2 to give 370 mg (64%) of **11***a* as an almost colorless solid, mp 218–220°C; nmr δ 6.7–7.3 (3H, m), 4.0–4.3 (1H, m), 2.5–3.8 (7H, m), 2.44 (3H, s), 0.8–2.4 (6H, m). *Anal.* calcd. for $C_{16}H_{21}NO_2$: C 74.10, H 8.16, N 5.40; found: C 74.21, H 8.37, N 5.25.

17-Cyclopropylmethyl-3-hydroxy-8-oxyisomorphinan ***11b***

The oxyisomorphinan **11***b* (an oil) was similarly prepared from **10***b* in 65% yield, isolated as the oxalate salt with $\frac{1}{2}CH_3OH$ of crystallization; mp 178–180°C (from methanol–acetone). *Anal.* calcd. for $C_{20}H_{27}NO_2 \cdot C_2H_2O_4 \cdot \frac{1}{2}CH_3OH$: C 64.42, H 7.44, N 3.44; found: C 64.47, H 7.57, N 3.22.

2,9α-Dimethyl-9β-hydroxy-2′-methoxy-5-[3″-(1″-hydroxypropyl)]-6,7-benzomorphan ***13a***

The diol **13***a* was prepared from **12** in 69% yield by the procedure given for the preparation of **8***a*; mp 146–148°C from *i*-propanol; nmr δ 6.5–7.1 (3H, m), 3.76 (3H, s), 3.4–3.8 (2H, m), 2.4–3.3 (5H, m), 2.32 (3H, s), 1.12 (3H, s), 0.9–2.3 (6H, m). *Anal.* calcd. for $C_{18}H_{27}NO_3$: C 70.79, H 8.91, N 4.59; found: C 70.78, H 9.05, N 4.61.

14,17-Dimethyl-3-methoxy-8-oxyisomorphinan ***14***

This compound was prepared from **13***a* in 64% yield, by the method given for the preparation of **10***a*: The hydrochloride salt of **14** crystallized from methanol–acetone with 1 mol of methanol of crystallization, mp 229–231°C; nmr (free base) δ 6.6–7.2 (3H, m) 3.8–4.1 (2H, m, 7-H_2) 3.78 (3H, s, O—CH_3), 2.4–3.6 (5H, m), 2.39 (3H, s, N—CH_3), 1.27 (3H, s, 14-CH_3), 0.7–2.4 (6H). *Anal.* calcd. for $C_{18}H_{25}NO_2 \cdot HCl \cdot CH_3OH$: C 64.12, H 8.50, N 3.93; found: C 63.98, H 8.40, N 3.85.

17-Cyano-3-methoxy-8-oxyisomorphinan ***15a***

To a solution of **14** (7.2 g, 25 mmol) in dry benzene (40 ml) was added cyanogen bromide (5.3 g, 50 mmol) and the mixture heated under reflux for 2 h. This was concentrated *in vacuo* and the residual oil was dissolved in CH_2Cl_2, washed with aqueous hydrochloric acid, and water, dried, and concentrated *in vacuo*. The residue was chromatographed (silica gel, ether) to give 5.4 g (72%) of solid **15***a*, mp 143–145°C (from acetone–ether); nmr δ 6.5–7.2 (3H, m), 3.8–4.1 (2H, m), 3.73 (3H, s), 1.15 (3H, s), 0.7–3.6 (11H). *Anal.* calcd. for $C_{18}H_{22}N_2O_2$: C 72.45, H 7.43, N 9.39; found: C 72.43, H 7.43, N 9.41.

3-Methoxy-14-methyl-8-oxyisomorphinan ***15b***

A solution of **15***a* (5.0 g, 16.7 mmol) in anhydrous THF (20 ml) was added dropwise over a 15 min period to a boiling solution of lithium aluminum hydride (2.5 g) in THF (60 ml). The whole was heated under reflux for 2 h, cooled, and treated with 1 *N* NaOH (12.5 ml). A solid was removed by filtration and washed several times with ether. The combined filtrate and washings were concentrated *in vacuo* to give 4.57 g (quantitative yield) of crude **15***b* as an oil. An analytical sample was purified as the oxalate salt by recrystallization from 95% ethanol. It crystallized as neutral oxalate with ½ mol of water of crystallization; mp 145–148°C. *Anal.* calcd. for $C_{17}H_{23}NO_2 \cdot \frac{1}{2}C_2H_2O_4 \cdot \frac{1}{2}H_2O$: C 66.03, H 7.70, N 4.28; found: C 65.69, H 7.76, N 4.15.

17-Cyclopropylcarbonyl-3-methoxy-8-oxyisomorphinan ***15c***

To a cooled (ice bath), stirred solution of **15***b* (1.48 g, 5.4 mmol) in dry CH_2Cl_2 (15 ml) and triethylamine (1 ml, 7.2 mmol) was added a solution of cyclopropane carboxylic acid chloride (0.62 g, 6 mmol) in dry CH_2Cl_2 (5 ml). The mixture was stirred for 10 min, and then washed with water followed by dilute hydrochloric acid. Drying and evaporation of solvent gave 1.82 g (quantitative yield) of **15***c* as an oil. A sample for analysis was purified by distillation at 220–230°C/0.5 Torr. *Anal.* calcd. for $C_{21}H_{27}NO_3$: C 73.87, H 7.97, N 4.10; found: C 74.03, H 8.11, N 3.99.

17-Cyclobutylcarbonyl-3-methoxy-8-oxyisomorphinan ***15d***

The amide **15***d* was similarly prepared from **15***b* in quantitative yield. An analytical sample was distilled at 220–230°C/0.4 Torr. *Anal.* calcd. for $C_{22}H_{29}NO_3$: C 74.35, H 8.22, N 3.94; found: C 74.02, H 8.32, N 3.65.

17-Cyclopropylmethyl-3-methoxy-8-oxyisomorphinan ***15e***

This compound was obtained by reduction of amide **15***c* in a procedure similar to that described for the preparation of **15***b*. The product (an oil) was isolated by column chromatography (Al_2O_3, ether) in 75% yield. The oxalate salt was recrystallized from methanol–acetone; mp 195–197°C; nmr δ 6.4–7.1 (3H, m), 3.75–4.05 (2H, m), 3.7 (3H, s), 1.15 (3H, s), 0.0–3.4 (18H). *Anal.* calcd. for $C_{21}H_{29}NO_2 \cdot C_2H_2O_4$: C 66.17, H 7.48, N 3.36; found: C 66.04, H 7.40, N 3.26.

17-Cyclobutylmethyl-3-methoxy-8-oxyisomorphinan ***15f***

This compound (an oil) was prepared similarly from **15***d* in 77% yield and purified as the oxalate salt; mp 204–206°C (from methanol–acetone); nmr δ 6.5–7.2 (3H, m), 3.88 (3H, s), 1.15 (3H, s), 0.6–4.2 (22H). *Anal.* calcd. for $C_{22}H_{31}NO_2 \cdot C_2H_2O_4$: C 66.80, H 7.71, N 3.25; found: C 66.58, H 7.68, N 3.15.

14,17-Dimethyl-3-hydroxy-8-oxyisomorphinan ***16a***

To a solution of **14** (0.73 g, 2.54 mmol) in dry THF (5 ml) was added under a nitrogen atmosphere a 0.78 *M* solution of lithium diphenylphosphide in THF (14 ml) and the whole heated under reflux for 6 h. The reaction mixture was treated with 0.5 *N* hydrochloric acid (40 ml) and extracted with ether (2 × 50 ml). The ether extract was discarded and the aqueous phase was made basic with ammonium hydroxide and extracted with CH_2Cl_2, to give after drying and evaporation 0.65 g of an oil. The oil crystallized from acetone to give 0.34 g (49%) of **16***a* as a white solid; mp 261–263°C, nmr δ 6.4–7.0 (3H, m), 3.7–4.0 (2H, m), 2.36 (3H, s), 1.15 (3H, s), 0.6–3.3 (11H). *Anal.* calcd. for $C_{17}H_{23}NO_2$: C 74.69, H 8.48, N 5.12; found: C 74.35, H 8.47, N 5.05.

17-Cyclopropylmethyl-3-hydroxy-14-methyl-8-oxyisomorphinan ***16b***

To a cooled (ice bath), stirred slurry of sodium hydride (580 mg, 24 mmol) in dry DMF (15 ml) was added ethane thiol (1.5 g, 24 mmol) followed by a solution of **15***e* (0.79 g, 2.4 mmol) in DMF (2 ml). The cooling bath was removed and the whole was heated under reflux for 4 h. After cooling, the reaction mixture was partitioned between water and CH_2Cl_2. The organic phase was washed with water, dried, and concentrated *in vacuo* to give an oil. This was dissolved in acetone and treated with a solution of dry HCl in ether to give 0.51 g (49%) of the hydrochloride of **16***b* as white solid. Recrystallization from ethanol–acetone–ether gave an analytical sample

containing 1 mol of ethanol of crystallization; mp 235–238°C. *Anal.* calcd. for $C_{20}H_{27}NO_2 \cdot HCl \cdot C_2H_5OH$: C 67.63, H 8.38, N 3.76; found: C 67.48, H 8.47, N 3.56.

17-Cyclobutylmethyl-3-hydroxy-14-methyl-8-oxyisomorphinan **16***c*

This compound was prepared from **15***f* by the procedure given for the preparation of **16***a*. It crystallized from acetone in 53% yield; recrystallization from methanol–acetone gave an analytical sample; mp 203–205°C. *Anal.* calcd. for $C_{21}H_{29}NO_2$: C 77.02, H 8.93, N 4.28; found: C 77.39, H 9.16, N 4.09.

5-Allyl-9α-hydroxy-2′-methoxy-1-methyl-6,7-benzomorphan **17***a*

To a cooled (−50°C), stirred 25% solution of diisobutyl aluminum hydride in hexane (50 ml, 77 mmol) was added dry THF (25 ml) followed by a solution of ketone **1** (10.5 g, 38.7 mmol) in dry THF (30 ml) over a period of 20 min. The whole was kept for 15 min at −50°C, treated cautiously with methanol (8 ml), and then poured onto a mixture of ice (200 g) and concentrated hydrochloric acid (40 ml). The layers were separated and the organic layer was extracted with 1 *N* hydrochloric acid (60 ml). The combined aqueous phase was extracted with CH_2Cl_2 (3 × 50 ml), and the extract washed with 2 *N* ammonium hydroxide (50 ml), dried, and concentrated *in vacuo* to give 10.5 g (100%) of essentially pure **17***a* as an oil which crystallized on standing. An analytical sample was prepared by recrystallization from ether – petroleum ether; mp 74–78°C; nmr δ 6.5–7.1 (3H, m), 5.0–6.5 (3H, m), 3.9 (1H, d, J = 5 Hz, 9-H), 3.82 (3H, s), 2.35 (3H, s), 1.1–3.3 (9H). *Anal.* calcd. for $C_{17}H_{23}NO_2$: C 74.69, H 8.48, N 5.12; found: C 74.26, H 8.73, N 5.19.

5-Allyl-1,9β-dimethyl-9α-hydroxy-2′-methoxy-6,7-benzomorphan **17***b*

A Grignard reagent was prepared by addition of a solution of iodomethane (26 g, 0.184 mol) in dry ether (30 ml) to a stirred suspension of magnesium turnings (3.71 g, 0.159 mol) in dry ether (30 ml) over a period of 2 h. Then the ether was evaporated *in vacuo* under a stream of nitrogen. To the dry solid was added in one portion a solution of **1** (9.78 g, 0.036 mol) in petroleum ether (250 ml, bp 30–60°C) and the whole vigorously stirred for 18 h. This was treated cautiously with water (70 ml) and p*H* was adjusted to 8 by addition of diluted (1:1) hydrochloric acid. The emulsified mixture was cleared by the addition of ammonium hydroxide and the layers were separated. The water layer was extracted with ether and the combined organic phase was dried and concentrated *in vacuo* to give 9.4 g (91%) of essentially pure **17***b* as an oil; nmr δ 6.5–7.1 (3H, m), 4.8–6.4 (3H, m), 3.73 (3H, s), 2.6–3.0 (5H, m), 2.3 (3H, s), 1.58 (3H, s), 1.0–2.5 (4H, m). A sample for analysis was purified as the oxalate salt by recrystallization from methanol–ether; mp 208–209°C. *Anal.* calcd. for $C_{18}H_{25}NO_2 \cdot C_2H_2O_4$: C 63.65, H 7.21, N 3.71; found: C 63.78, H 7.41, N 3.92.

5-Allyl-1-cyano-9α-hydroxy-2′-methoxy-6,7-benzomorphan **18***a*

This compound was prepared from **11***a* by the method given for the preparation of **15***a*. It crystallized from ether – petroleum ether in 70% yield as a white solid; mp 92–93°C. *Anal.* calcd. for $C_{17}H_{20}N_2O_2$: C 71.81, H 7.09, N 9.83; found: C 71.69, H 7.15, N 9.87.

5-Allyl-1-cyano-9α-hydroxy-2′-methoxy-9β-methyl-6,7-benzomorphan **18***b*

This compound was similarly prepared in 73% yield from **17***b*; mp 103–104°C (from chloroform–ether). *Anal.* calcd. for $C_{18}H_{22}N_2O_2$: C 72.45, H 7.43, N 9.39; found: C 72.56, H 7.48, N 9.23.

5-Allyl-9α-hydroxy-2′-methoxy-6,7-benzomorphan **19***a*

This compound (an oil) was obtained in quantitative yield from **18***a* by the method given for the preparation of **15***b*, except that dioxane was used as solvent. An analytical sample was purified by molecular distillation at 150°C/0.01 Torr; nmr δ 6.5–7.1 (3H, m), 5–6.5 (3H, m), 3.87 (1H, d, J = 3.5 Hz, 9-H), 3.78 (3H, s), 1.1–3.5 (9H). *Anal.* calcd. for $C_{16}H_{21}NO_2$: C 74.10, H 8.16, N 5.40; found: C 73.92, H 8.27, N 5.36.

5-Allyl-9α-hydroxy-2′-methoxy-9β-methyl-6,7-benzomorphan **19***b*

This compound was prepared similarly by reduction of **18***b* in THF, and isolated by column chromatography (silica gel; ether – 5% methanol) in 62% yield as an oil. The hydrochloride salt was recrystallized from methanol–ether; nmr δ 6.5–7.1 (3H, m), 4.8–6.4 (3H, m), 7.8 (3H, s), 1.55 (3H, s), 1–3.5 (9H). *Anal.* calcd. for $C_{17}H_{23}NO_2 \cdot HCl$: C 65.90, H 7.81, N 4.52; found: C 65.60, H 7.76, N 4.40.

5-Allyl-17-cyclopropylcarbonyl-9α-hydroxy-2′-methoxy-6,7-benzomorphan **20***a*

The hydroxyamide **20***a* was prepared from **19***a* in 80% yield by the procedure given for the preparation of **15***c*; white solid; mp 146–147°C (from benzene–ether). *Anal.* calcd. for $C_{20}H_{25}NO_3$: C 73.37, H 7.70, N 4.28; found: C 73.53, H 7.71, N 4.32.

5-Allyl-17-cyclopropylcarbonyl-9α-hydroxy-2′-methoxy-9β-methyl-6,7-benzomorphan **20***b*

The hydroxy amide **20***b* was similarly prepared in 65% yield from crude **19***b*; mp 144–145°C (from acetone). *Anal.* calcd. for $C_{21}H_{27}NO_3$: C 73.87, H 7.97, N 4.10; found: C 73.80, H 8.00, N 4.01.

5-Allyl-1-cyclopropylmethyl-9α-hydroxy-2′-methoxy-6,7-benzomorphan **21***a*

Reduction of **20***a* with lithium aluminum hydride in boiling dioxane in a procedure similar to that given for the preparation of **15***b* gave **21***a* (an oil) in 86% yield. An analytical sample was purified by molecular distillation at 180°C/0.01 Torr; nmr δ 6.6–7.1 (3H, m), 4.5–6.5 (3H, m), 3.9 (1H, d, J = 4 Hz), 7.78 (3H, s), 0.0–3.5 (16H). *Anal.* calcd. for $C_{20}H_{27}NO_2$: C 76.64, H 8.68, N 4.47; found: C 76.77, H 7.78, N 4.43.

5-Allyl-1-cyclopropylmethyl-9α-hydroxy-2′-methoxy-9β-methyl-6,7-benzomorphan **21***b*

This compound (an oil) was similarly prepared in 96% yield from **20***b*. The hydrochloride salt was recrystallized from methanol–ether; mp 236–238°C; nmr δ 6.5–7 (3H, m), 4.8–6.4 (3H, m), 3.7 (3H, s), 1.6 (3H, s) 0.0–3.1 (16H). *Anal.* calcd. for $C_{21}H_{29}NO_2 \cdot HCl$: C 69.31, H 8.31, N 3.81; found: C 69.08, H 8.44, N 3.79.

5-Allyl-2′,9α-dihydroxy-1-methyl-6,7-benzomorphan ***22a***

The diol **22***a* was prepared in 58% yield from **17***a* by the method given for the preparation of **16***b* and purified by recrystallization first from methanol–benzene and then from toluene; mp 154–156°C, nmr δ 6.4–7.1 (3H, m), 4.8–6.4 (3H, m), 3.88 (1H, d, J = 3.5 Hz), 2.4 (3H, s), 1–3.3 (9H). *Anal.* calcd. for $C_{16}H_{21}NO_2$: C 74.10, H 8.16, N 5.40; found: C 74.45, H 8.20, N 5.01.

5-Allyl-1-cyclopropylmethyl-2′,9α-dihydroxy-6,7-benzomorphan ***22b***

The diol **22***b* was similarly prepared in 87% yield from **21***a*, as an amorphous solid. It was purified by recrystallization from methanol–ether; mp 171–174°C. An analytical sample was purified by molecular distillation at 160°C/0.01 Torr, nmr δ 6.4–7.0 (3H, m), 4.9–6.3 (3H, m), 3.75 (1H, t, J = 4 Hz, 9-H), 0.0–3.5 (16H). *Anal.* calcd. for $C_{19}H_{25}NO_2$: C 76.22, H 8.42, N 4.68; found: C 76.19, H 8.50, N 4.72.

5-Allyl-1-cyclopropylmethyl-2′,9α-dihydroxy-9β-methyl-6,7-benzomorphan ***22c***

The diol **22***c* was similarly prepared in 67% yield from **21***b* and purified by recrystallization of the hydrochloride salt from methanol–acetone; mp 220–223°C; nmr δ 6.4–7.0 (3H, m), 4.9–6.3 (3H, m), 1.62 (3H, s), 0.0–3.2 (16H). *Anal.* calcd. for $C_{20}H_{27}NO_2 \cdot HCl$: C 68.65, H 8.07, N 4.00; found: C 68.64, H 8.06, N 3.96.

Tetrahydrofuranobenzomorphan ***24a***

The diol **22***a* (0.50 g, 1.9 mmol) was treated with concentrated hydrochloric acid (10 ml) at reflux for 5 min. The reaction mixture was concentrated to *ca.* 5 ml, made basic with ammonium hydroxide, cooled, and filtered to give crude solid **24***a*. This was purified by recrystallization first from toluene and then from ethanol to give 160 mg of pure **24***a*; mp 207–208°C; nmr δ 6.5–7.1 (3H, m), 3.7–4.1 (2H, m), 3.3–3.6 (1H, m), 2.8–3.0 (2H, m), 2.46 (3H, s), 1.5–2.6 (6H, m), 1.25 (3H, d, J = 5 Hz). *Anal.* calcd. for $C_{16}H_{21}NO_2$: C 74.10, H 8.16, N 5.40; found: C 73.81, H 8.08, N 5.12.

Tetrahydrofuranobenzomorphan ***24b***

This compound was obtained in two steps from **17***b* as follows. A solution of **17***b* (820 mg, 2.85 mmol) in concentrated hydrochloric acid (10 ml) was heated under reflux for 5 min, cooled, made basic with sodium hydroxide, and extracted with ether, to give after drying and concentration 800 mg of crude **23***a* as an oil; nmr δ 6.4–7.1 (3H, m), 3.65 (3H, s, O—CH_3), 3.4–3.9 (1H, m, 2′′-H), 2.6–3.0 (3H, m), 2.3 (3H, s, N—CH_3), 1.5–2.7 (6H, m), 1.45 (3H, s, 9-CH_3), 1.22 (3H, d, J = 6 Hz, 3′′-H_3). This was demethylated without further purification by the procedure given for the preparation of **16***a* to give crude solid **24***b*. This was purified by recrystallization from ethanol–water to give 530 mg (68%) of the pure product; mp 217–219°C; nmr δ 6.4–7.1 (3H, m), 3.4–3.9 (1H, m) 1.2–3.2 (11H, m) 1.52 (3H, s, 9-CH_3), 1.3 (3H, d, J = 6 Hz, 3′′-H_3). *Anal.* calcd. for $C_{17}H_{23}NO_2$: C 74.69, H 8.43, N 5.12; found: C 74.52, H 8.41, N 5.06.

Tetrahydrofuranobenzomorphan ***24c***

This compound was similarly prepared in two steps (via **23***b*) in 78% yield from **21***b*, isolated as the hydrochloride salt from acetone. Recrystallization from methanol–acetone gave an analytical sample; mp 246–249°C; nmr δ 6.5–7.0 (3H, m), 3.4–3.9 (1H, m, 2′′-H), 3.1–3.3 (1H, m, 9-H), 1.5–2.9 (10H, m), 1.55 (3H, s, 9-CH_3), 1.32 (3H, d, J = 6 Hz, 3′′-H_3), 0.0–1.1 (5H, m, c-C_3H_5). *Anal.* calcd. for $C_{20}H_{27}NO_2 \cdot HCl$: C 68.65, H 8.07, N 4.00; found: C 68.68, H 8.06, N 3.87.

Crystal and molecular structure of hexadecamethylcyclooctaphosphazene, $(NPMe_2)_8$

RICHARD T. OAKLEY, NORMAN L. PADDOCK, STEVEN J. RETTIG, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received December 23, 1976

RICHARD T. OAKLEY, NORMAN L. PADDOCK, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **55**, 2530 (1977).

Crystals of hexadecamethylcyclooctaphosphazene are tetragonal, $a = 13.637(1)$, $c = 8.215(1)$ Å, $Z = 2$, space group $P4/n$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to a final R of 0.033 and R_w of 0.032 for 1306 reflections with $I \geq 4\sigma(I)$. The molecule has crystallographic fourfold (C_4) symmetry with weighted mean bond lengths P—N, 1.590(13), P—C, 1.811(2), and C—H, 0.95(2) Å (those not involving hydrogen have been corrected for libration, rms deviations from the mean are given in parentheses). Angles in the 16-membered ring are 119.2(1) and 115.1(1)° at P and 131.5(1) and 148.2(1)° at N.

RICHARD T. OAKLEY, NORMAN L. PADDOCK, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **55**, 2530 (1977).

Les cristaux de l'hexadécaméthylcyclooctaphosphazène sont tétragonaux, $a = 13.637(1)$, $c = 8.215(1)$ Å, $Z = 2$, groupe d'espace $P4/n$. On a résolu la structure par les méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.033 et R_w de 0.032 pour 1306 réflexions avec $I \geq 4\sigma(I)$. La molécule a une symétrie cristallographique quaternaire (C_4) avec des longueurs de liaison moyennes pondérées P—N, 1.590(13), P—C, 1.811(2) et C—H, 0.95(2) Å (les longueurs n'impliquant pas d'hydrogène ont été corrigées pour la libration; les déviations rms à partir des valeurs moyennes sont données entre parenthèses). Les angles dans le cycle à 16 chaînons sont 119.2(1) et 115.1(1)° au niveau du phosphore et 131.5(1) et 148.2(1)° au niveau de l'azote.

[Traduit par le journal]

Introduction

A method for preparing methylphosphazenes of large ring size ($n \geq 6$) has recently been described along with the crystal structure of the heptameric derivative $(NPMe_2)_7$ (1). We now report the crystal structure of the octamer $(NPMe_2)_8$. A detailed analysis of molecular geometry for the series $(NPMe_2)_{3-10}$ is planned upon completion of the structural work presently in progress. The structures of $(NPMe_2)_4$ (2) and $(NPMe_2)_5$ (3) have been determined.

Experimental

$(NPMe_2)_8$ was prepared as previously described (1). Crystals suitable for X-ray analysis were obtained by recrystallization from benzene. The crystal chosen for study was mounted with c parallel to the goniostat axis and had dimensions of *ca.* 0.2 × 0.2 × 0.4 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least-squares treatment of $\sin^2\theta$ values for 18 reflections measured on a diffractometer with Cu K_α radiation. Crystal data are:

$C_{16}H_{48}N_8P_8$ fw = 600.4

Tetragonal, $a = 13.637(1)$, $c = 8.215(1)$ Å, $V = 1527.7(2)$ Å^3, $Z = 2$, $\rho_c = 1.305$ g cm^{-3}, $F(000) = 640$ (22°C, Cu K_α, $\lambda = 1.5418$ Å, $\mu = 43.7$ cm^{-1}). Absent reflections: $hk0$, $h + k \neq 2n$. Space group $P4/n$ (C_{4h}^3, No. 85).

Intensities were measured with nickel-filtered Cu K_α radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 2° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed. Background counts (10 s) were measured at each end of the scan. Data were measured to $2\theta = 160°$. The intensity of the check reflection, measured every 40 reflections throughout the data collection, remained constant to within ±2%. The structure amplitudes were derived and an absorption correction was applied by a computer program using a Gaussian integration method (4, 5). Transmission factors ranged from 0.306 to 0.487. Of the 1678 independent reflections measured, 1312 had intensities greater than $4\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.05S)^2$ with S = scan count and B = time-averaged background count. These reflections were used in the solution and refinement of the structure.

The structure was solved by direct methods with use of tangent formula refinement (6–8). An E-map calculated from the set of phases with the lowest value of R_k gave the positions of the eight non-hydrogen atoms among the 18 highest peaks. Two cycles of isotropic, followed by two cycles of anisotropic full-matrix least-squares refinement of the non-hydrogen atoms gave $R = 0.058$. The 12 highest peaks on a difference map calculated at this point accounted for the 12 hydrogen atoms. The entire structure (including hydrogen atoms with isotropic thermal parameters) was refined for four cycles giving a final R of 0.033 and R_w of 0.032 for 1306 reflections with $I \geq 4\sigma(I)$ (6 reflections which had $|F_o| - |F_c| > 3\sigma(F)$ were removed from the data set in the final stages of refinement; for all 1678 reflections $R = 0.048$ and $R_w = 0.039$).

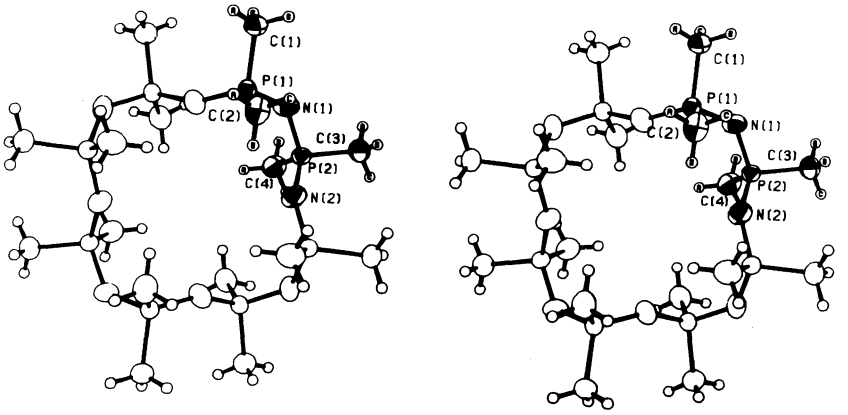

FIG. 1. A stereo view of the hexadecamethylcyclooctaphosphazene molecule. 50% ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned artificially small temperature factors for the sake of clarity.

TABLE 1. Final positional parameters (fractional × 10^4, P × 10^5, H × 10^3, origin at $\bar{1}$) with estimated standard deviations in parentheses

Atom	x	y	z
P(1)	84284(3)	98171(3)	33326(6)

C(4)	9311(2)	8307(2)	−417(3)
H(1a)	804(2)	1134(2)	430(3)
H(1b)	917(2)	1129(2)	417(3)
H(1c)	853(2)	1148(3)	259(5)
H(2a)	803(2)	956(2)	597(4)
H(2b)	848(3)	861(3)	523(4)
H(2c)	913(2)	953(2)	577(4)
H(3a)	1118(2)	926(3)	65(4)
H(3b)	1131(2)	882(3)	235(5)
H(3c)	1135(2)	815(2)	83(4)
H(4a)	862(2)	821(2)	−39(4)
H(4b)	944(2)	890(3)	−102(4)
H(4c)	964(2)	775(3)	−85(4)

The least-squares refinement was based on the minimization of $\Sigma w[|F_o| - |F_c/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was 6.8×10^{-7}. The scattering factors of ref. 9 were used for the non-hydrogen atoms and those of ref. 10 for the hydrogen atoms. Anomalous scattering factors from ref. 11 were used for the non-hydrogen atoms. The anisotropic thermal parameters employed in the refinement are U_{ij} in the expression:

$$f = f^0 \exp [-2\pi^2(U_{11}\, h^2a^{*2} + U_{22}\, k^2b^{*2} + U_{33}\, l^2c^{*2} + 2U_{12}\, hka^*b^* + 2U_{13}\, hla^*c^* + 2U_{23}\, klb^*c^*)]$$

where f^0 is the tabulated scattering factor and f is that corrected for thermal motion (for H atoms $f = f^0 \times \exp [-8\pi^2 U \sin^2 \theta/\lambda^2]$). The weighting scheme: $w = 1/[1.5360 - 0.12297|F_o| + 0.002314(|F_o|)^2 + 0.000020 \times (|F_o|)^3]$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

On the final cycle of refinement the mean parameter shift was 0.32σ, the largest shift, 1.8σ, being associated with a hydrogen atom. The mean error in an observation of unit weight was 1.059. The final positional and thermal parameters appear in Tables 1 and 2 respectively.[1] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation (**T**), libration (**L**), and screw (**S**) motion (12) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0011 Å^2. Analysis of the entire molecule as a rigid body was unsuccessful, but each of the phosphorus tetrahedra behaves as a rigid body (rms $\Delta U_{ij} = 0.0011$ Å^2 for P(1) and 0.0013 Å^2 for the P(2) group).

The appropriate bond distances have been corrected for libration (13, 14), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values.[1] Corrected angles differ from the uncorrected values in Table 4 by less than 1σ.[1]

Results and Discussion

Figure 1 shows the molecule viewed along the fourfold axis with the crystallographic numbering scheme and Fig. 2 shows the packing arrange-

[1]The structure factor table and Tables 2 (thermal parameters), 3(*b*), and 4(*b*) (individual bond lengths and angles involving hydrogen atoms) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

H—C—H	106(3)–117(3)	110(3)

ment viewed along *c*. Bond angles are given in Table 4 and the unique intraannular torsion angles in the 16-membered ring in Table 5. The mean structural parameters for $(NPMe_2)_8$ are compared with those of related molecules $(NPMe_2)_4$ (2), $(NPMe_2)_5$ (3), and $(NPMe_2)_7$ (1) in Table 6.

The crystal structure (Fig. 2) consists of well-separated molecules of hexadecamethylcyclooctaphosphazene. All intermolecular nonbonded contacts correspond to normal van der Waals interactions. There are no intermolecular H. . .H separations shorter than 2.5 Å.

The molecule has crystallographic (exact) C_4 symmetry. Idealized local conformations (G = gauche, T = trans, ref. 15) at the phosphorus atoms are defined in terms of the intrannular torsion angles about the two P—N bonds. The ideal GG local conformation has both torsion angles 60° and the ideal GT local conformation has one torsion angle of 60° and one of 180°. In $(NPMe_2)_8$ P(1) has a GG and P(2) a GT local conformation, thus adjacent phosphorus atoms have alternately GG and GT local conformations around the ring. This arrangement is similar to that observed for the heptamer (1) in which the local conformations are alternately GG and GT except for one pair of adjacent phosphorus atoms which both have GT local conformations.

The mean structural parameters in Table 6 show that the mean P—N and P—C bond lengths are nearly the same in all three compounds. The

TABLE 5. Intraannular torsion angles (deg) 16-membered ring*

Bond	Value
N(2′)— P(1)	−76.8(2)
P(1) —N(1)	−61.3(2)
N(1) — P(2)	−27.8(2)
P(2) —N(2)	−156.5(3)

*Symmetry related torsion angles have the same signs as those listed above.

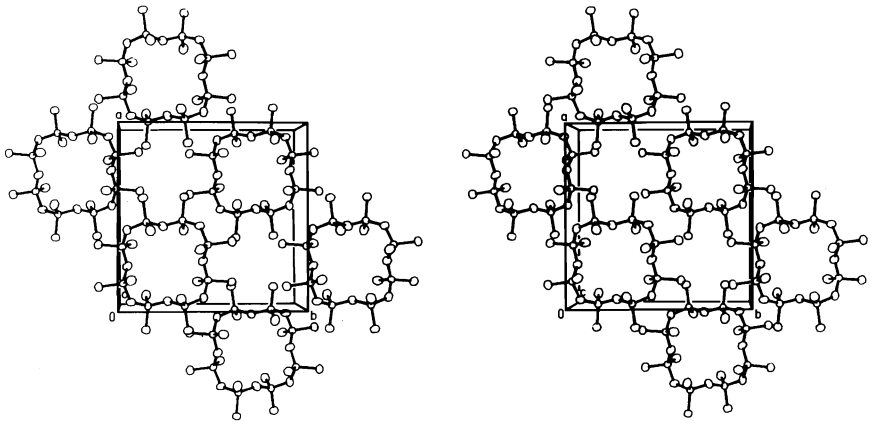

FIG. 2. The crystal structure of hexadecamethylcyclooctaphosphazene viewed along c (origin at $\bar{1}$).

TABLE 6. Mean structural parameters for $(NPMe_2)_n$ (n = 4, 5, 7, and 8) (distance in Å and angles in deg)*

	Length (Å) for n =			
Bond	4	5	7	8
P—C	1.804(3)	1.801(4)	1.804(11)	1.811(2)
P—N	1.596(5)	1.586(4)	1.592(6)	1.590(13)
	Angle (deg) for n =			
Bonds	4	5	7	8
N—P—N	119.8(2)	118.7(18)	117.1(16)	117.2(21)
P—N—P	132.0(2)	132.9(17)	132.9(20)	139.9(84)
C—P—C	104.1(2)	104.3(8)	103.9(5)	103.5(10)

*Root-mean-square deviations from the mean in parentheses.

N—P—N and C—P—C angles decrease slightly and the P—N—P angles increase with increasing ring size. In hexadecamethylcyclooctaphosphazene the corrected P—C bond lengths are equal within experimental error but the corrected P—N distances and the corresponding angles at both the P and N atoms differ significantly. This appears to result from differences in both local conformation and σ-hybridization between the unique P and N atoms in the structure.

Crystals of 2,2,4,6,6-pentamethyl-5-benzoyl-4-(*N*-methylbenzamido)-1,3-diaza-2,4,6(P^v)-triphosphorin are triclinic, $a = 13.375(1)$, $b = 11.313(1)$, $c = 7.925(1)$ Å, $\alpha = 107.72(1)$, $\beta = 98.23(1)$, $\gamma = 87.00(1)°$, $Z = 2$, space group $P\bar{1}$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to a final R of 0.067 and R_w of 0.089 for 3954 reflections with $I \geq 3\sigma(I)$. The P_3N_2C ring is nearly planar and has a conformation corresponding to a flattened version of the chair – twist boat. Bond lengths in the azaphosphorin ring, P—N, 1.579–1.614(2), and P—C, 1.752(3) and 1.777(3) Å, indicate conjugation with the *C*-benzoyl group. The exocyclic P—N bond length, 1.742(3) Å, is longer than those in related compounds as a result of competitive electron withdrawal from the *N*-benzoyl group. Other bond lengths (corrected for libration) are: mean P—Me, 1.796(4); C=O, 1.242(3) and 1.247(4); C—N, 1.472(3) and 1.369(4); mean C—C(phenyl), 1.391(10); other $C(sp^2)$—$C(sp^2)$; 1.417–1.518(4) Å.

RICHARD T. OAKLEY, NORMAN L. PADDOCK, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **55**, 2534 (1977).

Les cristaux de la pentaméthyl-2,2,4,6,6 benzoyl-5 (*N*-méthylbenzamido)-4 diaza-1,3 triphosphorine-2,4,6 (P^v) sont tricliniques $a = 13.375(1)$, $b = 11.313(1)$, $c = 7.925(1)$ Å, $\alpha = 107.72(1)$, $\beta = 98.23(1)$, $\gamma = 87.00(1)°$, $Z = 2$, groupe d'espace $P\bar{1}$. On a résolu la structure par la méthode des synthèses de Patterson et de Fourier et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de $R = 0.067$ et $R_w = 0.089$ pour 3954 réflexions avec $I \geq 3\ \sigma(I)$. Le cycle P_3N_2C est pratiquement planaire et a une conformation correspondant à une version aplatie d'une chaise – bateau croisée. Les longueurs de liaison dans le cycle azaphosphorine, P—N, 1.579–1.614(2) et P—C, 1.752(3) et 1.777(3) Å, indiquent qu'il existe une conjugaison avec le groupe *C*-benzoyle. La longueur de liaison P—N exocyclique 1.742(3) Å est plus grande que celle observée dans des composés semblables et ceci est le résultat d'un enlèvement d'électron compétitif du groupe *N*-benzoyle. D'autres longueurs de liaison (corrigées pour la libration) sont: la moyenne P—Me, 1.796(4); C=O, 1.242(3) et 1.247(4); C—N, 1.472(3) et 1.369(4); moyenne C—C(phényle), 1.391(10); autre $C(sp^2)$—$C(sp^2)$; 1.417–1.518(4) Å.

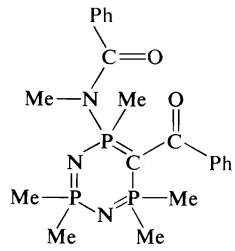
Introduction

In recent years, the molecular structures of many neutral and protonated phosphazene derivatives have been reported. The present paper represents a departure from these more well known compounds, and describes the crystal and molecular structure of the azaphosphorin derivative $Me_5(NMeCOPh)P_3N_2CCOPh$, **1**, in which a nitrogen atom of a P_3N_3 phosphazene ring has been replaced by a carbon atom (1).



1

Experimental

Crystals suitable for X-ray analysis were obtained by recrystallization from benzene/octane. The crystal chosen for study was mounted with c^* parallel to the goniostat axis and had dimensions of *ca.* 0.35 × 0.40 × 0.60 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least-squares treatment of $\sin^2\theta$ values for 28 reflections measured on a diffractometer with Cu K_α radiation ($\lambda = 1.5418$ Å). Crystal data (at 22°C) are:

$C_{21}H_{28}N_3O_2P_3$ fw = 447.4

Triclinic, $a = 13.375(1)$, $b = 11.313(1)$, $c = 7.925(1)$ Å, $\alpha = 107.72(1)$, $\beta = 98.23(1)$, $\gamma = 87.00(1)°$, $V = 1130.4(2)$ Å^3, $Z = 2$, $\rho_c = 1.314$ g cm^{-3}, $F(000) = 472$, μ(Cu

K_α) = 25.7 cm^{-1}. Space group $P\bar{1}$ (C_i^1, No. 2) from structure analysis.

Intensities were measured with nickel-filtered Cu K_α radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 2° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed. Background counts (10 s) were measured at each end of the scan. Data were measured to 2θ = 146°. The intensity of the check reflection, measured every 40 reflections throughout the data collection, had an rms deviation of 6.5% from its mean value. Lorentz and polarization corrections and check reflection scaling were applied, and the structure amplitudes were derived. No absorption correction was made. Of the 4524 independent reflections measured, 3969 had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time averaged background count. These reflections were used in the solution and refinement of the structure.

The analysis was carried out in the centrosymmetric space group $P\bar{1}$ on the basis of the $|E|$ statistics. The positions of the three phosphorus atoms were determined from the three-dimensional Patterson function. Two cycles of isotropic full-matrix least-squares refinement of the phosphorus atoms gave R = 0.468. The positions of the remaining non-hydrogen atoms were located on a difference map calculated at this point. The non-hydrogen atoms were then refined isotropically for two cycles and then anisotropically for two cycles giving R = 0.089. A subsequent difference map gave positions for all 28 hydrogen atoms which were included in later cycles of refinement with isotropic thermal parameters. The entire structure (375 variables) was refined for two cycles giving a final R of 0.067 and R_w of 0.089 for 3954 reflections with $I \geq 3\sigma(I)$ (15 reflections which had $|F_o| - |F_c| > 3\sigma(F)$ were removed from the data set in the final stages of refinement; for all 4524 reflections R = 0.073 and R_w = 0.092).

The least-squares refinement was based on the minimization of $\Sigma w[|F_o| - |F_c|/(1 + gI)|]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was 3.1 × 10^{-8}. The scattering factors of ref. 2 were used for the non-hydrogen atoms and those of ref. 3 for the hydrogen atoms. Anomalous scattering factors from ref. 4 were used for the non-hydrogen atoms. The anisotropic thermal parameters employed in the refinement are U_{ij} in the expression:

$$f = f^0 \exp\,[-2\pi^2(U_{11}\,h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}\,l^2c^{*2} + 2U_{12}\,hka^*b^* + 2U_{13}\,hla^*c^* + 2U_{23}\,klb^*c^*)]$$

where f^0 is the tabulated scattering factor and f is that corrected for thermal motion (for H atoms $f = f^0 \exp[-8\pi^2 U \sin^2\theta/\lambda^2]$). The weighting scheme: $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

On the final cycle of refinement the mean parameter shift was 0.37σ, the largest shift (1.8σ) being associated with a hydrogen atom. The mean error in an observation of unit weight was 2.238. The final positional and thermal parameters appear in Tables 1 and 2 respectively.

(*b*) Bonds involving hydrogen atoms

Bond	Length	Mean
C(ar)—H	0.81(6)–1.10(5)	0.98(8)
C(Me)—H	0.84(7)–1.03(4)	0.95(5)

Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation (**T**), libration (**L**), and screw (**S**) motion (5) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0016 Å^2. Analyses were successful for the two phenyl groups (rms ΔU_{ij} = 0.0021 Å^2 for C(7)—C(13) and 0.0017 Å^2 for C(16)—C(21)) and for the 13 atom group P(1)—P(3), N(1)—N(3), and C(1)—C(7) (rms ΔU_{ij} = 0.0040 Å^2).

[1]The structure factor table and Tables 2 (thermal parameters), 3(*b*), and 4(*b*) (individual bond lengths and angles involving hydrogen atoms), 6 and 7 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

H—C(sp^3)—H	83(5)–131(5)	108(11)

The appropriate bond distances have been corrected for libration (6, 7), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3[1] along with the uncorrected values.

Results and Discussion

The crystal structure (the first of a compound containing the P_3N_2C heterocycle) consists of discrete molecules of 2,2,4,6,6-pentamethyl-5-benzoyl-4-(*N*-methylbenzamido)-1,3-diaza-2,4,6-(P^v)-triphosphorin. A general view of the molecule with the crystallographic numbering scheme is shown in Fig. 1; Fig. 2 shows the packing arrangement viewed along *c**. The only intermolecular interaction is a possible C(14)—H-(14a). . .O(1) (x, y, $1 + z$) hydrogen bond (C. . .O = 3.309(4) Å); all other intermolecular contacts correspond to normal van der Waals interactions.

Bond angles are given in Table 4,[1] and intra-annular torsion angles in Table 5. Distances of atoms from weighted least-squares mean planes (Table 6) and non-bonded distances and details of the C—H. . .O interaction (Table 7) have been deposited.[1] Some of the key molecular dimensions are shown schematically in Fig. 3.

The P_3N_2C ring is slightly non-planar; the mean displacement from the mean plane is 0.075 Å, the maximum 0.226 Å (N(3)). The torsion angles in Table 5 indicate that the ring conformation corresponds closely to a flattened version of the chair – twist-boat transition (8). The bond angles are similar to those found in P_3N_3 rings (see *e.g.* ref. 9), but, in contrast to the marked alternation in bond lengths found in the structures of protonated phosphazenes (10–14), the P—N bonds vary only slightly in length. The averages of the P(1)—N(3), P(2)—N(2), and P(3)—N(2), P(3)—N(3) pairs are 1.586, 1.605 Å respectively, both close to the values found in $(NPMe_2)_{4,7,8}$ (1.596, 1.592, 1.590 Å (15–17)), indicating that the net effect of replacing a nitrogen atom by a carbon atom is small. The

mean length[2] (1.765 Å) of the significantly different P(1)—C(1) and P(2)—C(1) bonds (1.752(3) and 1.777(3) Å) is somewhat greater than the mean of a single P—C bond (1.80 Å (18)) and a P=C bond found in a simple ylid (1.66 Å (19, 20)). The additional lengthening is probably the result of charge delocalization into the *C*-benzoyl group, as found in *C*-benzoyl ylids $Ph_3PCXCOPh$ (X = Cl, I) (21).[3] Conjugation with the *C*-benzoyl group is indicated by a lengthening of the C(7)=O(1) bond from 1.23 Å (18) to 1.247(4) Å, and a significant shortening of the C(1)—C(7) bond to 1.419(4) Å, compared to the 1.485 Å expected for a $C(sp^2)$—$C(sp^2)$ single bond (23). Because of the competing influence of the azaphosphorin ring, the extent of these effects is less marked than in the *C*-benzoyl ylids $Ph_3PCXCOPh$ (Table 8).

The coordination groups of the trigonal atoms C(1) and C(7) are significantly non-planar, though chemically the deviation is unimportant. Probably for steric reasons, the P—C(1)—C(7)-[O(1)]—C(8) unit is not planar. Torsion about the central C(1)—C(7) bond (7.7°) is small enough to allow conjugation between the P—C(1) and C(7)=O(1) bonds, but, consistently with the C(7)—C(8) distance of 1.518(4) Å, conjugation with the phenyl group is prohibited by a large torsion angle, as in $Ph_3PCXCOPh$ (Table 8). The geometry of the *N*-benzoyl group is somewhat different. The C(15) carbonyl group is planar within experimental error, and the co-

[2]Here and elsewhere in this paper when mean values are quoted they refer to weighted means with rms deviations from the mean in parentheses.

[3]For a recent summary of P=C bond lengths in substituted ylids $R_3PCR^1R^2$, see ref. 22.

TABLE 8. Bond lengths and torsion angles (τ) in *C*-benzoylated ylids

Compound	Length (Å)			Angle (deg)	
	P=C	C—C	C=O	τ(C—C)†	τ(C—Ph)†
$Ph_3P{=}CICOPh$*	1.71	1.35	1.28	12	52
$Ph_3P{=}CClCOPh$*	1.736	1.361	1.301	4.8	57.7
$Me_5(NMeCOPh)P_3N_2CCOPh$	1.765	1.431	1.244	7.7‡	73.5

*Reference 21.
†Mean value.
‡53.1° for the *N*-benzoyl group.

ordination group at N(1) is nearly so. The relative conjugative abilities of the azaphosphorin ring and the benzoyl group are indicated by the long P(1)—N(1) bond. At 1.742(3) Å, this bond is much longer than the exocyclic P—N bonds (1.651–1.678 Å) in the dimethylaminophosphazenes $(NP(NMe_2)_2)_{3,4,6,8}$ (9, 24–26), and approaches the value of 1.77 Å expected for a P—N single bond (27). It is similar to the unique exocyclic P—N bond length in $N_4P_4(NMe_2)_8 \cdot W(CO)_4$ (28), which is lengthened to 1.75 Å through the action of the metal as a competitive acceptor for the formally unshared electrons of a dimethylamino group. In both molecules, conjugation of the exocyclic nitrogen atom with the ring is reduced. Nevertheless, comparison of the N(1)—C(15) bond length (1.369(4) Å) with the corresponding distance in benzamide (1.342(3) Å) (29) offers direct evidence that some conjugation with the azaphosphorin ring still occurs.

Both phenyl groups are slightly but significantly non-planar. The mean phenyl C—C distance of 1.391(10) Å is as expected. The N—Me distance of 1.472(3) Å is significantly greater than the value of 1.446 Å expected for a $C(sp^3)$—$N(sp^2)$ single bond. The mean P—Me distance of 1.796(4) Å is somewhat less than the values of 1.804, 1.804, and 1.811 Å found in the methylphosphazenes $(NPMe_2)_{4,7,8}$ (15–17). The bond lengths involving hydrogen atoms (mean C(ar)—H, 0.98(8) and mean C(Me)—H, 0.95(5) Å) are as expected for X-ray data.

N,N-Ethylenebis(salicylideneimine) derivatives of gallium trimethyl: crystal and molecular structure of *N,N*-ethylenebis(salicylideneiminato)bis(dimethylgallium)

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received January 13, 1977

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **55**, 2540 (1977).

Crystals of *N,N*-ethylenebis(salicylideneiminato)bis(dimethylgallium) are orthorhombic, $a = 22.781(1)$, $b = 9.4869(6)$, $c = 19.700(2)$ Å, $Z = 8$, space group *Pbca*. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to a final R of 0.036 and R_w of 0.029 for 2248 reflections with $I \geq 3\sigma(I)$. Details of the preparation and physical properties of $(C_{16}H_{14}N_2O_2)(GaMe_2)_2$ and $(C_{16}H_{15}N_2O_2)(GaMe_2)$ are given. The $(C_{16}H_{14}N_2O_2)(GaMe_2)_2$ molecule is approximately centrosymmetric in the solid state. A "$GaMe_2$" unit is coordinated to each of the two salicylideneiminato moieties of the *N,N*-ethylenebis(salicylideneiminato) ligand. The gallium atoms have a distorted tetrahedral coordination geometry, with bond angles at gallium ranging from 92.7(1) to 124.6(3)°. Important bond lengths (corrected for libration) are: Ga—O, 1.886(2) and 1.884(2), Ga—N, 2.033(3) and 2.042(3), and weighted mean Ga—C, 1.959(9) Å.

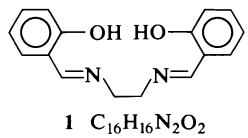
KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **55**, 2540 (1977).

Les cristaux du *N,N*-éthylènebis(salicylidèneiminato)bis(diméthylgallium) sont orthorhombiques, $a = 22.781(1)$, $b = 9.4869(6)$, $c = 19.700(2)$ Å, $Z = 8$, groupe d'espace *Pbca*. On a résolu la structure par les méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.036 et R_w de 0.029 pour 2248 réflexions avec $I \geq 3\sigma(I)$. On donne les détails pour la préparation ainsi que les propriétés physiques de $(C_{16}H_{14}N_2O_2)(GaMe_2)_2$ et $(C_{16}H_{15}N_2O_2)(GaMe_2)$. La molécule $(C_{16}H_{14}N_2O_2)(GaMe_2)_2$ est approximativement centrosymétrique à l'état solide. Une unité "$GaMe_2$" est coordonnée à chacune des deux portions salicylidèneiminato du ligand *N,N*-éthylènebis(salicylidèneiminato). Les atomes de gallium possèdent une géométrie de coordination tétraédrique déformée avec des angles au niveau du gallium allant de 92.7(1) jusqu'à 124.6(3)°. Les longueurs de liaison importantes (corrigées pour la libration) sont: Ga—O, 1.886(2) et 1.884(2), Ga—N, 2.033(3) et 2.042(3) et la moyenne pondérée de Ga—C, 1.959(9) Å.

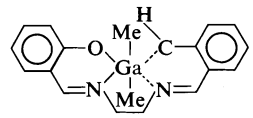
[Traduit par le journal]

Introduction

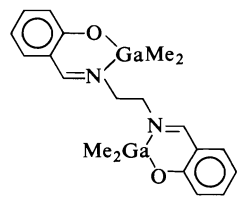
Gallium trimethyl reacts readily with compounds containing "active hydrogen", eliminating methane to yield products containing either four- or five-coordinate gallium (1–9). These products are often associated and frequently occur as dimers. The present study involves the reaction of gallium trimethyl with the "active hydrogen" compound *N,N*-ethylenebis(salicylideneimine), **1**. Two products have been isolated. The 1:1 complex, **2**, may contain an octahedrally coordinated gallium atom, but the material is polycrystalline and thus unsuitable for X-ray analysis. The crystal structure of the 2:1 complex, **3**, has been determined to discover if oligomerization *via* oxygen lone pair coordination to gallium occurs to give five-coordinate gallium.



1 $C_{16}H_{16}N_2O_2$



2 $(C_{16}H_{15}N_2O_2)GaMe_2$



3 $(C_{16}H_{14}N_2O_2)(GaMe_2)_2$

Experimental

All solvents were dried and distilled before use and reactions involving gallium trimethyl were initiated in a glove box filled with dry nitrogen, with subsequent

handling occurring under a blanket of dry nitrogen or on a high vacuum line. Gallium trimethyl was prepared as described previously (10) and *N,N*-ethylenebis(salicylideneimine), **1**, was prepared from ethylenediamine and salicylaldehyde by standard methods.

*$(C_{16}H_{15}N_2O_2)(GaMe_2)$, **2***

This 1:1 compound was prepared by reacting **1** (3.57 g, 13.32 mmol) with gallium trimethyl (1.53 g, 13.34 mmol) in benzene solution at room temperature. Methane was briskly evolved and after completion of the reaction the solvent was removed to yield a yellow solid product. This was recrystallized from toluene to give an air-stable yellow material. *Anal.* calcd. for $(C_{16}H_{15}N_2O_2)(GaMe_2)$: C 58.9, H 5.7, N 7.6; found: C 58.6, H 5.6, N 7.59. Mass spectrum data (recorded on a Varian MAT CH4B mass spectrometer at 70 eV with an ion source temperature of approximately 70°C) are

353	36.0	$(C_{16}H_{15}N_2O_2)GaMe^+$
351	55.0	
338	38.0	$(C_{16}H_{15}N_2O_2)Ga^+$
336	57.0	
267	100	$(C_{16}H_{15}N_2O_2)^+$

^1H nmr (C_6D_6 soln.): τ_{GaMe_2} = 10.06 ppm singlet, τ_{OH} = 2.34 ppm singlet, $\tau_{"CH_2CH_2"}$ = 6.91 ppm "triplet" (J = 6 Hz), $\tau_{C_6H_6}$ = 2.84 ppm.

*$(C_{16}H_{14}N_2O_2)(GaMe_2)_2$, **3***

A stoichiometric 1:2 ratio of reactants, *N,N*-ethylenebis(salicylideneimine) and gallium trimethyl, failed to give the desired product, even under forcing conditions. It is necessary to react *N,N*-ethylenebis(salicylideneimine) with an excess of gallium trimethyl.

N,N-Ethylenebis(salicylideneimine) (0.41 g, 1.53 mmol) was dissolved in xylene and transferred quantitatively into a break–seal apparatus. Gallium trimethyl (1.6 g, 13.95 mmol) was condensed onto the frozen **1** solution at −196°C, and the apparatus evacuated and sealed. The reaction bulb was then maintained at 110°C for 48 h. The methane evolved was measured (calcd. 34.5 ml; found 41.0 ml at STP). The solvent was removed to yield a yellow powdery solid as product. This was recrystallized from benzene to yield an air-sensitive yellow crystalline material. Crystals suitable for X-ray study were positioned in capillary tubes which were subsequently sealed to prevent atmospheric interference. *Anal.* calcd. for *N,N*-ethylenebis(salicylideneiminato)bis(dimethylgallium): C 51.6, H 5.6, N 6.0; found: C 51.9, H 5.8, N 5.9. Mass spectrum data are

^1H nmr (C_6D_6 soln.): τ_{GaMe_2} = 9.96 ppm singlet, $\tau_{"CH_2CH_2"}$ = 7.04 ppm singlet, $\tau_{C_6H_6}$ = 2.84 ppm.

*X-Ray Crystallographic Analysis of $(C_{16}H_{14}N_2O_2)(GaMe_2)_2$, **3***

The crystal chosen for study was mounted with c parallel to the goniostat axis and had dimensions of *ca.* 0.09 × 0.25 × 0.49 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least-squares on 2 sin θ/λ values for 20 reflections measured on a diffractometer with Cu K_α radiation (λ = 1.5418 Å). Crystal data (at 22°C) are:

$C_{20}H_{26}Ga_2N_2O_2$ fw = 465.9
Orthorhombic, a = 22.781(1), b = 9.4869(6), c = 19.700(2) Å, V = 4257.8(6) Å^3, Z = 8, ρ_c = 1.4535(2) g cm^{-3}, $F(000)$ = 1904, μ(Cu K_α) = 34.8 cm^{-1}. Absent reflections: $0kl$, $k \neq 2n$, $h0l$, $l \neq 2n$, and $hk0$, $h \neq 2n$ define uniquely the space group $Pbca$ (D_{2h}^{15}, No. 61).

Intensities were measured with nickel-filtered Cu K_α radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 2° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ was employed. Background counts (10 s) were measured at each end of the scan. Data were measured to 2θ = 140°. The intensities of two check reflections, measured every 40 reflections throughout the data collection, remained constant to within ±5%. Lorentz and polarization corrections and batch check reflection scaling were applied, and the structure amplitudes were derived. An absorption correction was applied by a computer program using a Gaussian integration method (11, 12). Transmission factors ranged from 0.395 to 0.744. Of the 4046 independent reflections measured, 2263 (56%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + B + (0.06S)^2$ with S = scan count and B = time averaged background count.

The solution and initial stages of refinement were carried out with 1443 observed reflections with 2θ ≤ 90°. The structure was solved by direct methods (13). The positions of the two gallium atoms were determined from an E-map calculated from the set of signs with the second highest consistency index (0.94). Two cycles of full-matrix least-squares refinement of the coordinates and isotropic thermal parameters of the gallium atoms gave R = 0.323. The positions of the remaining non-hydrogen atoms were given by a difference map calculated at this point. The non-hydrogen atoms were refined isotropically for two cycles and then anisotropically for two cycles reducing R to 0.056. The hydrogen atom positions were given by a subsequent difference synthesis. The entire structure (hydrogen atoms with isotropic thermal parameters) was refined using the full data set for six cycles giving a final R of 0.036 and R_w of 0.029 for 2248 reflections with $I \geq 3\sigma(I)$ (15 reflections which had $|F_o| - |F_c| > 3\sigma(F)$ were treated as unobserved in the final stages of refinement; for all 4046 reflections R = 0.088 and R_w = 0.030).

The least-squares refinement was based on the minimization of $\Sigma w[|F_o| - |F_c|/(1 + gI)]]^2$ where g is the extinction parameter and I the uncorrected intensity. The final value of g was 6.6 × 10^{-8}. The scattering factors of ref. 14 were used for the non-hydrogen atoms and those

of ref. 15 for the hydrogen atoms. Anomalous scattering factors from ref. 16 were used for the non-hydrogen atoms. The weighting scheme: $w = (|F_o|/55.0)^2$ for $|F_o| < 55.0$, $w = (55.0/|F_o|)^2$ for $|F_o| \geq 55.0$, and $w = 0.01$ for the unobserved reflections gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

On the final cycle of refinement the mean parameter shift was 0.11σ and the largest shift (0.94σ) was associated with the thermal parameter of H(4). The mean error in an observation of unit weight was 0.742. The final positional and thermal parameters appear in Tables 1 and 2 respectively.[1] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation (**T**), libration (**L**), and screw (**S**) motion (17) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0024 Å^2. Analyses were successful for the two Ga coordination groups (rms $\Delta U_{ij} =$ 0.0027 Å^2 for Ga(1), O(1), N(1), C(9), C(10) and 0.0032 Å^2 for Ga(2), O(2), N(2), C(19), C(20)), and for the two 11 atom groups Ga(1), O(1), N(1), C(1)–C(8) (rms $\Delta U_{ij} = 0.0051$ Å^2) and Ga(2), O(2), N(2), C(11)–C(18) (rms $\Delta U_{ij} = 0.0046$ Å^2).

The appropriate bond distances have been corrected for libration (18, 19), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3[1] along with the uncorrected values. Bond angles changed by less than one standard deviation in all cases, thus only the uncorrected values are reported in Table 4.[1]

Results and Discussion

$(C_{16}H_{15}N_2O_2)(GaMe_2)$, **2**, displays a broad ν_{OH} vibration in its infrared spectrum and a signal due to the OH group in its ^{1}H nmr spectrum with τ_{OH} at 2.34 ppm compared with τ_{OH} at 2.29 ppm in *N*,*N*-ethylenebis(salicylideneimine) itself. The unsymmetrical nature of compound **2** was demonstrated by the "triplet" signal in its ^{1}H nmr spectrum due to the "ethylene" protons, these protons giving a singlet in the ^{1}H nmr spectra of the symmetrical compounds **1** and **3**.

As expected, $(C_{16}H_{14}N_2O_2)(GaMe_2)_2$, **3**, displayed no ν_{OH} in its infrared spectrum and no τ_{OH} in its ^{1}H nmr spectrum. The forcing reaction conditions needed to introduce a second "$GaMe_2$" moiety into the $(C_{16}H_{15}N_2O_2)(GaMe_2)$ compound suggest that some type of interaction of the "$GaMe_2$" group already present in **2** with the OH group and/or the second N atom is already taking place. This is indicated by the dotted lines in **2**. The introduction of the second

[1]The structure factor table and Tables 2 (thermal parameters), 3(*b*) (bond lengths involving H), 4(*b*) (angles involving H), 6 (mean planes), and 7 (nonbonded distances) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

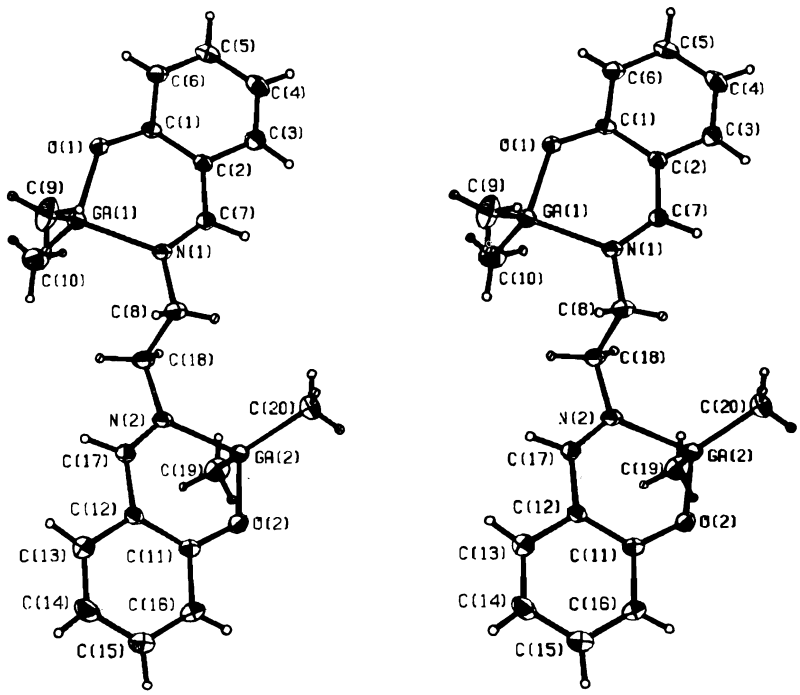

FIG. 1. A stereo view of the *N,N*-ethylenebis(salicylideneiminato)bis(dimethylgallium) molecule. 50% ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been given artifically small temperature factors for the sake of clarity. Hydrogen atoms labelled "b" and "c" in Table 1 are represented above by ⊘ and ⊗ respectively.

"$GaMe_2$" moiety necessitates a drastic ligand rearrangement in which any interaction of the type posulated in **2** must first be broken and then the molecule rearranged to accommodate the second "$GaMe_2$". In the arrangement illustrated by the X-ray structure of *N,N*-ethylenebis(salicylideneiminato)bis(dimethylgallium), **3** (see Fig. 1), steric crowding is reduced to a minimum and the gallium atoms are tetrahedrally coordinated, there being no evidence of association via O → Ga type linkages.

The mass spectra of the two compounds **2** and **3** displayed amongst their most intense peaks signals due to the parent ions minus one methyl group (see Experimental section) *viz.* $(C_{16}H_{15}N_2O_2)GaMe^+$ and $(C_{16}H_{14}N_2O_2)Ga_2Me_3^+$, respectively. The relative intensities of the peaks in the multiplet signals agree well with those predicted from the isotopic distribution of the metal atoms (^{69}Ga (60%); ^{71}Ga (40%)). The parent ions themselves were not detected, but this is not unusual in the mass spectra of this type of compound containing the dimethyl gallium moiety (1, 7).

The X-ray crystallographic analysis shows that the *N,N*-ethylenebis(salicylideneiminato)-bis(dimethylgallium) molecule (see Fig. 1) is somewhat distorted from C_i symmetry. This may be due to crystal packing forces, since the ^1H nmr spectrum in solution (Me and "CH_2-CH_2" singlets at $\tau = 9.96$ and 7.04 ppm respectively) requires the molecule to have at least C_i symmetry. The distortions from C_i symmetry are seen as differences between the two chelate rings (intraannular torsion angles are given in Table 5) and unequal torsion angles about the N(1)—C(8) and N(2)—C(18) bonds (C(7)[N(1)—C(8)]C(18) = −122.0(3) and C(17)-[N(2)—C(18)]C(8) = 107.0(3)°). The torsion angle about the central bond, N(1)[C(8)—C(18)]N(2), is 173.8(3)°, close to the value of 180° required by a centre of symmetry, but quite different from the value of ~30° expected for the quadridentate configuration of the *N,N*-ethylenebis(salicylideneimine) ligand postulated for **2**.

In the present structure, a "$GaMe_2$" unit is coordinated to each of the two salicylideneimine

moieties of the *N,N*-ethylenebis(salicylideneimine) ligand. Both gallium atoms have distorted tetrahedral geometry, the bond angles (listed in Table 4) ranging from 94.0(2) to 124.6(3)° at Ga(1) and from 92.7(1) to 123.8(3)° at Ga(2). The mean[2] Ga—O (1.885(1) Å) and Ga—C (1.959(9) Å) bond lengths are close to the mean values observed for related structures containing tetrahedral gallium (Ga—O, 1.87 Å (20 and references therein), and Ga—C, 1.954(4) Å (7 and references therein)). The mean Ga—N bond length (2.038(5) Å) is significantly longer than the mean value of 1.998(1) Å for "long" Ga—N bonds in related molecules (7 and references therein). This lengthening is due, at least in part, to σ-hybridization effects (21). The mean angle at Ga involving N (103.2°)

[2]Here and elsewhere in this paper, mean values refer to weighted means with rms deviations from the mean in parentheses.

TABLE 5. Intraannular torsion angles (deg)

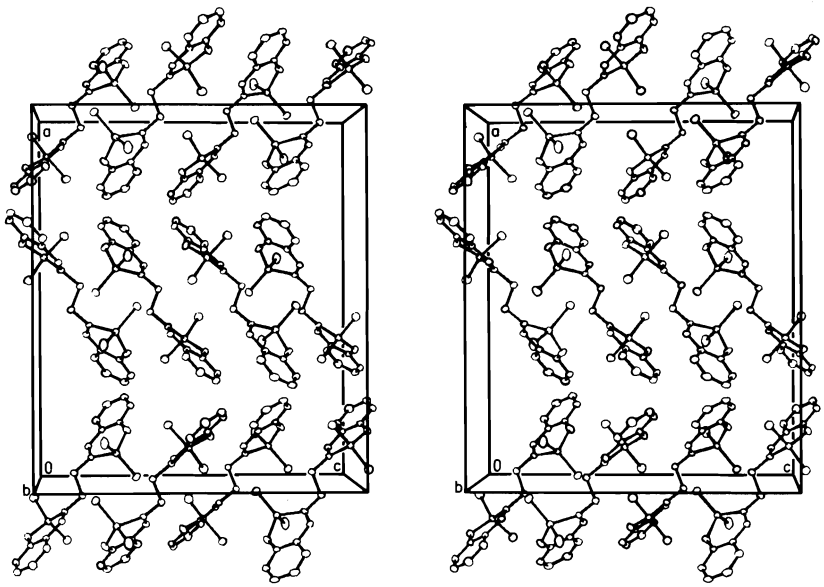

FIG. 2. The packing arrangement viewed along *b*.

implies that the bonding orbital of gallium (involved in the Ga—N bond) has a high degree of *p*-character which increases the bond length. The bond lengths in the remainder of the molecule are as expected.

The five atom OCCCN segments of both chelate rings are nearly planar (mean and maximum displacements from the OCCCN mean planes being 0.012 and 0.029 Å for the Ga(1) ring, 0.021 and 0.035 Å for the Ga(2) ring), with Ga(1) and Ga(2) displaced 0.0951 and −0.3887 Å respectively from the OCCCN mean planes. Both aromatic rings are planar within experimental error. The ring containing Ga(1) is more nearly planar (resembling the GaO_2C_3 chelate ring in the (salicylaldehydato)-dimethylgallium dimer (9)) than that containing Ga(2) (which has a conformation similar to that of the BO_2C_3 ring in (salicylaldehydato)-diphenylboron (22)). Torsion angles in the chelate rings are given in Table 5.

The crystal structure (Fig. 2) consists of well-separated molecules of *N,N*-ethylenebis(salicylideneiminato)bis(dimethylgallium). The shortest intermolecular distances (listed in Table 7[1]) correspond to normal van der Waals interactions.

Acknowledgments

We thank the National Research Council of Canada for financial support, the University of British Columbia Computing Centre for assistance, Mr. P. Borda for the C, H, and N analyses, and Mr. J. Nip for recording the mass spectra.

Juvabione and its analogues. IV.[1] Isolation, identification, and occurrence of juvabione, juvabiol, and epijuvabiol from the whole wood of *Abies lasiocarpa*

JOHN F. MANVILLE AND CHARALYN D. KRIZ

Fisheries and Environment Canada, Western Forest Products Laboratory, 6620 N.W. Marine Drive, Vancouver, B.C., Canada V6T 1X2

Received January 26, 1977

JOHN F. MANVILLE and CHARALYN D. KRIZ. Can. J. Chem. **55**, 2547 (1977).

Juvabione (**1**), 1′*Z*-dehydrojuvabione (**10***a*), 1′*E*-dehydrojuvabione (**10***b*), juvabiol (**3**), epijuvabiol (**6**), and the epimeric 2′-dehydrojuvabi-1′-ols (**11**) occur in the whole wood of a number of North American *Abies lasiocarpa* trees. Wide variability of occurrence of these juvabione analogues and other previously characterized extractives is noted. The co-occurrence of **1** and **6**, with *opposite* configurations at C-1′, as shown by ^{13}C nmr indicates the necessity of accurately determining the *complete* structure of naturally occurring compounds *even* if isolated from the same source.

JOHN F. MANVILLE et CHARALYN D. KRIZ. Can. J. Chem. **55**, 2547 (1977).

Les composés suivants furent isolés du bois entier d'un certain nombre de Sapins subalpins (*Abies lasiocarpa*) nord-américains: le juvabione (**1**), le 1′*Z*-déhydrojuvabione (**10***a*), le 1′*E*-déhydrojuvabione (**10***b*), le juvabiol (**3**), l'épijuvabiol (**6**) et un mélange épimère de 2′-déhydrojuvabi-1′-ols (**11**). On remarque une grande variabilité de présence de ces composés analogues au juvabione. La co-présence de **1** et **6** avec les configurations opposées à C-1′, tel que démontré par ^{13}C rmn, indique la nécessité de déterminer avec précision la structure *complète* des composés qui apparaissent naturellement *lorsque* isolés d'une même source.

Introduction

The wood of balsam fir (*Abies balsamea* (L.) Mill.) contains compounds exhibiting juvenile hormone activity on the hemipteran bug *Pyrrhocoris apterus* L. (1, 2). To date five active insect juvenile hormone analogue (IJHA) components have been isolated and identified (3–5). They are juvabione (**1**), 4′-dehydrojuvabione (**2**), juvabiol (**3**), isojuvabiol (**4**), and 3′-dehydrojuvabi-5′-ol (**5**). These compounds and possibly others (5) present in the whole wood of balsam fir are responsible for the "paper factor" effect, first noted by Sláma and Williams (1).[2]

It is well known that balsam fir and alpine fir (*A. lasiocarpa* (Hook.) Nutt.) are two closely related fir species found across Canada (7). The balsam fir predominates in eastern Canada, whereas the alpine fir is found extensively in western Canada from the Pacific Coast to central Alberta. In view of the recently noted (4, 5) extensive occurrences of juvabione and related sesquiterpenoids in the whole wood of balsam fir, it was of interest to study the extractives of alpine fir wood to determine if similar compounds were present.

Alpine fir wood was previously shown to contain both the *Z*- and *E*-α-atlantones (**7**), manool (**8**), and lasiocarpenone (**9**); the occurrence of other sesquiterpene ketones, which were not fully characterized, was also reported (8–11).[3]

This paper reports the isolation and identification of juvabione (**1**) and an unresolved mixture of juvabiol (**3**) and epijuvabiol (**6**). Their variability of occurrence together with that for the atlantones (**7**), manool (**8**), lasiocarpenone (**9**), an isodehydrojuvabione (tentative structure 1′*E*-dehydrojuvabione (**10***b*)), and an unresolved mixture of tertiary alcohols (**11**) in the whole wood of alpine fir is noted.

Isolations

The petroleum ether extracts of the whole wood of nine alpine firs from three sites were pale yellow mobile oils. The individual tree extracts were examined by gas-liquid chromatographic (glc) analysis, which revealed the presence of at least seven major components which did not correspond to any of the common fatty

[1]For part III see ref. 13.

[2]Naturally occurring C-1′ epimers of **1** and **2** (epijuvabione and 4′-dehydroepijuvabione) have been isolated from a Czechoslovak fir (4, 6) growing in an arboretum in Czechoslovakia; both are active IJHAs.

6

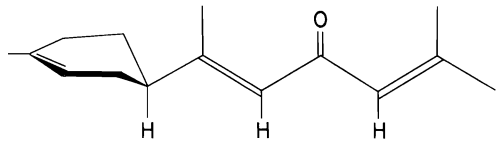
or resin acid methyl esters. A composite sample was obtained by combining wood from all nine trees and obtaining the petroleum ether extract which was used for isolation and identification of components. Using procedures given in the experimental section, silicic acid column chromatography effected separation of some of the major components from this extract mixture.

Results and Discussion

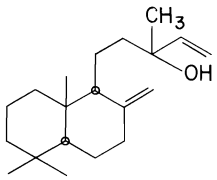
The first three major components were identified by glc retention times (r_t) (relative to internal **1**), thin-layer chromatogram (tlc) R_f values, and color reactions. They had been previously characterized as constituents of the wood of alpine fir (8–10) and balsam fir (4), and are the atlantones (**7**) r_t 0.24, manool (**8**) r_t 0.53, and lasiocarpenone (**9**) r_t 0.63.

Whereas previous studies (8–10) had identified these compounds as constituents of the wood of alpine fir, the present glc analyses (Table 1) indicated a considerable degree of variation in the amounts of these compounds in the nine trees sampled. Substantial, yet variable, amounts of the atlantones (**7**) (8–33%) were detected in all samples. Most wood samples contained only trace amounts of manool (**8**) and lasiocarpenone (**9**); in contrast tree 4 had 4.7% **8** and 8.0% **9** and in tree 1, from a different site, we found 0.4% **8** and 8.4% **9**. No other trees examined had more than trace amounts of **9**, while trees 5 and 6 contained substantial amounts of **8**. Site 2 (trees 4–6) had consistently large amounts of **8** in comparison with the other sites. The large degree of variation in the amounts of **9** supports the possibility of inconsistent or variable results in correctly identifying alpine fir wood as noted in the method proposed by Fraser and Swan (11).

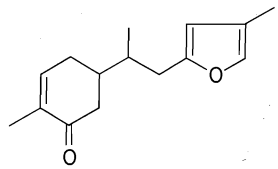
The combined fractions 15–32, which gave rise to glc peaks at r_t 1.00 and 1.23 were studied next. Thin-layer chromatography indicated the presence of two ketones (yellow spots with 2,4-DNPH). Hydrogenation (4) of a portion of this mixture resulted in the formation of *cis* and *trans* dihydrojuvabiones, confirming only one monocyclic sesquiterpenoid skeleton to be present in this mixture (4). However, high performance liquid chromatography (hplc) of another portion of this mixture revealed the presence of three components by uv detection; one was juvabione (**1**) ($r_t' = 1.00$); the other two ($r_t' = 0.86$ and 0.94) absorbed much more strongly than did **1** (nmr indicated approximately 70% of the mixture



7 (E)



8



9

was **1**) indicating that they were α,β-unsaturated ketones, but neither was 4′-dehydrojuvabione (**2**) (r_t' = 0.80 (4)). A portion of this mixture was isolated in pure form by rechromatographing on a silicic acid column. This compound gave a glc peak at r_t 1.00 and had $[\alpha]_D$, ^{1}H nuclear magnetic resonance (nmr), infrared (ir), and mass spectra (ms) in accord with those reported for **1** (3, 4). The stereoconfigurations were proven by comparing the ^{13}C nmr chemical shifts observed for **1** with those obtained from samples of previous isolations (13). Juvabione (**1**) was a major component in all nine petroleum ether extracts and appeared to range in amounts from 16 to 65%.

However, further examination of some intermediate fractions from the above separation, which appeared to be pure **1** by glc, contained a second component when observed by hplc and ^{1}H nmr. This minor component had two ^{1}H nmr resonances distinct from those observed for **1**. A vinyl methyl resonance was observed at δ 1.82 (J = 1.6 Hz) (*cf.* δ 1.88 for *trans* methyl of **2** (4)) and an olefinic proton at δ 6.08 (br s, coupled to above methyl). These were assigned to the C-1′ methyl and C-2′ hydrogen of **10***a* respectively. This proposed structure (**10***a*) would account for the observations noted. Thus, reported (Table 1) amounts of **1** noted by glc may be due, in part (*ca.* 5%), to 1′*Z*-dehydrojuvabione (**10***a*).

A second (major) unsaturated ketone, responsible for the observation of a glc peak, at r_t 1.23 was isolated by silicic acid column chromatography together with **1** and was therefore only partly characterized. The ^{1}H nmr spectrum of this mixture revealed the presence of an additional olefinic resonance, at δ 6.08, and a

11

vinyl methyl resonance at δ 2.13 (J = 1.25 Hz) (*cf.* δ 2.14 for *cis* methyl of **2** (4)), which was coupled to this olefinic proton. The methyl ester protons were observed at δ 3.78 *vs.* δ 3.77 for **1**. This compound was tentatively assigned structure **10***b*, in accord with that proposed by Leach and Thakore (12). This 1′*E*-dehydrojuvabione (**10***b*) is a major constituent and accounts for from 5–25% of the petroleum ether soluble extract of alpine firs.

Next, the polar components (see isolations) were investigated and characterized by chromatographic and spectroscopic techniques. One portion was recovered unaltered by acetylation attempts. It gave rise to a glc peak at r_t 1.11 and proved to be identical with a mixture of tertiary alcohols (**11**) previously isolated by E. P. Swan[3] of this laboratory. The complete description of these alcohols, which account for up to 16% of the petroleum ether soluble material, will be reported separately. The acetylated portion was efficiently separated (5) into two major portions. The phytosterol acetates were isolated in the first portion and were not investigated further. The compounds present in the intermediate fractions had ^{1}H nmr, r_t, and R_f values which were indicative of juvabiol (**3**) and/or isojuvabiol (**4**) acetates except that $[\alpha]_D$ was different to that found previously (5).

The original alcohols were recovered by deacetylating a portion of the above acetates, the ^{1}H nmr, r_t, and R_f values were indicative of juvabiol and/or isojuvabiol (**3** and **4**) but the $[\alpha]_D$ was different (5). High performance liquid chromatographic analysis of this alcohol fraction showed that it was a mixture and that the ratio of isomers (1:10) was different than observed previously for balsam fir (approximately 1:1, (5)). The major alcohol corresponded with the 4*R*,1′*R*,3′*R* isomer (**4**) obtained previously from sodium borohydride reduction of **1** (5). The minor alcohol co-chromatographed with the 4*R*,1′*R*,3′*S* configurational product (**3**). However, ^{13}C nmr showed that the major alcohol or its acetate was identical with the 4*R*,1′*S*,3′*S* isomer (**6**) obtained from sodium borohydride reduction of epijuvabione (13). (Table 2 lists the ^{13}C nmr shifts for the epimeric alcohols and their acetates, obtained previously from sodium borohydride reduction of **1** and epijuvabione (5, 13).) The minor alcohol (this study) was identified as **3**. These alcohols can account for up to 24% of the petroleum ether soluble material isolated from alpine firwood.

The whole wood of alpine fir contains several juvabione-related compounds that are different from those found in balsam fir (3–5). Moreover, the fact that we observe both (*R* and *S*) C-1′ epimers, but only one C-3′ epimer (*S*), for this species, suggests a possible biosynthesis scheme as outlined in Scheme 1.

In order to rationalize the synthesis of **6**, the major alcohol isolated from alpine fir, one might postulate the stereoselective reduction of **10** to the allylic alcohol **12** with *S* stereochemistry at C-3′ (not isolated, but see below). The latter could then be reduced to either **6** or **3**. This scheme and the existence of **12** is supported by the isolation of the tertiary alcohols **11** (which could be formed in a manner analogous to that reported earlier for the formation of **5** (5)) and by the absence of any alcohols with the *R* configuration at C-3′.

The results of this study contrast those found previously (4, 5) for balsam fir in two important respects. First, both the *R* and *S* epimers at C-1′ were found in alpine fir, whereas only the *R*-epimer at C-1′ was found in balsam fir. Second, whereas the alcohols in balsam fir were epimeric at C-3′, only the *S* epimer at C-3′ was observed in alpine fir. These results suggest two different

biosynthetic pathways, for alpine fir and balsam fir, to the various juvabione-type products. No evidence of the occurrence, in alpine fir, of 4′-dehydrojuvabione (**2**) or 3′-dehydrojuvabi-5′-ol (**5**) was noted.

Experimental

The ^{1}H nmr spectra were determined on samples dissolved in deuteriochloroform containing tetramethylsilane as internal standard using a Varian XL-100 spectrometer. Mass spectra were recorded in the Department of Chemistry, University of British Columbia, using Atlas-4 and AEI-DS-50 spectrometers. Accurate mass measurements were made by reference to appropriate ions of the perfluorokerosene spectrum. Infrared spectra were recorded with a Perkin-Elmer 521 spectrophotometer. Samples were placed as liquid films on the surface of KBr discs. Optical rotations were recorded on a Perkin-Elmer 141 polarimeter made available by the Department of Chemistry, University of British Columbia. Gas–liquid chromatographic analyses were performed on a Hewlett Packard model 7620A equipped with flame-ionization detector. The column used was a 6 ft × $\frac{1}{8}$ in. o.d. stainless steel packed with 10% EGSS-X on 100–120 mesh Gas Chrom. P. The column was held isothermally at 185°C. The carrier-gas flow rate was 25 ml/min. The detector and injector ports were maintained at 270°C. All glc retention times (r_t) are relative to internal **1**.

The hplc analyses were performed on a Spectra-Physics 3500B liquid chromatograph equipped with their chromatronix Model 230 uv (280/254 nm) detector. The column used was 3 × 250 mm Spherisorb ODS (10 μm). The solvent system was water–acetonitrile; isocratic elution was used (40% acetonitrile); the flow rate was 1 ml/min at approximately 600 psi. All hplc retention times (r_t') are relative to internal **1**. Thin-layer chromatograms were performed on Mallinckrodt Chromar plates 7GF using petroleum ether – diethyl ether (3:1) as developer.

Extraction

In each case, debarked whole wood was air dried and ground in a Wiley mill to pass a 5-mm screen. Wood meal for each tree and a composite sample was first extracted over a 12-h period in an all-glass soxhlet apparatus with petroleum ether (bp 60–90°C) followed by benzene–ethanol extraction, prior to obtaining o.d. wood weights. The extracted yellow-brown oil was dried (Na_2SO_4) and the petroleum ether removed under reduced pressure. The petroleum ether soluble material obtained from a composite sample from all nine trees used for isolations of individual compounds contained 88% neutral components as determined by DEAE Sephadex A-25 chromatography using the method of Zinkel and Rowe (14).

Separation

Partial separation of the compounds present in the petroleum ether soluble material was achieved by repeated column chromatography using Woelm silicic acid and petroleum ether – diethyl ether (PE–DE) as eluent. A total of 6.71 g of extract was applied to column 1 (Table 3).

Fractions 33–52 were combined, concentrated to a syrup, and treated with acetic anhydride and pyridine, in

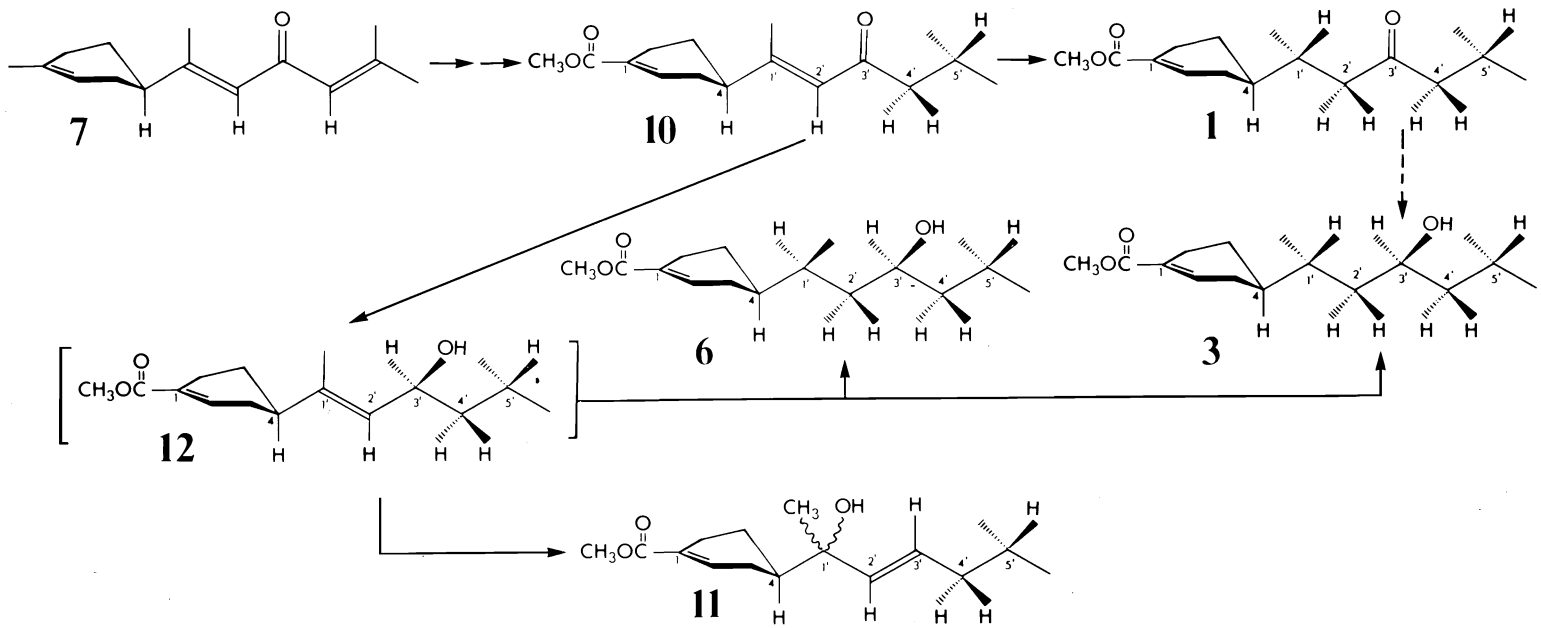
*Assignments may be interchanged.
†These compounds were available from earlier studies (refs. 4 and 5 and unpublished results (J. F. Manville and K. Bock)). ^{13}C nmr spectra were recorded in *ca.* 1 *M* $CDCl_3$ solutions on a Varian CFT-20 spectrometer at 20 MHz. Chemical shifts (± 0.1 ppm) are given with respect to Me_4Si using $CDCl_3$ (δ 76.9 ppm) as internal standard. Generally a pulse width of 10 μs (α = 45°), 8K data points and sweep width of 4000 Hz (digital resolution ± 0.98 Hz = ± 0.05 ppm) were used. All spectra were multiplied with an exponential function (sensitivity enhancement, *SE* = −0.4 s) prior to Fourier transformation.
‡Locants are 4, 1′, 3′, respectively.



SCHEME 1. Postulated biosynthetic pathways for juvabione and its analogues in *Abies lasiocarpa*.

TABLE 3. Separation of compounds in the petroleum ether soluble fraction

Solvent ratio (PE:DE)	Volume (ml)	Fractions (19 ml)	Peak no. (glc)	Weight (g)
		Column 1

1:1	300	42′–47′	V	0.19
0:1	300	48′–50′	V	0.11

the usual manner, to yield a syrup which was partly resolved by column chromatography (column 2) after most of the phystosterol acetates were removed by crystallization.

Deacetylation

Part (306 mg) of fractions 15′–24′ was dissolved in 25 ml of methanol, to which was added 108 mg of sodium methoxide. The solution was heated under reflux for 12 h; 90% of the acetate groups were removed (glc). The reaction mixture was diluted with H_2O, neutralized (H_2SO_4), and extracted with $CHCl_3$ (3 × 10 ml). The resulting syrup was re-chromatographed (column 2) to recover a colourless, viscous oil (139 mg).

*Compound **1** (Juvabione (4R, 1′R))*

Compound **1** was a colourless oil, which by glc was better than 90% pure; it had physical and spectral parameters in accord with those published (4). The ^{13}C nmr δ 209.8, 167.3, 138.9, 129.8, 52.1, 51.0, 47.4, 32.3, 29.4, 24.5, 24.2, 22.3, and 16.2 was identical to that found previously (13) for **1**.

*Compounds **3** and **6** (Juvabiol (4R,1′R,3′S) and Epijuvabiol (4R,1′S,3′S)*

Compounds **3** and **6**, isolated together as a colourless oil and characterized as an epimeric mixture (at C-1′), had most physical and spectral parameters in accord with those published (5) for the C-3′ epimeric mixture of juvabiol (**3**) and isojuvabiol (**4**). The $[\alpha]_D^{24}$ was +57.1° (*c* 0.92, CH_3OH) (*cf.* $[\alpha]_D^{23}$ +67.8° (5)). High performance liquid chromatographic analysis revealed a mixture of isomers (r_t′ 0.76 and 0.83) in a ratio of 1:10 (lit. 9:11 (5)). The ^{13}C nmr δ 167.8, 139.7, 129.8, 68.1, 67.2, 51.2, 47.5, 46.7, 42.3, 42.0, 38.2, 37.2, 33.3, 32.7, 29.6, 28.1, 25.7, 24.7, 24.3, 23.8, 23.4, 22.9, 21.8, 16.2, and 15.2. The observed intensities were consistent with a 1:10 ratio of **3** and **6** (see Table 2 for comparison). *Mol. Wt.* calcd. for $C_{16}H_{28}O_3$: 268.2038; found (high resolution mass spectrometry): 268.2023.

*Acetates of **3** and **6** [Juvabiol Acetate (4R,1′R,3′S) and Epijuvabiol Acetate (4R,1′S,3′S)]*

Acetates of **3** and **6**, isolated together as a colourless oil and characterized as an epimeric mixture (at C-1′), had most physical and spectral parameters in accord with those published (5) for the C-3′ epimeric mixture of juvabiol (**3**) acetate and isojuvabiol (**4**) acetate. Again, the $[\alpha]_D^{24}$ +68.6° (*c* 0.90, CH_3OH) was different from that observed previously ($[\alpha]_D^{23}$ +54.3°) (5). They had R_f 0.53 (incorrectly printed as 0.33 in ref. 5). The ^{13}C nmr δ 170.4, 167.4, 139.2, 129.9, 71.3, 70.4, 51.0, 44.1, 43.2, 39.2, 38.8, 37.8, 37.3, 33.3, 32.8, 29.5, 27.9, 25.7, 24.7, 24.4, 23.0, 22.6, 22.0, 20.8, and 15.5. The observed intensities were consistent with a 1:10 ratio of **3** and **6** acetates (see Table 2 for comparison). *Mol. Wt.* calcd. for $C_{18}H_{30}O_4$: 310.2143; found (high resolution mass spectrometry): 310.2144.

Acknowledgments

We wish to thank Mr. C. R. Daniels for obtaining the hplc results and Dr. K. Bock for help in determining the ^{13}C nmr assignments.
